It has been demonstrated that high resolution patterns can be delineated in poly(methyl methacrylate) (PMMA) using x-ray radiation modulated by an absorbing mask (1-3). PMMA is at present the most widely used resist material for x-ray (1) and electron lithography, and has been used with both techniques to delineate high resolution patterns. PMMA dissolves more rapidly after irradiation (4) and is classified as a positive resist. A negative resist crosslinks and becomes insoluble on exposure to actinic radiation.

Recently, several new positive and negative polymeric resists sensitive to electron beam irradiation have been developed. The evaluation of these seven materials as resists for x-ray lithography is reported here.

Key words: x-ray resists, x-ray lithography, polymer resists, electron resists.

When a moderate energy electron (5-20 kV) or an x-ray photon enters a polymer film multiple chemical events are initiated. It is commonly accepted that organic polymers (those containing carbon, hydrogen, oxygen and/or nitrogen) will exhibit similar sensitivities (G-values) to both x-ray or electron irradiation. Two reactions of interest which may occur are chain scission and/or crosslinking. Energy absorption in the resist film is an important consideration when comparing x-ray and electron sensitivities. Electron energy absorption using a phenomenological approach has been described elsewhere (5) and is used in calculating electron doses in this paper. X-ray energy absorption is more straight forward to calculate, utilizing the following general expression (6)

Table I. Dose values of several polymer resists to both x-ray radiation and electrons

Material	Electron,[a] coulombs cm^{-2}	Electron, joules/cm^{-3}	X-ray, joules/cm^{-3}	Ratio of electron to x-ray dose
PMMA (POS)	1×10^{-5}	400	500	0.8
PBS (POS)	2×10^{-6}	80	14	5.71
PVFc	1×10^{-4}	4400	150	29.0
PDOP	1×10^{-6}	32.5	14	2.3
CER	8×10^{-7}	26	25	1.0
P (GMA-co-EA)	3×10^{-7}	9	5	1.8
EPB	1×10^{-7}	3	1	3.0
PB	2×10^{-6}	65	20	3.2

[a] Electron doses for negative resists are those required to yield ~50% gel remaining with a 0.5μ initial film and a 10 kV electron beam. The positive resist doses are those to result in a relief image in a 0.5μ initial film without affecting unirradiated film.

$$I = I_0 e^{-(\mu/\rho)\rho t} \quad [1]$$

where I_0 is the intensity of incident x-rays; I the intensity of x-rays after penetration through a thickness, t, of a homogeneous material having a linear absorption coefficient μ for x-rays; and ρ the bulk density of the material.

The absorption coefficient (μ) is an additive function of the various atomic species present in the material (6). For a 0.5-1.0 μm film of an organic polymer, it has been found that ~5-10% of the incident intensity of an 8Å x-ray is absorbed. The effective sensitivity of a resist to x-ray radiation can be increased by chemically incorporating atoms of higher atomic number into the resist to increase the x-ray absorption, and poly(vinylferrocene) has been used as a model compound to illustrate this point, cf. Table I.

Experimental

The preparation of poly(vinyl ferrocene) (PVFc) (7), crosslinking electron resist (CER) (8), poly(butene-1-sulfone) (PBS) (9, 10), epoxidized poly(butadiene) (EPB) (11, 12), poly(glycidyl methacrylate-co-ethylacrylate) [P(GMA-co-EA)] (13), and poly (diallyl-*ortho*-phthalate) (PDOP) (14) has been described elsewhere.

The resists were spin coated on the substrate and processed as shown in Table II. X-rays were produced by bombardment of an Al target with 6.25 keV electrons and the 8.34Å Kα line (1.486 keV) was the primary radiation used. X-ray exposure doses were determined as described by Lenzo and Spencer (3). An x-ray dose of 500 j/cm^3 (2.5×10^{-2} j/cm^2 for a 500 nm film) was used as a standard reference exposure for PMMA (1, 2).

Some consideration should be given to doses used in the paper (both electron and x-ray) for positive and negative resists. The dose for negative resists was that necessary to result in 250 nm of an initial 500 nm film after development. The electron sensitivities were determined (or normalized) with a 10 kV electron beam. The bulk doses listed in Table I (joules/cm^{-3}) have been corrected for the energy absorbed in the developed volume of film. Sensitivity of a positive resist is the dose which results in complete dissolution of the irradiated polymer while not dissolving unirradiated material. Bulk doses are for a 500 nm initial film. The ratio of x-ray to electron dose is given for convenience of comparing relative sensitivities of these materials used for both applications.

X-ray exposure requires a mask which consists of a substrate somewhat transparent to x-rays and a patterned absorber. This is described in detail by Smith, Spears, and Bernacki (2). The mask used in this paper consisted of a silicon substrate with gold absorbers. The Si/Au masks were fabricated with electron lithography using either EPB or P(GMA-co-EA) as electron resists. The resist was exposed using a flying spot scanner (15) interfaced to a Cambridge Mark II SEM and processed as previously described (12). The 400 nm Au absorption layer was subsequently ion etched and the Si transmission windows thinned to 3-10μ using electrochemical etching (16).

Results and Discussion

The resists evaluated in this study are listed below and summarized in Tables I and II.

1. Poly(butene-1-sulfone (PBS) (9, 10) is a positive resist exhibiting an electron sensitivity of $\sim 2 \times 10^{-6}$ coulombs cm^{-2} when a 500 nm film is exposed with a 10 kV electron beam. The material is resistant to most chemical etching solutions, but does not withstand ion beam etching.
2. Epoxidized polybutadiene (EPB) (11, 12) is a low contrast, negative electron resist with a sensitivity of $\sim 8 \times 10^{-8}$-2×10^{-7} coulombs cm^{-2}. The polymer is highly reactive and must be handled carefully.
3. A terpolymer of methyl methacrylate, ethyl acrylate, and glycidyl methacrylate partially esterified with methyl acrylic acid (CER) (8, 17) is a medium contrast negative resist which exhibits a sensitivity of $\sim 8 \times 10^{-7}$ coulombs cm^{-2}. It is resistant to acidic and basic etching solutions and to ion etching.
4. Poly(diallyl *ortho*-phthalate) (PDOP) (14) is a negative resist that has a sensitivity of $\sim 2 \times 10^{-6}$ coulombs cm^{-2} and withstands high temperature processing (>150°C).
5. Poly(glycidyl methacrylate) (PGMA) and especially copolymers with ethyl acrylate [P(GMA-co-EA)] (13) are high contrast negative resists with a range of sensitivities between 8×10^{-9} and 1×10^{-6} coulombs cm^{-2}. The copolymers exhibit high contrast and have excellent resistance to both chemical and ion etching.
6. Polybutadiene (PB) is a low sensitivity (1-2×10^{-6} coulombs cm^{-2}) medium contrast negative resist.

Table II. General processing conditions for several electron resists used as x-ray resists

Material	Spinning solvent	Prebake, °C	Electron dose, coulombs/cm^2	Developer[d]	Postbake	Etching
PMMA	Ethylcellosolve	150°C, 1 hr	5×10^{-5}	MIBK-[g]2-propanol	170°C, 10-40 min	[a],[b],[c]
EPB	Dioxane	No	3×10^{-7}	Dioxane-MEK[f]	140°C, 5 min	[a],[b],[c]
P (GMA-co-EA)	Chlorobenzene	65°C, 5 min	3×10^{-7}	5:2 MEF-[f]ethanol	70°C, 30 min	[a],[b],[c]

Fig. 1. Scanning electron micrographs of gold absorber pattern on a thin silicon substrate used as an x-ray mask.

7. Poly(vinylferrocene) (PVFc) is an extremely high contrast, low sensitivity negative resist, containing 24% iron, and used as an archtype compound to illustrate a method of enhancing x-ray sensitivity.

The x-ray doses for organic resists containing only first and second row elements are in good agreement with electron doses as expected, Table I. For these polymers the ratio of x-ray to electron doses was found to be 1-3. Poly(butene-1-sulfone) contains a heavier atom, sulfur, and the ratio was 5.2. Incorporation of ~24% iron into the polymer resulted in a ratio of 29, a gain of ~10 in sensitivity toward x-ray radiation. A gain of 3-4 was expected on the basis of absorption considerations. Clearly, this method of increasing the amount of energy absorbed by the resist by incorporating materials with high linear absorption coefficients for the exposing wavelength, is a powerful technique that, in principle at least, permits a resist to be specifically designed for the wavelength of irradiation employed.

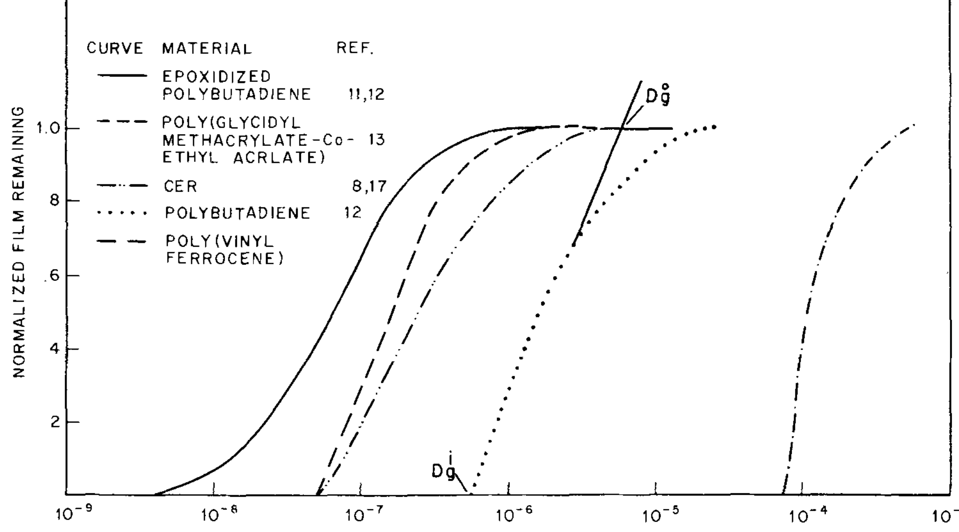

Fig. 2. Electron dose-thickness curve for several electron resists.

Masks.—Some typical mask patterns that were fabricated for x-ray lithography by electron lithography are shown in Fig. 1. There were 25 similar patterns ion beam etched in 400 nm of Au on Si on each substrate. Patterns with less than 2μ resolution were readily produced. The Si was subsequently thinned electrochemically to ~3-7 μm. Beryllium may also be an acceptable substrate material since it has a low absorption coefficient and may be obtained sufficiently thin to eliminate the need for the electrochemical thinning step.

Unlike electron exposure, x-ray exposure results in the entire resist surface receiving some dose, because the mask absorber will transmit an x-ray beam diminished according to Eq. [1]. Due largely to this effect the contrast, γ, of a resist becomes an important parameter. Contrast for a negative resist is defined as the slope of the extrapolated linear portion of a plot of normalized film remaining as a function of log dose and may be expressed as

$$\gamma = \left[\log \frac{D_g^o}{D_g^i}\right]^{-1} \quad [2]$$

where D_g^i is the dose at 0 film thickness and D_g^o is the dose at 100% film remaining (5, 17), using the extrapolated linear portion of the dose-thickness curve, Fig. 2. The contrast has been found similar for both electron and x-ray exposure. Figure 2 represents electron exposure characteristics for several negative resists and is included to clarify the above definitions.

The ratio of x-ray transmission through the absorber to substrate will determine the contrast and exposure levels required for the resist. Table III gives electron contrasts for several negative resists and may be used as a guide in selecting an x-ray resist.

Conclusions

This paper shows (*i*) that there is a good correlation between x-ray energy absorbed and electron energy absorbed for 1st and 2nd row elements; (*ii*) that absorption can be increased for x-rays more than for electrons with a resist containing a 3rd row element, and (*iii*) the transmission ratio of the transparent and opaque region of an x-ray mask will determine the resist contrast required.

Manuscript submitted Dec. 3, 1973; revised manuscript received May 15, 1974.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1975 JOURNAL.

Table III. Values of the contrast, γ, for various negative electron resists

Material	Contrast
PVFc	1.5
P (GMA-co-EA)[(a)]	1.07
CER	0.78
PDOP	0.78
EPB	0.56

(a) High contrast form.

Photolithographic Contact Printing of 4000Å Linewidth Patterns

Henry I. Smith, N. Efremow, and P. L. Kelley

Massachusetts Institute of Technology, Lincoln Laboratory, Lexington, Massachusetts 02173

ABSTRACT

Surface acoustic wave transducers with 4000Å linewidth interdigital electrodes have been fabricated by photolithographic contact printing using conformable photomasks and AZ 1350H photoresist. The exposure time could be varied over a factor of three, indicating that line broadening due to diffraction is suppressed either by the optical nonlinearity or by the exposure development characteristics of the photoresist, or both.

Photolithographic contact printing, or "shadow printing," is widely used in the fabrication of semiconductor, surface acoustic wave, thin-film optical, and bubble domain devices. It is generally believed that the technique cannot be used to expose submicrometer linewidth patterns, and that optical projection (1, 2), electron lithography (3, 4), or x-ray lithography (5-8) must be used in this domain. In this paper we will show that interdigital electrode structures of 4000Å linewidth can be readily produced on smooth, flat sub-

Key words: photolithography, photoresist, submicron lines, conformable masks, acoustic surface waves.

strates, through the use of conformable photomasks and AZ 1350 type photoresists.[1]

In order to contact print submicrometer linewidth patterns in photoresist films, the detrimental effects of optical diffraction outside the photoresist have to be avoided by eliminating any gap between the photomask and the top surface of the photoresist. Diffraction still occurs in the photoresist. In principle, the gap can effectively be made zero by employing photomasks and substrates which are much flatter than an optical wavelength, by making the thickness of photoresist films uniform to the same tolerance, by excluding all dust and surface asperities, and by bringing the photomask into optical contact with the photoresist. Such an approach is impractical because photomasks and most substrates are not so flat. Moreover, for substrates of large area, it is generally impossible to completely exclude all dust. An alternative approach to intimate contact is to use conformable photomasks (9-11). A conformable photomask consists of a pattern in thin-film chromium (500-1000Å) or Fe_2O_3 (1300Å) on Corning Type 0211 glass,[2] 0.2 mm thick. Such photomasks readily conform to the contours of a substrate, and wherever an occasional dust particle occurs, they deform so as to minimize the area of noncontact (usually <1 mm diameter) as well as the local stress. A simple vacuum frame can be used to obtain uniform intimate contact over large areas (11). The standard type of photomask used in the semiconductor industry is on 1.5 mm thick glass, and it is not well suited to obtaining uniform intimate contact. Commercially available mask alignment systems are likewise unsuitable for submicrometer linewidth photolithography.

[2] Corning Type 0211 glass for use as conformable photomasks is obtained from Corning Glass Works, Electronic Materials Department, Corning, New York 14830. Chromium and Fe_2O_3 coated 0211 glass can be obtained from Electronic Materials Corporation, Sierra Madre Villa, Pasadena, California 91107.

Figure 1 shows a cross-sectional profile of a portion of an 8000Å periodicity grating exposed in AZ 1350 H photoresist, 9800Å thick on a glass substrate, using a mercury arc lamp and a conformable photomask in intimate contact. The photomask was made by scanning electron beam lithography. With intimate contact, the photoresist thickness and the exposure time are found experimentally not to be critical parameters. The same 4000Å linewidth patterns have also been exposed in 15,000Å thick AZ 1350 H on glass substrates. Using photoresist relief structures such as shown in Fig. 1, together with the metal lift-off process (10), surface acoustic wave transducers with five interdigital electrodes of 4000Å linewidth have been routinely fabricated in 2000Å thick aluminum on $LiNbO_3$ substrates. When the exposure time was varied by a factor of three, the linewidth increased by only about 20%. It has been established that the metal lift-off technique will work only if the photoresist sidewalls are vertical or slightly undercut (10). Transducers with 8000Å linewidths have been used in high performance L-band

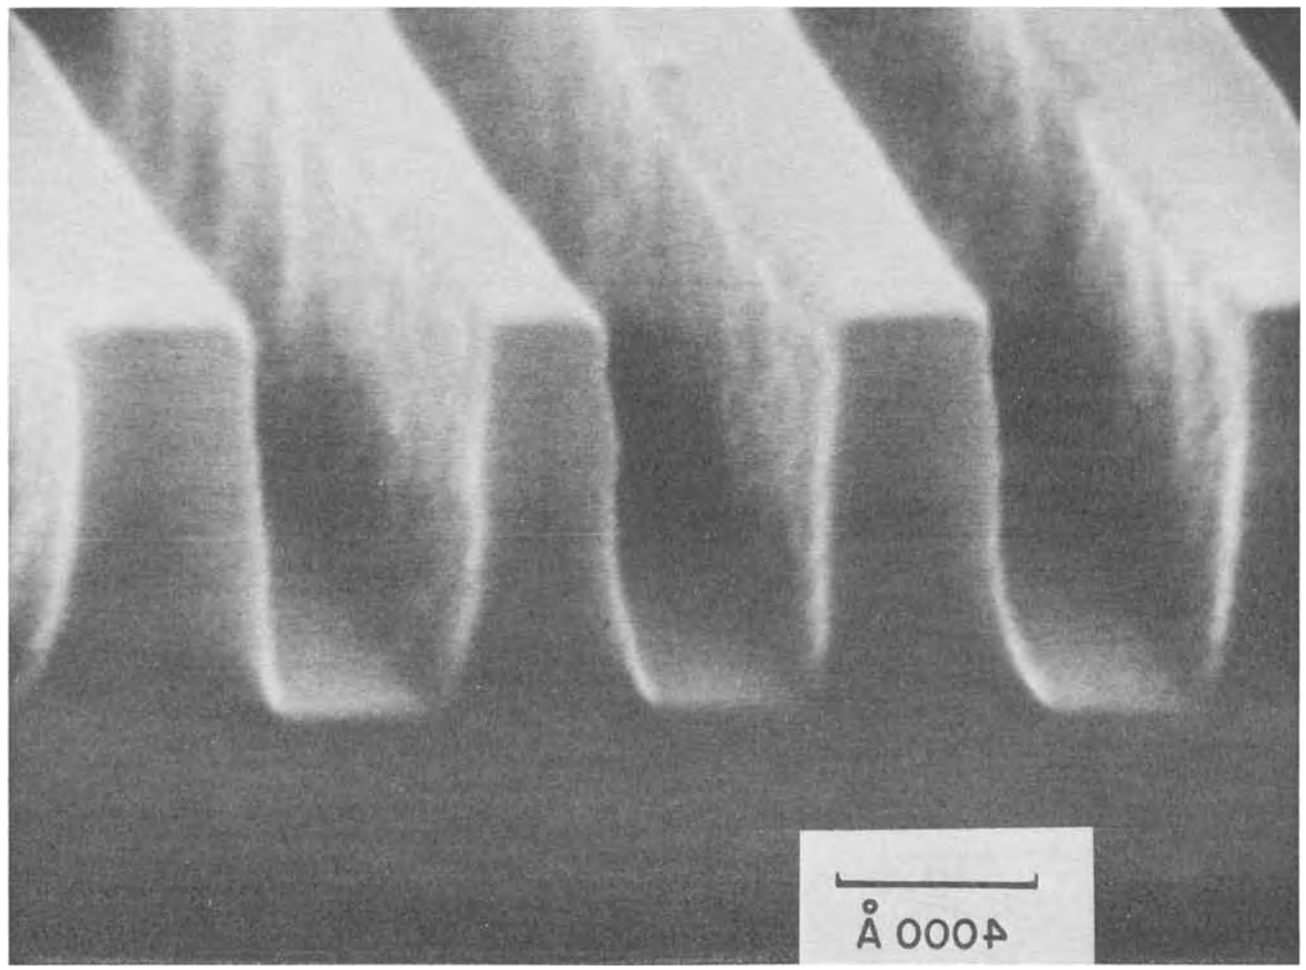

Fig. 1. Scanning electron micrograph of the cross section of a grating pattern exposed in AZ1350H photoresist on a glass substrate using a high pressure mercury arc lamp and the conformable photomask intimate contact technique. The photoresist is 9800Å thick. Because of the angles used in microscopy, vertical dimensions are foreshortened relative to lateral dimensions. The scale refers to lateral dimensions only. The photomask consisted of five slits in an 800Å thick chromium film. It was made by scanning electron beam lithography and chemical etching of the chromium, which caused irregularities along the edges of the slits. These small irregular features are replicated in the photoresist. The smaller space between two of the slits was in the original mask and was caused by an error in the scanning electron beam pattern generator.

reflective-array pulse compression filters (12). In exposing these patterns, the latitude in exposure time was a factor of eight for $LiNbO_3$ substrates and 10,000Å thick AZ 1350 H. Grating of 7000Å period, with several thousand lines, have been exposed in 3500Å thick AZ 1350 photoresist on silicon and other reflecting substrates. Following development, gratings in thin-film chromium were produced by metal lift-off. The exposure time was not critical to within almost a factor of two. Although no effort has been made to explore the ultimate limitations of the conformable mask photolithography, our observations lead us to speculate that narrower linewidths than reported here are probably possible, but may require the exercise of finer control over photoresist thickness and exposure parameters.

When a photoresist film is exposed by contact printing using a photomask in intimate contact, the relief structure obtained is determined by the near-field diffraction pattern of the photomask, and the exposure development characteristics of the photoresist. The near-field diffraction pattern of the photomask used to expose the structure in Fig. 1 is difficult to calculate exactly. Existing rigorous diffraction theory (13) deals only with perfectly conducting masks. Moreover, AZ 1350 H photoresist is not a simple linear medium. As discussed below, the light intensity (and perhaps also the phase delay) at any position in the photoresist changes with time during the course of an exposure, and this greatly complicates any diffraction calculations. For linear media, B. J. Lin has developed an approximation method for calculating the very near-field diffraction from narrow apertures in perfectly conducting opaque masks (14). Some of his results are presented in Fig. 2 for the case of a plane wave incident normally on a mask having three slits of width 2λ, with E polarized parallel to the slits (15). For the case of unpolarized polychromatic radiation, somewhat more diffraction broadening occurs (15).

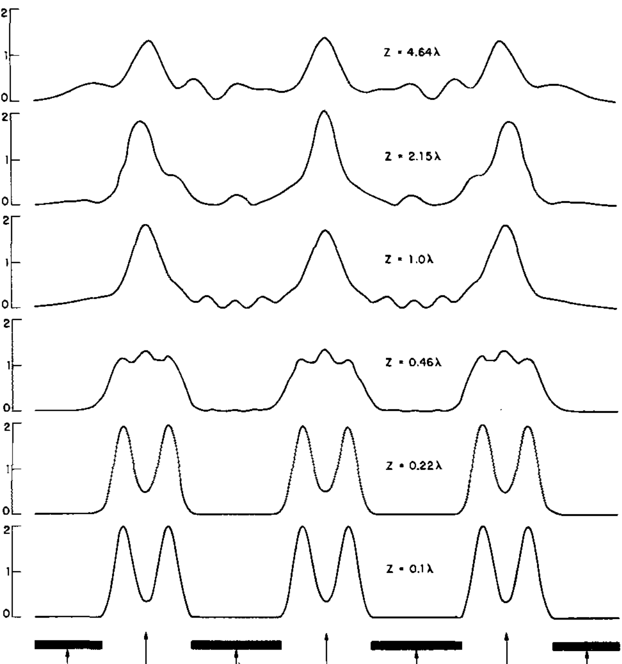

Fig. 2. Plots of light intensity in the near field of a grating consisting of three slits of width 2λ. The strips between the slits are also 2λ wide, as indicated by the solid bars at the bottom of the figure. Z is the perpendicular distance away from the grating into the near field. The plots were made from calculations provided through the courtesy of B. J. Lin, and they are for the case of a normally incident plane wave whose E field is polarized parallel to the slits. Note that at a distance $Z = 2.15\lambda$ there is significant intensity in between the slits.

It is interesting to compare the intensity distribution of Fig. 2 with the results of Fig. 1. If we assume that the index of refraction of the AZ 1350 H photoresist ($n = 1.612$) is merely a scaling factor, then the wavelengths of the prominent lines of the mercury arc lamp used (4358, 4047, and 3663Å) become 2700, 2510, and 2270Å, respectively, inside the photoresist, and the slit widths in the photomask correspond to less than 2λ. The photoresist thickness in Fig. 1 is approximately $z = 4\lambda$. For a given exposure time, one can construct from Fig. 2 surfaces of equal energy deposition per unit volume for a linear medium. These surfaces would have shapes similar to the structure shown in Fig. 1, but the "linewidth" would rapidly widen as a function of exposure time. The fact that the photoresist relief structures obtained by intimate contact printing do not change rapidly as a function of exposure time indicates that they cannot be identified as surfaces of equal energy deposition per unit volume. Indeed, because of the exposure development characteristics of AZ 1350 H photoresist one would not expect this to be the case.

The AZ 1350 type photoresists are composed of a base resin plus diazide compounds. The latter are strong absorbers at blue and ultraviolet wavelengths, and undergo photochemical decomposition leading to reduced optical absorption or "bleaching." The ultraviolet transmission of AZ 1350 is thus a function of an absorber concentration which decreases with exposure time. Herrick (16) has given solutions to the nonlinear partial differential equations which describe the bleaching of photoresist films. The development of AZ 1350 photoresist is based on the fact that as the diazide compound is decomposed, the solubility of the photoresist in an aqueous alkaline solution increases very rapidly in an almost thresholdlike manner (17-19). Dill and Neureuther have shown that by using Herrick's solutions to the bleaching equations, together with a mathematical model of the development process, one can calculate numerically the relief structure obtained in an AZ 1350 film given the light intensity distribution, the exposure time, and the development time for the case of negligible diffraction in the photoresist (17-19). Incorporating the effects of diffraction in the photoresist is a more difficult problem, and has not yet been treated rigorously. Nevertheless, we believe that the present results, in particular the insensitivity of linewidth to exposure time, indicate that line broadening due to diffraction is suppressed to some degree either by the optical nonlinearity or the exposure development characteristics of the photoresist, or both. In a future publication (20) we will discuss this tentative conclusion more thoroughly and describe in detail various equipment and techniques which have been developed for conformable mask photolithography, including means for registering a conformable photomask relative to patterns already existing on a substrate surface.

Acknowledgments

The authors are especially grateful to B. J. Lin for making his calculations of near-field diffraction patterns available to us. A. R. Neureuther and F. H. Dill kindly provided some of their unpublished work. We thank R. J. Hawryluk and R. C. Williamson for helpful discussions and R. Eager for the scanning electron microscopy.

Epitaxial Growth of $In_xGa_{1-x}As$ Waveguide Detectors for Integrated Optics

C. M. Wolfe,* G. E. Stillman, and I. Melngailis

Lincoln Laboratory, Massachusetts Institute of Technology, Lexington, Massachusetts 02173

ABSTRACT

An $In_xGa_{1-x}As$-GaAs growth process, which reduces the effects of lattice mismatch, is used to integrate regions of $In_{0.2}Ga_{0.8}As$ into GaAs waveguide structures by selective epitaxial deposition. With this technique an optimal waveguide detector configuration for 1.06 μm radiation is obtained.

The compound semiconductor system $In_xGa_{1-x}As$-GaAs has several advantages for use in integrated optics: (*i*) It can be used to generate and detect radiation at wavelengths compatible with low-loss optical fibers. (*ii*) It exhibits a variety of physical phenomena which can be used to process optical signals at these wavelengths. (*iii*) It has a well-developed technology, *i.e.*, large area, single crystal GaAs is readily available for device fabrication and epitaxial substrates, and most of the devices to perform the above functions are well understood and can be fabricated with reasonable yield in their discrete form. (*iv*) It is possible to integrate a number of these devices into a monolithic structure by epitaxial techniques.

The principal disadvantage of the $In_xGa_{1-x}As$-GaAs system is the lattice mismatch between GaAs and the alloy, which can be as high as 7.2% for $x = 1.0$ and tends to degrade the crystalline quality of the material. Thus, it is desirable to utilize a graded compositional region between the GaAs substrate and the desired alloy composition to reduce the effects of lattice mismatch. In this paper we discuss the epitaxial growth system used to provide compositional grading and describe the incorporation of regions of $In_xGa_{1-x}As$ into GaAs waveguide structures (1) by selective epitaxial deposition.

Epitaxial Growth System

The method we have used to grow $In_xGa_{1-x}As$ on GaAs substrates is different from methods previously described (2-7) and is shown schematically in Fig. 1. The epitaxial growth system consists of two separate chambers for indium and gallium melts with $AsCl_3$ as the source for arsenic and chlorine to transport the indium and gallium. An electronic feedback system is used to control flow rates and hence the alloy composition. Mass flow transducers produce output voltages which are directly proportional to flow rates. These voltages are fed into error detection networks where they are compared to reference voltages. The difference signals are then used to drive motorized needle valves. Palladium-purified hydrogen is bubbled through two $AsCl_3$ reservoirs which are temperature controlled at 12.0°C by a circulating bath. The hydrogen is saturated with $AsCl_3$ at this temperature, and the resulting gas mixtures are then passed over presaturated indium and gallium melts (8) which are maintained at 850°C. A mixing chamber at 900°C is located between the source and growth regions to homogenize the vapors and to smooth out small fluctuations in gaseous composition. Epitaxial growth is obtained on GaAs substrates at a temperature of 700°C in a gradient of about 8°C/min. Growth is initiated with zero flow over the indium melt [1] and this flow is gradually increased [2] until the desired alloy composition is attained.

Under the conditions described above the alloy composition of the epitaxial layer is largely determined by the flow rates of $AsCl_3$-H_2 over the indium and gallium melts.[3] In Fig. 2 we have plotted the mole per cent (m/o) InAs in the constant composition region of the growth [4] *vs.* the ratio of the flow rate over the indium

* Electrochemical Society Active Member.

Key words: epitaxy, InGaAs, detector, waveguide.

[1] The flow rate over the gallium melt was held constant at a value that gave a total flow of 250 ml/min after the grading process. This rate depends on the desired alloy composition and can be obtained from Fig. 2.

[2] The desired rate of change of this flow varies with growth rate, which in turn varies with substrate orientation and the desired final alloy composition. Thus, it must be changed empirically to achieve the approximate required compositional gradient.

[3] The boats for the indium and gallium melts were 10 cm long with linear flow rates over the melts from 10 to 40 cm/min. Thus, the melts and gas mixtures were close to equilibrium.

[4] Alloy compositions were determined by electron microprobe analyses and were typically uniform over the layers to within 3% of the mole fraction.

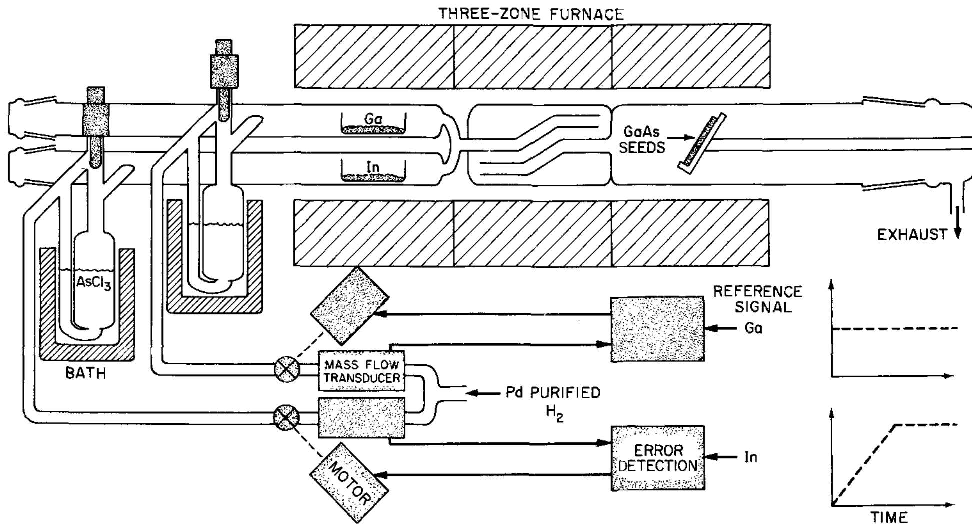

Fig. 1. Epitaxial $In_xGa_{1-x}As$ growth system showing the electronic feedback circuit used to control flow rates.

melt to the flow rate over the gallium melt. The dashed lines indicate the approximate run-to-run scatter in the data (open circles) which is largely due to different melt depletion rates. These results show that alloy composition is a linear function of the ratio of flow rates. Thus, for relatively constant growth rate (which is indicated by experiment) and constant flow rate over the gallium melt, a linear increase with time in the flow rate over the indium melt produces an approximately linear increase in alloy composition.

Continuous epitaxial layers of $In_{0.2}Ga_{0.8}As$ for 1.06 μm avalanche photodiodes (9) have been grown on GaAs {100}, {111}Ga, and {111}As substrates using this grading process with compositional gradients of 0.01 mole fraction InAs/μm. These layers are free from gross defects, and preliminary study of the defect structure, using etchants developed for GaAs (10), indicates dislocation densities of the order of 10^6 cm^{-2} and stacking fault densities of the order of 10^4 cm^{-2}. These values show that about 99.999% of the lattice mismatch is maintained elastic (11) with the grading and growth process employed. Under equivalent conditions the small area growth discussed in the next section exhibits substantially less defect structure, and comparable quality material can be obtained with compositional gradients of about 0.05 mole fraction InAs/μm.

Selective Epitaxial Deposition Process

Using this growth process, we have integrated small regions of $In_{0.2}Ga_{0.8}As$ into GaAs waveguide structures by the selective epitaxial deposition (12) process shown in Fig. 3. The waveguide structures shown in Fig. 3(a) are formed by growing a 5-20 μm layer of high purity ($N_D + N_A \sim 10^{14}$ cm^{-3}) GaAs on a heavily doped ($n \sim 10^{18}$ cm^{-3}) GaAs substrate using techniques previously described (13). Optical guiding can be obtained in the high purity n-layer since plasma effects reduce the refractive index in the heavily doped n+ substrate. A pyrolytic SiO_2 is then deposited over this waveguide structure and circular regions are opened in the SiO_2 using standard photolithographic techniques. This patterned SiO_2 is then used as an etch mask and holes are etched through the high purity layer to the heavily doped substrate to obtain the structure shown in Fig. 3(b). Depending on the crystallographic orientation and etchant, a variety of hole geometries can be pro-

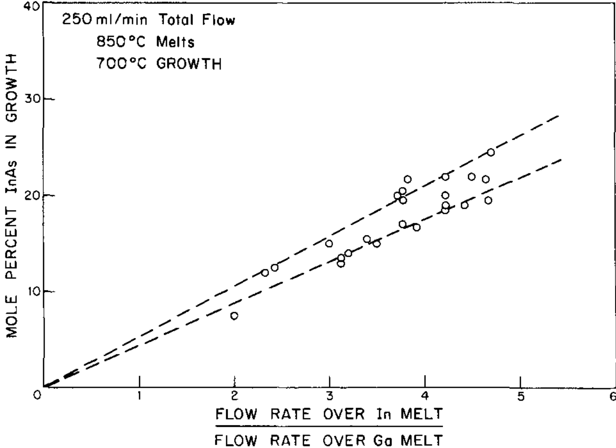

Fig. 2. Mole per cent InAs in the constant composition region of the epitaxial growth as a function of the ratio of flow rates. The dashed lines bracket the approximate scatter in the data (open circles).

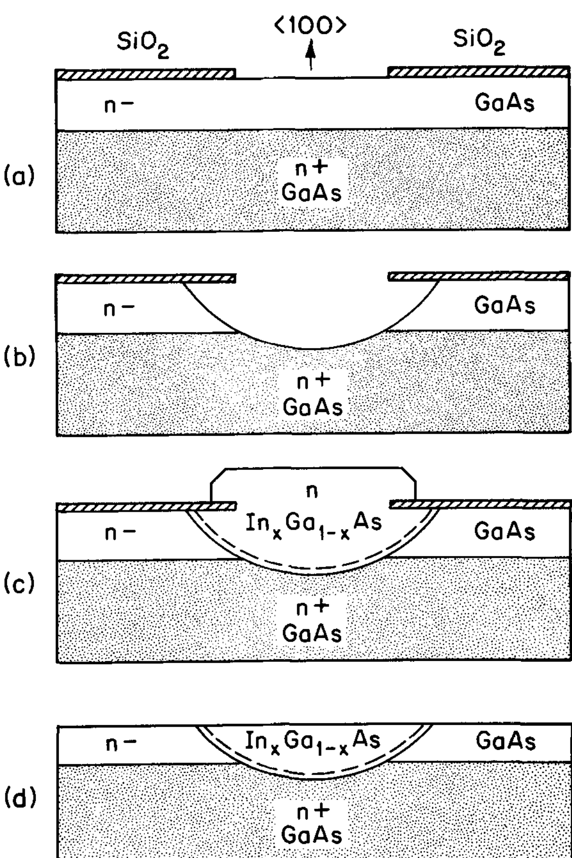

Fig. 3. Selective epitaxial process for forming waveguide detector structures.

duced (14). However, as will be discussed later, the most suitable geometry for a waveguide detector is a hemisphere. To obtain a hemispherical hole we use a nonpreferential etch of 5 H_2SO_4:1 H_2O_2:1 H_2O on a {100} surface. This etchant is allowed to cool for about 10 min to approximately room temperature before use to obtain a slower etch rate.

The resulting structure shown in Fig. 3(b) is then placed in the epitaxial reactor, where the SiO_2 now serves as a mask against growth. Thus, epitaxial growth of $In_xGa_{1-x}As$ is obtained only in the holes etched in the GaAs waveguide structure. The composition of the alloy is graded out to some region, indicated by the dashed line in Fig. 3(c), where the alloy composition is maintained constant at the desired value. For reasons discussed below, the $In_xGa_{1-x}As$ should be doped to a value at least a factor of five higher than the GaAs waveguide (15). Although it would be desirable to terminate growth at the edge of the SiO_2, in practice this is somewhat difficult. Generally, the growth proceeds out of the hole and over the SiO_2, giving a faceted structure as indicated in Fig. 3(c). To obtain the waveguide structure indicated in Fig. 3(d), the SiO_2 is removed and the faceted $In_xGa_{1-x}As$ and the GaAs waveguide are mechanically chemically polished to the desired thickness with 20 CH_3OH:1 Br on a rotating pad.

Waveguide Detector Structures

Figure 4 shows a scanning electron micrograph, a diagram of the upper surface, and a cleaved cross section of a region of $In_{0.2}Ga_{0.8}As$ grown in a GaAs waveguide structure. The faceting indicated in Fig. 3(c) is evident and is typical of that obtained for <100>-orientated growth in GaAs (14) as well as in $In_xGa_{1-x}As$. The diameter of the grown-in region is about 125 μm. The interfaces between the grown-in 10^{16} cm^{-3} $In_{0.2}Ga_{0.8}As$, the 10^{14} cm^{-3} GaAs waveguide, and the 10^{18} cm^{-3} GaAs substrate are delineated by a 1 HF:3 HNO_3:4 H_2O etch. The change in curvature at the interface between the waveguide and the grown-in region, which is undesirable for reasons discussed below, is caused by a slight *in situ* furnace etch. The desired structure can be obtained by polishing below this change in curvature.

Figure 5 shows an optical micrograph and a diagram of the cleaved cross section through a similar grown-in region in a 5 μm thick waveguide. A Schottky barrier placed over this hemispherical region of $In_{0.2}Ga_{0.8}As$ and over part of the waveguide surrounding this region produces an essentially ideal detector structure for 1.06 μm radiation propagating through the GaAs waveguide. This structure has the following advantages: (*i*) The heavily doped 10^{18} cm^{-3} GaAs substrate, in addition to giving the change in refractive index to provide guiding in the 10^{14} cm^{-3} GaAs layer, also acts as a closely spaced back contact for a low resistance, high band-

Fig. 4. Scanning electron micrograph and diagram showing the upper surface and cleaved cross section of an $In_{0.2}Ga_{0.8}As$ region grown in a GaAs high purity waveguide.

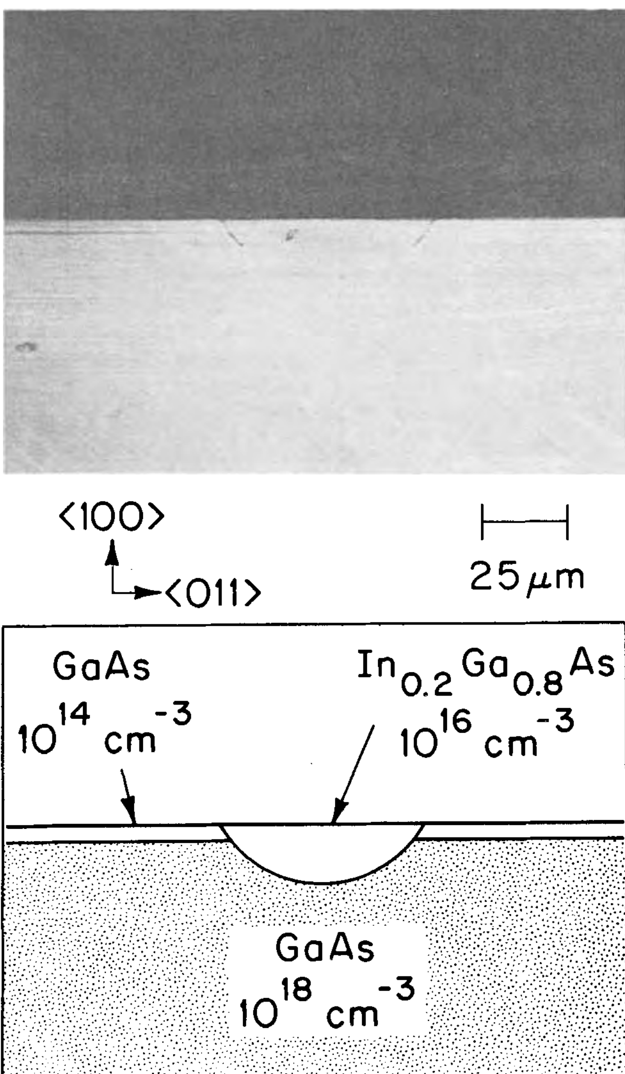

Fig. 5. Optical micrograph and diagram showing the cleaved cross section through a waveguide detector structure.

width device. (*ii*) The 10^{14} cm^{-3} GaAs waveguide also serves as a guard ring (15) for the 10^{16} cm^{-3} $In_{0.2}Ga_{0.8}As$ device material, since the reverse bias breakdown voltage is higher in the lighter doped waveguide material than in the heavier doped detector material. (*iii*) The hemispherical geometry produces an inverted mesa structure, which reduces the component of electric field along the critical interface region and thereby tends to suppress edge breakdown. (*iv*) The increased refractive index in the inverted mesa alloy region tends to deflect radiation from the waveguide into the high field region of the diode.

With this guarded, inverted mesa geometry, one should be able to reverse bias these detector structures to sufficiently high voltages to observe multiplication or avalanche gain. Present device results show that bulk breakdown voltages can be achieved in these structures with dark currents comparable to those observed in discrete GaAs Schottky barrier devices (about 10^{-7}A at breakdown). These structures have also been used to detect 1.06 μm Nd-doped YAG radiation propagating along the GaAs waveguide with a quantum efficiency of 60% and with multiplication gain (16).

Conclusion

From the results described above, we conclude that this selective epitaxial deposition process provides a useful means of fabricating optimal waveguide detector structures for integrated optics at wavelengths compatible with low loss optical fibers. The small area growth is of better crystalline quality than continuous layers grown under equivalent conditions. Thus, we anticipate that with additional development, the performance of such integrated avalanche photodiodes should be equal or superior to the performance of similar discrete devices (9).

Compatibility of Oxide Passivation and Planar Junctions with Al, Ga, and P Diffusions

P. Rai-Choudhury,* Y. C. Kao,* and G. G. Sweeney

Westinghouse Research Laboratories, Pittsburgh, Pennsylvania 15235

ABSTRACT

With the emergence of sophisticated high voltage devices it is becoming necessary to integrate deep junctions with the planar technology. Because of the many disadvantages of the conventional p-type dopant, namely boron, use of aluminum and gallium is common practice in the fabrication of deep junctions. Sealed tube Al or Ga diffusion results in a damaged surface layer (~1 μm) on silicon wafers. During subsequent heat-treatment in oxidizing ambient these dopants outdiffuse, causing depletion in the silicon and forming their respective oxides at the Si-SiO_2 interface. The pile up of the dopants near the silicon surface and their interaction with the SiO_2 seriously degrade the masking properties of the oxide during phosphorus diffusion. Phosphorus induced crystallization of the amorphous oxide compounds the problem of mask failure. Possible solutions to minimize the degradation of the thermal oxide during device processing are discussed.

In the fabrication of planar devices, phosphorus and boron diffusions have been commonly used. Due to their small ionic radii (1.07Å for P^+ and 0.98Å for B^-) these dopants frequently cause massive dislocation generation in silicon (1). Presence of any surface oxides and/or precipitates in the bulk silicon could prevent boron diffusion locally and thus cause nonuniform diffusion. Boron diffusion is also sensitive to ambient gases (2). Boron is known to form stable

* Electrochemical Society Active Member.

Key words: oxidation, segregation, masking, passivation, crystallization.

compounds with silicon, such as SiB_4 and SiB_6 (3). Thus, boron is unattractive as a dopant and is used because it is the only p-type dopant that can be effectively masked by silicon dioxide. Phosphorus diffusion, on the other hand, is not commonly used to form a high voltage blocking junction. Its use as an emitter dopant has some merits in providing high surface concentration and gettering of undesirable metallic ions. For deep emitters (typically 10-20 μm) diffusion induced (shallow) dislocations are not considered harmful.

The use of aluminum or gallium as diffusant to form blocking junctions has some attractive features. The ionic radii of these two dopants (1.29Å for Al^- and 1.27Å for Ga^-) compare favorably to the tetrahedral covalent radius of silicon (1.17Å) and the elastic limit of silicon is not reached, even at the solid solubility limit (4). Therefore, dislocations cannot be generated in silicon by the diffusion induced stress alone. Compared to boron, both aluminum and gallium (at higher temperature) diffuse more rapidly, which is a desirable feature for deep junctions. Neither Al nor Ga form any intermetallic compounds with silicon. The use of Al and Ga diffusions has some additional advantages from the point of view of device performance. The diffused junctions yield better blocking voltages than that formed by boron diffusion.

Both Al and Ga diffusions, however, suffer from a few disadvantages of their own. When the diffusion is carried out in a sealed system under vacuum or an inert ambient, a thin layer of damaged silicon is produced at the surface. Also, due to the high diffusivity of Al and Ga species in silicon dioxide, they cannot be diffused selectively in the usual way to fabricate planar junctions. In addition, during any subsequent oxidations and heat-treatments both Al and Ga atoms outdiffuse and produce an inhomogeneous oxide film which is not an effective mask against phosphorus diffusion. Furthermore, the oxide may be degraded during the phosphorus diffusion due to catalyzed crystallization (5). This degraded oxide also does not etch uniformly during the delineation of the metallization mask. As a consequence of the dopant outdiffusion and crystallization of the oxide, direct shorting of the emitter junction at the surface is frequently observed.

This investigation is undertaken to explore the compatibility of the oxide passivation and the planar junction with Al, Ga, and P diffusion. Here we examine the surface of the Si wafers following Al and/or Ga diffusion, the quality of the oxide grown on these surfaces, the outdiffusion of the dopants during oxidation, and the effects of P diffusion. The purpose of the study is to compare the various diffusion processes, which is helpful in selecting a compatible process for a given device.

Experimental Procedure

Silicon wafers used were n-type, 1.25 in. in diameter, 28-44 ohm-cm, float zoned, having a (111) oriented surface. The wafers were chemically polished prior to diffusion (nonselective) with Al or Ga in a temperature range of 1050°-1175°C for 16 hr. The wafers were then thermally oxidized at 1200°C or 1235°C for 2-3 hr. Following photolithography and etching steps to open emitter windows, wafers were phosphorus-diffused at 1150°-1200°C for 1-2 hr and redistributed at 1200°C for 4-16 hr in an oxidizing ambient. After each high temperature treatment, five wafers were withdrawn from the batch for evaluations.

The impurity concentration profiles following diffusion and various heat-treatment operations were measured by the spreading resistance technique (6). Secondary ion mass spectrometry (SIMS) and electron beam microanalysis were used to detect any Al and Ga pile up at or near the oxide-silicon interface. X-ray topography was used to examine the silicon surface layers, the quality of the oxide, and in the identification of any second phase particles. Reflection electron diffraction was used to detect very shallow damaged layers on the silicon surface following various processing steps. Finally, the reverse current voltage characteristics of the emitter junctions were checked to establish their quality.

Results

The results are presented in four sections, namely, outdiffusion of Al and Ga, defects at the silicon-silicon dioxide interface, phosphorus induced defects in the silicon and the oxide, and the quality of the emitter junction.

Outdiffusion of Al and Ga.—Both Al and Ga diffusions were carried out in an inert or vacuum ambient which results in a diffusion from a constant surface concentration with a complementary error function type of profile. Surface concentrations begin to deplete only during subsequent heat-treatment operations. Fig. 1 (a and b) shows the effect of the outdiffusion of Al and Ga during oxidation and phosphorus diffusion. Here the impurity concentration is plotted as a function of the normalized junction depth. In Fig. 1(a) the impurity profiles following the sealed tube Al diffusion, the oxidation, and after phosphorus redistribution are shown. Similarly, in Fig. 1(b) the impurity profiles after the sealed tube Ga diffusion, after oxidation and redistribution of Ga at 1235°C for 16 hr, after a second oxidation and phosphorus redistribution are shown. Results shown in Fig. 1 indicate significant outdiffusion of both Al and Ga. In the case of Al, the concentrations at the surface is found to decrease from 2.5×10^{18} atoms/cm^3 after Al diffusion to 1.5×10^{16} atoms/cm^3 after phosphorus diffusion. The outdiffusion permits larger penetration of the emitter junction in the lateral direction at the surface than that in the vertical direction, as is observed by beveling and staining technique. The decreased surface concentration leads to a higher emitter junction breakdown voltage.

The Al diffused wafers were examined by secondary ion mass spectrometry to further explore the nature of outdiffusion and any clustering of electrically inactive dopants. The technique used has been described elsewhere (7) and is shown to be reproducible. Figure 2 shows the Al concentration profile (relative intensity) near the surface in a silicon wafer that has been processed through Al diffusion to phosphorus emitter redistribution. The processed wafer was cleaned to remove any oxide and surface films before analysis using O_2^+ as the primary ion beam. The figure shows the Al pile up near the silicon surface which is electrically inactive. This is followed by a depletion region and a maximum Al concentration, which is probably bonded to oxygen. The intense peak at the surface is usually attributed to a chemical enhancement, *i.e.*, the ionization efficiency of Al is much higher when it is bound to oxygen.

It is suspected that any Al pile up at the SiO_2-Si interface and electrically inactive Al in silicon may be bound to oxygen. To investigate this point, SIMS measurements were carried out through the oxide layer using argon as the primary ion beam. Figure 3(a) shows the Al profile (relative intensity) through SiO_2 and into the silicon. The SiO_2 layer extends to about 5000Å and contains relatively little Al. At depths below 5000Å a large number of Al clusters are observed in the SiO_2-Si interface regions and in the surface layers of silicon. Figure 3(b) was obtained by monitoring the AlO^+ ionic species and indicates a rise in the intensity just before the SiO_2 interface is reached, suggesting some reaction between Al and the SiO_2 layer. The initial rise is followed by a depletion region (above about 5000Å) which corresponds to the maximum of Al clustering in Fig. 3(a). The fact that AlO^+ clustering is observed indicates that aluminum is present in oxidized form. Thus, it appears that Al is rejected by the silicon during various

Fig. 1. Effects of oxidation and phosphorus diffusion on the depletion of Al and Ga concentrations. a (left), Al diffusion conditions: 1050°C for 16 hr; oxidation conditions: 1200°C for 2 hr; phosphorus diffusion conditions: 1200°C for 4 hr. b (right), Ga diffusion conditions: 1175°C for 16 hr; oxidation conditions: 1235°C for 12 hr; phosphorus diffusion conditions: 1200°C for 16 hr.

oxidation heat-treatment operations and is piled up as Al and Al-O clusters at and near the silicon surface.

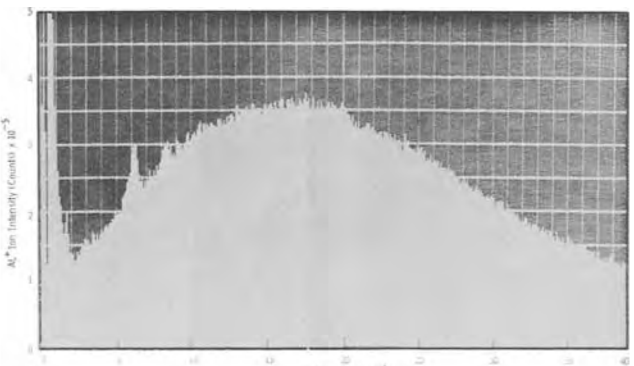

Fig. 2. Al concentration (relative intensity) profile showing depletion and clustering of Al near the surface. The silicon wafer has been processed through Al diffusion to P emitter redistribution and is analyzed by SIMS using O_2^+ ion beam. Vertical: 5×10^3 counts full scale; horizontal: 4 μm full scale.

A similar analysis of Ga diffused samples by SIMS indicates that Ga is piled up in the oxide and, unlike Al, no accumulation in the silicon is noticeable.

Defects at the silicon-silicon dioxide interface.—The surface of the silicon wafer appears to be damaged following the sealed tube diffusion in the case of both Al and Ga. The presence of these damaged surfaces is revealed by the reflection electron diffraction patterns shown in Fig. 4 and 5, both of which indicate the presence of a polycrystalline component. These damaged regions are very shallow and disappear when 1μ or so of the surface is chemically etched. The damage from Ga diffusion seemed to be more pronounced or extensive than that from Al diffusion. Both Al and Ga diffused wafers are free from any diffusion induced dislocations as revealed by the x-ray topography.

The outdiffusion of Al becomes increasingly noticeable with increasing heat-treatment time and temperature in an oxidizing ambient. Figure 6 shows a reflection electron diffraction pattern of a silicon surface which received an oxidation of 2 hr at 1200°C followed by phosphorus diffusion (4 hr at 1200°C). The wafer is dipped in HF to remove the phosphorus glass and the thermal oxide, and the diffraction pat-

tern is obtained from the areas that were masked during the phosphorus drive. The extra reflections in the figure resemble η-Al_2O_3 and could not be removed by boiling in HCl, H_2SO_4, or H_3PO_4.

The outdiffusion of Ga is similar to that of Al in many respects. Figure 7 shows a diffraction pattern from a silicon surface following Ga diffusion at 1175°C for 16 hr and an oxidation cycle for Ga redistribution. The wafer was dipped in HF prior to examination in the electron microscope. The diffraction patterns indicate the presence of polycrystalline silicon and β-Ga_2O_3. The reflections due to gallium oxide disappear when the sample is boiled in hot acids (*e.g.*, HCl, H_2SO_4, aqua regia), but the polycrystalline silicon component is still present. Gallium oxide is found to reappear if the cleaned sample is oxidized again. When the oxide near the silicon-silicon dioxide interface is examined by transmission electron microscopy (TEM), a dispersed second phase could be detected as shown in Fig. 8. This second phase does not give any diffraction pattern and is believed to be induced by the outdiffusion of gallium. A freshly grown oxide on the same wafer after the original oxide was removed and the

wafer cleaned in boiling acids, is found to be free of this second phase particles. However, the silicon surface under the oxide is still damaged, and a polycrystalline component could be observed from the diffraction pattern.

The surface of the diffused silicon wafer, following Ga redistribution heat-treatment, was examined by an electron probe microanalyzer. Spectral line analysis indicated the presence of both Ga and O on the surface. This is a good indication of the fact that Ga is clustering with oxygen at the silicon-silicon dioxide interface. A similar test with the Al diffused samples failed to detect any Al on the silicon surface.

Phosphorus induced defects.—The diffusivity of P in the phosphosilicate glass region has been found to vary over several orders of magnitude, depending on the concentration of P_2O_5 in SiO_2 (8). The catalytic influence of P leading to crystallization of amorphous oxide has been observed by several investigators (5). Schmidt *et al.* (9) have identified one of the main crystalline phases to be $SiO_2 \cdot P_2O_5$. In this study we have observed highly crystallized regions of the oxide along with the frequent presence of polycrystalline silicon within the oxide. Figure 9 shows a TEM and a diffraction pattern of crystallized regions in the oxide following a 16 hr phosphorus redistribution heat-treatment at 1200°C. The fact that the crystallization was P induced was confirmed by the absence of any polycrystalline regions in the original amorphous SiO_2 following prolonged heat-treatments (up to 64 hr at 1200°C). It is interesting to note the presence of very

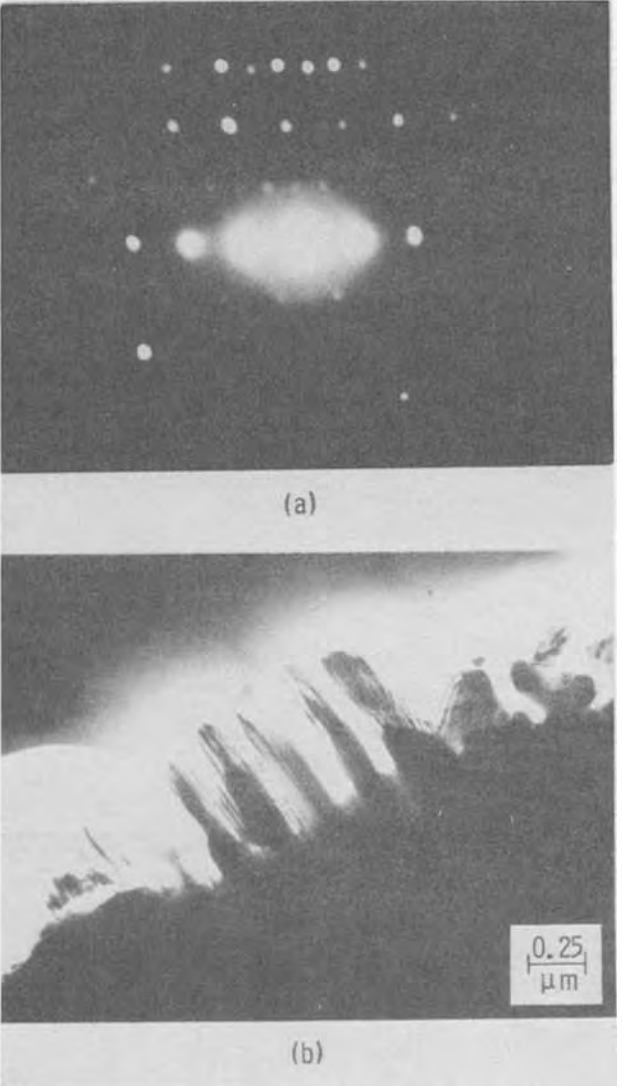

Fig. 9. Diffraction pattern (a) and transmission of electron micrograph (b) of crystallized regions in the oxide following 16 hr P redistribution heat-treatment at 1200°C.

fine grain (1000Å) silicon at various stages of growth inside the oxide film. Figure 10 shows a fairly large aggregate of polycrystalline silicon growth in oxide following P redistribution heat-treatment. The presence of such crystallized oxides and elemental silicon could increase the conductivity of the passivation oxide and might severely affect the junction leakage current.

Different types of interdigitated emitter patterns were used for phosphorus diffusion. X-ray topographs of wafers indicate the phosphorus diffused regions to be heavily dislocated. The delineation of the emitter fingers and the oxide along the emitter base junction appear to be very nonuniform, as shown by the XRT in Fig. 11. Frequently, initial masking oxides grown at high temperature and degraded by dopant outdiffusion gave poor results. Such oxides either became crystallized and failed to passivate the emitter junction or gave rise to numerous n^+ pipes in the p-base region during phosphorus diffusion. These crystallized oxides also have poor etching properties. Figure 12 shows a scanning electron micrograph of the emitter base junction prior to metallization. Note the complete absence of the passivation oxide near the center of the photograph, thus exposing the bare junction. The presence of bare silicon in the supposedly passivated region was confirmed by using the x-ray attachment of the scanning electron microscope. This type of inhomo-

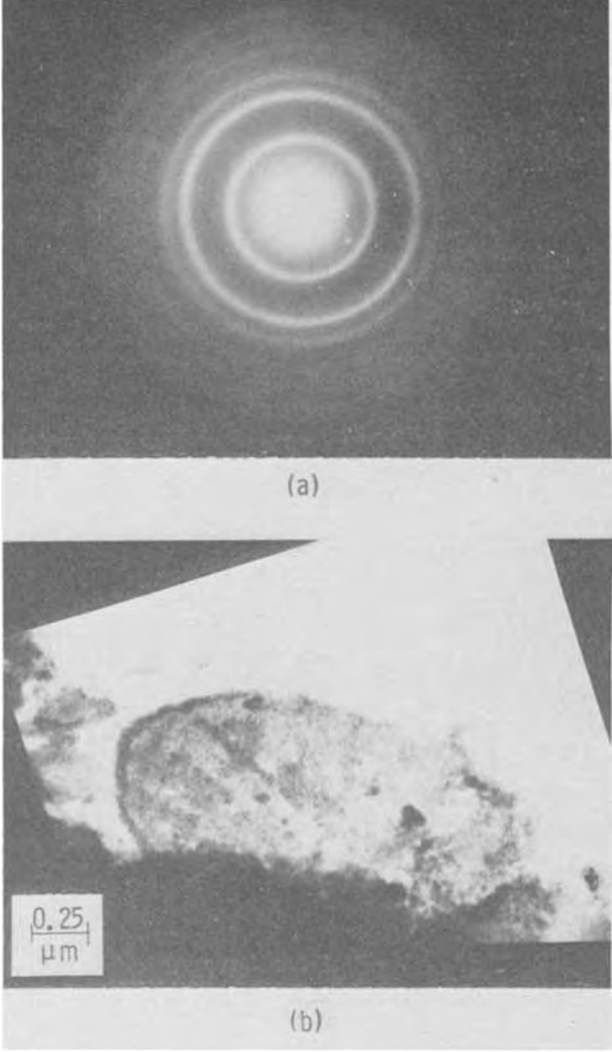

Fig. 10. Diffraction pattern (a) and transmission electron micrograph (b) showing the presence of very fine grain silicon within the oxide.

geneous etching of the oxide is avoided by minimizing P induced crystallization of the oxide.

Emitter junction.—At the end of the diffusions the emitter junction I-V characteristics of the devices were measured. On devices with an Al diffused base layer the emitter junction was found to be shorted after metallization. This shorting could be removed by etching the silicon surface between the emitter and the p-base contacts. After etching the measured breakdown voltage was around 20-25V, and the leakage current of the mesa junction ranged between microamperes to milliamperes. On the best units the leakage current density was around 10^{-6} A/cm^2.

On devices with a Ga diffused base layer, planar emitter junctions with acceptable I-V characteristics have been obtained when the silicon surface was cleaned and boiled in acids prior to oxidation and when the oxidation temperature was lowered from 1235° to 1200°C. After metallization, the measured breakdown voltage ranged from 15 to 20V with a leakage current less than 1 mA. However, the measured I-V curve indicated that the leakage current was dominated by a channel current with a pinch off voltage between 1-3V. The leakage current density at 5V was around 10^{-4} A/cm^2. Comparing with boron diffused devices on which the measured breakdown voltage was around 10V and the leakage current density at 5V around 10^{-7} A/cm^2, Al or Ga diffused devices showed a higher breakdown voltage but a much

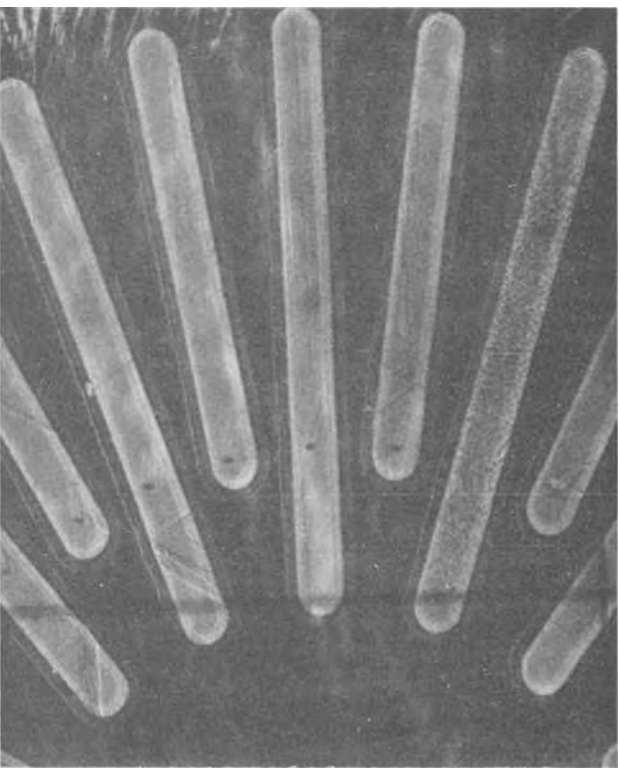

Fig. 11. X-ray topograph of a diffused wafer showing heavily dislocated emitter fingers, inhomogeneous etching of the passivation oxide along the emitter-base junction, and the poor quality oxide giving additional contrasts in the topograph.

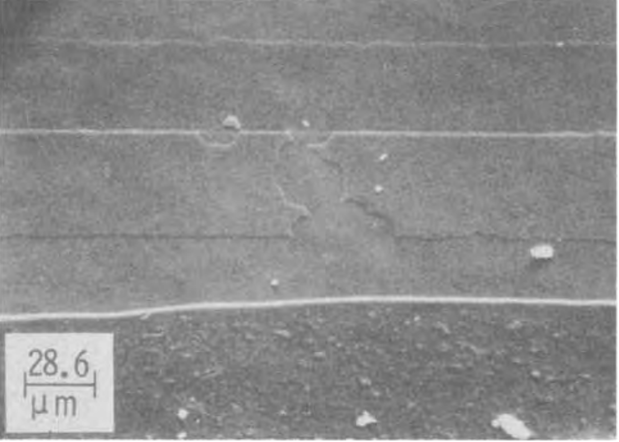

Fig. 12. Scanning electron micrograph of the emitter base interface region showing the absence of the passivation oxide near the center.

higher leakage current. The presence of the surface channel current on devices with a Ga diffused base layer and the need to etch the silicon surface on devices with an Al diffused base layer strongly suggested that high leakage currents were originated at the surface. With an Al diffused base, the continuous interaction between the aluminum and the oxide during the oxidation period rendered the oxide ineffective against phosphorus diffusion. This problem, together with localized phosphorus penetrations through crystallized oxides, have led to the shorting of the emitter junction at the surface. With Ga diffusion, cleaning the silicon surface in boiling acids seemed to improve the oxide quality in masking against the phosphorus diffusion

and resulted in devices with acceptable emitter junction I-V characteristics.

Discussion

The damaged silicon surface that results from the sealed tube Al and Ga diffusions appears to be related to the formation of the respective alloys. Examining the case of Al first, we note that the eutectic composition is 12.3% silicon. The vapor pressure of Al at 1050°C is about 3×10^{-4} mm Hg, and it reacts with the quartz walls until a protective coating of silicon and Al_2O_3 is built up. Al is also a fast diffusant in silicon when compared with Ga. Thus, the formation of Al-Si eutectic at the wafer surfaces is limited by the availability of Al. Consequently, the lattice disorder introduced at the silicon surface is confined to a very shallow depth. In the case of Ga, however, the damage to the silicon lattice could be more extensive. At a diffusion temperature of 1175°C the vapor pressure of Ga is about 10^{-1} mm Hg, and its interaction with the quartz tube is negligible. Thus, a relatively large quantity of Ga is available for diffusion and formation of surface alloys. Further, Ga-Si eutectic requires very little silicon (10) and could easily form during cooling of the wafers following diffusion. As may be expected, the damage to the silicon lattice due to Ga is more extensive than that from Al (see Fig. 4 and 5). In order to remove these damaged layers about 1-2 μm of silicon should be etched from the wafers following the sealed tube diffusion. Otherwise, the silicon-silicon dioxide interface over the planar junction would contain a damaged silicon layer which will introduce excess junction leakage current (generation current under reverse bias and recombination current under forward bias).

Even if the damaged silicon is removed following the sealed tube diffusion, subsequent oxidation causes both Al and Ga to outdiffuse and form disordered mixed phases at the interface. The important parameters governing the redistribution of impurities during thermal oxidation are the segregation coefficient ($m = C_{Si}/C_{ox}$) of the impurity at the oxide-silicon interface, the ratio of the diffusion coefficient of the impurity in the oxide to its diffusion coefficient in Si, and the ratio of the parabolic rate constant of the oxidation to the square root of the impurity diffusion coefficient in silicon ($A/\sqrt{D^{Si}}$). The case of Ga outdiffusion has been treated by Grove *et al.* (11). At about 1200°C the segregation coefficient for Ga is approximately 20, indicating that Ga should be rejected by the oxide and should pile up in the silicon. The reason for depletion of Ga during oxidation is its high diffusivity in the oxide ($D^{ox}/D^{Si} \approx 322$). Reasonably high vapor pressure of Ga at 1200°C allows it to escape to the gas phase. At a given temperature, the value of $A/\sqrt{D^{Si}}$ is higher for wet oxidation (steam) than for dry oxidation (O_2), and the impurity depletion is reduced by lowering this ratio. Thus, dry oxidation would result in minimum redistribution and depletion of impurities.

The case of Al outdiffusion during thermal oxidation is somewhat more complex because of its interaction with SiO_2. In this case a segregation coefficient ($m < 10^{-3}$) is difficult to define because Al, instead of dissolving in SiO_2, reduces it to Si or SiO. In contrast with Ga, the oxide here accepts Al until all the SiO_2 is reduced. This point has been substantiated by diffusing Al through an oxidized silicon and noting the disappearance of the oxide. Significant interaction between Al_2O_3 and SiO_2 may not be expected at the typical diffusion temperature (12) (the eutectic is at 1595°C). The value of the diffusivity ratio is much greater than 1, similar to Ga. Unlike Ga, however, Al is not likely to be transported to the gas phase due to its considerably lower vapor pressure and strong affinity for oxygen. About the only form in which Al could leave the surface is by forming suboxides such as Al_2O and AlO. The outdiffused Al should, therefore, be found as Al_2O_3 in the silicon-silicon dioxide interface. This is consistent with our experimental results. As long as we have an Al diffused junction, oxidation will always result in a disturbed silicon-silicon dioxide interface. Thus, at a high Al surface concentration this process is incompatible with a silicon dioxide masked planar junction.

The presence of elemental silicon in the oxide was occasionally observed in steam or dry oxygen grown oxide on high resistivity, undiffused wafers. This tends to indicate that the presence of impurities, such as Al and Ga, is not essential in the formation of the silicon phase. Nucleation of the silicon clusters does not seem to be associated with any observable crystallographic defects. One possibility is through the formation of SiO in the presence of excess silicon, and the subsequent disproportionation to Si and SiO_2 on cooling. The activity of SiO is expected to be significant at the diffusion temperatures of interest (*e.g.*, $p^e_{SiO} \sim 6 \times 10^{-4}$ atm at 1500°K).

Summary

The compatibility of Al, Ga, and P diffusion with oxide passivation and planar junction is briefly examined. Al and Ga diffusion introduce a surface layer of damaged silicon through formation of respective alloys and eutectics during cooling. These damaged silicon layers may be removed by chemical etching. During heat-treatments under oxidizing ambients both Al and Ga outdiffuse and could adversely affect the silicon-silicon dioxide interface, the bulk of the oxide, and the shape of the impurity profile. Consequently, compatibility with oxide passivation is difficult to achieve, unless high surface concentration of the dopants is avoided. By maintaining a reasonably low surface concentration, rejecting the redistribution oxide, and growing a fresh oxide along with suitable acid treatments of the wafers, a significant improvement is made in the quality of the junction passivation. Phosphorus emitter diffusions frequently catalyze the formation of crystalline oxide which has poor masking and etching properties. Mask failure in the base regions results in n^+ pipes, and inhomogeneous etching exposes the emitter base junctions resulting in increased leakage current. With gallium diffusion, cleaning the silicon surface in boiling acids improves the oxide quality in masking against the phosphorus diffusion and resulted in devices having acceptable emitter junctions.

ABSTRACT

The vapor-hydride method of GaAs epitaxial growth permits separate control of the flow rates of both the AsH_3 and HCl reactant species. In the present work, these variables have been independently adjusted to provide gas-phase compositions ranging from Ga-rich to As-rich. The surface defect morphology has been found to be a strong function of the HCl flow rate, changing from pits at low flow rates to hillocks at higher flow rates. In contrast, the AsH_3 flow rate for constant HCl flows principally affects the size of the defects. The growth rate increases slightly with increasing AsH_3 flow rate, but decreases with increasing HCl flow rate over the range normally used. The Se-donor and Zn-acceptor concentrations both decrease with increasing HCl flow rate, suggesting that crystal stoichiometry is not strongly influenced by the HCl flow rate.

Electroluminescent diode efficiencies range between 0.1 and 0.5% at room temperature and between 1 and 2.6% at 80°K. Peak efficiency values have been attained with slightly As-rich gas-phase conditions.

Vapor-grown p-n junctions of GaAs are useful for a variety of electroluminescence (1-3) and microwave (4-6) applications. Several of the first-order, vapor-growth parameters relevant to such structures have been examined previously (1), such as the carrier concentrations, layer thicknesses, growth temperatures, etc.; however, the role of gas-phase stoichiometry (and perhaps crystal stoichiometry) is more subtle and has only recently begun to be determined.

For example, several workers (7-9) have examined the influence of Ga/As flow ratios on the background (reactor) concentrations of unintentionally doped GaAs with $n \sim 10^{14}$-10^{15} cm^{-3}. In these studies, the gas-phase stoichiometry was found to influence the incorporation of the donor and/or acceptor impurities; however, the effects of gas-phase stoichiometry on the electrical properties of epitaxial layers with significantly higher impurity concentrations have not been previously explored. Furthermore, the relative (and perhaps absolute) flow rates used to transport the Group III and Group V atoms have recently been found to directly influence the defect morphology (pits and hillocks) on the surface of vapor-grown GaAs (10-12) and $GaAs_{1-x}P_x$ (13) epitaxial layers. For the case of GaAs, the absolute amount of Ga in the vapor is found to determine the defect morphology (10-12), whereas for $GaAs_{1-x}P_x$, the ratio of Group III to Group V vapor species seems to be the dominant factor (13). Gas-phase stoichiometry is also known to influence the growth rate of GaAs under certain vapor-growth conditions (14).

As a result of the effects described above, it becomes essential to examine the influence of gas-phase stoichiometry on a practical device structure, whose ultimate performance depends critically on the interdependence of several factors. In the present study, we specifically consider the effects of vapor stoichiometry on the surface defect morphology, growth rate, impurity incorporation, and electroluminescence efficiency of heavily doped (10^{17}-10^{19} cm^{-3}) p-n junction structures of GaAs. For this study, we have employed the vapor-hydride growth technique (15), where the amounts of Ga and As species in the gas phase can be independently varied over a relatively wide range. In contrast, the other commonly used vapor-growth technique (16, 17) for preparing GaAs utilizes $AsCl_3$, where the ratio of Ga to As vapor species is fixed at 3/1. As we will show in the sections below, both the surface defect morphology and the incorporation of donors and acceptors are relatively strong functions of the HCl flow rate, but are not nearly as strongly affected by the amount of As species in the vapor phase.

Experimental Procedure

The apparatus and procedures used for the vapor growth of the p-n junction layers have been described in detail previously (15, 18). In brief, AsH_3, HCl, and Ga are the reactant species, and Pd diffused H_2 is used as a carrier gas. The gases in all cases are of high purity so that background impurity concentrations of less than 1×10^{15} donors/cm^3 are generally achieved (7). The metal (Alusuisse, 99.9999% pure) is transported as GaCl (19) by passing HCl over a 75g metallic Ga source with a surface area of approximately 15 cm^2. In these experiments, the HCl flow rate was varied from 2 to 20 cm^3/min, and the flow rate of AsH_3 (Precision Gas Products), employed as a 10% AsH_3 in H_2 mixture, was varied from 25 to 350 cm^3/min. The effec-

Key words: III-V compounds, crystal growth, vapor-phase epitaxy, chemical vapor deposition.

tive flow rate of the AsH_3 alone therefore ranged between 2.5 and 35 cm^3/min. All other vapor-growth conditions were held approximately constant. The total H_2 flow was about 2500 cm^3/min, which is much higher than that used for $AsCl_3$ vapor-growth experiments. The growth temperature was approximately 725°C.

The p-n junction structures used in the present study consisted of n^+-n-p^+ epitaxial layers prepared sequentially in a single vapor-growth operation. The substrates were Czochralski-grown GaAs oriented 3° off <100> toward <110>, and were chemically polished prior to growth. The thicknesses of the epitaxial layers were determined by cleaving and measuring {110} transverse cross sections and were typically 7-15 μm for the n^+-layer, 10-35 μm for the n-layer, and 3-10 μm for the p^+-layer. The n-type epitaxial layers were doped with a 100 ppm H_2Se in H_2 mixture using a flow rate of 50 cm^3/min of the mixture for the initial n^+-layer and 20 cm^3/min for the n-layer. These flow rates yield GaAs donor concentrations on the order of 1×10^{18} and 5×10^{17} cm^{-3}, respectively, for our typical vapor-growth conditions. The flow rates of the HCl and H_2Se were measured to within about 0.1 cm^3/min with mass flow meters.[1] The p-type layers were prepared by doping with zinc acceptor impurities to a concentration of 5×10^{18} cm^{-3} from a heated metallic zinc source. No intentional acceptor impurities were introduced on the n-side of the junction, and no intentional donor impurities were introduced on the p-side.

The impurity concentrations incorporated into the p- and n-type epitaxial layers of these structures were determined from photoluminescence measurements on the as-grown wafers and from capacitance-voltage measurements on the p-n junctions after diode fabrication. For the photoluminescence measurements, a pulsed argon laser emitting at 5145Å was focused to a spot size of 0.25 mm on the surface of the p-type GaAs layers. Since the optical absorption coefficient for the high energy radiation is about 2×10^4 cm^{-1}, the penetration of the light was restricted to within 1 μm of the surface. The p-n junction diodes were prepared using procedures described previously (1). Briefly, the junction wafers were lapped to about 100 μm thickness, after which ohmic contacts were applied using gold and silver base alloys (20). The diode electroluminescence efficiencies at 300° and 77°K under direct-current forward bias were measured with a Hoffman 2A silicon solar cell.

Results and Discussion

Defect morphology.—A striking feature of the vapor-grown layers was the occurrence of surfaces having either pits or hillocks. Initial examination showed that the pits occurred for low HCl flow rates, whereas the hillocks were associated with higher HCl flow rates. Accordingly, the conditions leading to each type of defect were investigated further.

For the growth of GaAs, about 17.5 cm^3/min of AsH_3 and 5 cm^3/min of HCl are routinely used. The effect on the morphology of varying the HCl flow rate between 2 and 20 cm^3/min for a constant AsH_3 flow rate of 17.5 cm^3/min is illustrated in Fig. 1. The 2 cm^3/min flow of HCl [Fig. 1(a)] results in a matte surface, consisting of an array of fine pits, while the 20 cm^3/min flow of HCl [Fig. 1(d)] results in a smoother surface, containing only a few hillocks. A transition from pits to hillocks is seen to occur at an HCl flow rate between 5 and 10 cm^3/min [Fig. 1(b) and 1(c)]. It should be noted that the surfaces prepared at about 10 cm^3/min of HCl are of good crystalline quality and have a low average defect density.

The effect of the AsH_3 flow rate on the defect morphology was examined for HCl flow rates producing either pits or hillocks. The effect on the pit morphology of varying the AsH_3 flow rate, while keeping the HCl flow rate fixed at 5 cm^3/min, is shown in Fig. 2. Here, variations in the AsH_3 flow rate are shown to affect only the size and density of the defect, in this case a pit, but do not change the type of defect. It appears that for an HCl setting of 5.0 cm^3/min, an AsH_3 flow rate between 8 and 17.5 cm^3/min is best to minimize the density and size of the pits.

The effect of the AsH_3 flow rate on the hillock morphology for an HCl flow rate of 20.0 cm^3/min is shown in Fig. 3. Here we see that increasing the AsH_3 flow rate from 3 to 17.5 cm^3/min increases the size and the definition of the hillock, but does not result in pits. Hence, in both of the experiments illustrated in Fig. 2 and 3, the type of defect was not altered over a wide range of AsH_3 flow rates. From further examination of Fig. 2 and 3 we also conclude that the pit-to-hillock transition is related to the HCl flow rate rather than to the HCl/AsH_3 ratio, since Fig. 2(a) (HCl/AsH_3 ratio = 1.43) shows pits and Fig. 3(c) (HCl/AsH_3 ratio = 1.14) has very pronounced hillocks for similar gas flow ratios. These conclusions are consistent with those of Kennedy and Potter (12) for vapor-grown GaAs, and those of Blakeslee (10) for vapor-grown $GaAs_{1-x}P_x$, but differ from those of Wu (13), who found the absence of pits or hillocks related to the gas-phase stoichiometry (Ga/As+P ratio).

The present results on the transition from pits to hillocks on {100} GaAs surfaces shed light on the defect morphology in alloy systems prepared by the hydride method. Epitaxial layers of GaAs and $GaAs_{1-x}P_x$ prepared with AsH_3 and PH_3 tend to form pits (18), while $In_xGa_{1-x}As$ and $In_{1-x}Ga_xP$ form hillocks (21). The present work suggests that this difference is observed because the GaAs and $GaAs_{1-x}P_x$ alloys are generally prepared with low HCl flow rates (15) (less than 10 cm^3/min), whereas $In_xGa_{1-x}As$ (HCl = 20 cm^3/min) (22) and $In_xGa_{1-x}P$ (HCl $\simeq$ 40 cm^3/min) (21) alloys have much higher HCl flows because of two-metal transport.

Our results also help to explain the morphology (23-25) of <100>-oriented GaAs prepared by the $AsCl_3$ method. Increasing the flow rate of $AsCl_3$ from low to high values causes a transition from pits to hillocks (23). This transition may be explained by the increasing GaCl partial pressure rather than by a changing Ga/As ratio in the vapor phase, as suggested earlier (26).

The normally observed defect type for GaAs prepared by the $AsCl_3$ technique is the hillock (27), while that for the hydride method is the pit (18, 28). This difference probably arises from a difference in the GaCl species concentration in the two types of systems, as shown below.

For GaAs grown in the AsH_3 system at 725°C, pits are observed at a gas-phase concentration of about 1×10^{-3} (HCl/H_2 = 2.5/2500) and hillocks are predominant at 8×10^{-3}, with relatively smooth surfaces observed at 2-4 $\times 10^{-3}$. For the $AsCl_3$ system (25) at 710°C, a concentration of 4-6 $\times 10^{-3}$ of $AsCl_3$ in H_2 produces smooth surfaces, while a value of 10-18 $\times 10^{-3}$ of $AsCl_3$ produces many hillocks. Thus, the regimes for hillock formation are about the same for <100>-oriented GaAs prepared by both the hydride and the $AsCl_3$ growth systems (about 10×10^{-3}). For smooth growth, a concentration of about 4×10^{-3} is used in both systems, but values range on the low side of 4×10^{-3} for hydride growth and on the high side for $AsCl_3$ growth, thereby leading to pits and hillocks, respectively.

Finally, the cross-sectional structures of the two types of defects are compared in Fig. 4. For the hillock, the thickness of both the n- and p-type layers is increased considerably at the defect site, whereas for the pit, the thickness of the n-layer is locally reduced. The n^+-substrate interface is flat for both types of defect, and the defects start in the n-layer rather than at the substrate.

Growth rate.—Examination of the cleaved {110} edge of multilayer wafers prepared under the various growth conditions shows that the growth rate also is a function of the gas-phase composition, consistent with

[1] Hastings-Raydist and Tylan Corporation.

the previous observations of Shaw (14). In Fig. 5(b), for a constant HCl flow rate, it is seen that the n-layer thickness increases with increasing AsH_3 flow rate, as might be expected from mass-action considerations for the reaction (19)

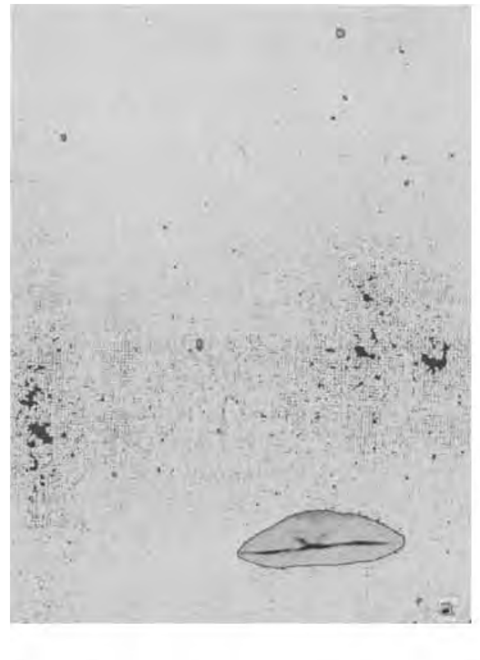
$$GaCl_{(g)} + 1/2\ As_{2(g)} + 1/2\ H_{2(g)} = GaAs_{(s)} + HCl_{(g)}$$

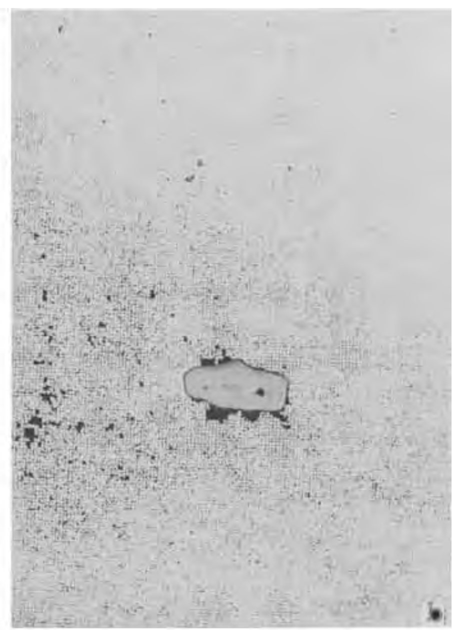
That is, as more reactant (*e.g.*, As_2 or As_4) is added, the amount of product (GaAs) increases. The curve saturates at high AsH_3 flow rates because of the limited amount of GaCl available to react with the As-vapor species. The increase in growth rate with increasing values of AsH_3 or As_4 partial pressure has also been observed by several other investigators (9, 14). It should be noted that a growth rate of 30-35 μm/hr is about the maximum value normally observed for growth of GaAs on the {100} surface.

In contrast, for a given AsH_3 setting, the growth rate first increases, then decreases [Fig. 5(a)] with increasing HCl flow rate. The decrease does not result from incomplete reaction of HCl with the Ga metal source. In separate experiments, comparison of the moles of Ga and HCl gas consumed, as determined by weight loss and wet chemical analysis, respectively, showed that 98% of a 20 cm^3/min HCl flow rate reacts with the Ga metal source to form GaCl in the vapor-growth tube used for the present experiments. Thus, virtually all of the HCl in the range 2-20 cm^3/min injected into the vapor-growth apparatus is converted to GaCl.

The reduced growth rate for increasing HCl flow rates shows that the growth rate is not directly related to the reactant partial pressures, as is the case for AsH_3. Instead, the limitation of the growth rate at 725°C is probably related to adsorption of GaCl (14, 29) and subsequent reaction with As_x on the GaAs crystal surface to form the epitaxial GaAs layer. The nature of this reaction has been examined previously by Shaw (14), whose data are also shown in Fig. 5. Surprisingly good agreement is found for the dependence of the growth rate on the HCl and AsH_3 flow rates in the present study and on GaCl and As_4 partial pressures determined previously by Shaw (14), who used significantly different growth conditions (*i.e.*, growth on the reactor walls prevented by injecting auxiliary unreacted HCl, an 80% lower total H_2 flow rate, and a solid As source).

Several authors (8, 26) have previously related the growth rate to the Ga/As ratio in the vapor phase, and have shown a peak value of the growth rate in the range of 1-4 Ga/As. However, the present study, as





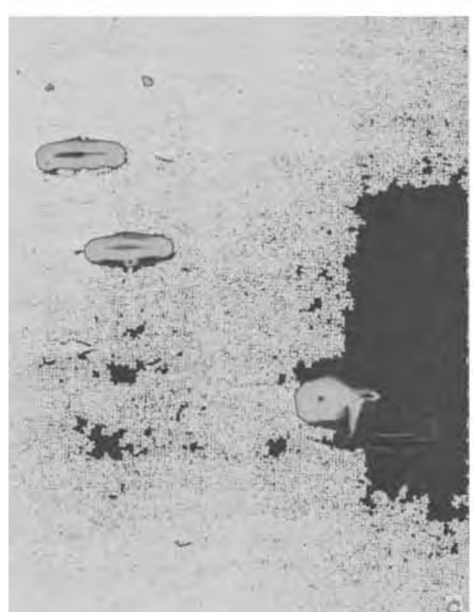


Fig. 2. Optical photomicrographs of GaAs vapor-grown layers prepared with 5 cm^3/min of HCl and AsH_3 flow rates varying from 3.5 to 35 cm^3/min. 200× magnification. All defects are pits. a, Run 881, 3.5 cm^3/min of AsH_3; Ga/As = 1.43. b, Run 905, 8 cm^3/min of AsH_3; Ga/As = 0.65. c, Run 910, 17.5 cm^3/min of AsH_3; Ga/As = 0.28. d, Run 880, 35 cm^3/min of AsH_3; Ga/As = 0.14.

well as other recent works (9, 12, 14), suggests that the growth rate is related to the partial pressure of the individual reactants, GaCl and AsH_3 or As_4, rather than to the Ga/As gas ratio. Since increasing AsH_3 flow rates increase the growth rate, in accord with thermodynamic expectations, and increasing HCl flow rates decrease the growth rate, contrary to equilibrium thermodynamics (17), it appears that GaCl is the chemical species limiting the growth rate. This could arise at high HCl flow rates by nearly complete filling of adsorption sites with GaCl on the crystal surface, to the exclusion of the As-species. Adsorbed As-species atoms on the crystal surface are necessary for reaction with the GaCl to form GaAs, and if insufficient As is available, a lower growth rate should result. Since our experiments with Zn- and Se-doped vapor-grown layers (to be described in the next section) show that both the donor and acceptor concentrations are strong functions of the HCl flow rate, it is not unreasonable to suspect that the incorporation of dopant atoms is also affected by the preferential adsorption of GaCl on the growing surface.

The growth rate was also found to decrease with increasing elapsed growth time. This probably occurs because growth of GaAs on the quartz tube walls increases with time, and these polycrystalline deposits increasingly compete with growth on the single-crystalline substrate. It was also observed that the GaAs deposits on the walls of the quartz tube increased in thickness as the HCl flow rate increased. For low HCl flow rates (2 cm^3/min) only a thin GaAs layer formed on the quartz, whereas for higher HCl flow rates (20 cm^3/min) a dense GaAs wall deposit was observed.

Impurity doping.—Since the epitaxial layers used in this investigation were prepared in the form of p-n junction structures, the carrier concentrations could not be determined by Hall measurements. However, as described in detail below, straightforward photoluminescence and capacitance measurements could be used to characterize both the outermost Zn-doped layer and the adjacent Se-doped layer, respectively.

Zn doping.—The hole concentration in the p-type layer was evaluated from room temperature photoluminescence measurements. The spectral halfwidth was used as a measure of the free hole concentration, since it depends directly on doping for concentrations greater than about 2×10^{18} cm^{-3} (30). This correlation allowed us to correctly label the right-hand ordinate in the plots of spectral halfwidth *vs.* gas flow rate shown

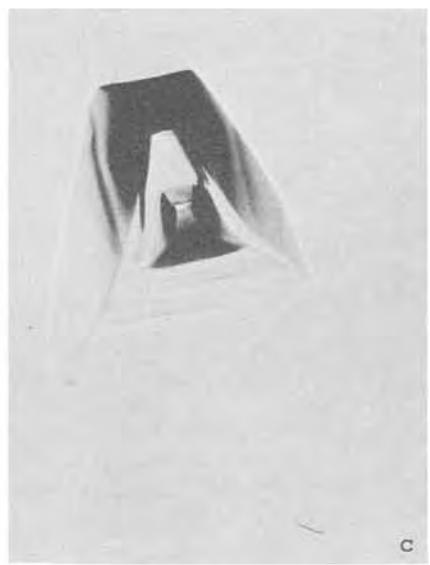

Fig. 3. Optical photomicrographs of GaAs vapor-grown layers prepared with 20 cm^3/min of HCl and AsH_3 flow rates varying from 3.0 to 17.5 cm^3/min. 200× magnification. All defects are hillocks. a, Run 907, 3.0 cm^3/min of AsH_3; Ga/As = 6.66. b, Run 904, 10 cm^3/min of AsH_3; Ga/As = 2.0. c, Run 882, 17.5 cm^3/min of AsH_3; Ga/As = 1.14.

in Fig. 6. Here, for HCl flow rates increasing from 2 to 20 cm^3/min, the Zn carrier concentration decreases from approximately 2×10^{19} to 5×10^{18} cm^{-3} for a Zn source at 450°C, and from 5×10^{18} to 1.5×10^{18} cm^{-3} for a source at 410°C. The hole concentration depends less strongly on the AsH_3 flow rate, increasing from 5×10^{18} to 1×10^{19} cm^{-3} over the range evaluated (3.5-35 cm^3/min).

The relative photoluminescence intensity of each of the Zn-doped GaAs layers is plotted in Fig. 7 as a function of the Zn concentration (determined from the halfwidths in Fig. 6). The increase in intensity with increasing carrier concentration is consistent with Cusano's (30) cathodoluminescence data for p-type GaAs. Since the carrier concentrations for our experiments are less than about 2×10^{19} cm^{-3}, an intensity degradation usually associated with Zn precipitation (30) at high concentrations is not observed. The self-consistency of the photoluminescence data of Fig. 6 and 7 clearly indicates that large HCl flow rates give rise to a reduction in the amount of Zn incorporated into the GaAs lattice.

Se doping.—Since the n-type layer of our vapor-grown structures is sandwiched between the GaAs substrate and the p-type layer, it is not exposed for photoluminescence measurements. Accordingly, the donor concentration in the n-type layers was estimated from standard capacitance-voltage and reverse-bias breakdown measurements performed after complete diode fabrication. The donor concentrations determined by both methods were in excellent agreement.

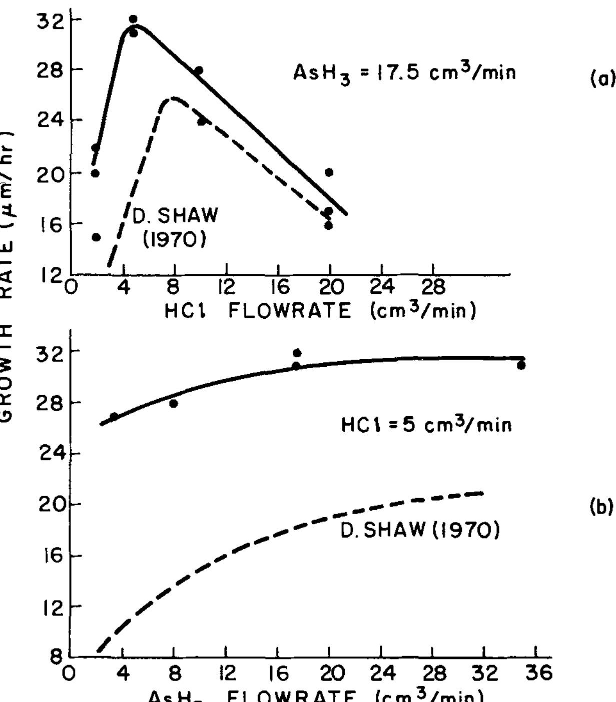

Fig. 5. (a) Growth rate vs. HCl flow rate for GaAs epitaxial layers prepared with AsH_3 flow rate of 17.5 cm^3/min. (b) Growth rate vs. AsH_3 flow rate for GaAs epitaxial layers prepared with HCl flow rate of 5 cm^3/min. Substrate orientation is <100>. Dashed lines are from Shaw's previous study (14).

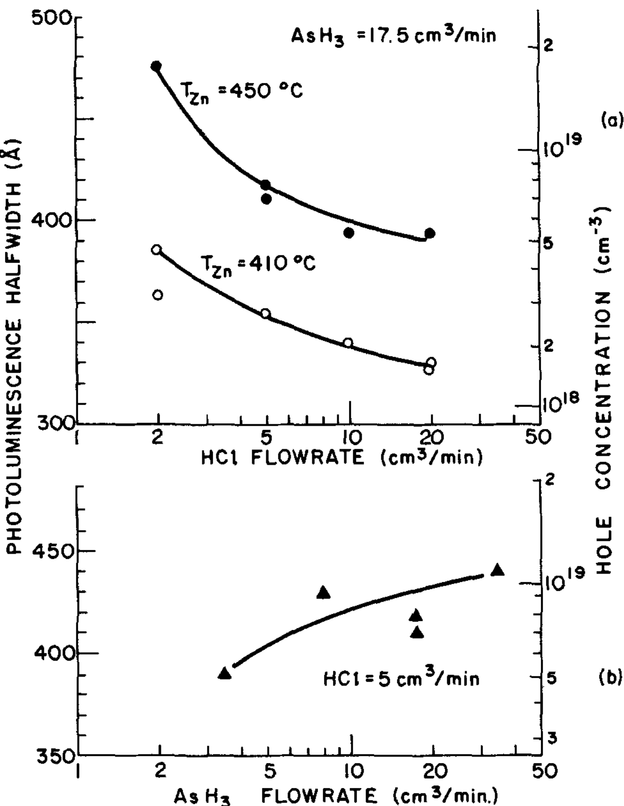

Fig. 6. Room temperature photoluminescence halfwidth (in angstroms) vs. (a) HCl flow rate, and (b) AsH_3 flow rate. Two different Zn source temperatures (410° and 450°C) were used for the layers whose halfwidths were evaluated in the top figure. The right-hand vertical axis (hole concentration) was calibrated from the known relationship [Ref. (30)] between spectral halfwidth and hole concentration in GaAs.

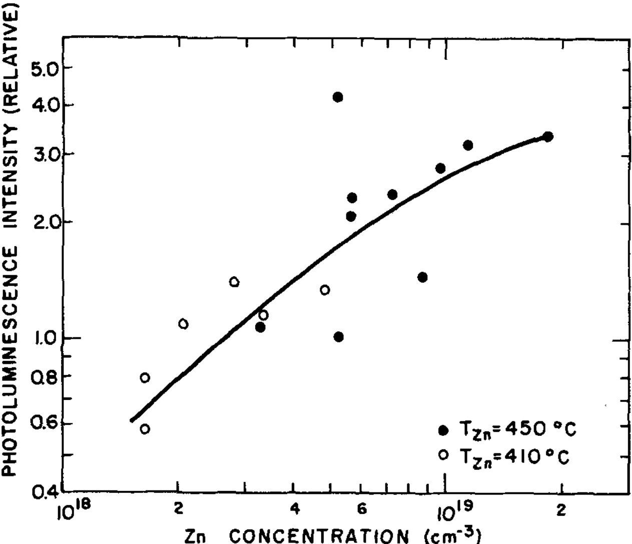

Fig. 7. Photoluminescence intensity vs. Zn acceptor concentration for the GaAs layers whose halfwidths are shown in Fig. 6 (a and b).

The free electron concentration, as determined from the above measurements, is plotted as a function of the HCl and AsH_3 flow rates in Fig. 8. In Fig. 8(a) the electron concentration decreases from 6×10^{17} to 1×10^{17} cm^{-3} for HCl flow rates increasing from 2 to 20 cm^3/min. For these samples, the AsH_3 flow rate was held at 17.5 cm^3/min. In Fig. 8(b), the effect of AsH_3 flow rate on the electron concentration is shown for growths where the HCl is held constant at 5 cm^3/min.

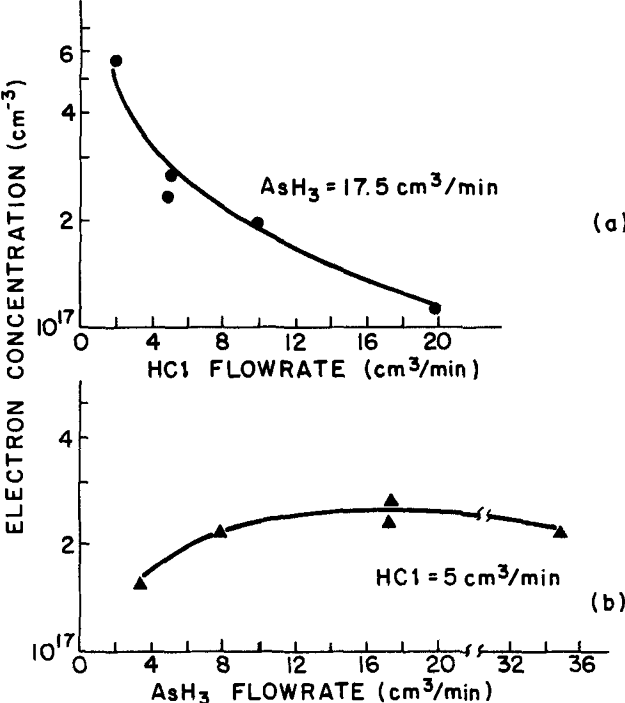

Fig. 8. Electron concentration on the n-side of the junction vs. (a) HCl flow rate, and (b) AsH_3 flow rate. The electron concentration was determined from C-V and voltage-breakdown measurements.

The electron concentration is only weakly dependent on the AsH_3 flow rate, increasing by about 40% over the range of flow rates used here.

Several different mechanisms are possible to explain the flow rate dependence of the doping concentration, including changes in crystal stoichiometry and differences in the rate of adsorption of impurity atoms. Concerning crystal stoichiometry, a change in the Ga or As vacancy concentration with changing gas flow conditions should enhance the incorporation of one type of impurity (either donors or acceptors), while retarding the incorporation of the other. In fact, previous work has shown that the background donor concentration of vapor-grown GaAs layers can be influenced by gas-phase (Ga/As) ratios for donor concentrations in the range of 10^{14}-10^{15} cm^{-3} (7, 9). But the impurity concentrations here, particularly for the case of Zn where $p \sim 10^{19}$ cm^{-3}, are probably too large to be directly affected by deviations in crystal stoichiometry. Accordingly, since both the Zn-acceptor and the Se-donor concentrations were found to decrease with increasing HCl flow rate, it appears that varying the gas-phase stoichiometry alters the rate of incorporation (*i.e.*, the sticking coefficient) of both types of impurity atoms from the gas phase into the growing solid layer rather than changing the crystal stoichiometry or unintentional reactor impurity concentrations.

In addition, changes in the crystal stoichiometry might be expected to alter the characteristics of the low-energy luminescence spectra of the GaAs samples (31, 32). In our work, both the photoluminescence spectra of the p-type layers and the electroluminescence spectra of the p-n junctions were examined at 300° and 77°K; although weak, low energy emission at 1.2-1.3 eV was observed for all samples at 77°K, the magnitude of this emission (relative to the near band-gap emission at $\sim$ 1.5 eV) did not change significantly over the range of gas-flow conditions studied here. Therefore, consistent with our electrical data described above, the luminescence spectra at 77°K give no indication of significant changes in crystal stoichiometry.

External electroluminescent diode efficiency.—The diode electroluminescence efficiency at 300°K is given

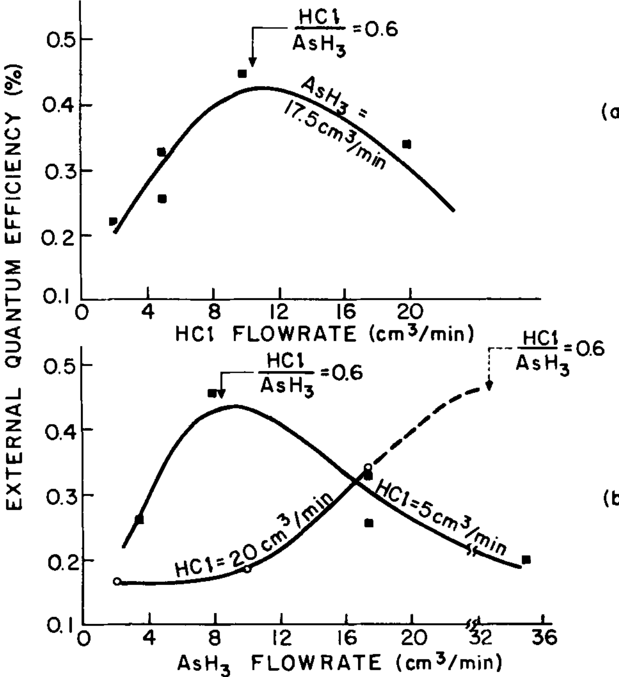

Fig. 9. The room temperature external quantum efficiency vs. (a) HCl flow rate, and (b) AsH_3 flow rate for GaAs electroluminescent diodes fabricated from the vapor-grown layers.

in Fig. 9 as a function of the HCl and AsH_3 flow rates. Here, two rather unexpected results are observed. First, the external quantum efficiency in Fig. 9(b) is seen to depend strongly on the AsH_3 flow rate, in contrast to the weak dependence on AsH_3 found for the defect morphology (Fig. 2 and 3), growth rate (Fig. 5), and doping concentrations (Fig. 6 and 8). Second, for both the solid curves in Fig. 9(a and b), a maximum efficiency of approximately 0.45% is attained at an HCl/AsH_3 ratio of 0.6, in contrast to each of the early dependences (Fig. 1, 5, 6, and 8) on HCl only. Thus, empirically it appears that a slightly As-rich, gas-phase composition is desirable for our vapor-grown electroluminescent diodes. For comparison, vapor-grown GaAs produced by the $AsCl_3$ method has an HCl/As ratio of 3, which, according to the present results, might limit electroluminescent diode efficiencies.

The maximum values of 0.45% at 300°K are about the same as previously attained with optimized Se and Zn concentrations (1). At 80°K, efficiencies approaching 3% were attained, close to the theoretical maximum for a single-surface, rectangular emitter with no absorption losses (33).

The shape of the curves in Fig. 9 probably reflects the variation of several factors, including defects, carrier concentrations, and layer thicknesses. These affect the bulk radiative recombination efficiency in the p-layer, the injection efficiency of electrons into the p-layer, the effectiveness of shunting nonradiative centers at the junction, and optical absorption of the light passing through the p-layer. Because of the complex manner in which these many parameters interact, it is difficult *a priori* to predict the effect of HCl or AsH_3 flow rates on the electroluminescent diode efficiencies. However, in view of the earlier results of this study, it is not surprising that extreme flow rates of either AsH_3 or HCl are detrimental. For example, at the low HCl flow rates in Fig. 9(a), the high density of pits would be expected to reduce the junction perfection. Similarly, large HCl and small AsH_3 flow rates would reduce the acceptor concentration in the p-layer, thereby reducing the radiative recombination efficiency there, as shown in Fig. 7.

Summary and Conclusions

The defect morphology of vapor-grown, <100>-oriented GaAs epitaxial layers is not related to the HCl/AsH_3 (or Ga/As) gas-phase ratio. Rather, the occurrence of pits is associated with low HCl flow rates (2-5 cm^3/min), and hillocks are associated with high HCl flow rates (10-20 cm^3/min). These results are consistent with observations for GaAs prepared by the $AsCl_3$ growth method, where low flow rates of $AsCl_3$ (*i.e.*, GaCl or HCl) produce pits and higher $AsCl_3$ flow rates produce hillocks. The AsH_3 flow rate appears to influence the size and density rather than the type of defect present.

The crystal growth rate increases monotonically with AsH_3 flow rate but shows a maximum at intermediate values of increasing HCl flow rate. The growth rates obtained in a $Ga/HCl/AsH_3/H_2$ growth system using high H_2 flow rates (2500 cm^3/min) are in nearly quantitative agreement with Shaw's earlier results (14) for significantly different vapor-growth conditions. Since both the Zn-acceptor and Se-donor concentrations decrease with increasing HCl flow rate, it appears that varying the gas-phase stoichiometry alters the rate of incorporation of both types of impurity atoms from the gas-phase into the growing solid layer rather than changing the crystal stoichiometry (Ga and As vacancy concentrations) or unintentional reactor impurity concentrations. The electroluminescent diode efficiency depends strongly on both the AsH_3 and HCl flow rates, in contrast to the weak dependence on AsH_3 found for the defect morphology, growth rate, and doping concentrations. A maximum efficiency of 0.45% at 300°K is attained for a slightly As-rich, gas-phase mixture. At 80°K, efficiencies approaching 3% are attained, close to the theoretical maximum for this geometry.

Antimony Diffusion into P-Type $Pb_{1-x}Sn_xTe$

R. L. Guldi and G. A. Antcliffe

Texas Instruments Incorporated, Dallas, Texas 75222

ABSTRACT

The characteristics of Sb diffusion into p-type $Pb_{1-x}Sn_xTe$ with $0.08 < x < 0.21$ were investigated by measuring radioactive Sb profiles and n-p junction depths. Values for the Sb diffusion coefficient in $Pb_{0.79}Sn_{0.21}Te$ range from 2×10^{-14} cm²/sec at 500°C to 4×10^{-10} cm²/sec at 750°C. The Sb diffusion coefficient and solubility are essentially independent of Sn content and substrate hole concentration. In contrast the rate of n-p junction diffusion increases with decreasing substrate hole concentration. The Sb concentration at the n-p junction, determined by using the radioactive Sb profiles, is considerably higher than the hole concentration before diffusion. Mechanisms that might account for this behavior include the formation of Sb precipitates, compensation of Sb by native defect acceptors, or amphoteric doping behavior of Sb.

$Pb_{1-x}Sn_xTe$ is a pseudobinary semiconductor compound with a bandgap that depends upon alloy composition. The phase fields for undoped $Pb_{1-x}Sn_xTe$ of various Sn compositions have been well established (1). Samples containing a stoichiometric excess of metal (*i.e.*, Pb and Sn) show n-type conductivity while those containing excess Te are p-type, because the native defects responsible for these deviations from stoichiometry act as donors and acceptors, respectively. The alloys discussed in this paper fall in the composition range $0.08 < x < 0.21$. Crystals of such alloys grown within 100°C of the melting point always contain excess Te and are therefore strongly p-type. A common method for obtaining n-p junctions in $Pb_{1-x}Sn_xTe$ is to diffuse a metal-rich layer into the p-type substrate (1). An alternative method which has proven quite successful involves diffusing a donor impurity such as Sb into the p-type substrate (2, 3). This paper will discuss some of the characteristics of Sb diffusion into p-type $Pb_{1-x}Sn_xTe$ determined from radioactive Sb profiles and junction depths found by thermoelectric probe measurements. The ranges of temperatures, alloy compositions, and substrate hole concentrations which were studied are those of importance in the fabrication of junction lasers and photovoltaic detectors for the 8-12 μm spectral region.

Experimental Procedure

The crystals used were either 9 or 25 mm diameter single crystals grown at temperatures from 820° to 850°C by vapor transport from metal-rich source material (4). The dislocation density was typically in the mid 10^4 cm^{-2} range. The hole concentration in the as-grown crystals, as determined by van der Pauw measurements at 77°K, was equal to 2×10^{18}, 5×10^{18}, and 2×10^{19} cm^{-3} for the 8, 12.4, and 21 mole per cent (m/o) SnTe compositions, respectively. The as-grown ingots were cut with a string saw into either (100)- or (111)-oriented wafers. Saw damage was removed by polishing and etching, using HBr + 2% Br_2 as a final etch. The diffusion slices were typically 0.5-1.0 mm thick. In some cases, prior to Sb diffusion, the slices were preannealed in metal-rich vapor to adjust the stoichiometry, giving material with lower hole concentrations (1) (see Table I).

The diffusion samples were sealed in quartz ampuls which were evacuated to a pressure of approximately 10^{-6} Torr and backfilled with H_2 to a pressure of about 2 atm in order to prevent thermal etching of the samples. Radioactive Sb-124 (half-life = 60.2 day) was obtained by neutron activation of Sb (6-9's) at the Union Carbide reactor facilities at Tuxedo, New York. In the majority of the diffusions, a 1-2 mg charge of metallic Sb was used as a diffusion source. Some diffusions however used an Sb-doped $(Pb_{0.79}Sn_{0.21})_{0.505}Te_{0.495}$ source. [The Sb content was approximately 5 atomic per cent (a/o).] In either case the Sb charge was in contact with the crystal

Antimony Diffusion into P-Type $Pb_{1-x}Sn_xTe$

R. L. Guldi and G. A. Antcliffe

Texas Instruments Incorporated, Dallas, Texas 75222

ABSTRACT

The characteristics of Sb diffusion into p-type $Pb_{1-x}Sn_xTe$ with $0.08 < x < 0.21$ were investigated by measuring radioactive Sb profiles and n-p junction depths. Values for the Sb diffusion coefficient in $Pb_{0.79}Sn_{0.21}Te$ range from 2×10^{-14} cm²/sec at 500°C to 4×10^{-10} cm²/sec at 750°C. The Sb diffusion coefficient and solubility are essentially independent of Sn content and substrate hole concentration. In contrast the rate of n-p junction diffusion increases with decreasing substrate hole concentration. The Sb concentration at the n-p junction, determined by using the radioactive Sb profiles, is considerably higher than the hole concentration before diffusion. Mechanisms that might account for this behavior include the formation of Sb precipitates, compensation of Sb by native defect acceptors, or amphoteric doping behavior of Sb.

$Pb_{1-x}Sn_xTe$ is a pseudobinary semiconductor compound with a bandgap that depends upon alloy composition. The phase fields for undoped $Pb_{1-x}Sn_xTe$ of various Sn compositions have been well established (1). Samples containing a stoichiometric excess of metal (*i.e.*, Pb and Sn) show n-type conductivity while those containing excess Te are p-type, because the native defects responsible for these deviations from stoichiometry act as donors and acceptors, respectively. The alloys discussed in this paper fall in the composition range $0.08 < x < 0.21$. Crystals of such alloys grown within 100°C of the melting point always contain excess Te and are therefore strongly p-type. A common method for obtaining n-p junctions in $Pb_{1-x}Sn_xTe$ is to diffuse a metal-rich layer into the p-type substrate (1). An alternative method which has proven quite successful involves diffusing a donor impurity such as Sb into the p-type substrate (2, 3). This paper will discuss some of the characteristics of Sb diffusion into p-type $Pb_{1-x}Sn_xTe$ determined from radioactive Sb profiles and junction depths found by thermoelectric probe measurements. The ranges of temperatures, alloy compositions, and substrate hole concentrations which were studied are those of importance in the fabrication of junction lasers and photovoltaic detectors for the 8-12 μm spectral region.

Experimental Procedure

The crystals used were either 9 or 25 mm diameter single crystals grown at temperatures from 820° to 850°C by vapor transport from metal-rich source material (4). The dislocation density was typically in the mid 10^4 cm^{-2} range. The hole concentration in the as-grown crystals, as determined by van der Pauw measurements at 77°K, was equal to 2×10^{18}, 5×10^{18}, and 2×10^{19} cm^{-3} for the 8, 12.4, and 21 mole per cent (m/o) SnTe compositions, respectively. The as-grown ingots were cut with a string saw into either (100)- or (111)-oriented wafers. Saw damage was removed by polishing and etching, using HBr + 2% Br_2 as a final etch. The diffusion slices were typically 0.5-1.0 mm thick. In some cases, prior to Sb diffusion, the slices were preannealed in metal-rich vapor to adjust the stoichiometry, giving material with lower hole concentrations (1) (see Table I).

The diffusion samples were sealed in quartz ampuls which were evacuated to a pressure of approximately 10^{-6} Torr and backfilled with H_2 to a pressure of about 2 atm in order to prevent thermal etching of the samples. Radioactive Sb-124 (half-life = 60.2 day) was obtained by neutron activation of Sb (6-9's) at the Union Carbide reactor facilities at Tuxedo, New York. In the majority of the diffusions, a 1-2 mg charge of metallic Sb was used as a diffusion source. Some diffusions however used an Sb-doped $(Pb_{0.79}Sn_{0.21})_{0.505}Te_{0.495}$ source. [The Sb content was approximately 5 atomic per cent (a/o).] In either case the Sb charge was in contact with the crystal

only through the vapor phase. The diffusions were conducted in furnaces which were controlled to ±0.5°C and had isothermal heat pipes to provide a constant temperature zone. At the termination of a diffusion run the ampuls were removed from the furnace and allowed to cool in air. Each diffused sample was characterized by measuring either the Sb-124 diffusion profile or the n-p junction depth.

The radioactive Sb diffusion profiles were measured by conventional lapping and counting techniques. The samples were sectioned by successively lapping away thin (typically 1-2 μm) layers on 4/0 Emery paper and counting the activity in the material which collected on the paper. A 7.5 × 7.5 cm NaI(Tl) well detector in conjunction with a single-channel analyzer and timer scaler was used to count in the integral mode with the discriminator at 470 keV. The thickness of the removed layers was determined from the sample area, the density of $Pb_{1-x}Sn_xTe$ (5), and the difference in sample weight before and after lapping. Autoradiograms taken at various stages of lapping indicated that the Sb concentration was uniform in the plane normal to the diffusion direction.

Measurements of n-p junction depths were made by the standard technique of angle lapping (1° angle) and thermoelectric probing. Junction depths were measured at 300° and 77°K and found to be the same at both temperatures. The position of the junction can be measured to within ±2 μm, and the measured depths were quite reproducible within that range.

Results and Discussion

Radioactive Sb diffusion profiles.—We have measured Sb-124 profiles for diffusions into as-grown $Pb_{0.92}Sn_{0.08}Te$ and $Pb_{0.79}Sn_{0.21}Te$ with hole concentrations of 2×10^{18} and 2×10^{19} cm^{-3}, respectively, and for diffusions into annealed $Pb_{0.79}Sn_{0.21}Te$ with lower hole concentrations. In all cases the Sb concentration is well described by a complementary error function. In a few cases, there is a small deviation from this function within the region 0-5 μm from the surface, where the Sb profile is less steeply graded. The fact that the profiles can be described by error functions, except possibly near the surface, suggests that the diffusion coefficient is constant throughout most of the sample. We have verified the constancy of the diffusion coefficient and the dependence of the profiles on the square root of time by diffusing $Pb_{0.79}Sn_{0.21}Te$ samples at 600°C for 72, 168, and 576 hr.

Table I summarizes the values for the solubility of Sb and for the Sb diffusion coefficients which have been obtained by fitting complementary error functions to our data. Each of these values was obtained by fitting each of several profile measurements to obtain a surface concentration (C_o) and a diffusion coefficient (D) and averaging the C_o and D values for the different profiles. The accuracy of the average values thus obtained is estimated to be ±15%. The surface concentrations have been taken to be the Sb solubility values. The Sb solubilities are essentially independent of Sn content and temperature over the range 500°-750°C. A lower surface Sb concentration was observed, however, in annealed $Pb_{0.79}Sn_{0.21}Te$ which was diffused from a Sb-doped $(Pb_{0.79}Sn_{0.21})_{0.505}Te_{0.495}$ source instead of from a metallic Sb source. The diffusion coefficient at a given temperature is also essentially independent of the Sn content, even though the hole concentrations which reflect native defect concentrations differ by an order of magnitude for the two Sn compositions. Similarly D is independent of substrate hole concentration for the diffusions into $Pb_{0.79}Sn_{0.21}Te$ at 700° and 561°C.

Since the donor behavior of Sb has been attributed to the substitution of Sb on Pb sites (6), it is interesting that the D values are independent of native defect concentrations. The temperature dependence of the Sb diffusion coefficient in $Pb_{0.79}Sn_{0.21}Te$ is shown in Fig. 1. The data can be represented by an Arrhenius-type expression in which D (cm^2/sec) $= 1.08 \times 10^{-4} \exp(-2.74 \text{ eV}/kT)$. The Sb diffusion coefficients are at least two orders of magnitude smaller than the interdiffusion coefficients responsible for controlling the stoichiometry of PbTe (7, 8). The measured D values are also independent of substrate orientation. This is consistent with the cubic symmetry of the rocksalt lattice structure of $Pb_{1-x}Sn_xTe$ (9).

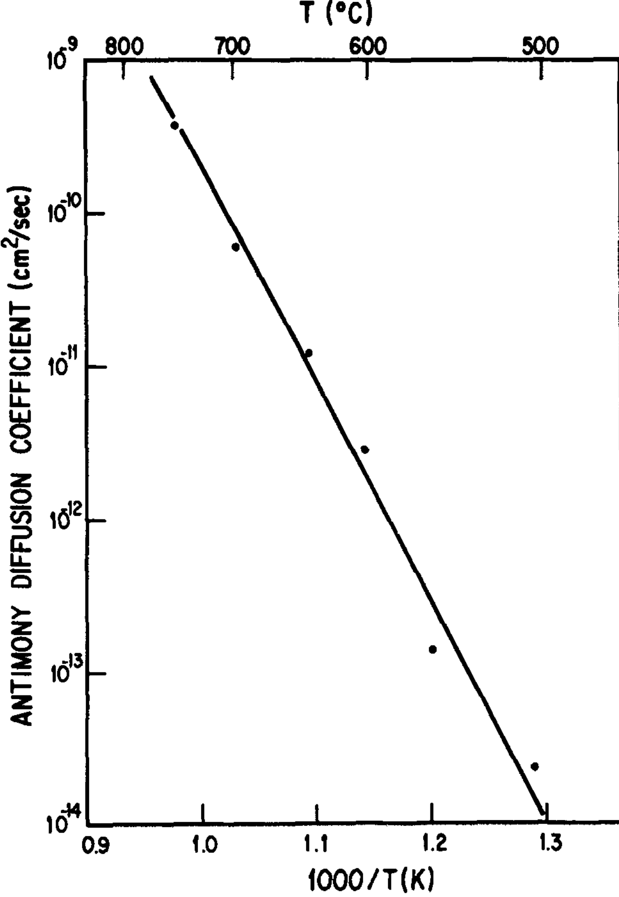

Fig. 1. Antimony diffusion coefficient in $Pb_{0.79}Sn_{0.21}Te$ as a function of temperature.

It should be pointed out that our experiments were not carried out under true "tracer diffusion" conditions (in which there are no gradients other than the tracer) (8, 10), but rather under conditions appropriate for the fabrication of devices. Under these conditions, it is not rigorously correct to interpret the data in terms of diffusion mechanisms, jump frequencies, and activation energies because the defect conditions may vary during the diffusion if the Sb doping is amphoteric or if native defects compensate the Sb (see following section).

