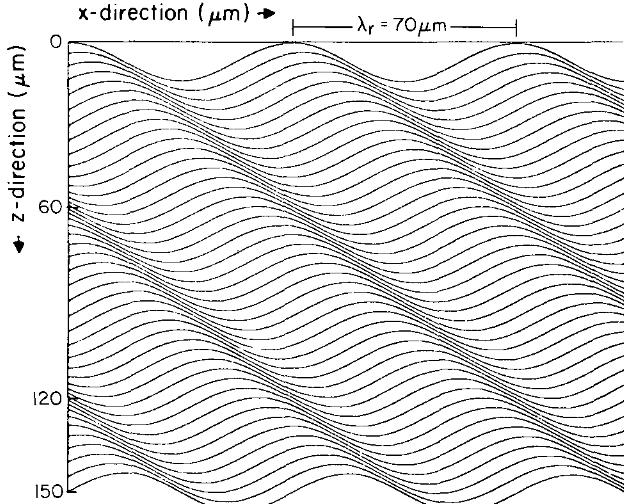

Fig. 5. Graphic presentation of oscillatory growth interface instability (Eq. [12]) in the absence of thermal asymmetry; $\alpha = 0$. The time interval between successive lines is 0.28 sec. (For numerical values used in Eq. [12] see text).

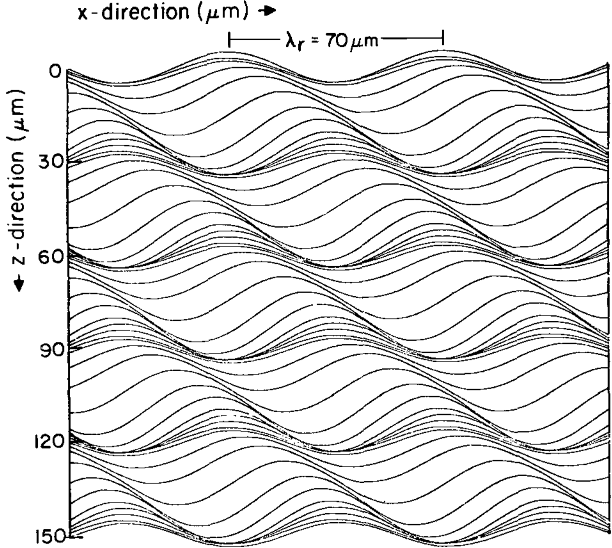

Fig. 6. Graphic presentation of oscillatory growth interface instability in the presence of thermal asymmetry ($\alpha = 0.9$). The interval between successive lines is 0.24 sec (see text).

rotational pulling in the absence of thermal asymmetry, is never encountered in real systems.

In the presence of thermal asymmetry ($\alpha > 0$) the exact solution of Eq. [11] requires the knowledge of the constitutional supercooling parameter (which changes continuously during rotation) since $Re[p_j(\omega)]$ is a function of S.

This behavior is a result of the growth rate dependence of the constitutional supercooling parameter, S; changes in S lead to corresponding changes in $Re[p_j(\omega)]$ between positive and negative values averaging about zero. Depending on whether $Re[p_j(\omega)]$ assumes positive or negative values for extended periods of time, the system will "break down" or revert to stability, respectively. In the presently considered situation characterized by oscillatory instability, the values of $Re[p_j(\omega)]$ remain close to zero. The amplitude of the interface instability, in contrast to that in Fig. 5, is not constant but increases and decreases periodically with the variation of the microscopic growth rate within each rotational cycle. Concurrent with the variation $Re[p_j(\omega)]$, the phase velocity $Im[p_j(\omega)]$ varies periodically; these variations, however, are small. Since S and its variations, during rotation, could not be determined, a graphic representation of a realistic situation ($V_o = 4.5$ cm/hr, $R = 25$ rpm, and $\lambda_r = 70$ μm) was obtained by selecting reasonable values of the phase velocity (ranging from 0 to 30 μm/sec) and amplitude of perturbation (ranging from 4 to 8 μm) for $\alpha = 0.9$ (Fig. 6). The individual lines represent the dynamics of the growth interface morphology at time intervals of 0.24 sec. In this case the microscopic growth rate, dz/dt (which is constant in the absence of thermal asymmetry and oscillatory instability) is modulated simultaneously by: (*i*) the sinusoidal growth rate variation along the z direction (independent of x) resulting from thermal asymmetry and (*ii*) the periodic growth rate variation along both the x and z directions resulting from the traveling wave nature of the oscillatory instability.

When the average value of $Re[p_j(\omega)]$ becomes positive, oscillatory instability can no longer be sustained and the amplitude of the perturbation increases continuously as shown in Fig. 7 and ultimately leads to interface breakdown.

The dynamic behavior of the growth interface under conditions leading to remelting ($\alpha = 1.1$) is presented in Fig. 8. Since in this case the variation of the microscopic growth rate within each rotational cycle is larger than in the case $\alpha = 0.9$, the corresponding variations in phase velocity and amplitude of the perturbation are expected to be larger. Accordingly, the values for the phase velocity were selected to range from 0 to 35 μm/sec and those of the amplitude ranged from 4 to 10 μm. The dotted lines within each rotational cycle represent the grown regions which were remelted during rotation through the hot region of the melt (17). The onset of growth following remelting is indicated in Fig. 8 by heavy lines which correspond to remelt striations (see for example Fig. 2). These

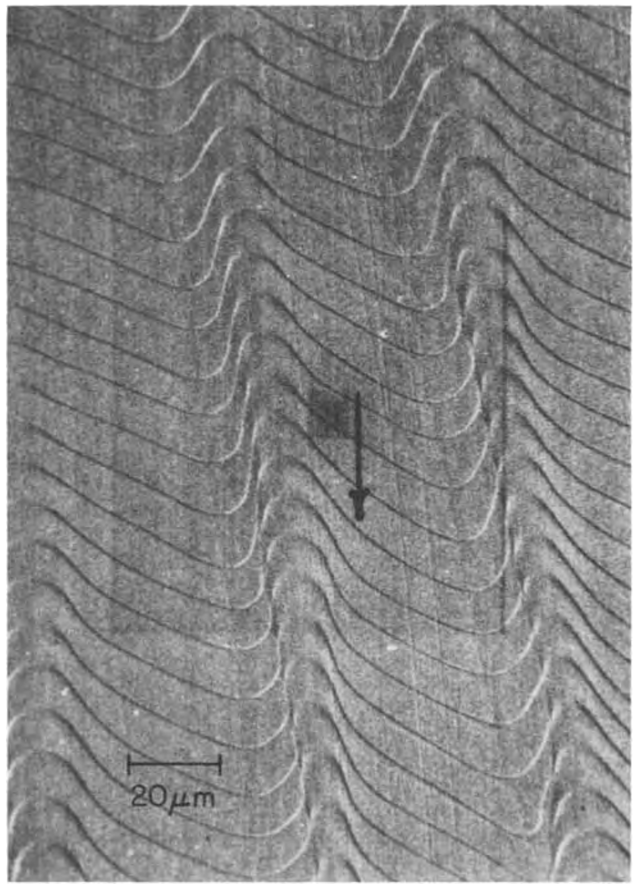

Fig. 7. Interface instability in Ga-doped Ge for growth conditions where the average value of $Re[p_j(\omega)]$ is positive. Oscillatory instability is not sustained; note progressive increase (from top to bottom) of the amplitude of the perturbation.

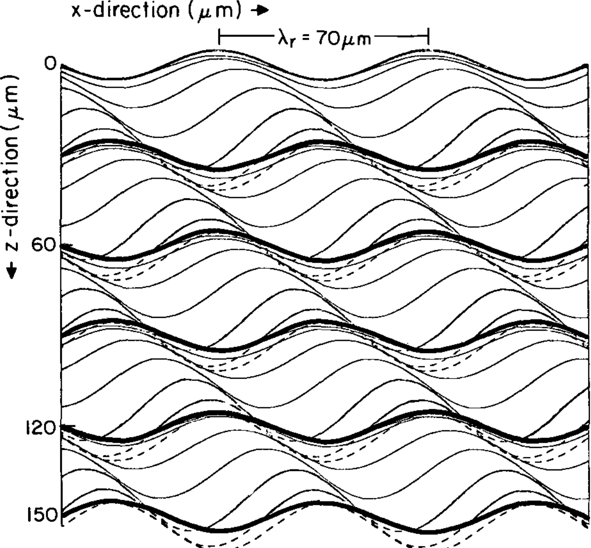

Fig. 8. Graphic presentation of oscillatory growth interface instability under partial remelt conditions ($\alpha > 1$). The dotted lines, within each rotational cycle, represent the grown regions which were remelted. The heavy lines represent the remelt rotational striations. (For comparison with the experimental findings of Fig. 2, see text.)

remelt striations have the wavelength of the oscillatory instability but not its amplitude (the resulting amplitude is significantly reduced).

Comparison with experimental results.—All results in this investigation were obtained on crystals grown in the presence of thermal asymmetry leading to remelting; thus, comparison with theory will be focused on conditions as depicted in Fig. 8. This comparison is based on the premise that the experimentally observed segregation behavior is controlled by the microscopic growth rate.

Consistent with the theoretical considerations outlined above, sustained oscillatory interface instability ("wavy" remelt striations) is observed in all crystals investigated (Fig. 1-4). The traveling wave nature of the oscillation, as predicted from theory, is confirmed by the lateral displacement of the maxima (and the minima) in successive rotational striations, as seen in Fig. 2; the direction of the phase displacement is in agreement with that predicted from theory. The "inclined" segregation inhomogeneities within rotational cycles (between successive rotational striations) seen in Fig. 2 are readily explained on the basis of the preceding analysis; as seen in Fig. 8, the microscopic growth rate, dz/dt, varies along the x direction during each rotational cycle; thus, the traveling wave nature of the oscillations results in the formation of "cells" (between successive remelt striations) bounded laterally by regions of decreased growth rate (inclined bands). The complex segregation inhomogeneities between rotational striations in Fig. 3 cannot be explained exclusively on the basis of growth rate controlled segregation, as discussed below.

Theoretical assumptions and experimental conditions.—The preceding comparison must be viewed in the light of the following basic assumptions underlying the theoretical model (14): (*i*) the growth system is at steady state; (*ii*) the perturbations at the growth interface are small, so that the linearized theory is applicable; (*iii*) fluid flow at the momentum boundary layer is laminar with a parabolic velocity distribution within the boundary layer (diffusion of heat and convective solute transport are dominant); (*iv*) kinetic supercooling is absent; (*v*) there are no radial temperature and concentration gradients.

During rotational crystal growth by the Czochralski technique "steady state" [assumption (*i*)] prevails on a macroscopic level for conditions of constant pulling rate and constant crystal diameter (constant macroscopic growth rate). However, since thermal asymmetry is inherent in Czochralski growth, the microscopic growth rate is not constant but varies periodically within each rotational cycle.

When $\alpha < 1$ the effects of varying microscopic growth rates on interface instability can in principle be quantitatively accounted for through corresponding variations of the constitutional supercooling parameter, S. The growth and segregation behavior under such conditions has been discussed in the previous section. When $\alpha > 1$, as in the presently discussed experiments, partial remelting takes place within each rotational cycle. Since the solute redistribution within the boundary layer associated with the remelt process cannot be assessed, the magnitude of the constitutional supercooling parameter cannot be determined and the applicability of the instability theory cannot be quantitatively tested. The good agreement between theory and experiment in the case of Fig. 2 is attributed to marginal remelt conditions (α very close to 1).

The exact amplitude of the perturbations at the growth interface [assumption (*ii*)] could not be experimentally determined. However, the fact that the oscillatory perturbations were sustained over a considerable period of growth, without leading to interface breakdown, is direct evidence that, even during maximum microscopic growth rate (within each rotation), the amplitude of the perturbation was small enough to keep the system on the verge of instability.

The condition of laminar flow and parabolic velocity distribution in the momentum boundary layer [assumption (*iii*)] was met, in the present system, at the pulling rates (2.0-5.8 cm/hr) and the rotational rates (13-40 rpm) employed. Apparently, under these conditions diffusion of heat and convection controlled solute transport were dominant (15).

The presence of oscillatory instability in all crystals investigated was limited to their outer regions where kinetic supercooling [assumption (*iv*)] approaches zero; oscillatory instability was never encountered in "facet" regions.

Radial temperature and concentration gradients do exist in Czochralski growth; however, their magnitude is small over the regions investigated and can be neglected [assumption (*v*)].

The theoretical treatments of interface instability indicate that crystal rotation during Czochralski pulling has a stabilizing effect through changes in the characteristics of the boundary layer. This conclusion is based on the assumption that rotation takes place in a thermally symmetric environment in which rotation does not affect the microscopic growth rate. Since, however, thermal asymmetry is inherent in Czochralski growth, this assumption is valid only at high rates of rotation since increased stirring tends to minimize thermal asymmetry. At moderate rates of rotation (say, up to 50 rpm) the microscopic growth rate does not remain constant, particularly under remelt conditions where the actual growth rate ranges from negative values (remelting) to positive values which may exceed the pulling rate by more than a factor of ten. It is, thus, clear that in this range of rotational rates, the modulation of the microscopic growth rate can have pronounced destabilizing effects on the growth system. These effects can dominate the concurrent stabilizing effects of stirring. In fact, at moderate rates, seed rotation will induce interface instability rather than have the expected stabilizing effects.

A Diffusion Model for Oxidation of Nickel-Iron Alloys at 1000°C

A. D. Dalvi*,[1] and W. W. Smeltzer*

Department of Metallurgy and Materials Science, McMaster University, Hamilton, Ontario, Canada

ABSTRACT

A generalized diffusion model involving ternary oxides is used to formulate the oxidation mechanism of Ni-Fe alloys containing 2 and 4 weight per cent Fe. A defect structure, adopted for the inner nickel oxide layer containing iron, yields the variation of its cation diffusion coefficients which, when substituted in the diffusion equations, yield the cation concentration and the oxygen activity profiles in the oxide and the oxidation constants for the respective alloy. Thermodynamic considerations are used in deriving the oxygen activity profile in the outer two-phase nickel oxide-spinel layer of an external scale. A solution to the diffusion problem in the alloy is considered. The experimentally derived composition path in an alloy and the scale is superimposed on the Fe-Ni-O phase diagram. This path is shown to be consistent with the structural observations and composition determinations, and it is also consistent with thermodynamic and kinetic considerations.

In an earlier work (1) the present authors discussed the kinetics and morphological development of the oxide scales formed at 1000°C on Ni-Fe alloys containing 0-25 weight per cent (w/o) Fe. It was demonstrated that continuous and reproducible long-time kinetic curves could be obtained in dry oxygen. Since the over-all reaction kinetics and growth of individual layers followed a parabolic time dependence, it is reasonable to assume that conditions of ambipolar diffusion and local equilibrium at interfaces would occur at this high temperature. Accordingly one may postulate a mechanism based on diffusion through the different phases. The purpose of this paper is to present experimental results for the iron and nickel distributions in the various phases present during the oxidation of these alloys and to rationalize the oxidation kinetics for these alloys on the basis of a ternary diffusion model.

Experimental Procedures and Results

The alloys oxidized contained 0-25 w/o Fe. The samples, which were in the form of $1 \times 2 \times 0.1$ cm plates, were sectioned after oxidation and mounted and polished for metallographic examination and electron-probe microanalyses. Oxidation was carried out at 1000°C in pure oxygen contained in a volumetric apparatus at 400 Torr pressure. Details of the experimental procedures are given in Ref. (1). The nominal and actual compositions of the alloys of interest here are reproduced in Table I.

Concentration profiles of nickel and iron across the samples were determined from samples oxidized for various periods up to 55 hr. The instrument used was a CAMECA MS-24 Model electron microprobe. Counts on Ni and Fe K_α x-rays were taken at regular intervals across the samples and the concentrations were obtained using the pure metals as standards and a procedure described in Ref. (2).

Table I. Compositions of the investigated alloys based upon wet chemical analyses for nickel and iron

Nominal composition	Actual composition	
	w/o Fe	w/o Ni
Ni-2% Fe	1.85	98.15
Ni-4% Fe	4.5	95.5
Ni-6% Fe	6.6	95.4
Ni-8% Fe	8.3	91.7

Key words: Ni-Fe alloys, NiO, $(Ni,Fe)_3O_4$, alloy oxidation, diffusion model.

In a diffusion controlled process, the solutions to the equations are parametric such that all concentrations can be described by an expression of the type

$$C_i = C_i(\lambda);\ \lambda = \lambda(x, t) \qquad [1]$$

where x is the distance coordinate and t is the time coordinate. For parabolic kinetics, the parametric function λ is given by

$$\lambda = x/\sqrt{t} \qquad [2]$$

Hence all concentration profiles are invariant with respect to λ. Accordingly, the experimental results for the metal concentrations across an oxidized sample are plotted against this parameter.

For the scale, a dimensionless parameter, y, is used instead of λ where

$$y = x/x_s \qquad [3]$$

Here x is the distance from the metal/oxide interface and x_s is the total thickness of the external scale. Since the scaling of the alloys follows parabolic kinetics

$$x_s = k\sqrt{t};\ y = x/k\sqrt{t} \qquad [4]$$

Thus y has the same parametric form as λ except for the constant k which is the parabolic rate constant for thickening of the scale.

Concentration profiles for iron across the sample are illustrated in Fig. 1-4 for alloys containing 2, 4, 6, and 8 w/o iron, respectively. The nickel profile is essentially complimentary to that of iron. This is shown for the Ni-6 w/o Fe alloy (Fig. 3). It is seen from these plots that the metal concentration profiles are indeed invariant in λ-space. Profiles at times significantly lower than 50 hr could not be obtained for the Ni-8 w/o Fe alloy due to spalling of the scale upon quenching.

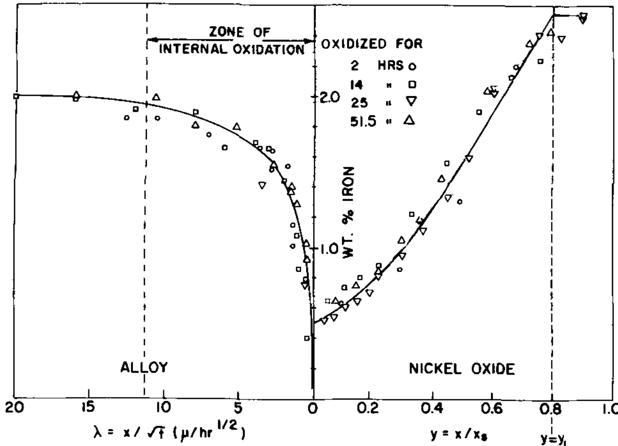

Fig. 1. Concentration profile for iron in alloy and external scale plotted in the λ-space for the Ni-2 w/o Fe alloy.

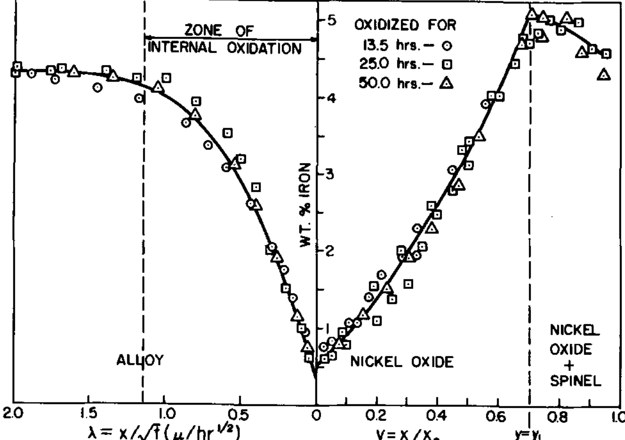

Fig. 2. Concentration profile for iron in alloy and external scale plotted in the λ-space for the Ni-4 w/o Fe alloy.

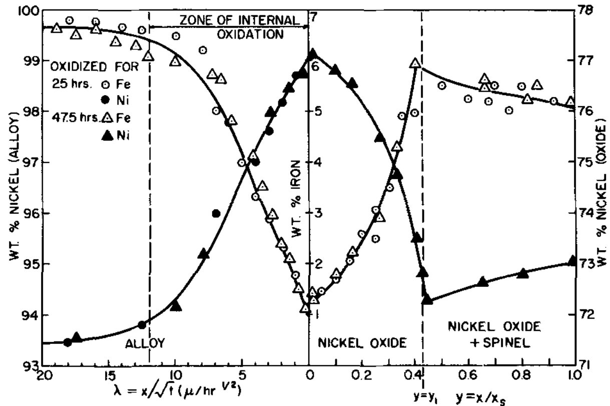

Fig. 3. Concentration profile for iron in alloy and external scale plotted in the λ-space for the Ni-6 w/o Fe alloy.

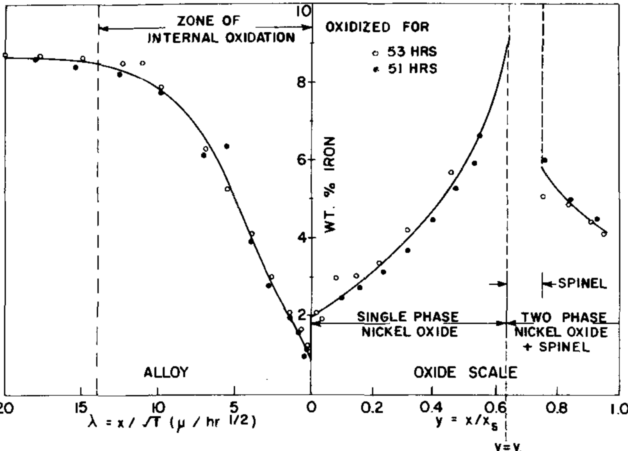

Fig. 4. Concentration profile for iron in alloy and external scale plotted in the λ-space for the Ni-8 w/o Fe alloy.

Four distinct zones could be observed in all samples: the unoxidized alloy matrix, a zone of internal oxidation near the metal/scale interface, an inner single-phase nickel oxide layer, and an outer two-phase spinel-nickel oxide layer. This typical structure is illustrated by the micrograph in Fig. 5 of an oxidized Ni-8 w/o Fe alloy. As can be seen from Fig. 1-4, iron is severely depleted from the alloy in the zone of internal oxidation. Its concentration at the alloy surface was below 1 w/o; this concentration is low enough to stabilize nickel oxide in the external scale (2). The concentration of iron increases toward the outer surface in the nickel oxide layer and it then decreases within the nickel oxide matrix of the outer spinel-nickel oxide layer. Thus iron diffuses against its concentration gradient in the innermost nickel oxide layer and down the concentration gradient within nickel oxide matrix in the outer two-phase layer. This peculiar behavior of iron is discussed in the following sections.

Theory and Analysis

Wagner (3) has published a theory for binary alloy oxidation which applies to situations in which an alloy of metals A and B forms a scale consisting of a solid solution of the corresponding oxides, A(O) and B(O). Coates and Dalvi (4) have reviewed and, to some extent, generalized, Wagner's analysis. The model discussed by these authors can be applied to the present results as it has been done previously for Ni-Co and Fe-Mn alloys (5, 6) with some modification of the boundary conditions for diffusion.

Oxide defect structure model.—Before considering the diffusion model, it is necessary to establish the

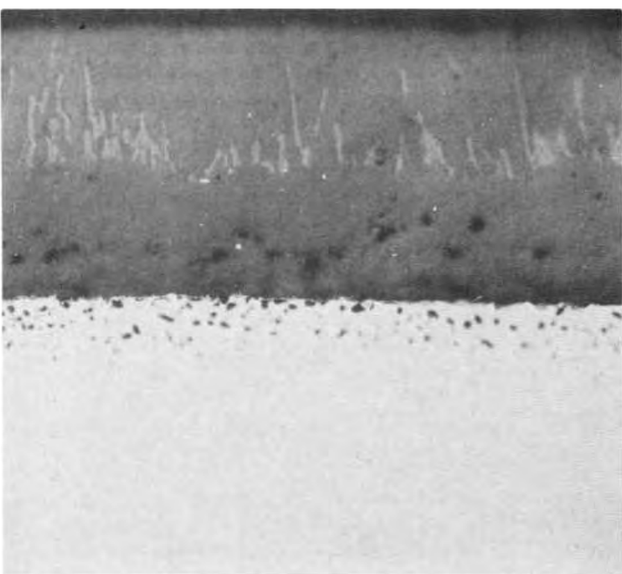

Fig. 5. A cross section of a Ni-8% Fe alloy oxidized for 48.5 hr at 1000°C illustrating the zone of internal oxidation, the inner single phase nickel oxide layer, and the outer spinel-nickel oxide scale layer.

effect of solute cations on the defect structure and consequently on the diffusivities of cations in mixed oxides when the solute cations exhibit variable valence. Zintl (7) has considered the general case for an oxide solid solution containing two transition metals.

If association of positive holes and vacancies may be neglected, the defect equation for a pure p-type oxide AO may be written as

$$\tfrac{1}{2}O_2(\text{gas}) + 2A^{2+}(\text{cation sublattice}) \rightarrow O^{2-}(\text{anion sublattice}) + \square + 2A^{3+}(\text{cation sublattice}) \quad [5]$$

where $\square$ represents a cation vacancy. Substitution of a divalent cation B^{2+} for A^{2+} would sustain electrical neutrality. If the energy required for the formation of trivalent B^{3+} from its divalent cation is much less compared to the corresponding energy for an A cation, then reaction [5] will shift to the right and lead to a higher vacancy concentration. The corresponding reaction for B ion is

$$\tfrac{1}{2}O_2\ \text{gas} + 2B^{2+}(\text{cation sublattice}) \rightarrow O^{2-}(\text{anion sublattice}) + \square + 2B^{3+}(\text{cation sublattice}) \quad [6]$$

For electrical neutrality in the mixed AO-BO oxide

$$2X_{\square} = X_{\oplus} = X_{A^{3+}} + X_{B^{3+}} \quad [7]$$

where X's are atom fractions. If ideal solution behavior is assumed, the variation of vacancy concentration with the composition and oxygen pressure is given by

$$X_{\square} = (K_6/4)^{1/3}(P_{O_2})^{1/6}\xi^{2/3} \quad [8]$$

In Eq. [8] ξ is the mole fraction of the solute oxide BO and K_6 is the equilibrium constant for reaction [6]. It is assumed here that the tendency of the cation A^{2+} to go into the trivalent state is much smaller than the corresponding tendency for the solute cation B^{2+}.

The diffusion coefficient D_M for a cation M^{2+} is given by

$$D_M = D_{\square}(M^{2+})\, X_{\square} \quad [9]$$

where $D_{\square}(M^{2+})$ is the vacancy mobility in the sublattice of M^{2+} ions. From Eq. [8] and [9] we obtain expressions for the self-diffusion coefficients of A and B in the oxide solid solution. Thus

$$D_A = D^{\circ}_A (P_{O_2})^{1/6}\xi^{2/3} \quad [10]$$

$$D_B = D^{\circ}_B (P_{O_2})^{1/6}\xi^{2/3} \quad [11]$$

where

$$D^{\circ}_M = D_{\square}(M^{2+})(K_6/4)^{1/3} \quad M = A, B \quad [12]$$

The proportionality constants D°_A and D°_B thus contain the mobility terms for the respective cations. Equations [10]-[12] are used for the iron and nickel self-diffusion coefficients in (Ni, Fe)O. In this case ξ is the FeO mole fraction.

Diffusion model.—We may give a theoretical basis to our results utilizing the diffusion theory and the thermodynamics of the Fe-Ni-O system. Although the qualitative aspects of the diffusion model are valid for all the alloys, quantitative analysis is attempted only for the dilute alloys. For the underlying assumptions and the mathematical formalism the reader is referred to Ref. (3-5).

As noted earlier, a scale consists of two layers. The outer layer consists of spinel precipitates in a nickel oxide matrix and the inner layer is composed only of nickel oxide. For the purpose of simplifying the mass balance to obtain a tractable mathematical solution, we assume that the amount of spinel in the outer layers of the scales formed on the 2 and 4 w/o Fe alloys is negligible. We also assume that the matrix composition in the outer layer is nearly constant. These assumptions are justified for the dilute alloys from the experimental observations, notwithstanding the observed compositional variations as explained in the following discussion; this is because the observed variations do not affect the mass balance seriously. The proposed diffusion model and the metal concentration profiles are illustrated in Fig. 6.

Although the metal concentrations in the outer layer are assumed constant for the solution of the equations describing diffusion in the inner layer, they can be qualitatively predicted from thermodynamic considerations. There is only one degree of freedom in this two-phase layer from the Gibb's phase rule. Hence specification of the local oxygen activity automatically specifies the corresponding metal concentration from the following reaction

$$3FeO(N) + \tfrac{1}{2}O_2 = Fe_3O_4(S) \quad [13]$$

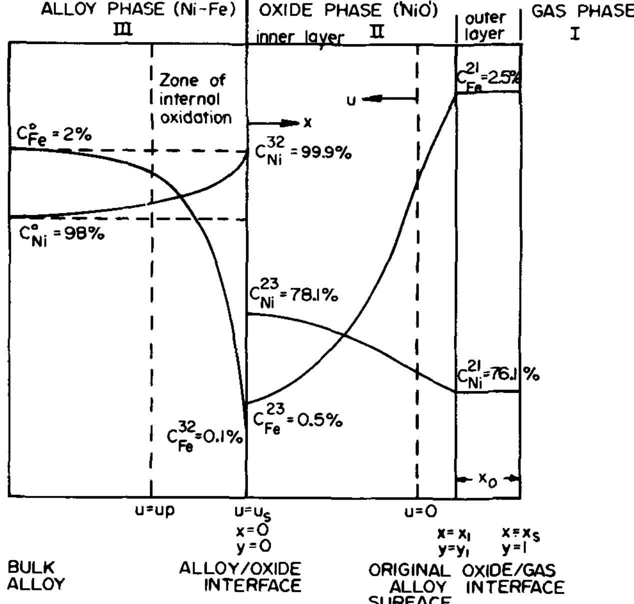

Fig. 6. Diffusion model for the oxidation of a Ni-2 w/o Fe alloy in oxygen at 1000°C. $u = 0$ is the original alloy surface.

where N and S denote the (Fe, Ni)O solid solution and spinel, respectively. The equilibrium constant for reaction [13], K_{13}, is

$$K_{13} = \frac{a_{Fe_3O_4}}{a^3_{FeO} \cdot a_O} \quad [14]$$

where a's denote activities; $a_O \equiv P_{O_2}^{1/2}$. Equation [14] could be rewritten as

$$\frac{(N_{FeO})^3}{N_{Fe_3O_4}} = \frac{K}{a_O} \quad [15]$$

where

$$K = \frac{\gamma_{Fe_3O_4}}{(\gamma_{FeO})^3 K_{13}} \quad [16]$$

$\gamma_{Fe_3O_4}$ and γ_{FeO} are activity coefficients of Fe_3O_4 and FeO in the coexisting $(Ni, Fe)_3O_4$ and (Ni, Fe)O solid solution phases, respectively.

Thermodynamically, with decreasing value of N_{FeO}, the value of $N_{Fe_3O_4}$ also decreases (2, 8). It can be shown that the decrease in the values of N_{FeO} in NiO and $N_{Fe_3O_4}$ in the spinel phase are similar, *i.e.* $N_{FeO} \simeq$ const. $N_{Fe_3O_4}$. Hence, Eq. [15] may be written as

$$(N_{FeO})^2 \simeq K''/a_O \quad [17]$$

N_{FeO} is thus inversely proportional to $(P_{O_2})^{1/4}$ in the outer two-phase layer. Since the values of N_{FeO} and a_O are known in the three-phase spinel-nickel oxide-alloy region (2, 8), the value of K'' could be estimated. For $a_O = 5 \times 10^{-6}$ and $N_{FeO} = 0.15$, $K'' \simeq 10^{-7}$. Hence

$$N_{FeO} = \frac{3.2 \times 10^{-4}}{(P_{O_2})^{1/4}} = \frac{3.2 \times 10^{-4}}{a_O^{1/2}} \quad [18]$$

The observed boundary compositional values for the alloys containing 2-8 w/o Fe are given in Table II. The oxygen activities at $y = 0$ and $y = y_1$ may then be calculated from Eq. [14] and [18], respectively.

Diffusion equations for the nickel oxide layer.—One arrives at Eq. [19] and [20] by an analysis similar to that in Ref. (3-6) using the functional values of D_{Ni} and D_{Fe} as given in Eq. [10]-[12] where Ni $\equiv$ A and Fe $\equiv$ B in the flux equations for these species in the oxide, and applying the mass balance condition at the interface given by $y = y_1$ (see Fig. 6). These expressions are differential equations describing the variation of the mole fraction of FeO, ξ, and oxygen activity, a_O, in the inner nickel oxide layer of the scale

$$\frac{d \ln a_O}{dy} = \left[\frac{k'}{\xi^{2/3} a_O^{1/3}} + (p-1)\frac{d\xi}{dy} \right] \Big/ [1 + (p-1)\xi] \quad [19]$$

and

$$[1 + (p-1)\xi]\xi \frac{d^2\xi}{dy^2} + \frac{2}{3}\left(\frac{d\xi}{dy}\right)^2 + \left(\frac{\xi''}{\xi}\right)^{-1/3} \left(\frac{a_O''}{a_O}\right)^{1/3} \left\{ \frac{y[1+(p-1)\xi]^2 - 2p/3}{(p-1)(1-\xi'')} \right\} \left(\frac{d\xi}{dy}\right)_{y=y_1} \left(\frac{d\xi}{dy}\right) = 0 \quad [20]$$

where y_1 is the value of y, a dimensionless parameter defined in Eq. [3] at the boundary between the inner and outer layers in the scales (see Fig. 6), $\xi'' = \xi(y = y_1)$ and $a_O'' = a_O(y = y_1)$. p is the ratio of jump frequencies of iron and nickel cations, respectively, to an adjacent vacancy. That is

$$p = \frac{D^\circ_{Fe}}{D^\circ_{Ni}} \quad [21]$$

where D°_{Fe} and D°_{Ni} are defined by Eq. [12]. p is assumed to be constant at all concentrations. $k' = k/D^\circ_{Ni}$ where k is the parabolic scaling constant for the external scale defined in Eq. [4].

Equations [19] and [20], which are simultaneous, nonlinear, differential equations in the dependent variables ξ and a_O, can be solved in the same manner as in Ref. (4). The values of the concentrations in nickel oxide obtained as a function of x by the electron microprobe can be converted to mole fractions of FeO and NiO. This yields the boundary values $\xi(y = 0)$ and $\xi(y = y_1)$. The oxygen activity $a_O'' = a_O(y = y_1)$ is obtained from Eq. [18] after substituting the experimental value of ξ, *i.e.*, N_{FeO} at that point. The value of k defined in Eq. [4] is obtained from the experimental weight gain curves (1). The constant k is related to k_p in g^2/cm^4-sec as follows

$$k = (k_p/2)(V/16)^2 \text{ cm}^2/\text{sec} \quad [22]$$

where V is the molar volume of the oxide. Thus for the Ni-2 w/o Fe alloy, $k = 4.44 \times 10^{-10}$ cm²/sec and for the Ni-4 w/o Fe alloy, $k = 6.8 \times 10^{-10}$ cm²/sec. Equations [19] and [20] need only three boundary conditions for the solution; viz., the values of ξ', ξ'', and a''_O, where $\xi' = \xi(y = 0)$ and ξ'' and a_O'' have been defined earlier. However, if an additional boundary condition $a'_O = a_O(y = 0)$ is utilized, these equations yield the value of k' and consequently of D°_{Ni} since

$$k' = k/D^\circ_{Ni} \quad [23]$$

The value of a'_O may be estimated from the oxidation reaction for pure Ni, Eq. [14], as discussed earlier and from the displacement reactions between FeO and NiO. This procedure yields the following expression for a'_O as function of ξ'

$$a'_O = (1 - 0.966\xi')6.7 \times 10^{-6} \quad [24]$$

One of the parameters of the diffusion equations is the ratio, p, of the mobilities of iron and nickel in the nickel oxide layer. We estimate the value of p as follows (7). The self-diffusion coefficients D_M are related to the vacancy diffusivity $D_\square$ and the vacancy concentration by Eq. [9]. For pure nickel oxide, the value of D_{Ni} at 1000°C and $P_{O_2} = 1$ atm is 10^{-11} cm²/sec (9-12). The corresponding value of $X_\square$ at 1 atm is $\sim 10^{-4}$ (13-14). Thus from Eq. [9]

$$D_\square(\text{NiO}) = 10^{-7} \text{ cm}^2/\text{sec} \quad [25]$$

The value of D_{Fe} in FeO in equilibrium with Fe corresponding to $P_{O_2} = 1.32 \times 10^{-14}$ atm at 1000°C is 3.5×10^{-8} cm²/sec (15, 16). The value of $X_\square$ is 0.05 (11). Thus

$$D_\square(\text{FeO}) = 7.0 \times 10^{-7} \text{ cm}^2/\text{sec} \quad [26]$$

Table II. Interfacial compositions for Ni-Fe alloys containing 2-8 w/o Fe, oxidized at 1000°C

Bulk alloy composition (microprobe analyses)	Interfacial compositions			
	Alloy phase		Oxide phase	
	$C(\lambda = \lambda_I)$	$C(y = 0)$	$\xi(y = 0)$	$\xi(y = y_1)$
Ni-2 w/o Fe	1.9 w/o Fe	0.2 w/o Fe ~150 ppm O	0.0068	0.034
Ni-4.3 w/o Fe	4.2 w/o Fe	0.35 w/o Fe ~150 ppm O	0.0069	0.066
Ni-6.6 w/o Fe	6.4 w/o Fe	0.65 w/o Fe ~150 ppm O	0.017	0.075
Ni-8.5 w/o Fe	8.4 w/o Fe	0.9 w/o Fe ~150 ppm O	0.026	0.090

$\lambda = \lambda_I$, position of the boundary between unoxidized alloy and the zone of internal oxidation.
$y = 0$, alloy-oxide interface.
$y = y_1$, position of the boundary between inner single-phase zone and outer two-phase zone.
C, alloy composition.
ξ, mole fraction of FeO in FeO-NiO solid solution.

Table III. Data for the solution of diffusion equations in NiO-FeO mixed oxide and the resultant solution

Ni-2 w/o Fe alloy	
$p = D^\circ_{Fe}/D^\circ_{Ni} = 3$	
$y_1 = 0.8$	
$\xi'' = \xi(y = y_1) = 0.0340;$	$a''_O = a_O(y = y_1) = 1.1 \times 10^{-4}$
$\xi' = \xi(y = 0) = 0.0068;$	$a'_O = a_O(y = 0) = 6.65 \times 10^{-6}$
$k = 4.7 \times 10^{-10}$ cm²/sec	
$D^\circ_{Ni} = 6.7 \times 10^{-8}$ cm²/sec;	$k' = k/D^\circ_{Ni} = 0.0070$
$\left(\frac{d\xi}{dy}\right)_{y=y_1} = 0.0385;$	$\left(\frac{d\xi}{dy}\right)_{y=0} = 0.0148$

These values of $D_\square$(NiO) and $D_\square$(FeO) involve one order of magnitude uncertainties. From Eq. [25] and [26] we obtain

$$p = \frac{D_\square(\text{FeO})}{D_\square(\text{NiO})} \simeq 7 \qquad [27]$$

For iron to accumulate at the outer interface, it is necessary that the ratio p be greater than unity (3). In solving the differential Eq. [19] and [20] the value which resulted in best fit to the data was chosen. This yielded $p = 3.0$.

Using the above values of the various parameters, Eq. [19] and [20] were solved numerically with the aid of a computer to obtain ξ and a_O as functions of y in the scale formed on the Ni-2 w/o Fe alloy. The boundary values and values of required parameters and the resultant solution are given in Table III. The calculated and observed values of ξ as a function of y are illustrated in Fig. 7. The corresponding values of the oxygen activity in the nickel oxide layer are given in Fig. 8. By comparing the value of a'_O obtained from the solution of Eq. [19] and [20] to the value obtained from Eq. [24], the value of k' can be obtained by an iterative process. For this alloy, the value of k' was 0.0070. Since k is known, D°_{Ni} could be calculated. This yields $D^\circ_{Ni} = 6.4 \times 10^{-8}$ cm²/sec.

The above analysis lacks a true experimental closure. This is because p and D°_{Ni} were obtained from the analysis using experimental data as boundary conditions. Equations [19] and [20], however, can be solved for the scale on the Ni-4 w/o Fe alloy with similar assumptions using the same values of the above parameters. The solution obtained should show agreement with the experimental data since the form of these equations remain the same for (Ni,Fe)O formed on the alloys because the ratio of cation jump frequencies remains constant if interaction correlations do not prevail. The various boundary values could be obtained in the manner discussed above. The boundary values, the

values of required parameters, and solution to the equation for the 4 w/o Fe alloy are summarized in Table IV. The calculated and observed values of ξ as a function of the normalized distance parameter y are given in Fig. 9. Excellent agreement is obtained between these values. The corresponding oxygen activity profile is given in Fig. 10. The value of D°_{Ni} was also calculated and for the value $k' = 0.0089$, $D^\circ_{Ni} = 7.8 \times 10^{-8}$ cm²/sec. This value agrees within 25% of the values obtained from the analysis for the Ni-2 w/o Fe alloy.

Diffusion in the alloy.—Estimates may be made for the concentration profiles in the alloy when an internal oxidation zone is present. Kirkaldy (17) has shown that if the variation of oxygen solubility in an alloy with respect to the concentration of the alloying element is negligible, *i.e.*, $dC_O/dC_B << 1$, then the effective diffusion coefficient in the internal oxidation zone is the interdiffusion coefficient of the metallic constituents where diffusion is regarded as being uninfluenced by the oxide precipitate particles. An estimate of this interdiffusion coefficient, D_{alloy}, can be made from the solution of the diffusion equation for the alloying element (iron).

Let the parameter α be defined as

$$u_s = \alpha\sqrt{t} \qquad [28]$$

where u_s is the coordinate of the alloy-oxide interface with respect to the original alloy surface. Therefore α defines the recession rate of the alloy/oxide interface with respect to the original alloy surface. The solu-

tion to the diffusion equation assuming D_{alloy} to be constant is

$$C_{Fe} = C'_{Fe} + (C°_{Fe} - C'_{Fe}) \frac{\text{erfc}\,(x/2\sqrt{D_{alloy}\,t})}{\text{erfc}\,(\alpha/2\sqrt{D_{alloy}})} \quad [29]$$

where x is the distance from the alloy/oxide interface and C'_{Fe} and $C°_{Fe}$ are the concentrations at the alloy/oxide interface and in the bulk alloy (4). Since erfc denotes the complimentary error function, we obtain from Eq. [29]

$$\frac{dC_{Fe}}{d\lambda} = \frac{(C°_{Fe} - C'_{Fe})}{\text{erfc}\,(\alpha/2\sqrt{D_{alloy}})} \cdot \frac{1}{2\sqrt{D_{alloy}}} \exp\left(-\frac{\lambda^2}{4D_{alloy}}\right) \quad [30]$$

where $\lambda = x/\sqrt{t}$

At the alloy/oxide interface, $x = 0$ and hence

$$\left(\frac{dC_{Fe}}{d\lambda}\right)_{\lambda=0} = \frac{(C°_{Fe} - C'_{Fe})}{\text{erfc}\,(\alpha/2\sqrt{D_{alloy}})} \cdot \frac{1}{2\sqrt{D_{alloy}}} \quad [31]$$

If the values of $C°_{Fe}$, C'_{Fe}, $(dC_{Fe}/dx)_{x=0}$, and α are known, Eq. [31] can be solved for D_{alloy}. An estimate for D_{alloy} may now be made from the experimental results for the alloys containing 2 and 8 w/o Fe (1). The values of α for these alloys are 2.4×10^{-5} and 1.8×10^{-5} cm/sec$^{1/2}$, respectively. From the values of $C°_{Fe}$, C'_{Fe}, and $(dC_{Fe}/d\lambda)_{\lambda=0}$ in Fig. 1 and 4, D_{alloy} is estimated to be $\sim 10^{-10}$ cm^2/sec. This value is an order of magnitude higher compared to the literature data (16, 17) but the agreement may be regarded as a first approximation considering the difficulty involved in estimating the value of error functions for large arguments and the approximation made that boundaries between the oxide precipitates and the alloy play no role in the diffusion mechanism.

Oxygen solubility in Ni-Fe alloys and internal oxidation.—No results are available on the maximum oxygen solubility in the solid alloys as a function of composition. This solubility for pure iron and nickel at 1000°C is 3 ppm (18) and 150 ppm (19), respectively. From these terminal values, the oxygen solubility curve for the alloys can be estimated by a method given by Smith (20). Using the Gibbs-Duhem equations for the oxide and alloy phases in equilibrium and the Wagner formalism (21) for the activity coefficients, the variation of oxygen solubility with alloy composition can be determined in terms of the compositions of the alloy and oxide phases and the interaction parameters ϵ_{ij} in the alloy defined by

$$\epsilon_{ij} = \frac{\partial \ln \gamma_i}{\partial X_j} \quad [32]$$

Here, γ_i is the activity coefficient of species i and X_j is the mole fraction of species j. In the limiting case where the oxygen solubility is very small, *i.e.*, $X_O^A << 1$, the slope of the solubility curve is given by

$$\left.\frac{dX_O}{dX_2}\right|_{X_2 \to 0} = [1 - (1 + \epsilon_{12}) X_O^{ox}] \frac{X_O^{o}}{X_O^{ox}} \quad [33]$$

where X_O^o is the oxygen solubility in pure metal 1, and 2 is the solute metal. $X_O^{ox} = 0.5$ for an MO type compound and $X_O^{ox} = 4/7$ for an M_3O_4 compound. This equation may be applied in the nickel oxide-alloy region since the maximum iron content of the alloy is less than 1%. Since $X_O^o << 1$, $dX_O/dX_{Fe} \sim 0$ from Eq. [33], and the oxygen solubility line in this region may be drawn parallel to the Fe-Ni binary axis. Since the Fe-Ni system is nearly ideal (2, 8), the interaction parameters ϵ_{ij} are expected to be small. Grundmann (22) has found the interaction parameter $\epsilon_O^{Ni} = 1.64$ for $N_{Ni} < 0.5$ and $\epsilon_O^{(Ni)} = 3.34$ for $N_{Ni} > 0.5$, in liquid Fe-Ni alloys at 1600°C. These values are expected to increase with decreasing temperature. This interaction parameter, however, would not be expected to be much greater than unity, and the change in oxygen solubility with nickel content over the wustite-alloy region as given by Eq. [33] would be negligible.

The oxygen solubility curve for the alloys based upon the above considerations may be plotted semiquantitatively as illustrated in Fig. 11. This behavior

Table V. Equilibrium oxygen pressures over phases in the Fe-Ni-O system at 1000°C (2, 8)

Equilibrium phases	Oxygen partial pressure, atm
Fe/FeO	1.32×10^{-15}

Fe	(Fe,Ni)O; $N_{FeO} \sim 0.01$	$2 \times 10^{-9} (P_{O_2} = 1$ atm$)$	Present work
O	NiO	5.3×10^{-15}	30

may also be inferred from the corresponding equilibrium oxygen pressures given in Table V. The variation in the oxygen pressure over the nickel oxide-alloy region is small. Its variation over the wustite-alloy region is about one order of magnitude, whereas the variation over the spinel-alloy region is about three orders of magnitude.

The diffusion coefficients of iron, nickel, and oxygen in the various phases are given in Table VI. The diffusion coefficient of oxygen in the metal is more than four orders of magnitude higher than that for iron or nickel. This will result in a steep concentration gradient for the alloying elements (Fig. 1-4) and a shallow gradient for oxygen. For the shape of the solubility curve illustrated in Fig. 11, this will easily result in constitutional supersaturation and hence internal oxidation. Figure 11 also shows schematic virtual diffusion paths for the alloys containing 5 and 20 w/o Fe, consistent with the above consideration. It can be seen from the shape of the oxygen solubility curve in the spinel-alloy region that constitutional supersaturation is readily attained even for this steepest range of the oxygen concentration gradient. As a consequence supersaturation could be easily produced in the alloys investigated (0-25 w/o Fe) with the extent of internal oxidation increasing with increasing alloy iron content.

Composition paths.—The results in Fig. 1-4 show that the concentration profiles in the phases of the oxidized samples are invariant in λ-space. Since a solution of the diffusion equation is parametric in λ, the concentration profile can be transposed onto the phase diagram by eliminating λ. This transposition reflects the condition of mass conservation and monotonic activity gradients for the diffusing species.

A composition path for an investigated alloy is stationary-state oxidation consistent with metallographic and electron-probe observations is shown in Fig. 12. The oxide layer adjacent to the gas contains spinel and nickel oxide since a single phase of nickel oxide containing a high iron concentration cannot be sustained at high oxygen potentials. Below this two-phase layer, nickel oxide exists as the innermost layer in which iron is enriched toward the outer interface due to its higher mobility (corresponding to $p = 3$). The metal-external scale interface corresponds to nickel oxide-alloy equilibrium. The composition path then crosses over to the spinel-alloy region via the three-phase spinel-nickel oxide-alloy region. This corresponds to the internal oxidation zone where the alloy and spinel compositions are given by the corresponding ends of the tielines which are cut. Since the iron content of spinel increases with increasing iron content of the bulk alloy, the spinel particles in the internal oxidation zone are enriched in iron with increasing penetration distance into the alloy. The final segment of the composition path is traversed in the region corresponding to the unoxidized alloy.

This composition path shows monotonically decreasing values of oxygen activity from the outer oxide surface to the bulk alloy, as required from thermodynamic considerations. The flux equations for the cations in the oxide phase from which Eq. [19] and [20] were derived are written in terms of decreasing cation activities toward the oxide/gas interface. Equations [19] and [20] are therefore consistent with monotonically decreasing cation activities outward. Recall that the concentration profiles in the nickel oxide-spinel layer satisfy the thermodynamic relation given by Eq. [18] consistent with a decreasing oxygen activity inward. Interfacial compositions corresponding to the depicted composition path in Fig. 12 for alloys contain-

ing 2-8% Fe are given in Table II from which the actual paths can be estimated.

Application of Eq. [18] to the oxide/gas interface indicates that the wustite content of nickel oxide should be ~0.03 mole per cent (m/o). However, the experimental results (Fig. 1-4) show that the concentration of wustite is much higher, up to within a few microns of the interface. Consequently the iron concentration gradient is extremely steep near the scale/gas interface but its exact shape could not be determined in this region due to experimental limitations. An oxygen activity profile through a section of the oxidation zones of the alloy is illustrated in Fig. 13. It is drawn such that the spinel-nickel oxide-alloy equilibrium occurs at the interface of alloy and the external scale. However, this three-phase equilibrium need not actually correspond to the alloy-external scale interface since a slight amount of nickel oxide containing iron could occur as internal precipitates (as corresponding to the diffusion path illustrated in Fig. 12). This would not significantly affect the oxygen activity at the above interface since the variation in oxygen activity in the alloy-nickel oxide region is very small.

Discussion

In this investigation, Eq. [19] and [20] giving the cation distributions and oxygen activity in the scale were derived from the ternary diffusion analysis. The effect of ternary interactions in causing uphill diffusion of cations is well demonstrated in this system through these equations. The driving force for cation diffusion through the scale is associated with the vacancy gradient caused by the variation in oxygen activity. Although iron diffuses against its concentration gradient in the nickel oxide layer it is actually diffusing down its activity gradient. This situation merely suggests the importance of writing diffusion fluxes in terms of activity gradients in mixed oxide systems. Wagner (3) has postulated a formalism which showed that the cation with the higher mobility (iron in the present case) is the one that preferentially concentrates toward the oxide/gas interface. In a ternary system at constant temperature and pressure, a single phase region has two degrees of freedom one of which is fixed at any coordinate point by the oxygen pressure. The extra degree of freedom thus cannot be fixed by a pure thermodynamic parameter and hence a kinetic parameter (relative jump frequency for cations) comes into play and determines the distribution of cations in the oxide.

The effect of an oxygen activity gradient and the relative jump frequencies of iron and nickel are such

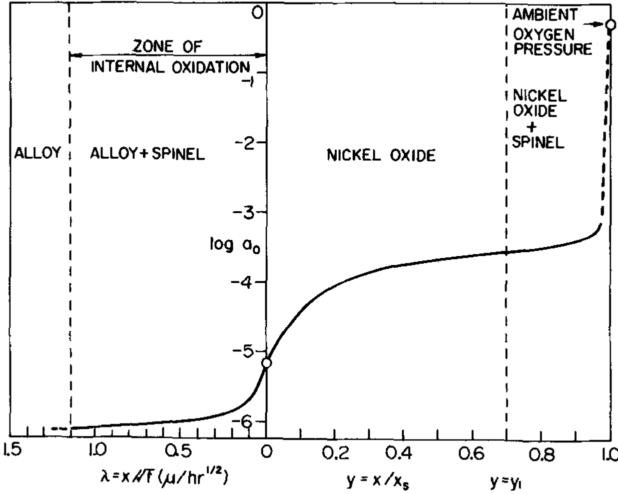

Fig. 13. An oxygen activity profile through a section of the oxidation zones of an oxidized Ni-4 w/o Fe alloy. The dashed section of the oxygen activity profile near the surface of the oxide scale has been extrapolated to ambient oxygen pressure.

as to preferentially concentrate iron toward the outer interface of nickel oxide. However, when this concentration becomes high, spinel precipitates from nickel oxide. The explanation for this is as follows. At very low oxygen potentials iron in nickel oxide is present in the form of ferrous ions. Since this does not require creation of additional vacancies, solubility of iron in this oxide is high at low oxygen potentials (2, 8). Iron tends to pass from the ferrous to the ferric state with increasing oxygen potential. Since nickel oxide cannot incorporate ferric iron in large concentrations without sustaining a high concentration of vacancies, the iron solubility rapidly decreases with increasing oxygen pressure. Iron solubility in nickel oxide is negligible at $P_{O_2} \sim 1$ atm, and correspondingly iron is preferentially concentrated in the spinel phase which can accommodate ferric ion easily in its crystal lattice. Most of the spinel in the external scale appears to be precipitated at a value of the spatial coordinate where nickel oxide first supersaturates with respect to iron (the location nearest the source), and hence the peculiar scale structure seen in Fig. 5.

The experimental closure of the theoretical analysis is not entirely satisfactory. This situation arises mainly due to lack of independent measurements on the relative jump frequencies of iron and nickel in nickel oxide. In the absence of these values, constancy of these parameters has to be assumed for a closure which neglects any correlation effects in the system. Thus it is assumed that the jump frequency of a cation into a vacancy is independent of the composition gradient and that the vacancies do not show preferential affinity for one or the other cation. The extent to which these assumptions are valid for nickel oxide containing dissolved iron is not presently known.

Summary

Ni-Fe alloys containing up to 25 w/o Fe upon exposure to oxygen at 1000°C form by parabolic kinetics a zone of internal oxidation containing spinel particles and an external scale consisting of an inner nickel oxide layer and an outer two-phase nickel oxide-spinel layer. The concentration gradients of iron and nickel in the alloys and reaction product layers could be determined by electron-probe microanalyses. The oxidation phenomena were interpreted by a diffusion model which is consistent with diffusional parameters for the various phases and thermodynamics of the Fe-Ni-O system. The composition paths in an alloy and the scale were superimposed on the ternary isotherm. Sufficient results were available to demonstrate that the ternary diffusion equations in conjunction with a defect model for nickel oxide containing iron quantitatively predicted the cation concentration and the oxygen activity profiles in the nickel oxide layer and the parabolic oxidation constants for the alloys containing 2 and 4 w/o Fe.

A Study of SnO_2 Thin Films Formed by Sputtering and by Anodizing

Enrico Giani and Roger Kelly*

Institute for Materials Research, McMaster University, Hamilton, Ontario, Canada

ABSTRACT

SnO_2 films have been prepared by reactive sputtering in an oxygen-containing glow discharge, by ion-beam sputtering in an accelerator, and by anodizing with an ethylene-glycol-based electrolyte. The sputtered films were amorphous if deposited on KCl or Ta at temperatures from −100° to +200°C, though were crystalline if deposited on SnO_2 at 200°C. The anodic films were variously crystalline or microcrystalline, though clearly nonamorphous. The crystallization temperatures ranged from <200°C for crystalline SnO_2 substrates, to 250°-300°C for KCl substrates, to 400°-450°C for Ta substrates, to 475°-550°C for unsupported films. The crystallization product was consistently cassiterite (*i.e.*, rutile type). The thickness (d) of the reactively sputtered films was estimated by noting the interference colors when using a Ta substrate and assuming the validity of the relation $n_{SnO_2}d_{SnO_2} = n_{Ta_2O_5}d_{Ta_2O_5}$, where n is the index of refraction. The thickness of the anodic films was estimated by sputtering the films with 20-keV Kr ions until metal was exposed and noting the weight change. The anodization of Sn has a rather low efficiency (4-21%), and this could be shown to be due to electronic conduction rather than to dissolution.

SnO_2 is nearly unique among electronic materials in being a fairly good conductor when oxygen deficient yet in having a high degree of transparency to visible light (1). By contrast, oxides such as MoO_3, Nb_2O_5, or V_2O_5 are strongly absorbing when oxygen deficient and therefore conductive (2, 3). This has led to a considerable amount of work on the electrical and optical properties of SnO_2, and has resulted in SnO_2 being proposed, among other things, for transparent heating elements (4), for transparent antistatic coatings (5), and for making transistors or other devices where transparency was required (6, 7).

Typically, three different approaches have been used to form SnO_2 films. (*i*) Most commonly the films have been formed chemically, for example by passing $SnCl_4$ or $SnCl_4$ plus water vapor over a substrate held at 500°-750°C (8, 9) or by a similar procedure involving other volatile tin compounds (9, 10). (*ii*) In other work vacuum evaporation of SnO_2 (11) has been used so as to take advantage of the unusually high vapor pressure (12). Closely related is the reactive evaporation of Sn (9). (*iii*) Finally, SnO_2 films have been successfully prepared by reactive sputtering either of Sn cathodes (6, 13-17) or of SnO_2 itself (18).

There has been an enormous amount of electronic and optical characterization in this work, though notably lacking has been structural characterization. Thus present knowledge is largely confined to two results: chemically deposited layers are invariably crystalline (8-10), while evaporated or reactively sputtered layers are normally (6, 9, 11, 13, 14, 16, 17) though not always (15, 17, 18) amorphous. Evidently the range of crystallization temperatures for supported SnO_2 films lies in the interval between the substrate temperatures used in chemical deposition and those used in evaporation or sputtering. We regard structural characterization to

* Electrochemical Society Active Member.
Key words: tin, thin films, sputtering, anodization, amorphousness.

be nearly as important as other characterization in view of the fact that both the magnitude of conductivity, as well as its temperature stability, are affected by crystallinity. Striking examples of this interdependence occur with V_2O_3 and VO_2 (19).

Also lacking has been virtually any degree of success in producing SnO_2 films by anodizing Sn at high voltages. Work with both acidic (20-22) and basic (23-25) electrolytes has generally involved low voltages ($\leq$ 5V) and never values ($>>$ 5V) characteristic of the growth of thick, uniform, protective films analogous to those formed on Si (26) and Ge (27). More specifically, Hampson and Larkin (21) showed that the capacitances of anodically polarized Sn had values appropriate to perhaps a monolayer of oxide when acidic electrolytes were used. Kerr (23), by contrast, obtained thick films (up to 10^5Å) with basic electrolytes but the films neither showed interference colors nor supported a significant voltage. Only Bianchi (28) appears to have succeeded in polarizing Sn at a high voltage. Using an electrolyte of water with NaOH and potassium silicate he reached 100V, though the film was described as a thick, black crust.

We would propose in the present work to explore the properties of 500-5000Å SnO_2 films as formed by reactive sputtering, ion-beam sputtering, and high-voltage anodizing. These properties will include the crystal form, crystallization behavior, thickness, and anodizing efficiency. Other properties, especially those relating to radiation damage, will be treated separately (29).

Experimental

Reactive sputtering.—The preparation of SnO_2 films by reactive sputtering is an already well-understood process. In the present work the equipment was of the diode type (*e.g.*, 15, 17), with a 50 mm diameter Sn cathode. The substrates, consisting of pieces of chemically polished Al, Ta, or V, or of cleaved KCl, or of air-annealed SnO_2, were laid on a 42 mm diameter anode table placed 30 mm beneath the cathode. The dark-space region of the discharge usually extended about 20 mm away from the cathode when the gas pressure was about 1×10^{-2} Torr. The gas was a 1:1 mixture of oxygen and argon which was purified by being passed through a liquid-nitrogen trap. Applied d-c voltages ranged from 1000 to 3000 and the discharge current was typically 10 mA. Those films which were deposited on KCl could be stripped using water.

Ion-beam sputtering.—SnO_2 films were also prepared by sputtering Sn anodized to 50V with 10-30 keV Kr ions at doses ranging from 25 to 200 μAmin/cm^2. The sputtering was performed using a high-current ion accelerator and collecting the deposit on unheated KCl (30). This method of film preparation involves a vacuum of 10^{-6} Torr and the sputtered particles therefore reach the substrate with their full energy [1-60 eV (31)] and without contamination.

High-voltage anodizing.—Finally, anodizing was considered. The anode was a chemically degreased 20 $\times$ 30 mm Sn sheet, while the cathode was either a 20 $\times$ 30 mm Al sheet or a 23 mm ID Pt cylinder. Previous work (20-25, 28) has shown that water-based electrolytes, whether acidic or basic, do not permit Sn to be anodized to high voltages, and an organic-based one was therefore chosen. It consisted of 330 g/liter of ammonium pentaborate in ethylene glycol which was varied by adding water (subsequently indicated in units of ml/liter). Most films were formed using a preset voltage of 50 and a preset current of 10 mA/cm^2 as obtained with a Hewlett-Packard Model 6186B constant-current power supply.

The difference between electrolytes with different additions of water is brought out in Fig. 1. Electrolyte (a) (0 ml/liter) yields opaque, white films, though the time variation of current and voltage is sometimes unpredictable. Electrolyte (b) (150 ml/liter) gives opaque, gray films. Electrolyte (c) (300 ml/liter) leads

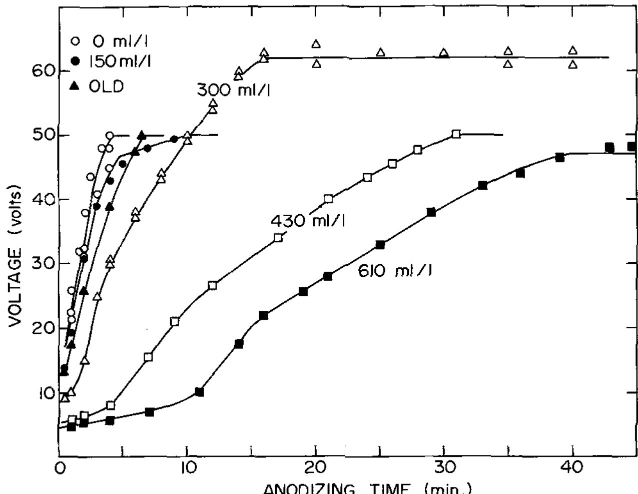

Fig. 1. Voltage-time curves for anodizing Sn at 10 mA/cm^2 in electrolytes consisting of ethylene glycol, 330 g/liter of ammonium pentaborate, and varying amounts (indicated in ml/liter) of water. "Old" refers to an electrolyte containing 300 ml/liter water which had aged owing to use. The upper voltage limit is due to presetting in all cases except "△" and "■", where it is a true upper limit.

to a voltage rise of 50-65 and the films show interference colors over approximately six orders, in agreement with the behavior of most other substances which permit anodizing to high voltages.

Electrolyte (c) is subject to aging, through use or storage. This gives rise to electrolyte (c'), yielding opaque, white films. Electrolyte (d) (430 ml/liter) gives films which show slight interference effects though are better described as opaque, yellowish brown. Finally, electrolyte (e) (610 ml/liter) gives opaque, grayish brown films.

Contrary to previous work, Sn can evidently be anodized in a "normal" manner provided a correct electrolyte is chosen. The normalcy is further shown by the existence of a well-defined fall in current when the preset voltage is reached (Fig. 2).

We have centered our attention on films obtained using electrolytes (c) and (c'), subsequently referred to as "colored" and "white." When necessary, the films were stripped by placing the specimens in 1% HCl for several hours.

Results

Film continuity and crystal form.—The state of the films that were obtained was determined using transmission electron microscopy as well as electron diffrac-

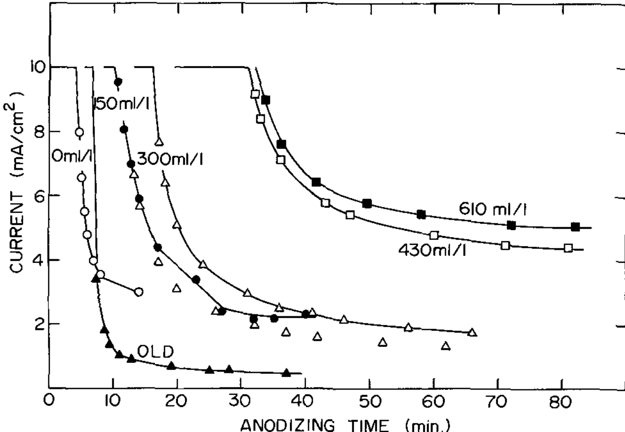

Fig. 2. Current-time curves for anodizing Sn when both current and voltage are preset. The anodizings are the same as in Fig. 1 in all cases except "△" and "■", where the preset voltages are 50 and 40V. Note that, to avoid crowding, only one set of points "△" has been joined.

tion. Some 400 specimens were examined, the main trends being as follows:

(*i*) Reactive sputtering onto KCl substrates at −100°C gave amorphous films, sometimes with an island structure and sometimes continuous (Fig. 3). Though the island structure is not understood, the amorphousness is a reasonable result given that most oxides deposit amorphously at low temperatures (16, 30).

(*ii*) Reactive sputtering onto KCl or Ta at 25° or 200°C, as well as ion-beam sputtering onto KCl at 25°C, gave amorphous films which were continuous (Fig. 4). Apparently 25° and 200°C also constitute "low" temperatures as far as SnO_2 is concerned.

(*iii*) Reactive sputtering onto SnO_2 single crystals or sintered pellets at 200°C gave finely polycrystalline films with the structure of cassiterite. This result is consistent with the ready availability of crystallization nuclei in spite of the temperature being "low."

(*iv*) Colored anodic films, as formed with electrolyte (c), were continuous and showed a characteristic cellular structure with mean dimensions of 200-700Å (Fig. 5). The diffraction pattern was borderline between showing halos and rings, though was judged to be more nearly of a ring type with d spacings corresponding to cassiterite. Note that the grains are much smaller than the cells.

(*v*) White anodic films, as formed with electrolyte (c′), were polycrystalline with the structure of cassiterite (Fig. 6). Though continuous they were characterized by a variation in thickness as if random crystal growth had occurred.

In effect. SnO_2 films can be formed in either an amorphous or crystalline state, the result depending on whether sputtering or anodizing is used, and in addition depending on the substrate and/or temperature.

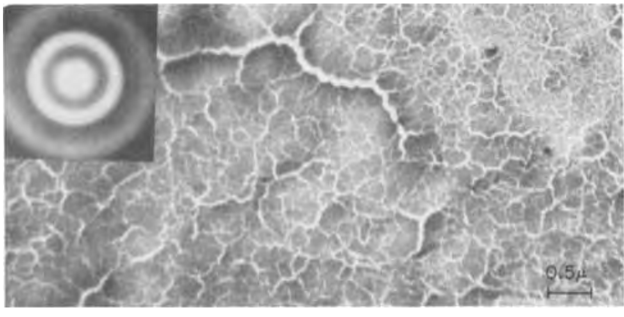

Fig. 3. Micrograph with mag. 22,000 of SnO_2 film formed by reactive sputtering onto KCl at −100°C. The example is amorphous (obvious from the diffraction pattern) and shows an island structure, though in other instances the films were amorphous and continuous.

Fig. 4. Micrograph with mag. 22,000 of SnO_2 film formed by reactive sputtering onto KCl at 200°C. Films formed at 200°C were always amorphous (again obvious from the diffraction pattern) and continuous.

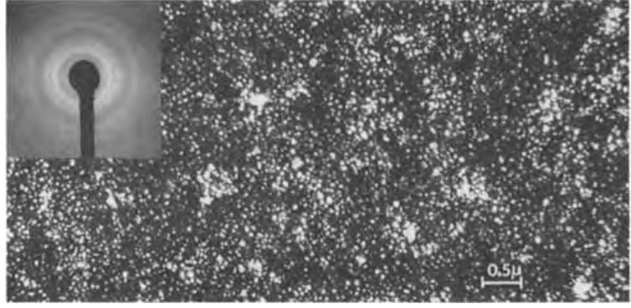

Fig. 5. Micrograph with mag. 22,000 of SnO_2 film formed by anodizing Sn using electrolye (c). The film has a cellular structure on a scale of ~500Å but consists of crystallites on a much smaller scale. The diffraction pattern was judged to be more nearly indicative of crystallinity than amorphousness.

Crystallization behavior.—Amorphous SnO_2 shows four well-defined halos at low angles together with others at greater angles. It was found that these halos persisted when specimens were heated to gradually increasing temperatures (6 min hold times) until they split abruptly to yield the ring pattern of cassiterite. This splitting has been taken as signalling the onset of crystallization, with the main trends as follows:

(*i*) Unsupported amorphous films, whether formed by reactive or ion-beam sputtering, crystallized at 475°-550°C (Fig. 7) to yield grains having sizes of 100-250Å (shown in dark-field photographs). A similar crystallization temperature was obtained for heating both in air and vacum (10^{-5} Torr).

(*ii*) Supported films showed reduced crystallization temperatures, with a value of about 400°-450°C when

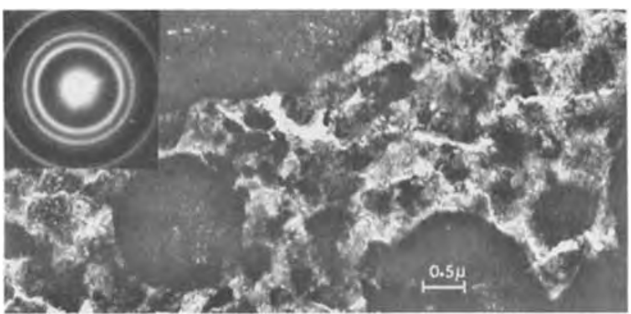

Fig. 6. Micrograph with mag. 22,000 of SnO_2 film formed by anodizing Sn using electrolyte (c′). The film consists in part of thin regions and in part of thick regions, the latter appearing as large black areas. Such films had better defined crystallinity than those of Fig. 5 and the diffraction pattern could be readily shown to be that of cassiterite.

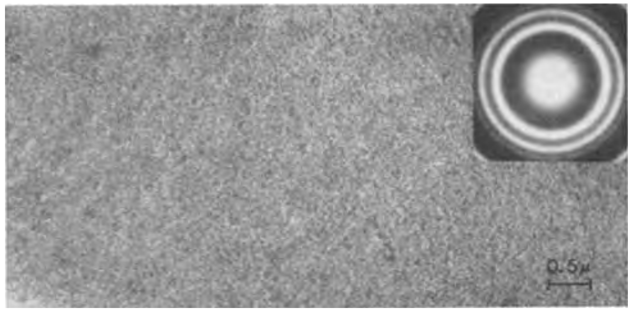

Fig. 7. Bright-field micrograph with mag. 22,000 of SnO_2 film formed by reactive sputtering onto KCl at 200°C. The film was stripped and then heated for 10 min in air at 600°C in an unsupported state. The corresponding diffraction pattern (given) was that of cassiterite, while dark-field views (not given) revealed grains with a size range of 100-350Å.

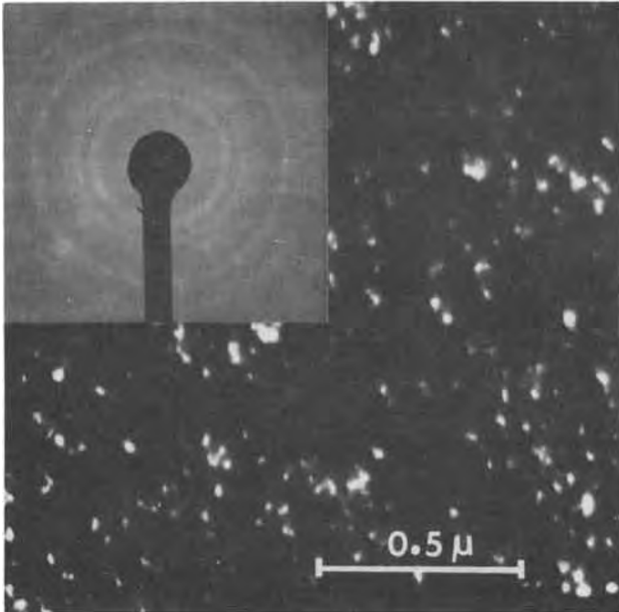

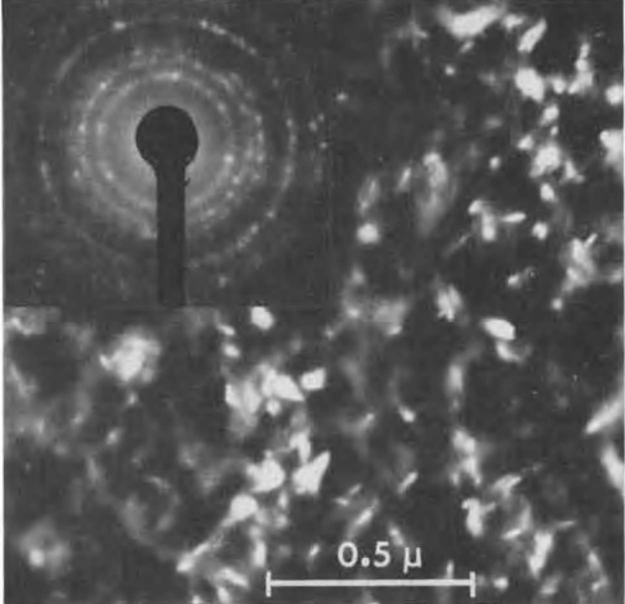

Fig. 8. (a, left) Bright-field micrograph with mag. 54,000 of SnO_2 film formed by anodizing Sn using electrolyte (c). The film was stripped and then heated for 6 min in air at 1000°C in an unsupported state. The diffraction pattern is still best described as consisting of rings. (b, right) As in (a) but dark-field and heated at 1100°C. The diffraction pattern now shows a tendency to be spotty.

in contact with Ta, 250°-300°C when in contact with KCl, and <200°C (thence crystalline as deposited) when in contact with crystalline SnO_2. The grains formed had a broad range of sizes from 200 to 1500Å and were therefore larger than those formed in unsupported films. The differences in crystallization temperature and in grain size suggest that nucleation rather than growth is the rate-controlling step in the crystallization of SnO_2.

(*iii*) Colored anodic films which had been stripped were found to undergo a continuous increase in the sharpness of the rings with increasing temperature. This can be taken as confirming their polycrystalline nature in the sense that an amorphous film would have shown an abrupt increase in ring sharpness.

Higher temperatures led to relatively little change until 1000°C was exceeded. For example, the films retained their island-type or continuous form, the diffraction patterns persisted as rings corresponding to cassiterite, and the grains remained small (*e.g.*, 100-400Å in Fig. 8A). Only once a temperature of 1100°C was reached was there evidence for major grain growth. The diffraction patterns became spotty and dark-field photographs revealed larger grains (*e.g.*, 500-1000Å in Fig. 8B).

Thicknesses of reactively sputtered films.—In order to determine the thicknesses of the reactively sputtered films, substrates of Al, Sn, Ta, and V were included among the KCl cleavings on the anode table. It was hoped that well-defined interference colors would develop, and indeed satisfactory results were obtained with Ta. The colors for SnO_2 on Ta were then described in terms of a voltage such that when Ta was anodized to this voltage the same color was obtained. It was then assumed that the films had a similar "optical thickness," *i.e.*

$$n_{SnO_2} d_{SnO_2} = n_{Ta_2O_5} d_{Ta_2O_5}$$

where n, the index of refraction, was taken as 1.95 for SnO_2 (1) and 2.20 for Ta_2O_5 (32). Since the thickness of anodic Ta_2O_5 is given by 16.7 Å/V (33), we finally have

$$d_{SnO_2} \approx 19\text{Å/V} \qquad [1]$$

where the voltage refers to that to which Ta is anodized. The results are summarized in Table I.

Thicknesses of anodic films.—The film thicknesses on anodized Sn were estimated in several ways. (*i*) They were judged in the first place to be nearly independent of voltage between 6 and 50V on the grounds that the interference colors changed only slightly with voltage for specimens anodized as in Fig. 2. (*ii*) Explicit thicknesses were obtained by measuring the weight increases due to anodizing and interpreting them in the light of the result (see below) that dissolution during anodizing is normally unimportant (column 2 of Table II). (*iii*) Explicit thicknesses were also deduced by a sputtering technique in which anodized specimens are bombarded with 20-keV Kr until the metal is exposed. The thicknesses follow gravimetrically (column 3 of Table II), while one obtains as an extra benefit values for the sputtering coefficient (29).

The inferred independence of thickness and voltage is seen to be fairly well, though not completely, borne

Table I. Thicknesses of reactively sputtered SnO_2 films

Interference color of SnO_2 on Ta	Voltage to which Ta must be anodized to show same color[a]	Thickness of SnO_2 film from Eq. [1] (Å)
Dark blue	24	470
Intermediate blue	40	760
Light blue	48	910
Blue with bit of yellow	54	1030
Yellow with bit of red	80	1520
Purple	85	1620
Yellowish green	120	2280

[a] The Ta was anodized for 3 min in 0.2% KF.

Table II. Thicknesses of anodic SnO_2 films[a]

Anodizing voltage (V)	Thickness as inferred from weight increase due to anodizing (Å)	Thickness as inferred from weight loss due to sputtering (Å)
6	3700 ± 300	3100 ± 300
8	6900 ± 100	6200 ± 600
15	4300 ± 700	4400 ± 400
25	2800 ± 500	3000 ± 300
35	2500 ± 500	4200 ± 400
50	2600 ± 300	4700 ± 500

[a] The current density was initially 6.5 or 10 and finally 2 mA/cm^2. The conversion from $\mu g/cm^2$ to angstroms was made using the assumed value 6.95 $\mu g/cm^3$ for the density of SnO_2; the real density would be somewhat lower.

Table III. Anodizing efficiency

Anodizing voltage (V)	Charged passed (coulombs/cm²)	Anodizing efficiency (%)	Hypothetical weight loss if low efficiency is due to dissolution (μg/cm²)
6	2.7	20 ± 2	600
8	5.25	21 ± 2	1200
15	7.92	10 ± 1	2100
25	8.64	6 ± 1	2500
35	11.8	6 ± 1	3400
50	21.2	4 ± 0.5	6200

[a] The current density was initially 6.5 and finally 2 mA/cm².

out. In fact the films are thickest for a voltage in the vicinity of 8-15, an effect which will be studied in future work.

Anodizing efficiency.—The anodic-film thicknesses are of additional interest in that they enable the anodizing efficiency to be deduced. To this end it is sufficient to compare the film weights as obtained by integrating current-time curves as in Fig. 2 with observed weights. The results are summarized in Table III (columns 2 and 3). The efficiency is 20% for a 6V film but decreases with increasing voltage.

A low efficiency can arise either from electronic conduction or from film dissolution. These can be distinguished firstly from the fact that anodized specimens tended to gain weight approximately as required from the explicit film weights (columns 2 and 3 of Table II). Evidently electronic conduction is occurring, for had dissolution been important there would have been pronounced weight losses as in column 4 of Table III.

The origin of the low efficiency can be shown secondly from an experiment in which a specimen is first labeled with 30-keV Kr^{85} and is then anodized to 50V as in Fig. 2. During the anodizing about 30 ± 10% of the activity is lost from colored films and about 90 ± 6% is lost from white films. Such losses can be expressed in terms of Sn dissolution provided the integral depth distribution of the 30-keV Kr is known. The relevant relation is

$$C^{\text{int.}} \approx \tfrac{1}{2} \operatorname{erfc}\left[\frac{x - \langle x \rangle}{2^{1/2}\Delta x}\right] \quad [2]$$

where $\langle x \rangle$ is the mean projected ion range [10.1 μg/cm² as for CdTe (34)] and Δx is the mean projected ion straggling [5.8 μg/cm² (34)]. This relation is shown graphically in Fig. 9, from which we conclude that the amount of Sn dissolving is 7-21 μg/cm². Such an amount is small compared with the 350 μg/cm² of Sn contained in a 5000Å film and one again concludes that the low efficiencies are due mainly to electronic conduction.[1]

Discussion

Reactive sputtering.—The preparation of SnO_2 by reactive sputtering has a long precedent in the literature and we have little to add, at least from the point of view of preparation as an end in itself. The structural characteristics of SnO_2 films have, on the other hand, been largely neglected. Even such a basic concept as the crystallization temperature has not been previously determined in a satisfactory way. The work has in all cases applied to supported films (where nucleation problems enter) and the temperature was normally given as a limit [*e.g.*, >280°C (9), <400°C (13), <500°C (8)]. The present work suggests that the crystallization temperature depends on the nucleation conditions as governed by the substrate, varying from <200°C for crystalline SnO_2 substrates, to 250°-300°C for KCl substrates, to 400°-450°C for Ta substrates, to 475°-550°C for unsupported films.

[1] Equation [2] is strictly valid only if channeling is minimal. Nothing is known about channeling in Sn, and the estimated dissolution loss of 7-21 μg/cm² should therefore be regarded as a lower limit.

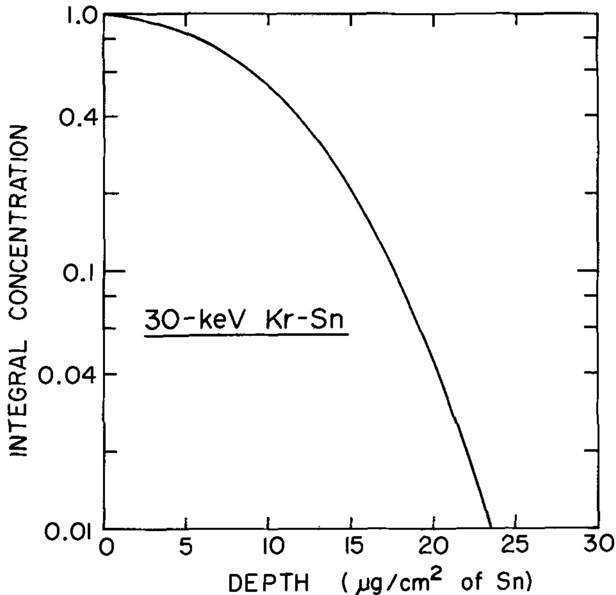

Fig. 9. Integral depth distribution of 30-keV Kr in Sn according to Eq. [2]. The range parameters $\langle x \rangle$ and Δx in Eq. [2] were assigned values as for CdTe (34), which has a mean mass similar to that of Sn.

As far as agreement with other work on SnO_2 is concerned, the range 250°-450°C for crystallization on KCl or Ta substrates is compatible with virtually all previous work (8-10, 13, 15, 16) except that of Hecq and Portier (17) and of Yamanaka and Oohashi (18). The former authors obtained crystalline SnO_2 films at 90°C for sufficiently large anode-cathode separations. The argument was made that the density of nucleation sites should be low (leading to a crystalline film) for low sputtered-particle energies such as would result with large anode-cathode separations. A similar effect may have occurred also with Ref. (18), as the product (pressure) × (separation) was here as large as with Ref. (17).

By way of comparison with substances other than SnO_2, we would first of all point out that certain other amorphous oxides also show a substrate effect. They include the following examples:

oxide	Al_2O_3 (35)	SiO_2 (36, 37)	Nb_2O_5 (38)	Ta_2O_5 (38)
cryst. temp. in contact with metal (°C)	500	700	475	550
cryst. temp. when unsupported (°C)	680	>1300	590	715

SiO_2, GeO_2, and SnO_2 constitute a homologous series and here the main feature to emphasize is that the crystallization temperatures decrease along the series. For example, we have >1300°C for SiO_2 (37) ~630°C for GeO_2 (39), and 475°-550°C for SnO_2 (present work), in all cases for unsupported material.

Anodizing.—While SnO_2 is frequently prepared by reactive sputtering, there is as far as we know no precedent for films being formed by high-voltage anodizing except for the instance in which a "thick black crust" was obtained (28). This lack of success is not really surprising when it is remembered that Mo and V, for example, were long regarded as being incapable of supporting high anodizing voltages yet have been recently found to yield uniform, protective films with thicknesses of ~1200Å at 100V. The key lay in choosing an appropriate nonaqueous electrolyte (40-42). The present work makes it clear that, though the process is far from perfect, high-voltage film growth is readily achieved with Sn. The main problem still to overcome is probably that of exploring alternative electrolytes or anodizing cycles until one is found which yields

Table IV. The crystallization products of amorphous oxides

Oxide	Crystallization product	Stability	Ref.
Al_2O_3	Gamma	Always metastable	(46)
Nb_2O_5	Low temp. form	Always metastable	(47)
Ta_2O_5	Low temp. form	Always metastable	(38)
TiO_2	Anatase	Always metastable	(48)
Bi_2O_3	Cubic	Stable above 717°C	(16)
GeO_2	Hexagonal	Stable above 1033°C	(39)
HfO_2	Cubic	Stable above ~2700°C	(49)
WO_3	Orthorhombic	Stable above 330°C	(16)
ZrO_2	Cubic	Stable above 2285°C	(30)

films which, due either to their structure or to doping, show the expected linearity between thickness and voltage.

Unexpected was the result that anodic SnO_2 is crystalline as formed, for anodic films are nearly invariably amorphous. ZrO_2 appears to be an exception, as it forms in the cubic modification (38), while anodic BeO (43) and TiO_2 (44) are sometimes crystalline. Perhaps there is precedent in the work of Lakhiani and Shreir (45), where normally amorphous anodic Nb_2O_5 was shown to crystallize at high voltages due to voltage breakdown. Alternatively, it is a simple temperature effect governed by the current (43, 44).

The low anodizing efficiency found here for Sn (4-21%) finds a parallel in the behavior of Si and Ge. Thus the value 2% has been quoted for Si (26) and 11-17% for Ge (27). The low efficiency with Sn was attributed to electronic conduction, a result which is not surprising in view of the numerous examples where the carrier densities in SnO_2 films have been found to be nearly as high as in metals. Groth *et al.* (1), for example, found carrier densities of 1-6 $\times$ 10^{20} electrons/cm^3.

Polymorphism in SnO_2.—A consistent result in this work has been that amorphous SnO_2, formed by either reactive or ion-beam sputtering, crystallized to cassiterite. Likewise SnO_2 films formed anodically were cassiterite as formed. In view of the fact that other amorphous oxides often yield metastable or high-temperature phases when crystallized (Table IV), a possible conclusion is that SnO_2 lacks metastable or high-temperature phases. Whether or not this conclusion is warranted will be shown in part when the phase relations of SnO_2 in the still unstudied region above about 1600°C are determined.

Acknowledgments

The authors are grateful to Dr. J. P. Marton (McMaster University) for discussions on the properties of SnO_2 and in particular for having supplied SnO_2 single crystals.

This research was supported by a grant from the Defence Research Board, Ottawa.

Manuscript submitted June 4, 1973; revised manuscript received Aug. 13, 1973.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1974 JOURNAL. All discussions for the December 1974 Discussion Section should be submitted by Aug. 1, 1974.

The Relation Between Environmental pH, Porosity, and the Impedance of Anodic Aluminum Oxide Films

T. A. Libsch and O. F. Devereux*

Department of Metallurgy, Institute of Materials Science, University of Connecticut, Storrs, Connecticut 06268

ABSTRACT

The capacitance and resistance of an electrochemical cell have been measured to determine the effect of the pH (3.6-8.2) of aqueous potassium nitrate and perchlorate electrolytes upon 360Å thick anodic oxide films formed on polycrystalline 99.99% aluminum. While the film has been found to be quite stable upon exposure to electrolytes having pH values in the range 5.1-8.2, frequency dependent capacitance increases and resistance decreases have been observed during a 3000 min test period for cells having electrolytes of pH 3.6. The data for electrochemical cells having 1.0M KNO_3 electrolytes of pH 3.6 have been corrected for the presence of the electrolyte by two electrical analogs. This corrected aluminum cell data represent average anodic oxide film properties. The authors have interpreted the large capacitance increases and resistance decreases of electrochemical cells having an electrolyte of pH 3.6 in terms of the growth of pores in the anodic oxide film. The data for cells having 1.0M KNO_3 electrolytes of pH 3.6 have been quantitatively analyzed as a function of exposure time and frequency by modeling the electrochemical cell as a parallel combination of two parallel RC circuits in series with a third parallel RC circuit. Transmission electron microscopy of films before and after testing supports the interpretation of the data in terms of a porous film structure. Some comments are forwarded on the defect structure of the film before and after environmental exposure.

Oxide surface films, formed in air at elevated temperatures, or formed anodically, provide substrate metals with corrosion protection, but concurrently affect substrate mechanical properties (1, 2). Several investigators (3-7) have proposed the existence of these surface films and their interaction with the environment to play a significant role in the engineering problems of stress corrosion cracking, corrosion fatigue, and creep rupture. Forty and Humble (8) have proposed a repeated film formation-film rupture mechanism to be operative in the stress corrosion cracking of α-brass in ammoniacal solutions. A similar mechanism has been proposed by McEvily (9) for the elevated temperature creep rupture behavior of Cu, Cu-7Al, and Al-Zn-Mg alloys. A more thorough knowledge of environment-surface film interactions is a necessary prerequisite to an understanding of the elusive mechanisms which control these engineering problems.

Previous investigations have revealed that liquid environments are capable of modifying the defect structure of and/or deteriorating anodic oxide films formed on the valve metals. Vermilyea (10-12) has determined that in acidic electrolytes the capacitance of thin niobium, tantalum, tungsten, titanium, and antimony anodic oxide films is a marked function of the electrical potential difference applied across the film during measurement. Vermilyea proposed that these capacitance changes were the result of changes in a space charge which was created by the evaporation of protons at the oxide/electrolyte interface into the oxide film. Anodic aluminum, beryllium, and zirconium oxide films did not exhibit these capacitance changes, presumably due to lower proton mobility. Pryor and co-workers (13-17) have reported the effects of aqueous environments of sodium chloride, sodium fluoride, and sodium chromate on the dielectric properties of anodic aluminum oxide films. These studies suggest that fluoride, chloride, and hydroxyl ions from aqueous electrolytes can penetrate anodic aluminum oxide films by exchange with oxide ions in the film lattice. Pryor and co-workers determined that chromate solutions in the pH range 7-9 uniformly thin the anodic oxide to a passive layer thickness of 20-25Å without modifying the film during the dissolution process. This result enabled these investigators to examine the ionic and electronic resistivity as a function of film thickness, and also the changes in the resistivity-thickness profiles resulting from preexposure of films to other aqueous electrolytes. Richardson *et al.* (18-20) have examined the effect of near neutral chromate, dichromate, chloride, bromide, iodide, fluoride, and sulfate aqueous electrolytes on the dielectric characteristics of anodic and air-formed aluminum oxide films. These investigators found that chromate and dichromate electrolytes heal flaws originally present in air-formed films and thin anodic oxide films to a passive thickness of 25Å. Bromide, chloride, and iodide electrolytes were purported to pit the substrate metal at the base of film flaws. Little attack occurred in sulfate solution, whereas in fluoride the film was rapidly removed and replaced by a complex oxyfluoride.

The aforementioned investigations have been primarily oriented toward the effects which electrolytes of near neutral pH have upon uniform anodic aluminum oxide films. The purpose of the current investigation was to determine the effect of the pH of aqueous electrolytes upon these films (21). Potassium nitrate and potassium perchlorate electrolytes were chosen as environments because potassium, nitrate, and perchlorate ions had previously been reported to be indifferent to the surface of alumina (22). Impedance measurements were made on electrochemical cells having anodized aluminum electrodes as a function of exposure time over the frequency range 5×10^2 to 5×10^4 Hz. A frequency range was utilized since resulting frequency dispersions are useful in analyzing both modifications in the film defect structure and nonuniform film deterioration (14, 15). Platinum specimens were utilized as dummy specimens in order to determine the impedance attributable to the electrolytic double layer, solution, and counterelectrode. The platinum data were subsequently used to correct measurements made on cells having anodized aluminum specimens.

Experimental Procedure

Small cylindrical specimens of 99.99% aluminum and 99.5% platinum were machined and mechanically polished. The surface of each aluminum specimen was stress-relieved by heat-treatment for a short period

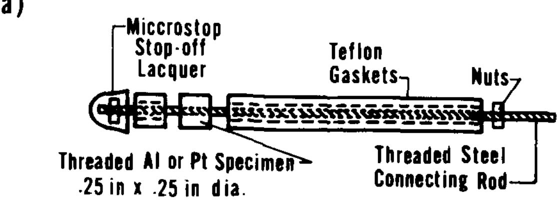
* Electrochemical Society Active Member.

Key words: aluminum, anodic oxidation, impedance, porosity.

at 345°C in argon (23) and subsequently chemically polished using the sodium hydroxide-nitric acid method (24). Electropolishing was avoided as a means of surface preparation due to reports by previous investigators that films formed on electropolished surfaces yield erratic impedance data (18, 20). Electrode assembly is illustrated in Fig. 1.

Anodizing and test electrolytes were prepared with double distilled water and reagent grade chemicals. Several electrolytes, *e.g.*, boric acid (13) and tartaric acid (25), have been used by previous investigators to form barrier layer anodic oxide films on aluminum. The anodizing electrolyte employed in this investigation was that used by McMullen and Pryor (13) and Richardson and Wood (20), *i.e.*, an aqueous 3.0 weight per cent (w/o) solution of ammonium tartrate adjusted to *p*H 7.0 by the addition of several drops of dilute ammonium hydroxide. Three test electrolytes were prepared. The *p*H of 0.1M and 1.0M potassium nitrate solutions was adjusted to values of 3.6, 5.1, 6.6, or 8.2 by the addition of several drops of dilute nitric acid or potassium hydroxide. The *p*H of the 0.1M potassium perchlorate solution was adjusted to the same *p*H values by the addition of several drops of dilute perchloric acid or potassium hydroxide. Test electrolytes were stored under a nitrogen atmosphere to prevent carbon dioxide absorption and resulting *p*H uncertainty (22).

Anodizing was performed in the cell of Fig. 1, which was maintained at 30.0° ± 0.3°C by a constant temperature water bath. The potential between the aluminum specimen and platinum grid counterelectrode was raised to 30V in such a manner that the current surge did not exceed 1 mA/cm^2. The importance of maintaining a current limit in the initial stages of a constant voltage anodizing procedure has not been well established. Many investigators do not report a current limit, and the current limits that have been reported vary widely, *e.g.*, McMullen and Pryor (13) used 5 mA/cm^2, while Smith (26) used 20 mA/cm^2.



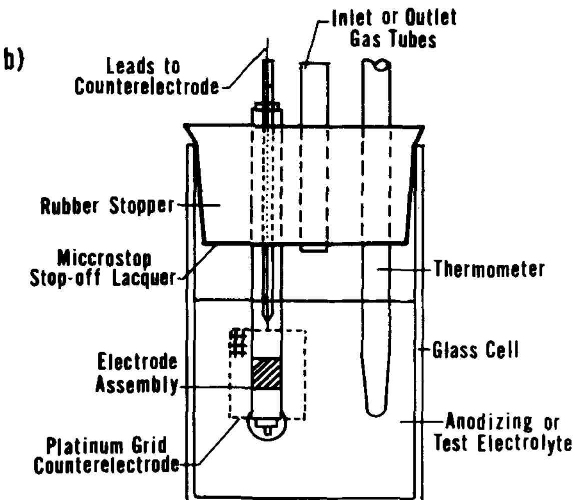


Fig. 1. *(a) Electrode assembly diagram (expanded view). (b) Electrochemical cell used for anodizing and testing.*

The 30V potential was maintained for 45 min during which time the current normally decayed to less than 30 μA/cm^2. Specimens having leakage currents in excess of this value were discarded. McMullen and Pryor (13) have used 20 μA/cm^2 as an upper limit of leakage current for acceptable anodized specimens. This value, however, applies to 99.995% aluminum substrates rather than 99.99% as used in this investigation. Anodization constants for barrier layer anodic aluminum oxide films vary by several Å/V depending primarily on the anodizing electrolyte utilized. Utilizing the anodization constant of 12.0 Å/V determined by McMullen and Pryor (13) for a 3.0 w/o ammonium tartrate electrolyte of *p*H 7.0, the anodization procedure formed a 360Å thick barrier layer anodic aluminum oxide film on the cylindrical aluminum surface. While a film formed in this manner is normally regarded as uniform, several investigators (27, 28) have suggested that a slight tendency exists toward a cellular structure and porosity.

Testing was also performed in the cell of Fig. 1 maintained at a constant temperature of 30.0°C. The dielectric properties of test cells having anodized aluminum or platinum electrodes were measured with a General Radio capacitance measuring assembly consisting of a Type 1310-B oscillator, a Type 1615-A capacitance bridge, a Type 1232-A null detector, a Type 1419-B decade capacitor, and a Type 1434-QC decade resistor. A 2 mV peak to peak signal was applied to the test cell in all cases. Utilizing the test electrolytes of different *p*H values, the dielectric properties of test cells having anodized aluminum or platinum electrodes were measured as a function of applied frequency (½, 1, 5, 10, 20, 50 kHz) and test time (0-4000 min). The terms aluminum cell and platinum cell will be used for convenience in subsequent sections to designate a test cell having an anodized aluminum specimen or a platinum specimen, respectively.

Results

Aluminum cell data.—Negligibly small capacitance increases and resistance decreases were recorded during the 3000 min test period for aluminum cells having electrolytes of *p*H 5.1, 6.6, or 8.2. This result suggests that little film-environment interaction occurs under these conditions. Large capacitance increases and resistance decreases were recorded during the same test period for aluminum cells having electrolytes of *p*H 3.6. Time related capacitance increases and resistance decreases indicate some type of film-environment interaction, *i.e.*, uniform film thinning, nonuniform film deterioration, and/or a modification of the film defect structure.

The capacitance and resistance values for all the aluminum cells are presented in Fig. 2 and 3, respectively. In Fig. 3, the resistance has been plotted as resistance times frequency for graphical convenience. Several general comments apply to both figures. Each figure has been constructed from thirty-six average curves—each average curve being characterized by an electrolyte concentration and composition (1.0M KNO_3, 0.1M KNO_3, or 0.1M $KClO_4$), a *p*H value (3.6, 5.1, 6.6, or 8.2), and a frequency value (½, 10, or 50 kHz). Each average curve was determined from three specimens, except for the average curves determined from cells having 1.0M KNO_3 electrolytes of *p*H 8.2, in which case the average was ascertained from two specimens. In both figures a number of the average curves lie in close proximity; in such cases the curves were condensed into bands. The scatter brackets included represent data extremes except for the scatter brackets on the two curves labeled 0.1, 1.0M KNO_3, 0.1M $KClO_4$; *p*H (5.1, 6.6, 8.2) and 1.0M KNO_3; *p*H (5.1, 6.6, 8.2) in Fig. 3. In these two cases the scatter brackets illustrate the extremes of average curves.

Platinum cell data.—Capacitance and resistance values were measured for platinum cells having 1.0M

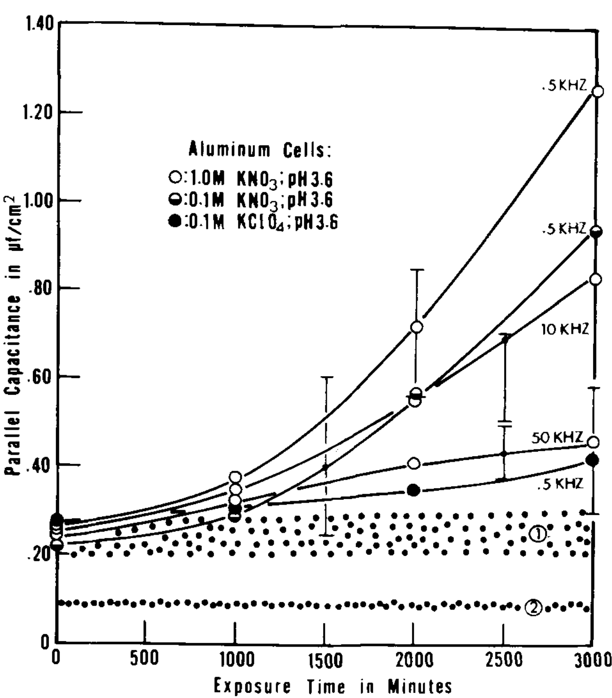

Fig. 2. Average capacitance-time relationships at ½, 10, and 50 kHz for aluminum cells having 1.0M KNO_3, 0.1M KNO_3, and 0.1M $KClO_4$ electrolytes of pH 3.6, 5.1, 6.6, and 8.2. Band 1 contains the averages: 1.0M KNO_3, pH (5.1, 6.6, 8.2), (½, 10, 50 kHz); 0.1M KNO_3, 0.1M $KClO_4$, pH 3.6, 10 kHz; 0.1M KNO_3, 0.1M $KClO_4$, pH (5.1, 6.6, 8.2), (½, 10 kHz). Band 2 contains the averages: 0.1M KNO_3, 0.1M $KClO_4$, pH (3.6, 5.1, 6.6, 8.2), 50 kHz. Error bars typical.

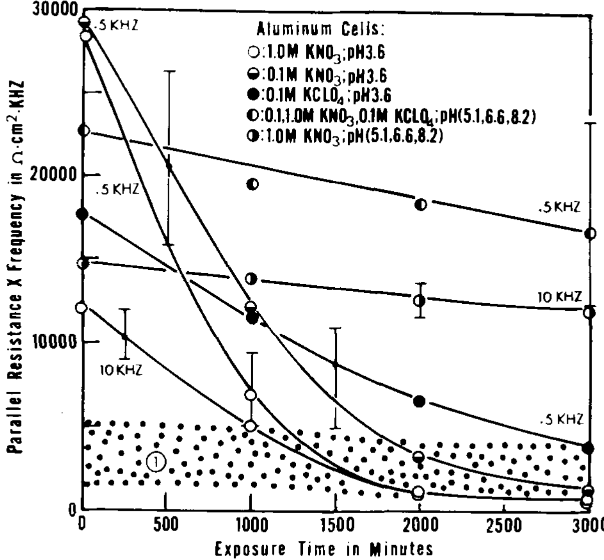

Fig. 3. Average resistance-time relationships at ½, 10, and 50 kHz for aluminum cells having 1.0M KNO_3, 0.1M KNO_3, and 0.1M $KClO_4$ electrolytes of pH 3.6, 5.1, 6.6, and 8.2. Band 1 contains the averages: 1.0M KNO_3, pH (3.6, 5.1, 6.6, 8.2), 50 kHz; 0.1M KNO_3, 0.1M $KClO_4$, pH (3.6, 5.1, 6.6, 8.2), (10, 50 kHz). Error bars typical.

KNO_3 electrolytes as a function of electrolyte pH, exposure time, and applied frequency. No definitive effect of electrolyte pH was observed. At constant frequency, the dielectric properties of platinum cells were observed to stabilize after a short induction period. Frequency effects were pronounced. Table I lists the average steady-state values (4000 min) of parallel capacitance (Cp_2), parallel resistance (Rp_2), and series resistance (Rs_2) on a unit area basis for three platinum cells having 1.0M KNO_3 electrolytes of pH 3.6 as a function of the applied frequency. Rs_2 values were calculated from Cp_2 and Rp_2 values from the equation

Table I. Values of parameters used in Analog 1, Analog 2, and Analog 3

ω (rad/sec)	Cp_2* (μf/cm²)	Rp_2* (ohm · cm²)	Rs_2* (ohm · cm²)	ρ_s* (ohm · cm)
3.14×10^3	11.1	114	6.78	5.17×10^6
6.28×10^3	9.88	49.9	4.70	2.34×10^6
3.14×10^4	5.22	7.00	3.03	2.81×10^5

* Definitions can be found in the list of symbols.

$$Rs_2 = Rp_2/(1 + \omega^2 Cp_2^2 Rp_2^2)$$

These values will be subsequently used to correct and interpret the data of aluminum cells having 1.0M KNO_3 electrolytes of pH 3.6.

An unsuccessful attempt was made to determine the capacitance and resistance of platinum cells having 0.1M KNO_3 and 0.1M $KClO_4$ electrolytes. Proper bridge balances could not be made for these cells at frequencies greater than 10 kHz, presumably due to the fact that the bridge was designed to measure capacitance with resistance as a minor component.

Correction procedures for aluminum cell data.—The authors have corrected the aluminum cell capacitance and resistance because it was necessary to determine the series film resistivity as a function of frequency to explain the capacitance increases and resistance decreases of aluminum cells having 1.0M KNO_3 electrolytes of pH 3.6. Also, regardless of the type of film-environment interaction occurring, the corrected aluminum cell capacitance and resistance values would represent average data for the film alone.

Two analogs were investigated for correcting the aluminum cell data. These analogs, their equivalent circuits, and the notation utilized are illustrated in Fig. 4 under the headings Analog 1 and Analog 2. A complete list of parameters and definitions is provided at the end of the paper. Analog 1 models the aluminum cell as a resistor in series with a parallel RC circuit—the resistor representing the electrolyte and the RC circuit representing the anodic oxide film. Analog 2 is similar but somewhat more sophisticated in that the electrolyte has been modeled as a parallel RC circuit instead of a simple resistance. Both Heine and Pryor (15) and Richardson *et al.* (18), have suggested Analog 2 to represent an aluminum cell of the type utilized in this investigation.

The experimental data recorded for the aluminum cells represent coupled film-electrolyte properties. In order to employ Analogs 1 and 2 the electrolyte properties must be determined in some manner. Richardson *et al.* (18) suggest the three following methods for determining electrolyte properties: (*i*) measurement with a dummy electrode of low impedance, (*ii*) calculation from the cell geometry and specific conductivity of the electrolyte, and (*iii*) extrapolation of a plot of series resistance *vs.* reciprocal frequency to infinite frequency. Both Heine and Pryor (15) and Richardson *et al.* (18) chose to determine electrolyte properties by using a dummy platinum electrode. This technique has also been utilized in this investigation.

The corrected aluminum cell data derived from Analog 1 can be determined from the equations

$$Cp_1 = Cs_5/[1 + \omega^2(Rs_5 - Rs_2)^2 Cs_5^2]$$

$$Rp_1 = 1/[\omega^2(Rs_5 - Rs_2)Cs_5 Cp_1]$$

where Cp, Cs, Rp, and Rs represent the parallel ca-

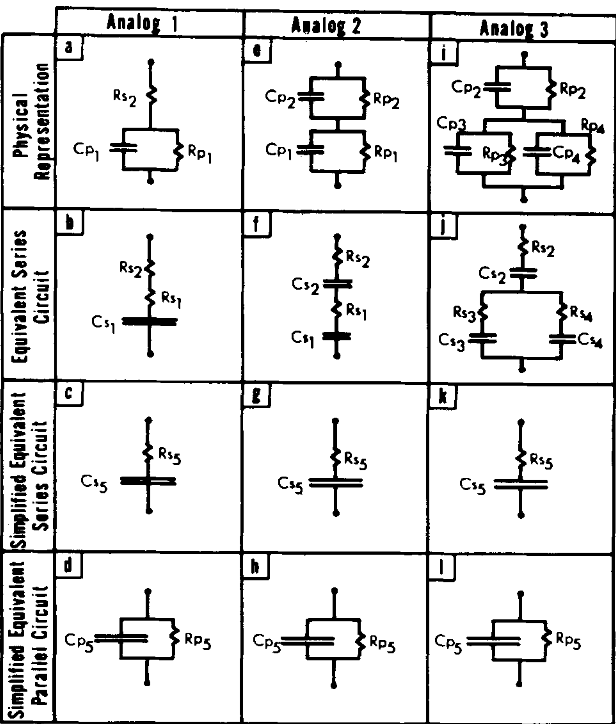

Fig. 4. Electrical analogs, equivalent circuits, and notation. Analogs 1 and 2 have been used to correct the measured aluminum cell data for the presence of electrolyte; Analog 3 has been used to interpret the large capacitance and resistance variations of aluminum cells having electrolytes of pH 3.6.

pacitance, series capacitance, parallel resistance, and series resistance, respectively, and the subscripts 1, 5, and 2 refer these quantities to a corrected aluminum cell, a measured aluminum cell, and a platinum cell, respectively. The corrected aluminum cell data derived from Analog 2 can be determined from the equations

$$Cp_1 = Cs_2Cs_5/\{(Cs_2 - Cs_5)\{1 + [(Cs_2D_5 - Cs_5D_2)/(Cs_2 - Cs_5)]^2\}\}$$

$$Rp_1 = (Cs_2 - Cs_5)/[\omega Cp_1(Cs_2D_5 - Cs_5D_2)]$$

where D represents the dissipation factor and the remainder of the notation is identical to that described above. Calculations for both Analog 1 and Analog 2 were performed on a unit area basis in the MKS system of units.

As mentioned previously, data could not be obtained for platinum cells having 0.1M KNO_3 or 0.1M $KClO_4$ electrolytes. The correction procedure has consequently been confined to aluminum cells having 1.0M KNO_3 electrolytes using the platinum cell data listed in Table I. Figures 5 and 6 show the corrected aluminum cell data derived from both Analogs 1 and 2 for aluminum cells having 1.0M KNO_3 electrolytes of pH 3.6. Both analogs provide the same general corrections listed below. The difference between the corrected and measured aluminum cell capacitance is observed to increase at constant frequency with increasing exposure time, and to increase at constant exposure time with increasing frequency. The difference between the corrected and measured aluminum cell resistance is observed to increase at constant frequency with decreasing exposure time, and to increase at constant exposure time with increasing frequency. The resistance curves for Analogs 1 and 2 are virtually identical and have not been differentiated in Fig. 6.

Discussion

Analog 3.—The interpretation given to the large capacitance increases and resistance decreases observed for aluminum cells having electrolytes of pH 3.6 (Fig. 2 and 3) is based upon the growth of pores in the oxide film. A model has been developed in such a manner as to furnish the average capacitance and resistance of the aluminum cell as a function of exposure time and frequency. Only aluminum cells having 1.0M KNO_3 electrolytes of pH 3.6 have been quantitatively analyzed with Analog 3 because (*i*) data was unavailable for platinum cells having 0.1M KNO_3 or 0.1M $KClO_4$ electrolytes, and (*ii*) little film-environment interaction occurs during the 3000 min test period for aluminum cells having 1.0M KNO_3 electrolytes of pH 5.1, 6.6, or 8.2.

The electrical analog selected to represent the aluminum cell, circuits equivalent to it, and the symbols employed in the analysis are illustrated in Fig. 4 under the heading Analog 3. The physical representation of the aluminum cell is presented in Fig. 4i. The parallel combination of two parallel RC circuits represents the oxide film—one RC circuit represents the region of nonporous film, the other, the pores. The parallel RC circuit in series with the film represents the electro-

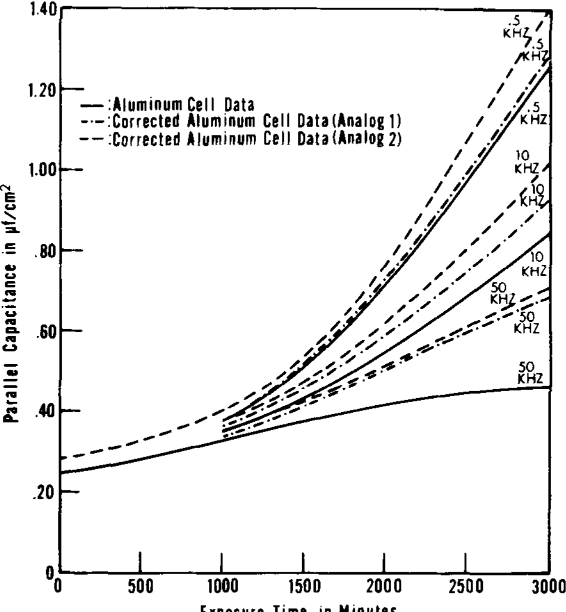

Fig. 5. The average measured and corrected capacitance of aluminum cells having 1.0M KNO_3 electrolytes of pH 3.6 as a function of exposure time and frequency.

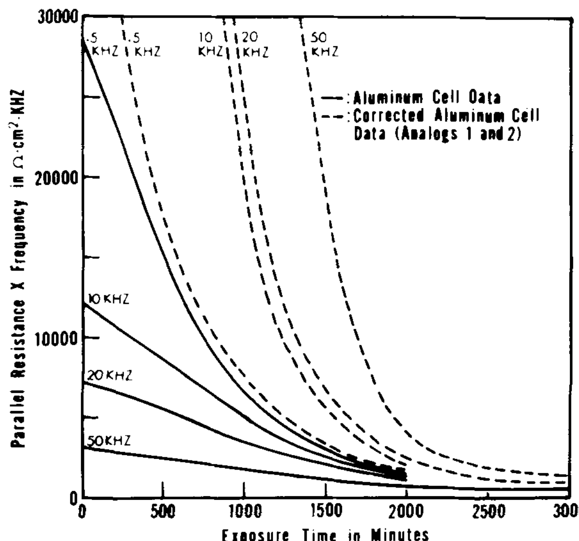

Fig. 6. The average measured and corrected resistance of aluminum cells having 1.0M KNO_3 electrolytes of pH 3.6 as a function of exposure time and frequency.

lyte. Figure 4j shows the equivalent circuit in terms of series capacities and resistances. The following notation has been used in Fig. 4j: Cs_2, Rs_2: series capacitance, series resistance of platinum cell; Cs_3, Rs_3: series capacitance, series resistance of the nonporous area of the film; Cs_4, Rs_4: series capacitance, series resistance of the porous area of the film. Figures 4k and 4l show simplified series and parallel RC circuits equivalent to Fig. 4j. The following notation has been used in Fig. 4k: Cs_5, Rs_5: series capacitance, series resistance of the aluminum cell. Calculations for Analog 3 were performed on the total electrode area (A_5) in the MKS system of units, and subsequently transformed to a unit area basis.

Cs_2 was determined from the measured parallel capacitance (Cp_2) and parallel resistance (Rp_2) of the platinum cell (Table I) from the expression

$$Cs_2 = Cp_2 + 1/(\omega^2 Rp_2^2 Cp_2)$$

The calculation of Rs_2 from Cp_2 and Rp_2 has been described previously. Expressions for Cs_3, Rs_3, Cs_4, and Rs_4 as functions of exposure time (t) were formed in the following manner. Immediately subsequent to immersion in the testing electrolyte the film was considered to possess n cylindrical pores, uniformly distributed, of constant depth, and of zero radii. It was further considered that the radius of each pore (r) grew linearly with increasing exposure time, *i.e.*, $r = R_o t$, where R_o is a radial growth constant for pores. The porous area of the film (A_4) as a function of exposure time is then given by the expression $A_4 = n\pi R_o^2 t^2 = A_o t^2$, where A_o is the rate constant for the growth of the porous area of the film. The nonporous area of the film (A_3) as a function of exposure time is given by the expression $A_3 = A_5 - A_o t^2$, where A_5 represents the total film area. The capacitance and resistance of the nonporous film area (Cs_3, Rs_3) and porous film area (Cs_4, Rs_4) can be given as functions of exposure time by

$$Cs_3 = \kappa\epsilon_o(A_5 - A_o t^2)/d_3$$

$$Rs_3 = \rho_s d_3/(A_5 - A_o t^2)$$

$$Cs_4 = \kappa\epsilon_o A_o t^2/d_4$$

$$Rs_4 = \rho_s d_4/(A_o t^2)$$

where κ is the dielectric constant, ϵ_o the permittivity constant, d_3 the original film thickness, ρ_s the series resistivity, and d_4 the thickness of the film at the pore base.

An a-c circuit analysis (29, 30) of the analogs in Fig. 4j and 4k yields Rs_5 and Cs_5 to be

$$Rs_5 = s_2 \cos\theta_2 + s_3 s_4 \cos\theta_3/(s_3 + s_4)$$

$$Cs_5 = 1/\{\omega[s_2 \sin\theta_2 + s_3 s_4 \sin\theta_3/(s_3 + s_4)]\}$$

where

$$s_2 = [Rs_2^2 + 1/(\omega^2 Cs_2^2)]^{1/2}$$

$$s_3 = d_3(1 + \omega^2\kappa^2\epsilon_o^2\rho_s^2)^{1/2}/[\omega\kappa\epsilon_o(A_5 - A_o t^2)]$$

$$s_4 = d_4(1 + \omega^2\kappa^2\epsilon_o^2\rho_s^2)^{1/2}/(\omega\kappa\epsilon_o A_o t^2)$$

$$\theta_2 = \tan^{-1}[1/(\omega Rs_2 Cs_2)]$$

$$\theta_3 = \tan^{-1}[1/(\omega\rho_s\kappa\epsilon_o)]$$

Cs_5 and Rs_5 of Fig. 4k have been transformed to the parallel capacitance (Cp_5) and parallel resistance (Rp_5) of Fig. 4l and put on a unit area basis by the following expressions

$$Cp_5/A_5 = Cs_5/[A_5(1 + \omega^2 Rs_5^2 Cs_5^2)]$$

$$Rp_5 A_5 = A_5(1 + \omega^2 Rs_5^2 Cs_5^2)/(\omega^2 Cs_5^2 Rs_5)$$

Table I lists the values of the parameters used to analyze the average data for aluminum cells having 1.0M KNO_3 electrolytes of pH 3.6 (Fig. 2 and 3). The parameters listed in Table I, where applicable, represent the average data of three aluminum or platinum cells having 1.0M KNO_3 electrolytes of pH 3.6. The only exception is the series resistivity values which were determined from the corrected aluminum cell data (Analog 2). The series resistivity values were calculated at time zero before the film was subject to nonuniform deterioration.

A computer analysis of Analog 3 was performed in the following manner. First, values for the rate constant for the growth of the porous area of the film (A_o) and the pore depth ($d_3 - d_4$) were selected such that the ½ kHz capacitance-time curve of Analog 3 fit the ½ kHz measured aluminum cell curve in Fig. 5. An A_o value of 1.40×10^{-15} m²/sec² and a pore depth of 320Å yielded good results. Using these values, the frequency dependence of the capacitance and resistance were generated. Figure 7 illustrates the results of the model compared to the average aluminum cell data. The A_o, $d_3 - d_4$ pair utilized in Fig. 7 does not appear to be unique, *i.e.*, for any value of A_o a value of $d_3 - d_4$ can be located such that the ½ kHz capacitance-time curve of Analog 3 fits the corresponding aluminum cell curve. However, the value of the rate constant for the growth of the porous area of the film (A_o) is bounded in that physically it cannot be much greater than 1.40×10^{-15} m²/sec² (corresponding to complete consumption of the area by the pores in 4000 min) and as it decreases the pore depth ($d_3 - d_4$) increases to unrealistic values, *i.e.*, the pores extend nearly to the substrate metal. The frequency dependence remains virtually unchanged for acceptable A_o, $d_3 - d_4$ pairs.

While it is difficult to distinguish in Fig. 7, at time zero the capacitance and resistance of Analog 3 are slightly less than and greater than, respectively, the corresponding aluminum cell data. A more sophisticated model considering the time dependence of radial pore growth to be $r = r_o + R_o t$, where r_o is the initial pore radius, would create somewhat better agreement at time zero while creating a negligible change at greater exposure times.

Consideration of defects at test initiation.—Figure 8 portrays the zero time capacitance-pH relationships for 1.0M KNO_3, 0.1M KNO_3, and 0.1M $KClO_4$ aluminum cells at ½ kHz. Each symbol used in this figure represents the average of the data of three aluminum cells. The symbols have been slightly displaced from pH values of 3.6, 5.1, 6.6, or 8.2 for graphical clarity.

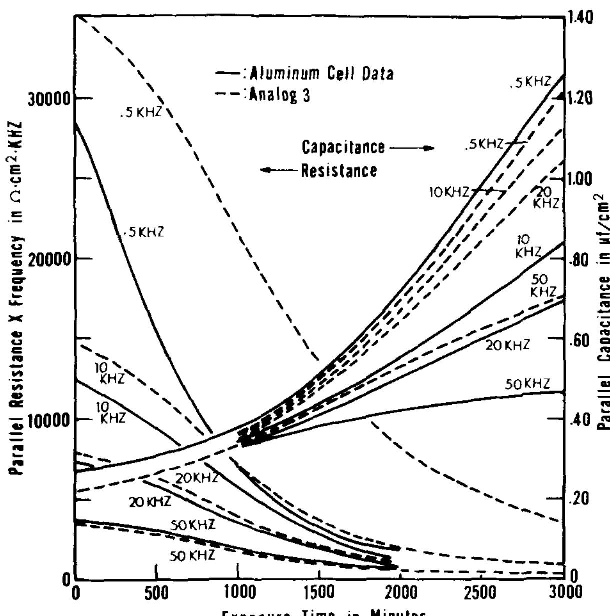

Fig. 7. Capacitance and resistance data calculated from Analog 3 for aluminum cells having 1.0M KNO_3 electrolytes of pH 3.6 as a function of exposure time and frequency. The measured aluminum cell data for these conditions have been added for comparison.

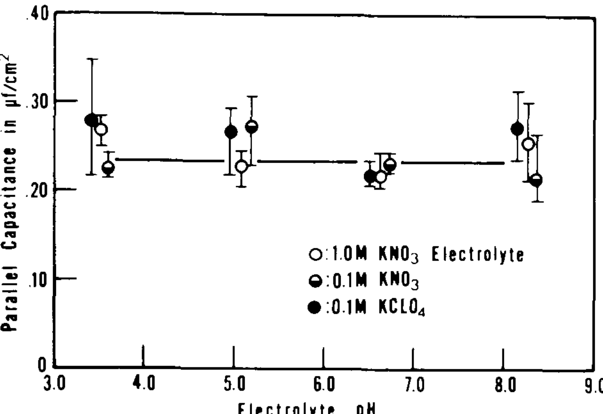

Fig. 8. Capacitance-pH relationship at ½ kHz and time zero for aluminum cells having 1.0M KNO_3, 0.1M KNO_3, and 0.1M $KClO_4$ electrolytes.

The data illustrated in this figure, while that of the aluminum cell, can be regarded with negligible error as that of the film. The corrected aluminum cell relationships in Fig. 5 substantiate this. The capacitance is observed to be independent of electrolyte *p*H. The data scatter present in this figure is attributed to slight variations between specimens rather than to an effect of electrolyte *p*H. This conclusion was drawn by successively immersing one anodized aluminum electrode in electrolytes of the same concentration and composition, but increasing *p*H. No capacitance variations were observed in these tests.

The charge density at the film/electrolyte interface is known to be a function of the electrolyte *p*H (31). One would expect the motion of film defects to become limited as the magnitude of the surface charge is increased, thereby altering the measured film capacitance. Apparently even the maximum surface charge at *p*H 3.6 is insufficient to cause enough defect immobility to be recorded as a capacitance change. The maximum surface charge in an experiment of this type is limited by two phenomena. First, the surface charge is zero at the zero point of charge of the oxide (~*p*H 8.0) (32) and its magnitude increases when the *p*H is either increased or decreased. Second, the *p*H range is practically limited to that studied since electrolytes of very low or very high *p*H cause rapid film deterioration resulting in capacitance variations not associated with defect mobility. The result of the present investigation, *i.e.*, the capacitance is independent of electrolyte *p*H, is in accord with the work of Vermilyea (11) cited previously.

Consideration of defects with increasing exposure time.—Two aspects of the present investigation strongly suggest that the defect structure of the anodic aluminum oxide film is modified upon continued exposure to electrolytes of *p*H 3.6. First, it is apparent by comparison of the derived and measured aluminum cell capacitance curves in Fig. 7 that the growth of film pores cannot fully account for the frequency dispersion of capacitance in the experimental data, *i.e.*, at constant exposure time for any frequency change, the change in the proposed model capacitance (Analog 3) is less than the corresponding change in the measured aluminum cell capacitance. The frequency effect of the model would more closely resemble the experimental data if the model were amended to include the continuous absorption of defects, characterized by relatively long relaxation times, from the electrolyte. Film defects can be generally classified as either ionic or electronic in nature (14). Each ionic or electronic defect has a distribution of relaxation times. There is, however, a mean relaxation time for each defect, and this value is many orders of magnitude greater for an ionic defect than for an electronic defect. Pryor and coworkers (14, 15) have cited slightly less than 10^{-5} sec as an approximate relaxation time for several ionic defects in anodic aluminum oxide films. In order for defects to create any capacitance dispersion in the frequency range under consideration, the defects must necessarily be ionic in nature. As the frequency is increased at a constant exposure time an increasing fraction of the ionic defects will no longer be able to alternate their position in accordance with the applied alternating potential, and their capacitance will thus be lost to the recorded measurement. It is in this manner that absorbed ionic defects can create a capacitance dispersion.

The second aspect of this investigation suggesting a modification of the defect structure is the result of limited reversibility testing of the phenomenon occurring at *p*H 3.6. Reversibility testing has been conducted by transferring anodized aluminum electrodes which have been tested in electrolytes of *p*H 3.6 to electrolytes in the *p*H range 5.1-8.2. This testing indicates that a small fraction of the capacitance increases and resistance decreases are in fact reversible. Continued efforts are being made into the area of reversibility in order to clarify the modifications in defect structure which have occurred. Vermilyea (11, 12), Onoda and deBruyn (33), McMullen and Pryor (13), and Richardson and Wood (20) have previously suggested that ions from an electrolyte may penetrate anodic oxide films resulting in a modification of the film defect structure.

Microscopic examination of films.—It was deemed advisable to test the interpretation given to the large capacitance increases and resistance decreases of aluminum cells having electrolytes of *p*H 3.6 by examining the films microscopically. Freshly anodized and tested films were prepared for transmission electron microscopy by stripping in saturated mercuric chloride solution, rinsing in double distilled water, and mounting on 100 mesh copper screens (34). Mercuric chloride solution is purported to remove the film without deterioration. Transmission electron micrographs (100 kV) of the film before and after a 3000 min test period in a 1.0M KNO_3 electrolyte of *p*H 3.6 are presented in Fig. 9a and 9b, respectively. It should be noted in regard to these figures that light areas in transmission electron microscopy of amorphous films generally represent areas of lesser mass thickness (34, 35). In this regard, the freshly anodized film appears to possess a minor degree of surface roughness as suggested by Franklin (28) and others. The tested film (Fig. 9b) appears porous. Three points should be noted in regard to Fig. 9b: (*i*) the pores are generally cylindrical in shape and many have coalesced after 3000 min exposure time, (*ii*) the darker halos around the pores are presumed to be the result of electron diffraction from the pore walls, and (*iii*) the surface roughness of the freshly anodized films is absent. Considering the pore structure of Fig. 9b in relation to Analog 3, one finds the rate constant for radial pore growth (R_o) to be 1.75×10^{-13} m/sec and the number of pores per unit area (n/A_5) to be $1.80 \times 10^{10}/cm^2$, *i.e.*, $A_o = n\pi R_o^2 = 1.40 \times 10^{-15}$ m²/sec².

Summary and Conclusions

The authors have measured the capacitance and resistance of an electrochemical cell to determine the effect of the *p*H of aqueous potassium nitrate and perchlorate electrolytes upon 360Å thick anodic oxide films formed on polycrystalline 99.99% aluminum. Negligible capacitance and resistance variations were observed over the 3000 min test period for films exposed to aqueous potassium nitrate and perchlorate electrolytes in the *p*H range 5.1-8.2. The authors conclude that little film-environment interaction occurs under these conditions. Large capacitance increases and resistance decreases were recorded during the same test period for electrochemical cells having elec-

trolytes of pH 3.6. At this pH, the dielectric property changes for cells having potassium nitrate electrolytes were greater than those having potassium perchlorate electrolytes. The data for electrochemical cells having 1.0M KNO_3 electrolyte of pH 3.6 have been corrected for the presence of the electrolyte by two electrical analogs. The corrected cell data represent average properties for the film alone. Both analogs show the film capacitance and resistance to be greater than the same properties of the electrochemical cell, the amount of difference varying with the exposure time and frequency.

The authors have interpreted the large capacitance increases and resistance decreases of electrochemical cells having electrolytes of pH 3.6 to be due to the growth of pores within the anodic oxide film. The data for cells having 1.0M KNO_3 electrolytes of pH 3.6 have been quantitatively analyzed as a function of exposure time and frequency by modeling the electrochemical cell as a parallel combination of two parallel RC circuits in series with a third parallel RC circuit. The results of this analog show that the experimental data can be explained by the growth of deep cylindrical pores whose radii are a linear function of exposure time. The interpretation of the data in this manner has been supported by transmission electron microscopy of freshly anodized and tested films. The model and limited reversibility testing indicate that in addition to pore growth, films exposed to electrolytes of pH 3.6 continually absorb defects of ionic nature from the electrolyte.

Optimized Spectral Power Distributions for Mercury Vapor Lamps

Thomas F. Soules and Mary A. Maier

General Electric Company, Lighting Research and Technical Services Operation, Nela Park, Cleveland, Ohio 44112

ABSTRACT

Ways of optimizing the spectral power distribution (SPD) of mercury vapor lamps by adding spectral lines and bands to the discharge spectrum are investigated. The performance of simulated SPD's is judged on the basis of luminous efficiency and color rendition. Maximum performance and the highest value for the color rendition index (CRI) is achieved by adding narrow gaussian bands at 490 and 620 nm to the discharge spectrum. This is true for lamps with colors at 6500°, 4000°, and 3000°K on the Plankian locus. However, for the lower color temperatures, 4000° and 3000°K, it is necessary to filter some of the radiation from the mercury lines in the blue. For maximum efficiency without regard to color rendition, a band should be added around 590 nm. The spectral power distributions of phosphors are also investigated. In addition to the CRI, we evaluated the color rendering ability of spectral power distributions by computing changes in hue, chroma, and value of Munsell color samples under different test sources.

During the past few years a number of papers have been written on optimum spectral power distributions (SPD's) for lamps. White light can be composed of two or more spectral wavelengths of continuous distributions. An optimum spectral power distribution is one having maximum lumen efficiency and good or "preferred" color rendition. Ivey (1) showed that two asymmetric gaussian emission bands give the highest luminous efficiency when the two bands have their peaks near 445 and 580-590 nm. For maximum efficiency, these bands have small widths at half-maximum (WHM). However, this two-component spectral power distribution has poor color rendition. Einhorn and Einhorn (2) showed that for a continuous SPD, restricting the wavelength range from about 440 to 660 nm improves the luminous efficiency without significantly reducing the color rendition. Walter (3) found that good performance, *i.e.*, high luminous efficiency and good color rendition, could be obtained with two-component SPD's consisting of a broad band in the blue-green region and a narrow red band to form white light. Thornton (4) showed that higher luminous efficiency and quite good color rendition

Key words: mercury vapor lamps, color rendition, phosphors.

could be achieved with a SPD consisting of three narrow bands: one in the red at 610 nm, one in the green around 540 nm, and one in the blue near 450 nm. Koedem and Opstelten (5) and Koedem, Opstelten, and Radielovic (6) investigated similar three-line SPD's for high pressure discharge lamps. In these studies the color rendering capability of the light was measured by the color rendition index (CRI) (7).

The purpose of this study is to find the optimum SPD for high pressure mercury vapor (HPMV) lamps. HPMV lamps are used for street lighting and other commerical applications. The SPD's of these lamps are dominated by the atomic mercury lines in the visible region of the spectrum. However, phosphors are used in HPMV lamps to improve color and color rendition. Cadmium and zinc metals and some metal iodides have also been added to the discharge to improve color rendition and luminous efficiency. Hence, it is important to ask, What is the optimum SPD for these lamp types? Ivey (8) found the addition of two phosphor components with emission bands near 445 and 590 nm to yield the highest output for a white HPMV lamp. These same wavelengths were found to give the maximum output for white light in the absence of the visible mercury line spectrum. Wanmaker *et al.* (9) suggested two phosphor components with peaks in the blue-green between 480 and 510 nm and in the red between 610 and 635 nm would increase the CRI of the HPMV lamp to between 60 and 70. In our study, both the luminous efficiency and CRI of SPD's are evaluated.

Method of Calculation

The spectrum of the HPMV lamp was obtained from a prototype 400W lamp manufactured by the General Electric Company. The SPD of the clear mercury lamp is shown in Fig. 1. It consists of the intense atomic mercury lines in the visible region and much weaker continuous emission. When operated at 120V, the lumen output of this lamp was measured at 21,500 lumens. The color rendition of the HPMV lamp is poor. CRI $\approx$ 23.

Using a computer program, one and two spectral lines and bands were added to the SPD of the HPMV lamp. The relative intensity of the added emissions was determined by prescribing suitable chromaticity coordinates for the lamp (1-5).

For each simulated SPD, the four response variables shown in Table I are computed. Q is the quantum conversion fraction. It is the fraction of ultraviolet photons available which are converted to visible radiation. The uv from a 400W mercury vapor lamp was measured between 250 and 420 nm[1] and the results were used to compute the denominator in the expression for Q. (If there is a significant amount of radiation below 250 nm which is transmitted through the arc tube, more photons may be available. However, a reasonable value for Q is probably 0.85. This is the value found for a mercury vapor lamp with a heavy coating of the standard deluxe phosphor.) The color rendition index, CRI, is evaluated according to CIE interim method (10).

Table I. Response variables utilized in this study. Integrals were evaluated numerically between 400 and 700 nm unless otherwise indicated. The effect of the mercury line emission was added separately after the integration.

L.E. (Luminous Efficiency)	$\frac{\int P(\lambda)\bar{y}(\lambda)d\lambda}{\int P(\lambda)d\lambda}$
Lumens	$\int P(\lambda)\bar{y}(\lambda)d\lambda$
Q (Quantum Efficiency)	$\frac{\int P(\lambda)\lambda d\lambda}{\int_{250}^{420} P(\lambda)\lambda d\lambda}$
CRI (Color Rendering Index)	

Results on Adding Gaussian Bands

Data was obtained for all combinations of the mercury vapor lamp SPD plus one and two gaussian distributions.[2] Color temperatures of 3000°, 4000°, 5000°, and 6500°K were investigated. However, the lower color temperatures of 3000° and 4000°K are of greater commercial interest. The added gaussian bands were chosen to have representative WHM of 5, 30, and 100 nm and the peaks were spaced at about 10 nm. Zero, 30, 50, and 70% filters were simulated to remove the indicated amounts of radiation from the mercury discharge between 400 and 450 nm. For the lower color temperatures, 3000° and 4000°K, it is necessary to remove some of the blue radiation from the discharge to attain the color points on the Plankian locus, and as we will show, to obtain high CRI values. The response variables were plotted on graphs, *e.g.*, Fig. 2, which is a plot of CRI *vs.* luminous efficiency. Lamps with maximum performance have the highest values of the CRI and luminous efficiency. Hence, only the outer envelope of points is shown for 3000° and 4000°K SPD's. For SPD's of maximum performance, it is seen that a high luminous efficiency results at the expense of high CRI. As shown in the figure, 3000°K SPD's with the highest values of the CRI have 70% of

[1] The authors gratefully acknowledge the General Electric Company Product Testing Section at Nela Park for making these measurements.

[2] When one gaussian band was added, the intensity was computed for different correlated color temperatures.

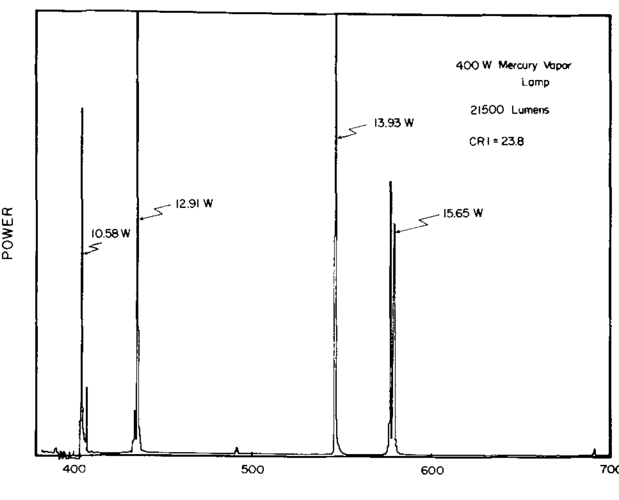

Fig. 1. The visible spectral power distribution of a mercury vapor lamp (400W). Power is measured in units of W/0.5Å. The numbers indicate the total power radiated in the dominant mercury lines.

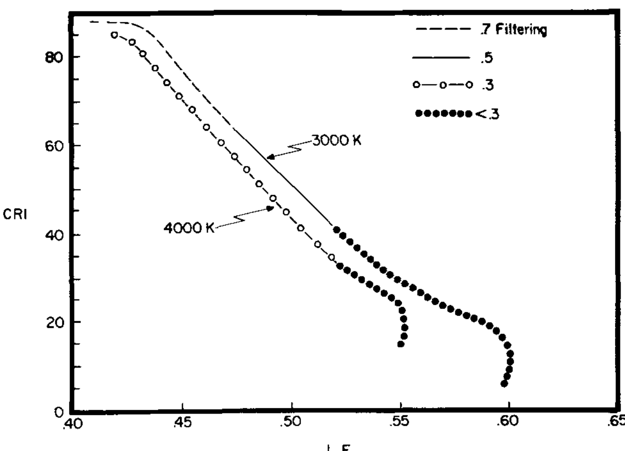

Fig. 2. The effect of adding one or two gaussian bands to the HPMV lamp spectrum. CRI is plotted against luminous efficiency. The envelopes indicate the maximum performance SPD's at 3000° and 4000°K.

the blue radiation from the discharge removed while a high CRI at 4000°K is achieved with about 30% of this radiation removed. Similar results are obtained for higher color temperatures with no filter. For narrow emission bands, Fig. 3 and 4 show the CRI to be a sensitive function of the peak positions of the added bands. The CRI peaks sharply when emission bands are added near 490 and 620 nm. This is true for 3000°-6500°K color temperatures. However, maximum luminous efficiency occurs with the addition of a peak at 580-590 nm and a peak between 450 and 470 nm depending on the color temperature.

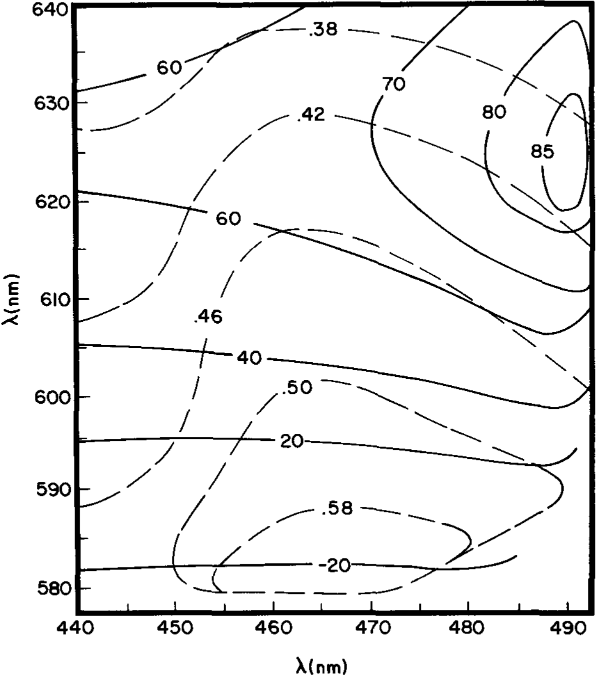

Fig. 3. The effect of adding two narrow gaussian bands to the mercury vapor lamp spectrum to form white light at 3000°K. Contours indicate the value of the CRI (solid line) and luminous efficiency (dashed lines). The x and y axes label the wavelengths of the added emission bands. The bands have a width-at-half-maximum (WHM) of 5 nm. 70% of the mercury radiation in the blue between 400-450 nm is removed.

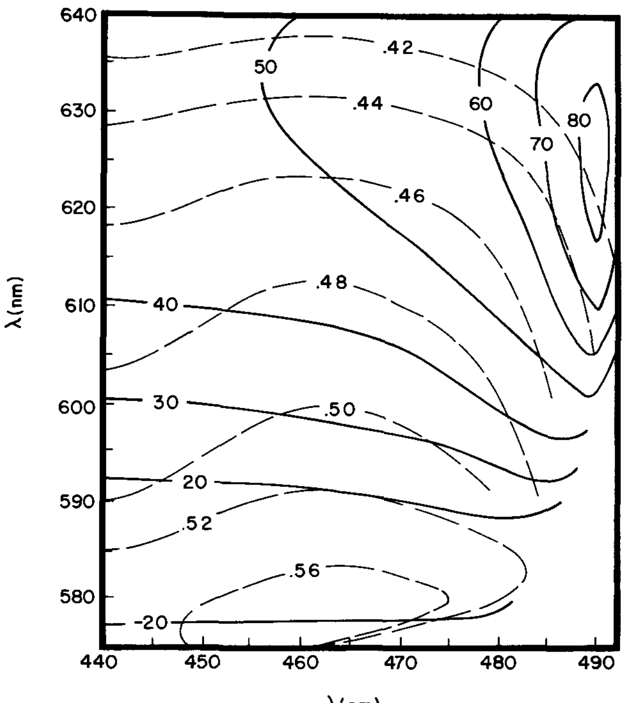

Fig. 4. The same as Fig. 3 for 4000°K. 30% of the mercury radiation in the blue is removed.

Figure 5 shows the spectra of lamps having the highest CRI and maximum luminous efficiency at a source color corresponding to 4000°K. The spectrum with the highest CRI has two narrow bands added at 490 and 620 nm. Broad gaussian bands were not selected for maximum performance. The spectra are, in fact, very similar to optimized five-line spectra found by Mahr (10) to give excellent color rendition and higher luminous efficiency than continuous spectra of comparable color rendition.

The spectrum corresponding to the highest luminous efficiency and maximum performance has a broader band centered at 590 nm (WHM = 30 nm). The single broad band in this case extends the emission into regions of higher luminous efficiency and provides a higher CRI than a narrow band at comparable luminous efficiency.

In Fig. 6 and 7, CRI is plotted *vs.* lumen output, and contours of maximum performance are indicated at different computed values of Q. The figures show that the highest values of the CRI are not attainable for 4000° and 3000°K chromaticities with quantum efficiencies restricted to 1 or less. The maximum CRI is around 65 for both 3000° and 4000°K. For quantum efficiencies between 0.6 and 0.8, the CRI does not significantly improve until a quantum efficiency of near 1 is reached. On the other hand, the lumen output of

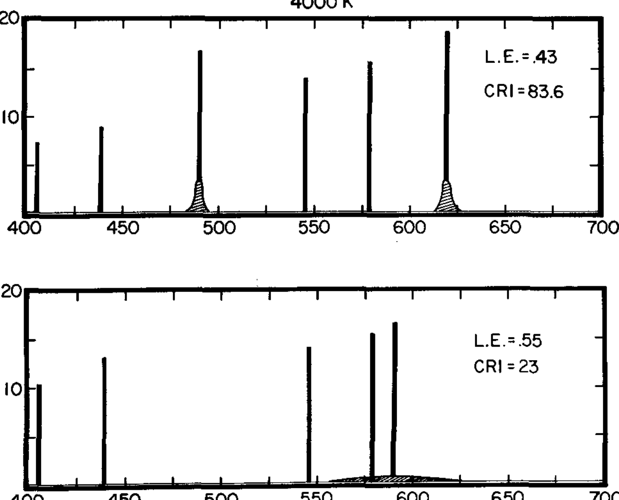

Fig. 5. The spectra giving the highest CRI (top) and highest luminous efficiency (bottom) for a color temperature of 4000°K. The intensities of the added gaussian bands are indicated by the lines above them. The total power radiated in mercury lines and added bands is given on the y-axis (in watts).

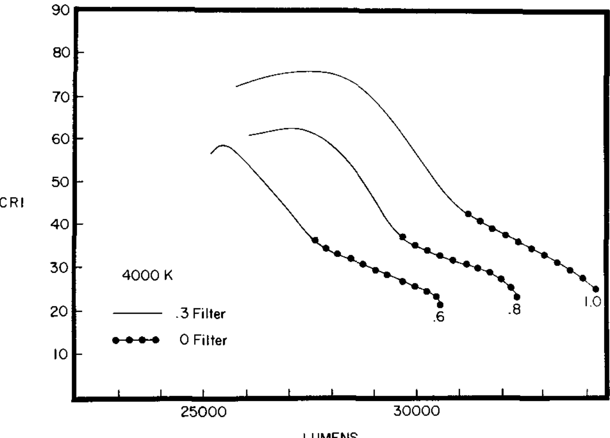

Fig. 6. Envelopes of maximum performance SPD's with contours indicating the quantum conversion fraction for 4000°K.

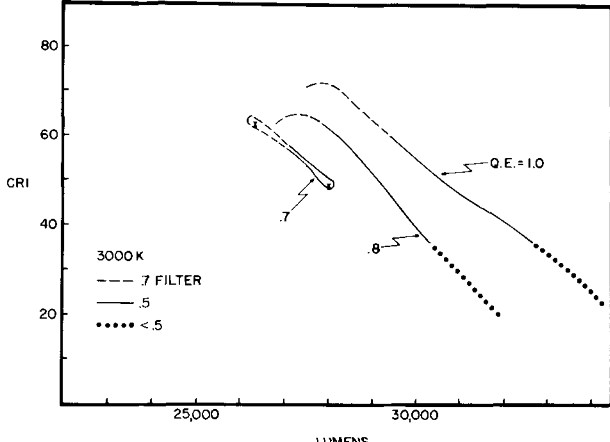

Fig. 7. Envelopes of maximum performance SPD's with contours indicating the quantum efficiency for 3000°K.

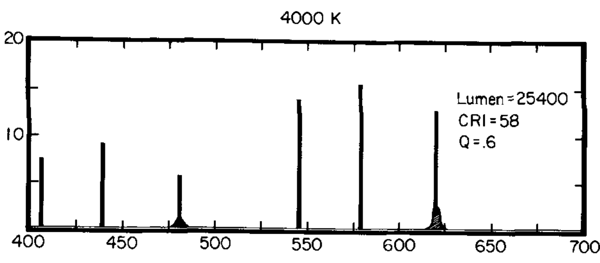
the maximum performance SPD's increases significantly for both color temperatures with increasing quantum efficiencies. Efficiencies up to around 80 lumens/W are theoretically possible if the quantum efficiency of 0.8 is reached.

In Fig. 8 we show the spectrum with maximum color rendition and lumen output for a lamp at 4000°K with the quantum efficiency restricted to 0.6 or less. In general, restricting the quantum efficiencies reduces the intensity of the red emission and the blue-green emission in SPD's with the highest CRI. The blue-green emission also moves to shorter wavelengths.

If the quantum efficiency is restricted to ~0.7 for a 3000°K lamp, the choice of emission bands is very limited. All the radiation must be added in the red region to color-correct the mercury lamp. Maximum lumen output is achieved with a narrow band peaking near 610 nm. Higher CRI is attained by shifting the band just slightly toward 620 nm and filtering more of the blue radiation from the discharge. Broad red bands cannot be used nor can emission bands at wavelengths longer than 620 nm. These will not sufficiently shift the color of the mercury lamp. Except for the filtering in the blue, these spectra are very similar to the standard deluxe white lamps.

Discussion

Phosphors employed in HPMV lamps must: (*i*) be efficient at the operating outer bulb wall temperature which for a 400W lamp is between 300° and 400°C



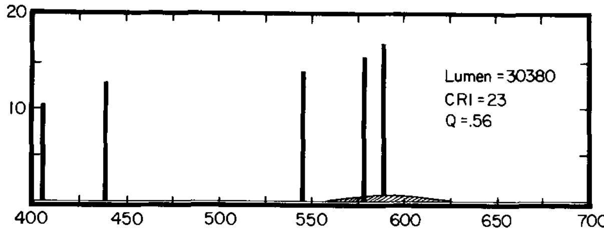


Fig. 8. The spectra corresponding to maximum CRI (top) and maximum lumen output (bottom) for 4000°K lamps with the quantum conversion fraction of added emission bands limited to Q <0.6.

and (*ii*) be excited by the long wavelength ultraviolet radiation of the high pressure mercury discharge. Because of these limitations, only a few practical phosphors for such applications are known today. Table II shows a list of phosphors considered in this study. Not all of these phosphors are equally suitable for use in HPMV lamps but they do give a range of peak positions and half-widths in the red and blue regions of the spectrum.

Calculations were performed in which all possible combinations of one and two of these phosphors are taken together with the mercury discharge spectrum for lamp colors at 3000° and 4000°K. No account was taken of absorption of visible radiation by the phosphor except in the case of the Mn^{4+} activated magnesium germanate. Magnesium germanate and a similar magnesium arsenate phosphor have significant absorption in the blue region of the spectrum. To study phosphor combinations including the magnesium germanate phosphor, two lamps were made with different weights of the germanate phosphor. The spectral power distributions of these lamps were then used in combinations with the other phosphors.

The optimum spectral power distributions cannot be achieved with the existing commercial phosphors in Table II. In fact, our computed results show that the maximum lumen output with a relatively high CRI is attained with the standard deluxe phosphor for color temperatures of 3500°-4000°K. A higher lumen output at some expense to color rendition should be achieved by adding a yellow emitting phosphor in combination with the yttrium vanadate-phosphate phosphor. The calculated results show that the $Dy^{3+}:YVO_4$ phosphor may be used for this purpose. However, in practice, the Dy^{3+} activated phosphor is much too inefficient.

The merits of adding a blue or blue-green emitting phosphor are questionable. Combinations employing the europium-activated strontium chloraphatite phosphor and the standard deluxe phosphor give only a small improvement in the CRI, 43 *vs.* 38, at a color temperature of 4000°K. Values of the CRI of 50-52 are achieved with blends containing the tin-activated, pyrophosphate or the strontium chlorosilicate phosphor together with the standard deluxe phosphor. However, color temperatures are generally greater than 4000°K. Also, a rather high quantum conversion fraction, $Q \geqq 0.9$, is computed for combinations with either phosphor. A mixture of the chlorosilicate phosphor, the standard deluxe phosphor, and either a filter to remove 30% of the mercury radiation in the blue or the Mn^{4+}-activated phosphor, whose SPD strongly resembles Fig. 8, requires a quantum conversion fraction of 1.3 when real phosphor emission bands are used.

On the other hand, values for the CRI of approximately 50 can be achieved at lower color temperatures, 3500°-3100°K, with combinations consisting of the standard deluxe phosphor and either the Mn^{4+}:magnesium germanate or magnesium arsenate or a filter for some of the blue radiation from the discharge. The Mn^{4+} phosphors have the additional advantage of using the radiation in the blue mercury lines and re-emitting it in the red, making the lower color temperatures possible. Blue or blue-green phosphors cannot be used if the lower color temperatures are desired.

Table II. Phosphors whose spectra were used in the calculations

Phosphors		
Description	Main peak (nm)	Range (nm)
$Eu^{3+}:YVO_4:YPO_4$	618	617-620
Mn^{4+}:magnesium germanate	660	625-676
Sn^{2+}:strontium orthophosphate	630	570-700
$Dy^{3+}:YVO_4$	575	565-585
Eu^{2+}:strontium chloroapatite	450	435-465
Eu^{2+}:strontium chlorosilicate	485	450-530
Sn^{2+}:strontium pyrophosphate	465	410-525

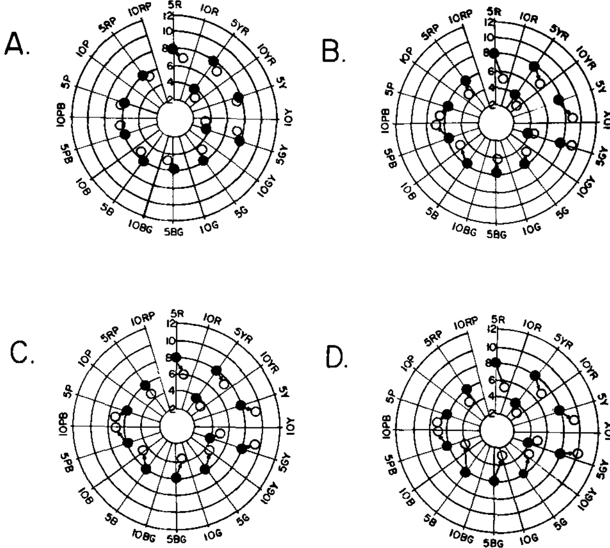

Fig. 9. Calculated color shifts of twelve Munsell samples under four different SPD's whose color coordinates are at or near 4000°K. A, The SPD in Fig. 5 (top) consisting of HPMV lamp and two narrow gaussian bands at 490 nm and 620 nm; B, the SPD in Fig. 8 (top); C, a simulated deluxe lamp with the standard deluxe phosphor plus Mn^{4+}: magnesium germanate; D, a commercial deluxe white lamp with a heavy coating of the deluxe phosphor. The open circles show the color shifts relative to a 4000°K Plankian illuminant. Color shifts are calculated as described in the text.

In Fig. 9, we show color shifts for some of the spectral power distributions investigated on hue *vs.* chroma Munsell diagrams. The CIE color coordinates, X, Y, and Z, were calculated in the usual way for Munsell color chips under both the reference and test illuminants. The color coordinates are then transformed to Munsell color space using the modification of Adam's "chromatic value space" given by Saunderson and Milner (11). The set of Munsell color chips is the same as that chosen by Eastman, Allen, and Brecher (12). These colors were chosen to span the entire hue circle plus the CIE colors representing foliage (5GY4/14) and skin complexion (5YR8/4).

Color shifts on the Munsell diagram were computed to give a more complete description of the color rendering properties of SPD's studied. The CRI is a single number representing the average displacement of eight CIE colors on the uv diagram relative to a Plankian reference source.

The Munsell color space has the advantage of being more uniform than the CIE-UCS and being familiar to most workers in the field of color. It also has the advantage that the source color is always at the center of the cylindrical color system. A von Kries type of transformation to correct for chromatic adaptation to different source colors is built into the transformation to chromatic value space. The consequences of chromatic adaptation to different source colors have been investigated by many workers using different experimental methods (13-16) although corrections for chromatic adaptation do not agree (6, 16). In a future report, we will show that some of the results of recent experiments by Eastman and Brecher (17) and Eastman, Allen, and Brecher (12) to measure the effects of chromatic adaptation are accounted for by the transformation to chromatic value space. On the other hand, chromatic adaptation is not accounted for on the CIE-UCS except by simply subtracting the difference in source colors.

In Fig. 9, the test lamp colors are at or near 4000°K. The reference illuminant is a 4000°K Plankian radiator.[3] Figure 9A shows that the SPD with the high CRI, shown in Fig. 5, shifts the Munsell colors only very slightly relative to their appearance under the Plankian radiator. This is true even though the source in Fig. 5 is very much different from a Plankian radiator and, in fact, has no broad emission bands. The color chips shown in the figure are a greater sampling of the entire hue circle and are more saturated than those used in computing the CRI. They would be expected to emphasize differences between the test and reference illuminants.

Figure 9B shows the calculated color shifts under the spectral power distribution given in Fig. 8. Unlike the results for the high CRI SPD, colors viewed under this test source are significantly different from when viewed under a Plankian radiator illuminant. Reds become much less saturated and shift in hue toward the yellow as a result of the decreased emission in the added red band. The shift of the chip representing flesh tones toward the yellow-red region is probably undesirable (18). Blues and blue-greens are shifted toward the deeper blue colors of the mercury lines. Also, most of the colors appear less saturated or shifted toward lower chroma values than under the Plankian radiator. Only the yellow and yellow-green colors appear more saturated or more vivid. The shift of the foliage chip toward a deeper and more saturated green is probably not undesirable (18).

Figures 9C and 9D show calculated color shifts from two phosphor coated HPMV lamps. The two SPD's include: (C) a simulated combination of the standard europium-activated yttrium vanadate-phosphate phosphor and the Mn^{4+}:magnesium germanate phosphor and (D) an SPD from a commercial lamp with a heavy coating of the deluxe phosphor. Neither SPD has any added emission in the blue or blue-green region. Most of the color shifts are the same as those discussed above for Fig. 9C. The only color chip which appears to be better rendered by the blue-green emission is 5BG6/6. When comparing the two phosphor coatings, the phosphor blend consisting of the standard deluxe phosphor and the Mn^{4+}-activated phosphor which also filters some of the blue radiation from the discharge, appears to be somewhat better in its color rendering ability.

Conclusions

Various ways of optimizing the SPD of HPMV lamps were investigated by computer calculations. By adding gaussian emission bands of varying position and half-width, we found that emission bands located near 490 nm in the blue-green and 620 nm in the red region of the spectrum result in the greatest improvement in color rendition. In fact, excellent color rendition and good luminous efficiency are achieved if sufficient radiation can be added in narrow bands in these regions. For lamps with the color temperatures of 4000° and 3000°K, it is necessary to remove some of the discharge radiation in the blue region. The highest luminous efficiency is not obtained with the red and blue-green emission bands but rather by the addition of radiation near 590 nm.

Present commercial phosphors do not provide the optimum SPD for a HPMV lamp. While the $Eu^{3+}:YVO_4:YPO_4$ phosphor is a natural choice for providing some of the red emission in order to improve the color rendition of the lamp, it is not clear whether a blue-green emitting phosphor should be used, especially if low color temperatures are desired. Little effort appears to have been made in finding a yellow emission source to provide a lamp with considerably higher luminous efficiency.

By calculating changes in hue, chroma, and value for Munsell colors, we provide a more complete description of the color rendering properties of the SPD's studied. In general, the effects of colorimetric shifts can be calculated for lamps which vary in spectral quality but have the same source color. Halstead, Palmer, and Stainsby (19) carefully studied CIE color rendering tolerances. They observed that just

[3] The colors under the reference are not at the nominal notations indicated which were assigned by Munsell when the colors were viewed under the Standard Illuminant C. This does not effect the measured or calculated color shifts.

noticeable differences in color rendition did correlate with calculated color shifts of individual color samples on a uniform chromaticity scale. Furthermore, the just noticeable color differences under their experimental conditions, which involved viewing the samples in optically isolated sections of a room, correspond to approximately 5.5 times the minimum perceptible color differences of the MacAdam's observer. This is about 1½ units of length in the Munsell system. With current phosphor coatings, calculated color shifts are of this magnitude for the red, blue-green, and blue hues.

Preparation and Properties of Boron Arsenide Films

T. L. Chu* and A. E. Hyslop

Electronic Sciences Center, Southern Methodist University, Dallas, Texas 75222

ABSTRACT

Boron arsenide films have been deposited on the basal plane of hexagonal silicon carbide and {111} oriented sodium fluoride and silicon substrates at 800°-850°C by the thermal decomposition of a diborane-arsine mixture in a hydrogen atmosphere. Adherent films were deposited on silicon carbide substrates and were identified by electron diffraction as boron arsenide with random orientations. Boron arsenide deposits on sodium fluoride substrates were not adherent due to the large differences in their thermal expansion coefficients. Boron arsenide films deposited on silicon substrates were found to be amorphous by electron diffraction. Optical absorption measurements implied that boron arsenide is a direct gap material with a room temperature energy gap of about 1.45 eV. The current-voltage characteristics of metal-boron arsenide-silicon structures have indicated that the current-controlling mechanism is similar to that of an insulator containing traps of uniform energy. The density of traps was calculated to be approximately $10^{17}/cm^3$ eV.

Boron forms two arsenides. The direct combination of the elements at 800°-850°C yields the cubic monoarsenide, BAs, with a lattice parameter of 4.777Å and an optical energy gap of 1.46 eV (1, 2). The monoarsenide is stable up to 920°C and undergoes irreversible decomposition to an orthorhombic subarsenide, $B_{13}As_2$, at higher temperatures (3). Thus, boron monoarsenide can only be formed at temperatures below 920°C, and chemical vapor growth techniques are most suited for the preparation and crystal growth of boron monoarsenide. For example, the reversible reaction between boron monoarsenide and boron triiodide has been used for the growth of boron monoarsenide crystals at 850°C by the chemical transport technique (4). Chemical reactions between gaseous boron and arsenic compounds may also be used for the preparation of boron monoarsenide. Since the hydrides of boron and arsenic are thermochemically unstable at room temperature and above, the thermal decomposition of a diborane-arsine mixture is feasible for the preparation of boron monoarsenide.

In this work, the thermal decomposition of a diborane-arsine mixture in a hydrogen atmosphere was used for the deposition of boron monoarsenide, referred to as boron arsenide hereafter, on the basal plane of hexagonal silicon carbide platelets and sodium fluoride and silicon substrates of {111} orientation. Sodium fluoride and hexagonal silicon carbide were selected on the basis of crystal symmetry and lattice parameter considerations. Sodium fluoride crystallizes in the sodium chloride structure with a lattice parameter of 4.62Å as compared with 4.777Å for boron arsenide. The

basal plane of silicon carbide has a sixfold symmetry with an interatomic distance of 3.095Å which is approximately 8.2% lower than that of boron arsenide in a {111} plane. The structural and electrical properties of the deposited films were studied. The experimental procedures and results are summarized in this paper.

Preparation of Boron Arsenide Films

The deposition of boron arsenide was carried out in a gas flow system by the thermal decomposition of a diborane-arsine mixture in a hydrogen atmosphere using the apparatus shown schematically in Fig. 1. The flow of various gases was directed by using appropriate valves and measured with flowmeters. Hydrogen was purified by diffusion through a palladium-silver alloy. Diborane and arsine were in the form of hydrogen-hydride mixtures, each containing about 5% of the hydride. These hydrides decompose rapidly at 500°C and above, thereby promoting the gas-phase nucleation and yielding nonadherent deposits. Thus, the gas-phase nucleation must be suppressed by optimizing the experimental conditions such as the use of a water-cooled reaction tube, a low partial pressure of hydrides in the reactant, and a high gas velocity over the substrate surface.

The substrates, sodium fluoride, hexagonal silicon carbide, and silicon, were supported on a boron arsenide coated graphite susceptor in a water-cooled reaction tube of 55 mm ID, and the susceptor was heated externally with an rf generator. The sodium fluoride substrates were in the form of platelets with cleaved faces of a {111} orientation, and water was used as an etchant. The silicon carbide substrates were also in the form of platelets with main faces parallel to the basal plane, and molten potassium hydroxide was used as an etchant. The silicon substrates were of a {111} orientation, p-type, and 0.01 ohm-cm resistivity; a 5:3:3 nitric acid-hydrofluoric acid-acetic acid mixture was used as an etchant. The mechanically polished and chemically etched substrates were thoroughly cleaned and were heated *in situ* in a hydrogen atmosphere before the deposition of boron arsenide. Boron arsenide was usually deposited at 800°-850°C. Typical flow rates of hydrogen, diborane, and arsine were 2×10^4, 2, and 8 ml/min, respectively (a large As/B ratio was always used to prevent arsenic deficiencies in the deposit). The deposition rate was 3-4 μm/hr as measured directly on angle-polished boron arsenide-silicon carbide and boron arsenide-silicon structures.

The deposition of adherent boron arsenide films on sodium fluoride substrates was not successful. The deposits always cracked off during the cooling process, due mainly to the difference in the thermal expansion coefficients of the two materials.

Adherent and uniform boron arsenide films have been deposited reproducibly on the basal plane of hexagonal silicon carbide substrates under a wide range of experimental conditions. No structural features were observed when the as-deposited films were examined with an optical microscope. Reflection electron diffraction examinations with a Hitachi Hu-11B2 electron microscope indicated that films deposited at 800°-850°C were all boron arsenide with random orientations. Figure 2 shows the reflection electron diffraction pattern of a boron arsenide film deposited on the silicon face of a hexagonal silicon carbide substrate at 850°C. The lack of single crystallinity is presumably related to the large difference in lattice parameters of boron arsenide and silicon carbide and to the relatively low temperature used in the deposition process.

The boron arsenide films deposited on silicon substrates at 800°-850°C at rates of a few micrometers per hour were highly adherent and were found to be amorphous by the electron diffraction technique. If a boron arsenide film of 10 μm or greater in thickness is deposited on a silicon substrate of 400 μm thickness, the resulting structure became convex upon cooling, indicating that the thermal expansion coefficient of amorphous boron arsenide is smaller than that of silicon. Amorphous boron arsenide is chemically inert, insoluble in aqueous acids and alkalis at room temperature and above. It can be etched in a 1:9 sodium peroxide-sodium hydroxide molten mixture at about 400°C at a rate of approximately 1 μm/min.

Properties of Amorphous Boron Arsenide Films

Due to the chemical inertness of boron arsenide, the silicon substrate can be readily etched off from the boron arsenide-silicon structures by using a mixture of nitric acid and hydrofluoric acid. The resulting film transmitted dark red light. A boron arsenide film of about 2 μm thickness was placed between two quartz plates, and its optical absorption was measured using a Perkin-Elmer Model E-1 monochromator. The results are shown in Fig. 3 where the square and the square root of the absorption coefficient, α, are plotted *vs.* photon energy, E. The dependence of the absorption coefficient on photon energy can be used to distinguish between direct and indirect electron transitions (5). In practice, the plot of α^2 *vs.* photon energy

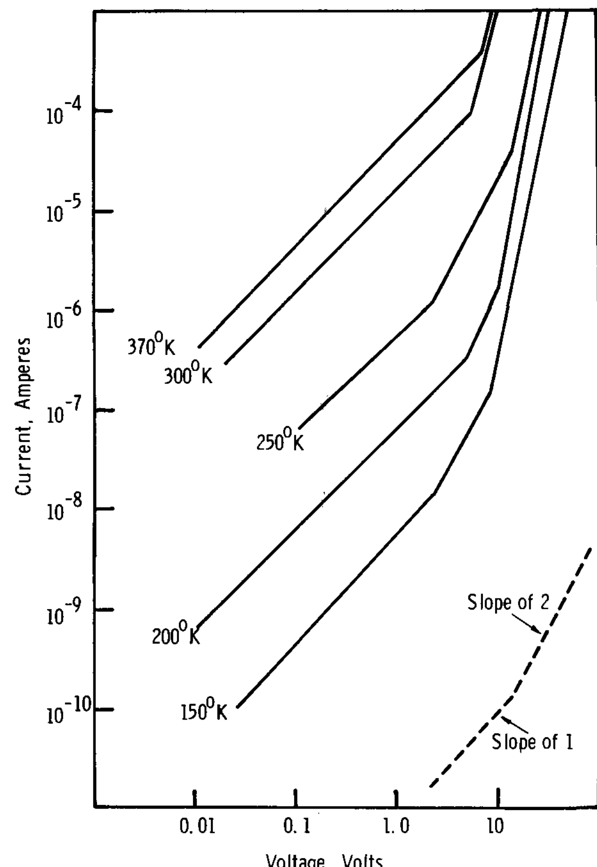

Fig. 4. Typical current-voltage characteristics of an aluminum-boron arsenide-silicon structure with a boron arsenide film of 1 μm thickness.

gives a straight line for direct transitions, and the intercept on the energy axis gives the bandgap for direct transitions. For indirect transitions, the plot of $\alpha^{1/2}$ against photon energy gives a straight line, and the intercept on the energy axis gives the bandgap for indirect transitions. The energy gap of boron arsenide deduced from the α^2 *vs.* E plot in Fig. 3 is approximately 1.45 eV, while the plot of $\alpha^{1/2}$ *vs.* E yields an energy gap of only 0.67 eV. Since the former is in agreement with the reported optical bandgap of microcrystalline boron arsenide, 1.46 eV (2), boron arsenide presumably is a direct gap material.

The electrical conduction mechanism in amorphous boron arsenide films was studied by measuring the current-voltage characteristics of metal-boron arsenide-silicon structures over a wide temperature range. Boron arsenide films of various thicknesses deposited on 0.01 ohm-cm, p-type silicon substrates were used. Aluminum contacts were deposited on silicon, and aluminum or gold contacts of 1 mm diameter were deposited on boron arsenide by evaporation. The specimens were scribed and mounted on TO-5 headers. Aluminum wire was bonded onto the metal electrodes by an ultrasonic bonder, and the header was sealed. The current-voltage characteristics of these units were then taken in the temperature range 100°-400°K.

Typical current-voltage characteristics of aluminum-boron arsenide-silicon structures are shown in Fig. 4 where the current-voltage relations over a wide temperature range for a boron arsenide film of 1 μm thickness are plotted on logarithmic scales. At low bias levels, the slope is unity designating the ohmic region, and the room temperature resistivity of boron arsenide is approximately 10^7 ohm-cm. The slope of the plot of the logarithm of the conductance *vs.* the reciprocal temperature yielded an activation energy of about 0.24 eV, indicating that the electronic conduction is responsible for the ohmic behavior. As the bias is increased, the slope of the log I *vs.* log V plot increases to two, indicating a space-charge-limited current situation. This is expected because of the relatively large energy gap of boron arsenide. At lower temperatures, further increase in bias results in a large increase in slope which subsequently decreases to two (this decrease in slope is not shown in Fig. 4).

The high slope region could be related to Schottky emission, Poole-Frenkel emission, tunneling, internal field emission, and space-charge-limited currents in the presence of traps. However, the Schottky and Poole-Frenkel emissions are both associated with a lowering of the metal-insulator barrier height under the influence of an electric field, and the logarithm of the current varies linearly with the square root of the voltage. Also, if any of these mechanisms except the space-charge-limited current were to occur, their effect on the current-voltage characteristics would continue to prevail at still larger bias. However, the log I *vs.* $V^{1/2}$ plot of the data in the high slope region did not yield a straight line, and the high slope region subsequently reverts back to a square law at higher bias. The space-charge-limited current mechanism therefore prevails, and the current-voltage characteristics are influenced by the presence of traps of a concentration much greater than the equilibrium carrier concentration. This region has been designated as the trap filled limit (TFL) region. Extensive theories for insulators containing traps have been developed, and current-voltage characteristics attributable to this type of trapping mechanism have been reported (6).

The reasoning for the appearance of the high slope region is briefly as follows. As the bias is increased, the quasi-Fermi level for the charge carrier moves away from its thermal equilibrium value toward its respective band. If, for example, there is one discrete trap level, single-carrier space-charge-limited current should behave as $I \propto V^2$ until the quasi-Fermi level moves within a few kT of the trap level. When the quasi-Fermi level is at the trap level, the injected

charge will be condensed into this trap level, thus giving a sharp rise in current, the TFL region. Since a discrete trap level is assumed, the slope of the log I *vs.* log V plot in the TFL region should be very large because the excess injected charge will only go into this trap level over an exceedingly small voltage range while the current increases by orders of magnitude. As the bias is increased further, the quasi-Fermi level moves away from the trap level, and the current again becomes proportional to the square of the applied voltage.

The slope of the log I *vs.* log V plot in the TFL region and its temperature dependence are determined by the energy distribution of traps. Detailed analysis has been carried out for the situation where an exponential energy distribution of traps exists in the forbidden band, and the current-voltage relationship has been deduced (7). Attempts to correlate this relationship with the current-voltage data on amorphous boron arsenide produced no meaningful results, suggesting that a different energy distribution of traps should be used. Assuming that all traps have the same energy according to the relation

$$N_T(E_T) = N_n/\text{cm}^3\,\text{eV}$$

The current-voltage relation for such a distribution is (8)

$$J = 2qn_0\mu(v/L)\exp(2\epsilon V/N_n kTqL^2)$$

where n_0 is the equilibrium carrier density, μ is the carrier mobility, L is the insulator thickness, and ϵ is the dielectric constant. The slope of the log I or log J *vs.* log V plot in the TFL region is

$$m = \frac{d\log J}{d\log V} = 1 + \frac{2\epsilon V}{2.3\,N_n kTqL^2}$$

for which a temperature variation in slope should be

$$\frac{1}{m-1} = \left[\frac{2.3\,N_n kTqL^2}{2\epsilon V}\right] T$$

Using current-voltage characteristics shown in Fig. 4, the quantity $1/(m - 1)$, is plotted *vs.* the absolute temperature in the range 200°-300°K in Fig. 5. This linear relationship indicates that the traps presumably have a uniform energy distribution in the temperature range under consideration. The density of traps calculated from the slope of this line is approximately $10^{17}/\text{cm}^3$ eV.

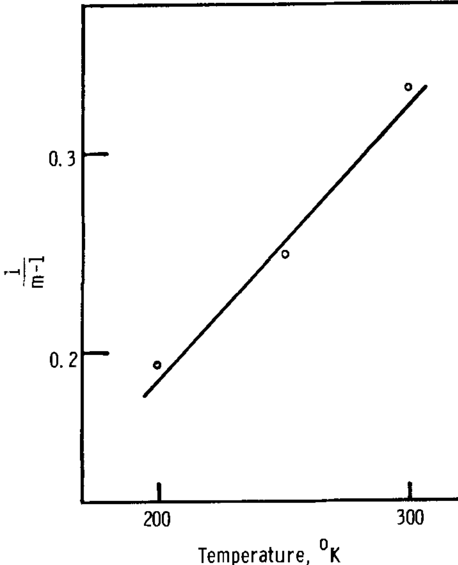

Fig. 5. A plot of 1/(*m*-1) *vs.* absolute temperature of data shown in Fig. 4.

Growth and Characterization of GaAsSb-GaAlAsSb Lattice-Matched Heterojunctions

G. A. Antypas* and R. L. Moon*

Corporate Research Laboratories, Varian Associates, Palo Alto, California 94303

ABSTRACT

Liquid phase epitaxial layers of $Ga_{1-y}Al_yAs_{1-x}Sb_x$ on GaAs (100) substrates were grown from beginning growth temperatures of 760° and 720°C, and have been characterized by electron microprobe, x-ray, and photoluminescence measurements. The solubility of As as a function of Al was experimentally determined at $x^l_{Sb}/x^l_{Ga} = 0.178$ for 760° and 720°C. In the concentration range and temperatures investigated, the distribution coefficient of As was found to vary drastically as a function of Al concentration. For layers grown at 720°C the distribution coefficient of As varied between 78 and 220 for x^l_{Al} of 0 and 0.3×10^{-2}, respectively. However, the distribution coefficient of Sb appeared to be practically independent of the Al concentration in the liquid. Thermodynamic and physical properties of the quaternary liquid and solid solutions were compared whenever possible with ternary AlGaAs (the case of zero Sb) properties.

The solid solution properties of III-V compounds have promoted the development of solid-state light emitting diodes, near-infrared photoemitters and detectors, and solid-state heterojunction lasers. In most instances, however, the epitaxial growth of ternary solid solutions on binary III-V substrates results in junctions with high dislocation and stacking fault densities. In cases where the heterojunction is an active part of the device, such as heterostructure lasers, super-lattice formation, transmission photocathodes, etc., a high defect density at the interface results in high recombination losses.

With the exception of the Al-Ga-V ternary compounds, which exhibit lattice matching over the whole concentration range, other ternary compounds cannot be grown on III-V binary substrates without the introduction of appreciable mismatch dislocations at the interface. This limitation of the ternary solid solutions can be relaxed by the addition of a fourth component that introduces an extra degree of freedom and permits the independent variation of lattice constant and bandgap. Thus lattice matching in III-V quaternary systems can be achieved over a wide range in bandgap energy.

From a practical point of view, however, the fabrication of lattice-matched heterojunction on commercially available substrates is limited to the growth of Al_x-Ga_{1-x}-V alloys on Ga-V substrates, the quaternaries $In_{1-y}Ga_yAs_{1-x}P_x$ on InP or GaAs and $In_{1-y}Ga_yAs_{1-x}Sb_x$ on GaSb or InAs. The ternary-quaternary lattice-matched structures, although theoretically extending over the whole concentration range, are limited by the nonavailability of appropriate substrates. So for systems such as GaAlAsP-GaAsP, and GaAlAsSb-GaAsSb, a buffer layer is usually grown on the substrate in order to minimize the effects of lattice mismatch between the substrate and the active epitaxial layer.

Liquid phase epitaxy has been used for the growth of $GaAs_xSb_{1-x}$ alloys for photoemission (1) and light emission applications (2). In both cases layers of good crystallinity could only be grown having GaSb concentration of less than 20%. This is primarily due to the large lattice mismatch between GaAs and GaSb (7.8%). Sugiyama and Saito (3) using growth procedures and a boat design similar to that used by Panish *et al.* (4) for the growth of GaAs-GaAlAs heterojunctions, prepared a GaAsSb-GaAlAsSb heterostructure laser. The growth of GaAlAsSb-GaAsSb heterojunctions is very similar to the GaAlAsP/GaAsP system reported by Burnham and co-workers (5). In these systems the variations in heterojunction barriers are controlled by the x^s_{Ga} to x^s_{Al} ratio while constancy of the lattice parameter across the junction is controlled by the x^s_{As} to x^s_P or x^s_{As} to x^s_{Sb} ratios.

Growth and Materials Characterization

Consistent with our earlier work on GaAsSb, the epitaxial layers were grown on (100) oriented GaAs substrates. A horizontal growth system using a palladium purified hydrogen environment and a graphite boat similar in design reported by Rosztoczy *et al.* (6) was used. Epitaxial layers were grown in the temperature range of 720° and 760°C with a cooling rate of 1°C/min over a temperature interval of 20°C. Layer thicknesses were between 10 to 15μ.

In addition to the epitaxial growth experiments, As solubility experiments were performed at 720° and 760°C by initially preparing a Ga-Al-Sb solution and saturating with As from a GaAs substrate. The weight loss of the GaAs substrate establishes the solubility limit of As. Interpretation of this type of solubility experiment implicitly assumes that the prevention of complete dissolution of the saturating source is due to a quaternary layer which is in equilibrium with the melt at the saturating temperature.

Figure 1 shows the resulting liquidus isotherms at 720° and 760°C for a liquid of x^l_{Ga} and x^l_{Sb} of 0.84 and 0.15, respectively. The solubility behavior of As in Ga-Sb solutions as a function of Al concentration in the liquid is very similar to the case of the ternary Al-Ga-As system. For comparison, the data of Alferov *et al.* (7) for the GaAlAs system at 712° and 757°C are shown. In both cases the As solubility limit decreases rapidly with the addition of small amounts of Al.

In order to achieve lattice match across the heterojunction between GaAlAsSb and GaAsSb a constant x^s_{Sb}/x^s_{As} ratio must be maintained. Due to the lack of any phase diagram calculation and the drop in As solubility upon adding Al to the solution, the growth of lattice-matched heterojunctions requires some experimentation. To investigate this, a series of epitaxial layers were grown from solutions with constant Ga and Sb concentrations while varying the As concentration by saturating at 720° and 760°C. The epitaxial layers were characterized by microprobe, x-ray, and photoluminescence measurements to determine the composition of the solid solution, the lattice constant, and bandgap.

Detailed characterization of the epitaxial layers is shown in Table I. For the layers grown at 720°C the

distribution coefficient of Sb decreased slightly as a function of Al concentration, while at 760°C it appeared to remain practically constant. This change in the distribution coefficient of Sb is also reflected on the lattice parameter of the epitaxial layers. The series of layers grown at 720°C indicated a decrease in the lattice constant as a function of Al, while for those grown at 760°C the lattice parameter remained constant. The dependence of the lattice parameter on the Al concentration is shown in Fig. 2 for both series of runs.

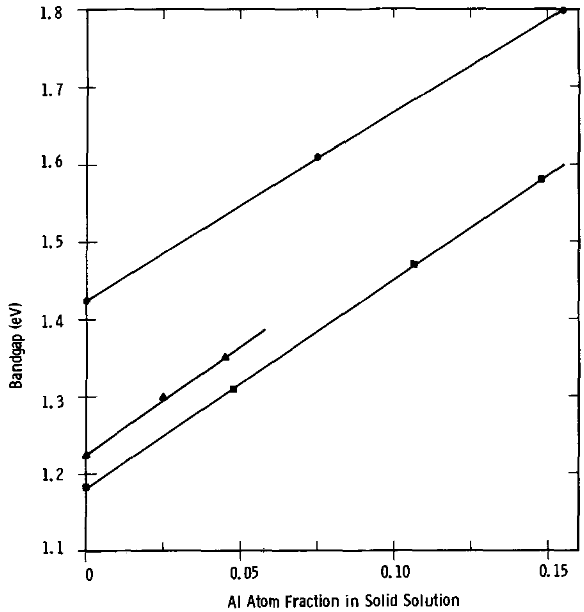

Fig. 3. Dependence of the room temperature bandgap on the Al concentration in the solid solution for ●, AlGaAs (8) and GaAlAsSb layers grown from solutions with x^l_{Sb}/x^l_{Ga} = 0.178 at ▲, 760°C and ■, 720°C.

The bandgap energy was determined by photoluminescence measurements at 77° and 300°K. The excitation source was a chopped 0.5W argon ion laser. A Perkin-Elmer 301 spectrophotometer was used with a dry-ice-cooled S-1 photomultiplier. The PL spectra of all the layers consisted of intense near-bandgap radiation, along with a defect line of lower energy. Figure 3 shows the variation of bandgap on the Al concentration in the solid. The linear dependence of bandgap on Al for the two series of runs is almost identical to the GaAlAs case as indicated by the slopes 2.65 and 2.55 × 10^{-2} eV per Al atom per cent, for the GaAlAsSb and GaAlAs lines, respectively.

The reproducible growth of heterojunctions requires detailed knowledge of the distribution coefficient of the various components. For the growth of GaAlAsSb, epitaxial Al and As have appreciably higher distribution coefficients than either Ga or Sb. Furthermore, since these epitaxial layers normally are grown from As saturated solutions the distribution coefficient of As is strongly dependent on the Al concentration in the liquid solution. This behavior is shown in Fig. 4 and 5. Figure 4 simply shows the distribution of Al for quaternary epitaxial layers grown at 760° and 720°C. For comparison, the data of Alferov *et al.* (7) are shown for the distribution coefficient of Al in GaAlAs. From microprobe measurements the distribution coefficient of Sb remains practically independent from the Al concentration in the liquid, and since the As solubility decreases drastically by the presence of Al in the solution, the effective distribution coefficient of As increases as a function of Al. This behavior is

shown in Fig. 5 for the epitaxial layer grown at 760° and 720°C.

Conclusions

During this investigation we have shown that GaAlAsSb layers can be prepared by liquid phase epitaxy similarly to the procedures developed for the growth of GaAsSb. Furthermore, it was observed that although the addition of Al in the liquid solution results in a decrease in the As solubility limit, the concentration ratio of Sb to As in the solid solution remains practically constant in the concentration range and temperatures investigated. This implies that lattice-matched heterojunctions in this system can be routinely grown from solutions having constant Ga and Sb concentrations and varying Al concentrations necessary for the desired heterojunction barrier. In order for this type of behavior to occur the activity of As in the solution must increase in the presence of Al to counteract the decrease in the solubility limit.

Acknowledgments

Microprobe Technique for Determination of Thickness and Phosphorous Concentration of Gate Oxide Phosphosilicate Glass in FET Devices

Giulio DiGiacomo

IBM System Products Division, East Fishkill Facility, Hopewell Junction, New York 12533

ABSTRACT

This microprobe technique is capable of determining the thickness and phosphorous concentration of the phosphosilicate glass in FET gate oxide. The technique is equally applicable to wafers and devices. The latter application is unique since there is no other way, at present, to obtain this information on actual FET gates. In addition to the extended capability to real devices, this technique yields the phosphorous concentration with a precision of ± 0.1 mole per cent about one order of magnitude better than that obtainable by the etch rate method. The oxide and phosphosilicate thickness are determined with a precision of ± 5Å, comparable to that achieved by ellipsometry, with the advantage of applicability to actual devices.

It is necessary to measure accurately the phosphorous concentration and thickness of the PSG and the thickness of the total gate oxide in FET devices. The PSG serves as a stabilizer since it traps impurity ions such as Na^+ which otherwise would drift to the oxide/silicon interface and affect the electrical properties of the device; *e.g.,* threshold voltage shift. If the phosphorous concentration of the PSG is increased, say, from $4P_2O_5$ m/o (mole per cent), its ability to retain trapped ions improves since the activation energy required for Na^+ ion release increases greatly with phosphorous concentration (1-3). However, a higher phosphorous concentration will produce significant polarization effects, affecting the voltage threshold, causing it to shift in the same direction observed with Na^+ drift. The manufacture of stable devices requires a compromise at an intermediate PSG composition sufficient to minimize threshold voltage shifts resulting from either polarization or ion drift effects.

Since threshold shifts depend strongly on phosphorous concentration an accurate knowledge of the phosphorous concentration is imperative for studying the ion-drift and polarization effects and establishing a criterion for quality control. On the basis of recent works (1-3), predictions on the threshold shifts can be made if the phosphorous and Na^+ ion concentrations are known accurately. The present microprobe technique applies directly to the problem of phosphorous polarization (P concentration measurement) and indirectly to Na^+ ion drift, since phosphorous controls Na^+ ion trapping and the activation energy for ion release. At temperatures of 200°C or higher, the polarization is strongly dependent on temperature and the polarization rate appears to be proportional to the concentration squared. No polarizability saturation is noted at these temperatures at P_2O_5 mole concentrations of less than 12% for a few hundred hours (2). At temperatures lower than 120°C, the polarizability saturates quickly and therefore one is concerned with the saturated value which is proportional to the threshold shift and which depends on the square of the P concentration. At low, as well as high temperatures, the ratio of PSG thickness to total SiO_2 and PSG thickness is of importance since the threshold shift depends also on this ratio. One can assume a linear dependence at small ratios such as those prevailing in the FET's. At the higher temperature, an analysis of the data reported in this recent work (2) shows an activation energy of 0.37 eV/atom. From the same data the voltage threshold shift relationship was evaluated to be

$$\Delta V = \Delta V\ (1\ \text{hr}, T) + 750\ e^{-0.37/kT} \log t \qquad [1]$$

For a P_2O_5 concentration of 4%, temperature of 140°C, and a ratio, t_{PSG}/t_{SiO_2} of 0.14, the threshold shift due to polarization is $\sim$0.1V for 1000 hr. Concentration and thickness ratio factors can be included in the above relationship to take into consideration their effects.

Experimental

Method.—Full characterization of the PSG in terms of phosphorous concentration and thickness requires the measurements of both phosphorous and oxygen characteristic radiation before and after a layer of the PSG is removed by etching. The removal produces x-ray intensity decrements of both elements proportional to the thickness of the layer removed and makes possible, with the original intensity values, the calculation of thickness and phosphorous concentration of the PSG and the total thickness of the gate oxide. An illustration of the principle of the microprobe approach appears in Fig. 1a which also defines the x-ray values measured and shows the thickness and concentration quantities. The proportionality constants between these quantities and the x-ray intensities have been determined experimentally utilizing samples of known phosphorous content and oxide thickness. X-ray intensities yielded straight lines as expected when plotted against phosphorous content and oxide thickness. For thin films these relationships are linear at sufficiently high voltage. Figure 1a also shows that the electron beam penetration is greater than the thickness of the silicon oxide. Figure 1b shows the x-ray intensi-

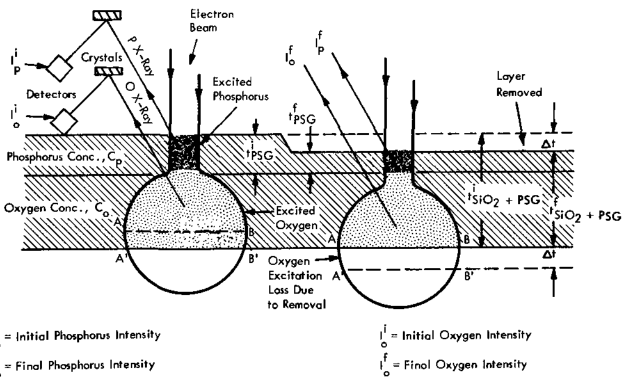

Fig. 1a. Principle of microprobe technique

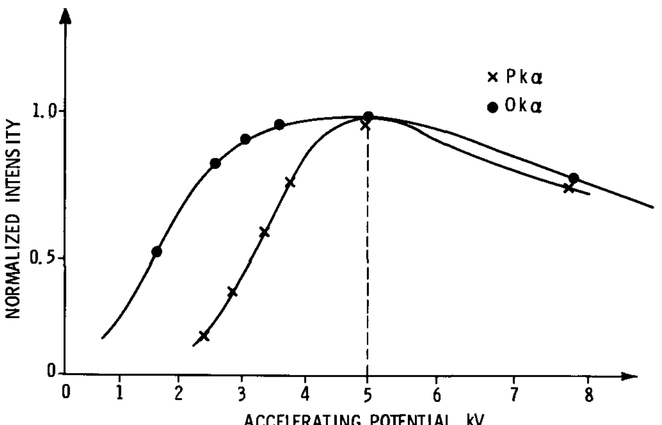

Fig. 1b. Intensity optimization

ties of both elements *vs.* the accelerating potential. From the plot it is evident that approximately 5 kV gives maximum intensities. At this potential we also obtain optimum detectability. At higher keV, the detectability degenerates quite fast because of a rising background and decreasing ionization cross section; at lower voltages the ionization efficiency is low.

Figure 1a exhibits the initial x-ray measurements of both elements I^i_o and I^i_p. These two intensity values when used in Fig. 2 and 3, respectively, yield the initial oxide plus PSG thickness, $t^i_{SiO_2+PSG}$, and the initial phosphorous content in terms of thickness X concentration units, $t_{PSG} \cdot C_p$. After the x-ray measurement is completed, the wafers are etched for 1½ min with DP etchant to remove approximately 40Å of PSG which contains ~4% P_2O_5. (The etchant is a dilute solution of HF and HNO_3 acids, 3 parts of HF and 2 parts of HNO_3 in 645 parts of water.) Having etched a part of the PSG, a second microprobe measurement is made for both elements. The intensities I^f_o and I^f_p, thus obtained are again used in Fig. 2 and 3 to determine the new oxide thickness, $t^f_{SiO_2+PSG}$, and the new phosphorous content $t^f_{PSG} \cdot C_p$ (refer to Fig. 1a also). It is to be noted that the technique requires PSG removals equal or less than the total PSG thickness. From the above measured values, the thickness and phosphorous concentration of the PSG are determined in the following manner

$$t^i_{SiO_2+PSG} - t^f_{SiO_2+PSG} = \Delta t_{SiO_2+PSG} = \Delta t_{PSG} \quad [2]$$

$$t^i_{PSG} \cdot C_p - t^f_{PSG} \cdot C_p = \Delta t_{PSG} \cdot C_p \quad [3]$$

$$I^i_p - I^f_p = \Delta I_p \propto \Delta t_{PSG} \cdot C_p \quad [4]$$

$$I^i_o - I^f_o = \Delta I_o \propto \Delta t_{PSG} \quad [5]$$

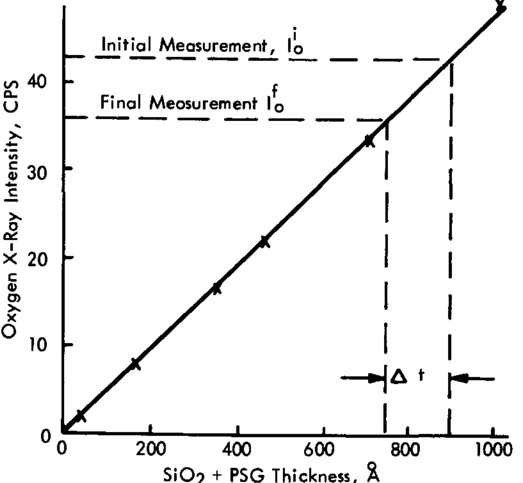

Fig. 2. Determination of PSG layer removed

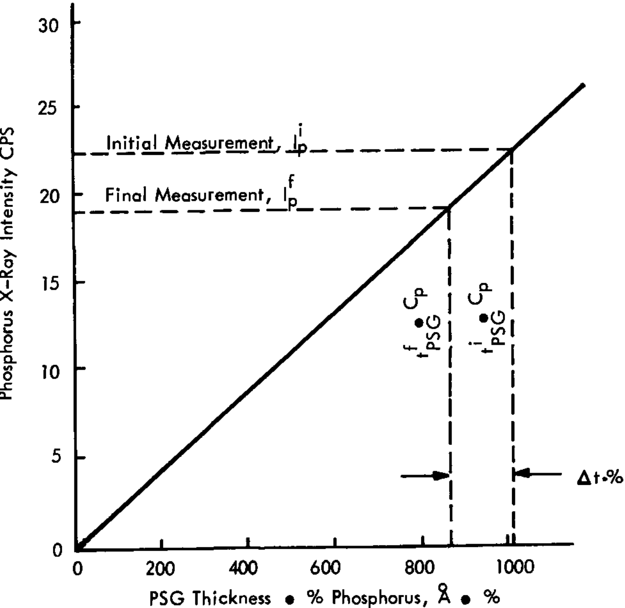

Fig. 3. Determination of phosphorous content in Å·% units

The two values of thickness and phosphorous content, Δt_{PSG} and $\Delta t_{PSG} \cdot C_p$, are read directly from the calibration curves. Having obtained $C_p \cdot \Delta t_{PSG}$ from phosphorus and Δt_{PSG} from oxygen intensities, division of the former by the latter yields the phosphorous concentration. Having obtained the phosphorous concentration, one can obtain the thickness t_{PSG} from the graph of phosphorous intensity *vs.* mass thickness, by dividing the initial mass thickness of phosphorus by the concentration as obtained above

$$C_p = \frac{\Delta t_{PSG} \cdot C_p}{\Delta t_{PSG}} \quad [6]$$

and

$$t_{PSG} = \frac{t_{PSG} \cdot C_p}{C_p} \quad [7]$$

and

$$\text{Thickness ratio} = \frac{t_{PSG}}{t_{(SiO_2+PSG)}} \quad [8]$$

C_p and the thickness ratio are the two parameters needed for determining the polarization. Measurement of both PSG thickness and composition are thus obtained with two microprobe measurements and only one etching operation. To perform the above measurements in one operation, black wax is used to cover a portion of the region to be analyzed before the PSG is removed such that the covered PSG is not etched. Upon removal of the black wax, the probe analysis is performed on both etched and unetched portions. Thus, all microprobe information is obtained with a minimum of error. This refers to errors due to time-dependent instabilities.

Procedure and results.—To obtain calibration curves for both phosphorous and oxygen, eleven wafers with known oxide thicknesses were analyzed by the probe. The SiO_2 thicknesses which ranged from 30 to 2000Å has been determined by the ellipsometry method. The x-ray intensities obtained from these samples by microprobe were plotted *vs.* the known thicknesses. The plot was a straight line passing through the origin and having a slope of about 0.05 cps (counts per second)/Å, which is the x-ray sensitivity for SiO_2 thickness. In other words one needs a 20Å thick layer of SiO_2 to get 1 cps intensity at electron beam conditions of 5 kV and 10^{-7}A. The minimum detectable limit was found to be 5Å for a 1 min x-ray count. The analysis was performed with an ARL probe which has a take-off angle of 52°. Lead stearate and ADP

crystal monochromators were used for determining oxygen and phosphorous, respectively.

A similar linear plot was obtained with phosphorous content *vs.* x-ray intensity using a set of samples which had been analyzed by neutron activation or compared to neutron activation standards. Since thickness multiplied by concentration is a convenient and practical measure of phosphorous content the concentration-thickness unit, Å·%, was adopted. Following the method of analysis outlined, the phosphorous sensitivity was determined to be 0.023 cps/Å·% which yields a minimum detectable limit of 15 Å·% for 100 sec of x-ray count. (There are 4.4×10^{12} at/cm²/Å·%.) This means that the thickness of a PSG having 3% P concentration can be determined within 5Å. The accuracies for phosphorous and oxygen are comparable although it requires a slightly longer x-ray count for phosphorous determination. The counting time requirement for a desired accuracy is dictated by the x-ray statistics which are based on the photon distribution in time. The minimum detectable limit (MDL) for both elements was calculated according to the following relationship

$$\text{MDL} = \frac{\left(\frac{1}{t_p} + \frac{1}{t_b}\right)^{1/2} B^{1/2}}{S} \qquad [10]$$

where T_p = time to count the peak signal for a fixed total count (sec),
t_b = time to count background for the same total count (sec),
B = background in counts per second (cps), and
S = concentration sensitivity in cps/A·%.

The background was measured in both sides of the peak and averaged. This agreed with the calibration line intercept on the intensity axis. By increasing the total count and therefore t_p and t_b, the MDL is made sufficiently small to meet the desired accuracy. There is a limit, however, to how far one can increase the total count or counting time since there are other factors such as equipment power instability and carbon build-up on the specimen which finally limit the MDL. Carbon build-up is minimized by a decontaminator. Contamination is minimized by circulating liquid nitrogen in the water cooling coils of the objective lens (ARL probe), which promotes vapors condensation. This reduces contamination by more than a factor of ten. The effect of carbon build-up is within experimental error which is reflected in the accuracy stated.

Since we are dealing with x-ray signals just above background, the minimum detectable limit as calculated above is also the precision with which a measurement is made and, when a sample of known composition and thickness is used as a control it represents the accuracy. Dozens of samples, wafers and devices alike, have been analyzed to show in practice that the accuracy calculated on the basis of the x-ray statistics was indeed attainable. The reproducibility of the x-ray readings, and therefore the accuracy of the oxide thickness and phosphorous content, were found to be within the MDL calculated. Figures 4 and 5 show how oxygen and phosphorous x-ray intensities from the above samples plot linearly against SiO_2 thickness and phosphorous content. Considering the composition and thickness ranges, the calibration lines in both cases are satisfactorily straight. The samples have been analyzed many times and the straight lines reproduced each time. Figure 6 is another graph obtained from a number of SiO_2 samples analyzed later. The graph includes also three samples originally used in the intensity-thickness calibration curve shown in Fig. 4. The original samples were included to show the reproducibility at a different time. In Fig. 5, only one sample (No. 3005) was analyzed directly by the neutron activation method; the others were simultaneously analyzed by the x-ray fluorescence technique with standards of comparable composition whose phosphorous content had been determined by neutron activation analysis. These wafer samples were analyzed within an accuracy of ±5% of the amount of phosphorous. Hundreds of wafers and devices have been fully analyzed by this technique recently. Each of them has gone through the etching and microprobe measurement steps. Typical oxide removals of ~60Å have been obtained with etching times of about 2 min. The technique has become, therefore, part of the characterization process of wafers and devices.

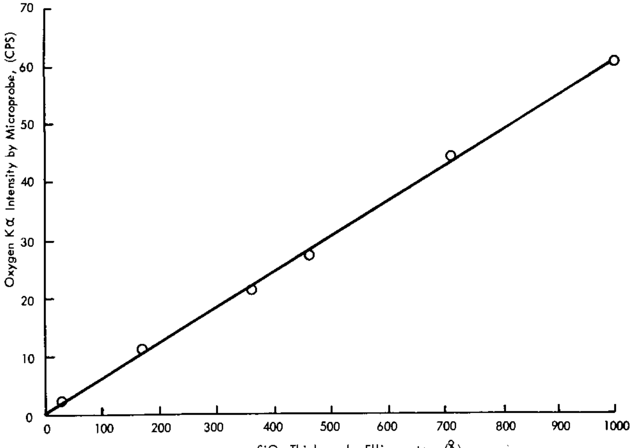

Fig. 4. SiO_2 thickness calibration curve

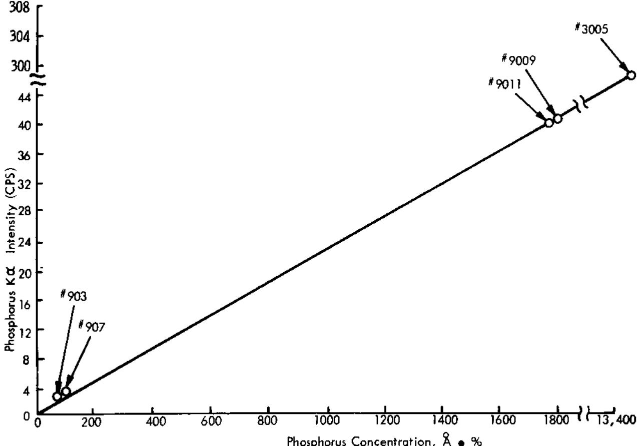

Fig. 5. Calibration curve for PSG phosphorous content

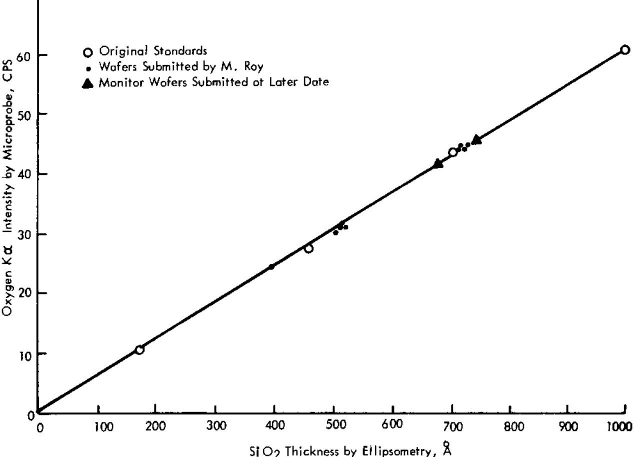

Fig. 6. FET gate oxide and PSG measurement of samples

Discussion and Conclusions

Measurements of the SiO_2 thickness are based, as already indicated, on the intensity of the oxygen $K\alpha$ x-ray generated in the oxide layer as a result of electron bombardment. At 5 kV, the x-ray intensity is directly proportional to the oxide thickness for oxide layers <2000Å. Since oxygen is present in both SiO_2 and PSG, the x-ray technique gives the total thickness of SiO_2 and PSG. There is a slight difference, however, in the oxygen content between SiO_2 and the PSG because of the presence of a few per cent of phosphorous. This difference is either small (3% or less) and therefore neglected, or it is easily accounted for when a high phosphorous concentration warrants it. For thin gate oxide PSG's, this correction is not necessary. After going through the zeroing procedure, the electron beam current is adjusted to give 100 nA specimen current. The adjustment is made on the specimen itself. The P_2O_5 and SiO_2 standards (measured originally by the independent method as specified) are analyzed simultaneously with the specimen under the same conditions to standardize the intensity values and generate calibration curves for both phosphorus and oxygen as illustrated in Fig. 2 and 3. It is important that the specimen current remains constant during the test.

The phosphorous analysis, as already indicated, is carried out simultaneously with oxygen using a different spectrometer. This is advantageous in terms of time and accuracy because the x-ray intensities of both elements come from sample volumes irradiated and analyzed at the same time, thus, allowing a faster analysis and preventing any error that might arise from possible inhomogeneities and an instrumental power instability.

Because of the linearity with which x-ray intensities are related to the thickness and the phosphorous concentration of the PSG, and because of the accuracy with which the x-ray intensity can be measured, this technique can be used with little effort to evaluate other techniques such as the etch-rate technique which is known to have an accuracy on the order of $\pm$ 1% P_2O_5. The microprobe technique has revealed upon extensive application that this error is at times greater than $\pm$1%. Consequently it is concluded that (*i*) the etch rate technique may not be adequate when applied to study the effects of phosphorous polarization and Na^+ ion drift, and (*ii*) the present microprobe technique is unique for determining silicon oxide thickness in FET gate oxide, PSG thickness, and PSG phosphorous concentration within the accuracy required in the study of P-polarization and Na^+ ion drift for finished devices.

Acknowledgment

The author wishes to acknowledge J. J. Gniewek for his guidance, helpful suggestions, and assistance in procuring the materials and Watson Research Center, Yorktown, for the wafer sample analyses. Mr. Maurice Roy and Mrs. Donna Bouer are acknowledged for providing the oxide and PSG wafers used in this work. The assistance of D. Stabell in providing the help for etching the wafers and devices is appreciated.

Some Device Applications of Spreading Resistance Measurements on Epitaxial Silicon

Bernard L. Morris

Bell Telephone Laboratories, Incorporated, Allentown, Pennsylvania 18103

ABSTRACT

Thin epitaxial silicon should not be characterized by simply specifying a thickness and resistivity. The success of a device can depend on knowledge of the entire epitaxial impurity profile. In most cases the complete profile can only be obtained by the spreading resistance technique. The information obtained by this method should then be correlated with the results of the more commonly used characterization techniques; infrared thickness measurement and diode capacitance-voltage profiling. Examples of such correlations are presented for a number of thin epitaxial device structures such as GIMIC, OXIM, a 50 GHz IMPATT diode, a PIN phase modulator, and a large area power Schottky diode.

If a flat circular voltage probe of radius a is brought into contact with a semi-infinite conducting material, practically all of the potential drop occurs within 1.5 $\times$ a of the point of contact (1). For a metal-semiconductor contact in which the surface barrier resistance (Schottky resistance) may be neglected, the resistance of the contact, which is called the spreading resistance, is

$$R_s = \rho/4a \quad [1]$$

Key words: spreading resistance, epitaxial silicon, resistivity profiles, integrated circuits.

where ρ is the semiconductor resistivity. Since real metal-semiconductor contacts can have appreciable barrier resistance, an empirical calibration of R_s *vs.* ρ is necessary. For silicon with a given value of resistivity, the spreading resistance depends on the conductivity type, orientation, and surface finish. Calibration curves have been constructed by measuring both ρ and R_s on a large number of samples, both N and P, <111> and <100>, with resistivities from approximately 0.001 to 100 ohm-cm. All of the calibration samples are Syton polished.

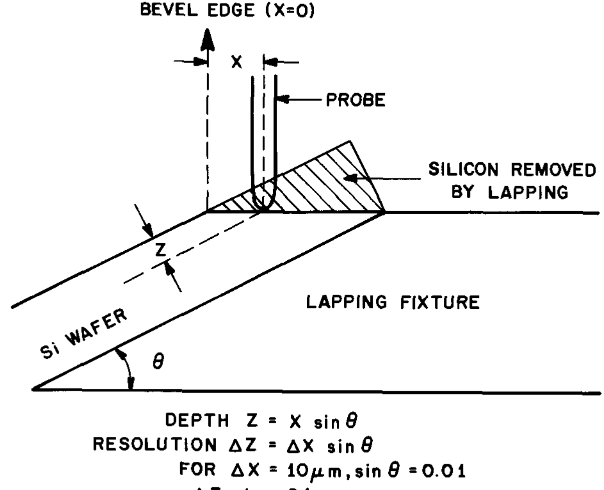

Fig. 1. Side view of spreading resistance profiling technique

The spreading resistance (SR) set used in this work is the model ASR-100 built by Solid State Measurements, Inc.[1] The probes are made of an osmium-tungsten alloy, and pressure is applied by 45g weights. The sample is placed on an X-Y stage, and the X drive is automatically stepped after each measurement; the step sizes used vary from 10 to 250 μm. If a measurement of the uniformity of surface resistivity is required, the sample is either waxed onto a block or held on a vacuum chuck, and the SR is automatically scanned and recorded with the selected step size. If a resistivity profile in depth is desired, the sample must be angle lapped on a special fixture supplied with the ASR-100. This is shown in Fig. 1. Since the ρ-R_s calibration is strongly dependent on the surface finish (2), the initial lapping with Linde-A is followed by a final polish with Syton.

The assumption of semi-infinite material from which Eq. [1] was derived does not hold for thin epitaxial layers. A thin film correction factor (*CF*) must be used, so that Eq. [1] now reads

$$\rho_{corr} = 4aR_s/CF \qquad [2]$$

The value of the *CF* depends on the relative resistivities and types of the epitaxial layer and substrate, and on the ratio t/a where t is the epitaxial layer thickness, and a is the effective contact radius as defined by Eq. [1]. Values of the *CF* for different types of profiles are available in the literature (3, 4). The two limiting cases for the *CF* are shorting and insulating boundaries. The former is a good representation of steep N/N^+ (or P/P^+), while the latter holds for a P/N (or N/P) epi-substrate boundary. These *CF*'s are shown schematically in Fig. 2.

The contact radius of the ASR-100 probes is approximately 3 μm. For insulating boundaries, Fig. 2 shows that the *CF* begins to change rapidly for $t/a \lesssim 5$, that is for $t \lesssim 15$ μm. Due to the uncertainty in the (calculated) *CF* in this range, the errors in the calculated values of ρ will tend to become large as the junction is approached. For N/N^+ (or P/P^+) the actual resistivity profile can be more accurately determined, since the *CF* tends toward unity as the resistivity of the epitaxial layer approaches the substrate resistivity. Therefore as the N-N^+ boundary (which in practice is always graded) is approached, ρ_1 smoothly approaches ρ_2, and even though t/a becomes very small the *CF* goes to unity.

The over-all accuracy of the SR profile depends on: the measurement of the depth, z; the reproducibility of the measured spreading resistance, R_s; the accuracy of the ρ-R_s calibration; and the accuracy of the *CF* calculation. The error in depth measurement is $dz =$

[1] Solid State Measurements Inc., Murrysville, Pennsylvania.

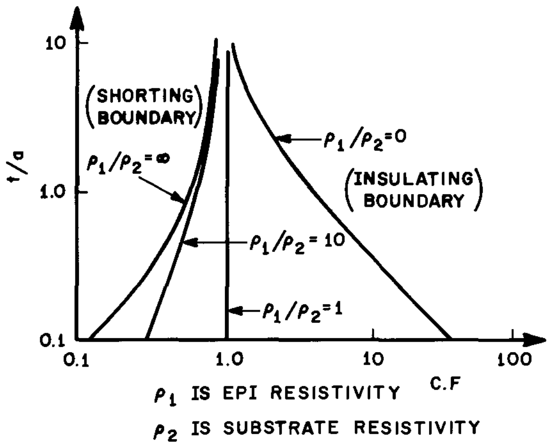

Fig. 2. Spreading resistance correction factors

$\pm$ $(0.05 \times z + 0.1)$ μm, where z is the depth in micrometers. The first term, $\pm 5\%$ of z, is the error in θ (see Fig. 1) and the second term, 0.1 μm, is due to possible alignment error and error in the definition of the bevel edge.

The reproducibility of R_s is better than $\pm 5\%$ for $\rho \lesssim 5$ ohm-cm. At higher resistivities R_s is increasingly influenced by adsorbed water and by minor variations in surface quality.

There is no simple way of judging the accuracy of the ρ-R_s calibration or the *CF* calculations. The best measure of the accuracy of the SR technique is to compare its results with those of diode *C-V* profiles. Such comparisons suggest an over-all accuracy of $\pm 10\%$ for N/N^+ or P/P^+ profiles, and $\pm 20\%$ for P/N or N/P profiles.

Measurement of Effective Epitaxial Thickness

In the days when Si epitaxial thickness was typically $\gtrsim 8$ μm, with an (assumed) flat resistivity profile, the exact definition of the thickness was not a problem. Angle lap and stain and/or infrared (IR) thickness measurements were used to define t, and the resistivity was usually defined at a single point on the profile.

Device technology has now advanced to the point where many epitaxial thicknesses are in the region 1-4 μm, with the newest IMPATT diodes requiring submicron epitaxial layer, $t = 0.6$-0.8 μm.

For this thin epitaxial material, it is not enough to specify a thickness and a resistivity; the complete profile must be known.

Every device design assumes some number which is supposed to characterize the epitaxial thickness. This is the electrical or effective epitaxial thickness, t_{eff}. For epitaxial layers with a conductivity type different than that of the substrate (or buried layer), this thickness usually corresponds to the point at which the net carrier concentration is zero. For N/N^+ (or P/P^+) structures t_{eff} will correspond to some value of N_D (or N_A) on the (graded) boundary profile.

Once the desired thickness (t_{eff}) is known, the next step is to correlate it with a practical production technique.

The two methods commonly used for epitaxial layer thickness measurement are IR and angle lap and stain. The former technique is nondestructive, fast (5 sec/measurement with the FTG-12[2]), operator independent, accurate, and reproducible to within ± 0.1 μm. Angle lap and stain is destructive, slow, operator and stain dependent, with a multi-laboratory precision of $\pm$ $(0.15t + 0.5)$ μm (5). For these reasons the use of the IR thickness is preferred.

It must be emphasized that the correlation between t_{eff} and t_{IR} for a particular device depends on the

[2] Digilab Inc., Cambridge, Massachusetts.

epitaxial resistivity profile. This depends on the reactor time-temperature cycle and the surface impurity concentration of the substrate or buried layer. If any of these parameters are changed, the correlation must be re-established. Two specific examples of the application of SR to the t_{eff}-t_{IR} correlation will now be discussed.

The Oxim (Oxide Isolated Monolithic) structure has epitaxial specifications similar to those of thin CDI (6). The epitaxial layer is low resistivity P-type, $t_{IR} = 2.0$ μm, grown over a standard Sb diffused buried layer. The effective thickness of this device is the point at which the material changes from P- to N-type, that is the point of maximum resistivity. This is shown in Fig. 3. This figure also shows the IR and stain thicknesses. Note that t_{IR} thickness falls at the point of maximum impurity concentration (minimum value of SR). This has been found always to be the case when the substrate, or buried layer, concentration is in the region of 10^{19} cm^{-3}, which is the range of the standard Sb diffused buried layer. It is also obvious that the stain depth, t_{st}, does not coincide with t_{eff} as is often assumed. Since t_{eff} corresponds to an easily identifiable point on the SR profile, it is not necessary to calculate the resistivity (or carrier concentration) profile.

Another device, GIMIC (Guard Ring Implanted Monolithic Integrated Circuit) (7) is shown in Fig. 4. In both GIMIC and Oxim as in CDI, the epitaxial layer forms the base region. In CDI and Oxim the base doping is determined by the epitaxial resistivity. In GIMIC the epitaxial layer is grown with the highest possible resistivity, and the effective base doping (the Gummel number) is implanted into this "intrinsic" layer. The actual transition between the intrinsic epitaxial layer and the heavily doped buried layer is quite graded. It was decided that t_{eff} for this device corresponds to the point on the outdiffusion profile where the concentration is 10^{15} cm^{-3}, all material from this point to the surface is considered intrinsic. For six different epitaxial runs, the correlation of t_{eff} and t_{IR} had a maximum spread of ± 0.1 μm, that is, $(t_{IR} - t_{eff}) = 0.9 \pm 0.1$ μm in all cases. The same correlation between t_{eff} and t_{st} had a maximum spread of ± 0.4 μm. Since t_{eff} corresponds to a specific concentration, the raw SR data had to be converted to a concentration profile. As the critical area can be considered to be an N/N$^+$ structure, the *CF* is sufficiently well known to do this conversion with the necessary accuracy.

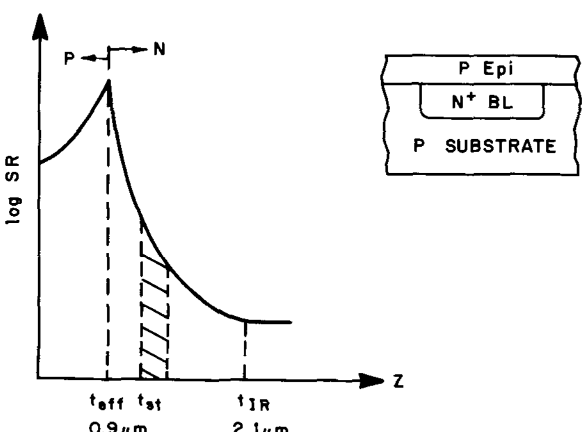

Fig. 3. Spreading resistance profile of Oxim-II epitaxial layer

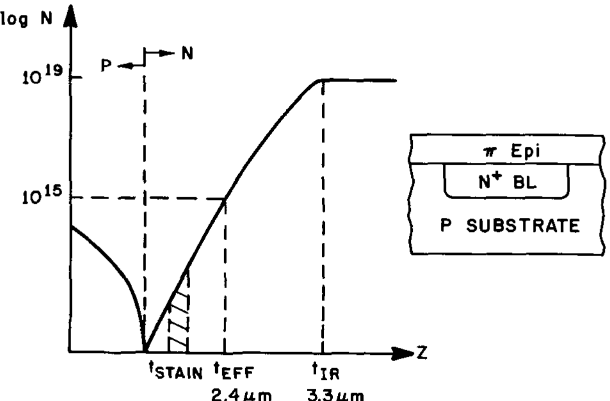

Fig. 4. Spreading resistance profile of GIMIC epitaxial layer

Measurement of the Complete Epitaxial Profile

For N/N$^+$ or P/P$^+$ epitaxial structures, the diode capacitance-voltage (*C-V*) method is often used to determine the carrier concentration profile (8). Analog methods such as the Copeland (9) or Miller Feedback Profilers (10) use the same basic phenomenon as the C-V method to record the profile.

All of these methods are quite useful as they provide a direct measure of the carrier concentration profile N(x) without the necessity of calibration curves for different materials. However, they all suffer the same basic limitation; the minimum and maximum depths over which *C-V* profiles may be obtained are limited respectively by the zero bias depletion width and the depletion width at breakdown. The minimum value of the depletion width is obtained using simple evaporated Schottky diodes; however, these have an inherently soft breakdown, so the maximum depth reached falls short of the theoretical one.

For many types of profiling these limitations are not serious, but if the resistivity at the true surface, or the exact shape of the epitaxial-substrate interface are needed, *C-V* techniques cannot be relied upon.

A 50 GHz IMPATT diode requires an epitaxial structure with the following specifications: substrate—As doped, $\rho \lesssim 0.0015$ ohm-cm; epitaxial layer—As doped, $N_D = 5.3 \times 10^{16}$ cm^{-3} ($\pm 10\%$); and $t_{eff} = 1.5$ μm.

It is required that the carrier concentration, N_D, in the epitaxial layer be constant from the true surface to t_{eff}. After that point N_D should rise as sharply as possible. At $N_D = 5.3 \times 10^{16}$ cm^{-3}, the total distance that a *C-V* profile can cover is approximately 0.35 μm. To measure a complete profile of this epitaxial layer using *C-V* techniques, five different diodes with diffusion depths ranging from 0.0 μm (*i.e.*, a Schottky diode) to 1.3 μm would be needed. Even then the first 0.2 μm could not be measured. Figure 5 shows N(x) profiles of two attempts to fabricate this structure. The *C-V* data were obtained by combining the results of two different diode diffusion depths. The first structure would make good devices while the second would not. This last fact, however, is not readily apparent from the C-V data.

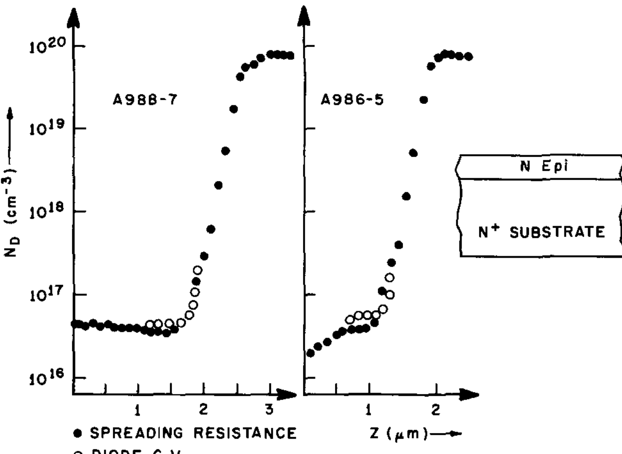

Fig. 5. Spreading resistance and diode *C-V* profiles of IMPATT diode epitaxial layers.

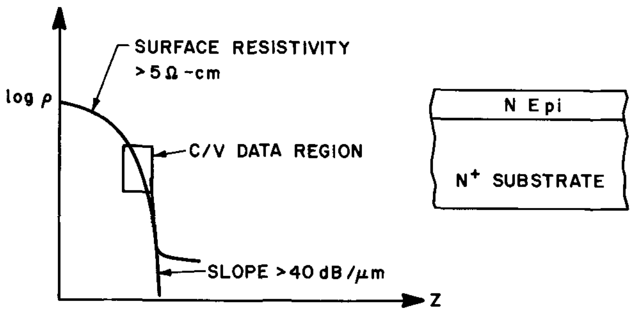

Fig. 6. Spreading resistance profile of PIN phase modulator

The epitaxial profile required for a new PIN phase modulator is shown in Fig. 6. This device requires that the epitaxial resistivity be ≧5 ohm-cm near the surface, and that the resisitvity rise sharply at the epitaxial-substrate interface, $\Delta\rho/\Delta X \geqq$ two orders of magnitude (40 db) per micron. Only a small region of this profile is accessible to C-V profiling, as the zero bias depletion width is typically 1μ, and the breakdown voltage is quickly reached as the epitaxial resistivity starts to decrease. Figure 6 shows schematically the complete profile as determined by SR, and the small portion of the profile acccessible to C-V methods.

Outdiffusion and Autodoping

The ability of SR to measure the entire epitaxial substrate interface makes it a powerful tool to study outdiffusion and autodoping. For the purposes of this paper, outdiffusion is defined as the change in the resistivity profile resulting from solid-state diffusion mechanisms. This process occurs during both epitaxial growth and subsequent heat-treatments. Autodoping is defined as the change in resistivity profiles due to impurities which are evaporated from the substrate and reintroduced into the solid during epitaxial growth. The effective diffusion constant of the substrate during epitaxial growth can be two orders of magnitude greater than the usual solid-state diffusion constant. In Fig. 3 the total outdiffusion is $t_{IR} - t_{eff} = 1.2$ μm. The epitaxial layer was grown over an Sb buried layer heated for 13 min at 1050°C. The corresponding solid-state diffusion length, $2\sqrt{DT}$, in the literature (11) is 0.066 μm. The "effective" diffusion is approximately 180 times greater than this. This enhancement is in good agreement with recent calculations (12) of autodoping-outdiffusion effects over Sb substrates. Detailed knowledge of this phenomenon can be vitally important in the design of new devices utilizing thin epitaxial material.

The initial epitaxial profile will be altered by heat-treatments associated with oxidation and diffusion during processing. Two examples of this on actual device structures are shown in Fig. 7 and 8. Figure 7 shows that in Oxim the average change in t_{eff} after heating is 0.15 μm. Figure 8 shows that after the GIMIC heat-treatments the effective thickness has changed by 0.9 μm, and the "surface" layer has changed from p-type to n-type.

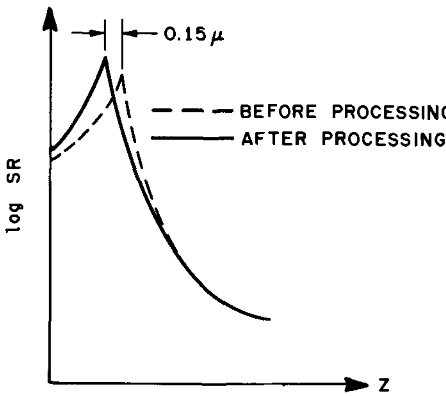

Fig. 7. Oxim-II profile after heat-treatments

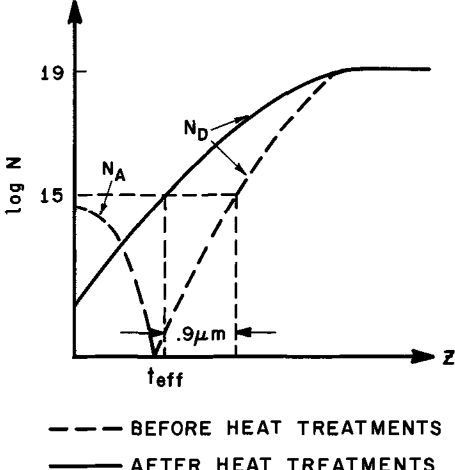

Fig. 8. GIMIC profile after processing heat-treatments

Measurements of Completed Devices

In order to make SR profile measurements in a material t microns thick, a minimum area of approximately 1.5 mm × 150t μm is needed. The first limit is due to the 1 mm spacing between the two probes, the second comes from the 100X magnification of the angle lap. For epitaxial layers grown over a low resistivity substrate (no buried layer) this is not a problem, but for most buried layer patterns this limit cannot be easily satisfied, and a blanket diffused control wafer must be used.

This area limit makes it difficult to do SR profile measurements on most completed device structures; however, measurements can be made on these wafers if there is a large control bar, or if the device itself is one with a large area. An example of the second case is shown in Fig. 9. A power Schottky diode with a large area (160 mil diameter) had been designed for low series resistance and medium breakdown voltages. It was found that the BV map of some completed wafers was very nonuniform, and it was suspected that inhomogeneities in the epitaxial resistivity profile could be the cause of the soft breakdowns. One wafer which showed both good and bad breakdowns was profiled. The measurement results, as shown in Fig. 9, showed that the epitaxial profiles were identical in both diodes, and thus the "soft" breakdowns are not due to nonuniformity of the resistivity profile.

Uses in a Manufacturing Area

The discussion of SR up to this point has emphasized its use as an aid in the development of new epitaxial devices. In addition to these uses, SR measurements can be of use in production environments.

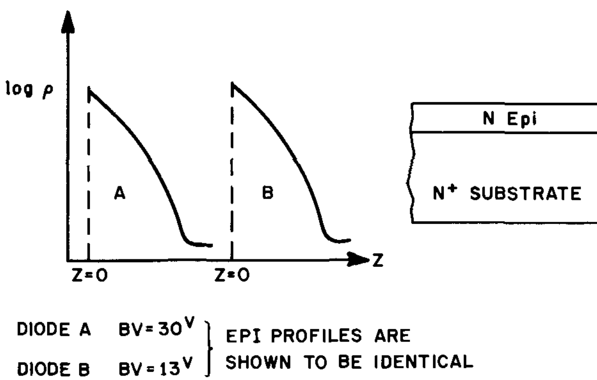

Fig. 9. Spreading resistance used as diagnostic tool

There are two distinct uses of SR in manufacturing; measurement of epitaxial surface resistivity and measurement of the complete epitaxial profile. The first use merely requires placing a wafer in a vacuum chuck in the ASR-100 and measuring R_s at a few points on the epitaxial surface, which has a finish equivalent to a Syton polished surface (2). No angle lapping is required. This measurement is basically nondestructive, the total surface damage being limited to the probe marks which are roughly 8 μm in diameter. In order to calculate the actual resistivity, the layer thickness must be known from IR measurements. Total measurement time for this technique is less than 1 min per wafer, and it may be used on either control or product wafers.

The second use of SR in production requires that a chip be scribed from a wafer for angle lapping. The complete profile of the epitaxial material could then be measured. This technique would take approximately 10-20 min per profile and would thus be limited to a small sample size.

Since this method would significantly contribute to the total wafer cost, its use would be justified only where control of the complete epitaxial profile is vital to the success of the device.

Conclusions

Thin epitaxial material should not be characterized by simply specifying a thickness and resistivity. An awareness of the entire resistivity profile can be essential to the success of the device. In most cases the complete profile can only be obtained by the SR technique.

Once the profile has been established, a correlation of the "effective" epitaxial thickness and the IR thickness may be made. The results of diode C-V profiling, which necessarily covers a limited thickness range, may also be compared to the SR results. Once established, these correlations should remain constant as long as the epitaxial growth conditions and the substrate impurity concentration are unchanged. Changes in the heat-treatment schedule during device processing can also affect these correlations.

Fabrication of GaAs IMPATT Devices Using Electroplated Heat Sinks

II. Control of Water Curvature

G. A. Rozgonyi,* J. V. DiLorenzo,* and E. Heinlein

Bell Laboratories, Murray Hill, New Jersey 07974

ABSTRACT

It has been found that wafer curvature due to the use of electroplated heat sinks in the processing of Pt/GaAs IMPATT device material can be kept to levels low enough to make an essential difference in the yield of processed devices. This has been achieved in a two-step procedure. First, the stresses in the metal layers are determined using an x-ray lattice curvature technique, then a thin metal film with a stress of the opposite sign, compressive tungsten in this case, is used to compensate the bending due to the initial layers. As a result of the multilevel, stress-compensating approach, large area electroplated wafers have been successfully thinned to less than 15 μm without cleaving. Also, preliminary device data show efficiencies and degradation properties comparable to the best data reported thus far for equivalent GaAs material.

Discrete silicon solid-state devices which require low thermal impedance for the dissipation of high input power have traditionally been fabricated by thermal compression (TC) bonding the device to a heat sink of high thermal conductivity. The silicon IMPATT device, where a mesa is TC bonded to a

* Electrochemical Society Active Member.

Key words: GaAs devices, plated heat sinks, wafer curvature.

diamond heat sink (1), is a good example of the application of TC bonding technology. It was, therefore, logical that TC bonding be used in the initial fabrication of compound semiconductor devices such as GaAs Gunn effect (2), IMPATT (3), and heterojunction laser (4) devices. Recently, however, there have been reports (5-8) that the TC bonding processing step leads to material degradation such as dislocation generation and the formation of acceptor states which adversely effect the electrical performance of III-V devices. This is not unexpected since the yield stress in GaAs is considerably lower than that in silicon (9, 10) and dislocation generation is much more likely to occur in the compound. In addition, Brantley and Harrison (11) have found that the degradation rate of electroluminescent GaAs diodes increases by an order of magnitude when the diodes are mechanically stressed beyond a reproducible threshold level. This stress correlated with that necessary for dislocation generation.

Because of the above-mentioned problems of TC bonding applied to compound semiconductors, an alternate approach using electroplated heat sinks (PHS) has been pursued in order to reduce the thermal resistance of GaAs IMPATT devices. The PHS approach has recently been used by DiLorenzo (12) in the fabrication of Gunn diodes of exceptionally high power, efficiency, and uniformity. Carey (13), in a comparison of Gunn devices fabricated by TC bonding and PHS, concluded that the efficiency and yield of PHS devices were consistently better than TC bonded devices.

Although the PHS technology has also improved the reproducibility of the thermal resistance of GaAs IMPATT's (14) new problems have arisen because the stresses inherent in the thin-film platinum Schottky barrier contact and electroplated gold or silver layers cause the GaAs substrate to warp severely. Using x-ray diffraction lattice curvature measuring procedures (15) radii of curvature of less than 1m are typically observed for 0.004 in. thick PHS's on 0.010 in. thick GaAs substrates.[1]

After electroplating. the original GaAs substrate must be removed by lapping and polishing the back side of the wafer. During the thinning step two problems are encountered. First, it has been observed that the GaAs substrate breaks apart by cleaving into as many as a dozen separate pieces after thinning. Although the PHS does serve to hold the pieces of GaAs together, the yield per wafer is necessarily reduced. A second problem arises because a 2 cm wide substrate bent to a radius of curvature, R, equal to 1m has a center to edge deflection of $\sim 25\mu$. Therefore, the wafer will not lie flat on the polishing block during the GaAs substrate thinning procedure. These variations are quite serious since the thickness of the final GaAs thin film/substrate combination is eventually reduced to $10\text{-}20\mu$.

[1] It should be noted that this is an elastic phenomenon and no permanent damage or plastic flow are observed at this stage, contrary to the case with TC bonding procedures.

In the present report we first identify the origins of certain mechanical problems such as wafer warpage and fracture. A particular solution using a multilayer, stress-compensation. thin-film approach is then described. Electrical data are also presented to show that by properly monitoring each stage of device metalization, measurable improvements in the over-all yield and uniformity of actual devices can be achieved. At the same time the efficiency and degradation properties have been as good as the best results reported thus far.

Wafer Curvature in Multilayer Systems

In this section, the substrate lattice curvature due to sputtered platinum films and electroplated gold layers is discussed along with procedures for achieving flat wafers using a multilayer deposition scheme. Initially, the stresses in Pt layers were tensile and varied from 8 to 14 $\times 10^9$ dynes cm^{-2} (see Table I, samples K404 and K398). This was enough for a 0.2 μm film to bend a 0.010 in. GaAs substrate to a radius of curvature $R_{Pt} = +6$m, where the plus sign signifies a tensile film stress. Although the average tensile stress in an electroplated Au layer was only from 2 to 4 $\times 10^8$ dynes cm^{-2}, the 75-100 μm thick Au layer required resulted in an R_{Au} of less than 1m. Since the Au stress was also tensile the R_{Pt+Au} was reduced further. Subsequent work by Murarka (16) showed that compressive Pt films could be deposited by proper control of the sputtering plasma. Although this did serve to counteract the tensile Au plate, the magnitude of the compressive stress required, which would be greater than 10^{10} dynes cm^{-2} for films less than 1μ thick has not yet been achieved.

Concurrent with the attempts to control the sign and magnitude of the Pt film a multilayer scheme was proposed which took advantage of the fact that sputtered tungsten films can be grown with an intrinsic compressive stress of greater than 10^{10} dynes cm^{-2} (15). Initially, a wafer was processed as outlined in Table I, sample K404. As shown, the compressive W film does serve to compensate the effects of the tensile Pt and Au layers. The calculated Au plate required to obtain an $R_{Au} = +3$m was 22 μm. However, due to an unusually severe taper in the Au plate a thickness variation of 17.5-30 μm was obtained. The taper resulted in the GaAs wafer having regions of positive or negative curvature depending on whether R_{Au} was locally greater or less than $+3$m. The measured values of $R_{Pt+W+Au}$ varied from $+120$m to -13m. This represents an improvement of more than an order of magnitude over a nontungsten coated sample. Since the Au surface is made parallel to the back surface of the GaAs substrate in a later processing step, the taper, if present, can be used to pinpoint the optimum thickness for an $R > 100$m. Unfortunately, because of adherence problems between the Au PHS and the stress-compen-

sating W film the PHS separated from the W during subsequent processing of K404. This problem was easily solved by backsputter cleaning the W and then depositing a 2000Å encapsulating layer of Pt over the W. Seventy-five microns of Au were then plated over the Pt cap and no further adherence problems were encountered. Device data on K404 are discussed below.

Because of the incompatibility of Au PHS's and W, and also the high tensile stress in the Pt, two more samples were prepared in a system capable of sequentially sputtering low tensile Pt and highly compressive W. Tungsten-stress compensated, Pt capped structures were then obtained as shown in Table I, samples K398 and S220. In these samples the stress compensation was not as close as in K404 due to the much thicker PHS. Therefore, improvements of only ~3 times that of a non-W coated sample were obtained. However, good PHS adherence was obtained to the top Pt film. Sample S220 was successfully processed through the substrate thinning operation without undergoing any cleavage or fractures. The mechanical stability of the sample is illustrated in Fig. 1(a) which shows that even after thinning to the point where complete removal of GaAs has occurred over a portion of the wafer, thereby exposing part of the Pt layer, the remaining GaAs has not failed. The final GaAs thickness was 15 μm at the top of the wafer shown in Fig. 1(a) tapering off to zero when the Pt metalization was reached.

For comparison, a 0.010 in. thick GaAs sample with a 0.005 in. thick PHS and no stress-compensating W film is shown in Fig. 1(b). Note that this sample, which has not yet been thinned, has already cleaved in at least eight places (see arrows C and white lines orthogonal to C and 45° to C). The radius of curvature of this sample was 0.8m. The calculated maximum stress in the substrate for the sample shown in Fig. 1(b) is only $\sim 1 \times 10^8$ dynes cm^{-2}, which is well below the yield point of GaAs. However, close examination of plated wafers which have spontaneously cleaved indicates that the failure is usually initiated at a flaw near the edge of the wafers. Therefore, it is believed that local stresses can be significantly higher than the

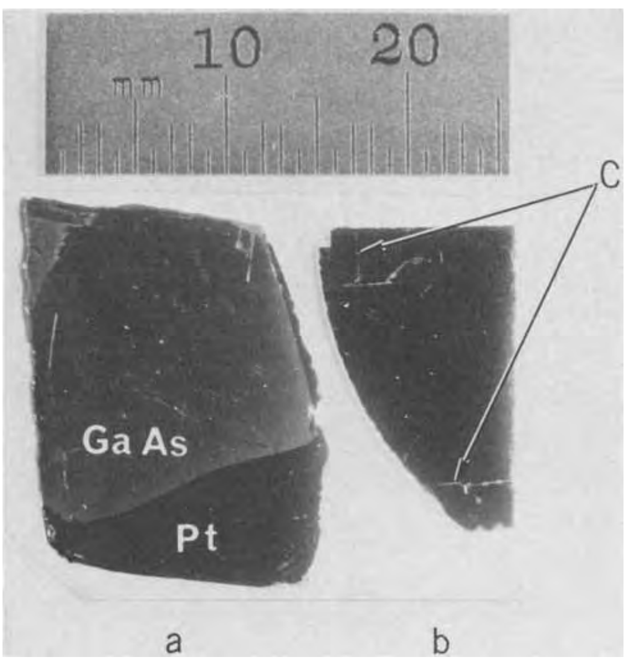

Fig. 1. a, Plated heat sink Pt/W/Pt on GaAs IMPATT wafer after chemical thinning GaAs to remove substrate. The GaAs remaining is tapered from 0 to ~15 μm at the top of the wafer. b, Plated heat sink Pt/GaAs IMPATT wafer which *spontaneously cleaved*, see arrows C, due to handling highly stressed wafer. Substrate has not yet been thinned.

average stress calculated from the radius of curvature. The stress in the chemically thinned sample shown in Fig. 1(a) is estimated to be $\sim 2 \times 10^9$ dynes cm^{-2}. The absence of cleavage and the elastic character of the sample is partly attributed to stress relief by chemical etching of damage at potential cleavage sites during the chemical thinning operation. The actual stress profile in a multilayer, stress-compensated structure depends on the relative thicknesses of the layers and the exact position of the neutral axis, as well as possible gradients in the stress as a function of individual layer thickness. More detailed analyses of the quantitative aspects of this problem will be presented in a separate report. The main point to be emphasized here is that the only two GaAs IMPATT wafers to be successfully thinned without mechanical failure have been stress-compensated, multilayered structures (see Table I S220 and S272B).

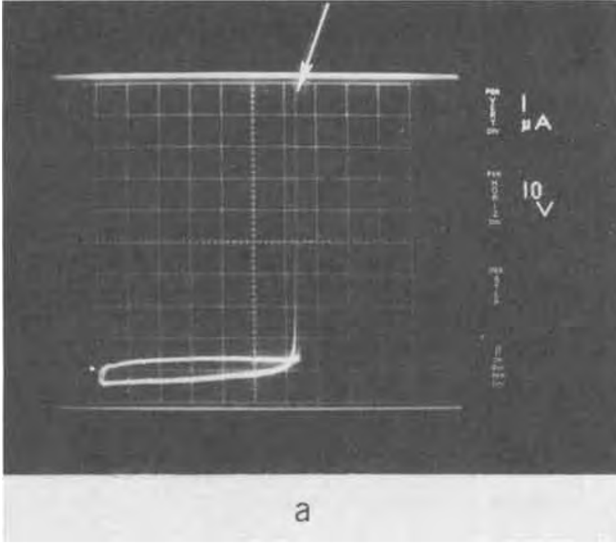
Although sample S220 did not cleave, the substrate thinning did not proceed uniformly, as shown in Fig. 1(a). This is due, in part, to the fact that the wafer curvature, at just under 3m, is still significant enough to cause center-to-edge deflections comparable to the final thickness of the GaAs device, *e.g.*, 5-15μ. However, this is not considered to be a serious problem since recent results show that much larger radii of curvature can be obtained by careful attention to each step of the process. For example, the final sample listed in Table I, S272B, was processed using the dual target sputtering station to obtain a Pt-W-Pt metalization which yielded a -1.2m radius of curvature. This was followed by a 100 μm thick Ag PHS layer which brought the radius over to $+2.0$m. Calculation of the average stress in the Ag layer necessary to effect this bending yielded a value of 1.8×10^8 dynes cm^{-2}. Further calculations showed that thinning the Ag PHS to ~55μ would more effectively balance the compressive stress of the W film. This was done and a sample was obtained with a final radius of 500m over several millimeters of the wafer.

Electrical Characteristics

Device structures and Schottky barrier data.—In this section device data on three wafers, K404, S272B, and S220, processed using the multilayer, stress-compensated PHS technique are discussed. Sample K404 was fabricated into single mesa IMPATT devices 125 μm in diameter on a PHS with dimensions 0.625 in. × 0.625 in. × 75 μm thick. Slices S220 and S272B were processed into distributed four mesa structures (14) with each 150 μm diameter mesa connected by 8 μm Au leads on a 1.25 mm diameter PHS (Au PHS for S220 and Ag PHS for S272B).

The reverse I-V characteristics of a representative device from slice K404 are presented in Fig. 2. A negligible amount of leakage current is observed prior to breakdown at approximately -62V for both 10 μA and 10 mA per division sensitivities. The abruptness of this reverse characteristic at both current values indicates that the Schottky barrier resulting from the Pt-W-Pt PHS IMPATT is free of microplasmas. The absence of microplasmas at the edge of the mesas on sample K404 at reverse biases up to 55V was recently confirmed by S. E. Haszko of these laboratories during a series of electron beam induced current studies of GaAs IMPATT's with the scanning electron microscope.

Ten devices from slice K404 were bonded into diamond V-3 packages using an Au-Sn eutectic bond. These devices were RF tested at X band (10-11 GHz). The efficiencies (and performance) of these devices at 10.8 GHz were very uniform giving values from 11% yielding 1.5W out for 13.7W in, to as high as 15% for 6.8W input. The efficiency of these units is equal to the best obtained to date for single mesa devices with Pt Schottky barriers. The power output of these devices was limited primarily because of size and package limitations and not for any fundamental reason. Eight devices from slice S272B were bonded into V-8



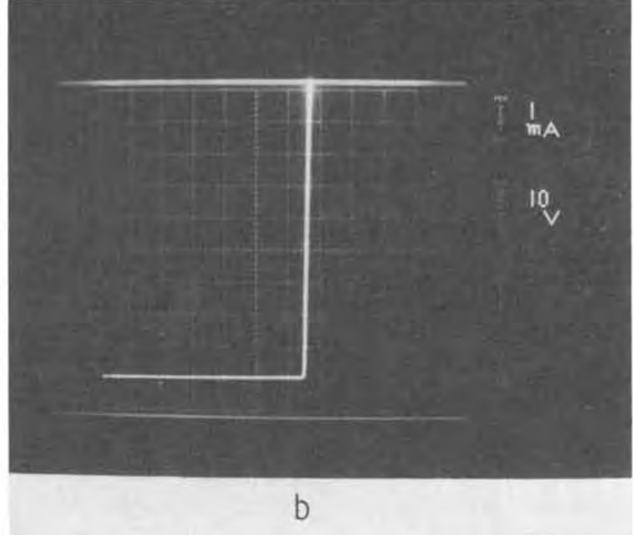


Fig. 2. Reverse I-V characteristics of representative device from slice K404. a, 1.0 μA/cm sensitivity; b, 1.0 mA/cm sensitivity.

Cu packages (14) and RF tested at C band (≈4-6 GHz). The average peak efficiency of these devices was 11.6% at 5.4 GHz with 18W input, and ≈10% at 32W. The performance of the multimesa devices from S272B is comparable to single mesa TC bonded diodes on diamond heat sinks.

Units from slice S220 also had extremely sharp reverse I-V characteristics and were bonded into packages for reliability tests which are discussed below.

Preliminary aging data.—Recently great emphasis has been placed on obtaining an estimate of the expected life of a GaAs IMPATT diode at a junction temperature of 200°C. One approach which has been used is to monitor the softening of the d-c characteristics of a packaged diode at an elevated temperature as a function of time. Based on previous data of this type from Irvin (17) for Pt/GaAs single mesa IMPATT devices, aged at temperatures of 350° and 323°C, the expected life, or time to failure,[2] of an IMPATT should be approximately 500 hr [3] at 300°C and greater than 10^6 hr at 200°C. The six diodes packaged from sample S220 were aged for 532 hr at 300°C and resulted in only one diode failure. Therefore, following Irvin's analysis, the extrapolated life of the remaining diodes would be greater than 10^6 hr.

Discussion and Conclusions

Although the primary objective of this work was to maintain the mechanical integrity of a wafer by keeping it from warping or cleaving during processing, it is important to note that the final product, assuming a balanced stress compensation has been achieved, will have an epitaxial GaAs layer with very low stress. This is due to the fact that the initial deposit is a stress-free, homoepitaxial layer. Stresses in the layer are encountered only after metalization, and the maximum GaAs stress generated, even for a Pt film stress of 1×10^{10} dynes cm^{-2}, would be less than 5×10^7 dynes cm^{-2} for a final GaAs thickness of 20 μm, provided the wafer is kept flat. Although the initial device performance is not expected to be critically dependent on stress, many of the degradation mechanisms proposed for device failure invoke phenomena which are enhanced by stress and strain.

Summarizing the results described above, it has been shown that the wafer curvature introduced during the processing of GaAs IMPATT device material using plated heat sink technology can be kept to levels low enough to make an essential difference in the processing yield. This has been achieved by proper characterization of the stresses in the Pt and Au or Ag layers, and by the introduction of a stress compensating W thin film. As a result of the multilayer, stress-compensating approach, wafers have been successfully thinned to less than 15μ without undergoing any cleavage or fracture. Initial electrical data show extremely hard I-V characteristics with uniformly high breakdown voltages. Also, the degradation properties and efficiencies are comparable to the best data reported thus far for similar GaAs IMPATT devices. Finally, it is noted that the analytical procedures used for film stress studies and wafer curvature control would generally be applicable to a wide variety of semiconductor devices which are subjected to processing conditions which bend the device wafer, *e.g.*, heterojunction lasers and silicon integrated circuits.

[2] Failure is defined here to mean a 2% reduction in the reverse voltage needed to draw 10 μA current.

[3] Five hundred hours based on an activation energy of 1.9 eV and 1000 hr for an activation energy of 1.0 eV.

The Reaction Between Silica and Aluminum

K. Prabriputaloong and M. R. Piggott

Department of Chemical Engineering and Applied Chemistry, Materials Research Centre, University of Toronto, Toronto 5, Ontario, Canada

ABSTRACT

Earlier studies on this reaction, using thin aluminum films on silica substrates, have been extended to temperatures below the melting point of aluminum, and the effect of crystallinity in the silica has also been investigated. Electron and x-ray diffraction were used for detection and identification of reaction products. Between 400° and 850°C the reaction obeys the Arrhenius equation, but suffers an abrupt change of activation energy at the melting point of aluminum. With quartz, the activation energy is greater and the reaction rate is less than with vitreous silica. The main products of reaction are θ-Al_2O_3 and Si below the melting point of aluminum, but above the melting point a volatile oxide of aluminum is formed (probably Al_2O) when thin films are used. The reaction seems to be influenced very little, if at all, by the physical form of the film, or by the presence of water or air.

Solid-state reactions are important in at least two areas. In the field of electronics, solid-state circuitry is in widespread use, and often involves potentially reactive materials in close contact, *e.g.*, the aluminum contacts on oxidized silicon (1). In the field of structural materials, fibrous composite materials are being considered for use in turbines and in other high temperature applications (2). Nearly all combinations being considered are potentially reactive. (The only exceptions are the directionally solidified off-eutectic alloys which contain long fibers or platelets of the eutectic alloy in a matrix of the excess metal.)

Some studies on the solid-state reaction between aluminum and silica have already been carried out. Cratchley and Baker (3) observed some reaction product when they examined etched sections of silica fiber reinforced aluminum in the microscope after 500 hr at 500°C. This was thought to account for the drastic reduction in strength of the material at this temperature. Silverman (4) examined the electrical resistance of 0.2μ thick condensed aluminum films on various types of silica substrates after heating to temperatures between 400° and 625°C in various atmospheres, for periods of from 1 to 21 hr. X-rays were used to analyze the products on some of the specimens. He found that moisture either on the silica, or in the atmosphere had a considerable effect on the reaction rate, as determined by resistivity changes, but did not report detecting any reaction below 550°C. X-rays only revealed Si as reaction product. Chou and Eldridge (1) did detect some reaction product (γ-Al_2O_3) after 2 hr at 500°C using electron diffraction and microprobe analysis.

Key words: silica substrates, aluminum, x-ray diffraction.

Moisture in the silica was also felt to be important by Standage and Gani (5), who did experiments above the melting point of Al and used light microscopy to determine reaction rates, and x-rays to determine products of reaction. Their x-ray results indicate that more than one crystallographic form of Al_2O_3 was produced by the reaction, as well as Si. They observed an induction time before reaction started, which they ascribed to the effect of moisture, but which was later shown (6) to be due to adventitious oxide on the molten Al surface.

Silica fiber reinforced aluminum is weaker at 400°C than at room temperature (7), and the effect is probably due to a solid-state chemical reaction, since storing the material at this temperature for a period of 3 months halves the room temperature strength (8). The reaction is therefore worth investigating in more detail at temperatures lower than 550°C, and with more sensitive techniques than hitherto. Prabriputaloong and Piggott (9) have demonstrated the sensitivity of electron diffraction for this purpose at temperatures above 700°C, and the work described here is an extension of those studies down to a temperature of 400°C.

Experimental Method

The apparatus used has already been described in detail (8). The experimental method consisted of

evaporating a sufficient amount of high purity (99.999%) aluminum wire to condense a film of about 0.1μ thick on a piece of silica (also 99.999% pure). Two forms of silica were used: vitreous silica ("Suprasil II" obtained from Amersil Incorporated) having a density of 2.2 g/cm^{-3}, and quartz single crystals. The surfaces used for the reaction were polished to optical smoothness. The quartz crystal surface was a (0001) plane, and the crystal was initially the low temperature (α) form. Heating prior to reaction caused its transformation to the high temperature (β) form. The silica was solvent cleaned, and was placed inside a box made of thin tantalum strip that could be heated and cooled very rapidly. Prior to the condensation, water absorbed at or near the surface was removed by heating the silica to 800°C for at least 10 min in vacuum, except in cases where the effect of absorbed water on the reaction was being investigated.

