Galvanic Cells Containing Cathodes of Iron-Doped Beta-Alumina

John H. Kennedy* and Anthony F. Sammells**

Department of Chemistry, University of California, Santa Barbara, California 93106

ABSTRACT

Galvanic cells of the form Na/β-alumina/$Na_2O \cdot 11(Fe_xAl_{2-x}O_3)$ where x varied between 0.9 and 1.2 were operated at 120°C, and currents of 50 mA/cm^2 could be drawn. The cells were electrochemically regenerative, and the cathodes could be thermally regenerated. Initial open-circuit voltages varied between 2.37 and 2.45V. Cells were discharged at constant current, and two distinct voltage regions were observed. The reduction process was investigated by Mössbauer spectroscopy. The lower voltage region was shown to involve the reduction of Fe^{3+} to Fe^{2+}. The higher voltage region is possibly explained by the filling of holes in the valence band of the iron-doped spinel-type structure, created during the sintering process.

Sodium β-alumina $Na_2O \cdot 11\ Al_2O_3$ has become increasingly attractive as an electrolyte in recent years due to its relatively high conductivity and its applicability to alkali metals (sodium in particular) as potential anode materials. Beta-alumina single crystals have been shown to exhibit rapid sodium ion diffusion in the plane perpendicular to the c-axis (1), and the sodium ions can be almost completely exchanged in molten salts for Ag, K, Li, Rb, and to a lesser extent Cs ions. This ion exchange property infers ion conductivity and makes β-alumina an electrolyte also worthy of consideration in any battery systems that incorporate K or Li as anode materials. Sodium ions, however, exhibit the largest diffusion coefficient, the mechanism of which has been shown to be interstitial. Interest in β-alumina as a sodium ion conducting electrolyte has revolved around its use in the sodium/sulfur battery first reported by Kummer and Weber (2). This battery operates in excess of 300°C due to the high melting point of the sodium polysulfide cathode material used. Many of the early investigations with β-alumina as a sintered polycrystalline material were concerned not only with the achievement of high conductivity but also with the deterioration of the electrolyte at such temperatures. The development of batteries operative at temperatures considerably below 300°C has been limited by low conductivities of the sintered electrolyte material and the availability of suitable cathode materials. Recent investigations (3-5) have shown that sodium ion conductivity in sintered β-alumina can be sufficiently increased by the incorporation of MgO to make β-alumina feasible as an electrolyte at temperatures considerably below 300°C.

Cathode materials for β-alumina galvanic cells present more formidable problems. The substitution of M^{3+} transition metals for Al^{3+} sites in β-alumina was first suggested for cathode material by Hever (6) who synthesized cathode materials of the stoichiometry (*a*) $Na_2O \cdot 5(Fe_{0.95}Ti_{0.05}AlO_3)$, and (*b*) $1.3\ K_2O \cdot 0.2Na_2O \cdot 10$ $(Fe_{1.9}Ti_{0.1}O_3)$. Cell (*a*) used the electrolyte M-brick (Harbison-Carborundum) which consists of an α-alumina/β-alumina eutectic in which the presumed mobile species was Na^+. The electrolyte used in cell (*b*) was $1.3\ K_2O \cdot 0.2\ Li_2O \cdot 10\ Al_2O_3$ in which K^+ was assumed to be the mobile species. In these cells both of the electrodes consisted of the same material, and the cell was charged after fabrication. The transition metal ions were considered to be immobile, and the electrochemical process taking place in the cathode did not involve a phase change. It was postulated that the measured voltage came from the reduction of M^{3+} to M^{2+} accompanied by the migration of Na^+ through the electrolyte to maintain electroneutrality. Titanium dioxide was added to the cathode material to increase the electronic conductivity by providing Fe^{2+} donor ions. These cells ran at 300°-500°C under vacuum (10^{-4} Torr) and exhibited potentials of $< 1V$. The cells had identical electrodes in which one acted as an anode while the other acted as a cathode. The charge capacity was limited by the availability of Na^+ in the electrolyte material. In order to devise a cell using sodium β-alumina electrolyte which is not limited by the amount of electrolyte material, the anode must supply the needed sodium ions. The natural choice for such an anode is sodium metal. We report here electrochemical cells which were operated at temperatures just above the melting point of sodium and contained sintered cathodes in which some of the Al^{3+} sites were replaced by Fe^{3+} in the β-alumina structure.