Junction depths.—Figure 2 shows the depth of the n-p junction produced by Sb diffusion at 700°C as a function of the square root of time for as-grown $Pb_{0.92}Sn_{0.08}Te$, $Pb_{0.876}Sn_{0.124}Te$, and $Pb_{0.79}Sn_{0.21}Te$. The junction depth increases linearly as the square root of time for junctions less than 25 μm deep. For longer diffusion times, however, there is a more rapid increase in depth. The rate of junction penetration is about three times faster for $Pb_{0.92}Sn_{0.08}Te$ than for $Pb_{0.79}Sn_{0.21}Te$. The more rapid junction movement in the lower Sn content alloys is expected because these materials have lower as-grown hole concentrations than the higher Sn content alloys. Indeed, we have found that $Pb_{0.79}Sn_{0.21}Te$ annealed to 2×10^{18} holes/cm^3 shows the same junction depth as as-grown $Pb_{0.92}Sn_{0.08}Te$ with the same hole concentration. Thus an interesting comparison can be made between the junction diffusion data and the Sb diffusion coeffici-

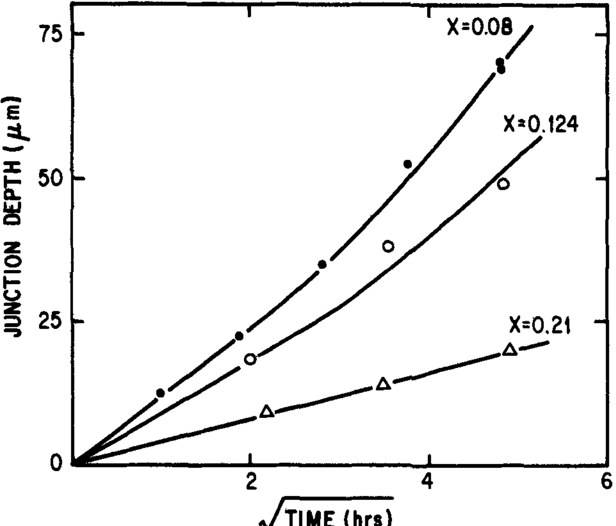

Fig. 2. Junction depths produced by Sb diffusion at 700°C into as-grown $Pb_{1-x}Sn_xTe$.

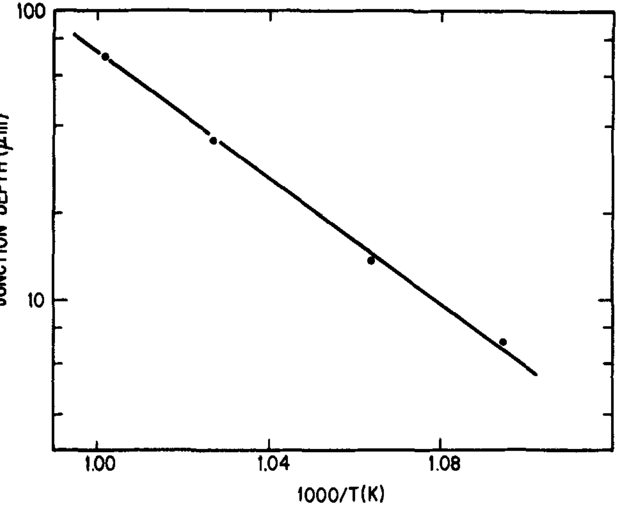

Fig. 3. Temperature dependence of junction produced by Sb diffusion into as-grown $Pb_{0.92}Sn_{0.08}Te$ (normalized to 8-hr diffusion).

ents in that the junction depths correlate with substrate hole concentration, while the Sb diffusion coefficients are essentially independent of substrate hole concentration.

Values for the Sb concentration at the position of the electrical junction were determined by locating the position of the junction on the Sb-124 profile measured for the same diffusion conditions. Table II compares values for the Sb concentration at the junction with values for the substrate hole concentration before diffusion. The Sb concentration at the junction is always higher than the initial hole concentration, with a larger discrepancy observed for diffusions into substrates with low hole concentrations. This behavior suggests that the doping of Sb in $Pb_{1-x}Sn_xTe$ is amphoteric, as has been suggested by Strauss for PbTe (6), or that the introduction of Sb into $Pb_{1-x}Sn_xTe$ may be accompanied by the formation of compensating native defect acceptors. However, other effects such as the formation of Sb precipitates cannot be ruled out at this point.

Figure 3 shows the temperature dependence of the junction depth for an 8 hr diffusion of Sb into as-grown $Pb_{0.92}Sn_{0.08}Te$. It is not possible to obtain junction diffusion coefficients from these data because of uncertainties in the boundary conditions. The difference between the donor and acceptor defect concentration at the surface of the material is not known because the extent of compensation of the Sb by native defects and the extent of amphoteric Sb doping have not been determined. Nevertheless, a qualitative comparison can be made between the temperature dependence of the junction depth and that of the Sb diffusion coefficient by comparing the ratio of the squares of the junction depth at 700° and 640°C to the ratio of the diffusion coefficients at these temperatures. The former ratio is equal to 26, while the latter is 7. Hence, the junction depth exhibits a stronger temperature dependence than the diffusion coefficients.

Table II. Comparison of antimony concentration at the n-p junction with substrate hole concentration

Composition	Temperature (°C)	Diffusion time (hr)	Substrate hole concentration (cm^{-3})	Sb concentration at n-p junction (cm^{-3})

Summary

Antimony diffusion profiles and n-p junction depths in $Pb_{0.92}Sn_{0.08}Te$ and $Pb_{0.79}Sn_{0.21}Te$ have been measured under experimental conditions of interest for device fabrication processes. The solubility of Sb is essentially independent of temperature between 500° and 750°C. Both the solubility and diffusion coefficients are independent of Sn content even though the substrate hole concentration varies by a factor of ten between the two different alloys. In contrast, the n-p junction depth shows a strong dependence on Sn content with the junction depth about three times deeper for $Pb_{0.92}Sn_{0.08}Te$ than for $Pb_{0.79}Sn_{0.21}Te$. The junction depths can be correlated with substrate hole concentration.

This study has clarified many aspects of Sb diffusion in $Pb_{1-x}Sn_xTe$. However, there are other aspects that could be studied. These include the identification of the mechanism for Sb diffusion, the extent of compensation of Sb by native defects, the extent of precipitation of Sb, and possible amphoteric doping behavior.

Effects of Calcium, Tin, and Bismuth on the Early Strength of Calcium-Lead Alloys

M. Myers, H. R. Van Handle, and C. R. DiMartini

American Smelting and Refining Company, Central Research Laboratories, South Plainfield, New Jersey 07080

ABSTRACT

The effects of calcium content as well as additions of tin and bismuth on the mechanical properties of calcium-lead alloys have been investigated. The alloys were wrought and heat-treated in order to avoid the problems raised by the presence of casting variables. The previously reported increase in the rate of hardening with increasing calcium content was confirmed. Binary alloys containing less than 0.04% calcium showed no strengthening 1 hr after quench from the solution treatment temperature, while 0.1% calcium nearly doubled in tensile strength in only 5 min. Tin, in additions of 0.5 and 1%, completely restrained hardening in the first hour after quench in both 0.06 and 0.1% calcium alloy. Bismuth additions were made up to 1000 ppm. No effect was noted on the early strength of the 0.1% calcium alloys, but the rate of hardening of the 0.06% calcium alloys was significantly enhanced by the presence of bismuth. This effect, as well as the increase in hardening rate due to increased calcium are shown by means of transformation kinetics calculation to be the result of grain refinement in the alloys caused by calcium and bismuth. These findings show that early strength of calcium-lead alloys may be improved by: (*i*) limiting tin content; (*ii*) increasing calcium content; or (*iii*) adding bismuth to lower calcium alloys.

Over the last several years, interest in calcium-lead alloys for use as grids in SLI batteries has greatly increased due to the expected requirement for maintenance-free (low gassing) batteries in the automotive industry.

The effect of calcium level in these alloys has been well studied (1, 2, 7). The literature also contains many articles on calcium-lead, covering such subjects as aging behavior (1-4, 6, 7), casting properties (2, 3, 6, 7), battery grid growth (3, 5), and corrosion resistance (3, 5).

An area of interest which has not heretofore been reported upon in detail is the effects of tin and bismuth on the early strength of the calcium-lead system. The "early strength" is the strength during the first minutes of age hardening. This strength is important to the successful handling of cast grids up to and during the pasting operation and could conceivably be affected by impurity content or alloy composition.

Bismuth is of interest in this regard as it is usually present in primary and secondary lead as an impurity and has been reported to be deleterious to the early strength of grid alloys (3). Tin is of interest as it is frequently added in amounts of 0.5-1.0% in calcium-lead alloys. Caldwell and Sokolov (6) have studied the superficial hardness during aging of cast calcium-lead of various bismuth contents up to 180 ppm. They found essentially no effect on the hardness or on the electrochemical properties of the alloys. They also reported that the presence of tin slowed the onset of hardening.

An understanding of the age hardening characteristics of cast calcium-lead grids is the practical interest of this investigation However, because of the many difficult to control variables introduced by any casting operation, the authors decided to use wrought, heat-treated specimens to insure uniform distribution of calcium in the individual tensile bars. This allows for the study of the metallurgical behavior of the alloy system under highly reproducible conditions.

Key words: grids, batteries, calcium, tin, bismuth.

Experimental Procedures

Four categories of alloys were prepared; they were: (*i*) calcium-lead binaries with varying calcium levels and minimum impurities; (*ii*) 0.06 and 0.1% (0.09% Ca actual) calcium-leads with 3-1000 ppm bismuth and no tin; (*iii*) 0.06 and 0.1% calcium-leads with 0-2% tin and 5 ppm bismuth; and (*iv*) 0.06% calcium with combined additions of tin and bismuth.

The materials used for all of these alloys were low bismuth 1% calcium-lead hardener and 99.99+% pure lead (see spectrographic analysis, Table I). Tin and bismuth were added as pure metal.

Individual 2000g melts containing the desired levels of calcium, bismuth, and tin were prepared under a dynamic inert gas atmosphere to protect the calcium from oxidation. They were cast at 400°-450°C into a graphite book mold. The resultant ingots were 4 × 5 × 1 in. These ingots were sampled, top and bottom. Segregation was found to be minimal.

The ingots were rolled at room temperature to sheet approximately 0.1 in. thick. This sheet was then

sheared to strips which were, in turn, milled to standard tensile bar shape. Gauge lengths were 1 in. long and 0.25 in. wide. All specimens were numbered individually.

With the exception of aging time at room temperature, all specimens were treated alike. The as-rolled test bars were solution heat-treated at 300°±5°C for 5 hr and then rapidly water quenched to room temperature. Time of quench was accurately recorded for each specimen. At predetermined intervals (1, 5, 10, 20, and 60 min after quench), the specimens were tested in tension on an Instron Machine at a strain rate of 0.5 min^{-1}. Elongation was measured using inscribed 1 in. marks on the specimen gauge length.

Variations in strength and the rate of hardening were noted with varying compositions. The surface appearance of the specimens after fracture, which was related to grain size, also seemed to vary with composition. A study of grain size *vs.* strength and composition was, therefore, made using x-ray techniques.

Results and Discussion

The data presented herein show calcium, bismuth, and tin concentrations to have very marked effects on the early strength of calcium-lead alloys.

In the lead-calcium binary system, no significant hardening is noted 1 min after quench for calcium levels below 0.06% (Fig. 1). After 1 hr at room temperature, no hardening is noted for alloys with up to 0.04% calcium. A rapid increase in strength at 1 min is obtained between 0.06 and 0.08%, the UTS improving from 1900 to 3500 psi over that range. Above 0.08% calcium, the rate of improvement in strength with increasing calcium content is much less rapid.

The effect of bismuth on binary 0.06% calcium-leads is shown to be beneficial for aging up to 1 hr (Fig. 2). For longer aging periods, upwards of 24 hr, all 0.06% calcium-lead alloys had the same tensile strengths irrespective of bismuth content. Variations in bismuth content, up to 500 ppm, have no effect on higher calcium level alloys (0.09%, Fig. 3). This may be due to a grain refining of the 0.06% calcium alloy by bismuth which is masked by the grain refining effect of calcium at higher calcium levels.

This is more clearly illustrated by Fig. 4 in which effects of bismuth on the strength of 0.06 and 0.09% calcium-leads at 1 min after quench are shown.

The effects of tin content on 0.06 and 0.1% calcium-lead alloys (low bismuth) are shown in Fig. 5 and 6.

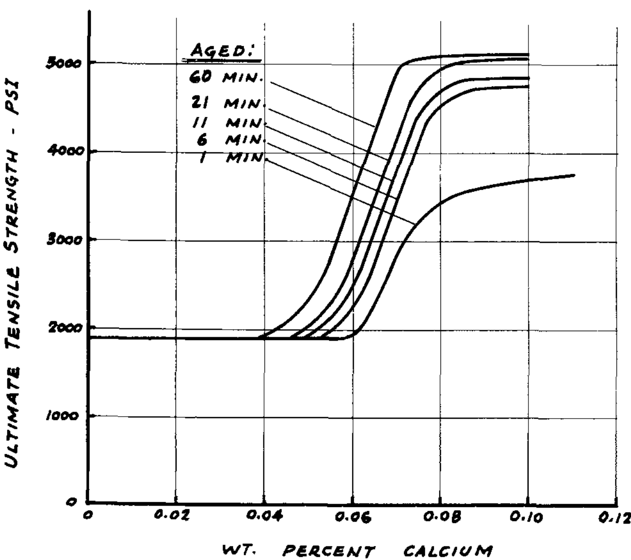

Fig. 1. Tensile strength vs. Ca content showing effect of aging time. All specimens solution treated for 5 hr at 300°C and water quenched.

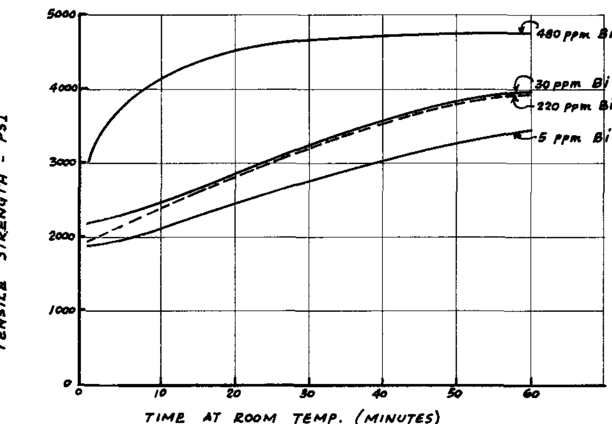

Fig. 2. Tensile strength vs. aging time for 0.06 Ca at varying Bi levels.

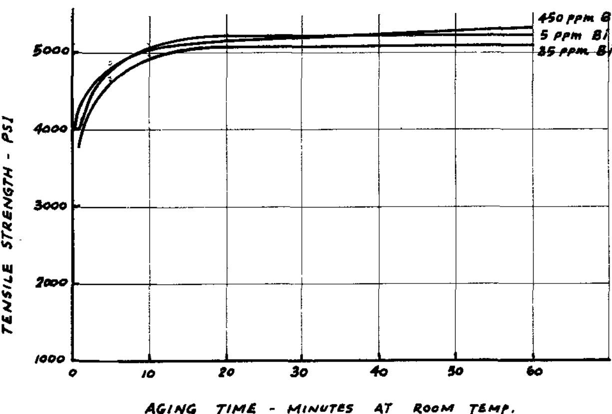

Fig. 3. Tensile strength vs. aging time for 0.09 Ca at varying Bi levels.

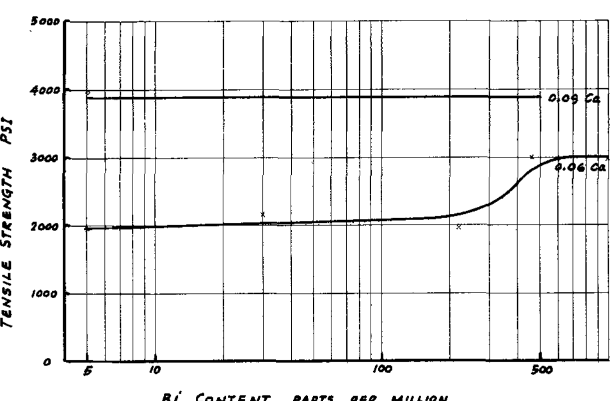

Fig. 4. Tensile strength vs. Bi content for 0.06 and 0.09 Ca aged at room temperature for 1 min.

Clearly the addition of tin inhibits all hardening during the first hour after quench in these alloys. As the addition of tin to 0.06% calcium-lead caused behavior opposite in nature to that caused by additions of bismuth to that alloy, it was interesting to observe the behavior of alloys containing both tin (0-1%) and bismuth (500 ppm). The results obtained from these alloys are plotted in Fig. 7. It may be seen that some increase in strength is obtained at 0.5% tin, but that at 1% tin no hardening occurs even in the presence of 500 ppm bismuth.

An attempt was made to predict from theory the increase in the rate of hardening with increasing bismuth and calcium. The work of Scharfenberger and

Henkel (7) is a detailed study of the mechanism and kinetics of precipitation in the calcium-lead system. It has long been known that hardening in this system occurs by the precipitation of extremely fine $CaPb_3$ particles at low temperature from the high temperature solid solution structure. Scharfenberger and Henkel reported the interesting finding that age hardening of calcium-lead occurs by two discontinuous nucleation and growth transformations, each analogous to the growth of pearlite in steel. This differs from most aging alloys which harden as a result of a continuous precipitation, as in, for example, aluminum-copper alloys. This finding is of significance in explaining the results of this report, as grain size, which has been shown herein to vary with alloy composition, is an important variable in determining the rate of discontinuous transformation.

This mode of transformation is modeled mathematically by Cahn and Hagel (8) by the equation

$$X = 1 - e^{-2BGt} \quad [1]$$

where X = volume fraction transformed, B = grain surface area, (mm^2/mm^3) [Fig. 8, Ref. (9)], G = cell growth velocity (mm/min) [Fig. 9, Ref. (7)], and t = time after quench (min).

Equation [1] models the over-all transformation rate for the case in which nucleation of the new, hard structure occurs rapidly all along the grain boundary surfaces. The only variables which affect the rate of transformation in this mechanism are growth rate, G, and grain size, upon which the grain boundary area per unit volume depends. For a specific composition, the only variable is grain size. (Variations in grain boundary area per unit volume with alloy chemistry are shown in Fig. 8. Grain boundary area varies inversely with the grain size.)

Thus, Eq. [1] can be used to predict the rate at which transformation from the solid solution to the hardened state occurs. This, in turn, can be used to compare the predicted rate with our experimental results and thus determine if the means by which alloy composition changes hardening rate is, in fact, grain refinement.

The growth rates used in our calculations are taken from Ref. (7). Growth rates were reported which varied with calcium content and with the amount of transformation completed. For ease of calculation, we assume that the rate reported at 50% transformed is constant for each calcium level. A plot of growth rate G *vs.* calcium level derived from the data of Ref. (7) is presented in Fig. 9.

Using this growth rate chart, and the grain size data of Fig. 8, time transformation curves were calculated. The calculated curves of volume fraction transformed *vs.* time for three conditions of interest (combinations of growth rate and grain size) are shown in Fig. 10. A growth rate of 0.008 mm/min corresponds to a calcium content of about 0.08%, while 0.0055 mm/min corresponds to about 0.06% calcium.

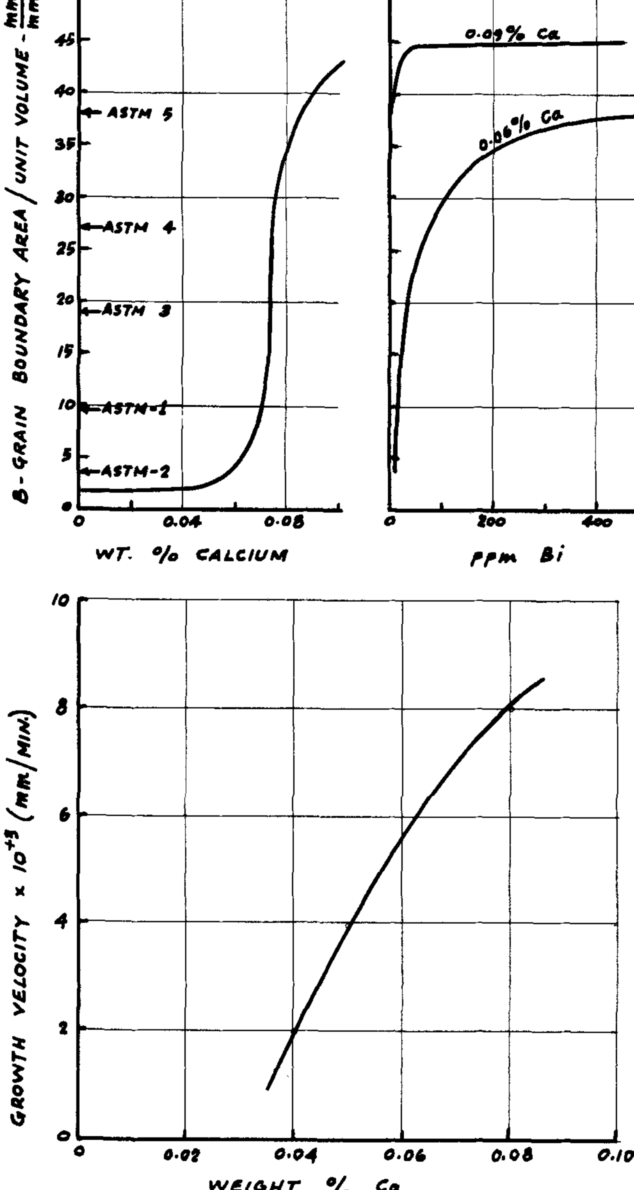
These curves are clearly similar in shape to the curves of tensile strength *vs.* time shown in Fig. 2 and 3. By employing two assumptions, it was possible to transpose the curves of Fig. 10 to the form of the curves of Fig. 2 and 3. These assumptions are: (*i*) that immediately after quench, all specimens had the same tensile strength, S_o = 1900 psi (this is implied by the data of Fig. 1); and (*ii*) that the fraction change in strength on age hardening is directly related to the volume fraction transformed.

These assumptions are combined in the equation

$$S_t = S_o + X_t(S_f - S_o) \quad [2]$$

where: S_t = tensile strength (psi) at aging time, t; S_o = tensile strength at time = 0, 1900 psi; X_t = volume fraction transformed at time t; and S_f = tensile strength at the end of hardening (strength at which the aging experimental curve levels off).

Values for S_f are approximate and were taken from the data of Fig. 1 and 2. The curves obtained by applying Eq. [2] to the data of Fig. 10 are shown in Fig. 11 as calculated tensile strength *vs.* time, compared to experimental data. The calculated curves agree reasonably well with the experimental curves for the rapid hardening alloys. The disagreement is somewhat larger for the slow transforming alloy. This may be due to the inherent error introduced in determining the grain size of large-grained specimens. In any case, the agreement is good enough to support grain refinement as a mechanism by which bismuth and calcium increase the rate of hardening in calcium-lead alloys.



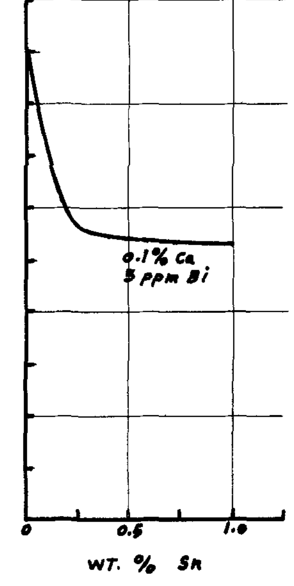


Fig. 8. Effects of calcium, bismuth, and tin on grain boundary surface area [Ref. (9)]. a (left), Grain boundary area vs. calcium content. b (center), Grain boundary area vs. bismuth content. c (right), Grain boundary area vs. tin content.

Fig. 9. Approximate growth velocity at 50% completion of the first reaction. Derived from the data of Scharfenberger and Henkel (7).

This effect was noted in Ref. (7) for calcium, although it was felt that grain refinement did not account for all of the change.

Additions of tin to calcium-lead have the effect of increasing the grain size (Fig. 8) and inhibiting completely the early hardening reaction (Fig. 5 and 6). It seems likely that the presence of tin has the effect of changing the mechanism of hardening in the calcium-lead system, perhaps to a continuous precipitation mechanism with an extended incubation period.

Alloys containing combinations of bismuth and tin show some hardening at the 0.5% tin level but none in alloys containing higher levels of tin (see Fig. 7).

Conclusions

Calcium and bismuth are shown to increase the rate at which calcium-lead alloys age harden. Increasing calcium also increases the ultimate aged strength, while bismuth additions (up to 1000 ppm) only increase the rate of hardening.

The mechanism by which calcium and bismuth achieve the rate increase is shown to be grain refinement. The finer grains have a larger surface area and smaller diameter thus allowing the growth of the hardened structure to proceed to completion more rapidly. No deleterious effects on strength associated with bismuth have been observed.

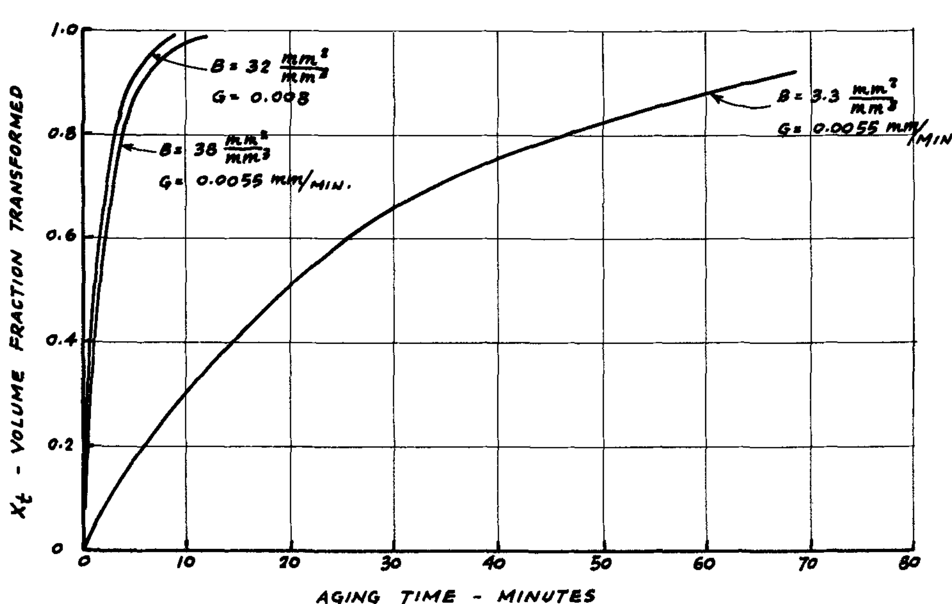

Fig. 10. Calculated curves of volume fractions transformed vs. aging time.

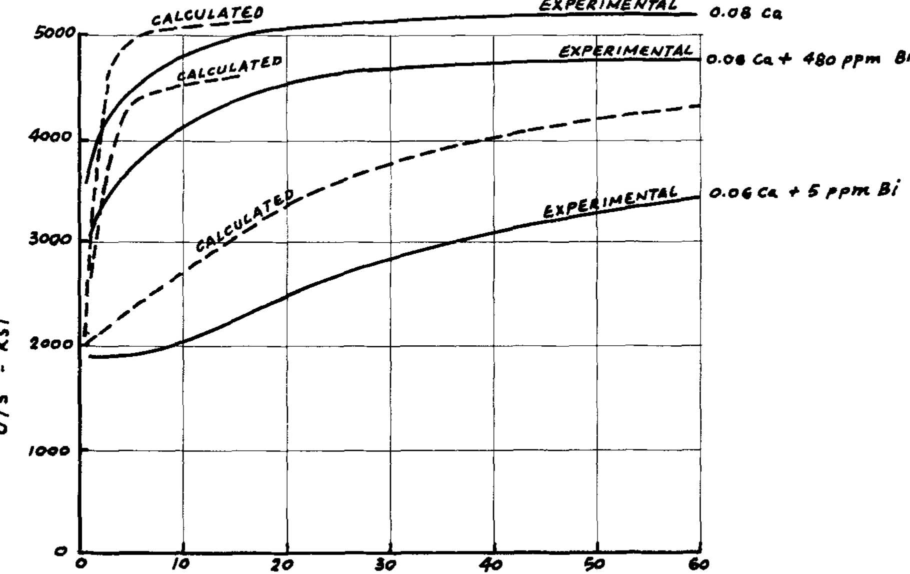

Fig. 11. Calculated and experimental aging curves for three alloys.

Additions of tin have been found to increase grain size and to strongly inhibit the early hardening process. It is likely that tin changes, basically, the mechanism of hardening in this system.

Although these conclusions are based upon studies of wrought alloys, such grain size effects should be similarly manifested in cast alloys. Work is currently underway to validate this and will be reported upon at a later date.

A Thermodynamic Investigation of Cubic Sodium Tungsten Bronze, Na_xWO_3

T. A. Ramanarayanan and W. L. Worrell*

Department of Metallurgy and Materials Science, University of Pennsylvania, Philadelphia, Pennsylvania 19174

ABSTRACT

The partial molar free energy of solution of sodium in cubic sodium tungsten bronze, Na_xWO_3, has been measured in the composition range from $x = 0.45$ to $x = 0.8$ and at temperatures between 500° and 800°C. An electrochemical cell using Pyrex as a sodium ion conducting solid electrolyte has been employed. The standard state for sodium is chosen such that the activity of sodium is unity for the composition $NaWO_3$. Using this standard state, the partial molar free energy of solution of sodium is -16.6 kcal/g atom of sodium in $Na_{0.45}WO_3$ and -6.1 kcal/g atom of sodium in $Na_{0.8}WO_3$ at 700°C. The thermodynamic factor $\partial \ln a_{Na}/\partial \ln x$ has been calculated from the variation of the cell emf with composition. The thermodynamic factor is combined with values for the chemical diffusivity of sodium to evaluate the partial sodium ion conductivity in cubic $Na_{0.78}WO_3$.

Sodium tungsten bronzes are nonstoichiometric compounds having the general formula, Na_xWO_3, where x is less than 1. At values of x between 0.15 and 0.28, two tetragonal phases coexist; the tetragonal phase of higher sodium content has a homogeneity range from $x = 0.28$ to 0.38 (1). A cubic phase occurs at values of $x > 0.43$ (1). The crystal structures of the various sodium tungsten bronzes have been estab-

* Electrochemical Society Active Member.
Key words: sodium thermodynamics, cubic sodium tungsten bronze, partial sodium ion conductivity.

lished by Hägg and Magneli using x-ray techniques (2). The crystal structure of $NaWO_3$ is that of perovskite, in which a tungsten atom is at the center of a cube, surrounded octahedrally by six oxygen atoms at the face centers. The corners of the cube are occupied by sodium atoms. In cubic sodium tungsten bronzes with the general formula Na_xWO_3, a fraction $(1 - x)$ of sodium atoms is missing from the corners (3). The bronzes can be regarded as a solution of sodium in WO_3. The conductivity of the cubic bronzes is metallic (4, 5).

The present study is a measurement of sodium activities in the cubic bronzes using Pyrex as a solid electrolyte. Sodium ions are the predominant conducting species in Pyrex. Several investigators (6-8) have used a sodium ion conducting glass as a solid electrolyte to determine the thermodynamic properties of alloys containing sodium.

Experimental Procedure

Tungsten (99.99%), WO_3 (99.95%), and Na_2WO_4 (99.95%) powders were used to prepare the sodium tungsten bronzes. The preparation was based on the reaction (3)

$$\frac{x}{2} Na_2WO_4 + \frac{(3-2x)}{3} WO_3 + \frac{x}{6} W \xrightarrow{850°C} Na_xWO_3$$

The reactants were weighed accurately in the appropriate proportions, mixed thoroughly, and heated for approximately 10 hr at 850°C in an alumina boat under purified argon. The weight change after reaction was within 0.1% of the original weight, and an x-ray diffraction pattern of the reaction product indicated that only the bronze phase was present. The bronzes were crushed to a powder, pressed in a 1 cm diam die without binder at 20 tsi, and sintered at 850°C under purified argon to yield pellets of approximately 1 cm diam by 0.5 cm thickness.

Pyrex disks of 0.5 cm thickness were cut from a rod of 1 cm diam. The faces of the Pyrex disk were polished to a smooth finish using 6μ diamond polishing compound, and thoroughly cleaned with acetone.

The composition of the reference electrode was $Na_{0.2}WO_3$, which was a mixture of two tetragonal phases. The other electrode was a cubic bronze, Na_xWO_3, with x between 0.45 and 0.8. The electrochemical cell

$$Na_xWO_3(0.45 \leq x \leq 0.8) \mid \begin{matrix}\text{Pyrex}\\ \text{Electrolyte}\end{matrix} \mid Na_{0.2}WO_3 \quad [A]$$

was assembled in an alumina tube as shown in Fig. 1. Platinum wires were used as leads, and a Pt-Pt (10% Rh) thermocouple, placed within 0.5 cm of the cell, was used to measure the temperature. The cell was heated to 700°C under an argon atmosphere (purified by passing through anhydrous $CaSO_4$, anhydrous magnesium perchlorate, and Ti-Zr chips held at 800°C) in the constant temperature (± 1/2°C) zone of a Hoskin's alloy resistance furnace. Light pressure was exerted on the cell by means of an alumina push-rod to ensure good electrode-electrolyte contact. The open-circuit voltages were measured to within ± 0.02 mV using a Keithley 630 high impedance (> 10^{13} ohms) potentiometric electrometer. Equilibrium was taken to be established when the open-circuit cell voltage remained constant (± 0.5 mV) over a 5 hr period. Cell voltages were measured on heating and on cooling over a temperature range from 500° to 800°C.

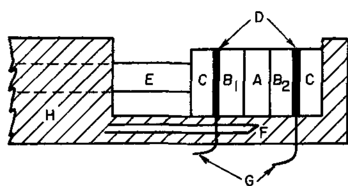

Fig. 1. Electrochemical cell arrangement

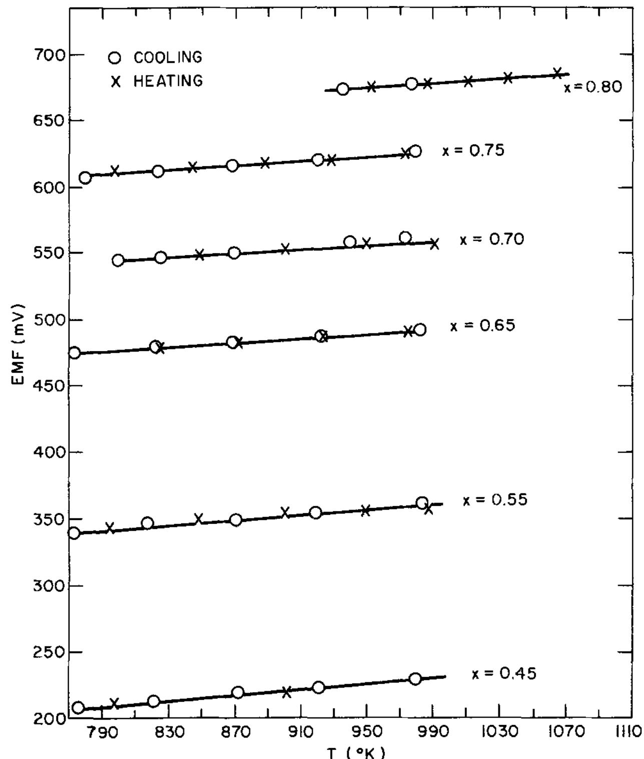

Fig. 2. Emf of cell [A] as a function of temperature

Results and Discussion

The measured open-circuit cell voltages for cell [A] are shown as a function of temperature in Fig. 2. The reproducibility of the data is ± 2 mV. Table I shows the temperature-dependent equations for the cell emf. At a given temperature, the cell emf is related to the sodium activities at the electrodes through the relation

$$E = \frac{RT}{\mathbf{F}} \ln \frac{a_{Na}}{a_{Na}^*} \quad [1]$$

where a_{Na} is the sodium activity in the cubic bronze and a_{Na}^* is the activity in the reference bronze $Na_{0.2}WO_3$. To describe the thermodynamics of the various Na-WO_3 solutions, a standard state is selected such that the sodium activity is unity for the composi-

Table I. Emf values as a function of temperature for cell [A]

x	Expression for cell emf (mV)
0.45	$E = 126.58 + 0.104\,T$
0.55	$E = 270.01 + 0.091\,T$
0.65	$E = 418.31 + 0.074\,T$
0.70	$E = 477.61 + 0.083\,T$
0.75	$E = 540.38 + 0.086\,T$
0.80	$E = 592.75 + 0.086\,T$

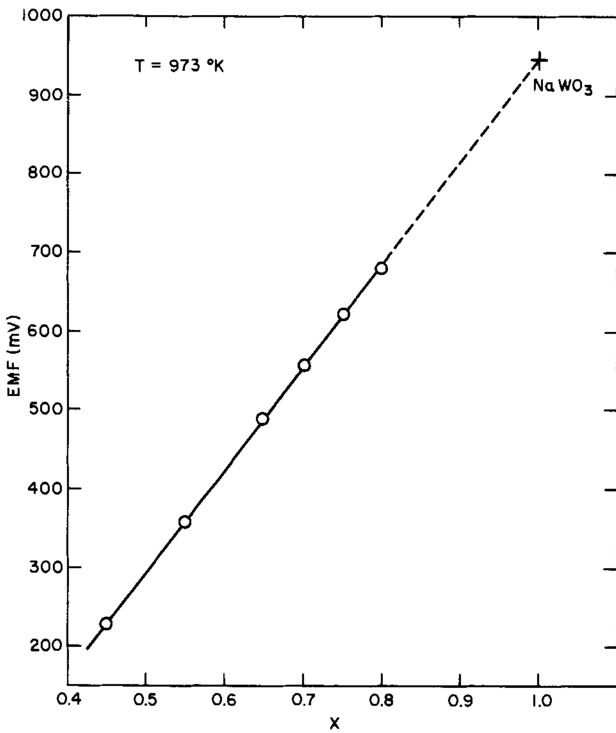

Fig. 3. Emf of cell [A] as a function of x at 973°K

tion $NaWO_3$. In $NaWO_3$, all the available sodium positions are occupied, and it is reasonable to assign unit sodium activity to the bronze of this composition.

The emf of cell [A] at 973°K has been plotted *vs.* x in Fig. 3. An extrapolation of the straight line in Fig. 3 to $x = 1$ gives 944 mV for the emf of the cell

$$NaWO_3 \mid \text{Pyrex} \mid Na_{0.2}WO_3 \quad [B]$$

at 973°K. The temperature dependence of the emf of cell [B] follows the equation

$$E = 875.75 + 0.07T \quad [2]$$

On subtracting the emf's of cell [A] shown in Table I from Eq. [2], one obtains the emf's for the cell

$$NaWO_3 \mid \text{Pyrex} \mid Na_xWO_3 \quad [C]$$

Expressions for the temperature dependence of the emf of cell [C] are presented in Table II. For the selected standard state, the emf of cell [C] is given by

$$E = \frac{RT}{\mathbf{F}} \ln a_{Na} \quad [3]$$

where a_{Na} is the sodium activity in the cubic bronze relative to that in $NaWO_3$. The partial molar free energy of solution of sodium ($\overline{\Delta G}_{Na}$) per g atom of sodium is related to the emf of cell [C] through the equation

$$\overline{\Delta G}_{Na} = \overline{\Delta H}_{Na} - T\overline{\Delta S}_{Na} = -\mathbf{F}E \quad [4]$$

where $\overline{\Delta H}_{Na}$ and $\overline{\Delta S}_{Na}$ refer to the partial molar heat and entropy of solution, respectively, of sodium in the cubic bronze. Table III lists the values of $\overline{\Delta G}_{Na}$ at 973°K *vs.* y, the atom fraction of sodium in the Na-WO_3 binary; y and x are related by

Table II. Emf values as a function of temperature for cell [C]

x	Expression for cell emf (mV)
0.45	$E = 749.17 - 0.034\,T$
0.55	$E = 605.74 - 0.021\,T$
0.65	$E = 457.44 - 0.004\,T$
0.70	$E = 398.14 - 0.013\,T$
0.75	$E = 335.37 - 0.016\,T$
0.80	$E = 283.00 - 0.016\,T$

Table III. Partial molar free energies of solution of sodium in cubic bronzes, Na_xWO_3, as a function of the sodium atom fraction, y, at 973°K

$y = x/(1+x)$	$\overline{\Delta G}_{Na}$ (kcal/g atom)
0.310	−16.6
0.355	−13.5
0.394	−10.5
0.412	−8.9
0.429	−7.4
0.444	−6.1

$$y = x/(1+x) \quad [5]$$

In Fig. 4, the partial molar free energies of solution at 973°K are plotted as a function of the atom fraction of sodium. Using Eq. [4] and the emf equations tabulated in Table II, one obtains very small $\overline{\Delta S}_{Na}$ values (< 0.8 eu). Thus the partial molar heat of solution is approximately equal to the partial molar free energy of solution. It should be noted that $\overline{\Delta G}_{Na}$ and $\overline{\Delta H}_{Na}$ are not the usual solution quantities, but represent the energy changes which occur on removing sodium atoms from the $NaWO_3$ lattice. In view of the small entropy changes, the large free energy changes shown in Table III most likely indicate a decreasing Fermi level with decreasing sodium content in Na_xWO_3.

The thermodynamic factor of sodium in cubic bronze, $\partial \ln a_{Na}/\partial \ln C_{Na}$ (where C_{Na} is the sodium concentration in moles/cm^3), may be evaluated from the present experiments. The sodium concentration, C_{Na}, is related to x in the formula Na_xWO_3 by

$$C_{Na} = x/V_m \quad [6]$$

where V_m (cm^3/mole of Na_xWO_3) is the molar volume of the cubic bronze. From Eq. [6]

$$d \ln C_{Na} = d \ln x - d \ln V_m \cong d \ln x \quad [7]$$

if changes in molar volume with composition are ignored. The variation of the lattice parameter of the cubic bronze with composition (9) indicates that the molar volume changes only by 2% when x is changed from 0.45 to 0.8. Thus, using Eq. [7], one obtains

$$\frac{\partial \ln a_{Na}}{\partial \ln C_{Na}} = \frac{\partial \ln a_{Na}}{\partial \ln x} \quad [8]$$

Differentiation of Eq. [1] with respect to $\ln x$ for a given temperature yields

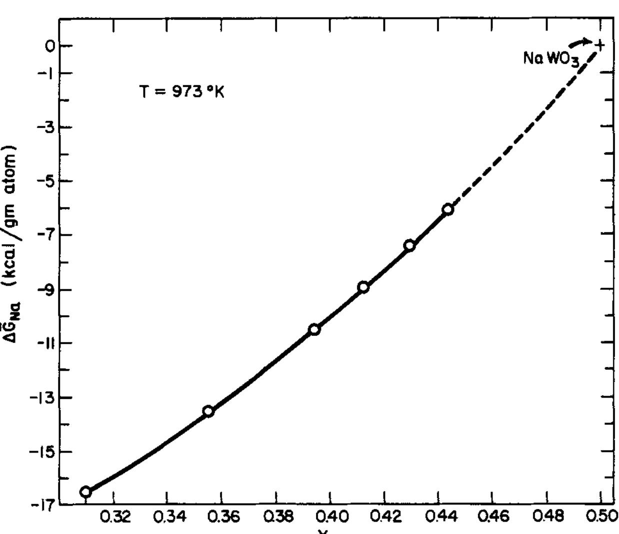

Fig. 4. The partial molar free energy of solution of sodium in cubic Na_xWO_3 as a function of y at 973°K.

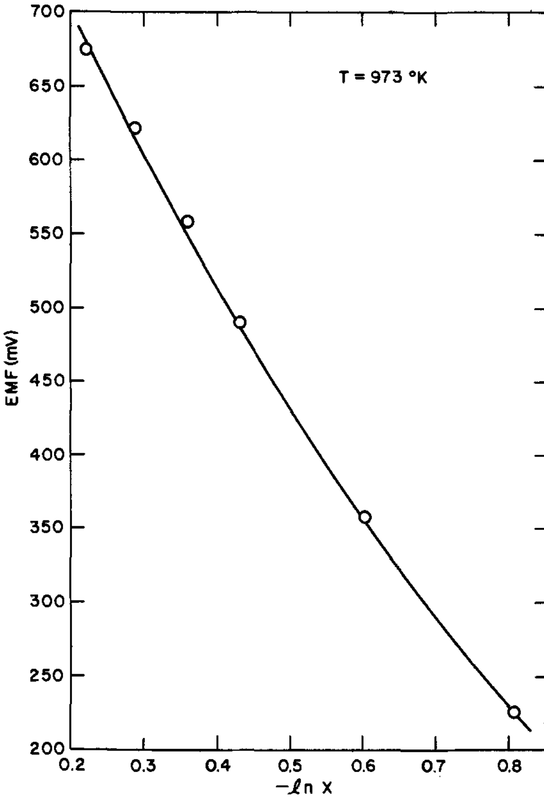

Fig. 5. Emf of cell [A] as a function of ln x at 973°K

$$\frac{\partial E}{\partial \ln x} = \frac{RT}{\mathbf{F}} \left(\frac{\partial \ln a_{Na}}{\partial \ln x} \right) \quad [9]$$

A plot of E vs. ln x at $T = 973°K$ is shown in Fig. 5. From the slope of the line in Fig. 5, the thermodynamic factor may be calculated for any composition using Eq. [9].

The thermodynamic factor may be combined with data for the chemical diffusivity of sodium in the cubic bronze to obtain the partial sodium ion conductivity. In the presence of a concentration gradient and in the absence of an electrical potential gradient, the flux of sodium in the z direction may be written (10) as

$$J_{Na} = -\frac{C_{Na}B_{Na}}{N} \left(\frac{\partial \mu_{Na}}{\partial z} \right) \quad [10]$$

where J_{Na} is the sodium flux (moles/cm²-sec), B_{Na} is the absolute mobility of the sodium ion (particle-cm²/cal-sec), N is the Avogadro number (particles/mole), and μ_{Na} is the chemical potential of sodium (cal/mole). In view of Eq. [8], Eq. [10] may be written as

$$J_{Na} = -\frac{B_{Na}RT}{N} \left(\frac{\partial \ln a_{Na}}{\partial \ln x} \right) \frac{\partial C_{Na}}{\partial z} \quad [11]$$

From Fick's first law, the sodium flux, J_{Na}, is given by

$$J_{Na} = -D_{Na} \left(\frac{\partial C_{Na}}{\partial z} \right) \quad [12]$$

Upon combining Eq. [11] and [12]

$$D_{Na} = \frac{B_{Na}RT}{N} \left(\frac{\partial \ln a_{Na}}{\partial \ln x} \right) \quad [13]$$

The partial sodium ion conductivity of the bronze is related to the concentration of sodium and its mobility (10) through

$$\sigma_{Na} = z^2_{Na}e\mathbf{F}B_{Na}C_{Na} = \frac{z^2_{Na}e\mathbf{F}B_{Na}x}{V_m} \quad [14]$$

Here σ_{Na} is the sodium ion conductivity in (ohm cm)$^{-1}$

Table IV. Partial sodium ion conductivity in $Na_{0.78}WO_3$ as a function of temperature

Temp (°K)	D_{Na}† (cm²/sec)	$\frac{\partial \ln a_{Na}}{\partial \ln x}$	$\sigma_{Na} T$ (ohm cm^{-1}
873	9.35×10^{-14}	14.75	1.6×10^{-7}
923	4.70×10^{-13}	14.15	8.7×10^{-7}
973	2.01×10^{-12}	12.17	4.1×10^{-6}
1023	7.45×10^{-12}	12.00	1.5×10^{-5}

† From Ref. (11).

z_{Na} is the valence of the sodium ion, and e is the electronic charge. Combining Eq. [13] and [14] and noting that $eN = \mathbf{F}$ and $z_{Na} = 1$, one obtains

$$\sigma_{Na}T = \frac{D_{Na}\mathbf{F}^2x}{V_mR} \bigg/ \left(\frac{\partial \ln a_{Na}}{\partial \ln x} \right) \quad [15]$$

Values of the thermodynamic factor, $\partial \ln a_{Na}/\partial \ln x$, for $x = 0.78$ are shown in Table IV for four different temperatures. Smith and Danielson (11) have measured the chemical diffusivity of sodium in $Na_{0.78}WO_3$ under a concentration gradient. On combining values of $\partial \ln a_{Na}/\partial \ln x$ from Table IV with the D_{Na} values according to Smith and Danielson, one can calculate values of $\sigma_{Na}T$ for $Na_{0.78}WO_3$ using Eq. [15]. The values so obtained are shown in Table IV. Figure 6 is a plot of log $\sigma_{Na}T$ vs. $\frac{1}{T}$; the straight line fits the least squares expression

$$\sigma_{Na}T = 5.9 \times 10^6 \exp(-54{,}200/RT) \text{ohm}^{-1}\text{cm}^{-1} \text{°K} \quad [16]$$

According to measurements of Brown and Banks (4), $Na_{0.77}WO_3$ has a total conductivity, σ_t, of approximately 10^4 (ohm cm)$^{-1}$ at 973°K. From Eq. [16], σ_{Na} for $Na_{0.78}WO_3$ at 973°K is 3.7×10^{-9} (ohm cm)$^{-1}$. Thus the ionic transference number ($t_{Na} = \sigma_{Na}/\sigma_t$) is 3.7×10^{-13} for a bronze of approximate composition $Na_{0.78}WO_3$.

The Oxidation of Thin Single Crystals of Iron

P. L. Fan and L. O. Brockway

Department of Chemistry, University of Michigan, Ann Arbor, Michigan 48104

ABSTRACT

Single crystal (001) films of iron treated with mixtures of oxygen and nitrogen at 10^{-7} Torr and 700°C form individual oxide grains observable in transmission electron microscopy. The three reaction products (FeO, Fe_3O_4, and "Fe_4N") all have a fixed epitaxy with (001) parallel to the iron film. The grain size and distribution of the product phases are reported as well as a curious growth behavior of FeO.

The reaction of iron with oxidizing atmospheres has been the subject of very many investigations. Most of the reported work has dealt with the formation of continuous oxide layers on polycrystalline iron surfaces. Some oxidation work on single crystals of iron has been done by Sewell and co-workers (1-3) and by Graham and Cohen (4). Gulbransen (5) worked with the formation of iron oxide whiskers. Epitaxial formation of iron oxide on iron was reported and the identities of the oxide phases have been studied, but very little work has been done under conditions affording observations on the formation and growth of individual oxide grains. Such observations seem necessary for the understanding of the earlier stages of the reaction between oxygen and metal surface.

The use of thin metal films and transmission electron microscopy for the study of the formation of individual oxide grains has been employed by Brockway, Marcus, Rowe, and Adler (6-10) on copper. A similar technique has now been applied to the study of the formation, epitaxy, nucleation sites, and growth rate of individual iron oxide grains on iron.

Experimental

Single crystal (001) iron films of about 1000Å thickness were obtained by deposition of iron vapor from an electron beam evaporator onto polished (001) surfaces of sodium chloride at 350°C with a deposition rate of 8-10 Å/sec and a residual pressure of 5×10^{-6} Torr. The films were floated off of the substrate onto water and mounted on stainless steel support grids. They were annealed and oxidized in a bakeable vacuum line constructed of 1-1/2 in. diam stainless steel tubing and fittings with a 1 in. diam quartz tube in a tubular furnace as a reaction zone. The ultimate vacuum attained after baking for 8 hr at 250°C (the temperature limit imposed by the materials of the valves) was about 4×10^{-8} Torr. A typical composition read on a residual gas analyzer was 45% nitrogen, 25% water, and 25% hydrogen.

Key words: iron, film, oxidation, epitaxy.

The iron films mounted on grids were annealed in hydrogen at 1 atm and 700°C for 1 hr. Because of the strong preferential adsorption of water on the stainless steel walls, it was imperative to reduce the water content of the hydrogen as far as possible. Electrolytic hydrogen filtered through palladium contained a troublesome amount of water (on the order of 10^{-7}), which was significantly lowered by passage through a trap filled with glass beads at liquid nitrogen temperature.

The oxidation experiments were carried out immediately following the anneal treatment and a subsequent baking at 250°C under vacuum for 8 hr. The oxidation pressures used ranged from 1×10^{-7} to 2×10^{-6} Torr; the reaction times were from 15 to 240 min, and the temperature was 550° or 700°C. Only the reactions at 700°C and pressures in the range from 1 to 8×10^{-7} Torr gave distinguishable individual oxide grains. Since this pressure range of interest was not far above the residual background pressure (4×10^{-8} Torr), it was not feasible to achieve high purity of oxygen in the unit as constructed. A typical composition observed at a total pressure of 2×10^{-7} Torr was 38% oxygen, 40% nitrogen, 9% water, and 7% hydrogen. It may be noted that carbon monoxide has the same mass number as nitrogen (*i.e.*, 28), but any appreciable fraction of CO present would have been indicated by a much higher peak for C (12) than was observed in any of the mass spectra recorded by the residual gas analyzer.

The annealed and oxidized films were examined by electron micrographs and diffraction patterns taken on JEOLCO 6A and JEOLCO 7 microscopes.

Results

The annealed films gave good single crystal (001) diffraction patterns with no deviation greater than

about 1°. Micrographs (Fig. 1) showed smooth films with areas of about 0.1 μ^2 enclosed by low angle boundaries running along the <110> directions. Dislocations appeared with an average density of 5×10^9 cm^{-2} usually piled up along the boundaries; no stacking faults were observed.

The identification and epitaxial orientation of the oxidation products was determined with the aid of a series of diffraction patterns taken at room temperature; one example is shown in Fig. 2 for an iron film treated at 700°C for 240 min at 2×10^{-7} Torr total pressure. Table I lists the primary reflections observed for Fe, FeO, and Fe_3O_4; all reflections are of the form (hk0). All of the reflections possible for these three phases within the range of scattering angle recorded are observed, when it is recognized that the (001) planes of the oxides are parallel to the (001) plane of the iron and the [110] directions of the oxide grains are parallel to the [100] of iron. For all these reflections the observed d values agree with the calculated ones (using the cubic cell edges listed in Table I) within the experimental error of the measurements, amounting to about 3% for the smallest angles and to less than 1% at the larger angles; moreover, the individual reflections in each of the (hk0) forms are correctly positioned. The phases Fe and FeO contribute most strongly in Fig. 2.

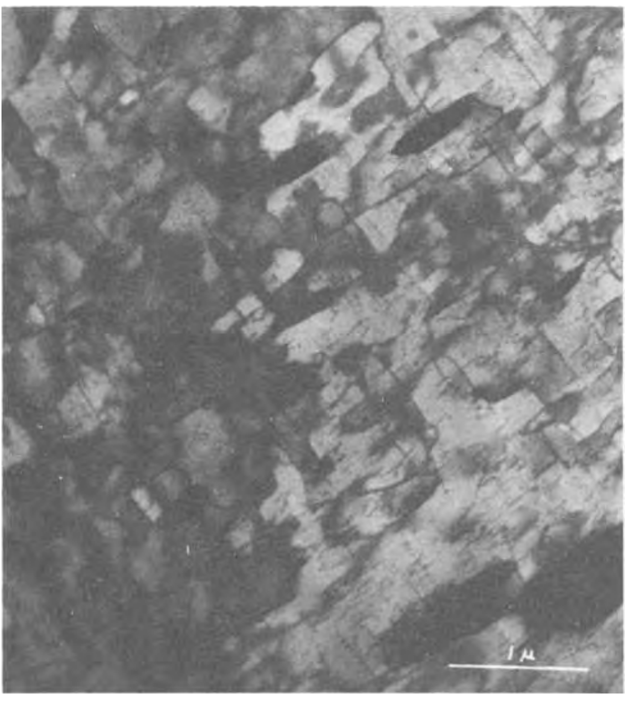

Fig. 1. Electron micrograph of grid-annealed film. Low angle grain boundaries are marked by piled-up dislocations.

Fig. 2. Diffraction pattern of oxidized film (700°C, 2×10^{-7} Torr, 240 min). Four phases show: Fe, FeO, Fe_3O_4, Fe_4N.

330	620	660	
420		840	
		10·2·0	

The diffraction patterns illustrated in Fig. 2 show many more spots than can be accounted for by the individual planes of the forms listed in Table I. There are evidently many double diffraction spots formed when the electron beam incident on the specimen is reflected strongly by one phase and the reflected beam passes through a layer of a second phase and is partially scattered again. A few of the extra spots arise from combinations of Fe and FeO reflections. The presence of a fourth cubic phase with cube edge of approximately 3.80Å and oriented with its axes parallel to those of the iron film does account for all of the many extra spots. Three primary reflections observed from this phase are listed under "γ'-Fe_4N" in Table I. The double reflections are of the following kinds: (200), (400), and (420) of FeO each reflected by (110), (200), and (220) of the extra phase; (110), (220), and (310) of Fe reflected again by the three planes of the extra phase. No second scattering of Fe_3O_4 reflections was found.

A search of the current A.S.T.M. Powder Diffraction File discloses only one compound containing iron and having three strong diffraction lines with d values of 2.67, 1.89, and 1.33Å; for this reason the fourth phase is designated γ'-Fe_4N, whose strongest (hk0) reflections do correspond to the observed spacings.

The oxidation experiments at 550°C yielded Fe_3O_4 as the only oxidized phase, while all oxidations at 700°C produced both FeO and Fe_3O_4 in treatment times ranging from 15 to 240 min. The Fe_4N also appeared with treatment times of 120 to 240 min at 2×10^{-7} Torr. The amounts of Fe_4N indicated by the relative intensities of the diffraction spots were less in the treatment having a N_2/O_2 ratio of 3.4 than in the others where the N_2/O_2 ratio was 1.0 or less.

The appearance and distribution of oxide grains is illustrated in the micrographs of Fig. 3 (15 min) and Fig. 4 (240 min). After the short treatment well-defined grains of uniform size (about 0.03μ) are distributed randomly over the film without any observable relation to the dislocation sites or grain boundaries of the iron. After the long treatment the sizes are far from uniform; some of the grains have scarcely grown at all while others have reached sizes in the 0.3-0.5μ range. Grains of intermediate sizes are rare. The average diameters of the thirty largest grains at different treatment times are shown in Fig. 5. The standard deviations for such measurements are indicated by the magnitude of the bars. The lineal growth rate appears to be uniform at 0.088μ hour^{-1} at 700°C and 2×10^{-7} Torr.

Further examination of the treated films by electron microscopy and diffraction gave information on the distribution of the phases. By the use of dark field microscopy the large grains produced at longer times are shown to be mainly FeO with some Fe_4N included. Fe_3O_4 is spread across the whole film. This is supported by selected area diffraction experiments showing that FeO and Fe_3O_4 are distributed across the film while Fe_4N is scarcely detected away from

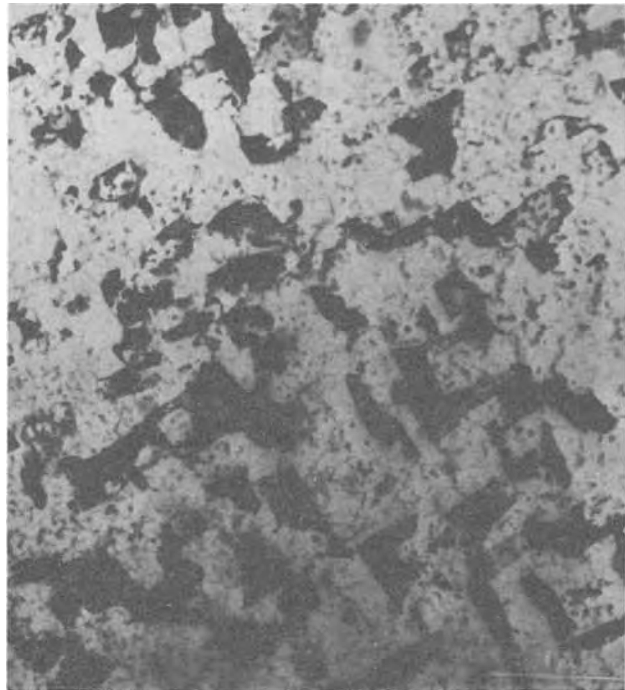

Fig. 3. Electron micrograph of oxidized film (700°C, 2 x 10^{-7} Torr, 15 min). FeO grains are randomly distributed.

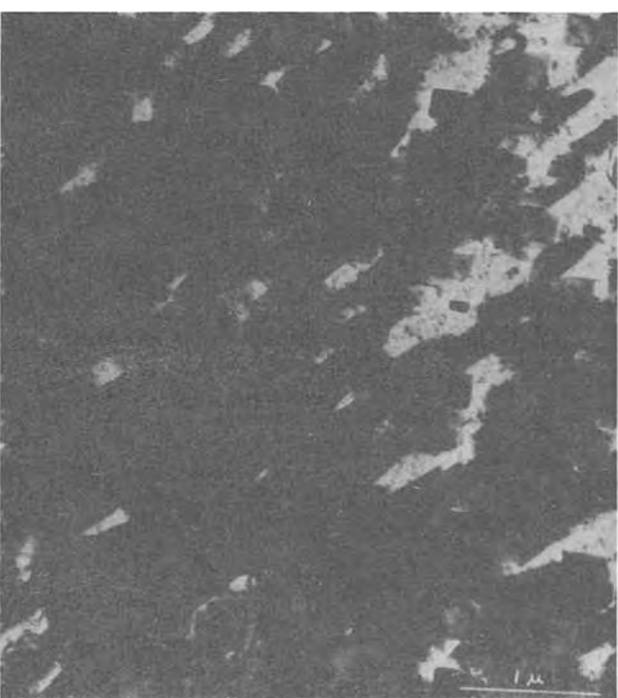

Fig. 4. Electron micrograph of oxidized film, (700°C, 2 x 10^{-7} Torr, 240 min). Large FeO grains appear.

the large FeO grains. Further corroboration comes from the Moire fringe patterns observed in the high resolution micrograph of Fig. 6; the fringe spacings inside the large grain can be accounted for only by an overlay of Fe_4N on FeO while the spacings away from the large grain arise, respectively, from FeO on Fe and Fe_3O_4 on Fe.

Discussion

The observed epitaxy of FeO and Fe_3O_4 agrees with the results of Bardolle and Benard (11) for oxidation at 10^{-1} Torr and with the calculations of Collins and Heavens (12). The presence of imperfections (dislocations and low angle boundaries) in the iron failed to influence the sites of oxide nucleation in agreement with the observations of Pease and Ploc (13), who reported a dependence of nucleation sites on dislocations only when the iron contained impurities much in excess of the 0.001% concentration in the present experiments.

A possible effect of imperfections in the iron may lie in the greatly disparate oxide growth rates observed in the treatments at 700°C and 2 × 10^{-7} Torr. About 0.8% of the oxide grains observed after 15 min grow to ten times their original diameters in 4 hr while a very large fraction of the grains have not shown any apparent growth. Some variation in the texture of the iron film causes abnormal growth at certain grain sites; accelerated diffusion of iron atoms at dislocations could plausibly account for the unusual growth. It should be noted that a new phase,

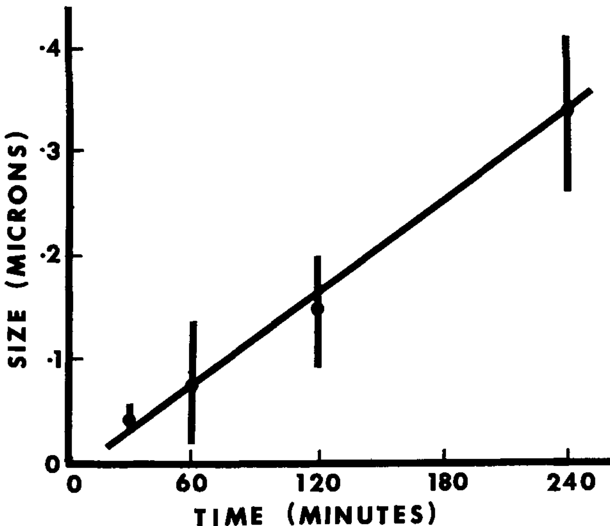

Fig. 5. Relation between average diameter of large FeO grains (700°C, 2 x 10^{-7} Torr) and oxidation time.

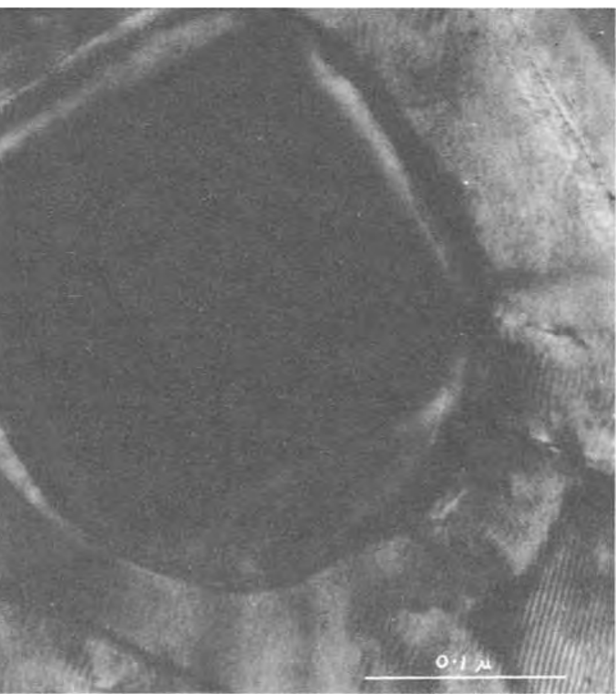

Fig. 6. Electron micrograph of oxidized film (700°C, 2 x 10^{-7} Torr, 240 min). At high resolution three distinct sets of moire fringes appear.

Fe_4N, is being formed on the larger grains at the later times, and the growth rate observations can not be interpreted in terms of the increase of a single phase.

The apparent formation of Fe_4N was surprising. It is found only after FeO and Fe_3O_4 have been well established. Because it is associated almost exclusively with the large FeO grains, it might be supposed that the surface of the large FeO grains enables the formation of the nitride in a way which does not occur with the small-grained FeO, with Fe_3O_4, or with iron. The thermodynamic possibilities for the reaction of formation cannot be confidently assessed since the standard free energies are not adequately known for the conditions here, *i.e.,* mixtures of fine particles (0.3μ and much smaller) in specific crystallographic orientations. The dilemma could be resolved by reactions with the nitrogen pressure varied from very low to very high with respect to oxygen; this would require a new ultrahigh vacuum line capable of reaching a background pressure far below the total pressure required ($\sim 10^{-7}$ Torr) to yield isolated grains of oxide.

Finally it is possible to suggest a series of stages in the formation of oxide layers under the conditions of the present experiments. The first step of adsorption of oxygen and other gases is not observed by electron microscopy or transmission diffraction. Next (in less than 15 min) is the formation of grains of two phases, FeO and Fe_3O_4, too small to show contrast effects in micrographs but detected by their diffraction patterns. Later, individual grains of FeO are detected with diameters of 0.03μ. Many of these remain practically the same size after 4 hr while a few grow to more than ten times the original diameters. During the last half of this period Fe_4N is formed on the FeO large grains, but the growth of the grains is mainly due to added FeO. The space between the large grains continues to show the small FeO grains but never does develop detectable individual grains of Fe_3O_4. A continuous thick layer of oxide is finally formed by the lateral growth and coalescence of the larger FeO grains.

Summary

Single crystal (001) films of iron were exposed to oxidizing atmospheres under conditions which permitted the formation of individual oxide grains observable in transmission electron microscopy. These conditions were a temperature of 700°C and a pressure range of 1-8 $\times$ 10^{-7} Torr for a gas composition of about 40% each of oxygen and nitrogen with the balance mainly water and hydrogen. Grains of FeO and Fe_3O_4 were observed for treatment times from 15 to 240 min; for the longer treatment times Fe_4N was also formed. All three phases were oriented with (001) planes parallel to the iron film. By contrast at 550°C the only oxidized phase observed was Fe_3O_4 in continuous films with no grains resolved.

The FeO grains originally observed at 15 min showed a uniform size of about 0.03μ diameter. While most of these appeared to be unchanged after 4 hr, about 1% had grown to ten times greater diameters at a rate of 0.088μ $hour^{-1}$.

Acknowledgments

We are grateful to Professor W. C. Bigelow, Mrs. A. P. Rowe, and Mr. L. F. Allard of The University of Michigan for technical assistance and valuable discussions. We also wish to thank Mr. T. A. Nolan of the Oak Ridge Gaseous Diffusion Plant operated by the Union Carbide Corporation, Nuclear Division, for the Atomic Energy Commission, for preparing high resolution micrographs and diffraction patterns.

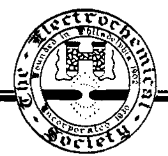
Technical Note



An Investigation of the Structure of Pd_2Si Formed on Si

S. S. Lau and D. Sigurd[1]

California Institute of Technology, Pasadena, California 91109

Recent investigations of the electrical and metallurgical properties of palladium silicide (Pd_2Si) have shown that this metal silicide is a useful contact material in integrated circuit applications (1-4). It has been reported that of the possible intermetallic compounds in the Pd/Si system Pd_2Si is predominantly formed when a Si wafer with an evaporated layer of Pd (<10,000Å) is heat-treated at temperatures up to 750°C (2, 3, 5-7). In a few cases small amounts of Pd_3Si and PdSi have been observed (5).

Experimental observations indicated (6, 7) a strong tendency for Pd_2Si to grow with the hexagonal basal plane parallel to the substrate surface ([001] fiber texture) regardless of the substrate orientation, and in particular, Pd_2Si grown on (111)-oriented Si substrate is epitaxially oriented.

The transformation kinetics of the Pd_2Si phase has been investigated in our laboratory by MeV $^4He^+$ ion backscattering in a previous investigation (7). The formation rate of the Pd_2Si layer on Si wafers in the temperature range of 200°-275°C was found to be diffusion limited, and independent of the substrate orientation, *i.e.*, the same transformation kinetics were observed on (111), (100), and (110) oriented Si single crystal substrates as well as on amorphous (evaporated Si on single crystal substrate) Si substrates. The growth kinetics can be described by an Arrhenius type of equation and the activation energy for growth was found to be 1.5 ± 0.1 eV. A lower activation energy of 1.27 eV was reported by Hutchins and Shepela (6) for the growth of Pd_2Si on (111) Si substrates using an optical technique. This discrepancy might be due to the sensitivity of different analytical techniques. They also observed a $t^{1/2}$ time dependence for the Pd_2Si growth rate. They further suggested that the growth kinetics should be the same for Pd_2Si formed on (100), (110), and (111) oriented Si substrates since Pd_2Si grows with a [001] fiber textures on these substrates.

It is our objective in the present work to investigate the structure, such as grain size and preferred orientation, of the as-deposited Pd films and the silicide films formed on Si substrates of various orientations, and their possible relationship with the transformation kinetics of the Pd_2Si phase.

Experimental

Samples were prepared by e-gun evaporation of 500-3000Å Pd films onto (100) and (111) Si wafers and on Si wafers with approximately 3000Å thick evaporated Si (amorphous) films. The evaporation rate was about 10 Å/sec, and the pressure during evaporation was $\sim 5 \times 10^{-7}$ Torr. The temperature of the substrates at the end of the evaporation was estimated to be about 100°C. Pd films were evaporated on all three types of substrates at the same time. Prior to evaporation, the Si substrates were treated in HF followed by rinsing in H_2O.

Heat-treatments of the samples at 260° and 550°C for 30-60 min were performed in a vacuum furnace operated at pressures between 1 to 5×10^{-5} Torr. After the vacuum annealing, the compositions of the reacted samples were examined by backscattering and the phase structure was identified using the x-ray thin film camera technique.

Transmission electron microscopy was used to examine the structure of the Pd and the Pd_2Si films. The Pd films were stripped off from the Si substrate in a HF solution and the Pd_2Si samples were prepared by chemically etching away the Si substrate in a water-amine solution (8).

Results

Amorphous Si substrate.—The as-deposited Pd film (~500Å) on amorphous Si substrate had grains ranging from 50 to 150Å in size (Fig. 1). There were apparently some very fine precipitates of Pd_2Si distributed throughout the film. It has been suggested (6) that Pd_2Si was formed by a rapid nondiffusion controlled process during the deposition of the Pd films, therefore, the actual thickness of the Pd films may have been thinner than the expected 500Å. The diffraction pattern for the as-deposited Pd films shows a random orientation (Fig. 2). When the Pd/Si (amorphous) composite structure was heat-treated for 30 min at 260°C, a Pd_2Si phase with grains of 50 to 150Å in size was formed (Fig. 3). Selective area diffraction (SAD, aperture size ~25 μm) experiments indicated

Key words: silicide formation, electron microscopy, diffusion.

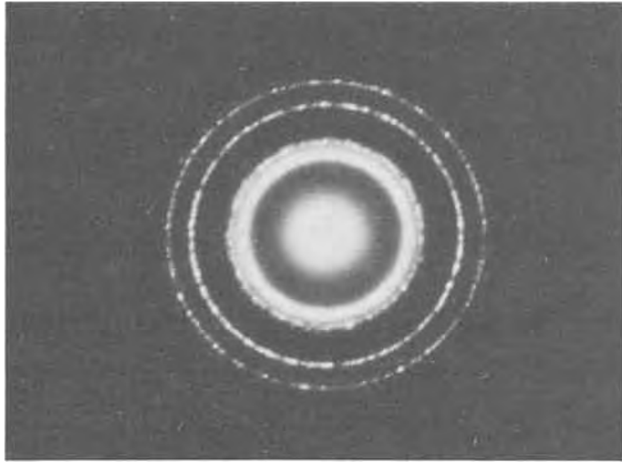

Fig. 2. Diffraction pattern of the as-deposited Pd film on amorphous substrate.

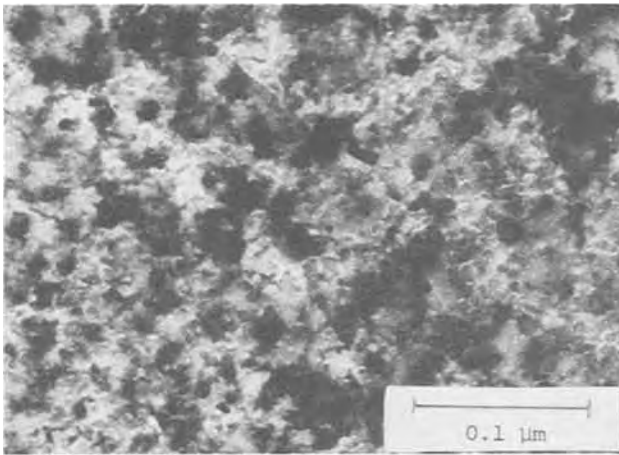

Fig. 3. Transmission electron micrograph of Pd_2Si formed on amorphous Si substrate at 260°C.

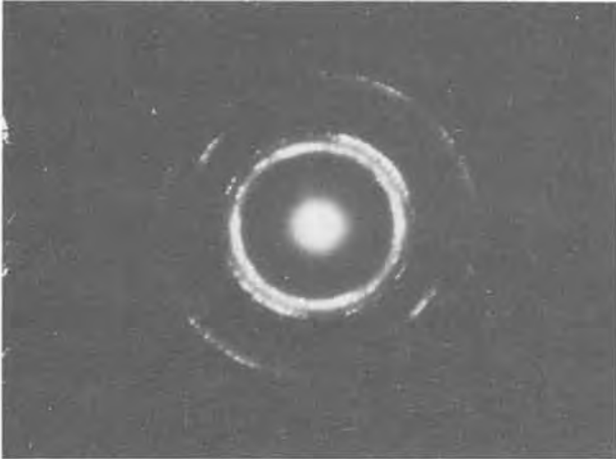

Fig. 4. Diffraction pattern of as-deposited Pd film on (100) Si substrate.

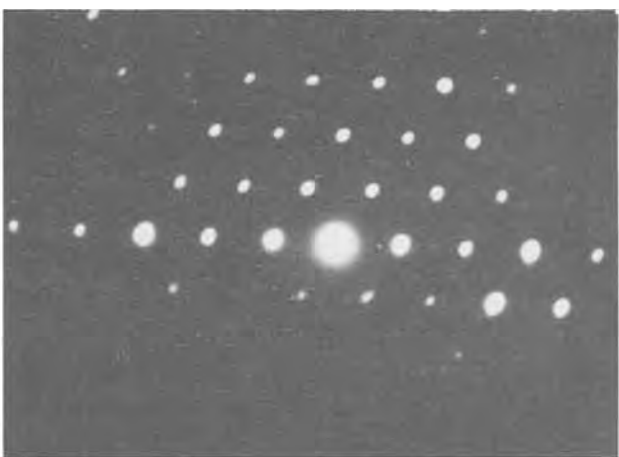

Fig. 5. Diffraction pattern of Pd_2Si formed on (100) Si substrate at 550°C.

that the basal planes of these grains were preferentially oriented parallel to the substrate surface, in agreement with reported observations (6, 7). No specimens were heat-treated at 550°C to avoid possible crystallization of the amorphous Si film.

(100) Si substrate.—The as-deposited Pd films on (100) Si substrates had grains ranging from 100 to 400Å in size. It is interesting to note that the SAD pattern (Fig. 4) indicated a fiber texture (weak 220 reflection) for the as-deposited Pd films, while a random SAD pattern for Pd films deposited on amorphous Si substrates was observed (see Fig. 2 and 4). When the samples were heat-treated at 260°C, polycrystalline Pd_2Si with grains ranging between 200 and 500Å was formed. Heat-treating the samples at 550°C resulted in the formation of the Pd_2Si phase with grains ranging from 100 to 300Å. The reasons for this reduction in grain size when the heat-treatment temperatures were increased from 260° to 550°C are not clear at present. In localized areas of the Pd_2Si layer formed at 550°C single crystal diffraction patterns with the basal plane parallel to the substrate surface were observed (Fig. 5). This can be possibly related to the crystallographic structure of the oriented as-deposited Pd films deposited on (100) Si substrates. Voids were observed in the Pd_2Si films formed both at 260° and 550°C.

(111) Si substrates.—The as-deposited Pd films had grains ranging between 50 and 200Å. The SAD pattern showed random orientation of the Pd films. The Pd_2Si phase formed at 260°C was generally epitaxial and the grains had mosaic block structure (9) with block size ranging between 200 and 500Å (Fig. 6). No voids were observable at 80,000×. The Pd_2Si phase formed at 550°C was also generally epitaxial with 200-500Å mosaic blocks, however, small voids in the films were observed.

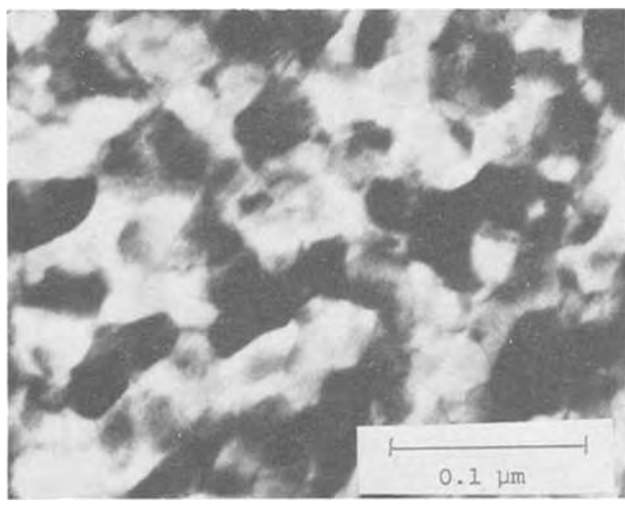

Fig. 6. Transmission electron micrograph of Pd_2Si formed on (111) Si substrate at 260°C.

Discussion and Summary

Judging from the experimental observations in the present study and those obtained from the previous backscattering investigation (7), we propose that the lattice diffusion of materials through the Pd_2Si layer is the rate-controlling step for Pd_2Si formation. The reasons are as follows: It was observed that the grain sizes of the as-deposited Pd films were different for various substrates. The grain size of Pd_2Si formed on amorphous Si at 260°C (50-150Å) was smaller than the grain size or the mosaic block size (200-500Å) of Pd_2Si formed on (100) and (111) substrates, respectively. This observation in conjunction with the previously reported MeV $^4He^+$ backscattering results that the transformation kinetics of the Pd_2Si phase was independent of the substrate orientations (7) seem to suggest that the grain size of the Pd films and the grain size or the grain structure (large angle grain boundaries *vs.* small angle mosaic block boundaries) of Pd_2Si do not play a role in the growth kinetics of the Pd_2Si phase. At 550°C, the transformation kinetics are expected to follow the same Arrhenius equation that governs the growth rate of Pd_2Si at lower temperatures for all substrates investigated. The grain size of Pd_2Si formed at 550°C was found to be different on different substrates in the present work, again the results suggest the independence of growth rate of Pd_2Si on grain size or grain structure.

If the transformation process is governed by the diffusion of Si along the grain boundaries of Pd_2Si and/or Pd and subsequent diffusion and transformation in the Pd grains, then the transition front between the Pd_2Si and Pd layers will not be uniform and would cause a gradual slope in the backscattering spectra. The fact that sharp edges were observed in the spectra [see Fig. 2 in Ref. (7)] indicating a sharp and uniform front for the Pd_2Si layer seems to rule out the grain boundary diffusion process. Buckley and Moss (3) suggested that at least in the case of growth of Pd_2Si on (111) Si substrates, the controlling step is the diffusion of Si atoms through the Pd_2Si lattice. Our observations on grain size and the backscattering data reported earlier (7) are in agreement with the hypothesis that lattice diffusion of materials through the Pd_2Si layer is apparently the rate-controlling step. Experiments to determine the moving species are now in progress.

Acknowledgment

The authors would like to express their gratitude to Dr. J. W. Mayer for his encouragement during the course of this work, to Mr. Henri Arnal for his assistance in electron microscopy, and to the Air Force Cambridge Research Laboratory for their financial sponsorship.

Polymer-Bonded Negative Electrodes for Lead-Acid Batteries

J. L. Weininger and F. W. Secor

General Electric Company, Corporate Research and Development, Schenectady, New York 12301

ABSTRACT

Negative lead electrodes were pasted and bonded to lead alloy substrates with activated carbon and a polymer. Scanning electron microscopy was used to follow structural changes of the polymer-bonded electrodes during cycle life. With lead-calcium alloy substrates the electrode performance of the polymer-bonded electrode was superior to conventionally pasted electrodes with respect to cycle life, charge acceptance, and lack of gassing. Different substrates of the same Pb-0.06%Ca-1%Sn alloy gave similar results.

It is common practice to blend polymers with active materials of an electrode in order to improve physical and electrochemical properties of the electrode. In the patent literature there are many descriptions of electrode structures incorporating a variety of polymers. This is exemplified by the work of Duddy (1) who was one of the first to introduce polyethylene, polyvinyl chloride, and their copolymers as porous carriers of electrode materials. Other examples of processes which are based on the principle of polymer bonding are (*a*) bonding fuel cell electrodes with polytetrafluoroethylene to render them hydrophobic and to bind the catalyst (2); (*b*) compounding metal oxides with polymers to produce conductive coatings (3); and (*c*) forming rechargeable electrodes with a polymeric binder (4).

This report describes polymer bonding the active material of the negative lead electrode. The method improves the cycle life, charge acceptance, and lack of gassing of the lead-acid cell over that of commercially available ones. Scanning electron microscopy (SEM) was used to follow structural changes of the polymer-bonded electrodes during cycle life. This also supplied corroborating evidence for the dissolution-precipitation mechanism of the electrode reaction (5).

Method of Polymer Bonding

For use in the lead-acid cell, a solution of neoprene in toluene was mixed with carbon black and Grenox battery grade PbO, a product of NL Industries. The mixture was suitable for pasting battery grids and after evaporation of the solvent no further curing of the electrode was needed.

Several paste formulations were developed for the negative electrode. The two preferred compositions are given in Table I.

Composition 1 was used for the series of experiments described below. Sodium benzoate was added to composition 2 for making a more porous electrode structure by removing the benzoate in a further leaching step in water. This more porous structure was believed to give greater flexibility and larger high-rate discharge capability. Preliminary tests showed even a longer life for a composition 2 electrode. Nevertheless, composition 1 was chosen for the present experiments, because the primary objective of this work was to prove out the efficacy of polymer bonding without the introduction of another component.

Key words: lead-acid battery, lead electrode structure, lead-calcium alloy, polymer bonding, scanning electron microscopy.

Experimental

The negative electrodes had an area of 5 × 5 cm, 0.3 cm thickness, and a theoretical capacity of 3.0 A-hr. They were placed in bags of Daramic (W. R. Grace Company) porous polyethylene separators and were sandwiched between two conventional, pasted, positive electrodes (Type B-80, Atlantic Battery Company). The positive electrodes had a combined higher capacity (9.8 A-hr) than the negative electrode.

Table II lists the structure and function of the six negative electrodes which were life-tested.

The two control electrodes were pasted and cured in the conventional manner; the polymer-bonded electrodes were prepared as described above. Formation of the plates was performed at charge rates of C/20 for 24 hr in 1.05 sp gr acid, followed by C/24 for 20 hr in 1.28 sp gr acid, except that positive and negative electrodes had to be formed separately against corresponding counterelectrodes because of the above-indicated imbalance of their capacities.

The cells were cycled at constant current to cut-off voltages of 2.70V on charge and 1.75V on discharge. Cycling was performed manually for the first two cycles at about a 6-hr rate (see Table III); thereafter cycling was automatic at the 4-hr rate.

Table III indicates that the normal controls had a slightly higher initial utilization and capacity compared to the polymer-bonded electrodes. These first two cycles also established the normal capacity for determining cycle life.

Table I. Composition of polymer-bonded negative electrodes

Decrease in capacity (%)	5	5	5	5	1	2

Starting with cycle 3, at the higher C/4 rate, the negative electrodes had a steady 1.16-1.20 A-hr discharge capacity for many cycles. Their behavior over the total cycle life is shown in Fig. 1. The curves in this figure are drawn through experimental points, ignoring only a few excursions, which were clearly due to instrumental error, *e.g.*, a premature cut-off of discharge due to electronic noise or cycles in which the positive electrodes became limiting.

In spite of the initial mismatch of capacities the positive electrodes had a much shorter cycle life so that they had to be replaced twice, or even three times in cells lasting over 200 cycles. In all cases, Fig. 1 shows the cell performance in which the negative electrode limited the discharge capacity.

The behavior of individual cells is described below.

Cell PN-C1 had a discharge capacity of 1.16 A-hr to cycle 50 and a decrease to 0.6 A-hr at cycle 155.

Cell PN-C2 maintained a discharge capacity of 1.18 A-hr only for the first 20 cycles, then dropped rapidly to 0.6 A-hr at cycle 90. For both these control cells the efficiency, *i.e.*, the percentage of discharge capacity with respect to charge, was in the 95-98% range when the cells had a steady discharge. It was 80% or less during the decline of cell performance.

Cell PN-12 held steady at 1.18 A-hr until cycle 150, then declined to 0.6 A-hr at cycle 183. Efficiency was in the range 90-100% even during the period of decline.

Cell PN-13 had a discharge capacity of 1.19 A-hr to cycle 185 with only a small decline to 1.11 A-hr at cycle 257 (end of test). Efficiency was 90-100% throughout cycle life; it was 100% during the cycle period 230-257.

Cell PN-14 was comparable in cycle life to PN-12, having a discharge capacity of 1.16 A-hr to cycle 110, followed by a slow decrease to 0.6 A-hr at cycle 191. Efficiency of this cell was nearly 100% to cycle 170 and between 85 and 95% for the last 20 cycles.

The discharge capacity of cell PN-15 was unchanged at 1.16 A-hr for the duration of the test to cycle 233. Efficiency was 95-100%.

Scanning Electron Microscopy

Electrode PN-12 was chosen for monitoring the structure of the polymer-bonded electrode during cycle life. Small samples were taken from a location near the edge of the electrode, washed in distilled water, and mounted for examination in the scanning electron microscope (SEM). Micrographs were obtained during cycles 5, 29, 73, and at the end of the life test after cycle 204.

Some of these micrographs have been published in a report (5) that related the morphology of the electrode to the solution-precipitation mechanism of the electrode reactions of the lead acid cell. Other micrographs are included in the present report. For example, Fig. 2 and 3 are the previously shown views of the electrode at the end of the 73rd charge (5). Figure 4 represents the same general location of the electrode after the discharge of cycle 73. The flowerlike crystal structures as well as the underlying bandlike crystals have been converted into finely divided small crystalline particles, interspersed between large rhombohedral crystals. This appearance was typical for both the edge of the electrode and its interior. It signifies that the crystalline structures of Fig. 2 and 3 represent active lead in the charged condition. The rhombohedral crystals after discharge are $PbSO_4$ crystals which were at least partially passivated.

The remaining SEM's, Fig. 5-11, were taken of different electrodes at the end of the cycle life of the cells. This was defined as the time when the cell failed to accept a minimum charge. Consequently, the electrodes were removed at the end of a charge cycle but this does not imply that the particular areas examined by SEM were of charged active material. At least

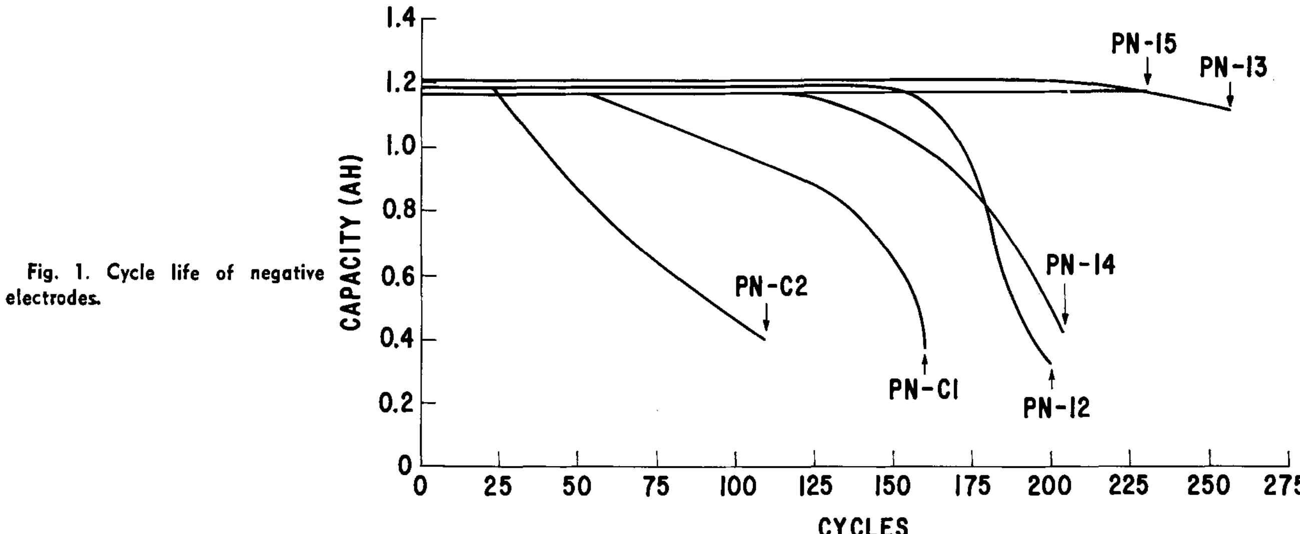

Fig. 1. Cycle life of negative electrodes.

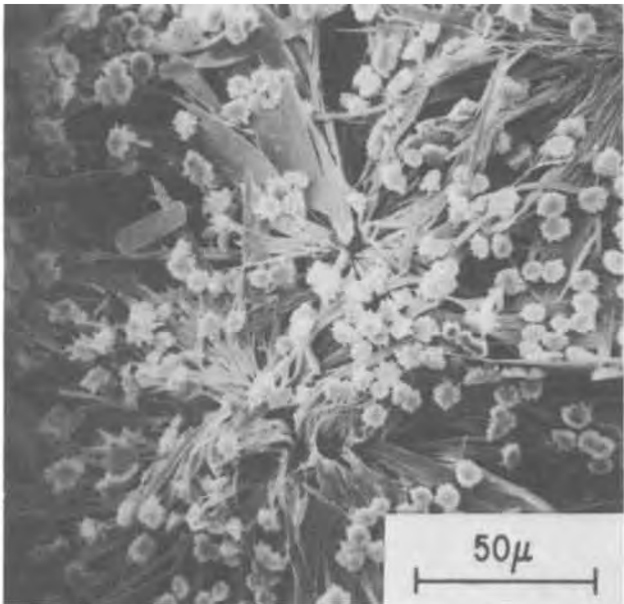

Fig. 2. Negative electrode PN-12 at end of charge 73. Magnification 500X.

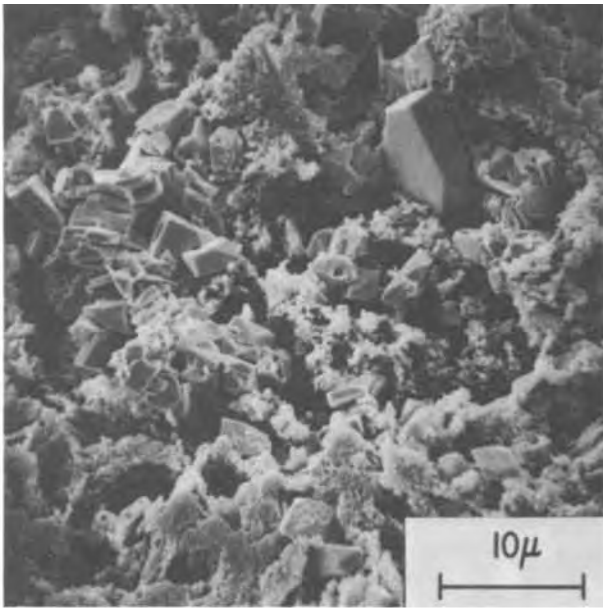

Fig. 4. Negative electrode PN-12 at end of discharge 73. Magnification 2000X.

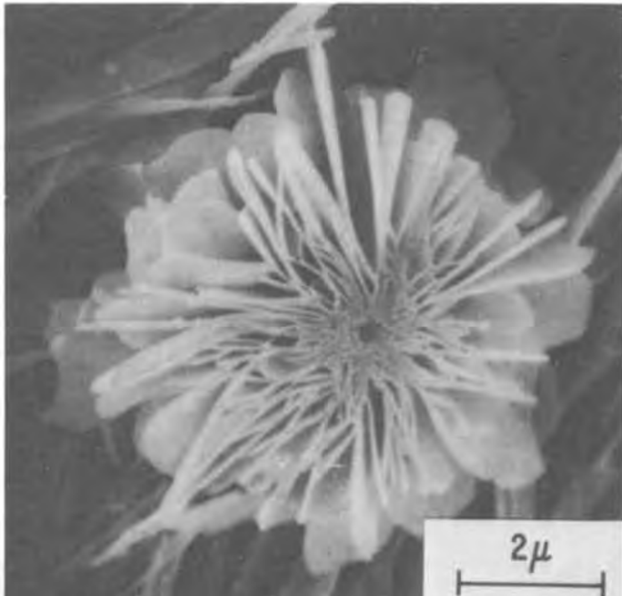

Fig. 3. Negative electrode PN-12 at end of charge 73. Magnification 5000X.

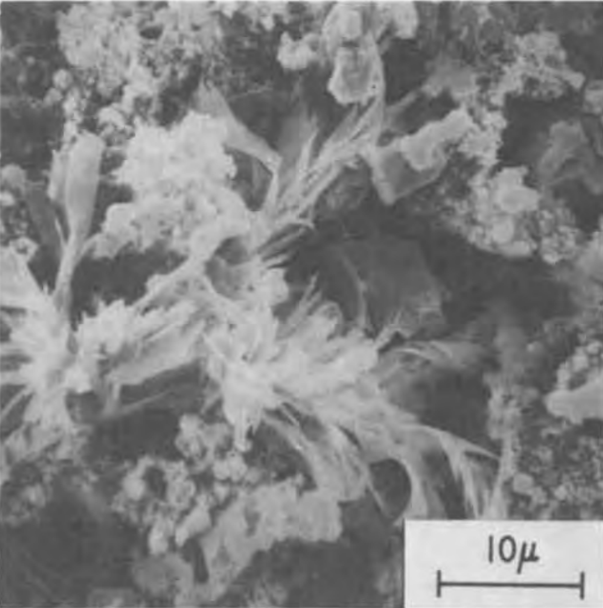

Fig. 5. Surface of negative electrode PN-12 at end of cycle 204. Magnification 2000X.

some of the crystals appear to be large passivating $PbSO_4$ crystals.

Figures 5, 6, and 7 represent the electrode at the end of cycle life (cycle 204) when the discharge capacity had dropped below 0.6 A-hr. Figures 5 and 6 are views of the surface of electrode PN-12. In one case (Fig. 5) there are still needlelike crystals, resembling the active material in Fig. 2 and 3, but in Fig. 6 there are large passivated crystals. They result from the growing together of smaller ones. Such crystals, some of them larger than 15μ, were only observed at the electrode surface. Figure 7 is typical of the structure and crystal size in the interior of the electrode after cycle 204.

By comparison, the interior of the negative electrode at the end of cycle life of the control cell PN-C1 is shown in Fig. 8. It has an entire crystal field of rhombohedral crystals, characteristic of spongy electrodes without any active material [see also Fig. 9 of Ref. (5) for a SEM of the surface of this electrode].

Although the presence and effect of the polymer in the electrode structure is implicit in the above discussion, the polymer phase cannot be seen in the micrographs. One can see the polymer phase in a different polymer-bonded electrode for which SEM's are shown in Fig. 9, 10, and 11. Samples for these micrographs were taken from a negative electrode with the same polymer-bonding formulation as above, but the electrode had larger external dimensions and was one of two negative electrodes used in a 10 A-hr cell. Figures 9-11 represent this electrode at the end of the cell's cycle life (68 cycles) which was limited by the positive and not by these negative electrodes. Figure 9 is a top view of the polymer-bonded electrode. Crystalline shapes appear to be coated and held together by a porous polymer. Figure 10 is taken from the same general area as Fig. 9. On further enlargement of Fig. 10, the crystalline structure near the center of the SEM appears in Fig. 11 as a hollow, three-dimensional, leaf-

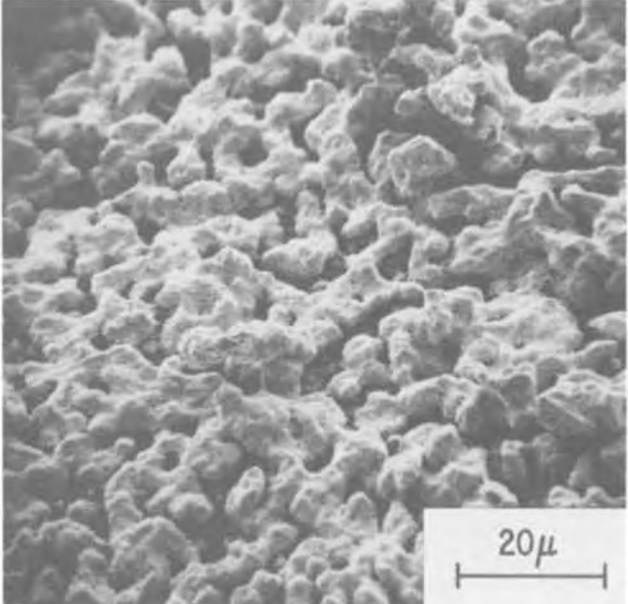

Fig. 9. Polymer-bonded electrode. Magnification 1000X

like structure. From this series of SEM's the large porosity, crystalline nature of the active material and the presence of polymer are apparent.

Discussion

Tests have shown that polymer-bonded electrodes have a life of 200 or more cycles in a 4-hr rate, 100% depth of discharge cycling regime. Under the same conditions, control cells having pasted electrodes had a shorter cycle life. Taking 1.2 A-hr as the nominal capacity of the electrodes (equivalent to 40% utilization) and considering a 50% drop in capacity as the end of cycle life, Table IV gives the life-times of the tested electrodes.

Comparison of polymer-bonded electrodes with each other is less certain. Although PN-12 and PN-14 had a shorter life than PN-13 and PN-15, it may have been caused by instrumental difficulties or by the deleterious influence of the positive electrodes. The SEM sampling procedure for PN-12 may also have shortened the life of that electrode.

The close to 100% efficiency of all the polymer-bonded electrodes indicated that charge acceptance limited the discharge capacity. Inspection of the electrodes at the end of cycle life showed that all of the polymer-bonded electrodes were in good condition and had not changed in appearance from the start of the life test. Nor was any of the active material sloughed-

Table IV. Cycle life of negative electrodes

Cycles	155	90	183	>257*	191	>233*

* End of cycle life test; electrodes still functioning satisfactorily.

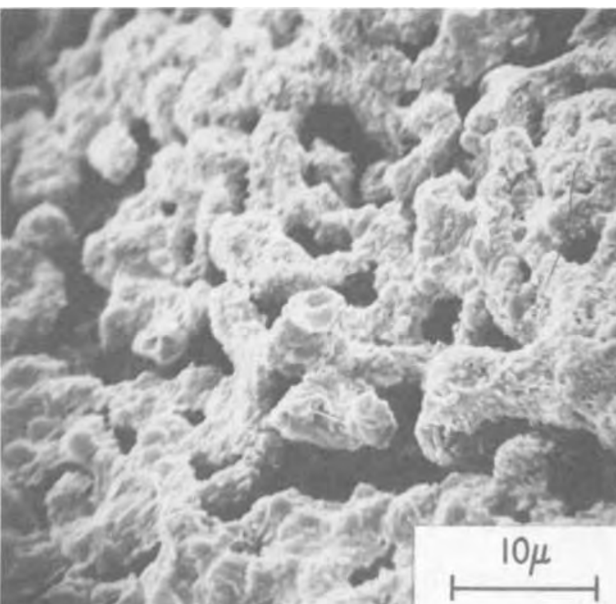

Fig. 10. Polymer-bonded electrode. Magnification 2000X

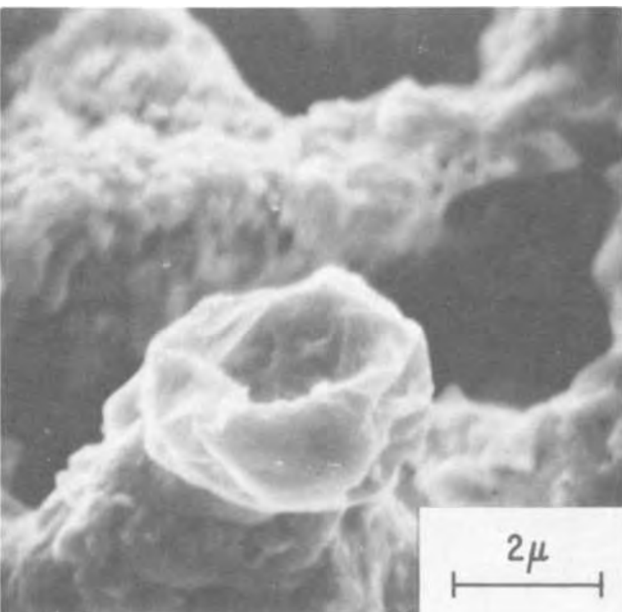

Fig. 11. Enlargement of Fig. 10. Magnification 10,000X

off into the separator bag. By contrast, the control electrodes had badly corroded grids, were spongy and very porous, had swelled to 3 or 4 times their original thickness, and a considerable amount of sloughed-off material was found in their separator bags.

The change of efficiency as the electrodes deteriorated also showed a different mechanism of failure of the control cells *vs.* those containing polymer-bonded electrodes. In the control cells the efficiency changed from 90-100% to less than 80% as the electrodes deteriorated. This indicated that the accepted charge could no longer be maintained or that it was partly lost to the corrosion of the grid, to gas evolution, or to passivation of previously active material. This was not the case with polymer-bonded electrodes. Where discharge capacity dropped off (cells PN-12 and PN-14) the efficiency of the cells still remained higher than 90%. This supports the above suggestion that in these cases charge acceptance may have been limited by other causes than by the negative electrodes and confirms the post-mortem observation of the serviceable appearance of electrodes PN-12 and PN-14.

The consistently high value of efficiency for the polymer-bonded electrodes also showed that there was little loss of charge due to gassing at the negative electrode. This is important because the addition of carbon black to the electrode mix required a high hydrogen overvoltage at carbon as well as at the Pb/Ca/Sn alloy. This is now confirmed.

In summary, it is concluded that polymer-bonded electrodes were superior to conventional (control) electrodes with respect to cycle life, charge acceptance, and lack of gassing. This has also been consistently the case in other tests in which pasted and polymer-bonded electrodes were studied under comparable conditions. Comparison of the effect of different substrates based on the St. Joe RDP-16 alloy is uncertain. The Dystex pattern in the expanded grid of PN-15 appeared to give best results but the difference to other patterns was too marginal to draw any conclusions concerning the most favorable substrate structure. In fact, a nonantimonial molded grid, possibly of the same alloy, would be equally effective in combination with polymer bonding the active materials by the present method.

Acknowledgments

The authors greatly appreciate discussions of polymer bonding with J. H. Lupinski and the scanning electron microscopy performed by M. D. McConnell and W. T. Hatfield. Thanks are due also to J. Young of St. Joe Minerals Company for making available the expanded grids of the Pb/Ca/Sn alloy.

Thermal Decomposition Mechanism of Formed and Cycled Lead Dioxide Electrodes and Its Relationship to Capacity Loss and Battery Failure

S. M. Caulder*

International Lead Zinc Research Organization Research Associate at the Naval Research Laboratory, Washington, D.C. 20375

and A. C. Simon*

Electrochemistry Branch, Naval Research Laboratory, Washington, D. C. 20375

ABSTRACT

The structural changes accompanying capacity loss in the $PbO_2/PbSO_4$ electrode were followed using differential thermal analysis. The thermal decomposition mechanism of formed plates was found to differ, depending on the method of manufacture. All cycled plates, however, gave the same decomposition mechanism after a few cycles. The major changes in the DTA curves, as the positive electrode was cycled to failure, was the gradual disappearance of the exothermic peak at 200°C and the endothermic peak at 358°C. It is believed that these peaks are associated with an electrochemically active amorphous form of PbO_2. As the electrochemically active PbO_2 is cycled to failure it is converted to an electrochemically inactive form of PbO_2. This latter form of PbO_2 gives DTA results similar to those obtained on reagent PbO_2. The continual conversion of electrochemically active PbO_2 to the electrochemically inactive PbO_2 is one of the major factors that accounts for the loss in battery capacity and ultimate failure.

The structure of the lead dioxide electrode after formation and cycling has been studied by optical (1) and electron microscopy (2, 3), neutron and x-ray diffraction (4), nuclear magnetic resonance (5), and by thermal analysis (6). The thermal analysis study was limited to one type of formed electrode and to an electrode with only a few cycles. Previous investigations (1-3, 7) have shown that parameters such as grid alloy, oxide blend, and curing process affect the microstructure of formed lead dioxide electrodes and subsequently, the initial part of the life cycle.

The thermal decomposition of active material obtained from the $PbO_2/PbSO_4$ electrode involves the nucleation of PbO_x compounds on the PbO_2 active material particles. These nucleation sites may be the same as the nucleation sites involved during the electrochemical oxidation and reduction of the $PbO_2/PbSO_4$ electrode. No information is available regarding the PbO_2 thermal decomposition mechanism of formed electrodes with respect to their method of preparation or microstructure. Information is also lacking as to whether the mechanism is altered along with the structural changes the $PbO_2/PbSO_4$ electrode undergoes during subsequent reduction and reoxidation.

The purpose of this investigation was to determine whether the method of electrode preparation and subsequent cycling would influence the thermal characteristics of the PbO_2 active material and, if so, how the structural changes of the active material are related to battery life and failure mechanism. The thermal results of this paper were correlated with results obtained from optical microscopy, mass spectrometry, x-ray diffraction, and nuclear magnetic resonance.

Experimental Method

The four series of commercial electrodes used in this investigation were selected on the basis of their similarity in cycling routines, similarity in points at which oxidized and reduced samples were removed from cycling, and the dissimilarity in appearance of the as-formed active material, as observed by optical microscopy. The last criterion was used since it was anticipated that these electrodes would give different microstructures upon cycling. The plates that were used were obtained from four different manufacturers, two in the United States and two overseas. Two of the series were prepared in the laboratory of the concerned companies, while the others were taken from production and routinely plant cycled. The active material of all plates were pasted on Pb-Sb alloy grids.

The DTA, TGA, NMR, x-ray diffraction, and mass spectroscopy samples were obtained by punching out sections of positive active material and then grinding with a mortar and pestle. Additional sample sections were cut from the electrodes, impregnated with a catalyzed polyester resin, and examined microscopically (1).

Reference samples of α-PbO_2 were prepared chemically and electrochemically using the methods of Angstadt (8) and Bode (9). Samples of reagent β-PbO_2 were obtained from various chemical manufacturers.

The thermal decomposition equipment utilized in this investigation was a du Pont Model 900 differential thermal analyzer and a Model 950 thermogravimetric analyzer. The DTA samples (25 mg) were placed in 4 mm quartz sample holders. No diluent was added to the samples. A thermally inert reference sample, Al_2O_3, was placed in two adjacent quartz holders. Chromel-Alumel thermocouples were placed in the center of the sample and reference materials. Two of the thermocouples measured the temperature difference (Δt) between sample and reference, while the third measured the temperature of the heating block. The heating block assembly was then covered by a thermal shield. The entire sample cell assembly was enclosed in a bell jar. Careful control of parameters such as sample weight, particle size, sample assembly geometry, and heating rate was maintained.

Prior to running the PbO_2 samples the DTA apparatus was calibrated by measuring the melting and freezing points of pure samples of AgCl, Ag_2SO_4, and

Key words: differential thermal analysis, lead dioxide electrode, lead dioxide, electrochemically inactive PbO_2, capacity loss, battery failure.

Pb. A heating rate of 15°C min^{-1} in stationary air, using 4 mm tubes, was used on all subsequent runs. Isothermal decomposition products were obtained by heating PbO_2 samples in aluminum blocks at 225°, 315°, and 355°C for varying periods of time.

X-ray diffraction patterns were obtained using a Norelco diffractometer equipped with a scintillation counter. Nickel-filtered copper radiation was used. The decomposition products were identified by their diffraction patterns.

In the thermogravimetric experiments a sample of 5-25 mg was placed in a platinum weighing boat. The boat was attached to the balance arm incorporated within the instrument. The sample was heated at 15°C min^{-1} in a nitrogen atmosphere. A Chromel-Alumel thermocouple approximately 4 mm above the sample measured the temperature of the environment.

Thermal Analysis Results

Basis of the problem.—Lead dioxide contains sufficient adsorbed water, as well as lattice water and/or hydroxyl ions, to provide for a Pb:O ratio of 1:2. Upon heating, PbO_2 loses O_2 and H_2O down to a Pb:O ratio of about 1.80 before experiencing a phase change. Between $PbO_{1.90}$ and Pb_3O_4 a nearly continuous series of nonstoichiometric lead oxides with decreasing oxygen content have been reported (10-14).

Recent investigations (15-17) on the thermal properties of the lead-oxygen system have shown that only two distinct oxide phases exist between $PbO_{1.90}$ and Pb_3O_4. These intermediate oxides, designated α-PbO_x and β-PbO_x by Byström (10), have very similar crystal structures. The crystallographic system to which these oxides belong is still subject to controversy. The Pb:O ratio over which α-PbO_x exists is generally accepted as 1.60-1.51 and that for β-PbO_x as 1.50-1.44. These oxides are based on an oxygen deficient metal fluoride type structure containing both divalent and tetravalent lead ions. It is the reordering between the divalent and tetravalent lead ions and the oxygen lattice vacancies that account for these intermediate oxides. This ordering of the lattice with the evolution of O_2 and H_2O is accompanied by an enthalpy change, as shown on the DTA curves. Additional evidence for this reordering is obtained from x-ray diffraction patterns which show a shifting of major lines, accompanied by intensity changes. Thermal gravimetric analysis also shows weight plateaus for these intermediate oxides.

Certain experimental parameters must be carefully controlled to obtain reproducible thermal results, since maximum peak temperatures are not solely dependent on the decomposition reaction. Careful control of parameters such as sample weight, particle size, sample assembly geometry, and heating rate are all important. The effect of heating rate and sample size, for example, have been summarized in Table I. The DTA results were obtained with chemically prepared PbO_2.

Thermal analysis of reference samples of α- and β-PbO_2.—The positive electrodes used in these experiments contained both α- and β-PbO_2 so that it was necessary to subject reference samples of these two allomorphs to thermal analysis in order to obtain reference DTA curves. The DTA curves, x-ray analysis, and mass spectroscopy results, obtained from the reference samples, were used to interpret the DTA results obtained from the positive plate active material.

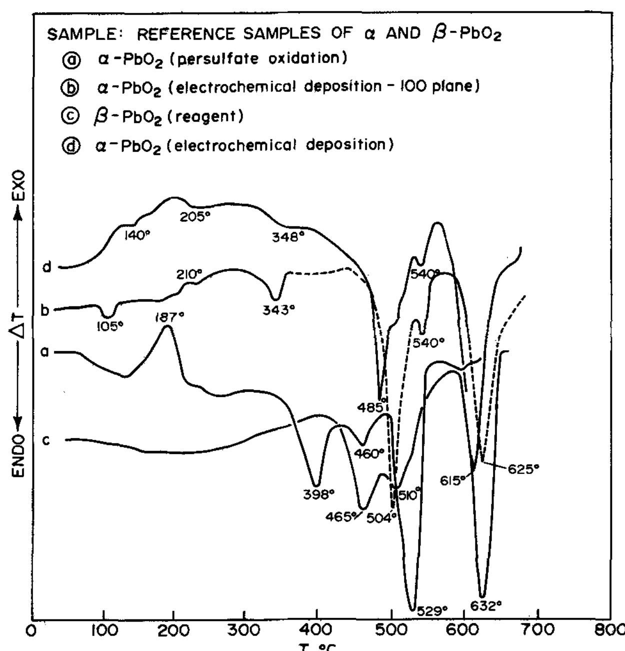

Fig. 1. DTA curves of reference samples of α- and β-PbO_2. Curve a, α-PbO_2 prepared by ammonium persulfate oxidation of lead acetate; curve b, α-PbO_2 prepared by electrochemical deposition (preferred orientation); curve c, General Chemical Corporation reagent β-PbO_2; curve d, α-PbO_2 prepared by electrochemical deposition.

The DTA curves of the α-PbO_2 prepared by ammonium persulfate oxidation of ammoniacal lead acetate (8) and by electrochemical oxidation of an alkaline solution of $Pb(NO_3)_2$ (9) are given in Fig. 1. Also shown is the curve for General Chemicals reagent β-PbO_2. The x-ray analysis of the decomposition reaction intermediates, α-PbO_x and β-PbO_x, are summarized below in Table II and III. These results are compared with those of Bystrom (10), Weiss (12), and Angstadt (8).

The chemically prepared α-PbO_2 gave a broad exothermic peak at 187°C and a series of endothermic peaks at 398°, 460°, 529°, and 595°C. These peaks were associated with the following decomposition reactions

$$\alpha\text{-}PbO_2[OH] \text{ disordered} \xrightarrow{187°} \alpha\text{-}PbO_2 \text{ ordered}$$
$$\alpha\text{-}PbO_2 \xrightarrow{398°} \alpha\text{-}PbO_x$$
$$\alpha\text{-}PbO_x \xrightarrow{460°} \beta\text{-}PbO_x + Pb_3O_4$$
$$\beta\text{-}PbO_x + Pb_3O_4 \xrightarrow{529°} PbO\text{(tetragonal)}$$
$$PbO\text{(tetragonal)} \xrightarrow{595°} PbO\text{(orthorhombic)}$$

Angstadt *et al.* (8) in their thermal studies on α-PbO_2 prepared by persulfate oxidation did not observe a second intermediate compound (β-PbO_x). However, they employed a different experimental technique. Gillibrand and Halliwell, using DTA, obtained curves similar in shape to the one shown in Fig. 1, except

they did not observe an exothermic peak at 187°C. Kordes (4), using x-ray and neutron diffraction, found this α-PbO_2 compound to be between 40-60% crystalline when compared to a reference PbO_2 standard. His DTA results on this material are in excellent agreement with ours. It was concluded from our DTA-TGA and x-ray diffraction results that due to the noncrystallinity of the α-PbO_2 it decomposed along two simultaneous reaction paths. It is believed that the noncrystalline material decomposes to Pb_3O_4 without going through the α- β-PbO_x intermediates. Low temperature (225°-250°) isothermal studies on this compound as well as other α- and β-PbO_2 compounds have shown that a small amount of Pb_3O_4 appears after extended heating periods, along with the original ordered PbO_2 compound.

Electrochemical oxidation of an alkaline solution of $Pb(NO_3)_2$ produced two products. The initial compound deposited was a hard black form of α-PbO_2 with preferred orientation of the (100) planes parallel to the surface. The DTA curve for this product is shown in Fig. 1. The second product, which could be scraped from the surface of the electrode, was a softer, less crystalline, brownish form of α-PbO_2 with no preferred orientation. Its DTA curve is also given in Fig. 1. The DTA curve (Fig. 1) of a predominantly black sample gave endothermic peaks at 105°, 343°, 504°, 540°, and 625° and a small exothermic peak at 210°C. These peaks were associated with the following reactions

$$\alpha\text{-}PbO_2[OH]\cdot H_2O \xrightarrow{105^\circ} \alpha\text{-}PbO_2[OH]$$

$$\alpha\text{-}PbO_2[OH] \xrightarrow{210^\circ} \alpha\text{-}PbO_2$$

$$\alpha\text{-}PbO_2 \xrightarrow[\text{isothermal}]{343^\circ} \alpha\text{-}PbO_x$$

$$\alpha\text{-}PbO_x \xrightarrow[\text{quenched}]{504^\circ} \beta\text{-}PbO_x + Pb_3O_4$$

$$\beta\text{-}PbO_x \xrightarrow[\text{quenched}]{540^\circ} Pb_3O_4$$

$$Pb_3O_4 \xrightarrow{625^\circ} PbO\,(\text{tetragonal} + \text{orthorhombic})$$

The reagent β-PbO_2 gave no exothermic peak in the vicinity of 200°C, thus indicating no structural reordering. X-ray analysis of samples that had been preheated gave identical patterns to those not heated. The following mechanism was found for the β-PbO_2

$$\beta\text{-}PbO_2 \xrightarrow[\text{quenched}]{465^\circ} \alpha\text{-}PbO_x + \text{residual } \beta\text{-}PbO_2$$

$$\alpha\text{-}PbO_x \xrightarrow[\text{quenched}]{510^\circ} \beta\,PbO_x + Pb_3O_4$$

$$\beta\text{-}PbO_x + Pb_3O_4 \xrightarrow{632^\circ} PbO \text{ tetragonal} + PbO \text{ orthorhombic}$$

Other preparations of β-PbO_2 gave results similar to those obtained by Gillibrand and Halliwell (6). In all cases it was found that α-PbO_2 decomposed before β-PbO_2.

Thermal analysis of formed electrodes.—The DTA curves obtained from the four formed electrodes are shown in Fig. 2. The x-ray diffraction analysis and maximum peak temperatures of the quenched products are given in Table IV.

The formed plate from each series gave its own characteristic DTA curve with respect to the number

of peaks, maximum peak temperature, and relative area under each peak. However, the over-all decomposition mechanism for three of the four electrodes (B, C, D) were the same. Series A deviates from the general decomposition mechanism in that no peak was observed for an α-PbO_x intermediate.

The exothermic peak exhibited by the formed active material between 180°-198°C was associated with the reordering of the α- and β-PbO_2 and the evolution of O_2, adsorbed and bound water. A portion of this water was incorporated in the anion lattice network as was evidenced by the results obtained by heating samples in conjunction with a mass spectrometer. The mass spectra taken under isothermal conditions at various temperatures and at 10^{-6} mm pressure showed that as the temperature increased from 27° to 180°C three water peak maxima occurred. The reordering of the PbO_2 lattice was evidenced by comparing the x-ray diffraction patterns of the original samples with those obtained before and after the exothermic peak. The original sample did not show the high 2θ angle K_α doublets for β-PbO_2. After heating to 180°-190°C these doublets were resolved, in addition to a shifting of the low 2θ angle values. A few additional lines also appeared for both α- and β-PbO_2. The mass spectra of the active material effluent also showed peaks for CO_2, occluded air (O_2 and N_2), and organic compounds. These organics were due to leaching out of organic materials from the separators and the migration of these expander products from the negative to the positive electrode.

X-ray studies on the active material held isothermally at 225° for periods of time ranging from 2 hr to several weeks gave x-ray patterns for ordered α- and β-PbO_2. Thermogravimetric experiments over the temperature range 100°-225°C showed a very small weight loss which could be attributed to absorbed water since mass spectrometry showed that every sample contained some. After prolonged heating, duration of up to several months, some of the samples gave lines for Pb_3O_4. However, three of the four electrodes had contained residual Pb_3O_4 in the formed electrode. Series D, which contained no Pb_3O_4 in the original oxide blend, also showed several Pb_3O_4 diffraction lines.

Continued heating of the electrode active material showed that each sample began to decompose endothermically at 290°C with the active material from series B, C, and D giving peak maxima at 440°, 434°, and 437°C, respectively. No temperature maxima in this range was observed for series A. X-ray analysis of quenched and isothermally held samples of series B, C, and D gave patterns for α-PbO_x. X-ray analysis of quenched and isothermally held samples of series A taken between 375°-440°C gave x-ray patterns for β-PbO_x. Isothermal runs on a number of A series samples held at 325° for varying periods of time gave a few samples whose x-ray patterns were close to α-PbO_x.

The third endothermic peak maximum was observed between 480°-487°C for all electrode samples. X-ray analysis showed the major product to be β-PbO_x.

The fourth endothermic peak maxima were between 515°-530°C and were associated with the decomposition of β-PbO_x to Pb_3O_4. The area under this peak varied considerably. Series B and D gave peaks which were more characteristic of pure samples of chemically prepared α- and β-PbO_2 while series A and C gave much smaller peaks thus indicating that simultaneous decomposition reactions were occurring. This was confirmed by x-ray diffraction analysis of samples quenched from the 480° endothermic peak.

The final endothermic peak between 610°-618°C was due to the decomposition of Pb_3O_4 to PbO tetragonal.

Thermal analysis of cycled lead dioxide electrodes.—Thermal analysis of the four samples of active material gave identical DTA curves. A representative DTA curve is shown in Fig. 3. The DTA curves obtained from these cycled electrodes were unlike any of the curves obtained from the active material of the formed electrodes. The main differences between the formed and cycled electrodes were that there was a general decrease in area under the first exothermic peak at 200°C; the occurrence of an endothermic peak at 358°C; and the appearance of one large endothermic peak at 465°C which replaced the two endothermic peaks observed with three of the formed electrodes (B, C, and D) between 434°-480°C.