Condensation was carried out at the reaction temperature and at room temperature. The reaction was allowed to take place in air, as well as in vacuum ($\sim 10^{-6}$ Torr). For the experiments in air, the specimen was cooled rapidly immediately after condensation, when this had been carried out at reaction temperature, so that a significant amount of reaction product was not formed during the condensation process. The specimen was then transferred to a small commercial laboratory furnace for the reaction. For reactions in vacuum the same chamber was used as for the condensation.

After the reaction experiment was completed, the specimen was transferred to an electron diffraction camera for examination. The topography of some films was also examined in the light microscope, and using palladium shadowed carbon replicas, in the electron microscope. In addition, x-ray patterns were obtained from the reaction products by grinding several similar specimens together and removing glassy particles under a light microscope.

Air-formed oxides on aluminum were also examined. They were made by first condensing aluminum on rock salt, then oxidizing the aluminum while on the salt.

Experimental Results

Figure 1 shows the results for the reaction in different environments, *i.e.*, for films condensed on hot substrates, on cold ($\sim$20°C) substrates, and on water-soaked cold substrates. (Water soaking was carried out by immersion in water at room temperature for 1 week.) The substrates in all these cases were vitreous silica, and the reaction rate was evaluated by determining the time required to produce enough silicon to be detected by electron diffraction.

It can be seen that in air the reaction seems to take place slightly more slowly than in vacuum. Condensation onto cold substrates also resulted in a slight decrease in reaction rate, but these differences were barely any greater than the spread of results. The reduction in reaction rate due to water soaking appears to be more significant, however.

The films formed by condensation at the reaction temperature were in the form of droplets, while those condensed at room temperature were continuous, whether or not the silica contained substantial amounts of water (Fig. 2-4). The appearance of the films after reaction for 15 hr at 500°C is also shown in Fig. 2-4. It will be seen that, while the appearance of the film condensed on the hot substrate showed very little change as a result of the reaction, both continuous films changed considerably. The film on the initially dry substrate was still substantially continuous, but became very uneven, while the film on the water-soaked substrates broke up into disconnected, irregular patches, a few microns in extent.

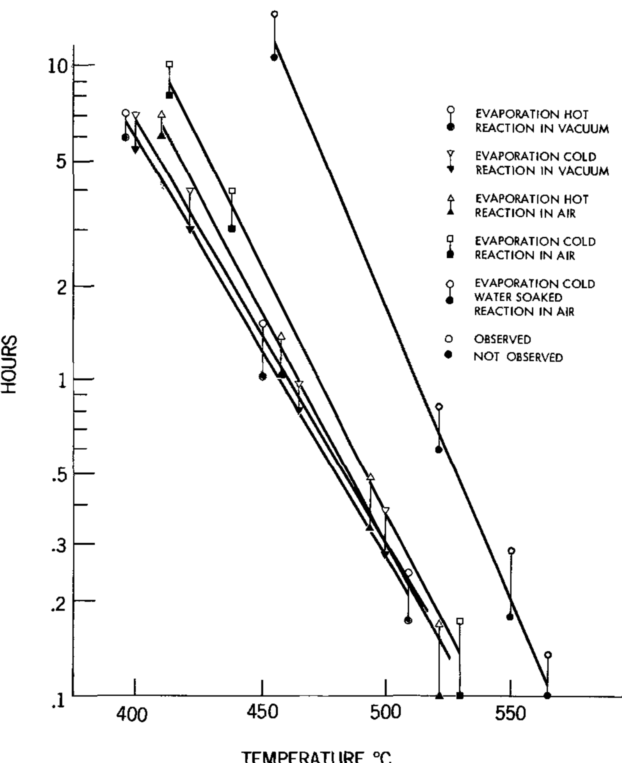

Fig. 1. Curves showing time of first appearance of reaction products in thin-film reaction under different experimental conditions.

Quartz crystals were also used as substrates, and were found to react more slowly than vitreous silica under the same conditions. All the results in the temperature range 400°-850°C, for vitreous as well as crystalline silica, are summarized in the Arrhenius plot shown in Fig. 5.

No crystalline alumina was observed as a result of the air oxidation of the thin aluminum films. The electron diffraction pattern, all rings which were due to elementary aluminum, became less distinct as a result of the oxidation, but no extra rings were observed (Fig. 6).

However, the oxide formed as a result of the Al-SiO_2 reaction below the melting point was crystalline, and consisted mainly of θ-Al_2O_3, with traces of α-Al_2O_3. Si was also detected in the reaction products. A typical electron diffraction pattern, obtained after the reaction had been allowed to proceed almost to completion, is shown in Fig. 7. The detection of θ- and α-Al_2O_3 was confirmed by x-ray examination of the crushed reaction products. The only product observed from the reaction above the melting point of the aluminum was Si.

Discussion

The results reported here appear to be in good agreement with the earlier electron diffraction work (9), except for the anomalous result that had been obtained at 700°C. This result appears to have been slightly in error, and it now seems likely that the change in slope of the Arrhenius plot occurs at the melting point of aluminum (Fig. 5). The activation energies indicated by the slopes of the lines in this figure are:

vitreous silica

31 kcal/mole ($T < T_m$) 17 kcal/mole ($T > T_m$)

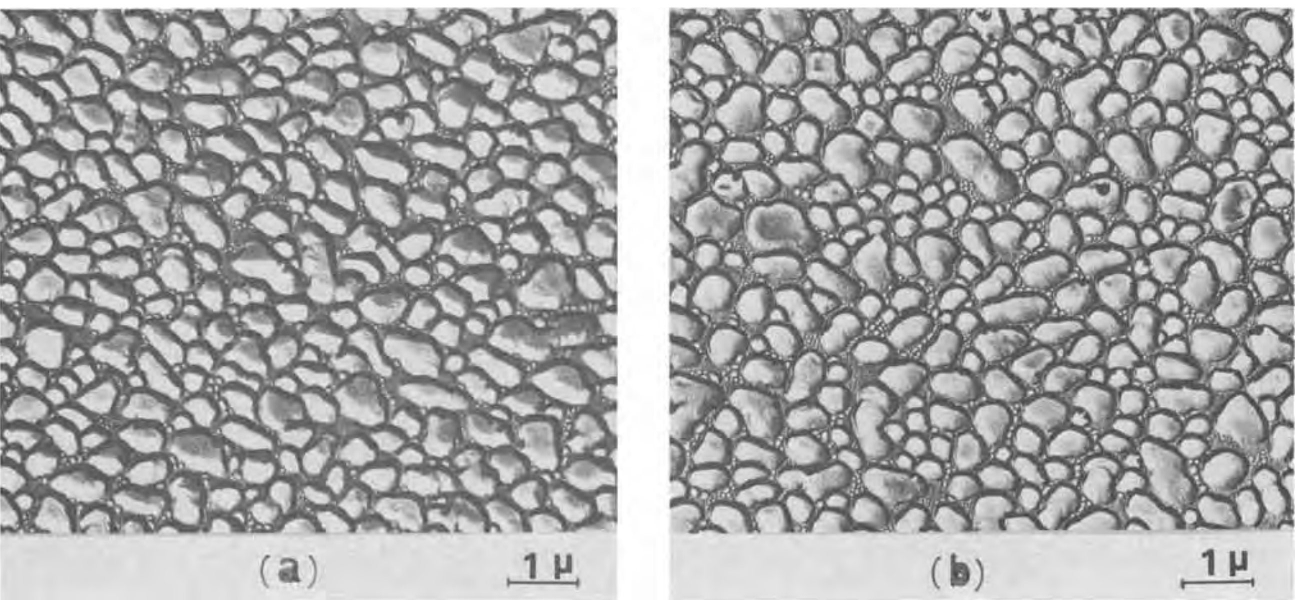

Fig. 2. Micrographs of Al films evaporated onto hot silica substrate (a) before and (b) after reaction at 500°C for 15 hr.

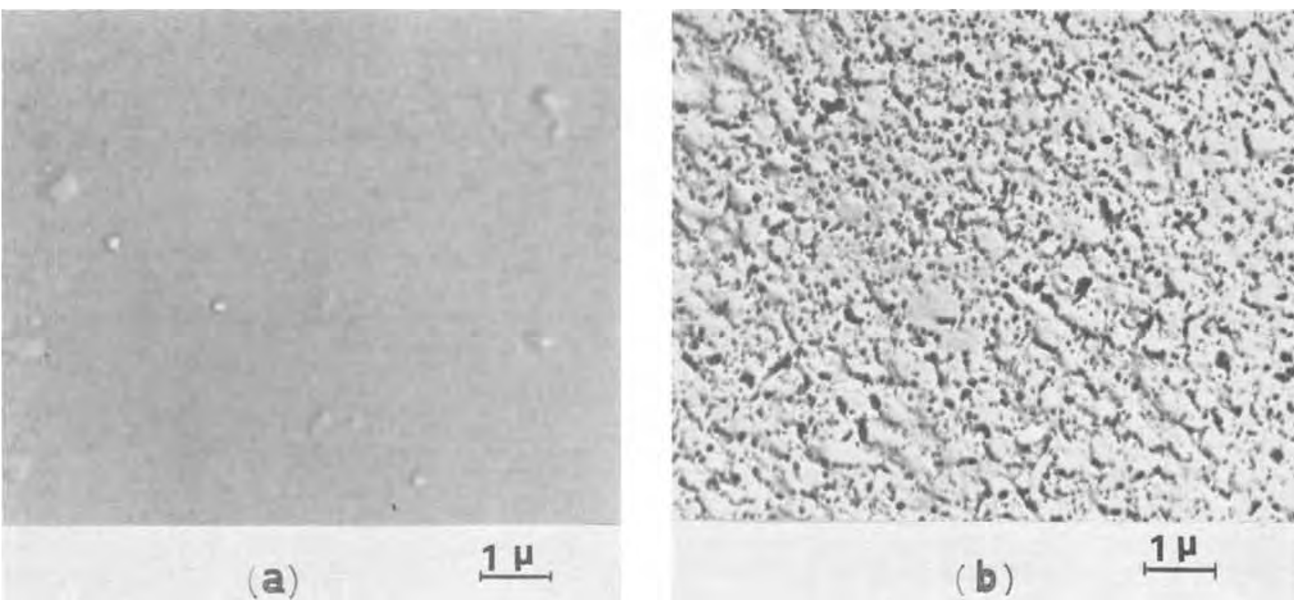

Fig. 3. Micrographs of Al film evaporated onto silica substrate at room temperature (a) before and (b) after reaction at 500°C for 15 hr.

quartz

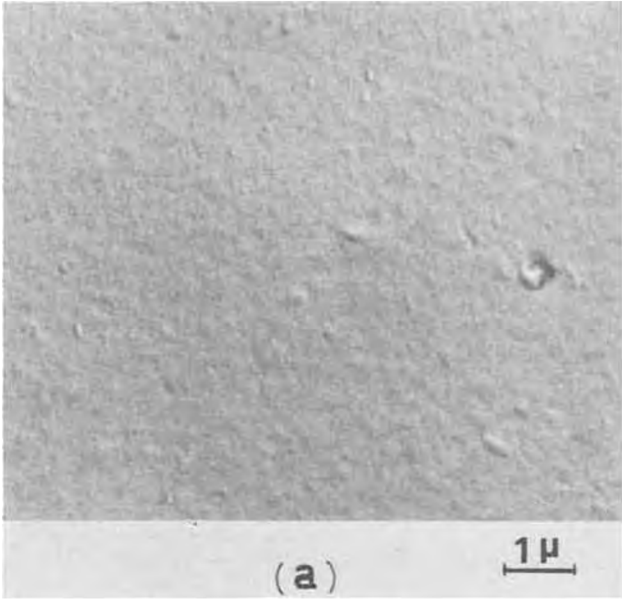
64 kcal/mole ($T < T_m$) 27 kcal/mole ($T > T_m$)

(all results accurate to about ±10%).

The higher activation energies and lower reaction rates observed when the silica is crystalline are in keeping with the observation that quartz is the least reactive form of silica (10), but the differences between the activation energies (above) seem not to be related in any simple way to the heat of fusion of quartz, or to differences in the heats of formation of the different forms of silica.

The products of reaction also change abruptly at the melting point of aluminum when thin films are used. Below the melting point, the products are θ-Al_2O_3, traces of α-Al_2O_3, together with elemental Si. Above the melting point, the only product observed has been silicon, whether the silica was vitreous or crystalline. The oxide of aluminum produced above the melting point was probably the volatile Al_2O (9), but attempts to detect it with a mass spectrometer have not, so far, been successful. [This lack of success is not surprising since the Al_2O would condense on any cool surface it met (*e.g.*, the walls of the vacuum vessel) and the quantity produced would anyway be very small.] The reaction with quartz gave the same products as the reaction with silica under the same conditions.

In the case of the reaction below the melting point, the bulk reaction, and the thin-film reaction above the melting point, direct formation of Al_2O vapor at the SiO_2-Al interface and its escape should be impossible (its vapor pressure, even at 800°C, is sufficient only to support a column of aluminum 5Å high). The reaction is therefore considered to take place as follows (9). First the Si-O bond is ruptured, and Si and O go into solution in the aluminum. When the aluminum is liquid and in the form of a thin layer, the O can quickly diffuse to the surface and escape as Al_2O. In the case of the bulk reaction, the diffusion of oxygen is not sufficiently fast since the distance it has to go is much greater than in the thin-film case, and the rate of formation of θ-Al_2O_3 becomes significant. The results obtained for the reaction below 660°C suggest that, in this case also, the rate of diffusion of oxygen atoms to the surface of the film is slower than the rate of formation of Al_2O_3.



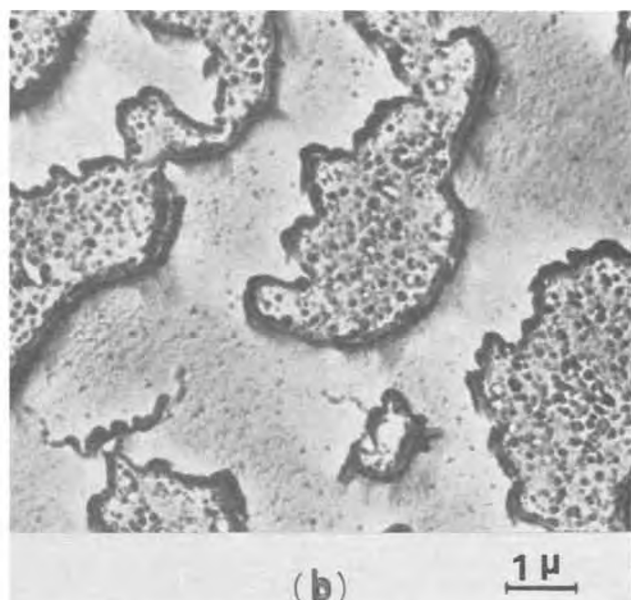


Fig. 4. Micrographs of Al film evaporated onto water-soaked silica substrate at room temperature (a) before and (b) after reaction at 500°C for 15 hr.

The lowering of the melting point of aluminum by solution of silicon[1] does not appear to influence the reaction significantly. The discontinuity in activation energy does not occur at the Al-Si eutectic point; drawing lines through the experimental points of Fig. 5 on the assumption that the change in slope occurs at

[1] We are grateful to the referee for drawing this point to our attention.

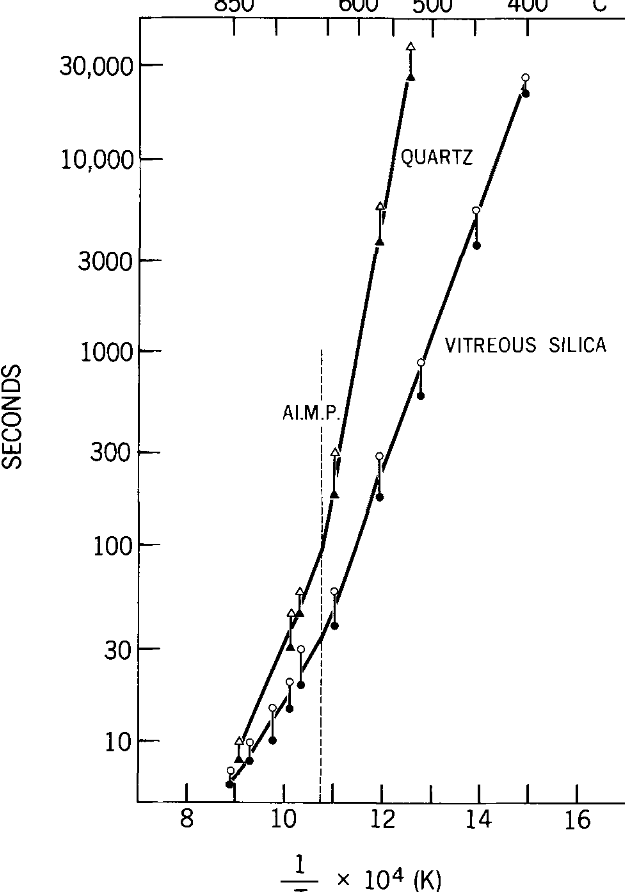

Fig. 5. Arrhenius plots of reactions between Al and quartz and silica at temperatures both above and below the melting point of Al.

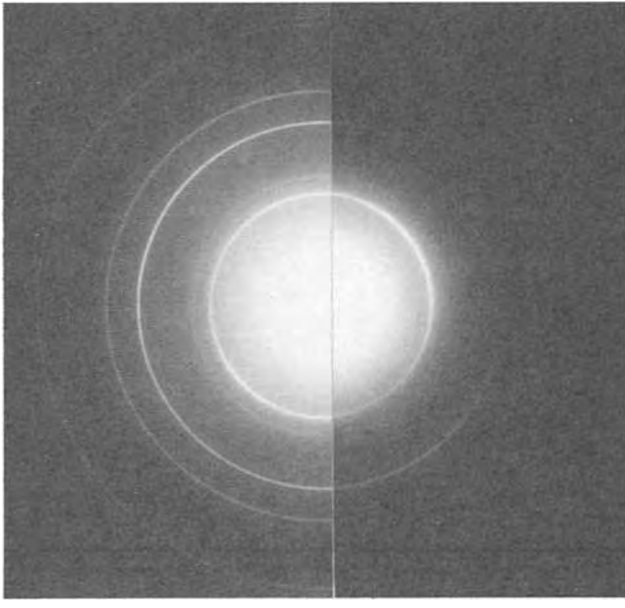

Fig. 6. Electron diffraction patterns of Al film (left) before and (right) after being oxidized by air.

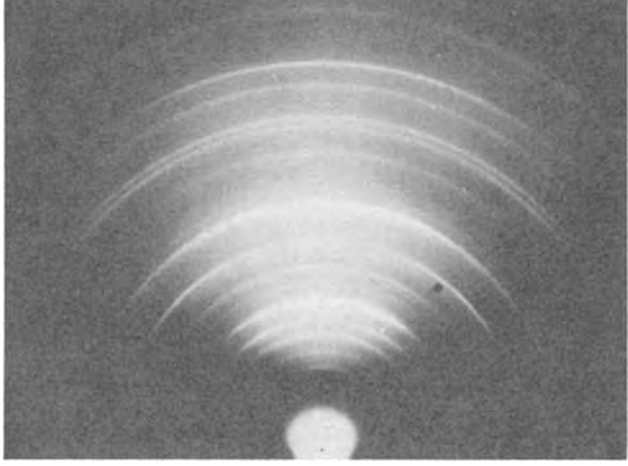

Fig. 7. Typical electron diffraction pattern of reacted Al film showing Si, α-Al_2O_3, and traces of θ-Al_2O_3.

577°C gives a very poor fit, especially in the case of the quartz crystals. This suggests that the role of the oxygen produced when the first few atomic layers of silica decomposes must be decisive. If it can diffuse away (the thin-film, molten aluminum case), Al_2O is formed. If it cannot diffuse sufficiently quickly (the solid aluminum case) the Al_2O_3 barrier is formed before sufficient silicon has been produced to significantly lower the melting point of aluminum.

The effect of condensation conditions on the reaction was very small, despite the difference in physical form of the film. The presence of water in the silica, however, did have a significant effect, but this may well have been due simply to the water lifting the aluminum film off the silica surface; it certainly appears to have caused disruption of the film (Fig. 4).

The presence of air during the reaction had very little effect. This conflicts with the results of Silverman. However, Silverman failed to detect any reaction at all at temperatures below 550°C, so his method seems not to have been very sensitive. It could be that the method he used is not reliable either; disruption of the film, observed when the silica contained some water, would certainly lead to misleading electrical resistance values. So would sintering of the film, which is very likely to occur at 550° and 600°C. Such disruption could also account for some of the visual changes he described. Finally, x-ray diffraction is not sensitive enough to detect the very small quantities of reaction products very reliably; this is confirmed by Silverman's failure to detect θ-Al_2O_3, which electron diffraction shows is produced in similar quantities to the Si.

The apparent lack of much effect due to the presence of air is not surprising. Air can be expected to affect the thickness of the amorphous oxide film on the side of the aluminum exposed to the atmosphere (such an increase in thickness of this oxide was indirectly observed, Fig. 6). However, such films are good barriers to further oxygen penetration, so the aluminum should contain little oxygen from this source compared with the amount available from reduction of the silica. Similarly, it seems unlikely that water vapor in the environment or in the silica has much effect. The results of Standage and Gani (5) and Silverman (4) appear to be in conflict on this point, while the results herein reported suggest that water in the silica only has a slight effect even when there is enough water for physical disruption of the aluminum film.

Conclusion

Reaction between aluminum and silica occurs below the melting point of aluminum with the formation mainly of θ-Al_2O_3 and Si. The rate is governed by the Arrhenius equation

$$R = R_0\, e^{-E/kT}$$

where E has the value 31 ± 3 kcal/mole for vitreous silica, and 64 ± 6 kcal/mole for quartz. This equation is obeyed at least down to 400°C. The activation energy for the reaction decreases abruptly at the melting point of the aluminum, and a volatile oxide (probably Al_2O) is formed.

The water content of the silica has only a slight effect on the reaction, and this effect may be entirely due to disruption of the film by escaping water vapor when the specimen is heated. Under clean conditions, the physical form of the film has little effect on the reaction, and whether the reaction is carried out in air or in vacuum (10^{-6} Torr) has very little effect on the results.

Manuscript submitted April 2, 1973; revised manuscript received Sept. 11, 1973.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1974 JOURNAL. All discussions for the December 1974 Discussion Section should be submitted by Aug. 1, 1974.

Interaction Between Phosphosilicate Glass Films and Water

Naoyuki Nagasima, Hisako Suzuki, Keizo Tanaka, and Sumio Nishida

Semiconductor and Integrated Circuits Division, Hitachi, Limited, Kodaira, Tokyo, Japan

ABSTRACT

Phosphosilicate glass (PSG) films were deposited onto silicon substrates by the oxidation of SiH_4 and PH_3 at 350°C. Densities, phosphorus oxide concentrations, and infrared absorption spectra were measured for the evaluation of the film structure. It was found that nearly all the phosphorus oxide in a PSG film containing more than about 8 mole per cent P_2O_5 was dissolved into water by exposing to saturated water vapor at 120°C. By heating at elevated temperatures, the phosphorus oxide concentration value at which phosphorus oxide began to dissolve shifted toward the higher concentration region. Water absorption in the PSG film also can be lessened considerably by heat-treatment.

Since Kerr *et al.* (1) reported in 1965 that a phosphosilicate glass film (PSG film) is effective for stabilizing the surface of silicon planar transistors, it has been confirmed by many investigators to decrease surface instabilities due to ionic drift (2). However, application of a PSG film to silicon devices has been accom-

Key words: PSG film, activation analysis, phosphorus concentration, infrared absorption, moisture resistance.

panied by some problems. One of them is the influence of water on the PSG film, which is the subject dealt with in this paper.

Corl *et al.* (3) and Esch *et al.* (4) examined the water stability of their PSG films by infrared absorption spectroscopy. Yamada *et al.* (5) reported that the dissolution of phosphorus oxide in their passivated film on a transistor into water resulted in degradation of the p-n junction. Daghir (6) used a PSG layer as a moisture detector to evaluate overcoatings of rf-sputtered and CVD SiO_2 films.

Phosphorus oxide concentration is an important parameter of the PSG film. It is known empirically that, as the phosphorus oxide concentration increases, the film will absorb water more easily. However, to our knowledge, no report concerning the effect of phosphorus oxide concentration on interaction between PSG film and water vapor has been made available.

In the present paper, the influence of water on CVD PSG films having various phosphorus oxide concentrations are treated. Some considerations on the structure of the PSG film are also given.

Experimental Procedure

PSG films used in the present study were prepared on Si surfaces by oxidizing SiH_4 (diluted to 4% by N_2) and PH_3 (diluted to 1% by N_2), using an apparatus shown schematically in Fig. 1. The Si substrate was p-type (B-doped), 10 ohm-cm, cut parallel to the (111) plane or (100) plane, and mirror polished. The flow rates of SiH_4, O_2, and N_2 were 0.04, 0.35, and 25 liters/min, respectively; phosphorus oxide concentration in the PSG film was controlled by changing the flow rate of PH_3. The substrate temperature was kept at 350°C during the film formation.

The phosphorus content in the PSG film was measured by means of neutron activation analysis. The sample together with the standard sample ($NH_4H_2PO_4$) were irradiated for 5 hr in the atomic reactor with a thermal neutron flux of about 2×10^{12} n cm^{-2} sec^{-1}, and then cooled for about two weeks for reducing the ^{31}Si activity (the half-value periods of ^{31}Si and ^{32}P are 2.62 hr and 14.3 days, respectively). After cooling, the β-activity of the ^{32}P was measured by a gas flow GM counter. The phosphorus content was also measured by means of an electron probe microanalyzer. In this measurement, the sample whose phosphorus content was determined by neutron activation analysis was used as a standard sample, and correction of the phosphorus content was made in consideration of the penetration depth of electrons into the PSG film.

Immediately after deposition, the sample was weighed on a Mettler microbalance with an accuracy of 1 μg, and the infrared absorption spectrum was taken by a Hitachi 225 double-beam spectrophotometer. The moisture test was conducted by exposing a sample to the saturated water vapor at 120°C (vapor pressure, 1.96 atm.) for 4 hr. After exposure, the sample was kept in the room at a temperature of 20°C and a relative humidity of 50% for 24 hr, and then the weight and infrared absorption spectrum were measured again. The thickness of the PSG film was determined by means of a Taylor-Hobson stylus instrument "Talystep 1" of which the resultant accuracy was ±30Å in the range of 0.5-1μ. Electron microscopic observation was also made.

Results

Figure 2 shows an example of the relationship between the PH_3/SiH_4 ratio and the phosphorus oxide concentration in the PSG film. Figure 3 shows electron microphotographs of PSG film surfaces, CVD SiO_2 and thermally grown SiO_2 films are also shown for comparison. Surfaces of the thermally grown SiO_2 and CVD SiO_2 films appear rather smooth, but the PSG film surface is coarse. It seems that surface roughness of the PSG film is not very dependent on the phosphorus content.

The change of film density after the moisture test is shown in Fig. 4, together with the result of the moisture test of the PSG film heat-treated in dry N_2 at 900°C for 15 min. In the range of the low phosphorus concentration, the as-deposited PSG film after the moisture test did not show a change in density. However, in the range where the phosphorus oxide concentration exceeded about 8 mole per cent (m/o), the film density showed a remarkable decrease by the moisture test.

It is well known that SiO_2 film deposited at low temperatures decreases in thickness when heated at a higher temperature. In the present case, when the sample was heated for 15 min in dry N_2 at 900°C, the film thickness was reduced by about 7% irrespective of phosphorus oxide concentration. The phosphorus oxide concentration value at which phosphorus oxide began to dissolve shift towards the higher concentration region by heating.

To find the cause of density change by the moisture test, the phosphorus oxide concentration of PSG films before and after the moisture test were measured. The results are shown in Fig. 5. In the figure, the abscissa shows the phosphorus oxide concentration before the moisture test, while the ordinate shows that after the moisture test. This figure indicates that the data point will be plotted on the 45° angle straight line in the case where there is no change in phosphorus oxide concentration by the moisture test. It was revealed that phosphorus oxide in the PSG film with

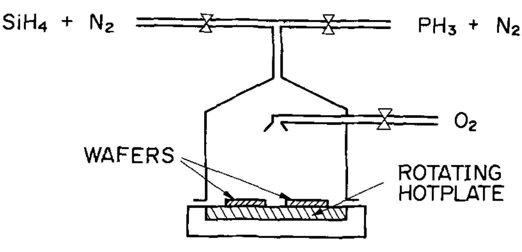

Fig. 1. Schematic drawing of apparatus for vapor deposition of PSG films.

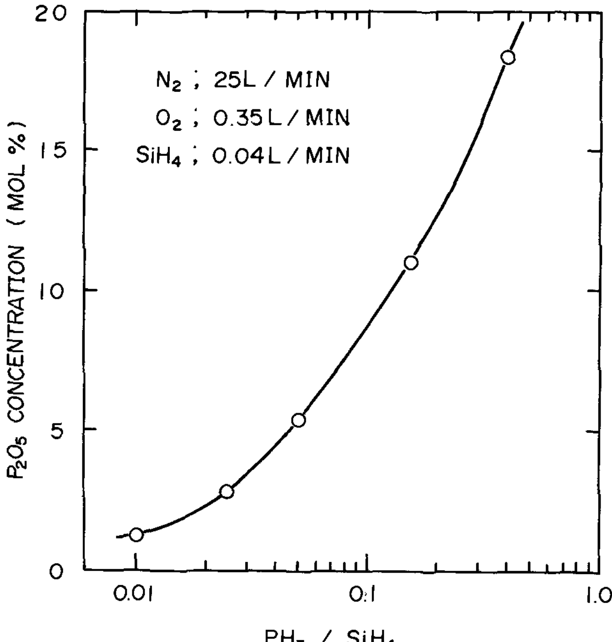

Fig. 2. Phosphorus oxide concentration in PSG film vs. PH_3/SiH_4 volume ratio.

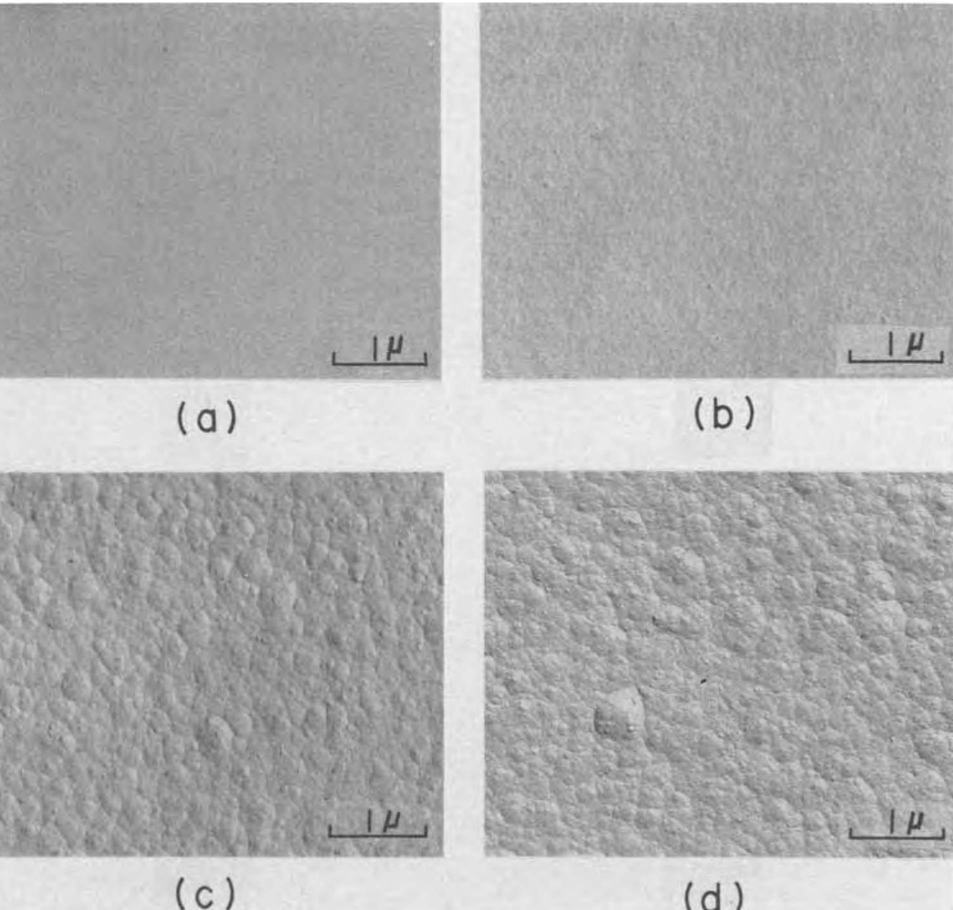

Fig. 3. Electron micrographs of surfaces of (a) thermally grown SiO_2, (b) CVD SiO_2, (c) PSG film containing 2.8 m/o P_2O_5, and (d) PSG film containing 10.5 m/o P_2O_5.

the concentration above a certain value is mostly dissolved into water by exposing to the saturated water vapor at 120°C for 4 hr. This concentration value is conveniently termed the "critical concentration" in the present paper. The critical concentration corresponds with the point in Fig. 4 at which the film density begins to decrease by the moisture test. Figure 6 shows the relationship between heating temperatures and the critical concentrations of PSG films heat-treated in dry N_2. As an ambient for heat-treatment, dry O_2 was proved to have the same effect as dry N_2 in improving resistance to moisture. Here, we named the α-phase the region (0-8 m/o) where phosphorus oxide in the as-deposited film does not dissolve by the moisture test, the β-phase the region (more than 8 m/o) where phosphorus oxide dissolves, and the $\alpha\beta$-phase the region where dissolving ceases to occur by heat-treatment.

Figures 7(a) and 7(b) show the infrared absorption spectra of the PSG films before and after heating at 900°C. The intensity of the P-O absorption peak at 1300 cm^{-1} increases with an increase in the phosphorus oxide concentration, and the Si-O absorption band near 1100 cm^{-1} is influenced by the existence of phosphorus oxide. In the film which allowed the phosphorus oxide to dissolve by the moisture test, the P-O peak disappeared. At the same time, absorption peaks emerged in the neighborhood of 3700 cm^{-1} and 910 cm^{-1}, because of the existence of the water and silanol. Except for the absorption peaks due to water

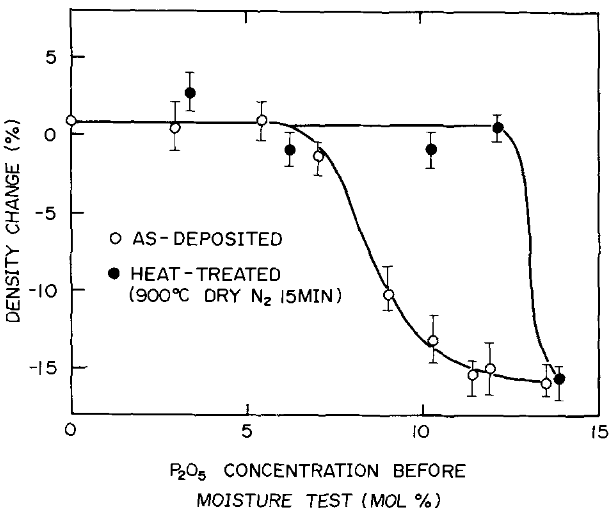

Fig. 4. Change of film density after moisture test

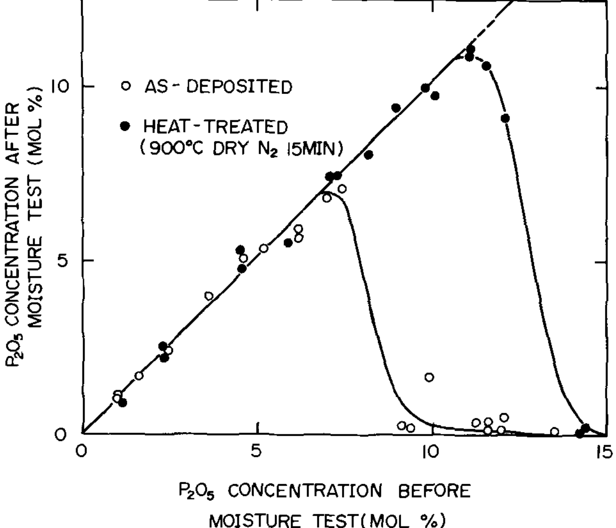

Fig. 5. Change of phosphorus oxide concentration after moisture test.

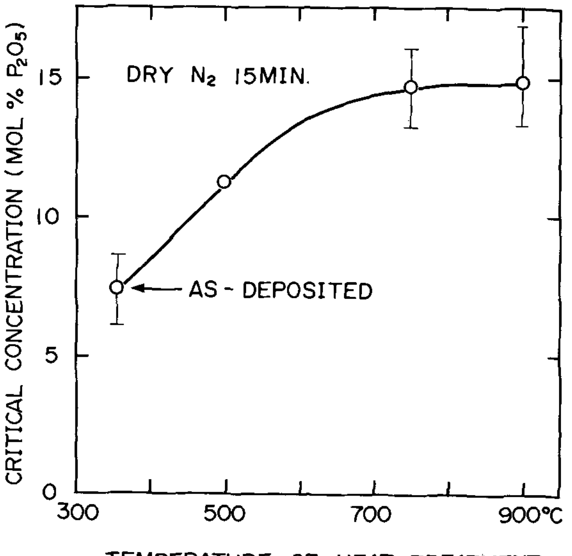

Fig. 6. Relationship between critical concentration of phosphorus oxide in PSG film and heating temperatures.

and silanol, the infrared absorption spectra of a film in which phosphorus oxide dissolved out resemble those of CVD SiO_2 films.

While the heat-treatment causes the infrared absorption peaks to shift slightly towards the higher frequency side, it is difficult to observe any variation in the shape of spectrum. As can be seen in Fig. 7(b), the infrared absorption spectrum of a film belonging to the α-phase did not cause any noticeable change by the moisture test. Also, no absorption due to water occurred. On the other hand, in the case of film with a higher phosphorus oxide concentration (β-phase), heat-treatment could not prevent the P-O peak from disappearing by the moisture test, and the absorption peaks due to water and silanol occurred.

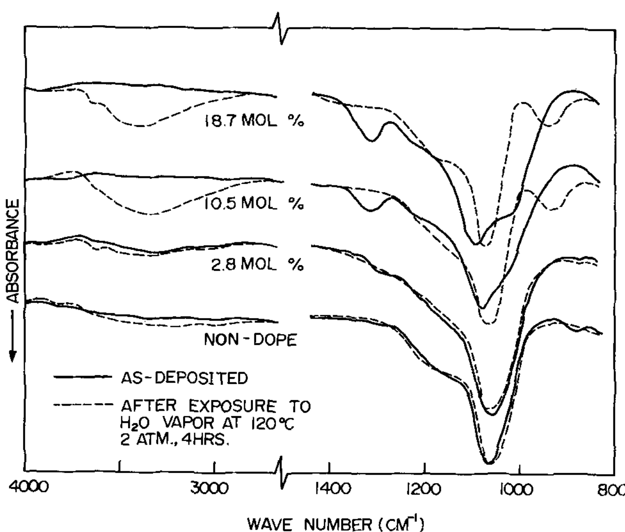
It has been confirmed that beyond the critical concentration, the phosphorus in the PSG film is reduced below the detecting limit by the moisture test. Thus, the quantity of water absorbed in the film was calculated by considering changes of the phosphorus oxide concentration and film weight by the moisture test. In this calculation, phosphorus oxide was assumed to be lost in the form of P_2O_5. Figure 8 shows the results of calculation. As can be seen from the figure the quantity of water contained in the heat-treated film is negligibly small as compared with that of the as-deposited film.

Discussion

As a result of the present study, it became evident that the phosphorus oxide in the PSG film is not allowed to dissolve out into water in the range where the phosphorus oxide concentration is low; however, in the range where the phosphorus oxide concentration exceeds the critical concentration, the phosphorus oxide tends to begin dissolving by the moisture test, and that such critical concentration can be raised by heat-treatment.

Since electron diffraction of the PSG film gives halo pattern in every case, as shown in Fig. 9, sufficient knowledge of the film structure has not yet been obtained. A phase diagram of SiO_2-P_2O_5 system has been reported by Tien *et al.* (7), by saturated equilibration and quenching technique on bulk materials. Eldridge *et al.* (8) dealt with PSG films which were formed by the reaction of SiO_2 film with gaseous P_2O_5 over a temperature range from 800° to 1200°C. According to their results, small, water-soluble crystallites were formed on the surface of a film formed at 870°C or less, and from the SiO_2-P_2O_5 phase diagram of Tien *et al.*, these small crystallites were assumed to be $2SiO_2 \cdot P_2O_5$ or $SiO_2 \cdot P_2O_5$.

The PSG films used in the present experiment were formed at a relatively low temperature of 350°C. Therefore, phosphorus in the film can be considered to be in such a state that small particles of phosphorus oxide P_2O_5, rather than a compound such as $2SiO_2 \cdot P_2O_5$ or $SiO_2 \cdot P_2O_5$, are dispersed in the SiO_2 matrix. At low phosphorus oxide concentration in the PSG film, the SiO_2 matrix which is water-insoluble protects the phosphorus oxide from being attacked by water vapor. However, as the phosphorus oxide concentration increases to the critical concentration, the volume fraction of phosphorus oxide to the SiO_2 matrix increases, and the SiO_2 matrix is no longer effective in protecting the phosphorus oxide from a moisture attack. The SiO_2 matrix has a larger angular distribution width of Si-O-Si bond because it is formed at low temperature (9). Also, it is highly porous (10). This probably allows water to penetrate into the film with ease causing phosphorus oxide to dissolve. These considerations are based on the fact that apparent film thickness does not change by the moisture test, and that the infrared absorption spectrum of a sample whose phosphorus oxide is dissolved by the moisture test closely resembles that of CVD SiO_2 film which never contained phosphorus. Thus, the film deprived of phosphorus oxide by the moisture test becomes to



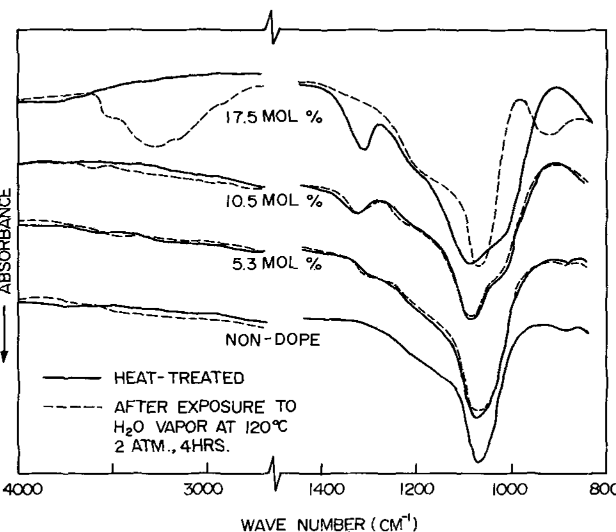


Fig. 7. Infrared absorption spectra of (a) as-deposited films and (b) heat-treated films

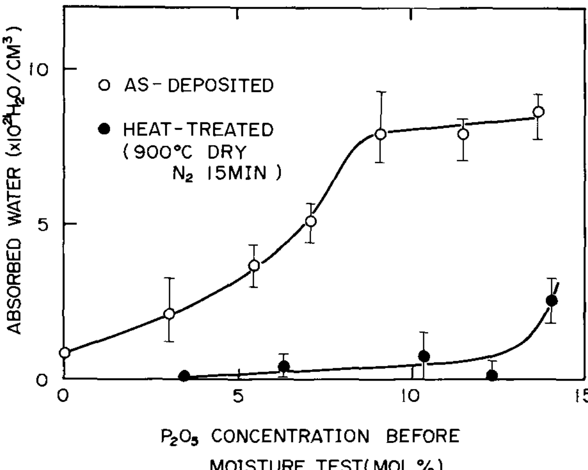

Fig. 8. Water absorbed in PSG film as a result of moisture test

Fig. 9. Reflecting electron diffraction pattern of PSG film

have a sponge-like structure and is capable of absorbing much water. That is, water replaces phosphorus oxide, and so the infrared absorption peak appears in the neighborhood of 3700 cm^{-1} which is characteristic of the OH stretch.

Heat-treatment densifies the SiO_2 matrix, which in turn makes it hard for water vapor to diffuse and attack the phosphorus oxide. It is likely that heat-treatment leads to reaction of the phosphorus oxide with the SiO_2 matrix, and results in formation of a water-insoluble compound such as $(SiO_2)_x(P_2O_5)_y$. Further detailed discussions on this problem will be made when the analysis of film structure is completed.

The as-deposited film is not soluble in water as long as its phosphorus oxide concentration is less than about 8 m/o, but it absorbs a fairly large quantity of water depending on the phosphorus oxide concentration, as shown in Fig. 8. This water absorption can be considerably lessened by heat-treatment. This may be attributed to the narrowing of the angular distribution width of the Si-O-Si bond, the resulting decrease in porosity, and the phase transformation.

Acknowledgments

The authors wish to express their thanks to Dr. K. Sugawara for his support in preparing samples, and to Messrs. H. Enari and Y. Shimizu for their aid in electron microscopic study.

Growth and Evaluation of Epitaxial GaAs for Microwave Devices

Ferenc E. Rosztoczy* and Joshyo Kinoshita*

Varian Associates, Palo Alto, California 94303

ABSTRACT

Using liquid phase epitaxy (LPE), single, double, and triple epitaxial layers are grown. The layers have well-controlled, uniform thicknesses and good surface characteristics on wafers 1½ in. long. Individual layers in multilayer structures are grown with thicknesses from 0.3 to 30 μm. Hall mobilities at 77°K vary from 73,800 $cm^2 V^{-1} sec^{-1}$ ($N = 1.4 \times 10^{15} cm^{-3}$) to 24,000 ($N = 1.3 \times 10^{16} cm^{-3}$). A segregation coefficient for the net carrier concentration *vs.* Sn concentration in the melt is calculated as 7.9×10^{-5} for $<100>$ GaAs and 2.6×10^{-4} for $<111B>$ GaAs substrates. Gunn devices fabricated from this material using conventional flip chip design give up to 4% cw efficiency at 54 GHz, gradually increasing to 12.5% cw efficiency at 9-10 GHz. This technique has also been successfully used to grow epitaxial layers for varactors, avalanche diodes, FET devices, and photocathodes.

The great potential of GaAs Gunn diodes or transferred electron devices is well documented (1). Although the experimentally measured cw data for these devices are rapidly improving, there is still a significant gap between the predicted limits, *i.e.,* 30% efficiency for Gunn devices (1) compared to the best published experimental results of 12.5% for Gunn diodes (2). The relatively low experimental values are due in a great extent to shortcomings in circuit design and heat sinking, but the quality of the epitaxial layer and the contacting technology are also important limiting factors. Quality includes such properties as: crystalline perfection, minimum amount of unwanted impurities and deep level traps, good uniformity, well-controlled, smooth doping profile, and exact carrier concentration and thickness. For example, in the case of avalanche devices <0.5 μm thick layers are required with the above properties, including a thickness control of ± 0.05 μm and carrier concentration ± 5% or better.

The purpose of this paper is to describe in detail the growth of GaAs by liquid phase epitaxy in our laboratory for microwave application; to describe studies related to the distribution coefficient of Sn in GaAs when grown from Ga solutions, as well as the orientation dependence of this distribution coefficient; and to correlate GaAs epitaxial crystal quality with rf device performance for both Gunn and avalanche devices.

Epitaxial GaAs has been grown from liquid or vapor phase. For large scale mass production, like the GaAsP LED requirements, the cheaper, more efficient vapor phase technology is preferred. For microwave applications where high quality is important and cost is secondary, liquid phase epitaxy has significant advantages.

Since its introduction in 1963 (3) and later its application to grow GaAs with high Hall mobility (4) liquid phase epitaxy went through numerous changes. The simple tipping technique was replaced by wiping (5-7), dipping (8), or rotating (9).

A version of the wiping technique was developed at Varian four years ago (10). The results indicate that it is suitable for growing high quality epitaxial GaAs for microwave specifications (2, 11).

Epitaxial Crystal Growth

Growth apparatus.—To obtain low doped material with well-controlled, flat doping profile, special care is taken to operate a vacuum-tight, leak-tested gas train from the palladium diffused hydrogen purifier to the low vapor pressure oil bubbler. The gas train is made of stainless steel and quartz. There is no intentional temperature gradient applied to the boat in any direction. A temperature, constant within ± 0.1°C along the boat, is sought. To assure such a flat temperature profile during the dynamic temperature program of the epitaxial growth, a three-zone furnace with three controlling thermocouples is used. To assure flat doping profiles, the hydrogen is saturated with the partial pressure of arsenic from high purity GaAs dendrites inside the hot furnace just prior to reaching the graphite boat.

For different applications there are some variations in the design of the graphite boat. A schematic drawing of the basic boat design has been published (11). Figure 1 presents a photograph of a slightly different design. The boats are approximately 6-8 in. long, precision machined from the highest purity graphite available and carefully cleaned prior to melt preparation, including degreasing, acid cleaning and high temperature vacuum and hydrogen firing. As the figure indicates, the substrate wafers are recessed in the bottom of the boat. A movable slider with three or five compartments containing two melts is kept in exact position by special railing. The typical growth area varies between 0.75-1.8 in. (2). The slider is positioned with a quartz push rod within ± 0.3 mm.

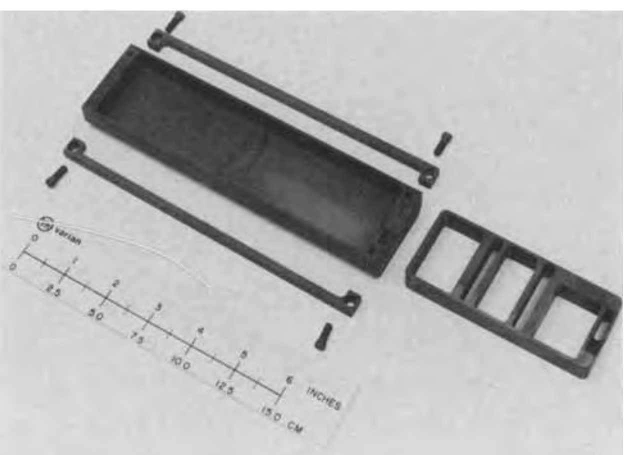

Fig. 1. Graphite boat with five-compartment slider to grow epitaxial GaAs double or triple layers.

* Electrochemical Society Active Member.

Key words: gallium arsenide, crystal growth, liquid phase epitaxy, distribution coefficients in GaAs, microwave devices.

Growth technique.—The transient method is employed with starting temperatures usually around 725°C and the cooling rates, usually 0.2-2°C/min, are calculated in such a way that the growth of a single layer should take 3-30 min. The procedure for growing the epitaxial layer structures consists of the following steps:

1. Dendrite preparation. To obtain better quality epitaxial layers, the GaAs source material is prepared "in-house" by crystallizing GaAs from Ga solution.
2. Melt preparation. The melts contain gallium, Sn as the donor or Ge as the acceptor dopant and slight excess of GaAs to saturate the melt at growth temperature. Precautions are taken to drive out all oxygen and/or other volatile contaminants from the melts prior to growth and to keep the unwanted Si contamination to a minimum. One hundred hours at 900°C for a 50g melt is used prior to the first growth. Twelve to sixteen hours at 900°C is used prior to subsequent growths.
3. Substrate preparation. The substrates are Czochralski grown Sn-doped GaAs with carrier concentrations in the 5-10 $\times$ 10^{17} cm^{-3} range, or Cr-doped semi-insulating crystals. Efforts are made to use substrates with the lowest possible unwanted impurity concentrations, especially avoiding Si. The wafers are <100> oriented, rectangular-shaped according to <110> cleavage faces and Br_2-methanol polished.
4. Substrate cleaning. The method described by DiLorenzo is used and gives satisfactory results (12).
5. Melt saturation. The freshly cleaned substrates are placed in the slots on the bottom of the boat. For Hall measurements, a small, Cr-doped semi-insulating wafer is also included. The system is flushed with hydrogen for at least 30 min, then heated to ~10°C above the desired growth temperature, and kept there for 30 min. The system is then cooled with the preselected cooling rate.
6. Layer growth. To grow an n^+-n^--n^+ triple layer, the appropriate melts are positioned over the substrate as the system is being cooled. After the last growth, the wafers are wiped clean and the system is quenched to room temperature.
7. Removal and cleaning. When the system is under 35°C, it is opened, the wafers are taken out and evaluated for breakdown voltage, then boiled in concentrated HCl to dissolve any excess Ga.

P-N junction growth.—According to the literature, most GaAs p-n junctions are prepared through Zn diffusion. This technique gives satisfactory results for LED application, but has definite limitations regarding carrier concentration profiles, compensation in the p layer, and precipitate formation (13). For microwave applications, the quality of the epitaxial GaAs is very important. The epitaxial layers have to be uncompensated with well-controlled uniform carrier concentrations and a high degree of crystalline perfection. The liquid phase epitaxial technology described above can be used to grow n and p layers of GaAs consecutively in one heat cycle, with the required quality, if suitable dopants are selected (11). To insure minimum or zero cross-contamination and compensation, the dopants must have low vapor pressure and low distribution coefficient under the epitaxial growth conditions.

Table I compares the vapor pressure (14) and the distribution coefficient of the best known uncompensated dopants of GaAs (7, 9, 15, 16). Sn and Ge have the lowest distribution coefficients and also have vapor pressure many orders of magnitude lower than the other dopants. To insure uncompensated layers and an abrupt junction, Sn and Ge are selected as dopants.

When Ge-doped epitaxial GaAs layers are grown from Ga solution under 900°C, the Ge atoms act as uncompensated acceptors like Zn in the crystal (6, 16). The distribution coefficient for Ge is 8 $\times$ 10^{-3} and its vapor pressure at 1000°K is 7 $\times$ 10^{-10} Torr compared with 90 Torr for Zn. The distribution coefficient for Sn is 8 $\times$ 10^{-5} and the vapor pressure at 1000°C is 7 $\times$ 10^{-8} Torr.

Table I. Vapor pressure and distribution coefficients for dopants in GaAs when grown from Ga solution

Donors	Vapor pressure (14) (in Torr, at 1000°K)	Distribution coefficient
Te	8 $\times$ 10	3 (15)
Se	1 $\times$ 10^3	10 (15)
Sn	5 $\times$ 10^{-8}	8 $\times$ 10^{-15} (9)
Acceptors		
Zn	1 $\times$ 10^2	1 $\times$ 10^{-2} (7)
Ge	6 $\times$ 10^{-10}	8 $\times$ 10^{-3} (16)

Wafer Evaluation

Breakdown voltage measurement.—The simplest, fastest qualitative evaluation of GaAs is done by measuring the point breakdown voltage between two tungsten probes. Figure 2 presents some of our empirical data. The semi-insulating substrates have breakdown voltage over 200V. The n^+, approximately 1 $\times$ 10^{18}, substrates have breakdown voltages around 4-5V. The typical n^- layer for Gunn devices with carrier concentrations between 1 $\times$ 10^{15} and 5 $\times$ 10^{15} cm^{-3} has breakdown voltage between 30 and 70V.

Thickness measurements.—Each wafer is cleaved and stained to measure the thickness of the epitaxial layer under a microscope. Figure 3 shows the photograph of a cleaved and stained epitaxial triple layer. The buffer layer is about 2 μm, the n^- active layer is 10 μm and the contact layer is 5 μm. Notice the relatively stronger line between the substrate and the buffer layer compared to the lines defining the interfaces between the three epitaxial layers. This gives a qualitative indication of the relative defect and impurity concentrations at the different interfaces,

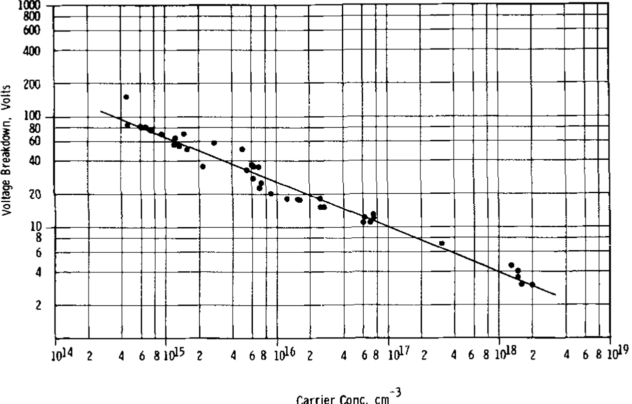

Fig. 2. Variation of breakdown voltage with carrier concentration in n-type GaAs as determined on an I-V scope between two tungsten point contacts.

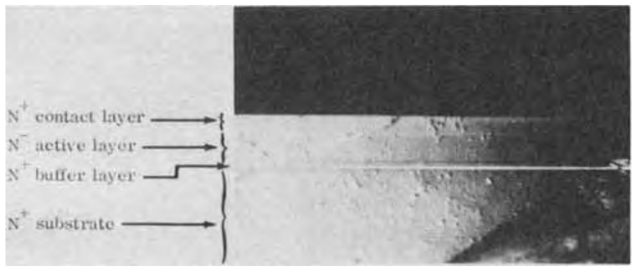

Fig. 3. Cleaved and stained GaAs $N^+/N^-/N^+$ triple layer on N^+ GaAs substrate.

showing the beneficial effect of introducing the buffer layer to separate the relatively high concentration "surface" defects and impurities from the active layer.

If the layer structure is n^- on n^+, then *IR* spectrum measurements are also used to determine thickness uniformity across the wafer. For n^- layers, 7-30 μm thick, the thickness is determined by measuring the distance between interference fringes in the 16-40 μm wavelength range (17).

Figure 4 is a photograph showing the surface quality of GaAs layers with epitaxial thickness of approximately 20 μm. The thickness uniformity for a high percentage of the wafers is better than ±2.5% $in.^{-1}$ or ±0.10 μm $in.^{-1}$, whichever is higher, for 90-95% of the surface area. For example, X-band wafers are prepared with 8 μm active layer length uniform within ±0.2 μm.

Doping profiles.—Gold or gold-tin Schottky barriers of 20 mils diameter are evaporated on the GaAs and the doping profiles are determined using the capacitance depletion technique. This is done by measuring capacitance *vs.* voltage manually and then using a computer program to calculate carrier concentration *vs.* depth.

Figure 5 shows the doping profile of an epitaxial triple layer and the substrate. The individual layer thicknesses are determined by the cleave and stain technology. The carrier concentrations in the contact layer and in the substrate are established by Hall measurements. The doping profile of the n-layer is determined by depletion capacitance measurements.

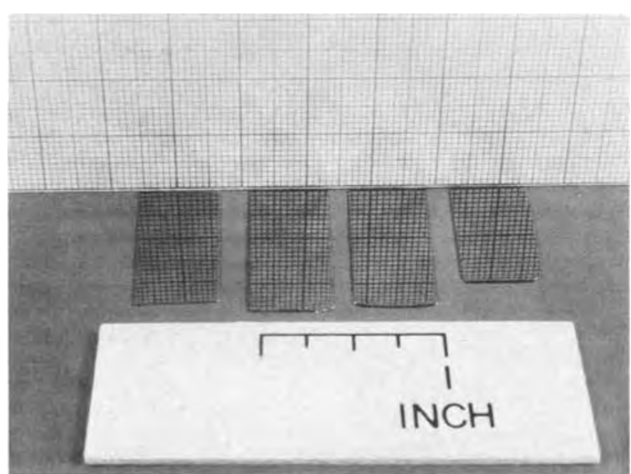

Fig. 4. Surface quality of LPE GaAs

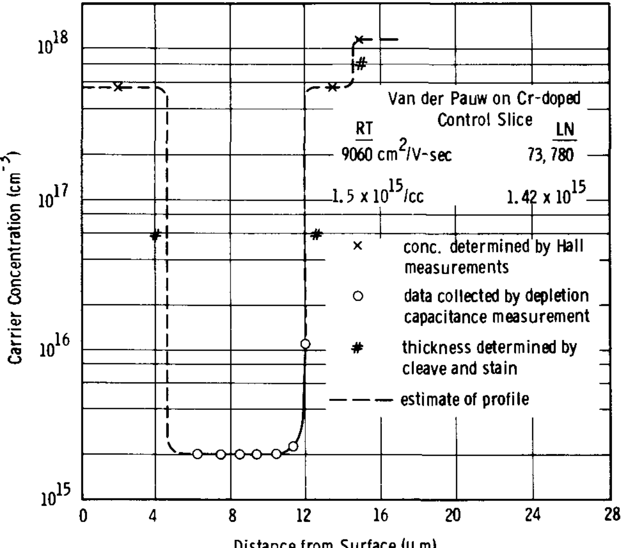

Fig. 5. Doping profile of epitaxial GaAs with triple layers

Hall measurements.—Van der Pauw crosses, 100 × 100 mils, are used for Hall measurements (18) with a 1200 gauss magnetic field. The Hall mobility, carrier concentration and resistivity are measured at room temperature and at 77°K using Cr-doped substrate pieces added to each growth.

The combination of the room temperature and 77°K Hall mobility *vs.* carrier concentration data is a good way to judge the quality of GaAs layers. The higher and closer to the theoretical value these data are, the better is the epitaxial GaAs.

Figure 6 presents data for various n-layers grown in our laboratory for microwave applications along with various published experimental and theoretical data. The data of DiLorenzo (19) and Wolfe *et al.* (20) are based on vapor phase epitaxy, while those of Vilms and Garrett (9) and our laboratory are based on liquid phase epitaxy.

Distribution Coefficient of Sn for <100> and <111B> Substrates

Figure 7 presents some representative data showing how the free carrier concentration determined by room temperature Hall measurements varies with increasing Sn concentration in the growth solution. The growth temperature is around 725°C for these layers and the substrates are <100> oriented. For comparison, recently published data by other authors are also presented (9, 24, 25). Based on our data, the distribution coefficient for GaAs grown from Ga solutions at 725°C is 7.9×10^{-5} for <100> substrates, where the distribution coefficient is defined $k = n/(Sn_l)$. This is in good agreement with prior work, which indicates a decreasing distribution coefficient with decreasing temperature. Migitaka *et al.* (26) recently reported $k = 8.2 \times 10^{-5}$ at 730°C.

To determine the orientation dependence of the distribution coefficient, epitaxial layers are grown on <100> and <111B> Cr-doped substrates side-by-side from the same melts at the same temperature. Figure 8 presents the data showing 3.3 times higher carrier con-

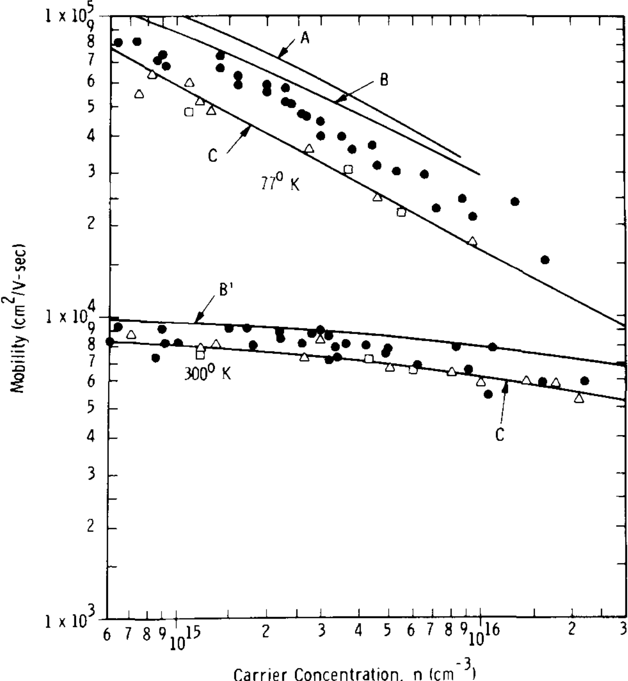

Fig. 6. This figure compares theoretical maximum mobility curves from Wolfe *et al.* (21) (A), drift mobility (B), and Hall mobility (B′) from Rode and Knight (22, 23), with experimental data by Wolfe *et al.* (20) (C), DiLorenzo (19) (□), Vilms and Garrett (9) (△), and this work (●).

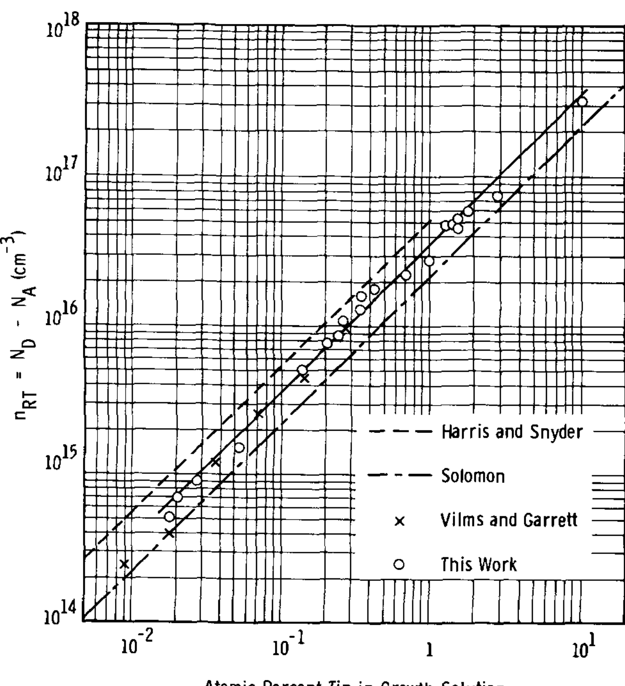

Fig. 7. Carrier concentration in <100> GaAs vs. Sn-concentration in GaAs-Ga melt.

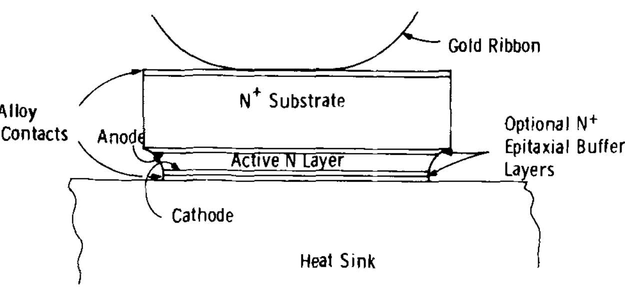

Fig. 9. Typical epitaxial Gunn diode structure

centration on the <111B> substrates. This indicates a distribution coefficient of 2.6×10^{-4} at 725°C for n *vs.* Sn in the melt for <111B> oriented substrate crystals. This is in good agreement with the work of Kang and Greene (27), which is reported in terms of resistivity *vs.* carrier concentration for various orientation of GaAs substrates, and implies a value of approximately 3 for <111B> *vs.* <100>. Vogel (28) estimated a ratio of distribution coefficients of $k_{111B}/k_{100} = 2$ at 770°C for the incorporation of Sn.

Gunn Diodes

Figure 9 shows the cross section of a typical Gunn diode. The results reported in this paper are based on devices made with the simple flip-chip technology, where the GaAs chip is thermo-compression or ultrasonically bonded epi down to the heat sink (2). The alloyed contacts are AuGeNi. As Fig. 9 indicates, the buffer layers on both sides of the N active layer are considered optional. The carrier concentration of the buffer layers is $1\text{-}10 \times 10^{17}$ cm^{-3}. The buffer layers not only reduce the defect density at the two sides of the active layer but (*i*) they also protect the active layer from out-diffusion of unwanted impurities from the substrate, (*ii*) diminish bonding damages to the active layer, and (*iii*) make it easier to form good ohmic contact between the metals and the GaAs. The regrown contact, *i.e.*, the buffer layer on the surface of the active layer, adds unwanted thermal resistance to the device, reducing cw efficiency, and it is also suspected to have detrimental effects on the boundary definition on the cathode side, which becomes significant in the case of mm-wave devices, with active layer thickness around 2.0-2.5 μm only.

In Fig. 10 experimental data are presented to show the threshold voltage (V_{th}) vs. active layer length (l) relationship for Gunn devices. The V_{th} values are measured pulsed with $< 1\%$ duty cycle. For comparison, the data measured on wafers with regrown contact are presented with a different symbol (△) as data measured on wafers with metallic contact (○). The majority of the thickness data is based on cleave and stain measurements on production-run wafers prior to contacting, but in a few cases completed diodes are cross sectioned after the determination of V_{th}, to measure l more accurately. The symbols ▲ and ● denote these corresponding points in Fig. 10. The points measured on regrown wafers (△ and ▲) tend to be higher than the ones measured on wafers with metallic contact (○ and ●) indicating shorter l values for the same V_{th} on regrown wafers.

Table II summarizes certain key parameters to fabricate high efficiency or wide-tuning Gunn devices. It lists for the different frequency bands the optimum carrier concentration (n), active layer length (l) and

Table II. Nominal device parameters for Gunn diodes

Frequency band (GHz)	Active layer length (μm)	Carrier conc. (ncm^{-3})	Type of contact	Application	$n \times l$ product ($\times 10^{12}$ cm^{-2})	V_{th} (Volts)
C-band, 4-8	10-20	1.6×10^{15}	Regrown	High efficiency	2.4	4-7
		8.5×10^{14}	Regrown	Wide tuning	1.3

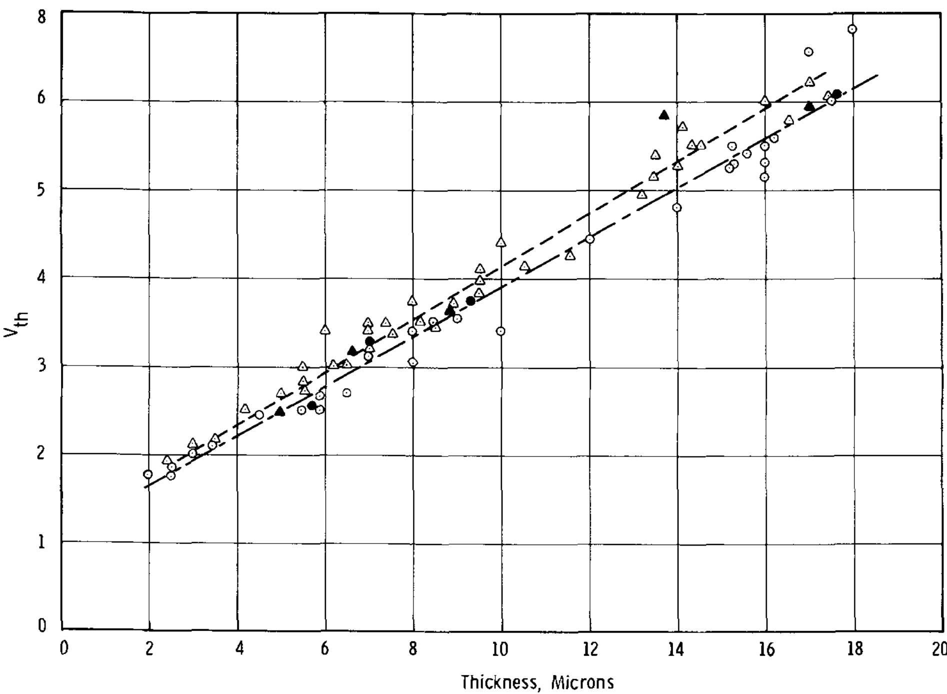

Fig. 10. Pulse threshold voltage vs. active layer thickness for GaAs Gunn diodes. △, ▲, and --- represent results with regrown contact, while ⊙ ●, and — are based on data with direct metal contact. △ and ⊙ represent average values on epitaxial wafers. ▲ and ● are based on cross sectioning individual diodes.

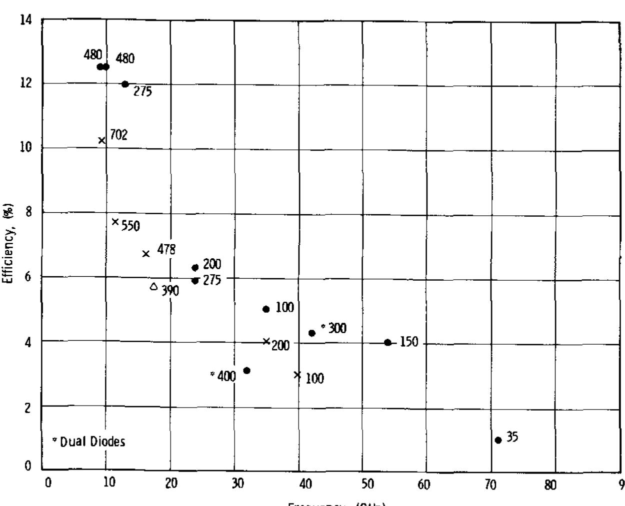

Fig. 11. Cw efficiency vs. frequency is plotted for Gunn diodes and the power output in mW is listed alongside each data point. The results of this work (●) are compared with those of Hasty *et al.* (30) (X) and DiLorenzo (19) (△). * is for two diodes measured in a dual diode circuit.

corresponding V_{th}. For high efficiency devices the optimum $n \times l$ product is about 2.3×10^{12} cm^{-2} and with the exception of C-band devices, metallic contacts are recommended. For wide-tuning applications on the other hand, the optimum $n \times l$ product is around 1.3×10^{12} cm^{-2} and regrown contacts are preferred up to 26 GHz.

Table III. RF performance data for GaAs microwave devices

Type of diodes	Frequency (GHz)	Efficiency (%)	P_o (mW)
Gunn devices	9-10	12.5	480
	13	11.9	275
	24	6.3	200
	35	5.0	100
	54	4.0	150
	71	1.0	35
Double drift avalanche devices	8.9	16.3	2350
	8.9	15.8	3000
High-low structure avalanche devices	10.3	19.6	2200

Device Performance

The ultimate judgment on epitaxial wafer quality for microwave applications must be based on the rf performance of the resulting devices. It is the main objective of this paper to describe the crystal growth technology and the properties of the epitaxial wafers together with the rf performance data of the corresponding devices. Figure 11 charts the rf performance of the Gunn diodes. Cw efficiency *vs.* frequency is plotted and the cw output power is listed alongside each data point. The best efficiency, 12.5%, is measured at 9 and 10 GHz, with output power of 480 mW (2). At 54 GHz. 4% efficiency is observed with 150 mW power output. At 71 GHz, 1% efficiency and 30 mW is the best recorded data (29). For comparison, the best published results by DiLorenzo (19) and Hasty *et al.* (30) are also presented.

Table III summarizes the most notable rf data on our microwave devices. Besides the Gunn device data, results with double drift and high-low structure avalanche devices are also listed. Double-drift avalanche devices are fabricated with 20.7% pulsed and 16.3% cw efficiency and power outputs of 4.1W and 2.35W, respectively, in X-band (11, 31). High-low avalanche devices give 19.6% efficiency and 2.2W cw at around 10 GHz (32). These results are only preliminary data and significant improvements are imminent.

Using some of the above described Gunn diodes, transferred electron amplifiers are built with 110 mW saturated power output and 3 GHz bandwidth at 35 GHz; 13 db small-signal gain and 16.2 db noise figure are observed (33).

ABSTRACT

Phosphosilicate glass gettering of silicon wafers in which diodes had been formed has been studied. The amount and identity of the gettered impurities were determined by means of Rutherford backscattering of 2 MeV He^+ ions. The principal gettered impurities are Cu and Fe ($\sim 10^{15}$ cm^{-2}) and a heavy mass species in the range Pt-Pb, presumably Au ($\sim 10^{13}$ cm^{-2}). Gettering behavior is correlated with diode properties; the diode quality increases with increased amounts of gettered impurities.

In view of the renewed interest in the role of transition metals and other impurities, either initially present in the material (1) or introduced by the process, in the degradation of p-n junction properties, we have initiated a study of phosphosilicate glass gettering, using ion backscattering as the diagnostic technique. Phosphosilicate glass gettering has long been used to remove unwanted electrically active impurities from silicon wafers (2-7). The purpose of the present work is to identify, qualitatively and quantitatively, the impurities present in typically processed device wafers and to examine their effect on diode properties as an aid to subsequent studies where controlled amounts of appropriate impurities are intentionally introduced.

Experimental

Diode preparation.—Two groups of wafers were studied; both were p-type (111) slices with 3μ of 0.5 ohm-cm n-type epi grown on them. One group (from epi run H2114) gave nearly 100% very soft base-collector junctions when boron was diffused from either a BN or ion-implanted source. (A soft junction is one whose *I-V* characteristic on a curve tracer clearly shows curvature below the avalanche breakdown voltage on the 10 $\mu A/cm^2$ scale.) The other group of wafers, having substrate material different from the group just described (from epi run H2067), gave much better properties wth 80% of the junctions being hard as diffused.

After reoxidation to protect the base from phosphorous diffusion, wafers were gettered for various times in a 1000°C, PBr_3 phosphorous furnace in which the bare back side of the wafer was exposed to the phosphosilicate glass. The glass was stripped off, the diode properties remeasured, and the ion scattering spectrum was taken.

Ion scattering.—The Rutherford backscattering technique for chemical analysis was pioneered by Davies

et al. (8), and Bogh (9) and has been recently reviewed by Buck and Wheatley (10) and by Nicolet *et al.* (11).

For energetic ions undergoing Rutherford scattering from a target atom the scattering yield per unit solid angle is given by

$$\frac{dn}{d\Omega} = \frac{n_0 N b^2}{16} \sin^{-4}\left(\frac{\theta_c}{2}\right) \quad [1]$$

where

$$b = \frac{Z_1 Z_2 e^2}{\frac{1}{2}\left(\frac{M_1 M_2}{M_1 + M_2}\right) V^2} \quad [2]$$

Z_1 and Z_2 are the atomic numbers of incident particle and target atom, M_1 and M_2 are the respective masses, and θ_c is the center of mass scattering angle; e is the electronic charge, V is the velocity of the incident ion, n_0 is the number of incident ions, and N is the number of target atoms cm^{-2}. The center of mass and laboratory scattering angles are related by

$$\sin(\theta_c - \theta_L) = \frac{M_1}{M_2} \sin\theta_L \quad [3]$$

Since the scattering is elastic, ions scattered from a target atom of given mass at a given θ_L have a characteristic energy, E, given by

$$\frac{E}{E_0} = \frac{M_1^2}{(M_1 + M_2)^2} \left\{ \cos\theta_L + \left(\frac{M_2^2}{M_1^2} - \sin^2\theta_L\right)^{1/2} \right\}^2 \quad [4]$$

where E_0 is the ion energy before the scattering event.

For scattering from target atoms of given mass distributed in a substrate, the energy scale may be converted to a depth scale by use of the kinematic energy loss and the specific energy loss rate in the material; namely

$$\Delta t = \Delta E \left\{ \left(\frac{dE}{dx}\right)_{E_{in}} \left(\frac{E_{out}}{E_{in}}\right) + \left(\frac{dE}{dx}\right)_{E_{out}} \frac{1}{|\cos\theta_L|} \right\}^{-1} \quad [5]$$

which relates the energy shift ΔE to thickness increment Δt.

In these experiments a beam of 2 MeV He^+ ions collimated to $\sim$0.05° through two Ta collimators 1 mm in diameter about 2m apart was used. The backscattered He ions were detected at $\theta_L = 177°$ in a 50 mm^2 surface barrier detector having an energy resolution of 16 keV. This energy resolution corresponds to a depth resolution of about 200Å. Secondary electron suppression and pile-up rejection electronics were used. Samples were surrounded by a baffle cooled to liquid nitrogen temperature and were mounted in a two axis goniometer. The scattering chamber was maintained at 10^{-6} Torr and the He ion fluence was typically 10^{16} cm^{-2}.

Results

Ion scattering spectra from the back side of typical wafers before phosphosilicate glass gettering are seen in Fig. 1 for the poorer material and in Fig. 2 for the better. After reoxidation to protect the base from phosphorus diffusion and a 60 min getter in a 1000°C, PBr_3 phosphorus furnace in which the bare back side of a Si wafer from the poor group was exposed to phosphosilicate glass, about 25% of the junctions had become hard. This glass was stripped off and the spectrum taken. It is presented in Fig. 3.

In Fig. 2 and 3 particularly, impurities are seen at energies corresponding to transition and heavy metals. From the shape and magnitude of the spectra [especially the channeled spectra which separate lattice-site and off-lattice-site scatterers and shows in some cases two separate peaks (see Fig. 3), the upper edges of which correspond to Fe and Cu] we conclude that the transition metals present include Cu and Fe. (Secondary ion mass analysis confirms this.) The impurities are contained in a layer about 2000Å wide at the back surface (determined from Eq. [5]). The heavy metal present lies in the Pt-Pb range and we presume it is Au. Figure 1 (the poor material before gettering) shows a maximum of $2(10)^{14}$ cm^{-2} of Cu and Fe and 10^{13} cm^{-2} Pt-Pb near the back surface. After gettering (Fig. 3) there are $2(10)^{15}$ cm^{-2} of Cu and Fe and $4(10)^{13}$ cm^{-2} of the Pt-Pb group. Since the glass was removed before the spectra were taken, no information is available on the impurities contained in the glass itself. This will be discussed in a future publication (12), where it will be shown that they are in fact almost entirely in the silicon.

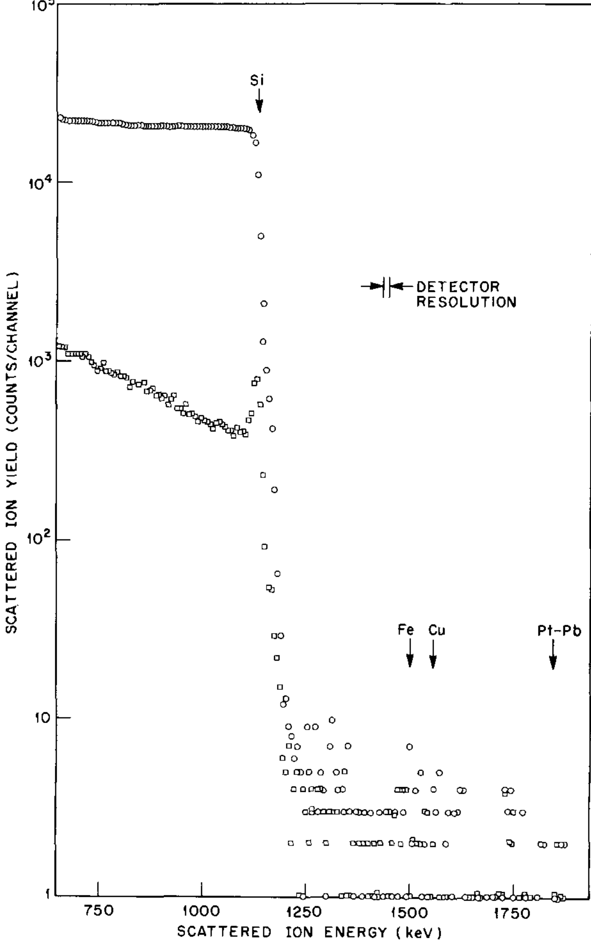

Fig. 1. Scattered ion spectrum from the back side of material which formed poor diodes (before gettering).

Figure 2 is for ungettered material which originally produced good diodes. Note that impurities are apparently already "self-gettered" to the back surface by some mechanism [$(10)^{15}$ cm^{-2} of Cu and Fe and $2(10)^{13}$ cm^{-2} of Pt-Pb]. The implications of and the possible reasons for this are under study. It is tentatively suggested that it may be due to residual damage or defects left at the back surface. The silicon <110> minimum yield was 2% for the poor material and 3% for the good material before any phosphosilicate glass gettering. After gettering it is 3%. After diffusion gettering of the good material 80-100% of the diodes are hard and the amounts of impurities on the back surfaces are essentially unchanged.

In Fig. 4 is plotted the gettered impurity concentration *vs.* gettering time for the material which initially formed soft diodes. The number in parentheses beside each data point is the ratio of counts in the (110) chan-

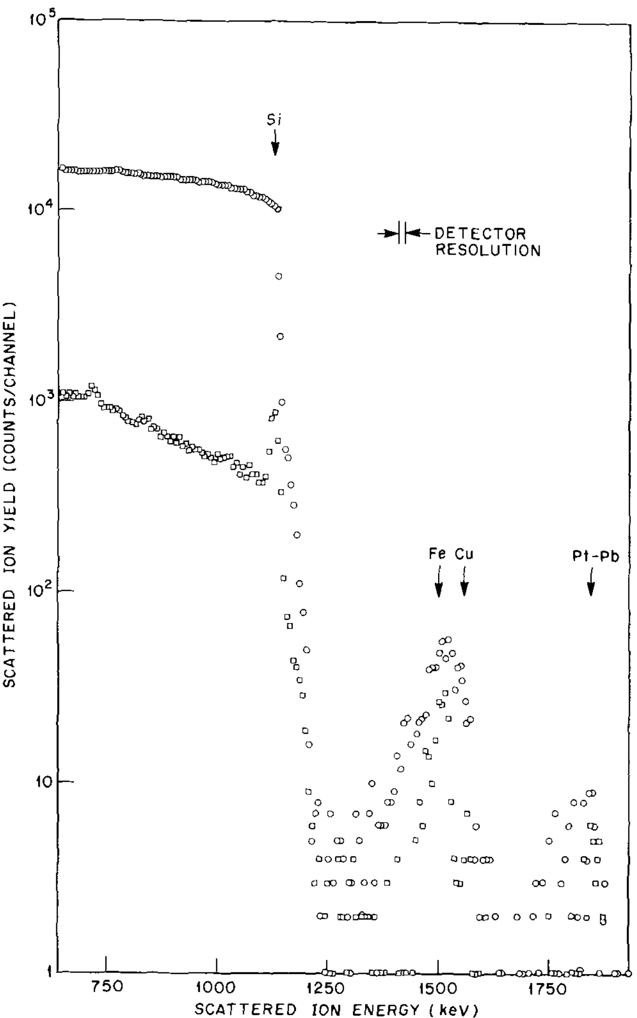

Fig. 2. Scattered ion spectrum from the back side of material which formed good diodes (before gettering).

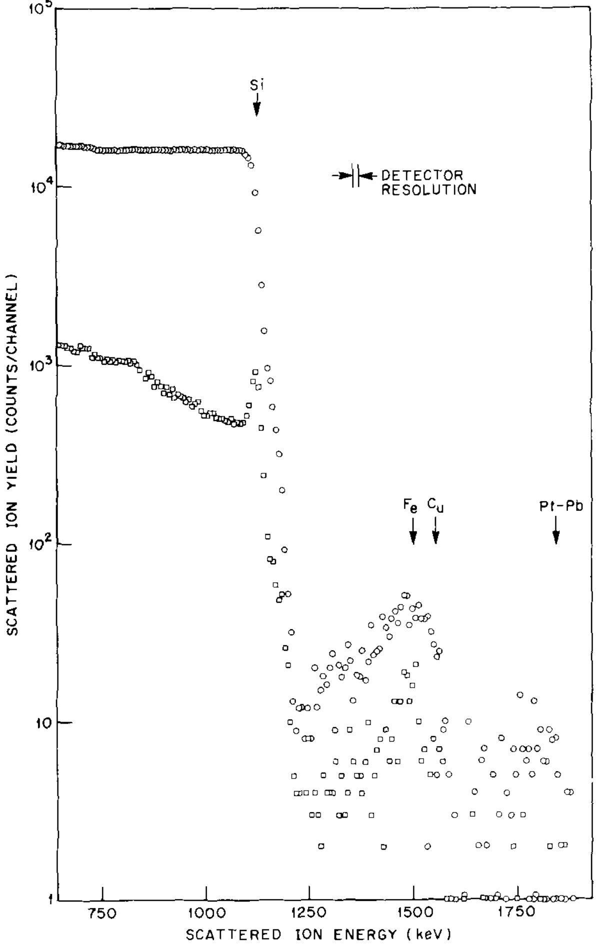

Fig. 3. Scattered ion spectrum from the back side of material which formed poor diodes before gettering, after phosphosilicate glass gettering (1000°C, 1 hr) and removal of glass from back side.

neled spectrum to those in the random spectrum and gives essentially the fraction of the impurity atoms which lie off silicon lattice sites. Since the effective diffusion coefficient for Cu in silicon (13) is $\sim 10^{-4}$ cm^2 sec^{-1} and that for Fe and Au (14, 15) is $\sim 10^{-8}$ cm^2 sec^{-1}, it is fair to assume that all of the Cu should have been gettered even in the shortest gettering time. (The characteristic time for Cu to diffuse across the wafer thickness is ~1 sec and for Fe and Au is ~1 hr.) Since a steady increase in the amount of gettered impurity Cu and Fe is observed for times up to 1 hr, it appears that most of the Cu + Fe is in fact Fe. The shape of the spectra also appears to support this interpretation, the peak occurring at Fe, not Cu. In the case of Au, the high value on the ungettered material is felt likely to be due to surface contamination. In fact examination of the spectrum (Fig. 1) indicates that a significant fraction of the counts attributed to Au might in fact be due to a lighter surface impurity.

Figure 5 shows the median voltage at 10 μA leakage current (the "10 μA breakdown voltage") for 96 diodes after each gettering treatment. An avalanche breakdown voltage of 25-30V would be expected on this material for a hard diode. There is a clear trend to lower leakage currents at a given voltage indicated on this curve which corresponds to increased accumulation of impurities on the backs of the slices shown on Fig. 4.

The question of course arises as to where the impurities originate. Previous work on polishing and preoxidation cleaning has shown that they should not originate with these steps (18). Furthermore, gettering of unprocessed wafers indicates that such large amounts of impurities are not likely to be present in

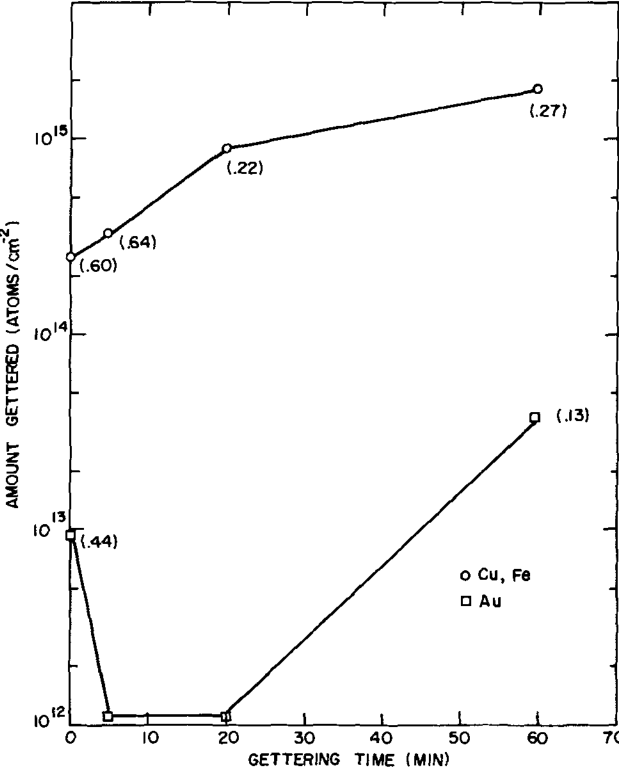

Fig. 4. Gettered impurity concentration vs. gettering time at 1000°C for material which initially formed poor diodes.

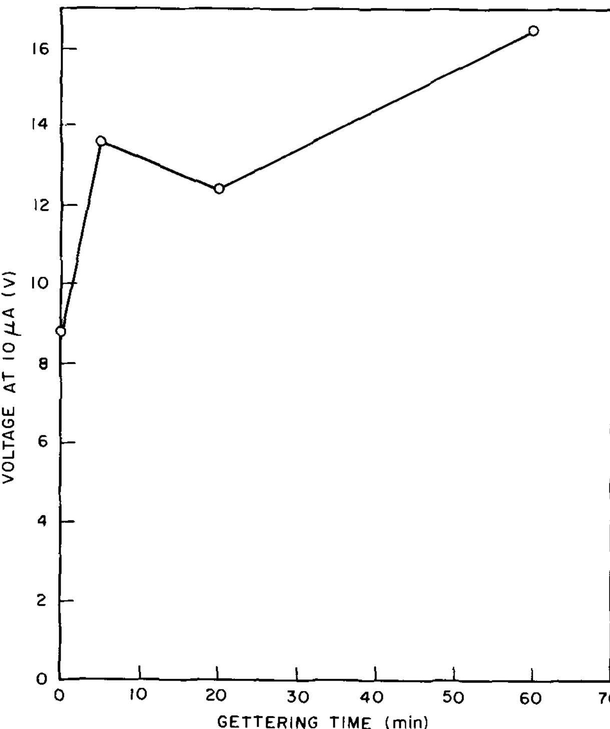

Fig. 5. Breakdown voltage vs. gettering time for the same material as Fig. 4.

the starting material (12). Further work is in progress in an attempt to identify the point in the processing sequence at which the impurities are introduced. However, we have noted that often cleaning procedures are ineffectually applied and that furnaces sometimes become contaminated with Cu or Au (12). Ion scattering from control sample surfaces furnishes a fast, reliable quality control technique for determining when such processing steps are resulting in contaminated wafers (18, 19).

Segregation Behavior in a Stationary Vertical Zone with Converging Interfaces: Pressure-Induced Segregation Effects

K. M. Kim, A. F. Witt,* and H. C. Gatos*

Department of Metallurgy and Materials Science, Massachusetts Institute of Technology, Cambridge, Massachusetts 02139

ABSTRACT

Crystal growth and segregation behavior in a confined, vertical melt zone in an InSb system were studied by allowing the upper and lower crystal-melt interfaces to converge through controlled power reduction. Segregation inhomogeneities during the initial stages of solidification appeared exclusively in the upper crystal segment which grew under destabilizing thermal gradients. At decreased zone height, irregular dopant inhomogeneities, identical in appearance, were simultaneously formed in both the upper and lower crystal segments. With continuing solidification the irregular and random inhomogeneities became periodic (oscillatory) in nature. Periodic dopant striations of decreasing frequency were observed to the coalescence point of the two interfaces. The random and periodic segregation inhomogeneities, which formed simultaneously at the converging growth interfaces, were attributed to isostatic pressure effects which originate in the volume expansion of the confined solidifying melt.

It has been found that during stationary vertical crystal growth under destabilizing thermal gradients (1), with decreasing height, the melt exhibits successively, turbulent convection, oscillatory instability, and thermal stability. Both turbulent convection and oscillatory thermal instability in the melt lead to corresponding characteristic dopant inhomogeneities in a growing crystal. On the other hand, under stabilizing thermal gradients, uniform dopant distribution has been observed (2).

In the present study, crystal growth and segregation were investigated in a confined vertical melt zone in which the upper solid-melt interface advanced under destabilizing and the lower under stabilizing thermal gradients.

Experimental Procedure

The technique reported earlier (1) for crystal growth by controlled power reduction was employed in the present study, modified as shown in Fig. 1. A wire-wound resistance heater (1.5 cm ID and 1.5 cm long) was placed coaxially inside the longer external heater. Both heat sources were operated (in series) by proportional power control with the control thermocouple in the external heater. The solid-melt interfaces were made to converge by decreasing the furnace temperature at a constant rate of 0.54°C/min.

Two tin-doped (10^{17} atoms/cm^3) InSb single crystals with <111> orientation were machined and etched to fit into the quartz tube (0.8 cm ID). The lower crystal was placed on a graphite holder and the upper was mounted on a water-cooled holder. Polycrystalline charge, heavily doped with tin (about 10^{20} atoms/cm^3), was placed between the two crystals and was melted together with a portion of both crystals. After melting, the upper crystal segment was lowered to establish a cylindrical melt zone. The molten zone (about 1.3 cm long) was held at temperature to achieve homogenization before proceeding with solidification.

"Time markers" were introduced simultaneously in both growing crystals by applying current pulses (18A) of 50 msec duration at a repetition rate of 20 sec through leads attached to the upper and lower crystal. Each current pulse caused Peltier cooling on one crystal-melt interface (electron flow: melt to solid) and simultaneously Peltier heating on the other crystal-melt interface (electron flow: solid to melt).

The growth and segregation characteristics of the system were studied on etched (211) planes exposed by cutting the solidified zone along the <111> growth axis.

Experimental Results

Interface morphology and growth rate.—The photomicrograph of an etched (211) plane from a typical solidification experiment is shown in Fig. 2. In the figure, the solid-liquid interface with the destabilizing thermal gradient advanced from the top down (crystal segment A) while the solid-liquid interface with stabilizing thermal gradient advanced from the bottom up (crystal segment B). The A and B time markers bearing the same numbers grew simultaneously. The pronounced time markers appearing alternatingly in the two crystal segments were introduced by pulsed Peltier

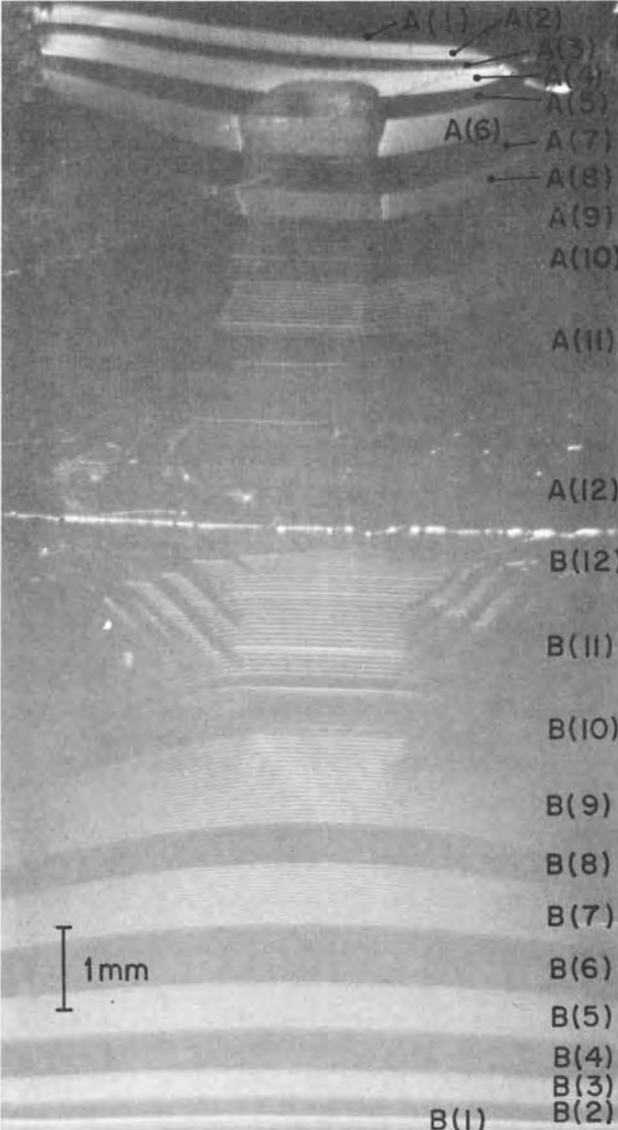

Fig. 2. Photograph of an etched cut along the growth axis. The upper crystal segment grew (downwards) under destabilizing and the lower grew (upwards) under stabilizing thermal gradients. The coalescence plane of the two growth interfaces is clearly visible between regions A(12) and B(12). The A and B regions bearing the same number grew simultaneously in time. The striations across the crystal are "time markers" introduced by current pulses (see text).

cooling. Time markers due to Peltier heating are not pronounced; thus, to insure the formation of clearly visible time markers in both solidifying segments the polarity of the current pulses was reversed at predetermined intervals. Since the time markers reflect the interface morphology at the instant of their incorporation, Fig. 2 shows that initially both growth interfaces were virtually flat, but became increasingly convex, toward the melt, with continuing growth. This behavior reflects the presence of radial temperature gradients which increase with decreasing zone height. The occurrence of facet growth (core formation) at both advancing interfaces is clearly visible. It is of interest to note that in all experiments facet growth occurred earlier at the upper, water-cooled, crystal segment with the larger thermal gradient in the melt. The coalescence of the two interfaces took place in a virtually horizontal front and was preceded by off-core interface breakdown due to high dopant concentration in the melt.

The microscopic growth rates of both solidifying segments were determined from the spacing of the time markers in the inner region of the crystal. Their values are plotted in Fig. 3 as a function of zone height. It can be seen that the over-all growth behavior of the two interfaces is the same: the growth rate is initially small, increases with decreasing zone height, and decreases again prior to coalescence. The consistently lower microscopic growth rate of the upper crystal segment is due to the prevailing steeper thermal gradient in the upper melt zone.

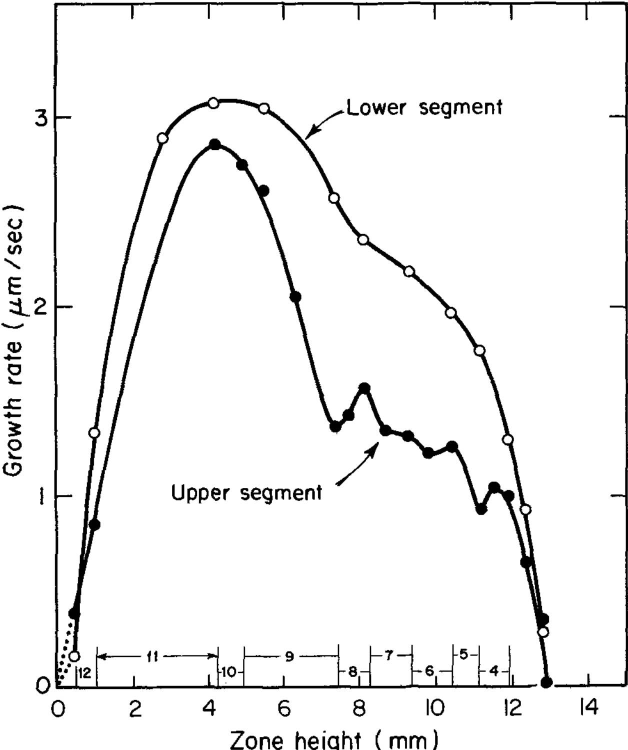

Fig. 3. Microscopic growth rates of the upper and lower crystal segments as a function of zone height. The regions (4 to 12) indicated on the horizontal axis correspond to the regions shown in Fig. 2 and in subsequent photomicrographs.

It can also be seen that the growth rate of the upper segment, with destabilizing thermal gradient in the melt, exhibits significant fluctuations in contrast to that of the lower crystal segment which grows under stabilizing thermal gradients.

Dopant segregation.—The segregation behavior during the initial stages of growth is the same at both advancing interfaces as seen in Fig. 4. The dopant distribution, as revealed by etching, is uniform (the regularly spaced striations are the time markers introduced by Peltier cooling). Dopant inhomogeneities appear first in the upper segment as seen in Fig. 4a, region A(4), and coincide with core formation. Since this upper segment grows under destabilizing vertical and radial thermal gradients in the melt, the observed dopant inhomogeneities are attributed to thermal convection (3). The uniform dopant segregation observed at the simultaneously grown region of the lower segment, Fig. 4b, indicates that convection under the present experimental conditions does not affect the thermally stable melt region and is, thus, confined to the melt region subjected to destabilizing thermal gradients.

With continuing growth a striking change in the segregation behavior takes place; dopant inhomogeneities appear in both the upper and the lower segments as shown in Fig. 5. These inhomogeneities (striations) form simultaneously in both growth segments and are identical in detail [see for example regions A(9)-14/15 and B(9)-14/15]. They are at the onset irregular in intensity and periodicity and become periodic with continuing growth (Fig. 5 and 6). These periodic inhomogeneities persist to the point of coalescence of the interfaces and resemble in all respects segregation be-

Fig. 4. Photomicrographs of etched cuts along the growth axis of the crystal segments grown concurrently under destabilizing (a) and stabilizing (b) thermal gradients. For convenience, the growth direction of both segments is here shown from bottom to top. In segment b, dopant inhomogeneities are absent. In segment a, random inhomogeneities are visible (between successive time markers) beginning with region A(4). The onset of core formation appears in the same region.

havior associated with oscillatory thermal instability (1). Their frequency, initially 0.8/sec, decreases to 0.5/sec near the point of coalescence.

Discussion

The appearance of segregation inhomogeneities in the upper crystal segment during the early stages of growth can be explained as the result of convective melt flow due to the presence of destabilizing thermal gradients (1). Since the simultaneously grown lower crystal segment exhibits uniform dopant distribution, it is apparent that convective instability is confined to the melt region with a destabilizing thermal gradient and does not propagate into the thermally stable lower part of the molten zone.

The ensuing simultaneous incorporation of irregular dopant inhomogeneities, which are identical in detail in both the upper and the lower crystal segments, cannot be attributed to convective instability; temperature and melt composition are time-dependent variables in convective systems, thus the simultaneous formation of identical, random segregation effects at interfaces which are several millimeters apart cannot be reconciled with convective behavior. Moreover, the presence of such periodic segregation inhomogeneities at both crystal segments cannot be explained on the basis of thermal oscillatory instability since they are formed up to the point of interface coalescence where the Rayleigh number of the melt approaches zero (1). Temperature measurements in the center of the melt zone (by means of a thermocouple inserted through the lower crystal segment) showed that the melt was thermally stable (within $\pm 0.01°C$) during the growth period in question; accordingly, the present segregation inhomogeneities are not due to thermal convective instability.

In the present confined system, with fixed geometric boundaries, solidification of InSb must lead to pronounced pressure build-up since it is associated with a $\sim 14\%$ volume increase (4). It is, thus, believed that the growth and segregation inhomogeneities formed simultaneously on both crystal segments are due to isostatic pressure effects. Indeed excessive pressure build-up caused, in seven out of fifteen growth experiments, during the late stages of solidification, breakage of the quartz tube (1 mm wall thickness) containing the melt zone.

During the early stages of growth the volume expansion was apparently accommodated by corresponding retraction of the upper and/or lower crystal segments since the normally expected segregation behavior was observed: absence of dopant inhomogeneities in the lower segment grown with stabilizing gradients in the melt and dopant inhomogeneities in the upper segment in which growth took place under destabilizing gradients.

As solidification proceeds, further retraction of the crystal segments in the present experimental arrangement is expected to be increasingly impeded, and, thus pressure must build up in the molten zone. The pressure build-up, with continuing growth, is rapid since the compressibility of solid InSb is small (2.4×10^{-6}/kg cm^{-2}) (5). Due to the pressure dependence of the melting point of InSb ($-0.008°C$/atm) (6), any pressure increase will in turn affect the established growth rate. Under the present experimental conditions, involving a continuous temperature decrease (constant growth rate), the pressure increase associated with the convergence of the growth interfaces must lead to a slow-down or even a temporary arrest of the growth process. Under continuing temperature decrease the growth interfaces must continue to converge. The as-

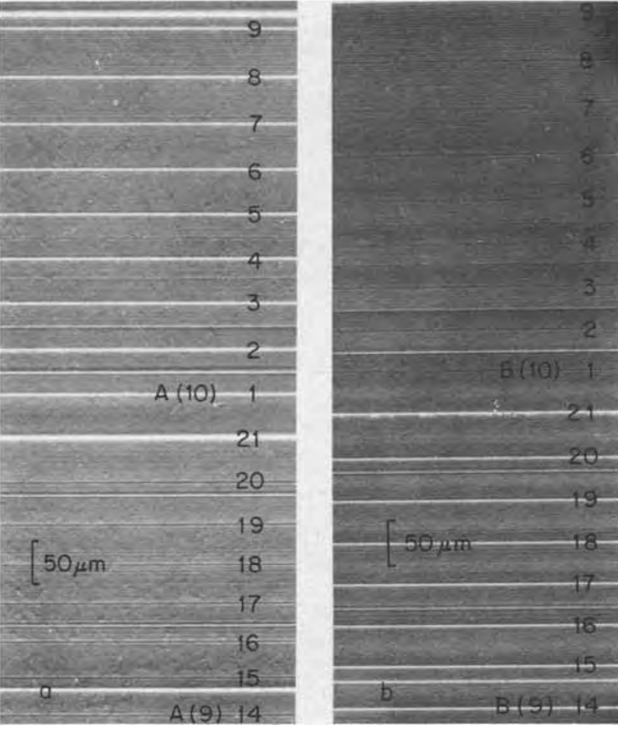

Fig. 5. Photomicrographs of etched cuts along the growth axis of the crystal segment grown under destabilizing (a) and stabilizing (b) thermal gradients (growth direction of both segments is here shown from bottom to top). Dopant inhomogeneities identical in detail are simultaneously incorporated in both segments (grown at slightly different rates, see Fig. 3) beginning with region A(9)14 and B(9)14. Note for example the pronounced striation between time markers 14 and 15 (see text).

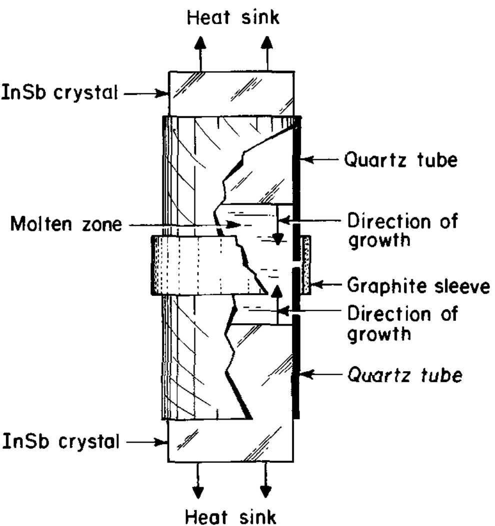

Fig. 7. Schematic diagram of the apparatus used to provide continuous pressure release during growth. The upper and lower quartz tubes were tight-fitted into a graphite sleeve exposing the melt to a "graphite window" 1 mm in height.

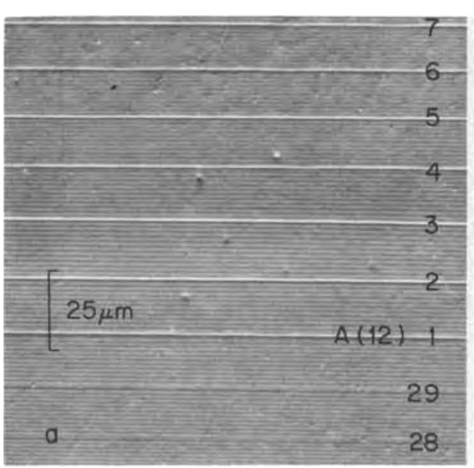
sociated pressure increase will either lead to forced retraction of the crystal segments or to breakage of the quartz tube.

The dopant inhomogeneities formed simultaneously in both advancing interfaces can be explained on the basis of pressure induced segregation effects. In the early stages of pressure build-up abrupt, "jerky," retraction of the crystal segments results in irregular isostatic pressure fluctuations which thus affect simultaneously the growth rate at both interfaces. Since temperature fluctuations as low as 0.01°C have been shown to result in segregation inhomogeneities (1), pressure fluctuations in excess of 1 atm (corresponding to a melting point decrease greater than 0.01°C) are expected to cause detectable segregation inhomogeneities. The periodic inhomogeneities, which persist to the point of the interface coalescence, may be interpreted as the result of periodic, discontinuous crystal retraction (periodic increase and decrease in pressure). Alternatively, the retraction may be continuous and the inhomogeneities reflect "oscillatory pressure instability." As seen in Fig. 3, in the region of the periodic segregation inhomogeneities, the microscopic growth rate decreases steadily. Although it is unlikely, the decreasing growth rate could be attributed to changing characteristics of the thermal gradients in the melt; it is more likely that this growth rate behavior is the result of a steadily increasing pressure which is only partially released through retraction of the crystal segments.

To confirm the origin of the periodic segregation inhomogeneities, growth experiments were performed in a system with identical geometry as in Fig. 1, in which continuous pressure release (constant pressure) during growth was provided for by a 1 mm thick annular "graphite window" located in the region of coalescence of the converging growth interfaces (Fig. 7). In this configuration, constant (moderate) pressure prevailed during growth, since the volume expansion was accommodated by continuous leakage of liquid InSb through the graphite window. The growth and segregation behavior under these conditions is shown in Fig. 8. It can be seen that dopant segregation remains uniform to the point of coalescence with no evidence of dopant inhomogeneities (Fig. 8a). It is seen further that the



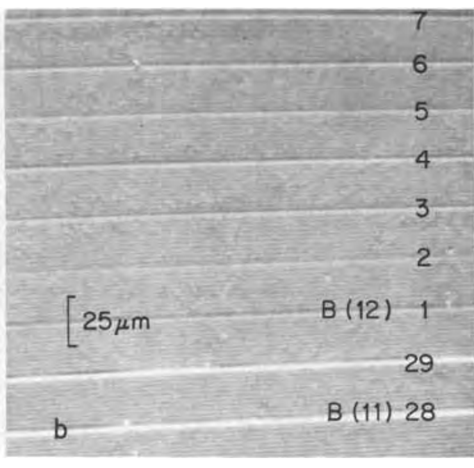


Fig. 6. Photomicrographs of etched cuts along the growth axis of the crystal segment grown under destabilizing (a) and stabilizing (b) thermal gradients (growth direction of both segments is here shown from bottom to top). Note periodic (oscillatory) inhomogeneities, in both segments, persisting to the coalescence of the two interfaces (see Fig. 2 and text).

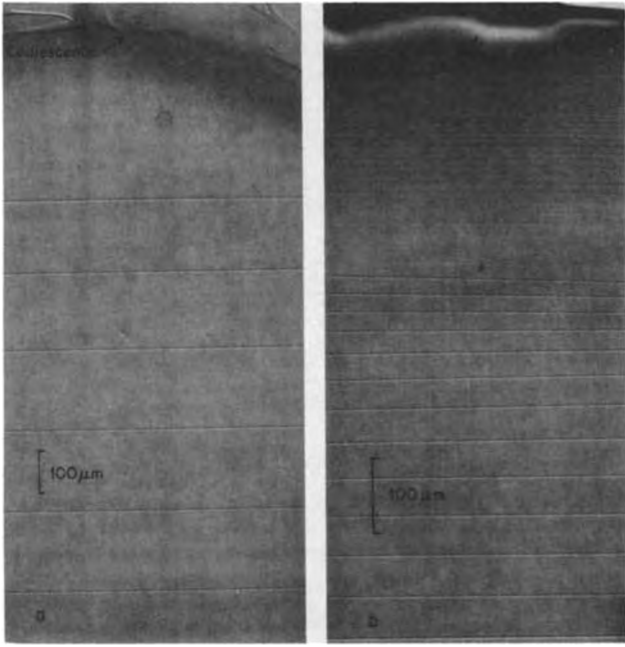

Fig. 8. Photomicrographs of etched cuts along the growth axis of a crystal segment grown in the apparatus providing for continuous pressure release (a) and a segment grown in the confined arrangement of Fig. 1. Note that in (a), the distance between the time marker remains constant to the point of interface coalescence in contrast to the segment (b), where the microscopic rate decreases gradually. The periodic inhomogeneities (between successive time markers) in segment (b) are visible at the lower region of the segment but with decreasing growth rate their spacing in the upper region is beyond resolution.

microscopic growth rate remained virtually constant (virtually constant spacing of time markers) to the point of the interface coalescence. This behavior is in pronounced contrast to that seen in Fig. 3 where the growth rates approach zero at the interface coalescence. Thus, it is concluded that the dopant inhomogeneities incorporated simultaneously in the two crystal segments are due to pressure effects and that the continuous growth rate decrease is the result of a steadily increasing hydrostatic pressure.

Acknowledgment

The authors are indebted to Dr. J. R. Carruthers who suggested that the presently observed segregation behavior could be attributed to pressure effects. The authors are also indebted to the National Aeronautics and Space Administration and the National Science Foundation for financial support.

Field Effect Modulated Photoluminescence in ZnO

T. O. Sedgwick*

IBM Thomas J. Watson Research Center, Yorktown Heights, New York 10598

The photoluminescent intensity of ZnO has been modulated by the surface adsorption of the gases H_2 and O_2 (1, 2). It is known that adsorbed O_2 raises the surface potential and therefore depletes the normally n-type ZnO surface. U.V. excitation of the ZnO produces hole-electron pairs and it has been postulated that the photoluminescence (or luminescence) results from the recombination of the minority carrier holes with a luminescent center. The decrease in photoluminescent intensity upon O_2 adsorption is thought to occur because the field induces transport of the holes away from the luminescent centers and to the surface where they undergo recombination with radiationless recombination centers (1). Hydrogen adsorption, on the other hand, results in electron accumulation at the ZnO surface and causes the photoluminescence to increase since the holes are repelled from the radiationless recombination centers at the surface.

However, it is difficult to know whether the changes in emitted light-intensity are due to surface potential changes alone or whether they depend on the presence of the adsorbed gases directly. Conceivably, the adsorbed gases could act as recombination centers or alternatively, they could react chemically with surface recombination centers already present and hence render them inactive. In this note we report on the observed modulation of photoluminescence in ZnO coated with a SiO_2 film whose surface is charged with a corona to produce the modulating field at the ZnO surface and thus completely avoid the effects of gas ambients.

Photoluminescent measurements were made on samples of single crystal ZnO and layers of ZnO powder about 1 cm^2 in area. Some samples were coated with 3000-3500Å pyrolytic SiO_2 deposited at 420°C in oxygen (3). The single crystal ZnO was supplied by Airtron and was lightly doped with Li (the Li concentration was estimated to be *ca.* 100 ppm by electron spin

resonance which did not agree for some unknown reason with a determination of < 3 ppm Li by emission spectroscopy). The measured surface was the oxygen face, $000\bar{1}$, which had been polished down ~ 5 mils to remove cutting damage using ¼% conc HCl in H_2O on a Pellon cloth. The back surface of the SiO_2 coated single crystal sample exhibited high resistivity after SiO_2 deposition so it was annealed at 510°C for 1 hr in 10% H_2 in N_2 to increase the conductivity. The four point probe resistivity of the back surface after annealing was 11 ohm-cm which agrees with that found by Thomas and Lander (4) for a similar exposure of ZnO crystals to hydrogen. A contact was made with gallium to the back of the sample for subsequent electrical measurements.

The ZnO powder was a commercial P-15 phosphor supplied by Sylvania which was settled without binder onto Ta plates before coating with SiO_2. The powder samples were used without further treatment.

The photoexcitation was made (Fig. 1) using radiation from a medium pressure mercury lamp filtered through Corning filters 7-51 and 7-737 to give a band centered at 3600Å. The photoluminescence was measured with a 1P21 phototube after passage through a Corning 3-72 filter to remove radiation of wavelength shorter than 4400Å.

Before making photoluminescent measurements on the SiO_2-coated single crystal sample, 2 mm diameter Pd dots were evaporated on the SiO_2 surface and capacitance-voltage (C-V) measurements (5) were made at 150 kHz and room temperature. Although most devices were leaky due to the large area dots, several C-V curves were obtained and one is shown in Fig. 2. The capacitance was constant from 0 out to +60V but showed the expected decrease for an n-type sample at sufficiently negative voltage. The existence of the capacitance drop shows that the applied voltage of −40 to −80V does in fact deplete the n-type ZnO surface. The gradual drop of capacitance with voltage over the whole negative voltage range indicates the presence of a large density of surface states (~ $4 \times 10^{12}/cm^2$) which become positively charged as a result of the applied field. The Pd dots were then removed with a $KI\text{-}I_2$ solution.

The sample surfaces were charged in air either positive or negative using a ± 4 kV corona charging wire held for 1-10 sec about 1-2 cm from the surface. Although the surface potential of these particular oxide films was not measured, we have found that thermally grown SiO_2 films retain surface charge densities corresponding to fields across them of $\pm$ 5-10 $\times 10^6$ V/cm for days after charging (6). Even SiO_2 films which have been etched and otherwise handled showed a minimum retention field of 1×10^6 V/cm. If we assume that the present films could support a field of 1-10 $\times$

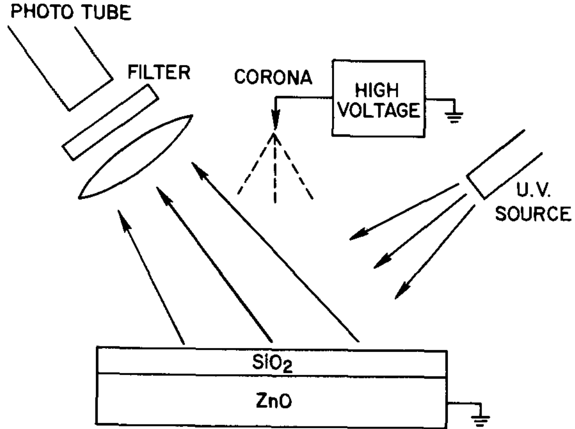

Fig. 1. Schematic of sample charging and photoluminescent measuring apparatus.

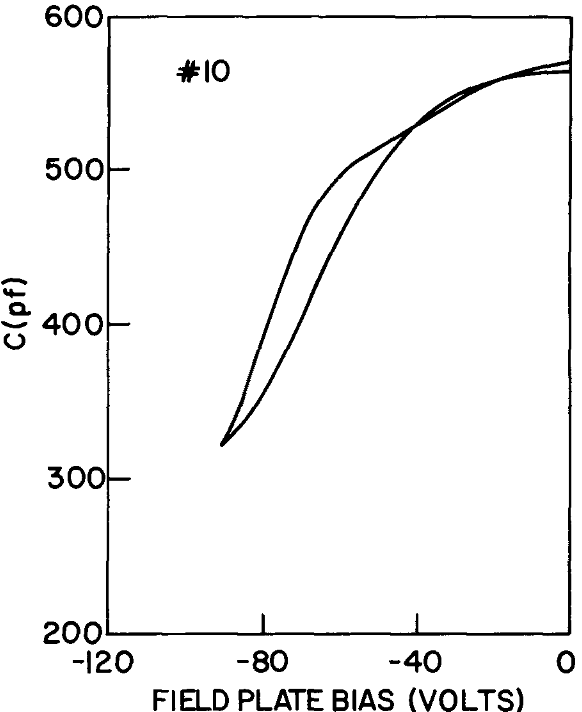

Fig. 2. Capacitance-voltage curve of Pd field plate/3000-3500Å SiO_2/ZnO single crystal measured at 150 kHz in room light at 300°C.

10^6 V/cm, then the potential on the surface which could be retained for a long time was 30-350V.

The basic experimental result that we would like to present is shown in Fig. 3a for the SiO_2 coated single crystal ZnO sample. The initial luminescence of the uncharged sample is constant in time. Upon negative charging the intensity decreases immediately and drastically. When the charging is terminated the luminescent intensity rises slowly, henceforth called the "luminescent relaxation" and reaches a new constant value which is lower than for the uncharged sample. Upon positive charging the luminescence immediately rises to a level higher than that of the uncharged sample and remains essentially constant although a slight decrease is often observed in time. All the subsequent figures show data using the same experimental sequence. Figure 3b shows a very similar result at ten times the luminous intensity and Fig. 3c shows that a structure without any SiO_2 does not exhibit any appreciable modulation of intensity as a result of charging. In Fig. 3a time was indicated schematically since the time elapse was not exactly recorded.

Similar measurements were made on powder ZnO samples in Fig. 4 and with similar results. The last data point of Fig. 4a taken at ~ 110 min shows that the luminescent intensity is stable after the initial and relatively short duration (~ 10 min) "luminescent re-

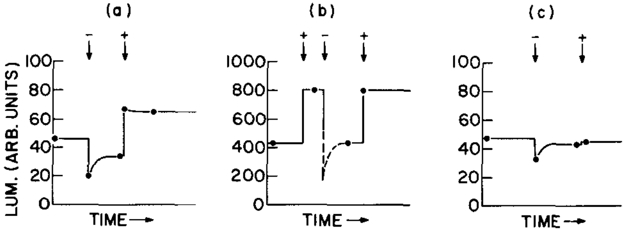

Fig. 3. Photoluminescent intensity as a function of time (schematic) for single crystal ZnO samples. (a) SiO_2 coated, (b) SiO_2 coated at 10X intensity, (c) no SiO_2 on ZnO; $\overset{-}{\downarrow}$, $\overset{+}{\downarrow}$ indicates first measurement of intensity after negative or positive charging, respectively.

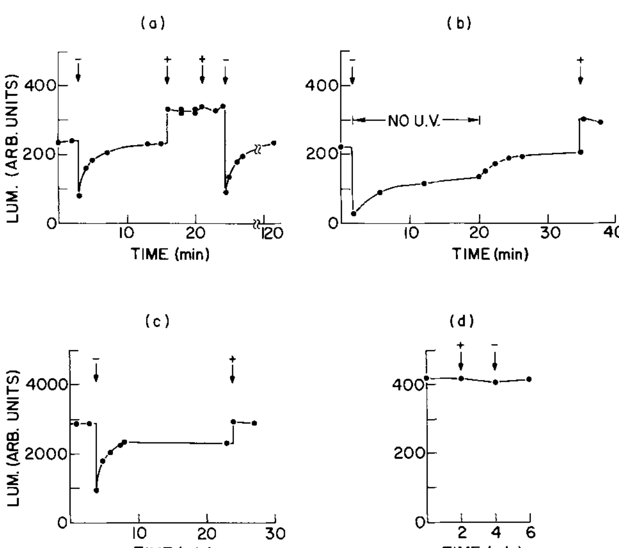

Fig. 4. Photoluminescent intensity as a function of time for powder ZnO samples (a) SiO_2 coated, (b) SiO_2 coated, u.v. was blocked from sample from 1½-20 min except during measurement of data points, (c) SiO_2 coated at 10X intensity, (d) no SiO_2 on ZnO.

laxation." The time required for this relaxation to occur is significantly increased when the u.v. radiation is blocked (Fig. 4b) or significantly decreased when the u.v. intensity is increased (Fig. 4c). No modulation in luminescent intensity was observed in a sample without SiO_2 coating (Fig. 4d). Although not shown in Fig. 4, it was also determined that repeated sequential negative charging always was followed by the "luminescent relaxation" process. It was not possible to lower either the initial or stable intensity level by repeated negative charging.

The ratio of the intensity after the "luminescent relaxation" to the intensity after positive charging for all SiO_2 coated samples varied from about 1.3 to 1.9. If instead the initial intensity after negative charging is used, the ratio is typically 3 or 4 and can be as high as 10 (Fig. 4b).

These results show that the luminescent intensity of both single crystal and powder ZnO samples can be significantly modulated by the application of either a negative or a positive bias to the surface via an oxide layer where gas adsorption on the ZnO surface plays no role. The change in intensity is consistent (depletion lowers intensity) with what was observed previously for H_2 and O_2 modulation of surface potential (1). Thus photoluminescent intensity changes are primarily a function of surface potential changes and not gas-solid interactions.

There is a stable difference between the photoluminescent intensity of the negatively and positively charged surfaces which is, at least to first order, independent of u.v. intensity and for which we have a satisfactory explanation given immediately below. On the other hand, the rate of change of the initial "luminescent relaxation" is clearly dependent on u.v. intensity and is not so readily explained.

The stable change in photoluminescence with applied field may be explained conveniently using Fig. 5. Figure 5a shows the photoluminescent process in a field free structure, where the holes produced by u.v. excitation are neither preferentially drawn to nor repelled from the $ZnO\text{-}SiO_2$ interface. Hence moderate luminescence results. (We are not specifying the actual photoluminescent mechanism other than to assume that hole density is related to the light production process.) Figure 5b shows that when the SiO_2 is positively charged the holes are repelled from the surface and hence are relatively more available for the luminescent process than for radiationless recombination at the recombination centers and hence the luminescence is more intense. Initially after negative charging (Fig. 5c or 5e), holes move preferentially to the interface. They are consumed at the radiationless recombination centers (circles) and by other nonradiative processes and the luminescent intensity is at a minimum.

There are, however, two basic models which account for the "luminescent relaxation" and although we feel the "oxide discharge" model (Fig. 5e and f) is more consistent with our data we cannot rule out a "trapping model" (Fig. 5c and d). In the "trapping model" we envision that some of the holes moving toward the

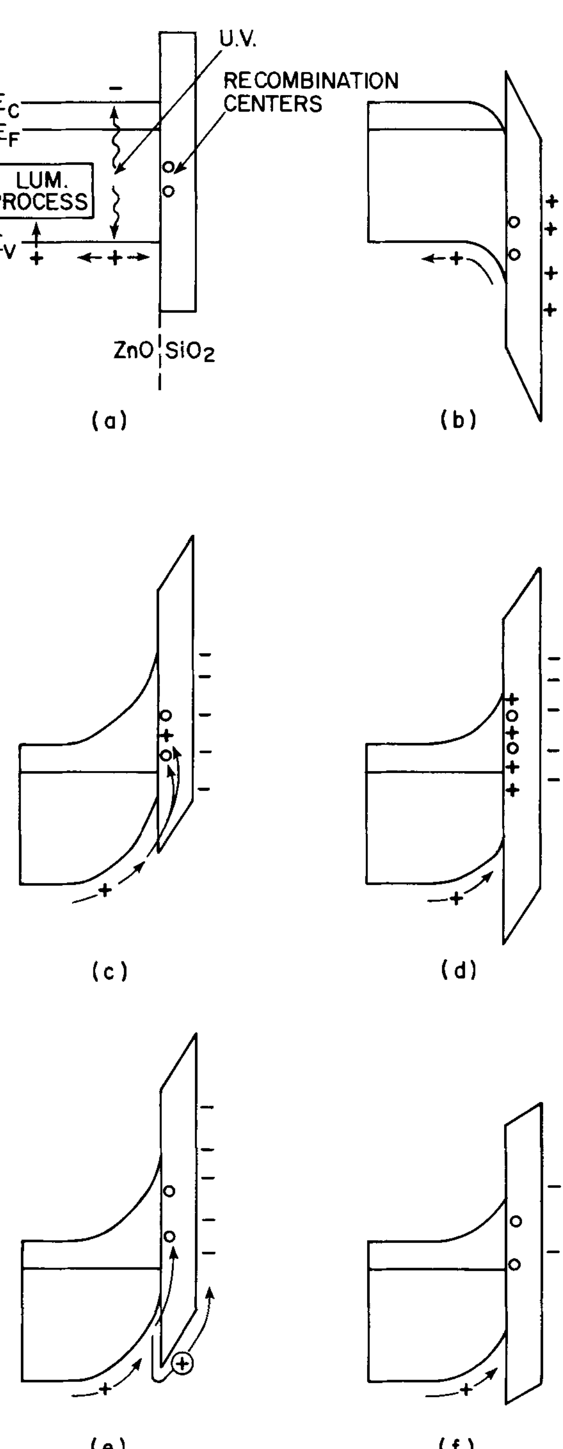

Fig. 5. Schematic of band model of SiO_2-ZnO structure to explain field effect modulation of photoluminescence after the surface was charged as follows: (a) none; (b) positive, "trapping model;" (c) negative initial configuration; (d) negative after "luminescent relaxation;" "SiO_2 discharge model;" (e) negative initial; (f) negative after "luminescent relaxation."

surface, due to the electric field, become trapped in interface states and result in a slow build up of positive charge at the interface. As the positive charge increases, the electric field in the semiconductor decreases. In turn the preferential flow of holes toward the surface is lowered, and hence the photoluminescence decreases. The extent of the "luminescent relaxation" would be dependent on the hole supply and hence on u.v. intensity, and would probably stop when the traps are saturated or the trapping rate becomes insignificant because of the lowered surface potential. The existence of hole traps at the ZnO interface is consistent with the capacitance voltage data obtained on the single crystal sample. If this model is correct, subsequent repeated negative charging of this structure (Fig. 5d) should no longer produce an initial "luminescent relaxation" because the SiO_2 already supports the maximum field across it. Our experimental results indicate clearly that the "luminescent relaxation" recurs after every new negative charging. Thus, we feel that the charge on the SiO_2 is probably discharged by excitation of holes (Fig. 5e) from the ZnO into the valence band of the SiO_2 and which finally neutralize the negative charge on the surface of the SiO_2. The structure (Fig. 5f) could then be recharged with the corona and returned to the state indicated in Fig. 5e and could exhibit the "luminescent relaxation" repeatedly which is observed experimentally. The validity of the "oxide discharge" model could be resolved unambiguously by making surface potential measurements of the SiO_2 surface as a function of time and luminescent intensity to determine whether the charge on the SiO_2 is in fact discharged by the u.v.

Acknowledgment

The author would like to thank B. Kazan for many helpful discussions and suggestions. He is indebted to E. Bassous for depositing the SiO_2 films, C. Kircher for depositing the Pd field plate dots, and to B. Agule who made many of the measurements.

Manuscript submitted July 26, 1973; revised manuscript received Sept. 21, 1973.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1974 JOURNAL. All discussion for the December 1974 Discussion Section should be submitted by Aug. 1, 1974.

Controlled Chemical Etching of GaP

Lillian Rankel Plauger

Bell Laboratories, Murray Hill, New Jersey 07974

Gallium phosphide electroluminescent diodes suitable for inclusion in alphanumeric matrix displays have been described recently (1, 2). One of the important requirements in the fabrication of beam lead gallium phosphide electroluminscent diodes (1) is the development of a technology for the controlled chemical etching of GaP. Chemical etching procedures are required for the formation of light emitting mesas on the GaP, for air isolation of diodes, for final separation of individual display devices from the wafer, and also for shaping of the matrix array (see Fig. 1 and 2). Although there are many techniques available for mesa etching such as SiO_2 masking following etching with aqua regia (1), Br_2 in MeOH (3), or Cl_2 in MeOH (3), these etches are unsatisfactory for separation etching of beam lead diodes since they attack gold beam leads. An etching solution is needed that: (*i*) rapidly etches GaP and results in a polished unpitted surface; (*ii*) does not attack dielectrics such as SiO_2 or Ti-Pd-Au beam lead metalizations.

Both (111) and (100) oriented GaP are used for diodes. There is a significant difference between the {111} surface (Ga plane A-face) and the $\{\bar{1}\bar{1}\bar{1}\}$ (P plane B-face). The outermost surface layer of atoms consists of either Ga or P atoms which are triply bonded to the lattice. This leads to pronounced chemical differences between the (111) or A-face and the $(\bar{1}\bar{1}\bar{1})$ or B-face (4, 5). For the (100) oriented GaP, the {100} planes are made up of Ga and P atoms and therefore are chemically the same.

During this study, it was found that alkaline ferricyanide solutions in certain concentration ranges (KOH: 0.25-3.0M and $K_3Fe(CN)_6$: 0.50-1.00M) polished all faces of GaP except the Ga-face (which developed a smooth "orange-peel" texture), and did

Key words: polishing GaP, masking GaP, alkaline ferricyanide etching, LED, separation etching.

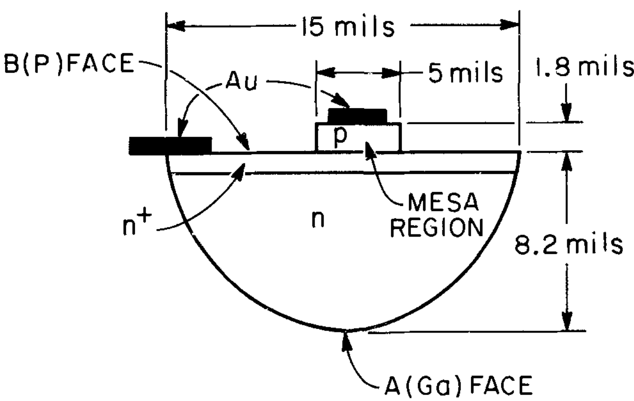

Fig. 1. GaP beam lead diode

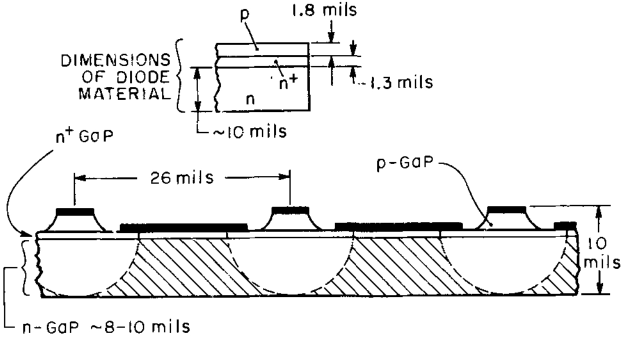

Fig. 2. Planar beam lead devices

not attack gold. Solution systems of this type have been previously used to mechanically polish (6) or reveal dislocations and stacking faults (7) in (111) GaP. Masking materials such as SiO_2 (silane deposited and sputtered), Ti (evaporated and sputtered), and Biwax were evaluated to determine compatibility with alkaline ferricyanide solutions.

Experimental

Both n-type (selenium-doped) and p-type (zinc-doped) (111) and (100) oriented GaP slices were used for this study. Before use, all mechanically polished material was further polished using a solution of 0.5M KOH + 1.0M $K_3Fe(CN)_6$ at 95°C for 10 min [the Ga-face of (111) material was not so etched]. This chemical polishing step removes surface damage and abrasive particles from the mechanical polishing step. This results in less undercutting of all the masking materials evaluated for selective GaP etching (see Table I for a listing of masking materials). Forty-eight per cent fluoroboric acid (J. T. Baker Chemicals) was used to remove Ti metal masking material. Ten to fifteen seconds in fluoroboric acid at room temperature dissolved 1000-3000Å Ti layer with no attack of the GaP, dielectrics, or gold metallization.

Reagent grade Fisher Chemicals were used to prepare the etching solutions listed in Table II. All solutions were maintained at a constant temperature using a Colora Model I NB Temperature Bath circulation through jacketed beakers. During this investigation, the concentrations of $K_3Fe(CN)_6$ and KOH were varied to optimize the etch rate of GaP. Some of the concentration ranges listed in Table II could only be achieved at temperatures greater than 40°C.

Measurements of the depth of etching were made with a calibrated microscope using a SiO_2 mask as a reference point. The separation of individual diodes from a large piece of material is accomplished by a partial saw cut into the Ga face of n-GaP (Fig. 3a), and chemically etching the remaining GaP. Air isolation of individual diodes results (Fig. 3b).

Table I. Masking material lifetime*

Masking material	(111) n-GaP	(100) n-GaP
Silane SiO_2—5000Å[a]	0.5 hr	1.5 hr
Sputtered SiO_2—6000Å[b]	0.8 hr	0.8 hr
Sputtered SiO_2 with Biwax solution	1.5 hr	>2.0 hr
Ti 1000Å evaporated	1.0 hr	2.0 hr
Ti 3000Å sputtered	>2.0 hr	>2.0 hr

80°C	100		80	125

* P face of (111) n-GaP.

Results and Discussion

$K_3Fe(CN)_6$ +KOH is an excellent etch for n-GaP where etch rates of 100-250 μ/hr can be obtained by adjustment of solution concentration and temperature (see Table II). Since p-GaP was found to etch at the same rate as n-GaP, n-GaP was used more extensively because of availability. The P-face of $(\overline{111})$ GaP etched about two times faster than the Ga-face of the (111) material [see Table II for etch rate of (111) P-face at 95°C]. In this etching solution, GaP probably dissolves in the following manner

$$GaP + 4KOH + 3K_3Fe(CN)_6 \rightarrow K[Ga(OH)_4] (8) + 3K_4Fe(CN)_6 + P \quad [1]$$

where P dissolves chemically to PH_3 and H_3PO_4 (9), being easily oxidized by $K_3Fe(CN)_6$. All etching solutions studied were of $pH > 13$. At these high pH values the gallium ion exists as GaO_3^{-3} where compounds of gallium such as $K[Ga(OH)_4]$, $KGaO_2 \cdot 1\frac{1}{2}H_2O$, and $KGaO_2 \cdot H_2O$ have been isolated from KOH solutions, and four or six coordinate species such as $[Ga(OH)_4]^-$ or $[Ga(OH)_4(H_2O)_2]^-$ can form in solution (10, 11). These complexes are sparingly soluble (8) but since large volumes of etching solution are used (100 ml) to dissolve small pieces of GaP (wt < 0.1g), no precipitation of gallium complexes could be detected.

The activation energy E_a calculated from the data in Table II for basic ferricyanide stirred solutions was found to be ~10 kcal/mole for the Ga-face of (111) n-GaP and ~6 kcal/mole for (100) oriented n-GaP. It was also found that stirring the etching solution does not appreciably affect the etch rate of the Ga-face of (111) material while the etch rate is increased by a factor of ~1.5 for (100) n-GaP in stirred solution. From this one can conclude that dissolution of the Ga-face of (111)-GaP is limited by the rate of heterogeneous chemical reaction, and is independent of diffusion processes. (100) n-GaP dissolution is diffusion limited which is to be expected for covalently bonded substances (12). The bonding of gallium atoms to underlying phosphorus atoms on the Ga-face of the (111)-surface has a slightly ionic or metallic nature (4, 5, 13) which accounts for the higher E_a value.

Etching solution No. 2 [0.5M KOH + 1.0M $K_3Fe(CN)_6$] was chosen as the best solution for selectively etching GaP. With this solution it is possible to dissolve the most GaP [4-9 mils/hr on the Ga-face and up to 15 mils/hr on P-face of (111)-material, and up to 10 mils/hr on (100)-material] with the least attack on the masking materials listed in Table I. The optimum temperature is 80°C when using unprotected SiO_2 or 1000Å Ti masking (see Table I). With thicker Ti metal layers or Biwax protected SiO_2, higher temperatures can be used without corrosion of the masking layer so that a slightly faster etch rate of GaP can be obtained. In all cases, masking material adheres better to (100) n-GaP than to the Ga-face of (111) n-GaP.

After partial saw cutting, chemical etching is used to complete the air isolation of individual diodes in the matrix array (see Fig. 3b). The gold metallization, that can be seen under the GaP diodes in Fig. 3b, is not attacked during this separation etching step. When thinner GaP (2-5 mils) is used for diode fabrication, partial saw cutting could be eliminated and selective shadow mask defined Ti used for a separation etching mask. Shadow mask defined Ti metal is a one step procedure which eliminates photoresist processing. The Ti metal can easily be removed in 10-15 sec with 48% fluoroboric acid (with no attack to the device structure).

Summary

Alkaline ferricyanide solutions such as 0.5M KOH + 1.0M $K_3Fe(CN)_6$ are excellent etches for (100) and

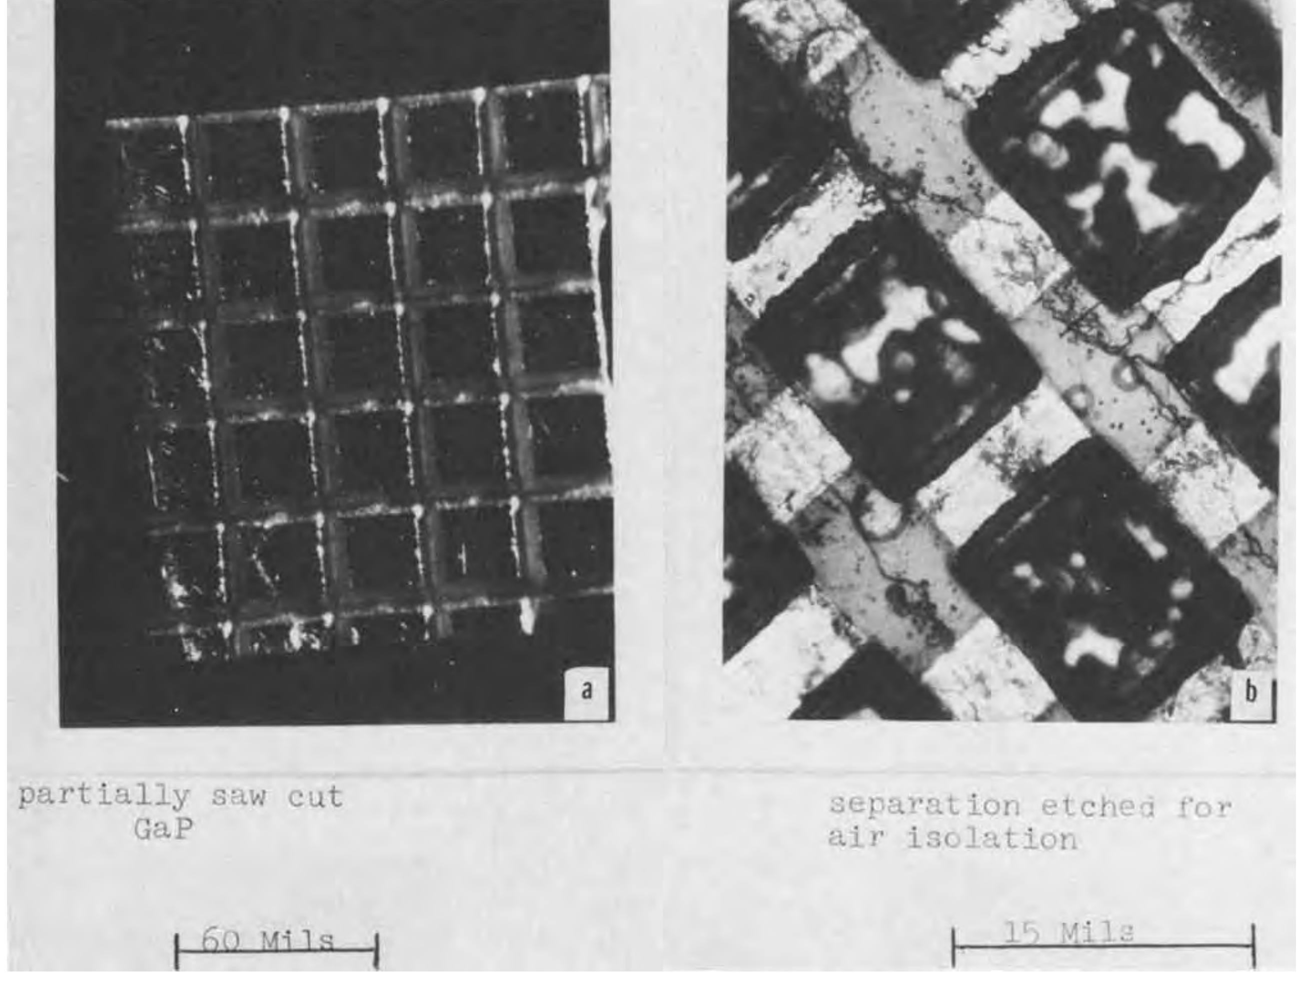

Fig. 3. Separation etching with alkaline ferricyanide solution

(111) oriented GaP diode processing because a fast rate can be obtained 4-9 mils/hr (~100-200 μm/hr), a polished surface results on all faces (except the Ga-face), compatible masking materials such as sputtered SiO_2 and Ti are available (Ti can be shadow-mask defined), and no attack of the dielectrics or Ti-Pd-Au metallization of the device structure occurs.

Decomposition Reaction of Concentrated Lithium-Ammonia Solutions

M. H. Miles*[,1] and W. S. Harris*[,2]

Naval Weapons Center, Corona Laboratories, Corona, California 91720

ABSTRACT

The self-decomposition reaction of concentrated solutions of lithium in ammonia at atmospheric pressure was studied at various temperatures in polyethylene and in glass containers by observing the change in weight of the solution. The reaction follows a first-order rate law and is apparently heterogeneous. An unusually large, negative value for the activation entropy and a relatively low activation energy is found for this reaction. Possible explanations for these results include the concepts that the solvated electron is involved in the decomposition reaction and that electron transfer occurs by a tunneling mechanism.

Lithium, like other alkali metals, forms solutions with ammonia which have very unusual properties. For example, a solution saturated with lithium in ammonia has a metallic, bronze-like luster, an electrical conductivity approaching that of metals, and the lowest density of any known liquid (1-5). These concentrated metal-ammonia solutions are generally believed to contain solvated metal ions and free or solvated electrons (2-9). The electronic properties of the concentrated solutions are similar to those of liquid metals (5).

With the high energy theoretically available from lithium, concentrated lithium solutions in ammonia, represented by $Li(NH_3)_x$, could be an electrochemical fuel of exceptional interest for fuel cells or batteries. The usefulness of such a fuel would be limited by the parasitic decomposition reaction

$$Li(NH_3)_x(l) \rightarrow LiNH_2(s) + (x-1)NH_3(g) + \tfrac{1}{2}H_2(g) \quad [1]$$

which takes place in the liquid. Of prime interest in this work is the study of the self-decomposition reaction in concentrated lithium solutions where the equilibrium vapor pressure of NH_3 is maintained at about 1 atm.

Experimental

Lithium is capable of forming solutions with ammonia through exposure of the metal to dry ammonia gas at ambient conditions of temperature and pressure (1). Both the formation of the concentrated lithium-ammonia solutions and the self-decomposition reaction involve large weight changes which can be correlated with the reactions taking place. Metallic lithium was exposed to a stream of ammonia gas at atmospheric pressure, and weight *vs.* time was recorded by using a specially modified du Pont 950 thermogravimetric analyzer. By means of an electronic adapter (consisting of a power supply and op-amp follower), the output of the electrobalance was recorded on a Honeywell 10 in. strip chart recorder. Weights of greater precision were obtained from a digital voltmeter and were manually recorded on the chart at various times. Figure 1 shows detailed views of parts of the apparatus and a flow diagram for the complete system. The lithium was contained in a special sample boat constructed entirely of polyethylene with baffles to prevent loss of material by effervescence during the reactions. The ammonia gas, after passing over the boat, was vented through an oil bubbler to the atmosphere. The flow rate used was approximately 80 ml/min. The thermostat jacket was supplied with circulating fluid by an external constant temperature bath to maintain accurate temperature control within the Pyrex furnace tube containing the sample boat.

Additional studies of the decomposition reaction of lithium-ammonia solutions were made in 5 ml soft glass vials modified with baffles consisting of several indentions on the sides. The vials were soaked overnight in warm, concentrated nitric acid, rinsed well with distilled water and acetone, and then taken inside an inert atmosphere dry box where a known weight of lithium was added to each. The vials were then placed in a wide mouth stainless steel bomb which was sealed, removed from the dry box to a constant temperature bath, and connected to a vacuum line. After evacuating the bomb, ammonia gas was admitted through the vacuum line to form the metal-ammonia solution. The pressure inside the bomb was maintained at about 1-3 atm by frequent venting of excess gas. Later the decomposition reaction was interrupted by again using the vacuum line to remove the ammonia and hydrogen present. The bomb containing the vials was taken back into the dry box, opened, and the weight of the contents, Li + $LiNH_2$, in each vial was determined. Using the known weight of Li added initially, the extent of the reaction in each vial could then be calculated.

In a third experiment, three larger glass vials (30 ml) with known weights of lithium were placed inside

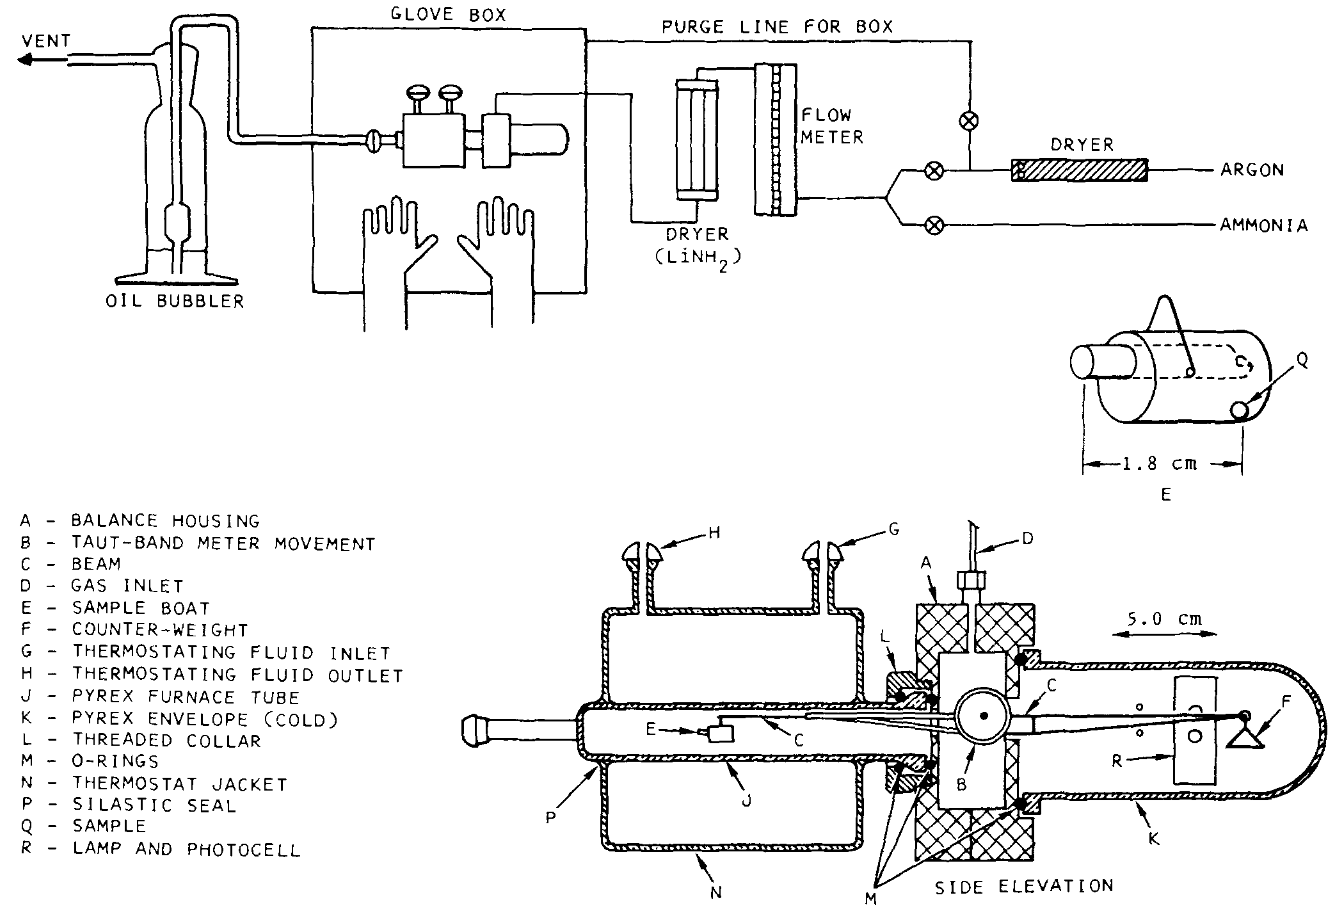

Fig. 1. Modified du Pont 950 thermogravimetric analyzer and flow diagram

a glass vacuum system and exposed to flowing ammonia gas vented through an oil bubbler. This arrangement permitted visual observation of the changes occurring. Upon admitting ammonia gas at atmospheric pressure, the bronze lithium-ammonia solution forms readily at 25°C, usually being completely formed within 1 or 2 hr.

Results and Discussion

A relatively large and rapid weight increase is observed as the bronze-colored, lithium-ammonia solution forms according to the reaction

$$Li(s) + xNH_3(g) \rightarrow Li(NH_3)_x(l) \quad [2]$$

where x is about 4 for saturated lithium solutions in ammonia at atmospheric pressure (3, 10). A much more gradual loss of weight is observed as the self-decomposition reaction occurs (reaction [1]), and the gaseous products of NH_3 and H_2 are swept out of the system leaving only unsolvated $LiNH_2$. Although the decomposition reaction of alkali metals in liquid ammonia is reversible (11, 12), the continuous removal of hydrogen by the flowing ammonia gas in this open system ensures that the reaction goes to completion.

At an instant the weight, W, is given by

$$W = n_1M_1 + n_2M_2 + n_3M_3 \quad [3]$$

where n_1, n_2, n_3, and M_1, M_2, M_3 represent the number of moles and molecular weights of Li, $Li(NH_3)_x$, and $LiNH_2$, respectively. Here $Li(NH_3)_x$ represents the bronze-colored, concentrated lithium-ammonia solution. After the first few hours required for complete formation of $Li(NH_3)_x$, $n_1 = 0$ and

$$W = n_2M_2 + (n - n_2)M_3 \quad [4]$$

where n represents the number of moles of lithium initially present. The rate of change of W is then given by

$$\frac{dW}{dt} = (M_2 - M_3)\frac{dn_2}{dt} \quad [5]$$

Assuming that reaction [1] obeys a first-order rate law with respect to the amount of $Li(NH_3)_x$ present, then

$$\frac{dn_2}{dt} = -kn_2 = -k\left(\frac{W - nM_3}{M_2 - M_3}\right) \quad [6]$$

where Eq. [4] was used to obtain the last expression. Substituting Eq. [6] into Eq. [5] and integrating gives

$$\log(W - W_\infty) = \frac{-kt}{2.303} + \text{constant} \quad [7]$$

where $W_\infty = nM_3$ and represents the weight when all the lithium has been converted into $LiNH_2$. This first-order rate law can also be expressed in terms of the volume of the $Li(NH_3)_x$ solution since this volume is directly proportional to the amount present.

The test of assumption of first-order kinetics which leads to Eq. [7] is shown in Fig. 2 for experiments in the polyethylene sample boat at 0° and 50°C. Two linear segments are observed in each experiment suggesting that the self-decomposition reaction is indeed first-order and that a change to a slower rate later occurs. Similar results were observed by Jackman and Keenan in dilute lithium-ammonia solutions using a spectrophotometer to follow the reaction (13, 14). They report two linear, first-order segments and that the change to the slower rate occurs at about the time $LiNH_2$ begins to precipitate on the walls of the reaction vessel. In fact, the decomposition reactions of all alkali metal-ammonia solutions seem to take place at the cell walls since the homogeneous reaction is apparently immeasurably slow (13, 14). The observed linearity in Fig. 2 may simply reflect that the rate is propor-

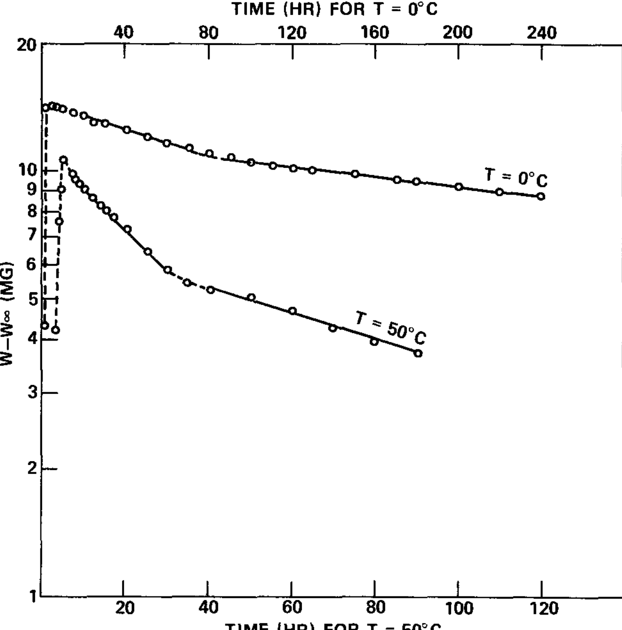

Fig. 2. First-order plot for the decomposition of lithium-ammonia solutions at 0° and 50°C. Initial weights of lithium were 1.72 and 1.48 mg, respectively.

tional to the surface area of the cell walls in contact with the solution since this surface area would likely be proportional to the amount of $Li(NH_3)_x$ present.

Eventually, as the self-decomposition reaction nears completion, the experimental sample weight should approach the weight calculated for complete conversion of the sample to unsolvated $LiNH_2$. Although several long duration experiments gave approximate agreement with the calculated weight of $LiNH_2$, complex processes which tend to occur in late stages of the reaction made it difficult to verify this result accurately. Growth of solid $LiNH_2$ in a branching, tree-like fashion was often observed late in the decomposition reaction. Frequently the $LiNH_2$ "tree" would grow right out of the tube of the sample boat forcing discontinuation of the experiment due to loss of material. Occasionally, a shift of the bronze solution to new surfaces free of $LiNH_2$ was observed which produced a perceptible increase in the rate of self-decomposition. When any such complex processes occurred, the data was not used to calculate any kinetic parameters. Fortunately, the reactions were usually well-behaved for at least the first half-life.

Further experiments were conducted at 50°C where small amounts of LiI, a typical electrolyte readily soluble in liquid ammonia, were intentionally added to the reaction mixture. No large change was observed in the rate of the self-decomposition reaction during the early stages of the reaction. In fact, a slight decrease in rate was detected in the presence of the LiI. This result is significant for any use of lithium in ammonia in fuel cells or batteries where there is contact of this fuel with the electrolyte.

For the experiments in the glass vials, the extent of the self-decomposition reaction can be determined by the relationship

$$\alpha = \frac{W - W_o}{W_\infty - W_o} = \frac{\%\ \text{weight increase}}{231\%} \qquad [8]$$

where α represents the fraction reacted, W is the weight of Li and $LiNH_2$ present after pulling off the ammonia, W_o is the initial weight of lithium added to the vial, and W_∞ is the weight when all lithium is converted into $LiNH_2$.

Table I presents the kinetic data for the self-decomposition reaction in the three different reaction vessels.

Table I. Kinetic data for the reaction $Li(NH_3)_x(l) \rightarrow LiNH_2(s) + (x - 1)\ NH_3(g) + \frac{1}{2}H_2(g)$ during the first half-life.

Temp, °C	Rate constant, sec⁻¹	Standard deviation	Reaction vessel
25.0	1.1×10^{-6}	$\pm 0.06 \times 10^{-6}$	5 ml glass vials
25 ± 1	0.9×10^{-6}	$\pm 0.02 \times 10^{-6}$	30 ml glass vials
0.0	0.97×10^{-6}	About ± 5%	Polyethylene boat
50.0	6.2×10^{-6}	About ± 5%	Polyethylene boat

Thirteen experiments in the small glass vials with initial weights of lithium ranging from 18 to 159 mg established that the fraction reacted after 117 hr is independent of the initial amount present. This result supports a first-order rate law. Running the experiments for longer times in the glass vials indicated also that a change to a slower rate later occurs. The "Student t" statistical test indicates that the average rate constants for the large and small glass vials differ significantly at the 90% confidence level. The slightly larger rate constant for the small vials may reflect a somewhat larger ratio of surface area per unit volume for the smaller vials. However, experimental conditions also differed somewhat for these two measurements. The rate constants for the reaction in the polyethylene container were calculated from the data in Fig. 2 by using the method of least squares to determine the slopes of the linear regions. Other measurements in the polyethylene container established that these results are reproducible with a standard error of about ±5%. Surface effects are again indicated by the fact that the reaction is faster in the polyethylene containers than in the glass containers.

From the Arrhenius equation and the Eyring equation

$$k_r = Ae^{-E_a/RT} = \frac{kT}{h} e^{\Delta S^{\ddagger}/R} \cdot e^{-\Delta H^{\ddagger}/RT} \qquad [9]$$

values for E_a, $\Delta S^{\ddagger}$, $\Delta H^{\ddagger}$, and $\Delta G^{\ddagger}$ can be determined from the experimental rate constant, k_r, determined at two different temperatures assuming a transmission coefficient of unity (15, 16). Using the experimental rate constants at 0° and 50°C given in Table I for the polyethylene container, an unusually large, negative value is calculated for the activation entropy, $\Delta S^{\ddagger}$ (-65 cal deg^{-1} mole^{-1}), for this reaction while the activation energy, E_a, is relatively low (6 kcal/mole). The probable error is ±0.5 kcal/mole for E_a and ±2 cal deg^{-1} mole^{-1} for $\Delta S^{\ddagger}$. In terms of the Arrhenius equation, $k_r = 15.3 \times 10^{-2}$ sec^{-1} $e^{-6500/1.987T}$ during the earlier stages of the reaction and changes to $k_r = 1.9 \times 10^{-2}$ sec^{-1} $e^{-5900/1.987T}$ during the later stages. The rare reactions with such strikingly small frequency factors show some tendency to be heterogeneous reactions with sensitivity to the reaction-vessel surface (17). As in electrochemical kinetics, the kinetic parameters can still be determined for heterogeneous reactions whenever surface conditions are constant. The eventual precipitation of $LiNH_2$ on the walls of the reaction vessel, which changes the surface, produces slight changes in the kinetic parameters.

Experiments in water-ammonia mixtures indicate that the rate of the solvated electron reaction is controlled mainly by the entropy of activation which likely decreases to large negative values as the ammonia content increases (18). Lepoutre *et al.* (19-21) have shown that the absolute entropy of the ammoniated electron is abnormally high. Their interpretation is that the electron breaks the hydrogen-bonded structure of ammonia in order to become "ammoniated." During the self-decomposition reaction, the electron loses its high entropy as the loose solvent structure collapses and hydrogen bonds reappear in the activated complex.

The fact that reaction [1] involves the transfer of an electron to a surrounding ammonia molecule sug-

gests that quantum-mechanical tunneling through the potential-energy barrier is possibly an important factor in this reaction. A tunneling mechanism would account for the first-order rate law observed. Anbar (22) suggests that the low, nearly constant values of activation energies found for reactions involving solvated electrons is due to an electron-tunneling mechanism, and that the different rates observed are due to different probabilities for this tunneling. Eyring (23) and Laider (24) indicate that electron-transfer reactions occurring by a tunneling mechanism will be characterized by apparent negative entropies of activation if the energy of activation is low. As the tunneling distance increases, the apparent entropy of activation becomes more negative. It is reasonable that for the unusually low density lithium-ammonia solution, the tunneling distance would be relatively large. The abnormally small frequency factor found for this decomposition reaction is predicted for reactions where there is tunneling (25). Perhaps the observed surface effects on the reaction rate result from a favored tendency by adsorbed NH_3 to accommodate the tunneling electron. Jackman and Keenan propose that an ammonia molecule bound to a surface acid group is more open to attack by a solvated electron (14). The eventual precipitation of the Lewis base, $LiNH_2$, would tend to neutralize surface acid groups, thus causing a decrease in the rate.

The electrochemical oxidation reaction of concentrated lithium solutions in liquid ammonia can be represented as

$$Li(NH_3)_x(l) \rightarrow Li^+ + xNH_3(g) + e^- \quad [10]$$

where the electrons produced enter the electrode. The potential-energy barriers for both reactions [1] and [10] are probably similar since both involve destruction of the unusual electronic structure of $Li(NH_3)_x$ and incorporation of the electron into another substance. Therefore, a large Gibbs free-energy of activation, $\Delta G^{\ddagger}$, resulting from a large, negative entropy of activation, $\Delta S^{\ddagger}$, can also be expected for reaction [10]. Studies of the electrode reaction of solvated electrons in hexamethylphosphoric triamide support this conclusion (26). The heat of activation is much too small (4.2 kcal/mole) for the observed rate constant, and a large and negative entropy of activation is postulated.

APPENDIX

The Franck-Condon principle implies that tunneling cannot occur until the structure of the $Li(NH_3)_x$ system is modified in such a way that transfer of the electron leaves the total energy unchanged. The rate will be determined by a compromise between the tunneling probability, W, and the free energy of rearrangement (23), $\Delta G^{\ddagger}_r$, hence

$$k = \frac{kT}{h} \cdot W \cdot e^{-\Delta G^{\ddagger}_r/RT} = \frac{kT}{h} \cdot W \cdot e^{-\Delta S^{\ddagger}_r/R} \cdot e^{-\Delta H^{\ddagger}_r/RT} \quad [A\text{-}1]$$

The subscripts r and t will be used to indicate contributions due to rearrangement and tunneling, respectively. Comparing this equation with Eq. [9] above gives

$$\Delta H^{\ddagger}_{exp} = \Delta H^{\ddagger}_r + \Delta H^{\ddagger}_t = \Delta H^{\ddagger}_r \quad [A\text{-}2]$$

since $\Delta H^{\ddagger}_t = 0$, hence an experimental heat of activation reflecting only the rearrangement energy would account for the low activation energies observed in reactions involving tunneling. Furthermore

$$\Delta S^{\ddagger}_{exp} = \Delta S^{\ddagger}_r + \Delta S^{\ddagger}_t = \Delta S^{\ddagger}_r + R \ln W \quad [A\text{-}3]$$

For a rectangular energy barrier of height $E - E_o$

$$\Delta S^{\ddagger}_t = R \ln W = -R \frac{4\pi a}{h} [2m(E - E_o)]^{1/2} \quad [A\text{-}4]$$

The actual height of the energy barrier involved must be greater than $\Delta G^{\ddagger}_{exp}$; otherwise the rate due to crossing over the barrier would exceed the rate due to tunneling. Taking a lower limit of

$$E - E_o \approx \Delta G^{\ddagger}_{exp} = 24 \text{ kcal/mole}$$

and using the separation between electron cavities (5) to estimate $a \approx 8$Å gives a value of

$$\Delta S^{\ddagger}_t \approx -17 \text{ cal/deg mole} \quad [A\text{-}5]$$

More negative values for $\Delta S^{\ddagger}_t$ would result if larger estimates of $E - E_o$ were used. Despite the approximations used, this result indicates that a tunneling mechanism could contribute significantly to the experimental $\Delta S^{\ddagger}$. Assuming that the reacting electron loses its high entropy in the structure rearrangement (20, 21)

$$\Delta S^{\ddagger}_r = -S^o_{e,\,am} \approx -30 \text{ cal/deg mole}$$

Hence $\Delta S^{\ddagger}_r$ might also contribute significantly to the large, negative entropy of activation observed experimentally.

ABSTRACT

An investigation has been made of the effect of lignin and $BaSO_4$ on the capacity and life of the negative plate. $BaSO_4$ alone, lignin alone, and combinations of the two improved cycle life. Of the combinations tested, 0.5% $BaSO_4$ and 1.0% lignin gave the greatest improvement on SAE cycle life tests. Lignin alone was as effective as the lignin-$BaSO_4$ combination in high-rate, low-temperature discharges. Lignin decreased the diameter of the lead particles and passivated portions of the lead surface, so that lead sulfate crystal growth was away from the surface, leaving considerable open space in the mass of crystals at the end of discharge. Without lignin the lead particles were larger, more closely spaced, and lead sulfate grew solidly along the lead surfaces, so that there was little void space at the end of charge. Microscopic examination showed nothing to explain the beneficial effect of $BaSO_4$.

The effect of lignin and its derivatives on the performance of the negative plate, specifically under the conditions of low-temperature and high-discharge rate, has been reported by a number of investigators (1-6). This work has been recently reviewed (7). Despite these investigations, however, there is still considerable uncertainty about the exact function of an organic expander, such as lignin, and a question as to why it should function better in the company of an inorganic material such as $BaSO_4$.

Several years ago, a cooperative investigation was undertaken by Globe Union, Incorporated and the Naval Research Laboratory in an attempt to elucidate the function of the negative plate additives. More recently, the International Lead Zinc Research Organization has supported this project, among others, by maintaining a Research Associate at the Naval Research Laboratory.

As a result of this cooperative effort, it has been found that when lignin is present in the paste, it modifies the structure of the lead crystals that grow during the formation process. The modifying action produces crystals of smaller diameter with larger surface area and a more porous structure. $BaSO_4$, on the other hand, had no appreciable effect on the growth of the lead crystals during the formation process (1).

The present paper reports on further investigations made to determine the function of lignin and $BaSO_4$ during low-temperature, high-rate discharge of the cell, and their effect on the SAE cycle life and negative electrode morphology.

Experimental Method

It was decided that nine different active material compositions would be adequate to study the effect of lignin alone, $BaSO_4$ alone, and practical combinations of the two. The amount of lignin or $BaSO_4$ used in the nine pastes are shown in Table I. The $BaSO_4$ had a mean particle size of 5.2 μm. The lignin used in the experiments was sodium lignosulfonate, marketed under the trade name of Maracell E by the Marathon Paper Company.

With the exception of the different amounts of lignin and $BaSO_4$, the paste mixes were as identical to one another in preparation and composition as could be managed. All pastes were very nearly of the same weight and paste density, and every step in the preparation, from mixing to formation, was carefully controlled to eliminate as many extraneous variables as possible. The negatives so prepared were matched with production type positive plates and then assembled. When assembled, each cell contained 5 negatives and 4 positives. The nominal capacity of the batteries used was 50 A-hr. In the various phases of the investigation the samples used for analysis, microscopic examination, and other tests were taken from the center of the negative group. The two end plates were always discarded.

A series of plates was placed on cycling life test, using the procedure outlined in SAE specification

Table I. Amounts of additives used in the experimental plates

Mix No.	$BaSO_4$ (%)	Lignin (%)
1	none	none
2	none	0.5
3	none	1.0
4	0.5	none
5	0.5	0.5
6	0.5	1.0

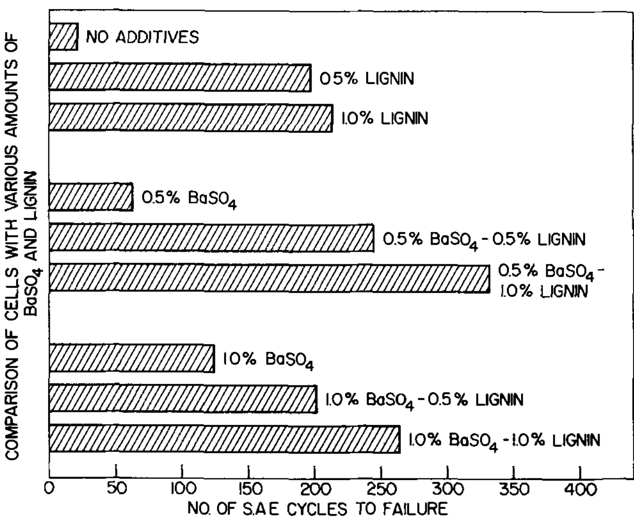

Fig. 1. Comparison of cycle life obtained by the use of various additive combinations. Termination of the bars represent the end of cycle life.

J537d. Using this procedure, there were 27 cycles per week, and low temperature (-17.8°C), 150A discharges were made initially and at the 54th and 135th cycles. Sufficient cells were included in the series so that representative samples of the plates were available at the end of life, at the end of low-temperature discharge, and at the end of the recharge that followed the low-temperature discharge.

Since cycling itself had an effect on the microstructure of the lead crystals, a series was also run where a low-temperature, high-rate discharge followed only 5 SAE discharge-charge cycles.

Each of these series involved the use of cells containing the nine different paste compositions shown in Table I, and enough cells were constructed to insure samples for removal at the various designated points during the cell tests. In addition, individual cells of the series were run through duplicate testing when the first results seemed ambiguous.

Samples of each of the series were removed at the points indicated above and were impregnated with plastic,[1] polished, and examined by microscopy.

Results of Experiment and Examination

Effects noted in the SAE life cycle test.—As shown in Fig. 1, $BaSO_4$ alone produced a considerable increase in cycle life with each 0.5% addition. Lignin alone produced a more marked effect with the first 0.5% addition than did the $BaSO_4$, but the contrast between the 0.5 and the 1.0% addition was much less than for $BaSO_4$. Also evident was the fact that $BaSO_4$ and lignin were more effective in increasing life when used together, although this effectiveness decreased when too much $BaSO_4$ was used. The addition of 1.0% lignin was in all cases more effective than 0.5%. Since the battery industry uses between 0.1 and 0.5% lignin in its negative plates, the use of 1.0% lignin seemed high when planning this investigation. It now appears that even higher amounts might have proven to be beneficial.

Although lignin was found to increase cycle life in SAE tests, when discharge was at the 20 hr rate (Table II), neither lignin nor $BaSO_4$ caused any appreciable increase in initial capacity, either before or after a 150A discharge.

Microscopic examination of the cycled plates, in the charged state, revealed that the lead crystals were influenced by the lignin in the same manner as they had been in the formation process. The lead dendrites in plates containing lignin were much smaller with individual branches of smaller diameter than were those seen in the plates without lignin. Repeated cycling tended to destroy this effect, as the size of the lead particles increased with the amount of cycling. However, even in this case, the particles remained smaller in the plates containing lignin than in those with no additives. There was a general tendency for the lead particles to increase in size and to become roughly spherical as the cycling continued. One effect of the lignin was to retard this lead particle size increase.

The lignin-free plates showed many needle-like dendritic arms growing in parallel arrangement and extending for considerable distance. These growing needles extended in such a manner as to form long and quite narrow channels between the individual branches. Since this type of structure seemed to be nearly absent from the lignin-containing plates, and since in this case the small particles showed little relation to one another, another apparent function of the lignin is to restrict the extent of growth of dendritic arms in the individual crystals, during the conversion of $PbSO_4$ to Pb.

The above description refers to the structural effect that lignin produced on the lead dendrites which appeared in the charged plates. The effect of lignin on the structure of the $PbSO_4$ crystals formed during discharge was somewhat more difficult to observe clearly with the optical microscope. The $PbSO_4$ crystals grew close together, so that individual outlines were difficult to separate from the group. In addition, the cross sections of the crystals, as seen in the polished sections, bore little relation to their actual three-dimensional shapes, so that comparisons, based on these cross sections, left a considerable amount to the imagination. Certain facts were evident, however.

Cycled plates, of similar capacity, discharged at the 20 hr rate, showed $PbSO_4$ crystals grouped around the lead particles, evidently of about the same amount, size, and shape, whether or not the plates contained lignin. There was a marked difference, however, in the manner in which the $PbSO_4$ crystals were arranged. Those $PbSO_4$ crystals in the lignin-free plates were tightly grouped close to the surface of the lead dendrites in a continuous layer (Fig. 2). Those $PbSO_4$ crystals in the lignin-containing plates were much more loosely attached and extended further from the surface (Fig. 3).

Since the charged, lignin-free plates had dendritic lead crystals of large diameter, and since these tended to form parallel and closely spaced dendritic branches, the growth of the $PbSO_4$ during discharge acted to block the resulting channels as well as to leave a large amount of unreacted lead at the core of the particles. In the lignin-containing plates, on the other hand, the lead particles were smaller and the $PbSO_4$ crystals were more openly spaced and less unreacted lead was left at the core of the particles. Under the condition of discharge at the 20 hr rate it seemed that passivation was more dependent upon a sufficient diameter being present in the lead particle so that a $PbSO_4$ layer of sufficient thickness could be built up to cause passivation to occur before all the lead was utilized, rather than upon the formation of $PbSO_4$ crystals of a particular small size.

The so-called expansion of the plates was another noteworthy effect of SAE cycling that could be at-

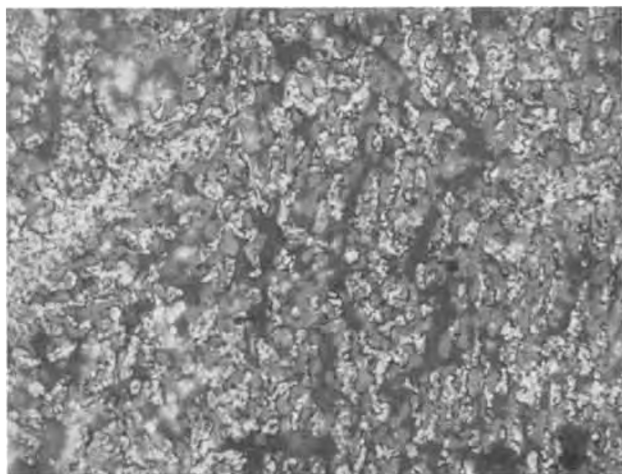

Fig. 2. Appearance of a negative that failed at 19 cycles, had no additives, and is shown in the discharged condition. Note the large amount of lead (bright particles). The $PbSO_4$ (light gray) is close packed around the lead surfaces and there is relatively little void space (dark gray) shown. Original magnification 1000×.

Fig. 4. The appearance of a cross section of a negative plate containing no lignin but 0.5% $BaSO_4$ after 27 cycles. Compare thickness of plate with that of Fig. 5. Magnification 17×. Plate is charged.

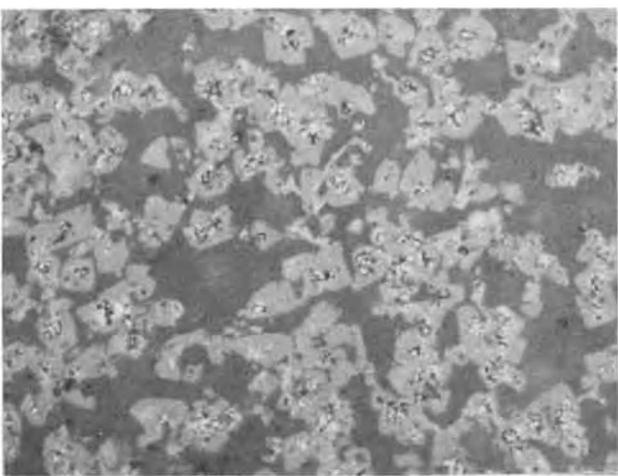

Fig. 3. Appearance of a negative plate containing 0.5% $BaSO_4$ and 1.0% lignin, that has not yet failed but is shown discharged at 27 cycles. Note the large void spaces (dark gray), the small amount of lead (bright particles), and the relatively ungrouped spacing of the $PbSO_4$ crystals (light gray). Original magnification 1000×.

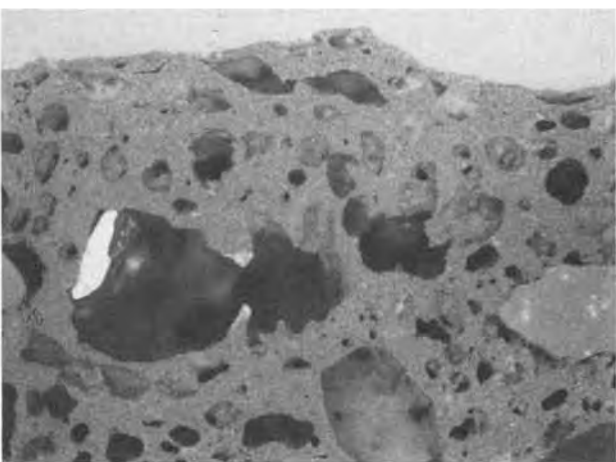

Fig. 5. The appearance of a cross section from a negative plate containing 0.5% $BaSO_4$ and 1.0% lignin, after 27 cycles. Note the wide cross section and the numerous large voids. Magnification is 17×. Plate is charged.

tributed to lignin and which was evident on a macroscale. Those plates which were lignin-free maintained practically the same thickness and density throughout their cycle life (Fig. 4). No large voids were formed, and the size and spacing of the dendrites seemed to remain constant, or nearly so. The plates containing $BaSO_4$ expanded only slightly during cycle life. They showed a few small voids and there was a very slight increase in the separation between particles at the end of life.

The lignin-containing plates behave quite differently. During their life there was a remarkable increase in the thickness of the plate, the interiors became filled with large and interconnected voids, and the particles themselves became more separated (Fig. 5). The increase in thickness and the decrease in density were gradual. At 5 cycles hardly any change could be detected from the appearance that was shown by the freshly formed plates, but the difference became more marked with increasing cycling. Low-magnification examination of the surface of the lignin-containing plates revealed many volcano-like, cone-shaped openings, with raised rims and an accumulation of particles around them. This was not found in the lignin-free plates. Cross sections showed such openings at the surface were connected with the internal large voids. The appearance left no doubt that these large voids were the result of gas action, and that the same process had caused the voids that were present throughout the plates.

Since the observation has been made repeatedly that additives increase both the cell potential and the overvoltage at the negative electrode, it was hard to explain why the gassing should be greater on the plates containing lignin. Careful examination of the plates led to the conclusion that the small size and open-spaced structure of the dendrites in the plates with lignin made them structurally weaker than the large diameter branches of the plates without lignin. For this reason the surface tension effects produced by the formation of large bubbles literally blasted the lignin-containing plates apart, while an equivalent amount of gassing was without effect on the lignin-free plates.

In SAE cycle tests, such as were run here, the negative is not usually expected to limit the reaction. It is obvious from Fig. 1, however, that the cycle life test results were, in fact, influenced by whether or not the negative contained lignin. The termination of life for a given cell is determined by the loss of a definite proportion of its initial capacity. It is evident from Table II that the presence or absence of lignin or $BaSO_4$ did not initially affect the capacity of these

cells, so that it is logical to think that the effect on capacity must have been from something that occurred during the continued cycling. The most evident effect of the lignin was to limit the growth of the lead dendrites that were formed during charge. In order for the lead sulfate film, formed during the discharge, to become passivating, it must build up to a definite thickness, produced at the expense of the underlying lead. If the diameter of the lead particle is small enough, complete reaction can take place before a film of sufficient thickness can build up. Conversely, too large a particle will form a passivating film before the original lead is all converted to lead sulfate and this condition reduces the available capacity. It is precisely this condition that the lignin prevents by limiting the diameter of the lead particles.

A secondary effect of the lignin is to limit the normally extensive growth of individual crystals. This extensive growth frequently produces parallel-growing dendritic filaments that in turn produce long, narrow, or complex channels in the active material. Such channels are undoubtedly easily clogged with growing $PbSO_4$ crystals, thus rendering portions of the active material relatively inactive.

A third effect may involve a change in the mode of crystal growth, since the observation was made repeatedly that the lead sulfate crystals were less densely packed and extended from the surface of the lead particle when lignin was present in the plate.

It is evident that the so-called expander action is of little value, since the least expansion of the plate occurs at the beginning, when the capacity is the greatest. When the expansion is the greatest, the capacity has dropped to a very low value.

In SAE cycling, the most important function of the lignin appears to be the regulation of the size of the lead dendritic crystals.

Effects noted in the low-temperature, high-rate discharges.—The results of the −17.8°C temperature, 150A discharges are shown in Fig. 6 as obtained initially, and after 5, 54, and 135 cycles. The graph represents the averages of several results. It can be seen that additions of $BaSO_4$ resulted in only slight improvement in capacity, whereas lignin produced a considerable increase in capacity over that obtained in its absence. However, a combination of lignin and $BaSO_4$ produced little if any, improvement over the use of lignin alone.

Microscopic examination revealed no $PbSO_4$ crystals around the lead dendrites in the plates which contained no additives, except for an occasional large crystal that was probably an unconverted remainder from a previous discharge at the normal rate. Examination with polarized light is usually extremely effective in detecting films of any sort, because of the light scattering caused by the latter, but it was ineffective in this case. In the plates containing lignin, lead sulfate crystals were found present in sufficient abundance to account for the capacity obtained (at the best, about one fifth of that obtained at the 20 hr rate). In those plates containing no additives or only $BaSO_4$ as an additive, the amount of $PbSO_4$ would be about 3-5g per 100g of lead. Considering the large surface area of lead in the negative plate, it is not surprising that this amount could not be detected with the optical microscope.

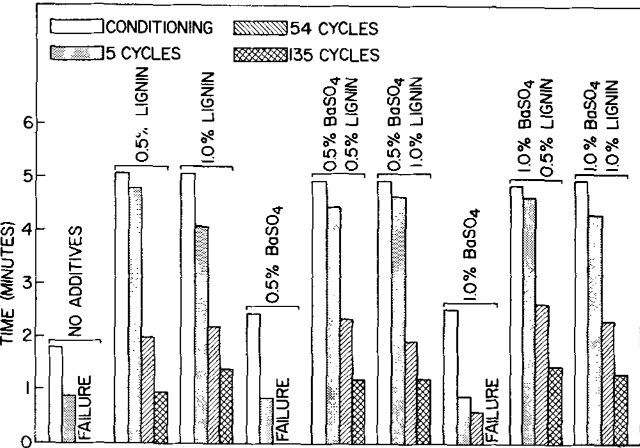

Fig. 6. Relative times of discharge at −18.8°C and the 150A rate, with and without the use of additives. Shows the effect of additives on high-rate discharge at the beginning of cycle life and after 5, 54, and 135 cycles.

The self-passivation of the lead electrode is a well-known phenomena that has been studied by a number of investigators (8-11), and it is very likely that all charged lead electrodes become covered with a layer of lead sulfate crystals as soon as the charging current is removed. After any prolonged stand the number of such crystals would increase rapidly. None of these, of course, have been seen with the optical microscope. Kabonov and co-workers (4) showed that lead sulfate crystals of about 400-500Å in size formed on pure lead sheet in the absence of additives. Pavlov and Popova (11) report that on lead without additives, the effective thickness of the layer which causes passivation was between 800 and 5000Å. Both of these investigations revealed the presence of individual crystals, with open spaces in between.

According to Pavlov and Popova (11) the growth of $PbSO_4$ crystals leads to a decrease of the free lead surface, bringing an increase in current density at those points. When the Pb^{+2} ions formed exceed the flux of the SO_4^{-2} ions flowing toward the lead surface, the solution at the active metal surface becomes alkaline in order to remain electroneutral. With the increase in *p*H, basic lead sulfates and lead oxide are formed. These compounds then proceed to fill the spaces between the $PbSO_4$ crystals, and thus a continuous layer is formed which passivates the electrode. When the current is interrupted, these basic sulfates rapidly disappear. These authors postulate that the rate of passivation depends in part upon the number and area of intercrystalline spaces. Such a mechanism would explain how a thin and discontinuous layer of small $PbSO_4$ crystals could become passivating and would also explain our inability to detect a lead sulfate layer in the sections examined.

Otherwise, it is extremely difficult to accept that such a thin layer of lead sulfate could become passivating. Considering the excessive supersaturation that would exist at the negative plate under the onset of a 150A discharge, it is inconceivable that relief of this supersaturation would not lead to dendritic growth in the $PbSO_4$ crystals. Such dendritic growth has already been observed at both the negative (12) and positive electrode (13) under much less severe current densities. It would be logical to expect nucleation to proceed to a two-dimensional dendritic growth along the lead surface because of the very steep concentration gradient developing immediately following the relief of supersaturation. Such dendritic structures would not be ideal candidates for the formation of an impervious layer unless a mechanism such as that of Pavlov and Popova was in operation.

While it was evident that lignin had a decided effect on the lead crystal structure during SAE cycling, and that this would also be effective during the high rate discharge, it was not evident what mechanism caused the $BaSO_4$ to become effective. Nothing in the microscopic examination indicated that any physical change took place as a result of the presence of $BaSO_4$. However, since it was difficult to determine the true shapes of the $PbSO_4$ crystals, it is possible that $BaSO_4$ had some effect that was not detected.

Certainly, if $BaSO_4$ provides nucleating points for the growth of $PbSO_4$ crystals, as has been suggested by previous investigators, the prevention of supersaturation should act to promote the growth of fewer and larger crystals. It has been evident throughout

this examination, however, that whatever effect $BaSO_4$ has on the discharge process, this effect cannot be detected with the optical microscope.

Conclusions

The data on cycling and low-temperature discharge agreed in general with previously reported work, although $BaSO_4$ and lignin, when used together, did not provide as great an increase in effectiveness as some previous reports would lead one to expect.

A new effect of lignin, modification of the structure of the lead particles in the charged electrode, has been found as a result of this investigation. It appears that lignin provides lead particles of sufficiently small diameter to permit their complete conversion to $PbSO_4$ before a sufficiently thick film can be formed to cause passivation. Lignin also appears to retard the growth of the larger lead particles that are the result of continuous cycling. These effects were noted during formation and SAE cycling.

During SAE cycling, lignin also produced a difference in the manner of deposition of lead sulfate crystals, those electrodes containing lignin having a more open and porous crystalline deposit than those containing no lignin. Although details of this deposit were somewhat obscure using optical microscopy, there was no evidence of a marked difference in lead sulfate crystal size in those plates with lignin as compared with those without.

In low-temperature, high-rate discharges, the optical microscope failed to show any evidence of lead sulfate crystal formation in those plates containing no lignin, although a definite crystalline film could be easily observed in those electrodes in which lignin was present. Failure to detect any lead sulfate might be used as evidence that crystals of extremely small size, forming an extremely thin passivating film, were formed, as postulated by Willihnganz (6), but would not be conclusive as the small amount of reaction product formed would be difficult to detect with the microscope in any case.

No effect of $BaSO_4$ on either the structure of lead or of lead sulfate was detected, although the data indicated that $BaSO_4$ in some manner increased reactivity slightly, both alone and in the presence of lignin.

Acknowledgments

The authors wish to thank the Naval Research Laboratory, Globe-Union, Incorporated, and the International Lead Zinc Research Organization for permission to publish this report and for their cooperation and support that have made this investigation possible.

Initiation of Pitting at Sulfide Inclusions in Stainless Steel

Göran S. Eklund

Swedish Institute for Metal Research, Stockholm, Sweden

ABSTRACT

Equilibrium calculations on some sulfide systems actual in commercial stainless steel have shown that the sulfides cannot thermodynamically exist at the potential of the passive steel. The ions released by the dissolution of the sulfides give rise to an acid solution in microareas. A pitting corrosion mechanism based on the sulfides themselves is suggested. The sulfides are polarized to the potential of the passive steel surface and tend to dissolve. During the dissolution a virgin metal surface is exposed to the environment. When the solution in the microarea thus developed has reached a certain composition, the contacting metal can no longer passivate and the metal starts to dissolve.

It is well accepted that pitting of stainless steels is effected in two steps: one initiating step and one propagating step (1). The initiation is still the subject of contention, and no mechanism for the pitting of stainless steels has been developed to the point that one can make quantitative predictions pertaining to the pitting resistance.

Most of the proposed mechanisms involve either an activating ion, such as chloride, penetrating and destroying the passive film locally, or the activating ion being adsorbed at the metal/solution interface displacing the adsorbed passive layer and thus destroying

Key words: initiation of pitting corrosion, sulfide equilibria in aqueous solutions, diagram of manganese sulfide potential-pH.

the passivity locally. The potential setup between the locally disrupted film and the rest of the surface leads to anode formation and attack of the metal at some point (2-4). In both mechanisms the adsorption of the anion is important.

The composition of the oxide film on the metal surface, which depends sensitively on the production history of the steel (5-8), must also have a great influence on the adsorption. It is therefore difficult to attempt a quantitative treatment, especially since information on the energies involved is not readily available.

Based on another approach, Vermilyea (9) has developed a theory that allows a semiquantitative prediction of pitting potentials. He assumes that the pitting potential is the potential at which the protective metal oxide, the salt of the metal, and the aggressive anion are in equilibrium. The theory successfully predicts the critical potential for Al, Mg, Fe, and Ni. However, it does not say which ions should be aggressive. It also appears difficult to apply this treatment to alloys.

The experimental determination of the pitting potential also seems to be very difficult and values reported by different authors for the same system differ greatly. The critical potential is evidently a function of time, film history, and metal surface preparation. In addition, the early history of the steel, such as deoxidation practice, speed of solidification, and heat-treatment, also exerts a certain influence.

The sites at which pitting starts on a stainless steel surface have been the subject of much discussion. It has been suggested that local disturbances in the oxide layer at grain boundaries and other inhomogeneities should make these areas more accessible to adsorption of the chloride ions. Streicher (3) and Uhlig (10) indicated that nonmetallic inclusions could be possible sites for pit nucleation. Lately it has been shown that pitting starts almost exclusively at nonmetallic inclusions and that the sulfides are especially detrimental (11-13). One can then assume that the oxide layer close to inhomogeneities such as inclusions has a composition slightly different from the rest of the surface. This means that a potential difference can exist which then is amplified by preferential adsorption of the anions. Further, in the presence of microcrevices pitting can also be induced by a crevice corrosion mechanism. The evidence for such mechanisms is, however, inadequate.

Another explanation of the initiation of a pit and its subsequent propagation is based on the sulfides themselves (13). It is known that the sulfides in a commercial stainless steel containing manganese comprise manganese sulfides with variable amounts of dissolved iron and chromium. The sulfides are electronic conductors and can be polarized to the potential of a passive stainless steel surface. At this potential the sulfides, as shown below, are not thermodynamically stable and tend to dissolve.

When such a dissolution takes place, virgin metal is exposed to the environment. The solution developed in that microarea must, as a result of the dissolution, have a different composition to that of the bulk. The metal ions from the sulfide, manganese, iron, and chromium, can undergo complex reactions and give rise to a low pH as well as a certain concentration of hydrogen sulfide and its protolyzed products. At a certain composition of the solution, the exposed metal can no longer passivate and metal ions enter the solution and the potential drops drastically, thus becoming more active. The metal ions thus released develop their own environment and maintain the attack provided the geometrical conditions are such that a dilution of the solution is prevented.

In order to establish if a pit initiation mechanism based on the sulfides themselves is thermodynamically justified, equilibrium calculations on manganese sulfides and manganese sulfides with iron substitutionally dissolved have been carried out. Thermodynamic data on CrS are not available and so calculations on (MnCr)S systems have not been possible; however, since chromium can be of importance for the formation of an acid solution from the dissolution of chromium-containing sulfides, the system Cr-H_2O-Cl has been considered.

To test the validity of the calculations some experiments with synthetic sulfides were carried out as well as studies of corroded steel samples.

Equilibrium Calculations

The calculations were made using a program developed by Sillén and co-workers (14). The program calculates the equilibrium concentration of any number of species in mixtures of any number of components, which in turn can form any number of complexes and solid phases. In the calculations, concentrations are used postulating that the activity coefficient f (on moles per liter concentration scale) is equal to unity. The equilibrium data must be known and enough data be given about the gross composition. From the input information the program itself devises an efficient plan for solving the simultaneous equations. The program also provides an efficient means for finding out which of many possible solid phases can actually appear in a certain equilibrium mixture.

All calculations are based on a given input concentration of Cr^{2+}, Mn^{2+}, Fe^{2+}, SO_4^{2-}, Cl^-, H^+, and e^- where the latter here is considered as an ion. The concentration of any species can be changed stepwise and the concentration of the complexes and solid phases can be calculated for any point of the system. For the construction of potential-pH diagrams, the pH has been kept constant and pe has been changed stepwise; pe is here the negative logarithm of the electron activity defined as

$$pe \equiv \frac{EF}{RT \ln 10} \quad [1]$$

In short, the program handles the electrons in such a way that no redox process takes place at equilibrium, which means that no electron transfer is effected. It is the equilibrium composition at that particular pe which is calculated.

The symbols and reactions used in the calculations are found in the List of Symbols below.

Equilibrium constants for the reactions used in this paper are given in Table I.

MnS-H_2O-Cl^-.—In the calculations, the total concentrations of Mn, S, and Cl^- are each 0.1 mole/liter. This means that at any point of the diagram, the sum of, for example, manganese is 0.1 mole irrespective of whether the manganese is present as a solid phase, ion, or complex. The same is valid for sulfur and chloride. In the calculations $\Delta G^o_f = -48{,}750$ calories/mole has been used for the free energy of formation of MnS (15). The numbers and symbols in Fig. 1 and 4 refer to the reactions listed in Table II.

From Fig. 1 it is seen that MnS can exist between pH 4.8 and 13.8 (lines 6 and 8). At pH values less than 4.8, MnS dissolves forming H_2S, Mn^{2+}, and $MnCl^+$. The concentration of the latter complex is about 10^{-2} mole/liter. One-tenth of the total amount of the manganese is thus present as $MnCl^+$. At pH values higher than 13.8, MnS dissolves forming S^{2-}, $Mn(OH)_2$, and $HMnO_2^-$. Line 7, at pH 10.2, corresponds to the formation of $Mn(OH)_2$ due to the increase in solubility of MnS when the pH is raised.

The domain of MnS at higher potentials is limited by the formation of $Mn(OH)_2$ and SO_4^{2-} (line 5). At still higher potentials, MnS dissolves without forming any solid substance (line 4). The highest potential at which MnS can exist is about -100 mV (line 3). The dissolution at this potential takes place with the formation of sulfur.

Figures 2 and 3 show the correlation between concentration and potential at equilibrium in a mixture containing 0.1 mole each of Mn^{2+}, SO_4^{2-}, and Cl^-. The domain for the solid phases is shown above the diagrams. For simplicity two figures are drawn, one containing the manganese complexes and the other the sulfur complexes. Going from left to right in these it is clear that the concentration of the different species is constant up to −400 mV. The concentrations then begin to increase and the coexistence of $Mn(OH)_2$ and MnS ceases. pH 10.2 and log $H^+ = -10.2$ correspond to line 7 in Fig. 1. The concentrations of Mn^{2+} and $MnCl^+$ increase with the potential up to −100 mV and are then constant up to +300 mV, where the formation of $MnSO_4$ makes these decrease slightly.

The formation of sulfur takes place at −100 mV. At the same potential the H_2S concentration reaches a

maximum of 10^{-2} mole/liter. This potential also corresponds to the boundary between the domains for MnS and S as shown above Fig. 2 and 3. The equilibrium pH at this particular point is 5.8 as can be seen

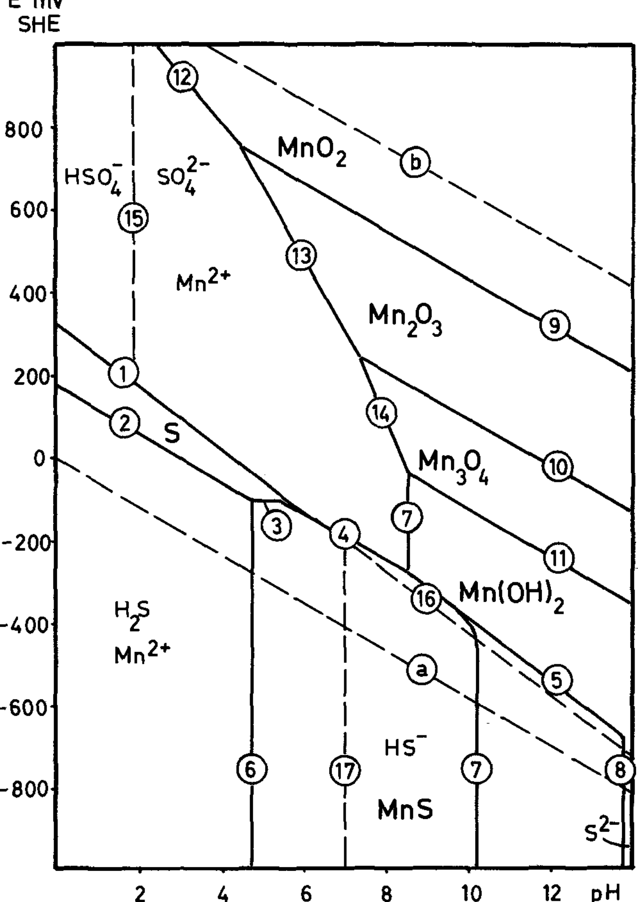

Fig. 1. Potential-pH diagram for the system $MnS-H_2O-Cl^-$ calculated on basis of 0.1 mole/liter for SO_4^{2-}, Cl^-, and Mn^{2+}, respectively.

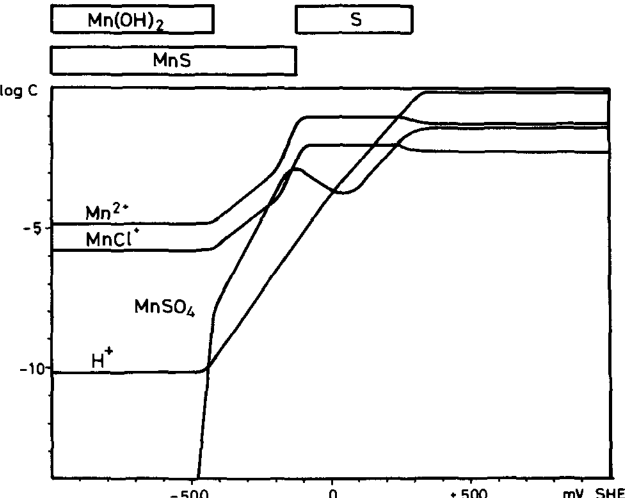

Fig. 2. Equilibrium potential-concentration diagram for the $MnS-H_2O-Cl^-$ system at a total concentration of 0.1 mole/liter for SO_4^{2-}, Cl^-, and Mn^{2+}. For clarity only manganese compounds are drawn. The stability ranges for the solid phases are shown over the diagram.

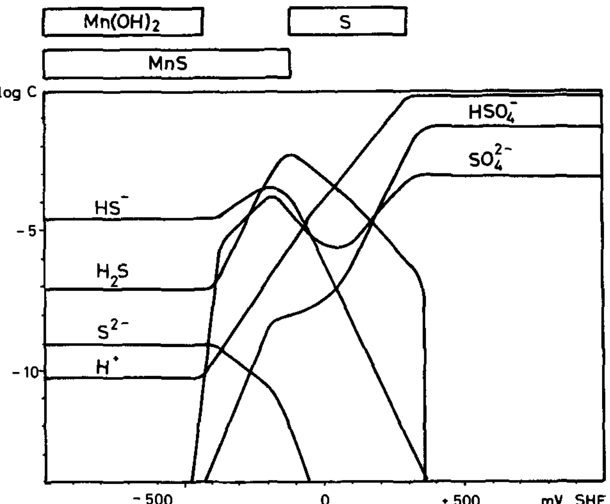

Fig. 3. Equilibrium potential-concentration diagram for the same system as in Fig. 2, only sulfur-containing complexes are shown.

from the H^+ lines in the figures. At +100 mV all the sulfur containing complexes reach a minimum, which means that most of the sulfur is present in elemental form.

$(Mn_{0.9}Fe_{0.1})S-H_2O-Cl^-$.—The thermodynamic data for the free energy of formation and the entropy of mixing of MnS and FeS available in the literature are very inconsistent. For this reason it was considered justified to add the free energies for each sulfide in their proportions. The value for $(Mn_{0.9}Fe_{0.1})S$ thus obtained is −46 200 calories/mole. By using this value and the data listed in Table I, Fig. 4 has been calculated. The total amount of the metal ions is 0.1 mole/liter in addition to the other components.

Comparing Fig. 1 and 4, it is evident that the domain of the sulfide is smaller and that the domain of the complete solubility has been considerably reduced due to the formation of $Fe(OH)_2$, $Fe(OH)_3$, and $Fe(OH)_{2.7}Cl_{0.3}$. This latter compound has earlier been described as β-FeOOH, but investigations by Biedermann and Chow (16) have shown that β-FeOOH is in fact the hydroxy-chloride complex $Fe(OH)_{2.7}Cl_{0.3}$.

The equilibrium pH follows, as in the afore-mentioned case, the lines of coexistence between sulfide and hydroxide (line 18) and at higher potentials lines 4 and 1.

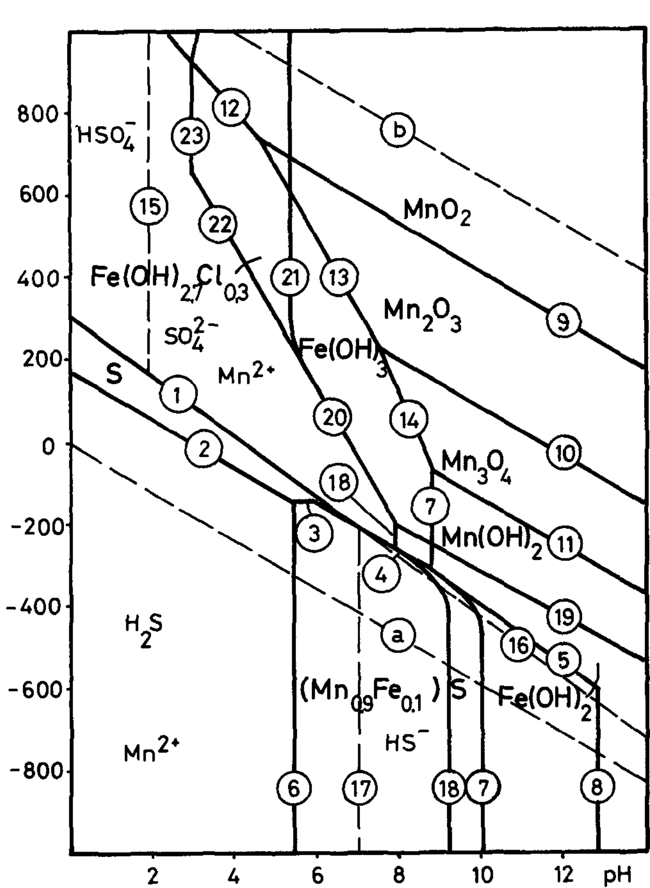

Fig. 4. Potential-pH diagram of the system $(Mn_{0.9}Fe_{0.1})S$ calculated on the basis of 0.09 mole/liter Mn^{2+}, 0.01 mole/liter Fe^{2+}, 0.1 mole/liter SO_4^{2-}, and 0.1 mole/liter Cl^-.

$Cr-H_2O-Cl^-$.—The manganese sulfides in stainless steel usually contain chromium to some extent. Chromium ions must therefore enter the solution when the sulfide is dissolved, and when these enter a solution containing chloride several different complex reactions can take place.

In order to find how the pH and the concentration of the complexes can vary with the potential, equilibrium calculations on the $Cr-H_2O-Cl^-$ system at different concentrations of Cr^{2+} and Cl^- have been carried out.

Figures 5 and 6 show how the pH, the chloride, and the hydroxy complexes vary with the potential at equilibrium. The diagrams are based on a total concentration of 0.1 mole/liter of Cr^{2+} and Cl^-.

When the potential is raised, the formation of hydroxy complexes will give an increase in hydrogen ion concentration. At potentials higher than −400 mV, coinciding with the equilibrium between Cr^{2+} and Cr^{3+}, the concentration of the complexes does not change with the potential.

A solution containing chromium in contact with an electrode will thus tend to a low pH at potentials higher than −400 mV. The acidity of the solution is dependent on the chromium concentration as shown in Fig. 7 where the equilibrium pH has been calculated at different Cr^{2+} concentrations. The curve is only valid for potentials higher than −400 mV. The concentration of the chloride ions does not influence the pH since the amount of the chloride-containing hydroxy complexes is small.

Discussion

Figure 1 shows the range of stability for MnS. From this it is clear that MnS cannot exist at potentials higher than −100 mV, and since the potential of a

passive stainless steel surface is considerably higher, the embedded MnS particles should tend to dissolve.

When a manganese sulfide was polarized to +200 mV in an air-free, unbuffered 0.1M NaCl solution, the sulfide dissolved and elemental sulfur in the form of small spherical particles was formed on the surface (Fig. 8). The preparation of the sulfides and the apparatus used are described elsewhere (17). The *p*H of the solution decreased to 5.8 after 6 days, a value corresponding to the equilibrium log C_{H^+} at the MnS/S boundary as shown in Fig. 2 and 3. The current, of the order of 0.1 mA/cm^2, was constant with time indicating that the sulfur did not form any compact layer. When the same experiment was carried out at *p*H 6.5, x-ray investigations of the layer showed no evidence as to the presence of any manganese compound. Addition of $BaCl_2$ to the solution gave a precipitate of $BaSO_4$, which showed that some of the sulfur was oxidized to SO_4^{2-}. When the MnS electrode was polarized to +200 mV at *p*H 10, no elemental sulfur could be observed.

Experiments with manganese sulfide electrodes containing *ca.* 6% Cr and *ca.* 8% Fe substitutionally dissolved showed the same behavior as pure MnS. Elemental sulfur was formed on the surface when the electrodes were polarized to +200 mV in the same solution as above. The *p*H in the unbuffered solution changed with time and reached a value of *ca.* 4 for the sulfide containing Cr. It is therefore assumed that the sulfides containing Fe and Cr dissolve in a similar way to pure MnS. In addition, the complex reactions and hydrolysis of the metal ions released decrease the pH of the solution.

It seems unlikely that the elemental sulfur particles shown in Fig. 8 should be the result of a surface diffusion mechanism associated with the dissolution of MnS to elemental sulfur and Mn^{2+}. The form of the sulfur suggests that it is precipitated from the solution. For this reason the following mechanism is suggested for the dissolution of MnS when polarized in a positive direction in an unbuffered solution.

$$MnS + 4H_2O = Mn^{2+} + SO_4^{2-} + 8H^+ + 8e^- \quad [I]$$

$$MnS + 2H^+ = Mn^{2+} + H_2S \quad [II]$$

$$H_2S = S + 2H^+ + 2e^- \quad [III]$$

At the moment when the sulfide is polarized, reaction [I] takes place. Due to the oxidation of MnS to SO_4^{2-} the pH at the interface will decrease making reaction [II] possible. The hydrogen sulfide thus released will form S and sufficient hydrogen ions to continue the dissolution according to reactions [II] and [III]. The reaction takes place at the MnS interface making the electron transfer for reaction [III] possible and the sulfur layer will be built up from underneath.

Analysis of inclusions from commercial steels, mainly based on isolates, show that the sulfides are MnS with various amounts of Fe and Cr substitutionally dissolved (18, 19). The Fe and Cr substituted sulfides have a higher S content than that corresponding to the formula (Mn,Fe,Cr)S (20). The sulfide lattice of these solid solutions apparently has metal vacancies, which are formed to compensate for the change in valency when Mn(II) is substituted by metals of valency III; this makes the sulfides p-type semiconductors. Investigations of the solubility of the transition metals in MnS have shown that it is possible to substitute as much as 60-70 weight per cent (w/o) Cr and Fe in the α-MnS lattice (18). In a commercial 18-8 steel the composition of the sulfides can vary from one inclusion to another but the manganese sulfides usually contain from 10 to 40 w/o substitutionally dissolved Cr and Fe, the exact amounts depending on the way the steel is produced, heat-treated etc.

In this connection, it can be mentioned that the metal at the interface between the sulfides and the matrix cannot have any oxide layer since the sulfides are formed directly from the melt. A dissolution of a sulfide will therefore reveal a virgin metal surface.

As mentioned in the introduction, pitting on a stainless steel surface starts preferentially at sulfide inclusions. When such a steel is subject to a potentiostatic pitting corrosion test only a few pits will develop per unit area despite the fact that the number of sulfide inclusions on the same area is several orders of magnitude greater. The number of pits will increase with the applied potential as the latter is increased from the critical potential. This is probably due to the different chemical behavior of the sulfides because of compositional differences. The higher the potential, the more sulfide inclusions will become active.

The corrosion process within a pit is a unique type of anodic reaction and produces conditions which are both stimulating to, and indeed necessary for, continuing activity of the pit. In the pit itself there is a high concentration of metal and chloride ions and as a result of hydrolysis, a high concentration of hydrogen ions. The question is how a low pH is created.

The exposed surface of the inclusions is small compared with the surface of the passive steel. When a piece of steel is submerged in a solution the potential against the solution changes to a rather noble value, usually above 250 mV in a neutral aerated sodium chloride solution. As the inclusions are electronic conductors to some extent they will be polarized towards the potential of the steel surface. Thus the sulfides are polarized to a potential at which they cannot exist thermodynamically.

Since the electronic conductivity of the sulfides is lower than for the metal matrix, the dissolution takes place preferentially at the boundary between the sulfide and the matrix and for this reason a small crevice will develop (Fig. 9). This crevice has two walls, one consisting of the sulfide and the other of the metal matrix. In the beginning, the metal matrix will immediately passivate, but as the reaction proceeds, the dissolution of the sulfide in the crevice will increase the metal ion content and ion complexing and hydrolysis reactions can take place in the microarea. On the metal wall the dissolved ions, *e.g.*, iron, can form $Fe(OH)_{2.7}Cl_{0.3}$, as shown earlier, thus lowering the pH locally. Furthermore, the chromium ions can undergo

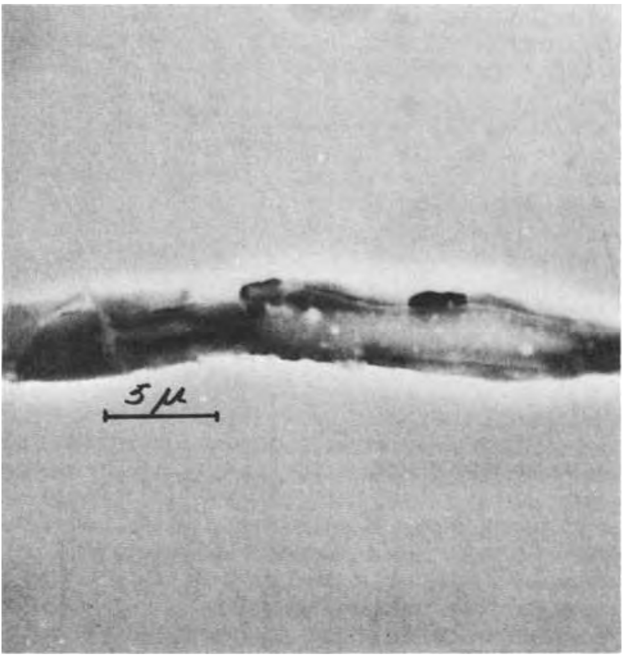

Fig. 9. 18-8 steel with 2.5 Mo containing 0.28 S galvanostatically corroded at 0.1 mA/cm². 800 mAs/cm² has passed the sample. The dissolution of the sulfide has preferably taken place close to the metal matrix.

hydrolysis and contribute to the formation of hydrogen ions; the higher the chromium content the lower the pH as shown in Fig. 7. When the pH decreases in this local region the passivation of the exposed metal will be difficult. At a certain moment metal atoms from the metal lattice will enter the solution and the potential will drop drastically and the pit turn active (21, 22). The electrochemical dissolution of the sulfide will then stop since the potential is now within the domain of thermodynamic stability. If the rate of formation of hydrogen ions from the increased metal ion hydrolysis exceeds that of the chemical dissolution reaction of the sulfide itself, a sustaining pit will develop, otherwise the hydrogen ions will be neutralized by the formation of H_2S and the bared metal will passivate. This reaction probably takes place at a number of sites on the metal surface. These pitting attempts can be observed as potential drops when a steel is left to corrode freely and the potential is followed with time (Fig. 10).

This means that initiation of pitting is a kinetic problem in which the formation and neutralization of hydrogen ions are of importance. If attack occurs at the wall between the metal and the sulfide, the pit can continue to propagate as long as the solution is

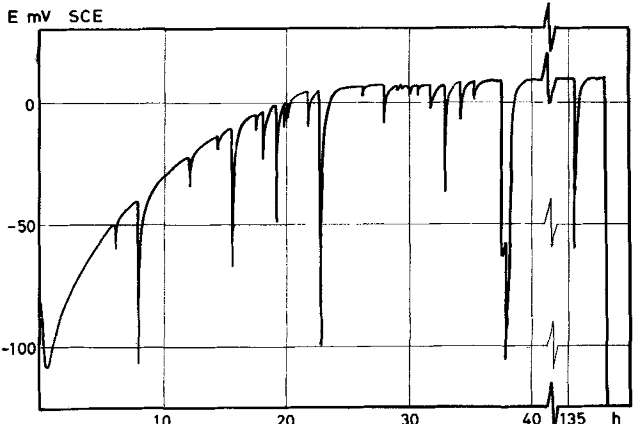

Fig. 10. Potential-time relation for an 18-8, 0.25 S stainless steel corroding freely in 0.1M NaCl solution.

not diluted or neutralized, which means that certain geometrical conditions must be fulfilled; here the presence of oxide particles in the sulfides can be significant.

Figure 11 shows a pit developed at the boundary between a sulfide particle and the matrix; the sulfide is partly dissolved and some sulfur particles can be observed on the surface. The pits spread from these points and propagate under the metal surface. In certain places, the attack will reach the surface giving rise to an irregular network (Fig. 12). The passive layer usually remains intact but probably breaks down mechanically when the size of the subsurface pit becomes too great. The solid parts of the lacelike lattice are metal covered by the passive layer (23, 13).

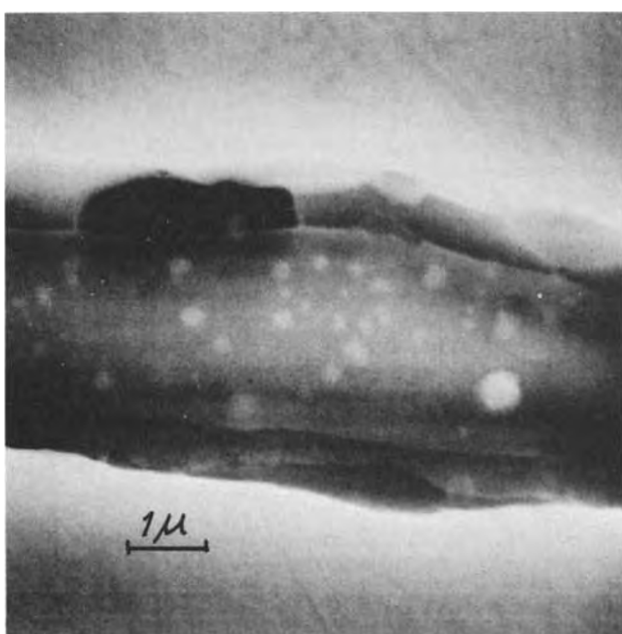

Fig. 11. Same steel and inclusion as in Fig. 9. Notice the beginning of a pit (dark area) at the metal wall in the ditch between the sulfide and the metal matrix. Elemental sulfur particles are visible on the sulfide surface.

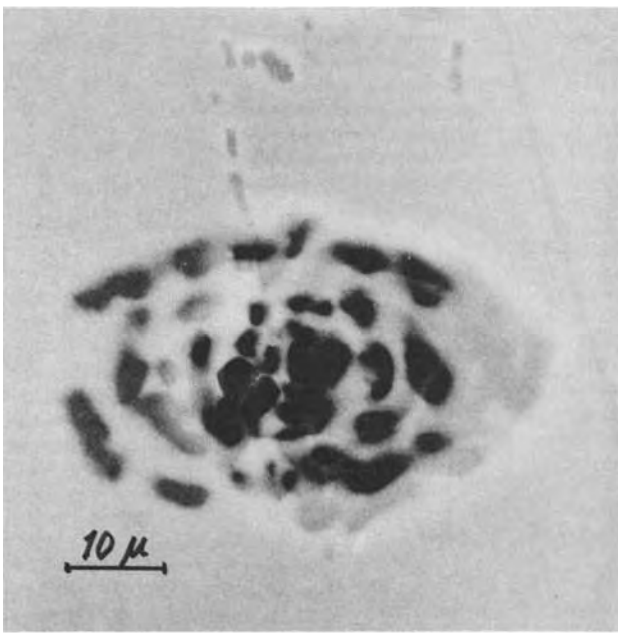

Fig. 12. Same steel as in Fig. 9 corroded at 1 mA/cm^2. 800 mAs/cm^2 has passed the sample. The corrosion pit has started at the sulfide inclusion. The metal is dissolved from underneath and the passive layer still remains at some places as light gray parts of the lacelike pattern.

The pitting or critical potential should then refer to the potential at which the metal oxide and the solution within the microarea are in equilibrium. Since the composition of the solution in the microarea will depend on the original composition of the sulfide inclusion, the critical potential will be dependent on factors influencing the composition of the sulfides.

It must, however, be remembered that the proposed mechanism is not limited to sulfides only, but can also be applied to other inclusions provided they are capable of being polarized and releasing metal ions.

Optical and Electrochemical Studies of Underpotential Deposition of Lead on Gold Evaporated and Single-Crystal Electrodes

Radoslav Adzic,[1] Ernest Yeager,* and B. D. Cahan*

Chemistry Department, Case Western Reserve University, Cleveland, Ohio 44106

ABSTRACT

Linear sweep voltammetry and reflectance spectroscopy have been used to examine the underpotential deposition of lead on gold in Pb^{2+} containing $HClO_4$ solutions. The voltammetry curves and reflectance-change data provide evidence that the lead is first deposited as ions although their effective ionic charge is probably reduced substantially from +2 through their strong interaction with the band structure of the gold substrate. At more cathodic potentials, still well below the reversible potential of bulk lead, a sharp transition is observed over a 5-10 mV range. On the basis of the reflectance and voltammetry data, this transition appears to involve a two-dimensional phase transition leading to a metalliclike lead layer. Adsorption isotherms have been evaluated from the reflectance changes. Alternating potential electromodulation techniques and complex plane analysis have been used to examine the kinetics of the lead adsorption-desorption and to evaluate the apparent exchange current density for the process.

The underpotential deposition (UPD) of various metals on foreign metal substrates involves monolayer or submonolayer formation at potentials anodic to that for the reversible electrodeposition of the bulk metal. UPD is particularly important to the understanding of the early stages of metal electrodeposition and also electrocatalysis. This phenomenon has received the attention of a number of electrochemists (1-11). Early work has been reviewed by Rogers (3).

UPD is clearly the result of a strong interaction between the monolayer and the substrate. Breiter (5) and also Tindal and Bruckenstein (6) have found large differences between the first and subsequent layers of copper on platinum. Schultze (10) has concluded that the copper in monolayer or submonolayer amounts on platinum is only partially discharged. Schmidt and Gygax (4), however, believe that UPD involves the formation of a metallic monolayer of electrically neutral atoms. The Mossbauer spectroscopic data of Bowles and Cranshaw (8), obtained *in situ,* indicates that tin is in the metallic state on platinum, although this finding is not necessarily applicable to the UPD of other metals on other substrates. Astley *et al.* (9) have expressed the view that the UPD is not just an adsorption process but may involve the formation of a crystalline phase.

Despite the rather extensive electrochemical studies already reported in the literature on UPD, many questions still remain to be answered, *i.e.,* What are the state of charge and the nature of the interactions among the species within the layer and between the species of the layer and the substrate metal and electrolyte phase? How are these interactions influenced by electrode potential? Is there ordering within the layer? What is the origin of the multiple peaks observed in linear sweep voltammetry in the potential regime corresponding to UPD?

Substantial information is available concerning these questions in the instance of foreign layers at metal-vacuum interfaces. For example, field emission studies (12, 13) have helped to identify the nature of the electronic interactions involved with alkali and alkali earth metals adsorbed on tungsten. A quantum mechanical picture of the valency orbitals of the adsorbate with the conduction and valence bands of the substrate metal has been developed [see, for example, Ref. (14)]. LEED studies of such monolayers have often shown ordering in such systems [see, for example, Ref. (15)]. Unfortunately these findings are not transferable to the corresponding electrochemical interfaces since solvent interactions with the monolayer are usually strong and are expected to modify substantially the interactions of the monolayer with the foreign metal substrate.

Ordinary electrochemical techniques are able only to provide very limited atomic level information concerning UPD and consequently use has been made of *in situ* specular reflectance spectroscopy in the present work. During a linear potential sweep, specular reflectance measurements allow changes of the electronic properties of the adsorbed layer to be followed continuously with increasing coverage, from submonolayer to monolayer and multilayer amounts of foreign metal. Prior studies (16, 17) have already shown that UPD of various metals on gold causes a pronounced change of reflectance with an interesting wavelength dependence.

In the present investigation specular reflectance spectroscopy together with linear sweep voltammetry have been used to study the UPD of lead on evaporated gold electrodes. Some voltammetry experiments have also been performed with single-crystal gold electrodes. A-C electromodulation reflectance measurements and complex plane analysis (18) have been used to check on the extent to which kinetic *vs.* diffusion control are involved and to evaluate the coverage with lead. Some complementary *non-in situ* information concerning the lead layers on gold also has been obtained from x-ray photoelectron spectroscopy (ESCA).

Experimental

The specular reflectance measurements have been carried out with the optical system[2] shown in Fig. 1. The electrochemical cell was constructed from an optically ground Pyrex cylinder[3] of 5 cm ID. The light source was a tungsten-halogen 150W lamp, operated with a Power Mate Corporation regulated power sup-

Key words: underpotential deposition, reflectance spectroscopy, lead deposition, adsorption isotherms.

[2] This optical system was designed by J. Horkans and B. Cahan.
[3] The internal and external grinding of this cylinder was carried out by Potts Optics, Tulsa, Oklahoma.

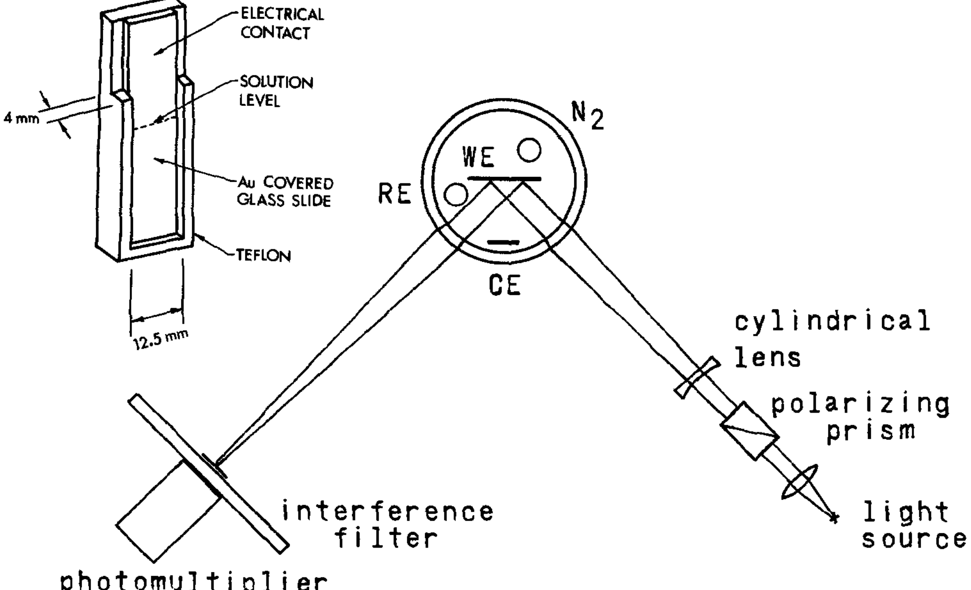

Fig. 1. Optical electrochemical cell with associated optics. Insert: evaporated gold electrode mount for a-c electromodulation reflectance measurements.

ply. All measurements herein reported were carried out at an angle of incidence of 45° with the light polarized parallel to the plane of incidence with a Nicol prism. A cylindrical concave lens together with the cylindrical wall of the optical-electrochemical cell collimated the light incident on the electrode. Wavelengths in the visible were selected through the use of a linear second-order interference wedge with a half-band width of 12 nm. The whole system was mounted on a θ-2θ goniometer.

For some experiments the d-c signal from a Hamamatsu R-374 photomultiplier was amplified and then directly recorded on an X-Y recorder during the linear sweep of the electrode potential with a Wenking potentiostat. In the a-c electromodulation reflectance measurements, the electrode potential was modulated with a sinusoidal potential of 20-30 mV p-p, in some instances superimposed on a linear sweep (typically 20 mV/sec), using an *IR* drop compensated potentiostat.[4] Both the in- and out-of-phase components of the signal from the photomultiplier were measured with a PAR-129A lock-in amplifier together with an X-Y recorder.

These studies have been carried out in 1*M* $HClO_4$ containing 10^{-6} to $10^{-2}M$ Pb^{2+}. The solutions were prepared from Baker reagent grade $HClO_4$ and triply distilled water with the first distillation from alkaline permanganate. The lead salt was Johnson-Matthey spectrographic standard $Pb(NO_3)_2$. In some experiments the $HClO_4$ was pre-electrolyzed by circulating it for 24 hr over 8 × 8 cm, 52 mesh gold gauze electrodes, wrapped on a glass rod and fitted within a glass tube. The applied voltage across the gold electrodes was 1.1-1.3V. At 1.3V some dissolution of gold at the anode and deposition of gold black at the cathode were observed but no detrimental effects on the subsequent measurements of lead UPD were detected.

The evaporated gold electrodes were prepared by vapor-depositing gold to a thickness of 0.5-1μ in a vacuum evaporator on a glass slide with an undercoating of Nb, which provides good adhesion and has no detrimental electrochemical or optical effects (19). This glass slide electrode (WE) was mounted at the center of the cell with an area of 6.3 cm^2 in contact with the electrolyte (without any mask) for the linear sweep voltammetry measurements and simultaneous reflectance measurements. For the a-c electromodulation reflectance measurements, four successive gold evaporations were used to obtain gold films of 2-4μ, so as to reduce *IR* drop in the films. The gold-coated glass slides were fitted into the Teflon mask, shown in Fig. 1, to obtain more uniform current distribution. The area in contact with electrolyte was ~3 cm^2.

Single-crystal gold electrodes with (111), (110), and (100) orientations, and polycrystalline bulk gold electrodes, were pressure-fitted into Teflon rods and polished mechanically to obtain a mirror finish. The final polishing was performed electrolytically in a cyanide solution to remove the cold-worked surface layer. After polishing, the electrodes were washed with KOH and HNO_3 solutions and stored in triply distilled water. The gold electrodes used in the ESCA experiments were bulk gold plates, which were mechanically polished and then treated in the same way as the single-crystal electrodes but not electrochemically polished.

The counterelectrode (CE) in the electrochemical measurements was a hydrogen-saturated palladium plate, mounted parallel to the working electrode at a distance of 2 cm, just outside the optical path. The reference electrode (RE) was an α-PdH bead of 1 mm diameter mounted on the end of a fine glass tube with the center of the bead located typically at a distance of 1.0 mm from the working electrode.

Nitrogen gas, purified by passing it over treated copper turnings and then through molecular sieves (Linde 4A and 13X), was bubbled through the solution before measurements to remove dissolved O_2, and a N_2 atmosphere was maintained above the solution during the measurements. All measurements were carried out at room temperatures (22°-23°C).

Before measurements, the potential of the gold electrode was cycled several times up to 1.6V re RHE.[5] This procedure substantially improved the reproducibility of the measurements, probably through the redistribution of gold on the surface to form a reproducible surface microtopography and also perhaps the removal of adsorbed organic impurities.

Results

Linear sweep voltammetry.—The linear sweep voltammetry curve (Fig. 2) for evaporated gold with $1 \cdot 10^{-3}M$ Pb^{2+} indicates two principal peaks, the first at ~0.30V and the second at ~0.05V. The first peak is predominantly under diffusion control for Pb^{2+} concentrations of up to $10^{-3}M$ at a sweep rate of 20 mV/sec. This peak is more drawn out and more rounded than expected for adsorption under Langmuir behavior. At lower concentrations of Pb^{2+}, the anodic and cath-

[5] Unless otherwise indicated, all potentials are stated relative to a reversible hydrogen electrode in the same solution.

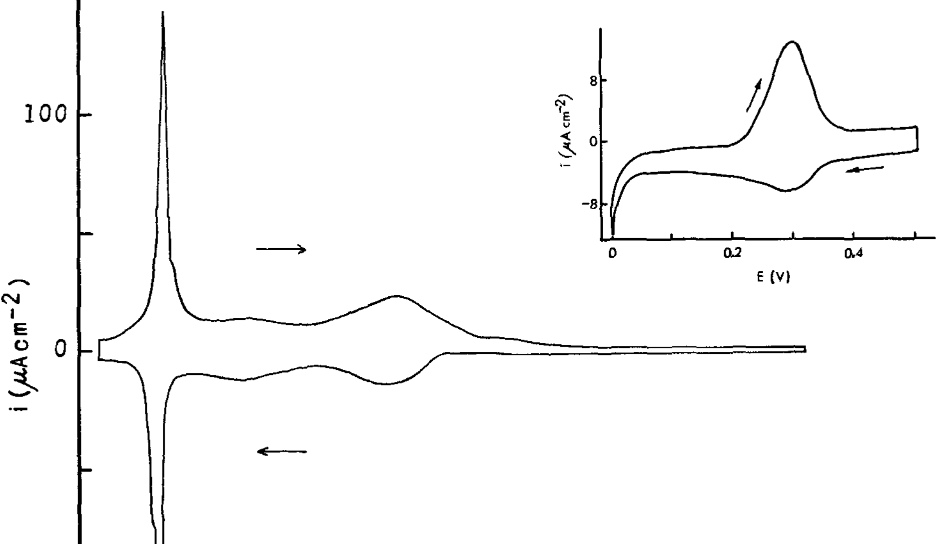

Fig. 2. Voltammetry curve for the UPD of lead on evaporated gold in 1 mM $Pb(NO_3)_2$ + 1M $HClO_4$. Sweep rate, 20 mV/sec. Insert: behavior in 1 × $10^{-5}M$ Pb^{2+}.

odic peaks differ in height and shape, as is to be expected as diffusion control becomes more predominant (see insert in Fig. 2).

The second peak observed with $10^{-3}M$ Pb^{2+} is extraordinarily narrow for the gold electrode shown in Fig. 2, with a half-width of ~10 mV and a peak separation between anodic and cathodic sweeps of ~5 mV. The narrowness of this peak indicates that it is not an adsorption-desorption peak despite the substantial charge (70-90 μcoulombs/cm^2) associated with it. A surface transformation appears to be involved, which is not dependent on the transport of further Pb^{2+} ions to the electrode surface. The finite peak width and separation are probably caused almost entirely by surface heterogeneity and nonuniform current distribution.

Close examination of the anodic sweep in Fig. 2 indicates that the second peak may actually consist of two peaks and further work is required to establish this fine structure with certainty.

The width and general shape of the second voltammetry peak are very sensitive to electrode pretreatment as well as potential sweep range, as is evident from a comparison of Fig. 2 and 3. The greater peak width in Fig. 3 probably results from more surface heterogeneity. The potential and shape of the second peak are rather insensitive to sweep rate for 5-100 mV/sec at a Pb^{2+} concentration of 1 *mM*. As the Pb^{2+} concentration is decreased, the peak height decreases but the effective width and anodic-cathodic sweep peak separation are relatively insensitive to Pb^{2+} concentration for $C_{Pb^{2+}} \geqq 10^{-4}M$. At concentrations below $10^{-4}M$ Pb^{2+}, the second peak completely disappears for a sweep rate of 20 mV/sec (see insert in Fig. 2).

The voltammetry curves in Fig. 3 also indicate further minor peaks at 0.13 and −0.08V. The voltammetry curves for polycrystalline gold are similar to those shown in Fig. 3. A large change in reflectivity is observed at ~ −0.22V where the deposition of mossy or dendritic lead occurs. The total surface charge is only ~300 μcoulombs/cm^2 (apparent area) corresponding to less than a monolayer of lead atoms when this three-dimensional crystal growth commences.

The voltammetry curves on the (100), (110), and (111) faces of single-crystal gold (Fig. 4) are quite distinctive. The first voltammetry peak is evident at ~0.3V for each orientation but its relative height and shape are highly dependent on the orientation. An additional very pronounced peak is evident for the (111) orientation although its potential is approximately 25 mV more cathodic than that of the second peak for the evaporated gold electrodes (Fig. 2 and 3) or for ordinary polycrystalline gold. A peak is observed for the (110) orientation at the same potential as for the (111) but is far less pronounced. The base current also is larger and not as well defined for these voltammetry curves as for the evaporated gold. Clavilier *et al.* (20) have noted a similar effect in their studies of single-crystal gold and have attributed it to a layer of electrolyte between the Teflon holder and the gold crystal.

While the over-all surface orientation of the single-crystal electrodes is known, information is lacking as to the microstructure of the surface. The cycling of the electrode potential several times up to 1.6V prior to

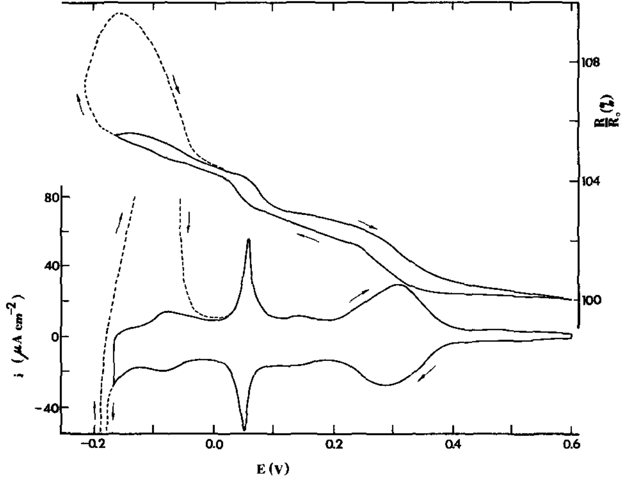

Fig. 3. Voltammetry and specular reflectance curves for UPD of lead on evaporated gold in 1 mM $Pb(NO_3)_{1/2}$ + 1M $HClO_4$. Sweep rate, 20 mV/sec; wavelength, 431 nm. Differences between Fig. 2 and this figure are due to differences in potential sweep range and minor variations in pretreatment.

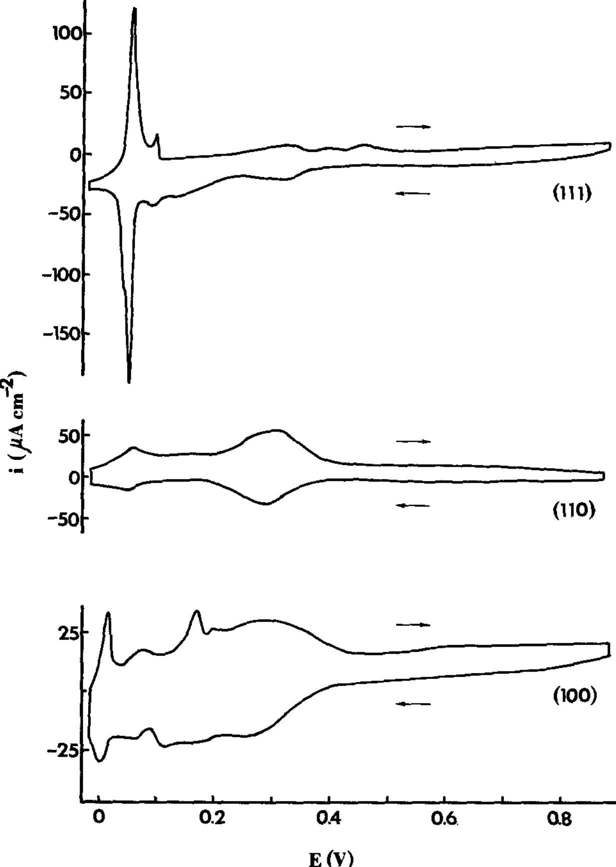

Fig. 4. Voltammetry curves for single-crystal gold electrodes with (100), (110), and (111) orientations in 1 mM $Pb(NO_3)_2$ + 1M $HClO_4$. Sweep rate, 20 mV/sec.

recording the voltammetry curves probably modified the micro-orientation of the single-crystal surfaces. The microsurface structures of the single-crystal gold electrodes probably involved several orientations and hence the relative complex peak structure is not surprising, particularly for the (100) orientation. On the basis of the voltammetry curves, however, it appears that the surface of the evaporated gold electrode used for Fig. 2 was at least as homogeneous as that of either the (111) or (110) orientations of the gold single crystals and much more homogeneous than that of the (100) orientation.

The charge density *vs.* potential curves for the UPD of lead on evaporated and single-crystal gold (Fig. 5) have been calculated by integrating the voltammetry curves as a function of potential, and then subtracting the charge obtained from the voltammetry curves for gold in the absence of lead. This procedure involves the dubious assumptions that the charge associated with the formation of the lead layer and ordinary double-layer charging can be separated, and that the double-layer charging of the gold and lead-covered gold surfaces are the same. It is difficult, however, to avoid this or some equally dubious assumption in calculating the charge density associated with the formation of the lead layer. In any event the implications of the charge density-potential curves are not affected by this assumption since the charge associated with the formation of the lead layer is large compared to the ordinary double-layer charge. All three of the single-crystal surfaces approach 225-250 μcoulombs/cm^2 (apparent area) at 0.00V. A slightly higher value of ~275 μcoulombs/cm^2 is approached at this potential for the evaporated gold surface but this may reflect differences in the ratio of true-to-apparent area. Each of the charge-potential curves are otherwise quite distinctive indicating differences in these surfaces and the UPD on them. For the (110) orientation, the majority of the charge is associated with the first peak, whereas for the (111) orientation much of the charging occurs at more cathodic potentials.

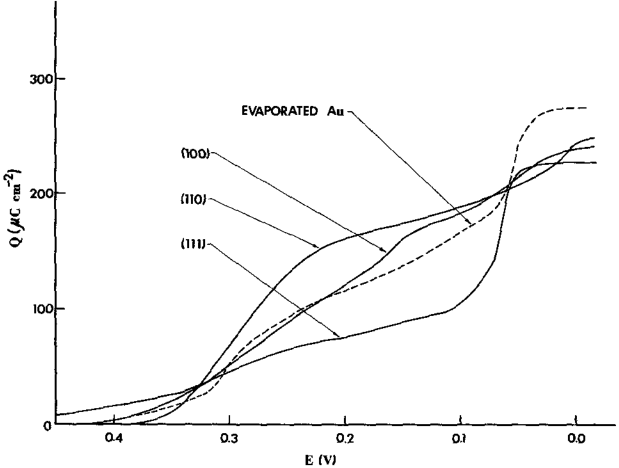

Fig. 5. Charge density *vs.* potential curves for the UPD of lead, obtained from the voltammetry curves in Fig. 2 and 4.

Specular reflectance.—The specular reflectance measurements on evaporated gold electrodes indicate that the voltammetry peaks are attended by large changes in the reflectance (Fig. 6). For the measurements reported in this figure, the reflectance has been normalized to unity at 0.5V for each wavelength. The hysteresis is, for the most part, the result of the response time (~1 sec) of the filter used to suppress noise in the recording system. The changes in reflectance are particularly pronounced at ~0.05V where the second peak in the voltammetry curve occurs, indicating that a very large change in the optical properties of the layer occurs, most likely as a result of a change in the elec-

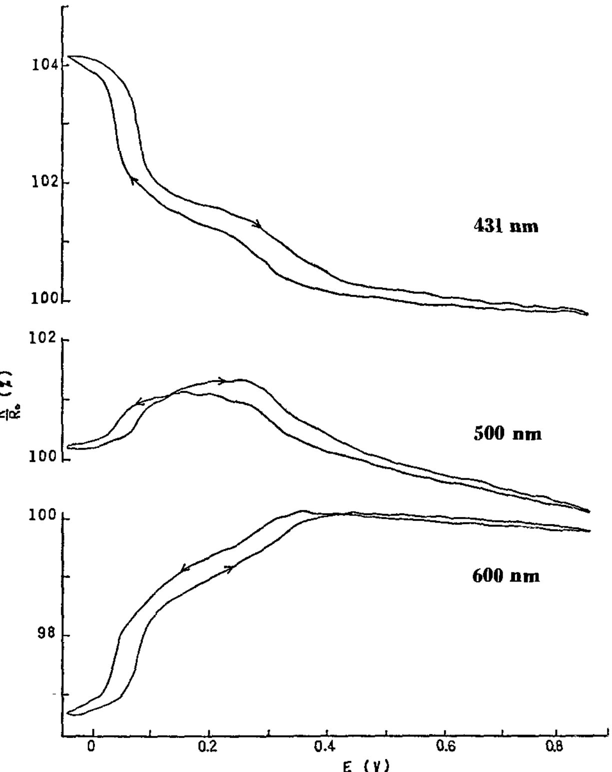

Fig. 6. Reflectance vs. potential curves for UPD of lead in evaporated gold at three wavelengths. Conditions the same as for Fig. 3.

tronic properties of the surface lead layer and its interaction with the gold substrate and solvent molecules.

Figure 6 indicates that the reflectance changes attending the UPD are highly wavelength dependent. The wavelength dependence of the relative reflectance changes are given in Fig. 7 for various Pb^{2+} ion concentrations in 0.2*M* $HClO_4$ at a potential of 0.33V, which corresponds to the first voltammetry peak in this electrolyte. The values on the ordinate correspond to the difference in the reflectance of the polished bulk gold electrode at 0.33V in the Pb^{2+} containing solutions normalized at 0.5V, and the corresponding value for this electrode in a lead-free solution, also normalized to 0.5V. The various Pb^{2+} ion concentrations correspond to different surface coverages with lead, as will be evident from a consideration of the adsorption isotherms discussed below. Similar results have been obtained with evaporated gold. The reflectance spectrum of the lead layer on the gold is strongly influenced by the absorption edge of gold at ~500 nm. The reflectance increases with the formation of the lead partial monolayer at wavelengths below the absorption edge of gold and decreases at longer wavelengths. This effect, however, is quite potential dependent (see the 500 nm curve in Fig. 6).

All the curves in Fig. 7 have a nearly common intersection at ~510 nm. This behavior is rather analogous to the isobestic point encountered in absorption spectroscopy when the sum of the concentrations of two forms of an absorbing species is constant. The analogous situation for the reflectance spectra are the occupied and unoccupied surface sites, the sum of which is a constant. Apparently at 0.15V the contribution to the reflectance from occupied and unoccupied sites is the same at $\lambda \cong 510$ nm.

The dependence of the normalized reflectance change on charge density is shown for three wavelengths for

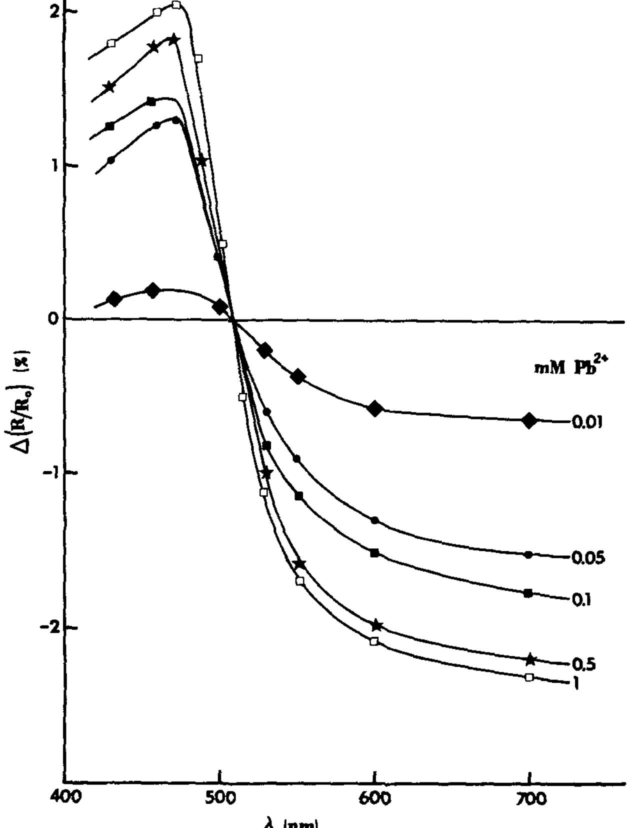

Fig. 7. Wavelength dependence of normalized reflectance change for the UPD of lead on polished bulk gold for various $Pb(NO_3)_2$ concentrations in 0.2*M* $HClO_4$ at 0.33V. Data evaluated from reflectance vs. potential curves obtained with sweep rate of 20 mV/sec.