Experimental

Preparation of β-alumina cups prior to sintering.— Beta-alumina (Alcoa 325 mesh) was ground to particle size 0.5-1μ in an alumina grinding mill using alumina balls. Ethylene glycol was used as a grinding aid, and the final particle size was determined with a Unitron 11 microscope. The 2% MgO and 1.7% Na_2CO_3 of similar particle size were mixed with the ground β-alumina in a mechanical Fisher alumina mortar and pestle. To this material was then added a binder (2% carbowax 1000 as a 10% aqueous solution). Thick pellets (0.85 cm) were made in a KBr-type press using pressures of

Key words: battery cell, beta-alumina, iron spinels, Mössbauer spectroscopy, sodium electrode.

80,000 psi, and the binder was removed by slowly heating to 400°C and leaving 24 hr. The pellets were then prefired at 1100°C for 1 hr so that a cup could be drilled with a 11/32 in. flat bottom drill bit, while holding the pellet in a wooden jig.

Sintering conditions.—The prefired β-alumina cups were sintered in an Astro ultra-high temperature graphite resistance furnace Model No. 1000A-2560 under oxidizing conditions with the use of an alumina muffle tube assembly. The graphite heating elements surrounding the alumina muffle tube were protected by a nitrogen atmosphere. The cups were placed face down and covered with coarse 325 mesh β-alumina during the sintering so as to provide an alkaline atmosphere and hence reduce the loss of sodium. The cups together with the β-alumina packing were kept covered in an alumina crucible during the sintering. Heating rates of 250°C/hr were employed so as to prolong the muffle tube life. Temperatures of 1750°-1860°C were controlled with a boron-graphite thermocouple and maintained for extended periods of time up to 8 hr. Recorded temperatures were measured directly by use of a Micro-Optical pyrometer (Pyrometer Instrument Company) through a viewing port in the side of the furnace.

Cathode materials and cell fabrication.—In the β-alumina care was given to the particle size and homogeneity of the 2% MgO added. Excess sodium was incorporated by the addition of 1.7% Na_2CO_3 before sintering the electrolyte. The thick pellets (*ca.* 1g) were made at 80,000 psi and did not give laminations as have been found with thinner pellets (*ca.* 0.3g, 0.25 cm thick). Attempts to drill the pellet immediately after pressing were unsuccessful, and a prefiring at 1100°C after binder removal gave the pellet sufficient cohesion to allow the use of a flat bottom drill-bit.

Cathode materials were synthesized by heating stoichiometric amounts of Al_2O_3, Fe_2O_3, TiO_2, and Na_2CO_3 at 1100°C for between 1 and 24 hr until an x-ray pattern was observed, indicating the presence of the β-structure. The cells were fabricated by placing a sintered cup face down in β-alumina packing and resting a pressed pellet of cathode material on the cup base. Care was taken that the packing was not in contact with the cathode material. This pair was then sintered at between 1520° and 1620°C in a closed alumina crucible for between 5 min and 1 hr, after which the cathode fused to the electrolyte.

The sodium electrode.—All procedures with molten sodium were carried out in an Overly Model B-100 dry box equipped with a nitrogen recirculating system, consisting of heated catalysator-pellets (BASF) to reduce O_2 to H_2O. Molecular sieves were used to trap water. The molten sodium was transferred rapidly from a heated beaker by means of a small dropping pipette into the recess of the heated cell. After the sodium had been added to the cell, it was found necessary to press the sodium down into the cup to ensure contact with the electrolyte. The cell was then transferred rapidly with the molten sodium (the sodium was not allowed to solidify) to the heated conductivity jig.