The DTA curves of the oxidized material from cycled electrodes consisted of five peaks. An exothermic peak at approximately 200°C and four endothermic peaks at 358°, 465°, 536°, and 617°C. These peaks were associated with the following thermal decomposition reactions. This decomposition mechanism applies only to nonequilibrium runs with samples removed at each peak maximum. All of the cycled samples contained adsorbed water.

$$\alpha\text{-}PbO_2(OH) + \beta\text{-}PbO_2(OH) + \text{amorphous } PbO_2(OH) \xrightarrow{200^\circ} \alpha\text{-}PbO_2 \text{ (ordered)} + \beta\text{-}PbO_2 \text{ (ordered)} + \text{amorphous } PbO_2 \quad [1]$$

$$\alpha\text{-}PbO_2 + \beta\text{-}PbO_2 + \text{amorphous } PbO_2 \xrightarrow[\text{quenched}]{358^\circ} \alpha\text{-}PbO_2 + \beta\text{-}PbO_2 \quad [2]$$

Fig. 3. A representative DTA curve of a PbO_2 electrode cycled 100 SAE cycles.

$$\alpha\text{-}PbO_2 + \beta\text{-}PbO_2 \xrightarrow{465^\circ} \beta\text{-}PbO_x + \text{small amount } (\alpha\text{-}PbO_x, \beta\text{-}PbO_2, Pb_3O_4) \quad [3]$$

$$\beta\text{-}PbO_x \xrightarrow{536^\circ} Pb_3O_4 + \text{small amount PbO tetragonal} \quad [4]$$

$$Pb_3O_4 \xrightarrow{617^\circ} \text{PbO tetragonal} \quad [5]$$

The exothermic peak at 200° was the result of reordering of the PbO_2 lattice with the evolution of H_2O and O_2. This reaction was also observed in each of the formed electrodes. Continued heating of the active material produced an endothermic peak at 358°C. X-ray diffraction patterns of quenched samples showed lines for ordered α-PbO_2 and β-PbO_2. TGA showed a slight weight loss over the 290°-360°C temperature range. A rerun of a sample which had previously been run to 358° gave no endothermic peak. X-ray analysis of this sample showed lines for β-PbO_2 and α-PbO_x. The material in this sample responsible for the endothermic peak at 358° must therefore be associated with α-PbO_2 or a possible amorphous form of PbO_2. Evidence strongly favors the existence of such an amorphous form since samples containing no α-PbO_2 still gave an endothermic peak at 358°C. Microscopic studies of the original active material show two distinct forms of PbO_2 (1). The predominant form, approximately 85-95% of the total, occurs at brown, brownish-orange, or bright orange, individual crystals of small size and translucent appearance. The other form occurs in dense black or slate gray masses, of glassy appearance and with no definite form, and does not appear to be translucent. Both forms appear unreactive to ammonium acetate and appear in electrodes which show only β-PbO_2 lines, as well as those showing both α- and β-PbO_2 thus indicating that the material is not α-PbO_2. Microscopic examination of samples that were heated to the 358° peak, and then quenched, showed that most of the black material had been replaced by a red material. Samples of this red material gave the major lines for Pb_3O_4.

The black form of α-PbO_2, which was prepared electrochemically (Fig. 1) gave an endothermic peak of similar magnitude at 345°, whereas all of the β-PbO_2 preparations studied gave much larger enthalpy changes at around 400° or higher. DTA curves run on discharged electrodes gave a 358° endothermic peak of approximately the same magnitude as that observed in the charged plate. These samples had not experienced large capacity losses at this time. The other peaks associated with PbO_2 decomposition had diminished in area. Microscopical studies showed that the black material was still present in a discharged electrode. This material evidently does not undergo oxidation or reduction to an appreciable extent after the first few cycles. The most logical explanation of the above facts appears to be that the black PbO_2 is an amorphous form or contains an amorphous form of PbO_2 that is relatively inactive.

While as yet no evidence has been obtained that would directly link the two cases of unreactive material, recent pulsed nuclear magnetic resonance studies (5) have revealed the presence of a hydrogen species in the electrochemically prepared PbO_2 structure which appears to be related to the loss of capacity of the lead acid battery. This hydrogen species has not been found in chemically prepared β-PbO_2, and the latter is known to be unsatisfactory as a battery electrode. Upon heating the electrochemically prepared PbO_2 to 150°C this hydrogen species disappears. This temperature roughly corresponds to the exothermic peak observed at 180° on the differential thermal analyzer. This peak was not observed when the chemically prepared β-PbO_2 was heated.

The endothermic peak at 463°C was due to the decomposition of α-PbO_x and residual PbO_2 to β-PbO_x. Also occurring simultaneously was the decomposition of α-PbO_x and β-PbO_x to Pb_3O_4.

The endothermic peak at 535°C was due to the decomposition of β-PbO_x (from β-PbO_2) to Pb_3O_4 and the decomposition of Pb_3O_4 to PbO tetragonal (from α-PbO_2). As the amount of α-PbO_2 increased in the original sample the peak at 535°C decreased. This would be expected if this peak was due to the decomposition of β-PbO_2 to Pb_3O_4.

The endothermic peak at 618°C was due to the decomposition of Pb_3O_4 to tetragonal PbO.

The above analysis was based on cycled samples taken from electrodes which had showed only a slight loss in its initial capacity. As the electrodes were cycled to failure the major changes in the DTA curves were the gradual disappearance of the exothermic peak at 200°C and the endothermic peak at 358°C. The other endothermic peaks were only reduced slightly indicating that the plate still possessed a high PbO_2 content. This PbO_2 was electrochemically inactive. X-ray analysis also showed that the electrode had a high PbO_2 content and a low $PbSO_4$ content at failure. The DTA curve obtained from this electrochemically inactive PbO_2 resembled the DTA curves obtained from reagent PbO_2.

Conclusions

1. From the evidence that has been obtained it is concluded that an amorphous form of PbO_2 exists in positive plate active material, in addition to α- and β-PbO_2. This material appears to possess thermal properties similar to α-PbO_2.

2. It was concluded from thermal, mass spectroscopy, NMR, and microscopy results that as the $PbO_2/PbSO_4$ electrode was cycled the electrochemically active PbO_2, which may be an amorphous compound, underwent a structural reordering with the loss of a hydrogen species. This structural reordering lead to an electrochemically inactive PbO_2 compound which gave NMR, DTA, and mass spectroscopy results similar to those obtained on reagent PbO_2. The continual conversion of electrochemically active PbO_2 to the electrochemically inactive form is one of the major factors that causes battery capacity loss and ultimate failure.

3. The thermal decomposition mechanism of formed plates has been found to differ, depending on the method of manufacture. However, after a number of cycles all plates gave the same thermal decomposition mechanism.

4. It was also concluded that similar DTA, NMR, and mass spectroscopy results are obtained when electrochemically active PbO_2 is cycled to failure or when it is heated isothermally at 225°C.

Effect of Gaseous Pretreatment on Oxidation of Iron

A. W. Swanson*[,1] and H. H. Uhlig*

Department of Metallurgy and Materials Science, Massachusetts Institute of Technology, Cambridge, Massachusetts 02139

ABSTRACT

Gaseous pretreatment of pure iron surfaces may either increase the subsequent thin film oxidation rate or decrease it, depending on the gas. The effect is less than for copper. Traces of impurities including carbon may explain diminished faceting of iron, and also lower oxidation rates in low-pressure O_2.

In previous papers (1, 2) it was shown that gaseous pretreatment of single-crystal and polycrystalline Cu has a large effect on subsequent thin film oxidation rates in oxygen. Surface facets are formed, the orientation and oxidation rate of which vary with the gas used for pretreatment. It was found that the pretreatment of single-crystal Cu, whatever the crystal face, in hydrogen at 350°-450°C favors formation of the slowly oxidizing (111) face; on the other hand pretreatment in nitrogen favors formation of the much more rapidly oxidizing (100) face. Both pretreated and untreated copper surfaces follow two-stage logarithmic oxidation kinetics when oxidized at 175°-225°C in 1 atm O_2.

Tammann and Köster (3) first observed that oxidation of Fe at low temperatures (thin oxide films) follows the direct logarithmic equation. Similar behavior for Fe in air at 300°C was reported by Lustman and Mehl (4), in air up to 200°C by Vernon *et al.* (5), in air up to 300°C by Davies *et al.* (6), and in 1.3×10^{-2} Torr O_2 up to 200°C by Graham *et al.* (7). Runk and Kim (8) observed two-stage logarithmic behavior for 0.2, 0.4, and 0.8% C steels in 100 Torr O_2 at 200°-350°C; similar behavior was reported by Needham *et al.* (9) for zone-refined Fe in 4×10^{-6} Torr O_2 up to 350°C. In some of these investigations, a wide variety of oxide thicknesses were reported under otherwise comparable conditions but various metal surface treatments were used prior to oxidation. It was the purpose of the present investigation to determine to what extent Fe similar to Cu oxidizes in the thin film region at rates dependent on the type of gaseous pretreatment.

Experimental

Two kinds of iron were used. The first was Armco iron sheet 0.0037 in. (0.0094 cm) thick decarburized in wet H_2 to 0.0013% C (by chemical analysis). The second was Battelle zone-refined iron containing <0.0005% C, with other impurities consistently low, cold rolled to 0.015 in. (0.038 cm), and subsequently annealed in argon at 800°C for 1 hr.

Oxidation and pretreatment tests were run in a 3 cm ID fused silica tube inserted into a horizontal tube furnace maintained automatically at ±1.5°C. A 0.5 cm wall stainless steel tube surrounding the silica tube insured a more uniform furnace temperature. The furnace could be slid along runners bringing it into or out of the specimen zone. Gases were led through an inner small diameter silica tube to the rear of the larger silica tube, thereby preheating the gas before it impinged on the specimen.

Dried nitrogen, hydrogen, and argon were purified by passing over Cu chips at 400°C; the argon was additionally purified over Ti chips at 800°C. All the foregoing gases were then dried through a trap immersed in solid CO_2 and acetone. Oxygen was dried using $CaCl_2$. Specific mixtures of CO-CO_2 were obtained by monitoring the flow of the individual gases through flow meters. Specific H_2O-H_2 mixtures were obtained by bubbling H_2 through distilled H_2O maintained at a prescribed temperature.

The 3×10 cm iron sheet specimens bent into a semicircle were pickled for 2 min at room temperature in 10 volume per cent (v/o) conc HNO_3, rinsed four times in distilled water, and then dried by immersing in acetone, followed by benzene in a nitrogen atmosphere. It was suspected that carbon tended to migrate to the metal surface during heating of the specimens (as detected by reduced oxidation rates of the iron), requiring a further oxidation-reduction treatment of the surface in order to remove it. Holm (10) earlier observed that carbon migrating to the surface of iron reduced the thickness of a previously formed oxide film; Uhlig *et al.* (11) noted the same effect with nickel. Sewell (12) found similarly that the oxidation rate of nickel is affected by only a few parts per million of carbon migrating to the surface. Blickwede (13) showed through surface analysis of commercial steels that marked surface enrichment in carbon occurs after annealing in N_2-H_2 mixtures.

To avoid such effects with the present specimens, both Armco and zone-refined iron were subjected to

the following procedure: the specimen was heated in O_2 at 1 atm to 250°C for 1 min, followed by heating at 720°C in N_2 at 1 atm. Any carbon diffusing to the metal surface in the N_2 atmosphere reduced the thin oxide. If the oxide was visibly changed, the oxidation treatment was repeated until the oxide remained unaffected by the 720°C treatment. The residual oxide film was then reduced with H_2 at 250°C.

Surface pretreatment runs were made by bringing the specimen to temperature in N_2, then flowing the pretreatment gas over the specimen at 1000 mliters/min for the required time. The specimen was then allowed to cool to 250°C in the same gaseous atmosphere. After flushing with N_2, the introduction of O_2 marked the beginning of oxidation time. Cooling of the specimen after oxidation was carried out in N_2.

Oxide Thickness Measurements

Iron oxide thickness, in contrast to cuprous oxide thickness, could not be determined by the convenience of coulometric reduction. An attempt was made to use coulometry employing various fused salt electrolytes, but without success. Cohen and co-workers (14, 15) tried to electrochemically reduce Fe_3O_4 films on iron in aqueous electrolytes but never achieved a well-defined current efficiency even closely approaching 100%. The method we finally adopted employed an oxide film stripping technique using a 10% solution of iodine dissolved in anhydrous methyl alcohol previously distilled over metallic Ca. The method was similar to that described by Vernon *et al.* (16) and made use of a glass setup equipped with ball and socket joints and Teflon stopcocks (Fig. 1). Purified N_2 filled the apparatus and was also used to circulate the methanolic solution or methanol itself. A sample of oxidized iron specimen cut to 1.3 × 8.1 cm was placed in the stripping cell C and covered with the I_2-CH_3OH solution. The stripped oxide was rinsed five times with small portions of CH_3OH from flask A, thereby insuring removal of stripping solution and ferrous iodide (as checked by chemical tests of aqueous wash solutions). The washed oxide was then dissolved in 6*N* HCl and both the ferrous iron and total iron determined using the *o*-phenanthroline method in conjunction with a spectrophotometer operating at a wavelength of 508 mμ. The oxide by such analysis was found to have a ratio of total iron to Fe^{++} of 2.95 ± 0.05 corresponding to Fe_3O_4. This composition for the oxide formed on iron in the 250°C range is in agreement with that determined by others (17-19), employing mostly x-ray. The thickness of the oxide film was calculated from the iron analyses assuming a density for Fe_3O_4 of 5.18 and a surface roughness factor of unity.

Results

Oxidation data for polycrystalline Armco and zone-refined iron were found to follow the direct logarithmic equation and in particular two-stage logarithmic behavior as shown in Fig. 2-3. The data for first-stage oxidation follow the relation $y = k_1 \log (t/\tau + 1)$ where y is oxide thickness, t is the time, and k_1 and τ are constants. Values of τ were obtained by extrapolating y *vs.* $\log t$ to $y = 0$, emphasizing points for which $t >> \tau$. Values of τ' for second-stage oxidation were obtained on the basis of the following equation

$$y - L = k_1' \log (t/\tau' + 1)$$

where L is the thickness of oxide at the transition from 1st to 2nd stage oxidation. The value of τ' is then the time at which y equals L. Values of k_1, k_1', τ, and τ' are listed in Table I

The oxidation data for preoxidized Armco iron, the air-formed film of which was reduced at 250°C, are shown in Fig. 2 ("No Pretreatment"). Within experimental variations, these data coincide with those for iron specimens pretreated in dry H_2, in dry N_2, or in dry Ar at 800° and 1000°C. Zone-refined iron pretreated in dry H_2 or in dry N_2 behaves essentially the same as does Armco iron. Impurities normal to Armco iron, therefore, are not important. However, for both

irons, pretreatment with reducing H_2O-H_2 mixtures with $p_{H_2O}/p_{H_2} = 10^{-0.5}$, $10^{-1.0}$, and $10^{-1.5}$ for 150 min increased the subsequent oxidation rates by an amount equal to about 25-35%. A longer time of pretreatment in H_2O-H_2 for up to 300 min did not alter subsequent rates (Table II). Pretreatment in noncarburizing $CO-CO_2$ mixtures ($p_{CO}/p_{CO_2} = 2.33$ and 3.00) caused a slight decrease (10-20%) in the first-stage oxidation rate. These data are shown in Fig. 4. The pretreatment gas ratios were chosen at values which avoided either carburization on the one hand, or oxidation on the other, in accord with data provided by Austin (20).

Discussion

The observed changes of oxidation rate produced by various gaseous pretreatments are much smaller than parallel effects observed for Cu. The changes in iron can be ascribed either to changes in surface roughness or to the development of surface facets having an orientation corresponding to the lowest metal surface energy. In view of the pronounced and reversible effects of pretreatment on faceting of Cu, as confirmed by electron micrographs, a similar explanation for the oxidation behavior of Fe based on faceting is plausible. A change of roughness factor is not an equally valid explanation for the results on Cu, and probably not for the results on Fe. Electron micrographs of H_2O-H_2 and CO_2-CO pretreated Fe showed a definite surface rearrangement but the facets were less pronounced than those appearing on Cu and the resolution was not of sufficient quality to justify reproduction. The electron micrographs were similar to those pictured by Sewell *et al.* (21) for Fe after vacuum or H_2 treatment at 800°C for 120 min. Although the latter authors indicate that all low index planes of Fe develop similar facets, one would assume that, as in the case of Cu and in accord with discussions by Gjostein (22), the orientation of facets which develop on any single-crystal face is a function of the kind and partial pressure of the gas in contact.

Since thin film oxidation of iron, as for Cu, increases in the order (111) < (100) (23), the lesser

† Averaged for 3 or 4 specimens. Deviations are maximum values.

effects of gaseous pretreatment on oxidation of Fe may result from a lesser tendency of Fe to facet in the pretreatment gases presently chosen. The latter tendency in turn may be inherent to Fe or it may be caused by surface contamination by carbon or other impurities, which, despite all precautions, reached the metal surface in monolayer or lesser amounts during gaseous pretreatment or O_2 exposures. Such a partial monolayer is expected to exert a major effect on surface energies and, in turn, on facet formation.

A comparison between presently reported oxide thicknesses on Fe and values previously reported by other investigators also suggests an effect of surface contamination rather than of differences in faceting. The results divide themselves into two categories. All investigations carried out in relatively high O_2 pressures are reasonably consistent. For example, at the end of 10 min, presently measured thickness of the Fe_3O_4 film on iron at 250°C, 1 atm O_2, is 297Å; Wagner *et al.* (23) (1 atm O_2) obtained about 450Å at 250°C; Boggs *et al.* (17) (0.01-100 Torr O_2) reported about 350Å at 270°C; and Runk and Kim (8) (100 Torr O_2) for 0.2% C steel reported 420Å at 300°C. On the other hand, at consistently lower pressures, the reported oxide thickness is about an order of magnitude less. At the end of 10 min, Graham *et al.* (7) (1.3×10^{-2} Torr O_2) reported 60Å at 200°C although their O_2 pressure overlapped the lowest pressure employed by Boggs *et al.*; and Needham *et al.* (9) (4×10^{-6} Torr O_2) reported 36Å at 285°C.

The zone-refined iron used by Needham *et al.*, Boggs *et al.*, and by us was supplied by Battelle Memorial Institute and hence observed differences in oxidation rates are not likely to be caused by differences in impurities. Our present similar results on Armco and zone-refined Fe also make it clear that impurities are not a major factor. Furthermore the oxidation rate in low pressure in contrast to higher pressure O_2 is not controlled by diffusion of O_2 to the surface in view of observed logarithmic behavior, and also because the time separating first- from second-stage oxidation is about 10 min in our measurements and also in those of Needham *et al.* and in those of Runk and Kim, the latter investigators working with 0.2-0.8% C steels. There is the possibility that the semiconducting properties of the Fe_3O_4 film are affected by oxygen pressure in such a direction as to decrease the rate as the pressure is lowered. Such a trend, however, is opposite to the effect of oxygen pressure within the range 0.01-100 Torr reported by Boggs *et al.* Graham and Cohen (24) reported an increasing rate with O_2 pressure at 350° and 400°C but their results apply to the parabolic region of oxidation and not necessarily to the logarithmic range presently considered. Boggs *et al.* found little if any pressure dependence in the definitely parabolic region at 450°C. It seems reasonable to suggest,

therefore, that contamination of an iron surface by monolayer or lesser amounts of carbon (which is difficult to avoid) has a much larger effect on oxidation rates carried out in low pressure O_2 than in higher pressure O_2 approaching 1 atm, the carbon contamination in low pressure measurements markedly reducing the oxidation rate. This suggestion is in accord with the results of Needham *et al.* showing that surface carbon contamination in their low pressure measurements exerted a retarding effect on oxidation. In addition, the low oxidation rates they reported at 4×10^{-6} Torr O_2 are also explained by a diminished electric field within the Fe_3O_4 film caused by decreased adsorption of oxygen on the outer oxide surface. Such a reduced electric field slows down the oxidation-rate controlling escape of electrons from metal to adsorbed oxygen in accord with the theory of thin film oxidation described by one of us (25).

In accord with the theory of thin film oxidation referred to (25), it is possible from observed values of k_1 to calculate the density of sites n at which electrons become trapped in oxide adjacent to the metal surface. The increasing thickness of negative space charge thus created retards the escape of electrons from metal to oxygen adsorbed on the oxide surface. On the basis of the values of k_1 observed for Fe reduced in H_2 at 250°C, $n = 6.4 \times 10^{15}$. This is intermediate between values for Cu at 250°C (0.6×10^{14}) (25) and for Zn at 206°C (2.4×10^{17}) (26). Accordingly, one of the reasons Cu oxidizes more rapidly and Zn less rapidly than Fe in the thin film region is the differing oxide space charge densities.

Conclusions

1. Gaseous pretreatment of iron with reducing H_2O-H_2 mixtures at 800°-1000°C increases the subsequent oxidation rate in 1 atm O_2 at 250°C by 25-35%.

2. Similar pretreatment with noncarburizing CO-CO_2 mixtures decreases oxidation by 10-20%.

3. Both decarburized Armco iron and zone-refined iron oxidize in 1 atm O_2 at 250°C at the same rate; both follow similar two-stage logarithmic kinetics. A much lower oxidation rate reported by other investigators in low pressure O_2 is probably caused by the retarding effect of contaminating surface carbon; such carbon contamination does not similarly retard oxidation in 1 atm O_2. In addition, diminished adsorption of oxygen on oxide may also explain lower oxidation rates in low pressure gas.

4. Iron in the thin-film region oxidizes at a rate intermediate between Cu and Zn. This is interpreted in terms of an intermediate space charge density in Fe_3O_4 compared to that in Cu_2O and ZnO adjacent to the metal surface.

Electrochemically Generated Colored Films of Insoluble Viologen Radical Compounds

H. T. van Dam and J. J. Ponjeé

Philips Research Laboratories, Eindhoven, The Netherlands

ABSTRACT

Electrochemical reactions that produce a change of light absorption in the visible region can be used in display devices. The reduction of the 4,4'-dipyridinium compounds or viologens to stable blue radicals is very promising in this respect. It was found that in aqueous solution the solubility of the radical is remarkably lower than that of the oxidized form. It turned out that the solubility depends on the kind of anion and the magnitude of the viologen radical ion.

An increasing demand for all sorts of display devices with which electrical information can be made visible, has stimulated the search for electrochemical processes to provide the electro-optical effect in such a device. The most obvious processes are electrochemical reactions in which the light-absorbing characteristics of one of the reacting substances change dramatically. The reduction of metal ions to a metal film on a transparent electrode and the color change of *p*H or redox indicators are examples of such reactions (1).

In our laboratory the feasibility of a display based on an electrochemical color change was investigated using the group of redox indicators known as the viologens. This name was given by Michaelis and Hill (2) to the 4,4'-dipyridinium compounds (I) because they become deeply blue-purple on reduction. Designating I as dipy X_2 we have the following reactions

$$\text{dipy}^{2+} + e \leftrightharpoons \text{dipy}^{+} \qquad \text{(blue)}$$
$$\text{dipy}^{+} + e \leftrightharpoons \text{dipy}$$

$$R\text{—}\overset{+}{N}C_5H_4\text{—}C_5H_4\overset{+}{N}\text{—}R, \quad 2X^{-}.$$

I

From several investigations (3) it is known that the first step is a simple, reversible, one-electron reduction giving the stable blue, radical ion. There is no reaction with a proton involved, a rare occurrence in organic redox reactions. The electron transfer reaction is so fast that the reduction is diffusion controlled only, even at large current densities. This property is of importance in display applications where a response as fast as possible is required. Response times of 10 msec have been obtained.

The stability and the intensive color of the radical ion result from the extensive delocalization of the electron that is added on reduction to the π-electron system of the dipyridium skeleton. As long as the substituent R does not influence this π-electron system one expects no influence of R on the energy needed to add an electron, *i.e.*, the viologens should all have more or less the same redox potential. This argument is supported by the fact that the EPR spectra of some of the viologens with different substituents are practically identical (4). The respective redox potentials measured in water at inert electrodes however, show large differences, *e.g.*, ethyl viologen -0.680V *vs.* SCE and benzyl viologen -0.597V *vs.* SCE. In addition, the value of the redox potential of a particular viologen in an organic solvent such as acetonitrile differs from that in aqueous solution. One wonders whether this last fact is connected with the differences in color in the above solvents: blue ($\lambda_{max} = 605$ nm) in acetonitrile as well as in dilute aqueous solutions, purple (increase of shoulder at $\lambda = 545$ nm) in more concentrated aqueous solutions. This behavior has been explained (3, 5) in terms of a dimer formation in aqueous solutions. The absence of the dimer in organic solvents is attributed to ion-pair formation which somehow prevents dimerization. However Dimroth and Frister (6) noted the deepening of the purple color and even the possibility of salting-out the radical compound of 4,4'-dipyridyl by adding iodide ions, which suggests that the kind and the concentration of the anion are important. Some of the viologens we synthesized gave insoluble purple products on reduction even in dilute solutions. In order to find an explanation for the differences in redox potentials we have determined the half-wave potentials of a number of substituted viologens at various concentrations and in one case with different supporting electrolytes. The existence of insoluble reduction products is of practical importance in display applications. On electrodes of any desired shape these products can be deposited in the form of thin films. This property provides a memory effect without any power consumption and ensures that the oxidation of the colored product to the colorless state is fast (7). Erasure times of 10 msec have been obtained.

Key words: viologen, electrochromics, display.

Experimental

The dipyridinium salts were prepared with the use of the Menschutkin reaction in which an amine is quarternized with an alkyl halide (8). The halides obtained in this way were transformed into compounds with different anions by double displacement reactions. Simply by adding concentrated solutions of their sodium salts the tetrafluoroborates as well as the perchlorates could be precipitated.

A Metrohm Polarograph E 261 R was used for the polarographic measurements, in some cases together with the iR-compensator E 446. Large Ag/AgCl electrodes were used as reference and counterelectrodes. In the measurements of solutions in acetonitrile these electrodes were connected through a bridge filled with acetonitrile saturated with supporting electrolyte. The viologen concentration was 10^{-3} mol liter^{-1}. A series of measurements was performed at 25° ± 0.1°C but since the influence of the temperature on $E_{1/2}$ is slight this practice was discontinued and most experiments were done at room temperature.

The preparation of viologen radical films for measurement of the static emf of the cell

Pt/viologen radical film/viologen soln/AgCl/Ag

was done with the help of a Wenking potentiostat in that cell at about -0.70 *vs.* Ag/AgCl. This potential was maintained until the current became negligibly small. In this way the poor reproducibility of these

Heptyl	0.41	0.88

measurements, due to changes inside the layers, especially in the case of heptyl viologen bromide, could be improved upon. Pt electrodes of different shapes were used. They were cleaned in 2*N* nitric acid, rinsed with water, and kept in a dilute $FeSO_4$ solution.

The solutions were stirred continuously and oxygen-free nitrogen was bubbled through. A heptyl viologen bromide film was prepared electrolytically on a transparent conducting SnO_2 substrate part of a cell filled with a heptyl viologen dibromide solution. Its spectrum was measured with a Cary 15 spectrophotometer. A matched cell filled with the same solution was placed in the reference beam.

Results

The half-wave potentials for the first and second reduction steps for a number of viologen tetrafluoroborates in acetonitrile are given in Table I. It is noted that, irrespective of the substituent, all values are close together compared with the differences observed between, *e.g.*, ethyl and benzyl viologen in water, as pointed out earlier in this paper. In acetonitrile only the tetrafluoroborates and the perchlorates are sufficiently soluble to allow variation of the anion concentration over two decades. No change in the half-wave potentials was found over this range. A similar result holds for acetonitrile water mixtures 1:1.

Heptyl viologen is one of the compounds that gives an insoluble product on reduction in water and we selected this compound for polarographic measurements with different supporting electrolytes. The results for KCl and NH_4BF_4 are given in Fig. 1. For anions other than these a comparison at a fixed concentration of 10^{-1} mol liter^{-1} was made and a sequence could be set up for monovalent anions in which the absolute value of the measured half-wave potential of the first reduction step decreases $F^- > Cl^- > Br^- > BF_4^- > ClO_4^-$. It is noted that the radius of the anions increase in this sequence. Since a precipitate is formed the approximate equivalence of the half-wave potential and the redox potential is no longer true, but now stationary measurements are possible after the formation of a layer of the insoluble product on an inert electrode. Measurements of the emf of the following cell are given in Fig. 2

$$Pt/dipy\ X/dipy^{2+}, X^-, K^+, (H_2O)KCl_{sat}/AgCl/Ag$$

A number of different viologens have been prepared primarily to test their possible usefulness for display applications. We observed therefore whether it was possible to prepare a permanent film by electrochemical reduction in the aqueous solutions of the dibromides. In Table II we give the results, where + indicates the fact that the solubility of the bromide is sufficiently small to make a permanent film. We have arranged the substituents in the order of increasing length of the alkyl groups and we have compared other substituents with these in terms of the number of CH_2 units. With less than 4-5 of these units in R the films dissolve slowly or do not exist at all.

In Fig. 3 the spectrum of the heptyl viologen bromide layer formed electrochemically on a SnO_2 electrode is given as well as that of the solution in acetonitrile and that of ethyl viologen chloride in water for

comparison. The absorption band with a maximum at 605 nm is no longer present in the solid layer and the shoulder at 545 nm, present in both solutions, is now the major absorption band. One can say that the anomalous spectral behavior of aqueous solutions of viologens becomes extreme in the case of heptyl viologen.

Discussion

The dependence of the half-wave potential on the anion concentration found for several substituents R suggests that a solubility product $L = [dipy^+][X^-]$ for the insoluble radical compounds can be defined, for with the help of such a product we have the following Nernst-type equations for the two reduction steps

$$E^{(1)} = E_0^{(1)} + 0.06 \log \frac{[dipy^{2+}][X^-]}{L} \quad \text{1st step} \quad [1]$$

$$E^{(2)} = E_0^{(2)} + 0.06 \log \frac{L}{[X^-][dipy]} \quad \text{2nd step} \quad [2]$$

These are the equations of the lines in Fig. 1 for adjusted E_0 values. These E_0 values cannot be identified with the redox potentials for the following reason. Such an identification is based on the fact that at the half-wave potential just half of the amount of the reacting substance present at the electrode is reduced. This makes the concentration ratio in the Nernst equation equal to 1 and the whole concentration term vanishes. When however the reaction product precipitates on the electrode surface this is no longer true. It also follows that we do not know the value of $[dipy^{2+}]$ in the first step. We do know this value when no current flows and the first step can therefore be used in conjunction with the measurements in Fig. 2 to calculate L. Now E_0 can be identified with the redox potential and all we need to know is its value for the couple $dipy^{2+}/dipy^+$. If we take the half-wave potential of ethyl viologen in water, which does not depend on the anion concentration in the range studied, to be equal to

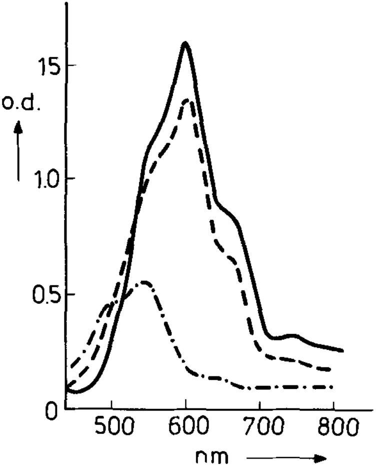

Fig. 3. Spectra of viologens: (- - - - -) ethyl viologen chloride 10^{-4} mol liter^{-1} in water; (———) heptyl viologen tetrafluoroborate 10^{-4} mol liter^{-1} in acetonitrile; (-.-.-.-.) heptyl viologen bromide film on SnO_2 substrate.

$E_0^{(1)} = -0.66V$ *vs.* Ag/AgCl, we find for heptyl viologen chloride $L = 8.5 \times 10^{-6}$, for the corresponding bromide $L = 3.9 \times 10^{-7}$. Noting further that the absolute values of the redox potentials of the first and second reduction step are lower and higher, respectively, in acetonitrile than in water we are led to the following reaction scheme. For the first step

$$dipy^{2+} + e \rightleftharpoons dipy^+ \quad (H_2O) \quad [3]$$

$$dipy^+ + X^- \rightleftharpoons dipy\,X/solid \quad (H_2O) \quad [4]$$

$$\updownarrow$$

$$dipy\,X^+ + e \rightleftharpoons dipy\,X/soln \quad (CH_3CN) \quad [5]$$

and for the second step

$$(dipy\,X)_{soln} + e \rightleftharpoons dipy + X^- \quad (CH_3CN) \quad [6]$$

$$dipy^+ + e \rightleftharpoons dipy \quad (H_2O) \quad [7]$$

The difference in the redox potentials in acetonitrile and in water can now be interpreted as a consequence of equilibrium [4] on the one hand and the strong association of the second X^- ion with the viologen cation in CH_3CN on the other. The assumption of this association, which holds for all the viologens, seems reasonable in view of measurements by Brody and Fuoss (9) of the conductivity of *bis*-quaternary salts in methanol such as diethyl sulfide *bis*-trimethyl ammonium diiodide, which resemble the viologens somewhat in their charge distribution; they find that all such salts show association of one anion to the doubly charged cation. From our own measurements of the conductivity of heptyl viologen dibromide in water, to be published later, we know that ionization is complete which justifies Eq. [3], but that already a strong association exists which increases when the dielectric constant becomes lower and therefore supports the assumption underlying [5].

The influence of the substituent R and the anion X^- on the redox potential can now be found in reaction [4] and not in the reduction reaction [3] itself, as expected. We see that a correlation exists between the size of R as well as X^- and the solubility of the radical compound. This correlation can be understood if a sandwich-type structure is formed in which the anion knits the dipyridinium ions together and the R groups protect the anion from the solvent molecules. The larger the radius of X^- the smaller the electrostatic repulsion between the dipyridinium ions and the greater the stability of such a structure. Normally the double positive charge prevents the formation of large clusters in this way, but on reduction such clusters are electrically neutral and precipitation results. When R and X^- are not large enough to cause a precipitate to be formed the spectral changes in concentrated solutions point to similar smaller clusters. Because of the essential role of the anion and the fact that the solid precipitate is strongly paramagnetic (4) we feel that a description of spectral anomalies in terms of dimers, where spin-pairing would be expected, is confusing.

Theoretical and Experimental Study of Hydrodynamically Modulated Current-Potential Curves at Rotating Disk Electrodes under Conditions of Mixed Electron and Mass Transfer Control

Barry Miller* and Stanley Bruckenstein*,[1]

Bell Laboratories, Murray Hill, New Jersey 07974

ABSTRACT

When a rotating disk electrode is subjected to an appropriate superimposed sinusoidal modulation of its rotation speed, the modulated component of the disk current may be governed by both mass transport and kinetic processes. In this study, mixed electron transfer and convective diffusion control conditions are considered, and the relationships among modulated current response, average current, potential, relevant species concentrations, and kinetic and transport parameters are derived. The theoretical predictions are experimentally verified for the two limiting cases of totally reversible and irreversible reactions, and for the general case of mixed control.

Sinusoidal modulation of a disk electrode's rotation speed about a center value produces a disk current having a component at the modulation frequency. This modulated current is governed by mass transport and kinetic processes, provided the amplitude and frequency of modulation are chosen to maintain an effective hydrodynamic steady state (1, 2). In this paper we consider, under these conditions, the case of mixed electron transfer and convective diffusion control in order to obtain the relationships that exist among modulated current response, average current, potential, relevant species concentrations, and kinetic and transport parameters. The theoretical results permit comparing conventional rotating disk electrode (RDE) data with hydrodynamically modulated rotating disk electrode (HMRDE) data.

These developments make it feasible to consider determining electron transfer kinetics at electrodes that are undergoing simultaneous electrochemical surface processes, only one of which is controlled by convective diffusion. For example, one might determine the variation of the rate of an electron transfer step proceeding with concurrent formation of a surface oxide on the electrode and then correlate the electron transfer rate constant and surface oxide coverage. As another example, one might separate modulated current kinetic data from the currents occurring at the limits of supporting electrolyte stability.

The theoretical predictions obtained below have been verified for the case of the totally irreversible limit using the Pd/Pd(II) couple, for the case of mixed kinetic and convective diffusion control using the Fe(III)/Fe(II) couple at gold in 1*M* HCl, and for the case of fast electron transfer (convective diffusion control) using the $Fe(CN)_6^{-3}/Fe(CN)_6^{-4}$ couple at gold in 1*M* KCl.

Key words: electrode kinetics, convective diffusion, sinusoidal modulation.

Theoretical

The process we consider is Ox + *ne* = Red, with standard rate constant k_o and standard potential $E°$, at some applied current, *i*. The general rate equation is

$$i = n\mathbf{F}Ak_o\{C^s_{red}\mathrm{Red}(E) - C^s_{ox}\mathrm{Ox}(E)\} \quad [1]$$

where

$$\mathrm{Ox}(E) = \exp\{-\alpha_c\mathbf{F}(E - E°)/RT\} \quad [2]$$

$$\mathrm{Red}(E) = \exp\{\alpha_a\mathbf{F}(E - E°)/RT\} \quad [3]$$

anodic currents and overpotentials are taken as positive, and electrons transferred are not separated out of the exponential factor in this paper.

According to the Levich equation

$$C^s_{ox} = C^o_{ox} + i/L_{ox}\omega^{1/2} \quad [4]$$

and

$$C^s_{red} = C^o_{red} - i/L_{red}\omega^{1/2} \quad [5]$$

where C^s represents the surface concentration and C^o the bulk concentration of the subscripted species, ω the angular velocity, and L the remaining constant factors of the Levich equation $(0.62n\mathbf{F}AD^{2/3}\nu^{-1/6})$.

Substituting Eq. [2]-[5] into Eq. [1] and solving for *i* yields

$$i = \frac{n\mathbf{F}Ak_o\{C^o_{red}\mathrm{Red}(E) - C^o_{ox}\mathrm{Ox}(E)\}}{1 + \frac{n\mathbf{F}Ak_o}{\omega^{1/2}}\left[\frac{\mathrm{Ox}(E)}{L_{ox}} + \frac{\mathrm{Red}(E)}{L_{red}}\right]} \quad [6]$$

If we differentiate *i* in Eq. [6] with respect to $\omega^{1/2}$ at constant potential and define

$$k_E = n\mathbf{F}Ak_o\{\mathrm{Ox}(E)/L_{ox} + \mathrm{Red}(E)/L_{red}\} \quad [7]$$

it can be shown that

$$di/i = (d\omega^{1/2}/\omega^{1/2})\{k_E/(k_E + \omega^{1/2})\} \quad [8]$$

In our experiments we have used an angular velocity program of the form

$$\omega^{1/2} = \omega_o^{1/2}\{1 + \Delta\omega^{1/2}(\sin 2\pi ft)/2\omega_o^{1/2}\} \quad [9]$$

where f is the frequency of modulation, ω_0 is the center angular velocity, and $\Delta\omega^{1/2}$ is the peak-to-peak amplitude of the sinusoidal modulation of the square root of the angular velocity. If $\Delta\omega^{1/2} << \omega_0^{1/2}$, then

$$d\omega^{1/2}/\omega^{1/2} \approx \Delta\omega^{1/2}/\omega_0^{1/2} \quad [10]$$

Also

$$di/i \approx \Delta i/\bar{i} \quad [11]$$

where Δi is the peak-to-peak amplitude of the sinusoidal current response at frequency f and $\bar{i}$ is the current at ω_0. Hence

$$\Delta i/\bar{i} = (\Delta\omega^{1/2}/\omega_0^{1/2})k_E/(k_E + \omega_0^{1/2}) \quad [12]$$

If Eq. [12] is rearranged in the form

$$\frac{\Delta\omega^{1/2}/\omega_0^{1/2}}{\Delta i/\bar{i}} = 1 + \omega_0^{1/2}/k_E \quad [13]$$

the result suggests a convenient plot to be used for determining k_E. Since k_E can be determined as a function of E, for $E = E°$ it follows from Eq. [7] that

$$k_{E°} = n\mathbf{F}Ak_0(1/L_{ox} + 1/L_{red}) \quad [14]$$

Equation [14] is suitable for calculating k_0 from $k_E°$ after the transport factors, L, are measured.

For any couple with reasonably symmetrical parameters ($L_{ox} \cong L_{red}$, $\alpha_a \cong \alpha_c$), k_E will be a minimum at or very close to $E = E°$ and k_E will be a relatively slowly changing function near $E°$. For example, with $\alpha_a = \alpha_c = 1/2$ and $L_{red} = L_{ox}$, k_E increases by only 50% for a 50 mV excursion either side of $E°$, and by only 12% for one of 25 mV. Very little error would be made in estimating the value of $k_{E°}$ by assuming that the minimum of a k_E *vs.* E plot occurs at $E°$ and Eq. [14] applies.

We next consider three limiting cases of the general result, Eq. [12].

Case 1.—At either a cathodic or anodic limiting current, the quantity containing k_E in Eq. [12] goes to unity. The resulting expression, where the subscript L refers to the disk electrode limiting convective diffusion condition

$$\Delta i_L/\bar{i}_L = \Delta\omega^{1/2}/\omega_0^{1/2} \quad [15]$$

is the one predicted by the Levich equation, and it has been amply confirmed for pure convective diffusion controlled situations (1, 2).

Case 2.—If the standard rate constant is very large (as with a reversible reaction), then at all potentials $k_E >> \omega^{1/2}$ and Eq. [15] without the subscript L applies. Thus, the normalized plots of $\bar{i}/\bar{i}_L$ *vs.* E and $\Delta i/\Delta i_L$ *vs.* E should superimpose, as should the corresponding logarithmic forms of these data.

Case 3.—For a totally irreversible reaction, k_E approaches one of two limits. On the cathodic side

$$k_E = n\mathbf{F}Ak_0\{\mathrm{Ox}(E)/L_{ox}\} \quad [16]$$

and on the anodic side

$$k_E = n\mathbf{F}Ak_0\{\mathrm{Red}(E)/L_{red}\} \quad [17]$$

If Eq. [16] or [17] is substituted into the correspondingly limited form of [1] and L_{ox} or L_{red} is eliminated using [4] or [5], we obtain

$$k_E/(k_E + \omega_0^{1/2}) = (C^o - C^s)/C^o = \bar{i}/\bar{i}_L \quad [18]$$

for both situations. Substituting Eq. [18] into [12] and using Eq. [15] yields the simple interrelationship between modulated and conventional disk electrode currents

$$\bar{i}_L/\bar{i} = \sqrt{\Delta i_L/\Delta i} \quad [19]$$

For this totally irreversible case, Eq. [19] permits facile comparison of RDE and HMRDE data. The equation for the irreversible wave of the Ox/Red couple is given by

$$E = E_{1/2} \pm RT/\alpha\mathbf{F}\ln[(\bar{i}_L/\bar{i}) - 1] \quad [20]$$

where $E_{1/2}$ is the observed half-wave potential, which is related to the kinetic parameters of the electron transfer process, not to $E°$. The positive sign applies on the cathodic side, and the negative on the anodic. Substituting Eq. [19] into Eq. [20] yields the potential observed under HMRDE conditions, E^{mod}, in terms of the conventional $E_{1/2}$ found from the $\bar{i}$-E curve and the modulation currents.

$$E^{mod} = E_{1/2} \pm RT/\alpha\mathbf{F}\ln[\sqrt{\Delta i_L/\Delta i} - 1] \quad [21]$$

Defining $E^{mod}{}_{1/2}$ as the potential at which $\Delta i = 0.5\Delta i_L$, it follows from Eq. [21] that at 25°C

$$E_{1/2} - E^{mod}{}_{1/2} = \pm 0.02265/\alpha \text{ volt} \quad [22]$$

i.e., the HMRDE half-wave potential is shifted about 45 mV when $\alpha = 1/2$. The direction of the shift is cathodic for reductions and anodic for oxidations. Also, we see from Eq. [20] and [21] that $E_{1/2} = E^{mod}{}_{1/4}$ and that $E_{0.707} = E^{mod}{}_{1/2}$.

The various relationships that exist between the RDE and HMRDE curves for the completely reversible and irreversible extremes are summarized in Fig. 1. The ordinate represents a normalized current variable, either $\bar{i}/\bar{i}_L$ or $\Delta i/\Delta i_L$. For the reversible electrode reaction, the normalized RDE and HMRDE plots superimpose, while this is not the case for the completely irreversible process. In the latter situation, the difference between the RDE and HMRDE plots decreases as the normalized current variable approaches unity. This property is advantageous in applications involving limiting current measurements, since, for practical purposes, the same potential can be used to determine both $\bar{i}_L$ and Δi_L.

The totally irreversible reduction of a metal ion, $M^{+n} + ne = M$, follows the cathodic forms of Eq. [18] through [22] found for the Ox/Red couple.

Experimental

The speed control methodology and electronic elements are identical to those recently described (2), parts of which derive from an earlier version (1). Experiments were run in two different hydrodynamic modes with the usual one involving fixed sinusoidal modulation superimposed on a constant speed. The second mode was only employed in the testing of Eq. [13] and utilized fixed amplitude sinusoidal modulation superimposed on a linear increase of $\omega_0^{1/2}$ with time. All measurements were made under potentiostatic or potential scan conditions at ambient temperature, ~24°C.

A gold disk electrode of 0.178 cm² area, polished to a 0.3μ Linde A finish, was employed for all experiments. Solutions were prepared from triply distilled water and reagent grade chemicals without further

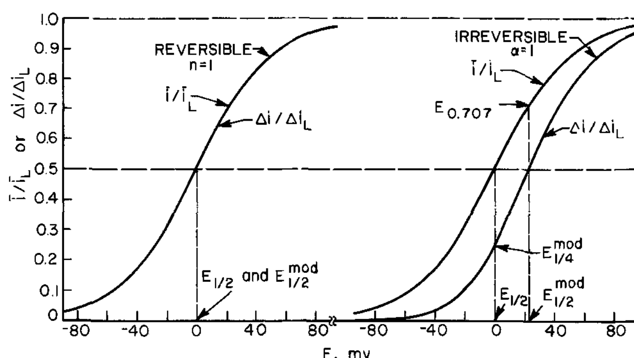

Fig. 1. Normalized current plots of $\bar{i}/\bar{i}_L$ and $\Delta i/\Delta i_L$ vs. potential for the cases of a reversible one-electron reaction and an irreversible reaction with an α of one.

purification. Pd(II) and $Fe(CN)_6^{-4}$ solutions were prepared determinatively from K_2PdCl_4 and $K_4Fe(CN)_6$, respectively. The Fe(III) stock solution was standardized by $SnCl_2$ reduction and ceric titration. All experiments were run under deaeration by house nitrogen.

Results and Discussion

Oxidation of $Fe(CN)_6^{-4}$.—Plots of RDE and HMRDE curves for the oxidation of 1.57 m*M* $Fe(CN)_6^{-4}$ in 1*M* KCl at gold are given in Fig. 2 along with the conventional RDE logarithmic analysis. A potential scan rate of 0.5 mV/sec was employed, and the time constant was 2 sec in the electronics that converted the modulated current response to a d-c voltage. Under these conditions, the experimental HMRDE curve is shifted no more than a few millivolts from the curve found at constant potential, *i.e.*, a couple of time constants. The measured separation at $E_{1/2}$ in Fig. 2 is between 3 and 4 mV. A point by point determination of RDE and HMRDE *i-E* curves was not practical since trace impurities present in solution are adsorbed and poison the electrode surface in such experiments. Poisoning also occurs when very slow scan rates are used. However, averaging the traces for an anodic-cathodic cycle obtained at a finite scan rate eliminates any time constant induced hysteresis when the electrode surface is stable.

The conventional wave analysis of the single scan RDE data in Fig. 2 confirms that the oxidation of $Fe(CN)_6^{-4}$ proceeds reversibly under the experimental conditions used (59 mV/decade slope). Thus, according to the result obtained in the theoretical section under limiting case 2 and shown in Fig. 1, the RDE and HMRDE curves should superimpose if the RDE and HMRDE current data are properly weighted. This weighting was accomplished during the experiment by adjusting the $\bar{i}$ and Δi current scales so that the chart recorder pen deflection for $\bar{i}_L$ equaled that for Δi_L. As is seen in Fig. 2, the RDE and curves do essentially superimpose as required for a reversible system.

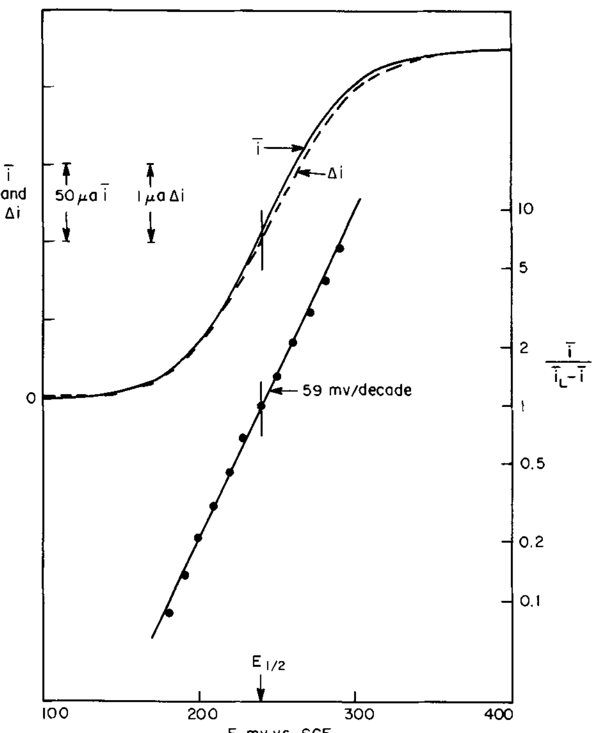

Fig. 2. RDE and HMRDE current-potential curves (left ordinate) for the oxidation of 1.57 mM $Fe(CN)_6^{-4}$ in 1M KCl at a 0.178 cm^2 gold disk. Logarithmic analysis of RDE curve also given (right ordinate). Potential scan rate = 0.5 mV/sec, averaging time constant = 2 sec, rotation speed = 3600 rpm, $\Delta\omega^{1/2}$ = 1.3 $rpm^{1/2}$, modulation frequency = 3 Hz. Current sensitivities, $E_{1/2}$, and log slope as marked.

Reduction of Pd(II).—The RDE and HMRDE curves for the reduction of 1.01 m*M* K_2PdCl_4 in 2*M* KCl are given in Fig. 3. These curves are appreciably different in shape and clearly do not superimpose as they would for a reversible system. Figure 4 gives normalized plots of these data for comparison with the theoretical predictions, *i.e.*, the RDE curve is plotted as $\bar{i}/\bar{i}_L$ *vs.* *E*, while the HMRDE data are plotted in two forms, that for the reversible case, $\Delta i/\Delta i_L$ *vs.* *E*, and that for the irreversible one, $\sqrt{\Delta i/\Delta i_L}$ *vs.* *E*. The irreversible HMRDE plot virtually superimposes on the RDE data for $\bar{i}/\bar{i}_L > 0.35$, while there is no agreement of the reversible HMRDE plot with the RDE data at any potential outside of the limiting current region. A gold disk electrode was used in this experiment, and the deviation at the lower part of the reduction wave probably arises because the palladium activity on the surface varies until the gold is entirely covered.

The data for the fully covered, palladium electrode ought then to conform to the expectations of a totally irreversible cathodic reaction, case 3 in the theoretical section, for metal ion reduction. Thus,

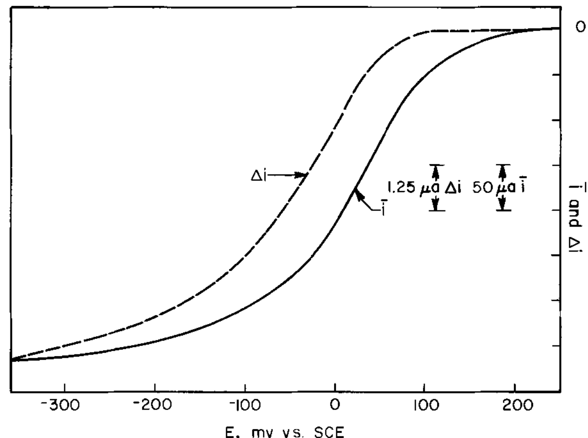

Fig. 3. RDE and HMRDE curves for the reduction of 1.01 mM K_2PdCl_4 in 2M KCl. Potential scan rate = 1 mV/sec, averaging time constant = 1 sec, rotation speed = 3600 rpm, $\Delta\omega^{1/2}$ = 1.6 $rpm^{1/2}$, modulation frequency = 3 Hz.

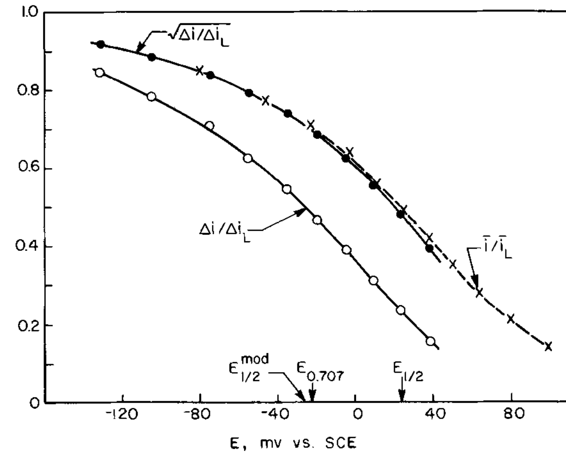

Fig. 4. Normalized Fig. 3 current plots, $\bar{i}/\bar{i}_L$ and $\Delta i/\Delta i_L$, vs. potential. Calculated plot of $\sqrt{\Delta i/\Delta i_L}$ also shown. Ordinate common to the three current functions. Values of $E^{mod}{}_{1/2}$, $E_{0.707}$, and $E_{1/2}$ indicated on abscissa.

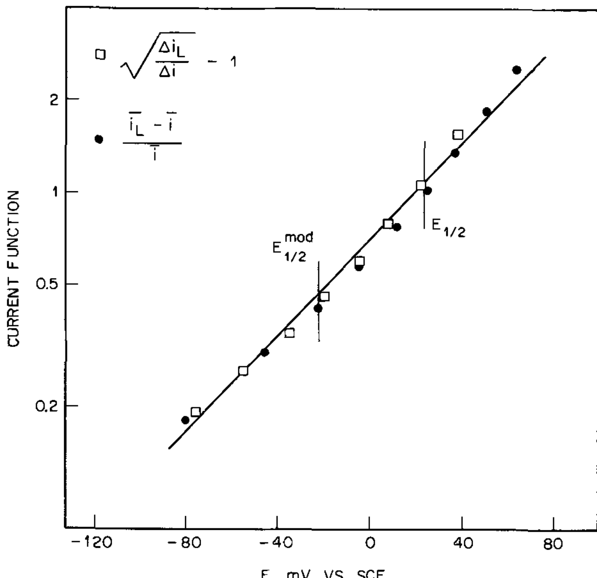

Fig. 5. Plots of $(\bar{i}_L - \bar{i})/\bar{i}$ and $\sqrt{\Delta i_L/\Delta i} - 1$ vs. potential for Fig. 3 data. $E_{1/2}$ and $E^{mod}_{1/2}$ as indicated on plot.

these i-E data are plotted logarithmically against potential according to Eq. [20] and [21] in Fig. 5. The RDE and HMRDE data are coincident, within the experimental scatter and the anticipated small shift due to the response lag of a 1 mV/sec scan rate and a 1 sec averaging time constant in the modulation current electronics. The average line thus drawn has a slope of 130 mV/decade. This corresponds to $\alpha_c = 0.45$. α_c can also be obtained using Eq. [22]. From Fig. 4, $E_{1/2} - E^{mod}{}_{1/2} = +50$ mV, hence $\alpha_c = 0.45$, in agreement with the estimate from the RDE data. This agreement is significant because it shows that the value of α obtained by varying E at constant ω is the same as the value obtained by varying ω at constant E.

Reduction of Fe(III).—The general case of mixed electron and mass transfer control was tested with Fe(III) reduction in 0.1*M* HCl-1*M* NaCl at a gold disk. This system had been previously examined under identical solution and electrode conditions by means of the technique of isosurface concentration voltammetry (3).

A potential scan showing the normalized $\Delta i - E$ and $\bar{i} - E$ curves at 1.94 m*M* Fe(III) is given in Fig. 6. A clear separation between the Δi and $\bar{i}$ curves is shown, particularly near the limiting current region. The data were actually scaled by rotation speed adjustment to superimpose the limiting currents, Δi_L and $\bar{i}_L$, in the recorded traces. Included in Fig. 6 is a calculated curve of $(\bar{i}/\bar{i}_L)^2$, clearly well separated from the measured $\Delta i/\Delta i_L$ result with which it would have superimposed in the irreversible case. Similarly, considering Eq. [19], $\sqrt{\Delta i/\Delta i_L}$ is well separated from the unmodulated result. This implies that the general relationship of Eq. [12] may be needed to interpret the data and the k_E and $\omega_o{}^{1/2}$ are comparable quantities, rather than one or the other being dominant as in the limiting cases already discussed. The departure from reversibility, case 2, is much more apparent from the difference between the $\Delta i/\Delta i_L$ and $\bar{i}/\bar{i}_L$ curves in Fig. 6 than it is from the slope of a conventional E vs. log $[(\bar{i}_L - \bar{i})/\bar{i}]$ plot, which gives 67 mV/decade, not far from the reversible 59 mV/decade. Thus, the comparison of modulated and conventional currents, when scaled as described, is a useful diagnostic test for the presence of a departure

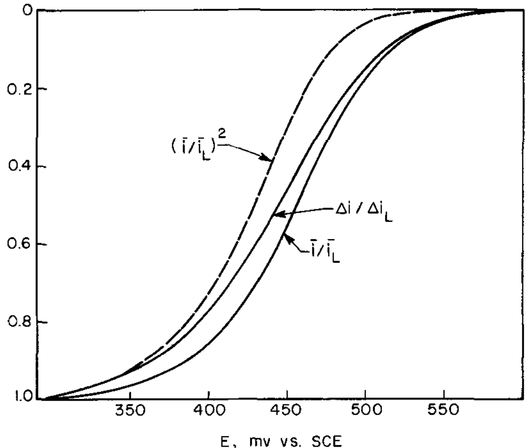

Fig. 6. Normalized current plots, $\bar{i}/\bar{i}_L$ and $\Delta i/\Delta i_L$, vs. potential for RDE and HMRDE reduction of 1.94 m*M* Fe(III) in 0.1*M* HCl-1*M* NaCl at 0.178 cm² gold disk. Calculated plot (dashed line) of $(\bar{i}/\bar{i}_L)^2$ also shown. Cathodic potential scan rate = 1 mV/sec, averaging time constant = 1 sec, rotation speed = 3600 rpm, $\Delta\omega^{1/2}$ = 1.3 rpm$^{1/2}$, modulation frequency = 3 Hz. Actual current values $\bar{i}_L$ = 250 μA, Δi_L = 5.00 μA, on original recording.

from mass transfer control, *i.e.*, some kinetic factor in the $\bar{i}$-E behavior.

In order to test Eq. [13], the following experiment was carried out at a set of 10 fixed potentials on the rising part of the wave and at one potential in the limiting current region. A fixed, small $\Delta\omega^{1/2}$ (about 1 rpm$^{1/2}$) was chosen and $\omega_o{}^{1/2}$ slowly scanned linearly with time so as to retain effective hydrodynamic equilibrium (1) over a considerable range of $\omega_o{}^{1/2}$. Concurrently Δi and i were measured and recorded *vs.* $\omega_o{}^{1/2}$. The gold disk was held at +800 mV *vs.* SCE between $\omega_o{}^{1/2}$ scans to activate the surface by slight anodic etching and cleaning.

Several plots of Eq. [13] for this experiment are shown in Fig. 7 for the range of $\omega_o{}^{1/2}$ from 40 to 90 rpm$^{1/2}$. The scan data for the run at the limiting current (E = 0.00V *vs.* SCE), included in Fig. 7, were used to confirm the lower $\omega_o{}^{1/2}$ limit (~40 rpm$^{1/2}$),

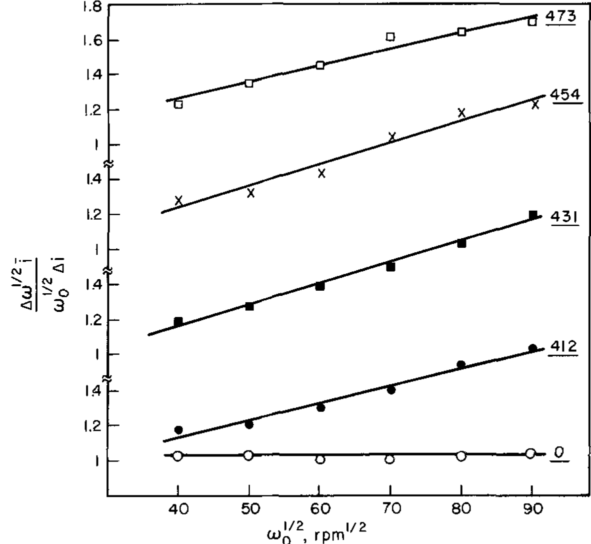

Fig. 7. Plots of $\Delta\omega^{1/2}\,\bar{i}/\omega_o{}^{1/2}\,\Delta i$ vs. $\omega_o{}^{1/2}$ for Fe(III) system of Fig. 6. Constant potential in millivolts vs. SCE for each $\omega_o{}^{1/2}$ scan shown at right of corresponding line. Fixed $\Delta\omega^{1/2}$ of 1.09 rpm$^{1/2}$ for each scan. Rotation speed scan rate = 0.25 rpm$^{1/2}$/sec, averaging time constant = 4 sec, modulation frequency = 1 Hz.

above which Levich conditions were met for the experiment. It further served to check the predicted unit value of the ordinate and the zero slope of the plot of Eq. [13] in the limiting condition of $k_E >> \omega_o^{1/2}$. In that case, trace O in Fig. 7, a least squares fit gave $1.019 + 0.00014\ \omega_o^{1/2}$. The value of 1.019 is in excellent agreement with the expected value of one, especially considering the data were not corrected for a typical loss of 2% in Δi due to the filtering network, which would account for the total difference. The slope is nearly zero (*i.e.*, $k_E \sim 7000$), as expected. The plots for the other representative potentials shown are acceptably linear in the measured region of $\omega_o^{1/2}$, although the extrapolations all fall below unity at $\omega_o^{1/2} = 0$, for reasons that are presently unresolved.

Figure 8 shows a plot of the values of k_E determined from slopes of the least squares fits according to Eq. [13] *vs.* potential, for all 10 potentials employed. The range of potentials in Fig. 8 is 82 mV and includes the Fe(III)/Fe(II) standard potential in this medium, which was estimated from the 1*M* HCl formal potential to be ~0.45V *vs.* SCE.

Previous limiting current measurements in this system (3) gave $L_{red}/L_{ox} = 1.06$, from $D_{Fe(II)} = 5.58 \times 10^{-6}$ cm²/sec and $D_{Fe(III)} = 5.12 \times 10^{-6}$ cm²/sec. These are sufficiently close in magnitude to allow approximating an average Levich constant by their arithmetic mean, L_{avg}, of 2.3 A-cm³/mole-rpm$^{1/2}$. The kinetic parameters for this system were determined previously using the independent rotating disk method of isosurface concentration voltammetry, and gave $k_o = 5.6 \times 10^{-3}$ cm/sec and $\alpha = 0.48$ (3). This value of k_o and the above L_{avg} yield a calculated k_{E° of 83 rpm$^{1/2}$ assuming $E^\circ = 445$ mV *vs.* SCE, $L_{red} = L_{ox} = L_{avg}$, and $\alpha = \frac{1}{2}$. k_E may readily be calculated from Eq. [7] as a function of potential and such a plot is shown as the dashed line in Fig. 8. Also shown in Fig. 8 are the experimental points obtained in this study. Within experimental error, the agreement of the present theory and experiment with the previous values of $k_o = 5.6 \times 10^{-3}$ cm/sec and $\alpha = 0.48$ is satisfactory.

The repeated electrode activation steps required in this experiment produced a gradual trend toward higher k_E values with time because the etching pretreatment at +800 mV *vs.* SCE roughened the electrode surface. Probably, it is the major source leading to scatter in the k_E *vs.* E plot. For example, three of the four points above the dashed line in Fig. 8 result from the last three experiments. Similar activation sensitivity was noticed in the previous study (3), where it was found that, without the anodic pretreatment, the electrode surface is both less active and less reproducible during constant potential experiments.

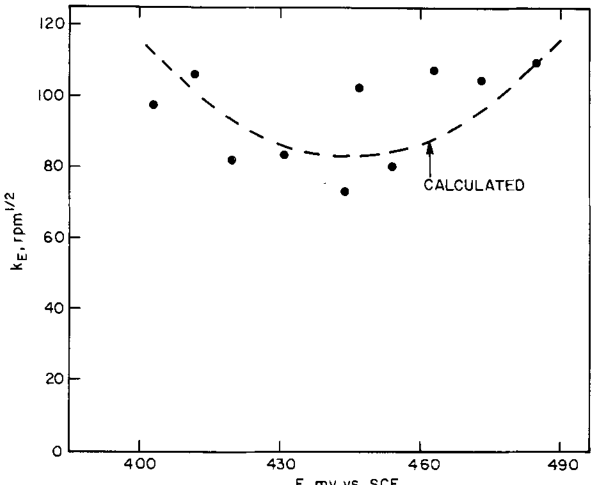

Fig. 8. Values of k_E from least squares slope of Fig. 7 type plots vs. potential. Dashed line calculated (see text) with k_E taken as 83 at 445 mV vs. SCE.

At the E° of the Fe(III)/Fe(II) couple, $k_{E^\circ} = 83$ rpm$^{1/2}$ and the factor $k_E/(k_E + \omega_o^{1/2})$ in Eq. [12] would be ½ at a rotation speed of $(83)^2$ or about 6900 rpm. Considering this and the fact that both constant speed and hydrodynamic modulation data begin to deviate from convective-diffusion theory below about $(20)^2$ rpm, it is clear that mixed mass and electron transfer control will be seen for this couple at all feasible rotation speeds.

The average literature value (4) for k_o in the $Fe(CN)_6^{-3}/Fe(CN)_6^{-4}$ system is at least ten times higher than that of the Fe(III)/Fe(II) system in Cl^- media at gold. This higher value of k_o accounts for the essentially reversible appearance of the $Fe(CN)_6^{-4}$ wave in the modulation experiment depicted in Fig. 2. A rotation speed of the order of 40,000 rpm would be required before significant effects due to kinetics would be observable.

Summary and Conclusions

A theoretical analysis of superimposed sinusoidal modulation of the rotation speed of a disk electrode for the situation of mixed mass and electron transfer control of the electrode current has been carried out and has been shown to yield relatively simple forms for the modulated current response as a function of potential, rate and transport parameters, and concentration of electroactive species. These results have been confirmed experimentally for the limiting cases dominated by either electron or mass transfer kinetics and for the general case of mixed control.

The significance of the hydrodynamic modulation technique for obtaining kinetic parameters with the RDE becomes particularly evident when its unique application to situations obscured in conventional RDE approaches by interfering contributions to the total current is considered. As has been shown in an application to trace electroanalysis (2), convective-diffusion limited currents may be isolated by HMRDE methods from, among others, currents due to purely surface processes, double layer charging processes, and irreversible supporting electrolyte reactions. By the use of the transformations of Δi and $\bar{i}$ discussed in this paper, considerable information may be obtained about the current-potential relation of many reactions that are inaccessible to ordinary solid electrode voltammetric techniques. Further applications will be considered elsewhere (5). It may also be noted that, even for simple conditions in which conflicting sources of current are absent, the ratio of modulated current to average current has a marked diagnostic sensitivity and produces an attractive direct readout convenience for the detection of kinetic complications, when compared to other means of analyzing voltammetric curves.

Precipitation and Dissolution Potentials of Electrolytes in D_2O, Acetone, and Formamide

R. P. Rastogi, R. D. Shukla,[1] and S. Bhagat[2]

Department of Chemistry, University of Gorakhpur, Gorakhpur, Uttar Pradesh, India

ABSTRACT

Precipitation, dissolution, diffusion, and phase potentials of KCl, KBr, and NaCl have been measured in D_2O, acetone, and formamide in nitrogen atmosphere. The techniques adopted were similar to those used previously by Rastogi and Shukla for KCl, NaCl, $BaCl_2$, and NH_4Cl in H_2O. The true dissolution and precipitation potentials were found to be negative for KCl and NaCl in H_2O and D_2O (smaller numerically in the latter) and for KBr in D_2O. However, the dissolution potential of KCl and KBr in acetone and formamide and of NaCl in acetone is positive and of higher magnitude. The temperature, concentration, and time dependence of the dissolution potentials have been investigated. The decay of the precipitation potential and of the apparent diffusion potential with time has been studied. The experimental results show that the precipitation potential increases with undercooling. The transport number of K^+ and Br^- in formamide has also been measured. The results support the hypothesis that the precipitation and dissolution potentials arise on account of the unequal mobilities of the ions moving to and away from the crystal face.

A comprehensive study of the precipitation and the dissolution potentials of several chlorides in H_2O has been reported in a recent communication (1). These potentials were discovered by Rastogi, Dass, and Batra (2) in 1961. It has been pointed out that these potentials arise because of the unequal mobilities of the ions being incorporated into or detached from the crystal lattice (1). These mobilities would depend on the crystal binding energy and the medium. Obviously, for the same electrolytes, the sign as well as the magnitude of the potentials would be determined by the nature of the medium. Accordingly, the present investigation was undertaken. D_2O, acetone, and formamide were chosen as the solvents. D_2O was chosen since it is known that the ionic mobility of K^+ is considerably reduced (3) in D_2O, while the latter two were chosen since the cationic mobility for several electrolytes is known to be less than the anionic mobility in acetone and formamide. For the detailed study experiments were made with KCl, KBr, and NaCl. In order to assess the ionic mobilities of KBr in formamide, transport number measurements were made in this system.

When the crystallization or dissolution of an electrolyte occurs on a bright platinum electrode surface, concentration and temperature gradients tend to be developed in the region near the electrode on which these processes are occurring. These tend to give rise to diffusion and thermodiffusion potentials. The observed P.D. measured relative to a bare bright platinum electrode dipping in the same medium and corrected for any asymmetry potentials between two electrodes would include Nernst and phase potentials at the solution/crystal interface. Thus, the observed P.D. would be made up of the true precipitation or dissolution potential, the apparent diffusion potential, the thermodiffusion potential, the phase potential, and the Nernst potential as defined in the Appendix. In order to estimate the true precipitation or dissolution potential, these potentials have to be measured experimentally or estimated from theory. For this purpose, the apparent diffusion potential and the phase potentials have been measured. The thermodiffusion potential and the Nernst potential are found to have low magnitude and therefore these can be neglected. In order to throw light on the mechanism, the temperature and concentration dependence of the dissolution potential in the temperature range 10°-95°C and in the concentration range 0.0001-2.0M have been investigated.

Experimental

Materials.—B.D.H.(A.R.)KCl, KBr, and NaCl were purified by recrystallization in conductivity water. Acetone was purified by the method described by Weissberger and Proskauer (4). Heavy water of isotopic purity >99.4% supplied by Bhabha Atomic Research Centre (India) was used without any further purification. The density of acetone at 30°C was 0.7794 g/cm^3 [literature (5) 0.7793]. Formamide (E. Merck) was purified by distillation under reduced pressure three to four times. It was further purified by fractional crystallization. The specific conductivity and density of a purified sample were $1.0\text{-}1.5 \times 10^{-5}$ ohm^{-1} cm^{-1} and 1.1296 g/cm^3, respectively. The corresponding values reported in the literature (6) are $0.9\text{-}1.5 \times 10^{-5}$ ohm^{-1} cm^{-1} and 1.1296 g/cm^3. It was stored in a dry nitrogen atmosphere.

Platinum electrodes.—Platinum electrodes as described earlier (1) were used in this investigation. The asymmetry potential was estimated for each run.

Measurement of potentials.—Because of the high resistance of the system (about 10^7-10^{10} ohms) under investigation a Lindemann electrometer was used for the measurement of the potentials. In order to annul the effects of stray external fields, coaxial cables were used. The experimental cells for the measurement of the dissolution potential, the precipitation potential, the apparent diffusion potential, and the phase potentials were similar to those described earlier (1). All the measurements were made in a nitrogen atmosphere. The decay of the dissolution, precipitation, and diffusion potentials with time was studied. The effect of temperature and solute concentration on the magnitude of the potentials in the three solvents was also investigated. The consistency of the phase potential was checked from the decay experiments as described earlier (1).

Measurement of transport number of K^+ in formamide.—A conventional Hittorf's apparatus as modified by Steel and Stokes (7) was utilized. Platinum electrodes in the form of a helix were used. These

Table I. Transport number of K^+ in solution of KBr in formamide

Temperature = 30°C; C_1 (eq dm^{-3}) = 0.07788

Run	C_2 (eq dm^{-3})	q (coulombs)	V (cm^3)	t_{K^+}
1	0.083566	39.6410	31.642	0.4380
2	0.082626	32.8676	31.502	0.4389
3	0.081316	23.8442	31.642	0.4400
4	0.082356	31.3140	31.682	0.4370
			Mean	0.4385 ± 0.0010

were coated with silver and one of the electrodes to be used as cathode was subsequently reduced to silver bromide electrolytically.

Stable current for electrolysis (4-5 mA for 3-4 hr) was obtained using a storage cell and an electronic current stabilizer. The current was measured by a Leeds and Northrup potentiometer employing a sensitive galvanometer across a standard 100 ohms resistance placed in series with the experimental cell. The total current could be estimated correct to ±0.01%.

The change in concentration was estimated by conductivity measurements. When the current was switched off the specific conductance of the solution was determined. In order to estimate the change in concentration, a measured quantity of the original solution was taken in a conductance cell. A known amount of concentrated solution was added dropwise from a weight pipette until the specific conductance of the solution became exactly equal to that of the cathode solution. Since the concentration of the solution added was known, the change in concentration could easily be estimated. This procedure is simple and straightforward but it is not very accurate since the specific conductance is very small and is not very sensitive to changes in concentration. However, it is adequate for the present investigation.

The transport number of the cation t_{K^+} was estimated from the equation

$$t_{K^+} = \mathbf{F}(C_2 - C_1)V/1000q \quad [1]$$

where $\mathbf{F}$ is the Faraday, C_1 and C_2 are initial and final concentrations in eq dm^{-3}, q is the quantity of electricity in coulombs, and V is the volume of the cathode compartment expressed in cubic centimeters. The results of the transport number measurements are summarized in Table I.

Results.—The observed dissolution and precipitation potential, the phase potential, and the apparent diffusion potentials of electrolytes are recorded in Table II. The results on the transport number of K^+ in a solution of KBr in formamide are recorded in Table I.

Discussion

Following the operational definition of the different types of potentials described in the Appendix, the true precipitation and the true dissolution potentials would be given by the following

True dissolution potential = Observed dissolution potential − (Phase potential + Apparent diffusion potential + Nernst potential − Thermodiffusion potential) [2]

True precipitation potential = Observed precipitation potential − (Phase potential − Theoretical diffusion potential − Nernst potential + Thermodiffusion potential) [3]

For a typical case of KCl in D_2O the thermodiffusion potential for ΔT = 12.5 kelvins was experimentally found to be 1.57 mV. The Nernst potential at 30°C for C_1 = 5.01 mol/liter and C_2 = 4.38 mol/liter was calculated to be 3.51 mV. Since these are much smaller than the experimental uncertainty we can write

True dissolution potential = Observed dissolution potential − (Phase potential + Apparent diffusion potential) [4]

Thermodiffusion and Nernst potentials would also have a much smaller magnitude for the case of the precipitation potential. Further the calculated diffusion potential is found to be +0.0385 mV when C_1 = 5.01 mol/liter and C_2 = 4.38 mol/liter in the case of KCl in D_2O. Since this can also be neglected, we have

True precipitation potential = Observed precipitation potential − Phase potential [5]

Using Eq. [4] and [5], the true precipitation and dissolution potentials can be estimated from the experimental data. These are recorded in Table II in columns 8 and 9.

The results recorded in Table II lead to the following conclusions:

1. The true dissolution potential of KCl and NaCl (Table II) is negative in H_2O and D_2O but has a lower magnitude in D_2O. However, in acetone[3] and formamide, the potentials are positive and considerably larger in magnitude.

2. The true precipitation potentials of KCl, KBr, and NaCl (Table II) have the same sign (negative) and magnitude both in D_2O and H_2O within experimental error.

3. The phase potential has similar sign (negative) in D_2O, H_2O, and acetone but in acetone the magnitude is quite high. However, in formamide the phase potential is positive.

The magnitude of the dissolution potential decreases with the increase in temperature in D_2O. The data are plotted in Fig. 1. The behavior is similar to that ob-

[3] Preliminary measurements were made by Prashant Rastogi.

(a) Saturation temperature = 50°C, undercooling of the experiment = 12 kelvins.
(b) This work.
(c) When the Nernst potential (3.355 mV) and the thermodiffusion potential (1.57 mV) for KCl in D_2O are taken into account the true dissolution and precipitation potentials would be equal to −56.79 mV and −47.177 mV, respectively. The difference between these and the values in the last column in this table is well within the experimental error.
(d) Rastogi and Shukla (1).

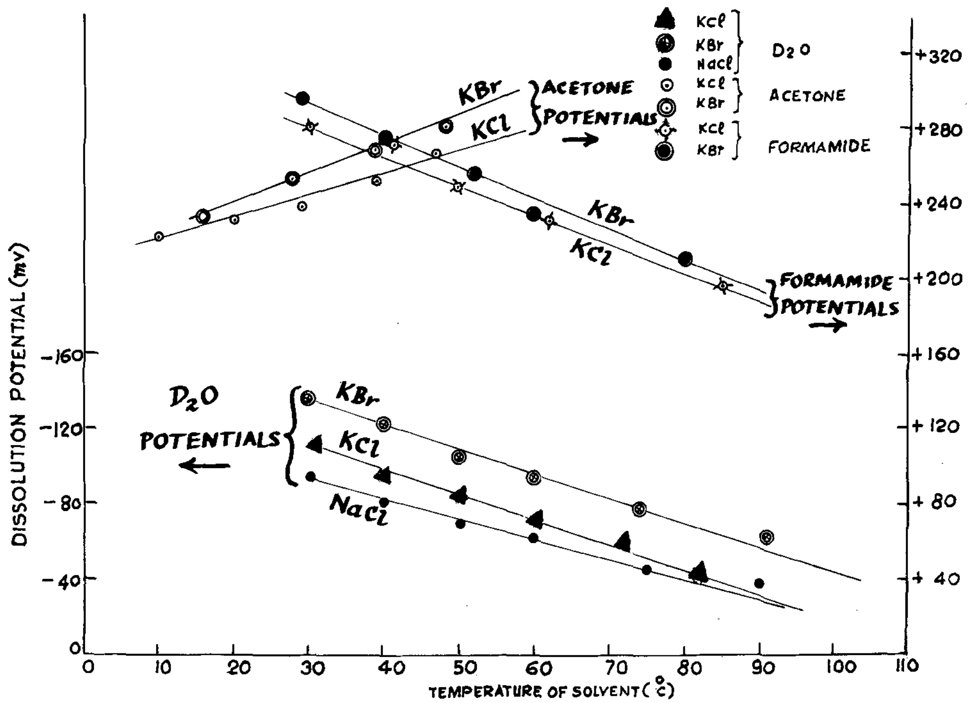

Fig. 1. Dependence of dissolution potential on temperature. (Minus scale on left refers to D_2O and plus scale on right to acetone and formamide.)

served in H_2O earlier (1). As expected (1), the dissolution potential also decreases with the increase in molarity of the solution (Fig. 2). The disssolution potential decays exponentially with time (Fig. 3) in conformity to the behavior observed in water. Similar is the decay behavior in acetone (Fig. 4). The precipitation potentials of KCl, KBr, and NaCl in D_2O (Fig. 5) increase (in the negative direction) with the increase in the degree of undercooling below the saturation temperature of 50°C. The precipitation potentials of KCl, KBr, and NaCl decay exponentially, the plot of log $|\Delta\phi|$ against time is a straight line (Fig. 6) where $\Delta\phi$ = observed precipitation potential − phase potential. The decay of the apparent diffusion potential with time is plotted in Fig. 7, which shows a similar pattern. The plot of the logarithm of the apparent diffusion potential against time gives a straight line (Fig. 8) as is found in the case of H_2O (1). This behavior is similar to the decay of a condenser through a resistance.

The apparent dissolution potential of KCl, KBr, and NaCl decays exponentially with time in D_2O and acetone (Fig. 3 and 4). The trend is similar in formamide (Fig. 9). The decay curve is similar to that observed for the diffusion potential (Fig. 8) showing that the functional dependence of both the diffusion and the dissolution potential on an electrolyte concentration which is varying with time, is perhaps similar. This is further confirmed by the study of the dependence of the dissolution potential on the concentration of the medium in which the dissolution takes place. Figure 10 shows that the plot of the dissolution potential *vs.* the logarithm of concentration is a straight line. The slopes for KCl, KBr, and NaCl are 21.8, 26.0, and 9.26 mV, respectively, whereas the Nernst slope (2.303 RT/F) is equal to 60.16 mV at 30°C.

The above results can easily be explained in the light of the mechanism postulated by Rastogi and Shukla (1) which is as follows. In a growing crystal, anions and cations separately migrate to the solution/crystal interface and get attached to the lattice. Both ions do not get attached to the growing crystal simultaneously because of the unequal mobilities of the ions. Hence, a certain P.D. is developed. In the case of dissolution, there would be a competition between the two ions to get detached from the lattice which would ultimately be responsible for the development of P.D.

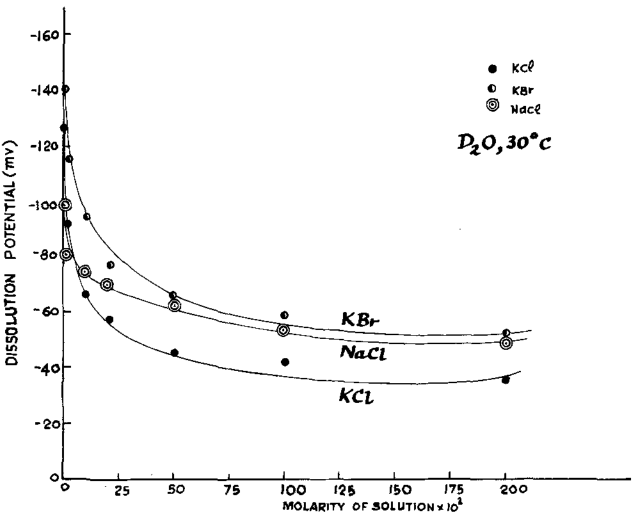

Fig. 2. Dependence of dissolution potential on the concentration of solution.

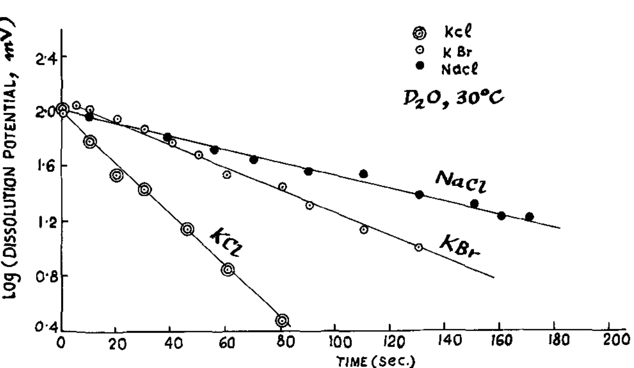

Fig. 3. Dependence of dissolution potential on time in D_2O

The values of ionic mobilities are recorded in Table III. From Table III, it is obvious that (*i*) the precipitation potential and the dissolution potential of the alkali

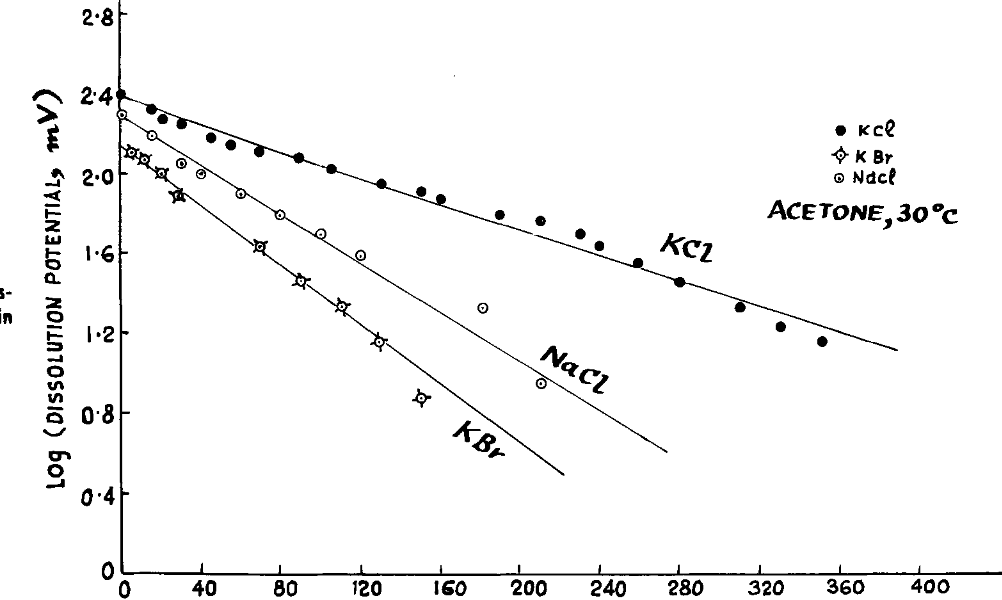

Fig. 4. Dependence of dissolution potential on time in acetone.

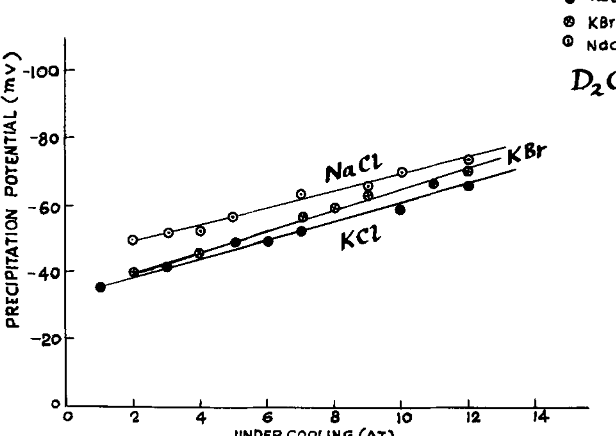

Fig. 5. Dependence of precipitation potential on undercooling. Saturation temperature 50°C.

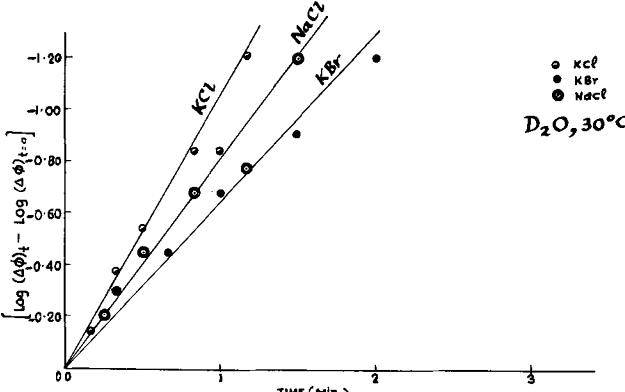

Fig. 6. Plot of $\log|\Delta\phi|_t - \log|\Delta\phi|_{t=0}$ vs. time where $|\Delta\phi|$ is the absolute value of $\Delta\phi$ = observed precipitation potential — phase potential.

halides in D_2O are negative and (*ii*) the magnitude is about half the corresponding value for water. As pointed out above these potentials arise because of the unequal mobilities of the ions moving to and away from the lattice. The mobility of the halide ion is greater than the metal ions and the former also has less tendency for hydration. Hence, the electrode on which crystallization is taking place would be negative. However, during dissolution, cations would leave the lattice faster on account of hydration and hence the dissolution occurs on the negative electrode. Since the magnitude of $(U_{K^+} - U_{X^-})$ is less in D_2O as compared to that in H_2O, the magnitude of the precipitation and dissolution potentials is less in D_2O as compared to water. X^- represents the halide ion.

The results obtained in the case of acetone as the medium can also be explained on the basis of the hypothesis suggested earlier (1). The values of the ionic mobilities of K^+ and Cl^- in acetone, recorded in Table III, show that in acetone the chloride ion moves faster than the cation. This trend is also observed for other electrolytes in acetone. On account of this fact as well as the fact that the ions have less tendency to be solvated in acetone as compared to water, the dissolution potential would be expected to be positive as is found to be the case. Further, since the difference between the ionic mobilities of the cation and the anion is much greater as compared to the other case, the magnitude of the dissolution potential is higher. This is also the situation in formamide (cf. Table I).

It is therefore clear that the dissolution potential and the precipitation potentials depend on (*i*) temperature, (*ii*) time, (*iii*) concentration of the medium, and (*iv*) nature of the electrolyte. It would be worthwhile to guess the functional dependence. Results for the dissolution potential in D_2O, acetone, and formamide show (*i*) linear dependence on temperature, (*ii*) exponential dependence on time, (*iii*) linear dependence on the logarithm of the concentration of the medium, and (*iv*) dependence on the nature of the electrolyte which probably governs the relative speed of detachment or attachment of the ions on the crystal lattice. Evidently the precipitation and dissolution po-

* The values agree with that estimated from ionic conductance at infinite dilution (11) and transport number (12).

tentials depend on temperature, concentration, and time in the same manner as in the case of the diffusion potential. Exponential dependence of potentials on time would somehow be related to the capacitative-resistive properties of the system. Linear dependence on log concentration would appear to tie in with the Nernst equation but the slope is not identical with the Nernst slope.

Since the speeds of attachment and detachment of the ions on the crystal lattice are not known, we may assume in the first instance that these are related to ionic mobilities. Accordingly, the true precipitation and dissolution potential would be related either to $U - V$ or $(U - V)/(U + V)$ where U is the mobility of cation and V that of anion at infinite dilution. The latter factor is known to be important in diffusion potentials. In Table IV values of $U - V$ and $(U - V)/(U + V)$ for KCl in various solvents have been recorded. Keeping in view the fact that the dissolution potential decreases with an increase in temperature in D_2O and formamide, it is obvious from Table IV that the dissolution potential would be related to $(U - V)/(U + V)$ and not to $U - V$ since the former decreases with a rise in temperature. In acetone, the dissolution potential increases with an increase in temperature. Here again Table IV clearly indicates that the dissolution potential would be related to $(U - V)/(U + V)$ and not to $U - V$. Further studies are needed to corroborate the above conclusions.

Table IV. Variation of $U - V$ and $(U - V)/(U + V)$ with temperature in different solvents for KCl

Solvent	T °C	$(U - V) \times 10^5$	$(U - V)/(U + V)$
D_2O (13)	18	−1.471	0.0134

Acknowledgments

The authors are grateful to C.S.I.R. (India) for supporting the investigation. We wish to thank Dr. Kehar Singh for useful discussions.

Manuscript submitted June 15, 1972; revised manuscript received June 6, 1974.

Any discussion of this paper will appear in a Discussion section to be published in the June 1975 JOURNAL. All discussions for the June 1975 Discussion Section should be submitted by Feb. 1, 1975.

APPENDIX

Dissolution potential.—Operational definition—The dissolution potential is the potential of a platinum electrode coated with a uniform thick layer of an electrolyte deposited by controlled crystallization from a solution of the electrolyte saturated at 75°C and dipped mechanically in a cell filled with conductivity water, measured by reference to the potential of another similar bare platinum electrode dipping in the same conductivity water. The observed dissolution potential is corrected for any asymmetry (bias) potential existing between the two platinum electrodes as determined before and after the dissolution run. The potential difference is measured electrostatically by means of a Lindemann electrometer.

Conceptual definition.—The dissolution potential is the potential difference arising from an electrical double

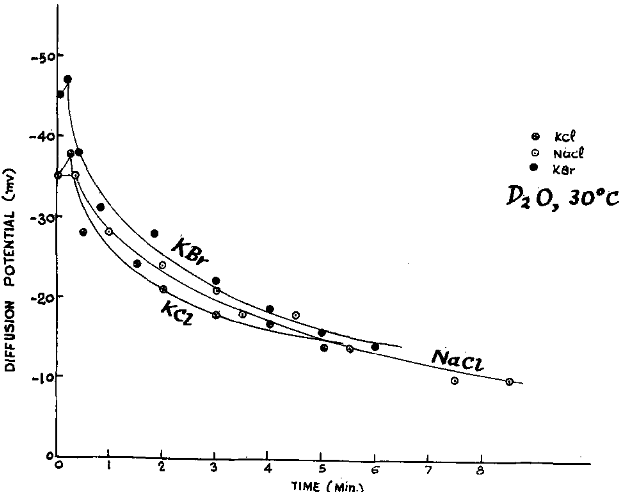

Fig. 7. Decay of diffusion potential in D_2O

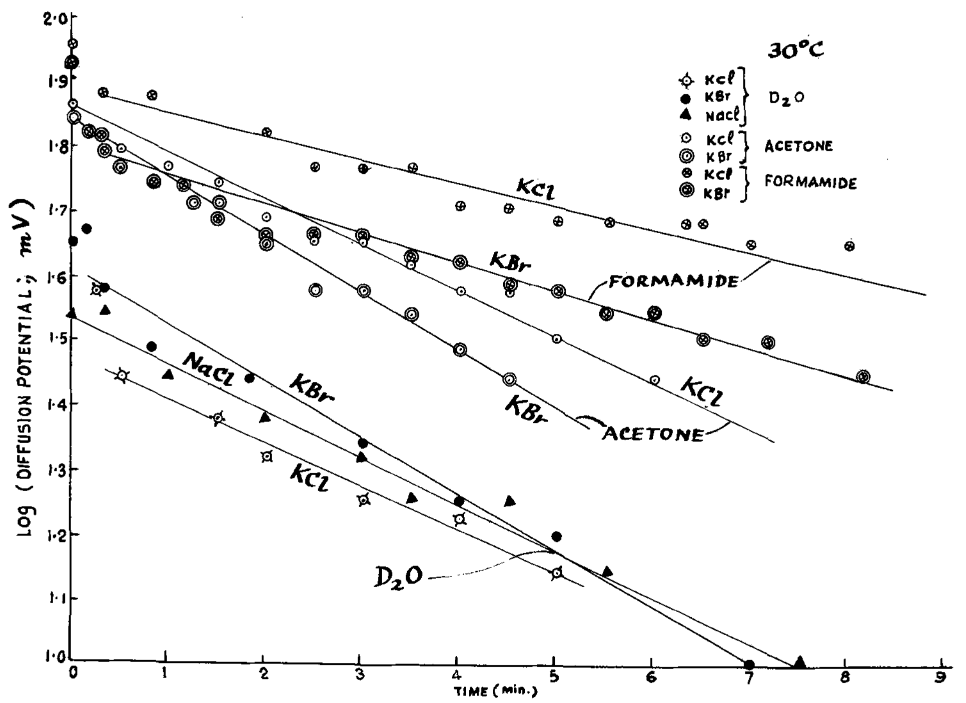

Fig. 8. Dependence of diffusion potential on time.

layer developed at a liquid/crystal interface by the process of crystal dissolution (ion migration) into the liquid phase. The algebraic sign of the dissolution potential is the same as the electrostatic polarity, (+) or (−), of the end of the dipolar double layer on the crystal side of the interface.

Precipitation potential.—Operational definition.—The precipitation potential is the potential of a platinum electrode coated with a layer of an electrolyte deposited by crystallization from a supersaturated solution at a temperature T less than the saturation temperature T_s. $T_s - T$ is called the degree of undercooling. The reference potential is a similar bare platinum electrode which is dipped in the above supersaturated solution once the crystallization has started. The observed precipitation potential is corrected for any asymmetry potential existing between the two platinum electrodes before the precipitation run. The potential difference is measured electrostatically by means of a Lindemann electrometer.

Conceptual definition.—The precipitation potential is the potential difference arising from an electrical double layer developed at a liquid/crystal interface by the ion migration from the liquid phase. The algebraic sign of the precipitation potential is the same as the electrostatic polarity, (+) or (−), of the end of the dipolar double layer on the crystal side of the interface.

Phase potential.—Operational definition.—The phase potential is the potential of a platinum electrode coated with a uniform thick layer of an electrolyte deposited by controlled crystallization from a solution of the electrolyte saturated at 75°C, and dipped mechanically in a cell filled with saturated solution of the electrolyte

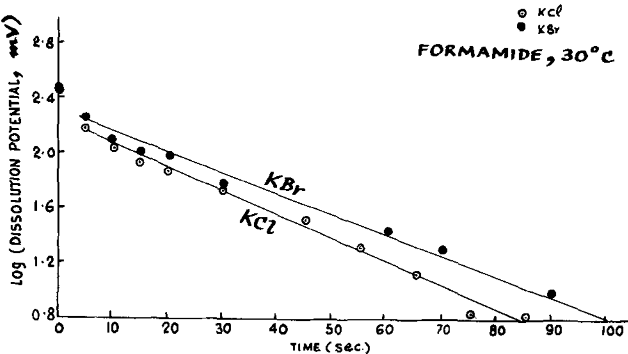

Fig. 9. Dependence of dissolution potential on time in formamide.

at the saturation temperature T_s. The phase potential is measured by reference to the potential of another similar bare platinum electrode dipping in the saturated solution. The observed phase potential is corrected for any asymmetry potential existing between the two platinum electrodes as determined before the run. The potential difference is measured electrostatically by means of a Lindemann electrometer.

Conceptual definition.—The phase potential is the potential difference arising from an electrical double layer developed at a liquid/crystal interface as a result of the dynamic equilibrium of ion migration from the liquid phase to the crystal phase and vice versa. The algebraic sign of the phase potential is the same as the electrostatic polarity, (+) or (−), of the end of the dipolar double layer on the crystal side of the interface.

Phase potential from decay.—Experiment.—Operational definition.—The phase potential from the decay experiment is the potential of a platinum electrode coated with a thick layer of an electrolyte dipped mechanically in a supersaturated solution when the concentration of the solution approaches the concentration corresponding to the saturation concentration at the temperature of observation. This situation is obtained when the observed potential attains a steady value on decay. The potential is measured by reference to the potential of another similar bare platinum electrode dipping in the saturated solution. The potential difference is measured electrostatically by means of a Lindemann electrometer.

Conceptual definition.—The conceptual definition of the phase potential from the decay experiment is the same as that of the phase potential.

Apparent diffusion potential.—Operational definition.—The apparent diffusion potential is the potential of a platinum electrode dipped mechanically in a cell filled with a saturated solution at a particular temperature, T_s. The potential is measured by reference to the potential of another similar bare platinum electrode dipping in pure solvent, the solvent being connected to the saturated solution by a narrow opening in the cell. The observed apparent diffusion potential is corrected for any asymmetry potential existing between the two platinum electrodes after the diffusion run. The potential difference is measured electrostatically by means of a Lindemann electrometer.

Conceptual definition.—The apparent diffusion potential is the potential difference arising at the interface of the solutions of two concentrations C_1 and C_2 by the process of ion migration from one solution to the other. The algebraic sign of the diffusion potential depends on the difference in the ionic mobilities of the ions leaving the dilute solution/concentrated solution inter-

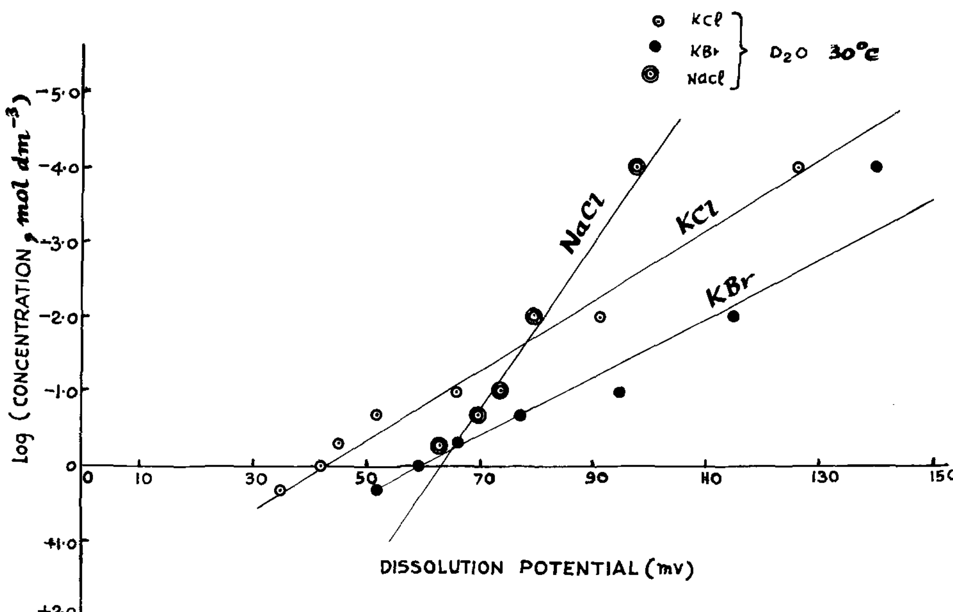

Fig. 10. Dependence of dissolution potential on the concentration in D_2O.

face. If cations move faster, the concentrated solution will be negatively charged.

Thermodiffusion potential.—Operational definition.— The thermodiffusion potential is the potential of a silver/silver chloride electrode kept in a solution of an electrolyte saturated at the ice-point ($T_s = 0°C$) and maintained at a temperature higher than that of the reference electrode (which is maintained at a temperature higher than 0°C). The thermodiffusion potential is related to the temperature difference ΔT. The observed thermodiffusion potential was corrected for any asymmetry potential by making the measurement for $\Delta T = 0$. The potential difference was measured by means of a Pye precision potentiometer.

Conceptual definition.—The thermodiffusion potential is the potential difference arising from the migration of ions at the interface of two solutions on account of temperature difference. The algebraic sign of the thermodiffusion potential depends on the difference in ionic mobility when a temperature difference is imposed in the system.

True dissolution potential.—Operational definition.— The true dissolution potential is given by the following equation

True dissolution potential = Observed dissolution potential − (Phase potential + Apparent diffusion potential + Nernst potential − Thermodiffusion potential)

In the above equation the Nernst potential is given by $(RT/\mathbf{F}) \ln C_1/C_2$, where C_1 and C_2 are the concentrations in the two regions ($C_1 > C_2$). The Nernst potential is the difference between the potential of the electrode in the concentrated solution and the potential of the electrode in the dilute solution. In most of the cases the calculated Nernst potential and the experimentally measured thermodiffusion potential are well within the experimental uncertainty in the observed dissolution potential and hence can be neglected.

Conceptual definition.—The conceptual definition of the true dissolution potential is the same as that given earlier for the dissolution potential.

True precipitation potential.—Operational definition. —The true precipitation potential is given by the following equation

True precipitation potential = Observed precipitation potential − (Phase potential − Theoretical diffusion potential − Nernst potential + Thermodiffusion potential)

where the theoretical diffusion potential is given by $-[(U - V)/(U + V)] (RT/\mathbf{F}) \ln C_1/C_2$. The theoretical diffusion potential is the potential at the dilute solution/concentrated solution interface so that the sign is determined with respect to concentrated solution. C_1 is the concentration of the supersaturated solution and C_2 is the concentration prevailing at the crystal interface, *i.e.*, the saturation concentration at the temperature of the experiment. The theoretical diffusion potential is usually found to be less than 1 mV and hence the sum of the theoretical diffusion potential, the Nernst potential, and the thermodiffusion potential can be neglected.

Conceptual definition.—The conceptual definition of the true precipitation potential is the same as that given earlier for the precipitation potential.

SYMBOLS

- t_{K^+} transport number of cation
- $\mathbf{F}$ Faraday, coulomb eq^{-1}
- C_1 initial concentration, eq dm^{-3}
- C_2 final concentration, eq dm^{-3}

and W. N. Hansen**

Physics Department, Utah State University, Logan, Utah 84322

ABSTRACT

A quantitative theory of the electrode surface conductance decrease caused by adsorbed ions is discussed that shows good agreement with the measured results. Conductance measurements are shown to provide a reliable measure of adsorbed ion surface concentration. The sensitivity of conduction measurements to adsorbing ions and surface free electron density changes is discussed. Changes in the adsorbed state are detected as a function of electrode potential. The conductance measurements are used to measure the ionic diffusion rate of I^- through an aqueous electrolyte.

Thin film electrode conductance measurements have proved to be a sensitive method of observing the electrode surface, *in situ,* in an electrochemical cell. This technique was first developed by Shimizu (1-3) to investigate the hydrogen evolution and dissolution mechanism at the platinum electrode. Bockris *et al.* (4) later used conductivity measurements to detect ionic adsorption from concentrated solutions on thin platinum films. Recently Niki and Shirato (5) have discussed the applicability of the electrode resistance measurements to detect the adsorption of organic compounds on thin gold electrodes. The resistance measurements have been shown to be sensitive to electrode charging (6, 7) and adsorption on the electrode surface (4, 8). As the electrode potential is varied, the relative change in conductance is equal to the relative change in the total number of conduction electrons in a metallic film. In addition to this effect, when point charges are adsorbed on the electrode surface, they increase the conduction-electron surface scattering thus causing a decrease in electrode conductance (9). The change in electrode conductance caused by the change in free electrons per unit of electrode area and the surface scattering can easily be detected in a thin film electrode, thus providing a sensitive method of observing fundamental electrode processes. All of our results have been obtained on thin (approximately 10 nm) gold and copper electrodes (8).

The purpose of this paper is to quantitatively develop the conductance theory for adsorbed ions, compare the results to measurements, and to demonstrate the versatility of conductance measurements in understanding ionic adsorption. The relative conductance change of a thin film electrode is shown to decrease linearly with the specifically adsorbed ion surface concentration, for small surface coverages. The magnitude of this conductance change is calculated from a previously developed theory of surface scattering and shown to be in good agreement with the measured values. The sensitivity of conduction measurements to electrode charging and ionic adsorption is derived as a function of the film thickness, free electron concentration, and conduction electron mean free path length.

The diffusion coefficient of I^- is calculated from the change in conductance as a function of time. Conductance measurements on thin film electrodes are shown to be useful as a fundamental electrochemical technique of monitoring the electrochemical interphase.

Key words: conductance, electrode surface, adsorption, thin film electrode.

Theory

The conductance of a thin film is a function of its free electron concentration, expressed in electrons per unit area, as can be seen from simple solid-state theory. Bonfiglioli *et al.* (10) have shown experimentally that the conductance of a thin gold film varies linearly with the film's charge. The conductance, G, of a thin gold film electrode has been shown to vary with the total number of conduction electrons per unit area, N, as

$$\Delta G/G = \Delta N/N \qquad [1]$$

where ΔG and ΔN are small changes in G and N, respectively (7).

The sensitivity of the conductance measurements, S_N, to a change in N can be defined as

$$S_N \equiv 1/(\Delta N)_{\text{min.}} = 1/(N\,\Delta G/G)_{\text{min.}} \qquad [2]$$

where $(\Delta N)_{\text{min.}}$ is defined as the minimum observable (ΔN).

$$S_N = (1/N)\,(G/\Delta G)_{\max} \qquad [3]$$

The minimum relative change in conductance that can be detected with our experimental setup is 10^{-4}. Then $(G/\Delta G)_{\max}$ is at least 10^4. For a 10 nm film with electron density of bulk gold (6×10^{22} cm^{-3}) then $N = 9.6 \times 10^{-3}$ coulomb/cm^2 and $S_N \cong 96$. S_N is increased by either decreasing N or by decreasing the fractional change in conductance that we can observe. For example, the maximum thickness of a gold film (bulk electron density of 5.9×10^{22} cm^{-3}) that can be used to detect a change in N is approximately 0.1 μm while for a semiconducting film such as tin oxide (electron density $\cong 10^{20}$ cm^{-3}) a 10 μm film can be used. The film thickness is limited even further if the temperature of the film does not remain constant as the current is changed although no problems have been observed in our measurements.

Conductance measurements provide a reliable method of quantitatively measuring the adsorbed ion concentration on an electrode surface. Several investigators (11-13) measuring adsorption from the gas phase have shown that the relative change in conductivity of thin metal films (10-40 nm thick) decreases in direct proportion to the fractional coverage of the adsorbed species. They attributed the decrease in conductivity to a localizing of the conduction electrons caused by the formation of chemical bonds.

Another effect that better explains conductance change is the surface scattering of free electrons caused by the adsorbed particles. The conductance of a thin

film is strongly dependent on the surface scattering of the free electrons when the film thickness is approximately equal to or less than the free electron mean free path length in the bulk material. Fuchs (14) has derived an expression for the conductance of a thin film as a function of the probability of specular reflection from the film surface by the conduction electrons, P, and their angle of incidence, θ. The conductivity, σ is

$$\sigma = \sigma_0 \left\{ 1 - (3/4) \int_0^\pi \sin^3\theta[1 - P]K'd\theta + (3/4) \int_0^\pi \sin^3\theta[1 - P]^2 K' \exp(-K') \times [1 - P\exp(-K')]^{-1} d\theta \right\} \quad [4]$$

where

$$K' = (\lambda_0/h)|\cos\theta|$$

σ_0 is the bulk conductivity, λ_0 is the electron mean free path length, and h is the film thickness. The derivation of Eq. [4] assumes elastic collisions with the surface.

The film surface roughness causes some inherent scattering that decreases the film conductivity. Adsorbed ions on the film surface cause bumps in the equipotential surfaces as shown in Fig. 1. These deformations increase the surface scattering thus decreasing the conductance. The adsorbed ions only have an effect approximately 0.1 nm into the metal because of the free electron screening. The electron wavelength for a metal such as gold is about 0.5 nm [see Ref. (15), p. 248, Table 1, where $\lambda_f = 2\pi/k_f$]. This model treats the adsorbed ion as a point charge at the surface with no electron sharing between the ion and the electrode. Greene (16) has derived an expression for $P(\theta)$ as a function of the charge density of point charges adsorbed on the film surface. A screened coulomb potential, V, is used to approximate the scattering potential so that

$$V = (e^2/r)\exp(-q_0 r) \quad [5]$$

where

$$q_0 = (4me^2/\hbar^2)(3n_0/\pi)^{1/3}$$

r is the distance from the film surface, e, m, and n_0 are the free electron charge, mass and volume density, respectively, and $\hbar$ is Planck's constant/2π [see Ref. (15), p. 227]. Equation [5] is for spherical symmetry and only approximates adsorbed charges on a plane surface. The expression for $P(\theta)$ is derived by considering the perturbation of the free electron wave functions caused by Eq. [5] using the Born approximation such that

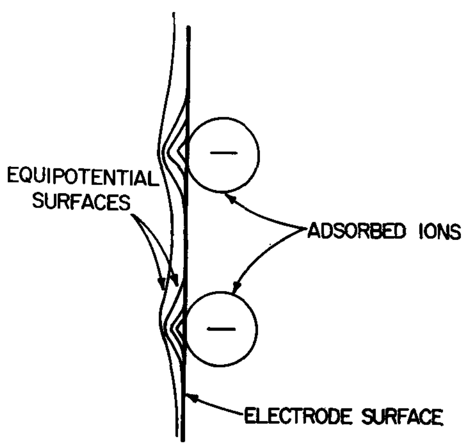

Fig. 1. The metal electrode surface with adsorbed ions

$$P = 1 - (2\pi\Gamma/\mu)(me^2/h^2k^2)[-2(\epsilon^2 + 2)^{-1} - \mu^2(1 - \mu^2)^{-1}\ln((2 + \epsilon^2)/\epsilon^2) + (\epsilon^2 + \mu^2)(1 - \mu^2)^{-1}(s\mu)^{-1}\ln((s + \mu)/(s - \mu))] \quad [6]$$

where

$$\epsilon^2 = q_0^2/2k^2, s = [(1 + \epsilon^2)^2 + \mu^2 - 1]^{1/2}, \mu = \cos\theta$$

k is the free electron wave vector, and Γ is the area concentration of adsorbed surface charges. Reference (16) contains a more thorough discussion of the derivation of Eq. [6].

The change in P, calculated from Eq. [6], caused by an adsorbed charge density of 5 μcoulombs/cm^2 is zero at grazing angles of incidence increasing to 0.0023 at normal incidence for a gold film electrode. (Although impossible to obtain because of electrostatic repulsion effects, a complete monolayer coverage would be approximately 200 μcoulombs/cm^2.) As an approximation for the purpose of estimating the conductance change, P was assumed to be 0.002, independent of angle of incidence. Equation [4] assumes P is the same for both sides of the film. Since the ions adsorb only one side of the film, P only changes on one side. Juretschke (17) has shown that for a film whose surfaces scatter differently, the P in Eq. [4] is approximately the average of both surfaces. Therefore, the P in Eq. [4] changes by approximately 0.001 for an adsorbed charge density of 5 μcoulombs/cm^2. The relative change in G caused by a change in P is dependent on the initial value of P. The surface scattering of a thin film cannot be calculated from film resistance measurements because thin films probably have other scattering mechanisms, *e.g.*, film thickness variations can cause an additional decrease in conductance (18). The predominant scattering mechanism in thin films is more likely to be due to structural imperfections than surface effects. An initial value for P of 0.20 is a reasonable specular reflection probability for a gold film. With these assumptions and using Eq. [4] the relative change in conductance, $\Delta G/G$, is 0.0011 for a 5 μcoulombs/cm^2 adsorbed charge density.

The surface scattering term varies linearly with Γ. The conductivity σ, varies almost linearly with P for small change in P; therefore

$$\Delta G/G \simeq K\Gamma \quad [7]$$

where K is a constant. By the above calculations K is equal to 3.5×10^{-7} cm^2.

This is only a rough approximation and could vary by as much as a factor of two depending on the assumptions made in the calculation. The calculation only considers the surface scattering caused by the perturbed equipotential lines at the electrode surface and does not include other possible effects, *i.e.*, electron tunneling between adsorbed particles and the conduction band, creation of chemical bonds at the surface, or new surface states created by the adsorbed particle, all of which will affect the conductance.

The sensitivity of the conductance to a change in P can be defined as

$$S_p \equiv |\Delta G/G|/\Delta P \quad [8]$$

Sondheimer (19) has derived approximations for Eq. [3] good when $h >> \lambda_0$

$$\sigma = 8h\sigma_0/\lambda_0(8(h/\lambda_0) + 3P) \quad [9]$$

and when $h << \lambda_0$ and $P \approx 0$

$$\sigma = 3\sigma_0(h/\lambda_0)\ln(\lambda_0/h)/4P \quad [10]$$

This gives for $h >> \lambda_0$ and $P \approx 0$

$$S_p \approx 3\lambda_0/8h \quad [11]$$

and for $h << \lambda_0$ and $P \approx 0$

$$S_p \approx 1/P \quad [12]$$

From Eq. [11] and [12] it can be seen that a thin film made of a substance whose conduction electrons have a long mean free path length compared to the film thickness will be most sensitive to the surface scattering. A 6 nm thick gold film with $\lambda_0 \cong 3.5$ nm should be very sensitive to adsorbed ions while a 1 μm thick tin oxide film with $\lambda_0 \cong 5$ nm should not permit detection of adsorbed charges.

Experimental Method

Standard techniques are used with the electrochemical cell. The cell and electrode used for most of the measurements along with the conductance monitoring technique have previously been described in Ref. (7). All potentials are referred to a saturated calomel electrode (SCE). The electrode used in Ref. (7) performed well for slow potential sweep rate measurements (0.1 V/sec) but as the sweep rate was increased a slight electrode resistance difference between each contact of the conductance bridge and the potentiostat contact caused a fickle voltage to appear on the conductance bridge. The electrode design of Fig. 2 was devised to eliminate this problem. Resistances R_2 and R_4 are 10 ohm potentiometers used to balance the electrode current. The potential difference between contacts 1 and 3 caused by the potentiostat current can be made zero by adjusting either R_2 or R_4 (one is always left at zero to eliminate any serious error in the true potential measurement of the system). This electrode design was used when the potential sweep rate exceeded approximately 5 V/sec.

A standard bridge circuit is used to monitor the conductance change of the thin-film electrode as a function of potential [see Ref. (7) and (8)]. Relative changes in conductance of 0.0001 could be measured without difficulty. The conductance was plotted as a function of potential with an x-y recorder for the slow sweep rates and with a storage oscilloscope for the fast sweep rates.

The preparation and properties of the gold film electrodes are described in Ref. (7). The film thicknesses were measured optically using the method described in Ref. (20). The tin oxide film was approximately 1 μm thick and had a resistance of 38 ohms-$\square^{-1}$. The electron density was unknown.

Experimental Results and Discussion

The relative conductance change is equal to the relative change in free electron density when no change in ionic adsorption occurs. Figure 3 contains the voltammetric electrochemical curve and conductance change for a 1 μm tin oxide electrode. The total free electron change per unit area of the tin oxide film is calculated from the charging current to be 22.5 μcoulombs/cm^2. The free electron density of the tin oxide film is then calculated from the conductance change using Eq. [1] and the measured tin oxide thickness. The effective free electron density of the tin oxide film is calculated to be 1.4×10^{20} electrons/cm^3. No ionic adsorption (conductance dip) could be detected on the tin oxide film by the conduction measurement. The film thickness for the tin oxide film is much larger than the free electron mean free path, therefore the surface scattering should not affect the conductance by a detectable amount. There is a slight hysterisis in the charging curve in Fig. 3 that is probably the result of a small oxidation-reduction reaction at the electrode surface.

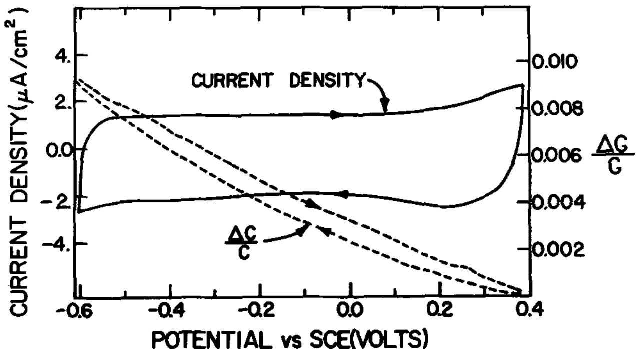

Fig. 3. Voltammetric electrochemical curve (———) and conductance change (- - - -) for a 1.04 μm tin oxide electrode in a 0.01M Na_2SO_4 solution with a pH of 6. The curves are traversed every 19 sec.

Ionic adsorption at the electrode surface causes the conductance to decrease linearly with the adsorbed charge density as in Eq. [6]. The conductance-change proportionality constant, K, is different for each film and depends on a variety of fickle film characteristics, *e.g.*, film surface roughness, surface impurities, thickness, free electron properties, and lattice defects. Figure 4 contains the cyclic voltammetry curves for a 6 nm gold film with and without I^- adsorption. The shaded area represents the increased charge density caused by I^- specifically adsorbing on the electrode surface. The model we have used in both the anion and cation adsorption involves no Faradaic current. The adsorption current is caused only by the increase in the double layer capacitance as the charged ion adsorbs on the surface of the electrode (21, 22). The adsorbing I^- charges add an additional component to the electrode current as they adsorb. The adsorbed I^- charge density is 4.8 μcoulombs/cm^2 and represents approximately a 2.0% surface coverage. We will assume this small surface coverage of adsorbed charges

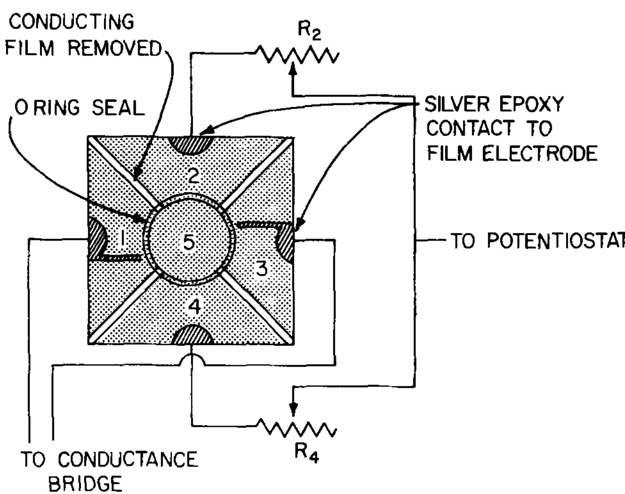

Fig. 2. The electrode design for fast potential sweep rates

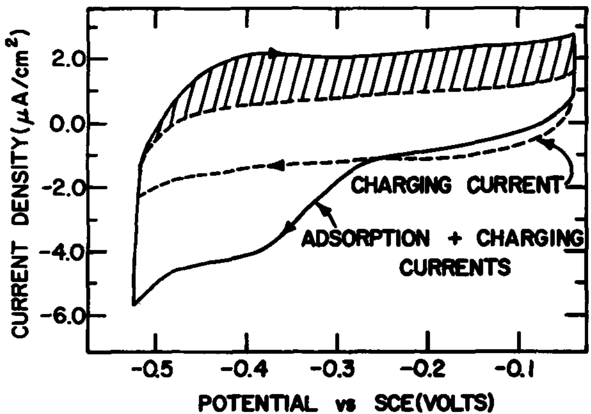

Fig. 4. Voltammetric electrochemical curves for a 6.0 nm thick gold film electrode. The electrolytes are 0.1M Na_2SO_4 (- - - -) and 0.1M Na_2SO_4 plus 5.9 mM NaI (———) with a pH of 3.0. The curves are traversed every 13 sec.

probably affects the electrode charging current only slightly. Therefore, the change in the conductance caused by the I^- adsorption is the difference between the conductance change with and without I^- adsorption. The conductance change with and without I^- adsorption was 0.0038 and 0.0011, respectively, for the cyclic voltammetric curves of Fig. 4. This gives a K of 9.0×10^{-17} cm² for this gold film. This is more than a factor of two larger than the value predicted previously of 3.5×10^{-17} cm². Figure 5 contains the results of several similar gold films of the same thickness (curves a-c) compared to the theoretical value (curve d). The variation in the sensitivity to adsorbed ions of the different gold films is probably caused by the slightly different surface characteristics of each film. These results do show that the electron scattering by point-surface charges is probably a major contributor to the conductance decrease although there probably are other effects occurring as previously mentioned. A partial sharing of electrons or formation of surface states will increase the surface scattering. For a more detailed theory of adsorption see Ref. (23).

As the adsorbed ion surface coverage increases above a few per cent the adsorbed ion charge density is no longer equal to the difference between the cyclic voltammetric curves as in Fig. 4. The adsorbed ionic layer acts more like a charged plane than a few randomly spaced point charges and thus the electron charging contribution to the conductance change is affected also. Figure 6 contains the conductance change as a function of apparent charge density (calculated as mentioned above) for Cs^+ and I^- adsorption for a potential sweep from 0.0 to −1.0V *vs.* SCE. The Cs^+ ion probably causes a greater change in the conductance because the electrode is charged negatively for Cs^+ adsorption, increasing the electron density near the adsorbed charges at the surface while for I^- adsorption the electrode is charged positively. The value of K for these curves appears to be about three times larger than measured with smaller surface coverages. The approximate adsorbed ion surface concentrations can be calculated by using Eq. [6], the measured conductance change, and a K of 9.0×10^{-17} cm². Figure 6 also shows the similarity in surface scattering by ions of opposite charge as predicted by Eq. [6].

Measuring the conductance can be a very sensitive way of detecting ionic adsorption. Figure 7 is the conductance change for Cd^{++} adsorption as the ionic concentration is increased. An ionic concentration on the order of 100 nM can easily be detected using a thin gold electrode. As is discussed in the remainder of this section, the ionic adsorption is diffusion limited for small concentrations, therefore, the sensitivity can be improved by decreasing the voltage sweep rate. The impurity ion adsorption then becomes the limiting factor in detecting small adsorbed ion concentrations.