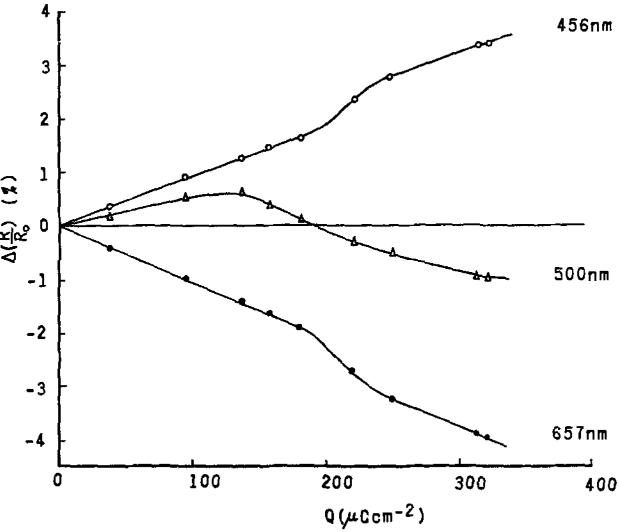

Fig. 8. Normalized change in reflectance vs. charge density for the UPD of lead on evaporated gold in 1 m*M* $Pb(NO_3)_2$ + 1*M* $HClO_4$. Charge density evaluated as in Fig. 5.

evaporated gold in a 1 m*M* $Pb(NO_3)_2$ + 1*M* $HClO_4$ solution in Fig. 8. The charge density, obtained from the integration of the voltammetry curves with the lead-free gold surface as a reference, should be at least approximately proportional to the amount of lead on the gold surface if all of the adsorbed lead species on the surface have the same charge. The outer Helmholtz plane and diffuse layer contributions to the total charge density should be small compared to the charge associated directly with the formation of the lead layer, regardless of whether the latter is faradaic, nonfaradaic, or partially both. Consequently, the linearity in Fig. 8 up to a charge density of ~175 μcoulombs/cm^2 (apparent area) for wavelengths of 456 and 657 nm implies that the reflectance changes under these conditions are proportional to the amount of lead adsorbed. This proportionality facilitates the determination of adsorption isotherms from reflectance measurements, but care must be exercised to avoid wavelengths near the absorption band edge of gold where linear behavior is not observed over any appreciable range of charge densities.

At ~200 μcoulombs/cm^2 an abrupt change in slope occurs in Fig. 8 at 456 and 657 nm. This charge density corresponds to the occurrence of the second voltammetry peak and is indicative of a large change in the electronic structure of the lead layer.

The dependence of the differential reflectance coefficient [$\chi = (1/R)(dR/dE)$] on potential and wavelength also has been examined using the a-c electromodulation technique (18). The in-phase component of the reflectance is given as a function of potential for three wavelengths in Fig. 9 for a 70 Hz, 30 mV p-p sinusoidal modulation of the electrode potential superimposed on a 20 mV/sec linear voltage sweep. At this modulation frequency, the out-of-phase component is not small compared to the in-phase component in the potential regime corresponding to the UPD of lead. Consequently, the potential dependence of χ is influenced by the dependence of the adsorption-desorption kinetics on potential as well as the change of the optical properties of the surface with coverage and potential. The hysteresis in Fig. 9 is the result of the relatively long time constant (1 sec) of the filter used to minimize noise. The changes in sign and magnitude of χ at these wavelengths and at the various potentials are as would be expected from the d-c reflectance data in Fig. 6.

The wavelength dependence of the in-phase component of χ is shown in Fig. 10 for the same conditions as for Fig. 9. While these derivative curves have some similarity to those for the integral reflective

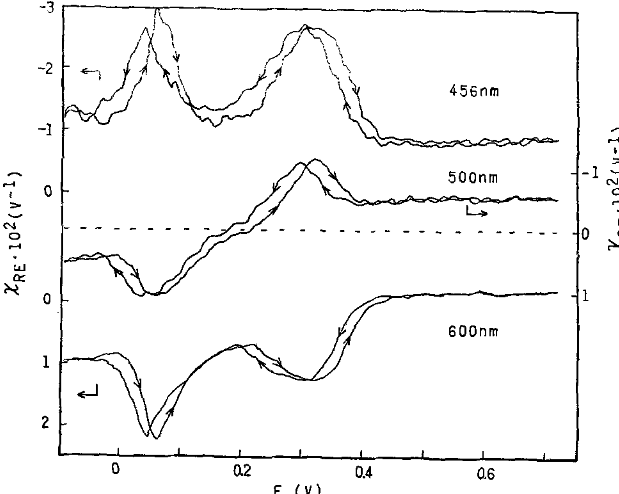

Fig. 9. Differential reflectance-potential curves for the UPD of lead on evaporated gold. Only the in-phase component is shown. A-C modulation potential, 30 mV p-p; 70 Hz, sweep potential rate, 20 mV/sec; electrolyte, 5 mM $Pb(NO_3)_2$ + 1M $HClO_4$.

changes in Fig. 7, the common crossover or isobestic point is no longer found. This is a consequence of the fact that the curves have been evaluated at potentials above and below the second voltammetry peak where marked changes occur in the electronic properties of the lead layer. For comparison purposes, the differential reflectance spectra of evaporated gold in the absence of Pb^{2+} is also shown. The UPD of lead on the surface produces layers whose optical properties are quite dependent on potential and coverage, and quite different from that of gold. The comparison of the lead-free gold and lead-covered surfaces, however, must be made with caution. The differential electromodulation reflectance χ is given by

$$\chi = \frac{1}{R}\left(\frac{dR}{dE}\right) = \frac{1}{R}\left[\left(\frac{\partial R}{\partial E}\right)_{N_i} + \Sigma_i\left(\frac{\partial R}{\partial N_i}\right)_E \frac{dN_i}{dE}\right] \quad [1]$$

where N_i represents the surface concentration of the various types of lead species on the surface. For the lead-free systems, the second summation term within the bracket is zero, whereas for the lead-covered surfaces involved in Fig. 10, the second term is predominant at low modulation frequencies. Evidence as to the relative magnitudes of these terms from complex plane analysis is presented below. Much of the variation of χ with potential at λ = 456 and 600 nm in Fig. 9 results from the potential dependence of (dN_i/dE).

Adsorption isotherms.—The adsorption isotherms have been determined from the reflectance data at 600 nm for potentials well anodic to the second voltammetry peak and are given in Fig. 11. After sweeping the potential several times up to 1.6V, the potential was maintained constant at the potential specified on the curve in Fig. 11 so as to allow sufficient time for adsorption equilibrium to be reached. The normalized reflectance change was then determined by comparing the reflectance of the partially lead-covered gold electrode with that of the lead-free gold surface.

Linear behavior of the reflectance change, and hence lead surface concentration on log $C_{Pb^{2+}}$ is evident in Fig. 11 over the concentration range $C_{Pb^{2+}} = 3 \times 10^{-6}$ to $5 \times 10^{-4}M$, as is to be expected if the lead adsorption obeys a Temkin isotherm. The slopes of these portions of the plots are indicative of the Temkin parameter. The potential dependence of these slopes is not surprising since the interaction between the adsorbed species and therefore the Temkin parameter would be expected to depend on electrode potential, particularly for charged adsorbed species.

Rather surprising, however, is the abrupt leveling off of the isotherms at concentrations of $\sim 5 \times 10^{-4}M$ Pb^{2+} for all three potentials. The surface coverage even at 0.12V only corresponds to ~100 μcoulombs/cm² and is much less for the other two more anodic potentials. Rather similar leveling off of the adsorption isotherms at well below monolayer coverage has been observed by Bagotzky *et al.* (21) for Cl^- on Pt although not so abruptly. The precision of the points in Fig. 9 makes it unlikely that this abrupt feature of the curves is the result of a statistical variation.

Specular reflection study of adsorption-desorption kinetics.—The kinetics of UPD of lead have been investigated with both the potential step method and complex plane analysis of a-c electromodulation measurements, using reflectivity as a readout. The potential step measurements were performed by stepping

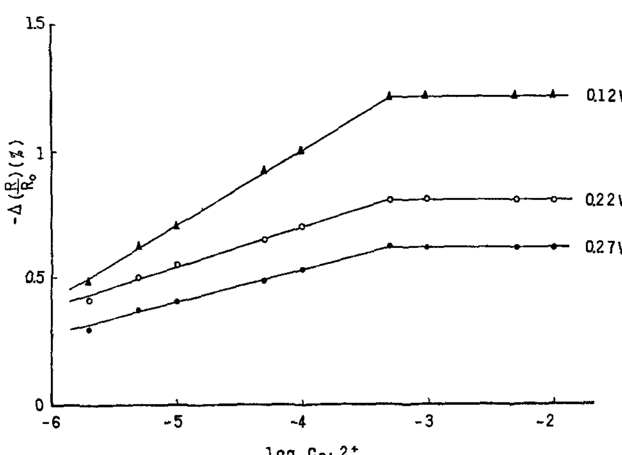

Fig. 11. Adsorption isotherm for lead UPD on gold in 1M $HClO_4$ evaluated from reflectance measurements on evaporated gold at 600 nm. Potentials indicated on curves.

the potential from 0.5 to 0.1V where UPD of lead occurs. The change of reflectivity with time was followed with an X-Y recorder. Such curves show initially a virtually instantaneous change of reflectivity which corresponds to the intrinsic dependence of reflectivity of gold on potential. This is followed by a gradual change of reflectivity attending the deposition of lead. The plots of $\Delta(R/R_o)$ *vs.* square root of time for various concentrations of Pb^{2+} are linear (Fig. 12). This indicates diffusion control and also confirms the linearity of the change of reflectivity with the surface concentrations of lead. The ratios of the slopes correspond experimentally to the ratios of the solution concentrations of Pb^{2+}, as is to be expected for pure diffusion control of the adsorption process.

The kinetics of the UPD of lead have been examined using complex plane analysis of the in-phase and out-of-phase components of the change of reflectivity as a function of frequency obtained in a-c electromodulation experiments. This technique was more attractive than attempting to extend the potential step method to shorter times because of a better signal-to-noise ratio and the possibility of following faster processes. The complex plane analysis of electromodulation reflectance data has been described elsewhere (18). The plot of the out-of-phase *vs.* in-phase components at various frequencies yields a semicircle for pure kinetic control for an adsorption process and a quarter circle for pure diffusion control. With mixed control, an intermediate curve is obtained, which approaches perpendicular to the in-phase axis of the plot at the high frequency end of the complex plane curve and at 45° at the low frequency end. The intercept with the in-phase axis at the high frequency end should correspond to the term $(\partial R/\partial E)_{N_i}$ in Eq. [1], while the low frequency intercept with the in-phase axis corresponds to the total derivative (dR/dE).

Complex plane plots are presented in Fig. 13 for the UPD of lead on evaporated gold in 1 m*M* $Pb(NO_3)_2$ + 1*M* $HClO_4$ for two potentials. The high frequency intercepts with the real axis indicate that $(1/R)(\partial R/\partial E)_{N_i}$ is -8×10^{-3}/V at a potential of 0.268V, and -2×10^{-3}/V at 0.00V at 600 nm. These values are three- and twofold larger, respectively, than the corresponding values for lead-free gold surfaces (evaporated) at the corresponding potentials, indicating that the presence of lead on the surface substantially modifies the intrinsic electromodulation coefficient. Further measurements are needed to establish the wavelength dependence of this coefficient. The low frequency limiting values of the in-phase component of χ verify that at both potentials the change of reflectance with potential is mostly due to the $\Sigma_i(\partial R/\partial N_i)\, dN_i/dE$ term in Eq. [1].

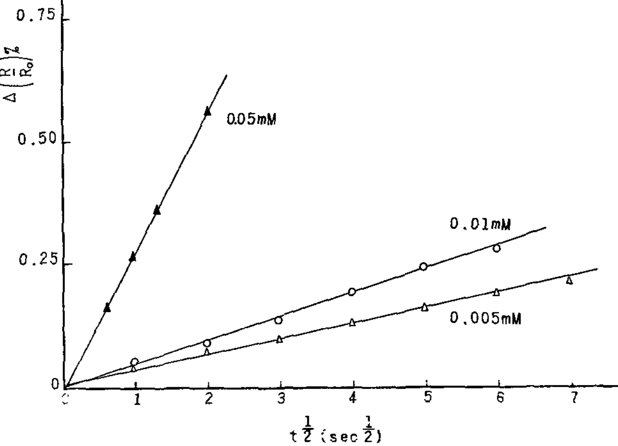

Fig. 12. Time dependence of the reflectance change at 431 nm attending the UPD of lead on evaporated gold following a potential step from 0.5 to 0.1V at various Pb^{2+} concentrations in 1M $HClO_4$. (Pb^{2+} concentrations indicated on curves.)

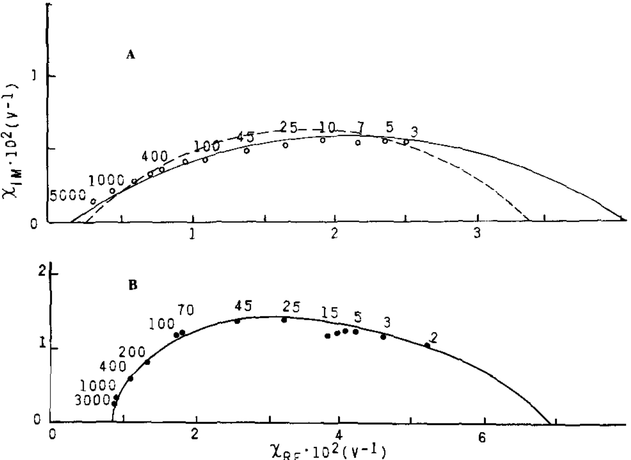

Fig. 13. Complex plane analysis of electromodulation reflectance data for the UPD of lead on evaporated gold in 1 mM $Pb(NO_3)_2$ + 1M $HClO_4$ at λ = 600 nm. A, potential = 0.00V; solid curve, best portion of circle through points; dashed curve, quarter circle; B, potential = 0.268V. Numbers in figure correspond to frequencies in Hertz.

The curve for 0.268V in Fig. 13 corresponds to mixed kinetic and diffusion control.[6] The equation describing the electromodulation coefficient χ under such circumstances is (18)

$$\chi = \frac{1}{R}\left[\left(\frac{\partial R}{\partial E}\right)_N + \left(\frac{\partial R}{\partial q}\right)_E \cdot \frac{1}{j\omega Z_{ad}}\right]\frac{Z_{int}}{Z} \quad [2]$$

assuming only a single type of adsorbed species, where $\chi = (1/R)(dR/dV)$, R is the reflectance, E is the potential across the interface, q is the charge associated with the UPD of the lead, ω is the angular frequency of the modulation signal, Z_{ad} is the adsorption impedance, Z_{int} is the over-all impedance of the interface, and Z is the total impedance (including ohmic drop within the solution) across which the modulation potential (V) is applied. With the IR drop compensated potentiostat used in the present study, $Z = Z_i$. The impedance Z_{ad} involves the following series components: the capacitance C_{ad}, the kinetic resistance r, and the Warburg impedance W, where

$$W = L(1 - j)/\sqrt{\omega} \quad [3]$$

with

$$L = \frac{RT}{z^2F^2\sqrt{2}} \cdot \frac{1}{C_{Pb^{2+}}\sqrt{D_{Pb^{2+}}}} \quad [4]$$

where $C_{Pb^{2+}}$ and $D_{Pb^{2+}}$ are the concentration and diffusion coefficient of the Pb^{2+} ion, $z = 2$, and the other symbols have their usual meaning. Thus

$$Z_{ad} = \frac{1}{j\omega C_{ad}} + r + \frac{L(1-j)}{\sqrt{\omega}} \quad [5]$$

Equation [2] can be rearranged, using Eq. [3]-[5], to the form

$$\chi = \frac{1}{R}\left[\left(\frac{\partial R}{\partial E}\right)_{n_i} + \left(\frac{\partial R}{\partial q}\right) \cdot \frac{(1+x) - j\,(1 + r\sqrt{\omega}/L)x}{(1+x)^2 + (r\sqrt{\omega}/L + 1)^2x^2}\right] \quad [6]$$

where $x = LC_{ad}\sqrt{\omega}$. Using $D_{Pb^{2+}} = 0.98 \times 10^{-5}$ cm^2 sec^{-1} (22) yields $W = 15\,(1 - j)/\sqrt{\omega}$ ohm-cm^2. The data for 0.268V in Fig. 13 yield a value of $C_{ad} \cong 3 \times 10^{-3}$ farad/cm^2 and $r = 1.0$ ohms-cm^2. The apparent

[6] The curve for 0.268V in Fig. 13 differs from the experimental curve for lead adsorption on gold at 0.30V in Ref. (18) because in the earlier experimental work the a-c electromodulation data were recorded without complete compensation for IR drop and with the sinusoidal potential modulation superimposed on a linear potential sweep rather than at a fixed potential.

exchange current density corresponding to this value of r is

$$i_o = \frac{\nu RT}{n\mathbf{F}} \cdot \frac{1}{r} = 1.3 \cdot 10^{-2} \mathrm{A/cm^2} \quad [7]$$

where ν is the stoichiometric number for the over-all adsorption (assumed to be 1) and n is the charge transferred (taken as 2).

The potential of 0.00V used for the other plot (A) in Fig. 13 is cathodic to the second voltammetry peak where a transition in the electronic properties of the layer appears to occur. These data cannot be fitted closely to a quarter circle (dashed line). Although part of a circle (solid curve) can be drawn through the points, the center is well below that for the quarter circle predicted by theory for pure diffusion control. Such deviation may be the result of having two forms of lead on the surface or an instrumental artifact such as slight overcompensation of the solution phase *IR* drop. Further work is required to clarify this point.

ESCA.—Some preliminary measurements were made with ESCA in an attempt to establish whether any differences could be found between the lead monolayer in gold and that of the surface of bulk lead. The lead layer was formed on bulk gold at 0.02V. The electrode was then withdrawn from solution at this potential and washed with H_2 saturated methanol in an attempt to prevent the reoxidation and loss of lead in the rinse upon removal of the potential control. The electrode was subsequently allowed to dry in a N_2 atmosphere. The sample was then transferred into the vacuum of the ESCA spectrometer (Varian VIEE-15, with MgK(α) x-ray source) without exposure to air.

The sample exhibits peaks at 138.5 eV ($4f_{7/2}$) and 143.6 eV ($4f_{5/2}$), as shown in Fig. 14. These values are much higher than those for pure metal lead [137 eV ($4f_{7/2}$) obtained with this instrument] and comparable to the values reported recently for lead film evaporated on gold after exposure to oxygen for an extended time (23). Thus the lead monolayer film formed electrochemically is not lost during the washing in hydrogen saturated methanol but it is apparently oxidized in subsequent operations. The peak width in Fig. 14 is broader than can be attributed to instrument broading, probably as a result of surface heterogeneity and adsorbed water molecules in the modest vacuum (10^{-7} Torr) obtained with the ESCA equipment in this study.

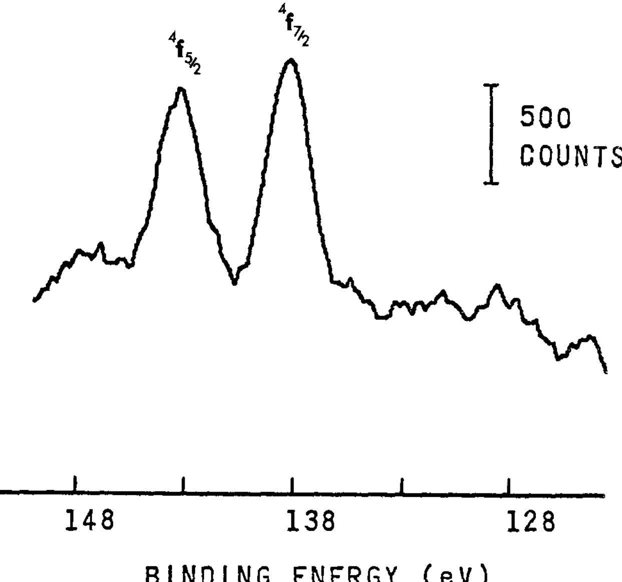

Fig. 14. ESCA spectrum (4 farads) for partial monolayer of lead on gold.

Discussion

On the basis of the linear sweep voltammetry and reflectance studies, it is proposed that the UPD of lead involves two processes

$$Pb^{2+}(\text{soln}) + (2-y)e^- \rightleftharpoons Pb^{y+}(\text{ads}) \quad [8]$$

$$Pb^{y+}[\text{ads}] + ye^- \rightleftharpoons Pb(\text{ads}) \quad [9]$$

The first is the adsorption of lead, probably in ionic form. This process appears to occur over a wide range of potentials, commencing with the first cathodic voltammetry peak at ~0.3V. In solutions of less than $10^{-3}M$ Pb^{2+} at a sweep rate of 0.02 V/sec, reaction [8] is under diffusion control. The second process (reaction [9]) appears to be a phase transition attended by a change in the state of charge within the adsorbed layer since it is characterized by a quite sharp peak in the voltammetry curves and is not under diffusion control. Theoretically a potential sensitive reversible phase transition within a two-dimensional layer should occur at a single potential, but surface heterogeneity and lack of complete reversibility can easily smear this peak out over a range of potentials. The disappearance of the second voltammetry peak at concentrations below $10^{-4}M$ Pb^{2+} for a sweep rate of 20 mV/sec can be explained by the fact that the diffusion control of the process in reaction [8] prevents the surface coverage from reaching the critical value necessary for this transition.

The pronounced difference in the second voltammetry peak on the various gold single-crystal surfaces is not surprising since this phase transition leading to a metallic layer should be dependent on crystallographic orientation. Apparently the recycling of the evaporated gold surface produced a relatively homogeneous surface at least with respect to this phase transition.

The charge of the adsorbed species resulting from the first process is expected to be substantially less than the +2 charge of the lead ions in solution. While it is not possible to distinguish between the charge of a faradaic process and that of nonfaradaic ionic adsorption in the voltammetry experiments, nonetheless, the 100-200 μcoulombs/cm² or more of charge passed before reaching the second voltammetry peak is too high for simple ion adsorption, even with strong interaction between the adsorbed ions and the substrate.

The additional charge (70-90 μcoulombs/cm²) involved in the second peak is too high to be associated with a change in the charge of the outer Helmholtz and diffuse ionic layers attending the phase transition within the lead layer. Consequently, the phase transition is accompanied by a change in the charge of the adsorbed lead species, most likely to zero charge. This behavior and the pronounced change in the reflectivity and its wavelength dependence accompanying the second voltammetry peak can be readily explained by having the phase transition involve the formation of a metallic lead layer in which the valence bands of the lead merge with the band structures of the gold substrate.

A monolayer or near monolayer of a metalliclike lead layer on gold should have optical properties which differ substantially from those of bulk lead because of the two-dimensional nature of the layer and the strong interaction with the band structure of the gold substrate. Nonetheless, it is interesting to compare the reflectance changes calculated for a metallic lead layer using the refractive index of bulk lead with the experimental values at potentials cathodic to the second voltammetry peak (Fig. 15). The calculation has been carried out with the following equation (24)

$$\left(\frac{\Delta R}{R}\right)_p = \frac{8\pi d n_1 \cos\phi_1}{\lambda} Im \left\{ \frac{\hat{\epsilon}_2 - \hat{\epsilon}_3}{\hat{\epsilon}_1 - \hat{\epsilon}_3} A \right\} \quad [10]$$

$$\text{where } A = \frac{1 - [\hat{\epsilon}_1/(\hat{\epsilon}_2\hat{\epsilon}_3)](\hat{\epsilon}_2 - \hat{\epsilon}_3)\sin^2\phi_1}{1 - (1/\hat{\epsilon}_3)(\hat{\epsilon}_1 + \hat{\epsilon}_3)\sin^2\phi_1} \quad [10a]$$

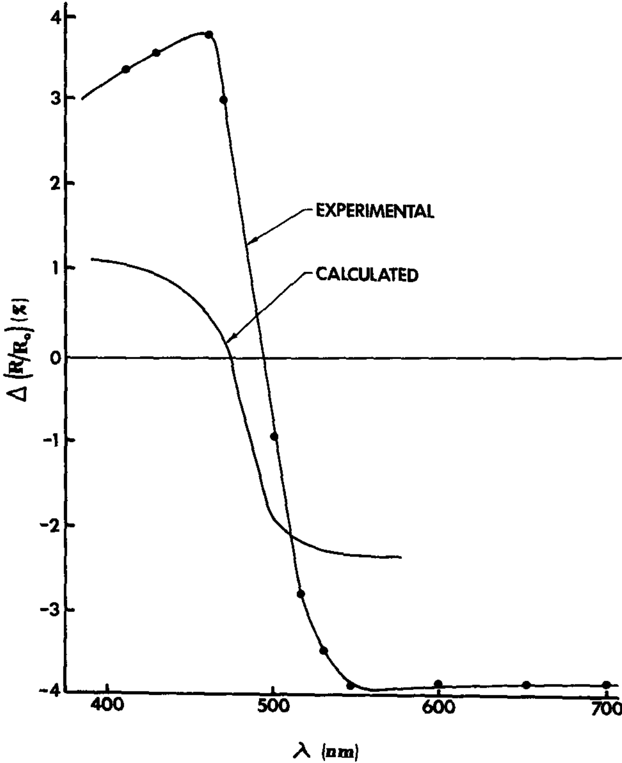

Fig. 15. Comparison of experimental values for the reflectance change with calculated values for a 3Å thick layer of lead on gold with the optical properties of the layer taken as those of bulk lead. Experimental data for a potential of 0.00V in 1 m*M* $Pb(NO_3)_2$ + 1*M* $HClO_4$ at angle of incidence of 45°.

$\hat{\epsilon}_1$, $\hat{\epsilon}_2$, and $\hat{\epsilon}_3$ are the complex dielectric constants of the solution, lead layer, and gold substrate, respectively, at the wavelength λ (*in vacuo*); n_1 is the refractive index of the solution; d is the thickness of the lead layer; and ϕ_1 the angle of incidence. For the 45° angle of incidence used in the present work, the term A contributes relatively little to the wavelength dependence compared to the other term within the bracket in Eq. [10] and will be approximated as 1 for the purposes of this discussion of wavelength dependence. Equation [10] can be rearranged to the form

$$\left(\frac{\Delta R}{R}\right)_p = U[X(\epsilon_2' - \epsilon_3') + Y(\epsilon_2'' - \epsilon_3'')] \quad [11]$$

$$X = \left[(\epsilon_1' - \epsilon_3') \left(\frac{\epsilon_1' - \epsilon_3'}{\epsilon_1'' - \epsilon_3''} + \frac{\epsilon_1'' - \epsilon_3''}{\epsilon_1' - \epsilon_3'} \right) \right]^{-1} \quad [11a]$$

$$Y = -\left[(\epsilon_1'' - \epsilon_3'') \left(\frac{\epsilon_1' - \epsilon_3'}{\epsilon_1'' - \epsilon_3''} + \frac{\epsilon_1'' - \epsilon_3''}{\epsilon_1' - \epsilon_3'} \right) \right]^{-1} \quad [11b]$$

$$U = (8\pi d n_1 \cos\phi_1)/\lambda \quad [11c]$$

The values of U, X, and Y have been calculated from the values of ϵ_3' and ϵ_3'' for pure gold (see Table I), evaluated from the ellipsometric measurements of Horkans (25) for evaporated gold and with the layer thickness taken as ~3Å. The values of ϵ_2' and ϵ_2'' (Table I) have also been calculated from the complex refractive index data determined ellipsometrically for a bulk lead sample by Horkans (25). This lead sample was not of high optical quality, but the calculation is relatively insensitive to small errors in the refractive index data for lead.

The calculated changes in reflectance for a metallic lead layer are compared with the experimental values corresponding to the difference in the reflectance with and without the lead layer at 0.00V for an evaporated gold electrode on 1 m*M* Pb^{2+} solution in Fig. 15. As indicated earlier, this subtraction assumes that the intrinsic dependence of the reflectance on potential for the lead-covered gold electrode is the same as for pure gold. This certainly is not true, but the error should be small except in the vicinity of crossover (475-500 nm) in Fig. 15 where the change of the reflectance with lead coverage passes through zero. At wavelengths remote to this region, the change of reflectance associated with the lead layer is due principally to the term $(\partial R/\partial N_i)_E(dN_i/dE)$ in Eq. [1] and not to the intrinsic electromodulation term $(\partial R/\partial E)_{N_i}$. While the calculated reflectance change passes through zero, the values at λ remote from 500 nm are in large discrepancy. This is not surprising since the optical properties of the monolayer should be quite different from those of lead. Further, the electronic properties and optical constants of the surface layer of gold should be strongly perturbed by the lead.

Even at the less cathodic potentials where the lead is believed to have much ionic character, the interaction of the lead with the substrate gold must be very strong. The first voltammetry peak occurs at potentials of +0.3-0.4V anodic to the potential of zero charge, which is estimated to be −0.1V in 1*M* $HClO_4$ on the basis of the work of Bockris and co-workers (26). This and the relatively high charge density (~200 μcoulombs/cm² prior to the second voltammetry peak) indicate strong specific adsorption with no water interposed between the lead and the gold substrate. Such specific adsorption requires not only the displacement of water molecules on the gold surface but also the removal or at least gross distortion of water in the inner coordination sphere of the lead ions. On the basis of the behavior of similar divalent ions (27), the heat of hydration of Pb^{2+} should be at least 400 kcal/mole of which approximately one-half is associated with the inner coordination sphere. All things considered, the minimum energy required to reorganize the inner coordination sphere of the lead ions to accommodate the direct interaction with the gold substrate is certainly at least 20 kcal/mole if the lead retains its +2 charge, and probably much more, particularly if the charge of the adsorbed lead ions is effectively reduced through interaction with the band structure of the gold. Consequently, the strength of the interaction of the lead and gold is at least 20 kcal/mole.

Prior to the sharp transition associated with the second peak, the lead should be distributed randomly on various adsorption sites with water molecules surrounding each lead ion on the surface. Direct inter-

actions (horizontal) between the adsorbed lead ions would be expected to be coulombic and relatively weak under these circumstances. Indirect interactions (vertical) between adsorbed lead ions resulting from modifications in the surface electronic structure of the gold are probably more important. Even so, the linearity of the reflectance changes *vs.* charge density (Fig. 8) up to ~175 μcoulombs/cm² (apparent area) at wavelengths remote from 500 nm indicates that the interactions among the adsorbed lead species are small, whether direct or indirect, for coverages up to 0.4-0.5. [The charge density of 175 μcoulombs/cm² corresponds to 0.4 on the (111) plane and 0.46 on the (100) plane, assuming two charges per lead adsorbed, one adsorption site per gold surface atom, and a true-to-apparent area ratio of unity.] At and near the wavelength (500 nm) corresponding to the threshold for the 5d-6s interband transition of gold, the reflectance is extremely sensitive to small changes in the surface electronic properties of the gold and hence the much more limited range of linearity at 500 nm in Fig. 8 is not surprising.

The reflectivity change *vs.* wavelength data in Fig. 7 indicate an increment in reflectance with formation of the adsorbed layer at wavelengths less than 500 nm and a decrease at longer wavelengths for a potential of 0.15V where the layer should have substantial ionic character. A simple adsorbed ionic layer without any appreciable imaginary refractive index component (k), however, cannot explain this wavelength behavior. Consideration of Eq. [11] indicates that for $k_2 = 0$ and $n_2 > n_1$, only a negative change in reflectance with layer formation is possible, contrary to observation. Taking into account the electronic polarizability of the core Pb^{2+} ion [4.34×10^{-24} cm³ at 589 nm, based on measurements for Pb^{2+} in ionic salts of cubic symmetry (28)], n_2 for an ionic layer should certainly be greater than that of the bulk solution. The explanation for the wavelength dependence in Fig. 7 must lie in either a substantial value of k_2 for the lead layer as a consequence of the lead-gold interaction and/or a failure of the three-layer model upon which Eq. [11] is based because of pronounced changes in the surface electronic properties of the gold.

The authors have refrained from speculating as to the origin of the shallow maxima in the reflectance changes *vs.* wavelength curves in Fig. 7 and 15. The three-layer model used in obtaining Eq. [11] is too oversimplified to be used to interpret relatively minor features of the reflectance *vs.* wavelength curves.

A probable model for the interactions of the adsorbed lead with the gold substrate and other adsorbed lead ions or atoms is presented in Fig. 16A and B for low and moderate coverage where the lead is ionic and in Fig. 16C and D for high coverage where the lead is metallic. The representation is that usually employed for adsorption at metal-gas interfaces (29) and makes no attempt to show solvent states. Further, these figures are applicable at or near the pzc where the potential gradients associated with differences in the potentials of the metal and solution phases are small compared with those intrinsic to the electronic structure of the interface. Figures 16A and C represent the potential energy profiles perpendicular to the gold surface through the center of a lead ion or atom while Fig. 16B and D represent the corresponding profiles parallel to the surface through the center of nearest neighbor lead ions or atoms. The dashed lines represent the potential energy of an electron when there is no interaction, electrostatic or otherwise, between the gold and lead. The solid curves are the combined potential energy curves. In Fig. 16A and C the potential energy curve between the metal surface and the lead is lowered near the intersection of the two separate curves by resonance splitting. At high coverages, this resonance splitting is much larger than at low coverages because of the three-dimensional aspect as

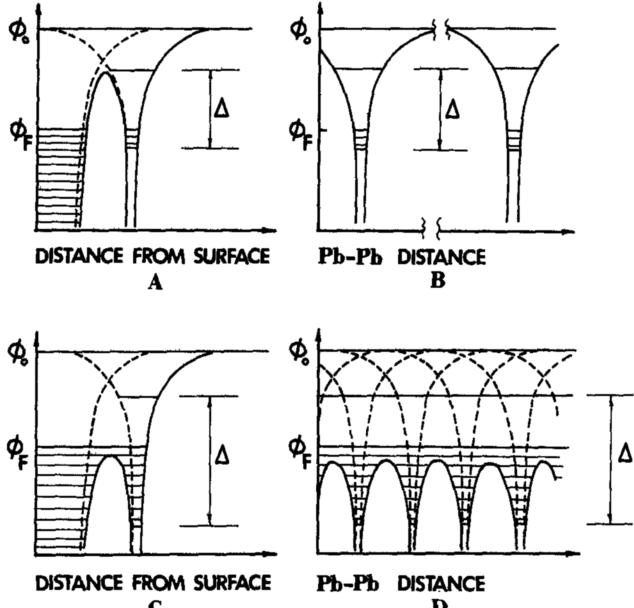

Fig. 16. Energy level diagram for lead on gold. A and B, Behavior at low and moderate coverage. C and D, Behavior at high coverage. A and C, Perpendicular to surface. B and D, Parallel to surface. ϕ_o, Potential energy of electron in unbound state; ϕ_F, Fermi energy; Δ, band width in Pb. Solid curves, combined metal substrate-lead potential curves; dashed lines, parallel curves with no interactions of lead with gold substrate or other adsorbed lead.

lead-lead as well as lead-gold interactions become important.

In Fig. 16A the valence orbitals (6p) of the adsorbed lead are broadened through interaction with the orbitals of the gold with part of the lead valence orbital band below the Fermi level. This results in a charge on the adsorbed lead of less than +2. The depression of the potential energy barrier between the lead and gold, however, is not sufficient to reduce the top of the barrier below the Fermi level and thus in this case, the lead-gold interaction is not yet metalliclike. The energy of the gold valence and conduction bands is modified even remote from the intersection of the two potential energy curves because of interaction of the lead with these orbitals with the result that substantial changes in the real and imaginary components of the optical dielectric constant of the gold are to be expected, as seems to be the situation from the relatively large changes in reflectivity and its wavelength dependence even at low coverage. (No attempt has been made to represent the valence and conduction bands of the gold substrate in Fig. 16.) The possibility that the barrier has been pulled down below the Fermi level, even at low coverages, cannot be ruled out at this time without separate values for n and k for the surface layer, but this is unlikely without the three-dimensional interactions within the layer as well as between the layer and the substrate.

Such three-dimensional interactions are to be expected at high coverages. In Fig. 16C and D, the barriers are shown depressed below the Fermi level, *i.e.*, the lead layer is metallic. The phase transition to which the second voltammetry peak is ascribed serves to bring the lead spheres into the close proximity required to achieve metallic properties for the layer.

The potential energy plots in Fig. 16 will change with electrode potential, at least qualitatively, in a manner similar to that used to represent the situation in field emission at metal-vacuum interfaces (29). In Fig. 16A, the barrier will be lowered as the electrode potential is driven cathodic. Once the barrier falls below the Fermi level, however, the fraction of the electrode potential difference felt by this barrier will become very small because of the metallic properties

of the lead and the smallness of the Thomas-Fermi screening distance.

Figure 16 is qualitative. To convert this figure to quantitative diagrams for lead on gold and other similar systems requires far more information than is presently available. A next step is the *in situ* measurement of the real and imaginary components of the refractive index as a function of wavelength using ellipsometry.[7]

Electrical Resistivity of Silver Deposited by Aerosol Spray

W. R. Momyer* and D. J. Levy*

Lockheed Palo Alto Research Laboratory, Lockheed Missiles & Space Company, Incorporated, Palo Alto, California 94304

ABSTRACT

The silver ligands and reducing agents found most effective for producing low resistivity silver films by spray chemical reduction are in the order: NH_3, en, EDTA for ligands and HCHO, N_2H_4 for reductants. No silver was deposited from Ag^+ complexed with CN^- or I^-, and deposition rates were low with SCN^- and Br^-. Reduction of $(EDTA)_xAg^+$ with N_2H_4 results in deposits with a high (20-35 μohm-cm) initial resistivity due to inclusion of Ag_2O and an unstable bluish coating which appears to be a silver carboxylate. $(NH_3)_2Ag^+$ reduced with HCHO produces deposits with the lowest initial resistivity (1.7 μohm-cm). The resistivity of all films can be reduced to 1.6 μohm-cm (pure silver) by thermal treatment within the 120°-300°C range. En is the preferred ligand because of the possibility of forming explosive compounds when using NH_3. Silver deposition rate is linear with $(en)_2Ag^+$ up to at least 1.6 μm/min. The optimum molar composition of the silver solution is en/Ag^+ = 2.5 at pH 10.6 The reductant composition should be prepared with the molar ratios HCHO/$(en)_2Ag^+$ = 9 and NaOH/HCHO $\sim$ 0.08.

Aerosol plating was known even before the turn of the century (1) but it was not perfected for commercial use (silvering mirrors) until some 40 years later. Silvering processes that have been widely used include the dual-spray chemical reduction of ammoniacal silver nitrate, $(NH_3)_2Ag^+$, with hydrazine (2), formaldehyde (3), glyoxal (4), and dextrose (5), and the reported use of hydroxylamine (6).

Upton *et al.* (7) studied the $(NH_3)_2Ag^+$-HCHO system and determined the deposition rate and efficiency as a function of solution concentration and spray conditions. The effect of atomization parameters on deposition rate and efficiency of an aerosol plating process has also been reported (8).

* Electrochemical Society Active Member.

Key words: silver, resistivity, aerosol plating, spray plating, formaldehyde, hydrazine.

Copper (9) and gold (10) films with the electrical resistivity of the pure dense metal can be aerosol plated under proper conditions. This fact, plus the observation that plating will not initiate on unsensitized nonconductors, suggests that deposition may sometimes proceed via an autocatalytic plating mechanism.

The present study was undertaken in an effort to evaluate the quality of aerosol-plated silver films as determined by electrical resistivity measurements. Ethylenediamine (en) and ethylenediamine-NNN'N'-tetra-acetic acid (EDTA) were the principal ligands evaluated with either formaldehyde or hydrazine as the reducing agent. However, some plating was performed with the ammoniacal silver complex for comparison, and bromide, iodide, cyanide, and thiocyanate ligands were evaluated in the initial experiments. Consideration was also given to the hazard of forming explosive silver compounds in the metal solution.

Experimental

Apparatus.—The plating solutions were sprayed with a stainless steel, dual-nozzle, pneumatic atomizing spray gun fitted with glass siphon cups. A Binks Manufacturing Company Model 181 SS Spray Gun with 0.5 mm (0.022 in.) liquid orifices and 66SH air nozzles was used. All surfaces in contact with the metal solution were plastic or plastic coated. Metal and reductant solution flow rates were each 50 ml/min and plating was conducted at 22°C using exhaust ventilation. Filtered compressed air was used at *ca.* 0.04 kg/mm^2 (60 psig) for atomization. These conditions were previously determined (8) to yield efficient aerosol plating.

The *p*H of the silver solutions was adjusted using a Beckman Model H2 meter in conjunction with a multipurpose glass electrode (0-14 *p*H, 0-100°C) and a silver/silver chloride reference electrode. Unstable *p*H readings were sometimes encountered when adjusting *p*H of the $(en)_2Ag^+$ complex. This instability was due to the deposition of silver and/or silver chloride in the capillary of the reference electrode. The problem was circumvented by coupling the reference electrode to the circuit through a sodium nitrate-agar gel bridge.

More accurate *p*H adjustment was required when studying stability of the $(en)_2Ag^+$ complex. An Orion Research Model 601 digital *p*H meter with a Beckman "Perma-Probe" silver/silver chloride solid-state reference electrode and a multipurpose glass electrode was used for this study. The gel bridge was again used in the reference circuit and a dual-buffer standardization technique was employed. Readings were accurate to ±0.02 *p*H unit with this system.

A Hewlett Packard Model 5750 gas chromatograph with a Poropak Q column and thermal conductivity detector was used to analyze the gases evolved during thermal treatment of some aerosol-plated silver films. Helium was used as the carrier gas. The silver was deposited on fiber glass knit mesh substrates in order to provide a high silver surface area per unit volume. The fiber glass substrates were heat-cleaned at 650°C before silver plating in order to remove any organic contaminants (sizing, lubricants, etc.). The silver-plated panels were then placed in a vacuum-tight container of known volume, evacuated, given a thermal treatment at 125°C for 2 hr to decompose the unstable compound, and the gases evolved analyzed both qualitatively and quantitatively.

Materials.—The reductant solutions were prepared with purified grade 64% hydrazine and U.S.P. 37% formaldehyde. The formaldehyde solutions were prepared fresh daily to minimize the effects of the Cannizzaro reaction (12). The silver complexes were prepared with 98-100% en, 99% EDTA (tetrasodium salt), and reagent grade ammonium hydroxide. Additional en purification is required if the $(en)_2Ag^+$ complex is to be stored for several weeks before use. Ninety-nine and eight tenths per cent silver nitrate was used in preparation of the metal solutions and all other chemicals were of reagent grade quality. The substrates were 5 × 5 cm frosted borosilicate glass panels.

Procedure.—The substrate panels were cleaned in chromic acid, heated to 200°C for 1 hr, cooled, and weighed to the nearest 0.1 mg. The glass squares were then sensitized with stannous chloride (0.25 g/liter), rinsed with deionized water, and aerosol silver plated for 30 sec unless specified otherwise. The panels were again rinsed, dried, and reweighed to the nearest 0.1 mg after plating. In some instances the silver films were heated before reweighing when it was found that film resistivity was sensitive to postbake temperature. An average film thickness was calculated using the density of pure silver, 10.5 g/cm^3 at 20°C (13), and the geometrical area. Electrical resistance of the silver film was measured with a 4.4 cm square, parallel bar probe (gold plated to minimize contact resistance) and a Hewlett-Packard Model 412A d-c vacuum tube voltmeter. Electrical resistivity was calculated using the measured resistance and the calculated film thickness. A comparison with the accepted resistivity for pure silver, 1.60 μohm-cm at 22°C (13), gives a good indication of film quality (density and purity).

Frosted glass substrates were used in these tests in order to obtain adequate adhesion of the aerosol silver film to the glass. It might be expected, therefore, that the calculated resistivity values would be higher than the true values because the actual surface area of frosted glass is somewhat greater than the geometrical area. However, this difference was not observed in practice and, evidently, the geometrical area is quite close to the true area for the silver thickness deposited. A reported resistivity value is the average of several measurements which normally varied less than ±0.1 μohm-cm for any given set of spray conditions.

Selection of Silver Complexes for Aerosol Plating

The silver complex is one of the principal factors determining both the plating rate and the quality of the silver deposit in this process. The silver ion activity must be maintained at a low value in order to prevent silver oxide from forming in the metal solution either prior to or during spraying. Natarajan and Krishnan (14) recently surveyed the literature and found a broad spectrum of silver complexes effective for electrodeposition. Table I lists the instability constants for the more important silver complexes found in this survey. However, only the cyano and, to a lesser extent, the iodo silver complexes have been used commercially for electroplating.

Aerosol plating places greater restrictions on the choice of the silver complex than electroplating. The cyano and iodo silver complexes are too stable and no metal deposition is observed in aerosol plating.

Thiocyanato and bromo silver complexes produce bright, metallic deposits but the plating rates are rather low. High quality silver deposits are obtained at rapid plating rates with NH_3, en, and EDTA silver complexes. The EDTA complex is anionic and is slightly less stable than the ammonia complex (15). Silver complexes with instability constants from 10^{-7} to 10^{-8}, therefore, appear to be optimum for aerosol plating. It is not possible to use silver complexes with instability constants greater than 10^{-7} because silver

oxide precipitates in the alkaline media used for aerosol plating.

The EDTA complex is probably in the form of the ethylenediamine tetraacetato silver ion $(EDTA)Ag^{-3}$. However, the designation $(EDTA)_xAg^+$ is used since it was beyond the scope of this work to establish the number of coordinated ligands. The ammoniacal silver complex was invariably chosen in the past although it is not a particularly desirable complex because of possible side reactions which can form explosive compounds. In preparing $(NH_3)_2Ag^+$ only a slight excess of ammonia is used over that required to redissolve the silver oxide precipitate which forms during mixing. Under this condition, and particularly in the presence of additional alkali, explosive compounds may form in solution. $Ag(NH_3)_2OH$ is a soluble strong base which forms a highly explosive nitride, probably Ag_3N (silver azide) or Ag_2NH (silver imide), upon standing (16).

Aerosol Silver Plating with Hydrazine

The silver-EDTA complex produced the most specular deposits on smooth glass surfaces in preliminary screening experiments with hydrazine. The spray formulations were therefore optimized using this complex. Initial tests indicated that the resistivity of the deposited silver film was not constant with time. The resistivity immediately after plating was quite high but decreased substantially over a period of 1 week to a value only 4-5 times that of pure silver (Fig. 1). A similar observation without data was reported by Ollard (17) in the discussion comments of another paper. Silver had been deposited from a Rochelle salt bath onto glass and it was found that the electrical resistance "fell after a few hours to half its value."

Figure 2 shows that heating the films decreases the time required to reach a steady-state resistivity and produces a lower final value (resistivity of pure silver at 300°C). It is not difficult to explain the resistivity decrease observed at 200° and 300°C. Silver oxide is unstable at elevated temperatures with the partial

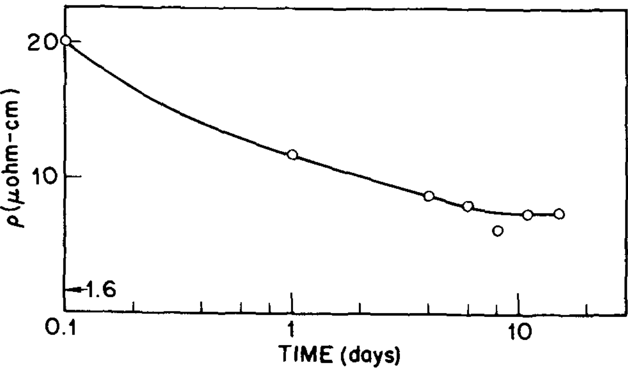

Fig. 1. Change in electrical resistivity of silver deposit at 22°C. 0.3 μm Ag (on smooth glass). Plating solutions: 0.02M Ag^+, 0.08M EDTA, pH 10.5; 0.5M N_2H_4, 0.03M NaOH.

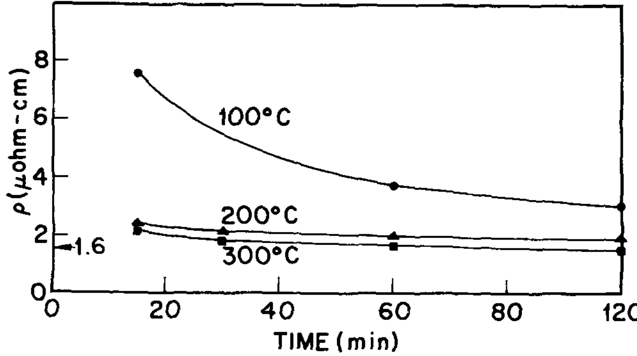

Fig. 2. Thermal treatment of silver. Plating solutions: 0.04M Ag^+, 0.12M EDTA, pH 10.5; 0.5M N_2H_4, 0.03M NaOH.

pressure of oxygen over silver oxide reaching 1 atm at 184°C (16). Decomposition of the oxide is also catalyzed by metallic silver. However, the decrease in resistivity at room temperature is not due to oxide decomposition.

These silver films were observed with a scanning electron microscope in the as-plated condition and after heating at 100°C. There was no apparent change in film morphology either with time or the 100°C bake. A weight loss of 0.5-1.0 mg is typically observed upon heating to 100°C and the silver films have a whiter luster. The weight loss observed is also independent of film thickness. Therefore it appears that a compound is deposited on the surface of the silver that is either volatile or decomposes to silver and a volatile compound.

It is generally undesirable and in many cases impossible to heat-treat a silver deposit at 300°C to achieve the resistivity of pure silver. However, it is often possible to lower the resistivity of the metal film by proper adjustment of the reactant concentrations. The net reaction for the reduction of silver ion by hydrazine can be presented by the following equation

$$4Ag^+ + N_2H_4 + 4\,OH^- \rightarrow 4Ag + N_2 + 4H_2O$$

Although this equation does not show all the steps involved in the actual reduction of silver ion by hydrazine, it does indicate that such factors as silver ion activity, hydrazine concentration, and reaction pH will be important in determining plating rate and film quality (oxide content, porosity, etc.)

Figure 3 shows the effect of hydrazine concentration on silver plating rate at several concentrations of the silver-EDTA complex. Hydrazine has little effect on plating rate above a molar ratio of 10. This is in marked contrast to the dependence observed when aerosol plating copper with hydrazine (9). The slight increase in plating rate at the higher hydrazine concentrations is due to an increase in the total alkalinity of the reductant by the additional hydrazine. The silver film resistivity did not vary appreciably over N_2H_4/Ag^+ molar ratios from 10 to 100.

Figure 4 illustrates the dependence of plating rate on concentration of the $(EDTA)_xAg^+$. There is no substantial difference in film resistivity over the range of plating rates investigated (0.3 to 0.9 μm/min).

The silver ion activity in the metal solution can be decreased by increasing the ligand/metal ion ratio. Figure 5 indicates that the film resistivity decreases with decreasing silver ion activity. However, this is an inefficient method by which to decrease film resistivity because the plating rate also decreases substantially. Figure 6 indicates that the plating rate at the high ligand/metal ion ratio can be increased slightly without adversely affecting silver resistivity by increasing the pH of the silver-EDTA solution. The plating rates are somewhat lower in this test because the metal

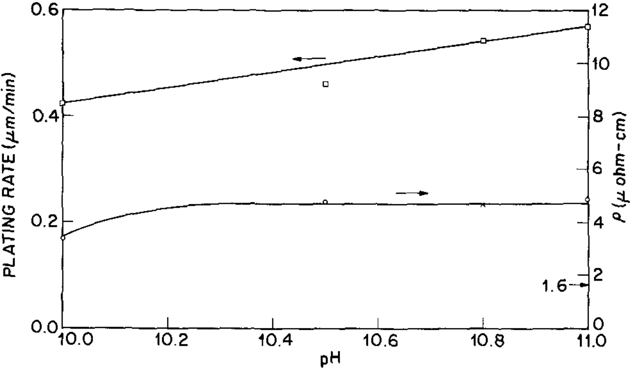

Fig. 6. Effect of pH of metal solution. Plating solutions: 0.08M Ag^+, 0.8M EDTA; 1.0M N_2H_4, 0.1M NaOH. 43 ml/min, 120°C bake.

solution flow was about 10% lower than desired. The optimum molar ratio of $EDTA/Ag^+$ would appear to be from 2 to 4 on the basis of both plating rate and film resistivity.

The most critical parameter in aerosol silver plating is the pH of the spray mixture. Changes in atomization and mixing conditions, liquid flow rates, pH of the metal solution, and sodium hydroxide in the reductant all affect this reaction parameter. The pH of the silver-EDTA complex was controlled to ± 0.1 pH unit in this work. Plating rate was adjusted to the desired value with sodium hydroxide additions to the reductant. Figure 7 shows plating rate and film resistivity as a function of sodium hydroxide additions to the hydrazine solution. A substantial increase in plating rate is obtained upon increasing the sodium hydroxide concentration from 0.03 to 0.05M. However, more silver oxide is codeposited with the silver at the higher sodium hydroxide concentrations.

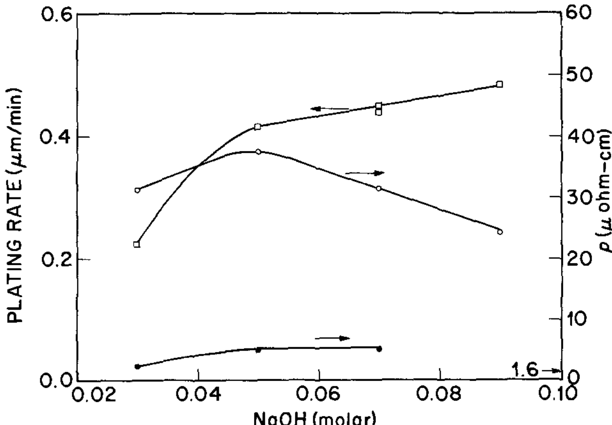

Fig. 7. Effect of OH^- concentration in N_2H_4 solution. Plating solutions: 0.04M Ag^+, 0.16M EDTA, pH 10.5; 0.5M N_2H_4. Resistivity: initial, ○; 200°C bake, ●.

Pure silver films were not obtained with the silver-EDTA complex by adjustment of either the hydrazine concentration, silver and EDTA concentration, or reaction pH. The steady-state resistivity of the deposited silver films typically ranged from 4 to 10 µohm-cm. The deposits have a metallic appearance but evidently some silver oxide and an unstable silver compound are codeposited with the silver. The film resistivity of pure silver can only be achieved by a thermal treatment at 300°C.

Aerosol silver plating with the en and ammonia complexes was also evaluated with hydrazine using the optimum reducing conditions found for the EDTA complex. Table II compares typical plating results of the three silver complexes with hydrazine. The silver-en complex was tested at an en/Ag^+ molar ratio of 2 and pH 10.5 while the silver-ammonia complex was tested at a NH_3/Ag^+ molar ratio of 4 without pH adjustment (pH slightly greater than 11). It is evident that the ammonia and en complexes are far superior to the EDTA complex for aerosol plating silver with hydrazine. The plating rates are much more rapid and the resistivities substantially lower. However, even the silver films deposited from the en and ammonia complexes exhibit a significant decrease in resistivity during a thermal treatment at 120°C. There also appears to be some silver oxide codeposited with the silver as evidenced by the final resistivity readings after the 120°C bake.

Aerosol Silver Plating with Formaldehyde

Aerosol silver films deposited with formaldehyde are considerably brighter than those deposited with hydrazine. A milky brown cast generally develops on thick silver films deposited with hydrazine, indicating the presence of silver oxide. Initial aerosol plating experiments with formaldehyde indicated that en was a suitable ligand for the silver but that EDTA was not. Blue deposits were obtained with the EDTA complex which have quite high resistivities (greater than 1000 µohm-cm). A thermal treatment at 120°C reduces the resistivity to about 20 µohm-cm but the deposit is still of poor quality. The aerosol silver process was therefore optimized with the silver-en complex.

Table II. Aerosol silver plating* with hydrazine

Ligand	Plating rate (µm/min)	ρ(µohm-cm) 22°C	ρ(µohm-cm) 120°C
EDTA	0.9	7	3-5
en	1.3	3-4	1.8
NH_3	1.9	2.8	1.9

* 0.08M silver complexes. Resistivity at ambient temperature and after heating.

The net reaction for the reduction of silver ion by formaldehyde can be represented by the following equation if complete oxidation of formaldehyde is assumed

$$4Ag^{+} + HCHO + 2\,OH^{-} \rightarrow 4Ag + CO_3^{=} + 4H^{+}$$

The reduction of silver ion by formaldehyde is analogous to the hydrazine reduction and therefore the same general reaction parameters can be expected to affect plating rate and film quality. Lower plating rates are obtained with formaldehyde because it is a slightly weaker reducing agent than hydrazine (18). The most important parameter is again the pH of the reaction mixture.

Figure 8 shows that the silver plating rate varies directly with the concentration of alkali in the reductant. Unlike the hydrazine process, the resistivity of pure silver can be achieved by a thermal treatment at 120°C. This indicates that the silver oxide content of the deposit is quite low under the proper plating conditions. In this test, the silver oxide content of the film is significant only at sodium hydroxide concentrations above 0.06M. However, the films still exhibit a resistivity 2-3 times greater than pure silver in the as-plated condition. A 0.5-1.0 mg weight loss is also noted after a 120°C bake.

Figure 9 shows that the formaldehyde concentration is not very critical in this process. A molar rate of $HCHO/Ag^{+}$ near 9 appears to be the optimum. The decrease in plating rate at the higher formaldehyde concentration is a pH effect. Commercial formaldehyde is marketed as a mildly acidic solution to minimize chemical decomposition. Total alkalinity of the reductant is therefore lower at higher formaldehyde concentrations when a fixed amount of sodium hydroxide is added.

An attempt was made to identify the unstable compound deposited with the silver during aerosol plating.

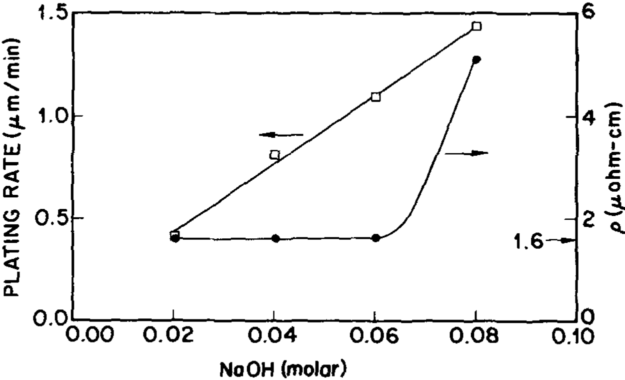

Fig. 8. Effect of OH^{-} concentration in HCHO solution. Plating solutions: 0.08M Ag^{+}, 0.16M en, pH 10.5; 0.75M HCHO. 120°C bake.

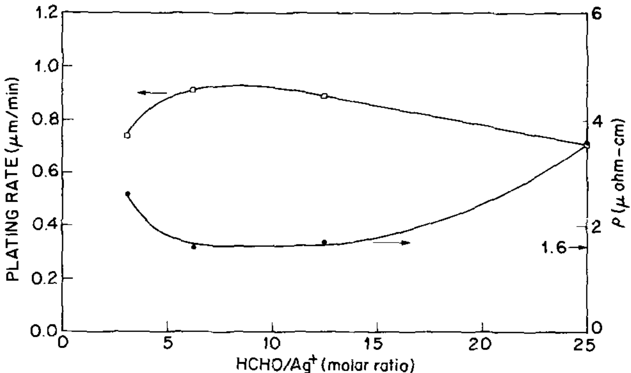

Fig. 9. Effect of $HCHO/Ag^{+}$. Plating solutions: 0.08M Ag^{+}, 0.16M en, pH 10.5; 0.05M NaOH. 120°C bake.

The silver films in the as-plated condition generally have a blue-gray tint, the degree dependent upon which spray solutions are used. The films become noticeably whiter after a thermal treatment at 120°C and exhibit a corresponding weight loss and decrease in resistivity. The weight loss is independent of sample size in the range from 0.4 to 1.8g silver and the weight loss is greater in films deposited from the EDTA complex (3-6 mg) than from the en complex (1-2 mg).

Gas chromatographic analysis of the gases evolved during thermal treatment of the silver films indicates that carbon dioxide is the principal species. The carbon dioxide detected was a hundredfold higher than the background level in silver films deposited from the en complex and a hundredfold higher from the EDTA complex. Water, oxygen, and nitrogen were also generally detected but those constituents were not substantially higher than the background levels. Immersing the films in a dilute sulfuric acid solution after plating produced a significant decrease in resistivity and a weight loss. The films were also noticeably whiter. The carbon dioxide detected after thermal treatment was 50-75% less for silver films immersed in sulfuric acid. These data suggest that the unstable material is either silver carbonate or a silver carboxylate compound.

It is unlikely that the unstable compound is silver carbonate. Silver carbonate is a brilliant yellow-green color and decomposes at a temperature of 218°C (13). The material in the silver films is a blue-gray color and decomposes rapidly at 120°C. The silver films after thermal treatment have the metallic white luster of silver and exhibit the electrical resistivity of pure silver. If silver carbonate were decomposing at this low temperature it would yield silver oxide (brown) and the films would not exhibit the resistivity of pure silver. The resistivity data and color observations would, therefore, tend to eliminate silver carbonate as the contaminant.

The unstable material in the aerosol silver films would appear to be a silver carboxylate, probably silver formate in the case of the en-HCHO system. Formate is present in the HCHO reductant as a result of both the Cannizzaro reaction (12) and incomplete HCHO oxidation during reduction of the silver complex. The color of pure silver formate would probably be white; however, some metallic silver in the material might tend to impart color (analogous to AgCl). Formic acid is a weaker reducing agent than HCHO (18) but is capable of reducing silver in alkaline media. The addition of sodium formate to the $(en_2)Ag^{+}$ complex produced no visible reaction at a pH of 10.6. Increasing the pH to 11.5 produced a gray powder and the solution had a light bluish cast. Thermal decomposition of silver formate would yield only metallic silver, carbon dioxide, and hydrogen. Hydrogen was not detected in the gas chromatographic analysis due to the helium carrier gas.

The silver-en complex is not as stable to decomposition as either the silver-ammonia or silver-EDTA complexes. Part of the difficulty appears to arise from impurities in the commercial 98-100% en and further purification (19) is desirable for best solution stability. The stability of the silver-en complex is also affected by molar ratio of en/Ag^{+}, pH, and mixing conditions. The complex is not very stable at a ligand/metal ion molar ratio below 2.5 but good stability is achieved at a molar ratio of 5. Figure 10 shows a substantial reduction in plating rate at the higher molar ratio although film resistivity does not change appreciably over the range of molar ratios from 2 to 8. Stability of the silver solution is diminished at pH values below 10 or above 11. In preparing the $(en)_2Ag^{+}$, the pH of the en solution should be adjusted to 10.60 with nitric acid and cooled to 23°C before addition of the silver nitrate. During addition of the silver nitrate, maintain pH near 10.6 by adjustment with sodium hydroxide.

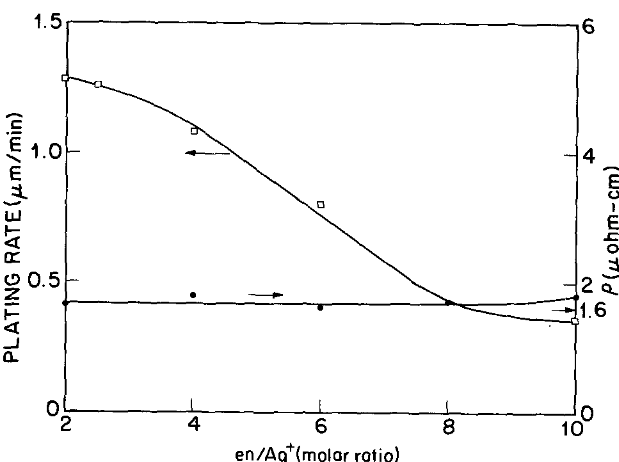

Fig. 10. Influence of en/Ag^+. Plating solutions: 0.08M Ag^+, pH 10.5; 0.75M HCHO; 0.06M NaOH. 120°C bake.

Filter the solution through a glass frit if any silver decomposition (black precipitate) is noted within 24 hr after preparation. A moderately stable metal solution is obtained at an en/Ag^+ molar ratio of 2.5 by this procedure. The pH of the solution remains constant at 10.60 ± 0.02 over a period of 1 week without silver decomposition, although the plating rate tends to decrease somewhat with solution age.

Figure 11 shows the relationship between plating rate and silver-en concentration when an attempt is made to neutralize the acid added with the formaldehyde. A linear dependence is apparent and good quality films are obtained over the entire concentration range. The data obtained in this test indicate that the molar ratio of NaOH/HCHO should be near 0.08. The data points at 0.02 and 0.04M silver-en concentrations were at NaOH/HCHO molar ratios of 0.17 and 0.11, respectively. Higher plating rates than 1.6 μm/min can be achieved by using silver-en concentrations greater than 0.12M. However, aerosol plating efficiency (7, 8) generally decreases with increasing metal ion concentration and economics of the process will be affected accordingly.

The deposition efficiency of the en-HCHO spray formulation was determined at 0.15M Ag^+. At this concentration, 55% of the Ag^+ sprayed was obtained in the deposit. It should be possible to increase efficiency slightly by reducing the Ag^+ concentration and optimizing spray parameters. However, 60-70% efficiency would appear to be the practical upper limit for aerosol plating processes (7, 8).

Table III summarizes the plating results with formaldehyde. The EDTA complex is unsuitable with this reducing agent. The ammonia complex produces the purest deposits in the as-plated condition and the rates are somewhat higher than with the en complex. However, care must be exercised in storage of this complex to prevent the formation of the explosive silver imide or azide. The en complex produces plating results comparable to the ammoniacal complex and may be less hazardous. Silver-en solutions have been stored for periods in excess of 1 year without any difficulty.

Summary

Aerosol silver films deposited with formaldehyde have a lower electrical resistivity than those deposited with hydrazine (compare Tables II and III). The electrical resistivity of pure silver can be achieved with deposits from formaldehyde by a brief thermal treatment at 120°C. The films as deposited appear to contain a small amount of some compound, probably silver carboxylate, on the surface which decomposes to silver and carbon dioxide at temperatures above 22°C. Films deposited with hydrazine also exhibit a weight loss and decrease in resistivity in this temperature range. Some silver oxide is also codeposited with the silver in the hydrazine process and a thermal treatment at 200°-300°C is required to achieve the resistivity of pure silver.

The ligand used in the aerosol process has an effect on the electrical resistivity of the deposited film. EDTA produces the highest resistivity films while en and ammonia produce deposits with or near the resistivity of pure silver. Ammonia is not preferred because it has the potential to form explosive compounds in the silver solution upon standing.

The recommended aerosol silver process for producing low resistivity films utilizes en as the silver ligand and formaldehyde as the reducing agent. This system produces deposits comparable in quality to those obtained from the ammonia complex and the metal solution may not be as hazardous. The optimum composition of the silver solution is en/Ag^+ molar ratio ≥2.5. The pH should be maintained at 10.5-10.6 for best stability. The reductant consists of a mixture of formaldehyde and sodium hydroxide with the molar ratio of NaOH/HCHO near 0.08. The optimum molar ratio of HCHO/Ag^+ is near 9. Plating rates from 0.3 to 1.6 μm/min have been obtained by varying the concentration of the silver-en complex from 0.02 to 0.12M. As-plated films have an electrical resistivity twice that of pure silver. A brief thermal treatment at 120°C reduces resistivity to the value for pure silver.

Carbon in Gold Electrodeposits

H. A. Reinheimer*

Bell Laboratories, Incorporated, Reading, Pennsylvania 19604

ABSTRACT

Gold electrodeposits plated from pure phosphate and citrate buffered $KAu(CN)_2$ solutions can become contaminated with carbonaceous material which originates from the metal complex. The level of impurity in gold foils can be made to vary in a range from essentially 0 to 1300 ppm of carbon as a function of plating temperature, and, at room temperature, as a function of solution pH, current density, and buffer ion composition. The morphological characteristics of the deposited gold surface, however, were found to be influenced by the extent of bath usage, and such plating parameters as current density and bath temperature, rather than by carbon content. Hardness and brittleness increase with carbon content.

It has been recognized in recent years that carbonaceous materials can be incorporated into electrodeposited gold (1-10). Primary attention was paid to baths containing hardening agents, such as cobalt and nickel, as it became apparent that in deposits plated from such formulations rather large quantities of carbon were imbedded, namely as much as tenths of a per cent by weight.

In this investigation so-called pure, soft-gold bath formulations were utilized exclusively, which contain only potassium cyanoaurate(I) and a buffer system in aqueous solution.

Objectives of this work were (*i*) to establish relationships between the appearance of electrodeposited gold and its content of carbonaceous contaminants; (*ii*) to determine the conditions under which incorporation of such carbon-containing materials are enhanced; and (*iii*) to trace the origin of these contaminants.

In order to analyze for carbon in gold a commercially available apparatus[1] was used, which combines a classical type of combustion with a gas chromatographic means of detection, and an automatic readout by which it is capable of detecting as little as 1 ppm. With metallic samples (such as standard steel materials supplied by the National Bureau of Standards) at a 20 ppm level a precision of ± 1.5 ppm was generally achieved.

Observations of surface features were performed with a scanning electron microscope (MAC 700).

Results and Discussion

Aging of baths operated at 65°C.—It is commonly known that the appearance of gold electrodeposits undergoes undesirable changes from bright yellow to dark brown as the age of a bath increases with use, although all operating parameters are kept constant or within a narrow range during the deposition process.

Two different buffer systems similarly operated [a potassium phosphate buffer at pH 10, and an ammonium citrate buffer at pH 4.7 (Table I)] were used to study these changes in morphology of the deposits and the carbon incorporation in the gold. Hardness and brittleness characteristics were also determined.

From 1.5 liters of the phosphate buffered plating solution, sets of two gold-struck Rodar[2] disks (10 cm^2 each) and one molybdenum rectangle (2.5×5 cm) were plated at 7.5 mA/cm^2 to yield sufficient gold (approx. 1g) on the molybdenum substrate for carbon analyses and a thickness of more than 30 μm on the disks to determine hardness. A total of 23 sets were plated from the phosphate-buffered solution. The bath was replenished whenever it had been depleted by ~30% of its original gold metal content. By replenishing the bath four times, a total of 65g of gold was plated out, corresponding to 95g of gold potassium dicyanoaurate(I). The objective of working the bath to this extent was to enhance any side reactions that might occur, such as the formation of polymeric material, which could lead to subsequent incorporation of carbon into the gold deposit. The anode was a platinum wire (0.08 mm diameter). Vigorous agitation was provided by attaching the cathode specimens horizontally onto a vertical moving impeller (3 cm vertical stroke at ~250 rpm). A small anode area was found to provide much more uniformly plated deposits when used with this type of agitation than those obtained with a larger geometry. This effect may be due to the rapidly changing position of the cathode.

The cathodic current efficiencies were found to be 95-99+%, except for the plating of the last 4 sets when the bath was electrolyzed to full depletion of its gold content. Since pH changes were minute (slight increases), corrections were made only when the bath was replenished.

Carbon analyses of the foils indicated practically no organic contamination. As the age of the solution in-

creased with use, no increase of carbon was found in the deposits (see Fig. 1). The general level was 0-20 ppm with maxima approaching slightly over 30 ppm.[3]

The morphology of the deposits, however, exhibited marked alterations as the age of the bath increased, when the gold concentration was replenished, or when solution purification by charcoal treatments were applied.

As the plating process was continued at a constant current density of 7.5 mA/cm², the structure gradually changed from a lateral smooth weblike type growth with high reflectivity or bright appearance to an acicular outward type growth with low reflectivity and brown color (see SEM micrographs, Fig. 2, parts 1-8, representing deposits plated in sequence). The latter structure is very similar to what can be observed when a current density higher than ~10 mA/cm² is applied with a freshly made-up bath. As the gold concentration is restored to its original level, some brightening of the color, and consequently decreased acicular features, may be observed in the SEM micrograph (Fig. 2, part 4). However, very soon after less than 10% of further gold has been removed, (Fig. 2, part 5), the rough surface characteristic returns, and additional replenishments made later in the aging process do not reproduce the brightening effect (Fig. 2, part 6).

Thus, a decrease in gold concentration which occurs during continuous plating at constant current density is not the only reason for morphological changes. Since the deposited gold does not contain any increased amounts of imbedded organic materials, there is an implication that constituents are generated in solution which cause alterations in the deposition process, or alternatively, an inherently present species is being depleted.

Upon further continued plating and without implementation of a purification treatment, the deposit will only appear darker (Fig. 2, part 7). Once the gold concentration reaches very low levels near the depletion of the bath, the gold becomes almost dendritic, discontinuous, and very dark in appearance (Fig. 2, part 8).

The change in morphology is also accompanied by a change in the cathodic deposition potential. When operating a bath at constant current density and a narrow range of gold concentration (*e.g.*, 12.5 g/liter ±10%) the deposition potential after an initial stabilization period decreases slowly toward more negative values, *e.g.*, at pH 10, 65°C, and 7.5 mA/cm², a cathodic potential[4] range from approximately −800 to −980 mV can be observed during an aging process that involves several turnovers of the original gold content of the bath. At potential readings between approximately −800 and −900 mV a bright surface develops, whereas an off color or brownish deposit is obtained once the deposition potential drops below −900 to −930 mV.

Chemical analysis of the depleted bath supplied information about polymeric matter, free cyanide ions, and residual gold concentration. Extraction of the major portion of the depleted solution with ethyl acetate yielded a small quantity (<100 mg/liter) of oily yellowish polymeric material, which was characterized by *IR* (see Experimental Appendix) and found to be similar to samples, which were isolated from potassium cyanide solution polymerization reactions. At high pH and 65°C most of the liberated cyanide would undergo hydrolysis to formate and carbonate, as was reported by Silver (8); consequently, the concentration of free cyanide ion in solution would vary with its rate of hydrolysis. In this bath, immediately after completion of the plating experiments, a total of 6.7 g/liter of free cyanide ions was found by titration with silver nitrate (potassium iodide as indicator) to account for almost 40% of all cyanide liberated. After storing the solution for several days, much less free cyanide was found. The residual gold concentration in solution was determined to be 0.015 g/liter.

Hardness data were found to vary between 85 and 100 Knoop[5] for a 25g load. No up or downward trends were observed, although large morphological variations were found. The deposits are very ductile and pass wire wrap tests (see Experimental Appendix).

The second series of hot bath aging experiments was done with a citrate formulation as shown in Table I, bath composition 2. Plating conditions were the same as for the phosphate bath, namely 7.5 mA/cm² current density, at 65°C. Sets of 2 rodar disks and 1 molybdenum rectangle were plated from 1.5 liters solution volume. A total of 60g of gold was plated from the bath, corresponding to 88g of $KAu(CN)_2$. Cathodic efficiency was 91-99%.

Basically the same information was obtained, namely, very low carbon content (Fig. 1), and gradu-

[3] Handling of the parts (rinsing, boiling in deionized water, drying, bottling, weighing, transferring, etc.) should be regarded as a potential source of contamination at this very low level. Great care was taken to avoid any contact with organic contaminants from outside origins.

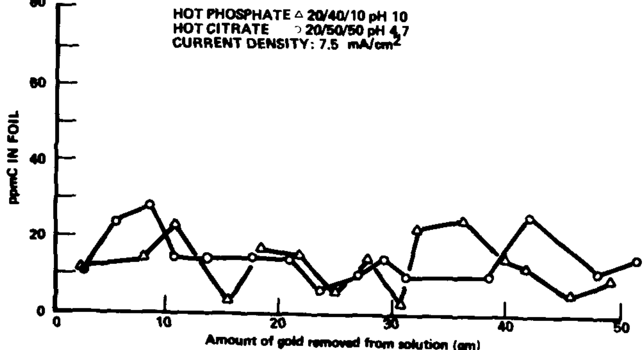

Fig. 1. Carbon content of gold deposits as a function of bath age

[4] Cathodic potentials referred to calomel electrode.

[5] These values are high, due to the manner of agitation, as explained in Table II.

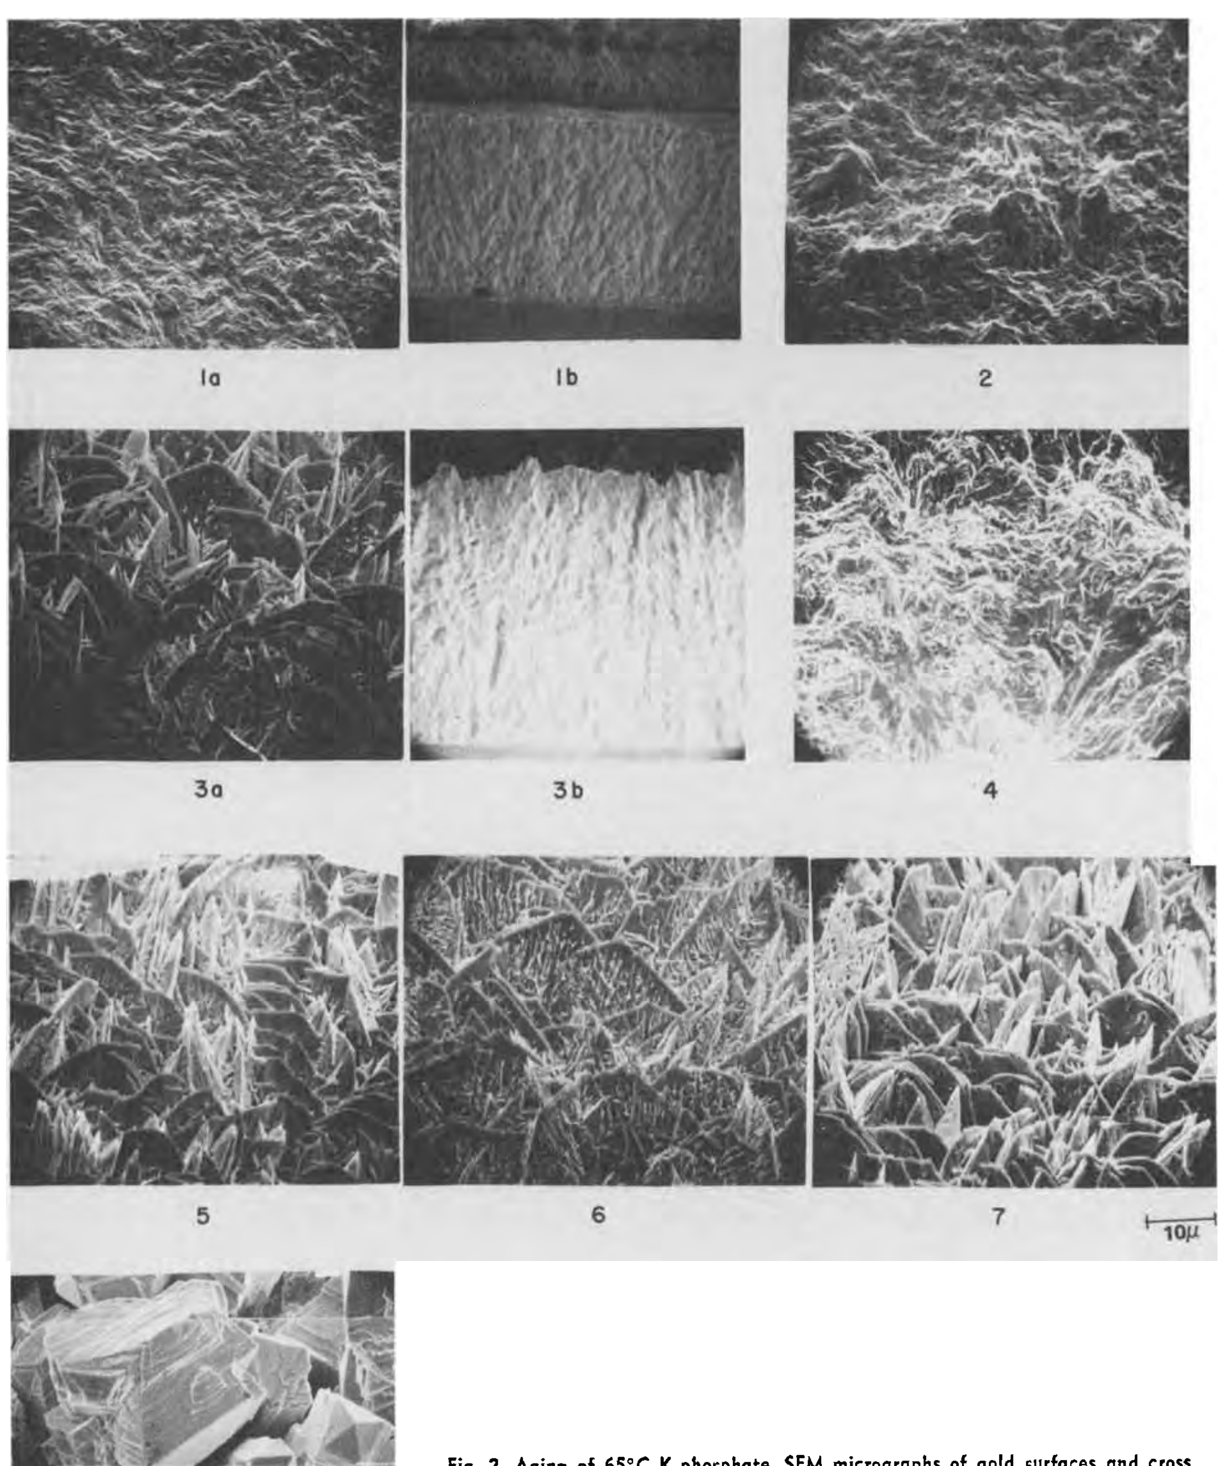

Fig. 2. Aging of 65°C K-phosphate. SEM micrographs of gold surfaces and cross sections of deposits plated from the potassium phosphate buffered bath, part 1, Table I. 2000× magnification. Parts 1a and b, new bath; part 2, approximately 20% of gold removed; parts 3a and b, approximately 30% of gold depleted; part 4, after replenishment with $KAu(CN)_2$ to 20 g/liter; part 5, after again 10% of gold depleted; part 6, after third replenishment with $KAu(CN)_2$ to 20 g/liter; part 7, 30% depleted; part 8, bath near depletion.

ally changing surface features from a lateral crystalline to an outward type growing pattern (Fig. 3, parts 1-4).

Hardness values obtained were between 99 and 109 Knoop for a 25g load. The average thickness of the deposits was 40 μm.

The results of chemical analysis of the depleted solution diverged somewhat from what was found in the phosphate bath. It was observed that after removal of about 20% of gold by electrolysis, the solution had turned visibly to clear yellow. Extraction of the depleted citrate gold bath with ethyl acetate now showed a small quantity of a product, which was identified and shown to consist of a mixture of a product due to a citrate degradation and a cyanide derivative. Separation of both constituents was not undertaken since the quantity was too small. A similar discoloration was obtained when a solution of dibasic ammonium citrate alone was electrolyzed. Anodically, the citrate is oxidatively attacked to form an orange brownish oil, which could be isolated from electrolyzed pure dibasic ammonium citrate solutions. Ex-

Table II. Properties of deposits from hot baths

Bath	pH	Current (mA/cm^2)	Appearance*	Hardness** (Knoop)	Brittleness	ppm C*** (avg)

cept for *IR* spectroscopic characterization further identification was not pursued.

Free cyanide was present to only 0.05 g/liter (after the *p*H was adjusted to 11 in the analysis sample), indicating that free hydrogen cyanide (HCN) does not accumulate to high concentrations in the bath at *p*H 4.7. A strong smell was recognized during the operation of the bath, indicating the probable escape of HCN.

Although the basic bath composition changed in a different way with respect to the free cyanide and citrate constituents, electrolysis of the bath produced similar changes in the morphology of the deposits. Also, the yellow oily citrate derivative, isolated from electrolyzed dibasic ammonium citrate solutions, proved to be cathodically inactive and did not change morphological characteristics when added to a fresh plating bath.

In view of these results, effort was directed toward obtaining information about the material which causes the change in the deposition process to promote the undesirable outward-type growth of deposit. Since it was not codeposited in sufficient quantities for routine characterization, an indirect approach was adopted.

Contamination of a bath with organic materials.—A variety of materials, which can be derived from cyanide ions in an aqueous environment, was purposely added to a phosphate bath to study the influence upon the appearance of the deposit. The Hull cell represents a sensitive tool for such tests, because a current density range from 0 to 22 mA/cm^2 can be obtained on one panel (10 × 6.8 cm). Thus, the current density at which the deposit changes from a bright to a dark appearance can readily be observed on the rectangularly shaped panel. Quantities of approximately 500 mg of each of the following materials per 550 ml solution (size of Hull cell) were added to samples of a fresh phosphate buffered bath and allowed to dissolve:

CN^-	free cyanide ions as potassium cyanide
HCN	hydrogen cyanide
$HCONH_2$	formamide
HCO_2K	potassium formate
H_2CO	formaldehyde
$(HCN)_4$	tetramer of HCN, diaminomaleonitrile
CN-polymer	isolated from KCN polymerization by extraction
$(CONH_2)_2$	oxamide
$(CONHOH)_2$	oxalhydroxamic acid
H_2NCH_2COOH	glycine
$C_5N_5H_5$	adenine

Subsequently, a panel was plated at 0.5A total current for 5 min plating time.

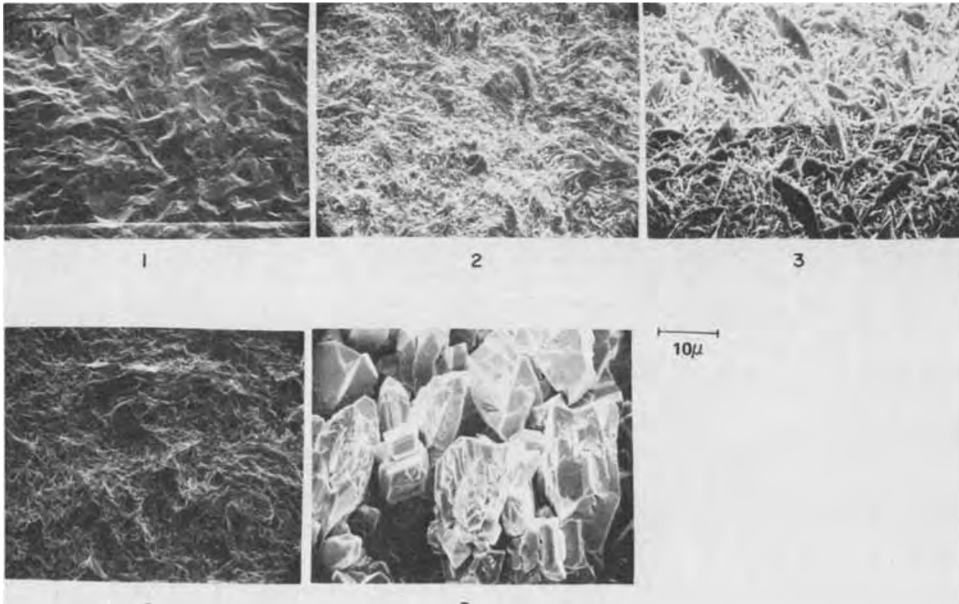

Fig. 3. Aging of 65°C ammonium citrate. SEM micrographs of gold surfaces of deposits plated from the ammonium citrate buffered bath 2, Table I. 2000× magnification. Part 1, new bath; part 2, after approximately 20% of gold was depleted; part 3, after approximately 30% of gold was depleted; part 4, after first replenishment with $KAu(CN)_2$ to 20 g/liter; part 5, bath near depletion.

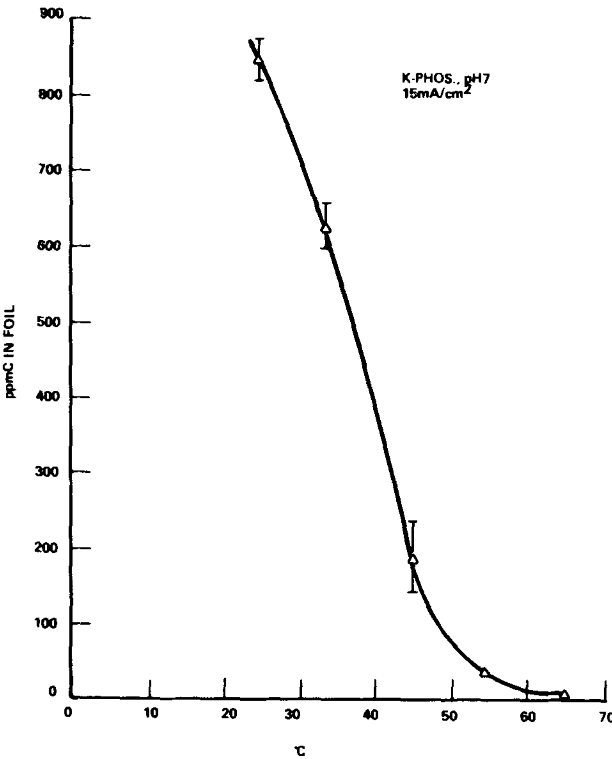

Fig. 4. Carbon content in gold deposits vs. bath temperature

None of the components listed influenced the appearance of the deposit visibly. This rather negative result suggests that either the electrochemically active species would be a chemically unstable intermediate, or that a new bath would contain a hitherto undetected desirable species, which quite independent of any buildup of organic materials, is continuously depleted during the electrodeposition, and thereby would cause the change in morphology.

Table III. Appearance classification

	Visual		SEM	
No.	Appearance	Color	Characteristics	Growth
1	bright, glossy	yellow	sectional sphericals	lateral
2	bright, hazy	yellow	sphericals, irregular	lateral
3	matte, hazy	ochre	needle-type	outward
4	bright	yellow	crystalline	lateral
5	matte, smooth	yellow	"webblike"	lateral
6	matte	dark yellow	transitional*	lateral/ outward
7	matte	ochre	mostly acicular	outward
8	dull	brownish	acicular or spherical or crystalline	outward
9	dull	brown	same as 8**	outward
10	dark	brown	same as 8**	outward

* Beginning structural change from lateral to outward type.
** Increase in vertical growth and discontinuity.

Fresh baths.—When using freshly made up solutions under a variety of conditions at 65° ± 2°C as outlined in Table II (hot baths), it was determined that none or very small amounts of carbon were contained in the deposits. Dark deposits plated at high current density were found to be equally pure as compared to bright deposits plated at low current density.

However, when the plating temperature was lowered in steps of 10°C, a subtle increase of carbon in the gold deposits was discovered. Figure 4 shows this as an example for a potassium phosphate buffered bath at pH 7, operated at a current density of 15 mA/cm^2.

A repetition of all plating experiments at 25°C instead of 65°C, gave insight into the conditions under which the incorporation of carbonaceous matter appeared to be enhanced, such as increasing current density, decreasing solution pH, and changing buffer ions. Table IV summarizes the experimental findings. Specifically, the relationships of the carbon incorporation into the deposit *vs.* current density and solution pH are depicted in Fig. 5 and 6 for the potassium phosphate and ammonium citrate buffered formulations, respectively.

An increase of current density increases the carbon, though the gradient of the increase is not constant. There is a pH dependency, notably in acidic and neutral media, where the current density affects the level of contamination significantly. At increasing alkalinity of the solution, the carbon contamination diminishes. In deposits from a potassium phosphate system at pH 12 and 3 mA/cm^2, a minimum of approximately 300 ppm, and at pH 4.5 and 15 mA/cm^2, a maximum of around 1300 ppm, were detected (Fig. 5). When ammonium ion acts as the cation of the buffering salt, then a much lower level of carbonaceous contamination is obtained. The same general trends, however, are observed: an increase of carbon content with increasing current density, and a slight increase of contamination with decrease of pH. However, the maximum now is only about 600 ppm of carbon, whereas the minimum contents are below 100 ppm at low current densities (Fig. 6).

Bright, glossy, yellow deposits can be obtained, *e.g.*, from a phosphate or citrate buffered formulation at 10 mA/cm^2 to approximately 50 mA/cm^2, although at the high current densities (higher than 20 mA/cm^2), it becomes more and more dependent on the mode of agitation. Vigorous agitation is required to obtain best results. "Bright" in this context means glossy yellow, as compared to the matte crystalline yellow appear-

ance of deposits from hot baths (Table III, parts 1 and 4).

Morphological differences as viewed by the scanning electron microscope are pronounced as well. Whereas surfaces of hot bath plates are crystalline with lateral growths, a rather featureless topography characterized with spherical segments is observed on deposits from room temperature baths (Fig. 7, part 2; Fig. 8, part 1; Fig. 9, part 1).

The bulk of the deposit, as shown in Fig. 8 and 9, is very homogeneous, displays columnar type growth, and does not contain any layers of foreign material.

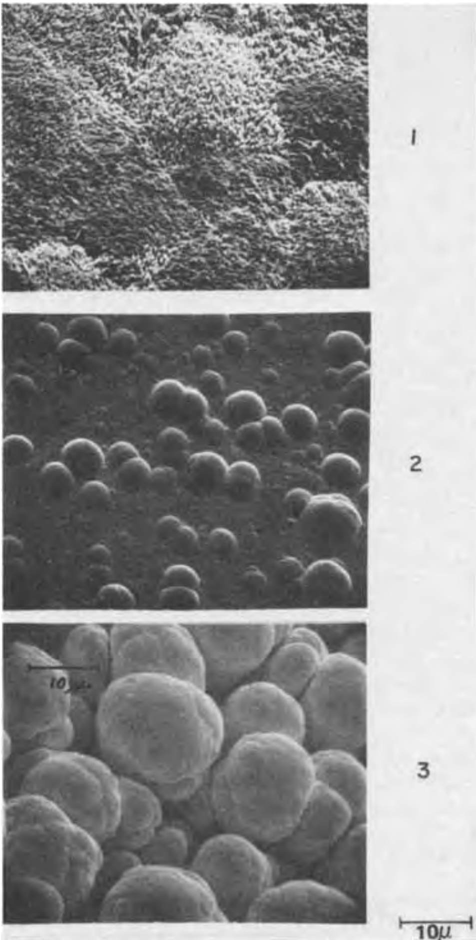

Fig. 7. SEM micrographs of gold surfaces of deposits generated in a potassium phosphate buffered bath at room temperature (100 g/liter KH_2PO_4, 40 g/liter $KAu(CN)_2$, pH 4.5). Part 1 at 3 mA/cm^2; part 2 at 25 mA/cm^2; part 3 at 60 mA/cm^2.

Dark deposits are obtained both at low current densities (<5 mA/cm^2) and at very high current densities (>50 mA/cm^2). It should be noted that this differs significantly from the behavior of the hot plating baths, which exhibit yellow crystalline deposits preferably at very low current densities, and extend only to a general maximum of about 10 mA/cm^2. The matte brownish surface observed at low current densities is shown in Fig. 7, part 1. This is a typical outward-type growth of very fine needlelike features, less than 1 μm in width. Quite different from this is the growth at the very high current densities, which consists of discrete sphericals packed randomly on top of one another, and resulting in a very weakly adherent, porous deposit. The particle size varies between 1 and 15 μm and the color of the surface appears brown as well (Fig. 7, part 3).

Further information about the physical properties of gold deposits was gained by determination of hardness and brittleness (See Tables II and IV).

The following relationships could be established for deposits plated from baths at 25° and 65°C:

(*i*) Much harder deposits result from high as well as low current density plating at room temperature *vs.* plating at 65°C.

(*ii*) Hardness increases with current density for both 25° and 65°C baths.

(*iii*) Hardness decreases with an increase in *p*H. A similar trend exists for the carbon content in foils plated from cold baths, although no direct relationship with hardness could be established.

Fig. 8. Aging of 25°C K-phosphate. SEM micrographs of gold surfaces (a) and cross sections (b) of deposits plated from the potassium phosphate buffered bath 1, Table VI. Part 1, fresh bath; part 2, after approximately 20% of gold depleted; part 3, approximately 30% gold depleted; part 4, bath replenished with $KAu(CN)_2$ to 40 g/liter; parts 5 and 6, further increased age of the bath; part 7, bath near depletion.

(*iv*) The hardness of a deposit does not depend on the kind of buffering salt. Ammonium salts delivered a hardness similar to that of potassium salts, when plated under identical conditions. The carbon content, however, does depend strongly upon the kind of cation used. Thus, it can be concluded that the similarity in trend between carbon content and hardness is coincidental.

Brittleness of deposits from cold baths, however, appears to show a relationship to the level of carbonaceous contamination (Table V). All foils from hot baths, containing very low quantities of organic materials, as well as all deposits from cold formulations, which contained less than 350 ppm of carbon, passed wire wrap tests. All coatings with more than 520 ppm of carbon very clearly appeared to be brittle, and resulted in cracking upon wrapping. In the range between 350 and 500 ppm inconsistent results were obtained with some of the deposits exhibiting definite cracks, and others showing only slight evidence of cracking.

Undoubtedly it is surprising to discover that relatively large quantities of carbon-containing materials can be codeposited electrolytically, especially when working with freshly prepared cold baths. Therefore, it was essential to determine if any change in the content of this unknown material in gold deposits would occur as the bath was exposed to continuous use.

Aging of baths operating at room temperature.—Experiments were carried out with both baths at room temperature (see Table VI for formulations and plating conditions). From the phosphate bath, 26 sets of 2 rodar disks and 1 molybdenum sheet were plated, corresponding to a total of 75.8g of gold removed from a 1.5 liter solution volume. From the citrate formulation a total of 33 sets of parts were plated with a total of 70g of gold from the same solution volume.

A carbon analysis was obtained from every set, so that it was possible to follow the change or possible

Fig. 9. Aging of 25°C citrate. SEM micrographs of gold surfaces (a) and cross sections (b) of deposits plated from the dibasic ammonium citrate buffered bath 2, Table VI. Part 1, fresh bath; parts 2 and 3, increased age of solution (approximately 20 and 30% gold depleted); part 4, bath replenished with $KAu(CN)_2$ to 40 g/liter; part 5, after further 20% of depleting; part 6, bath near depletion.

increase of carbon in the gold as a function of accumulation of organic materials in solution with increasing age of the bath.

Foils plated from the phosphate bath contained on the average 1000 ppm of carbon, including those plated at the initial stages (Fig. 10). Towards the end of the experimental series, when the gold concentration dropped to very low levels, the carbon content in the foil decreased markedly. At the same time the cathodic efficiency decreased drastically, since more and more hydrogen was evolved.

The citrate bath produced somewhat different results for the codeposition of this carbonaceous material. As found earlier with fresh baths in the presence of ammonium ions, a lower concentration of carbon was found initially. After about 15g (25%) of gold were plated from the bath, a significant increase in carbon content occurred which averaged about 800 ppm. Though somewhat lower in carbon content than the foils plated from the phosphate bath, the carbon level remained high with fluctuations until toward the end of the experiment when the depletion of gold was ap-

proached. The carbon content together with the current efficiency then decreased rapidly.

It is of interest to note that the carbon content was not markedly changed when either of the baths were replenished after depleting about 30-40% of the original gold concentration. The variation of carbon level is due to inconsistencies probably in the deposition process, which have not yet been ascertained. Plating conditions were maintained constant within experimental capability from one set to the next. Contamination from handling can be considered negligible at a level higher than several 100 ppm.

Successive plating from room temperature baths results in very similar morphological changes to those which are observed in hot baths. (For deposits from the potassium phosphate formulation, see Fig. 8, parts 1-8, and for the dibasic ammonium citrate buffered bath see Fig. 9, parts 1-6.)

Initially, the surface of deposits from the phosphate bath are very glossy yellow, exhibiting flat spherical segments without crystalline features (Fig. 3, part 1). The cross-sectional micrograph shows a very homogeneous bulk of columnar appearance (Fig. 8, part 1b). As the age of the bath increases, a loss in smoothness can be noticed and a randomly oriented outward-type growth occurs (Fig. 8, part 1-3). When the bath is replenished, a definite brightening effect becomes apparent (Fig. 8, part 4a). Characteristics of the bulk of the metal remain practically unchanged. Depleting of about 30-40% of the original gold concentration and replenishing is related to a marked brightening of the deposit the first time only. The second time replenishment is made, the deposit does not regain its initial bright appearance, and with further successive additions, hardly any brightening, or none at all, is observed. Again the carbon content in the foil is not apparently related to the structural changes on the surface. As the gold concentration approaches depletion, the deposit becomes discontinuous and dendritic (Fig. 8, part 7a) which is also demonstrated in a cross-sectional micrograph (Fig. 8, part 7b). Hydrogen is the major cathodic product under these conditions, and does not allow the gold to form an adherent deposit.

Hardly any different information was obtained when the citrate formulation was substituted. The initial deposit appears highly lustrous, but as the plating process is carried on, the coatings get dull and the morphological features again change towards an outward-type growth pattern. Similarily, the homogeneity in the bulk of the gold becomes less, as can be seen from cross-sectional micrographs (Fig. 9, part 1b-3b). The first replenishment then brings back the very smooth and glossy surface, which changes into a brown-appearing, acicularly crystallized deposit (Fig. 9, part 5). Again as the gold in solution approaches very low concentrations, a discontinuous almost dendritic growth is observed. This deposit is dark brown and easily mechanically destructible (Fig. 9, part 6).

Plating in a cell with separated anode and cathode compartments.—In order to decide whether the carbon constituent in gold deposits is of anodic or cathodic origin, a cell with separated anodic and cathodic compartments was employed. Plating solution was used as the bridge electrolyte, and the cell separation was implemented by use of semipermeable membranes at each end of the bridge. A potassium phosphate and an ammonium phosphate buffered solution, respectively [40 g/liter $KAu(CN)_2$ and 100 g/liter buffer salt], were used for the experiments at 25°C. In the potassium phosphate buffered solution, a maximum cathodic current density of only 4.5 mA/cm² was obtained because of bridge resistance, while 6 mA/cm² was achieved in the ammonium phosphate buffered bath. The initial pH was adjusted to 4.5 in both solutions. Two gold foils of 3g each were plated from the potassium phosphate bath, and one foil of 4g from the ammonium phosphate bath.

The following results were obtained by carbon analyses: (*i*) potassium phosphate bath, first foil—945 ppm carbon, second foil—746 ppm carbon; (*ii*) ammonium phosphate bath, 349 ppm carbon.

These data unequivocally demonstrate that the codeposition of this carbon-containing material observed in gold foils plated from room temperature baths is a cathodically formed product. In fact, both the pH sensitivity and the cation dependency are also reflected in these figures. In a bridged cell the pH stability upon exposure to electrolysis is very low, resulting in a marked increase of pH in the cathodic compartment and an equivalent decrease of pH in the anodic compartment. It was found that the pH in the potassium phosphate bath rose from 4.5 to 5.6 after plating of both foils. Consequently, the carbon content of the second foil is somewhat lower, as would be predicted in accordance with the relationship of carbon *vs.* pH given in Fig. 5. Also, the result from the ammonium phosphate bath at pH 4.2 and 6 mA/cm² falls fairly well in the expected range, being well below the values obtained from the potassium phosphate system.

Total amount of gold plated	75.8g		70g

Conclusions

Our study of gold electrodeposits plated from pure buffered potassium gold cyanoaurate(I) solutions lead to the following facts:

1. At solution temperatures of 65°C and above the incorporation of carbonaceous contaminants into cathodic deposits is minimized and practically negligible. Varying any operating parameters, as well as changing the concentration of solution components, does not increase the carbon content in the gold, as long as the bath temperature remains high.

Even, as the used age of a bath increases and the appearance of the deposit changes from bright yellow to dull brown, the carbon content of these deposits stays unchanged and very low. Undoubtedly this marked change of morphological characteristics is related to a simultaneous alteration of the solution composition. However, there are indications that the cathodic liberation of cyanide ions, and the subsequent buildup of known hydrolysis and polymerization products are not the only cause of the change in morphology of the deposits.

It was further found that characteristic surface morphologies are generated at certain cathodic deposition potentials, whereby bright yellow deposits are formed at less negative potentials than dull brown ones, *e.g.*, in a pure phosphate buffered bath at *p*H 10 and 65°C, bright yellow gold is plated to as low as −900 mV and at values of −950 mV and more negative, typically dark gold is cathodically deposited. As a bath is operated at constant current density and its used age increases, the gradual darkening of the deposit is also accompanied by a potential shift towards more negative values. If organic buildup in the bath were the sole cause for this phenomenon, intentional addition of hydrolysis or polymer products derived from cyanide ions should then effect similar changes. However, hardly any morphological changes or potential deviations were observed upon addition of such derivatives to freshly prepared solutions. Similarly, a change of appearance and deposition potential could also be expected, if a hiterto unknown inherent species would be depleted from the bath as electrolysis proceeds.[6]

2. By lowering the bath temperature below 60°C a subtle increase of carbon in the deposit was discovered, which reaches a maximum of approximately 1300 ppm at 25°C, *p*H 4.5, and high current density (15 mA/cm^2). Solution *p*H, current density, and solution composition affect the degree of carbonaceous incorporation at room temperature (see Fig. 5 and 6). At the same time a change in morphology is also observed. The surface, however, is bright, glossy yellow characterized by spherical segments. Bright deposits can be obtained even at very high current densities (up to approximately 50 mA/cm^2) when vigorous agitation is provided.

Other properties such as hardness and brittleness are also changed. Deposits plated from 65°C baths are soft and ductile (see Table II) in contrast to those plated from 25°C baths which are much harder and brittle where the carbon content is high (see Table IV and V).

By plotting the carbon content *vs.* bath age (or amount of gold plated) it was learned that, at least in the case of the phosphate buffered solution at 25°C, there was no increase of carbon in the deposit. Once the bath was no longer replenished with potassium cyanoaurate(I) there was indeed a marked decrease of carbon in the deposited gold with decreasing gold concentration in solution (see Fig. 10). This result clearly reveals that the amount of incorporated carbonaceous material is not related to the accumulation of free cyanide or subsequently formed reaction products. Although the carbon content throughout the main part of the experiment was found to remain at around 1000 ± 100 ppm, a gradual change in appearance was observed also here extending from lustrous yellow to dark brown.

The carbon data obtained from the ammonium citrate formulation at 25°C were more inconsistent (see Fig. 10), suggesting interaction of the ammonium ions in some unknown way. Principally, however, similar results were obtained, namely, deposits of lustrous yellow appearance gradually darkening as the age of the bath increased, and high hardness and brittleness at high current density, together with relatively high carbon content.

3. Further, the fact that carbon was also found in deposits where anode and cathode were placed in separate compartments excludes that anodically oxidized or polymerized cyanide derivatives would contribute to the carbon content in electroplated gold.

Most likely, therefore, cyanide, as potassium cyanide, gold(I)cyanide, potassium cyanoaurate, and hydrogen cyanide are incorporated into the metal during the deposition process.

EXPERIMENTAL APPENDIX

Sample Preparation for Carbon Analysis

Onto a molybdenum substrate (2.5 × 5 cm) gold was plated to accumulate generally approximately 1 or 2g of metal. The deposits were rinsed thoroughly with deionized (DI) water and peeled from the substrate, again rinsed, then immersed in approximately 100 ml DI water, boiled for 5 min, and subsequently rinsed with cold DI water to assure complete removal of bath residues. For drying, the foil was placed into a clean oven for approximately 2 hr at 125°C. If not analyzed immediately the gold was stored in clean glass containers. Approximately 1g was used per analysis.

Wire Wrap Test

Annealed Dumet[7] wire (0.45 mm) was plated to approximately 6.5 μm with gold, rinsed, air-dried, and subsequently, with the help of a mechanical tool wrapped around a gold-plated brass mandrel of a square cross section (0.1 cm side length). A ductile deposit as defined here must not show any cracks in the gold surface at 20X optical magnification.

Solution Extraction

Five hundred milliliters of solution (electrolyzed potassium cyanide solution, dibasic ammonium citrate solution, or depleted plating bath) was placed into a separatory funnel. Approximately 150 ml of distilled ethyl acetate were then added and shaken energetically. The organic phase was separated and new ethyl acetate added to the aqueous phase. Three extractions were sufficient to remove organic materials quantitatively. After combining all solvent portions, ethyl acetate was stripped off on a rotatory evaporator, and the residual oily or greasy materials transferred into a crystallization dish in which they were dried in a desiccator over $CaCl_2$ or silica gel.

Due to small quantities obtained from most of the operations, no further purifications were undertaken. *IR* spectra of the products were recorded.

IR absorptions were determined of products isolated by ethyl acetate extraction from the following: (*i*)

[7] Dumet: a 57% iron, 42% nickel, and 1% manganese alloy wire core with copper cladding.

KCN solution polymerization (orange brownish partially crystalline oil), 3320s, 2955s, 1672w, 1446m, 1375s, 1320m, 1186m, 1122s, 1089s, 1043s, 944m, 926m, 878w, 842m, 792w; (*ii*) electrolyzed dibasic ammonium citrate solution (yellow brownish oil), 3150s br, 2630sh, 1728s, 1380s br, 1250v br, 1178sh br, 1048m; (*iii*) depleted potassium phosphate plating bath (65°C, pH 10), (brownish, partially crystalline oil), 3260s, 2195w, 1668w, 1445m, 1375w, 1229m, 1046s, 1010m, 793s; (*iv*) depleted dibasic ammonium citrate plating bath (65°C, pH 4.7), (brownish oil), 3150s br, 2640sh, 2210s, 2170w, 1728s br, 1428s, 1380s, 1263m, 1165sh br, 1098m, 1049m, 1022sh, 873w br, 802s br.

The Surface Tension of the Molten Binary System LiCl-KCl

D. A. Nissen and R. W. Carlsten

Exploratory Power Supplies Division 2523, Sandia Laboratories, Albuquerque, New Mexico 87115

ABSTRACT

Surface tension measurements are reported for the binary molten salt system LiCl-KCl over the composition range 10-90 mole per cent KCl and at temperatures ranging from the melting point to 850°C. All measurements were made using the maximum bubble pressure method. The surface tension is linearly dependent on temperature, and the experimental results for the mixture at constant temperature are best explained on the basis of regular solution behavior. However, there is an indication that some local structure exists in the melt.

The physical-chemical properties of molten salts are of interest because they can reveal the type and extent of ionic interactions in these systems. The entire spectrum of ionic interactions can be obtained in molten salt mixtures: from the $NaNO_3$-KNO_3 system which approximates ideal behavior (1) to those which deviate considerably from ideal behavior and have been explained on the basis of complex ion formation (2) or polarization effects due to large differences in cation size (1, 3, 4). The correlation of solution behavior with surface properties has been a common and fruitful approach.

Even though molten LiCl-KCl has been used extensively as a solvent in both electrochemical and chemical studies, little is known about its physical properties. Except for the rather sparse data of Mizuno (5) and Jaeger (6), studies that have been made of the surface tension of the binary alkali metal halides (1, 2) have not included the LiCl-KCl system in spite of the fact that deviations from ideal solution behavior may exist as indicated by the conductivity data of Van Artsdalen (7). The purpose of the present study is to extend the available surface tension data to include mixtures of LiCl and KCl and to examine these data in the light of current models of molten salt mixtures.

Experimental

Of the numerous techniques available for determining the surface tension of molten salts, the maximum bubble pressure method was chosen for this investigation. This method is capable of giving precise results at high temperatures in a moderately corrosive medium, and has been used in many investigations of the surface tension of molten salts. It involves the slow formation of a bubble at the inner diameter of a very carefully fabricated capillary orifice immersed in the liquid of interest. Simultaneously, the pressure of the gas used to form the bubble is measured in order to determine the maximum pressure developed inside the bubble, *i.e.*, at the minimum radius of curvature.

Schrödinger (8) showed that the relationship between the pressure and surface tension is given by the equation

$$\gamma = \frac{\bar{p}r}{2}\left[1 - \frac{2}{3}\frac{r}{h} - \frac{1}{6}\left(\frac{r}{h}\right)^2 \cdots\right]$$

where γ is the surface tension in dynes/centimeter, $\bar{p}$ is the maximum pressure difference between the inside and outside of the bubble, r is the radius of the capillary, and $h = \bar{p}/g\ (D - d)$, where g is the acceleration due to gravity, D is the density of the liquid, and d is the density of the vapor. If the density of the vapor phase is disregarded, it is possible to express the above equation in the more tractable form (9)

$$\gamma = \frac{rg}{2}(hd_1 - id_2) - \frac{1}{3}d_2 r^2 g - \frac{1}{12}\frac{r^3 g d_2^2}{hd_1 - id_2}$$

where h is the height of the manometer column, d_1 is the density of the manometer fluid, i is the depth of immersion of the capillary, and d_2 is the density of the liquid under study. The third term was not used in our calculations since it is negligible, $<10^{-4}$ dyne/cm.

Sugden (10, 11) has objected to the use of Schrödinger's equation because it assumes an elliptical bubble profile and thus should only be applied to small bubbles. However, Tripp (12) has pointed out that if the bubbles are formed slowly, about five bubbles per minute, the mathematical theory is in accordance with experiment and has criticized Sugden's conclusions on the grounds that the bubble rate used in his experi-

* Key words: regular solution, molten salts, coulombic interaction, solution theory.

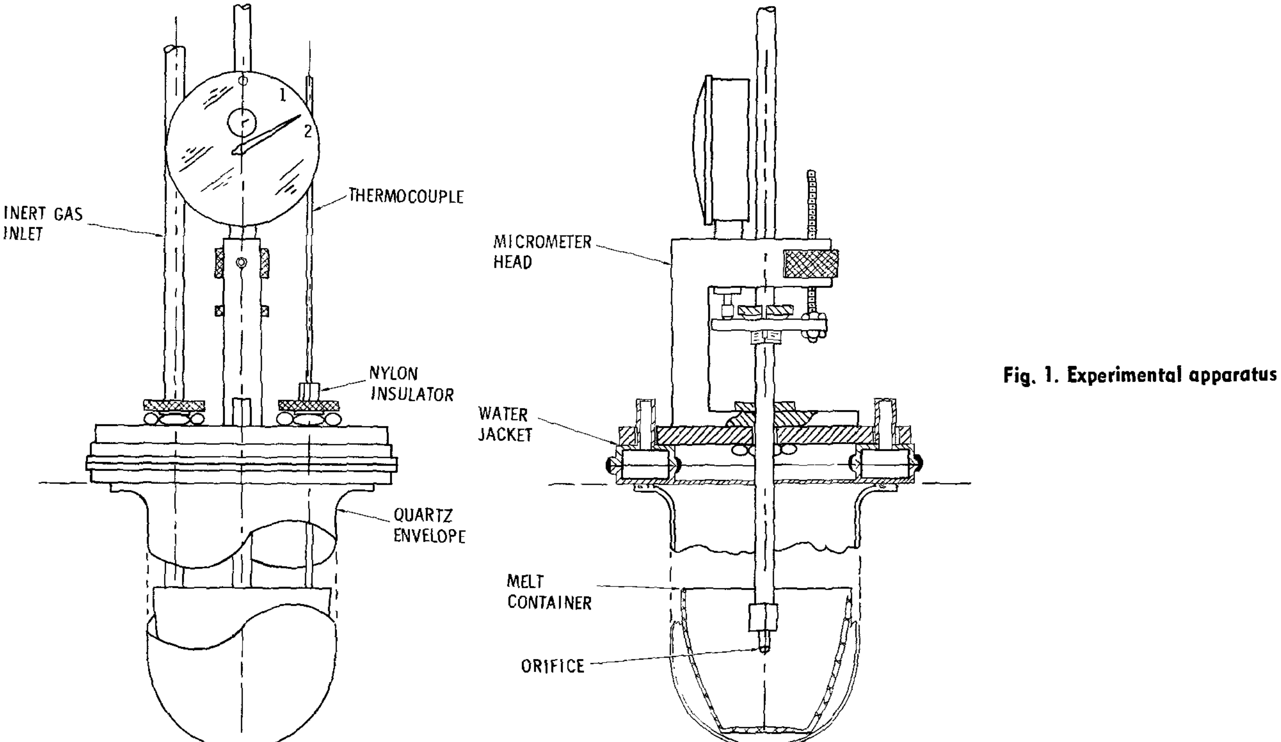

Fig. 1. Experimental apparatus

ments was too high. Since our surface tension data for both $NaNO_3$ and KNO_3 (13) agree with that obtained by other investigators using both the maximum bubble pressure method (9) and the Wilhelmy slide plate technique (14), any errors involved in the use of Schrödinger's equation for surface tension appear to be negligible for slow bubble rates.

The literature provides a more extensive review of the historical background, theory, and practice of this technique for measuring surface tension (9, 12).

Apparatus.—The apparatus used in this investigation was similar to that of Dahl and Duke (2, 9) and is shown in Fig. 1. In this investigation the capillary tip was fabricated from pure gold and was 2.25 cm long with an orifice approximately 0.8 mm in diameter. It was joined to the graphite gas delivery tube by means of a graphite collar.

In order to obtain precise results, it is necessary that careful attention be paid to the capillary tip. We have found that the bore must be as accurately round as possible, the end flat and perpendicular to the axis of the capillary, and the edge of the orifice very sharp. Furthermore, this condition must be maintained throughout the measurements. For accurate, reproducible results, these requirements cannot be too strongly emphasized.

A Lietz Ortholux microscope was used to check the condition and the diameter of the orifice. The capillary tip was magnified 60× and photographed with a superimposed filar, ruled to 0.01 mm. This photograph was then used to measure the diameter of the capillary and determine its condition. All measurements were corrected for thermal expansion of the capillary orifice (15).

The graphite tube which supported the gold capillary was rigidly clamped to the micrometer head which allowed the depth of immersion of the tip to be measured within ±0.01 mm. The level of the vapor-liquid interface was determined by measuring the resistance between the capillary and a gold-sheathed thermocouple placed in the melt as the tip was being slowly lowered by means of the adjustment screw attached to the micrometer head.

A dibutyl phthalate manometer was used to measure the gas pressure in the system. Its temperature was maintained at 25° ± 0.1°C by a constant temperature bath. The height of the meniscus was read by a cathetometer accurate to ±0.001 mm.

The temperature of the melt was measured with a gold-sheathed Chromel-Alumel thermocouple and was maintained constant within ±0.5°C of the set temperature. The vertical temperature gradient through the sample was less than 1.0°C.

Materials.—Both the LiCl and KCl used in these experiments were of analytical purity and were carefully vacuum dried before use. The appropriate composition was made up by accurately weighing the dried salts directly into the container. After the salts were melted, they were further purified by the use of chlorine and hydrogen chloride gas (16). All weighing and other manipulations of the dried salts were done in an atmosphere whose water content was less than 100 ppm. After a set of measurements on a sample was finished, the sample was analyzed for both lithium and potassium by atomic absorption to determine its exact composition to within ±0.1 weight per cent (w/o). In every case the weighed composition agreed with the analyzed composition to within ±0.2 mole per cent (m/o).

Purified argon was used to form the bubbles and to maintain an inert atmosphere over the sample. The argon was purified by passing over hot copper turnings and $Mg(ClO_4)_2$.

Results

Prior to determining the surface tension of LiCl-KCl mixtures, we measured the surface tension of both $NaNO_3$ and KNO_3. The agreement between our results and the accepted literature values (17) is within 1% (13). To check the accuracy of our measurements on the LiCl-KCl system, we periodically remeasured the surface tension of KNO_3. In each case the agreement was well within a reasonable experimental error (±0.2 dyne/cm, ~ ±0.2%).

For each composition the surface tension shows the usual linear temperature dependence, $\gamma = A - Bt$, where t is the temperature in degrees centigrade. Table I summarizes these results analytically. The equations which relate the surface tension and temperature are the result of a least squares computer analysis of the data points. The standard deviation of the points about the line is shown in the last column in Table I and is about 0.3 dyne/cm.

Table I. LiCl-KCl[a]

KCl, m/o	γ, dyne/cm	s, dyne/cm
10	164.9-0.0676t	0.275
21	164.4-0.0714t	0.496
31	165.4-0.0755t	0.308
42	165.3-0.0780t	0.215
50	165.3-0.0808t	0.275
60	166.4-0.0846t	0.376
70	167.2-0.0869t	0.262
78	166.9-0.0857t	0.193
85	165.6-0.0840t	0.287
90	166.2-0.0850t	0.357

[a] Density data used in calculating these surface tensions were taken from Van Artsdalen and Yaffee (7).

With the exception of the rather sparse data of Mizuno (5) and Jaeger (6), there are no other surface tension data on the LiCl-KCl system in the literature that can be used for comparison. Mizuno (5) reports surface tension data for the compositions 20, 40, and 60 m/o KCl. For these compositions, his values are about 4-5% higher at 800°C than ours. Jaeger (6) reports only one data point for 447°C and a composition of 42 m/o KCl; it is 5% lower than our value for the same composition. Based on the agreement between our values for the surface tension of KNO_3 and $NaNO_3$ (13) and those reported by Janz (17), and the precision of all our data for the surface tension of LiCl-KCl for which we estimate an accuracy of better than ±1%, we are unable to explain the differences between our values and those of Mizuno and Jaeger.

Discussion

Figure 2 shows a plot of surface tension as a function of composition at a constant temperature of 800°C. It can readily be seen that there is a large deviation from additive behavior, reaching a maximum of 7.7 dyne/cm at 50 m/o KCl. There is a pronounced minimum in the curve in the region of 65-70 m/o KCl.

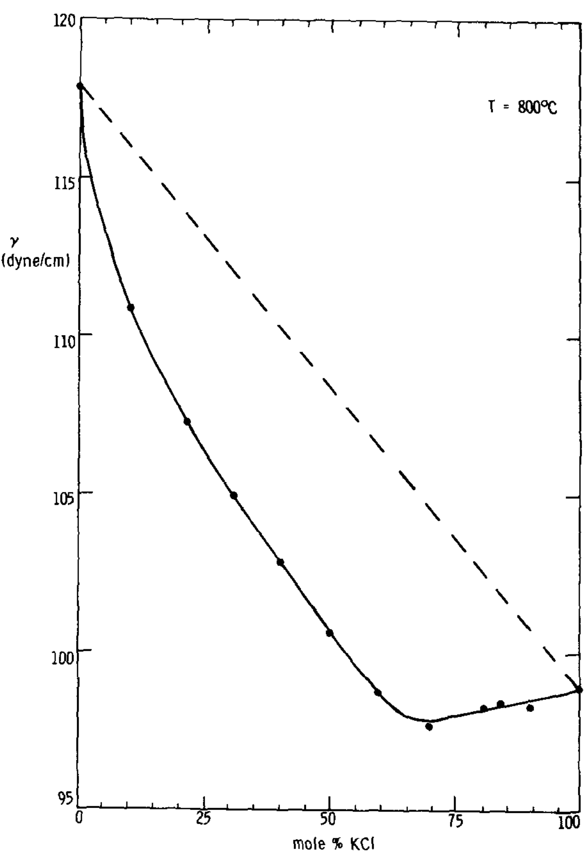

Fig. 2. Isothermal surface tension curve for the LiCl-KCl system at 800°C.

There have been a number of theoretical treatments of the surface tension of mixtures (18, 19) whose object it has been to evolve a model which would allow the prediction of the surface tension of a mixture at constant temperature, for any composition, provided the surface tensions of the pure components are known. These models and their correlation with our experimental data are discussed below.

The surface tension of nearly all binary mixtures deviates negatively from additivity; behavior which is, in fact, predicted by Guggenheim's equation for the surface tension of an ideal solution (18). The surface tension of the LiCl-KCl system similarly exhibits negative deviations from additivity. However, neither Guggenheim's equation for ideal solutions nor modifications of it (20, 21) are able to describe the LiCl-KCl experimental surface tension isotherm. This is not particularly surprising since the heat of mixing studies of Aukrust, *et al.* (22) show that mixtures of LiCl and KCl exhibit considerable negative deviations.

In a series of studies of the surface tension of binary molten salt systems, Bertozzi (14, 23, 24) advocated the use of the semiempirical expression

$$\gamma = x_1\gamma_1 + x_2\gamma_2 - \beta x_1 x_2 \qquad [1]$$

to represent the data. In this equation x_i is the mole fraction of component i, γ_i is the surface tension of pure component i, and β is a constant which may be empirically determined. For those mixtures which behave as ideal solutions, β is, of course, equal to zero.

If deviations from ideal behavior are considered to be purely coulombic in origin, the constant β can be expressed as a size parameter

$$\beta = \frac{-e^2}{2a}\left(\frac{1}{d_1} + \frac{1}{d_2}\right)\left(\frac{d_1 - d_2}{d_1 + d_2}\right)^2 \qquad [2]$$

where d_i is the sum of the radii of the cation and anion of the pure salt indicated, e is the electronic charge, and a is the mean area of the molecules and is given by the formula

$$a = \frac{1}{2}\left[\left(\frac{V_1}{N}\right)^{2/3} + \left(\frac{V_2}{N}\right)^{2/3}\right]$$

where N is Avogadro's number and V_i is the molar volume of the ith component. This form of β is the result of calculations made by Forland (25) on the energy change which results from mixing a linear array of ions, considering only nearest and next neighbor interactions. Equations [1] and [2] were used by Kleppa to represent heat of mixing data for alkali nitrate systems (26, 27).

Using the cation-anion distances obtained by Levy and Danford from their diffraction studies of molten salts (28) and Van Artsdalen's values of the molar volumes of LiCl and KCl (7), we calculate a value of β = 17.7 dynes/cm. A computer fit of Eq. [1] to the experimental data using β as an adjustable parameter was made and is shown in Fig. 3. It was found that the best fit was obtained for a value of β = 32.5, considerably larger than that calculated from Eq. [2].

Equation [1] predicts that, if deviations from ideal behavior are coulombic in nature, then for a given composition, the deviation from ideal behavior, $\Delta\gamma = \gamma - (x_1\gamma_1 + x_2\gamma_2)$, should be approximately a linear function of the size parameter $[(d_1 - d_2)/(d_1 + d_2)]^2$; since the factor $\frac{1}{a}\left(\frac{1}{d_1} + \frac{1}{d_2}\right)$ is nearly constant for the various binary alkali chlorides shown in Fig. 4. Figure 4 shows the deviation from ideal behavior, $\Delta\gamma$, at a composition of 0.5 mole fraction plotted against the size parameter, $[(d_1 - d_2)/(d_1 + d_2)]^2$, for several different binary alkali chloride systems (2, 5, 23). This plot shows that a model based on a one-dimensional array of the ions and purely coulombic considerations cannot completely describe the deviations of the surface

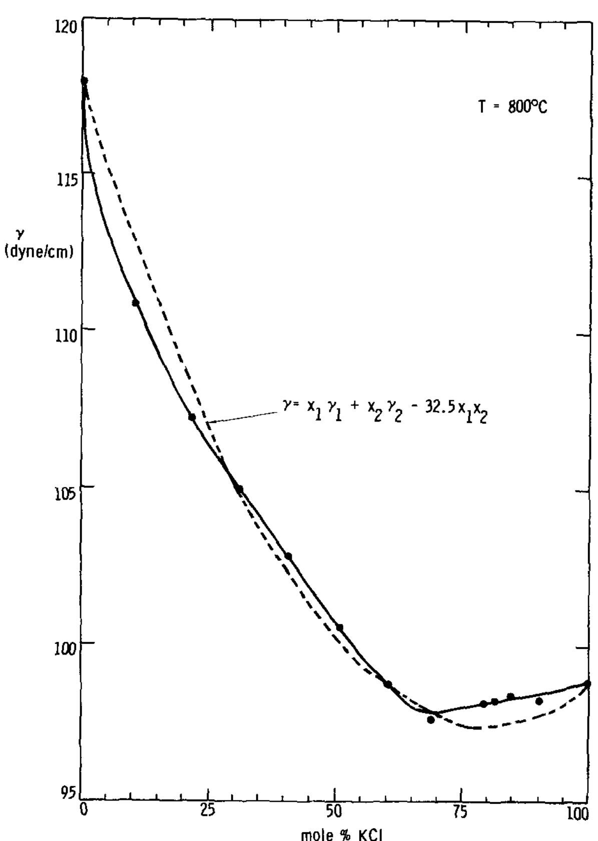

Fig. 3. Comparison of the experimental surface tension with that calculated from Eq. [1] for $\beta = 32.5$ dynes/cm at 800°C.

tension from ideal behavior in all binary molten salt systems with a common anion. If polarization effects were taken into account as well as an extension of the one-dimensional model for coulombic interaction into three dimensions, it is possible that this model would more closely parallel the experimental results. This conclusion is similar to that suggested by Grojtheim (20) in his study of the surface tension of binary mixtures of alkali and alkaline earth chlorides, and discussed by Blander (29).

Based on calculations of the activity of molten salt mixtures with a common ion, Bloom (30) has shown that these mixtures may be treated as regular solutions.

Guggenheim (18) and Prigogine (19) have derived an equation for the surface tension of regular solutions based on a quasi-crystalline model in which each molecule in the liquid is treated as though it were arranged on a lattice and on the zeroth approximation in which it is assumed that there is complete randomness in both the bulk and in the surface layer. In this case the surface tension is given by

$$\gamma = \gamma_1 + \frac{kT}{a}\ln\frac{x_1'}{x_1} + \frac{wl}{a}[(x_2')^2 - (x_2)^2] - \frac{wm}{a}(x_2)^2$$

$$= \gamma_2 + \frac{kT}{a}\ln\frac{x_2'}{x_2} + \frac{wl}{a}[(x_1')^2 - (x_1)^2] - \frac{wm}{a}(x_1)^2 \quad [3]$$

where l and m refer to the fraction of nearest neighbors which occupy the same lattice plane and an adjacent lattice plane, respectively, and satisfy the relationship $l + 2m = 1$, w is the interaction parameter in the theory of regular solutions, and the primed quantities refer to the surface layer.

According to Prigogine (19), if one neglects the adsorption of atmospheric gases, or excludes them from the experimental system, an extreme value of the surface tension can occur from which it follows that the equilibrium surface phase at this point has the same composition as the bulk solution, *i.e.*, $x_1' = x_1$ and $x_2' = x_2$. In these circumstances, Eq. [3] reduces to

$$\gamma_{\text{extr.}} = \gamma_1 x_1 + \gamma_2 x_2 - \frac{wm}{a} x_1 x_2 \quad [4]$$

Inserting the appropriate experimental values of $\gamma_{\text{extr.}}$, x_1 and x_2 into Eq. [4], we obtain $wm/a = 32$ dynes/cm and $wm/kT = 0.352$ for $T = 1073$°K.

With the value of wm/a calculated from Eq. [4], we used Eq. [3] to calculate values of the surface tension for various LiCl-KCl compositions. A computer was used to do the actual calculations and the program was written so that the ratio l/m could be varied. The best fit to the experimental surface tension data was obtained for the ratio $l/m = 2$. Table II and Fig. 5 show a comparison of the experimental and calculated values of the surface tension. The minimum in the calculated curve comes at about 80 m/o KCl as against 65-70 m/o KCl in the experimental curve; otherwise the agreement is excellent, lending support to the idea that the LiCl-KCl system behaves as a regular solution.

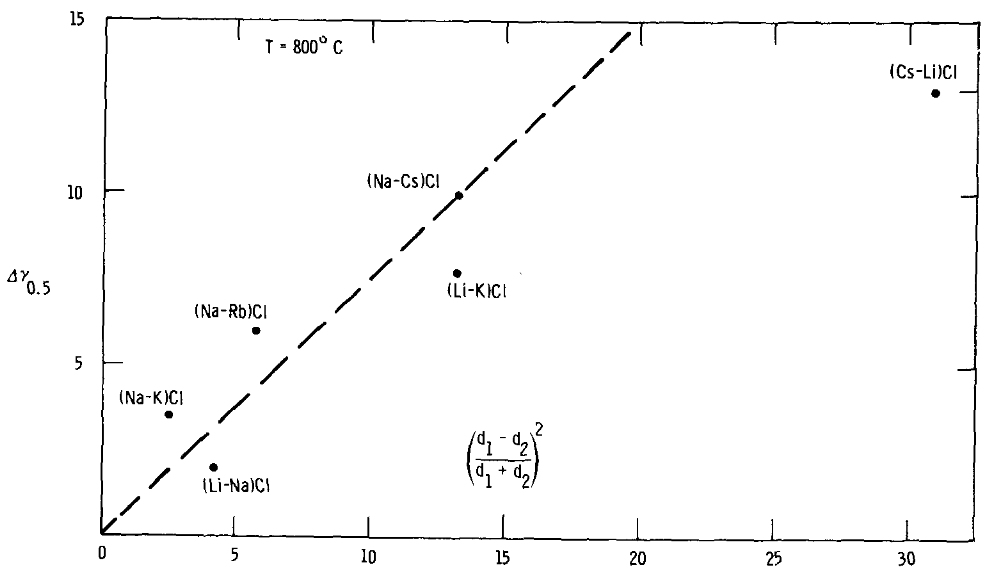

Fig. 4. Deviation from ideal behavior at 0.5 mole fraction as a function of the size parameter $(d_1 - d_2/d_1 + d_2)^2$ for several binary alkali metal chloride systems.

Table II. Comparison of calculated and experimental values of the LiCl-KCl surface tension at 800°C

KCl, m/o	γ(calc., Eq. [3]), dyne/cm	γ(expt'l.), dyne/cm
10	111.76	110.91
20	107.04	107.29
30	103.63	104.98
40	101.24	102.90
50	99.58	100.62
60	98.44	98.72
70	97.75	97.68
80	97.50	98.30
90	97.81	98.20

We believe, however, that there are indications of some type of specific interaction in the LiCl-KCl mixture. Van Artsdalen's measurements of the conductivity of the LiCl-KCl system (7) show a pronounced minimum in the equivalent conductance isotherm in the region of 70-80 m/o KCl. In a similar fashion, the surface tension isotherm shows a minimum between 65-70 m/o KCl, cf. Fig. 2. Furthermore, our calculations of the surface entropy S^γ and surface energy E^γ show maxima at about 67 m/o KCl, Fig. 6. These facts suggested evaluation of a model which considers possible specific interaction between the components of the mixture.

Kaufman (31) has shown that molecular-type aggregates or clusters of ions which possess unique stoichiometric relationships to one another are theoretically capable of producing minimum or maximum values of the surface tension. A molecular type which is surface active will cause a minimum and one which concentrates in the bulk phase will cause a maximum value of the surface tension. Based on the Gibbs adsorption isotherm and using a restrictive equation for the chemical potential of the surface active-species, Kaufman (31) derived an equation of the form

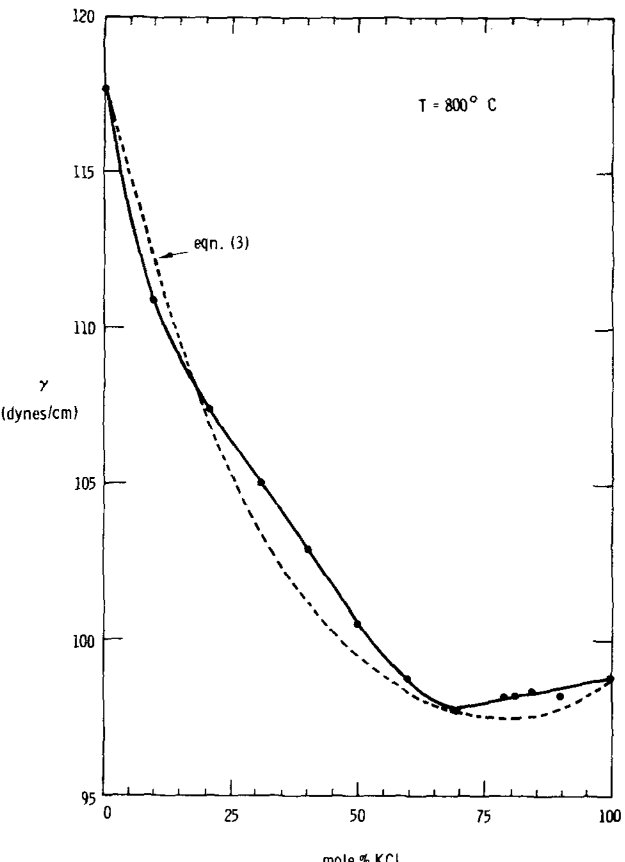

Fig. 5. Comparison of experimental surface tension with that calculated from Eq. [3] at 800°C.

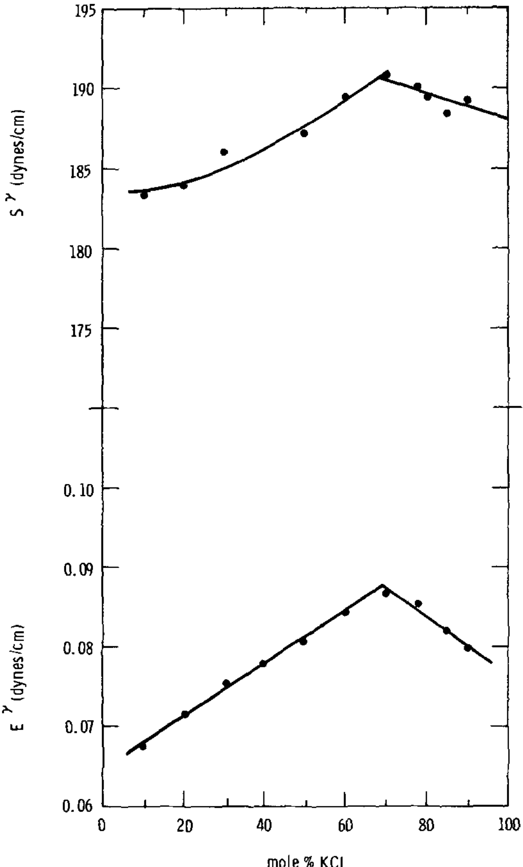

Fig. 6. Surface entropy, S^γ and surface energy E^γ as a function of composition for the LiCl-KCl system at 800°C.

$$\gamma = x_1\gamma_1 + x_2\gamma_2 + \left(\frac{x_1}{r_1}\right)^{r_1}\left(\frac{x_2}{r_2}\right)^{r_2}(r_1+r_2)^{(r_1+r_2)} + \left(\frac{f_1}{f_1\,\mathrm{max}}\right)^{r_1}\left(\frac{f_2}{f_2\,\mathrm{max}}\right)^{r_2}[(\gamma_c-\gamma_1)+(\gamma_1-\gamma_2)]x_2 \quad [5]$$

In this equation r_1 and r_2 are constants and represent the stoichiometric ratios in which the various components occur in a particular aggregate, f_1 and f_2 are the activity coefficients of the two components, and γ_c is the surface tension of the bulk at a composition corresponding to some particular stoichiometric ratio. In the limit of weak interactions between the constituents of the mixture, the surface-active species can be assumed to behave like pure solute in the unassociated state and Eq. [5] can be shown to reduce to a form similar to Eq. [4] (31); *i.e.*, in the limit of weak interaction the mixture will behave as a regular solution.

Equation [5] was used to calculate the surface tension of the LiCl-KCl mixture. For this calculation it was assumed that the minimum in the isothermal surface tension curve, cf. Fig. 2, could be ascribed to the presence of a surface-active species in the melt, and the values of γ_1, γ_2, and γ_c were chosen accordingly. Thus, $\gamma_1 = 1$, $\gamma_2 = 2$, and $\gamma_c = 97.5$ dyne/cm. It was also assumed that f_1/f_1 max $= f_2/f_2$ max $= 1$.

The results of this calculation are shown in Fig. 7 superimposed on the experimentally measured isothermal surface tension curve. The agreement between the calculated and experimental values of the surface tension, particularly in the region of the minimum, is quite reasonable considering the approximations involved.

We do not believe that any sort of complex-ion in the generally accepted sense, *e.g.*, $AlCl_4^-$, BeF_4^{-2}, $CdCl_4^{-2}$, etc., is formed in the LiCl-KCl melt. How-

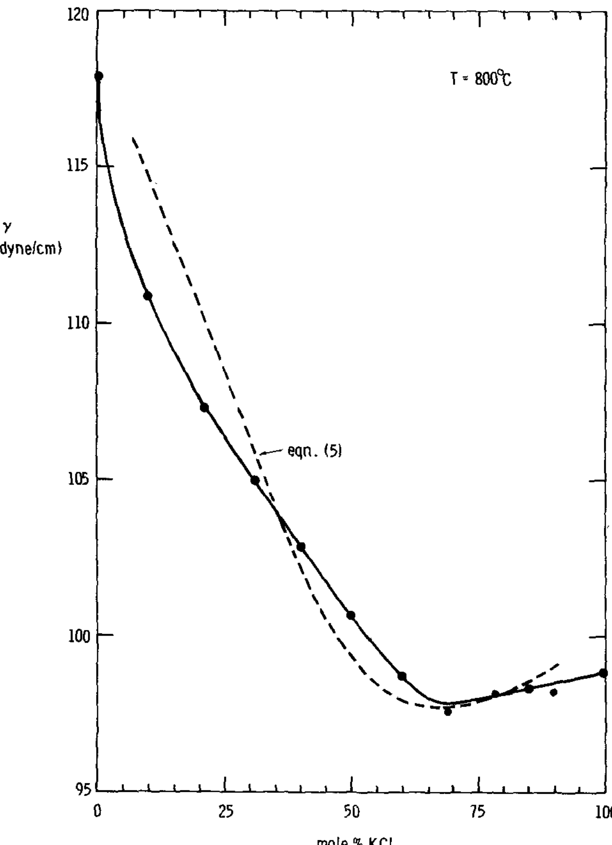

Fig. 7. Comparison of the experimental surface tension with that calculated from Eq. [5] at 800°C.

ever, the correspondence between the calculated and experimental data shown in Fig. 7 do suggest that some sort of loose aggregation or "complex-like" arrangement of the ions is formed in the melt, and that this entity is surface active. The strong polarizing power of the lithium ion is probably responsible for changes in local structure about itself.

In the NaCl-KCl system, where the sodium ion is much less strongly polarizing than the lithium ion, there appears to be no evidence of local structure or preferential ion groupings in the melt (5, 9). The essential features of this association model have also been proposed to explain the observed heats of mixing in binary alkali metal halide systems (32).

The preferential ion groupings discussed above have not been observed experimentally, and therefore, the conclusions based on their existence are speculative. Furthermore, as Kaufman (33) points out, because these compound like groups of ions can have effects on surface properties orders of magnitude greater than might be expected from their relative influence on bulk properties, they might represent only an insignificant fraction of the total mass of liquid. However, a model in which these ion groupings are assumed does seem to account for the LiCl-KCl surface tension data, cf. Fig. 7, and may also explain the conductivity data for this same system.

Conclusion

We have attempted to fit our surface tension data for the LiCl-KCl system to four different theoretical models of the surface tension of mixtures. The first of these is Guggenheim's model for ideal behavior. The second, an outgrowth of heat of mixing studies on binary molten systems, considers that deviations from ideal solution behavior are due to purely coulombic interactions. The third is Guggenheim's zeroth approximation treatment of regular solutions which assumes complete randomness in the surface layer as well as the bulk. In the fourth model, the regular solution model is, in essence, modified by assuming compositional variations at the interface which could be completely specified by the preferential adsorption of a stoichiometric multi-atomic species from the bulk phase.

Our experimental data cannot be adequately described by either the ideal solution model or by the coulombic interaction model, most probably because these models do not take into account the polarization effects which undoubtedly exist in the LiCl-KCl system.

The experimental surface tension data are well fitted by Guggenheim's regular solution model of liquid mixtures except that the positions of the minima in the calculated and experimental isothermal surface tension curves are displaced from each other.

Because values of the surface tension calculated from the fourth of these models which assumes discrete atom groupings fit the experimental data reasonably well, particularly in the region of the minimum, we believe that, while regular solution theory can adequately explain our results, there may be some local structure in the LiCl-KCl melt. That is, the constituents of the melt, at least at the interface, do not seem to be randomly distributed. This view is also supported by the plots of surface entropy and total surface energy against composition which show maxima at 67 m/o KCl.

Oxygen Transfer Kinetics Between Ga-Ga_2O_3 Electrodes and the Solid Electrolyte Calcia-Stabilized Zirconia

L. F. Donaghey* and Raymond Pong**

Inorganic Materials Research Division of the Lawrence Berkeley Laboratory and the Department of Chemical Engineering of the University of California, Berkeley, Berkeley, California 94720

ABSTRACT

The kinetics of oxygen transfer between Ga-Ga_2O_3 composite electrodes and the solid electrolyte calcia-stabilized zirconia, $ZrO_2(CaO)$, were studied with the symmetric, galvanic cell

$$W/Ga\text{-}Ga_2O_3/Ca_{0.15}Zr_{0.85}O_{1.85}/Ga\text{-}Ga_2O_3/W$$

over the temperature range from 800° to 900°C. Chronopotentiometric studies were conducted using current densities from 0.3 to 130 $\mu A/cm^2$ to obtain overpotentials for faradaic oxidation and reduction reactions at the Ga-Ga_2O_3/$ZrO_2(CaO)$ interface. A linear dependence of the overpotential on current density was obtained, corresponding to a local electrode resistance of 3.8 ohm/cm^2 of electrode-electrolyte interface at 800°C. The data are in agreement with a solution-diffusion mechanism of oxygen transport through liquid Ga in the electrode between the $ZrO_2(CaO)$ electrolyte and Ga_2O_3 particles.

Solid electrolytes have become important in recent years for use in thermodynamic and kinetic studies with solid-state electrochemical cells (1-4) and more recently, in fuel cells and other power sources (5-11). Major areas of concern in kinetics and power source applications of solid electrolytes are the structure of the solid electrolyte-electrode interface and the electrochemical, rate-controlling process for ionic transport across this interface (12). Considerable theoretical and experimental work has been reported concerning space charge polarization in liquid and solid systems where it is well established that static concentration gradients of ionic species and diffuse, charged double layers play an important roll (13-17). Most previous investigations of electrode processes in solid systems have been limited to single-phase electrodes (18) in asymmetric cells containing both nonpolarizable and polarizable electrodes (19). The oxygen transfer between the two-phase, liquid metal-metal oxide electrode $Ga_{(l)}$-Ga_2O_3, and the solid electrolyte $ZrO_2(CaO)$ is studied in the present paper.

Oxygen transfer kinetics at interfaces between two-phase electrodes and solid electrolytes is important in many electrochemical applications. Metal-metal oxide mixtures are the most commonly used reference electrodes in thermodynamic studies with solid-state galvanic cells (3), where electrode polarization is undesirable. Kinetic studies with such cells require oxygen transfer for coulombic titration experiments (20), for measurements of oxygen diffusion in liquid and solid metals (1, 3), and for phase boundary reaction rate determinations (21).

Oxygen transfer kinetics from metal-metal oxide electrodes to solid electrolytes has only recently received attention. The reversibility of electrode polarization in symmetric cells has been studied by Steele (22) for several such electrodes. Recently Worrell and Iskoe (23) measured overpotentials for Cu-Cu_2O, Fe-FeO, and Ni-NiO electrodes in symmetric cells and found that the steady-state overpotentials were independent of the direction of current flow. Thes authors have shown that the magnitude of the overpotential for a given current is consistent with an oxygen transfer mechanism which is kinetically limited by bulk diffusion of oxygen through the metal component of the electrode.

The oxygen transfer kinetics from liquid metal-metal oxide electrodes to solid electrolytes has not been studied previously. If the same or similar mechanism limits oxygen transfer for such electrodes as for solid metal-metal oxide electrodes, then the measured overpotentials should be significantly lower for the liquid metal-metal oxide electrodes, owing to the high oxygen permeability of liquid metals. On this assumption, kinetics for the $Ga_{(l)}$-Ga_2O_3 electrode should be exceptionally fast because of the exceptionally high oxygen diffusivity in liquid gallium.

In this study the oxygen transfer kinetics of $Ga_{(l)}$-Ga_2O_3 electrodes to $ZrO_2(CaO)$ is studied in a nearly symmetric cell. Because no reference electrode is included, the cell arrangement does not allow the inde-

** Electrochemical Society Student Member.
Key words: emf measurements, solid electrolyte, oxygen transfer kinetics.

pendent measurement of overpotentials at individual electrode-electrolyte interfaces. It will be shown, however, that measurement of the total overpotential is sufficient to test alternative kinetic mechanisms provided that oxygen diffusion is rate controlling and that the solid electrolyte is an oxygen anionic conductor. Study of the oxygen transfer kinetics of the $Ga_{(l)}$-Ga_2O_3 electrode has become important because of the increasing application of this electrode in solid-state electrochemical cells for thermodynamic and kinetic studies (24, 25). The understanding of transfer kinetics for this electrode system should provide a basis for employing liquid metal-metal oxide electrodes in electrochemical systems.

Experimental

Materials.—Gallium metal[1] of 99.9999% purity and Ga_2O_3 powder[2] (−325 mesh) of 99.99% purity for coexistence electrodes and the ZrO_2(CaO) electrolyte[3] were obtained from commercial sources. High purity, recrystallized Al_2O_3 was used in the remaining components of the cell assembly. An inert purge gas manifold was constructed of stainless steel throughout with KEL-F sealed, bellows valves. Viton and rubber O-rings were employed in seals between steel and ceramic components.

Apparatus.—The experimental cell configuration is shown schematically in Fig. 1. A closed-end, 0.64 cm diameter ZrO_2(15 mol per cent [m/o] CaO) solid electrolyte tube separated one electrode contained within it from a second Ga-Ga_2O_3 electrode supported on Ga_2O_3 powder within a 1.5 cm ID alumina crucible. This assembly was contained in a closed-end alumina reaction tube which was sealed at the top by an O-ring seal contained in a water-cooled stainless steel cap. The cap contained two additional O-ring seals through which the electrolyte tube, a thermocouple protection tube, and a purge gas inlet tube passed. Two of these tubes were also sealed at their tops by O-ring closures to a purge gas manifold. The tube assembly was positioned in a Kanthal A-1 alloy resistance furnace whose temperature was regulated by a triac-controlled, integrating proportional controller. The cell temperature was held constant (±0.5°C) at the electrode assembly by a control thermocouple placed outside the alumina reaction tube. Convection in the liquid gallium was prevented by maintaining a vertical thermal gradient of 0.3°C/cm over the electrode assembly. Electrical interference from current transients in the furnace winding was prevented by encasing the reaction tube in an electrically grounded stainless steel tube to shield the electrode circuit from induced potentials.

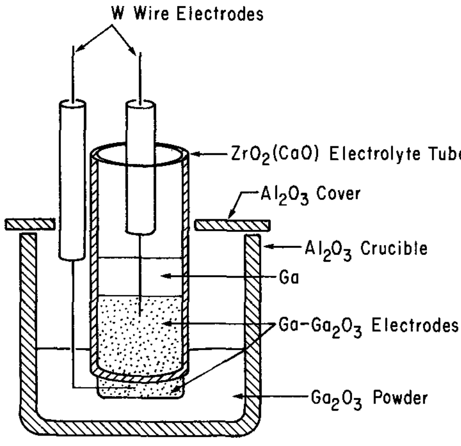

Fig. 1. Galvanic cell configuration

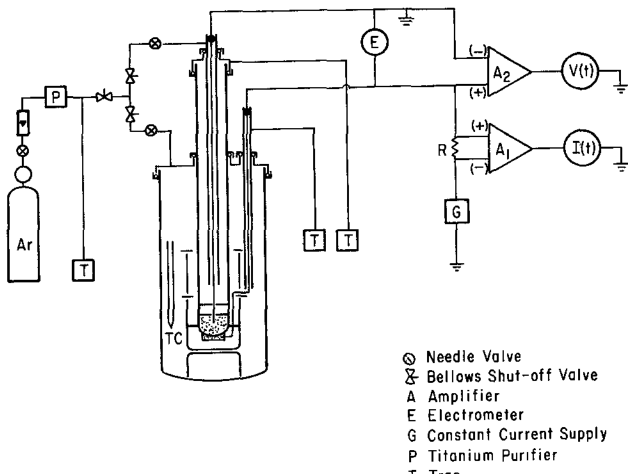

Fig. 2. Schematic of the gas manifold and electrical circuit employed in chronopotentiometric experiments.

The electrical circuit and purge gas manifold are shown schematically in Fig. 2. The emf of a Chromel-Alumel thermocouple used to measure the cell temperature was determined with a Leeds and Northrup K-3 potentiometric facility. The tungsten wire contacts to the Ga-Ga_2O_3 electrodes were passed through De Khotinsky cement and glass seals to isothermal copper connectors, then to coaxial cables. Cell currents were produced with an Electronics Measurements, Model C636 constant current power supply (G, Fig. 2). The ohmic component of the voltage response to current changes was measured with a dual beam Tektronic Type RM35A oscilloscope with a high speed Type G differential input preamplifier plug-in (A_2, Fig. 2). The cell emf was measured with a Keithley 610C electrometer (E, Fig. 2) having a sensitivity of ±0.02 mV and an offset current of 5×10^{-15}A.

Procedure.—Following assembly, the cell was well purged with flowing argon. Both electrode compartments were leak tight, as checked with a He leak detector. The initially 99.998% pure Ar was purified by passing it through a Centorr gas-purification furnace containing Ti chips heated to 800°C. After thorough purging, the cell temperature was raised to the operating temperature at 75°C/hr to minimize thermal stress on the ZrO_2(CaO) electrolyte. The cell was equilibrated overnight at the working temperature to anneal the electrodes and to allow a check on cell emf stability. During measurements both electrode compartments were sealed off from the gas manifold to prevent emf errors from gas flow sources.

Experiments were conducted with constant current density pulses between 0.3 and 130 $\mu A/cm^2$. The open cell voltage was measured after equilibration and before current was applied. The ohmic voltage was measured from the abrupt change in oscilloscope trace occurring when the current to the cell was applied or terminated. Following the onset of each pulse the cell voltage was monitored intermittently for a period of 10-20 min during which the current was applied, followed by intermittent voltage measurements with no current for an additional 10-30 min period during which equilibrium was established. After all experiments were completed the cell temperature was lowered at 70°C/hr under flowing Ar. The cell was then dismantled for inspection of the electrodes and electrode-electrolyte interface to insure that the electrode remained two-phase during the experiments, and that wetting of the electrolyte by liquid gallium had occurred.

Results

Chronopotentiometric studies were carried out with the cell

$$W/Ga_{(l)}\text{-}Ga_2O_3/Zr_{0.85}Ca_{0.15}O_{1.85}/Ga_{(l)}\text{-}Ga_2O_3/W \quad [I]$$

Wagner (1) has shown that the cell emf is a function of the oxygen partial pressure at the two electrode-electrolyte interfaces

$$\text{emf} = \frac{RT}{4F}\int_{\ln P_{O_2}''}^{\ln P_{O_2}'} t_{ion} d \ln P_{O_2} \qquad P_{O_2}' > P_{O_2}'' \quad [1]$$

where t_{ion} is the ionic transference number. Thus, for the symmetric cell [I] at equilibrium, the cell emf should be zero. In practice, however, a small emf, V_O, can arise from small differences in temperature, composition, or ambience between the two electrodes. When a current density, i, is passed through the cell, an oxygen ion flux of magnitude $i/2$ flows in the opposite direction for which an ohmic voltage component $L\rho i$ appears across the electrolyte of thickness L and resistivity ρ. In addition a local overpotential, η, appears at each of the two electrode-electrolyte interfaces which, for small oxygen partial pressure gradients, are

$$\eta' = \frac{RT}{4F} \ln (P_{O_2}'/P_{O_2}'^{e}) \quad [2a]$$

$$\eta'' = \frac{RT}{4F} \ln (P_{O_2}''/P_{O_2}''^{e})^{-1} \quad [2b]$$

where $P_{O_2}'^{e}$ and $P_{O_2}''^{e}$ are the oxygen partial pressures far from the electrolyte in electrodes 1 and 2, respectively. Thus, the cell voltage measured during current flow is

$$V = V_O + \eta' + \eta'' + L\rho i \quad [3]$$

The total, steady-state overpotential $\eta_t = \eta' + \eta''$ is a function of current density whose magnitude depends on the oxygen transfer kinetic mechanism. The magnitude of $\eta_t(i)$, and thus information on this mechanism, is readily deduced from $V(i)$ measurements and independent determinations of V_O, L, and ρ.

The cell voltage response to a long galvanostatic pulse is shown schematically in Fig. 3a. The experimentally measured voltages during, and following a

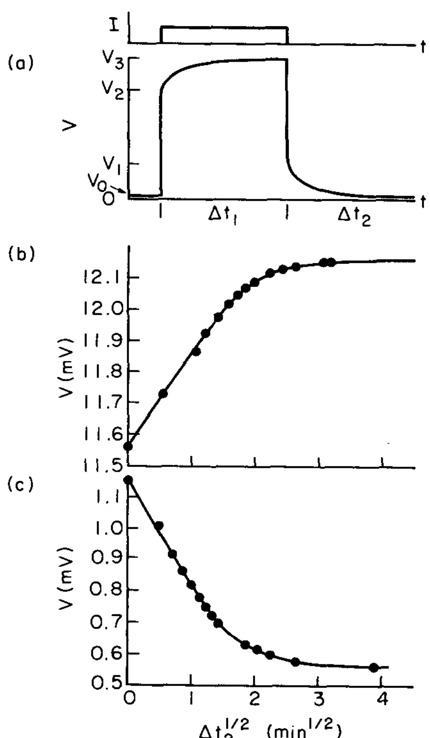

Fig. 3. Cell voltage response to a galvanostatic pulse of 56 μA/cm² and long duration. (a) Schematic time dependence; (b) galvanostatic voltage rise following current initiation; (c) voltage decline following current termination.

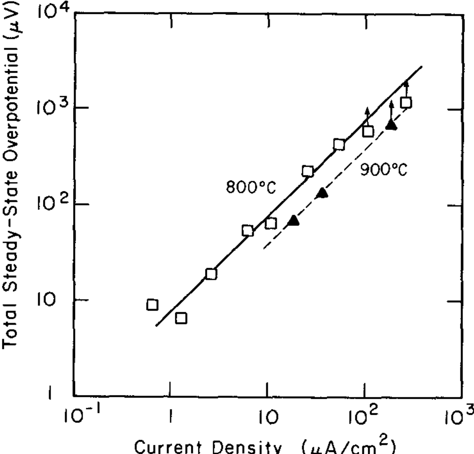

Fig. 4. Total steady-state overpotential as a function of current density for the cell $Ga\text{-}Ga_2O_3/ZrO_2(CaO)/Ga\text{-}Ga_2O_3$.

pulse of 56 μA/cm² are shown in Fig. 3b and c, respectively. The data are plotted as a function of the square root of the incremental time following the current change to show the parabolic time dependence of the voltage transients.

The total steady-state overpotential η_t was calculated for each chronopotentiometric experiment from the magnitude of the galvanostatic voltage transient ($V_3 - V_2$, in Fig. 3a). The dependence of η_t on current density passed through the cell at 800°C is shown in Fig. 4. Measurements at current densities well above 100 μA/cm² were hindered by the failure of the overpotential to reach steady state in a convenient period of time. On the other hand, measured overpotentials below ~25 μV were in error because of the finite noise level in the measurement circuit. A linear dependence of η_t on i was observed which, at 800°C, had a slope of 7.6 ± 2 ohms/cm² of electrode-electrolyte interface. Measurements of steady-state overpotentials at 900°C also showed a linear dependence of η_t on i with a slope of 4 ± 2 ohms/cm² of interface.

Discussion

Oxygen transfer mechanisms.—During passage of current between electrodes, charge-carrying oxygen ions are transferred across the solid electrolyte. Gallium oxidation occurs at the positive cell electrode and oxide reduction, at the negative electrode.

Several mechanisms for oxygen transfer between the electrodes operate in parallel, and these are summarized in Fig. 5. Oxygen flowing from the solid electrolyte into liquid gallium supersaturates the metal after charge transfer. In the solution-diffusion mechanism I the dissolved oxygen diffuses across a narrow liquid layer to an oxide surface where oxidation is assumed to take place. The oxide can form on the solid electrolyte if a nucleation and growth mechanism II is operative. Alternately, the dissolved oxygen can adsorb onto and diffuse along the solid electrolyte-liquid metal interface, III, to an oxide grain contacting the electrolyte. At points of three phase contact a metal-oxide-electrolyte reaction mechanism IV can operate without diffusion.

Oxygen transfer across the electrolyte-oxide interface can also occur by point defect migration through the oxide. For the anion diffusion mechanism V, interstitial oxygen ions diffuse to metallic regions, or alternately, oxygen vacancies diffuse from the metal following local oxidation toward the electrolyte. In the cation diffusion mechanism VI, interstitial cations diffuse from the metal to the electrolyte where oxidation displaces the oxide phase in the direction away from the solid electrolyte.

Each oxygen transfer mechanism involves the series of kinetic steps. The charge transfer and oxidation

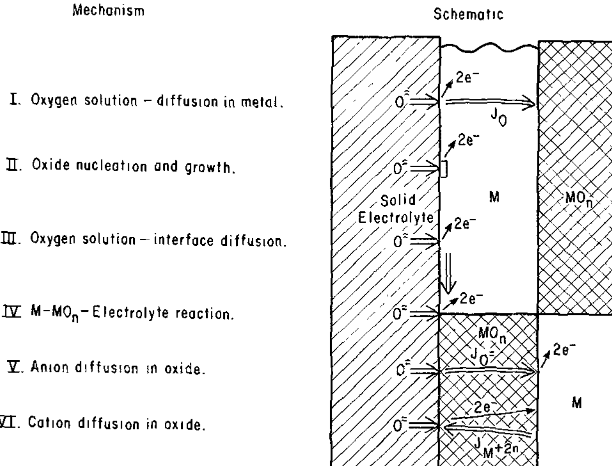

Fig. 5. Mechanisms for charge transfer from a solid electrolyte to a metal-metal oxide electrode.

processes are common to all oxygen transfer mechanisms, while dissolution and liquid-phase or solid-state diffusion are required by several. Usually one step will be rate limiting.

Several of the oxygen transfer mechanisms do not contribute significantly to the total oxygen flux. Oxide nucleation by mechanism II cannot operate at sufficiently low oxygen supersaturation of the liquid phase (10^{-2} in this study). The oxygen solution-interface diffusion mechanism III is probably rate limited by the interfacial diffusion process for which the interfacial oxygen permeability is less than that for the bulk liquid phase. The extent to which the metal-oxide-electrolyte reaction mechanism IV can operate is limited by the amount of oxide contacting the electrolyte.

For the oxygen transfer mechanisms V and VI, diffusive transport of point defects should be rate limiting. Cation interstitial diffusion is known to predominate over anion diffusion mechanisms in Ga_2O_3. In a study of the oxidation kinetics of GaAs (27), an oxide film of Ga_2O_3 was found to form after evaporation of arsenic. Further oxidation proceeds by interstitial diffusion of Ga through the oxide layer. This mechanism is corroborated by Rosenberg (28) for InSb oxidation. The Sb remains metallic because the diffusivity of Sb as well as oxygen is much lower than that of the trivalent metal in the oxide. Thus, the anion diffusion mechanism V is virtually inoperative compared to the cation diffusion mechanism VI. The cation diffusivity of the oxide, however, is significantly lower than the oxygen diffusivity of liquid gallium (29).

A study of the mechanisms shown schematically in Fig. 5 indicates that the solution-diffusion mechanism I should predominate in the temperature range studied, owing to the large permeability of liquid gallium. This mechanism is explored in the following section.

Solution-diffusion model.—The solution-diffusion model for aqueous reactions between sparingly soluble reagents and conducting electrodes has been investigated extensively by Dunning *et al.* (30) and studied experimentally by Katan *et al.* (17). The numerous local complex reaction paths operating at the electrode-electrolyte interface can easily be combined by expressing the over-all rate constant k as a function of the rate constants for the ith step, k_i

$$k = [\sum_i A_i k_i^{-1}]^{-1} \quad [4]$$

The numerical value of the coefficients, however, must be determined experimentally, unless the rate-controlling step can be deduced by relative magnitude estimates. Such estimates suggest that liquid-phase diffusion of dissolved oxygen is rate controlling in the Ga-Ga_2O_3 electrode, and thus the over-all rate constant k is approximately D_O, the diffusivity of oxygen in liquid gallium. This estimate of the rate-controlling step is supported by a recent study of oxygen transfer between solid metal-metal oxide electrodes and solid electrolytes, where oxygen diffusion in the metal was found to be rate controlling (23).

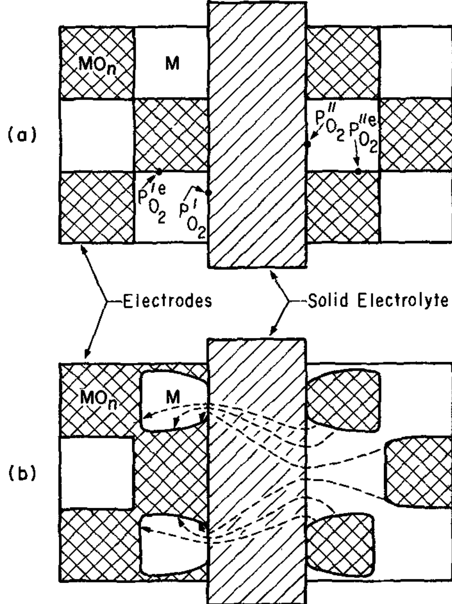

Fig. 6. Schematic of a symmetric liquid metal-metal oxide electrode, solid-state galvanic cell. (a) Before current flow; (b) after current flow assuming a solution-diffusion mechanism for oxygen transfer.

Oxygen transport through the experimental cell by mechanism I under a galvanostatic driving force is shown schematically in Fig. 6. The overpotential at each electrode can be calculated from Eq. [2] and [3] with the oxygen partial pressures at the electrolyte surfaces, P_{O_2}' and P_{O_2}'', and from the equilibrium partial pressures at the metal-metal oxide interfaces within the electrode, $P_{O_2}'^{e}$ and $P_{O_2}''^{e}$. The average partial pressure drops within the electrodes can be defined by $\overline{\Delta P'} = P_{O_2}' - P_{O_2}'^{e}$ and $\overline{\Delta P''} = P_{O_2}''^{e} - P_{O_2}''$. The electrode overpotentials in the electrodes are then

$$\eta' = \frac{RT}{4F} \ln\left(1 + \frac{\overline{\Delta P'}}{P_{O_2}'}\right) \simeq \frac{RT}{4F}\frac{\overline{\Delta P'}}{P_{O_2}'} \quad [5a]$$

$$\eta'' = \frac{RT}{4F} \ln\left(1 - \frac{\overline{\Delta P''}}{P_{O_2}''}\right)^{-1} \simeq \frac{RT}{4F}\frac{\overline{\Delta P''}}{P_{O_2}''} \quad [5b]$$

The oxygen partial pressures can be converted to oxygen molar solubilities by Sievert's law from which it follows, for the reaction $O_2 \rightarrow 2\ O_{diss.}$, that the solubility is proportional to P_{O_2} and, therefore, $\Delta c/c = \frac{1}{2} \Delta P/P_{O_2}$.

The oxygen solubilities at the electrolyte surfaces will differ from the equilibrium solubility c_O at the cell temperature. However, in the limit of small supersaturations, the overpotential for electrode 1 becomes

$$\eta' = \frac{RT}{2F}\frac{\overline{\Delta c'}}{c_O} \quad [6]$$

The oxygen ion molar flux J is related to the cell current density by Faraday's law, which for divalent ions is $it_{ion} = 2FJ$. The oxygen flux within the electrode metal phase is related to the oxygen diffusivity by Fick's first law

$$J = -D \overline{\frac{\partial c}{\partial z}}\bigg|_{z=0} = D \frac{\overline{\Delta c}}{l} \quad [7]$$

where $\overline{\partial c/\partial z}$ is the average concentration gradient at the electrolyte and l is a characteristic length. The dependence of the solubility drop on cell current is then

$$\overline{\Delta c} = \frac{i t_{\text{ion}} l}{2\mathbf{F}D} \quad [8]$$

Finally, the dependence of the electrode overpotentials on cell current is obtained by combining Eq. [6] and [8]

$$\eta' = \frac{RT\, l'}{4\mathbf{F}^2 Dc_O} t_{\text{ion}} i \quad [9]$$

An identical expression applies to the second electrode. The ratio η'/i is the specific electrode resistance $R_{\eta'}$.

All coefficients in Eq. [9] are experimentally known except for the oxygen permeability of liquid gallium, Dc_O, and the characteristic diffusion lengths, l'.

The oxygen permeability of liquid gallium can be deduced from the measured oxygen solubility c_O and the liquid-phase diffusivity D. The solubility of Ga_2O_3 in liquid gallium was determined by Foster and Scardefield (30) by a gravimetric method over the temperature range from 900° to 1200°C. Their experimental data on oxide mole fraction is represented here by the relation

$$x_{Ga_2O_3} = 1.175 \times 10^2 \exp\left[(-35{,}850 \pm 1{,}140)/RT\right] \quad [10]$$

The solubility of atomic oxygen is then found by assuming that the dissolved oxide dissociates into atomic components, from which it follows that the molar solubility c_O ($\cong 3x_{Ga_2O_3}d_{Ga}/M_{Ga}$) is

$$c_O = 30.63 \exp\left[(-35{,}850 \pm 1{,}140)/RT\right] \quad [11a]$$

The activation energy for dissolution is 35,850 ± 1,140 cal for the available data, and thus the extrapolation of the oxygen solubility to low temperatures produces an error which increases with the extent of extrapolation. The diffusivity of oxygen in liquid gallium was measured by Klinedinst (29) by galvanostatic titration experiments. The diffusion coefficient was expressed by the equation

$$D_{O,Ga(l)} = (3.68 \pm 0.42) \times 10^{-3} \exp\left[(-8{,}370 \pm 0.25)/RT\right] \quad [11b]$$

The permeability of atomic oxygen in liquid gallium is, finally

$$Dc_O = 0.11273 \exp\left[(-44{,}220 \pm 1{,}140)/RT\right] \quad [12]$$

Thus, the permeabilities at 800° and 900°C are 1.11×10^{-10} and 6.49×10^{-10}, respectively.

A general dependence of the local overpotential on temperature and current density for the solution diffusion model can now be found by combining the permeability Eq. [12] with Eq. [9], for $t_{\text{ion}} \simeq 1$

$$\eta' = (1.98 \times 10^{-9})\, l' i T \exp(44{,}220/RT) \quad [13]$$

Again, the diffusion length l' depends on the electrode structure. The Ga-Ga_2O_3 electrode resistivity associated with the local overpotential can be defined by

$$\rho_{\eta'} \equiv \frac{\eta'}{l' i} = (1.98\ 10^{-9})\, T \exp(44{,}220/RT) \quad [14]$$

Unlike the overpotential resistance per unit area ($R_{\eta'} = \eta' i$), the local electrode resistivity is independent of the electrode structure and is a property of the oxygen transfer through the liquid phase.

Ga-Ga_2O_3 electrode properties.—If the solution-diffusion mechanism controls oxygen transfer between the Ga-Ga_2O_3 electrode and the solid electrolyte with dissolved oxygen diffusion in liquid gallium as the rate-controlling step, then the interfacial transfer resistivity $\rho_{\eta'}$ should be given by Eq. [14]. This rate control can be tested by comparing experimental data for η'/i with $\rho_{\eta'}$, calculated from Eq. [14]. The effective diffusion length required is then given by

$$l' = 5.05 \times 10^8\, T^{-1} \exp(-44{,}220/RT) \cdot (\eta'/i)|_{\text{meas.}} \quad [15]$$

At 800°C, ρ_η equals 2162 ohm-cm, whereas the measured η'/i is 3.8 ohm-cm^2. The diffusion length deduced from these data is then

$$l' = 1.76 \times 10^{-3}\ \text{cm}$$

This diffusion length is consistent with the actual electrode structure in which loosely packed Ga_2O_3 particles with an average diameter of 2.5×10^{-3} cm are infused with liquid gallium. The experimental data at 900°C indicates an effective diffusion length of 5.0×10^{-3} which is somewhat larger than expected for diffusion-limited kinetics, but within the limits of error and reproducibility of the electrode structure.

Another test of the mechanism and rate control lies in the time dependence of the overpotential following initiation of a constant cell current. Transport of oxygen ions through the electrolyte causes a local supersaturation of dissolved oxygen which, in the quasi-steady state, can be shown to be related to the diffusion flux J and time t by

$$\Delta c \simeq J\sqrt{2t/D} \quad [16]$$

The time dependence of the local electrode overpotential is then

$$\eta'(t) \alpha \eta'(\infty)\sqrt{2Dt}/l' \quad [17]$$

A linear dependence of η' on $t^{1/2}$ for short times was observed in all experiments, again supporting the diffusion-limited kinetics.

The measured overpotentials were independent of the direction of current flow to within 5%. The asymmetry of the experimental cell was minimized by limiting the interfacial area of the outer electrode in contact with the electrolyte tube. The dependence of overpotential on the direction of current flow is assumed to indicate differences in oxide packing within the two Ga-Ga_2O_3 electrodes.

The total oxygen flux transferred during the experiments is not expected to significantly alter the electrode structure at the solid electrolyte interface according to mechanism I. A calculation, based on the fact that 1 coulomb passing through the cell transfers 5.18×10^{-6} moles of oxygen, shows that an oxide thickness of only 200 Å/cm^2 of electrode-electrolyte interface was transferred during all experiments. For the idealized interface structure shown in Fig. 6, the ratio of oxide-metal area to metal-electrolyte area is 2.5, and thus the average oxide-metal interface displacement is only 80Å. Most of the oxide-metal interface displacement takes place near the electrolyte where the diffusion distance is short, however, and this effect leads to the current-modified electrode structure shown in Fig. 6b. For the actual electrode containing irregular oxide particles in a liquid matrix, the oxide transfer processes has less effect on the electrode structure because of limited three-phase contact.

A comparison of the present results with earlier studies shows that the Ga-Ga_2O_3 electrode exhibits an exceptionally low overpotential-associated resistance. Worrell and Iskoe (23) have measured the dependence of steady-state overpotentials on cell current for symmetric cells of the type M-MO_n/ZrO_2(CaO)/M-MO_n, in which the M-MO_n electrodes were Ni-NiO, Fe-FeO, and Cu-Cu_2O. The steady-state overpotentials per unit area of electrode-electrolyte interface calculated from their data are shown in Fig. 7 along with the measurements from this study. From this comparison it can be seen that the Ga-Ga_2O_3 electrode exhibits a lower

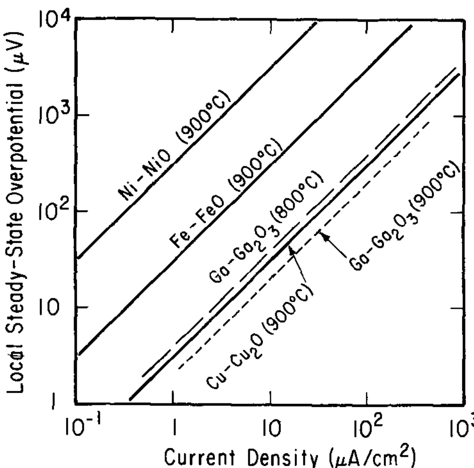

Fig. 7. Local steady-state overpotentials as a function of current density for Ni-NiO, Fe-FeO, Cu-Cu_2O, and Ga-Ga_2O_3 electrodes.

electrode overpotential than do the three most commonly employed reference electrode and, therefore, promises to be a superior reference electrode for kinetics and phase equilibria applications in the low partial pressure range.

The Triangular Voltage Sweep Method for Determining Double-Layer Capacity of Porous Electrodes

III. Porous Nickel in Potassium Hydroxide

E. G. Gagnon*

Electrochemistry Department, Research Laboratories, General Motors Corporation, Warren, Michigan 48090

ABSTRACT

The effects of faradaic current and distributed capacity on the measurement of double-layer capacity of porous nickel were analyzed as a function of electrode thickness and temperature. Faradaic current observed with electrodes at −46°C was negligible compared to results obtained at 22°C. Distributed capacity effects increased with electrode thickness and with decreasing temperature; the results agreed well with values predicted from a previously developed model. In the potential range of 0 to −0.40V *vs.* Hg/HgO, the capacity based on the BET area of the electrode was about 30 $\mu F/cm^2$.

The electrochemically active surface area of a porous electrode can be determined directly and simply from double-layer capacity (DLC) measurements. Faradaic currents and distributed reactions, however, may interfere with the analysis. Unless these effects can be eliminated or minimized, spurious results will be obtained. This paper shows how faradaic current and/or distributed capacity effects can be handled using a triangular voltage sweep (TVS) technique. The system investigated was porous nickel in 31 weight per cent (w/o) KOH.

Theory

The physical model of the porous electrode-electrolyte system considered was discussed before (1). Triangular voltage sweep results, where DLC is constant, will be analyzed for cases where faradaic current, i_F, and/or distributed capacity effects are present.

Faradaic currents are often caused by processes which are complex and difficult to describe mathematically (*e.g.*, removal of impurities on an electrode or the adsorption of species present in the electrolyte). The results are difficult to analyze because the electrode reactions are often unsteady-state processes.

Distributed capacity effects arise when the outer surface of a porous electrode charges or discharges faster than the interior. Increasing the resistance of the electrolyte in the pores of the electrode enhances this effect. Four cases for the TVS method will now be discussed.

Case A: Faradaic current and distributed capacity effects negligible.

In the absence of faradaic current, i_F, and distributed capacity effects, an electrode which behaves as a plane capacitor will produce a current-time curve of the type illustrated in Fig. 1A; DLC is calculated simply from

$$C = i_c/k \quad [1]$$

where i_c is the capacitative current (milliamperes); C is capacity (farads); and, k is the sweep rate (millivolts/second).

Case B: Faradaic current significant, but distributed capacity effects negligible.

If the electrode is passing faradaiç current, i_F, the total measured current is $i = i_c + i_F$. Thus, the resulting i-t curve is illustrated in Fig. 1B. If i_F is not too large compared to i_c, i_F will have about the same value just before and after the reversal point of the sweep. Then, $i_1 = i_F + kC$ and $i_2 = kC - i_F$. It can be easily seen that

$$C = (i_1 + i_2)/2k \quad [2]$$

and a capacity corrected for i_F is obtained.

Case C: Distributed capacity effects significant, but faradaic current negligible.

In the absence of i_F effects, distributed capacity gives rise to behavior illustrated in Fig. 1C. It has already been shown (1) that the current density (milliamperes/square centimeter) at the face of the electrode, $i(L)$, may be predicted in region abcd (Fig. 1C) from

$$i(L) = \beta_1 kC' \quad [3]$$

where

$$\beta_1 = 1 - \sum_{n=1}^{\infty} \exp\left[-M_n^2 \frac{t}{\rho_e C' L}\right]\left[\frac{2\psi^2}{M_n^2(\psi^2 + M_n^2 + \psi)}\right]$$

$$\psi = \frac{L\lambda}{d} = \frac{\rho_e}{R_e A} = M_n \tan M_n \quad [4]$$

$$\rho_e = \rho\lambda \quad [5]$$

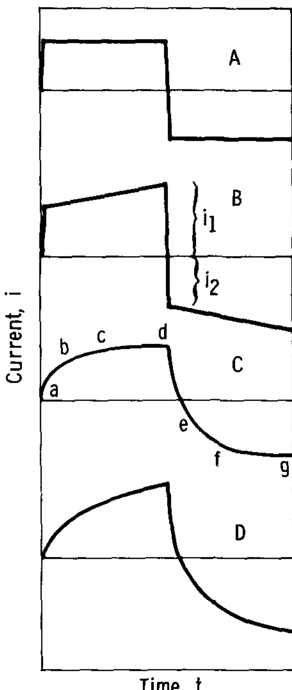

Fig. 1. TVS results illustrating faradaic and/or distributed capacity effects. A, i_F and distributed capacity effects negligible; B, i_F effects significant; C, distributed capacity effects significant; D, i_F and distributed capacity effects significant.

* Electrochemical Society Active Member.

Key words: porous electrodes, double-layer capacity, nickel electrode.

and k is sweep rate (millivolts/second); C' is capacity (farads/square centimeter) based on the geometric area, A (square centimeters), of the electrode; L is electrode thickness (centimeters); t is time (seconds); ρ is the specific resistance (ohm-centimeter) of the bulk electrolyte; ρ_e is the specific resistance (ohm-centimeter) of the electrolyte in the pores of the electrode; R_e is the resistance (ohms) of the bulk electrolyte; λ is the labyrinth factor; d is the distance (centimeters) between the surface of the electrode and the tip of the Luggin capillary; M_n are the various roots of the transcendental equation $\psi = M_n \tan M_n$. Clearly, as time decreases, as electrode thickness increases, or as the specific resistance of the electrolyte increases, distributed capacity effects become more significant.

At the reversal point of the TVS, the current density at the face of the porous electrode was also predicted (1) from

$$i(L) = \gamma k C' \quad [6]$$

where

$$\gamma = \beta_1 - \beta_2$$

and

$$\beta_2 = \sum_{n=1}^{\infty} \exp\left[-M_n^2 \frac{t}{\rho_e C' L}\right] \cdot \left[\frac{2(\psi^2 + M_n^2)}{M_n^2(\psi^2 + M_n^2 + \psi)}\right] \sin^2 M_n$$

Case D: Faradaic current and distributed capacity effects significant.

When both faradaic current and distributed capacity effects are significant, the i-t curve obtained is illustrated in Fig. 1D. This case is difficult to handle mathematically. If possible, it is best to handle the situation experimentally by selecting the experimental conditions to minimize one or both of the effects.

Experimental

The electrochemical cell and instrumentation used in this study were discussed previously (1). The test electrodes were punched from a sheet of sintered, porous nickel battery plaque. They were disk-shaped, had a thickness of about 0.046 cm, a diameter of 3.5 cm, and a BET area of 0.049 m^2/g. Electrodes of different thicknesses were obtained by stacking a number of the 0.046 cm thick disks into a special electrode holder (2); only one face of the electrode was exposed to the electrolyte.

All measurements were performed using an Hg/HgO (31 w/o KOH) reference electrode with a Luggin capillary positioned about 10 mm from the face of the test electrode. The cell and the reference electrode were placed in a constant temperature cabinet; measurements were made at 22° and −46° ± 0.5°C.

Results and Discussion

Figures 2-5 show results obtained using electrodes of different thickness at 22° and −46°C. In all cases, a starting potential of −0.10V *vs.* Hg/HgO was used; a sweep excursion of about 200 mV was selected to keep i_F not too large compared to i_c. In all of the work reported here, a sweep rate of 86.5 mV/sec was used. The i-t results obtained may be categorized according to the four cases, illustrated in Fig. 1; the results are summarized in Table I.

Table I. Characterization of i-t data as a function of electrode thickness and temperature

Electrode thickness (cm)	Case types	
	22°C	−46°C
0.046	A	C
0.092	B	C
0.137	B	C
0.183	D	C

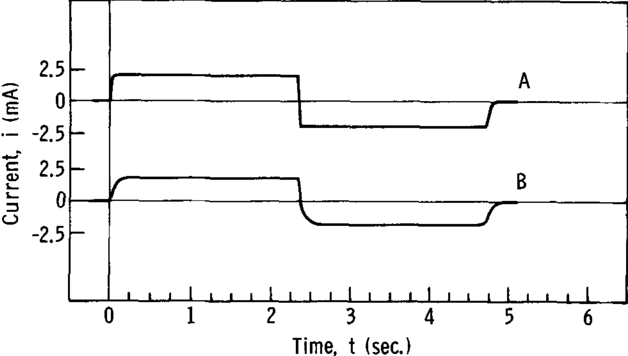

Fig. 2. Sweep data obtained for a 0.046 cm thick porous nickel electrode using a sweep rate of 86.5 mV/sec. A, At 22°C; B, at −46°C.

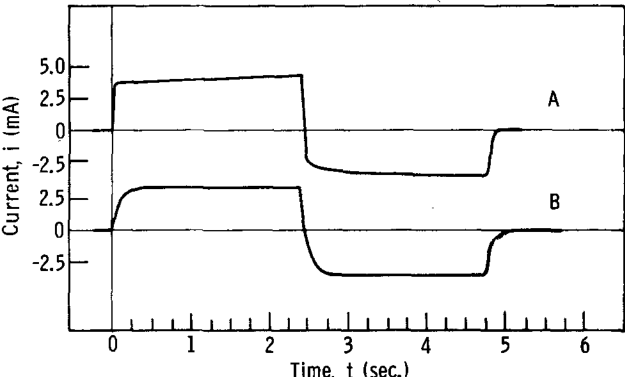

Fig. 3. Sweep data obtained for a 0.092 cm thick porous nickel electrode using a sweep rate of 86.5 mV/sec. A, At 22°C; B, at −46°C.

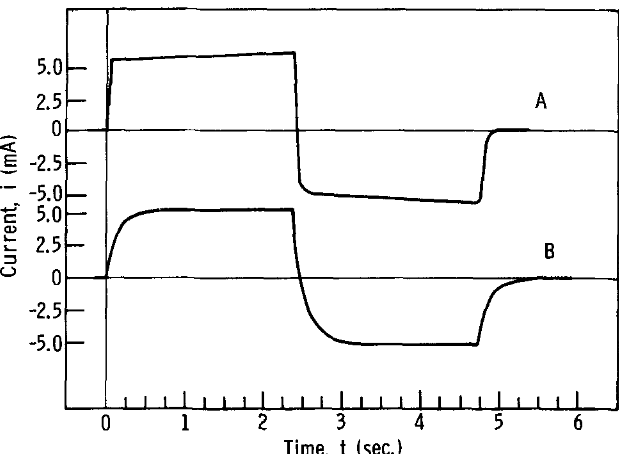

Fig. 4. Sweep data obtained for a 0.137 cm thick porous nickel electrode using a sweep rate of 86.5 mV/sec. A, At 22°C; B, at −46°C.

At 22°C, the i-t curve for the thinnest electrode (Fig. 2A) was essentially symmetrical about zero current and approximated the square wave illustrated in Fig. 1A. This is characteristic of an electrode behaving as a plane capacitor. The capacity of the electrode, C, was calculated (using Eq. [1]) to be 0.021 farads which, based on the BET area of the electrode, gives a value of 30 $\mu F/cm^2$. A similar shape was observed at −46°C (Fig. 2B) except that some rounding effects were noted at the start and at reversal point of the sweep, showing the presence of some distributed reactions. The calculated capacity was the same as at room temperature.

As the electrode thickness increased, faradaic current effects also increased; the thickest electrode (Fig. 5A) showed signs of distributed reactions in addition to faradaic current effects (Case D, Fig. 1D).

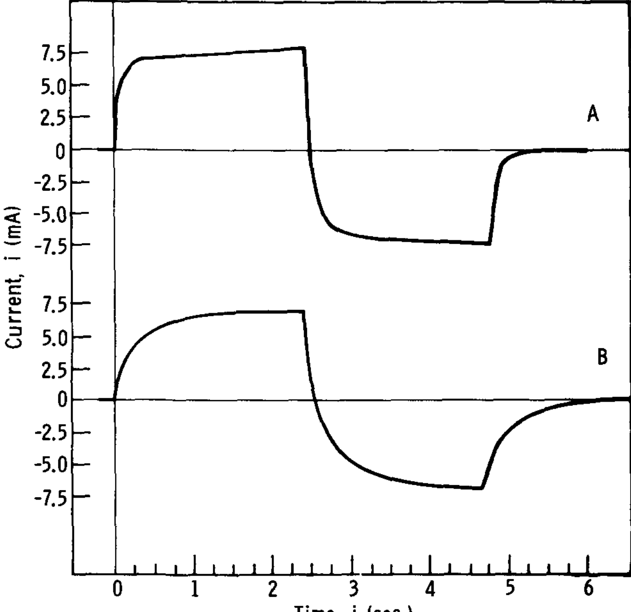

Fig. 5. Sweep data obtained for a 0.183 cm thick porous nickel electrode using a sweep rate of 86.5 mV/sec. A, At 22°C; B, at −46°C.

At −46°C, all four electrode thicknesses (Fig. 2B, 3B, 4B, and 5B) displayed the same general shape illustrated in Fig. 1C; the time, however, for the current to reach a steady value both at the start and after the reversal point of the sweep increased with electrode thickness. A plot of the steady current as a function of electrode thickness at −46°C, given in Fig. 6, is linear. This is expected since the double-layer capacity of an electrode is proportional to electrode area in the absence of distributed capacity and i_F effects.

Distributed capacity effects.—To test if the times observed initially and at the reversal point of the sweep at −46°C could be predicted from Eq. [3] and [6], respectively, estimates of the parameters ψ, λ, d, and ρ_e were made to calculate β and γ, for each electrode thickness.

The distance, d, was obtained, as in earlier work (3), using galvanostatic transient measurements performed at temperatures ranging from 22° to −46°C. Ohmic polarization, taken as the discontinuity on the oscilloscopic potential-time trace, was found to be due primarily to the resistance of the electrolyte between the electrode and the tip of the Luggin capillary. The distance d, was then estimated from $d = R_eA/\rho$; a value of $d = 0.94$ cm was determined.

A labyrinth factor, λ, of 1.3 was estimated similarly to earlier work with porous silver (1). It was accomplished by matching one set of experimental results (Fig. 2B) with data predicted from Eq. [3] and [6], thus fixing a value of ψ. These parameters were then used to predict i-t results for other electrode thickness. Predicted and experimental i-t results obtained as a function of electrode thickness are shown in Fig. 7

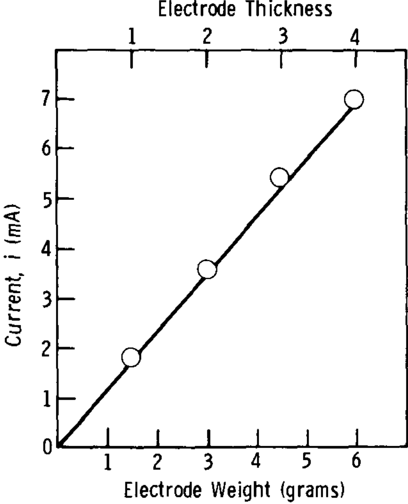

Fig. 6. Capacitive current vs. electrode thickness

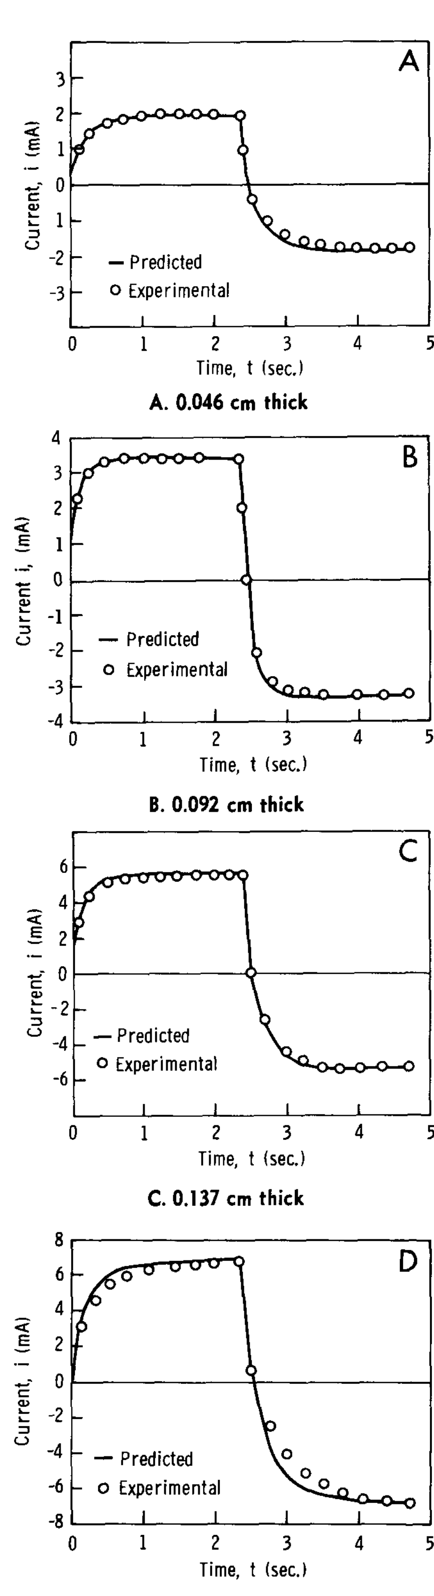

Fig. 7. Predicted and experimental data for electrodes of different thickness at −46°C.

Table II. Parameters used in the distributed capacity predictions

Thickness (cm)	Predicted		Experimental
	ψ	Capacity, C (farads)	Capacity, C (farads)
0.046	0.063	—	0.021
0.092	0.126*	0.042*	—
0.137	0.190*	0.063*	—
0.183	0.253*	0.084*	—

* Values predicted using the 0.046 cm thick electrode data at −46°C and a value of λ = 1.3.

Table III. A comparison of capacitive currents corrected for i_F effects at 22°C vs. values measured at −46°C

Electrode thickness (cm)	Capacitive currents	
	22°C*	−46°C**
0.046	1.8	1.8
0.092	3.4	3.6
0.137	5.0	5.4
0.183	4.3	7.1

* Corrected.
** Experimental.

A-D. Table II gives some of the important parameters used.

Faradaic current effects.—Calculations using Eq. [2], which correct for faradaic current, were made for all electrode thicknesses at 22°C. The capacitive currents corrected for i_F are compared to the low temperature data in Table III.

The i_F corrected capacitive currents calculated for the first three electrode thicknesses agreed reasonably well with the low temperature values; for the thickest electrode, however, a significant deviation was noted. The discrepancy noted with the thickest electrode was due to distributed capacity effects which interfered with analysis of the data (*i.e.*, excessive rounding of the *i-t* curve after sweep reversal). The faradaic current observed was a transient effect, since the current just prior to the start of the sweep was zero.

Effect of potential.—Apparent capacities were calculated from a series of *i-t* curves where the start of each sweep was at a different potential, but each was run in the cathodic direction at the same sweep rate, *k*, of 86.5 mV/sec; conditions were such as to minimize distributed capacity and faradaic current effects. The capacity, based on the BET area of the electrode, appears to be nearly constant at about 30 $\mu F/cm^2$ in the potential range of 0 to −0.40V *vs.* Hg/HgO.

Summary and Conclusions

This work showed that by properly selecting the test conditions, effects due to distributed capacity and for faradaic current could be minimized, thus enabling one to measure the double-layer capacity of porous nickel in 31 w/o KOH. With very thin electrodes, at 22°C, faradaic current and distributed capacity effects were negligible, and the electrode behaved simply as a plane capacitor. As the thickness of the electrode increased, transient faradaic currents also increased at 22°C, which made it somewhat difficult to estimate the capacity using the conventional approach. At −46°C, however, faradaic current effects were found to be negligible, but distributed capacity effects became more predominant with increasing electrode thickness. It was shown that the distributed capacity effects could be predicted using a mathematical model which had been previously developed.

When faradaic current effects were significant and distributed capacity effects were negligible, the capacity corrected for faradaic current at the reversal point of the sweep was about the same as the capacity determined at −46°C.

The capacity based on the BET area of the electrode was nearly constant at about 30 $\mu F/cm^2$ in the potential range of 0 to −0.40V *vs.* Hg/HgO. This compares well with a value of 29 $\mu F/cm^2$ in 1M Na_2SO_4 at −0.4V *vs.* SCE (4).

Polarographic Behavior of *p*-Dihalosubstituted Benzenes and Related Compounds

S. Wawzonek* and S. M. Heilmann

Department of Chemistry, University of Iowa, Iowa City, Iowa 52240

ABSTRACT

p-Diodobenzene and *p*-iodophenyltrimethylammonium iodide show a normal polarographic behavior in dimethylformamide in contrast to that reported for *p*-dibromobenzene. 9,10-Dibromoanthracene and 9-bromoanthracene gave an abnormal polarographic behavior which suggested the intermediacy of dibenzo Dewar benzene in the electrode reaction. Macro electrolyses of 9-bromoanthracene were unsuccessful in preparing this compound.

p-Dibromobenzene has been reported (1) to show an unusual polarographic behavior in dimethylformamide and acetonitrile. The second reduction wave occurred at a slightly more positive potential than that for bromobenzene and the diffusion current was larger than that observed for the corresponding wave for *m*-dibromobenzene. This behavior was considered to be caused by the synergistic effect of the intermediate anion on the reduction of the second halogen with the possible formation of *p*-dehydrobenzene.

The work has now been extended to a study of the reduction of *p*-diiodobenzene, *p*-iodophenyltrimethylammonium iodide, and 9,10-dibromoanthracene to determine whether the tendency for *p*-dehydrobenzene would be increased. The first two compounds have better leaving groups than *p*-dibromobenzene and the last compound would possibly form a *p*-dehydrobenzene which would be stabilized by resonance.

Experimental

The solutions were studied in a cylindrically shaped cell with a mercury pool anode and fitted with side arms for the admission of nitrogen and for the anode connection. All measurements were made in a water thermostat at 25° ± 0.1°C.

The current-voltage curves were obtained with a Sargent Model XXI Polarograph.

The dropping mercury electrodes were operated at 70 cm pressure and had drop times of (*i*) 6.10 and (*ii*) 5.0 sec in dimethylformamide (open circuit). The $m^{2/3}t^{1/6}$ values were (*i*) 1.36 and (*ii*) 1.71 $mg^{2/3}\ sec^{-1/2}$, respectively.

Cyclic voltammetric studies were made using a Beckman Electroscan 30 and a Chemtrix Model SSP-2 Polarograph with a Tektronix Oscilloscope.

The compounds used were obtained from a stock with the exception of *p*-iodophenyltrimethylammonium iodide (2), phenyltrimethylammonium iodide (3), 9,10-dibromoanthracene (4), and hexamethylbicyclo[2,2,0]hexa-2,5-diene. The first three were prepared by methods given in the literature and the fourth compound was purchased from Columbia Chemical Company.

Electrolytic reduction of 9-bromoanthracene.—A solution of 9-bromoanthracene (3.0g) in dimethylformamide (100 ml) containing 0.2*M* tetrabutylammonium tetrafluoroborate was reduced at a controlled potential of −1.65 (SCE) at a mercury cathode (19.6 cm²). The cathode compartment was connected to a saturated calomel electrode by a 70% dimethylformamide-agar bridge. The anode compartment was separated from the cathode compartment with a medium porosity glass frit and contained a platinum foil cylinder anode. The initial current of 60 mA decreased to 1 mA in 4.5 hr and was terminated. A plot of current *vs.* time indicated the use of one electron per molecule of 9-bromoanthracene. The mercury was separated and the catholyte was filtered. The yellow solid (0.33g) obtained melted at 356°-358° [dec. lit. (5) > 300°] and was identified as *bis*-9-anthryl-mercury by its ir and mass spectra: m/e 556, (M), 197-202 (Hg).

The red filtrate when poured into a mixture of water (400 ml) and hexane (400 ml) gave a solid which was filtered; yield, 0.69g. This solid upon preparative chromatography on silica gel plates using hexane and methylene chloride as eluting solvents gave anthracene (0.55g). trace amounts of 9,9′-bianthryl and anthraquinone (0.02g). Identification of the last two solids was made by comparison with authentic samples.

The hexane extract was separated from the water layer and upon removal of the solvent gave 1.5g of a yellow solid. This solid which showed many components by thin layer chromatography (tlc) on silica using hexane was dissolved in a minimal amount of benzene and adsorbed on silica gel. The silica gel was dried and upon extraction with hexane for 36 hr in a Soxhlet extractor gave 0.96g of anthracene. Further extraction of the silica gel with chloroform gave 0.11g of a yellow solid. Preparative chromatography on two silica plates gave anthracene-9-mercuribromide (0.02g) and anthraquinone (0.03g). Identification was made by comparison with authentic samples. Other components were present in amounts too small to characterize.

The use of uncontrolled potential in this reduction gave *bis*-9-anthrylmercury (4%), anthracene (63%), anthraquinone (trace), and 9,10-dihydroanthracene (trace). An applied potential of 37V gave an initial current of 55 mA which decreased to 18 mA after 12 hr when the electrolysis was terminated.

Reduction at a platinum cathode using uncontrolled potential gave a dark brown semisolid residue. Tlc analysis of the crude mixture showed seven components. The only solid isolated was anthracene (76%). The applied potential of 20V gave a current of 80 mA which decreased to 26 mA at the termination of the electrolysis (12 hr).

Anthracene-9-mercuribromide.—A solution of anthracene (8.9g) and trichloroacetic acid (16.3g) in carbon tetrachloride was treated with yellow mercuric oxide (10.9g) and the resulting mixture was stirred at room temperature for 12 hr. The yellow solid obtained was filtered, washed with methanol, suspended in methanol (200 ml), and treated with a solution of sodium bromide (20.6g) in water (100 ml). Filtration of the resulting yellow green mixture gave a solid (13.33g) which upon crystallization from benzene gave yellow needles melting at 272°-275°. ir (KBr) 3.28, 3.30, 3.38, 6.10, 6.95, 7.65, 7.90, 8.75, 9.90, 10.85, 11.20, 11.90, 12.10, 13.05, 13.70, 13.90, 16.40, 19.70, 27.00μ; mass spectrum, *m/e* 459.

Results

The polarographic behavior of various halogenated aromatic compounds in dimethylformamide containing 0.2*M* tetrabutylammonium bromide is given in Table I.

To aid in formulating a mechanism of reduction for 9-bromoanthracene macro scale reductions were performed and the results are given in the Experimental Section.

Discussion of Results

Examination of the data in Table I indicates that the reduction of *p*-diiodobenzene and *p*-iodophenyltrimethylammonium iodide is normal and proceeds stepwise with no synergistic effect of the intermediate anion formed by the reduction of the iodine on the reduction of the second group.

The polarographic behaviors of 9,10-dibromoanthracene and 9-bromoanthracene were unusual and are shown in Fig. 1 and 2. The diffusion current for the first wave of anthracene resulting from the reduction of the halogen decreased to a point which was less or slightly higher than that of the reduction wave for 9-bromoanthracene.

Cyclic voltammetry of 9-bromoanthracene at a platinum cathode showed three cathodic peaks and one anodic peak for the oxidation of the anion radical of anthracene. A similar study at a stationary mercury

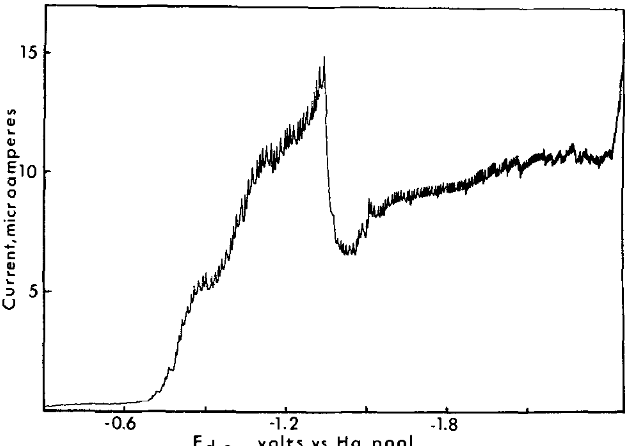

Fig. 1. Polarogram of 1.0 mmole 9,10-dibromoanthracene in dimethylformamide-0.2M tetrabutylammonium bromide.

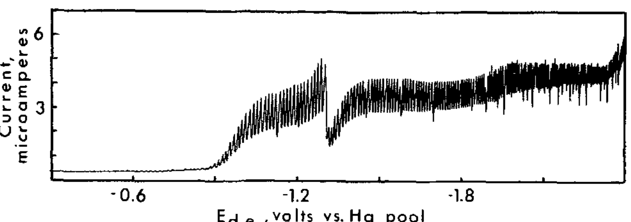

Fig. 2. Polarogram of 0.5 mmole 9-bromoanthracene in dimethylformamide-0.2M tetrabutylammonium bromide.

electrode was normal at a fast scan rate (10 V/sec) but showed an inverted peak for the 9-bromoanthracene portion at a slow scan rate (0.5 V/sec). Such inverted peaks have been observed in the one-electron reduction of oxymercurials (6), and cyanopropyltriphenylphosphonium bromide (7) and have been ascribed to the formation of rapidly absorbed radical intermediates (6). This type of explanation is unlikely for a two-electron reduction wave and was not substantiated by adsorption studies. The electrocapillary curve for the reduction of 9-bromoanthracene was similar to that obtained for the supporting electrolyte using either tetrabutylammonium bromide or perchlorate.

Another possible explanation for the unusual behavior of 9-bromoanthracene is formation of a Dewar benzene III

Br 2e⁻ I II III

The intermediate carbanion I formed by the reduction of 9-bromoanthracene protonates directly to anthracene or rearranges to the carbanion II which on protonation would give the Dewar benzene III. This compound (III) would probably be stable to further reduction since hexamethylbicyclo[2,2,0]-hexa-2,5-diene was not polarographically active under similar conditions.

Studies of the polarographic behavior of 9-bromoanthracene in the presence of excess phenol favored such reactions. In the presence of excess phenol, which would increase the rate of protonation of carbanion I the dip in the diffusion current was reduced and the diffusion current for the first anthracene wave became normal.

Attempts to isolate the Dewar benzene III by macroscale electrolytic reductions of 9-bromoanthracene were not successful. Electrolysis at controlled potential at a mercury cathode using a potential before the drop in current gave a complex mixture of products. Plotting the current used *vs.* electrolysis time indicated that only one electron was transferred per molecule of 9-bromoanthracene. Products isolated and identified were anthracene (73%), di-9-anthrylmercury (10%), anthraquinone (1%), *bis*-9-anthryl (trace), and 9-anthrylmercuric bromide (trace). The use of uncontrolled potential at the same electrode gave anthracene (63%), 9,10-dihydroanthracene (trace), di-9-anthrylmercury (4%), and anthraquinone (trace).

In order to avoid the formation of mercury compounds electrolysis was carried out at a platinum cathode at uncontrolled potentials and gave anthracene (76%) as the only isolable product.

Separations of products were made in all cases by chromatography on silica gel. The assumption was made that such treatment would not isomerize the

Dewar benzene III since other Dewar benzenes have been isolated by chromatography on both silica gel (8) and alumina (9). The Dewar benzene III is a bent molecule and in contrast to its planar isomer anthracene should interact less strongly with silica than the latter, and migrate more readily than anthracene. A similar relationship has been found in other Dewar benzene-aromatic systems (10).

If the assumptions made about the stability of the Dewar benzene III are valid, then this compound is not produced by the macroscale reduction of 9-bromoanthracene. The conditions for the latter are no longer diffusion controlled and products are obtained mainly from the carbanion I and from a one electron reduction of 9-bromoanthracene which results in the 9-anthryl radical.

Br
$\xrightarrow[-Br^-]{e^-}$

This radical is the precursor of the mercury compounds and di-9-anthryl isolated. This radical may also react with traces of oxygen and form anthraquinone.

Electrochemistry in N,N-dimethylformamide

I. The H_2(g,Pt) | HCl(DMF) | TlCl(s) | Tl(Hg) Cell

Leonard F. Silvester and Peter A. Rock

Department of Chemistry, University of California, Davis, California 95616

ABSTRACT

This paper reports the results of our electrochemical measurements on the cell

$$H_2(g,Pt)|HCl(DMF)|TlCl(s)|Tl(Hg,X)$$

where DMF is the solvent N,N-dimethylformamide. The cell was found to behave reversibly over the HCl concentration range of 0.017-0.24*M*, and over the $H_2(g)$ pressure range of 550-750 Torr. Data obtained from this cell were combined with literature data for the activity of Tl in Tl(Hg) and for the dissociation of HCl in DMF to obtain the standard cell voltage, $\mathcal{E}°$, of the cell

$$H_2(g,Pt)|H^+Cl^-(DMF)|TlCl(s)|Tl(s)$$

The value obtained is $\mathcal{E}°_{ion} = -886.8 \pm 2.0$ mV at 296.7K [molality composition scale, and strong electrolyte standard states for HCl(DMF)]. The behavior of the hydrogen electrode in DMF is discussed.

N,N-dimethylformamide (DMF) shows considerable promise as an aprotic solvent for use in electrochemical cells (1-4). DMF has a high dielectric constant (36.7 at 25°C), a low vapor pressure (3.7 Torr at 25°C), and it is not difficult to prepare in a high purity, anhydrous state (3, 5).

We have investigated the cell

$$H_2(g, Pt)|HCl(DMF)|TlCl(s)|Tl(Hg) \quad [1]$$

as part of an electrochemical study of the thermodynamics of hydrogen-isotope-exchange reactions (6). This paper reports the results of our electrochemical measurements for reversible cells of type [1]. The hydrogen electrode has been found to behave reversibly in anhydrous HCl (DMF) solutions.

Key words: N,N-dimethylformamide, hydrogen electrode, aprotic solvents, thallium electrode, reversible cell.

Experimental

Because of the need to exclude oxygen and water from the cell, the entire cell was set up and studied as a closed system on the vacuum line (6, 7).

Samples of $H_2(g)$ [99.999 atomic per cent (a/o)] were obtained from the Matheson Chemical Company. The purity of the $H_2(g)$ was checked by mass spectrometry. Before use in the emf cells, the H_2 was run through a "DEOXO" hydrogen purifier (Englehard Industries) and then through $CaSO_4$ drying towers. Thallium amalgams were prepared from weighed quantities of reagent grade Tl (precleaned with 0.01*M* H_2SO_4) and reagent grade Hg. The amalgam was washed with dilute (0.001*M*) HNO_3, thoroughly dried under high vacuum, and stored in a reservoir on the vacuum line. The DMF used was Mallinckrodt analytical reagent grade, and it was purified as follows

(8): The DMF was stored over 4Å molecular sieves for at least 1 week; the DMF was then transferred to the distillation apparatus on the vacuum line and 30g of P_2O_5 was added per 400 ml of DMF; the DMF was then vacuum distilled with a pot temperature of about 80°C and a head temperature of 33°-49°C. The distillation column was a ¾ in. Pyrex tube 4 ft in length that was packed with 3 × 5 mm Raschig rings. Only the middle 60% of the distillate was used to make the cell solutions. The purified DMF was stored on the vacuum line in a reservoir which was painted black to inhibit the photochemical decomposition of DMF (9). Samples of HCl(g) were prepared on the vacuum line via the reaction of H_2O(l) with PCl_5(s). [This is a violent reaction and the water must be added dropwise to the PCl_5 with cooling. This method is a convenient and economical way to prepare just the desired amount of anhydrous HCl(g) or DCl(g).]

The evolved gas was run first through a dry ice ethanol trap and then through three $CaSO_4$ drying towers (each 30 cm × 25 mm). The resulting anhydrous gas was then run into purified DMF in a mixing flask on the vacuum line (10). The HCl (DMF) solution was stored in the mixing flask on the vacuum line until its introduction to the cell. Samples of TlCl were obtained by bubbling anhydrous HCl(g) into a solution of $TlNO_3$ in purified DMF under a nitrogen atmosphere. The resulting TlCl(s) was thoroughly washed with purified DMF, vacuum dried at room temperature, and stored over $CaSO_4$. Cells of the type

$$\mathrm{Tl(Hg)|TlCl(s)|HCl(DMF)|TlCl(s)|Tl(Hg)} \quad [2]$$

had emf values < |0.005| mV when set up with TlCl(s) prepared as described above. Cells of this type set up with commercial, reagent grade TlCl gave emf values in the range 0.1-0.6 mV. Consequently, the commercial TlCl was not used.

The hydrogen electrodes were prepared as follows (11). Four feet of 0.020 in. diameter gold wire was wound in a closed-loop coil 40 mm in length and 11 mm in diameter. The coil leads were fused about 25 mm above the top of the coil to a platinum lead that exited via a Pt-to-soft-glass seal through the top of the hydrogen electrode cell compartment. The coils were cathodically cleaned in 3*M* H_2SO_4(aq), washed with distilled water, and given a coating of Pt black in a 2% $PtCl_4$ in 2*M* HCl(aq) plating solution; 15 min at 20 mA, followed by 5 min at 40 mA. The platinized electrodes were washed several times with distilled water and vacuum dried at room temperature. Cells of type

$$\mathrm{(Pt)H_2(g)|HCl(DMF)|H_2(g)(Pt)} \quad [3]$$

with identical hydrogen pressures rapidly gave emf values < |0.004| mV; the cells maintained these low emf values for periods ranging from 12 hr to several days. However, all such cells eventually gave rise to much larger, unstable emf values. The development of instability was always a rapid process which took place over a 1-2 hr period. The onset of such instabilities was readily recognized in cells of type [1], and the data reported here were obtained from the cells in their stable period.

The cell construction was of the simple H-type with a central large-bore stopcock. The cell was set up to operate as an automatically controlled, closed system on the high vacuum line. Samples of Tl(Hg), TlCl(s), and HCl(DMF) were run into the cell from their respective storage compartments after the cell was mounted on the vacuum line. The H_2(g) was continuously recycled through the cell by means of a Toepler-type, short-stroke, small displacement (10 cm^3/min^{-1}) pump (12). The gas bubbling rate in the hydrogen electrode compartment was set at about 2-3 bubbles per second. Pressure fluctuations from the operation of the pumps were observed to be less than 0.05 Torr at the pressures used in our cells. Pressures were measured on a differential manometer with a cathetometer; atmospheric pressure was read with a barometer.

The emf measurements were made with a Keithley 630 potentiometric electrometer, and an L and N certified K-3 potentiometer and L and N 9834 electronic mull detector. All cells were run at room temperature (23.5° ± 1°C), which was periodically recorded while the measurements were in progress. The cells must be run at room temperature or below in order to prevent condensation of the vapor phase in the pump systems or the manometers.

The molalities of the HCl(DMF) cell solutions were determined as follows. Samples of the cell solution were obtained from the cells and weighed; the weighed samples were then added to water and rapidly titrated with standardized, carbonate-free sodium hydroxide (0 ~ 0.01*M*) solution to a methyl red plus bromcresol green end point (pH ~ 5.4); the NaOH solution was standardized against an HCl(aq) solution of known concentration, which was obtained by dilution of constant-boiling HCl(aq). The possible interference of DMF with the analysis was ruled out by titration of known quantities of standardized HCl(aq) in the presence and absence of added DMF. The mole fraction of thallium, X_{Tl}, in the thallium amalgams was determined by a slightly modified version of the acidimetric method of Richards and Daniels (13, 10). The calculations described in the Results section were carried out in double precision on a DEC PDP-8 computer.

Results

The results of our measurements on cells of type [1] are presented in Table I. The emf, pressure, and temperature measurements were taken at 1 hr intervals during the life of the cell and the results were averaged. The period of stability of the cells ranged from 12 to 170 hr with a mean lifetime of 110 hr. The pressures reported have been corrected for the vapor pressure of the cell solutions (~ 3.5 Torr). Barometer location and temperature corrections have also been applied.

Reversibility checks (emf *vs.* meter scale position) gave no evidence of a hysteresis loop; this is strong evidence that the cells were operating under reversible conditions.

Measurements are reported only for the period during which the emf measurements with the gas bubblers on agreed within experimental error with those with the gas bubblers off. When this condition was not met the cells deteriorated rapidly, and the measured emf drifted when the gas bubblers were turned off.

* The last six cells in this table were run with 99.5% D_2 and 99.9% DCl, rather than H_2 and HCl. The reported emf values for the deuterium cells were converted to hydrogen cells by subtracting 7.64 mV from the measured emf value [see Ref. (6) and (15)].

† The values of $\mathcal{E}$ given in this column were calculated from Eq. [9] using $\mathcal{E}^\circ_{ion}$ = 854.0 mV and $2\omega A$ = 187.3 mV.

standard state) were obtained from a large-scale graph of $\ln \gamma_{Tl}$ *vs.* X_{Tl} at 23.5°C. The graph was constructed using the emf data on thallium amalgams of Richards and Daniels (13); the details of the method are described in the literature (14, 10).

The postulated cell reaction for cell [1] is

$$H_2(g) + 2TlCl(s) = 2Tl(Hg) + 2HCl(DMF) \quad [4]$$

Application of the Nernst equation to this reaction yields ($\omega = RT/F$)

$$\mathcal{E} = \mathcal{E}^\circ_{neut} - \frac{\omega}{2} \ln \left\{ \frac{a^2_{Tl(Hg)}\, a^2_{HCl(DMF)}}{a_{H_2(g)}\, a^2_{TlCl(s)}} \right\} \quad [5]$$

where the subscript neut refers to undissociated HCl in DMF. If we take $a_{H_2(g)} \simeq (P_{H_2}/760)$, $a_{Tl(Hg)} = X_{Tl}\gamma_{Tl}$, and $a_{TlCl(s)} = 1$, then

$$\mathcal{E} = \mathcal{E}^\circ_{neut} + \frac{\omega}{2} \ln \left(\frac{P_{H_2}}{760} \right) - \omega \ln X_{Tl}\gamma_{Tl} - \omega \ln a_{HCl(DMF)} \quad [6]$$

Hydrochloric acid in DMF is a weak electrolyte; the dissociation constant on the molality composition scale for the reaction

$$HCl(DMF) \rightleftarrows H^+(DMF) + Cl^-(DMF) \quad [7]$$

is $K_d = 2.68 \times 10^{-4}/0.9458 = 2.83 \times 10^{-4}$ (15) at 25°C, and

$$K_d = \frac{a_{H^+} a_{Cl^-}}{a_{HCl}} = \frac{m^2_{ion}\gamma^2_\pm}{a_{HCl}} \quad [8]$$

Substitution of Eq. [8] into Eq. [6] yields

$$\mathcal{E} - \frac{\omega}{2} \ln \left(\frac{P_{H_2}}{760} \right) + \omega \ln \gamma_{Tl} X_{Tl} + 2\omega \ln m_{ion} = \mathcal{E}_H$$

$$\mathcal{E}_H = \mathcal{E}^\circ_{neut} + \omega \ln K_d - 2\omega \ln \gamma_\pm \quad [9]$$

where $\mathcal{E}_H$ is the Hitchcock extrapolation function. The value of m_{ion} was estimated at each value of m from the expression

$$2.83 \times 10^{-4} \simeq \frac{m^2_{ion}}{m - m_{ion}} \quad [10]$$

The value of $\ln \gamma_\pm$ should be given at low concentrations by the Debye-Hückel equation

$$\ln \gamma_\pm \simeq -3.593\, m^{1/2}_{ion}/(1 + m^{1/2}_{ion}) \quad [11]$$

Thus a plot of $\mathcal{E}_H$ *vs.* $m^{1/2}_{ion}/(1 + m^{1/2}_{ion})$ should have a slope of (Eq. [9]) $2\omega A = 2 \times 25.562 \times 3.593 = +183.7$ mV at 23.5°C and an intercept of $\mathcal{E}^\circ_{ion} = \mathcal{E}^\circ_{neut} + \omega \ln K_d$. A least-squares analysis of the data in Table I in terms of Eq. [9], [10], and [11] yields a slope of 187.3 ± 31.2 mV and an intercept of $\mathcal{E}^\circ_{ion} = -854.0 \pm 2.0$ mV at 23.5°C.

The agreement between the experimental and theoretical slopes provides strong evidence that we have reliably established the value of $\mathcal{E}^\circ_{ion}$.

Discussion

The value of $\mathcal{E}^\circ_{ion} = -854.0$ mV for the reaction

$$H_2(g) + 2TlCl(s) = 2Tl(Hg) + 2H^+(DMF) + 2Cl^-(DMF) \quad [12]$$

can be combined with the value of $K_d = 2.83 \times 10^{-4}$ to compute a value of $\mathcal{E}^\circ_{neut} = \mathcal{E}^\circ_{ion} - \omega \ln K_d = -645.2$ mV at 23.5°C. The value of $\mathcal{E}^\circ_{neut}$ refers to reaction [4] with undissociated HCl(DMF).

The emf values for the reactions

$$Tl(Hg, X_{Tl} = 3.259 \times 10^{-3}) = Tl(Hg, satd) \quad [13]$$

and

$$Tl(Hg, satd) = Tl(s) \quad [14]$$

are (13) $\mathcal{E}_{13} = -175.6$ mV at 23.5°C and $\mathcal{E}_{14} = -2.6$ mV. The emf value for the reaction

$$Tl(Hg, X_{Tl} = \gamma_{Tl} = 1) = Tl(Hg, X_{Tl} = 3.259 \times 10^{-3}, \gamma_{Tl} = 1.040) \quad [15]$$

is (23.5°C)

$$\epsilon_{15} = 25.562 \ln (3.259 \times 10^{-3} \times 1.040) = +145.4 \text{ mV}$$

Consequently, the emf of the reaction

$$Tl(Hg, X_{Tl} = \gamma_{Hg} = 1) = Tl(s) \quad [16]$$

is $\mathcal{E}_{16} = \mathcal{E}_{13} + \mathcal{E}_{14} + \mathcal{E}_{15} = -32.8$ mV, and the standard potential for the reaction

$$H_2(g) + 2TlCl(s) = 2Tl(s) + 2H^+(DMF) + 2Cl^-(DMF) \quad [17]$$

is $\mathcal{E}^\circ_{ion} = -854.0 - 32.8 \text{ mV} = -886.8$ mV at 23.5°C.

The hydrogen electrode is the most important reference electrode in aqueous solution, and there has been considerable interest in the development of the hydrogen electrode as a reference electrode in nonaqueous media as well (3). In addition to its use as a reference electrode, the hydrogen electrode can be used in nonaqueous media to obtain Gibbs energies of transfer for Brönsted acids between aqueous and nonaqueous solvents. Gibbs energies of transfer can be used to test various models for the nature of the solvated proton in such media. Of special interest in this connection are aprotic organic solvents, because of the inherent freedom of the solvent molecules from intermolecular hydrogen bonding.

The standard potential for the reaction

$$H_2(g) + 2TlCl(s) = 2Tl(s) + 2H^+(aq) + 2Cl^-(aq) \quad [18]$$

is $\mathcal{E}^\circ = -556.8$ mV at 25°C (16). Combination of this result with our value of $\mathcal{E}^\circ$ for reaction [17] yields, for the reaction

$$H^+(aq) + Cl^-(aq) = H^+(DMF) + Cl^-(DMF) \quad [19]$$

a value of $\Delta G^\circ \simeq 31.8 \text{ kJ} \cdot \text{mol}^{-1}$ for the standard Gibbs energy of transfer of HCl from water to DMF. The positive value of ΔG° reflects the much stronger solvation of the proton in water than in DMF.

An Asymptotic Solution for the Warburg Impedance of a Rotating Disk Electrode

Robert V. Homsy and John Newman*

Inorganic Materials Research Division, Lawrence Berkeley Laboratory, and Department of Chemical Engineering, University of California, Berkeley, California 94720

ABSTRACT

The Warburg impedance of a rotating-disk electrode is treated by a regular perturbation expansion valid for large alternating-current frequencies. This solution agrees well with the exact numerical solution, the error in the Warburg impedance being less than 2% for a dimensionless frequency of 10.

When an electrode is subjected to an alternating current, the concentration on the surface and thus the concentration overpotential vary in a time-dependent manner. This variation gives rise to what is known as the Warburg impedance. Early studies of the frequency dependence of this impedance were made around the start of the century by Warburg (1). More recently (2), the impedance of a rotating-disk electrode was studied and numerical results presented for large Schmidt numbers. We investigate here the asymptotic behavior of the Warburg impedance for large frequencies.

It is assumed in the treatment of the problem that the Schmidt number is large and that radial convection and diffusion are negligible. The radially dependent problem is currently being studied at this laboratory (3). It is further assumed that dilute-solution theory, with constant transport and thermodynamic properties, is applicable, and that there is an excess of supporting electrolyte so that migration effects are negligible.

Mathematical Formulation

The dimensionless, time-varying equation of convective diffusion is given by

$$\frac{\partial^2 c}{\partial \zeta^2} + 3\zeta^2 \frac{\partial c}{\partial \zeta} - \frac{\partial c}{\partial t^*} = 0 \qquad [1]$$

where c is the concentration of reactant, $\zeta = y\sqrt{\Omega/\nu}(a\nu/3D)^{1/3}$ is a dimensionless distance from the disk, $a = 0.51023$ is a constant (4), and $t^* = t\Omega D(a\nu/3D)^{2/3}/\nu$ is a dimensionless time. We may express the concentration as a sum of its steady and time-varying contributions

$$c = \bar{c} + \tilde{c} \qquad [2]$$

The steady problem was first treated by Levich (5). For an alternating current of frequency ω, the time-varying concentration may be expressed as[1]

$$\tilde{c} = Ae^{jKt^*}\theta \qquad [3]$$

where $K = \omega\nu(3D/a\nu)^{2/3}/\Omega D$ is a dimensionless frequency. Substitution into the convective diffusion equation yields the complex equation

$$\theta'' + 3\zeta^2\theta' - jK\theta = 0 \qquad [4]$$

subject to the boundary conditions

$$\theta = 1 \text{ at } \zeta = 0, \ \theta \to 0 \text{ as } \zeta \to \infty \qquad [5]$$

The Warburg impedance is related to the concentration overpotential by the expression

$$Z_W = \frac{\tilde{\eta}_c}{\tilde{i}} = \frac{RT\sqrt{\nu/\Omega}}{n^2\mathbf{F}^2\bar{c}_0 D\theta'(0)}\left(\frac{3D}{a\nu}\right)^{1/3} \qquad [6]$$

where $\tilde{\eta}_c = RT\tilde{c}_0/n\mathbf{F}\bar{c}_0$ is the time-varying concentration overpotential (valid for $\tilde{c}_0 << \bar{c}_0$).

Asymptotic solution.—We are concerned here with the behavior of Eq. [4] and [5] for large K. This system appears to comprise a singular perturbation problem (6); however, a closer examination shows that the solution is regular for large K if we modify the variables. If we let

$$\theta = \exp\{-(jK)^{3/4}Y(x)\} \qquad [7]$$

and

$$x = \zeta/(jK)^{1/4} \qquad [8]$$

Eq. [4] and [5] become

$$(Y')^2 - 3x^2Y' - 1 = Y''/(jK)^{3/4} \qquad [9]$$

$$Y = 0 \text{ at } x = 0, \ \mathrm{Re}\{(jK)^{3/4}Y\} \to \infty \text{ as } (jK)^{1/4}x \to \infty \qquad [10]$$

Y can evidently be expanded in a regular expansion in $K^{-3/4}$

$$Y = Y_0(x) + (jK)^{-3/4}Y_1(x) + (jK)^{-3/2}Y_2(x) + 0(K^{-9/4}) \qquad [11]$$

Substituting this expansion into Eq. [9] and equating terms of equal order in K, we obtain relatively simple differential equations for Y_0, Y_1, Y_2, etc. Solving these, we have that $Y'_0(0) = 1$ and $Y'_2(0) = 3/4$, while odd terms give no contribution to $Y'(0)$. The concentration derivative on the surface of the disk is thus given by

$$\theta'(0) = -\sqrt{jK}\,Y'(0) = -\sqrt{jK} + 3j/4K + 0(K^{-5/2}) \qquad [12]$$

so that we may write

$$Re\left\{\frac{1}{\theta'(0)}\right\} = \frac{4K(2\sqrt{2}\,K^{3/2})}{16K^3 - 6\sqrt{2}\,K^{3/2} + 9} \qquad [13]$$

* Electrochemical Society Active Member.

Key words: Warburg impedance, rotating disk.

[1] Strictly speaking, one takes the real part of such complex expressions: $\tilde{c} = Re\{Ae^{jKt^*}\theta\}$.

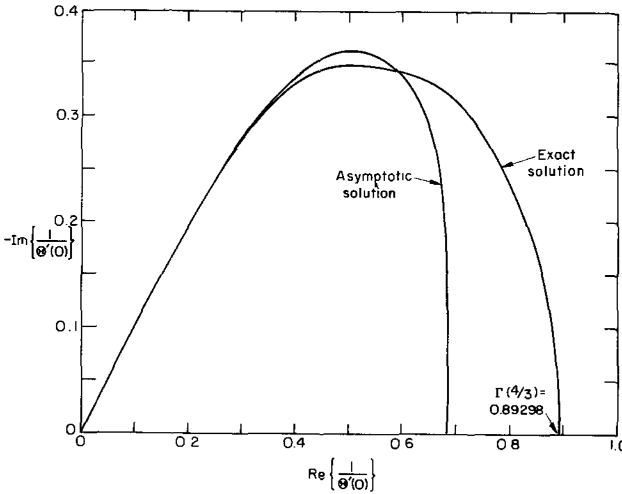

Fig. 1. The complex 1/Θ'(0) plane showing the asymptotic and exact numerical solutions.

$$-Im\left\{\frac{1}{\theta'(0)}\right\}=\frac{4K(2\sqrt{2}K^{3/2}-3)}{16K^3-6\sqrt{2}K^{3/2}+9} \quad [14]$$

These latter expressions may be used to evaluate the real and imaginary parts of the Warburg impedance (see Eq. [6]).

Results and Discussion

Figure 1 shows $1/\Theta'(0)$ plotted on the complex plane with the dimensionless frequency K as a parameter. The exact numerical solution is shown along with the asymptotic solution represented by Eq. [13] and [14]. These results are summarized in Table I. Also shown in the table is the impedance of a stagnant Nernst diffusion layer (7)

$$\frac{1}{\Theta'_N(0)}=\Gamma\left(\frac{4}{3}\right)\frac{\tanh\sqrt{j\omega\delta^2/D}}{\sqrt{j\omega\delta^2/D}}$$

$$=\frac{\tanh\left(\Gamma\left(\frac{4}{3}\right)\sqrt{jK}\right)}{\sqrt{jK}} \quad [15]$$

where the Nernst diffusion layer thickness, δ, is taken to be

$$\delta=\Gamma\left(\frac{4}{3}\right)\sqrt{\frac{\nu}{\Omega}}\left(\frac{3D}{a\nu}\right)^{1/3} \quad [16]$$

At large K the asymptotic expansion agrees well with the exact solution, the error in the Warburg impedance for $K = 10$ being less than 2% for both real and imaginary parts. As K decreases, the asymptotic solution departs radically from the exact solution. It should be pointed out that it is in the region of intermediate to large values of K that the Nernst diffusion-layer approximation is most in error in predicting the Warburg impedance. It appears, therefore, that the asymptotic expansion developed here offers an improved approximate solution in this region of K.

Summary

A regular perturbation expansion valid for large alternating-current frequencies has been developed to predict the Warburg impedance of a rotating-disk electrode. This asymptotic solution compares favorably with the exact solution and offers an improvement over the Nernst diffusion-layer approximation in the region of intermediate to large K.

The Short-Time Response of a Disk Electrode

Kemal Nisancioğlu* and John Newman*

Inorganic Materials Research Division, Lawrence Berkeley Laboratory, and Department of Chemical Engineering, University of California, Berkeley, California 94720

ABSTRACT

An asymptotic treatment of the transient response of a disk electrode is given for short times. Results are obtained by expressing the potential in terms of an integral equation at the surface. A similar formulation is used also to calculate the steady-state current distribution for large exchange-current densities.

The authors have recently reported (1, 2) a theoretical study of the transient behavior of a disk electrode in the presence of faradaic and capacitive effects. Series expressions were obtained for the potential and the current under galvanostatic and potentiostatic control, respectively. Those results are readily applicable to describe the long-time response of the disk and determine the relaxation time of the overpotential after a step change in the applied current or the current decay after a step change in the potential. However, a large number of terms need to be included in the series to express the short-time behavior accurately. This can be accomplished more efficiently by deriving an asymptotic solution to the problem valid at small times.

Shortly after the cell current is switched on, the current distribution on the surface is given by the primary distribution (3, 4) everywhere except at a small region near the edge of the disk. Since the primary current density is infinite at the edge, the double-layer capacity is charged more rapidly in this region than at other parts of the disk, so that the current density is reduced to a finite value.

From a mathematical standpoint, we have a singular perturbation problem at hand. A similar problem at high frequencies for the alternating-current distribution on a disk electrode has been treated earlier (5). We follow here the same guidelines in the mathematical formulation as developed in that paper. Another problem of the same type is encountered for large values of the exchange-current density (6). The singular nature of this problem has been recognized (5); however, its consequences were not of immediate interest. It nevertheless conforms with the context of the present paper, and an analysis is outlined in Appendix II, thereby rendering more complete the over-all treatment of the secondary current distribution at a disk electrode.

Mathematical Model

The potential in the solution satisfies Laplace's equation

$$\nabla^2\Phi = 0 \quad [1]$$

The current density vanishes on the insulating plane of the disk, which implies

$$\frac{\partial\Phi}{\partial z} = 0 \text{ at } z = 0,\ r > r_o \quad [2]$$

Away from the edge region, the potential in the solution is given by the primary distribution, Φ^p. Furthermore, at the surface, the passage of current is primarily due to the charging of the electric double layer

$$i = -\kappa\frac{\partial\Phi}{\partial z} = C\frac{\partial(V-\Phi)}{\partial t} \text{ at } z = 0,\ r \le r_o \quad [3]$$

where V is the potential of the electrode, κ is the conductivity of the solution, and C is the double-layer capacity. Charge transfer may also occur by means of a faradaic reaction. This effect is small at short times as long as the exchange-current density is not too large, and it is neglected here. The other extreme, where the faradaic reaction dominates over the double-layer charging, is discussed in Appendix II. Diffusion is also neglected. The transient response of a rotating-disk electrode under mass transfer controlled situations has been treated elsewhere (7, 8).

Analysis and Results

In terms of the rotational elliptic coordinates, the potential distribution outside the edge region with the counterelectrode placed at infinity is given by (3)

$$\Phi^p/\Phi^p_o = 1 - \frac{2}{\pi}\tan^{-1}\xi \quad [4]$$

where Φ^p_o is the potential in the solution adjacent to the electrode surface corresponding to the primary distribution (1). If the electrode potential is kept at a constant value V, then $\Phi^p_o = V$. If, however, the electrode is under galvanostatic control, $\Phi^p_o = I/4r_o\kappa$. With this difference in mind, the present analysis applies to both galvanostatic and potentiostatic cases unless stated otherwise. For small ξ, Eq. [4] can be approximated by

$$\Phi/\Phi^p_o = 1 - 2\xi/\pi \quad [5]$$

which may be regarded as the outer solution for the potential, with which the potential in the edge region must match. For instance, in the inner region, the potential approaches Eq. [5] asymptotically as $\xi \to \infty$ and also as $t \to 0$. The rotational elliptic coordinate system reduces to parabolic coordinates in the edge region (5), and Laplace's equation can be expressed as

* Electrochemical Society Active Member.

Key words: singular perturbation, galvanostatic control, potentiostatic control, exchange-current density, current distribution.

$$\frac{\partial^2 \Phi}{\partial \eta^2} + \frac{\partial^2 \Phi}{\partial \xi^2} = 0 \quad [6]$$

Let us now introduce the stretched variables appropriate to the edge region

$$\bar{\phi} = \frac{\pi}{2\sqrt{\theta}} \left(\frac{V - \Phi}{\Phi^{p}_{o}} \right) \quad [7]$$

$$\bar{\eta} = \eta/\sqrt{\theta}, \ \bar{\xi} = \xi/\sqrt{\theta} \quad [8]$$

where $\theta = \kappa t/r_o C$ is the dimensionless time. Equation [7] represents a separation of variables, such that $\bar{\phi}$ is a function of $\bar{\eta}$ and $\bar{\xi}$ only. When the basic equations are transformed into the stretched coordinates, the problem reads

$$\frac{\partial^2 \bar{\phi}}{\partial \bar{\eta}^2} + \frac{\partial^2 \bar{\phi}}{\partial \bar{\xi}^2} = 0 \quad [9]$$

$$\frac{\partial \bar{\phi}}{\partial \bar{\xi}} = \frac{1}{2} \bar{\eta} \bar{\phi} - \frac{\bar{\eta}^2}{2} \frac{\partial \bar{\phi}}{\partial \bar{\eta}} \text{ at } \bar{\xi} = 0 \quad [10]$$

$$\frac{\partial \bar{\phi}}{\partial \bar{\eta}} = 0 \text{ at } \bar{\eta} = 0 \quad [11]$$

$$\bar{\phi} \rightarrow \bar{\xi} \text{ as } \bar{\eta}^2 + \bar{\xi}^2 \rightarrow \infty \quad [12]$$

These results indicate that the inner region is of order $r_o\theta$ in the original, cylindrical coordinate system. Moreover, the dimensionless potential is of order $\sqrt{\theta}$, and the dimensionless current density, given by

$$\frac{i r_o}{\kappa \Phi^{p}_{o}} = - \frac{V - \Phi_o}{2 \Phi^{p}_{o} \theta} \quad [13]$$

is of order $1/\sqrt{\theta}$.

One possible way of solving the system of Eq. [9] to [12] is by finite-difference methods (9). This scheme did not prove to be straightforward in converging to a stable solution due to the complex nature of the surface boundary condition, Eq. [10]. The problem for the potential at the surface can also be expressed (see Appendix I) in terms of the integral equation

$$\bar{\phi}_o(\bar{\eta}) = \frac{1}{\pi} \int_0^\infty \ln |\bar{\eta}_*^2 - \bar{\eta}^2| \left[\frac{\bar{\eta}_*}{2} \bar{\phi}_o(\bar{\eta}_*) - \frac{\bar{\eta}_*^2}{2} \frac{\partial \bar{\phi}}{\partial \bar{\eta}} \bigg|_{\substack{\bar{\xi}=0 \\ \bar{\eta}=\bar{\eta}_*}} - 1 \right] d\bar{\eta}_* \quad [14]$$

In order to bring the problem into a finite domain, the integral can be written in the form

$$\bar{\phi}_o = \frac{1}{\pi} \int_0^{\eta_s} \ln |\bar{\eta}_*^2 - \bar{\eta}^2| \left(\frac{\bar{\eta}_*}{2} \bar{\phi}_o - \frac{\bar{\eta}_*^2}{2} \frac{\partial \bar{\phi}_o}{\partial \bar{\eta}_*} - 1 \right) d\bar{\eta}_* + \frac{1}{2\pi} \int_0^{1/\eta_s^4} \ln \left| \frac{1}{\sqrt{x_*}} - \frac{1}{\sqrt{x}} \right| \frac{1}{x_*^{3/4}} \frac{\partial \bar{\phi}'_o}{\partial x_*} dx_* \quad [15]$$

where

$$\bar{\phi}'_o = (\bar{\phi}_o - 1/\bar{\eta})/\bar{\eta}, \ x = 1/\bar{\eta}^4 \quad [16]$$

and η_s is a convenient breaking point. Equation [15] can now be integrated for the entire range of $\bar{\eta}$, whereas Eq. [14] has to be truncated at some point with the possibility of neglecting an important contribution to the integral. Numerical solution of this integral equation (10) turned out to be more efficient than the finite-difference technique in obtaining results for the present problem.

The results are shown in Fig. 1. The shape of the curves is also characteristic of the current distribution near the edge since the dimensionless potential $\bar{\phi}_o$ is proportional to the current density as indicated by Eq. [13]. The current distribution approaches the primary distribution toward the center of the disk. However, it remains finite and much more uniform than the primary distribution in the edge region; the finite capacity of the electric double layer does not allow it to become infinite.

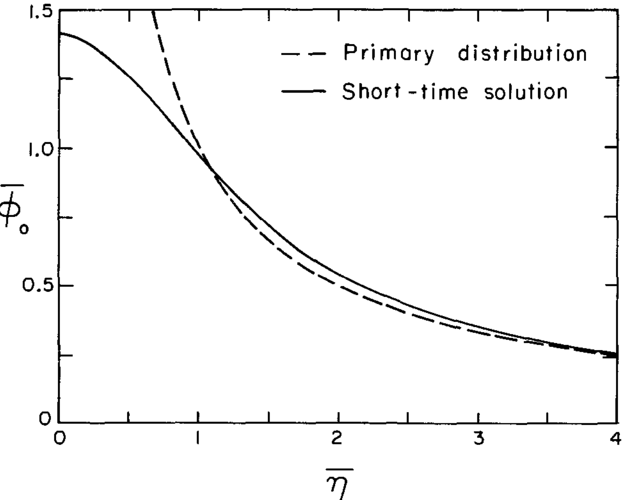

Fig. 1. The surface potential distribution at short times near the edge of a disk electrode.

The electrode potential for the galvanostatic case or the applied current for the potentiostatic case is given by

$$\left. \begin{array}{l} \text{(galvanostatic) } V/\Phi^{p}_{o} - 1 \\ \text{(potentiostatic) } 1 - I/4 r_o \kappa \Phi^{p}_{o} \end{array} \right\} = \int_0^1 \left(\frac{V - \Phi_o}{\Phi^{p}_{o}} \right) d\eta \quad [17]$$

Substitution of the stretched variables and integration yields

$$\int_0^1 \left(\frac{V - \Phi_o}{\Phi^{p}_{o}} \right) d\eta = - \frac{1}{\pi} \theta \ln \theta + A\theta \quad [18]$$

where (5)

$$A = \frac{2}{\pi} \left\{ \int_0^b \bar{\phi}_o d\bar{\eta} + \int_b^\infty \left(\bar{\phi}_o - \frac{1}{\bar{\eta}} \right) d\bar{\eta} - \ln b \right\} \quad [19]$$

The integral is broken up this way as a convenience in numerical calculation since the first integral does not converge as $b \rightarrow \infty$ and the second integral as $b \rightarrow 0$. Equation [19] was integrated (10) for the whole range of $\bar{\eta}$ using the numerical solution obtained from Eq. [15], and the value of A was thus found to be 0.841. Equation [18] is plotted in Fig. 2 using this value and compared to previous calculations (1, 2). The long-time series approaches the present short-time solution as an asymptote for small values of θ.

Conclusions

The present work demonstrates once more the efficiency and convenience of the singular perturbation method in obtaining asymptotic solutions to problems which would otherwise be laborious to solve numerically. In electroanalytical applications, one usually focuses attention on the conditions at the electrode surface, and the conditions in the bulk can be accounted for adequately by using the expression for the primary distribution, Eq. [4]. Therefore, expressing the surface potential in terms of an integral equation provides additional economy in the numerical work since the bulk of the solution does not enter the calculations explicitly.

The results reported above are universally applicable since no parameters appear in the problem, and

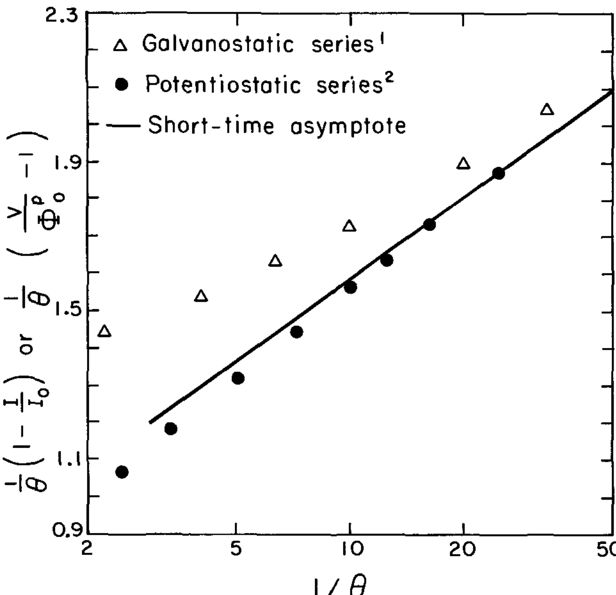

Fig. 2. Comparison of the short-time solution and the long-time series (1, 2) for the transient response of a disk.

numerical calculations need not be repeated. Furthermore, the results are independent of the disk geometry because the formulation is confined to a small region near the edge. Hence, they can also be made to apply under similar conditions to any electrode geometry embedded in an insulating plane.

APPENDIX I

Integral Representation for the Potential at Short Times

It is possible to solve Laplace's equation by superposing solutions due to current sources on an electrode. For a disk, this is given by (11)

$$\Phi(r,z) = \frac{2}{\pi\kappa}\int_0^{r_0} \frac{i(r_*)K(m)r_*dr_*}{\sqrt{z^2+(r+r_*)^2}} \qquad \text{[A-1]}$$

where $K(m)$ is the complete elliptic integral of the first kind (12)

$$K(m) = \int_0^{\pi/2} \frac{d\alpha}{\sqrt{1-m\sin^2\alpha}} \qquad \text{[A-2]}$$

and

$$m = \frac{4rr_*}{z^2+(r+r_*)^2} \qquad \text{[A-3]}$$

After converting into the rotational elliptic coordinates (3) and substituting Eq. [3], one obtains

$$\frac{\Phi_0}{\Phi^p{}_0} = \frac{2}{\pi}\int_0^1 \frac{K(m)}{1+\sqrt{1-\eta_*^2}} \frac{\partial}{\partial\theta}\left(\frac{V-\Phi_0}{\Phi^p{}_0}\right)\eta_* d\eta_* \qquad \text{[A-4]}$$

where the assumption $\eta << 1$ has been introduced for the edge region. The assumption cannot be applied to the dummy variable η_* because the integration has to be carried over the entire surface of the disk.

Define

$$\mathbf{F}(\eta,\eta') = \frac{2}{\pi}\int_0^{\eta'} \frac{K(m)}{1+\sqrt{1-\eta_*^2}} \frac{\partial}{\partial\theta}\left(\frac{V-\Phi_0}{\Phi^p{}_0}\right)\eta_* d\eta_* \qquad \text{[A-5]}$$

The potential distribution in the outer region is approximated by Eq. [5]. Substitution into Eq. [3] and integration gives

$$\frac{V-\Phi_0}{\Phi^p{}_0} = \frac{2}{\pi}\frac{\theta}{\eta} \qquad \text{[A-6]}$$

Hence, for the outer region, Eq. [A-5] can be written as

$$\tilde{\mathbf{F}}(\eta,\eta') = \mathbf{F}(\eta,1) - \frac{4}{\pi^2}\left[\int_0^1 \frac{K(m)}{1+\sqrt{1-\eta_*^2}}d\eta_* - \int_0^{\eta'} \frac{K(m)}{1+\sqrt{1-\eta_*^2}}d\eta_*\right] \qquad \text{[A-7]}$$

The first integral in the brackets corresponds to the primary distribution. Proof:

Let us write Eq. [A-1] for the primary distribution by replacing Φ with Φ^p and i with the primary current density (3)

$$\Phi^p{}_0 = I/4\kappa r_0 = \frac{2}{\pi\kappa}\int_0^{r_0} \frac{I}{\pi r_0^2}\frac{0.5}{\sqrt{1-(r_*/r_0)^2}}\frac{K(m)r_*dr_*}{r+r_*}$$

$$= \frac{4\Phi^p{}_0}{\pi^2}\int_0^1 \frac{K(m)}{\sqrt{1-\eta^2}+\sqrt{1-\eta_*^2}}d\eta_* \qquad \text{[A-8]}$$

Thus, independent of the value of η, we have

$$\frac{4}{\pi^2}\int_0^1 \frac{K(m)}{\sqrt{1-\eta^2}+\sqrt{1-\eta_*^2}}d\eta_* = 1 \qquad \text{[A-9]}$$

For small values of η', the second integral in Eq. [A-7] can be approximated by

$$\int_0^{\eta'} \frac{K(m)}{1+\sqrt{1-\eta_*^2}}d\eta_* \approx \int_0^{\eta'} \ln\frac{4}{\eta}d\eta = \eta'\left(\ln\frac{4}{\eta'}+1\right) \qquad \text{[A-10]}$$

Equation [A-7] for the outer region therefore reduces to

$$\tilde{\mathbf{F}}(\eta,\eta') = \mathbf{F}(\eta,1) - 1 + \frac{4\eta'}{\pi^2}\left(\ln\frac{4}{\eta'}+1\right) \qquad \text{[A-11]}$$

In the inner region, Eq. [A-5] can be expressed in the form

$$\bar{\mathbf{F}}(\eta,\bar{\eta}') = \frac{\sqrt{\theta}}{\pi^2}\int_0^{\bar{\eta}'} K(m)\left[\bar{\phi}_0(\bar{\eta}_*) - \bar{\eta}_*\frac{\partial\bar{\phi}_0}{\partial\bar{\eta}}\bigg|_{\bar{\eta}=\bar{\eta}_*}\right]\bar{\eta}_* d\bar{\eta}_* \qquad \text{[A-12]}$$

Both η and η_* are small in the inner region. Therefore

$$\lim_{\eta,\eta_*\to 0} K(m) = \lim_{\eta,\eta_*\to 0}\frac{1}{2}\ln\frac{16}{1-m} = \ln\frac{16/\theta}{|\bar{\eta}^2-\bar{\eta}_*^2|} \qquad \text{[A-13]}$$

Equation [A-12] can now be broken up into several parts

$$\bar{\mathbf{F}}(\bar{\eta},\bar{\eta}') = \frac{2\sqrt{\theta}}{\pi^2}\left\{\int_0^\infty \ln(16/\theta)G(\bar{\eta}_*)d\bar{\eta}_* - \int_0^\infty \ln|\bar{\eta}_*^2-\bar{\eta}^2|G(\bar{\eta}_*)d\bar{\eta}_* - \int_{\bar{\eta}'}^\infty \ln\frac{16/\theta}{|\bar{\eta}_*^2-\bar{\eta}^2|}G(\bar{\eta}_*)d\bar{\eta}_* + \int_0^{\bar{\eta}'} \ln\frac{16/\theta}{|\eta_*^2-\eta^2|}d\eta_*\right\} \qquad \text{A-14}$$

where

$$G(\eta_*) = \frac{\bar{\eta}_*}{2}\phi_0(\eta_*) - \frac{\bar{\eta}_*^2}{2}\frac{\partial\bar{\phi}_0}{\partial\eta}\bigg|_{\eta=\eta_*} - 1 \qquad \text{[A-15]}$$

In the original unstretched coordinate system, the first

integral can be expressed as

$$\ln(16/\theta)\int_0^\infty G(\bar{\eta}_*)d\bar{\eta}_* = -\frac{\ln(16/\theta)}{\sqrt{\theta}} \int_0^1\left(\frac{\pi}{2\Phi^p{}_o}\frac{\partial\Phi}{\partial\xi}\bigg|_{\xi=0}+1\right)d\eta$$
$$= \frac{\ln(16/\theta)}{\sqrt{\theta}}\left(\frac{1}{4\kappa r_o\Phi^p{}_o}\int_0^{r_o}2\pi i r dr - 1\right)$$
$$= \frac{\ln(16/\theta)}{\sqrt{\theta}}\left(\frac{I}{4\kappa r_o\Phi^p{}_o} - 1\right) \quad \text{[A-16]}$$

Under galvanostatic control, $I = 4\kappa r_o\Phi^p{}_o$, and the integral is identically zero. For potentiostatic control, the current is given by Eq. [18], and the integral is therefore of order $\sqrt{\theta}$ and still small compared to the second integral, which is of order unity. For large $\bar{\eta}'$, the last integral in Eq. [A-14] can be approximated by

$$\int_0^{\bar{\eta}'} \ln\frac{16/\theta}{|\bar{\eta}_*^2-\bar{\eta}^2|}d\bar{\eta}_* \approx \bar{\eta}'\ln\frac{16}{\theta} - \bar{\eta}'\ln\bar{\eta}'^2 + 2\bar{\eta}' \quad \text{[A-17]}$$

Equation [A-14] for the inner region thus becomes at large $\bar{\eta}'$

$$\bar{\mathbf{F}}(\bar{\eta},\bar{\eta}') = -\frac{2\sqrt{\theta}}{\pi^2}\left\{\int_0^\infty \ln|\bar{\eta}_*^2-\bar{\eta}^2|G(\bar{\eta}_*)d\bar{\eta}_* + \int_{\bar{\eta}'}^\infty \ln\frac{16/\theta}{|\bar{\eta}_*^2-\bar{\eta}^2|}G(\bar{\eta}_*)d\bar{\eta}_* - \bar{\eta}'\ln\frac{16}{\theta} + \bar{\eta}'\ln\bar{\eta}'^2 - 2\bar{\eta}'\right\} \quad \text{[A-18]}$$

Finally, the matching condition

$$\lim_{\eta'\to 0}\tilde{\mathbf{F}}(\eta,\eta') = \lim_{\bar{\eta}'\to 0}\bar{\mathbf{F}}(\bar{\eta},\bar{\eta}') \quad \text{[A-19]}$$

has to be satisfied. Substitution of Eq. [A-11] and [A-18] gives, after canceling the matching terms

$$\bar{\phi}_o(\bar{\eta}) = \frac{1}{\pi}\int_0^\infty \ln|\bar{\eta}_*^2-\bar{\eta}^2|G(\bar{\eta}_*)d\bar{\eta}_* \quad \text{[A-20]}$$

which is identical to Eq. [14].