Cell measurements.—A Bissett-Berman Corporation E-cell digital coulometer was used for constant current discharge and charge of cells. A Harrison 6112A d-c power supply across suitable resistances was used as a constant current source when small changes in current were required.

Application of thin films.—Gold evaporations were performed in a Veeco 776 automatic high vacuum evaporator and an Edwards Model E12E3 thin film evaporator.

Mössbauer spectroscopy.—A 256 multichannel analyzer (Northern Scientific Company) was used in the multiscaler mode. The constant acceleration mode was used with a triangular wave form. For detecting the 14.4 keV Mössbauer line a proportional counter was used. The source was a 20 mcurie Co^{57}/Pd.

X-ray diffraction.—X-ray diffraction of cathode materials was performed with Philips Electronics Instruments x-ray diffraction equipment using CuKα radiation, a Philips Type 52572 scintillation counter, and a chart recorder.

Results

Before the development of cathode materials could be pursued, the nature of sodium as an anode material was investigated. A cell of the form Na/β-alumina/Au was fabricated by using a pool of sodium in the cup and evaporated gold on the cup base. The 1 kHz resistance values were measured at different temperatures above and below the melting point of sodium. Figure 1 shows that at temperatures above the melting point of sodium (98°C), the resistance of the cell was about 20 ohms or less. When the high temperature line was extrapolated back to 25°C, the resistivity (300 ohm-cm) was about the same as that observed during our previous conductivity studies for β-Al_2O_3 compositions containing 2% MgO and using two inert metal electrodes (4). Below 98°C the cell resistance rose rapidly and was not stable with time. The two lines intersected at the melting point of sodium indicating that molten sodium formed a satisfactory electrode/electrolyte interface while solid sodium did not. It appeared that the loss of contact between solid sodium and β-alumina was probably caused by a lack of wetting by molten sodium allowing it to pull away when cooled. Wetting could be improved by heating the cell to $>$ 300°C for 16 hr before cooling, but the contact was still not satisfactory. Therefore, all subsequent investigations with cells containing pure sodium were performed at temperatures above its melting point.

Cathode materials were synthesized directly from Al_2O_3, Fe_2O_3, Na_2CO_3, and TiO_2, with the initial stoichiometries $Na_2O \cdot 5(Fe_{0.95}Ti_{0.05}AlO_3)$ and $Na_2O \cdot 11(Fe_xAl_{2-x}O_3)$ where x ranged from 0.9 to 1.2. The incorporation of TiO_2 in some of the samples was intended to increase the electronic conductivity by giving rise to Fe donor ions as reported by Hever (6). However, we found no significant reduction in our cell resistances for material containing TiO_2. X-ray diffraction data indicated the presence of a small amount of α-Al_2O_3 in all samples.

During sintering the cathode material rested on top of the electrolyte and conditions had to be determined which would sinter the cathode both to itself and the electrolyte. Too high a temperature allowed the cathode material to diffuse all the way through the electrolyte, whereas too low a temperature resulted in

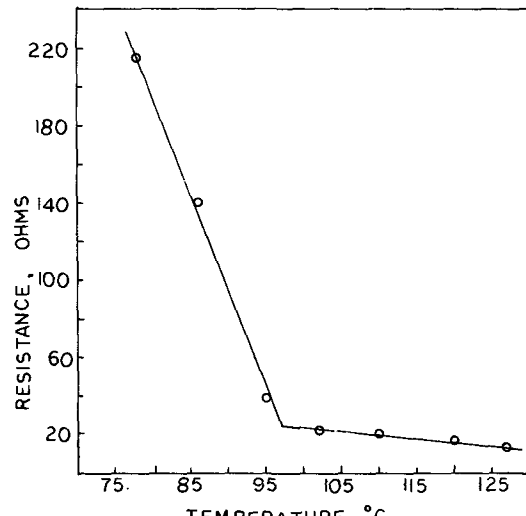

Fig. 1. Variation of pellet resistance at 1 kHz with temperature for the cell Na/β-Al_2O_3/Au.