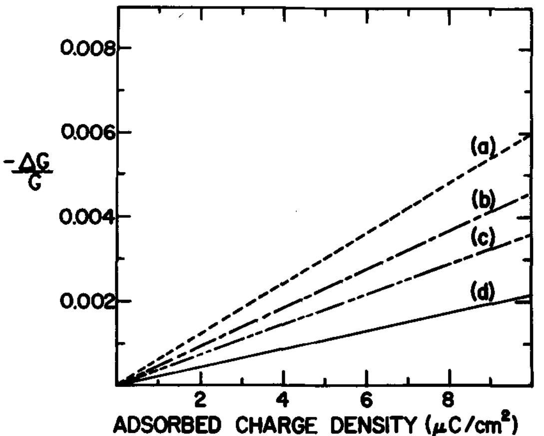

Fig. 5. The measured (curves a-c) and calculated (curve d) electrode conductance change for several different 6.0 nm thick gold electrodes as a function of adsorbed charge density.

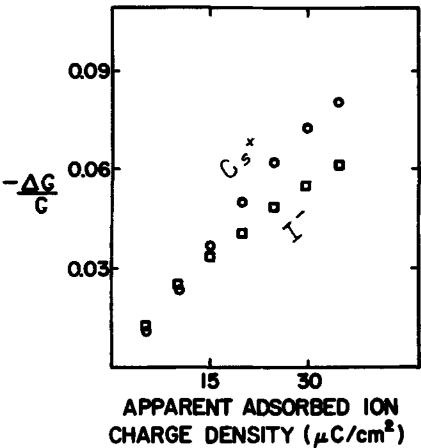

Fig. 6. The conductance change for Cs^+(○) and I^-(□) adsorption as a function of the apparent adsorbed ion charge density. The potential sweep was from 0.0 to −1.0V at a rate of 0.06 V/sec. The electrolyte was 0.1M Na_2SO_4 and 0.01M NaI or 0.01M Cs_2SO_4 with a pH of 4.0.

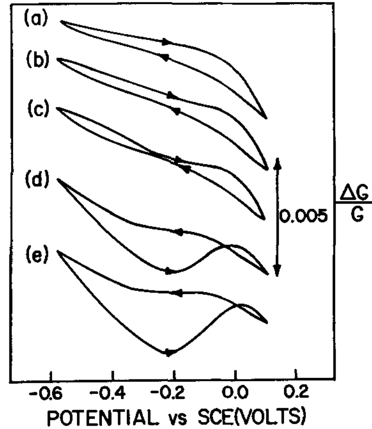

Fig. 7. Conductance curves for a gold electrode with a 0.01M Na_2SO_4 electrolyte with a pH of 3.9 and (a) no $CdSO_4$, (b) 0.2 mM $CdSO_4$, (c) 0.53 mM $CdSO_4$, (d) 6.9 mM $CdSO_4$, (e) 13.5 mM $CdSO_4$. The curves are traversed every 18 sec.

The conductance curves in Fig. 7 appear to have more occurring than simple charging and surface scattering. There seems to be two different adsorbed states for the Cd^{++} ion as observed from the decrease in conductance caused by adsorption, than the increase in conductance possibly caused by the reduction of Cd^{++}. A better explanation of this effect will require a more detailed study. Figure 7 illustrates the usefulness of conductance measurements in detecting differences in the adsorption process.

The ionic adsorption rate becomes diffusion limited with an increase in the electrode potential sweep rate. Figure 8 is the conductance change for a 10 mM NaI electrolyte with a pH of 6 for several different sweep rates. The conductance decrease at 0.0V is not as great for the faster sweep rates because the I^- adsorption is diffusion limited. The conductance at −1.0V does not change as the sweep rate is increased indicating that the desorption is complete at −1.0V.

Conductance measurements provide a reliable method of measuring the ionic diffusion coefficient, D. The conductance decrease caused by the ionic adsorption is a direct measure of Γ, as already demonstrated. Stepping the electrode potential from a position of no adsorption to a value where adsorption occurs and observing $\Delta G/G$ as a function of time is a di-

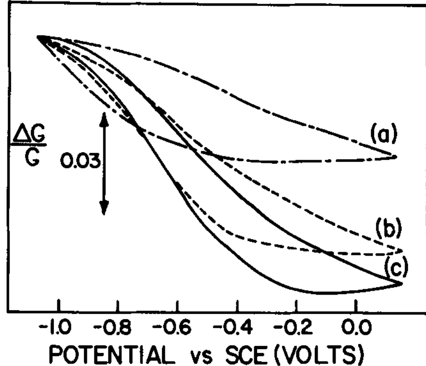

Fig. 8. The conductance of a gold film electrode with a 10 mM NaI electrolyte. The potential sweep rate is (a) 20 V/sec, (b) 2 V/sec, (c) 0.2 V/sec.

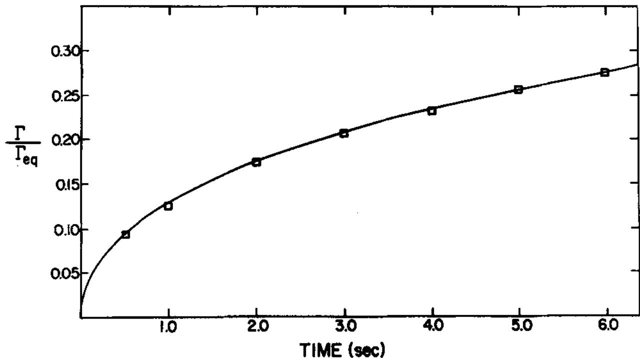

Fig. 10. The calculated (———) and observed (□) fractional change in the I^- surface coverage of a gold film electrode as a function of time. The observed values are taken from Fig. 9.

rect measure of the ionic adsorption. The solid line in Fig. 9 is the electrode conductance, as a function of time, for the gold electrode and electrolyte used in Fig. 4 as the electrode potential is stepped from -0.05 to -0.55V. The dotted line is the electrode conductance as the electrode potential is stepped without any NaI in the electrolyte. The difference between the dotted and solid lines should be directly proportional to Γ. Since the electrode charge is effectively screened within the first 1 nm of the electrolyte, the diffusion constant is the dominant factor controlling the rate of change of Γ as a function of time. Parsons (24) has shown that Γ depends upon the time, t, as

$$\Gamma/\Gamma_{eq} = 1 - \exp (Dt/K_0^2) \operatorname{erfc} [(Dt)^{1/2}/K_0] \quad [10]$$

where Γ_{eq} is the equilibrium value of Γ for the potential step used and K_0 is the isotherm constant. The equilibrium surface coverage, Γ_{eq}, is measured by holding the potential at -0.05V for 300 sec and measuring the change in the conductance, $(\Delta G/G)_{eq}$. The equilibrium value of $\Delta G/G$ was 0.0088. The isotherm constant is approximated by using the relationship

$$K_0 = \Gamma_{eq}/C_0 \quad [11]$$

where C_0 is the bulk adsorbing ion concentration. From Eq. [7] it is obvious that

$$(\Delta G/G)/(\Delta G/G)_{eq} = \Gamma/\Gamma_{eq} \quad [12]$$

The squares in Fig. 10 are the fractional surface coverage as a function of time measured from Fig. 9. The solid line is the fractional surface coverage calculated from Eq. [10] and using a $D = 1.21 \times 10^{-5}$ cm^2/sec. The similarity in shape of the measured and calculated curves is a good indication of the reliability of the data. The conductance measurements have provided a reliable method of measuring ionic diffusion coefficients.

Conclusions

The conductance decrease caused by adsorbed ions is probably a result of the free electron scattering by the surface point charges. Other effects probably contribute to the conductance change, *e.g.*, electron tunneling, creation of chemical bonds at the surface, or surface states created by the adsorbed particle. The conductance measurements provide a reliable method of quantitatively measuring the adsorbed ion density at the electrode surface. The sensitivity of the conduction measurements to changes in surface free electron concentration is inversely proportional to the free electron charge density per unit area of the film. The sensitivity to changes in adsorbed ion concentration is directly proportional to the ratio of electron mean free path length to film thickness. Conductance measurements can be sensitive to different types of adsorption as demonstrated with the adsorption of Cd^{++} on gold. Thin film conductance measurements provide a versatile method of studying many basic electrode processes.

Studies of a Nitrogen Dioxide Sensitive, Chalcogenide Glass Electrode

Raymond Jasinski,* Gabriel Barna, and Isaac Trachtenberg*

Texas Instruments Incorporated, Dallas, Texas 75222

ABSTRACT

Properly activated $Fe_nSe_{60}Ge_{28}Sb_{12}$ electrodes, when exposed to nitrogen dioxide in air, develop shifts in their steady-state potentials and, at constant potential, develop cathodic currents which are functions of the NO_2 concentration in the gas phase. This reversible response, and the selectivity in the presence of O_2, CO, SO_2, CH_4, NO, NO_3^-, and NO_2^-, cannot be reconciled with conventional redox, pH, or solubility product mechanisms, but must involve a specific chemisorption of the NO_2 by the electrode surface.

The potentiometric measurement of species in solution may be accomplished through a number of physicochemical processes, *e.g.*, selective diffusion of ions within membranes (the glass pH electrode) and the mass action control of electrode solubility coupled with selective diffusion of ions within the electrode structure (the silver sulfide and lanthanum fluoride electrodes). The catalysis of electron transfer processes by otherwise inert electrodes such as platinum has been used to measure, potentiometrically and amperometrically, the concentration of oxidizing and reducing agents.

Described in this paper are some of the properties of a chalcogenide glass electrode ($Fe_nSe_{60}Ge_{28}Sb_{12}$), in an aqueous electrolyte, for sensing directly nitrogen dioxide in air and other gases. As will be shown, the performance of this electrode cannot be readily reconciled with such "classical" sensing mechanisms but appears to involve specific adsorption of NO_2 onto the electrode surface.

Experimental

Two test cell configurations were used to provide the sample, electrolyte, electrode interface necessary for sensing electroactive gases. The first, the "gas diffusion electrode configuration," consisted of porous sensor, reference and counterelectrodes separated by an inert matrix containing the electrolyte. This system was particularly well suited: (*a*) for the measurement of current generated, at constant potential, by sensors exposed to NO_2, (*b*) for minimizing reaction of nitrogen dioxide with the bulk of the aqueous electrolyte, as well as (*c*) for providing short term, steady-state potential data. The sensor electrodes used with this configuration were formed by heating to 290°C for 3 min, a paste of Teflon emulsion and approximately 0.12g of powdered glass ($\simeq$200 mesh) that had been spread onto a 5 cm^2 tantalum screen disk. The electrolyte was contained in two 30 mil thicknesses of fiber glass filter paper. The cell end plates were machined from Teflon block. Gas was delivered into the cell via stainless steel fittings screwed into the end plates; electrical contact was accomplished by screwing these fittings onto tantalum screens in contact with the test, counter, and reference electrodes. Anodized silver chloride and silver sulfate on silver screen were used as the reference electrodes in the appropriate electrolytes.

The second test assembly, more suited for long term, quantitative potentiometric studies was the "ion specific electrode configuration" (subsequently designated as "ISE configuration") and made use of the sensor material in the form of a nonporous disk, 7 mm in diameter. The assembly, discussed in more detail elsewhere (1),

* Electrochemical Society Active Member.

Key words: nitrogen dioxide, gas sensors, chalcogenide glass electrodes, ion selective electrodes, specific chemisorption.

involved a wick taped over the sensing surface of the electrode. In this way the sensing element, which protruded above the surface of the electrolyte, was directly exposed to the gas being monitored, while only that minimal amount of electrolyte necessary to complete the solution circuit reached the electrode surface by capillary action from an electrolyte reservoir.

A perforated commercial Teflon membrane was used to separate the ISE sensor electrode from the gas phase, serving primarily to minimize drying of the electrolyte on the wick, while still permitting access of the gas to the sensor surface. The same selectivities and sensitivities were obtained in the ISE configuration with the membrane in place and in the gas diffusion electrode configuration in which a membrane was not used. The PermaProbe (Beckman Instruments Inc.) was used as the reference electrode in these experiments.

Preanalyzed gas mixtures of NO_2 in air and in N_2 were purchased from Matheson Company in concentrations of 1.2, 25, 100, 350, and 392 ppm. Mixtures of CH_4, CO, and NO in nitrogen were obtained from the same supplier.

The glass sensing materials were prepared as described in Ref. (2) and (3). The term "Fe 1173" is used to designate the material $Fe_nSe_{60}Ge_{28}Sb_{12}$, where n falls between 1.3 and 2. A correlation of composition with performance was not made for the sensing process described in this paper. Since there was a variation in activity from batch to batch of glass melt, a dependence of activity on composition must exist. A similar situation was found in the use of this glass for sensing ferric ion in solution (3).

The pretreatment steps necessary to convert this glass material into a NO_2 selective sensor are discussed below.

Potential measurements were made with a Hewlett-Packard 3440A digital voltmeter; a Keithley Model 610C electrometer provided the necessary impedance matching. A Wenking Model 61-TR potentiostat was used for the constant potential measurements.

Results and Discussion

Shown in Table I are the potentials of a properly activated, (see below) porous, Teflon-bonded, Fe 1173 electrode exposed to a series of gases; the electrolyte was 7*N* H_2SO_4. The electrochemical activity of these gases on platinum is also shown in the table. Results similar to these were obtained with an electrolyte of 1M KCl, *p*H 6 and with $(NH_4)_2HPO_4$, *p*H 8 in the ISE configuration.

Essentially then, the Fe 1173 electrode responded only to NO_2, and gave no response to reducing agents and to oxygen. Stronger oxidizing agents such as H_2O_2 also gave significant responses, similar to results reported previously (2).

Included in the table are the responses of the undoped 1173 glass. Since the parent glass itself responds to reducing agents, in much the same manner as does a poor platinum black, and the iron-doped glass does not, it can be concluded that the two phase, iron-doped material does not consist of a particular iron-rich phase in a matrix of substantially unreacted, excess 1173 glass.

The potentiometric response of the Fe 1173 glass to NO_2 in air and in nitrogen, over the concentration range of 1-392 ppm, yielded a potential-log concentration dependence of a nominal slope of 70 mV/decade (1).

Table I. Sensor potentials *vs.* gas composition (*vs.* Ag/Ag_2SO_4)

Gas	Platinum black, mV	Fe 1173, mV	1173, mV
N_2	+620	+41	+152
Air	+720	+45	+161
NO_2 (350 ppm in N_2)	+791	+365	+415
NO (100 ppm in N_2)	—	+44	—
CO (1% in N_2)	+100	+47	+106
SO_2 (100%)	−52	+48	−30
CH_4 (1% in N_2)	—	+44	—

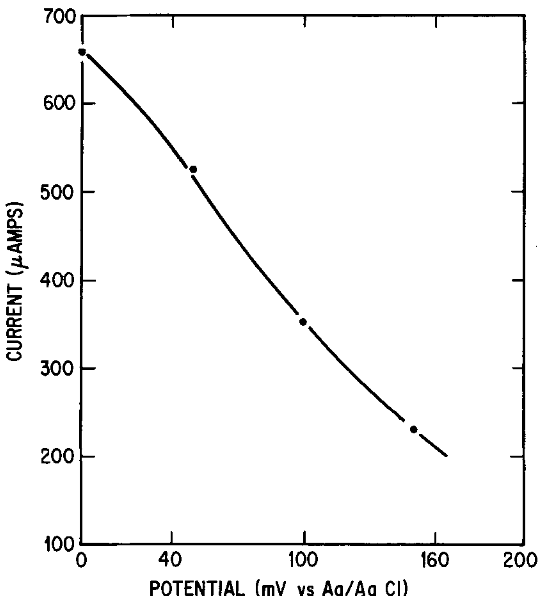

Fig. 1. Shown is the cathodic current-potential relationship for a Teflon-bonded, porous Fe 1173 electrode exposed to 350 ppm NO_2 in N_2; 1M KCl, *p*H 2 was the electrolyte.

As previously described (3), Fe 1173 is an electronic conductor, which property is apparently maintained after heating in air (during the preparation of the Teflon-bonded structure). This therefore provided the possibility of sensing NO_2 in air amperometrically as well as potentiometrically. Shown in Fig. 1 is the potential dependence of the steady-state current for one Teflon-bonded electrode exposed to a constant 350 ppm NO_2 in nitrogen; 1M KCl, *p*H 2 was the electrolyte. At potentials more positive than +100 mV (*vs.* Ag/AgCl) no signal was observed from air, SO_2, or 100 ppm NO in the gas cavity. These results then are consistent with the potentiometric selectivity data shown in Table I. At more negative potentials, cathodic oxygen reduction was observed; at zero millivolts, a current of 40 μA was generated by 100% SO_2. The fact that this sensing current is potential dependent does not, of course, obviate a concentration dependence; the exchange current for a general redox process involves concentration terms (5). For this particular experimental system, the cathodic current resulting from the passage of variable concentrations of nitrogen dioxide over the electrode surface held at a potential of +150 mV, was directly proportional to the concentration of nitrogen dioxide in the gas phase. Similar potential-concentration dependence situations have been reported for the amperometric determination of CO and ethanol on platinum (6, 7).

The upper operating limit of NO_2 concentration has not been explored in any detail. A concentration of 10% NO_2 was detrimental, concentrations of 390 ppm had not brought about any immediate adverse effects. However daily exposure (≥4 weeks) of the sensor to 390 ppm nitrogen dioxide resulted in a slow deactivation of the electrode surface. This was signaled by a gradual increase in the response time and a slow decrease in the net signal observed, which, of course, may have also involved the slow approach to steady state. The initial potential remained relatively constant; altering the position of the wick on the ISE configuration did not restore activity. Teflon-bonded electrodes, not continuously exposed to NO_2, maintained their activity for at least 6 months.

These then are the general performance characteristics of this material for sensing nitrogen dioxide directly. The remainder of this paper is concerned with

establishing, at least in general terms, some of the characteristics of the sensing mechanism.

First of all, the experiments carried out to develop the potentiometric response indicated that the sensing process was reversible, *i.e.*, removal of NO_2 from the gas phase restored the electrode to its initial potential and hence its initial condition.

Second, the chemical composition and oxidation state of the electrode surface were particularly critical features of the sensing process. An "activation" step was required before the sensitivity and selectivity properties could be reproducibly observed. Mechanical removal of the surface of a deactivated electrode, followed by a repetition of the activation step restored performance. Of the variety of techniques considered for "activation," only heating in air at 290°C for 3 min was effective in generating reproducibly, a highly active surface with fast response time and a high degree of selectivity. A number of sensors showed activity and selectivity for sensing NO_2 without pretreatment. The majority yielded slow responses, if at all, to nitrogen dioxide and varying degrees of selectivity relative to oxygen. Such electrodes could not be activated by chemical oxidation, such as equilibration with 30% H_2O_2, or by potentiostating at +400 mV *vs.* Ag/AgCl. Equilibration of these electrodes with 10^{-1} molar ferric nitrate did not produce sensitivity to NO_2, although such a procedure was effective, in almost all cases, in generating activity for ferric ion (3).

Although the ferric ion sensitive electrodes were not particularly sensitive to NO_2, the NO_2 active electrode was indeed sensitive to ferric ion, after, not before, subsequent equilibration in 10^{-1}M Fe^{+3} solution, the normal activation procedure (3) for ferric ion sensing. The potential-log ferric ion concentration dependence was identical to that reported for the ferric ion activated electrode, except that the actual potentials were shifted more cathodic by about 300 mV after activation for nitrogen dioxide by heating in air. Since air normally affords a potential shift of the order of 30-40 mV (*vs.* N_2) on a low selectivity, nonactivated electrode, this 300 mV shift cannot solely represent a deactivation of the electrode toward oxygen sensing.

It would appear from these experiments that: (*i*) there is a similarity, if not an identity in the electrode sites involved in sensing NO_2 and Fe^{+3} (before adsorption of Fe^{+3}), (*ii*) additional sites are involved, at least in part, in determining the base line potential (*i.e.* in the absence of nitrogen dioxide and ferric ion), and (*iii*) these sites are distinctly different in the two sensing systems. This point is discussed again below.

The sensitivity of the NO_2 electrode to ferric ion could imply a sensing mechanism "of the second kind," *i.e.*, whereby the electrode surface is in equilibrium with iron species dissolved off the electrode surface, which concentration is altered by NO_2. Using ferrous ion as an example, the following processes could, in principle, take place

$$\text{Glass} \rightleftharpoons Fe^{+2} + e^-$$

followed by

$$Fe^{+2} + NO_2 \rightleftharpoons Fe^{+3} + NO_2^-$$

The ferric ion would then be sensed by the electrode. There are a number of problems with this mechanism. For example, (*i*) oxygen in the air has the same potential as 350 ppm NO_2 to bring about the oxidation of ferrous ion or other reduced species, and yet there is no response to oxygen, Table I, and (*ii*) there is no obvious process by which the electrode would be reversible, after nitrogen dioxide is removed from the gas phase, *i.e.*, by which the ferric ion or other oxidized species would be removed from the electrode surface in order to restore the electrode to its initial potential.

Consider next a number of possible redox mechanisms to account for the sensitivity and selectivity of the electrode material. The lack of interaction of the glass with NO (Table I) and the high potential-log concentration slope (1) precludes catalysis of the NO_2/NO couple. If the surface were interacting with the NO_2/NO_2^- couple, as might be implied by this slope, it would be expected that the electrode would be responsive to nitrite ion, *i.e.*, equilibrium must be approachable from both ends of the redox couple.

Shown in Table II are the potentials for the sensor (ISE configuration) in the following cell

Fe 1173/0.1M KNO_3, variable NO_2^-/PermaProbe

Thus over at least three orders of magnitude the electrode is insensitive to nitrite ion. The small increase in potential between 10^{-4} and 10^{-3}M could be ascribed to air oxidation of nitrite, which was likely. Furthermore it would be expected that exposure of the electrode to the reduced half of the couple would lower potential rather than increase potential. Identical responses of the electrode to NO_2 were obtained with and without 10^{-2}M nitrite in a 1M KNO_3, *p*H 9.2 electrolyte. The generation of a cathodic current in the amperometric sensing of nitrogen dioxide removes the possibility of involvement of the NO_2/NO_3^- couple.

A possible, indirect sensing mechanism would be that the electrode is actually detecting a *p*H change via a solution reaction of NO_2, *e.g.*, $2NO_2 + H_2O \rightarrow HNO_2 + H^+ + NO_3^-$.

However the potential of the NO_2 active electrode was independent of *p*H in the range of 2.5-8.5. This observation is also consistent with an electrode mechanism not involving the dissolution of iron species off the electrode, as described above, since the solubilities of ferric and ferrous hydroxides vary considerably over this *p*H range while the electrode potential does not.

Thus to explain sensor performance we are left with specifying some form of interaction of NO_2 with the electrode rather than a conventional catalysis of solution redox couples. The argument has been put forth, for Fe^{+3} sensing (1), that the electrode itself was the reduced form of the couple. This may well be true, and would account for the sensitivity of the electrode to strong oxidizing agents such as peroxide and persulfate (3). However it is still necessary to explain, or rationalize, why the electrode is not further reducible by an atmosphere of 100% SO_2. It is also necessary to explain why this "reduced" electrode is not responsive to oxygen in air, even though weaker oxidizing agents such as 1 ppm NO_2 and 10^{-5}M Fe^{+3} evoke electrode responses.

It is therefore proposed that this specific interaction of nitrogen dioxide and the sensor surface is one of reversible chemisorption, *i.e.*

$$NO_2 + G \rightleftharpoons NO_2G \rightleftharpoons (NO_2^- + G^+)_{\text{solid}}$$

where G represents the properly activated surface. This mechanism then can be viewed as a redox process but preceded by adsorption reaction which provides the specificity observed. The absence of a *p*H response implies that this adsorption process does not involve displacement of hydroxide ion from the surface.

If charge is delivered to the surface, as in the amperometric sensing mode, the above reaction could continue, presumably through the irreversible generation of nitrite ion in solution: $(NO_2^- + G^+) + e^- \rightarrow NO_2^- + G$, restoring the original activated glass.

A somewhat heuristic rationalization for the behavior of the electrode relative to the activation step and electrode activity can be made as follows. There are two classes of electrochemically active sites (desig-

Table II. Sensor response in variable nitrite solution

Concentration NO_2^- added, M	Potential, mV
0	+122
10^{-6}	+119
10^{-4}	+119
10^{-3}	+126

nated as G and G′) initially present in the original Fe 1173 glass, but differing in concentration from sensor slice to sensor slice. It is postulated that sites G′ can catalyze the O_2/H_2O couple, resulting a dependence of potential for untreated sensors on the oxygen content of the atmosphere above the sensor. Since this would be a mixed potential, the degree of oxygen sensitivity would depend on the concentration of G′ sites in the particular glass. It is also postulated that these G′ sites strongly adsorb O_2 which is only slowly displaced via purging the gas cavity with nitrogen, accounting for the small change in potential (30 mV) obtained on substituting N_2 for air in the gas phase. This is consistent with the behavior of platinum black electrodes under identical experimental conditions (Table I). It is also likely that the G′ sites also set the initial potential via a corrosion-dissolution process. In any event, air oxidation at 290°C destroys these sites, while leaving sites G appreciably unaffected and it is these sites that are active to adsorption of nitrogen dioxide. This destruction of potential-determining G′ sites would account for the 300 mV cathodic shift in potential for Fe^{+3} sensing obtained by heating the electrode in an oxidizing atmosphere (air). Since these G′ sites are removed, the NO_2 active sites now dominate the potential-determining properties of the glass and high sensitivity of NO_2 results.

Since activity to ferric ion remains after activation for nitrogen dioxide but at more cathodic potentials, it is inferred that these G sites are the same described previously (3) as "oxidized Fe 1173." These are the sites which interact strongly with ferric ion to generate a new set of sites which are active in ferric ion sensing. Since the ferric ion activated electrodes are poorly sensitive to nitrogen dioxide, if at all, it is to be inferred that these "new" sites do not adsorb nitrogen dioxide, being blocked by the presence of strongly adsorbed ferric ion. Following from this argument then is a possible mechanism for electrode deactivation. Slow solubility product dissolution (or corrosion) of the electrode injects ferric ion into the electrolyte, which then adsorbs onto the nitrogen dioxide active sites. Further data are required to evaluate this deactivation mechanism.

Now is such an adsorption-sensing mechanism plausible? The energy of the adsorption process was estimated as follows. Little potential change was observed below 0.3 ppm NO_2. Extrapolating the potential change from 1 ppm NO_2 (mole fraction 10^{-6}) to mole fraction unity, at 70 mV/decade, and converting to units of kilocalories/equivalent yields a value of 8-9 kcal, which is of a reasonable order of magnitude for weak and reversible chemisorption.

As precedence, are cited the adsorption of chloride ion onto platinum which has been shown (8) to provide linear potential-log concentration plots over the range of 10^{-1}-10^{-4}M chloride. Such processes are apparently characterized by potential log concentration slopes in excess of the values expected from the Nernst equation based on charge transfer.

The adsorption of chloride onto platinum gave a slope of approximately 90 mV/decade.

Summary

A properly activated Fe 1173 electrode is inherently sensitive to nitrogen dioxide in air. With the use of a porous, Teflon-bonded gas diffusion electrode, measurements of NO_2 can also be made amperometrically, *i.e.*, current proportional to concentration at fixed potential.

The electrode response is reversible, *i.e.*, removing NO_2 from the gas phase restores the initial potential, and hence the initial state of the electrode surface. This precludes any mechanism involving permanent change of the electrode surface and/or the electrolyte by NO_2.

The absence of an electrode response of NO, NO_2^-, NO_3^-, and H^+, in both the amperometric and potentiometric modes, precludes sensing mechanisms based on redox couples involving these species. The absence of an electrode response to high concentrations of oxygen, CO, and SO_2, normally electroactive gases, further precludes a general redox mechanism and implies a specific reaction between the glass and nitrogen dioxide. The necessity for appropriately pretreating the electrode surface to generate selectivity and sensitivity, taken together with the variable initial performance of freshly prepared (unactivated) sensor, leads to a dual site theory for the determination of electrode potential. The response of electrodes, as activated for nitrogen dioxide, to ferric ion reinforces this dual site concept and identifies similarities in surface composition for the two sensing systems.

It is further postulated that these nitrogen dioxide active sites function via a specific chemisorption mechanism, which involves the glass itself as the "reduced half of the couple." The energy calculated from the observed potential shifts on contacting the electrode with nitrogen dioxide is consistent with such a mechanism. Precedence is also available for adsorption effects resulting in linear potential-log concentration dependencies and with slopes greater than expected from charge transfer processes.

A Palladium Hydride *p*H Electrode for Use in Buffered Fluoride Etch Solutions

Raymond Jasinski*

Texas Instruments Incorporated, Dallas, Texas 75222

ABSTRACT

*p*H measurements can be made in aerated, concentrated, aqueous NH_4F-HF etch solutions with palladium electrodes cathodically charged to palladium hydride. Electrode life and stability in ammonium fluoride, as well as in NH_2SO_4, *p*H 3.6 sodium citrate and in *p*H 8 ammonium phosphate are enhanced by maximizing the palladium hydride concentration, electrode volume as well as volume to surface ratio. Electrode lifetimes have been measured in the range of 7-14 days for all solutions, times which are significantly longer than have been reported previously in the literature for palladium hydride electrodes.

Ammonium fluoride-hydrogen fluoride solutions are widely used in the electronics industry as etchants (1, 2). The etch rates of these solutions are a function of pH, a parameter which must therefore be monitored and controlled. Because of the reactivity of these solutions, the glass *p*H electrode, obviously, is not applicable to this measurement. Use of the platinum H_2/H^+ electrode for *p*H measurements on a routine basis is complicated: (*i*) by the need for a constant partial pressure of hydrogen in the test solution; and, to a lesser extent, (*ii*) by the possibility of evaporating HF during the hydrogen equilibration period and thus altering the *p*H. The use of the quinhydrone electrode to measure *p*H in HF solutions has been described (3-5). Besides the inconvenience of adding a chemical (quinhydrone) to the test solution, this electrode is subject to interference by the large amounts of ammonium ion present in these "buffered etch" solutions (6); indeed pronounced discoloration and potential drift were found. Interference from ammonium ion is also to be expected with ion exchange membrane *p*H electrodes recently proposed for use with acid HF solutions (7).

This paper describes the application of the palladium hydride/H^+ couple to the direct measurement of *p*H in concentrated, undiluted NH_4F-HF solutions.

The literature on palladium/palladium hydride electrodes up to 1961 is reviewed in Ref. (6); subsequent developments are summarized in Ref. (8); other and more recent examples of application are given in Ref. (9-12). No literature is available, however, on application of this electrode system to the buffered fluoride etch solutions. Furthermore, the published lifetimes of the palladium hydride electrode in solutions containing dissolved air have been of the order of a few hours to a day, times which are too short for the purposes of routine, quality control *p*H monitoring.

According to the literature (13-16), dissolved oxidants (including oxygen) also result in inaccurate *p*H and reference electrode potentials due to depolarization of the palladium hydride electrode. It is shown below that electrode lifetimes of the order of 1-2 weeks can be obtained by proper selection of the electrode volume and surface to volume ratio, even in the presence of dissolved oxygen.

Experimental

The palladium metal used in these experiments (99.99% pure) was obtained from Engelhard Industries, Incorporated. Electrodes were formed from: (*i*) foil, 1 cm^2 10 mil thick (after plating with palladium black), sealed into acrylic plastic; (*ii*) rod, 0.25 in. diameter, 1 cm long, imbedded in acrylic plastic and imbedded in Teflon; (*iii*) rod, 0.25 in. diameter, with a 2 cm length exposed to the test solution, and with 0.5 cm imbedded in the acrylic rod; (*iv*) rod, 0.25 in. diameter, 2 mm exposed to solution, and 8.0 mm imbedded in Teflon. The second test electrode configuration will be referred to in the text as the "disk configuration." Ohmic contacts were made within the electrode bodies so that palladium was the only metal in contact with the solution (17). Some testing was made with palladium wire (2 cm × 50 mil diameter) containing 1000 ppm nickel, as well as some copper (200 ppm) and gold (100 ppm). The trends observed with this electrode were comparable to those obtained with the purer material, except that the potentials were about 20 mV more negative.

Before use, all electrodes were cleaned with aqua regia and immediately plated with palladium black in the standard manner (6). It was also possible to form palladium black by first charging the smooth cleaned surface to palladium hydride and then immersing the electrode in standard palladium plating solution. Electrodes which were previously plated and used in the studies to be described, were replated in this manner without removal of the previous plate. This reactivation procedure was carried out before and after each recharging cycle. Unless this was done, abnormal, pronounced stirring dependencies were observed.

Palladium hydride was always formed by cathodizing the electrode in 1*N* H_2SO_4 under nitrogen at constant current or at constant potential (provided by a Wenking Model 70 HC 3 potentiostat). The details of the charging procedure are discussed below. Platinum screen was used as the counterelectrode; Orion double junction electrodes (designated "dj") and the Beckman PermaProbe were used as references. The maximum theoretical input charge is based on the mass of palladium present and the composition $PdH_{0.6}$.

It has been pointed out in Ref. (8), that a constant current charge is 60-90% efficient in forming palladium hydride, the remainder of the charge going into the formation of H_2. It is assumed, in this work, that the charging process approaches 100% in efficiency. As will be shown, this assumption is consistent with the observed forms of the charging curves at constant current and at constant potential. The general conclusions to be drawn from this work remain valid as long as a constant fraction of the total input charge is converted to palladium hydride. Since the most likely mechanism for loss of PdH during charges is recombination to H_2 (see below), the assumption of "constant fraction" is likely to be valid.

The platinum H_2/H^+ electrode was established by purging with tank hydrogen for 30 min the appropriate

* Electrochemical Society Active Member.

Key words: palladium hydride, pH electrode, fluoride etch solutions.

electrolyte containing a platinized platinum wire sealed with heat-shrinkable Teflon tubing.

Electrolytes were prepared from reagent grade chemicals. No attempt was made to remove the trace heavy metal content which might plate on the palladium hydride electrode. The primary test solutions used to evaluate electrode design and consistency of performance with published data (6-12) were: 1*N* H_2SO_4, 0.1M sodium citrate (*p*H 3.6), and 0.5M $(NH_4)_2HPO_4$ (*p*H 8). *p*H calibration was accomplished with commercial buffers. The compositions of the various ammonium fluoride-hydrogen fluoride solutions used are given in the text.

Stirring was accomplished with a paddle stirrer rotated at approximately 250 rpm in a constant solution volume of 175 ml. The stirring dependencies discussed below refer to the potential shifts obtained 1 min after this stirrer was turned off. There was no distinguishable effect of purging the test solutions with air *vs.* stirring in an open beaker after first saturating the solution with air. Since the *p*H 8 solution absorbed carbon dioxide from the air resulting in a decrease in *p*H, the data reported were taken after readjusting the *p*H to 8 with sodium hydroxide.

The measurements in the aerated *p*H 3.6 citrate solution were complicated by the formation, after about 5 days, of a gelatinous precipitate on the electrodes. This was accompanied by a slow drift of the cell potentials to more negative values and a decrease in the stirring dependence. Daily replacement of the test solutions avoided repetition of this phenomenon; data was taken immediately after the electrodes were exposed to fresh aerated solution.

The electrode life studies in semiconductor grade Texas Instruments Incorporated "common oxide etch" were made on stirred, aerated solutions. Because of the evaporation of water, fresh solution was put into the electrode twice daily, before recording data.

Potentials were measured to 0.1 mV with a Corning Model 101 Digital Electrometer.

Results

Shown in Fig. 1 is a typical cathodic charging curve for palladium foil electrodes subjected to a constant 6 mA charge in the sulfuric acid electrolyte. Curves of similar form were also obtained with constant potential charge (current *vs.* time). $PdH_{0.6}$ corresponds, in Fig. 1, to a charging time of 6.9 hr. The correspondence in the break in the charging curve with that expected from the literature (8, 17, 18) implies that substantially all the charge put into the electrode resulted in the formation of palladium hydride, and thus formed the basis of assuming essentially 100% charging efficiency, as discussed above.

Shown in Fig. 2 is the subsequent potential-time curve for the same electrode subsequently immersed in aerated sulfuric acid. Both curves obviously resemble the potential-time behavior and the potential-Pd/H ratio curves in Ref. (8), (17), and (18). These same general forms were obtained with all the palladium electrodes studied. The duration of the constant potential plateau did vary with the geometry of the electrode, which is the primary subject of this paper. In subsequent discussion, electrode life is arbitrarily taken as the time at which the electrode potential reached a value 20 mV more positive than the plateau voltage (16 hr in Fig. 2). This is a reasonable criterion for the 1*N* H_2SO_4 solutions, but is much less rigorous for the higher *p*H solutions (see Fig. 4 and 5).

That the potential of the palladium electrode in the plateau region is *p*H dependent has been well demonstrated in the literature. The palladium foil electrode discussed above yielded a slope of -59 mV/*p*H, over the range of *p*H 4-7, a response identical to that obtained with a glass *p*H electrode in the same solutions.

The lifetime of the electrode described by Fig. 2 is similar to published data (6-12). However such times are too short for the purposes required, *i.e.*, an electrode suitable for routine quality control measurements. As mentioned above, a prime reason given for this low lifetime is the reaction of the palladium hydride at the electrode surface with oxygen dissolved in the electrolyte. It is to be expected, therefore, that, if this is indeed the case, decreasing the area for a fixed electrode volume would proportionately increase electrode life. Accordingly the foil electrode was coated with paraffin wax over half its surface after charging to caoacity as shown in Fig. 1. Indeed the expected doubling in electrode life was obtained.

It is also to be expected that electrodes containing more charge (palladium hydride) would also have a proportionately longer electrode life. The quantity of charge which can be delivered to the electrode is, of course, proportional to electrode volume. Listed in

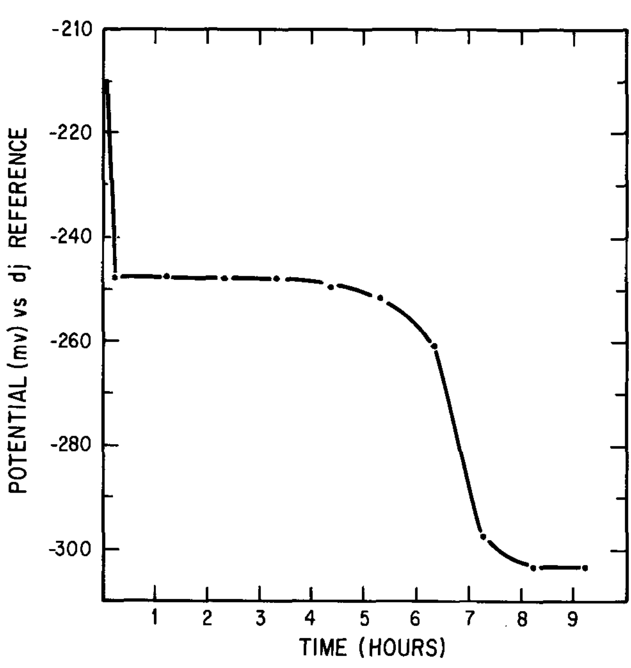

Fig. 1. Charging curve for the palladium foil electrode at 6 mA in 1*N* H_2SO_4 under N_2.

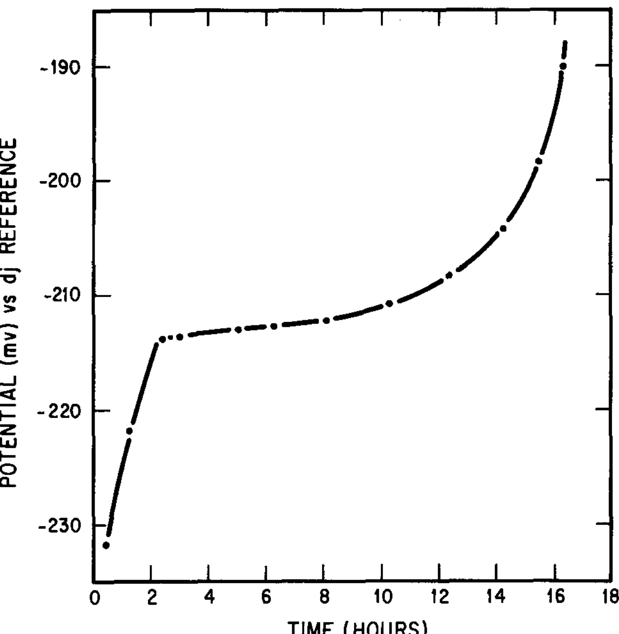

Fig. 2. Potential-time (in hours) curve for the charged palladium foil in aerated 1*N* H_2SO_4.

Table I. Comparison of electrode performance with configuration ($1N\ H_2SO_4$)

Electrode	Volume (cm^3)	V/S ratio (cm)	Change (A-min)	Life (days)	Loss rate (mA)
Wire	0.024	0.016	2.8	1.0	1.9
Foil	0.025	0.012	2.4	0.7	2.5
Disk	0.317	1	3.9	7.0	0.39
Rod (2 mm)	0.317	0.44	11.9	8.0	1.0
Rod (2 cm)	0.793	0.18	58.2	10.0	4.0

Table I are typical lifetimes (in aerated $1N\ H_2SO_4$), the dimensional parameters, and the input charge for the five palladium hydride electrode configurations investigated. Since each electrode had been charged and discharged prior to taking the data listed, they contained a residual ampere-hour capacity over and above that shown in Table I. This point is discussed more fully below. Also given in Table I are the rates of loss (in milliamperes) of palladium hydride to the solution. These numbers are the input charge (in milliampere-minutes) divided by the electrode life (also in minutes). Shown in Fig. 3 is the potential-time stability curve of the palladium rod electrode.

The following general trends are apparent: (*i*) increasing electrode volume increased electrode life; (*ii*) electrode lifetimes in excess of 1 week were achieved; (*iii*) for a constant electrode volume, decreasing the electrode surface area exposed to the solution decreased the rate of loss of palladium hydride to the solution. A more quantitative correlation of electrode life with total charge in the electrode and the dimensional parameters is developed below.

Taking advantage of the lower self-discharge rate of the disk electrode configuration in order to obtain a long-lived electrode is influenced, in practice, by the time available for electrode charging. Shown in Table II are the times required to reach $PdH_{0.6}$ at a constant current density of 2.3 mA/cm^2, the maximum value used with the 2 cm palladium rod which avoided hydrogen evolution throughout the charge period. Thus from the point of view of rapid charging with a reasonable electrode lifetime, the palladium rod with the greater exposed surface is the more desirable electrode.

Illustrated in Table III is the effect of electrolyte *p*H on the lifetime of this palladium rod electrode (2 cm exposed length). Shown in Fig. 4 is the potential-time curve for the rod electrode in the *p*H 8 ammonium phosphate solution. Note the compressed time scale relative to Fig. 3. As implied above, deciding on the electrode "life" is much less rigorous than for the sulfuric acid solutions; here electrode life is taken as 15 days. Similar curves were developed with the citrate and ammonium fluoride solutions (see Fig. 5). The slopes of the various portions of the potential-time curve are also listed in Table III.

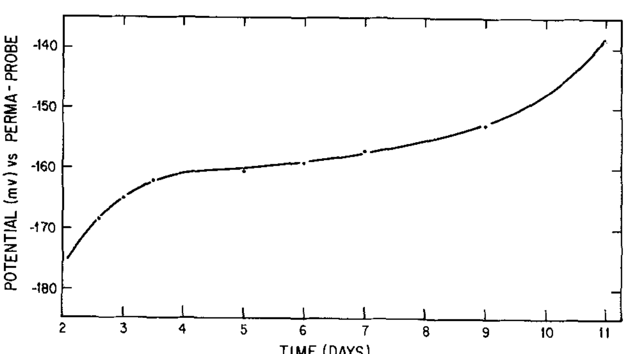

Fig 3. Potential (*vs.* PermaProbe)-time (in days) relationship for charged palladium rod in aerated $1N\ H_2SO_4$.

Table II. Charging times as a function of configuration (in N_2 saturated $1N\ H_2SO_4$)

Configuration	Current (mA)	Time (days)
Rod (2 cm length)	10	5.7
Rod (2 mm length)	1.4	16.2
Disk	0.5	45.4

0.06	−4.2				
0.03	−5.3	0.03	−10.4		

Obviously the electrode life increased with increasing *p*H, and obviously periodic recalibration will be required, particularly with a freshly charged electrode.

As mentioned above, palladium hydride electrodes have been reported to have stirring dependence in aerated solutions. Shown in Table IV are the shifts in potential for the palladium rod electrode (2 cm exposed length), as a function of Pd/H ratio, after the stirring was terminated in aerated $1N\ H_2SO_4$, *p*H 3.6 citrate and *p*H 8 phosphate.

Obviously, the stirring dependence is dependent upon the PdH content of the electrode. It would also seem that the higher *p*H solutions have a higher stirring dependence, particularly as the Pd/H ratio increases. Essentially identical results were obtained with the disk configuration, except that the potential shifts below $PdH_{0.05}$ were of the order of 7-10 mV. The practical significance of these stirring dependencies is determined, of course, by the accuracy of the results desired; a 2 mV shift corresponds to a *p*H shift of 0.03 *p*H units. These data do point out the

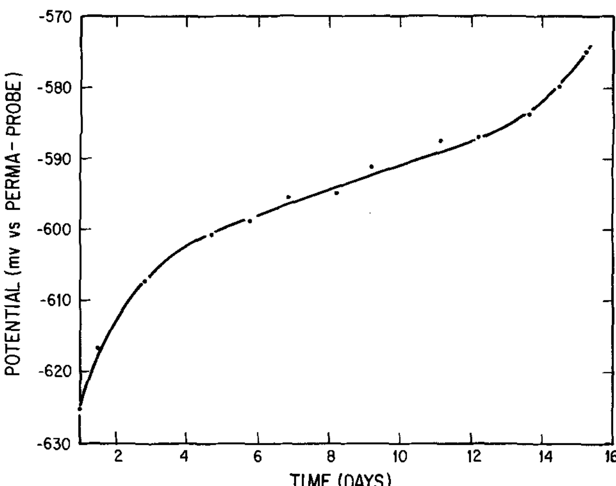

Fig. 4. Potential (*vs.* PermaProbe)-time (days) relationship for a cathodically charged palladium rod in *p*H 8 $(NH_4)_2HPO_4$.

Table V. pH of fluoride etch solutions

Composition	PdH electrode	Pt H_2/H^+ electrode
13.4M NH_4F + 4.54M HF	4.50	4.52
15.9M NH_4F + 5.40M HF	4.74	4.80
18.9M NH_4F + 6.4M HF	5.03	5.08

desirability of working with a fully charged electrode to minimize this problem. The specific sources of these stirring dependencies are discussed below.

Having thus demonstrated that long electrode lifetimes (11-15 days), with minimal perturbation from dissolved oxygen, can be achieved by large volume, high charge capacity, palladium hydride electrodes, performance in the ammonium fluoride-HF etch solutions was studied. Shown in Table V are the pH values obtained with the palladium rod (2 mm exposed length) Teflon holder electrode, charged to $PdH_{0.22}$. Also shown are the pH values obtained with the platinum H_2/H^+ electrode. Corrections for the different ionic strengths of the standard buffers and the concentrated fluoride solutions have not been made. Application and interpretation of these data will be discussed in a subsequent paper.

The glass pH electrode gave pH values of the order of 6.4, reflecting the influence of the etching reaction of these solutions. On return of the PdH electrode to the 1N H_2SO_4 test solution, in which the electrode life was being monitored, potential readings were obtained which were identical to those measured before the fluoride solution experiments, implying no degradation of the electrode surface. These pH measurements in the etch solutions were repeated 5 times over a 7 day period with the same pH electrode. Values identical to those shown in Table V were obtained, as long as the electrode was recalibrated in the standard buffer solutions before each test.

Shown in Fig. 5 is a potential-time curve for a palladium disk, Teflon electrode, charged at constant potential to $PdH_{0.14}$ and operated as described in Texas Instruments Incorporated semiconductor grade common oxide etch (nominal 16M NH_4F + 5.4M HF). For this electrode, life was taken as 11.5 days, giving a loss rate of 0.30 mA. As with the rod electrode in pH 3.6 sodium citrate, this loss rate was less than observed in 1N H_2SO_4 (Table I). The slope of the curve between 2 and 11.5 days corresponds to 2×10^{-4} pH/hr. Data on the stirring dependence in these etch solutions, as a function of PdH content, is given in Table VI.

It is not possible to compare these data directly with those given in Table V because of the differences in electrode configuration. The same general trend,

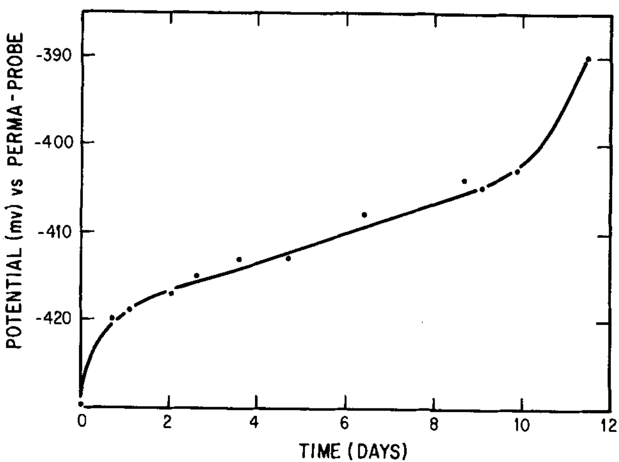

Fig. 5. Potential (vs. PermaProbe)-time (days) relationship for a cathodically charged palladium disk electrode in NH_4F+HF etch.

Table VI. Stirring dependencies vs. PdH content

PdH content	Δ potential (mV)
0.22*	<0.1
0.14	1
0.09	4
0.07	5
0.04	9

* Previous test.

however, is observed as with the other electrodes in other solutions, *i.e.*, lower PdH contents result in higher stirring dependencies, and a highly charged electrode, ≧ $PdH_{0.22}$, has a negligible stirring dependence.

This electrode was then used to monitor a titration with 1N NaOH of 1/100 diluted etch. The curve so obtained is compared in Fig. 6 with that measured by a commercial glass electrode. Identical results, within experimental error for these experiments, were obtained with the electrodes in separate and in the same solutions. For the purposes of direct comparison, the potentials of both electrodes were normalized to the millivolt readings at 1 ml NaOH added. Readings were taken in static solution, 2 min after the increment of titrant was added and the electrolyte volume was stirred. The magnitude of the potential drifts throughout the titration was essentially identical for both electrodes, although generally in the opposite direction. Although the titration curves were somewhat different in form, the end points were obviously identical. This subject of the shape of the titration curve as a function of the H^+ chemistry in these solutions will be treated in another paper.

The operational life of a glass pH electrode used on a routine basis in the titrations was of the order of 5 days. A PdH electrode has been used continuously for over 1 month, at the present writing, with overnight recharge every 2 days. An electrode charged to $PdH_{0.22}$ lasted 11 days without recharge. However, as indicated, the stirring dependence became unacceptable after about 5 days.

Discussion

In order to obtain a more rigorous correlation of electrode performance in terms of dimensional parameters, consideration must be given to the electrode mechanism in terms of the depolarization processes involved. The shape of the potential-time curve (Fig.

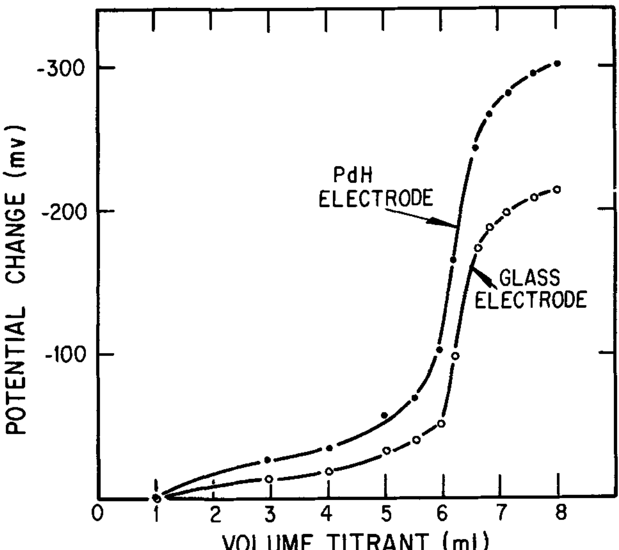

Fig. 6. Potentiometric titration of 1/100 diluted common oxide etch with 1N NaOH. (●, Glass electrode; ○, PdH electrode.)

2 and 3) of a charged palladium hydride electrode in the test solutions is rationalized as follows. The initial portion of the curve (up to 3 days in Fig. 3) represents the loss of PdH from the electrode surface to the test solution and to the bulk of the electrode, eventually establishing a surface hydrogen-palladium ratio of less than 0.6 [0.36 according to Ref. (7)]. Immediately after charge, it is reasonable that the surface concentration is in excess of this value, particularly in view of the low diffusion coefficient of hydrogen in palladium. This same bulk diffusion mechanism has been proposed in Ref. (8). Throughout the midtime region, palladium hydride, in the $\alpha + \beta$ phase, slowly reacts with the solution. At the latter portion of the curve (>11 days, Fig. 3), sufficient hydride has been removed from the surface to reduce the H/Pd ratio to below 0.03. There is at this point insufficient palladium hydride remaining in the bulk of the electrode to deliver hydrogen to the surface at a rate equal to or faster than the surface reaction rate. As a consequence, potential of the palladium electrode becomes more positive (17, 18).

One of the major solution processes accounting for this continual loss of palladium hydride from the surface is reported to be the reaction with dissolved oxygen (13, 14). The extent of this process, as a function of electrolyte pH, is indicated by the stirring dependencies shown in Table IV. The rates of oxygen depolarization are higher at and above pH 3.6 than in 1*N* H_2SO_4. However, as shown in Table IV, the life of the electrode is significantly less in 1*N* H_2SO_4 than in the pH 3.6 and 8 solutions. This implies an additional electrode degradation process in the acid solution that does not proceed at as rapid a rate in the more basic solutions. It is postulated that this process is the acid catalyzed recombination of PdH to yield H_2. It is presumably this process which accounts for the observation (17) that "when the circuit is opened, hydrogen is spontaneously evolved until a potential of 0.050V and a H/Pd ratio of 0.36 is reached."

Not all the hydride formed by cathodic charging of the palladium electrode is "available" for maintaining a constant potential. According to the proposed mechanism for the electrode discussed above, sufficient hydride to establish solely the α-PdH phase, *i.e.*, $PdH_{0.03}$, must remain in the electrode bulk at the end of electrode life as defined above. However, it was also observed that when solution stirring was stopped for such a "depleted" electrode, the potential fell to that of the $\alpha + \beta$ phase, indicating a greater PdH content in the bulk of the electrode structure. It was also observed that charge inputs to a previously uncharged electrode (1 cm $\times$ 0.256 in. diameter) equal to or less than 2.3 A-min yielded short lived electrodes ($\leqq$3 hr). Thus the residual hydride can be separated into two parts, that for the α-phase ($PdH_{0.03}$) and an additional concentration to establish the minimal diffusion concentration gradient, yielding a total of $PdH_{0.042}$ (equivalent to the 2.3 A-min referred to above). These considerations then result in the following empirical formula relating electrode life to the charge input and electrode dimensions

$$t(\text{days}) = k(ch - 5.17V - 2.08V)/A$$

with A the exposed surface area in cm^2, V the electrode volume in cm^3, and ch the total charge in the electrode in A-min. The two numerical coefficients (in units of charge per cm^2) were derived from the residual charge considerations described above. This equation then is the quantitative representation of the general concept expressed above, that electrode life is proportional of the volume to surface ratio.

As indicated, electrode life, for a given electrode configuration, is also a function of pH and a function of the dissolved oxygen content as well as its mass transport rate. For the experimental setup described above, in 1*N* H_2SO_4, the proportionality constant k has a value of 0.569. Shown in Table VII is a comparison

Table VII. Application of correlation formula

Electrode	Charge input (A-min)	Measured life (days)	Calculated life (days)
Disk, Teflon	6.0*	7.0	6.8
Disk, Teflon	5.3*	5.2	4.9
Disk, Acrylic	3.9	7.0	6.3
Rod, 2 mm exposed	11.9	8.0	8.0
Rod, 2 cm exposed	58.2	10.0	8.0
Rod, 2 cm exposed	83.6*	8.8	10.0
Rod, 2 mm exposed	9.8	6.8	6.2
Wire, 2 cm exposed	2.8	1.0	1.2
Foil	2.88*	0.69	0.76

* Containing no residual PdH.

of the measured lifetimes with those calculated from the electrode dimensions and the input charge.

Thus the correlation formula does account within ±25% for the geometric and residual charge factors involved in establishing the electrode life. This is not an unreasonable agreement considering the method of determining electrode life. Interpretation of the constant k in terms of solution processes has not been possible with the cells studied due to poor definition of the mass transport conditions for this particular experimental setup, and due to the lack of information on the PdH recombination processes involved in the acid solution.

The data for the performance of these electrodes in concentrated NH_4F-HF solutions indicates similar electrode mechanisms to those operating in the other test solutions. Electrode life is superior to that in 1*N* H_2SO_4, and the stirring dependencies are less, due probably to a lower solubility of air in the concentrated fluoride salt solutions and a lower PdH recombination rate. Constant k has a value of approximately 0.70 in the empirical formula given above for concentrated NH_4F-HF etch solutions.

The Complex Solubilities of Silver Halides in Acetone-Water Mixtures

Mark Salomon*

Power Sources Technical Area, U.S. Army Electronics Technology and Devices Laboratory, Fort Monmouth, New Jersey 07703

ABSTRACT

The over-all formation constants and solubility products for the silver chlorides, bromides, and iodides have been determined at 25°C in acetone-water mixtures of the following weight per cent acetone: 80.03, 91.23, and 98.53. In the concentration ranges studied, values of β_2 and β_3 corresponding, respectively, to the formation of AgX_2^- and AgX_3^{-2} (X = Cl, Br, I) could be determined. AgX_2^- is the predominant species and the formation of AgX_3^{-2} decreases rapidly as the water content is increased. Log K_{s0} and log β_2 values for pure acetone were evaluated by an extrapolation procedure and the results are compared to previous work.

The work reported in this paper is a continuation of our studies on the effect of solvent composition on the complex solubilities of the silver halides (1). In particular, the following equilibria have been studied

$$Ag^+ + 2X^- = AgX_2^- \qquad \beta_2 \qquad [1]$$

$$Ag^+ + 3X^- = AgX_3^{-2} \qquad \beta_3 \qquad [2]$$

and

$$\underline{AgX} = Ag^+ + X^- \qquad K_{s0} \qquad [3]$$

In Eq. [1]-[3], X = Cl, Br, and I; the β's are the over-all formation constants (or stability constants) and K_{s0} is the solubility product. Once determined, the above equilibrium constants can be used to evaluate the solubility of $\underline{AgX}$ according to

$$\underline{AgX} + X^- = AgX_2^- \qquad K_{s2} \qquad [4]$$

and

$$\underline{AgX} + 2X^- = AgX_3^{-2} \qquad K_{s3} \qquad [5]$$

The effect of solvent composition on these equilibria are of interest in theoretical treatments of ionic solvation and in treatments concerning ion-solvent interactions. In the present paper, the above equilibria have been studied in several mixtures of water and acetone.

Experimental

Materials.—All salts were treated as reported earlier (1). Tetrapropylammonium halide (TPAX) and perchlorate (TPAP) solutions were prepared such that the total ionic strength was maintained at a constant 0.1000M (molar). These solutions were titrated with 0.1000M $AgClO_4$ using a Gilmont 2.0 ml microburette.

Histological grade acetone (Fisher) was refluxed with $KMnO_4$ for at least 5 hr and then distilled onto vacuum dried type 4A molecular sieves. This solvent was further distilled in a Nester-Faust spinning band still and a constant boiling fraction (56°-57°C) was collected at atmospheric pressure. Distilled water was used to prepare three solvents of the following weight per cent acetone: 80.03, 91.23, and 98.53. All solutions were prepared in the laboratory atmosphere at 25.0° ± 0.1°C. The halide solutions were prepared the day prior to their use; each $AgClO_4$ solution was prepared prior to each solvent run and stored in the dark for a period of 1-2 weeks.

Emf measurements.—A Doric model DS-100 microvoltmeter was used for the emf measurements. Reproducibility of this instrument is ± 0.1 mV. The emf measurements were generally stable to within ± 0.2 mV in unsaturated solutions and ranged from ± 0.2 to ± 1 mV in the saturated solutions: Cl and Br solutions were consistently stable while I solutions were the least stable (particularly near the saturation point).

The electrochemical cell was a 125 ml three-neck flask which is represented by

$$Ag(ref)/Ag^+ \;\vdots\vdots\; \text{halide solution}/Ag(ind) \qquad [A]$$

Here "ref" and "ind" refer, respectively, to the reference and indicator electrodes. The dashed lines indicate the liquid junction and since all solutions were of a constant ionic strength of 0.1M, it is assumed that the liquid junction potential is virtually constant. A silver wire plated with silver from a cyanide bath served as the indicator electrode and a silver wire in ~0.02M $AgClO_4$ in TPAP served as the reference electrode. The reference electrode was separated from the study solution by a sealed ST 7/25 joint. Twenty milliliters of TPAX + TPAP solution were placed in the cell which was fitted with a Gilmont 2.0 ml burette containing 0.1M $AgClO_4$ in the given solvent mixture. The sealed cell was thermostated at 25.0° ± 0.1°C and vigorous magnetic stirring was maintained during each potentiometric titration.

Results and Calculations

The measured emf of the above cell, E, is given by

$$E = E' + (2.3RT/\mathbf{F})\log[Ag^+] \qquad [6]$$

where E' is a formal potential; *i.e.*, it contains contributions from the liquid junction and nonideality of the electrolyte solutions. E' was determined by titrating 0.1M $AgClO_4$ into 25.0 ml of 0.1M TPAP solution. The Nernst slope of 59.2 mV was obeyed to within 0.2 mV in all solutions except the 98.53% acetone solution for which a slope of 60.0 mV was obtained. This is probably due to ion-pairing effects (see below). Activity coefficient effects will be discussed further on in conjunction with the Davies equation (Eq. [14]).

* Electrochemical Society Active Member.
Key words: silver halides, water-acetone mixtures, over-all formation constants, solubility products, medium effects.

The over-all formation constants are calculated from the titration data in unsaturated solutions by a nonlinear least squares method in which the relative error, U, is minimized. For i data points, U is defined (1-3) by

$$U = \sum_{1}^{i} (1 - x_i/fx_i)^2 \quad [7]$$

where

$$x_i = (C_{X,i} - [X^-]_i)/[Ag^+]_i \quad [8]$$

and

$$fx_i = \beta_1[X^-]_i + 2\beta_2[X^-]_i^2 + \ldots\ldots\ldots\ldots + n\beta_n[X^-]_i^n \quad [9]$$

In these equations $[X^-]$ is the halide ion concentration, $[Ag^+]$ is the silver ion concentration which is obtained from the measured emf via Eq. [6], and C_X is the total halide concentration present in solution (below C_{Ag} is used for the total silver concentration in solution). All concentrations are based on the molar scale. To obtain $[X^-]_i$ values, an iterative procedure was used which is based on the average ligand number, $\bar{n}$, defined by

$$\bar{n} = (C_{X,i} - [X^-]_i)/C_{Ag,i} \quad [10a]$$

and

$$\bar{n} = \sum_{1}^{n} n\beta_n[X^-]^n \Big/ \sum_{0}^{n} \beta_n[X^-]^n \quad [10b]$$

Equation [10a] is used to start the calculations by assuming a value for $\bar{n}$ (usually around 1.5-2.5) and obtaining initial $[X^-]_i$ values. The β's are obtained from the least squares using Eq. [7] to minimize the relative errors. The iteration is begun by using these β's to calculate new $\bar{n}$ values via Eq. [10b] and the process is continued until the β's converge to within 0.001%. The standard deviations of the β's were calculated by Sillén's method (4). The solubility product, K_{s0}, was calculated from each point in the saturated region of the titration curve using the relation

$$\{C_x - C_{Ag} + [Ag^+]\}/[Ag^+] = \frac{K_{s0}}{[Ag^+]^2} + \sum_{2}^{n} (n-1)\beta_n \left\{ \frac{K_{s0}}{[Ag^+]} \right\}^n \quad [11]$$

The Newton-Raphson iterative method is used to solve Eq. [11] and the average K_{s0} value is reported along with the standard deviation. The solubility constants K_{s2} and K_{s3} are obtained from

$$K_{s2} = K_{s0}\beta_2 \quad [12]$$

$$K_{s3} = K_{s0}\beta_3 \quad [13]$$

The experimental data are given in the Appendices. It should be noted that those data points marked with an asterisk were omitted from the calculations because they gave rise to abnormally large errors. The majority of these rejected points lie very close to the saturation point; this is attributable to supersaturation and the failure to reach equilibrium. Each point was recorded usually within 10-30 min and if equilibrium was not reached within 1 hr, additional titrant was added and the experiment continued. For the concentration ranges studied, statistically meaningful solutions to Eq. [7] were obtained only for β_2 and β_3. In the 80.03 and 91.23% acetone solutions, β_3 values for the iodides could not be refined. The results of the calculations are given in Table I. Activity coefficient corrections were made by use of the Davies (5) equation

$$\log \gamma_\pm = -\frac{AM}{1 + M^{1/2}} + 0.3AM \quad [14]$$

where A is the Debye-Hückel "A" factor and M is the molarity. Dielectric constants and densities of the acetone-water mixtures were interpolated from the data of Albright (6). The Debye-Hückel "A" factors for the present acetone-water mixtures are given in Table I. The Davies equation was chosen for activity coefficient corrections rather than a simpler Debye-Hückel equation because of its successful application to a variety of other nonaqueous solvents (9, 20).

Above it was pointed out that the high Nernst slope in the 98.53% acetone solution was probably due to ion pairing. It is well known (7-9) that ion-association constants in pure acetone are quite large ($\sim 10^2$) even for the tetraalkyl halides, perchlorates, and picrates. In correcting for ion-pair formation in the 98.53% acetone solution, the following equilibria were assumed to be of importance

$$TPA^+ + ClO_4^- = TPAClO_4 \qquad K_{a1} \quad [15]$$

$$TPA^+ + X^- = TPAX \qquad K_{a2} \quad [16]$$

$$TPA^+ + AgX_2^- = TPAAgX_2 \qquad K_{a3} \quad [17]$$

$$TPA^+ + AgX_3^{-2} = TPAAgX_3^- \qquad K_{a4} \quad [18]$$

The possible formation of the triple-ion TPA_2AgX_3 was not considered. Because specific data on the K_a's in Eq. [15]-[18] are not available, it was assumed that $K_{a1} = K_{a2} = K_{a3} = K_{a4} = K_a$. An approximate value of 50 was found for K_a by a method discussed below. The results of these calculations are given in Table II. The standard deviations are not included in this table: they are expected to be about 5-10% higher than the corresponding values given in Table I due to the uncertainties in the use of Eq. [14]-[18]. It is noted that K_{s2} is independent of the effects described by Eq. [14]-[18].

The ion association constant in 98.53% acetone and values for the equilibrium constants in pure acetone were evaluated as follows. First the log K°_{s0} data for the 80.03, 91.23, and 98.53% acetone solutions were fit to the equation

$$\log K = a + bP + cP^2 \quad [19]$$

where P = per cent acetone. K_a for the 98.53% acetone solution was varied until the predicted value of log K°_{s0} in pure acetone agreed with the published values (9) for AgBr and AgCl. Once K_a was evaluated, Eq.

d is from Ref. (9).

[19] was used to calculate $\log K^\circ_{s0}$ for AgI and the β°_2 values in pure acetone. Table III lists the calculated values along with those values obtained by other workers. The values obtained by Luehrs *et al.* (10) are certainly in error as they are generally much too large. There is some discrepancy between the present results for the AgI data and Mackor's data (11). In the Discussion section below, evidence is presented which indicates that some of Mackor's data may be in error.

Discussion

Table IV lists the available data for the silver halide equilibrium constants in various water-acetone mixtures. The data in pure water were obtained from Ref. (12), (13), and (14) for AgCl, AgBr, and AgI, respectively. Data for the AgCl and AgI sytems, other than those reported here, were obtained from Ref. (15) and (11), respectively. Using the data in Table IV, some function was sought to give linear relationships between the equilibrium constants and water or acetone composition. The only functions that could be found were those of $\log \phi_w$ or $\log a_w$ (ϕ_w is the volume fraction of water and a_w is the activity of water); other functions, including the volume fraction of acetone, were not linear. Figures 1 and 2 are examples of plots of $\log K$ *vs.* $\log \phi_w$ for the AgCl and AgI systems. The plot for the AgBr system is not shown but is very similar to the AgCl system (Fig. 1). Mackor's data for β°_2 (AgI) do not fall on a single line which is contrary to the analogous results for AgCl and AgBr. For

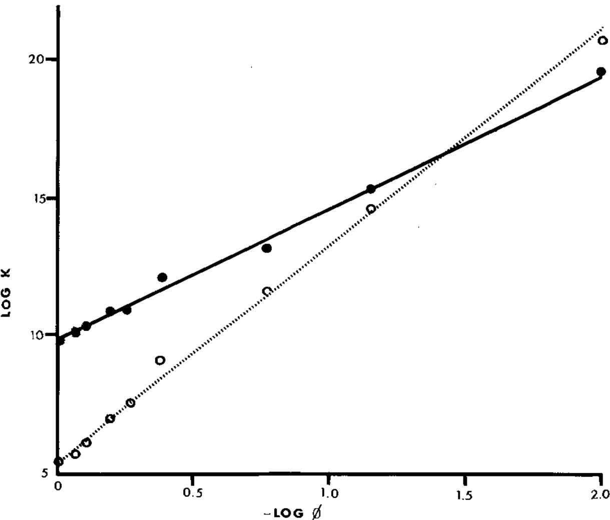

Fig. 1. Plots of $\log K^\circ_{s0}$ and $\log \beta^\circ_2$ for the AgCl systems against $\log \phi$ (ϕ is the volume fraction of water). ○, Log β°_2 values; ●, $-\log K^\circ_{s0}$ values.

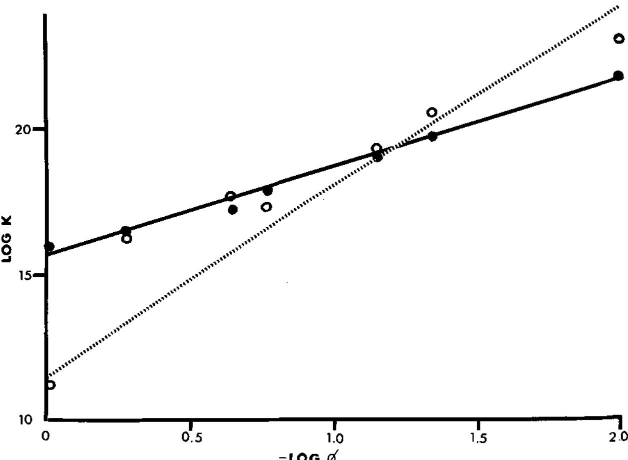

Fig. 2. Plots of $\log K^\circ_{s0}$ and $\log \beta^\circ_2$ for the AgI systems against $\log \phi$ (ϕ is the volume fraction of water). ○, Log β°_2 values; ●, $-\log K^\circ_{s0}$ values.

this reason it is suggested that the accuracy of these β°_2 values is questionable. The dashed line in Fig. 2 (for β°_2) was drawn neglecting Mackor's values. Figures 1 and 2 were suggested by Feakins and French (16) and by Marshall (17) to have the following significance. Equations [1] and [3] can be written to include the solvent, H_2O, involved in hydrating the various ionic species: *i.e.*,

$$\underline{AgX} + (m + n)H_2O = Ag^+(H_2O)_m + X^-(H_2O)_n \quad [20]$$

$$Ag^+(H_2O)_m + 2X^-(H_2O)_n = AgX_2^-(H_2O)_p + (m + 2n - p)H_2O \quad [21]$$

Plots of $\log K^\circ_{s0}$ and $\log \beta^\circ_2$ should be linear with slopes, respectively, of $m + n$ and $m + 2n - p$. For AgCl the plot in Fig. 1 gives $m + n = 5$; assuming $m = 2$ and $n = 3$, it is found that $p = 16$ which seems unreasonably large. The failure of this treatment over a large range of solvent compositions is not surprising as the original treatments (16, 17) were intended to apply to those systems where the cosolvent (acetone in the present case) is inert. Over the range where the cosolvent composition is small, the relations in Eq. [20] and [21] apparently hold (15, 16). Over the solvent composition range studied here, no particular

theoretical significance can be attached to the plots shown in Fig. 1 and 2.

Inspection of Table IV shows monotonical behavior: for each salt K°_{s0} becomes smaller and β°_2 becomes larger as the acetone content is increased. In solutions of high acetone content, the AgX_2^- and AgX_3^{-2} species becomes more stable than X^- which is typical of these salts in aprotic solvents (1, 3, 9-11, 14). That the AgX_2^- species is indeed more stable can be demonstrated by considering individual ionic medium effects. Table V gives values of the individual ionic free energies of transfer, ΔG°_t(ion), from water to pure acetone. The data are based on the extrathermodynamic assumptions of: Bax *et al.* (18) who used an extrapolation procedure, and Parker *et al.* (9) who assumed that there is negligible liquid junction potentials for the reference half cells

$$Ag/AgClO_4(0.1M)//0.1M \text{ tetraethylammonium picrate}//$$

and the present values which are based on the approximate relation (1)

$$\Delta G^\circ_t(Ag^+,AgCl_2^-) + \Delta G^\circ_t(Ag^+,AgBr_2^-) \approx 2\Delta G^\circ_t(Ag^+) \quad [22]$$

In Table V, those values given in parenthesis were obtained by the additivity rule using the present values for $\Delta G^\circ_t(Ag^+,X^-)$ and $\Delta G^\circ_t(Ag^+,AgX_2^-)$. Using Parker's (9) and the present values for $\Delta G^\circ_t(Cl^-)$ a value for $\Delta G^\circ_t(H^+)$ was obtained from the calculated value of $\Delta G^\circ_t(HCl)$. This latter quantity was calculated from the emf's of the cells

$$Pt, H_2/HCl \text{ in water or acetone}/AgCl,Ag$$

using the relation

$$\Delta G^\circ_t(HCl) = \mathbf{F}(E^\circ_w - E^\circ_{ac}) \quad [23]$$

For acetone $E^\circ_{ac} = -0.542V$ (19) and in water, $E^\circ_w = 0.222V$. Inspection of Table V shows that even though the ΔG°_t(ion) values are not very consistent for the three works, the relation $\Delta G^\circ_t(AgX_2^-) < \Delta G^\circ_t(X^-)$ holds for each method of evaluation. While it is desirable to produce a common list of ΔG°_t(ion) values, it is not necessary if our primary object is to qualitatively understand the nature of ion solvation in the various solvents. One inherent difficulty involved in producing common ΔG°_t(ion) values is that values of ΔG°_t(salt) often differ considerably. For example the value of $\Delta G^\circ_t(HCl)$ calculated from Eq. [23] is 12.6 kcal $mole^{-1}$. Bax *et al.* use a value of 12.6 kcal $mole^{-1}$, and Parker and the present author arrive at a value 7.4 kcal $mole^{-1}$ for $\Delta G^\circ_t(HCl)$. Additional but less severe discrepancies can be found for the values of $\Delta G^\circ_t(Ag^+,Br^-)$ and $\Delta G^\circ_t(Ag^+,I^-)$ obtained by Parker *et al.* and by the present author.

Manuscript submitted Sept. 10, 1973; revised manuscript received July 15, 1974.

Table V. Free energies of transfer for single ions from water to acetone at 25°C

Ion	ΔG°_t (ion), kcal $mole^{-1}$

Any discussion of this paper will appear in a Discussion Section to be published in the June 1975 JOURNAL. All discussions for the June 1975 Discussion Section should be submitted by Feb. 1, 1975.

The publication costs of this article have been assisted by the U.S. Army Electronics Technology and Devices Laboratory.

LIST OF SYMBOLS

- β_n — over-all stability constant for the formation of species Ag_n^{1-n} uncorrected for activity effects.
- β°_n — over-all stability constant corrected for activity effects
- U — relative error defined by Eq. [7]
- C_X — total concentration of species X in moles per liter or millimoles per liter as denoted in text
- $\bar{n}$ — average ligand number
- $\Delta G^\circ_t(X)$ — free energy of transfer of species X from water to the mixed or pure acetone solvent
- $[Ag^+]$ — concentration of silver ion in moles per liter or millimoles per liter

APPENDICES

The experimental data are given below. All concentrations are reported in units of mM (millimoles per liter) and potentials are given in volts. Those points marked with an asterisk were not used in the least squares refinement of the equilibrium constants. The symbols used below have the following significance: E' = formal potential; E = potential measured during the titration; $[Ag^+]_{ref}$ = silver ion concentration in the reference electrode solution; C_{Ag} = total silver concentration in the experimental solution; C_X = total halide concentration in the experimental solution.

Contributions of Dissolved Hydrogen to Potential and Irreversible Behavior of the Hydrogen Electrode

M. A. Fullenwider*[,1]

B-B Laboratory, Carlisle, Pennsylvania 17013

ABSTRACT

A statistical theory of hydrogen in metals is developed, and isotherms relating surface coverage to bulk hydrogen concentration in the metal are derived. It is shown that in certain circumstances of high concentration and energy, bulk hydrogen can contribute to irreversible behavior of the hydrogen electrode. Irreversible behavior can also be expected in the vicinity of a phase transformation.

In treatments of the hydrogen electrode to date, all (1) have involved the concept, logical from the thermodynamic point of view, that the substrate material affects the reactions involved only in as much as it participates in determining the fate of adsorbed intermediates, free radicals, etc., at the surface of the electrode. Irreversible effects, *e.g.*, those occurring in the presence of adsorbing cations and anions and in particular the −50 mV (*vs.* RHE) rest potential of the palladium-hydrogen system (2) are also generally ascribed to surface effects such as the formation of covalent bonds with the surface in the case of adsorbing cations and anions and the diffusion to the surface of protons in the case of the palladium-hydrogen system.

It has long been known that atomic hydrogen penetrates into the bulk of many metals, and that the properties of the resulting systems vary considerably from metal to metal. Recently the effect of dissolved hydrogen on the thermodynamics of the platinum-hydrogen electrode under reversible conditions was discussed by Frumkin *et al.* (3), the conclusion being that dissolved hydrogen, even in large concentrations would have little or no effect. It is the purpose of this paper to examine these conclusions in more detail using statistical arguments. It will be shown that dissolved hydrogen has the possibility under certain circumstances of causing irreversible effects with the platinum-hydrogen electrode and with other metal-hydrogen systems, notably the palladium and iron system.

Preliminaries

The hydrogen atom, or partially shielded proton as it is believed to exist within the bulk of a metal will obey Fermi-Dirac statistics. Thus we have for a total of N particles, the number n_r in state r of energy ϵ_r and weight w_r

$$n_r = w_r/[1 + \exp(\epsilon_r/kT)/\lambda] \quad [1]$$

where λ, the absolute activity, is given for a particle of chemical potential μ

$$\lambda = \exp(\mu/kT) \quad [2]$$

and determined by the condition

* Electrochemical Society Active Member.

[1] Present address: RKP Industries, Incorporated, Allentown, Pennsylvania 18103.

Key words: hydrogen electrode, irreversible behavior, hydrogen in metals, hydrogen embrittlement.

$$\sum_r n_r = N \quad [3]$$

It can be shown that for systems such as we will be treating, that is, dilute systems and systems at temperatures far elevated from zero Kelvins, we will have the condition

$$\lambda << \exp(\epsilon_r/kT) \quad [4]$$

Thus Eq. [1] and [3] reduce to

$$\lambda \sum_r w_r \exp(-\epsilon_r/kT) = N \quad [5]$$

and we have

$$n_r = N w_r \exp(-\epsilon_r/kT)/f(T) \quad [6]$$

where $f(T)$ is the ordinary partition function and Eq. [6] is the distribution law of classical statistics. Therefore the systems we will be treating here may be approximated by classical statistics.

We will be dealing with a quantity ϕ, the spreading pressure, defined

$$\phi = -\partial F^{ads}/\partial A \quad [7]$$

where F^{ads} is the free energy of adsorption of a species and A is the area of the surface.

ϕ is related to the variables we will be interested in by the relation

$$RT\,\Gamma_H = \partial\phi/\partial \ln a_H \quad [8]$$

where Γ_H is the surface coverage with hydrogen atoms in moles of H cm^{-2} and a_H is the bulk hydrogen concentration in the metal in moles of H cm^{-3}. Equation [8] will result in isotherms relating surface coverage to bulk hydrogen concentration. Now isotherms usually express surface coverage as a function of electrochemical potential, generally expressed as a function of concentration in a bulk electrolyte solution or potential across the interface (4). Our isotherms will contain this dependence since a_H is certainly dependent on these quantities, but the dependence will be hidden.

Most generally our model for the hydrogen electrode will be an ideal layer of hydrogen atoms on the surface of the electrode in equilibrium with a gas of protons or partially shielded protons within the bulk of the metal which will be assumed first to be very dilute and then, in another treatment, more concentrated. Equilibrium with hydrogen in aqueous solution will in general not be assumed, especially where there is the possibility of irreversibility, and it must be remembered, particularly in the application of the resulting isotherms, that they only apply in the approximation that the atomic hydrogen dissolved in the metal is in equilibrium with the layer of hydrogen atoms on the surface.

For the free energy of the ideal layer of adsorbed hydrogen atoms on the electrode surface we have from classical statistics (5)

$$F_H^{ads} = -kT\lambda_H f_H(T) + N_H kT \ln \lambda_H \quad [9]$$

where the symbols have the same definition as previously, and

$$f(T) = 2\pi m_H kT\,A/h^2 \quad [10]$$

the partition function for a two dimensional monatomic gas.

For the condition of equilibrium between surface and bulk hydrogen we need an expression for λ_H for hydrogen dissolved in the metal. This combined with Eq. [9], [10], and [7] will give us an expression for ϕ, and Eq. [8] will result in the final isotherms.

To obtain an expression for λ_H we use the grand partition function for hydrogen in the metal which in general form is given by (6)

$$\Gamma(T,\lambda_H) = \sum_{N_H} [(\alpha N)!/N_H!(\alpha N - N_H)!]\,(\lambda_H f_H'(T)\rho)^{N_H}$$
$$\exp[-(N_H w_H + \tfrac{1}{2}N_H^2 w_{HH}/\alpha N)/kT] \quad [11]$$

where αN is the number of interstitial sites, N_H is the number of hydrogen atoms distributed among the αN sites in the metal, ρ is the nuclear spin weight, w_H is the potential energy of the protons relative to the state of infinite dispersion outside the metal, and where

$$f_H'(T) = (2\pi m_H kT)^{3/2}\,V/h^3 \quad [12]$$

simply the partition function of a three-dimensional monatomic gas, and V is the volume of the metal-hydrogen system.

The factor

$$\exp(-\tfrac{1}{2}N_H^2 w_{HH}/\alpha NkT) \quad [13]$$

deserves special attention. It is just this quantity, corresponding to interactions between the protons, which in some treatments of electrolytic solutions and the electric double layer is expanded in the cluster formalism of Mayer and Mayer (7). This does not suit our purposes here since it would be very complicated and there is not exact information available of, for example, the variation of the heat of solution with concentration, the nature of the species involved, etc., for the systems we will be discussing. What we have done instead is to, as Lacher (8), ignore the effect of the actual arrangement of the protons on the rate of increase of absorption energy and assumed that this rate is directly proportional to the number of holes filled, w_{HH} being a proportionality constant.

Very Dilute Approximation

In this approximation we put the following requirements on Eq. [11]

$$w_{HH} = 0 \quad [14]$$

$$N_H << \alpha N \quad [15]$$

This gives us for the grand partition function

$$\Gamma(T, \lambda_H) = \sum_{N_H} (1/N_H!)\,(\lambda_H f_H'(T)\rho)^{N_H} \exp(-N_H w_H/kT) \quad [16]$$

Equation [16] is treated in the usual way to obtain the equilibrium value of N_H by taking

$$\partial \ln(\text{term of sum: }[\Gamma(T,\lambda_H)])/\partial N_H = 0 \quad [17]$$

that is, replacing the series by its maximum term, we obtain

$$N_H = \lambda_H f_H'(T)\rho \exp(-w_H/kT) \quad [18]$$

and from Eq. [9], [10], [12], and [18] we have

$$F_H^{ads} = -kT\left[\frac{N_H h^3 \exp(w_H kT)}{(2\pi m_H kT)^{3/2}\rho V}\right]\frac{2\pi m_H kT}{h^2}A + N_H kT \ln\left[\frac{N_H h^3 \exp(w_H/kT)}{(2\pi m_H kT)^{3/2}\rho V}\right] \quad [19]$$

and with Eq. [7] and the relation

$$A = V^{2/3} \quad [20]$$

that is taking a cubic symmetry, we get for ϕ

$$\phi = \frac{3}{2} N_{H,surface}\,kT/A - \frac{N_{H,bulk}kTh \exp(w_H/kT)}{2V\rho(2\pi m_H kT)^{1/2}} \quad [21]$$

which may be written

$$\phi = K\Gamma_H + K'a_H \exp(w_H/kT) \quad [22]$$

and from Eq. [8] we obtain the linear, first order differential equation

$$RT\Gamma_H = Ka_H\,\partial\Gamma_H/\partial a_H + K'a_H \exp(w_H/kT) \quad [23]$$

which has the solution

$$\Gamma_H = Ca_H^{2/3} - \frac{3}{2}K'a_H \exp(w_H/kT) \quad [24]$$

where C is a constant of integration. Equation [24] provides a relation between surface coverage and a small quantity of hydrogen dissolved in a metal for the case that the two are in equilibrium and the interactions between the dissolved species are negligible.

Approximation for More Concentrated Systems

In this approximation we take Eq. [1] without any restrictions, and together with Eq. [17] we obtain the relation

$$N_H/(\alpha N - N_H) = \lambda_H f_H'(T)\rho \exp[-(w_H + N_H w_{HH}/\alpha N)/kT] \quad [25]$$

and from Eq. [9], [10], [12], and [25] we have

$$F_H^{ads} = -kT\left(\frac{N_H h^3 \exp[(w_H + N_H w_{HH}/\alpha N)/kT]}{(\alpha N - N_H)(2\pi m_H kT)^{3/2}\rho V}\right) \times \frac{2\pi m_H kT}{h^2} A + N_H kT \times\left(\ln\left[\frac{N_H h^3 \exp(w_H + N_H w_{HH}/\alpha N)/kT}{(\alpha N - N_H)(2\pi m_H kT)^{3/2}\rho V}\right]\right) \quad [26]$$

and from Eq. [7] for ϕ with Eq. [20]

$$\phi = \frac{3}{2} N_{H,surfcae}\, kT/A - \frac{N_H kTh \exp[(w_H + N_H w_{HH}/\alpha N)/kT]}{(\alpha N - N_H) 2V\rho(2\pi m_H kT)^{1/2}} \quad [27]$$

which may be written

$$\phi = K\Gamma_H + K' a_H' \exp[(w_H + N_H w_{HH}/\alpha N)/kT] \quad [28]$$

where

$$a_H' = N_H/(\alpha N - N_H)V \quad [29]$$

the reduced concentration. Again from Eq. [8] we have a relation similar to Eq. [24]

$$\Gamma_H/a_H'^{2/3} = C - \int (K'/a_H'^{2/3}K) \exp[(w_H + N_H w_{HH}/\alpha N)/kT] \times [1 + a_H' w_{HH} V/kT(1 + Va_H')^2]\, da_H' \quad [30]$$

where the integral may be expanded in different ways. Equation [30] extends Eq. [24] into regions where interactions between dissolved species are not negligible. It should be noted, however, that equilibrium between the adsorbed and absorbed protons is still assumed.

Discussion

First of all the quantities w_H and $(w_H + N_H w_{HH}/\alpha N)$ of Eq. [16]-[24] and Eq. [25]-[30], respectively, can be roughly taken as the heats of solution from the gas phase, since the experimental heats of solution are only rough estimates, values generally being for unspecified concentrations, and where there is more than one value in the literature considerable spread exists. Some values of the heat of solution are given in Table I, and it should be noted that some are endothermic and others exothermic. Strictly speaking the quantity in the equations, the protonic work function, refers to the process

$$H(\text{zero pressure gas}) = H(\text{dissolved in metal}) \quad [31]$$

Table I. Solubilities at the reversible potential and heats of solution of hydrogen for various metals

Metal	a_H (mol H cm^{-3})	Ref.	ΔH_s (kcal per half-mol H_2)	Ref.
Pt	1×10^{-5}	11	8.9	12
Ni	1.4×10^{-5}	13	3.60	14
Pd	2.7×10^{-4}	13	−9.5	15
Fe	7.0×10^{-9}	13	7.04	16

while the values of ΔH_s in Table I refer to the process

$$\tfrac{1}{2} H_2(\text{gas}) = H(\text{dissolved in metal}) \quad [32]$$

Secondly, there exists no correct data at the present time to test Eq. [24] and [30]. The recent paper of Breger and Gileadi (9) lists values of coverages and bulk hydrogen concentrations for the palladium-hydrogen system. However, this paper was based upon assumptions which have since been found to be erroneous (10), *i.e.*, that of a concentration independent diffusion coefficient and an anodic stripping coverage time independent of bulk hydrogen concentration.

Equation [22] will be used first to reach some conclusions regarding the platinum-hydrogen system. Assuming a full monolayer coverage and inserting standard values for the constants we obtain the relation

$$\phi = (3 \times 10^{-9})RT - a_H[2.5 \times 10^{-9} \exp(w_H/kT)]RT \quad [33]$$

where units for ϕ might be, for example, ergs cm^{-2}, and a_H is again moles of H cm^{-3}. Table I lists some values of a_H at the reversible potential and heats of solution, as stated previously. w_H should be taken with the same sign as the heat of solution.

Now whenever the bulk term (second in Eq. [33]) predominates over the surface term (first in Eq. [33]) we will have irreversible behavior because this is thermodynamically impossible at the reversible potential. For platinum it can be seen that the bulk term is slightly larger than the surface term, and for other metals the surface term predominates. However, the value of a_H cited for platinum is in the presence of As_2O_3, a hydrogen diffusion promoter, and under normal conditions a_H would be much lower, *i.e.*, there would be reversible behavior. Thus it is quite likely that irreversible behavior of the platinum-hydrogen electrode observed in the presence of some adsorbing cations and anions is due to their hydrogen diffusion promoting properties. Also, whereas the conclusion of Frumkin *et al.* (3) was that when there is a large quantity of bulk hydrogen present and reversibility this hydrogen has no appreciable effect, we must make the point that when there is a large quantity of bulk hydrogen present there is no reversibility.

Referring to Eq. [27] with reference to the palladium-hydrogen system we can see that the surface term will predominate except when N_H approaches αN. When this happens the bulk term becomes large, and again we will have irreversible behavior. Before ϕ gets too large, however, the β phase should start to form, and it is this that results in the −50 mV rest potential of the palladium-hydrogen system, the −50 mV corresponding to the energy increment between the α and β phases.

We have shown how hydrogen in large concentrations dissolved within the bulk of a metal can contribute toward irreversible behavior of the hydrogen electrode. For most metals behavior of this type can usually be expected in the vicinity of a so-called phase transition. In a manner of speaking the word "phase" is inappropriate in the case of hydrogen in metals. The work of Gosar (17), for example, showed that mobile interstitials in the semiclassical approximation exist within the host lattice rather in "bands" possessing energies, band widths, and energy gaps, much the same as electrons in a lattice. This seems to explain qualitatively the fact that iron undergoes its irreversible embrittlement at such small concentrations (18), *e.g.*, 10^{-7} moles cm^{-3}, *i.e.*, its first band apparently fills in this concentration range. Here the tendency for the protons to collect in regions of high tensile stress (19) acts to "pump" gaseous hydrogen into cracks and voids as the spreading pressure becomes large at their surfaces, causing embrittlement.

LIST OF SYMBOLS

A	surface area
a_H	concentration of protons
a_H'	reduced concentration of protons
F^{ads}	free energy of adsorption
$f_H(T)$	partition function of ideal two-dimensional gas of protons
$f_H'(T)$	partition function of ideal three-dimensional gas of protons
h	Planck's constant
k	Boltzmann's constant
m_H	proton mass
N	number of particles
N_H	number of protons
n_r	number of particles in state r
R	gas constant
T	temperature in Kelvins
V	volume
w_H	potential energy of protons in the metal with respect to infinite dispersion outside the metal, protonic work function
w_{HH}	a proportionality constant
w_r	weight of state r
αN	number of interstitial sites
Γ_H	surface coverage with protons
$\Gamma(T, \lambda_H)$	grand partition function for hydrogen in the metal
ΔH_s	heat of solution of hydrogen in a metal
ϵ_r	energy of particles in state r
λ	absolute activity
μ	chemical potential
ρ	nuclear spin weight
ϕ	spreading pressure

Dissolution of Mild Steel with a Rotating Ring Hemispherical Electrode

Der-Tau Chin*

General Motors Corporation, Research Laboratories, Electrochemistry Department, Warren, Michigan 48090

ABSTRACT

A rotating ring hemispherical electrode was used to study the active dissolution of mild steel in sulfate electrolytes. Using potentiostatic transients for the deposition of a monolayer of an iron oxide on a platinum ring electrode, the soluble $FeOH^+$ complex ion was identified as an intermediate product during the dissolution reaction. The $FeOH^+$ concentration was found to increase with pH of the electrolyte and to decrease with sulfate concentration. In concentrated sulfate solutions, the $FeOH^+$ concentration also decreased with increasing dissolution current density at the mild steel hemispherical electrode. The results indicate that the dissolution reaction did not fully follow the commonly accepted Bockris or Heusler mechanism. This discrepancy is discussed with a parallel mechanism, in which sulfate ion participates in the anodic reaction.

Although numerous studies have been made of the anodic dissolution of iron and carbon steels in sulfate electrolytes, the exact mechanism of iron dissolution is still a controversial question (1-5). One of the major mechanisms as proposed by Bockris *et al.* (6) involves the following steps

$$Fe + OH^- \rightleftarrows FeOH_{ads} + e$$

$$FeOH_{ads} \rightarrow FeOH^+ + e, \text{ rate determining} \quad [1]$$

$$FeOH^+ \rightleftarrows Fe^{++} + OH^-$$

* Electrochemical Society Active Member.

Key words: dissolution of mild steel in sulfate solution, iron oxide deposition.

Equation [1] has been supported by a number of polarization measurements (7-9). Nevertheless, the FeOH complexes in each step are still hypothetical in nature; no positive identification has been thus far reported in the literature. These complexes are also suggested in Heusler's catalysis mechanism (1). Therefore, it is of theoretical importance to determine if the principal intermediate, $FeOH^+$ ion, is generated by iron dissolution.

Previous studies (10-11) have shown that $FeOH^+$ ions can deposit on a platinum substrate to form a γ-FeOOH film from sulfate solutions. On a rotating platinum ring electrode, the deposition reaction follows a mathematical model describing two-dimensional nu-

cleation and growth of a monolayer of oxide on the electrode surface (12).

This evidence suggests the use of a rotating ring hemisphere for the study of iron dissolution reactions. By properly setting the potential of a platinum ring electrode within the region for the iron oxide deposition reaction, it should be possible to detect the soluble $FeOH^+$ complex ion produced by iron dissolution at the central hemispherical electrode. The rationale for the use of a ring hemisphere combination has been discussed previously (13). Easy replacement of the central hemisphere and less change in the electrode geometry are the advantages of this combination in studying metal dissolution reactions.

Such a study has been made in this laboratory for the dissolution of mild steel in $(NH_4)_2SO_4$ electrolytes. The methods of galvanostatic dissolution at the central hemisphere and the potentiostatic transient at the platinum ring were used for the experiments. This paper summarizes the results of the study.

Experimental

The rotating ring hemispherical electrode used consisted of a platinum ring and a replaceable central mild steel[1] hemispherical electrode mounted concentrically on a Teflon support rod. The hemisphere was 0.635 cm in diameter and the dimension of the ring electrode was 0.798 cm ID × 1.003 cm OD. This arrangement had a collection efficiency of 32% as calibrated with a ferricyanide/ferrocyanide redox reaction. The details of the experimental setup have been described previously (13).

The method of galvanostatic dissolution at the central hemisphere and a potentiostatic transient at the ring were used for the study. The mild steel hemisphere was first dissolved in a test electrolyte at the steady-state conditions. To detect $FeOH^+$ complex ions generated during the dissolution reaction, a constant potential of 0.9 V/SCE (12) was applied to the ring electrode and the ring current was recorded on a strip-chart recorder.

Two independent electrical circuits composed of two separate counterelectrodes (one for the hemisphere and the other for the ring) were used for the experiment. The constant current to the hemisphere was supplied from a Magna 4700M potentiostat, whereas the ring potential was controlled by a battery powered potentiostat which was floating with respect to ground.

For each run, the surface of the ring electrode was first polished with a 600 grit Carbimet wet grinding paper. The mild steel hemispherical electrode was then fastened to the Teflon support. The assembled ring hemisphere was cleaned with methanol and cathodically treated in 2M NaOH followed by a rinse in distilled water. The electrode was then transferred to a cell filled with the test electrolyte and was installed on a high speed rotator. At this point, a constant rotational speed was selected for the rotator and a constant current was applied to the mild steel hemisphere. The potential of the hemisphere was recorded on a strip-chart recorder. After the hemisphere potential reached a steady-state value, a constant potential of 0.9 V/SCE was applied to the ring electrode and the ring current was subsequently recorded on a Sanborn 296 recorder.

Nitrogen-saturated 0.5-2M $(NH_4)_2SO_4$ was used as the electrolyte. The pH of these solutions was maintained at a constant value by adding proper amounts of dilute NH_4OH and H_2SO_4 during the runs. All the experiments were performed at a constant temperature of 24° ± 1°C.

Results and Discussion

Figure 1 shows the recorder traces of current transients on the platinum ring when the mild steel hemispherical electrode was dissolving at a constant current density of 31 mA/cm² into pH 5, 1M $(NH_4)_2SO_4$ electrolyte. The speed of electrode rotation for these runs varied from 400 to 2500 rpm. It is seen that the ring current jumped to a large value at the beginning of the potential step and then decreased with time. This behavior is the same as that of a previous characterization study (12) on the deposition of iron oxide from ferrous sulfate solutions.

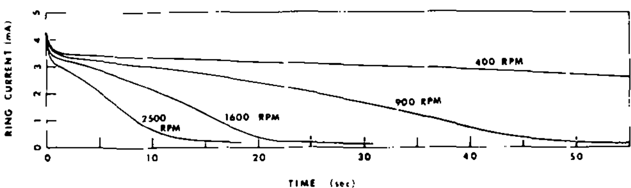

Fig. 1. Recorder traces of ring current when the central mild steel hemisphere was dissolving at a constant current density of 31 mA/cm². The electrolyte used was pH 5, 1M $(NH_4)_2SO_4$.

The current jumps to a large value at zero time; this suggests that the ring picked up the dissolution product, Fe^{++} ion, and oxidized it to Fe^{+++} ion at the limiting current potential of 0.9 V/SCE. Since the amount of Fe^{++} ions transferred to the ring was limited by the rate of Fe^{++} generation at the central hemisphere, the magnitude of that current was relatively independent of the rotational speed. The sharp current peak near time zero (less than 0.5 sec from the start of the potential step) was due to establishment of a diffusion layer on the ring and is irrelevant to the results of the present study.

The dissolution intermediate, $FeOH^+$ complex ion, is also picked up at the ring, where it was oxidized to form a monolayer of γ-FeOOH film (12). The current consumption for the monolayer oxide deposition reaction was very small as compared to that of the Fe^{++}/Fe^{+++} oxidation reaction; however, the oxide film reduced the active area available to the Fe^{++}/Fe^{+++} reaction, resulting in a decrease of the ring current as shown in Fig. 1. That the rate of current drop increased with the speed of rotation is in agreement with Eq. [1] that the $FeOH^+$ complex ion dissociates in the electrolyte into ferrous and hydroxyl ions. The faster the speed of rotation, the less the time required for $FeOH^+$ ions to travel from the central hemisphere to the ring, and hence more $FeOH^+$ ions reached the ring undecomposed, resulting in a higher rate of the film deposition reaction. Consequently, the rate of current drop was faster at higher rotational speeds.

Figure 2 is a semilogarithmic plot of ring current *vs.* cube of time for three of the curves shown in Fig. 1. The exact linear relationship indicates that the oxide deposition reaction follows a model for two-dimensional nucleation and growth of a film of monolayer thickness (14)

$$I_{\text{ring}} = I_{\text{lim}} \exp\left(-\frac{\pi}{3} v^2 N t^3\right) \quad [2]$$

Here I_{lim} is the initial limiting current for the Fe^{++}/Fe^{+++} oxidation reaction at the platinum ring whose entire surface is free from oxide contamination, N is the rate of nucleation of two-dimensional centers, v is the rate of spreading of the monomolecular layer film, and t is the time. Equation [2] describes the diminishing of the current for the Fe^{++}/Fe^{+++} oxidation reaction due to the film coverage on the ring surface. The total current on the ring is actually the sum of three components. They are (*i*) Fe^{++}/Fe^{+++} oxidation reaction, (*ii*) formation of a monolayer of γ-FeOOH film, and (*iii*) other possible electrochemical processes occurring at the oxide/electrolyte interface. In the present study, the currents for the last two components were negligibly small as compared with the first component (12); thus, the ring current transient obeyed Eq. [2] as shown in Fig. 2.

[1] Composition of mild steel other than iron: Mn, 0.98%; S, 0.29%; C, 0.1%; P, 0.06%; Si, 0.005%.

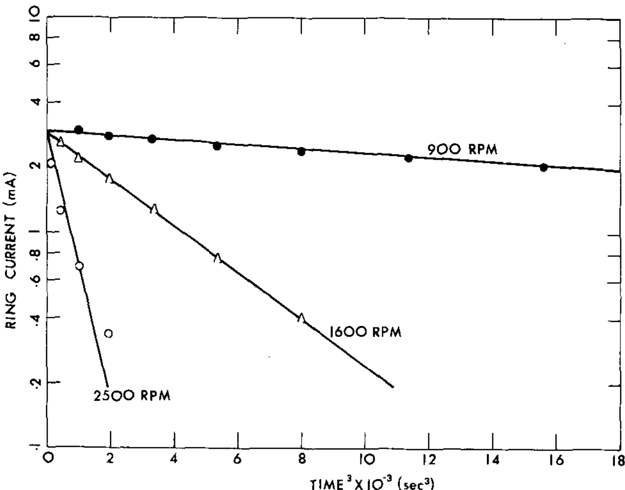

Fig. 2. Interpretation of current transients at the ring with a two-dimensional nucleation and film growth model. The data shown here were taken from a pH 5, 1M $(NH_4)_2SO_4$ when the mild steel hemisphere was dissolving at a constant current density of 31 mA/cm^2.

Equation [2] indicates that I_{lim} can be obtained by extrapolating the straight lines on the semilogarithmic plot of I_{ring} *vs.* t^3 to the zero time. The collection efficiency for ferrous ions on the ring electrode free from oxide contamination can then be calculated by $(2I_{lim}/I_{hemisphere}) \times 100$, where $I_{hemisphere}$ is the total dissolution current on the mild steel hemispherical electrode. The collection efficiency thus calculated, using the data points shown in Fig. 2, is found to be 30 ± 2%, in close agreement with the calibrated value of 32%.

According to Eq. [2], the quantity, $-\pi/3\ v^2N$, is the slope of the straight lines shown in Fig. 2; the cube root of the product, v^2N, is the composite rate constant for the over-all oxide deposition reactions. Since the γ-FeOOH film is formed by the oxidation of $FeOH^+$ complex ion on the ring electrode, the magnitude of this composite rate constant should then reflect the rate of $FeOH^+$ ions transferred to the ring, and consequently the amount of $FeOH^+$ ions generated at the central hemisphere during the mild steel dissolution reaction. Figure 3 is a plot of the composite rate constant *vs.* pH of the electrolyte when the mild steel hemisphere was dissolving into 1M $(NH_4)_2SO_4$ at a constant current density of 8 mA/cm^2 and at an electrode rotational speed of 1600 rpm. The effect of the dissolution current density at the central hemisphere on the composite rate constant at the ring is shown in Fig. 4 for three sulfate concentrations; in these particular runs the pH of the electrolyte was kept at 5, and the electrode rotation at 1600 rpm.

The results given in Fig. 3 and the curve for 0.5M sulfate in Fig. 4 are seen to agree with Eq. [1] in which the concentration of the dissolution intermediate, $FeOH^+$ ion, increases with the rate of iron dissolution as well as with pH of the electrolyte. However, the curves for 1 and 2M $(NH_4)_2SO_4$ in Fig. 4 are quite different. The horizontal relation between the composite rate constant and the dissolution current density in 1M sulfate indicates that the concentration of $FeOH^+$ complex ion is independent of the iron dissolution rate. The curve for 2M sulfate reflects a trend contrary to Eq. [1]; it says that the rate of $FeOH^+$ generation decreases with increasing current density at the mild steel hemispherical electrode. For a given dissolution current density, Fig. 4 further shows that the composite rate constant decreases with increasing sulfate concentration.

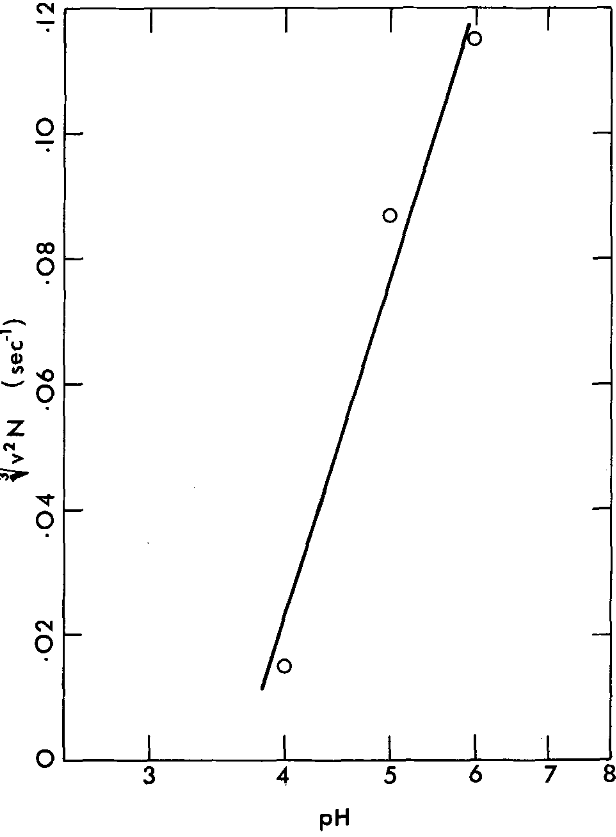

Fig. 3. Composite rate constant for the growth of the monolayer oxide on the ring *vs.* pH values for 1M $(NH_4)_2SO_4$. The current density at the mild steel hemisphere was maintained at 8 mA/cm^2; the speed of electrode rotation was 1600 rpm.

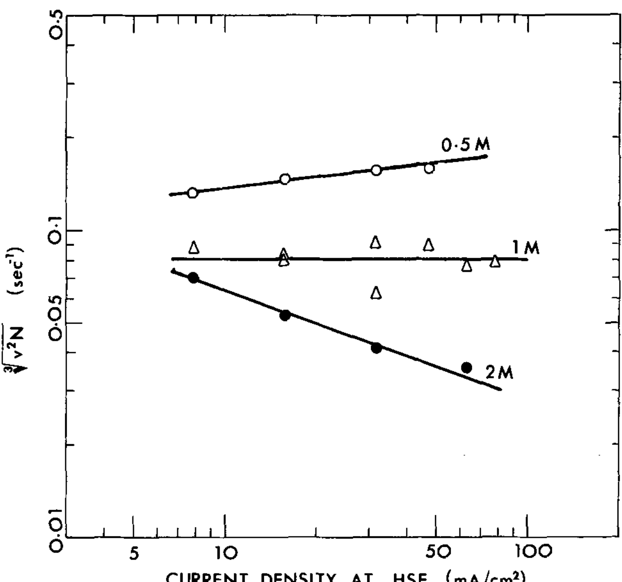

Fig. 4. Composite rate constant for the growth of the monolayer oxide on the ring *vs.* the dissolution current density at the mild steel hemispherical electrode for three sulfate concentrations. The pH of the electrolytes was maintained at 5; the speed of electrode rotation was 1600 rpm.

At this point, one is apt to think that this behavior is probably caused by the participation of sulfate ions in the oxide deposition reaction. That this is not true has been shown in a previous characterization study (12) of the deposition of iron oxide on a rotating platinum ring electrode from ferrous sul-

fate solutions. In that study it was found that changes in the concentration of $(NH_4)_2SO_4$ supporting electrolyte had no effect on the composite rate constant.

One might also thing that the $FeOH^+$ collected at the ring is not a reaction intermediate, but a product formed by the hydrolysis of the final dissolution product, Fe^{++}, during the course of traveling to the ring. That this is not true can be attributed to the following two reasons:

(*i*) If $FeOH^+$ is formed by the hydrolysis of ferrous ion, then the faster the rotational speed, the less would be the amount of $FeOH^+$ formed before it reaches the ring. Consequently, for a given dissolution rate at the hemisphere, the rate of current decrease at the ring would be lower at higher rotational speeds. This contradicts the results given in Fig. 1.

(*ii*) The rate of film deposition reaction has been found to increase linearly with the concentration of ferrous ions in the test electrolyte (12). If the iron dissolution does not proceed through the intermediate stage of $FeOH^+$ ion, it would then be expected that the composite rate constant at the ring would increase rapidly with increasing dissolution rate at the hemisphere. This contradicts the results shown in Fig. 4.

Thus, the present results indicate that dissolution of mild steel in sulfate electrolytes does not follow fully Eq. [1]. These results seem to support the evidence that in addition to the Bockris or the Heusler mechanism, mild steel is also dissolving via a parallel mechanism, such as the one proposed by Geana, Miligy, and Lorenz (5)

$$\begin{aligned} &Fe + H_2O \rightleftarrows FeOH_{ads} + H^+ + e \\ &FeOH_{ads} + H_2O \rightleftarrows [Fe(OH)_2]_{ads} + H^+ + e \\ &[Fe(OH)_2]_{ads} + SO_4^{--} \rightleftarrows FeSO_4 + 2\,OH^- \\ &FeSO_4 \rightleftarrows Fe^{++} + SO_4^{--} \end{aligned} \qquad [3]$$

The data shown in Fig. 4 suggest that the Bockris or the Heusler mechanism probably occurs at low dissolution current densities and at low sulfate concentrations. With increasing sulfate concentration and current density, more and more sulfate ions are adsorbed on the anode and some of the iron atoms start to dissolve via the parallel mechanism. The proportion of current consumption by the parallel mechanism increases with increasing current density at high sulfate concentrations.

Conclusions

Using the rotating ring hemisphere technique, $FeOH^+$ complex ion has been identified as a reaction intermediate during the dissolution of mild steel in $(NH_4)_2SO_4$ electrolyte. For a given dissolution current density, the concentration of $FeOH^+$ ion was found to decrease with increasing sulfate concentration. The effect of the dissolution current density on the amount of $FeOH^+$ detected varied according to sulfate concentration. In dilute sulfate, the rate of $FeOH^+$ produced was an increasing function of dissolution current density, whereas in more concentrated $(NH_4)_2SO_4$ it was either independent of, or a decreasing function of, the dissolution current density. The results indicate that the dissolution reaction did not fully follow the commonly accepted Bockris or Heusler mechanism. It appears that mild steel also dissolves via a parallel mechanism, in which sulfate ion participates in the dissolution reaction.

Reflectance Changes during Formation and Reduction of Oxide Films on Gold and Platinum: Corrections for "Double-Layer Effects"

B. E. Conway, H. Angerstein-Kozlowska,* and L. H. Laliberté[1]

Chemistry Department, University of Ottawa, Ottawa, Ontario, Canada

ABSTRACT

Hysteresis between the processes of formation and reduction of thin oxide films on Au and Pt have been investigated by ellipsometric (Δ) and relative reflectance ($\delta R/R$) measurements. The interpretation of results obtained by optical methods where thin films are in the course of formation towards a monolayer, or beyond, requires consideration of optical effects due to contributions from changing ion concentration and metal surface electron charge density in the double-layer since substantial changes of optical parameters for reflectance at Au and Pt interfaces arise with changing electrode potential. Resulting changes of Δ and $\delta R/R$ must therefore be corrected for continuing double-layer effects as the ad-layer is laid down or removed (in the reduction process). The theoretical basis for evaluation of double-layer optical effects is reviewed but it is proposed that, at the present time, empirical correction procedures may be preferable. Three methods are examined and an optimum procedure is recommended. The procedure is applied to the evaluation of hysteresis effects in the formation and reduction of thin oxide films at Au and Pt where evaluation of the true hysteresis effects depends in an important way on a proper correction procedure for the double-layer optical effects.

In recent papers (1-4), the state of surface oxide films on Pt (1-3) and Au (4) has been examined by electrochemical [cyclic voltammetry (3) and charging curves (1, 2)] and optical [reflectance (4) and ellipsometry (5, 6)] methods. It has been shown (3) that both after, and simultaneously with, oxygen deposition in distinguishable successive arrays [cf. similar indications from LEED work (7)], the initially chemisorbed species undergoes a rearrangement (probably place-exchange with underlying substrate metal atoms) to a more stable surface oxide phase which is reducible only at potentials less positive than those required for the initial anodic electrosorption (8). This leads to the well-known hysteresis (8, 9) between formation and reduction of surface oxide films on most metals.

In the present paper, we compare the optical and electrochemical behavior of these surface oxide films on Pt and Au, especially with regard to evaluation of the optical behavior of the film during its reduction in relation (6, 10) to that during its formation; that is, the question to be addressed is how optical measurements can be used to provide a basis for distinction between the state of a thin oxide film in the direction of its formation and its reduction, for given extents of oxidation in the forward (anodic) and backward (cathodic) directions of charging curves or cyclic-voltammetry current-potential profiles.

Ellipsometry and electric-modulated reflectance (11) measurements which are currently of great interest in the study of surface processes (10, 12-14) and adsorption (20-24) at electrodes are especially valuable for indicating the state of oxide film formation at metals, including submonolayer films of OH discharged from water at Pt (10), Ir (10), and Au (15) and the irreversibility of surface oxide formation and reduction processes exhibiting hysteresis (10, 16).

The interpretation of optical properties of thin oxide films from ellipsometric (Δ) and relative reflectance ($\delta R/R$ or $\frac{dR}{R}/dV$) measurements is, however, complicated, especially at Pt or Au, by the substantial dependence of ellipsometric phase-shift parameter Δ or relative reflectance change $\delta R/R$ on potential (and hence surface and ionic charge on the double-layer) which is observed already over the potential ranges in which no chemisorbed H- or O-species are present on Pt or Au electrode surface. We shall refer to this behavior as the "double-layer" optical effect at the metal surface.

These double-layer optical effects will continue during the surface oxidation up to a monolayer in some way related to the fraction of free metal surface available ($1 - \theta_{oxide}$); in addition, and beyond a monolayer of surface oxide, some different double-layer effect will arise corresponding to the properties of the interface of that fraction of the surface which is covered by the surface oxide film.

The interpretation of Δ or $\delta R/R$ changes measured during film formation or reduction must therefore allow for a changing component due to the double-layer effects on Δ and $\delta R/R$ which maintain themselves, in some degree to be considered below, during film formation and are especially important at low coverage by the "O"-species. Corrections of this kind do not appear [cf. *e.g.*, (5, 12, 23)] to have been made in previous work except in a preliminary presentation (6) of the present work,[2] so that the Δ and $\delta R/R$ changes actually due to oxide film formation have remained incorrectly evaluated.

This question is of particular importance if the optical condition of a surface oxide film at a given degree of oxidation, q_o, in an anodic-going potentiodynamic linear sweep (18) is to be compared with the condition at the same q_o in the cathodic sweep, thus providing indications of any intrinsic changes in the nature of the films associated with the hysteresis (8, 10, 16), commonly observed between formation and reduction of surface oxide films, with respect to electrode potential (8, 16). The double-layer corrections will be particularly important as the coverage by the electrosorbed film changes from zero to that corresponding to a monolayer, *e.g.*, OH on Pt and Au, with increasing anodic potential. These

[1] Present address: Pulp and Paper Research Institute, Pointe Claire, Quebec, Canada.

Key words: oxide films, platinum, gold, ellipsometry, hysteresis in surface processes.

[2] Since this paper was submitted (6), McIntyre and Peck (24) have proposed similar corrections for elucidation of the optical behavior of electrosorbed H at Pt.

double-layer optical effects are experimentally more important (4, 6, 16) at Au than at Pt, since the double-layer optical effects are larger for Au than Pt.

Basis for "double-layer" optical effects.—The theoretical basis of the corrections for double-layer effects in optical studies of oxidation of metals depends on the extent to which electron density changes (11, 19-21) in the metal surface (ER effect) and changes of ionic concentration (22, 23) in the solution-side of the double-layer determine the double-layer effect in Δ or $\delta R/R$. Work in press (13) at electrodeposited Hg indicates that the ER effect is never negligible; hence it may be expected that electrosorption of OH and O species in the initial stages of surface oxide formation will have an important effect on the electronic double-layer contribution to Δ or $\delta R/R$. Such effects can arise because chemisorbed species tend to induce image charges (24) in the metal substrate or more realistically, equivalent short-range effects leading to electron density changes in the metal surface as evidenced in other work by changes of surface conductivity (34) and paramagnetic susceptibility. Related changes will be expected in the solution-side contribution to Δ or $\delta R/R$ since oxidation of the metal surface will change the pzc and hence the relative populations of anions and cations in the double-layer, and displace ions adsorbed, as is known (17) in the case of SO_4^{2-} or HSO_4^-. Correspondingly, when an oxide film is reduced, revealing bare metal, the double-layer contribution will again change in the course of the reduction of the film.

From the theoretical point of view, according to McIntyre and Aspnes (19), and McIntyre (21), the effect of metal surface charge, q_m, and hence potential, on the optical properties of the surface layer of a metal is determined mainly by field modulation of the free-electron contribution $\epsilon_{3,f}$ to the dielectric constant ϵ_2 of the transition layer between bulk solution and bulk metal extending over *ca* 1.6 times the Thomas-Fermi screening length. Expressed in these terms, the change $\Delta\epsilon_2$ in this transition layer by the applied field is given by

$$\Delta\epsilon_2 = -(\epsilon_{3,f} - 1)\,\Delta q_m/Nd \qquad [1]$$

where N is the free-electron concentration in the bulk metal and d is the thickness of the transition layer, Δq_m the change of surface charge. Corresponding relative reflectance changes $\frac{1}{R}\left(\frac{\delta R}{\delta q_m}\right)$ can be evaluated (24) for p and s polarization conditions, and the p-polarization behavior is dependent on both d and the rational potential, E. This treatment (24) assumes that the variation of $\delta R/R$ with q_m or E arises mainly from modulation of free-electron effects, *i.e.*, the ionic double-layer contributions to $\delta R/R$ can be neglected (24), at least for the noble metals. This is a controversial point [cf. (20)] and has been discussed elsewhere (25). However, by suitable choice of angle of incidence and polarization conditions, some progress towards experimentally separating the metal electron and ionic double-layer effects can, in principle, be made (20, 24). In terms of free-electron effects, $\delta R/R$ would be expected to be proportional to q_m and would thus scale with the differential double-layer capacitance (24). Unfortunately $\delta R/R$ is also a complex function of charge-dependent ion accumulation in the double-layer (22, 23), solvent orientation and compression (20), and local molar refraction of ions in the double-layer.

The problems of allowing for double-layer contributions in the proper evaluation of the reflectance effects due to accumulation of a chemisorbed species are illustrated (24, 25) by the recent controversy concerning the significance of reflectance changes due to electrosorbed H at Pt where even the real relative signs of the effects are under discussion (25). Changes of electron density in the metal surface due to binding of electrosorbed OH and O, or of H, we believe, can be a major factor in determining reflectance changes which could not be calculated *a priori* by the MA theory (19, 21). Withdrawal of electrons due to chemisorptive bonding, *e.g.*, of H has been recognized (36).

For the purposes of the present paper, where possible differences of optical properties of thin films during their formation and reduction are to be demonstrated, it therefore seems best, because of the above complexities, to correct the $\frac{\delta R}{R}$ or Δ changes (caused by electrosorption processes) for double-layer electroreflectance contributions by an empirical procedure (rather than an *a priori* calculation) based on extent of coverage of the free metal surface by the electrochemisorbed species. We outline three procedures by which this might be accomplished and propose one of them as the preferred method.

Experimental

Full details of the experimental procedures have been given in other recent papers (6, 8, 10, 26). The following summary of conditions and methods is given here to provide a basis for the results to be discussed in this paper as examples of the correction procedures and with respect to evaluation of hysteresis in the optical behavior.

Methods.—Electrochemical study of the processes of oxide film formation at Au and Pt was made by the potentiodynamic method which, for pure surface reactions not involving coupled diffusion-controlled processes, gives an exact measure of: (*i*) the ranges of potential over which various oxidation or reduction processes occur, and hence information on reversibility; and (*ii*) the coulombic charges associated with resolvable processes (3, 10) in the anodic-going or cathodic-going directions of potential change. The oxidation or reduction charges can be evaluated to an accuracy equivalent to 0.02*e* per metal atom of the surface.

The circuit and apparatus for potentiodynamic studies was as described previously [*e.g.*, (10)]. The various systems and precautions necessary for evaluation of oxidation/reduction charges of the above accuracy were as indicated in previous papers (3, 16, 26), especially the requirements of solution purity. All potentials were referred to an H_2 electrode in the same solution. This scale is referred to as E_H in this paper.

Ellipsometric studies of the formation and reduction of very thin oxide layers were made using a Rudolph ellipsometer by the off-null intensity transient method described originally by Cahan and Brusic in Ref. (27) with modifications discussed in a later communication (28) [cf. (29)].

Relative and differential reflectance measurements were made as described previously (10). The phase-sensitive amplifier system also enabled direct measurements of a-c capacitance to be made during formation and reduction of the oxide films.

Solutions.—In order to achieve the required level of high purity of solutions, water subjected to 48 hr pyrocatalytic distillation (26) was employed to make up solutions. 1M aq. H_2SO_4 solutions were used as electrolyte and made up in the pyro-distilled water from B.D.H. "Aristar" grade 98% H_2SO_4 (the purest grade of acid available for electrochemical purposes). Experiments were conducted at 25° ± 0.5°C.

Cells.—A standard all-glass cell of the type used in our previous work was employed. The ellipsometer cell was of basically similar design except that it was provided with two optically flat windows allowing light to be reflected from the electrode at an angle of incidence of 71° without further refraction at the windows.

Electrodes.—Johnson Matthey high-purity grade Pt and Au plates *ca.* 1 mm in thickness were used for the optical measurements. Wires of the same grade metals were used in some of the electrochemical measurements. Surfaces of the plate electrodes were polished with a ceric oxide slurry and then thoroughly washed before use in optical experiments.