APPENDIX II

Current Distribution on a Disk Electrode at Large Exchange-Current Densities

Previous numerical calculations for the rotating disk (6) have shown that the secondary current distribution approaches the primary distribution as the exchange-current density goes to infinity. For large but finite exchange-current densities, the current distribution approximates closely the primary distribution on the disk except near the edge, where the faradaic impedance is large enough to force the current density to remain finite.

When the current density is small compared to the exchange-current density ($i << |i_o|$), one may assume linear kinetics (6). The dimensionless, exchange-current density can then be defined as

$$J = (\alpha_a + \alpha_c)\frac{i_o r_o \mathbf{F}}{RT\kappa} \quad \text{[A-21]}$$

where α_a and α_c are the kinetic parameters of the general kinetic expression for an electrode reaction (11). The condition at the electrode surface can be expressed by

$$i = -\kappa\frac{\partial\Phi}{\partial z}\bigg|_{z=0} = J(V-\Phi_o) \quad (r \le r_o) \quad \text{[A-22]}$$

The stretched variables appropriate for this problem are

$$\bar{\phi} = \frac{\pi}{2}\left(1-\frac{\Phi}{V}\right)\sqrt{J} \quad \text{[A-23]}$$

$$\bar{\eta} = \eta\sqrt{J}, \quad \bar{\xi} = \xi\sqrt{J} \quad \text{[A-24]}$$

Substitution into Laplace's equation and the boundary conditions gives a system identical to Eq. [9], [11], and [12], and the condition at the surface becomes

$$\frac{\partial\bar{\phi}}{\partial\bar{\xi}}\bigg|_{\bar{\xi}=0} = \bar{\eta}\bar{\phi} \quad \text{[A-25]}$$

The finite-difference method by successive over-relaxations was successful in this case in obtaining a stable solution. The results are plotted in Fig. 3.

The steady-state current or potential can be calculated from

$$1-\frac{\Phi^p{}_o}{V} = 1-\frac{I}{4r_o\kappa V} = \int_0^1\left(1-\frac{\Phi_o}{V}\right)d\eta = \frac{1}{\pi J}\ln J + \frac{A}{J} \quad \text{[A-26]}$$

where A has the same form as Eq. [19] and the numerical value of 0.708. The quantity $V/\Phi^p{}_o$ can be characterized as a dimensionless, effective, direct-current resistance (5), $4r_o\kappa R_{eff}$, and is fixed once J is specified. A few values were reported earlier (1, 5), and these are reproduced in Table I along with some additional results. These results are compared with the present asymptotic solution in Fig. 4.

Characterization of the Deposition of Iron Oxides on a Platinum Ring Electrode

Der-Tau Chin*

Electrochemistry Department, Research Laboratories, General Motors Corporation, Warren, Michigan 48090

ABSTRACT

A potentiostatic transient study has been made of the deposition of iron oxides on a rotating platinum ring electrode from pH 4-5 ferrous sulfate solutions. The current-time relation is described by a two-dimensional nucleation and growth model for the formation of a monomolecular layer of an oxide film. The rate of film deposition is found to increase with ferrous concentration, pH, and rotational speed. The results indicate that the oxide deposition is a diffusion-controlled process, possibly due to the transport of $FeOH^+$ ions to the ring surface and of H^+ ions to the bulk of the electrolyte. The use of the potentiostatic transient as a simple diagnostic method for identifying passivity mechanisms on iron and carbon steels is discussed.

Deposition of iron oxides on a platinum substrate from neutral ferrous sulfate solution was recently studied by Leibenguth and Cohen (1) and by Ehrenfreund and Leibenguth (2). Using x-ray and electron diffraction methods, these authors have found that the oxide is a thin layer of γ-FeOOH, and is formed by the anodic oxidation of $FeOH^+$ ions in the solution. This evidence suggests the use of a ring-disk or a ring hemisphere (3) for the study of iron dissolution reactions in which $FeOH^+$ complex ion has been assumed to be a reaction intermediate (4). By properly setting the potential of a platinum ring electrode within the region for the iron oxide deposition reaction, it is possible to detect the soluble $FeOH^+$ species produced by iron dissolution at the central disk or hemispherical electrode.

* Electrochemical Society Active Member.

Key words: iron oxides from ferrous sulfate solutions, limiting current for the oxidation of ferrous to ferric ions, potentiostatic transient, passivation of iron and carbon steels.

For this reason, a series of runs has been made in this laboratory to determine the characteristics of the iron oxide deposition reaction under the convective conditions. This paper reports the results of these studies in ferrous sulfate solutions.

Experimental

The experimental setup was the same as described in a previous ring hemisphere study (3). The rotating ring hemispherical electrode used consisted of a platinum ring and a gold hemisphere of smaller diameter, mounted concentrically on a Teflon support. The platinum ring was 0.798 cm ID $\times$ 1.003 cm OD, and had a surface area of 0.291 cm^2 exposed to the electrolyte. In the present study, the gold hemispherical electrode was kept at open circuit; its purpose was to provide a hydrodynamic condition similar to that in the subsequent dissoluion experiments.

A potentiostatic transient method was used to study the anodic deposition of ferric oxide from 0.01-0.1M $FeSO_4$ solutions. Nitrogen-saturated 1-2M $(NH_4)_2SO_4$ was used as the supporting electrolyte. The *p*H of these solutions was maintained at a constant value (between 4 and 5) by adding proper amounts of NH_4OH and H_2SO_4 during the experiments. For each run, the surface of the platinum ring electrode was polished with a 600 grit wet grinding paper, cleaned with ethanol and 6*N* HCl, and cathodically treated in 2M NaOH for 2 min followed by a rinse in running water. The clean electrode was then installed on a high speed rotator, and transferred immediately to a 2 liter acrylic cell equipped with a saturated calomel reference electrode and a platinum counterelectrode. At this point, a constant speed was selected for the rotator, and the ring potential was examined with a strip-chart recorder. After the potential reached a steady-state value at open circuit, a constant anodic potential pulse of 0.9V *vs.* SCE (controlled by a Magna 4700M potentiostat) was applied to the ring, and the current transient was recorded on a Sanborn 296 recorder. All the experiments were performed at a constant temperature of 24° ± 1°C.

Results and Discussion

Polarization measurements.—Before the transient measurements, a voltametric sweep was made for the platinum ring electrode to determine the potential range within which meaningful results could be obtained with the potential pulse method. The sweep procedures were described in a previous report (3). Figure 1 is a set of anodic sweep curves obtained in a *p*H 4 solution containing 0.01M Fe^{++} and 1M $(NH_4)_2SO_4$ at a scan rate of 1.2 V/min. It is seen that the limiting current potentials for the oxidation of Fe^{++} to Fe^{+++} are within 0.7-1.2V *vs.* SCE. The curve at 2500 rpm is interesting because the current began to decrease after reaching a maximum value at 0.8V *vs.* SCE. Apparently at the limiting current potentials, in addition to the Fe^{++}/Fe^{+++} oxidation reaction, there is a parallel reaction for the deposition of a thin layer of an iron oxide on the ring surface. The current consumption for the iron oxide deposition reaction is very small as compared to that of the Fe^{++}/Fe^{+++} reaction; however, the oxide film reduces the active area available to the Fe^{++}/Fe^{+++} oxidation reaction, thus resulting in a decrease of the current. For these reasons, a limiting current potential of 0.9V *vs.* SCE was chosen for the transient experiments reported in this paper.

Typical transient results.—The two-reaction scheme discussed can be more clearly seen in Fig. 2, where a series of current transient curves in response to the potential pulse of 0.9V *vs.* SCE is given for the same electrolyte at various rotational speeds. Notice that

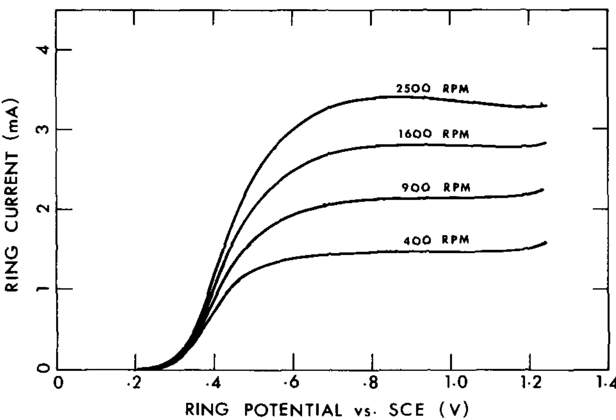

Fig. 1. Anodic sweep curves for a platinum ring electrode in a *p*H 4 solution containing 0.01M Fe^{++} and 1M $(NH_4)_2SO_4$. The scan rate was 1.2 V/min.

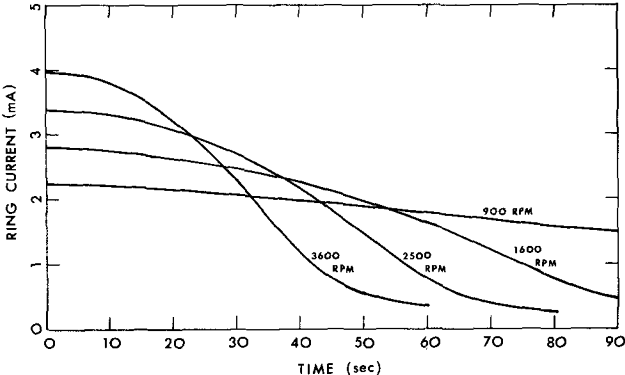

Fig. 2. Recorder traces of transient ring current in response to a constant potential pulse of 0.9V *vs.* SCE in a *p*H 4 solution containing 0.01M Fe^{++} and 1M $(NH_4)_2SO_4$.

the time scale in Fig. 2 is 10 sec/div; thus the curves should represent a steady-state current under the mass transfer conditions.[1] For each rotational speed, the current jumps to a limiting current level for the oxidation of Fe^{++} to Fe^{+++} ions at the onset of the transient, and then decreases with time due to the deposition of the iron oxide on the ring surface. The rate of current drop increases with increasing rotational speeds, implying that the oxide deposition reaction is also a diffusion limited process.

Some insight into the composition of the iron oxide can be gained by observing the typical potential decay curves shown in Fig. 3. These curves were obtained in a *p*H 4 ferrous sulfate solution after switching off the cell current. The curves exhibit a potential arrest at 0.25V *vs.* SCE (indicated by the crosses) before it reaches a steady-state value at open circuit. This arrest potential corresponds to the reduction of Fe_2O_3 to FeO (6), which is subsequently dissolved in the slightly acidic electrolyte. Since the arrest time increases with decreasing rotational speeds, the dissolution of FeO is probably the rate-controlling step for the reduction of the oxide film after switching off the current. That the oxide film is a layer of Fe_2O_3 is supported by the works of Leibenguth and Cohen (1) and Ehrenfreund and Leibenguth (2), who investigated the deposition of the iron oxides on a platinum substrate from ferrous sulfate solutions at *p*H 6.5-9.5. Using the electron diffraction method these authors have found that the oxide film is a hydrated Fe_2O_3, identified as γ-FeOOH.

Interpretation of transient results with a two-dimensional film model.—It was found that during the current drop period, the logarithm of the transient current varied linearly with the cube of time. Figure 4 is a semilogarithmic plot of ring current *vs.* cube of time for each of the curves shown in Fig. 2. The exact linear relationship suggests that the oxide deposition reaction follows a two-dimensional nucleation and growth model developed by Thirsk and his associates (7-9). The model was used to describe the formation of a monomolecular layer of passive films during anodic

[1] According to a ring theory (5), the transient time under conditions of mass transfer control can be calculated from the following equation

$$\tau \simeq \frac{3}{0.510^{2/3}} \frac{(\nu/D)^{1/3}}{\omega}$$

Using $\nu/D = 1000$ and $\omega = 100$ rad/sec, corresponding to typical conditions in the present experiments, τ is equal to 0.47 sec.

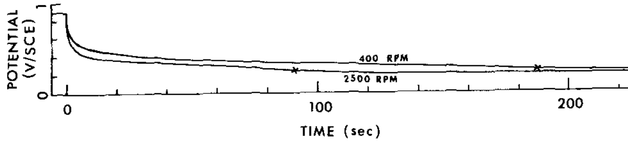

Fig. 3. Typical ring potential decay curves after switching off the current. These curves were obtained in a *p*H 4 ferrous sulfate solution.

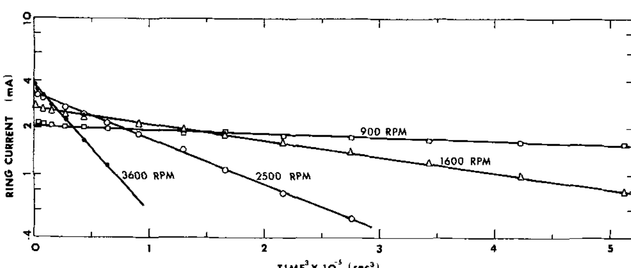

Fig. 4. Interpretation of transient currents with a two-dimensional nucleation and film growth model. The data shown here were obtained from a pH 4 solution containing 0.01M Fe^{++} and 1M $(NH_4)_2SO_4$.

dissolution of metals. Since the model treated the metal dissolution and the passive film formation as two parallel reactions, we may analogously formulate the following equations to describe the current/time transients obtained in the present study:

(*i*) current due to the deposition of a monolayer of ferric oxide on the ring electrode

$$I_1 = Q_{mon}\, \pi\, v^2\, N\, t^2 \exp\left(-\frac{\pi}{3} v^2 N t^3 \right) \qquad [1]$$

(*ii*) current for the oxidation of ferrous to ferric ions on the oxide-free portion of the ring electrode

$$I_2 = I_{lim} \exp\left(-\frac{\pi}{3} v^2 N t^3 \right) \qquad [2]$$

(*iii*) current for the oxidation of ferrous to ferric ions on the oxide-covered ring surface

$$I_3 = I_\infty \left[1 - \exp\left(-\frac{\pi}{3} v^2 N t^3 \right) \right] \qquad [3]$$

The total current for each potential pulse is the sum of Eq. [1]-[3]. In the present study, I_1 and I_3 were too small to be observed under the experimental conditions, and the current during the drop period directly obeyed Eq. [2] as shown in Fig. 4.

Equation [2] implies that the limiting current for the oxidation of ferrous to ferric ions on the clean ring electrode can be obtained from the current transient curves by extrapolating the $\ln(I)$ *vs.* t^3 plot to $t = 0$. Figure 5 is a plot of limiting current *vs.* square root of rotational speed for various ferrous concentrations in a 1M $(NH_4)_2SO_4$ supporting electrolyte. The curve for 0.01M Fe^{++} is given for two pH values. As expected, changes in the pH of the supporting electrolyte had no effect on the limiting current values. It is seen that the data points for each ferrous concentration fall on a straight line passing through the origin as predicted by the ring theory (5). For a narrow ring, the following relation gives a good approximation of the limiting current (10)

$$I_{lim} = 0.645\, n\, \mathbf{F}\, A [Fe^{++}] (r_i/\Delta r)^{1/3} D^{2/3} \nu^{-1/6} \omega^{1/2} \qquad [4]$$

This equation indicates that the diffusion coefficient of ferrous ion in 1M $(NH_4)_2SO_4$ can be calculated from the slopes of the straight lines in Fig. 5. The average diffusion coefficient thus obtained is 5.0×10^{-6} cm²/sec, in good agreement with a value of 5.7×10^{-6} cm²/sec for ferrous ion in 1M $KClO_4$ (11).

Kinetic considerations of the iron oxide deposition reaction.—The mathematical model discussed above reveals that the deposition of iron oxides from ferrous sulfate solutions is initially characterized by formation of a monolayer of γ-FeOOH on the electrode surface. According to Eq. [2], the product, $\pi v^2 N/3$, is the slope of the straight lines in Fig. 4; the cube root of $v^2 N$ can be regarded as a composite rate constant for the overall monolayer deposition process.

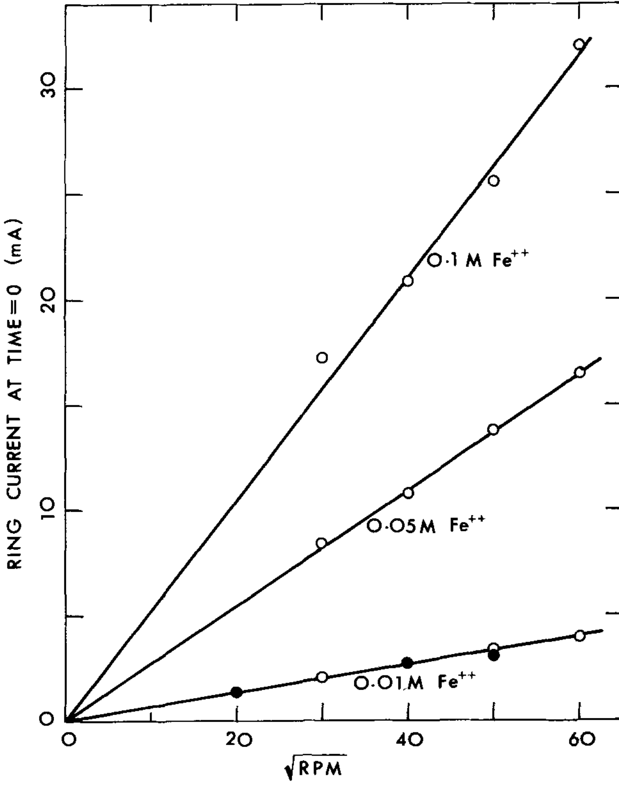

Fig. 5. Limiting current for the oxidation of ferrous to ferric ions vs. the square root of rotational speeds for three different ferrous concentrations. The supporting electrolyte was 1M $(NH_4)_2SO_4$. The pH of the solution was 4 for the open circles and 5 for the filled circles.

Figure 6 is a linear plot of $\sqrt[3]{v^2 N}$ *vs.* ferrous ion concentrations for three different rotational speeds. The supporting electrolyte was pH 4, 1M $(NH_4)_2SO_4$. It is seen that the composite rate constant increases linearly with concentration of ferrous ion; it also increases with increasing rotational speed. No direct correlation was found between the composite rate constant and the limiting current for the oxidation of ferrous to ferric ions. The effect of pH and of concentration of $(NH_4)_2SO_4$ on the composite rate constant are shown in Fig. 7 and 8, respectively. In these two figures, $\sqrt[3]{v^2 N}$ is plotted against rotational speed on a log-log scale, and the data points are seen to fall on a straight line. The slopes of the straight lines are approximately equal to 1; it increases slightly with increasing pH and Fe^{++} concentrations. Figure 7 shows that an increase of pH from 4 to 5 results in a fivefold increase in $\sqrt[3]{v^2 N}$. Changes in the concentration of the supporting electrolyte apparently have no effect on the composite rate constant (Fig. 8). This implies that SO_4^{--} ions are not participating in the film deposition reaction.

Previous works have shown that the γ-FeOOH film is formed from $FeOH^+$ ions (1, 2). In a slightly acidic or a neutral electrolyte, the following ionic equilibria are the possible cause for the formation of $FeOH^+$ ions and the film deposition reaction

$$Fe^{++} + H_2O \rightleftarrows FeOH^+ + H^+ \qquad [5]$$

$$FeOH^+ + H_2O \rightleftarrows FeOOH + 2H^+ + e \qquad [6]$$

The equilibrium constant for reaction (5) is given (12) as

$$K = \frac{[FeOH^+][H^+]}{[Fe^{++}]} \simeq 10^{-8} \text{ mole/liter} \qquad [7]$$

Using $[Fe^{++}] = 10^{-2}$-10^{-1} mole/liter, and $[H^+] = 10^{-5}$-10^{-4} mole/liter, corresponding to the experimental conditions shown in Fig. 6-8, $[FeOH^+]$ can be cal-

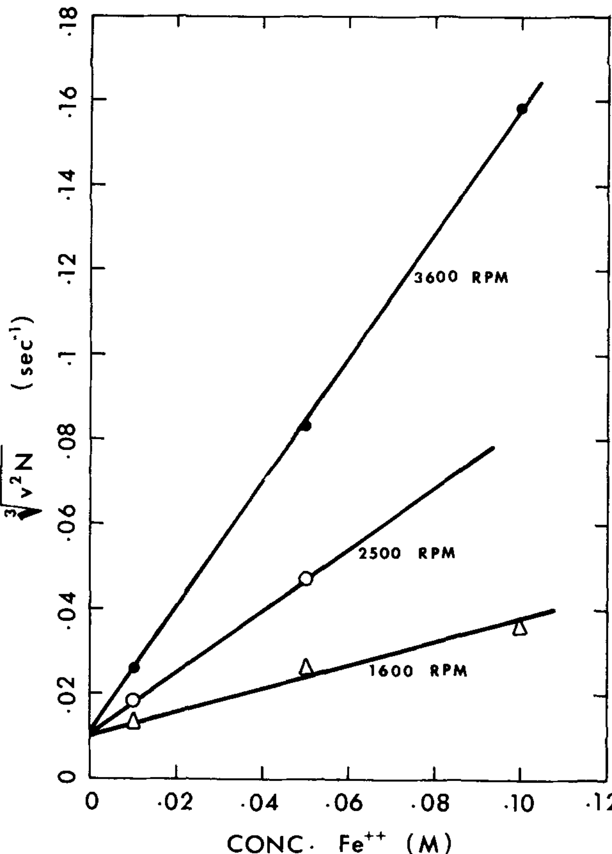

Fig. 6. Rate of oxide deposition as a function of ferrous concentration in pH 4 1M $(NH_4)_2SO_4$.

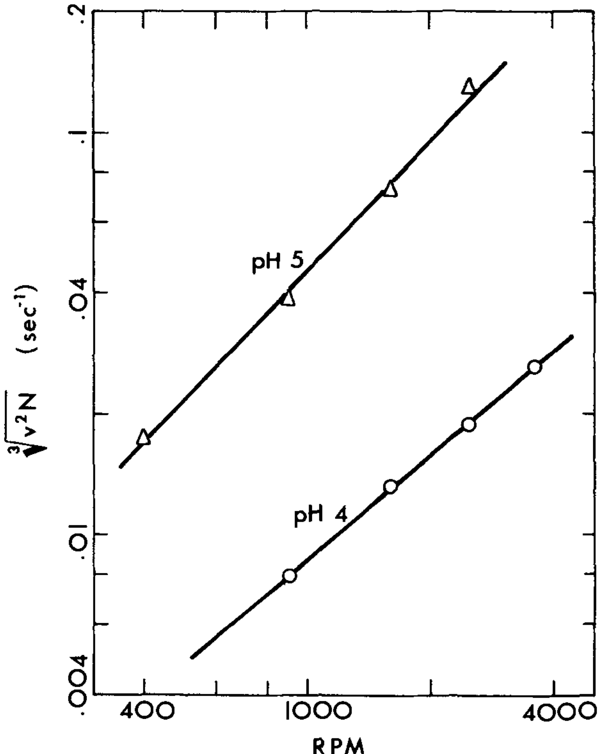

Fig. 7. Rate of oxide deposition vs. rotational speeds for two different pH values. The electrolyte used was 0.01M Fe^{++} and 1M $(NH_4)_2SO_4$.

culated to be approximately 10^{-6}-10^{-5} mole/liter. This concentration is of the same order of magnitude as that of hydrogen ion in these solutions. Thus, it is possible that transport of $FeOH^+$ ions to the ring surface and of H^+ ions to the bulk of the electrolyte are

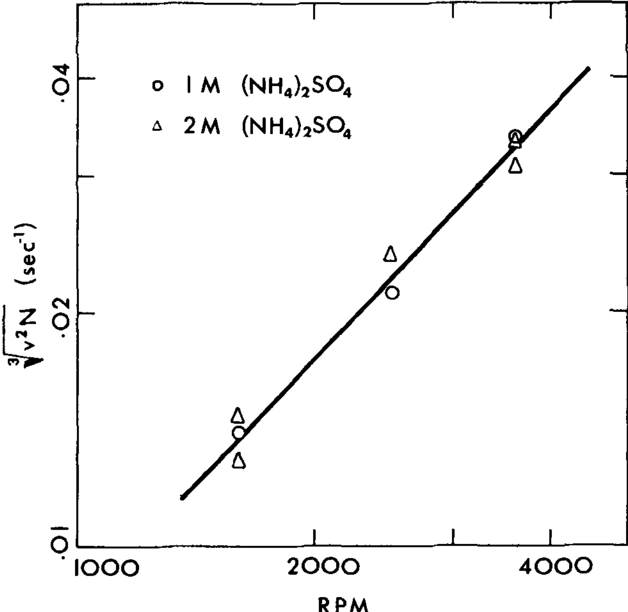

Fig. 8. Rate of oxide deposition vs. rotational speeds for two different sulfate concentrations at pH 4. The concentration of ferrous ion was 0.015M.

the rate-determining steps for the film deposition process under the present experimental conditions.

Application to passivation studies.—The cause of passivity on iron and its alloys has been generally attributed to one of the following processes: (*i*) solid-phase anodic oxidation in which the metal reacts with adsorbed anions to form an oxide without the metal ion entering the solution; (*ii*) dissolution precipitation in which the passivity is initiated by precipitation of a dissolution product from its supersaturated solution in the immediate neighborhood of the anode; and (*iii*) anodic deposition of oxides (1) in which a soluble dissolution product, such as $FeOH^+$ ion, is further oxidized at the anode to form a monolayer of passive film. How to distinguish these mechanisms has been a controversial subject discussed extensively in the literature (13-17). The distinction between mechanisms (*ii*) and (*iii*) is especially difficult, for both are preceded by a metal dissolution reaction. However, the potentiostatic transient seems to be a simple diagnostic criterion for identifying these two mechanisms. A typical example of mechanism (*ii*) is the passivation of mild steels in neutral sulfate and perchlorate solutions, in which the current/time relation is described by Muller's dissolution precipitation model and the active/passive transition potential is convection dependent (18). The present results suggest that for mechanism (*iii*), the transient current in response to a potential step in the passive region should follow Eq. [1]-[3]. The onset of passivation for mild steels in neutral nitrate solutions is a good example of this third mechanism; in this system, the logarithm of the transient current has been found to vary linearly with the cube of time (19).

Summary

A study has been made of the deposition of γ-FeOOH on a rotating platinum ring electrode from ferrous sulfate solutions at pH 4-5. It is found that the transient current in response to a potential step in the limiting current region for the oxidation of ferrous to ferric ions, follows a two-dimensional nucleation and growth model for the formation of a monolayer of oxide on the electrode surface. The rate of film formation increases with increasing concentrations of ferrous ion, pH of electrolytes, and rotational speeds of the ring electrode. The results imply that the oxide deposition reaction is a diffusion-controlled process under the

present experimental conditions, possibly due to the transport of $FeOH^+$ ions to the ring and of H^+ ions to the bulk of the electrolyte. The diffusion coefficient of ferrous ion as calculated from the limiting current measurement, is 5.0×10^{-6} cm²/sec. The use of the potentiostatic transient as a simple diagnostic method for identifying the mechanisms of passivity on iron and carbon steels was discussed.

LIST OF SYMBOLS

A	surface area of ring electrode, cm²
D	diffusion coefficient, cm²/sec
$\mathbf{F}$	Faraday constant, 96,500 coulombs/g-equiv
I_1	current for deposition of a monomolecular layer of iron oxides on ring electrode, A
I_2	current for oxidation of ferrous to ferric ions on the oxide-free portion of ring electrode, A
I_3	current for oxidation of ferrous to ferric ions on the oxide-covered portion of ring electrode, A
I_{lim}	limiting current for oxidation of ferrous to ferric ions on ring electrode whose entire surface is free from oxide contamination, A
I_∞	steady-state current of I_3, A
n	number of electrons transferred in electrode reactions, g-equiv/g-mole
N	rate of nucleation of two-dimensional centers, nuclei/cm²/sec
Q_{mon}	charge required to form a monomolecular layer of oxide on ring surface, coulombs
r_1	inner radius of ring electrode, cm
Δr	width of ring electrode, cm
t	time, sec
v	rate of film spreading from nucleus centers, cm/sec
τ	transient time required to reach a steady state, sec
ν	kinematic viscosity of electrolyte, cm²/sec
ω	angular velocity of ring electrode, rad/sec
$[X]$	bulk concentration of species X, g-mole/cm³ or g-mole/liter

Technical Note

Influence of Active Material Thickness on Positive Grid Corrosion in the Pb-Acid Battery

A. C. Simon*

Electrochemistry Branch, Naval Research Laboratory, Washington, D. C. 20375

and S. M. Caulder*

International Lead Zinc Research Organization Research Associate at the Naval Research Laboratory

The problem of Pb/Sb grid corrosion due to repeated anodizations and acid attack has been the subject of numerous investigations (1-5). However, all of these investigations were made on alloys which were unprotected by a covering of the active material. No report has been found in which the possible beneficial effect of an active material covering over the grid was investigated or discussed. In a pasted plate the active material surrounds the grid member and, since these plates are often overpasted, the grid may lie buried at some depth below the surface. This depth is not the same at all grid bars because of unequal pasting, bent grids, or other problems of manufacture. With this unequal covering it is likely that there could be a direct correlation between corrosion and the thickness of the active material covering at each point of the grid.

The positive plate offers the means for determining the effect of such a covering. When a battery plate is cross sectioned (Fig. 1), the horizontal grid bars will usually appear in the section as small isosceles triangles. The apex of each triangle is at or near the surface of the plate and the base of the triangle is at or parallel to the center line of the plate. Since these

Key words: lead-acid battery, lead-antimony corrosion, active material protection.

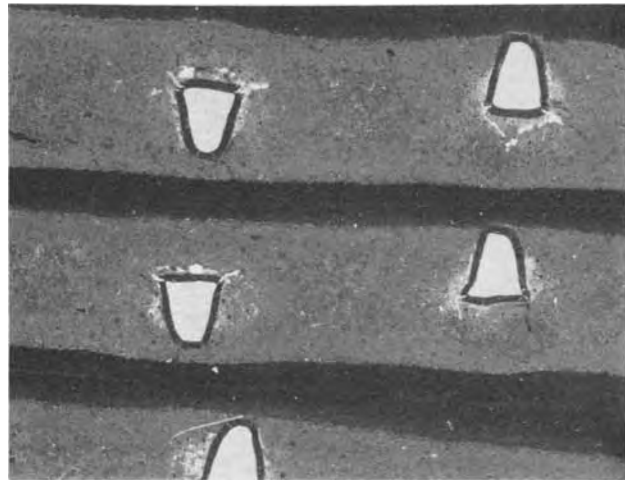

Fig. 1. Cross-sectioned battery plate showing relative positions of grid bars.

horizontal grid bars are alternately placed to one or the other side of the center line of the plate, the plate is approximately twice the thickness of the individual grid bars (measured from apex to base). In many cases the plate is also overpasted so that an additional layer of active material then covers the apex of the grid triangle or adds to the thickness between the base and the surface on the other side of the plate. Most important is the fact that the depth of active material covering the grid triangle at the apex and at the base will be quite different, as measured from the surface of the plate. Advantage can be taken of this difference in thickness to determine if the thickness of the corrosion product is different at these two points, as would be the case if the active material offers a protection that varies with its thickness.

In cross sections of grid bars, the width of the corrosion product is an accurate measure of the extent of the grid corrosion that has taken place. In lead-antimony grid alloys, the corrosion product is very clearly defined and is distinct from both the metal from which it forms and from the active material which surrounds it. If the plate has not received too many cycles, the corrosion product is still firmly attached to the metal and has not separated into layers.

The lead dioxide plates used in the measurements reported here were of two paste formulations. One plate group contained an 80-20% litharge-red lead mechanical blend and the other group contained a persulfate "watermix" mechanical blend with 18% red lead. Both of these paste formulations were prepared in two paste densities and all were pasted on 6% Pb-Sb grid alloys.

The metallurgical specimens used for measurements consisted of three or four pieces from the same plate, each piece containing five or six horizontal grid bar cross sections, and all the pieces were contained in the same plastic mount. Most of the bars in the metallurgical section met the requirements for measurement and each of these was measured for thickness of corrosion product.

The plates selected for measurement had an average corrosion layer thickness that varied from approximately 60 to 150 μm, depending upon active material composition and porosity. Three corrosion thickness measurements were made on each side of the triangle and base at the ¼, ½, and ¾ position along its length. Measurements were also made at the apex of the triangle, where it was nearest to the surface.

Results and Comments

The corrosion thickness data obtained from the two electrodes of different active material composition but with the same number of charge-discharge cycles, are given in Table I. From these data, which were typical of all other samples examined, no significant difference in corrosion thickness was observed at different depths in the active material. Measurements made on a series of plates containing different oxide blends, of which two are reported here, indicated that the amount of corrosion might be influenced to some extent by the plate composition (Fig. 2 and 3).

Table I. Grid corrosion product measurements
Average (μ)

Grid bar	(base, arrow ↑)	(right side, arrow)	(apex, arrow ↓)	(left side, arrow)
80-20 litharge-red lead mechanical blend	80.0	72.9	87.3	71.5
	81.3	72.9	89.7	70.6
	81.3	79.1	90.2	76.0
Persulfate "water mix" mechanical blend containing 18% red lead	119.1	112.6	108.8	115.5
	116.9	112.8	106.2	112.9
	110.2	108.8	107.9	113.7

The corrosion product around the grid section builds up during continued cycling to a point where internal stress generated within the film is relieved by cracking which extends outwards from the grid at the points of critical stress. This stress is then transferred to the active material and may result in dislodgment of the pellet. While not dependent on a definite thickness, the presence of overpasting may help to prevent this radial cracking until a later stage in the corrosion process.

The active material composition, and to a certain extent, the original paste density, are in some manner related to the corrosion process. It was found that, in some cases, the protective lead dioxide layer did not form immediately when the plate was cycled. This inability to form the adherent and dense PbO_2 layer on the surface of the grid resulted in the intermediate formation of a film that consisted of large $PbSO_4$ crys-

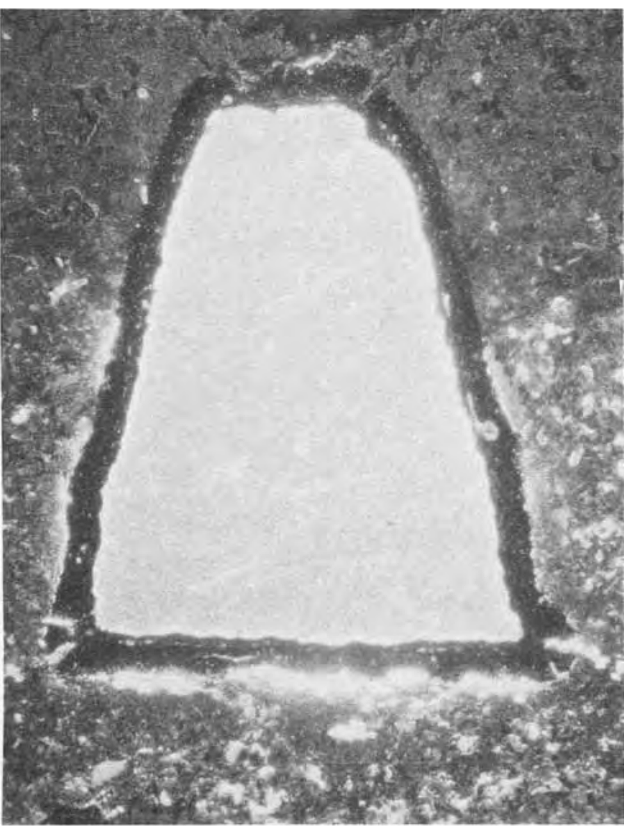

Fig. 2. Corrosion product of grid bars pasted with a 80-20 litharge-red lead mechanical blend.

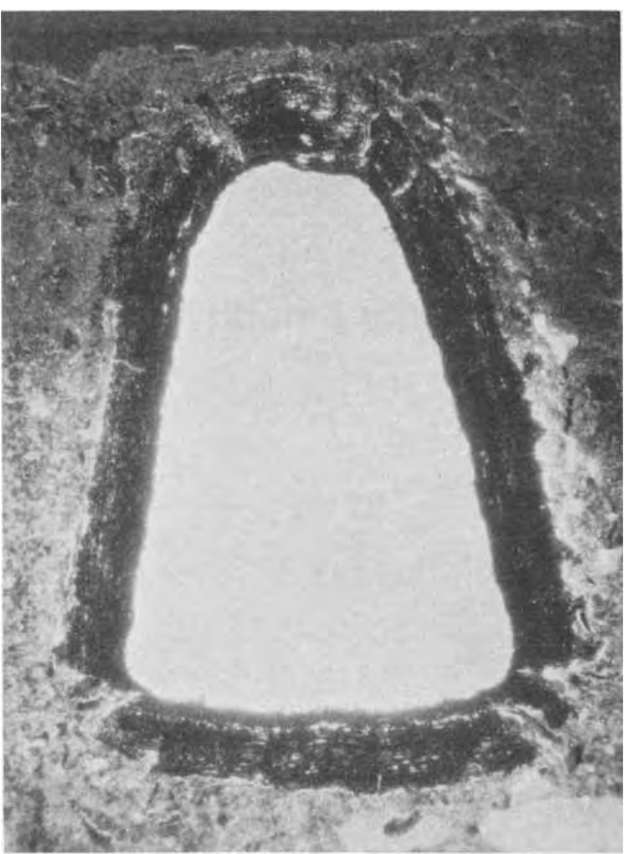

Fig. 3. Corrosion product of grid bars pasted with a persulfate "water mix" mechanical blend containing 18% red lead.

tals which were subsequently converted to PbO_2 upon continued cycling.

In a case where a high and low density paste were both used by the same manufacturer, the grids of the plate with the high density paste showed this inability to form a protective layer on the first cycle, while the grids of the low density paste developed a PbO_2 corrosion layer in a normal manner. However, after eleven capacity cycles, no appreciable difference in the amount of corrosion product was observed between high and low density plates.

Conclusions

Attempting to gain protection against corrosion by overpasting the grid or by increasing the thickness of the active material above the grid is ineffective. The composition of the paste from which the active material is made, or the paste density, has an effect on the thickness of the corrosion product during the first few cycles, but the thickness of the active material does not. Any possible effect of overpasting is due to mechanical support of the corrosion product at the critical stress areas which thus may delay cracking and delay dislodgment of active material.

Electrochemical Determination of the Stability of Mono- and Dicalcium Stannates

K. T. Jacob and J. C. Chan[1]

Department of Metallurgy and Materials Science, University of Toronto, Ontario, Canada M5S 1A4

ABSTRACT

The thermodynamic properties of mono- and dicalcium stannates have been determined in the temperature range 973°-1423°K from the electromotive force measurements on solid oxide galvanic cells

Pt, Ni + NiO//CaO-ZrO_2/Y_2O_3-ThO_2//SnO_2 + Sn, W, Pt

Pt, Ni + NiO//CaO-ZrO_2/Y_2O_3-ThO_2//$CaSnO_3$ + SnO_2 + Sn, W, Pt

Pt, Ni + NiO//CaO-ZrO_2/Y_2O_3-ThO_2//Ca_2SnO_4 + $CaSnO_3$ + Sn, W, Pt

and

Pt, Ni + NiO//CaO-ZrO_2/Y_2O_3-ThO_2//Ca_2SnO_4 + CaO, W, Pt

The Gibbs free energy changes accompanying the formation of the stannates from component oxides may be represented by the equations

$$2CaO + SnO_2 \rightarrow Ca_2SnO_4$$

$$\Delta G^\circ = -17{,}040 + 0.85T\ (\pm 300)\ \text{cal}$$

$$CaO + SnO_2 \rightarrow CaSnO_3$$

$$\Delta G^\circ = -17{,}390 + 2.0T\ (\pm 300)\ \text{cal}$$

The partial pressures of the tin bearing oxide species resulting from the decomposition of the stannates have been calculated as a function of the oxygen partial pressure by combining the results of this study with published information on the partial pressures and composition of oxide species over stannic oxide.

Quantitative information on the stability of calcium stannates is of importance in the pyrometallurgy of tin and its alloys. Tin smelting slags frequently contain considerable amounts of calcium oxide. Recently Shelley and Shelley (1) have illustrated the importance of calcium oxide in increasing the solubility of stannic oxide in glassy matrix. The traditional use of stannic oxide as an opacifier in glass is related to its precipitation as $CaSnO_3$, $CaSnTiO_5$, etc. Application of alkaline-earth stannates as dielectric materials (2) has raised considerable interest in the stability of these compounds under different environmental conditions. The tendency of these compounds to change composition at high temperatures and reducing conditions, due to the volatilization of SnO and its polymeric forms, can be quantitatively assessed from an accurate knowledge of the stabilities and published information (3) on the vapor composition and pressures over Sn + SnO_2 mixtures.

The phase diagram (2,4) indicates the occurrence of two compounds in the CaO-SnO_2 system; mono- and dicalcium stannates. The oxygen chemical potential in equilibrium with tin and stannic oxide was measured by Belford and Alcock (5) using a galvanic cell incorporating a yttria-doped thoria electrolyte and Ni + NiO reference electrode, in the temperature range 773°-1023°K. In this study the Gibbs free energies of formation for calcium stannates were measured using a similar technique. Equilibration of tin with two adjoining phases of the CaO-SnO_2 system fixes the oxygen potential, measurement of which permits the calculation of the partial and integral thermodynamic properties of the system.

[1] Present address: Canada Wire and Cable Limited, 147 Laird Drive, Toronto, Ontario, Canada.

Key words: thermodynamics, solid electrolyte, galvanic cell, calcium stannates, vaporization.

Experimental

Materials.—The stannic oxide was supplied by the British Drug House Limited and was 99.95% pure. Calcium oxide was prepared by calcination of calcium carbonate, 99.99% pure, supplied by the Electronic Space Products Incorporated. The stannates were prepared by mixing fine powders of the component oxides in the required stoichiometric ratio, compacting the mixture into pellets, and sintering at 1273°K in oxygen atmosphere for 8 hr in a closed platinum dish. X-ray diffraction analysis of the products confirmed the formation of the stannates.

Tin of 99.99+ purity was supplied by the Fisher Scientific Company. Calcia-stabilized zirconia tubes were supplied by the Zirconia Corporation of America. Thoria pellets stabilized by 15 mole per cent (m/o) yttria, were prepared from mixed nitrate solution by evaporation and subsequent decomposition. The resulting powder was pressed into pellets at a pressure of 30 tons/sq in.$^{-1}$, and sintered under an atmosphere of 90% N_2 + 10% H_2 at 2073°K. The argon gas used as the atmosphere for the emf runs was 99.98% pure, and was dried by passing through magnesium perchlorate and deoxidized by passage through a column of titanium granules maintained at 1170°K.

Apparatus.—It has been observed in earlier studies (6,7) that at temperatures above 1273°K the calcia-stabilized zirconia electrolyte is corroded by pure stannic oxide in equilibrium with tin. Preliminary studies indicated that yttria-doped thoria electrolyte, used by Belford and Alcock (5) up to a temperature of 1023°K, is suitable in contact with pure stannic oxide till 1173°K and in contact with the stannates till 1423°K. At higher temperatures, discoloration of the electrolyte was noticed.

A schematic diagram of the apparatus is shown in Fig. 1. The Ni + NiO reference electrode was placed inside a closed end, flat bottomed, lime-zirconia tube, with a platinum wire spring loaded against the reference electrode. The platinum lead is enclosed in an alumina sheath, through which prepurified argon gas is passed at a rate of 100 ml/min^{-1}. The lime-zirconia tube is placed inside an alumina tube, one end of which is attached to a yttria-doped thoria pellet by means of alumina cement and glass seals. The outer end of the lime-zirconia tube and the surfaces of the yttria-thoria pellets were polished with diamond paste to facilitate good contacts when pressed together. The entire assembly was mounted inside a reaction tube in a vertical molybdenum wound resistance furnace in such a way that the assembly could be moved up and down through a sliding rubber seal.

Pellets of Sn + SnO_2 were made by compacting a mixture of their powders in the molar ratio 1:2. The pellet was placed inside an alumina crucible which was supported on an alumina tube. The pellet was pressed down against the bottom of the alumina crucible with a spring loaded ring sleeve of alumina. When the Sn + SnO_2 pellets of 1:2 mixture were heated under inert gas, fine droplets of molten tin were found to be held against the yttria-thoria pellet by surface tension. They do not settle to the bottom of the alumina crucible unless the ratio of tin in the pellets is increased.

Electrical contact between the Sn + SnO_2 pellet and the platinum wire passing over the outside of the alumina tube, *e*, was affected by lowering the overhanging electrolyte-tube onto the pellet. Attack of the platinum contact by the molten tin was observed, but was minimized by recessing the platinum lead in a small groove cut into the yttria-thoria pellet and then adding a 1 cm long tungsten wire extension to the platinum-lead to make contact with the Sn + SnO_2 pellet. Times varying from 30 min to 3 hr were found necessary to attain equilibrium emf's. The emf's were measured with "Solartron" digital voltmeter, which has an input impedance of 10^{12} ohms. The design of the emf cell permitted the electrolyte material to be detached from the Sn + SnO_2 pellet during heating and cooling periods. Pellets containing tin and a mixture of stannates were prepared in a manner similar to the Sn + SnO_2 pellets; the respective stannates being mixed in 1:1 molar ratio. Reversible emf's of the following cells were measured as a function of temperature

and

Pt, Ni + NiO//CaO-ZrO_2/Y_2O_3-ThO_2//Ca_2SnO_4 + CaO + Sn, W, Pt [4]

The reversibility of the cells was checked by passing a small current ($\simeq$50 μA) through the cell for 2-5 min in either direction, and it was found that the emf

returned to its initial value in a few minutes, after which it remained constant for up to 8 hr. Emf's were also found to be independent of the flow rate of inert gas through the cell.

Results and Discussion

The emf's were reproducible within ±2 mV on repeated temperature cycling. The emf's of cells [3] and [4] were found to be a linear function of temperature, as shown in Fig. 2, in the temperature range 975°-1423°K. At lower temperatures higher emf's were observed which tend to increase with time, suggesting that equilibrium may not have been attained. The emf's of cells [1] and [2] varied linearly with temperature in the range 875°-1175°K, above which the emf's were found to decrease with time. Reproducible emf's could not be obtained once the cells were heated above 1175°K. Examination of the cell components indicated that SnO vapor penetrated the Y_2O_3-ThO_2 pellets and the supporting alumina tube above 1175°K.

The emf of cell [2] was on the average 2.5 mV above the emf of cell [1]. If the solid solubility of calcium oxide in stannic oxide is negligible, the emf's of cells [1] and [2] should be identical. While the slightly higher emf obtained with cell [2] indicates some solid solubility, it is not possible to calculate the solubility limit accurately from the present results because of a scatter of ±2 mV in the measured emf. The variation of the emf's of cells [1], [3], and [4] with temperature may be represented by the equations

$$E_1 = 300.5 - 0.1088T\ (\pm 2)\ \text{mV}$$

$$E_3 = 492.7 - 0.143T\ (\pm 2)\ \text{mV}$$

$$E_4 = 485.2 - 0.1032T\ (\pm 2)\ \text{mV}$$

The emf of cell [1] obtained in this study is almost identical to that reported by Belford and Alcock (5). Recent work by Carbo-Nover and Richardson (7) have confirmed that both solid and liquid SnO are unstable below 1373°K and decompose to a mixture of Sn and SnO_2. Above 1373°K, liquid SnO is the stable phase in equilibrium with tin. Information on electrolytic conduction domains for both calcia-zirconia and yttria-thoria has been reviewed by Patterson (8). An analysis of the emf of bielectrolyte cells has been proposed by Shores and Rapp (9), which indicates that at the oxygen potentials prevailing at the electrodes employed in this study, significant electronic contributions to the total conductivity of the electrolyte would be absent. Therefore, the standard free energy changes accompanying the following cell reactions can be calculated from the measured emf

$$2NiO + Sn \rightarrow SnO_2 + 2Ni$$

$$\Delta G^\circ = -27{,}720 + 10.04T\ (\pm 200)\ \text{cal}$$

$$2NiO + Sn + Ca_2SnO_4 \rightarrow 2CaSnO_3 + 2Ni$$

$$\Delta G^\circ = -45{,}455 + 13.19T\ (\pm 200)\ \text{cal}$$

$$2NiO + Sn + 2CaO \rightarrow Ca_2SnO_4 + 2Ni$$

$$\Delta G^\circ = -44{,}765 + 10.89T\ (\pm 200)\ \text{cal}$$

Using a value of

$$\Delta G^\circ = -55{,}965 + 20.29T\ \text{cal}$$

for the standard free energy of formation of NiO (10), the free energy of formation of calcium stannates from the component oxides can be obtained from the above equations

$$2CaO + SnO_2 \rightarrow Ca_2SnO_4$$

$$\Delta G^\circ = -17{,}040 + 0.85T\ (\pm 300)\ \text{cal}$$

$$CaO + SnO_2 \rightarrow CaSnO_3$$

$$\Delta G^\circ = -17{,}390 + 2.0T\ (\pm 300)\ \text{cal}$$

Figure 3 shows the integral free energy and enthalpy of mixing in the CaO-SnO_2 system. The uncertainty limits on second law enthalpies are also indicated on the diagram. Within experimental error limits the integral heat of formation of dicalcium stannate is a linear additive function of the heats of formation of monocalcium stannate and pure calcium oxide. A slightly higher entropy of formation appears to be responsible for the high temperature stability of the dicalcium stannate with respect to monocalcium stannate and calcium oxide.

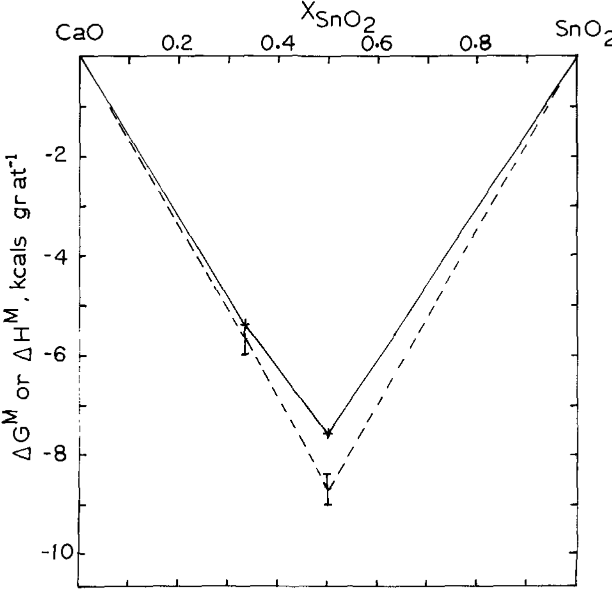

Fig. 3. The integral free energy and enthalpy of mixing in the CaO + SnO_2 system; ——— ΔG^M, 1000°K; - - - - - ΔH^M.

Table I. Standard free energy change accompanying the volatilization of SnO_2 (3)

Reaction	ΔG°, cals
$SnO_2(s) \rightarrow SnO(g) + O_2(g)$	138,420 − 60.947T
$2SnO(g) \rightarrow Sn_2O_2(g)$	−64,570 + 30.76T
$3SnO(g) \rightarrow Sn_3O_3(g)$	−131,740 + 67.84T
$4SnO(g) \rightarrow Sn_4O_4(g)$	−200,220 + 102.68T

The mass-spectrometric studies of Colin, Drowart, and Verhaegen (3) have shown that the vapor above stannic oxide consists of Sn, SnO, Sn_2O_2, Sn_3O_3, and Sn_4O_4 species. On the basis of their mass-spectrometric measurements and earlier studies of the vapor pressures over Sn + SnO_2 mixtures, the standard free energy changes for the reactions involved in the vaporization of stannic oxide have been derived (3), and are summarized in Table I. Due to the change in the stoichiometry of the oxide during vaporization, the volatility of stannic oxide and the stannates would be dependent on the oxygen partial pressure as discussed by Kellogg (11). The partial pressures of the oxide species over mono- and dicalcium stannates can readily be calculated by combining the information in Table I with the results of the present study. Figure 4 shows the variation of the partial pressure of the various gaseous species over mono- and dicalcium stannates with the oxygen partial pressure at 1400°K. The pressures of SnO and its polymeric forms increase as the oxygen partial pressure decreases, until pure liquid tin is obtained as a seoarate phase by the reduction of the stannates. A further decrease in the oxygen partial pressure results in a decrease in the partial pressure of the oxide species. The main contribution to the total pressure arises from SnO species. The relative contribution of the polymeric species to the total pressure increases as the oxygen pressure is reduced, and attains a maximum value at the oxygen partial pressure corresponding to the reduction of the stannates to form liquid tin. The total

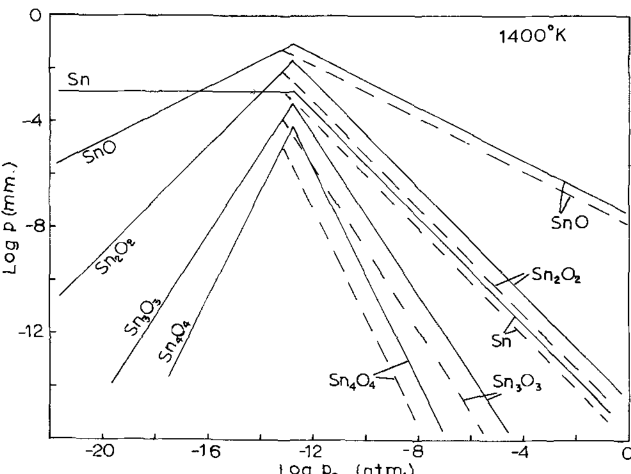

Fig. 4. The partial pressures of the tin bearing oxide species in equilibrium with the stannates at 1400°K as a function of the oxygen partial pressure; ——— monocalcium stannate, - - - - - dicalcium stannate.

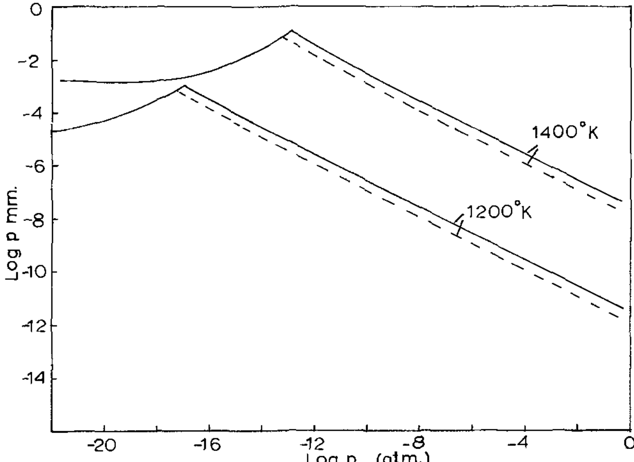

Fig. 5. The total vapor pressure over the stannates as a function of the oxygen partial pressure; ——— monocalcium stannate, - - - - - dicalcium stannate.

pressure, obtained as a summation of the individual partial pressures over mono- and dicalcium stannates, is shown in Fig. 5, as a function of the oxygen partial pressure. If the stannates are kept under an inert gas or in vacuum, the volatility would be restricted by the requirement that $P_{SnO} = 2P_{O_2}$. The values for the partial and total pressures of the tin bearing oxide species, shown in Fig. 4 and 5, enable the estimation of the composition changes upon prolonged use of the stannates at high temperatures.

Diffusional Growth of Cobaltous-Ferrous Oxide Scales on Cobalt-Iron Alloys

P. Mayer*[,1] and W. W. Smeltzer**

Department of Metallurgy and Materials Science, McMaster University, Hamilton, Ontario, Canada L8S 4M1

ABSTRACT

Co-Fe alloys containing up to 10 weight per cent Fe oxidize parabolically by formation of a cobaltous-ferrous oxide scale when exposed at 1200°C to oxygen at 10^{-4} and 10^{-3} atm. The values of the parabolic oxidation constants were directly dependent on the iron contents of the alloys. Scale iron contents corresponded to those in the bulk alloys. The iron gradients within the scales increased with increasing outward distance due to iron migrating more rapidly than cobalt. A diffusion model based on equations derived by Wagner for metal transport through a scale under chemical activity gradients leads to a correlation between the parabolic oxidation constants and the iron gradients.

There is only limited knowledge available on the distributions of cations in metal conducting scales on binary alloys which is sufficiently extensive for interpretation by a diffusion model describing metal transport under chemical activity gradients. Wagner (1) has advanced methods for calculating these distributions in scales grown by parabolic kinetics. Dalvi and Coates (2) and Dalvi and Smeltzer (3) have demonstrated that the cobalt and iron profiles in nickel oxide scales formed on Co-Ni and Fe-Ni alloys, respectively, are consistent with ternary diffusional properties. Cobalt and iron were enriched toward the outer surfaces in these scales due to mobilities higher than that for nickel. Mayer and Smeltzer (4) have also employed this model to describe growth of the manganeseo-wustite scale on Fe-Mn alloys and to evaluate the metal self-diffusion coefficients and the nonstoichiometry of manganeseo-wustite as a function of manganese content. In this case, the metal gradients were small and linear due to very small differences in the cation mobilities.

Formation of the cobaltous-ferrous oxide [(FeCo)O] scales on Co-Fe alloys has not been investigated. Carter and Richardson (5, 6) have shown that cobalt diffusion in cobalt oxide and growth of this oxide on cobalt at high temperatures can be interpreted by the Wagner theory for parabolic scaling (7). Crow (8) has determined the tracer diffusion coefficients of cobalt and iron in (CoFe)O. At 1200°C, the ratio D_{Fe}/D_{Co} equals 1.6 at an oxygen pressure of 10^{-3} atm, and it equals 0.7 at pressures greater than 10^{-1} atm. Thermodynamic properties and compositions of (CoFe)O have been determined by Aukrust and Muan (9, 10).

Metal diffusion in (CoFe)O is much more rapid than in Co-Fe alloys (8, 11). One would therefore expect that a superficial scale would form as the major reaction product with only a relatively small degree of internal oxidation when these alloys are oxidized at high temperatures. In the present work, the reaction kinetics, morphological development, and compositions of the scales have been determined upon exposing cobalt alloys containing up to 10 weight per cent (w/o) Fe to oxygen atmospheres at 1200°C. These alloys were found to oxidize parabolically at 10^{-4} and 10^{-3} atm. Consequently, an attempt could be made to interpret these results by equations deduced from the ternary diffusion model for oxidation of a binary alloy using metal diffusional determinations for (CoFe)O and thermodynamic properties of the Co-Fe-O system.

Key words: Co-Fe alloy oxidation, cobaltous-ferrous oxide, diffusional scale growth.

Experimental

Oxidation kinetics of the alloys were determined gravimetrically by exposing metal disks, 10 mm diameter and 2 mm thick, to a flowing atmosphere of research grade oxygen, <25 ppm impurities. The reaction assembly is schematically represented in Fig. 1. Zero time for initiation of a test was taken as the instant when the specimen was lowered into the reaction chamber. The atmospheric pressure was monitored by Pirani

gauges located at the entrance and exit of the reaction tube. A pressure drop was not detected through the reaction tube at the experimental pressures of 10^{-4} and 10^{-3} atm. Temperature of the reaction zone was controlled to 1200° ± 2°C. At completion of a run, the specimen was quenched by rapidly raising it into the section of the reaction tube maintained at room temperature by means of a magnetic device.

Alloys were prepared as rods, 8 cm in length and 14 mm in diameter, by vacuum melting in required proportions of cobalt (>99.997 w/o pure) and iron (>99.875 w/o pure). Actual iron contents of the nominal 1, 2, 4, 6, 8, and 10 w/o Fe alloys were 0.93, 2.1, 4.1, 5.5, 7.7, and 9.6 w/o Fe, respectively. The rods were sealed in quartz tubes containing argon and annealed for periods up to 10 days at 1200°C to homogenize the compositions. They were then machined to uniform diameter and cut into disks with a multiple wire saw. The disks were finally metallographically polished to 1μ diamond abrasive using kerosene as lubricant, washed with petroleum ether, and stored in acetone.

Oxidized specimens for metallographic observations and microprobe analyses were mounted in room-setting epoxy resin and the cross sections polished to 1μ diamond abrasive using kerosene as lubricant. Specimens subjected to analyses were covered by an evaporated thin carbon film. The analyses were carried out using a Cameca electron probe microanalyzer operating at 15 keV and a specimen current of 100-150 nA. Standards for constructing alloy calibration curves for (CoFe)O were constructed according to the method given by Friskney and Howarth (12) and consisted of successively applying atomic number (13), absorption (14), and fluorescence (15, 16) corrections to a composition set.

Results

Figures 2 and 3 show the oxidation curves plotted in parabolic form for cobalt and the six alloys containing up to 10 w/o Fe exposed to oxygen at 10^{-4} and 10^{-3} atm. It is seen that parabolic kinetics describe scale growth. The parabolic oxidation constants calculated from the slopes of these plots are shown in Fig. 4; they were accurate to within ±10% based on the deviations from the average value for four runs completed on each alloy. These constants show a direct dependence on the iron contents of the alloys and larger values at the higher oxygen pressure. The parabolic constants of cobalt are in good agreement with previously reported values (17).

Internal oxidation was insignificant. This behavior is illustrated by the photomicrographs shown in Fig. 5 and 6 of the oxidized alloy specimens containing the maximum iron concentration of 10 w/o. The scales were compact and uniformly thick except for small irregularities of the outer surfaces associated with development of the individual oxide grains. Based on microscopic measurements at different regions, positions within scales could be reproduced within ±10%. X-ray diffraction lattice parameter measurements on the powdered scales confirmed that they were composed of (CoFe)O.

Iron compositions within the scales formed on each alloy at the two investigated pressures are shown in

Fig. 7a, 7b, 8a, and 8b. These determinations are based on analyses taken from scales formed on four specimens of each alloy using the electron microprobe point count method at normalized distances $y = x/x_s$, where x_s is a total scale thickness. The iron content increased with increasing outward distance and the average content of a scale corresponded to the alloy content.

Discussion

A correlation between the reaction kinetics and the normalized iron profiles within scales are quantitatively assessed by means of the ternary diffusion model advanced by Wagner. To complete this analysis it is necessary to obtain an empirical relationship for the nonstoichiometry of (CoFe)O as a function of iron content and oxygen activity. This nonstoichiometry, in turn, is related to the metal diffusivities in order to obtain differential equations describing the metal gradients. The equations are subsequently numerically integrated using the experimentally determined parabolic rate constants to generate the iron profiles within the scales.

Cobalt oxide behaves as a p-type semiconductor containing metal vacancies in the singly and doubly ionized states, the former state being predominant over a major portion of its oxygen stability range (18-20). Iron substituted into this oxide is considered to give rise to the following defect equilibrium

$$\tfrac{1}{2} O_2 + \alpha Fe^{2+} = O^{2-} + V_M^{\alpha-} + \alpha Fe^{3+} \quad [1]$$

where the designated iron and oxygen ions occupy normal lattice sites and $V_M^{\alpha-}$ and αFe^{3+} represent metal vacancies and ferric ions with effective charges $\alpha-$ and $+1$, respectively. There are insufficient results, however, for analyzing this defect equilibrium in detail. It is reasonable, nevertheless, to suggest that the vacancies occur predominantly from the influence of iron by the displacement of the above reaction far to the right. Assuming to a first approximation that the fraction of the total iron content ionized to the ferric state remains constant, at fixed oxygen activity, the atom fraction of vacancies is of the form

$$N_V = \gamma a_o^n \xi \quad [2]$$

Here, a_o is the oxygen activity, ξ is the iron fraction in the cation sublattice of (CoFe)O, γ and n are empirical constants.

Vacancy concentrations were calculated from the compositions of (CoFe)O reported by Aukrust and Muan (9) using the formula $N_V = (X - 1)/X$ where X is the oxygen atom fraction per metal atom fraction

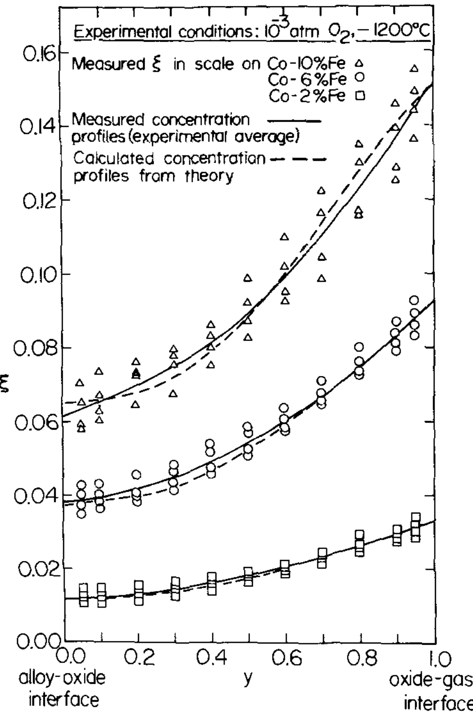

Fig. 8a. Iron composition within the (CoFe)O scales formed on the Co-10 w/o, 6 w/o, and 2 w/o Fe alloys at 10^{-3} atm oxygen pressure.

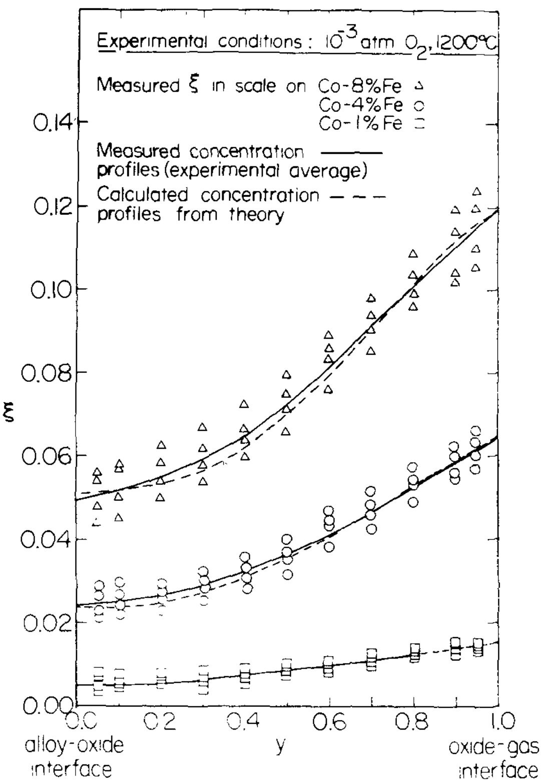

Fig. 8b. Iron composition within the (CoFe)O scales formed on the Co-8 w/o, 4 w/o, and 1 w/o Fe alloys at 10^{-3} atm oxygen pressure.

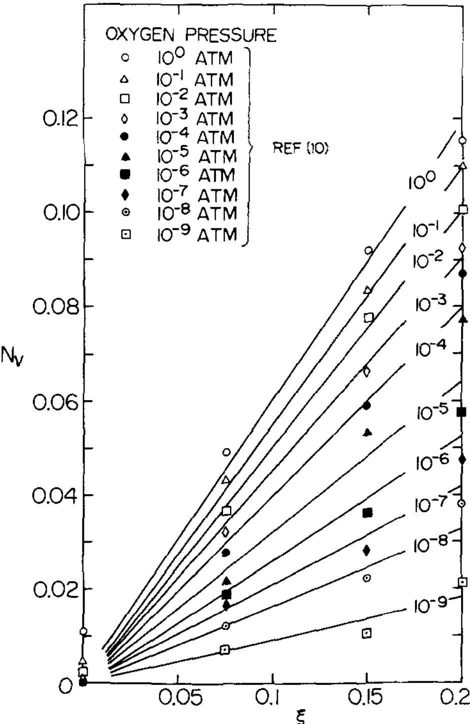

Fig. 9. Metal vacancy concentration plotted vs. iron atom fraction in (CoFe)O for several oxygen pressures ranging from 10^{-9} to 1 atm. The experimental results were obtained from Ref. (9) and (10).

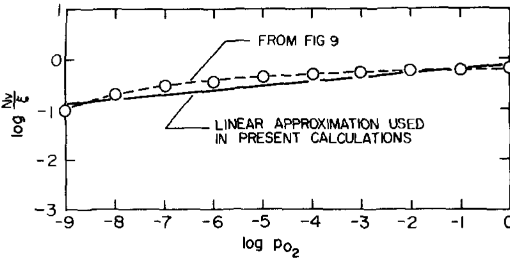

Fig. 10. Atom fraction of vacancies per atom fraction of iron in (CoFe)O plotted vs. oxygen pressure. The experimental results were obtained from Ref. (9) and (10).

$X = (O/(Fe + Co))$. N_V is plotted *vs.* ξ for several values of oxygen pressure in Fig. 9. Linear plots relate these variables for the oxide compositions encountered in the present investigation (Fig. 7a, 7b, 8a, and 8b). Figure 10 shows the vacancy concentration expressed as N_V/ξ at each pressure on logarithmic scales. It is seen that a constant power relationship for the oxygen activity dependence is an adequate approximation although the additionally depicted plot exhibiting a small curvature may account in a more factual manner for the vacancy behavior. Accordingly, the constants in Eq. [2] are expressed as $\gamma = 0.60 \pm 0.11$ and $n = 0.15 \pm 0.03$.

It is essential to represent the metal self-diffusion coefficients by appropriate analytical expressions involving their dependence on the iron concentrations and oxygen activities in order to numerically integrate the differential equations to be subsequently introduced. These diffusion coefficients are therefore expressed as the product of the individual vacancy diffusivities and the vacancy concentration

$$D_{Co} = D^V_{Co} N_V = D^o_{Co} \gamma a_o^n \xi \quad [3]$$

$$D_{Fe} = D^V_{Fe} N_V = D^o_{Fe} \gamma a_o^n \xi \quad [4]$$

and

$$p = D_{Co}/D_{Fe} = D^o_{Co}/D^o_{Fe} \quad [5]$$

Carter and Richardson (6) expressed the tracer diffusion coefficient of cobalt in cobalt oxide as a function of oxygen activity by a constant power relationship. Using this result and those reported by Fisher and Tannhauser (18) for the dependence of the cobalt vacancy concentration on oxygen activity, the cobalt vacancy diffusivity at 1200°C was calculated to be $D^o_{Co} = 1.46 \pm 0.04 \times 10^{-6}$ cm²/sec. The constant p, the rates of the cobalt and iron vacancy diffusivities, was determined from the results obtained by Crow (8) for the

tracer diffusivities as a function of oxygen activity. The ratio of these diffusivities was $p = 1.63 \pm 0.03$ at pressures of 10^{-4} and 10^{-3} atm.

Equations to describe growth of a metal conducting scale on a binary alloy are now invoked. The formalism of Wagner is used and the reader is referred to the original paper for mathematical derivations. The (CoFe)O scale growth is determined by the outward diffusion of cobalt and iron via vacancies and Eq. [11] from Ref. (1) for the parabolic oxidation constant becomes

$$D_{Co}(1-\xi)\left(\frac{-d\ln a_{CoO}}{d\xi}\frac{d\xi}{dy}+\frac{Z_{Co}}{Z_o}\frac{d\ln a_o}{dy}\right) + D_{Fe}\xi\left(\frac{-d\ln a_{FeO}}{d\xi}\frac{d\xi}{dy}+\frac{Z_{Fe}}{Z_o}\frac{d\ln a_o}{dy}\right) = k \quad [6]$$

In this expression, D is a metal self-diffusion coefficient, a is a local activity, Z is a valency, ξ is the atom fraction of iron or mole fraction of wustite in (CoFe)O, and $y = x/x_s$ is the normalized scale thickness.

The solubility of wustite in cobalt oxide exhibits Henrian solution behavior (10). Hence, the Gibbs-Duhem equation for this solid solution leads to

$$\frac{d\ln a_{FeO}}{d\xi} = \frac{1}{\xi};\ \frac{d\ln a_{CoO}}{d\xi} = \frac{-1}{1-\xi} \quad [7]$$

Substituting Eq. [2], [5], and [7], $Z_{Co} = Z_{Fe} = |Z_o| = 2$ and $k' = k/D^o{}_{Co}\gamma$ in Eq. [6] yields

$$\frac{d\ln a_o}{dy} = \left[\frac{k'}{a_o{}^n\xi} + (p-1)\frac{d\xi}{dy}\right] \Big/ [1+(p-1)\xi] \quad [8]$$

Equation [19] from Ref. (1), which describes the metal gradient in a scale using the divergence equation for the metal flux, becomes

$$yk\frac{d\xi}{dy} = \frac{-d}{dy}\left[D_{Fe}\xi\left(\frac{d\ln a_{FeO}}{d\xi}\frac{d\xi}{dy} - \frac{d\ln a_o}{dy}\right)\right] \quad [9]$$

Upon substituting into Eq. [9] parameters from Eq. [2], [5], and [7]

$$yk'\frac{d\xi}{dy} = -p\frac{d}{dy}\left[a_o{}^n\xi\left(\frac{1}{\xi}\frac{d\xi}{dy} - \frac{d\ln a_o}{dy}\right)\right] \quad [10]$$

An expression including the parabolic oxidation constant and the limiting iron concentrations and gradients in (CoFe)O at either the inner or outer scale interface serves as an auxiliary equation for solving Eq. [8] and [10]. Since an insignificant degree of internal oxidation occurred, the ratio for the flux of cobalt to iron in the scale at its inner interface is equivalent to the metal ratio in the bulk alloy. Equation [35] in Ref. (1) for material balance at this interface gives upon substituting Eq. [2], [5], and [7]

$$\left(\frac{d\xi}{dy}\right)_{y=0} = \frac{k'}{a'_o{}^n\xi'}\left\{\frac{p\xi' - [1+(p-1)\xi']\,\xi_{alloy}}{p}\right\} \quad [11]$$

where the prime refers to the inner scale surface and ξ_{alloy} is the atom fraction of iron in the alloy.

Iron concentration and oxygen activity profiles in the scales were generated within the range from $y = 0$ to $y = 1$ by simultaneously numerically integrating Eq. [8] and [10] with boundary values at $y = 0$ established by Eq. [11] using a computer knowing the values of the constants $D^o{}_{Co}$, p, γ, n, the experimental values of a_o', ξ', and the parabolic constant k. The calculated iron profiles in the scales formed on each alloy at 10^{-4} and 10^{-3} atm are shown in Fig. 7a, 7b, 8a, and 8b. They correspond to those experimentally determined in both magnitude and form. The typical shape of the oxygen activity gradient is illustrated by the plot in Fig. 11 for the scale formed on the Co-10 w/o Fe alloy at 10^{-3} atm. Iron was most significantly enriched in the outer region of a scale where the influence of the oxygen activity gradient was most pronounced on the more rapidly diffusing iron cations.

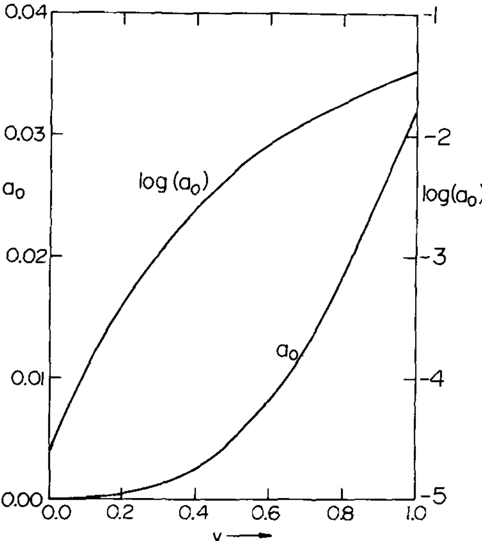

Fig. 11. Oxygen activity profile in (CoFe)O scale formed on the Co-10 w/o Fe alloy at 10^{-3} atm oxygen pressure.

An excellent correlation has been obtained by the diffusion analysis for the parabolic reaction kinetics and the normalized metal profiles in the scales formed on the alloys containing up to 10 w/o Fe at oxygen pressures of 10^{-4} and 10^{-3} atm. The analysis based on ternary diffusion equations, nevertheless, is to be regarded as a simplified empirical description of the oxidation phenomena. A more fundamental analysis cannot be attempted until additional definitive knowledge becomes available on the structures, thermodynamics, and mobilities of the lattice defects in (CoFe)O. Because of the paucity of information, the nonstoichiometry of this oxide was directly related to estimates for the vacancy concentration in the cation sublattice. These vacancies, moreover, were assumed to exhibit Henrian solution behavior and constant mobilities. This type of solution behavior is only a suitable approximation for analysis purposes as illustrated by the empirical expression (Eq. [2]) used to relate vacancy concentration to iron and oxygen activities. Also, the metal mobilities can be regarded as constant within the framework of presently available results only to the upper investigated pressure of 10^{-3} atm since the tracer diffusivities of cobalt and iron in (CoFe)O undergo variations between oxygen pressures of 10^{-3} to 10^{-1} atm (8).

Oxygen and Metal Activities of the Chromium-Nickel-Oxygen System Between 900° and 1100°C

Haydn Davies*,[1] and W. W. Smeltzer**

Department of Metallurgy and Materials Science, McMaster University, Hamilton, Ontario, Canada L8S 4M1

ABSTRACT

The equilibrium oxygen pressures for Cr-Ni alloys existing as the alpha (α) and gamma (γ) phases and coexisting with chromium oxide (Cr_2O_3), nickel oxide (NiO), and nickel chromite ($NiCr_2O_4$) were determined at 900°, 1000°, and 1100°C using an electrochemical cell with a calcia-zirconia electrolyte. These pressures were related to compositional determinations of the solid phases and the Cr-Ni-O isotherms. The free energies of formation of chromium oxide and nickel chromite were determined. With increasing nickel content of the alloy, the oxygen pressure increases from the dissociation pressure of pure chromium oxide to that of the univariant phase field, α-γ-Cr_2O_3, with chromium oxide containing <0.2 weight per cent (w/o) nickel. At higher oxygen pressures, the γ-Cr_2O_3 phase field extends up to the univariant γ-$NiCr_2O_4$-Cr_2O_3 phase field. Nickel chromite was essentially stoichiometric the nickel content of chromium oxide was ~0.5 w/o, and the γ-alloy contained only a very small chromium content, $\sim 10^{-4}$ w/o. No variation was detected in the spinel composition across the γ-$NiCr_2O_4$ region but the chromium content of the alloy decreased to $\sim 10^{-8}$ w/o at the univariant γ-$NiCr_2O_4$-NiO phase field, with nickel oxide containing 4.5 w/o Cr.

The thermodynamic behavior of the Cr-Ni-O system has not been extensively investigated, probably due to the very low oxygen activities encountered and to the consequent experimental difficulties. The free energy of formation and dissociation pressures of nickel oxide have been well defined (1-3), but these parameters for chromium oxide are less accurately known (1, 4-9). The Cr-Ni phase diagram has often been investigated but its shape above 1200°C is still controversial. The diagram determined by Bechtoldt and Vacher (10) is judged to be the most accurate; the maximum solubilities of chromium in the α(bcc) and γ(fcc) alloy phases at the eutectic temperature of 1345°C are 40 and 58 atom per cent (a/o), respectively. An isothermal section of the Cr-Ni-O system has been proposed by Croll and Wallwork (11) based upon chemical analyses of five binary Cr-Ni alloys that were oxidized and equilibrated at 1000°C for periods up to 5 days. They found very small solubility of chromium in nickel oxide and of nickel in chromium oxide, and a nickel chromite of stoichiometric composition. Gas equilibration (12), electrochemical cells (9, 13), and Knudsen cell (14, 15) techniques have been used to determine the alloy chromium and nickel activities, but the results show wide divergences. There is a need, therefore, for systematic determinations of the thermodynamic parameters governing phase equilibria in this system. Accordingly, we have determined the equilibrium oxygen pressure diagram for the Cr-Ni-O system and the compositions of the phases coexisting at temperatures in the range 900°-1100°C.

Experimental

A solid-state electrochemical technique was used to determine the dissociation pressures of the oxides. The cell assembly, which we have described (16), contained a 12 in. long tube of calcia stabilized zirconia (B grade) which acted as the electrolytic membrane between the separated anode and cathode compartments.

Electromotive force measurements were made on the following cells

Fe, FeO	| electrolyte |	Cr_2O_3, Cr	[I]
Cr, Cr_2O_3	| electrolyte |	Cr_2O_3, (Cr-Ni)γ	[II]
Cr, Cr_2O_3	| electrolyte |	Cr_2O_3, (Cr-Ni)γ, (Cr-Ni)α	[III]
Fe, FeO	| electrolyte |	Cr_2O_3, $NiCr_2O_4$, (Cr-Ni)γ	[IV]
Fe, FeO	| electrolyte |	$NiCr_2O_4$, NiO, (Cr-Ni) alloy	[V]

Since a cell reaction involves oxygen transfer across

Key words: Cr-Ni-O thermodynamics; Cr, Ni, and O activities; Cr_2O_3 and $NiCr_2O_4$ free energies of formation.

the electrolyte, a cell emf is (17)

$$E = \frac{RT}{4\mathbf{F}} \ln (P_{O_2}''/P_{O_2}') \quad [1]$$

where R is the gas constant, $\mathbf{F}$ is Faraday's constant, P_{O_2}'' and P_{O_2}' are the dissociation pressures of the oxides in the cathode and anode compartments.

The electrodes were fabricated as tablets 0.25 in. diameter by 0.10 in. thick by compressing, at 15,000 psi, powders of iron, nickel [99.99 weight per cent (w/o) pure], and chromium (>99.95 w/o pure) in predetermined proportions with one, or more, of the oxides (99.6 w/o pure) magnetite, nickel oxide, and nickel chromite. Two tablets of the same composition were sealed into a quartz capsule under 10^{-4} Torr purified argon and annealed for at least 30 days at 1000°C. Samples representing three-phase equilibria were also annealed at 1100°C. Capsules containing tablets for these latter systems contained chromium powder to act as an oxygen getter. After annealing, the samples were quenched, reaching room temperature within 1 min. One tablet was used in the cell while the other tablet was analyzed. Tablets were mounted in epoxy cold-setting resin; best polishing was obtained using a Rotopol mechanical polisher, the lubricant being a slurry of 0.3μ alumina in water. The oxides were readily etched in a solution of 10 volume per cent (v/o) concentrated hydrochloric acid in ethanol with the exception of nickel chromite which required etching in a solution containing 50 v/o concentrated hydrochloric acid. The α and γ alloy phases were easily distinguished without etching. The calibration of the electron probe microanalyzer consisted of sequentially applying atomic number, absorption, and fluorescence corrections (18,19). The calibration curves were checked using materials of known compositions, *i.e.*, Ni-Cr alloys and pure oxides analyzed by wet chemical methods.

The compositions of the solid phases in the electrode compartments must remain unchanged for measurement of reversible potentials by the galvanic cell technique (16). The coulometric technique introduced by Diaz and Richardson (20) was used to determine these reversible potentials in this investigation. A cell was disturbed from any supposed equilibrium state by passing a small current equivalent to 0.04 coulombs and the emf value subsequently determined from the plateau in the cell emf *vs.* time curves. Work was initially carried out using cell [I] to verify the reliability of the electrolyte for use at oxygen pressures below 10^{-20} atm since this cell generated the maximum voltages ranging up to 500 mV. The emf was measured at five temperatures, allowing 2 days for equilibration at each temperature. Since the emf always slowly decreased at a constant temperature, the cell was coulometrically disturbed and the reversible potential determined from the plateau value which lasted for approximately 1 hr. Cell temperatures were then cycled over the range 900°-1100°C and the emf was recorded immediately upon attaining temperature stabilization. These values agreed within ±2% of the plateau values obtained from coulometry.

Equilibrium oxygen pressures of chromium oxide coexisting with Cr-Ni alloys were measured with cell [II]. The emf values at five temperatures were measured using coulometric disturbance; the emf did not decrease by more than 1 mV from the plateau values even after 2 hr. The temperature was cycled and emf values also noted on immediately attaining temperature stability, and alternate values were checked by coulometric disturbance. Cell [III] was used to determine the oxygen pressure for the phase field α-γ-Cr_2O_3 with each of three electrode tablets which had been annealed at 900°, 1000°, and 1100°C for 60 days. For each tablet, the cell emf was measured at the corresponding annealing temperature. Cells [IV] and [V] were used

to measure the oxygen pressures of the phase fields alloy $NiCr_2O_4$-Cr_2O_3 and alloy $NiCr_2O_4$-NiO, respectively. The oxygen pressures of the tablets which had been annealed at 1100°C for 50 days were determined only at this temperature over periods of 8 days. The samples annealed at 1000°C for 60 days were held at this temperature for 10 days to measure the cell potentials, and then at 900°C for 16 days during which the emf was again measured.

Results

Cell [I].—The variation with temperature of the emf is shown in Fig. 1, and the deviation of the reported values is within ±2% of the least-squares line

$$E(\text{mV}) = 534.5(\pm 6.7) - 0.0874(\pm 0.0223)T \;(\pm 3.4\,\text{mV}) \quad [2]$$

Cell [II].—Emf *vs.* temperature plots for results governing alloy-Cr_2O_3 equilibria are given in Fig. 2-4 and the compositions of the designated alloys are recorded in Table I. The least-squares analyses of emf measurements between 900° and 1100°C are given in Table II and in all cases, the correlation coefficients exceeded 0.99.

Cells [III]-[V].—The emf's representing the univariant equilibria α-γ-Cr_2O_3, γ-$NiCr_2O_4$-Cr_2O_3, and γ-$NiCr_2O_4$-NiO are listed in Table III. The compositions of the solids are recorded in Tables IV-VI. The

values in Table IV for the compositions of the equilibrated α-γ alloy phases are in agreement with those selected by Shunk (21).

Discussion

The Fe,FeO electrode was used as a reference to determine the potential of the Cr,Cr_2O_3 electrode, and these two electrodes were subsequently used to determine the dissociation pressures of oxides coexisting with Cr-Ni alloys. As a consequence, the variation of the oxygen activity over the Cr-Ni-O isotherms at the several investigated temperatures can be obtained. Each phase field within this ternary system is discussed and, in addition, thermodynamic in-

formation is given which can be calculated by appropriate assumptions and approximations.

Cr-Cr_2O_3 equilibrium.—The variation of the emf of cell [I] with temperature, Eq. [2], may be combined with the corresponding relationship for the Fe, FeO electrode (2,16) to obtain the emf of the Cr,Cr_2O_3 electrode

$$E(\text{mV}) = 1371.3 - 0.340T \ (\pm 2.7 \text{ mV}) \quad [3]$$

The free energy of formation of chromium oxide is therefore

$$\Delta G^\circ_f(\text{cal/mole } Cr_2O_3) = -263{,}350 + 59.15T \ (\pm 610 \text{ cal}) \quad [4]$$

(ii) Sample annealed at 1100°C.
* The specimens NiO and $NiCr_2O_4$ were prepared from the pure materials (>99.8% purity) and had been annealed at 1100°C in 10^{-4} Torr purified argon.

These results were combined with previous work, as shown in Fig. 5, and a least-squares analysis of all data gave

$$\Delta G^\circ_f(\text{cal/mole } Cr_2O_3) = -265{,}020(\pm 1960) + 60.15(\pm 5.40)T \quad [5]$$

over 1173°-1373°K, with a standard deviation of ±980 cal. The results of this investigation are within this estimate which supports the validity of the use of the calcia-zirconia electrolyte. The dissociation pressure of chromium oxide can thus be expressed as

$$\log(P_{O_2} \text{ atm}) = \frac{-38{,}619(\pm 286)}{T} + 8.765(\pm 0.787) \quad [6]$$

Variation of equilibrium oxygen pressure with alloy composition.—The results given in Table VII are shown in Fig. 6 for 900°, 1000°, and 1100°C. The maximum nickel solubility in chromium oxide equilibrated with the Ni-Cr alloys was found to be 0.5 w/o and the oxygen pressure of the oxide varied over approximately two orders of magnitude at constant temperature. The analyses of the very small nickel contents of chromium

oxide showed large relative errors and no attempt was made to describe its dependence upon oxygen pressure.

Thermodynamics of Cr-Ni alloys.—Equilibrium between chromium oxide and the Cr-Ni alloy can be represented as

$$2Cr^A + 3/2\ O_2 = Cr_2O_3 \qquad [7]$$

Then, for a particular temperature, and assuming $a_{Cr_2O_3} \approx 1$ (maximum nickel content was 0.5 w/o)

$$a_{Cr}{}^A = (P^*_{O_2}/P_{O_2})^{0.75} \qquad [8]$$

where $a_{Cr}{}^A$ is the chromium alloy activity, and $P^*_{O_2}$ and P_{O_2} are the dissociation pressures for chromium oxide equilibrated with pure chromium and an alloy,

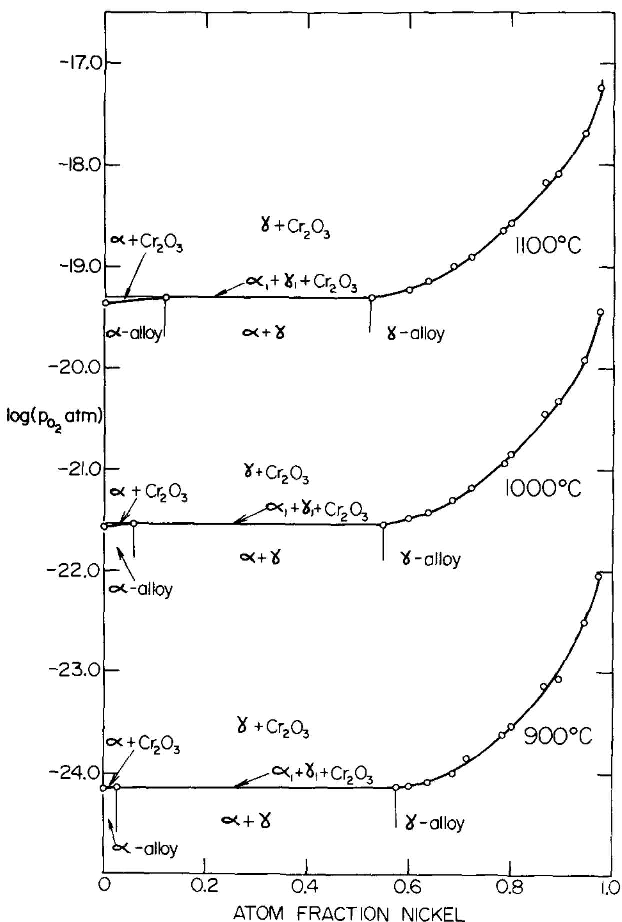

Fig. 6. Dissociation pressures of Cr_2O_3 coexisting with Cr-Ni alloys at 900°, 1000°, and 1100°C.

respectively. The emf's of cells [II] and [III] using Eq. [1] and [8] can therefore be expressed as

$$E = -\frac{RT}{3\mathbf{F}} \ln a_{Cr}{}^A \qquad [9]$$

Values of chromium activities calculated using this equation and data of Tables I, II, and IV are given in Table VIII; uncertainties in the values were estimated for an error of ± 1 mV, which is larger than the standard deviations from the least-squares lines, and a ± 5°C temperature error. The nickel activities recorded in Table VIII were determined from the chromium activities and compositions by numerically integrating the Gibbs-Duhem equation, following a method described previously (16).

Typical behavior of the metal activities over the investigated temperature range is illustrated by the plots in Fig. 7.[2] When the chromium activity is taken as one for the pure metal in the bcc structure, chromium shows positive deviations from ideality at compositions $N_{Cr}{}^A > 0.08$ and small negative deviations at lower concentrations. The activity curves from pure chromium to the terminal α-phase composition are only tentatively proposed since the experimental method is not sufficiently sensitive in this region.

Mean values for the partial heats of metal mixing in the γ-alloy and the integral heats of solution are recorded in Table IX. For chromium,

$$\Delta\overline{G}_{Cr} = RT\ln a_{Cr} = \Delta\overline{H}_{Cr} - T\Delta\overline{S}_{Cr} = 3\mathbf{F}(A + BT) \qquad [10]$$

when the emf results in Table II are represented by $E = A + BT$. $\Delta\overline{G}_{Cr}$, $\Delta\overline{H}_{Cr}$, and $\Delta\overline{S}_{Cr}$ are the partial free energy, heat, and entropy of mixing of chromium, respectively. The corresponding partial heats of mixing of nickel could be evaluated from its activity data and the relationship

$$\Delta\overline{H}_{Ni} = \frac{RT_1T_2}{T_2 - T_1} \ln a_{Ni}{}^{(T_1)}/a_{Ni}{}^{(T_2)} \qquad [11]$$

[2] Determinations of chromium and nickel activities in Ni-Cr alloys have been reported during course of this paper's publication by F. N. Mazandarany and R. D. Pehlke (22).

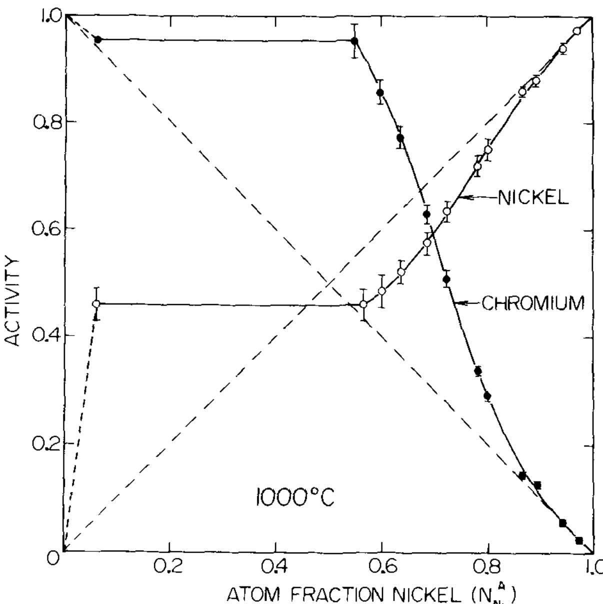

Fig. 7. Chromium and nickel activities in Cr-Ni alloys at 1000°C

Integral heats of mixing were calculated from the relationship

$$\Delta\overline{H} = N_{Cr}\Delta\overline{H}_{Cr} + N_{Ni}\Delta\overline{H}_{Ni} \quad [12]$$

where the N's are mole fractions in the alloy.

There is an uncertainty of ±70 cal/gram atom in $\Delta\overline{H}_{Cr}$ for an error of ±1 mV in the determination of the coefficient A. Although the standard deviation for each determination of this coefficient, Table II, is within this error limit, the values show that this deviation is larger and that it does not vary systematically with compositions of the alloy samples ranging from 10.8 to 40.1 a/o Cr. Average values of A and $\Delta\overline{H}_{Cr}$ can, therefore, only be given for this alloy composition range equal to 67.7 ± 12.0 mV and 4690 ± 830 cal/gram atom, respectively. The corresponding average value for $\Delta\overline{H}_{Ni}$ is −380 ± 290 cal/gram atom.

Alloy-$NiCr_2O_4$-Cr_2O_3 phase field.—The oxygen pressures were calculated from the emf's of cell [IV]. This field is the upper bound, with respect to oxygen pressure, of the γ-Cr_2O_3 equilibria and so the value of a_{Cr} at this terminal composition can be calculated using Eq. [9]. These activities are $1.6(\pm0.4) \times 10^{-7}$, $3.4(\pm0.4) \times 10^{-7}$, and $8.0(\pm0.5) \times 10^{-7}$ at 900°, 1000°, and 1100°C, respectively. Compositional results (Table V) show the chromium contents of the alloy to be <0.01 w/o which taken together with the values of the activities demonstrate that the terminal alloy chromium compositions of the γ-Cr_2O_3 phase field are ≈1 ppm.

The free energy of formation of nickel chromite can be obtained from the reaction

$$Ni^{A} + 2Cr^{A} + 2\,O_2 = NiCr_2O_4 \quad [13]$$

Table IX. Partial and integral heats of mixing in Cr-Ni alloys

Atom fraction		Partial heat of mixing (cal/gram atom)		Integral heat of mixing (cal/gram atom)
Cr	Ni	Cr	Ni	
0.028	0.972	560	0	20
0.056	0.944	530	0	30
0.108	0.892	4930	−290	270
0.133	0.867	5090	−370	350
0.200	0.800	4270	−430	510
0.218	0.782	5060	−450	760
0.278	0.722	4310	0	1200
0.313	0.687	6130	−840	1350
0.363	0.637	4330	0	1570
0.401	0.599	3340	−650	1730

The analytical data (Table V) permit one to assume $a_{Ni}^{A} > 0.999$ and $a_{NiCr_2O_4} > 0.99$, and so

$$\Delta G^{o}_{f}(NiCr_2O_4) = 9.150T\,[\log a_{Cr} + \log P_{O_2}] \quad [14]$$

giving $\Delta G^{o}_{f}(NiCr_2O_4)$ equal to −234.9, −226.1, and −217.7 kcal/mole at 900°, 1000°, and 1100°C. The estimated error in these values is ±1.2 kcal. This analysis can be extended to determine the free energy change, ΔG^{o}_{N}, for the formation of nickel chromite from nickel oxide and chromium oxide, where

$$\Delta G^{o}_{N} = \Delta G^{o}_{f}(NiCr_2O_4) - \Delta G^{o}_{f}(NiO) - \Delta G^{o}_{f}(Cr_2O_3) \quad [15]$$

The values of ΔG_{N}^{o} are −8300, −7500, and −7200 cal/mole $NiCr_2O_4$ at 900°, 1000°, and 1100°C, respectively, with an estimated uncertainty of ±1300 cal.

Alloy-$NiCr_2O_4$-NiO phase field.—Oxygen pressures calculated from the emf's of cell [V] were $9.5(\pm0.6) \times 10^{-13}$, $4.2(\pm0.3) \times 10^{-11}$, and $1.0(\pm0.05) \times 10^{-9}$ atm at 900°, 1000°, and 1100°C. The dissociation pressures of pure nickel oxide at these temperatures are 1.02×10^{-12}, 4.43×10^{-11}, and 1.11×10^{-9} atm. Since the chromium content of the alloy is less than the critical value of 10^{-4} w/o determined for the alloy Cr_2O_3 equilibrium, the relationship

$$P_{O_2} = P^{*}_{O_2}(a_{NiO})^2 \quad [16]$$

describes this system, giving a value of ~0.97 for a_{NiO} at the three investigated temperatures. The chromium contents of nickel oxide given by the electron probe determinations of samples annealed at 1000° and 1100°C (Table VI) correspond to 0.955 atom fraction nickel oxide.

The chromium activity in the γ-alloy can be estimated from Eq. [14] as 1×10^{-10}, 8×10^{-10}, and 5×10^{-9} at 900°, 1000°, and 1100°C. Thus, the alloy existing with nickel chromite and nickel oxide is almost pure nickel.

Equilibrium oxygen pressure diagram for the Cr-Ni-O system.—This diagram, which has the same shape between 900° and 1100°C, is shown only as a schematic in Fig. 8 because several of the experimentally determined parameters are too small to be represented graphically. With increasing nickel content of the alloy, N_{Ni}^{A}, the oxygen pressure increased from the dissociation pressure of pure chromium oxide to that associated with the univariant phase field, α-γ-Cr_2O_3, with chromium oxide containing <0.2 w/o Ni. The compositions of the α and γ alloy phases at 900°, 1000°, and 1100°C were 97.5 and 42.5, 94.2 and 45.0, and 88.2 and 47.5 a/o Cr, respectively. The α-alloy is unstable at larger oxygen pressures and γ-Cr_2O_3 phase field extended up to the univariant phase field, γ-spinel-Cr_2O_3. At both 1000° and 1100°C the nickel chromite spinel was found to be essentially stoichiometric, the nickel content of chromium oxide was 0.2 w/o while the chromium content of the γ-alloy phase, A_1, was estimated to be in the order of 10^{-4} w/o. The measurements did not detect any variation in the spinel composition across the two-phase field, alloy-spinel, but the chromium content of the alloy decreased to $\sim10^{-8}$ w/o, *i.e.*, alloy A_2 is effectively pure nickel and spinel S_2 is $NiCr_2O_4$, at the three-phase γ-$NiCr_2O_4$-NiO univariant oxygen pressure. The maxi-

A Rutherford Scattering Analysis of Anodic Tantalum-Silicon Oxides

P. J. Silverman[1]

Bell Laboratories, Indianapolis, Indiana 46206

and N. Schwartz*

Bell Laboratories, Murray Hill, New Jersey 07974

ABSTRACT

Reactively sputtered films consisting of ~65 atom per cent (a/o) Ta and ~35 a/o Si are of considerable interest for forming thin film capacitors and resistors. Oxides have been anodically grown on Ta-Si films and examined by the Rutherford backscattering technique. This analysis revealed that the outer layer of the oxide is greatly enriched in Ta and almost devoid of Si, while the inner layer has a lower Ta:Si ratio than the as-sputtered film. This indicates that Ta cations are very mobile within the oxide and are migrating to the surface under the influence of the applied field during anodization. No appreciable dissolution of either Ta or Si takes place. The Ta:Si:O stoichiometry of the oxide is consistent with a film composed of Ta_2O_5 and SiO_2.

At the present time in tantalum thin-film circuit technology (1), anodized β-tantalum (2, 3) is used for capacitors, while reactively sputtered tantalum nitride (4) is used for resistors. The fabrication of these circuits would be greatly simplified if a single thin film starting material were utilized for both of these components, especially if higher stability devices were obtained. Studies have been performed to use tantalum alloy compositions to improve the properties of capacitors. Alloys of tantalum with carbon, nitrogen, and oxygen (5) as well as tantalum-aluminum mixtures (6) have been investigated in the past. The use of tantalum-silicon alloys should have some considerable advantages:

1. Both elements are high melting point materials which should result in a film having high thermal and electromigration stability in resistors.
2. Some of the bulk tantalum silicides are reported to have resistivities (7) of the same order as tantalum nitride and tantalum-aluminum.
3. Both elements may be anodized (8) to form protective stable oxide films, and mixtures of them would presumably behave similarly.
4. As the tantalum-silicon alloy films can be deposited by reactive sputtering, all of the basic processes for thin film component fabrication can be retained and only the initial film material changed.

In another report (9) the initial characteristics of the tantalum-silicon alloy films were described, as well as the properties of the passive devices formed from them. In summary, however, quite stable resistors and very stable capacitors are formed from a composition in the neighborhood of 35 atom per cent (a/o) silicon.

The purpose of the present study was to determine the composition of the anodic oxide films formed on tantalum-silicon alloys. Relatively little work has been devoted to the analysis of anodic oxides grown on compounds or alloys (10); however, a recent Rutherford scattering study of anodic oxides on GaP (11) proved to be quite relevant to the present work. Rutherford ion scattering is an excellent technique for the determination of thin film composition as a function of depth. It is the only surface analytical method which will provide this information nondestructively. The technique has been used to examine a wide variety of thin film systems in addition to GaP, including the oxides of aluminum (12), silicon (13), and niobium (14). In the present study, Rutherford backscattering provided depth profiles of the elements comprising the Ta-Si films and their oxides, allowing us to speculate on the oxide growth mechanism. In addition, since a small loss (~20%) in capacitance had been found for thin film Ta-Si capacitors (9) compared to β-tantalum capacitors, it was of interest to determine whether this capacitance change was attributable either to incorporation of a low dielectric constant material (SiO_2) in tantalum oxide or to a change in film thickness.

Experimental Procedure

Sputtering and anodization.—The films were prepared by d-c diode reactive sputtering of tantalum in silane-argon mixtures in a 6-in. oil diffusion pump system with a liquid nitrogen trap and a glass bell jar. Sputtering from a 36 in.^{2} cathode was conducted at a potential of 5 kV, a current density of 0.5-1.2 mA/in.^{2}, a gas pressure of 1×10^{-2} Torr, and an interelectrode spacing of 2.75 in. The deposition rate varied from 80-120 Å/min, depending on the partial pressure of silane, which ranged from 7×10^{-6} to 8×10^{-4} Torr. This technique resulted in film compositions varying from 0-92 a/o silicon. Substrates were fused silica cleaned by a trichloroethylene boil, hydrogen peroxide boil, ultrasonic detergent wash, deionized water rinse, hot nitrogen dry with a final bake at 400°C in air for 30 min. In the vacuum station, the substrates were heated to 550°C for 2 hr and then cooled for 2 hr to a temperature of 100°C. Silane was admitted into the chamber to the desired partial pressure through a needle valve, and then argon was added to a total pressure of 1×10^{-2} Torr. After a presputtering period of 45 min with a shutter covering the substrates, the films were deposited for 45 min. Beta-tantalum films were prepared in pure argon, and the structure was identified by x-ray diffraction.

For the anodization, the 1 × 3 in. coated fused quartz slides were scribed and broken into six ½ × 1 in. slices. On each small slice, a thin strip of electroplaters tape was used to mask off the section where the electrolyte-air interface would form, and contact was made to the film with a small alligator clip. Anodization was performed in 0.01% citric acid using a tantalum cathode with an Electronic Measurements Inc. constant current/constant voltage power supply. Tantalum-silicon alloy films were anodized at 3-4 mA/cm^2; one set of slices was then soaked for about 20 min at constant voltage until the current dropped an order

* Electrochemical Society Active Member.

Key words: ion backscattering, thin films, anodic oxides.

of magnitude. Beta-tantalum films were anodized at 1 mA/cm^2 and then similarly soaked at the given anodizing voltage.

Backscattering.—Rutherford backscattering of $^4He^+$ ions was employed to analyze the composition and to obtain depth profiles of the Ta-Si films and their anodic oxides. In this technique a well-collimated, mono-energetic beam of ions is directed onto the sample. The ions lose energy in a solid by two processes: (*i*) elastic scattering by the repulsive Coulomb force between the nuclei of the incident ion and a target atom; and (*ii*) inelastic collisions with the electrons of the material. The nuclear scattering allows identification of the constituent elements of a thin film by the amount of energy the incident ion loses to the recoil of the target atom; light atoms, such as oxygen, can take up a large portion of the energy of the ion, while heavy atoms, like tantalum, absorb relatively little energy in recoiling. The stopping power of the electrons provides information about the depth distribution of elements in the sample, since ions scattered from atoms deep in the sample will have lost more energy than those scattered from atoms of the same element at the sample surface. Interpretation of the backscattered energy spectrum thus permits a nondestructive determination of the identity and position of the elements composing a thin film.

All measurements in this experiment were performed on the Bell Laboratories Van de Graaff accelerator with 1.9 MeV $^4He^+$ ions. The experimental apparatus and the basic equations pertinent to Rutherford backscattering analysis have been described elsewhere (15). Two backscattered energy spectra were taken for each sample: one on the anodic oxide and one on an adjacent unanodized area. Typically, the beam current was ~2.5 nA, and the total integrated beam charge for each spectrum was 6 μC. Because of the Z^2 dependence of scattering cross section, there is relatively little backscattering from the O and Si atoms present compared to that from the Ta atoms, and consequently a period of about 50 min was required to obtain a spectrum with adequate statistics (statistical uncertainties in total counts of ~1%) for the O and Si yields from a sample. The energy resolution of the system, determined mainly by the resolution of the surface barrier silicon detector, was 15 keV.

Results

A backscattered energy spectrum for an as-sputtered Ta-Si film is shown in Fig. 1; the relatively small yields of the low energy side have been magnified by a factor of 20. The energies with which 1.9 MeV He ions are backscattered from Ta, Ar, and Si atoms at the surface are shown on the abscissa. These energies correspond to the half-heights of the leading edges of the respective scattering peaks, indicating that all of these elements are present at the sample surface.

The shaded areas give the yields corresponding to elements in the Ta-Si film. The background under the Ar yield, probably due to multiple scattering from Ta within the film, is taken simply by drawing a horizontal straight line; such long tails are always present in scattering from thin films. Because the trailing edge of the Ar yield is overlapped by the leading edge of the Si yield, it is necessary to determine (using a knowledge of the kinematics of the scattering process and the electronic stopping powers) the expected Ar peak width from the observed Ta peak width, assuming that the Ar is uniformly distributed throughout the film. For the Si, some criterion must be established to determine the position of the interface between the film and the underlying quartz (SiO_2) substrate. Here we use the energy of the midpoint between the substrate and film plateaus as the energy of the half-height of the trailing film edge; Mitchell *et al.* (16) have shown this to be an accurate method. A straight line is then drawn from the leftmost point of the film

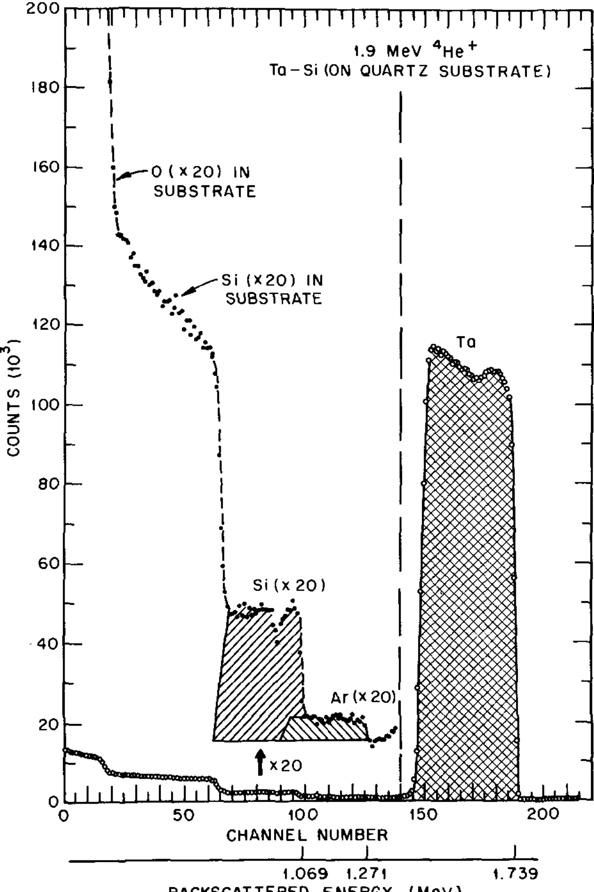

Fig. 1. Backscattered energy spectrum of 1.9 MeV ^4He ions from a sputtered Ta-Si film about 4200Å thick. The low energy side of the spectrum is also shown magnified by a factor of 20. The shaded areas are the scattering yields of the elements in the film. The energies with which the ions are backscattered from Ta, Ar, and Si are shown on the abscissa (energy scale = 7.5 keV/channel).

plateau through the half-height to approximate the trailing edge of the film scattering for Si.

For a thin film of uniform composition, the backscattered yield should increase with decreasing energy due to the E^{-2} dependence of the Rutherford cross section (the stopping power is essentially constant in this energy region). Thus, the slope observed in the Ta yield is expected, but the slight peak at the surface is not. This peak represents an increase in the Ta level present; the corresponding decrease in Si concentration is not as easily discerned in the scattering spectrum. Similar nonuniformities were observed in samples with different over-all compositions from sputtering runs at different silane partial pressures.

The integrated composition of a film is obtained from the elemental scattering yields after allowing for the Z^2 dependence of scattering cross section. The ratio of Ta:Si:Ar in the film of Fig. 1 is 2.9:1:0.10, or 72% Ta, 25% Si, and 3% Ar. The average film composition, obtained from spectra taken on six unanodized samples, was 69% Ta, 28% Si, and 3% Ar, or a ratio of 2.5:1:0.13. Argon is incorporated into the film during the sputtering process, and similar levels have been previously observed in sputtered films (17). The actual numbers of Ta, Si, and Ar atoms per square centimeter were obtained by comparing the yields to that from a bulk gold or tantalum sample. Converting these numbers to a surface density (grams per square centimeter) and dividing by the weighted average of the densities of β-Ta and bulk Si (ignoring the small amount of Ar), the film thickness was calculated to be about 4200Å.

Figure 2 is the spectrum obtained from a Ta-Si film anodized at constant current to 249V and soaked at

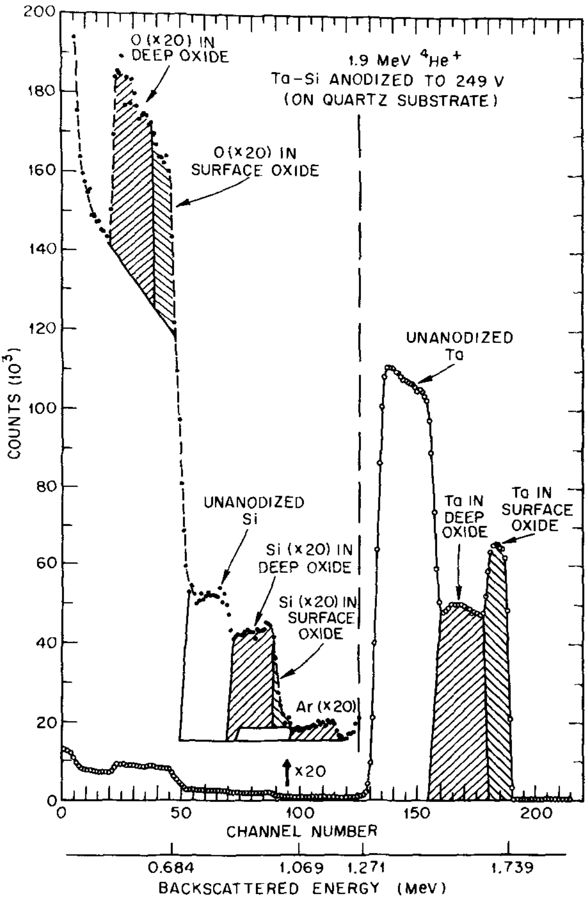

Fig. 2. Backscattered energy spectrum of 1.9 MeV ^4He ions from a Ta-Si film anodized to 249V. The yields of Si and O from the surface layer are shaded the same as the surface Ta peak; similarly, the Ar, Si, O, and Ta in the deep oxide layer are shaded alike. There is essentially no Ar yield from the surface layer. Elemental yields from the unanodized Ta-Si film beneath the oxide are shown as enclosed, unshaded areas. Within experimental uncertainties, the measured amount of O corresponds to an oxide composed of Ta_2O_5 and SiO_2. (Energy scale = 7.5 keV/channel.)

this voltage as previously described. Several interesting features of this spectrum are immediately apparent. The large Ta peak indicates an excess of Ta at the outer surface of the oxide. There is a corresponding deficiency of Si in this region, as shown by the difference between the observed position of the Si half-height and the position expected if Si were present at the oxide surface. Similarly, the Ar leading edge occurs at a reduced energy, indicating a lack of Ar in this surface layer. Virtually every oxide grown exhibited these nonuniformities, including oxides formed on films of other Ta-Si compositions. The small dip in the Ta yield at the back edge of the deep oxide indicates a slight Ta deficiency, although this was not observed in any other oxides.

Since the composition of the surface and deep oxide layers are obviously different, the areas corresponding to these layers have been shaded differently in Fig. 2 to facilitate interpretation. Boundaries of the Si and O yields were determined kinematically from the width of the surface Ta peak. The background under the O peak, due mainly to scattering from Si in the quartz substrate, is determined simply by extrapolating a smooth line from the points to the left of the peak. The Ta:Si:O ratio was calculated to be ~9:1:26 for the surface layer and ~1.8:1:6.5 for the deep layer. (Argon was not included as it was not expected to enter into stoichiometric combinations with the other elements and was present at such low levels.) Despite the large difference in Ta:Si ratios, the amount of O observed in each layer is consistent, within 6%, with the presence

Table I. Integrated stoichiometries of Ta-Si oxides produced by constant current anodization followed by a constant voltage soak period

of Ta_2O_5 and SiO_2. The integrated Ta:Si:O stoichiometry for the oxide of Fig. 2 is 2.6:1:8.8. The stoichiometries of oxides produced at various voltages, and the agreement between the expected and observed levels of O, and listed in Table I. The close agreement between expected and observed O levels indicates that only Ta_2O_5 and SiO_2 are being formed.

Figures 3 and 4 show the elemental depth profiles extracted directly from the backscattering spectra of Fig. 1 and 2. To obtain these profiles, backgrounds were subtracted from each point of the O, Si, and Ar peaks. The number of counts represented by each of the shaded areas was normalized to allow for the Rutherford backscattering cross-section ratios for O:Si:Ar:Ta of 1:3.36:5.69:95.2. The widths of the O, Si, and Ar peaks were linearly increased by 34, 16, and 11%, respectively, relative to the Ta peak, to adjust for the kinematic decrease in width with decreasing mass; corresponding decreases of the peak heights were then made to conserve the total number of counts. Also, the E^{-2} slope of the peaks was allowed for so that a film of uniform composition would show constant concentration levels in the depth profile. The profiles reflect a depth resolution of roughly 200Å, as calculated from Bragg's additivity rule for stopping powers (18) and the 15 keV energy resolution.

The depth profile of Fig. 3 clearly shows the variation in composition of the Ta-Si film as-sputtered. The outer layer is about 75% Ta, 22% Si, and 3% Ar,

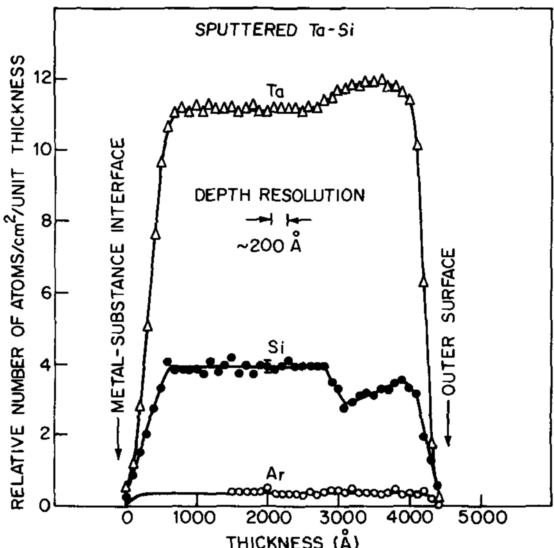

Fig. 3. Depth profile extracted from the Ta-Si spectrum of Fig. 1. The increased Ta and reduced Si concentrations at the surface of the Ta-Si film are clearly seen. A uniform distribution of Ar deep within the film is extrapolated back from the observed Ar yield not overlapped by the Si scattering. A typical error bar is shown on the Si profile; the uncertainties on the Ta and Ar are approximately the dot size.

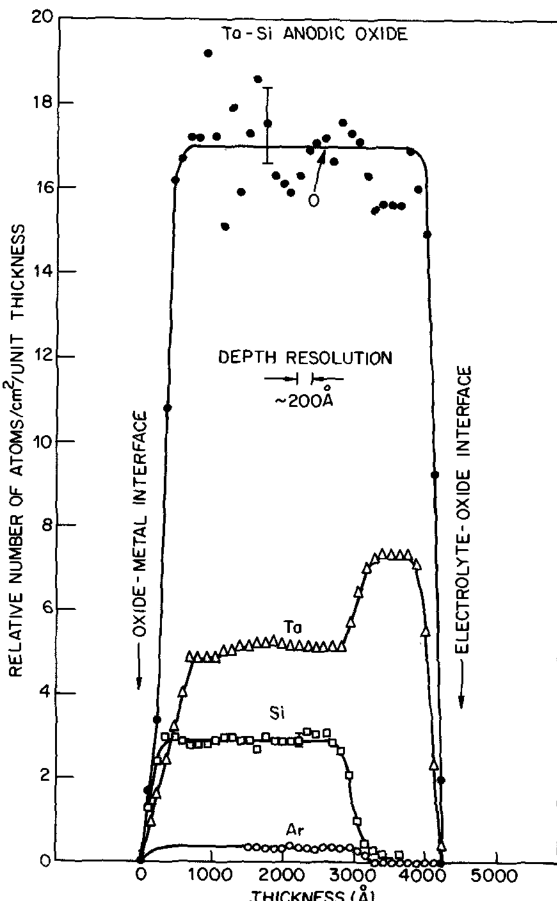

Fig. 4. Depth profile of the 249V anodic oxide layer, extracted from the spectrum of Fig. 2. The surface layer is evidently almost devoid of Si and Ar, with a correspondingly large excess of Ta. The lines are drawn simply to guide the eye, not necessarily as a best fit for the data points.

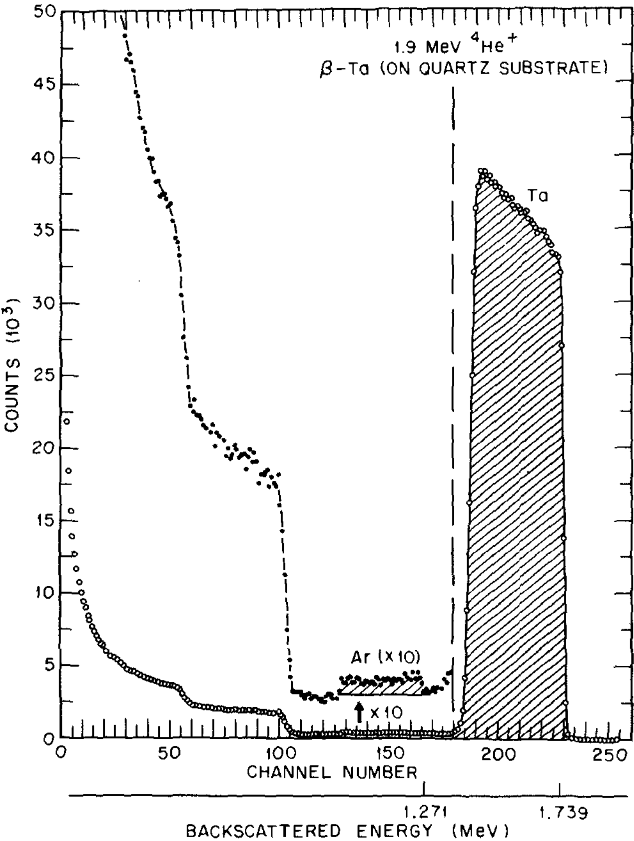

Fig. 5. Backscattered energy spectrum of 1.9 MeV ^4He ions from a sputtered β-Ta film. The composition appears to be constant throughout the thickness of the film; the slope of the Ta peak is due to the E^{-2} dependence of the scattering cross section. (Energy scale = 7.5 keV/channel).

while the inner layer is composed of 70% Ta, 27% Si, and 3% Ar. This results in an over-all composition of 72% Ta, 25% Si, and 3% Ar, as noted earlier. The positive slope of the Si profile within the outer layer seems to indicate that the Si level increases near the surface. However, this slope may simply reflect a small error in the extrapolated width and shape of the Ar yield underlying the Si yield in the backscattering spectrum.

Figure 4 is the depth profile of the 249V oxide layer of Fig. 2, excluding the underlying unanodized layer. The large pile-up of Ta and the deficiency of Si at the surface are evident. Argon is apparently almost totally absent from the surface of the oxide. By comparison with Fig. 3, it can be seen that the Ta:Si ratio in the deep oxide is much smaller than in the unanodized film, while in the surface oxide the ratio is far higher than usual. Within the uncertainties of the statistics for the O yield, the level of O seems to be fairly uniform throughout the oxide.

Information about the loss of elements into solution can also be obtained from the spectrum of an anodized film. This is accomplished simply by summing the entire film scattering yield for Ta, Si, and Ar rather than just that part which corresponds to the oxide layer. The average of the values obtained in this fashion from all of the anodized film spectra was a Ta:Si:Ar ratio of 2.6:1:0.09 or about 70% Ta, 27% Si, and 3% Ar, quite close to the average composition of the unanodized films. In addition, the actual numbers of Ta atoms in the anodized films were within 2% of the numbers in the as-sputtered films, indicating that no appreciable dissolution of the constituent elements of the films occurred during anodization.

Because of the interesting nonuniformities observed in Ta-Si and its oxides, a scattering analysis of sputtered β-Ta film and its anodic oxide was performed. Figure 5 shows the backscattering spectrum from a sputtered β-Ta film. Again, the yields at low energy are shown expanded (by a factor of 10) so that the Ar present in the film may be seen more readily. It is obvious that the Ta concentration is uniform throughout the Ta film; the slope of the Ta peak is simply that expected from the E^{-2} cross-section dependence. The composition of 96% Ta and 4% Ar was essentially constant for all samples analyzed.

Figure 6 is the spectrum obtained from a Ta film anodized to 82V and soaked as before. The Ta and O levels are seen to be reasonably constant throughout the thickness of the oxide. The Ta:O ratio was found to be 1:2.4 for this oxide, corresponding closely to the Ta_2O_5 stoichiometry as expected. Indeed, all measurements on β-Ta oxides of various thicknesses resulted in ratios within 6% of 1:2.5.

In every scattering spectrum for the β-Ta oxides, the leading edge of the Ar scattering fell close to or on the trailing edge of the Ta scattering and consequently was obscured, making the Ar level near the oxide surface difficult to determine. For this reason, the area corresponding to the Ar yield is not delineated in Fig. 6. Despite this uncertainty, it can be stated that in most cases more Ar is present at or near the β-Ta oxide surface than was found in the surface layer of the Ta-Si oxide. However, small peaks in the Ta yields, corresponding to increases of 2-3% in the amount of Ta present at the surface, were observed in the spectra of the two thickest β-Ta oxides, anodized to 210 and 249V. While this could be attributed to the presence of some Ta in a valence state less than +5 (and a consequent decrease in the amount of O present), we be-

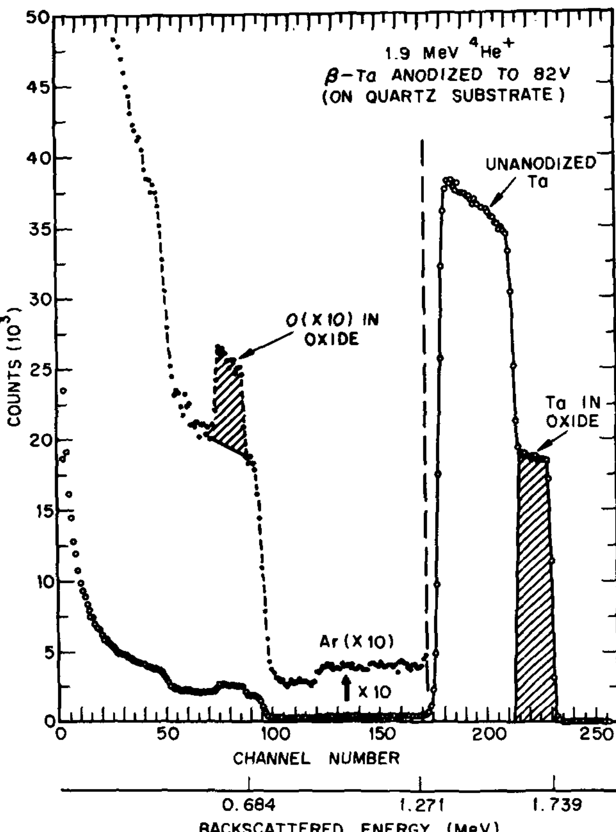

Fig. 6. Backscattered energy spectrum of 1.9 MeV He ions from a β-Ta film anodized to 82V. The Ta and O concentrations are uniform throughout the oxide and correspond to the Ta_2O_5 stoichiometry. The Ar yield is not determined because of the overlap of its leading edge with the Ta trailing edge. (Energy scale = 7.5 keV/channel).

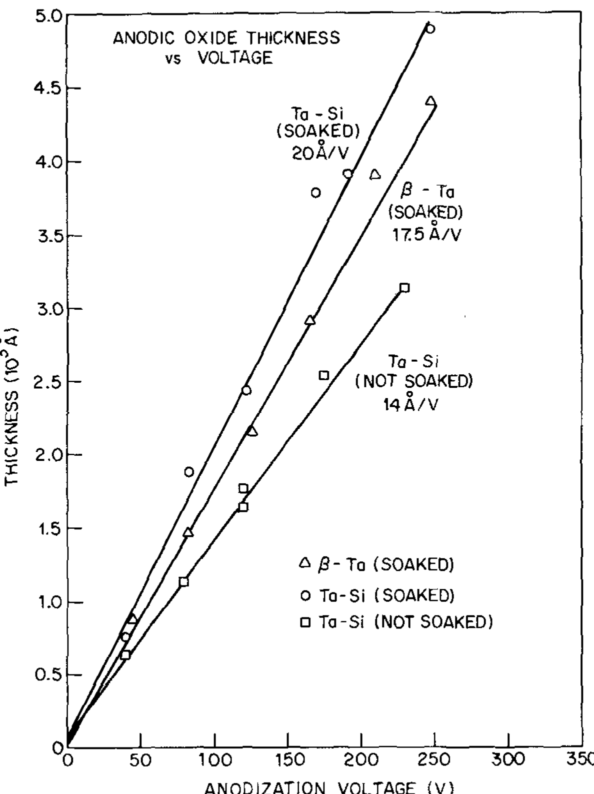

Fig. 7. Comparison of anodic oxide thickness vs. anodization voltage for β-Ta and Ta-Si. Ta-Si produces a thicker oxide than β-Ta for a given anodizing voltage when a constant voltage soak period is included in the anodization.

lieve that it is more likely to be correlated with a lack of Ar in the outer layer (about one-fourth of the total oxide thickness) similar to that seen in the Ta-Si oxides.

All of the Ta-Si oxides exhibited brilliant uniform interference colors similar to those seen in the anodic Ta_2O_5 films. Thicknesses were calculated for the oxides by the method mentioned previously for the unanodized Ta-Si film: determining the number of atoms per square centimeter from the spectra, converting this to a surface density (grams per square centimeter), and dividing by the weighted average of the densities of anodic Ta_2O_5 (8.0 g/cm^3) (19) and anodic SiO_2 (1.8 g/cm^3) (20). Film thickness *vs.* anodized voltages is plotted in Fig. 7. The growth rate of β-Ta oxide was 17.5 Å/V and falls within the range of 16-18 Å/V that is usually quoted for β-Ta (19, 21, 22). The Ta-Si oxides formed at a somewhat higher rate, about 20 Å/V. The fact that the thickness *vs.* V plots intercept ~50-100Å at zero volts must be due in part to experimental error, however, the statistics of the yield in Fig. 1 at the energy corresponding to oxygen atoms at the surface do not preclude the possibility of a 20Å native oxide layer existing on the as-sputtered film.

In addition to the β-Ta and Ta-Si oxides produced by the usual anodizing method, Ta-Si oxides were formed simply by anodizing at constant current up to a given voltage, omitting the constant voltage soak period. The results obtained from backscattering spectra of unsoaked Ta-Si oxides showed these films to be quite similar in many respects to the soaked Ta-Si oxides; the over-all average oxide composition was the same within experimental error and similar nonuniformities in Ta levels, etc., were observed. However, as shown in Fig. 7, the growth rate of the unsoaked oxides was only 14 Å/V, much lower than for the films which did undergo a soak at the final anodized voltage. This is to be expected, at least qualitatively, since the soaked oxide continues to grow at a decelerating rate as the current drops when held at a constant voltage.

The rates at which the films were consumed during anodization were also calculated. About 7.5Å of β-Ta or Ta-Si was consumed per volt when a constant voltage soak period was used; the value dropped to 5 Å/V for unsoaked Ta-Si. From these values it was then easy to determine the conversion factor between initial film thickness and anodic oxide thickness. It was found that 2.7Å of oxide resulted for each angstrom of Ta-Si consumed, with or without a soak period, slightly more than the 2.3Å of Ta_2O_5 produced per angstrom of β-Ta.

Discussion and Conclusions

Oxides have been anodically grown on Ta-Si films by a method typically used for forming Ta_2O_5 on Ta. Our measurements indicate the following important compositional features:

1. The Ta-Si films have slightly enhanced concentrations of Ta and decreased levels of Si near the surface prior to anodization.
2. The outer layer of the Ta-Si oxide is apparently largely Ta_2O_5 and is nearly devoid of Si (and Ar).
3. The inner oxide layer is probably composed of Ta_2O_5 and SiO_2, with a lower Ta:Si ratio than in the unanodized film.
4. There is no appreciable dissolution of Ta or Si from the films during anodization.

The concentration nonuniformities in the as-sputtered film were seen in film samples from several sputtering runs, indicating that the effect is not just an artifact of some abnormal sputtering condition (*e.g.*, a change in silane partial pressure) that may have occurred during a particular run. The nonuniformity indicates that less Si is being incorporated into the film toward the end of the sputtering process. This

may be caused by a rise in the substrate temperature during deposition, which might decrease the sticking coefficient of Si on Ta. In any case, the significance of the nonuniformity to our results is only that the oxides are formed mainly from a slightly Ta-rich and Si-poor layer. While none of the Ta-Si film used in this study was exactly 35% Si, a Ta-Si sintered alloy cathode may make film composition and reproducibility more easily controlled in the future.

The concentration profiles of the Ta-Si oxides are strikingly similar to those found by the backscattering technique in anodic oxides of GaP (11); unlike the GaP case, however, there is no complication of interpretation due to dissolution of the film. Apparently, the Ta cation is much more mobile than Si (or Ar) within the oxide. Under the influence of the applied anodizing electric field, a large fraction of the available Ta migrates to the surface of the oxide through a stationary matrix of Ta_2O_5 and SiO_2. In a study of the anodic oxidation of various alloys, Wood and Khoo (10) found a similar profile in Nb-Ta oxides except that Nb was the more mobile ion and was found in excess in the outer film surface. According to Pringle (23), the transport number of O is about three times that of Ta in the anodization of Ta films, so that one Ta ion migrates outward for every seven or eight O ions that move inward. Thus, the in-migration of the oxidizing species may also be a major feature of the growth mechanism of Ta-Si oxide.

It is significant that the film seems to anodize to form only Ta_2O_5 and SiO_2. While Ta will anodize in almost any solution, SiO_2 is considerably more difficult to form anodically in aqueous electrolytes. Although the agreement (shown in Table I) between the theoretical (assuming only Ta_2O_5 and SiO_2) and observed amounts of O is quite good, there is a large variation of the Ta:Si ratios. These variations are probably caused in part by the uncertainty (perhaps 15%) of the Si yield, a result of the procedure for determining the background counts underlying the Si portion of the spectrum; however, the near equality of the average Ta:Si ratios for the unanodized and anodized films indicates the basic validity of the measurements. Figure 7 demonstrates that the oxide film thickness for the soaked Ta-Si and β-Ta differ by about 2.5 Å/V for a given anodizing voltage. The lower capacitance of Ta-Si oxide capacitors, compared to those made with Ta_2O_5, is therefore due mainly to the greater oxide thickness, although incorporation of Si and SiO_2 in the oxide film may also be a contributing factor.

Diffusion of Phosphorus in Gallium Melt

Kunio Kaneko, Masaaki Ayabe, Masashi Dosen, Kenji Morizane, Setsuo Usui, and Naozo Watanabe

Sony Corporation Research Center, 174 Fujitsuka-cho, Hodogaya-ku Yokohama, Japan

ABSTRACT

Crystal growth rate of GaP in the SSD (synthesis, solute diffusion) method is limited by the diffusion process of phosphorus in the gallium melt. The diffusion process was analyzed and the diffusion coefficient was derived as $D = 1.8 \times 10^{-2} \exp(-0.65 \text{ eV}/kT)$ cm² sec⁻¹.

We have recently developed the SSD (synthesis, solute diffusion) method for growing GaP crystals (1, 2). Diffusion of the solute phosphorus in a gallium melt plays an important role in the crystal growth process of this method. Pertinent data are, however, scarce. The only published value of the diffusion coefficient is 5×10^{-5} cm² sec⁻¹ at temperatures from 700° to 1300°C, used by Tiller (3) and by Plaskett (4). Rodot *et al.* (5) adopted a value of 1×10^{-4} cm² sec⁻¹ from an analogy to GaAs. But a temperature dependent diffusion coefficient is not available.

In the SSD method, a thin film of GaP exists at the surface of the gallium melt, so the phosphorus concentration at the melt surface is fixed to the saturation concentration determined by the surface temperature. After a nucleus is formed at the bottom of the melt where the temperature is lower than at the surface of the melt, the concentration at the growth front is also fixed to the saturation concentration determined by the temperature at the growth front. Diffusion of phosphorus continues in the melt between these two saturation concentrations and limits the growth rate of the crystal (1).

In this paper the diffusion process of the SSD method is analyzed and the diffusion coefficient is evaluated as a function of temperature using the growth rate data obtained by this method.

Evaluation of Diffusion Coefficient

That the growth process is limited by diffusion of the solute makes it possible to evaluate the diffusion coefficient from the experimental data of the growth rate (1), provided due assumptions and approximations are made. As the crystal grows, the growth front moves upward into a higher temperature region and at the same time the melt itself moves upward in the crucible because of volume increase which accompanies the conversion of gallium into GaP. Thus, taking a moving coordinate system which is stationary with respect to the melt, the requirements of the conservation of gallium and phosphorus at the growth front are expressed respectively as

$$(\rho^{M} - C^{M}) \frac{dR}{dt} = \rho_{GaP}{}^{M} V \quad [1]$$

and

$$D \frac{\partial C^{M}}{\partial x} + C^{M} \frac{dR}{dt} = \rho_{GaP}{}^{M} V \quad [2]$$

where x is the position variable, ρ^{M} is the density of the melt, $\rho_{GaP}{}^{M}$ the density of GaP, and C^{M} the concentration of phosphorus in the melt (all in mole cm⁻³). D is the diffusion coefficient of the solute, R the position of the growth front expressed in the coordinate system as a function of time, t, and V the growth rate of the GaP crystal. Then from Eq. [1] and [2]

$$D \frac{\partial C^{M}}{\partial x} = \rho_{GaP}{}^{M} V \left(1 - \frac{C^{M}}{\rho^{M} - C^{M}}\right) \quad [3]$$

Since the mole fraction of phosphorus, C, is defined as $C = C^{M}/\rho^{M}$, we obtain from Eq. [3]

$$V = \frac{\rho^{M}}{\rho_{GaP}{}^{M}} \frac{1 - C}{1 - 2C} D \frac{\partial C}{\partial x} \quad [4]$$

Equation [4] holds strictly only at the growth interface, and necessary information to evaluate D using this equation is not obtainable experimentally. However, we can simplify the treatment as follows.

The diffusion coefficient is assumed to be independent of C and T over the temperature range of each run. Although our aim is to obtain the temperature dependence of D, this assumption will be justified if the dependence is not strong. The concentration profile, which is fixed at both the growth interface and at the melt surface to the saturation concentration, C_P, becomes nearly linear, because diffusion proceeds in nearly steady fashion (the diffusion coefficient is of the order of 10^{-4} cm² sec⁻¹ while the growth rate is of the order of 10^{-6} sec⁻¹). The growth front moves, as the crystal grows, from the bottom of the crucible to a height almost twice the initial depth of the melt, W, if the total gallium is exhausted. Therefore, the values of the temperature, T_H, the concentration, C_{PH}, and dC_P/dx at the initial melt surface may serve as average values for T, C_P, and $\partial C/\partial x$ at the growth front, respectively, taken over the whole period of growth. The left hand term of Eq. [4], V, can now be replaced by the average growth rate, V_{av}, or the length of the crystal divided by the time of growth.

Thus from Eq. [4] a new relation is obtained

$$\frac{V_{av}}{\nabla T} = KD \quad [5]$$

where ∇T is a temperature gradient in the melt

$$\nabla T = \frac{dT}{dx} = \frac{T_H - T_L}{W}$$

and

$$K = \frac{\rho_{Ga}{}^{M}}{\rho_{GaP}{}^{M}} \frac{1 - C_{PH}}{1 - 2C_{PH}} \left(\frac{dC_P}{dT}\right)_{T=T_H}$$

T_L is the temperature at the bottom of the crucible. ρ^{M} was approximated by the density of pure gallium, $\rho_{Ga}{}^{M}$, in mole cm⁻³, because C_P was small compared to unity in the temperature regions investigated. The saturation concentration, C_P, as a function of temperature, or the liquidus of gallium-phosphorus system, has been given by M. Rubenstein (6), R. N. Hall (7), and C. D. Thurmond (8), which is approximately expressed in the form

$$C_P = C_{Po} \exp(-E_C/kT)$$

with the constants $C_{Po} = 1.998 \times 10^{-3}$ and $E_C = 1.28$ eV. Assuming that the diffusion coefficient can be expressed in the form

$$D = D_o \exp(-E_D/kT)$$

the following relation is obtained

Key words: gallium phosphide, crystal growth, diffusion coefficient, phosphorus, gallium melt.

$$KD = \frac{\rho_{Ga}{}^{M}}{\rho_{GaP}{}^{M}} \frac{1 - C_{PH}}{1 - 2C_{PH}} C_{Po} D_o \frac{E_C}{kT_H{}^2} \exp - (E_C + E_D)/kT) \quad [6]$$

Using Eq. [5] KD was calculated from the experimental results (1), and $\log KDT_H{}^2(1 - 2C_{PH})/(1 - C_{PH})$ has been plotted as a function of $1/T_H$ in Fig. 1. Values for $\rho_{Ga}{}^{M}$ and $\rho_{GaP}{}^{M}$ at room temperature, 8.5×10^{-2} and 4.1×10^{-2} mole cm^{-3}, respectively, were employed in the calculation. A straight line was drawn through the points, from which D_o and E_D were obtained using Eq. [6]. The results are

$$D_o = 1.8 \times 10^{-2} \text{ cm}^2 \text{ sec}^{-1}$$
$$E_D = 0.65 \text{ eV}$$

Figure 2 shows the same result as Fig. 1 with the ordinate changed to D. The diffusion coefficient thus obtained, 8×10^{-5} cm^2 sec^{-1} at 1100°C is in fair agreement with the values 5×10^{-5} to 1×10^{-4} cm^2 sec^{-1} adopted by Tiller (3) and other authors (4, 5). D. L. Rode recently measured the diffusion coefficient in his study of the liquid phase epitaxy process of GaP (9). He obtained D equal to 5.7×10^{-5} cm^2 sec^{-1} at 1020°C, which is on the extrapolated line in Fig. 2.

Estimation of the Time of Nucleation

The foregoing analysis is based, among others, on the approximation that the growth proceeds nearly steadily throughout a run. Actually, however, the growth does not start until the melt reaches supersaturation. Once the growth starts, its rate is at first greater than the steady-state growth rate because of the supersaturation in the melt. Thus in the calculation of the average growth rate, the error due to neglecting the time of supersaturation and that due to neglecting the transient growth should partially cancel each other, resulting in an over-all error smaller than either of the two. Therefore, it suffices to estimate the time from the start of the run to nucleation in order to estimate the over-all error.

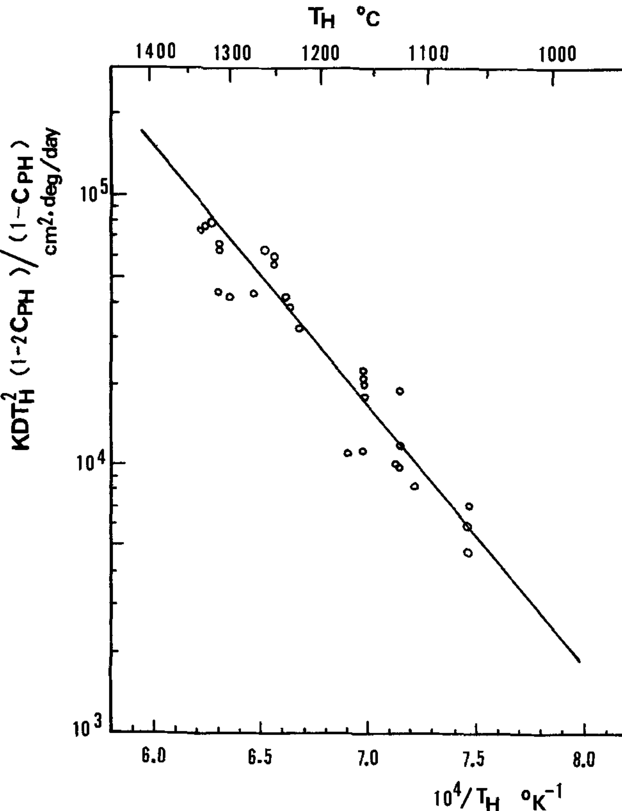

Fig. 1. Relation of $KDT_H{}^2\ (1 - 2C_{PH})/(1 - C_{PH})$ vs. $1/T_H$. D is the diffusion coefficient of phosphorus in gallium and

$$K = \frac{\rho_{Ga}{}^{M}}{\rho_{GaP}{}^{M}} \frac{1 - C_{PH}}{1 - 2C_{PH}} \left(\frac{dC_P}{dT}\right)_{T=T_H}.$$

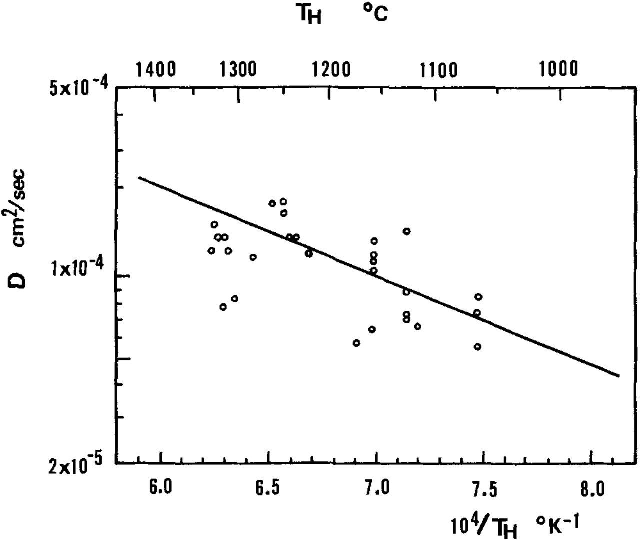

Fig. 2. Temperature dependence of the diffusion coefficient. The straight line is given by $D = 1.8 \times 10^{-2} \exp(-0.65\ \text{eV}/kT)$ cm^2 sec^{-1}.

Initially the concentration of phosphorus in the gallium melt is zero everywhere. At time $t = 0$, a thin film of GaP is formed on the surface of the melt and remains there throughout a run, thereby keeping the concentration at the surface constant. Then the concentration of phosphorus in the melt is given by Ref. (10). Here the concentration is expressed in mole fraction in place of mole cm^{-3} because the density of the melt is nearly constant in the concentration range in question.

$$C = C_{PH} \sum_{n=0}^{\infty} (-1)^n \left\{ \operatorname{erfc} \frac{(2n+1)W - x}{2\sqrt{Dt}} + \operatorname{erfc} \frac{(2n+1)W + x}{2\sqrt{Dt}} \right\}$$

where the origin of x coincides with the bottom of the crucible because no solidification occurs yet. The volume increase of gallium due to dissolution of phosphorus is ignored. Figure 3 shows the concentration profiles at various times. In Fig. 4 the concentration at the bottom of the crucible, C_L, is shown as a function of a parameter Dt/W^2. For a rough estimate take $D = 0.9 \times 10^{-4}$ cm^2 sec^{-1} and $W = 3$ cm, then from Fig. 4 $t \sim 10^5$ sec is obtained for $C_L = 0.9C_{PH}$, which gives a small amount of supersaturation. In our experiments the saturation concentration at the bottom, C_{PL}, ranged from 0.5 C_{PH} to 0.8 C_{PH}. The times necessary for C_{PL} to reach 0.5 C_{PH} and 0.8 C_{PH} are 4×10^4 and 8×10^4 sec, respectively. Experimentally small crystals were observed in one day's run. Since the time of a run is of

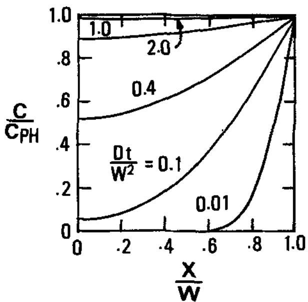

Fig. 3. Concentration of phosphorus in the melt as a function of time and position. W is the depth of the melt, D the diffusion coefficient, and t the time. The surface concentration is fixed at C_{PH}, and the initial concentration in the melt is zero.

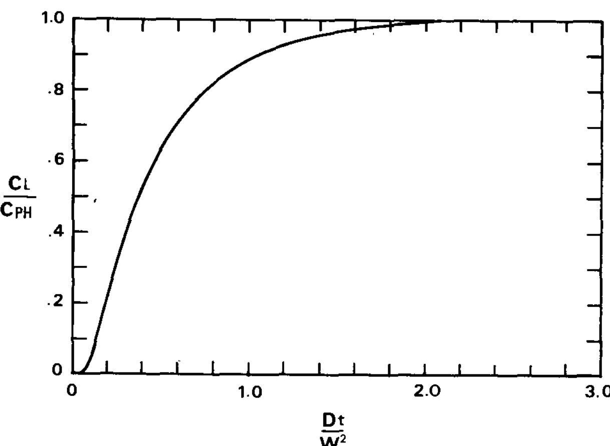

Fig. 4. Concentration of phosphorus in the melt at the bottom of a crucible as a function of time. Initial and boundary conditions are the same as those of Fig. 4.

the order of 10^6 sec, we may be overestimating the time of growth by less than 10% by equating it to the time of a run.

Conclusions

The diffusion process in SSD method was analyzed and the relation between the diffusion coefficient and the growth rate was derived. From experimental data the diffusion coefficient of phosphorus in gallium was obtained as $D = 1.8 \times 10^{-2} \exp(-0.65 \text{ eV}/kT)$ cm^2 sec^{-1}. The calculated values are in fair agreement with the diffusion coefficients published by other authors.

Acknowledgments

We would like to express our hearty thanks to Messrs. H. Nagasawa and K. Sawada of the Research Center for their cooperation. Continual encouragement by Drs. S. Shima and Y. Kanai have been of strong support to us through this work. We also would like to express our thanks to Dr. A. Shibata for his critical comments on the manuscript.

Implantation of Argon into SiO_2 Films Due to Backsputter Cleaning

F. B. Koch,* R. L. Meek,* and Daniel V. McCaughan[1]

Bell Laboratories, Murray Hill, New Jersey 07974

ABSTRACT

Argon in concentrations up to $2(10)^{16}$ cm^{-2} has been found in SiO_2 after backsputter cleaning with 150V Ar^+ ions in a low voltage triode sputtering apparatus. The argon has been detected directly by Rutherford backscattering analysis with 2 MeV He^+ ions. The highest argon content was found in a sample subjected to 2 min of backsputtering at a rate of about 50 Å/min. Immediately after this backsputtering, 2000Å of tungsten was sputter deposited. During a subsequent vacuum anneal at 850°C for 20 min, bubbles about 10 μm in diameter appeared under the tungsten metallization. The bubbles apparently were caused by internal pressure resulting from the outdiffusion of the entrapped argon. Surface contamination of the backsputtered SiO_2 by W, Cu, and Fe was also detected. This was evidently caused by redeposition of sputtered material from adjacent parts of the sputtering apparatus since these elements increased steadily in concentration with backsputtering time. The maximum contamination of $8(10)^{14}$ copper atoms per cm^{-2} after 10 min is nearly a monolayer. Annealing experiments established that 20 min at 600°C was sufficient to reduce the argon level to near or below detection limits [$\sim 5(10)^{13}$ cm^{-2}] in both backsputtered Si and SiO_2.

Low voltage triode sputtering is attractive for metallization of silicon-integrated circuits since a wide variety of metals and even insulators may be deposited. The possibility of sputter cleaning the surface by Ar^+ ion bombardment immediately prior to the deposition is an important feature in certain applications such as contact metallizations where the cleanliness of the Si/metal interface is crucial. The fact that all materials sputter at varying rates presents some problem in the design of a sputtering apparatus. All electrically isolated surfaces exposed to the plasma assume a negative potential (the wall potential) and are thus subject to Ar^+ ion bombardment. This paper describes an application of the highly sensitive technique of Rutherford ion backscattering to evaluate the extent of surface contamination and argon implantation under typical operating conditions for a particular triode sputtering apparatus.

Key words: backsputtering, ion trapping, metallization, sputtering.

Experimental Procedure

Low voltage triode sputtering.—In a triode sputtering system, a discharge is run between an anode and a hot cathode to maintain a high density plasma. The sputtering target is an auxilliary electrode, located and biased so that it can extract ions from the plasma. In this case, the main discharge runs at 4A and is maintained by a potential of about 100V between anode and cathode. A high current discharge at low voltage is possible because the cathode is a copious source of thermionic electrons. The cathode, a 0.125 cm diameter Ta wire, is heated to incandescence by an a-c current of 65A. The pressure was fixed at 2 mTorr of high purity argon. Figure 1 illustrates the apparatus. The plasma is confined by an aluminum tunnel as shown, with openings to allow the Ar^+ ions to be extracted from the plasma so that they bombard the sputtering target or the sample surface as desired. The silicon sample wafers rest on a stainless steel gridwork as shown, and can be heated to 950°C during the deposition by tantalum heater coils if so desired. Sputter deposition of tungsten at about 120 Å/min occurs when a voltage of -200V is applied to the source target (relative to the cathode) so that sputtered metal atoms pass through both tunnel openings and are deposited on the sample surface. It is also possible to sputter material (50Å of SiO_2/min) from the sample surfaces to effect a cleaning by applying an 800 kHz rf voltage to the pedestal bearing the samples (backsputtering). The Ar^+ ions are accelerated to the sample surface during the negative half-cycle by a voltage adjusted for a peak value of -150V relative to the cathode. Contamination of the sample surface may conceivably occur during the backsputtering due to redeposition of sputtered material from structural parts of the apparatus such as the sample pedestal, the plasma confinement tube, or the tantalum cathode.

Rutherford backscattering analysis.—Surface analysis using Rutherford backscattering (1-3) of mega-electron volt He^+ ions has been described in detail elsewhere (1, 2). Briefly, the energy of a backscattered ion identifies the mass of the atom it scattered from, and the number of backscattered ions determines the number of scattering atoms. For scattering from target atoms of a given mass, the energy scale may be converted to a depth scale through a knowledge of the kinematic energy loss and the stopping power.

In these experiments, a beam of 2 MeV He^+ ions collimated to ~0.05° through two Ta collimators 1 mm in diameter and about 2m apart was used. The backscattered He ions were detected at $\theta_L = 177°$ in a 50 mm^2 surface barrier detector having an energy resolution of 16 keV. This energy resolution corresponds to a depth resolution of about 200Å. Secondary electron suppression and pile-up rejection electronics were used. Samples were surrounded by a baffle cooled to liquid nitrogen temperature and were mounted in a two axis goniometer. The scattering chamber was maintained at 10^{-6} Torr and the He ion fluence was typically 10^{16} cm^{-2}. Typical detection limits are 10^{13} cm^{-2} for masses near Cu and 10^{12} cm^{-2} for masses near Au.

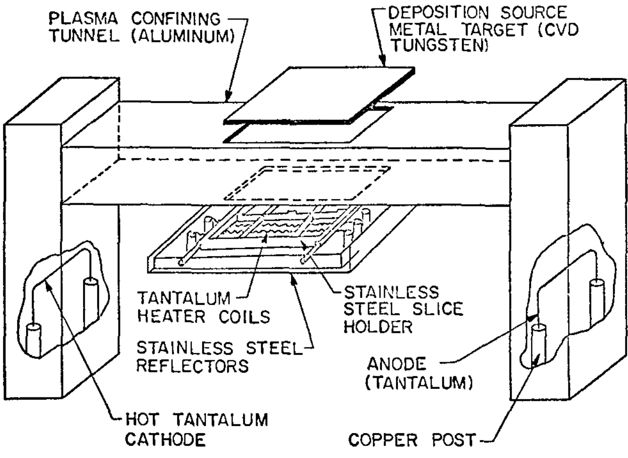

Fig. 1. Low voltage triode sputtering apparatus

Experimental Results

The initial impetus for the present investigation was to explain the formation of what are apparently bubbles under a 2000Å thick sputtered tungsten film. The tungsten had been deposited over a 2800Å steam oxide through which contact holes had been etched to the underlying silicon wafer. The substrate had been rf backsputtered for 2 min with 150V, immediately prior to the W deposition, to remove about 100Å of the oxide. Following the deposition, the tungsten was etched to give a contact test pattern and the sample was vacuum annealed for 20 min at 850°C. During this anneal the tungsten metallization took on the microscopic appearance shown in Fig. 2. Shown are an optical micrograph (upper photograph) and a scanning electron micrograph taken at 55° sample tilt (lower photograph) showing bubbles about 10 μm in diameter and with an area concentration of about $5(10)^5$ cm^{-2}. Neither did a sample backsputtered for 1 min only, nor did a control sample which was not backsputtered show any bubbles when subjected to the same annealing treatment.

The bubbles seen in Fig. 2 are not always seen after metallization of backsputtered surfaces but are not an isolated instance. They have not been observed with metal silicides (PtSi, NiSi) formed on backsputtered silicon (4, 5) nor in deposition on SiO_2 of metals such

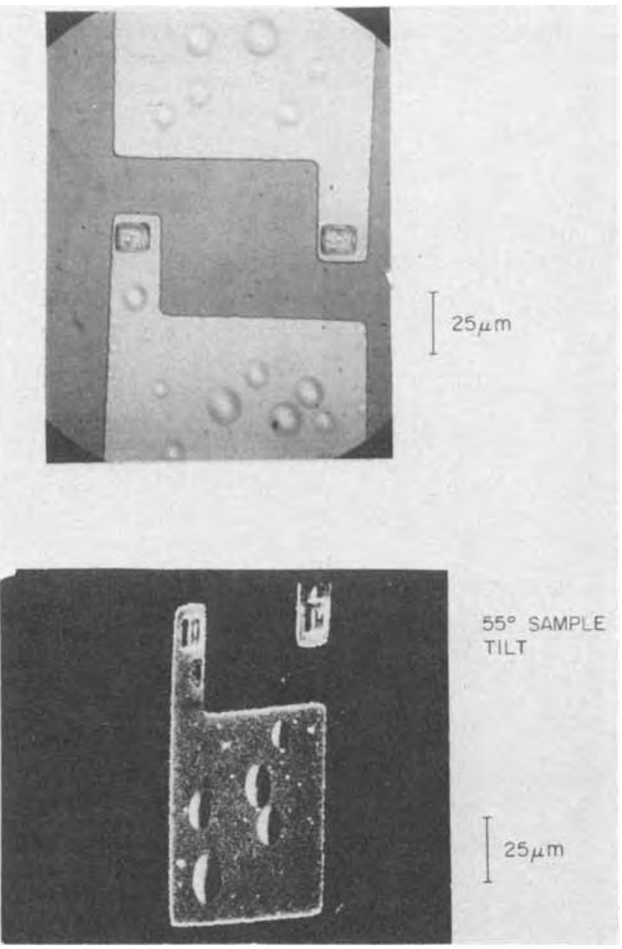

Fig. 2. Upper micrograph shows tungsten metallization at 660× where bubbles have apparently formed at the W/Si interface. Lower photograph shows SEM. secondary electron images taken with sample tilt of 55°.

as Cr or Ti which react strongly with SiO_2. Bubbles have only been observed after prolonged backsputtering followed by tungsten metallization.

We have attempted to investigate whether these bubbles resulted from argon entrapped in the oxide during backsputtering and subsequently released during the vacuum annealing. The tungsten was etched from unannealed portions of the samples backsputtered for 1 and 2 min. These samples and other backsputtered samples were then analyzed by ion backscattering for argon content and surface contaminants. The analysis shows that the sample in which the bubbles were formed did indeed contain a large amount of argon, more argon, in fact, than some other samples which had been backsputtered for up to five times as long.

Figure 3 shows a representative energy spectrum (scattered ion yield as counts per channel *vs.* scattered ion energy) for a sample which was backsputtered for 8 min at 150V. The energy of ions scattered from oxygen, silicon, argon, iron, copper, and tungsten at the surface are indicated. The iron, copper, and tungsten undoubtedly result from redeposition of sputtered material from adjacent structures in the sputtering system since the impurity peaks grow steadily with backsputtering time (as will be discussed later). The size and width of the argon peak shows that $1.2(10)^{15}$ argon atoms have been trapped within 200Å of the surface (the resolution of the measurement).

Figure 4 is the spectrum for the sample which showed the bubbles. In this case the argon surface concentration is $2(10)^{16}$ cm^{-2} and the argon distribution extends considerably further into the oxide. The argon volume concentration is plotted in the insert to Fig. 4, and at the surface is $2(10)^{21}$ cm^{-3}. The argon distribution was confirmed by a controlled etching removal of the 2800Å oxide. Removal of 200Å of oxide gave a spectrum with only the expected small change in energy scale and peak height, whereas removal of 1500Å of oxide eliminated the peak. On the surface of

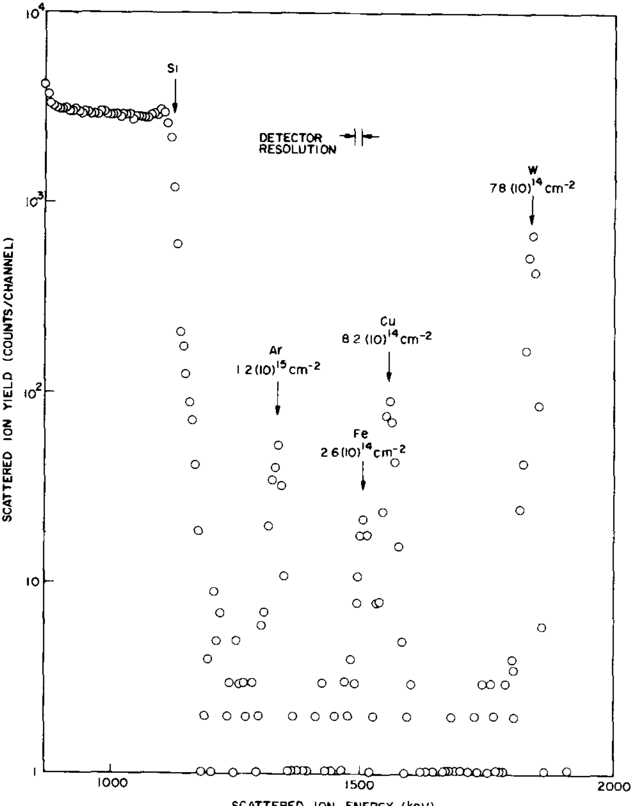

Fig. 3. Backscattered ion energy spectrum from a representative sample which had been backsputtered 8 min. It shows $1.2(10)^{15}$ argon atoms/cm^2.

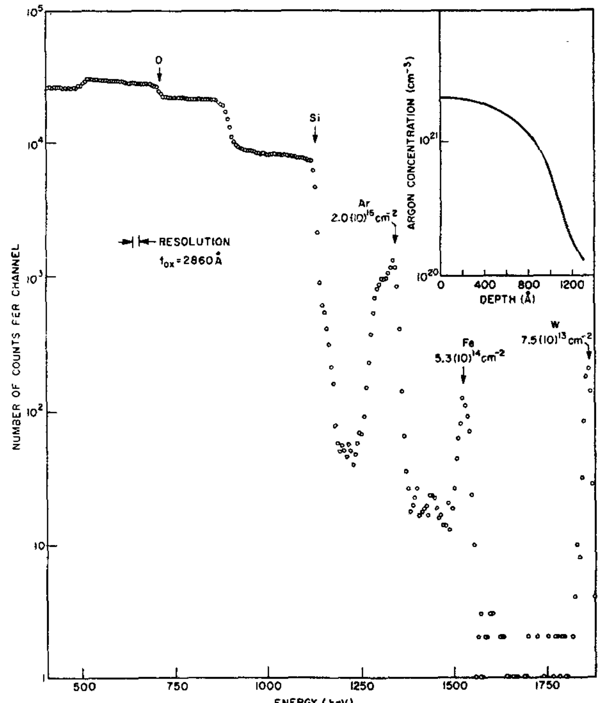

Fig. 4. Backscattered ion energy spectrum from sample which formed the bubbles shown in Fig. 2. Argon profile is indicated in the insert.

this sample iron and tungsten are present at a concentration of $5.3(10)^{14}$ cm^{-2} and $7.5(10)^{13}$ cm^{-2}, respectively.

Table I presents the measured argon content for bare and oxidized silicon samples subjected to backsputtering for various times. The 2 min backsputtered oxide which formed bubbles had the highest argon concentration of $2(10)^{16}$ cm^{-2}; only one other sample had an argon concentration in the 10^{16} cm^{-2} range. Some samples with 3-10 min backsputtering times had argon content about one order of magnitude less. This variability in argon concentration, together with the deep penetration of argon in the two samples with the high argon content, constitute some of the most interesting findings reported here. The projected range of 150 eV Ar^+ in SiO_2 has not been measured, but certainly would be less than 100Å since the calculated range of 10 keV Ar^+ in SiO_2 is only 123Å (6). In the Discussion section, the possibility will be considered that thermal diffusion of the argon during backsputtering is responsible for the observed penetration depths of about 1000Å for some samples.

Figure 5 shows the buildup of surface contaminant tungsten, copper, and iron with backsputtering time. This buildup with backsputtering time strongly indicates that the contamination originates from redeposition of sputtered material from adjacent parts of the apparatus (7). This finding is not surprising in view of

Table I.

Substrate	Sputtering time (min)	Argon concentration (cm^{-2})
SiO_2 on Si	1	$2.4\ (10)^{13}$
SiO_2 on Si	1	$2.8\ (10)^{15}$
SiO_2 on Si	2	$2.0\ (10)^{16}$*
SiO_2 on Si	3	$1.9\ (10)^{15}$
SiO_2 on Si	5	$1.3\ (10)^{16}$
SiO_2 on Si	8	$1.2\ (10)^{15}$
SiO_2 on Si	10	$2.4\ (10)^{15}$
Bare Si	5	$3.0\ (10)^{14}$
Bare Si	10	$2.8\ (10)^{14}$

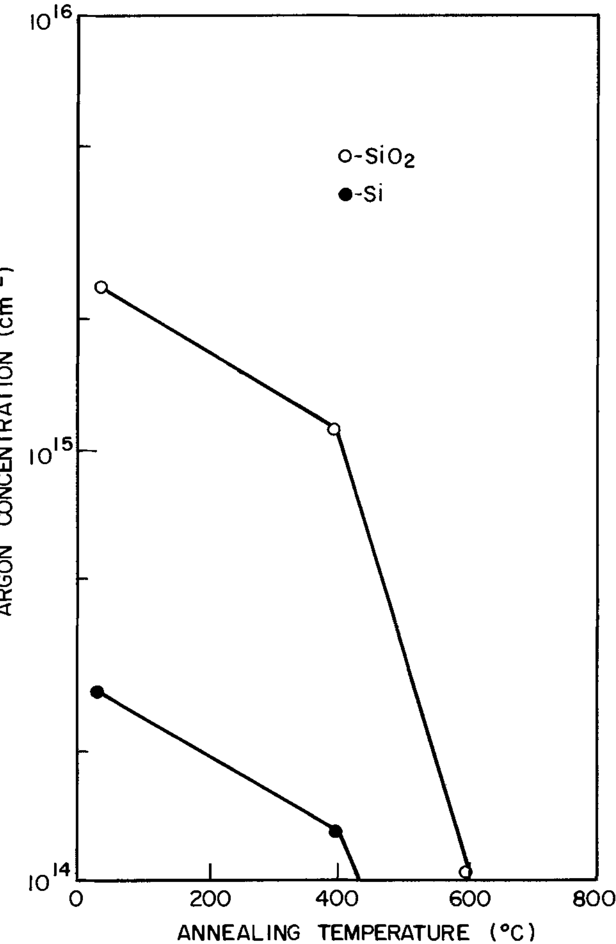

Fig. 6. Decrease in argon concentration as determined from the integrated area under the argon peak as a function of the vacuum annealing temperature. Samples of SiO_2 and bare Si were backsputtered for 10 min and annealed for 20 min.

the results of Vossen *et al.* (8) who found sputter redeposition of up to ten monolayers of Pt, Cu, or Mo when a silicon wafer was sputtered while resting on a plate consisting of one of these metals. The tungsten comes from that which was deposited in the apparatus on previous depositions. The copper and iron probably originate from the copper vacuum feedthroughs and the stainless steel pedestal, respectively. No Al from the tunnel was detected although the large background from silicon lowers the detection sensitivity to about 10^{16} atoms per cm^2. It should be noted that the observed impurity deposition rates are the net difference between an arrival rate, which might be significantly higher, and the backsputter removal rates.

Finally, we have studied argon outdiffusion during vacuum annealing as a function of temperature. Figure 6 shows the amount of argon remaining in samples of bare Si and SiO_2, previously backsputtered for 10 min *vs.* the annealing temperature; portions of the sample were annealed for 20 min at each temperature. A slight decrease in argon content was observed after a 400°C anneal. The argon was no longer confined to the surface but had penetrated about 500Å. After a 600°C anneal no argon could be detected in either sample.

Discussion

It is well known that ions used for sputtering can be incorporated into the bombarded substrate. Comas and Wolicki (9) showed that more than 10^{16} argon atoms/cm^2 could be trapped in silicon by sputtering at less than 200 eV.

Their method, using neutron activation, gives, however, no depth information. Schwartz and Jones (10) used x-ray fluorescence to show that an argon/Si ratio of up to 0.1 could be achieved by varying sputtering parameters, but again their method gives no depth information. All this work is consistent with results on ion trapping in metals (11-13) in which it has been shown that up to many monolayers of inert gas can be incorporated in films ion bombarded at low to medium energies. We believe, however, that our work is one of the first to show accurately the location and concentration profile of argon buried in SiO_2, and relate these parameters to bubble formation.

The best explanation for the bubbles shown in Fig. 2 seems to be that argon diffuses from the SiO_2 to the SiO_2/tungsten interface. At a critical concentration of argon at this interface, adhesion of the metal to the insulator will be lost and a small blister will be formed under the metal. The blister will then easily grow to an observable size with further argon diffusion due to the stress concentration around the periphery. One might inquire whether a concentration of $2(10)^{16}$ argon atoms/cm^2 would be sufficient for this process. If we assume that this amount of argon is confined at 850°C to the observed $5(10)^5$ hemispherical bubbles, each with a diameter of 10 μm, the pressure inside the bubbles is calculated to be a surprisingly high 40 atm.

Thermal diffusion of argon into the film during backsputtering of the surface seems to be required to explain the large concentrations and penetration depths of argon seen in several samples. Diffusion of argon in fused silica was studied by Perkins and Begeal (14) in the temperature range 650°-900°C. They found their data could be represented by the equation $D = D_O \exp(-E/kT)$ where $D_O = 1.21 \pm 0.007$ cm^2 sec^{-1} and $E = 28{,}670 \pm 120$ cal/g-atom. A plot of the expected diffusion distance, $\sqrt{2Dt}$, *vs.* temperature for diffusion times of 2 and 20 min is shown in Fig. 7. In order to account for argon penetration of 1000Å in 2 min, a slice temperature of about 475°C would be required. The condition $\sqrt{2Dt} < 200$Å limits the sample temperature to a maximum of 375°C for the bulk of the samples where argon penetration was not observed.

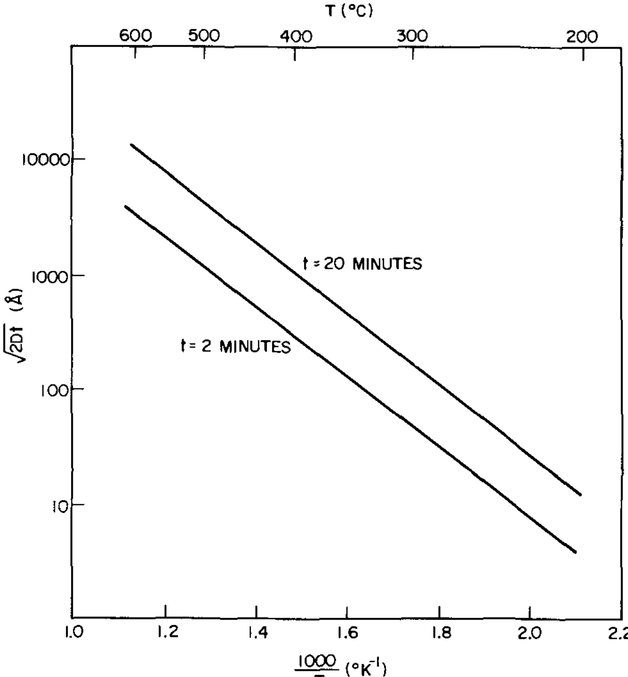

Fig. 7. The diffusion length $\sqrt{2Dt}$ vs. the diffusion temperature for times of 2 and 20 min. The values of D as function of temperature were extrapolated from the data of Perkins and Begeal (14).

These temperatures may be compared to the substrate temperatures found in previous calibration runs using a Pt-Pt 10% Rh thin-film thermocouple to measure the heating during 150V backsputtering (15). There a temperature rise of 200°C was usually observed. On some calibration runs, however, the temperature rise was as much as 400°C. This larger temperature rise resulted in intense local melting of the thin-film thermocouple. There was some tendency for discharges to occur during the first backsputtering of an oxide after exposure to the atmosphere (16). The unusual heating of a sample during an occasional run where these discharges occurred seems to be the most likely explanation for the higher than normal argon content in some samples.

The change in argon content with vacuum annealing temperature shown in Fig. 6 is not surprising in view of the expected diffusion coefficients. Referring to Fig. 7, $\sqrt{2Dt} = 1000$Å for 20 min at 400°C, so diffusion will cause considerable escape to the surface. At 600°C, $\sqrt{2Dt} \simeq 1$ μm. So it is expected that the argon which has not been lost at the surface will have diffused sufficiently into the bulk to be undetectable.

A quantitative theory for the amount of argon entrapped during backsputtering would have to take into account the total dose of Ar^+ impinging on the surface, the trapping probability, the sputter removal rate of argon already entrapped, and the redistribution and surface loss caused by thermal diffusion. In this case, the flux of Ar^+ is roughly 1 mA/cm^{-2}, corresponding to a total dose of $7.5(10)^{17}$ Ar^+ cm^{-2}. Without attempting to formulate a detailed model, we note that less than 1% of the total dose of argon is usually trapped but that somewhat more than 1% was trapped in two samples. Most samples will have an argon content limited by a steady-state concentration at the surface, but thermal diffusion away from the surface when the sample temperature is unusually high will increase the steady-state value considerably.

Summary

We have profiled the argon concentration in rf backsputtered SiO_2 films by Rutherford scattering. Some samples showed anomalously high argon concentration, up to $2(10)^{16}$ cm^{-2}. In such a sample, which, after backsputtering, had 2000Å of tungsten deposited by triode sputtering, vacuum annealing for 20 min at 850°C caused lifting of the tungsten film in bubbles of 10 μm in diameter at an area concentration of $5(10)^5$ cm^{-2}. Samples with lower argon content did not show bubble formation.

In one sample which showed an argon concentration of $2(10)^{16}$ cm^{-2}, argon in the oxide was still detectable at a depth of 1200Å. In other samples with lower argon concentration, the profile did not extend below 200Å (the depth resolution limit of the measurement). Annealing in vacuum to 600°C for 20 min was in all cases sufficient to reduce the argon concentration below detection limits.

The concentration of surface contaminants has also been determined as a function of backsputtering time. Iron, copper, and tungsten have been observed on the SiO_2 surface in concentrations of up to $8.4(10)^{14}$ cm^{-2}. These seem to be associated with redeposition of material from surrounding surfaces onto the sample.

Impurity Redistribution during Silicon Epitaxial Growth and Semiconductor Device Processing

Paul H. Langer

Bell Laboratories, Allentown, Pennsylvania 18103

and Joseph I. Goldstein

Department of Metallurgy and Materials Science, Lehigh University, Bethlehem, Pennsylvania 18015

ABSTRACT

A model has been developed that can account for both front and back "autodoping" effects during epitaxial growth as well as impurity redistribution during further high-temperature processing. The model incorporates three dopant fluxes, *i.e.*, (*i*) the flux from the solid into the gas phase at the rear of the wafer, (*ii*) the flux from the solid to the front surface of the wafer, and (*iii*) the flux from the bulk gas phase into the boundary layer near the front surface of the wafer in which transport of dopant occurs by diffusion only. The redistribution of impurities both within the solid semiconductor and in the gas phase are investigated from a theoretical viewpoint. Numerical solutions are obtained using the Crank-Nicolson method. Implications of differences between this approach and previous work are discussed. Calculated results are presented to illustrate the variety of problems that may be solved using this mathematical approach.

The distribution of impurities in epitaxially grown silicon layers plays a major role in the operation of diodes, transistors, and integrated circuits. The impurity redistribution that occurs during silicon epitaxial processing and semiconductor device fabrication is dependent upon processing times and temperatures, diffusivities, evaporation rates, and segregation coefficients of the dopants in the solid and gaseous phases. A model for the redistribution process would enable one to assess the critical steps in the fabrication sequence and predict the effect of process changes on the impurity distribution in the semiconductor. A typical device processing sequence may consist of fifteen discrete high-temperature steps that affect the impurity redistribution. Since the results of the prior step form the initial conditions for the present step, analytical solutions to the diffusion or transport equations are not available. Therefore, a sequential numerical technique is the obvious choice to solve this type of processing problem. At present only fragmentary parts of this problem have been solved and no complete model exists.

Background—Epitaxial Growth

Since the largest single unknown in calculating the impurity redistribution during device fabrication is the redistribution due to epitaxial growth, this process step will be treated in great detail. The prior efforts on modeling the substrate and layer impurity redistribution during epitaxial silicon growth can be divided into three categories based upon the source of the impurity. The first and earliest approach involved the transfer of dopant from the front surface of the substrate (1-2), mixing of this dopant with the gas phase, and subsequent reincorporation of this dopant into the growing epitaxial layer. This treatment completely ignored solid-state diffusion as the other major mechanism for dopant transport. The second approach to the redistribution involved the transport of dopant by diffusion in the solid only (3-4). The effects of the ambient gas phase were neglected. A more detailed analysis of this approach was made by Abe *et al.* (5). A numerical approach was used in order to treat the steps prior to the deposition of the epitaxial layer. The influence of the gas phase on the redistribution process was ignored and the case of slow layer growth was not successfully treated. The third approach to the redistribution problem involved the transfer of dopant from the back surface of the wafer into the ambient and its subsequent incorporation into the growing epitaxial layer (6-8). However, the effects of solid-state diffusion were ignored.

All three approaches have been used and the results of the models have been verified over a limited range of experimental conditions. The three approaches give a wide range of predictions when applied to any one common system. Since front and back surface evaporation and diffusion of dopant are all occurring simultaneously throughout the epitaxial growth and other high-temperature processing steps, a model incorporating all of the three approaches would provide a better description of the process.

The type of dopant transport phenomenon that will predominate in a given epitaxial deposition cycle is a function of the distribution of dopant in the substrate along with the dopant intentionally added to the gas phase. Three dopant fluxes must be considered to completely define the boundaries of the gas-solid composite system. The first flux is that between the solid and the gas at the back boundary. This flux is the one that has been treated by Joyce *et al.* (6), Shepherd (7), and Skelly (8) as the sole contributing factor to the "autodoping" phenomenon. A similar flux existing at the front surface of the wafer gives the rate of transfer of dopant from the solid to the front gas-solid interface. This flux is of great importance in understanding autodoping associated with the first few microns of growth.

After the first few microns of growth in normal epitaxy (*i.e.*, lightly doped layer on highly doped substrate) the back transport effect predominates. The third flux is that flux which controls the rate of transport of dopant from the bulk of the gas phase to the gas-phase boundary layer near the front interface. In the gas-phase boundary layer, diffusion is the sole transport mechanism. This flux can include intentionally added dopant as well as the dopant released at the back surface.

The following treatment will determine the three dopant fluxes and establish the boundary conditions for the problem. The doping of a layer with the same dopant as in the substrate as well as different dopant species is considered. Also nonuniform initial conditions are treated by the numerical method employed to solve Fick's Second Law in the solid.

Key words: silicon, epitaxy, semiconductor, device processing redistribution.

Theory

The solution of the problem will involve the treatment of three regions: (*i*) the bulk gas phase where all the dopant is uniformly distributed; (*ii*) the gas-phase boundary layer where transport of dopant is by diffusion only; and (*iii*) the solid where transport of dopant occurs only by diffusion. Figure 1 depicts a section of an epitaxial reactor with the wafer on a heated susceptor. The various sources of dopant are shown schematically. To reduce this situation to a one-dimensional case consider a line $z = zo$, perpendicular to the wafer in the plane A-A. Figure 2 shows the concentration distribution along the line $z = zo$ from the wall of the reactor, $x = w$ to the back surface of the wafer, $x = b$. This line also passes through the boundaries $x = d$ and $x = i$ which respectively separates the bulk gas phase from the gas-phase boundary layer, and the gas-phase boundary layer from the front surface of the wafer. All subsequent analysis of impurity redistribution problems will refer to the dopant movement along the line $z = zo$. A mathematical model describing the redistribution sequence can be formulated since the impurity redistribution within the solid and within the gas-phase boundary layer is diffusion controlled. For a diffusion-controlled process Fick's Second Law (for constant diffusivity, D) in one dimension is

$$\frac{\partial C(x,t)}{\partial t} = D\,\frac{\partial^2 C(x,t)}{\partial x^2} \qquad [1]$$

where $C(x,t)$ is the concentration and x and t are the spatial and time variables, respectively. The one-dimensional assumption is applicable to the case of uniformly doped epitaxial structures normally encountered in semiconductor device fabrication since the diameter to thickness ratio of the wafer is usually greater than 150 to 1. For analysis of subdiffused substrates encountered in integrated circuit fabrication the one-dimensional analysis does not strictly apply, since transport of dopant from the diffused regions to the nondiffused areas occurs parallel to the surface of the wafer. This dopant transfer may still be analyzed in one dimension by treating the diffused and nondiffused regions as separate structures linked by an intermediate gas phase. In order to obtain the boundary condition at the front gas-solid interface ($x = i$) the mass balance will be constructed about the interface. The flux $F(i,t)$ in the solid at the interface $x = i$ will then be expressed in terms of solid concentrations and concentrations of dopant in the bulk of the gas phase. Both of these concentrations may be measured experimentally.

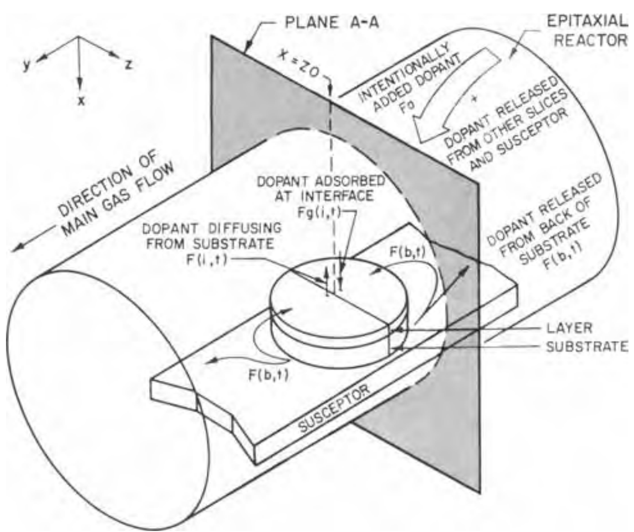

Fig. 1. Schematic representation of an epitaxial reactor showing sources of dopant.

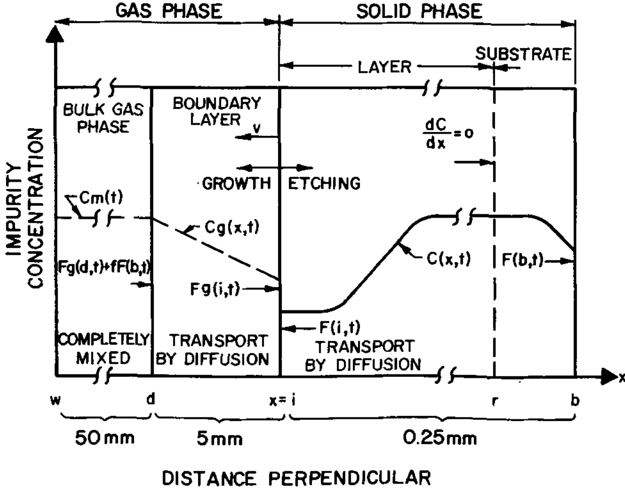

Fig. 2. The concentration distribution along the line $z = zo$, in plane A-A through the epitaxial reactor from the reactor wall to the back surface of the wafer.

As can be seen from Fig. 1 there are two sources of dopant that may enter the growing epitaxial layer by way of the gas phase. These sources are the flux of intentionally added dopant, F_a and the flux of dopant escaping from the back and sides of the wafer $F(b,t)$. These dopant fluxes will be used to define the time rate of change of dopant, $Q' = dQ/dt$, in control region 1 shown in Fig. 3. Let one consider the dopant flow into and out of region 1. This area is in the x-y plane between $x = w$ to $x = d$ and $y = y_1$ to $y = y_2$. The dopant entering this region consists of the flux of intentionally added impurities, $F_{a_{in}}$, plus some fraction (f_1) of the flux of dopant escaping from the back of the wafer $f_1F(b,t)$. Of this dopant entering region 1 across y_1 some will leave in the y-direction across y_2. The rest will enter region 2 in the x-direction, toward the solid, crossing the boundary, $x = d$.

Therefore, the rate of change of dopant in region 1, Q'_1, may be written as

$$Q'_1 = F_{in} - F_{out} \qquad [2a]$$

or

$$Q'_1 = \{F_{a_{in}} + f_1F(b,t)\} - \{[F_{a_{out}} + (f_1 - f)F(b,t)] + [F(g)(d,t) + fF(b,t)]\} \qquad [2b]$$

where f is the fraction of dopant from the back of the wafer that is crossing the boundary $x = d$, in the x-direction, and going toward the solid. $F(g)(d,t)$ is the fraction of the intentionally added dopant also going toward the solid in the x-direction. Therefore, $[Fg(d,t) + fF(b,t)]$ is the flux of the dopant leaving region 1 and crossing the boundary, $x = d$.

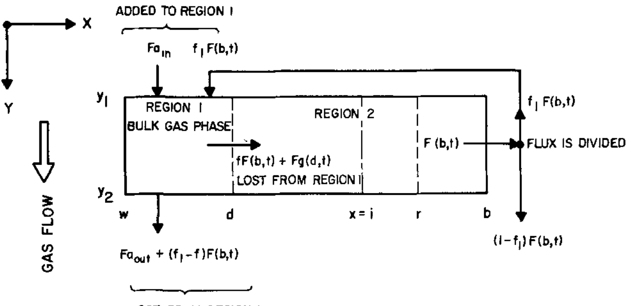

Fig. 3. Control region

Now let one consider the rate of change of dopant Q'_2 (region 2, Fig. 3) in the gas-solid composite system between $x = d$ and $x = r$. r is a point in the wafer where the concentration gradient is always equal to zero. For semiconductor device fabrication such a point always exists since wafers are usually $\sim 250\mu$ thick, while diffusion lengths in the solid are almost never more than 10μ. To obtain Q'_2 one first must integrate the concentration distribution in region 2 to obtain Q_2. Q_2 is the total number of dopant atoms per unit area in region 2

$$Q_2 = \int_d^i C(g)(x,t)\,dx + \int_i^r C(x,t)\,dx \quad [3]$$

where the symbol (g) refers to terms in the gas, while the absence of (g) refers to terms in the solid. To obtain Q'_2 one differentiates Eq. [3] with respect to time

$$Q'_2 = \int_d^i \frac{\partial C(g)(x,t)}{\partial t}\,dx + C(g)(i,t)\frac{di}{dt} - C(g)(d,t)\frac{dd}{dt} + \int_i^r \frac{\partial C(x,t)}{\partial t}\,dx + C(r,t)\frac{dr}{dt} - C(i,t)\frac{di}{dt} \quad [4]$$

The terms containing the expression $\int_\alpha^\beta \frac{\partial C}{\partial t}\,dx$, when α and β are arbitrary limits, can be simplified using the following substitution

$$\int_\alpha^\beta \frac{\partial C}{\partial t}\,dx = \int_\alpha^\beta D\frac{\partial^2 C}{\partial x^2}\,dx = F(\alpha,t) - F(\beta,t)$$

which is the integral of Fick's Second Law for constant diffusivity. Using the above substitution in Eq. [4] and defining $v_\alpha = d\alpha/dt$ (where α is the position of a boundary in the x-direction), one obtains

$$Q'_2 = -F(g)(i,t) + F(g)(d,t) + v_i C(g)(i,t) - v_d C(g)(d,t) - F(r,t) + F(i,t) + v_m C(r,t) - v_i C(i,t) \quad [5a]$$

Inspecting Eq. [5a] there are a number of terms that will go to zero. Since the boundary, $x = r$, is not moving, v_m is zero. The velocity at $x = d$ is set equal to zero since the movement of the front interface is small compared to thickness of the gas-phase boundary layer (9). Therefore, only the velocity v_i is not zero. Since $x = i$ is the only moving interface, the subscript will be omitted. The flux at $x = r$ is zero since r was defined as a point where the concentration gradient is always zero. Eliminating the zero terms from Q'_2 one obtains

$$Q'_2 = -F(g)(i,t) + F(g)(d,t) - v[C(i,t) - C(g)(i,t)] + F(i,t) \quad [5b]$$

Since dopant only enters or leaves region 2 at the boundary $x = d$, one already knows the flux across d from the analysis of region 1, *i.e.*, $[F(g)(d,t) + fF(b,t)]$. This flux may now be set equal to Q'_2 to obtain the boundary condition at the front gas-solid interface

$$F(i,t) = F(g)(i,t) + v[C(i,t) - C(g)(i,t)] + fF(b,t) \quad [6]$$

The assumptions used to simplify Q' and to derive the boundary condition at the gas-solid interface, $(x = i)$, are summarized as follows:

(*i*) The bulk gas phase is completely mixed at all times.

(*ii*) A linear concentration gradient exists across the stagnant gas-phase boundary layer.

(*iii*) Dopant transport in the solid phase can be characterized by Fick's Second Law.

(*iv*) The diffusivity of the dopant is independent of concentration.

(*v*) The dopant escaping from the back surface of the wafer is not influenced by the flux of dopant at the front interface.

(*vi*) During growth, etching, or oxidation steps only the front solid interface is moving.

Equation [6] implies that the flux $F(i,t)$ is not only a function of dopant transported from the gas $[F(g)(i,t)]$, but is also a function of the dopant leaving the back surface or sides of the wafer $[F(b,t)]$, as well as the velocity of the front gas-solid interface, v.

Equation [6] contains flux terms that cannot be easily evaluated. Therefore the terms $F(b,t)$ and $F(g)(i,t)$ will be approximated with the following relationships

$$F(b,t) = -h[C(b,t) - kC(g)(b,t)] \quad [7]$$

and

$$F(g)(i,t) = h[C(i,t) - kC(g)(i,t)] \quad [8]$$

These equations assume that the driving force for dopant transport at the interfaces, $x = b$ and $x = i$, respectively, is the concentration difference across the interface. k is the equilibrium segregation coefficient defined at zero growth rate as

$$k = \frac{C(i,\infty)}{C(g)(i,\infty)} \quad [9a]$$

and

$$k = \frac{C(b,\infty)}{C(g)(b,\infty)} \quad [9b]$$

This type of flux approximation (Eq. [7] and [8]) is used to describe a situation, at an interface, where a restriction to dopant transport exists [see Crank (9)]. The restriction coefficient h has the units of velocity, and will be referred to in this work as the "evaporation coefficient." The evaporation coefficient is a constant that depends upon the temperature, pressure, dopant species, wafer orientation, gas velocity, and reactor geometry. Small values of h effectively keep the ratio of concentrations on either side of an interface from reaching the equilibrium value as defined in Eq. [9a] and [9b]. The evaporation coefficient therefore controls the time rate of approach of the ratio of concentrations on either side of an interface to its equilibrium value. For large values of h (*i.e.*, $h >> \sqrt{D/t}$) the escape of dopant will be diffusion controlled since all the dopant reaching a surface will rapidly transfer into the gas phase. Also for large h the back flux term will rapidly approach a constant value and have the same effect as an increased constant concentration level of dopant in the gas phase. For small values of h there will be a large time dependence of the flux at the front interface, resulting in a graded dopant distribution in the growing layer. Substituting Eq. [7] and [8] into Eq. [6], and regrouping terms, one obtains an equation for the flux in the solid at the front interface in terms of solid- and gas-phase concentrations and the constants h, v, and f

$$F(i,t) = h[C(i,t) - kC(g)(i,t)] - fh[C(b,t) - kC(g)(b,t)] + v[C(i,t) - C(g)(i,t)] \quad [10]$$

Equation [10] still contains terms of $C(g)(i,t)$ and $C(g)(b,t)$ which cannot be easily measured in practice. Since the distance between the front and back surfaces of the wafer (0.25 mm) is small compared to the total boundary layer thickness (5 mm) (10), we will assume $C(g)(b,t) = C(g)(i,t)$. Equations [7] and [8] still contain a term, $C(g)(i,t)$, which cannot be easily measured. One approach to this dilemma would be to write the flux across the gas-phase boundary layer ($x = d$ to $x = i$) as

$$F = h(g)[C_m(t) - C(g)(i,t)]$$

where $Cm(t)$ is the mean gas-phase concentration and $h(g)$ is the gas-phase mass transfer coefficient. Then one could simultaneously solve the above equation in conjunction with Eq. [6] to eliminate the term $C(g)(i,t)$ in favor of the mean gas-phase concentration $Cm(t)$. This is a cumbersome method. Since the diffusivity in the gas is much larger (twelve orders of magnitude) than in the solid, and since the velocity of the gas-solid interface is small compared to the transport across the boundary layer, a simple relationship between the mean gas-phase concentration and the gas-phase concentration at the interface will be assumed

$$C(g)(i,t) = k_g\, C_m(t) \quad [11]$$

where k_g is an arbitrary constant that will depend upon the gas velocity distribution in the boundary layer. For all of the systems investigated by the authors, k_g was usually very close to unity for most conditions encountered during epitaxial growth and semiconductor processing.

Finally substituting Eq. [11] into Eq. [10] and assuming $C(g)(b,t) = C(g)(i,t)$, one obtains the boundary condition at the front interface in terms of readily measurable or easily calculable quantities

$$F(i,t) = h[C(i,t) - k_e\, C_m(t)] - fh[C(b,t) - k_e\, C_m(t)] + v[C(i,t) - k_g\, C_m(t)] \quad [12]$$

where $k_e = kk(g)$. This flux term $F(i,t)$ completely describes the movement of dopant both from the solid and from the gas across the front gas-solid interface. The flux of dopant will only go to zero under a set of stringent conditions. These three conditions must be met simultaneously for a zero flux to occur. (*i*) The velocity, v, of the gas-solid interface is zero. (*ii*) The concentration in the solid at the front interface must be equal to $keC_m(t)$. (*iii*) The concentration in the solid at the back interface must be equal to $keC_m(t)$. If one lets $C_m(t) = 0$, and assumes that no dopant from the back is reincorporated into the growing layer ($f = 0$) then Eq. [12] reduces to

$$F(i,t) = (h + v)\, C(i,t)$$

which is Grove's (4) boundary condition for the solid neglecting gas-phase contributions.

An alternate approach to the solution of the composite gas-solid system involves the solution of the transport problem in both the gas-phase boundary layer and in the solid phase. This approach eliminates the assumptions about the fluxes at $x = i$ and $x = b$ inherent in the method outlined above. For practical reasons as outlined later, the approximation approach was chosen over the solution of the composite system.

The boundary condition at the front gas-solid interface (Eq. [12]), and the boundary condition at the back of the wafer (Eq. [7]) can be used to solve Fick's Second Law (Eq. [1]) in the solid using numerical techniques.

Numerical Solution

A number of numerical techniques have been used in the past to obtain solutions to a parabolic partial differential equation (*e.g.*, Eq. [1]). The simplest approach is the forward finite difference method (FFDM). This technique suffers in two major respects. The first of these is the poor approximation (only first order correct) to the time derivative of concentration. The second restriction is the limit on the stability criterion which requires that the value of the dimensionless quantity $R = D\Delta t/(\Delta x)^2$ cannot exceed 0.5, where Δt and Δx are the time and spatial increments, respectively. This limit on R forces one to employ very small values of Δt (and to use extremely long computation times) if a stable solution is to be obtained. The implicit Crank-Nicholson Method (CNM) has the disadvantage of more mathematical operations than the FFDM but offers higher accuracy for the same total expenditure of computer time. Also there is no bound on the stability parameter R for interior points (11). Some problems may occur at a boundary when large values of R are used, especially if a large concentration discontinuity exists. Since the CNM involves analogs for the various concentration derivatives centered in the time interval Δt, they are second order correct. Another advantage of the CNM is the ease in which Δx and/or Δt may be varied. It is this flexibility that leads to shorter run times for the same level of accuracy compared to the FFDM. For the initial stages of a problem where large changes in concentration with time are occurring one would like to use small values of Δt. In the final stages of the problem, where little or no concentration changes are taking place a much larger value of Δt would permit substantial savings in computer time. The spatial grid size Δx is usually only limited by the available amount of computer core storage. The finite difference equations used to solve Fick's Second Law are given in the Appendix.

A computer program called CASPER (Computer Aided Semiconductor Processing and Epitaxial Redistribution) was written to solve the diffusion equation (Eq. [1]) using the boundary conditions of Eq. [7] and [12] and nonuniform initial conditions, using the Crank-Nicholson method (17).

To test the accuracy of the CNM, a comparison was made with the known analytical solution for the moving boundary and evaporation problem (MBEP) where the gas concentration, C_m, is set equal to zero. The analytical solution to the moving boundary and evaporation problem as given by Grove *et al.* (4) is presented below

$$C(x,t) = \frac{C_s}{2}\,\mathrm{erfc}\left(\frac{x}{2\sqrt{Dt}}\right) - \left(\frac{h+v}{2h}\right) \cdot \exp\left[\frac{v}{D}(vt - x)\right]\mathrm{erfc}\left[\left(\frac{2vt - x}{2\sqrt{Dt}}\right)\right] + \left[\frac{v+2h}{2h}\right] \cdot \exp\left\{\left[\frac{v+h}{D}\right] \cdot [(v+h)t - x]\right\} \mathrm{erfc}\left\{\left[\frac{2(v+h)t - x}{2\sqrt{Dt}}\right]\right\} \quad [13]$$

where C_s is the original concentration level in the solid.

Equation [13] was compared to the solutions obtained by the CNM for the following set of numerical conditions

dopant, boron
temperature, 1294°C
diffusivity, 0.0500 μ^2/min
$0.01 \leq h/(\sqrt{D/t}) \leq 10^{10}$
$0.00 \leq v \leq 2.0\ \mu$/min
substrate thickness, 5.0μ
time, 5.0 min

First let us consider the evaporation case ($v = 0$) using the CNM solution. The accuracy of the CNM will depend not only upon the size of the time and spatial parameters Δt and Δx, but also upon the rate of change of concentration in the interval Δx. The error relative to the analytical solution is defined below

$$\text{Relative error} = \frac{C_{\text{analytical}} - C_{\text{CNM}}}{C_{\text{analytical}}} \times 100$$

A variable Δt Crank-Nicholson solution is used to solve Eq. [1] under the boundary conditions of Eq. [12] and the resultant numerical solution is compared to the analytical solution given in Eq. [13]. In this method, a very small value of Δt is initially chosen. This value corresponds to an R value of 0.0001. With each successive solution of the grid equations, Δt is increased by 40% until the total elapsed time is expended. This technique offers good accuracy while allowing one to minimize the amount of computer time per total cal-

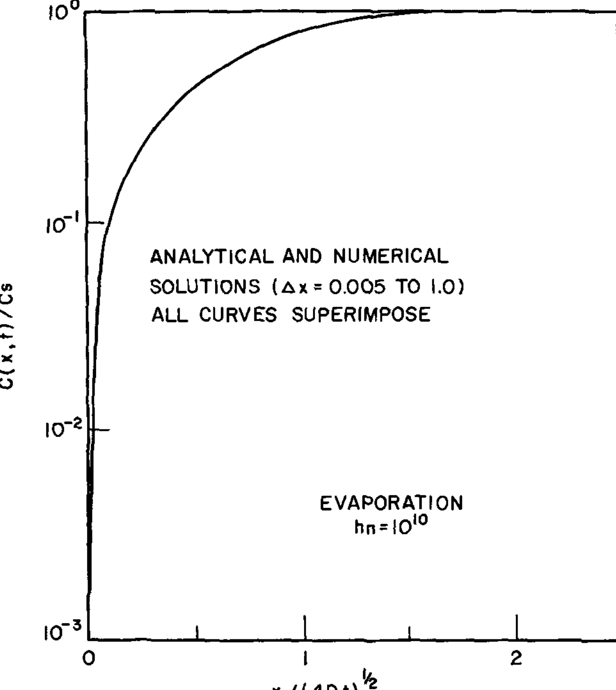

Fig. 4. Plot of relative concentration vs. normalized depth for a simple evaporation problem. The numerical and analytical solutions agree to better than 1% over the entire depth range. Time, 5 min; temperature, 1294°C; dopant species, boron.

culation. Figure 4 graphically displays both the analytical and numerical solutions to Eq. [1] using the boundary condition of Eq. [12] with the normalized evaporation coefficient $h_n = 10^{10}$, where $hn = h/(\sqrt{D/t})$, and $v = 0$ (evaporation only). At the smaller values of hn the curves tend to flatten out. For the numerical solution, Δx was varied from 0.005 to 1.0, *i.e.* the solid which was 5μ thick was divided into a number of steps which varied from 1000 to 5. Even for the largest Δx, the numerical solution and the analytical solution cannot be resolved on this plot. The error associated with the evaporation solution is very small over the entire range of Δx that was investigated. The maximum error occurs at the gas-solid interface. For a Δx of 0.05, which is the interval size normally used, the error at the interface is 0.4%. The variable Δt solution is highly accurate for the solution of the evaporation problem. This variable time interval solution is particularly useful in the treatment of long diffusion problems where little or no dopant movement occurs over a large part of the time cycle. For an 8 hr oxidation cycle at 1100°C the computer run time was reduced by a factor of 230 when using the variable Δt solution. If the concentration distribution was continuously varying, a fixed interval Δt method would be preferred over the variable Δt solution.

To achieve the highest level of accuracy, using the CNM, the smallest value of Δx consistent with the amount of computer core storage available should be chosen. For systems where the active diffusion zone is small relative to the total dimensions of the body under simulation, the smallest practical value of Δx that may be chosen may still be too large to give the required level of accuracy desired. Therefore, a numerical solution that allows the use of small values of Δx in the active diffusion region and larger values of Δx in regions where little or no transport of dopant is taking place, would allow one to conserve large amounts of computer core storage while significantly reducing the calculation time. When treating a problem where little change in concentration is expected to occur at the interface (*e.g.*, an evaporation problem with $hn << 1.0$) Δx may be taken large. But if one is working in a region where the concentration gradient is large, *i.e.*, the concentration change over $1\Delta x$ is greater than a factor of two, then a small value of Δx should be used. This would result in a variable Δx solution where Δx would be small in regions of large concentration changes and would be large in regions where the concentration gradient was close to zero.

Since small values of $\Delta x/(\sqrt{Dt})$ lead to higher accuracy, one would use this solution in regions where rapidly changing concentration gradients occur. There are savings in both computer time and core if one has a prior knowledge of where these regions of large concentration changes are occurring throughout the solid. The "split grid approach" was developed for a continuous material but it is also extremely useful in treating problems where a boundary or discontinuity exists such as the gas-solid interface or the boundary between two phases. It allows one to choose values of Δx in each region that will result in the minimum total error for the smallest amount of computer core and time. There may be as many breaks in the grid size as is required by the particular problem under study. An example of where this variable grid size solution would be useful is the growth (Fig. 5) of a thick epitaxial layer at very low temperatures such that the region between the layer and the substrate would have a very large concentration gradient, while in the substrate and in the layer the concentration gradient would be close to zero. If one tries to model this problem using a large value of Δx, the transition region appears more graded than it actually is. If one tries to employ a very fine Δx solution, large amounts of core are required since the regions in which the concentration gradient is zero may be 20μ thick while the transition region may only be 2μ in size. The optimum treatment of this type of problem is to use a large value of Δx ($\Delta x = 0.5$) in the regions of small concentration change (*i.e.*, the layer and the substrate) and to use a very fine Δx ($\Delta x = 0.002\mu$) in the 2μ transition region. Errors in the numerical solution occurring in the region of fine Δx are comparable to the errors that occurred when using a uniform grid size $\Delta x = 0.002$. The saving in both computer run time and core storage for this particular problem is almost a factor of 10.

The errors resulting from the CNM treatment of the MBEP will now be discussed. In the growth mode, the following sequence is used to obtain a numerical solution:

(*i*) A growth step equal in size to Δx or some whole number times Δx is added. These steps are added on using $Ca = ke^*Cm$ where Ca is the concentration of the added step. For most elements, ke decreases with temperature and approaches unity with increasing growth velocity (12).

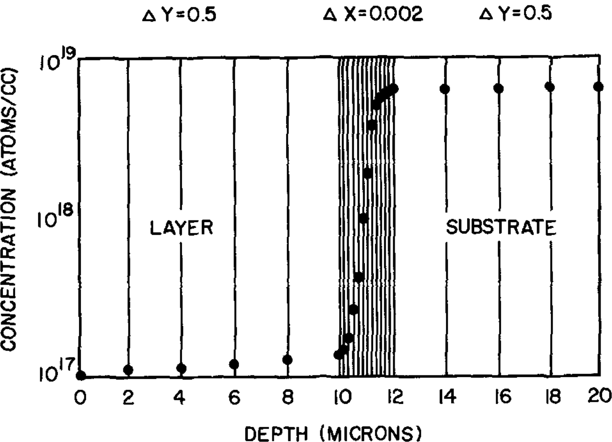

Fig. 5. Example of variable grid size solution. Concentration vs. distance plot of an epitaxial layer in which the graded region between the layer and the substrate is divided into a finer mesh size than the rest of the structure to minimize the computational errors as well as computer time.

(*ii*) An adjustment is made to the concentration at the prior original interface to conserve mass across the added solid step and a region of equal size already in the solid phase. This is accomplished by averaging the concentration of the added step with the prior interface concentration value.

(*iii*) The problem is now solved under static conditions using a fixed Δt method. One time iteration is usually sufficient.

(*iv*) Steps (*i*) through (*iii*) are repeated until the specified growth is complete.

The errors resulting from the CNM solution to the growth case are somewhat larger than one obtains from the evaporation problem. A comparison of the analytical solution and the CNM for the MBEP for a number of values of Δx, $hn = 10^{10}$, and $vn = v/(\sqrt{D/t})$ is shown in Fig. 6. These results, are representative of values of the normalized growth rates (0.2-2.0 μ/min), and are typical of semiconductor epitaxial processing. Since the examples are for boron, other elements with smaller diffusivities will experience even smaller errors since $vn \geqq 50$.

Errors in general are largest at the smallest growth rates and at larger values of Δx. While the errors appear larger the further one gets from the original interface ($x = 0$) the concentration gradient at distances far from the interface is also large. At a depth of 3.3μ from the original boundary, the concentration may have dropped by six orders of magnitude, while the concentration change over 0.05μ is almost a factor of two. Therefore, errors less than 50% are really quite small relative to the large changes in concentration. Even when the calculated error is greater than 1000%, a lateral shift in the concentration distribution of less than 1Δx is all that is needed for perfect agreement. For a $\Delta x = 0.005$, the calculated error at a concentration level ten orders of magnitude below Cs was only 4%.

In summary, a numerical model has been developed than when compared to available analytical solutions yields highly accurate results. The CNM is used to solve the diffusion equation in the solid for arbitrary initial and boundary conditions. Savings in computer time and core storage can be realzed by using a variable increment size solution.

Analysis of Processing Problems

To design or modify a semiconductor device the single most important parameter is the concentration distribution in the wafer. This distribution affects every single electrical function of the device. Unfortunately, at present, no experimental method exists to determine this concentration distribution. The computer program CASPER offers the designer a powerful tool for performing processing experiments in a short time at a reasonable cost. With CASPER the designer can easily perturb a particular set of materials' properties or a given processing sequence to optimize the electrical characteristics of the device.

In this section CASPER is applied to actual semiconductor processing problems supplied to the author by device designers. In most cases the designers could not accurately define the boundary conditions for the diffusion and "drive-in" operations. All experimentally determined electrical parameters were obtained from the device engineers and represent averages taken over hundreds of thousands of processed devices. In treating certain steps in the device fabrication sequence, specific simplifying approximations were used. During a step involving oxidation of the silicon surface it is assumed that all n-type dopants have zero evaporation coefficients, *i.e.*, no dopant is lost through the oxide. For p-type dopants the evaporation coefficient is modified (lowered) and 30% of the dopant consumed by the oxide is lost to the silicon. The values of the segregation coefficient, k, were taken from the work of Shepherd (12). The limiting concentration allowed in the solid in all cases is the solubility limit of the individual dopant species taken from the work of Trumbore (13). Conversions from concentration to resistivity were made using the polynomial fit developed by T. P. Lee (14) which is used in the calculation of sheet resistance. Emitter discussions were carried out under a constant surface concentration boundary condition, while base diffusions were simulated as a two-step process consisting of a predeposition at low temperature followed by a high-temperature drive-in step.

Example 1.—In the first example, an integrated circuit device pictured in Fig. 7 is analyzed. This example shows how CASPER is used to isolate a critical step in the processing sequence relative to a given parameter (buried layer-sheet resistance) that can be easily calculated from the resultant concentration *vs.* depth distribution. In this structure, the sheet resistance of the antimony buried layer must be kept below 20 ohms/square. It was found in some devices after processing that the sheet resistance had exceeded this value. Since the antimony distribution itself was formed by a deep predeposition and drive-in process, no analytical solution existed for the impurity distribution. Therefore the CNM was used to calculate this distribu-

tion and subsequently integrate it to obtain the sheet resistance of the structure at all subsequent processing steps. R_s is defined below

$$R_s = \left\{ \int_{x_1}^{x_2} q\, \mu(x)\, C(x,t)\, dx \right\}^{-1}$$

where q is the electronic charge and $\mu(x)$ is the majority carrier mobility. Table I shows the change in antimony sheet resistance as a function of high-temperature processing. Since this calculation established that the HCl vapor etch was the principal culprit, further analysis was undertaken to reveal the extent of this effect. Calculations were performed simulating the HCl vapor etching of the silicon surface, removing from 0 to 2μ of silicon. Figure 8 shows both the calculated and experimental results for the percentage change in R_s *vs.* the amount of silicon removed. The agreement between the predicted increase in R_s and the measured values is excellent. This calculation enabled the specification of the HCl cycle as a function of the sheet resistance and therefore resulted in the more efficient utilization of the subdiffused wafers.

Example 2.—In the second example the movement of a minor impurity in a heavily doped substrate during epitaxial growth and subsequent high-temperature processing was explored. Again one is confronted with a problem with nonuniform initial conditions for the second and all subsequent steps. In this case the substrate was doped to 5×10^{18} atoms/cm^3 with antimony, and the layer was intentionally doped with 2×10^{14} atoms/cm^3 of phosphorus. The boron in the substrate (due to contamination of the polycrystalline silicon raw material or contamination during crystal growth) was believed to diffuse out during growth and form a p-region about 1μ from the original interface in the epitaxial layer. In some cases this region apparently escaped detection after epitaxial growth but appeared to form sometime during subsequent high-temperature processing. Figure 9 shows the calculated concentration distribution for 1×10^{16} atoms/cm^3 of boron originally in the substrate. The CNM solution showed that the p-layers did indeed grow with subsequent processing by almost a factor of 2.5. The calculation also showed that if the boron level in the substrate was less than 5×10^{15} atoms/cm^3 no layer could be detected by the MOS capacitance technique being used. This suggested that slices should be subjected to a high-temperature soak directly after epitaxial deposition to enhance the presence of the p-layers if they existed. Figure 10 shows the comparison between the calculated width of the p-region before and after the high-temperature processing steps. These calculated p-region widths are in good agreement with the boron concentrations found in the substrates using the ion microprobe (15).

Example 3.—The third example deals with the back autodoping phenomenon. This example shows how CASPER may be used on a problem where multiple sources of dopant are present (*i.e.*, intentionally added to the gas phase, diffusing from the substrate into the layer, and transported through the gas phase from the sides and back of the substrate). This effect involves the transport of dopant originally in the substrate through the gas phase and back into the growing layer. Therefore epitaxial layers deposited on lightly doped substrates would have a lower layer doping level than layers deposited on heavily doped substrates in the same reactor. Dopant from one substrate may affect other wafers in the reactor with the effect decreasing as the distance from the heavily doped wafer in question. The back of the substrate which is unsealed during the deposition cycle is usually the prime source of this extra dopant after the first micron or two of growth. Subdiffused regions on the surface have been shown by Pogge (16) to also give rise to the same

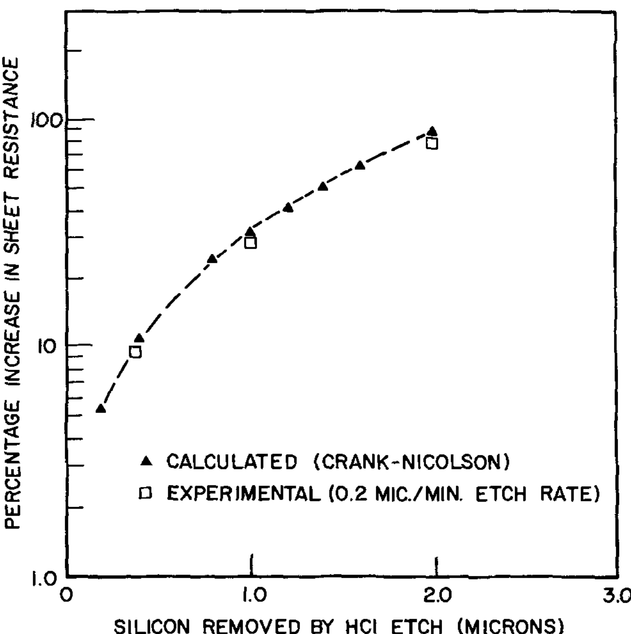

Fig. 8. Plot of change in sheet resistance vs. amount of silicon removed by HCl etching for a 0.2 μ/min etch rate. Etch temperature was 1250°C; dopant species in the diffused region was boron.

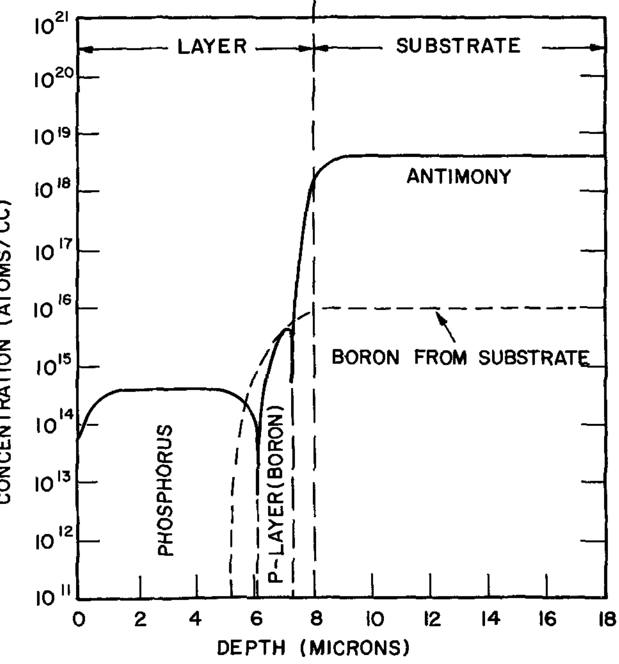

Fig. 9. Plot of impurity concentration vs. depth showing the formation of p-type region in an n-type epitaxial structure due to boron contamination in the starting substrate. Growth rate 0.8 μ/min at 1170°C for 10 min.

autodoping effect, though this source of dopant modifies the impurity profile near the original interface more than in the layer far from the interface. Shepherd (7) developed a mathematical treatment of the autodoping problem that considered the back surface of the wafer as the sole source of dopant that could enter the growing epitaxial layer over and above the transport of dopant by solid-state diffusion. Using this approach and the initial conditions that the distribution of dopant originally in the substrate was uniform, he developed a calculation that involved a knowledge of the growth rate and the transport parameters of the dopant in both the gas and solid system. His final equation ignores the effects of solid-state diffusion so that his model is applicable from about two diffusion lengths from the original interface to the surface of the epitaxial structure. Figure 11 is a comparison between the autodoping model developed by Shepherd and the CNM solution of the same problem. The agreement is quite good between the two approaches. Both calculations were performed assuming that 4% of all dopant leaving the back surface was available for reincorporation into the growing layer. The conditions of growth were as follows: temperature 1200°C, time 6 min at a growth rate of 0.75 μ/min and 114 min at a growth rate of 0.13 μ/min. The scatter in Shepherd's data is a factor of five greater than the disagreement between his calculation and the results of the numerical model.

Conclusions

In conclusion, a one-dimensional computer model has been developed that can predict the impurity distribution in a silicon wafer that has been subjected to a sequence of high-temperature device processing steps. Particular attention has been paid to the modeling of dopant transport during epitaxial growth in order to explain both front and back surface autodoping phenomena. The Crank-Nicholson method has been used to solve the resultant equations numerically to a high order of accuracy with the aid of a split grid approach to minimize computer run time. At present the accuracies of CASPER's predictions are limited only by the experimental values of the constants employed in the analysis, *e.g.*, diffusivity, evaporation coefficient, and segregation coefficients. A better understanding of the dopant interchange at the gas-solid interface will permit extension of this model to the analysis of submicron epitaxial structures.

Acknowledgments

The authors wish to acknowledge the help of Dr. K. E. Benson for many useful discussions.

They also wish to thank Mr. W. R. McCormack of Western Electric who allowed P. H. Langer the time and support necessary to accomplish this investigation.

This paper was submitted as a partial requirement by one of the authors (P.H.L.) for the degree of Ph.D. to the Department of Metallurgy and Materials Science, Lehigh University, Bethlehem, Pennsylvania 18015.

Manuscript submitted Oct. 5, 1972; revised manuscript received Aug. 15, 1973.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1974 JOURNAL. All discussions for the December 1974 Discussion Section should be submitted by Aug. 1, 1974.

APPENDIX

The finite difference equation used in the Crank-Nicholson method to solve Fick's Second Law (Eq. [1]) is presented below. At the front interface the equation is

$$C'_o \left[-1 - \frac{1}{R} - \frac{\Delta x(h+v)}{D} \right] + C'_{+1}$$

$$= C_o \left[1 - \frac{1}{R} + \frac{\Delta x(h+v)}{D} \right] - C_{+1}$$

$$- \frac{2\Delta x}{D} \{hk_e C_m - fh[C_b - k_e C_m]\} + v\, k_g C_m \quad \text{[A-1]}$$

Equation [A-1] is the analog to Eq. [12].

For all the interior grid lines an equation of the following type is used

$$C'_{j-1} + C'\left[-2 - \frac{2}{R}\right] + C'_{j+1} = -C_{j-1} + C_j\left[2 - \frac{2}{R}\right] - C_{j+1} \quad \text{[A-2]}$$

$$\text{for} \quad 1 \leq j \leq b-1$$

At the back boundary the following finite difference equation may be derived from Eq. [7]

$$C'_{b-1} + C'_b\left[-1 - \frac{1}{R} - \frac{\Delta xh}{D}\right] = -C_{b-1} + C_b\left[1 + \frac{1}{R} + \frac{\Delta xh}{D}\right] - \frac{2\Delta xhk_e}{D} C_m$$

Epitaxial Growth and Properties of GaAs on Magnesium Aluminate Spinel

C. C. Wang,* F. C. Dougherty, P. J. Zanzucchi, and S. H. McFarlane III

RCA Laboratories, Princeton, New Jersey 08540

ABSTRACT

Heteroepitaxial GaAs films have been grown by the vapor phase organometallic process on magnesium aluminate spinel substrates prepared by various methods. The effects of variations in growth parameters on the epitaxial GaAs film characteristics have been studied. These growth parameters include substrate surface preparation, substrate composition, substrate orientation, growth temperature, gas flows, reactor geometry, and source materials. The substrate orientation and the purity of the source materials were found to play a critically important role in determining both the crystallinity and the electrical properties of the films. Unintentionally doped GaAs films with electron and hole mobilities up to 70 and 100%, respectively, of bulk GaAs values were grown in the carrier concentration range 10^{15}-10^{16}/cm^3. The epitaxial composites have been characterized by physical and electrical methods. Information on the crystalline perfection, optical properties, and carrier transport characteristics has been obtained.

Single-crystal growth of large-area semiconductor films on oxide insulating substrates is of technical importance to many solid-state electronic devices. Extensive studies of the epitaxial growth of elemental semiconductors, silicon and germanium, on oxide insulating substrates have been reported (1-6) in the past few years. These studies have led to a basic understanding of the composite material systems and to the development of devices (7-9) constructed in silicon grown on sapphire. With the significant progress made on elemental heteroepitaxial semiconductor films, the trend of development was extended to compound semiconductors. Recently, the successful growth of several III-V and II-VI compounds has been reported (10-15), and many properties of GaAs grown on sapphire have been characterized (11, 16). In this paper research results are presented on the epitaxial growth and properties of GaAs grown on magnesium aluminate spinal.

Experimental

Substrate Preparation

Spinel substrate wafers used for GaAs epitaxy were obtained from crystals grown at RCA Laboratories. Stoichiometric spinel ($MgAl_2O_4$) was grown by the flux (17) and the Czochralski (18) methods. Low alumina-rich spinels ($MgO{:}1.5Al_2O_3$-$MgO{:}2.5Al_2O_3$) were grown by the Verneuil method (19). Selected Czochralski spinel wafers of good quality from commercial sources were also used. Initial growth experiments indicated that single-crystal GaAs films can be grown on spinel prepared by all three methods. However, it was found that most films grown on flux spinel exhibited very high resistivities due to unintentional doping of the GaAs films by flux impurities in this

type of spinel, and emphasis was therefore shifted to films grown on Czochralski and Verneuil materials.

The proper preparation of substrate wafers from the spinel single crystals is of essential importance in obtaining good epitaxial growth. Orientation of the spinel crystals for cutting was determined by the x-ray Laue back-reflection method. Substrate wafers (about 1 cm^2 $\times$ 0.06 cm thick) of (111), (100), and (110) orientations were obtained by cutting the x-ray oriented crystals using a diamond wheel. An accuracy of better than one-quarter degree is maintained throughout the operation. The spinel substrate wafers were mechanically lapped and polished to produce the flat and smooth surface which is required for epitaxial growth. Lapping was carried out with about 30μ boron carbide abrasives to obtain a flat coplanar surface. The lapped surface was further polished using successively finer grades of alumina, ending with the 0.05μ grade. After polishing the wafers generally have a flatness of better than $\pm$0.4 μ/cm, as measured by interferometry.

Epitaxial Growth

Epitaxial growth of GaAs on spinel was obtained by using the reaction (15) between trimethylgallium [$(CH_3)_3Ga$] and arsine (AsH_3).

The growth system, as shown in Fig. 1, consists of a water-cooled vertical quartz reactor (6.25 cm diameter $\times$ 40 cm long) equipped with an adjustable quartz pedestal, a trimethylgallium source reservoir (kept at 0°C) and dispenser, an arsine supply (10% by volume in H_2), all stainless steel gas lines and valves, and precision gas flow controls. Hydrogen purified by a Pd-diffuser was used as the carrier gas. The growth of doped GaAs films was explored using $(C_2H_5)_2Zn$ and H_2Se (also H_2S) as the p- and n-dopants, respectively. A Lepel radio frequency induction heating system (with precision electronic control unit) and pyrolytic graphite or SiC-coated graphite susceptors were employed for the deposition. The substrate temperature was measured by an infrared pyrometer.

In a typical growth run, the reactor is first thoroughly flushed by H_2 to purge the system of air. Predetermined and equilibrated AsH_3 and $(CH_3)_3Ga$ gas flows are then sequentially admitted to the reactor in which the substrate is heated to the growth temperature. The crystal growth is carried out for the desired length of time after which the $(CH_3)_3Ga$ carrier gas is turned to the exhaust. The AsH_3 gas valve is then turned off, and the substrate is cooled at an average rate of about 50°C/min in the H_2 ambient. Extensive studies were made on the growth parameters to achieve optimum properties and to develop a basic understanding of the growth process. The parameters include growth temperature, flow rates, substrate orientation, substrate surface preparation, and source material purification.

Physical and Electrical Characterization

The GaAs-spinel composite structure was characterized by x-ray diffraction, electron diffraction, electron microscopy, and optical techniques. Information on the epitaxial orientation relationship, defect structures, and surface perfection has been obtained.

The conventional x-ray Laue back-reflection method has been used for the determination of orientation relationship and the assessment of crystalline perfection. In addition, x-ray diffractometric measurements were made to determine the orientation mismatch and the line broadening of the diffraction peaks as the film-substrate structure is rotated in a well-collimated beam of x-rays. A Jarrell-Ash microfocus x-ray generator and the attached diffractometric tracer has been employed for this study.

The crystalline perfection of the surface of the epitaxial GaAs films has been examined by glancing angle electron diffraction and by optical and electron microscopy. An RCA Model EMU electron microscope, a Cambridge scanning electron microscope, and a Lietz high power optical microscope were employed for this study. Optical transmission and reflection of the GaAs spinel composite were measured in the spectral range u.v. to infrared to determine a variety of properties (20-23), including film thickness, film uniformity, surface quality, doping type, and carrier concentration. These measurements were made using spectrometers (Cary 14, Perkin Elmer 457, and Perkin Elmer 301).

The carrier transport properties of epitaxial GaAs grown on spinel were determined by Hall measurements. Bridge-shaped Hall bar samples with six terminals were prepared by chemical etching and conventional photolithographic techniques. Ohmic contacts to the GaAs samples were made by an alloying process (24) at about 500°C in a hydrogen atmosphere. For n-type materials, In was used as the contact metal. For p-type materials, both In and Au (2% In) were used. The resistivity and Hall coefficient were experimentally measured by the conventional method (25) in a magnetic field of 3000 gauss. The Hall mobil-

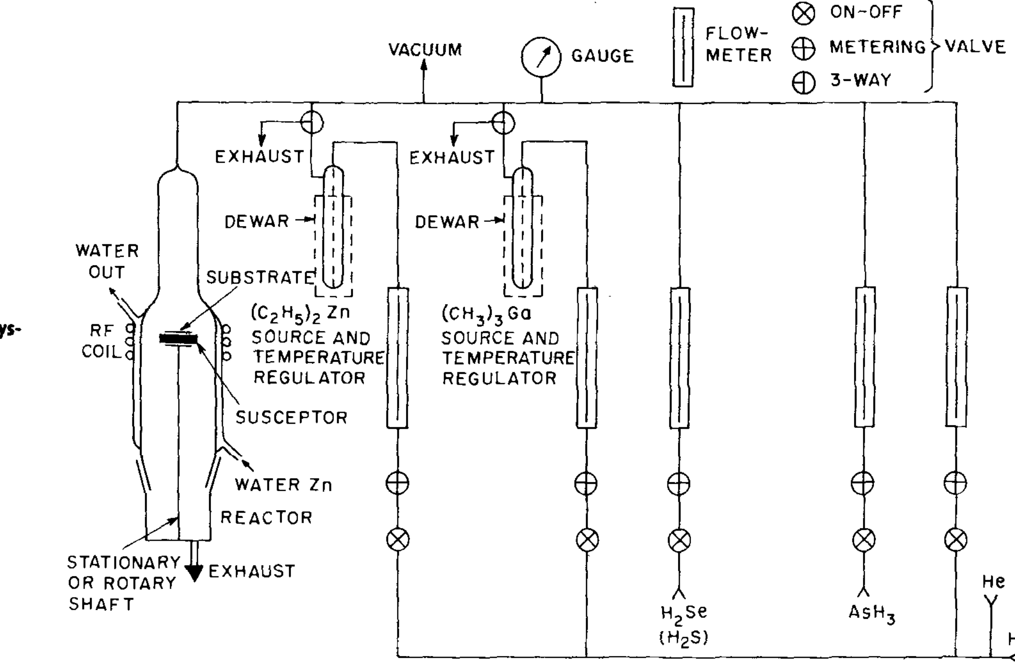

Fig. 1. Epitaxial growth system.

ity was determined by the ratio of the Hall coefficient and the resistivity. The net carrier concentration was derived from the Hall mobility and resistivity using $N = 1/(\rho e \mu)$, where N is the carrier concentration, ρ is the resistivity, e is the electronic charge, and μ is the Hall mobility.

Results and Discussions

Growth Parameters and Characteristics

Growth temperature and gas flows.—Single-crystal GaAs films with thicknesses up to 70 μm were grown on spinel substrates. The flow conditions that yield the best results for the particular apparatus geometry used are: H_2 carrier gas flow, 3.0 liters/min; AsH_3 (10% in H_2) flow, 200 cm^3/min; and H_2 carrier gas for $(CH_3)_3Ga$,[1] 5 cc/min. Under these conditions, the average film growth rate is about 0.5 μm/min for 10 μm thick films. Higher flow rates than these favor heavy deposition at the center of the substrate, while slower rates favor deposition at its periphery. The optimum growth temperatures varied with substrate orientations. A series of growth experiments was carried out in the temperature range 500°-800°C, with other variables being held constant, to determine the effect of growth temperature on the GaAs crystalline quality. The substrates were heated in AsH_3 (10% by volume in H_2) at 700°C for 3 min prior to the admission of $(CH_3)_3Ga$ for growth.

The general trends observed were: (*i*) At low temperatures (<600°C), the GaAs films are polycrystalline in nature. (*ii*) At high temperatures (>800°C), the gases in the reactor are highly turbulent and the films tend to be inhomogeneous with high densities of growth defects. (*iii*) Within a limited temperature range, 680°-720°C for (111) spinel and 630°-700°C for (110) spinel, highly reflective GaAs of good crystallinity can be grown. Figures 2 and 3 show the surface structures of (111) and (100) GaAs films grown, respectively, on (111) and (110) spinel at various temperatures. The growth rate (determined from infrared film thickness measurements) was varied with growth temperature, as shown in Fig. 4, until a plateau was reached corresponding to the optimum growth temperature range. The growth rate then decreased with further increasing temperature.

The growth rate and film optical quality depend also on the ratio of $AsH_3/(CH_3)_3Ga$ introduced into the system. This is illustrated in Fig. 5, which shows plots of growth rate and optical reflectance factor (Q) of (111) GaAs films (~10 μm thick) *vs.* the H_2 carrier gas setting for $(CH_3)_3Ga$. The AsH_3 (10% in H_2) gas flow was held constant (200 cm^3/min). The growth rate (film thickness) was determined by infrared reflection measurement, and Q was derived from the measured and calculated reflectivities (R_m and R_{calc}) as defined in Eq. [1]. It is seen that there is an optimum range of source gas ratios at which high-quality films are grown.

$$Q = \left(1 - \frac{R_{calc} - R_m}{R_{calc}}\right) \times 100 \qquad [1]$$

Effect of substrate orientation.—Extensive studies revealed that the substrate orientation plays a critical role in the ease with which the epitaxial layers grow. The ease of growth of GaAs on spinel increases with spinel orientation in the order (111) > (110) > (100) under normal growth procedures described above. The epitaxy[2] of (100) GaAs on (110) spinel is more sensitive to substrate surface quality than that of (111) GaAs on (111) spinel. Moreover, the films tend to grow epitaxially at relatively lower temperatures (see

[1] Kept at 0°C.

[2] The (100)GaAs || (110)spinel relationship was previously noted (11). Details of the GaAs-spinel orientation relationship are discussed in the section on Orientation Relationship and Crystallinity.

section on Growth temperature and gas flows). The (100) GaAs grown on substrates with generally inferior surface quality exhibits fairly well-defined band or strip structures across the crystal with a high degree of crystallite misorientation (26). Scanning electron micrographs of GaAs films grown on (111), (110), and (100) spinel in Fig. 6 show the crystalline structures. The films were grown simultaneously onto the substrates at 700°C. The oriented single-crystal growth was obtained on both (111) and (110) spinel orientations, but not on (100) orientation. Films grown on (100) spinel substrates were polycrystalline with isolated (100) GaAs single-crystal areas (see section on Orientation Relationship and Crystallinity).

The effect of substrate orientation on the GaAs growth characteristics was further studied by growth on off-oriented substrates. Substrate wafers were prepared with off-orientations [in <211> for (111) and (110); <110> for (100)] up to 5° from the (111), (100), and (110) major orientations. Epitaxial growth was carried out using the three sets of substrates under, respectively, the most favorable conditions previously determined for the individual orientations. The films (10-15 μm thick) were examined by x-ray Laue back-reflection and by scanning electron microscopy to determine the crystalline nature and the surface perfection. Infrared reflection measurements were further made on the films providing an assessment of the film surface quality.

The experimental results are presented in Table I. The significant surface structures of the three sets of films are shown in the scanning electron micrographs (Fig. 7). A general trend is observed for all three orientations. Smooth epitaxial surfaces with the least surface imperfections were obtained on misoriented substrates. The optimum degree of misorientation, as shown in Table I, is slightly different for the three major surfaces studied. The improvement of epitaxial surface crystallinity by growth on substrates with off-orientation was previously reported (27) for the homoepitaxial growth of GaAs and Ge, and for the heteroepitaxial GaAs/Ge growth. Another important and interesting finding in this study is on the growth characteristics of films on (100) spinel. As reported above, the growth of (100) GaAs on (100) spinel was difficult, and the grown films were polycrystalline in

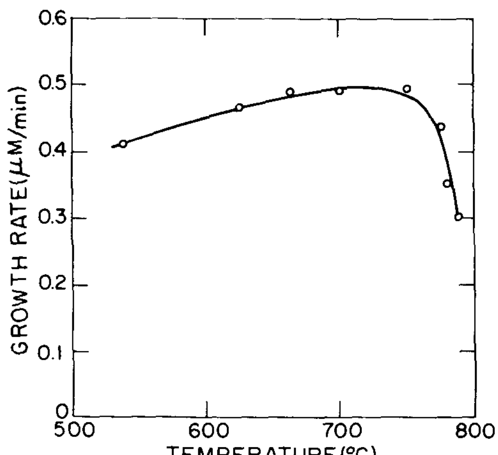

Fig. 4. Growth rate as a function of growth temperature of (111) GaAs.

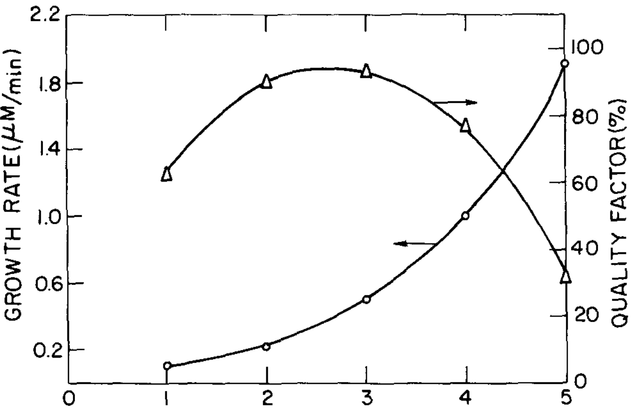

Fig. 5. Growth rate and quality factor as a function of $(CH_3)_3Ga$ feed rate.

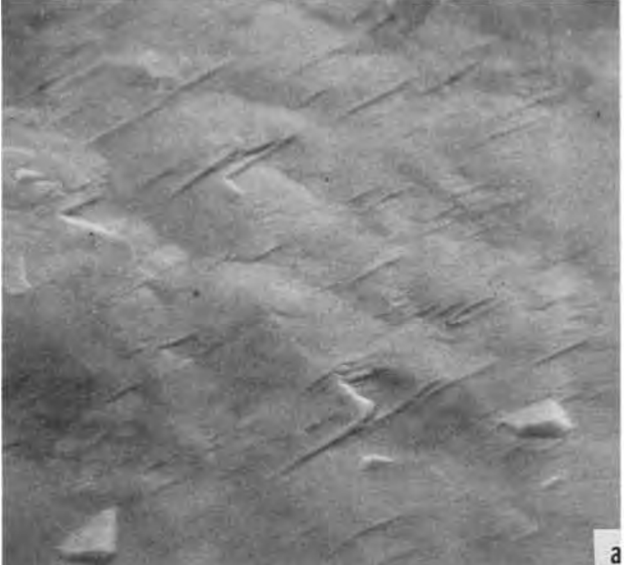

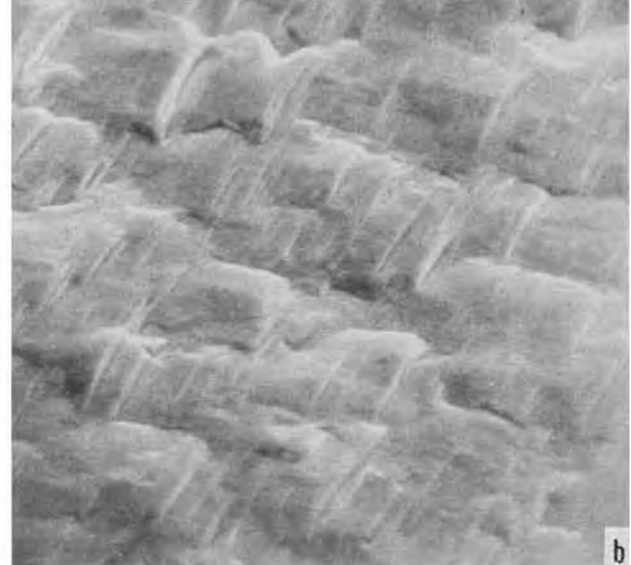

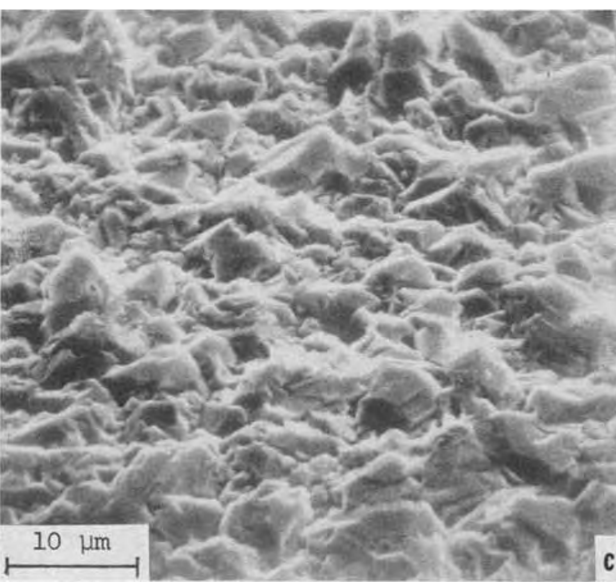

Fig. 6. Scanning electron micrographs of GaAs films (~20 μm) grown simultaneously; beam-sample angle 45°. (a) (111) GaAs on (111) spinel, (b) (100) GaAs on (110) spinel, and (c) polycrystalline GaAs on (100) spinel.

nature, with isolated single-crystal areas. However, with a substrate off-orientation as small as 1°, the growth was enhanced remarkably with (111) GaAs grown on (100) spinel. GaAs grown on (100) and 1° off-(100) spinel orientations exhibits a pronounced difference in crystallinity.

Because of the lack of a center of symmetry, there exist the (111)A and (111)B faces for GaAs (28). The physical and chemical characteristics of the two faces

Table I. Effect of substrate off-orientation on film characteristics

Substrate orientation	Apparent film orientation	Optical reflectance factor, Q (at 2.5 μm) (%)
(111)	(111)	80
1° off (111)	(111)	70
2° off (111)	(111)	92
3° off (111)	(111)	100
4° off (111)	(111)	100
5° off (111)	(111)	100
(110)	(100)	86
1° off (110)	(100)	93
2° off (110)	(100)	90
3° off (110)	(100)	85
4° off (110)	(100)	72
5° off (110)	(100)	18
(100)	(100)	20
1° off (100)	(111)	100
2° off (100)	(111)	100
3° off (100)	(111)	83
4° off (100)	(111)	83
5° off (100)	(111)	52

are distinctly different. Simultaneous growth on (111) and off-oriented (100) spinel substrates and on the (111)A and (111)B faces of GaAs reveals that the surface of (111) GaAs grown on spinel resembles the growth on the (111)A face of GaAs. The (111)A face of GaAs grown on spinel was further confirmed by studying the etching behavior (see section on Optical Properties) of the GaAs films and bulk materials.

Effect of substrate surface preparation.—Substrate surface perfection has a direct effect on the GaAs heteroepitaxy. The quality of the mechanical polishing was critically important for obtaining good GaAs growth. It was found that surface scratches on the substrates provide preferential nucleation sites. Absorbed layers and impurity aggregates on the substrate surfaces can also cause defects in the GaAs films.

The effect of preannealing of substrate on the film crystallinity was studied. (111) and (100) GaAs films (about 10 μm thick) were grown, respectively, on (111) and (110) spinel substrates preannealed at 1200°C in H_2 for 20 min and on substrates without this treatment. The growth conditions were those optimized for the (111) and (110) orientations. This annealing has been used (4, 6, 19) to improve the surface crystallinity of spinel for silicon epitaxy. Annealing at high temperatures (in air at 1500°C) followed by chemical polishing was also reported to minimize mechanical damage of oxide substrates (29). Experimental results indicate that the films grown on preannealed

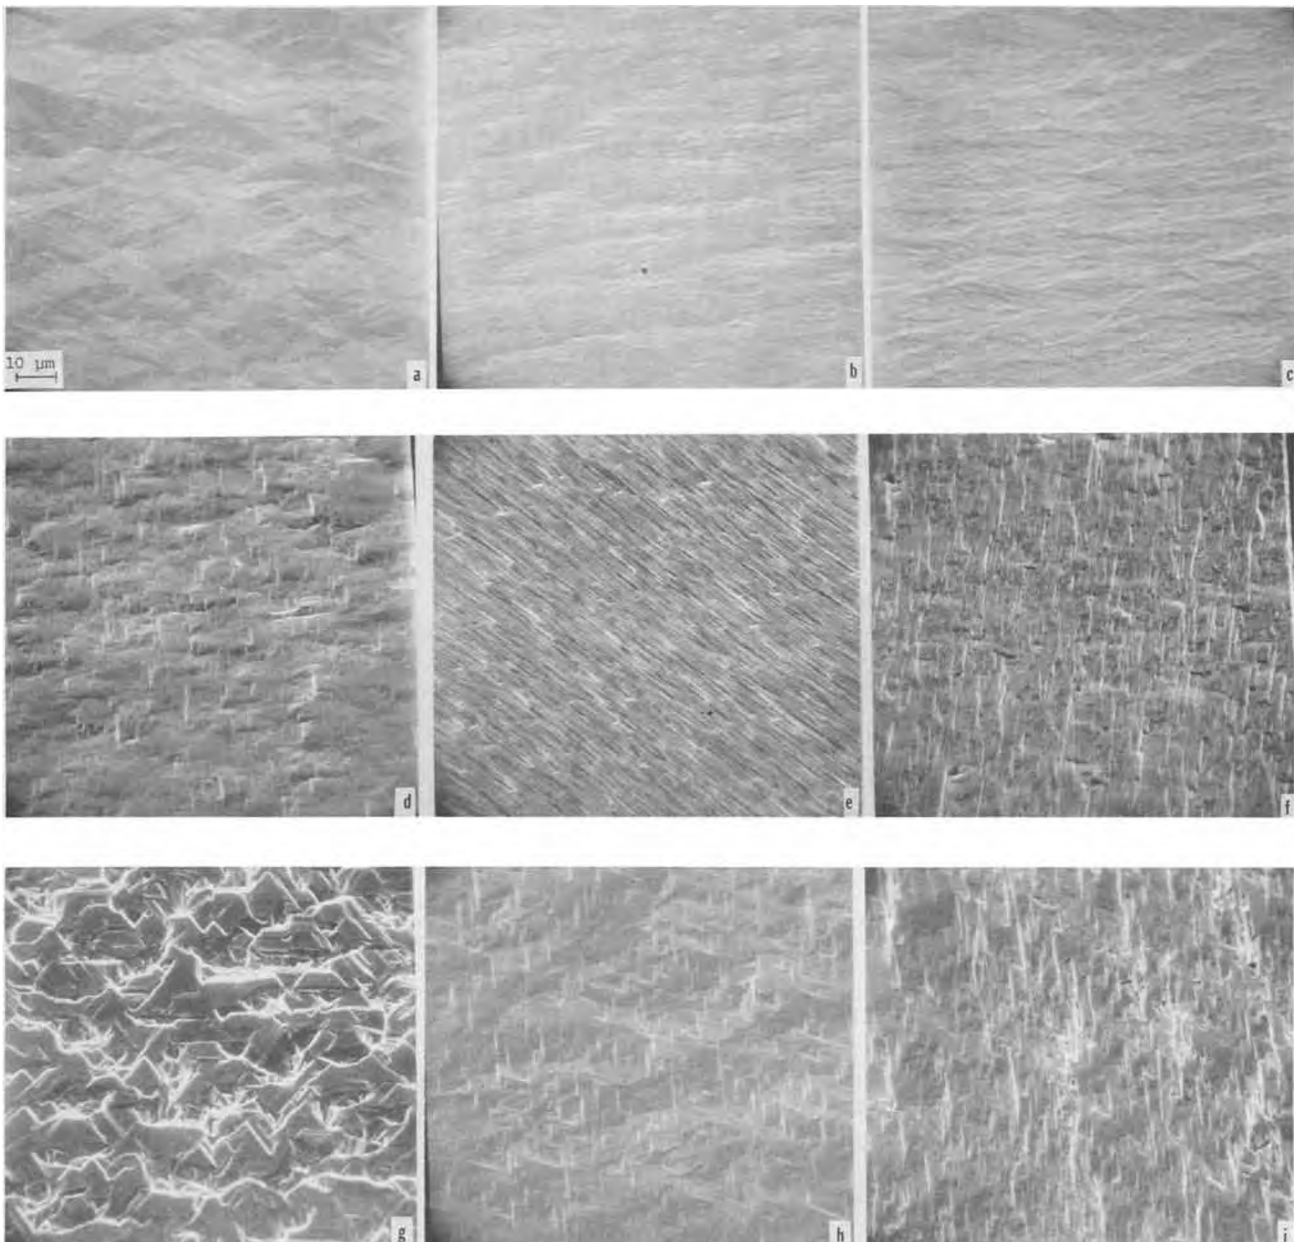

Fig. 7. Scanning electron micrographs of GaAs films (~10 μm thick) grown on off-oriented spinel substrates. (a) (111) 0° off, (b) (111) 2° off, (c) (111) 5° off, (d) (110) 0° off, (e) (110) 2° off, (f) (110) 5° off, (g) (100) 0° off, (h) (100) 2° off, (i) (100) 5° off.

substrates are always inferior in quality and that the hydrogen annealing of the substrate is, therefore, not desirable for the growth of GaAs by the organometallic process. Scanning electron micrographs of films grown on the unannealed and preannealed substrates are shown in Fig. 8.

Early growth stage studies.—The nature of the initial film growth was qualitatively explored by terminating the growth after predetermined growth periods (in the order of seconds) and examining the films by scanning electron microscopy. Experimental results indicate that the early stage of growth involves the formation of discrete nuclei which coalesce, forming growth islands. The islands finally grow together, producing complete coverage of the substrate surface. Similar growth mechanism was observed for heteroepitaxially grown Si (2, 4) and GaAs on sapphire (30). The scanning electron micrographs in Fig. 9 show the growth islands of (111) GaAs on (111) spinel just before complete coverage of the substrate. A slight difference is seen in the percentage of coverage for substrates grown by different methods. This may be due to differences in surface perfection.

The scanning electron micrograph of a typical (111) spinel substrate, grown by flame fusion, in Fig. 10(a) shows the surface structure of a substrate that was cleaned by standard procedures for epitaxial growth. The substrate was heated in AsH_3 (10% by volume in H_2) at 700°C for 3 min. This treatment was made on wafers prior to the admission of $(CH_3)_3Ga$ to initiate growth. The surface structure of the substrate is shown in the scanning electron micrograph [Fig. 10(b)]. The micrographs show that the surface is featureless before the heat-treatment in AsH_3. However, after the treatment, scratches caused by polishing damage are observed. This indicates that AsH_3 etches the spinel substrates at a temperature of about 700°C. The etched single crystalline surfaces promote the epitaxial growth of GaAs. The etching of spinel by AsH_3 was also observed on flux and Czochralski-grown materials.

Effect of substrate composition.—Growth experiments were made to investigate the effect of substrate composition on the film characteristics. A series of (111) spinel substrates with compositions in the range $MgO:1.5Al_2O_3$ to $MgO:3.0Al_2O_3$ was prepared for the epitaxial growth of (111) GaAs. The substrate crystals

were grown by the Verneuil method and were polished under conditions that the degree of variation in substrate polishing quality is minimized. For comparison, Czochralski $MgAl_2O_4$ wafers were also used for this study. The growth experiments were carried out under the optimum conditions so that the effect of substrate composition on the film quality may be elucidated. The film characteristics are shown in Table II.

Table II. Characteristics of GaAs grown on spinel of various compositions

Substrate material	Film thickness (μm)	Growth rate (μm/min)	Optical reflectance factor, Q (%)	Conductivity type	Resistivity (ohm-cm)	Hall mobility (cm^2/V-sec)
$MgO:Al_2O_3$	17.2	0.29	69.9	n	0.17	3100
$MgO:Al_2O_3$	25.0	0.42	55.7	n	0.81	2200
$MgO:1.5Al_2O_3$	18.9	0.32	55.7	n	0.43	3300
$MgO:1.7Al_2O_3$	25.3	0.42	49.0	n	0.29	2100
$MgO:2.0Al_2O_3$	25.0	0.42	40.0	n	2.10	1800
$MgO:2.5Al_2O_3$	25.3	0.42	33.2	n	0.27	2600
$MgO:3.3Al_2O_3$	25.0	0.42	55.7	n	1.87	1200

It is seen that for the Verneuil substrates there is no significant trend to dependence of film electrical characteristics on substrate composition. Moreover, there is no significant difference in growth rate and quality factor between films grown on Czochralski and Verneuil substrates. The only difference between films grown on the two kinds of substrates is the physical appearance. Films grown on the Verneuil material exhibit the subgrain structures originating from the substrates, and films grown on the Czochralski substrates do not show subgrain structures. An important variable in the growth of GaAs on Verneuil spinel is the degree of misorientation (19) of subgrains. As described in the section on Orientation Relationship and Crystallinity the film surface quality depends highly on the substrate orientation. This orientation factor affects the film characteristics in addition to the composition. Substrates with minimum subgrain misorientation are desired for the epitaxial growth of GaAs.

Growth experiments were also made to study the difference between Czochralski spinel and sapphire as substrates for GaAs epitaxy. The film growth characteristics were very similar between GaAs/(111) spinel and GaAs/(0001) sapphire grown under identical conditions. However, a significant difference between sapphire and spinel for GaAs epitaxy is that (100) GaAs of good quality can be grown on (110) spinel but not on any known sapphire orientation. Besides the (0001) orientation it is relatively difficult to grow single-crystal GaAs of good quality on other sapphire orientations, and the films, in most cases, exhibit a (111) orientation. For certain device applications the (100) GaAs which can be obtained on spinel is desirable (7).

Source materials.—Experimental results indicate that the purity of the source material is of critical importance in determining the electrical properties of the epitaxial films. High purity AsH_3 is commercially available. The purity of the AsH_3 gas used for the GaAs growth on spinel was evaluated in a homoepitaxial GaAs growth system employing the reaction between gallium chloride and arsine (31). However, the quality of the $(CH_3)_3Ga$ varies from lot to lot. The impurities generally found, by emission spectroscopy, in typical lots of $(CH_3)_3Ga$ include Cu, Fe, Zn, Al, Si, and Mg on the order 10^{-1}-10^2 ppm (by weight). These impurities may cause significant unintentional doping of the GaAs films. Analysis of $(CH_3)_3Ga$ samples by infrared spectroscopy was also made. The results indicated that there are hydrocarbons (mainly CH_4 and minute higher alkanes) present in some samples with widely varying concentrations from sample to sample.

Electrical measurements of the heteroepitaxial GaAs indicate that categorically, three kinds of films (unintentionally doped), depending mainly on the quality of $(CH_3)_3Ga$, were obtained under the optimum growth conditions and using a high-purity arsine source. The first kind of films exhibited very high resistivity ($>10^3$ ohm-cm) independent of thickness. The films are highly compensated and contain localized p-n junctions. Several films in this class were angle-lapped and chemically stained to reveal the p- and n-regions. It was found for all the films examined that a p-region is next to the spinel substrate. With subsequent growth the sample either becomes n-type or forms further n-p regions. Experiments on the homoepitaxial growth of GaAs were also carried out using the organometallic process. It has been found that the interface p-region was not present. The results indicate that the initial p-region is only formed in heteroepitaxial GaAs grown on oxide substrates such as spinel and sapphire (16). It is likely that this p-region is a result of autodoping from the substrate.

The second class of the as-grown unintentionally doped films exhibited p-type conductivity. As described above, many lots of $(CH_3)_3Ga$ contain appreciable amounts of Cu and Zn which are well known to be effective acceptors in GaAs. These p-type GaAs films are most probably Cu- and/or Zn-doped. The carrier transport properties[3] are dependent on film thickness crystallinity, orientation, and other parameters.

It is significant to note that the p-type films (>10 μm thick) with mobilities (~ 300 cm^2/V-sec) close to the bulk values (32) were prepared in the carrier concentration range mid-$10^{15}/cm^3$ to low-$10^{17}/cm^3$. It was also found that in the p-type films the mobility gradually decreases, starting from about $3 \times 10^{16}/cm^3$, with increasing carrier concentration. This trend is consistent with that of the bulk GaAs.

The third class of films was n-type and was grown on spinel under the optimum growth conditions using particular lots of $(CH_3)_3Ga$ and high-purity arsine sources. The electrical properties of the n-type films were less consistent than that of the p-type films. Electron mobilities (carrier 10^{15}-$10^{17}/cm^3$) in the range 1-4 $\times 10^3$ cm^2/V-sec were measured for films with thicknesses greater than 10 μm. The inconsistency of the electrical properties in n-type films is primarily due to the fact that the films are electrically compensated and because a p-type GaAs layer is often present during the initial film growth on a substrate. Moreover, the crystalline defects may act as charged imperfections containing an accumulation of traps, thus lowering the mobility. To date, the highest electron mobility measured has a value of 4500 cm^2/V-sec which is about 70% of the bulk value. Typical results of unintentionally doped GaAs films are shown in Table III.

Doped films.—The growth characteristics of the Zn-doped films were found similar to those of the unintentionally doped films. The film crystallinity improves with increasing film thickness, and the substrate preparation has a pronounced effect on the film quality, in particular for thin films. The net carrier concentration of the film was found to be dependent primarily on the $(C_2H_5)_2Zn$ reservoir temperature and on the $(C_2H_5)_2Zn$ carrier gas flow. In the present study, films with a carrier concentration in the range 8×10^{18} to $5 \times 10^{19}/cm^3$ were grown. Emphasis was placed on the growth of thin (~ 1 μm thick) degenerate GaAs films. The thin epitaxial GaAs grown on transparent substrate is of interest for use as negative electron affinity photocathode (33).

The thin films generally exhibit hole mobilities less than the thick films. In the carrier range of 1-3 $\times 10^{19}/cm^3$ the mobility ranges from 50 to 70% of the bulk values. In an effort to eliminate the problem of the presence of a high defect region near the film/substrate

[3] The electrical properties of GaAs-on-spinel will be reported in detail in a separate paper.

Table III. Electrical properties of (111) epitaxial GaAs* grown on spinel

Substrate	Film thickness (μm)	Conductivity type	Resistivity (ohm-cm)	Carrier concentration (cm^{-3})	Hall mobility (cm^2/V-sec)
Flux $MgAl_2O_4$	30	n	9	9.4×10^{14}	740
Verneuil $MgO:1.7Al_2O_3$	50	n	0.40	4.1×10^{15}	3820
Czochralski $MgAl_2O_4$	23	n	0.31	4.7×10^{15}	4200
Czochralski $MgAl_2O_4$	26.4	p	0.58	3.4×10^{16}	320

* Unintentionally doped films.

interface, several growth experiments were carried out with encouraging results[4] by growing (100) thin GaAs 1 μm thick on heteroepitaxial (100) GaP grown on either (100)Si/(1$\bar{1}$02)sapphire or (110) spinel.

Studies were also made on the growth of doped n-GaAs on (111) and (100) spinel. It was found that the control of the degree of doping was more difficult for H_2Se than for H_2S because the H_2Se gas was not chemically stable in storage. Thick films (>10 μm) with carrier concentration in the range 2×10^{17} to $1 \times 10^{19}/cm^3$ were grown with mobility ranges from 50 to 90% of the bulk values.

Orientation Relationship and Crystallinity

The film-substrate orientation relationship was determined and a preliminary assessment made of the crystalline perfection of the GaAs films, using the Laue x-ray back-reflection method. Some thin (<5 μm thick) GaAs films were also examined by reflection electron diffraction at a glancing angle of less than 1° using a 100-kV electron beam. Laue x-ray back-reflection patterns and electron diffraction patterns are shown, respectively, in Fig. 11 and 12 for typical films grown on (111) spinel substrates prepared by different methods. It is seen that the Laue patterns show complete zone lines (superposition of film/substrate poles) of threefold symmetry and sharp Laue spots with no polycrystalline structures, indicating the good monocrystallinity of the GaAs films and the parallel orientation relationship. The electron diffraction patterns were indexed. The results obtained further confirm the (111) film/substrate parallel orientation relationship. As described before, the film quality improves with increasing thickness. The (111) thin films (<5 μm) generally exhibit a high degree of twinning about the <$\bar{1}$11> directions.

[4] Electrical characteristics of the films will be reported elsewhere.

Table IV. Departure of (111) GaAs from exact parallel epitaxy

Substrate	Misorientation from exact parallel epitaxy
Flux spinel	0.15°
Czochralski spinel	0.32°
Flame fusion spinel	0.43°

The departure of the films from exactly parallel epitaxy was determined, as previously described (26), by measuring the angular separation of diffracted peaks from the layer and substrate and comparing this observed value with that expected for parallel epitaxy. Typical results are shown in Table IV. It is interesting to note that the flux spinel crystals exhibit high crystalline perfection without lattice distortion and that the GaAs grown on the flux spinel exhibits the least misorientation from exact parallel epitaxy.

Besides the (111) GaAs films, (100) GaAs films have been grown on both (100) and (110) spinel substrates. As described in the section on Growth Temperature and Gas Flows, the growth results of GaAs on (100) spinel substrate have not been consistent. Because of the lack of a film of uniform quality, the x-ray single-crystal oscillation technique (34) was employed to examine a selected single crystalline area (~30 mil diameter) of a GaAs film grown on spinel. The results indicate that the (100) GaAs exhibits the parallel epi-

taxial relationship with the (100) spinel substrates. The epitaxy of GaAs on (100) spinel is most interesting in that an apparent orientation relationship of (111)GaAs||(100)spinel has also been discovered.

The experimental evidence is shown in Fig. 13(a) and (b) which are the x-ray Laue back-reflection patterns of the GaAs layer and spinel substrate sides of a sample. The substrate is (100) oriented with 1° off in <110>. The sample was aligned optically such that it was within ±¼° of being normal to the x-ray beam, and the films were taken with exposure long enough to reveal all the Laue spots. The misorientation between the film and substrate was measured, and a value of 1° was found from exact parallel epitaxy. Research results on the epitaxial orientation relationship between GaAs and spinel are summarized in Table V.

The crystallinity of the heteroepitaxial GaAs was characterized in detail by x-ray diffraction topography. The results (26) indicate that the single-crystal layers are composed of grains which are misoriented ±0.1° from the nominal orientation of the layers.

Table V. Epitaxial relationship between GaAs and spinel

Parallel plane		Parallel direction	
Spinel	GaAs	Spinel	GaAs
(111)	(111)	$[01\bar{1}]$	$[01\bar{1}]$
(100)	(100)	[010]	[010]
(110)	(100)	$[\bar{1}10]$	[011]
(100) 1°-5° off	(111)	$[\bar{1}10]$	$[01\bar{1}]$

Optical Properties

Optical properties of the heteroepitaxial GaAs were studied. The transmission characteristics of (111) GaAs films grown on spinel, 0.4, 5.1, and 14.0 μm thick, are given as a function of wavelength (in the bandgap region) in Fig. 14. It is seen that the sharpness of the absorption edge increases with increasing thickness. The absorption observed below the bandgap region is due, in part, to reflection losses from the air-GaAs interface ($R \simeq 0.28$), the GaAs-spinel interface ($R \simeq 0.10$), and the spinel-air interface ($R \simeq 0.07$). Reflection losses account for an apparent optical density of about 0.25, in agreement with optical density values obtained for polished, vapor-deposited GaAs films shown in Fig. 15. From Fig. 15 it is apparent that below the bandgap absorption occurs which is not due to simple reflection losses. Reflection measurements indicate that the absorption is due to light scattering from GaAs surface structures. A fundamental characteristic of as-grown, vapor-deposited GaAs films on oxide substrates is, therefore, a surface structure which scatters near infrared light. Reflection characteristics of the films in the lattice band region were also determined. The films all exhibit a sharp transition in reflectivity near 300 cm^{-1}, consistent with the characteristics for bulk material (35-36). The reflection data suggest that the 0.4 μm thick GaAs is not significantly different from thicker vapor-deposited GaAs films. This means that the initial 4000Å of vapor-deposited GaAs is not grossly autodoped by the spinel substrate nor grossly divergent in stoichiometry and crystal structure.

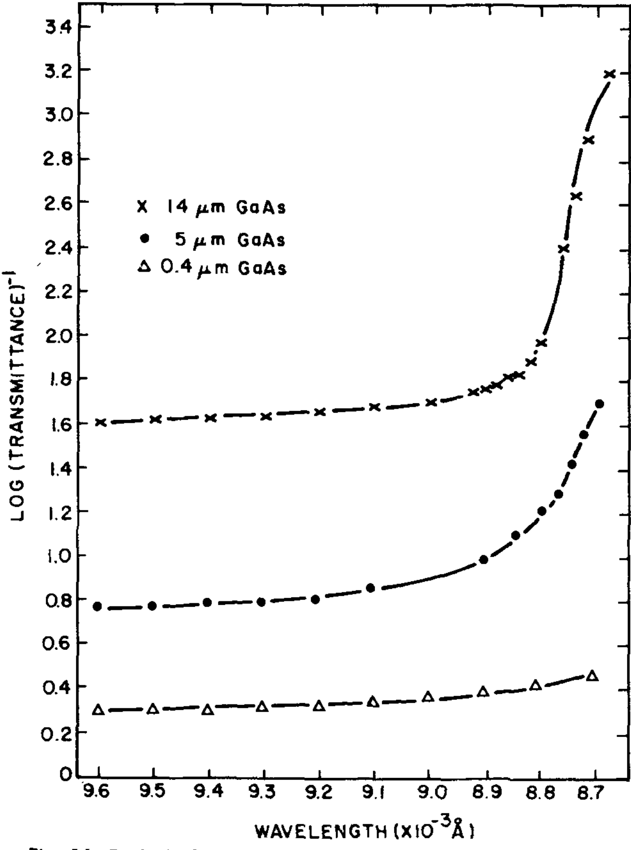

Fig. 14. Optical absorption as a function of wavelength of GaAs films.

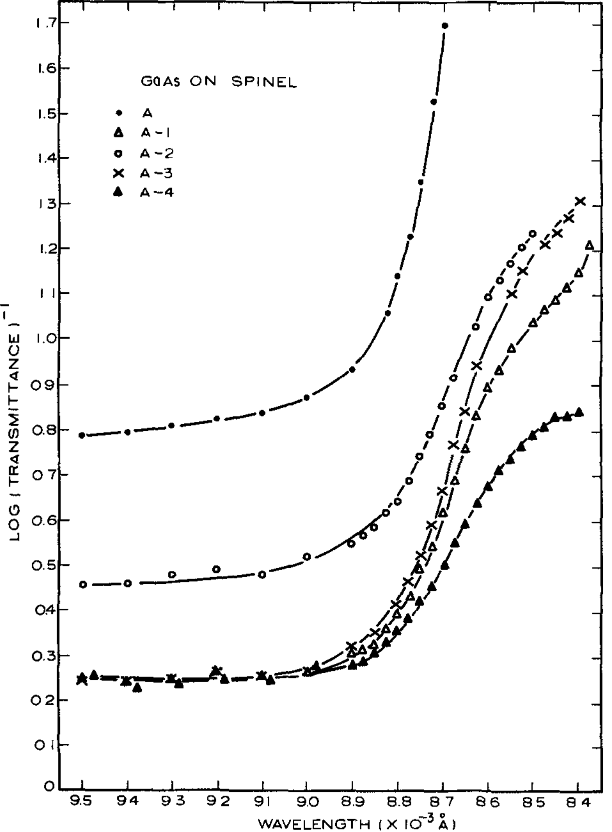

Fig. 15. Optical absorption as a function of wavelength of polished and unpolished GaAs films.

To determine the effects of various polishing methods on the optical properties of GaAs vapor-deposited films, an as-grown (111) GaAs film on (111) spinel, designated A, was split into five sections. Each section of the original GaAs film was polished by the methods conventionally used for (111) GaAs listed in Table VI.

Table VI. Polishing methods for GaAs

GaAs designation	Polishing method	GaAs film thickness, μm
Film A	Film as-grown, untouched	5.1
Film A-1	0.3 μm Linde mechanical polish	2.4
Film A-2	Br_2-CH_3OH* chemical etch	1.8
Film A-3	0.3 μm Linde mechanical polish followed by a H_3PO_4 chemical etch	2.5
Film A-4	H_3PO_4* chemical etch only	1.5

* Br_2 (0.5%)-CH_3HO; H_3PO_4 (85%)-H_2O; etching was done at room temperature.

The results showed that the film and bulk (111)A faces can be polished by H_3PO_4 but not by Br_2-CH_3OH, which is a polishant for (111)B GaAs. Optical transmission and reflection characteristics of the A-film series are shown, respectively, in Fig. 15 and 16. Films A and A-2 exhibit rough surfaces, and the transmission of these samples above the absorption edge is lower than A-1, A-3, and A-4. The films designated A-1, A-3, and A-4 have a smooth surface structure and consequently have identical transmission above the absorption edge. Below the absorption edge, transmission of the A-film series is somewhat different due to differences in film thickness (see Table VI).

The reflection spectra showed that the as-grown sample, A, yields the best over-all band structure while all other spectra exhibit a degraded band structure with the reflectivity minimum shift to a higher wave number. This degradation, originated from surface damage, may cause disorder in the surface lattice structure and introduce electron traps (36).

Ellipsometric measurements were made at a wavelength of 5461Å on epitaxial GaAs grown on spinel

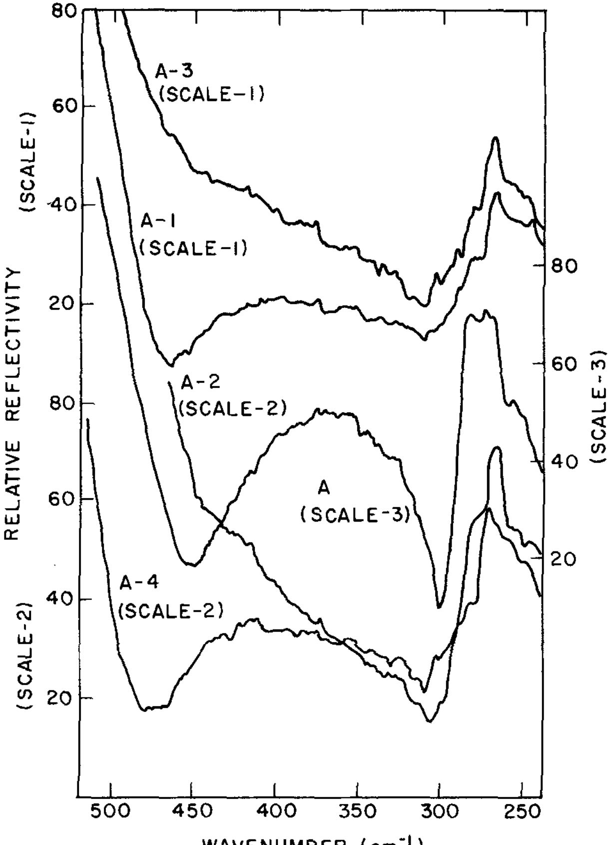

Fig. 16. Reflectivity as a function of wave number of polished and unpolished GaAs films.

Table VII. Optical and dielectric constants of epitaxial GaAs films on spinel at $\lambda = 5461 Å$

Description of the sample	ϵ_1	ϵ_2	n	k
Epitaxial GaAs* on spinel. Film thickness = 25 μm	15.195	3.602	3.925	0.459

* (111) surface.

using an ellipsometer and associated equipment as described in the literature (37). Prior to the measurements, the samples were polished and etched by mechanical and chemical means so that damaged surface structure was removed if present.

The optical constants (the real and imaginary parts of the refractive index n-ik) and the dielectric constants ϵ_1 and ϵ_2 (the real and imaginary parts of the complex dielectric constant ϵ_1-$i\epsilon_2$) were derived from the measurements. Typical values of n, k, ϵ_1, and ϵ_2 of the films were compared with those obtained on epitaxial GaAs grown on bulk GaAs, as shown in Table VII. It is apparent that the optical and dielectric constants of the heteroepitaxial GaAs are quite close to that of the homoepitaxial films.

Summary

Using the vapor-phase, organometallic deposition process, heteroepitaxial GaAs films on magnesium aluminate spinel substrates have been prepared and characterized. Data show that the GaAs epitaxial films are similar in physical and electrical properties to bulk GaAs. Ease of growth of GaAs on spinel increased with spinel orientation in the order (111) > (110) > (100). Small substrate off orientations (>1°) markedly change the ease of GaAs growth. Preanneal of the substrate in hydrogen at 1200°C prior to growth is not desirable, leading to poor film quality.

Electrical properties of the GaAs films are markedly affected by the purity of the source materials. Semi-insulating, p- and n-type GaAs films can be produced depending mainly on the impurity content of the source materials. Deliberate doping of the GaAs p-type using $(C_2H_5)_2Zn$ or n-type using H_2Se (and H_2S) is demonstrated. Both acceptor and donor mobilities are affected by crystalline defects in the film. The crystalline quality of the films improves with thickness. Optical properties of the films are consistent with bulk GaAs. Chemical polishing characteristics have been studied. Over-all, the characteristics of vapor-deposited GaAs films in spinel are adaptable to device fabrication.

Acknowledgments

The authors are grateful to B. J. Seabury, R. T. Smith, and J. T. McGinn for x-ray diffraction and electron microscopy work. They also wish to thank A. N. Saxena for ellipsometric work, D. A. Kramer for optical measurements, and N. Pastal for film deposition work. Valuable discussions with G. W. Cullen are appreciated. This research was jointly sponsored by the Air Force Materials Laboratory, Wright-Patterson Air Force Base, under Contract F33615-70-C-1536 and RCA Laboratories, Princeton, New Jersey.

Manuscript submitted June 4, 1973; revised manuscript received Sept. 7, 1973.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1974 JOURNAL. All discussions for the December 1974 Discussion Section should be submitted by Aug. 1, 1974.

Technical Notes

Microsegregation of Iron in Electrolytic Capacitor Grade Aluminum

Ronald B. Diegle

Corporate Research and Development Center, General Electric Company, Schenectady, New York 12301

Aluminum foil for use in electrolytic capacitors is customarily electrolytically and/or chemically etched to increase the surface area exposed to electrolyte. Impurity content of the Al has long been known to exert a profound influence on the response of foil to a particular etching process, *i.e.*, on its etchability.[1] However, although composition limits for major impurities are usually specified, there is still little understanding of how the identity, concentration, and distribution of these impurities affect the etching process.

Relatively little work is reported in the literature which elucidates the influence of trace impurities on Al etchability. Bakish *et al.* (1) noted a correlation between etchability and the concentration of major impurities in commercial grade Al, but variations in the microscopic distribution of these elements, that is, the states of microsegregation, were not investigated. (The term microsegregation as used in this paper refers to heterogeneities in impurity concentration, either in solid solution or as second-phase particles, on a microscopic scale.) Investigations into other areas of Al corrosion have also shown the importance of impurity content (2, 3), but microsegregation has not been considered. A notable exception was a two-part study by Biloni *et al.* (4) and Bond *et al.* (5), which conclusively demonstrated that distribution could be even more important than total impurity content in determining the tendency for pitting corrosion of Al in NaCl solution.

In this note preliminary results of the effect of microsegregation of Fe on the etchability of cold-rolled Al are reported. Iron was chosen as the impurity element for investigation for two reasons. First, it is the only element in the higher purity grades (Al content greater than about 99.8%) of Al for electrolytic capacitor use that precipitates extensively as a second phase during metallurgical processing. Such precipitates, nominally $FeAl_3$ from phase diagram considerations, could conceivably initiate undesirable corrosion during electroetching and thereby impair etchability (6). Second, the response of etchability to high temperature (600°-650°C) heat-treatments applied at various stages of ingot reduction was shown (7) to be both favorable, possibly indicating a detrimental role of impurity microsegregation established during casting, but quite sluggish, in accord with the very small diffusion rate of Fe in Al (8).

Material Preparation

Extensive equilibrium and nonequilibrium microsegregation of impurities occurs during the commercial casting of Al for capacitor use (7). It was therefore desired to produce microsegregation, in this case of Fe, in a controlled manner in laboratory ingots, and to preserve it to the foil stage for evaluation of its influence on etchability. Precipitation from supersaturated solid solution was chosen as the technique, both because it is more conveniently performed than controlled solidification, and because it has already been studied in detail in the Al-Fe system (9).

An Al-400 ppm (weight) Fe alloy was prepared from 99.9999% Al[2] and an Al-1.8 weight per cent (w/o) Fe master ingot. The melt was homogenized and vacuum chill cast, after which the ingot was sectioned into slices 0.95 by 1.41 by 0.18 cm. Some of the slices were homogenized by soaking at 645°C in air for 96 hr followed by water quenching. The quenched slices were next annealed for 1 min in a fused salt bath at 250°C to reduce the concentration of vacancies and dislocation loops formed during quenching from 645°C (9). Examination in the transmission electron microscope (TEM) of thinned sections of homogenized ingot verified that essentially all of the Fe was in solid solution. To produce different stages of nucleation and growth of $FeAl_3$, some of the homogenized slices were aged at 350°C for times ranging from 2 to 140 hr, quenched, aged 1 min at 250°C, and again quenched. Representative aged ingot specimens were selected for examination in the TEM. The remaining slices were lightly abraded and chemically etched to provide a clean surface for rolling, and were then cold-rolled in a hand mill to 90μ thickness, a reduction of 95%.

Determination of Etchability

As-rolled foil specimens were sectioned into strips 1.8 cm wide and 6 cm long and electropolished in an ethanol-perchloric acid mixture to establish a standard surface condition. To evaluate the effect of this surface preparation on etchability, some foils were instead etched 1 min in 30% NaOH solution at 23°C. Electroetching was performed for 54 sec at an anodic current density of 775 mA/cm^2 in 20% NaCl solution at 90°C. Certain foils were electroetched only 3 sec for the purpose of studying the morphology of etch initiation. Etched specimens were washed and dried, chemically etched in nitric acid diluted 2 to 1 with water for 2 min to remove traces of chloride ion, and again washed and dried. A 50V anodic film was formed on each specimen using previously described techniques (10), and the capacitance of specimens etched for 54 sec was measured (10).

Microstructural Evaluation

Specimens of unaged ingot and ingot aged for different times at 350°C were electrochemically thinned by conventional techniques and studied with the TEM. A nucleation time of slightly less than 48 hr was noted, since no precipitates could be resolved after 19 hr of aging, but they were beginning to develop after 48 hr. (Resolution was about 30Å.) The appearance of a few

Key words: aluminum etchability, tunnel corrosion, precipitation.

[1] Etchability as used here refers to the total area of foil contributing to capacitance after etching and anodic film formation. It is proportional to the specific capacitance of foils etched under identical conditions and anodically formed to a particular voltage.

[2] Purchased from United Mineral and Chemical Corporation, Metals Division, New York, New York.

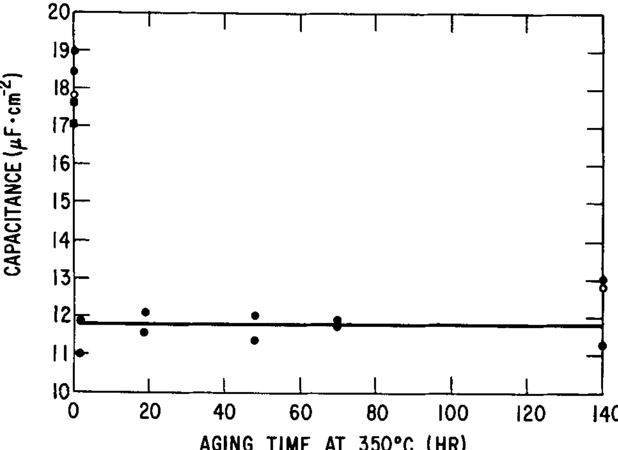

Fig. 1. Capacitance at 50V formation of cold-rolled Al-400 ppm Fe foil vs. ingot aging time at 350°C. Shaded circle, ingot homogenized and aged at 350°C for time indicated; open circle, ingot homogenized and aged for time shown, but foil etched in 30% NaOH instead of electropolished before electroetching; shaded square, ingot neither homogenized nor aged before rolling to foil.

particles after 48 hr of aging at 350°C is in good agreement with the work of Miki and Warlimont (9) who measured a nucleation time of 40-50 hr at 389°C for Al-400 ppm Fe.

Particles typically were 0.1μ long and 0.05μ wide after 48 hr of aging, and they grew to about 0.4 by 0.1μ after 140 hr. The number of particles per unit volume, which was determined from foil thickness and areal particle densities in TEM micrographs, was within a factor of 3 of 10^{13} cm^{-3} and was independent of aging time for times of 70 hr and greater.

Since dislocation substructure influences the etchability of cold-rolled foil, it was desired to know whether different degrees of microsegregation in the ingot affected the substructure produced by cold-rolling. The very large dislocation densities produced by 95% reduction in thickness precluded any attempts to study dislocation morphology in detail, so subgrain size was chosen to characterize dislocation substructure. Subgrain sizes, which were calculated by the linear intercept method from several micrographs of each foil, were between 0.7 and 0.85μ. Since variations in size were within the ±10% limit of experimental error, no effect of microsegregation on subgrain size was found.

Effects of Microsegregation on Etchability

A remarkable effect on etchability produced by microsegregation of Fe in ingot is shown in Fig. 1. Etchability decreased precipitously as a result of only 2 hr aging, which is far less than the minimum time required for homogeneous nucleation and growth of $FeAl_3$ in this alloy. Almost as surprising is the fact that etchability was not affected by the onset of precipitation of $FeAl_3$, which occurred between 19 and 48 hr of aging. (The foils used in this work certainly contained a sufficient number of particles to permit evaluation of their effect on etchability. For instance, a very conservative estimate of the number of particles intersecting the surfaces of foils rolled from ingots aged 70 hr or more is 2×10^7 cm^{-2}, based on the assumption that the only particles which intersect lay within an imaginary layer next to the surface of depth equal to the minimum particle dimension, about 0.02μ. This is three orders of magnitude greater than the surface particle density of about 10^4 cm^{-2} experimentally determined from a typical commercial foil lot of 99.88% purity. It should be noted, however, that solid-state precipitation produced particles of submicron size, whereas typical commercial casting results in precipitates several microns in diameter.)

To learn more about the effect of short time aging on etchability, oxide replicas were made of foils etched for 3 and 54 sec, lifted, and examined with the scanning electron microscope (11). Comparison of Fig. 2a and 2b shows that the formation of individual etch tunnels in the first 3 sec of electroetching was severely inhibited due to aging of the ingot for just 2 hr. The reason for the lower capacitance of fully etched foil is shown in Fig. 2c and 2d, which illustrates that a much coarser, less intricate tunnel structure developed as a result of ingot aging.

Prismatic dislocations formed by vacancy condensation during quenching from 645°C were largely removed during the first 250°C anneal, as observed by Miki and Warlimont (9) and verified in this study. Therefore, there are only two phenomena which might reasonably be expected to have occurred in ingot during the initial 2 hr of aging at 350°C. The first is clustering of Fe atoms in the Al matrix. Since particles as small as 30Å could not be detected after 19 hr, such clustering was certainly a preprecipitation or prenucleation phenomenon resulting only in solid solution microsegregation. (The morphology of preprecipitation in the Al-Fe system has not been studied in nearly as much detail as in, for example, the more important Al-Cu system.) The second occurrence is heterogeneous nucleation and growth of $FeAl_3$ on such preferred sites as grain boundaries and grown-in dislocations, thus producing two-phase microsegregation. The contribution to the final particle density of 10^{13} cm^{-3} by heterogeneous nucleation within 2 hr of aging was negligible for two reasons. First, since no precipitates were detected after 19 hr, relatively few nucleated as early as 2 hr. Second, it was demonstrated by both low temperature resistivity measurements and transmission electron microscopy that only homogeneous, not heterogeneous, nucleation occurs in Al-400 ppm Fe at aging temperatures below 470°C (9). Thus the most reasonable explanation for the disruption of tunnel corrosion during electroetching is preprecipitation clustering of Fe atoms during aging times somewhat less than 48 hr. Moreover, since etchability did not increase after the transition of these clusters to discrete $FeAl_3$ precipitates, which proceeded during aging beyond about 48 hr, it is evident that these precipitates were equally detrimental to etchability.

Conclusions

Evidence has been presented that microsegregation of Fe in Al occurring at the ingot stage can reduce the capacitance of cold-rolled foil by as much as 40%, or about 7 μfarad/cm^2. Such microsegregation initially was most likely caused by preprecipitation clustering of Fe atoms, but after about 48 hr of aging it was manifest as discrete submicron size $FeAl_3$ particles. Although the postnucleation stage of microsegregation could be detected by conventional electron optical techniques, prenucleation stages could not. The effect of microsegregation was to impede development of the intricate tunnel network normally produced during the electroetching process. Future work should attempt to establish the precise mechanism by which microsegregation disrupts tunnel corrosion in Al, and to determine the possible effects on etchability caused by segregation of other impurites, such as Si, Mg, and Cu, normally present in capacitor grade Al.

Acknowledgments

Optical Absorption and Electrical Conductivity of SiC Films Produced by Ion Implantation

W. Rothemund and C. R. Fritzsche*

Institut für Angewandte Festkörperphysik der Fraunhofer-Gesellschaft, D-78 Freiburg, West Germany

Within the past few years, silicon carbide has gained increasing importance as a material for high-temperature semiconductor devices. It is as well an interesting material from a scientific point of view. The preparation of this material by conventional techniques of crystal growth is difficult, and attempts have been made to produce carbide films by reaction of solid silicon with hydrocarbons or by pyrolytic deposition (1). Temperatures of 1100°C and more are needed for these techniques. Implantation of carbon ions into silicon and subsequent annealing at 800°C and above offers an alternate method of obtaining silicon carbide (2, 3). Until now, only results of implantations with one single energy have been reported, and only isolated grains of SiC surrounded by silicon have been obtained. The present paper reports on attempts to produce continuous SiC layers by multiple implantations with various energies and provides some information on the optical absorption in the visible and infrared regions and on the electrical conductivity of these layers from which their quality can be estimated.

Experimental

$C^+{}_{12}$ ions were implanted at room temperature into 500 ohm-cm, n-type, single-crystal silicon wafers. The wafers were (111) oriented and polished on both sides. Either three or four implantations were made with energies of 50, 30, and 15 keV or 70, 50, 30, and 15 keV, respectively. Typical beam current densities were approximately 10 μA cm^{-2} with respect to the implanted area. Fluences were chosen so that the peak concentrations for each single implantation were 10^{23} cm^{-3}, *i.e.*, the single fluences were on the order of 10^{18} cm^{-2}. These concentrations were calculated according to the theory of Lindhard, Scharff, and Schiott (LSS) from the tables of Johnson and Gibbons (4). Since the crystal axis was tilted 7° from the beam axis, we assume that LSS theory applies in good approximation at the beginning of the implantations. When the carbon concentration becomes high, the contribution of the implanted ions to the stopping power will cause a reduction of the penetration depth. No corrections according to this effect were made.

At high fluences, as used in our work, the maximum concentration can be limited by sputtering if the surface recedes substantially. Therefore, we investigated the step appearing at the border of a limited area implanted with 15, 30, 50, or 70 keV $C^+{}_{12}$ ions. While from the 15 keV implantation a sputtering coefficient of 0.2 atoms per incident ion was estimated, the other implantations did not result in a measurable surface erosion. EerNisse (5) has reported on the energy dependence of the sputtering yield of noble gas ions into silicon and his data consist well with our observations.

The effect of sputtering on the maximum ion concentration for Bi into GaAs was investigated by Tinsley *et al.* (6). They found a saturation of the retained dose at a fluence of about 5×10^{16} cm^{-2} at 60 keV. In this case, the sputtering coefficient is 4.4 atoms/ion and the projected range is 170Å. In our 15 keV implantation, the corresponding values are 0.2 atoms/ion and 480Å. Comparing all these data, we find that the saturation effect will be negligible at least for our 30, 50, and 70 keV implantations. This can also be concluded from the fact that after multiple implantations the implanted surface was always above the silicon surface.

The calculated implantation profile is shown in Fig. 1. It can be seen that over a range of about 3000Å the total ion concentration is higher than 5×10^{22} cm^{-3} and thus sufficient to convert all the silicon within this range into carbide. If the 70 keV implantation is omitted, the expected carbide range is only 2000Å.

Annealing was made in nitrogen or vacuum so that results of the *IR* absorption studies could be compared to those of Borders *et al.* (2). Only vacuum annealed samples were used for the electrical measurements. *IR* spectra were measured with a Beckmann IR 9 spectrometer. For the electrical measurements, gold electrodes of various sizes and shapes were evaporated onto the carbide layer. Contact to the back side of the silicon was also made by evaporated gold. The spectral distribution of the photovoltaic effect of the Au-SiC-Si-Au structure was determined using the monochromator section of a Baird SF-100 spectrophotometer.

Results

The *IR* absorption spectrum of the implanted silicon in the range of wave numbers 400-3600 cm^{-1} shows only one band which can be attributed to SiC. Before annealing, this band is wide and has its peak at 750 cm^{-1}. The effect of annealing in nitrogen is shown in Fig. 2. Isochronal 15 min anneal treatments were performed at progressively higher temperatures. The band moves towards higher wave numbers with increasing anneal temperature, and its half-width decreases considerably, both effects being most pronounced between 800° and 850°C. The band approaches the transversal optical (TO) phonon absorption at 794 cm^{-1} (7, 8) for both α- and β-SiC and the shift is almost finished at 1000°C. The half-width, however, decreases distinctly up to at least 1300°C. When annealing was carried out in vacuum at 10^{-2} Torr, or when the 70 keV implantation was omitted, the behavior of the TO phonon absorption was approximately the same as described by Fig. 2.

In the visible range, the optical properties cannot be investigated by transmission spectroscopy because of absorption by the silicon substrate. Reflectance was

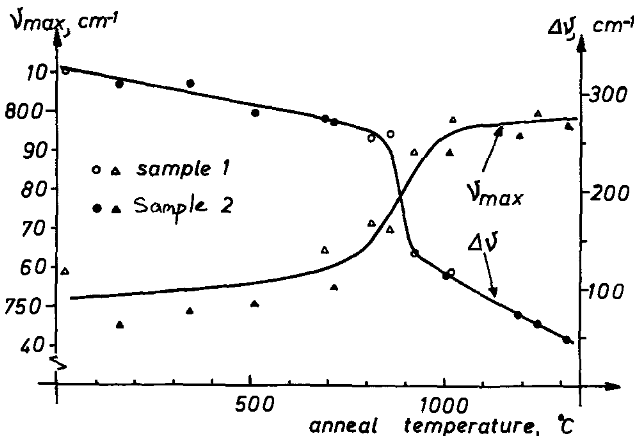

Fig. 2. Annealing of carbon implanted silicon; wave number ν_{max}, and half-width $\Delta\nu$ of the main *IR* absorption band as a function of anneal temperature.

measured and was found to be high in the range from 550 to 800 nm, but interpretation of the spectrum is difficult since reflection at the carbide as well as at the silicon surface, and consequently also absorption in the carbide, determine the reflected intensity. From the electrical measurements described below, we conclude that the range of high reflectance is determined by the transmittance of the carbide.

The electrical conductivity of layers implanted with four different energies was determined from bridge measurements between various combinations of electrodes on top of the implanted layer. After annealing for 30 min at 1300°C in vacuum of 10^{-1}-10^{-2} Torr, resistivities between 10^{-2} and 10^{-3} ohm-cm were found. No substantial current-voltage nonlinearity was observed. However, when contact is made to one electrode on top of the SiC layer and to one electrode on the back side of the silicon wafer, samples show rectifier characteristics and a photovoltaic effect on the carbide side. The devices are blocking if the carbide side is negatively biased, and the polarity of the carbide side is positive if the unbiased sample is illuminated. Because of the high conductivity of the carbide the photoelectric effect can be assumed to take place in the silicon, and we consider the device to be a Schottky diode with a transparent electrode rather than a heterojunction.

Since only a part of the silicon surface was implanted, we were able to compare photodiodes with and without a SiC cover. If the photocurrent, J_2, of the SiC-Si device is divided by that of the silicon diode, J_1, the intensity distribution of the light source as well as the spectral response of the silicon is eliminated, and the quotient is proportional to the transmittance of the carbide. The result of this evaluation is shown by the solid line in Fig. 3. The dashed line indicates the absorption edge of β-SiC after Lely and Kröger (9). Visually, the color of our layers is between green and yellow.

Discussion and Conclusions

The absorption band at 800 cm^{-1} in Fig. 2 corresponds to TO phonons in SiC, and the absorption edge at about 2.25 eV in Fig. 3 is close to that of cubic SiC. This indicates that implantation of carbon ions into silicon, with a profile according to Fig. 1 after annealing at 1300°C, results in silicon carbide which is similar to the cubic β-SiC, but probably has still a high disorder.

The infrared spectrum of our samples has some properties in common with the one reported by Borders *et al.* (2) which was obtained after single-energy implantation. In both cases, the broad, featureless absorption band at 750 cm^{-1}, which is observed immediately after implantation and after annealing to temperatures less than 800°C, can be interpreted to be due

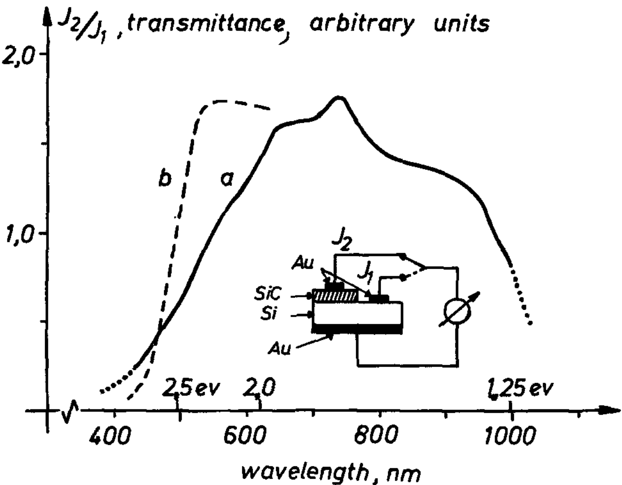

Fig. 3. (a) Transmittance spectrum of the SiC layer as estimated from photovoltage measurements. (b) Band edge of β-SiC, as in Lely and Kröger (9).

to Si-C stretching modes in regions of high disorder possibly overlapped by the local mode of highly concentrated carbon in silicon. In both cases, the band approaches the transversal optical frequency of SiC [see Spitzer *et al.* (7, 8)] after annealing at temperatures close to 900°C. An essential difference is found after annealing at temperatures above 900°C. While Borders *et al.* state that annealing is complete by 875°C and no change is observed in the band upon further anneals to 1000°C, we observe a pronounced decrease in the band half-width up to 1300°C. It is likely that at the carbide/silicon interface disorder and deviations from stoichiometry cannot completely be removed by annealing. A lower limit of the half-width is thus determined by the volume ratio of bulk SiC and disordered interface regions. Therefore, our results mean that the interface is relatively small in our samples and a continuous layer may have formed. That maximum order is not yet achieved, even in our samples, can be concluded from the lack of saturation in the half-bandwidth annealing curve.

As to the optical properties in the visible range, Knippenberg (10) has concluded from an investigation of several SiC polytypes that the bandgap is the smaller the lower the single-bond energy. Thus, the difference between the band edge of β-SiC and the edge resulting from our measurements could possibly be explained by a lower, single-bond energy in our samples. However, according to Lely and Kröger (9), the edge could also be shifted by a high nitrogen content. These authors also report that nitrogen-doped hexagonal SiC shows a narrow band at 620 nm and a broad band extending from 900 nm into the near infrared. Corresponding bands seem to appear in our material, and it may be the superposition of these bands which causes the transmittance peak at 720 nm in Fig. 3. Lely and Kröger (9) have correlated quantitatively their optical and electrical measurements with the nitrogen content. Comparison of the spectra indicates a nitrogen concentration of about 2×10^{19} cm^{-3} in our samples.

Approximately the same value is obtained from the electrical measurements. For high carrier concentrations, Lely and Kröger (9) report mobilities of about 14 and 9 cm^2/V-sec for electrons and holes, respectively. The resistivity of our samples is less than 10^{-2} ohm-cm, hence the carrier concentration is higher than 4.5×10^{19} cm^{-3} if the layer is n-type and 7×10^{19} if the layer is p-type. There definitely are no donors or acceptors other than nitrogen or lattice defects that could have been introduced in such high amounts during implantation or annealing. The assumption of n-type conductivity results in a better agreement of the carrier concentrations estimated from electrical and optical measurements, respectively. Nitrogen is likely

to be the donor, since its presence in our layers is indicated by the absorption spectrum as discussed above.

The high conductivity indicates that the layer cannot consist of SiC grains imbedded in low-conductive, 500 ohm-cm silicon. To get direct information on the structure, we investigated electron diffraction patterns of layers implanted only with an energy of 50 keV and of layers formed by multiple implantations. Neither of these layers showed the pattern of cubic β-SiC. However, in contrast to the single-energy implanted layer, the multiple-energy implanted layer showed a pattern which definitely is not caused by silicon. It resembles the pattern of a mixture of the diamond and the cubic form of graphite reported by Aust and Drickamer (11), but differs from it in the ring diameters by more than the experimental error. Whether or not this is due to a special form of SiC cannot be stated by these preliminary measurements. At least they indicate that the two types of implantations result in different layer structures.

We have shown that multiple-energy implantations of carbon into silicon result in a carbide which is amenable to more detailed physical investigations than reported until now. Because of its high conductivity and the low half-width of the TO phonon band obtained after annealing at 1300°C, the carbide is supposed to form a continuous layer. Improvement of the layer quality may be possible with respect to the nitrogen content, which is perhaps due to a pressure gradient from the pump to the hot parts of the furnace tube used for annealing. A lower nitrogen content should be obtainable with suitable experimental arrangements, as for instance annealing in argon instead of in a vacuum. Improvement of the crystal quality will be difficult, since at still higher anneal temperatures, one approaches the melting point of the silicon. Also, with respect to the lattice constant, silicon is not an ideal substrate for the growth of silicon carbide.

Acknowledgments

Thanks are expressed to J. Baars for helpful discussions and to W. Haydl for his suggestions concerning the manuscript. We are also very indebted to P. Buck who carried out the electron diffraction investigations.

Numerical Calculation of Impurity Redistribution during Thermal Oxidation of Semiconductors

R. H. Krambeck

Bell Laboratories, Murray Hill, New Jersey 07974

During a thermal oxidation, the impurities in a silicon wafer are redistributed; some impurity atoms are incorporated in the growing oxide and others diffuse to new locations in the silicon. By using Green's functions, Kato and Nishi (1) have obtained a solution to this problem, but a simplified numerical calculation is very much needed to obtain results quickly and cheaply. Recently this need has intensified because of the use of ion implantation followed by thermal oxidation to achieve threshold voltage control in IGFET's (2).

This note describes a calculation which solves the redistribution problem by the method of finite differences. The technique gives agreement with analytically checkable solutions to within less than 1%, an accuracy which is quite satisfactory for most applications. Moreover, the computer time used is low enough that the calculations can conveniently be carried out on a time sharing facility. The results of the calculations are in good agreement with published data (1) on the thermal oxidation of boron-doped silicon.

Key words: numerical analysis, silicon dioxide, solid-state diffusion, silicon.

Analysis

The motion of impurities during thermal oxidation of silicon is governed by the diffusion equation, but the solution of this equation is complicated by the motion of the oxide-silicon interface. Kato and Nishi (1) have shown that if diffusion in the oxide is neglected, and the spatial coordinate is transformed so the moving interface is always at $x = 0$, then the impurity concentration in the silicon, $C(x, t)$, obeys a modified diffusion equation of this form

$$\frac{\partial C}{\partial t} = D\frac{\partial^2 C}{\partial x^2} + mf'\frac{\partial C}{\partial x} \quad [1]$$

where x is the distance into the silicon in the direction normal to the interface, m is the thickness ratio of silicon consumed to oxide grown (0.44) (3), f' is the time derivative of the oxide thickness, and D is the diffusion constant of the impurity in silicon.

At the boundary between oxide and silicon ($x = 0$) the number of impurity atoms must be conserved. During a small time interval, Δt, the amount of silicon oxidized is $mf' \cdot \Delta t$. The impurities present in this layer,

$mC(0,t)f' \cdot \Delta t$, must be incorporated into the oxide or diffused into the silicon. The amount incorporated into the oxide is $kC(0,t)f' \cdot \Delta t$, where the segregation coefficient k is the ratio at the interface of impurity concentration in the oxide to the concentration in the silicon. The amount diffused into the semiconductor is $-D \frac{\partial C(0,t)}{\partial x} \cdot \Delta t$. Conservation of impurity yields

$$mC(0,t)f' \cdot \Delta t = kC(0,t)f' \cdot \Delta t - D \frac{\partial C(0,t)}{\partial x} \cdot \Delta t$$

or

$$D \frac{\partial C(0,t)}{\partial x} = (k - m)f' C(0,t) \qquad [2]$$

The initial impurity distribution $C(x,0)$ is presumed to be a known function.

Although the diffusion equation is normally solved for the semi-infinite case in which the distance x extends to infinity, for the purposes of numerical calculation it is necessary to confine the sample mesh to a finite interval. Further, the region within a micrometer or two of the interface is of most interest, so it is desirable to concentrate the mesh points near the interface to increase both resolution and precision. These objectives have been achieved by transforming the distance x, which extends over the interval $0 \leq x \leq \infty$, to a new spatial variable u which is defined on the interval $0 \leq u \leq 1$. The particular transformation chosen was hyperbolic, since this gives the best compromise between a high density of points at the interface and a reasonable density deeper in the semiconductor

$$x = \frac{1}{A} \frac{u}{(1-u)}$$

where A is a scaling constant. Substitution into Eq. [1] gives

$$\frac{\partial C}{dt} = DA^2(1-u)^4 \frac{\partial^2 C}{\partial u^2} - 2DA^2(1-u)^3 \frac{\partial C}{\partial u} + mf'A(1-u)^2 \frac{\partial C}{du} \qquad [3]$$

for the basic equation, and from Eq. [2] the condition at the growing interface is

$$AD \frac{\partial C(0,t)}{\partial u} = (k-m)f'C(0,t) \qquad [4]$$

To solve Eq. [3], the interval $0 \leq u \leq 1$ is divided into N equal segments, and the value of C at each node is designated $C_0, C_1, \ldots, C_N$. Time is divided into appropriate increments also but these are not necessarily equal. In using the finite difference technique, the time derivative is taken to be constant over a given time increment. Since the derivative actually changes with time, it is necessary to decide what value to adopt for the calculation. The only way to obtain a stable solution is to choose the value at the end of the increment, and this is the choice that was made. When Eq. [3] is rewritten in terms of finite differences in this way, it becomes

$$\frac{(C_{j,n+1} - C_{j,n})}{\Delta t} = DA^2(1-u)^4 \frac{C_{j+1,n+1} + C_{j-1,n+1} - 2C_{j,n+1}}{(\Delta u)^2} - DA^2(1-u)^3 \frac{C_{j+1,n+1} - C_{j-1,n+1}}{\Delta u} + mf'A(1-u)^2 \frac{C_{j+1,n+1} - C_{j-1,n+1}}{2\Delta u} \qquad [5]$$

where the first subscript to C indicates a position on the transformed spatial mesh and the second subscript indicates a time. Note that from Eq. [3], the right side of Eq. [5] equals the value of the time derivative at the end of the time increment, and that Eq. [5] sets the average time derivative equal to this. There are $(N-1)$ of these equations, corresponding to $j = 1$ through $j = (N-1)$, but there are a total of $(N+1)$ unknowns. One additional equation is

$$C_{N,n+1} = C_{N,n} \qquad [6]$$

because C_N is the concentration at $x = \infty$ and cannot change with time. Finally, the boundary condition, Eq. [4], provides

$$AD \frac{C_{1,n+1} - C_{0,n+1}}{\Delta u} = (k-m)f'C_{0,n+1} \qquad [7]$$

This set of $(N+1)$ equations can now be solved simultaneously for the values of C at the time $(n+1)$. (The solution of the simultaneous equations is simplified by the tridiagonal nature of the matrix. The method of solution is described in the Appendix.) These values can then be used to obtain the values of C at the end of the next time increment, again using Eq. [5]-[7]. To obtain results with at least 1% accuracy, the following parameters have been used

$$N = 500$$

$$t(\text{hr}) = n^2(10^{-4})$$

$$A(\text{cm}^{-1}) = \left(\frac{0.02}{D}\right)^{1/2} (5 \times 10^4)$$

where D is in μm^2/hr.

The selection of a nonlinear mapping of time does not affect the solution of Eq. [5] at all, and it allows the solution to proceed expeditiously even though the diffusion process slows as time goes on.

Results

Solutions were obtained for various conditions of oxide growth for both phosphorus- and boron-doped silicon. Two mathematical tests were made to check the accuracy of the results. For the first test, k was set equal to 0. For this value all impurities remain in the silicon, and the integral of impurity concentration must be constant. Therefore, the total change in the calculated value of this integral is a good measure of the error in the calculation. This test was used for an initial implanted doping 0.1 μm deep with a Gaussian distribution contour and a straggle of 0.02 μm. In Fig. 1, contours of constant error (using this test) are shown as a function of parabolic growth rate constant and diffusion constant. Also shown are representative points indicating the values of these constants for the wet and dry oxidation of phosphorus- or boron-doped silicon. The errors are generally no more than 1% in the region of interest.

For the second test, a uniform initial impurity distribution and a parabolic oxide growth rate were assumed. Under these conditions the surface concentration becomes constant at a value that can be determined analytically (4). The values obtained by using the numerical calculations did become constant. Figures 2 and 3 show the contours of constant difference between the numerical and analytical values of surface concentration for segregation coefficients of 3 and 0.03, respectively. The errors in surface concentrations calculated numerically are generally below 1%. It should be noted that the lower segregation coefficient (greater rejection of impurity by the oxide) produced larger errors than the higher coefficient. These results, together with those of the first test, indicate that the numerical solution is accurate to $\pm 1\%$ for a wide range of conditions, including those associated with the wet or dry oxidation of silicon doped with boron or phosphorus in the temperature range 1000°-1150°C.

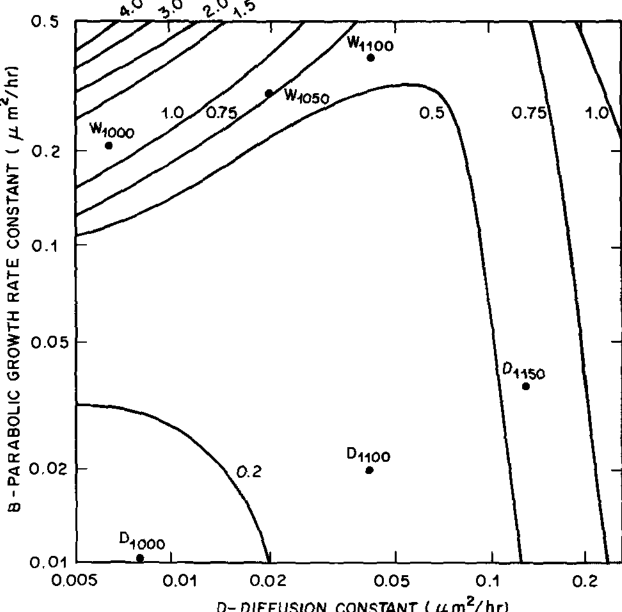

Fig. 1. Contours of constant error (as a percentage) in retained impurity dose when the oxide completely rejects the impurity ($k = 0$). The error shown is the highest error found in the first hour of growth. Initially, implant depth = 0.1 μm and spread is 0.02 μm. Typical conditions of silicon oxidation are indicated by W for wet and D for dry with the subscript showing temperature (°C), using as diffusion constant the average of the diffusion constants of boron and phosphorus.

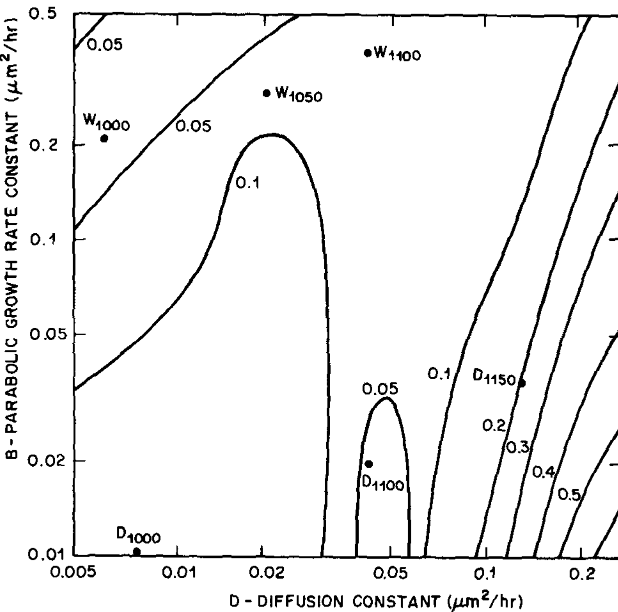

Fig. 2. Contours of constant error (as a percentage) for surface concentration, assuming parabolic oxide growth, an initially uniform impurity distribution, and a segregation coefficient of 3. The concentration was calculated for 2 hr of growth. The points labeled W and D again show typical oxidation conditions, as in Fig. 1.

Next, solutions were compared to experimental data previously published. Figures 4 and 5 show the diffusion data presented by Kato and Nishi (1). Here the predeposition of boron was made by diffusion. The diffusion constant and oxide growth rate are the same as those used by Kato and Nishi to match the data with their calculation. The segregation coefficient was found to be 8 using the method described in this paper, as compared to 10 in their work. The reason for the difference is not clear.

Conclusions

A straightforward numerical solution has been obtained for the problem of redistribution of impurities during thermal oxidation of a semiconductor. The solution matches known analytical solutions and gives good agreement with experimental data. The fact that the program is fast enough to use on a Honeywell 600 time sharing facility with less than 1 min delay for a 2 hr oxidation should make it a valuable tool for investigation and process characterization.

Also shown is the calculated curve for $k = 8$, $D = 0.72$ μm²/hr, $t = 3100$ sec, $f = (0.0367$ μm²/hr$)^{1/2}$ cm. The theoretical value for retained dose is 8.7%.

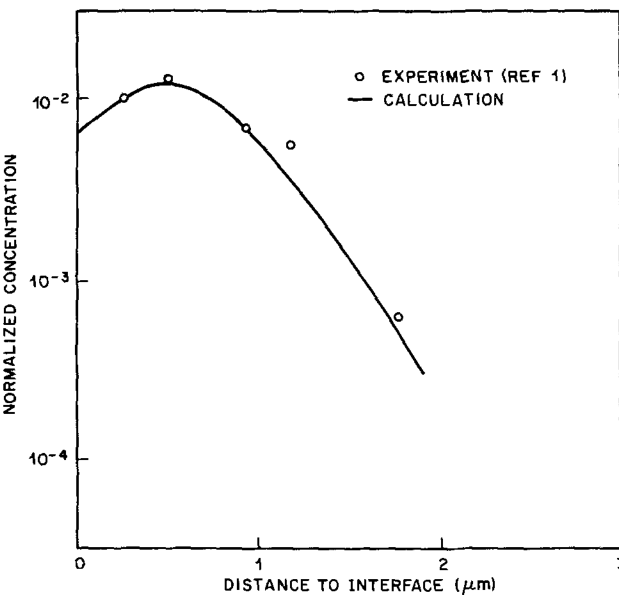

Fig. 5. As for Fig. 4 but with $D = 0.216$ μm²/hr. The theoretical value for retained dose is 2.6%.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1974 JOURNAL. All discussions for the December 1974 Discussion Section should be submitted by Aug. 1, 1974.

APPENDIX

The first step in solving Eq. [5]-[7] is to rewrite Eq. [5] with the unknowns on the left

$$C_{j-1,n+1}A_j + C_{j,n+1}B_j + C_{j+1,n+1}E_j = F_j \quad \text{[A-1]}$$

where

$$A_j = -DA^2(1-u)^4/(\Delta u)^2 - DA^2(1-u)^3/\Delta u + mf'A(1-u)^2/(2\Delta u) \quad \text{[A-2]}$$

$$B_j = +2DA^2(1-u)^4/(\Delta u)^2 + 1/(\Delta t) \quad \text{[A-3]}$$

$$E_j = -DA^2(1-u)^4/(\Delta u)^2 + DA^2(1-u)^3/\Delta u - mf'A(1-u)^2/(2\Delta u) \quad \text{[A-4]}$$

$$F_j = C_{j,n}/(\Delta t) \quad \text{[A-5]}$$

Thus F_j is determined by the impurity distribution at the beginning of the time increments. The other two equations are

$$C_{N,n+1} = C_{N,n} \quad \text{[A-6]}$$

and

$$\frac{C_{0,n+1}}{C_{1,n+1}} = \frac{AD/(\Delta u)}{(k-m)f' + AD/(\Delta u)} \quad \text{[A-7]}$$

The tridiagonal nature of the matrix associated with these equations makes a solution rather easy to obtain. The technique [as shown, for example, by Strain and Schryer (5)] begins with the calculation of two intermediate sets of numbers

$$G_j = -\frac{A_j}{B_j + E_jG_{j-1}} \quad \text{[A-8]}$$

and

$$H_j = \frac{F_j - E_jH_{j-1}}{B_j + E_jG_{j-1}} \quad \text{[A-9]}$$

where G_0 is the ratio of $C_{0,n+1}$ to $C_{1,n+1}$ given by Eq. [A-7] and $H_0 = 0$. Values of G and H are calculated for all values of j from 1 to $N - 1$. Next these values of G and H are used to find the new values of concentration

$$C_{j,n+1} = G_jC_{j+1,n+1} + H_j \quad \text{[A-10]}$$

where C_N is given by Eq. [A-6]. This gives values for concentration at the end of the time increment. These values can now be used to obtain new values for F_j in Eq. [A-5] and the process repeated to obtain the values of C at the end of the next time increment. This procedure can be followed very easily in a computer analysis.

Brief Communications

Effect of Dielectric Insert on Surface Charge Density of Electrets

K. Ikezaki, I. Fujita, and K. Wada

Department of Instrumentation, Faculty of Engineering, Keio University, Yokohama, Japan

and J. Nakamura

Research and Development Department, Aiwa Company, Limited, Tokyo, Japan

In electrets there are two kinds of surface charge, referred to as heterocharge and homocharge. The heterocharge is associated with the internal volume polarization and has the opposite polarity to that of the adjacent forming electrode. On the other hand, it is widely believed that the homocharge, which has the

Key words: FEP Teflon, spray charge, thermoelectret, homocharge.

same polarity as that of the electrode, is due to a sparking break down in an air gap between sample and electrode (1).

The decay of the heterocharge is so rapid as compared with that of the homocharge in most electrets, that an electret with a net homocharge has attracted much attention because of its practical application to the electret microphone (2).

In order to produce a film electret with a large homocharge without destruction of the sample by arcing during the polarization process, an appropriate dielectric is inserted between sample and electrodes (3,4). Perlman and Reedyk produced FEP Teflon film electrets with a large homocharge (about 5×10^{-8} coulombs/cm^2) by applying a field of about 20 kV/cm at 120°C (3). They pointed out that the volume polarization of the dielectric inserts plays an important role for producing a large homocharge electret.

On the other hand, Sessler and West reported an ingenious method to get a large homocharge electret (about 5×10^{-7} coulombs/cm^2) at higher electric fields by preventing back-discharges which occur during removal of the electrode (4).

Recently we found that a fairly large charge density (about 2×10^{-8} coulombs/cm^2) is produced with applying relatively low fields (about 10 kV/cm) at room temperature by inserting a sheet of glass disk between a film sample and a negative (not positive) electrode. In this note we report the effect of the dielectric insert.

As we used one sheet of dielectric insert, there are two kinds of geometrical arrangement of the polarizing holder which are depicted schematically in Fig. 1: Case A, where a sheet of soda glass disk (0.75 mm thick) is inserted between the film and the negative forming electrode; and case B, where the glass disk is inserted between the film and the positive electrode.

The electret material used in this study is FEP Teflon film (12μ thick). Electrets were produced by applying a polarizing voltage V_p across the electrodes for a period of 10 min at room temperature. The net surface charge density of the electrets was measured by the vibration electrode method developed by Reedyk and Perlman (5).

The time variations of the surface charge density on the anode side of the sample stored at room temperature are shown in Fig. 2 for two kinds of electret, both of which were produced at room temperature by applying the same polarizing voltage of 700V. The absolute value and the time variations of the surface charge density on the cathode side of the sample are almost the same as those on the anode side, so that they are not presented in the figure. As shown in Fig. 2, the value of the produced surface charge density depends strongly on the position in which the glass disk is inserted. This effect also takes place when the electret is polarized at elevated polarizing temperatures.

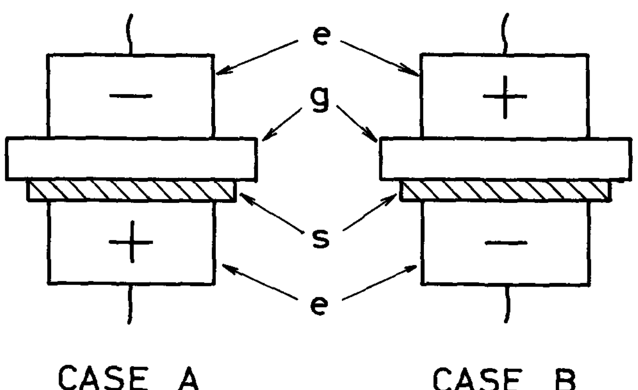

Fig. 1. Geometrical arrangements for electret forming. g, Glass disk; s, sample film; e, metal electrode.

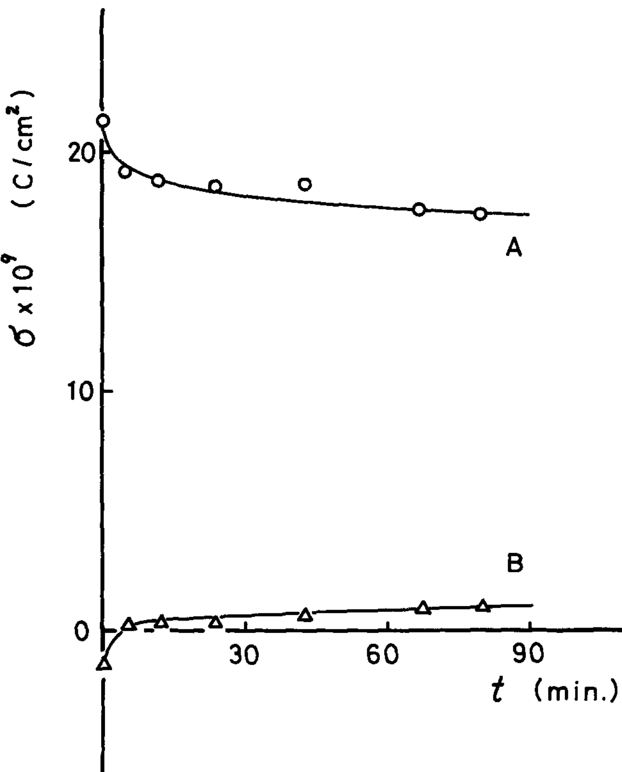

Fig. 2. Time variations of the surface charge density σ on the anode side of the FEP Teflon electrets. Curve A, polarized in the geometrical arrangement of case A; curve B, polarized in the geometrical arrangement of case B.

In our experimental conditions, when the polarizing voltage V_p is lower than about 300V, the produced surface charge density of the electrets was small both in case A and case B (Fig. 1). This is simply explained by the fact that the field strength in the air gap between the sample and the inserted glass disk is too low to bring about discharges in the gap. When V_p is higher than about 1000V, the surface charge density was very large in both cases. This large charge density is also explained simply by consideration of the fact that the field strength is high enough to spray charges in the gap. On the contrary, when V_p is between about 500 and 800V the value of the surface charge was different depending on the position of the inserted glass disk. Before the spray discharges occur, the field strength in the air gap between the sample and the glass disk are the same both in case A and case B. According to the theory of Perlman and Reedyk (3), applying a voltage between electrodes increases the polarization of the inserted glass disk and the field in the air gap. Eventually, this field will exceed the breakdown strength of the air in the gap and the spray discharge will occur. The homocharge deposition by this spray discharge reduces the field in the gap to a value below breakdown and the discharge is quenchd. The polarization of the inserted glass then continues to increase, and the cycle repeats. Therefore, the produced surface charge should be independent of the position where the glass disk is inserted.

Polarity effects which are often observed in the electrical breakdown of solid dielectrics in the nonuniform field (6) suggest that our observed effect of the dielectric insert may be associated with the different initiation voltages for the breakdown in the gap.

The observed effect of the inserted glass disk cannot be fully explained at this stage. This problem is now under investigation.

Determination of Boron and Oxygen Surface Contamination due to Common Solvents by Nuclear Microanalysis

J. C. North and E. C. Lightowlers[1]

Bell Laboratories, Murray Hill, New Jersey 07974

During the course of our work on nuclear microanalysis (1), a source of large background signal was traced to boron contamination of sample surfaces which originated from the solvents used to "clean" the samples. Following this discovery, a systematic study has been made of several commonly used chemical solvents to determine the expected surface boron contamination from use of these solvents in cleaning wafers. Boron contamination levels can be large enough such that if a significant fraction of the boron were diffused into a Si device slice as electrically active acceptors during subsequent processing steps, the device characteristics could be adversely affected.

Experimental

Samples were prepared from polished high purity Si wafers cleaved into pieces ~1 cm square. They were cleaned by agitating them for ~10 sec in each of the following sequence of chemicals: deionized water, HF, deionized water, HNO_3, deionized water, HF, and deionized water. The cleaned slices were hydrophobic. Several of these pieces were used as controls. A new sealed bottle of each solvent to be tested was then opened, and some of the contents was poured directly over the surface of one of the Si samples while it was held from the back side by vacuum forceps. The solvent was allowed to dry on the sample. In general, as a solvent dries, it recedes to small droplets on the surface of the Si. After these droplets evaporate, several of the solvents left visible residue spots.

Nuclear microanalysis was used to determine both the surface boron and surface oxygen concentrations. Prompt α-particles resulting from the reaction of 685 keV incident protons with ^{11}B and ^{18}O were detected. The nuclear reactions are

$$^{11}B(p,\alpha_1)^8Be^* \rightarrow 2\alpha_2 \text{ and } ^{18}O(p,\alpha)^{15}N$$

The relevant parameters of these reactions are given in Table I.

Figure 1 shows the α-particle spectra obtained from calibration standards which were prepared by implantation of ^{11}B and ^{18}O at 3 keV (range ~100Å) (7) into polished Si wafers, which closely approximate surface layers. The energy of the α-particles at the detector is reduced by a graded foil (1) which was used to prevent backscattered protons from reaching the detector. Figure 1 illustrates the relative sensitivity of this technique for surface ^{11}B and ^{18}O since the proton doses used were the same for both spectra and the ^{11}B and ^{18}O surface concentrations were nearly the same.

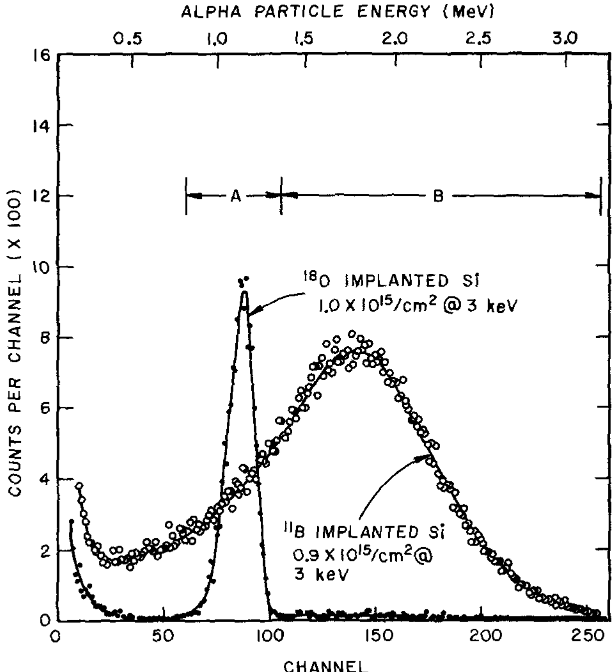

Fig. 1. Alpha-particle spectra obtained from calibration standards prepared by 3 keV implantations of ^{11}B and ^{18}O. Both spectra represent irradiations of 240 μcoulombs of 685 keV protons. The quantities of ^{11}B and ^{18}O represented by the spectra obtained from test samples were determined by comparison with these two spectra.

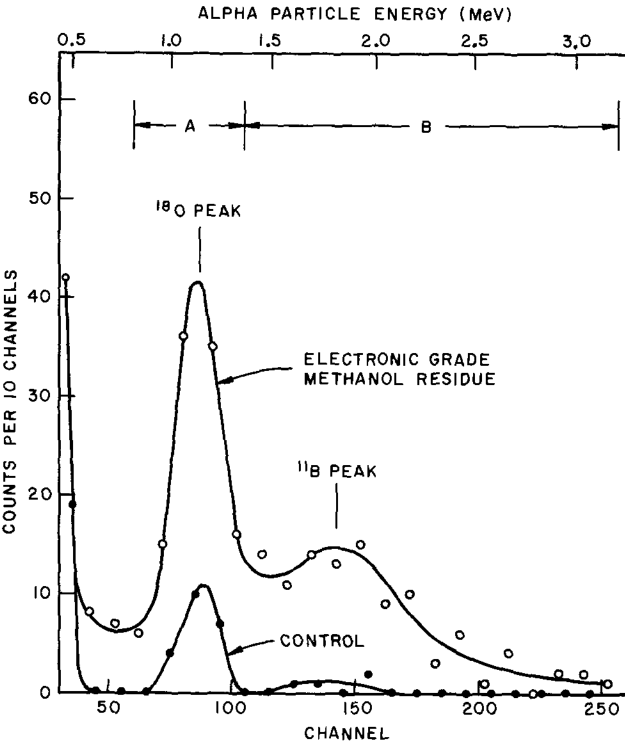

Fig. 2. Alpha-particle spectra of a control sample and a sample having residue on the surface from electronic grade methanol. The area of analysis included one of the visible residue spots left by the evaporated solvent. Both spectra represent proton irradiations of 120 μcoulombs. The average concentrations over the area of the incident proton beam for the control sample are $0.2 \pm 0.1 \times 10^{12}$ boron/cm^2 and $1.4 \pm 0.3 \times 10^{15}$ oxygen/cm^2. The corresponding concentrations for the methanol contaminated sample are $4.0 \pm 0.4 \times 10^{12}$ boron/cm^2 and $5.1 \pm 0.7 \times 10^{15}$ oxygen/cm^2.

Figure 2 shows spectra obtained for a control sample and a sample having residue on the surface from electronic grade methanol. The boron and oxygen concentrations are both much larger on the methanol contaminated sample.

The total surface concentration of boron or oxygen, N_2/cm^2, on the test samples was calculated by comparison with the calibration spectra of Fig. 1 using the expression

$$N_2 = N'_1 Q_1 n_2 / f Q_2 n_1$$

where the subscripts 1 and 2 refer to the calibration standard and test sample respectively, N'_1 is the concentration of ^{11}B or ^{18}O in the standard, f is the fractional natural abundance of the isotope ^{11}B or ^{18}O, Q is the proton flux, and n is the number of counts in the spectra attributable to ^{11}B or ^{18}O. With reference to Fig. 1, the count rate in spectral region B is due only to boron, while the count rate in region A is due to both oxygen and boron. Therefore, the quantities n in the above equation can be set equal to B (*i.e.*, the number of counts in region B) for boron. For oxygen, the boron background can be subtracted by setting n equal to $A - XB$ where X is the ratio of A/B for the boron spectrum of Fig. 1. The quantity $X = 0.275$.

Results

The polished silicon wafers as received from the supplier[2] were found to have surface boron concentrations of $\sim 4 \times 10^{12}$/cm^2. If a solvent such as methanol was poured onto the sample, the boron compounds were apparently dissolved by the solvent, and as the solvent evaporated the boron was collected into the residue spots. Average boron concentrations of $> 10^{14}$/cm^2 over the proton beam spot area have been observed if the beam area included one of these evaporation spots. After the samples were given the cleaning treatment described earlier, the surface boron concentrations were reduced to $\sim 0.2 \times 10^{12}$/cm^2.

The results for the solvents tested are shown in Table II. All samples were given the same initial cleaning procedure. For the solvents tested which left visible spots, two measurements were taken, one in an area containing no visible spots and another in a region which included one or more spots. The residue spots were much smaller than the proton beam diameter of 1.5 mm. The results given are the average concentrations over the entire area analyzed by the proton beam. Therefore, the concentrations of boron and oxygen in the evaporation residue spots were greater than the numbers shown by more than an order of magnitude. The absence of visible spots does not necessarily mean that residue spots of higher concentrations do not exist.

Among the solvents tested, the lower grades of methanol were particularly bad. The evaporation spots were clearly visible, and the measured average concentrations over the incident beam area were in the mid 10^{12}/cm^2 range, which means that the concentration in the evaporation spots was $\sim 10^{14}$/cm^2. To appreciate the significance of these concentration levels, it should be noted that if 10^{12} boron/cm^2 diffuses ~ 1 μm into the Si, the resulting volume concentration is $\sim 10^{16}$/cm^3.

If the measured boron concentration in an area containing no visible evaporation spots is smaller than the concentration of the control samples, as in the case of isopropanol, then it cannot be concluded that the boron in the evaporation spot originated from the isopropanol. The solvent may have collected some of the residual boron that was left from the cleaning procedure from a larger area and concentrated it in the residue spot. However, if the boron concentration is higher than the controls even in those areas where there are no visible residue spots, then the additional boron must have come from the solvent tested.

The total oxygen concentration on the control samples and on the test samples in regions of no evaporation spots was $\sim 1.5 \times 10^{15}$ oxygen atoms/cm^2. This

[2] Western Electric Corporation, Allentown, Pennsylvania.

Table II. Average boron and oxygen surface concentrations over the incident proton beam area following evaporation of the solvents listed. When visible residue spots remained, measurements were made both in areas which included such spots and in areas free of visible spots. The errors quoted are standard errors determined from the counting statistics alone.

Solvent	Brand	Grade	Boron (10^{12}/cm^2) Including spot(s)	Boron (10^{12}/cm^2) No spots	Oxygen (10^{15}/cm^2) Including spot(s)	Oxygen (10^{15}/cm^2) No spots
Average of 4 controls			—	0.2 ± 0.1	—	1.6 ± 0.4

Trichloroethylene			—	0.8 ± 0.2	—	1.7 ± 0.4
Cobene	Cobene		—	0.2 ± 0.1	—	1.1 ± 0.3
Chloroform	Baker	Reagent	—	0.1 ± 0.1	—	1.0 ± 0.3

corresponds to a SiO_2 thickness of only ~3Å. At least 30 min elapsed between the time that the samples were cleaned and the time that they were put in the vacuum chamber of the accelerator. The same samples were measured by ellipsometry which indicated that a film thickness of ~40Å was present. In a separate series of experiments (8) it was verified that the prompt α-particle technique and ellipsometry gave the same results for oxide thickness >50Å, but diverged significantly for thinner layers.

The nature of this surface layer which appears ~40Å thick by ellipsometry, but yet contains only enough oxygen to comprise ~3Å of SiO_2 is not yet understood.

It can be seen that in those cases where the boron concentration was large, the oxygen concentration was also much larger. The additional oxygen which appears as a result of the solvent is ~10^3 times the additional boron concentration due to the solvent.

Conclusions

1. Methanol, acetone, and trichloroethylene leave measurable quantities of boron on the surface of Si samples. Reagent and electronic grade methanol are particularly bad, since they leave visible evaporation residue spots having concentrations as high as ~10^{14}/cm^2.

2. Chemical solvents can collect an existing uniform surface boron contamination into spots of much higher concentration.

3. The $^{18}O(p,\alpha)$ technique is a usable method of determining oxide thickness down to the 3Å range, even though ^{18}O is only 0.2% abundant.

Acknowledgments

Etching Solution for Revealing P-N Junctions in PbS and $PbS_{1-x}Se_x$

H. Preier and H. Pfeiffer

AEG-Telefunken Forschungsinstitut, D-6000 Frankfurt am Main, Germany

Lead salts are of great interest as materials for light detection and light emission in the infrared region. The p-n junctions of such laser and detector diodes are mainly fabricated by diffusion. However, thus far no etchants have been reported which optically display p-n junctions in lead salts. Here we will report about an etching procedure for revealing p-n junctions in $PbS_{0.6}Se_{0.4}$ and PbS. The composition of the room temperature etch is as follows: 40 ml deionized H_2O, 1.5g $K_2Cr_2O_7$, 10 ml HCl (37%), 1.5 ml H_3PO_4 (85%). Before use, this etching solution was diluted in water (2 parts water, 1 part etchant).

An example for an etched p-n junction in PbS is shown in Fig. 1a. Here an n-type crystal grown by sublimation from the vapor phase with the carrier concentration of 3 × 10^{18}/cm^3 (77°K) was diffused in sulfur rich PbS powder ($Pb_{0.49}S_{0.51}$) at 550°C for 1 hr. Diffusion and etching occurred perpendicular to as-grown (100) faces. Before etching, the crystal was embedded in an epoxy resin and mechanically polished to remove the p-layer from the exposed (100) surface. For chemical polishing an etching procedure was used which was described recently (1). The embedded crystal was then dipped into the etching solution for 3-5 sec and afterwards was quickly rinsed in deionized water and methanol. As can be seen from Fig. 1 p-type PbS is more strongly attacked by the etchant. Therefore, the junction is revealed by the step which occurs between the p- and n-region as shown in Fig. 1a. The variation of the thermoelectric power across the sur-

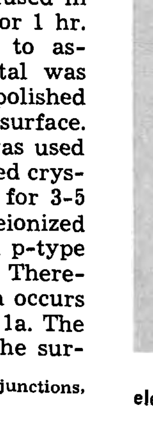

Fig. 1. a, Etched p-n junction in PbS; b, variation of the thermoelectric power across the junction.

Key words: PbS, $PbS_{0.6}Se_{0.4}$, etchant for revealing p-n junctions, IV-VI compounds.

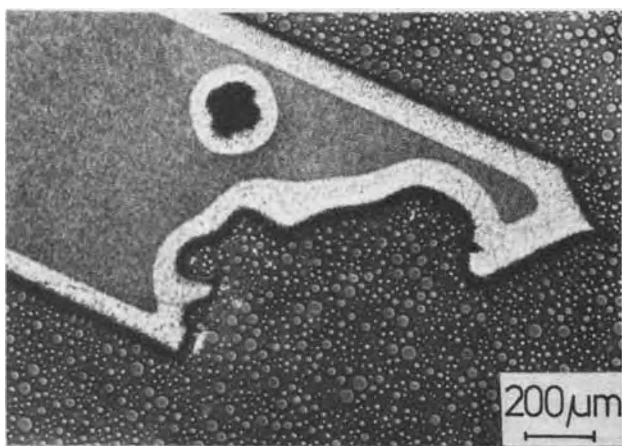

Fig. 2. Etched n-type $PbS_{0.6}Se_{0.4}$ crystal after diffusion in chalcogenide rich powder.

face of the etched PbS crystal was used as a controlling experiment for revealing the actual position of the p-n junction. The corresponding result is shown in Fig. 1b. A change of the sign of the thermoelectric power occurs exactly at the position of the etched step. This proves the agreement of the step with the position of the p-n junction and the usefulness of this etchant.

The same etching solution was also successfully applied to ternary lead salts. Here an n-type $PbS_{0.6}Se_{0.4}$ crystal with a carrier concentration of $4 \times 10^{18}/cm^3$ was diffused in $(S_{0.6}Se_{0.4})$ rich vapor at 550°C for 2 hr. An etched p-n junction in an irregularly shaped crystal is shown in Fig. 2. As can be seen, diffusion occurred also from a defect of the crystal surface. The junction depth as measured by thermal probe at 77°K was here about a factor of two smaller than the one revealed by etching. The latter effect is not fully understood yet and is presently being studied in detail.

The High Pressure Crystal Growth of Sodium Beta-Alumina

F. H. Cocks

Duke University, School of Engineering, Durham, North Carolina 27706

and R. W. Stormont

Tyco Laboratories, Incorporated, Waltham, Massachusetts 02154

Sodium beta-alumina is of considerable interest because of the high mobility of its sodium ions (1-4). Indeed, it has been suggested that beta-alumina may be "a prelude to a revolution in solid state electrochemistry" (5). Such high ionic mobility makes possible, for example, its use as an ionic membrane separator material in high energy density batteries, such as the sodium-sulfur battery (6-9). Due to the highly anisotropic ionic conductivity of the beta-alumina crystal structure, single-crystal plates or tubes would result in membranes with improved conductivities and would also eliminate problems associated with the electrical short circuiting due to possible sodium metal diffusion along grain boundaries or through interconnected pores. For these reasons we addressed ourselves to the growth of single-crystal tubes of beta-alumina, oriented such that the high ionic conductivity planes of the resulting crystal are normal to the tube axis. There are considerable difficulties associated with the crystal growth of sodium beta-alumina, due principally to the fact that beta-alumina appears to decompose peritectically (10, 11) as well as to the high vapor pressure of sodium over beta-alumina at its decomposition temperature (11). In order to produce tubular crystals, we have made use of a recently developed crystal growth method called edge-defined, film-fed growth (EFG), which enables a variety of crystals to be grown having any constant cross-sectional shape (12-19). To counter the problem of sodium vaporization, a high pressure (300 psi), inert gas, EFG crystal growth chamber has been constructed, and to contain the reactive melt, both the crucible and the crystal-shaping dies were fabricated from iridium.

In the basic EFG procedure for crystals having a tubular shape, the liquid melt rises by capillary action to fill the feeding orifice in the tubular die (12-15). A seed crystal is then brought into contact with the melt at the top of the capillary feed slot. After adjustment of the melt temperature and seed withdrawal rate, the melt spreads across the top surface of the die until further spreading is prevented by the 90° change in contact angle at both the inner and outer edges of the die. The growth of a tubular shape from a thin liquid meniscus is then established.

The design of the high pressure EFG chamber needed to suppress sodium vaporization during growth is shown schematically in Fig. 1. A water-jacketed Type 304 stainless steel chamber comprises the basic pressure vessel. This vessel is fitted with two quartz viewing ports, each 4 in. in diameter. In addition, both x-y and linear feedthroughs enable the position of the crucible and EFG die to be controlled both vertically and horizontally. The crystal withdrawal mechanism is of standard design[1] and has a water-cooled shaft which can apply pulling rates between 0.01 and 10

Key words: beta-alumina, crystals, membranes.

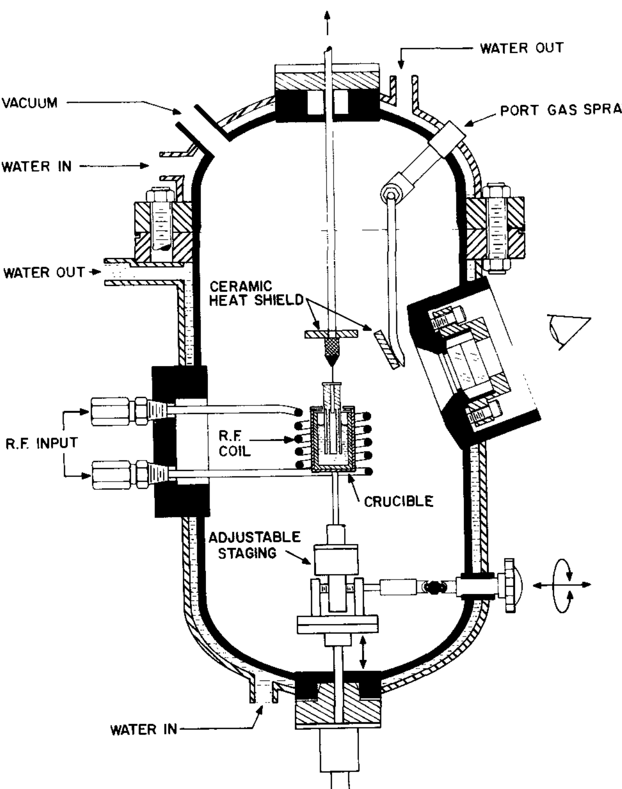

Fig. 1. Schematic drawing of the high pressure chamber and growth arrangement used to produce both alumina single-crystal tubes.

in./hr. The power feedthroughs are standard Conax fittings,[2] modified to accept fiberglass-reinforced Teflon pressure plugs in order to minimize localized rf heating. In order to prevent arcing from the interior coil, due to the presence of sodium vapor, the rf coil has been coated with a high dielectric constant film.[3] In addition, both the crucible and seed holder have been electrically insulated from the pressure chamber using boron nitride inserts. This system permits crystals to be grown under inert gas overpressures of up to 300 psig. Higher overpressures may not be useful in suppressing sodium vaporization due to gas convection effects (20).

Seeding was initiated in all cases using Monofrax H,[4] beta-alumina crystal pieces oriented so as to produce tubular shapes whose high sodium-ion conductivity planes are everywhere perpendicular to the tube axis. The influence of inert gas overpressure is shown in Table I, which gives the approximate relative beta-alumina and Al_2O_3 composition $Na_2O \cdot 11\ Al_2O_3$. As may be seen, there is a tendency for the relative percentage of beta-alumina present in the crystal tube to increase as the overpressure is increased from atmospheric to a maximum of 200 psi. This limit may be due to local convection currents (20), as well as to the incongruent melting of beta-alumina. The phase diagram for the system $Na_2O \cdot Al_2O_3/Al_2O_3$ deduced from a critical evaluation of the literature by DeVries and Roth (21) shows that beta-alumina decomposes peritectically at approximately 2000°C. The beta-alumina compositions shown in Table I were determined by comparison of the intensities of alumina (Al_2O_3) and beta-alumina x-ray reflections observed in Debye-Scherrer photographs as well as from metallographic observations. Although a single beta-alumina crystal was used as a seed in every case, none of the tubes whose beta-alumina content was less than 100% was found to be single crystalline. In each case, these tubes showed a two-phase alumina-beta alumina structure, indicating a deficiency of Na_2O.

To prepare tubes having a 100% beta-alumina composition as well as a substantial single crystallinity, it is necessary to use melts containing an enriched concentration of Na_2O. For the case of tube No. 5 (Table I), the use of a melt composition containing 20 mole per cent Na_2O enables tubes having a 100% beta-alumina content to be grown. A photograph of two 100% beta-alumina tubes produced by this EFG growth procedure is shown in Fig. 2. X-ray analysis confirms that these tubes are single crystalline and have assumed the orientation of the seed crystal, that is, with their high conductivity (cleavage) planes normal to the tube axis. Similar single crystal, 100% beta-alumina tubes doped with 0.8 weight per cent MgO have also been produced.

The sodium and aluminum content of a 100% beta-alumina tube was determined by wet chemical analysis, and the composition of this tube was $1.54\ Na_2O \cdot 11\ Al_2O_3$. This is well within the range of Na_2O contents (1.16-1.86) determined by Harata to lie within the single-phase field of beta-alumina (22).

Table I. Melt compositions and beta-alumina contents of tubes grown by EFG under inert gas overpressures. Beta-alumina compositions determined by x-ray reflection intensities and by metallographic measurement of the relative volume of Al_2O_3 present.

Tube No.	Melt composition	Inert gas overpressure, psig	Per cent beta-alumina content of tubes
1	$Na_2O \cdot 11\ Al_2O_3$	15 (argon)	40
2	$Na_2O \cdot 11\ Al_2O_3$	100 (argon)	75
3	$Na_2O \cdot 11\ Al_2O_3$	200 (argon)	85-90
4	$Na_2O \cdot 11\ Al_2O_3$	300 (argon)	85-90
5	$Na_2O \cdot 4\ Al_2O_3$	200 (argon)	100

Acknowledgments

The authors gratefully acknowledge the support of this work by the National Aeronautics and Space Administration, Lewis Research Center, Contract No. NAS3-15385, the initial work on this program carried out by Dr. J. T. A. Pollock, and many helpful discussions with F. V. Wald.

Most of this work was performed while both of the authors were associated with Tyco Laboratories, Incorporated, Waltham, Massachusetts 02154.

Manuscript submitted Oct. 16, 1972; revised manuscript received Nov. 19, 1973.

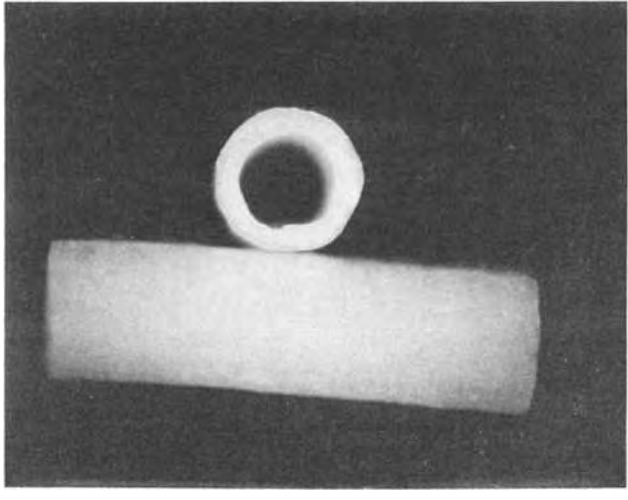

Fig. 2. Macrophotograph of two single-crystal beta-alumina tubes. The outside tube diameter is 0.5 cm.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1974 JOURNAL. All discussions for the December 1974 Discussion Section should be submitted by Aug. 1, 1974.

William G. Pfann—Solid State Science and Technology Award Medalist

N. Bruce Hannay[1]

Dr. N. Bruce Hannay delivers introductory remarks about the Solid State Science and Engineering Award Medalist

It is a great pleasure for me to be able to speak to you tonight about Bill Pfann, the first recipient of The Electrochemical Society Award in Solid State Science and Technology. In the next few minutes I hope to give you some flavor of the work he has done and an impression of the enormous impact it has had on solid-state science and technology. To those of you who are solid-state people his name is already a household word.

I shall also tell you something about Bill as a person, because he has wide-ranging talents, and he never fails to surprise his friends with his unusual approach to things. I am told that one of the people he often surprised was his mother. It seems that when Bill was of preschool age, it was not clear whether he would be left-handed or right-handed, but there were early indications that he would be left-handed, as ultimately proved to be the case. His mother, however, was encouraging him to use his right hand and in order to fix in his mind right from left, she purchased a ring for him to wear on his right hand. One day he returned home from play without the ring. When his mother asked him what had happened, he replied, "I now know my right hand from my left hand, so I threw the ring away."

This early strong display of pragmatism foretold Bill's approach to life, as well as his approach to the science that became his career. He has always been quick to find the practical solution to problems; for example, during World War II, when faced with food rationing he managed to negotiate with an associate the exchange of a used camera for 24 dozen eggs, to be delivered at weekly intervals.

Now you might think that practicality, then, is clearly the essential ingredient for extraordinary inventiveness and for success in science. But I should tell you of another side of Bill's character and that is his writing of poetry, and perhaps this reveals even more about the forces that have inspired him. Thus he has written:

The old values neither
Pinned him down,
Nor sustained him.

Therein lay
His sucess. . . .
And his despair.

Or, as another example,

The tempo of science
Increases with
Each passing year.

Brilliant achievement
Is swept away
In the swift stream
Of her advance,
And sinks from sight
Almost before
Recognition.

Bill was born in New York City and lives in Bedminster, New Jersey. His biography next says that he graduated from Cooper Union School of Engineering with the degree of B.Ch.E. in 1940 and has been a member of the Metallurgical Research Department at Bell Labs since 1936. Now, these bare facts are worth more careful examination. Bill first came to work for Bell Labs in 1935 at the age of 17. His first job was messenger boy, and, given the prevailing economics in those years, he was glad to have the job, as well as the $15 a week. Seven months later he received first the good news, that he was raised to $16, but the bad news that came next was that the work week was cut, so he actually was reduced to $14.74. Bill was undaunted, however, and he began night school at Cooper Union, graduating with a B.Ch.E. in 1940. At Bell Labs he delivered the mail so effectively that a year after he began work he was moved into the technical department, where he, of course, delivered the goods. His initial assignment was relatively modest, as a Technical Assistant, but in a few years he had reached full status as a Member of Technical Staff. I am glad to report also that he was no longer at $14.74 a week.

Now I have told you about this for a reason. Living as we do in a day when many expect that there is something automatic about success, and that it will be handed to them merely because they are there, it is reassuring to know people like Bill, who began at the

[1] Introductory remarks by N. Bruce Hannay, Bell Laboratories, Murray Hill, New Jersey, on the occasion of the presentation of the first Solid State Science and Technology Medal Award to William G. Pfann on May 15, 1973, at the Chicago Meeting of the Society.

bottom and then put together natural talents and a desire to succeed so effectively that he went on to accomplishments which have been rewarded by the Mathewson Gold Medal of the AIME in 1955 for his original papers on zone melting, a citation from Cooper Union for work in this field, the Clamer Medal of Franklin Institute in 1957, the Albert Sauveur Award of ASM in 1958, the Professional Progress Award of AIChE in 1960 for the invention and development of zone melting, the Moissan Medal from the School of Chemistry of the University of Paris in 1962, the Gano Dunn Medal for Professional Achievement of Cooper Union in 1963, the Award for Creative Invention of the American Chemical Society in 1968 (and, by the way, he was the first recipient of this award, for which the selection was made from all U.S. patents issued in the past 17 years in the chemical field) and, finally, in 1972 the Carborundum Company Award for Excellence in Non-Ferrous Materials. Many other scientific honors have also come to Bill, including Visiting Lectureships at Berkeley and at Cambridge University, where he was elected an Overseas Fellow at Churchill College.

We must then look more closely at Bill's record, to see how he went from messenger boy at Bell Labs in 1935 to these richly deserved honors, and what we find running throughout his work is a keen sense of what is important, and the simple way to do it. At least, it is simple after he has shown us what to do.

Zone melting is a particularly simple and elegant process. It revolutionized science and technology as it made possible the pure materials that not only provided the foundation for the semiconductor materials technology, that is, the cornerstone of solid-state electronics, but also launched us into an era of new understanding of the fundamental properties of solids, based on research on exceedingly pure and well-defined compositions. One measure of its impact is the approximately 1000 papers on the subject that were published in the decade immediately following Pfann's first paper. Actually, this is a completely inadequate measure, because it does not count the far larger number of papers that were possible only because of zone melting, which put pure materials in the hands of solid-state scientists and electronic device engineers for the first time.

The most important of zone melting techniques is probably zone refining, originally applied to semiconductors for the achievement of ultrahigh purities, of the order of one part in 10 billion. Purification in metals, organic materials, and other substances is also important, however, the tool is a universal one, and applicable in both research and manufacture.

There are other uses of zone melting also. One is zone leveling, a technique for distributing impurities uniformly through the solids. Another, developed by a colleague of Pfann's, is the floating zone method of crystal growth, an enormously valuable technique which eliminates the crucible in crystal growth, thus avoiding contamination.

Bill Pfann's zone melting processes have brought him his greatest fame, but his other scientific and technical achievements have also been notable. He made striking contributions to the development of silicon microwave detectors for use in radar receivers during World War II. One of the first of these followed some experiments which conclusively demonstrated that the noise output of the radar detector for use at 3000 MHz was related to surface irregularities on the point contact. These point contacts were fabricated from a 0.005 in. tungsten wire which had been sharpened in a sort of pencil sharpener grinding fixture. Pfann found that electrolytic polishing drastically reduced the noise of the detector, a factor directly related to the radar's sensitivity and range. Later he devised a process for producing the point contacts themselves by electrolytic means, and this dramatically increased the output of detectors, then in short supply to the armed services. Again we see the simplicity of Bill's approach to the solution of technical problems, in this and again in later work on fundamental materials aspects of electrical contact erosion, in which he discovered the phenomenon of self-limiting transfer, and through this, a method of eliminating contact "bridge" erosion, a problem of long standing.

Bill conceived and developed the prototype of the first transistor to be manufactured (Type A), and he holds basic patents relating to alloying and diffusion methods of making transistors. He was co-author of the first paper describing an MOS device.

One of Bill's simplest experiments, which well illustrates the sort of spectacular result that has come naturally to him, investigated the effect of disturbing the solid-liquid interface. He did this by rubbing the interface of a solid as it was being frozen from the melt. Now you might wonder how he got the idea for this. I cannot answer that, although I can say that when he was a Churchill Fellow at Cambridge he enjoyed making rubbings of cathedral tombstones. I can also tell you how he did the experiment; he used a wire brush, and simply reached into the molten metal and scrubbed the surface of the solid as it was being frozen. That is such an unsophisticated and direct way to do an experiment that no one else would have thought of it. It worked, and he was able to make spectacular changes in the metal texture, producing an extremely fine grained eutectic alloy.

Just one more of Bill's scientific discoveries must be mentioned. If it were not for zone refining, we could well be honoring him tonight for this as it was one of the classic experiments in revealing the fundamental nature of solids. Dislocations were a concept that had to be invented to explain the mechanical properties of solids. Real solids were orders of magnitude away from what should have been found if lattices were simple, like those found in crystallography books, and so something that had never been seen was imagined to exist, to explain away these spectacular anomalies. For years dislocations were talked about as though they were real, and then Pfann and his colleagues showed that they indeed were real in the first experiments that unmistakably demonstrated the existence of dislocations using pure germanium. It had been observed that freshly etched surfaces of germanium often show rows of microscopic conical pits. This makes a beautiful photograph, which I would have shown you but our esteemed Executive Secretary told me that he would have had to employ a union operator at double-time rates for 4 hours to show the one slide, so those of you who did not see it in Bill's talk this afternoon will have to imagine it. The pits develop at the points where dislocations intersect with the surface, because the slightly disordered lattice at a dislocation is slightly more reactive chemically than is the perfect lattice. The spacing and position checked the theory beautifully, and these classic observations thus furnished a striking confirmation of dislocation theory.

Bill holds over 60 patents and he is the author of a book on "Zone Melting," as well as more than 60 papers. He has been a successful administrator of his research group, recruiting talented people and leading them so skillfully that on two occasions members of his group have won the Mathewson Gold Medal. He spent two weeks in Israel as an advisor to the National Council of Research and Development. He used to admire the Brooklyn Dodgers but gave them up in favor of the New York Mets, and he is an avid hockey fan. We could talk of many facets of Bill's character. But I return to his poetry for the final insight on the career and essential human quality of this remarkable person.

The mind goes on and on,
Exploring a vast universe
Of ideas
Without end.

But the body
Is subject to
The rhythm of day and night,
The need for sleep.

The mind
Must therefore bide its time,
And find the chance
To make that gallant leap
Between distractions of the day
And the magnetic pull of sleep.

The Semiconductor Revolution[2]

William G. Pfann

Mr. William G. Pfann presents Solid State Science and Technology Award Address

President McKinley, ladies and gentlemen: Although I have taken part in the revolution in solid-state science and technology from its beginning, in fact, perhaps, even before most people knew it had begun, and although I have known the crescendo of scientific and technical advances of this revolution, on many fronts, I was completely overwhelmed by the news from President McKinley that I had been chosen as the first recipient of the Award for Solid State Science and Technology of this Society. The news was both heartwarming for your Society's recognition of my past achievements, and also thought-provoking because of my personal knowledge of so many other prolific contributors in this field.

In any event, I hope to share with you some of the excitement of these years of the semiconductor revolution, together with some personal anecdotes and insights which I hope may lead others to experience the joys of contributing to our society and the joy of being recognized as a person. Finally, I plan to say a few words that may be of help to future innovators in this major field.

The name of this award is very general. In the letter of notification from President McKinley I was told that the choice of subject was open, but it was recommended that the topic be chosen from my own work. This I plan to do. This is not a critical review of the field; rather, it is the field as seen through the eyes and feelings of one person.

Prehistory

A very good review of early semiconductor research was written by G. L. Pearson and W. H. Brattain (1) from which some of the following was taken. An important addition to semiconductor science was the Hall effect, discovered by E. H. Hall in 1879 (2). In 1931 A. H. Wilson (3) came up with the band theory of semiconductors, and conduction by electrons and by holes, but of course there were no materials suitable for study at that time. Tamm (4) in 1932 introduced the concept of surface states, which Bardeen took up so aptly later on. In Russia in 1938 B. Davydov (5) actually came up with the idea of diffusion of minority carriers across a p-n barrier. In 1938, but no one believed him. No one took him seriously; and even to the very month before the discovery of the transistor (W. Shockley recently gave a talk in England about that) they just did not get this idea of carrier injection. It eluded them for some subtle reason. This kind of puzzlement runs through this whole story, and all of these events. You wonder how you could have been so obtuse for so long before you saw how easy something was to do.

Just before the transistor, Mott and Gurney's "Electronic Processes in Ionic Crystals" was used as a seminar subject organized by W. Shockley. I was lucky to be in the seminar, and then the thing broke. Conyers Herring at Bell Labs is probably the best person in the country in the referencing of the literature of physics, and when the Nobel Prize for the transistor was announced he gave a talk, along with the winners, in which he used Fig. 1. I just wish to point out something that is odd about it. You notice that the number of papers culled from abstract journals was very small compared to today. You notice that in the early years the number was actually going down. In fact, the subject was sort of dying out! Then, in the postwar years, a lot of things that had been found during the war were published. There was a rise. The transistor was found in 1948. There is this later drop which Conyers could not interpret very well, and then this sudden

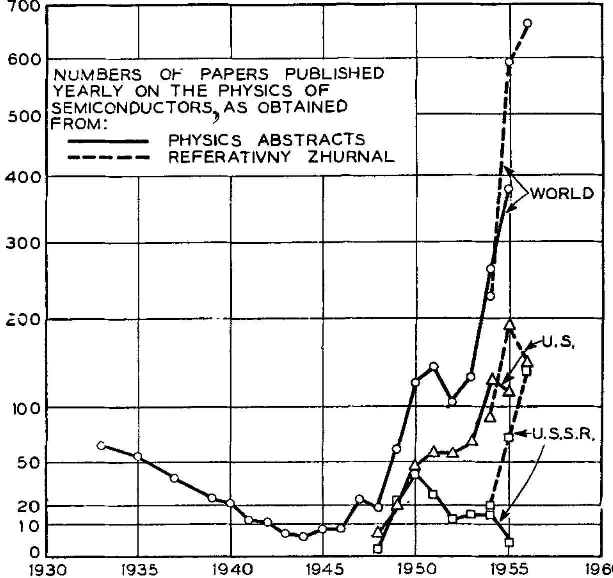

Fig. 1. Numbers of papers on the physics of semiconductors, 1933-1956 (after C. Herring).

[2] Solid State Science and Technology Award Address delivered May 15, 1973, at the Chicago Meeting of the Society.

the years many co-workers have helped shore up weak spots in my scientific training. As participation in more and more new topics has increased, so has my acquaintance with scientists the world over, and this has added to my development and led to many valued friendships. I will acknowledge the help of one man I recognized as a comer after hearing his first talk, my close friend and your incoming president, Bruce Hannay.

Some Problems of Electrochemical Kinetics

Benjamin G. Levich[1]

Institute of Electrochemistry, USSR Academy of Sciences, Moscow, USSR

My Dear Colleagues:

First I should like to express my gratitude to The Electrochemical Society for the high honor given me. Unfortunately, through no fault of my own, I am unable to present this paper myself and have had to be as brief as possible.

Electrochemical kinetics is a very distinctive field of research. Indeed, merely enumeration of the factors which determine the kinetics of electrode reactions—the chemistry of reagents; the structures and properties of fluid solvents; the properties of metals and semiconductors; the structural, adsorptive, and catalytic properties of their surfaces; the mechanism of charge transport in fluids; the movement of the solvent as a whole; and, finally, the mechanism of charge transfer in the elementary act of the electrode process—this listing shows that the most diverse fields of physics and chemistry converge in electrochemical kinetics. Therefore, electrochemical processes are not only very complex but also, as the present company would probably agree, very interesting.

In my paper I shall limit myself to the two aspects of the problem with which my own work has been connected, namely, studies of the macroscopic theory of the transport of species in moving solutions (diffusion kinetics) and studies of the charge transfer in the elementary act of the electrode reaction, electrode kinetics proper. Without going into details, I shall try to describe the present state of these questions, underlining the difficulties and the pressing problems that face theory and experimentation.

[1] The Palladium Medal Address was read for Professor Levich by Dr. David A. Vermilyea at the Boston Meeting of The Electrochemical Society, October 9, 1973. The medal was struck from palladium supplied by the International Nickel Company, New York, New York.

Transport of Species in Solutions

The problem of the transport of species in a solution is a comparatively old one in electrochemistry. However, there has been a growing interest in it in the last twenty-five years. There are two reasons for this. First, it was the use of effective methods of modern hydrodynamics that made it possible to produce a quantitative theory of the transport of species in a moving solution. Second, the development of new experimental methods made it necessary to obtain quantitative expressions for the diffusion current under diverse conditions in the implementation of electrochemical processes. Of course, the problem of the transport of reagents in a solution is a general question in the theory of heterogeneous reactions involving liquid phases, but it was in electrochemistry that the real need first arose for formulating a quantitative theory of transport that would meet the high level of precision of electrochemical measurements. Since the molecular coefficients of diffusion in fluids are exceedingly small, the convective transport of species predominates over molecular transport at the smallest velocities of the fluid. Therefore, the theory of the transport of reagents to and from the surface of the electrode, except in some special instances (in narrow capillaries or cracks, during high-frequency processes in fluids, or with immobilizing admixtures and the like), constitutes a problem of convective diffusion. Problems of this kind are very complex and that is why the ideas of electrochemistry were for a relatively long time limited to the qualitative theory of Nernst, according to which the existence of a limiting current is related to the slowness of the diffusion process through a stationary layer of fluid adjacent to a solid electrode. Though it was perfectly clear to all that no such stationary layer can exist,

the Nernst theory was accepted as a convenient empirical description of the convective diffusion process. The quantitative solution of the convective diffusion expressions for the specific instance of a dropping mercury electrode was first disclosed in the works of Ilkovic and Rideal. Later, in our work, the general hydrodynamic theory of the boundary layer was applied to the instance of convective diffusion in fluids. As early as the beginning of this century, Prandtl demonstrated that at large Reynolds numbers the entire fluid flow can be divided into a region of basic flow, in which there is viscosity independent motion of the fluid, and a hydrodynamic boundary layer, in which there is a viscous flow at a rate that diminishes to zero at a solid surface. When an electrode reaction occurs at a solid surface, causing a change in the concentration of species at that surface, the entire moving solution may be divided into a region of constant concentration and a diffusion boundary layer. The change in concentration takes place in the latter; moreover, the transfer of species in it occurs in equal measure by convection and by molecular diffusion, as well as by migration when there are ions and there is no supporting electrolyte in the solution. Because of the smallness of the molecular diffusion coefficient, the diffusion boundary layer is several times thinner than the hydrodynamic boundary layer (for water, for example, it is 1/10 as thick). The mathematical smallness of the diffusion coefficient makes it possible to take advantage of the method developed by Poincare for solving equations containing specific derivatives with small parameters. We used this method in dealing with a number of specific tasks. Exact solutions were obtained for problems of convective-diffusion when there was uniform accessibility of the surface (the rotating disk electrode), and later an approximate solution was found in a number of concrete instances and expressions were derived for currents in cases of mixed kinetics and limiting currents at the surfaces of electrodes of different geometries with laminar flow. A number of researchers, including present and past co-workers, have also developed the theory of convective diffusion in nonisothermal solutions, in moving thin films in phase boundaries of the fluid, in fluids with nonstationary currents and nonsteady-state conditions, in natural convection, and in a number of other cases. Along with these calculations, a theory of kinetic and catalytic currents on solid electrodes was developed. Finally, Acrivos and Chambre demonstrated that the solution of a problem in convective diffusion at an arbitrary surface may, by the law of kinetics, be reduced to the solution of an integral equation, and such an equation is convenient for obtaining a numerical solution. If one also takes into account the multitude of problems concerning diffusion and migration of species in an immobile medium that have been solved in connection with the development of a-c methods in electrochemistry, then it must be recognized that diffusion kinetics is one of the most advanced fields of electrochemistry. At present, the expression for the flow of a substance to an electrode of any geometrical shape under any and all conditions of electrode reactions is known or can be quantitatively obtained. However, this does not mean that all the problems of diffusion kinetics may be considered solved. For example, the transition to large current densities requires the transition from laminar to turbulent flow conditions and also to high solution concentrations. The question of the detailed mechanism of the convective transport of species in the turbulent flow of a fluid cannot as yet be considered as answered in full. There are two theories—the theory of Prandtl and the theory of Landau and this author, based on different concepts of the law of diminishing turbulence in proximity to a solid surface. Which of these two theories one chooses is very significant, both for obtaining the estimated formulas for the flows of species that interest electrochemists and for the general hydrodynamic theory of turbulence. It is only very recently that, thanks to the measurements carried out by Hanratty (U.S.) and also by Kishinevsky and co-workers (USSR), it has become possible to decide in favor of our hypothesis. The transport of species in a turbulent flow is an extremely complex process, the mechanism of which is closely connected with the mechanism of the turbulent pulsations themselves. As is known, there is at present no quantitative theory of turbulence in anisotropic flows. Hence, the study of the mechanism of the transport of species to a solid surface is not only of great practical importance for electrochemistry but also of basic significance for the theory of turbulence.

Diffusion and Migration

The diffusion and migration of ions in concentrated solutions are being studied intensively, both theoretically and experimentally, chiefly on the basis of the thermodynamics of irreversible processes. The difficulties of the theory in this field are connected primarily with the difficulties of the theory of concentrated solutions of electrolytes. However, I shall not deal with this question inasmuch as I myself have not worked on diffusion and migration in concentrated solutions. Another group of not yet elucidated but very important problems for electrochemistry are those connected with the transport of a substance in solutions containing a large number of gas bubbles, in porous media with fluid flow, and in gelatinous systems. Finding the solutions to problems of this kind, requiring a statistical approach, is now the order of the day.

Charge Transfer

The question of the mechanism of the elementary act of the electrode process is undoubtedly a central basic problem of electrochemistry. The first theoretical approaches to this problem are associated with the names of Gurney and Horiuti and Polanyi. A new stage in the development of the problem is associated with the work of Weiss, Marcus, Zwolinsky, and others, who have emphasized the importance of the processes connected with the influence of the polar solvent. The latter direction has been developed quantitatively in the works of Marcus and of this author and his former co-workers. Since I am, naturally, unable to present our theory in detail or give a historical survey and critical analysis of other theoretical ideas, I shall restrict myself to a discussion of the general approach to the problem, the principal conclusions, and the difficulties confronting the theory.

The process of transfer of an electron between an ion and an electrode is an extremely complex one even in the simplest case of a reduction-oxidation reaction on the surface of a metal electrode, taking place without the rupture or formation of chemical bonds and not complicated by adsorption phenomena. Indeed, the ion near the electrode is surrounded by a solvation shell, which is distorted, as compared with the same kind of shell in the bulk of the solvent, by a strong double-layer electric field. The structure of the polar solvent that surrounds the ion has not been studied sufficiently. We have only very approximate knowledge of the wave functions of electrons in complex ions. The surface properties of metals and, especially, of semiconductors contiguous with the solution are far from those of the ideal surfaces that figure in the modern theory of metals. Under such conditions, it is important to understand that it would be pointless to construct a theory that claimed to give a quantitative and detailed description of the process of charge transfer. This applies even more to the more complex electrode reactions that take place with the disruption or formation of chemical bonds. In our view, it makes more sense to limit ourselves to the construction of the kind of simplified model that will correctly convey the basic qualitative characteristics of the process. What are the tasks of the model theory? First, it should provide an explanation of one fundamental fact—the extremely

low velocities of electrode processes, that is, of the origin of slow discharge. The slowness of electrode processes, to which electrochemists are accustomed, distinguishes the processes taking place in a polar solvent from all other processes where opposite charges combine. Such processes always take place at enormous velocities, as, for instance, charge recombination processes in gases. The circumstance that the rate of the reaction between an ion and electrode of the same chemical nature does not differ from the rate of the reaction between an ion and electrode of different chemical nature is closely related to the slowness of the discharge. In other words, the phenomenon of resonant charge transfer that is always present in gaseous reactions is absent from electrode processes. Second, the theory must also clarify the nature of Tafel's law, or, equivalently, the nature of Bronsted's rules for homogeneous reactions occurring with charge transfer. Finally, the most complicated of the general tasks that confront the theory according to us is that the theory must calculate the magnitude of the transfer coefficient in Tafel's law and its dependence on overvoltage. The answer to the first question on the nature of the slow discharge is to be found in very general quantum mechanical considerations. To illustrate this point, let us examine a homogeneous reaction with transfer of an electron between two identical ions with different charges. The difference in the magnitude of the charge causes a difference in the degree of solvation of the ions. This latter circumstance indicates that the energy levels of both ions, surrounded by a polarized medium, have been shifted differently with regard to their positions in vacuum (where the energy levels of identical ions coincide). The transfer of the electron from one ion to the other must be accompanied by the absorption or release of energy from the above-mentioned shift. This indicates that there is some sort of energy reservoir which ensures the appearance of a reaction situation in the system. A reaction situation occurs when the positions of the energy levels of both ions temporarily coincide. Both the slowness of the reaction and the absence of resonant phenomena are due to the inertness, the slowness of the action of the energy reservoir. Basically, either the polar solvent or the thermal energy of inner molecular oscillations (if the reagent or product of the reaction is a molecular ion) can serve as the energy reservoir.

The thermal oscillations of the polar solvent alter its polarization (the optical branch). The change in the polarization, in turn, alters the positions of the energy levels of the solvated ions. The position of the energy levels also changes as a result of inner molecular oscillations. If the energy levels of the ions become the same as the result of these fluctuations, then it is very likely that the transfer of the electron will occur at that moment. The exchange of the electron between the metal electrode and the ion takes place in exactly the same way, at least in principle, in instances of electrode reactions, too. Thus, we see that slow discharge is a purely quantum mechanical phenomenon, arising from the discrete nature of energy levels. Along with this, the task of theory becomes clear: to describe the mechanism of the action of the energy reservoir. For this it is necessary, strictly speaking, to have detailed data on the nature of the thermal movement of the solvent and on the inner molecular oscillations of the molecules in the polar solvent, both while situated in the strong double layer electric field. There are, of course, no such data at present, and it is therefore necessary, on the one hand, to devise a simplifying hypothesis, and, on the other, to develop a theory of the above-mentioned phenomena. At first, R. Marcus (U.S.) and we independently restricted ourselves to describing the bulk medium as a continuum, with exactly the same properties as a polar crystal. It was also assumed that the oscillations of the molecules of the first solvated layer were suppressed, but later we were able to reject these oversimplifications and to develop further the theory of thermal movement in a polar fluid. In this theory the properties of the fluid are quite fully described by the dependence of its dielectric constant on frequency and wavelength. However, we do not at present know what kind of function this is near a solid surface for so complex a fluid as, say, water. In the simplest case of atomic and weakly solvated ions, only a polar solvent can serve as the energy reservoir. Its thermal fluctuations create a reaction situation. In more complex instances, as with molecular ions during the discharge of the hydronium ion and also in the case of strongly solvated ions, a significant role may be played, along with the thermal fluctuations of the solvent, by molecular excitation within the molecule as well as by oscillations along the molecule's bonds with the first hydration shell. All these processes contribute to the creation of a reaction situation. The theory of Horiuti and Polanyi took into account only inner molecular thermal excitation as the mechanism for creating a reaction situation. Actually, the relative roles of the two competing mechanisms creating the reaction situation, that is, the role of the thermal fluctuations of the solvent and the thermal fluctuations of molecular oscillations, are determined by the specific magnitudes of the frequencies and the properties of the thermal movement of the polar solvent. The latter also has certain characteristic frequencies. Hence, there is no point in counterposing the two coexisting, mutually competing mechanisms as some authors still try to do. As for the transfer of the electron, theory indicates that the corresponding probability of the process does not contribute to the temperature dependence of the current in the case of metal electrodes. However, the specific features of the energy spectra of semiconductors greatly affect the probability of the passage of the electron. At present, theory has made possible the derivation of Tafel's law, the calculation of the magnitude of the transfer coefficient, and the establishment of its dependence on overvoltage. Theory correctly conveys the nature of the isotope effect and describes the mechanism of the operation of the transfer of electrons across bridging species and several other experimental facts. Theory was applied to a number of specific electrode reactions and compared with the results of the theory of homogeneous reactions with charge transfer. Despite the favorable quantitative results of comparisons with experiment, one should not overestimate the quantitative preciseness and completeness of the theory, underestimate the crude assumptions on which it is based, or consider the theory devoid of difficulties.

Let us enumerate some of those difficulties. The theory of thermal movement of so complex a fluid as a polar solvent is only very approximate. As we have stressed, the properties of thermal movement near a solid surface differ from the properties of movement in the bulk. Yet existing theory does not take this into account. Nor does theory as yet take into account the influence of the strong, heterogeneous electric field of the double layer. The frequencies of oscillation along the bonds with solvated molecules and the dielectric constant when the waves are exceedingly short, which figure in the final formulas of the theory, together with a number of other circumstances have not yet been investigated either theoretically or experimentally. It seems to me, therefore, all the more surprising that theory has nevertheless made it possible to find a quantitative expression for the transfer coefficient and to give a qualitative description of the entire group of problems connected with electrode kinetics. The reason for this, I believe, is that the magnitude of the transfer coefficient, which is ½, is related to the shape of the potential energy surface and this is influenced by the potential energy of the solvent. If there is a parabolic surface in the potential energy, corresponding to the approximation of the small oscillations, the magnitude of the transfer coefficient obtained is ½, irrespective of the detailed mechanism of the process. However, in the case of hydrogen overvoltage, a trans-

fer coefficient of ½ is observed over such a wide range of overvoltage that it becomes very difficult to find a theoretical explanation for it. Apparently, the energy of reorganization, the basic characteristic of the fluctuation process, which was considered constant in the theory, depends, in fact, on the intensity of the electric field in the double layer. Hence, we see that despite the achievements of the theory, there are still extensive unexplored fields to be investigated. At the same time, and this is extremely important, it is necessary to develop the experimental technology that would facilitate the experimental testing of a number of the detailed qualitative and quantitative predictions of the theory.

Tribo-Ellipsometric Study of the Repassivation Kinetics of a Ti 8Al-1Mo-1V Alloy

J. R. Ambrose and J. Kruger*

Institute for Materials Research, National Bureau of Standards, Washington, D. C. 20234

ABSTRACT

The tribo-ellipsometric technique allows one to distinguish between film growth and other reactions that occur after removal of a film from a metal surface in a given environment. This technique was used to study the relationship between repassivation kinetics and stress corrosion cracking (SCC) susceptibility for Ti 8Al-1Mo-1V alloy. In these studies the effect of the rate of film growth on the amount of metal dissolution which occurs during the repassivation process was investigated by comparing the repassivation transient behavior in a 1.0*N* NaCl solution, where cracks have been found to propagate, to that in a 1.0*N* $NaNO_3$ solution where SCC susceptibility has never been detected. Film growth kinetics in both solutions were consistent with a Fleischmann-Thirsk mechanism of oxide patch nucleation and two-dimensional growth, although the film growth rate was significantly slower in the 1.0*N* NaCl solution. Low film growth rate led to an increase in metal dissolution in a solution where crack propagation velocities have been measured, but at an apparent rate slower than necessary to propagate such cracks by metal dissolution alone.

Theoretical treatments of the relationship between repassivation kinetics and susceptibility to stress corrosion cracking have recently been incorporated into mechanisms for cracking of a number of materials, noticeably mild steel (1) and titanium alloys (2). Studies by Beck (2) relating crack propagation velocities to anodic current densities measured following fast fracture of titanium alloy wire utilized an empirical relationship to estimate film growth rates during the repassivation transient.

The recently developed technique of tribo-ellipsometry (3, 4), with which a determination of both anodic current and film growth rates can be made following passive film removal by abrasion, makes possible a separation of the total repassivation process into film growth and metal dissolution components. The object of this technique is to simulate the production of bare metal by film rupture at the tip of a stress corrosion crack.

This work describes the results of a study comparing repassivation behavior of a commercial titanium alloy (Ti 8Al-1Mo-1V) exposed to 1.0*N* NaCl in solution where cracks are known to propagate and to 1.0*N* $NaNO_3$ where no susceptibility to cracking has been detected.

An attempt has been made to correlate measured film growth rates with the Fleischmann-Thirsk patch nucleation and growth mechanism (9) and to estimate crack propagation velocities which would result from metal dissolution during repassivation.

Experimental

The description of the experimental apparatus and technique of tribo-ellipsometry has been presented in prior publications (3, 4).

* Electrochemical Society Active Member.

Key words: repassivation kinetics, stress corrosion cracking, titanium alloy, tribo-ellipsometry.

A Ti 8Al-1Mo-1V commercial alloy was used in this study: 1.905 cm diameter × 0.635 cm thick cylindrical specimens were machined from rod stock and polished on silicon carbide metallographic papers followed by rotary polishing on nylon cloth with 6μ diamond paste. Air-saturated solutions of 1.0*N* NaCl (pH = 6.11) and 1.0*N* $NaNO_3$ (pH = 6.08) were prepared from ACS reagent grade chemicals and distilled water.

Specimen potentials were controlled potentiostatically. The repassivating current pulse generated upon cessation of abrasion was used to trigger the sweep of a dual channel oscilloscope. The scope also recorded the output of the photometer system used to monitor changes in ellipsometer light intensity.

Total coulombs, Q_T, passed during the transient were determined by graphical integration of the total current, i_T; film thickness, x, was determined from light intensity changes which were converted using predetermined calibration data.

The Repassivation Ratio, R_p

Measurement of the total current, i_T, and the film thickness, x, as a function of time during the repassivation transient is relatively straightforward. However, several uncertainties exist that make it difficult to render analysis of tribo-ellipsometric data completely unambiguous and quantitative. These uncertainties are as follows:

(*i*) The total current involved in repassivation, $i_T = i_a + i_c$, is the current supplied by the potentiostat to maintain the specimen potential at some fixed value with respect to a reference electrode potential. If any cathodic reduction were also to supply current (i_c) a determination of i_a, the anodic current used during repassivation, becomes difficult. Of course, i_c can be made negligible by operating at potentials 50 mV or so more positive than the open-circuit or corrosion potential.

However, this would defeat the point of attempting to predict susceptibility to SCC for materials immersed in specific environments.

(*ii*) The charge utilized in the formation of an oxide film is given by

$$Q_x = \int_0^t i_x dt = \frac{z_f \mathbf{F} \rho_f A_f x}{10^4 M_f} \quad [1]$$

It is difficult to obtain an accurate value of area, A, for the surface where film growth (and metal dissolution) occurs since the efficiency of the abrasion process is difficult to ascertain.

To get around these difficulties a recent paper (5) expressed the experimentally measured variables of total current, i_T, and film thickness, x, in the form of a ratio, designated R_p and given by

$$R_p = \frac{\int_0^t i_T dt}{x} \quad [2]$$

Since $\int_0^t i_T dt = Q_T$ and $x = \frac{10^4 M_f}{z_f \mathbf{F} \rho_f A} Q_x$, then

$$R_p = \frac{Q_T}{k Q_x} \quad [3]$$

where $k = \frac{10^4 M_f}{z_f \mathbf{F} \rho_f A}$. If we assume that $Q_T = Q_x + Q_d$, then

$$R_p = \frac{Q_x + Q_d}{k Q_x} = \frac{1}{k}\left[1 + \frac{Q_d}{Q_x}\right] \quad [4]$$

where Q_d = charge consumed by metal dissolution, and $\frac{dQ_d}{dt} = i_d$ is the current consumed by metal dissolution.

R_p is defined above using the experimentally measured total current rather than current density because an estimation of the area available for the repassivation reaction is difficult. However, it is sometimes useful to express R_p as a dimensionless variable, designated R_p^* and equal to

$$\frac{Q_t}{Q_x} = 1 + \frac{Q_d}{Q_x} \quad [5]$$

since results would be independent of the particular experimental procedures and apparatus employed. Although R_p and R_p^* differ in magnitude only by the constant, k, R_p values are determined directly from experimental measurements; therefore, discussion and conclusions will be based on R_p values. R_p is a cumulative index of the extent of corrosion attack. Its time derivative is also useful as an indicator of any abrupt variation which might occur during the repassivation process, for example, completion of monolayer coverage. Differentiating R_p with respect to time

$$\frac{dR_p}{dt} = \frac{1}{k}\left(\frac{Q_x \frac{dQ_d}{dt} - Q_d \frac{dQ_x}{dt}}{Q_x^2}\right) \quad [6]$$

$$= \frac{1}{k}\left[\frac{Q_x i_d - Q_d i_x}{Q_x^2}\right] \quad [7]$$

$$= \frac{1}{k}\left[\frac{i_d}{Q_x}\right] - \frac{1}{k}\left[\frac{Q_d i_x}{Q_x^2}\right] \quad [8]$$

In this derivation we have neglected the cathodic current, i_c. This is a reasonable assumption since it is generally quite low except in acid solutions, hence negligible compared to i_a when the anodic overvoltage is high.

The values of R_p and dR_p/dt can be used to distinguish between metal dissolution and film repair, and thus to provide parameters for predicting stress corrosion cracking susceptibility. Consider the following limiting conditions which could correspond to situations within a stress corrosion crack: (*i*) $i_d >> i_x$ and $dR_p/dt > 0$; this would correspond to a situation where general corrosion without any repassivation was occurring. (*ii*) $i_x >> i_d$ and $\frac{dR_p}{dt} \simeq -\frac{1}{k}\left[\frac{Q_d i_x}{Q_x^2}\right]$ (from Eq. [8]); this corresponds to virtually instant repassivation with no metal dissolution and little susceptibility to SCC. (*iii*) $i_x \simeq i_c$ and $dR_p/dt \simeq 0$. (*iiia*) $dx/dt > 0$ (at large values of t); in this case the film formed is not protective, but is similar in characteristics to (*i*) because general corrosion or pitting results. (*iiib*) $dx/dt \simeq 0$ (at large values of t). These conditions would be those most consistent with the initiation and propagation of stress corrosion cracks based on a metal dissolution mechanism which is dependent upon the rate of repassivation. In other words, a relatively large value of R_p, with small values of dR_p/dt and dx/dt, indicates that metal dissolution accompanies film regrowth. Repassivation eventually occurs, thus protecting the walls of the advancing crack and restricting propagation of the crack to the area directly at its tip. These conditions are summarized in Table I.

Light intensity *vs.* polarizer angle calibration plots were constructed prior to each experiment. From this, the ellipsometrically determined film thickness change was obtained using a proportionality constant of 0.15 nm/degree change in polarizer reading. This particular value was computed using the optical constants for film-free titanium reported by Melmed and Carroll (12) and assuming a nonabsorbing film with a refractive index of 2.75, a reasonable median value for oxides of titanium (13). Calculations show that a 20% error in this refractive index would lead to a variation of only ±0.06 nm in the thickness of a monolayer (0.3 nm).

Results

Effect of anions.—Results of the tribo-ellipsometric repassivation kinetics experiments conducted in 1*N* $NaNO_3$ (pH = 6.08) and 1*N* NaCl (pH = 6.11) solutions at −222 mV SHE[1] are shown in Fig. 1 and 2. At comparable film thickness, the value of the repassiva-

[1] This potential was the open-circuit value measured after 5 min exposure to the solution. Although corrosion potentials are extremely difficult to reproduce, depending for example, upon specimen surface treatment (6), the open-circuit potential established for the particular specimen used in these studies after several abrasion cycles was the same for Ti 8-1-1 in both solutions used and was fairly reproducible even when the specimen was repolished or solutions changed.

Table I. Prediction of type of corrosion process from measured repassivation parameters

Repassivation parameter					
R_p^*	dR_p/dt	x	dx/dt		Significance
>1	≧0	≃0	≃0	Case (*i*):	$i_d >> i_x$; very little film growth; general corrosion attack.
≃1	≦0	>0	≃0	Case (*ii*):	$i_x >> i_d$; most of current goes into formation of film; characteristic of the passive state.
>1	≧0	≧0	≧0	Case (*iiia*):	$i_x \simeq i_d$; film which forms either is not protective [similar to case (*i*)] or grows too slowly to cover the surface, characteristic of general attack or pitting.
>1	≦0	>0	≃0	Case (*iiib*):	$i_x \simeq i_d$; characteristic of a system which has eventually passivated after some metal dissolution has occurred. This would correspond to a system where the metal dissolution/film rupture model would apply.

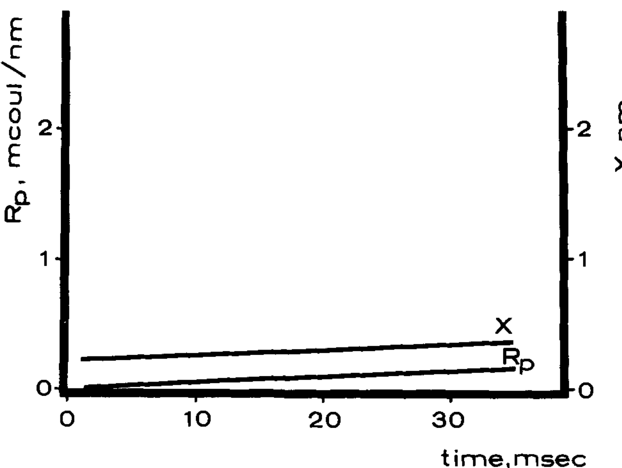

Fig. 1. Change in thickness, x, and repassivation ratio, R_p, after removal of the abrasion wheel of the tribo-ellipsometric apparatus for Ti 8-1-1 in 1N $NaNO_3$ at 25°C. The alloy is at the open-circuit (corrosion) potential −222 mV (SHE).

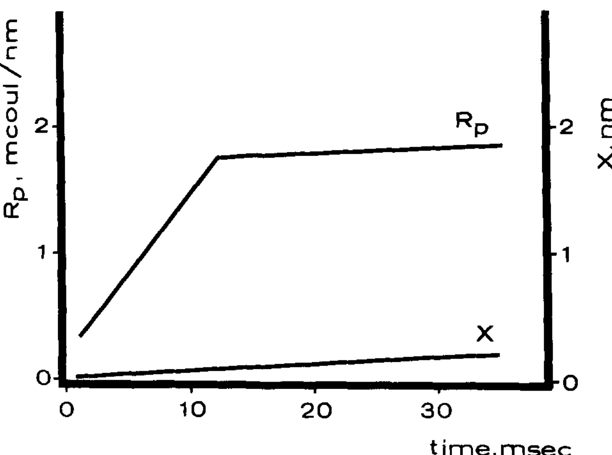

Fig. 2. Change in thickness, x, and repassivation ratio. R_p, after removal of the abrasion wheel of the tribo-ellipsometric apparatus for Ti 8-1-1 in 1N NaCl at 25°C. The alloy is at the open-circuit (corrosion) potential −222 mV (SHE).

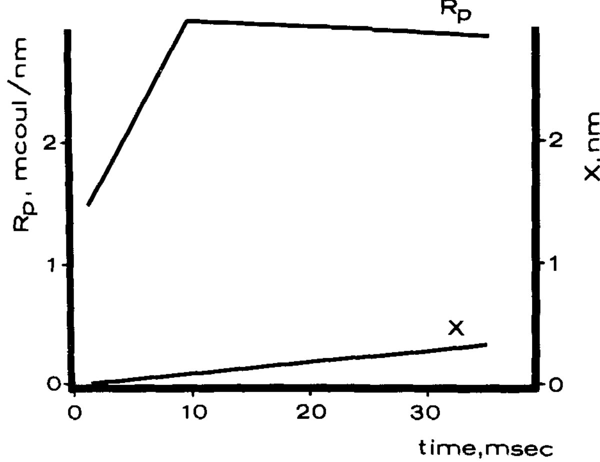

Fig. 3. Change in thickness, x, and repassivation ratio, R_p, after removal of the abrasion wheel of the tribo-ellipsometric apparatus for Ti 8-1-1 in 1N NaCl at 25°C. The alloy is at +706 mV (SHE).

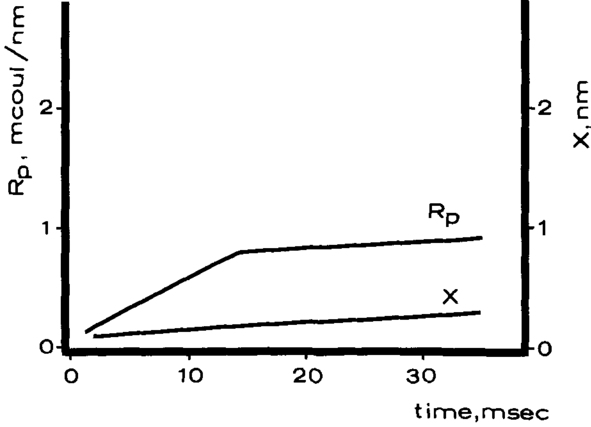

Fig. 4. Change in thickness, x, and repassivation ratio R_p, after removal of the abrasion wheel of the tribo-ellipsometric apparatus for Ti 8-1-1 in 1N $NaNO_3$ at 25°C. The alloy is at +706 mV (SHE).

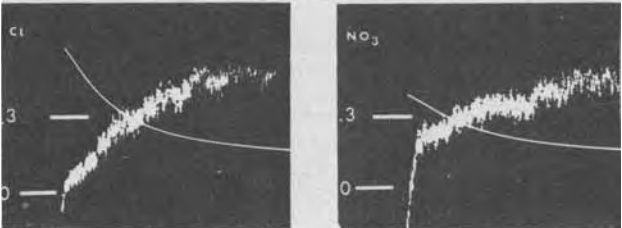

Fig. 5. A comparison of oscilloscope repassivation transients for Ti 8-1-1 in 1N NaCl (susceptible) and 1N $NaNO_3$ (nonsusceptible) solutions at +706 mV (SHE) (ellipsometric film growth, jagged trace; current, solid line trace). 0 and 0.3 nm film thickness values are shown.

tion ratio, R_p, is significantly higher in the NaCl solution than in the $NaNO_3$ solution, approaching a limiting value of about 2 mcoulombs/nm when at a monolayer coverage of 0.3 nm ($R_{p\lim} \simeq 0.3$ mcoulomb/nm). The values of the ellipsometrically determined film thickness are also shown. In $NaNO_3$, an oxide thickness of 0.30 nm is present on the metal surface by the time the abrasion wheel had retracted to allow ellipsometric measurements (~ 5 msec), indicating extremely rapid early stage film growth. In NaCl, on the other hand, film growth is so slow that a film thickness of 0.30 nm is not reached until 38 msec after cessation of abrasion.

Effect of potential.—The results of repassivation experiments conducted in the 1N $NaNO_3$ and 1N NaCl solutions at +706 mV SHE are given in Fig. 3 and 4. $R_{p\lim}$ values are significantly higher than at open circuit in both solutions (~3.00 for NaCl; ~1.02 for $NaNO_3$). Initial film thickness growth is substantially slower at +706 mV than at −222 mV for the $NaNO_3$ solution. A comparison of oscilloscope tracings for Ti 8-1-1 in 1N NaCl and 1N $NaNO_3$ at 706 mV SHE appears in Fig. 5.

Peak current densities for the transients in NaCl and $NaNO_3$ were 65.0 and 18.8 mA, respectively.

A straight line and zero intercept was obtained when film thickness in chloride solution was plotted against the square root of time, but some deviation from a parabolic growth law was observed at short times for the nitrate solutions. These plots for Ti 8-1-1 in 1N NaCl and 1N $NaNO_3$ at both potentials are given in Fig. 6. This particular figure is presented only to illustrate a problem of interpretation. Since data could be made to fit other growth laws (ln x vs. t^2 and x vs. t) as well, it was necessary to exercise caution in accepting one mechanism over another. The values of R_p, R_p^*, t_m (the time required for obtaining 0.30 nm film thickness), $dx/d(t^{1/2})$, and i_{max} are given in Table II. In the calculation of R_p^*, the oxide was assumed to be TiO_2 ($z = 4$). If lower valence oxides of titanium were to form, the net effect would be that the tabulated R_p^* could be too high by a factor of about 2. However, even if different oxides were to form in the respective solutions, the correction to R_p^* resulting from a change in z, M, and ρ would not be large enough to account for the relative differences in R_p^* determined for the two solutions.

Table II. Repassivation parameters for Ti 8-1-1 alloy in 1N $NaNO_3$ and 1N NaCl solutions

Solution	Potential SHE (mV)	$R_p(t_m)$* (mcoulombs/nm)	$R_p^*(t_m)$†	t_m (msec)	$\left(\frac{dR_p}{dt}\right)t < t_m$ (mcoulombs/nm/msec)	$\left(\frac{dR_p}{dt}\right)t > t_m$ (mcoulombs/nm/msec)	$\left(\frac{dx}{dt^{1/2}}\right)t < t_m$ (nm/msec)$^{1/2}$	$\left(\frac{dx}{dt^{1/2}}\right)t > t_m$ (nm/msec)$^{1/2}$	i_{max} (mA)
1N $NaNO_3$	−222	0.3	1.04	<5	—	+0.005	—	0.0350	4.2
1N NaCl	−222	2.0	6.94	38	+0.130	+0.004	0.0150	0.0405	24.0
1N $NaNO_3$	+706	1.0	3.47	20	+0.052	+0.006	0.0167	0.052	18.8
1N NaCl	+706	3.0	10.4	20	+0.174	−0.005	0.0272	0.072	65.0

* Good reproducibility was obtained for reported R_p values with a relative precision of less than ±5% being obtained for all measurements. This leads, for example, to a maximum range of ±0.2 mcoulombs/nm in the R_p determination for Ti 8-1-1 in 1N NaCl at +706 mV SHE.

† The R_p^* values reported here are based upon an approximate area of metal produced during abrasion of 0.14 cm^2. This value of area was computed by assuming that $i_T \simeq i_x$ after monolayer coverage on Ti 8-1-1 in 1N $NaNO_3$ solution, when metal dissolution can be assumed low. Hence

$$\int_{t_1}^{t_2} i_T dt \simeq Q_x = \frac{z_f F \rho_f A x}{10^4 M_f} \text{ or } A \simeq \frac{10^4 M_f \int_{t_1}^{t_2} i_T dt}{z_f F \rho_f x}$$

Discussion

Repassivation ratio and stress corrosion susceptibility.—From Fig. 1 and Table II it can be seen that for Ti 8-1-1 in 1N $NaNO_3$ at the corrosion potential of −222 mV SHE, a low value of R_p was observed throughout the repassivation transient. Here $dR_p/dt = 0$. Based on the size of the oxide ion, a monolayer of TiO_2 would be approximately 0.30 nm in thickness; it formed in < 5 msec in this environment. These results are characteristic for a case (*ii*) repassivation transient in which most of the current transient is utilized in rapid film growth without significant metal dissolution. When this is compared to the results obtained in 1N NaCl at the same potential, where crack propagation velocities on the order of 10^{-2} cm/sec have been measured (2, 7), it is seen that R_p is significantly higher as is dR_p/dt, indicating substantial metal dissolution which can be accounted for by low rates of film growth in 1N NaCl. Although monolayer coverage is not obtained until 38 msec following cessation of abrasion, R_p changes slope at about 12 msec. This indicates some inhibition of metal dissolution, perhaps by formation of a precipitated salt layer on the surface which results from saturation of the diffusion layer with $TiCl_3$ (Fig. 2). At any rate, repassivation is eventually achieved [case (*iiib*)]. Similarly, at an applied potential of +706 mV SHE, R_p is quite high in the chloride solution with R_p changing slope at about 10 msec which would substantiate a precipitated salt passivation mechanism since a saturated solution of $TiCl_3$ would be obtained more rapidly at these higher current densities. The time to complete monolayer coverage, t_m, is about 20 msec. R_p and dR/dt for 1N $NaNO_3$,

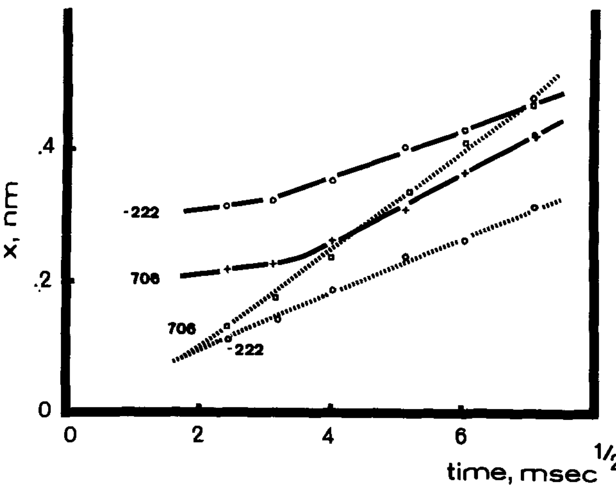

Fig. 6. Changes in film thickness, x, for Ti 8-1-1 in 1N $NaNO_3$ (dashed line) and in 1N NaCl (dotted line) at −222 and +706 mV (SHE) at 25°C.

although larger than at the lower potential, are far less than in the NaCl environment.

Based upon analysis of the R_p, dR_p/dt, and t_m parameters, it appears that, at least for titanium alloys, a case (*i*) → case (*iiib*) transition in dR_p/dt with an initial high R_p predicts susceptibility to stress corrosion cracking under the experimental conditions employed.

We should, nevertheless, not rule out some mechanism involving embrittlement by hydrogen through decohesion or fracture of titanium hydride (TiH_2) produced by the cathodic reduction reaction

$$Ti + 2H^+ + 2e^- \rightarrow TiH_2 \quad [9]$$

Since the results of our study show lower repassivation rates in the environment known to be susceptible to SCC, repassivation kinetics that can control or limit access of H^+ to the Ti surface may still be relevant. Secondly, fractographs of titanium alloys that have undergone SCC show a great deal of cleavage (8). This could rule out metal dissolution as a factor during crack propagation. However, the significantly higher metal dissolution in Cl^- solutions suggested by Beck (2) and confirmed in this study cannot be ignored. The effect of repassivation on metal dissolution must be important in the initiation stages of a crack when, because the pH of neutral chloride solutions would be near bulk solution values, the H^+ concentration would be too low for the reaction in Eq. [9] to play an important role. During later stages of propagation, where metal ion hydrolysis leads to pH and IR drops within the crack, hydride cleavage mechanisms must be considered in addition to the effects of environmental variations on film growth and metal dissolution kinetics.

Film growth kinetics.—The first stage of film growth appears to be consistent with the Fleischmann and Thirsk analysis of thin-film nucleation and growth (9). The extension of their model to interpret repassivation kinetic transient data was developed by Beck (2) who adopted the Fleischmann and Thirsk assumption of an instantaneous nucleation of n patches/cm^2 which spread in two dimensions until formation of an oxide monolayer is complete. His equation for the current density to the oxide patches is given by

$$i_f = 2mQ_fCt \exp[-Ct^2] \quad [10]$$

Since the patch thickness is assumed constant until complete monolayer coverage is obtained, Q_f would be constant; C would also be independent of time. This allows integration of Eq. [10] [from Ref. (2)]

$$1 - \theta = \exp[-Ct^2] \quad [11]$$

where θ is the fraction of surface coverage.

Taking logarithms of both sides gives

$$\log[1 - \theta] = -Ct^2 \quad [12]$$

Since θ is proportional to the ellipsometer parameter Δ which depends on average film thickness, hence also to ΔP (the change in polarizer reading), a plot of log ΔP *vs.* t^2 should be linear if the Fleischmann-Thirsk model is an appropriate one. Results are given in Fig. 7.

From Table II, we find that a monolayer (approximately 0.30 nm) has formed on Ti 8-1-1 in the $NaNO_3$ solution at the open-circuit potential in less than 5 msec. A comparison with the NaCl solution at the same potential shows that monolayer coverage is not obtained until some 30 msec later, and the log $(1 - \theta)$ *vs.* t^2 plot is linear, but two staged, indicating possible applicability of the Fleischmann-Thirsk model. The break in the −222 mV NaCl solution plot corresponds quite well with the change in slope of R_p *vs.* time plot (Fig. 2) indicating some change in the film growth process, perhaps the onset of the conversion of an already present salt film to an oxide film. The break in the +706 mV plot is not in good agreement with the R_p change in Fig. 3, however, indicating some delay in the onset of oxide growth. We have no explanation for this behavior. Experiments run at the higher anodic potential give approximately the same effect, that is, film growth is substantially slower in the chloride solution than in the nitrate. The fact that first stage growth rates at the higher potential are lower in the nitrate solution may be due to a localized pH lowering from solvated Ti^{+3} hydrolysis. This could measurably affect film growth kinetics. Such an effect would not be noticeable in the chloride solution where hydrolysis of the metal ions probably results in pH decreases in both potentials. The values of i_{max} for both solutions at the two potentials would substantiate this conclusion. In $NaNO_3$ the relative increase in peak current resulting from film removal at the higher potential is about 6:1 whereas only about a 3:1 increase is noted for chloride solution (Table II).

Simultaneous determination of both film thickness and total current allow an estimate of the amount of metal dissolution occurring during the repassivation transient. Such an estimate would allow prediction of the crack propagation velocities to be expected if propagation proceeds via an electrochemical dissolution mechanism as suggested by Beck (2).

Assuming that metal dissolution occurs by Tafel kinetics on the bare metal between patches

$$i_d = i_{d,o} \exp \left[\alpha(E_a - E_{o,t})/RT\right] \quad [13]$$

Total metal dissolution current over the entire surface is proportional to the area of bare metal exposed. It can be assumed, however, that the local dissolution current density on bare metal surfaces remains constant over the span of the repassivation transient until the patches coalesce. This would allow an estimate of the maximum penetration of metal by electrochemical dissolution. Since the local dissolution current density is given by $i_{max}/A, l_{pmax}$, the maximum penetration at those areas of surface last covered by the monolayer, is given by

$$l_{pmax} = \frac{i_{max} M_M}{10^3 z_M \mathbf{F} \rho_M A_M} t_m \quad [14]$$

Using data from Table II for Ti 8-1-1 in 1*N* NaCl at the open-circuit potential of −222 mV SHE, we obtain a value of l_{pmax} of 2.3×10^{-7} cm or a maximum propagation velocity of 6.0×10^{-6} cm/sec assuming metal dissolution as Ti^{+3}. Even if the $i_{max} \simeq i_d$ approximation is in error due to localized cathodic reactions, as well as overestimating bare metal surface area, propagation velocities based on electrochemical metal dissolution do not come close to the observed stress corrosion crack propagation velocities of 8×10^{-3} cm/sec by Beck at this potential (2).

However, propagation velocities are potential dependent, v_{pmax} being calculated as 16.2×10^{-6} cm/sec at a potential of +706 mV SHE. From this we would predict that upon increasing the applied potential by 1V the propagation velocity would increase by a factor of three, in agreement with Beck (2). This would suggest that although metal dissolution does not account for the observed crack propagation rates, it may be a necessary condition for such propagation.

The Fleischmann-Thirsk model for patch growth, coupled with the assumption of constant metal dissolution current density at the metal surface, would, however, predict creation of localized penetration sites. The geometry of these sites would lead to increased stresses at the point of maximum penetration as well as effecting environmental composition variations due to the occluded nature of these sites (Fig. 8).

Whether crack propagation then proceeds via a dissolution-assisted, mechanical, cleavage process or by fracture of a brittle region produced by entry into the metal of hydrogen formed by cathodic reduction cannot be determined on the basis of the results presented here. The specific function of halide ions (*e.g.*, Cl^-) in restricting lateral oxide growth is also highly speculative but may result from preferred ion adsorption inhibiting oxide growth kinetics. Green and Sedricks suggest that on the basis of their ellipsometric potential step experiments film growth kinetics play no part in determining SCC (7). However, they did not study film growth kinetics on bare metal surfaces, making their conclusions somewhat irrelevant to stress cracking. By varying the water content of 3.5% LiCl in dimethyl sulfoxide solutions they have been able to control crack propagation velocities in Ti 8-1-1 (10). Their results suggest the possibility of a hydrogen embrittling mechanism since no available hydrogen is present in pure DMSO; however, neglect in measuring their solution conductivities leaves open the possibility of crack propagation rates being limited by mass transfer of some rate-determining species. On the other hand, this work indicates that film growth rate and SCC susceptibility appear to be related for those environments studied.

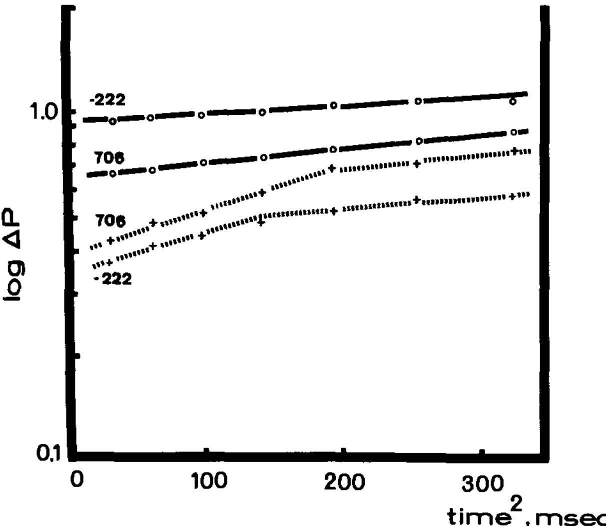

Fig. 7. Changes in $\log_{10}\Delta P$ for Ti 8-1-1 in 1*N* $NaNO_3$ (dashed line) and 1*N* NaCl (dotted line) at −222 and +706 mV (SHE) at 25°C.

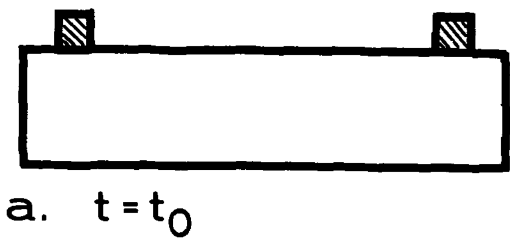
Conclusions

1. Ti 8-1-1 alloy repassivates rapidly in $NaNO_3$ solution as indicated by a low R_p and dR_p/dt with a monolayer of oxide being formed in less than 5 msec.

2. Ti 8-1-1 alloy repassivates less rapidly in NaCl solution than in $NaNO_3$ solution as indicated by a higher R_p with an initially higher dR_p/dt. Although monolayer coverage is not obtained until after 38 msec following oxide removal, a decrease in dR_p/dt is observed at 12 msec, probably to inhibition of metal dissolution by a precipitated salt layer.



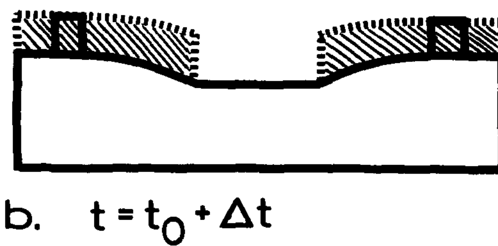


Fig. 8. Schematic of the effect of the Fleischmann-Thirsk model of oxide path nucleation and growth on substrate penetration by metal dissolution. (a) Nucleation of oxide patches at cessation of abrasion; (b) metal dissolution during lateral patch growth resulting in formation of localized crevices where patches coalesce (c).

3. An analysis of ellipsometrically determined film growth kinetics on Ti 8-1-1 shows that the Fleischmann-Thirsk model of oxide patch nucleation and growth is applicable in both 1*N* NaCl and 1*N* $NaNO_3$ solutions.

4. A calculation of the maximum penetration resulting from Ti dissolution in Ti 8-1-1 in NaCl solution during the 38 msec time interval for oxide monolayer formation shows that crack propagation velocities observed by others cannot be accounted for by metal dissolution alone.

Electrodissolution Kinetics of Iron in Chloride Solutions

IV. Alkaline Solutions Containing Benzotriazole

S. Asakura, C. C. Lu, and Ken Nobe*

School of Engineering and Applied Science, University of California, Los Angeles, California 90024

ABSTRACT

The anodic dissolution of iron in alkaline chloride solutions in the presence and absence of benzotriazole has been investigated by potentiostatic, galvanostatic, and potential sweep polarization. The steady-state and transient polarization experiments indicate that iron dissolution occurs in the absence (active region) and presence (prepassive region) of a porous prepassive surface film. Anodic Tafel slopes of 60 mV/decade were obtained below (active region) and above (prepassive region) the formation potential of the prepassive film on both uninhibited and inhibited iron indicating the same mechanism of iron dissolution. The results suggest that the prepassive film merely decreases the effective surface area for iron dissolution. The effect of benzotriazole is to decrease further the effective surface area.

There have been numerous investigations of benzotriazole (BTA) as a corrosion inhibitor of copper [*e.g.*, see Ref. (1-3)] but very little work has been reported on iron. Some recent studies have shown that BTA inhibits the hydrogen evolution reaction on iron (4, 5) and steel (6). Furthermore, the results of Chin (4) indicate that the adsorbed BTA does not affect the mechanism of the h.e.r. on iron. Although Santhianandhan *et al.* (6) reported that BTA increases the anodic polarization of mild steel in acidic solutions, no attempt was made by these workers to elucidate the role of BTA in the dissolution mechanism.

A previous paper in this series (7) describes an investigation of the mechanism of iron dissolution in alkaline chloride solutions. This earlier work forms the basis for this paper which reports on the effects of benzotriazole on the kinetics and mechanism of iron dissolution in alkaline chloride solutions. Both steady-state and transient polarization techniques have been used.

Experimental

Electrodes were prepared from Ferrovac E iron rod (1 cm diam). The cross-sectional surfaces were polished with 2/0 emery paper, and then the electrodes were degreased in detergent and washed several times with distilled water and benzene. Each electrode was sealed in Teflon tubes and inserted into electrode holders so that only one surface was exposed to the electrolyte. A three electrode, Pyrex glass, electrochemical cell was used. Specific pH values of the alkaline solutions were obtained by addition of appropriate quantities of KOH to the 1*N* KCl solutions. The inhibited system was prepared by the addition of 77 mM benzotriazole (BTA) to the electrolyte. The solutions were deaerated by bubbling prepurified nitrogen gas through the electrolyte for 24 hr before each experiment. The temperature was maintained at 25° ± 1°C.

Electrode potentials were measured with respect to the saturated calomel electrode (SCE). Linear potential sweep, potentiostatic, and galvanostatic polarization were used in the experiments.

After immersion in the electrolyte, the electrode was reduced at −1.5V *vs.* SCE until the cathodic current reached steady state. Subsequently, open-circuit conditions were initiated and then maintained until the rest potential was attained. After this procedure, either potential or current steps, or potential sweeps were imposed by a potentiostat coupled with function generators.

Results

Steady-state polarization.—Figure 1 shows the steady-state polarization of inhibited (in the presence of BTA) and uninhibited iron in solutions of pH = 12.8. For uninhibited iron (curve A) the current increased monotonically with increase in potential. Reproducibility of the data was very good. In contrast to the behavior of iron in the absence of BTA, inhibited iron showed a constant current region which was independent of the applied potential (*i.e.*, a limiting current). This constant current value was a function of the history of the inhibited electrode since a newly immersed electrode (curve B) exhibited a larger value than an aged one (curve C).

It was observed that both an increase in immersion time and repetitive anodic polarization decreased the constant current value. After the electrode was aged sufficiently by repetitive anodic polarization and/or long immersion, it exhibited a reproducible polarization (curve C) as shown in Fig. 1.

The polarization behavior on an expanded scale is shown in Fig. 2. Both potentiostatic (closed points) and galvanostatic (open points) polarization data are given, and it is seen that good agreement is obtained. In Fig. 2, the correction for the ohmic potential drop is made in the polarization plot of uninhibited iron, and it is seen that Tafel behavior with a slope of 60 mV/decade is obtained over the entire potential region examined. That is

$$\frac{\partial \phi_a}{\partial \log i_a} = 60 \text{ mV/decade} \quad [1]$$

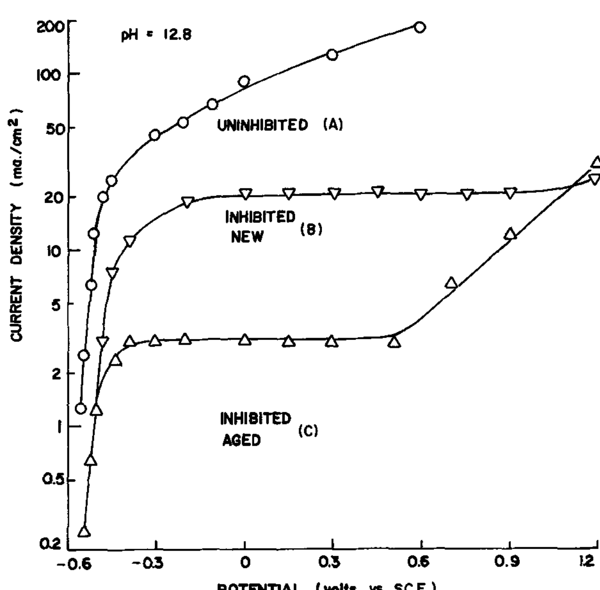

Fig. 1. Steady-state polarization of iron in chloride solutions of pH = 12.8.

* Electrochemical Society Active Member.

Key words: inhibition, anodic dissolution, corrosion.

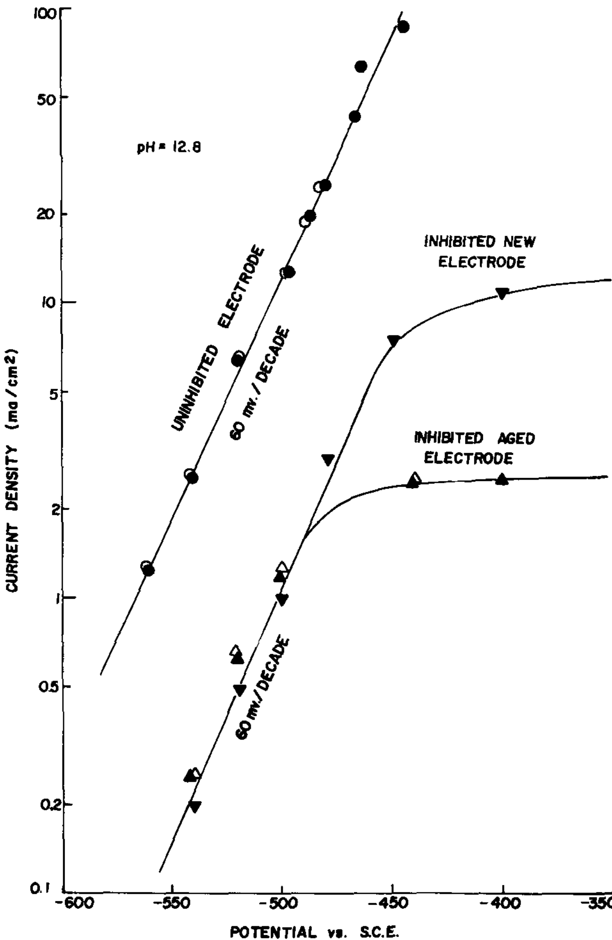

Fig. 2. Steady-state polarization of iron in chloride solutions of pH = 12.8 (expanded scale). Closed and open points represent potentiostatic and galvanostatic polarization, respectively.

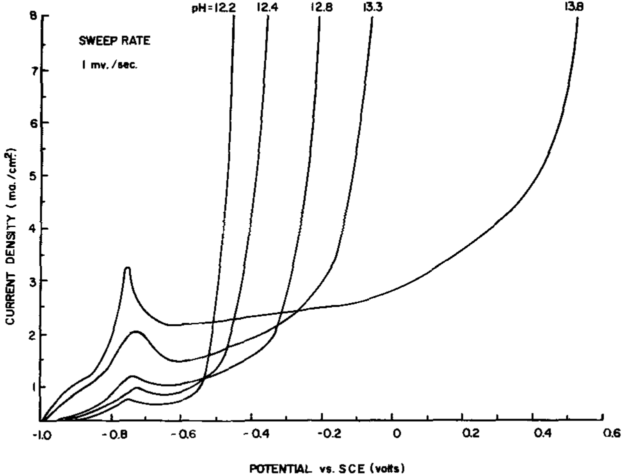

Fig. 3. Typical current-potential behavior of uninhibited iron at a constant potential sweep rate.

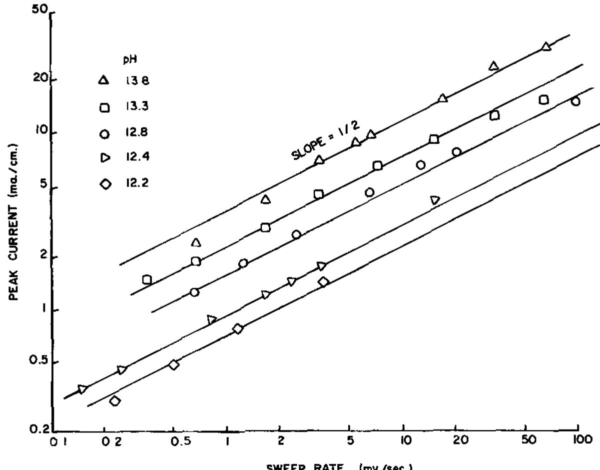

Fig. 4. Peak current vs. sweep rate of uninhibited iron

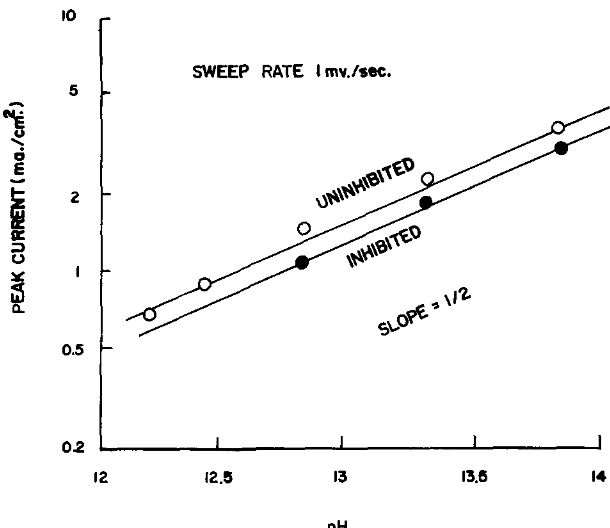

Fig. 5. Peak current vs. pH for uninhibited and inhibited iron

for uninhibited iron where ϕ_a and i_a are the anodic potential (corrected for ohmic potential drop) and the steady-state anodic current, respectively. In the low current density region, inhibited iron also showed Tafel behavior with a slope of 60 mV/decade

$$\frac{\partial E_a}{\partial \log i_a} = 60 \text{ mV/decade}, \quad i_a \leq 1 \text{ mA/cm}^2 \qquad [2]$$

where E_a is the apparent electrode potential. In the plots for the inhibited system, the ohmic potential drop was negligible in the low current density region. It should be noted that at pH = 12.8 the electrode potential ϕ_a was still within the region of active dissolution even at high current densities for the uninhibited system.

Potential sweep.—Figure 3 shows typical potential-current behavior of uninhibited iron in solutions of various pH obtained with a constant potential sweep rate. After the peak current, the current decreased and then increased again. Similar behavior was observed for inhibited iron. The peak current (i_p) is plotted *vs.* sweep rate (λ) in Fig. 4 for uninhibited iron in chloride solutions ranging from pH = 12.2 to 13.8. For both uninhibited and inhibited iron, log i_p is linearly related to log λ with a slope of 1/2 for all pH values

$$\left(\frac{\partial \log i_p}{\partial \log \lambda}\right)_{pH} = \frac{1}{2} \qquad [3]$$

The dependence of i_p on pH for both inhibited and uninhibited systems is shown in Fig. 5. In both cases linear relations were obtained for the log i_p *vs.* pH plots with slopes of 1/2

$$\left(\frac{\partial \log i_p}{\partial pH}\right)_{\lambda} = \frac{1}{2} \qquad [4]$$

However, the i_p values were decreased by addition of inhibitor. For example, the effect of the inhibitor on the value of i_p can be expressed as

$$\frac{i_p \text{ (inhibited)}}{i_p \text{ (uninhibited)}} = 0.8 \quad \text{for} \quad pH = 12.8 \qquad [5]$$

The peak potential E_p was also dependent on the sweep rate as shown in Fig. 6 for the inhibited system. Linear relations in the E_p *vs.* log λ plots with a slope of about 34 mV/decade were obtained for both inhibited and uninhibited iron, *i.e.*

$$\left(\frac{\partial E_p}{\partial \log \lambda}\right)_{pH} \approx 34 \pm 10 \text{ mV/decade} \quad [6]$$

As shown in Fig. 7, E_p did not depend on pH, *i.e.*

$$\left(\frac{\partial E_p}{\partial pH}\right)_{\lambda} = 0 \quad [7]$$

However, E_p values of inhibited iron were about 50 mV more positive than uninhibited iron.

Potentiostatic transients.—Typical current transients under potentiostatic conditions are shown in Fig. 8 and 9 in log-log plots of i and t where i and t are the transient current and time after imposition of a potential step, respectively. Electrodes used for the transient studies were aged before measurements were carried out. The log i *vs.* log t plots exhibited a linear relation with a slope of $-1/2$ during the initial part of the transient, *i.e.*

$$i = A/\sqrt{t} \quad [8]$$

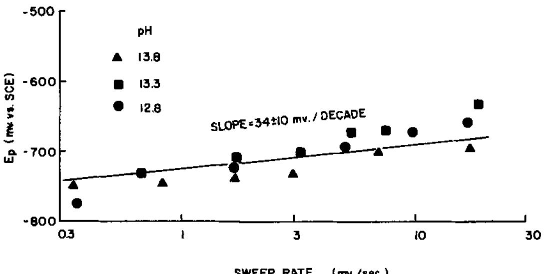

Fig. 6. Peak potential vs. sweep rate for inhibited iron

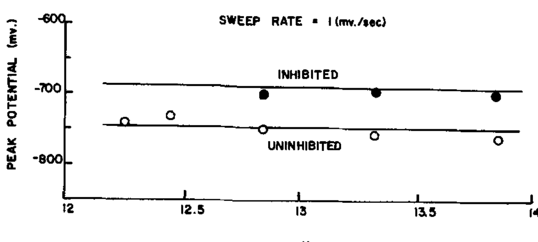

Fig. 7. Peak potential vs. pH for uninhibited and inhibited iron

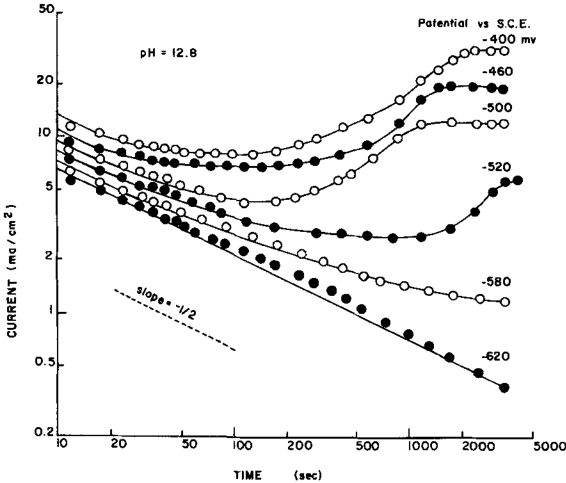

Fig. 8. Potentiostatic transients of the uninhibited system at pH = 12.8.

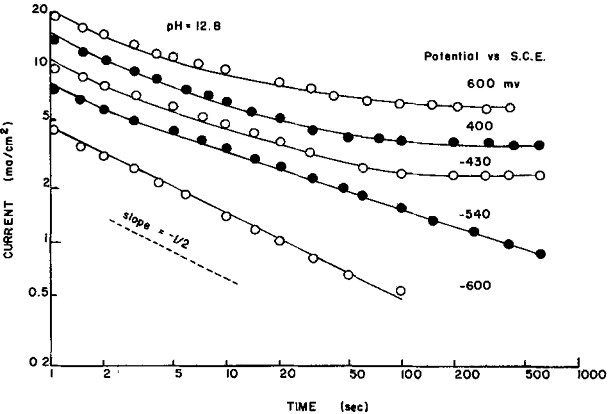

Fig. 9. Potentiostatic transients of the inhibited system at pH = 12.8.

where the constant A is a function of the potential step E.

Figure 8 shows that the current of uninhibited iron in $pH = 12.8$ solutions decayed initially and then increased after long polarization to steady-state values for $E > -520$ mV. On the other hand, Fig. 9 shows that the current of inhibited iron decayed monotonically with no increase with time observed.

Galvanostatic transients.—The potential immediately after charging of the double layer was plotted against the applied current in Fig. 10 [see Fig. 4, Ref. (7)]. These plots exhibit Tafel behavior with a slope of 60 mV/decade for different pH solutions in the presence and absence of BTA. The pH dependence of anodic dissolution is obtained by plotting the current at -750 mV *vs.* SCE (in Fig. 10) *vs.* the pH as shown in Fig. 11. For uninhibited iron the log current was linearly related to pH with a slope of 1/2. Thus, the initial

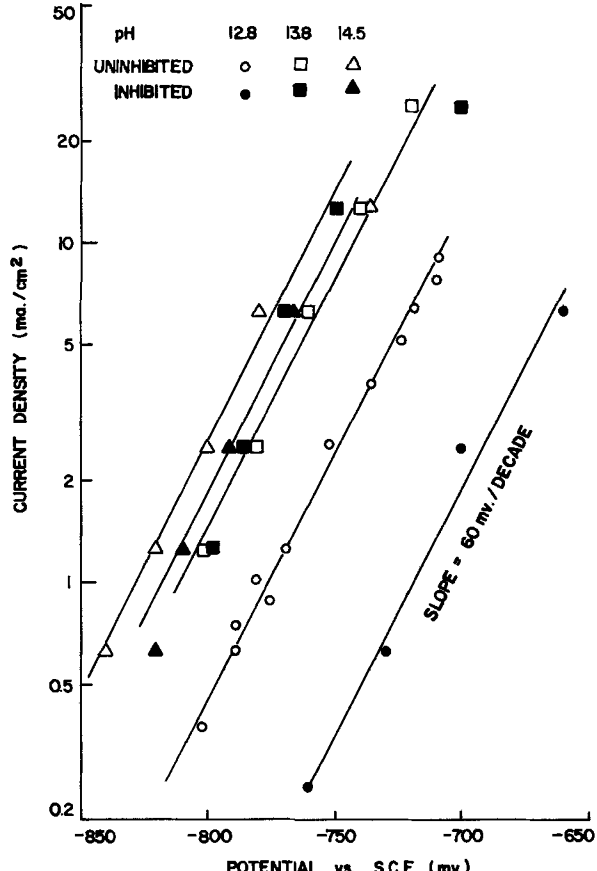

Fig. 10. Current-potential behavior immediately after galvanostatic charging of the double layer (active region).

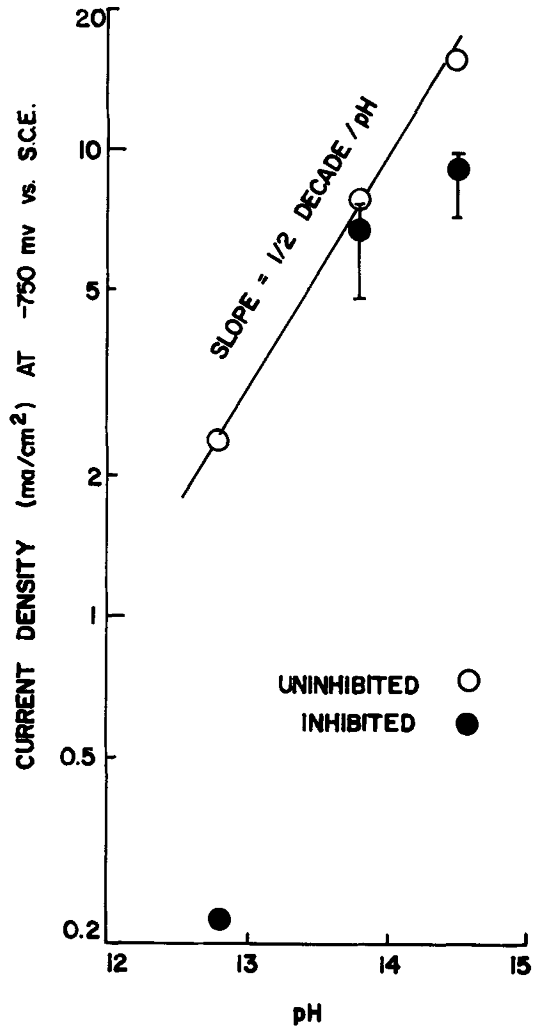

Fig. 11. The pH dependence of anodic dissolution in the active region. $E = -750$ mV vs. SCE.

potential-current relation which represents the active dissolution of uninhibited iron can be expressed as

$$i = K_1 \ (OH^-)^{1/2} \exp\left(\frac{FE}{RT}\right) \qquad [9]$$

For inhibited iron

$$i = K_2 \exp\left(\frac{FE}{RT}\right) \qquad [10]$$

where K_2 is some function of OH^- concentration.

Discussion

Potentiostatic and galvanostatic experiments.—In the previous paper (7) it was concluded that active iron dissolution was followed by passivation in 1*N* KCl solutions of $pH = 12.8$, and the peak potential was identified as the primary passivation potential. The more detailed studies reported in the present paper indicated that true passivation conditions were not attained; rather, the peak potential was actually the formation potential of a prepassive film similar to the phenomenon observed for nickel in sulfuric acid by Bockris and his co-workers (8). In the present paper, the potential range below and immediately above the peak potential will be referred to as the active region and the prepassive region, respectively.

The polarization curve of uninhibited iron in Fig. 2 shows the steady-state dissolution behavior of iron covered with the porous prepassive film. On the other hand, the dissolution of iron in the active region was only attained during transient conditions as shown in previous experiments (7) and in Fig. 10. The same value of the anodic Tafel slopes, 60 mV/decade, for iron dissolution in both the active and prepassive regions indicates that iron dissolution occurs by the same reaction mechanism. The difference in the apparent current densities of iron in the active and prepassive regions may be attributed to the difference in the effective surface area for the dissolution reaction. In other words, in the prepassive region, dissolution occurs only at that part of the surface not covered by the prepassive film.

Since Fig. 2 and Fig. 10 show iron dissolution in the prepassive and active regions, respectively, a relative measure of the surface area not covered by the prepassive film can be obtained by comparing the apparent current densities in the two regions, *i.e.*

$$\frac{i_{\text{prepassive}}}{i_{\text{active}}} \approx 10^{-3}, \quad \text{at} \quad pH = 12.8 \qquad [11]$$

In other words, during steady-state dissolution of iron, the ratio of the "true" surface area (*i.e.*, the surface area not covered by the prepassive film) to the apparent surface area is approximately 10^{-3}. The addition of BTA does not appear to change the reaction mechanism since anodic Tafel slopes remain the same. However, BTA does reduce the effective surface area for iron dissolution as seen in Fig. 2. The ratio, i (inhibited)/i (uninhibited) ≈ 0.1, gives a measure of the relative effective surface areas of inhibited and uninhibited iron.

In the previous study (7), the formation of the prepassive film was attributed to the precipitation of a hydroxochloro-iron complex. In this study, it seems reasonable to suppose that the prepassive films on inhibited iron contain BTA.

The constant current (limiting current) region of inhibited iron in $pH = 12.8$ solutions during steady-state polarization, as shown in Fig. 1 and 2, may be due to diffusion of this complex as the rate controlling step in the dissolution of iron. The mechanism of dissolution and precipitation of the prepassive film presented in Ref. (7) must be modified to include the participation of BTA for the inhibited system. The greater surface coverage of BTA on aged electrodes facilitates the precipitation of the complex on additional parts of the "bare" surface (*i.e.*, the complex film is less porous) at the onset of the limiting diffusion current region. Thus, the aged inhibited electrodes have considerably less "bare" surface than the unaged electrodes.

The potential-current relation for the active dissolution of iron as shown in Fig. 10 has been developed theoretically by the previous analysis (7). Furthermore, the results in Fig. 11 provide the experimental verification of the pH dependence of active dissolution of iron which has been derived theoretically in the previous paper [Eq. 15, Ref. (7)]. Thus, the empirical relationship, Eq. [9], obtained for the active dissolution of uninhibited iron is consistent with the relationship deduced theoretically by applying the Temkins isotherm to the Bockris mechanism for iron dissolution.

Potential sweep experiments.—The functional dependence of the peak current and peak potential on both the sweep rate and pH is not affected by the presence of BTA. These relations are given by Eq. [3] and [4] for the peak current while Eq. [6] and [7] give the relations for the peak potentials of inhibited and uninhibited iron. Although the functional dependence of these two parameters on sweep rate and pH are not affected by BTA, their absolute magnitudes are affected as shown in Fig. 5 and 7. It is seen that the presence of BTA decreases the peak current and increases the peak potential.

According to the previous theoretical analysis (7), the active dissolution of iron in alkaline chloride solutions followed the relation

$$i_a = k_b'' \ [OH^-]^{1/2} \exp \ (FE/RT) \qquad [12]$$

where k_b'' is a constant and $[OH^-]$ is the activity of hydroxyl ions. Furthermore, the peak current and peak

potential relationships were determined theoretically and confirmed experimentally as

$$i_p = 2\,\mathbf{F}k \exp(E_p/K) = 2\,\mathbf{F}C_S\sqrt{\frac{D\lambda}{K}} \quad [13]$$

and

$$E_p = \frac{K}{2}\ln\lambda + K\ln\left(\frac{C_S}{k}\sqrt{\frac{D}{K}}\right) \quad [14][1]$$

where $K = RT/\mathbf{F}$, $k = k_b''[OH^-]^{1/2}$, and C_S and D are the saturated concentration and diffusion coefficient of the iron complex, respectively.

Differentiation of Eq. [13] with respect to pH gives

$$\left(\frac{\partial \log i_p}{\partial \text{pH}}\right)_\lambda = \left(\frac{\partial \log C_S}{\partial \text{pH}}\right)_\lambda \quad [15]$$

Equations [4] and [15] give

$$\left(\frac{\partial \log C_S}{\partial \text{pH}}\right)_\lambda = \frac{1}{2} \quad [16]$$

Then

$$C_S \propto [OH^-]^{1/2} \quad [17]$$

This relation can also be obtained by differentiating Eq. [14] with respect to pH

$$\left(\frac{\partial E_p}{\partial \text{pH}}\right)_\lambda = \left(\frac{\partial \ln C_S/k}{\partial \text{pH}}\right)_\lambda = 0 \quad [18]$$

Thus

$$\ln\frac{C_S}{k} = \text{constant} \quad [19]$$

Since k is proportional to $[OH^-]^{1/2}$

$$C_S \propto k \propto [OH^-]^{1/2} \quad [20]$$

[1] Equation [37] in the previous paper (7) contains several typographical errors. Equation [14] in this paper is the correct form.

Equations [17] and [20] show that the pH dependence of the saturation concentration of the complex can be deduced from different experimental parameters by using the analysis described previously (7). Since the peak parameters for inhibited iron followed the relationships given in Eq. [3], [4], [6], and [7], the precipitation mechanism for prepassive film formation on both inhibited and uninhibited iron should be the same. The primary effect of BTA is to decrease the effective surface area.

Effect of Arsenic upon the Entry of Hydrogen into Mild Steel as Determined at Constant Electrochemical Potential

R. D. McCright* and R. W. Staehle*

The Ohio State University, Columbus, Ohio 43210

ABSTRACT

Arsenic added as arsenite (AsO_2^-) to acid solutions promotes the entry of hydrogen into steel structures during cathodic polarization. The extent of the hydrogenation depends on electrochemical potential. At the corrosion potential of the steel, arsenite inhibits the entry of hydrogen; the reduction of arsenite to elemental arsenic suppresses the hydrogen evolution reaction. Only when the specimen is polarized to sufficiently cathodic potentials is there noticeable entry and permeation of hydrogen in steel. The greater the concentration of arsenite is in the solution, the greater is the extent of cathodic polarization needed to bring about measurable permeation. The entry of hydrogen does not depend on arsine formation; the greatest relative permeation occurs in the potential range where arsenic is the stable phase.

The purpose of this investigation was to determine the effects of additions of arsenic compounds to solutions used for hydrogen-charging steel specimens when the entry kinetics of the hydrogen are controlled potentiostatically. Compounds of arsenic and other 5-A, 6-A, and even 7-A elements are known to increase greatly the amount of hydrogen entering an iron or steel specimen polarized cathodically (1-9). However, most experiments have been carried out by applying a constant current without measuring the accompanying electrochemical potential. Electrochemical processes such as electrodeposition, pickling, corrosion, and cathodic protection during which hydrogen can enter iron and steel occur over fairly narrow ranges of potential. Moreover, the role of potential is fundamental in explaining the mechanism whereby arsenic and the other elements enhance hydrogen entry. These elements are generically called either "promoters" because they promote hydrogenation of the specimen or "poisoners" because they poison the hydrogen evolution reaction on the metal surface.

At potentials encountered during the electrolytic production of hydrogen on an iron cathode, arsenic is

* Electrochemical Society Active Member.

Key words: permeation of hydrogen, arsenite, hydrogenation of steel, adsorption of hydrogen, cathodic polarization.

thermodynamically stable as the metallic phase (As°) or as the gas, arsine (AsH_3), at the most negative potentials. The form in which arsenic is added, arsenite (AsO_2^-), is not stable in the regime of potentials where H_2 is stable. Because arsenic is added to these solutions in an oxidized form (arsenite or arsenate), cathodic polarization reduces the compound and codeposits the As along with the hydrogen.

Several treatments of the hydrogen evolution reaction (HER) exist (10-14). This reaction occurs in two important steps: an ionic discharge step followed by either a chemical desorption step (recombination of two adsorbed H atoms to give H_2) or an electrodic desorption step (adsorbed H atom + H^+ to give H_2).

The hydrogen absorption reaction (HAR) occurs as a side reaction, since the hydrogen is adsorbed as the atomic species and enters the metal: $H_{ads} \rightarrow H_{abs}$. Thus, the HAR competes for the same population of H_{ads} as the HER. McBreen and Genshaw (15) summarized the rate equations and the predictions of the permeation rate for control of the HER by each of the steps, considering also the effect of the adsorption energetics on the permeation rate. Although the kinetics of the HER on an iron surface are less well characterized than on platinum and palladium, one investigation (16) showed that the rate-controlling mechanism in acid solution without promoter additions is coupled discharge-chemical desorption. This means that the two steps have nearly equal activation energy barriers, and the reasonable conclusion is that arsenic and other promoters somehow increase the barrier for the chemical desorption (recombination) step and thereby favor the competing absorption step.

Explanation of the enhanced hydrogenation effect in the presence of promoters involves the formation of a stable hydride according to some previous works. For example, when carbonyl Fe wires loaded in torsion were hydrogen charged from 1*N* H_2SO_4 containing As_2O_3 (17, 18) no embrittlement occurred until the potential became more active than about -400 mV_H. This value corresponds to a reversible potential for As/AsH_3 with As at unit activity and an AsH_3 fugacity of 10^{-7} atm. The conclusion reached was that arsine formation was necessary for significant hydrogenation. Using 1*N* H_2SO_4 with various promoter additions and measuring the elongation of hydrogen-charged iron wires or coils, Smialowski and Szklarska-Smialowska (4-6) found that the relative effectiveness of the promoter element correlated well with increasing bond strength and stability of the hydride ($H_2S > PH_3 > AsH_3$). Newman and Shreir (8), who reached essentially the same conclusion as in the Smialowski work, galvanostatically charged high-strength steel specimens for 24 hr and measured the hydrogen content afterwards. Having performed their experiments over a wide range of *p*H, they found that As and P were effective promoters at all *p*H's (their hydrides are stable over the entire 0-14 *p*H range); whereas S, Se, and Te were more effective in acid solution (their hydrides hydrolyze in more alkaline solutions). Furthermore, they obtained correlation between the *p*H at which hydrogenation of the specimen occurred and the pK_a for the ionization.

Radhakrishnan and Shreir (9) while hydrogenating shim steel specimens by the electropermeation technique, found that As, added as $NaAsO_2$ to 0.1*N* H_2SO_4 solutions, gave the highest permeation rates of all the 5-A and 6-A elements. However, the authors found that AsH_3, produced outside their permeation cell, did not enhance the hydrogen permeation rate when bubbled into the cell.

The discrepancy in the necessity of the presence of arsine in these last two papers cited (8, 9) emphasizes the need for an examination of the factors influencing the hydrogen entry in the presence of promoters. With regard to arsenic the following questions are of interest: Is arsine formation necessary for causing hydrogen to enter the metal? If so, how does the arsine accomplish this? Does the experimental technique used to charge or detect the hydrogen play an important role?

Experimental Procedure

The electropermeation technique, developed by Bockris and Devanathan (19) and subsequently used in other investigations (9, 16, 20-25), was used for simultaneously hydrogenating the specimen and measuring the outflux of hydrogen. In this technique a thin specimen is simultaneously cathodically polarized at one surface and anodically polarized at the other; the hydrogen is produced at the first surface, passes through the metal, and is oxidized at the second surface. The permeation current is calculated as the difference between the current at the exit side, when the entry side is cathodically polarized, and the current in the absence of cathodic polarization.

Instrumentation.—The instrumentation consisted of two potentiostats (Wenking Model 66-TS-10) for maintaining potential control and measuring the currents of cathodic and anodic polarization, an electrometer (Keithley Model 610B) that served to amplify the anodic currents, and a recorder (Esterline-Angus AZAS) for registry of these currents. Special attention was paid to the grounding of all these instruments.

Material.—The steel used for these tests was shim stock with a composition corresponding to AISI 1010: C, 0.08-0.13%; Mn, 0.30-0.60%; P, 0.40% max; S, 0.50% max. Two-mil thick specimens (5×10^{-3} cm) were used. The shim steel was cut into square coupons of 3.5 cm on the edge and vacuum annealed at 650°C for 2 hr. The structure consisted of large ferrite grains and pearlite colonies with inclusions mostly concentrated at the ferrite grain boundaries. Following annealing, the surface was cleaned in H_2SO_4 solution, lightly mechanically polished, and rinsed in acetone. The surface area exposed to the solution in the permeation cell was 2 cm^2.

Solutions.—Solutions used were 0.1*N* NaOH at the exit side and either 0.1*N* H_2SO_4 or an acetate buffer (0.25*N* CH_3COOH and 0.20M CH_3COONa; *p*H = 4.5) at the entry side. To the latter was added small amounts of sodium arsenite, $NaAsO_2$, as required. Reagent grade chemicals were used; no further purification of these was attempted. Solutions were deaerated by bubbling nitrogen gas for 2-3 hr in a separate cell before commencing the hydrogen charging. The solutions were transferred to the permeation cell and bubbling was continued during the permeation experiment to agitate the solutions. All experiments were performed at room temperature. Reference electrodes were saturated calomel.

In order to reduce the passivation current at the exit side, a thin plate of palladium was electrodelessly plated on this surface prior to insertion of the steel sample in the permeation cell. The palladization treatment has been discussed previously (19). Further, the Pd accelerates the kinetics of hydrogen oxidation, whereas on an Fe surface a significant part of the hydrogen undergoes the competitive recombination reaction to form molecular hydrogen. Since this last reaction is not electrochemical, it does not contribute to the measured current. Thus, the permeation current measured on a palladized steel specimen is much more nearly the true hydrogen flux.

Ancillary experiments.—Polarization and coulombic deposition experiments were performed to clarify important features of arsenic relative to hydrogen entry kinetics. Polarization experiments were performed on the shim steel in the sulfuric acid and acetate buffer solutions with and without additions of $NaAsO_2$. A special cell and holder for accommodating sheet specimens was constructed for these experiments (26). Polarization data were obtained by the potentiokinetic technique at a scan rate of 600 mV/hr, which approximates steady-state conditions. Coulombic deposition of arsenic was performed on specimens destined for study

of the effect of an As predeposit before permeation. The deposition was carried out in a more concentrated $NaAsO_2$ solution (41,000 μg As/mliter, pH 9) in which the deposition of hydrogen can be totally suppressed. The amount of As deposited was determined coulombically by graphically integrating the i-t plot with potentiostatic control throughout the deposition.

Results

Permeation experiments.—Generally, a permeation experiment is run until the permeation current establishes a steady-state value, the permeation transient showing a plateau under steady-state conditions. However, as the charging potential is made very active or the charging current is increased, a steady-state condition does not obtain. At first, the plateau of the permeation transient (i_p as a function of time) shows only a small decrease with time. Then as the potential is made more active, the deviation from a steady-state condition becomes more and more severe and there occurs a sharp decline of the permeation current with time. This same behavior has been noted before (15, 21); the explanation offered is that blisters form under the metal surface, these blisters resulting from hydrogen recombination at internal surfaces which act as hydrogen sinks. Accordingly, the permeation rate drops since less hydrogen evolves from the exit side. Other effects tending to prevent a steady-state permeation current are the local increase in pH at the entry surface during prolonged electrolysis and formation of hydrogen gas bubbles which reduce the effective surface area. These effects become important at high charging current densities. We indicate on the appropriate graphs where the deviation from steady-state permeation occurred. Thus, to avoid the above complications, comparisons of permeation behavior are best considered at modest cathodic polarizations and/or low charging current densities.

Two ways of presenting the permeation data as a function of the applied cathodic potential are used here. The first method plots the permeation current *vs.* the potential; the second involves the calculation of the permeation efficiency $i_p^\infty/i_c \times 100$ where i_p^∞ is the steady-state permeation current density, and i_c is the cathodic charging current density measured when the potential reached its steady-state value. The cathodic charging current is essentially equal to the hydrogen deposition current, except in the potential range where the concomitant deposition of arsenic consumes a significant part of the total current. The maximum of the permeation current density and the cathodic charging current density existing when the maximum obtains are used for calculating the permeation efficiencies when the hydrogen permeation decreased with time during cathodic charging.

The results obtained for permeation from $0.1N$ H_2SO_4 with and without additions of arsenite are illustrated in Fig. 1, the arsenite concentration being expressed in micrograms of elemental arsenic per milliliter. Evidently, very small amounts of arsenite are quite effective in promoting hydrogenation. The slashes through the points in Fig. 1 show where the anomalous behavior of the permeation transients occurred. This behavior is particularly noticeable in the acid solution, since an increase in the over-all hydrogen reduction kinetics (more active potential) actually decreases the hydrogen permeation in the metal.

In Fig. 2 are shown the curves of the permeation efficiency as a function of the cathodic potential at the entry side. A much larger fraction of the hydrogen produced at the entry side enters the steel in the presence of arsenite. Permeation efficiency expresses a relative or normalized permeation.

According to Fig. 1 and 2 enhanced hydrogenation occurs in the region of potential where elemental arsenic is the stable phase. These figures indicate the equilibrium potential between arsenic (metallic, unit activity) and AsH_3 at a fugacity of 10^{-7} atm. It was at the potential corresponding to this arsine fugacity

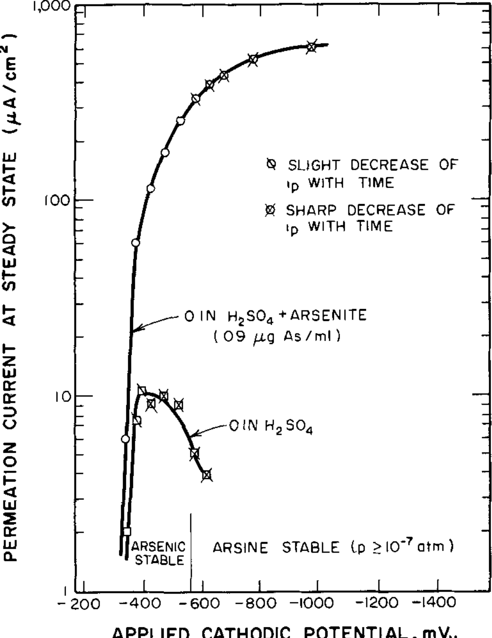

Fig. 1. *Steady-state hydrogen permeation of 1010 steel as a function of applied cathodic potential in sulfuric acid solutions.*

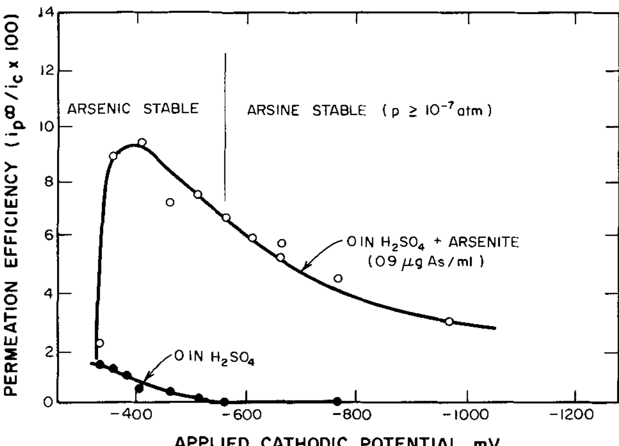

Fig. 2. **Permeation efficiencies of 1010 steel as a function of applied cathodic potential in sulfuric acid solutions.**

that the Polish experimenters noted hydrogenation of their specimens (embrittlement or elongation) (16, 17).

The results obtained by cathodic charging from the acetate buffer are shown in the next two figures. Figure 3 shows the permeation current density as a function of the applied cathodic potential, and Fig. 4 shows the permeation efficiency as a function of the applied cathodic potential. When these data are compared with those obtained from the H_2SO_4 solution, it appears that acetate itself might act as a weak promoting anion (by comparison with sulfate), since the acetate solution without arsenite gives a higher permeation efficiency (Fig. 4) than the sulfuric acid solution (Fig. 2). Moreover, when the hydrogen was charged from an H_2SO_4-K_2SO_4 solution at pH 4.5 (same pH as acetate), the permeation current was nil. A buffering system, such as acetate permits greater acidity near the cathodically polarized electrode. As the solution becomes more alkaline, the buffer produces more H^+ to restore the pH. This hydrolysis cannot occur so extensively in the strongly ionized sulfate solution.

Two other effects are also shown in Fig. 3 and 4. Curves 2 and 3 in the figures show the effect of arsenite concentration on the permeation behavior. Increasing the concentration acts to shift the potential range at

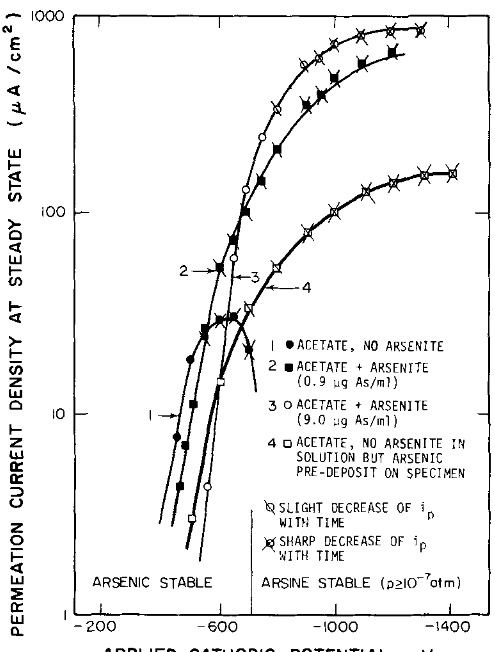

Fig. 3. Steady-state hydrogen permeation of 1010 steel as a function of applied cathodic potential in acetate solutions.

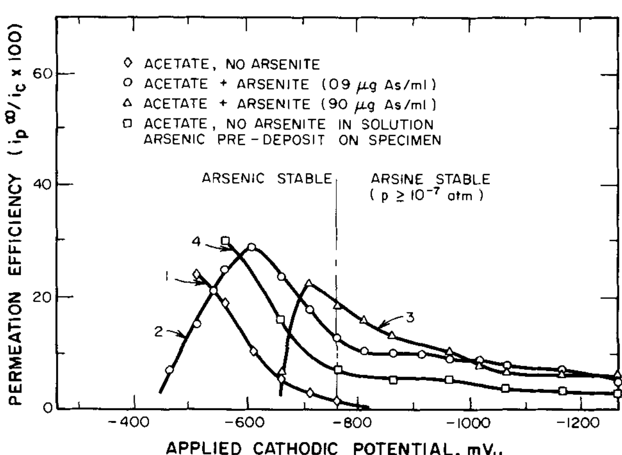

Fig. 4. Permeation efficiencies of 1010 steel as a function of applied cathodic potential in acetate solutions.

which the enhanced permeation occurs to more active values. Thus, adding arsenite in the solution suppresses hydrogen entry at the corrosion potential, although the permeation efficiency of the small amount of hydrogen produced is large. Curve 4 shows the effect of predeposition of arsenic where intermediate behavior is observed relative to that of pure acid (hydrogen deposition only) and the solution containing arsenite (codeposition of As and H). The amount of As predeposited was equivalent to 60 mcoulombs, or about 40-50 monolayers if uniformly deposited. During a typical permeation experiment this amount of As is reduced simultaneously with the production of hydrogen. However, examination of the surface verified that the surface was not uniform and tended to spall; the arsenic deposition was not crystalline. In the acetate solution, as well as in H_2SO_4, the highest permeation efficiency occurs in the potential domain where elemental arsenic is the stable phase.

When the hydrogen entry kinetics were galvanostatically controlled over a wide range of currents, the curves shown in Fig. 5 were obtained. Experimental conditions were similar to those used to obtain the data shown in Fig. 3. The highest permeation rates occurred during codeposition of As and H, the As predeposit giving significantly lower permeation currents.

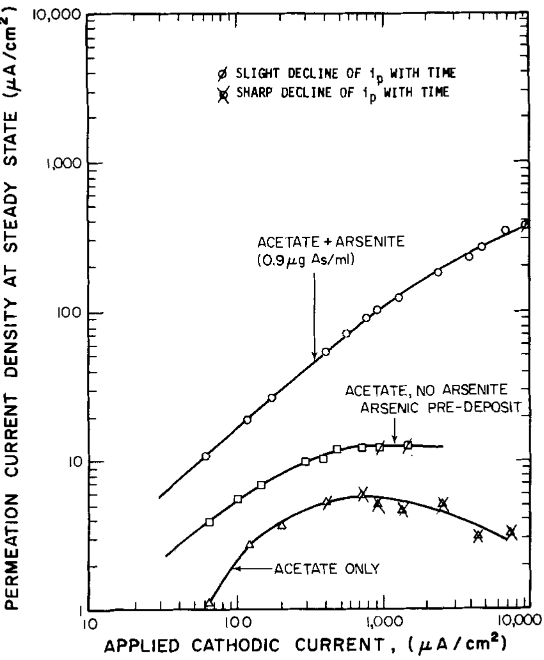

Fig. 5. Steady-state hydrogen permeation of 1010 steel as a function of applied cathodic current density in acetate solutions.

Polarization experiments.—Addition of arsenite shifts the corrosion potential to more noble values and particularly decreases the cathodic kinetics in the region of the corrosion potential. The influence of arsenite on the corrosion potential is seen in Fig. 6 where the experimental potential dependencies are near the 20 mV/decade value given by the Nernst equation for AsO_2^-/As equilibrium at room temperature. For the case of cathodic polarization, effects of concentration of arsenite in 0.1*N* H_2SO_4 are shown in Fig. 7 and in acetate buffer in Fig. 8. With regard to these figures in both the sulfuric and acetate solutions the shape of the polarization curves is changed when arsenite is added. Addition of arsenite produces an S-shaped curve, which is more pronounced for the larger arsenite additions and more prominent in the acetate solution than in the sulfuric acid solution. Comparable polarization work done in the U.S.S.R. (27) in 0.1*N* H_2SO_4 containing small As_2O_3 additions yielded curves of the same general shape as in the present work.

The effect of arsenite as a corrosion inhibitor is well documented in the literature (28). In the sulfuric acid solutions addition of arsenite reduced the cathodic kinetics in the vicinity of the corrosion potential. In acetate solution the first additions of arsenite appear to accelerate the cathodic kinetics, but further addi-

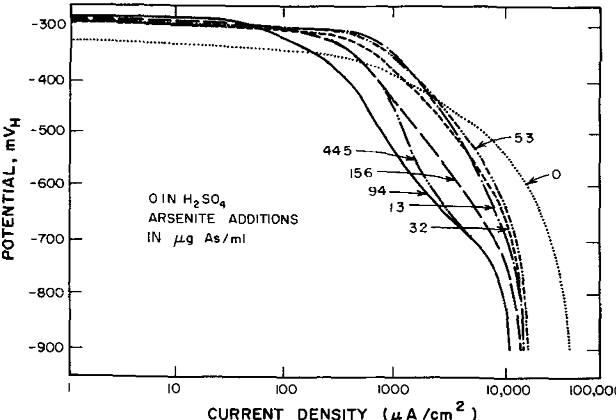

Fig. 7. Potentiokinetic polarization curves for 1010 steel in 0.1N H_2SO_4 with arsenite additions.

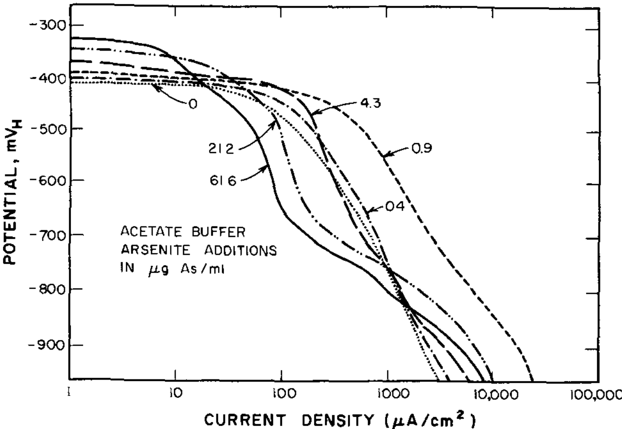

Fig. 8. Potentiokinetic polarization curves for 1010 steel in acetate solutions with arsenite additions.

tions greatly reduce the cathodic currents (Fig. 7 and 8).

In no case were we able to detect the presence of AsH_3 at the potentials used in these experiments (to -1300 mV_H) using H_2O_2 as a qualitative indicator. Arsine is appreciably soluble in water and all N_2 bubbling was stopped before the determination. A review of the kinetics of arsine formation indicated that the process occurs at very low current efficiencies; Salzberg and Goldschmidt (29) found that the efficiency was only about 1-2% in acid solution. This means that significant arsine evolution occurs only after the potential is made much more active than the As/AsH_3 coexistence potential. Likewise, Menzies and Owen (30) produced AsH_3 only at very high currents. They attributed the low current efficiencies to concomitant hydrogen evolution and the deposition of a solid brown substance, which could have been a subhydride, on their specimens along with arsenic.

At the most negative potentials in the acetate solution containing arsenite additions (Fig. 8) the current is higher than for the acetate solution without addition. This increase could not be due to arsine formation. Rather, the effect is related to a likely acceleration of the hydrogen kinetics (evolution and absorption) after the arsenic deposition on the surface. The effect is not seen in the sulfuric acid solutions because the over-all currents are always much larger due to the lower pH.

An interesting observation which illustrates the significant suppression of the HER brought about by the addition of arsenite is shown in Fig. 9. Initially, the acetate solution contained no arsenite. At a constant potential of -660 mV_H the current decreased gradually with time. When $NaAsO_2$ was added there occurred an abrupt current rise caused by the deposition of As. This

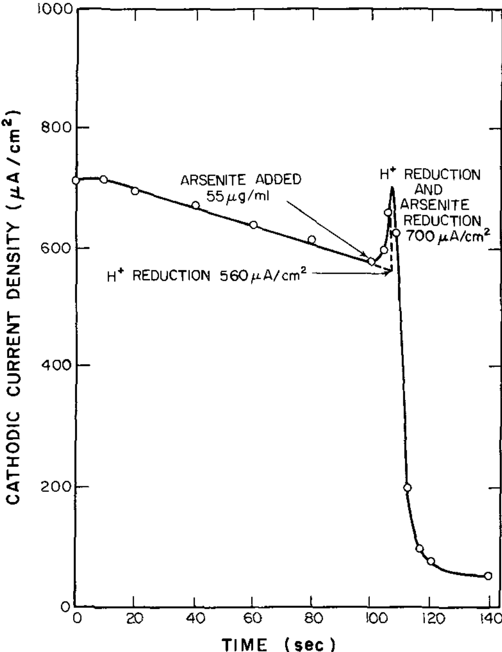

Fig. 9. Change of current upon adding arsenite to acetate solution at a potential of -660 mV_H.

event was followed by a sharp decrease of the current, and the subsequent depositions of As and H were hindered. The behavior in Fig. 9 is consistent with that observed in Fig. 8 where at a potential of -660 mV_H the cathodic current of the curve containing no arsenite is much higher than that for the curve corresponding to a concentration of 61.6 μg As/mliter, which is comparable to the 55 μg As/mliter concentration in Fig. 9.

Morphology of arsenic deposits.—Observation of arsenized surfaces (exposed to As-containing solutions) by scanning electron microscopy illustrates some interesting features of the arsenic deposits, three examples of which are depicted in Fig. 10. In (A) the deposit is estimated at several thousand monolayers and is apparently very brittle and poorly adherent. The arsenic in this photomicrograph is crystalline; its electron diffraction pattern served as the basis for the verification of thinner As plates. The ED pattern was obtained with a replica extraction of the surface exposed to a 100 kV beam. In (B) the deposit is typical of those with thicknesses of the order 50 to a few hundred monolayers. At less than about 50 monolayers, the structure is amorphous; deposits thicker than this value are crystalline, but not all reflections are observed. The deposit shows a tendency to crack. In (C) where the specimen was exposed to a very dilute arsenite solution for a long time without applied potential, deposits of As occurred along with attack of the steel substrate.

Discussion

The essential concern of these experiments relates to the criteria for the accelerating effect of arsenic-containing species in hydrogen absorption. The arguments in this discussion are directed toward pointing out that the stability of arsine is not critical for accelerating hydrogen entry and that there are other reasonable alternatives.

Analysis of the polarization and permeation behavior.—To explain the polarization behavior observed in Fig. 7 and 8, we must account for the acceleration of the cathodic kinetics in the vicinity of the corrosion potential for most of the solutions containing arsenite, the deceleration of the kinetics as the electrode is polarized cathodically, and the increase in the cathodic current as the electrode is further cathodically polarized. Aspects of the permeation behavior are related to the

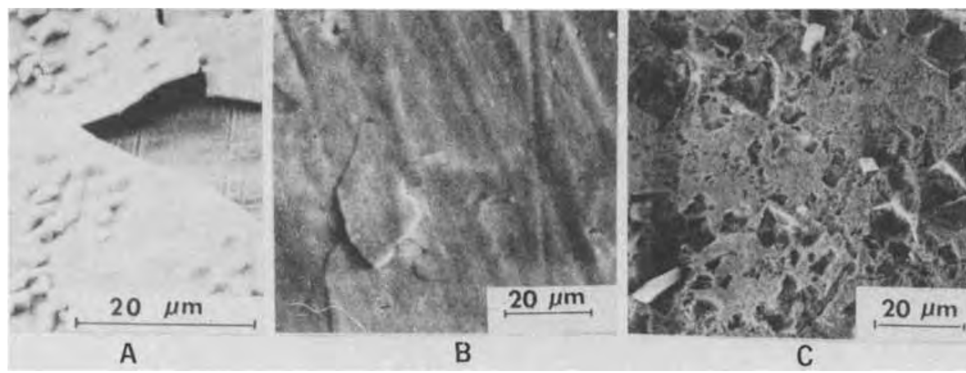

Fig. 10. Morphology of arsenic deposits. (A) Thick deposit from concentrated solution; crystalline structure. (B) Thin deposit from concentrated solution; amorphous structure. (C) Specimen exposed to dilute solution; condition simulating permeation experiment.

polarization behavior. Let us consider individual reactions that influence the observed polarization and permeation currents.

1. *Hydrogen evolution on iron.*—According to Bockris, McBreen, and Nanis (21) the mechanism for the HER on an iron surface in acid solution is coupled discharge-chemical desorption (recombination). This means that the activation energy barriers for the two steps are about equal so that both steps constitute the rds. These authors postulated Langmuir adsorption kinetics for the hydrogen; therefore, the resulting Tafel slope is $2RT/\mathbf{F}$ or about 120 mV/decade at room temperature. This seems to be the slope which obtains for the present work, although the Tafel region does not extend over the usual 2-3 orders of magnitudes, possibly due to impurities in the solution.

2. *Hydrogen evolution on arsenic.*—The very low estimated value of the exchange current density of hydrogen on arsenic (10^{-12} A/cm^2) suggests that the rds is the discharge of H^+. The measured slope of the HER on an arsenic electrode is reported as 110 mV/decade, close to the theoretical $2RT/\mathbf{F}$ for this mechanism (31).

3. *Anionic adsorption on iron.*—The potential of zero charge occurs at about -400 mV_H on Fe (32). Thus, adsorption of various chemical species can take place at potentials in this vicinity. An indication of chemical adsorption on an electrode is an S-shaped polarization curve, since the adsorption process causes an overpotential effect (33, 34). On Fig. 7 and 8 such an S-shaped curve is observed in the potential region from the corrosion potential to some 200-300 mV cathodic from it. Therefore, one interpretation of the S-shape part of the polarization curves in Fig. 7 and 8 is a double layer effect of, presumably, AsO_2^- adsorption. This effect is more noticeable in the acetate than in the sulfuric acid solutions, owing to the low ionic polarizability of sulfate ion and, thus, its lesser tendency to adsorb specifically (34). Over most of the potential region where the adsorption may occur, the hydrogen absorption reaction appears totally inhibited as the permeation current is zero or barely measurable. The hydrogen evolution reaction is also inhibited.

4. *Deposition of arsenic.*—The $HAsO_2$/As redox potential being more positive than for H^+/H_2, one would expect arsenic to electrodeposit easily from aqueous solution. The exchange current density for the $HAsO_2$/As couple ought to be around 10^{-6} A/cm^2 according to Piontelli's classification (35, 36). Arsenic in contact with As_2O_3 establishes equilibrium, and the couple can be used as a *p*H meter under certain conditions (37). However, studies of As deposition reveal that the process occurs with relatively low current efficiencies, in part due to simultaneous hydrogen evolution. As observed by Menzies and Owen (30) and by Wranglen (38), the deposition of As is governed by a film of amorphous As that stifles the further deposition of As due to its high resistivity. The resistivity of electrodeposited As was measured at 10^8 ohm-cm (39). Difficulties in polarographically analyzing solutions containing trivalent arsenic compounds have been explained in terms of a film that limits the reduction reaction instead of the usual diffusion limiting current (40).

On our Fig. 7 and 8 the plateau observed when the steel is polarized about 100 mV or so might seem to indicate that the electrodeposition of arsenic controls the cathodic kinetics. This reaction occurs as the arsenic deposits as the photomicrographs of Fig. 10 attest. Because of the small arsenite additions, the limiting current for the arsenite/arsenic reaction is of the order 10^{-5}-10^{-6} A/cm^2. Thus, the current values on the order 10^{-3}-10^{-4} A/cm^2 for the plateaus in 0.1*N* H_2SO_4 are larger than the limiting current for As deposition. It appears, therefore, that the double layer effects are responsible for the shape of the polarization in this region.

Piontelli and Poli (41) obtained crystalline As deposits and explained the required cell voltages as a cumulative overvoltage composed of the activation overpotential for As deposition, the activation overpotential for H reduction on As, an ohmic overpotential due to the poor conductivity of As, and perhaps an overpotential effect due to structural changes of the As. The significant factor seems to be the overpotential of H on As, which decreases with time perhaps because of a change in mechanism of the HER.

5. *Hydrogen evolution and absorption on an "arsenized" surface.*—The results described above for As electrodeposition, namely that the current efficiency with respect to As decreases and the cell voltage decreases as the current density increases, suggest that the HER proceeds on an "arsenized" surface in a manner different from that on an "unpoisoned" electrode. After polarization beyond the current plateau region where adsorption of AsO_2^- and deposition of As take place, a sharp rise in the cathodic current occurs. Copious gas evolution is experimentally observed in this region. If the over-all HER is controlled by the recombination step, the Tafel slope is $RT/2\mathbf{F}$ or 30 mV/decade whether the adsorption follows Langmuir or Temkin behavior. If the discharge step controls the over-all HER kinetics, arsenite may increase i_o for the HER by its double layer effects. Either of these effects would decrease the hydrogen overpotential. The i^o for the HER has not been measured on any arsenic electrode, massive or plated. Thus, the often-stated explanation for the effect of arsenic poisoning the HER by increasing the hydrogen overpotential may be misleading. Thus, an interplay between H^+ and other species present in the double layer could alter the H^+ concentration as well as the energetics of the adsorbed monatomic H. In particular, if H^+ concentration increases in the double layer, i^o increases and possibly the entry rate, too. This effect tends to lower the overpotential. If the M-H bond energy is lowered with respect to H^+ and H_2, the activation energy for discharge and for recombination is increased. This effect tends to raise the overpotential and promotes the hydrogen entry rate.

With regard to the hydrogen permeation behavior in Fig. 1-4, at the rest potential the inhibitive strength of the arsenite against hydrogenation is increased as

its concentration increases. Comparison of the polarization and permeation behaviors indicates that the higher the arsenite concentration, the more active the potential needed to hydrogenate the steel. These results are in qualitative accord with those of Hudson and Stragand (42) for a mild steel in a $2N$ H_2SO_4 pickling bath at 38°C. In their work an addition of 1 μg As/mliter doubled the pickling rate over the As-free acid, while the absorption of hydrogen remained constant. An addition of more than 4 μg As/mliter inhibited pickling while still hydrogenating the specimen, and an addition of more than 8 μg As/mliter inhibited the absorption of hydrogen. Both the pickling rate (and hence hydrogen evolution rate) and absorption rate decreased with time. These experiments were performed without applied potential. An explanation of these results is that the exchange current density is raised with the first arsenite additions, initially favoring the HER, but further additions of arsenite and the passage of time affect the bond energy of H_{ads} to the metal. An applied cathodic potential is then required to stimulate both the HER and HAR. This explanation requires that trivalent arsenic compounds be specifically adsorbed, replacing H_2O molecules and consequently inhibiting dissolution of the metal to corresponding aquo-ions.

We can write a mass balance for the hydrogen: $i_d = i_r + i_p$ where the i's represent the current equivalents for the discharge (d), recombination (r), and permeation (p) reactions, respectively. The rate of permeation is given by $k_p\,\theta$, and for discharge by $k_d(1-\theta)$. If recombination controls the over-all HER kinetics, then the permeation efficiency is $i_p/(i_p + i_r)$ or $k_p\theta/(k_p\theta + k_r\theta^2)$. As the potential becomes more active, θ increases. Therefore, for recombination control the permeation efficiency should be near unity for small θ values and should decrease as θ increases. The larger k_r is relative to k_p, the more the permeation efficiency declines with increased cathodic polarization. By contrast, discharge control yields a permeation efficiency given by i_p/i_d or $k_p\theta/k_d(1-\theta)$. In this case increasing the degree of cathodic polarization increases the permeation efficiency. Evidently, recombination control prevails when θ is large (more active potentials) since all the curves on Fig. 2 and 4 show a decrease of permeation efficiency.

However, in these experiments where arsenite adsorption, arsenic deposition, and possible hydride formation compete for the same surface sites, the above arguments for θ are somewhat invalidated by the complicated influences of other species on hydrogen adsorption. Nevertheless, from a phenomenological point of view, the presence of arsenic in whatever form it exists on the surface serves to keep θ less than unity over a wider range of potentials.

When a cathodic potential is applied, the effects of arsenite are more evident, as the permeation efficiency plots of Fig. 2 and 4 indicate. The curves obtained in solution containing arsenite show an ascending and descending branch. Thus, these particular curves have a permeation efficiency maximum. The ascending branch indicates the region where the effect of arsenite adsorption and its subsequent reduction to elemental arsenic dominates the cathodic kinetics. The amount of hydrogen entering and permeating the metal is not detectable until the specimen is polarized some 100-300 mV from the corrosion potential, the higher arsenite concentration requiring a greater polarization. As the potential is made more active, the hydrogen reaction becomes more dominant, hence the increase in the permeation rate. In the case of the solutions containing no arsenite and in the case of the As predeposit there is no ascending branch since hydrogen reduction is the only possible cathodic process. These show only a decline of permeation efficiency with cathodic polarization.

For the case with predeposited arsenic (curve 4, Fig. 4) the permeation efficiency at a given potential is lower than that for the codeposited case once the hydrogen reaction dominates over the arsenic deposition reaction, although the total amount of deposited As in both cases is approximately the same. The permeation efficiency for the codeposition goes to zero at the corrosion potential, but for the predeposited case the permeation efficiency at the corrosion potential is high. When the solution contains AsO_2^- (curves 2 and 3) the arsenic deposited helps to protect the metal from hydrogenation, whereas in the predeposited case (no AsO_2^- present) hydrogenation occurs at the corrosion potential. This suggests that a freely corroding steel containing an addition of As is prone to hydrogenation. Thus, arsenic is beneficial from the point of view of preventing hydrogen entry as long as the arsenic is present in the oxidized form in the solution. Upon sufficient cathodic polarization arsenic has a sinister effect as the arsenite is reduced and hydrogen evolution and absorption take place on the arsenized surface.

6. *Arsine formation.*—Arsine formation from As occurs by a series of one-electron transfer steps to form intermediate surface subhydrides or radicals (AsH and AsH_2). These subhydrides disproportionate to form AsH_3 and As, and the current efficiency based on expected arsine formation is very low in acid solution, around 1-2% (29). During arsenic electrodeposition from HCl + As_2O_3 solutions only traces of AsH_3 evolved after prolonged electrolysis at 300 mA/cm^2 (30). These results indicate that AsH_3 formation requires considerable overpotential. The value of the equilibrium potential is given by (44): $E = -0.608 - 0.0591\,pH - 0.0197 \log p_{AsH_3}$. This formula was used for calculating the equilibrium potential indicated on Fig. 1-4. A few remarks are needed here. Values of the free energy of formation in kilocalories of the Group V hydrides are: NH_3, -3.98; PH_3, $+4.36$; AsH_3, $+42.0$; SbH_3, $+35.5$; and BiH_3, $+55.3$. In the series the value of AsH_3 seems too high or that of SbH_3, too low. If the value for AsH_3 were too low, then the corresponding As/AsH_3 redox potential would be too active and AsH_3 would then be stable at potentials closer to the corrosion potential. The calculation of the redox potential is also based on unit activity of As. If As is present at an activity less than one, the redox potential is shifted to more active values. Possible dissolution of As in the steel substrate could reduce its thermodynamic activity. Notwithstanding the uncertainty of the equilibrium potential, the potential region where we first noted enhanced hydrogen permeation seems thermodynamically and kinetically unfavorable to AsH_3 production. Moreover, we detected no arsine formation throughout the potential region studied.

7. *Formation of arsenic subhydrides.*—Surface subhydrides are proposed as intermediates during arsine formation (29). Brown deposits, which may be lower hydrides, have been observed in connection with As electrodeposition (30). Solid arsenic hydrides of composition varying between $AsH_{0.001}$ to $AsH_{0.52}$ have been prepared by various techniques including electrochemical reduction (43). However, only small amounts of material were obtained so that the physical and chemical properties were not measured. Pourbaix reports solid arsenic lower hydrides with formulas As_2H_2 and As_4H_2 (44).

8. *Dissolved oxygen and other impurities.*—Residual dissolved oxygen and other impurities may influence hydrogen in the double layer in much the same way as arsenite. Their effect is probably most important near the corrosion potential.

9. *Concentration polarization of the HER.*—As the potential is made more active, hydrogen evolution eventually becomes limited by the diffusion of protons to the surface. Addition of pH buffering substances such as acetate and arsenite and alkalinization of the solution near the steel electrode due to rapid hydrogen evolution complicate the appearance of a true limiting current.

Mechanism of promotion.—A mechanism for the hydrogenation promotion effects due to the presence of arsenic must account for the following important observations: (*i*) Hydrogenation of the specimen is promoted to the greatest extent (maximum permeation efficiency) in the potential region where codeposition of hydrogen and arsenic takes place. (*ii*) The permeation rate and efficiency are higher for the arsenic-containing solutions than for those free of arsenic. The permeation efficiency decreases as the potential becomes more active. (*iii*) At the corrosion potential, addition of arsenite appears to inhibit hydrogenation; however, at modest cathodic polarization potentials hydrogenation occurs regardless of the arsenite concentration. (*iv*) The promoter effects of arsenic operate over a range of pH.

A number of explanations regarding the phenomenon of the sharply increased entry rate have been offered (15, 21). The general conclusion is that the metal to hydrogen bond is reduced in the presence of the promoting species. Reduction of this bond energy creates a more flexible, less directional bond so that the transition from adsorbed hydrogen to absorbed hydrogen is facilitated with less activation energy. This hypothesis is based partly on the observed phenomenology that the heat of adsorption (and hence the metal-hydrogen bond energy) decreases as the metal becomes more "catalytically active." Catalytically active metals (so-called because of their ability to hydrogenate organic compounds) have a higher inherent solubility of hydrogen (Pd > Ni > Pt > Fe). The disagreements or controversies range over what causes the decrease in the metal-hydrogen bond energy. A decreased metal-hydrogen bond energy has the kinetic effect of lowering the activation energy for the absorption process relative to the barrier for the recombination process. Because these processes compete for the adsorbed hydrogen, absorption is favored. Only slight changes in the bond energy is needed for accelerating the entry rate. The question is then: How can arsenic act to change the metal to hydrogen bond entry?

Three ways in which promoter species can lower the metal-hydrogen bond have been suggested (15, 21). One possibility is a lateral interaction between adsorbed H and the promoter species so that the surface energy of atoms is modified with the result that the Fe-H bond energy is lowered due to the lateral component. Secondly, the promoter species adsorbs or deposits first at the more energetic sites, leaving hydrogen to adsorb at less energetic sites. Thirdly, an electronic effect may occur between the promoter and Fe. Promoter species are characteristically electron rich and can conceivably influence the electronic energy levels at the surface. Hydrogen is more soluble in Pd, Pt, and Ni than in Fe. According to the valence bond theory the percentage d-character of the metallic bond is slightly higher for the first elements than for Fe (45). Thus, the promoter species furnishes additional bonding electrons. The electronic effect is apparently more important than the effect of the crystallographic structure, because the solubility of H in fcc-Fe at room temperature is about 2-3 times that in bcc-Fe (extrapolation to room temperature), whereas the solubility of H in Ni, for example, is 1000 times that in bcc-Fe.

Consider now the influence of arsenic in the above three explanations. The H-As and H-Fe bond energies are of comparable magnitudes (46). Attraction of the H atom toward an As atom may then reduce the bond energy between H adsorbed on Fe. It is reasonable that As would plate out at the most active sites leaving H to deposit elsewhere. Elemental As and various As-H radicals have more electrons available for bonding than AsH_3. Indeed, this fact agrees with the observation that the highest permeation efficiency effects occur where As is the stable phase. At these potentials the equilibrium partial pressure of AsH_3 would be infinitesimal. In view of the observation that arsine formation is relatively inefficient and that a number of subhydrides form as intermediates, the absolute permeation rates obtained from the arsenite solutions upon further cathodic polarization might be attributed to some As-H interaction at the surface. An As-H bond would deter recombination of the hydrogen atoms; upon further hydrogen deposition from the solution, the H atoms bonded to As could enter into the Fe lattice rather than evolve as H_2. We have no evidence that the subhydrides exist; no extraneous lines were observed on the electron diffraction patterns made from surface deposits. However, the greater number of unbonded electrons or unsaturated bonds in the subhydrides could more greatly influence the electronic energy levels in the substrate than could arsine.

Another possible explanation for hindered recombination is that the surface diffusion of hydrogen atoms deposited on this surface is low. An estimate of $D_{surface}$ for H on Fe is considerably lower than D_{bulk} for H in Fe (47). Hence, hydrogen atoms are more likely to stick where they are discharged and the likelihood of their absorption is increased because of the increased lifetime as H_{ads}. This factor is important at low coverages because the distance an H atom must move to recombine is relatively great. Recent work by Kim and Wilde (48) established that the surface coverage of hydrogen adatoms can be low in the vicinity of the corrosion potential. The role of As in suppressing the HER extends the range over which a small θ is possible. A small θ value permits a high permeation efficiency, although the absolute permeation rate is not high. The excellent "throwing power" attributed to the corrosion inhibiting properties by trivalent arsenic solutions suggests a leveling of the energy of surface sites due to adsorption and discharge of As (41). Although the coverage increases with applied cathodic potential, the presence of arsenic may increase the surface coverage of hydrogen on iron by crowding hydrogen onto adjacent available iron surfaces since the discharge process on As appears to have high kinetic barriers. Another effect, according to Smialowski (7), is that strong chemisorption of the promoter species may provoke the formation of surface defects which allow an easy passage of hydrogen at the surface to the bulk of the metal.

A reaction between iron and arsenic is possible. At room temperature the solubility of As in Fe is about 5% and arsenic forms arsenides FeAs and $FeAs_2$, at higher concentrations (49). However, Besnard (50-52) has considered that As is itself absorbed preferentially at the grain boundaries because of its lowering of the surface tension in addition to the chemical effects and believed this effect was responsible for premature cracking of the iron specimens. Absorption of arsenic could further enhance the hydrogen permeation as there would be greater opportunity for the electronic interaction between Fe and As.

An extremely useful, but lacking, piece of information is an analytical determination of the effect of arsenic on the solubility of hydrogen in iron. If arsenic raises the solubility significantly, then a higher concentration of hydrogen at the entry surface would drive a greater flux through the metal.

Considerable evidence exists in the literature that enhanced hydrogen promotion occurs in the presence of stable hydrides, such as AsH_3, PH_3, H_2S, H_2Se. In particular, the experiments of Newman and Shreir (8) correlate the hydrogen saturation very well with the stability of the hydride. Furthermore, in the case of arsenic, cathodic polarization must be applied to obtain a measurable increase of the hydrogen absorption over that occurring from the As-free solution, whereas the effects of sulfur as a hydrogen promoter are operable at the corrosion behavior. This behavior compares with the relative stabilities of the hydrides; H_2S is stable at the usual corrosion potential of iron in acid, while AsH_3 is stable at considerably more cathodic potentials. With regard to the work cited (9), in which AsH_3 was externally introduced into the charging compartment of the permeation cell, the authors did not give important experimental details: Was the cell saturated with the gas? Was the specimen cathodically polarized?

These details are important in establishing the necessity of AsH_3 presence toward promoting hydrogenation.

Furthermore, the sensitivity of the experimental technique used to arrive at this kind of conclusion can be very important. The permeation current technique is perhaps the most sensitive of the techniques used for hydrogen charging and determination. The investigations in which it was concluded that AsH_3 formation was necessary for significant hydrogen entry used techniques less sensitive than the permeation technique. Therefore, higher charging currents were necessary to effect observable hydrogen entry and these occurred at potentials well into the range where AsH_3 should form.

The present work shows considerable hydrogen permeation at modest cathodic potentials. Also, mechanistic arguments of promotion effects are sufficiently general that other As-containing species can act in this capacity as can AsH_3.

Conclusion

1. The role of As as a promoter of hydrogenation of mild steel depends on electrochemical potential. At the corrosion potential, addition of arsenite to the solution suppresses the hydrogen reaction. Hydrogenation of the specimen occurs at potentials polarized cathodically some 100-300 mV from the corrosion potential, with the more concentrated solutions requiring greater polarization. Once sufficiently polarized, specimens exposed to solution containing arsenite are hydrogenated more than specimens exposed to solutions free of arsenite.

2. The intensity of the hydrogenation, as indicated by both the permeation efficiency and the absolute permeation rate, is highest for solutions containing arsenite so that there is codeposition of As and H. The permeation efficiency drops with application of more cathodic potentials, although the permeation current increases.

3. Hydrogen permeation occurs at potentials where metallic arsenic is stable and arsine can be present only in infinitesimal quantities. Despite the experimental conditions which appear not to favor arsine formation, considerable hydrogenation of the steel specimens occurs. Thus, arsine formation is not a necessary condition for promoted hydrogenation.

4. From discussion presented on mechanistic arguments, arsenic in trivalent form adsorbed to the surface, arsenic in elemental form deposited on the surface, and arsenic subhydrides, as well as arsine, can enhance hydrogen entry.

A Comparison of the Immersion and Open-Circuit Scrape Methods for Determining the Potential of Zero Charge of Metal Electrodes

G. J. Clark, T. N. Andersen, R. S. Valentine, and H. Eyring

Department of Chemistry, University of Utah, Salt Lake City, Utah 84112

ABSTRACT

Open-circuit potentials were measured for freshly immersed metal surfaces and for metal surfaces renewed abrasively (scraped-off) *in situ* in aqueous electrolytes. Electrode materials included Au, Ag, Cu, Pt, Ga, In, Bi, and Sn and the electrolytes included alkali halides and alkali sulfates in acid, neutral, and alkaline solutions. The fresh-surface potentials for Au, Ga, In, Bi, and Sn were approximately the same following either immersion or scraping in solution and yielded the potential of zero charge at certain pH conditions. For Ag, Cu, and Pt the immersion potentials were several hundred millivolts more positive than the scrape potentials. This is attributed to the presence of adsorbed oxygen on these metals at the instant of immersing them in solution. For Ag, Cu, and Pt the scrape potentials are interpreted as the potential of zero charge for the bare metal while the immersion potentials reflect a superimposed dipolar effect or faradaic reduction of the oxygen.

Values for the potential of zero charge (pzc) of most solid metals have suffered from irreproducibility among various methods and workers (1, 2). Much of this variance is attributed to differences of impurities or other "foreign" species (*e.g.*, H or O) on the surface, or to the crystallographic state of the metal surface resulting from different electrode pretreatments. In some cases it is difficult to verify that faradaic reactions do not interfere.

In the present work the immersion and open-circuit scrape potentials are compared for a number of metals in aqueous solutions. Although both of these methods are based on essentially the same principle, there is some disagreement on published values obtained with the two methods (cf. Table I). There are other methods used to measure the pzc of solid electrodes which depend on various properties of the metal such as mechanical properties or capacity of the metal-solution interphase. These methods have a different basis than the kinetic methods being compared in this work. Inasmuch as they are reviewed elsewhere (1) we need not discuss them further here.

In the dip or immersion method a fresh metal test electrode, connected to a reference electrode through an external polarizing source, is immersed in an electrolytic solution. Upon immersion a transient potential is observed between the test and reference electrode which corresponds to charging the newly formed electrode. For the test electrode there is one state of external polarization at which the potential transient is of zero magnitude. The electrode potential at this condition is considered to be the pzc (3). In the open-circuit scrape method (5-8) the metal electrode surface is abrasively removed *in situ* with an insulating, inert scraper and the accompanying open-circuit potential is recorded. Depending on the system, reactions may or may not charge the electrode faster than the scraper removes it, and hence the recorded scrape potentials must be interpreted to determine whether or not they are the pzc. This interpretation depends on the influences of scraper speed, adsorbable ions, and pH as well as on the potential decay following scraping.

If very rapid faradaic reactions ($i \geqq 5 \times 10^{-4}$ A cm^{-2} for present scrape methods) occur before the pzc can be established or measured, then the pzc cannot be obtained by the open-circuit scrape method. It appears that the immersion method should suffer a similar limitation, however, since it is implicitly assumed that the pzc is developed unless an external current passes through the test electrode. In Table I,

Key words: electrical double layer, zero charge, fresh metal surfaces.

Table I. Potentials of zero charge (pzc) reported from immersion measurements compared to open-circuit scrape potentials

	Immersion results			Open-circuit scrape			
Metal	pzc *vs.* SHE[b]	Solution	Reference	Potential V *vs.* SHE	Solution	pzc or not	Reference
Al	−0.523[a]	0.01M KCl	(3)	−1.56	0.5M K_2SO_4, MKCl	No	(5)
Bi	−0.358	0.01M KCl	(3)	−0.34	0.01M KCl	Yes	(5)
Cu	−0.012	0.1M KCl	(3, 4)	−0.64	0.1M KCl	Yes	(8)
Ni	0.193[a]	0.01M KCl	(3)	−0.34	0.5M K_2SO_4, MKCl	No	(5)
Sn	−0.38	0.01M KCl	(3)	−0.43	0.5M K_2SO_4	Yes	(5)

[a] In the present study immersion potentials were obtained for Al and Ni which are substantially more negative than the above values and, in fact, are rather close to the above scrape potentials. As the presently obtained immersion values for Al and Ni are controlled by faradaic processes, they are not considered further in the present work.
[b] SHE = standard hydrogen electrode.

one notes that the open-circuit scrape potential and the dip potential agree for Bi and Sn and also purport to measure the pzc. For Cu the values differ, yet both methods are purported to measure the pzc. For Al and Ni the open-circuit scrape method yields a mixed potential while the dip method is purported to give the pzc. Even though the recorded values by the two methods are different for Ni and Al, it is not apparent why a pzc can be obtained by one method and not by the other. It is also not apparent why the pzc values for Cu are so different in the two cases. To better understand these problems we have measured immersion potentials for a variety of metals in various aqueous solutions, and have compared them with open-circuit scrape potentials. To eliminate the differences in Table I which may have been caused by impurities in the metal or by the crystal orientation of the electrode, we have used the same metal wire samples and have created the fresh metal surface in the identical manner for both methods. This method of surface renewal was by scraping the metal with a sapphire bit, while measuring the potential in the case of the open-circuit scrape and prior to immersing the electrode in the case of the dip method. It has been suggested (2) that the open-circuit scraping may produce active sites and more faradaic interference than other methods. The present work should indicate whether or not this is so.

Experimental

The apparatus for the open-circuit scrape method has been described in previous work (5-8). Basically, this consisted of a cell containing the reference and test electrodes which were connected to a high impedance oscillographic recorder or an oscilloscope. Measurement of transient, open-circuit potentials was made while the entire metal electrode face was scraped off with a sharpened sapphire bit inserted in a high speed drill. The electrolyte was saturated with a nonreactive gas such as N_2. For the dip experiments a two-compartment cell was utilized (Fig. 1). One compartment, A, contacted the salt bridge, B, of the saturated KCl, calomel reference electrode and was separated from the main compartment, C, by a stopcock. The top of the main cell compartment was usually fitted with first a thin sheet (cover), D, of polyethylene drawn tightly over the top and then an air-tight polyethylene bag, E, in which an inert atmosphere could be maintained. The polyethylene sheet served to separate the cell atmosphere from the atmosphere of the polyethylene bag where the electrode surface was prepared. Also fitted in the polyethylene bag was the electrode, F, and the dental handpiece, G, used to renew the metal surface prior to dipping.

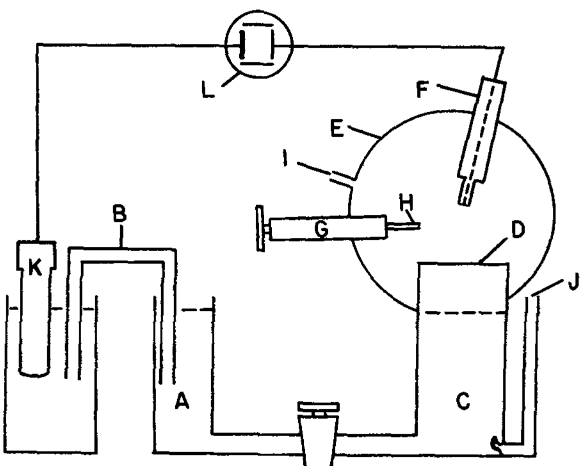

Fig. 1. Schematic diagram of experimental setup for obtaining immersion potentials: A, side compartment of cell; B, salt bridge; C, main cell compartment; D, polyethylene sheet; E, polyethylene bag; F, test electrode; G, dental handpiece; H, sharpened sapphire bit; I, gas inlet to polyethylene bag; J, gas inlet to main cell compartment; K, reference electrode; L, oscilloscope.

The electrode for both the open-circuit scrape and immersion tests consisted of a metal wire tightly encased in a Teflon sleeve such that only its cross-sectional end was exposed to the solution (Fig. 2). Gallium electrodes required a minor modification for enclosure in Teflon as this metal liquifies at 29.8°C. In this case a small quantity of bulk metal was melted, placed in contact with a platinum wire fitted in the electrode for electrical connection, and then forced through a hole drilled in the Teflon sleeve (Fig. 3). Upon solidification, the gallium expanded to produce a satisfactorily sealed electrode. The entire procedure was carried out in a dry atmosphere of high-purity (99.996+%) nitrogen to prevent oxidation of the metal.

After the electrolyte and the gas compartments were purged with an inert gas, the electrode was scraped with a sharpened sapphire rod inserted in the dental handpiece in order to produce the fresh surface. Immediately (5 to 10 sec) after the scraping, the electrode was plunged through the polyethylene cover into the solution.

Open-circuit transient potentials between the open-circuit test electrode and reference electrode resulting from immersion of the test electrode were observed by internally triggering the sweep on a Tektronix Model 564 storage oscilloscope (3A3 amplifier and 2B67 time base). The "initial" potential observed on the oscilloscope screen is the pzc in the absence of very rapid faradaic reactions. The potential generally drifted or decayed positive from this initial "dip potential," E_d. With a 10:1 input probe, the oscilloscope input impedance was approximately 11 megohms, which was considered sufficiently high to justify the open-circuit dip method employed rather than resorting to the compensation method of Jakuszewski and Kozlowski (3). For the polarizable metals (Cu, Sn, and Bi) our dip potentials agree with those of Jakuszewski and Kozlowski (3). The measured potentials were recorded relative to the standard hydrogen electrode (SHE) without correction for liquid junction potentials, which are assumed to be small compared to the precision of the results. The potential of the saturated calomel half cell was taken as 0.242V *vs.* SHE. Also assumed insignificant are variations due to fluctuations of the ambient temperature (25° ± 3°C) under which the experiments were conducted. The purities of all the metals studied was 99.995% or better except for Sn which was 99.95% pure. Solutions were prepared from reagent grade chemicals and water twice distilled from a basic permanganate solution. The predip gas environments were 99.995+% pure N_2; commercial, bottled He; He which was further purified by passing through a column of molecular sieve to further remove O_2;

electrolytic hydrogen; and air. The electrolyte was saturated in each case with the high purity N_2.

Results

Values of dip and scrape potentials.—Table II lists the dip potentials, E_d, along with the corresponding metal and solution. The third column in Table II shows the gaseous environment in which the fresh surface was produced prior to the dipping. Tests in which water vapor from the electrolyte contacted the electrode in the predip environment gave results equal to those in the corresponding dry predip environment. These tests were run by renewing the metal surface without a membrane over the mouth of the cell. The results from He were independent of whether the gas was prepurified or straight from the cylinder. The values of E_d were in general quite variable and hence the range of E_d or the individual values of E_d (if less than three experiments were performed) is shown in column 4. The number of data points determined is listed in column 5. Column 6 lists the scrape potential, E_{sc}, for the system shown on the corresponding line. The range of scrape values was generally narrower than that for dip potentials and many scrape tests were run for each system. Consequently only a single value for E_{sc} is shown in Table II.

Transient potential decays.—Immediately after the electrode scraping ceased, the potential decayed positive from the scrape potential (E_{sc}) due to the reduction of impurity oxygen in the solution or to the reduction of the electrolyte. Because the concentration of dissolved oxygen was low in N_2-saturated solutions, this factor produced slow decays of the order of 10 mV/sec. Under conditions favoring the rapid reduction of H_3O^+ ions (*i.e.*, in acid solutions) or of water (*e.g.*, Cu and Ag in neutral solutions) the decays were up to several orders of magnitude faster. After an electrode was dipped, potential decays similar to those following E_{sc} were observed. These are explicable on the basis of reduction of the solution or dissolved O_2. In addition Bi, In, Cu, and Ag frequently exhibited a very rapid (0.1-1 msec) decay of 0.1-0.2V. These rapid decays were only observed in conjunction with the more negative dip potentials. Thus dipping Bi in 1M KCl yielded an E_d value of -0.42V (Table II), and a potential decay to -0.2V occurred in 0.5 msec. However when E_d for the same system was -0.2, the very rapid decay was absent.

Significant experimental results.—An explanation of the results must rationalize the following observations:

1. $E_d \simeq E_{sc}$ for Au, and in most cases for In, Bi, Ga, and Sn. E_d is substantially positive of E_{sc} for Ag, Cu, and Pt.

2. The most negative values of E_d for Ag, Cu, In, and Bi are followed by a very rapid positive decay which does not appear to be explained by the reduction of solvent or of impurity O_2 dissolved in the solution.

3. Both E_d and E_{sc} exhibit anion effects whether or not E_d equals E_{sc}.

Table II. Dip potentials (E_d) under various conditions and corresponding open-circuit scrape potentials (E_{sc}). Potentials with respect to SHE

(a) All of the tabulated E_{sc} values are interpreted as pzc's except those with a superscript "(a)" in which cases faradaic reactions are considered to help establish the value of E_{sc}.
(b) E_{sc} values without reference in parenthesis were obtained in present study.

4. There is an intermediate pH range over which the values of E_d and E_{sc} reach a plateau and are independent of pH. In acidic solutions E_d and E_{sc} become more positive and in basic solutions they become more negative. The pH values at which E_{sc} and E_d shift from the plateau varies with the metal and also often differs between E_{sc} and E_d.