Results and Discussion

Methods for making "double-layer" corrections.—The basis for possible empirical correction procedures will be considered by reference to the working diagram (Fig. 1). The curve OCAPZ represents an anodic-going profile of changing Δ or $\delta R/R$ while ZQCO represents the corresponding cathodic-going changes in response to anodic and cathodic linear potential sweeps in optical cyclic voltammetry (4, 10). O is the origin of charge-dependent Δ and $\delta R/R$ changes taken as the potential of zero-charge. The regions OCA and CO represent changes of Δ or $\delta R/R$ due only to "double-layer" effects while the regions APZ or ZQC represent changes of Δ or $\delta R/R$ when a surface film of changing coverage is being electrochemically deposited or removed (reduced) from the surface. The heavier regions, AP and QC, represent, respectively, the transition from zero coverage to a monolayer of electrosorbed species, and from monolayer to zero coverage in reduction. The curve beyond P to Z represents changes of optical properties that can arise beyond a nominal monolayer (*e.g.*, from "PtOH" to "PtO") of, *e.g.*, OH on Pt, as experimentally observed.

Correction method (i).—The simplest approach would be to subtract from the "experimental" values (curve APZ) the double-layer Δ or $\delta R/R$ values corresponding to the line OCA and its production to B or beyond, with values being referred to the reference line AN. Similarly, over QC, values along the line CA would be subtracted from the experimental values along QC referred to a reference line CR. The lines CR or AN simply allow the differences of Δ or $\delta R/R$ which arise more anodic to C or A, respectively, to be evaluated with respect to reference values at the points C or A corresponding limitingly to zero oxide coverage in the respective cathodic or anodic directions of potential change. This method is obviously not generally correct since (*i*) it does not allow for changing coverage by the electrosorbed species along AP or QC and (*ii*) in the return (cathodic) curve ZQC, when the Δ or $\delta R/R$ value is found experimentally to be initially constant at Pt, *e.g.*, after holding[3] the potential at Z for $>$ 120 sec (Fig. 2), correction for the double-layer effects in Δ or $\delta R/R$ leads to an irrational increase of Δ or $\delta R/R$ as the initial part of the negative-going Δ or $\delta R/R$ potential profile is traversed (see below), in which range there is no increase in the extent of oxide formation or coverage after holding at Z (Fig. 2). Method (*i*) will therefore be rejected.

Correction method (ii).—Method (*i*) assumes that the whole of the normal double-layer change of Δ between A and P, or between Q and C, is made as a correction to the lines AP or QC. This is obviously incorrect since along AP or QC, the coverage by "oxide" is changing. Hence, the above double-layer corrections must be diminished progressively at each potential by a factor $1 - \theta$ for the anodic or cathodic curves. It is obviously more consistent to perform the above types of correction with respect to a common reference line CRL, applicable to both the anodic (APZ) or cathodic (ZQC) experimental lines.[4] Then the corrected Δ or $\delta R/R$ relations will correspond typically to the dashed curve AL for the anodic-going curve or RC for the cathodic-going one. A number of $\Delta - q_0$ relations were analyzed in this manner (see below) and compared with results obtained by a (preferred) third method (iii) described below.

Correction method (iii).—It would appear most satisfactory to refer all corrections not only to a common reference line but one (MSO) taken up to the potential of zero charge (pzc), since finite values of Δ due to double-layer charge effects are really relative to zero double-layer contribution to Δ or $\delta R/R$ at the pzc in the absence of specific adsorption. (A very small residual ionic double-layer effect may remain at the pzc due to the surface potential.) Hence, the correction on the basis of $1 - \theta_{oxide}$ starting from A or terminating at C will follow, respectively, curves such as AM or SC, but at potentials more positive than M or S, no further change of Δ or $\delta R/R$ would arise from double-layer effects on this model since at these potentials $\theta = 1$. This method was applied to a number of the experimental $\Delta - q_0$ relations. Both methods (ii) and (iii) assume that the metal/solution double-layer correction above "θ" = 1, becomes attenuated to zero, *i.e.*, the presence of OH or O species eventually reduces to zero (along the line PT) the

[3] On a repetitive sweep at Pt or Au, the optical parameters do continue to increase over the initial part of the cathodic-going sweep at Z. This, however, is consistent with the observed continuing anodic current at the beginning of the cathodic sweep, as expected for an irreversible surface process (see p. 1600).

[4] That this is a valid procedure is indicated in the Appendix.

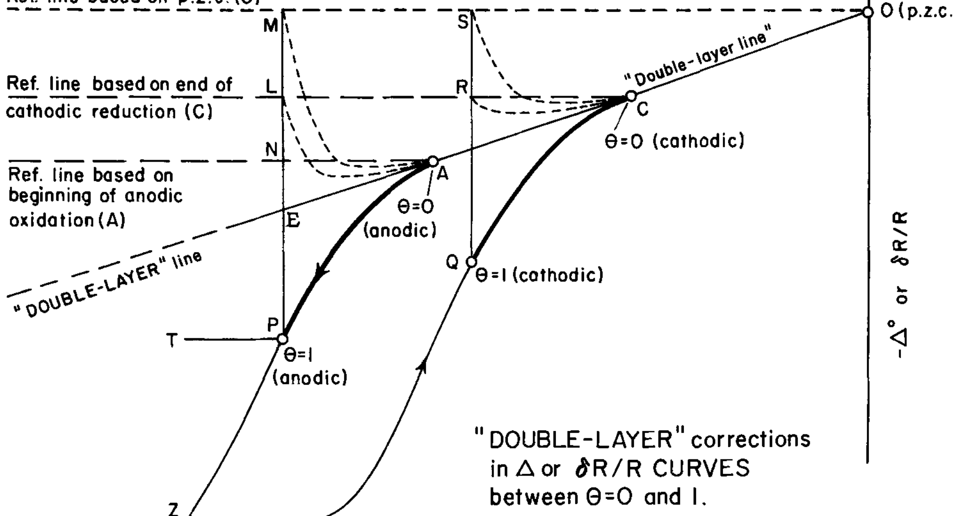

Fig. 1. Working diagram for discussion of double-layer corrections for Δ or $\delta R/R$ changes due to oxide film formation or reduction.

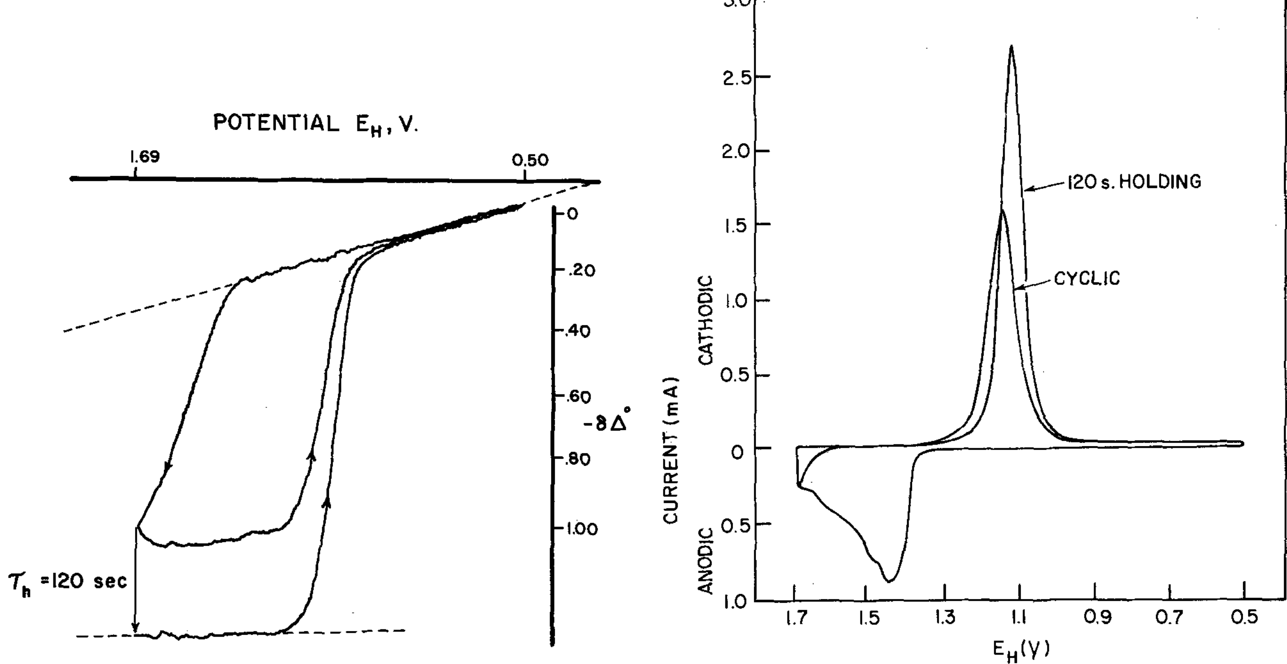

Fig. 2. (a, above left) Δ changes as a function of potential at an Au electrode in 1M aq. H_2SO_4 (25°C) in a single cyclic anodic/cathodic sweep and after holding at + 1.69V E_H for 120 sec before initiation of the sweep. (b, above right) The corresponding potentiodynamic i-V profiles for Au with and without holding at 1.69V for 120 sec.

normal double-layer optical effect associated with the metallic surface itself.

"Double-layer" effects at the oxide/solution interface.—In principle, the oxidized metal surface can also exhibit ER and ionic double-layer effects in Δ and $\delta R/R$. In the case of Au, however, the qualitative correctness of the assumption in method (iii) that the double-layer optical effects are reduced to negligible contributions as "θ" $\geqq$ 1 was indicated by observation of only very small Δ changes in a cathodic-going potential sweep after formation of an oxide film of almost constant thickness by holding the potential constant for some time as shown in Fig. 2a. Over the potential region involved, it is seen from Fig. 2b that no significant reduction charge passes in this part of the curve, so that only double-layer effects would be involved: they are quite small (~10%) in comparison with the effect over the potential region where the metal surface is without an oxide film. The behavior at Pt is similar (Fig. 3). The residual double-layer optical effects on the oxidized surfaces, although small, depend on the metal, so the details of the correction procedure should be chosen with reference to the metal concerned.

The significance of the small "double-layer" effect in the oxide region ($\theta_{OH} \geqq 1$) is also indicated by a-c modulated reflectance experiments (10) which give small but finite in-phase and zero out-of-phase differential reflectance effects at Pt and Au even at 1.4V for Pt or 1.6V for Au where almost no reversibly formed or reducible oxide can exist [cf. the cyclic voltammetry curves (3, 8)]. This residual effect must be distinguished from the resolvable region of reversible "PtOH" electrodeposition (3, 10) and reduction which can be seen in a-c modulated reflectance (10) up to *ca.* 0.95V.

In the case of Au (Fig. 5), the result of making further corrections for the residual double-layer effect on the oxide film itself is also shown in that figure. It is relatively small and at Pt it is even smaller. It is seen that corrections for double-layer optical effects at the oxide film interface do not change the main conclusions from Fig. 5 that hysteresis exists in the optical behavior of the oxide film itself (see below).

Δ-q_o relations for anodic and cathodic-going sweeps.—Figure 4 shows the Δ-q_o relations for Pt based on corrections for double-layer contributions to Δ made by (*i*) the sloping base-line method (i) assuming the double-layer Δ change extends up to and beyond the monolayer, and (*ii*) by method (iii). From Fig. 4 it is evident that appreciable hysteresis exists between Δ values for the positive-going and negative-going curves at the same degrees of oxidation q_o of the surface,[5] independently of the method of correction employed.

[5] In a given experiment, the accuracy in evaluation of Δ is ±0.02° and in q_o, 0.02e per metal atom. Hence the differences in the Δ-q_o lines for anodic- and cathodic-going sweeps are well outside the limits of experimental error.

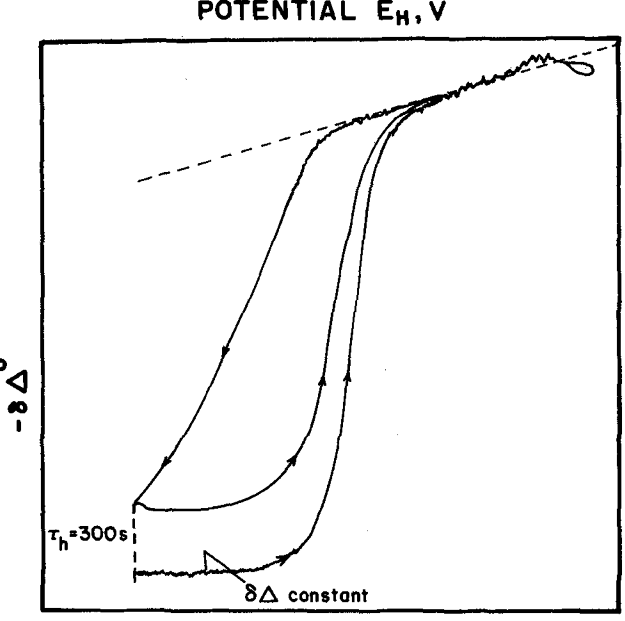

Fig. 3. As in Fig. 2a, but for Pt with 300 sec anodic holding at 1.4V E_H.

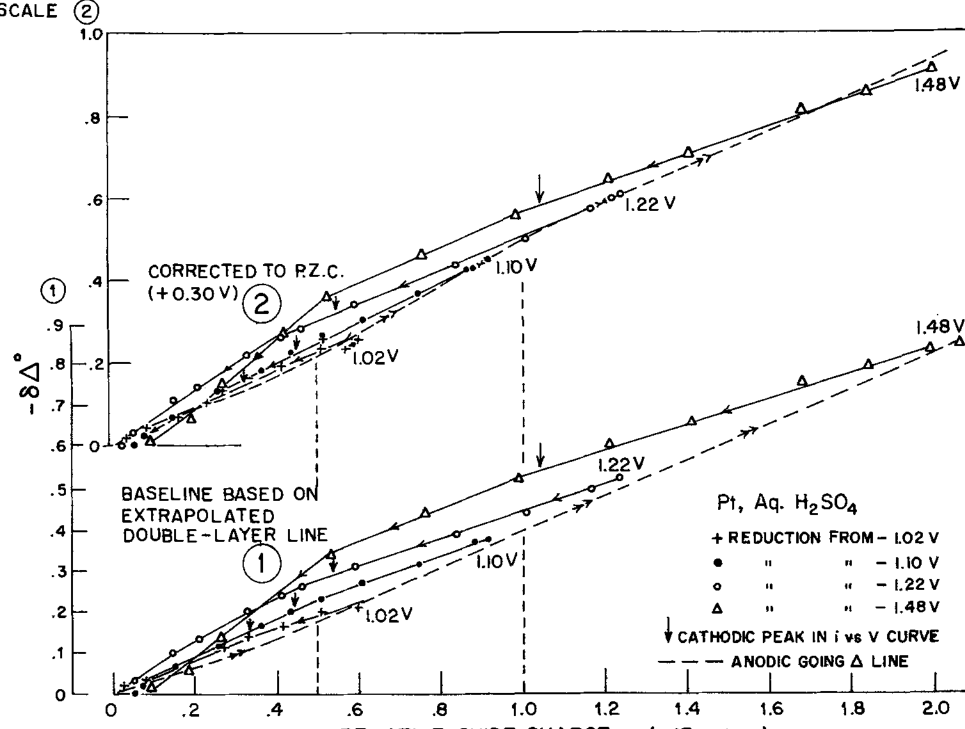

Fig. 4. Dependence of changes of Δ on relative oxidation charge q_o (e per Pt atom) in positive- and negative-going potential sweeps after correction of the initial data by *(i)* method (i) based on extrapolated double-layer line and *(ii)* method (iii) based on 1-θ correction referred to pzc base-line.

The necessity for corrections to the Δ change based on a principle other than that the double-layer Δ variation with potential continues into, and through, the surface oxidation region (>0.80V in the case of Pt or >1.375V in the case of Au) is clearly illustrated in Fig. 5 and 6. In these plots, the changes of Δ in an anodic- and cathodic-going potentiodynamic sweep are compared with those for a sweep in which there has been 120 sec holding of the potential at the positive and of the sweep (see program b in Fig. 5 and Δ-potential plot of Fig. 2a). With holding, both Δ and the oxidation charge q_o continue to change (as expected) in the same direction as in the cyclic experiment taken to the same potential; with reversal of the sweep direction after holding, Δ decreases, initially gradually, (curve a, Fig. 5) and similar behavior arises in the cyclic experiment (curve b, Fig. 5); for both these cases, curves a and b, the double-layer correction has been made with respect to the pzc base-line[6] up to q_o = full coverage of OH (1e per Au atom), in proportion to $1 - \theta_{OH}$.

If the double-layer Δ or $\delta R/R$ corrections were to be made not on this basis but by assuming that the double-layer Δ or $\delta R/R$ effect continues with the same slope w.r.t. potential through the surface oxidation region, then a ridiculous result is obtained as shown in Fig. 6 based on the same primary experimental data (Fig. 2a, b) as those which give the curves of Fig. 5.

[6] Relevant pzc values have been critically reviewed and tabulated by Perkins and Anderson (35).

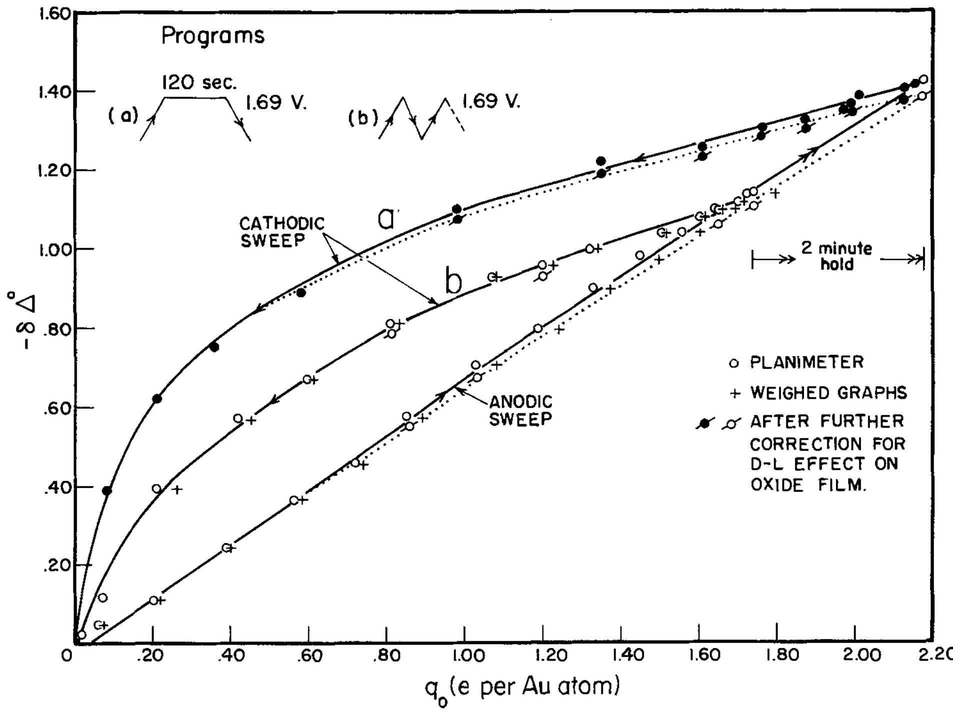

Fig. 5. Plots of Δ *vs.* oxidation charge q_o for Au in 1M aq. H_2SO_4 (25°C) in a positive- and negative-going cyclic sweep and after 120 sec anodic holding at 1.69V E_H. Relations shown are after correction by method (iii) for double-layer Δ effects applied to the results of Fig. 2a, b and after further correction for residual double-layer effects on the oxidized surface.

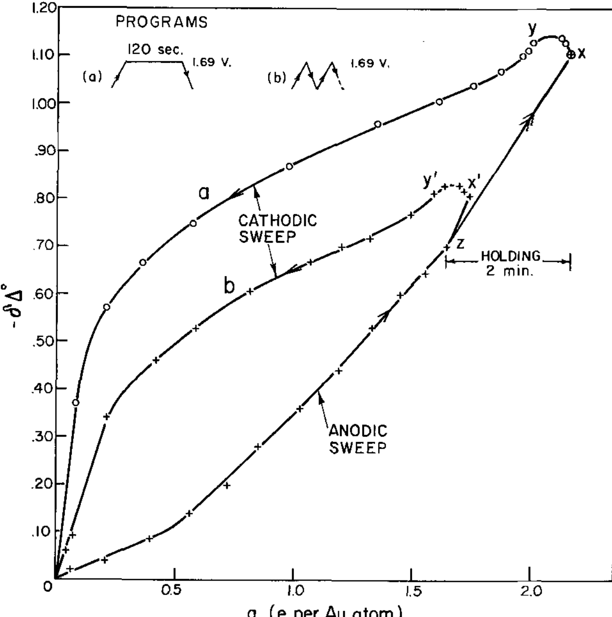

Fig. 6. Plots of Δ vs. q_0 for Au as in Fig. 5 but by the method (i) assuming double-layer Δ line applies continuously into the oxide formation, or over the oxide reduction regions.

After the holding time of 120 sec, which is sufficient for q_0 to reach a constant ($\pm 2\%$) value, it is seen from Fig. 6 that Δ apparently continues to increase on the negative-going sweep over the region xy of curve a in Fig. 6. That the double-layer optical effect for the free metal surface cannot continue with the same slope into the oxide region is also indicated indirectly by the double-layer capacity behavior studied by Rosen and Schuldiner (33).[7]

A similar but smaller effect arises over $x'y'$ in curve b of Fig. 6 for the cyclic experiment, but here the behavior is complicated by the normal effect observed at Pt and Au that some oxidation of the surface continues on the initial section of the negative-going sweep after reversal of the sign of dV/dt at the end of the positive-going sweep. This is the usual behavior (3, 6) for an irreversible electrochemical surface process as we have discussed elsewhere (3) and simply means that continuing surface oxidation can occur slowly over the most positive-potential range in the negative-going side of the potential sweep. Holding at the positive potential limit allows this residual oxidation to be virtually completed before the negative going sweep is initiated (program b), so that on the subsequent initiation of that negative-going sweep only the cathodic reduction process can eventually occur, so that both Δ and q_0 must decrease, or initially remain constant and then both decrease together.

Figures 5 and 6 therefore clearly demonstrate (*i*) the necessity of a double-layer correction in interpretation of Δ-(and/or ψ or $\delta R/R$) measurements in oxide-film forming experiments and (*ii*) that this correction cannot be made simply on the basis of a linear extension of the double-layer Δ base-line CAB (Fig. 1).

Irreversibility and hysteresis in the optical behavior of oxide films during formation and reduction.—The results of Fig. 5 show even more clearly than those for Pt (Fig. 4) that there is an intrinsic irreversibility in the properties of the oxide film w.r.t. quantity of oxide present on the surface in the formation direction (positive-going sweep) and in the reduction direction (negative-going sweep). This irreversibility is, however, only detectable for appreciable degrees of surface oxidation as the results of Fig. 7, for surface oxidation of Au up to *ca.* 0.3 and 0.45*e* per Au atom, show; in these cases, the (corrected) Δ-q_0 lines are almost reversible in the sense that the Δ-q_0 relations are almost identical for positive- and negative-going sweeps (there is, of course, still hysteresis in the i-V profiles for the two directions of sweep).

[7] A correction for double-layer effects in the H region was made by McIntyre and Peck (24) by extrapolating the ER background curve for the double-layer region into the H adsorption region but without any allowance for possible specific effects due to coverage by H.

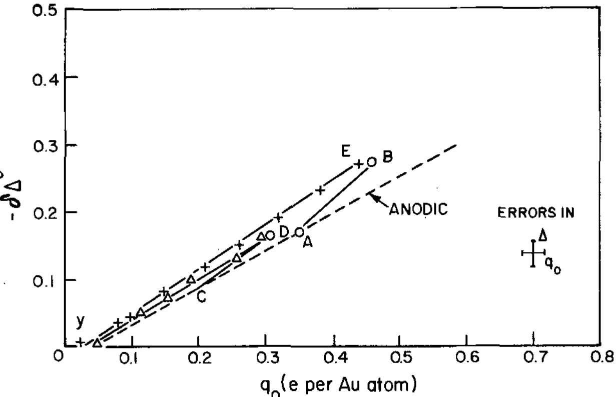

Fig. 7. Plots of Δ vs. q_0 for Au oxide formation in 1M aq. H_2SO_4 and reduction up to potentials of 1.440V (+) and 1.410V (Δ) E_H in repetitive cyclic voltammetry [Δ values corrected w.r.t. pzc baseline by method (iii)].

The irreversibility demonstrated here, we believe, is due to a progressive rearrangement of the surface layer of OH and O electrosorbed species[8] as their coverage increases, as we (3, 8) and others (12, 30) have discussed elsewhere. Thus, the state of the surface at a nominal value of q_0 in the reduction sweep is evidently not identical with that in the oxidation sweep at the same q_0. This result confirms, on the basis of optical properties of the oxide films at Au and Pt, that the irreversibility in the i-V profiles for anodic and cathodic-going potential sweeps is associated with a real irreversible change of properties of the film as it is laid down, *i.e.*, an intrinsic hysteresis (3, 16, 31).

The physical origin of the optical hysteresis can be understood in the following terms: in an anodic-going sweep, an element of continuing change of Δ will correspond to the last increment of charge passed at some typical potential E in the sweep, so the environment of the species laid down at that potential will be determined by the location of the discharged O or OH species in relation to the lattice (3) of previously existing and previously deposited oxide species. However, if the sweep continues beyond E, the relative contribution to Δ of the species deposited at E may change because its environment changes. Especially in the case of a surface rearrangement, removal of the given particle at some potential corresponding to a state of reduction of the oxide film (measured by q_0) will not necessarily result in the same change of Δ as in the electrodeposition of such a particle at the same level q_0 of oxidation of the surface during the anodic-going sweep. This is because the microscopic environment of particles being reduced at a given coverage corresponding to a typical level of surface oxidation q_0 can be different, in the rearranged surface layer, from that at a corresponding level of surface oxidation or coverage in the anodic-going sweep. This is one of the essential features of intrinsic (as opposed to "kinetic") hysteresis in terms of domain theory (31).

The results of Fig. 5 indicate, from the course of the Δ-q_0 relations, that the material first reduced in the negative-going sweep is not that which has immediately previously been laid down at the most positive potentials in the prior anodic sweep. The material electrosorbed at the most positive potentials on the

[8] Optically distinguishable states of the oxidized Pt surface corresponding to "PtOH" and "PtO" degrees of oxidation were noted by Conway (13) and by McIntyre and Kolb [in Ref. (14)].

anodic sweep is, in fact, that which is reduced only at the least positive potentials in the cathodic sweep, as observed and discussed previously (8, 16). This is consistent (cf. magnetization hysteresis loops) with the observed hysteresis behavior.

The aspects of the surface oxidation processes at Pt and Au are beyond the scope of the present paper but are examined in more detail in a theoretical publication (32).

Conclusion

It is to be concluded that significant double-layer corrections must be made not only in relating Δ or $\delta R/R$ to potential or film coverage at an electrode, but also in any quantitative interpretations of these optical parameters in terms of refractive index, absorption coefficient, and thickness of the film, especially in the case of development of films up to the monolayer limit.

APPENDIX

Relation between Δ Changes Referred to Different Origins, Including the Potential of Zero-Charge

The working diagram Fig. 8 is considered. A double-layer line OCAB is again taken. Elements of anodic-going and cathodic-going curves for Δ changes due to formation of a film are lines ψ and ϕ, respectively. The coordinates of "intersection" of ψ and ϕ with OCAB are V_2,Δ_2 at A, V_1,Δ_1 at C, respectively, and O,O are the coordinates of the pzc. The slopes (in supposed linear regions) of ψ and ϕ are $\overrightarrow{m}$ and $\overleftarrow{m}$, respectively, while the double-layer line OCAB has a slope m_o. A typical potential V is measured positively to the right.

Along ψ

$$\overrightarrow{\Delta} = \Delta_2 + \overrightarrow{m}(V - V_2)$$

and along ϕ

$$\overleftarrow{\Delta} = \Delta_1 + \overleftarrow{m}(V - V_1)$$

Corrected for double-layer effects with a $1 - \theta$ free metal area factor, these relations become for curve ψ

$$\overrightarrow{\Delta} = \Delta_2 + \overrightarrow{m}(V - V_2) - (1 - \theta)[\Delta_2 + m_o(V - V_2)]$$

while for curve ϕ

$$\overleftarrow{\Delta} = \Delta_1 + m(V - V_1) - (1 - \theta)[\Delta_1 + m_o(V - V_1)]$$

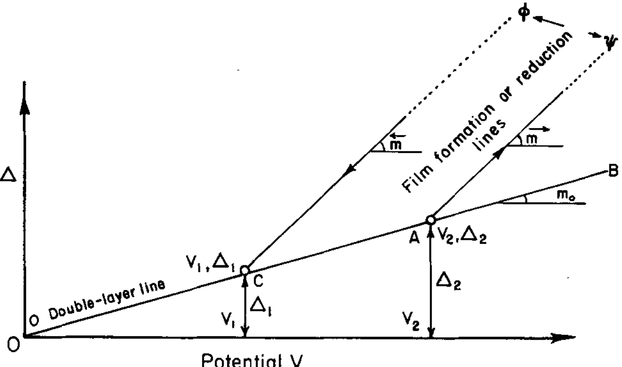

Fig. 8. Working diagram for analysis of double-layer Δ corrections based on different base-lines.

Corrections on ψ and ϕ curves are based on double-layer Δ changes referred to zero at the pzc and the $1 - \theta$ term is assumed to operate on the whole of the double-layer Δ contribution referred to zero at the pzc.

Referred to an origin V_1,Δ_1 at the end of the cathodic-going curve ϕ for film reduction, on line ψ

$$\overrightarrow{\Delta} = \Delta_2 - \Delta_1 + m(V - V_2 + V_1) - (1 - \theta)[\Delta_2 - \Delta_1 + m_o(V - V_2 + V_1)]$$

and

$$\overleftarrow{\Delta} = mV - (1 - \theta)m_oV$$

Then we can evaluate $\overrightarrow{\Delta} - \overleftarrow{\Delta}$ as a function of V. For an origin O,O

$$\overrightarrow{\Delta} - \overleftarrow{\Delta} = \Delta_2 - \Delta_1 + m(V_1 - V_2) - (1 - \theta)[\Delta_2 - \Delta_1 + m_o(V_1 - V_2)]$$

But, generally, $\Delta_2 = \Delta_1 + m_o(V_2 - V_1)$, therefore

$$\overrightarrow{\Delta} - \overleftarrow{\Delta} = (m_o - m)(V_2 - V_1)$$

Similarly for an origin Δ_1,V_1

$$\overrightarrow{\Delta} - \overleftarrow{\Delta} = \Delta_2 - \Delta_1 + m(V_1 - V_2) - (1 - \theta)[\Delta_2 - \Delta_1 + m_o(V_1 - V_2)] = (m_o - m)(V_2 - V_1)$$

Hence the difference of Δ values in the forward and backward-going Δ-V profiles is independent of the origin chosen for representing Δ changes.

Also, it is useful to calculate the difference of Δ values referred to the two origins O,O and V_1,Δ_1. We find

$$\overrightarrow{\Delta}_{V_1,\Delta_1} - \overrightarrow{\Delta}_{O,O} = \Delta_2 - \Delta_1 + m(V - V_2 + V_1) - (1 - \theta)[\Delta_2 - \Delta_1 + m_o(V - V_2 + V_1)] - \Delta_2 + m(V - V_2) - (1 - \theta)[\Delta_2 + m_o(V - V_2)] = (mV_1 - \Delta_1) - (1 - \theta)(m_oV_1 - \Delta_1)$$

and

$$\overleftarrow{\Delta}_{V_1,\Delta_1} - \overleftarrow{\Delta}_{O,O} = (m_1V_1 - \Delta_1) - (1 - \theta)[m_oV_1 - \Delta_1)]$$

so that the differences of forward or backward Δ changes expressed on different origins of the coordinate system are identical.

Thus, an individual series of corrected $\overrightarrow{\Delta}$ or $\overleftarrow{\Delta}$ values will depend on the choice of origin but differences $\overrightarrow{\Delta} - \overleftarrow{\Delta}$, or of $\overrightarrow{\Delta}$ or $\overleftarrow{\Delta}$ expressed on two origins, are independent of the choice of origin, as may be expected. Hence, the experimentally indicated $\overrightarrow{\Delta} - \overleftarrow{\Delta}$ values can be interpreted in terms of hysteresis and an irreversible change of state of the oxide between its progressive formation and progressive reduction.

DISCUSSION SECTION

This Discussion Section includes discussion of papers appearing in the *Journal of The Electrochemical Society*, Vol. 120, No. 12; December 1973; and Vol. 121, No. 1, 2, and 4; January, February, and April 1974.

Electromotive Force Measurements on Cells Involving Beta-Alumina Solid Electrolyte

N. S. Choudhury (pp. 1663-1667, Vol. 120, No. 12)

A. Sterten:[1] One of the cells in the paper under discussion (cell [V]) was described in the following manner

$$Al/\beta\text{-alumina}/AlF_3, NiF_2, Ni$$

The over-all cell reaction was proposed to be

$$2Al_{(s)} + 3NiF_{2(s)} = 2AlF_{3(s)} + 3Ni_{(s)} \quad [1]$$

assuming the transport number of sodium ions through β-alumina equal to unity. However, since AlF_3 and β-alumina are not coexistent,[2,3] reaction [1] above is not the correct one for cell [V] of the above-cited paper.

Aluminum fluoride and sodium oxide in β-alumina will probably react and give a thin layer of Al_2O_3 and Na_3AlF_6 at the interface β-alumina/AlF_3. Na_3AlF_6 may react further with AlF_3 and finally give $Na_5Al_3F_{14}$ in the layer. From these considerations it is proposed that one of the two following reactions is the most likely one for cell [V] of the paper being discussed

$$2Al + 3Na_2O_{in\ \beta\text{-}Al_2O_3} + 3NiF_2 + 2AlF_3 = Al_2O_3 + 2Na_3AlF_6 + 3Ni \quad [2]$$

$$2Al + 3Na_2O_{in\ \beta\text{-}Al_2O_3} + 3NiF_2 + 18/5\ AlF_3 = Al_2O_3 + 6/5\ Na_5Al_3F_{14} + 3Ni \quad [3]$$

still assuming the transport number of sodium ions through the solid electrolyte equal to unity.[4] The experimental data given by Choudhury in the paper under discussion can be compared with available data for these two reaction schemes.

The emf for cell [V], given in Fig. 5 in the paper being discussed, seems to be well described by the following equation

$$E = 1.666 + 0.060 \times 10^{-3}T \text{ (volt)} \quad [4]$$

The emf corresponding to the following reaction

$$3Ni + 6NaF + 3Cu_2O = 3NiF_2 + 3Na_2O_{in\ \beta\text{-}Al_2O_3} + 6Cu \quad [5]$$

is, according to Choudhury in the above-mentioned work

$$E = 0.6465 - 0.190 \times 10^{-3}T \text{(volt)} \quad [6]$$

Combination of Eq. [5] with Eq. [2] gives

[1] Department of Industrial Electrochemistry, The University of Trondheim, N-7034 Trondheim-NTH, Norway.

[2] P. A. Foster, *J. Chem. Eng. Data*, **9**, 200 (1964).

[3] J. Brynestad, K. Grjotheim, and J. L. Holm, *Bul. Inst. Politeh. Bucuresti*, **XXV**, 57 (1963).

[4] E. W. Dewing, *Met. Trans.*, **1**, 2211 (1970).

$$2Al + 6NaF + 2AlF_3 + 3Cu_2O = Al_2O_3 + 2Na_3AlF_6 + 6Cu \quad [7]$$

and combination of Eq. [5] and Eq. [3] gives

$$2Al + 6NaF + 18/5\ AlF_3 + 3Cu_2O = Al_2O_3 + 6/5\ Na_5Al_3F_{14} + 6Cu \quad [8]$$

The corresponding emf is obtained from Eq. [4] and [6]

$$E = 2.3125 - 0.130 \times 10^{-3}T(\text{volt})\ (800°\text{-}900°K) \quad [9]$$

The changes in standard free energy for the reactions

$$3NaF + AlF_3 = Na_3AlF_6 \quad [10]$$

$$5NaF + 3AlF_3 = Na_5Al_3F_{14} \quad [11]$$

have been determined by Dewing.[4] Data for reaction [11] above are also given by Grjotheim *et al.*[5] These data combined with data for Cu_2O[6,7] and α-Al_2O_3[8] have been used to calculate the standard free energy change for reactions [7] and [8] above. The calculated values are given in Table I together with free energy data derived from Choudhury's experimental results in the paper under discussion as expressed by Eq. [9] above. The results in Table I indicate that reaction [2] is probably the correct over-all reaction for cell [V] of the paper being discussed. However, as there are rather large uncertainties involved in the free energy calculations for reactions [7] and [8], reaction [3] cannot be excluded as a possible over-all reaction for the above-mentioned cell [V].

N. S. Choudhury:[9] The discussion and conclusions of Sterten above are based upon the assumption that AlF_3 reacts with β-alumina to form a layer of Na_3AlF_6 at the β-alumina/AlF_3, NiF_2, Ni interface. The equilibrium $RT \ln a_{Na_2O}$ values at 800°, 900°, and 1000°K for the reaction

$$3Na_2O + 4AlF_3 = 2Na_3AlF_6 + Al_2O_3 \quad [1]$$

are tabulated below (Table II). It is assumed that AlF_3, Na_3AlF_6, and Al_2O_3 are in the standard state. The second column lists computed values of $RT \ln a_{Na_2O}$ from the $\Delta G°_{Na_2O}$, $\Delta G°_{Na_3AlF_6}$, $\Delta G°_{Al_2O_3}$, and $\Delta G°_{AlF_3}$ values given in JANAF tables.[8] The third column lists $RT \ln a_{Na_2O}$ values estimated from $\Delta G°_{Na_2O}$, $\Delta G°_{Na_3AlF_6}$, and $\Delta G°_{Al_2O_3}$ values in JANAF tables[8] and the more recent $\Delta G°_{AlF_3}$ values reported by Skelton and Patterson.[10] The $RT \ln a_{Na_2O}$ values for β-alumina–α-alumina coexistence, reported in the paper under discussion, are listed in the fourth column for comparison.

It is apparent from the above table that the formation of Na_3AlF_6 at the β-alumina/AlF_3, NiF_2, Ni interface is thermodynamically possible if the data for $\Delta G°_{AlF_3}$ given in JANAF tables are used. On the other hand, if the data of Skelton and Patterson for $\Delta G°_{AlF_3}$ are used, β-alumina and AlF_3 should coexist without any formation of Na_3AlF_6 at these temperatures.

In Table I above the standard free energy change for the reaction, at 800° and 900°K

$$2Al + 6NaF + 2AlF_3 + 3Cu_2O = Al_2O_3 + 2Na_3AlF_6 + 6Cu \quad [2]$$

are tabulated from the data reported in the literature and from the emf values reported in the paper under discussion (with the assumption that Na_3AlF_6 did form at the β-alumina/AlF_3, NiF_2, Ni interface). The difference of 1.5 kcal at 800°K and 2.6 kcal at 900°K may perhaps be accounted for from the uncertainties in free energy calculations. However, these differences correspond to 11 and 18 mV, respectively, and cannot be simply accounted for from the scatter of the reported emf data.

It should be noted that the observed emf's for the cell Al/β-alumina (+α-alumina)/AlF_3, NiF_2, Ni agreed reasonably well with those reported by Skelton and Patterson for the cell Al, AlF_3/CaF_2/Ni, NiF_2 at above 540°C, which would correspond to the cell reaction

$$2Al + 3NiF_2 = 2AlF_3 + 3Ni \quad [3]$$

Thus, Sterten's assertions, that (*i*) the over-all cell reaction given by reaction [3] is incorrect and further that (*ii*) a layer of Na_3AlF_6 formed at the β-alumina/AlF_3, NiF_2, Ni interface to account for Sterten's reaction schemes are inconclusive.

Polarization Characteristics and Anodic Disintegration of Beryllium in Nonaqueous Solutions

H. Vaidyanathan, M. E. Straumanis, and W. J. James
(pp. 7-12, Vol. 121, No. 1)

I. Epelboin, M. Froment, and M. Garreau:[11] In a recent paper[12] we interpreted the anomalous dissolution of beryllium (apparent valency $V_i < 2$) in terms of a local inversion of the relative thermodynamic stability of Be^+ and Be^{++} ions in the anodic layer. Vaidyanathan *et al.* raised some arguments to this interpretation which led them to conclude that "the assumption of the transient univalent state in postulating a mechanism for the anodic dissolution of Be is superfluous."

To draw this conclusion, the authors of the paper under discussion based their theory mainly on results obtained during very interesting studies concerning the two following fields: (*i*) surface studies and (*ii*) valency-potential relations.

Our own investigations in these two fields[12-14] bring us to think it necessary to make some remarks regarding the results and conclusions of Vaidyanathan, Straumanis, and James in the above-mentioned paper.

(i) *Surface studies.*—In our paper[12] we showed that a scanning electron microscope examination of the surface state of the anode led us to exclude any participation of a mechanical disintegration of the metal lattice ("Chunk effect") during the dissolutions that occur at high anodic potential, with an apparent valency V_i of 1.00 ± 0.01. More recently[13,14] we confirmed this fact,

[11] Physique des Liquides et Electrochemie, Groupe de Recherches du C.N.R.S., accocié à l'Université de Paris VI, 75230 Paris, 05 Cedex, France.
[12] H. Aida, I. Epelboin, and M. Garreau, *This Journal*, **118**, 243 (1971).
[13] I. Epelboin, M. Froment, M. Garreau, and H. Aida *J. Microscopie*, **15**, 313 (1972).

which is fundamental to interpret anomalous dissolution, by determining the origin of the mechanism leading to anodic disintegration under certain experimental conditions. To this end, we first observed in transmission electron microscopy beryllium foils which were thinned electrolytically under conditions leading to $V_i = 1.00$. On the thin foils thus obtained, the grain boundaries and the arrangement of dislocations can clearly be seen; no trace of disintegration or oxidation could be revealed within the resolution limit of the method used for the observation (bright field or dark field observation, under an electron acceleration potential of 1 mV). The foils were subsequently subjected to very brief periods of dissolution under conditions leading to $V_i = 1$. After this last treatment, there appears, systematically, a heterogeneous dissolution due to the formation of beryllium oxide. The oxide was identified by electron microdiffraction on attacked areas (simultaneously, formation of very well-defined rings corresponding to the interreticular distances of hexagonal BeO with parameters, $a = 2.698$Å and $c = 4.38$Å, and formation of pattern points corresponding to the metal lattice).

The progression of the oxide is by no means affected by the presence of the various crystal defects (grain boundaries, dislocations). During its random progression, the oxide isolates small metal blocks which subsequently come off the electrode. The "Chunk effect" thus created can be easily identified, even before metal particles appear in the solution bulk and before its influence on the value of V_i be perceptible. Our observation technique not only constitutes a very sensitive method to reveal the existence of the "Chunk effect," but also removes all doubts on the origin of the metal particles that can be observed in the anolyte. As a matter of fact, it seems impossible to attribute such particles to a disproportionation of Be^+ ions as was sometimes stated, since their presence is always related to a random formation of oxide at the metal surface; and on this particular point, we agree with Vaidyanathan *et al.* in the paper under discussion. It is to be noted that we have already been led to refute the hypothesis on a disproportionation by our first observation in scanning electron microscopy, which we performed originally not in order to check this hypothesis as was reported in the work being discussed but in order to refute it.[12]

This method for studying dissolution provides further information on the mechanism, according to which the metal passes into the solution, when the oxide layer shows a porous structure analogous to that formed on aluminum (3). In the case of aluminum dissolution, and under the same conditions as for beryllium ($LiClO_4$-ethanol solution, where Al^+ reduces ClO_4^- to Cl^-[12]), the growth of oxide gives rise to the formation of small pockets within which lithium chloride (a salt very soluble in the electrolyte used here) is isolated from the bulk of the solution and then can crystallize. The LiCl crystallites thus formed are identified by electron microdiffraction. They are distributed randomly; their size ($\simeq$ 200Å) is of the same magnitude as that recently determined for the pores of amorphous aluminum oxides formed anodically.[15] These results, obtained at low anodic potentials, demonstrate that at such potentials an oxide layer is formed between the metal and the electrolyte. On the other hand, as soon as the anodic potential becomes sufficiently high, this porous oxide and the LiCl crystallites are no longer formed, and the "Chunk effect" no longer occurs.

This highly sensitive method permitted us to show that the experimental conditions required for obtaining anodic dissolutions without BeO oxide formation on the metal must be satisfied very accurately. And it is only under such conditions that the whole surface of the anode can undergo a dissolution process corresponding to the sequence

[15] P. Neufeld and H. O. Ali, *This Journal*, **120**, 479 (1973).

$$Be \rightarrow Be^+ + e^- \text{ (electrochemical step)} \quad [1]$$

$$Be^+ + \text{oxidizing agent} \rightarrow Be^{++} \text{ (chemical step)} \quad [2]$$

which leads to the critical value $V_i = 1.00$.

The experimental conditions leading to $V_i = 1.00$ are drastic, not only with respect to the solution, *i.e.*, high temperature and very low water concentrations ($[H_2O] < 0.01\%$), but also with respect to the metal. Thus we observed erratic values close to 1 for V_i with metal samples having a satisfactory chemical purity but presenting mechanical elaboration defects, and this phenomenon disappears when we used single crystals in the same conditions.[16]

These results allow us to think that the deductions made by the authors of the paper under discussion from the fact that the "Chunk effect" still occurs when V_i is equal to 1 (0.94-1.00-0.98) are not significant for the following reasons.

First, a deviation for V_i of about 2% from unity is sufficient for the "Chunk effect" to appear unambiguously. This can explain their experimental observations in the two cases leading to $V_i = 0.94$ and $V_i = 0.98$.

Secondly, even the value $V_i = 1.00$ obtained by the authors in the work being discussed is disputable, because, with the average water concentration (0.4%) used by these authors, a partial oxidation of the anode cannot be avoided. With a similar water concentration we have indeed obtained the same sort of curve as that depicted in Fig. 1 of the paper under consideration at potentials applied to the cell ranging between 0 and 5V approximately. In agreement with the paper under discussion the value of $V_i = 1.00$ can reasonably be considered as an upper limit of valency at high potentials when experiments are performed within this potential range. But if the curve is extended up to potentials equal to 20V, it can be seen that the value $V_i = 1.00$ is only reached during a continuous variation of valency which passes from a value less than 1.00 to a value close to 1.04. Consequently, the value $V_i = 1.00$ is only obtained in a purely fortuitous manner, and therefore cannot be compared to the meaningful limiting value $V_i = 1.00$ which we described in our paper[12] and which corresponds to the sequence of reactions [1] and [2] above.

As to the transitory Be^+ ions resulting from reaction [1], it is worth noting here that the presence of these uncommon monovalent ions in the vicinity of the anode, has been recently detected by Eckert and Forker, with the aid of the rotating ring-disk electrode.[17] The presence of such ions is also confirmed by the fact that ClO_3^- ions have been identified as intermediates in the reduction $ClO_4^- \rightarrow Cl^-$ by Be^+, by Kiss *et al.* using a similar method.[18]

(ii) *Valency-potential relations.*—As was recalled by Vaidyanathan *et al.* in the paper under present discussion it is doubtless that V_i must tend to the limiting value $V_i = 2$ when the anodic potential increases. With respect to this we pointed out some years ago that there must exist a more or less wide potential range which would lead to a dissolution following the sequence of reactions [1] and [2] exclusively. A minimal anodic potential is obviously necessary to create an anodic layer poor in solvent molecules within which the monovalent ion is thermodynamically more stable than the polyvalent ion; this was also confirmed by investigations we are performing on aluminum.[16] Once this layer formed, any subsequent increase of the potential can only facilitate the electrochemical oxidation of Be^+ to the detriment of the chemical oxidation (reaction [2]) and thereby increases V_i to the value $V_i = 2$ corresponding to the sequence

$$Be \rightarrow Be^+ + e^- \quad [1]$$

$$Be^+ \rightarrow Be^{++} + e^- \quad [3]$$

[16] M. Garreau *et al.*, To be published.
[17] J. Eckert and W. Forker, *Z. Physik. Chem. (Leipzig)*, **253**, 153 (1973).
[18] L. Kiss, M. L. Varsányi, and E. Dudás, *Acta Chim. Acad. Sci. Hung.*, **79**(1), 73 (1973).

The existence of a plateau in the curve V_i-E is by no means incompatible with this interpretation. The presence of the plateau only seems to indicate that a new potential threshold must be overpassed so that the electrochemical oxidation of Be^+ (reaction [3]) may compete with the chemical oxidation (reaction [2]). The fact that the value $V_i = 1.00$ was not possibly overpassed hitherto under the conditions at which the plateau appears, is due, in our opinion, to the fact that we have never succeeded in creating a sufficiently high electric field in the vicinity of the metal, despite the very high apparent anodic potentials we used ($E >$ 20V). The impossibility of obtaining important effective anodic potentials is due to the influence of an ohmic drop which is more important than that predicted by our first estimations.[12] By improving our measurement devices we possibly observed, for example, an ohmic drop close to 7V at a measured anodic potential of 8V.[16] The impossibility of reaching high effective anodic potentials in such solutions seems to be confirmed by the fact that, within the potential range studied, no electrochemical oxidation of either the solvent or other components of the solution has ever been observed, contrary to what happens in certain solutions used by the authors in the paper being discussed ($NaNO_3$/MeOH solution, for example, in which lK is anodically oxidized to I_2).

Despite the arguments put forward by Vaidyanathan *et al.* in the paper under consideration, we believe that the points developed here, as well as those proposed recently by other investigators,[17,18] allow us to assert that the hypothesis on a transitory monovalent state of the metal for interpretation of the anomalous anodic dissolution of beryllium cannot actually be ruled out.

Mutual Effect of Current Density, pH, Temperature, and Hydrodynamic Factors on Current Efficiency in the Chlorate Cell Process

M. M. Jaksic (pp. 70-77, Vol. 121, No. 1)

H. Vogt:[19] As Jaksic showed in the paper under discussion, optimum pH value to provide maximum conversion rate of hypochlorite to chlorate can be calculated from the constant K^*. While the dissociation constant of hypochloric acid, K_a, is known from experiments, K^* can only be calculated from K_a with the knowledge of activity coefficients. Based on data from several authors, Jaksic calculated[20]

$$\frac{K^*}{K_a} = \frac{f_{HClO} \cdot a_{H_2O}}{f_{ClO^-}} \approx 1$$

But from the analysis of experimental data of Landolt and Ibl[21] Jaksic later concluded[22] that the ratio must be higher

$$\frac{K^*}{K_a} \approx 10$$

In addition to Jaksic's considerations, it can be shown, that the higher value is more realistic and that the ratio is probably even higher.

Differentiating the equation for conversion rate as derived by Foerster

$$2HClO + ClO^- + 2H_2O \rightarrow ClO_3^- + 2Cl^- + 2H_3O^+$$

leads to the extreme condition $2K^* = a_{H_3O^+}$ or $pH_M = -\log K^* - \log 2$. From the scheme, introduced by Flis

$$HClO + 2ClO^- + H_2O \rightarrow ClO_3^- + 2Cl^- + H_3O^+$$

follows $0.5K^* = a_{H_3O^+}$ or $pH_M = -\log K^* - \log 0.5$. For both the schemes, the temperature dependence of pH_M over an extended range can be derived, if one optimum pH is known at one temperature.

From Jaksic's older experiments follows $pH_M \approx$ 6.0 at 40°C. Values of K_a were determined by Morris and by Caramazza. They do not differ considerably and can be approximated by the simplifying equation

$$-\log K_a = pK_a = 7.744 - \frac{0.0075}{°C} \cdot t$$

fitting in the range of practical application between 25° and 80°C with a deviation of $< \pm 0.3\%$.

For the Foerster scheme follows

$$\log \frac{K^*}{K_a} = -pH_M - \log K_a - \log 2 = 1.143$$

$$K^*/K_a = 14$$

Considering the Flis scheme to happen exclusively results in $K^*/K_a = 56$. Hence, these are the limits, situated in between the ratio, based on Jaksic's optimum pH.

Assuming $f_{HClO} = 1.4 \ldots 2$ and $a_{H_2O} = 0.8$, the activity coefficient of hypochlorite ion follows

$$f_{ClO^-} = 0.08 \ldots 0.12$$

for the Foerster scheme in good agreement with Jaksic's result.

The temperature dependence of optimum pH value can be expressed as

$$pH_M = C - \frac{0.0075}{°C} \cdot t$$

From Jaksic's experimental result follows $C = 6.3$, if one again considers the Flis scheme not to be essential. In this regard opinions are far from being unanimous. Claus, for instance, found an optimum pH value of about 7,[23] but more recent experiments seem to prove that pH_M is lower at about 6.3 . . . 6.5.

On the other hand, it must be postulated that one must distinguish clearly between pH in the reactor and pH at cell entrance, as Jaksic did in the paper under discussion. The optimum pH discussed here refers to a mean value in reactor.

Mechanism of Electrocrystallization

T. Vitanov, A. Popov, and E. Budevski (pp. 207-212, Vol. 121, No. 2)

K. J. Bachmann:[24] A crystalline surface in thermodynamic equilibrium with an electrolyte phase, established via a reversible charge-transfer reaction $Me = Me^{z+} + ze^-$, contains a definite density of surface sites, *e.g.*, steps, kink sites, adatoms, surface vacancies, and clusters thereof, which differ in their binding energy to the crystal surface. For the interfacial equilibria, crystal/vapor and crystal/melt, where the degree of surface roughening depends only on the deviation of the temperature from a critical surface roughening temperature, at which singular surfaces become thermally roughened to an extent that makes step edges indistinguishable, a detailed analysis of the distribution of surface sites has been made via Monte Carlo simulations.[25] Similar calculations may be applied to simulate the growth of simple crystals from the vapor phase and to some

hypothetical situations of solution growth.[26] Computer simulations concerning the problem of combined nucleation and step motion have been studied by Bertocci,[27] who considered, also, the conditions encountered during electrocrystallization and when impurities are incorporated at steps. However, his calculations require that the step velocity and nucleation rate be known and give no information on the detailed molecular structure of the crystal/electrolyte interface. Calculations of the roughness of the crystal/electrolyte interface from first principles are very difficult since the effects of adsorption of solvent molecules and of the complicated structure of the electrical double layer are so far not accessible to a quantitative evaluation. Although one cannot derive at present the details of surface structure for a crystal/electrolyte interface, general considerations suggest a relatively high degree of surface roughening since adsorption phenomena both lower the energy and increase the entropy of a roughened surface. This may in part explain why the electrode potential is quite insensitive to surface roughening. The effect of adsorption on surface properties will be influenced by the competition of solvent and impurity adsorption, which can never be completely disregarded when working with crystal/solution interfaces.

In the paper under discussion, Vitanov *et al.* reduce the above sketched complex problem to the question of whether the exchange between crystal surface and metal ions in the electrolyte occurs predominantly via adatoms or directly from and into kink sites. The authors attempt to find an answer to this question for the Ag/Ag^+ electrode by comparing the exchange C.D. measured on a (100) face containing no electrochemically active steps (in the following designated as type 1 face) with the exchange C.D. measured on a (100) face containing electrochemically active steps (type 2 face), the density of which depends on the overvoltage at which these steps have been generated. They conclude from their experimental evidence, that the electrocrystallization of silver is governed by direct charge-transfer on steps.

It should be noted that the same simplified model as used by Vitanov *et al.* in the paper under consideration which assumes that the crystal/ electrolyte interface is perfect except for steps with kink sites and adatoms, was utilized in the late 1950's by Gerischer,[28] Bockris *et al.*,[29] and Lorenz.[30] They concluded from their internally consistent experimental work that the electrocrystallization of silver is governed by surface diffusion of adatoms. Later experiments of Bachmann and Vetter[31] raised some doubts in this simplified picture which is now even more challenged by the work being discussed by Vitanov *et al.* who, using the same surface model as other authors in the field,[28-30] suggest a different path contradicting the adatom diffusion mechanism. Clearly, the capillary growth technique developed by Budevski *et al.*[32] results in much more well defined crystal surfaces than used in the previous work by others, but for reasons discussed below, I have some doubts about the validity of the interpretation given in the paper under discussion.

The type 1 face behaves within ±10 mV of the equilibrium potential of the Ag/Ag^+ electrode as an ideally polarizable electrode and contains, as shown by Budevski *et al.*,[33] no electrochemically active monoatomic steps. If such a surface is indeed free of impurities, which is difficult to assess, then after adjusting the electrode to the reversible equilibrium potential of the Ag/Ag^+ electrode its surface should attain the equilibrium distribution of surface sites including steps in the form of subcritical nuclei and vacancy clusters. The over-all exchange C.D., i_0, on such a surface is then the sum over the partial exchange C.D.'s of the various surface sites. Although not specifically stated in the paper under discussion, presumably it was checked that equilibrium is, in fact, established at the time of measuring i_0 and the result thus indicates that the over-all exchange C.D. on a perfect surface is much smaller than the exchange C.D. measured on surfaces of the same orientation but of nonequilibrium roughness.

Table I shows a number of literature values which were standardized for comparison to 1*N* Ag^+-concentration assuming $i_0(1N) \approx i_0/c^{\alpha}_{Ag^+}$. Note that the pronounced effect of roughening expressed in the large variation of i_0 does not result in large variations of the electrode potential. However, this does not indicate that all these electrodes have similar adatom concentrations since the surface activity entering into Nernst's equation becomes a complex expression when charge-transfer is understood in the statistical sense outlined above and nonequilibrium surfaces are con-

sidered. As a matter of fact, the values for the adsorption capacitance C_{ad} reported elsewhere[28-31] and in the paper under discussion vary as the exchange C.D.'s by orders of magnitude. If Vitanov *et al.* in the paper under discussion assume that C_{ad} is directly related to the adatom concentration, then all the different experimental results reported in the literature may be consolidated by assuming differences in roughening, including both the density of steps and adatoms. However, it is a pitfall of electrocrystallization studies that these phenomena may be explained as well by impurity adsorption and "activation" of an electrode could be simply understood as removal of dirt. Also, in my opinion, the separation of C_{ad} becomes very inaccurate when its value approaches that of the double layer capacity and the evaluation of C_{ad} on the basis of galvanostatic single pulse experiments described for the type 1 face appears to be in doubt.

It should be noted that the results of Vermilyea and Price[34] indicate that the exchange C.D. is not very sensitive to inhibitor adsorption. Also, there exists some experimental evidence for rearrangements on freshly prepared silver deposits[35,36] which indirectly support the ideas of Vitanov *et al.* in the paper under discussion as they point to the possibility that the much higher exchange C.D.'s observed by others are related to an increased step density on their electrodes and to the fact that the shift of the C.D. *vs.* overvoltage curves on low index silver surfaces immersed in a Ag^+ solution toward higher overvoltages described by Bachmann and Vetter[31] may, at least in part, be related to rearrangements of steps and not be entirely due to diffusion controlled inhibitor adsorption as assumed there.

However, if one accepts the value of 180 A/cm^2 given by Vitanov *et al.* in the work under consideration as the C.D. directly at steps in a 6*N* Ag^+ solution and compares it to the data of others (Table I), neglecting exchange with different surface sites but steps, then under the conditions of Gerischer and Tischer[28] and under those of Bachmann and Vetter[31], about 40 and 14%, respectively, of the surface atoms would have to be step sites. This is somewhat hard to conceive, since, even when starting with a nonsingular surface, at the large values of i_o observed, the surface should become rapidly faceted.[37]

The type 2 faces represent nonequilibrium surfaces since the step density on them was generated in a cathodic growth process at $\epsilon < \epsilon_o$. This is clearly stated in the above paper, since maintenance of the original nonequilibrium step density is considered by the authors as a prerequisite for being able to make their measurements. It is interesting to note that the rearrangement of a nonequilibrium step density on (111) faces, which represent the closest packed plane in the fcc lattice, is reported to be much faster than the rearrangement on (100) faces which remain unaltered for at least 30 min when the step generating cathodic current is switched off (see Footnote 1 of the paper under discussion). There exists thus an unusually strong kinetic hindrance for attaining equilibrium surface conditions on the (100) plane. Previous work[31] indicates that (100) faces of Ag crystals are more sensitive to inhibition by impurity adsorption than the (111) faces. The observed behavior suggests, therefore, that the (100) faces considered by Vitanov *et al.* in the work being discussed are perhaps not perfectly clean surfaces. The inhibition of step rearrangement on (100) as compared to (111) is hard to understand when one assumes a large exchange C.D. directly on steps which eliminates the necessity of considering surface diffusion of adatoms and surface vacancies during the rearrangement process.

When a nonequilibrium step density persists on the type 2 face after switching off the generating current, then there is, in my opinion, no reason to believe that the density of all the remaining surface sites is at equilibrium level or at the same nonequilibrium level, as on type 1 face. Hence, the difference between the exchange C.D.'s of type 1 and type 2 faces does not necessarily represent the exchange C.D. directly on steps. The controversy concerning the surface diffusion of adatoms *vs.* direct charge-transfer on steps, which was introduced 50 years ago by Kohlschütter *et al.*, Brandes, and Volmer *et al.*[40] is thus still undecided. Instead of adhering to these early models of electrocrystallization it appears to me that one ought to acknowledge the existence of a number of surface and bulk defects in electrodeposited metals. The nature and effect upon the mechanism of electrocrystallization of these defects is presently not completely understood. The answers derived from more realistic models of electrocrystallization will be necessarily less clear cut, *i.e.*, will be of statistical meaning, but that does not decrease their value. It should be emphasized that the simplified model used by Vitanov *et al.* in the paper being discussed remains to be an interesting approximation which might be useful in some special cases, but the present evidence is insufficient to consider it as the mechanism of electrocrystallization.

T. Vitanov, A. Popov, and E. Budevski: The mechanism of metal deposition is doubtless a very complex process, and the main idea of the paper under discussion was to utilize the extremely simple and theoretically comprehensible behavior of electrodes representing one single crystallographic plane for the investigation of this process. The very essential point of the experiment was that a surface structure with an exactly known configuration (dislocation-free intact plane or a plane with known monoatomic step density) can be produced and reproduced relatively easily. The main experimental results of the paper are: (*i*) that the over-all exchange current density i_o increases linearly with step density and (*ii*) that the extrapolated value of i_o for zero step density is exactly that measured on a dislocation-free plane.

These two facts show that the presence of a step creates along the step new sites with a higher exchange C.D. and does not affect the remaining part of the surface. How far away from the step line the region with increased exchange C.D. extends is a question which the experiment was obviously unable to answer.

To calculate the true exchange C.D. (A/cm^2) in the paper under discussion we made the simplest assumption that this range extended to the first closest atoms added to the step. It is unlikely that this assumption is very correct but it is sound as long as it is clearly understood and remembered. As we can assume every atom located on a step as an atom belonging to the crystal lattice we can call the transfer of an ion from the solution to a step a direct transfer process, *i.e.*, a transfer with simultaneous incorporation. This is why we call the exchange C.D. of these atoms the exchange C.D. of direct transfer. The calculation shows that it is by three orders of magnitude higher than the exchange C.D. of atoms on a flat surface (adatoms).

[37] Even higher exchange C.D.'s than that given by Gerischer and Tischer[28] have been observed by Frankenthal[38] in Ag^+ solutions of extreme purity. Linear voltage sweep polarography on freshly etched Ag/Ag^+ electrodes yields excellent agreement between experimental results and theory assuming pure diffusion control of the deposition process which, also, suggests an extremely high exchange C.D. on such surfaces.[39]

Using not specially prepared solid surfaces (unknown step density) it is now quite clear that a wide range of over-all exchange C.D.'s can be measured. If we assume Bachmann's remark, in the above discussion, that the same situation and roughly the same values for the exchange current densities can be applied to the experiments of Gerischer[28] and Bachmann and Vetter[31] we can calculate back the average step distances: 7.2Å in the first case and 22Å in the second, compared with 830Å for an electrolytically grown (100) plane in our case. The misfit of the orientation in Bachmann's case is 4.5° which is not very far from what could be expected for a cut and electropolished plane. Anyway we believe that this calculation is a very vague extrapolation to extremely different conditions ($AgClO_4 + HClO_4$ *vs.* $AgNO_3$).

The surface roughness produced by thermal motion cannot be neglected completely as we have done so far. It probably plays a major role in the process of roughening of the step edges and thus ensures a fast direct incorporation into the numerous kink sites. The two facts, however, which have been observed, namely two-dimensional nucleation on a dislocation-free plane and spiral growth mechanism on a plane with dislocations, show that the thermal surface roughening plays, in our case, a subordinate role for the process of growth and that we are really very far from that critical temperature, at which a normal mechanism of growth begins to be predominant. As a matter of fact, even propagating steps at a length of 100 $m\mu$ proved to be fairly straight.[41]

We are well aware of facts which show a surface contamination and adsorption. Many of them are still not so reproducible to allow theoretical speculations. But as we have not found dramatic changes in the electrochemical properties (exchange current density) changing the electrode potential in the allowed range of about 5 mV, we have no reason to use some ambiguous concepts to explain a very simple behavior of a face with a growing step on it.

Moreover, we have clearly stated that the direct transfer is a complementary process to the surface diffusion process and that in our specific case we have very good evidence for a predominance of the direct transfer mechanism. How far this can be generalized is a question which only the experiment can answer and we do not think that the title can be misleading in this respect.

Hydrogen and Nitrogen Evolution Reactions in Acid Liquid Ammonia

M. H. Miles and C. A. Yates (pp. 230-233, Vol. 121, No. 2)

S. Trasatti:[42] In the paper under consideration, the authors have attempted to discuss the results obtained for the reaction of hydrogen evolution on various metals in liquid ammonia on the basis of correlations between log i_o (exchange current) and Φ (work function), and log i_o and $q_{ad,H}$ (heat of hydrogen adsorption), respectively, proposed by the present author[43] for the case of aqueous solutions. The authors of the paper under discussion state that the correlation between log i_o and Φ is not so linear as suggested in the previous paper,[43] although the reactivity scale appears to be the same as in aqueous solution. On the other hand, the authors of the above cited paper report a linear correlation between log i_o and $q_{ad,H}$ with a slope of 0.3 whereas Kuhn *et al.*,[44] as they quote, have found 0.6 for aqueous solutions.

While the reactivity scale being the same as in aqueous solutions is a very interesting fact because it is a strong support to present views in electrocatalysis, it is the opinion of this writer that a discussion in terms of work function or heat of hydrogen adsorption is worthy of being brought into more detail than it is in the paper under discussion.

First of all, the authors of that paper state that the correlation between log i_o and Φ is not clearly linear. However, they rely just on six metals gathered within two orders of magnitude of i_o. If the values of i_o for the same metals in aqueous solutions are taken into consideration, a correlation between log i_o and Φ restricted to these metals does not appear to be better than that observable in the paper under discussion. From this point of view, it may be concluded, contrary to the authors of the paper under discussion, that the evidence for a linear correlation between log i_o and Φ may be considered as satisfactory.

However, various other points must be discussed before one can speak of correlation. What appears to have been overlooked by the authors of the abovementioned paper is that there is some internal inconsistency between their experimental results and their discussion in terms of Φ or $q_{ad,H}$. First of all, we notice that, apart from Ta whose behavior is puzzling, Mo, Cr, W, and Au present more or less the same i_o as in aqueous solutions, whereas Pt and Ir show lower i_o values than those in aqueous solutions by two orders of magnitude. This particular aspect does not appear to have been discussed in the paper under consideration. However, this point is particularly important. In fact, if on Pt and Ir the combination reaction is the rate determining step at 0°C as suggested by the authors in the paper being discussed, there should be evidence for some hydrogen adsorbed on the surface. The authors have not looked for and have not offered such evidence. Moreover, the rate of the combination reaction should be independent of the solvent and dependent only on the properties of the surface. From this point of view it is hardly understood why $i_o = 10^{-5}$ A/cm^{-2} in NH_3 and $i_o = 10^{-3}$ A/cm^{-2} in H_2O. If this difference is due to partial occupation of the surface by residues of the solvent, then the rate determining step is more likely to be the ion atom reaction as suggested by Brown and Thornton,[45] although these authors have worked at -30°C, a temperature at which the authors of the paper under discussion admit that a shift of the rds from the combination to the ion+atom reaction may be observed. However, if the low activity of Pt is due to strong interaction of the solvent with the surface, the opinion of this writer is that this effect should also be present with the other metals inasmuch as the strength of the metal-nitrogen bond certainly increases[46] from Pt to Ta. In any case, an explanation must be given for the apparent low activity of Pt and Ir before any test of correlations can be attempted using the experimental results in question.

Another point which appears to have been overlooked by the authors in the paper under discussion is that in a possible correlation between log i_o and Φ, Au is apparently lumped with all other metals. This point is certainly worthy of more consideration. For aqueous solutions two parallel straight lines have been found[43] in the log i_o *vs.* Φ plot. This has been interpreted in the case of sp-metals in terms of the reaction occurring on positive and negative surfaces, respectively. Now, if Au falls in the group of transition metals in the paper under discussion, this may have a meaning in connection with the position of the potential of zero charge with respect to E_{rev} in liquid ammonia. However, in the opinion of this writer, a plot of log i_o *vs.* Φ may be misleading in this case. If the measured log i_o for Pt and Ir are not equilibrium values, it is obvious that the position of Au turns

out to be false. If the value of i_o for Pt found by Brown and Thornton[45] is used, a slope for the log i_o *vs.* Φ correlation is found very similar to that for aqueous solutions, but in this case Au, as expected, is somewhat far from the correlation for transition metals.

One more point concerns the value of the slope of the log i_o *vs.* $q_{ad,H}$ plot. The authors of the paper under discussion claim a value of 0.3 for the slope, but in fact this is the value of the slope in terms of $E(M\text{-}H)$, the hydrogen-metal bond strength. The slope in terms of $q_{ad,H}$ is, in reality, 0.15, in fairly good agreement with the predicted slope[47] of 0.18. However, this is the slope predicted for the ion+atom reaction or the discharge reaction as the rate determining step. This means that the experimental plot is possible because i_o for Pt is low. Thus, there is some internal inconsistency between the position of Pt in the log i_o *vs.* $q_{ad,H}$ plot and the experimental results which suggest the combination reaction to be the rds. The authors of the paper under discussion have found a strong temperature effect for Pt and Ir. It is possible that the relative positions of the "volcano" curves for the ion+atom and the combination reactions shift with temperature. This would make a change in the mechanism for Pt and Ir understandable, in the case where the two metals would fall close to the intersection of the two curves. It would be interesting to know how i_o varies with changing temperature.

Finally, the Tafel slope shown by the authors in the paper being discussed for Pt and Ir is extended in a very narrow potential range close to E_{rev}. It would be interesting to know what the behavior is at higher overvoltages. Brown and Thornton[45] show that the Tafel slope region starts at some 0.2V below E_{rev}. For lower overvoltages the plot may apparently approach a lower Tafel slope. One may wonder if Fig. 6 in Brown and Thornton's paper could offer the way to understand some of the difficulties outlined above.

M. H. Miles and C. A. Yates: The proposed correlations suggested by Dr. Trasatti were discussed only briefly in the paper under consideration due to the limited data available for the hydrogen evolution reaction (h.e.r.) in liquid ammonia. More experimental data would be necessary to completely resolve the points under discussion, some of which remain unresolved despite the numerous studies in aqueous systems.

The correlation between log i_o and the work function, Φ, for the h.e.r. in liquid ammonia was not clearly linear due to the experimental value of i_o for Ta being very small (10^{-12} A/cm^{-2}). Of the seven metals studied, Ta has the greatest tendency to form interstitial hydrides and nitrides,[48] hence the electrode pretreatment evolving nitrogen and hydrogen may have produced pronounced changes in the surface properties. Omitting Ta, the correlation between log i_o and Φ is given reasonably well in acid liquid ammonia at 0°C by log $i_o = 4.3\ \Phi - 26$ which can be compared to Trasatti's relationship log $i_o = 6.7\ \Phi - 36.6$ for transition metals in aqueous solutions.[43]

We do not agree with Trasatti's suggestion that our value of $i_o = 10^{-5}$ A/cm^{-2} at 0°C on Pt and Ir in liquid ammonia should be closer to the $i_o = 10^{-3}$ A/cm^{-2} found in aqueous solutions at 25°C. Contrary to Trasatti's comments, the measured exchange current will be affected by the solvent even for a fast discharge and rate determining recombination mechanism. For such a mechanism the exchange current will be given by

$$i_o = 2\mathbf{F}k_2\left(\frac{k_1}{k_{-1}}\right)^2 a^2{}_{H^+}e^{-2F\Delta\Phi_e/RT} \qquad [1]$$

[47] R. Parsons, *Trans. Faraday Soc.*, 54, 1053 (1958).
[48] H. J. Goldschmidt, "Interstitial Alloys," p. 61, Butterworth and Co., London (1967).

where k_1 and k_{-1} are rate constants for the forward and reverse reactions of the discharge step, k_2 is the rate constant for the recombination step, and $\Delta\Phi_e$ is the absolute potential difference across the interface at equilibrium.[49,50] The solvent can influence k_1, k_{-1}, a_{H^+}, and even $\Delta\Phi_e$ and thus affect i_o. The close agreement between the experiments on Pt and Ir lend support to our results. Furthermore, difficulties in using the hydrogen reference electrode in liquid ammonia suggest a smaller exchange current than found for aqueous solutions. Our use of a lower temperature should also contribute to a smaller observed i_o value. Partial coverage of the Pt surface by adsorbed NH_x radicals may also be a factor as suggested by Brown and Thornton.[45]

By extrapolating from high overvoltages, Brown and Thornton[45] report $i_o = 2 \times 10^{-4}$ A/cm^{-2} on Pt at -30°C in liquid ammonia. From their Fig. 6, one can detect another linear Tafel region with a greater slope at lower overvoltages from which a value of $i_o = 1 \times 10^{-5}$ A/cm^{-2} could be extrapolated. As suggested by Parsons[51] and by Enyo,[52] increasing the overvoltage may produce a change in the reaction mechanism. The resulting dual Tafel slopes will give two different values for the exchange current, and one must then decide which i_o value should be used in the correlations sugested by Trasatti. We did detect a change in slope of our Tafel plots for Pt and Ir at higher overvoltages, but this was difficult to distinguish from effects due to the *IR* drop.

The Tafel slopes provide better evidence for the reaction mechanism than do the questionable log i_o *vs.* $q_{ad,H}$ plot mentioned by Trasatti.[43] Rate determining recombination of adsorbed hydrogen is usually found under conditions of low hydrogen coverage and low overvoltages and is almost the only mechanism which gives a transfer coefficient of two.[49]

LeChatelier's principle predicts that the equilibrium coverage of adsorbed hydrogen atoms will increase as the temperature decreases. Hence, on Pt it is likely that some other reaction will become rate determining at lower temperatures as found in our studies. Recent investigations of the hydrogen/tritium separation factor on Pt in aqueous H_2SO_4 solutions also indicate a change in the electrode reaction mechanism from a slow recombination step at temperatures above 10°C to a slow electrochemical desorption mechanism at lower temperatures.[53]

Optical and Electrochemical Studies of Underpotential Deposition of Lead on Gold Evaporated and Single-Crystal Electrodes

R. Adzic, E. Yeager, and B. D. Cahan (pp. 474-484, Vol. 121, No. 4)

E. Schmidt and N. Wüthrich:[54] In order to interpret the well-known undervoltage double peak observed when Pb is deposited at polycrystalline Au electrodes, the authors of the paper under discussion considered a consecutive mechanism of adsorptive charge transfer involving the formation of a partially discharged Pb adsorbate within the voltage region of the more anodic peak, followed by reductive transformation at higher cathodic potentials

$$Pb^{2+}(\text{soln}) + (2-y)e^- \rightarrow Pb^{y+}(\text{ads}) \quad (\text{first peak}) \quad [1]$$

$$Pb^{y+}(\text{ads}) + ye^- \rightarrow Pb(\text{ads}) \quad (\text{second peak}) \quad [2]$$

According to this model, the Pb surface concentration, Γ, should remain constant within the second peak,

[54] Institute für Anorganische, Analytische und Physikalische Chemie der Universität Bern, 3012 Bern, Switzerland.

whereas the charge/coverage stoichiometry of the undervoltage deposit should be given by

$$\mathbf{F}\, d\Gamma/d\Delta q(E,\Gamma) = \begin{cases} 1/(2-y) & \text{in the first peak} \\ 0 & \text{in the second peak} \end{cases}$$

where $\Delta q(e,\Gamma) = q(e,\Gamma) - q_0(E)$, q and q_0 being the (ionic) surface charges of the gold electrode in the presence of Pb^{2+} and in the lead-free supporting electrolyte, respectively.

This prediction of the model is at variance with the results of the direct determination of q and Γ data by means of a twin-electrode, thin layer method,[55] which has shown that Γ increases continuously with increasing q in the entire undervoltage region, the proportionality factor being equal to the nominal charge of the free Pb^{2+} ion within the limits of experimental precision

$$\mathbf{F}\, d\Gamma/d\Delta q \approx 1/2 \quad \text{in } E > E_{rev} \qquad [3]$$

This stoichiometry value almost certainly invalidates the mechanism proposed by Adzic *et al.* in the paper under discussion. It does, however, provide strong evidence in favor of a simple ionic adsorption process involving Pb^{2+}, whose charge contribution to the interphase is (approximately) compensated for by the electronic charge flow from the polarizing circuit, increasing the surface charge of the electrode

$$Pb^{2+}(\text{soln}) + (2-y)e^-(\text{circuit}) \rightarrow Pb^{2+}, (2-y)e^-(\text{interphase}) \qquad [4]$$

where $y \approx 0$.

Note that in all surface processes, electroneutrality of the interphase must be preserved. If there is substantial deviation from the "ideal" q/Γ-stoichiometry ($|y| >> 0$, as in Eq. [1] and [2]), which cannot be balanced by changes of the nonspecifically adsorbed Helmholtz layer, charge compensation by specific ad- or desorption of ionic species other than Pb^{2+} would be required. No conclusion should be drawn from stoichiometry determinations as to the actual state of charge of the Pb species adsorbed, since there is no way to decide by thermodynamic considerations whether a given amount of electronic charge delivered by the polarizing circuit is used for discharging any ionic species adsorbed, rather than being stored as free charge in the metal part of the electric double layer.

Within two orders of magnitude of the Pb^{2+} concentration, the potential dependence of the experimental Γ values[55] follows very closely a so-called pseudo-Nernstian ("metal monolayer") Γ-E-isotherm

$$E = E^o_{Pb/Pb^{2+}} + \frac{RT}{2\mathbf{F}} \ln[a_{Pb^{2+}}/a_{(\Gamma)}]$$

which is thermodynamically inconsistent[56] with any q/Γ stoichiometry other than Eq. [3].

Peak multiplicity is not an exclusive feature of Pb deposition but is known from several other undervoltage deposits (Tl, Bi, Sb, Cu, Ag) on Au as well. It may easily be explained as reflecting a more or less pronounced discontinuous decrease of the free energy of desorption with increasing coverage, resulting in a steplike shape of the Γ-E isotherm. There is evidence of a duplex layer structure of the adsorbate being built up, the second undervoltage peak corresponding to the formation of a metal layer more distant from, and therefore, less strongly bound to, the substrate.[57]

The existence of Γ values independent of $c_{Pb^{2+}}$ at higher concentrations, as claimed by the authors in the paper being discussed, is not confirmed by thin layer experiments.

R. Adzic,[58] E. Yeager, and B. D. Cahan: Schmidt and Wüthrich propose that the sharp second voltammetry peak in the underpotential deposition of lead is due to a discontinuous decrease of the free energy of desorption with increasing coverage and not a phase transformation accompanied by further reduction as proposed in the paper under discussion. Their explanation for this sharp peak, however, is not compatible with our studies, which show that the sharp second peak in the voltammetry curve is not under diffusion control under conditions where the first peak is under diffusion control. This means that the sharp second peak is not associated with the further adsorption of lead, as proposed by Schmidt and Wüthrich above, but rather is caused by a surface change occurring essentially at constant surface coverage. The pronounced change in reflectivity and of the spectral dependence of the reflectance changes (Fig. 6 in the paper under discussion) attending the sharp voltammetry peak confirm that a marked change in the state of the surface has occurred. The reflectance change *vs.* q plot is linear up to 200 μcoulombs/cm^2 when an abrupt change in the slope occurs (Fig. 8 in the paper under discussion). This charge density corresponds to the occurrence of the sharp second voltammetry peak. Ellipsometric measurements by Horkans *et al.*[59] provide evidence of a change of the layer and a shift toward more metallic properties attending this peak.

The principal argument put forth by Schmidt and Wüthrich against our explanation is that their Γ *vs.* q plot[55] should show some deviation from linearity in the vicinity of the sharp voltammetry peak and they did not observe such in their work with the twin-electrode thin layer cell. Perhaps their failure to observe such is the result of inadequate sensitivity of the method with the gold electrode and acetic acid-acetate buffered electrolyte used by Schmidt and Wüthrich.[55] The charge under the sharp peak in their voltammetry curves is estimated to be only ~7% of the charge for saturation coverage as compared with ~30% for the vapor deposited gold and ~50% for the single crystal gold of (111) orientation used in our work in the paper under consideration in 1*M* $HClO_4$. The charge under the second voltammetry peak in the work of Schmidt and Wüthrich would be expected to produce only a small shift in their Δq *vs.* Γ curve by an amount not very much greater than the scatter of their points. The use of the acetic acid-acetate buffer by Schmidt and Wüthrich[55] also may have introduced differences because of complexing of the lead by the acetic acid,[60] as well as possible specific adsorption on the lead partially covered gold electrode.

According to our explanation, the charge under the second voltammetry peak is associated with a change in the effective charge of the adsorbed lead attending the phase transformation. As indicated in our paper, it is not possible to separate the faradaic charge and the nonfaradaic charge associated with the adsorption. With our explanation of the sharp voltammetry peak, the charge passed through the external circuit does not correspond directly to the change in charge of the adsorbed lead, but rather to the change in the partially compensating double layer charge. This can be seen from the following consideration. For the two-step sequence proposed in our paper under discussion (Eq. [8] and [9]), the charge through the external circuit Δq is the sum of the faradaic, Δq_f, and nonfaradaic, Δq_{nf}, components. Therefore

$$\Delta q_f = (2-y)\mathbf{F}n;\ \Delta q_{nf} = y\mathbf{F}n + \Delta q_{DL} \qquad [1a, b]$$

$$\Delta q = \Delta q_f + \Delta q_{nf} = 2\mathbf{F}n + \Delta q_{DL} \qquad [2]$$

where n is the surface concentration of specifically adsorbed lead and Δq_{DL} is the change in the charge in the remainder of the double layer. For the sharp peak, n is essentially constant and therefore the charge under this peak must correspond to a change in q_{DL}, *i.e.*, for

the cathodic peak, the loss of anions in the double layer which had been compensating some of the charge of the specifically adsorbed lead as the lead layer takes on metallic properties.

We disagree with Schmidt and Wüthrich's statement that the extraordinarily narrow voltammetry peak (as narrow as 5 mV in some of our work) can be easily explained on the basis of a more or less pronounced discontinuous decrease in the free energy of adsorption with increasing coverage. Even with a very nonideal surface with various sites of different standard free energies of adsorption, it is difficult to see how the coverage of a particular set of sites of a given standard free energy can go from a low to high value over such a narrow potential range without involving the concept of some type of phase transition as proposed in the work being discussed.

In their last comment, Schmidt and Wüthrich indicate that they did not find the Γ values independent of lead ion concentration at higher concentrations in their thin layer experiments. Unfortunately they do not indicate either the electrolyte or the concentration range examined. If the electrolyte was the acetic acid-acetate-perchlorate system (pH 4.7) with the lead ion concentration extending only up to $5 \times 10^{-3}M$, as used in their published work,[55] we would not expect them to observe leveling off of the adsorption isotherms. In $1M$ $HClO_4$, we found leveling off to occur only above $5 \times 10^{-4}M$ in $1M$ $HClO_4$. In their electrolyte, complexing of the lead ions by acetic acid would depress the Pb^{2+} ion activity and probably make it impossible to reach a sufficiently high Pb^{2+} ion activity to observe leveling off of the adsorption isotherm. Adsorption of electrolyte components such as acetic acid or acetate and complexing with metal cations may introduce substantial complications in the use of the twin-electrode thin layer technique of Schmidt and Wüthrich to study cation adsorption in view of the assumption involved in their method concerning all changes in bulk cation activity being caused by specific ionic adsorption.

The unusually large change of the reflectance of gold attending the specific adsorption of lead is caused almost entirely by the modification of the surface electronic properties of the gold. In the paper under discussion in the range of coverages where the reflectance changes are directly proportional to charge, the reflectance should be a direct indication of the lead ion surface concentration in the inner Helmholtz plane. Consequently, for specific adsorption of lead on gold, the reflectance method should be a reliable indication of the adsorption isotherm.

The Effects of Trace Amounts of Water on the Thermal Oxidation of Silicon in Oxygen

E. A. Irene

IBM Thomas J. Watson Research Center, Yorktown Heights, New York 10598

ABSTRACT

The significance of the addition of 25 ppm of H_2O to O_2 has been studied for the thermal oxidation of (100), (110), and (111) oriented silicon. With 25 ppm water addition to O_2 a sharp increase in the over-all rate of oxidation was observed for each orientation and experimental temperature (800°, 927°, and 996°C). From data analysis in terms of a linear-parabolic oxidation law, orientation effects were found for both the linear and parabolic rate constants and for both dry O_2 and H_2O added oxidations. The major effect of trace H_2O appears to be on the parabolic rate constants. The experimentally derived kinetic constants are interpreted in terms of surface geometry for the linear rate constants and in terms of the SiO_2 structure for the parabolic rate constants. The large kinetic effects observed with trace amounts of H_2O might be a cause for the disparity of literature results for dry thermal oxidation of silicon.

The thermal oxidation of silicon produces a silicon dioxide (SiO_2) passivation film with excellent electrical properties. However, the fabrication of advanced thin film electronic devices requires a knowledge of the parameters affecting thickness control and impurity content of the thin films. To describe SiO_2 film growth via thermal oxidation of silicon by oxygen, a linear-parabolic model is assumed. Numerous publications confirm the adherence of the SiO_2 growth kinetics to the linear-parabolic model [see for example Ref. (1-3)]. The qualitative effects of water and sodium on the oxidation kinetics are also known (4). However, considerable differences exist for the reported oxidation rate constants both for studies considering impurities and for so-called clean oxidation studies.

The purpose of this study is to consider the kinetic role of trace quantities of H_2O (20-30 ppm) in O_2 on the thermal oxidation of (111), (110), and (100) oriented single-crystal silicon.

Experimental Procedures

Sample preparation.—Chem-mechanically polished silicon wafers measuring 3.2 cm in diameter and 0.025 cm thick with (111), (110), and (100) orientations supplied from three different vendors were utilized for this study. Both n- and p-type Si wafers with resistivities ranging from 0.5 to 10 ohm-cm were used. For a given orientation and under identical oxidation conditions no systematic differences in oxidation rate were found for different type or resistivity silicon in the above resistivity range.

Prior to oxidation each experimental Si wafer was cleaned according to the following schedule: (*i*) deionized H_2O rinse until H_2O resistivity is 18 mohm-cm; (*ii*) basic peroxide rinse at 65°C with ultrasonic agitation ($NH_4OH:H_2O_2:H_2O$ = 1:1:5); (*iii*) repeat step 1; (*iv*) acidic peroxide rinse at 65°C with ultrasonic agitation ($HCl:H_2O_2:H_2O$ = 1:1:5); (*v*) repeat step 1; (*vi*) 48% HF dip for 10-15 sec; (*vii*) repeat step 1; (*viii*) blow dry in clean N_2.

Samples treated as described above were found to have an SiO_2 film of 10-12Å thickness. Prior to oxidation the cleaned Si wafers were placed horizontally on a fused silica paddle and inserted into the furnace in a clean N_2 ambient. It was found that the samples reached the experimental temperature in 7-10 min and were therefore preheated for 15 min to insure temperature stability. After this warm-up in N_2 the residual oxide was found to be 9-11Å. This experiment served to check the quality of the N_2 gas which was used for initial warm-up and final flush and to establish the initial oxide thickness (d_0) of 10Å to be used later for data analysis.

Oxidation furnace.—A three-zone, resistance heated furnace with a high purity alumina liner was used for this study. The oxidation chamber was a double wall, fused silica tube. Between the outer and inner walls high purity N_2 was constantly flowing. The oxidation tube was suspended concentric to the alumina liner by means of fused silica wool. All fused silica components were thoroughly degreased and bathed in a mixture of HNO_3, HF, and H_2O and thoroughly rinsed in deionized H_2O.

A level temperature zone of ±1°C for about 25 cm in length could be achieved under oxidation conditions. Typically, three silicon wafers were oxidized simultaneously. The wafer load was positioned in the center of the level zone. Temperature was continuously monitored by means of a Pt/Pt-10% Rh thermocouple encased in a fused silica well. The thermocouple well was fused to the bottom of the paddle which held the Si wafers. No positional dependence of the grown oxide thickness was found for oxidations performed in the center of the level temperature region of the oxidation furnace.

Key words: insulating films, orientation effects, rate constants, silicon oxidation, trace impurity.

Gas purity.—Both the nitrogen and oxygen used in this study were supplied from boil off of liquid sources and delivered to the furnace through cleaned, leak tight, stainless steel plumbing.

Dew points were measured for the various gases by means of a Panametrics Model 1000 hygrometer with remote sensors. Each sensor was provided with calibration and dew point conversion tables. The dew point of the nitrogen gas at room temperature and 1 atm pressure was found to be $-80°C$ which corresponds to 0.5 ppm H_2O. The hydrocarbon content was measured by gas chromatography. A heated Al_2O_3 column and flame ionization detector yielded a 0.5 ppm detectability limit based on standard gas mixtures. An average of 2 ppm of CH_4 was detected in N_2 gas. The purity of N_2 was checked for O_2 content by attempting to oxidize cleaned Si wafers at 1000°C. No oxide growth was detected in 2-3 hr runs with an N_2 flow of 2 liters/min.

The dew point of O_2 at room temperature was $-72°C$ which corresponds to about 2 ppm H_2O. Gas chromatography revealed the presence of CH_4 in the amount of about 17 ppm. The O_2 dew point at the oxidation furnace exit was found to be $-54°C$ or 20-30 ppm H_2O, and CH_4 was not detected. These observations show that the methane was being combusted to H_2O and CO_2 in the furnace. The analysis of N_2 at the furnace exit was the same as the inlet thereby demonstrating that the double wall reaction tube is effective against the diffusion of H_2O through the furnace walls. It was found that the CH_4 in the O_2 could be removed by precombusting the CH_4 in O_2 at 1000°C and cold trapping the formed H_2O at $-78°C$ prior to the oxidation furnace. By either using or not using the precombustor and cold trap, it was possible to study the oxidation of Si with less than 1 ppm H_2O and with about 25 ppm H_2O in O_2.

Film measurements.—All SiO_2 thickness measurements were made by ellipsometry. The wavelength of light used was 5461Å. Two zone data was used to determine Δ and ψ values precisely. The real part of the refractive index of Si was taken to be 4.085 (5). The imaginary part was taken to be -0.028 (6). From computer analysis of the ellipsometric data for thicker films (~1000Å) both the film thickness and refractive index could be obtained. The average value for the refractive index was 1.465 ± 0.006. This value was used to obtain the film thicknesses for thin films (less than ~400Å). The error associated with the thickness measurement is estimated to be less than $\pm 2\%$.

To determine the over-all quality of the SiO_2 films, capacitance-voltage (C-V) measurements were made on oxidized (100) silicon wafers. Evaporated aluminum dots were used as electrical contacts. The C-V measurements revealed an average oxide charge level of $<5 \times 10^{10}$ charges/cm^2. Bias temperature stressing ($\pm 10^6$ V/cm, 200°C for 15 min, and cooling under bias) revealed an average mobile positive charge level of 5×10^{10} charges/cm^2. Systematic trends in charge levels were not found for oxidations with and without 25 ppm H_2O; more extensive electrical evaluation is in progress.

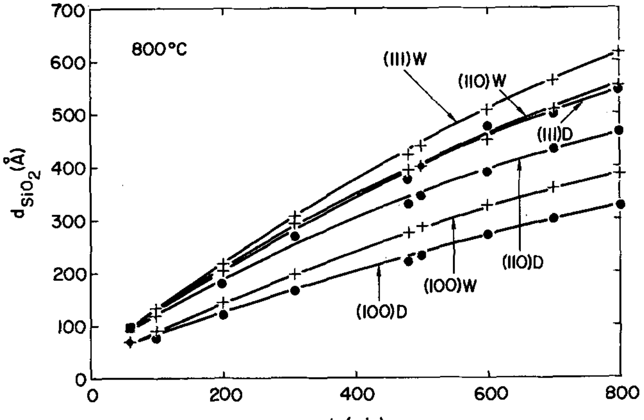
Experimental Results

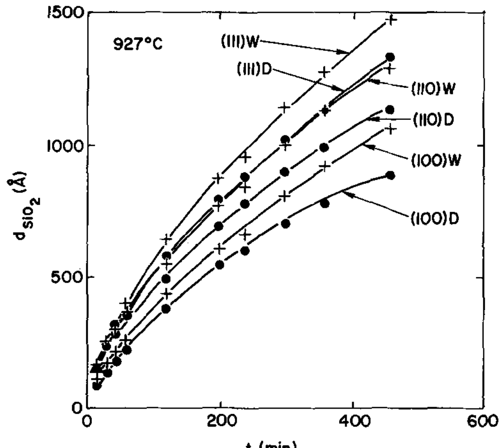
Data analysis.—Figure 1 contains plots of oxide thickness, d (Å), *vs.* oxidation time, t (min), at the three experimental temperatures, 800°, 927°, and 996°C for (111), (110), and (100) Si orientations for O_2 with (W) and without (D) 25 ppm H_2O. A total spread of 3% in thickness was found for the dry O_2 data and 7% for the 25 ppm H_2O in O_2 data.

Each d *vs.* t data set for a particular orientation, temperature, and H_2O content was fitted to a linear-parabolic equation of the form

$$t = A(d - d_o) + B(d - d_o)^2 \quad [1]$$

This equation was analyzed directly by linear least squares fit in terms of $t/d - d_o$ *vs.* $(d - d_o)$. The linear rate constant, k_{LIN}, is $1/A$ (Å/min) and the parabolic rate constant, k_{PAR}, is $1/B$ (Å^2/min). As previously mentioned d_o at $t = 0$ was found to be 10Å and this value was used throughout the data analysis.





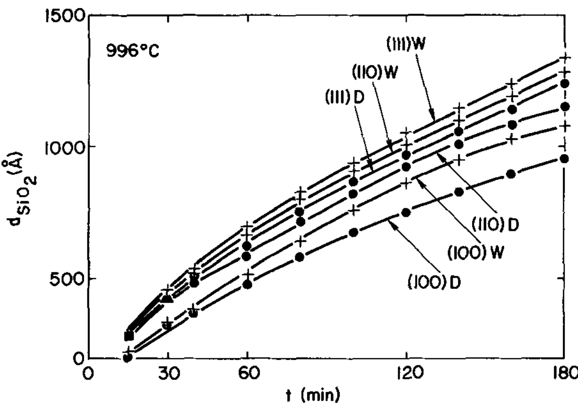


Fig. 1. SiO_2 thickness, d, *vs.* time, t, for (100), (110), and (111) orientations for both dry O_2 (D) and 25 ppm H_2O (W) in O_2 at temperature (a, top) 800°C, (b, center) 927°C, and (c, bottom) 996°C. For each curve the closed circles are for dry oxygen (<1 ppm H_2O); the crosses are for 25 ppm H_2O in oxygen. The symbols ✦, ▲, and ■ represent 2, 3, and 4 coincident points, respectively.

It was found that for the range of d and t of this study and for $d_o = 10$Å there is less than 1% difference between Eq. [1] and the more fundamentally based equation [see for example (1) and (5)]

$$t = A(d - d_o) + B(d^2 - d_o^2) \quad [2]$$

The linearization of Eq. [1] provides a numerical method to determine the extent of the logarithmic oxidation regime (1) which occurs at small oxide thicknesses. To determine the extent of the logarithmic

regime the following procedure was employed. First, for each complete data set of d vs. t from Fig. 1, a linear least squares fit in terms of $t/d - d_o$ vs. $(d - d_o)$ was performed. Then for each d-t data set small thicknesses were sequentially dropped from the least squares analysis starting from the smallest d-t value. For each linear least squares fit, the relative quality of the fit was determined from calculated standard deviation values for the fit of the data to the rate law and for the slope and intercept. The deviation values corresponding to the data fit are a relative measure of the regression line compared to the spread in the data. The standard deviations computed for the k_{LIN} and k_{PAR} values show their range. It was found that when small thickness values were sequentially eliminated from the least squares analysis the quality of the fit improved by a substantial amount ($\sim$ a factor of 2) for the first few (2 or 3) values eliminated and then leveled off. The values of k_{LIN} and k_{PAR} reported in Table I reflect the fit where small values of thickness were dropped until the quality of the fit remained constant. In no case were more than three small thickness data points dropped from the analysis. The logarithmic regime determined in this manner shifted to greater thicknesses with temperature, and values are given in Table II.

The k_{LIN} and k_{PAR} values from Table I have been fitted to an Arrhenius relation of the form

$$k = k_o e^{-E_a/RT} \quad [3]$$

and the resulting values of the preexponential factor, k_o, and activational energy, E_a, are listed in Table III.

Discussion

From the data presented there are several trends which relate to the mechanism for the oxidation of silicon in oxygen. The more pronounced effects observed are:

1. For each orientation and at each experimental temperature the over-all rate of oxidation is increased with the addition of $\sim$25 ppm H_2O to oxygen.

2. The parabolic mode for silicon oxidations is thought to be due to a purely diffusion limited process (1). However, it was found in the present study that k_{PAR} values varied with Si orientation for both dry and wet oxidations at each experimental temperature.

The first effect suggests that in addition to the role of H_2O as a silicon oxidant at higher concentrations, there is a catalytic and structural effect due to trace amounts of H_2O. The catalytic effect is primarily displayed in the linear mode of oxidation while the structural effects are related to the increase of the parabolic kinetic constants with trace amounts of H_2O. The second effect, the variation of k_{PAR} with silicon orientation, appears to be related to the observation that surface states and/or positive interface charge near the Si-SiO_2 interface vary in the same direction with orientation as k_{PAR} values.

These observations and suggestions are treated in the light of literature results.

Linear kinetics.—It is seen from Table I that there is a systematic trend of the linear rate constants with Si orientation at each experimental temperature for both dry and wet oxidations. In terms of the Si orientation, this trend is summarized as follows

$$(110) \geqq (111) > (100)$$

Ligenza (7) has shown that the number of Si-Si bonds is important for the consideration of the linear oxidation of Si. According to Ligenza, the number of Si-Si bonds per unit area relative to the (110) plane is as follows

$$(110) : (111) : (100) = 1 : 0.817 : 0.707$$

The k_{LIN} values of Table I agree qualitatively with the above ratios thereby confirming the importance of the silicon surface structure for linear oxidation kinetics.

The linear activation energies in Table III agree closely with a reported value for the Si-Si bond energy of 1.8 eV (8). For the (100) and (110) Si orientations the linear E_a values decrease with the addition of trace amounts of H_2O to the O_2. Coincident with this barrier lowering due to 25 ppm H_2O there is a rather sharp decrease in the linear preexponential factors. The total effect is a reduced linear rate constant for the (100) and (110) orientations at 927° and 996°C. These effects suggest a catalytic role for trace H_2O in O_2. At 800°C the trend in k_{LIN} reverses for the (100) and (110) orientations and for the (111) orientation the trends in k_{LIN}, E_a, and $k_{O,LIN}$ with trace H_2O are reversed as compared to the (100) and (110) orientations. An explanation of these results is not apparent within the present study but suggests that a series of competitive reactions are operative and each depends on orientation, temperature, and H_2O.

Parabolic kinetics.—The k_{PAR} values in Table I reveal a distinct trend with orientation for both dry and wet oxidations. This trend in k_{PAR} with Si orientation is as follows

$$(111) > (110) \geqq (100)$$

This order parallels electrical measurements (9, 10) which show the amount of positive interface charge and/or surface states for the (111), (110), and (100) Si orientations. The results of Deal and Grove (1) relative to the O_2 oxidation of Si demonstrate that the oxidant species is molecular. From the absence of paramagnetism in thermal oxides (14) and in light of the effects of electrical fields on the oxidation of Si (11,

12), an oxidant species is probably O_2^{--}. Therefore, in view of the above literature results and the observed parabolic nature of the oxidation data, a field enhanced diffusion mechanism for transport of oxidant through the SiO_2 is proposed. Interestingly, the studies (9, 10) which show the variation of positive charge and/or surface states with Si orientation also show that the region of charge is near the Si-SiO_2 interface and that the charge is immobile relative to ionic alkali impurities. If the region of charge is due to unsatisfied Si bonds, then the oxidant flux and oxidation reaction would restrict the charged region to near the origin of the charges (*i.e.*, the Si surface).

To explain the increase of k_{PAR} values with 25 ppm H_2O addition to O_2, a mechanism based on a structural alteration of SiO_2 due to H_2O is proposed. It is known that H_2O attacks the bridging oxygen atoms of the SiO_2 network (13, 14). The effect is a loosening of the SiO_2 network thereby enhancing the diffusion of O_2 (13). The $k_{PAR,D}$ and $k_{PAR,W}$ values of Table I show this effect of 25 ppm H_2O for the orientations and temperatures studied. Further insight is gained by considering the temperature dependence of the percentage change of the $k_{PAR,W}$ and $k_{PAR,D}$ values in Table IV. It is seen that for the (110) and (111) orientations the percentage change between $k_{PAR,W}$ and $k_{PAR,D}$ values is smaller at higher temperatures. According to Lee (15) the metastable hydroxyl content of SiO_2 is a maximum at 800°C and decreases sharply with increasing temperature to 1000°C. With respect to this percentage change, the (100) orientation behaves oppositely. In addition, $k_{O,PAR}$ and E_a values for the (110) and (111) orientations decrease with trace addition of H_2O, while again the opposite occurs for the (100) orientation. These differences in oxide growth behavior for different orientations suggest generic differences in the SiO_2 film networks. For bulk amorphous materials generic differences are reported to be closely associated with the exact method of preparation (16).

Summary

The significance of trace amounts of H_2O in O_2 on the over-all rate of oxidation of Si is clearly seen in Fig. 1. The SiO_2 thickness *vs.* time data have been found to fit a linear-parabolic equation if a region of rapid SiO_2 growth is eliminated. The linear-parabolic model allows interpretation in terms of interface and diffusion kinetics. Within the linear-parabolic model and the specific equation fitted the largest effect of trace H_2O appears to be related to the parabolic rate constants. The data analysis suggests a model based on Si surface geometry, interface charge, and what is known relative to the nature of H_2O in bulk SiO_2.

Table IV. Percentage change in k_{PAR} values with the addition of $\sim$ 25 ppm H_2O to O_2

Orientation	$[k_{PAR,W} - K_{PAR,D})/k_{PAR,D}] \cdot 100$		
	800°C	927°C	996°C

Identification of AgCl as a Surface Contaminant on Hybrid Microcircuit Capacitors Using Ion Microprobe Techniques

J. W. Guthrie

Sandia Laboratories, Albuquerque, New Mexico 87115

ABSTRACT

An ion microprobe mass analyzer (IMMA) was used for the identification analysis of a micron-sized surface contaminant on hybrid microcircuit barium titanate capacitors with silver frit terminations. A 18.5 keV O_2^+ sputtering ion beam was used to obtain characteristic positive and negative sputtered ion species for mass spectra, scanning ion micrographs, and depth profiles from clean and contaminated capacitors. The mass spectra from the contaminated capacitors contained significant peaks for $AgOH^+$, $BaCl^+$, Ag_2^+, Ag_2OH^+, Ag_2Cl^+, and Cl^- sputtered ion species. On the clean capacitors these species were detected only as low intensity peaks or not at all. Silver chloride was identified as a major contaminant by comparing AgCl calibration mass spectra with the mass spectra obtained from the clean and the contaminated capacitors. The calibration mass spectra were obtained by sputtering and analyzing AgCl deposited on Au, Mo, and Kovar substrates and AgCl deposited on the surface of a clean capacitor.

This paper describes the use of an ion microprobe mass analyzer (IMMA) (1-3) to identify AgCl as a major surface contaminant on silver frit terminations on hybrid microcircuit barium titanate capacitors. Micron-sized contamination was first revealed by scanning electron microscopy techniques. The primary problem concerned degradation of ultrasonically welded bond joints between aluminum wires (~ 75 μm diameter) and the silver frit terminations on capacitors from certain production batches. It is not the purpose of this paper to discuss possible sources and/or causes of the contamination or measures taken to remove or prevent the contamination problem.

Experimental

Figure 1 shows a 1.9 × 1.2 × 0.8 mm barium titanate capacitor and the silver frit termination areas. Besides silver, the frit contains bismuth oxide and a lead borosilicate glass. Figure 2 shows scanning electron micrographs from frit areas on clean and contaminated capacitors. The particles identified as contaminants are clearly visible.

Sputtered ion species for mass analysis were obtained by rastering a small diameter (< 5 μm) probe of 18.5 keV mass-analyzed O_2^+ ions of ~ 2 × 10^{-9}A over selected rectangular sample areas (viewed optically during analysis) of ~ 340 × 275 μm in size. The estimated sputtering rate for these conditions was < 0.1 Å/sec. Both positive and negative sputtered sample ions were detected and recorded in mass spectra. The vacuum in the ion microprobe was ~ 4 × 10^{-7} Torr during the sputtering process.

Results and Discussion

Figures 3 and 4 show the spectra obtained by mass analyzing the sputtered negative ions from the frit area of a clean and a contaminated capacitor. The more intense signals for chloride ions from the contaminated sample were an indication (4) that a chlorine compound was involved.

Figures 5 and 6 show the spectra obtained by mass analyzing the sputtered positive ions. The time for each mass scan was about 10 min, during which it is estimated that less than 100Å of sample material were removed. Figure 6 (same intensity scale as Fig. 5) shows an increase in intensity for all the species observed in Fig. 5, but more important are the high-intensity silver and barium species detected for the contaminated

sample. These species were detected at low intensities (Ag^+) or not at all ($AgOH^+$, $AgCl^+$, $BaCl^+$, Ag_2^+, Ag_2OH^+, and Ag_2Cl^+) in the spectrum from the clean sample. The $BaCl^+$, $AgCl^+$, and Ag_2Cl^+ present further evidence that the contamination is a result of some reaction between a chlorine-containing substance and the capacitor material as opposed to an added contamination (*e.g.*, barium chloride and silver chloride particulate matter). Because of the greater intensity and number of the silver-related sputtered species compared to the barium-related species, the identification effort was concentrated on silver compounds (actually silver chloride). By using isotopic abundance values for the two silver and the two chlorine isotopes,

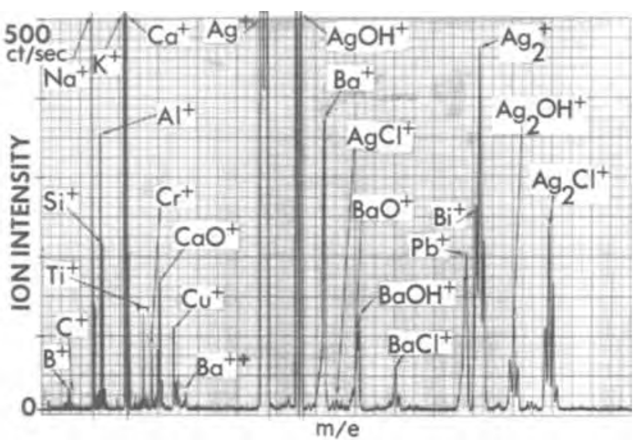

Fig. 6. Sputtered positive ion spectrum, contaminated capacitor

a near perfect match was obtained for the calculated relative intensities of the four possible Ag_2Cl^+ species and the four Ag_2Cl^+ peaks recorded in Fig. 6. This result implies a correct assignment of Ag_2Cl^+ for these peaks.

Figure 7 shows a depth profile and a scanning ion micrograph using the most intense peak (combination of $^{107}Ag^{107}Ag^{37}Cl^+$ and $^{107}Ag^{109}Ag^{35}Cl^+$) in the Ag_2Cl^+ spectrum. The depth profile was obtained by recording the intensity of the selected mass analyzed sputtered ion species as a function of time, thus depth. The scanning ion micrograph (3) was made by using the detected intensity of the selected Ag_2Cl^+ sputtered ion species to modulate the intensity of a cathode-ray tube (CRT) whose electron beam was rastered in synchronism with the rastered ion probe sputtering beam, thus producing a two-dimensional distribution map for the sample species responsible for the Ag_2Cl^+ sputtered species. The micrograph was made by photographing the CRT screen. The lateral resolution is limited by the size of the sputtered beam, which in this case was < 5 μm in diameter. The sequence of events for Fig. 7 were as follows: First, after selecting a raster size of 130×110 μm, the depth profile shown was made for about 750 sec in a previously unsputtered area. Second, immediately thereafter the raster size was increased to 260×220 μm and the raster conditions changed from 30 rasters/sec at 500 lines/raster to 1 raster/10 sec at 250 lines/raster (conditions for acceptable micrographs) which then allowed the area sputtered for the depth profile to be compared to the surrounding sample area using the contrast resulting from the intensity of the selected sputtered ion species. As seen in Fig. 7, and as expected, the micrograph shows a signal (Ag_2Cl^+ yielding material) de-

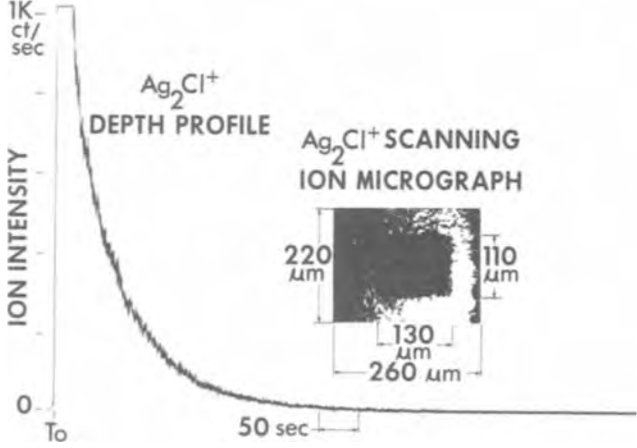

Fig. 7. Ag_2Cl^+ depth profile and scanning ion micrograph

pletion in the area used to make the depth profile. However, for the sputtering time used for the depth profile (750 sec) and an estimated sputtering rate range of 1-10 Å/sec it is possible that a depth less than the contamination particle size (~ 1-10 μm) was sputtered away. An attempt was made to locate the area of sputtering with a scanning electron microscope (SEM) to determine the degree of particle removal. The sputtered area could not be located, due in part to the original surface roughness and to the lack of contrast in the SEM (less than that provided by the scanning ion micrograph), and also due perhaps to incomplete removal of contamination particles.

Identification of the contaminant as silver chloride was verified by sputter analyzing deposits of AgCl on various substrates. Several substrates were chosen to avoid possible interferences from substrate ion species with the silver species spectra and to observe any unique characteristics. The deposits were prepared by evaporation of ~ 0.05 mliter of a solution of AgCl (5 mg/mliter) in NH_4OH. Figure 8 shows the positive sputtered ion spectrum from AgCl deposited on a Kovar substrate. The same sputtering conditions used for previous mass scans were duplicated. Besides the expected surface contaminant indicators (Na^+, Al^+, K^+, and Ca^+) and Kovar components (Fe^+, Co^+, and Ni^+) the silver species which were detected on the contaminated capacitor are evident, even though the relative intensities are different. Figure 9 shows the spectrum from AgCl deposited on a gold substrate, which was not clean as evidenced by several calcium sputtered ion species (Ca^+, CaO^+, $CaOH^+$, and $CaCl^+$). Again the silver species of interest are detected. $AuOH^+$ has the same nominal mass as $^{107}Ag^{107}Ag^+$ and thus interferes with the Ag_2^+ spectrum. Figure 10 shows the spectrum from the AgCl deposited on a molybdenum substrate. Here the AgCl deposit formed in a molybdenum oxide matrix (seen optically) apparently as a result of the solubility of surface MoO_3 in NH_4OH. The presence of a molybdenum oxide is confirmed by the presence of MoO^+ in the spectrum. Again the silver species of interest are evident. Note the increased intensities of the $AgOH^+$ and Ag_2OH^+ species, due in part to the oxide matrix. In each case the Ag_2Cl^+ species were more intense than the $AgCl^+$ species, which was the same as observed in the spectrum from the contaminated capacitor.

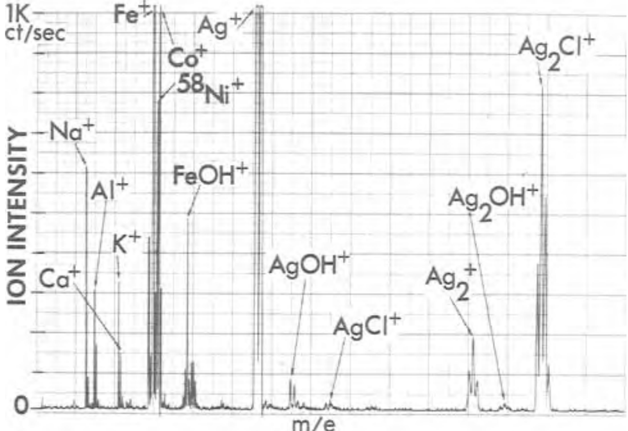

Fig. 8. Sputtered positive ion spectrum of AgCl deposited on Kovar.

There was a question about the relationship between the oxygen beam used for sputtering and the observed silver- and oxygen-containing sputtered species $AgOH^+$ and Ag_2OH^+. That is, was the O_2^+ sputtering beam "manufacturing" these species? Some evidence was obtained from the spectra taken from a spot of silver paint (Fansteel, Inc. Silpaint, 68% silver, thermosetting) used to mount ion microprobe samples. The spectrum indicated only Ag^+ ions, even at depths where the oxygen implanted by the sputtering ion beam was encountered at its maximum concentration (5-7). Therefore, the observed species in question ($AgOH^+$ and Ag_2OH^+) must be a result of the silver compounds on the sample or an enhancement (3) due to the matrix as in the previously discussed molybdenum oxide case. Because the material on the calibration samples (and the contaminated capacitors) probably contains other materials besides AgCl, the relationship between the $AgOH^+$ and Ag_2OH^+ species and a pure AgCl deposit is not known from the experiments made. The use of a N_2^+ beam for sputtering might have helped clarify the results obtained (8), but the N_2^+ beam was not conveniently available during the experiments.

Another possible test with the solution of AgCl in NH_4OH was, of course, to use the silver frit area of a clean capacitor as a substrate. Figure 11 shows the spectrum from the AgCl deposited on a clean capacitor. Again the silver species of interest are detected, but again not with exactly the same relative intensities as obtained from the contaminated capacitor. No attempts were made to obtain negative sputtered ion spectra for the AgCl deposits. Table I lists relative intensities of the silver species of interest normalized to the Ag_2Cl^+ species. The data in Table I were not taken from the figures used in this paper, but instead were taken from spectra where the peak height maxima were recorded by proper selection of counting rate attenuators.

Conclusions

Silver chloride was found to be a major contaminant on the silver frit areas of contaminated barium titanate

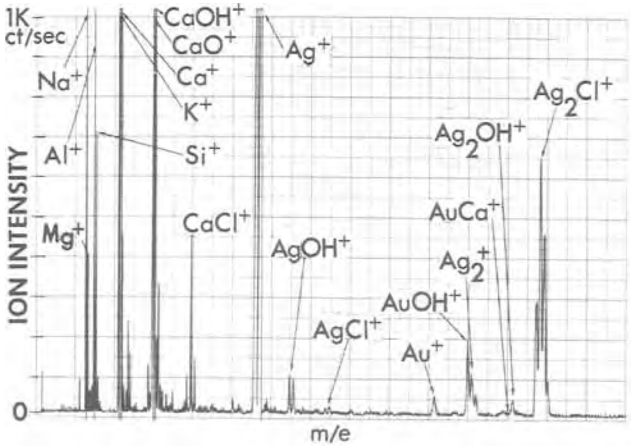

Fig. 9. Sputtered positive ion spectrum of AgCl deposited on gold.

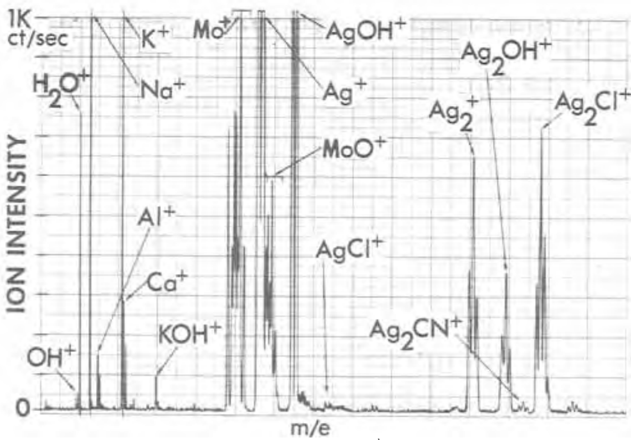

Fig. 10. Sputtered positive ion spectrum of AgCl deposited on molybdenum.

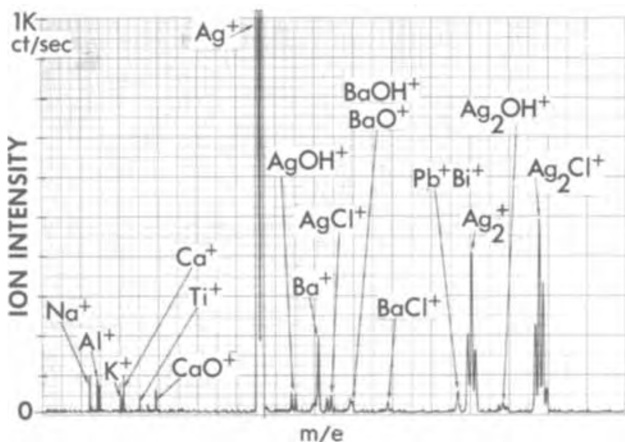

Fig. 11. Sputtered positive ion spectrum of AgCl deposited on a clean capacitor.

capacitors examined with the ion microprobe. Barium chloride was also identified as a contaminant. The $AgOH^+$ and Ag_2OH^+ species indicate the possible presence of other silver compound contaminants. Comparisons of mass spectra from contaminated capacitors with mass spectra from AgCl deposited on various substrates definitely identified the contaminant as one containing AgCl. It was determined (9) after the ion microprobe analysis that adequate bonding of aluminum wires to the silver frit terminations could be obtained after ultrasonically cleaning the capacitor (with frits) in a 50% NH_4OH-50% H_2O solution followed by an 800°C firing for 30 min in 0.2 Torr of argon. This process removes the contamination particles (SEM) and chlorine (Auger analysis), but the source of the particles or the mechanism of their formation remains a problem.

Table I. Relative intensities of sputtered positive silver ion species

	AgCl deposited on				
	Kovar	Au	Mo	Clean capacitor	Contaminated capacitor
Ag^+	8	6	9	34	Max of peak not recorded
$AgOH^+$	0.1	0.2	4	0.1	0.9
Ag_2^+	0.2	0.3	0.5	0.7	1.5
Ag_2OH^+	0.02	0.02	0.2	0.1	0.7
Ag_2Cl^+	1.0	1.0	1.0	1.0	1.0

Poly(Styrene Sulfone)—A Sensitive Ion-Millable Positive Electron Beam Resist

M. J. Bowden and L. F. Thompson

Bell Laboratories, Murray Hill, New Jersey 07974

ABSTRACT

Poly(styrene sulfone) is a 2:1 copolymer of styrene to sulfur dioxide which degrades under high energy irradiation. It has a sensitivity of 1×10^{-5} coulomb cm^{-2} when exposed to 5 kV electrons. The resist is thermally stable to 250°C and is an excellent ion milling mask with a milling rate of 0.5 nm sec^{-1}. It also serves as an etching mask for buffered HF. Polystyrene sulfone does not vapor develop.

Following pattern delineation in a polymer resist film, it is necessary to reproduce the developed pattern in an insulating or conducting thin film. This is frequently done by wet-etching processes, *e.g.*, buffered HF to etch SiO_2, which result in marked undercutting of the resist with attendant loss in resolution. This problem can be eliminated by ion milling which has the additional advantage of being a dry process. Recently developed techniques for producing fine gratings (spacing ~ 200 nm) demand ion milling procedures in order to realize such high resolution.

Key words: electron resist, polysulfones, degradation.

It has been found that positive electron resists, in particular, the poly(olefin sulfones), do not behave as good ion milling masks, *i.e.*, the rate of removal of the polymer film is too high relative to the rate of removal of exposed substrate (1). On the contrary, negative resists do not suffer this limitation. In the case of the poly(olefin sulfones) it is known that chain scission is accompanied by extensive depropagation (2, 3) of the radical chain end; hence when chain scissions are in-

duced during bombardment by the high-energy ion beam the rate of removal of the resist film will be greatly enhanced. Materials which tend to depolymerize will therefore not behave as good ion milling masks. This applies to poly(methyl methacrylate) (PMMA) which, apart from the poly(olefin sulfones), is the only significant positive resist. The temperature of the substrate can rise quite significantly during the ion milling process and, at elevated temperature, PMMA depolymerizes readily (4). The rate of ion milling of PMMA was found to be 1.2 nm sec^{-1} and therefore a substantial resist thickness is required, *e.g.*, 0.5μ film for 0.3μ Au substrate (5), for successful operation. The process also requires effective heat conduction to maintain the substrate below 100°C.

Unlike the poly(olefin sulfones) which are strictly alternating copolymers of SO_2 with the respective olefin, poly(styrene sulfone) may be synthesized with compositions ranging from a 1:1 copolymer through to homopolystyrene. Under bulk polymerization conditions in excess SO_2, the mole ratio of styrene to SO_2 is reported to be 2:1 (6).

The structure of this polysulfone has been shown to be (7)

$$[CH_2—CH(C_6H_5)—CH_2—CH(C_6H_5)—SO_2]_n$$

Hence cleavage of the C-S bond will result in a styryl radical with another styrene molecule in the penultimate position. Such a radical should therefore behave as a polystyrene radical and should not tend to depropagate under ion milling conditions, *i.e.*, poly(styrene sulfone) should have a low ion milling rate.

Experimental

Preparation.—Poly(styrene sulfone) (PSS) was prepared by copolymerization of styrene with sulfur dioxide. Thirty milliliters of freshly distilled styrene (Eastman Kodak) and 0.1g azobisisobutyronitrile were mixed together and the solution degassed on a high-vacuum line. Fifty milliliters of sulfur dioxide (Matheson) were condensed in the reaction flask which was then sealed under vacuum. Polymerization was carried out in a constant temperature bath at 50°C for 48 hr. The polymer was purified by precipitation from dioxane solution (twice) into methanol and dried at 40°C under vacuum for 48 hr.

Microanalysis yielded the following results corresponding to a 2/1 copolymer of styrene and sulfur dioxide; found: C = 69.7%, H = 6.0%, S = 12.2%; calculated: C = 70.5%, H = 5.9%, S = 11.8%.

The molecular weight determined by dilute solution viscometry was 2.7×10^5. Viscosity parameters are listed elsewhere (8).

Exposure and development.—The polymer was dissolved in methoxy ethyl acetate (Kodak photoresist thinner) and films ~300 nm thick were spun on SiO_2/Si and Au/Cr/Si substrates using techniques described previously (3). Prior to exposure the films were baked at 200°C in vacuo for 30 min.

The films were exposed using a programmed electron beam from a Cambridge Mark II scanning electron microscope equipped with a 1500 line flying-spot scanner.

Sensitivity was determined in the manner previously described (3). The exposed films were developed using a 60% dioxane/40% isopropanol mixture and postbaked at 200°C for 30 min in vacuo. The substrates were etched in buffered HF.

Ion milling rates were determined by exposing a 300 nm film to the ion beam for different times and measuring the depth of remaining film by first gilding the sample and then measuring the film depth using polarization interferometry. An average rate of 0.5 nm sec^{-1} was obtained.

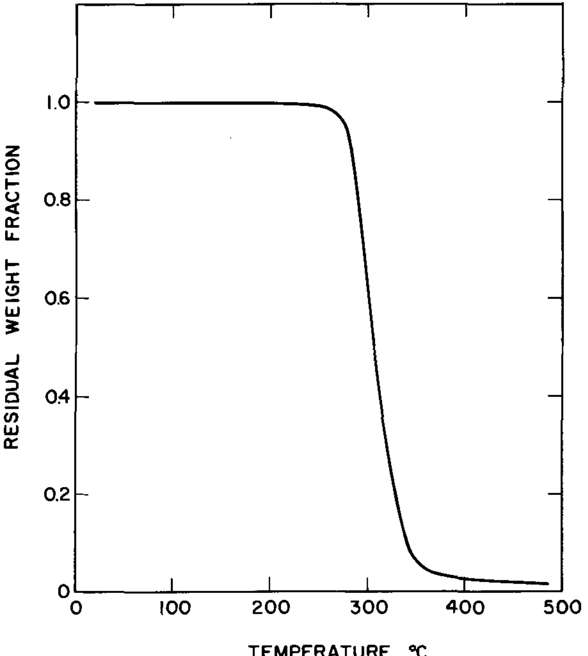

Fig. 1. TGA thermogram of PSS; atmosphere, N_2; heating rate, 5°C/min.

Results and Discussion

Thermal stability.—A TGA thermogram of PSS is shown in Fig. 1. The analysis was carried out in N_2 at 5° min^{-1} heating rate. The temperature at which degradation commences is over 100°C greater than for the corresponding poly(olefin sulfones) which makes the resist suitable in applications where thermal stability is required. An identical thermogram was obtained when the TGA run was conducted in an oxygen atmosphere. The glass transition temperature, T_g, was determined by DSC and was found to lie in the region 180°-200°C. Thus, 200°C appears to be the best temperature for pre- and postbaking since this is above the T_g (baking above the T_g is considered necessary to relieve strain in the film) yet well below the decomposition temperature.

Sensitivity.—PSS underwent rapid chain scission when exposed to a beam of high-energy electrons. Molecular weight distributions well removed from the initial distribution could be produced at doses of 1×10^5 coulomb cm^{-2}. The resist did not vapor develop, *i.e.*, there was no apparent loss of material during irradiation. This value of sensitivity is an order of magnitude less than that shown by the poly(olefin sulfones) and undoubtedly stems from the presence of the benzene group in the side chain. It is well known that aromatic compounds show relatively high resistance to radiation (9), *e.g.*, homopolystyrene is one of the most radiation resistant of long chain polymers; although it crosslinks, the energy required for crosslinking is nearly 100 times greater than in most linear polymers such as polyethylene. There is evidence to show that this "protective effect" of the benzene ring can extend to neighboring groups in the chain, *e.g.*, Alexander and Charlesby (10) demonstrated that for copolymers of styrene and isobutylene, the extent of degradation which the isobutylene units in the polymer suffer under irradiation is greatly reduced by the presence of neighboring styrene units.

PSS showed development characteristics similar to those of the poly(olefin sulfones), in that gamma (contrast) was extremely sharp. The 60% dioxane/40% isopropanol developing solution did not attack the unexposed parts of the PSS film and the sensitivity of 1×10^{-5} coulomb cm^{-2} may be compared with 5×10^{-5} coulomb cm^{-2} for PMMA under similar developing conditions. As is well known, the sensitivity of the lat-

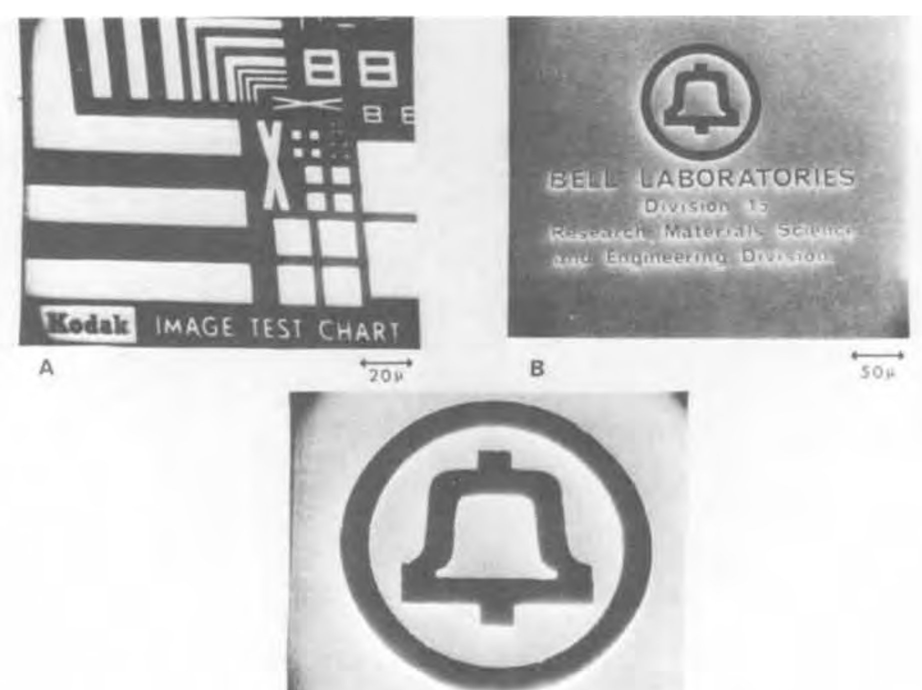

Fig. 2. Test patterns chemically etched in SiO_2 through PSS mask.

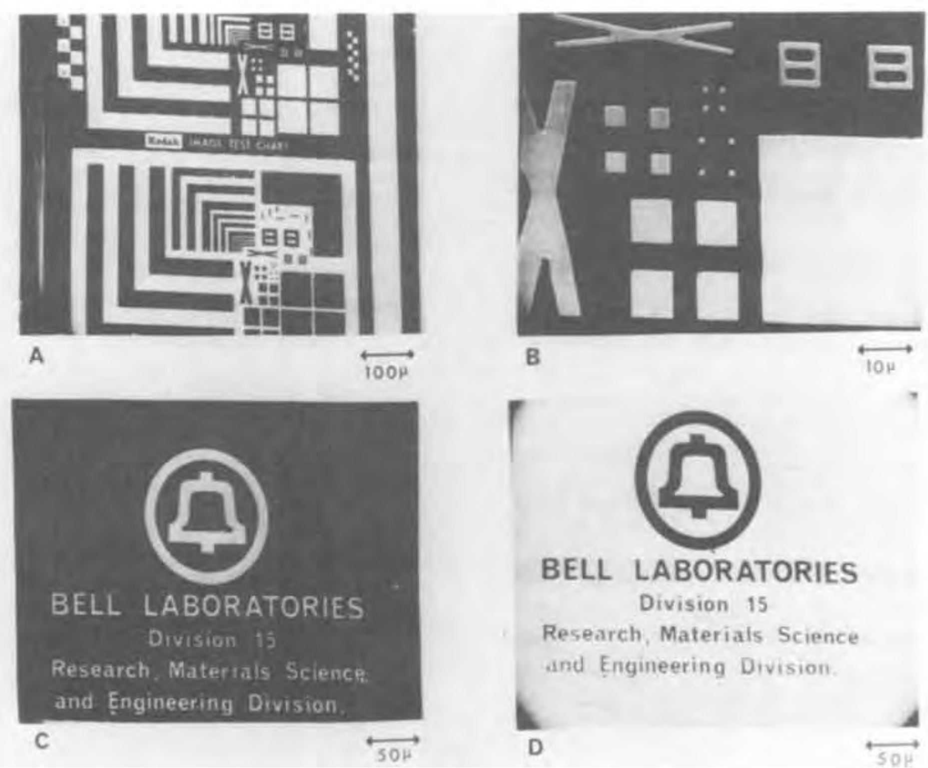

Fig. 3. Test patterns ion milled in Au through PSS mask.

ter may be enhanced by "force-developing" (using developing solutions which also attack the unexposed parts of the film but at a slower rate compared with the exposed areas) (11). Similarly, PSS may be "force-developed" resulting in sensitivities into the 10^{-6} range.

Wet-etching characteristics.—PSS was an excellent etching mask against buffered HF (for etching SiO_2). Figure 2 shows some typical patterns written using the flying spot scanner. The patterns are etched in SiO_2. These patterns were all written at magnification $\gtrsim$200. The reason for this is due to the high contrast of this resist which usually resulted in the production of gratings when writing patterns at a magnification less than 200.

Ion milling characteristics.—PSS was an excellent ion milling mask. The ion milling rate (0.5 nm sec^{-1}) is low and may be compared with rates for typical negative resists; *e.g.*, poly(glycidyl methacrylate co ethyl acrylate), a sensitive high contrast negative resist, has an ion milling rate of 0.4-0.5 nm sec^{-1}. Figure 3 shows some test patterns ion milled in Au. It was

found that the resist actually crosslinked during the ion milling process, presumably due to crosslinking of the polystyrene units in the chain. We therefore envisage the initial reaction as one of cleavage of the C-S bonds with the probable release of SO_2. Since polystyrene crosslinks under ionizing radiation, the residual polystyrene units in the chain will crosslink at high enough dose. Thus even during initial exposure to high-energy electrons, we would predict that PSS would behave as a negative resist given a high enough dose. Undoubtedly the crosslinking reaction which takes place during ion milling serves to reduce the ion milling rate.

As a result of crosslinking, the removal of residual polymer requires the use of an oxidizing ambient similar to that required for negative resists. This was conveniently accomplished using a dichromate-sulfuric acid cleaning solution.

Conclusions

Poly(styrene sulfone) has been shown to be a sensitive positive resist suitable for ion milling application. It is an order of magnitude less sensitive than the poly(olefin sulfones); this essentially limits the former to specialty applications where speed is not important. It is superior to other ion millable positive resists, notably PMMA, with respect to sensitivity and ion milling rate.

Acknowledgments

The authors would like to thank E. G. Spencer and P. V. Lenzo for ion milling PSS and PMMA samples. They also thank M. Y. Hellman for the viscosity measurement on PSS.

A Survey of a Group of Phosphors, Based on Hexagonal Aluminate and Gallate Host Lattices

J. M. P. J. Verstegen

N. V. Philips' Gloeilampenfabrieken, Light Division, Eindhoven, The Netherlands

ABSTRACT

A group of photoluminescent materials, which may have great influence on future fluorescent lamp development, is surveyed. The materials are based on hexagonal aluminates and gallates which are structurally related to the magnetoplumbites and β-alumina. When activated with Mn^{2+}, Eu^{2+}, Tl^{+}, Ce^{3+}, and Tb^{3+}, or combinations of these ions, they are phosphors, some of them having a high efficiency and good temperature dependence.

Crystallography of the Host Lattices

The cubic spinel $MgAl_2O_4$ has a gallate and a ferrite counterpart: $MgGa_2O_4$ and $MgFe_2O_4$. Structurally related are the mineral magnetoplumbite, $PbFe_{12}O_{19}$, and the ferrite, $BaFe_{12}O_{19}$, both hexagonal with the space group $P6_3/mmc$. They consist of spinel-like blocks, separated by intermediate layers of deviating structure, containing the large cation. The spinel-like blocks in the magnetoplumbites offer, apart from the tetrahedral and octahedral sites, also pentahedral sites to the Fe^{3+} ion. The aluminate counterparts of magnetoplumbite are $BaAl_{12}O_{19}$, $SrAl_{12}O_{19}$, and $CaAl_{12}O_{19}$. The intermediate layer may also contain large trivalent cations. We reported $LaMgAl_{11}O_{19}$ and $CeMgAl_{11}O_{19}$ to be isomorphous with $SrAl_{12}O_{19}$ (1) and recently described a number of isostructural gallates, such as $LaMgGa_{11}O_{19}$ and $SrGa_{12}O_{19}$ (2). The same analogy between aluminates and gallates as in magnetoplumbites was found in the closely related β-alumina structure. Lattice parameters of a number of new gallates are summarized in Table I.

Key words: new lamp phosphors, aluminate and gallate host lattices, hexagonal aluminates, rare earth-activated aluminates.

A large number of hexagonal ferrites has been described in the literature (3-5). Their structures are magnetoplumbite-like, but they differ in the arrangement of spinel blocks and intermediate layers. Their lattice parameter a, 5.8Å, is basically that of magneto-

* Magnetoplumbite.
** β-alumina.

plumbite, but their c parameter (22-23Å in magnetoplumbite) may reach values up to 1600Å (6). Some of the simpler compounds are designated by letters: W = $BaFe_2^{II}Fe_{16}^{III}O_{27}$, Y = $Ba_2Fe_2^{II}Fe_{12}^{III}O_{22}$, X = $Ba_2Fe_2^{II}Fe_{28}^{III}O_{46}$, and Z = $Ba_3Fe_2^{II}Fe_{24}^{III}O_{41}$ (3). The existence of Al and Ga analogues of $BaFe_{12}O_{19}$, suggested that also W, Y, X, and Z each had gallate and aluminate counterparts. So we tried to prepare the compounds W, Y, X, and Z, using MgO instead of FeO and Al_2O_3 or Ga_2O_3 instead of Fe_2O_3. X-ray diffraction showed that the phases obtained were hexagonal. No indications were found for the presence of phases alalogous to the corresponding hexagonal ferrites. Apparently large quantities of $MgAl_2O_4$ can be taken up by the magnetoplumbite. As is shown below, the introduction of Mg^{2+} ions strongly influences the Eu^{2+} luminescence.

Experimental

A number of experimental techniques was developed to synthesize the phosphors. In many of them F^- was used to decrease the reaction temperature and to stimulate grain growth.

A phosphor of the composition $(Ba_{0.86}Eu_{0.14})$-$Mg_2Al_{16}O_{27}$ was obtained by firing an intimate mixture of $BaCO_3$, Eu_2O_3, MgF_2, and Al_2O_3 first 2 hr at 1200°C in a stream of N_2 with 2% H_2 and afterward several times at 1200°C in a stream of N_2, H_2, and H_2O, in order to remove the fluoride. Only part of the magnesium may be added as a fluoride and also AlF_3 may be used, depending on the grain size required.

$Ce_{0.67}Tb_{0.33}MgAl_{11}O_{19}$ can be prepared by various methods: CeO_2, Tb_4O_7, MgO, and Al_2O_3 are ball-milled together in water for 4-6 hr. The wet oxide mixture is dried, fired twice for 1 hr at a temperature between 1550° and 1650°C in air, and cooled down in N_2. Lower firing temperatures are possible when, at the same time, the number of firings is increased. Another method is based on precipitation of the hydroxides. After drying and prefiring at 700°C two firings at 1500°-1550°C are sufficient.

$(Sr_{0.95}Ce_{0.05})(Mg_{0.05}Al_{11.95})O_{19}$ can be fired in air at 1500°C and cooled down in N_2, but a firing in slightly reducing atmosphere proved superior.

$Sr(Ga_{11.997}Mn_{0.003})O_{18.9985}$ is fired twice for 2 hr at 1400°C in air and afterward in N_2/H_2 mixtures at 1200°C. The phosphor quality is highly sensitive toward the oxygen pressure during the last firing.

$K(Ga_{10.995}Mn_{0.005})O_{16.9975}$ is prepared in the same way, except that an excess of 100% K_2CO_3 is applied for better reaction. The excess is washed out afterward.

$(K_{0.9}Tl_{0.1})Al_{11}O_{17}$ is prepared as follows: the unactivated $KAl_{11}O_{17}$ is prepared with an excess K_2CO_3, which is washed out. The fired product is brought into contact with a melt of $TlNO_3$ and KNO_3. In the melt exchange of K^+ for Tl^+ takes place. The final Tl^+ concentration in the phosphor can be regulated by the Tl^+/K^+ ratio in the melt.

Luminescence

Mn^{2+}-activated gallates.—The spinel $MgGa_2O_4$:Mn^{2+} is an efficient green emitting phosphor under ultraviolet excitation (7). The magnetoplumbite, as well as the β-alumina structure, contains spinel-like blocks, so incorporation of Mn^{2+} therein might produce similar emission. We already reported efficient green emission of Mn^{2+} in $SrGa_{12}O_{19}$ and $LaMgGa_{11}O_{19}$ (2). The luminescence of Mn^{2+} in $KGa_{11}O_{17}$ and in the higher hexagonal gallates is about as efficient as that in $MgGa_2O_4$ and $SrGa_{12}O_{19}$. The spectral energy distribution of the Mn^{2+} emission in $MgGa_2O_4$, $SrGa_{12}O_{19}$, and $KGa_{11}O_{17}$ is shown in Fig. 1.

In Ref. [2] we presented evidence that Mn^{2+} occupies a tetrahedral site. In addition we showed that efficient energy transfer from the lattice to the Mn^{2+} ion takes place. Indeed, there is good overlap of the host lattice emission band and the Mn^{2+} excitation lines. However, the nature of the luminescent center

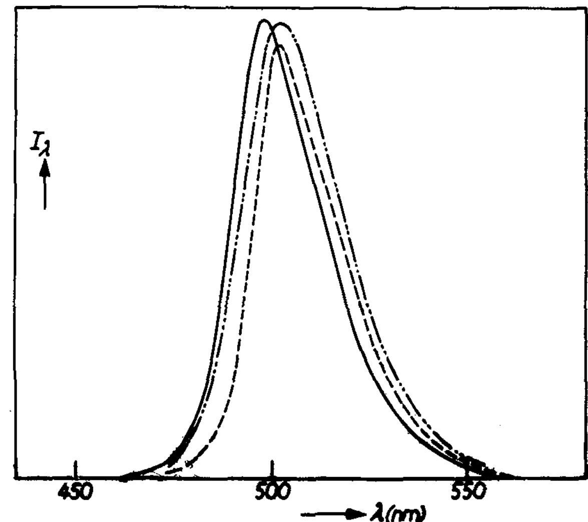

Fig. 1. Spectral energy distribution of $KGa_{11}O_{17}$ (solid curve), $SrGa_{12}O_{19}$ (dashed curve), and $MgGa_2O_4$ (-..- curve) activated with Mn^{2+}. I_λ gives the radiant power per constant wavelength interval in arbitrary units. Excitation with 254 nm radiation.

in the gallate host lattices is not known (2). Obviously the energy transfer takes place in the spinel block. The low Mn^{2+} concentration (0.3%) required for quenching the host lattice emission, indicates that the transfer process is very efficient. It is surprising that the quantum efficiency of the Mn^{2+} emission in $BaGa_{12}O_{19}$ is so much lower than that of the Mn^{2+} emission in $SrGa_{12}O_{19}$ and $LaMgGa_{11}O_{19}$ (Table II). At the moment we are unable to offer an explanation. Probably there is a connection with the crystallographic differences between $BaGa_{12}O_{19}$ and $BaAl_{12}O_{19}$ on the one hand and $SrGa_{12}O_{19}$ and $SrAl_{12}O_{19}$ on the other hand (8).

Eu^{2+}-activated aluminates.—Blasse and Bril described efficient luminescence of Eu^{2+} in $BaAl_{12}O_{19}$ and $SrAl_{12}O_{19}$ (9). We extended their work to more complicated aluminate compositions and found a shift of the emission toward longer wavelengths and an increase in the quantum efficiency upon addition of Mg^{2+} or Zn^{2+}.

The hexagonal aluminates with the composition W, Y, X, and Z (with Mg and Zn replacing Fe^{II} and Al replacing Fe^{III} and the large cation is either Ba or Sr) luminesce efficiently in the blue or the green, when activated with Eu^{2+}. For further optimization we rather arbitrarily selected a phosphor of the composition $(Ba,Eu)Mg_2Al_{16}O_{27}$, analogous to the W-ferrite, and a second one, $(Sr_5Eu_{0.5})Mg_6Al_{55}O_{94}$. The x-ray diagram of $(Ba,Eu)Mg_2Al_{16}O_{27}$ showed reflections of α-Al_2O_3 and $MgAl_2O_4$ with intensities depending on

Table II. Data on luminescent materials, based on hexagonal aluminate and gallate host lattices

* Depending on the amount of Mn^{2+} present.

the flux used. No analysis has been done to check the amounts of the optically inert phases. The x-ray diagrams can best be indexed on a hexagonal cell with a = 5.619 ± 0.005Å and c = 22.06 ± 0.03Å. The x-ray diagram of $(Sr_5Eu_{0.5})Mg_6Al_{55}O_{94}$ may contain reflections of $SrAl_2O_4$. The presence of that phase leads to a slight broadening of the emission band toward the green. For the magnetoplumbite phase the lattice parameters of a = 5.616 ± 0.009Å and c = 22.38 ± 0.07Å were calculated. $(Ba,Eu)Mg_2Al_{16}O_{27}$ emits at 450 nm with a quantum efficiency under 254 nm excitation of approximately 100%. $(Sr,Eu)_{5.5}Mg_6Al_{55}O_{94}$ emits at 465 nm with the same quantum efficiency. Figure 2 shows the emission spectra of $(Ba_{0.86}Eu_{0.14})$-$Mg_2Al_{16}O_{27}$ and $(Sr_5Eu_{0.5})Mg_6Al_{55}O_{94}$ together with their excitation and diffuse reflection spectra. Both phosphors can be applied in an 80 lumens/W "deluxe" fluorescent lamp, to be discussed in a separate paper (10).

Eu^{2+}-sensitized Mn^{2+} emission in magnetoplumbite-like aluminates.—Kröger (11) described cathodoluminescence of Mn^{2+} in $MgAl_2O_4$ and $SrAl_{12}O_{19}$. The emission is green and of the same type as that in the corresponding gallates, except for a small shift toward longer wavelengths. Obviously Mn^{2+} is incorporated on a tetrahedral site in the spinel lattice and a similar site in the spinel block of $SrAl_{12}O_{19}$. A comparison of the excitation lines of Mn^{2+} in the hexagonal aluminates, such as $BaMg_2Al_{16}O_{27}$, with those of Mn^{2+} in the gallates, supports this (Fig. 3). We found that photoluminescence of Mn^{2+} in the aluminates can be sensitized by Eu^{2+} ions. This sensitization is rather inefficient in $BaAl_{12}O_{19}$:Eu,Mn, moderately efficient in $Sr_{5.5}Mg_6Al_{55}O_{94}$:Eu,Mn, but very efficient in $BaMg_2$-$Al_{16}O_{27}$:Eu,Mn. The Mn^{2+} emission is essentially that in $MgAl_2O_4$ and $SrAl_{12}O_{19}$ under excitation with cathode rays. A detailed analysis of the $Eu^{2+} \rightarrow Mn^{2+}$ energy transfer is impossible, due to uncertainty of the precise structure of the aluminates. The amount of Mn^{2+} required to quench the Eu^{2+} emission is approximately 100 times as high as in the gallates, indicating a different energy transfer process. Since the shortest possible distance between Eu^{2+} in the intermediate layer and Mn^{2+} on a tetrahedral site is of the order of 6Å, a dipole-multipole energy transfer seems the most likely process. The interaction takes place between the intermediate layer and the spinel block.

Figure 4 shows the emission spectrum of $BaMg_2$-$Al_{16}O_{27}$:Eu,Mn for various Eu^{2+}/Mn^{2+} ratios. A phosphor of the composition $(Ba_{0.85}Eu_{0.15})(Mg_{1.4}Mn_{0.6})$-$Al_{16}O_{27}$ emits mainly in the green.

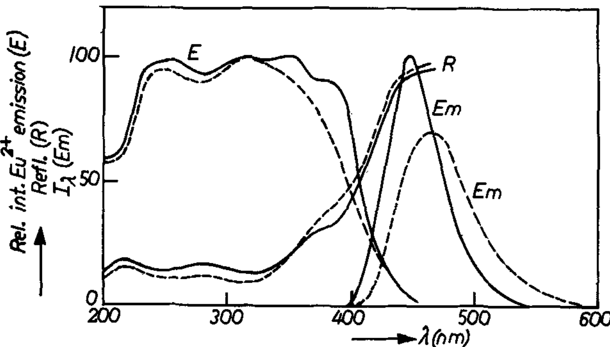

Fig. 2. Spectral energy distribution (Em), relative excitation spectra (E), and diffuse reflection spectra (R) of $BaMg_2Al_{16}O_{27}$ (solid curves) and $Sr_{5.5}Mg_6Al_{55}O_{94}$ (dashed curves) activated with Eu^{2+}. I_λ gives the radiant power per constant wavelength interval in arbitrary units. Excitation with 254 nm radiation.

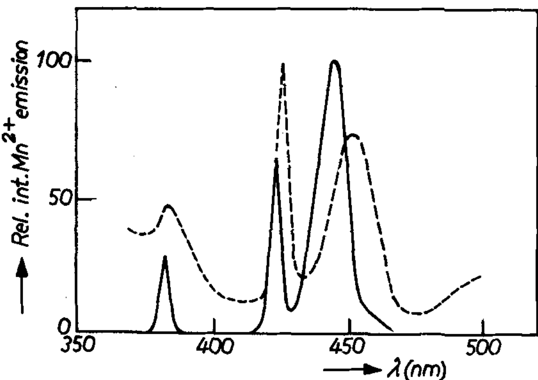

Fig. 3. Relative excitation spectra of Mn^{2+} emission in $BaMg_2Al_{16}O_{27}$:Mn^{2+} (dashed curve) and $SrGa_{12}O_{19}$:Mn^{2+} (solid curve).

Tl^+ and Tl^+,Mn^{2+} activation of $KAl_{11}O_{17}$ and $RbAl_{11}O_{17}$.—$KAl_{11}O_{17}$ and $RbAl_{11}O_{17}$ are excellent host lattices for Tl^+ emission. Tl^+ replaces K^+ and Rb^+ in the intermediate layer and emits in the long wavelength ultraviolet with a quantum efficiency approximately 60%. The emission overlaps reasonably well the Mn^{2+} excitation lines in β-alumina, which have the same shape as in magnetoplumbite. There is efficient energy transfer from Tl^+ to Mn^{2+} (12). The energy transfer is from the intermediate layer to a tetrahedrally surrounded Mn^{2+} in the spinel-block. Introduction of Mn^{2+} instead of Al^{3+} is compensated for by replacement of K^+ by Ba^{2+}. X-ray data show that the β-alumina structure during this operation is retained. In β-alumina the minimum distance between sensitizer and activator ion is as short as ~2.5Å.

Figure 5 shows the ultraviolet emission of $KAl_{11}O_{17}$ and $RbAl_{11}O_{17}$:Tl^+ and the green emission of a phosphor of the composition $(Na_{0.6}Ba_{0.3}Tl_{0.1})$-$(Mn_{0.3}Al_{10.7})O_{17}$, together with the excitation and diffuse reflection spectrum of the latter.

Ce^{3+}-activated magnetoplumbites (1).—Not only Eu^{2+} but also Ce^{3+} activation turns the magnetoplumbite into efficient phosphors. $SrAl_{12}O_{19}$:Ce^{3+} and $CaAl_{12}O_{19}$:Ce^{3+} are more efficient phosphors than $BaAl_{12}O_{19}$:Ce^{3+}. The best phosphors are obtained by double substitution $Sr^{2+} \rightarrow Ce^{3+}$; $Al^{3+} \rightarrow Mg^{2+}$.

Figure 6 shows the emission spectrum of $(Sr_{0.95}Ce_{0.05})Mg_{0.05}Al_{11.95}O_{19}$ together with the excitation and diffuse reflection spectrum. A similar phosphor is $LaMgAl_{11}O_{19}$:Ce^{3+} with an emission occurring at longer wavelengths. Complete substitution of La by

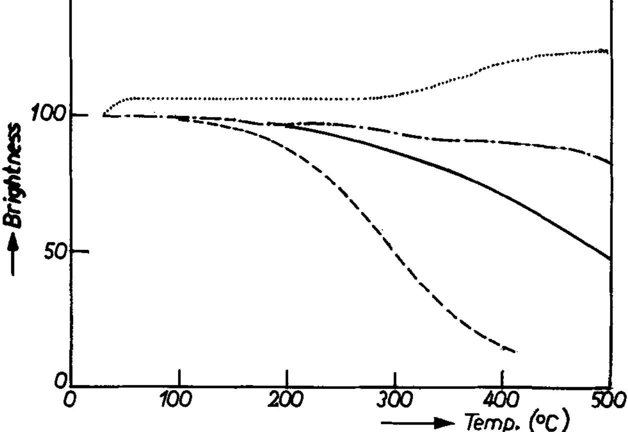

Fig. 9. Brightness vs. temperature in °C for $(Ba_{0.8}Eu_{0.2})(Mg_{1.6}Mn_{0.4})Al_{16}O_{27}$ (solid curve), $(Sr_{0.95}Ce_{0.05})(Mg_{0.05}Al_{11.95})O_{19}$ (dotted curve), $(Ce_{0.67}Tb_{0.33})MgAl_{11}O_{19}$ (-.- curve), and $(Sr_5Eu_{0.5})Mg_6Al_{55}O_{94}$ (dashed curve).

Ce leads to a new compound, $CeMgAl_{11}O_{19}$, with a = 5.605Å and c = 21.97Å, as described previously (1). The phosphor emits at 370 nm with a relatively high efficiency, indicating that $Ce^{3+} \rightarrow Ce^{3+}$ transfer is unimportant. A possible explanation for this phenomenon is found in the relatively long Ce^{3+}-Ce^{3+} distance (5.6Å) and the poor overlap of the Ce^{3+} excitation and emission bands (Fig. 7) (1). $(Sr_{0.95}Ce_{0.05})(Mg_{0.05}Al_{11.95})O_{19}$ is an excellent erythemal phosphor with a quantum efficiency of approximately 70%.

Tb^{3+} activation of $CeMgAl_{11}O_{19}$ (1).—Upon activation with Tb^{3+}, $CeMgAl_{11}O_{19}$ turns into a green phosphor

with a quantum efficiency of approximately 80%. The optimum phosphor has the composition $(Ce_{0.67}Tb_{0.33})MgAl_{11}O_{19}$. Comparison of the excitation spectra of the Ce^{3+} and the Tb^{3+} emission, as well as variation in the Tb^{3+} concentration, show that Ce^{3+} acts as a sensitizer and that the excitation energy is transferred to Tb^{3+}. Figure 7 shows the excitation and diffuse reflection spectrum of $(Ce_{0.67}Tb_{0.33})MgAl_{11}O_{19}$. The Ce^{3+} emission efficiently overlaps 4f excitation lines of Tb^{3+} which have been inserted in the figure. The emission of $(Ce_{0.67}Tb_{0.33})MgAl_{11}O_{19}$, compared to NBS zinc silicate, is shown in Fig. 8. Ce^{3+} as well as Tb^{3+} are accommodated in the intermediate layer. Energy transfer from Ce^{3+} to Tb^{3+} takes place within that layer, the Ce^{3+}-Tb^{3+} distance being 5.6Å. The distance between the layers is 11Å. Energy transfer occurs mainly via electric dipole-quadrupole interactions (1). The transfer probability for that process is inversely proportional to R^8, so that energy transfer from one layer to the other is negligible. Optimum Tb^{3+} luminescence was obtained at a Ce^{3+}/Tb^{3+} ratio $\approx$ 2. In that case the Ce^{3+} emission is very weak. Calculations on the energy transfer from Ce^{3+} to Tb^{3+} supported the experimentally found Ce^{3+}/Tb^{3+} ratio (13). The composition $(Ce_{0.67}Tb_{0.33})MgAl_{11}O_{19}$ suggests a superstructure but neutron diffraction experiments did not reveal the appropriate reflections (13).

The luminescent materials, discussed in this paper, are summarized in Table II.

Temperature dependence.—Figure 9 shows the influence of temperature on the brightness of some of the phosphors. In particular the Ce^{3+}-activated and the Ce^{3+}-sensitized, Tb^{3+}-activated magnetoplumbites show high efficiency at elevated temperatures.

A New Generation of "Deluxe" Fluorescent Lamps, Combining an Efficacy of 80 Lumens/W or More with a Color Rendering Index of Approximately 85

J. M. P. J. Verstegen, D. Radielović, and L. E. Vrenken

N. V. Philips' Gloeilampenfabrieken, Light Division, Eindhoven, The Netherlands

ABSTRACT

It has been shown previously that color-rendering capability and luminous efficacy of fluorescent lamps depend on the spectral composition of the emitted light. Three spectral regions appear to be of special interest, the blue at 450 nm, the green at 540 nm, and the orange-red at 610 nm. Among the hexagonal aluminates blue-emitting $(Ba,Eu)Mg_2Al_{16}O_{27}$ and green-emitting $(Ce,Tb)MgAl_{11}O_{19}$, together with orange-red-emitting $(Y,Eu)_2O_3$ are particularly suited in a new generation "deluxe" fluorescent lamps. Lamps with a color temperature >2350°K can be made. The efficacy of the lamps ranks from approximately 82 lm/W at 3000°K to 80 lm/W at 6000°K. The color-rendering index R_a is 81-85. A small increase of R_a is achieved when Mn^{2+} is incorporated in $(Ba,Eu)Mg_2Al_{16}O_{27}$, giving rise to an additional green emission at 515 nm. The new blend is compared to other blends and further prospects in fluorescent lamp developments are outlined.

Various paper have been published on the optimum emission spectra of light sources. Koedam and Opstelten (1) showed that a color rendering index (CRI) (2) $R_a \approx 80$ can be achieved by a proper choice of the wavelengths and intensity ratios of three spectral bands, each having a width of only 5 nm. Although the position of the bands in the spectrum is critical, a small shift of one of them can be compensated for by shifts in the same direction of the other two: the bands are interdependent.

Key words: fluorescent lamps, high efficacy "deluxe" fluorescent lamps, new generation fluorescent lamps.

Not only color-rendering capability but also luminous efficacy depends on the spectral composition of the emitted light as was shown by Koedam and Opstelten (1) and Thornton (3). The Koedam-Opstelten principle, described above, can be applied to fluorescent lamps. Koedam, Opstelten, and Radielović (4) stated that good color-rendering capability and high efficacy are combined when the three phosphor blend contains a red component with a narrow emission band at 615 nm. Further calculations by Opstelten (5) also showed that a decrease of the width of the blue emission band favors high efficacy, though the effect is less dramatic than for the red one. Relatively broad band green phosphors come up to the requirements (5).

Haft and Thornton (6) published data on experimental lamps based on the Koedam-Opstelten principle. They applied blue-emitting strontium chloroapatite activated with divalent europium, green-emitting zinc silicate activated with manganese, and orange-red emitting yttrium oxide, activated with trivalent europium. For a 40W cool white fluorescent lamp they reported 3100 lumens and a CRI of 83.

Opstelten, Radielović, and Wanmaker (7) evaluated a number of phosphors, most of them, unfortunately, being unsuited for lamp application. However, their work strongly supported the use of divalent europium, trivalent terbium, and trivalent europium as the most suitable activators. This result confirms the pattern outlined above: trivalent europium phosphors show line emission in the red or orange-red. The emission of divalent europium is, compared with blue halophosphate, narrow, although the band is much broader than the line emission of trivalent europium. The Tb^{3+}-activated phosphors with line emission at 545 nm behave as relatively broad band green phosphors, due to their subsidiary emission near 490 and 590 nm. The four transitions $^5D_4 \rightarrow {}^7F_J$ in the Tb^{3+} ion can be combined to a Gaussian emission band centered at 545 nm and with a width at half intensity of 80 nm (5). Tb^{3+}-activated phosphors conform very well to the three-spectral-color criterion which allows an increase of the width of the green band with hardly any loss in luminous efficacy.

The aim of the present paper is to show how the hexagonal aluminate phosphors, presented before (8), behave in lamps according to the Koedam-Opstelten principle. We compare the results with some other blends without being exhaustive. However, computer-aided calculations show that the aluminate phosphors together with $(Y, Eu)_2O_3$ constitute a blend which in the region of color temperatures $\geqq$ 2350°K is unsurpassed as far as lamp efficacy is concerned (9). We compare the new blend to results of current halophosphate lamps. A more detailed treatment of the lamp including a discussion of phosphor costs, maintenance, etc. will be presented elsewhere (10).

Selection of Phosphors

As stated above, the phosphor emission bands are interdependent. The choice of one phosphor fixes, to a certain extent, the position of the other two. Except for requirements such as a high quantum efficiency and a good lamp performance, it is necessary that the three phosphors match each other. Opstelten *et al.* (7) pointed out that a narrow band green phosphor should be located at 560-570 nm and a broad band one at 525-560 nm, depending on the type of fluorescent lamp involved.

An important step forward was made by the innovation and development of the efficient and excellently performing phosphor $(Ce_{0.67}Tb_{0.33})MgAl_{11}O_{19}$ (8, 11). In the course of our work we were able to increase the quantum efficiency of the phosphor from 65% (11) to 80% (8). In Table I we compare $(Ce_{0.67}Tb_{0.33})MgAl_{11}O_{19}$ to $ZnSiO_4:Mn^{2+}$, both green-emitting phosphors.

The following conclusions may be drawn from the comparison: (*a*) the maintenance of the aluminate is better, (*b*) the quantum efficiency of the aluminate is

Table I. Properties of $(Ce_{0.67}Tb_{0.33})MgAl_{11}O_{19}$ and $Zn_2SiO_4:Mn^{2+}$ in 40W fluorescent lamps

Phosphor	Quantum eff. (%)	Refl. 254 nm (%)	Chromaticity coordinates (x/y)	Efficacy (lumens/W) in 40W lamps 100 hr	2500 hr
$(Ce_{0.67}Tb_{0.33})MgAl_{11}O_{19}$	80	8	0.295/0.579	108	102
$ZnSiO_4:Mn^{2+}$	75	15	0.246/0.622	94	69

higher, and (c) the value of y/η, where y is the y chromaticity coordinate and η is the luminous efficacy, is smaller for the Tb^{3+} phosphor than for green zinc silicate, indicating that the three phosphor blends containing the first one will exhibit higher efficacy.

Calculations showed that the emission of $(Ce_{0.67}Tb_{0.33})MgAl_{11}O_{19}$ at 545 nm should be matched by an orange-red emitting phosphor. Nothing is to be gained in CRI when the red emission is shifted to wavelengths longer than about 615 nm, but, at the same time, the efficacy of the lamp decreases. This was confirmed by experimental lamps with $(Y,Eu)_2O_3$, emitting at 611 nm and $(Y,Eu)_2O_2S$, emitting at 627 nm as the red component of a cool white phosphor blend. $(Y,Eu)_2O_2S$ is suitable, in particular when the color rendering of deep red has to be improved, but the phosphor should be combined with a green-yellow one, emitting at 560-565 nm. The best match for $(Ce,Tb)MgAl_{11}O_{19}$ is therefore orange-red emitting $(Y,Eu)_2O_3$. A shift of the orange-red emission line toward shorter wavelengths [the amount of $(Ce,Tb)MgAl_{11}O_{19}$ in the blend at the same time decreasing] increases the lamp efficacy, the R_a values soon dropping below 80. However, no efficient line emitting phosphor at a wavelength of $\approx$600 nm is known. The properties of $(Y,Eu)_2O_3$ are given in Table II.

Calculations showed that a narrow band blue phosphor, peaking at 450 nm, is required for maximum luminous efficacy of the lamp. Two effects are noteworthy: (*a*) a shift of the blue emission toward longer wavelengths (or a shift of the chromaticity coordinates in the C.I.E. chromaticity diagram to higher y values) tends to decrease the luminous efficacy but to increase the CRI, and (*b*) a decrease of the width of the blue emission band tends to increase the luminous efficacy but to decrease the CRI.

The relevant aluminate blue phosphors are $(Ba_{0.86}Eu_{0.14})Mg_2Al_{16}O_{27}$ with an emission peaking at 450 nm and $(Sr_5Eu_{0.5})Mg_6Al_{55}O_{104}$, emitting at 465 nm (8). Incorporation of Mn^{2+} in both lattices gives rise to a second emission at 515 nm (8). This second emission leaves the x chromaticity coordinate of the phosphors virtually unaffected but the y coordinate increases drastically when the ratio Mn^{2+}/Eu^{2+} increases. In particular the Eu^{2+}-activated Ba compound is an excellent blue component for the new generation "deluxe" fluorescent lamps.

The trends mentioned under (*a*) will be illustrated with blue and blue-green aluminate phosphors, that under (*b*) with a comparison of $(Ba,Eu)Mg_2Al_{16}O_{27}$ to another blue phosphor, (Sr,Eu) chloroapatite (6). Both emit at 450 nm but the width at half intensity of aluminate blue is 50 nm against that of 30 nm of (Sr,Eu) chloroapatite. Our experiments on (Sr,Eu) chloroapatite showed that a quantum efficiency of 85% was within reach, 15% lower than that of the aluminates. However, one would expect the narrower emission band and the lower reflection for 254 nm radiation (see Table III) to make up for this as far as lamp effi-

Table II. Properties of $(Y,Eu)_2O_3$ in 40W fluorescent lamps

Phosphor	Quantum eff. (%)	Refl. 254 nm (%)	Chromaticity coordinates (x/y)	Efficacy (lumens/W) in 40W lamps 100 hr	2500 hr
$(Y,Eu)_2O_3$	100	10	0.597/0.331	65	57

Table III. Properties of some blue phosphors in 40W fluorescent lamps

Phosphor composition	Quantum eff. (%)	Refl. 254 nm (%)	Chromaticity coordinates (x/y)	Efficacy (lumens/W) in 40W lamps 100 hr	2500 hr
$(Ba_{0.86}Eu_{0.14})Mg_2Al_{16}O_{27}$	100	10	0.151/0.066	24	22
$(Ba_{0.9}Eu_{0.1})(Mg_{1.9}Mn_{0.1})Al_{16}O_{27}$	100	16	0.148/0.225	50	43
$(Sr_5Eu_{0.5})Mg_8Al_{55}O_{94}$	100	8	0.149/0.181	45	Poor
$(Sr_{4.93}Eu_{0.07})(PO_4)_3Cl$	85	3	0.159/0.038	12	9.5

cacy is concerned. We will give a detailed comparison in the section on phosphor blends. Conventional blue phosphors such as blue halophosphate, Sn^{2+}-activated $Sr_2P_2O_7$ and $MgWO_4$ with widths at half intensity of approximately 120 nm do not conform to the Koedam-Opstelten principle. The efficacy of lamps containing these phosphors is at least 10 lumens/W lower.

Table III gives some properties of blue-emitting phosphors. A few conclusions to be drawn from Table III are: (*a*) the behavior of $(Sr,Eu)_{5.5}Mg_8Al_{55}O_{94}$ in lamps is poor, and (*b*) the maintenance of (Sr,Eu) chloroapatite is a bit worse than that of the Ba aluminate blue. That the luminous efficacy η of the latter is twice as high is mainly due to the lower y coordinate of the (Sr,Eu) chloroapatite. The value of y/η of the aluminate blue is only approximately 15% lower, in agreement with its higher quantum efficiency.

Selection of Blends

Figure 1 shows the C.I.E. chromaticity diagram. The Planckian locus (BBL) as well as the chromaticity coordinates R of $(Y,Eu)_2O_3$, G of $(Ce,Tb)MgAl_{11}O_{19}$, and B of $(Ba,Eu)Mg_2Al_{16}O_{27}$ have been inserted. The line GR intersects the Planckian locus at a point corresponding to a color temperature of approximately 2350°K. Up to now, fluorescent lamps of low color temperature and good color rendering capability had to be made using a blue absorbing layer in order to suppress the blue and violet mercury lines at 405, 408, and 436 nm. In the new lamps the mercury lines add their contribution to the emission spectrum.

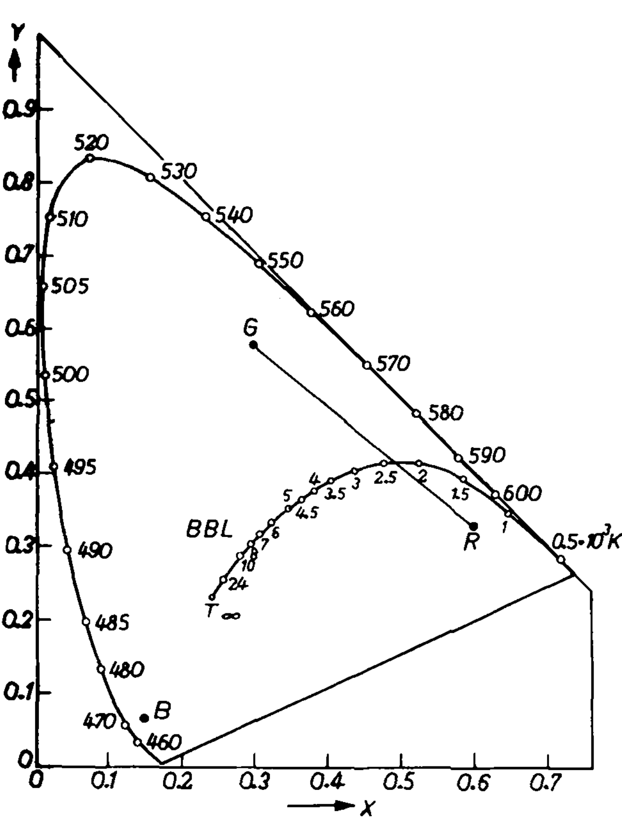

Fig. 1. C.I.E. chromaticity diagram with chromaticity coordinates R of $(Y,Eu)_2O_3$, G of $(Ce,Tb)MgAl_{11}O_{19}$, and B of $(Ba,Eu)Mg_2Al_{16}O_{27}$ and with the Planckian locus (BBL).

Table IV. Efficacy at 100 hr and CRI (R_a) of 4000°K fluorescent lamps with two different blue phosphors in the blend

Blue phosphor in 4000°K blend	Efficacy (lumens/W) 100 hr	CRI (R_a)
$(Sr,Eu)_{5.5}Mg_6Al_{55}O_{94}$	78.5	90
$(Ba,Eu)Mg_2Al_{16}O_{27}$	81.0	85

The effect of the shift of the blue emission toward longer wavelengths in a 4000°K fluorescent lamp is shown by comparison of $(Sr,Eu)_{5.5}Mg_6Al_{55}O_{94}$, emitting at 465 nm, with $(Ba,Eu)Mg_2Al_{16}O_{27}$ emitting at 450 nm. The green component, $(Ce,Tb)MgAl_{11}O_{19}$, and the red one, $(Y,Eu)_2O_3$, remain the same, although their amounts in the blend change. Table IV gives the results of experimental lamps with the two blue phosphors in the blend.

The effect of an increasing y value of the blue component in a 4000°K phosphor blend is suitably demonstrated with phosphors based on the general formula $(Ba_{0.9}Eu_{0.1})(Mg_{2-x}Mn_x)Al_{16}O_{27}$. The green component, $(Ce,Tb)MgAl_{11}O_{19}$, and the red component, $(Y,Eu)_2O_3$, remain the same. Figure 2 shows an enlarged part of the C.I.E. chromaticity diagram. The chromaticity coordinates of the Eu^{2+}-sensitized, Mn^{2+}-activated aluminates are found on the line PQ, Q corresponding to a phosphor $(Ba_{0.9}Eu_{0.1})(Mg_{1.7}Mn_{0.3})Al_{16}O_{27}$. Going from B to Q the lamp efficacy drops. The CRI increases in the region BP but decreases going from P

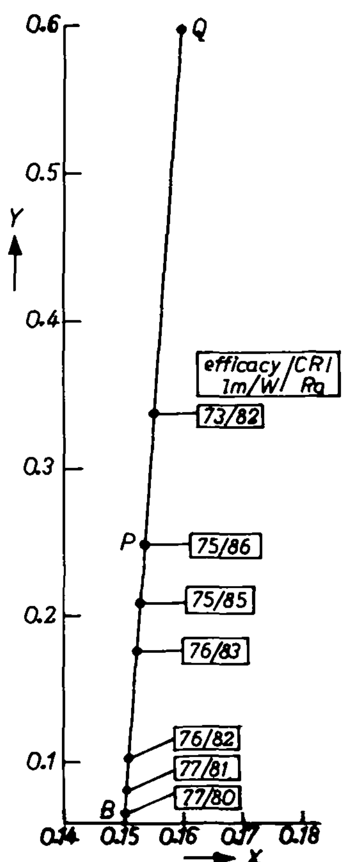

Fig. 2. Enlarged part of the C.I.E. chromaticity diagram with the chromaticity coordinates B of $(Ba_{0.9}Eu_{0.1})Mg_2Al_{16}O_{27}$, P of $(Ba_{0.9}Eu_{0.1})$ $(Mg_{1.9}Mn_{0.1})Al_{16}O_{27}$, and Q of $(Ba_{0.9}Eu_{0.1})$ $(Mg_{1.7}Mn_{0.3})Al_{16}O_{27}$. At various points of the line BQ the calculated luminous efficacy and the CRI (R_a) are given for cool white blends of $(Ce,Tb)MgAl_{11}O_{19}$, $(Y,Eu)_2O_3$, and $(Ba_{0.9}Eu_{0.1})$ $(Mg_{2-x}Mn_x)Al_{16}O_{27}$.

Table V. Efficacy at 100 hr and CRI (R_a) of 4000°K fluorescent lamps with $(Ba_{0.9}Eu_{0.1})(Mg_{2-x}Mn_x)Al_{16}O_{27}$ as the blue phosphor

x	Efficacy (lumens/W) 100 hr	CRI (R_a)
0	81.0	85
0.05	79.5	87
0.1	78.5	88

Table VI. Efficacy at 100 hr and CRI (R_a) of 4000°K fluorescent lamps with (Sr,Eu) chloroapatite and $(Ba,Eu)Mg_2Al_{16}O_{27}$ as the blue phosphor

Blue phosphor	Efficacy (lumens/W) 100 hr	CRI (R_a)
$(Ba,Eu)Mg_2Al_{16}O_{27}$	81.0	85
(Sr,Eu) chloroapatite	80.0	81

to Q. P is the chromaticity coordinate of the phosphor $(Ba_{0.9}Eu_{0.1})(Mg_{1.9}Mn_{0.1})Al_{16}O_{27}$. At various points along the line BQ calculated values of the lamp efficacy in lumens/watt and of the CRI (R_a) are given. Experimental lamps confirmed this trend. The results are given in Table V.

We consider an R_a of 85 as high enough for normal lighting and therefore decided to refrain from a further increase of R_a at the cost of the lamp efficacy. The effect of a decrease of the width of the blue emission band is demonstrated when lamps with (Sr, Eu) chloroapatite and (Ba, Eu)$Mg_2Al_{16}O_{27}$ are compared. In both cases (Ce,Tb)$MgAl_{11}O_{19}$ is the green and (Y, Eu)$_2O_3$ the red component. The results are shown in Table VI and demonstrate that the lower quantum efficiency of (Sr, Eu) chloroapatite is compensated for by its narrower emission band: there is hardly any difference in lamp efficacy. However, color rendering capability drops rather sharply.

Lamp Results

Many lamps at various color temperatures have been made by now, using the blend containing blue (Ba, Eu)$Mg_2Al_{16}O_{27}$, green (Ce, Tb)$MgAl_{11}O_{19}$, and red (Y, Eu)$_2O_3$. Measurements of luminous efficacy, color rendering indices, and maintenance show unambiguously that a new generation of "deluxe" lamps has been developed with a unique combination of properties. Table VII shows data of experimental 40W lamps of four different color temperatures and when lamps with equal CRI are compared, that the efficacy increases by 50%. Figure 3 shows the emission spectrum of a 40W fluorescent lamp of 4000°K coated with a blend of blue and green aluminate and (Y, Eu)$_2O_3$. The maintenance of the new lamp is comparable to that of the halophosphate lamp and we expect to be able to improve on that (10).

Further Prospects in Fluorescent Lamp Development

The increased luminous efficacy of our "deluxe" fluorescent lamp, resulting from the phosphor research described in a previous paper (8), is welcome in these

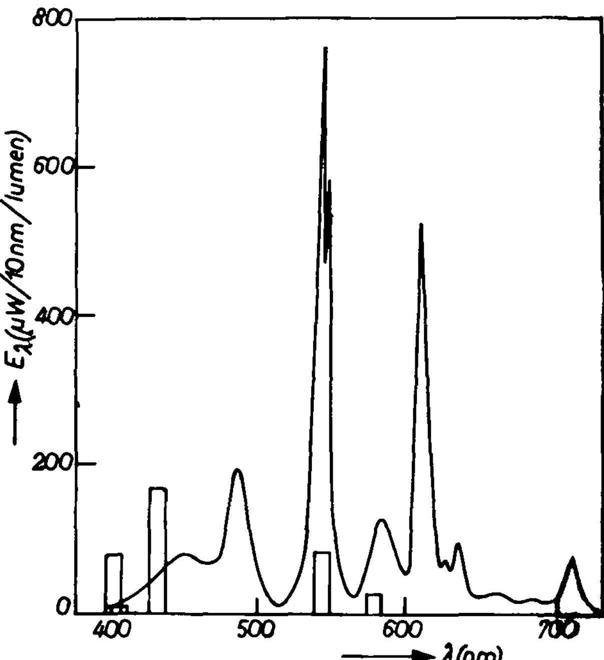

Fig. 3. Emission spectrum of a 40W fluorescent lamp of 4000°K, coated with a blend of $(Ba,Eu)Mg_2Al_{16}O_{27}$, $(Ce,Tb)Al_{11}O_{19}$, and $(Y,Eu)_2O_3$.

times of energy crisis. In a separate paper we will present calculations which show that the new generation "deluxe" lamp is profitable in "deluxe" lighting installations, even though the cost of the lamp is considerably higher (10). Whether the aluminate/(Y, Eu)$_2O_3$ blend will render the halophosphates obsolete depends on our progress in reducing the lamp price. Some possibilities to do so are outlined elsewhere (10). The high efficacy of the new "deluxe" lamp is partly due to the high quantum efficiency of the phosphors and partly to the localization of their emission close to the three wavelengths 450, 540, and 610 nm (6). Although we do not imply that the phosphor blend presented above is the ultimate one for "deluxe" fluorescent lamps of the Koedam-Opstelten principle, we believe that a dramatic increase in the efficacy of fluorescent lamps is only possible when the three-spectral-color criterion is left for the two-spectral-color one. When phosphors could be obtained with a Q (= quantum efficiency × absolute absorption of 254 nm radiation) of 1.0 and when 22W of ultraviolet radiation (254 and 185 nm) is available for excitation, a cool white and warm white 40W fluorescent lamp with an efficacy of ≈130 lumens/W could be obtained. Such a lamp would emit in two narrow lines at 445-450 nm and 570-580 nm in agreement with Ivey's earlier results (12). The three-phosphor blend presented in this paper has a Q ≈ 0.8. Table VIII shows the calculated efficacy of lamps according to the two-spectral-color criterion with Q = 1.0 and 0.8. The spectral energy distribution of the 3000°K lamp is

The Luminescence of Tb^{3+} in Borates of the Composition $X_2Z(BO_3)_2$ (X = Ba, Sr, Ca; Z = Ca, Mg)

J. M. P. J. Verstegen

N. V. Philips' Gloeilampenfabrieken, Light Division, Eindhoven, The Netherlands

ABSTRACT

Four new borates of the formula $X_2Z(BO_3)_2$, with X = Ba, Sr, Ca, and Z = Ca, Mg, are described. $Ca_2Mg(BO_3)_2$ is tetragonal, and $Ba_2Mg(BO_3)_2$ is hexagonal and isomorphous with the mineral buetschliite. $Ba_2Ca(BO_3)_2$ and $Sr_2Mg(BO_3)_2$ are related to buetschliite but their diffraction patterns point to a crystallographic system of lower symmetry. All four borates are good host lattices for Tb^{3+} luminescence. The maximum quantum efficiencies are approximately 75% and are strongly influenced by the method of charge compensation used. The emission spectrum shows the usual $^5D_4 \rightarrow {}^7F_J$ transitions, with J = 6, 5, 4, and 3, that with J = 5 being the strongest. The temperature dependence of the emission is good.

Efficient luminescence of Tb^{3+} is known (1). Excitation of the luminescence may occur in four different ways: (*a*) in the 4f-4f absorption lines of the rare earth ion; this does not result in a high luminescence output due to the low absorption strength of these transitions; (*b*) in the broad absorption band of Tb^{3+} in the shortwave ultraviolet region; this band corresponds to 4f-5d transitions (2); (*c*) in a sensitizer ion, followed by energy transfer to Tb^{3+}, as is found in $(Ce,Tb)MgAl_{11}O_{19}$ (3); sensitization of Tb^{3+} emission by Sn^{2+} and Cu^+ has been described previously (4); and (*d*) in the host lattice, followed by energy transfer to Tb^{3+} (5); phosphors such as $SrWO_4:Tb^{3+}$ (6) belong to this type.

Luminescence of Tb^{3+} in borates was previously described by Wanmaker and Bril (7), and by Wanmaker, Bril, and Ter Vrugt (8). In general the emission spec-

trum of Tb^{3+} consists of the $^5D_4 \rightarrow {}^7F_J$ ($J = 3, 4, 5, 6$) transitions, in which $J = 5$ dominates, giving rise to a more or less saturated green emission.

Experimental

We used luminescent grade $CaCO_3$, $SrCO_3$, $BaCO_3$, H_3BO_3, and MgO. Tb_4O_7 was obtained from the Michigan Chemical Corporation. Na_2CO_3 and K_2CO_3 by Merck were used.

The best results were obtained after prefiring for 1 hr at 600°C and 2 hr at 900°C, but a single firing at 900°C for 1 hr proved sufficient to obtain 95% of the maximum brightness of the phosphors. A slightly reducing atmosphere was used to convert Tb to the trivalent state. The optical measurements have been described before (9).

Results

Structure of the host lattices.—Borates and carbonates are often structurally isomorphous. $LaBO_3$ has, *e.g.*, the $CaCO_3$-aragonite type structure and $GdBO_3$ the $CaCO_3$-vaterite type structure (10). Isomorphism is also found in more complicated compounds, such as $YAl_3B_4O_{12}$ and the mineral huntite $CaMg_3(CO_3)_4$ (11-13). Many carbonate minerals of the composition $A_2B(CO_3)_2$ exist, in which A = K or Na, and B = Ca or Mg, such as buetschliite (ASTM File No. 21-980), fairchildite (ASTM File No. 21-1287), whereas a compound $Na_2Ca(CO_3)_2$ is also listed under No. 2-970. We found a number of new borates. $Ca_2Mg(BO_3)_2$ was isomorphous with $Na_2Ca(CO_3)_2$ and tetragonal with a = 5.14Å and c = 4.41Å. $Ba_2Mg(BO_3)_2$ was isomorpohus with the hexagonal buetschliite with a = 5.38Å and c = 19.21Å.

The diffraction patterns of $Ba_2Ca(BO_3)_2$ and $Sr_2Mg(BO_3)_2$ point to similar structures but some new reflections appear, possibly due to a different distribution of the cations over their sites. We were unable to index the diffraction patterns. Values of d and I/I_0 are given in Table I.

Tb^{3+} luminescence.—Figure 1 shows the excitation and diffuse reflection curves of the compounds $X_2Z(BO_3)_2$ activated with Tb^{3+}. The broad strong absorption bands correspond to $4f \rightarrow 5d$ transitions in the Tb^{3+} ion. Though at least the three compounds with X = Sr, Ba have related structures, the excitation spectra differ markedly, due to the fact that the 5d level is strongly influenced by the crystal field (14).

The emission spectra of Tb^{3+} in $Ba_2Mg(BO_3)_2$ and $Ba_2Ca(BO_3)_2$ are shown in Fig. 2 and 3. We observe the usual transitions $^5D_4 \rightarrow {}^7F_J$, with J = 6, 5, 4, and 3. The transition $^5D_4 \rightarrow {}^7F_5$ is the stronger one. Splitting of the levels is much the same in both host lattices, indicating that the 4f levels are only slightly affected by minor changes of the crystal field. Comparison of the emission curves with that of Tb^{3+} in the magnetoplumbite $CeMgAl_{11}O_{19}$ (3) shows marked differences.

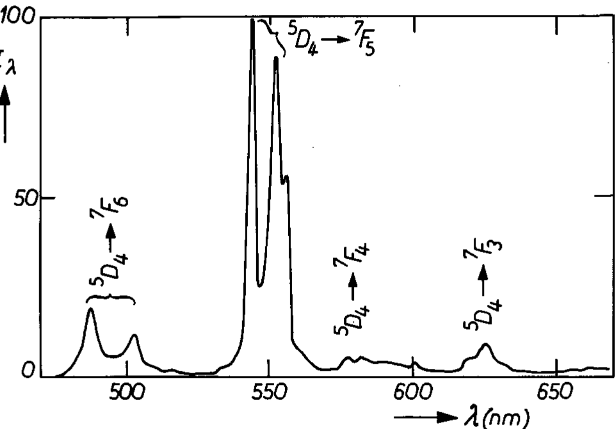

Fig. 2. Spectral energy distribution of the emission of Tb^{3+} in K^+-compensated $Ba_2Mg(BO_3)_2$. The relevant transitions are indicated. I_λ gives the radiant power per constant wavelength interval in arbitrary units. Mainly 254 nm radiation.

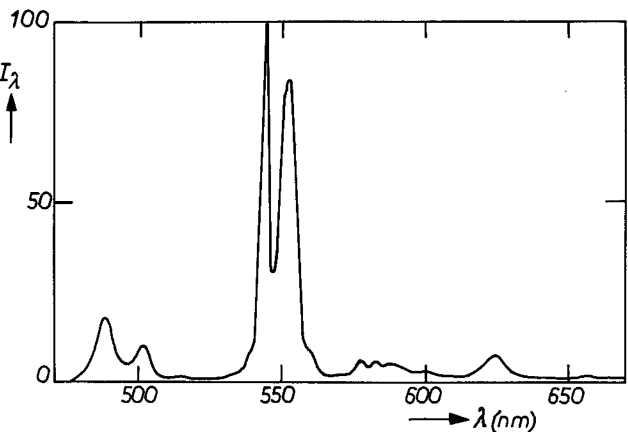

Fig. 3. Spectral energy distribution of the emission of Tb^{3+} in K^+-compensated $Ba_2Ca(BO_3)_2$. I_λ gives the radiant power per constant wavelength interval in arbitrary units. Mainly 254 nm radiation.

At least three explanations are possible: (*i*) the site symmetry in the borates is lower than that in the magnetoplumbites, D_{3h}, (*ii*) in the borates Tb^{3+} is incorporated at various sites, and (*iii*) the crystal forces acting on the Tb^{3+} ion are larger in the borates than in the magnetoplumbite. The latter point requires some explanation. In magnetoplumbites the 2d activator site is surrounded by 12 oxygen ions at relatively long distances (~3Å). Therefore the crystal forces, acting

Table II. Quantum efficiencies at the maximum excitation wavelength of various borates with the composition $X_2Z(BO_3)_2$, activated with Tb^{3+}. The quantum efficiencies of $Ba_2Mg(BO_3)_2$: Tb^{3+} with various ways of charge compensation and various activator concentrations, with 254 nm radiation

Composition	Quantum efficiencies, %
$Ba_{1.8}K_{0.1}Tb_{0.1}Mg(BO_3)_2$	70
$Sr_{1.8}Na_{0.1}Tb_{0.1}Mg(BO_3)_2$	70
$Ca_{1.8}Na_{0.1}Tb_{0.1}Mg(BO_3)_2$	70
$Ba_{1.8}K_{0.1}Tb_{0.1}Ca(BO_3)_2$	75
$Ba_{1.8}K_{0.1}Tb_{0.1}Mg(BO_3)_2$	70
$Ba_{1.8}Na_{0.1}Tb_{0.1}Mg(BO_3)_2$	65
$Ba_{1.9}Tb_{0.1}Mg(BO_{3.03})_2$	35
$Ba_{1.9}Tb_{0.1}Mg_{0.9}Li_{0.1}(BO_3)_2$	60
$Ba_{1.86}K_{0.07}Tb_{0.07}Mg(BO_3)_2$	65
$Ba_{1.80}K_{0.10}Tb_{0.10}Mg(BO_3)_2$	70
$Ba_{1.76}K_{0.12}Tb_{0.12}Mg(BO_3)_2$	75
$Ba_{1.70}K_{0.15}Tb_{0.15}Mg(BO_3)_2$	70
$Ba_{1.60}K_{0.20}Tb_{0.20}Mg(BO_3)_2$	70

on the 2d site, are relatively weak. This is strikingly illustrated by the emission behavior of the Eu^{2+}-activated magnetoplumbite $SrAl_{12}O_{19}$, which, at 77°K, shows 4f-4f line emission (15): obviously the crystal field is so weak that the lowest excited $4f^65d$ state lies at higher energy than the $^6P_{7/2}$ level. This is rather exceptional in oxidic lattices.

Borates, nitrates, and carbonates usually crystallize with calcite- or vaterite-like structures, depending on the size of the cation (16). The cations are surrounded by six or nine oxygen ions, respectively. More complicated carbonates do not deviate very much from this pattern. Dolomite, $CaMg(CO_3)_2$, has essentially the calcite and alstonite, $BaCa(CO_3)_2$, the aragonite arrangement (17). In calcite and vaterite the cation-oxygen distance is small, 2.1-2.5Å. The crystal field, acting on the cation in these structures as well as in our borates, will therefore be considerable.

Charge compensation.—We observed striking influence of charge compensation. The substitution

$$2Ba^{2+} \rightarrow Tb^{3+} + K^+$$

leads to the phosphor with the highest quantum efficiency, its quantum efficiency being twice as high as that of the noncompensated material. Other ways of charge compensation proved less effective (Table II). The maximum quantum efficiency is reached with an activator content of about 6% of Ba present (0.12 atom Tb per mole of the compound) and is 70-80% at the optimum excitation wavelength. However, only $Ba_2Mg(BO_3)_2$ and $Ba_2Ca(BO_3)_2$ respond favorably to the 254 nm radiation of the mercury discharge. The results are summarized in Table II.

The temperature dependence of $Ba_{1.8}K_{0.1}Tb_{0.1}$-$Mg(BO_3)_2$ is shown in Fig. 4. At elevated temperature the efficiency is still high, as is usually found for luminescence from 4f levels.

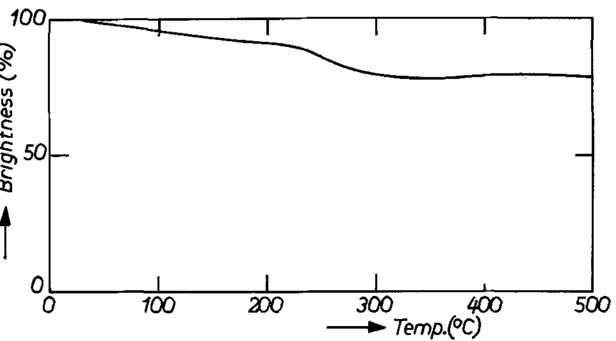

Fig. 4. Temperature dependence of the brightness of the Tb^{3+} emission in K^+-compensated $Ba_2Mg(BO_3)_2$.

Calculation of the Liquidus Isotherms and Component Activities in the Ga-As-Si and Ga-P-Si Ternary Systems

A. S. Jordan* and M. E. Weiner*,[1]

Bell Laboratories, Murray Hill, New Jersey 07974

ABSTRACT

Liquidus isotherms and thermodynamic activities have been calculated for the Ga-As-Si and Ga-P-Si ternary systems. The calculations are based on the assumption that the activities of the components in the liquid phase can be represented with sufficient accuracy by the ternary regular solution model. A least square analysis of the liquidus data for Si-doped GaAs yields the three ternary interchange energies (i.c.e.'s). These are then used to construct the liquidus isotherms for Si-doped GaAs, Ga- and As-doped Si, and the ternary eutectic valley, all of which are in excellent agreement with the experimental results over a wide temperature and composition range. The ternary Ga-As and Ga-Si i.c.e.'s are in very good accord with the i.c.e.'s derived from the binary data but a similar test for the Si-As i.c.e. shows a less satisfactory agreement. As the Ga-P-Si system has not yet been investigated, the calculations presented here are based solely on binary data and they need experimental confirmation. The implications of these results to crystal growth and the limitations of the regular solution model in the vicinity of the compound composition SiAs are also discussed.

Silicon is one of the most important dopants encountered in the compound semiconductors GaAs and GaP. For example, efficient GaAs infrared light-emitting diodes (LED's) have been fabricated by taking advantage of the amphoteric nature of Si doping (1), while an alloy of Au and Si is used for establishing ohmic contact to GaP LED's (2). However, in contrast to its demonstrated usefulness, the major role of Si in these compounds is that of an unintentional contaminant arising from the frequent use of fused silica crystal growing apparatus. In particular, the electrical properties of melt-grown boules of GaAs have been analyzed by assuming that Si is the dominant residual impurity (3).

Efforts toward a thermochemical understanding of Si contamination have been initiated by Cochran and Foster (4), who discussed the conditions under which liquid Ga reacts with silica. Recently, Si contamination in open flow silica systems for the epitaxial growth of GaAs and GaP has been treated by Weiner (5). Furthermore, DiLorenzo has succeeded in growing very high mobility (6) GaAs in an $AsCl_3$-Ga-H_2 vapor growth system by minimizing Si contamination via the careful adjustment of gas stream chemistry (7). Thermodynamic calculations have shown that the activity of Si in the growing crystalline phase, a^s_{Si}, is related inversely to the partial pressure of HCl (or $AsCl_3$) (7, 8). Although much of the work on Si contamination has been concerned with GaAs, GaP is expected to behave similarly with respect to unintentional Si incorporation. Indeed, work on the water vapor synthesis of GaP has indicated that Si is the dominant residual impurity (9). In addition to isolated Si acceptors and donors, Si-O complexes are also thought to be incorporated in GaP (10) and GaAs (11). These deep centers lead to doping and annealing anomalies in GaAs and to nonradiative recombination in n-type GaP.

To achieve a more complete understanding of Si incorporation in GaAs and GaP, it is necessary to obtain information concerning the thermodynamic properties of the Ga-As-Si and Ga-P-Si ternary systems. It is the objective of this paper to present systematic calculations of liquidus isotherms and component activities for both systems. The major assumption required in performing these calculations is that the activities of the liquid phase are satisfactorily described by the regular solution model (12), which has been previously applied successfully to the ternary phase diagrams of III-V compounds (13-14).

In the present work, first the adequacy of the regular solution model for Si-based systems is tested by a comparison of the ternary interchange energies (i.c.e.'s) (12) derived by a least square analysis of the liquidus data for Si-doped GaAs (no ternary data exist for Si-doped GaP), and the i.c.e.'s obtained from the liquidus of the three bounding binary systems. Second, the ternary liquidus isotherms are calculated over a wide temperature range for both the primary (Si-doped GaAs or GaP) and secondary (Ga- and As- or P-doped Si) solid phases. Third, the intersection of these phase fields as a function of temperature, *i.e.*, the ternary eutectic valley, for the Ga-As-Si and Ga-P-Si systems is given. Fourth, the thermodynamic self-consistency of the present treatment is demonstrated by a comparison of the experimental and calculated eutectic valleys for the Ga-As-Si system. Fifth, the thermodynamic activities for Si, Ga and As, or P in the liquid phase and Si in the solid phase are presented along the liquidus isotherms for the primary solid. Finally, the implications of the calculations for crystal growth and the limitations of the regular solution model in the vicinity of the compound SiAs are discussed.

Calculation of the Interchange Energies

In a previous paper (15) a general equation [Ref. (15), Eq. [11] has been derived for the liquidus surface of a doped binary compound (with doping levels less than 10^{20} cm^{-3}) in equilibrium with a regular ternary liquid solution. Applying this equation to the Ga-As-Si system, it follows that

$$2(\Delta H_f - T\Delta S_f) + RT \ln 4x^l_{Ga}x^l_{As} = \alpha_{Ga\text{-}As}[0.5 - x^l_{As}(1 - x^l_{Ga}) - x^l_{Ga}(1 - x^l_{As})] + \alpha_{Ga\text{-}Si}x^l_{Si}(2x^l_{Ga} - 1) + \alpha_{Si\text{-}As}x^l_{Si}(2x^l_{As} - 1) \quad [1]$$

where ΔS_f (8.3 eu g-atom^{-1}) and ΔH_f (12,540 cal g-atom^{-1}) are the entropy and heat of fusion of GaAs (14), the x^l's are the atom fractions of the components in the liquid solution, and the α's are the ternary i.c.e.'s. A similar equation also holds for the Ga-P-Si system.

Key words: compound semiconductors, crystal growth, doping, phase equilibria.

Table I. Interchange energies

	a (cal)	b (cal °K⁻¹)
Ga-As	4,810	−8.72
Ga-Si	2,460	—
Si-As	21,120	−16.40
Ga-P*	5,080	−5.75
Si-P*	−46,580	27.13

Heats and entropies of fusion

	ΔH_f (cal g-atom^{-1})	ΔS_f (eu g-atom^{-1})	T_f (°K)
GaAs	12,540	8.30	1511
GaP	13,820	7.95	1738
SiAs	8,340	6.15	1356
Si	12,000	7.12	1658
As	5,600	5.14	1090

* From analysis of binary data.

Based on previous studies of the contributing binary systems the temperature dependences of $\alpha_{\text{Ga-As}}$ (16) and $\alpha_{\text{Si-As}}$ (17) are satisfactorily described by relationships of the form

$$\alpha_{\text{Ga-As}} = a_{\text{Ga-As}} + b_{\text{Ga-As}}T \quad [2]$$

and

$$\alpha_{\text{Si-As}} = a_{\text{Si-As}} + b_{\text{Si-As}}T \quad [3]$$

while $\alpha_{\text{Ga-Si}}$ (17) is taken to be a constant at all temperatures. Substituting Eq. [2] and [3] into Eq. [1] the resulting equation at any liquidus temperature is linear in five unknown parameters which define the i.c.e.'s. Hence, the method of linear least squares permits the evaluation of the "best" values of the ternary i.c.e.'s from experimental data. In the calculations, the multidimensional linear least square computational technique of Businger and Golub (18) is applied via Eq. [1] to the 18 ternary liquidus points of Panish (19)[2] and Panish and Sumski (20) for the primary phase field of Si-doped GaAs and to the 14 binary liquidus points of Koster and Thoma (21) and Hall (22) for the Ga-As system. The i.c.e.'s thus obtained are listed in Table I and plotted as a function of temperature in Fig. 1 and 2.

To test the precision of fitting the liquidus data by Eq. [1] using the tabulated ternary i.c.e.'s, a comparison of the calculated liquidus temperature, T_c, with the experimental liquidus temperature, T_m, at known compositions (input data) is required. Employing the standard error of estimate defined by $\sqrt{\Sigma(T_c - T_m)^2/n}$, where n is the number of data points, as the index of precision, we find that the standard error is 2.4°, 5.1°, and 4.2°K for the binary, ternary, and combined binary and ternary points, respectively. Thus the calculated liquidus surface and the experimental data for the equilibrium of the primary solid phase are in excellent agreement, probably well within the experimental error.

[2] A + 10°C correction has been applied to the tabulated liquidus data of Panish (19), as recommended by Panish and Sumski (20), to take into account the effect of supercooling.

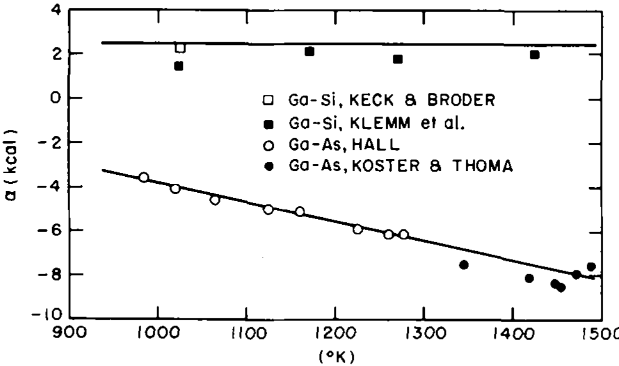

Fig. 1. Interchange energy vs. absolute temperature for the Ga-Si and Ga-As systems. The straight lines are based on the least square analysis of the ternary data.

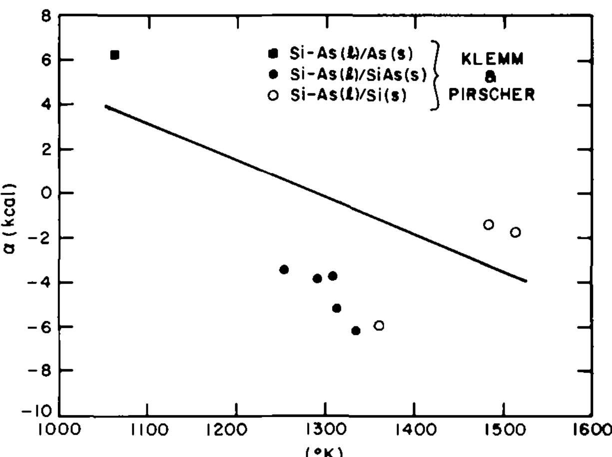

Fig. 2. Interchange energy vs. absolute temperature for the Si-As system. The straight line is based on the least square analysis of the ternary data.

Nonetheless, a realistic description of the liquidus surface in terms of the least square parameters defining the i.c.e.'s is an incomplete test for showing the applicability of the regular solution model to a given ternary system. The validity of the model can be demonstrated if the thermodynamic properties of the liquid solution, including the variation of the component partial pressures along the liquidus isotherms are satisfactorily predicted. In previous work, applying the regular solution model to the Ga-As-Zn system (14), good agreement was found between the calculated and experimental partial pressure isotherms over a wide temperature range. Unfortunately, no partial pressure data exist for the Ga-As-Si system. Consequently, other thermodynamic techniques must be invoked to check the consistency of the present treatment.

Since there are liquidus data for the three bordering binary regular solutions, i.c.e.'s can be readily calculated. In the case of the Ga-As system, $\alpha_{\text{Ga-As}}$ is obtained by applying Vieland's equation (23) (identical with Eq. [1] if $x^l_{\text{Si}} = 0$) to the data of Hall (22) and Koster and Thoma (21). The resulting discrete values of α_{GaAs} are plotted as a function of temperature in Fig. 1.

The values of $\alpha_{\text{Ga-Si}}$ or $\alpha_{\text{Si-As}}$ are derived from the solubility data for Ga- (24, 25) or As-doped (26) Si using the equation (17)

$$\alpha_{\text{Ga-Si}}(\text{or } \alpha_{\text{Si-As}}) = \frac{T\Delta S_f - \Delta H_f - RT\ln x^l_{\text{Si}}}{(1 - x^l_{\text{Si}})^2} \quad [4]$$

The accepted values of ΔH_f and the melting point of Si are 12,000 cal g-atom^{-1} and 1685°K (24), respectively, yielding $\Delta S_f = 7.122$ eu g-atom^{-1}. Although the Si-As system is rather complex (26), some additional values of $\alpha_{\text{Si-As}}$ can be evaluated from the liquidus data for SiAs(s) and As(s), employing Vieland's equation (23) and one similar to Eq. [4], respectively. The required ΔH_f for As(s) (5600 cal g-atom^{-1}) is based on the work of Horiba (28) which in combination with the melting point of As (1090°K) (29) leads to 5.15 eu g-atom^{-1} for ΔS_f. For SiAs(s), ΔS_f is estimated from the sum of the elemental entropies of fusion (30) to be 6.15 eu g-atom^{-1} giving $\Delta H_f = 8340$ cal g-atom^{-1} (the melting point of SiAs is 1356°K).

The discrete values of $\alpha_{\text{Ga-Si}}$ and $\alpha_{\text{Si-As}}$, derived from the binary liquidus data, are shown in Fig. 1 and 2, re-

spectively. It is immediately obvious from Fig. 1 and 2 that the least square lines of the ternary i.c.e.'s provide a very good description of the binary results for the Ga-As and Ga-Si systems. However, in the case of the complex Si-As system (Fig. 2), the total binary $\alpha_{Si\text{-}As}$ data [from equilibria with Si(s), SiAs(s), and As(s)] scatter more widely about the ternary least square line, representing less adequate agreement.

Unfortunately, no ternary data are available for the Ga-P-Si system. However, as a result of the reasonable over-all agreement achieved between the ternary and binary i.c.e.'s for the Ga-As-Si system, the calculation of the Ga-P-Si phase diagram, using the binary i.c.e.'s appears to be justified. Clearly $\alpha_{Ga\text{-}Si}$ is the same for both systems, while $\alpha_{Ga\text{-}P}$ and $\alpha_{Si\text{-}P}$ can be evaluated from the liquidus data for GaP (22, 31) and for P-doped Si (32) using Vieland's equation (23) and one similar to Eq. [4], respectively. As in previous work, ΔS_f for GaP is taken as 7.95 eu g-atom^{-1} (14) which yields $\Delta H_f = 13{,}920$ cal g-atom^{-1} [the melting point of GaP is 1738°K (16)]. In Fig. 3 discrete values of $\alpha_{Si\text{-}P}$ and $\alpha_{Ga\text{-}P}$ are presented together with the least square lines of the binary data. Numerical values of the α's are listed in Table I.

Calculations of the Liquidus Isotherms and Eutectic Valleys

The liquidus isotherms for the primary solid phase GaAs or GaP can be readily evaluated from Eq. [1] and the i.c.e.'s listed in Table I.[3] At a constant temperature Eq. [1] is an implicit transcendental equation in the variables x^l_{Ga} and x^l_{Si} (x^l_{As} or $x^l_P = 1 - x^l_{Ga} - x^l_{Si}$). A convenient procedure for finding x^l_{Ga} as a function of x^l_{Si} at a set temperature is Schonbrun's iterative technique (33) for nonlinear equations based on Newton's method, previously applied to the liquidus surfaces of the Ga-As-Zn and Ga-P-Zn systems (14). The initial values of x^l_{Ga} at $x^l_{Si} = 0$, required to perform these calculations, were interpolated from the Ga-As or Ga-P binary data. To assure convergence, x^l_{Ga} and x^l_{As} (or x^l_P) along the Ga- and As- (or P-) rich branches of the liquidus isotherms, respectively, were separately evaluated by incrementing x^l_{Si} from zero to a value very near the maximum in the liquidus isotherms for both branches.

[3] It should be reiterated that the liquidus surface of the Ga-As-Si system is calculated from the ternary i.c.e.'s, while that of the Ga-P-Si system is from the binary i.c.e.'s.

In addition to the calculation of the primary phase fields the relatively low solid solubility of Ga, As, and P in Si (34) facilitates the determination of the liquidus isotherms for the secondary solid phases of Ga- and As- or P-doped Si. Previously, a general thermodynamic equation has been given for an elemental semiconductor doped with two solutes in equilibrium with a ternary liquid solution (15). Introducing ternary regular solution activities into this general equation yields

$$\Delta H_f - T\Delta S_f + RT \ln x^l_{Si} = -\alpha_{Ga\text{-}As}(x^l_{Ga})^2 + (\alpha_{Si\text{-}As} - \alpha_{Ga\text{-}Si} + \alpha_{Ga\text{-}As})(1 - x^l_{Si})x^l_{Ga} - \alpha_{Si\text{-}As}(1 - x^l_{Si})^2 \quad [5]$$

where ΔH_f and ΔS_f are for Si. Note that for $x^l_{Ga} = 0$ or $x^l_{As} = 0$, Eq. [5] reduces to Eq. [4].

At a constant temperature Eq. [5] is quadratic in x^l_{Ga}. Thus at any temperature the liquidus isotherm of the secondary solid phase was obtained by incrementing x^l_{Si} and solving the quadratic equation for x^l_{Ga}.

The liquidus isotherms representing the equilibria of the primary solid phase (Si-doped GaAs) and of the secondary solid phase (Ga- and As-doped Si) with Ga-As-Si ternary melts are shown in Fig. 4 on a standard equilateral composition triangle. Similar liquidus isotherms for the Ga-P-Si system are presented in Fig. 6. For the Ga-As-Si system complete isotherms are shown at 1400°, 1300°, 1200°, and 1127°C. At 1127°C the primary and secondary phase fields are tangential; below that temperature the fields intersect at a point corresponding to the three-phase equilibria of GaAs, Si, and liquid. Thus, on the Ga-rich side between 1100° and 700°C and on the As-rich side at 1100°C, the isotherms are truncated at the three-phase points which lie on the ternary eutectic valley (dashed line). On the As-rich side, the available experimental data (19) dictate the termination of the valley by the ternary eutectic point (~1031°C) arising from the coprecipitation of SiAs, while the 1000° and 900°C liquidus isotherms of Si-doped GaAs are cut at the approximate compositions where SiAs and $SiAs_2$ appear, respectively (19).

The calculated liquidus isotherms in Fig. 4 are complemented by the ternary data of Panish (19) and Panish and Sumski (20). It should be pointed out that these are not the tabulated experimental points used in the computations but values interpolated in 100°C intervals from empirical pseudobinary liquidus curves.

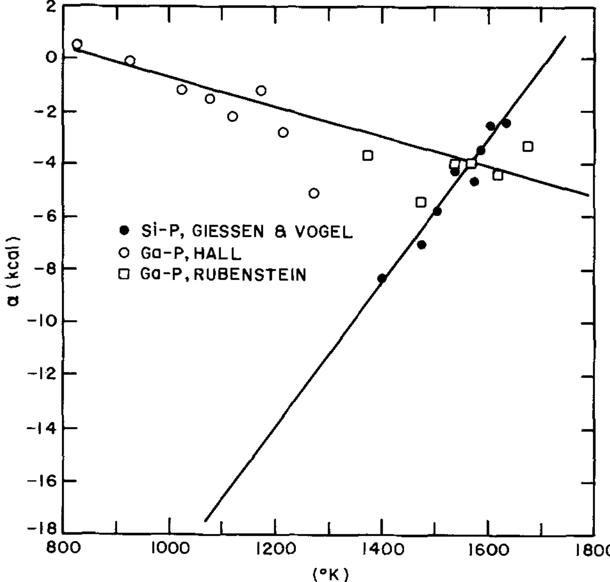

Fig. 3. Interchange energy vs. absolute temperature for the Si-P and Ga-P systems. The straight lines are from the least square analysis of the binary data.

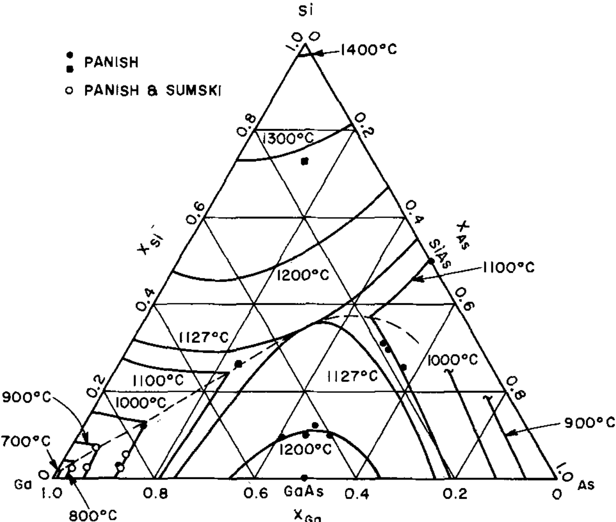

Fig. 4. Liquidus isotherms for the ternary Ga-As-Si liquid solution in equilibrium with Si-doped GaAs and Ga- and As-doped Si. The data (■) at 1100° and 1300°C correspond to equilibrium with Si. The dashed line is the ternary eutectic valley.

Reinforcing the conclusions of the error analysis in the previous section, the calculated isotherms provide a very good representation of the liquidus data for Si-doped GaAs and even for Ga- and As-doped Si.

An additional check on the thermodynamic validity of the present treatment can be obtained by a comparison of the calculated and experimental eutectic valleys in the Ga-As-Si system. In Fig. 5 the eutectic valley is replotted in the form of log x^l_{Si} and log x^l_{Ga} *vs.* reciprocal temperature. Superimposed in Fig. 5 is the experimental eutectic valley derived from published works (19, 20). It should be noted that the eutectic temperatures had been measured and the corresponding eutectic compositions were interpolated from the pseudobinary liquidus data. The agreement between experimental and calculated valleys over the entire composition range investigated is rather striking.

Along the ternary eutectic valley, $a^s_{Si} = 1$; hence the knowledge of x^l_{Si} and ΔH_f and ΔS_f for Si (27) permit the evaluation of γ^l_{Si} (activity coefficient for Si). As seen in Fig. 5 the experimental and calculated values of γ^l_{Si} are in excellent agreement.

For the Ga-P-Si system complete liquidus isotherms are given between 1400° and 1100°C in 100°C intervals (Fig. 6). At 1097°C the secondary and primary phase fields are tangential, while below that temperature the three-phase equilibria of GaP, Si, and liquid take place. On the Ga-rich side, the ternary eutectic valley is shown (dashed line) from 1097° to 800°C together with the three-phase points which terminate the isotherms drawn in 100°C intervals. The valley is replotted in Fig. 7 as a function of reciprocal temperature. The P-rich sides of the isotherms are not shown below 1100°C because of the complex phase relationships in the Si-P system resulting from compound formation and the high pressure of phosphorus (31).

Calculation of the Component Activities

It has been demonstrated in previous sections that the application of the regular solution model to the Ga-As-Si system provides an excellent description of the ternary liquidus surface, leads to an over-all consistency with the binary liquidus data, and predicts the ternary eutectic valley and the accompanying γ^l_{Si} in good agreement with experimental results. Consequently, a calculation of the component activities prevailing along the liquidus isotherms is warranted. The ternary regular solution activities for the Ga-As-Si system are given by (35)

$$a^l_{Si} = x^l_{Si} \exp\left[\frac{1}{RT}\left(\alpha_{Ga\text{-}Si}x^{l2}_{Ga} + \alpha_{Si\text{-}As}x^{l2}_{As} + x^l_{Ga}x^l_{As} \times (\alpha_{Ga\text{-}Si} + \alpha_{Si\text{-}As} - \alpha_{Ga\text{-}As})\right)\right] \quad [6a]$$

$$a^l_{Ga} = x^l_{Ga} \exp\left[\frac{1}{RT}\left(\alpha_{Ga\text{-}Si}x^{l2}_{Si} + \alpha_{Ga\text{-}As}x^{l2}_{As} + x^l_{As}x^l_{Si} \times (\alpha_{Ga\text{-}Si} + \alpha_{Ga\text{-}As} - \alpha_{Si\text{-}As})\right)\right] \quad [6b]$$

and

$$a^l_{As} = x^l_{As} \exp\left[\frac{1}{RT}\left(\alpha_{Ga\text{-}As}x^{l2}_{Ga} + \alpha_{Si\text{-}As}x^{l2}_{Si} + x^l_{Ga}x^l_{Si} \times (\alpha_{Ga\text{-}As} + \alpha_{Si\text{-}As} - \alpha_{Ga\text{-}Si})\right)\right] \quad [6c]$$

Where a^l_i is the activity of the subscripted component. A set of equations similar to Eq. [6] also holds for the Ga-P-Si system.

At any composition along a liquidus isotherm the activities for the components of the liquid phase in

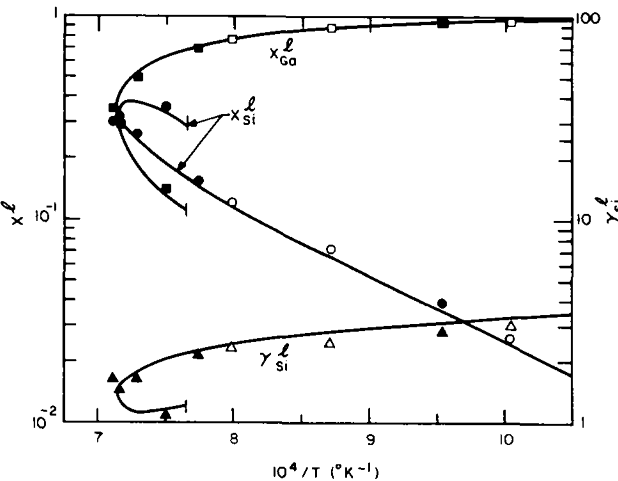

Fig. 5. The ternary eutectic valley of the Ga-As-Si system. The curves were calculated. The composition of the liquid solution (in atom fraction units) and the activity coefficient of Si are shown as a function of reciprocal temperature. The symbols □ and ○ represent values of x^l_{Ga} and x^l_{Si} from Panish and Sumski, while ■ and ● are values of x^l_{Ga} and x^l_{Si} from Panish. The data for γ_{Si} denoted by △ and ▲ are derived from x^l_{Si} ○ and ●, respectively.

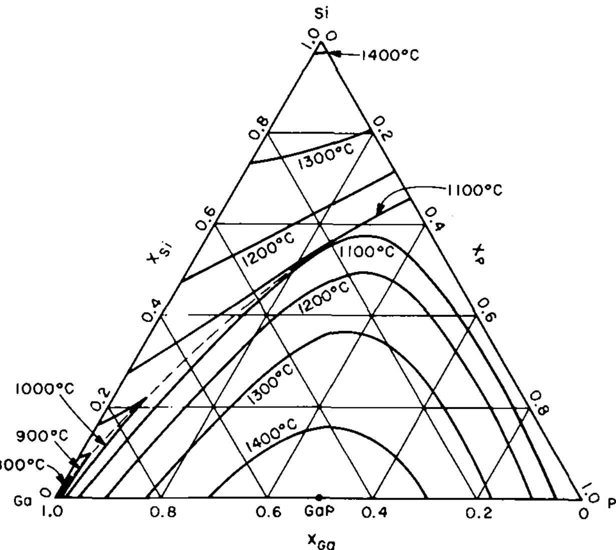

Fig. 6. Liquidus isotherms for the ternary Ga-P-Si liquid solution in equilibrium with Si-doped GaP and Ga- and P-doped Si. The dashed line is the ternary eutectic valley.

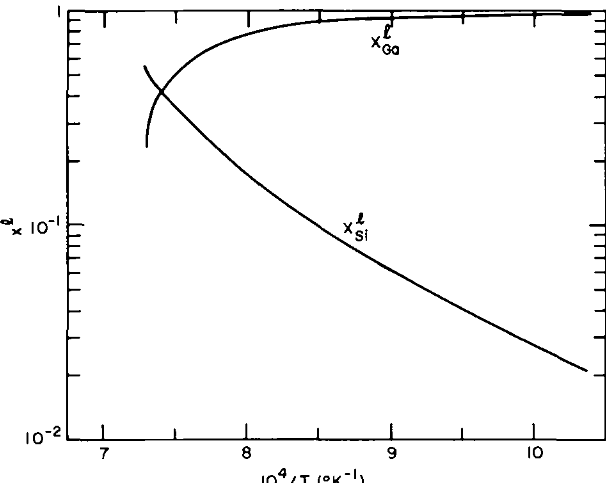

Fig. 7. The calculated ternary eutectic valley for the Ga-P-Si system. The composition of the liquid solution (in atom fraction units) is plotted *vs.* reciprocal temperature.

equilibrium with the primary solid phase can be readily calculated from Eq. [1], Eq. [6a-c], and the i.c.e.'s listed in Table I. The important activity function for silicon dissolved in GaAs, $a^s{}_{Si}$ is obtained from the relationship

$$a^s{}_{Si} = a^l{}_{Si} \exp \left[\frac{1}{RT} (\mu^{ol}{}_{Si} - \mu^{os}{}_{Si}) \right] \quad [7]$$

where $\mu^{ol}{}_{Si}$ and $\mu^{os}{}_{Si}$ are the standard chemical potentials for the supercooled liquid and solid phases, respectively, derivable from published heat capacity and heat of fusion data (27).

In Fig. 8 $a^s{}_{Si}$ and $a^l{}_{Si}$ are plotted as functions of $x^l{}_{Si}$ along the 800°, 1000°, and 1200°C liquidus isotherms of Si-doped GaAs. A complete isotherm is shown at 1200°C, while at lower temperatures the activities are for the Ga-rich branches and are terminated at the three-phase points (solid dots). In Fig. 9 and 10, $a^l{}_{Ga}$ and $a^l{}_{As}$ are presented as a function of $x^l{}_{As}$ and $x^l{}_{Ga}$,

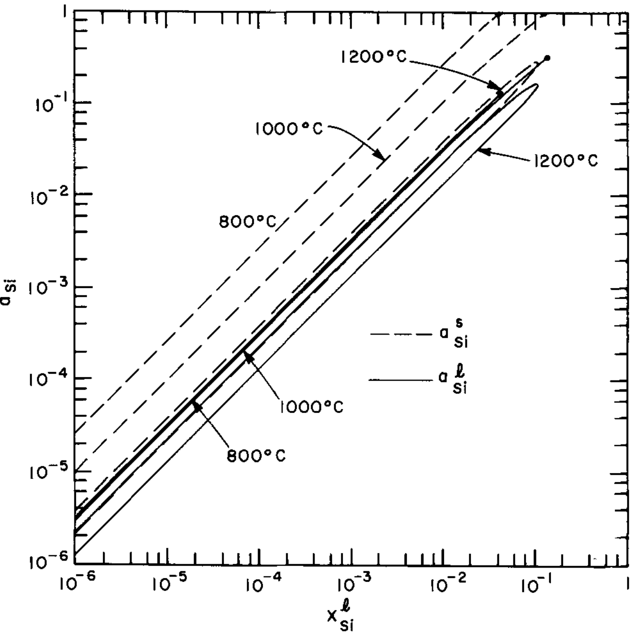

Fig. 8. The activity of Si in the liquid and the corresponding activity of Si dissolved in GaAs along the 800°, 1000°, and 1200°C liquidus isotherms for Si-doped GaAs. Only the Ga-rich isotherms are shown at 800° and 1000°C, and they are terminated at the three-phase points (solid dots).

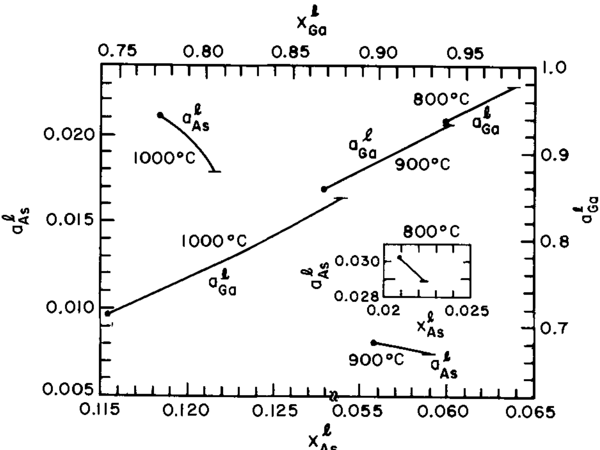

Fig. 9. Ga and As activities vs. $x^l{}_{Ga}$ and $x^l{}_{As}$, respectively, along the 800°, 900°, and 1000°C liquidus isotherms for Si-doped GaAs. The Ga-rich segments are shown from the binary limits (horizontal bars) to the three-phase points (solid dots).

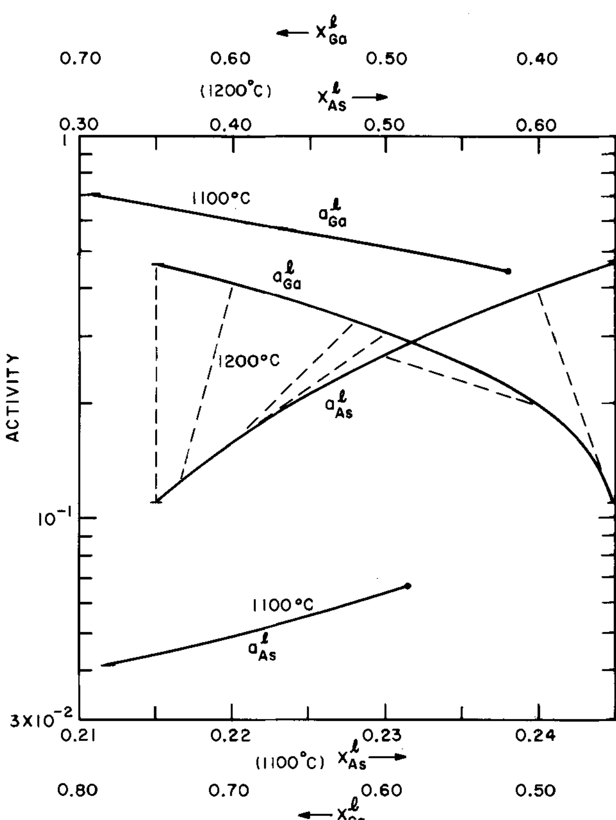

Fig. 10. Ga and As activities vs. $x^l{}_{Ga}$ and $x^l{}_{As}$, respectively, along the 1100° and 1200°C liquidus isotherms for Si-doped GaAs. At 1100°C only the Ga-rich segments are shown which terminate at the three-phase points (solid dots). The horizontal bars are drawn at the binary limiting values of the activities. At 1200°C dashed lines connect activity and liquidus information along the liquidus isotherm (see text).

respectively, from 800° to 1200°C in 100°C intervals. Between 800° and 1100°C only the Ga-rich segments of the activity isotherms are given and they are ended at the three-phase points. The dashed lines drawn in Fig. 10 at 1200°C demonstrate that the compositions along a liquidus isotherm can be combined with the activities on a single plot. At $x^l{}_{Ga} = 0.6$, 0.5, and 0.4, the $a^l{}_{Ga}$ line is connected to the $a^l{}_{As}$ line at a value of $x^l{}_{As}$ given by the liquidus isotherm of Fig. 4. A like construction for the $a^l{}_{As}$ line is given at $x^l{}_{As} = 0.4$, 0.5, and 0.6.

In Fig. 11, $a^l{}_{Si}$ and $a^s{}_{Si}$ are shown as functions of $x^l{}_{Si}$ along the 800°, 1000°, 1200°, and 1400°C liquidus isotherms for Si-doped GaP. At 800° and 1000°C only the Ga-rich branches of the activity isotherms are presented which terminate at the three-phase points. In Fig. 12, 13, and 14 $a^l{}_{Ga}$ and $a^l{}_P$ are plotted as functions of $x^l{}_{Ga}$ and $x^l{}_P$, respectively, from 800° to 1400°C in 100° intervals. Full isotherms are given at 1200°, 1300°, and 1400°C, while at lower temperatures the Ga-rich segments of the curves are truncated at the three-phase points.

Discussion

Implications of the ternary phase diagrams for heteroepitaxy.—Both the Ga-As-Si and Ga-P-Si ternary systems have the property that the eutectic valley along which Si and GaAs or GaP coexist extends to the high temperatures commonly used in the preparation of these compounds. This suggests the possibility of the technologically important heteroepitaxy of GaAs and GaP on Si. One of the major techniques of epitaxial growth is liquid-phase epitaxy (LPE). In practice, first a saturated solution of GaAs or GaP in Ga is formed; then the solution is brought into contact with a substrate. If the substrate is Si, we may analyze the

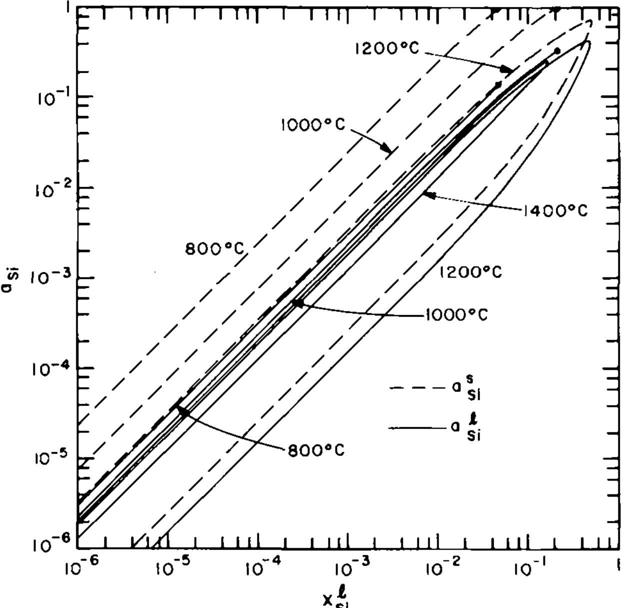

Fig. 11. The activity of Si in the liquid and the corresponding activity of Si dissolved in GaP along the 800°, 1000°, 1200°, and 1400°C liquidus isotherms for Si-doped GaP. Only the Ga-rich isotherms are shown at 800° and 1000°C, and they are terminated at the three-phase points (solid dots.)

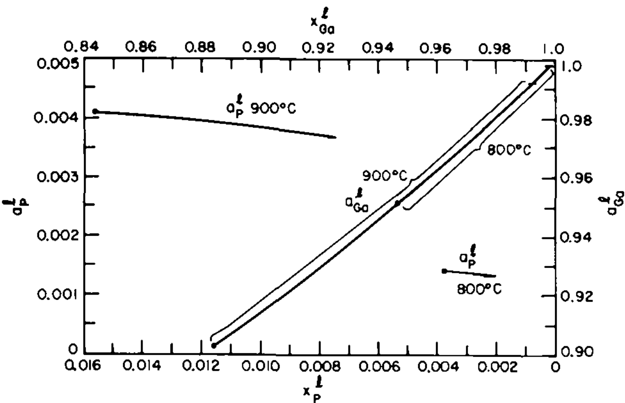

Fig. 12. Ga and P activities vs. x^l_{Ga} and x^l_P, respectively, along the 800° and 900°C liquidus isotherms for Si-doped GaP. The Ga-rich segments are shown from the binary limits (horizontal bars) to the three-phase points (solid dots).

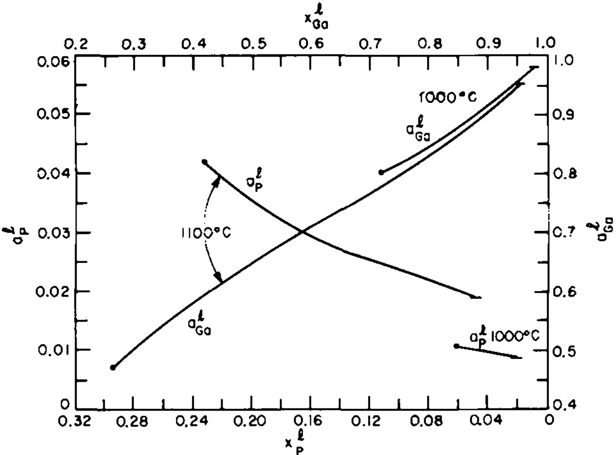

Fig. 13. Ga and P activities vs. x^l_{Ga} and x^l_P, respectively, along the 1000° and 1100°C liquidus isotherms for Si-doped GaP. The Ga-rich segments are shown from the binary limits (horizontal bars) to the three-phase points at 1000°C and its vicinity at 1100°C.

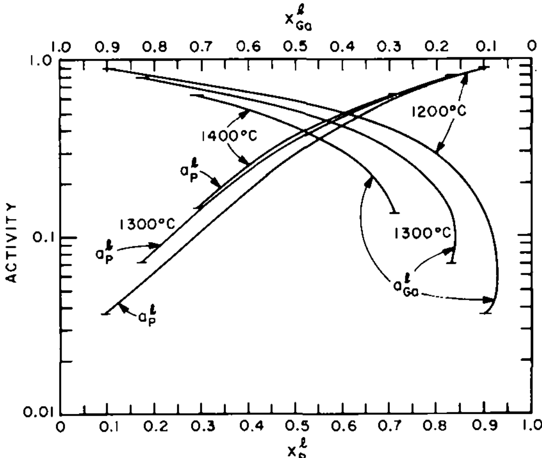

Fig. 14. Ga and P activities vs. x^l_{Ga} and x^l_P, respectively, along the 1200°, 1300°, and 1400°C liquidus isotherms for Si-doped GaP. The horizontal bars are drawn at the binary limiting values of the activities.

progress of the phase reactions with reference to Fig. 4 and 6.

As long as there is no precipitation in the ternary system the ratio of Ga/As or Ga/P in the solutions remains constant. Thus at any temperature the reaction proceeds along a line extending from the Ga-rich binary saturation point to the apex of the composition triangle ($x_{Si} = 1$). It can be seen in both systems at 1000°C that this line enters a single-phase liquid region, implying the dissolution of the Si-seed, until the isotherm for the secondary solid phase (Si) is reached. Upon cooling, Si will precipitate until the temperature is reached at which this line intersects the eutectic valley.

In order to deposit GaAs or GaP on Si it is required that the line described above immediately enter a two-phase liquid + GaAs or GaP region. According to Fig. 4 and 6, this appears possible below 900°C in the case of GaAs but not at any reasonable temperature for GaP. It is interesting to note that Rosztoczy and Stein (36) were unable to precipitate GaP on Si from a Ga-rich solution. However, they could achieve heteroepitaxy by using Pb or Sn as a solvent.

Some features of the activity diagrams.—Not unexpectedly, moving from the Ga-rich to the As- or P-rich regions of the liquidus isotherms, a_{Ga} and a_{As} or a_P decrease and increase, respectively (Fig. 9, 10, 12, 13, and 14). Appropriate combinations of a_{As} and a_P with thermodynamic data for the vapor pressure of pure liquid As (28) and P (27) yield the partial pressures of these components along the liquidus isotherms.

It is important to note that according to Fig. 8 and 11, a^s_{Si} for both systems is higher along the Ga-rich liquidus branch than along the As- or P-rich one. Hence, if the activity coefficient for Si dissolved in GaAs does not vary drastically with composition, vapor grown GaAs or GaP has a lower Si solubility (a^s_{Si} values enclosed by the branches) than crystals prepared by LPE (a^s_{Si} values along the Ga-rich liquidus isotherm).

Generally, the activities in the liquid phase are required in testing incorporation models. For example, for an amphoteric dopant such as Si, the analysis of solubility data as a function of temperature and doping level is quite complex because both Si acceptors (Si^-_{As}) and Si donors (Si^+_{Ga}) exist in the lattice.

However, based on the over-all incorporation reaction for the two species (11) viz.

$$Si(l) + As(l) = Si^{+}_{Ga} + As_{As} + e^{-} \quad [8]$$

and

$$Si(l) + Ga(l) = Si^{-}_{As} + Ga_{Ga} + e^{+} \quad [9]$$

it can be seen that the concentrations of Si^{+}_{Ga} and Si^{-}_{As} depend on the products $a_{Si}a_{As}$ and $a_{Si}a_{Ga}$, respectively. Obviously, the knowledge of the activities facilitates the separation of experimental solubilities into donor and acceptor contributions.

The limitations of the regular solution model.—It has been demonstrated in previous sections that the regular solution model provides an excellent description of the measured ternary liquidus data for the Ga-As-Si system. That the ideal solution model is inadequate to treat this system can be best illustrated with reference to the eutectic valley. According to Eq. [7], for an ideal liquid solution the equation of the eutectic valley is given by ($\gamma^{l}_{Si} = 1$, $a^{s}_{Si} = 1$)

$$x^{l,id}_{Si} = \exp\left[\frac{1}{RT}(\mu^{oS}_{Si} - \mu^{ol}_{Si})\right] \quad [10]$$

The results of sample calculations based on Eq. [10] in comparison with the data from Fig. 5 indicate that at 800° and 1100°C Eq. [10] overestimates the concentration of Si($x^{l,id}_{Si}$) at the eutectic valley by about a factor of 2.7 and 1.7, respectively.

However, as there exist no ternary liquidus data for $x^{l}_{As} > 0.6$ (19), the predictions of the regular solution model may be inaccurate in the As-rich region. One clue pointing in this direction has already been mentioned in relation to the wide scatter of the binary $\alpha_{Si\text{-}As}$ data about the ternary least square line (Fig. 2). Examining the binary data in detail, we find a minimum near the melting point of the compound SiAs. Note that a higher estimate for the ΔS_f of SiAs would decrease the $\alpha_{Si\text{-}As}$ values (full circles in Fig. 2), resulting in a steeper minimum. Clearly, according to regular solution theory, any i.c.e. such as $\alpha_{Si\text{-}As}$ measures the difference in nearest neighbor pairwise interaction energies between unlike and like bonds [$\alpha_{Si\text{-}As} = \omega_{Si\text{-}As} - 0.5\ (\omega_{Si\text{-}Si} + \omega_{As\text{-}As})$] and should be the same for a binary, ternary, or even multicomponent system. Hence, if the Ga-As-Si system at all compositions and temperatures were behaving as a perfectly regular solution then the binary $\alpha_{Si\text{-}As}$ values would not show a minimum and would exhibit a much closer agreement with the ternary least square line, as is the case for $\alpha_{Ga\text{-}As}$ and $\alpha_{Si\text{-}Ga}$.

At this time, we can only speculate about the cause of the apparent minimum in the binary $\alpha_{Si\text{-}As}$. In previous work on regular associated solutions (RAS) such a minimum in a α *vs.* composition (or temperature) curve in the Zn-Te and Cd-Te system has been interpreted in terms of the association of the atoms into ZnTe and CdTe molecules in the liquid phase (37). It is possible that the liquid phase of the Si-As system similarly consists of Si and As atoms and SiAs molecules. Unfortunately, a simple extension of the RAS theory to the ternary Ga-As-Si system was not successful because the transition from an RAS near the Si-As side to a completely dissociated ternary regular solution with the increasing addition of Ga is not rapid enough if the degree of dissociation is not a function of composition itself. Thus a good description of the Si-As binary can only be achieved at the expense of the ternary liquidus and eutectic valley data. Nevertheless, it seems qualitatively clear that the reason the ternary least square line provides no more than an approximate description of the total binary data is related to the progressive straightening out of the initially steep $\alpha_{Si\text{-}As}$ curve as the solution becomes dissociated with increasing x^{l}_{Ga}.

It is possible that the Ga-As-Ge and Ga-As-Sn systems behave similarly to the Ga-As-Si system. Recent studies show that the slope of the ternary least square lines of $\alpha_{Ge\text{-}As}$ (38) $\alpha_{Sn\text{-}As}$ (39) is of the same sign as of the ternary $\alpha_{Si\text{-}As}$. Moreover, the sign of the slope for $\alpha_{Si\text{-}As}$ and $\alpha_{Ge\text{-}As}$ are both the opposite of the slope of the line connecting the few binary $\alpha_{Si\text{-}As}$ and $\alpha_{Ge\text{-}As}$ data points for Si(s) and Ge(s) in equilibrium with their binary melts (17) (open circles in Fig. 2).

A comparison of the liquidus surface constructed from the ternary least square i.c.e.'s and the binary i.c.e.'s is instructive. To show the effect of $\alpha_{Si\text{-}As}$[4] on the ternary liquidus boundary, we selected the line going through the three data points for Si(s) (open circles in Fig. 2), thus ignoring the equilibria for SiAs(s) and As(s). Performing the calculations it is found that the standard error of estimate between the calculated and experimental ternary liquidus points is 19.1°K which should be compared with 5.1°K, obtained by the use of the ternary i.c.e.'s. The recomputed surface also possesses a ternary eutectic valley which intersects the liquidus isotherms at larger values of x^{l}_{Si}. For example, at 1000°C, the eutectic valley is at $x^{l}_{Si} = 0.251$ which should be compared with 0.135 resulting from the ternary i.c.e.'s. Obviously, the ternary least square calculation provides a superior description of the experimental data. However, even the calculation employing the binary i.c.e.'s would offer a useful guide to the phase relations in the Ga-As-Si system.

In view of the above discussion, the Ga-P-Si ternary liquidus surface which was calculated solely from the binary i.c.e.'s needs experimental confirmation. Certainly, it is not expected to depart more from the actual liquidus surface than is indicated for the Ga-As-Si system when the binary i.c.e.'s were used. To be sure, the fact that the slope of the $\alpha_{Si\text{-}P}$ line (Fig. 3) is opposite that of the ternary least square line of $\alpha_{Si\text{-}As}$ (Fig. 2) is puzzling. However, the eight discrete $\alpha_{Si\text{-}P}$ values seem to be reliable for they are located close to the least square line over a 200°K temperature range.

Conceivably, one should not trust one's intuition in expecting completely parallel bonding behavior of P and As in liquid solutions. Indeed, there are well-known differences between the chemistry of P and As. For instance, the prevalent oxide of As and P is trivalent (As_2O_3) and pentavalent (P_2O_5), respectively. Moreover, many binary phase diagrams of As and P (40), including the Si-As (26) and Si-P (32) systems. are not homologous.

In conclusion, the regular solution treatment provides a consistent analytical representation of phase equilibria in the Ga-As-Si system, in excellent agreement with experimental results over almost the entire liquidus surface. More sophisticated models which possibly involve association are needed to improve the calculation in the vicinity of the Si-As binary. In the absence of experimental data for the Ga-P-Si ternary system, the predictions presented here may only give approximate although valuable phase relations. Thus for this system, as well as for any other system, the regular solution theory should be accepted with caution and retested against fresh experimental evidence.

Acknowledgments

We express our gratitude to D. L. Rode and R. H. Saul for their critical reading of the manuscript.

Manuscript submitted Feb. 28, 1974; revised manuscript received July 5, 1974.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1975 JOURNAL. All discussions for the June 1975 Discussion Section should be submitted by Feb. 1, 1975.

The publication costs of this article have been assisted by Bell Laboratories.

[4] It should be noted that the binary and ternary least square lines for $\alpha_{Si\text{-}Ga}$ and $\alpha_{Ga\text{-}As}$ are nearly the same (see Fig. 1).

Heteroepitaxial InAs Grown on GaAs from Triethylindium and Arsine

I. Growth Characterization

B. Jayant Baliga and Sorab K. Ghandhi

Electrophysics and Electronic Engineering Division, Rensselaer Polytechnic Institute, Troy, New York 12181

ABSTRACT

Single-crystal films of InAs have been grown on semi-insulating GaAs substrates by the decomposition of triethylindium and arsine over a temperature range of 550°-650°C. The growth is mass-transport limited above 575°C and kinetically controlled below 575°C. Films of more than 0.5 μm have specular surfaces. Optimum growth conditions occur at a substrate temperature of 600°C, a flow of 2 mliters/min arsine (pure), and 2.5 liters/min hydrogen flow through the TEI bubbler.

The growth of epitaxial layers of III-V compounds using organometallic compounds as sources of the group III element and hydrides as sources of the group V element, was first reported by Manasevit and coworkers (1-3). Since then, other workers (4-6) have extensively studied the growth of GaAs by this technique, but have not investigated the growth of InAs. Although the feasibility of the epitaxial growth of InAs from triethylindium and arsine was demonstrated by Manasevit and Simpson (3), their investigations were mainly directed toward the growth and characterization of $Ga_{1-x}In_xAs$ alloys with $x \simeq 0.5$. In this paper, we wish to report on the characterization of the growth of InAs epitaxial films. The electrical properties of these layers are reported in the companion paper (7).

Experimental Conditions

Apparatus.—The epitaxial growth was carried out in a 50 mm ID quartz tube, 45 cm long, containing a molybdenum susceptor coated with SiO_2. The susceptor was heated by infrared radiation from a set of eight, 500W quartz-halogen lamps. This greatly simplified temperature measurement and allowed the use of a closed-loop temperature control. The temperature of the single hot zone was monitored by a platinum/platinum-rhodium thermocouple, enclosed in a quartz sheath and inserted into the molybdenum susceptor. A horizontal reactor system was used to simplify loading and cleaning operations. However, substrates were placed perpendicular to the gas flow to facilitate uniform growth over the entire surface.

Vapors of triethylindium[1] (TEI) were transported to the substrate by bubbling hydrogen through the liquid maintained at room temperature (25°C). Arsine gas,[2]

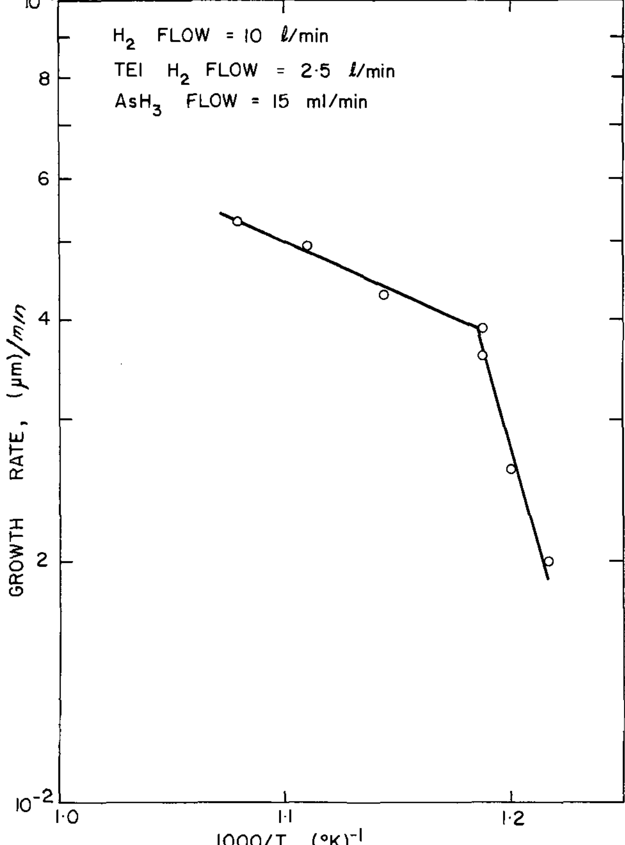

Fig. 2. Effect of substrate temperature on growth rate

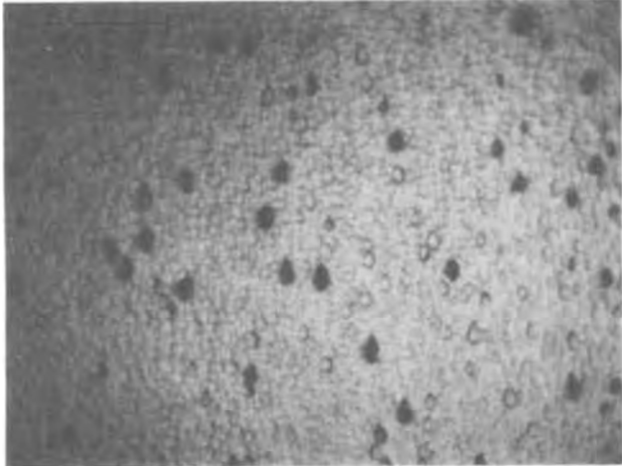

Fig. 3. Inclusions in InAs layer grown at 650°C. Layer thickness 2 μm.