5. E_d is independent of whether the fresh surface is produced in a N_2 or a He atmosphere, and whether or not this atmosphere contains water vapor. H_2 also has little or no effect on E_d except for Pt, in which case there is a tendency for the reversible hydrogen electrode potential to be established.

6. When an electrode surface is produced in an air environment, E_d is almost always several hundred millivolts positive of the value obtained using N_2.

Discussion

As the scrape potentials have been interpreted in previous studies (5-9), we first review the explanation of them and then discuss the dip results in light of the similarities and differences. After the surface of the immersed electrode is removed with its accompanying charge and double layer, the various processes of charge separation occur at the metal-liquid interphase and faradaic reactions start at a rate dependent, among other things, on the potential. The value of E_{sc} is determined by which processes occur more rapidly than the scraping process (the latter has been effected up to 500 times per second). The dipolar potentials due to electron relaxation within the metal, and solvent orientation are much faster than the scrape process. Also the specific adsorption of simple ions in most cases attains equilibrium by the time E_{sc} is detected. Therefore E_{sc} is considered to be the pzc if the faradaic reactions are slow enough. This is the case in the neutral pH range for all the metals here reported except for Ga; in that case the pzc is obtained in acid. The faradaic reactions which normally interfere with obtaining the pzc are the reduction of H^+ ions in acid solutions and oxidation of metals (*i.e.*, corrosion) in basic solutions. In the present study corrosion interferes with obtaining the pzc for In, Bi, and Sn in basic solutions, and for Ga in neutral and basic solutions. For most base metals (*e.g.*, Al, Fe, Ni, Zn, Pb) corrosion occurs so rapidly at any pH that it is not possible to obtain the pzc by the scrape method (5). In acid solutions H^+ ion reduction causes the rapid decay and in basic solutions there is usually no decay or only a slow decay caused by O_2 reduction on a passive film.

The potential transient of gold dipped from an inert gas environment closely resembles that after scraping the electrode, and we thus interpret E_d the same as E_{sc}. All of the other metals studied behave differently from gold in that E_d is either more positive than E_{sc} or a rapid positive potential decay occurs at E_d when $E_d = E_{sc}$. As gold is the only metal which does not tend to chemisorb oxygen (10), we believe that adsorbed oxygen is responsible for the differences observed in the scrape and dip potential transients for the other metals. The dip and scrape potentials are so far negative of known corrosion potentials that metal oxidation does not seem probable. Also, as water vapor has no influence on the potentials, it would seem that solvent reduction is not involved in the differences. The source of oxygen is believed to be in the predip gases (which were on the order of 99.995% pure) or in grain boundaries or other imperfections in the metals, themselves. When the electrodes are dipped, weakly adsorbed molecules such as He or N_2 are rapidly displaced by a layer of water molecules. Strongly adsorbed atoms such as oxygen (or hydrogen in the case of Pt) remain on the surface and may undergo faradaic reactions as contact is made with the solution.

The manner in which E_d is established for Ag, Cu, and Pt cannot be determined with certainty. However the very rapid decays observed for In, Bi, Ag, and Cu immediately after dipping indicate that faradaic reduction of the adsorbed oxygen occurs. It is easy to rationalize the magnitude of the decay (approximately 200 mV) with very small amounts of oxygen. For example, if we assume a double layer capacity of 30 μcoulombs/cm^2 only 6 μcoulombs/cm^2 of charge is required to cause the 200 mV decay. Reduction of oxygen atoms at only 1% surface coverage could effect this charge. Many times this amount of oxygen may be present in the 50 ml or so of predip environment, which contained gases on the order of 99.995% pure or in imperfections in the metal. In the case of scrape potentials more negative values were obtained for 99.999% pure Ag than for 99.95% Ag, so that internal impurities such as oxygen can also affect E_{sc}. The average rate of oxygen reduction following E_d for Ag, Cu, Bi, and In is approximated as $i \simeq 6$ μcoulombs cm^{-2}/10^{-4} sec $= 60$ mA/cm^2 (where 10^{-4} sec is the average decay time). This rate does not seem excessive when one considers that the potentials involved are 0.8-1.4V more negative than the reversible oxygen potential. Tafel lines for O_2 reduction on Pt (11) extrapolate to even larger values of i at such negative oxygen overvoltages.

Reduction of adsorbed oxygen can explain the rapid positive decay discussed above for Bi, In, Ag, and Cu and also the wide range of dip potentials observed for these metals. This phenomena may also be responsible for the significant differences observed for E_d and E_{sc} in the cases of Ag, Cu, and Pt. As the negative E_{sc} values are never approached by E_d values, the reduction corresponding to 400 mV (from E_{sc} to E_d) would need to be several orders of magnitude more rapid than that following E_d. In this case an alternative explanation to oxygen reduction may be that the adsorbed oxygen contributes a dipolar potential to metals such as Ag, Cu, and Pt before the O is reduced. Then the most negative value of E_d would correspond to the potential of zero charge but for a different surface than in the case of E_{sc}. Recent measurements by Belyaeva *et al.* (12) show that the electronic work function, W_e, of silver increases as oxygen is chemisorbed onto the surface. Moreover the data of the above authors indicate that the shift in W_e is approximately 0.25V if enough oxygen is added to give a surface atom ratio of O/Ag $= 0.06$. These data are therefore not inconsistent with the idea that E_{sc} corresponds to the pzc on a bare surface and E_d corresponds to the pzc on a surface which is partially covered with chemisorbed oxygen. In this connection a plot of pzc *vs.* electronic work function was made for the metals studied in addition to Hg. The plot was drawn through Hg (at pzc $= -0.2$V and $W_e = 4.5$ eV) with a slope of one. When the values of E_{sc} were used with the more negative W_e values for Ag (12) and Cu (13), the experimental points fell quite close to the line. When the values of E_d were used along with the more positive W_e values for Ag and Cu, the experimental points again fell quite close to the line.

Resistive Wire Electrodes

Richard Alkire* and Richard Varjian

Department of Chemical Engineering, University of Illinois, Urbana, Illinois 61801

ABSTRACT

Two-dimensional current and potential distributions have been calculated for cylindrical electrolysis cells having a resistive wire electrode along the cell axis. Cell behavior has been predicted for both monopolar and bipolar electrode situations. The calculations involve solving the Laplace equation for the electrolyte resistance, in conjunction with equations for charge-transfer overpotential and electrode resistance phenomena. Over a wide range of parameter space, which includes most practical applications of resistive electrodes, it was found that simple one-dimensional approximations to Laplace's equation yield reaction rate distributions which are in excellent agreement with more rigorous two-dimensional calculations. By using the one-dimensional approximations of monopolar and bipolar electrodes, it may be anticipated that future studies may be conducted with relative ease on mass transport phenomena during high-rate electrolysis at resistive wire electrodes.

During electrolysis, there may be a substantial ohmic loss in the electrode if its cross-sectional area is small. The resistive loss in the metal phase leads to a nonuniform potential in the metal which may thereby cause variations in the local reaction rate along the electrode surface. In electroplating operations it is known, for example, that deposits of high quality are usually obtained only over a certain range of current densities. As a consequence, a highly nonuniform current distribution may be detrimental to product quality owing to variations in plating thickness, adherence, hardness, composition, and appearance, to name a few. Industrial processes which involve resistive electrode effects include production of tinplate (1), plating of copper and steel wire (2), electrodeposition of magnetic alloys onto moving wires (3), manufacture of printed circuit boards (4), and copper plating on the interior of millimeter wave guides (5). In view of these practical applications, the present study has been undertaken in order to elucidate the behavior of resistive wire electrodes.

Figure 1(a) illustrates the geometry of the electrolysis cell under consideration. The wire electrode, having radius r_i, passes down the axis of a concentric tube of radius r_o. The end faces of the cylindrical region are insulated. The annular space contains electrolytic solution. Two different electrical connections, shown in Fig. 1(b) and (c), are examined in the study below. In Fig. 1(b), the resistive wire is a cathode while the concentric cylindrical tube is the counter-electrode. When a voltage is imposed on the cell, electrical current travels along the wire and passes into the electrolytic solution via electrochemical reaction at the wire surface. The applied voltage is consumed within the electrolysis cell by several irreversible phenomena. If ohmic losses in the wire electrode are negligible, then current passes between anode and cathode such that the secondary potential distribution along the wire surface is uniform owing to the cylindrical symmetry. On the other hand, if ohmic losses in the wire electrode are appreciable, then the potential in the electrode varies with position; the remainder of the applied voltage, available for other irreversible phenomena, also varies with position. As a consequence, the charge-transfer overpotential may vary with position so that the electrode reaction may occur at different rates along the electrode surface. In most cases, the reaction rate on the wire surface will tend to be highest near the electrical contact. In Fig. 1(c), the resistive wire passes through an insulator tube containing electrolyte; current passes through the wire, from one end to the other. Owing to the wire resistance, the potential difference between the two ends of the wire may serve to drive an electrochemical reaction provided that reactive species are present. Although one portion of the wire will act as a cathode while the remainder will act as an anode, one generally has no *a priori* knowledge of the precise location of these regions. The electrode in Fig. 1(c) will be called bipolar in contradistinction to the monopolar electrode of Fig. 1(b). Within the foregoing cells, the principal phenomena which determine the current distributions at low current densities are the electrolyte resistance, electrode reaction polarization, electrode resistance, and cell geometry. At high current densities, mass transport restrictions may also arise.

Several investigations of monopolar resistive electrodes have been conducted. With simple linear network models which included metal resistance, electrolyte resistance, and constant electrode polarization, Weisselberg (6) and Fomichev (7) predicted current

distributions which were in reasonable accord with a small number of experimental data. Waber (8) recognized the need to take better account of polarization phenomena and proposed a linear model. In a series of publications, Conway *et al.* (9-11) also used more realistic polarization laws, but did not include the effect of electrolyte resistance. In an advanced treatment, Böhnlein (12) accounted for electrolyte resistance effects and applied the results to magnetic wire-plating processes. None of the foregoing studies considered mass transport limitations which arise at high current densities. The effect of convective heat- and mass-transfer to moving wires and sheets has received considerable attention in the chemical engineering literature (13-18). The effect of wall conduction on the heat transfer from a boundary layer has also received attention (19, 20). The extensive experimental studies on high-rate wire-plating by Tvarusko (21) are especially noteworthy since they demonstrate that mass transport limitations are important for the operating conditions used commercially. Alkire (22) and Alkire and Tvarusko (23) modeled mass transport of reactants to resistive electrodes under conditions of uniform stirring and of unsteady-state diffusion, respectively, but did not include electrolyte resistance effects. In sophisticated studies, Tobias and Wijsman (24) and Ishizaka *et al.* (25) accounted for electrolyte resistance by solving the Laplace equation for cells having resistive electrodes, uniform concentrations, and linear polarization laws; these two analyses were sufficiently complex that further expansion to include mass transport effects would be difficult. However, in their study of planar electrodes, Tobias and Wijsman illustrated that substantial simplifications can be made when the current flow in the electrolyte is unidirectional.

The behavior of resistive bipolar wire electrodes has been the subject of a small number of investigations. The linear network model of Harvey (26) accounted for electrode resistance and linear polarization, while Nakata *et al.* (27) included electrolyte resistance phenomena in a one-dimensional manner. In a related work on one-dimensional bipolar porous metal diaphragms, Alkire (28) incorporated electrode and electrolyte resistance, nonlinear polarization, diffusion and convection phenomena. However, the porous diaphragm model may not be suitable for predicting behavior of bipolar resistive wire electrodes since the potential and concentration fields may not be one-dimensional.

Analyses of high-rate processes at wire electrodes need to include mass transport and electrolyte resistance phenomena as well as electrode resistance and reaction polarization effects. The foregoing survey indicates that studies to date on wire electrodes have not achieved this goal. The problem arises in coupling the solution of the Laplace equation, for the electrolyte resistance, to mass transfer processes occurring near the electrode surface. Even in the absence of electrode resistance effects, the successful studies to date (29, 30) have had to incorporate complex procedures for obtaining solutions by numerical methods. A simpler approach, initiated in the study below, is to investigate the range over which the solution of the Laplace equation may be approximated by unidirectional current flow. Over this range, it may be anticipated that the mass transport problem may be attacked with relative ease.

Mathematical Development

The following analysis of monopolar and bipolar resistive electrodes incorporates the effects of the ohmic resistance of the wire electrode, the activation overpotential of the electrochemical reaction, the ohmic resistance of the electrolyte, and the geometry of the electrolysis cell. The voltage applied to the electrolysis cell is assumed to be held constant during electrolysis. The following assumptions outline the model: (*i*) the potential in the wire electrode varies along its length in a one-dimensional manner; (*ii*) the electrolytic solution is of uniform composition so that the potential distribution obeys Laplace's equation; (*iii*) a single reversible electrochemical reaction occurs in accord with Butler-Volmer kinetics; (*iv*) no structural or geometric changes of significance occur during electrolysis; (*v*) the ohmic resistance of wire electrode external to the electrolysis is negligible; and (*vi*) the counterelectrode is unpolarized for the monopolar electrode cell.

As indicated in Fig. 1, the z-coordinate extends down the axis of the cell, while the r-coordinate extends from the wire surface, r_i, to the outer tubular surface, r_o. The current and potential within the wire electrode are related by Ohm's law

$$i_m(z) = -\sigma \frac{d\phi_m}{dz} \quad [1]$$

The electronic current in the wire, $i_m(z)$, varies with position owing to the electrochemical reaction which occurs on the wire surface

$$\frac{di_m(z)}{dz} = -\frac{2}{r_i} j(z) \quad [2]$$

The local electrochemical reaction rate, $j(z)$, proceeds at the wire surface ($r = r_i$) and is related to the potential difference between metal and solution phases by the Butler-Volmer expression

$$j(z) = i_o \left[\exp\left\{ \frac{\alpha n\mathbf{F}}{RT} [\phi_m(z) - \phi_s(z)] \right\} - \exp\left\{ \frac{(\alpha - 1)n\mathbf{F}}{RT} [\phi_m(z) - \phi_s(z)] \right\} \right] \quad [3]$$

where $\phi_s(z)$ denotes the potential in the solution ad-

jacent to the wire surface. For the sake of convenience, we will denote the right side of Eq. [3] as $i_o f[\phi_m(z) - \phi_s(z)]$. The local reaction rate, $j(z)$, is also related to the potential gradient in the electrolytic solution adjacent to the wire surface

$$j(z) = -\kappa \frac{\partial \phi(r,z)}{\partial r}\bigg|_{r=r_i} \quad [4]$$

Finally, the potential distribution in the electrolytic solution obeys the equation of Laplace

$$\frac{1}{r}\frac{\partial}{\partial r}\left[r\frac{\partial \phi(r,z)}{\partial r}\right] + \frac{\partial^2 \phi(r,z)}{\partial z^2} = 0 \quad [5]$$

The boundary conditions which apply to the foregoing equations are

$$\frac{\partial \phi}{\partial z}\bigg|_{z=0} = \frac{\partial \phi}{\partial z}\bigg|_{z=L} = 0$$
$$\frac{\partial \phi}{\partial r}\bigg|_{r=r_i} = -\frac{j(z)}{\kappa} \quad [6]$$

For the monopolar situation depicted in Fig. 1(b)

$$\phi\bigg|_{r=r_o} = \frac{d\phi_m}{dz}\bigg|_{z=L} = 0$$
$$\phi_m|_{z=0} = \phi_A \quad [7]$$

For the bipolar situation depicted in Fig. 1(c)

$$\frac{\partial \phi}{\partial r}\bigg|_{r=r_o} = \phi_m\bigg|_{z=L} = 0$$
$$\phi_m|_{z=0} = \phi_A \quad [8]$$

Equations [1], [2], [3], and [5], along with the boundary conditions, define the resistive electrode model. It is easy to recognize that the potential distribution must be determined in two separate phases: the metal and the electrolytic solution. For the general case given above, the solution to the problem is found by matching the potential distributions along the common boundary between the electrolyte and the electrode.

The procedure for obtaining a solution may be simplified a great deal if the flow of current through the electrolytic solution is approximately unidirectional. Two cases are possible, depending on whether the wire electrode is monopolar or bipolar. In order to ascertain the range of conditions under which such simplifications are appropriate, results obtained with the general model outlined above are compared with the following two approximate models.

Monopolar Approximation

If the current carried by the electrolytic solution travels only in the radial direction, then the z-derivative of Eq. [5] may be deleted; integration of what remains gives the result

$$\phi_s(z) = \frac{r_i}{\kappa}\ln\left(\frac{r_o}{r_i}\right) j(z) \quad [9]$$

since the potential of the counterelectrode is chosen to be zero. Combining Eq. [3] and Eq. [9] gives the algebraic expression

$$\phi_s(z) = \frac{r_i i_o}{\kappa}\ln\left(\frac{r_o}{r_i}\right)\{f[\phi_m(z) - \phi_s(z)]\} \quad [10]$$

Furthermore, Eq. [1], [2], and [3] may be combined to obtain the result

$$\frac{d^2\phi_m(z)}{dz^2} = \frac{2i_o}{r_i\sigma}\{f[\phi_m(z) - \phi_s(z)]\} \quad [11]$$

Equations [10] and [11] constitute two equations having the two unknown potential distributions $\phi_m(z)$ and $\phi_s(z)$. The boundary conditions needed for Eq. [11] are given in Eq. [7] above.

Bipolar Approximation

If passage of current in the electrolyte is primarily in the axial direction, then Eq. [5] may be abandoned in favor of a one-dimensional form of Ohm's law written for the solution phase

$$i_s(z) = -\kappa\frac{d\phi_s(z)}{dz} \quad [12]$$

Since the ionic current carried by the electrolyte varies with axial position owing to the electrochemical reaction source at the wire, one has

$$\frac{di_s(z)}{dz} = -\frac{2r_i}{(r_o^2 - r_i^2)} j(z) \quad [13]$$

By differentiating Eq. [12] and combining the result with Eq. [3] and [13], one has for the solution phase

$$\frac{d^2\phi_s(z)}{dz^2} = \frac{2r_i i_o}{(r_o^2 - r_i^2)\kappa}\{f[\phi_m(z) - \phi_s(z)]\} \quad [14]$$

Equation [11] applies in the electrode phase; taken together, Eq. [11] and [14] constitute two differential equations having the two unknown potentials $\phi_m(z)$ and $\phi_s(z)$. The four boundary conditions may be drawn from Eq. [6] and [8]. The one-dimensional bipolar approximation derived here is essentially identical to the treatment of bipolar porous metal diaphragms (28).

By introducing the following dimensionless variables

$$\rho = \frac{r}{r_i},\quad \zeta = \frac{z}{L},\quad \Phi = \frac{nF}{RT}\phi,\quad J = \frac{2Lj}{r_i i^o},\quad \beta = \frac{nFLi^o}{\sigma RT}$$

the number of independent system parameters is reduced to the following independent dimensionless quantities

$$\psi = \frac{r_i^2\sigma}{L^2\kappa},\quad \xi = \frac{2nFL^2 i_o}{\sigma r_i RT},\quad \rho_o = \frac{r_o}{r_i},\quad \gamma = \frac{r_i}{L}$$

A physical interpretation of each of these parameters will be provided in the discussion section below.

Methods of Solution

The equations and boundary conditions which describe the several models must be solved simultaneously. Owing to their complexity, analytical solutions are not convenient so that computations were made by numerical methods in conjunction with an IBM 360 digital computer. The method of solution varied according to the model.

General Monopolar and Bipolar Models

Equations [1], [2], [3], and [5], along with boundary conditions [6]-[8] define the general models. The procedure for solving the equations is complex because the equations are strongly coupled. The iterative scheme outlined below was found to converge rapidly over a wide range of parameter space.

In the electrolytic solution, Eq. [5] describes the potential distribution. Integration proceeded by separation of variables in order to obtain an expression for the potential distribution in the solution adjacent to the wire electrode surface

$$\Phi_S(\zeta) = B_o + \sum_{n=1}^{\infty} B_n \cos(\lambda_n \zeta) \quad [15]$$

The details of the derivation depend on whether the wire is monopolar or bipolar, and are outlined in Appendix I. The potential distribution within the wire electrode may be found by combining Eq. [1], [2], [4], and either [A-I-3] or [A-I-4], as outlined in Appendix

II. For the monopolar wire, the result is

$$\Phi_M(\zeta) = \Phi_A - \frac{2B_o\zeta}{\psi \ln \rho_o} + \frac{B_o\zeta^2}{\psi \ln \rho_o} - \frac{2}{\psi}\sum_{n=1}^{\infty} \frac{B_n R_n'(1)}{\lambda_n^2} [1 - \cos(\lambda_n\zeta)] \quad [16]$$

while, for the bipolar wire, one finds

$$\Phi_M(\zeta) = \Phi_A + \left\{ \frac{2}{\psi}\sum_{n=1}^{\infty} \frac{B_n R_n'(1)}{\lambda_n^2} [1 - (-1)^n] - \Phi_A \right\} \zeta - \frac{2}{\psi}\sum_{n=1}^{\infty} \frac{B_n R_n'(1)}{\lambda_n^2} [1 - \cos(\lambda_n\zeta)] \quad [17]$$

The B-coefficients which appear in Eq. [15]-[17] may be calculated from a trial guess of the potential distribution within the cell; the manipulation of Eq. [3], [4], [15], [16], and [17] to accomplish this goal is outlined in Appendix III. After achieving convergence, the dimensionless form of Eq. [3] is used to calculate the current distribution

$$J(\zeta) = \frac{\xi}{\beta} [\exp\{\alpha[\Phi_M(\zeta) - \Phi_S(\zeta)]\} - \exp\{(\alpha - 1)[\Phi_M(\zeta) - \Phi_S(\zeta)]\}] \quad [18]$$

For the monopolar electrode, integration of the current distribution over the entire electrode begets the total current flowing in the system

$$\int_0^1 J(\zeta)d\zeta = 1.0 \quad [19]$$

whereas, for the bipolar electrode, the anodic and cathodic currents must balance exactly

$$\int_0^1 J(\zeta)d\zeta = 0$$

$$\beta = - \left.\frac{d\Phi_M}{d\zeta}\right|_{\zeta=0} \quad [20]$$

The iterative procedure of solution consists of the following steps:

(*i*) Make some reasonable initial guess of the potential distributions $\Phi_M(\zeta)$ and $\Phi_S(\zeta)$. The approximate models may be employed to generate the initial guess.

(*ii*) From the procedure described in Appendix III, calculate trial values of the B-coefficients.

(*iii*) Calculate a revised trial distribution of $\Phi_S(\zeta)$ by substituting the B-coefficients into Eq. [15].

(*iv*) Calculate a revised trial distribution of $\Phi_M(\zeta)$ by substituting the B-coefficients into either Eq. [16] or [17].

(*v*) With the foregoing revised potential distributions in hand, return to iteration step (*ii*) and repeat the sequence of operations until convergence is achieved. The criterion for convergence is that two successive $\Phi_S(\zeta)$ distributions agree everywhere to within 0.01%.

(*vi*) With converged potential distributions in hand, calculate $J(\zeta)$ and β from Eq. [18]-[20].

It was found that the convergence scheme outlined above usually converged in less than ten iterations regardless of the crudeness of the initial guesses in step (*i*). If the approximate models were used to generate the first guess, convergence was generally achieved within four iterations. It was found that the results were essentially independent of mesh spacing if fifty or more mesh points were employed. For both monopolar and bipolar electrodes, 1000 B-coefficients were used.

Several other iterative schemes were tried, but none met with success over wide ranges of parameter space. For example, the B-coefficients are related to the current distribution along the wire as may be found by applying orthogonality requirements upon Eq. [A-I-3] or [A-I-4]. Thus a simple method for calculating the B-coefficients, in principle, is by appropriate integration of a trial guess of the current distribution along the wire. Knowledge of the B-coefficients can, in turn, provide a new estimate of the potential distribution along the wire surface and thereby permit calculation of a revised current distribution. During this study, several iteration schemes were developed along this line but all failed to converge, even when the approximate model was used to generate the initial guess. It seems reasonable that the difficulty in convergence is in part attributable to the nature of the reaction rate expression; even slight errors in the trial potential distributions become highly magnified since the errors appear in exponential terms. It is believed that the success of the convergence scheme used in this study is attributable to the fact that the current distribution, $J(\zeta)$, has been eliminated from all steps within the iterative procedure. It is not necessary to calculate the current distribution until a converged solution for the potential distributions is available.

Approximate Monopolar and Bipolar Models

Each approximate model consists of two equations to be solved simultaneously. The dimensionless equations which describe the two approximate models are:
Monopolar

$$\Phi_S(\zeta) = \frac{\xi\psi \ln \rho_o}{2} [e^{\alpha(\Phi_M - \Phi_S)} - e^{(\alpha-1)(\Phi_M - \Phi_S)}] \quad [21]$$

$$\frac{d^2\Phi_M(\zeta)}{d\zeta^2} = \frac{2}{\psi \ln \rho_o} \Phi_S(\zeta) \quad [22]$$

$$\Phi_M(0) = \Phi_A, \quad \frac{d\Phi_M(1)}{d\zeta} = 0$$

Bipolar

$$\frac{d^2\Phi_M(\zeta)}{d\zeta^2} = \xi [e^{\alpha(\Phi_M - \Phi_S)} - e^{(\alpha-1)(\Phi_M - \Phi_S)}] \quad [23]$$

$$\frac{d^2\Phi_S(\zeta)}{d\zeta^2} = -\frac{\chi}{\xi}\frac{d^2\Phi_M}{d\zeta^2} \quad [24]$$

$$\frac{d\Phi_S(0)}{d\zeta} = \frac{d\Phi_S(1)}{d\zeta} = \Phi_M(1) = 0$$

$$\Phi_M(0) = \Phi_A$$

where

$$\chi = \frac{2\, r_i\, i_o\, n\, \mathbf{F}\, L^2}{(r_o^2 - r_i^2)\,\kappa\, RT}$$

The equations were solved by first linearizing them about a trial solution and then placing them into finite difference form. The resulting tridiagonal matrices were then inverted (31) in order to obtain revised potential distributions. The solution of the nonlinear problem was obtained by iteration with successive correction of the approximate potential distributions obtained by each calculation. It was found that 50 mesh points gave results which were essentially independent of mesh spacing. The criterion for convergence upon the nonlinear solution was that two successive $\Phi_M(\zeta)$ distributions agree to within 0.001%.

Results and Discussion

The model described in the present investigation contains three phenomena which act to consume the applied potential: wire resistance, electrolyte resistance, and charge-transfer reaction resistance. The rel-

ative importance of these three effects is indicated by two dimensionless parameters. The first is proportional to the exchange current density divided by the metal conductivity

$$\xi = \frac{2nFL^2 i_o}{\sigma r_i RT}$$

A large value of the parameter ξ would therefore correspond to a system with a very reversible reaction occurring on an electrode of low conductivity. In such a system, the applied potential would be consumed primarily by the electrode resistance, not by charge-transfer overpotential; further, the electrochemical reaction would tend to occur primarily near the electrical contact end of the wire. That is, for large values of ξ, the ohmic resistance of the wire tends to cause a nonuniform current distribution. A second parameter contains information about the electrolytic solution

$$\psi = \frac{r_i^2 \sigma}{L^2 \kappa}$$

It is seen that if ψ has a small value (high solution conductance, low electrode conductance), then the applied potential would be consumed more by ohmic losses in the electrode phase than by ohmic losses in the electrolytic solution phase.

Two additional parameters define the geometric configuration of the cell

$$\rho_0 = \frac{r_o}{r_i}, \quad \gamma = \frac{r_i}{L}$$

Monopolar Electrode

Let us first discuss behavior of monopolar wire electrode models. Results given in Fig. 2, 3, and 4 were obtained with the general (two-dimensional) model. It was found that, over the entire range of parameter space investigated below, the approximate (one-dimensional) model gave current and potential distributions which agreed to within 4% of those given by the general model. As a consequence, the compilations presented in Fig. 5, 6, and 7 were performed with the approximate model. Discussion of the unusual agreement between general and approximate models will be postponed until the end of the section.

Figure 2 illustrates how the three overpotentials vary with distance along a wire electrode for one typical situation ($\xi = 1.0$, $\psi = 1.0$, $\Phi_A = 3$, $\rho_0 = 10$, $\gamma = 10^{-3}$). Although the three overpotentials vary with distance along the wire, their sum is always a constant (the applied potential). The trade-off among the three overpotentials, and their variation with distance along the wire, depends on the relative magnitudes of the dimensionless parameters outlined previously. Consider the position $\zeta = 0$, the electrical contact end of the electrode; the applied potential is distributed between the charge-transfer overpotential and the ohmic loss in the electrolyte. As we depart from the contact end and move down the wire, the ohmic resistance of the metal acts to consume an ever-increasing proportion of the applied potential. The consequence is that the charge-transfer overpotential decreases with distance along the wire.

Figure 2 illustrates that the variation of charge-transfer overpotential along the wire leads to a nonuniform current distribution. The local reaction rate is always highest at the contact end of the wire, and decreases with distance along the wire. For low values of ψ, the resistance of the electrolyte is low with respect to charge-transfer and wire resistance effects; the uniformity of the current distribution then depends solely on the value of parameter ξ. If ξ is large, the ohmic loss in the metal is large and the current distribution is nonuniform; if ξ is small, then the charge-transfer overpotential predominates and the current distribution is uniform. In Fig. 3 it may be seen that as the ohmic resistance of the solution is increased (by increasing ψ), the reaction rate distribution becomes more and more uniform. Thus, even though ξ may have a large value, the reaction distribution may nevertheless be quite uniform because of the resistance of the electrolytic solution.

Figures 2 and 3 illustrate the behavior trends of the potential and current distributions for a few typical parameter values. However, it is desirable to display a great deal of detailed data in a more convenient manner. The following figures illustrate several approaches.

The total cell current divided by the applied potential may be denoted as the over-all conductivity of the electrolysis cell. The over-all conductivity of the cell will depend on the system parameters. Figure 4 illustrates the variation of the over-all cell conductivity with the two parameters ξ and ψ ($\gamma = 10^{-3}$, $\rho_0 = 10$, $\Phi_A = 3$). Since the applied potential has the same value for all these curves, it is recognized that the current passing through the cell depends strongly on the system parameters. By increasing ξ, the cell current tends to increase; however a tenfold increase of ξ does not increase the cell current by tenfold since the

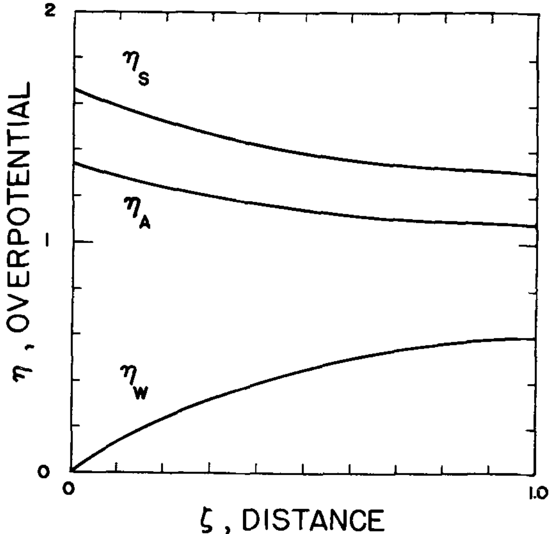

Fig. 2. Overpotential distributions along a resistive monopolar wire electrode ($\psi = 1$, $\xi = 1$, $\Phi_A = 3$, $\rho_0 = 10$, $\gamma = 10^{-3}$).

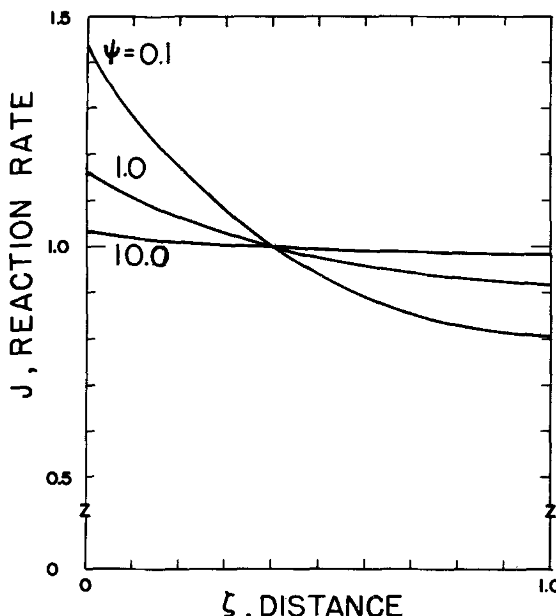

Fig. 3. Effect of electrolyte conductivity on monopolar current distribution ($\xi = 1$, $\Phi_A = 3$, $\rho_0 = 10$, $\gamma = 10^{-3}$).

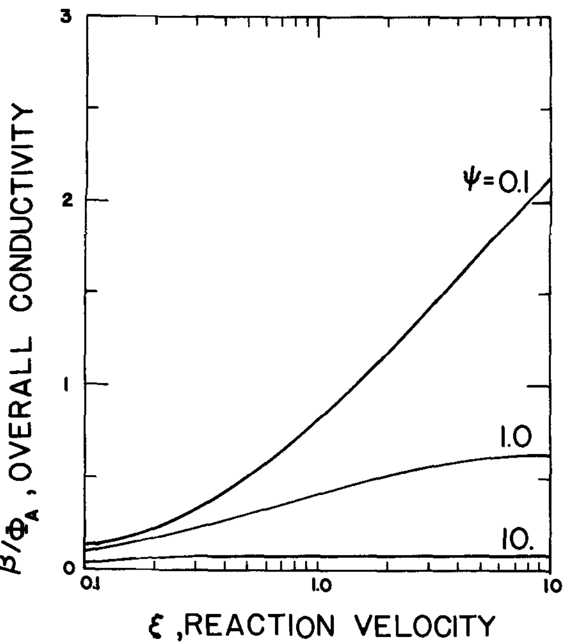

Fig. 4. Effect of exchange current density and electrolyte conductivity on monopolar cell behavior ($\Phi_A = 3$, $\rho_0 = 10$, $\gamma = 10^{-3}$).

current distribution is not uniform. For small values of ψ, the electrolytic solution is highly conductive; for large values of ψ, however, the electrolyte resistance is large with respect to other resistances. Thus for systems exhibiting large ψ, increasing the exchange current density (increasing ξ) would have little effect on cell current since the charge-transfer resistance is negligible. For intermediate values, such as $\psi = 1.0$, increasing ξ will act to increase the total cell current to a certain extent; however, the charge-transfer resistance may eventually become reduced to such values that further increases in ξ would have no effect on cell current. For example, one sees in Fig. 4 that the cell conductivity for $\psi = 1.0$ increases with ξ but reaches a plateau at about $\xi = 10$.

The over-all conductivity also varies with geometric configuration of the electrolysis cell. The effect of parameter ρ_0 on over-all conductivity is shown in Fig. 5. When ρ_0 has a small value, that is, when the distance between electrodes is small, then the electrolyte resistance tends to be low so that the parameter ξ exerts a strong influence on the system behavior. On the other hand, when ρ_0 is large, the ohmic resistance of the electrolyte is large, thereby decreasing the relative importance of parameter ξ. Also, it is recognized that the ohmic resistance of the electrolyte arises primarily adjacent to the wire, where the normal cross-sectional area for current flow is small. The effect may be seen in Fig. 5 wherein the downward shift of the curves becomes smaller with successively larger values of ρ_0. The effect of increasing ρ_0 from 2 to 10 is thus far greater than increasing it from 100 to 1000. Because of the nonlinear reaction rate expression, Eq. [3], the curves presented in Fig. 4 and 5 will vary as the applied potential is changed. In general, an increase in applied potential will act to shift the curves upward, that is, to increase the over-all conductivity.

A somewhat different approach to compiling system behavior is also available (22). The method takes advantage of the fact that the applied potential is partitioned into three overpotentials

$$\Phi_A = \eta_S(\xi) + \eta_A(\xi) + \eta_W(\xi)$$

where η_S = potential consumed by electrolyte resistance, η_A = potential consumed by the charge-transfer process, and η_W = potential consumed by wire resistance.

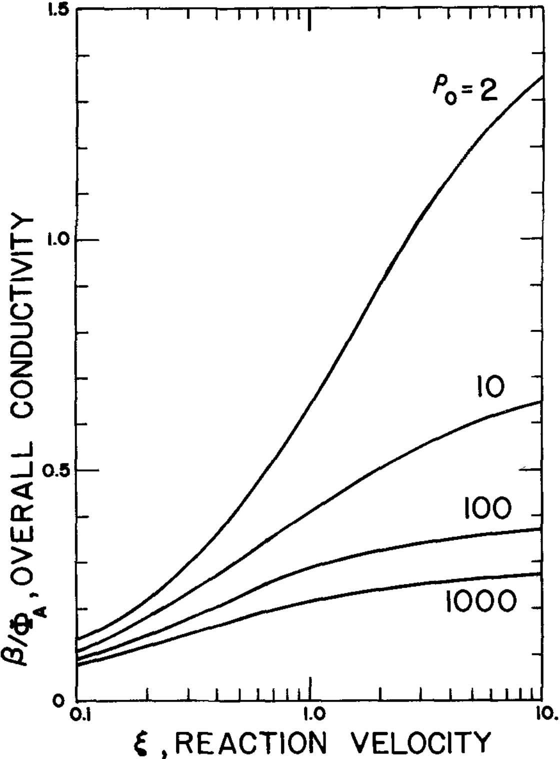

Fig. 5. Effect of exchange current density and counterelectrode radius on monopolar cell behavior ($\psi = 1$, $\Phi_A = 3$).

Although the three overpotenials may vary in magnitude with position along the wire, they always sum to the applied potential which is a constant. As a consequence, the relative magnitude of each overpotential may be depicted on an equilateral triangular graph as illustrated in Fig. 6. Each point within the triangle, designated as a partition point, corresponds to a different partitioning of the applied potential among electrode resistance, charge-transfer, and electrolyte resistance effects. For example, the partition point which corresponds to the insulated end of the electrode system depicted in Fig. 2 is denoted by point A in Fig. 6. The partition points at the insulated end of other systems may also be found in Fig. 6 at the intersection of the appropriate grid lines which are drawn for various values of ξ and ψ. Similarly, the partition point in Fig. 6 which corresponds to the electrical contact end of the

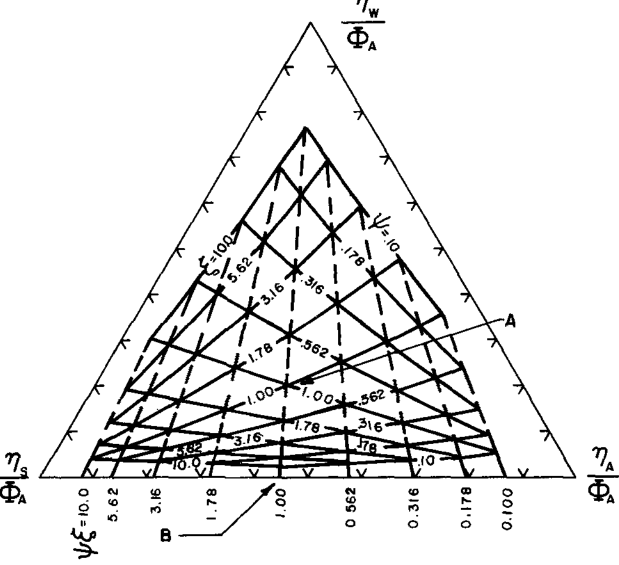

Fig. 6. Compilation of overpotential partitioning for monopolar resistive electrode ($\Phi_A = 3$, $\rho_0 = 10$).

electrode in Fig. 2 is shown as point B. Ohmic effects are always absent at the electrical contact end, so that such partition points always fall on the η_S-η_A "binary" base line at a position which is determined solely by the product $\xi\psi$. Therefore Fig. 6 allows us to determine the relative effects of the three overpotentials at the left and right ends of the cell.

A numerical example may illustrate the use of Fig. 6. Suppose that a particular system under consideration has the parameter values such that $\rho_0 = 10$, $\Phi_A = 3$, $\psi = 1.00$, and $\xi = 1.00$. The product $\xi\psi$ is 1.00. Since, at the electrical contact end of the cell, the ohmic loss in the wire electrode is zero, we find from the η_S-η_A base line that the ohmic loss in the solution equals 55% of the applied potential and the charge-transfer overpotential consumes 45% of the applied potential (point B). At the insulated end of the wire, we find the partition point where the lines intersect corresponding to $\xi = 1.00$ and $\psi = 1.00$ (point A). From the triangular graph, we read that the ohmic drop in the electrode has consumed 20% of the applied potential, the ohmic loss in the electrolyte has consumed 44%, and the charge-transfer overpotential has consumed 36% of the applied potential.

It is convenient to recall that the current distribution along the wire will tend to be nonuniform only if ohmic losses in the metal phase are appreciable with respect to other effects. Therefore if the insulated-end partition point lies near the η_W apex of Fig. 6, the current distribution will be nonuniform. If the insulated end partition point lies near the η_S-η_A base line, the current distribution will be uniform. Figure 7 is a triangular graph for a cell having radii ratio $\rho_0 = 1000$. By comparison with Fig. 6 ($\rho_0 = 10$), one may recognize that the ohmic loss in the electrolyte increases by increasing ρ_0, other conditions remaining equal. That is, an increase in ρ_0 shifts the partition points toward the η_s apex. However, the magnitude of the shift becomes smaller as ρ_0 increases, as was mentioned in conjuction with Fig. 5.

A change in applied potential affects the grids given in Fig. 6 and 7 owing to the nonlinear reaction rate equation. An increase in Φ_A tends to reduce the relative importance of charge-transfer overpotential and thereby shift the grid away from the η_A-apex, that is, upward and to the left.

The approximate model of unidirectional radial current flow in the electrolyte has been found to give current and potential distributions which are in excellent agreement with the two-dimensional model. Owing to the cylindrical geometry, it has been mentioned that the ohmic resistance of the electrolyte arises primarily near the wire surface where the cross-sectional area normal to current flow is small. Therefore it seems reasonable that differences between the two models in prediction of reaction rate distributions would depend primarily on whether unidirectional radial flow occurred near the wire surface. Far away from the wire surface, deviations from one-dimensional current flow may indeed occur, but their effect on over-all cell behavior would be minimal since the regions far from the wire surface do not contribute an appreciable ohmic resistance to the cell. In addition, it seems reasonable that differences between the two models would arise only when the resistance of the electrolyte consumed an appreciable fraction of the applied potential: that is, significant deviations from unidirectional radial flow may be anticipated when the reaction rate distribution is nonuniform and, at the same time, when the solution resistance is appreciable. On the basis of earlier discussion, the current distribution will be nonuniform when the parameter ξ has a large value. In addition, the resistance of the solution will be appreciable when ψ has a large value; however, too large a value of ψ will render the reaction rate distribution uniform as was shown in Fig. 4. Therefore deviations between one- and two-dimensional monopolar calculations are most likely to affect the predicted reaction rate distribution when ξ is large, and when ψ is in the range between 0.1 and 10.

The potential distribution in the solution is given by Eq. [A-I-3]. If the unidirectional approximation is suitable near the wire surface, then the ratio of axial to radial potential gradients must be very small everywhere along the wire surface. By appropriate differentiation of Eq. [A-I-3], one obtains the conditions

$$\frac{\left.\dfrac{\partial\Phi}{\partial\zeta}\right|_{\rho=1}}{\left.\dfrac{\partial\Phi}{\partial\rho}\right|_{\rho=1}} = \frac{-\sum_{n=1}^{\infty} B_n\lambda_n \sin(\lambda_n\zeta)}{-\dfrac{B_0}{\ln\rho_0} + \sum_{n=1}^{\infty} B_n R_n'(1)\cos(\lambda_n\zeta)} = \frac{2\sum_{n=1}^{\infty} B_n\lambda_n \sin(\lambda_n\zeta)}{\psi\beta J(\zeta)} \quad [25]$$

which may be evaluated if the B-coefficients are known from a converged two-dimensional solution. The ratio given by Eq. [25] is equivalent to the ratio of axial to radial current flowing near the wire surface. The ratio therefore has zero values at $\zeta = 0$ and 1, the insulating end planes, but takes on nonzero values at intermediate positions. From the right hand side of Eq. [25], it is seen that the assumption becomes worse as ψ becomes small; however, as noted above, small ψ corresponds to a situation where the electrolyte resistance is negligible so that errors would be of little consequence. For the conditions $\xi = 100$, $\psi = 1$, $\rho_0 = 10$, $\gamma = 10^{-3}$, the largest axial current was found to be 0.15% of the radial current at the wire surface. Larger deviations were found for very short, fat wires, but such geometries are not commonly found among practical situations involving resistive wires. For the geometries associated with the practical applications cited in the introductory remarks, the flow of current in the electrolyte may be taken to be unidirectional in the radial direction.

When ρ_0 has a small value, the current density at the counterelectrode may be large so that polarization would occur, violating assumption (*vi*). For unidirectional radial flow, the current density along the

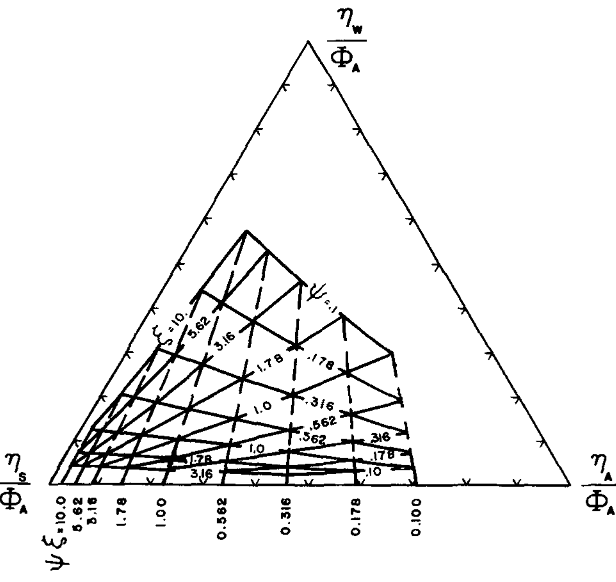

Fig. 7. Compilation of overpotential partitioning for monopolar resistive electrode ($\Phi_A = 3$, $\rho_0 = 1000$).

counterelectrode would be

$$j_{c.e.}(z) = \frac{r_1}{r_0} j_{wire}(z)$$

If, however, the maximum current density along the counterelectrode is not to be greater than the exchange current density of the counterelectrode reaction, then

$$j_{c.e.}^{max} \leq i_{oc.e.}$$

One thereby, arrives at a criterion for judging whether the counterelectrode would be polarized

$$\rho_0 \geq \frac{\beta_{wire} J_{wire}^{max}}{\xi_{c.e.}} \qquad [26]$$

Bipolar Electrode

The approximate bipolar electrode model has been treated in Ref. (28). Since the over-all qualitative features are discussed therein, we choose not to duplicate them here. Instead, attention will be focused on the region of validity of the one-dimensional model by comparing results with the two-dimensional bipolar model. The parameter χ, which arises in the one-dimensional treatment is related to the parameters of the two-dimensional model by

$$\chi = \frac{\xi\psi}{\gamma^2(\rho_0^2 - 1)} \qquad [27]$$

According to earlier discussion, it is anticipated that deviations between the two models will occur when two conditions are met: (I) the current distribution is nonuniform and (II) an appreciable fraction of the applied potential is consumed by electrolyte resistance effects. That is, ξ should be larger than unity, say 100. For the one-dimensional model, the range $1 < \chi < 1000$ was found to satisfy the second condition (28).

A simple basis for comparing the models is to examine the over-all cell conductivity (β/Φ_A) predicted by the models. Figure 8 shows how the ratio of two-dimensional to one-dimensional over-all conductivity varies with the parameters ψ, γ, and ρ_0. Deviations from one-dimensional behavior occur when the value of the ordinate differs from unity. Deviations always occur such that the ordinate-ratio is less than unity; that is, the two-dimensional β is less than the one-dimensional β. This observation is reasonable since the one-dimensional model does not take account of the added ohmic resistance caused by the radial component of current flow. For $\rho_0 = 10$, it may be seen that appreciable deviations set in when the value of γ exceeds 0.01, and when ψ lies in the range $10^{-3} < \psi < 10$. For $\rho_0 = 1000$, deviations occur over the range $10^{-4} < \psi < 10$.

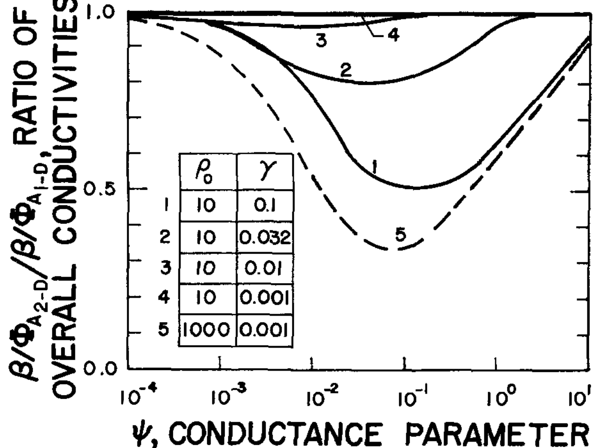

Fig. 8. Comparison of one-dimensional and two-dimensional bipolar electrode models ($\Phi_A = 1$, $\xi = 100$).

The basis chosen for comparing one- and two-dimensional models in Fig. 8 is arbitrary and may not be suitable for some purposes. Nevertheless, on that basis, the calculations carried out in this study indicate that the one-dimensional approximation is good provided that

$$\rho_0 \gamma < 0.1 \qquad [28]$$

That is, the cell length should exceed five times the cell diameter.

Conclusions

The powerful method developed above for calculating current and potential distributions is reasonably flexible with respect to the underlying assumptions. In particular, alternative reaction rate expressions characteristic of special applications may easily be substituted in place of the Butler-Volmer expression. In addition, multiple electrochemical reactions, such as during alloy deposition or gassing during cyanide plating, could be incorporated with ease. The one-dimensional monopolar model may easily be expanded to include effects associated with counterelectrode polarization, counterelectrode ohmic resistance, and multiple counterelectrode contacts; excessive costs would arise in investigation of these effects by expanding the two-dimensional model.

For geometric configurations typical of practical applications, both monopolar and bipolar electrode systems may be accurately approximated by unidirectional current models. The importance of this knowledge is that a relatively straightforward path is now available for superimposing mass transport considerations onto the theoretical models. For example, by incorporating Eq. [9], the mass transport models of Alkire (22) and of Alkire and Tvarusko (23) may be expanded to account for electrolyte resistance effects. For slow moving wires where the mass transfer boundary layer exists under laminar flow conditions, the convective diffusion equation may be incorporated into the model with use of the Lighthill transformation method (30). For turbulent flow, local mass transfer coefficients may be employed following the method of Ref. (22).

By taking into account simultaneously the phenomena of mass transfer, electrolyte resistance, electrode resistance, and charge-transfer overpotential, the above-suggested expansions of the present investigation will permit the analysis of high-rate processes at wire electrodes.

Acknowledgment

This study constituted partial fulfillment of requirements for a Master of Science degree in the Department of Chemical Engineering, University of Illinois, Urbana-Champaign. The investigation received the support of the National Science Foundation (Grant GK-36623). Computer costs were partially supported by the University of Illinois Research Board. The authors benefited from discussions with Professor John Newman, University of California at Berkeley. Part of this study was conducted while the junior author (R.V.) received a fellowship sponsored by the Esso Research and Engineering Company.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1974 JOURNAL. All discussions for the December 1974 Discussion Section should be submitted by Aug. 1, 1974.

APPENDIX I

In dimensionless notation, Eq. [5] is

$$\frac{1}{\gamma^2\rho}\frac{\partial}{\partial\rho}\left(\rho\frac{\partial\Phi}{\partial\rho}\right) + \frac{\partial^2\Phi}{\partial\zeta^2} = 0 \qquad [A\text{-}I\text{-}1]$$

which may be solved by separation of variables

$$\Phi(\rho,\zeta) = \sum_{n=0}^{\infty} R_n(\rho) Z_n(\zeta) \quad \text{[A-I-2]}$$

For the monopolar electrode, the result is

$$\Phi(\rho,\zeta) = B_o\left(1 - \frac{\ln \rho}{\ln \rho_0}\right) + \sum_{n=1}^{\infty} B_n R_n(\rho) \cos(\lambda_n \zeta) \quad \text{[A-I-3]}$$

where

$$\lambda_n = n\pi$$

$$R_n(\rho) = \frac{\left[K_o(\lambda_n\gamma\rho) - \frac{K_o(\lambda_n\gamma\rho_0)}{I_o(\lambda_n\gamma\rho_0)} I_o(\lambda_n\gamma\rho)\right]}{\left[K_o(\lambda_n\gamma) - \frac{K_o(\lambda_n\gamma\rho_0)}{I_o(\lambda_n\gamma\rho_0)} I_o(\lambda_n\gamma)\right]}$$

The λ_n are the eigenvalues in the ζ direction. The B_o-term in Eq. [A-I-3], for $\lambda = 0$, provides a logarithmic radial potential distribution in the electrolyte when current distribution along the wire is uniform. For the bipolar electrode, one finds

$$\Phi(\rho,\zeta) = B_o + \sum_{n=1}^{\infty} B_n R_n(\rho) \cos(\lambda_n \zeta) \quad \text{[A-I-4]}$$

where

$$\lambda_n = n\pi$$

$$R_n(\rho) = \frac{[I_1(\lambda_n\gamma\rho_0) K_o(\lambda_n\gamma\rho) + K_1(\lambda_n\gamma\rho_0) I_o(\lambda_n\gamma\rho)]}{[I_o(\lambda_n\gamma) K_1(\lambda_n\gamma\rho_0) + I_1(\lambda_n\gamma\rho_0) K_o(\lambda_n\gamma)]}$$

The B_o-term arises when $\lambda = 0$.

At wire surface ($\rho = 1$), Eq. [A-I-3] and [A-I-4] both have the form

$$\Phi(1,\zeta) = \Phi_S(\zeta) = B_o + \sum_{n=1}^{\infty} B_n \cos(\lambda_n \zeta) \quad [15]$$

APPENDIX II

By combining Eq. [1] and [2], setting them into integral form, and rendering them dimensionless, one obtains

$$\Phi_M(\zeta) = \beta \int_o^\zeta \int_o^\zeta J(\zeta)\, d\zeta d\zeta \quad \text{[A-II-1]}$$

The dimensionless form of Eq. [4] is

$$-\frac{\psi\beta J}{2} = \left.\frac{\partial \Phi}{\partial \rho}\right|_{\rho=1} \quad \text{[A-II-2]}$$

For the monopolar wire, substitution of Eq. [A-I-3] into [A-II-2] yields

$$-\frac{\psi\beta J}{2} = -\frac{B_o}{\ln \rho_0} + \sum_{n=1}^{\infty} B_n R_n'(1) \cos(\lambda_n \zeta) \quad \text{[A-II-3]}$$

Substituting Eq. [A-II-3] into Eq. [A-II-1] then gives

$$\Phi_M(\zeta) = \frac{2}{\psi} \int_o^\zeta \int_o^\zeta \left[\frac{B_o}{\ln \rho_0} - \sum_{n=1}^{\infty} B_n R_n'(1) \cos(\lambda_n \zeta)\right] d\zeta d\zeta \quad \text{[A-II-4]}$$

where the boundary conditions are

$$\Phi_M(0) = \Phi_A$$

$$\frac{d\Phi_M(1)}{d\zeta} = 0$$

After integration, the result for the monopolar wire is

$$\Phi_M(\zeta) = \Phi_A - \frac{2B_o\zeta}{\psi \ln \rho_0} + \frac{B_o\zeta^2}{\psi \ln \rho_0} - \frac{2}{\psi} \sum_{n=1}^{\infty} \frac{B_n R_n'(1)}{\lambda_n^2} [1 - \cos(\lambda_n\zeta)] \quad \text{[A-II-5]}$$

An analogous result may be found for bipolar electrodes by combining Eq. [A-I-4] with [A-II-1] and [A-II-2] to obtain

$$\Phi_M(\zeta) = -\frac{2}{\psi} \sum_{n=1}^{\infty} B_n R_n'(1) \int_o^\zeta \int_o^\zeta \cos(\lambda_n\zeta)\, d\zeta d\zeta \quad \text{[A-II-6]}$$

with boundary conditions

$$\Phi_M(0) = \Phi_A$$

$$\Phi_M(1) = 0$$

Integration yields

$$\Phi_M(\zeta) = \Phi_A + \left\{\frac{2}{\psi} \sum_{n=1}^{\infty} \frac{B_n R_n'(1)}{\lambda_n^2} [1 - (-1)^n] - \Phi_A\right\}\zeta - \frac{2}{\psi} \sum_{n=1}^{\infty} \frac{B_n R_n'(1)}{\lambda_n^2} [1 - \cos(\lambda_n\zeta)] \quad [17]$$

APPENDIX III

The following procedure illustrates the method used to calculate the B-coefficients from trial values of the potential distribution. By eliminating the current distribution, $J(\zeta)$, from Eq. [18] and [A-II-2], and by incorporating the derivative of Eq. [A-I-3], one obtains, for a monopolar electrode, the result

$$-\frac{\psi\xi}{2}[e^{\alpha(\Phi_M - \Phi_S)} - e^{(\alpha-1)(\Phi_M - \Phi_S)}] = -\frac{B_o}{\ln \rho_0} + \sum_{n=1}^{\infty} B_n R_n'(1) \cos(\lambda_n\zeta) \quad \text{[A-III-1]}$$

The exponential terms on the left side of Eq. [A-III-1] are then linearized about trial potential distributions: that is, let the unknown potential distributions be combined to form

$$\eta_A = \Phi_M - \Phi_S$$

and denote the trial distributions, known from the previous iteration step, by

$$\eta_A^* = (\Phi_M - \Phi_S)_{\text{trial values}}$$

The right hand side of Eq. [A-III-1] can then be made linear with respect to the unknown distribution, η_A

$$-\frac{B_o}{\ln \rho_0} + \sum_{n=1}^{\infty} B_n R_n'(1) \cos(\lambda_n\zeta) = -\frac{\psi\xi}{2}\{[e^{\alpha\eta_A^*} - \alpha\eta_A^* e^{\alpha\eta_A^*} - e^{(\alpha-1)\eta_A^*} + (\alpha-1)\eta_A^* e^{(\alpha-1)\eta_A^*}] + [\alpha e^{\alpha\eta_A^*} - (\alpha-1) e^{(\alpha-1)\eta_A^*}]\eta_A\} \quad \text{[A-III-2]}$$

Because subsequent equations become voluminous, only the basic outline will be described henceforth. Interested readers may find full details of the derivations in Ref. (32).

Substitute Eq. [15] and [16], for Φ_M and Φ_S, into the η_A term of Eq. [A-III-2] and denote the result as Eq. [A-III-3]. Now integrate both sides of Eq. [A-III-3] from $\zeta = 0$ to $\zeta = 1$. The result may be solved algebraically to obtain

$$B_o = f_1(B_n) \quad \text{[A-III-4]}$$

That is, B_o may be calculated if the B_n-coefficients are known. Now, by orthogonality, evaluate the B_n-coefficients by multiplying Eq. [A-III-3] by $\cos(\lambda_n\zeta)$ and then integrating from $\zeta = 0$ to $\zeta = 1$ in order to obtain an expression of the form

$$B_n = f_2(B_o) \quad \text{[A-III-5]}$$

That is, the B_n's may be calculated if B_o is known. Now multiply Eq. [A-III-5] by the quantity

$$\xi[\alpha\, e^{\alpha\eta_A^*} - (\alpha - 1)\, e^{(\alpha-1)\eta_A^*}] \frac{R_n'(1)}{\lambda_n^2}$$

and sum all the n-equations; substitute the result into Eq. [A-III-4] to eliminate the B_n terms therein. The coefficients B_o may now be calculated directly from the trial distribution, η_A^*. In turn, the B_n's are subsequently found from Eq. [A-III-5].

The procedure for determining the bipolar B-coefficients is identical to that given above except that Eq. [A-I-4] is used in place of Eq. [A-I-3].

Electrode Capacitance in Silver-Halide Solid Electrolyte Cells

I. Room Temperature Graphite and Platinum Electrodes

Douglas O. Raleigh*

Science Center, Rockwell International, Thousand Oaks, California 91360

ABSTRACT

Potentiostatic chronocoulometry on polarized graphite electrodes on AgI and AgBr solid electrolytes at room temperature shows an ideally fast, almost voltage-independent, double layer charging process for both electrolytes. Results on the more highly conductive electrolyte $2[(CH_3)_4NI] \cdot 13$ AgI are similar to AgI, but with moderate capacitance dispersion in the subsecond time range. For all three electrolytes, the results suggest charging by a compact, purely electrostatic, interfacial Ag^+-ion layer separated from the graphite surface by a strongly adsorbed anion layer. For platinum electrodes on AgI and AgBr, a variety of types of platinum and surface pretreatments gave the common result of a slow, broadly dispersed charging process. The Pt results are consistent with a previously proposed interface model in which charging involves both cation and anion motion, and suggests that slow charging results from the relatively immobile anions. The relationship between various types of double layer capacitance in solid electrolytes is discussed.

It has been of continuing interest in our laboratory to characterize the nature of electrode double layer capacitance in solid-electrolyte systems (1-4). Several years ago, Hull and Pilla (5) reported some intriguing findings with pressed-powder pellet cells Ag|AgI|C and Ag|AgI|Pt. It was of interest for a variety of reasons to pursue these experiments further, extending them to other Ag^+-ion electrolytes, other types of graphite and platinum electrodes, and above-ambient temperatures.

In the Hull-Pilla work, the cells were formed by successively compacting powders of their components in a cylindrical die, and included an embedded Ag wire reference electrode midway in the electrolyte, which was partially exposed after pressing. The experiments included applying small potential steps atop a polarizing d-c bias (Ag electrode negative, <0.5V) and observing the current-time behavior oscillographically with varying degrees of electronic *IR* compensation. With graphite electrodes, plots of log *i vs. t* were linear over several current decades for a wide range (tens of microsecond to second) of effective cell time constants, and indicated a single, bias-independent capacitance with ideally fast (undispersed) charging kinetics. With platinum electrodes, log *i vs. t* plots were not linear. Large ($\sim 10^4$ μf/cm^2), bias-dependent total capacitances were reported, with considerable dispersion on all time scales. It was suggested that the graphite capacitance, 8.0 μf/cm^2, involved a purely electrostatic compact charge layer of Ag^+ ions, while the platinum results represented large faradaic effects throughout the voltage range, involving silver and iodine deposition and stripping.

The graphite results were surprising, in view of the method of interface preparation and the capacitance dispersion generally reported for unpolished solid electrodes in aqueous systems (6). In our own laboratory, a previous study (2) showed considerable dispersion for pyrolytic graphite foil electrodes on AgBr at 244°-292°C. It was of interest to determine in the present work whether the dispersion-free behavior was specific to AgI, to graphite powder electrodes, and to ambient temperatures.

In the case of platinum, the large capacitances obtained were in contrast to our own work with polished Pt wire electrodes in AgBr in the neighborhood of its melting point (3). In this latter work, 30-fold smaller capacitances were obtained that showed a broad time range of undispersed behavior and could be fitted to a model involving an interfacial electrolyte layer of adsorbed anions and cations. It was felt that the Hull-Pilla results might reflect faradaic impurities specific to their use of platinum black as the electrode material, and that other forms of platinum might give different results. Additionally, we noted in our own work that the platinum capacitance progressively acquired dispersion on cooling from the AgBr melting point, and suggested that this might involve an interface strain due to differing thermal contraction rates of AgBr and Pt. For both these reasons, it was of interest in the present work to determine whether a properly prepared Pt|AgX interface would show undispersed charging at room temperature.

In the present work, the electrolytes investigated were AgI, AgBr, and the recently discovered (7) composition $2[(CH_3)_4NI] \cdot 13$ AgI. Silver bromide was studied in view of our previous investigations (1-3). Both AgI and AgBr have low bulk ionic conductivities at room temperature ($\sim 10^{-8}$ ohm^{-1} cm^{-1}), so their compacted powders conduct predominantly via grain boundary paths, with effective conductivities of 10^{-4}-10^{-6} ohm^{-1} cm^{-1}. Because of this, it was desirable to study an electrolyte with good room temperature bulk conductivity as well. The tetramethylammonium iodide-silver iodide (TMAI) composition has an Ag^+-ion conductivity of 0.041 ohm^{-1} cm^{-1} at 22°C (7) and was selected rather than the better known $RbAg_4I_5$, since the moisture sensitivity of the latter (8) would seem to lead to a questionable interface composition, even with careful inert-atmosphere handling techniques.

The preferred electrochemical technique in the present work was potential-step chronocoulometry rather than chronoamperometry, since it gives a direct visual indication of the charging process over a wide range of times scales. Chronoamperometry and cyclic voltammetry were occasionally used as supplementary techniques.

Experimental

Ag|AgX|C pressed-powder pellet cells with a 10-mil Ag wire reference electrode were prepared essentially by the Hull-Pilla procedure, except that a

* Electrochemical Society Active Member.
Key words: solid electrolyte, silver halides, double layer, electrode capacitance.

1/4 in. rather than 1/2 in. cylindrical die was used, so weights of materials were quartered. Finely (−325 mesh) powdered, 5N grades of Ag, AgI, and AgBr were used, and spectroscopic graphite powder. A sample of $2[(CH_3)_4NI]\cdot 13\ AgI$, which was obtained from Dr. B. B. Owens, was prepared as previously described (7). In one AgI cell, the carbon electrode was a freshly cleaved thin foil of the stress-annealed pyrolytic graphite used in the previous study (2). Additionally, two Ag|AgI compacts were pressed, leaving a smooth free AgI face which was spray-coated with a several-micron layer of Acheson "Dag 154" graphite dispersion in 1:5 methanol.

A variety of Ag|AgX|Pt cells were prepared, using AgI or AgBr. Cells employing −100 mesh platinum powder, Pt filings, or Pt foil were prepared essentially as above. The filings and foil were pretreated by boiling in concentrated HNO_3, rinsing, boiling in concentrated HCl, rinsing, and air- or oven-drying. The 99.95% Pt powder was used as is. Most experiments, however, were carried out with an embedded Pt wire electrode, as shown in Fig. 1. The embedded wire was partially exposed after pressing, and the two Ag end layers were electrically connected to serve as a single large counterelectrode. In general, the wire electrode pretreatment was the same as for filings and foil, except that the HCl boil was preceded by heating the wire to orange-yellow several times in the outer part of an air-gas torch flame. Additionally, in one embedded-wire cell, no pretreatment was used and, in two others (one each AgI and AgBr), the pretreatment was followed by argon-sputtering the wire in an Auger ion-bombardment apparatus directly prior to cell preparation.

All measurements were made in the ambient laboratory atmosphere, with the cell lightly springloaded between 1/4 in. metal rods in a Micarta cell holder. An 0.25V polarizing d-c bias was placed on the cell and measurements started after the steady-state cell current settled to $\lesssim$ 1 nA. In some cases, current settling was hastened by applying several voltage steps. Fifty millivolt potential steps of 10-μsec rise time in the bias voltage range 25-425 mV anodic to Ag were applied with a standard 3-electrode (2-electrode for Pt wire cells) potentiostat (2), and the current or integrated charge response followed oscillographically and by recorder. Resistance compensation was not employed. Cyclic voltammetry, when used, was carried out with a standard arrangement.

In addition, electron micrographs of the AgBr|C and AgI|C interfaces were taken, using fractured powder cells and an Etec scanning electron microscope.

Results

Graphite powder electrodes.—Oscillographic charge-time curves showed the same basic charging behavior for all three electrolytes. On applying a potential step, the integrated charge rose to a flat or slightly up-sloped "plateau" in a time of several RC constants, indicating a well-defined "fast" capacitance. Figure 2 shows this behavior for an AgI cell over two decades of time.

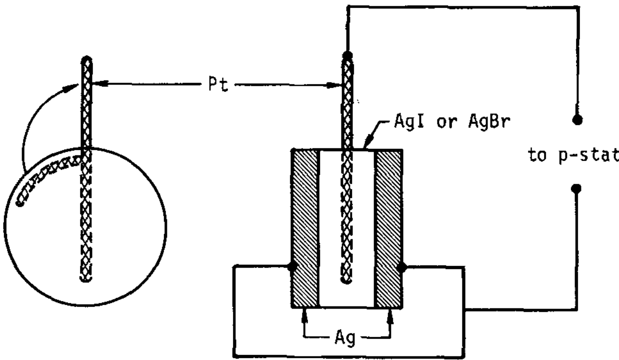

Fig. 1. Schematic of cell with embedded Pt wire electrode

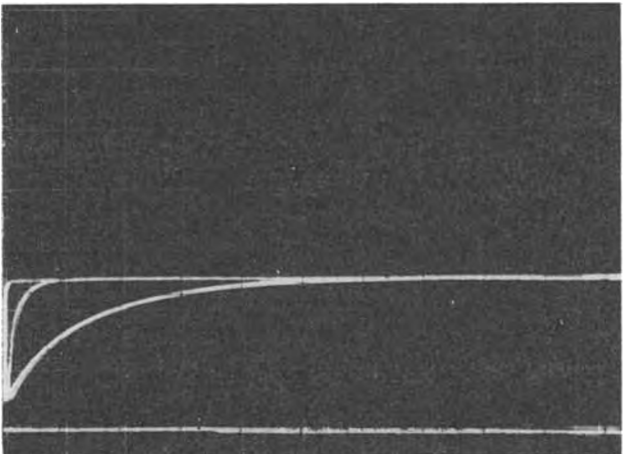

Fig. 2. Oscillographic charge-time traces for 0.25→0.20V step on Ag | AgI | C (pressed powder) cell. Sweep rates 5, 50, 500 msec/cm; ordinate 0.06 μcoulomb/cm. Bottom line is Q = 0 reference level.

For AgI and AgBr cells, supplementary measurements confirmed this picture. Potential-step oscillographic current-time data yielded exactly or closely linear log i *vs.* t curves whose capacitance slopes agreed well with capacitances obtained chronocoulometrically. On longer time scales, recorder charge-time data for $1 \leq t \leq 50$ sec and slow (~1 mV/sec) cyclic voltammetry showed in general 10-20% increased capacitances. However, plots of Q *vs.* $t^{1/2}$ from the recorder data were linear and back-extrapolation to $t = 0$ gave capacitances in agreement with the oscillographic data. Because of their random character from one cell to the next, these slow charge contributions are felt to reflect a diffusion-controlled faradaic impurity reaction. In view of the general slowness of impurity ion diffusion in solid electrolytes, the likely source of the impurity would be the graphite electrode. A Q *vs.* $t^{1/2}$ plot from recorder data for an AgBr cell is shown in Fig. 3.

Data from some four AgI cells and seven AgBr cells show an averaged fast capacitance of 9.3 ± 3% μf/cm² for the AgI|C (pressed powder) interface at the 0.225V voltage range midpoint and 5.5 ± 4% μf/cm² for AgBr. The capacitances per unit area are calculated from the geometric pellet area. For AgI, data from the various cells showed a 3-8% capacitance increase over the bias range 0.05 to 0.40V, while AgBr

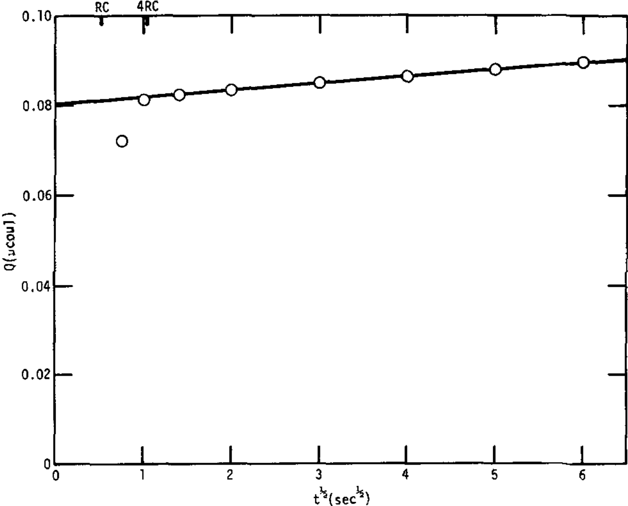

Fig. 3. Q vs. $t^{1/2}$ plot for Ag | AgBr | C (pressed powder) cell from recorder data (0.25→0.20V step).

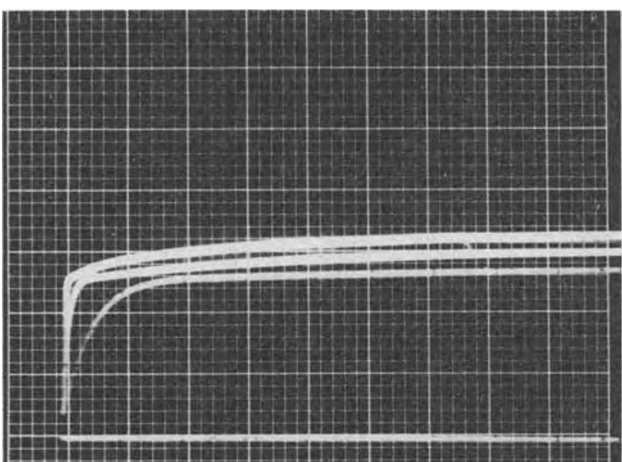

Fig. 4. Oscillographic charge-time traces for 0.25→0.20V step on Ag | TMAI | C (pressed powder) cell. Sweep rates 0.1, 0.5, and 2.0 msec/cm; ordinate 0.05 μcoulomb/cm.

cells showed no voltage dependence of capacitance within the accuracy of measurement (1-1/2%).

For the TMAI cells, the capacitance was not as cleanly describable in terms of an intrinsic "fast" component and a small, diffusion-like faradaic contribution. Figure 4 shows oscillographic charge-time traces for sweep rates of approximately 1.5, 7.5, and 30 RC rise times per centimeter for a typical cell. The fast sweep rate shows a nearly flat plateau, but slower sweeps show further charging. Chronocoulometric recorder data showed a "slow" capacitance amounting to ~50% of the total at $t = 1$ min. The data yielded linear Q *vs.* $t^{1/2}$ plots, but back-extrapolations to $t = 0$ gave capacitance values some 6-60% higher than from various types of oscillographic data.

Table I shows capacitance data for three TMAI|C cells, using four types of capacitance determination: (A) slope of log i *vs.* t plot from oscillographic current-time trace; (B) average Q value at 5-10 RC rise times from oscillographic chronocoulometry (Fig. 4); (C) $t = 0$ back-extrapolation of Q *vs.* $t^{1/2}$ plot from oscillographic data ($0.2 \leq t^{1/2} \leq 1.0$ sec$^{1/2}$); and (D) $t = 0$ back-extrapolation of Q *vs.* $t^{1/2}$ plot from recorder data ($1 \leq t^{1/2} \leq 7$ sec$^{1/2}$). As seen, individual cell values for a given type measurement agree well, but the various determinations do not suggest a well-defined "fast" capacitance. The bias dependence of the TMAI|C (pressed powder) capacitance was found to be in the range of that for AgI.

For all the graphite powder cells, some capacitance changes were seen on standing, though the direction and degree were highly variable. For AgI and AgBr cells, capacitances were stable for at least several days and, in some cases, changed only 5-10% over a two-year period. For TMAI cells, large changes often occurred, even over several days. These changes are possibly due to atmospheric contamination effects. In all cases, the data reported are initial data, which showed good agreement among duplicate cells.

Other graphite electrodes.—As noted before, two AgI cells were made with a spray-coated colloidal graphite electrode and one with stress-annealed pyrolytic graphite foil. Since these cells involved smooth electrode interfaces, one purpose of studying them was to see if their data could be used to estimate a roughness factor for the pressed-powder interfaces.

The pyrolytic graphite cell gave results quite similar to the pressed-powder cells. Flat chronocoulometric plateaus from oscillographic sweeps gave a capacitance of 8.3 μf/cm² at 0.225V and a bias dependence of +3.5% over the full voltage range. The result suggests a factor of 1.12 greater surface for the powder cell interfaces, relative to the smooth cleavage face of the pyrolytic foil. Further justification for this comparison will be presented in the Discussion section.

The spray-coated colloidal graphite cells also showed a well-defined fast capacitance, but the value was much smaller and its bias dependence differed. Well-defined oscillographic chronocoulometric plateaus showed a capacitance of 0.45 ± 2% μf/cm² at 0.225V. Plots of Q *vs.* $t^{1/2}$ from 1-25 sec recorder data were linear and the back-extrapolated $t = 0$ capacitance agreed well with the chronocoulometric data. Oscillographic log i *vs.* t plots were essentially linear, but gave capacitances some 10-15% smaller than the chronocoulometric data. Thus, some fast-time dispersion is indicated. The bias voltage dependence was negative, with capacitance at 0.40V being ~12% lower than at 0.05V. Because of the 20-fold smaller capacitance than pressed-powder cells and negative bias dependence, it was felt that more than a simple interface area reduction due to smoothness was involved. It would seem that the effect of solvent and binder residues in the spray coatings is not negligible.

Platinum electrodes.—A common result in all platinum electrode cells was the lack of any well-defined "fast" charging contribution. Figure 5 shows a typical set of oscillographic charge-time traces. The chronocoulometric capacitance was observed to increase continuously on all time scales from tens of microsecond to tens of second, with no plateau or "shoulder" feature. This result was common to both AgI and AgBr. to all the Pt electrode types (powder, filings, foil, wire), all surface pretreatments, and occurred throughout the voltage range. In addition, log i *vs.* t plots from oscillographic current-time traces were invariably seriously curved. The picture is one of a completely dispersed charging process.

Because of this behavior, well-defined "total" capacitances could not be obtained. However, even on the longest time scale (~10-15 min), effective chronocoulometric capacitances were several orders of magnitude smaller than the ~10⁴ μf/cm² values reported by Hull and Pilla for platinum black. Effective capacitances at $t = 0.1$ sec were of order 300 μf/cm² for filings, 60

Table I. TMAI | C capacitances

Run	Measured capacitance (μf/cm²)			
	Method A	Method B	Method C	Method D
1	6.8	8.6	9.3	10.0
2	7.2	9.0	10.6	11.0
3	6.7	8.4	11.4	12.1
Average	6.9	8.7	10.4	11.0

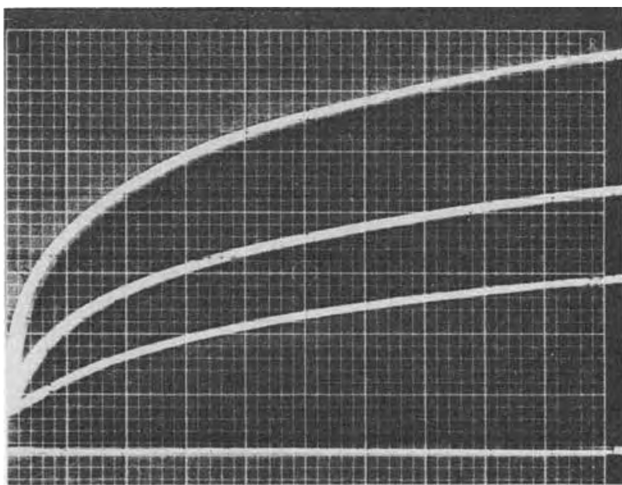

Fig. 5. Oscillographic charge-time traces for 0.25→0.20V step on Ag | AgI | Pt (embedded wire) cell. Sweep rates 0.05, 0.2, and 1.0 msec/cm; ordinate 500 pf/cm.

μf/cm² for powder, and 0.3 μf/cm² for foil and wire. Because of the uncertain effective interface areas and faradaic contributions for filings and powder, and poor adherency of the Pt foil, most experiments made use of embedded-wire cells (Fig. 1). While the electrode geometry in such cells should result in a "geometric" capacitance dispersion (16) due to nonuniform current distribution, such an effect with our geometry would involve only a small time span during the initial RC charging process. In view of the observed incompleteness of chronocoulometric charging over many decades of time, even in Pt cells with the cylindrical electrode geometry, this effect in the embedded-wire cells would be negligible. Results reported from this point are for embedded-wire cells.

It was not found possible to resolve potential-step chronocoulometric data into a partial diffusion-like contribution. Figure 6 shows a typical Q *vs.* $t^{1/2}$ plot from recorder data. Most such plots from both oscilloscope and recorder data had the continuous curvature seen, with back-extrapolation to $t = 0$ at the prevailing curvature leading toward the origin. In instances where a plot segment at the right side had a quasi-linear appearance, back-extrapolation gave a line from which the actual curve still deviated at times long compared with any estimate of RC rise time. Thus, the significance of the back-extrapolation would be in question. In several instances where a nearly linear plot was obtained, back-extrapolation brought the plot closely through the origin. The coexistence, then, of "fast" and diffusion-like charging components was not seen for the AgX|Pt interface.

Several duplicate AgI cells, in which the standard Pt wire pretreatment was used, gave similar interface charging characteristics, but gave capacitance magnitudes varying up to a factor of two among individual cells. Thus, random interface variations appear important. For a given cell, however, a consistent set of variations of capacitance behavior with voltage step direction, bias voltage, and time was observed which suggest a charging pattern in line with previous findings for the AgBr|Pt interface at elevated temperatures (3).

Figure 7 shows a set of Q *vs.* $t^{1/2}$ plots from chronocoulometric recorder data for a standard-pretreatment AgI cell, using 0.05V voltage steps over the full range of the bias voltage. While such plots are not generally linear, they offer a convenient means of displaying the charging behavior over an extended time span. At short times ($t \sim 1$ sec), charge values tend to cluster together in the mid-voltage range, rise slightly at low voltage, and fall somewhat at high voltage. Though not readily seen in Fig. 7, the curvature is slightly convex upward for average voltages below

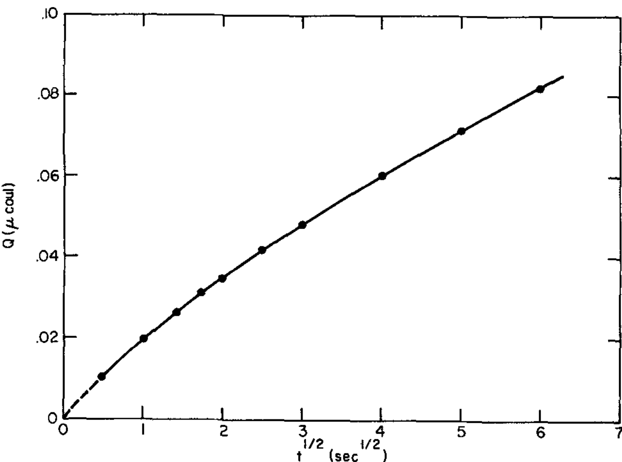

Fig. 6. Q *vs.* $t^{1/2}$ **plot for Ag | AgI | Pt (embedded wire) cell A from recorder data (0.25→0.20V step).**

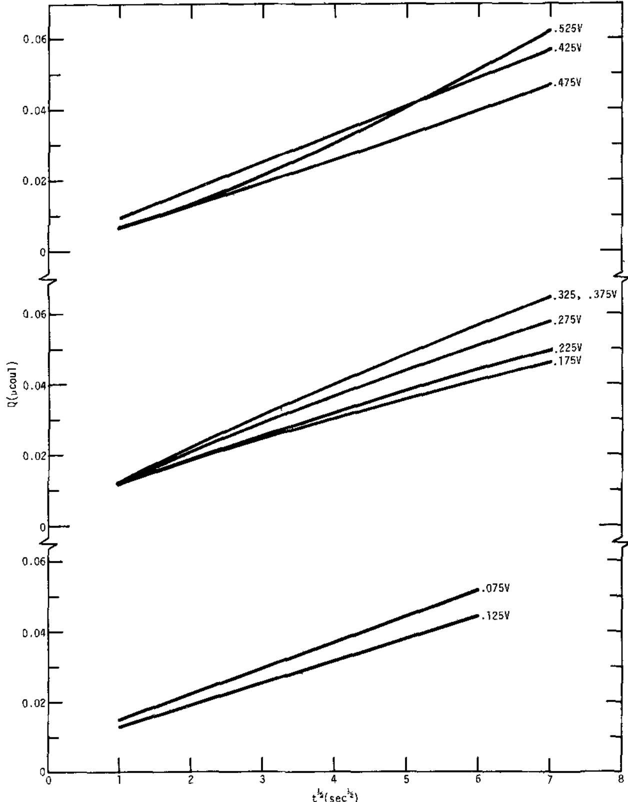

Fig. 7. Q *vs.* $t^{1/2}$ **plots for Ag | AgI | Pt (embedded wire) cell B for upward 0.05V step at various average bias voltages (*e.g.*, 0.225V is for 0.20→0.25V step). Curves displaced for clarity.**

0.425V, quasi-linear at 0.425V, and slightly concave upward above 0.425V.

Figure 8 shows the step direction dependence of charging for three voltage steps. The charging curve was always higher for the upward voltage step. The difference, however, was negligible below 0.25V, in-

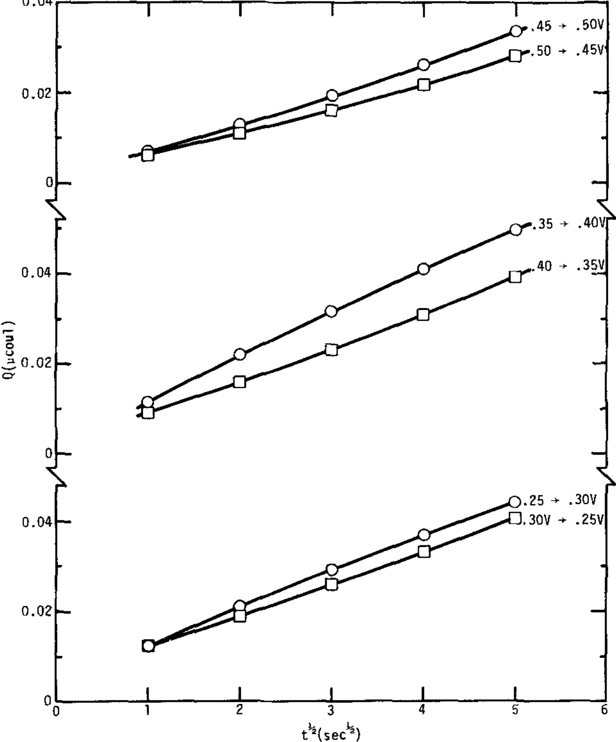

Fig. 8. Q *vs.* $t^{1/2}$ **plots for Ag | AgI | Pt (embedded wire) cell B for upward and downward 0.05V steps at three average bias voltages. Curves displaced for clarity.**

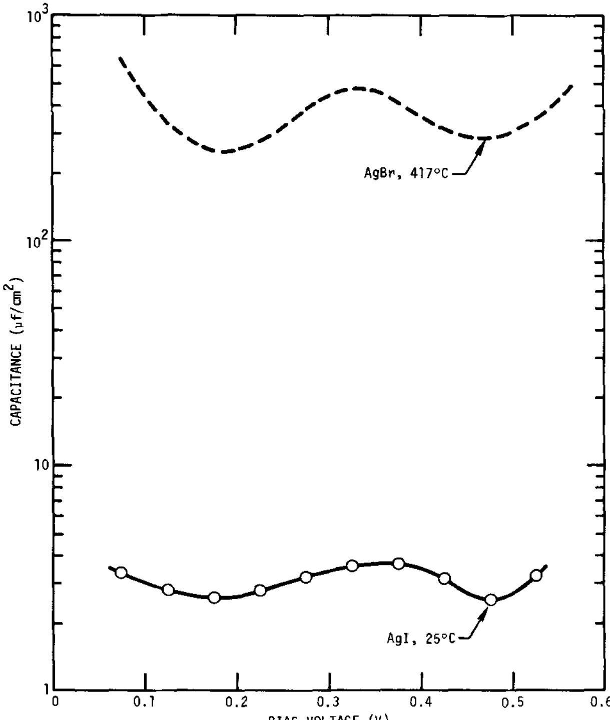

Fig. 9. A-C capacitance at 1 kHz for AgBr | Pt interface at 417° (3) compared with effective chronocoulometric capacitance for Ag | AgI | Pt cell B at $t = 36$ sec, as function of bias voltage.

creased to a maximum at the 0.35-0.40V step, and decreased thereafter.

To get an idea of the bias voltage dependence, the capacitance corresponding to the Q value at $t^{1/2} = 6$ (*i.e.*, 36 sec) from Fig. 7 is plotted in Fig. 9 as a function of bias and compared with the undispersed a-c capacitance-voltage curve for AgBr|Pt at 417° from the previous study (3). We observe qualitatively the same voltage dependence, though considerably flattened, and a factor of 100 reduction in absolute magnitude. The comparison suggests that the previously observed onset of dispersion on cooling is an intrinsic property of the AgX|Pt interface rather than a result of differential thermal contraction strain. The various other features of the Q *vs.* $t^{1/2}$ curves of Fig. 7 and 8 are discussed in terms of the previously proposed interface model in the Discussion section.

Results for AgBr cells were similar to those for AgI, except that serious irreproducibilities or "memory" effects were observed on bias voltage cycling unless inordinately long waiting times were employed at each voltage. Because of this, the above comparison with previous data was carried out with AgI rather than AgBr cells. However, capacitance magnitudes and the features of the Q *vs.* $t^{1/2}$ plots at various biases were basically the same for AgI and AgBr cells.

Cyclic voltammetric data from an AgI cell in which there was no Pt wire pretreatment showed poor reproducibility on cycling and severalfold lowered capacitance from cells with the standard pretreatment. Hence, detailed chronocoulometric data were not taken.

For the cells in which the standard Pt wire pretreatment was followed by argon-sputtering (one each with AgI and AgBr), Q *vs.* $t^{1/2}$ plots showed severalfold reduced capacitances and a slight concave-upward curvature for the 0.25 → 0.20V step data. Since these findings indicated generally reduced charging kinetics, this preparation technique was not pursued further. Results for the two cells, however, were extremely similar, again showing the basic similarity of the charging process with the two electrolytes.

As in the case of AgX|C cells, Pt electrode cells also showed capacitance changes on standing, possibly because of atmospheric contamination. With the Pt cells, however, the change was invariably a decrease.

Discussion

The findings for pressed-powder graphite cells with AgI and AgBr basically agree with those of Hull and Pilla in establishing that charging occurs predominantly by an intrinsically rapid process that depends but little on bias voltage. The average capacitance for AgI|C is some 16% higher than their value (8.0 μf/cm²), which may relate to the specific type of graphite used.

Hull and Pilla suggested that the capacitance arose from an ideal compact layer ("inner layer") of Ag^+ ions on the graphite surface, with the effective charge separation being the Ag^+ ionic radius and an assumed vacuum dielectric constant ($K_D = 1$). This yields a theoretical parallel-plate capacitance of 7.4 μf/cm². The assumption of a compact layer still seems reasonable, but the difference between AgBr and AgI capacitance (AgBr 41% lower) suggests the need for a modified picture. Further, the microscopic nature and roughness of the experimental interface needs consideration.

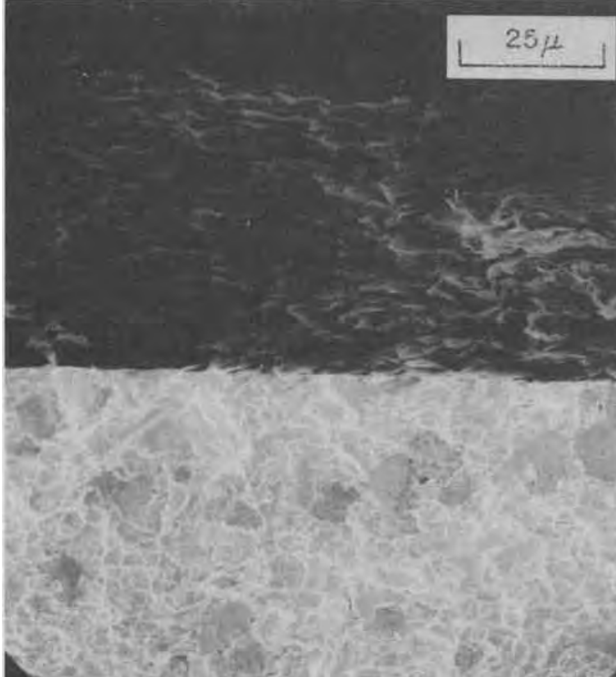
Figure 10 shows scan electron micrographs of an Ag|AgBr|C powder cell at two magnifications. A surprisingly flat interface is seen, with the roughness being a slight waviness at most. The AgBr crystallite particles appear to be pressed flat by a well-laminated graphite layer. The same results were seen for the AgI|C interface. An electron micrograph showed the unpressed graphite particles to be 5-10μ diameter platelets. On pressing, it appears that the graphite flakes form an intermeshed, nearly planar front that flattens the relatively soft silver halide crystallites. On this basis, the similarity of graphite capacitances between pressed powder and pyrolytic foil seems reasonable. The 11% lower capacitance with pyrolytic foil presumably results from a slightly smoother interface.

While these results show a relatively low topographical roughness, one still expects microscopic roughness on a smaller scale, given that we have a solid-solid interface. Aqueous electrochemical studies, for instance, indicate a 1.5-2.0 microscopic roughness factor for smooth platinum electrodes (9, 10). It seems not unreasonable, then, to expect an over-all roughness factor $\geqq 2$. Our experimental results then lead to maximal microscopic capacitances of 4.7 and 2.8 μf/cm² for AgI|C and AgBr|C, respectively. Using the parallel-plate capacitance expression

$$C = K_D \epsilon_0 / d \quad [1]$$

where C is the capacitance per unit area, K_D the dielectric constant, ϵ_0 the permittivity of free space, and d the plate separation, we find that even with the assumption of $K_D = 1$, these capacitances require d values greater than the Ag^+ ionic radius.

It would seem that both the electrolyte dependence of capacitance and the need for increased double layer charge separation d could be achieved by assuming a layer of strongly adsorbed anions between the Ag^+ cations and the graphite surface. From Eq. [1], both K_D and d help determine C. If d is the distance between the electrode surface and the centers of the mobile Ag^+ ions, then the larger crystal ionic radius for the iodide ion would in itself predict a larger capacitance for the AgBr cell. However, a stronger chemisorption and greater polarizability of I^- than Br^- may offset this by giving a substantially greater K_D for AgI. The chemisorption and polarizability of I^- may also explain the observed 4-8% voltage dependence of capacitance in AgI|C cells in terms of an anion-layer electrostrictive effect. Attempts to obtain a detailed fit of our capacitance results to a simple anion-layer model involving Br^- and I^- ionic radii and polarizabilities were not successful, but the



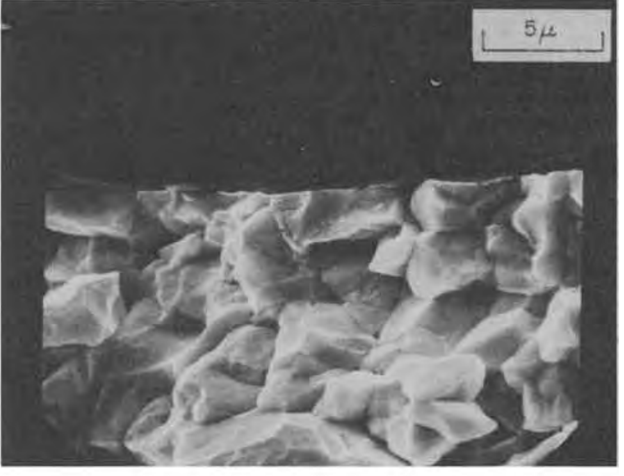


Fig. 10. Scanning electron micrographs of AgBr | C (pressed powder) interface at 800X (a, left) and 4000X (b, right). Dark areas are graphite, light areas AgBr.

general picture of an adsorbed anion layer seems useful and consistent with the experimental data.

We have noted the less clear-cut charging process in TMAI|C cells. One is struck, however, by the similar magnitudes of oscillographic capacitance in Fig. 2 and 4, the similar voltage dependence of capacitance for AgI and TMAI, and the fact the anions are I^- ions in both electrolytes. From these similarities one is disposed to suggest that the TMAI interface may be little more than a "perturbed" AgI interface, in which the altered composition and structure, or possibly an adsorbed atmospheric component, may supply the perturbation. The enlarged "slow" capacitance contribution and faster change of interface properties on standing observed with this electrolyte would favor the picture of atmospheric contamination. In all three electrolytes, we are suggesting that a fast charging process occurs which involves only Ag^+ ion motion to and from a compact interfacial layer, with a fixed, intervening anion layer.

Considering now the AgX|Pt results, we have already noted that our effective capacitances for Pt wire were at least several orders of magnitude lower than observed by Hull and Pilla for Pt black. The latter workers suggested their large apparent capacitances were primarily due to Ag dissolution in Pt black at reduced activity, and that the true double layer capacitance on Pt should be the same as on graphite.

Faradaic effects due to Ag deposition should result in a sharp upturn in effective capacitance as the Ag potential is approached, because of the exponential dependence of silver activity on $(V\text{-}V_{Ag})$. We have observed such an upturn for solid Pt electrodes in both the present and previous (1-3) work, but only below ~0.18V (Fig. 9). At higher potentials, the low value of the silver activity, voltage variation of the capacitance, and, in the previous AgBr|Pt study (3) at 417°-429°C, the disappearance of frequency-dependent electrode capacitance, all indicate negligible Ag deposition effects for solid Pt electrodes above ~0.18V anodic of V_{Ag}.

Hull and Pilla reported the presence of metallic Ag in their Pt black electrodes at various potentials from microprobe measurements, but did not specify the voltage range. From the rather modest capacitance variation they observed (9-16 mF/cm²) over the voltage range 0-0.4V anodic of V_{Ag}, it would seem either that Pt black displays quite different Ag dissolution characteristics from solid Pt or that a partial contribution from electroactive impurities in the Pt black may have been involved.

We feel, then, that our observed AgX|Pt capacitances over the bulk of the voltage range are true double layer capacitances, and are indeed different from the double layer capacitance on graphite. We recall the capacitance model previously (3) suggested for AgBr|Pt at high temperatures. The Pt surface is assumed to be covered by adsorbed layer of both anions and cations, whose anion:cation ratio depends only on the voltage. Capacitance (charge storage) occurs by change of the anion:cation ratio with voltage. The electrolyte behind the adsorbed first ion layer serves merely to transport charge in or out of the layer. This mechanism, however, requires both anion and cation motion in the charging process, and, in AgBr, anions are appreciably mobile only above or near the melting point. As AgBr cools in the solid state, the anions become successively more immobile. We propose that this, rather than interfacial strain, is the source of the increasing dispersion and drop in effective capacitance magnitude.

Thus, at room temperature, the graphite charging process is rapid because only the mobile Ag^+ cations are involved, while platinum charging is presumably rate-limited by anion motion. The distinction in charging behavior appears to arise from the situation that halide anions are adsorbed on both types of electrodes, but Ag^+ ions are adsorbed only on Pt. Thus, adsorbed anions form an immobile layer on graphite, but participate in the charging process on Pt. The adsorption of Ag^+ ions on Pt and not on graphite was proposed previously (2) in connection with "preplating" or "undervoltage" behavior observed for Ag^+ discharge on Pt and the dendritic nature of Ag^+ discharge on graphite from AgBr electrolyte.

The previously noted features of Fig. 7 and 8 all appear explainable in terms of the above AgX|Pt interface model. From Fig. 9, we see that only a small portion of the total charging (upper curve) has occurred on the time scale of Fig. 7 and 8. Thus, these

latter figures should basically show those charging kinetics characteristic of the interface composition at the initial side of the voltage step. Since Ag^+ ion motion is faster than anion motion, we assume initial kinetics will be fastest for the interface with the highest cation: anion ratio. Thus, for a given voltage step (*e.g.*, 0.30-0.35V), the upward step should give the higher charging curve. The degree of difference, however, should increase with increasing cation:anion compositional difference at the two sides of the step. We have previously (3) suggested that the interface layer contains mostly cations at low bias, anions at high bias, and a roughly equal mixture of them at the capacitance maximum. Thus, the greatest compositional change and, as Fig. 8 shows, the greatest step direction asymmetry, should occur in this mid-bias range. Also, in Fig. 7 and 8, it seems reasonable to expect that charging should involve primarily cation motion at early times and increasing degrees of anion motion at larger t values. Thus, the clustering of the curves at $t \leq 1$ sec may represent a fairly voltage-independent "cation surge," while greater anion involvement at longer times is required to show the voltage dependence (Fig. 9) more characteristic of the total charging process. Finally, the transition in Fig. 7 from convex-upward to concave-upward curvature with increasing voltage suggests a general reduction of initial charging kinetics with increasing interfacial anion concentration, since the convex-upward curvature suggests more early charging than the concave-upward curvature.

We have suggested, then, that AgX charging with graphite involves fast cation motion in a compact, purely electrostatic charge layer (with immobile adsorbed anions as the "dielectric") and charging on platinum involves the compositional change of a strongly adsorbed anion-cation layer. It seems useful at this point to try to explicate the relative roles of compact, diffuse, and adsorbed layer charging in solid-electrolyte systems. Figure 11 shows a suggested model, offered in a qualitative sense only. Diffuse and compact layer capacitances are in series, as is conventional. $C_{ADSORPTIVE}$ refers to capacitative charge storage realized by the change in composition of an adsorbed charged interface layer with voltage. Since this type of charge storage represents a thermodynamic distribution of ions between sites on the electrode surface and the bulk electrolyte, dependent for a given electrolyte and temperature on the voltage only, it should be independent of other sources of charge storage and hence be considered in parallel with them. However, $C_{COMPACT}$ and $C_{ADSORPTIVE}$ compete for interfacial area, so $C_{COMPACT}$ should be quite small in the case of large adsorptive capacitance.

For the graphite cells, a strongly adsorbed anion layer and nonadsorbed cations would result in $C_{ADSORBED} = 0$, so this capacitance could be removed. Diffuse layer capacitance in solid electrolytes was discussed in a previous publication (4). For the case of AgBr at 300°C, the entire accessible voltage range is thought to be far from the pzc and an accumulation-layer-type capacitance of several tens of microfarads/

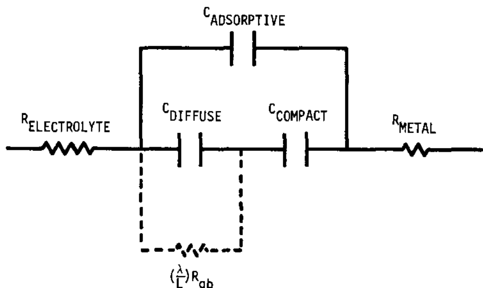

Fig. 11. Qualitative equivalent electrical circuit of solid electrolyte-inert metal interface.

square centimeter is predicted. One expects similar considerations to apply for AgBr and AgI at room temperature. Since our observed compact layer capacitances are at least several times smaller, and should be roughly halved by the roughness factor correction, they should dominate the series capacitance.

In the case of platinum, $C_{COMPACT}$ should be small, as mentioned above, because of the large adsorptive capacitance. In this case, the lower branch capacitance in Fig. 11 would be dominated by $C_{COMPACT}$ and the total capacitance by $C_{ADSORBED}$. Also, to be correct electrically, $C_{ADSORBED}$ for Pt electrodes should really be replaced by a more complex resistive-capacitive circuit element to account for the slow, dispersed charging behavior. Figure 11, however, is offered merely to show the relationship between the various capacitances.

In all polycrystalline solid electrolytes, still another circuit element should be considered; one which is unique to solid electrolytes. Grain-boundary conduction, as we have said, dominates the room-temperature ionic conductivity in AgI and AgBr. Even in more highly conductive electrolytes, however, it is assuredly present (11). The effective result in any case is that planar sheets of very high local specific conductivity extend across the electrolyte bulk and intersect the electrode interface. Since such planar sheets are too conductive to support a diffuse double layer, they should effectively "short-circuit" any diffuse layer developed in the bulk. Thus we have indicated in Fig. 11 that a portion of grain-boundary resistance R_{gb} is in parallel with $C_{DIFFUSE}$. Here, L is the electrolyte thickness and λ the effective path length across the diffuse layer.

We expect, then, that diffuse layer capacitance should not be observable in polycrystalline solid electrolytes. Even in single-crystal electrolytes, however, precautions would seem necessary. Several workers (12-14) have indicated a space-charge-layer thickness of several tenths of a micron for AgBr at room temperature. If electrode attachment develops thermal or mechanical surface damage (*e.g.*, in evaporating a metal film), such damage may breach the diffuse layer, such as by a network of cracks. On the other hand, we have seen that a sprayed graphite electrode gives anomalously small capacitance, presumably because of solvent and binder residues. It would seem that the best chance of observing diffuse layer capacitance in single-crystal solid electrolytes would be with the use of either inert liquid metal electrodes or adjacent electrolytic solutions.

Finally, in comparing our results with a recent study, we note that Armstrong and Mason (15) have measured the voltage dependence of a-c capacitance at 1-3 kHz for vitreous carbon and platinum electrodes on AgI, AgBr, and $RbAg_4I_5$ at various temperatures. Low (1.8-3.5 μf/cm^2), relatively voltage-independent capacitances were reported with vitreous carbon, which were interpreted in terms of compact layer capacitance, as we have done for graphite electrodes in the present work. In the case of Pt electrodes, compact or "inner layer" capacitance was also suggested, with possible effects due to specific ion adsorption. In view of our own results on Pt, we feel their results would be better explained by our proposed anion-cation adsorption model. This would account better, for instance, for their large (45-130 μf/cm^2) observed capacitances for α-AgI|Pt at 200°.

Acknowledgments

The author is grateful to Mr. W. Michael Moore for carrying out much of the experimental work, to Dr. Boone B. Owens for providing a sample of the tetramethylammonium iodide-silver iodide (TMAI) electrolyte, and to Dr. Harris Marcus and Mr. James Harris for the argon-sputtering operation on two of the platinum wire electrodes.

Manuscript submitted July 2, 1973; revised manuscript received Oct. 25, 1973.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1974 JOURNAL. All discussions for the December 1974 Discussion Section should be submitted by Aug. 1, 1974.

Electrode Capacitance in Silver-Halide Solid Electrolyte Cells

II. Temperature-Dependent Behavior of the AgBr-Graphite Powder Interface

Douglas O. Raleigh*

Science Center, Rockwell International, Thousand Oaks, California 91360

ABSTRACT

The nature and capacitance of AgBr-graphite pressed powder interfaces prepared at room temperature and heated to various temperatures were examined at 25°-375°C, using potentiostatic capacitance measurements and electron micrography. At temperatures to 250°C, electrolyte grain growth produces irreversible capacitance increases by progressive interfacial roughening. However, the primary interface charging process remains ideally fast (undispersed) and heating to a given temperature rapidly creates a stable, reproducible degree of roughening. At ~275°C, an irreversible solid-state "wetting" process occurs, in which the electrolyte "soaks" some 170μ into the graphite in 1-2 min. The capacitance increases 50-fold and becomes dispersed, with the charging process quantitatively following porous electrode behavior. The unique "wetting" process appears to involve a shallow network of graphite microcracks and requires a mechanism of rapid AgBr anion diffusion on graphite surfaces. Throughout the full 25°-375°C temperature range, the microscopic interface charging process appears to remain the same (Ag^+ compact layer capacitance).

In order to relate the capacitance results of Hull and Pilla (1), and of our own in the preceding paper (2) on AgX-graphite powder interfaces at room temperature to our previous study (3) of the AgBr-pyrolytic graphite interface at 244°-292°C, it was of interest to investigate graphite powder electrodes at above-ambient temperatures as well. The electrolyte chosen was AgBr, since it is stable and monophasic from room temperature to its melting point (425°C), and conducts by a single (Frenkel defect) ionic mechanism.

Experimental

Ag|AgBr|C pressed-powder cells with Ag wire reference electrodes were prepared as described in the preceding paper (2). In two cells, the graphite powder employed was first outgassed overnight at 250°C. Cells were springloaded in a Pyrex resistance furnace assembly described previously (3, 4). Various temperatures to 375°C were applied and maintained with a proportioning controller and read with a Chromel-Alumel thermocouple whose output was continuously recorded. A polarizing d-c bias, generally 0.25V, and a flowing argon atmosphere were maintained throughout a run.

The measurements carried out were potential-step chronocoulometry and chronoamperometry, using 0.05V steps in the range 0.05-0.40V anodic to Ag, as described in the preceding paper (2). Measurements were generally started at room temperature and the apparatus heated to successively higher temperatures. At each temperature, the cell current under d-c bias was allowed to settle to a steady-state value before starting measurements. These currents increased with increasing temperature, from < 1 nA at room temperature to ~ 1 μA at most, and generally did not interfere with potential-step measurements.

In addition, electron micrographs of the AgBr|C interface, before and after cell heats, were taken as described in Ref. (2).

Results

Temperatures to 250°C.—The first result of heating the AgBr|C interface from room temperature was to raise and make less distinct the previously noted chronocoulometric plateau. Figure 1 shows oscillographic charge-time data for a given cell at 25° and 75°C, plus the indicated charging course at higher temperatures. At above-ambient temperatures, the plateau feature disappears. At temperatures to 250°C, however, Q *vs.* $t^{1/2}$ plots showed fair to excellent linearity for times in excess of several RC. An example, employing both oscillographic and recorder data, is shown in Fig. 2.

In addition, potential-step oscillographic current-time curves, involving the relatively short time scale

* Electrochemical Society Active Member.
Key words: solid electrolytes, solid-state wetting, AgBr-graphite interface, electrode capacitance, solid-solid interface roughening.

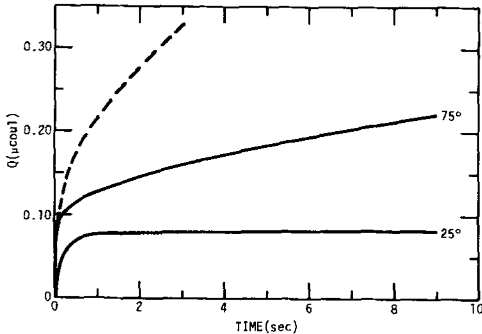

Fig. 1. Oscillographic charge-time traces for 0.25 → 0.20V step on Ag | AgBr | C (pressed powder) cell at 25° and 75°C. Dotted line indicates charging course at higher temperatures.

of RC charging, gave linear log i *vs.* t plots whose slope agreed well with $t = 0$ capacitances obtained from back-extrapolating the Q *vs.* $t^{1/2}$ plots. Even when the latter displayed some curvature, back-extrapolation at the prevailing curvature gave good agreement. From these results, we conclude that the AgBr|C (powder) capacitative behavior in this temperature range can still be described in terms of an ideally fast charging component plus a slower, diffusion-like contribution.

The behavior of the fast and slow charging components differed in several respects. At a given temperature, the magnitude of the slow component (as measured by the $dQ/dt^{1/2}$ slope) often dropped considerably on standing overnight, while that of the fast component remained constant. Slow-component values scattered several-fold from cell to cell, and were lower with outgassed graphite electrodes, where fast-component values agreed to an average deviation of ~10%. The slow-component value dropped several-fold over the bias voltage range 0.05-0.40V, while the fast component was roughly constant, increasing by 10-15% at most. On cycling back to a given temperature from a higher one, the slow-component contribution was considerably reduced.

Because of these findings, one again feels that the slow component represents a diffusion-controlled faradaic impurity reaction, with the impurity capable of at least partial depletion by continued electrolysis at a given temperature and bias voltage. Average values of the $dQ/dt^{1/2}$ capacitance slope from seven different cells are plotted logarithmically *vs.* $1/T$ in Fig. 3. The surprising linearity indicates that a single diffusing impurity species may predominate.

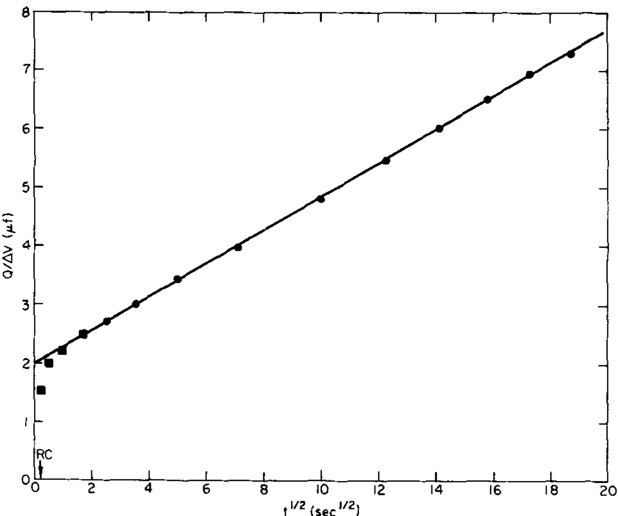

Fig. 2. Q vs $t^{1/2}$ plot for 0.25 → 0.20V step on Ag | AgBr | C (pressed powder) cell at 75°C. Squares are from oscillographic data; dots from recorder data.

Figure 4 shows a data-averaged plot of the "fast" capacitance as a function of temperature from seven different cell runs. In each run, the data employed were confined to measurements at successively increasing temperatures. As noted, the fast capacitance at a given temperature remained unchanged on overnight standing. However, on cooling to a lower temperature, the initial higher temperature capacitance was maintained. This is shown in Fig. 5 for Q *vs.* $t^{1/2}$ plots for a given cell at 250°C and on cooling the cell to 150°C. One sees the already noted reduction of the slow

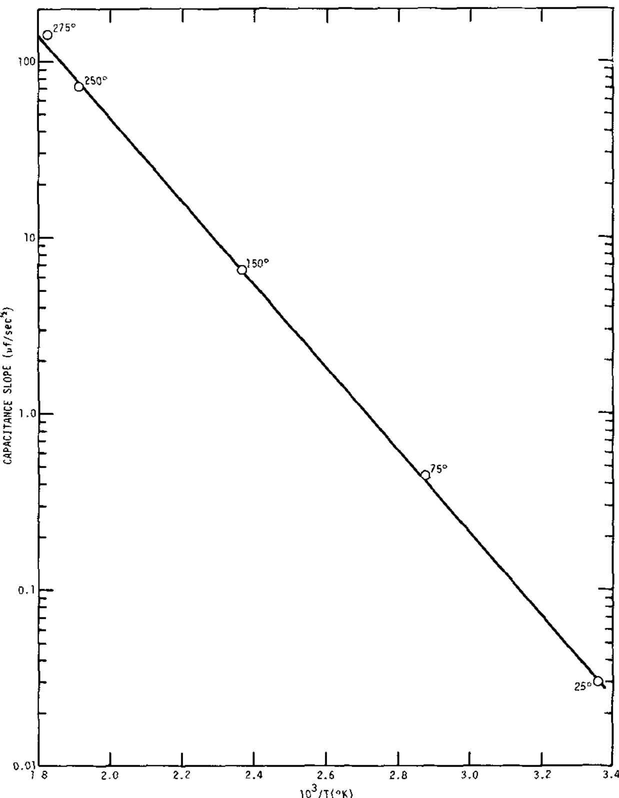

Fig. 3. Average diffusive capacitance slope $(1/\Delta V)$ $(dQ/dt^{1/2})$ vs. temperature.

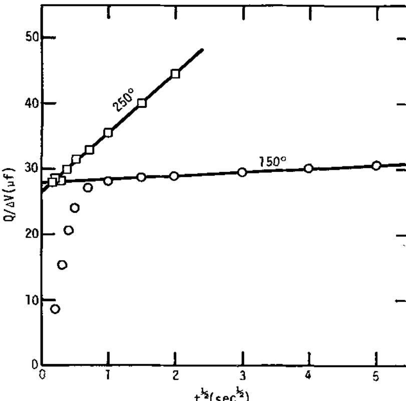

Fig. 5. Q vs. t½ plots for 0.25 → 0.20V step on Ag | AgBr | C (pressed powder) cell at 250°C and on cooling back to 150°C.

charging component, along with retention of the fast capacitance. The latter indicates that heating produces a permanent progressive change in the microphysical nature of the interface.

Temperatures above 250°C.—On heating to 275°C after overnight standing at 250°C, a fairly abrupt and considerable change in the qualitative nature of interface charging occurred. The effective chronocoulometric capacitance increased many-fold on all time scales. Plots of log i *vs.* t from oscillographic chronoamperometry became severely curved, indicating disappearance of the well-defined fast charging component.

Figure 6 shows a Q *vs.* $t^{1/2}$ plot at 275°C from oscillographic and recorder-scale chronocoulometry, using two time scales. On the longer time scale, a linear diffusion slope is still obtained, but only at times way in excess (500-fold in Fig. 6) of the RC charging time. The slope magnitude is in the line of the previous points on Fig. 3, indicating that the nature of the slow charging component is unchanged. The expanded-time plot of the initial-rise portion shows a linear slope that back-extrapolates approximately through the origin (actually, slightly below the origin because of finite RC rise time). The same type Q *vs.* $t^{1/2}$ plots were obtained at higher temperatures to 375°C and on subsequent cooling to as low as 175°. Moreover, the $t = 0$ capacitances obtained by back-extrapolating the linear diffusion slope were reproduced on temperature cycling. Thus, in contrast to results at 250°C and below, the new interface was stable to temperature cycling.

Figure 7 shows the back-extrapolated $t = 0$ chronocoulometric capacitance (*i.e.*, the capacitance corrected for the slow, diffusionlike component) over the full temperature range. The graph shows data from a single run at 275°C and above. A duplicate run with a new cell gave good agreement. We see that this presumed total interface capacitance increases 50-fold for 250° → 275°C and varies fairly gently with temperature thereafter. Thus, from Fig. 6 and 7 and the chronoamperometric results, the interface capacitance has both increased sharply and acquired considerable dispersion. Tests at 325°C showed the interface capacitance to be unchanged on overnight standing, or cooling to room temperature and reheating to temperature, and to be invariant (to within several per cent) to voltage step direction and bias voltage in the 0.05-0.40V range.

In view of the apparent abruptness of the capacitance increase, it was of interest to see how rapidly it occurred during the 250° → 275°C heatup and at what approximate temperature. For this purpose, a 7 Hz, 0.05V voltage square wave from the potentiostat was applied to a cell at 250°C, the Q waveform monitored visually on the oscilloscope screen, and the furnace control temperature changed to 275°C. At 270°-275°C, the expected large increase in the waveform amplitude occurred over a 1-2 min period. Thus, the increase is rapid, though not instantaneous.

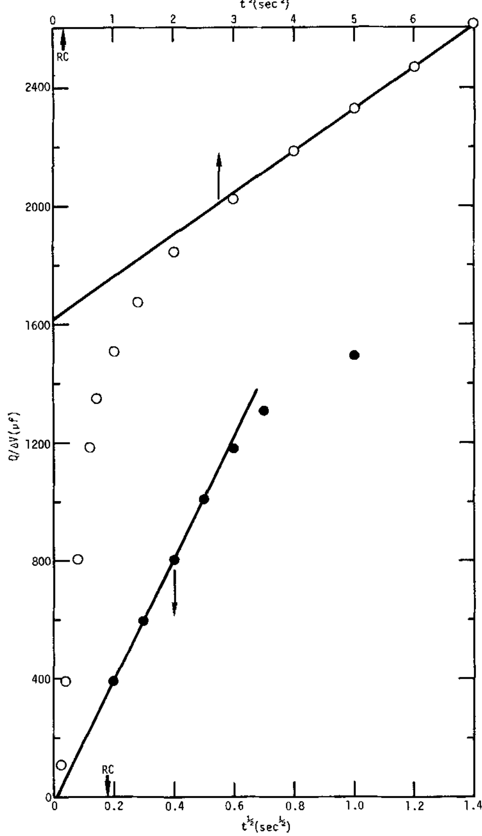

Fig. 6. Q vs. t½ plot for 0.25 → 0.20V step on Ag | AgBr | C (pressed powder) cell at 275°C (upper curve) and initial linear rise portion on 5-fold expanded abscissa (lower curve).

Micrographic data.—Following the capacitance studies, scanning electron micrographs of the AgBr|C in-

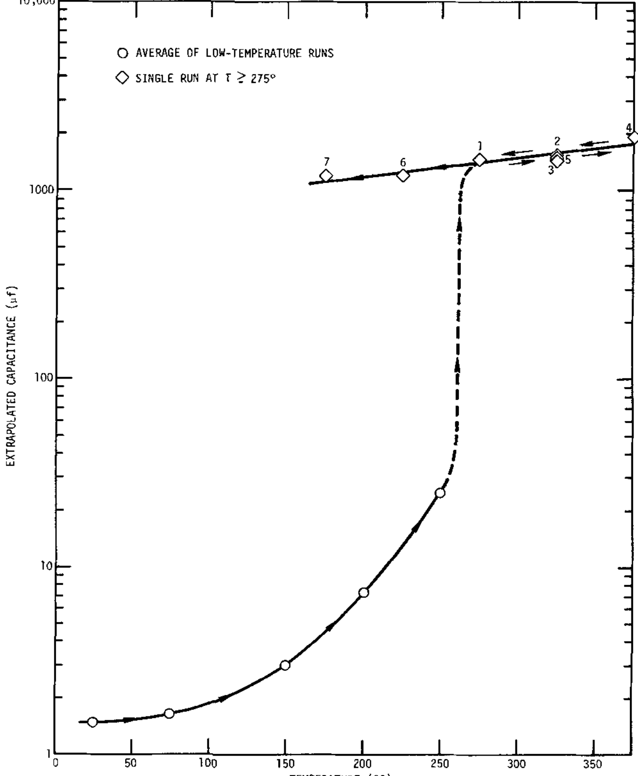

Fig. 7. Diffusion-corrected chronocoulometric capacitance of AgBr | C (pressed powder) interface as function of temperature before and after ~275°C transition. Point numbers show temperature sequence; 2, 3 represent 1½ day anneal at 325°C.

terface were taken for (a) cells that had been heated to 250°C, and (b) cells heated in the 275°-375°C range.

Figure 8 shows an interface (a). We see that a well-defined phase separation is still maintained, but considerable interfacial roughening has taken place, compared with Fig. 10 of Ref. (2). Also, the AgBr appearance has changed considerably, showing a good deal of grain growth, intergranular voiding, and the appearance of plastic deformation in individual grains. In line with this altered appearance, visual examination of the cells thus heated showed considerable "bulging" (swelling) of the electrolyte layer and change of this layer from a glassy translucence to an opaque, porous appearance.

Figures 9 and 10 show the interphase appearance near the AgBr and graphite, respectively, for a cell exposed to temperatures in the 275°-375°C range. Focusing problems prevented a clear photograph of the full interphase region, but a well-defined layer, some 170μ thick, was observed. To this degree, AgBr is seen to have penetrated or "soaked" into the graphite. Figure 11 shows a highly magnified portion of the interphase layer.

Discussion

We noted earlier that the characteristics of the slow, diffusionlike contribution to the charging process suggest it is due to a single faradaic impurity species. The size of this component and the effect of outgassing the graphite again suggests that an impurity in the graphite, rather than the electrolyte, is involved. Further, the effect of outgassing suggests a gaseous or volatile impurity. However, since its characteristics (several-fold scatter from cell to cell, effects of bias-annealing and graphite outgassing) seem to be those of an impurity rather than an intrinsic interface component, it seems justified to drop further consideration of this contribution. We will instead consider the capacitance remaining when it is corrected for, which is presumably the intrinsic capacitance of the AgBr|C (powder) interface. Further, the approximate voltage independence of the latter capacitance throughout the entire temperature range suggests that the double layer charging process is the same as suggested in the preceding paper (Ag^+ ion compact layer capacitance) and that such changes in characteristics as have been observed are due to changes in the physical nature of the interface.

Ionic conductivity studies by Shapiro and Kolthoff (5) show that pressed powder AgBr bodies exhibit

Fig. 8. Scanning electron micrograph of AgBr | C (pressed powder) interface after heating to 250°C.

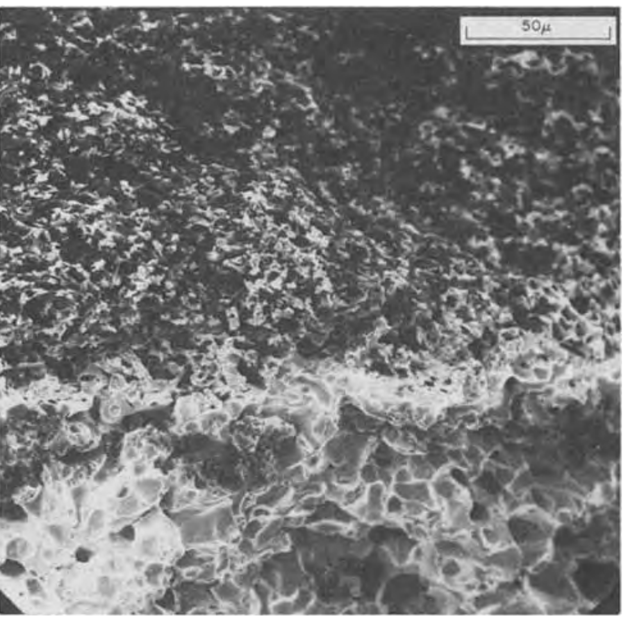

Fig. 9. Scanning electron micrograph of AgBr | C (pressed powder) interface after heating above ~275°C transition temperature.

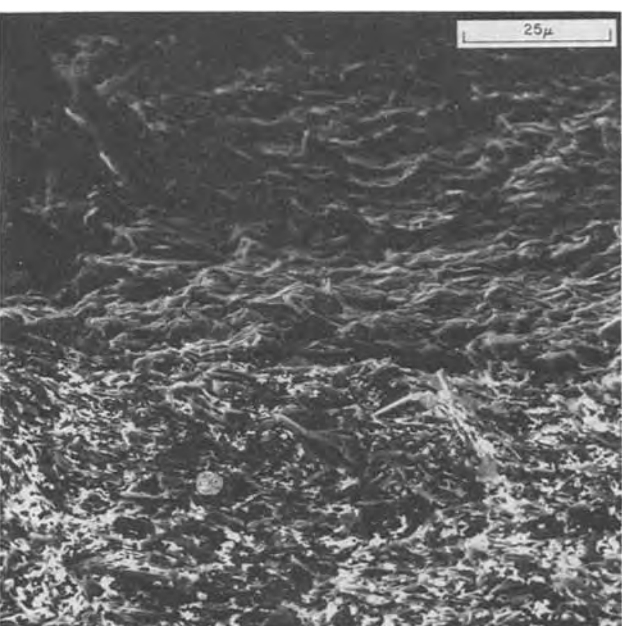

Fig. 10. Scanning electron micrograph of terminus of AgBr penetration zone in graphite after heating above 275°C transition temperature.

considerable grain growth on heating to various temperatures. Our visual and micrographic evidence shows the process to be characterized by swelling and porosity development. Thus, growth of large grains at the expense of small ones appears to enlarge grain dimensions without filling the space left by the digested grains. One expects this process to apply stress to and roughen the AgBr|C interface, both by topography change [see, for instance, Fig. 10 of Ref. (2)] and by lateral AgBr grain motion involved in the electrolyte swelling. The reduced AgBr grain size seen near the interface (Fig. 8) appears to show grain shattering associated with these stresses.

At temperatures to 250°C, the net electrical result seems merely to roughen the double layer interface without changing its fast charging characteristic. This would be expected if "necks" of electrolyte in the roughened interface are not appreciably resistive compared with the bulk electrolyte. From retention of the

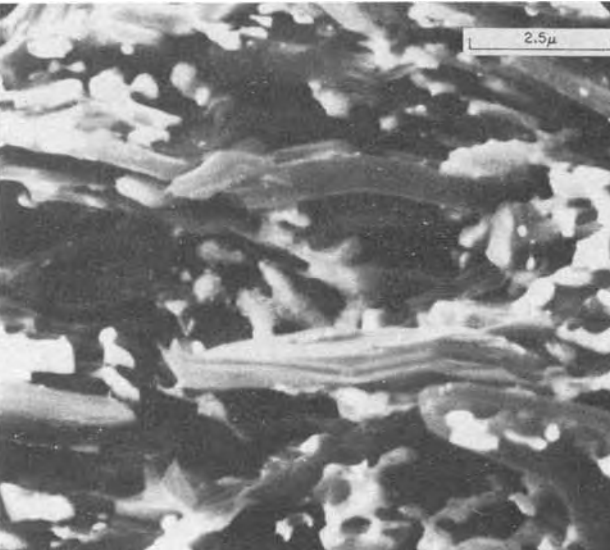

Fig. 11. Scanning electron micrograph of AgBr penetration zone in graphite in Fig. 10. Magnification 3500X.

increased capacitance on cooling (Fig. 5), the increase with temperature appears to result solely from the area increase due to roughening. From Fig. 3, heating 25° → 250°C is seen to produce a 16.7-fold increase in roughness factor.

It is of interest that stable increased capacitances are obtained shortly after heating to each new temperature. It would appear that each such heating rapidly produces a given degree of grain growth, interfacial stressing, and stress relaxation through roughening. While one would not *a priori* expect this result, our experimental findings are that overnight standing at, *e.g.*, 150° and 250°C, did not increase capacitance.

The micrographic and capacitance changes on heating to 275°C seem difficult to describe as other than a solid-state "wetting" process, despite the distance from the electrolyte melting point (425°). On heating, AgBr displays a continuously increasing plasticity. Comparison of Fig. 8 and 9, for instance, shows a rounding of void spaces and merging of crystallites in AgBr heated to the higher temperature. The increased capacitance and its dispersion are both strongly suggestive of a transition from compact to porous electrode behavior.

It is of interest to compare the chronocoulometric behavior after the ~275°C transition with a model of porous electrode charging. DeLevie (6) gives, for the capacitative charging current at the mouth of a semi-infinite cylindrical electrolyte-filled electrode pore, following a potential step ΔV

$$i(0,t) = \frac{\Delta V}{R}\sqrt{\frac{RC}{\pi t}} \quad [1]$$

where R and C are the electrolytic resistance and electrode capacitance per unit pore length. For a pore radius r, we may use $R = \rho/\pi r^2$ and $C = 2\pi r C_o$ to obtain

$$i(0,t) = \Delta V\sqrt{\frac{2\pi r^3 C_o}{\rho t}} \quad [2]$$

where ρ is the specific electrolyte resistivity and C_o the double layer capacitance per unit microscopic area. For an arbitrary pore radius distribution, $N = \Sigma n_i(r_i)$, the current per unit electrode area, ignoring its outer surface for the moment, is

$$i(0,t) = \Delta V\,\Sigma\, n_i\sqrt{\frac{2\pi r_i^3 C_o}{\rho t}} = \Delta V\sqrt{\frac{2\pi C_o}{\rho t}}\,\Sigma\, n_i\sqrt{r_i^3} \quad [3]$$

$$\equiv G\Delta V\sqrt{\frac{2\pi C_o}{\rho t}}$$

where $G \equiv \Sigma\, n_i\sqrt{r_i^3}$ may be considered a "porosity structure factor" characterizing a given electrode. Integrating to obtain the chronocoulometric charge

$$Q(0,t) = \int_o^t i(0,t)dt = Q_o + 2G\Delta V\sqrt{\frac{2\pi C_o}{\rho}}\,t^{1/2} \quad [4]$$

where the expression refers to a semi-infinite electrode, and where Q_o, the charge at the lower limit of integration, is introduced to account for any fast charging associated with the outer electrode surface. Then, for a porous electrode of finite thickness, Eq. [4] predicts a region of linear Q *vs.* $t^{1/2}$ behavior as $t \to 0$, as we have observed. We also note that, as previously discussed, both chronocoulometric and chronoamperometric oscillographic results indicate Q_o is negligible.

Equation [4] predicts that, for a given porous electrode body and C_o temperature-independent, the linear Q *vs.* $t^{1/2}$ slope for $t \to 0$ should vary as $\rho^{-1/2}$, the inverse square root of the electrolyte resistivity. In Fig. 12, these slopes are plotted from chronocoulometric data for a given "post-transition" cell in the temperature range 175°-375°C. On the same graph, a "theoretical" temperature dependence line was constructed by multiplying the experimental $dQ/dt^{1/2}$ slope at 275°C by $(\rho_{275°}/\rho_T)^{1/2}$ to predict the values at the other temperatures. A fair correspondence is seen, with the mid-point slopes of the two curves differing by 22%. We see, then, that the chronocoulometric results following the ~275°C transition can be reasonably well described in terms of porous electrode behavior.

It is of interest now to consider the nature of the porosity. Both the micrographic results (*e.g.*, Fig. 10) and the existence of stable, well-defined total capacitances, invariant to annealing and temperature-cycling, indicate the porosity is limited to a fixed interfacial zone. Thus, it seems unlikely to reflect the inherent porosity of the pressed graphite. We suggest instead that it represents a shallow network of fracture damage to the graphite surface, created by the previously described process of grain-growth-induced interfacial roughening on heating 25° → 275°C.

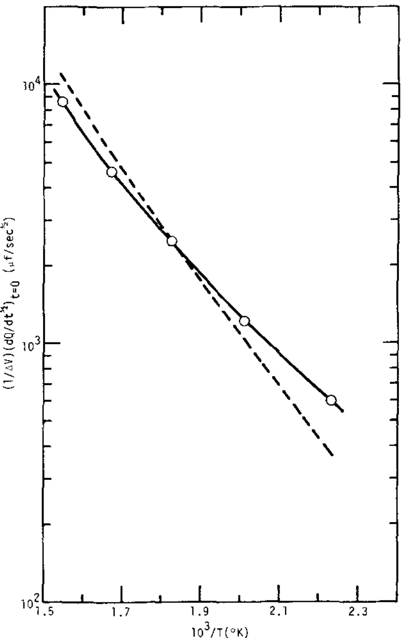

Fig. 12. Slope of initial linear rise of Q *vs.* $t^{1/2}$ plots (*e.g.*, Fig. 6) *vs.* temperature for cell after ~275°C transition (smooth line), and slope curve predicted by Eq. [4] (dashed line).

At ~275°C, an obviously rapid electrolyte "soak-in" occurs, some 150° below the AgBr melting point. While we may invoke high plasticity in the AgBr and capillary action in the fracture network, the abruptness of the "soak-in" requires consideration. As noted before, AgBr has no phase transition between 25°C and its melting point. Silver bromide and graphite are chemically inert to one another. Bulk phase properties, then, do not seem involved.

For capillary penetration of a porous solid by a liquid, it is required (7) simply that $W_a > \gamma_L$, where W_a is the work of adhesion and γ_L the liquid surface tension. Using

$$W_a = \gamma_L + \gamma_S - \gamma_{LS} \quad [5]$$

where γ_S refers to the surface tension of the solid and γ_{LS} to the interfacial tension, the criterion reduces to $\gamma_S > \gamma_{LS}$. Thus, if the surface tension of the solid is reduced by wetting, capillary penetration can occur. We expect, then, that γ_S and γ_{LS} for graphite and AgBr|C are different functions of temperature. Thus, it may simply be that ~275°C marks a cross-over from $\gamma_S < \gamma_{LS}$ to $\gamma_S > \gamma_{LS}$.

Since these relationships are thermodynamic ones, it makes no difference in principle whether they refer to wetting by a liquid or a mobile solid. The rapid penetration, however, seems quite unique. From the fact of penetration to 170μ in ~100 sec, we may use $x = 2\sqrt{Dt}$ to estimate (8) quite roughly an effective diffusion coefficient of $(1.7 \times 10^{-2})^2/4 \times 10^2 \approx 7 \times 10^{-7}$ cm²/sec, a high value for diffusion in solids. It would seem that a mechanism of rapid anion diffusion in the graphite microcracks, followed by the smaller cations, is required. Strong anion adsorption on the graphite surface, proposed in the previous paper (2), may provide a chemical driving force for the process, with cations drawn along coulombically. At any rate, a most unusual solid-state phenomenon seems involved.

The 50-fold increase in total capacitance at ~275°C, together with the previously noted 17-fold increase in roughness factor on heating 25° → 250°C, might be thought to indicate an over-all 850-fold increase in the effective interfacial area from the presumed near-planar room-temperature configuration. However, the temperature dependence of the "post-transition" capacitance (26% per 100°) puts this calculation in question. It may be that the AgBr "soaks" into a wide variety of crack widths and that capacitance associated with the narrowest electrolyte paths becomes increasingly more accessible with increasing temperature, since ionic conductivity in AgBr increases rapidly with temperature (900-fold for 175° → 375°C). If this is the case, the precise effective porosity factor is a function of temperature, and varies from 760 to 1220 in the 175°-375°C range.

Finally, the over-all results invite comparison with our earlier AgBr-graphite study at 244° and 292°C. In the latter work, the interface was formed by spring-loading a cylindrical AgBr single-crystal disk between silver and pyrolytic graphite foils and briefly heating the assembly above the AgBr melting point *in vacuo* to flash-melt the electrolyte to the electrodes. The cell was then cooled to the 292° and 244°C measuring temperatures. Oscillographic current-time and recorder scale charge-time data were taken, much as in the present work, except that Q *vs.* $t^{1/2}$ plots were not made. Log i *vs.* t plots were nonlinear. The chronocoulometric data showed a slow charging process with apparent closure at long times (in excess of several minutes), so "total" capacitance values were reported. These ranged from 25 to 45 μf/cm² and were interpreted as a diffuse double layer capacitance.

Clearly, the large capacitances reported in the present work were not seen, despite the fact that the interface formation temperature and one of the measuring temperatures were well above the 275°C "transition" temperature. This is consistent with our suggestion that the large capacitance results from the wetting of graphite porosity induced by surface damage from electrolyte grain growth. With single-crystal AgBr and pyrolytic graphite foil, the porosity may well be limited to that inherent in the graphite.

To examine this earlier charging process further, Q *vs.* $t^{1/2}$ plots were made from the chronocoulometric recorder data for 0.02-0.30V, 244° and 292°C, $1 \leq t^{1/2} \leq 7$ sec$^{1/2}$. The plots were linear for $t \gtrsim 4$ sec and back-extrapolated to an average $t = 0$ capacitance of 15 μf/cm². The oscillographic log i *vs.* t data could be fitted to current decay by a mixture of two RC time constants (9). The capacitance associated with the faster time constant averaged 5.3 μf/cm² and the total capacitance for the two components averaged 9.9 μf/cm².

The fastest capacitance, then, agrees roughly with that measured for the AgBr|C interface at room temperature in the previous paper. The occurrence of an appreciably larger sum capacitance and back-extrapolated Q *vs.* $t^{1/2}$ capacitance indicates a significant dispersed capacitance in the subsecond time range. This dispersed component may well reflect a small amount of natural porosity in the pyrolytic graphite foil, such as from microcracks, dislocations, and lamellar separations. In any event, the capacitance in this earlier study seems better described as some combination of fast and dispersed Ag^+ compact layer capacitance (with a possible diffusive impurity component), than as a diffuse layer capacitance, as previously (3) proposed.

Conclusions

We have seen, then, that heating a pressed-powder ceramic interface (AgBr-graphite) from room temperature first produces interfacial roughening via grain growth and, later, a rapid solid-state capillary penetration of the one phase into the other. Capacitance measurements made it possible to study both of these processes in detail. In the first, the charging process remained rapid despite a 17-fold increase in roughness factor. In terms of previous discussions of roughness and capacitance dispersion in electrochemical systems (10), it is seen that the former alone does not necessarily produce the latter; rather that capillary penetration, such as into microcracks, seems required.

The solid-state capillary penetration process would appear to be unique, but not *a priori* unlikely, given the appropriate surface energy situation and a mechanism for rapid capillary diffusion. It would seem that both the roughening and penetration processes would be of interest in the area of ceramic adhesion and bonding. Given a solid-solid interface between an ionic and an electronic conductor, capacitance measurements might well make possible a detailed study of its nature.

Acknowledgments

The author is grateful to Mr. W. Michael Moore for carrying out much of the experimental work. Special thanks are due to Mr. Leroy Hackett for the scanning electron micrographs in both these papers and for helpful discussions on their interpretation. Discussions on adhesion with Mr. D. H. Kaelble are gratefully acknowledged.

Note Added in Proof: The author is grateful to Dr. Kenneth Hay of Central Electricity Research Laboratories, U.K., for suggesting that at least part of the AgBr swelling, porosity development, and roughening of the interface with graphite which occurred on heating our pressed-powder cells to 250° may have resulted from the gradual expansion and outgassing of air entrapped in the electrolyte during the pressing process. This may explain better why heating to successively increasing temperatures in the 25°-250° range produced a stable increased degree of roughening rather quickly at each new temperature.

Ring-Disk Electrode Study of Palladium Dissolution

Steven H. Cadle[1]

Chemistry Department, Vassar College, Poughkeepsie, New York 12601

ABSTRACT

The corrosion rate of palladium is measured as a function of potential in 0.2*M* H_2SO_4. A typical corrosion rate is 0.35 $\mu A/cm^2$ at +1.1V *vs.* SCE for an electrode with a roughness factor of 1.6. Passivation of the palladium dissolution occurs and is monitored by collection of Pd(II) at the ring electrode. Soluble palladium is produced simultaneously with the reduction of an oxidized electrode. This soluble palladium is separated into two categories. One category is associated with the reduction of surface palladium oxide while the other is associated with the reduction of phase oxide. Dissolution processes cause significant roughening of the electrode surface at $E \geq +1.4V$.

Recent investigations (1, 2) of the anodic behavior of palladium in acid solution have shown that palladium dissolution occurs. Rand and Woods (1) used atomic absorption spectroscopy to determine the quantity of palladium dissolved during a potential cycle of the electrode in 1*M* H_2SO_4. Llopis *et al.* (2) determined the corrosion rate of palladium in 1*M* $HClO_4$ as a function of potential using a radiochemical technique. Neither of these experimental techniques can determine the instantaneous dissolution rate since the concentration of palladium in solution must be increased over a period of time. Thus, it has not been possible to determine if palladium dissolution occurs during both the anodic and cathodic potential cycle of the electrode. Also the rate of passivation of the dissolution process could not be measured. These problems have been overcome by the use of the rotating ring-disk electrode.

Experimental

Equipment and solutions.—The circuit for the ring-disk potentiostat, the cell, and the rotator are described elsewhere (3). A Beckman Electroscan 30 recorder was used.

A rotating palladium ring-palladium disk electrode (RPdRDE) was used. The collection efficiency, *N*, was 0.319. The projected area of the electrode was 0.452 cm^2. The roughness factor of the electrode was estimated by assuming that one monolayer of oxygen is adsorbed on the electrode at +1.0V (4, 5) and corresponds to 424 μcoulombs/cm^2 (6). The electrode was oxidized at +1.0V for 15 min before its potential was scanned to more negative potentials. The quantity of adsorbed oxygen was determined by integration of the palladium oxide reduction peak. On this basis the roughness factor of the electrode was 1.6.

A rotating gold ring-palladium disk electrode (RGPdRDE) was prepared by electroplating gold on the ring of the RPdRDE from a sulfuric acid solution of auric sulfate.

All solutions were prepared using triply distilled water. The 0.2*M* sulfuric acid supporting electrolyte was prepared from Fisher reagent grade sulfuric acid. Solutions were deoxygenated with nitrogen.

All potentials are reported *vs.* the saturated calomel electrode. Values of the apparent charge density (μcoulombs/cm^2) are reported using the projected area of the electrode, uncorrected for roughness factor.

Electrode pretreatment.—In order to obtain reproducible current-potential curves the RPdRDE was pretreated in the following manner. The electrode was polished occasionally with Buehler 0.05μ gamma micropolish. The electrode was introduced into solution and both the ring and disk were oxidized for 10 min at +1.4V and then reduced at 0.0V for 5 min. The electrode potential was then cycled repeatedly between 0 and +1.4V until a reproducible current-potential curve was obtained. Approximately ten potential cycles were required.

A similar pretreatment was required for the RGPdRDE. This electrode, however, was not polished between experiments. To remove the palladium which was collected at the gold ring during an experiment, the ring electrode potential was cycled repeatedly between −0.3 and +1.6V.

Corrosion rate determination.—The corrosion rate was determined by collecting soluble palladium on the gold ring of a RGPdRDE. Initially, the palladium disk was reduced at 0.0V for 1 min. Then it was stepped to the potential at which the corrosion rate was to be measured and was held at this potential 15 min to allow complete oxidation of the electrode to occur. After this time the ring electrode potential was stepped from +1.2V, a potential at which no collection of palladium occurs, to 0.0V. Palladium was collected at the ring for 4 min at a rotation speed of 900 rpm. The ring potential was then stepped to +0.40V and immediately scanned in the anodic direction. The quantity of palladium collected was determined from integration of the resulting ring current-ring potential curve using a procedure developed in this laboratory (5). Since considerable roughening of the electrode occurs at $E_D \geq +1.4V$ the roughness factor was determined after each measurement. All data were corrected to a roughness factor of 1.6. Assuming that all the palladium was collected as Pd(II) and taking into account the collection efficiency, the disk electrode current due to the Pd(II) dissolution was calculated.

Results and Discussion

Palladium dissolution.—Ring-disk electrode experiments using the RPdRDE were conducted in 0.2*M* H_2SO_4 in order to determine if any soluble species

[1] Present address: Research Laboratories, General Motors Corporation, General Motors Technical Center, Warren, Michigan 48090.

Key words: palladium, dissolution, ring-disk electrode.

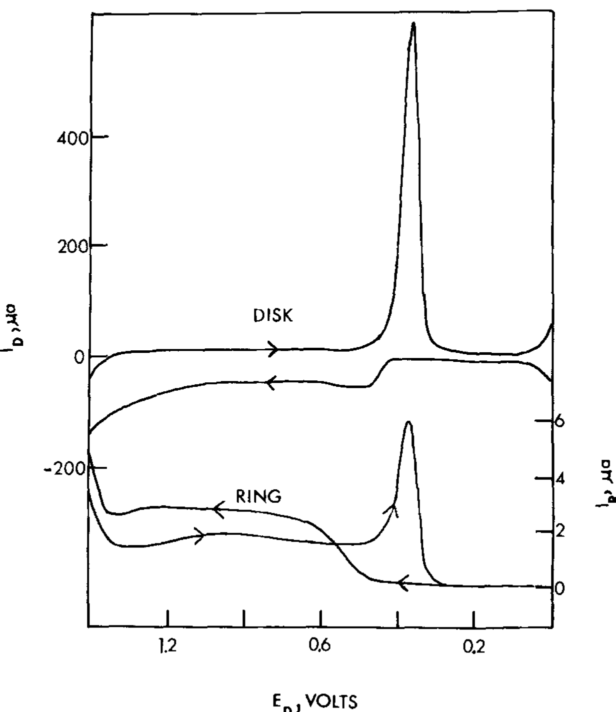

Fig. 1. Current-potential curves at a RPdRDE, showing collection of Pd(II) at the ring electrode. 0.2M H_2SO_4, rotation speed 2500 rpm, potential scan rate 100 mV/sec, E_R = 0.0V.

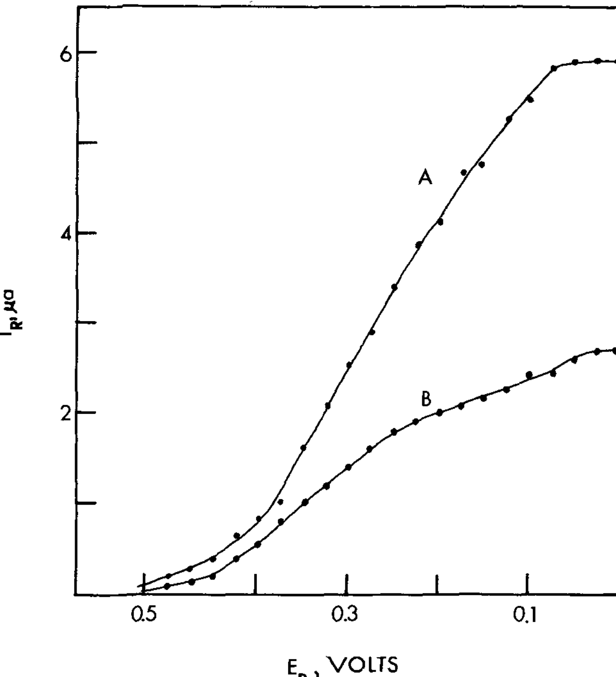

Fig. 2. Current-potential curve showing the effect of ring potential on the collection of Pd(II). 0.2M H_2SO_4, rotation speed 900 rpm, potential scan rate of the disk electrode 100 mV/sec. Curve A, ring current measured at E_D = +0.36V during the cathodic scan; curve B, ring current measured at E_D = +1.0V during the anodic scan.

could be detected during the oxidation and reduction of the palladium disk electrode. Figure 1 shows a disk current-disk potential (i_D-E_D) curve and the corresponding ring current-disk potential (i_R-E_D) curve obtained at a rotation speed of 2500 rpm. The potential scan rate was 100 mV/sec and the ring electrode potential was 0.0V. The i_D-E_D curve shows the oxidation of the palladium electrode at $E_D > +0.4$V and the corresponding reduction peak during the cathodic scan at +0.36V. The i_R-E_D curve shows that ring collection of an electroactive species commences during the anodic scan at the same potential that palladium oxide formation begins. The rapid increase in i_R at $E_D \geqq +1.13$V is due to the collection of oxygen. During the cathodic scan a ring current peak is observed at the same potential as the palladium oxide reduction peak. It is shown below that the ring current at $E_D \leqq +1.10$V is due to the collection of Pd(II).

I_R-E_D curves were recorded at several rotation speeds under the experimental conditions of Fig. 1. No dependence on the rotation speed was observed.

Identification of collected species.—I_R-E_D curves were obtained at a RGPdRDE under the same experimental conditions as in Fig. 1. A ring collection curve identical to the curve in Fig. 1 was obtained.

The soluble species was collected at the gold ring electrode, E_R = 0.0V, during several potential cycles of the palladium disk between zero and +1.1V. The disk electrode was then reduced at 0.0V and open circuited. An I_R-E_R curve was recorded at 100 mV/sec between 0 and +1.6V. The oxidation and reduction of thin layer palladium deposits on gold (5) were apparent, proving that palladium is collected at the ring electrode under these conditions. This procedure was repeated at a fresh electrode, with the soluble palladium being collected during only one potential cycle of the disk. Integration of the i_R-E_D curve showed that the charge required to reduce the Pd collected at the ring during one potential cycle was 34.7 μcoulombs. The quantity of palladium deposited on the ring was determined by measuring the charge required to oxidize this deposit to a known oxidation state (5). Assuming a two-electron reduction of Pd(II), it was found that 33.1 μcoulombs of palladium had been deposited. Comparison of these results leaves little doubt that the observed ring collection current is due to the reduction of Pd(II) under these experimental conditions.

Current-potential curves for the soluble Pd(II) were constructed from i_R-E_D curves obtained at different ring electrode potentials. Two such curves are shown in Fig. 2. The ring current for curve A was measured at the current peak observed during the cathodic scan at E_D = +0.36V (see Fig. 1). The ring current for curve B was measured at E_D = +1.0V during the anodic scan. The curves are irreversible and the shape of curve B gives some indication, although inconclusive, that more than one Pd(II) species is being collected. The limiting current is obtained by +0.05V. Thus, the collection efficiency of the soluble Pd(II) is equal to N at $E_R \leqq +$ 0.05V. It must be noted that the observed ring current decreased with time if the ring electrode was not frequently oxidized at +1.2V. This rate of decrease was dependent on the rotation speed of the electrode indicating that the inhibition was due to impurity adsorption.

Corrosion rate.—The corrosion rate of palladium was determined as a function of potential using the procedure described above (Experimental). The data is presented in Table I. The decrease in the corrosion rate observed when the potential is increased from +0.7 to +0.9V is assumed to be due to the partial passivation of the electrode caused by the formation of palladium oxide. This data is in reasonable agreement with that of Llopis *et al.* (2), who reported a corrosion rate equivalent to 0.32 μA/cm² at +0.9 and +1.5V in 1*N*

Table I. Corrosion of palladium

Electrode potential (V)	i_D (μA/cm²)
+0.5	0.00
+0.7	0.360
+0.9	0.306
+1.1	0.354
+1.3	0.374
+1.5	0.442
+1.7	0.832

$HClO_4$. A significantly higher corrosion rate than found in this study was reported at +0.75 and +1.75V (2.8 and 1.8 $\mu A/cm^2$, respectively). The difference at +0.75V may have been caused by an enhanced corrosion rate due to the presence of a trace amount of chloride in the perchloric acid supporting electrolyte. The disagreement at +1.7V is most likely due to an increase in roughness factor of the electrode used by Llopis *et al.* The roughness factor was not measured in their work.

Comparison of the data in Table I with the ring collection curve in Fig. 1 shows that a much larger (~30X) corrosion rate is observed at a given potential during an anodic potential scan at 100 mV/sec than is observed at the same potential after electrode oxidation is complete. Thus, it is apparent that oxidation of the electrode results in the passivation of the dissolution process, and that the corrosion rate will depend markedly on the electrode potential scan rate and the history of the electrode.

Passivation.—The ring electrode was used to monitor the passivation of the palladium dissolution process at disk electrode potentials where oxygen is not evolved, *i.e.*, $E_D \leq +1.1V$. In these experiments the disk electrode was reduced at +0.1V for 1 min before its potential was stepped to a more oxidizing potential. Palladium was collected at the ring electrode at 0.0V. The resulting ring current-time curves are shown in Fig. 3 for four different disk electrode potentials. Curve a, Fig. 3. was recorded for a potential jump to +0.4V, a potential at which no palladium dissolution occurs. The observed ring current was attributed to electroactive impurities being stripped from the disk electrode. This curve is also labeled the residual curve in Fig. 3. Curves b-d, Fig. 3, were recorded for potential steps to successively more positive potentials and show successively larger corrosion rates. The corrosion rate decreases rapidly during the first 10 sec and then more slowly for times up to 10 min. At times longer than 10 min no additional decrease in the ring collection current was observed and the electrode is passivated.

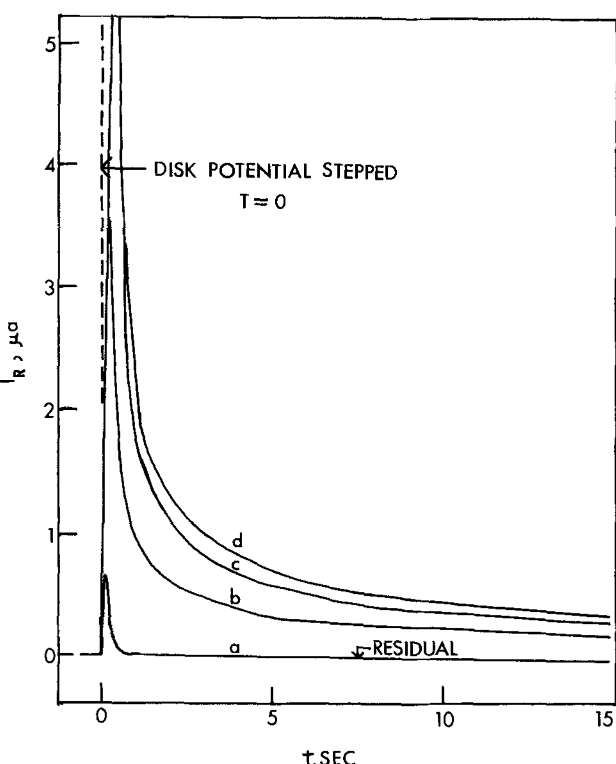

Fig. 3. Ring current *vs.* time curves for the collection of Pd(II). Disk potential stepped from +0.1V to E_D at time = 0. Curve a, E_D = +0.4V; curve b, E_D = +0.6V; curve c, E_D = +0.85V; curve d, E_D = +1.1V. 0.2M H_2SO_4, rotation speed 900 rpm.

Cathodic dissolution.—Once the electrode has been passivated via oxidation, it might be expected that no increase in palladium dissolution would occur if the electrode potential is scanned to more negative potentials. The i_R-E_D collection curves in Fig. 4 prove that this is not the case, since a much larger quantity of palladium is collected at the ring than is predicted from the corrosion rate observed at a passivated electrode. This palladium is termed cathodically soluble palladium. These curves were recorded at E_R = 0.0V after the disk electrode was oxidized for 15 min at the potential indicated in the figure. The i_D-E_D curves corresponding to Fig 4 are presented in Fig. 5.

The cathodically soluble palladium appears to be associated with two different reduction processes which occur at the disk electrode. The first is the reduction of the surface palladium oxide at E_D < +0.5V. This reduction is accompanied by the formation of soluble Pd(II) which is seen in Fig. 4 as a ring current peak, A. A similar phenomenon has been observed at both gold electrodes (7) and platinum electrodes (8). The second reduction process occurs at more positive potentials than the surface palladium oxide reduction peak (see Fig. 5). Reduction peaks at palladium electrodes have been previously reported in this potential region if the electrode is oxidized at potentials greater than +1.75V *vs.* SCE in 1*M* H_2SO_4 (6). These peaks were shown to be due to the reduction of a phase oxide. The data in Fig. 4 and 5 indicate that small quantities of phase oxide form at $E_D \geq +1.1V$ and that a considerable quantity of soluble palladium is generated when the phase oxide is reduced. This effect

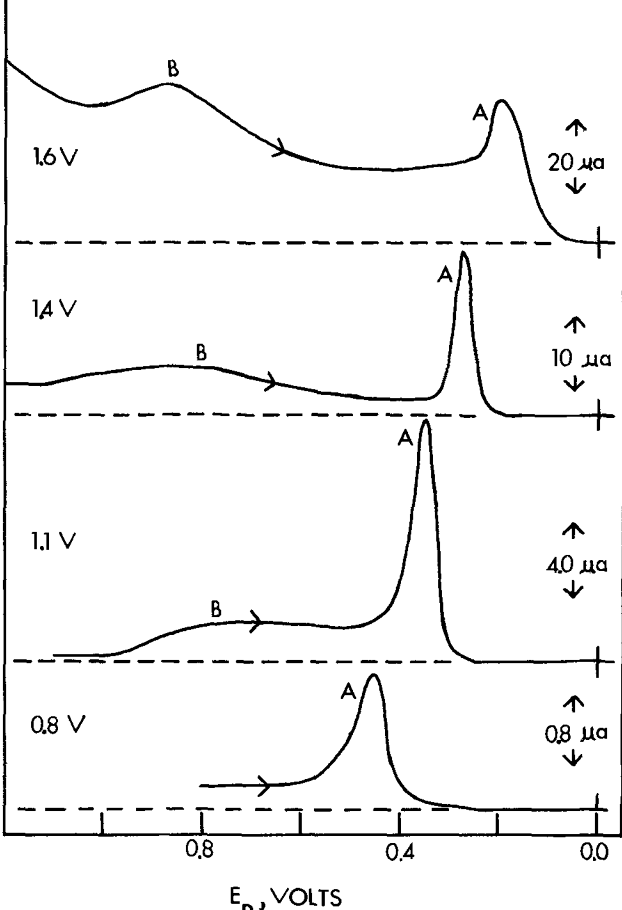

Fig. 4. Effect of disk oxidation potential on cathodic soluble palladium. Disk electrode oxidized at indicated potential for 15 min. 0.2M H_2SO_4, rotation speed 900 rpm, potential scan rate 100 mV/sec.

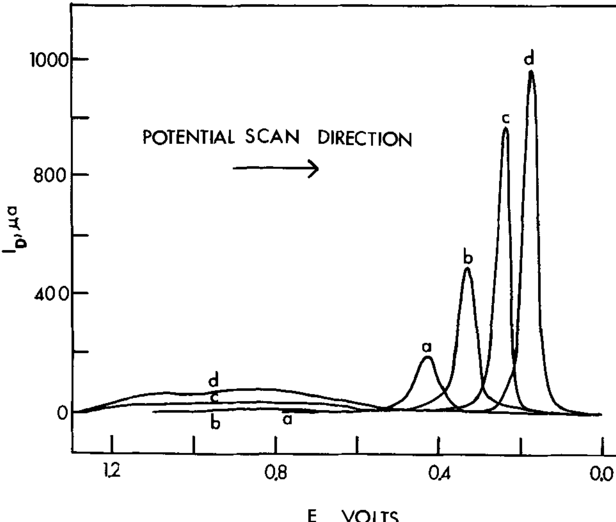

Fig. 5. Current-potential curve for a palladium disk electrode oxidized at E_D for 15 min. Curve a, $E_D = +0.8V$; curve b, $E_D = +1.1V$; curve c, $E_D = +1.4V$; curve d, $E_D = +1.6V$. 0.2M H_2SO_4, rotation speed 900 rpm, potential scan rate 100 mV/sec.

accounts for the tremendous increase in soluble palladium formed at $E_D \geq +1.4V$ and helps account for the observed increases in the surface roughness when the electrode is oxidized at $E_D \geq +1.4V$.

The quantity of cathodically soluble palladium produced at the disk electrode was calculated from i_R-E_D curves as a function of the disk oxidation potential and is presented in Table II. The soluble palladium produced during reduction of the surface palladium oxide reduction peak is designated Q_A, while that produced during reduction of the phase oxide is Q_B. It is not possible to directly measure the soluble palladium produced at $E_D > +1.1V$ because of the simultaneous collection of oxygen which is evolved at these potentials. Therefore, Q_B was measured between +1.1 and 0.0V and is not the total quantity of palladium dissolved during the cathodic scan if the disk is oxidized at $E_D > +1.1V$. The last column of Table II gives the ratio of Q_A/Q_{PdOx}. Q_{PdOx} is the number of coulombs passed for the reduction of surface palladium oxide at the disk electrode current peak, $E_D < +0.5V$. This quantity increases with increasing potential from 1.5% at +0.8V to 12.6% at +1.6V.

Experimental Determination and Calculation of Parasitic Currents in Bipolar Electrolyzers with Application to Chlorate Electrolyzer

I. Roušar* and V. Cezner

Department of Inorganic Technology, Institute of Chemical Technology, Prague, Czechoslovakia

ABSTRACT

Experimental determination of parasitic currents flowing through an electrolyzer in inlet and outlet channels was performed for a bipolar electrolyzer consisting of six cells, for production of chlorates. The average deviation of experimental values from theoretical was 14%.

The problem of parasitic currents was studied theoretically in an earlier paper (1). A comparison of theoretical values of parasitic currents with experimental ones is necessary since the theory is based on a very simplified model which replaces the individual cells and connecting channels by a system of parallel and series resistances (2).

The following relations for resistances of inlet channels to every cell were derived for the so-called W model (1)

$$R_{S1} = \rho_E\,(1 + 1.5\,K_3 + 1.5\,K_3')\left(\frac{L_1}{wd}\right) + 0.5(w + w_1)/L_2d + \rho_E(1 + 1.5(V_{GT}/V_p))\,(L_{ST}/F_{ST}) \quad [1]$$

$$R_{S2} = \rho_E(1 + 1.5\,K_3')\,(L_1/wd) + 0.5(w + w_1)/L_2d + \rho_E(L_{SB}/F_{SB}) \quad [2]$$

and connecting channels between cells

$$R_{Q1} = \rho_E(1 + 1.5(V_{GT}/V_p))\,(S_A + S_K + D)/F_{QT} \quad [3]$$

* Electrochemical Society Active Member.

Key words: bipolar electrolyzer, parasitic currents, chlorate electrolysis.

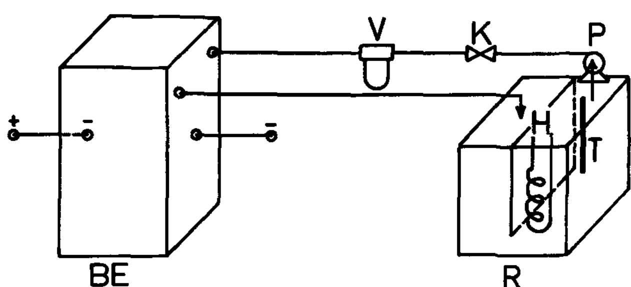

Fig. 2. Experimental setup BE, bipolar electrolyzer; V, Venturi tube; P, centrifugal pump; R, electrolyte reservoir; K, regulation stop cock; T, thermometer; H, titanium heat exchanger.

$$R_{Q2} = \rho_E(S_A + S_K + d)/F_{QB} \quad [4]$$

The single-cell voltage of the electrolyzer is given by

$$U = A + B\eta_{Sj} \quad [5]$$

The electric circuit, shown in Fig. 1, can be simplified (1) if it can be assumed that $R_{S1} \simeq R_{S2}$ and $R_{Q1} \simeq R_{Q2}$; however this was not the case in the present work. We introduce dimensionless parameters $I_{Rj} = I_j/I_o$; $\alpha_{R1} = A/I_oR_{S1}$; $\alpha_{R2} = \alpha_{R1}R_{S1}/R_{S2}$; $\beta_{R1} = R_{Q1}/R_{S1}$; $\beta_{R2} = R_{Q2}/R_{S2}$; $\gamma_{R1} = B/I_oR_{S1}$; $\gamma_{R2} = \gamma_{R1}R_{S1}/R_{S2}$. The currents flowing through the resistance network are determined by considering the voltage balance for every closed circuit and the current balance for every knot. The resulting system of $5n$-7 equations for n cells can be represented by a diagonal matrix (see Table I) and solved by the Thomas method (3).

Experimental

The bipolar electrolyzer (Fig. 2) consisted of six cells, each containing a bipolar electrode 13 × 58 cm made of impregnated Acheson graphite. The flowing electrolyte was pumped by pump P from reservoir R of 120 liters holding capacity passing Venturi tube V. The reservoir was provided with a thermometer and titanium heat exchanger connected with a thermostat. The electrolyzer was fed with current from a silicon rectifier and was assembled from frames (Fig. 3) and

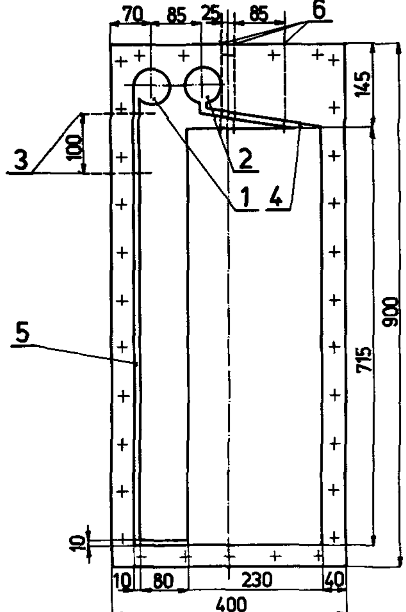

Fig. 3. Interelectrode frame. 1, main channel for electrolyte inlet; 2, main channel for outlet of electrolyte with bubbles; 3, platinum probes to measure voltage drops in inlet channel (U_{B12}'); 4, 5, connecting channels; 6, platinum probes to measure voltage drops in outlet channel (U_{T12},U_{T23}). Dimensions are given in millimeters.

plates (Fig. 4) made of organic glass (Plexiglas). The frames contained built-in platinized platinum wires. The voltage drop between them could be measured by a vacuum tube voltmeter and compared with the calculated voltage given by the parasitic current in the considered circuit and by the electrolyte resistance between the platinum probes. The frame assembled with the plate is shown in Fig. 5 indicating the direction of the electrolyte flow. Between the plate and the frame there was a soft rubber gasket 0.5 mm thick. The distance between the anode and the cathode in the complete assembly was 6 mm at the beginning of experiments. At the end of measurements, the electrodes were partly corroded on the anodic side and the distance between them was 7.7 mm. The electrodes were provided with platinum wires enabling measurement of the voltage, U, between individual cells.

Measurements were made at 40°C and pH was adjusted to 5.5-6.5 by addition of diluted hydrochloric acid. Two different electrolytes were used: (A) 600 g/liter $NaClO_3$ + 90 g/liter NaCl + 3 g/liter $Na_2Cr_2O_7$, (B) 500 g/liter $NaClO_3$ + 150 g/liter NaCl + 10 g/liter $Na_2Cr_2O_7$.

Results

For three values of the current density, 0.03, 0.06, and 0.09 A/cm², three rates of flow of electrolyte A or B were chosen, namely, 10, 20, and 30 kg/min. Thus, the total number of experiments amounted to 18. The resistances between probes in the outlet and inlet

channel were calculated as

$$R_{T12} = \rho_E(1 + 1.5(V_G/V_p))(L_{T12}/F_{ST})$$
$$R_{T23} = \rho_E(1 + 1.5(V_G/V_p))(L_{T23}/F_{ST})$$
$$R_{B12} = \rho_E L_{B12}/F_{SB}$$

The distance between the platinum probes were (Fig. 3): L_{T12} = 2.5 cm, L_{T23} = 8.5 cm, and L_{B12} = 10 cm. The voltage drops U_{T12}, U_{T23}, and U_{B12} on the resistances R_{T12}, R_{T23}, and R_{B12} were measured and calculated. Typical results obtained at a rate of flow of 10 kg/min and current densities of 0.03, 0.06, and 0.09 A/cm^2 with electrolyte B are presented in Table II. Measured values of the average cell voltage, U, at an electrode distance of 7.7 mm are given in Table III.

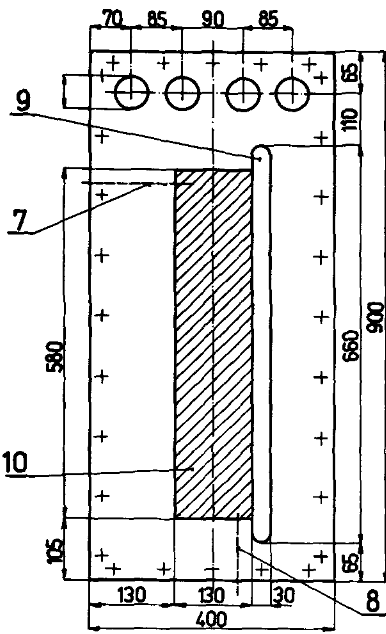

Fig. 4. Electrode frame. 7, 8, Platinum probes to measure cell voltage of electrolyzer (U); 9, Plexiglas separator; 10, graphite electrode. Dimensions are given in millimeters.

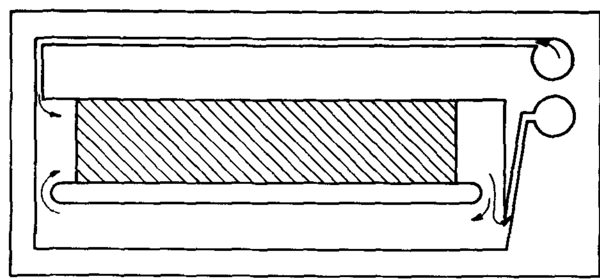

Fig. 5. Assembly of interelectrode and electrode frames. Direction of electrolyte flow is indicated by arrows.

Conclusions

The reproducibility of the measurement of the voltage drop using platinized platinum probes was checked for 5 couples of platinum probes built in the Plexiglas tube and using electrolyte B (without bubbles). The distance between these platinum probes was 5 cm. The reproducibility was 1% (10 mV) for a total voltage drop of about 1V. It follows that the main part of the deviation between experiments and theory is not due to the platinized platinum probes for the voltage drop measurement.

The deviations between theory and experiments are caused by the simplifications used in the mathematical description of the system and at the same time by the fact that the experimental conditions in each cell, such as local temperature and local flow rate of electrolyte, were not constant as assumed in the mathematical description. Unfortunately, it was not possible to distinguish exactly between these two sources of deviation on the basis of our data. The average deviation for the parasitic currents for the inlet channels (electrolyte without bubbles) was 14% and the same deviation was obtained for outlet channels (electrolyte with bubbles). It follows, that the presence of bubbles in the electrolyte has no influence on the average deviation.

Table III. Dependence of average cell voltage on current density and electrolyte rate of flow

Electrolyte	$\bar{i}$ (A/cm²)	Rate of flow through 6 cells (kg/min)	Cell voltage (V)
A	0.03	10	3.027
	0.03	20	3.027
	0.03	30	2.987
	0.06	10	3.174
	0.06	20	3.164
	0.06	30	3.144
	0.09	10	3.358
	0.09	20	3.340
	0.09	30	3.330
B	0.03	10	3.088
	0.03	20	3.046
	0.03	30	3.042
	0.06	10	3.175
	0.06	20	3.170
	0.06	30	3.160
	0.09	10	3.387
	0.09	20	3.380
	0.09	30	3.378

It is seen from the tables that the average error in all measurements was 14%. In view of the small absolute values of the parasitic currents the agreement is satisfactory. Our method therefore can be used in calculating the parasitic currents in practical bipolar electrolyzers.

Cyclic Voltammetry of Copper Metal in Lithium Hydroxide Solution at Elevated Temperatures

Digby D. Macdonald[1]

Whiteshell Nuclear Research Establishment, Pinawa Manitoba, Canada

ABSTRACT

A cyclic voltammetric study of copper metal in 1 mole kg^{-1} LiOH solution at 25°, 125°, 200°, and 250°C is described. The results are consistent with the formation of both soluble (CuO_2^{2-}) and insoluble (Cu_2O and CuO) products at the metal surface. The formation and reduction of Cu(III) was found to occur near oxygen evolution at 25°C but not at the higher temperatures due to a sharp reduction in the oxygen evolution overpotential with temperature.

The electrochemical behavior of copper metal in alkali solution at temperatures less than 100°C has been investigated extensively (1-12). These studies have shown that two principal oxidation processes occur at the copper surface in alkaline solutions at room temperature, *viz.*, the formation of Cu_2O followed by the formation of CuO or $Cu(OH)_2$. A third oxidation/reduction process has been observed at potentials close to oxygen evolution and was attributed to the formation of a copper(III) oxide, 'Cu_2O_3', (1, 7-12). However, recent cyclic voltammetry work indicates that this process may involve soluble species (8, 9).

Almost no experimental work has been reported on the electrochemical behavior of copper metal in aqueous solution at temperatures greater than 100°C. The need for studies on this system is clear, since copper and copper-containing alloys are frequently used in industrial plants which utilize high-temperature water. In this study, the oxidation/reduction behavior of copper metal in 1 mole kg^{-1} lithium hydroxide at 25°, 125°, 200°, and 250°C was investigated using cyclic voltammetry. This technique is capable of detecting very small amounts of charge consumed at the interface and has been used previously to investigate the electrochemical behavior of iron (13) and nickel (14) in high-temperature lithium hydroxide solutions. A thermodynamic study of the copper water system at temperatures to 300°C has been recently reported by Macdonald *et al.* (15) and provides a theoretical basis for the interpretation of the experimental electrochemical work reported here.

[1] Present address: Department of Chemistry, Victoria University of Wellington, Wellington, New Zealand.

Key words: copper, cyclic voltammetry, corrosion, elevated temperatures, lithium hydroxide.

Experimental

The high-temperature titanium electrochemical cell and the electronic apparatus used for the cyclic voltammetry studies have been described previously (13).

Copper electrodes (12.7 mm long, 9.53 mm diameter, and $3.8 \times 10^{-4}m^2$ apparent surface area) were machined from 99.99% bar stock. Spectrographic analysis revealed the following constituents besides copper in micrograms/grams: Sb 40, As 10, B 1, Ca 20, Cr 1, Fe 10, Pb 1, Mg 5, Si 1, Ag 5, and Sn 1. The electrode surface was initially polished with No. 400 and No. 600 grit silicon carbide paper, degreased in acetone, and finally washed with distilled water.

Lithium hydroxide solutions were prepared from AR lithium hydroxide monohydrate and doubly distilled water. The solutions were stored in tightly stoppered Teflon containers to minimize contamination by atmospheric carbon dioxide. The solutions were also purged *in situ* using 99.99% nitrogen gas before heating.

All potentials reported in this work were measured with respect to a saturated calomel electrode which was maintained at 25°C. Electrolytic contact between the cell contents and the reference electrode was maintained via a compressed asbestos plug as previously described (13).

Results

General.—Cyclic voltammograms for copper in 1 mole kg^{-1} lithium hydroxide solution at 25°, 125°, 200°, and 250°C are plotted in Fig. 1-4. The solid and broken lines represent the first and twentieth sweeps, respectively. In general, cyclic sweeping reduced the peak heights especially at the higher temperatures. At 25°C the peaks initially increased on cyclic sweeping although the reverse did occur if the system was swept over 50 or more cycles.

The cyclic voltammograms plotted in Fig. 1-4 show that two main anodic (I and II) and cathodic (V and VI) processes occur on copper over the potential range between hydrogen and oxygen evolution. At 25°C additional processes, corresponding to the formation and reduction of Cu(III) species, were observed close to oxygen evolution and are designated III and IV in Fig. 1. These processes were not observed at the higher temperatures due to reduction in overpotential for oxygen evolution at the metal surface (13).

At 25°C (Fig. 1) peaks II and VI frequently exhibited fine structure. This suggests that multiple redox processes occur in these regions of potential and may arise from the simultaneous existence of CuO and $Cu(OH)_2$ on the metal surface (6). At higher temperatures, the fine structure is no longer observed. This is consistent with the x-ray diffraction evidence of Bouillon *et al.* (6) which shows that only CuO is formed on copper at temperatures greater than 45°C.

A small cathodic peak (peak A, Fig. 2) with anodic "wings" (peaks B, Fig. 2) was often observed at about −0.1V *vs* SCE (25°C) at temperatures from 125° to 250°C. This peak occurs at too low a potential to be attributed to the process which is responsible for peak IV at 25°C and must represent an additional redox

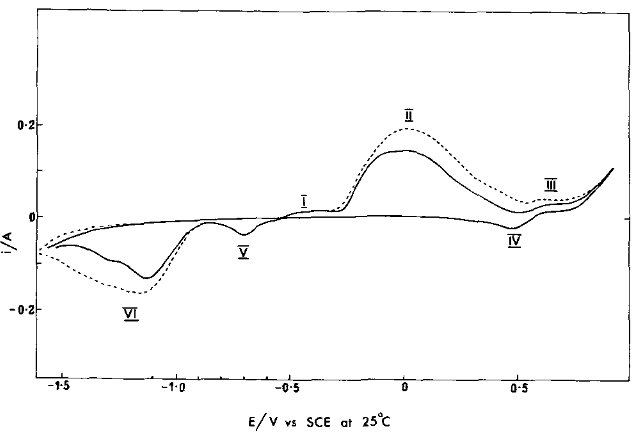

Fig. 1. Cyclic voltammogram for copper in 1 mole kg^{-1} LiOH solution at 25°C. dE/dt = 0.25 V/sec^{-1}. Solid line, first sweep; broken line, twentieth sweep.

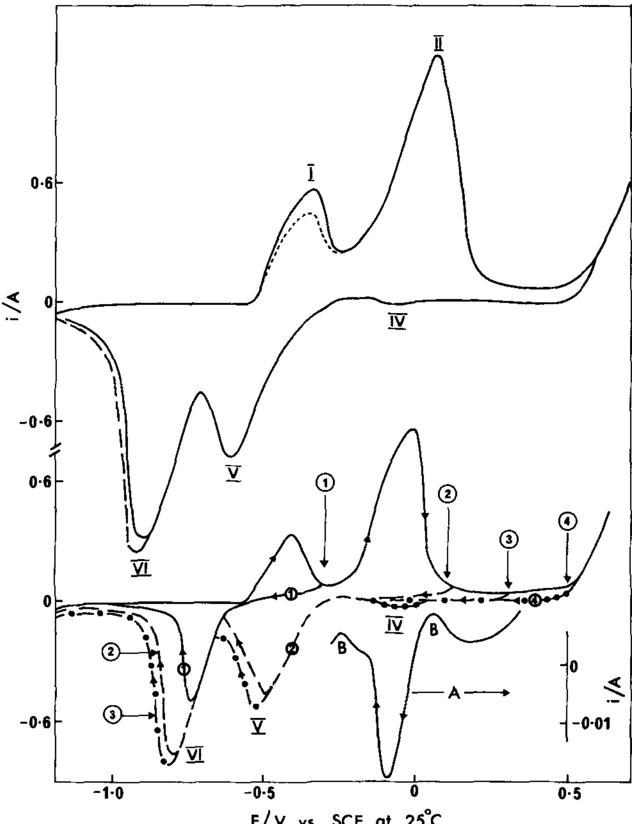

Fig. 2. Cyclic voltammograms for copper in 1 mole kg^{-1} LiOH solution at 125°C. dE/dt = 0.233 V/sec^{-1} (upper curves), 0.042 V/sec^{-1} (lower curves). Solid line, first sweep; broken line, twentieth sweep.

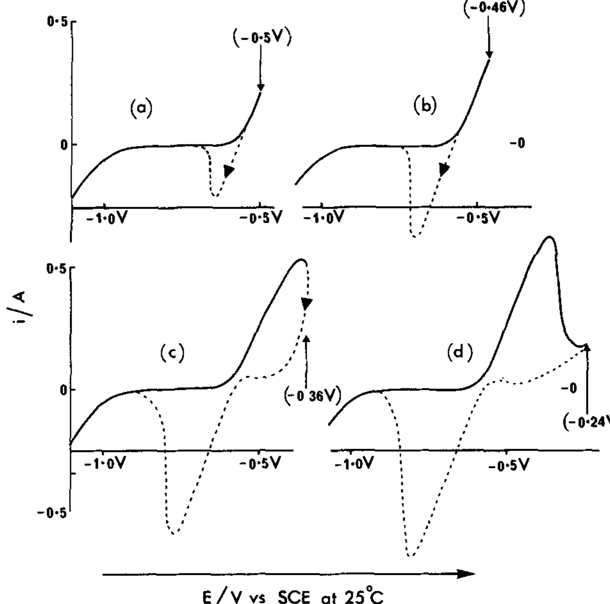

Fig. 5. Sweep reversal studies on copper in 1 mole kg^{-1} LiOH at 250°C. dE/dt = 0.042 V/sec^{-1}. Solid line, cathodic to anodic sweep; broken line, anodic to cathodic sweep.

reaction in the system. The anodic "wings" to this peak on the anodic to cathodic scan suggest that the peak arises from a reactivation process in which the passivating film is partially reduced. However, the amount of charge consumed is small and, in view of the total charge required to completely reduce the surface (peaks V and VI), the redox process probably involves only a small fraction of the total film.

Sweep reversal experiments.—An important feature of this study concerned the behavior of the cathodic peaks (IV-VI) after sweep reversal on the anodic scan at selected potentials. The potentials at which the anodic scans were reversed (E_R) are designated by vertical arrows in Fig. 2-5.

If the sweep was reversed before the start of peak I, the cathodic scan simply retraced the anodic sweep at all temperatures. The region from -1.0V to the start of peak I appears to be analogous to the "double layer" region observed on platinum (16) in which the major portion of the current is used to charge the double layer with very little being utilized in faradaic processes. At more cathodic potentials, hydrogen evolution becomes kinetically important as shown by the sweep behavior at potentials more negative than -1.0V.

Reversal of the anodic scans in Fig. 2-5 after peak I resulted in the cathodic peak designated VI. If the anodic sweeps were reversed after peak II, however, peaks V and VI resulted. Thus, we can conclude that the products formed at peaks I and II are reduced, at least to some extent, at peaks VI and V, respectively. The charges passed at peaks II and VI are considerably greater than those passed at peaks I and V. This is inconsistent with a mechanism involving simple consecutive one-electron transfer steps (*e.g.*, Cu → Cu_2O and Cu_2O → CuO). Instead, a more complex mechanism involving parallel charge-transfer reactions in the peak regions of potentials is indicated.

A number of experiments were carried out in which the anodic sweeps were reversed at potentials on the rising regions of peaks I and II in an attempt to ascertain the nature of the anodic processes responsible for the oxidation of copper in high-temperature hydroxide solutions. If the sweep was reversed on the rising part of peak I, then the reverse sweep retraced part of the forward sweep and then resulted in a cathodic peak as shown in Fig. 5. The cathodic charge passed on the reverse sweep, as represented by the area of the peak, was found to increase markedly as the potential of reversal on the rising part of peak I became more anodic. If the reversal potential exceeded the peak potential for peak I, then hysteresis between the ascending and descending scans in the peak I region of potential was observed. These results suggest that the electrode surface becomes completely covered with a resistive film of product at potentials greater than E_P, after which the faradaic process is essentially field-assisted film growth. The apparent reversibility of the anodic scan for $E_R < E_P$ implies that the current-voltage curve in this region of potential is determined principally by a fast reversible process such as dissolution. The oxide film which eventually passivates the surface at $E_R > E_P$ may then form either by direct nucleation from the metal or by precipitation of the dissolution product when the interfacial concentration exceeds the saturation value.

Sweep reversal on the ascending portion of peak II (Fig. 3) revealed that if $E_R < E_P$, then the current on the reverse scan was more anodic than for the forward scan. A similar phenomenon was noted by Ambrose *et al.* (8, 9) for copper in KOH solutions at 25°C. This observation indicates that the forward scan initially removes the passivating film formed at peak I, thus reducing the resistance to charge transfer by dissolution on the reverse sweep. Again, it was found that for $E_R > E_P$, hysteresis between the forward and reverse sweeps occurred, indicating the irreversible formation of a solid passivating film at the metal surface in this region of potential.

The cathodic peaks V and VI were found to shift to more negative potentials with increasingly anodic values for E_R (Fig. 2-5), or charge passed on the anodic scan. This behavior is similar to that found for the reduction of surface oxides on noble metals in 1 mole/liter^{-1} perchloric acid at 25°C (17) in which it was concluded that the total quantity of surface

oxide is the important factor determining the peak potential in the reduction profile and the progressive hysteresis between the anodic oxide formation and the cathodic reduction profile. This same factor is presumed to contribute to the observed shifts in E_P for peaks V and VI in the present work. Resistance polarization effects associated with the ohmic resistances of the films probably also contribute to the dependence of E_P on anodic charge and hence film thickness.

Sweep rate dependence.—Cyclic voltammograms were obtained at a number of sweep rates over the range 0.05-0.5 V/sec^{-1}. Both the peak currents and potentials were found to be sensitive to sweep rate at all temperatures, as has been previously observed for other metals in alkali solution at elevated temperatures (13, 14). In this work, it was found that neither the peak currents nor the peak potentials were sufficiently reproducible to determine their functional dependence on sweep rate. However, it was observed that the peak currents tended to increase with dE/dt. The potentials at which peaks occur on the forward sweep, *i.e.*, peaks I and II (and III at 25°C) were found to become more anodic with increasing sweep rate, whereas those peaks observed on the reverse sweep shifted to more cathodic potentials. This observed sweep rate dependence of E_P is inconsistent with the operation of reversible redox processes involving adsorbed species (17). Instead, this behavior, together with the general asymmetric nature of the peaks, is consistent with the proposed irreversible formation of passivating oxide films (Cu_2O and CuO) on the metal surface.

Charge considerations.—The total current passed at any potential during cyclic sweeping can be written as

$$i = (dq/dt)_f + CA(dE/dt) \quad [1]$$

where the first term is the current due to faradaic processes and the second represents the current associated with the nonfaradaic process of charging the double layer. Simple calculations (13) show that the charging current for sweep rates of the magnitude used here should be less than 10 μA. Hence, the charging current can be neglected, and the total charge passed during electrolysis is attributed to faradaic processes at the interface. The change in charge, Δq, due to sweeping between potentials E_1 and E_2 is therefore given as

$$\Delta q = \int_{E_1}^{E_2} idE/(dE/dt)$$

$$= \Delta q_D + \Delta q_F \quad [2]$$

where Δq_D and Δq_F are the charges associated with dissolution and film formation processes, respectively. Although the present experimental technique does not permit resolution of the total charge into these components, we can nevertheless draw important conclusions if it is assumed that the sweep rates were sufficiently slow so that dissolution products formed on the forward (anodic) sweep have sufficient time to diffuse into the bulk of the solution before being reduced on the reverse (cathodic) sweep. Thus, any discrepancy between the total anodic and cathodic charges on cyclic sweeping can be attributed to dissolution processes.

The charges passed on scanning the electrode between selected potentials were determined graphically from the recorded current/voltage curves. The total charges passed on anodic followed by cathodic sweeping were found to be not very reproducible and depended upon the previous history of the electrode. However, over a complete cycle from hydrogen evolution to oxygen evolution at 25°C, the total anodic charge passed was found to be about 10-15% greater than the total cathodic charge. This difference was found to increase slightly with temperature to about 20% at 250°C. This behavior is in sharp contrast to that observed for iron (13) and nickel (14) when it was found that the ratio of anodic to cathodic charge increased sharply with temperature between 25° and 200°C corresponding to the greater importance of dissolution processes in determining the electrochemical properties of these systems at elevated temperatures.

Cyclic voltammetry traces for Cu in 1 mole kg^{-1} LiOH at 250°C as a function of reversal potential are shown in Fig. 5. The reversal potentials were chosen within the peak I region as shown. The ratio of anodic to cathodic charge over a complete cycle, Q_A/Q_C, is plotted as a function of E_R in Fig. 6. Thus, as the reversal potential increases along the ascending portion of peak I, the ratio Q_A/Q_C decreases from 1.52 ± 0.05 to 1.25 ± 0.05. This behavior indicates the existence of a large dissolution charge on the ascending part of the peak followed by passivation of the surface by a solid film. The same general behavior was displayed at all temperatures from 125° to 250°C.

Discussion

Oxidation mechanism.—The following reactions are proposed to account for the oxidation/reduction behavior of copper metal in 1 mole kg^{-1} LiOH at temperatures from 25° to 250°C

(*i*) $Cu + 4\,OH^- \rightarrow CuO_2^{2-} + 2H_2O + 2e^-$ } Peak I
(*ii*) $2Cu + 2\,OH^- \rightarrow Cu_2O + H_2O + 2e^-$ } Peak I

(*iii*) $Cu_2O + 6\,OH^- \rightarrow 2CuO_2^{2-} + 3H_2O + 2e^-$ } Peak II
(*iv*) $Cu_2O + 2\,OH^- \rightarrow 2CuO + H_2O + 2e^-$ } Peak II
(*v*) $Cu + 2\,OH^- \rightarrow CuO + H_2O + 2e^-$ } Peak II

(*vi*) $2CuO + H_2O + 2e^- \rightarrow Cu_2O + 2\,OH^-$ Peak V

(*vii*) $CuO + H_2O + 2e^- \rightarrow Cu + 2\,OH^-$ } Peak VI
(*viii*) $Cu_2O + H_2O + 2e^- \rightarrow 2Cu + 2\,OH^-$ } Peak VI

Ambrose *et al.* (8, 9) have proposed the following reactions to account for the oxidation/reduction peaks near oxygen evolution at 25°C

$CuO_2^{2-} \rightarrow CuO_2^- + e^-$ Peak III

$CuO_2^- + e^- \rightarrow CuO_2^{2-}$ Peak IV

in which the copper(III) species is the ion CuO_2^-. On the other hand, Shams El Din and El Wahab (7) considered the Cu(III) product to be an oxide "Cu_2O_3" rather than a soluble species. Irrespective of the identity of this product, the present work demonstrates that it is only formed before oxygen evolution at tem-

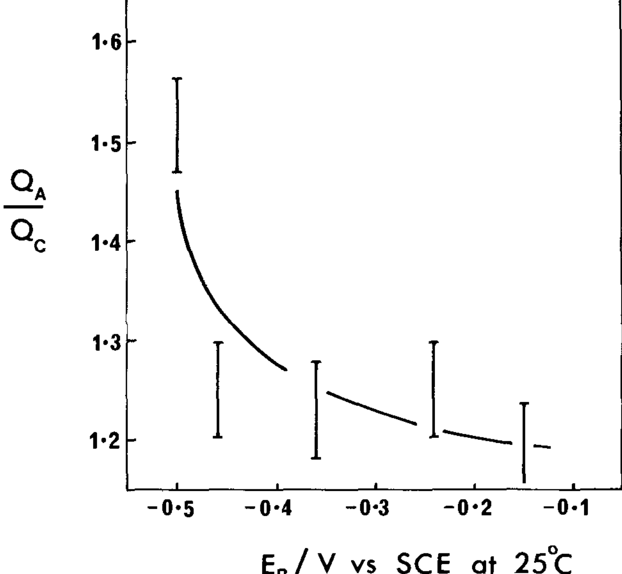

Fig. 6. Anodic to cathodic charge ratios for copper in 1 mole kg^{-1} LiOH at 250°C. dE/dt = 0.042 V/sec^{-1}.

peratures less than 125°C. At higher temperatures, the overvoltage for oxygen evolution is reduced to such an extent that it completely masks the Cu(III) formation reaction. A similar phenomenon was found to occur at the nickel anode in 1 mole kg^{-1} LiOH at elevated temperatures (14). Thus, at 22°C the formation and reduction of Ni(IV) oxide, possibly NiO_2 or nonstoichiometric $NiO_{1.8}$, results in clearly defined cyclic voltammogram peaks just before oxygen evolution; even though thermodynamics show that the equilibrium potential for the Ni_2O_3/NiO_2 couple is more positive than the equilibrium potential for oxygen evolution under the conditions employed. At higher temperatures (175° and 250°C) these peaks are no longer observed due to a sharp reduction in oxygen evolution overpotential.

Reactions (*i*) and (*iii*) account for the formation of soluble products at peaks I and II, respectively, while reaction (*ii*) describes the growth of Cu_2O which eventually passivates the surface and results in a decrease in current at peak I. The Cu_2O formed at peak I is envisaged to undergo two reactions at peak II. Initially, the Cu_2O is oxidized to produce a soluble CuO_2^{2-} species according to reaction (*iii*), resulting in the partial removal of the Cu_2O barrier to dissolution of the underlying metal. Consequently, if the sweep is reversed in this region the anodic current for the reverse sweep will be greater than that for the forward sweep, as observed (Fig. 3). Two further charge-transfer reactions are postulated to occur in the peak II region; *viz.*, reactions (*iv*) and (*v*). Both reactions can account for passivation in this region where the passivating film is considered to consist mainly of CuO. Reaction (*v*) also accounts for the greater charge passed at peak II than at peak I. On the reverse sweep, part of the CuO formed at peak II is reduced to Cu_2O at peak V according to reaction (*vi*). Further reduction of CuO and Cu_2O to copper metal occurs at peak VI as described by reactions (*vii*) and (*viii*). This two-stage reduction of CuO at both peaks V and VI accounts for the greater charge passed at the latter, *i.e.*, reduction of CuO to Cu_2O is incomplete at peak V. This may result in the formation of a duplex oxide film on the metal surface consisting of an inner layer of Cu_2O and an outer layer of CuO. The Cu_2O formed in this region of potential and the unreduced outer layer of CuO are then reduced to the metal at peak VI.

The curves plotted in Fig. 1-4 show that the ratios $Q(I)/Q(II)$ and $Q(V)/Q(VI)$, where $Q(Y)$ is the charge passed under peak Y, increase markedly with temperature between 25° and 125°C, but remain fairly constant thereafter. This suggests that an increase in temperature from 25° to 125°C favors the initial formation of Cu_2O as the potential of the metal is swept anodically. Likewise, this initial increase in temperature favors the reduction of CuO to Cu_2O at peak V over the reduction of this product to Cu at peak VI. It should also be pointed out that part of the increase in the charge ratio $Q(I)/Q(II)$ may be due to the influence of temperature upon the dissolution processes described by reactions (*i*) and (*iii*). This uncertainty cannot be resolved in the present study but will require detailed study by rotating-disk or ring-disk techniques of the type recently carried out by Ambrose *et al.* (9) for this system at 25°C.

Thermodynamic relationships.—In the present study for $T \neq 25°C$, the working and reference electrodes were maintained at different temperatures and pressures. Therefore, the measured potentials contain two irreversible contributions, *viz.*, a streaming potential due to the pressure gradient and a thermal junction potential due to the temperature gradient. For the low pressures employed (<4 MPa) the streaming potential is probably less than a few millivolts and will be ignored. The electromotive force of a cell containing a thermal junction in its initial state (*i.e.*, before significant thermal diffusion) is the result of three contributions (18); (*i*) the metallic thermocouple effect which is usually small and neglected (18); (*ii*) the electrode temperature effect; and (*iii*) the thermal liquid junction potential.

The reference electrode assembly used in this study may be formally represented as follows, where SHE designates the standard hydrogen electrode at the temperature of interest

E_{ext} (spanning SCE to WE)

SCE / SHE / LiOH / SHE / WE

(25°C) (25°C) (T) (T)

−0.244V (SCE–SHE) E_{21} (SHE–SHE) E_T (SHE–WE)

E_{ext} is the potential with respect to the external SCE at 25°C, E_{21} is the potential difference for the thermal cell containing a 1 mole kg^{-1} LiOH salt bridge, and E_T is the potential of the working electrode (WE) with respect to the SHE at the same temperature. It is this latter quantity which is calculated in a thermodynamic analysis of the system. Thus, in the absence of isothermal liquid junction potentials, the potential of the WE with respect to the external reference electrode (E_{ext}) is related to the thermodynamic potential E_T by Eq. [3]

$$E_{ext} = E_T + E_{21} - 0.244V(\text{SCE}, 25°C) \quad [3]$$

Now, the potential E_{21} is given by (*i*) and (*ii*) above, *i.e.*

$$E_{21} = \int_{T_1}^{T_2} \left(\frac{\partial E}{\partial T} \right)_{Th,SHE} dT + \int_{T_1}^{T_2} \left(\frac{\partial E}{\partial T} \right)_{TJ} dT \quad [4]$$

where $(\partial E/\partial T)_{Th,SHE}$ is the thermal temperature coefficient for the cell $SHE(T_1)/SHE(T_2)$ and $(\partial E/\partial T)_{TJ}$ is the thermal junction potential coefficient for the LiOH salt bridge. Studies by Seys and Van Haute (19) suggest that the thermal junction potential coefficient is not strongly dependent upon temperature, Thus, we write

$$\int_{T_1}^{T_2} \left(\frac{\partial E}{\partial T} \right)_{TJ} dT = 0.5 \times 10^{-3}(T - 25)V \quad [5]$$

where $(\partial E/\partial T)_{TJ}$ has been taken as 0.5 mV/°C^{-1} (18). The thermal temperature coefficient for the SHE at 25°C has been estimated to be 0.871 mV/°C^{-1} at 25°C (18). If we assume that this coefficient also is not strongly dependent upon temperature then

$$\int_{T_1}^{T_2} \left(\frac{\partial E}{\partial T} \right)_{Th,SHE} dT = 0.871 \times 10^{-3}(T - 25)V \quad [6]$$

The potential of the working electrode with respect to the SCE at 25°C is therefore

$$E_{ext} = E_T + 1.371 \times 10^{-3}(T - 25) - 0.244V(\text{SCE}, 25°C) \quad [7]$$

and the corrections to E_T are calculated to be −0.244, −0.17, 0, and 0.06V at 25°, 125°, 200°, and 250°C, respectively. The calculated E_{21} corrections are large, although it must be remembered that the thermal junction potential coefficient used is an estimated value and does not specifically apply to 1 mole kg^{-1} LiOH. Thermal junction potentials vary considerably from study to study (18, 19) and the corrections calculated above should be regarded as tentative estimates only.

Macdonald *et al.* (15) have recently published detailed thermodynamic calculations on the copper water system at temperatures to 300°C. Calculated equilibrium potentials for reactions (*i*) to (*v*) referred to the SHE at the temperatures of interest together with values corrected for reference to the SCE at 25°C (*i.e.*, $E_{o,ext}$) using Eq. [7] ($E_o = E_T$) are listed in Table I.

Table I. Equilibrium potentials* for reactions in the copper water systems at elevated temperatures

E_o (V vs. SHE at T)

Reaction	25°C	125°C**	200°C	250°C
(i)	−0.327	−0.51	−0.64	−0.74
(ii)	−0.355	−0.53	−0.66	−0.77
(iii)	−0.298	−0.49	−0.62	−0.71

* $[OH^-] = 1$ mole kg^{-1}. $pK°_w$ values were taken from Ref. (20). The interfacial concentration of CuO_2^{2-} has been arbitrarily set at 10^{-6} mole kg^{-1}. No activity coefficient corrections were applied.
** Interpolated from plots of E_o vs. temperature.

The thermodynamic consistency of the reactions proposed to account for the redox behavior of copper in high-temperature alkali solution can be judged by application of the following restrictions (13, 14): (i) for conjugate oxidation/reduction peaks on cyclic sweeping then $E_a > E_o > E_c$ where E_a and E_c are the anodic and cathodic peak potentials and E_o is the equilibrium potential for the process responsible for the peaks, and (ii) $E_{diss} > E_{o,diss}$ is the potential at which the proposed dissolution process with equilibrium potential $E_{o,diss}$ begins to pass significant current. Both restrictions (i) and (ii) are, of course, equivalent to the statement that the overpotentials for anodic and cathodic processes are positive and negative, respectively. Comparison of the equilibrium potentials listed in Table I with the peak potentials shown in Fig. 1-4 show that the relationships discussed above are obeyed. Therefore, the reactions proposed are consistent with the thermodynamics of the copper water systems over the temperature range studied.

Manuscript submitted May 31, 1973; revised manuscript received Nov. 10, 1973.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1974 JOURNAL. All discussions for the December 1974 Discussion Section should be submitted by Aug. 1, 1974.

The Cathodic Behavior of CuS, MoO_3, and MnO_2 in Lithium Cells

Fred W. Dampier*

ESB Incorporated, C. F. Norberg Technology Center, Yardley, Pennsylvania 19067

ABSTRACT

The cathodic behavior of CuS and MoO_3 was studied in lithium cells discharged at current densities in the neighborhood of 2 mA/cm^2. Two electrolytes, 1M $LiClO_4$/propylene carbonate (PC) and 1M $LiClO_4$/70% tetrahydrofuran (THF)-30% 1,2 dimethoxyethane (DME) were investigated for both of the cathodes, and it was found that the THF-DME electrolyte greatly increased the coulombic efficiency. The Li-MoO_3 cells that were discharged after one year of storage showed a 19% loss of capacity which has been attributed to trace impurities. A study of the rechargeability of the Li-MnO_2 cell was also undertaken, and for the fifth cycle an ampere-hour charging efficiency of 45.2% was obtained.

In recent years a number of new cathode materials (1, 2) have been found for nonaqueous batteries which give outstanding electrochemical performance, even after one year of activated storage. Previously, most of the cathode materials investigated, for example, CuF_2 and $CuCl_2$, were sufficiently soluble in organic electrolytes that self-discharge and dendrite formation were serious problems limiting the storage life to a month or less.

* Electrochemical Society Active Member.
Key words: batteries, primary; propylene carbonate; tetrahydrofuran; lithium.

All the cathode materials that were selected for the present study are essentially insoluble in organic electrolytes and discharge results for MoO_3 and CuS show minimal losses after one year of activated storage. The theoretical specific energies for lithium cells with CuS, MoO_3, and MnO_2 cathodes are 436, 442, and 845 Whr/lb, respectively. Although the CuS cathode has been described by Gabano (2, 3) and the MoO_3 cathode has been investigated by Knapp (4) and Campanella (1), much more needs to be known concerning the electrochemistry of these new systems if their full potential is to be realized.

In the present research, studies were conducted to more fully characterize the cathodic behavior of CuS and MoO_3 in lithium cells. Information was gained concerning the performance of the MoO_3 cathode in two electrolytes not previously used in lithium cells with this cathode: 1M $LiClO_4$/propylene carbonate (PC) and 1M $LiClO_4$/70% tetrahydrofuran (THF)-30% 1,2 dimethoxyethane (DME). MnO_2, which has previously (4, 5) been used as a cathode in lithium batteries, was also studied in the $LiClO_4$/THF-DME electrolyte. Although MnO_2 was found to have a lower specific energy than MoO_3, the results of cycling experiments have shown that the Li-MnO_2 cell is rechargeable.

Experimental

Cell construction.—The preparation of solutions and all electrochemical measurements were performed in a recirculating argon atmosphere glove box (Vacuum Atmospheres Corporation). The experimental cells consisted of two lithium anodes (1⅜ in. sq, 0.015 in. thick) on either side of a 1-in. sq cathode (0.035 in. thick) separated by one layer of 15-mil glass fiber filter paper (No. 934AH, Reeve-Angel).

The cathodes were prepared by pressing a blend of 85% active material, 10% graphite (No. 1651, Southwestern Graphite Company), and 5% polyethylene powder (Microthene FN-500, U. S. Industrial Chemicals) onto a 5-mil nickel 10-3/0 grid (Exmit Corporation). The active material and polyethylene powder were sieved through a 200 mesh screen, and the material that passed was mixed thoroughly with the graphite for 16-20 hr on a Fisher-Kendal mixer. A 0.015 in. diameter copper terminal wire was spot welded to the 1.0 in. sq nickel grid and the grid positioned in a steel pressing die lined with release paper. Next, approximately 1.5g of the cathode mixture was evenly spread in the cavity, a second sheet of release paper added, and the assembly compacted at 6400 psi for 3 min at 225°F. The active materials used to prepare the cathodes were MoO_3 (Baker analyzed reagent), CuS (Fisher certified reagent), chemically formed MnO_2 (Type "M," Diamond Shamrock Chemical Company), and electrolytic MnO_2 (E. J. Lavino and Company).

Cells were assembled by wrapping one cathode in a "U" fold of one thickness of glass fiber filter paper, then sandwiching the wrapped cathode between two lithium anodes. The element was then inserted into a polypropylene cell case, using polyethylene shims to insure a snug fit, and electrolyte was added.

Electrolyte.—The propylene carbonate (Jefferson Chemical Company), 1,2 dimethoxyethane (yellow label, Eastman Kodak Company), and tetrahydrofuran (E. I. du Pont Company, Electrochemicals Department) used to prepare electrolytes were all dried with 5A molecular sieves (Linde Division, Union Carbide Corporation) prior to distillation. Dry argon was then bubbled through each solvent for 24 hr to remove dissolved oxygen and CO_2 and the solvent distilled with a Nester/Faust NF-276 spinning band distillation apparatus (Nester/Faust Manufacturing Corporation, Newark, Delaware). The distillation column (ID 1.0 cm, length 95 cm) was equipped with a Monel spiral band which was rotated at 1170 ± 6 rpm by a motor. The receiver system, in order to maintain vacuum and avoid contamination with stopcock grease, was designed with glass drip tips, Teflon standard taper sleeves, and Teflon needle valve stopcocks. The THF and DME distillations were carried out at atmospheric pressure, but to avoid decomposition, PC was distilled at 2.0 ± 0.3 Torr while the column head temperature was kept between 73° and 79°C. The reflux ratio was regulated at 15:1 by an electric timer and the first 10% and last 20% of the solvent were discarded. Analysis of the distilled PC with an F & M Model 200 gas chromatograph (W filaments, 2-ft Poropak Q column) showed the water concentration was about 170 ± 30 ppm. Details concerning the gas chromatographic techniques used have been reported elsewhere (6).

Reagent grade $LiClO_4$ (G. F. Smith Chemical Company) was twice recrystallized from water and dried at temperatures up to 220°C in a stream of dry argon at pressures from 200 to 1 μm for 24 hr (approximately 4 hr at 220°C). The drying tube was equipped with ground glass joints and stopcocks so that the dry salt could be transferred under vacuum from the manifold to the glove box. Attempts to analyze the electrolyte using gas chromatography gave spurious results due to thermal decomposition in the injector port and other problems described by Butler (16).

Linear sweep voltammetry.—The voltammetric scans were performed using a Tacussel PIT-20 potentiostat programmed from a Tacussel GSTP function generator and the current-potential curves were recorded on a Tektronix 564 storage oscilloscope. The reference and counterelectrodes were 40 × 8 mm strips of 0.015 in. thick lithium foil (Foote Mineral Company) of 99.9% purity. The working electrode was a 0.256 in. diameter disk of bright platinum inlaid in glass (Beckman Instruments).

Results and Discussion

Discharge behavior.—The cathodic behavior of MoO_3, CuS, and MnO_2 during 2 mA/cm^2 constant current discharge is compared in Fig. 1 for cells using a 1.0M $LiClO_4$/70% THF-30% DME electrolyte. The complete discharge curve for MoO_3 in Fig. 2 shows that 70.5% of the theoretical capacity based on 2 electrons/mole can be obtained to a 2.00V cutoff at 2 mA/cm^2. By comparison only 31.8% of the theoretical capacity was obtained during discharge of CuS on the basis of a 1.52V instead of the regular 2.00V cutoff. Thus, MoO_3 has the highest specific energy of the three cathodes by a considerable margin.

The low voltage obtained during the discharge of the Li-CuS cell generally agrees with the results of Gabano and co-workers (2, 3) who were the first to investigate this cell using the THF-DME electrolyte. When Li-CuS cells were discharged using a 1M $LiClO_4$/PC electrolyte, CuS utilizations of only 4.3%

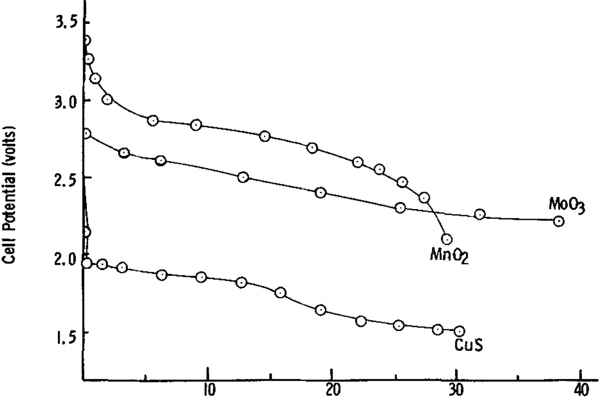

Fig. 1. Cathodic behavior of CuS, MoO_3, and MnO_2 in lithium cells. Electrolyte: 1M $LiClO_4$/70% THF-30% 1,2 DME. Current density: 2 mA/cm^2.

were obtained in the best case. A similar reduction in capacity was also observed for the MoO_3 cathode when THF-DME was replaced by PC and will be attributed to reduced $LiClO_4$ diffusion in PC, in a later discussion of mass transfer processes.

The results given in Fig. 1 for the discharge of MnO_2 were obtained using cathodes that contained 87.7% chemically formed MnO_2 (200 mesh). Electrolytic MnO_2 (80 mesh) was tested under similar conditions to a 2.11V cutoff and was found to yield only 17% of theoretical capacity compared to 29% obtained with chemical MnO_2.

Figure 2 shows a series of discharge curves at various current densities for Li-MoO_3 cells using a 1M $LiClO_4$/THF-DME electrolyte. The rapid polarization and low utilization obtained for the 8 mA/cm^2 discharge appears to be largely due to concentration polarization since the cell was found to have considerable unused capacity even though discharged to a 0.76V cutoff. The open-circuit voltage of the cell rose to 2.71V within an hour after the discharge was terminated, and the cell yielded an additional 46.7% of theoretical capacity (2.00V cutoff) when discharged through a 78 ohm resistor (2.05 mA/cm^2 at 2.02V).

When the discharge results of the Li-MoO_3 cells using the THF-DME electrolyte were obtained, calculations were carried out which showed that this system could be the basis of a high energy battery. Several D-size cells (1-11/32 in. diameter, 2-1/4 in. height) were therefore constructed with spiral wound electrodes, and it was found that they operated with a 27 ohm load for 85 hr above 2.0V. Since the cells weighed 82g, the specific energy corresponds to 105 Whr/lb.

The main limitation of the $LiClO_4$/THF-DME electrolyte is the loss in capacity that occurs during low temperature discharge. At $-18°C$ only 24.2% of the theoretical capacity (based on 2 electrons/mole) of MoO_3 discharged at 2 mA/cm^2 was obtained compared to 70.5% (to a 2.00V cutoff) at 25°C. The 72% loss in capacity that was observed is unusually large when compared with the minimal losses obtained when more volatile, less viscous solvents such as methyl formate are used in Li-MoO_3 cells. The choice of $LiClO_4$ as the solute may also be a contributing factor (8) because solubility limitations can lead to problems with concentration polarization. In particular, if the accumulation of $LiClO_4$ in the diffusion layer at the lithium electrode exceeds the solubility, film formation may occur.

In Fig. 3 the discharge characteristics for Li-MoO_3/$LiClO_4$-PC cells stored 6 and 12 months are compared with cells discharged immediately after being filled. To a 2.00V cutoff, the utilization dropped from 32.1% of theoretical for the immediate discharge to 25% after

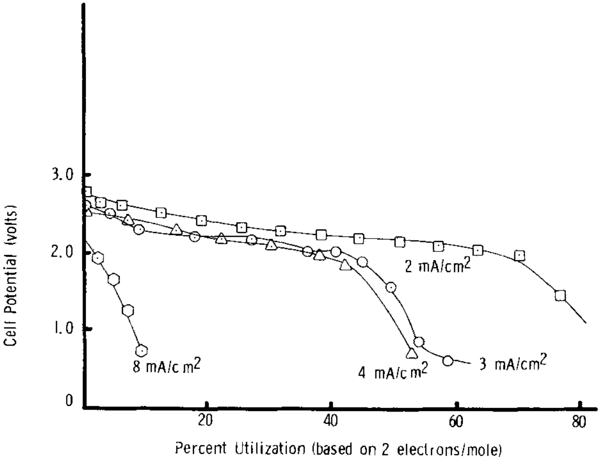

Fig. 2. Discharge characteristics of Li-MoO_3 cells at various current densities. Electrolyte: 1M $LiClO_4$/70% THF-30% 1,2 DME.

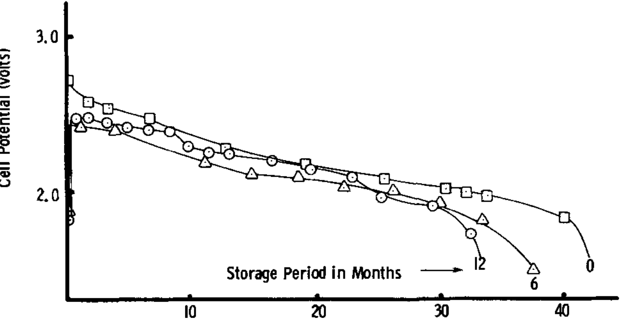

Fig. 3. Discharge characteristics of Li-MoO_3 cells after 6 and 12 months of storage. Electrolyte: 1M $LiClO_4$/PC. Current density: 2 mA/cm^2.

a one year stand. Since the PC used to prepare the electrolyte contained at least 170 ppm water, it may be possible to further reduce storage losses by using an even more highly purified electrolyte. The discharge results in Fig. 3 are for cells stored under argon in sealed Mason jars with several pieces of lithium foil and fresh potassium beside the open cell inside, to act as an oxygen and water vapor getter. It was found that cells stored six months with only a lithium getter showed a 50% greater loss in capacity than cells stored with a potassium getter. Thus it appears that the water concentration must be maintained considerably lower than 170 ppm if storage losses are to be kept to a minimum.

A transient voltage delay occurred during the first minutes of discharge for the Li-MoO_3/PC cells stored 6 and 12 months. For the cell stored 6 months (OCV 2.87V) a minimum voltage of 1.84V was observed after approximately 2 sec of discharge at 2 mA/cm^2. The voltage then recovered to 2.18V after 30 sec and to 2.33V after 1 min. The transient delay effect is most likely due to a thin film formed on the lithium anode and probably could be eliminated by reducing the amount of water and other impurities in the electrolyte and the cathode. Since no voltage minima were observed for cells containing either PC or THF-DME in the electrolyte when the cells were discharged after 45 days' storage, the transient delay effect may be both solvent and time dependent.

An examination of the lithium anodes of the Li-MoO_3 cell which had been stored one year, after the cell had been discharged, revealed a border of black film about 3 mm wide outlining the portion of the lithium anode that was adjacent to the outer edge of the cathode in the assembled cell. The lithium outside this border was bright and untarnished even though it was exposed to the $LiClO_4$/PC electrolyte for one year. It thus appears that the black film was formed by material that diffused out of the cathode during stand. If the film was formed in this way, then the area within the border was probably filled in with film before discharge, and the film was stripped off by the dissolution of lithium during the period when the transient voltage delay was observed. Since no serious attempt, other than vacuum drying at room temperature, was made to purify either the MoO_3 or graphite used to prepare the cathode, the use of more highly purified materials might further reduce the capacity losses during storage.

The exact cause of the large increase in capacity observed for both MoO_3 and CuS cathodes when THF-DME rather than PC was used to prepare electrolyte is of interest for both theoretical and practical reasons if even more effective electrolytes are to be developed. At 2 mA/cm^2, the capacities of Li-MoO_3 cells using $LiClO_4$/PC and $LiClO_4$/THF-DME electrolytes were 32 and 70% of theoretical, respectively, to a 2.00V cutoff. The 120% increase in capacity cannot be ac-

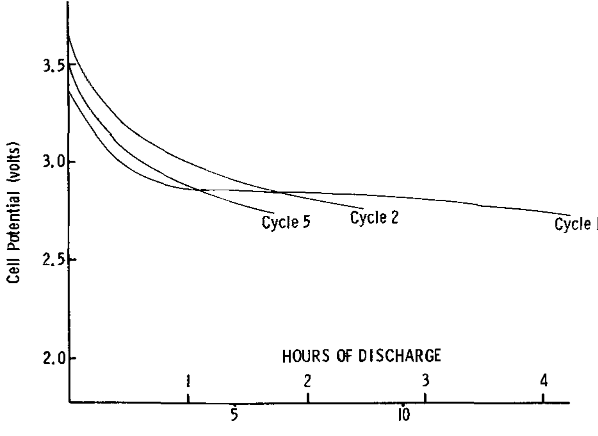

Fig. 4. Discharge characteristics of the Li-MnO_2 cell. Electrolyte: 1M $LiClO_4$/70% THF-30% 1,2 DME. Current density: 2 mA/cm^2.

counted for by the electrical conductance because the 1.0M $LiClO_4$/PC electrolyte [$\kappa = 5.3 \cdot 10^{-3}$ ohm^{-1} cm^{-1} (7) at 25°C] is 34% more conductive than 1.0M $LiClO_4$/70% THF-30% 1,2 DME [$\kappa = 3.8 \cdot 10^{-3}$ ohm^{-1} cm^{-1} (8)]. However, the viscosities of the 1.0M $LiClO_4$ electrolytes at 25°C are 7.08 cp (7) and 0.91 cp (9) for the PC and the THF/DME electrolytes, respectively.

In order to understand the effect of the electrolyte viscosity on the coulombic efficiency of porous cathodes one requires a theoretical model (17, 18). The recently developed model by Bennion and Dunning (10, 19) is probably best suited for this purpose. In their analysis, diffusion and conductance were found to be important factors in the mass transport and conservation equations. The electrolyte viscosity does not appear directly. However, the electrolyte viscosity is related to the diffusion coefficient to a first approximation by the Einstein Stokes equation (11). Thus the superior performance of the THF-DME, compared to the PC electrolyte, can be attributed to increased diffusion of $LiClO_4$ in the pores of the cathode when the THF-DME mixture was used as the solvent.

Cycling behavior.—The cell potentials for a Li-MnO_2 cell with a 1M $LiClO_4$/70% THF-30% 1,2 DME electrolyte during the first, third, and fifth discharges at 2 mA/cm^2 are shown in Fig. 4. The cutoff voltage for discharge was 2.74V and the charging current density was 0.75 mA/cm^2. The ampere-hour charging efficiencies, charging times, and cutoff voltages are summarized in Table I for the first five cycles. The decline in the charging efficiency is probably partially due to electrolyte oxidation during charging at potentials above 4.00V.

The nonaqueous Li-MnO_2 cell was found to resemble the alkaline Zn-MnO_2 cell both in having a similar sloping discharge curve and exhibiting a great decrease in cycle life (12) if discharged below a cutoff voltage about 25% higher than the normal cut-off voltage due to depleted capacity. For example, a Li-MnO_2 cell discharged to a 2.11V cutoff yielded a utilization of only 3.66% on the second cycle to a 2.73V cutoff compared to 8.88% for the cell described in Fig. 4.

On the basis of a comparison with the discharge results for Li-MoO_3, D-size cells, cycle 2 for the Li-MnO_2 cell shown in Fig. 4 would be expected to yield a specific energy of about 34 Whr/lb for a D-size cell. Therefore, the Li-MnO_2 secondary cell compares favorably at this early stage with the 30 to 45 Whr/lb that can be obtained from small silver-zinc cells (12). No attempt has yet been made to optimize the cathode formulation or charging conditions, thus some improvements in the charging efficiency and cycle life may be expected.

Table I. Charging conditions for Li-MnO_2 cell

Charge No.	Charge time (hr)	Charging cutoff (V)	A-hr charging efficiency (%)
1	11.50	4.20	58
2	11.00	3.98	51
3	9.76	3.82	41
4	10.33	4.08	45
5	15.25	4.22	10

Linear sweep voltammetry.—Voltammetric scans are given in Fig. 5 for the oxidation of 1.0M $LiClO_4$/THF and 1.0M $LiClO_4$/70% THF-30% DME using a platinum working electrode. Comparison of the curves shows that the addition of 30% DME to the electrolyte has little effect on its stability to withstand oxidation. The oxidation of the electrolyte does not appear to produce a gaseous product even at potentials over +4.5V with respect to Li/Li^+.

These results suggest that the charging of lithium cells using the $LiClO_4$/THF-DME electrolyte should be stopped once the charging voltage has reached 4.0V or else electrolyte oxidation will reduce cycle life. Since the Li-MnO_2 cell described earlier was charged to a 4.2V cutoff on the first charge, its limited cycle life may have been caused by oxidation of the electrolyte.

A precise determination of the maximum charging voltage is complicated by the difficulty of predicting the behavior of a high surface area carbon electrode using data obtained from voltammetric scans on platinum. In addition to surface area effects, the oxidation overpotential of an electrolyte can be greatly altered by the nature of the sometimes not so inert surface at which the reaction is being studied.

Cyclic voltammetry in the region of +4.3 to −0.2V with respect to Li/Li^+ (scan rate 80 mV sec^{-1}) revealed a reduction peak at about +1.2V for the THF-DME electrolyte which can be attributed to reduction of the oxidized electrolyte. As would be expected if oxidized electrolyte was the reactant, the peak increased as the scan limit was increased from +3.5 to +4.5V. Although the oxidized compounds formed from the electrolyte have not yet been identified, recent work by Dey (13) suggests the direct oxidation of THF to form THF cations. The formation of perchlorate radicals followed by reaction with the solvent (*e.g.*, to form tetramethylene peroxide and chlorate ion) is a possible alternative mechanism which has been found (14, 15) to occur during the electrolysis of $LiClO_4$/acetonitrile.

Conclusion

Lithium cells with MoO_3 cathodes were found to give a much higher specific energy than cells using

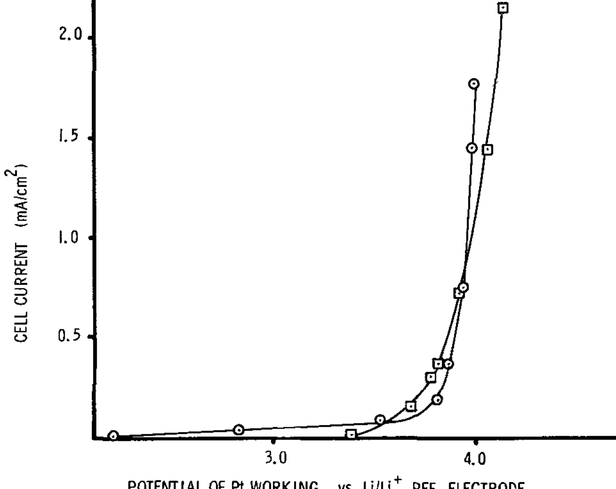

Fig. 5. Oxidation of THF and THF-DME/$LiClO_4$ electrolytes using a Pt working electrode at 25°C. ⊡, 1.0M $LiClO_4$/THF, scan rate 22 mV/sec.; ⊙, 1.0M $LiClO_4$/70% THF-30% 1,2 DME, scan rate 10 mV/sec.

either CuS or MnO_2 cathodes. At 2 mA/cm^2, 70.5% of the theoretical coulombic capacity of MoO_3 was obtained to a 2.00V cutoff for cells using a 1.0M $LiClO_4$/THF-DME electrolyte. Although Li-MnO_3/PC cells that were stored one year showed a 19% loss in coulombic capacity, substantial improvements may be possible if more highly purified materials are used.

The large increase in capacity observed for both MoO_3 and CuS cathodes when THF-DME rather than PC was used to prepare the electrolyte can be attributed to the increased diffusion of $LiClO_4$ in the THF-DME mixture.

Cycling experiments with the Li-MnO_2 cell indicate that transition metal oxides show promise as cathodes for rechargeable batteries. Oxidation reactions of the electrolyte which may occur during charging were investigated by cyclic voltammetry. The results suggest that the cycle life of the Li-MnO_2 cell could be improved if charging is stopped before the voltage reaches 4.0V, to prevent oxidation of the $LiClO_4$/THF-DME electrolyte.

Manuscript submitted June 26, 1973; revised manuscript received Dec. 12, 1973. This was Paper 4 presented at the Miami Beach, Florida, Meeting of the Society, Oct. 8-13, 1972.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1974 JOURNAL. All discussions for the December 1974 Discussion Section should be submitted by Aug. 1, 1974.

Technical Note

Measurement of Current Distribution on Wire

Aladar Tvarusko*,[1]

Engineering Research Center, Western Electric Company, Princeton, New Jersey 08540

The current density distribution is often not uniform even on an equipotential surface, *i.e.*, on a metal electrode of negligible electric resistance. The ohmic resistance of an electrode increases by decreasing its cross section and thus, the surface of these elongated electrodes can become nonequipotential, especially at higher current densities of practical use. The result is a nonuniform current density distribution along the electrode, such as wire (1), thin, narrow, and long metal patterns on printed circuit boards (2), etc., which leads to nonuniform electrodeposit thickness and quality, and compositional change in case of an alloy deposit (3). Another practical consequence of the nonuniform current distribution is the length of the electroplating (electrochemical) cell, *i.e.*, the length of the immersed wire or thin metal pattern. The more nonuniform the current distribution on the wire or thin metal pattern, the shorter the cell should be (the cell length is also affected by the current carrying capability of wire and contacts).

The current density distribution can be theoretically calculated for simple geometries [see references cited in Ref. (1, 2, 4-7)] or obtained from the analysis of the final electrodeposit layer (7) or measured by analog methods (8). These methods are time consuming and do not yield *in situ* current distribution.

This paper describes an experimental setup to measure the current distribution on wire and other elongated electrodes. The efficacy of the setup is illustrated by results obtained on various wires during the electrodeposition of copper and reduction of redox species.

Experimental

The heart of the experimental setup, shown schematically in Fig. 1, is a clip-on milliammeter which measures through a traveling probe the magnetic field existing around the wire carrying the electrolyzing current. The clip-on d-c milliammeter is commercially

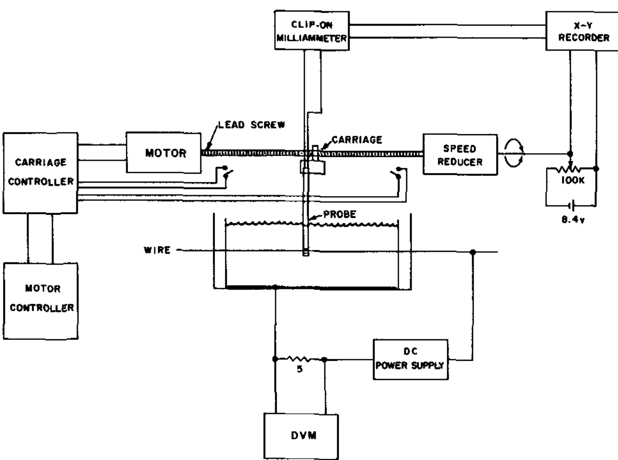

Fig. 1. Schematic of the experimental setup for the measurement of current distribution.

available (Hewlett-Packard Company, Model 428B) and its current range is 0.1 mA to 10A.

The current probe (a second harmonic flux-gate type magnetometer) is usually used in air. In order to prevent its corrosion in various electrolytes, the small current probe with a 4 mm aperture diameter (HP Model 428A-21A) was coated by a thin layer of plastic (*e.g.*, silicone rubber); its jaws were tightly closed. The inside of the aperture was covered only by a thin continuous layer. The other, large current probe with 64 mm aperture (HP Model 3528A) was inserted into a thin polyethylene tube to prevent its contact with the solution; this probe should be used only at larger applied current, I_A values (>50 mA). It should be noted that both probes measure a current which is the average current flowing through the wire within the length of the magnetic core of the probe. Therefore, the narrowest possible probe should be used, which would be advantageous also from viewpoint of hysteresis elimination to be discussed later.

The current distribution along the wire is obtained by moving the current probe parallel to the wire. The current probe is firmly held in the carriage as shown in Fig. 2. The carriage is supported and kept aligned by two stainless steel Thomson rods (59.5 cm long, ½ in. OD) and four stainless steel Thomson ball bushings (Type XA-B1420-SS). The two rods are anchored in the two end bearing blocks which are firmly screwed to mounting plates. The mounting plates rest on the top of the overflow cell (9) and are firmly screwed to the side rails. These features are shown in Fig. 2 and 3. Stainless steel (Type 316) was used for the construction.

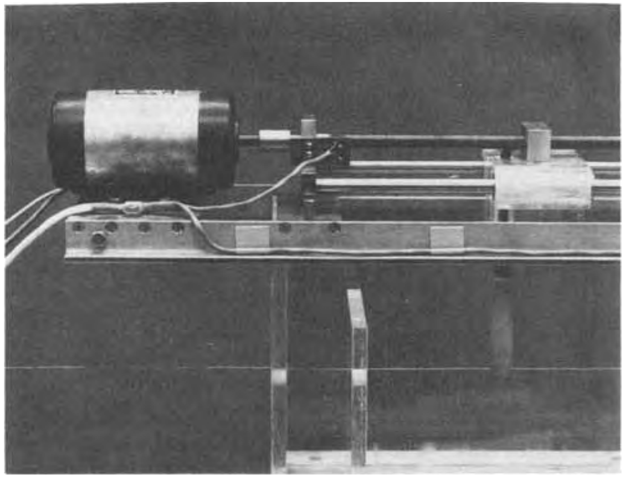

Fig. 2. Partial view of the setup. It shows the current probe in the carriage, aligning rods, lead screw, motor, and a basic switch.

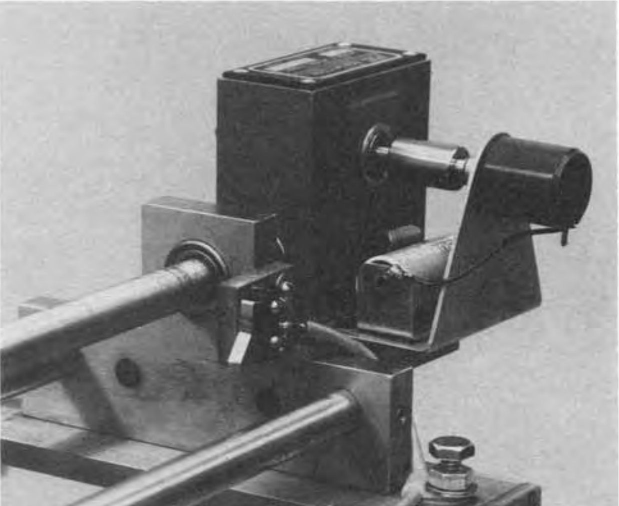

Fig. 3. View of the speed reducer and potentiometer arrangement

The brass feed screw nut is firmly screwed to the top of the carriage which is moved by the ½ in. rotating lead screw (20 threads per inch). The stainless steel lead screw is supported by two bearings (Hoover 77R6) which are mounted in the bearing blocks (Fig. 2, 3). The lead screw is driven through a coupler by a permanent magnet d-c motor-generator (Electro-Craft Corporation, Hopkins, Minnesota, Model E-650 with 80 oz. in. torque) which has two windings on the same armature to drive the motor and generate voltage proportional to the speed, respectively. The motor controller maintains the motor speed constant within a 3-3000 rpm range and provides dynamic braking at shutoff.

A carriage controller is inserted between the motor and its controller. The schematic diagram of the carriage controller is shown in Fig. 4. The carriage controller consists of a power supply for the relays (3PDT, 12V d-c, Potter & Brumfield, KM14D) which (*i*) reverse the voltage to the motor winding (RL1) and from the generator (RL4), and (*ii*) activate (RL2) and deactivate (RL3) the reversing relay (RL1). The signal for the relay action is obtained either from one of the subminiature basic switches (MS1, MS2, right or left side) mounted onto the bearing blocks (Fig. 2, 3) or manually from one of the push button momentary switches (4PDT, RS1, RS2, go right or left).

In automatic mode, the carriage continuously traverses the wire over a distance determined by the position of the two basic switches. The carriage can be stopped in the automatic mode at either end by switching to manual operation (SW3, off) during the last traverse. In manual mode, the carriage always stops at the other end. The carriage can be stopped at any position by interrupting (SW2) the power to the motor.

The rate of carriage traverse depends on the motor speed. Since the motor speed is maintained at a given constant rpm, the traverse rate will be linear and determined by the number of threads per unit length of lead screw.

The position of the current probe can be read off a linear scale placed near the carriage. This is cumbersome and is not suited for recording. A potential signal proportional to the position of the current probe was obtained in the following simple manner. The motor speed is reduced 50:1 by a worm and wheel assembly (PIC Design Corporation, No. DO-7) the input shaft of which is connected to the feed screw through a coupler. The output shaft of the assembly is connected by a coupler to the shaft of a 10-turn-precision wirewound, 100 kohm potentiometer (Fig. 3) which is electrically connected to an 8.4V mercury battery as shown in Fig. 1. The coupler between the

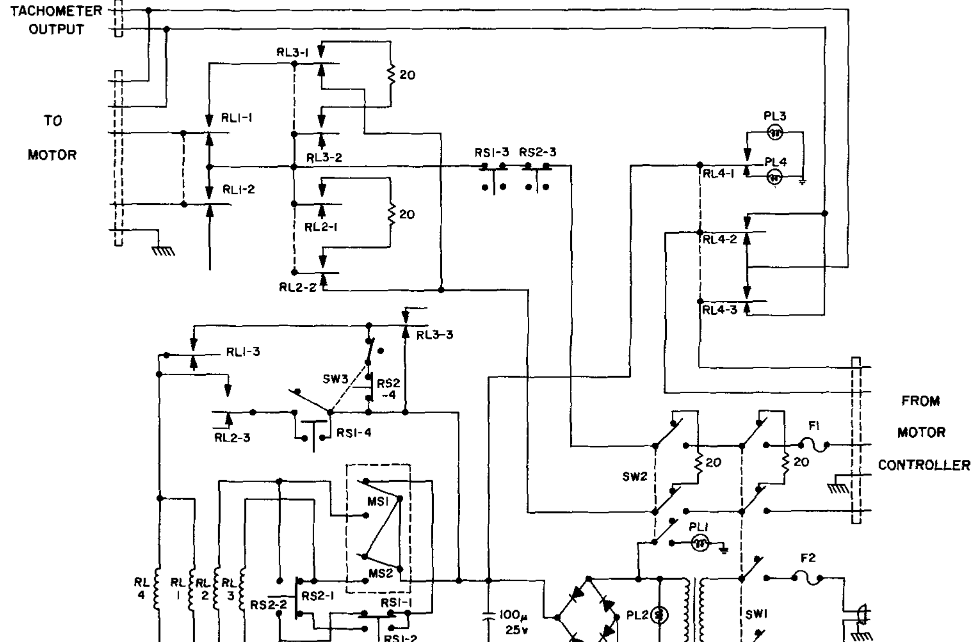

Fig. 4. Schematic diagram of the carriage controller.

worm and wheel assembly and potentiometer is tightly secured after both carriage and potentiometer are in one of their corresponding extreme positions.

Now, we have potential signals proportional to the position of the current probe and to the magnitude of the current flowing at that position. These signals can be easily recorded by an X-Y recorder (Varian Associates, Model F-80A) and thus, we obtain the current distribution curves automatically. The current can be easily differentiated by electronic means and thus, the local current density, *i.e.*, local reaction rate distribution can be obtained automatically on another X-Y recorder.

The electrolyzing current is supplied by a constant current power supply (Electronic Measurements, Model C 613). The magnitude of the applied current, I_A was measured as a voltage drop on a 5 ohm, precision resistor by a digital voltmeter (Fluke, 8100A).

Clean wires of various metals and diameters were used with a U-shaped, copper or stainless steel sheet anode. The electrodeposition of copper was studied in $CuSO_4$-H_2SO_4 solutions of various concentrations. The reduction of ferricyanide was investigated in a fresh, 0.04 equimolar solution of potassium ferro- and ferricyanide in 1M NaOH. The solution was not deaerated and was used in the presence of light. The measurements were made at 24° ± 2°C.

Results and Discussion

The clip-on milliammeter probe is usually used in air to measure direct current flowing in a wire contacted at two points. The current measured along this wire should not change with the position of current probe. This is shown in Fig. 5 to be the case in both air and aqueous electrolytic solution; the current along such a wire remained constant in all the solutions tested. This means that the clip-on milliammeter's reading is not influenced by the ions present in large concentration around the wire and thus, this instrument can be used for the measurement of current distribution in solutions.

Figure 5 also shows the current distribution along a copper wire of 0.5 mm diameter during the electrodeposition of copper from acidified $CuSO_4$ solution at

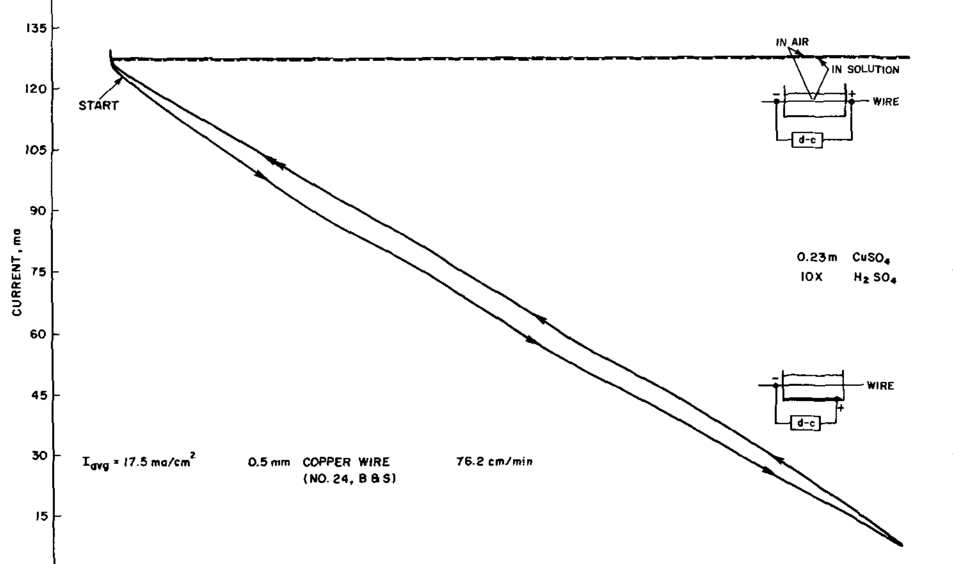

Fig. 5. Current distribution on a 0.51 mm diameter copper wire in the absence and presence of copper electrodeposition from acidified $CuSO_4$ solution. The current probe traveled from left to right and back.

17.5 mA/cm² average current density, I_{avg} which is the applied current divided by the surface area of the wire exposed to the electrolyte in the cell. It can be seen that (*i*) the magnitude of the current decreases with increasing distance from the point of contact, (*ii*) the rate of decrease varies somewhat along the wire, (*iii*) a hysteresis is present, *i.e.*, the magnitude of the current depends on the direction of the carriage sweep and is lower when the probe travels away from the contact point than toward it (indicated by the double arrow), (*iv*) the difference between the two curves is the greatest in the middle and decreases toward both ends, and (*v*) the current is not zero at the point of carriage reverse.

Before discussing the aforementioned observations, let us see the current distribution curves at other average current densities. Figure 6 shows the current distribution at low I_{avg} values, *i.e.*, up to *ca.* 30% of the average limiting current density, $\bar{I}_L$. In addition to the aforementioned observations, it can be seen that the magnitude of the hysteresis increases with increasing current density. The current measured at the turnaround point (Fig. 6) is 4-5% of the current measured near the wire contact. At this point, the current probe is 3-5 mm from the end wall and to a large extent, the rest current is due to the current flowing in the wire toward its end.

Figure 7 shows the current distribution at high I_{avg} values which are near and above the $\bar{I}_L$; H_2 evolves profusely along the entire wire length at $I_{avg} > 100$ mA/cm². The current distribution curves are basically similar to the previously mentioned ones. The deviation between the two curves obtained during the carriage traverse, *i.e.*, the hysteresis decreases with increasing I_{avg} values above $\bar{I}_L$. These and other values of deviations, expressed in percentage, are shown in Fig. 8 for an arbitrarily chosen point on the wire (20 cm). It can be clearly seen that the percentage of the deviation increases very rapidly with increasing average current density. It peaks out near the indicated average limiting current density above which it starts to decrease with increasing I_{avg} values. This behavior was also observed on other wires in all the investigated solutions and concentrations using both current

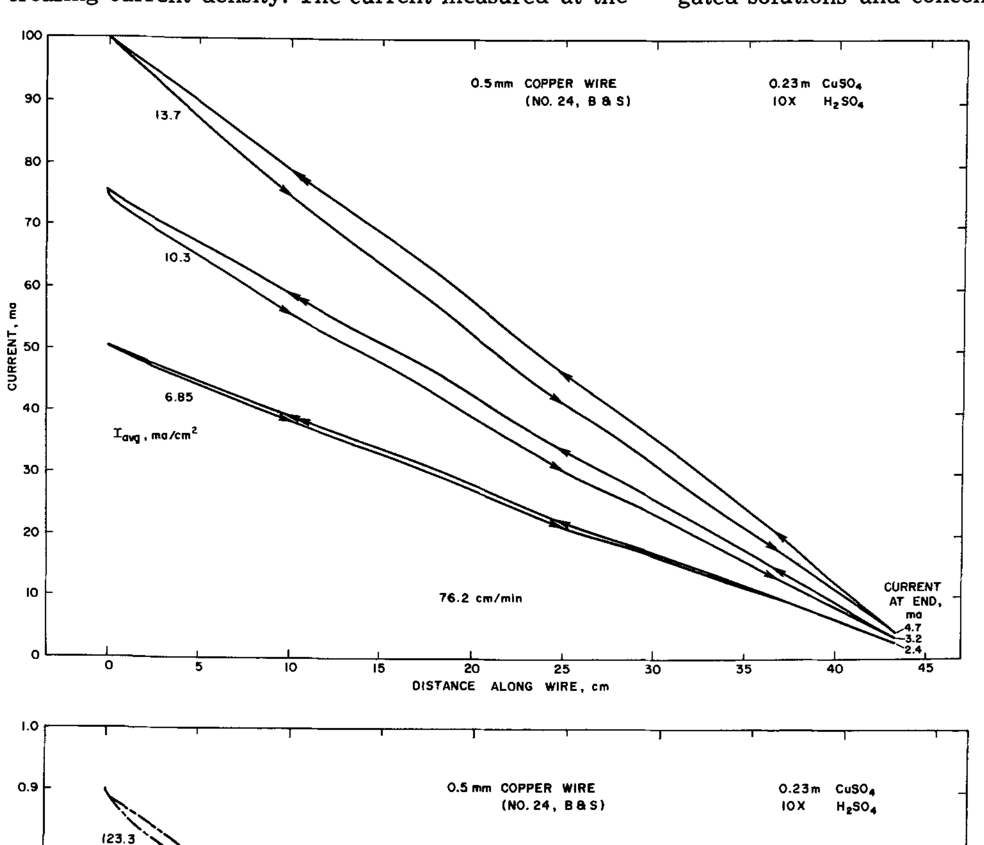

Fig. 6. Current distribution on a 0.51 mm diameter copper wire at low cathodic average current densities.

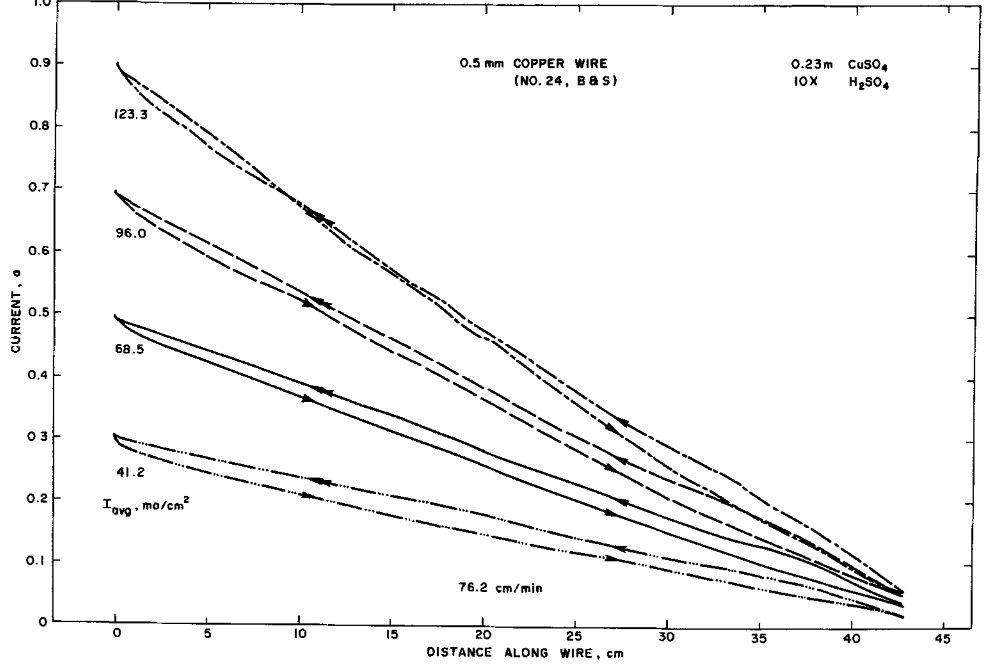

Fig. 7. Current distribution on a 0.51 mm diameter copper wire at cathodic average current densities which are near or above the average limiting current density.

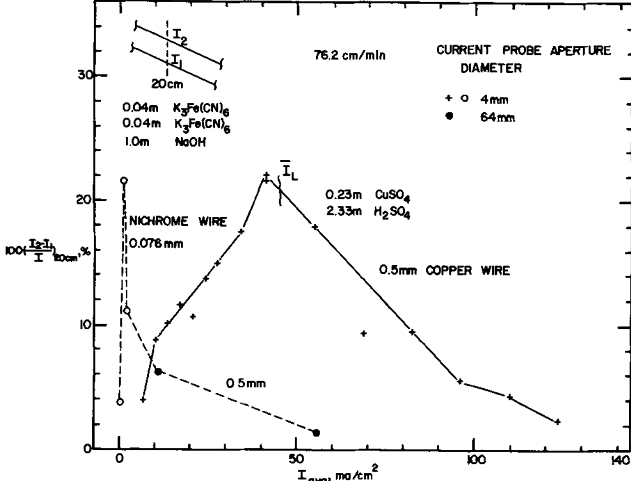

Fig. 8. Deviation between the upper and lower current distribution curves at an arbitrarily chosen point on the wire as a function of cathodic average current density in two solutions and three wires. Two current probes of different apertures were used.

probes. It should be noted that the deviation markedly decreased on a very thin Nichrome wire already at an I_{avg} value of 2 mA/cm^2 and H_2 evolved on this highly resistive wire near its contact (its resistance is 250X that of copper wire used). This means that the hysteresis decreases even if the limiting current density is reached only over a small portion of the wire.

It is obvious from the aforementioned results that the hysteresis is not a percentage error due to the intensity of the current flowing within the wire.

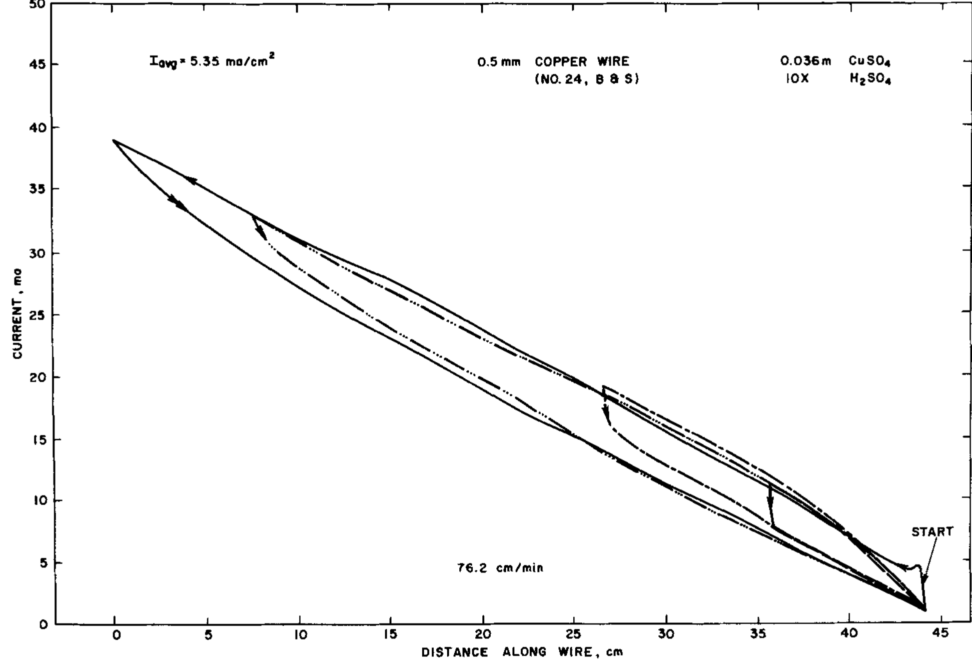
The increase of the deviation up to the average limiting current density and its subsequent decrease seem to point to an enhancement of the mass transfer by the fluid flow due to the moving current probe the influence of which decreases with increasing H_2 evolution. An additional evidence for the mass transfer effect can be seen in Fig. 9. The current decreases toward the lower curve when the carriage is stopped anywhere along the wire. Upon restarting the probe in the opposite direction, *i.e.*, toward the starting point, the current decreases and the trace becomes practically the same as that of the initial full cycle.

A comparison of Fig. 9 with Fig. 5-7 reveals that the hysteresis curve is not affected by the starting point of the current probe traverse: the upper curve of the hysteresis loop is always obtained during the current probe's travel toward the wire contact and the lower one while the probe moves away from it. These results seem to indicate that the mass transfer rate is increased within and behind the moving small current probe (4 mm diameter) due to the increased fluid velocity and wake, respectively. The result is that less electronic current flows through the current probe during its motion away from the contact. On the other hand, during the probe's motion toward the contact point more electronic current will flow through the probe to accommodate the larger mass transfer rate within and behind the probe.

Table I. Magnitude of hysteresis at various speeds of probe traverse (4 mm aperture)

Speed, cm/min	$100\left(\frac{I_2 - I_1}{I_1}\right)_{20\ cm}$, %
25.4	2.8
50.8	3.4
102	5.2
127	7.8
190	13
374	12

The aforedescribed results were obtained at one carriage speed, 76.2 cm/min. In view of the results, it is expected that the probe (carriage) traverse speed will be an important factor in determining the magnitude of the hysteresis. Table I clearly shows this influence for a 0.5 mm diameter copper wire in 0.23M $CuSO_4$-10X H_2SO_4 solution at I_{avg} = 10 mA/cm^2 (0.22 $\bar{I}_L$). The deviation increased with increasing probe speed up to 190 cm/min above which it remained practically constant. The rate of increase of the deviation doubles above approximately 90 cm/min which seems to give the impression of the presence of laminar or turbulent fluid flow around the wire, respectively. The probe speed should be kept small to minimize the magnitude of the hysteresis. On the other hand, a higher probe speed is desired to shorten the duration of the experiment which is important especially in experiments where the resistance of the substrate changes due to the electrodeposited metal layer or other processes taking place. The probe speed (76.2 cm/min) chosen for these experiments represents a compromise between these two criteria.



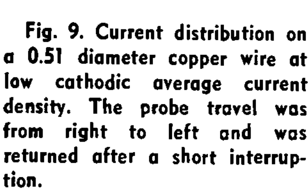


Fig. 9. Current distribution on a 0.51 diameter copper wire at low cathodic average current density. The probe travel was from right to left and was returned after a short interruption.

The presence of hysteresis is a limitation of this technique which measures the current distribution *in situ* by measuring the magnetic field existing around elongated electrodes, such as wire, thin, narrow, and long printed circuit patterns. The magnitude of the hysteresis can be markedly decreased (to *ca.* maximum 10% near the limiting current density) by making the measurement at slow probe traverse speed. Further improvement can be obtained by using probes of larger apertures which are limited, however, to higher average current values. The current probes commercially available are really designed to measure current flowing through a conductor in air at a certain position. In electrochemical systems, the current distribution on the electrode in solution is of interest and therefore, a narrow, *ca.* 1 cm diameter current probe should be used which is designed on the basis of hydrodynamic considerations; it could greatly improve or completely eliminate the undesirable hysteresis. Unfortunately, such a probe was not available for evaluation in this first attempt to measure the current distribution *in situ*.

Acknowledgments

The author wishes to thank Mr. W. E. Wilson, Jr. for the construction of the carriage controller and his valuable assistance in the preliminary experiments.

Brief Communications

A Preliminary Investigation of High Temperature Lithium/Iron Sulfide Secondary Cells

D. R. Vissers, Z. Tomczuk, and R. K. Steunenberg*

Argonne National Laboratory, Chemical Engineering Division, Argonne, Illinois 60439

High-specific-energy (>200 W-hr/kg) lithium/sulfur cells are under development for off-peak energy storage in electric utility networks and for electric automobiles (1-5). Such cells have a molten-salt electrolyte such as the LiCl-KCl eutectic (mp, 352°C) and operate at temperatures between approximately 375° and 425°C. When sulfur alone is used as the active material in the positive electrode, it tends to escape from the electrode both through vaporization and through the solubility of certain sulfur-bearing species, *e.g.*, S_2^-, S_2^{2-} (6-10) in the electrolyte. Although both of these effects can be suppressed by additives such as arsenic or selenium (1-5), which lower the activity of the sulfur, it is questionable whether they are sufficiently effective to permit long cell lifetimes (>1000 hr). The sulfur activity can be decreased further by the use of sulfur compounds rather than sulfur, in the positive electrode. Iron sulfides were investigated in this study on the premise that their free energies of formation are sufficient to eliminate sulfur losses by vaporization or solubility, but not large enough to cause an undue decrease in the cell voltage. Calculated values for the free energies of formation of FeS and FeS_2 at 400°C are 24.1 and 35.1 kcal/mole, respectively, based on data in the literature (11, 12). From a practical standpoint, iron pyrite (FeS_2), in particular, has the desirable characteristics of reasonably low equivalent weight, low cost, abundance, and lack of toxicity.

Experimental

Six cells of the general design shown in Fig. 1 were operated during the course of this investigation. The negative electrode in all of the cells consisted of a disk of Type 302 stainless steel Feltmetal[1] (90% porosity, 27 μm avg pore diam) that was filled with ~1g of liquid lithium. The 59 mole per cent (m/o) LiCl-41 m/o KCl eutectic was used as the electrolyte. The LiCl-KCl eutectic was obtained from the Anderson Physics Laboratories, Incorporated, Champaign, Illinois, where it was prepared and purified by the method outlined by Laitinen, Tischer, and Roe (13). Commercial-grade

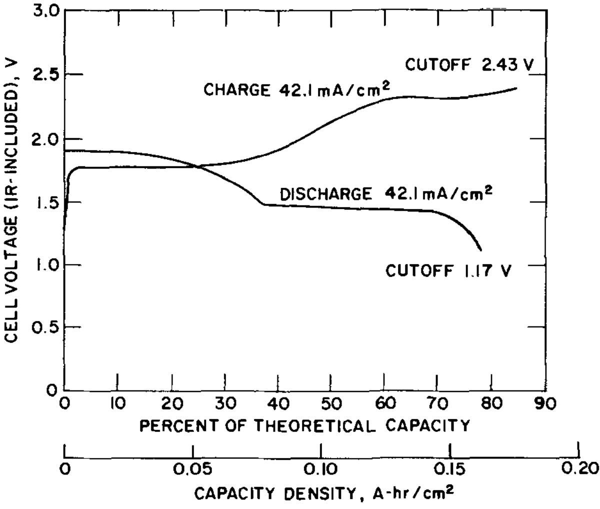

Fig. 3. Typical charge and discharge data for a Li/FeS_2 cell

FeS_2 [2] (iron pyrite) from Sargent-Welch was the active material in the positive electrode in five of the cells. In the other cell, the active material was a mixture of FeS and Li_2S. The Li_2S, from Foote Mineral, had a stated purity of 97% and the FeS, from Fisher Scientific, was of unspecified purity.

The cells were unsealed and were operated in a furnace well located in the floor of a high-purity (~3 ppm O_2, ~1 ppm H_2O) helium-atmosphere glove box. Four of the Li/FeS_2 cells had a positive electrode of the design shown in Fig. 1, in which the active material was contained in an ATJ graphite cup and was confined to the cup by a PG-60 porous graphite diffusion barrier, 0.63 cm thick. In the fifth Li/FeS_2 cell and in the sixth cell, which was a Li/FeS cell, the active material was contained in a molybdenum crucible that was covered with expanded molybdenum mesh[3] (~0.2 mm thick, ~50 openings/cm²), which served as a diffusion barrier. The geometric surface area of all the positive electrodes was ~5 cm².

Results and Discussion

Short-time voltage *vs.* current density data[4] that were obtained for a fully charged Li/FeS_2 cell over a temperature range of 383°-442°C are presented in Fig. 2. The results show no significant effect of temperature on the cell performance. The open-circuit voltage averaged 2.06V and the short-circuit current density was approximately 1000 mA/cm². The maximum power density was about 0.5 W/cm² and the cell had a resistance of 0.43 ohm. The relatively high resistance, which was not unexpected, should be reduced markedly by appropriate modifications of the cell design.

Typical charge and discharge data for a Li/FeS_2 cell are given in Fig. 3, where the cell voltage (*IR*-included) is shown as a function of capacity density and per cent of theoretical capacity. The *IR* voltage during both charge and discharge was about 0.1V. The theoretical capacity is based on the over-all reaction

$$4Li + FeS_2 \rightarrow 2Li_2S + Fe \quad [1]$$

The charge and discharge curves each show two plateaus, which suggest that the cell reaction may be occurring as a two-step process, possibly involving FeS as an intermediate. At 400°C the emf's for the Li/FeS_2 and Li/FeS couples are estimated to be 1.96 and 1.66V, respectively. These emf values are based on free-energy data from the literature (11, 12, 14) and are in fairly good agreement with the observed *IR*-free voltage plateaus of about 2.05 and 1.6V, respectively. Although the two plateaus may suggest FeS as a simple intermediate, metallographic examination of FeS_2 electrodes taken from cells that had been cycled several times and whose operation had been terminated at various stages of charge, revealed, in addition to the apparent phases FeS_2 and FeS, the presence of several additional phases which are complex and unidentified at this time. These phases appear to be complex compounds formed by the interaction of Li_2S with iron-sulfur compounds.

One experimental cell was operated over 28 discharge cycles (>200 hr) with no loss in capacity and no observable sulfur loss. With an *IR*-free charge cutoff of 2.15V, the average FeS_2 utilization, based on the reaction described by Eq. [1], was 49%. This behavior is generally consistent with the charge curve shown in Fig. 3. This value increased to an average of 82% when the charge cutoff was raised to 2.43V. However, the inability to convert the active material completely to FeS_2 suggests that it may be possible to achieve near theoretical capacities with the Li/FeS_2 cell if a higher charge cutoff potential is employed, and if sufficiently effective current collection is provided throughout the FeS_2 electrode to produce a more uniform reaction product when the cell is charged.

Operating characteristics of the Li/FeS cell were initially investigated by cycling, using an *IR*-free charge cutoff of 2.15V. The cell was operated for 14 days (28 cycles) at current densities of 30-40 mA/cm² with no observable loss in capacity. The average FeS utilization based on the reaction described by Eq. [2] was 87%, with an average coulombic efficiency of 89%

$$FeS + 2Li \rightarrow Fe + Li_2S \quad [2]$$

The open-circuit voltage remained nearly steady at 1.7V during charge and 1.6V during discharge. The open-circuit potential of 1.7V corresponds very closely to the calculated emf of 1.66V for a Li/FeS cell.

Conclusions

1. The $Li/LiCl\text{-}KCl/FeS_2$ system can be operated as a secondary cell at temperatures of about 380°-440°C for periods of at least 200 hr with no significant deterioration in electrical performance.

2. The capacities of the Li/FeS_2 cells were in the vicinity of 80% of the theoretical value based on the oxidation of four lithium atoms per FeS_2 molecule during discharge.

[2] This material was found to contain about 10 wt % SiO_2, which was removed by a sink-float separation with tetrabromoethane.
[3] Obtained from Climax-Molybdenum Company of Michigan.
[4] Individual measurements made by closing the circuit momentarily for a period of 10-15 sec.

3. The coulombic efficiencies ranged generally between 89 and 100%.
4. The open-circuit voltage was about 2.06V, with a short-circuit current density of ~1 A/cm² for the fully charged Li/FeS_2 cell.
5. The Li/FeS_2 cell performance appears to be essentially unaffected by changes in temperature between about 380° and 440°C.
6. The cells that were tested had a relatively high internal resistance, (0.3-0.5 ohm); however, no attempt was made to minimize the resistance by improving the cell design through the use of current collectors, favorable geometry, etc.
7. The Li/LiCl-KCl/FeS system can also be operated as a secondary cell, with the capacities corresponding roughly to the oxidation of two lithium atoms per FeS molecule during discharge.
8. The chemistry of the Li/FeS_2 cell reactions is not yet well characterized.

On the Ultraviolet Inhibition of Electroless Plating on Glass

M. Schlesinger

Department of Physics, University of Windsor, Windsor, Ontario, Canada

The process for metal patterning of dielectric substrates by u.v. light exposure and electroless plating has been discussed by members of our research group recently (1). It was pointed out there that u.v. inhibition is possible even after the activation ($PdCl_2/HCl$) bath. This we took as an indication that the simplistic redox reaction (2)

$$Sn^{+2} + Pd^{+2} \rightarrow Sn^{+4} + Pd^{o}$$

was clearly not enough to explain the chemistry of the palladium bath (3).

Since the publication of that paper we became even more interested in u.v. patterning of dielectric substrates after activation. This is so since we have found that the image definition of the photomask is much better if u.v. is applied at this stage.

The purpose of the present note is to report about the possibility of obtaining photoselective metal deposition, not only in the form of positive imaging, *i.e.*, generation of the replica of the photomask, but also in the form of negative imaging.[1]

Specifically, we have found that if u.v. light is applied after activation, but before the premetallizing rinse, positive imaging results. If, on the other hand, u.v. is applied after the premetallizing rinse a negative imaging results. A summary of the effect of u.v. light at various stages is shown schematically as follows:

S	→	R	→	A	→	R	→	M
	↑		↑		↑		↑	
	no image		positive (4)		positive (1)		negative[1]	

where S stands for the $SnCl_2/HCl$ bath, R stands for a D.I. water rinse, A stands for the $PdCl_2/HCl$ bath, and M stands for the Cu, or Ni or Co metallizing baths.

As an extension of our previous findings, we have found now that under the right conditions the growth of Cu can be also inhibited by u.v. irradiation after activation. These conditions relate mainly to rinse times between sensitization and activation and between activation and metallization.

The experiments referred to in the present note were carried out under conditions similar to those described in our previous work [Ref. (1)] except that deposition was made on glass and also that rinse times were shortened to 15 sec.

A detailed study of the foregoing effects is underway in our laboratory. This study includes the proper identification of the chemical processes accompanying the sensitization and activation steps in the conventional electroless systems.

In this connection it should be pointed out that u.v. is ineffective in the case of the catalyzing ($PdCl_2/SnCl_2/HCl$) accelerating (HCl or NaOH and similar) electroless systems.

Acknowledgment

Characterization of Thermally Grown SiO_2 Surfaces by Contact Angle Measurements

R. G. Frieser*

IBM System Products Division, East Fishkill Facility, Hopewell Junction, New York 12533

ABSTRACT

This paper discusses recent advances in the study of solid surfaces by contact angle measurements which appeared promising in developing a technique to characterize different types of amorphous or polycrystalline metal and oxide surfaces. The extent to which contact angle measurements and spreading-pressure values can be used to characterize various silica surfaces is explored. A practical scheme is offered using water and an organic solvent to characterize various silica surfaces in a simple and nondestructive manner.

To study photoresist-substrate interactions successfully, it was considered desirable to first develop a scheme for characterizing the substrate surface itself. Techniques to study heterogeneous and amorphous surfaces are few. Most techniques have been developed for single-crystal studies, clearly not applicable here. Infrared and ellipsometric techniques were briefly evaluated and dropped because such techniques "see" too much of the bulk, whereas our interest is the surface proper. Recent advances in the study of surfaces by contact angle measurements, however, have made this latter technique promising (1, 2). Surface characterization by contact angle techniques usually have been avoided because they can lead to erroneous results for absolute surface energies. The difficulty, however, does not lie with the technique, or theory, but with the difficulty of obtaining pure surfaces.

To define a "clean surface" outside a very hard vacuum is actually impossible. Because this sudy is concerned with surfaces under normal conditions, reproducibility of surfaces rather than absolute "cleanliness" was chosen as the criterion. This means that normal gas absorption of water vapors from the atmosphere was ignored. Thermally grown silicon dioxide was chosen as a substrate, because this surface is more reproducible than any of several other possible choices.

Surface Tension of Liquids

Several empirical attempts have been made by Zisman (3), Good and Girifalco (4) and others to derive an expression for the interfacial tension of two immiscible liquids from the surface tension of the liquids themselves. It was demonstrated by Fowkes (1) that the surface tension of a liquid is the sum of two terms, one due to dispersion forces only, and the second due to hydrogen bonding (in the case of water, for instance) or to metallic bond (in the case of mercury). For nonpolar liquids, such as saturated aliphatics, only dispersion forces are active. If we denote the surface tensions by γ and that portion of the surface tension due to dispersion forces by γ^d it follows that for saturated aliphatics

$$\gamma_{al} = \gamma^d{}_{al}$$

for water

$$\gamma H_2O = \gamma^d{}_{H_2O} + \gamma^{H^+}{}_{H_2O} \quad [1]$$

for mercury

$$\gamma Hg = \gamma^d{}_{Hg} + \gamma^M{}_{Hg}$$

Fowkes then postulated that the interfacial tension between two liquids is

$$\gamma_{H_2O/Hg} = \gamma_{H_2O} + \gamma_{Hg} - 2\sqrt{\gamma^d{}_{H_2O} \cdot \gamma^d{}_{Hg}} \quad [2]$$

This relationship was tested by measuring the interfacial tension between water or mercury and a series of saturated aliphatics, and γ^d's for both water (21.8 $\pm$ 0.7 dynes/cm) and mercury (200 $\pm$ 7 dynes/cm) were obtained. These two values then were used to calculate the interfacial tension of water and mercury. Fowkes (2) obtained 424.8 dynes/cm, which agrees well with the experimental value of 426-427 dynes/cm. Therefore, the original assumption seems justified. Furthermore, Eq. [2] was derived by Fowkes (1) from a purely geometrical model. He considered the exchange of molecules at a liquid-liquid interface where the major forces between the two molecules are dispersion forces and arrived at Eq. [2]. This is the same equation as previously proposed by others except for a factor before the square root term, which Fowkes maintains is equal to one. Since this relationship can be derived from a physical model it can be claimed to have a theoretical basis as well as an empirical one.

The Young equation relates the contact angle to the surface and interfacial tensions of two immiscible liquids (Fig. 1). Combining Eq. [2] with the Young equation, Fowkes obtained the following expression for the contact angle of a liquid (l) on a solid (s)

$$\cos\theta = 2\frac{\sqrt{\gamma^d{}_s\gamma^d{}_l}}{\gamma_l} - 1 - \frac{\pi_e}{\gamma_l} \quad [3]$$

where γ and γ^d have the same meaning noted earlier.

In Eq. [3], π_e is the equilibrium spreading pressure of adsorbed vapor on the solid surface, or, in other words, the lowering of the surface energy of a solid due to a very thin film or vapor of the same liquid as that forming the contact angle.

* Electrochemical Society Active Member.

Key words: SiO_2 surfaces, contact angle measurements, SiO_2 surface contamination.

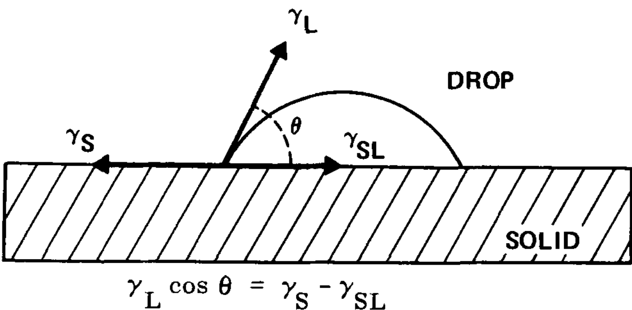

Fig. 1. In the Young equation θ is the contact angle between the liquid and the solid.

There has been some contention that the Young equation is not thermodynamically valid in the first place (5). While the surface tensions and energy can be equated for liquids, this is not valid for solids in general. However, Fowkes stated that, since Eq. [3] can be used to calculate contact angles from independently obtained thermodynamic measurements of the surface tensions and pressure, by Eq. [3] the contact angle, too, must be a true thermodynamic quantity. Therefore the Young equations should be valid (2). Furthermore, Swalin (6) pointed out that glasses like amorphous silica are liquids thus one might equate the surface energy with the surface tensions, which for crystallized solids would not be true.

In earlier publications (1, 2), Fowkes expressed the opinion that spreading pressures could be ignored if the contact angle is greater than zero. It is obvious, therefore, that in such a situation the contact angle measurement of an appropriate liquid on the surface in question should yield the dispersion force contribution of the surface energy of the solid, when plotting $\cos\theta$ *vs.* $\sqrt{\gamma^d_l}/\gamma_l$. Using Zisman's data (3), Fowkes has shown that this indeed is true for many low-energy liquids on low-energy solids (2). In more recent work (7), Fowkes has qualified this generalization, a position our present study will support. The equilibrium spreading pressure must be taken into account when liquids, especially polar liquids, interact with high-energy surfaces such as oxides. Making then a single contact angle measurement with appropriate liquids on the surface and knowing the surface energies of the liquids (plus the π_e), the particular surface can readily be characterized.

An earlier attempt to characterize the surfaces of solids by contact angle measurement was made by Zisman and co-workers (8). Their approach was based on the concept of the "critical surface tension" of a solid. This critical surface tension is an extrapolated value on a Zisman plot for a surface tension when the cosine of the contact angle is one; *i.e.*, under complete wetting conditions. A Zisman plot can be obtained by plotting the cosines of contact angles that a series of homologous liquids makes with a particular solid, and then extending this line (presumably a straight line) to $\cos\theta = 1$. While this approach is phenomenologically valid in some cases, it was not followed here for the following reasons: (*i*) It has no theoretical basis. (*ii*) In many cases, a Zisman plot is not a straight line, not even for a homologous series of liquids on a given solid, but forms a range, often curves toward lower cosine θ values. Thus, even phenomenologically, this approach does not seem justified (9).

An improvement of the Zisman plot was obtained by Good and Girifalco (4). These investigators plotted the cosine of the contact angle that a liquid made with a particular surface against the reciprocal of the square root of the surface tension. This gave them a straight line that could be unequivocally interpreted when extrapolated to $\cos\theta = 1$ as the critical surface tension. While it has just as little theoretical justification as the Zisman plot, it should be pointed out that for liquids where γ^d_l is equal to γ_l and $\pi_e = 0$, the Good-Girifalco plot is a special case of the Fowkes plot. It is therefore obvious that Fowkes' approach is not only more general but has the virtue of having a theoretical justification.

Experimental

Specimens.—Silicon wafers (10-25 ohm-cm, p type, [100]) were oxidized at 1000°C by a dry, wet, dry oxygen process in a tube furnace. Oxide film thicknesses employed were between 2000 and 3000Å. The thickness variations ranged from 4% from front to back to 10% from top to bottom of the wafer. Oxide thickness variations were determined by ellipsometric measurements. Some of these surfaces then were hydrated by boiling in deionized water (12-14 megohms). Water distilled from a potassium permanganate solution was used to measure water contact angles. The organic solvents were purified both by distillation and by passing through an appropriate Al_2O_3 absorption column. The purity of all the liquids was checked by measuring density, index of refraction, and surface tensions (and interfacial tensions between water and organics) with an automatic Fisher Tensiomat and comparing these values with those in the literature. The liquids were dispensed from a micropipette capable of delivering a drop of 0.01 mliter ± 0.5%.

Measurements.—The contact angle measurements were made on a Rame-Hart contact angle goniometer. Three Polaroid pictures were taken of each drop at equilibrium, *i.e.*, the point the drop reached as soon as it stopped spreading. The contact angles were then determined by a conventional geometric technique. This technique proved the most reliable in a trial experiment using two investigators and gave the best precision (standard deviation ±2°). Other techniques for measuring contact angles which were evaluated but not used were based on reading the position of the cross hairs in the goniometer eyepiece (which proved to be the least reliable technique), cross mirrors, and tangential mirrors. All measurements of the contact angle and the surface tensions were made in laminar flow hoods of class 100 at 24° ± 2°C and 30% relative humidity.

To check out this technique, the γ^d_s's of polyethylene and Teflon were derived using a series of organic liquids and Eq. [4] (ignoring the π_e term). Our results agreed within 5% of the literature values and thus the technique was considered adequate.

Contact angle vs. time.—Due to evaporation, the height of the drop forming the contact angle changed with time, but the diameter of the drop did not, especially for water. Since our technique of measuring the contact angle depended on the assumption that the drop is a "perfect" sphere, loss of drop height would have resulted in invalid data. After some experimentation in vapor saturated and unsaturated goniometer chambers, especially with the organic solvents, it was found undesirable to measure the contact angle of a liquid on a thin film of its own vapor. It was therefore decided not to measure contact angles in a saturated atmosphere. In general, errors due to evaporation were less severe (10-20% in 3 min) than those due to spreading (100% in 2 min) and could be avoided by taking a picture at the very moment the drop stopped spreading. As soon as the drop stopped spreading (usually within 1 or 2 sec after the drop breaks loose from the pipette), the picture was taken. With this technique, the repeatability of contact angle measurements on any given surface was $< \pm 2°$, which is usually accepted as the best precision possible with any goniometer. The precision of contact angle measurements on comparable surfaces was ±5°.

Contact angle vs. size of drop.—An almost 50% change in the contact angle as a function of drop size

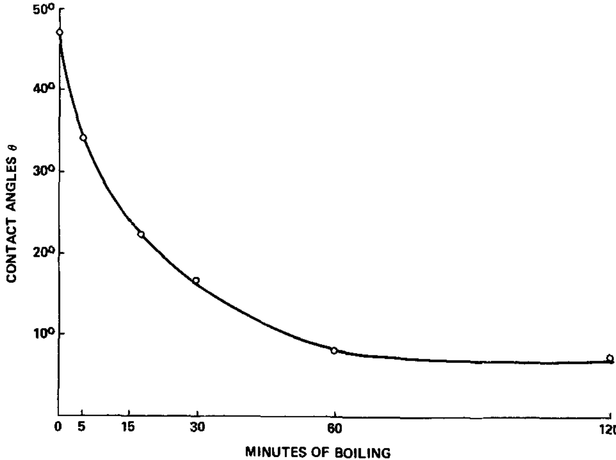

Fig. 2. Water contact angles on boiled thermal SiO_2

(3-8 mm diameters) has been reported (10). Since the drop diameter of water on thermally grown silica used in this study was small, because of the geometry of our instrument and its optics, 25 measurements were made, ranging in drop size from 0.6 to 3.0 mm. While there was some scatter, the average contact angle of these measurements was 38.2° ± 2°. This indicates that in the range below 3 mm diameter, the contact angle was not dependent on the drop size or on the volume. Thus, in this study, the drop size used turned out to be a volume of 2-3 × 10^{-5} ml for water at 25°. On a silica surface this corresponds to a drop having a diameter of 1.2-1.8 mm.

Results

Characterization of various silica surfaces.—For the purposes of this investigation three types of silica surfaces were differentiated. The surfaces were classified according to their wetting behavior toward water and common organic liquids. For convenience we called them "hydrophobic," "hydrophilic," and "organophilic" surfaces. The hydrophobic surface was achieved when the original oxide surface was removed from the furnace after the oxide was grown at 1000°C in an oxygen atmosphere. The hydrophilic surface was obtained when the hydrophobic surface was boiled in deionized water. Figure 2 shows the decrease in the contact angle of a thermally grown SiO_2 surface as a function of hydration in boiling deionized water. Beyond 1 hr of boiling the contact angle changes very little, but for practical reasons ½ hr was chosen as our standard time of hydration for subsequent work. At this stage of the experiment only gross differences in the contact angles were of interest. Organophilic surfaces were obtained by immersing the high-temperature SiO_2 surface in trichloroethylene and then drying the surface in a stream of filtered nitrogen.

Contact angles of a series of organic solvents on the various oxide surfaces were examined for their suitability to differentiate these surfaces. Both n-dodecane and n-decane spread too rapidly on SiO_2 surfaces to be useful for differentiation.

The solvents used and the resulting data are summarized in Table I. The contact angles in Table I represent the average of at least three different drops per

Table I. Contact angles on various silica surfaces

Liquids	Contact angle θ: Oxidized silicon 1000°C	Hydrated silica	Organic contamination on silica surfaces
n-Hexadecane	13° ± 1°	19° ± 1°	5° ± 1°
n-Decane	<1°	<1°	<1°
Decalin	7° ± 1°	15° ± 1°	14° ± 1°
α-Bromonaphthalene	18° ± 1°	22° ± 2°	22° ± 1°
Water	48° ± 2°	20° ± 1°	50° ± 1°

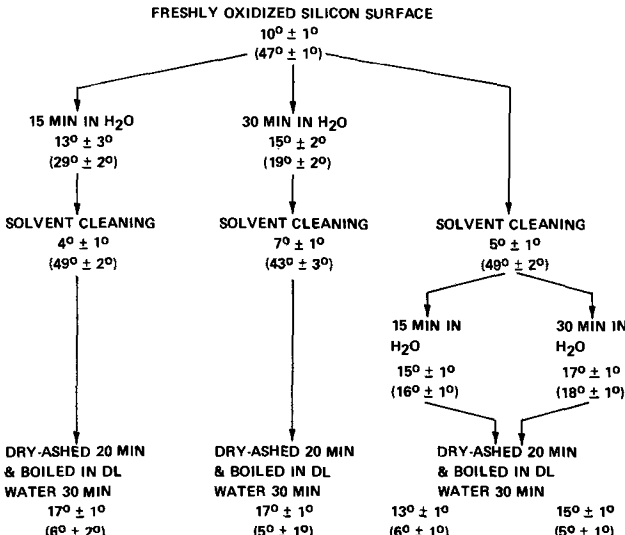

Fig. 3. Contact angles of n-hexadecane (upper line) and water (in parentheses) on surfaces given various treatments in sequence. All water treatments were at the boiling point.

surface, and at least six different surfaces for water and three different surfaces for n-hexadecane. It appears that with n-hexadecane alone, one could differentiate between the three surfaces and that these results are reproducible, but the combination of water and n-hexadecane is preferable. Figure 3 demonstrates the usefulness of differentiating between various SiO_2 surfaces by measuring contact angles of both water and n-hexadecane on the same surface. This technique obviously can be applied to a study of surface cleanliness on oxides.

In this experiment, solvent cleaning means boiling twice for 5 min in trichloroethylene, followed by boiling in acetone for 5 min, boiling in deionized water for 5 min, and then blowing the sample dry in filtered nitrogen at room temperature. Dry-ashing was performed for 20 min in an atmosphere of 100 ml/min of oxygen at an operating pressure of 1 Torr with a power output of 1-2W in an rf plasma furnace.[1]

Thus by measuring the contact angles that water and n-hexadecane made with the surface (a simple, nondestructive technique), differentiation of the various silica surfaces is possible.

It appears from the preceding data that on high-energy surfaces the spreading pressure π_e cannot be ignored. In Table II the data of Fig. 3 were used to calculate from Eq. [3] the γ^d of silica, ignoring π_e. The wide spread of the values for each treatment underlines the contention that the spreading pressure cannot be ignored. Since the surfaces are different one would expect different γ^d_s (and π_e). However, each surface ought to give the same γ^d when measured with water and n-hexadecane. Using a value of 76 dynes/cm for the dispersion force contribution to the surface energy of silica (1) the spreading pressure was now

Table II. Surface energies (ergs/square centimeter) and spreading pressures (dynes/centimeter) on various silica surfaces

Surface treatment	Water θ	Water $\gamma^d_{SiO_2}$ (a)	Water π_e (b)	n-Hexadecane θ	n-Hexadecane $\gamma^d_{SiO_2}$ (a)	n-Hexadecane π_e (b)
1000°C; O_2	47°	169	−39.9	10°	27.3	36.8
15 min at 100°C in H_2O	29°	210	−53.8	13°	27.0	37.1
30 min at 100°C in H_2O	19°	226	−58.9	15°	26.8	37.3
Trichloroethylene	49°	164	−38.1	56°	27.6	36.5
Dry-ashing	6°	237	−62.4	16°	26.6	37.4

(a) $\pi_e = 0$.
(b) $\gamma^d_{SiO_2} = 76$ ergs/cm².

calculated and tabulated in the last columns. The values for π_e obtained that way for the dry-ashed surfaces followed by water boiling are of interest. While spreading pressures can be obtained from vapor absorption measurements, this is a more cumbersome technique than simply measuring contact angles or the surface tension of liquids. Fowkes proposed (6) an equation for the spreading pressure

$$\pi_e = 2\sqrt{\gamma^d{}_s \gamma^d{}_l} - \gamma_l \qquad [4]$$

Although this formula is applicable only when dispersion forces are present using 76 dynes/cm for $\gamma^d{}_s$ the following values for π_e were obtained for: water, −62.4 dynes/cm; and n-hexadecane, 38.9 dynes/cm. These values are almost identical (certainly in sign and order of magnitude) with those calculated from the contact angle measurements on the thermally grown SiO_2 and dry-ashed (Table II). It is interesting to note that the spreading pressure calculated from thermodynamic and surface tension data alone agreed well with data observed and calculated from the contact angle measurements on dry-ashed samples, not only for water but for n-hexadecane as well. It may be assumed therefore, that the dry-ashed sample was the "cleanest" surface thermodynamically that was comparable to those studied by Zisman, Fowkes, and others by absorption data of vapors and gases.

It appears obvious, therefore, that the scheme presented here permits at least an approach to the characterization of surface changes. If the "true" surface energy of a clean solid is known by some other means, such as absorption data, then the spreading pressure can be calculated from a simple contact angle measurement by use of Eq. [3] or [4]. Surface changes from this "clean" thermodynamic surface (in other words, surface contaminations) can now be determined easily by measuring the contact angle and comparing the new with the "clean" spreading pressure. Such a technique will permit an estimate of the cleanliness of the surface and the repeatability of the technique. Either the difference or the ratios of the spreading pressures may be used as a measure. On the other hand, if π_e is determined the γ^d of the solid can equally easily be determined from Eq. [3] or [4]. Since conventional π_e's are not exactly easy to determine, a simple approximation would be useful. It may be assumed that as the liquid (polar or nonpolar) spreads over the polar surface an electrical double layer is set up. The atoms in the solids, of course, cannot reorient themselves but those of the liquid can. Such a liquid then may set up a zeta potential and permit a first approximation to the π_e values. Zeta potentials should be easier to measure than π_e.

If the above train of thought is valid, as a first approximation only (the actual relationship would be more sophisticated) then

$$\pi_e \text{ is proportional to a function of } \frac{\zeta}{\mu_1 + \mu_2} \qquad [5]$$

where ζ is the zeta potential in millivolts of the liquid moving across the solid and μ_1 is the dipole moment of the liquid and μ_2 the dipole moment of the solid in Debyes.

Using appropriate values in the literature or calculating the μ from the Clausius-Masotti equation and zeta potentials from molar refractions it appears that for π_e values we obtained:

	Calculated from Eq. [5]	Calculated from contact angle
Water	−50 to −70	−62.4
n-Hexadecane	+20 to +30	+38.9
n-Butanol	−1.6 to −2.2	−2.1

The agreement of the numbers may be fortuitous particularly since it must be pointed out that millivolt/Debye are not equal to dynes/centimeter. However, the suggestion is here made that a more sophisticated approach in this direction may be worthwhile to pursue.

Summary and Conclusions

Even though it is not possible to characterize high-energy surfaces unequivocally with one simple contact angle measurement, it is shown that two contact angle measurements with two different liquids can characterize the SiO_2 surfaces. It is further indicated that a technique can be worked out if the surface energy or the spreading pressure of the solid is known by other techniques, and for many materials used in the semiconductor industry this is possible. Changes in the surface energy can be determined easily with a simple contact angle measurement by using suitable liquids, even though polar forces do take part at the liquid-solid interfaces.

Investigation of Surface Oxide Layers by X-Ray Appearance Potential Spectroscopy

K. N. Ramachandran and C. D. Cox

Semco Instruments Company, Ottawa, Ontario, Canada

ABSTRACT

X-ray appearance potential spectroscopy using low energy electron excitation is a simple method for surface analysis sensitive to light elements. The spectra obtained from many elements show considerable structure which is presumably related to the valence band distribution. The apparatus consisted of a tungsten filament electron source and a large area, windowless, soft x-ray detector based on the photoelectric yield of a gold surface. The specimen, electron source, and detector were located in an all metal, bakeable vacuum system having demountable, gold wire sealed flanges. Facilities were provided for surface cleaning by ion bombardment and heating the specimen *in situ*. A 10Å layer of oxygen on nickel was readily detected using an electron current of 2 mA. The $L_{3,2}$ structure of iron in pure and known oxide forms was obtained by perfoming *in situ* oxidation of a pure iron specimen. Slight but reproducible changes in the structure were observed, indicating the potential capability of the technique to distinguish between different valence states of an element. The oxygen K spectrum also showed a multiple peaked structure.

During the past few years, soft x-ray appearance potential spectroscopy has been established as a simple but powerful tool for surface analysis. The light elements from beryllium to oxygen and a number of medium and heavy elements, when present as surface impurities, have been detected by this method (1-3). Though the detection sensitivity attained so far is low compared to that of conventional methods of microanalysis, the simplicity of the apparatus and the ability to provide information related to the valence band structure of elements make appearance potential spectroscopy an attractive technique. Most of the analysis work performed by this method has been qualitative. No effort has been made by the other authors to establish detection sensitivities of different elements or to relate the observed fine structure in the spectrum to known surface conditions developed in a specimen. The present work deals with a few quantitative results on oxides formed on nickel and iron specimens. The detailed fine structure in the K spectrum of oxygen and the $L_{3,2}$ spectrum of iron corresponding to different types of oxides formed *in situ* are also presented.

Apparatus

The appearance potential spectrometer was built in an all metal vacuum system consisting of several demountable flanges sealed by gold wire. A clean vacuum was obtained using a 20 liter/sec ion pump with titanium sublimation elements, initially backed up by a turbomolecular pump. After baking to about 250°C for 12 hr, a working pressure of about 2×10^{-9} Torr was reached, which ensured a reasonably clean specimen environment during the experiment.

The schematic diagram of the apparatus is shown in Fig. 1. The electron source located 0.5 cm away from the flat face of the specimen consisted of a U-shaped filament made of 0.125 mm tungsten wire. For heating currents lying between 2-3A, the filament was capable of delivering electron currents up to 2 mA to the specimen at a potential of 50V or more. An emission regulator was built into the filament heating circuit in order to keep the specimen current constant during the experiment. This was achieved by sensing the current at the specimen by a high-gain amplifier and using the output to control the filament current. The filament was biased positive with respect to the grounded mesh in front of the detector in order to prevent the back-scattered electrons from entering the detector box. The interior of the triangular-shaped box was coated with an evaporated layer of gold, and this served as the photocathode by releasing electrons under the action of the incident x-rays. These electrons were collected by a positively biased electrode which was coupled to a high-gain low-noise amplifier. The specimen potential was supplied from a motor-driven power supply, continuously variable from 50 to 1000V at rates varying from 0.5 to 5 V/sec. The derivative of the total x-ray yield was obtained by introducing a small modulation to the specimen potential and using a lock-in amplifier to detect the fundamental component of the photoelectron current, as shown in the diagram.

Key words: soft x-ray shifts, oxidation.

Results

The initial experiments were done on specimens in the shape of a disk of 1 cm diameter. The appearance potential spectra of beryllium, boron, carbon, nitrogen,

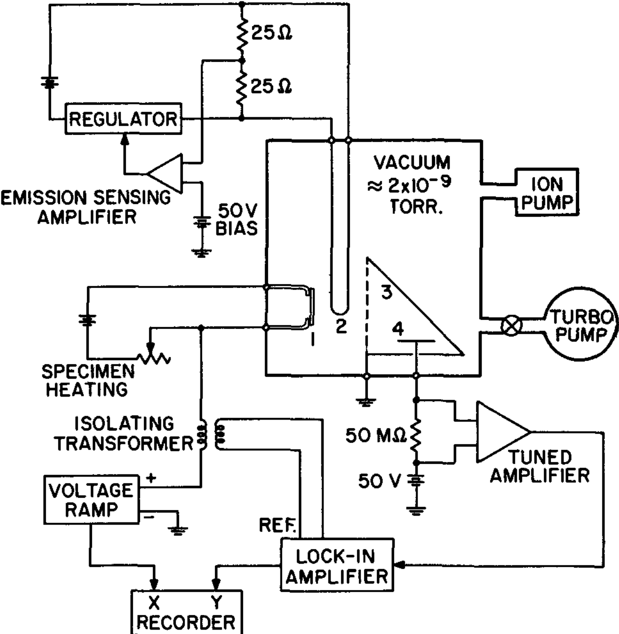

Fig. 1. Schematic diagram of the appearance potential spectrometer. 1, Specimen; 2, filament; 3, photocathode; 4, photoelectron collector.

and oxygen were obtained from such specimens (4). The results, however, were merely qualitative as there was no way of knowing the surface concentration of the different elements on the specimens used.

Oxidation of metals is a well-studied and documented process and it was therefore decided to use known oxide samples in order to establish the detection sensitivity of oxygen. A nickel specimen was prepared by vacuum deposition of a 1000-2000Å layer of nickel evaporated from a tungsten basket on to a stainless steel disk. It was then exposed to air at room temperature for a few minutes so as to oxidize the surface. This exposure is known to form a stable oxide layer of mean thickness 10Å on the surface (5). The appearance potential spectrum obtained from this sample is given in Fig. 2, showing strong $L_{3,2}$ structure of nickel and weak but clearly discernible K structure of oxygen. The sensitivity can be improved further (by a factor of about 5) at the expense of structure resolution by increasing the modulation amplitude. Thus it seems readily possible to detect a monolayer of oxygen on nickel with a reasonable signal-to-noise ratio. To confirm that the signal was derived from the surface oxide layer, the specimen was subjected to argon ion bombardment to sputter off the oxide layer. This was performed by admitting pure argon through a leak valve and sustaining a discharge current of 1 mA through the specimen at 800V for about 15 min at an argon pressure of about 10^{-2} Torr. The spectrum obtained after the above treatment showed marked reduction in the oxygen structure to the level of noise fluctuations.

Oxidation studies on iron.—The initial version of the apparatus using disk specimens was modified to carry out oxidation studies on iron. The specimen consisted of a high-purity iron foil (John Matthey 99.997%), 0.0125 mm thick and 1 × 0.5 cm size, spot welded to two nickel supports. By passing current through the specimen, it was possible to attain temperatures up to 600°C as measured by a 0.075 mm iron-constantan thermocouple junction spot welded to the back of the specimen. The appearance potential spectrum obtained before performing any heat-treatments revealed small amounts of carbon and oxygen as shown in Fig. 3. In order to remove these contaminants, the foil was first heated to about 500°C in vacuum for several minutes so that the carbon from the bulk diffused to the surface and combined with the oxygen on the surface to form CO. After cooling to room temperature, pure oxygen was admitted at about 1 Torr for a few minutes and the pressure brought down to 10^{-8} Torr. Further heating to 500°C removed more of the carbon diffusing to the surface and the cycle was repeated a few times to burn off the last traces of carbon from the specimen. Finally, the oxygen remaining on the surface was removed by heating to 300°C in pure hydrogen at 10^{-3} Torr. The technique described above is a standard procedure for the removal of carbon from the bulk of thin foils and oxygen from the surface (6).

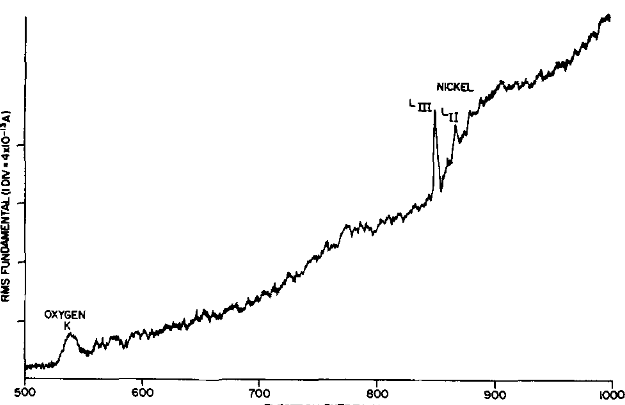

Fig. 2. Detection of oxygen (≃10Å) on nickel. Specimen current = 2 mA; modulation = 2V p-p at 500 Hz; lock-in time constant = 1 sec; residual pressure = 2 x 10^{-9} Torr.

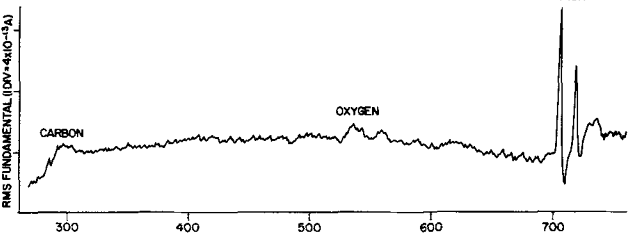

Fig. 3. Spectrum from the iron foil before surface treatments showing small amounts of carbon and oxygen. Specimen current = 2 mA; modulation = 2V p-p at 500 Hz; lock-in time constant = 1 sec; residual pressure = 2 x 10^{-9} Torr.

The $L_{3,2}$ spectrum of pure iron as obtained after the cleaning operations is shown in Fig. 4 (a). Oxygen was then admitted at about 1 Torr and the specimen heated to 200°C for 10 min to oxidize the surface. This resulted in the formation of an oxide layer of mean thickness 60Å, consisting of predominantly Fe_3O_4 and some γFe_2O_3 (7, 8). The spectrum of iron corresponding to this condition is given by the trace (b), Fig. 4. The specimen was then annealed in vacuum by heating

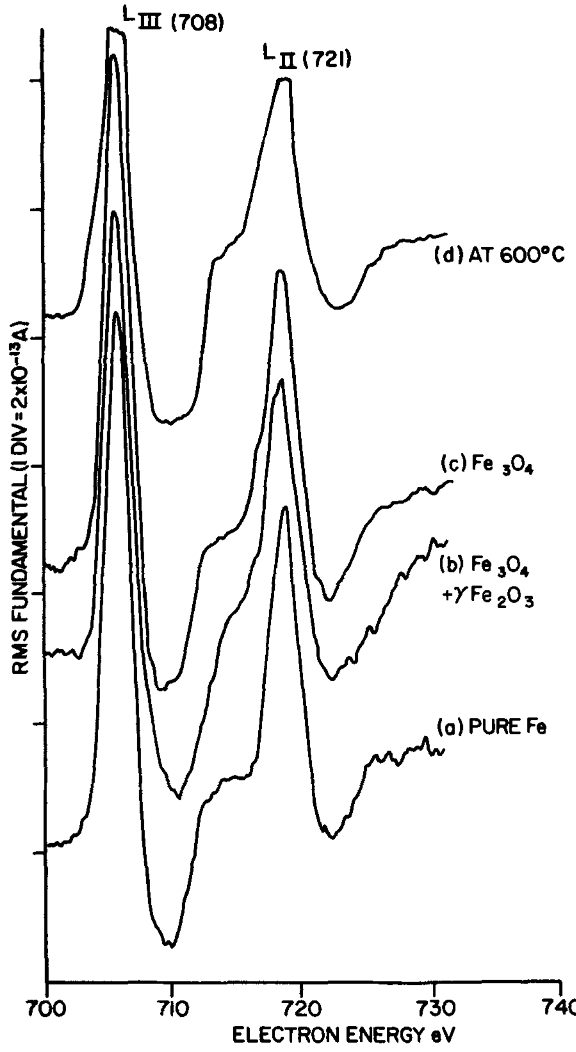

Fig. 4. L edge structure of iron in different forms. Absorption edge values from standard tables are given in brackets. The vertical shift between traces is arbitrary. Traces (a), (b), and (c) were taken at room temperature. Specimen current = 2 mA; modulation = 2V p-p at 500 Hz; lock-in time constant = 3 sec; residual pressure = 5 x 10^{-9} Torr (predominantly hydrogen).

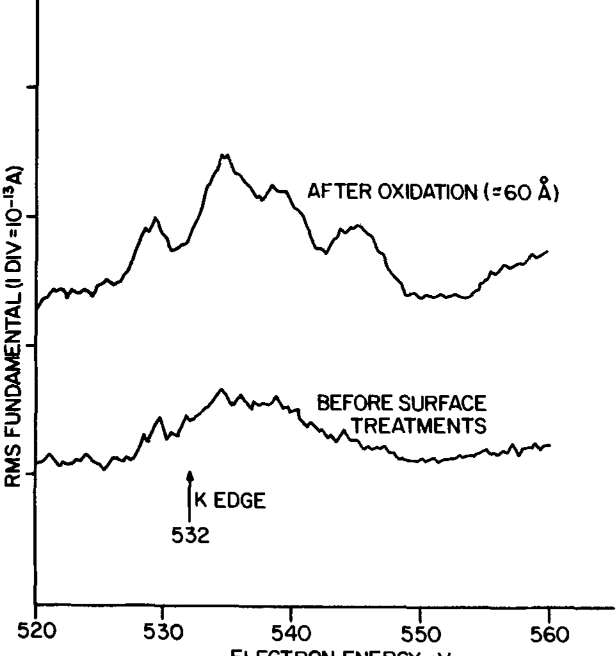

Fig. 5. K edge structure of oxygen before and after oxidation. The vertical shift between traces is arbitrary. Specimen current = 2 mA; modulation = 2V p-p at 500 Hz; lock-in time constant = 3 sec; residual pressure ≈ 5 x 10^{-9} Torr.

to 500°C for several minutes in order to change the oxide to nearly pure Fe_3O_4. The spectrum for iron in this form is shown by trace (c), Fig. 4. The trace (d), Fig. 4, was obtained while the temperature was held constant at about 600°C which is known to transform the oxide to FeO. The oxygen K structure before surface treatment and after the first oxidation is shown in Fig. 5.

Discussion and Conclusion

The $L_{3,2}$ appearance potential structure of iron in the pure and three different oxide forms is obtained using *in situ* heating and oxidation facilities. Except for the small noise fluctuations, the traces have good reproducibility. Within the energy resolution of the instrument (about 2 eV), there is no measurable energy shift between the positions of peaks in all these cases. However, there are slight but reproducible differences in the shape of the curves, especially in the region lying between the L_3 and L_2 peaks. The over-all structure is apparently sharpest in trace (a) in Fig. 4 corresponding to pure iron. In trace (b), Fig. 4, the peaks are broadest at the base and they almost merge into each other. Trace (d), Fig. 4, shows flattened peaks.

The changes in the iron structure are attributed to differences in the valence state of the element as it combines with oxygen. This is analogous to what is commonly known as chemical shift, which has been observed to some extent in other methods of surface analysis such as ESCA and Auger electron spectroscopy (9). The appearance potential spectrum is directly related to the initial ionization transitions from the inner levels to the outer empty levels in the valence band and can therefore be expected to be sensitive to changes in the valence band structure (10). Though the differences observed in the present case are small, they demonstrate the potential capability of the technique to reveal the valence band structure and thereby identify the various chemical forms of an element. Much more conspicuous "shifts" have been observed in the spectra of a few alloys and compounds (3, 11). These effects, however, have to be properly characterized before practical identification of the chemical species can be made. One answer to this problem is to combine appearance potential spectroscopy with more elaborate techniques such as LEED into the same apparatus so that the results can be directly correlated.

The oxygen K spectrum in Fig. 5 shows a multipeaked structure. Such multiple peaks are observed in the case of many other light elements, especially carbon for which the peaks have been related to plasmon effects caused by the incident electrons (12). Plasmon data on oxygen are not available at the present time in order to compare the results.

Water Adsorption in Chemically Vapor-Deposited Borosilicate Glass Films

E. Arai and Y. Terunuma

Musashino Electrical Communication Laboratory, Nippon Telegraph and Telephone Public Corporation, Midori-cho, Musashino-shi, Tokyo, Japan

ABSTRACT

Infrared absorption measurements have been made of physically adsorbed water and silanol in borosilicate glass films which were chemically vapor-deposited at 400°C and then exposed at room temperature to moist air of relative humidity 50 ± 10%. Both the physically adsorbed water and silanol were found to increase with time up to about 10^5 min and then to decrease. The process of water adsorption was limited by the diffusion of water in CVD glass. The adsorption sites of CVD glass were suggested to decrease with the increase of time. The diffusion coefficient of water in the as-deposited glass films at room temperature was estimated to be on the order of 10^{-15}-10^{-14} cm^2/sec and was found to decrease with the increase of B_2O_3 content of the glass and annealing temperature prior to exposure to moist air. Heats of physical adsorption of water were 1.2 kcal/mol below 120°C and 3.3 kcal/mol above 120°C for as-deposited borosilicate glass containing 8.7 molar per cent B_2O_3.

Low temperature vapor-deposited silicon dioxide doped with B_2O_3, P_2O_5, As_2O_3, etc. is currently becoming of industrial importance as a source for diffusion into silicon substrates and for device protection, but tends to be much more porous and active for water adsorption than thermally oxidized films. Water adsorption reduces adherence of photoresist on the oxide (1, 2) and adversely affects electrical characteristics of devices (3). Although many authors have studied the infrared absorption of borosilicate glass and silica (4-8), investigations of water adsorption in low temperature vapor-deposited silicon dioxide with much internal porosity have not been reported, except for Ref. (8), where changes of B-O, B-O-H, etc. absorption bands with time for various humidity have been measured for highly boron-doped glasses. In the present work, the rate of adsorption, the heat of water adsorption, and porosity for borosilicate glass films, which were chemically vapor-deposited at 400°C, were studied, using infrared technique and electron microscopy.

Experimental Procedure

The silicon dioxide films doped with boron oxide were deposited on substrates in an atmosphere of silane, diborane, and oxygen at 400°C, using nitrogen as a carrier gas. Growth rates of glass depend on the gas flow ratios. Typical rates were about 430 Å/min for boron-doped oxide (8.7 m/o B_2O_3) and 500 Å/min for nondoped oxide. Silicon or fused-silica wafers were used as substrates. The silicon wafers were 100 to 200 ohm-cm resistivity, n-type, and 0.4 mm thick with mirror polished surface. The fused-silica wafers were 0.3 mm thick with mirror polished surfaces. Infrared absorption was measured in transmission on a Model IR-27G Spectrophotometer made by Shimadzu Seisakusho, Ltd., with a bare companion wafer of approximately the same thickness of silicon or fused silica in the reference beam. The infrared transmission of silica is larger than silicon in the wave number range of 4000-2200 cm^{-1} and is much smaller below 2200 cm^{-1}. Moreover, infrared measurements of fused silica are not influenced by the absorption due to free carriers and curvature of the wafer due to the difference of the thermal expansion coefficient between deposited film and substrate. Fused silica was, therefore, used as a substrate to measure the absorbance of silanol at 3650 cm^{-1} and physically adsorbed water at 3400 cm^{-1}. Silicon substrates were used for measurements in the range of 2000-400 cm^{-1}, *e.g.*, the B-O band at 1320 cm^{-1}, the Si-O band at 1080 cm^{-1}, and the Si-O-B band at 930 cm^{-1}. In many cases in the present work, the adsorbed amount of water or silanol was plotted by log (I_0/I) at 3400 or 3650 cm^{-1}, where I_0/I is the relative intensity of transmitted infrared light. Thicknesses of the glasses were observed by interference colors in reflection with occasional checks by ellipsometer measurements. Compositions of the as-deposited films were determined by infrared absorption spectroscopy, using the published data for the infrared absorbance ratio *vs.* molar per cent B_2O_3 obtained by chemical analysis (5, 9). Porosity of glasses was measured by an electron microscope Model JEM-T5S made by Japan Electron Optics Laboratory Company, Ltd. Heat-treatments were carried out in a nitrogen atmosphere or in a vacuum of about 5×10^{-5} Torr.

Key words: infrared spectroscopy, physically adsorbed water, silanol, diffusion coefficient of water.

Experimental Results

Water adsorption in air.—Changes in the time of the infrared absorption near 3 μm of boron doped and nondoped oxide exposed at room temperature to air with a relative humidity 50 ± 10% are shown in Fig. 1 (a) and (b). Both oxides were about 1.0 μm thick. The boron content in the doped oxide was 8.7 molar per cent B_2O_3. It can be seen from these figures that a band at 3650 cm^{-1} was present initially only for nondoped oxide: the broad band at about 3 μm increased with

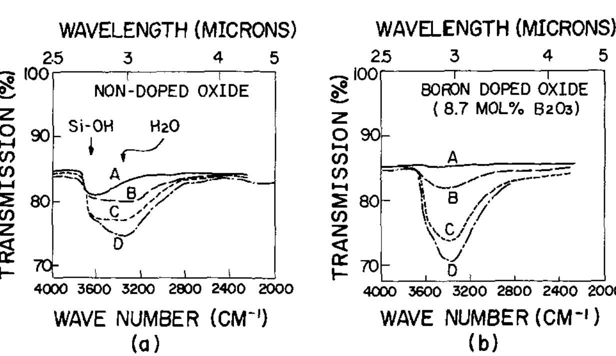

Fig. 1. Changes with time of infrared spectra of nondoped oxide and boron-doped oxide films (about 1 μm). (a) Nondoped oxide. (b) Boron-doped oxide (8.7 m/o B_2O_3). Curve A, Initial spectra (< 2 min exposure); curve B, 5 hr exposure; curve C, 6 days exposure; curve D, 100 days exposure.

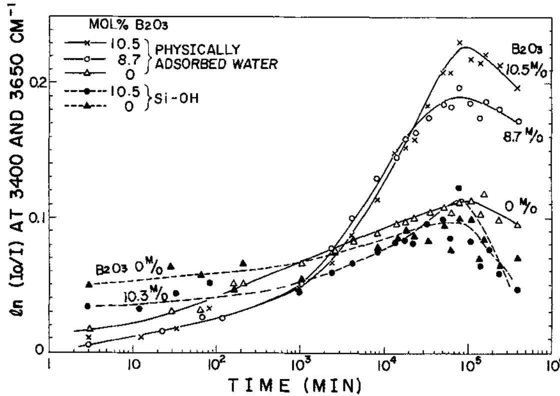

Fig. 2. Changes of ln (I_0/I) at 3650 and 3400 cm^{-1} with time for nondoped oxide and boron-doped oxide (about 1 μm).

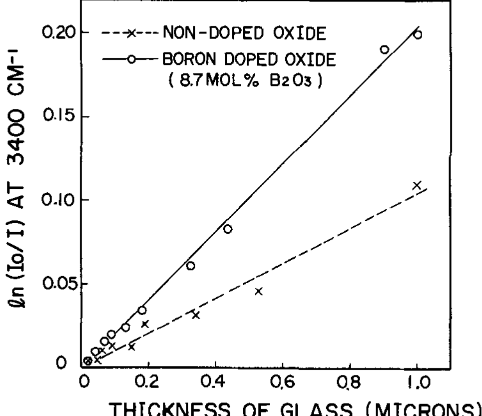

Fig. 3. Dependence of maximum values of ln (I_0/I) at 3400 cm^{-1} on thicknesses of glass.

time for both oxides. The broad band at 3 μm can be assumed to consist of peaks at 3650 cm^{-1} and at 3400 cm^{-1}. The former corresponds to an oxygen-hydrogen stretching vibration of silanol groups and the latter to that of physically adsorbed water (6, 7). It is, therefore, concluded that the silanol groups adsorb on the nondoped oxide but not on the boron-doped oxide in the deposition process and the physically adsorbed water does not adsorb on both oxides in the process. Figure 2 shows the changes with time exposed to moist air of ln (I_0/I) at 3650 cm^{-1} for oxides (0 and 10.5 m/o B_2O_3) and 3400 cm^{-1} for oxides (0, 8.7, and 10.5 m/o B_2O_3). From this figure, it is found that the adsorbed water reaches its maximum value at about 10^5 min and then decreases; the maximum value of physically adsorbed water increases with B_2O_3 content in glass. The dependence of the maximum value of physically adsorbed water on the thickness of the glass is shown in Fig. 3, where it is found that the maximum values are nearly proportional to the glass thickness. From this figure, it is concluded that the water adsorbs uniformly on the walls of the inner porous structure. Plotting d^{-1} ln (I_0/I) against t/d^2, it was found that d^{-1} ln (I_0/I) lays almost on a smooth curve for samples with various thicknesses, except below about 0.2 μm where experimental precision is poor, as shown in Fig. 4. From these facts, it is expected that the limiting process of adsorption for glass is the diffusion of water, not the adsorption itself. The diffusion coefficient of water is estimated in a later section, where these data are compared with the solution of the diffusion equation, which is shown as a solid curve in Fig. 4.

Outflow of boron oxide from highly doped glass films.—The infrared absorption spectrum of boron-doped oxide has B-O bands at 1320-1380, 670, and 470-520 cm^{-1} and an Si-O-B band at 930 cm^{-1}, in addition to the normal Si-O bands at 1070, 800, and 450 cm^{-1} (4, 5, 8). Changes of these bands with time were measured for films of differing boron content. For the low doping level (<8.7 m/o B_2O_3), the B-O and Si-O bands hardly changed with time and the bands of B-O-H at 3200, 1450, and 1197 cm^{-1} did not appear (10). With higher boron content, the absorption of B-O bands and Si-O-B band decreased with time, while the absorption in the 3400-3200 region and in the 1070 cm^{-1} region increased markedly, as shown in Fig. 5(a) and (b). In the spectra of Fig. 5(a), it is seen that the 3 μm band first appears at 3250-3200 cm^{-1}, and then approaches 3400 cm^{-1}. The 7 μm B-O band first has its peak at 1320 cm^{-1}, then becomes broad over 1450-1320 cm^{-1}, and disappears after 45 days exposure. The 9 μm Si-O band ranges from 1200 to 1000 cm^{-1} and first has its peak at 1070 cm^{-1} and becomes large and sharp later. These data suggest $B(OH)_3$ is formed early and then flows out from the glass, leaving water behind it. Further, it is thought that the increase of the absorbance near 1070 cm^{-1} is due to the increase of a bending vibration of B-OH but not of Si-O (4), which means that the infrared peak ratio of band at 1320 cm^{-1} to that at 1070 cm^{-1} is not always proportional to the B_2O_3 molar ratio in glass. Figures 6(a) and (b) show the correlations of the absorbance of B-O band in

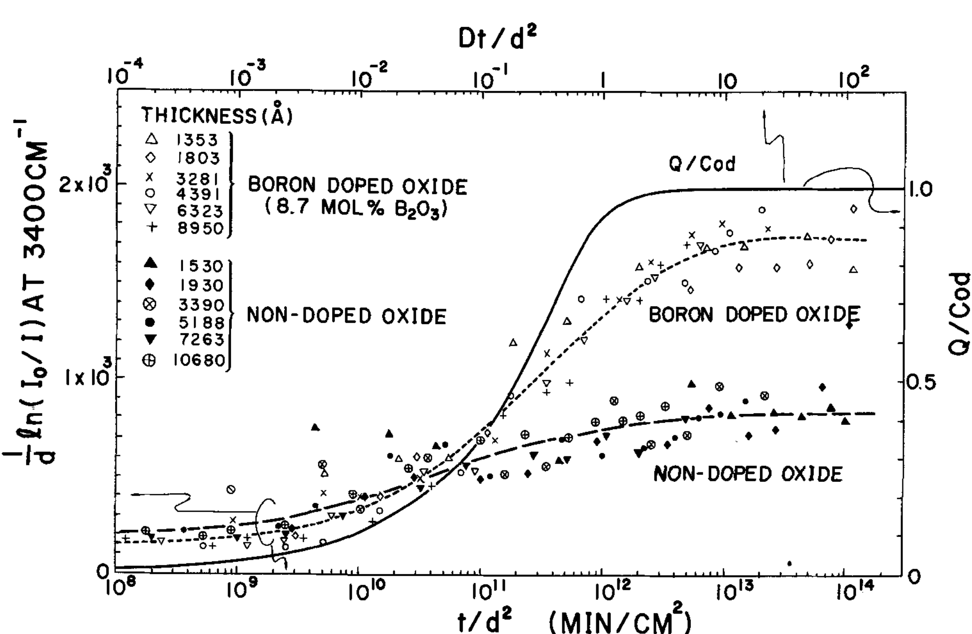

Fig. 4. Changes of d^{-1} ln (I_0/I) at 3400 cm^{-1} with t/d^2 for nondoped oxide and boron-doped oxide (8.7 m/o B_2O_3) and a calculated adsorption curve (Q/C_0d vs. Dt/d^2).

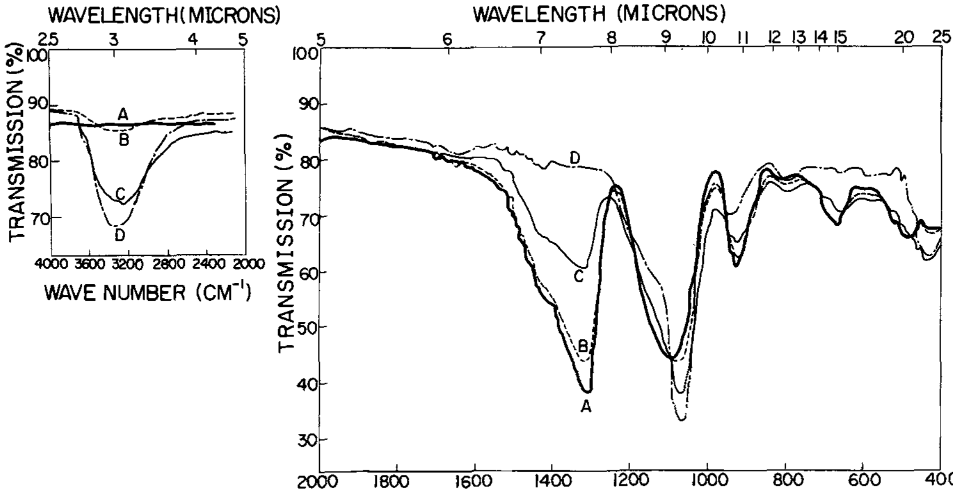

Fig. 5 (a). Changes with time of infrared spectra of boron-doped oxide (26.5 m/o B_2O_3 and about 1 μm). Curve A, Initial spectrum (< 2 min exposure); curve B, 1 hr exposure; curve C, 7 days exposure; curve D, 45 days exposure.

the 1320-1380 cm^{-1} region with the band of water in the 3200-3400 cm^{-1} region for the various B_2O_3 contents in glass. From these figures, it is seen that the decrease of the B-O band absorbance with time corresponds with the increase of the water band absorbance for various initial boron contents in glass. From these facts, it is assumed that the adsorption sites, *i.e.*, the internal surface area, increase with the outflow of B_2O_3 from glass.

Porosity and heats of adsorption.—To study the dependence of size and density of pores in the surface of glass on B_2O_3 content and heat-treatments, the glass surfaces were observed by electron microscopy. Figure 7 shows electron micrographs of surfaces for as-deposited glasses containing 0, 8.7, and 26.5 m/o B_2O_3, where the carbon-germanium replica was produced just after the deposition. From this figure, it is seen that the pore size is about 100-200Å on an average and decreases with boron content in glass. The pore density increased with boron content in glass, for example, about 100 in a square micron for nondoped oxide, 160 and 230 for boron-doped oxides containing 8.7 and 26.5 m/o B_2O_3, respectively. It was also found that the pore density decreased and surface texture became smoother with the increase of the temperature of heat-treatment for boron-doped oxides containing 8.7 and 26.5 m/o B_2O_3. This fact corresponds with the softening of glass. Further, no changes of glass surface with exposure in air for about 10^5 min were observed. To evaluate the heat of adsorption from the infrared absorption, the following treatments were carried out in vacuum. Water desorption in isochronal heat-treatment for 10 min was measured in the temperature range of 74°-243°C. A peak in the differential desorption curve of physically adsorbed water appeared at about 120°C, but silanol groups scarcely desorbed, as shown in Fig. 8. Changes in the physically adsorbed water during isothermal heat-treatments were measured in the temperature range of 76.5°-218°C after a large amount of water was initially adsorbed by immersion in water at 97°C for several hours, as shown in Fig. 9. Plotting the equilibrium values obtained at each temperature against $1/T$, heats

of physical adsorption were estimated to be 3.32 kcal/mol above 120°C and 1.15 kcal/mol below 120°C, as shown in Fig. 10. Further, the desorption in sulfuric acid was also measured. The amount of desorbed water increased with the temperature of sulfuric acid and the equilibrium values of water adsorbed in sulfuric acid were in agreement with those in vacuum above 120°C.

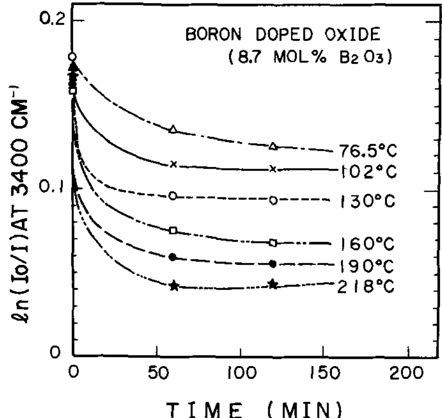

Fig. 9. Isothermal heat-treatments in vacuum for boron-doped oxide (8.7 m/o B_2O_3 and about 1 μm).

Water adsorption in heat-treated samples.—Samples 1 μm thick were heat-treated at 439°, 562°, 792°, and 1054°C for 10 min in a nitrogen atmosphere and then were exposed to moist air for various times. Figures 11(a) and (b) show changes with time of physically adsorbed water and silanol, where the latter is shown only for samples heated at 439° and 562°C to avoid confusion in the figures. From these figures, it is seen that the maximum values of physically adsorbed water appear behind those of silanol. Above 562°C, maximum values of physically adsorbed water decrease with the increase of temperature of heat-treatment, while those of samples heat-treated at 439°C are nearly the same as those of as-deposited samples. Re-adsorption of water is not observed in nondoped oxide heat-treated above 792°C for 10 min, while it is observed in boron-doped oxide (8.7 m/o B_2O_3) even if it was heat-treated at 1054°C. The re-adsorbed amount of water for boron-doped oxide heat-treated at 1054°C for 60 min was half of that for 10 min. The reason why the maximum values of physically adsorbed water appear behind those of silanol is suggested as being due to the diffusion of water to the silanol sites. The Si-O absorption band at about 9 μm shifted from 1060-1070 cm^{-1} to 1080 cm^{-1} by heat-treatment above 792°C for 1 min. On the other hand, the water contact angle of the glass surface was about 40° for nondoped oxide and about 10° for boron-doped oxide (8.7 m/o B_2O_3) due to the heat-treatment above 792°C for 10 min, while both oxides had a water contact angle of 0° unless they were heat-treated. The Si-O absorption band of thermally oxidized SiO_2 appears at 1080-1090 cm^{-1} and its water contact angle is about 40° (2). These results will be reported later elsewhere in more detail. From the above results and discussion, it is suggested that the glass structure of nondoped oxide nears that of ther-

mal SiO_2, *i.e.*, complete siloxane structure by heat-treatment above 800°C for 10 min. For boron-doped oxide, it is suggested that the B-O bond of the glass surface adsorbs the water even if it is heat-treated.

Discussion

Diffusion coefficient of water in glass.—From Fig. 4, it is confirmed that the rate of water adsorption is limited by the diffusion of water in glass. In this section, the diffusion coefficient of water in glass is estimated, assuming the diffusion equation. It is certain that the glass structure changes with time slowly because the adsorbed amount of water decreased beyond approximately 10^5 min, as shown in Fig. 2 and 11. In other words, the internal area for adsorption decreases with time. For simplicity, it is now assumed that the diffusion coefficient is independent of time and concentration of water in glass. The diffusion equation and the initial and boundary conditions which fit the present experiment are given by

$$\frac{\partial C}{\partial t} = D\frac{\partial^2 C}{\partial x^2} \quad [1]$$

$$C = 0 \text{ at } 0 \leqq x \leqq d \text{ and } t = 0 \quad [2]$$

$$C = C_o \text{ at } x = d \text{ and } t \geqq 0 \quad [3]$$

$$\partial C/\partial x = 0 \text{ at } x = 0 \text{ and } t \geqq 0 \quad [4]$$

where C, D, and d are the concentration of water, diffusion coefficient, and glass thickness, respectively. The boundary condition of Eq. [4] expresses the fact that there is no diffusing flow across the interface between glass and substrate. The solution is given by a series of error functions, as follows (11)

$$C = C_o \left\{ \sum_{n=0}^{\infty} (-1)^n \operatorname{erfc}\frac{(2n+1)d - x}{2\sqrt{Dt}} + \sum_{n=0}^{\infty} (-1)^n \operatorname{erfc}\frac{(2n+1)d + x}{2\sqrt{Dt}} \right\} \quad [5]$$

The total amount of water diffused into glass, Q is

$$Q = \int_0^d C(x)\,dx = C_o\sqrt{Dt} \left\{ \sum_{n=0}^{\infty} (-1)^n \operatorname{ierfc}\frac{nd}{\sqrt{Dt}} - \sum_{n=0}^{\infty} (-1)^n \operatorname{ierfc}\frac{(n+1)d}{\sqrt{Dt}} \right\} \quad [6]$$

where

$$\operatorname{ierfc}(x) = \int_x^{\infty} \operatorname{erfc}(\xi)\,d\xi \quad [7]$$

The values of Q/C_od calculated by digital electronic computer are shown as a solid curve in Fig. 4. Q/C_od should be proportional to d^{-1} ln (I_o/I) minus its initial value in the experiment. The diffusion coefficient of water is estimated, comparing Q/C_od with the experimental values of Fig. 2, 4, and 11, as shown in Table I, where calculations of the diffusion coefficient were carried out at 10^2, 10^3, and 10^4 min for results shown in Fig. 2 and 11, and at 10^{10}, 10^{11}, and 10^{12} min/cm^2 for results shown in Fig. 4. From this table, it is seen that the diffusion coefficient decreases with time for as-deposited and heat-treated samples, it decreases with the initial B_2O_3 content in glass for as-deposited samples and with temperature of heat-treatment. The dependence of the diffusion coefficient on time, obtained above, may be explained in terms of the decrease of the internal area for adsorption. The dependence of diffusion coefficient on B_2O_3 content in glass is consistent with the fact that the pore size decreases with B_2O_3 content. The dependence on heat-treatment temperature corresponds with the decrease of pore size and density.

Conclusions

The process of water adsorption in CVD glass is limited by the diffusion of water in glass. The diffusion coefficient of water in glass at room temperature is estimated to be on the order of 10^{-15}-10^{-14} cm^2/sec for as-deposited glasses. From the changes in the amount of adsorbed water with time, it is suggested that the adsorption sites decrease with time for as-de-

posited glasses, and it is probable that dangling bonds in glass, which are available for water adsorption, decrease with time. The adsorption sites for nondoped oxide decrease with the temperature and time of heat-treatment. On the other hand, the adsorption sites for boron-doped decrease by heat-treatment temporarily, but the new adsorption sites are made by exposure in air after heat-treatment.

Acknowledgments

The authors gratefully acknowledge discussions with Dr. M. Yoshida and Mr. H. Nakamura on diffusion and adsorption. The authors are also deeply indebted to Mr. T. Asaoka for his considerable assistance with the computations. Comments on electron microscope photographs by Dr. K. Ono and Mr. S. Hirota were extremely helpful.

Deformation Occurring during the Deposition of Polycrystalline-Silicon Films

T. I. Kamins

Research and Development Laboratory, Fairchild Camera and Instrument Corporation, Palo Alto, California 94304

ABSTRACT

The deformation sometimes observed during the deposition of thick polycrystalline-silicon films for dielectrically isolated integrated circuits has been investigated. The degradation of films deposited by the decomposition of dichlorosilane, silane, or silicon tetrachloride in a hydrogen carrier gas has been observed to occur during the deposition rather than during the cooling cycle and to be more severe at lower deposition temperatures. This degradation has been related to the inclusion of trace quantities of gaseous contaminants, especially oxygen, in the structure of the film. The elimination of these contaminants from the deposition chamber allows the reproducible fabrication of high quality films.

Most techniques for fabricating dielectrically isolated, silicon integrated circuits involve the deposition of a thick layer of polycrystalline silicon, which serves as the mechanical support of the structure (1). This layer is generally deposited by chemical vapor deposition (1) although rapid vacuum evaporation has also been used (2). Severe wafer deformation, which may preclude further processing, sometimes occurs during the polycrystalline-silicon deposition. This degradation has been briefly investigated during a study of thin, single-crystal, silicon films which are defined by an electrochemical etching process (3) and supported by thick layers of polycrystalline silicon (4). This paper reports the results of the investigation and shows that the deformation is related to the inclusion of gaseous contaminants, especially oxygen, in the film structure. The marked change in grain structure seen in degraded films is also described.

Experimental Method and Observations

The polycrystalline-silicon films were deposited in a standard, horizontal, rf-heated epitaxial reactor using a hydrogen carrier gas. The deposition temperature was generally 1100°C (corrected temperature), and the final film thickness was about 250 μm. While most of the films used in this study were deposited from dichlorosilane, silane and silicon tetrachloride have also been employed with similar results. In most cases the films were deposited directly onto oxidized, 2 in. diameter, silicon wafers.

Visual observation during the deposition cycle showed that the deformation occurred during the deposition, while the entire system was at constant temperature, and not during the cooling cycle. The degradation cannot, therefore, be attributed to differences in the thermal coefficients of expansion between the various materials in the structure but must rather be related to stresses built into the growing layer of polycrystalline silicon. In addition, since the incidence of degradation was sporadic, it cannot be caused by an intrinsic property of the materials system under investigation.

Several observations indicated that the presence of gaseous contaminant atoms in the reactor gas stream during the deposition was of prime importance in causing degradation. For example, severe degradation was encountered when a cylinder of silane containing gaseous impurity atoms was used to deposit polycrystalline-silicon films. Severe degradation has also been observed when small quantities of air were able to enter the reaction chamber through a poorly seated end plate. Furthermore, small amounts of deformation were usually reduced by eliminating any small leaks in the reactor. Therefore, we may conclude that gaseous contaminants, including some constituent of air, lead to the degradation.

Key words: dichlorosilane, chemical vapor deposition, oxygen contamination, neutron activation analysis.

Further observation indicates that the structure of the polycrystalline silicon is especially sensitive to the presence of gaseous contaminant atoms. Even when slight deformation was observed during the deposition of thick, polycrystalline-silicon layers, high quality epitaxial films could subsequently be grown in the same reactor. When severe deformation was observed during the deposition of thick polycrystalline layers, the sense of warping was opposite for simultaneously deposited epitaxial layers. The polycrystalline films were concave upward while the epitaxial layers were convex upward, and the deformation of the epitaxial layers was less severe.

Controlled experiments indicated that the degradation is not related to the type of wafer used. No difference in the severity of degradation was seen with heavily arsenic-doped wafers with either high or low dislocation density or with lightly boron-doped wafers. Thick polycrystalline-silicon films nucleated on thin layers of low-temperature, silane polycrystalline silicon deposited directly on single-crystal silicon also showed similar amounts of deformation, indicating that the degradation is not related to the presence of the silicon dioxide layer.

The effect of temperature is significant, however. Appreciably less degradation was seen at higher deposition temperatures when the same magnitude of contamination was present. This increase in film quality with increasing deposition temperature has been seen in different reactors and with silane and silicon tetrachloride as well as with dichlorosilane.

In order to determine the constituent of air which could cause the degradation, experiments were conducted in which controlled amounts of either nitrogen or oxygen were added to the hydrogen/dichlorosilane gas stream during the deposition of 250 μm thick, polycrystalline-silicon films at 1100°C (corrected temperature) and a rate of 4 μm/min. The addition of about 30 ppm of nitrogen did not induce any degradation, while the addition of about 20 and 44 ppm of oxygen caused moderate and severe degradation, respectively.

Photomicrographs of a high quality polycrystalline film together with photomicrographs of the moderately and severely degraded films are shown in Fig. 1-3. These photomicrographs illustrate the structure close to the outer edge of the 2 in. diameter wafer (a) and ⅛ in. from the outer edge (b). The high quality film is also shown ¼ in. from the outer edge (c) and near the center of the wafer (d). The location of the wafer on the susceptor was the same in each case. The control sample (Fig. 1) has a large-grained structure near the center of the wafer with a gradual decrease in grain size toward the edge. This decrease probably results from the outer edge of the wafer's being cooler than the center since the wafer sits on a raised pedestal. The moderately degraded wafer (Fig. 2) shows the same large-grained structure as the control sample near the center of the wafer with a decrease in grain size toward the edge. Immediately adjacent to the edge, however, a markedly different structure is seen [Fig. 2(a)]. As the wafer deformed during the deposition, the edges lifted from the susceptor and became cooler. Therefore, the different structure may be related to a markedly lower temperature near the edges of the wafer as well as to the greater oxygen inclusion in the lower temperature portions of the wafer.

Fig. 1. Photomicrographs of high quality polycrystalline-silicon film with no oxygen added during deposition. (a) Near edge; (b) ⅛ in. from edge; (c) ¼ in. from edge; (d) near center of wafer.

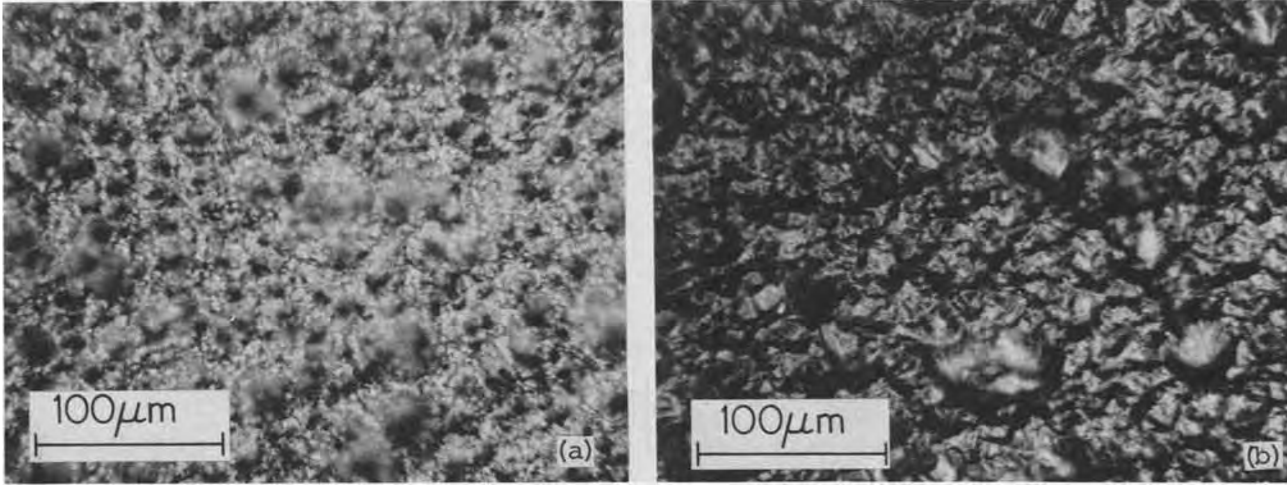

Fig. 2. Photomicrographs of moderately degraded polycrystalline-silicon film deposited with $[O_2]/[H_2]$ = 20 ppm. (a) Near edge; (b) ⅛ in. from edge.

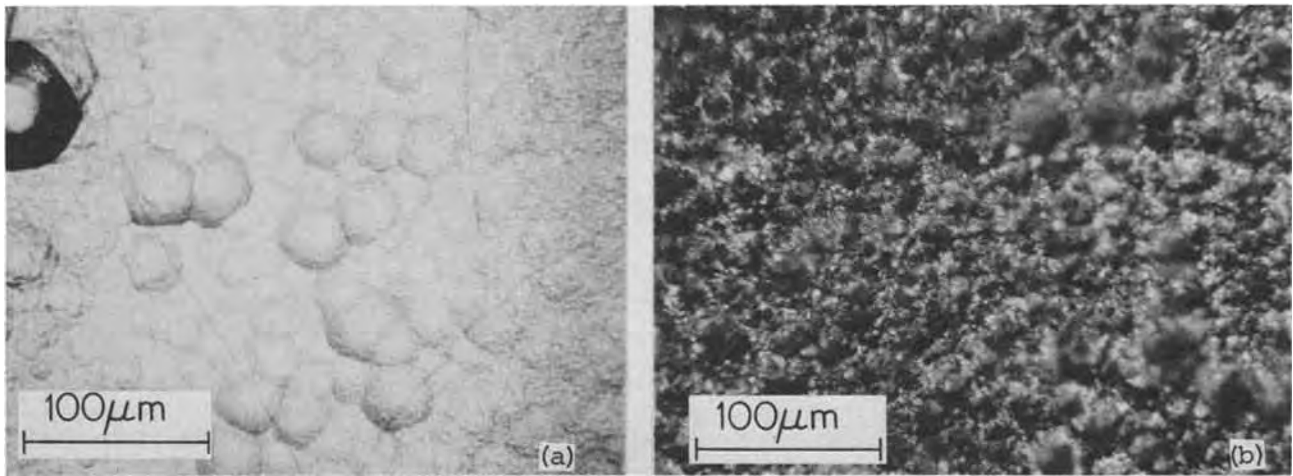

Fig. 3. Photomicrographs of severely degraded polycrystalline-silicon film deposited with $[O_2]/[H_2]$ = 44 ppm. (a) Near edge; (b) ⅛ in. from edge.

The severely degraded wafer (Fig. 3) again shows the same large-grained structure near the center, but the grain size diminishes more rapidly toward the edge of the wafer. [Compare position (b) of the severely degraded wafer with position (a) of the moderately degraded wafer.] Near the edge of the wafer, the structure appears to change completely. The faceted structure disappears and is replaced by a moundlike structure. Cracks are also seen in the silicon, probably indicating the inclusion of appreciable quantities of oxygen into the structure. The film is also much thinner near the edge than at the center because of the lower temperature near the edge during much of the deposition.

In order to determine if oxygen was actually included into the degraded polycrystalline-silicon films, wafers from the depositions shown in Fig. 1-3 were subjected to neutron activation analysis.[1] A total sample mass of approximately 3g was available for each analysis. The average oxygen concentrations indicated were approximately 370 ppm in the severely degraded sample (Fig. 3), 140 ppm in the moderately degraded sample (Fig. 2), and less in the control sample (Fig. 1), clearly showing that oxygen was incorporated into the structure of the degraded polycrystalline-silicon films during the deposition.

Although the oxygen concentration in the films increased monotonically with increasing oxygen addition to the reactor gas stream, the increase did not appear to be linear. The amount of degradation did not appear to be a linear function of the oxygen flow either, indicating that the degradation process accelerated once it started. Once the edges of the wafer started lifting from the susceptor and cooling, increasing quantities of oxygen were probably included into these areas of the film. On the other hand, the oxygen concentration indicated by the neutron activation analysis was an average over the entire sample.

A further series of depositions was performed in order to determine the relative importance of the deposition rate and the oxygen-to-silicon ratio in the deposition chamber. The conditions and results of these depositions are summarized in Table I. Some films were deposited at the normal rate of 4 μm/min (depositions 26 and 27) while others were deposited at half this rate (depositions 29, 30, and 31). A control deposition at each rate produced films of good quality (deposi-

[1] Analysis performed by Gulf Radiation Technology, San Diego, California 92100.

Table I. Deposition conditions and results

Deposition No.	Deposition rate (μm/min)	$[O_2]/[H_2]$ (ppm)	$[O_2]$ / $[H_2]$ × Dep. rate (10^{-6} min/μm)	Degradation
26	4.0	0.0	0.0	None
27	4.0	18.3	4.6	<No. 29
29	2.0	18.3	9.2	Severe
30	2.0	9.6	4.8	<No. 27
31	2.0	0.0	0.0	None

tions 26 and 31). The same oxygen flow was used for depositions at the two rates (depositions 27 and 29) so that the oxygen-to-silicon ratio was doubled for the lower deposition rate (deposition 29). Markedly less degradation was observed for the higher deposition rate (deposition 27), indicating that the oxygen-to-silicon ratio is more significant than is the oxygen partial pressure in the deposition chamber. The oxygen flow was halved in an additional deposition at the lower rate (deposition 30) so that a comparison of different deposition rates could be made for a similar oxygen-to-silicon ratio (depositions 27 and 30). Noticeably less degradation was observed in the film deposited at the lower rate (deposition 30), indicating the importance of the deposition rate, as well as the oxygen-to-silicon ratio, in determining the film quality.

Large quantities of nitrogen have also been found to induce severe degradation. Colored regions, probably indicating the presence of silicon nitride, as well as cracking of the wafers, were seen. Since moderate quantities of nitrogen do not induce marked degradation, and since both oxygen and nitrogen (as the principal constituents of air) will probably be present at the same time, oxygen is felt to be the contaminant of greater concern.

Discussion

In the previous section we have shown that the stress in the deposited films is related to the amount of gaseous contamination present in the system, the deposition temperature, and the deposition rate, that the stress is tensile rather than compressive, and that oxygen can be included into the growing film.

The origin of the stress may probably best be understood on the basis of the model proposed by Klokholm and Berry for the case of polycrystalline metal films (5). They argue that the tensile stress results from the internal rearrangement of deposited atoms beneath the growing surface of the film. The deposited material may be considered initially to have a disordered structure and a density less than that of the crystalline material. Consequently, any annealing which produces a more nearly perfect crystalline arrangement results in a tendency for the deposited layer to contract.

The necessity for internal rearrangement in the present case is probably related to the ease of surface diffusion of the depositing silicon atoms and the disorder present in the surface layer when it becomes buried by subsequently arriving atoms. If the surface atoms can reach low energy positions before they are buried, little internal rearrangement will be necessary, and little stress will be developed. However, a small quantity of adsorbed impurity atoms, such as oxygen, may severely impede surface diffusion of the deposited silicon atoms. The silicon atoms must then continue to rearrange after they have been covered by subsequently arriving atoms, resulting in the incorporation of a highly stressed layer in the depositing film.

At a given temperature and a given ratio of oxygen-to-silicon atoms arriving at the surface, the surface atoms will have a longer time to rearrange at lower deposition rates. Consequently, less internal rearrangement will be necessary, and less deformation will develop, as observed. However, more severe degradation was seen when the deposition rate was halved and the oxygen-to-silicon ratio was doubled, indicating that the number of adsorbed contaminant atoms is more significant than is the deposition rate.

As the temperature increases, several effects will occur. Surface diffusion will increase since it is a thermally activated process. The number of adsorbed oxygen atoms will decrease since they can re-evaporate more easily, either as oxygen or as SiO. Therefore, surface diffusion can proceed more easily and less stress will develop. On the other hand, the yield strength of the substrate will probably decrease as the temperature increases. This decrease must be less rapid than the decrease in the bending force since less deformation is observed at higher deposition temperatures.

At a first glance, the detrimental effect of only a few parts per million (about 10^{-3} Torr) of oxygen in the reaction chamber may seem unlikely. However, Adamsky (6) and Khan (7) have found that the presence of even 10^{-8} Torr of oxygen may severely affect the deposition of germanium films; so the influence of several orders of magnitude greater concentrations of oxygen in the present case is not unlikely.

Murbach and Wilman (8) have investigated the effect of oxygen on the stress in evaporated aluminum films and have found large stresses resulting from the formation of oxides at the grain boundaries. These stresses were compressive, however, unlike those in the present case, indicating that the presence of silicon oxide at the grain boundaries of the polycrystalline-silicon films is not dominant.

The less severe deformation in the simultaneously deposited epitaxial films indicates that the atoms can reach low energy positions in these films more easily since less surface diffusion is necessary. Then the major factor influencing the deformation is the inclusion of oxygen into the films. This can cause compressive stress and curvature in the opposite sense from that in the polycrystalline-silicon films.

Summary

The degradation sometimes observed during the deposition of thick polycrystalline-silicon films for dielectrically isolated integrated circuits has been related to the inclusion of trace quantities of oxygen into the structure of the films. The elimination of this contaminant from the deposition chamber allows the reproducible fabrication of high quality films.

Vacuum Deposited Silicon Devices on Fused Silica Substrates

Charles Feldman and Richard Plachy

Applied Physics Laboratory, The Johns Hopkins University, Silver Spring, Maryland 20910

ABSTRACT

A technique is described for fabricating diodes and MOS devices from vacuum deposited polycrystalline silicon films on insulating substrates. Extremely pure vacuum deposited amorphous silicon films on fused silica substrates were converted into the crystalline phase during device processing. The samples could be converted either during gaseous diffusion of boron or phosphorus at 850°-950°C to form n- or p-type layers or during the initial oxidation step at 1000°C in the device definition stage. Film purity was checked by sputter-ion source mass spectrometry. Gaseous diffusion and oxide masking procedures were similar to those used in silicon integrated circuit technology. The quality of the initial resulting planar devices indicates that the process has the potential for producing a variety of silicon devices.

A goal for many years in the field of microelectronics has been the achievement of active devices from vacuum deposited films on amorphous insulating substrates (1). All of the currently successful thin film devices, in contrast, are formed epitaxially onto single-crystal substrates (2, 3). Thin film majority carrier field-effect transistors were produced some time ago from vacuum deposited germanium (4), tellurium (5), and various chalcogenides (6, 7) onto glassy substrates. These devices, however, lacked the stability and versatility to compete with silicon devices and integrated circuits. Field effect devices have recently been fabricated with some success from polycrystalline silicon deposited by thermal decomposition of silane onto oxidized single-crystal silicon substrates (8). The amorphous oxide layers on these substratets are similar in some respects to the fused silica substrates used here.

It was believed that both the polycrystalline structure and the impurities in vacuum deposited semiconducting films prevented their use in practical devices. The formation of controlled n-type and p-type material in the films was considered extremely difficult. Vacuum deposited germanium and silicon are amorphous when condensed on ambient temperature or unheated substrates. Crystalline films must be formed by deposition onto hot substrates or by heating to a "crystallization temperature" after deposition. The crystalline films were, however, always p-type. There is controversy over whether intrinsic surface states and defects or impurities kept the film p-type (9, 10). There is a strong possibility that silicon films vacuum heated using Pyrex bell jars are p-type due to the presence of boron (11). It has been shown that impurities in germanium (and presumably also silicon) films could be reduced, however, if proper purification techniques in the vacuum were employed (12).

Most of the problems in producing pure films lay in the difficulty of determining the impurities present. The thickness of the samples and small amount of total material made analysis practically impossible. Recently a sputter-ion source mass spectrometry study of amorphous and crystallized silicon films was carried out in this laboratory (13). It was found that with proper precautions pure amorphous films could be produced in the vacuum and that if these films were heated in a pure inert atmosphere, they could be crystallized without the further introduction of impurities.

In this paper, the conversion of these pure amorphous films to n-type and p-type crystalline films is described. It was found possible to process the amorphous films directly into crystalline devices using standard silicon integrated circuit techniques, and details of this work are presented. It is believed that this study represents the first time that vacuum deposited polycrystalline silicon films on insulating substrates have been successfully processed into practical devices.

Key words: silicon films, thin film devices, thin film device processing, thin film p-n junctions, thin film transistors.

Preparation of Amorphous Silicon Films

The samples were deposited by electron beam heating of silicon contained in a well-cooled stainless steel crucible with a molybdenum liner onto fused silica substrates held at temperatures from 300° to 500°C. The initial pressure was approximately 5×10^{-9} Torr, and the pressure during deposition was approximately 5×10^{-6} Torr. This pressure rise appears to be largely due to CO_2 from the silicon melt. Details of the deposition technique and the sputter-ion source mass spectrometer study were given in a previous report (13). The impurities present in the amorphous films 82B and 97A used here are approximately those listed in the previous report as 82C, Table II, and 93C, Table III, respectively. The substrates were high purity semiconductor grade fused silica which were polished by the manufacturer.[1] They were cleaned ultrasonically in detergent and deionized-filtered 18 megohm-cm water.

Conversion to n- and p-Type Polycrystalline Films

The amorphous layers were converted to the crystalline phase and their electrical properties studied in order to assay the qualities of the layers for device application. The transition from amorphous to crystalline silicon films is a function of both time and temperature (14). During the conversion the short-range order of the amorphous phase with a coordination number of 4 is converted into the crystalline phase having the same coordination number, but with longer range order. A separate nucleation step was not observed in the silicon films crystallized here. Figure 1 shows a plot of time to crystallize *vs.* $1/T$. Note that the extrapolated portion of the curve gives a crystallization time of 3 sec at 850°C. Times and temperatures considerably greater than necessary for crystallization were employed in the device processing described here and considerable grain growth probably took place. The grain size in devices processed according to the steps listed in the next section was estimated by microscopic examination and found to be between 0.5 and 1μ in diameter.

In order to produce n- or p-type samples, the amorphous films were crystallized directly in a diffusion furnace where either phosphorus or boron dopants could be introduced into the film at the same time. Standard diffusion techniques using diborane and phosphene gases were employed. Both n- and p-type layers with smooth, uncrazed surfaces and with controllable resistivity were achieved. Because of the

[1] U.S. Fused Quartz Company, Fairfield, New Jersey.

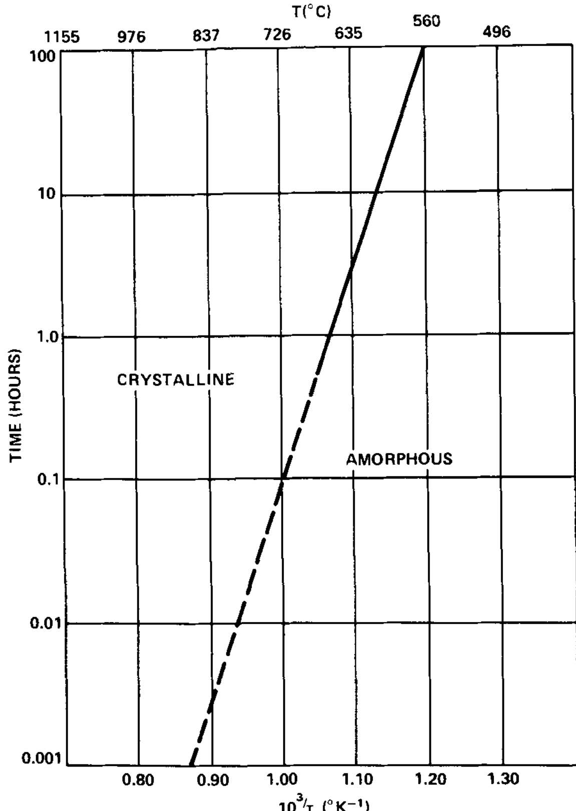

Fig. 1. Crystallization time vs. temperature in silicon films

thinness and polycrystalline structure of the films, diffusions were carried out at 850°-950°C instead of the 1000°-1200°C usually used in crystalline material. The sheet resistances resulting from doped and undoped crystallizations are given in Table I.

Conductivity type was checked with a thermoelectric probe and in every case there was agreement with the expected dopant type. In a typical doping experiment (sample 73B), phosphorus diffusion for 13 min at 950°C produced a surface layer having a sheet resistance of 450 ohms/□, while the undoped film, fired at the same temperature, had a sheet resistance of 2.6×10^{10} ohms/□. Note that the undoped crystallized sample (Si 73C-2) exhibited a higher sheet resistance than the companion unheated amorphous sample (Si 73 C-1). Some of this resistance may be due to grain boundaries. In films less pure, however, crystallized samples have a lower resistivity than their corresponding amorphous phase.

In another set of controlled diffusions (sample 82B), a crystal wafer of opposite conductivity to the dopant was placed alongside the thin films in the diffusion furnace. The phosphorus-doped film and the wafer showed approximately the same sheet resistance. The boron-doped film, however, exhibited a sheet resistance an order of magnitude higher than the corresponding wafer. The reason for this discrepancy is not clear. A quantitative comparison of film and wafer resistance is, of course, fraught with difficulties. A preliminary correlation of diffusion constants in the films was not possible because the diffusion times were of the same order of magnitude as the time to come to temperature equilibrium in the furnace. Note that the last three items listed in Table I concerning sample Si 97A were measurements made from the test pattern (Fig. 2) after the complete device processing which is described in the next section.

Table I. Diffusions in thin silicon films

Sample	Thickness, A	Dopant type	Temperature (°C)	Time (min)	Sheet resistance ohm/□
Si 73B	4400	n(phosphorus)	950	13	4.5×10^2
Si 73A-1	4400	n(phosphorus)	850	8	2.3×10^5

* After complete device processing.

Device Formation

The amorphous films were processed into active test devices using techniques similar to those employed in standard silicon wafer processing for monolithic integrated circuits (15). The initial steps in the processing consisted of oxidation in dry oxygen for several hours. During this step, the film was converted to its crystalline state, thus the conversion was completed before diffusion began. This is a slight variation in procedure over the samples described in the previous section which were converted during diffusion. Diborane and phosphene were used as gaseous diffusion sources. The films were subjected to the following steps: (*i*) oxidation at 1000°C in dry O_2 for 3 hr; (*ii*) photolithography; (*iii*) p-diffusion at 850°C for 13 min (deposition); (*iv*) p-diffusion at 1000°C in O_2 for 2 hr and argon anneal 20 hr at 1000°C; (*v*) photolithography; (*vi*) n-diffusion at 850°C for 15 min (deposition); (*vii*) n-diffusion, 1000°C in O_2 for 1 hr (drive-in); (*viii*) aluminum deposition; (*ix*) photolithography; (*x*) sintering at 450°C.

As in the simple doping experiments, the times and temperatures were less than those usually used since higher diffusion coefficients were expected for the films (16). The oxidation steps were designed to result in less than the normal oxide thickness so that the silicon films would not be consumed in the formation of the various required oxide layers. The films were annealed in argon during the lightly doped p-type drive-in diffusion (step *iv*). The processing sequence for active devices was intended to result in a lightly doped p-diffusion in order to obtain both a high breakdown voltage on the diodes and a substrate region for n-channel enhancement mode MOSFET's. A thin high concentration n-type region was used in order to simplify the processing yet have nonrectifying contacts with the aluminum metallization. The shallow depth was intended to be utilized when this diffusion was used for the gate of the junction field effect devices in the test array.

Device Characteristics

Three successful device runs using a special mask set were made following the techniques described above. A photomicrograph of a test pattern with the devices indicated by letters is shown in Fig. 2. The test mask included: junction FET's (A), n-channel enhancement mode MOSFET's (B), two types of p-channel depletion mode MOSFET's (C), four-point probe test devices for each diffusion and the substrate (D), two large diodes (E), and two types of Hall mobility test structures (F). With the exception of the junction FET's, all devices operated to some extent. The n-channel enhancement mode MOSFET's and p-n double diffused diode exhibited characteristics useful for normal circuit operation. Typical electrical test data taken from the diodes and n-channel MOSFET's and small Hall configuration are compared with estimated equivalent bulk data in Table II. The "bulk" data from the devices are considered typical of those devices fabricated in the same laboratory starting with single-crystal silicon wafers. The threshold voltage range for the films was determined at drain current 1 μA and was checked by a plot of the square root of the drain

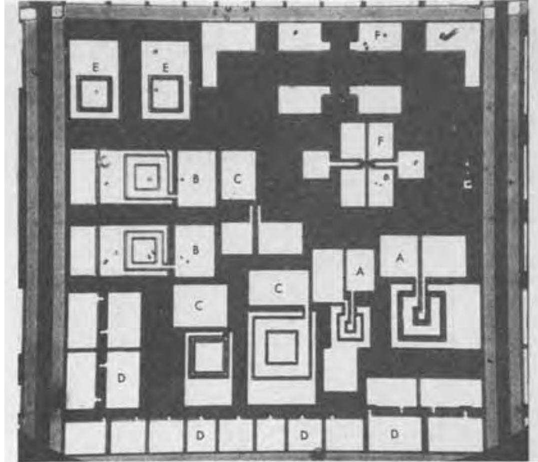

Fig. 2. Test pattern on silicon film (80x80 mil). Letters identify devices in the text.

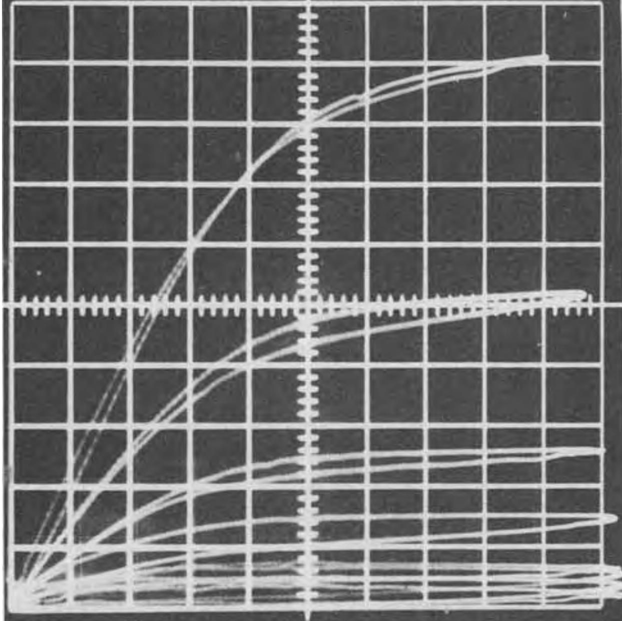

Fig. 3. n-channel MOSFET. Horizontal, 1 V/div; vertical, 1 μA/div; steps, 0.8V.

current *vs.* gate voltage in the manner suggested by Richman (17).

The junction FET's required a very shallow n^+ diffusion in order to leave a p-doped channel under the n^+ gate. In the runs where this device could have been fabricated, the n^+ diffusion was too deep.

The electrical characteristics of the n-channel MOSFET's are shown in Fig. 3, and the cross section of the device is shown in Fig. 4. The transconductance of these initial devices is lower than would be expected in single-crystal silicon. The capacitance is also low in this structure, however, and device operating speeds may be acceptable.

The p-channel depletion mode devices were a useful test vehicle. To fabricate a good p-channel depletion mode device, it is necessary to perform an extremely shallow and light impurity diffusion. Such a diffusion was not attempted, and these devices therefore showed the extremely low transconductance that one would expect from a thicker and more heavily doped channel region. The transconductance for these devices was approximately 0.1 μmho.

Table II. Electrical test data

	Film	Bulk
Junction breakdown voltage	8V	8V
g_m (n-channel FET)	2-25 μmhos	50-200 μmhos
Diode reverse recovery time	20-60 nsec	20-50 nsec
Threshold voltage	1-6V	0.5-1V
Gate breakdown voltage	15V	80V
(p-layer) Hall mobility	20-35 cm²/V-sec	80-90 cm²/V-sec

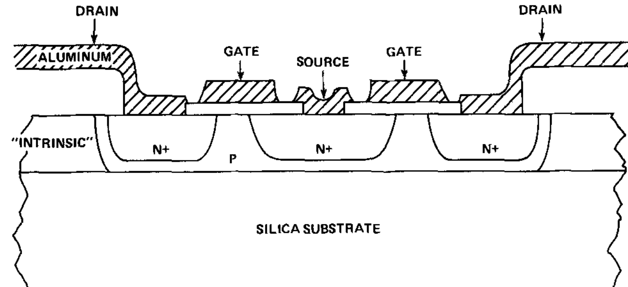

Fig. 4. Cross section of MOSFET

The Hall effect test structures were only used for p-diffusions. The data (Table II) indicate that the sample mobility is somewhat less than expected in bulk samples. The "bulk" Hall mobility was estimated from that expected for an equivalent thickness single-crystal semiconductor taking into account size and carrier concentration effects (18). The Hall effect device also provided data showing that the average concentration in the p-type layer was about 5×10^{17} carriers/cm³.

The four-point probe test devices made it possible to evaluate the effect of each diffusion into the samples. The results of these measurements on sample Si-97A are listed in Table I. Measurements of the sheet resistance coupled with measurements of film thickness yielded the average resistivity in the diffused layer. This resistivity was used to calculate the Hall mobility for the p-type layer listed in Table II.

The junction diodes appeared to be excellent and compared well with similar junctions made in single-crystal films. The forward and reverse diode characteristics are shown in Fig. 5.

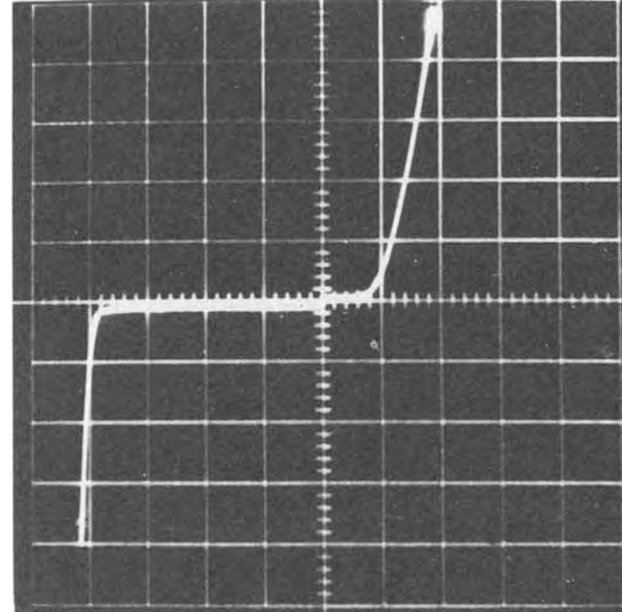

Fig. 5. p-n junction characteristics

	Forward	Reverse
Vertical	0.05 mA/div	0.01 mA/div
Horizontal	0.5 V/div	2 V/div

Discussion

It has been demonstrated that vacuum deposited silicon amorphous films 0.5-0.8μ thick on fused silica substrates can be successfully converted into n- or p-type crystalline films. The amorphous layers may be directly processed by standard microelectronic techniques, and polycrystalline devices with useful characteristics fabricated. Considerable study remains to be done, however, in order to maximize device quality. It is probable that both the high purity achieved in the amorphous films and the larger grain size developed during the processing contribute to the success in forming devices.

It is interesting to compare the properties of the polycrystalline films formed here by vacuum deposition and subsequent heat-treatment with those formed by decomposition of silane onto oxidized silicon wafers by Kamins (8, 19). Kamins measured a Hall mobility in 5μ thick p-type films with 5×10^{17} carriers/cm^3 of approximately 38 cm^2/V-sec, and his data indicate a far lower mobility for films 0.5-0.7μ thick. The films formed here with the same carrier concentration and approximately one-tenth the thickness have a mobility of 32 cm^2/V-sec. Kamins observed in p-channel MOSFET's a rather high threshold voltage which he attributed to defects and concluded that the polycrystalline films formed by him may not be generally useful. While defects and impurities generally behave differently in n-channel devices, the threshold voltages observed appear similar to those formed in crystalline devices. One may conclude that the vacuum formed layers contain fewer defects, impurities, and/or larger grains than the chemically deposited polycrystalline layers.

Since the presentation of this work, King *et al.* (20) have reported studying vacuum deposited silicon films on oxidized silicon wafers for resistor applications. They were able to dope and process their amorphous deposited layers directly into polycrystalline resistors in a process somewhat similar to that described here. The mobilities achieved, however, do not appear adequate for device formation and impurities which generally plague vacuum deposited films may be present in these films. The influence on layer properties of the oxidized silicon substrates used by King *et al.*, and Kamins, compared to the fused silica substrates used here, should be further explored. The SiO_2 surfaces differ in density, surface structure, and impurities, all of which affect the quality of the deposited silicon film.

Silicon Slice Analyzer Using a He-Ne Laser

H. J. Ruiz, C. S. Williams, and F. A. Padovani*

Texas Instruments Incorporated, Dallas, Texas 75222

ABSTRACT

Design criteria and performance characteristics are presented of an optical system capable of detecting imperfections (fractures, scratches, etc.) on the polished surfaces of semiconductor materials. This instrument is also capable of providing fast and accurate defect counting and distribution on polished, etched semiconductor surfaces. The principle involved is that of scanning a He-Ne laser beam which is focused on the surface of the slice, and analyzing the reflected and scattered light via polarizers and photomultipliers.

It would be very desirable in a production environment to have a device which could automatically analyze the surface quality of polished semiconductor surfaces. Such a device would provide a consistent and more objective scrutiny of slices than that obtained visually by an operator who has to make a value judgment on the appearance of the polished surface under strong light illumination. This device should be designed to be accurate, fast, and nondestructive, such that the tolerated surface imperfections meet today's strict requirements of polished substrates.

Minor modifications can make this device into an important tool in a research laboratory. Defects such as swirls, which exhibit a particular distribution on polished slices after preferential etching, have been shown to be correlated to impurities and/or vacancies which have been incorporated into the material during growth (1). A given distribution may be correlated to crystal-pull rate, rotation, or to the thermal profile of the crystal-puller environment. An accurate knowledge of the distribution of these defects will be extremely helpful in acquiring an understanding of the kinetics of impurity incorporation during crystal growth. This report describes below the modifications necessary for the instrument to provide accurate defect counts and their distribution over the surface of the slice. The focused spot size can be varied from about 50μ up to the beam diameter size which is 1 mm. The size of the focused spot is determined by the size of defects to be analyzed. The time required to obtain a defect count along the diameter of a 2 in. slice (see Fig. 7) is 3 min. The time required to assess surface quality on a 2 in. slice is estimated to be 10-15 sec. Here, surface quality assessment refers to the inspection of a slice for scratches, film, fractures, etc., with a predetermined amount of scattered light chosen as the criteria for accepting or rejecting a slice.

System for Surface Quality Inspection

A schematic diagram of the system used for surface quality inspection is shown in Fig. 1. The main optical element is a bispherical condenser (BC) which is a modification of a standard optical element often used in dark field illuminators of microscopes. In the slice inspection device, the BC becomes a collector of scattered light rather than a condenser of illuminating light. The two reflecting surfaces are aluminized and protective overcoated with MgF; the two transmitting surfaces are antireflection coated. The illuminating light is incident on the slice almost normally by passing through a hole that is centered on the BC optic axis. The collecting focusing optical system comprising the BC and the positive lens was computer designed to give an on-axis image of the illuminated spot on the slice. In the configuration shown, light scattered, as from a small surface defect, into the solid angle between the cones of half angles of approximately 32 and 62° is collected by the BC and subsequently enters the field stop. Specularly reflected laser light, as from a mirrorlike silicon surface, is outside the collection solid angle and, hence, will not pass through the optical system. A long wavelength pass optical filter (a Corning glass filter HR2-61) is used at the field stop. The cuton of the filter and the cutoff of the photomultiplier tube spectral response (110 or S-20) effectively form a bandpass filter centered approximately at 0.6328 nm. Thus light passing through the field stop is restricted to only laser light scattered from the slice surface. The polished silicon slice is mounted on a spinning vacuum chuck such that the polished surface lies in the object plane of the optical system and also at the focus of the laser beam. The laser beam undergoes scattering whenever it encounters a defect on the silicon surface. The scattered light is collected by the BC, focused, and passed through a field stop, and then detected by the photomultiplier. The laser used was a Spectra Physics Model 132. Figure 2(b) is a photograph of an oscilloscope trace for signals produced by a clean, defect-free silicon slice. The slice is being rotated so that the laser beam is scanning a circle about the center of rotation. Figure 2(a) is a similar picture for a slice exhibiting film (*i.e.*, surface roughness) and a scratch. The scans for Fig. 2(a) and (b) were done at a fixed radius from the axis of spin. In another mode of scan, the He-Ne laser is translated such that the beam moves out toward the edge of the slice as it is spun, thus scanning a spiral pattern over the surface. The scanning of the light is accomplished by translating the entire optical system, *i.e.*, optics and the laser together, which is mounted in a rigid single structure. To measure the total light scattered during one spiral scan, the electronic signal of the photomultiplier was inte-

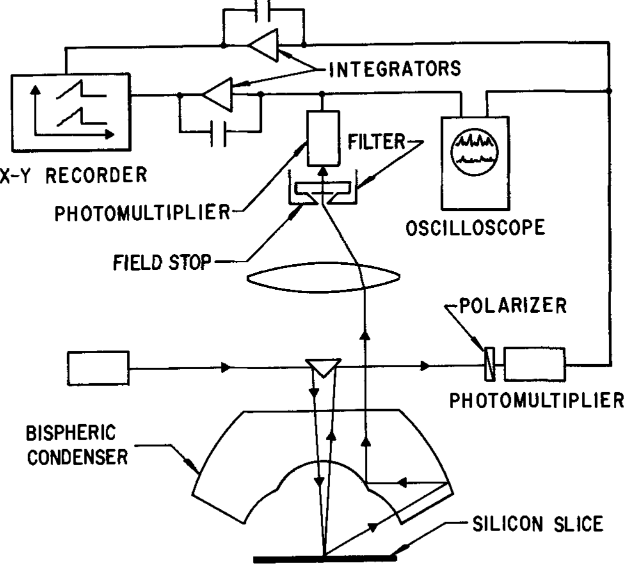

Fig. 1. Schematic diagram of slice inspector

Key words: surface defects, defect counting, slice inspection, laser analyzer.

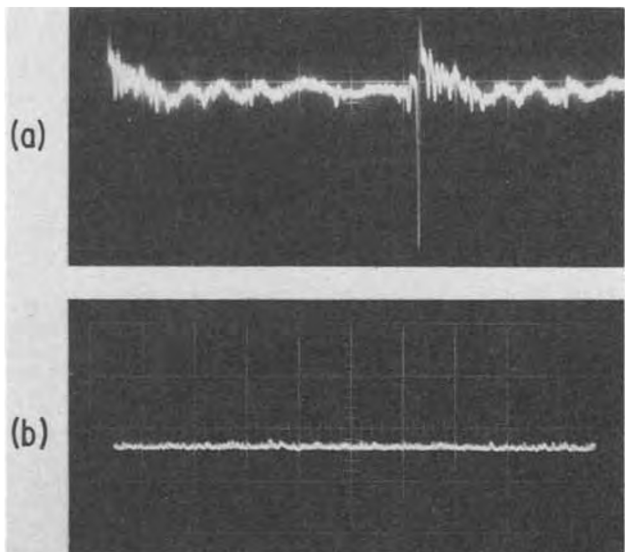

Fig. 2. Oscilloscope trace of signal obtained using (a) a slice with uniform film and a scratch, and (b) a clean defect-free slice.

grated (see Fig. 1). The output of the integrators, which is a summation of all the light scattered during a scan, provides information concerning the surface quality of the material. Figure 3 illustrates three different integrator outputs: Fig. 3(a) corresponds to a clean, defect-free slice; Fig. 3(b) corresponds to a slice with uniform film over the surface; and Fig. 3(c) corresponds to a slice exhibiting a number of defects. The shape of the electronic signal from the integrators is an indication of the surface condition, and the total integrated signal (the intensity of the electronic signal at the end of the scan) indicates the extent of surface imperfections.

By elliptically polarizing the incident beam and introducing an analyzer at the input to the photomultiplier detecting the reflected light (see Fig. 4), one is able to distinguish scratches from fractures. In the language of silicon material science, the word "fracture" refers to a special type of defect that appears too often on silicon slices. A furrow cut into a slice surface might be a scratch or a fracture, but a fracture in contrast with a scratch might be forked and the slice surface would slope gradually toward the fracture. Thus the polarization of a beam is different when reflected from the surface near a fracture whereas when reflected from a point near a scratch the beam is polarized just as it would be from a defect-free surface. The polarization ellipse and direction of its major axis can be adjusted by rotating the first analyzer and the quarter-wave plate. The ellipticity of the beam was chosen such that after reflection on a clean, defect-free, polished silicon slice, the beam would become linearly polarized, and thus be rejected by the linear analyzer. Because of surface slopes near fractures (see Fig. 5) these defects will cause the beam to retain some ellipticity thus allowing a second photomultiplier to detect this signal. The beam is shown in Fig. 4 to be incident at almost normal incidence; however, the polarization effects could be increased by increasing the beam angle of incidence.

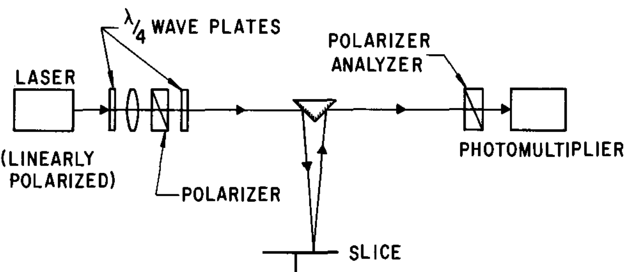

Fig. 4. Polarizing arrangement to differentiate scratches from fractures.

System for Quantitative Analysis of Surface Defects

The instrument described in the previous section has been slightly modified to provide the capability for accurate defect counting and defect distribution evaluation on a silicon slice. The slice is no longer mounted on a spinner, but rather on a translational stage, and the He-Ne laser is fixed. The schematic diagram of the optics is similar to that shown in Fig. 1. The laser beam enters from the left, passes through a 30 cm focal length lens, and after being reflected off an aluminized prism it is focused on the surface of a silicon slice. If the slice is "perfectly" flat and defect-free (an ideal mirror) the laser radiation will be specularly reflected onto the other side of the prism and exit to the right out of the system. (The photomultiplier which detects reflected light is removed.) However, if the laser beam encounters imperfections on the surface of the slice, *i.e.*, defects such as pits, dislocations, faults, etc., the radiation will then be scattered and collected by the BC. The collected scattered light is focused by a lens into a diffuser screen placed in front of the photomultiplier tube as shown in Fig. 1. The output of the photomultiplier tube is terminated by a 1 kohm resistor, and the voltage developed across this resistor is

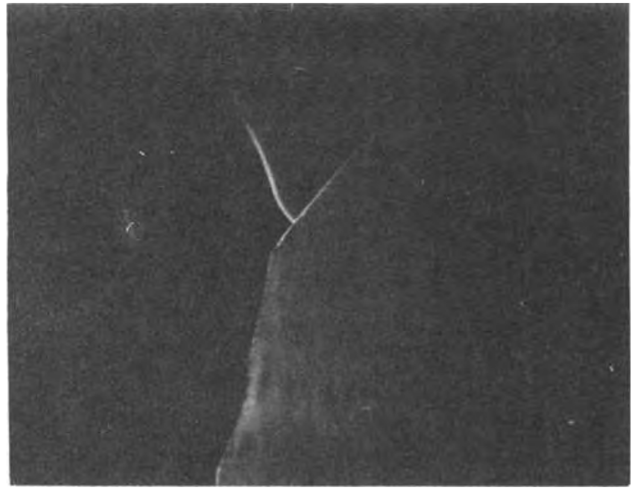

Fig. 5. Microscopic photograph (32×) of a fracture illuminated by polarized light and viewed through a polarizer (analyzer).

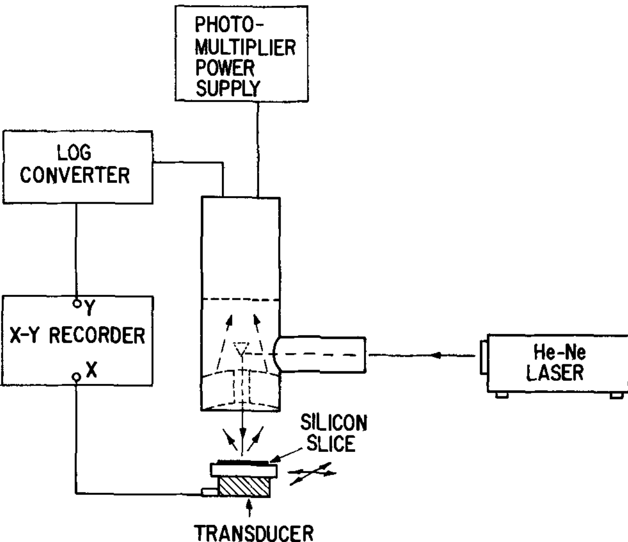

Fig. 6. System setup for defect counting and distribution evaluation.

fed into an electronic logarithmic amplifier (see Fig. 6). The output of the logarithmic converter drives the Y input to an X-Y recorder while the X input is driven by the output of a linear transducer which is coupled to a translatable stage that allows the slice to be scanned along a diameter. One thus obtains an output of linear distance (horizontal) *vs.* the logarithm of the defect density.

The performance of the instrument is based on the assumption that the defects one is trying to count scatter the light in a well-defined statistical distribution. Thus, let I_S be the average light scattered by a defect of a particular type, let N be the number of defects present in the sampled area, and K be a constant which relates the photomultiplier current I_{PM} to the amount of light received by the tube. Then

$$I_{PM} = KNI_S$$

Since I_S is constant for a given defect, and since the sampled area remains unchanged, the photomultiplier current is proportional to the defect density. Since I_S has a different value for every kind of defect, the instrument must be calibrated for each particular defect one wants to study. If the slice under inspection contains two types of defects, then one of the defects must have a uniform density across the slice such that an accurate count and distribution can be obtained on the other defect. If two defects, however, show marked variation in the distribution on a slice, then the apparatus can neither differentiate the two nor be offset so that only one defect can be studied. We have found this situation rarely present.

Some typical results obtained with this instrument are shown in Fig. 7. Upon Sirtl etching, a boron-doped silicon slice, about 15 ohm-cm, exhibited a distribution of shallow etch pits which formed a swirl pattern. The laser analyzer was used to scan the slice along a diameter, and the results are shown in Fig. 7, which illustrates the shallow etch pit density variations across the slice. A macrophotograph of the slice used is shown on the upper right-hand corner of the figure with the laser path marked.

Possible Extensions of the System

Coupling the system, as described here, with a cathode-ray tube display would prove very useful from the production standpoint of surface quality inspection. The spinner and/or translation position could be used to map out on the cathode-ray tube screen a picture of the slice (3). The photomultiplier output which detects the scattered light could then be used to control the intensity of the cathode-ray tube display, thus obtaining a picture of the slice with bright spots appearing at all scattering centers. The operator could then either count the bright spots (which could also be done electronically), or if all the defects are on the edge of the slice, make a judgment as to whether the slice would pass a given quality control test.

The He-Ne laser in this system could also be replaced by a combination of He-Ne and He-Cd lasers, such that the rastering beam will contain two different frequencies. Analyzers and/or filtering schemes could then be used to allow the photomultiplier to detect either wavelength separately. The relative intensity of the light scattered at the two wavelengths will provide information as to the relative size of different defects so long as the defect size is not larger than about 0.1 μm. This arises from the fact that the intensity of Ray-

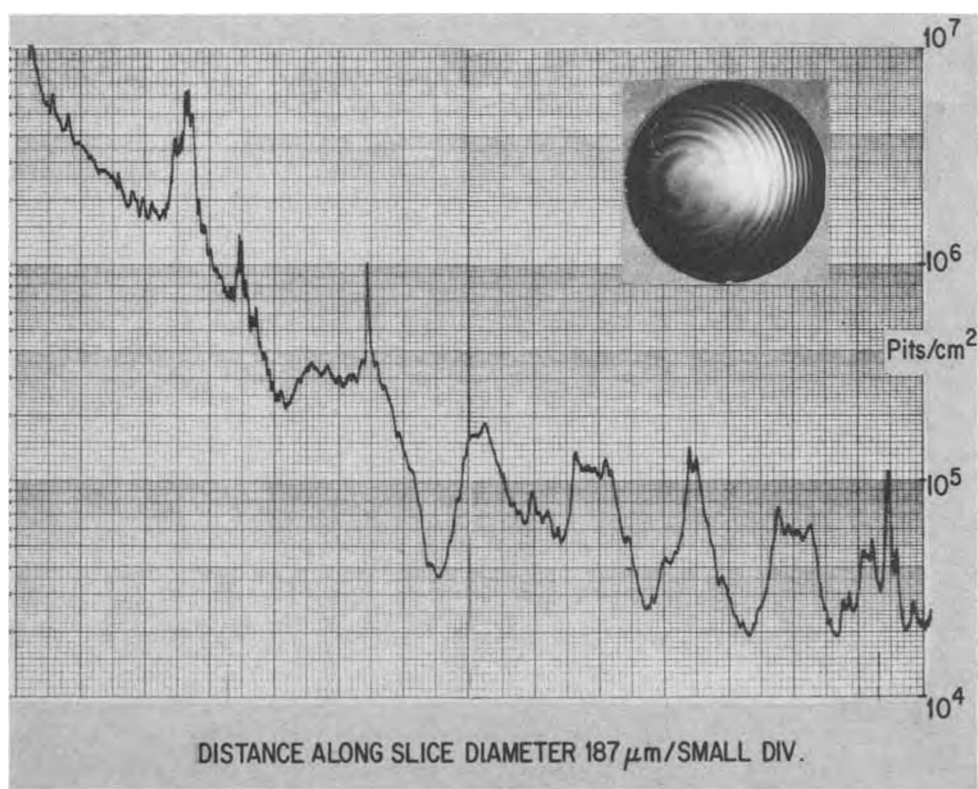

Fig. 7. Variations of shallow etch pits across a slice diameter as determined with the slice analyzer.

leigh scattering is proportional to the fourth power of the frequency of the incident radiation for scattering objects not larger than the wavelength of the incident light. The detection and differentiation of such small defects, however, might be below the range of present practical application.

Conclusions

This instrument is capable of providing an easy, accurate, fast, and objective method for assessing surface quality on polished silicon slices in production environment. In a research laboratory, it also provides an accurate and fast method for the counting and distribution determination of defects on polished surfaces of semiconductor materials. Except for isolated cases where two different defects show markedly different distributions, one can offset and/or calibrate the instrument such that only the defects of interest are counted.

Scanning Electron Microscope Studies of Premature Breakdown Sites in GaAs IMPATT Testers

R. B. Marcus, S. E. Haszko, S. P. Murarka, and J. C. Irvin

Bell Laboratories, Murray Hill, New Jersey 07974

ABSTRACT

Premature breakdown sites in Pt-GaAs IMPATT test diodes were examined with the scanning electron microscope operating in the electron beam induced current mode. Studies were made on mesa and planar structures, with and without air aging up to 350°C. The main conclusions of these studies are that (*i*) premature breakdown occurs primarily at sites of metallization defects and roughness around the periphery of the diodes; (*ii*) diode degradation and the lowering of the breakdown voltage following air aging is manifested at sites at the edge of the metallization; and (*iii*) very small sites of missing metallization ("pinholes") are sites of diode breakdown.

The reverse breakdown voltage in Schottky barrier diodes is thought to be in part limited by premature breakdown at the periphery of the metal where high field gradients are created (1). An identification of breakdown sites and a correlation of such sites with textural features of Schottky barriers has not yet been made. This paper reports on such a correlation made on Pt-GaAs IMPATT test diode structures using the scanning electron microscope (SEM) in the electron beam induced current (EBIC) mode. Experiments were made on both planar and mesa structures, some of which were aged at temperatures up to 350°C.

Experimental

Scanning electron microscopy.—The SEM used for this study was a Cambridge Stereoscan S-4 equipped with specimen current amplifier capable of covering a current range of 10^{-4}-10^{-11}A. An EDAX x-ray detector with a Northern 707 analyzer was used for x-ray analysis of selected regions. Bias was applied from a battery powered d-c source, current limited, covering the range 0-90V and 0-300 μA. Probes were constructed with X-Y motion and with vertical motion adjusted with a screw. The probes were mounted on standard 1¼ in. diameter specimen holders, and the probe tip consisted of electropolished 0.010 in. tungsten wire, gold plated.

In this study the Schottky barrier is made a part of a circuit which includes a battery and the input to an amplifier (Fig. 1). The sample is oriented in the SEM so that the incident beam strikes the active surface; the metal must be thin to allow sufficient penetration of the electron beam (see below). The minority carriers generated by the rastering SEM beam and swept across the depletion region constitute a signal which is amplified and used to modulate either the intensity or the Y-deflection of the CRT beam. Since both beams are traveling in synchronism the CRT beam displays a map of the two-dimensional distribution of reverse current at the Schottky barrier. The SEM beam current is typically $\sim 10^{-9}$A, and with one electron-hole pair produced per 3.5 eV incident electron beam energy (2) the total current generated by a 20 keV beam is of the order of 10^{-6}A, which is larger

Key words: Schottky diode, diode breakdown, SEM-EBIC.

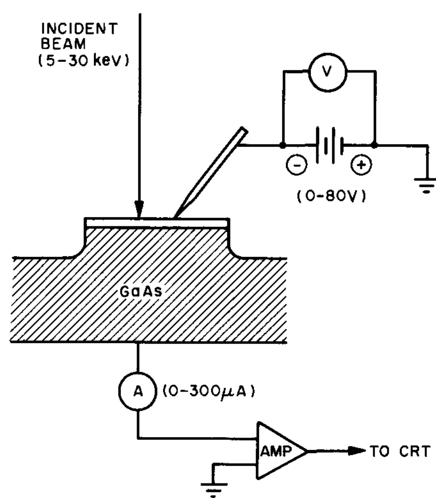

Fig. 1. Schematic diagram of circuit for obtaining EBIC signal from GaAs IMPATT tester structure.

than the zero-bias leakage currents of most diodes. Since the specimen current amplifier is capable of detecting less than 10^{-9}A current, the electron-beam induced current (EBIC) is more than sufficient to create a measurable signal at zero volts applied bias. As the reverse bias is increased a point is reached where the current begins to rise rapidly with increasing reverse bias. It is at this point that breakdown regions are first observed in the EBIC mode. These regions are sites of avalanche breakdown or sites of current enhancement due to other causes, such as tunneling; in either case the sites represent a limit to the nearly linear response of a diode under reverse bias. Since no distinction is made in this paper between diodes exhibiting "soft" and "hard" I-V character, these regions will be called "premature breakdown" (PB) regions. When breakdown sites are examined at sufficient bias to create currents in excess of 1 μA, well into the steeply ascending region of the I-V curve, the EBIC signal due to lower bias leakage is completely masked by the PB site current.

The signal created when the incident beam strikes a PB site under avalanche conditions is due in part to avalanche multiplication of the minority carrier cloud generated by the incident beam, and in part to an incremental increase in negative potential at that site. The multiplication factor is given by $M = I(\mathrm{W})/I(\mathrm{O})$, where $I(\mathrm{W})$ and $I(\mathrm{O})$ are the minority carrier currents at the end and beginning of the depletion regions, respectively. M is essentially infinite at the avalanche breakdown voltage (3), and this fact alone would permit a PB avalanche site to be imaged. The evidence for an incremental increase of negative potential at the site of the surface bombarded by the electron beam comes from two sources. In an earlier work (4) on an SEM study of silicon bipolar transistors it was found that a 20 keV electron beam directed on a highly doped n-type emitter region produced a "pinch off" of an emitter-collector short equivalent to biasing the base by ~1V negative. In the present work, as will be described below, directing a 20 keV beam on platinum at a PB site caused an apparent lowering of the breakdown voltage by ~2V. Both these observations indicate an increase in local potential of ~1V due to electron beam bombardment, which would have the effect of adding a significant increase to the measured PB current at a given reverse bias setting.

The beam "penetration" can be defined as the extrapolated value of electron transmission against film thickness to zero transmission and is expressed by the function (5) $R_Z = kE_0^n$. The incident electron beam energy is E_0. For Au the constants k and n have the values 45 and 1.5, respectively, over the energy range 5 to 15 keV (9), and the extrapolated range R_Z is 2600Å. The extrapolated range is expected to be slightly higher at 20 keV, which is the beam energy used in these experiments. Thus, a 2600Å thick Pt film is a conservative upper limit for these experiments. It was found that a 2000Å Pt film is sufficiently thin to permit an EBIC signal to be generated at a PB site under the film (see Fig. 11).

Material.—All GaAs IMPATT testers studied and reported here were made with Au/Pt and Pt metallization. Two types of structures were examined. One is a mesa structure, with the active region on the surface of the mesa as shown in Fig. 2a. The other is a planar

structure. All diodes were fabricated from vapor-phase epitaxial GaAs grown at 900°C. A Te, Se, S, or Si doped 1-3 $\times$ $10^{18}/cm^3$ n-type GaAs crystal was the substrate material. An n-type 4-7 $\times$ $10^{17}/cm^3$ S-doped "buffer" layer of 5-8μ thickness was grown on the substrate, and then an additional n-type 6-9 $\times$ $10^{15}/cm^3$ Si-doped layer was grown with a thickness of 6-9μ.

The mesa structures were formed by sputter deposition of 50-6000Å Pt followed by Au plating. Photolithography was used to form an array of dots of diameter ranging from 0.010 to 0.050 in. Mesa structures were formed on the substrate, and then the gold was dissolved in I_2 solution leaving the structure described in Fig. 2a.

The planar structures were formed by deposition of ~2000 SiO_2 at ~275°C, followed by the formation of photolithography of an array of holes in the oxide of diameters 0.010-0.050 in. Platinum was sputter deposited to a thickness of 1000-2000Å, and tape was used to remove the Pt selectively from SiO_2 where it adheres poorly; the Pt adheres well to the GaAs and an array of planar diode structures is produced as shown in Fig. 2b.

The depletion depth of this material ranges from 2 to 3.5μ over the reverse bias range 0-90V, which is the expected breakdown voltage for 8 $\times$ $10^{15}/cm^3$ n-type GaAs (7). The minority carriers are generated by the 20 keV electron beam well within the space charge region. Breakdown voltage is defined arbitrarily in this paper as the reverse voltage at 50 μA current. For all diodes examined in this study the I-V curves at 50 μA were nonlinear, and PB sites were first imaged at bias values less than or equal to the reputed "breakdown voltages." As mentioned earlier no distinction is made between soft and hard I-V characteristics, and the definition of breakdown voltage is therefore arbitrary

and is not to be considered a well-defined parameter for a particular diode.

Samples were aged in air over a temperature range of 290°-400°C for times ranging from 1½ to 216 hr; one planar structure was aged in vacuum for times up to 84 hr.

Results

General response of SEM.— The effect of the applied bias on the EBIC image for a given diode is illus-

trated in Fig. 3. The planar structure analyzed in Fig. 3 was made with 2000Å Pt, annealed in air at 29 hr 350°C, and has a breakdown voltage of 20V. At zero bias leakage is typically uniform across a diode (Fig. 3a), but distinct leakage areas appear upon application of bias (Fig. 3b). Premature breakdown sites are imaged when more than ~2 μA current is drawn and can first be imaged at bias voltages from 1 to ~15V below breakdown depending on the sharpness of the *I-V* curve. The PB sites shown at the edge of the diode in Fig. 3c were imaged at 30 μA current, 15V reverse bias. The large current response of PB sites with incremental increase of applied bias (under EBIC conditions) and the first appearance of PB sites at bias values near breakdown, both demonstrate that these are in fact sites of breakdown and not sites of diode leakage.

The change in intensity of the EBIC image at a leakage area for a constant gain setting is not a simple function of applied bias. Y-modulation EBIC images of diode A-11 on sample No. 7 were photographed at a number of bias settings over the range 2-20V; the sample was aged 1 hr in air at 350°C and breakdown was at 34V. The peak heights were measured at four sites and are plotted in Fig. 4. It can be seen that the EBIC signal is not linear with applied bias at any one site, and different sites show different responses. It was also found that the EBIC signal from regions between the visible leakage areas was at all times low and usually negligible compared with the signal from the leakage areas.

Mesa structures.—Five preparations of mesa structures were examined. These samples contained Pt metallization of thickness 50-6000Å. Details on the structure of these samples and results of the SEM studies are shown in Table I. Aspects of avalanche behavior in the mesa structures are described in Fig. 5-9.

Figure 5a shows a superimposed secondary electron emission (SEE) and EBIC image of sample 2, diode 3 after 345°C 5 hr air anneal. The EBIC image was recorded under avalanche conditions and shows PB sites at the diode edge. This is a typical observation on annealed and unannealed Pt mesa structures. Figure 5b shows a higher magnification of two of the PB sites; the PB site on the left is correlated with the Pt overhang shown in Fig. 5c (arrow). The behavior of diode 2 on the same sample is shown in Fig. 6. A superposition of SEE and EBIC images (Fig. 6a) shows metal overhang at PB sites. The Y-modulation EBIC image in Fig. 6b shows the fine structure of these sites; the fine structure is caused in part by the shape of the Pt over these regions.

The effect of electron beam bombardment of a PB site on the *I-V* characteristics was examined on sample 4, diode 12 (Fig. 7 and 8). This sample had been heated with Au for 1½ hr at 350°C; the Au was then removed before SEM study. The EBIC image of the PB site (Fig. 7b) corresponds spatially to part of the metal overhang shown in Fig. 7a (circle). A more exact identification of the location of the PB site was possible when the electron beam was used as a probe, while monitoring the *I-V* curve of the diode (Fig. 8). This

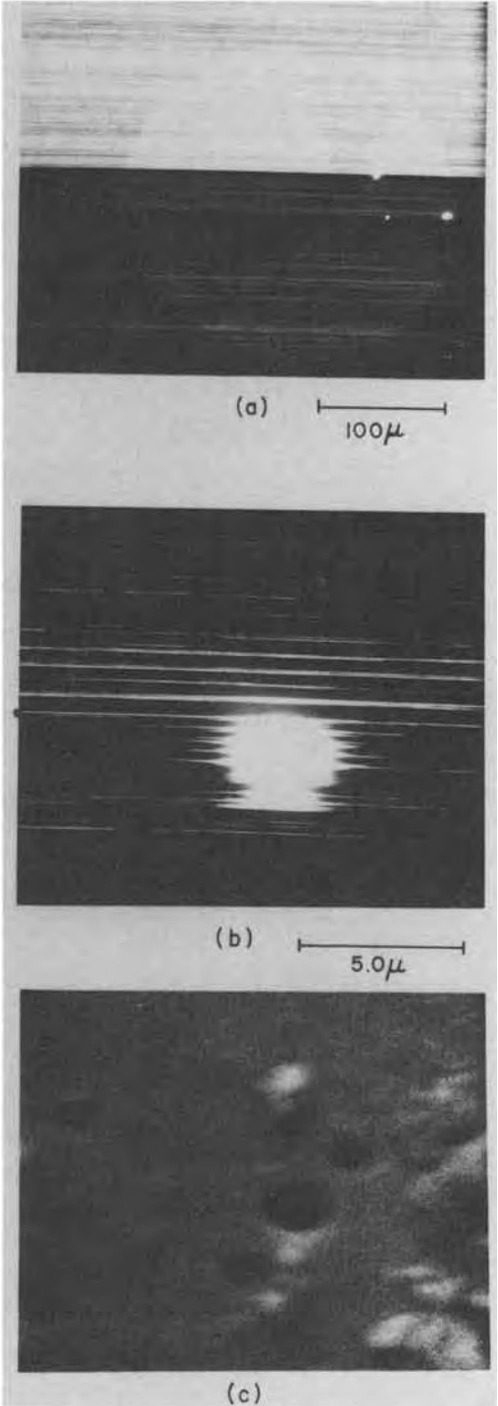

Fig. 9. PB sites away from edge of Pt mesa structure. (a) EBIC image at 30V, 230 μA showing three PB sites; (b) EBIC image of lower left PB site at higher magnification; (c) SEE image of same area as (b) showing missing Pt region corresponding to PB site. Sample 5, diode 1.

position is marked by a cross in Fig. 7a, and the effect of the beam on the diode *I-V* curve is easily seen (Fig. 8). This more careful analysis showed that the PB site was located along a sharp, well-defined crack in the overhanging metal film.

As shown in Table I, most PB sites occurred at the edge, and a comparatively small number of cases was observed where PB sites were found on the diode surface away from the edge. In all mesa structures these examined off-edge sites could be correlated with local regions of missing Pt or with other metallization defects.

Three off-edge PB sites from sample 5, diode 1 are shown in Fig. 9a. The higher magnification EBIC image

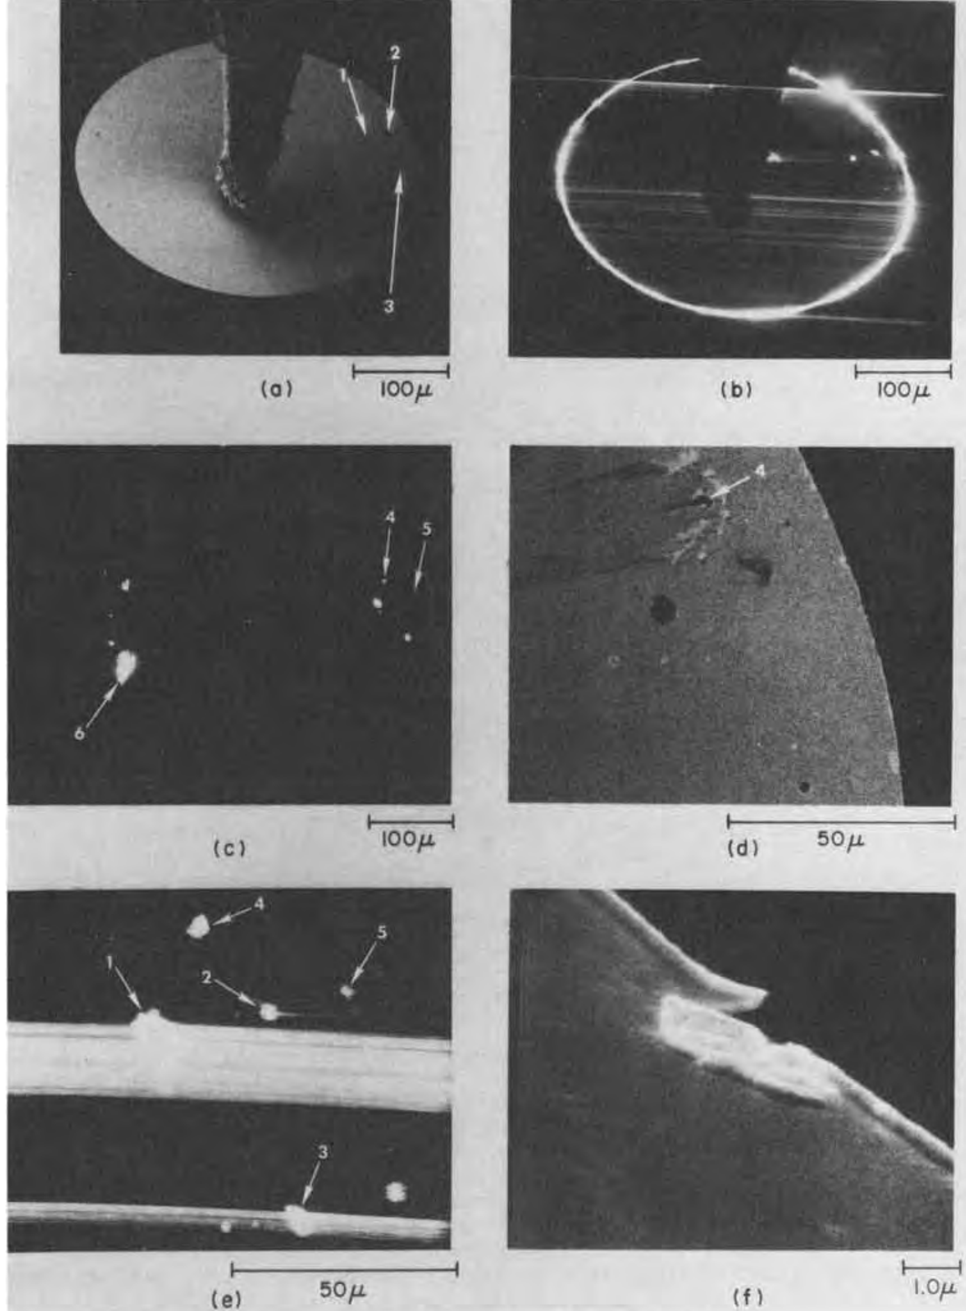

Fig. 10. PB sites at edge and away from edge of Pt planar structure. (a) SEE image showing Pt-missing regions 1, 2, and 3; (b) EBIC image at 30V, 10 μA showing PB sites at defects 1, 2, and 3; (c) EBIC image at 15V, 30 μA after aging 29 hr, 350°C in air showing additional PB sites (defect 3 is not visible at the low gain setting used); (d) enlarged SEE image showing additional defect 4 resulting from probe scratch; (e) EBIC image of same region as (d) showing edge location of additional PB site 5; (f) SEE image showing metallization defect at 5. Sample 7, diode A-11.

of the lower left PB site shown in Fig. 9b corresponds spatially with the large circular black area near the center of the SEE image in Fig. 9c. X-ray probe examination showed that the black areas are regions of missing Pt; no other element was detected in these regions. The same three PB sites shown in Fig. 9a were seen as microplasmas under an optical microscope. The microplasmas were seen only at higher current levels, above 500 μA. This observation shows that these PB sites are sites of avalanche. It is not known whether avalanche breakdown occurs because of high field gradients at the edge of the Pt, or if the same bulk or surface defect which led to loss of Pt also caused avalanche breakdown.

It is obvious from the above data on the Pt samples that avalanche tends to occur at the edge of metallization for samples aged with and without Au. Breakdown degradation for mesa structures with less than 6000Å Pt occurs faster when Au is present; this point is illustrated by the data for sample 4 in Table II. Thus, we concluded that the lowering of breakdown due to the presence of Au during aging is manifested first at the weakest point in the structure, namely, at the sites of metallization overhang around the edge of the diode. Other EBIC studies on unaged Pt mesa structures confirm that PB sites are located at metal overhang positions; *i.e.*, aging is not needed to create the Pt metal overhang sites responsible for breakdown.

Planar structures.—Nine preparations of planar structures were examined. The diodes of eight of the samples (samples 7-14) had the configuration shown in Fig. 2b; the metallization of the remaining sample (sample 15) was grown by electron beam deposition through a mechanical mask; this structure contained no deliberate surface oxide. Details on the structures of these samples are shown in Table III; avalanche behavior is described with the aid of Fig. 10-11.

Diode A-11 of sample 7 contained a number of PB sites that are present on the diode as formed, plus additional sites that occurred after aging in air at 350°C for 29 hr. These data are illustrated in Fig. 10 and 11. Figure 10a shows three missing Pt regions on the diode which serve as PB sites (Fig. 10b). It is known that these are PB sites rather than simply sites of increased EBIC signal due to missing metallization because these sites give a significantly stronger sig-

nal than the EBIC signal immediately surrounding the perimeter of the Pt; the latter signal, in general, is due only to increased current generated by the electron beam in the semiconductor because of missing Pt. In addition, Fig. 10b shows a very high linear density of PB sites around the edge of the Pt. After aging additional sites were noted at 4 and 6, and a group at 6 (Fig. 10c). PB site 4 was due to a probe scratch (Fig. 10d), and PB site 5 was correlated with a metallization defect (shown in Fig. 10f). The group of PB sites at region 6 are better resolved in Fig. 11, particularly in the Y-modulation EBIC image of Fig. 11b. The SEM studies of the surface of this region showed no discernible surface features, and it is concluded that the high density of discrete sites is due to contamination or defects at the Pt/GaAs interface or in the GaAs.

Discussion

Premature breakdown of unaged Au/Pt mesa, Pt mesa, and Pt planar structures occurs mostly at the edge of the metallization. Both methods of forming diodes leave edges which are rough. The calculated effect of junction curvature on the breakdown voltage for GaAs one-sided abrupt junctions (8) is listed below, for the case of an impurity level of $8 \times 10^{15}/cm^3$ and for spherical curvature of radius r

$r(\mu)$	V_B (V)
∞	85
10	60
1	30
0.1	9

The radius of curvature of metallization overhang correlated with PB sites is of the order of 0.1μ and less; these regions of high curvature may cause premature avalanche with an expected drop in breakdown voltage of ~90%. This may partially explain the generally low breakdown voltages found on the unannealed planar structures (theoretical value ~85V) compared with the mesa diodes, since the former structures had a significantly higher linear density of PB sites around the edge of the Pt than did the mesa structures. Whether premature breakdown sites imaged by EBIC in this study are due to avalanche, field emission, or tunneling is not known.

Although air aging degraded both the mesa and planar diodes, breakdown after aging still occurred primarily at the edge of the metallization. Careful examination of the SEE image of some of these regions shows that edge regions appear in different contrast compared with the rest of the Pt, including a possible preferred metallurgical interaction at the edge as in diode A-11, sample 7, after 29 hr, 350°C aging (see Fig. 10d). Although dislocation generation sources at the metal/GaAs interface have been noted in sample 1 using transmission electron microscopy, dislocations have not been found (9) in TEM samples prepared from GaAs just below the edge of Pt metallization in another diode of sample 7. We therefore tentatively conclude that the lowering of breakdown voltage in air-annealed mesa and planar Pt structures is due to a change in the properties of the diode which is first manifested at the weakest point, namely, at those sites at the edge of metallization where metal defects and metal overhang produce the high field gradients.

A few cases have been observed of breakdown in Pt structures away from the edge in regions not correlated with visible surface features (as diode A-11 of sample 7, Fig. 11). It is felt that important information on breakdown behavior of GaAs Schottky diodes would result from EBIC study under conditions where edge effects could be made negligible. This could be achieved by electrically isolating the edge from the rest of the diode, and has been done for Si by use of a p^+ guard ring (1) and metallization overlap of oxide (10, 11), and for GaAs using a high resistivity guard ring produced by proton bombardment (12). The experiments reported in this paper are being continued with the use of proton bombardment to electrically isolate the edge.

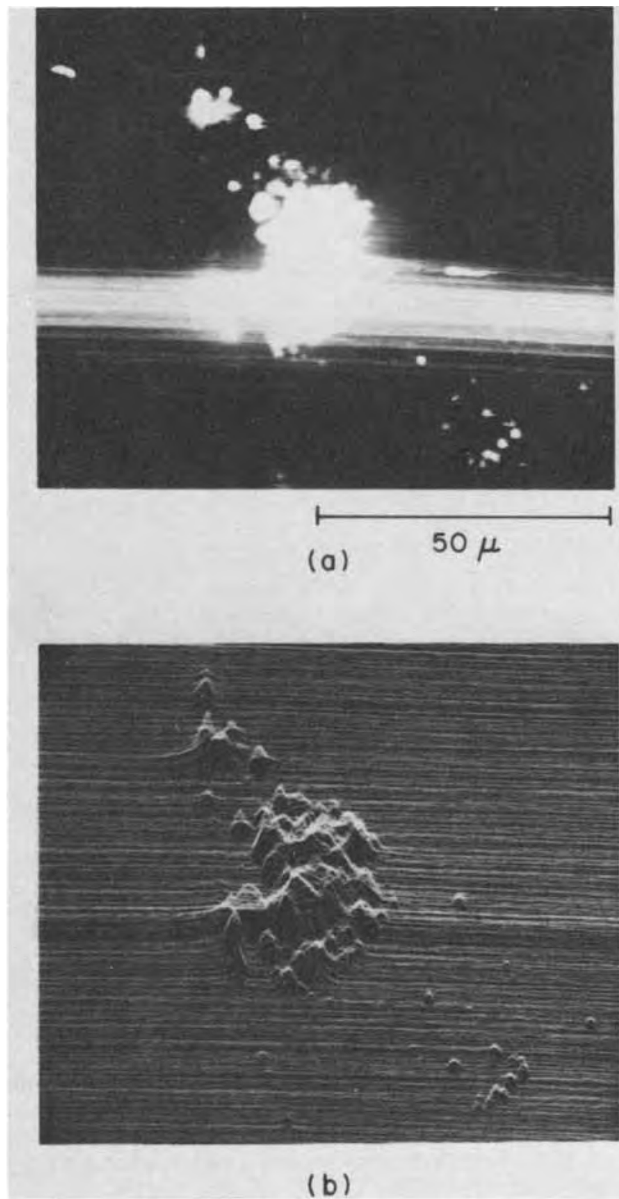

Fig. 11. High density of PB sites away from edge of Pt planar structure. Defect region 6 of Fig. 10c. (a) EBIC image at 17V, 50 μA; (b) Y-modulation EBIC image of same area showing the discrete nature of the PB sites.

Regions of missing Pt serve as sites for premature breakdown (diode 1 of sample 5, Fig. 9; diode A-11 of sample 7, Fig. 10). The appearance of these regions of missing Pt or pinholes is due to particle contamination on the GaAs surface prior to metallization.

Summary

The intent of this work was to obtain information on the origin and location of breakdown sites in Pt mesa and planar GaAs IMPATT tester diodes as a function of heat-treatment. The main results of this study are:

1. Breakdown sites have been identified using the SEM operating in the EBIC mode. These sites have been correlated with certain textural features of the diodes.
2. Premature breakdown in unaged and aged Au/Pt mesa, Pt mesa, and Pt planar structures occurs primarily at sites of metallization defects and metallization roughness around the periphery of the diodes. In the case of planar structures some of the roughness may have been due to metallurgical interaction between the Pt and GaAs after aging. These regions of high curvature produce high field gradients under bias and may cause premature avalanche. It is not known, however, whether breakdown results from avalanche, field emission, or tunneling.
3. The degradation of Pt diodes and the lowering of the breakdown voltage caused by air aging are manifested at PB sites at the edge of the metallization.
4. Very small sites of missing metallization ("pinholes") have been found to be sites of diode breakdown.
5. Leakage occurs in irreguar patches across a diode. The *I-V* characteristics of these patches are different, indicating nonuniform properties of the interfacial region with respect to leakage.

Acknowledgments

All epitaxial material was grown by L. Luther and electron beam deposited Pt films were grown by A. Sinha. Their cooperation is appreciated.

Polarization and Charge Motion in Metal-Al_2O_3-SiO_2-Si Structures

A. P. Gnadinger and W. Rosenzweig

Bell Laboratories, Allentown, Pennsylvania 18103

ABSTRACT

An investigation of the flatband voltage shifts of double insulator (Al_2O_3-SiO_2) MIS capacitors under bias temperature stress has been performed in order to assess and characterize the stability of double insulator IGFET's. These shifts were opposite to the applied bias voltage ("ionic" direction), and it was found that they are composed of two components: (*a*) A "fast" component which is linear with gate bias voltage and symmetric with bias polarity. Most of the shift occurs in less than 1 min at all temperatures used in this work (65°-260°C). Its magnitude is temperature activated (0.15 eV). This part of the flatband voltage shift is explained by a bulk polarization of the Al_2O_3 layer with a polarizability that is independent of Al_2O_3 thickness. (*b*) A "slow" component which is observed under positive bias. It is characterized by a linear dependence of flatband voltage shift on the logarithm of stress time for times larger than a delay time, which is thermally activated (1.2 eV). This component is interpreted to be due to motion of mobile, ionic charge, such as sodium, across the Al_2O_3 and SiO_2 layers. This charge motion is greatly reduced by increasing the Al_2O_3 thickness.

A low threshold voltage p-channel MIS (metal-insulator-semiconductor) technology in which a double dielectric sandwich of 1000Å of SiO_2 and 500Å of Al_2O_3 is used as the gate insulator (1, 2) has received considerable interest in the past. Devices made with this gate structure and a Ti-Pd-Au metallization (3, 4) have a nominal threshold voltage of −1.0V if a 10 ohm-cm, <100>, n-type silicon substrate is used.

One of the advantages of this technology is the excellent threshold voltage control and the inherently good stability of the threshold voltage under bias-temperature (BT) stress conditions.

A discussion of control of the initial threshold voltage is given by Clemens and Labuda (5). The question whether the inherently stable devices show any residual threshold voltage shifts during their operating life has been treated by Lampi and Labuda (6) who performed a reliability study by bias temperature aging discrete MIS transistors. They found that under negative gate bias two apparently independent types of drifts can cause small threshold voltage shifts. One is a rapid drift which shifts the threshold voltage to more positive values, and the other one is a long term drift which shifts the threshold voltage to more negative values. The latter type, referred to as "slow trapping," was shown because of its large activation energy to be negligible at normal operating temperatures and biases and can be neglected for most applications. The first type is potentially more important because it occurs at lower temperatures and in shorter times. On the basis of experimental evidence it can be interpreted to be due to polarization of the Al_2O_3 layer and charge motion across the insulator structure (7). The purpose of this work is to investigate and characterize this rapid initial threshold voltage shift for both negative and positive bias and to evaluate its effect on device reliability.

As test vehicles, MIS capacitors with insulator structures identical to those in MIS transistors were used. Capacitors instead of transistors were chosen because (*a*) they are simple to fabricate, (*b*) interface states which can be introduced by bias-temperature aging (8) can easily be detected, and (c) they are geometry independent so that a one-dimensional theory can be applied. MIS transistors with short channel length very often show geometry effects due to the fringing fields in the proximity of p-n junctions (9), obscuring the results of bias-temperature aging. By observing the flatband voltage shifts of MIS capacitors it is possible to characterize the physical mechanisms leading to the rapid initial shifts in the transistor-threshold voltage mentioned above.

Key words: MIS devices, aluminum oxide, sodium contamination.

Experimental Structures and Techniques

The double insulator MIS structure used in this work consists of a thermal SiO_2 layer grown on <100> n-type silicon of nominal 10 ohm-cm resistivity. The SiO_2 is grown in a wet oxidation at 1100°C with an O_2 ambient bubbled through 80°C water, followed by an 1100°C 30-min anneal in N_2. The second insulator is a layer of Al_2O_3 deposited pyrolytically at 900°C on top of the SiO_2 (1, 2). Right after Al_2O_3 deposition the structures are hydrogen annealed at 900°C for approximately 30 min. The metallization consists of 1000 and 2000Å of filament evaporated titanium and palladium, patterned into 20 × 20 mil square dots.

The polarization and charge transport effects were investigated by observing the flatband voltage shifts of these capacitors after bias-temperature treatment. This was done by making capacitance *vs.* voltage (*C-V*) measurements before and after stressing. The stressing was done by heating the sample under bias up to the stress temperature, keeping it at that temperature for the duration of the stress time, and then cooling it down rapidly to room temperature under bias. The slice was not removed from the stress apparatus for making *C-V* measurements. A stress apparatus similar to the one described by Goetzberger and Lopez (8) was used. Most of the bias temperature stress experiments were performed in air. It was found that the ambient had very little influence on the results. Capacitors stressed in a nitrogen or argon ambient showed essentially identical flatband voltage shifts.

The stress temperatures were between 65° and 260°C. The upper limit of 260°C was chosen to minimize competing effects such as carrier trapping at the Si-SiO_2 interface (slow trapping) as mentioned above. Below 65°C it was difficult to obtain measurable flatband voltage shifts in reasonable time. The bias voltages used were always less than the values corresponding to an electric field in the SiO_2 of about 1.5 × 10^6 V/cm (20V for a standard structure of 500Å Al_2O_3 and 1000Å SiO_2). This was done to avoid injection of

electronic charge from the metal contact (10, 11). The stress times were in the range of 20 sec to 4000 min with most of the points between 1 and 1000 min. This range was found to be adequate to investigate the fast initial shifts in flatband voltage.

All the flatband voltage shifts measured after bias-temperature treatment were small, typically less than 100 mV for a standard structure of 1000Å SiO_2 and 500Å Al_2O_3 stressed at 150°C with −10V gate bias. The shifts if any, resulting from room temperature stressing were less than the resolution of the measurement system which was about 10 mV.

Experimental Results and Discussion

All flatband voltage shifts ΔV_{FB} reported in this work are opposite in sign to the applied stress bias. That means ΔV_{FB} is negative for positive bias and vice versa. Figure 1 shows the absolute magnitude of ΔV_{FB} as a function of the logarithm of time with temperature as a parameter. This is a typical plot for a standard insulator structure (500Å Al_2O_3/1000Å SiO_2). The solid lines are for +10V bias and the broken lines for −10V. The salient characteristics of these curves are as follows: under negative bias there is an "immediate" shift, *i.e.*, a shift in a time shorter than 20 sec, followed by a small additional shift. This immediate component increases slowly with temperature. Under positive bias, particularly at the lower temperatures, one can observe an immediate shift nearly equal to that obtained under identical negative bias, followed by a "delayed" shift which increases nearly linearly with the logarithm of time. A delayed shift can also be seen under negative bias but is much smaller than the one observed under positive bias. Lampi and Labuda (6) also observe this behavior under negative bias at 100°C and find that the shift saturates at a value which is approximately twice the value of the initial shift. It is shown below that the negative bias shift is primarily produced by a single mechanism.

The delayed component under positive bias is seen to have a delay time of about 10 min at 125°C. At higher temperatures and positive bias, the observed shifts are already increasing functions with the logarithm of time even for the shortest times. This leads one to assume that the delay time is temperature activated and shorter than 20 sec (the shortest experimental cycling time) at 155°C. On the basis of the 125°C results it is also reasonable to assume that the immediate component is also present for positive bias at the higher temperatures, in magnitude equal to the negative bias shifts.

The above interpretation at the flatband voltage shifts can be represented in idealized form as shown in Fig. 2, which is a plot of the magnitude of the shift *vs.* logarithm of time. Under negative gate bias there is a single component of flatband voltage shift: the immediate component. Under positive bias there are two components: the immediate component with equal magnitude as under negative bias and a delayed component increasing logarithmically with time. Mathematically they are given as follows

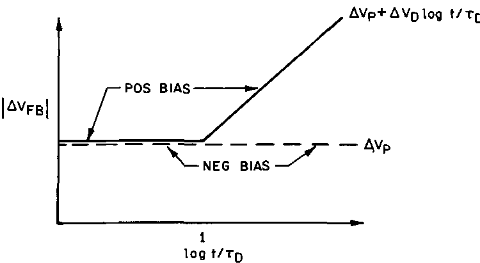

Fig. 2. Idealized representation of flatband voltage shift as a function of stress time.

$$V_B < 0: \quad \Delta V_{FB} = -\Delta V_P \qquad [1]$$

$$V_B > 0: \quad \Delta V_{FB} \doteq -\Delta V_P \qquad t \leq \tau_D$$

$$\Delta V_{FB} = -\Delta V_P - \Delta V_D \log t/\tau_D \qquad t > \tau_D \qquad [2]$$

It must be stressed that this model is intended to take into account only the salient features of flatband shift under bias-temperature aging. In the remainder of this section, experimental results are presented which show how ΔV_P, ΔV_D, and τ_D vary with bias magnitude, temperature, and insulator structure. On the basis of these results the immediate component is ascribed to polarization of the Al_2O_3 layer, and the delayed component to charge transport across the insulator.

Experimentally the immediate and delayed components under positive bias shown in Fig. 2 can only be separated readily at lower temperatures ($\lesssim$ 125°C) on the basis of shift *vs.* log (time) plots because the delay times are too short at higher temperatures. This is evident from Fig. 1. However, they are readily separable on the basis of their bias dependence. Figure 3 is a plot of the shift (ΔV_{FB}) as a function of positive applied bias (V_B) at 190°C with time as parameter. It may be seen that the shift is a linear function of bias voltage and that the slope of this function is established even at the earliest time and remains nearly constant thereafter. This behavior suggests that the immediate component is responsible for the slope, and the magnitude of the shift attributable to it is directly proportional to the applied bias. In addition, the ΔV_{FB} *vs.* V_B curves have intercepts with the vertical axis which vary nearly linearly with the logarithm of time. This suggests that the delayed component is responsible for the intercept and that it is nearly bias independent, requiring only a small positive bias to produce it. A similar experiment under negative bias shows only the immediate component but no intercepts, consistent with the interpretation of Fig. 1. It

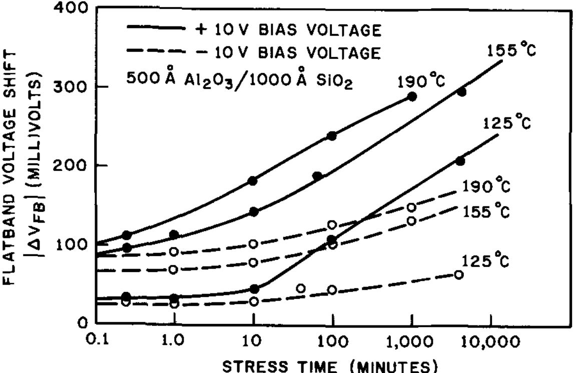

Fig. 1. Dependence of flatband voltage shift on stress time for standard double insulator structure (500Å Al_2O_3 on 1000Å SiO_2) with stress temperature and bias polarity as parameters.

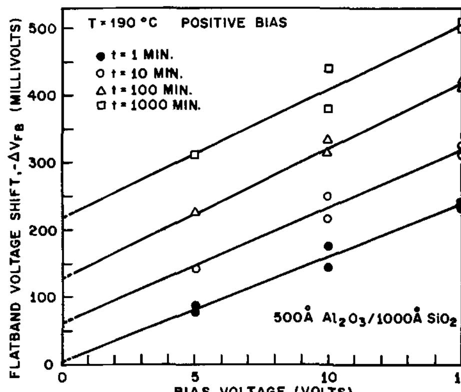

Fig. 3. Dependence of flatband voltage shift on positive-bias voltage with stress time as parameter (constant temperature).

must be noted that experimentally no discontinuity exists in ΔV_{FB} *vs.* V_B as V_B goes from positive to negative. It has been observed that under positive bias, ΔV_{FB} follows the linear variation with V_B down to about 0.5V. Below that value ΔV_{FB} rapidly decreases to zero as V_B is reduced to zero.

The temperature activation of the two components can also be seen more clearly on ΔV_{FB} *vs.* V_B plots. Figure 4 shows such plots for a stress time of 60 min with temperature as a parameter. Within experimental error and variability among devices the curves under negative bias have essentially zero intercepts, thus showing only the immediate component, represented by the slope, which increases slowly with temperature. More extensive experimental results, presented below, yield an activation energy of 0.15 eV. The positive bias curves contain both components. Since ΔV_{FB} resulting from the immediate component is the same for both positive and negative bias (of equal magnitude and at equal temperature), one can subtract the negative bias ΔV_{FB} from the corresponding points at positive bias and be left with only the delayed component. When this is done, nearly level lines remain, showing the field independence of the delayed component. Repeating this procedure for different stress times results in a different set of nearly level lines for each stress time. These nearly bias independent flatband voltage shifts can now be plotted as a function of the logarithm of stress time resulting in plots similar to the one shown in Fig. 1 but containing only the delayed component and not the immediate component. Figure 5 shows a plot of the logarithm of the delay times of these curves *vs.* reciprocal absolute temperature. It may be seen that the points closely follow a straight line indicating a thermally activated process. The activation energy calculated from the slope is 1.2 eV. This value is close to those reported for mobile ion transport across an insulator if the process is dominated by trap release (12).

The results presented thus far can be related to a physical model. The immediate component, which varies linearly with applied bias and which is present both under positive and negative stress is indicative of a polarization mechanism. The delayed component, observed only under positive bias, which is strongly thermally activated and independent of bias voltage, can be explained by a trap-release limited charge transport of positive charge moving toward the Si-SiO_2 interface or negative charge moving away from it. Additional experimental evidence is presented below which shows that it is the Al_2O_3 layer which is polarized and that the charge transport component is, most likely, the result of ionic contaminants penetrating the 500Å Al_2O_3 layer.

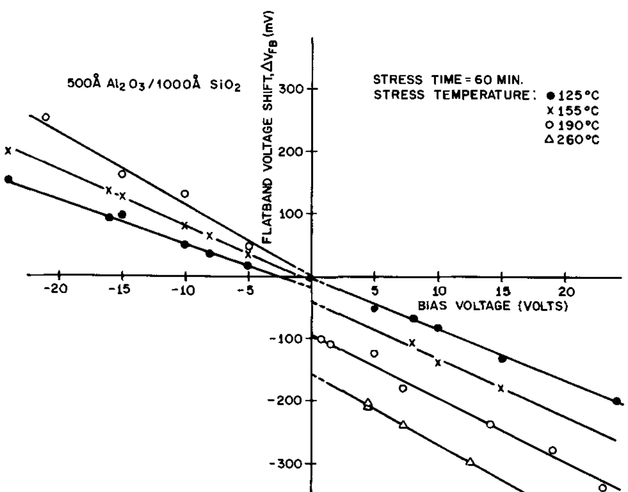

Fig. 4. Dependence of flatband voltage shift on bias voltage with stress temperature as parameter (constant stress time).

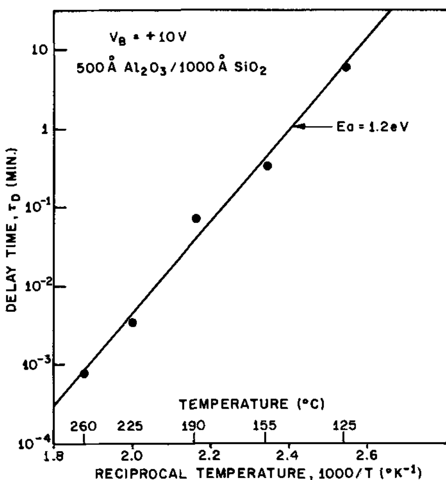

Fig. 5. Dependence of the logarithm of the delay time, τ_D, on the reciprocal of the stress temperature.

It is extremely unlikely that the SiO_2 layer is polarized because this effect has not been observed in single-layer MIS structures. The polarization model has been proposed for a phosphosilicate glass film by Snow and Deal (13) and for Al_2O_3 by Nigh[1] and Walden *et al.* (11). Snow and Deal have shown that

$$\Delta V_{FB} = -\frac{K_O x_A \chi_P V_B}{K_A[(K_A + \chi_P)x_O + K_O x_A]} \qquad [3]$$

where K_O, x_O and K_A, x_A are the relative dielectric constants and the thicknesses of the SiO_2 and the alumina layers, respectively, and χ_P is the polarizability of the alumina layer. Equation [3] predicts a linear dependence of ΔV_{FB} on the bias voltage V_B as was observed above.

Equation [3] can be rewritten in terms of electric field (13) in the alumina layer, and for $\chi_P << K_A$ simplifies to

$$\Delta V_{FB} = -\frac{x_A \chi_P E_A}{K_A} \qquad [4]$$

Equation [4] predicts that with constant electric field in the alumina, ΔV_{FB} increases directly with the alumina thickness and is independent of SiO_2 thickness. Both of these variations were observed experimentally with Al_2O_3 thicknesses ranging between 500 and 2400Å, and SiO_2 thicknesses between 1000 and 4000Å. Because of the proportionality of ΔV_{FB} with alumina thickness, interfacial polarization at the SiO_2-Al_2O_3 interface, as described by Iida *et al.* (15), can be ruled out as a possible mechanism in our devices. (As an example see the results in Fig. 10 for 1100Å of Al_2O_3 as compared to those in Fig. 3 and 4 for 500Å of Al_2O_3.) The absence of Iida's instability mechanism in our samples was probably due to the 900°C hydrogen anneal. The average polarizability, χ_P, at 225°C obtained on 25 samples subjected to positive and negative bias was 0.86 $\pm$ 0.25.

All the ΔV_{FB} *vs.* V_B curves at different temperatures were also analyzed to yield the activation energy for polarizability. The results are shown in Fig. 6 which is a plot of log χ_P *vs.* $1/T$. The best straight line fit gives an activation energy of 0.15 eV.

It is thus concluded that bulk polarization of the Al_2O_3 layer is primarily responsible for the negative bias instability and partially responsible for the positive bias instability which also has a charge transport component. The experimental evidence presented below elucidates the nature and location of this charge.

In order to determine in which insulator the charge motion occurs, a BT aging experiment was conducted using structures with varying SiO_2 thicknesses and

[1] The dipolar polarization model as proposed by H. E. Nigh will be treated in detail in Ref. (14).

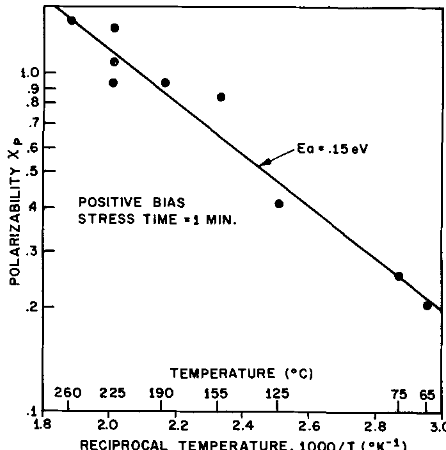

Fig. 6. Dependence of the polarizability, χ_p, on the reciprocal of the stress temperature for constant stress time and positive bias.

constant alumina thickness, x_A. Again, the flatband voltage shifts ΔV_{FB} were measured as a function of positive bias voltage V_B with temperature held constant and a fixed stress time larger than the delay time τ_D. From ΔV_{FB} *vs.* V_B plots similar to Fig. 3, the intercepts $\Delta V_{FB}(i)$ are extracted and plotted in Fig. 7 as a function of SiO_2 thickness. It was found that $\Delta V_{FB}(i)$ increases linearly with increasing x_O. This means that the charge is moving across the SiO_2 layer. From the slopes in Fig. 7, values for Q_i/q of 1.9×10^{10} cm^{-2} and 3.06×10^{10} cm^{-2} for two different slices from the same processing lot were obtained. A substantial slice to slice variation of the amount of mobile charge in the insulator structure is to be expected if this charge is due to some kind of contamination, such as sodium. The variability of the data plotted in Fig. 7 is too great to allow a determination of whether the charge moves through the Al_2O_3 as well as through the SiO_2. To clarify this point a bias-temperature stress experiment was conducted in which the bias voltage was cycled between positive and negative bias polarity starting with unstressed samples. The results of this experiment are shown in Fig. 8 which is a plot of the intercepts of ΔV_{FB} *vs.* V_B plots as a function of time within the indicated stress cycle. In the first cycle, the intercept is seen to rise relatively slowly, reaching about 210 mV after 3900 min. (On a plot against log time it is actually a delayed linear function as in Fig. 1 and 2.) With reversal of bias, in the second cycle, the intercept rapidly relaxes back, settling toward 40 mV. With reapplication of positive bias (third cycle) it now rises

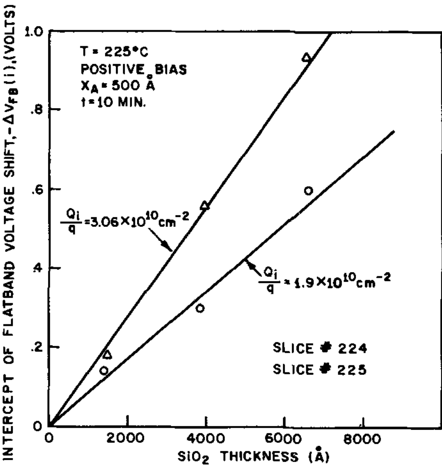

Fig. 7. Dependence of the intercept of the flatband voltage shift, $\Delta V_{FB}(i)$, of a ΔV_{FB} vs. V_B curve on SiO_2 thickness for two different samples.

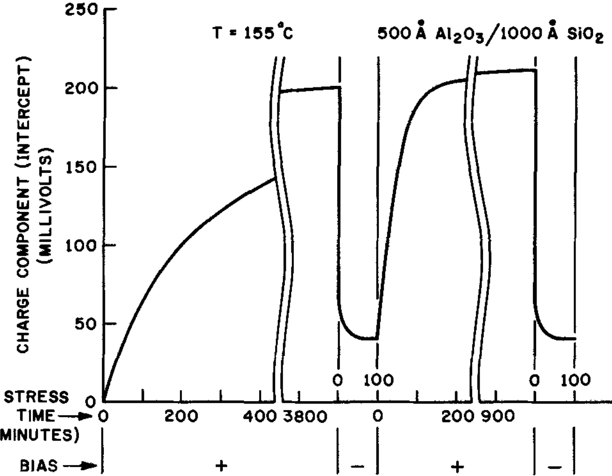

Fig. 8. Dependence of the intercept (charge motion) of a ΔV_{FB} vs. V_B curve on stress time for T = 155°C, with two complete cycles of positive followed by negative bias voltage.

much more rapidly, requiring only about 200 min to reach 210 mV. On reversal (fourth cycle) it rapidly relaxes back to about 40 mV.

The results of the cycling experiments may be explained as follows: during the first cycle, positive charge slowly moves from the metal-Al_2O_3 interface through the Al_2O_3 by a trap-release process that is thermally activated by a 1.2 eV activation energy. Once it is through the Al_2O_3 it is rapidly swept to the SiO_2-Si interface. This charge remains mobile so that on bias reversal (second cycle) it is rapidly swept back to the SiO_2-Al_2O_3 interface where it is retrapped. This retrapped charge must be trapped much more weakly than initially since it can be moved back to the Si-SiO_2 interface much more rapidly than initially (third cycle). Not only is the time varying behavior consistent with this model but the magnitudes of the shifts are also consistent. For the given structure, 1000Å SiO_2 and 500Å Al_2O_3, one expects the recovered shift to be 1/5 the stressed shift if the charge originates at the metal-Al_2O_3 interface, moves to the Si-SiO_2 interface, and then returns to the Al_2O_3-SiO_2 interface. This is consistent with the observed values of 210 mV for the stressed shift and 40 mV for the recovered shift. A similar model was previously proposed by Snow and Dumesnil (16) in order to explain long-term drift effects caused by Na migration in metal-glass-oxide-semiconductor double-layer capacitors.

The influence of Al_2O_3 thickness on the charge transport component was also studied. Figure 9 shows a plot of ΔV_{FB} *vs.* V_B for different stress times and fixed temperature (225°C) for a slice with a standard SiO_2 thickness ($\approx$1000Å) but an Al_2O_3 thickness of about twice the standard thickness (1110Å). It may be noted that these curves show essentially no intercepts. This means that if there is mobile charge in the insulator system it has not penetrated the Al_2O_3 to any significant extent. In addition, it may be seen, consistent with previous discussion, that the polarization is nearly symmetrical with positive/negative bias, increases directly with Al_2O_3 thickness (by comparison with Fig. 2 and 3), and increases slightly with time.

Preliminary data on samples with Al_2O_3 thicknesses of 1100 and 2400Å show that intercepts do develop after long periods of stressing with delay times increased by a factor of 50 times at 1100Å and 1300 times at 2400Å when compared to the standard 500Å Al_2O_3 thickness. The effectiveness of the Al_2O_3 as a barrier to ionic contamination is seen to increase nearly exponentially with thickness.

An etchback experiment was carried out to see whether the quality of the Al_2O_3 layer varied with thickness. The results are shown in Fig. 10. The Al_2O_3

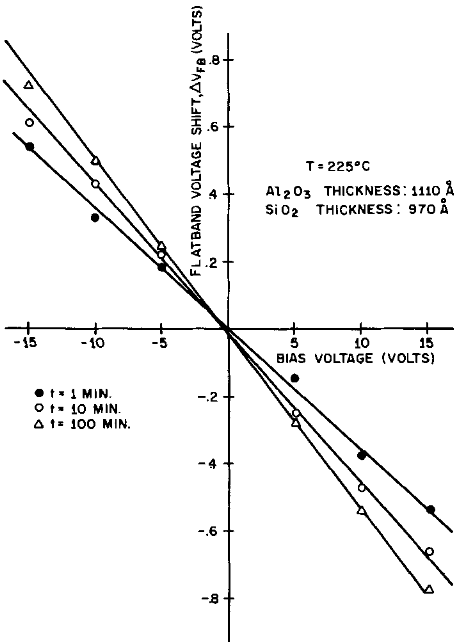

Fig. 9. Dependence of flatband voltage shift on bias voltage for thick Al_2O_3 sample (1100Å) with constant temperature and stress time as parameters.

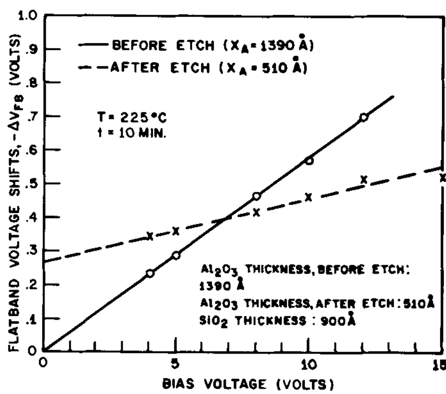

Fig. 10. Dependence of flatband voltage shift on bias voltage for constant temperature and stress time of a sample before and after etching the Al_2O_3 from ≈ 1400 to ≈ 500Å.

layer as originally grown (1390Å) shows only polarization. When the same layer is etched back to 500Å it shows both components (polarization as well as charge motion) just as a sample which was initially grown only to 500Å. This suggests that the ionic penetration properties of the Al_2O_3 layer depend primarily on its thickness and not on the way in which it was produced.

It has previously been suggested (17) that the stress gradient in Al_2O_3 on SiO_2 is responsible for the inhibition of sodium penetration in the double insulator structure. The experimental results presented here suggest that the stress, which is an increasing function of Al_2O_3 thickness, is still the controlling parameter and that trap depth is correlated with it. Thus, as the stress was relieved in the etchback experiment, the ions became more weakly trapped and the delay times shortened.

Summary and Conclusions

A study was made of the flatband voltage shifts of double insulator MIS capacitors after bias-temperature treatment. The shifts were opposite to the bias voltage and larger in magnitude for positive than negative bias. The delay times of the shifts under positive bias were thermally activated with an activation energy of 1.2 eV. The flatband voltage shifts were found to be linearly dependent on bias voltage with a time-varying offset for positive bias. This offset increases with increasing SiO_2 thickness, stress time, and temperature. It decreases strongly with increasing alumina thickness.

The flatband voltage shifts encountered under negative bias can be explained by a bulk polarization of the alumina layer under the influence of an electric field and elevated temperature. The exact nature of this polarization cannot be established from the present data but it can be characterized by a polarizability, $\chi_P = 0.86 \pm 0.25$ at 225°C, which was found to be independent of alumina and SiO_2 thickness, but which increases slightly with increasing stress temperature (activation energy = 0.15 eV) and stress time. Most of the polarization occurs after a very short stress time (<1 min).

The flatband voltage shifts encountered under positive bias can only be explained if in addition to polarization in the Al_2O_3 layer a charge motion through the insulator structure is assumed. This mobile charge is probably ionized sodium. The positively charged ions are initially located close to the metal-Al_2O_3 interface and are transported to the Al_2O_3-SiO_2 interface with an activation energy of about 1.2 eV. Subsequently they enter the SiO_2 and are swept rapidly to the SiO_2-Si interface where they are locked in during the cool down under bias. Heating the sample up again with reversed bias results in a strong reduction of the flatband voltage shift. This means the mobile ions are swept back toward the SiO_2-Al_2O_3 interface. This cycle can be repeated several times. The amount of mobile charge was found to be slice dependent with typical values around 2×10^{10} cm^{-2} depending on stress time and temperature. The charge motion through the Al_2O_3 and the Al_2O_3-SiO_2 interface was found to be relatively slow, the relaxation of the charge from the Si-SiO_2 to the SiO_2-Al_2O_3 interface was found to be very fast (<1 min at 200°C). For Al_2O_3 thicknesses larger than 500Å the amount of mobile charge penetrating the Al_2O_3 in the time frame of the experiment decreases sharply. It is estimated that the delay time increases over an order of magnitude for each additional 500Å of Al_2O_3. An etchback experiment showed that charge penetration at 500Å is insensitive to the way in which the thickness is obtained. It is suggested that the ionic trapping energy is correlated to the average stress in the Al_2O_3 layer which, in turn, increases with the Al_2O_3 thickness. In samples with 1390Å of Al_2O_3 the amount of mobile charge was unmeasurably small (<10^9 cm^{-2}).

The implications of these findings on the stability of MIS transistors using the standard double insulator structures are as follows: replacing threshold voltage shift for flatband voltage shift, and including explicitly the linear voltage dependence of the polarization component, one can rewrite Eq. [1] and [2] as follows

$$V_B < 0: \quad \Delta V_{TN} = -K_P V_B \quad [5]$$

$$V_B > 0: \quad \Delta V_{TP} = -K_P V_B \quad \text{for } t \leq \tau_D$$

$$\Delta V_{TP} = -K_P V_B - V_D \log (t/\tau_D) \quad \text{for } t > \tau_D \quad [6]$$

where ΔV_{TN} and ΔV_{TP} are the threshold voltage shifts under negative and positive bias, respectively. K_P is given by

$$K_P = \frac{K_O x_A \chi_P}{K_A[(K_A + \chi_P)x_O + K_O x_A]} \quad [7]$$

as introduced in Eq. [3]. V_D is assumed to be a constant independent of temperature and materials parameters and τ_D is the delay time introduced in Fig. 2, which is temperature activated with an activation energy of 1.2 eV and increases sharply with Al_2O_3 thickness. At the highest operating temperature assumed to be 85°C the following average numerical values apply

to a standard structure (500A Al_2O_3/1000A SiO_2): $K_P = 0.006$, $V_D \cong 65$ mV/decade, and $\tau_D \cong 200$ min.

For p-channel MOS transistors (negative bias) the expected shift after 40 years at 85°C with −10V bias is approximately 0.06V using the above values. For n-channel devices the threshold voltage shift under identical conditions (40 years, 85°C, +10V) is expected to be about −0.35V. The p-channel devices are, therefore, more stable than the n-channel devices, if 500Å of Al_2O_3 and 1000Å of SiO_2 are used as gate insulators. Since the polarization shift increases linearly with Al_2O_3 thickness but the charge transport delay time increases exponentially, stability under positive bias (n-channel) can be improved by increasing the Al_2O_3 thickness. The optimum occurs when τ_D is equal to end of life. Limited data suggest that this occurs at a thickness of 1400Å. Such an Al_2O_3 thickness is probably undesirable both from a processing and circuit performance point of view. If one asks, instead, for an average end-of-life shift of 0.2V, then the data suggest an Al_2O_3 thickness of about 700Å which is much more reasonable from both points of view and which gives adequate stability to both n- and p-channel devices.

Acknowledgments

Diffusion of Boron from Implanted Sources under Oxidizing Conditions

J. L. Prince and F. N. Schwettmann*

Semiconductor Research and Development Laboratories, Texas Instruments Incorporated, Dallas, Texas 75222

ABSTRACT

Diffusion of boron from sources implanted at 80 keV was investigated experimentally and mathematically over the range 1000°-1200°C for boron doses of 1×10^{14} cm^{-2}, 5×10^{14} cm^{-2}, and 2×10^{15} cm^{-2}. Diffusion was in steam ambient and oxide thickness grown ranged from 0.2 to 1.2 μm. The boron diffusion coefficient was determined over the range of temperatures investigated. The segregation coefficient of boron in the Si-SiO_2 system was found to range from 1.8 at 1200°C to 10 at 1000°C. "Normal" diffusion was observed in all cases except that of diffusion at 1000°C for short times.

Redistribution in silicon of a predeposited boron source during thermal oxidation is of technological importance in the fabrication of bipolar and MOS devices and circuits. During such a redistribution, boron is preferentially segregated into the growing oxide, in addition to diffusing into the bulk silicon material (1). The subject has been investigated for steam and dry oxygen oxidation for the cases of initially uniform boron concentration (1), predeposition from a B_2O_3 source (2), and predeposition from a boron nitride source (3). Diffusion from implanted, preannealed sources has been recently investigated for oxidation in a "purified argon" atmosphere (4). Oxide thicknesses grown in this last investigation were of the order of 100Å (*e.g.*, 200Å for oxidation at 1100°C for 2 hr). The segregation coefficient of boron in the Si-SiO_2 system, defined as the ratio of boron concentration in the oxide at the Si-SiO_2 interface to the boron concentration in silicon at the interface, was variously determined to be 3 (1), 9 (2,3), and 16 ± 5 (4). In a recent work (5) on boron diffusion in SiO_2, the segregation coefficient was found to be in the neighborhood of 10, with some temperature dependence. The diffusion coefficient determined by these investigators varied, but was in the neighborhood of previous work on boron diffusion in silicon by Kurtz and Yee (6a) and Fuller and Ditzenberger (6b).

This report describes experimental and mathematical investigation of diffusion of boron from implanted, but

* Electrochemical Society Active Member.

Key words: boron, segregation, coefficient, diffusion, ion implantation.

not preannealed, sources under conditions of steam oxidation during diffusion. The temperature range of investigation was 1000°-1200°C. Under these conditions, segregation and diffusion coefficients of boron were determined by comparison of experimental profiles (obtained by incremental sheet resistance) to calculated profiles obtained by computer solution of the diffusion equation and by comparison of experimental and calculated sheet resistance of the boron layer.

Experimental

Substrate slices were Czochralski-grown phosphorus-doped, (111) orientation, and had initial resistivity of 5-7 ohm-cm. Implanted ions were B^{11}, obtained from an rf source using BF_3 as the source gas. The ion beam was focused and electrostatically scanned over the substrate surface. Implantation energy was 80 keV and implanted doses used were 1×10^{14} cm^{-2}, 5×10^{14} cm^{-2}, and 2×10^{15} cm^{-2}. Slices were misaligned 7° during implantation to minimize channeling. After implantation and immediately before diffusion, slices were cleaned in an rf glow discharge with oxygen ambient and then in a mixture of sulfuric acid and hydrogen peroxide.

Each slice was oxidized in steam atmosphere at a temperature in the range 1000°-1200°C. The oxidation cycle consisted of a 5-min heat-up in dry O_2 and subsequent oxidation in steam ambient for times ranging from 15 to 180 min. Resultant oxide thickness and refractive index were measured by ellipsometry. The refractive index of the oxide was found to be independent of the implanted dose and the diffusion time to within experimental error. Oxide thickness *vs.* steam oxidation time is shown in Fig. 1 for the five temperatures used. These curves were calculated using the growth kinetics discussed by Grove (7) and using values for the oxidation rate parameters which provided the best fit to oxide thicknesses observed in the experiment. The curves of Fig. 1 replicate experimental oxide thickness observations to within a few per cent. The oxidation rate parameters used in Fig. 1 were 10-20% higher than those given by Grove (7).

Oxide layers were stripped in dilute HF and slices were rinsed in flowing deionized water. The sheet resistance was read using a four-point probe with light probe pressure. The depth distribution of boron was obtained for some slices by profiling using the incremental sheet resistance method (8). Some slices diffused at 1100°, 1150°, and 1200°C were analyzed using the ionic probe technique.

Resistivity data from the incremental sheet resistance analysis were converted to boron concentration through use of recent mobility data (4, 9) which indicates higher hole mobility for high boron concentrations than has been indicated previously (10). Accuracy of the more recent mobility data has been independently corroborated to a certain degree by the authors using incremental sheet resistance analysis on slices having low implanted boron doses. In the case of the low dose boron implants annealed at 900°C with no oxidation, use of the previously accepted hole mobilities to reduce the incremental sheet resistivity data consistently resulted in calculated integrated doses 10-20% higher than the actual dose, whereas use of the more recent values for hole mobilities resulted in calculated integrated doses within 5% of the actual dose.

Analysis

The coordinate system used in formulating the diffusion equation and boundary conditions is shown in Fig. 2. Origin of coordinates is taken at the Si-SiO_2 interface. In this coordinate system, the diffusion of the boron atoms is governed by

$$\frac{\partial N}{\partial t} = \frac{\partial}{\partial y}\left(D\frac{\partial N}{\partial y}\right) + m\frac{dX_o}{dt}\frac{\partial N}{\partial y} \qquad [1]$$

where $N(y,t)$ = boron concentration; D = boron diffusion coefficient in silicon; m = thickness of silicon consumed in growing unit thickness of SiO_2, assumed to be 0.44; and $X_o(t)$ = SiO_2 thickness.

The initial condition is

$$N(y,o) = f(y,o) \qquad [2]$$

where $f(y,o)$ is presumed known through LSS theory or experiment. Boundary conditions are

$$N(\infty,t) = 0 \qquad [3]$$

$$D\frac{\partial N}{\partial y} = (k - m)N(0,t)\frac{dX_o}{dt} \qquad [4]$$

where k is the segregation coefficient of boron in the Si-SiO_2 system, $k = [N(0^-,t)]/[N(0^+,t)]$. This last boundary condition is derived from the requirement of conservation of boron atoms and under the assumption that boron diffusion in the oxide is slow relative to the oxidation rate $(dX_o)/(dt)$. This last condition is met for steam oxidation.

The boron diffusion coefficient was assumed to be the low-concentration value D_i enhanced by the local electric field effect (11). In addition, possible increase of the diffusion coefficient due to vacancy solubility enhancement (12) caused by heavy doping was accounted for by including a multiplicative factor $[1 + (AN)/(n_i)]$, where A is a constant between 0 and 1, N is boron concentration, and n_i is the intrinsic carrier concentration at the diffusion temperature. Uncer-

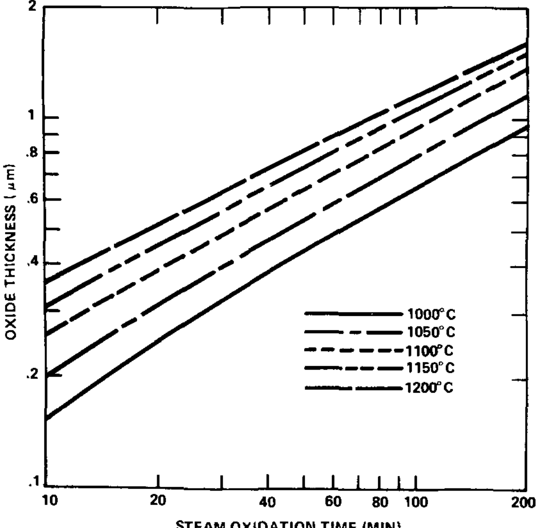

Fig. 1. Oxide thickness *vs.* steam oxidation time

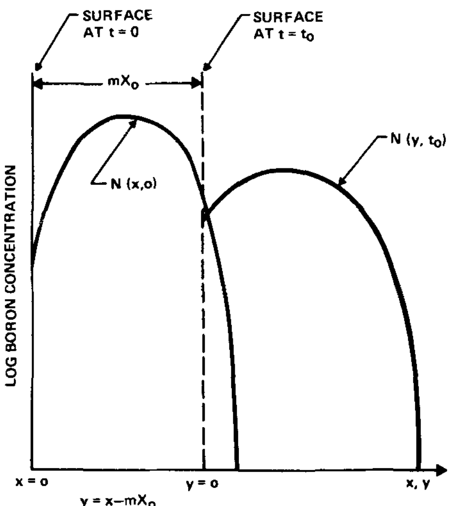

Fig. 2. Coordinate system for solution of diffusion equation

tainties in energy band and defect parameters at diffusion temperatures prevent accurate calculation of A. However, estimates (12, 13) range from 10^{-1} to 2×10^{-2} depending on temperature. The total expression used for the diffusion constant was thus

$$D = D_i \left(1 + \frac{AN}{n_i}\right) \left[1 + \frac{1}{\sqrt{1 + 4\left(\frac{n_i}{N}\right)^2}}\right] \quad [5]$$

Implicit in this formulation is the assumption of total activation of boron atoms. This total activation has been verified by the authors for the range of doses used in the experiment and for anneal temperatures in excess of 900°C.

Oxide thickness was taken to be (7)

$$X_o = \frac{k_p}{2k_l} \left\{ \left[\frac{4(t + t^*)k_l^2}{k_p} + 1 \right]^{1/2} - 1 \right\} \quad [6]$$

where k_p and k_l are, respectively, the parabolic and linear oxidation rate coefficients, t is the oxidation time, and t^* is a parameter related to the oxide thickness which exists prior to the beginning of an oxidation cycle.

The system of Eq. [1] through [4] was solved on a computer by finite difference techniques using a Crank-Nicolson type approach (14). The nonlinearity engendered by the concentration dependence of D required use of a two-step (iterative) solution algorithm. Truncation error of the solution algorithm was found to be on the order of 0.01% for the concentration levels examined. The output of the computer solution was boron concentration *vs.* depth into the silicon, and sheet resistance of the boron layer. Sheet resistance was calculated using the recent hole mobility data (4, 9) discussed earlier.

Results and Discussion

Figures 3 through 7 show experimental values of sheet resistance as a function of steam oxidation time for three boron doses and five diffusion temperatures. The maximum error is ±10% in sheet resistance for this data. Figures 8, 9, and 10 show boron profiles obtained by incremental sheet resistance profiling. Accuracy of this data is estimated to be ±5% for the distance scale and ±20% for concentration. Table I gives average values of surface-to-peak boron concentration

Table I. Boron peak concentration to surface concentration ratio, from ion probe data (15)

Diffusion temp (°C)	Peak to surface concentration ratio
1000	2.7
1100	1.8
1200	1.3

ratios from ion-probe data (15). Accuracy of the ratios is estimated to be ±5%.

Boron diffusion coefficients at 1000°, 1100°, and 1200°C were determined by iterating the computer calculation and comparing the part of the calculated boron profile past the peak concentration point to the experimental boron profiles shown in Fig. 8 through 10. The initial boron profile was taken to be of gaussian form with range 0.285 μm and range straggling 0.075 μm for these calculations. These values for range and range straggling are different from the theoretical values (16). However, it has been determined through compilation of results in the literature and independent experiments that these values best characterize an 80 keV boron profile, which is in fact not gaussian (17). No explicit account was taken in the numerical solution of annealing of implantation damage. This annealing was assumed to occur in times short in comparison with the diffusion times. Within wide bounds, the value of

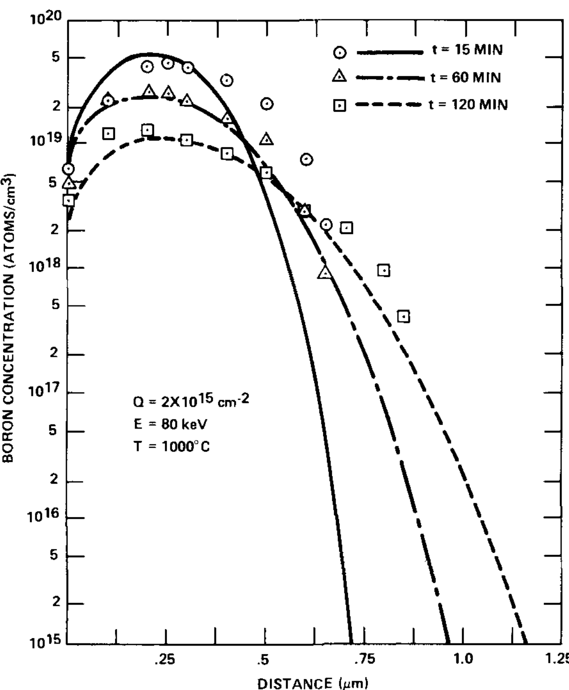

Fig. 8. Calculated and actual boron concentration profiles for oxidation at 1000°C.

segregation coefficient used in this comparison does not affect the calculated profile past the peak concentration point.

Various values for the constant A were used in making the above comparison. No values for A within the limits of 10^{-1} to 2×10^{-2} gave profiles significantly different from those obtained for $A = 0$ for the dose levels used in the experiment. Figure 11 shows the boron diffusion coefficient as a function of inverse temperature, as determined by the comparison. For diffusion at 1000°C, heavier weight was given to matching experimental profiles at longer times. For this temperature, experimental profiles exhibited apparent enhanced diffusion for short (*e.g.*, 15 min) diffusion times. Also shown in Fig. 11 are examples of the boron

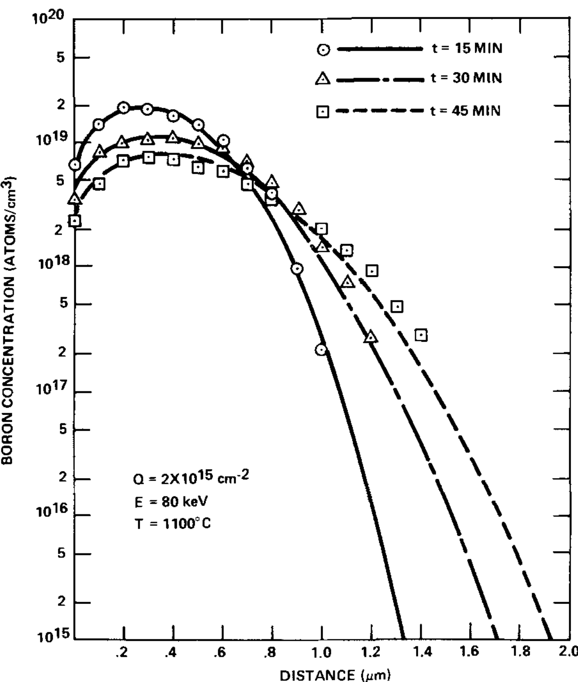

Fig. 9a. Calculated and actual boron concentration profiles for oxidation at 1100°C.

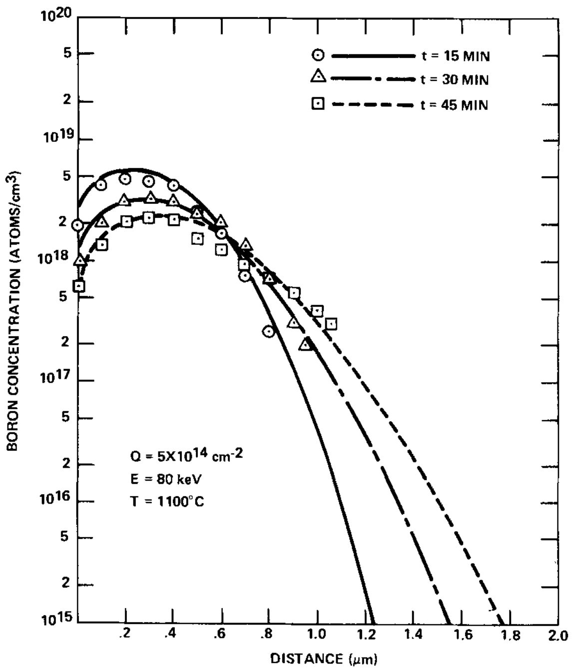

Fig. 9b. Calculated and actual boron concentration profiles for oxidation at 1100°C.

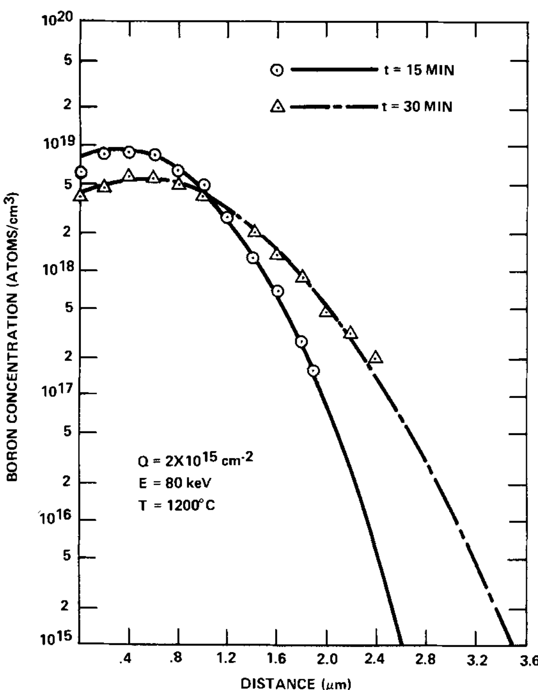

Fig. 10a. Calculated and actual boron concentration profiles for oxidation at 1200°C.

diffusion coefficient as determined by other workers. It is seen that results of this work are in general agreement with previous results over the range of common diffusion temperatures. The diffusion coefficient shown in Fig. 11 is approximated by

$$D_i = 0.0322 \exp(-3.02/kT) \quad [7]$$

Segregation coefficient k was determined by iteration of the computer solution, using values for the diffusion coefficient calculated from Eq. [7]. Boron concentration profiles and values of sheet resistance calculated in the iteration process were compared to experimental profiles and experimental values of sheet resistance. Sensitivity of the calculated results to variations in value of the segregation coefficient is illustrated in

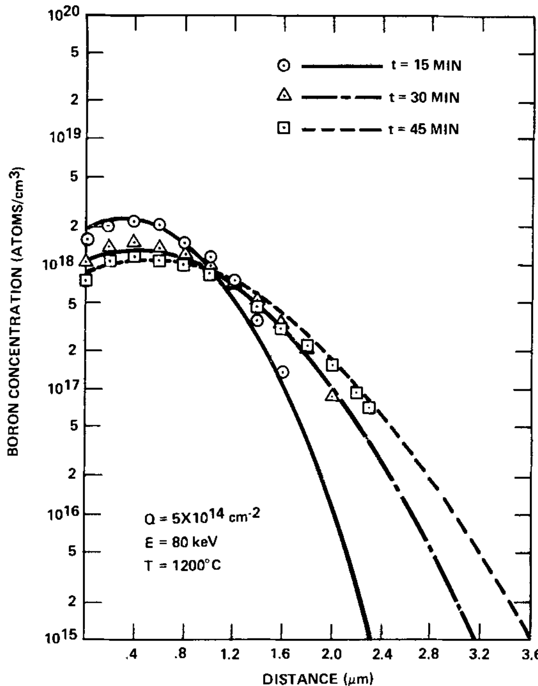

Fig. 10b. Calculated and actual boron concentration profiles for oxidation at 1200°C.

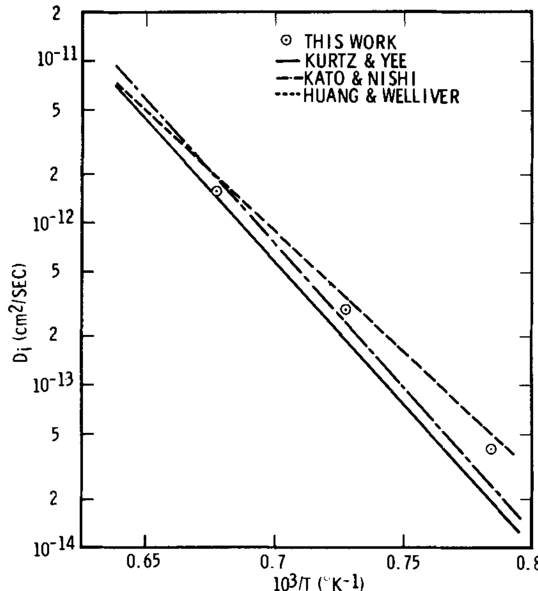

Fig. 11. Intrinsic boron diffusion coefficient vs. inverse temperature.

Fig. 12 and 13. This comparison was made for diffusion at 1200°C and for boron dose equal to 2×10^{15} cm^{-2}. Results calculated for temperatures lower than 1200°C show reduced sensitivity to k. This is due to the increase in the ratio of the parabolic oxidation rate coefficient to the boron diffusion coefficient, with decreasing temperature.

Figure 14 shows the segregation coefficient determined in this work as a function of inverse temperature. The "error bars" in Fig. 14 indicate the range of values of k for which satisfactory fit to experimental data was obtained. The value of k was found to range from 1.8 to approximately 10 over the range 1200°-1000°C. The relative sizes of the boron diffusion coefficient and the parabolic oxidation rate coefficient at 1000°C are such that the comparison of experiment and calculation is insensitive to the value of the segre-

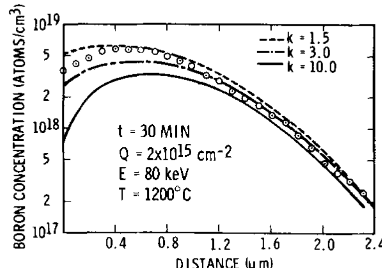

Fig. 12. Actual boron concentration profile and calculated profile for three values of segregation coefficient.

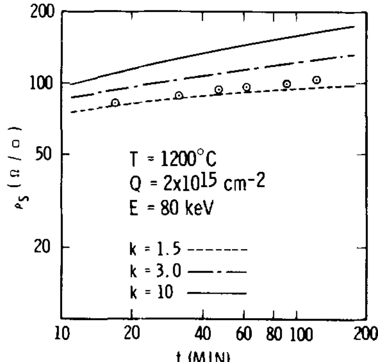

Fig. 13. Actual sheet resistance of boron layer and calculated behavior for three values of segregation coefficient.

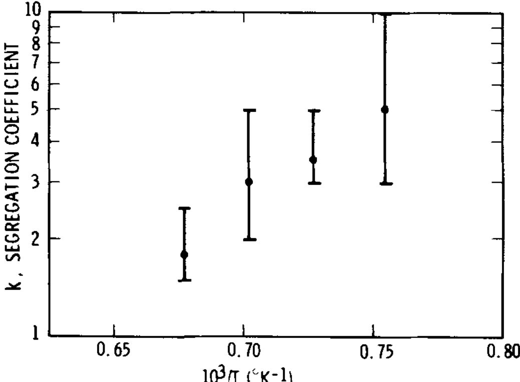

Fig. 14. Segregation coefficient vs. inverse temperature

gation coefficient. Thus, the value $k = 10$ at 1000°C is an estimation and is not shown in Fig. 14. It could be in error by a factor of two in either direction. The segregation coefficient of Fig. 14 is best fit by the expression

$$k = 2.33 \times 10^{-4} \exp (1.135/kT) \quad [8]$$

The best-fit calculated boron concentration profiles and sheet resistance of the boron layers are superimposed on the experimental data of Fig. 3 through 10. These calculated quantities were obtained assuming $A = 0$, using the diffusion coefficient of Fig. 11, and using values of the segregation coefficient shown as experimental points in Fig. 14. Note that in the iteration process and in the calculated curves of Fig. 3 through 10, the segregation coefficient was allowed to vary with temperature but was assumed to be independent of surface concentration.

In comparing the best fit calculated boron profiles and experimental profiles, it is seen that agreement is good for all cases but diffusion for short times at low temperatures (*e.g.*, 15 min at 1000°C). The discrepancy evident in Fig. 8 may be due to the annealing of implantation-related damage, which at 1000°C could take an amount of time appreciable compared to 15 min. Investigations by the authors of 8×10^{14} cm^{-2} B^{11} implantations annealed without oxidation at 900°C indicate a value for the boron diffusion coefficient at 900°C in agreement with Eq. [7].

Conclusion

Diffusion from ion-implanted boron layers in an oxidizing atmosphere can be successfully predicted by numerical solution of the diffusion equation. Concentration enhancement of diffusion beyond the field-aiding effect was not found to be necessary to predict profiles for doses used in this work. The boron diffusion coefficient determined in the course of this work is near that found by previous workers. The boron segregation coefficient was found to be in the range 1.8 to 10 depending on temperature.

Standard Free Energy of Formation of Cr_2O_3

F. N. Mazandarany*,[1] and R. D. Pehlke

Materials and Metallurgical Engineering, The University of Michigan, Ann Arbor, Michigan 48104

ABSTRACT

The standard Gibbs free energy of formation of Cr_2O_3, $\Delta G^\circ_f(Cr_2O_3)$, was measured using an electrochemical technique incorporating a ThO_2-Y_2O_3 electrolyte. The following two cells were investigated

Cell (I): $Cr,Cr_2O_3|ThO_2\text{-}8\ m/o\ YO_{1.5}|Co,CoO$

Cell (II): $Cr,Cr_2O_3|ThO_2\text{-}8\ m/o\ YO_{1.5}|Mn,MnO$

$\Delta G^\circ_f(Cr_2O_3)$ calculated from emf results for the above two cells are in good agreement, also in close agreement with a previous study of the Cr-Cr_2O_3 equilibrium by the gas equilibration technique. The results of the present investigation lead to the following expression for the standard Gibbs free energy of formation of Cr_2O_3

$$\Delta G^\circ_f(Cr_2O_3) = -266{,}600 + 59.78T \pm 350 \text{ cal}$$
$$(1150^\circ\text{-}1540^\circ K)$$

The thermodynamics of the Cr-Cr_2O_3 equilibrium has been the subject of numerous previous investigations. However, the results obtained by various techniques and investigators are in poor agreement.

Jeannin *et al.* (1) equilibrated Cr,Cr_2O_3 samples with H_2/H_2O mixtures between 1040° and 1300°C to determine the standard Gibbs free energy of formation of Cr_2O_3. The results of Jeannin *et al.* were in poor agreement with previous investigations of the system (2-4) using a similar technique. However, the study of Jeannin *et al.* was in agreement with those calculated from calorimetric data within experimental error (1).

Both Tretjakow and Schmalzried (5), and Pugliese and Fitterer (6) measured the free energy of formation of Cr_2O_3 between 800° and 1200°C using the solid oxide electrolyte technique. These investigators used a calcia-stabilized zirconia tube as the electrolyte with air as the reference electrode and a Cr,Cr_2O_3 mixture as the "unknown" electrode. While the results of these investigations agree well at 800°C, there is as much as 15 mV difference between the measured cell potentials at 1175°C, indicating a large difference in the temperature dependence of the free energy. The results of both of these investigations are in disagreement with those of Jeannin *et al.*

The purpose of the present investigation was to measure the standard Gibbs free energy of formation of Cr_2O_3 using the solid oxide electrolyte technique incorporating a ThO_2-Y_2O_3 solid electrolyte. The following two cells were investigated

$$Cr,Cr_2O_3|ThO_2\text{-}8\ m/o\ YO_{1.5}|Co,CoO \quad (900^\circ\text{-}1250^\circ C) \qquad [I]$$

$$Cr,Cr_2O_3|ThO_2\text{-}8\ m/o\ YO_{1.5}|Mn,MnO \quad (875^\circ\text{-}1175^\circ C) \qquad [II]$$

Experimental Technique

Equipment.—The galvanic cell arrangement used in the present study is shown schematically in Fig. 1. The cell consisted of a ThO_2-Y_2O_3 electrolyte pellet, 11, sandwiched between two electrodes, 10. A mullite tube, 13, pressed against the upper surface of electrolyte, 11, helped to minimize oxygen transport in the gas phase from one electrode to another. A Pt O-ring was placed between tube, 13, and the electrolyte, 11, in runs involving cell [I] to improve the separation of the gas phases in equilbrium with the two electrodes.

The cell was fixed at the end of the mullite tube, 9, by the compression of springs, 15, transmitted through tube 13, and push rod 12. This alumina push rod was a four-hole insulator; two holes of which accommodated a Pt/Pt-10% Rh thermocouple. A third hole accommodated the lead wire for the inner electrode, 10. Both electrode lead wires were Pt-10% Rh, gauge 26. The photograph of Fig. 2 shows the cell as it was fixed at the bottom of the mullite tube, 9, of Fig. 1.

The cell potentials were measured with a high impedance (10^7 ohms) potentiometric voltmeter (Keithley Model 660). The temperature voltages were measured with a Model K-2 L&N potentiometer. Both instruments were checked periodically against a known voltage source. The instruments are rated to measure voltages with an accuracy level of ±0.02% of the reading.

Materials.—ThO_2-8 mole per cent (m/o) $YO_{1.5}$ electrolyte pellets were obtained from the Zirconium Corporation of America. These pellets were prepared from high purity starting materials (99.9% Y_2O_3 and 99.5% ThO_2) and were sintered at temperatures exceeding 1950°C for 24 hr in an Ar/H_2 atmosphere to give maximum density and homogeneity. The electrolyte pellets were 2 mm high with a diameter of 12 mm. Before use in a cell, the electrolyte pellets were heated to 1000°C for 24 hr in a dry argon atmosphere with Cr chips present. Then they were polished on a 50μ wheel before use in a cell. The electrolyte pellets were white in color before and after use in a cell.

The Cr_2O_2 electrodes were prepared by mixing high purity Cr powder (99.5%) with analytical grade

Cr_2O_3 in a 10/1 weight ratio, and compressing in a steel die at about 60,000 psi to obtain pellets with the dimensions: 6 mm diameter by 2 mm high. The pressed pellets were sintered in a dry argon atmosphere for 24 hr at 1000°C. The sintered pellets were polished on a 50μ wheel before use in a cell.

The Mn,MnO electrodes were prepared by first pulverizing electrolytic grade Mn flakes (99.8%) to obtain relatively fine Mn powders. The Mn powders then were mixed with analytical grade MnO_2 in a 10/1 weight ratio and pelletized at about 100,000 psi. The pellets were placed in a Vycor tube which was evacuated to 10^{-5} atm and sealed. The sealed capsule was heated to 900°C for 24 hr to ensure complete conversion of MnO_2 to MnO.

The Co,CoO electrodes were prepared by mixing high purity Co powder (99.9%) with analytical grade CoO and pressing at 100,000 psi. No sintering was necessary for the Co,CoO electrodes after pressing.

Procedure.—The assembled cell was placed vertically in the hot zone of a Pt resistance furnace. The furnace temperature was controlled by a Pt/Pt-10% Rh thermocouple that activated a proportionating controller. Temperature fluctuations in the hot zone were approximately ±0.5°C. The temperature gradient in the hot zone of the furnace was about 1°C/in. over a distance of about 1½ in.

Before the furnace power was turned on, the cell atmosphere was evacuated several times and filled with purified argon. This prepurified grade argon gas was purified further before entering the cell tube by passing over anhydrous $Mg(ClO_4)_2$, over activated CuO (BTS catalyst), over activated Cu (reduced BTS catalyst), and finally over anhydrous P_2O_5 and ascarite.

After the cell was completely degassed and finally filled with argon, the furnace power was turned on to heat the cell to an intermediate temperature (1100°C for cell [I] and 950°C for cell [II]). After thermal equilibration the cell was allowed to come to thermodynamic equilibrium over the next 5-12 hr. The criteria for the attainment of thermodynamic equilibrium was adopted such that at constant temperature the cell potential should not vary by more than ±0.5 mV over a period of 1 hr and that such variation be random and not systematic.

Upon the attainment of equilibrium at the first temperature the furnace temperature was either raised or lowered by 50°C and the cell was allowed to equilibrate at the new temperature. This procedure was repeated until an equilibrium measurement had been made at every 25°C interval over the temperature range as a minimum. In this manner, the cell was cycled through the reported temperature range at least twice before the furnace power was shut off to terminate the run. A typical run lasted for 3-6 days.

Reversibility in the cells was generally inferred from the high stability of measured potentials and high linearity of cell potential-temperature relationships which were unaffected by temperature cycling and reproducible from run to run. A further check of the reversibility was made by the following procedure. Once cell [I] had equilibrated at 1250°C, the cell was perturbed by connecting a 1.5V dry battery across the leads for 15 sec. The perturbed cell was then allowed to re-equilibrate overnight. The steady measured potential the next morning was within ±1 mV of the value before the cell was perturbed. This procedure was repeated over the next night passing current in the opposite direction with similar results.

Results and Discussions

The results of this study from cell [I] obtained from the cumulative data of three independent runs are listed in Table I. The data are represented by the following least squares line

$$\text{cell I:} \quad E(\text{mV}) = 706.6 - 0.0640T \pm 1.7\,\text{mV} \quad (1173°\text{-}1523°\text{K})$$

The standard errors of estimate of the coefficients in this equation are, respectively, ±2.8 mV and ±0.0015 mV/°K.

Similarly, the cumulative data of two independent runs on cell [II] are given in Table I. These data may be represented by the following line

$$\text{cell [II]:} \quad E(\text{mV}) = 90.67 - 0.0347T \pm 0.8\,\text{mV} \quad (1148°\text{-}1430°\text{K})$$

The standard errors of estimate of the coefficients in this equation are, respectively, ±1.7 mV and ±0.0008

mV/°K. The above two lines are shown in Fig. 3 and 4, respectively, along with those calculated from previously published data in the literature. In calculating the lines for the previous investigations, their reported results for the Cr,Cr_2O_3 equilibrium were combined with the data of Kiukkula and Wagner (7) for the Co-CoO equilibrium and those of Alcock and Zador (8) for the Mn-MnO equilibrium.

Figures 3 and 4 indicate that the results of this study are consistent and in close agreement with the data of Jeannin *et al.* (1). The disagreement between the results of this study and those of Pugliese and Fitterer (6), and Tretjokow and Schmalzried (5) may have resulted from the use of a calcia-stabilized zirconia electrolyte by these investigators. A small amount of electronic conduction in calcia-stabilized zirconia at the very low oxygen potentials associated with the Cr-Cr_2O_3 equilibrium ($\sim 10^{-22}$ atm at 1000°C) could result in a continuous transport of oxygen ions from the high potential electrode (air in these cases) to the Cr,Cr_2O_3 electrode-electrolyte interface. This continuous short-circuiting of the cell can polarize the Cr metal at the interface substantially to give rise to nonequilibrium cell potentials that are below the equilibrium potentials (Fig. 3). The calculated lines from the data of these investigators appear too high in Fig. 4 for the same reason. Since the equilibrium potential of the Mn,MnO electrode is higher than that of the Cr,Cr_2O_3 electrode, the low values reported by these investigators when subtracted from the appropriate Mn,MnO potential gives rise to cell potentials that appear too high (Fig. 4).

The measured cell potentials of this study from cells [I] and [II] are related to the standard Gibbs free energy of formation of Cr_2O_3 by the expression

$$\Delta G^\circ_f(Cr_2O_3) = 3[-2E\mathbf{F} + \Delta G^\circ_f(MO)] \quad [1]$$

where E is the measured cell potential in mV, $\mathbf{F}$ is Faraday's constant, 23,066 cal/mV gram equivalent, and $\Delta G^\circ_f(MO)$ is the standard Gibbs free energy of formation of CoO or MnO for cells [I] and [II], respectively.

Equation [1] was used in conjunction with the measured potentials from cells [I] and [II] to calculate $\Delta G^\circ_f(Cr_2O_3)$. The data of Kiukkola and Wagner (7) for $\Delta G^\circ_f(CoO)$ and those of Alcock and Zador (8) for $\Delta G^\circ_f(MnO)$ were used in this calculation. The results are as follows

from cell [I]

$$\Delta G^\circ_f(Cr_2O_3) = -266{,}990 + 60.15T \pm 250 \text{ cal} \quad (1173°\text{-}1540°K)$$

where $\Delta H^\circ_f = -266{,}990 \pm 400$ cal and $\Delta S^\circ_f = -60.15 \pm 0.21$ cal/°K

from cell [II]

$$\Delta G^\circ_f(Cr_2O_3) = -266{,}270 + 59.55T \pm 100 \text{ cal} \quad (1148°\text{-}1460°K)$$

where $\Delta H^\circ_f = -266{,}270 \pm 240$ cal and $\Delta S^\circ_f = -59.55 \pm 0.11$ cal/°K. Considering the uncertainty in the Co,CoO data (±100 cal) and in the Mn,MnO data (±150 cal) the agreement between the $\Delta G^\circ_f(Cr_2O_3)$ calculated from the two cells (±200 cal) is good. The following expression determined by the average of the results of cells [I] and [II] is recommended to represent the standard Gibbs free energy of formation of Cr_2O_3 based on the results of this study

$$\Delta G^\circ_f(Cr_2O_3) = -266{,}600 + 59.78T \pm 350 \text{ cal} \quad (1150°\text{-}1540°K)$$

where $\Delta H^\circ_f = -266{,}600 \pm 640$ cal and $\Delta S^\circ_f = -59.78 \pm 0.32$ cal/°K. Table II shows a comparison of standard Gibbs free energy of formation of Cr_2O_3 as reported by various investigators. The agreement between the results of this study and those of Jeannin *et al.* is excellent.

Summary and Conclusions

The standard Gibbs free energy of formation of Cr_2O_3 has been measured using the solid oxide electrolyte technique incorporating a ThO_2-Y_2O_3 electrolyte with reference to the Co-CoO and Mn-MnO equilibria. The two separate measurements are consistent and are in excellent agreement with the gas equilibration results of Jeannin *et al.*

Fibrous Growth of Tantalum Carbide by A-C Discharge Method

Takehiko Takahashi* and Kohzoh Sugiyama

Department of Applied Chemistry, Faculty of Engineering, Nagoya University, Nagoya, Japan

ABSTRACT

The growth of tantalum carbide fiber by an a-c discharge method was studied. Maximum growth rates of up to 40 mm/min were obtained under the following conditions: the discharge current (60 Hz) was 0.4-0.6 mA; the concentrations of hydrogen, argon, tantalum pentachloride, and propylene were 4.9, 94.4, 0.2, and 0.5%, respectively; and the reactant gas temperature was 400°-600°C. The minimum diameter of the grown fiber was 3.5μ. By x-ray diffraction, the structure of the grown fiber was identified as tantalum carbide (Fm3m). The tensile strength was a relatively low value of 2.7 kg/mm².

Tantalum carbide is characteristic of high temperature materials (mp, 3880°C). From considering the complexity of the Ta-C phase diagram (1), the phase reversion of tantalum carbide grown at high temperature is also interesting. Fibrous or filamentous growth of carbides, nitrides, and borides of the IVa group elements has been investigated by means of the a-c discharge method by the present authors (2-4). In this method, the growing tip of the fiber can easily be heated to or near its melting point even in a gas mixture of the reactants heated at 300°-600°C. The formation reaction of tantalum carbide is expressed by

$$TaCl_5 + C_xH_y + nH_2 \rightarrow TaC + 5HCl + C_{x'}H_{y'} \quad [1]$$

where n is an arbitrary number, x and y are three and six in the case of propylene, and $C_{x'}H_{y'}$ represents various hydrocarbon residuals. A rapid growth rate up to 40 mm/min can be obtained.

Some investigators have reported the deposition rate of tantalum carbide by the van Arkel method and the carburization rate of tantalum metal (5). However, no papers have dealt with fibrous growth of this compound. In this paper, the growth conditions of tantalum carbide fiber by the a-c discharge method are described.

Apparatus and Experimental Procedure

The outline of the apparatus is shown in Fig. 1. A vertical quartz tube, the inner diameter of which was 27 mm, was used as the reaction tube. The upper half had an inner tube into which a gas mixture of hydrogen and 99.3% propylene was introduced. A gas mixture of chlorine and deoxygenated argon was introduced into the outer zone of the double tube, where chlorine reacted with the packed tantalum ribbon to form tantalum pentachloride. This gas mixture met at the middle of the tube. Two electrodes were inserted from the upper and lower ends of the tube via syringe-type fine quartz tubes and a high a-c voltage was applied across them. The electrodes were molybdenum wires of 0.1 mm diameter. The a-c source, 60 Hz commercial power, was fed to a high voltage transformer regulating a source voltage with a Slidac (transformer). One to thirty megohm resistance was added in series in the discharge circuit to stabilize the current. Within a temperature range of 250°-650°C and a discharge current of 75 μA-2 mA, tantalum carbide

fiber grew on the tips of the electrodes. The interelectrode distance was kept constant at 1-5 mm by moving one of the electrodes upward or downward. As the fiber length reached 30 or 50 mm, spontaneous fluctuation occurred due to gas convection. Thus grown fibers were broken off by giving a shock to each electrode and were gathered in a quartz receiver. The growth rate of fibers under a given condition was evaluated by measuring half of the moving rate of one electrode relative to the other, since the growth rates of fibers on the upper and lower electrodes were approximately equal.

Results and Discussion

Relation between the temperature of gases and the growth rate.—The temperature of the reactant gases had to be held high enough to keep the tantalum chloride in the gaseous phase. Figure 2 shows the growth rate dependence of the temperature of the reactant gases between 250° and 650°C. The reaction of chlorine with tantalum ribbon began to take place above 230°C, and the amount of tantalum chloride transported by the argon carrier to the discharge zone increased gradually as the temperature ascended to 400°C, at which point a maximum growth rate of 40 mm/min was obtained. The decrease in growth rate above 400°C may be attributed to a deficiency of carbon produced in the reactant gases by pyrolysis of propylene. The diameter of the grown fiber was in the range of 3.5-12μ. As shown in Fig. 2, the diameter was slightly affected by the gas temperature having a minimum value at 400°C. In these experiments, since the fiber grown at higher temperatures exhibited a smooth appearance microscopically, most of the experiments thereafter were performed at 500°C.

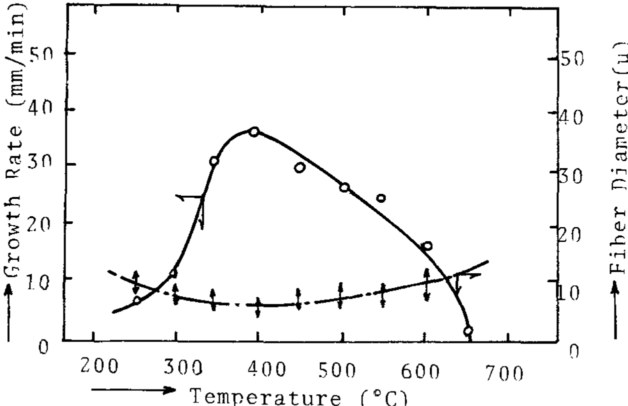

Fig. 2. Variation of growth rate and fiber diameter with reactant gas temperature. The growth conditions were: discharge current 0.15 mA; flow rate of argon, hydrogen, chlorine, and propylene 3.8, 0.2, 0.008, and 0.01 cm^3/sec, respectively; added resistance in discharge circuit 30 megohms; and interelectrode distance 2 mm.

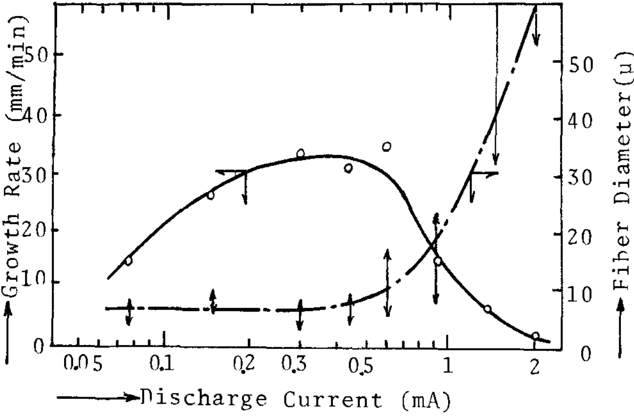

Fig. 3. Effect of the discharge current. The reactant gas temperature was 500°C, other conditions were the same as for Fig. 2.

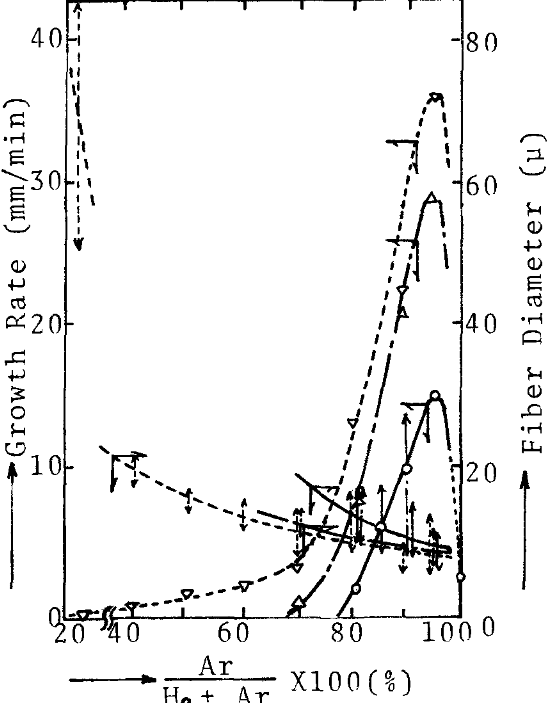

Fig. 4. Effect of the argon concentration. The reactant gas temperature was 500°C; the discharge currents were 0.15 mA (○), 0.30 mA (△), and 0.45 mA (▽); and the total, chlorine, and propylene flow rates were 4, 0.005, and 0.1 cm^3/sec, respectively.

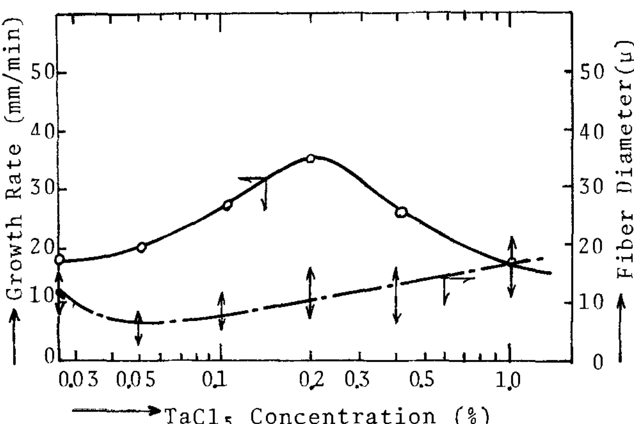

Fig. 5. Effect of tantalum pentachloride concentration. The reactant gas temperature was 500°C; the discharge current was 0.15 mA; the flow rates of argon, hydrogen, and propylene were 3.8, 0.2, and 0.01 cm^3/sec, respectively; the inserted series resistance was 20 megohms; and interelectrode distance was 1 mm.

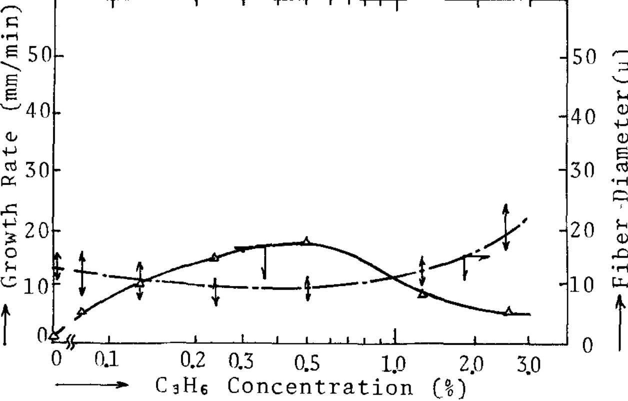

Fig. 6. Effect of propylene concentration. The conditions were the same as for Fig. 5, except that the chlorine flow rate was 0.005 cm^3/sec.

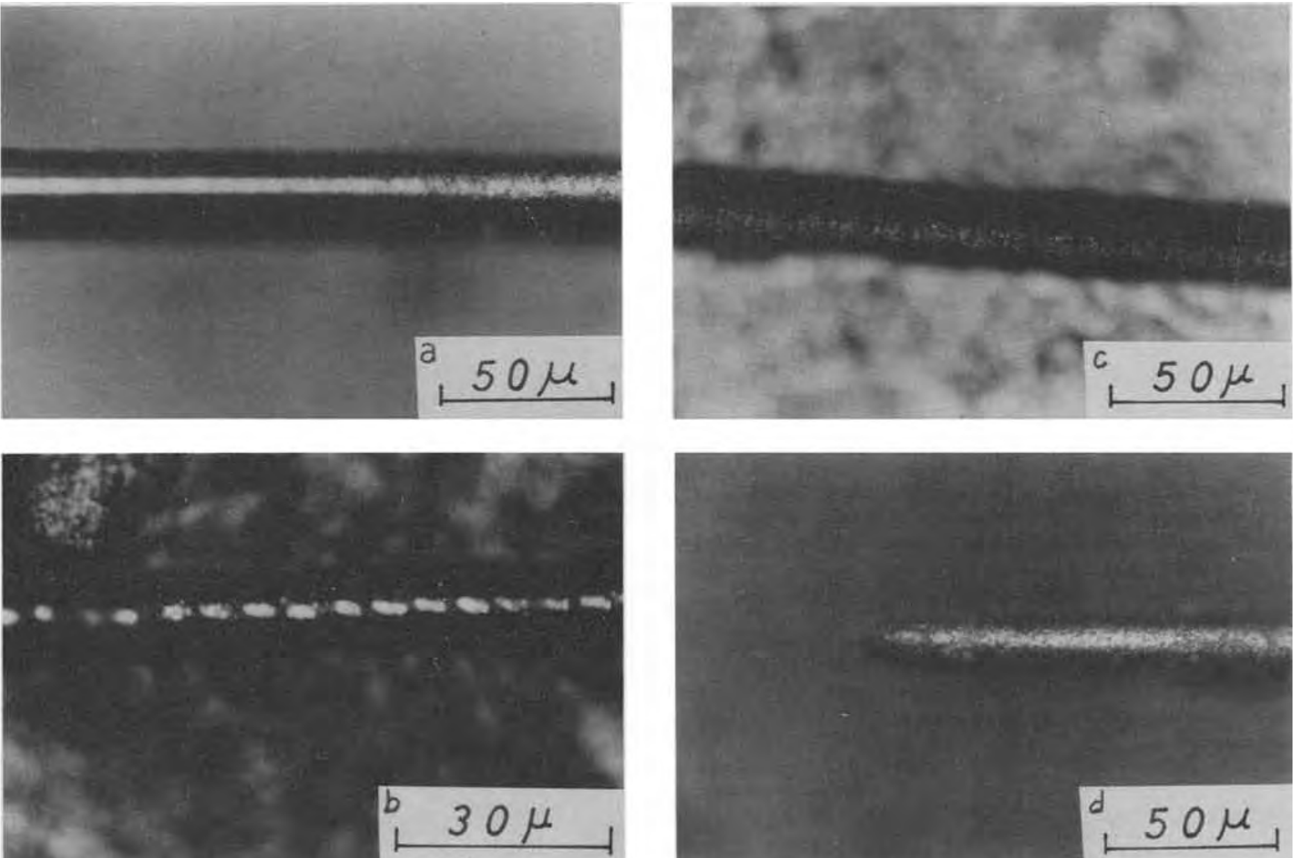

Fig. 7. Microscopic appearance. The samples were grown under the following conditions with reactant gas temperature of 500°C:

No.	Discharge current (mA)	Flow rate (cm^3/sec) H_2	Ar	Cl_2	C_3H_6	Series resis-tance (megohm)	Inter-electrode distance (mm)
a	0.15	0.2	3.8	0.005	0.0025	20	1-2
b	0.15	0.2	3.8	0.005	0.005	20	1-2
c	0.6	0.2	3.8	0.008	0.01	30	3-5
d	0.45	2.4 (60%)	1.6	0.005	0.01	30	5-8

Effect of discharge current.—The most important factor affecting growth rate and fiber diameter was the discharge current as shown in Fig. 3. The maximum growth rate is found at 0.4-0.6 mA. With lower discharge currents, heating of the fiber tips to promote fiber growth might be insufficient to overcome the heat loss away from the fiber by conduction, radiation, and convection. With higher currents, however, partial melting and radial growth accompanied growth along the fiber axis. These were the conditions above 0.9 mA, where the growth rate began to decrease, while the diameter of the fibers increased markedly. The power corresponding to 30-45 mW was 75 μA discharge and to 360-540 mW was 0.9 mA discharge. The heat loss via radiation is only a trivial portion and was roughly estimated by the Stefan-Boltzmann equation to be 10^{-3} mW. This estimation was obtained assuming the average temperature to be 3000°K, the fiber diameter to be 10μ, the effective length of fiber for radiation to be 30μ, and the emissivity of tantalum carbide to be 0.3. Accordingly, most of the heat loss is considered to arise from conduction and convection.

Mixing ratio of hydrogen and argon.—In Fig. 4, the effect of the mixing ratio of hydrogen and argon under a constant gas flow of 4 cm^3/sec (STP) and constant propylene concentration of 2.5% is indicated. The growth rate for various discharge currents increases with argon concentration up to 95%, and the growth rate increases with discharge current. The fiber diameter tends to be thinner as the argon concentration is higher. At an argon concentration near 100%, where the propylene concentration was nearly zero, the product was not tantalum carbide but metallic tantalum.

The appearance of the fiber was metallic when grown at low argon concentration and was dull and rough at high argon concentration. The effects of argon concentration would arise from low thermal conductivity of argon compared with hydrogen. At higher argon concentration, therefore, the growing tip is more easily heated to higher temperature than at lower argon concentration.

Effect of concentrations of tantalum pentachloride and propylene.—The relation between the growth rate and the tantalum chloride concentration, which is calculated from the flow rate of the inlet chlorine, is shown in Fig. 5. The maximum growth rate is found at 0.2% tantalum pentachloride, while the minimum diameter of grown fiber is found at 0.05%. The degradation of growth rate at a tantalum pentachloride concentration higher than 0.2% could be attributed to the collision loss of arc-electrons with the tantalum chloride molecule.

Figure 6 shows the effects of propylene concentration on growth rate. With a reactant gas temperature of 500°C and a discharge of 0.15 mA, the maximum growth rate of 18 mm/min was obtained at 0.5% propylene concentration. In the previous paper (6), the effect of hydrocarbon concentration in the van Arkel method was discussed and it was concluded that the concentration range below that corresponding to maximum growth rate was a carbon deficient range, while the concentration range above that corresponding to the maximum growth rate was a carbon excess range where the carbon deposit interfered with the carbide growth. By microscopic observation of a fiber grown at propylene concentration above 0.5%, however, the carbon deposition on the surface of the fiber could not be

found explicitly in this experiment. Although the carbide growth rate in the van Arkel method depends on the structure and carbon number of the hydrocarbon (7), the predominant factor may be heat stability of the hydrocarbon. As the most important factor is the high reaction temperature under the conditions of this experiment (*i.e.*, at relatively low temperature of the reactant gases and sufficiently high temperature at the growing tips), the influence of the kind or structure of hydrocarbons would be a minor factor.

Microscopic appearance and x-ray diffraction.—The micrographs of the grown fiber are shown in Fig. 7. Figure 7a shows a fiber of 12μ diameter grown at a discharge current of 0.15 mA, and Fig. 7b is a fiber of about 10μ grown with the same discharge current but at a higher propylene concentration. In Fig. 7b, a number of gaps can be seen, and the distance from one gap to the next one was determined to be about $5\text{-}7\mu$. The growth rate of the fiber shown in Fig. 7b was about 20 mm/min, which corresponds to a growth rate of 5.6 μ/Hz. From these results, it is considered that fiber growth took place during the half cycle, either cathodically or anodically. A fiber grown with a higher discharge current and a growth rate of 36 mm/min was found to show gaps about 10μ apart as shown in Fig. 7c, and the above calculation can be applied again with good agreement. Figure 7d shows a growing tip with a taper indicating that growth along the fiber axis is followed by radial growth.

The x-ray diffraction samples were prepared by pasting some tens of fibers on a glass plate with their axes parallel to the surface. Metallic tantalum was identified only at zero propylene concentration, and tantalum carbide, designated as Fm3m, was detected at a propylene concentration of 0.12% accompanied by weak peaks of metallic tantalum. At propylene concentrations above 0.25%, only tantalum carbide was detected, and higher propylene concentrations gave broader peaks as shown in Fig. 8. The diffraction peak intensities were in agreement with the values of the ASTM card (7). In the figure, no structural orientation was found that could be attributed to the successive nucleus formation of carbide on deposited carbon which occurred at high temperature and at high concentration of hydrocarbon. This tendency is different from the results obtained in the previous papers on zirconium boride and titanium nitride where their respective peaks of (001) and (111) were weaker than ASTM values. Ramqvist (8) reported on the variation of lattice parameter of tantalum carbide with carbon concentration indicating that the lattice parameter increased linearly with the carbon content, from 4.420Å when C/Ta was 0.75 to 4.455Å when C/Ta was 1.0. The precise lattice constants, however, were not obtained in this experiment because the quantity of the grown sample examined was small. Sometimes the diffraction peaks δ-TaO were detected. The oxide might be formed by the hydrolysis of tantalum chloride with atmospheric moisture when the TaC fibers were taken from the receiver. The relation between the discharge current and the structure of the product was studied, and it was found that the former had a minor influence on the tantalum carbide structure.

Tensile strength and diameter of the fiber.—The tensile strength of the grown fiber was measured at room temperature with a spring balance. A fiber was held by epoxy resin between two plates, one of which was suspended from a spring. The spring hanger was gradually moved upward until the sample fiber snapped and the breaking load was determined from a calibration curve. The diameter of the broken fiber section was measured microscopically. The strength *vs.* diameter relation is plotted on log-log scale in Fig. 9. The highest strength observed is 27 kg/mm², which is very low compared with zirconium diboride and zirconium carbide fibers grown by the same method, the strengths of which were 210 and 50 kg/mm², respectively.

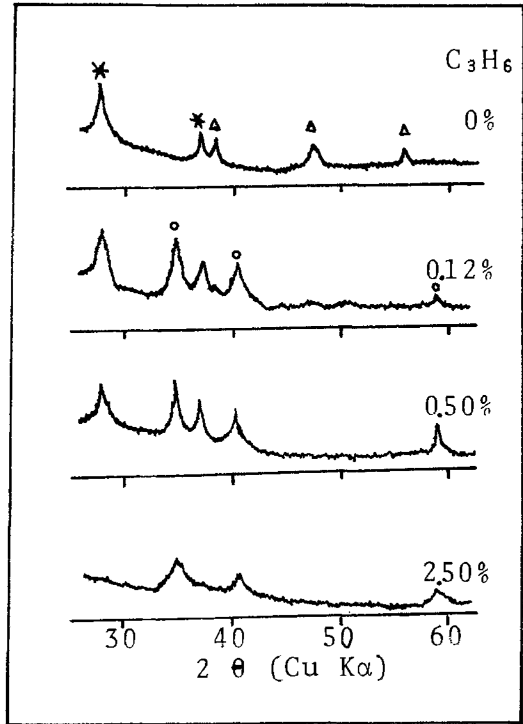

Fig. 8. X-ray diffraction diagrams. The samples were grown under the following conditions: the reactant gas temperature was 500°C; the discharge current was 0.45 mA; the flow rates of argon, hydrogen, and chlorine were 3.8, 0.2, and 0.02 cm³/sec, respectively. Legend: * TaO, ○ TaC, and △ Ta.

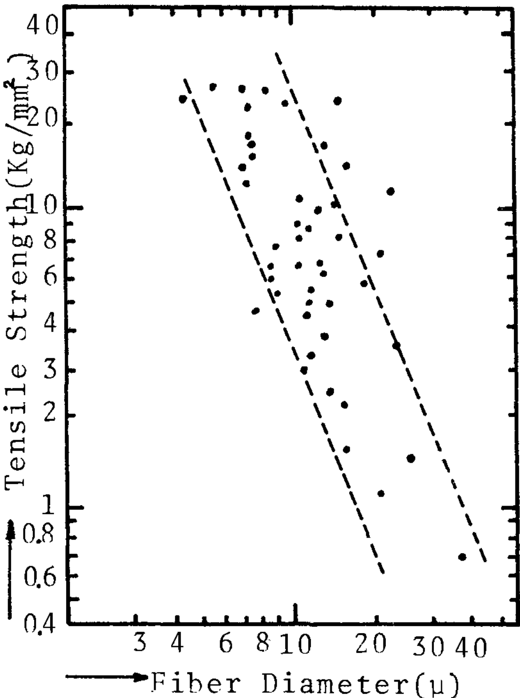

Fig. 9. Relation between the fiber diameter and tensile strength at room temperature.