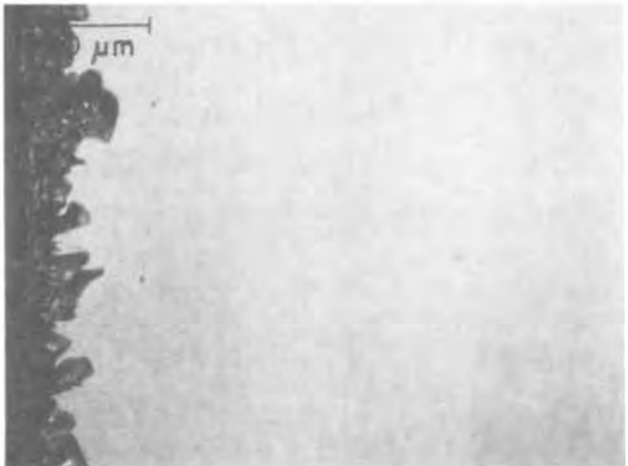
diluted to 2% in hydrogen was mixed with the TEI vapors just before entering the quartz tube. Due to the reaction between the TEI and arsine at room temperature, they were not premixed before entry to the hot zone. In addition, a separate source of ultra high purity hydrogen was used, at a flow rate of 10 liters/min in all the experiments. This carrier gas flow served to transport the reactants down the quartz tube and to minimize the formation of reaction products upstream of the susceptor. Stainless steel tubing was used throughout, in order to reduce system contamination. A schematic of the apparatus is shown in Fig. 1.

Substrate.—Epitaxial growth was carried out on (100) oriented chromium doped semi-insulating GaAs substrates, to facilitate subsequent electrical evaluation. The substrates were obtained commercially with one face polished.[3] No further attempts were made to polish the wafers. Before epitaxy, however, the substrates were thoroughly cleaned in methanol[4] and checked under an optical microscope to ensure the absence of dust particles.

Procedure.—Substrates were heated up to 500°C in hydrogen, at which point arsine was introduced into the reaction tube to suppress the sublimation of arsenic from the GaAs substrates. Arsine flows greater than 0.5 mliter/min (pure) were sufficient to prevent this dissociation from occurring up to a substrate temperature of 750°C. After stabilizing the arsine flow for 2 min, the substrate temperature was raised to the growth temperature and maintained for an additional 2 min before the introduction of TEI. Typical flow rates used were 2-15 mliters/min arsine gas (pure), and 1-2.5 liters/min hydrogen flow through the TEI bubbler. Typical growth rates under these conditions were 0.05-0.07 μm/min.

Growth rate determination.—Angle lapping and staining techniques were initially used to measure the thickness of the epitaxial layers. However, etching of the surface by the staining and plating solutions, and the presence of large depletion layer widths at the interface resulted in considerable error in determining layer thickness. Consequently, this technique was abandoned in favor of a gravimetric determination of epitaxial layer thickness. Early in the growth studies, it was determined that no loss in weight of the substrate GaAs took place in the presence of arsine flows greater than 0.5 mliter/min (pure) up to a substrate temperature of 750°C. Since the TEI-arsine reaction does not contain any etchant species, the increase in mass of the substrate after epitaxy could be directly used to determine the thickness of the epitaxial layers.

[3] Electronic Materials Corporation, Pasadena, California 91107.
[4] Substitution of methanol with more sophisticated cleaning solutions and procedures did not produce any significant change in the growth rate or surface quality of the epitaxial films.



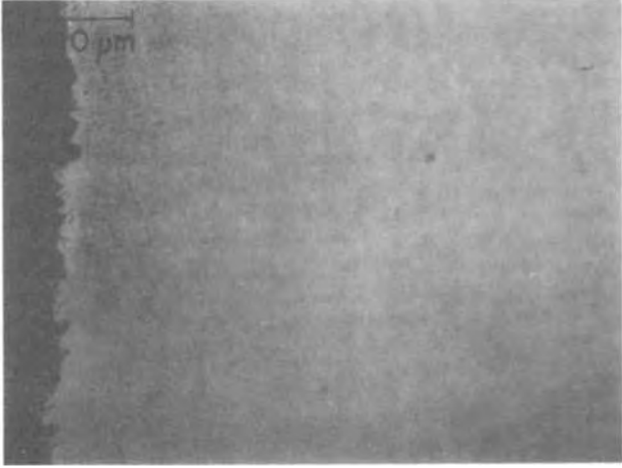


Fig. 4. Effect of substrate temperature on surface quality. (a, top) 650°C, thickness 0.53 μm; (b, center) 600°C, thickness 0.43 μm; (c, bottom) 540°C, thickness 0.57 μm.

Experimental Results

Temperature.—The effect of temperature on growth rate was determined using a flow of 2.5 liters/min of hydrogen through the TEI bubbler and a flow of 15 mliters/min of arsine (pure). Under these conditions, the growth was approximately mass-transport limited at temperatures above 575°C and kinetically controlled below this temperature, as shown in Fig. 2. The activation energy of the reaction was measured as 2.3 eV/

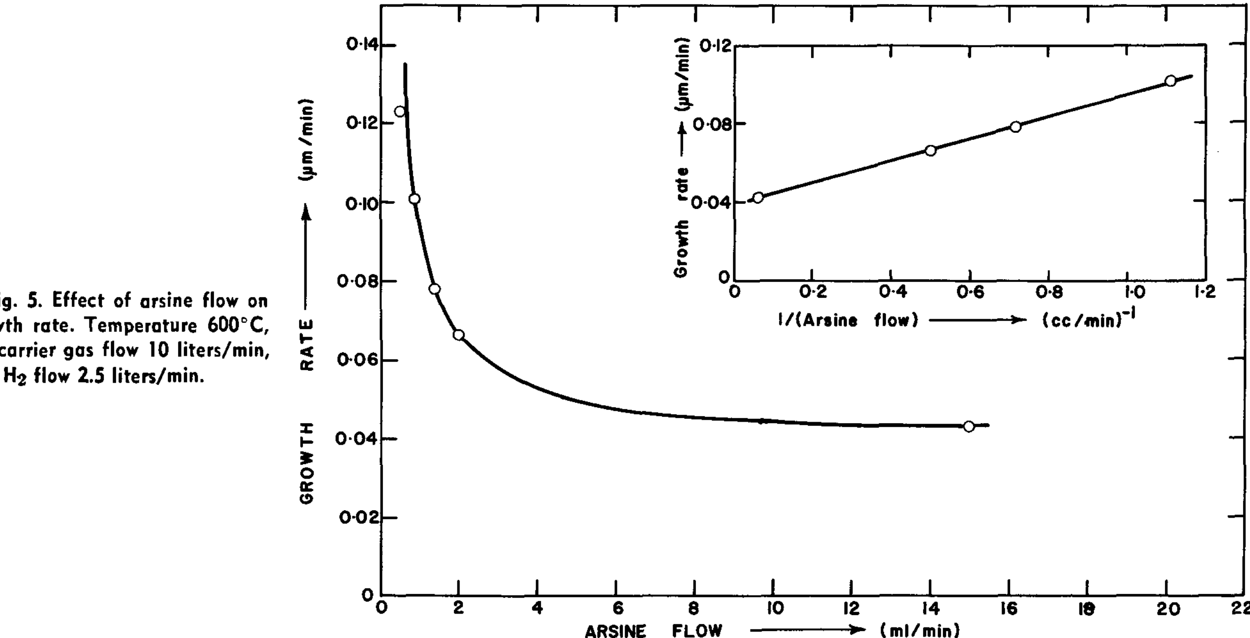

Fig. 5. Effect of arsine flow on growth rate. Temperature 600°C, H_2 carrier gas flow 10 liters/min, TEI H_2 flow 2.5 liters/min.

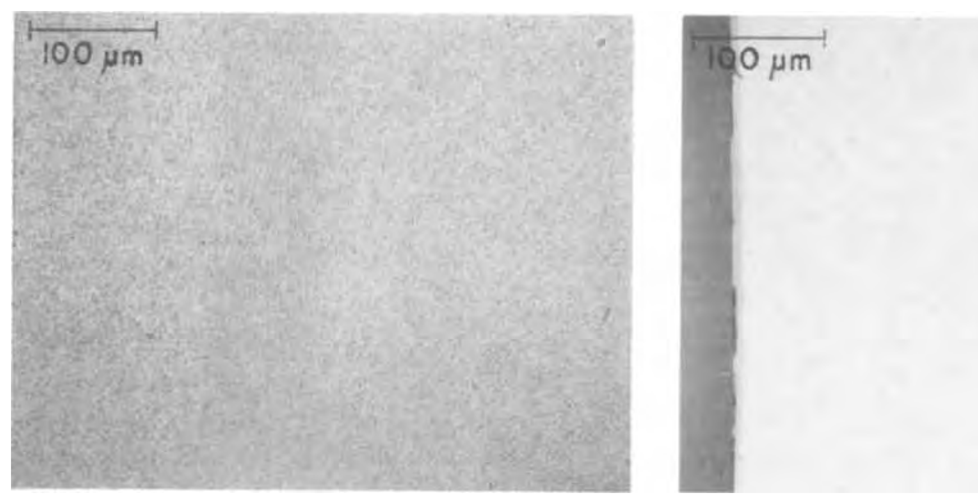

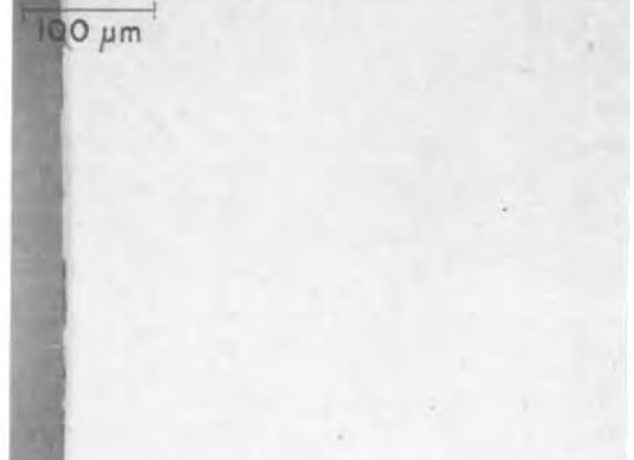

Fig. 6. Effect of arsine flow on surface quality. (a, left) 0.9 mliter/min, thickness 1.2 μm; (b, right) 1.4 mliters/min, thickness 0.80 μm; (c, bottom right) 2 mliters/min, thickness 0.65μ.

molecule. Below 550°C, polycrystalline layers were obtained with growth rates exceeding 0.05 μm/min.

Optical examination of the epitaxial layers showed that best surfaces were obtained at 600°C. At both higher, as well as lower, temperatures the surface quality deteriorated with the appearance of small black inclusions as shown in Fig. 3. The surface also changed to a poorly reflecting gray color from the bright-shiny appearance obtained at 600°C. Photomicrographs of typical surfaces are shown in Fig. 4.

Arsine flow.—The arsine flow was found to have a strong effect on the growth rate and on the surface

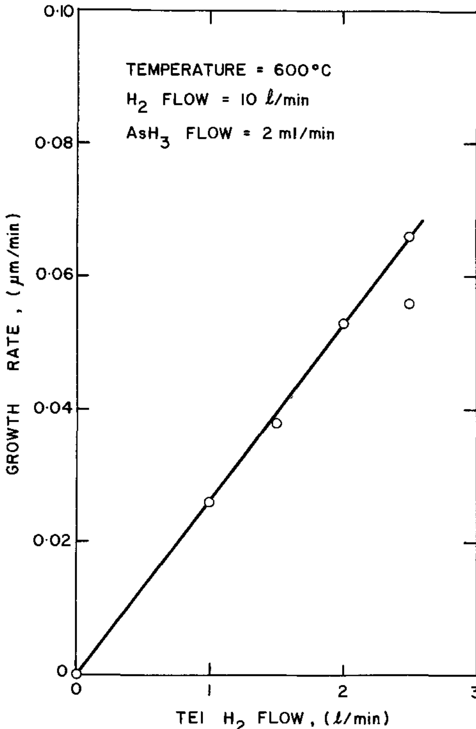

Fig. 7. Effect of increasing hydrogen flow through TEI bubbler on growth rate.

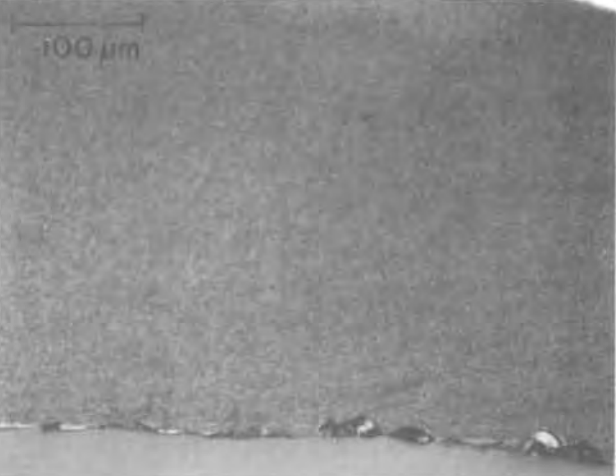
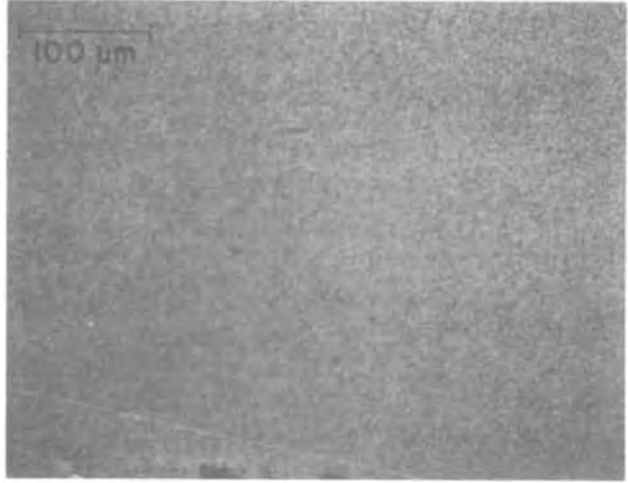
quality of the layers. Figure 5 shows the variation of growth rate with arsine flow, when the hydrogen flow through the TEI bubbler was 2.5 liters/min and the substrate temperature was 600°C. The growth rate decreased rapidly with increasing arsine flow. Retardation (8) of the heterogeneous reaction by the adsorption of arsine on the surface was verified by the linear variation of growth rate with reciprocal arsine flow, as shown in the inset of Fig. 5.

Good specular surfaces were obtained for arsine flows (pure) ranging from 1.4 to 15 mliters/min. However, a marked degradation in surface quality was observed for arsine flows less than 1.4 mliters/min (pure). Photomicrographs of typical surfaces are shown in Fig. 6.

TEI flow.—Figure 7 shows the growth rate of the epitaxial films as a function of hydrogen gas flow through the TEI bubbler for a substrate temperature of 600°C and an arsine flow (pure) of 2 mliters/min. This data has not been presented using an equivalent flow of TEI because of the unknown vapor pressure of this metalorganic compound at room temperature. Note, however, the use of high flow rates necessitated by its low vapor pressure (estimated to be less than 0.1 mm of Hg at 25°C). The growth rate is seen to be linear with gas flow through the bubbler, indicating an absence of saturation in the transported TEI over this flow range.

An improvement was observed in the surface quality of the epitaxial layers with increasing gas flow through the TEI bubbler, as shown in Fig. 8. Since the arsine flow used in these experiments was sufficient to produce specular surfaces over the entire range of hydrogen flow through the TEI bubbler, we conclude that the improvement in surface quality is primarily due to increasing film thickness. This is to be expected, in view of the large mismatch between the lattice parameters of the GaAs substrate and the InAs epitaxial film. The effects of strain induced by this mismatch decrease as each atomic layer is grown, resulting in a consequent improvement of surface quality with film thickness.





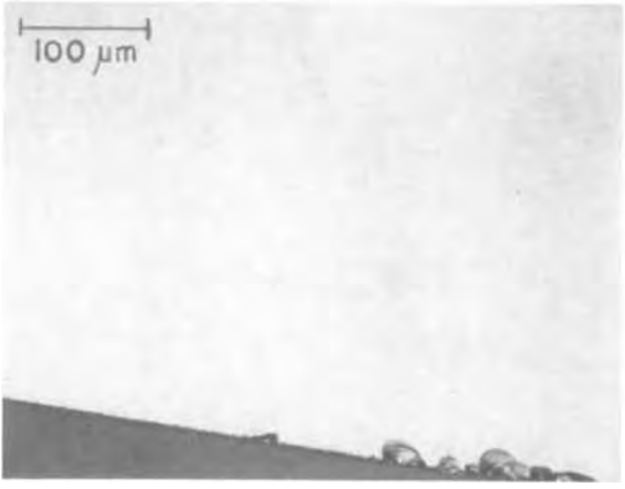


Fig. 8. Effect of increasing film thickness on surface quality. (a, top) Thickness 0.26 μm, 1.0 liter/min H_2 flow in TEI; (b, center) thickness 0.38 μm, 1.5 liters/min H_2 flow in TEI; (c, bottom) thickness 0.53 μm, 2.0 liters/min H_2 flow in TEI. AsH_3 flow in all cases was 2 mliters/min.

Conclusions

Heteroepitaxial InAs films with specular surfaces can be grown on GaAs substrates using the reaction between triethylindium and arsine. The growth is mass-transport limited above 575°C and kinetically controlled below 575°C, with an activation energy of 2.3 eV/molecule under our experimental conditions. Polycrystalline layers are obtained below 550°C. Lay-

ers of less than 0.5 μm have poor surfaces due to the large mismatch in lattice constants between InAs and GaAs, but become specular at large thicknesses. Best surfaces are obtained at a substrate temperature of 600°C, a flow of 2 mliters/min arsine (pure), and 2.5 liters/min hydrogen flow through the TEI bubbler. Since the reaction is mass-transport limited at the optimum growth conditions, good control over the growth rate can be obtained without stringent requirements on the substrate temperature. Furthermore, the growth rate can be varied over a wide range by adjusting the gas flows in the system.

Heteroepitaxial InAs Grown on GaAs from Triethylindium and Arsine

II. Electrical Properties

B. Jayant Baliga and Sorab K. Ghandhi

Electrophysics and Electronic Engineering Division, Rensselaer Polytechnic Institute, Troy, New York 12181

ABSTRACT

Heteroepitaxial films of InAs on GaAs substrates, grown by the decomposition of triethylindium and arsine, have been characterized. Films with mobilities of up to 10,000 cm^2/V-sec have been obtained. The mobility remains approximately constant with decreasing thickness up to an epitaxial layer thickness of 1 μm. A theory is presented for the variation in defect density in epitaxial layers as a function of the growth temperature and layer thickness. The carrier concentration of the InAs layers decreases exponentially with increasing substrate temperature and decreases inversely with increasing layer thickness, in accordance with this theory.

In the preceding paper (1), the growth characteristics of InAs films made by reacting triethylindium (TEI) and arsine were described. InAs films were first grown by this technique by Manasevit and Simpson (2) on sapphire and GaAs substrates. Films of 0.5-1.1 μm in thickness were reported to have carrier concentrations of greater than 10^{17} cm^{-3} and mobilities ranging from 6700 to 11,200 cm^2/V-sec. No details of the variation of the electrical properties of these layers with growth parameters were reported for these films. In this paper, we wish to describe the electrical properties of InAs layers grown on GaAs substrates, under the growth conditions described in the companion paper (1).

Experimental Conditions

Epitaxy was performed on (100) oriented, chromium-doped semi-insulating GaAs wafers to facilitate electrical characterization. The films were grown over a temperature range of 550°-650°C with typical gas flow rates of 15 mliters/min arsine and 2.5 liters/min hydrogen flow through the TEI bubbler. Typical growth rate under these conditions was 0.05 μm/min. Details of the growth characteristics are described in the companion paper (1).

Key words: heteroepitaxy, chemical vapor deposition, organometallic compounds, indium arsenide, gallium arsenide.

The mobility and carrier concentration of these films were measured by using conventional bridge samples in a Hall effect apparatus. The bridge samples were obtained by coating the epitaxial layer with silicon dioxide at 400°C using the oxidation of silane, followed by conventional photolithographic delineation of the oxide. The oxide was then used as a mask for etching the epitaxial layer in Caro's etch (1:1:1 = H_2O_4:30% H_2O_2:H_2O). Ohmic contacts were made to the arms by using silver conducting paint, applied at room temperature.

Mobility

The lattice constants of GaAs and InAs are 5.654 and 6.058Å, respectively, resulting in a lattice mismatch of more than 7%. This large mismatch is accommodated during epitaxy by the generation of defects in the InAs layer. The electrical properties of the epitaxial layers are expected to be dominanted by the presence of these defects.[1] Since the defect density is expected to vary within the epitaxial layer, the mobility and carrier concentration are expected to be functions of layer thickness. The interpretation of Hall measurements must be made with due consideration to this variation (3).

[1] The mean free path of carriers in InAs is much smaller than the thickness of the thinnest films considered in this work. Therefore, we do not expect surface scattering effects to be important in our films.

The conductivity voltage can be shown to be proportional to

$$\left[\int_0^d n\mu\, dz\right]^{-1}$$

where n and μ are the carrier concentration and mobility of a layer of thickness dz at thickness z, and d is the total layer thickness. The Hall voltage is proportional to the ratio of

$$\left[\int_0^d n\mu^2\, dz\right] \text{ to } \left[\int_0^d n\mu\, dz\right]^2$$

To determine the mobility in the layers as a function of thickness, plots of

$$\int_0^d n\mu\, dz \text{ and } \int_0^d n\mu^2\, dz$$

were made *vs.* d for a 7.2 μm layer which was successively etched down. The slopes of these curves were used to calculate μ *vs.* d. The calculated mobility varied between 10,000 and 12,000 cm^2/V-sec. Therefore, we conclude that the mobility in the layers was essentially constant between 1 and 7.2 μm. This result indicates that polar optical scattering is dominant in layers greater than 1 μm in thickness. The defect density is expected to be large at the GaAs-InAs interface, and lower mobilities are expected for layers much thinner than 1 μm. The mobility of a large number of different epitaxial samples is shown in Fig. 1. These films have been grouped according to their thickness in order to show the strong influence of this parameter on mobility. The carrier concentration is averaged over the layer thickness.

Mobilities of 20,000 cm^2/V-sec have been reported for heteroepitaxial InAs on GaAs substrates, grown by using the chloride transport of indium, and either arsine (4) or arsenic trichloride (5, 6) as a source of arsenic. These layers had thicknesses on the order of 50 μm. Lower values of 10,000 cm^2/V-sec, with comparable carrier concentration and thickness, have been obtained by Allen and Mehal (7), using the chloride transport of indium with arsine as the source of arsenic.

The mobility of our 7 μm (thick) epitaxial layer is comparable to that reported by the above authors. However, comparison of the mobility of our thin epitaxial layers with those grown by the above-mentioned techniques is not possible because of the lack of available information on thin epitaxial layers grown by the above techniques. Godinho and Brunnschweiler (8) have reported on the mobility of thin InAs films on GaAs substrates, produced by vacuum evaporation. They find a similar variation in mobility with decreasing thickness.

Carrier Concentration

Figure 2 shows the variation of carrier concentration with growth temperature for a number of films of InAs, keeping the other growth parameters constant. This behavior is significantly different from that observed during the growth of GaAs epitaxial layers on GaAs substrates, where it is usually found that the carrier concentration increases with increasing substrate temperature, because of doping from the gas phase (9). We believe that the doping concentration *vs.* growth temperature dependence of our films can be explained by considering the point defects in the layers as the primary source of the carrier concentration.

Theory.—Since the InAs epitaxial layers are grown on GaAs substrates, a large density of point defects is present at the interface between the film and the substrate. This defect density is given by 4 $(a_{GaAs}^{-2} - a_{InAs}^{-2}) = 1.61 \times 10^{14}$ cm^{-2} for the (100) surface, if an abrupt interface between GaAs and InAs is assumed (10). Additional defects can arise from thermal cycling, due to the difference in lattice expansion coefficients. Since the substrate orientation is (100), equal numbers of defects can be expected to occur at the indium and the arsenic sites. However, because of the large hole to electron effective mass ratio, the donor defect level will be shallower than the acceptor level, leading to a net n-type doping of the epitaxial layers. All the InAs layers, grown in the absence of intentional doping, were indeed found to be n-type as expected from the above argument.

The variation in defect density with temperature and film thickness can be theoretically calculated using a simple atomic layer growth model. In this model, it is

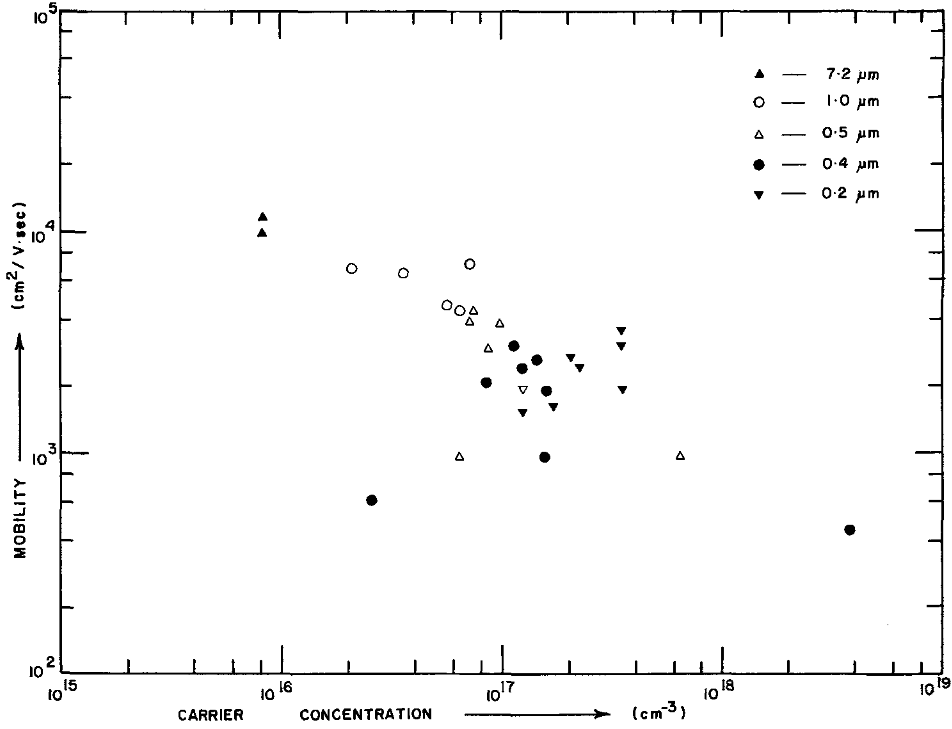

Fig. 1. Mobility vs. carrier concentration of InAs epitaxial layers.

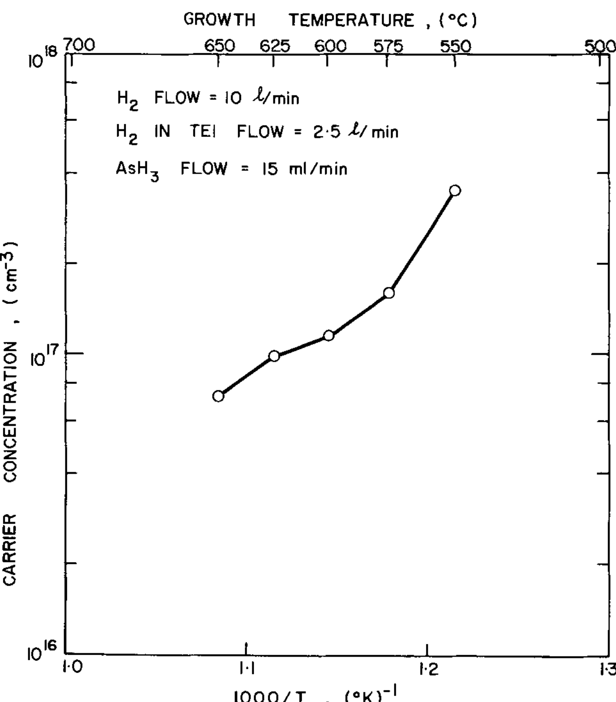

Fig. 2. Effect of substrate temperature on carrier concentration

assumed that g defects per unit area are present at the substrate layer interface. During epitaxial growth, annihilation of defects takes place by the encounter between atoms from the gas phase and lattice voids on the growing surface. The probability of such encounters is proportional to the concentration of voids in the lattice and the mobility of gas atoms on the epitaxial surface.

The concentration of defects in each growing monolayer is, therefore, proportional to their concentration in the previous monolayer. Thus, the addition of each atomic monolayer to the epitaxial film will reduce the defect density by a constant fraction q. The defect density in the first monolayer is thus $g\ (1 - q) = gp$, in the second monolayer gp^2, in the third monolayer gp^3, etc., until there is a defect density of gp^m in the mth monolayer. The thickness of the epitaxial layer, composed of m monolayers, is ma, where a is the lattice constant of the growing film. The average volume concentration of defects in the epitaxial layer is thus given by

$$n_D = \frac{1}{ma} \sum_{r=1}^{m} gp^r \quad [1]$$

$$= \frac{g}{ma} \frac{(1 - p^m)}{(1 - p)} \quad [2]$$

since $p < 1$. For epitaxial layers of even a few thousand angstroms in thickness, m becomes very large. Hence

$$n_D \simeq \frac{g}{(1 - p)} \cdot \frac{1}{ma} = \frac{g}{q} \cdot \frac{1}{d} \quad [3]$$

where d is the layer thickness.

The quantity q, the probability of annihilation of defects due to the addition of each monolayer, is proportional to the surface mobility of atoms arriving from the gas phase. In general, this surface mobility follows an Arrhenius law, exp $(-W/kT)$, where W is on the order of 0.5 eV/molecule (11). Therefore

$$n_D \propto \frac{e^{W/kT}}{d} \quad [4]$$

In other words, the defect density of thin epitaxial layers should vary inversely with the thickness of the layer and decrease exponentially with increasing growth temperature. Decrease in defect density with epitaxial layer thickness is expected to occur in both homoepitaxial growth, where defects at the interface may arise from the presence of defects in the substrate and from contaminants on the substrate surface, and in heteroepitaxial growth, where defects at the interface arise primarily from lattice mismatch. Such behavior has been reported for homoepitaxial GaAs films by Williams (12) and for heteroepitaxial films by Takahashi *et al.* (13). In both cases, although a large number of defects were observed at the epi-substrate interface, a decrease in defect density was reported with increasing epitaxial film thickness, as evidenced by a corresponding decrease in etch pit density. This type of behavior is expected to occur in all epitaxial films. If the defects are active and give rise to energy levels which lie in the bandgap of the epilayer, a variation in carrier concentration according to Eq. [4] is also expected to occur in these epitaxial layers.

An exponential decrease in the product of the carrier concentration and the thickness of the epitaxial layers was observed in the case of our InAs layers, as shown in Fig. 3. Here, the data of Fig. 2 is replotted after accounting for the thickness of the layers. From this data, W is approximately 0.4 eV/molecule. These results show that the carrier concentration is due to the presence of defects produced by the large lattice mismatch and is not sensitive to the growth rate.

It was shown earlier that the mobility of the InAs layers was essentially constant in the range of thicknesses used in this study. Using a constant μ we can obtain

$$\left[\int_0^d n dz \right]$$

from the measured Hall and conductivity voltages. Therefore, the measurements yield average values of the carrier concentration as a function of the layer thickness and can be directly compared with the results predicted by the theory. Figure 4 shows the measured average carrier concentration as a function of thickness for a 7.2 μm layer (grown at 600°C), which

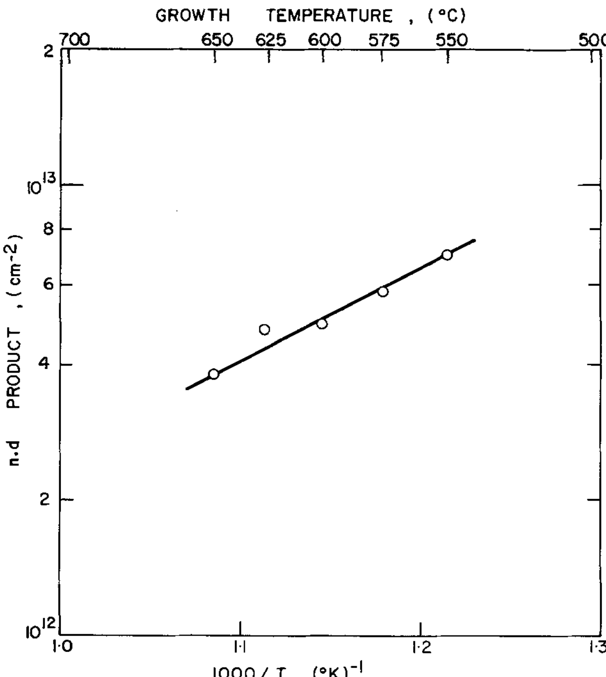

Fig. 3. Product of carrier concentration and thickness of epitaxial layers vs. substrate temperature.

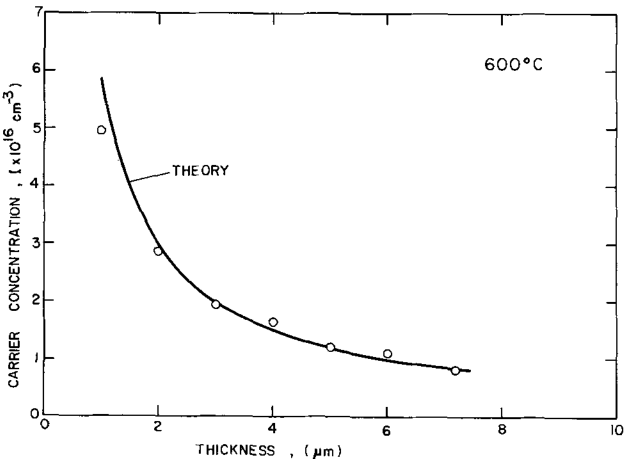

Fig. 4. Carrier concentration vs. thickness for 7 μm InAs layer which has been successively etched down.

was successively etched down, together with the theoretical curve based on an $n \cdot d$ product of 4.9×10^{12} cm^{-2} as obtained from Fig. 3. Excellent agreement between theory and data is observed. Further confirmation was obtained by plotting the carrier concentration of layers, grown under the widely varying growth conditions of Table I, as a function of thickness. Figure 5 shows the results for films grown at 600°C with hydrogen flow through the TEI bubbler ranging from 1 to 2.5 liters/min, and arsine flows ranging from 0.9 to 15 mliters/min. The theoretical curve is again based on an $n \cdot d$ product of 4.9×10^{12} cm^{-2} obtained from Fig. 3. These results show that the carrier concentration of layers of InAs grown in this study is due to the presence of defects in the epitaxial layer and not due to doping from impurities in the source material.

No data are available on the carrier concentration *vs.* thickness of thin InAs layers grown on GaAs substrates by other techniques. The carrier concentration of thin getter-evaporated InAs films on glass substrates has been reported by Howson and Malina (14), and decreased inversely with film thickness in agreement with our theory. The $n \cdot d$ product, calculated from a fit to their data, was on the order of 10^{14} per cm^2. This large value is probably caused by the low growth temperatures (200°-500°C) and the amorphous substrates used for their depositions.

From the above, it is seen that the $n \cdot d$ product of epitaxial layers is determined by two important factors: the defect density at the interface, g, and the surface mobility of the gas atoms during growth. These factors are dependent on the temperature of the reaction, the type of reactants used, and the type of surface treatment prior to epitaxial growth. The $n \cdot d$ product of epitaxial layers could, therefore, be used as a figure of merit for the technique used to grow the layers. A small $n \cdot d$ product would be indicative of low defect densities at the epi-substrate interface and/or a fast fall off in defect density with increasing epitaxial layer thickness, indicating a superior method for epitaxial growth. This method, of course, would be valid only for those semiconductors in which defects are active and produce unequal carrier densities in the conduction and valence bands. This is indeed the case for the majority of III-V and mixed III-V compounds.

Table I. Data on InAs layers grown at 600°C

Sample	TEI H_2 (liters/min)	AsH_3 (mliters/min)	d (μm)	n (cm^{-3})	$n \cdot d$ (cm^{-2})

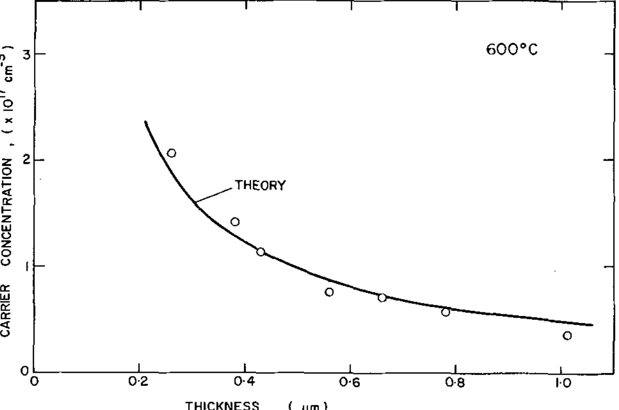

Fig. 5. Carrier concentration vs. thickness for InAs layers grown at 600°C under a wide range of TEI and arsine flows.

Conclusions

Heteroepitaxial InAs layers on GaAs substrates can be produced using triethylindium and arsine with electrical properties comparable to those obtained by vacuum evaporation and chloride transport techniques. The carrier concentration of these films is dominated by the presence of defects created at the interface between the film and the substrate by the large difference in lattice constants.

A theory has been developed for the variation in defect density with epitaxial layer thickness and substrate temperature for general heteroepitaxial growth. The carrier concentration of the InAs layers varies inversely with layer thickness and decreases exponentially with increasing substrate temperature, in agreement with this theory. It is suggested that the $n \cdot d$ product of heteroepitaxial layers be used as a figure of merit for the epitaxial growth technique, a smaller $n \cdot d$ product indicating a superior technique. This technique can also be used to establish the minimum thickness of interface layer which must be grown before good quality material is achieved and should have considerable technological importance in electro-optic and other heteroepitaxial systems.

Asymmetric Cracking in III-V Compounds

G. H. Olsen, M. S. Abrahams, and T. J. Zamerowski

RCA Laboratories, Princeton, New Jersey 08540

ABSTRACT

Experimental evidence for unidirectional cracking in III-V compounds is presented. The crack direction is shown to be a function of the sign of the applied stress and follows the asymmetry of the zinc blende structures. The critical stress for cracking in InGaP/GaAs in tension was found to be $E/660$ ($\sim 4.5 \times 10^9$ dynes/cm^2). Cracks in InGaP and GaAsP grown on GaAs substrates are related to the zinc blende asymmetry with the aid of Sirtl's etch. A fracture mechanism which introduces asymmetric dislocations into the Cottrell fracture mechanism is advanced. Asymmetries in elastic bending and "cross-hatch" patterns are discussed. The question of "glide" *vs.* "shuffle" dislocations is also considered.

Asymmetry in zinc blende structures has recently been discussed by Abrahams *et al.* (1). These authors demonstrate the general asymmetries found in zinc blende structures (as compared to the diamond structure) and go on to show how these considerations predict the existence of like-sign asymmetric dislocations along <110> directions. They then present experimental evidence which demonstrates that misfit dislocations in graded InGaP and GaAsP structures do indeed exhibit asymmetry in that their configurations along one [011] direction are different than those along the perpendicular [01$\bar{1}$] direction. These asymmetric configurations are in turn used to justify previous assertions (2, 3) of differing dislocation velocities between group III (α) and group V (β) dislocations. The purpose of this paper is to present evidence for asymmetric fracture in several III-V vapor phase epitaxy (VPE) crystals and to show how this phenomenon may be explained by a fracture mechanism which involves asymmetric dislocations. Some related phenomena will also be discussed.

Experimental

Single-crystal alloys of InGaP and GaAsP were deposited via chemical vapor deposition on (100) GaAs substrates by well-known techniques (4, 5). Growth temperatures were typically ~700°C. No compositional grading was employed during the growth of these alloys. The alloy composition was determined by photoluminescence (6) and in some cases by x-ray diffraction. Etch procedures have been described elsewhere (7, 8).

Asymmetry in Zinc Blende Structures

The asymmetry between <011> and <01$\bar{1}$> type directions in zinc blende is a well-known property which may easily be demonstrated in GaAs with the aid of Sirtl's etch (7, 8). Strictly speaking, two <011> directions in zinc blende cannot be called "asymmetric" since by definition of the zinc blende structure, they are not symmetrically equivalent. However, since the cracking phenomena along these two directions is asymmetric, the term "asymmetry" will be used here to denote the asymmetric cracking. Figure 1(a) shows a (100) polished wafer of GaAs etched in the Sirtl solution (8) for 3 min. The unequal sides of the rectangular etch figures (which are "hillocks" as opposed to pits) lies parallel to [011] and [01$\bar{1}$] directions and may be used to distinguish the two directions in the (100) plane. This behavior contrasts with Sirtl etch figures on (100) Si, which are square (8), and demonstrates the nonequivalence of <011> and <01$\bar{1}$> type directions lying in a {100} plane. The Sirtl etch figures on GaAs have not yet been related to a defect structure, although they have been related to dislocations in Si. A startling difference may be observed on the opposite ($\bar{1}$00) face of the GaAs wafer [Fig. 1(b)]. It is seen that the rectangular etch figures on ($\bar{1}$00) are rotated by 90° with respect to those on (100). However, this rotation is entirely consistent with the 90° rotation of symmetry which is observed in zinc blende structures when changing from one sublattice to another or when a 180° rotation is performed about an <011> direction (see Fig. 2). It is evident then that one side of the etch figure (*e.g.*, the long or short side) may be associated with an <011> direction of particular symmetry. The asymmetry of this direction is evidenced not by the atoms lying in the direction, but by the positions of the nearest neighbor atoms. The following discussion, which describes how directions in zinc blende structures may be uniquely referenced, will clarify this point.

Let the two sublattices be labeled A and B (see Fig. 2). Any atom in a {111} plane contains four bonds to its opposite species. However, only one of these bonds is normal to the given {111} plane. This bond direction is conventionally used as a vector to identify the plane. Inspection shows that parallel A and B planes have identification vectors which are antiparallel. Thus, if a unit cell is chosen with B atoms at its corners, then the $\{111\}_B$ planes may be referred to as ($\overline{111}$), (1$\bar{1}\bar{1}$), ($\bar{1}\bar{1}$1)...

The nature of the Sirtl etch figures is not well understood, although much work has been devoted to this

Key words: Sirtl etch, misfit, cross-hatch, asymmetric dislocation.

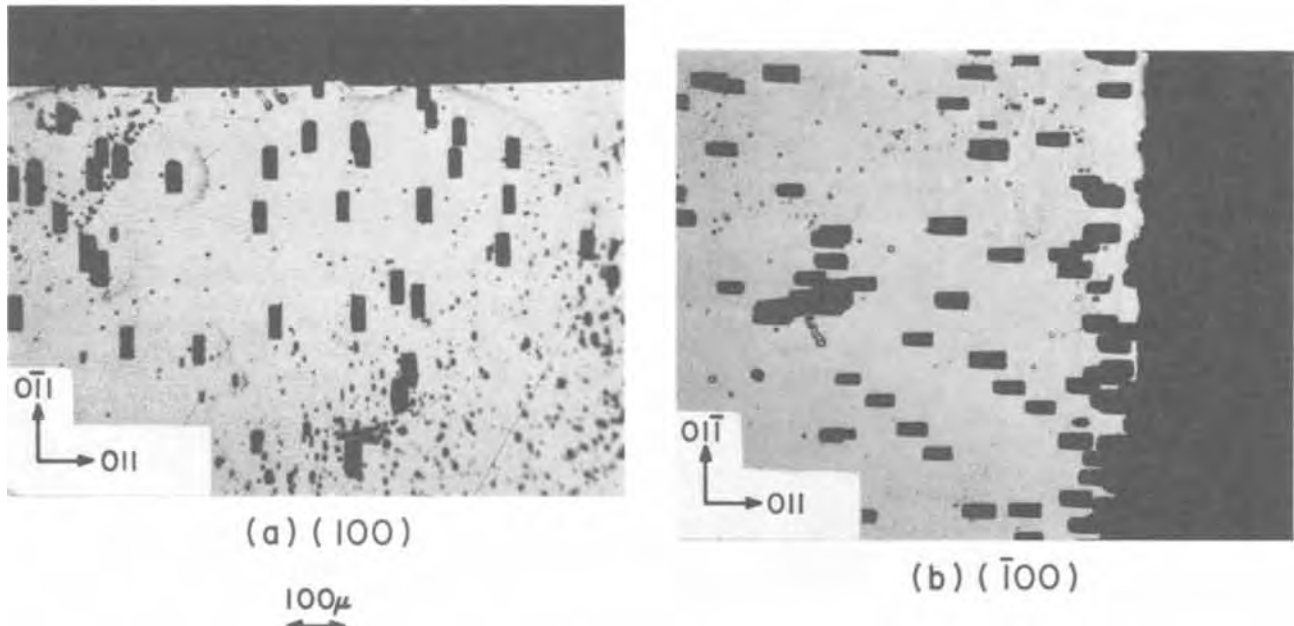

Fig. 1. Sirtl etch figures on both sides of a (100) GaAs substrate. The axis of rotation between (a) and (b) is [011].

problem. Figure 3 shows SEM photographs of a Sirtl-etched (100) GaAs wafer. Although the geometries of the etch figures were found to vary considerably, the length/width ratio was found to be relatively constant (~2·3). Nevertheless, the work of Tarui *et al.* (8) on GaAs shows that the angle between $\langle 111 \rangle_{As}$ directions and the $\langle 100 \rangle$ direction in $\langle 011 \rangle$ planes is 54° 44′ along the short axis of the Sirtl etch figure and 125° 16′ along the long axis. Therefore, Sirtl etching of GaAs provides a means for the unique determination of crystallographic directions as well as a differentiation of $\langle 011 \rangle$ and $\langle 01\bar{1} \rangle$ type directions.

Cracking in InGaP and GaAsP on GaAs

The growth of InGaP/GaAs will be considered first. One advantage of this system is that a lattice-matched condition can be approached by the direct deposition of ~$In_{0.49}Ga_{0.51}P$/GaAs. The alloy can then be graded (if desired) to a different composition in order to achieve desired electrical and/or optical properties. An exact lattice match can occur only at one temperature since the thermal expansion coefficients of the two materials are different (9). If a lattice match occurs at 700°C (~49.5% In), then a compressive strain of ~0.09% will exist in the InGaP at room temperature. However, if a room-temperature lattice match is to be achieved, a tensile stress of ~0.09% must be incurred at the growth temperature. (From a mechanical point of view, the high-temperature match is to be preferred since slip is less likely to occur at lower temperatures.) A plot of strain in the InGaP layer *vs.* In composition is shown in Fig. 4 for the two temperatures.

During the preparation of such structures, unidirectional striations were sometimes observed on the composite crystal as seen in Fig. 5. Close examination revealed that these striations were cracks which extended along a single $\langle 011 \rangle$-type direction and that they only appeared in structures where a critical misfit between the InGaP and GaAs had been exceeded. Structures in which the InGaP was strained in tension by the GaAs substrate ($a_{InGaP} < a_{GaAs}$) appeared to exhibit cracks when the misfit exceeded ~0.15%, whereas those in compression ($a_{InGaP} > a_{GaAs}$) were rarely observed to crack, even with misfits as large as 0.4%. These figures may vary somewhat with growth temperature, thickness, etc., but it was invariably true that InGaP layers in tension cracked at smaller misfits than those in compression. The crack direction was referenced to GaAs by angle lapping the composite wafer and Sirtl etching the exposed GaAs. Figure 6(a) shows an InGaP layer which was put in tension by the GaAs substrate. Figure 6(b) shows a rare example of an InGaP layer which cracked in compression. Note that the tension cracks are parallel to the long axis of the Sirtl etch figures while the compressed layer has cracks perpendicular to the figures. These figures serve as a clear illustration that fracture in InGaP is asymmetric and follows the polarity of the zinc blende lattice. Further evidence of this type may be seen in Fig. 7 which shows the (100) and ($\bar{1}$00) surfaces of an InGaP layer placed in tension by a GaAs substrate where growth has occurred on both sides. The crack direction is seen to rotate 90° with the zinc blende polarity as do the Sirtl etch pits in Fig. 2.

Similar behavior was observed in GaAsP. Abrupt deposits of GaAsP on GaAs result in structures which exhibit unidirectional cracks (due to tensile stresses) which lie parallel to the long axis of Sirtl etch pits on the substrate. However, cracking was not observed in samples subjected to compressive stresses (GaAsP/GaP).

It must be emphasized that the above results apply only to abrupt depositions. In most cases it was found that cracking could be eliminated by grading the alloy composition. In systems which have large misfits (~1% or more) cracking is often not observed because of poor crystal growth.

Fracture Mechanism

Cottrell (10) has suggested a fracture mechanism whereby dislocations on intersecting slip planes combine to form sessile dislocations whose missing half planes may be viewed as microcracks. Repeated slip of this type can cause the microcracks to grow and complete fracture to eventually occur. Abrahams and Ekstrom (11) have extended this model to zinc blende structures in order to explain cleavage along {011} planes. These models may be used to explain asymmetric cracking in III-V compounds by invoking asymmetry of the dislocations involved in the microcrack formation.

Figure 8 shows two orthogonal {011} planes of an InGaP layer which has been strained in tension by the GaAs substrate. It has been shown (1) that a large fraction of the misfit strain in InGaP [as in GaAsP (14)] is relieved by 60° like-sign dislocations, which

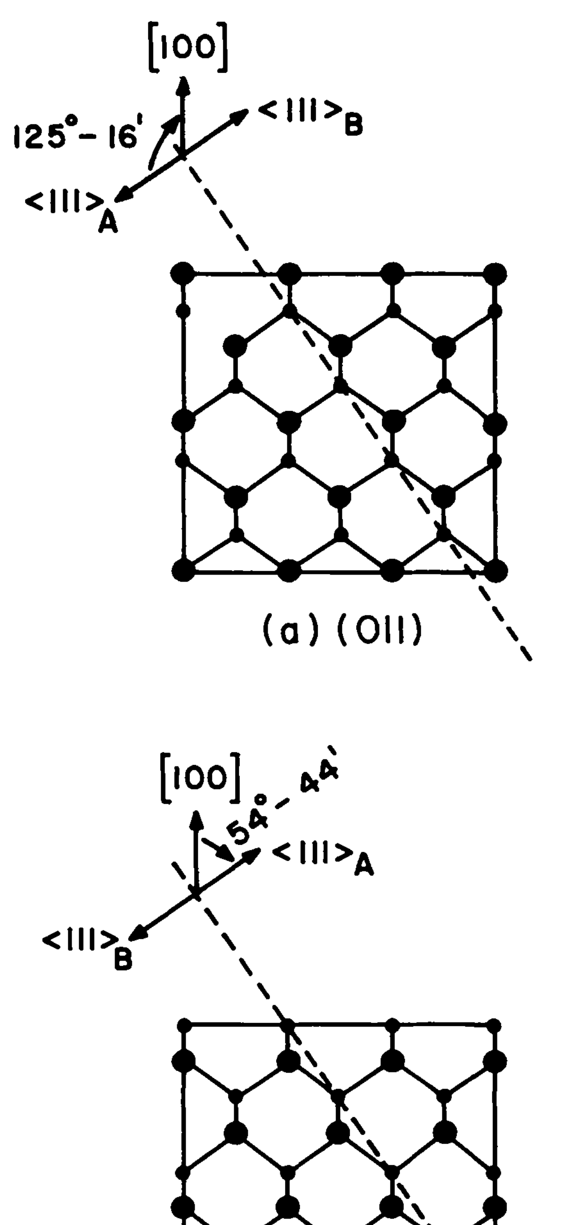

Fig. 2. A projection of two perpendicular {011} planes which shows the interchange of atomic species in zinc blende structures upon a 90° rotation.

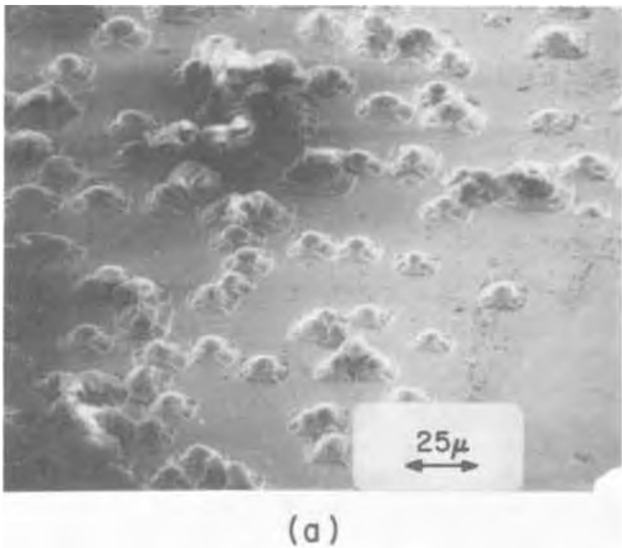
are mobile and can bend in and out of the misfit plane during crystal growth. These dislocations are thought of as sources of glissile dislocations which eventually combine and lock up as in the above fracture mechanism. Since extensive dislocation motion is required, climb does not appear to be a likely mechanism for this process. Because the misfit is tensile, the signs of the dislocation (*i.e.*, location of extra half-plane) must be as shown in the figures. Thus, if the dislocations in Fig. 8(a) are of the α-type (lying on $\{111\}_A$ planes), then the dislocations in Fig. 8(b) must be of the β-type (lying on $\{111\}_B$ planes) by virtue of the zinc blende symmetry. Since the mobilities of these two types of dislocations are not expected to be equal (1,2), it follows that one set will move at lower stress levels than the other, and thus give rise to fracture which appears only along the one direction. As with other crack mechanisms (12), compression would tend to keep the microcracks from opening up (as they do in tension) and thereby inhibit complete fracture. The operation of this mechanism depends on the configuration of the misfit dislocation. With abrupt deposits, many dislocations would be generated over a small volume after the critical thickness (13) had been exceeded. The probability for dislocation pileup would be much greater here than with graded structures where the dislocations would be spread out over a larger volume (14). Furthermore, due to the gradual relief of strain, the local misfit stress in a graded layer would never approach that in an abrupt layer (for the same total strain).

Discussion

The proposed model is consistent with the experimental results and appears to be the most likely mechanism for asymmetric fracture. It is also supported by the observations of Abrahams *et al.* (1) who showed that misfit dislocations in InGaP and GaAsP have different densities along the [011] and $[01\bar{1}]$ directions in (100) growths. Substrate orientation was also considered as a possible cause for the unidirectional cracks. Vapor-phase epitaxy is typically performed on substrates that are misoriented by 3°-5° from a major crystallographic axis. In the present work, (100) GaAs wafers, which were misoriented about <011> directions, were used as substrates. The applied misfit strains were therefore not contained in the (100) plane, but in a plane slightly inclined to it. [This effect has been demonstrated (15) in Ge/GaAs where the epitaxial strain was shown to vary with deviations from a <111> growth axis.] Following the method of Wayman (16), the resolved shear stress on a {111} <110> slip system due to such an applied stress may be calculated using matrix methods with a computer. The results are shown in Fig. 9 for misorientation about an $[01\bar{1}]$ axis. It can be seen that the resolved shear stress (τ) on a slip system of a crystal misoriented by only 3° can differ by as much as 10% from those in a crystal with no misorientation. Thus, it is conceivable that differences caused by misorientation could cause preferential slip on a particular slip plane. However, the results described in the section on cracking in InGaP and GaAsP on GaAs were found to be independent of substrate orientation, *i.e.* +3°, 0°, and −3° misorientation about a single axis all yielded identical results. Hence, substrate orientation was ruled out as a cause of asymmetric cracking.

One interesting application of these results was the estimation of the critical yield stress in InGaP placed in tension by a GaAs substrate. Figure 10 shows a composite photograph of such a crystal which contained a compositional gradient along the wafer—not along the growth axis. The region about the zero strain condition is essentially featureless. As the strain increases, a "cross-hatch" pattern (17) becomes evident. Further strain leads to a more pronounced cross-hatch and finally to cracking at ~0.15% strain. (Misfit strain was obtained from compositional determinations, together with Fig. 4). This value was found to be reproducible (it was also observed in several similar wafers) and leads to a critical tensile stress of $\sim E/666$ ($\sim 4.5 \times 10^9$ dynes/cm²). This in turn leads to a critical resolved shear stress on the {111} <110> slip system of $\sim G/770$ ($\sim 1.5 \times 10^9$ dynes/cm²; E = Young's modulus and G = Shear modulus). Such stress levels should be able to support slip at the growth temperature of 700°C. The onset of cracking appeared to be less critical in GaAsP than InGaP and no threshold stress levels could be ascertained. This result is consistent with that of Abrahams *et al.* (1), who found the asymmetry of the



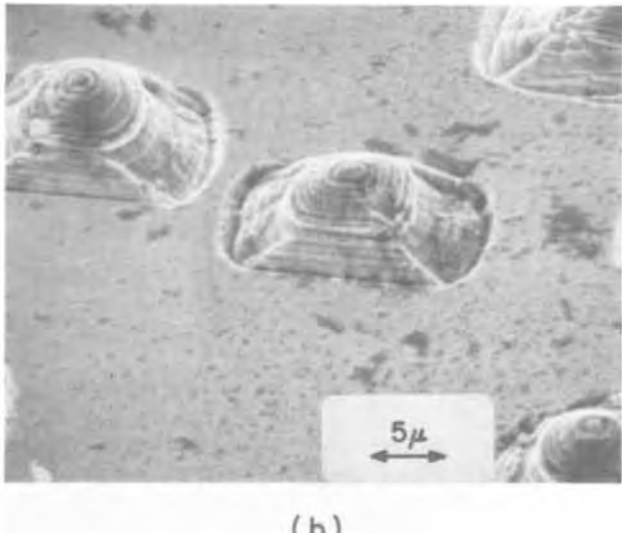


Fig. 3. Scanning electron microscope pictures of Sirtl etch figures on a (100) GaAs substrate.

dislocation arrays to be more pronounced in InGaP than GaAsP. It also suggests that the amount of asymmetry depends on the alloy constituents.

The question of whether the α- or β-type dislocations (see Fig. 11) have higher mobilities cannot be answered without stating whether these dislocations exist as a "glide" or "shuffle" set (18). This problem has been discussed recently and apparently is still an open question. The atomic configurations about these types of dislocations are illustrated in Fig. 11. If the shuffle set is assumed in the case of InGaP and GaAsP in tension, then consideration of the section on asymmetry in zinc blende structures, together with Fig. 6 and 11, will show that in order for misfit dislocations to contribute to the crack mechanism, they must lie on $\{111\}_B$ planes. Thus, the more mobile dislocations in both InGaP and GaAsP would be of the β-type. This may be seen in Fig. 11(d) if the InGaP (under tension) is assumed to be below the dislocation and the GaAs (containing the extra half plane) on top. [Interestingly, the α-type dislocations were claimed to have higher mobilities in InSb when the shuffle set was assumed (2)]. For samples under compression, the Burgers vector of the dislocation would be reversed and the crack direction would have to rotate 90° in order to maintain the same type of dislocation.

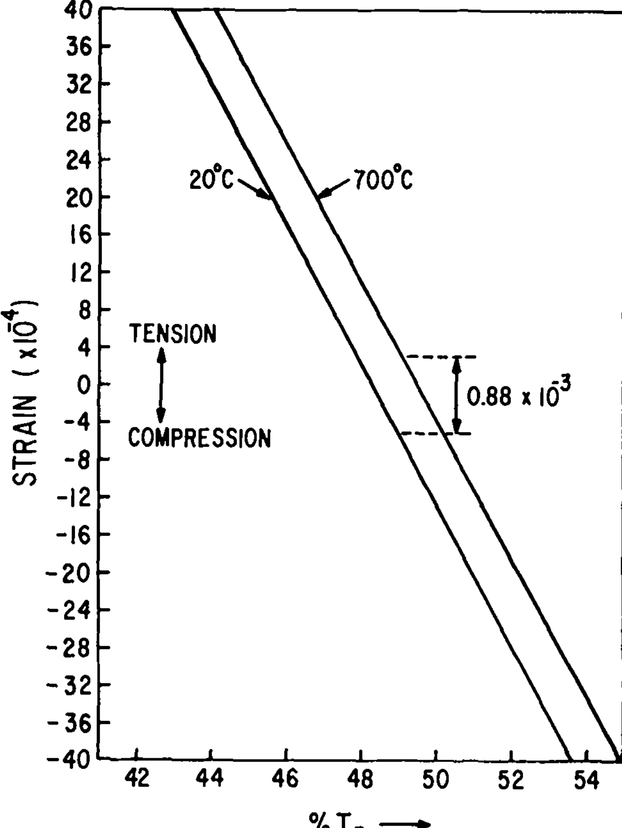

Fig. 4. Strain present in InGaP grown on GaAs due to thermal expansion effects as a function of In composition and temperature.

Assuming the shuffle dislocation to be dominant, Erofeeva and Osip'yan (20) have recently shown that the α-type dislocations have higher mobilities in InSb and GaAs. This, together with the above results, may indicate that a "size-effect" governs dislocation mobilities since P atoms are smaller than Sb and As atoms. However, all such discussion is mere speculation until the question of whether the "shuffle" or "glide" dislocations predominate in III-V compounds is settled.

Another manifestation of this phenomenon is asymmetric bending. Nagai (21) has demonstrated asymmetric bending about [011] and [01$\bar{1}$] directions in InGaAs and GaAsP grown on (100) GaAs substrates and has shown that if growth occurs on both sides of the wafer, a "saddle-like" curvature is observed, i.e., convex about one <011>-type direction but concave about the other. Similar observations have been made during the present work and are entirely consistent with the concept of asymmetric slip. Although the misfit strain is applied equally along the two directions, slip would occur more easily about one of these directions (as in the crack mechanism) and thus less bending (due to elastic strain) would take place about this axis as compared to the other. Furthermore, the zinc blende symmetry demands that these axes interchange on the opposite side of the substrate and therefore explains the concave *vs.* convex bending. Nagai also presents data which indicate that the bending in $In_{1-x}Ga_xAs$/GaAs, although asymmetric, shows no systematic variation with composition between $x = 0$ and $x = 1$. This suggests that only a critical amount of strain can be accommodated by elastic bending before plastic deformation occurs. In fact, if Nagai's data are averaged, a crude calculation (17) can be made to find the stress along the [011] and [01$\bar{1}$] directions. The results are $\epsilon \sim 6 \times 10^{-4}$ *vs.* $\epsilon \sim 3 \times 10^{-3}$. The higher value is reasonably close to the critical value found in InGaP, considering the simplifications involved.

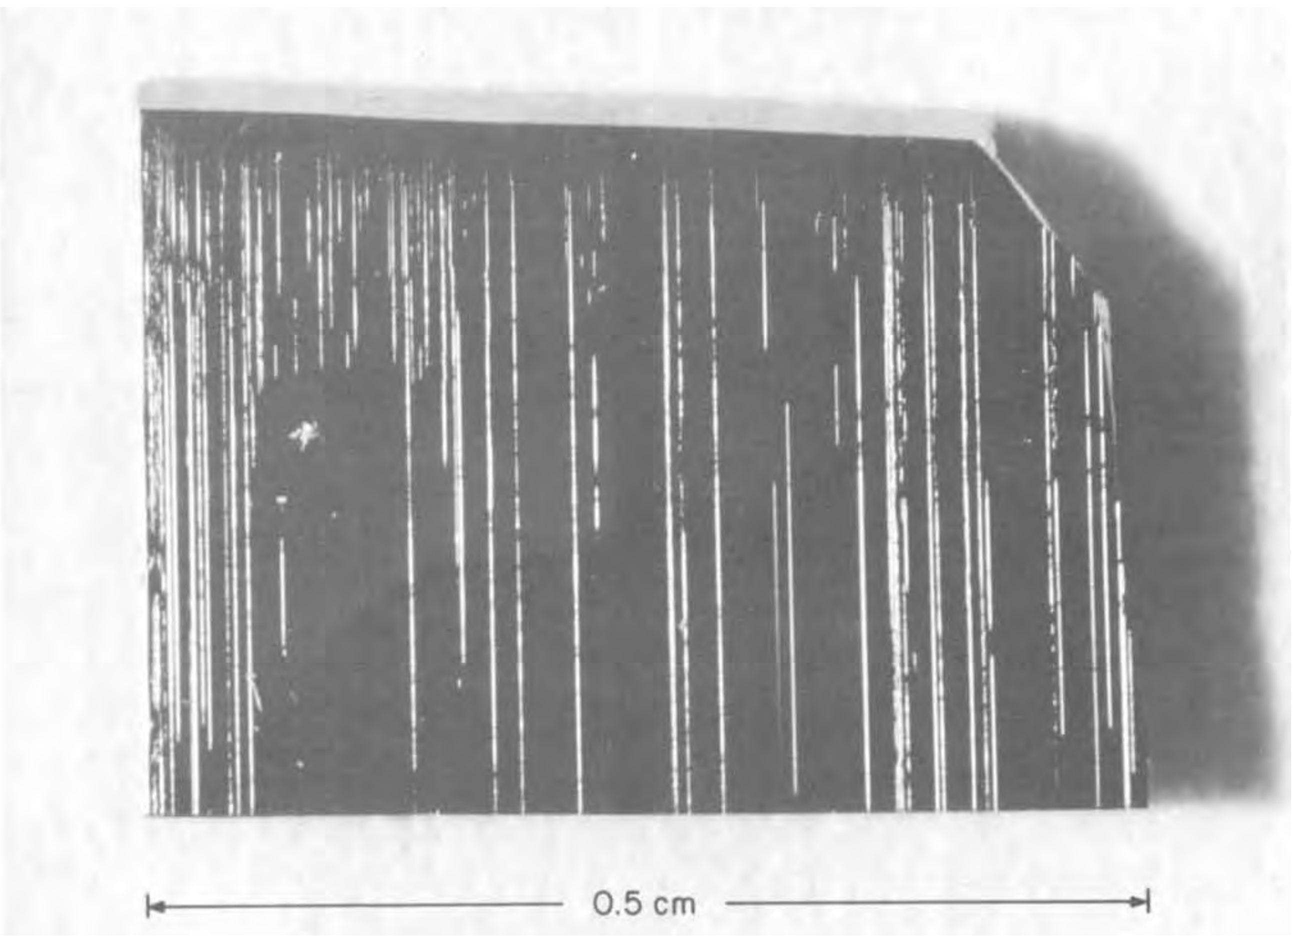

Fig. 5. Unidirectional cracks in InGaP grown on a (100) GaAs substrate. The InGaP is under tension.

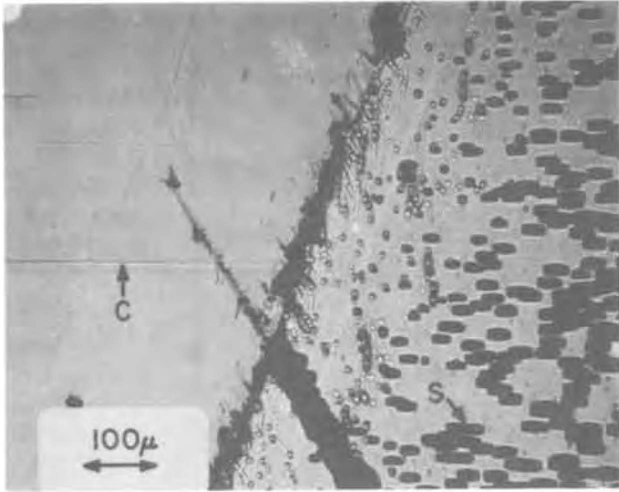

Fig. 6. InGaP/GaAs wafers which have been angle-lapped (~3°) to expose the GaAs substrate which exhibits rectangular etch figures (S) due to Sirtl etching. The InGaP portion exhibits cracks (c) due to (a) tension and (b) compression.

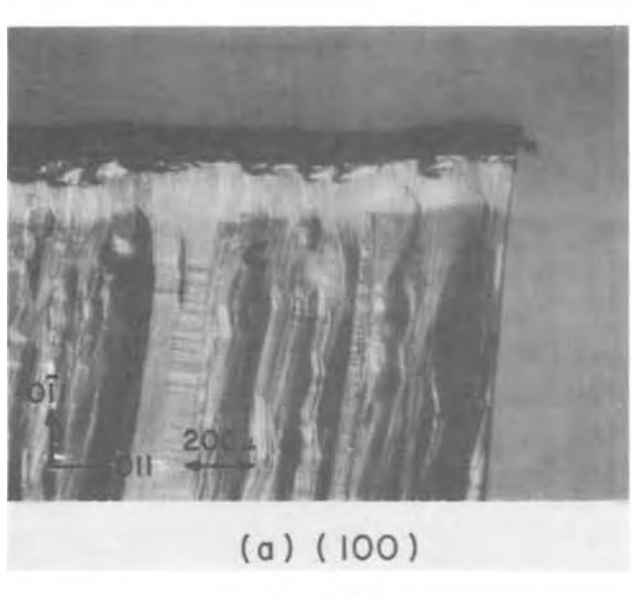
Finally, a few remarks will be made about the so-called "cross-hatch" patterns (17). These patterns have been associated with misfit dislocations in epitaxial layers which contain regions of graded alloy composition (17). However, "cross-hatching" may also be observed in abrupt (nongraded) deposits as is seen in Fig. 10 for InGaP/GaAs. Here, an asymmetry in the pattern is to be noted. The [011] set of lines runs fairly straight, while the [$01\bar{1}$] set is not as closely spaced and more irregular. This is to be compared with the asymmetric dislocation configurations of Abrahams *et al.* (1). Although the precise origin of this pattern is not clear, the following facts have been obtained: (*i*) The patterns can be removed by mechanical polishing. Therefore, they are surface defects. (*ii*) Dislocation etches enhance the original cross-hatch pattern.



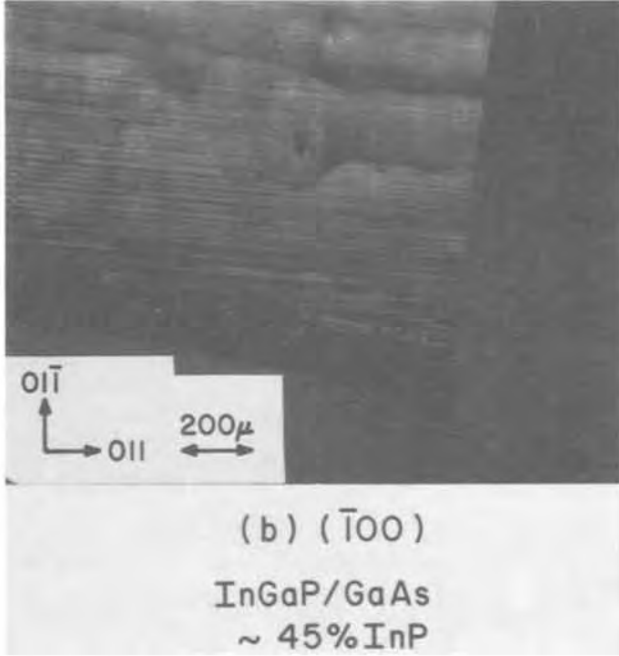


Fig. 7. Identical regions of an InGaP layer (under tension) grown on both sides of a GaAs substrate. The axis of rotation between (a) and (b) is [011].

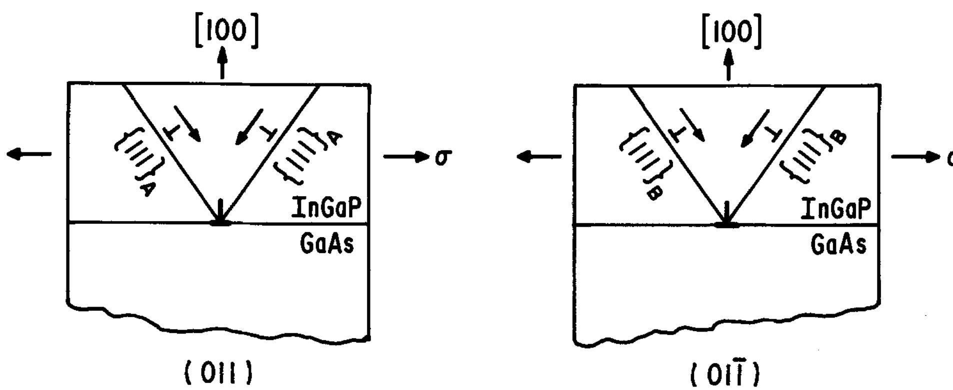

Fig. 8. Dislocation motion on perpendicular {011} planes in an InGaP layer placed in tension by a GaAs substrate. Dislocations intersect and combine as shown to form microcracks which eventually open up to form unidirectional cracks as in Fig. 5. The two gliding dislocations are 60° types with Burgers vectors pointing into and out of the plane of the figure. The bottom sessile dislocation would have a Burgers vector which lies in the (100) plane.

Therefore, there is a definite association between each line in the cross-hatch pattern and a dislocation.

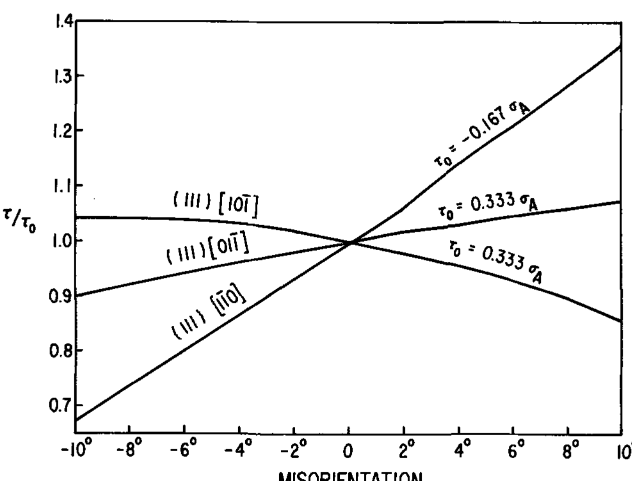

Fig. 9. The effect of substrate misorientation [from exact (100)] about the [011] direction upon resolved shear stress (τ) in the indicated (111) <011> slip systems. The applied misfit stress in the substrate plane is σ_A and τ_0 is the resolved shear stress when σ_A is applied in the exact (100) plane.

Kishino *et al.* (17) concluded that the cross-hatch patterns observed in GaAsP/GaAs were caused by growth rate variations due to impurity concentration differences at dislocations in the compositionally graded region or to the screw components of these same dislocations. We suggest that the cross-hatch pattern is initially caused by accelerated crystal growth about misfit dislocations and that once initiated, these "growth perturbations" will continue to propagate with growth as will any defect (such as a scratch or pit) on a crystal surface. This effect implies the existence of some type of defect along the boundaries of the pattern such as impurity segregation or point defects. This would be consistent with the observations and propositions of Kishino *et al.* (17).

ABSTRACT

The SEM has been used to study the crystal perfection and chemical homogeneity of $In_{1-x}Ga_xP$ crystals. Secondary electron micrographs were used to study the surface topography and microstructure away from and at inhomogeneities. Chemical and crystallographic data were obtained using the x-ray wavelength dispersive and energy dispersive analyzers and selected area channeling patterns. The channeling patterns showed that In and Ga can be substituted directly into a common (column III) sublattice without gross distortion of the lattice and without generation of unacceptable levels of structural defects. The crystals were chemically homogeneous (less than 2% maximum) except at or near inclusions.

The light-emitting properties of the $In_{1-x}Ga_xP$ crystal system, which is very promising for LED applications, are dependent on the crystalline perfection of the lattice. There are few reported studies of the crystalline perfection (lack of bulk lattice distortion) of these materials. These materials are sometimes adversely affected by the presence of inclusions (*e.g.*, indium) introduced during crystal growth. The very small samples used in photoexcitation experiments (1, 2) may be taken from inclusion-free regions, but for junction device applications this is not possible. The environment of the inclusions was studied and the defect sites related to these inclusions were characterized in terms of their microstructure and the attendant chemical composition and crystallographic changes relative to the bulk material.

The crystals were studied using a JEOL JSM-U3 and Cambridge Stereoscan S-4 scanning electron microscope (SEM). The SEM is a versatile electron probe which can provide various forms of information through the signals generated by the action of the scanning electron beam. These signals include backscattered electrons, secondary electrons, characteristic x-rays, or light emission. In the present study three operational modes were correlated to obtain an integrated view of the crystals and the defect sites therein. Secondary electron micrographs were used to study the surface topography and microstructure of the defect sites. The characteristic x-rays generated by the electron beam were used to evaluate chemical composition and homogeneity near the defect sites. Information on the orientation of the samples and the deterioration of crystallinity near the sites was obtained using selected area electron channeling patterns (SACP's).

Experimental

Samples.—The $In_{1-x}Ga_xP$ crystals were grown by a modified Bridgman method and varied in composition from $x = 0.95$ to $x = 0.34$ as shown in Table I. The $In_{1-x}Ga_xP$ is grown at constant temperature from an indium solution that is fed with source InP and GaP held at a temperature 10°-20°C higher than that of the growth site. The constant temperature synthesis reduces crystal composition inhomogeneities and consequent defects. The high quality of this $In_{1-x}Ga_xP$ in the inclusion-free regions is demonstrated by the fact that most of the direct bandgap samples can be made to lase when photoexcited (1, 2).

In the present study, slices from the grown ingots were mechanically polished and then chemically etched. This preparation removes any inclusions at the surface and leaves behind a characteristic defect site which was investigated with the SEM.

Secondary electron micrographs.—The operating principles of the SEM are well known (3). A focused electron beam or probe is scanned across the specimen in a square raster in synchronization with a second beam on a CRT. The secondary operating mode consists of the collection of the secondary emitted electrons at each point of the scan. These electrons provide the signal used to modulate the brightness of the CRT. Thus a point by point image is built up on the CRT which corresponds to the secondary electron emission at each specimen point. Other signals generated by the action of the beam can be displayed in a similar fashion.

X-ray microanalysis.—The characteristic x-rays excited by the electron beam were used to study the compositional variations in the samples. Compositional variations for In, Ga, and P were obtained near the defect sites and across grain boundaries. The methods used involved the use of the SEM equipped with both energy dispersive (EDX) and wavelength dispersive (WDX) x-ray spectrometers.

X-ray scans across the grain boundaries and defect sites utilized the EDX analyzer. The x-ray scans were obtained with a 25 kV electron beam and a probe current of 2×10^{-9}A, resulting in a 0.2 μm beam diameter (4). Two methods were used for the x-ray scans. Initially the beam was held stationary and the sample moved at the rate of 20 μm/min. In the second method the sample was fixed and the beam moved across the sample at a speed dependent on magnification and scan time. This resulted in an effective scan rate of 1 μm/sec around the defect sites.

Selected area electron channeling patterns.—Crystallographic information on the bulk specimens was obtained from electron channeling patterns (ECP's) taken in the SEM. The information that can be obtained by this technique includes orientation, lattice

parameters, and qualitative evaluation of the crystalline perfection of the sample (5).

Recently the ECP techniques have been refined to the point where this information can be obtained from selected areas of less than 10 μm diameter (6). The SAC pattern arises because of an angular dependence of electron reflection and absorption. The basic features of the contrast in ECP's has been interpreted by Hirsch and Humphries (7) in terms of the anomalous absorption effects in the dynamical theory of electron diffraction (8).

The SACP is obtained by holding the beam at a selected spot on the sample while the incident angle of the beam is rocked through a large solid angle. This leads to the formation of pronounced bands and lines at the Bragg angles of the specimen. The ECP's resemble the geometry of Kikuchi patterns and can be indexed by analogous methods. This technique was applied to determine the orientation of the $In_{1-x}Ga_xP$ samples and to evaluate the influence of the defect sites on local crystalline perfection. The qualitative evaluation of the surface perfection is possible because the ECP's are sensitive to the perfection in the top 100Å of the specimen and any lattice distortion degrades the pattern quality.

Results and Discussion

Crystal uniformity.—X-ray scans across the large grained samples and electron channeling patterns of the individual crystals revealed the local uniformity of the In-Ga composition and the freedom from lattice stretch-compression. Figure 1 shows the small fluctuations in the concentration of the indium and gallium exhibited by the bulk material as well as the negligible effect on the concentration of the boundary. The phosphorus scan does show a concentration variation within 10μ of the boundary of one grain. However, as shown in Fig. 2, not all boundaries affect the local phosphorus concentration. The average phosphorus concentration in all three grains depicted in Fig. 2 is the same, although there was a slight variation (approximately 2% maximum) within a given subgrain.

The pronounced bands and lines of the selected area channeling pattern of Fig. 3, which was taken in a defect-free area of sample 236, and the sharpness of the

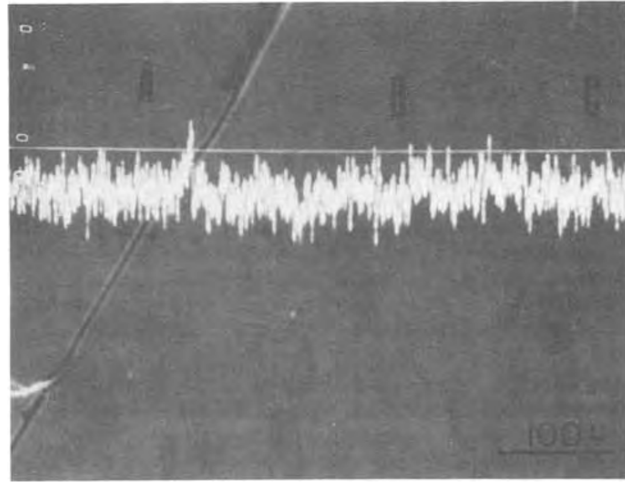

Fig. 2. Scanning micrograph with P concentration across grain boundaries in sample 150.

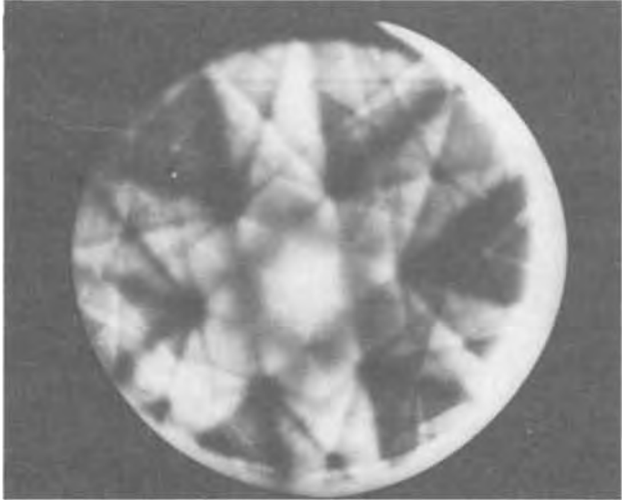

Fig. 3. Selected area channeling pattern showing typical (111) pole on sample 236. To obtain the orientation, the specimen was tilted until the (111) pole came into view.

lower part of the electron channeling pattern of Fig. 4, which represents the area away from the defects, shown in Fig. 5, confirms the presence of distortion-free areas of the crystals. The local uniformity is also demonstrated by the fact that the $In_{1-x}Ga_xP$ crystals will lase all the way to the green (1).

Defect site microstructures.—The inclusions are loosely bound second phase particles (*e.g.*, indium) resulting from local inhomogeneities during crystal growth. In all samples observed the inclusions at the surface were removed during the surface preparation

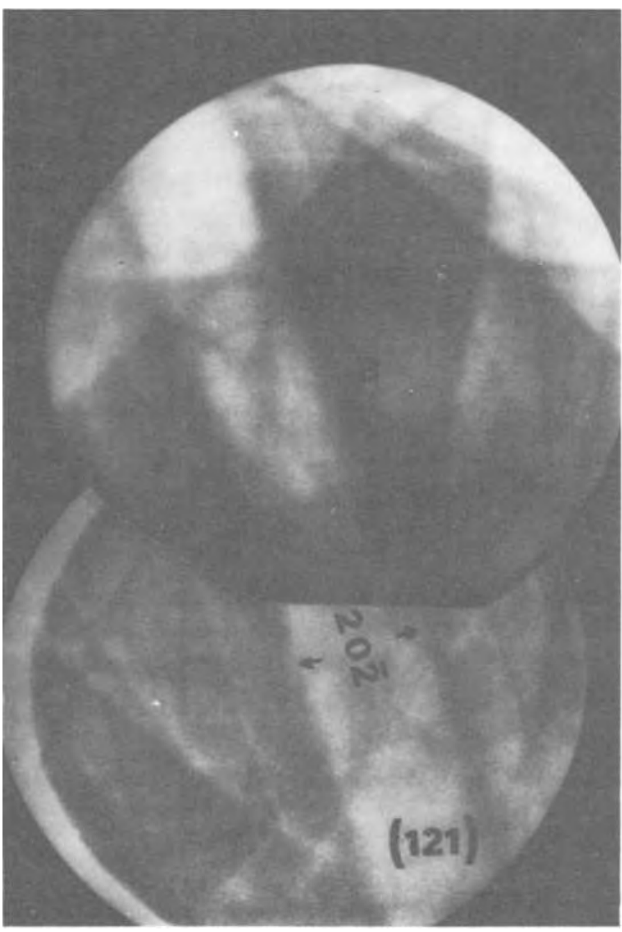

Fig. 4. Composite SACP showing the orientation of sample 236

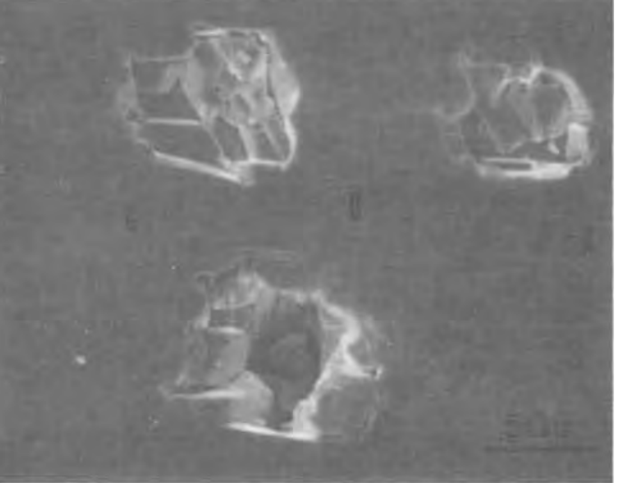

Fig. 5. Cluster of defect sites in sample 236 selected for analysis

leaving a characteristic defect site of trapezoidal shape. Figure 6 shows such a defect site which penetrated completely through sample 299. However, most defects penetrated only part of the way as shown in Fig. 7 from sample 236. At the bottom of the trapezoidal pit, bulk matrix material can be seen.

Defect sites, composition and crystallographic effects.—The influence of the defects on local compositional variations and crystalline perfection were evaluated using characteristic x-ray line scans and selected area ECP's. Figure 5 shows a cluster of three defect sites in sample 236 selected for this analysis.

The orientation of the surface normal can be determined by locating a low index crystallographic pole at the intersection of the bands of the channeling pattern. The SACP of Fig. 3 shows the (111) orientation obtained by tilting sample 236 through a large angle. The orientations of the area near the sites in Fig. 5 were determined from Fig. 4. This figure is a composite of two SACP's containing the (121) pole. The orientation corresponding to the point marked B in Fig. 5 is shown in Fig. 4 (also marked B). From measurements on the ECP's it was determined that the surface normal lies at an angle of 6.8° to the (121) pole along the $(20\bar{2})$ band.

Comparing the ECP with the defects of Fig. 5 shows that some of the edges of the defect site must be nearly along $(1\bar{1}1)$. This suggests that the straight edges of

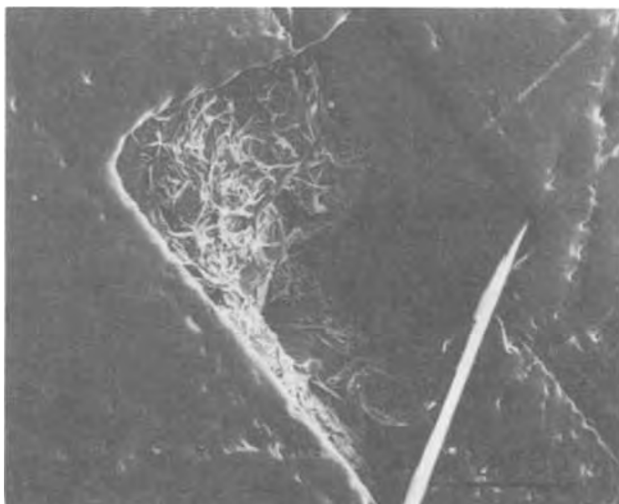

Fig. 6. Typical trapezoidal-shaped defect site in sample 299. The site penetrated completely through the specimen.

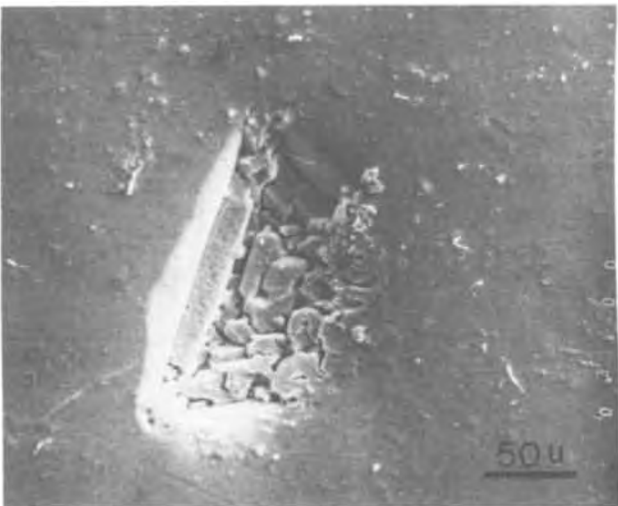

Fig. 7. Typical trapezoidal defect site in sample 236. Matrix material is seen at the bottom of the pit.

the defect sites may have resulted from a fixed crystallographic relationship between the matrix and the defects. However, the information obtained as yet is insufficient to establish the definite existence of this relationship.

X-ray scans of In, Ga, and P across the defect sites of Fig. 5, shown in Fig. 8-10, reveal deviations from stoichiometry near the defects. In particular, the P concentration in Fig. 10 changes by as much as 10% around the defect sites. The In and Ga concentrations appear to mirror each other near the defect sites with the In concentration following the P concentration profile. The deviation from stoichiometry for the indium and gallium is less than for the phosphorus, but the approximate 5% variation of the indium is higher than that encountered in the bulk material. The lower concentration of gallium and the resulting lower count rate causes the observed gallium fluctuation to fall within the counting error limits.

The influence of the defect sites on local crystalline perfection can be seen by comparing the SACPs taken near the defects with the ECP shown in Fig. 4. Figures 11-13 are the SACPs obtained from areas approximately 10 μm in diameter at the sites marked A, B, and C, respectively, in Fig. 5. The degradation in the patterns near the defect sites is clear from the lines

which are washed out of the patterns. Note that the (202) band is clearly apparent in all the ECP's. This

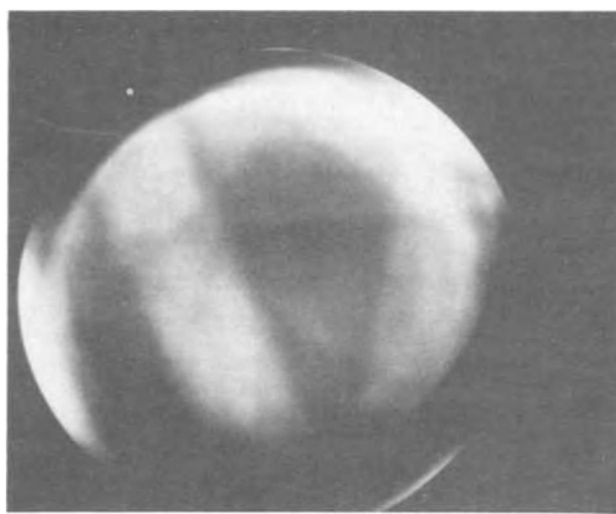

Fig. 12. SACP at inclusion site B in Fig. 3

indicates that the defect sites introduce local damage but do not cause any orientation change in the sample.

Conclusions

1. In and/or Ga can be substituted directly over a wide composition range into a common group III sublattice so as to yield a continuous series of $In_{1-x}Ga_xP$ crystals without changing crystal structure or severely distorting the structure.

2. Although these crystals contained large inclusions (or defect sites after surface treatment), crystal growth defects have only a limited effect on the surrounding crystal in terms of lattice distortion as determined by ECP's.

3. The localized chemical inhomogeneities caused by the defects did not significantly affect the LED qualities of the crystals.

4. Electron channeling patterns have been shown to be a valuable aid in characterizing the crystal perfection of ternary systems, in particular the LED systems.

A Lattice Parameter Criterion for Miscibility Gaps in the III-V and II-VI Pseudobinary Solid Solutions

L. M. Foster*

IBM Thomas J. Watson Research Center, Yorktown Heights, New York 10598

ABSTRACT

A smooth relationship is obtained when the excess free energy of mixing parameter, B^s, is plotted against the relative difference in the lattice parameters of the two components of a number of miscible III-V pseudobinary semiconductor alloys. Extrapolation of this plot to values of the size disparity in systems for which experimental phase diagram information is lacking gives estimates of B^s sufficiently large to predict miscibility gaps in the AlSb-AlAs, InSb-InP, GaSb-GaP, and AlSb-AlP systems, when the thermodynamic criterion for phase separation, $B^s > 2RT_c$, is employed. A cutoff point for miscibility across the entire phase diagram appears to occur at a relative lattice parameter difference of about 7.5%, the value for GaSb-GaAs. This same relative difference is found to divide miscible from immiscible II-VI zinc blende alloys as well.

In earlier studies various experimental and theoretical aspects of the phase relationships in the III-V compound semiconductor pseudobinary alloys were investigated (1-4). One of the principal concerns was the limit of miscibility in the solid phase, since this restricts the compositions that are potentially useful for device applications.

The compound semiconductor systems present onerous experimental problems in the determination of phase boundaries. Many of the systems are high melting and in most instances melting is accompanied by high dissociation pressures, so containment is difficult when the usual techniques for phase diagram determination, such as differential thermal analysis, are attempted. In view of these problems it would be desirable to develop a criterion for miscibility that is based on some easily measured property of the compounds, so as to obviate the difficult experimental determination of each system.

A miscibility gap will appear in a phase diagram if the chemical potential of a component is the same in two different compositions of the phase. The chemical potential changes in forming alloys are obtained from the free energies of mixing of the phases which, for the liquid and solid in a binary system, are

$$\Delta F^{M(l)} = RT[(1-x^l)\ln(1-x^l) + x^l \ln x^l] + B^l(1-x^l)x^l \quad [1]$$

and

$$\Delta F^{M(s)} = RT[(1-x^s)\ln(1-x^s) + x^s \ln x^s] + (1-x^s)L_1[(T/T_1)-1] + x^s L_2[(T/T_2)-1] + B^s(1-x^s)x^s \quad [2]$$

where x^l and x^s are the mole fractions of the second component. The terms which contain the heats of fusion, L_1 and L_2, are the free energies of fusion apportioned between the two components. The last term in relations [1] and [2] is the excess free energy of mixing of the phase and accounts for the departure of the system from ideal behavior.[1]

A miscibility gap occurs when the positive excess free energy of mixing becomes sufficient, compared with the negative free energy of mixing, for the ΔF^M *vs.* composition curve to go through a local maximum. This results in a range of compositions where a single-phase solid solution is unstable with respect to two immiscible solid solution phases on either side.

If the excess free energy of mixing, $Bx(1-x)$, is a maximum near $x = (1-x) = 0.5$, as will be the case if B does not vary greatly across the phase diagram, it can be shown that there will be a miscibility gap when $B > 2RT_c$, where T_c is the critical temperature for phase separation (5). In the present application, T_c is taken to be the solidus temperature at $x^s = 0.5$, since, as will be seen, B^s is evaluated only along the solidus boundary. Thus, when $B^s = 2RT_c$, the miscibility gap extends up to the solidus boundary and continuous solid solution formation across the entire phase diagram is not possible at any temperature.

If, on the other hand, $B^s < 2RT_c$ at the solidus boundary, this does not preclude the existence of a miscibility gap at some lower temperature. No predictions concerning this possibility can be made without knowledge of the temperature dependence of B^s. This aspect is not considered in the present study.

If both the liquidus and solidus boundaries of a binary diagram are known, the B parameters, and hence the excess free energies, can be calculated by equating the expressions for the chemical potential of a component derived from Eq. [1] and [2] for the condition of the liquid and solid phases in equilibrium at constant temperature. In an earlier paper in this series (1), B^l and B^s were expressed in a form amenable to computer solution.

It has been established experimentally that a single-phase solid solution exists across the entire phase diagram of many of the III-V compound semiconductor alloys (6). Exceptions appear to be the III-(Sb,P) alloys, although these have not been investigated fully. Other exceptions might be expected among alloys of the higher melting aluminum compounds about which little is known. Also, there are conflicting reports about miscibility in GaSb-GaAs alloys, depending on the method employed to determine the phase diagram.

It is shown here that for the miscible systems where there are sufficient data for the calculation to be made, there is a smooth relationship between relative size difference of the two components of an alloy and the excess free energy of mixing. This relationship can be used to predict which of the remaining systems should be miscible and which should exhibit miscibility gaps. These predictions are confirmed by experiment, where information is available, which has shown that the alloys in which miscibility gaps have either been

Key words: compound semiconductors, phase diagrams, thermodynamics.

[1] The designation of the parameter as B in this and earlier papers by the author (1-4) is consistent with the usage of Scatchard *et al.* [*J. Am. Chem. Soc.*, 57, 1809 (1935)] and is intended to be noncommittal as to the makeup of the excess free energy. This symbol was chosen over Ω, which was originally intended to imply enthalpic interactions in liquid solutions, or α which in metallurgical literature is frequently $\alpha = \ln \gamma_1/(1-x_1)^2$ [L. S. Darken and R. W. Gurry, "Physical Chemistry of Metals," McGraw-Hill Book Co., New York (1935)] whereas in chemical literature it is usually $\alpha = RT \ln \gamma_1/(1-x_1)^2$.

demonstrated or suspected all have rather substantial size differences between their components.

From the limited information on the II-VI alloys with the zinc blende structure it appears that the same relationship between size difference and miscibility applies to those materials as well.

Procedure and Results

For only six systems are there sufficient reliable phase diagram data for B^s to be evaluated. These are GaAs-AlAs, GaAs-GaP, InSb-GaSb, InAs-GaAs, InP-GaP, and GaSb-GaAs. Liquidus data are available for only the last four. To enable the calculation to be made for GaAs-AlAs and GaAs-GaP, the assumption was made that $B^l = 0$. Justification for this assumption was given in Ref. (3) and (4).

Table I gives the relative lattice parameter differences for the 18 III-V pseudobinary alloy systems. The excess free energy parameter, B^s, at $x^s = 1 - x^s = 0.5$ for the six systems for which calculations were made, and the literature reference for each value, are also given. There are somewhat different values for some of these systems in the literature (6, 7) resulting from different ways of drawing phase boundaries through the data, from different methods of averaging data, or from use of different assumptions in the calculations. The choices made here reflect a bias on the part of the author for his own experimental data.

In Fig. 1, B^s for the six alloys is plotted against $(\Delta a_o/\bar{a}_o)100$, the relative difference in lattice parameter between the two end members of each alloy expressed in per cent of their average lattice parameter, $\bar{a}_o$.

A striking feature of Fig. 1 is the steep ascent of the curve at relative lattice parameter differences greater than about 7%. Reasonable extrapolation of the curve to higher values of $(\Delta a_o/\bar{a}_o)100$ would give very large values of B^s. For example, at about an 8% lattice mismatch, corresponding to AlSb-AlAs (the next alloy after GaSb-GaAs), B^s would be of the order of 8,000-10,000 cal, rising thereafter to extremely large values. As will be shown below, these large values of B^s are incompatible with complete miscibility in both the liquid and solid across the phase diagram. The implication is, of course, that systems with relative lattice parameter differences between the two components of greater than about 7.5-8% have miscibility gaps in the solid. As seen in Table I, there are four systems, AlSb-AlAs, InSb-InP, GaSb-GaP, and AlSb-AlP clearly outside that range, and a fifth, GaSb-GaAs, with a difference of 7.52% just within the lower end of the range.

A large value of B^s by itself does not require that there be phase separation, which occurs only if B^s exceeds $2RT_c$. Although T_c, the solidus temperature at $x = 0.5$, is not known for the last four systems of Table I, the average of the melting points of the end members of each alloy will be the maximum value and can be used as a very rough estimate. With these

estimates for T_c, $2RT_c$ for each of the four alloys in question is for AlSb-AlAs, 6700 cal; for InSb-InP, 4200 cal; for GaSb-GaP, 5500 cal; and for AlSb-AlP, 7000 cal. Any reasonable extrapolation of the curve of Fig. 1 gives B^s for the four alloys greatly in excess of these values.

We will now examine the situation for the GaSb-GaAs system which, as shown in Fig. 1, has a value of B^s on the rapidly ascending part of the curve. It was shown in Ref. (2) that for this system $B^s = 4000 \simeq 2RT_c$, if the calculation is made as though the solid were a continuous solid solution and the solidus were smooth throughout the composition range near the center of the diagram where there are no data [see Fig. 1 or Ref. (2)]. Thus, there should be a miscibility gap extending just to the solidus. It will be useful now to see if this is borne out by experimental observations.

Muller and Richards (8) used a flash evaporation technique to deposit very thin III-V alloy films onto cold substrates, then examined the deposits for miscibility by x-ray diffraction. Several compositions of each of nine III-V alloys, including GaSb-GaAs, were prepared (all systems except those containing aluminum compounds). Complete miscibility was observed in all except GaSb-GaP and InSb-InP. Speculating that all of the III-(Sb,P) alloys would have miscibility gaps because of the large size difference between Sb and P, they predicted that AlSb-AlP would be a third exception.

Clough and Tietjen (9) prepared GaSb-GaAs samples by vapor phase epitaxy and examined them by x-ray diffraction. They reported continuous solid solution formation across the entire phase diagram. No data were reported between $x_{GaAs} = 0.38$ and 0.69, however.

Recently, Gratton and Woolley (10) reported results on directionally frozen GaSb-GaAs alloys that were examined by x-ray diffraction and x-ray fluorescence techniques. They found a miscibility gap of maximum range $0.38 < x_{GaAs} < 0.69$, corresponding to a peritectic reaction.

The results of these three investigations are not necessarily discordant. The flash-evaporated samples of Muller and Richards might not have been equilibrated because of the low deposition temperature, and a immiscibility range in the middle of the diagram might have been missed by Clough and Tietjen through failure to prepare a sample there.

The experiments cited above for GaSb-GaAs serve to illustrate the difficulty in determining a phase boundary near the limit of miscibility and lead to the conclusion that GaSb-GaAs is indeed a borderline case between miscible and immiscible alloys, consistent with the relative size difference between the two components.

Application to II-VI Alloys

Since the II-VI compounds are isoelectronic with the III-V's and most of them have the zinc blende structure, at least in some temperature range, it might be expected that the relation between relative lattice parameter difference and miscibility that was observed for the III-V alloys might apply to the II-VI alloys as well. Table II gives the relative difference in the lattice parameter for the possible pseudobinary alloy combinations. The CdSe-CdS system is included even though the room temperature stable structure for CdSe and CdS and their mutual alloys appears to be wurtzite. The alloys are divided into two groups depending on whether or not miscibility has been demonstrated experimentally over the entire phase diagram (11).

It is seen in Table II that the relative lattice parameter difference of about 7.5% that was found to separate miscible from immiscible alloys in the III-V systems also separates the II-VI alloys into similar groupings.

Discussion and Conclusions

It has been shown that there is a smooth relationship between the excess free energy of mixing of the solid phase of a number of III-V pseudobinary systems and the size disparity between the two components of the alloys, as expressed by the relative difference in their cubic lattice parameters.

Extrapolation of the plot of the excess free energy parameter, B^s, *vs.* the size difference, $(\Delta a_o/\bar{a}_o)100$, to values of the latter corresponding to the four alloys, AlSb-AlAs, InSb-InP, GaSb-GaP, and AlSb-AlP, gives approximate values of B^s in excess of $2RT_c$, where T_c is the estimated solidus temperature at $x = 0.5$. Thus, a miscibility gap near the center of the diagram that intersects the solidus boundary is predicted for these alloys. A relative lattice parameter difference of about 7.5% appears to separate the miscible from immiscible III-V alloy systems.

From the limited information available for the phase diagrams of the II-VI compounds, it appears that the same relative size difference also separates those systems into groups of miscible and immiscible alloys, and thus is a characteristic of the zinc blende structure rather than of a particular class of compounds.

Restriction of mutual solubility in binary alloys as the result of size differences between the two components is of course well known. Hume-Rothery proposed an empirical "size effect" rule for metal alloys to the effect that solid solution formation will be severely limited if the atomic radii of the components differ by more than 15% (12). That rule cannot be applied directly to mixtures of compounds, partly because of the difficulty in defining the compound radii. There is a 13% difference in the tetrahedral radii of Ga and In, for example. Since these occupy sites on the same sublattice in the zinc blende structure, it might be expected that their size difference would be the principal factor in determining the excess free energy of mixing in their pseudobinary alloys where there is a common group V element. This would imply that the degree of nonideality in InSb-GaSb, InAs-GaAs, and InP-GaP systems, as expressed by the parameter B^s, might be similar. As seen in Fig. 1 however, this is not the case, and only when the "size" of the components is expressed as their lattice parameter is there a correlation with the excess free energy.

Size can enter into calculation of alloy stability in various ways. Phillips and Van Vechten (13) showed that from spectroscopic theory the heat of formation of III-V compounds could be estimated from fundamental properties of the materials, including the lattice constant, the ionicity, and a quantity obtainable from the band gaps. From the observation that in alloys the bandgap does not vary strictly linearly with composition, Van Vechten (14) showed that the spectroscopic theory of the heat of formation could be extended to the alloys and the range of stability [*i.e.*, the compositions where $\Delta H < T\Delta S$(random)] of a number of them was estimated.

Using a similar procedure for calculation of the solid and employing Hildebrand's solubility parameters (15) and electronegativities of the constituent elements for calculation of the liquid, Stringfellow (7) calculated the liquidus and solidus boundaries of the III-V alloys, but the agreement with experimentally determined phase boundaries was poor in a number of cases.

One might expect that a size difference between the two components of a binary alloy would be manifest principally as lattice strain, and there is a great deal of background to support this in metal alloy systems (16). The simplest calculation of strain energy did not give good agreement with experiment in the case of several III-V pseudobinary alloys, however (1). Moreover, the concept of lattice strain becomes vague for the virtual lattice model of semiconductors where all atoms are on lattice points and all III-V bond lengths are identical (*i.e.*, in InP-GaP, for example, In-P and Ga-P distances are the same).

A problem in understanding the nature of the excess free energy of mixing in the III-V alloys, and therefore the role that size difference might play, is the difficulty in identifying separately the contributions of excess enthalpy and entropy. As pointed out by Panish and Ilegems (6), the gross features of the phase diagrams are principally determined by the separation in melting points of the two components and their entropies of fusion. The contribution from the excess free energy, which near the center of the phase diagram is only approximately one fourth of the interaction parameter in magnitude, is relatively small in most instances. In view of the considerable scatter in the literature data for some systems, therefore, systematic trends that might suggest the makeup of the excess free energy are difficult to establish and depend strongly on the choice of data. We found that for the systems shown in Fig. 1, the quantity B^s/RT was approximately constant, when T was the temperature along the solidus boundary (2). This is in contrast to the findings of Panish and Ilegems that most of the III-V alloys could be described fairly well by a constant B^s (their α^s) (6). If $B^s/RT \simeq$ constant, the excess free energy would come largely from an excess entropy. If $B^s \simeq$ constant, it would be largely en-

Note added in proof: After this paper was submitted, a note by Stringfellow appeared [*J. Phys. Chem. Solids*, **34**, 1749 (1973)] in which it was shown that reasonable agreement with published values of the solid interaction parameters of the III-V pseudobinary alloys could be obtained if the parameter is identified with an enthalpy of mixing that is the difference between the heat of atomization of the alloy (at $x = 0.5$) and the sum of heats of atomization of the pure components. These quantities in turn were assumed from the relation $\Delta H^{at} = Ka_0^{-2.5}$, and thus a dependence of the interaction parameter on lattice constant was demonstrated.

Technical Notes

Anodic Oxidation of Gallium Phosphide in Aqueous Hydrogen Peroxide

F. Ermanis and B. Schwartz*

Bell Laboratories, Murray Hill, New Jersey 07974

The feasibility of growing a native oxide by anodic methods on gallium phosphide in a 30% aqueous solution of hydrogen peroxide was demonstrated recently by Schwartz and Sundburg (1); they established an apparent upper voltage limit of about 200V for obtaining uniformly thick oxide films. The present note provides additional data relating oxide thickness to the forming voltage. The effects of varying the pH of the solution and the etching characteristics of the formed oxide in aqueous HCl and NH_4OH are also described.

Experimental Procedure

The anodic oxidations of GaP were carried out using 30% H_2O_2 as the electrolyte, in the quartz beaker system described previously (1). The pH of the electrolyte was decreased or increased by the addition of H_3PO_4 or NH_4OH, respectively. The samples were (111)-oriented, n-type slices, selenium or tellurium doped in the concentration range 10^{17}-10^{18} cm^{-3}. All samples were polished with a 0.075% bromine-in-methanol solution on a Pan-W polishing cloth (2). The experiments were performed using a constant voltage source. During the anodization most of the samples were completely immersed in the bath while being held in self-anodizing aluminum tweezers (3). With few exceptions, the oxidized slices were routinely bake-dried in a nitrogen-purged oven as described earlier (1). Oxide film thickness and index of refraction were determined subsequent to growth on a Rudolph ellipsometer with a He-Ne laser light source at 6328Å.

Results and Discussion

Effects of solution pH.—The thickness and uniformity of the anodically grown films were found to depend not only on the applied voltage but also quite strongly on the pH of the solution; Fig. 1 shows the variation of oxide thickness with pH, for films grown at 100V for 5 min. The shape of the curve is similar to that presented by Logan *et al.* (4) in their work on the anodization of GaAs; there is a minimum near pH = 3.6, and an increase on both sides reaching maxima near pH = 2 and pH = 6. Over the entire range $2.5 \leq$ pH ≤ 7.5, the thickness of the oxide films was nonuniform; it was only near pH = 2 that films of uniform thickness could be grown. In addition to nonuniformity, between pH = 3.5 and 5, pitted surfaces of GaP were produced.

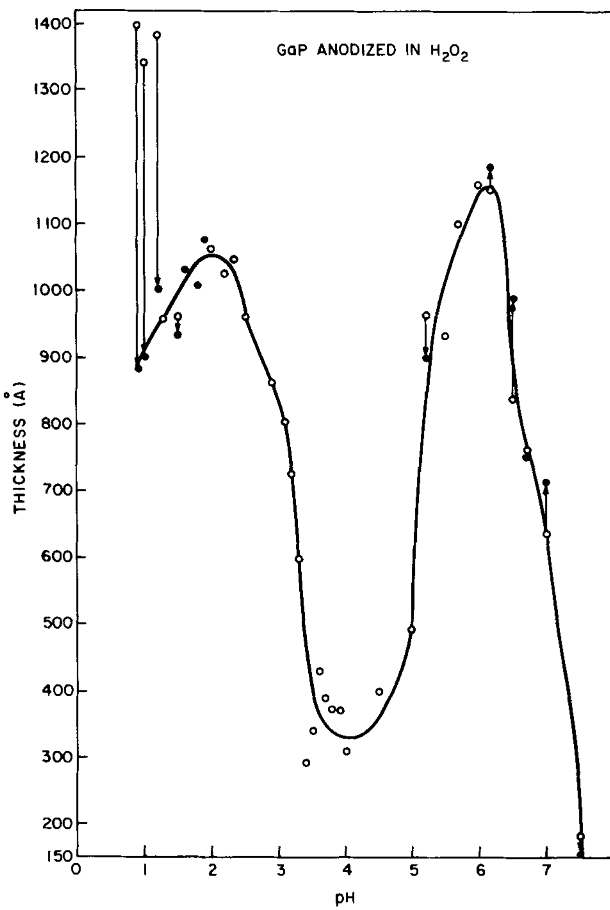

Fig. 1. Thickness of the anodically grown (100V, 5 min) oxide on GaP as a function of the pH of the H_2O_2 solution. ○ = as grown; ● = baked at 250°C. Uniform oxides were grown only in the pH region of 1.5-2.5.

Oxides grown in the pH range between 1.5 and 2.5 showed insignificant (less than 5%) decrease in thickness upon being baked at 250°C for 2 hr. The same baking cycle, however, caused a drastic 25-35% decrease in thickness for samples anodized at a pH $\leq$ 1.3. Oxides grown at a pH $\gtrsim$ 5 were so nonuniform, that the effects of baking on these samples could not be determined. Films grown in basic solution (*i.e.*, pH > 7.0) were always nonuniform, due to the fact that the NH_4OH is a fast acting etchant for the oxides and partly dissolves them during the time interval between the turning off of the bias and the blot-drying of the sample.

Oxide thickness as a function of voltage and time.—In general, the anodization behavior followed the pattern established earlier (1, 4); application of a constant voltage resulted in a fast initial growth rate followed by a slowdown of the growth process as the increasing thickness of the oxide raised the resistance of the circuit and decreased the current flow. In 2 min, about 80% and in 5 min about 90% of the ultimate thickness obtainable in a half hour was achieved. Oxides grown in 2 min, however, were not always uniform in thickness. As a routine, therefore, all oxidations were of 3-6 min duration.

A plot of oxide thickness *vs.* applied voltage (Fig. 2) reveals some scatter in the data for which there may be several reasons.. First, the oxidation time was not identical for all samples. Secondly, a range of pH (2.0-2.5) and not a constant pH was used for the oxidizing solutions. Thirdly the carrier concentration in the material varied and was known only to within an order of magnitude (10^{17}-10^{18} cm^{-3}). It is known that for a given time of oxidation and a given pH, the more

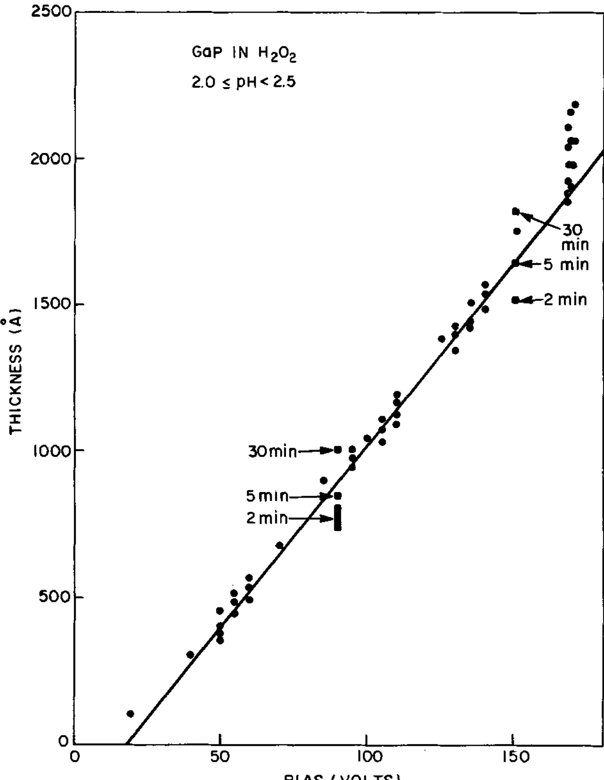

Fig. 2. Thickness of the anodically grown oxide on GaP as a function of the applied constant voltage. The time of reaction is variable, between 3 and 6 min, except for the samples anodized at 90 and 150V, where the data points are plotted after anodization of 2, 5, and 30 min. Except for the 90V anodization, all samples were baked at 200°C.

heavily doped material will develop a thicker oxide than the less heavily doped samples (5). Nevertheless, an approximately linear thickness-voltage relationship can be deduced with a slope of approximately 12 Å/V assuming an average growth time of 5 min.

The voltage above which smooth oxides could not be grown was found to be 170V. Since oxides grown in the range between 160 and 170V were not always uniform, 160V must be considered a safe upper voltage for reliable oxide growth.

The refractive index, which is determined concurrently with thickness from ellipsometric measurements, varied from 1.49 to 1.65 and appears to be a function of the oxide thickness (*i.e.*, forming voltage) as shown in Fig. 3. It could not be determined from the available data, however, whether the index of re-

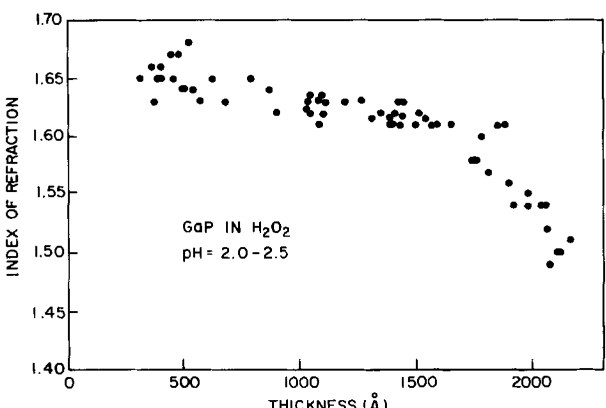

Fig. 3. Ellipsometrically determined index of refraction of anodically grown GaP oxide as a function of oxide thickness (*i.e.*, applied bias).

fraction decreases over the entire film as the film thickens above about 1500Å, or whether a layered oxide structure with a variety of indices was present.

Etching.—It had been found in earlier work (1) that the native GaP-oxide is attacked by most mineral acids and common bases. In the present study two of these, HCl and NH_4OH, were evaluated somewhat more closely. Samples with oxides ranging in thickness from 400 to 2000Å were dipped into several dilutions of the reagents and the disappearance of the oxide was observed visually and the time recorded. The average etch rates obtained in this manner are illustrated in Fig. 4. It is quite obvious that HCl removes the oxide much more slowly than NH_4OH. Sample surfaces which had been etched in HCl also showed that acid etching left stains, and some areas, such as those near the oxidant-air boundary of the few partly immersed samples, were almost untouched. These surfaces could be markedly improved by a subsequent dip in NH_4OH; in most cases not only was the surface residue "cleaned up" but a relatively constant average etch rate by the NH_4OH was exhibited over a wide range of dilution.

The nonlinear etching characteristics of both etchants were also revealed by the use of a stepwise etching technique which involved a 5 or 10 sec etch followed by a measurement of the remaining thickness. Owing to an obvious in-depth chemical nonuniformity of the film, the etch rate was found to be dependent on the film thickness. The behavior of a 3/1:HCl/water solution under the above stated conditions for 4 samples with original film thicknesses of 600, 1000, 1500, and 2150Å demonstrated that the initial etch rate of the surface of the oxide is higher (30-100 Å/sec) than the

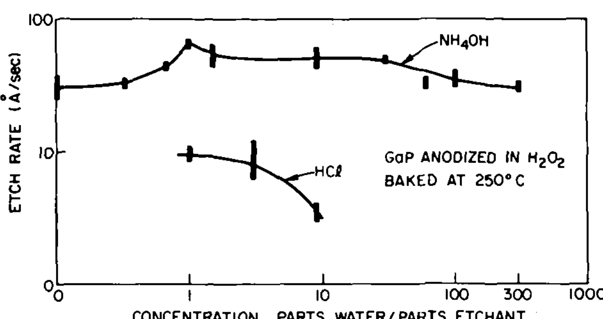

Fig. 4. Oxide etch rate *vs.* concentration of HCl or NH_4OH. The rate was determined by timing the removal of oxides 500-2000Å thick which had been baked at 250°C.

rate (5-20 Å/sec) found after a fraction of the film has been removed. The initial etch rate increases also with increasing original thickness of the oxide at an apparent linear rate of 0.05 Å/sec per angstrom. On the other hand, ammonium hydroxide exhibits the opposite behavior: a 9/1:water/NH_4OH solution in 5 sec steps showed an initial etch rate of 30-50 Å/sec, which increased to about 200 Å/sec at the oxide-substrate interface. Thus, if for some purpose a partial removal of an oxide film is necessary, the application of the average etch rate to calculate the fraction of the film to be removed might lead to erroneous results.

Summary

The main findings of this work may be summarized as follows:

1. Anodic oxidation of GaP in 30% aqueous solution of H_2O_2 can be reproducibly performed within the pH range $1.5 \leq pH \leq 2.5$, obtained by adding H_3PO_4 to the H_2O_2.
2. A maximum safe voltage for uniform oxide growth is 160V and the oxide thickness *vs.* applied bias curve has a slope of approximately 12 Å/V.
3. The index of refraction, as determined by ellipsometry, of oxide films up to 1500Å thick is 1.65 ± 0.05.
4. NH_4OH, in concentrated form, as well as diluted to 1 part in 300 parts water, is a more efficient etchant of the anodic oxide than is HCl. Its action is nonlinear; the oxide at the surface is dissolved more slowly than that near the substrate-oxide interface. On the average, the etching rate is about 60 Å/sec. In contrast, the etching of the oxide in HCl proceeds faster at the surface of the oxide than near the substrate-oxide interface.

U.V. Imaging with Nematic Chlorostilbenes

W. E. Haas,* K. F. Nelson, J. E. Adams, and G. A. Dir

Research Laboratories, Xerox Corporation, Webster, New York 14580

Imaging processes based on the interaction between u.v. radiation and liquid crystals have been the subject of several studies. The first reference is contained in a report by Jones *et al.* (1) which merely states that u.v.-sensitive liquid crystals exist and could be used in imaging. Haas *et al.* (2) showed that cholesteric mixtures containing cholesteryl iodide or bromide change their reflection colors in response to u.v. irradiation due to irreversible photochemical reactions, whose products shift the helical pitch and, consequently, the reflection colors of the cholesteric mixtures. Sackmann (3) described an imaging process based on the *cis*⇄*trans* conversion of nonmesomorphic azobenzene. Mixtures of cholesteryl chloride and nonanoate were added to azobenzene and the cholesteric reflection colors were altered by irradiation of the samples with 313 nm light. Irradiation at this wavelength causes the *trans*→*cis* conversion of the azobenzene, which results in a pitch change of the cholesteric mixture. Another imaging process was described by Goldberg and Fergason (4). Their approach is similar to Sackmann's, but instead of the nonmesomorphic azobenzenes they utilized the *cis*→*trans* isomerization of cholesteryl p-phenylazophenyl carbonate, which is a liquid crystal, to produce color changes.

* Electrochemical Society Active Member.
Key words: nematics, ultraviolet, imaging, liquid crystals, stilbenes.

The imaging process described here is not based on color changes, but on the optical differences between the liquid crystalline and isotropic states. Thermotropic liquid crystals do not scatter light if heated above the isotropic transition temperature and appear dark between crossed polars due to the absence of birefringence. Below the isotropic transition point they usually scatter light and are birefringent. Between crossed polarizers the samples appear bright except in cases of special alignment. In the imaging process the isotropic transition temperature is locally lowered through u.v. irradiation at 300 nm. If the isotropic point is depressed to the observation temperature, the exposed regions appear dark between crossed polarizers, and the unexposed areas appear bright. The process is thus positive to negative. Without polarizers the contrast is weak, relying solely on the optical difference between scattering and nonscattering areas.