Summary

Data were obtained on growth of tantalum carbide fibers by a weak a-c discharge method. The results obtained were as follows:

1. To obtain a growth rate of 40 mm/min, the temperature of the reactant gases must be between 400° and 500°C.

2. The mixing ratio of hydrogen and argon had a strong effect on growth rate and appearance of the product. Maximum growth rate was obtained at 95% argon.

3. A discharge current of 75-600 μA was favorable for obtaining a thin fiber.

4. Some of the fibers produced were identified as tantalum carbide with a Fm3m structure. Fibers made with low propylene concentration were found to contain metallic tantalum.

5. Crystal growth took place in the half-cycle of a.c., and growth along the fiber axis was followed by radial growth.

6. The highest tensile strength of the fibers produced was 27 kg/mm^2 and less.

Manuscript submitted Feb. 8, 1971; revised manuscript received Sept. 7, 1973.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1974 JOURNAL. All discussions for the December 1974 Discussion Section should be submitted by Aug. 1, 1974.

Technical Notes

The Oxidation of Two-Phase Aluminum-Copper Alloys

A. F. Beck, A. J. Brock,* and M. J. Pryor*

Metal Research Laboratories, Olin Corporation, New Haven, Connecticut 06504

Despite considerable past study of the oxidation behavior of aluminum and its alloys (1-4), much of the work has been conducted on solid solutions with only incidental impurities. Accordingly, the influence, if any, of second phase intermetallic compounds on oxidation behavior has not been clearly defined.

The aluminum-copper system provides a good opportunity for studying the effect of the tetragonal θ phase ($CuAl_2$) on oxidation behavior. The aluminum-rich end of the aluminum-copper equilibrium diagram is shown in Fig. 1. Oxidation kinetics were determined on two solid solution alloys, Al-1% Cu (A) at 365°C and Al-4% Cu (C) at 500°C. At these temperatures the respective alloy compositions are very close to the $\alpha - \alpha + \theta$ phase boundary. Two additional alloys were provided, Al-2% Cu (B) which was examined at 365°C and Al-5% Cu (D) which was examined at 500°C. The alloys (B) and (D) contain 1% by weight excess copper at the appropriate oxidation temperature. This is equivalent to 1.85 weight per cent (w/o) of the θ phase and 1.15 volume per cent (v/o) of this intermetallic compound. Detailed compositions of the alloys are contained in Table I.

Ingots of the four alloys measuring 7.6 × 15.2 × 91.5 cm were cast after being chlorine fluxed to remove dissolved hydrogen. They were subsequently homogenized at 550°C for 8 hr. After cooling to room temperature, the ingot faces were machined to remove 0.32 cm per side. The slabs were reheated to 800°F and hot rolled to a thickness of 0.51 cm. The hot-rolled slab was etched in 1.0*N* NaOH solution at room temperature for 5 min, rinsed, and dipped in 50% nitric acid at 70°C for 10 sec. All alloys were cold rolled to a thickness of 0.37 mm. Specimens of alloys (C) and (D) were held at 500°C for 72 hr in order to obtain complete dissolution of θ phase in alloy (C) and in order to stabilize the distribution of θ phase in alloy (D). The alloys

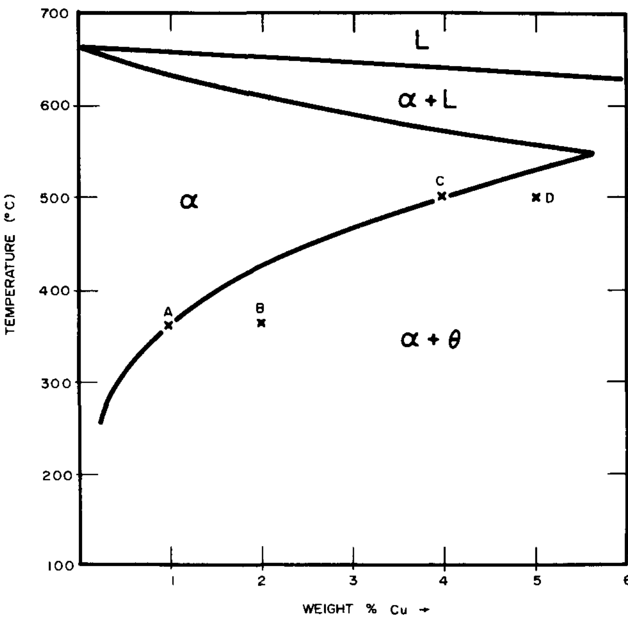

Fig. 1. Aluminum-rich end of the Al-Cu equilibrium diagram.

Key words: oxidation, aluminum-copper alloys, microstructure.

Table I. Composition of Al-Cu alloys (w/o)

Alloy	Cu	Fe	Si
A	0.97	0.002	0.001
B	2.02	0.003	0.001
C	3.92	0.003	0.001
D	5.07	0.003	0.001

were water quenched after this treatment. Alloys (A) and (B) were held at 365°C for 72 hr and water quenched. These two alloys were then cold rolled to a thickness of 0.06 mm so as to provide larger areas for oxidation at 365°C where the total weight gains are quite small. After the foregoing thermal treatments the specimens were etched in 0.5*N* NaOH solution at 70°C for 4 sec followed by a dip in 50% nitric acid at 85°C. This procedure was repeated 5 times.

For oxidation at 500°C specimens measuring 1 × 4 × 0.037 cm were used. For oxidation at 365°C foil specimens measuring 4 × 12 × 0.006 cm were used. These specimens were wound around a glass rod; on removing the rod spirals with suitably large surface areas and low masses were obtained. Oxidation temperatures of 365° and 500°C were selected because at the lower temperature only gamma alumina with poorly developed long range order forms as an oxidation product. At 500°C, in addition to the formation of the gamma alumina with poorly defined long range order, well developed crystalline γ-Al_2O_3 nucleates at the amorphous oxide interface and grows as a series of expanding cylinders. The oxidation behavior of aluminum-copper alloys solid solutions up to and including 4% has been described earlier (4).

In this work, oxidation studies were conducted using the same experimental method as described previously (4). The oxygen pressure used was 76 Torr. Figure 2 shows the results obtained at 365°C for an Al-1% Cu solid solution (A) and for an Al-1% solid solution containing 1.15 v/o of θ phase (B). It may be seen that the kinetic results are indistinguishable between the two alloys. The gravimetric results obtained at 500°C for the Al-4% solid solution (C) and for the Al-4% Cu solid solution containing 1.85 w/o of θ phase were also indistinguishable within the limits of experimental error and were also identical to the results reported in our earlier publication for the same alloy (4). Clearly, the presence of a modest volume fraction (1.15%) of θ phase has no detectable effect on over-all oxidation kinetics.

It was found previously that the presence of increasing copper contents in solid solution results in an increase in the rate of formation of the amorphous film and its thickness albeit at somewhat higher temperatures than the 365°C used in this study. Accordingly, the film formed on alloy (B) after oxidation for 100 hr was stripped in 10% mercuric chloride dissolved in methanol and examined by transmission electronmicroscopy (AEI EM6G at 100 kV). The areas of amorphous film formed over the θ phase are relatively easy to detect because this phase is subject to somewhat more chemical roughening during the specimen cleaning (Fig. 5). Electron opacity measurements made on the amorphous film formed on the θ phase suggested that the film was no thinner and probably somewhat thicker than that formed on the solid solution matrix. Further, there were no discontinuities in the oxide film associated with the θ phase particles.

The film formed on the Al-5% Cu alloy (D) in 16 hr at 500°C is shown in Fig. 3. The crystal density in the Al-4% matrix is characteristic of that found in earlier work (4). However, the crystals formed on the θ phase are extremely small. Since in the solid solution regime crystal density decreases and crystal size increases with increasing copper content, the oxidation

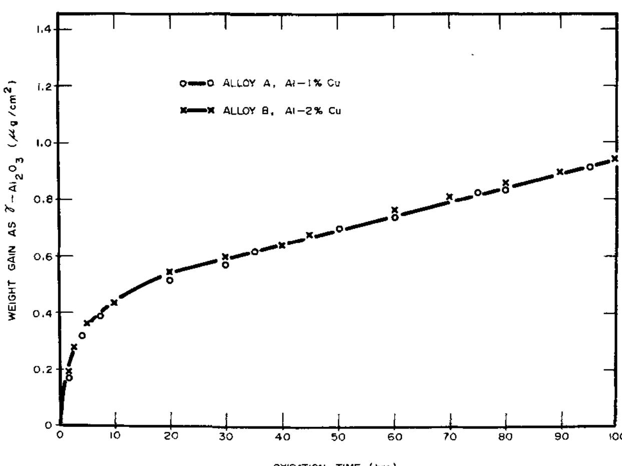

Fig. 2. Relationships between weight of γ-Al_2O_3 and time for Al-1% Cu (A) and Al-2% Cu (B) at 365°C in oxygen at a pressure of 76 Torr.

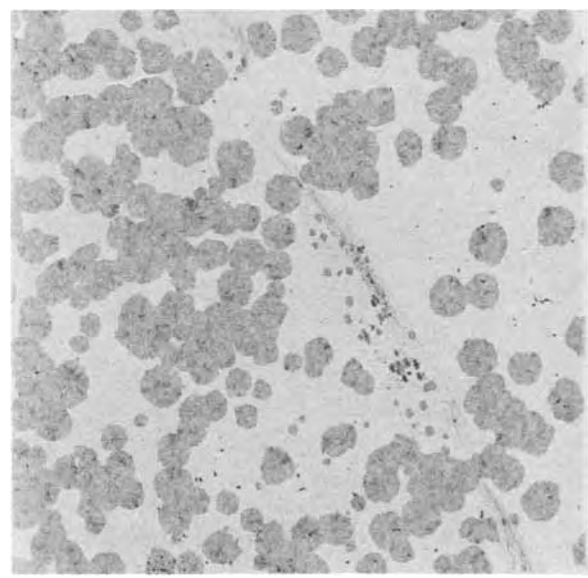

Fig. 3. Transmission electron micrograph of oxide film formed over a two-phase region of Al-5% Cu alloy (D) after oxidation for 16 hr at 500°C. Magnification 1500×.

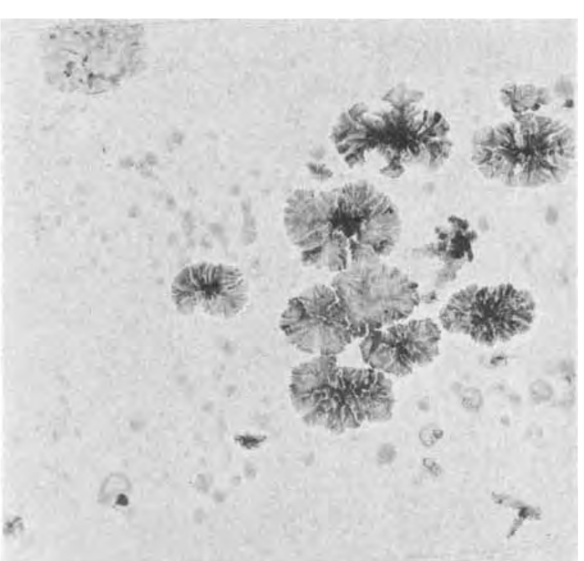

Fig. 4. Transmission electron micrograph of oxide film formed on θ phase after oxidation for 16 hr at 500°C. Magnification 16,000×.

behavior of the θ phase is not characteristic of this relationship. The thickness of the gamma alumina crystals formed on the α matrix is around 170Å. The thickness of crystals formed on the θ phase is only around 90Å. Some of the crystals formed on the θ phase have more contrast than those formed on the matrix (Fig. 4). Since they are substantially thinner, this suggests the crystalline oxide has a substantially higher copper content than that formed over the matrix.

Electron opacity measurements were made on the amorphous oxide between the crystals formed on the θ phase. The results were somewhat variable from one θ phase particle to another presumably because of some roughening of this phase in the specimen cleaning. This is shown in Fig. 5, a backside replica of the oxide film stripped from alloy (D) after 16 hr oxidation at 500°C. However, the electron opacities measured

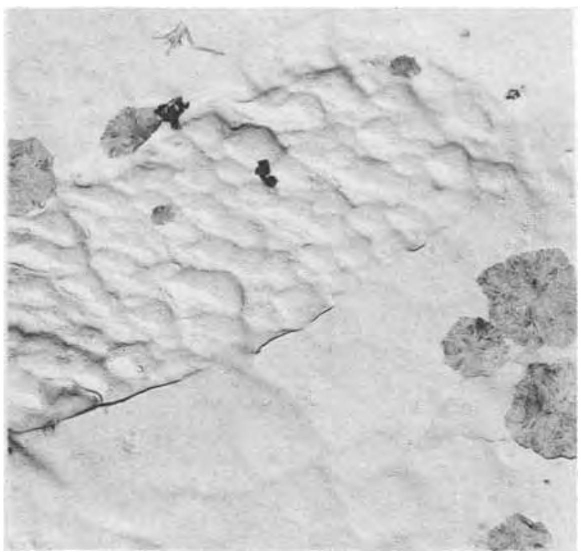

Fig. 5. Electron micrograph of underside of oxide film formed on two phase region of Al-5% Cu alloy (D) after oxidation for 16 hr at 500°C. Magnification 6000×.

at different locations ranged from being approximately equal to that measured on the matrix to some 50% higher. Selected area diffraction confirmed that the film formed over the θ phase was a composite of gamma alumina with poorly developed long range order and well defined γ-Al_2O_3 crystals. Accordingly, the amorphous film formed over the θ phase at 500°C is no thinner than that formed on the Al-4% Cu matrix and is probably somewhat thicker. Again, no evidence of film discontinuity associated with θ phase particles could be found.

In summary, the presence of 1.85 w/o (1.15 v/o) of θ phase has no detectable influence on the bulk oxidation kinetics of Al-Cu alloys at 365° and 500°C. Local examination of the films formed over the θ phase suggests that the amorphous film is no thinner and is probably thicker than that formed over the matrix. Crystalline γ-Al_2O_3 nucleation and growth at the base of the amorphous film is radically modified when there is a θ phase substrate. Lateral growth rate of the crystals is substantially retarded and their terminal thickness is only around 50% of those formed on the matrix. Crystal nucleation on the θ phase appears to be strongly orientation dependent although the details of this dependency have not been determined in this work.

A Method for Determining the Optimum Thickness of Graphitic Coatings Used in Electron Devices

Joseph D. Reardon

GTE Sylvania Incorporated, Electronic Components Group, Electronic Tube Division, Seneca Falls, New York 03148

In the manufacture of CRT devices, evacuated glass envelopes are exposed to high-energy electrons. Bombardment of glass with 15-20 keV electrons causes the evolution of O_2, CO, H_2 (1, 2), and CO_2 (2). When certain glasses are thermally heated in vacuum, chlorine (2, 5) and fluorine (2) compounds are evolved which then may cause cathode poisoning during subsequent electron bombardment (8). Oxygen (3, 4), carbon dioxide (4), fluorine (5-8), and chlorine (2-7) have long been recognized as being harmful to the thermionic emission of oxide cathodes.

It is common practice, especially in the manufacture of color television picture tubes, to cover some portion of the exposed glass with an internal conductive coating, usually a graphite-silicate mixture. Although the primary purpose of the internal coating is to provide a conductive path for electrons, the coating can also help to preserve the cathodic emission, providing that the coating thickness is sufficient to shield the glass envelope from high-energy primary electrons. This investigation was undertaken to determine the optimum coating thickness necessary to completely shield a glass surface from 25 keV electrons, the energy of electrons in an operating color TV picture tube.

Key words: electron penetration, graphite-silicate coating, cathode ray tubes.

Experimental

Apparatus.—A schematic diagram of the demountable plaque-scanning apparatus is shown in Fig. 1. A standard pumping arrangement consisting of a mechanical fore pump and an oil diffusion pump operating with liquid nitrogen trapping was used. The apparatus itself consists of a glass envelope fitted with a

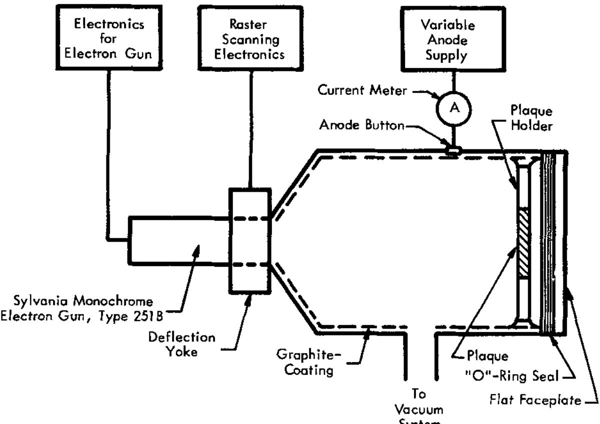

Fig. 1. Schematic diagram of the demountable electron penetration apparatus.

monochrome electron gun (Sylvania Type 251B) and a detachable faceplate. A stainless steel plaque holder was positioned in the faceplate and held in place with spring snubbers.

The glass envelope was equipped with an anode button to allow a positive potential to be applied to the plaque. Electrical continuity between the plaque and anode supply was achieved by means of a graphite coating.

The associated electronics include (*i*) a variable anode supply and current meter, (*ii*) the deflection yoke and scanning electronics, and (*iii*) the electron gun cathode heater and grid supplies.

Procedure.—Clean 2 in. × 2 in. glass plaques were masked so as to leave exposed an area of approximately one inch square in the center. Using a hand spray gun, a commercially available graphite-silicate coating (Dixon 217 coating, Joseph Dixon Crucible Company) was deposited on the plaques. By increasing the number of spray passes from one plaque to the next, the plaques were coated in varying degrees of thickness from 30,000 to 185,000Å. After the coating was allowed to air dry, the masking was removed and the plaques were fired in air at 430°C for ½ hr to set the coating.

The coating thickness of each plaque was determined using a Sloan surface profilometer. In all cases, the thickness measurements were taken at several places on the coated square. Since considerable peak-to-valley variation was observed on the thin plaques, the average minimum thickness was assumed to be the effective coating thickness.

The coated plaques were then individually placed in the demountable unit. In all cases, the vacuum system was allowed to pump down to the low 10^{-5} Torr region before measurement was begun. At this point the room was darkened and a blue fluorescence was observed when the electron beam was allowed to strike the uncoated glass. With approximately 5.0 keV anode potential on the plaque, the raster and biasing controls were adjusted so as to give an anode current of 8 μA and a surface area of approximately 0.5 cm^2.

When the electron beam was positioned on the coated portion of the plaque, no fluorescence was noted. The anode potential then was gradually increased. Periodically, the raster size was adjusted to maintain the beam area of 0.5 cm^2. When the blue fluorescence was just visible, the raster size was again checked and the voltage recorded. The threshold voltage (the voltage at which fluorescence is first noted) was determined for each plaque.

Using uncoated plaques, the onset of fluorescence was observed at 500 eV. Each of the threshold voltages was corrected for the so-called "dead voltage."

Results and Discussion

Range-energy data for graphite-silicate coatings are shown graphically in Fig. 2. The electron range, R, is

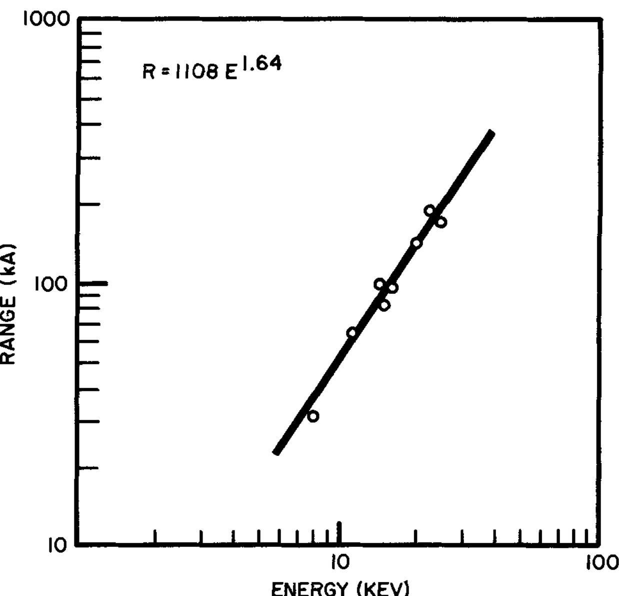

Fig. 2. Range-energy data for graphite-silicate coatings

the measured effective coating thickness. The energy, E, is the primary electron energy corresponding to the initial electron penetration for each coating sample. On a logarithmic scale the relation between R and E is linear for film thicknesses between 30,000 and 185,000Å. A computer least squares curve fit has determined that the data obeys the empirical relation

$$R = 1108\, E^{1.64} \qquad [1]$$

where R is expressed in angstroms and E in keV.

The optimum coating thickness for any electron device may be calculated by simply substituting the appropriate operating voltage into Eq. [1]. For the case of color TV picture tubes operating at 25 keV, a coating thickness of 220,000Å is necessary to completely shield the glass envelope from high energy electrons. Covering the glass envelope of electronic devices with graphite-silicate films in excess of this value should help to preserve the thermionic emission of oxide cathodes by reducing the level of harmful gaseous residuals.

The visual detection method used in the investigation for determining the electron range was chosen because of the experimental difficulties involved in handling graphite-silicate coatings of the type normally used in electron tubes. Kanter and Sternglass (11) have shown that range determinations using luminescent detectors give higher threshold energy values for electron penetration (smaller effective range) than can be expected by either theoretical calculations or absorption techniques. Calculations based upon the Bethe theory of energy loss (9) and the integration method of Lane and Zaffarano (10) show the calculated integrated path length, I, to be smaller than the experimental range (Fig. 3). That is, the experimental range is considerably larger than would be expected.

Sprayed coatings of the type considered here would be expected to have a porous structure. This is supported by the relatively low bulk density of the graphite-silicate coating (1.4 g/cm^3 compared to 2.2 g/cm^3 for crystalline graphite). Since it is likely that electrons should penetrate porous materials more easily than dense substances, the observed high experimental ranges may be attributed to the high void content of the graphitic coating.

Because of the probable dependence of the experimental range data on the void characteristics of the coating material, caution should be exercised in applying the electron penetration results obtained for graphite-silicate coatings to other systems. However, for

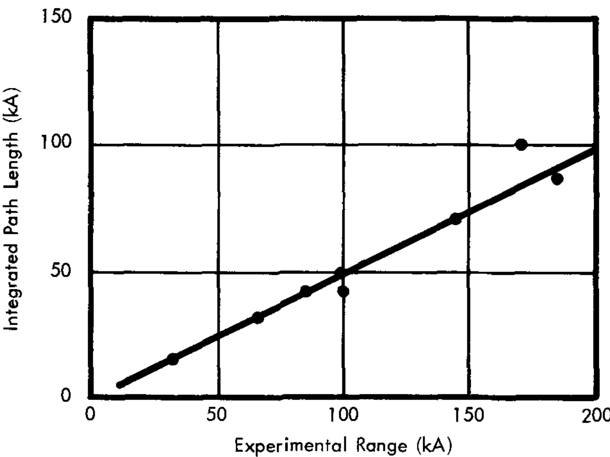

Fig. 3. Comparison of calculated and experimental ranges of electrons in graphite-silicate coatings.

films which have a high void content and do not readily lend themselves to evaluation by absorption techniques, the visual range determination employed for this investigation should give a reasonable approximation of the electron penetration.

Brief Communications

Anomalous Boron Diffusion in Silicon from Planar Boron Nitride Sources

Joseph Stach* and Alfred Turley

Solid State Device Laboratory, Department of Electrical Engineering, The Pennsylvania State University, University Park, Pennsylvania 16802

This communication describes experimental results of boron diffusions using boron nitride wafers as the boron source. High surface concentrations are generated by the boron nitride diffusion system (1-3). As such, nonideal effects are introduced into the diffusion process, the most notable being anomalous diffusion profiles which exhibit dependence on the inert diffusion gas ambient.

Experimental

The silicon wafers used throughout the investigation were polished, <111> oriented, and 1.5 in. in diameter with a 3-7 ohm-cm arsenic doped 10-30 μm thick epitaxial layer. Prior to diffusion, the silicon was cleaned by accepted techniques (4) and stored in covered polypropylene containers. The procedures for preparing the boron nitride sources were those developed in previous investigations (1, 2).

Extensive use was made of linear four-point probe sheet resistance measurements in the evaluation of the diffused layers. The unit used consisted of an A&M Fell four-point probe head with wear resistant tungsten carbide probes of a 0.04 mm ± 10% tip radius loaded in ruby bearings and spaced 1.00 ± 0.01 mm apart with 200g ± 2% applied pressure when fully depressed; an A&M Fell four-point probe head mount; and a K&S Pacific Model 192 resistivity tester consisting of a 0.001-10 mA ± 0.1% full scale current source and a 0-20 mV ± 0.5% full scale digital voltmeter.

Boron diffusion profiles were obtained from incremental sheet resistance measurements (5, 6). Layer sectioning of silicon was performed by anodic oxidation (7) and a computer program adapted to the work of Donovan (8) and Irvin (9) was used in calculating profiles from the incremental sheet resistance data.

All diffusions were performed in a Thermco-Spartan 60 mm inside diameter furnace with a flat zone of 15 in. (±½°C). Diffusions were performed in helium, argon, and nitrogen ambients and the effects of these ambients were studied in terms of sheet resistance, diffusion profiles, and deposition of surface films during the diffusion process.

* Electrochemical Society Active Member.

Key words: boron nitride, boron diffusion, planar sources.

Figure 1 shows actual diffused profiles for the three ambients. Notice the surface concentrations and junction depths.

$$N_{S\mathrm{He}} > N_{S\mathrm{Ar}} > N_{S\mathrm{N_2}} \quad [1]$$

and

$$X_{j\mathrm{He}} < X_{j\mathrm{Ar}} < X_{j\mathrm{N_2}} \quad [2]$$

One cannot be sure of the validity of the surface concentrations due to the uncertainty in the measurement technique; however, the junction depths are significant and are supported by Fig. 2 which shows sheet resistance *vs.* time with gas ambient and temperature as parameters. The sheet resistance is consistent with junction depth measurements in that

$$\rho_{S\mathrm{He}} > \rho_{S\mathrm{A}} > \rho_{S\mathrm{N_2}} \quad [3]$$

The following argument is proposed to explain these results. At very high surface concentrations, "excess" boron above solid solubility reacts with the silicon to form a new phase on the surface. Such a phase was visually observed and remained on the silicon surface after conventional borosilicate glass removal. The thickness of the phase, t_{ph}, varied with diffusion ambient as follows

$$t_{ph\mathrm{He}} > t_{ph\mathrm{A}} > t_{ph\mathrm{N_2}} \quad [4]$$

The relative thicknesses of the phase layers were determined by comparison of the numbers of interference minima observed on an ultraviolet-visible spectrophotometer. The experimentally determined diffused layer profiles show that diffusions which formed a heavy borosilicate glass and Si-B phase resulted in shallower junctions and higher sheet resistances for constant times and temperature. This can be explained by making the following plausible assumptions: (*i*) the formation of surface films (glass and phase) consumes silicon; (*ii*) only "excess" boron above solid solubility combines with the silicon to form a new phase on the surface; and (*iii*) the diffusion coefficient of boron in the surface phase is greater than boron's diffusivity in silicon. Assumption (*iii*) was based on the observation that for long diffusion times, the surface concentration of boron was not reduced as

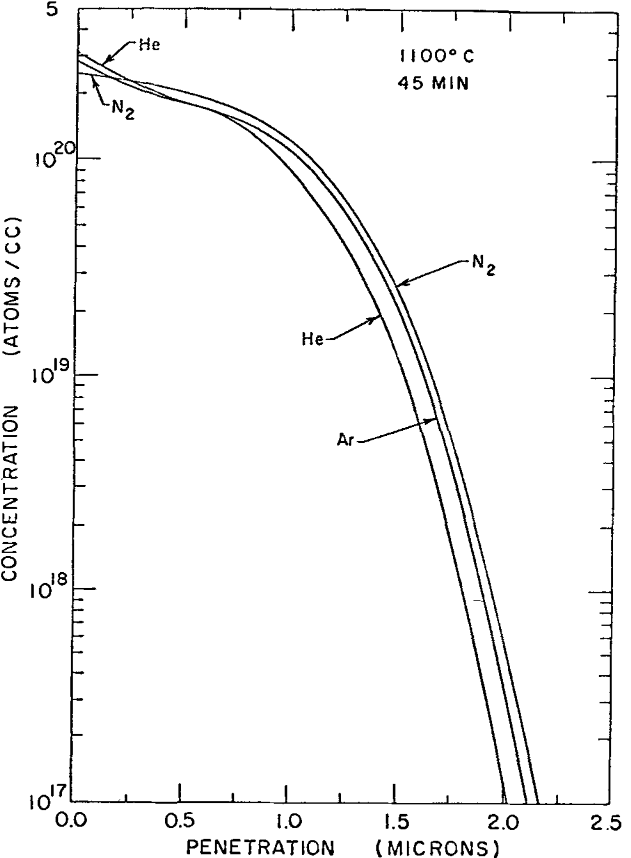

Fig. 1. Diffused impurity profile showing the effects of inert gas ambient.

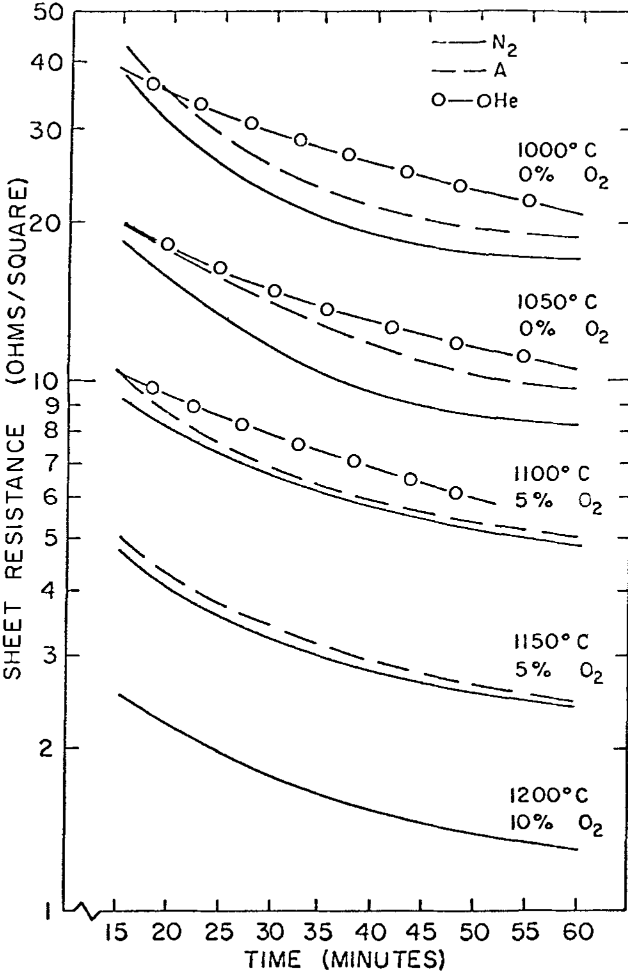

Fig. 2. Sheet resistance as a function of time with temperature and gas ambient as parameters.

would occur if the phase layer acted as a diffusion barrier. Busen *et al.* (10) have also observed such a phase following boron diffusions. They report that the phase is highly porous, with pore sizes as large as 0.75μ.

Before profiling or sheet resistance measurements were performed, the surface films were removed. This amount of silicon removed might account for the observed differences in junction depth and sheet resistance if the three assumptions presented are true.

Ideally, diffusions of this type should follow a complementary error function profile. Diffusions in the nitrogen ambient showed little or no surface phase formation. Two profiles of N_2 ambient diffusions along with an erfc profile as shown in Fig. 3. One sees that the real profile differs considerably from the erfc distribution. Deeper penetration in the high concentration area suggests a concentration dependent diffusivity giving enhanced diffusion at high concentrations; however, the concentration gradient near the surface indicates that the diffusivity probably reaches a maximum value and then begins to decrease with higher concentrations. A similar type of diffusivity concentration dependence for arsenic has been reported by Kennedy and Murley (11). Concentration dependence of boron diffusion coefficient has been previously reported in the literature; but no quantitative data have yet been presented (12-14).

Summary

Diffusion profiles which indicate concentration dependent diffusivity and inert gas ambient dependence have been experimentally observed when boron diffusions were performed using boron nitride wafers as the boron source at temperatures between 1100° and 1200°C. Actual profiles show steeper junctions than predicted from an erfc profile.

Complete Removal of Sodium from Silicon Dioxide Films by Formation of Phosphosilicate Glass

Daniel V. McCaughan, Richard A. Kushner, and Sigurd Wagner

Bell Laboratories, Murray Hill, New Jersey 07974

Alkali ion contamination of thermally grown SiO_2 films on silicon is a serious problem in semiconductor technology. One technique which has been used with some success in alleviating this difficulty is the formation of a layer of phosphosilicate glass over either gate dielectric or passivating oxide. Phosphosilicate films are known to getter mobile ionic impurities (1,2). Most investigations of mobile charge have been carried out with capacitance-voltage methods (3) whose sensitivity to charged impurities depends strongly on their location in the insulator and is highest for charges at the SiO_2/Si interface. The ionic drift techniques (4-6) on the other hand do not determine the location of charge. A drawback common to all electrical methods is that they measure either the total or the time derivative of the dielectric displacement and cannot, therefore, distinguish between ionic migration and dielectric polarization on an atomic scale. An experimentally independent but less widely used approach is afforded by the measurement of the distribution of radioactive tracers. Using ^{24}Na tracers, Yon, Ko, and Kuper (7), Kuper (8), and Buck *et al.* (9) have obtained results which show that sodium, initially distributed throughout the SiO_2, is partially gettered, during the growth of a phosphosilicate glass layer, into the PSG layer. The area density of sodium, in the experiments of Kuper and co-workers (7, 8), 6.4×10^{14}/cm^2, and of Buck and co-workers (9), $>1 \times 10^{14}$/cm^2, was unrealistically high. Here we present evidence that sodium initially present only near the SiO_2/Si interface in amounts comparable to those found in contaminated gate oxides ($\leq 10^{12}$/cm^2 Na) is removed to less than detection limits during phosphorus diffusions of short duration.

About 1×10^{13} cm^{-2} NaCl containing 1% radioactive sodium-22 as a tracer was evaporated onto 5000Å thick SiO_2 layers thermally grown on ~5 ohm-cm n-type (100) silicon wafers (9, 10). ^{22}Na is a positron emitter whose radioactivity was measured by counting the coincident gamma rays resulting from positron annihilation. The samples were then bombarded with 1×10^{14} cm^{-2} Ar^+ ions at 500 eV. This procedure drives sodium from the vacuum/oxide interface to the oxide/silicon interface (10-13).

The apparatus (13) consists of a glow discharge ion source with a 2 keV accelerator, a 60° sector mass analyzing magnet, and deflection plates for scanning the beam. The target is surrounded by a secondary electron suppressor, and the target current is measured. The energy spread at the sample is a few electron

Key words: gettering, mobile charge, ionic charge, device processing.

volts. No radioactive sodium was lost during the ion bombardment. After bombardment, 1000Å were etched off the silicon dioxide. This procedure removes all sodium not drifted to the SiO_2/Si interface, and counting of the ^{22}Na tracer showed that 1×10^{12} cm^{-2} total sodium remained in the oxide. [Prior experiments (10-13) have shown that virtually all of this sodium resides in the SiO_2, within about 200Å of the SiO_2/Si interface.] Phosphorus was then diffused into the oxide for 4 min at 925°C in an atmosphere of 0.01% PBr_3 and 0.8% O_2 in nitrogen at a flux of 23 cm · sec^{-1}. As determined by etch rate, this procedure converts approximately the top 200Å of SiO_2 to a phosphosilicate glass. The samples were again counted for ^{22}Na. It was

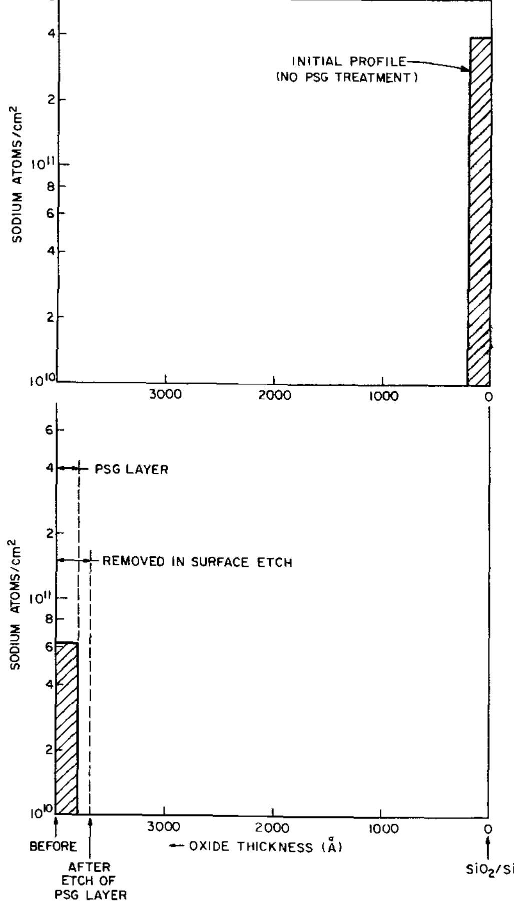

Fig. 1 (a, top). Profile of sodium in SiO_2 after ion bombardment and the top 1000Å removed by etching, leaving a profile of sodium at the SiO_2 interface only. (b, bottom) Profile of sodium in SiO_2 after the phosphorus diffusion step. No sodium remains at the SiO_2/Si interface; etching of the top 300Å (including the phosphorus glass layer) removes all remaining sodium.

observed that ≈80% of the sodium had been removed during the phosphorus diffusion. [We believe that the bromine gas resulting from the oxidation of PBr_3 forms the very stable but volatile NaBr which then evaporates from the SiO_2 into the furnace atmosphere. At 925°C the vapor pressure of NaBr is 6.8 Torr (14).] Removal of the top 350Å of the oxide in 15:1 = H_2O:HF, which removes SiO_2 at a rate of 200Å min^{-1} showed that all the remaining sodium was contained in this top 350Å of the oxide, which included the phosphosilicate film.

The remaining oxide was devoid of any radioactive sodium to within the sensitivity limits of the measurement (4×10^9 total sodium/cm^2). Figure 1 illustrates the concentration profiles of sodium in this sequence of experiments.

Thus, we have shown that sodium ions mobilized in device-type structures by ion bombardment can be completely eliminated by a phosphorus gettering step followed by an etchoff of the phosphosilicate layer. From past experience we know that sodium, once it is made mobile by ion bombardment, is equivalent to mobile sodium introduced by any other method. We therefore conclude that mobile sodium in SiO_2/Si structures in the 10^{11}-10^{12} Na · cm^{-2} range can be completely removed by the described procedure regardless of its origin or its location.

Reduction of the Silver Oxide Electrode in CsOH Solutions

Charles P. Wales

Electrochemistry Branch, Naval Research Laboratory, Washington, D. C. 20375

The publication costs of this article have been assisted by the Naval Research Laboratory.

ABSTRACT

The electrical characteristics and changes in structure when sintered Ag electrodes were cycled in 8.4M or 3.6M CsOH solutions were compared with results for similar electrodes cycled in KOH solutions. The products of reduction were the same in the two electrolytes. Solutions of CsOH gave a better capacity when the Ag electrodes were cycled repeatedly using slow discharges, because the Ag which formed during reduction had a smaller average particle size in CsOH than in KOH as a result of lower ionic mobility in the CsOH. But polarization was higher in CsOH, so KOH was preferable to CsOH at moderate and high rates of discharge.

Reduction of the silver oxide electrode has usually been studied in aqueous KOH solutions [(1-7) and references in (8)]. Since the ionic radius and atomic weight of Cs are larger than those of K, the use of CsOH instead of KOH should indicate if the cation of the electrolyte has a strong effect on the Ag electrode. In addition, CsOH and KOH solutions having the same molar concentration contain different amounts of water. It is of interest, therefore, to determine some of the characteristics of Ag electrodes in aqueous CsOH solutions, because results may differ significantly from those obtained in KOH solutions.

A previous paper has described the oxidation of sintered silver electrodes in CsOH solutions (9). The present work is concerned with reduction or discharge of these electrodes and gives the effect of CsOH on electrical characteristics and on electrode structure.

Experimental

Only a brief description of experimental procedure is given here, since details have already been presented (9). Test cells contained sintered silver electrodes whose average dimensions were 43.7 mm wide, 36.0 mm high, and 0.87 mm thick. Particle size distribution in an unused electrode was given earlier (7). Cells contained an excess of electrolyte. Two other sintered Ag electrodes served as counterelectrodes. All electrodes were wrapped with five layers of either cellulosic separator or crosslinked polyethylene separator. Each cell also contained a Ag/Ag_2O reference electrode. Electrodes were always charged (anodically oxidized) to oxygen evolution before beginning a discharge. The 20-hr constant current charge rate was used except where otherwise stated. Temperature was 24° ± 1°C. Discharges began immediately after the end of a charge, without any stand period. Some electrodes were always discharged (reduced) using the 20-hr rate of constant current, and others were always discharged at the 1-hr rate. Discharges were ended when potential dropped about 200-250 mV below the observed Ag/Ag_2O potential plateau. One or more samples were cut from most of the electrodes and cross sections were prepared for optical microscopic examination.

Key words: silver oxide, electrolyte, electrode structure, reduction.

Results

Capacity changes with cycling.—Figure 1 gives the general trend of discharge capacity for the first 15 cycles, the period of greatest change. Each curve given in Fig. 1 is a smoothed composite of measurements from two or three electrodes, except only one electrode was cycled at the 1-hr rate in 3.6M CsOH. During the first cycle of a new electrode the largest capacity was obtained in 3.6M CsOH. Capacity in this electrolyte dropped rapidly in the first few cycles.

The rate of capacity loss decreased after a few cycles. Rates of loss given in Table I for slow discharges were measured starting at cycle 1, except for

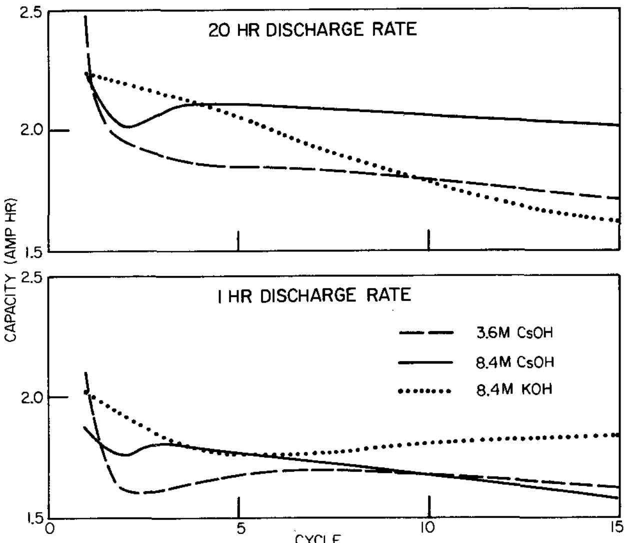

Fig. 1. Effects of cycling and of discharge rate on capacity of Ag electrodes in aqueous CsOH and KOH. All charges were done at the 20-hr rate.

Table I. Rates of capacity loss per cycle when using the 20-hr discharge rate

Electrolyte	20-Hr charge rate, %		Various charge rates from 0.7 to 50 hr, %	
	To cycle 15	To cycle 30	To cycle 15	To cycle 30
3.6M CsOH	2.1	—	2.1	1.4
8.4M CsOH	0.7	—	0.9	0.5
5.5M KOH	2.3	1.4	2.7	1.4
8.4M KOH	1.9	1.0	1.3	0.8
11.6M KOH	1.7	1.2	1.4	0.9

the rare occasions when maximum capacity occurred at cycle 2 instead of 1. The results given in Table I were calculated from data taken from Ref. (7) and (9) and the present work. Rates of loss tended to be highest in the most dilute solutions. The loss in 3.6M CsOH became low after the initial sharp drop in capacity between cycle 1 and 2 (Fig. 1). The rates of loss beginning at cycle 2 were 0.9, 0.6, and 1.1% per cycle in 3.6M CsOH, in contrast to the 2.1, 2.1, and 1.4%, respectively, given in Table I.

Electrode potentials during discharge.—A few discharges are shown in Fig. 2 for electrodes cycled under the conditions of Fig. 1. All potentials reported in this paper are given with respect to the Ag/Ag_2O reference electrode. Shapes of discharge curves at cycle 4 can be regarded as typical for later cycles, since there was little change between cycle 4 and 15 except for the total length of discharge. The greatest capacity was obtained at cycle 1 in 3.6M CsOH. Capacity at cycle 4 had dropped more rapidly in 3.6M CsOH than in 8.4M CsOH. Results at the 1-hr rate in 3.6M CsOH were not included because potentials during most of cycle 1 and 4 discharge were close to those already shown and would make Fig. 2 hard to decipher. These discharges in 3.6M CsOH resembled cycle 4 in 8.4M KOH, and at cycle 1 lacked the high initial potential shown for 8.4M CsOH. The length of the discharges differed, however, according to the trend indicated in Fig. 1.

The Ag electrodes in Fig. 1 and 2 were always charged at the 20-hr rate of constant current. Charge acceptance in CsOH decreased when charges were done at a higher current (9). Figure 3 gives examples of discharges that followed three rates of charge. The charges lasting approximately 0.8, 4, and 43 hr were done at currents that were 16, 4, and 0.5 times the 20-hr rate, respectively. Capacity that an electrode delivered was changed by a factor of two over this current range.

Discharge at the AgO/Ag_2O potential.—Most of the active material is converted to AgO during the charge of a sintered Ag electrode to oxygen evolution. The remainder of the active material consists of Ag_2O and Ag in varying amounts depending on electrode structure, electrolyte, and cycling conditions (7, 9-11). Re-

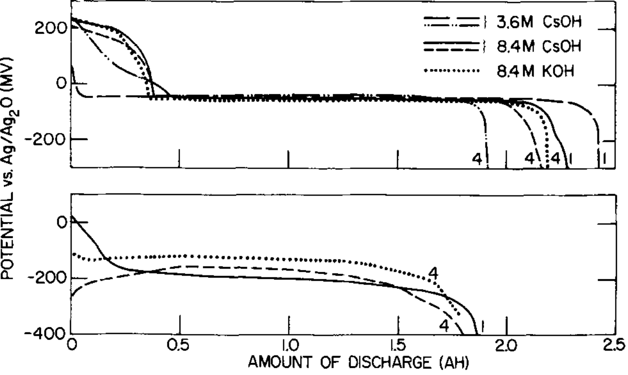

Fig. 2. Potentials of Ag electrodes when discharged at the 20-hr rate (upper half of figure) and at the 1-hr rate (lower half of figure). Cycle numbers are given beside the curves. All charges were done at the 20-hr rate.

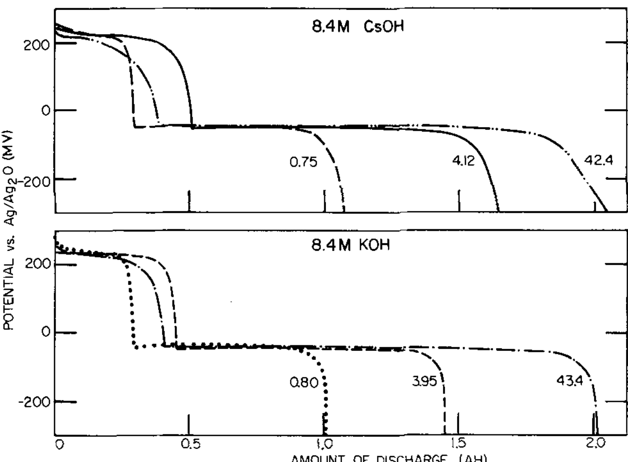

Fig. 3. Discharges at the 20-hr rate following charges at various rates. Numbers on curves give length of preceding charge in hours.

duction of this AgO gives the familiar potential plateau usually found at the beginning of a discharge, except when current is high enough to polarize the electrode down to the Ag_2O/Ag potential during the entire discharge. The AgO/Ag_2O potential can be seen at the beginning of most of the discharges in Fig. 2 and 3.

Figure 4 shows the variation in discharge capacity at the AgO/Ag_2O potential plateau when electrodes were cycled in three solutions. Since capacity was changing rapidly during the first few cycles, as indicated in Fig. 1, the proportion of a discharge that took place at the AgO potential did not change in exactly the same way as in Fig. 4. Table II gives the per cent of discharge that took place before potential fell to the lower or Ag_2O/Ag plateau. Percentages in Table II are averages of three electrodes in each electrolyte. The AgO/Ag_2O length reached a minimum at cycle 1 or 2.

Another factor affecting the length of the AgO/Ag_2O potential was the rate at which an electrode was charged (Fig. 5). The proportion of a discharge that took place at this higher potential usually reached a maximum when a sintered Ag electrode was charged at the 5- to 10-hr rate. The curve for 8.4M KOH is repeated in both sections of Fig. 5. Since there was some scattering of individual measurements, small differ-

Table II. Variation in length of AgO/Ag_2O potential when electrodes were cycled using the 20-hr discharge rate

ences between the various curves may not be significant.

Structural changes during a discharge.—Structure was relatively unform throughout electrodes that were always discharged at the 20-hr rate. Figure 6 shows a low magnification view of an electrode discharged until 32% of the total capacity had been removed. The Ag_2O/Ag plateau had been reached when the discharge was 22% completed, so 44% of the AgO had been reduced to Ag_2O before formation of Ag began. Then, after the potential fell to the Ag_2O/Ag plateau, Ag_2O was reduced to Ag and simultaneously some of the remaining AgO was reduced to Ag_2O. A visual estimate of the entire cross section indicated that approximately 65% of the active material was Ag_2O. The highest Ag_2O concentration was near grid members, although all areas of the electrode had some Ag_2O. Initial formation of metallic Ag occurred most often near the grid (Fig. 6).

Figure 7 gives a higher magnification view of another electrode that had been discharged until 10% of total capacity was removed while at the Ag_2O/Ag potential plateau. All photographs are of cross sections through the electrode and, therefore, show cross sections through individual particles and crystals. The surface of AgO was reduced to Ag_2O during the early part of the discharge. Porosity increased as Ag formed. Some AgO usually remained near the newly formed Ag in partly discharged electrodes, as in Fig. 7. The Ag had formed in the vicinity of the grid members and near the surfaces of the electrode, although seldom actually on the surface when the 20-hr discharge rate was used. The metallic Ag (white) that was entirely surrounded by Ag_2O in Fig. 7 was residual from the preceding charge. The rest of the Ag had formed during the discharge and had rounded, convoluted shapes typical of most Ag particles after several slow discharges.

After a complete discharge at the 20-hr rate almost all oxide had been reduced to Ag (Fig. 8). About 10% of a discharged electrode consisted of small Ag particles. These small Ag particles resulted from the reduction of areas that had contained closely packed AgO with little or no Ag present. Large Ag particles, the most common form, tended to have smoother surfaces at the end of a discharge than when partly discharged (compare top of Fig. 8 with Fig. 7). Some crevices in the Ag had been filled in during the additional discharge.

Dependence of structure on discharge rate.—In contrast to a discharge at the 20-hr rate, during a discharge at the 1-hr rate only a small amount of Ag_2O formed before reduction to Ag began taking place (Fig. 9). It was typical to have a region 50-100 μm wide where Ag_2O was forming from AgO. The amount of Ag_2O that formed reached a more or less constant value, and then the Ag formation rate became equal to

Fig. 6. Photomicrograph of electrode in 8.4M CsOH at cycle 6 after a partial discharge at the 20-hr rate had removed 32% of capacity. Potential had been at the Ag_2O/Ag plateau for 2 hr when discharge was interrupted. In this cross section metallic Ag is white, Ag_2O is dark gray, AgO is light gray, and empty areas (formerly filled with electrolyte) are black. Large white object is part of the Ag grid. Electrode thickness (from left to right in photograph) was 0.87 mm.

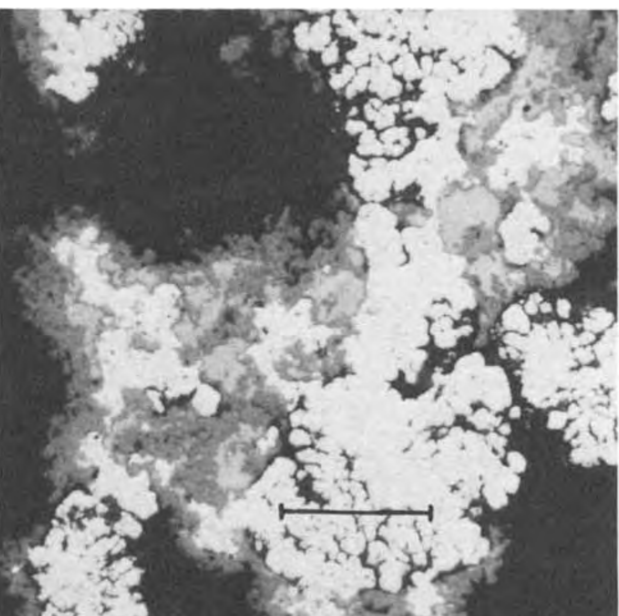

Fig. 7. Electrode that was discharged 37% in 8.4M CsOH at cycle 15. Discharge at the 20-hr rate was ended after potential had been at the Ag_2O/Ag plateau for 2 hr. Surface of electrode is at the left. Most of the Ag_2O and Ag shown here had formed from AgO during the partial discharge. Marker indicates 25 μm.

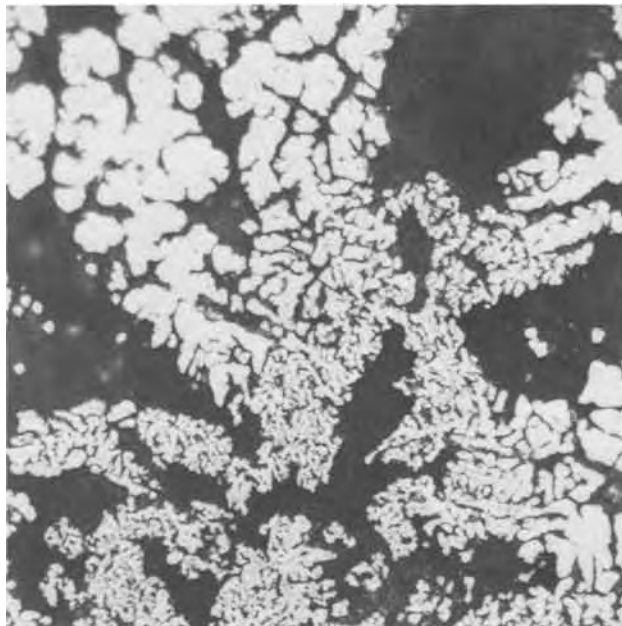

Fig. 8. Cross section of Ag particles at the end of cycle 6 discharge at the 20-hr rate in 8.4M CsOH. Approximately 7% of the volume of this electrode contained small particles such as those at the bottom of this photograph, and the rest contained larger particles as shown at the top. Same magnification as Fig. 7.

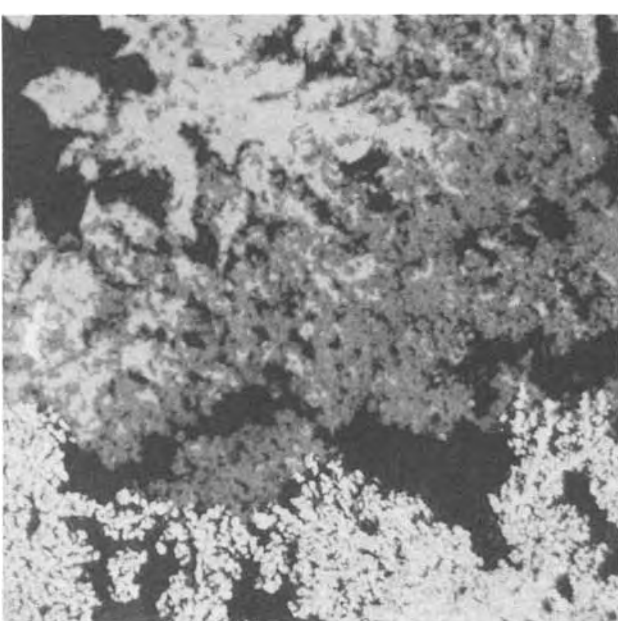

Fig. 9. Active material of electrode discharged 45% at the 1-hr rate at cycle 6 in 8.4M CsOH. Under these conditions partial reduction of AgO to Ag_2O was followed by reduction to Ag in preference to formation of thick Ag_2O layers. Active material is predominately AgO at the top of this photograph, Ag_2O in the middle, and Ag at the bottom. To see the effect of discharge rate compare with Fig. 7 at the same magnification.

the rate of Ag_2O formation. The Ag formed into smaller particles at the 1-hr rate than at the 20-hr rate (Fig. 7).

The active material near a grid was almost entirely AgO at the end of a charge. After electrodes had been discharged 10% at the 1-hr rate both Ag_2O and Ag had formed in a narrow area near the grid. Also Ag had formed at the surface of the electrodes in areas that had been mainly Ag + Ag_2O at the beginning of the discharge, nucleating from Ag that remained within the Ag_2O. The surface of an electrode discharged at the 1-hr rate is included in Fig. 10. In this area the Ag particles were smaller than those shown at lower magnification in Fig. 9. After electrodes had been discharged 35-50% their surfaces were mostly the white color of Ag when the 1-hr was used, and largely the color of Ag_2O when the 20-hr rate was used.

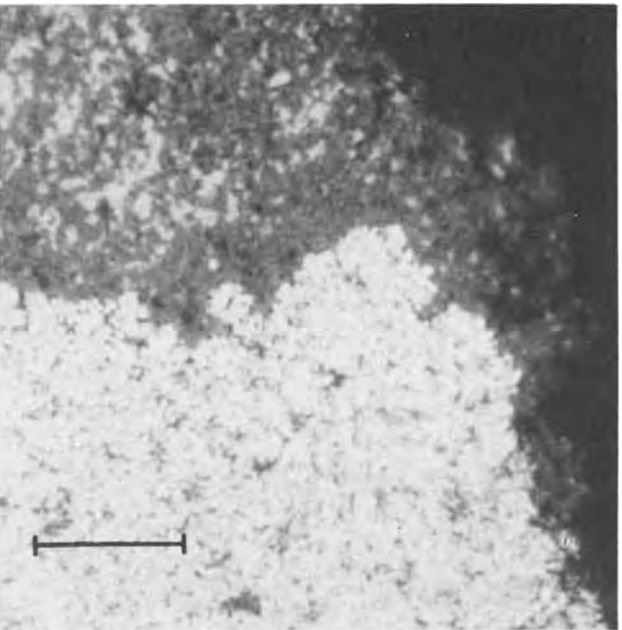

Fig. 10. Electrode discharged 50% at the 1-hr rate at cycle 30 in 8.4M CsOH, showing border between silver oxides and newly formed small particles of granular Ag. One surface of the electrode was at the right. Marker indicates 10 μm.

Particles of Ag that formed at the 20-hr rate are shown in Fig. 11. The Ag particles that formed during the slow discharge usually had 2 μm as a smallest dimension, while many particles that formed during the 1-hr discharge were about 0.5 μm in diameter and were more uniform in size and spacing. Since typical Ag particles were about four times larger after a 20-hr

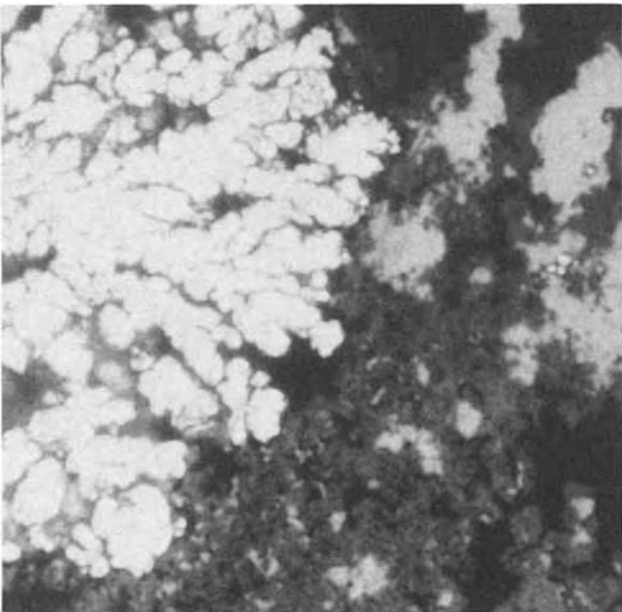

Fig. 11. Appearance of reduction products in electrode discharged 32% at the 10-hr rate in 8.4M CsOH at cycle 6. This is a high magnification view of another area of the electrode shown in Fig. 6. Compare with Fig. 10 at the same magnification to see the effect of different discharge rates.

discharge, they contained on the order of 64 times as much Ag, if a spherical shape is assumed for ease in calculation. The Ag_2O also formed into smaller particles when using the 1-hr discharge rate than when using the 20-hr rate, although the differences were not as great as for Ag.

Several cross sections that included half the width of an electrode were divided into 25 to 30 equal viewing areas the size of Fig. 6 and examined at 108× magnification. The percentage of AgO, Ag_2O, and metallic Ag was estimated for electrodes discharged at the 20-hr rate until potential had been at the Ag_2O/Ag plateau for 2 hr. Estimates were also made for electrodes 45% discharged at the 1-hr rate. Here the small particle size made it impractical to give separate estimates for Ag_2O and AgO, but high magnification indicated that half of the oxide was AgO.

Figure 12 shows the composition of horizontal cross sections that reach the center of two electrodes. The left side of Fig. 12 gives the composition at one edge of the electrodes and the right side gives the composition at the centers. When the 20-hr discharge rate had been used (upper part of Fig. 12) Ag_2O had formed in most areas of the electrode, with a slight preference for the grid of expanded sheet Ag. The right-hand grid member in the upper part of Fig. 12 is also shown in Fig. 6. Formation of metallic Ag had a definite preference for grid members and for the electrode surface during a discharge at the 20-hr rate. Concentrations of AgO had become lower at the grid than elsewhere.

When a partial discharge was done at the 1-hr rate a much higher proportion of active material was reduced to Ag (lower part of Fig. 12). Initial formation of Ag had taken place preferentially at the grid, but then formation spread rapidly to more distant areas at or near the surface of the electrode. Metallic Ag concentration was high at the edges of both partly discharged electrodes (left side of Fig. 12).

Structural changes that occur with cycling.— When an electrode was charged and discharged at the 20-hr rate in 8.4M CsOH the most noticeable difference was that particles had dendritic shapes at the end of cycle 1 discharge (Fig. 13) in place of the irregular shapes present in the unused electrode (7, 10). The average size of Ag particles gradually increased as an electrode was cycled using the 20-hr discharge rate. The change between cycles 1 and 6 can be seen by comparing Fig. 13 with Fig. 8 at the same magnification. There was little additional increase in average size

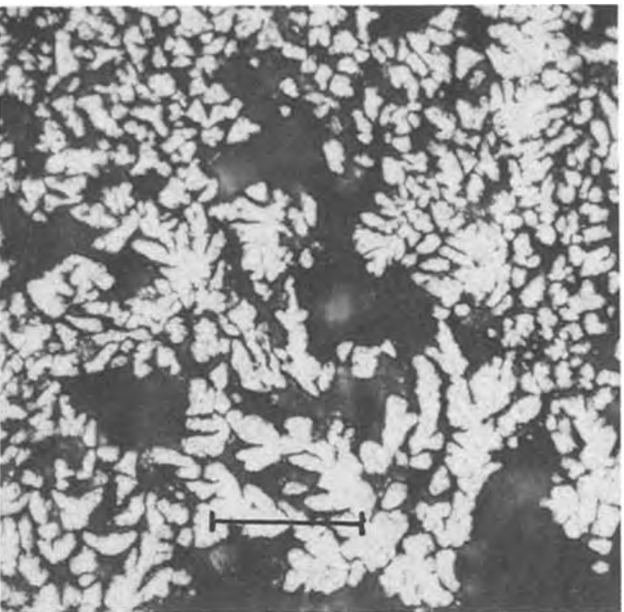

Fig. 13. Cross section through typical Ag particles that formed at the end of cycle 1 discharge at the 20-hr rate in 8.4M CsOH. Some larger particles had also formed but were less common. Marker indicates 25 μm.

between cycle 6 and 15, but Ag particles became more rounded. Large areas of small particles developed in some places during the first few cycles, but then the size and amount of small particles decreased with additional cycling. As for the oxides, the size of Ag_2O clumps increased between cycle 6 and 15, and Ag_2O layers on AgO became thicker.

When the 1-hr discharge rate was used particle sizes had less variety with the greatest structural change being the decrease in average particle size after the first discharge. In addition, a moderately large proportion of the Ag had assumed thin dendritic shapes during the discharge at the 1-hr rate (Fig. 14). The

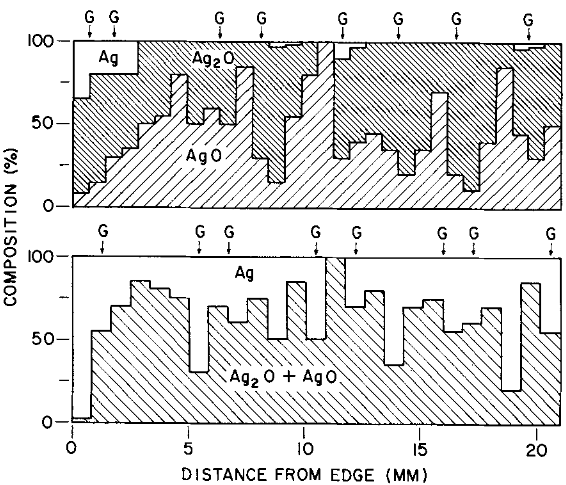

Fig. 12. Composition of active material in partly discharged electrodes at cycle 6 in 8.4M CsOH. Upper half is based on a cross section of an electrode that had been discharged 32% at the 20-hr rate (Fig. 6 and 11). Lower half refers to an electrode discharged 45% at the 1-hr rate (Fig. 9). Letter G indicates location of the grid members.

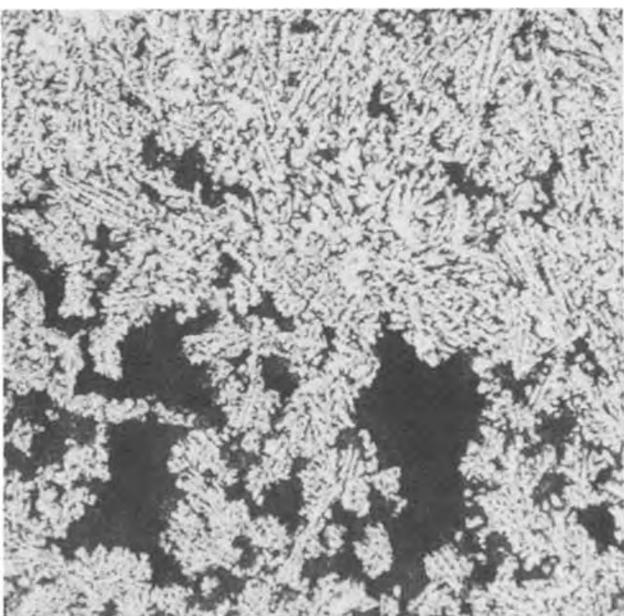

Fig. 14. Partially oriented Ag particles were fairly common after cycle 1 discharge at the 1-hr rate in 8.4M CsOH, but most of the Ag was in small granular particles such as those shown at the center and lower left. Compare with Fig. 13 at the same magnification to see the effect of a single discharge at different rates. Both electrodes had the same original structure.

proportion of thin Ag particles gradually decreased as an electrode was cycled. Thin shapes became rare by cycle 15. Areas of very closely packed small particles were not found at cycle 1 but developed with cycling in 8.4M CsOH (Fig. 10 and 15). Thin Ag particles were uncommon after a discharge at the 20-hr rate.

Effect of electrolyte on electrode structure.—The main difference between structures in KOH and CsOH solutions was that Ag particles tended to be smaller in CsOH. Although structural differences were not great, a smaller average particle size in CsOH was noted at both discharge rates. At the 20-hr discharge rate the size difference was greatest in the first few cycles. Another difference was that smaller and more porous Ag_2O formed in CsOH than in KOH during a discharge at the 1-hr rate.

The Ag particle sizes in discharged electrodes at cycles 6 and 15 were probably not significantly different between 3.6M and 8.4M CsOH when the 20-hr discharge rate was used, although Ag often tended to form into larger particles and in bigger clumps near the surface of an electrode cycled repeatedly in 3.6M CsOH. When the 1-hr discharge rate was used the average particle size was about twice as large in 3.6M CsOH as in 8.4M CsOH. Typical particle sizes after discharges at the 1-hr rate were 0.3-1 μm in 8.4M CsOH, while in 3.6M CsOH 50-65% of an electrode consisted of particles 1-2 μm in their smaller dimension with most of the remainder 0.4-1 μm.

During a charge in 3.6M CsOH the AgO had a tendency to form into elongated shapes (9). During a discharge at the 1-hr rate the elongated AgO was reduced to many small Ag particles that remained in groups having shapes similar to the AgO (Fig. 16). When similar elongated AgO crystals were discharged at the 20-hr rate the Ag formed into larger particles which usually were not in noticeably elongated groups.

Some of the active material developed an alignment when electrodes were discharged at the 1-hr rate in 3.6M CsOH. These aligned groups of particles often, but not always, pointed at a grid member or at large Ag particles in the active material. The aligned particles did not actually touch the grid or large particles. Aligned Ag particles were not found in 8.4M CsOH or in KOH, except for a slight alignment in 5.5M KOH, the lowest KOH concentration used.

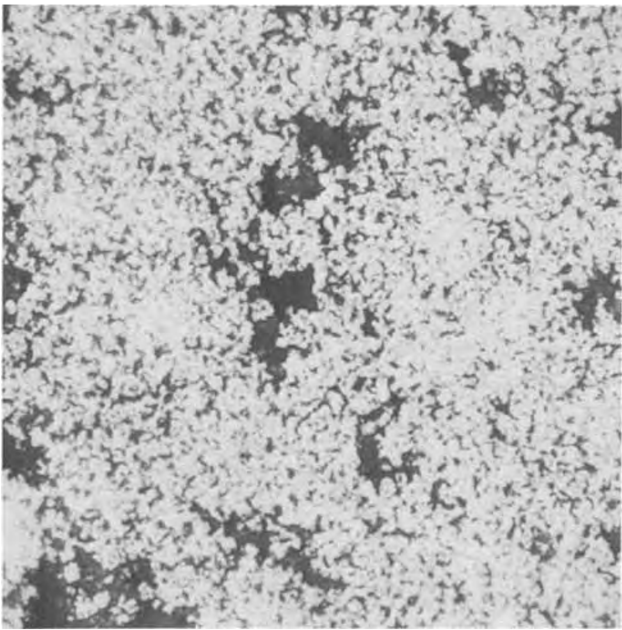

Fig. 15. Small Ag granules typical of the active material at the end of cycle 30 discharge at the 1-hr rate in 8.4M CsOH. Compare with Fig. 14 at the same magnification to see the effect of cycling. The partially oriented Ag particles of Fig. 14 had become scarce by cycle 15.

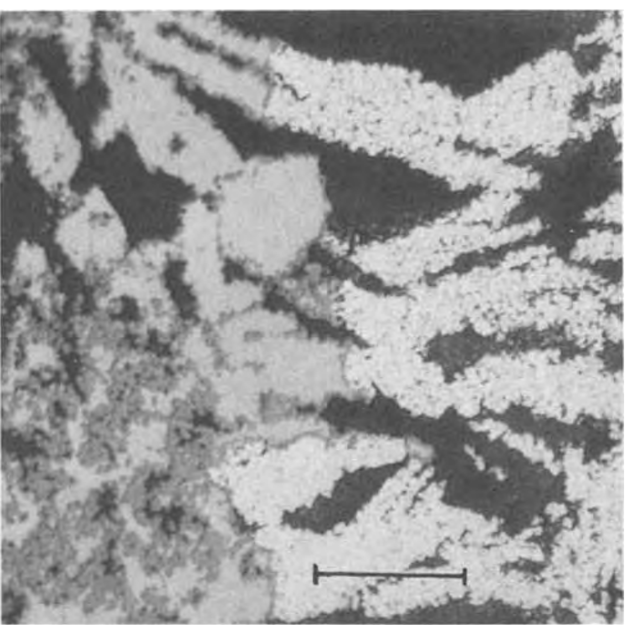

Fig. 16. An electrode discharged at the 1-hr rate at cycle 6 in 3.6M CsOH showing Ag_2O that formed on the surface of AgO (left side) and reduction of oxides to Ag (right side). The smallest Ag particles that formed at the 1-hr rate in 3.6M CsOH often were in groups that retained the shapes of the AgO particles. About two-thirds of the electrode consisted of Ag particles two to four times larger than those shown here. Marker indicates 20 μm.

Discussion

Comparison of discharge potentials and of electrode structures indicated that the products of reduction were the same in CsOH solutions as in KOH. Discharge potentials in KOH were more nearly level during both plateaus and then fell more rapidly (Fig. 3), indicating that reduction in KOH took place under conditions that were closer to equilibrium. Earlier work showed that oxidation of Ag also occurred closer to equilibrium in KOH than in CsOH (9). This difference probably occurred because conductivity in 8.4M CsOH was lower and viscosity was higher than in 8.4M KOH.

A gradual decrease in capacity following slow discharges is a general finding. The rate of capacity decrease appears to be relatively unaffected by charge rates. For example, from Fig. 10 of Ref. (12) one can calculate that a sealed Ag-Zn battery had capacity loss rates of about 1.2 and 0.9% per cycle to cycle 15 and 30, respectively. This battery was discharged at about the 15-hr rate and charges were done at the 26-34-hr rate followed by a float for 2 days at 1.95V per cell. These rates of loss are in the middle of the range of those in Table I despite the differences in cell construction and in cycling conditions.

Reduction of AgO to Ag_2O.—Cycle 1 in 3.6M CsOH always gave a shorter AgO plateau than later cycles or the other electrolytes when the 20-hr discharge rate was used (Table II and upper part of Fig. 2). At cycle 1 a new sintered Ag electrode always accepted more capacity in 3.6M CsOH than in 8.4M CsOH (9). It was concluded that formation of an unusually large amount of AgO resulted in a smoother AgO having a smaller surface area, since oxygen evolution potentials were about 80 mV higher than in other electrolytes, although formation of Ag_2O and AgO had taken place at normal potentials. Less Ag_2O formed on the surface of this smoother AgO during discharge before Ag_2O became sufficiently thick that polarization caused electrode potential to reach the Ag_2O/Ag plateau. Electrode capacity dropped rapidly during the first few cycles in

3.6M CsOH (Fig. 1) and the differences between the AgO discharge plateau in 3.6M and 8.4M CsOH had largely disappeared by cycle 3 or 4, except for the tendency of potentials at the AgO/Ag_2O plateau to have a fairly linear decrease in 3.6M CsOH rather than the curved form usually found (upper part of Fig. 2). Slow charges promoted formation of AgO having a smaller surface area. In both CsOH and KOH the proportion of a discharge that took place at the AgO/Ag_2O potential was smallest following a charge at the lowest current (Fig. 5) although this low current gave maximum total discharge capacity.

Formation of Ag.—Supersaturation of dissolved Ag(I) was produced from the beginning of a discharge and continued until near the final fall in potential (3). The dissolved species is usually considered to be $Ag(OH)_2^-$. This forms according to Eq. [1]

$$Ag_2O + 2\,OH^- + H_2O \rightarrow 2Ag(OH)_2^- \quad [1]$$

Reduction of the dissolved species gives metallic Ag

$$2Ag(OH)_2^- + 2e \rightarrow 2Ag + 4\,OH^- \quad [2]$$

The structure of Ag that formed during reduction was greatly different than the structure of the Ag_2O, because of the dissolution-precipitation mechanism given in Eq. [1] and [2]. Important factors in determining the form of Ag were differences between the solubility of Ag_2O in CsOH and KOH, the degree of supersaturation, and the rate of reduction.

The over-all reaction for the formation of Ag from Ag_2O is obtained by combining Eq. [1] and [2]

$$Ag_2O + H_2O + 2e \rightarrow 2Ag + 2\,OH^- \quad [3]$$

As a result of this reaction the hydroxyl ion concentration tended to increase in the interior of the electrode.

During a discharge at the 1-hr rate groups of small Ag particles took the shape of the AgO (Fig. 9 and 16). During a discharge at the 20-hr rate sufficient time was available for greater diffusion of $Ag(OH)_2^-$, allowing Ag to grow larger and to deposit in an orientation that differed from the AgO (Fig. 11) although groups of Ag particles still kept shapes much the same as the AgO. A small space was often noted between Ag that formed during a slow discharge and adjacent oxide (Fig. 7). This space indicated that the soluble Ag species had diffused from Ag_2O to nearby Ag before being reduced. During a fast discharge time was insufficient for much diffusion of $Ag(OH)_2^-$, so Eq. [2] followed rapidly after Eq. [1]. As a result, Ag formed at the site of the Ag_2O in small particles during a fast discharge and the variety of particle sizes was more limited.

Results of both the oxidation of Ag in CsOH (9) and the reduction of silver oxides indicated that concentration gradients were higher in CsOH than in KOH of the same molarity. An 8.4M CsOH solution has a lower conductivity and higher viscosity than 8.4M KOH. The lower conductivity indicated a lower ionic mobility, as one would expect since the Cs^+ ion is larger than the K^+ ion. Mobility decreased in concentrated solutions, probably because of the formation of ion pairs in the electrolyte, with KOH mainly in the form of water-bridged ion pairs and Cs^+ associated directly with the hydroxyl ion. The formation of ion pairs may also have lowered the $Ag(OH)_2^-$ mobility in concentrated solutions, and this would make it more difficult for large Ag particles to form, particularly in concentrated CsOH solutions. Therefore Ag did not grow into large particles as readily in CsOH as in KOH.

After initial Ag formation at the 1-hr rate took place near the grid and close to the surface, Ag formation then occurred at the electrode surface at a distance from the grid. Most of the active material near a grid had been oxidized to AgO by the time that a charge ended, but in areas more than 1 or 2 mm from a grid the active material was mainly Ag_2O + Ag in electrodes always discharged at the 1-hr rate (9). The lack of AgO formation at a distance from the grid during a charge was the result of a lowered internal conductivity and was only found when two conditions were met: (*a*) the original sintered Ag electrode contained a low proportion of large Ag particles; and (*b*) the electrode was discharged at a sufficiently high rate that average particle size decreased (7, 9). When an electrode was discharged 50% at the 1-hr rate no reduction had occurred in most areas near the center, except within about 0.05-0.1 mm of the grid, and Ag had mainly formed in areas near the electrode surface that were not close to a grid.

A discharge at the highest rate caused the greatest hydroxyl ion concentration gradients between the interior of the electrode and the bulk of the electrolyte, from the reaction of Eq. [3]. Because of these concentration gradients, reduction tended to spread along the surface of an electrode during a discharge at the 1-hr rate, in preference to spreading inward. Under these conditions the reduction of AgO was much more difficult than reduction of regions largely Ag_2O. As a result, most active material in regions close to the grid remained AgO during the first half of the discharge and one or both of the silver oxides almost always remained at the surface of the electrode near a grid even though large areas further away had been converted to Ag. The preferred locations for reduction to Ag were controlled by both diffusion in the electrolyte and conductivity in the electrode.

The development of aligned groups of particles, with the alignment often pointing at the grid members and at large Ag particles, was believed to be the result of Ag precipitating from $Ag(OH)_2^-$ on sites where current density was highest during a discharge at the 1-hr rate. Grid members distributed the current throughout the electrode, with the largest Ag particles in the active material forming important supplementary low resistance current paths. Internal resistance had less of an effect when discharging at the 20-hr rate, so current distribution was more even and alignment of active material did not develop. The fact that alignment was only found in the more dilute CsOH or KOH solutions indicated that mobility of $Ag(OH)_2^-$ was also a factor. Evidence for mobility of $Ag(OH)_2^-$ being higher in 3.6M CsOH than in 8.4M CsOH was that Ag particles grew to a larger average size in 3.6M CsOH during a discharge at the 1-hr rate.

Conclusions

Capacity declined more slowly in CsOH solutions than in KOH when Ag electrodes were cycled using slow discharges. At high rates of discharge KOH was the preferable electrolyte, because polarization was lower as a result of higher ionic mobility in KOH. An additional disadvantage to the use of CsOH was its higher cost. Thus CsOH is not a practical replacement for KOH under many conditions. However, the electrolyte cost is but a small proportion of the total cost of a Ag-Zn or Ag-Cd storage battery. The preferred electrolyte can be CsOH when it is necessary to obtain the best possible capacity while using slow discharges.

Metallic Ag began to form in both electrolytes while large amounts of AgO remained, because reduction of AgO to form large amounts of Ag_2O was more difficult than reduction of Ag_2O to Ag. The Ag did not have the same structure as Ag_2O, since the formation mechanism involved a soluble intermediate. The most important factor in determining the form of Ag was the reduction rate. Preferred sites for reduction to Ag in a partly discharged electrode were controlled by a combination of diffusion in the electrolyte and electrode conductivity.

Size of Ag particles tended to be smaller in CsOH solutions than in KOH, although differences were not

great. The retention of smaller particle sizes during cycling was the reason for capacity not decreasing as rapidly in CsOH as in KOH when an electrode was given a series of slow discharges. since large Ag particles were not completely oxidized during a charge. The Ag particles that formed during reduction at the 1-hr rate were smaller in 8.4M CsOH than in 3.6M CsOH. These size differences indicated that mobility of dissolved Ag_2O was lower in 8.4M CsOH than in 3.6M CsOH, and lower in CsOH than in KOH of the same concentration.

Lithium-Magnesium Electrodes in Propylene Carbonate

M. M. Nicholson*

ABSTRACT

Lithium was cathodically deposited on magnesium from 1M $LiClO_4$ in propylene carbonate. Anodic stripping measurements by constant-current and linear potential-scan techniques indicated the presence of both alloyed and unalloyed lithium on the plated surfaces. The alloying energy was approximately 7 kcal/mole of lithium. The anodic recovery of lithium was limited by its diffusion into the underlying metal. Potential-time curves recorded on open circuit revealed two penetration stages, with $D_1 = 1.3 \times 10^{-11}$ and $D_2 = 3.9 \times 10^{-14}$ cm^2/sec. The faster process was attributed to the transport of lithium along the grain boundaries, and the slower, to penetration of the magnesium grains. The plated electrodes were insensitive to added water at concentrations from 0.01 to 0.1M.

Dey has reported that a lithium-magnesium alloy is formed by cathodic deposition of lithium from a solution of lithium perchlorate in propylene carbonate (PC) onto a magnesium substrate at potentials differing only slightly from that of pure lithium (1). Chemical analysis of the alloy indicated 100% current efficiency for the deposition process. In the present investigation, the anodic behavior of thin alloy layers prepared in this manner was examined in dry 1M $LiClO_4$-PC and in this electrolyte containing added water at concentrations from 0.01 to 1M. The conclusions from this work will be of interest in organic battery applications requiring long-term storage of nonreserve cells under humid conditions. A further result was the determination of diffusion coefficients for lithium in magnesium at room temperature.

Experimental

The magnesium electrodes were polished cross sections of 1.55-mm diameter wire which was insulated on the sides with heat-shrinkable Teflon tubing. The exposed surface was renewed between measurements, when desired, by polishing with Grade 600A silicon carbide paper, followed by buffing on dry filter paper. Contact of the electrode to the external circuit was made through a copper wire attached to the upper end of the magnesium by low-melting indium solder. The magnesium was high-purity material from Gallard-Schlesinger Chemical Manufacturing Corporation, with seven specified impurities totaling less than 0.1%. Lithium perchlorate and propylene carbonate were purified by procedures that were described in detail elsewhere (2). Gas chromatographic analysis indicated 10 ppm water in the dried solvent, while the dried salt contained $\leq$ 100 ppm water. From these data, the total water content of the dry 1M $LiClO_4$ solution was estimated to be $\leq$ 1 mM. Solutions containing 0.01-1M H_2O were prepared by volumetric additions of water to the dry electrolyte.

The cell was of a conventional H design, with a fritted glass disk separating the working and counter-electrode compartments. The reference and counter-electrodes were both of high-purity lithium metal. The cell was assembled and housed during the electrochemical measurements in an argon-atmosphere dry box at room temperature. Data were obtained under open-circuit, constant-current, and linear potential-scan conditions on a Princeton Applied Research Model 170 Electrochemistry System. The equivalent thickness of the plated lithium ranged from 0 to 1.6μ.

Results and Discussion

Anodic behavior of lithium-plated surfaces.—Two active-lithium phases were distinguishable on the plated surfaces. This is evident in the curves of Fig. 1, which were obtained by depositing lithium at -0.05V[1]

* Electrochemical Society Active Member.
Key words: alloys, battery anodes, intermetallic diffusion.

[1] All potentials are reported with respect to the lithium electrode in the electrolyte used.

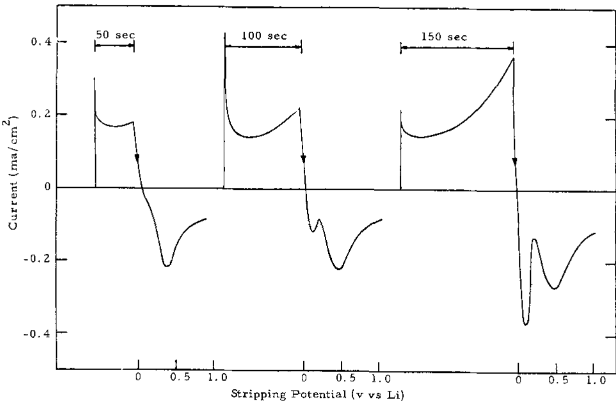

Fig. 1. Plating at −0.05V, followed by stripping at 10 mV/sec. Plating times indicated above curves.

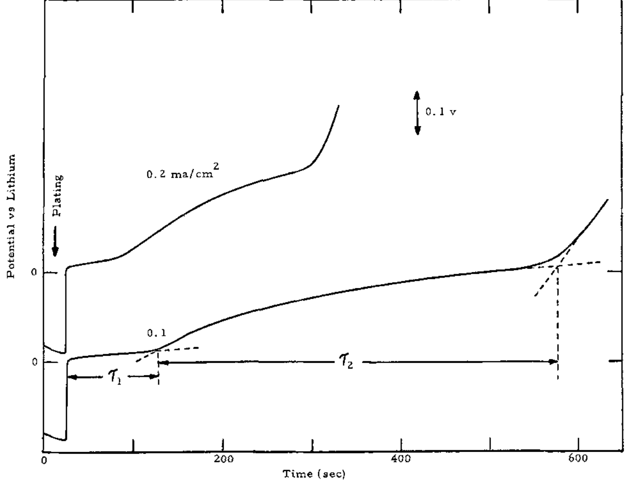

Fig. 2. Potential-time curves for immediate stripping at different rates. Q_p = 250 mcoulombs/cm²; i_p = 10 mA/cm²; i_s indicated on curves.

for different times and stripping immediately thereafter with a potential scan at 10 mV/sec. The first anodic peak may be identified by its position near 0.1V as that due to the oxidation of unalloyed lithium. This peak was sharply intensified by a threefold increase in the plating time. The second peak, at 0.4-0.5V, would correspond to an alloying energy of ~8 kcal/mole of lithium, if rapid charge transfer is assumed for the electrode reaction. This value is comparable to the free energy of formation of −8.9 kcal/mole for the compound LiAl, which was estimated by extrapolating the high-temperature data of Yao, Heredy, and Saunders to 25°C (3). The height of the second peak increased only slightly with the plating time; apparently part of the alloyed lithium became inactive or was lost by penetration to the interior of the substrate.

Two anodic processes are also apparent in the constant-current stripping curves of Fig. 2, where Q_p represents the plating charge density, i_p and i_s are the plating and stripping current densities, and the corresponding transition times are designated as τ_1 and τ_2. A complete glossary of symbols is provided at the end of this paper. At the current densities applied in Fig. 2, the unalloyed lithium was oxidized near 0.03V. Most of the alloyed lithium was stripped with an additional 0.25V, *i.e.*, with the expenditure of ≤ 6 kcal/mole beyond that required for the unalloyed metal. The total lithium recovery in the curves of Fig. 2 was 16-18% of the amount plated.

The loss of lithium from a freshly plated surface persisted in experiments covering a wide range of conditions. Table I gives the results of immediate and delayed stripping from surfaces that had been renewed by polishing before the deposition step. Figure 2 is representative of the two-stage, undelayed stripping curves. When the standing time was long enough for the open-circuit potential to rise above 0.05V, only the second oxidation stage for alloyed lithium was observed. The recovery charge Q_2 for the second stripping stage was low compared to the plating charge Q_p, in all of the measurements reported in Table I. The Q_2 deficiency could not have been due to a bound monolayer, however, as described by Fried and Barak in the stripping of lithium from platinum (4), since a monolayer would correspond to ~0.2 mcoulomb/cm², assuming a roughness factor of unity, while Q_p was 10-1200 mcoulombs/cm² in the present study. The open-circuit transients provided a clue to the loss of lithium from the magnesium surfaces. These results are interpreted in the section on penetration rates.

The effect of repeated plating and stripping without mechanical renewal of the surface was also examined. It was found that the cyclic curves eventually reached a steady state, as in Fig. 3, with unalloyed lithium as the predominant phase during immediate stripping. These curves and others were unaffected by stirring. It may be inferred from this fact that the disappearance of lithium was a solid-state phenomenon, rather than an interaction with impurities in the solution. The delayed recovery of lithium from an electrode which had been conditioned by cycling at 0.2 mA/cm² is shown in Fig. 4. The recovery charge for alloyed lithium, Q_2, then increased with the standing time,

while Q_1, for unalloyed lithium, decreased. The percentage recovery per cycle, based on Q_2, was also much improved on the conditioned electrode compared to that on a fresh electrode (Table I). Furthermore, when an electrode was conditioned at 2 mA/cm^2 and stripped immediately at this higher current density ($20 \leq Q_p \leq 50$ mcoulombs/cm^2), Q_2 was essentially zero and Q_1 then accounted for 70% recovery.

Lithium penetration rates.—The open-circuit potential-time curves exhibited two transitions similar to those observed under anodic current. By the proper selection of Q_p, it was possible to obtain a measurable τ_1, or to observe τ_2 with an essentially negligible τ_1. This resolution of the transition times permitted treatment of the lithium loss in two stages, as discussed below. It was found that $\sqrt{\tau_1}$ and $\sqrt{\tau_2}$ were both linear functions of Q_p, passing near the origin, as shown in Fig. 5 and 6, respectively. The corresponding least squares equations are

$$\sqrt{\tau_1} = 1.11 + 0.03285 Q_p \qquad [1]$$

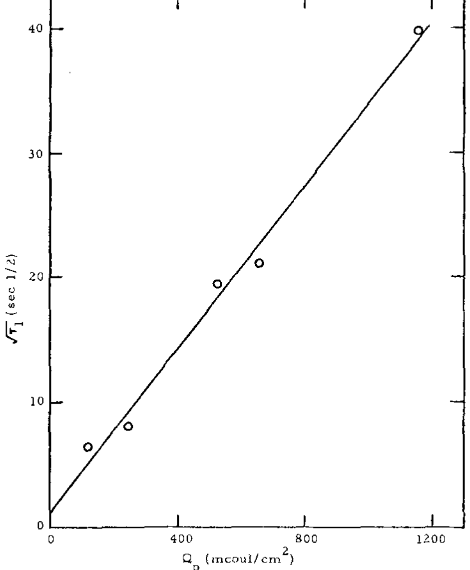

Fig. 5. First-stage penetration of lithium into magnesium

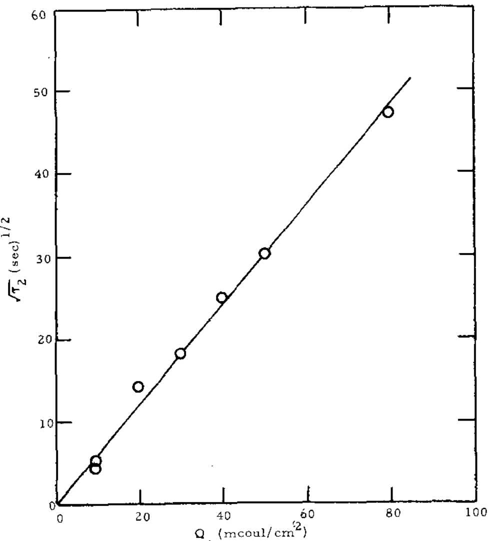

Fig. 6. Second-stage penetration of lithium into magnesium

$$\sqrt{\tau_2} = -0.07 + 0.6067 Q_p \qquad [2]$$

where the τ's are expressed in seconds and the Q's in millicoulombs per square centimeter.

Several investigators have reported evidence of film formation on lithium in propylene carbonate solutions (5-8). Although such films can have a pronounced effect on electrode kinetics and double layer properties (5, 6), it is very unlikely that filming reactions accounted for a substantial part of the lithium loss observed in the present study. In well-purified $LiClO_4$-PC solutions, the film thickness apparently ranges from submonolayers to several molecular layers (5, 7), and little or no corrosion has been observed visually in some tests lasting hundreds of hours (7). In contrast, the Li-Mg electrodes lost the equivalent of 50-5000 molecular layers in less than 0.5 hr. These results may be interpreted on the basis of a solid-state diffusion model by means of the following analysis:

Let C^o represent the concentration of lithium in a plated layer that is adjacent to pure magnesium at the beginning of the penetration process. As the lithium diffuses, a concentration gradient is established within the magnesium, but the boundary concentration remains at C^o until the layer of pure metal is suddenly depleted. A transition then occurs in the potential-time curve. The concentration variable is expressed as C^o —

C, where C is the lithium concentration in the magnesium as a function of time t and distance from the surface. This problem is equivalent to that involved in the Cottrell method for determination of diffusion coefficients by electrolysis at constant potential (9). The flux of lithium across the lithium-magnesium boundary on open circuit is then

$$\frac{dM}{dt} = -C^o \sqrt{\frac{D}{\pi t}} \quad [3]$$

where M is the weight of lithium per unit area and D is its diffusion coefficient. The weight M^o of lithium corresponding to the plating charge Q_p will have disappeared in a time τ which is found by integrating Eq. [3]

$$\int_{M^o}^{0} dM = -C^o \sqrt{\frac{D}{\pi}} \int_0^\tau \frac{dt}{\sqrt{t}} \quad [4]$$

The result may be expressed by Eq. [5]

$$\sqrt{\tau} = \frac{1}{2}\sqrt{\frac{\pi}{D}} \cdot \frac{M^o}{C^o} \quad [5]$$

which predicts direct proportionality between $\sqrt{\tau}$ and Q_p.

From the slope of the line in Fig. 5, Eq [5] leads to a diffusion coefficient $D_1 = 1.3 \times 10^{-11}$ cm²/sec for the first penetration process, if C^o is taken as the density of pure lithium. This value may be compared with 4×10^{-11} cm²/sec for sodium in lead at 20°, computed from a potentiostatic transient in aqueous NaOH (10), and 5×10^{-12} cm²/sec for potassium in zinc, determined in a membrane cell (11). For self-diffusion at grain boundaries in zinc, D is estimated to be 7×10^{-12} cm²/sec (11). It is probable, therefore, that the first-stage penetration of lithium into magnesium occurs along the grain boundaries.

Formally, the same analysis can be applied to the data in Fig. 6 for the second-stage penetration process. If C^o is again taken as the density of pure lithium, Eq. [5] yields $D_2 = 3.9 \times 10^{-14}$ cm²/sec. This slower process may be plausibly interpreted as diffusion within the magnesium grains. It must be realized that the effective interfacial area for the second process will be larger than the projected area of the electrode if the grain boundaries have been penetrated, as visualized, before the second stage begins. If the true area were taken into account, the second diffusion coefficient would be several orders of magnitude lower than that reported. For comparison, the self-diffusion coefficient in monocrystalline zinc is $\sim 10^{-18}$ cm²/sec at room temperature (11).

Kiseleva *et al.* evaluated penetration coefficients for the cathodic injection of sodium into cadmium from aqueous NaOH on the basis of a reactive diffusion model (12). In that system, the intermetallic layer grew periodically, reaching an incremental thickness a, which was equated to the grain diameter, in a time t. From the relation

$$\sqrt{t} = \frac{a}{\sqrt{P}} \quad [6]$$

the penetration coefficient P was found to be 5×10^{-10} cm²/sec for fine-grained cadmium and 1.4×10^{-9} cm²/sec for coarse-grained. Equation [5] resembles Eq. [6] in that the ratio M^o/C^o represents a layer thickness, and the quantity $\sqrt{\pi}/2$ is not very different from unity. Thus, the linear diffusion model and the parabolic growth law for reactive diffusion give similar values for D and P when the thicknesses a and M^o/C^o are about the same.

The anodic behavior described in the preceding section can be explained on the basis of the three penetration processes: (*i*) The unalloyed lithium was exterior lithium that had not yet penetrated the grain boundaries. (*ii*) Most of the alloyed lithium which was recovered anodically was grain-boundary material that had become bonded to magnesium. (*iii*) The unrecovered lithium in the longer experiments was lithium that had penetrated further into the magnesium grains.

Effects of water.—The lithium-plated electrodes showed little sensitivity to water at concentrations below 1M. Lithium-magnesium alloys have even been recommended for use in aqueous batteries (13). It is known, however, that water decreases the exchange current on a freshly cut lithium surface in $LiClO_4$-PC (6). The recovery of lithium from magnesium electrodes that had been repolished before plating in the water solutions is recorded in Tables I and II. The charge densities Q_1 and Q_2 were essentially independent of the water content until the latter reached the 1M level where no recovery was obtained with Q_p = 250 mcoulombs/cm². An electrode freshly plated at 1160 mcoulombs/cm² retained enough of the alloy to be detectable on open circuit for approximately 4 min. A transition occurring at that time apparently was due to the chemical reaction of lithium with water.

Repeated plating and stripping at constant current in solutions containing 0.01-0.1M H_2O produced results very similar to Fig. 3 for the dry electrolyte. The curves for this conditioning sequence in 1M H_2O were significantly different. The cathodic process, which may have included hydrogen evolution, then occurred at potentials as much as 0.5V below that of the reference electrode. Table III indicates the lithium recovery from conditioned electrodes at various water concentrations. Both Q_1 and Q_2 were measurable in this series and there was, again, no obvious trend due to the water content through the level of 0.1M. Even at 1M H_2O, some of the plating charge was recovered, apparently as alloyed lithium, on the conditioned electrode.

Conclusions

1. Two types of anodically active lithium were produced on a magnesium surface by electrodeposition from a lithium perchlorate-propylene carbonate solution. The active material appeared to consist of unalloyed lithium and of alloyed lithium that had undergone a free energy decrease of 6-8 kcal/mole.

[a] Q_p = 50 mcoulombs/cm²; i_p = 0.2 mA/cm²; i_s = 0.2 mA/cm²; Q_1 and Q_2 (unstirred) from 5th cycle.
[b] Later cycle, with stirring.

2. The anodic recovery of lithium was limited by diffusion into the solid metal structure, which occurred in two stages, with a diffusion coefficient of 1.3×10^{-11} cm^2/sec for the first stage and an apparent value of 3.9×10^{-14} cm^2/sec for the second. The faster process probably involved the transport of lithium along the grain boundaries, while the slower diffusion was attributed to penetration of the magnesium grains.

3. In experiments lasting up to 20 min, the plated electrodes showed little sensitivity to added water at concentrations as high as 0.1M; the investigation of long-term exposure to water was precluded by the diffusional loss of lithium metal. In a 1M water solution, the alloy phase was still detectable, but the recovery of lithium was low.

ABSTRACT

The present investigation represents a detailed study involving transmission electron microscopy and electron diffraction of surfaces treated by the catalyzing system ($SnCl_2/PdCl_2/HCl$) in conjunction with various accelerating solutions and in some cases a subsequent electroless copper bath. Results give additional information demonstrating the proper procedure(s) necessary in the preparation of the catalytic system. In addition it was found the best plating results are obtained whenever Pd_3Sn is present on the treated surface prior to the metallization step.

In the art of electroless plating of dielectric substrates, a number of catalytic chemical systems are used prior to the deposition step. To date, all practical systems are based on the combination of tin and palladium. The various available processes can be classified into two systems as follows: (*i*) sensitization step ($SnCl_2$/HCl) followed by an activation step ($PdCl_2$/HCl) and (*ii*) catalyzation step ($PdCl_2/SnCl_2$/HCl) followed by acceleration (HCl or NaOH and similar).

With the increased interest of commercial applications, several investigators have examined the me-

chanisms of the above systems leading to the following basic conclusions.

1. The redox reaction (1-3) between tin(II) and palladium(II) is not a prerequisite for the successful results of system (*i*). The substrate used also plays a significant role in the chemistry of the catalyzation process.

2. In the system based upon tin(II), palladium(II), and HCl, an ionic complex is formed (4-11) rather than a colloid based on elemental palladium (12).

More recently significant improvements in the performance of system (*i*) were reported (13-15). These improvements were especially noted with respect to the successful plating of hydrophobic surfaces as well as increasing the density of catalytic sites (15, 16) of hydrophilic surfaces.

In the plating of dielectric substrates, several investigators (16-19) have examined the nature of the treated surfaces as well as the nucleation and growth of thin metallic films (cobalt, nickel, and copper). It has been generally demonstrated that the nucleation and growth of the electroless thin film is initiated at catalytic sites. In the microscopic examination of the treated surfaces, investigators (1, 16-19) de-

voted special attention to the system (*i*) with complete omission of system (*ii*). Only recently (20) was an attempt made to elucidate the mechanism of activation of system (*ii*).

In the current investigation it was decided to examine the dielectric surface at the different stages of pretreatment, including the early stages of nucleation and growth. This investigation is especially intended to provide further insight into various debated aspects of this system. Specifically: (*i*) the makeup of the solution; whether it is a palladium colloid or rather a tin(II) and palladium(II) ionic complex; (*ii*) preferred technique(s) in the preparation of such solutions; (*iii*) the role of the accelerator solution and its chemical nature; and (*iv*) the chemical nature of the catalytic surface prior to plating.

Experimental

In the present study, four distinct solutions of $SnCl_2$/$PdCl_2$ and HCl were employed. They are given in Table I. Immersion time was 2 min in both steps, with a 1 min rinse in deionized water between the steps.

For the purpose of evaluating the electroless product from the surface treatment, an electroless copper bath was chosen. The compositions were bath A, $CuSO_4$, $5H_2O$ 40 g/liter, $KNaC_4H_4O_6$ 100 g/liter, and KOH 40 g/liter; bath B, HCHO 130 g/liter and KOH 120 g/liter. Fresh solutions were made for each run and they were mixed in the ratio of 1 part B to 2 parts A. Depositions were carried out at room temperature.

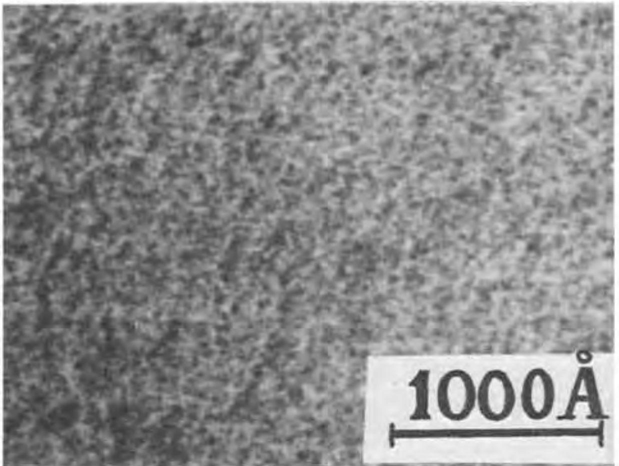
In some of the experiments, aged stannic solutions were added to the catalyzer (16). This was done for the purpose of comparing the influence of aged stannic solutions on the present system.

Transmission electron micrographs and electron diffraction patterns were obtained from a Hitachi HU-12 electron microscope operated at 100 kV.

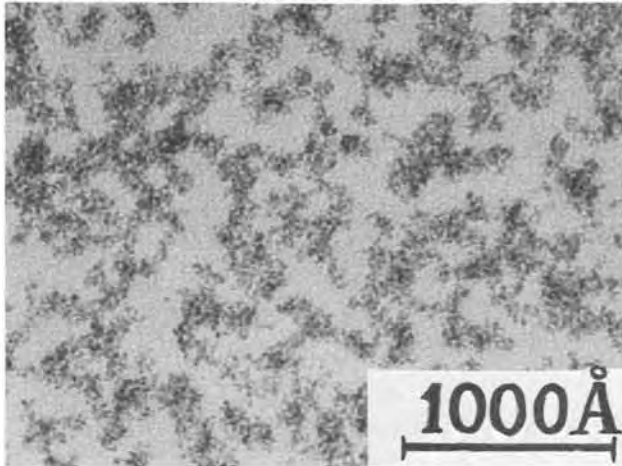
Formvar coated surfaces were floated off in distilled water from the glass base and were mounted in the sample holder of the electron microscope. (The Formvar solution consisted of 4g polyvinylformal in 1 liter ethylene dichloride.)

Results and Discussion

In Fig. 1 we present in succession transmission electron micrographs of Formvar coated surfaces obtained, using catalytic solution A, with Fig. 1a taken after catalyzation, Fig. 1b after acceleration, and Fig. 1c after 10 sec immersion in electroless copper plating bath. Figure 2 shows the corresponding diffraction patterns. From Fig. 1a and 1b it should be noted that



(a) Before the acceleration step



(b) After the acceleration (solution A) step

Fig. 5. Electron micrographs of the deposit obtained on a Formvar surface using catalytic solution A with additional aged 0.5M $SnCl_4$

the distribution of active components(s) is rather homogeneous. Comparison of this distribution to that obtained using a conventional sensitizer ($SnCl_2$/HCl) shows a marked difference [see Ref. (18), Fig. 1a]. Inspection of Fig. 1a shows a density of sites of approximately 10^{12} centers/cm^2. These centers are composed of particles of approximately 20Å in size. After acceleration (Fig. 1b), a tendency for cluster formation is evident. By contrast to the cluster formation in conventional sensitizer [see Ref. (18), Fig. 2a and 2b], in the current system, the clusters seem to form in a wormlike fashion. This tendency seems to be preserved as well in the early stages of the metallic end product as seen in Fig. 1c.

From the diffraction patterns (Fig. 2a and 2b) the following conclusions can be drawn: (*i*) The end product after the catalyzing stage is amorphous. (*ii*) The product after the acceleration step is face-centered cubic with lattice parameters closely matching those of Pd_3Sn.

It should be noted that Pd_3Sn is the only Pd-Sn compound known to crystallize in fcc form (21).

Table II summarizes the derived lattice parameters corresponding to Fig. 2b.

Comparison of the current experimental results to those derived from the literature (21) for Pd_3Sn, offers a convincing proof that the noted deviations of the order of 1% could be best accounted for by the size of the crystallites present affecting the definition of the diffraction rings. The present finding is also in agreement with conclusions made by Cohen *et al.* (10), using Mössbauer spectroscopy. However, these

conclusions are not in agreement with recent results by Rantell *et al.* (20). In their work, it was concluded that metallic palladium is present at the conclusion of the acceleration step, suggesting that the redox reaction between Sn(II) and Pd(II) does take place. This lack of agreement was initially conceived as being due to possible differences in experimental conditions.

Rantell used etched ABS as substrate, while we have used Formvar deposited on glass. Secondly, the chemical composition of both the catalyzer and the accelerator solutions was different.

The following additional experiments were therefore carried out. Samples were prepared using all four possible combinations of the two catalyzers and accelerators referred to in Table I as A and D. The results obtained with the ammonium bifluoride accelerator are illustrated in Fig. 3a and 4a for catalyzer A and Fig. 3b and 4b for catalyzer D. Figure 4a shows that the post-accelerator product in this case has fcc structure with the same lattice constant as for the deposit shown in Fig. 2b. It appears that although the distribution of particles in the deposit is affected by the nature of the accelerator its chemical composition is not. In Fig. 4b no evidence of metallic palladium can be seen; indeed the nature of the deposit cannot be inferred from the electron diffraction pattern. Essentially the same results were obtained using Rantell's catalyzer with the 19F accelerator. It is possible that the deposits obtained with Rantell's catalyzer contain insufficient amounts of Pd to be observable by electron diffraction. It is also conceivable that the chemical nature of the substrate plays a role in the Sn(II) Pd(II) interaction as suggested previously by Feldstein (2).

Figures 5 and 6 show the effects on (a) the post-catalyzer deposit and (b) the post-accelerator deposit of the addition of 0.5M $SnCl_4$, aged for one week, to the 9F catalyzer. (About 1 ml of aged $SnCl_4$ to 10 ml of the catalyzer was used.)

In Fig. 5b, it should be noted that the wormlike microstructure has disappeared and instead the char-

acteristics of an improved conventional sensitizer ($SnCl_2$/HCl) have resulted [see Ref. (16), Fig. 2b]. Table III represents the lattice parameters corresponding to the surface used in Fig. 5b. It would appear that the presence of an aged $SnCl_4$ component nullified the characteristics of the present system, with respect to the presence of Pd_3Sn and characteristic microstructure. Further work is in progress to clarify this point.

In the next phase of this investigation Formvar surfaces treated by catalytic solutions B and C were examined. In general, surfaces treated by the catalytic solution B with and without the accelerating solution step showed a diffused microstructure in the electron micrographs. The corresponding diffraction pattern also exhibits an amorphous characteristic. However, aging the working solution (solution B) for approximately two weeks was sufficient to result in a major change. Specifically, the aged solution B exhibited results similar to Fig. 1 and 2, *i.e.*, the presence of Pd_3Sn in the post-acceleration deposit is evident. In both cases, good metal distribution was obtained following the plating step. Employing unaged catalytic solution C has provided results similar to those obtained using unaged catalytic solution B, except that the diffraction pattern revealed the presence of SnO_2 at the conclusion of the acceleration step. Aged solution C exhibits plating characteristics similar to aged solution B. Figure 7 shows Cu deposits obtained with the use of (a) fresh catalytic solution B followed by an accelerating solution of 1.2M NaOH and (b) same as (a) except that the catalytic solution was aged prior to use for 7 days. Figures 8a and b are the corresponding diffraction patterns. Note the marked difference between the deposits in Fig. 7a and b; whereas in Fig. 7a, there are large islands and a relatively poor coverage, in Fig. 7b a good coverage is obtained with small islands. This is also seen in Fig. 8a and b, where the difference in crystallite size is evident. Comparison of Fig. 7b with Fig. 1c, and of the corresponding diffraction patterns (Fig. 8b and

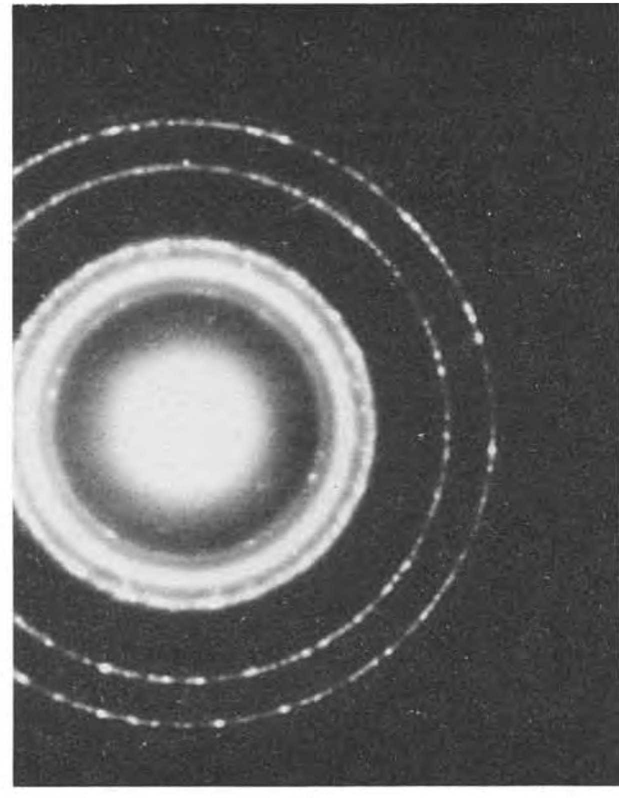
(a)



(b)

Fig. 8. Electron diffraction patterns corresponding to Fig. 7

2c) reveals a similarity in terms of surface coverage, in contrast to that seen in Fig. 7a.

Finally, it is interesting to note that the effect of aging the catalyzer on the copper deposit is also to render the product similar to that employing an improved conventional sensitizer [see Ref. (16), Fig. 3b].

The Electro-Oxidative Coupling of N,N-Dimethylaniline: A Rotating Ring-Disk Electrode Study

G. Neubert and K. B. Prater*

Department of Chemistry, University of Texas at El Paso, El Paso, Texas 79968

The publication costs of this article have been assisted by the Petroleum Research Fund and the Robert A. Welch Foundation.

ABSTRACT

The electro-oxidation of N,N-dimethylaniline (DMA) has been studied in strongly acidic aqueous media by cyclic voltammetry and rotating ring-disk electrode voltammetry coupled with digital simulation. The ring-disk data are inconsistent with the simulation of a mechanism involving coupling between two DMA cation radicals to produce N,N,N',N'-tetramethylbenzidine. The results are qualitatively consistent with a mechanism involving deprotonation of the DMA cation radical and subsequent coupling between neutral radicals.

The electro-oxidation of N,N-dimethylaniline (DMA) in aqueous media has been studied in some detail by Adams *et al.* (1-3). They found that in acidic media the product was N,N,N',N'-tetramethylbenzidine (TMB). Two mechanisms were proposed for the reaction. One involved the initial production of the dication of DMA at the electrode followed by an attack of this dication on a parent molecule to produce, with loss of two protons, TMB. The second mechanism suggested that the DMA cation radical (DMA†) is formed at the electrode and that two such cation radicals couple with loss of two protons to form TMB. Based on later work on triphenylamines (4, 5) and the work of Nelson (6) on DMA in acetonitrile, it is now felt that the cation radical is the species which is first produced at the electrode. There is little data, however, to indicate the mechanism by which TMB eventually arises from DMA†. This paper reports the results of cyclic voltammetry and ring-disk electrode voltammetry studies of the electro-oxidation of DMA in strongly acidic aqueous media. The results are inconsistent with a radical cation-radical cation coupling mechanism but may be consistent with a mechanism involving deprotonation of the cation radical and subsequent reaction between neutral radicals.

Experimental

The N,N-dimethylaniline (J. T. Baker) was distilled from 85% formic acid solution (10 ml acid/100 ml DMA) using the procedure of Ritter (14). The N,N,N',N'-tetramethylbenzidine (Eastman-Kodak) was recrystallized from ethanol and acetone. All other chemicals were reagent grade and were used without further purification. The water was deionized.

The fabrication of the ring-disk electrode (15), the method of its calibration (16), and the compounding of the carbon paste (17) have previously been described. The simulation representation of the electrode used in this study is given by IR1 = 80, IR2 = 92, and IR3 = 158. The electrode was rotated with a motor-matic E-550 motor with feedback controller which was obtained from Electro Craft, Hopkins, Minnesota. All potentials are reported with respect to the SCE.

A Wenking Model 66TS10 potentiostat was used with a Hewlett Packard 7004A X-Y recorder with 17171A d-c preamp plug-ins for cyclic voltammetry, for obtaining limiting disk currents, and for obtaining ring voltamograms for collection efficiency measurements. In making collection measurements, a constant current obtained from two paralleled 90V batteries in series with a large variable resistor was applied to the disk. This current was measured with a Keithly Digital Multimeter, Model 160. All experiments were carried out in a constant temperature bath at 25.0° ± 0.1°C.

Cyclic Voltammetry Results and Discussion

The cyclic voltamogram in Fig. 1 is typical of those obtained for DMA at a carbon paste electrode in 1-6M H_2SO_4 over a range of DMA concentrations from 0.5 to 5.0 mM. This cyclic is consistent with those obtained by Adams (1) in less acidic media. Peak 1 corresponds to the primary oxidation of DMA. The work of Adams *et al.* (4) leads one to conclude that the cation radical, DMA†, is the species which is initially produced at the electrode. At the potential of peak 1, any TMB that is formed will be further oxidized to the TMB dication, TMBox. Peak 5 corresponds to the reduction of TMBox to TMB and peak 6 corresponds to the oxidation of TMB to TMBox. In less acidic media, Adams (1) observed no net cathodic current in the region of peak 4, the region in which DMA† would be expected to be reduced. It is found that in the strongly acidic media studied here, net cathodic current is observed in this region, suggesting an increased stability of DMA† in more acidic media.

It has been suggested that peak 4 might result from the presence of either *ortho-para* or *ortho-ortho* TMBox rather than DMA†. In an attempt to eliminate this possibility a bulk electrolysis of a 1 mM solution

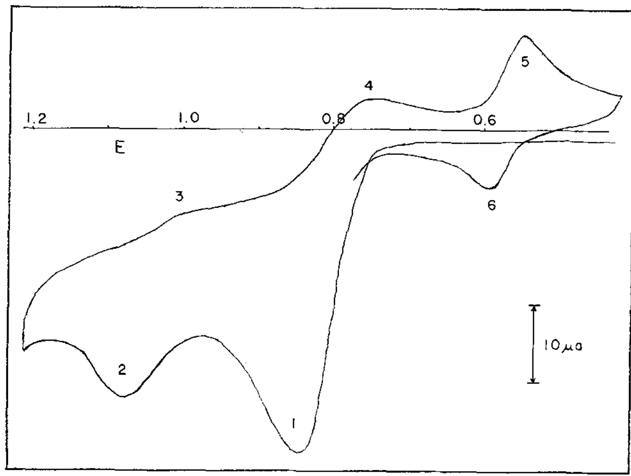

Fig. 1. Cyclic voltamogram of 1.15 mM DMA in 3M H_2SO_4 at a carbon paste electrode and at a scan rate of 2.4 V/min.

* Electrochemical Society Active Member.

Key words: N,N-dimethylaniline, rotating ring-disk electrode, mechanism, digital simulation.

of DMA in 1M H_2SO_4 was carried out at a carbon paste electrode in an H-cell. The potential of the working electrode was 0.9V *vs.* SCE. Halfway through the electrolysis, a slow potential scan was made on the stationary working electrode in the stirred solution. A steady-state anodic current was observed in the region of peak 1, indicating the presence in the bulk of the solution of unoxidized DMA. A steady-state cathodic current was observed in the region of peak 5, indicating the presence of TMBox in the bulk solution. No steady-state current was observed in the region of peak 4. The stirring was then stopped and a cyclic voltamogram obtained, which was quite similar to Fig. 1 except for an enhancement in peaks 5 and 6. The significant point, however, is that peak 4 was present in the cyclic voltamogram. These results indicate that the species giving rise to peak 4 is not a stable bulk species but is present only in the diffusion layer.

The remaining DMA was electrolyzed and the resulting solution was reduced at 0.0V *vs.* SCE to convert the TMBox to TMB. The solution was then neutralized with Na_2CO_3 and the products extracted with ether. The ether solution was then evaporated to dryness. The residue was extracted with benzene and the benzene solution was chromatographed on silica gel TLC plates using benzene, acetone, and methanol as solvents. Only a single spot was observed for each of these solvents. That spot corresponded to the *para-para* TMB. There was no indication of any other product being formed. As a result, it is felt that peak 4 is probably due to the reduction of $DMA^{+\cdot}$.

Finally, mention should be made of peaks 2 and 3 in the cyclic voltamogram. These peaks were not reported in less acidic media. They are definitely not background phenomena (as had been suggested) but appear to be due to the production of DMA^{+2} and its subsequent reduction. This possibility is being further studied.

With this background, a further study of the nature of the coupling reaction to produce TMB was undertaken. It was felt that a ring-disk electrode study of the rate of disappearance of $DMA^{+\cdot}$ would be the most informative approach.

Ring-Disk Electrode Results

A rotating ring-disk electrode (RRDE) (7-9) study was carried out on solutions which were 0.62, 1.15, and 4.49 mM in DMA and 3M in H_2SO_4. A voltamogram typical of those observed at the disk electrode is shown in Fig. 2. Two plateau regions are observed, one corresponding to peak 1 in Fig. 1 and the other corresponding to peak 2. The experimental procedure which was followed involved obtaining such a voltamogram for each rotation rate on a given solution and then applying a constant current to the disk electrode equal to the limiting current for peak 1 (production of $DMA^{+\cdot}$). A voltamogram was then obtained for the ring electrode under these conditions. A second ring voltamogram was obtained with no current being passed at the disk electrode. Figure 3 shows typical ring voltamograms for a DMA solution as well as a voltamogram for a solution of TMB. Note that there are two plateaus for the DMA solution and only one for the TMB solution. The plateau which corresponds to peak 4 in Fig. 1 thus reflects the presence of $DMA^{+\cdot}$. But, the actual current in this region is the difference between the cathodic current due to reduction of $DMA^{+\cdot}$ and the anodic current due to the oxidation of any TMB present.

The important parameter in the RRDE experiment is the kinetic collection efficiency, N_k, which is defined in Eq. [1]

$$N_k = -i_r/i_d \quad [1]$$

where i_r is the limiting current at the ring electrode due to the current i_d at the disk electrode. The collection efficiencies in region 4 were determined for the three solutions above over a range of rotation rates from 200 to 8000 rpm. The results are presented in Fig. 4. Each point is the average of from five to ten separate determinations. Due to electrode filming and other problems associated with carbon paste in 3M H_2SO_4, the uncertainty in the points is about ±10%. In the 4.49 mM solution, filming became an even greater problem. It is felt that this may have resulted in curve c not coinciding with curve a and b.

Digital Simulation Results and Discussion

A technique for the digital simulation of the RRDE has been presented previously (10-13). This technique permits the calculation of the collection efficiency as a function of various dimensionless parameters for essentially any imaginable mechanism. This technique with the modifications mentioned below has been used to calculate the collection efficiency behavior of two possible mechanisms for the oxidation and coupling of DMA.

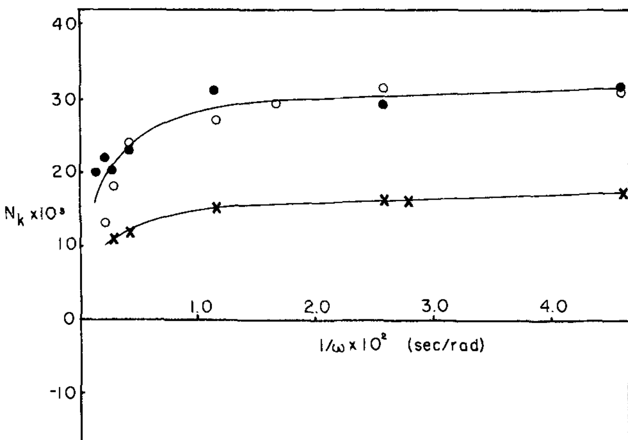

Fig. 4. Experimental collection efficiencies for peak 4 as a function of $1/\omega$. ● 0.625 mM DMA, 3M H_2SO_4; ○ 1.151 mM DMA, 3M H_2SO_4; X 4.49 mM DMA, 3M H_2SO_4.

Mechanism I

The first mechanism which was considered involves coupling between two $DMA^{+\cdot}$ species and is given below

$$DMA - e^- \rightarrow DMA^{+\cdot} \text{ (disk)} \quad [2]$$

$$2DMA^{+\cdot} \xrightarrow{k_2} TMB + 2H^+ \quad [3]$$

The TMB thus produced is subject to further oxidation at the disk

$$TMB - 2e^- \rightarrow TMBox \text{ (disk)} \quad [4]$$

and is also subject to chemical oxidation by $DMA^{+\cdot}$

$$2DMA^{+\cdot} + TMB \xrightarrow{k_3} 2DMA + TMBox \quad [5]$$

At the ring electrode, $DMA^{+\cdot}$ and TMB are both electroactive

$$DMA^{+\cdot} + e^- \rightarrow DMA \text{ (ring)} \quad [6]$$

$$TMB - 2e^- \rightarrow TMBox \text{ (ring)} \quad [7]$$

Following the procedures outlined in Ref. (10) and (13), the collection efficiency, N_K, was calculated for the electrode in question and Mechanism I for various values of two dimensionless rate parameters, XKTC2 and XKTC3, which are defined by

$$XKTC2 = (0.51)^{-2/3} k_2 \omega^{-1} \nu^{1/3} D_A^{-1/3} C^\circ_A \quad [8]$$

and

$$XKTC3 = (0.51)^{-2/3} k_3 \omega^{-1} \nu^{1/3} D_A^{-1/3} (C^\circ_A)^2 \quad [9]$$

where ω is the rotation rate (radians/second), ν is the kinematic viscosity (cm^2/sec), D_A is the diffusion coefficient of, in this case, DMA (cm^2/sec). C°_A is the bulk concentration of DMA (moles/liter) and the rate constants refer to Eq. [3] and [5].

Note that

$$XKTC3/XKTC2 = (k_3/k_2) C^\circ_A \quad [10]$$

or, since k_3 and k_2 are constants, the ratio of XKTC3 to XKTC2 is directly proportional to the bulk concentration of DMA. Similarly

$$(XKTC2)^2/XKTC3 = (0.51)^{-2/3} (k_2/k_3) \omega^{-1} \nu^{1/3} D_A^{-1/3} \quad [11]$$

Since all terms in Eq. [11] except the rotation rate are constant for a given experiment, Eq. [11] reduces to

$$(XKTC2)^2/XKTC3 = K\omega^{-1} \quad [12]$$

Thus, a plot of the simulated values of N_K for a constant value of XKTC3/XKTC2 as a function of $(XKTC2)^2$/XKTC3 is in fact a plot of the expected values of N_K for a fixed concentration of DMA as a function of $1/\omega$. This is the same format in which the experimental data were presented (Fig. 4). The results of the simulation of Mechanism I are presented in Fig. 5 for three values of the concentration parameter.

Note that while the simulated values of N_K are in the same range as those observed experimentally, the shapes of the simulated curves are distinctly different from those obtained experimentally. Furthermore, the simulation predicts a distinct concentration dependence which was not observed experimentally at the lower concentrations. This lack of agreement casts serious doubts on the acceptability of Mechanism I under the experimental conditions.

Mechanism II

The second mechanism which was considered took account of the apparent increased stability of $DMA^{+\cdot}$ in strongly acidic media and the apparent first-order nature of its disappearance (little if any concentration dependence). This mechanism differs from Mechanism I in one respect only. In lieu of Eq. [3], the reaction is proposed to proceed in two steps. The initial step consists of the deprotonation of the cation radical, a first-order process, to yield the free radical as shown

CH_3 CH_3
N
H H
$DMA^{+\cdot} \longrightarrow$ [ring] $+ H^+$ [13]
H · H

The free radical then dimerizes very rapidly (at an infinite rate, compared to k_1) by the second-order reaction

CH_3 CH_3
N
H H
2 [ring] $\rightarrow TMB$ [14]
H H

The net reaction is thus pseudo first order

$$DMA^{+\cdot} \xrightarrow{k_1} 1/2\, TMB \quad [15]$$

The collection efficiency was calculated for Mechanism II for various values of the first-order rate parameter XKT1, where

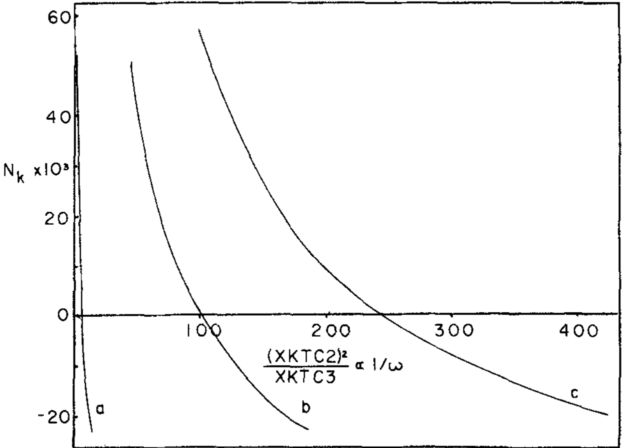

Fig. 5. Simulated collection efficiency as a function of $1/\omega$ for Mechanism I. Curve a, XKTC3/XKTC2 = 1.0; curve b, XKTC3/XKTC2 = 0.05; curve c, XKTC3/XKTC2 = 0.02.

$$XKT1 = (0.51)^{-2/3} k_{1}\omega^{-1} \nu^{1/3} D_A^{-1/3} \quad [16]$$

and XKT3 as defined in Eq. [9]. Note that

$$XKTC3/XKT1 = (k_3/k_1)(C^{\circ}_A)^2 \quad [17]$$

while XKT1 is a function only of rotation rate for a given experiment. Thus, a plot of the simulated values of N_k *vs.* XKT1 for a constant value of XKTC3/XKT1 is a plot of N_k *vs.* $1/\omega$ at constant concentration. The simulation results for Mechanism II are presented in Fig. 6 for three concentrations differing by up to a factor of 10. The curves show no concentration dependence over this range. Furthermore, for XKT1 greater than about 3, the simulated curve has the same shape as the experimental curve. Quantitatively, however, the simulation predicts a net anodic current while the experimentally observed current is cathodic.

This discrepancy may be explained by considering that if the neutral radical were formed by deprotonation of $DMA^{+\cdot}$, it would seem that reprotonation would be more probable than coupling especially in these media. This suggests that the irreversible deprotonation step in Mechanism II should be replaced by a fast acid-base equilibrium in which DMA^+ is considered to be a very weak acid. This would be consistent with the apparent increased stability of $DMA^{+\cdot}$ in acidic media and would result in a simulated prediction of a greater cathodic contribution to the current in region 4.

A second weakness in Mechanism II is the assumption that the oxidation of TMB at the ring electrode is diffusion controlled at the potential at which the measurements were made (about 0.7V). A glance at Fig. 3 would suggest that this is probably not the case. Taking this into account in the simulation would decrease the anodic contribution to the current in region 4.

Each of the above modifications to Mechanism II would result in a simulation which would better fit the experimental data. However, such a simulation would have at least four independently variable parameters and even then would involve some simplifying assumptions. Such a simulation is certainly feasible but it should be remembered that there are only two meaningful experimental variables, *i.e.*, rotation rate and concentration of DMA.

It is strongly felt by the authors that there are limits beyond which it is fruitless to carry the simulation of a proposed mechanism. These limits are dictated by both practical and philosophical considerations. On the practical side, as the complexity of the mechanism increases so does the time required to simulate all of the possible permutations of values of the independent variables. As there are limits on the availability of both computer and investigator time, the potential gain from the simulation of a mechanism must be considered. This potential gain, however, is subject to philosophical limitations.

It is clear that one can never prove that a given mechanism is correct: that is, there is no reason to contend that, because the predictions based on a specific mechanism are in agreement with experiment, the mechanism is unique in that respect. We are prone to feel that, if a mechanism consisting of two parameters adequately predicts the behavior of a system with two observables, the mechanism is probably correct, at least in its significant features. If a mechanism containing four or more parameters is needed to adequately fit a system with two observables, we should feel much less confident of its uniqueness.

It is in this latter situation that the authors find themselves. It is felt that one can safely conclude from the results presented here that the data are inconsistent with the mechanism involving cation radical-cation radical coupling but that the data are not necessarily inconsistent with a mechanism involving deprotonation of the cation radical before coupling. It is further felt that even if a more complex mechanism were simulated and found to fit the data, one should not make any stronger statement than that above without additional evidence. It would seem reasonable then, to consider whether there is any other evidence for the deprotonation mechanism and what other experiments might yield such evidence.

Carrington, Dravnieks, and Symons (18) have argued that "in sufficiently basic medium, hydrocarbon positive ions could lose ring protons." Osa, Yildiz, and Kuwana (19) proposed such a mechanism to explain results obtained in the electro-oxidation of benzene in acetonitrile. Drews and Jones (20), in a study of the stabilities of the cation radicals of the *p*-tert-butyl-, *p*-trimethylsilyl-, and *p*-trimethylgermyl-N,N-dimethylanilines, proposed the loss of the *para* substituent and production of the neutral DMA radical in order to explain their results.

While the fact that a similar mechanism has been proposed by others for similar systems is encouraging, additional information on the DMA system itself would be desirable. To this end, isotope effect studies on this reaction will soon begin. The possibility of substituting DMA in the 3 and 5 positions with groups which would be sufficiently bulky as to prevent coupling at the *para* position is being considered. Meanwhile, a mass spectrometer study of what may be an analogous loss of hydrogen from gas phase cation radicals is underway.

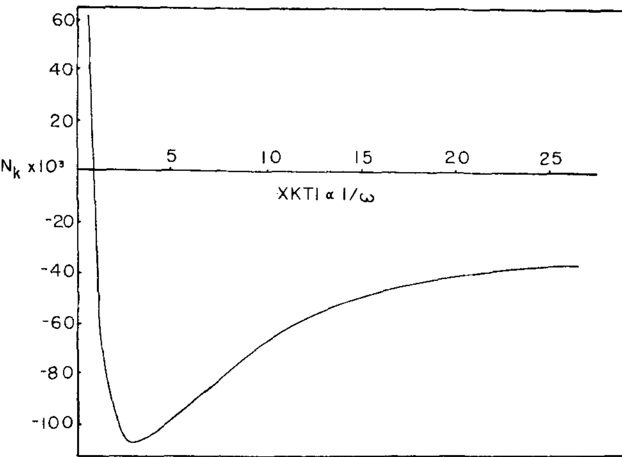

Fig. 6. Simulated collection efficiency as a function of $1/\omega$ for Mechanism II. Results identical for XKTC3/XKTC1 = 1.0, 0.1, and 0.01.

Summary

Rotating ring-disk electrode studies of the anodic oxidation of N,N-dimethylaniline (DMA) in strongly acidic media are inconsistent with digital simulation results for a mechanism involving the direct coupling of the corresponding cation radicals to produce N,N,N',N'-tetramethylbenzidine (TMB). The experimental results are qualitative consistent with a mechanism involving deprotonation of the DMA cation radical and subsequent coupling of the neutral radicals thus produced.

Chlorine and Oxygen Electrode Processes on Glasslike Carbon, Pyrolytic Graphite, and Conventional Graphite Anodes

ABSTRACT

The polarization behavior of glasslike carbon, pyrolytic graphite, and conventional graphite electrodes, in acidic solutions with and without Cl^-, has been studied. The electrode surface is covered by carbon oxides of two types depending on the electrode potential. Formation of these oxides is also affected by the Cl^- concentration, temperature, electrode material and its preparation. Electrode processes involving O_2, CO, and CO_2 were found to occur at high current densities. Transition from the chlorine evolution process to the over-all oxygen electrode process is irreversible because of irreversible exchange between adsorbed chlorine and oxygen on the working electrode. The Tafel line for the chlorine formation reaction on a fresh carbon and/or graphite anode has the slope of 130-150 mV/decade, and the reaction order with respect to Cl^- is unity.

The main reaction on graphite anodes in chlorine cells (both diaphragm and amalgam types) is, of course, evolution of chlorine gas, at more than 99% of current efficiency. Formation of some CO, CO_2, and O_2 may take place as a side reaction, and the latter is a controlling factor in consumption or corrosion of the graphite anode during electrolysis. This is one of the serious problems in the chlor-alkali industry (1, 2).

It is believed that the charge-transfer reaction of H_2O and/or OH^- takes place on the surface of the graphite anode, followed by formation of an oxide layer. Subsequent processes, *i.e.*, formation of CO and CO_2 (which consumes graphite), occur (2). On the other hand, adsorption of Cl^- and/or Cl-adatoms on the surface of graphite anodes immersed in aqueous solution containing Cl^- is significant. This retards the formation of the oxide layer and reduces consumption of the anode.

Possible electrode processes and their standard potentials ($E°$ in volts at 25°C) in acidic solution containing Cl^- are as follows

$$C + H_2O = CO + 2H^+ + 2e \qquad 0.52V \textit{ vs.} \text{ SHE} \qquad [1]$$

$$C + 2H_2O = CO_2 + 4H^+ + 4e \qquad 0.21V \qquad [2]$$

$$2H_2O = O_2 + 4H^+ + 4e \qquad 1.23V \qquad [3]$$

$$2Cl^- = Cl_2 + 2e \qquad 1.36V \qquad [4]$$

The standard potential for the chlorine evolution reaction is the highest. But the overvoltage for reactions [1], [2], and [3] is high compared to that of reaction [4], so that the graphite anode is useful in chlor-alkali cells.

In solutions free of Cl^-, formation of CO, CO_2, and O_2 occurs after adsorption of oxygen atoms by the graphite anodes, or after formation of a carbon oxide layer, or both (3-6). Very few papers concerning the characteristics of the oxide layer can be found (3, 7, 8).

Experiments with the linear potential sweep (LPS) method and the galvanostatic cathodic transient (GCT) method can be used for studying the properties of the oxide layer and of the process of its formation. On the other hand, formation of the surface oxide is limited in concentrated Cl^- solution because Cl^- and/or Cl-adatoms cover the graphite surface. Exchange between the surface oxide and chlorine is an irreversible process, and hence separate observation of these processes can best be made by means of the nonsteady-state method.

The electrochemical process may take place not only on the external surface of a commercial graphite anode, but in the pores a few millimeters deep (9).

* Electrochemical Society Active Member.

Key words: Cl_2 electrode, O_2 electrode, surface oxide, glasslike carbon, pyrolytic graphite, graphite.

Such an electrode is unsuitable for studying the processes of adsorption and desorption of species on the working electrode by means of the LPS method. Due to the large area of effective surface of the porous electrode, a large amount of polarizing current may be consumed for charging of the double layer capacity (10, 11). We can avoid this difficulty by using glasslike or glassy carbon (designated GC hereafter), having a smooth surface like glass, as the working electrode. Pyrolytic graphite (PG) was also examined. Physicochemical properties of these materials can be found elsewhere (12).

Experimental Procedure

A GC electrode (0.196 cm^2) and a PG electrode (0.2 cm^2) were used. Since the electrical resistance of PG was very dependent on the direction (12), the surface perpendicular to the deposited layer was used as the working electrode. A platinum wire counter-electrode, 0.5 mm diam and 3 cm long, was placed in a compartment separated by a sintered glass diaphragm from the compartment of the working electrode.

The working electrode was oxidized at a noble potential (+2.5V *vs.* SCE) for a few seconds, then reduced cathodically at about −2.0V prior to the measurements to eliminate any contaminants on the surface. When the galvanostatic anodic transient (GAT) method was used, the electrode was polarized cathodically (at −2.0V) before every run.

The electrode potential was measured with a Luggin probe connected to a saturated calomel electrode (+235 mV *vs.* SHE at 25°C).

The potential scanning rate for the LPS method (with conventional equipment) was usually 200 mV/sec. For the galvanostatic transient method, both anodic and cathodic, a high voltage dry cell (90V) with a high variable resistance (10 megohms) in series was employed as the power source. A sensitive mercury relay was of great use for switching from potentiostatic to galvanostatic polarization.

The electrolyte used was either 1M $HClO_4$, or mixtures of $HClO_4$ and $NaClO_4$ (ionic strength = 1M). NaCl and HCl were added if necessary to examine the influence of Cl^- on the formation of carbon oxide. The temperature was 50° ± 0.5°C. The electrolyte was deoxygenated prior to the experiments.

Results

Formation and reduction of carbon oxide and adsorption and desorption of hydrogen atoms in $HClO_4$ solutions.—We present potential sweep diagrams for the GC in Fig. 1-3, and one for the PG in Fig. 4. The electrolyte was 1M $HClO_4$ and the temperature 50°C in all four sets. The sets differ only in the limits of the polarization voltage applied, as shown in Table I.

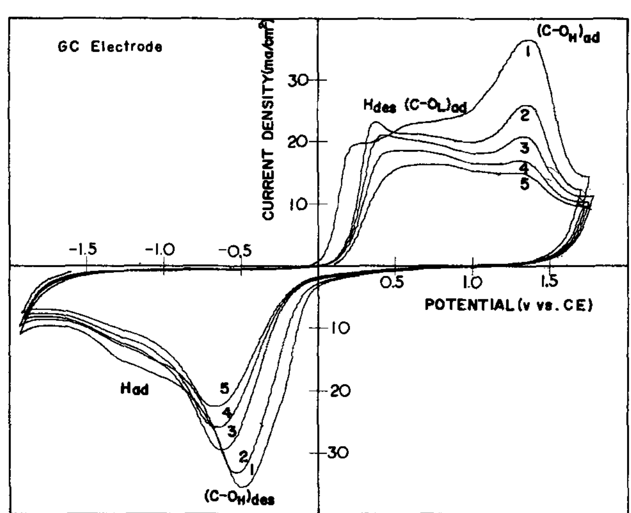

Fig. 1. Potential sweep diagrams with a glasslike carbon electrode in 1M $HClO_4$ at 50°C. Sweep rate 200 mV/sec. Curves are numbered in order of runs.

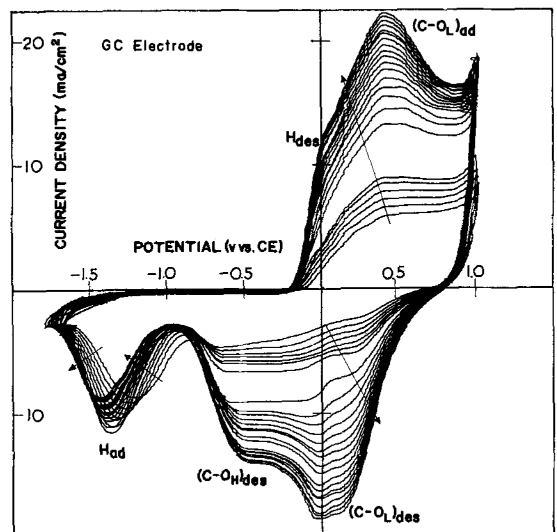

Fig. 2. Potential sweep diagrams with a glasslike carbon electrode in 1M $HClO_4$. Sweep rate 200 mV/sec.

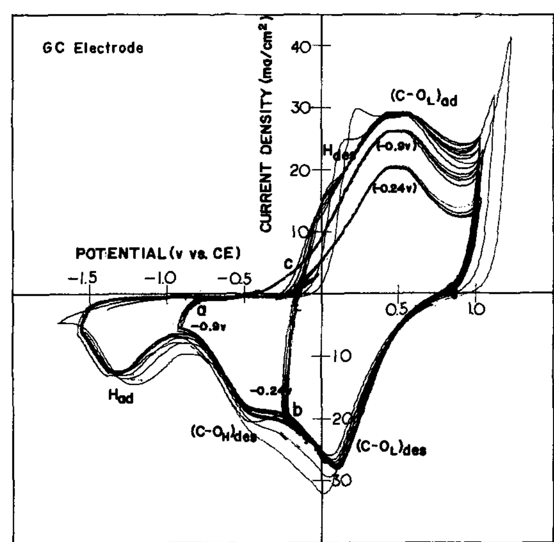

Fig. 3. Potential sweep diagrams with a glasslike carbon electrode in 1M $HClO_4$. Sweep rate 200 mV/sec.

Note that evolution of CO, CO_2, and O_2 occurs at potentials above *ca.* +1.7V (13, 14), and that evolution of H_2 occurs at potentials below *ca.* −1.9V. Thus, in Fig. 1 and 4, the electrodes are completely oxidized and reduced, while in Fig. 2 and 3, the effect of partial oxidation or reduction is observed.

In these figures, the sequented order of sweeps is indicated by numbers or by arrows. Thus, in Fig. 1, the areas enclosed by successive sweeps decrease, while in Fig. 2, they increase.

The processes that occur are identified as follows: H_{ad} and H_{des} represent adsorption and desorption of H atoms, respectively. Also, ($C-O_H$) and ($C-O_L$) represent the higher and lower oxides of carbon, re-

Table I. Limits of polarization voltage in potential sweep

Figure No.	Electrode	Limits of sweep (V *vs.* SCE) Anode	Cathodic
1	GC	+1.8	−1.9
2	GC	+1.0	−1.8
3a	GC	+1.0	−0.9
b		+1.0	−0.24
4	PG	+1.8	−1.8

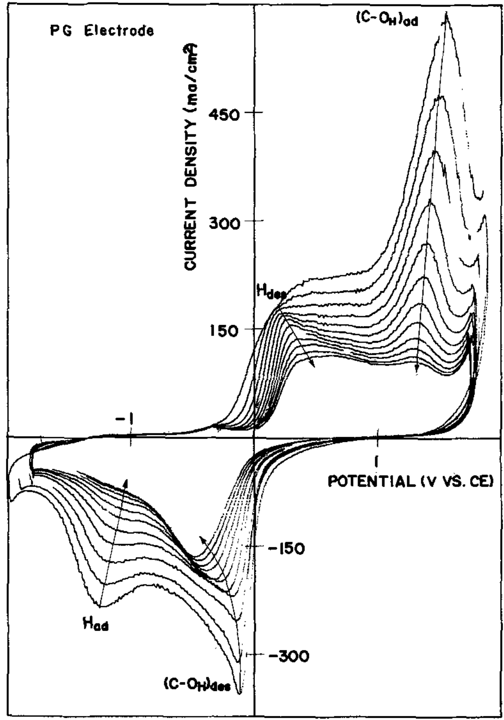

Fig. 4. Potential sweep curve with pyrolytic graphite electrode in 1M $HClO_4$ at 50°C. Sweep rate 200 mV/sec. The curve tends to the direction shown by the arrows when the electrode is polarized repeatedly.

spectively, and the subscripts ad and des refer to formation or reduction of these species.

The results for the PG electrode, Fig. 4, are essentially the same as for the GC electrode, Fig. 1, although the current density is surprisingly larger for the PG. The surface became rough after repeated scanning over a wide voltage range.

In Fig. 1, the +0.5 and +1.3V peaks of the anodic scan correspond to the −1.3 and the −0.5V peaks of the cathodic scan, respectively. The oxide layer on the wotking electrode appears to be renewed if the electrode is polarized at +1.7V or more, where oxygen evolution takes place. The potential sweep curve becomes stable under such a condition.

As seen in Fig. 2, the adsorption and desorption of (C-O_H) does not take place if the anodic scan is limited to +1.0V. The peak current at −0.5V during cathodic scan decreases but not to zero, and the new peak at *ca.* +0.1V appears. It corresponds to the +0.5V peak of the anodic scan. The curves in Fig. 2 stabilized after several hundreds of scans. It is also significant that new peaks at *ca.* +0.5V (anodic scan) and +0.1V (cathodic scan) appear.

In Fig. 3, the hump of the anodic scan H_{des} at *ca.* +0.1V disappears, provided the start of the sweep, marked "a," is more positive than −0.9V. The +0.5V peak for (C-O_L) diminishes, but is still prominent when the anodic scan starts at −0.24V, marked "b."

At anodic potentials corresponding to evolution of oxidic gases, as in Fig. 1, the anodic scan peak at +1.3V and its corresponding cathodic scan peak at −0.6V indicate the formation and reduction of a surface complex which we identify as a higher oxide of carbon (C-O_H). When the anodic scan potential is only +1.0V, as in Fig. 2 and 3, a different anodic scan peak at about +0.5V and its corresponding cathodic scan peak at +0.1V are observed. We attribute this to the formation and reduction of a lower oxide of carbon (C-O_L).

The great range of 1.9V for the formation and reduction of (C-O_H) indicates that this is quite an irreversible process. On the contrary, the range for the formation and reduction of (C-O_L) is only about 0.4V, which indicates that it is an unstable intermediate and that the process approaches reversibility. Figure 3 shows both $(C\text{-}O_L)_{des}$ and $(C\text{-}O_H)_{des}$, showing that some (C-O_H) may form even if the polarization is limited to +1.0V.

The results of several hundreds of experiments are summarized in Fig. 5. The circles represent peak potentials. The heavy lines represent data for GC, and the light lines for PG electrodes.

Adsorption and desorption of hydrogen seem to be irreversible on graphite and carbon, while they are quite reversible on noble metal such as Pt (15).

The peak potentials, E_p, *vs.* pH in the mixed solutions are shown in Fig. 6. The curves for $(C\text{-}O_L)_{ad}$ and H_{des} overlap as shown above. The potential for $(C\text{-}O_H)_{ad}$ is almost independent of pH, while that for $(C\text{-}O_H)_{des}$ is a small function of pH. On the other hand, H_{ad} depends much on pH, and the slope of the potential *vs.* pH curve is −0.146 V/pH. The potential for H_{des} is not affected by pH.

This is quite reasonable if $H^+ + e \rightleftharpoons H_{ad}$ is assumed. For example, Böld and Breiter (16) have described the pH dependency of the adsorption and desorption of hydrogen and oxygen on Pt. We have also studied with carbon and graphite electrodes in alkaline solutions, where $H_2O + e \rightleftharpoons H_{ad} + OH^-$ is proposed (17).

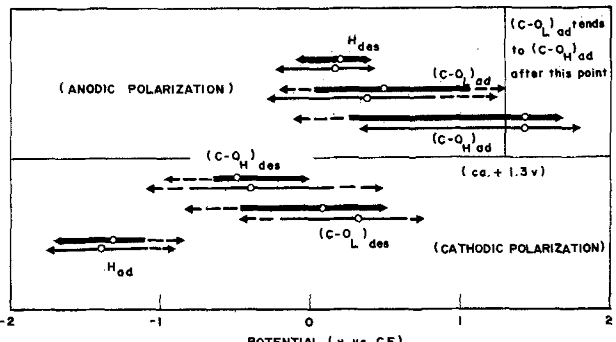

Fig. 5. Potential ranges for existing adatoms and intermediates in 1M $HClO_4$ at 50°C. Heavy lines, glassy carbon; light lines, pyrolytic graphite.

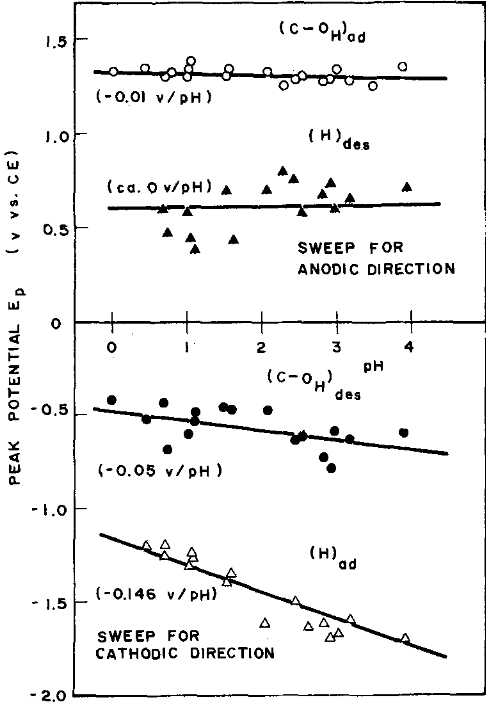

Fig. 6. Peak potential E_p vs. pH curves with glassy carbon electrode in mixed solutions of $NaClO_4$ and $HClO_4$($C_{ClO_4^-}$ = 1M) at 50°C. Potential sweep rate 200 mV/sec.

The +0.1V peak of the cathodic scan diminishes when the electrode is polarized at more than +1.3V. Therefore, we consider that ($C\text{-}O_H$) is not reduced to ($C\text{-}O_L$), or only insignificantly.

The surface of the working electrode becomes rough and the potential sweep diagram shrinks when polarization is repeated between +1.7 and −1.9V. However, the curve is stable if anodic polarization is limited up to the potential for $(C\text{-}O_L)_{ad}$.

Determination of carbon oxide and hydrogen adatoms.—Since the specific peaks for H, ($C\text{-}O_L$), and ($C\text{-}O_H$) overlap as described above, the GCT method was employed.

The test electrode was treated at +2.5V for 5 sec, then reduced at *ca.* −2.0V for 10 sec prior to the measurements. The electrolysis was carried out at a given potential, E_{st}, for about 15 sec to maintain a steady state. Then, the circuit was changed by the mercury relay to give the GCT measurement.

Figure 7 shows an example of the oscilloscope trace obtained. Coexistence of ($C\text{-}O_L$) with ($C\text{-}O_H$) on the electrode pretreated at +1.0V is evident, and its reduction potential in this photograph agrees with Fig. 5. τ_H and τ_O are the transition times for adsorption of hydrogen atom and reduction of carbon oxide, respectively. The amount of charge, Q_O, for reduction of carbon oxides was represented as follows

$$Q_O = Q_{(C\text{-}O_L)} + Q_{(C\text{-}O_H)} = i_c\tau_O \quad [5]$$

If adsorption and desorption are electrochemical processes

$$Q = i_c\tau = nF\Gamma \quad [6]$$

where Γ is the amount of adsorption (moles/square centimeter), and Q the amount of charge (coulombs/square centimeter) (18, 19). Figure 8 shows that Q is independent of i_c. The Q's for the reduction of carbon oxide and for the adsorption of hydrogen depend much on the "set" potential, E_{st}.

The Q_O and Q_H on both GC and PG electrodes, as functions of E_{st}, are shown in Fig. 9. When E_{st} is less than +1.0V, Q_O and Q_H increase, and hence the oxide and hydrogen adatoms on the electrode both increase. The charges diminish suddenly at $E_{st} > +1.3V$, where ($C\text{-}O_L$) converts into ($C\text{-}O_H$) as described above. Since ($C\text{-}O_H$) is reduced hardly at all during cathodic polarization, its reduction potential shifts to less noble, and overlaps the peak for H_{ad}. These results agree well with Fig. 1-4. The oscilloscope trace from a noble potential is unsuitable for this discussion because τ_O and τ_H cannot be determined.

Adsorption of hydrogen atoms may take place at the active sites on the working electrode after O_{ad} leaves, and vice versa. The ratio Q_O/Q_H reaches about 2 at noble potentials as shown in Fig. 10, and hence all the surface would be covered by O_{ad}, this is, one adatom of oxygen would be bound with an active site on the carbon electrode as either ($C\text{-}O_L$) or ($C\text{-}O_H$). Since only higher oxide forms above +1.3V, complete reduction is difficult by cathodic polarization, thus it causes decrease in both Q_O and Q_H.

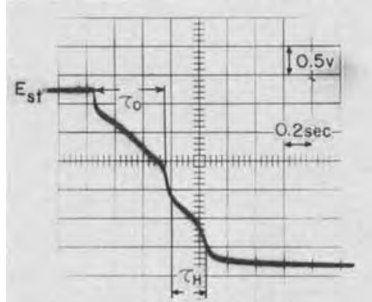

Fig. 7. Oscilloscope trace with glassy carbon electrode in 1M $HClO_4$. E_{st} = 1.0V *vs.* SCE. i_c = 10.5 mA/cm².

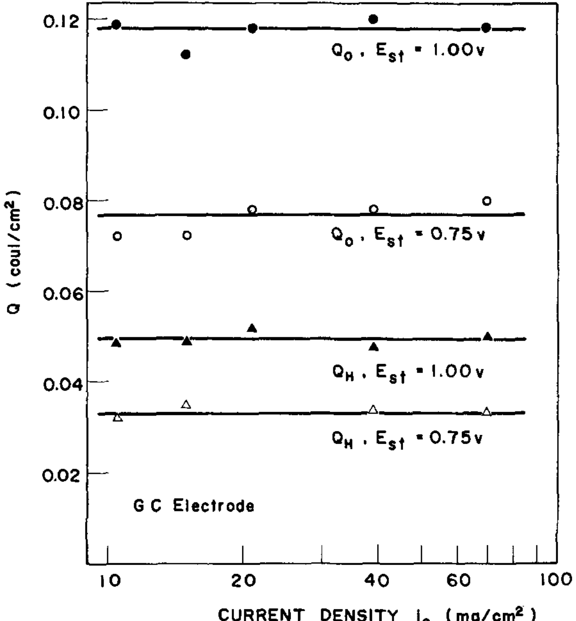

Fig. 8. Coulombs *vs.* current density. 1M $HClO_4$ at 50°C. Glassy carbon electrode.

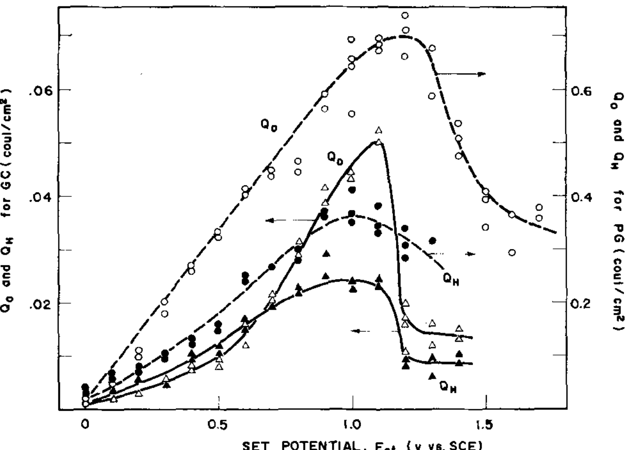

Fig. 9. Q_O and Q_H as functions of set potential. Solid lines, glassy carbon electrode; dotted lines, pyrolytic graphite electrode.

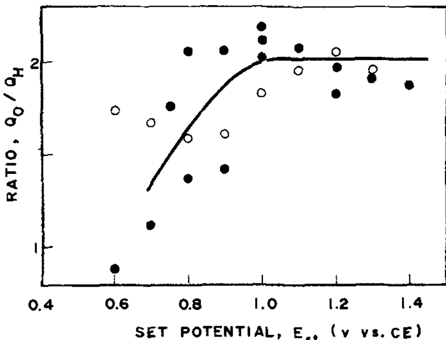

Fig. 10. Coulombs *vs.* set potential in 1M $HClO_4$ at 50°C. Solid points, glassy carbon electrode; open points, pyrolytic graphite electrode.

From Fig. 9, the maximum Q_O is 5×10^{-2} and 7×10^{-1} coulombs/cm² for the GC and PG electrodes, respectively. Therefore, the number of the active sites per unit area on PG electrode is about 14 times larger than for GC.

Since the electrode potential was scanned many times (sweep rate 200 mV/sec) until the polarization curve was stabilized, the working surface of the elec-

trode became rough. The roughness factor of GC electrode after such treatment was estimated to be about 200. It agrees with the SEM observation (20). It would be a major reason for the large coulombs/square centimeter described above.

Effect of Cl^- *on formation of carbon oxide.*—It is known that halide ions easily adsorb on the surface of noble metals such as Pt, if the potential is greater than the potential of zero charge (pzc). This disturbs formation of the oxide layer on the electrode surface to an extent that depends much on the electrode material, composition of solution, potential, and temperature (21, 22).

Examples of the potential sweep curves with a GC electrode in 1M $HClO_4$ containing HCl are shown in Fig. 11. The peak current for $(C\text{-}O_H)_{ad}$ at *ca.* +1.4V decreases with increase in the HCl concentration, the potential for Cl_2 evolution shifts toward the less noble and becomes less than the potentials for oxidic gas evolution (*i.e.*, O_2, CO, and CO_2). For the cathodic scan, the height of the peak for $(C\text{-}O_H)_{des}$ becomes lower with increase in the Cl^- concentration. The +0.5V peak appears on the cathodic scan if electrolysis is carried out for a long time at potentials higher than needed for chlorine evolution, in concentrated Cl^- solutions. The peak height is affected by agitation of solution. This peak represents the reduction of Cl_2 and it is controlled by diffusion.

Figure 12 shows Q *vs.* E_{st} in both 1M $HClO_4$ and a mixed solution (1M $HClO_4$ + 1M NaCl). Both Q_O and Q_H decrease with addition of Cl^- and depend on the Cl^- concentration (Fig. 13).

Chlorine electrode vs. oxygen electrode.—It is well known that when concentrated aqueous chloride solutions are electrolyzed, the main reaction at the anode is the evolution of chlorine gas. In a competitive reaction, some oxygen is also evolved. If the anode is some form of carbon or graphite, the oxidic gases are mainly CO_2, with some CO and O_2.

Figure 14 shows the potentiostatic polarization curves for PG anode in 1M $HClO_4$ (broken line) and in 1M $HClO_4$ + 3M NaCl (solid line). The oxygen electrode process has a Tafel slope of 210-240 mV/decade.

The chlorine electrode process with a fresh anode (cathodically reduced at −2.0V before the anodic polarization) shows a Tafel line with the slope of 135 mV/decade, but the curve deviates at noble potentials more than +1.3V, and the electrode potential tends to

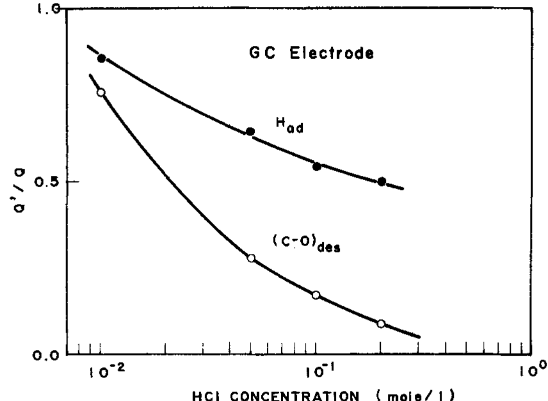

Fig. 13. Effect of Cl^- on amount of electricity for H_{ad} and $(C\text{-}O)_{des}$ in 1M $HClO_4$ at 50°C. E_{st} = 1.0V *vs.* calomel. Current density = 47.5 mA/cm². Q = coulombs in 1M $HClO_4$. Q' = coulombs in solutions containing Cl^-.

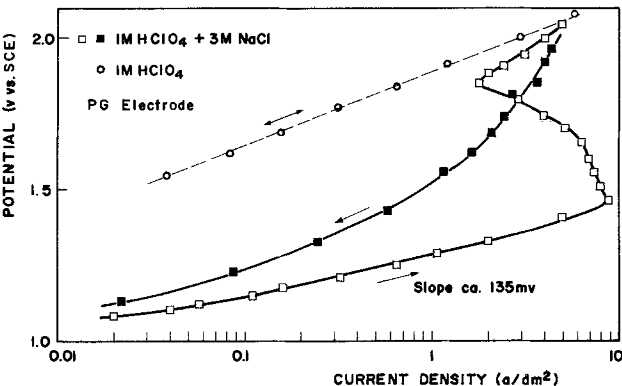

Fig. 14. Polarization curves of pyrolytic graphite anode at 50°C (potentiostatic method). Broken line shows the polarization curve of oxygen evolution reaction in 1M $HClO_4$.

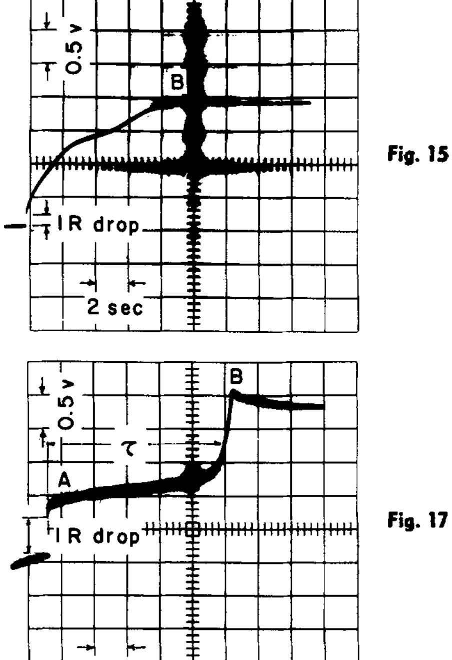
that of the oxygen electrode process. A large hysteresis of the polarization curve of PG and GC electrodes with increase and decrease of the current was obtained. On the other hand, a graphite anode (not shown) did not show such a phenomenon, but the Tafel slope was larger than the predicted value ($2RT/F$). A large area of porous surface of graphite anode would be a reason.

Figures 15-17 are the oscilloscope traces obtained by the GAT method. In $HClO_4$ (Fig. 15), charge-up of the double layer capacity is followed by charge-up of the pseudocapacitance due to formation of carbon oxide layer as well as oxidation of H_{ad}, then the plateau for the over-all oxygen electrode process (B)



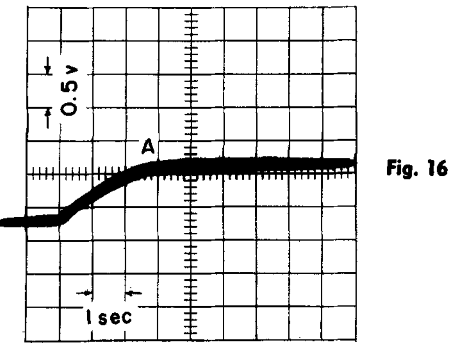


Fig. 15-17. Galvanostatic anodic transient curves

Fig. No.	Electrode	Current density (mA/cm^2)	Solution

17	GC	200	1M $HClO_4$ + 5M NaCl

Center line = 0.5V *vs.* SCE. Temperature = 50°C.

appears. In solutions containing Cl^-, the potential plateau for the chlorine electrode (A) appears after charge-up of the double layer capacitance and the pseudocapacitance due to oxidation of H_{ad} and formation of Cl_{ad}. At low current densities, only plateau A appeared (Fig. 16), but plateau B was observed after few seconds at high current densities (Fig. 17).

The transition time, τ, depends on agitation of the electrolyte, thus the process at high current densities would be controlled by diffusion of Cl^-. The log i *vs.* log τ curves are straight with a slope of *ca.* −0.5 at high current densities (Fig. 18). Figure 19 shows the polarization curves of the GC electrode obtained by points A and B in Fig. 16 and 17. Only oxygen evolution takes place in $HClO_4$ containing a small amount of Cl^- (*e.g.*, less than 0.1M), but the chlorine evolution reaction takes place easily in concentrated Cl^- solutions, at relatively low current densities. It is also important that the potential for the over-all oxygen electrode process in concentrated Cl^- solution is noble in comparison with that in $HClO_4$. Similar results with PG and graphite anode have also been obtained.

Discussion

Evolution of mixed gas containing O_2, CO, and CO_2 may take place at the surface of carbon and/or graphite anode in solutions free of halide ions (13, 14). While the mechanism of formation of these gaseous substances has not been clarified yet in detail, the intermediate, probably carbon oxide or adatom of oxygen, may form on the electrode surface in aqueous solutions through the anodic charge transfer of H_2O or OH^- prior to gas evolution (14, 23, 24).

Two peaks at *ca.* +0.5V for (C-O_L) and +1.4V for (C-O_H) are observed in 1M $HClO_4$. The surface of the working electrode becomes exceedingly rough when potential scanning is repeated at noble potentials such as +1.7V. Thus, we suppose that CO and/or CO_2 may form at high potentials through the higher oxide (C-O_H). On the contrary, the strength of the bond between C- and O-atoms as the lower oxide (C-O_L) would be weak, because the process of adsorption and desorption is relatively reversible. Therefore, oxygen adatoms can be reduced cathodically.

(C-O_L) converts into (C-O_H) at noble potentials more than +1.3V, and (C-O_H) is hardly reduced by cathodic polarization.

The ratio Q_O/Q_H tends to 2 at noble potentials. It becomes larger than 2 if the anode is polarized at high potentials for several minutes instead of few seconds, probably due to penetration of oxide in the porous surface. It can be recognized that the adsorption and de-

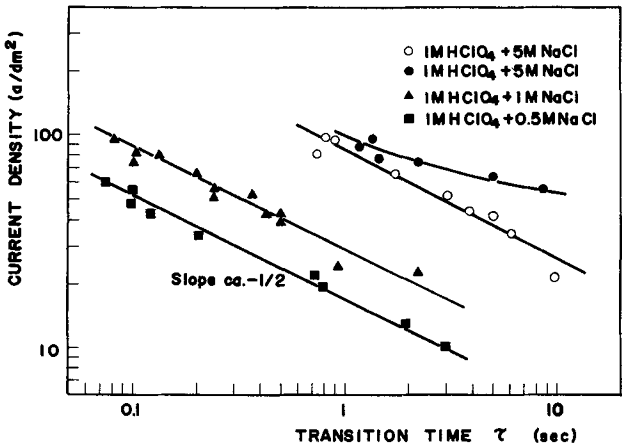

Fig. 18. Current density *vs.* transition time curves at 50°C. Open circle, glassy carbon electrode; solid symbols, pyrolytic graphite electrode.

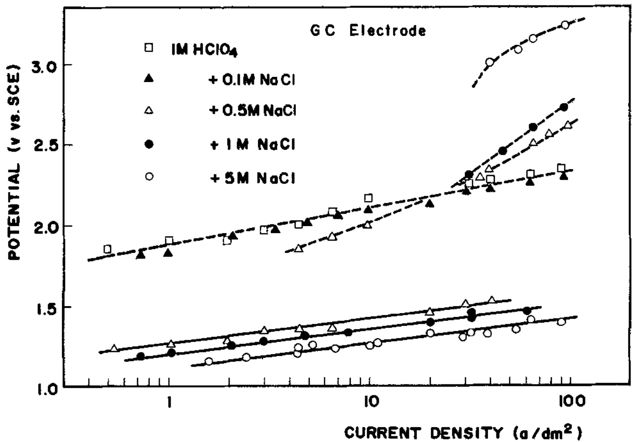

Fig. 19. Polarization curves of glassy carbon anode by means of the galvanostatic anodic transient method at 50°C. Solid line, chlorine electrode process; broken line, over-all anodic (oxygen) process.

sorption of H-adatom and the formation and reduction of carbon oxide take place at the active sites on the electrode by the following processes

$$C - H_{ad} \rightleftarrows C + H^+ + e \quad [7]$$

$$C + H_2O \rightleftarrows (C\text{-}O_L) + 2H^+ + 2e \quad [8]$$

$$C + H_2O \rightleftarrows (C\text{-}O_H) + 2H^+ + 2e \quad [9]$$

and

$$(C\text{-}O_L) \rightarrow (C\text{-}O_H) \text{ at more than } +1.3V \quad [10]$$

The differential capacitance of the double layer on the GC electrode by the galvanostatic method is about 3.8 mF/cm^2, thus the roughness factor is estimated to be about 200. With the assumption of existence of *ca.* 10^{15} atoms of carbon for 1 cm^2 of the true surface (25), the amount of electric charge per unit area for adsorption of hydrogen atom with carbon is calculated to be

$$(10^{15}\,\mathbf{F}/6 \times 10^{23})\,(2 \times 10^2) = ca.\ 33 \text{ mcoulombs/cm}^2$$

and it is in good agreement with the maximum value of Q_H in Fig. 9 (*ca.* 25 mcoulombs/cm^2).

An unstable oxide layer of carbon which can be reduced at the potential of few millivolts more noble than of hydrogen evolution is called the "oxidic layer," and is clearly divided from the "oxide layer" which is stable at the same potential (3, 5, 6).

We suppose that so-called "lower oxide" may correspond to the "oxidic layer," on the other hand, the "higher oxide" would be the "oxide layer." These two oxides are stable in solutions free of any reducing agent. They form on the electrode surface immersed in solutions for a long time. The oxide layer can be reduced easily by HCOOH and hydrogen. But any specific profile does not appear on the open-circuit potential *vs.* time curve obtained in solutions containing reducing agent, and its mechanism is not discussed.

The oxide layer of the electrode formed in solutions containing chloride ions reduces exceedingly slowly, and the exchange process between adatoms of oxygen and chlorine is very irreversible with respect to the electrode potential. Displacement of the higher oxide *in situ* on the carbon electrode would be difficult. The higher oxide is displaced as CO and/or CO_2 at potentials of +2.5V and then chlorine adatoms can form.

The specific adsorption of Cl^- can take place at noble potential above the potential of zero charge, if the surface oxide does not already exist on the electrode. The pzc for carbon electrode varies from −0.13 to +0.25V *vs.* SHE depending on electrolyte and other conditions (26). The differential capacitance on the stress-annealed PG in NaF solution (*p*H *ca.* 6) has the minimum at *ca.* 0V *vs.* SHE (27).

Therefore, formation of the surface oxide is a squeeze process on the carbon electrode occupied already by chlorine. Transition from chlorine evolution to the over-all oxygen electrode process occurs in acidic solution containing Cl^- at high current densities, but in alkaline solution the opposite transition (from oxygen to chlorine) takes place (17). The chlorine electrode and the over-all oxygen electrode processes in acidic solution are independent of *p*H (14, 23, 24). But the oxygen electrode process is affected by *p*H in alkaline solution. The chlorine electrode process is still independent of *p*H in this range.

The plateau A in Fig. 16 and 17 is the chlorine electrode potential because the oxide does not exist yet on the electrode. The Tafel slope of the polarization curve for the chlorine electrode process is 130-150 mV/decade (Fig. 19) and the reaction order with respect to Cl^- is about unity (Fig. 20).

The "super polarization" phenomena (28) is found after plateau A, then the second plateau B appears (Fig. 17). The slope of the log i *vs.* log τ curve is about −0.5 (Fig. 18). Therefore, the process would be controlled by diffusion (29). For the diffusion controlled

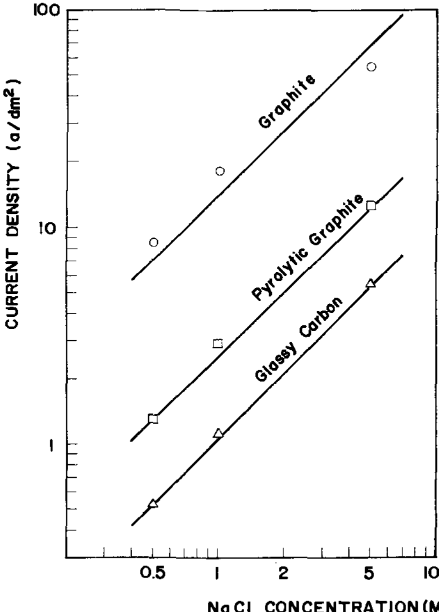

Fig. 20. Current density *vs.* Cl^- concentration curves at 1.2V *vs.* SCE.

process

$$i\sqrt{\tau} = n\mathbf{F}\,C^o\sqrt{\pi D}/2 \quad [11]$$

where C^o is the concentration in the bulk of solution. The Cl^- concentration near the electrode decreases with increase in time after switch-on due to slow diffusion. The chlorine overvoltage and the formation of the oxide layer on the PG and GC electrodes increase. Any slow diffusion process is not observed up to 100 A/dm^2 of the superficial current density on the graphite anode because of its rough surface.

The Tafel slope of the polarization curve for the over-all oxygen electrode process in 1M $HClO_4$ is 210-240 mV/decade and is independent of the anode material and the method of polarization measurement. It agrees with reference data obtained in the phosphate buffer solution (14, 24). The potential for the over-all oxygen electrode process in the solution containing Cl^- is significantly noble compared to that in $HClO_4$, probably due to preferential adsorption of Cl on the working electrode.

The PG electrode polarized in a concentrated NaCl solution shows the Tafel line with the slope of *ca.* 135 mV/decade (Fig. 14), because the anode surface under the steady-state polarization is covered by a small amount of the lower oxide at the potential range not exceeding +1.3V, and the chlorine electrode process takes place sufficiently. At more noble potentials, on the other hand, all the surface would be covered by the higher oxide, and hence the potential moves to that for the over-all oxygen electrode process. Since its surface oxide is removed slowly with decrease in the polarizing current, the potential comes down with a large hysteresis.

The rate of the chlorine electrode process is represented as follows

$$i = k(Cl^-)\exp(\alpha\mathbf{F}E/RT) \quad [12]$$

where i is the apparent current density, k the rate constant, and α the transfer coefficient. When the active sites for the chlorine electrode process are covered by surface oxide, Eq. [12] should be corrected (30)

$$i' = k(Cl^-)\,(1 - \theta_o)\exp(\alpha\mathbf{F}E/RT)\exp(-(1-\alpha)f\theta_o) \quad [13]$$

where i' is the current density at the covered surface, θ_o is the coverage, and fRT is "Temkin's parameter." From Eq. [12] and [13]

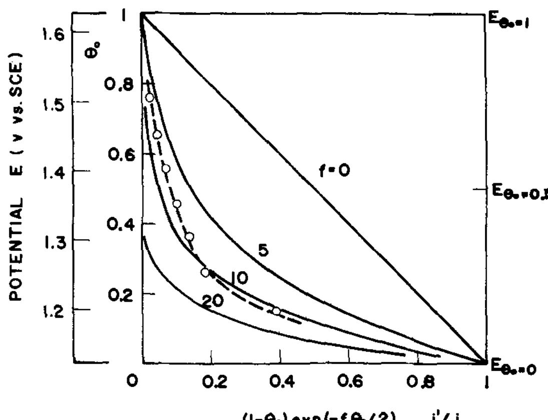

Fig. 21. θ_0 vs. $(1-\theta_0)\cdot\exp(-f\theta_0/2)$ curves. Broken line, E vs. (i'/i) under assumption of $\theta_0 \sim E$.

$$i'/i = (1-\theta_0)\exp(-f\theta_0/2) \quad [14]$$

We assume that the line with the closed points in Fig. 14 shows the E vs. i', whereas the straight line with the open points represents the E vs. i curve. Since θ_0 is a function of E, i'/i varies with E as shown by the dotted line in Fig. 21, which is evaluated from Fig. 14.

Suppose that θ_0 is a linear function of E in a small range of potential, and $E_{\theta_0=1} = 1.62V$ and $E_{\theta_0=0} = 1.125V$. Figure 21 also shows θ_0 vs. i'/i curves under given f's (solid lines). Note that f is positive, thus, it is considered that the apparent activation energy of the chlorine electrode process increases with θ_0 and/or E with formation of the surface oxide, and mutual retardation between O_{ad} and Cl_{ad} may occur. This will be described in detail in a separate paper (17).

Acknowledgment

This work has been conducted as a part of the PhD thesis of M. Yasuda, at Kyoto University. Graphite and carbon were supplied by Nippon Carbon Company, Tokyo, and Tokai Denkyoku Manufacturing Company, Nagoya. The authors wish to express many thanks for support of Olin Corporation, New Haven, Connecticut. We also thank Dr. W. C. Gardiner, Stratford, Connecticut, Dr. R. B. MacMullin, R. B. MacMullin Associates, Niagara Falls, New York, and Dr. H. Kita of Hokkaido University for their kind suggestions and advice.

Manuscript submitted Aug. 30, 1973; revised manuscript received Dec. 26, 1973.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1974 JOURNAL. All discussions for the December 1974 Discussion Section should be submitted by Aug. 1, 1974.

ABSTRACT

Transport modes were determined from examinations of morphology for electrochemical oxidation and reduction within electrodes consisting of beds of silver spheres 37.2 μm in diameter in 1*N* KCl and subjected to 5.0 mA cm^{-2} applied current density. Oxidation proceeded via silver dissolution, probably at dislocation sites, followed by diffusion and, then, deposition of AgCl in characteristic, bulbed mounds which grow together to form layers of approximately uniform thickness. AgCl film thickness, for the case of partially covered underlying silver, was about 3500Å and distance from silver dissolution pits to AgCl deposition sites was found to be increased from 4,000 to 40,000Å as the local transfer current density became larger within the sphere bed. Reduction of anodically formed AgCl on partially covered silver proceeded by an opposite path: solution and diffusion of AgCl, and deposition of silver on preferred sites of surrounding bare silver surface.

The mechanism of AgCl formation and reduction at silver electrodes in KCl electrolyte has been the subject of numerous publications (1-9). The work of Jaenicke *et al.* did much to clarify modes of reduction in thick films of AgCl, and Briggs and Thirsk (2) contributed valuable evidence which clarified the anodic growth of films thicker than 1-2 μm. Little has been done, however, to gain an understanding of the mechanism of growth and reduction of AgCl that partially covers silver surfaces before films of AgCl start to become appreciably thick.

Thin films of silver chloride, which partially cover the surface of an underlying silver substrate, were first studied by Kurtz (3) who observed anodic growth of patches of AgCl with an optical microscope and noted that complete surface coverage appeared after passage of some 8 mA min cm^{-2} in 0.1*N* KCl. More recently, Giles (4) suggested that anodic growth of the AgCl phase proceeds by progressive nucleation of three-dimensional centers of unspecified geometry and that diffusion contributes to the over-all processes. In our previous communication (5), we indicated that the reduction mechanism occurs via solution diffusion and surface diffusion to growth sites on the silver surface and that AgCl dissolution becomes rate limiting when silver chloride crystallites become small. Although these studies have contributed to establishing the over-all mechanisms involved, they have not presented a clear connection between the electrochemical reactions and the morphological changes. Direct observations of the type of Kurtz (3) were needed to elucidate the phenomenon of film formation and growth if critical distances required by modeling theory were to be determined experimentally (10, 11).

Recent theoretical work has shown that many secondary electrodes, including the Ag/AgCl electrode, may be described by a "solution-diffusion" model consisting of a set of elementary processes occurring in series (10, 11). To apply such theories it is necessary to establish the effects of surface morphology on electrode performance through isolation of morphologically dependent, rate-determining steps from among a series of elementary steps and associated changes as the electrode undergoes discharge or charge.

A direct approach was used in this work by employing a scanning electron microscope to examine inner surfaces of a porous silver electrode structure after anodic and cathodic treatment. The electrode consisted of a bed of loose silver spheres so that it could be dismantled easily and the spheres examined individually after charging and discharging. The spheres were all the same size so that local current densities and associated morphological transformations could be related to depth within the sectioned electrode. This technique extends the usefulness of scanning electron microscopy (SEM) which has recently become popular in electrode studies (12-16).

Experimental

Electrode construction and structure.—The porous electrode used in this investigation is shown in Fig. 1. It was constructed in the following manner. A disk-shaped silver stage, 1.41 cm in diameter and 0.30 cm in thickness, was slip-fitted inside a truncated, 10 cm^3, tubular, hypodermic syringe housing. A silver strip, spot-welded to the stage and passing through a rubber gasket below the stage, served as the electrical connection to the external circuit. A bed of silver spheres, 37.2 $\pm$ 4.2 μm in diameter, was placed on top of the stage, completing construction of the porous structure. Specific resistance of these beds was measured as *ca.* 1.0 ohm-cm. A micrometer shaft attached to the stage permitted microtoming of the porous structure into sections with an accuracy of $\pm$0.0005 cm.

External circuit of electrolytic cell.—An Electronics Model C 612 galvanostat was used to control the im-

Electrochemical Society Active Member.
Key words: surface morphology, silver/silver chloride electrode, anodic oxidation of silver.

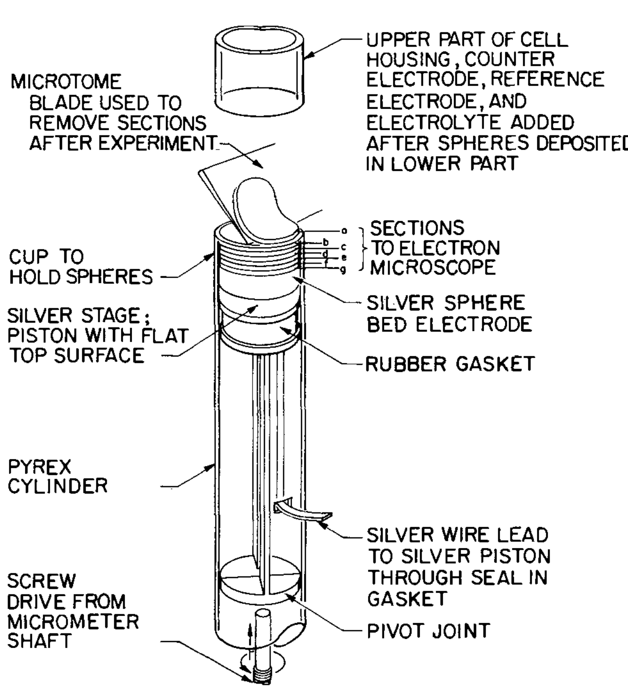

Fig. 1. View of the sphere bed electrode assemblage. (Section a, 0.0050 cm thick; subsequent sections, 0.0100 cm thick.)

posed current, which was measured with a Greibach Model 500 milliammeter. The electrode potential *vs.* that of an Ag/AgCl reference electrode, 4 cm above the bed, was recorded continuously using a Sargent MR recorder.

The electrolytic cell consisted of two parts as indicated in Fig. 1. The lower part contained the porous electrode and the upper part housed the counter and reference electrodes. These parts were joined together in a flush fit using Teflon pipe-thread sealant tape wrapped around both parts. The counterelectrode consisted of a porous silver matrix which was charged in a separate cell containing 1*N* KCl to form AgCl in excess of the expected total coulombs passed. The electrolyte was 1*N* KCl dissolved in triply distilled water which was deaerated prior to assembly.

Experimental procedure.—Prior to assembly of the working electrode, the silver spheres were immersed in concentrated ammonium hydroxide solution, rinsed thoroughly in distilled water, and air dried at 105°C for about 30 min. Just before use, the silver spheres were placed in 1*N* KCl and added as a slurry with a spatula onto the lowered stage to form the experimental structure that comprised the electrode. After filling, the silver stage was raised until the spheres protruded above the flat-cut edge of the tubular glass housing, and the excess was sliced off with the straight edge of a large stainless steel spatula. After a bed thickness of 1.00 cm was secured, assembly of the electrolytic cell was completed by attaching the upper part of the cell, placing the counter and reference electrodes, and adding electrolyte slowly so as not to disturb the sphere bed.

Upon completion of a prescribed mode of charging and discharging at room temperature (23° ± 1°C) the electrolyte was removed from the cell with the aid of a small diameter Teflon tube, and the upper part of the cell was detached. The electrode sections were removed (microtoming) and, after being washed in distilled water and air dried at 105°C for about 20 min, were examined using electron scan microscopy. The first section removed was 0.0050 cm thick, and all subsequent sections were 0.0100 cm.

Surface morphology was examined using a Cambridge Stereoscan Model Mark II. For the given results, electrodes were either charged for 11.0 min or charged for 11.0 min and then discharged for 4.0 min, all at rates of 5.0 mA cm^{-2} applied current density, *i.e.*, experiments were conducted galvanostatically. Polarization during these cycles was between 2 and 10 mV, measured with respect to the frontal surface.

Properties of spheres constituting sphere-bed electrode.—Regularity in sphere size and shape can be seen from the hundreds of silver spheres shown in Fig. 2. About 20 million of such spheres are estimated to constitute the electrode 1 cm thick, assuming 39% porosity. The uniformity shown here serves to confirm consistent sphere-module surface area throughout each sliced section of the electrode. Changes in surface morphology can thus be interpreted in terms of perpendicular distance of any parallel planar section from the bed's frontal plane without the usual unknown variations in specific surface area which obscure overall relations between morphology and perpendicular distance when microscopic examinations are made at high magnifications.

Additionally, each sphere has good sphericity and appears to have no appreciable surface roughness, aside from naturally occurring grain boundaries, even when viewed at 10,000X. A typical sphere is shown in Fig. 3; deviations from this general shape accounted for less than 1% of the particles. Spheres are prepared commercially by air quenching of atomized liquid silver of 99.9% purity, so that a degree of surface smoothness can develop before the droplets solidify.[1]

Average sphere diameter was determined to be 37.2 μm with an average deviation of ±4.2 μm.

After the single anodizing of the spheres and the cycle of anodizing and subsequent cathodizing, an exploratory series of scanning electron microscope (SEM) photographs were made of sections taken from the electrode. Representative photographs of this series taken from the single charging and the cycle of charge with about one-quarter discharge are shown in Fig. 3-10a and 10b-12, respectively. In these photographs, silver chloride appears as a white growth upon the darker silver surface.

Decomposition of the AgCl deposit takes place in the electron microscope if observations are longer than about 15 min at 20 kV or 60 min at 10 kV. The smooth,

[1] Spheres were purchased from Metz Refining Company, South Plainfield, New Jersey.

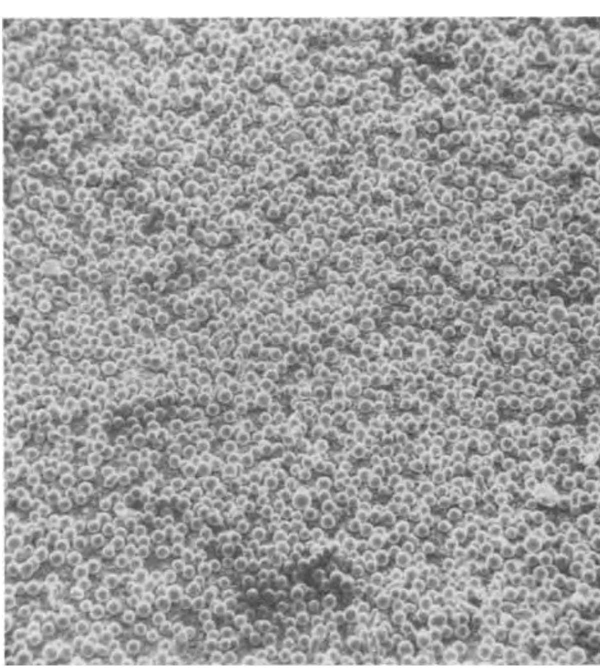

Fig. 2. Electrode structure, silver spheres 37 μm in diameter

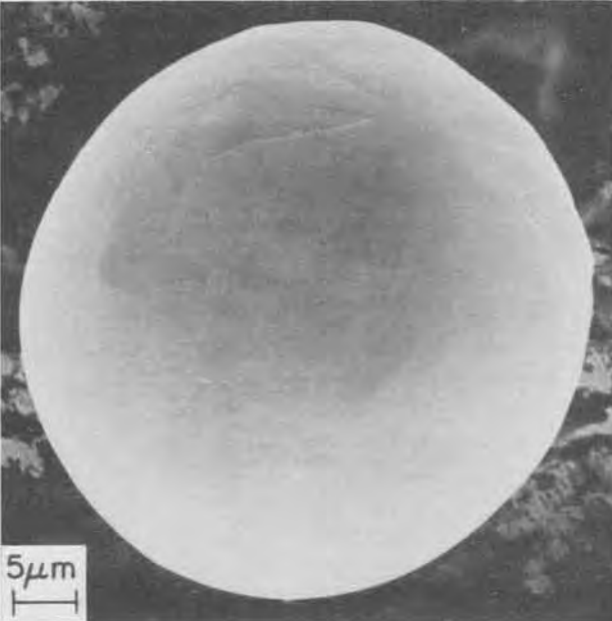

Fig. 3. Typical silver sphere used in the electrode assemblage

white AgCl is then observed to be gradually converted into a dark spongy mass which could only be metallic silver formed by a disproportionating reaction, initiated by the electron beam, $E(e^-)$.

$$AgCl + E(e^-) \rightarrow Ag + Cl \quad [1]$$

This spongy Ag deposit should not be confused with the Ag formed by the electrochemical reduction of AgCl. The disproportionation is easily avoided by limiting SEM observations to 10 min or less.

Results

Representative photographs, selected from the over one hundred viewed, are shown in Fig. 3-12. The first series, Fig. 3-10a, illustrates changes in surface coverage and morphology upon charging the sphere bed electrode for 11 min at a rate corresponding to an applied current density of 5.0 mA cm^{-2}. Figures 10b-12 are assembled to illustrate the effect of subsequent discharge at the same applied current density for a period of 4.0 min.

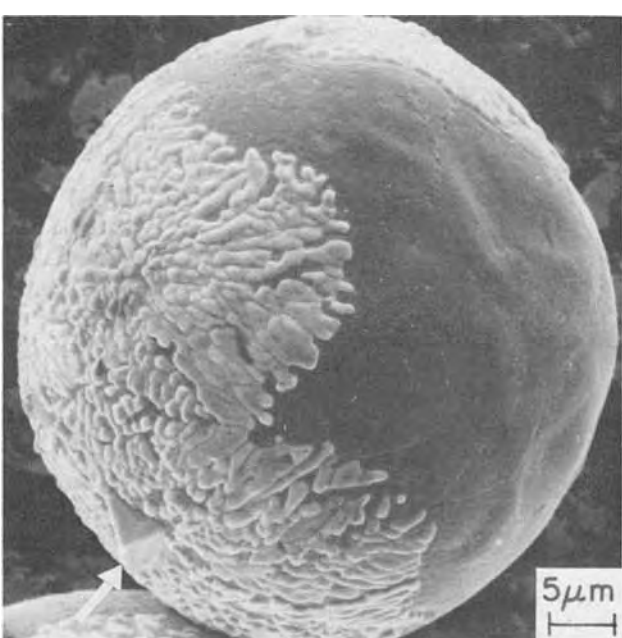

Fig. 4. Silver sphere with partially reacted surface, taken at a depth of 0.035 cm. Rare appearance of well-defined crystal planes (arrow).

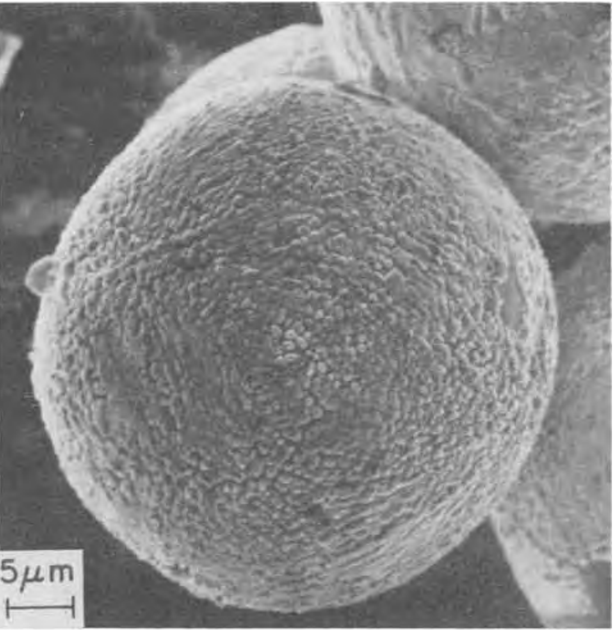

Fig. 5. Silver sphere with nearly totally reacted surface, taken at the electrode's front surface.

Reaction profile.—After anodizing, surface coverage by AgCl was observed to be increased for spheres taken from sections closer to the electrode/bulk-electrolyte interface, *i.e.*, closer to the frontal plane of the electrode. For example, surface coverage of spheres by AgCl was less than 10% in the seventh section taken 0.065 cm from the frontal plane, 30% in the fourth section 0.035 cm from the front, and it increased to 90-95% in the first section (0.005 cm thick). The reaction zone penetrated to a depth of approximately 0.07 cm, as evidenced by the disappearance of substantial amounts of AgCl at depths greater than 0.065 cm in the remainder of the electrode. Figures 3-5 show typical spheres taken from a depth greater than 0.065 cm, from the fourth and first sections, respectively. The manner of change in coverage by AgCl is seen by comparing these figures.

Morphology of AgCl growth.—The AgCl deposits appear without manifestations of crystal planes, ex-

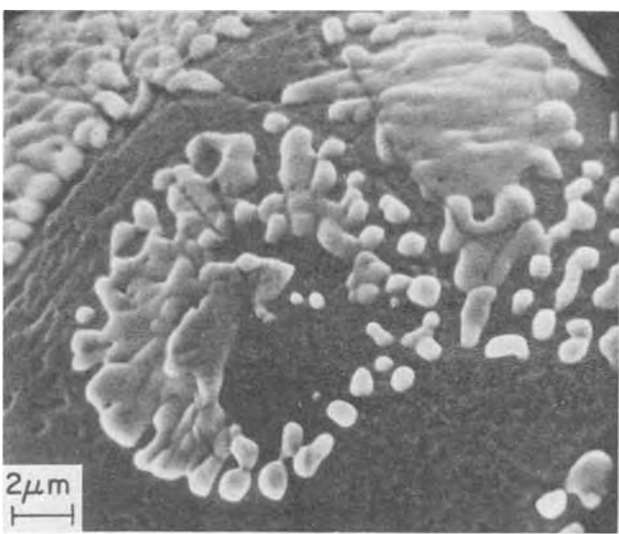

Fig. 6. Example of AgCl growth at a depth of 0.015 cm

Fig. 7. Glancing view, note the characteristic overhang

hibiting rounded, smooth surfaces (Fig. 4 and 5). Occasional exceptions are seen as in the lower left part of the sphere in Fig. 4 where a cubic crystal has formed. Only three such AgCl crystallites were observed in examinations of hundreds of spheres in the photographs for the given conditions.

A change in the form of the AgCl deposit occurs along the electrode's thickness. In the electrode, at depths greater than about 0.025 cm, the AgCl coating is more continuous, sometimes branchlike in appearance, and usually with interconnection of branches. The over-all breadth of continuity of the deposit then depends on the surface area covered, and this breadth may extend to at least 60 μm, half or more of the sphere's circumference as shown in Fig. 4. Toward the front, the AgCl assumes the form of relatively small, discrete bulbed mounds, each about 7000Å in effective diameter, as shown in Fig. 5. The surface density of the AgCl mounds is then 1.1×10^8 mounds cm^{-2}. A gradual transition from the continuous form to the bulbed form is noted in the sphere bed as samples are taken toward the frontal plane. In Fig. 6, bulbed mounds were formed along with the continuous patches of film at a 0.015 cm depth within the electrode, showing an intermixing frequently seen at this depth.

Glancing views of the AgCl layers showed that the thickness remained fairly constant, always less than about 5000Å, and the AgCl deposits usually formed an overhanging structure at their perimeter as shown in Fig. 7. The extent of overhang of the upper portions of the AgCl deposit beyond the lower AgCl/Ag perimeter varied, being always less by about 1000Å.

Morphology of pit growth.—Holes or pits could be seen in the silver after anodic treatment at a surface density of about 1.0×10^8 pits cm^{-2}. Their surface density remained fairly constant, increasing somewhat at silver grain boundaries (*e.g.*, see upper part of sphere, Fig. 4) and tended to decrease sharply beyond zones of pitting on the surface which surrounds the AgCl layers (*e.g.*, see Fig. 8a). The area adjacent to the AgCl layer marked with pits extended farther from the deposit in sections taken closer to the electrode's frontal surface. The observed variation in this extension of pitting is 4,000-40,000Å. Consequently, the bare silver patches, less than about 10,000Å across, were pitted uniformly throughout at depths less than 0.005 cm measured from the front of the electrode. Characteristically, pits were angular in shape; sometimes perfect triangles were observed. The pits were typically 3000Å across, on the average, but varied in size from 1000 up to 6000Å.

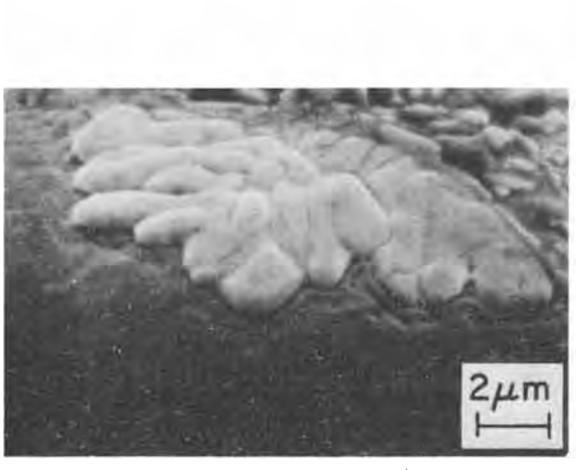
Exploratory examinations were made at high magnification (10,000X) of very low AgCl coverage to locate the inception of the anodic processes. Then the pits were more rounded, sometimes circular, and usually smaller, *ca.* 2000Å or less across (Fig. 9). Together with these pits, small deposits of AgCl could be seen around the mouths of the pits and as irregular deposits nearby, varying in average over-all size from 1000 to 8000Å across. The surface densities of the initially formed silver chloride deposits and pits were determined as 1.1×10^8 and 1.0×10^8 cm^{-2}, respectively, remaining independent of depth into the sphere bed.

Morphology of AgCl reduction.—The morphology of AgCl reduction was examined after a partial, rather than complete, reduction of the anodically produced films had taken place. This was done to identify the progress of reduction and to describe the cathodic process. The respective times of anodic and cathodic processes at 5 mA cm^{-2} were 11 and 4 min.

After the partial electrochemical reduction of the AgCl coatings, no darkening or structural change in the AgCl was found as evidence for metallic silver formation in the remaining AgCl layer as observed after the electron beam disproportionation in the SEM. Instead, a trend toward the formation of isolated AgCl mounds could be discerned, and a "smoothing out" of the sharp, angular edges of the pits occurred (*e.g.*, compare Fig. 10a and 10b).

Glancing views of the AgCl deposits indicated a general loss of overhang or loss of undercutting of the amorphous AgCl. A typical view after partial reduction is shown in Fig. 11. Figures 7 and 11 may be compared for the appearance before and after cathodic treatment of the anodically formed AgCl, respectively.

Spheres taken from the same section depth, before and after cathodic treatment, revealed that the extent of the area covered with pits around each AgCl deposit increased after the cathodic process. Figures 8a



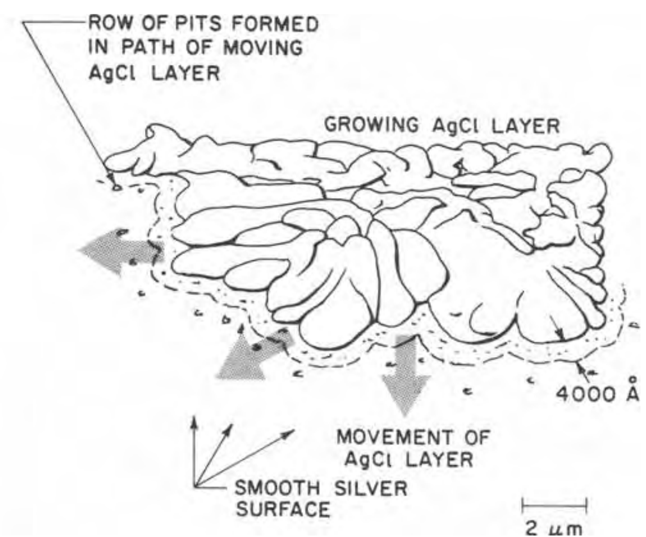


Fig. 8. Location of pits with respect to advancing silver chloride deposit. a (left), SEM photograph; b (right), graphical representation

and 12a, for example, can be directly compared to show this effect. Here, for a depth of 0.065 cm into the sphere bed, *i.e.*, for the seventh section, the zone of pitting was extended from 4,000 to 14,000Å after the 4 min treatment at a galvanostatically held 5 mA cm^{-2} external current density.

Discussion

Anodic process.—The appearance of pits in the silver with AgCl mounds nearby indicates that silver is transported from the pits to AgCl sites where it deposits as AgCl. No other morphological change on the surface is evident that could account for this displacement. Silver could not be appreciably lost to bulk

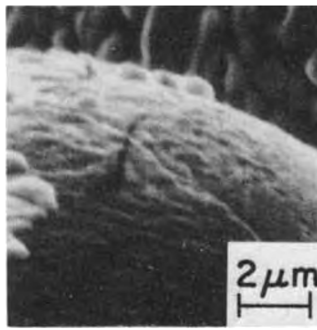

Fig. 11. Glancing view showing clearing of overhang (cf. Fig. 7)

solution; complete coulombic reversibility of porous Ag/AgCl electrodes was repeatedly obtained for the given conditions. The volume of AgCl deposited appears to be larger than the pit volume in accord with the ratio of the respective molar volumes, 2.51 to 1.

Transport of silver is believed to involve bulk diffusion. The known soluble species have the formula $AgCl_{n+1}^{-n}$, $0 \leq n \leq 3$ (17), which are in mutual equilibrium in aqueous KCl solutions and which can be precursors to AgCl nucleation and subsequent precipitation. For silver dissolution to occur, silver must first be oxidized to a stable, singly charged state, and then the necessary chloride ions must combine with Ag^+, forming species of the type $AgCl_{n+1}^{-n}$.

The nearly constant thickness of the AgCl layers suggests that AgCl growth occurs along growing edges of the layers. This concurs with the concept of $AgCl_{n+1}^{-n}$ transport from the dissolution pits around the layers. Deposition of AgCl from $AgCl_{n+1}^{-n}$ species would take place primarily at AgCl which is closest to the dissolution pits.

Typical overhang of AgCl shown in Fig. 7 indicates that $AgCl_{n+1}^{-n}$ species arrive from bulk solution from above the silver surface at the edge of the AgCl. This is the strongest evidence for bulk diffusion offered here. For both surface diffusion, acting exclusively, and ion transport through the AgCl product, there should be no overhang of AgCl. For bulk diffusion, a lag in growth or retardation at the three-phase junction is anticipated in view of relative difficulties in nucleation of AgCl at the silver surface compared to the AgCl surface. The observations above are in accord with those of Giles (4) who used an independent method to postulate the existence of an intermediate diffusion transport step to a growing AgCl edge.

On the basis of these observations the anodic processes are summarized as follows

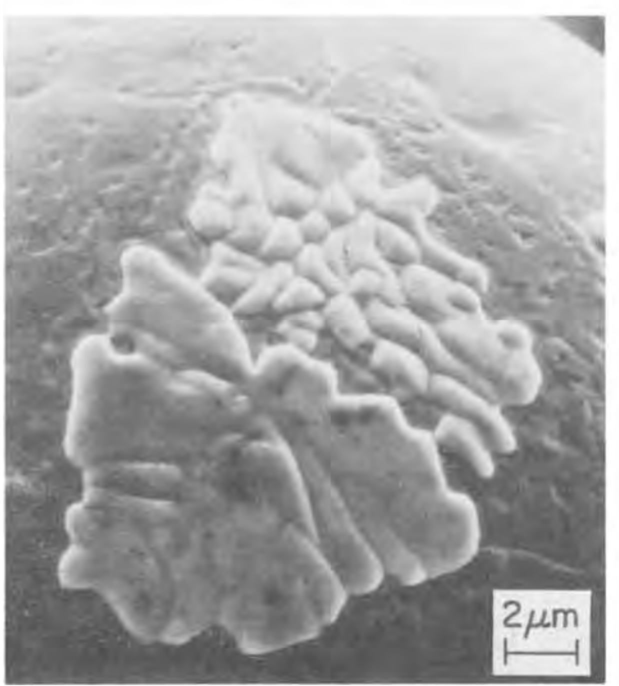
$$Ag \rightarrow Ag^+ + e^- \quad \text{(dissolution)} \quad [2]$$

$$Ag^+ + (n+1)Cl^- \rightarrow AgCl_{n+1}^{-n} \quad \text{(complex formation)} \quad [3]$$

$$AgCl_{n+1}^{-n}\,(a) \rightarrow AgCl_{n+1}^{-n}\,(b) \quad \text{(solution transport)} \quad [4]$$

$$AgCl_{n+1}^{-n} \rightarrow AgCl(s) + nCl^- \quad \text{(deposition and growth)} \quad [5]$$

Other steps, such as embryo and swarm formation (18), are considered irrelevant to the present discussion and have been omitted. Transport of the silver bearing species is represented by Eq. [4] which is believed to constitute the principal characteristics of the anodic process. No evidence for surface diffusion could be found although its existence cannot be ruled out because of limitations of the technique used here. The relative concentrations of silver-bearing species in mutual equilibrium have been calculated for 1*N* KCl (5) and would be expected to change somewhat



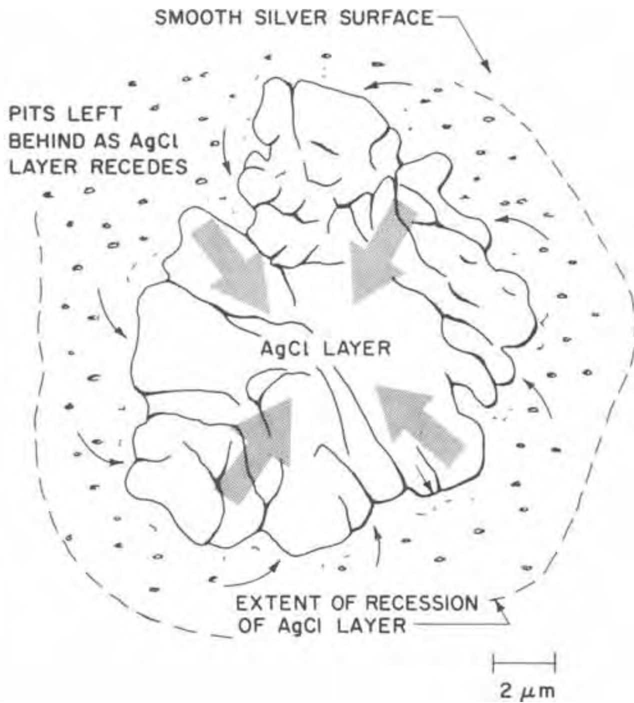


Fig. 12. Location of pits with respect to receding silver chloride deposit. a (left), SEM photograph; b (right), graphical representation

during transport to accommodate driving concentration gradients. Equilibrium constants for equilibrium between the species are established (17).

Cathodic process.—The absence of darkening, porosity, or structural change in layers of AgCl after partial electrochemical reduction suggests a corresponding absence of extensive cathodic reduction within the AgCl. On the other hand, the typical change everywhere in pit shape by smoothing and buildup on the previously sharp edges shows that deposition by reduction of silver species occurred at some distance from the AgCl. A transport of silver from AgCl to the surrounding surface is thus strongly indicated. This mode also has been given as the interpretation of potentiostatic current-time curves obtained during reduction of AgCl films in an earlier study by the present authors (5).

The increase in extension of the zone containing the pits surrounding the AgCl layers occurs when pits previously covered by the AgCl layers are exposed. This process is shown in Fig. 12a and 12b; AgCl located along the perimeter is being preferentially removed where the adjacent bare-silver surface is depleting the dissolved species. The typical disappearance of the overhanging AgCl upon reduction (Fig. 11) shows that dissolution occurs with transport toward the bulk region of the electrolyte. Other steps tend to increase the extent of overhang. For example, if dissolution was immediately followed by surface diffusion away from the AgCl along the silver surface, the AgCl would be preferentially dissolved at the three-phase junction. Similarly, if direct reduction of solid AgCl took place at the three-phase junction, the overhang would increase.

Examinations of the bare-silver surface indicate areas of silver deposition at small nodules and at the edges of the pits (Fig. 10b). Apparently, electroreduction of $AgCl_{n+1}^{-n}$ occurs at preferred sites removed by some distance from the dissolution sites in accord with theory (18). The solubility of AgCl is increased by complexing from *ca.* 10^{-5} to 10^{-4}M in the presence of 1*N* KCl (20).

The above leads to the following set of events comprising the reduction process

$$nCl^- + AgCl(s) \rightarrow AgCl_{n+1}^{-n} \quad \text{(dissolution and complex formation)} \quad [6]$$

$$AgCl_{n+1}^{-n}(a') \rightarrow AgCl_{n+1}^{-n}(b') \quad \text{(solution transport)} \quad [7]$$

$$e^- + AgCl_{n+1}^{-n} \rightarrow Ag + (n+1)Cl^- \quad \text{(charge transfer)} \quad [8]$$

Steps such as surface diffusion following solution transport have been omitted, and it could not be determined from which silver bearing species electroreduction occurs (Eq. [8]).

Dissolution and deposition.—It has been shown that dissolution and deposition occur in both the anodic and cathodic processes. It is interesting to examine these steps with reference to changes in local transfer current density which is known to increase from the rear toward the front of the electrode in accord with the corresponding increase in AgCl coverage (Fig. 3-5).

The presence of discrete pits in the silver after anodic dissolution (Fig. 10a) shows that only certain sites are attacked. The nearly constant pit surface density, even with strongly varying external conditions of transfer current density, indicates that the sites are determined by properties specifically connected with the solid. Similarly, the tendency previously noted for increased pitting at silver grain boundaries (Fig. 4) persists throughout the reaction zone (0.07 cm depth of penetration). We conclude that the silver surface contains preferred sites at a nearly constant density. These are most likely dislocation sites. The observed pit surface density of *ca.* 10^8 cm^{-2} is in fair accord with previously reported dislocation site surface density of 1×10^{-8} cm^{-2} for silver (21).

The observed increase in pitted area with increase in local transfer current under anodic conditions in an outward direction from the AgCl deposits shows that all pit sites are not exactly the same energetically with reference to their distance from the deposits. It may be assumed that at the high anodic transfer currents local surface, concentration, and resistance overpotentials act to spread the area of pitting. Local transfer current density gradients are formed relative to the AgCl deposits and exist together with the over-all transfer current density profile through the electrode.

At the higher anodic transfer current densities, *i.e.*, in sections near the electrode's frontal plane, a larger number of AgCl nucleation sites are formed with a sub-

sequent increase in number of discrete, bulbed mounds (Fig. 5). At increased reaction rates, the increased concentration of silver bearing species must favor nucleation of AgCl in accord with developed theories of nucleation (18).

Separation of pits from discrete AgCl deposition sites (Fig. 6, 9, and 10a) indicates that discrete centers for nucleation of AgCl on the silver surface must exist just as dislocation sites are postulated to exist for pit formation. At the lowest transfer current densities, before discrete AgCl particles grow together, the number of AgCl particles are counted as $0.9 \times 10^8 \pm 0.2 \times 10^8$ centers/cm^2 according to photographs of the type shown in Fig. 9. At the highest transfer current density, counting the discrete, bulbed mounds of AgCl, we obtain $1.3 \times 10^8 \pm 0.3 \times 10^8$ centers/cm^2 (Fig. 5). The number of AgCl nucleation centers on the surface thus remains essentially constant despite widely varying external conditions, as with the pits. The correspondence in surface densities of pit sites and AgCl deposition centers suggests a corresponding periodic occurrence of associated surface states on the silver.

During the cathodic process, the sites of AgCl dissolution are favored where curvature is sharpest (22), as evidenced by loss of overhang (Fig. 11) where concentrations of dissolved silver-bearing species is lowest, and where chloride ion concentration is highest, as evidenced by perimeter loss (Fig. 8). Both geometrical position and shape together with electrolyte concentrations influence dissolution. For electrodeposition, the formation of separated nodules of silver indicates the presence of discrete metal nucleation sites (18).

As seen, when deposition and dissolution act as the principal processes, a range of interactions is possible depending on locations, densities, and distances of separation of respective sites on the pore walls of a porous electrode.

Modes of transport.—The series of transport steps during anodic treatment is reconstructed as follows. Originally, sites of high potential energy, such as dislocation sites or grain boundaries, are attacked electrochemically to form rounded pits by silver dissolution, *e.g.*, Eq. [1] and Fig. 9. The slightly soluble AgCl is deposited at nucleation sites around the pit as discrete nuclei which subsequently grow into bulbed mounds (Fig. 6). The mounds continue to grow and coalesce by diffusion of silver-bearing species through bulk electrolyte to eventually form a continuous layer (Fig. 8a) which also grows along its perimeter. Finally, cubic crystals of AgCl are formed when the deposits grow to substantial proportions (Fig. 4). At the same time, the pits become angular in shape. Generally, the transport modes can be simply represented as shown in Fig. 13.

Cathodic treatment involves retraction of the AgCl layer, as indicated, along the perimeter of the layer (Fig. 12). There is evidence for diffusion through bulk electrolyte from the AgCl deposits (Fig. 11). A surface diffusion step could not be distinguished from the SEM photographs, but definite nucleation sites for silver deposition were identified (Fig. 10b). Cathodic transport modes are simply represented by Fig. 14.

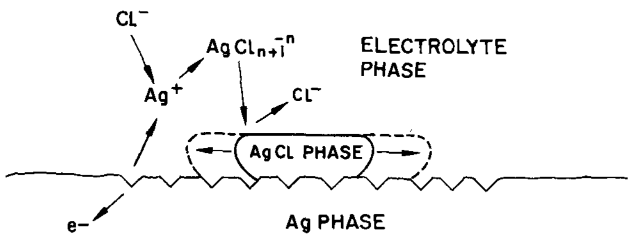

Fig. 13. Graphical representation of transport during anodic treatment.

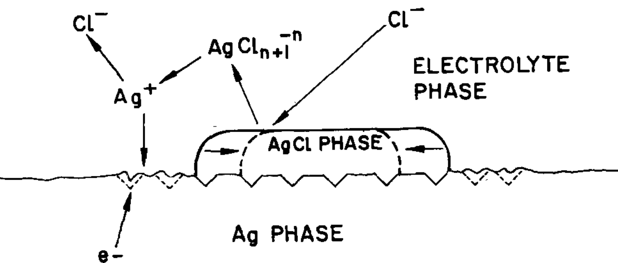

Fig. 14. Graphical representation of transport during cathodic treatment.

Parameters affecting reaction profile.—Observations reported here provide a basis for establishing numerical values of physical parameters for modeling theories of electrodes having sparingly soluble reactant or product in a conductive matrix (10, 11). Parameters for the tested electrode are summarized in Table I. For the determined depth of penetration by AgCl into the sphere bed, 0.07 cm, and from the calculated specific surface area of the spheres in the electrode, 986 cm^2/cm^3, an average transfer current density of 80 μA cm^{-2} could be calculated.

The chloride content of the electrolyte within the pores of the reaction zone can be calculated as being depleted in about 8 min at the imposed 5 mA cm^{-2} superficial current density by formation of AgCl (Table I)

$$Cl^- + Ag = AgCl + e^- \quad [9]$$

However, diffusion rates of chloride ion into the pores can be estimated to be able to accommodate the Cl^- loss, taking Fick's first law and assuming zero Cl^- in the pores (see Table I). Values for diffusion coefficients of silver bearing species in 2 and 4*N* KCl have been reported (5), and the solubility of AgCl in KCl solutions is known (20).

Thickness of the anodically formed AgCl remained remarkably constant for the regime of partial silver coverage by AgCl, varying from 3000 to 5000Å and being about 3500Å on the average. This finding suggests a limit on the initial minimum pore size and makeup particle size for porous silver electrodes. For a structure used as a secondary Ag/AgCl electrode, the smallest pores should be larger than at least twice the AgCl layer thickness to prevent pore blockage, or larger than about 2 × 5000Å or 1.0 μm. If the porous silver elec-

Table I. Physical parameters of silver sphere-bed electrode after anodizing in 1*N* KCl at 5.0 mA cm^{-2} for 11.0 min

Parameter	Value
Diameter of spheres	37.2 μm
Smallest pore diameter fitting through sphere bed	5.75 μm
Sphere-bed porosity	38.8%
Sphere-bed specific surface area	986 cm^2/cm^3
Electrode thickness	1.00 cm
Electrode diameter	1.41 cm
Depth of penetration by AgCl deposits into electrode	0.07 cm
Surface area in region of penetration depth	97.3 cm^2
Average transfer current density in region of penetration depth	80.2 μA cm^{-2}
Equivalents of anodic current passed	53.3 μ equiv.
Equivalents of Cl^- in pores in penetration depth region	38.3 μ equiv.
Equivalents of Cl^- diffused into pores*	71.2 μ equiv.
AgCl deposit thickness, bulbed mounds and patches	3,500Å
Diameter of bulbed mounds of AgCl	7,000Å
Maximum distance of pits to advancing AgCl	4,000-40,000Å
Surface density of pit nuclei	1.0×10^8 cm^{-2}
Surface density of AgCl nuclei	1.1×10^8 cm^{-2}

* This is a limit based on the following expression:

$$N = \frac{\epsilon^{1.5} D_o (C_b - C_p)}{\Delta}$$

where N = flux of Cl^-; ϵ = porosity; the 1.5 power is based on the paper of De La Rue and Tobias (23); D_o is the bulk diffusion coefficient, assumed to be 10^{-5} cm^2 sec^{-1}; C_b is the bulk KCl concentration, 10^{-3} moles/cm^{-3}; C_p is the concentration at the center of the region of penetration depth, assumed to be zero; and Δ is half the penetration depth, 0.035 cm.

trode is thus made of spherical particles or particles resembling spheres which are pressed or sintered together, the average minimum sphere diameters can be calculated to be about 6.5 μm, if one considers that the smallest pore diameter for a sphere bed is determined by the diameter fitting between three mutually touching spheres.

Conclusions

Anodic oxidation of porous silver electrodes in 1*N* KCl progresses within the pores by pitting at dissolution sites of silver, probably at dislocation sites, and by deposition of AgCl at some distance from the pits at nucleation sites. For the regime of partial coverage of the silver by AgCl, the distance from pit formation to AgCl deposition varies from 4000 to 40,000Å, being increased with increased local transfer current density. The deposited AgCl forms bulbed mounds, about 3500Å high and 7000Å in diameter, which appear to grow together to form a coating of more or less uniform thickness, 3500Å. For silver electrodes consisting of a bed of silver spheres 37 μm in diameter, the reaction zone characterized by the presence of AgCl is about 0.07 cm for a superficial anodic current density of 5.0 mA cm^{-2} applied for 11 min.

Cathodic reduction of the anodically formed AgCl in these electrodes proceeds via dissolution of the deposits of AgCl, mostly along their boundaries, and by electrochemical reduction to silver on the bare-silver surface.

ABSTRACT

A relatively simple, fast, and reliable electrical method for determining the surface area of powders is described. The oxygen loss from a flowing oxygen-helium mixture, caused by adsorption on the sample at liquid nitrogen temperatures, is sensed by a high-temperature galvanic cell. Operating conditions are chosen so as to conform to the one-point BET method. The method is absolute and a direct readout in terms of surface area can be obtained.

The surface area of a powder is usually determined by adsorbing an inert gas like nitrogen or krypton on the specimen cooled to liquid nitrogen temperature. By volumetric measurements giving the amount of gas physically adsorbed as a function of gas pressure, the amount of gas required to produce a surface coverage of one monolayer and hence the surface area itself can be calculated. The theory made use of is the BET theory (1). The method is accurate but is very time consuming, even when a computer is available to handle the data.

The ultimate accuracy is usually not required; the surface area may then be determined from a single adsorption measurement (2). In our method, oxygen serves as the adsorbate, and an electrochemical cell is

* Electrochemical Society Active Member.

Key words: surface, galvanic cell, particle size, instrument, adsorption.

used to convert the changes in gas concentration by adsorption into an electric signal. Oxygen-ion-conducting high temperature cells are particularly suited because their response is fast and accurate; the transference number for oxygen ions is very close to one over a wide temperature range (3). In the present method, oxygen is adsorbed from a flowing oxygen-helium gas mixture by cooling the adsorbent to liquid nitrogen temperature. The oxygen content of the mixture after passing the sample is monitored continuously by means of the electrochemical cell which is used as an oxygen pump (4). A suitable voltage is applied so as to obtain the limiting current corresponding to the total removal of the oxygen from the gas stream. The time integral over the decrease in current due to adsorption gives the charge equivalent of the oxygen physically adsorbed on the sample at low temperatures. The charge in turn is a measure of the surface area if the proper conditions are chosen.

A rough calculation showed that for inert gas-oxygen mixtures containing 2-6% oxygen, as required by the method, a tubular solid electrolyte cell of the dimensions generally used in this laboratory will pump enough oxygen to allow a surface area measurement to be carried out within a few minutes. Flow rates of a few cubic centimeters per minute can be employed that do not present the sealing problems that are encountered with the electrolyte tubes at very low flow rates or in static systems.

Theoretical

The BET theory.—In the derivation of the BET theory, as originally given (1, 5), the multilayer adsorption equilibrium is derived by considering the detailed balancing between the part of the surface not covered (S_0) with the part covered once (S_1), then the latter with the part covered twofold (S_2), etc. For each pair, the rate of adsorption is equal to the rate of desorption

$$a_i p S_{i-1} = b_i S_i e^{-E_i/RT} \quad [1]$$

where E_i is the heat of adsorption in the layer covered i-fold, a_i and b_i are constants, and p is the gas pressure.

If V is the adsorbed gas volume and V_m is the volume required to cover a monolayer, then

$$\frac{V}{V_m} = \frac{\Sigma i S_i}{\Sigma S_i} \quad [2]$$

The simplifying assumptions are made that, for all surface fractions covered twice or more

$$E_2 = E_3 = \ldots = E_i$$
$$b_2/a_2 = b_3/a_3 = \ldots = b_i/a_i$$

The summation (5) of Eq. [2] then leads to the form of the BET equation

$$\frac{x}{V(1-x)} = \frac{1}{V_m c} + \frac{(c-1)}{V_m c} x \quad [3]$$

where $x = p/p^o$ is the relative pressure of the gas (p^o is the equilibrium vapor pressure of the condensed gas at the temperature of adsorption). c is a constant $= a_1 b_2/a_2 b_1 e^{(E_1-E_L)/RT}$, where E_L is the heat of liquefaction of the gas. In a "BET plot" the function $x/V(1-x)$ is plotted *vs.* x, usually giving a straight line for the range $0.05 < x < 0.3$ (see, for example, Fig. 6). According to Eq. [3], the slope of the line is $(c-1)/V_m c$, the intercept with the ordinate is $1/V_m c$. The sum of the two then is $1/V_m$. Thus, V_m, the gas volume in cubic centimeters (STP) required to cover the surface with one monolayer, is obtained.

The one-point approximation.—The value of the constant c usually is of the order 10^2. Thus, in Eq [3], $1/V_m c \approx 0$. This amounts to drawing the straight line from one measured point in the BET plot through the origin. The larger the value of x chosen within the range of validity of the BET equation, the smaller the error in the slope will be. The range of validity usually is from $x = 0.05$ to $x = 0.30$. With $(c-1)/c \approx 1$, Eq. [3] assumes the simple form

$$V_m = V(1-x) \quad [4]$$

In terms of the surface area S, Eq. [4] may be written as

$$S = NA(1-x) \quad [5]$$

where N is the number of adsorbed molecules and A is the cross-sectional area of the adsorbed molecule.

In our method N is substituted by a measured amount of electric charge q which is found by integration of the loss in pumping current due to adsorption of oxygen on the sample. From Faraday's law and a value of A of 1.40×10^{-15} cm^2 for oxygen, a charge q of 1 A-sec corresponds to a covered area (NA in Eq. [5]), of 0.218 m^2. Equation [5] then becomes

$$S \text{ (in m}^2) = 0.218\,(1-x)\, q \text{ (in A-sec)} \quad [6]$$

Two different mixtures were used in the experiments. With a liquid nitrogen bath at an average atmospheric pressure (in Pittsburgh) of 730 Torr, p^o for oxygen is 160 Torr. With 3.23% O_2 in helium, $(1-x) = 0.85$, therefore

$$S \text{ (in m}^2) = 0.186q \text{ (in A-sec)} \quad [6a]$$

With 6.7% O_2 in helium, $(1-x) = 0.67$, therefore

$$S \text{ (in m}^2) = 0.146q \text{ (in A-sec)} \quad [6b]$$

Apparatus and Procedure

Figure 1 illustrates the setup of the apparatus. The oxygen-inert gas mixture, contained in cylinder C, passes through a flow regulator F and a flowmeter M over the sample S contained in a U-shaped sample holder and then passes through the electrochemical cell P in furnace F.

The cell consists of a tubular solid electrolyte made of calcia-doped zirconia which is heated by the furnace. The temperature must be chosen high enough that the current is not limited by the resistance of the electrolyte, but only by the amount of oxygen in the mixture passing the cell. An additional volume V and a capillary at the end prevent the air from entering the cell when the sample is cooled. A constant voltage E is applied to the electrodes on the inside and the outside of the electrolyte tube (the + pole is connected to the outside which is exposed to air). The current through the cell is monitored by a recorder R.

The experimental procedure is best illustrated by a typical example. Experimental details and a close examination of the method will follow. One hundred seventy-four milligrams of a cobalt oxide (Co_3O_4) powder were placed at the bottom of the U-shaped sample holder. A mixture of 6.7% oxygen in helium was passed over the sample, and the latter was heated to 150°C to drive off adsorbed gases. The heater was taken off and the flow was adjusted to give a certain current. This results in the initial portion of the recorder trace shown in Fig. 2 giving a plot of current *vs.* time. Choice of a suitable voltage and current is discussed below. When the sample holder was dipped

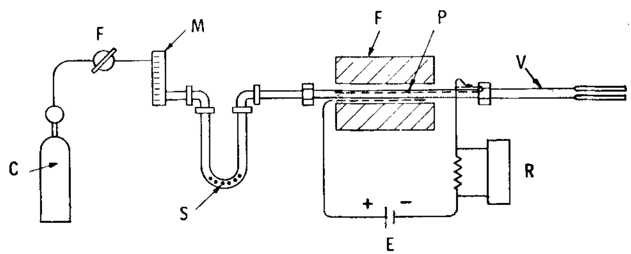

Fig. 1. Schematic of complete apparatus

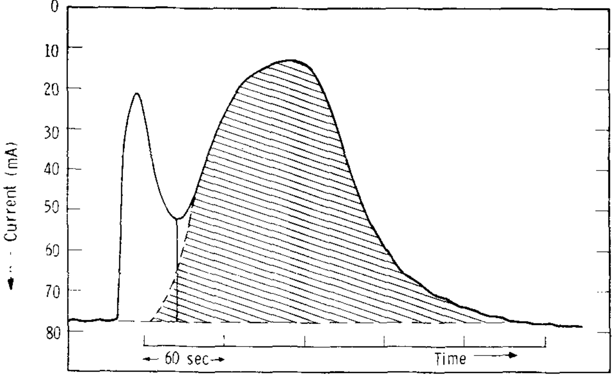

Fig. 2. Current through oxygen pump on cooling 174 mg Co_3O_4. Shaded area under second current minimum is proportional to surface area. Solid vertical line indicates point at which integrator is started (Exp. No. 15 in Table II).

in a liquid nitrogen bath, two current minima were observed as may be seen in Fig. 2. The first portion of the curve containing the first minimum is due to contraction of the gas in the cooled portion of the sample holder. The pure helium in the ballast volume V at the exit of the cell is here drawn back into the electrochemical pump. When the cooling is almost completed, adsorption of the oxygen on the sample causes the second decrease in current, a second minimum, and the return to the initial constant current. The shaded area under the curve corresponds to an electric charge $q = 10.6$ A-sec. With the 6.7% O_2 used in this experiment, according to Eq. [6b], surface area $S = 0.146\ q = 1.55\ m^2$ for the 174 mg used, or 8.9 m^2/g.

Instead of integrating the area under the curve (by weighing the paper or by planimeter), an electronic integrating device was also used. It is zeroed with respect to the base current and is started at the first maximum as indicated by the vertical line in Fig. 2. The device can be calibrated directly in terms of surface area and is read when the indicated area no longer increases.

The drawing back of pure helium into the electrochemical pump during the cooling period eliminates the need of a numerical correction for the change in gas volume on cooling the adsorption vessel and makes it possible to measure a signal directly proportional to the surface area.

Experimental

Two gas mixtures were used in the experiments, first 3.23% O_2 in He, then 6.7% O_2 in He. The flowmeter was a Matheson No. 610 flowmeter (0-100 cm^3/min) which was calibrated against a bubble flowmeter. (It was required for the tests described below, but it is not required for the area measurement since the cell current itself provides a more accurate measure of oxygen flow.) Beckman Teflon connectors were used throughout and provided a satisfactory seal. The sample holder was a ¼ in. OD U-shaped tube of 15 cm length. Only the bottom of the tube was filled with the sample. Solid electrolyte tubes, made of "pure" calcia-stabilized zirconia, were obtained from Zircoa Incorporated, and were about 4 mm ID, 5 mm OD, and 18 cm long. Inside and outside electrodes consisted of silver paste (Engelhard Industries) fired on at 800°C in two applications. A ¼ in. nickel bellows was attached to the far end of the electrolyte tube to avoid damage to the latter by stress or shock.

A temperature regulator kept the temperature constant to about 1°C. Too large temperature fluctuations must be avoided because they induce changes in the cell current. Cell temperatures varied from 750° to 850°C with 830° later used as the preferred temperature. To extend the life of the silver electrodes 650°C was chosen as a "standby" temperature. A Tacussel potentiostat provided initially the constant voltage between the electrodes. Later we used a homemade potentiostat which was built into the current integrator. The preferred voltage chosen in the later experiments was 750 mV. A Moseley recorder connected across a 10 ohm standard resistor was used as a current monitor.

800	64.0
900	64.0
1000	64.5

Results and Discussion

The first results were obtained with a 3.23% O_2 in He mixture, corresponding to a $p/p^o = 0.15$. In the later experiments, another electrolyte tube was used (requiring a slightly higher temperature and voltage of operation) and a 6.7% O_2 mixture, corresponding to a $p/p^o = 0.33$. It is important that the cells are operated at a high enough temperature and voltage and a low enough flow rate so that the entire oxygen content of the mixture is removed on pumping the cell. When choosing too high a voltage, the measured current may become too high due to incipient electronic conduction of the electrolyte. As an example, in Table I, the current-voltage characteristic of the second cell used is given for a flow of 5.5 cm^3/min of the 3.23% O_2 mixture with a cell temperature of 800°C.

It may be seen that up to 700 mV, the current increases rapidly. In this range, the current is determined by the cell resistance and, to a lesser extent, by cell polarization due to the difference in oxygen potential at the two electrodes. At about 800 mV, the current has reached a constant value corresponding to complete removal of the oxygen. This is the minimum voltage at which the cell must be operated if the cell temperature of 800°C is chosen.

Figure 3 shows a plot for the same cell at 830°C obtained at a constant voltage of 750 mV with the 6.7% oxygen mixture. Here the current is given as a function of flow rate. The latter was measured by means of a bubble flowmeter attached to the end of the cell. At low flow rates, the current is equal to the faradaic current calculated for the total amount of oxygen passing, as represented by the straight line through the origin. The small deviation of the experimental points, increasing with decreasing flow rates, is probably due to loss of helium in the rubber hose connection to the flowmeter and does not affect the reliability of the electrical measurements. Up to about 5 cm^3/min,

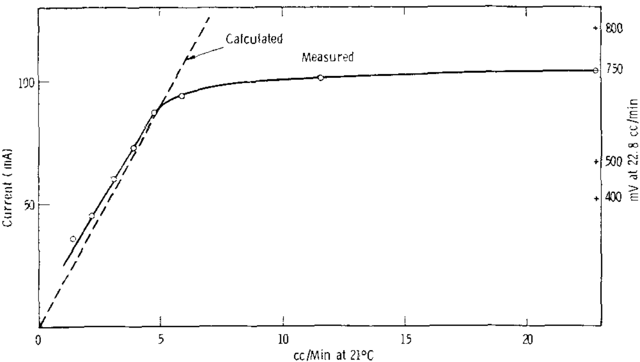

Fig. 3. Plot of cell current vs. flow rate, as determined by a bubble flowmeter, at 750 mV for 6.7% O_2 in He. Cell temperature 820°C. Maximum currents at other voltages are given at 22.8 cm^3/min flow. Dashed line is calculated faradaic current.

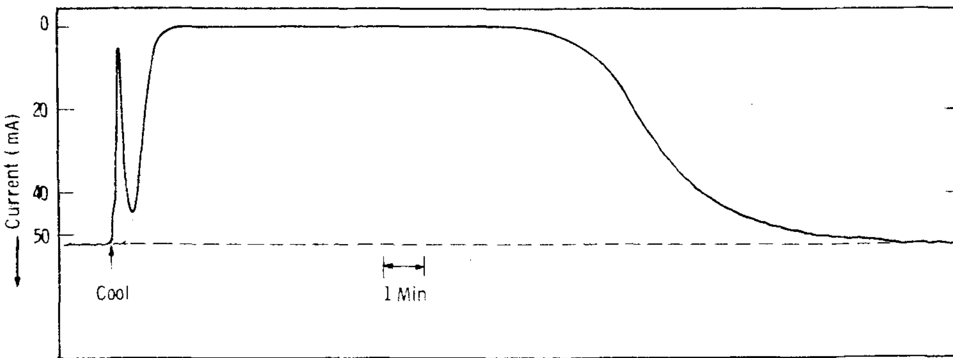

Fig. 4. Current-time recording for 7.5 mg Nuchar charcoal (7.38 m^2, 980 m^2/g, 3.23% O_2, Exp. No. 9 in Table II).

the current represents the true flow rate under the given conditions. This is the region in which the cell should be operated. In the surface area determinations, the flow rate was generally adjusted so as to give a current about 25% below the maximum current at the chosen voltage.

At the right hand margin of Fig. 3, the voltage-current relationship is indicated for the constant flow rate of 22.8 cm^3/min. At this high flow rate, the current appears to be limited essentially by the electrolyte resistance, about 7-8 ohms at 830°C, decreasing somewhat with current due to heating at the electrolyte-electrode contacts. There is no appreciable limitation of the oxygen diffusion in the gas phase or in the electrode, as may also be concluded from the sudden changes in slope from the oxygen limited to the resistance limited region. This is probably helped by the choice of helium as a diluent for the oxygen and of silver as an electrode material.

Some of the results of surface area determinations are presented in Table II. In the first series, up to Exp. No. 11, experiments were performed with the first cell at 800°C, with 3.23% oxygen, and at a voltage of 0.6V. In the subsequent experiments, the voltage and temperature had to be raised, as already discussed, due to a larger electrolyte resistance connected with poorer silver coverage of the electrolyte tube. The higher oxygen concentration (6.7%) used here helps to decrease the error involved in the one-point approximation (see section below). In columns 1 to 10, results with the present method are given. In columns 11 to 13, results with the complete BET method are presented, as obtained by Kr-adsorption (except for Co_3O_4 which was also measured with oxygen, Exp. No. 15). The base current is given in column 7. With the 3.23% O_2 mixture, the flow rate at room temperature is 0.119 cm^3/min per milliampere base current, and with the 6.7% O_2, it is 0.056 $cm^3\ min^{-1}\ mA^{-1}$ (cf. Fig. 3). The charge given in column 8 is obtained by integration of the area between the second current minimum and the base current (the shaded area in Fig. 2); it was carried out in the earlier experiments by marking the recording on a cellophane film and weighing the cut-out. The electronic integrator used in the last experiments typically yielded surface area values in agreement with those obtained by weighing to better than 2%.

In the first experiments, different powders were measured ranging in specific surface area from 0.6 to 1100 m^2/g. The weight of the samples used in the measurements varied from 7.5 to 250 mg, and the actual surface areas varied from 0.06 to 7.4 m^2. It may be seen from the table that throughout the wide range of surface areas, there is agreement between the results obtained by the two methods (columns 10 and 13) to within about 15-30%, except for the smallest area where our measured value is about 50% higher. As will be shown, the largest part of the (generally not serious) discrepancy is due to the difference in pretreatment of the samples before the measurements, stated in columns 5, 6, 11, and 12 and not due to the methods themselves.

Figures 4 and 5 show the current recording for two extremes of surface area. In Fig. 4, 7.5 mg of "Nuchar" charcoal was measured (Exp. No. 9 in Table II). The integrated area represents a charge of 39.7 A-sec and a calculated area of 7.38 m^2/g. The separation of the two minima is obviously no problem here and also for smaller areas. A similar recording for 104 mg Co_3O_4 I is shown in Fig. 5 (Exp. No. 7 in Table II). The integrated area gives a charge of 0.03 A-sec, which corresponds to an area of only 0.06 m^2. The overlap between the two minima is here considerable, and the area cor-

responding to oxygen adsorption is therefore relatively uncertain. The calculated value appears too high by about 50%. Nevertheless, if one is only concerned with the correct order of magnitude of the area, it is possible to estimate areas of the order of 0.01 m^2. It is important that the cooled volume be kept small, about 1 cm^3 or less, otherwise the first minimum becomes too broad and covers up the second minimum.

It may be possible to narrow down further the first minimum by redesigning the reaction vessel and using a thinner glass to improve the rate of heat transfer. Optimization of the design may lead to improvement of the accuracy of measurement of low surface areas, but also to an extension of the range of measurement to below 100 cm^2. This would surpass the conventional BET method in range of applicability. Measurement of low areas of this order of magnitude have been claimed; but the reliability is open to doubt. The reason is that in a conventional adsorption experiment the amount adsorbed on a small surface is the small difference between two larger quantities, *viz.*, (gas volume plus adsorbed volume) minus gas volume. The significance of the calculated difference is not easy to judge. In the present method inspection of the curve gives an immediate idea of the significance of the measurement.

Effect of pretreatment.—Most of the discrepancy in the surface areas obtained by the two methods (cf. columns 10 and 13 in Table II) is due to the difference in pretreatment of the samples before measurement. The values in column 13 were obtained by the complete BET method with krypton after pumping, mostly for prolonged periods (15-40 hr) and at an elevated temperature (~140°C). This is a much more rigorous degassing treatment than was applied with our samples in the first experiments. Even when applied for the same temperature and time, removal of vapor from the pores of solids in a gas stream is not as rigorous as in a vacuum. A considerably higher temperature would have to be applied to obtain the same cleaning effect. The values obtained after prolonged degassing at a high temperature are not necessarily more meaningful than those obtained after milder degassing. The surface of the micropores bared by the rigorous degassing usually is of no interest, except when the powders are to be used as adsorbents.

The increase in apparent surface area on increasing the pretreatment temperature of the cobalt ferrite may be seen on comparing the results in Exp. No. 12 (25°), No. 4 (60°), and No. 17 (250°). Similarly, in Exp. No. 16, a bonechar was tested after pretreatment at increasingly higher temperatures. It was supplied by the Micromeritics Company as a standard having a surface area of 70 m^2/g. The pretreatment temperature used by the company is not known. As may be seen, the value of 68 m^2/g is reached after degassing in the 6.7% O_2-He mixture for 15 hr at 340°C; this is in agreement with the given value to within 3%.

With Co_3O_4 II (cf. Exp. No. 15), the complete isotherm was also determined with oxygen as the adsorbate and after two different pretreatments in a vacuum. The BET plots, in accordance with Eq. [3], are shown in Fig. 6. Two good straight lines were obtained, the lower one after degassing 90 min at 150°, the upper one after exposure to air overnight and evacuation at room temperature for 15 min. The respective surface areas were 10.4 m^2/g (in good agreement with the value obtained with krypton as adsorbate, cf. Exp. No. 8) and 9.05 m^2/g. The lower value is in good agreement with the 8.9 m^2/g obtained by our method after pretreatment in a gas stream at 150°C for 60 min.

Error involved in the one-point method.—The error involved in using the one-point approximation (cf. theoretical section) depends on the value of c, which is a measure of the strength of interaction of the oxygen with the substrate, as well as on the chosen value of x. For the two lines in Fig. 6, the c values are 120 for the larger surface area (lower line) and 80 for the smaller area. By comparing the expressions for the monolayer gas volume V_m in Eq. [3] and [4], one finds that the fractional error involved in the approximation is $(1 - x)/(1 - x + cx)$. For c values of 100, use of the 3.2% oxygen mixture ($x = 0.15$) gives an error of

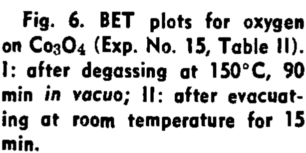

Fig. 6. BET plots for oxygen on Co_3O_4 (Exp. No. 15, Table II). I: after degassing at 150°C, 90 min *in vacuo*; II: after evacuating at room temperature for 15 min.

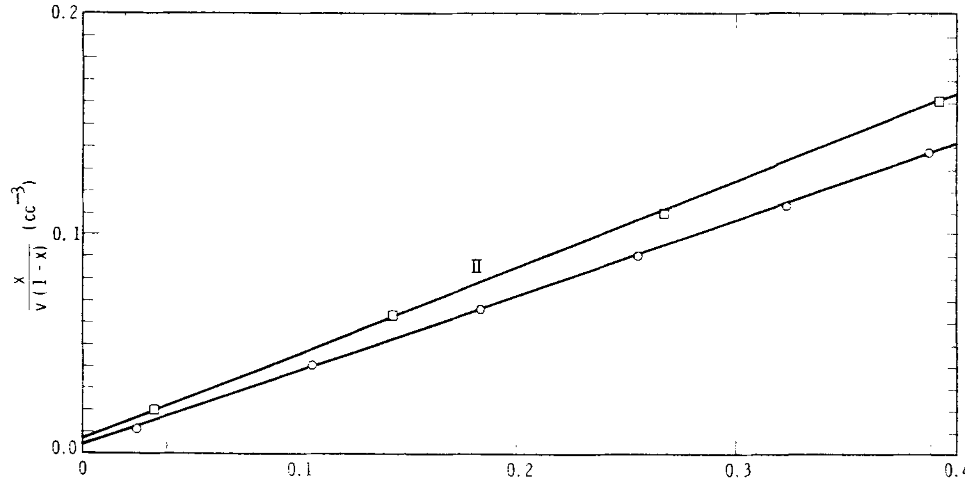

5.4%, while for the 6.7% oxygen ($x = 0.33$), as used in the later experiments, the error is only 2.0%.

The c values of about 100 are in the range usually encountered. The higher the value of c, the less the error involved in the approximation. It is not known what the lowest c value could be, but it probably will not be so low as to cause a considerable error in the method. With rare gases like krypton, low values have occasionally been observed (6), but this is not likely to occur with oxygen.

The experience with oxygen as an adsorbate is so far limited, but we do not foresee any difficulties. The agreement for Co_3O_4 (Exp. No. 15 and 8, Table II) with the krypton value for equal pretreatment is excellent.

Conventional BET adsorption measurements are usually not made with oxygen because of the possibility of additional oxygen uptake at liquid nitrogen temperature due to chemisorption after pretreatment of the sample in a vacuum. This difficulty does not arise in the present case because, if chemisorption is possible, it will occur at the higher temperatures before cooling and will not interfere with the physical adsorption at liquid nitrogen temperature.

The accuracy to within a few per cent attainable by the described method is amply adequate for most practical purposes.

Acknowledgment

The author is indebted to R. M. Garretson for carrying out the surface area measurements by the conventional BET method.

ABSTRACT

A current-reversal chronopotentiometric technique has been developed to facilitate the determination of the reaction pathway of radical anions generated during electrolytic reductive coupling reactions. The technique permits discrimination between dimerization of the anion radicals and a reaction scheme involving reaction of a radical anion with unreduced starting material followed by one-electron reduction. The reduction of *trans*-4,4-dimethyl-1-phenyl-1-penten-3-one was studied at mercury cathodes in dimethylsulfoxide with a tetra-*n*-butylammonium perchlorate as supporting electrolyte. In the presence of 0.05*M* water, the reaction proceeds by dimerization of the anion radicals. At higher water concentrations a parallel pseudo first-order reaction of the radical anions was detected.

In an earlier study of the electrolytic reductive coupling of various α,β-unsaturated ketones (1), conditions were established under which the reduction proceeded in an over-all one-electron process giving good yields of the β-β coupled dimers. In particular, it was found that *tert*-butylstyrylketone, **1** (*trans*-4,4-dimethyl-1-phenyl-1-penten-3-one) formed good yields of dimer when reduced in dimethylsulfoxide (DMSO) and was less susceptible to polymerization side reactions than were less hindered enones. Therefore, the reduction of **1** was thoroughly studied using cyclic voltammetry. Though these studies demonstrated clearly that the primary electrode reaction was the reversible, one-electron reduction of **1** to its radical anion, **2**, the exact pathway for the subsequent reactions of **2** could not be determined (1)

Key words: reductive coupling, electrohydrodimerization, α,β-unsaturated ketones, current-reversal chronopotentiometry.

$$\underset{\mathbf{1}}{C_6H_5CH{=}CH{-}\overset{\overset{\displaystyle O}{\|}}{C}{-}C(CH_3)_3} + e \rightleftharpoons \underset{\mathbf{2}}{C_6H_5\dot{C}H{-}CH{=}\overset{\overset{\displaystyle O^-}{|}}{C}{-}C(CH_3)_3} \quad [1]$$

Two schemes were envisioned for the reactions of the radical species **2**. The first, referred to in this paper as scheme A, involved the direct dimerization of **2** to form product, **3**

$$\mathbf{2} + \mathbf{2} \xrightarrow{k_A} \begin{matrix} O^- \\ | \\ C_6H_5CH-CH=C-C(CH_3)_3 \\ | \\ C_6H_5CH-CH=C-C(CH_3)_3 \\ | \\ O^- \end{matrix} \qquad [2]$$

3

The second scheme (scheme B) envisioned the reaction of the radical anion, **2**, with a molecule of the parent, **1**, to give the dimeric radical anion, **4**

$$\mathbf{1} + \mathbf{2} \xrightarrow{k_B} \begin{matrix} O^- \\ | \\ C_6H_5CH-CH=C-C(CH_3)_3 \\ | \\ C_6H_5CH-CH=C-C(CH_3)_3 \\ | \\ O\cdot \end{matrix} \qquad [3]$$

4

Since species **4** is assumed to be reducible at a more positive potential than **1**, it immediately gains an electron at the electrode surface thereby decreasing the portion of the total flux utilized for the reduction of **1** by the amount necessary to maintain the surface concentration of **4** at zero. It is also possible instead, that species **4** gains the electron in the solution via electron transfer from **2**

$$\mathbf{4} + \mathbf{2} \rightleftharpoons \mathbf{3} + \mathbf{1} \qquad [4]$$

Peak current ratios in cyclic voltammetry or double potential step chronoamperometric data (2) are very similar for schemes A and B making experimental discrimination between the two very difficult.