The nematic liquid crystals used in the experiments were *trans*-4-butyl-α-chloro-4'-ethoxystilbene (BCES) and *trans*-4-octyl-α-chloro-4'-ethoxystilbene (OCES) (5) and also mixtures between these nematics and cholesteryl oleyl carbonate (COC). The reasons for using mixtures of stilbenes and COC were twofold. First, the isotropic transition temperature of mixtures between BCES or OCES and COC is lower than the transition temperature of pure nematic stilbenes. Therefore, smaller energy levels of irradiation are required to depress the isotropic transition point to or below room temperature. Second, the scattering of the cholesteric mixtures, that is, mixtures containing cholesteryl oleyl carbonate, is more intense than the scattering of stilbenes. The contrast without polarizers is therefore increased. The mixtures had the optical characteristics of cholesterics and were obtained by heating the two components jointly above the isotropic transition temperature.

The images are only visible in a limited temperature range whose span depends on the u.v. energy absorbed per unit volume. For example, if a mixture prior to irradiation has an isotropic transition temperature of 40°C and this temperature is imagewise lowered to 20°C, observation of the image is only possible in the temperature interval 20°-40°C. Above 40°C the whole sample is isotropic and below 20°C the sample is completely birefringent. Images obtained with positive and negative inputs are shown in Fig. 1 and 2, respectively. The dark regions are isotropic and the bright regions are liquid crystalline (cholesteric focal-conic texture). The liquid crystal, BCES with 20% by weight COC, was sandwiched between two quartz slides and contact-exposed through a photographic negative. The imaged slides were then placed on the stage of a Leitz polarizing microscope and photographed between crossed polarizers.

Fig. 1. Image obtained by contact exposure through photographic negative.

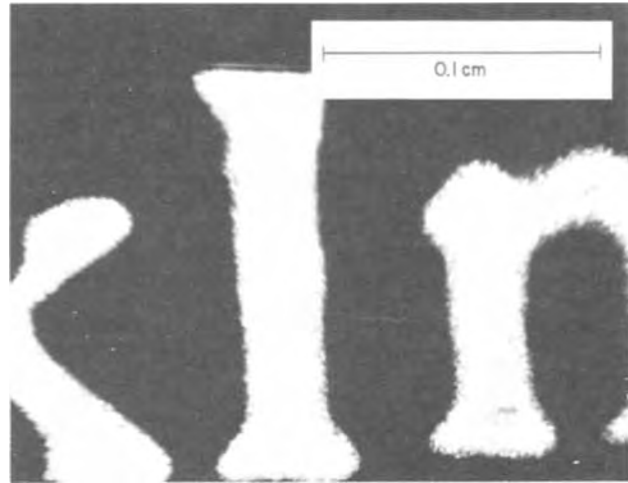

Fig. 2. Image obtained by contact exposure through photographic positive.

The changes in isotropic transition temperature of nematic stilbenes and mixtures with COC were measured as a function of irradiation. Since the absorption coefficient of stilbenes is very high in the u.v. (ϵ = 28,000 at 305 nm) (5), measurements were made on films 0.38-0.50μ thick.

The films were prepared by deposition from petroleum ether solutions and the thickness estimated from the interference color. Quartz slides proved to be unsuitable substrates for very thin films. Due to surface tension effects the films showed a tendency to break up shortly after deposition. The problem was circumvented by the use of 0.5 mil Tedlar[1] films as substrates. Tedlar has a suitable absorption spectrum for measurements at 3000Å. Samples were irradiated with a filtered xenon-Hg source equipped with quartz optics. The u.v. filter used had a half width of 120Å. The light levels were measured with an United Detector Technology Incorporated light metering system. The transition temperatures were measured on a Leitz polarizing microscope equipped with a Mettler temperature control-hot stage unit.

The results obtained for BCES and OCES are shown in Fig. 3 where the nematic isotropic transition temperatures $T_{n\text{-}i}$ are plotted *vs.* absorbed energy. Measurements of the cholesteric-isotropic transition temperature $T_{c\text{-}i}$ *vs.* absorbed energy are shown for two compositions in Fig. 4.

The liquid crystals, BCES, OCES, and COC, were used in the experiments as received from the sup-

[1] Trade name for du Pont PVF films.

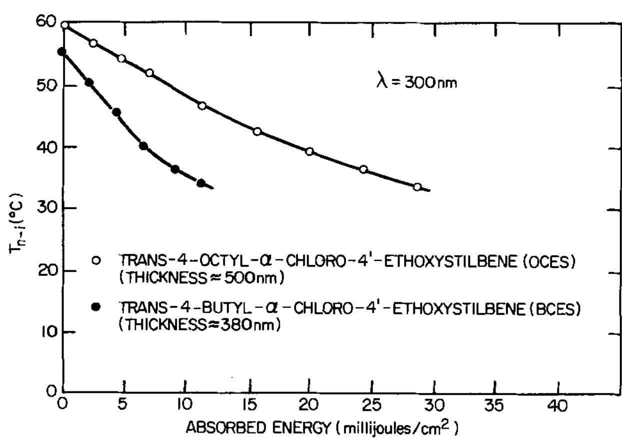

Fig. 3. Nematic-isotropic transition temperature vs. absorbed u.v. energy.

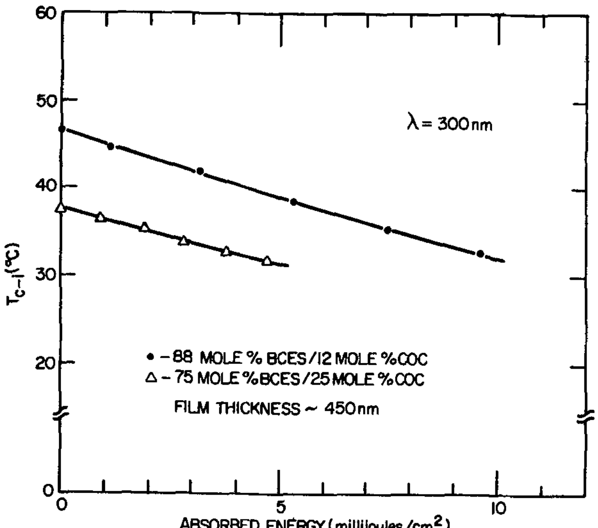

Fig. 4. Cholesteric-isotropic transition temperature vs. absorbed u.v. energy.

pliers.[2] Purification was deemed unnecessary because it was initially established that the isotropic transition temperatures were in good agreement with literature values, which is an indication of high purity. Further evidence for sample purity is the high resistivity of the stilbenes, which was of the order of 10^{11} ohm-cm. The effect is tentatively attributed to a *trans*→*cis* conversion of the stilbenes in which the u.v.-generated *cis*-stilbene acts as an impurity which depresses the liquid crystal-isotropic transition temperature. The role of impurities in the depression of liquid crystal-isotropic transition points is well known (6) and evidence to support the assumption that a *trans*→*cis* conversion takes place is given in Fig. 5, which shows a comparison of the u.v. absorption spectrum of BCES before and after irradiation with the known spectra of nonmesomorphic *trans*- and *cis*-α-chloro-4-methylstilbenes (7).

Solubility Rate of Poly-(Methyl Methacrylate), PMMA, Electron-Resist

James S. Greeneich

Electronics Department, General Motors Research Laboratories, General Motors Technical Center, Warren, Michigan 48090

Poly-(methyl methacrylate), PMMA, is a widely used positive electron-beam resist (1). The resist sensitivity is an important property in determining its usefulness in semiconductor device fabrication. For a typical solvent developer, 1:3 methyl isobutyl ketone: isopropyl alcohol, the reported sensitivity, experimentally determined as the minimum charge per unit area to develop an area pattern, is in the range 5×10^{-5} to 5×10^{-4} coulombs/cm². The spread in reported sensitivities is primarily attributed to varying exposure conditions, such as incident energy, film thickness, substrate, geometry of irradiated pattern (2), and developer temperature. A more fundamental quantity for expressing resist sensitivity is in terms of the absorbed energy density, ϵ (3). For degrading polymer resists with a large original number average molecular weight, $\overline{M}_n$, this description is adequate; however, for certain values of $\overline{M}_n$, the most meaningful quantity is the num-

Key words: electron resist, poly-(methyl methacrylate), electron-beam lithography, developer solubility rate, contrast function.

ber average fragmented molecular weight, $\overline{M}_f$, given by (4)

$$\overline{M}_f = \frac{\overline{M}_n}{1 + \dfrac{g\epsilon\overline{M}_n}{\rho A_o}} \qquad [1]$$

where ρ is the resist density, A_o is Avogadro's number, and g is an efficiency factor relating the susceptibility of the polymer to electron beam degradation.

Hatzakis and Broers report (5) an improved sensitivity for PMMA by using a developer system based on methyl isobutyl ketone, MIBK. For this developer system, Ting (6) reports the solubility rate for a single molecular weight as a function of an effective charge, αQ, where Q is the incident charge per unit area and α is the normalized depth-dose function (7)

$$\alpha(f) = 0.74 + 4.7f - 8.9f^2 + 3.5f^3 \qquad [2]$$

where f is the depth, z, normalized to the Grun range, R_G (7).

For an area exposure the absorbed energy density at a depth z in the resist is found from

$$\epsilon = \frac{Q}{q}\frac{E_o}{R_G}\alpha(f) \qquad [3]$$

where q is the electronic charge, and E_o is the incident energy. For thin resist films and large incident energies, $\alpha(f)$ is nearly constant and the absorbed energy density is a weak function of penetration depth. Furthermore, according to Eq. [1], the fragmented molecular weight is nearly constant.

We report on the solubility rate of PMMA in room temperature (23°C) MIBK for various original number average molecular weights. We establish an empirical relationship between the solubility rate and the fragment molecular weight. Using this relationship and Eq. [1], we define a contrast function, Γ, and determine the influence of $\overline{M}_n$ on Γ.

Experimental Procedure

Silicon wafers spin-coated with ~3000A of PMMA and baked at 160°C for longer than 90 min, received various doses of 20 keV electron-beam radiation deposited over typical areas of 10^{-3} cm^2. An exposed sample was developed in MIBK and periodically the thickness determined by the interference color of the partially developed areas. Ellipsometer measurements determined the refractive index to be 1.48 ± 0.02. Ellipsometer measurements on the solubility in MIBK of nonirradiated samples established the accuracy to be better than ±150Å.

Various original molecular weight materials were investigated. The values of $\overline{M}_n$ as determined by gel permeation chromatography were between 10^4 and 2×10^5. The molecular weight distributions of these samples were nearly identical with the ratio of the weight average molecular weight to $\overline{M}_n$ of ~3; no attempt was made to alter the PMMA distribution. The resist solution was prepared by dissolving the polymer in trichlorethylene.

Results

A typical result, Fig. 1, shows the thickness remaining *vs.* developer time for the indicated absorbed energy densities calculated from Eq. [3]. The linear relationship for all but very small doses is indicative of uniform energy absorption. The nonlinear behavior at very small doses for short developer times is consistent with ellipsometer measurements on high molecular weight samples receiving no electron dose.

The solubility rate, R, for a given polymer-developer system is given by the slope of the thickness-time curve. Using Eq. [1] we show R *vs.* $\overline{M}_f$ in Fig. 2 for several original values of $\overline{M}_n$. We establish that the solubility rate of the degraded polymer in MIBK at a given temperature is only a function of the fragmented

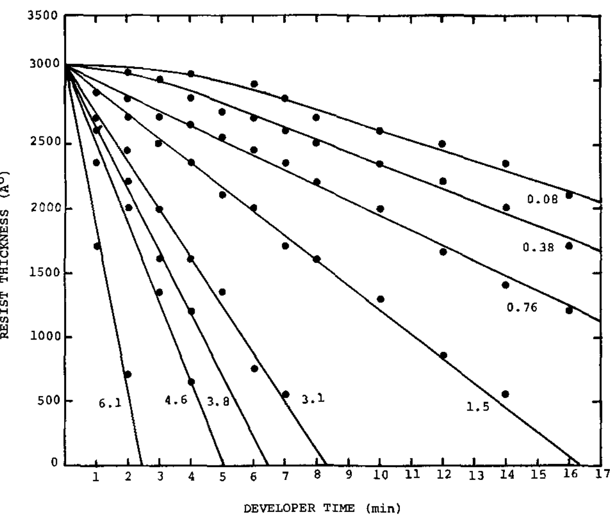

Fig. 1. PMMA resist thickness vs. MIBK development time for indicated absorbed energy densities given in units of 10^{21} eV/cm^3.

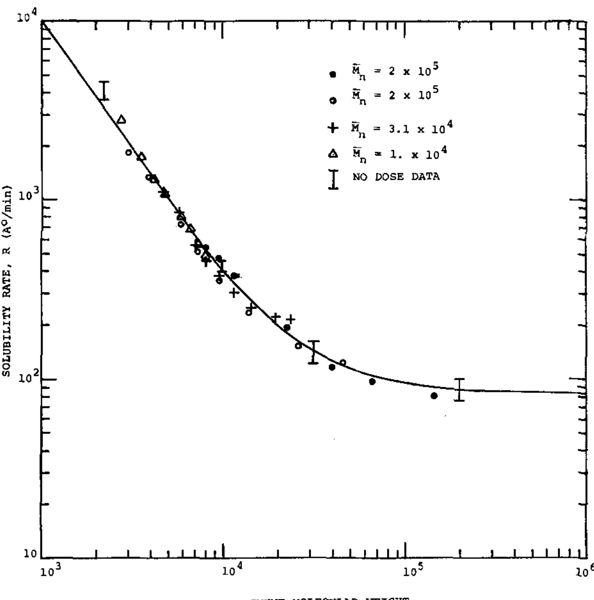

Fig. 2. Solubility rate vs. fragmented molecular weight for PMMA in MIBK at 23°C. Data from various initial molecular weight polymers is shown.

molecular weight. The no dose data shown in Fig. 2 are also consistent with the solubilty rate curve. The solid curve in Fig. 2 is given by the relationship

$$R = R_o + \frac{\beta}{\overline{M}_f^{\,n}} \qquad [4]$$

where in this case $R_o = 84$Å/min, β is the proportionality constant $3.14 \times 10^8 \dfrac{\text{Å}}{\text{min}}\left(\dfrac{\text{gm}}{\text{mole}}\right)^{1.5}$ and $n = 1.5$.

The solubility rate is a strong function of the developer solvent and its temperature; however, the general form of the relationship given by Eq. [4] is found to hold in the cases investigated thus far. We are investigating other temperatures and additional solvent developers, including mixtures of MIBK and isopropyl alcohol. The form of the solubility rate also holds for these mixtures and temperatures; these results will be reported later.

For a given solvent developer, the relative solubility of the irradiated region compared to the nonirradiated region determines the contrast of the developed pattern

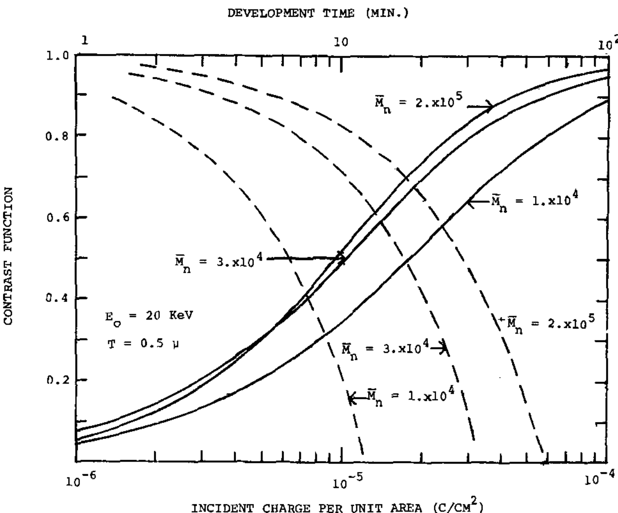

Fig. 3. The contrast function (solid lines) is plotted vs. incident charge per unit area for 5000Å of resist subjected to 20 keV electrons and developed in MIBK. The required development time (dashed lines) for a given Γ is found using the upper, time, axis.

and hence its suitability in device processing. The contrast, Γ, is determined by R which is a strong function of the incident electron dose. For a film of thickness T, original molecular weight $\overline{M}_n$, Γ is found as

$$\Gamma = 1 - \left(R_o + \frac{\beta}{\overline{M}_n{}^n} \right) \frac{1}{T} \int_o^T \frac{dz}{R_o + \dfrac{\beta}{\overline{M}_f{}^n}} \qquad [5]$$

where the dependence of $\overline{M}_f$ on z is found from Eq. [1], [2], and [3]. In Fig. 3 we show Γ *vs.* Q for three values of $\overline{M}_n$ for the developer system used. The initial energy is 20 keV and $T = 0.5\mu$. The dotted lines in Fig. 3 show the required development time as a function of Γ for the given exposure condition. To obtain a high contrast exposure for a given Q, a high molecular weight polymer is preferred at the expense of longer development times than for lower molecular weight polymers.

Analysis of Zone Melting Processes

E. Y. Wang

Electrical Engineering Department, Wayne State University, Detroit, Michigan 48202

For different pertinent boundary conditions Pfann (1) has derived equations which describe the impurity distribution along a crystal after passage of one molten zone. In this note, starting from the conservation of total number of impurity atoms, a general and expedient method of deriving those well-known analytic results is presented.

General Formula

As shown in Fig. 1, the molten zone, l, is passed from left to right. The impurity concentration in the molten zone is designated C_l, that in the melting solid C_{ms}, and that in the solidified solid C_{fs}. It is assumed that C_l is homogeneous in the molten zone, that the impurity diffusion is negligible, and that no evaporation of impurity occurs during the melting. From the conservation of impurity atoms, N, one has

$$\int_o^x C_{fs}(x')A(x')dx' + C_l(x)\int_x^{x+l(x)} A(x')dx' + \int_{x+l}^{L} C_{ms}(x')A(x')dx' = N \qquad [1]$$

Key words: zone melting, crystal growing, zone leveling.

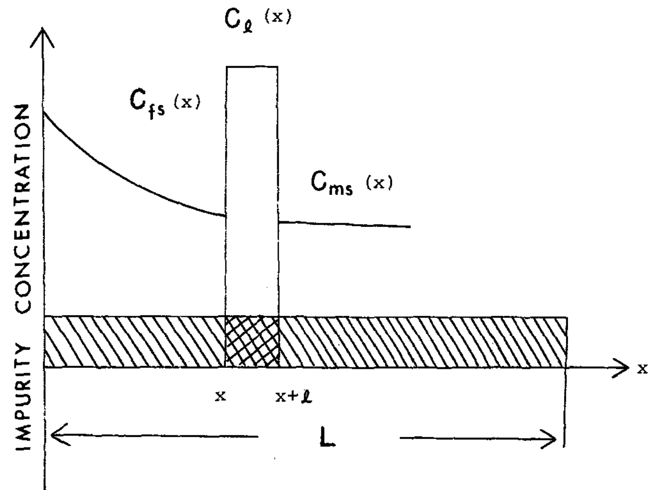

Fig. 1. Schematic representation of zone melting

Analysis of Zone Melting Processes

E. Y. Wang

Electrical Engineering Department, Wayne State University, Detroit, Michigan 48202

For different pertinent boundary conditions Pfann (1) has derived equations which describe the impurity distribution along a crystal after passage of one molten zone. In this note, starting from the conservation of total number of impurity atoms, a general and expedient method of deriving those well-known analytic results is presented.

General Formula

As shown in Fig. 1, the molten zone, l, is passed from left to right. The impurity concentration in the molten zone is designated C_l, that in the melting solid C_{ms}, and that in the solidified solid C_{fs}. It is assumed that C_l is homogeneous in the molten zone, that the impurity diffusion is negligible, and that no evaporation of impurity occurs during the melting. From the conservation of impurity atoms, N, one has

$$\int_0^x C_{fs}(x')A(x')dx' + C_l(x)\int_x^{x+l(x)} A(x')dx' + \int_{x+l}^L C_{ms}(x')A(x')dx' = N \quad [1]$$

Key words: zone melting, crystal growing, zone leveling.

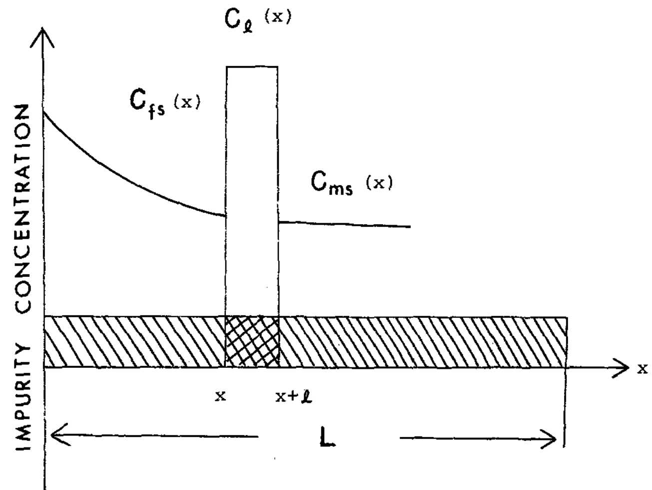

Fig. 1. Schematic representation of zone melting

where $A(x)$ is the cross-section area of the crystal. Differentiating Eq. [1] with respect to x yields

$$C_{fs}(x)A(x) + \left[\int_x^{x+l(x)} A(x')dx'\right]\frac{dC_l(x)}{dx} + C_l(x)A(x+l)\left(1+\frac{dl}{dx}\right) - A(x)C_l(x) - C_{ms}(x+l)\,A(x+l)\left(1+\frac{dl}{dx}\right) = 0 \quad [2]$$

where $C_l(x)$ is considered as a function of x related to the location of the molten zone along a crystal, but $C_l(x)$ is constant in the molten zone, and A, l, are treated as functions of x

By the definition of the distribution coefficient $C_{fs}(x)/C_l(x) \equiv k$, Eq. [2] can be written

$$\left[\int_x^{x+l(x)} A(x')dx'\right]\frac{dC_{fs}(x)}{dx} + C_{fs}(x)\left[A(x+l)\left(1-\frac{dl}{dx}\right) - A(x)(1-k)\right] - k\,A(x+l)\left(1+\frac{dl}{dx}\right)C_{ms}(x+l) = 0 \quad [3]$$

Both Pfann's zone leveling conditions and impurity distributions of a single pass, multipass, and steady state can be readily obtained from Eq. [3]. The former will be presented first.

Zone Leveling Conditions

For an initially pure rod and an addition of impurity in the first molten zone, $C_{ms}(x+l)$ usually is several orders of magnitude smaller than $C_{fs}(x)$. Equation [3] can be reduced to

$$\left[\int_x^{x+l(x)} A(x')dx\right]\frac{dC_{fs}(x)}{dx} = A(x)(1-k) - A(x+l)\left(1+\frac{dl}{dx}\right)C_{fs}(x) \quad [4]$$

The zone-leveling condition along a crystal requires that

$$C_{fs}(x) = \text{constant, or } \frac{dC_{fs}(x)}{dx} = 0$$

Equation [4] can be further reduced to

$$A(x)(1-k) - A(x+l)\left(1+\frac{dl}{dx}\right) = 0$$

or

$$\frac{dl}{dx} = \frac{A(x)}{A(x+l)}(1-k) - 1 \quad [5]$$

Case I: If $A(x)$ = const, $l(x) \neq$ const. Equation [5] gives

$$\frac{dl}{dx} = -k, \text{ or } l = l_0 - kx \quad [6]$$

Equation [6] is the condition for a uniform impurity distribution along the crystal if one varies the zone length and retains a constant cross-section area. l_0 is the initial molten zone length.

Case II: If $l(x)$ = const, $A(x) \neq$ const. Eq. [5] gives

$$A(x)(1-k) = A(x+l)$$

or

$$\frac{A(x+l) - A(x)}{l} = \frac{kA(x)}{l} \quad [7]$$

Equation [7] gives an exact $A(x) = A_0(1-k)^{x/l}$, which is identical with Pfann's solution $A(x) = A_0e^{x/D}$, where $D = \frac{l}{\log_e(1-k)}$.

For small l

$$\frac{A(x+l) - A(x)}{l} \simeq \frac{dA(x)}{dx} = \frac{kA(x)}{l}$$

which yields

$$A(x) = A_0 \exp\left(-k\frac{x}{l}\right) \quad [8]$$

where A_0 is the initial cross-section area. Equation [8] gives the variation of cross-section area necessary to maintain a uniform impurity distribution along a crystal.

Impurity Distribution

Now consider the impurity distribution along a crystal for the conditions $A(x)$ = const and $l(x)$ = const. Equation [3] becomes

$$\frac{dC_{fs}(x)}{dx} + \frac{k}{l}C_{fs}(x) - \frac{k}{l}C_{ms}(x+l) = 0 \quad [9]$$

which is exactly the same equation derived by Read (1) and Reiss (2). Lord (3) also used Eq. [9] to compute the impurity distribution for various passes by replacing $C_{ms}(x+l)$ for $C_{fs}(x+l)$ in preceding pass. Steady state, or ultimate impurity distribution, can easily be obtained by letting $C_{fs}(x+l) = C_{ms}(x+l)$ and substituting into Eq. [9]. The solution of Eq. [9] is then $C_{fs}(x) = Ae^{Bx}$ where A, B are constants obtainable from $k = \frac{Bl}{e^{Bl}-1}$ and $A = \frac{NB}{e^{BL}-1}$. The solution again is identical with Pfann's ultimate distribution (4).

Brief Communications

Synthesis and Properties of $ZnGeN_2$

William L. Larson, H. Paul Maruska,*[,1] and David A. Stevenson*

Department of Materials Science and Engineering, Stanford University, Stanford, California 94305

The search for new semiconductor materials with optimum properties for specific applications has led to the synthesis and characterization of new ternary compound semiconductors. One class of ternary compounds is a pseudobinary solid solution, such as the III-V compounds $Ga_xIn_{1-x}As$ or $GaAs_xP_{1-x}$. Another class of ternary compounds, much less extensively studied, is a solid solution formed from the isoelectronic replacement of one element in a binary compound by two different elements, such as a II-IV-V_2 analogue of a III-V compound (1). In addition to a great variety of combinations for the latter class of compound, there is the possibility of significant alteration in the electrical properties by variation of the ratio of the II to IV element. The present note describes the synthesis and properties of $ZnGeN_2$, which is the II-IV-V_2 analogue of the III-V compound GaN.

The compound $ZnGeN_2$ has been prepared by the reaction of Zn with Ge_3N_4 and by the reaction of ammonia with Zn_2GeO_4 (2). In these preparative techniques, there is the possibility of incorporating a significant amount of oxygen in the final product. (The GeN_4 in the first synthetic scheme is prepared by the reaction of GeO_2 with NH_3.) A recent study of the stability of $ZnGeN_2$ established that the compound may be synthesized from the metal chlorides in atmospheres of partially dissociated ammonia (3). In the present study, layers of $ZnGeN_2$ were grown in an open flow vapor growth system, similar to that used for GaN (4). An HCl-N_2 gas mixture (4.93×10^{-4} moles HCl/minute plus 2.57×10^{-2} moles N_2/minute carrier gas) was successively flowed over elemental zinc (59 grade) and Ge (69 grade) at respective temperatures of ~550° and ~950°C, and the resulting vapor was mixed with an NH_3-N_2 atmosphere (2.69×10^{-2} moles NH_3/minute with 2.25×10^{-2} moles N_2/minute carrier gas) in the reaction chamber where deposition occurred. Deposition was made on sapphire substrates with (0001) and $(1\bar{1}02)$ orientations and a growth temperature of 850°C; (higher temperatures resulted in the deposition of zinc-doped elemental germanium). Deposition rates were typically 1 μ/hour and the final samples were yellow polycrystalline materials approximately 1-2μ in thickness. A scanning electron micrograph of the surface revealed small particle sizes of the order of 0.1-0.5μ (Fig. 1).

The crystal structure and the lattice parameters, measured using a Debye-Scherrer powder pattern technique, indicated a wurtzite structure with a = 3.193Å and c = 5.187Å at room temperature. There was a small amount of line broadening observed, presumably caused by slight distortion of the lattice resulting from the mismatch between the sapphire substrate and the $ZnGeN_2$ film. These x-ray results may be contrasted with those of Maunaye and Lang (2), who reported that $ZnGeN_2$ is monoclinic, with a = c = 3.167Å, b = 5.194Å and β = 118°53′. It should be

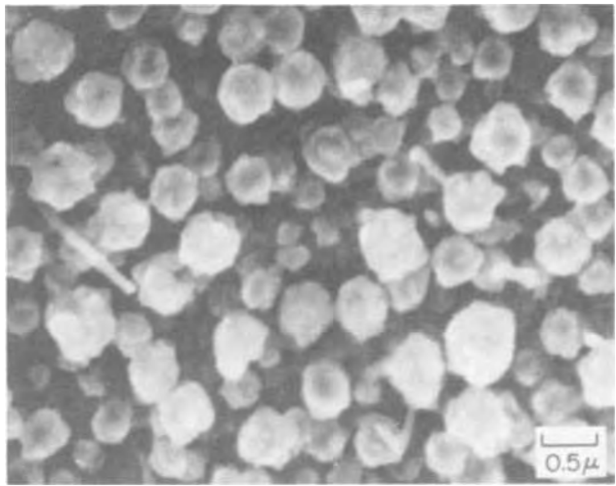

Fig. 1. Scanning electron micrograph of a layer of deposited $ZnGeN_2$.

Key words: ternary compound, chemical vapor deposition, crystal structure, bandgap, carrier concentration.

noted that their results differ from a wurtzite structure only by a discrepancy of 1°7′ in the angle β, hence one might describe their structure as slightly distorted wurtzite. This distortion might be caused by the incorporation of residual oxygen impurity, since the reactants were oxides. The structure and lattice parameters are almost identical to the isoelectronic III-V compound, GaN (wurtzite structure with a = 3.189Å and c = 5.185Å).

The resistivity and Hall coefficient of the $ZnGeN_2$ films were measured using a six contact method. Pure $ZnGeN_2$ was always n-type with electron concentrations of 10^{18}-10^{19} cm^{-3} and resistivities between 0.3 and 0.4 ohm-cm at room temperature. As might be expected for polycrystalline samples, room temperature mobilities were low, ranging from 0.5 to 5 cm^2/V-sec. Hall constants and resistivities measured *vs.* temperature were found to be constant throughout the temperature range from 100° to 300°K. Optical absorption measurements of polished $ZnGeN_2$ samples, displayed in Fig. 2, indicate a bandgap of approximately 2.67 eV. In this particular sample, the absorption coefficient at 3.2 eV is approximately 58,000 cm^{-1}. The similarity between $ZnGeN_2$ and the analogous III-V compound GaN is noteworthy, particularly the crystal structure and the high carrier density.

Manuscript submitted May 6, 1974; revised manuscript received July 26, 1974.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1975 JOURNAL. All discussions for the June 1975 Discussion Section should be submitted by Feb. 1, 1975.

Confirmation of Existence of Phase Transitions in InSe by Specific Heat Measurement and X-Ray Analysis

Kazuaki Imai, Minoru Sato, and Yutaka Abe

Department of Nuclear Engineering, Hokkaido University, Sapporo 060, Japan

Indium monoselenide has been known as one of the layered semiconductors and several investigations have been reported concerning the electronic (1) and optical (2) properties of this material. However, experimental results are widely scattered, and it seems very difficult to find consistent results among the various investigators. We have supposed that the above inconsistency is, at least partly, due to certain inhomogeneity of the crystal which is introduced inherently during the crystal growth by Bridgman or Czochralski method.

In this short note, we report the existence of several, well-defined temperatures of phase transitions in indium selenide and the experimental result of annealing in the specimens of quenched phase.

Differential Thermal Analysis (DTA) and Specific Heat Measurement (SHM)

The DTA and SHM have been carried out with the following types of specimens:

1. Stoichiometric amounts of indium (99.999%) and selenium (99.999%) were enclosed in a quartz holder in vacuum of 10^{-5} Torr. After direct fusion, the compound was cooled down slowly to room temperature. Hereafter, we shall refer to these specimens as A.

2. A large ingot of indium selenide was prepared by the Bridgman method. The specimens were carefully cut out of the ingot by wire sawing machine. We shall refer to these specimens as B in what follows. It was confirmed by x-ray fluorescence analysis that our specimens had the composition of $In_{1.00}Se_{0.99}$.

The DTA was performed with α-Al_2O_3 as the standard sample and the heating rate was about 1°C/min. The typical experimental result is shown in Fig. 1. Here we can clearly observe that there are four definite endothermic peaks between room temperature and 700°C. The SHM was carried out with apparatus similar to the one for DTA. In our method, the time for the unit temperature increase (which is proportional to the specific heat under the test) was measured. As shown in Fig. 2, the peaks which correspond to the ones in the DTA were observed. The DTA has a tendency that the measured temperatures are shifted to the side of higher temperature compared with the results from the SHM. We prefer the results of SHM in designating the characteristic temperature. The above experimental results are reproducible, and the temperatures of the peaks are found to be in good agreement among the various specimens of types A and B. The sharpness of the above endothermic peaks indicates that these peaks are due to finite phase transitions rather than to the recovery of defects in the crystal. The observed transition temperatures are 156° ±

Key words. compound semiconductor, semiconductor materials, layered semiconductors, crystal structures, crystal structures and phase changes.

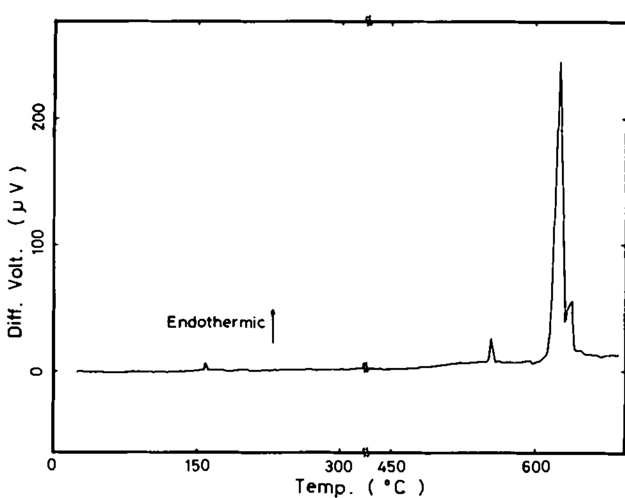

Fig. 1. A typical result of DTA. The longitudinal axis is differential thermal voltage of chromel-alumel thermocouple from the standard sample. The weight of the specimen is about 1.3g.

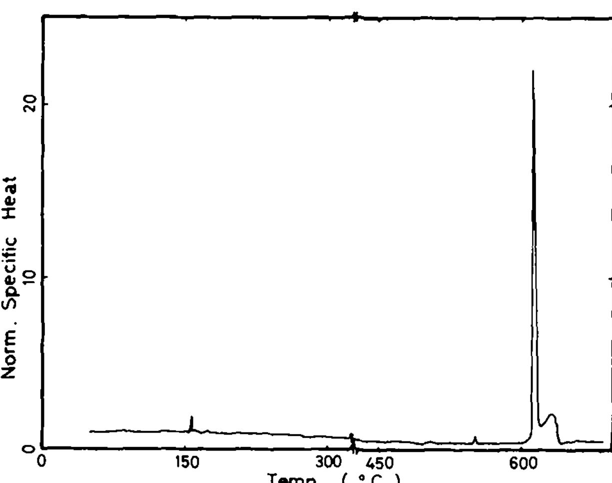

Fig. 2. A typical result of SHM. The longitudinal axis is the specific heat which is normalized at room temperature. The weight of the specimen is 14.4785g, quartz holder is 5.0042g, and the internal heater is about 60 mW.

2°, 554° ± 3°, 614° ± 3°, and 636° ± 3°C, respectively. The melting point is 614° ± 3°C, and this value is lower than the one previously reported (3).

Annealing Effect

In order to find the experimental criteria for getting the single crystal of InSe of homogeneous phase, we have investigated the effect of annealing by x-ray analysis. The annealing of specimens was performed at 480°C for 70 hr in vacuum of 10^{-5} Torr. The variation of x-ray Laue pattern by the above anneal is shown in Fig. 3. The specimens in this experiment are of type B in the previous section and cleaved surface parallel to c-plane were used. As far as we have observed the annealed specimens by high resolution optical microscope we have found no indications of local excess of indium or selenium during the annealing process. As seen from Fig. 3(a), the Laue pattern of the as-grown specimen has diffused spots and the spot itself has fine structure. However, the pattern seems to have sixfold symmetry. After the annealing, the Laue spots become focused and have threefold symmetry as distinctly observed in Fig. 3 (b).

For specimens of type A we have investigated the annealing effect by the Debye-Scherrer photograph. However, with the obtained profile we cannot confirm the hexagonal crystal structure of D^4_{6h} which was previously reported (4).

Concluding Remarks

We have shown experimentally the existence of the definite phase transitions in stoichiometric indium-selenium system between room temperature and 700°C. We have also shown the characteristic variation of Laue pattern in the specimens of quenched phase. These results throw light on the physical origin of widely scattered experimental results of the electronic and optical properties in InSe. We conjecture that similar situations are likely to occur in other layered semiconductors such as GaSe and GaS. To clarify the conditions for getting the perfectly monophase crystals, further quantitative investigations of SHM are in progress.

Acknowledgment

The authors would like to thank Professors M. Kaneko and K. Hikichi of Department of Polymer Science, for the provision of experimental facilities and for their valuable suggestions on the method of the present measurements.

DISCUSSION SECTION

This Discussion Section includes discussion of papers appearing in the *Journal of The Electrochemical Society*, Vol. 121, No. 1, 2, 4, and 5; January, February, April, and May 1974.

The Temperature and Compositional Dependence of the Electrical Conductivity of Nonstoichiometric CeO_{2-x}

R. N. Blumenthal and R. L. Hofmaier (pp. 126-131, Vol. 121, No. 1)

B. Claudel:[1] In the afore-mentioned paper, the authors report that they find a low temperature conductivity σ for CeO_{2-x} which can be expressed as

$$\sigma = \sigma_0 \exp\left(-\frac{Q}{kT}\right)$$

where Q, independent of x is found equal to 0.61 ± 0.03 eV. We had previously reported[2] the same value for the activation energy of the electrical conductivity of a ceria powder put under a nitrogen atmosphere at temperatures below 400°C. Although our experiments were certainly carried out under cruder conditions than those of Blumenthal and Hofmaier, this agreement seems remarkable. In connection with the interpretation given by these authors in the paper under discussion to the occurrence of a two phase domain, it is worth noting that our samples were prepared by a low temperature process [calcination of $(NH_4)_2Ce(NO_3)_6$ at 450°C] which could hardly yield solid phases in thermal equilibrium, and that we were unable to detect any other phase than CeO_2, either by x-ray or by electron diffraction.

Comments on the Article "On the Theory of Thermal Quenching of Luminescence"

by H. Payen de la Garanderie and D. Curie

R. Pappalardo (pp. 312-313, Vol. 121, No. 2)

H. Payen de la Garanderie[3] **and D. Curie:**[4] Quite recently the paper under discussion which criticizes one of our papers[5] was published.

First, confusion must be carefully avoided between: (*i*) the radiative transition probability per unit time interval, which is denoted by I_r in our paper,[5] and (*ii*) the light efficiency, η, of the material, which is commonly referred to by the expression

$$\eta = \frac{I_r}{I_r + I_{nr}}$$

I_{nr} is, in the same way as for I_r, the probability of nonradiative transitions per unit time interval.

[5] H. Payen de la Garanderie and D. Curie, in "Luminescence of Organic and Inorganic Materials," Kallmann and Spruch, Editors, p. 334, John Wiley and Sons, Inc., New York (1962).

Of course, in the thermal quenching temperature region I_{nr} increases *vs.* temperature much faster than I_r does, and therefore this increase of I_r does not mean that "the fluorescence intensity can be enhanced by temperature increases," as is stated in the paper under discussion.

However, some enhancement effects have been reported in some cases, but they are generally ascribed to additional mechanisms, for instance to displacements in the peak positions of the absorption spectra.

A second point is the following one. We considered the case of a monochromatic excitation occurring in a large band emitting and absorbing phosphor. Then the following set of equations was used

$$\frac{dn_j}{dt} = An_{j-1} - (A + E)n_j + En_{j+1} - pn_j = 0 \quad [1]$$

(The notations are described in both the paper under discussion and in our article,[5] n_j refers to the population of vibrational level j.) But this equation must be modified for the vibrational level which is reached by excitation; let us call j_0 this level

$$\frac{dn_{j_0}}{dt} = An_{j_0-1} - (A + E)n_{j_0} + En_{j_0+1} - pn_{j_0} + q = 0$$

where q is the pumping intensity. A similar modification occurs for the level corresponding to the crossing point of the excited state and fundamental state configurational curves. For other levels, Eq. [1] remains unchanged. The complete set of equations used is, of course, described in a more detailed fashion in our paper.[5]

On the other hand, Pappalardo in the paper under discussion considers indeed the case when pumping occurs by means of a large band excitation and thus leads to the whole set of vibrational levels. In such a case all sets of Eq [1] for the populations of the vibrational levels must be changed in the way described above

$$\frac{dn_j}{dt} = An_{j-1} - (A + E)n_j + En_{j+1} - pn_j + q = 0 \quad [2]$$

If one assumes, as Pappalardo did in the above mentioned work, the case of an approximate Boltzmann distribution to be valid, then Eq. [2] has for equilibrium

$$pn_j = q$$

and

$$I_r = p\Sigma n_j = \text{the total pumping intensity } \Sigma q$$

in agreement with expression [3] of the paper under discussion. Σq here must be performed upon any vibrational levels of the center that are reached by excitation.

The reader will notice, however, that the "pump intensity" q in the work being discussed means actually the sum of populations Σn_j, *i.e.*, an expression which is proportional to the pumping intensity, but not the pumping intensity itself, for if this were the case, Eq.

[2] and [3] of the paper under discussion would not be dimensionally correct.

R. Pappalardo: In Payen de la Garanderie's and Curie's comments above about my criticism of their article[5] in the paper under discussion, they point out in particular that the dimensions of q in Eq. [2] and [3] of my paper are not correct. In these equations I have used q as a pump-energy term (proportional to the total number of exciting transitions). Since q is used in their work as a pump-power term (proportional to the rate of exciting transitions) their criticism is justified.

My basic objections to the article in question,[5] which I stated in the paper being discussed, are not clearly refuted. Since some of the remarks in that paper seem to have been misinterpreted, I shall briefly summarize my previous observations. Quotation marks are used for statements contained in the article by Payen de la Garanderie and Curie.[5]

My criticism was basically aimed at such statements as:[5] "But usually I_r is considered to be a constant term, while here I_r increases with increasing temperature," and also "I_r increases because the effective number of states leading to a light transition increases with temperature." I have pointed out that this conclusion is incorrect, even within the context of quasi-monochromatic excitation[5] because of inconsistencies in the mathematical derivation.

The "radiatively emitted light intensity I_r" is expressed[5] in approximate form as a product of three factors: the constant p (the "light-emitting transition rate"); the population n_0 of the lowest vibrational level in the excited electronic state; and the factor $[1 - \exp(-h\nu_e/kT)]^{-1}$. My objection is to Payen de la Garanderie's and Curie's implicit assumption[5] that the factor containing the exponential is the only temperature dependent quantity. Actually, with the increase in temperature the increase in the $[1 - \exp(-h\nu_e/kT)]^{-1}$ factor will be compensated by a decrease in n_0, so that the over-all value of I_r will not increase with temperature. This was already discussed in my paper under present consideration. This conclusion can also be proved as follows. When the equilibrium rate Eq. [I] and [II] of Payen de la Garanderie's and Curie's paper[5] are summed together the resulting expression is

$$q = sn_{j_1} + \Sigma'_j pn_j \quad [1]$$

where the prime indicates that the summation is carried out over the vibrational levels up to. and including, the vibrational level j_1 from which radiationless decay takes place with rate s. This is a mathematical formulation of the obvious result that in the particular physical model under discussion, the excitation (expressed via q) will be dissipated as radiative emission from all the vibrational levels of the excited state up to j_1, and as radiationless transitions from the latter vibrational level. (Incidentally, since equilibrium conditions have been assumed, it is irrelevant which vibrational level is excited, as long as it is below the j_1 level.)

Since the rate p, s, and q are assumed to be constant and temperature independent in the particular model under discussion, and since n_{j_1} increases monotonically with temperature, the radiative intensity term $I_r = \Sigma'_j pn_j$ can only decrease when the temperature increases, in agreement with physical intuition.

Effect of Dielectric Insert on Surface Charge Density of Electrets

K. Ikezaki, I. Fujita, K. Wada, and J. Nakamura (pp. 591-593, Vol. 121, No. 4)

B. Gross:[6,7] K. Ikezaki, I. Fujita, K. Wada, and J. Nakamura describe in the paper under discussion the process of generation of homocharge as follows: "According to the theory of Perlman and Reedyk,[8] applying a voltage between electrodes increases the polarization of the inserted glass disk and the field in the air gap. Eventually, this field will exceed the breakdown strength of the air in the gap and the spray discharge will occur. The homocharge deposition of this spray discharge reduces the field in the gap to a value below breakdown and the discharge is quenched . . . ." I wish to point out that this theory is contained in a series of papers which I have published since 1944.[9-12] To quote from a paper published in 1949:[10] "With increasing polarization of the dielectric, the field . . . in the interface rises to high values. Finally the interface breaks down and a considerable amount of charge is rushed from the electrode to the surface of the dielectric. This charge has a polarity which is contrary to that of the original charge of the dielectric; it neutralizes part of the latter and thus reduces the field in the interface below sparking threshold." As indicated in a previous comment,[11] the detailed theory of the effect, involving the Paschen curve, has also been developed at an early stage.[12] It has been confirmed by later authors.[13, 14]

Anomalous Boron Diffusion in Silicon from Planar Boron Nitride Sources

J. Stach and A. Turley (pp. 722-724, Vol. 121, No. 5)

D. M. Brown:[15] The anomalous boron diffusion effects reported in the paper under discussion by Messrs. Stach and Turley ("Deeper penetration in the high concentration area suggests a concentration dependent diffusivity giving enhanced diffusion at high concentrations; however, the concentration gradient near the surface indicates that the diffusivity probably reaches a maximum value and then begins to decrease with higher concentrations.") indicate probable confirmation of previously published data on this phenomenon.[16] Figures 5 and 6 of this earlier work[16] show that the boron diffusivity does indeed increase until the concentration reaches about $3 \times 10^{20}/cm^3$ whereupon it peaks and then rapidly decreases by a factor of three or four for concentrations above this. Possible causes of this effect were also discussed. Similar results were also observed by L. F. Cordes.[17] The similarity between these boron diffusion results and those observed for arsenic diffusions have also been previously presented in detail and comparatively discussed.[18]

Stach's and Turley's preliminary conclusions, on the anomalous diffusion of boron in the paper under discussion were correct and consistent with the earlier work cited here.[16-18]

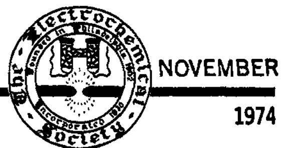
JOURNAL OF THE ELECTROCHEMICAL SOCIETY

REVIEWS AND NEWS



NOVEMBER 1974

Report of the Electrolytic Industries for the Year 1973[1]

J. Parker*
Electrode Corporation, Chardon, Ohio 44024

and R. S. Karpiuk*
The Dow Chemical Company, Midland, Michigan 48640

Chlorine—Caustic Soda

I. Production.—U.S. production of chlorine reached a record level of 10,421,115 tons in 1973, an increase of 6.2% over 1972 and of 11.4% over 1971. Canadian production was 1,006,473 tons, up 9.1% from the preceding year (1).

Production rates in the U.S. were very high throughout the year of 1973, averaging 95.9% of capacity (2). In the last two months of 1973, production was 99.1% of capacity, and a record production was established in December at 29,710 tons per day (1, 2). In Canada, for 1973, production averaged 92.6% of capacity.

The year saw the start-up of expanded or modernized chlorine facilities at six locations in the U.S., while two plants were shut down. In Canada, there was one expansion, plus two shutdowns. Total capacity increased in both countries, but the increase was less than 1% in the U.S. and about 6.5% in Canada (1-3).

Both chlorine and caustic were in short supply throughout 1973, and it is expected that the shortage will continue to exist throughout most of 1974. However, at the beginning of 1975, chlorine capacity should begin to overtake consumption (4).

The combination of short supply and skyrocketing energy costs forced the prices upward for both chlorine and caustic. During the first half of 1973, chlorine prices went up about $5/ton, finally rising from discount levels to its long posted $75/ton, in tank car quantities. The second half brought some boosts to $80-81/ton. Caustic's 1972 move to list prices, meanwhile, was all but completed; the price at year's end was about $76/ton for 50% solution (4, 5).

No relief from price increases for chlorine and caustic appears in the offing for 1974 because of the continuing shortage and increasing power costs.

The Chlorine Institute estimates that by January 1, 1975, expansions underway will boost U.S. capacity from the present 30,000 to about 35,000 tons/day, an increase of about 16.7% (1,4). Of this increase, about 2000 tons will come on-stream during the first three-quarters of 1974, and the remaining capacity the last quarter of that year. Diaphragm cell plants in the size ranges of 800-1200 tons/day will contribute about 4000 of the 5000 ton capacity. The remaining tonnage will come from the Kellogg nonelectrolytic HCl oxidation process, Kel Chlor (600 tons/day), from by-product chlorine from magnesium production (200 tons/day), and from small increases from expansion of existing diaphragm and mercury cell facilities (4, 9).

In 1973, 71.8% of U.S. chlorine production was from diaphragm cells and 24.6% from mercury cells; miscellaneous production from all other sources accounted for 3.6% (9).

The market breakdown for chlorine remains about the same as in the past (4):

Vinyl chloride monomer (VCM)	20%
Chlorinated organic solvents	25%
Other chlorinated organics	20%
Chlorinated inorganics	10%
Pulp and paper	10%
Water and waste treatment	5%
Miscellaneous	10%

As noted above, VCM is the largest single product user of chlorine, and much of the growth in chlorine is dependent on the growth rate of this product. With the exception of 1971-1972, the VCM chlorine demand increased at the rate of 12-15%/year over the last decade. In 1974, the growth rate is expected to be 10-15% if VCM makers can get enough ethylene, the coingredient with chlorine, and build new facilities (4). Also an unknown factor is the O.S.H.A. standard with regard to VCM concentration in air. If the maximum allowable concentration is fixed at 1 ppm in air, which most plants presently feel they would be unable to meet, this regulation would have serious implications on chlorine production.

The demand for chlorine in the chlorinated organics area will be largely dictated by the availability of hydrocarbons.

The chlorine shortage was reported to be affecting municipal drinking water supplies. Legislation is being considered by Congress to assure adequate supplies. Chlorine suppliers, such as Dow Chemical and Diamond Shamrock, say they can meet any municipal needs and that legislation is not required (6-8).

The biggest threat seen to meeting production goals is inadequate electrical power. In 1973, power interruptions were more frequent and more severe than ever before. Plants in the Northwest were affected most, with the Northeast close behind (4).

Caustic is in continuing short supply because of the high demand by the paper, glass, and aluminum industries. Generally, even with the expansion of the natural soda ash facilities, chlor-alkali producers do not expect any excess caustic for several years (4).

All chlorine producers, whether using mercury or diaphragm cells, are facing government regulations in water and air pollution and also in the areas of working conditions at both Federal and State levels. It has been predicted that the net effect of these regulations will be to increase plant costs by 2-5%; how-

II. Current changes in chlorine operations (4, 9)

Company and location	Type of cell	Total capacity, tons/day	Completion date
A. Production Started			
BASF Wyandotte Geismar, La.	Added Hooker H-2 cells	—	September 1973
Linden Chlorine Products Linden, N.J.	Krebs cells	—	December 1973
Dow Chemical of Canada Sarnia, Ontario	Dow diaphragm cells	1000	September 1973
The Dow Chemical Co. Pittsburg, Calif.	Cell replacement	—	July 1973
The Dow Chemical Co. Midland, Mich.	Modernization	—	1st Quarter 1973
FMC Corp. South Charleston, W. Va.	Conversion to DSA®	—	November 1973
Pennwalt Corp. Portland, Ore.	Diamond DS-43, modernization	330	January 1973
B. Plant Shutdowns Scheduled			
Olin Corp. Pisgah Forest, N.C.	Sorensen (mercury cell)	—	July 1973
Canadian Industries, Ltd. Hamilton, Ontario	ICI (mercury cell)	—	July 1973
Dow Chemical of Canada Sarnia, Ontario	Dow (mercury cell)	700	July 1973
Dow Chemical of Canada Thunder Bay, Ontario	Dow (mercury cell)	—	September 1973
Oregon Metallurgical Co. Albany, Ore.	Alcan—magnesium	—	—
BASF Wyandotte Geismar, La.	Uhde mercury cells	150	December 1974
Hooker Chemical Corp. Niagara Falls, N.Y.	Gibbs and Hooker S cells	—	1973-1974
Weyerhaeuser Co. Longview, Wash.	de Nora mercury cell	265	1st Quarter 1975
Pennwalt Corp. Tacoma, Wash.	Gibbs diaphragm	—	When new facility is completed

III. New or expanded plants planned or under construction (4, 9)

Plant and location	Type of cell	Capacity, tons/day	Completion date
Olin Corp. McIntosh, Ala.	Olin E-8	—	2nd Quarter 1974
Pennwalt Corp. Calvert City, Ky.	Conversion to DSA®	—	1st Quarter 1974
PPG Industries Lake Charles, La.	Glanor V bipolar	1500	Not announced
Kaiser Aluminum Chemical Gramercy, La.	Conversion of S3B and S3C to DSA®	—	Middle 1974
Sobin Chlor-Alkali, Inc. Orrington, Maine	Additional de Nora cells	—	3rd Quarter 1974
Hooker Chemical Corp. Niagara Falls, N.Y.	Phase I, convert Hooker cells to DSA® Phase II, new Hooker cells	— —	1974
Hooker Sobin Corp. Niagara Falls, N.Y.	Conversion to DSA®	—	3rd Quarter 1974
Olin Corp. Charleston, Tenn.	Conversion to Marstolin anodes Modest expansion, Olin E812	—	3rd Quarter 1974
Shell Chemical Co. Deer Park, Texas	Convert to DSA® and 50% ex- with Hooker diaphragm	375	2nd Quarter 1974
The Dow Chemical Co. Freeport, Texas	Dow diaphragm	1000	2nd-4th Quarter 1974
Aluminum Co. of America Port Comfort, Texas	Conversion to DSA®	—	4th Quarter 1974
Hercules, Inc. Hopewell, Va.	Conversion to DSA® Modest expansion	—	2nd Quarter 1974
Allied Chemical Corp. Moundsville, W. Va.	Conversion to DSA® Modest expansion	—	4th Quarter 1974
PPG Industries, Inc. New Martinsville, W. Va.	Conversion to DSA® Columbia N-3 and N-6 cells	— 800	4th Quarter 1974 4th Quarter 1974
Georgia Pacific Corp. Plaquemine, La.	Hooker H-4	400	1975
Hooker Chemical Co. Taft, La.	Hooker H-4	1000	4th Quarter 1974
E. I. du Pont de Nemours Corpus Christi, Texas	Kel Chlor process Diamond MDC-55 diaphragm	600 1000	1st Quarter 1974 2nd Quarter 1976
Diamond Shamrock Corp. Deer Park, Texas	Diamond MDC-29 diaphragm	1200	4th Quarter 1974
NL Industries, Inc. Rawley, Utah	Bayer (magnesium)	220	3rd/4th Quarter 1974
Weyerhaeuser Co. Longview, Wash.	Diamond MDC-29 diaphragm	385	1st Quarter 1975
Pennwalt Corp. Tacoma, Wash.	PPG bipolar diaphragm	—	3rd Quarter 1975
Dow Chemical of Canada Ft. Saskatchewan, Alberta	Dow diaphragm	50% expansion	1st Quarter 1974
Canadian Occidental Petrol. N. Vancouver, B.C.	Conversion to DSA®	10% expansion	3rd Quarter 1974
Canadian Industries, Ltd. Becancour, P.Q.	Hooker H-2A diaphragm	385	1st Quarter 1974
BASF Wyandotte Wyandotte, Mich.	Conversion Hooker S-3 to DSA®	—	4th Quarter 1974

ever, there should be some inherited benefits from these legislated environmental controls (27).

IV. Developments.—A. Metal anodes.—The installation of metal anodes has continued at an increasing tempo during the year. Over 10,000 tons of chlorine is now produced each day on metal anodes in North America. Known contracts indicate that half the total industry will be operating with metal anodes by the end of 1974.

The rate of conversion in North America is similar to that worldwide. All new plants are using coated titanium anodes, and new designs of cells are reaching

the market to optimize the characteristics of the metal anodes. Three new designs of diaphragm cells are now operating at high loads with metal anode components.

The Marstolin Electrolytic Systems have announced their ability to supply metal anodes, thus joining the Electrode Corporation, which has now produced over 250,000 anodes as suppliers (11, 12).

Conversion of chlorate cells to titanium-based anodes has been continued and new designs of cells are being finalized which will use systems to take full advantage of the titanium-based anode characteristics. A variety of hypochlorite cells is now available using brine or seawater to produce low strength hypochlorite on site. Several precious metal coatings on titanium are used in these systems.

Metalwinning cells with titanium-based anodes are being developed for various hydrometallurgical processes. Expanded research and development efforts to produce titanium-based anodes with the performance that will justify the economics involved are being continued (13).

B. New chlorine process developments.—E. I. du Pont de Nemours introduced the first new diaphragm material which is being used in commercial development work. The material called Nafion is made from sulfonated polyperfluoroethylene. Ionics offers a sodium hypochlorite cell using the material, and others have this or a very similar material under evaluation (14, 15).

Apart from a complete substitute, polymers such as Halar are being researched as a possible binder in an asbestos diaphragm to prolong operational life (15).

The first large nonelectrolytic plant to produce chlorine from hydrochloric acid using the Kel Chlor process is scheduled for start-up in early 1974. The reference is to du Pont's 600 ton/day plant at Corpus Christi, Texas (15, 16).

The NL Industries, Inc. magnesium plant at Rawley, Utah, is designed to produce 220 tons chlorine/day as a by-product (17).

Ionics, Engelhard Industries, Pacific Engineering, de Nora, and Diamond Shamrock offer cells with coated metal anodes for on-site generation of sodium hypochlorite, which is used in water purification, waste treatment, and paper bleaching, particularly where gaseous chlorine handling may present a problem (14, 18, 26).

Asahi Glass will use Friedrich Uhde GmbH electrolytic process to recover chlorine from effluent hydrochloric acid from a refrigerant plant. Capacity will be 37,200 tons chlorine/year. A number of electrolysis plants that process effluent HCl from toluene diisocyanate plants are in operation, but this is the first application to a refrigerant plant (19, 20).

The first oceangoing liquid chlorine tanker is now being built by Friedrich Uhde GmbH for Spain's Energear Industries Arogonesas S.A. The vessel will hold 1000 tons and is to be in operation next spring (21).

Dow Chemical USA has phased out its last caustic soda flake unit at Freeport, Texas. All anhydrous caustic soda flake units (Freeport, Texas; Midland, Michigan; and Pittsburg, California) have been converted to the caustic bead form (23).

C. Mercury cells.—No new mercury cell plants were built in 1973; however, there was some modernization of a few existing plants. In the U.S. one plant was shut down while in Canada two plants were shut down in 1973 (1, 9).

Though much of the public furor has abated over mercury cells, companies hesitate investing money for existing and, particularly, for new plants since they have no way of knowing the eventual standards for mercury emissions. In the foreseeable future, all new capacity will probably come from diaphragm cells (17, 22).

U.S. chlorine plants have made great strides in cutting down mercury emissions. According to the Chlorine Institute surveys, mercury discharges have been reduced 95% since February 1971. An Institute spokesman estimates that the cost of this clean-up effort and process tightening has been about one-tenth the original cost of the chlorine plants (22).

The Japanese chlorine producers are, by government decree, to have 65% of their mercury cell plants converted to diaphragm cells by September 1975 (22). The diaphragm cell technology is almost totally furnished by U.S. firms, such as Hooker Chemical, PPG Industries, and Diamond Shamrock.

Yet there are areas in the world where mercury cell installations are being made and apparently will continue to be made, for instance, South America, Africa, Asia, and parts of Europe (24).

U.S. consumption of mercury during 1973 was estimated at 54,550 flasks, slightly higher than 1972. Mercury for the production of chlorine-caustic required 12,780 flasks or an increase of about 11%.

U.S. mercury production in 1972 was 1968 flasks. At year's end there were seven producing mines in the U.S.

The average New York price of mercury during 1973 was $286/flask compared to $218 in 1972 and $295 in 1971. Early in 1973, the average quarterly price of mercury was $300; a low of $269 was established in the second quarter of the year, and gradually the price increased so that the last quarter average was $294. In 1973, GSA sold 2583 flasks of mercury compared to 512 flasks for 1972.

Imports of mercury during 1973 amounted to 46,076 flasks compared to 30,000 flasks for 1972. Imports were from Canada (37.8%), Algeria (25.7%), Spain (15.8%), and Yugoslavia (8%) (25).

Other Alkalis and Electrolytic Processes

Caustic potash—Caustic potash production in 1973 was 188,454 short tons as 88-92% liquid; this represents an increase of 6.5% over 1972 but is still 5% lower than 1971 production (33).

While production of caustic potash increased during 1973, domestic production of marketable natural potassium chloride, sulfate, magnesium sulfate, and manure salts decreased 2.4% to 2.6 million tons of K_2O equivalent, but increased 2.9% in value (28). The government of Saskatchewan continued prorationing of production during 1973, allowing production to increase to 70% of rated capacity (29). The Canadian potash producers posted price increases of $0.03-0.04/unit of K_2O effective November 1, 1973 (30).

Diamond Shamrock expanded its potassium carbonate facilities at Muscle Shoals, Alabama, to 36,000 tons/year. Production is scheduled to be expanded to 54,000 tons during 1974 (32).

Government price controls held the price of caustic potash at the list price level established in early 1973. Price of 45% liquid caustic potash in bulk shipments was $4.25/cwt and $7.00/cwt for 50% liquid caustic potash from West Coast terminals (34).

Price controls were scheduled for removal on April 30, 1974.

Soda ash.—Soda ash was in short supply during 1973 in spite of a 22% increase in production of natural soda ash from the trona beds of Wyoming (35). There was a drop, however, in the production of synthetic (Solvay) soda ash caused by stricter controls over pollution of waterways by the soda ash plants. For the first time in history, over half of the soda ash production came from natural sources, and also for the first time there was importation of soda ash. Exports of soda ash decreased by one-third in view of the rising domestic demand. The unit value of soda ash rose about 7% during the year. Production of soda ash is now running at about 4.4 million tons/year sodium oxide equivalent. Trona-based capacity is now about 4.5 million tons/year and total soda ash capacity is about 8.5 million tons/year (36).

Four suppliers of natural soda ash have announced sizable increases in their installed capacity over the next 2 years and a fifth company has announced its intention to open a new soda ash mine and processing

plant (35). Texasgulf, Inc. has awarded contracts for the construction of a $75 million soda ash mine and processing plant at Granger, Wyoming, with completion expected in 1976. The capacity of the plant is 1 million tons/year soda ash (37). The only foreseen problems in the future soda ash picture are a lack of processing fuel, a shortage of skilled labor, and possibly insufficient railroad shipping capacity.

Although soda ash mines are being expanded, PPG shut down its 600,000 tons/year Solvay process plant at Barberton, Ohio, at the end of March because of environmental problems (38).

Soda ash capacity in India will double in the next five years. The new units will be based on the modified Solvay process which produce ammonium chloride as a by-product. It is expected that the by-product will be used in fertilizers (39).

BASF Wyandotte raised soda ash prices in late 1973, subject to approval by the Cost of Living Council. The prices were up $2.50/ton to $38 for bulk; up $5/ton to $54.50 for bags, carload, and truckload lots. The company says the increases recover only part of its higher costs under Phase IV guidelines (40). This announcement was followed by similar increases by Food Machinery Corporation and by Stauffer Chemical Company (41).

Soda ash supplies are tight worldwide, and will remain this way for about 2 years when additional production is scheduled to be on-stream. The price of soda ash is expected to increase, unless the economy falls well short of its anticipated performance in 1974 and 1975 (36).

The threat of discontinuation of the depletion allowance for trona mines by the Treasury Department is being countered by the introduction of an amendment which would guarantee continuation of depletion allowances (42).

Sodium chlorate.—Preliminary data from the U.S. Department of Commerce indicates that U.S. production of sodium chlorate in 1973 was 198,300 tons, an increase of about 9.6% from 1972 production of 182,500 tons (43).

Sodium chlorate production facilities in the U.S. and their 1973 listed capacities are as follows (46, 50).

Company	Capacity (tons/year)
Brunswick Chemical Co. Brunswick, Ga.	7,000
Georgia-Pacific Corp. Bellingham, Wash.	3,500
Hooker Chemical Corp. Columbus, Miss.	62,500
Hooker Chemical Corp. Niagara Falls, N.Y.	15,500
Hooker Chemical Corp. Taft, La.	20,000
Huron Chemicals Co. Butler, Ala.	4,000
Huron Chemicals Co. Riegelwood, N.C.	7,000
Kerr-McGee Hamilton, Miss.	32,500
Kerr-McGee Henderson, Nev.	30,000
Pacific Engineering & Production Co. Henderson, Nev.	6,000
Penn-Olin Corp. Calvert City, Ky.	31,000
Pennwalt Corp. Portland, Ore.	16,500
Total	235,500

Erco Industries Ltd. of Canada is expanding its chlorate facility (9000 tons/year) in Vancouver. The technology, from Krebs and Cie., Paris, includes NC-12 electrolytic cells, equipped with metal anodes and natural electrolyte circulation (44).

The Dow Chemical Company may change the product mix at its proposed Dallesport, Washington, plant on the Columbia River. The unit was designed as a $20 million project to produce magnesium with chlorine as a by-product. Word now is that sodium chlorate used by the pulping industry as a bleach may be the primary product (45).

Hooker Chemical brought on-stream in July a 20,000 ton/year sodium chlorate facility at Taft, Louisiana. The plant is being further expanded to 45,000 tons/year with additional electrolytic cells (46).

Erco Industries is to expand its sodium chlorate plant at Buckingham, Quebec, by 5000 tons/year to 38,000 tons/year. The new cell line is expected to be completed in the third quarter of 1974 (47).

PPG Industries, Inc. of Pittsburgh has purchased a license (U.S. and Canada) for KemaNord's bimetal electrode for the production of sodium chlorate. The electrode assembly is presently used in KemaNord's 25,000 ton/year plant at Stockviksverken, Sweden (48).

Because of Government price controls, the list price for pulp and paper grade sodium chlorate remained at $135/ton throughout 1973 (49). Price controls were scheduled for removal April 1974.

Sodium.—The American production of sodium in 1973 by three producers totaled 176,903 short tons, an increase of 10.5% from the 160,054 tons in 1972 (51). The demand was fairly uniform throughout 1973, although the production did slacken slightly during the last quarter of the year.

As over 80% of the sodium produced goes into tetraethyl and tetramethyl lead manufacture, the production of sodium is tied very closely with the demand for gasoline. The current regulations of the Environmental Protection Agency require a reduction in the average lead content of gasoline to 2.00 g/gal in 1975, 1.70 g/gal by 1976, 1.5 g/gal by 1977, and 1.25 g/gal by 1978. Thus, the regulations will have a direct effect on sodium production over the next four years.

Ethyl Corporation has filed a suit to block the standards for the lead content in gasoline set by EPA (52). Ethyl contends that EPA did not meet legal requirements of the Clean Air Act by failing to prove that lead emissions from automobiles are a health hazard. There was also considerable opposition to the reduction of lead from gasoline by the oil companies, citing the increased refinery cost to meet the federal standards and the 10-20% increase in consumption of gasoline due to the reduction in lead (53). The lower miles per gallon for unleaded gasoline has been estimated to be equivalent to dumping 1 million barrels of crude per day (54).

It has been estimated by a consulting firm that $4370 million will have to be expended for refinery modifications by the oil industry by 1980 to produce gasolines which meet federal standards (53). In contrast, EPA estimates that $250 million in capital investment must be spent on existing refineries to comply with the new regulations (54).

Aluminum.—A new record for the U.S. aluminum industry was established this year with production of primary metal at about 4,529,117 short tons. This represents an increase of about 10.5% over last year's production (55). Record production was made even though an electric power shortage prevented the aluminum industry in the Pacific Northwest from reaching its full production potential (56).

There was an 18% increase over last year in domestic consumption of aluminum and a severe aluminum supply deficit was averted by sales of about 800,000 tons of aluminum by the Government (56). It is predicted that primary aluminum producers will be operating at 100% of their capacity in 1975 and 1976 (57).

Under price controls, the domestic price for primary aluminum from large producers remained at 0.25/lb throughout most of 1973. On December 6, the Phase IV base price for aluminum was increased to $0.29/lb and some of the domestic producing companies raised their price to that level. Prices on the major world markets approached $0.275/lb in midyear and by December were reportedly in the $0.30-0.45 range (56).

Easing of the power shortage in the Northwest at year's end and high demand for aluminum had re-

sulted in decisions by Anaconda, Kaiser Aluminum & Chemical Company, Intalco, Reynolds Aluminum, Alcoa, and Martin Marietta Aluminum to restart and/or increase production capacity of existing potlines (59).

Anaconda Aluminum in Sebree, Kentucky, and Columbia Falls, Montana, and Alcoa at Massena, New York, and Rockdale, Texas, also installed new potlines, or reactivated or increased capacity during 1973 (58).

Aluminum Company of America, Alcoa, broke ground late in 1973 for a plant at Palestine, Texas. The plant, expected to be operational in 1975, will test a new type of electrolytic process for obtaining aluminum metal. Alcoa expects to receive sixteen U.S. patents for the process, which is expected to cut environmental pollution dangers as well as electrical power needs. In this process, the aluminum-containing raw material is combined with chlorine in a reactor to form anhydrous aluminum chloride. The aluminum chloride is then electrolytically reduced in a molten electrolyte of controlled oxide content to molten aluminum and chlorine. The chlorine is then available for recycle. Indications thus far are that this process will require 30% less electric power than the 6.5 kW-hr/lb needed by the most efficient Hall process cells. In addition, there will be no fluoride in the process, so fluoride emission control will not be necessary, and the process apparently will work on a variety of aluminum-bearing minerals, such as alunite, kaolin, and anthorsite. Initial capacity for the plant will be 15,000 tons/year, to be expanded to 30,000 tons/year with eventual expansion planned to be to 300,000 tons/year (60).

A joint venture by three companies, National Steel Corporation of Pittsburgh, Southwire Company of Carrollton, Georgia, and Earth Sciences, Inc. of Golden, Colorado, to test the feasibility of extracting aluminum from domestic alunite is underway. The three companies are planning to use a technique developed in the USSR because of a bauxite shortage there; the plant will cost $1 million and will process 12 tons/day of alunite into 1-2 tons/day of alumina. The long range goal is a commercial plant to feed a 180,000 tons/year aluminum plant. The plant will be constructed at Cedar City, Utah (61, 62).

Applied Aluminum Research of New Orleans, Louisiana, announced a new process for obtaining aluminum from clay material. The process involves chlorinating the clay, then reducing the mixture of metal chlorides (including aluminum chloride, titanium chloride, silicon chloride, etc.) with molten manganese to form aluminum, manganese chloride, and metal chlorides. The manganese chloride is then oxidized with oxygen to give chlorine, for recycle, and manganese dioxide, which is smelted to recover the manganese for recycle. The group is now putting up a 1 ton/week pilot plant at New Orleans, and is trying to raise $25 million through a London firm for a 100 ton/day plant to be built in Europe. The method uses much less power than the Bayer-Hall process, and the company, headed by the inventor of the process, Charles Toth, claims prices will be as low as $0.10/lb (63, 64).

Recycling is the aim of Combustion Power, Inc. of Menlo Park, California, as they have developed a method which may make recovery of aluminum more practical. The method, mainly for separating aluminum can stock from other solid wastes, begins with an air classification and conventional magnet system, which remove paper and ferrous materials, respectively. Then the remaining shredded scrap is moved into the field of a new "magnet." This induces eddy currents in the aluminum scrap which interacts with the producing field to repel the scrap off the belt (65).

American Metal Climax announced in early August that it was going ahead with plans for construction of a two-potline 160,000 tons/year aluminum plant near Warrenton, Oregon. The company expected to meet strong opposition from shrimp and tourist industries, but said they planned to limit fluoride emissions to 1.5 lb/ton of aluminum, presently the lowest in the industry. By the end of October, however, it was apparent that the plant was in trouble. Oregon Governor Tom McCall withdrew support for the project, citing the energy crisis and pointing to the 240 MW contract Amax holds with the Bonneville Power Administration for the plant. Because the contract already exists, however, the State has turned to the Department of Environmental Quality, which may recommend that fluoride emissions must be no more than 1 lb/ton which industry says is technologically infeasible (66, 67).

Consolidated Aluminum Corporation of USA, owned 60% by Swiss Aluminum, Ltd., Zurich, and 40% by Phelps-Dodge Corporation, New York, has purchased the aluminum business of Olin Corporation of Hannibal, Ohio, a 600,000 ton/year alumina plant at Burnside, Louisiana, and seven other mill and fabricating plants. The transaction does not include Olin holding in the Friguia bauxite plant in the Republic of Guinea (68).

Alcoa is in the process of expanding the aluminum smelting plant at Massena, New York, from 135,000 tons/year to 190,000 tons/year. Also announced by Alcoa were plans for construction of an aluminum reduction plant in Valleyfield, Quebec. The power will be supplied by Hydro-Quebec, and initial production is expected to be 60,000 tons/year. Target date for both projects is 1976 (69).

Meanwhile, Georgia still is looking for a way to profit from its kaolin deposits, considered to be the largest in the world. The Senate passed a resolution that would give $250,000 to the first person or company to produce either alumina or aluminum chloride from the deposits. Now the bill must go to the State House. The resolution also states that the plant must produce a minimum of 300,000 tons in its first year (70).

Magnesium—While U.S. magnesium production rose only 1.3% to 122,431 tons in 1973, shipments increased 23.5% to 137,277 tons from 111,185 tons in 1972. About 29% of last year's shipments were to the export market. In 1973, the U.S. exported 39,585 tons of magnesium and only imported 3,282 tons (71, 72). NL Industries, Inc. produced a small quantity of magnesium at its 45,000 ton/year primary magnesium plant located on the shore of the Great Salt Lake in Utah (73). Since the plant experienced considerable difficulties during the year, its contribution to total U.S. production was less than expected. The electrolytic magnesium plant of the American Magnesium Company in Snyder, Texas, remained closed during the year. However, the plant was expected to resume production during the first quarter of 1974 (74), although problems may cause slippage to the second quarter. The installation has a capacity of 10,000 tons/year of magnesium.

U.S. secondary production was around 15,000 tons, exports 36,600 tons, and consumption of primary magnesium 126,000 tons in 1973.

Magnesium metal was in tight supply in the U.S.A. Demands were also high worldwide. Dow Chemical U.S.A. processed stockpile metal (6,000,000 lb) at its Freeport, Texas, plant (75). Dow recently disclosed that it has purchased an additional 21,420 tons of magnesium from GSA to be transferred monthly through 1974 and 1975 (76). NL Industries also purchased 10,000 tons of magnesium from the GSA stockpile to fill its substantial in-house requirements and possibly some outside orders (77).

Higher magnesium prices will take effect on January 1, 1974, when the Dow price will be from 38.25 to 42¢/lb for 99.8% pig, and from 33.75 to 42¢/lb for AZ91B die cast alloy, f.o.b. Freeport, Texas. Higher energy costs were given as the reason for the increase (78).

Alcoa announced a 40,000 ton/year magnesium and silicon plant at Addy, Washington. Construction was

slated for early 1974 with a completion date in 1976, at a cost of $50 million (79). After conducting a feasibility study of producing magnesium, silicon, and ferrosilicon from dolomitic limestone and quartzite deposits in the Addy area in November 1970, Alcoa signed contracts with the Bonneville Power Administration for power to become available in October 1974. The plant, now called Northwest Alloys, Inc. (80), as a subsidiary of Alcoa, will use the Magnetherm Process (licensed by France's Pechinney Ugine Kuhlmann), the only plant in the U.S.A. to use this process (81).

Environmentalists are seeking to prevent the construction of the Alcoa plant by forcing cancellation of its power contract with Bonneville Power Administration (82).

Norsk Hydro will build a 50,000 ton/year magnesium plant in Mongstad, north of Bergen, Norway. The plant should be operational by 1980 (83).

Considerable optimism has prevailed in the industry, and a new era of growth has been predicted (84). Factors which brighten the outlook are: (*i*) the automobile industry's intensified quest for lighter weight components; (*ii*) improved hot chamber casting techniques; (*iii*) improvement in the competitive cost relationship with aluminum and zinc; (*iv*) prospects for new sources of supply; and (*v*) the new developments in fluxless melting (84).

A new market is the use of magnesium as a sulfur-sequestering agent in the production of special grades of steel. Steel desulfurized with magnesium has better strength and formability properties (81).

A growth rate of 7-8%/year has been forecasted, a rate which would bring 1980 demand to some 500,000 tons/year worldwide (85).

Manganese.—Strong demand for manganese in steel, which was not met by any increase in mine production of manganese, created a tight supply situation in 1973. Steel production was at a record in 1973 and accounted for 95% of manganese consumption (96).

As is 1972, there was no actual production of manganese ore, nodules, or concentrates, with a concentration of 35% or more manganese in the U.S. in 1973 (88).

General imports of manganese ore were down 1.2% from the level of 1972 to 1,600,000 short tons. Major suppliers of the ore were Brazil and Gabon. Imports of ferromanganese, on the other hand, were up 12% from last year to 384,000 short tons. As in the previous year, the major suppliers of the ferromanganese were the Republic of South Africa and France (87, 88, 96).

Domestic consumption of manganese ore was down 6%, from the 1972 level of 2,050,000 to 1,922,000 short tons, although consumption of alloy and metal increased substantially (88).

Manganese ore, alloys, and metal were sold by the General Service Administration (GSA) from its stockpile (96).

Prices for metallurgical manganese ore containing 48% manganese, minimum, increased 85%, from 58 to 61¢ nominal per long ton unit in 1972, when a drop occurred, to $1.05-1.15/long ton unit by the end of December 1973 (86, 87).

A bill was signed by President Nixon continuing the suspension of import duties on manganese ore from favored nations. The bill will be in effect for three more years until June 30, 1976 (88).

The Electrolytic Manganese plant belonging to Delta Manganese in Nelspruit, Republic of South Africa, will begin production in the second quarter of 1974. The firm, a subsidiary of Delta Metal Company, Ltd., London, expects 14,500 tons/year immediately, with a capacity of 16,000 tons/year to be reached within 2 years (95).

Delta Manganese also concluded, earlier in 1973, an agreement with Foote Mineral, in which Foote will be the U.S. and Mexican distributor for electrolytic manganese chip and other related products (94).

The processing of manganese nodules is now considered to be no problem by most major organizations involved in the study of deep ocean mining. Summa Corporation, an affiliate of Hughes Tool Company, has a large 324 ft long barge, resembling a floating dry dock, which will be sunk to the ocean floor at a suitable site to collect manganese nodules and pass them through a pipe to the surface ship.

Tests of the much publicized continuous bucket line system of nodule recovery developed by the Japanese were reported to have experienced difficulties under conditions of rough ocean floor topography and rapidly changing currents.

Kennecott Copper of New York has joined with four other international firms in a $50 million joint venture to research the mining of manganese nodules from the floor of the ocean. Kennecott's interest is basically in the copper-nickel values of the nodules. Kennecott's partners are mostly interested in the manganese content of the nodules (91-93, 96).

Kerr-McGee Chemical announced an expansion of its Henderson, Nevada, manganese dioxide electrolytic plant with a proposed completion date of early 1975. The expansion will increase capacity an additional 260% from 3,300 to 12,000 tons/year (90).

Mitsui Denman (Ireland), newly created part of Mitsui Mining and Smelting (Japan), will build a 12,000 ton/year electrolytic manganese dioxide plant in County Cork, Ireland. The plant will be designed and built by Lummus Company, and will cost $15 million (89).

Beryllium.—The over-all American consumption of beryllium ores appeared to be slightly higher in 1973 than in 1972 (97). The increase resulted from a larger demand for alloy products. Domestic production of beryllium ore increased, although there were no reports of beryl production from any state. Imports of beryl, however, decreased to an estimated 1700 tons valued at $510,000. Imports were principally from Brazil, the Republic of South Africa, and Argentina.

Brush-Wellman uses bertrandite and beryl ores for the production of beryllium. The pure metal is then shipped to Delta, Utah, or Elmore, Ohio, for refining. The other American producer, Kawecki Berylco Industries, has plants at Hazelton and Reading, Pennsylvania, and only uses beryl ore.

One of the two companies processing beryl has put its equipment on standby basis and will have the imported beryl it purchases toll processed.

Beryllium is used as the metal, as an alloying agent, and as an oxide. Major uses for the metal are for aerospace applications, utilizing its light weight and high strength and rigidity, and for nuclear applications where its low thermal-neutron absorption and high neutron scatter cross section are required. About three-fifths of the beryllium is used as a beryllium-copper alloy, in which it imparts qualities of strength and resistance to fatigue and corrosion that are superior to those of copper. Beryllium copper molds are used to give plastic furniture the appearance of a woodgrain surface.

Beryllium consumption was 47% in nuclear reactors and aerospace applications, 29% as an alloy in electrical equipment, 13% in electronic components, and 10% in other applications. About 1% of the beryllium was used as the oxide.

At midyear Government stockpile inventories contained 17,988 short tons of beryl (11% BeO equivalent), 7,387 tons of beryllium-copper master alloy (approximately 4% Be), and 229 tons of beryllium metal. Since the stockpile objectives for both beryl and the master-alloy were set at zero, the full inventory of both items is surplus. The stockpile objective for beryllium metal is 88 short tons, leaving 141 tons surplus.

At the end of 1973, the price of beryl ore ranged from $30 to $35 per stu. In the U.S., beryllium-copper 25 alloy was quoted at $3.54/lb, cast ingot at $2.39/lb, and the master alloy at $56/lb. Beryllium rod was priced at $102.83/lb during June 1973 (98).

Chromium.—In 1973, the U.S. continued to rely on imports and purchases from Government stockpiles of excess material for its chromium requirements. Domestic consumption of chromite was 1.4 million tons, 23% higher than in 1972. Increases were registered by all three consuming categories: metallurgical consumption was up 26%; the refractory industry increased by 16%; the chemical industry increased by 7% (99).

Imports for consumption of chromite followed the same trend as in 1972; namely, they were less than consumption as industry drew from its own stocks and previously sold Government stockpiles. Imports for ferrochromium were expected to reach a level of 150,000 gross tons, up 6% from last year's total of 141,000 gross tons. Major sources were the Republic of South Africa, Southern Rhodesia, Japan, and Finland.

Late in December, Union Carbide announced price hikes effective on January 1, 1974. Electrolytic chrome is $1.53/lb, vacuum grade is $1.60 f.o.b. Marietta, Ohio, and 9% carbon chrome is unchanged at $1.50/lb (100).

Foote Mineral shut down its Steubenville, Ohio, plant at the end of 1973, while pollution regulations forced Ohio Ferro-Alloys to drop its chrome alloy production. The future of ferrochrome production in the U.S. is dependent upon the E.P.A.'s final decision on its proposed standards for ferroalloy plants as well as the availability of ore and the ability to compete with low cost South African and Rhodesian material (102).

In December of 1973, the Senate passed a bill to repeal the "Byrd Amendment" of 1971. This "Amendment" has ended U.S. observance of the U.N. sponsored embargo of Rhodesia due to that nation's racial policies. Next, the new bill will go to the House, where its future is uncertain. Support for this bill will probably be due in part to the "energy crisis," in view of black Africa's economic boycott of Rhodesia. Proponents feel that taking a stand against Rhodesia will help U.S. negotiations for Nigerian oil. In any event, the drop in imports from Rhodesia makes the matter less critical (100, 101).

Titanium.—Outstanding features of the titanium market during the year were increased production of titanium sponge, continued strong demand for pigment, and rising prices for ores and concentrates (103).

Production of titanium sponge in the U.S. increased by more than 40% during the year. Much of this increase was due to production under contract with GSA for the national stockpile; deducting quantities produced for this account, the increase in production was more modest. Consumption of sponge and scrap was about 19,250 and 10,000 tons, respectively. Production of ingot was about 28,000 tons, a 39% increase over that of 1972. Imports of sponge for consumption were about 6700 tons, a 64% increase. Of this quantity, 59% came from Japan, 28% from the USSR, and 13% from the United Kingdom.

Only RMI (Reactive Metals) and TMCA currently produce sponge in the U.S., at Ashtabula, Ohio, and Henderson, Nevada, and only RMI sells its material on the market. Oregon Metallurgical has a partially completed sponge facility at Albany, Oregon, which is not in operation. Both TMCA and RMI are currently supplying GSA with some 14 million pounds of sponge combined in a 2 year upgrading program implemented in early 1972. GSA has recently sliced its titanium stockpile objective to zero from the old 33,500 ton level, and the Government apparently hopes to eventually sell off its present holdings as part of its new accelerated disposals. Japan's two major producers, Osaka Titanium and Toho Titanium, are the principal suppliers of imported sponge, while the United Kingdom's Imperial Metals Industries also ships some material to the U.S. The USSR, which uses a magnesium reduction method in its production, has been moving increasingly large quantities to the U.S., renewing the old debate over titanium dumping (104).

Howmet Corporation and The Dow Chemical Company were jointly engaged in developing a continuous electrolytic process for making titanium metal at a pilot plant in Whitehall, Michigan. Howmet says the process should have several advantages over the present widely used processes such as a 40% energy reduction and fewer pollution control problems (105).

Dow has considerable experience in titanium, and was in fact the first commercial domestic producer, at that time using the Kroll process for its production. Dow later teamed up with Crucible Steel, now Colt Industries, in a partnership to examine the potential of producing sponge, but the two companies later decided to drop the venture (104).

Higher labor, power, and rutile costs, among others, have forced domestic sponge prices upward. The prices for Japanese sponge were reported as $1.34-1.37/lb for contract material and $1.46-1.50 on a spot basis. RMI, which sells some sponge, has boosted its U.S. quote from $1.32 to a $1.42-1.45 range (104).

Field erection of big titanium or titanium-clad vessels will be possible by a suitable welding technique developed by Wyatt (Houston), a division of U.S. Industries. Previously, clean-room conditions were needed for fabricating titanium. Consequently, vessels had to be shop built in one piece and shipped to the construction site, limiting the size of equipment. The new welding technique was demonstrated at an Olin plant in Augusta, Georgia, where two sections of a 15 ft diameter, 20,000 gal solid titanium tank were welded together successfully (106).

According to a survey by the Bureau of Mineral Resources, Australia's titanium ore deposits may be exhausted in less than 30 years. The country presently supplies 90% of the world's rutile and 20% of its ilmenite (107).

The U.S. patent covering the alloy Ti-6Al-4, which accounts for 80% of all titanium used by defense contractors, expired in July 1973.

Mine production of titanium minerals was about 850,000 short tons, an increase of 14% over the 1972 figure. Titanium Enterprises, at Green Cove Springs, Florida, had its first full year of production, and the American Smelting and Refining Company mine in Ocean County, New Jersey, began production at the end of June. Both mines shipped their product to titanium pigment plants.

Imports of ilmenite increased to about 70,000 tons, while imports of slag remained about constant at 295,000 tons. Imports of rutile, including synthetic rutile, increased to 212,000 tons, up slightly from the previous year.

In April the stockpile objective for rutile was reduced to zero. Thereafter, during the last half of the year, the General Services Administration (GSA) sold 13,756 tons from the Defense Production Act stockpile.

The price of rutile increased from $175 to $210/short ton in May and the rutile released by GSA commanded prices up to $226/ton. Ilmenite prices increased from $22-24/long ton to $32 in August, and the price of Sorel slag increased from $53 to $61/long ton in August. The declared valuation of imported synthetic rutile ranged from $90 to $100/short ton. A bill, H. R. 9246, to suspend the tariff on synthetic rutile through 1976, was before Congress during the year, but no final action was taken.

In response to continued strong demand, production of titanium pigment reached 770,000 tons, a 12% increase over 1972 levels, in spite of a few short-lived strikes and some brief period of mechanical difficulty. Production at the New Johnsonville, Tennessee, plant of E. I. du Pont de Nemours and Company, passed the 200,000 ton/year mark by year's end; however, that company's plans for construction of a 100,000 ton/year plant near Brunswick, Georgia, were being restudied.

Imports of pigment were about 67,000 tons during the year, 22% less than in 1972. Heavy demand for pigment in Western and Central Europe and in Japan reduced the quantity available for export, and higher

priced markets elsewhere reduced the quantity coming to the U.S. Domestic prices for various grades of pigment held generally at or below 30¢/lb during the year (103).

An Ashtabula, Ohio, plant will be the world's first user of an Australian rutile process. The Sherwin-Williams Company facility, due ready for start-up late next year, will use an ilmenite-to-rutile process developed by Rutile and Zircon Mines (Newcastle), Ltd., which up to now has performed only in pilot plant units. Ultimate capacity and cost of the facility will be 50,000 tons/year and $2 million, respectively (108).

Process details are unavailable. Sherwin-Williams discloses merely that the technology dovetails well with the company's manufacture of titanium dioxide from rutile via the chloride process (108)

Worldwide, the increased demand for titanium ores and titanium pigment was encouraging geological investigations in Uruguay, Mauretania, and Liberia; mine development in the Republic of South Africa and Sierra Leone; expansion of mine production in Sri Lanka, Australia, and Norway; pilot plant investigations into synthetic rutile in Australia, where a currently producing plant is also being expanded; and planning, construction, or expansion of pigment plants in Mexico, Spain, Poland, Yugoslavia, Finland, West Germany, and India. Activities of environmentally concerned groups were, however, acting as a brake on the industry in Italy, France, and on the Australian east coast (103).

Lithium.—Domestic production of spodumene and lithium carbonate was the largest ever reported according to the Bureau of Mines (111). Domestic and international consumption of lithium products was also at record high levels; the three leading consumers were the U.S., Europe, and Japan (111).

It is probable that domestic lithium production has been extended to its maximum and further increases may require installation of additional capacity.

Actual production figures were not available for 1973, but world consumption was estimated at 49,500,000 lb of Li_2CO_3 equivalent which represents a 33% increase in the last year.

During 1973, Foote Mineral increased capacity by tapping additional wells and adding more evaporation pond acreage. Foote Mineral also put on-stream the first commercial plant to chemically remove iron from spodumene ore (112).

Lithium Corporation of America expanded its operation at Bessemer City, North Carolina, during 1973 and is essentially self-sufficient in lithium raw material (112).

International producers of lithium compounds include Russia, Germany, France, and Japan, although little information is available on production (112).

Work is being continued on the development of lithium batteries for use in the electric transportation industry. Both ESB and Argonne National Laboratories are developing systems for their commercial production (113).

Foote Mineral announced a 12 million lb/year lithium carbonate plant to be built at Kings Mountain, North Carolina; production is scheduled to begin in early 1976 (109).

Lithium prices were raised in December 1973 by both U.S. producers to between 55 and 56¢/lb for bulk lithium carbonate. Foote Mineral and Lithium Corporation of America also raised lithium metal ingot prices from $8.18 to $8.53/lb (110). Anhydrous lithium chloride was $0.94/lb; anhydrous lithium bromide was $1.70/lb (111).

Copper.—On a refined copper basis, the U.S. experienced reduced production, net exports, near record high consumption, and a drawdown of industrial stocks (114). A shortage of available copper relative to demand developed in the first quarter and became a critical supply problem for some users. Salient factors causing the imbalance included: a surge in world demand; disruptions to production in Chile, Canada, and Belgium; some curtailment in domestic output to meet air quality standards, as required by the Environmental Protection Agency; transport problems in Canada and Zambia; the fuel shortage; and the effect of U.S. price controls coupled with a rapid escalation of world prices. Several of the supply disruptions were resolved, but the continuing high demand and depleted inventories left supplies tight at year's end. The national copper stockpile objective was reduced to zero in March, making available 252,000 tons of surplus copper pending congressional authorization.

Mine production was 1.73 million tons, a 3% increase and approximately equal to the record high of 1970. Principal copper producing states were Arizona with 54% of the total, Utah (15%), New Mexico (12%), Montana (8%), Nevada (5%), and Michigan (4%).

Smelters, despite some curtailment of operations to meet air quality standards, increased output 2% to an indicated 1.73 million tons from primary materials, a record high quantity for the second successive year. Refinery production from primary materials was projected to decline 2% from the 1972 record high to 1.83 million tons. Production of refined copper from secondary materials was 465,000 tons, compared with 423,000 tons in 1972.

Consumption of refined copper advanced 6% to 2.40 million tons. This increase reflected the greater activity in the general economy for most of the year and was approximately equal to the record high consumption of 1966.

Stocks of refined copper at primary producers were drawn down from 57,000 tons at the start of the year to 28,600 tons at the end of October. Stocks of copper at brass plants and wire mills were reduced from 77,200 tons at the start of the year to 61,400 tons by the end of June, increased to 95,100 tons during July, and then declined to 49,000 tons by the end of October.

Imports of refined copper were 201,500 tons, a 14% increase from the preceding year and equal to 1971 imports. Imports of blister were indicated to be 154,000 tons compared with 157,400 tons in 1972. Public Law 93-77 suspended the 0.8¢/lb duty on copper from July 1, 1973 to June 30, 1974, reinstating the suspension that had been in effect from 1966 to June 30, 1972.

Exports of refined copper increased 3.5% to 189,400 tons, the largest quantity since 1970. There was a 27% increase in exports of copper-base scrap (alloyed and unalloyed) to 109,000 tons. Scrap exports were particularly large during June, July, and August following the domestic price ceilings imposed in early June and the escalation of foreign copper prices. Copper-base scrap was exempted from price controls, effective August 6, and there was a significant reduction in exports following this action.

Domestic copper price quotations were increased by 9.5¢/lb in three steps during the first quarter of 1973 to a quoted price of 60-60.25¢/lb. Price controls prohibited any price increase between early June and December 6, after which most quotes were increased by approximately 8¢ to a range of 68.15-69.25¢/lb. Prices on the London Metal Exchange increased from an average 50.7¢/lb equivalent for January to $1.029 for November, and were $0.906 in mid-December.

World refined copper output rose 3% to 6,550,000 tons in 1973, while consumption rose 8% to 8,542,000 tons, according to preliminary figures from the World Bureau of Metals Statistics. World mine production was up 6% to 7,463,000 tons from 1972 (115, 116).

Zambia, Zaire, Chile, and Peru produced a total of 2.16 million tons, a rise of 3% over 1972 and 36% of the total for the Western world. Canadian mines produced 783,000 tons in 1973, up 10%.

Refined copper production in Japan rose 17% to 945,000 tons in 1973. Consumption of refined copper in Japan was a remarkable 1,199,000 tons in 1973, a 26% increase over 1972. Western European consumption rose 7% last year.

Cominco Ltd. and Sherritt Gordon Mines Ltd., both of Canada, are planning a pilot plant ($10 million) on their new copper recovery process (S-C process) at Fort Saskatchewan, Alberta. The program is funded by both firms and the Canadian Government. The pilot unit initially will be operated on copper sulfide concentrates from Sherritt-Gordon mines at Fox and Rutton in Manitoba. The process is applicable to low-grade and complex ores; its produces a high purity copper, elemental sulfur, and recovers precious metals in addition to zinc and molybdenum (117).

Cyprus Mines will establish a new open pit copper mine at a site midway between Benson and Wilcox, Arizona, where it operated a 200 ton/day copper-zinc mine and concentrator until the high-grade ore body was exhausted and the plant dismantled in 1960. Reserves stand at 14.7 million tons of oxidized copper ore averaging 0.5% copper, of which 1.4 million tons/year will be mined and 5000 tons/year of 99.9% cathode copper produced by a process of leaching and electrowinning. The cost of the project, scheduled to go into production in the first quarter of 1975, will be $6 million (118).

Cyprus Mines has delayed the start-up of its demonstration plant just outside of Tucson, Arizona, which is to use the new Cymet process for recovering copper. Delays in equipment delivery have postponed the opening until sometime in the second quarter of 1974 (118).

The military government of Peru formally took over the operations of Cerro de Pasco on January 1, 1974. Cerro is confident that Peru will pay prompt compensation for the book value of the operation. The expropriation does not apply to other Cerro holdings in Peru (119).

A massive copper find 250 miles southwest of Mexico City in the State of Michoacan is attracting the interest of two of the world's largest mining corporations, Hudson Bay Mining and Smelting Company, Ltd., Manitoba, Canada, and Anglo American Corporation of Canada, Ltd., Toronto. A representative of the Patino Society N.V. of The Hague, Netherlands, which owns the field, reveals that Patino has agreed to sell its interest to the two other companies. Details on the negotiations and possible future development have not yet been revealed (120).

A major copper smelting complex has been put into operation near Dzhezkazgan, in the Soviet central Asian Republic of Kazakhstan. Copper reserves in the area, which have traditionally been the largest in the USSR, are shallow lying and lend themselves to low cost, open-pit mining (120).

Poland's Heavy Industry Ministry is working on plans for a Western-financed, multimillion-dollar project that could make the country a leading world copper producer by the early 1980's. Major new copper deposits were discovered in 1957 in Lower Silesia near Wroclaw. Two mines, one in Lubin and the other in Polkowice, have been in operation since 1969. The new mine and smelter, which are expected to be built by 1982, could, according to Western experts, put Polish copper production at well over 200,000 tons/year (121).

Texasgulf Inc. is planning to increase copper mining and concentrates production at Kidd Creek Mines, Timmins, Canada. Capacity will increase from the present 3.6 million to 5 million tons/year (122).

Peru plans to increase copper production capacity from the present 215,000 to 560,000 tons/year in 1976 and 1 million tons/year in 1980, according to the Minister of Power and Mines. Projects that will be commissioned this year are: 150,000 tons/year copper at Ilo and 75,000 tons/year at Zajamarquilla (123).

A recent in-depth report on copper (124) listed the Free World copper producers. Plants under construction are the Phelps Dodge plant at Tyrone, New Mexico (100,000 tons), the Hindustan copper plant at Khetri, India (34,200 tons), the Black Sea copper plant at Samsum, Korea (44,100 tons), and the AMMI plant at Ausso-Corno, Italy (66,200 tons).

The same article described the environmental confrontation in the copper industry with government requirements. The regulations for new plants will be even stricter than those of existing plants. The copper industry commitment to the prevention of air pollution has increased annually. During 1972, the industry spent 22% of the capital expenditures on the problem. The copper companies have until 1975 to comply with the primary air standards, unless technology is not available.

In the report, the state-of-the-art of copper extraction, particularly smelting, is reviewed. The new technology, its uses, and its reasons for use, such as improved emissions control and improved economics, are also reported. Newer Mitsubishi, WORCRA, and Noranda smelting processes, and the Cymet and the Arbiter hydrometallurgical processes are described. Other processes, still in various stages of development, are also briefly outlined. The cleaning up of sulfur dioxide by a number of routes in various stages of development is also reviewed (124).

An ion exchange and solvent extraction method was developed for extracting copper, cobalt, nickel, and zinc by Bayer in association with Duisburger Kupferhutte, a copper smelter owned by other hydrometallurgical operations. In the process, the metals (except manganese) are taken up by Bayer's ion-exchange resin, Lewatit TP 207, Acid treatment then frees the metals, which can be separated. The big plus for its method, Bayer claims, is that the acid is reduced to only 12% of its original volume, making it adaptable to leach solutions with high manganese content (125).

A new approach to chemically treating sulfide ores to obtain metal will get its first large-scale commercial test in a $22 million plant that Anaconda is building in Anaconda, Montana. It will produce 36,000 tons/year of copper (126, 127).

All copper companies have investigated hydrometallurgical methods in which the metal is leached from the ore with a solvent, then recovered from the solution in a relatively pure form. The big advantage is that there are no smelters, fumes, dust, or sulfur dioxide pollution problems. Moreover, much of the solids-handling equipment can be replaced by simpler liquid-handling techniques. However, corrosion problems have been formidable, and producers have had trouble applying the technique to sulfide ores.

Anaconda's method, called the Arbiter process, begins with ammonia leaching of copper concentrate milled from sulfide ores. The leaching is carried out in a series of low-temperature and low-pressure vats. The copper in the leach solution is then separated by ion exchange and recovered by electrolysis.

The basic technique also has been piloted on nickel and other nonferrous metal ores with good results.

Anaconda says it is also doing engineering work on combining the leaching and certain other stages of the Arbiter process with conventional smelter design. The work could help control sulfur dioxide emissions from smelters that are now in operation. By late December, the construction was 50% complete and engineering 80% complete (128).

The copper market for 1974 has been predicted to be tight in early 1974, since copper output increases are not likely until the second or third quarter (129).

Consumers have been living hand-to-mouth. The stockpile release of 170,000 tons to U.S. consumers will help achieve a finer balance between supply and demand. The 1974 prospects of a 300,000 ton increase in Free World primary production capacity may not be realized because of the energy crisis. Economic growth, and consequently copper consumption, will be slowed by energy limitations. Despite a slow down in the economy, there will be inflation at home and abroad, and inflation spells higher prices. Decontrol of copper

in April 1974, should this occur when wage-price controls end, may see a producer price increase to above 70¢/lb to compensate for increased production costs (129).

Nickel.—A balance was finally reached throughout the world in the latter part of 1973 between nickel supply and demand. This balance was due to a cutback of mine production in Canada and New Caledonia, as well as a greatly increased demand in the U.S., Western Europe, and Japan. The part played by the U.S. in this was significant, as consumption was 196,000 tons during the year, a 19% increase from the 165,000 tons consumed in 1972. Production in the U.S. in 1973 was approximately equivalent to that of the last 5 years. The main American producer was Hanna Mining, with 17,000 tons of nickel (130).

World trade in nickel was marked by the changing supply base. Imports of Russian nickel for consumption in the U.S. increased more than tenfold compared to 1972; imports from the Dominican Republic increased almost fivefold; and Southern Rhodesian producers supplied more than 6,000,000 lb of nickel to the U.S. markets, A new trade channel was opened as Canadian nickel was sold to the People's Republic of China (130).

The price of pure nickel was stable throughout the year of 1973. International Nickel Company (INCO) raised the price of nickel pellets and electrolytic nickel from $1.53 to $1.62/lb, which went into effect on January 4, 1974. Falconbridge Nickel Mines followed suit and hiked prices 9¢/lb for the pure metal (131).

The price of ferronickel, which accounted for the major part of the U.S. consumption, was raised by several companies. On July 9, Societé Le Nickel increased its price 6-7¢/lb and Falconbridge increased its prices by 11¢ for the same product. Hanna Nickel Mining Company raised its prices from $1.38 to $1.53/lb following exemption by the Cost of Living Council from price controls, effective January 15, 1974. INCO raised the price on nickel in oxide sinters 90 and 75 to $1.43, and $1.40, respectively, an increase of 3¢. The price was effective July 20, 1973 (130, 131).

According to INCO, the most technologically advanced nickel refinery was opened late in 1973 at its $140 million plant at Copper Cliff, Ontario. This facility will be the only one in North America to produce nickel pellets, at a rate of 100 million lb/year. The plant will also make 25 million lb/year of nickel and nickel-iron powders. By-products are expected to be electrolytic copper, cobalt carbonate, and precious metal concentrates. The plant is the first to use top-blown rotary converters in nonferrous metallurgy and employs the INCO Pressure Carbonate process (132, 133).

Major nickel exploration projects were in progress in Australia, the South Pacific Islands, the Philippine Islands, and Indonesia. Exploration throughout Canada and in the Duluth gabbro of northern Minnesota was undiminished (130).

In New Caledonia, exploration activities at the Penamarx nickel prospect have been effectively completed. Joint research by Penarroya and Amax at the site continues as they try to find a way to extract nickel, cobalt, chrome, and iron from the ore. One Amax spokesman remarked that the $400 million venture could probably be a reality by 1980. The ore contains 400 million tons of 1.4% nickel (134).

Amax Nickel Refining's plant in Plaquemine Parish, Louisiana, should go into operation in the second quarter of 1974. Amax will import nickel ore from Africa and refine it to 80 million lb/year of usable nickel (135).

A significant part of the nickel supply in the U.S. came from nickel scrap. The consumption of nickel scrap in November 1973 was 738,711 lb (131).

Zinc.—The continuing rise in the demand for zinc in 1973 created a short supply situation compelling record imports of metal, a large release of stockpiled zinc, and record levels for the prices of domestic and foreign zinc in the U.S. (136).

Mine production in 1973 was approximately 485,000 tons, 1% higher than that of 1972. Eighteen states reported mine production, one more than in 1972. Nine states showed increases and nine registered decreases. New York moved up to first place, Missouri's by-product zinc recovery from mines of the lead-belt was second, Tennessee was third, Colorado was fourth, and Idaho fifth. In Tennessee, production was lost from the Flat Gap mine that closed near the end of 1972 and the Young and Coy mines which were shut down early in 1973. The Young mine was reopened in October and construction began at its new concentrator to replace the present Mascot mill. New Jersey Zinc Company's New Elmo mine at Carthage in central Tennessee is scheduled to begin operations soon (136).

Smelter production of slab zinc from ore was 500,000 tons, a decline of 133,000 tons from that of last year. AMAX Lead and Zinc Company discontinued zinc production at the horizontal retort smelter at Blackwell, Oklahoma; however, the roasting facilities will continue to operate until May or June 1974. Rehabilitation of the AMAX Zinc Company electrolytic plant (closed by the American Zinc Company in mid-1971) was completed. The National Zinc Company obtained permission from the State of Oklahoma to continue operating the Bartlesville horizontal retort plant. The Texas Air Control Board, on July 26, 1973, rescinded a previous notice for the Amarillo horizontal retort smelter to be in compliance with air quality standards or close by December 31, 1973, and issued a variance permitting the smelter to continue operating until May 30, 1975. Construction plans for two more electrolytic zinc plants were announced during the year: the American Smelting and Refining Company reported plans for erection of a plant at Stephensport, Kentucky, with an annual capacity of 180,000 tons; and the New Jersey Zinc Company is considering construction of one along with a zinc oxide plant near Clarksville, Tennessee. With a favorable labor picture, large deposits of zinc ore in the area, and the availability of low-cost TVA power, the final decision depends on relaxation of price control on zinc (137).

Park City Ventures, jointly owned by Anaconda Company (60%) and American Smelting and Refining Company (40%), is in the process of completing a development program at its Ontario Mine in Park City, Utah, where a production of 5000 tons/week of ore is expected. By early 1975, mining and processing operations will produce 43,000 tons/year of zinc concentrate, 25,000 tons/year of lead concentrate, and 1.2 million oz/year of silver (138).

The $30 million expansion of the zinc plant at Canadian Electrolytic Zinc in Valleyfield, Quebec, is expected to be completed at the end of 1975 (139).

General imports of zinc in ores and concentrates declined 22% to approximately 200,000 tons, the lowest since 1940; the major sources continued to supply less. Receipts from Canada were down 4% and those from Mexico, Honduras, Peru, and Ireland were substantially lower than last year. Imports for consumption of zinc in ores and concentrates decreased 5% from those in 1972 to 165,000 tons. General imports and imports for consumption of slab zinc were practically the same at 590,000 tons with increases over last year of 14% and 15%, respectively. Canada accounted for approximately 60% of the slab zinc imports, Japan 8%, Belgium-Luxembourg 7%, Australia 7%, and Zaire 4%.

Consumption of slab zinc increased 6% to a record high of over 1.5 million tons. The quantities used for all major categories increased: galvanizing was up 6% from 1972; brass and bronze, 5%; zinc base alloy, 8%; and zinc oxide, 20%. The minor uses declined: rolled zinc was off 12%; and other uses including zinc dust, wet batteries, desilverizing lead, and light metal alloys declined 6%.

The General Services Administration (GSA) continued to release zinc from the national stockpile as authorized by Public Law 92-283. Effective July 1, 1973, GSA increased the quarterly quota to 25,000 tons/quarter (including 5000 tons Special High Grade) and permitted the participating producers to draw more zinc from the stockpile. GSA sales of Government stockpiled zinc in 1973 amounted to approximately 285,000 tons. Sales from the set-aside program totaled 62,477 tons, and 223,000 tons were sold to the participating domestic primary producers who remelted 149,400 tons and shipped 73,600 tons directly to customers. The balance of 40,000 tons will be released in the first quarter of 1974. In early April the stockpile objective for zinc was reduced from 560,000 to 202,700 tons creating an additional surplus of 357,300 tons. New legislation authorizing disposal of this quantity was signed by the President on December 31, 1973.

The lead and zinc flexible-tariff bill and the bill to suspend the duty on imports of zinc concentrates were reintroduced in Congress in March. Each incorporates a significant change from the previous bills. The new flexible-tariff bill permits a larger quantity of zinc metal to enter the U.S. before the higher duties become effective, and the duty suspension bill on zinc concentrates is for 2 years instead of 1 year. At year's end, both bills were in the House Ways and Means Committee. Another bill, also in the House Ways and Means Committee, proposed suspension of the duty on imports of slab zinc (140).

Texasgulf and Canada Development Corporation have patched up their differences, with the CDC now controlling about 30% of Texasgulf stock.

Mitsubishi has cut production of zinc by more than 20% and of lead by some 12% during December, probably due to the energy crisis.

Early in the year, prices advanced from a range of 18-18.52¢/lb to 20.25-21¢/lb where they were frozen June 13 by Presidential order. The ceiling prices prevailed until December 6, 1973, when the Cost of Living Council abolished the control on zinc. One company raised its price to 32¢/lb and the others quoted prices between 28 and 30¢/lb. The European producer price for zinc quoted at 18.5¢/lb (U.S. equivalent) in January rose after five increases to 32.5¢/lb at year's end. The London Metal Exchange price for zinc was 17.5¢/lb at the beginning of the year, 31.5¢ at the end of June, and advanced to a high of 99¢ on December 4, 1973, then declined to 60¢/lb at the end of the year.

Electrical Energy

U.S. power generation.—The following tables give a preliminary summary of the production and consumption of electrical energy for the twelve-month period January through December, 1973 (141, 142).

Production of Electrical Energy in 1973 (Billion-kW-hr)

	1972	1973	% Change
Production by electric utilities			
Coal-fired plants	770.6	843.6	9.5
Gas-fired plants	375.7	337.5	−10.2
Oil-fired plants	272.5	314.7	15.5
Nuclear plants	54.0	81.3	50.5
Total fuel burning	1472.8	1577.1	7.1
Hydroelectric plants	272.7	277.6	1.8
Total	1745.5	1854.7	6.3
Private industry, self-generated	106.1	106.1	0
Total U.S. power generated	1851.6	1960.8	5.9

Installed Generating Capacity* (Millions-kW)

	1972	1973
Public owned		
Steam	46.6	51.0
Hydro	37.3	39.6
Nuclear**	0.9	2.4
Total	84.8	93.0
Investor owned		
Steam	281.1	301.5
Hydro	19.3	21.9
Nuclear**	14.4	19.3
Total	314.8	342.7
Total electric utility industry capacity	399.6	435.7

* Not including privately owned capacity.
** Nuclear plants having about 4000 MW capacity received operating licenses but were not placed into operation. This capacity not included in the above figures.

Electric Utility Fuel Consumption in 1973

Fuel	1972	1973	% Change
Coal, million tons	351.0	386.6	10.1
Gas, billion cu ft	3,978.7	3,754.2	−5.6
Oil, million barrels	493.9	565.5	14.5
Coal and coal equivalent, million tons	646.3	723.7	12.0

Total Electric Utility Sales to Ultimate Consumers in 1973 (Billions-kW-hr)

Consumer	1972	1973	% Change
Residential	511.4	554.2	8.4
Commercial	361.8	396.9	9.7
Industrial	639.5	687.2	7.5
Other	64.9	64.9	—
Total	1577.6	1703.2	8.0

The year 1973 was marked with intensive concern by all sectors of society with all forms of energy. The growing demands of the U.S. and recent foreign political actions have brought national awareness of the reality of the energy crisis.

Project Independence was launched by President Nixon with the objective of meeting U.S. energy needs without depending on foreign resources by 1980 (143). He also asked for consideration by the Congress for the formation of an Energy Research and Development Administration. Initial funding of the increased energy Research and Development Program called for $1.0 billion in the 1974 fiscal year, followed by a 5 year $10 billion program. Dixie Lee Ray, Chairman of the Atomic Energy Commission (AEC), presented the details of the urgent proposed programs toward the end of the year. William E. Simon was named the new energy advisor and head of the Federal Energy Office (144).

With electrochemical plants and other high energy-consuming industries operating at near capacities, power sporadically became in short supply in localized areas.

Late in the year, the sudden Arab oil embargo became a reality, intensifying the energy shortage. Although knowledgeable people and agencies proclaimed the coming fuel shortage for a decade, the embargo rudely awakened the complacent that the U.S. cannot indefinitely rely on foreign sources of fuel to meet the increasing domestic demands.

The Arab oil embargo created a national crisis as well as a sudden shift from apparent abundance to an immediate scarcity. However, the crossover point of foreign and domestic supply and increasing domestic demand was fast approaching, and the scarcity would inevitably arrive. The embargo only hastened the day of scarcity and made us aware that dependence on foreign oil would be exceedingly dangerous to the U.S. economy and our national defense obligations.

To achieve minimal dependence on imported oil in the immediate future, it is necessary to encourage the development of four major areas: provide stronger incentives for bringing new domestic natural gas and oil to the market, accelerate the drilling of the Outer Continental Shelf for oil and gas, increase the use of coal, including the conversion of coal to gas and the opening of new mines, and increase the construction of nuclear power plants. The development of other forms of energy, such as shale oil deposits, geothermal power, and solar energy, is not expected to have any perceptible impact on energy production within the next decade.

The significance of the huge resources of American coal is reported by the National Petroleum Council on coal availability. This review of the U.S. energy outlook concludes that domestic coal reserves can make a major contribution to the nation's future energy demands (145).

The conventional domestic demand for coal is expected to increase at an annual growth rate of 3.5%, or 863 million tons in 1985. Exports were predicted to grow by 4.5% annually, or up to 138 million tons in 1985. The big unknown in coal demand over the next decade is that required for production of gaseous and synthetic fuels.

Total coal reserves are estimated by the U.S. Geological Survey to be a 3.2 trillion tons, with 2 trillion tons potentially recoverable. The Bureau of Mines has converted a ton of coal into two barrels of low sulfur, low ash oil. At this rate, the recoverable coal in the U.S. is equivalent to 4 trillion barrels of oil, or 10 times the known worldwide oil reserves.

The survey concludes much remains to be done if this potential is to be reached. Mining technology must be improved to offset the severe impact of the Coal Mine Health and Safety Act of 1969 on production capacity. New mine workers and mining engineers must be developed to produce the increased production. Technology must be developed to permit use of high-sulfur coal in power generation without air pollution. Expanded and reliable transportation must be constructed, including railroads, river systems, and coal handling (145).

The construction of the trans-Alaskan pipeline to move crude oil from the Northern Slope was delayed by a lawsuit based on the width of the right-of-way, initiated by environmentalists (146). However, legislative action was taken to amend the law to permit the pipeline to be built (147).

New developments.—In new technology, nickel-plated aluminum conductor has been produced at half of the cost of copper with easy connectability of the conductor. The nickel thickness ranges from 0.1-10μ. For telecommunication applications, copper-clad aluminum conductor is produced by means of hydrostatic extrusion (148).

The possibility of manufacturing methanol offshore in the North Sea has been proposed. Previous studies have centered on land-based plants in the Middle East. The conversion of natural gas to methanol simplifies the ocean shipping of fuel, but with an energy loss (149).

According to the U.S. Bureau of Mines, methane from coal mines, obtained by hydraulic fracturing of the coal bed to release more gas and by drilling horizontal drainage holes through the coal bed, could double U.S. gas reserves. The Bureau of Mines estimates 260 trillion cu ft of methane, about equal to U.S. proved natural gas reserves, lie in coal beds between strip mining depth and 3000 ft. In conducted experiments, methane from coal beds was produced as fast as from commercial gas wells (150).

The U.S. and USSR have agreed to exchange ideas on magnetohydrodynamics (MHD) as a means of energy conversion. The Soviets already have a 25 MW pilot plant in Moscow, whereas U.S. research on MHD is at a less advanced stage. However, the Soviets have run into technical problems, and both countries agreed that an exchange of data will be mutually beneficial (149).

The feasibility of piping coal in oil is being studied by Shelpac Research and Development, Ltd., for Interprovincial Pipe Line Company of Canada. Using an existing pipeline to minimize capital costs, the slurry would contain up to 35% coal. The coal would be separated in Eastern Canada by the refiners and the oil left with the low-sulfur Alberta subbituminous coal would be used as fuel by the power companies (151).

A limestone process for removing sulfur dioxide from stack gases will be getting a full-scale tryout at the Detroit Edison 170 MW Saint Clair generating station in the spring of 1974. The trial follows a successful 1 MW pilot plant test of the process (145).

A new process for combining the sulfur from coal is the intimate mixing of the coal fines with lime before firing. The lime ties up the sulfur as sulfate with up to 95% sulfur removal. Further tests with pulverized coal are planned (152).

The Tymponic Corporation, developers of a device employing ultrasonic emulsification of fuel oil with up to 25% water, has demonstrated the reduction of fuel oil consumption in boilers by more than 20% (153).

Interest in the so-called hydrogen economy, advocated by proponents of clean fuel and those concerned with energy beyond the year 2000, has been accelerating with increasing shortages of fossil fuel. Hydrogen, derived from water by one of several methods, is proposed to supplant all fossil fuels. Basically, a remotely sited nuclear reactor (fission or fusion) supplies the energy to form oxygen and hydrogen from water. The hydrogen, acting as an energy carrier, can be pumped through pipelines either as a compressed gas or a liquid to a populous center, where the hydrogen is burned with oxygen or air in a steam generating plant, or piped to homes and burned catalytically, or to a fuel cell to provide electrical energy (154).

The hydrogen energy system was the topic of two national meetings in 1973, at the American Chemical Society meeting in Boston in the spring and at the annual Intersociety Energy Conversion Engineering Conference in San Diego in the fall. Conferences in 1974 were slated for Houston in January, Miami in March, and at the Fall Meeting of The Electrochemical Society in New York.

Nuclear power.—Fourteen nuclear power plants received operating licenses during 1973, thereby boosting the nuclear generating capacity by more than 70% to 25,670 MW. The Atomic Industrial Forum listed 42 U.S. nuclear units as operable, 56 under construction, an additional 101 under firm order, and 14 others covered by options or letters of intent. By the end of 1973, nuclear facilities had 7% of the total U.S. generating capacity. It has been predicted that by 1980, 1985, and 1990 the nuclear-based energy sources for electrical utilities will be 20, 35, and 44%, respectively. Of the power plants under construction, 18 may get their operating licenses in 1974 (155).

During 1973, the fuel costs for San Diego Gas and Electric Company were estimated at $0.763/million BTU on fuel oil compared with $0.163/million BTU on nuclear fuel. These costs do not consider the 50% plus increase in price of petroleum products in the last 2 months of 1973 (155). The operating performances of nuclear *vs.* nonnuclear plants were compared by Commonwealth Edison Company (Chicago) from data on their fossil-fueled and nuclear-

fueled plants (68 and 32%). The latest 12 month figures for average plant capacity availability were 82.6% for nuclear and 79% for fossil plants (155).

The Atomic Energy Commission announced a new reduced rate of $36/unit of separation for uranium enriching services. The total uranium enrichment revenues from the nuclear power industry in U.S.A. and abroad have exceeded a billion dollars (156).

Kerr-McGee signed a $150 million contract with a group of utilities to supply nuclear fuel for electrical power plants (157).

The National Petroleum Council urged stepped-up uranium exploration to be prepared to supply the fuel for the U.S. nuclear energy generating capacity of 240,000-450,000 MW by 1985. It is estimated that 8-10 years will be required for exploration to find the 400,000-700,000 tons of U_3O_8 that will be needed (150).

Westinghouse has increased its activity in supplying nuclear fuel in Europe by a formation of a new company with Belgian interests. Previously, Westinghouse formed Euro Fuel with French participation to supply fuel for light water reactors, as well as fuel production in Italy and West Germany (158). Bechtel, Union Carbide, and Westinghouse have proposed joint study with Japan's Enrichment Survey Committee to determine the feasibility of building a U.S.-Japanese uranium enrichment plant (159).

KMS Industries, Inc., Ann Arbor, Michigan, sponsored by Texas Gas Transmission Corporation, will carry out laboratory and theoretical work on producing hydrogen and combustion fuels by KMS nuclear fusion techniques (1969).

A European effort in controlled nuclear fusion research, named Joint European Tokamak (JET), has been proposed to start in 1976. This program will continue the joint efforts in nuclear fusion after the present 5 year research program terminates (170).

Hydrogen fuel from water by a nuclear route is being sought by Gulf General Atomic Company, sponsored by Southern California Edison and Northeast Utilities, Gulf General's high temperature reactor technology may provide a method of obtaining hydrogen fuel. In the process, heat and catalytic chemicals split water at a temperature of 1500°-1800°F (160).

A new company, Nuclear Power Products Company, a joint venture of Gulf Atomic Company and Foster Wheeler, will make steam generator equipment for high temperature, gas-cooled reactor (HTGR) nuclear power plant systems (161).

The closing of 20 nuclear power plants is the aim of environmentalists led by Ralph Nader and the Friends of the Earth. At issue is the safety of the emergency core cooling system. Failure of this system could lead to vertical melting of a plant and widespread radiation damage (162). A moratorium on nuclear plants in California was urged by environmentalists, who are planning to put an initiative to that effect on the November 1974 ballot (1968). Environmentalists were active in many hearings on nuclear power plants throughout the U.S. and have been successful in delaying the issuance of construction and start-up permits.

The Atomic Energy Commission is sponsoring development of geothermal energy, with a goal of 20,000 MW by the year 2000 (163). The only dry steam unit in commercial operation is the 400 MW plant at The Geyers in northern California. Hot water fields are estimated to be 10-20 times as abundant as dry steam fields. The high concentration of dissolved solids in the water presents processing and corrosion problems. Field trials of using hot rocks, which are close to the surface, as a geothermal energy source are under way. It has been estimated that hot rock fields could provide 10 times the power of dry steam and hot water fields combined. The total power generation potential of geothermal sources has been estimated at about 400,000 MW by the year 2000 (164).

One of the stronger incentives to bring natural gas to the market is an increase in price. The Federal Power Commission has generally approved applications at prices above ceilings in effect at the beginning of the year. For instance, the price of gas coming from offshore Louisiana wells was raised to $0.45/1000 cu ft, compared to an earlier ceiling of $0.26 (a 73% increase) (165).

Significant increases in electricity costs, especially from utilities dependent on Mideast oil, are projected for 1974. Power charge increases from 5-26% have been requested by New England and mid-Atlantic area power companies, hardest hit by the Arab embargo and new oil price schedules (166).

The Bonneville Power Administration which serves the Pacific Northwest will hike the price of power 20-30% beginning in December 1974. The 25% boost in rates charged aluminum producers would amount to less than 2% of the 1973 price of aluminum. Other electroprocess industries would be affected to a lesser degree (167).

Manuscript received July 17, 1974. This report was presented at the Industrial Electrolytic Division Luncheon at the San Francisco, California, Meeting of the Society, May 12-17, 1974.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1975 JOURNAL. All discussions for the June 1975 Discussion Section should be submitted by Feb. 1, 1975.