poor contact between the electrolyte and cathode and thus gave high cell resistances. Different sintering procedures were necessary for each cathode material used. Generally temperatures in the range 1520°-1600°C for 5 min to 1 hr were adequate. For material of stoichiometry $Na_2O \cdot 11(Fe_xAl_{2-x}O_3)$ all attempts to sinter this cathode material with x values of 0.3 and 0.6 to the electrolyte were unsuccessful. With higher iron content the cell fabrication became easier. Above x values of 1.2 x-ray patterns indicating the β-structure were not observed. All the iron-containing cathode materials indicated the presence of some Fe_2O_3. Mössbauer spectroscopy also showed the presence of Fe^{2+} (even in the absence of TiO_2).

All cells were discharged and charged in a dry box. The experimental setup of the cells is shown in Fig. 2. The cells were operated at 120°C to avoid the sodium/electrolyte interface problem described above. Open-circuit voltage for these cells was 2.37-2.45V, and currents as high as 40-50 mA/cm² could be drawn from them. A typical load curve is shown in Fig. 3. Up to about 30 mA/cm² the slope indicated a d-c cell resistance of 40 ohms compared to the a-c value of 26 ohms. Above 30 mA/cm² the voltage dropped more rapidly indicating the presence of significant polarization effects. Most cells were discharged under constant current conditions although constant load was used in some cases. An open-circuit potential of 2.37V has been maintained by a cell for 12 months at 120°C without any apparent variation due to electronic shorting or chemical effects leading to self-discharge.

Cells discharged either by constant current (*ca.* 0.7 mA/cm²) or constant load (10 kohms) exhibited two distinct voltage regions as shown in Fig. 4. Approximately one-third of the total discharge was in the high voltage region in which the cell voltage fell almost linearly with depth of discharge. The second voltage region was observed around 0.9V and exhibited a slower voltage decay until 20-40% of the iron atoms had been reduced an average of one electron/iron atom. The total amount of charge which could be drawn was dependent on the current density used in the discharge. Cells discharged at 350 μA delivered *ca.* 25% of theoretical for one electron/iron atom, Fig. 4, whereas cells discharged at 36 μA delivered in excess of 40% of theoretical, Fig. 5. In each case the cell could be recharged to the starting potential by the passage of an equivalent amount of charge at a similar current density. The cell voltage during charge at 350 μA tracked the voltage during discharge quite closely, Fig. 6. Cells have undergone as many as ten charge-

discharge cycles with no apparent damage and coulombic efficiency close to 100% (Table I). Cells could also be charged to a higher voltage than the original value up to 2.7V (Fig. 7). At this point the charging voltage at constant current rose rapidly while the open-circuit voltage reached a plateau value.

The possible thermal regeneration of the cathode material was investigated after the complete discharge of cell No. 18 (Fig. 8, curve B) containing the cathode material $Na_2O\cdot11(Fe_{0.9}Al_{1.1}O_3)$ on the second discharge. The sodium was carefully removed in the dry box, the cell was heated to 1500°C for 10 min in an oxidizing atmosphere, and a fresh gold thin film electrode was deposited on the cathode. Upon addition of a molten sodium anode at 120°C the cell again gave an open-circuit potential of 2.3V and was discharged at 315 μA as shown in Fig. 8, curve A.

A Mössbauer spectrum (Fig. 9) was run on a cell prior to its discharge to determine the electrochemical process taking place in the cathode material $Na_2O\cdot11(FeAlO_3)$. A gold electrode was then evaporated onto the cathode, sodium was added to the cup in the dry box, and the cell was then discharged at 36 μA (Fig. 5) to zero voltage. It was necessary for a successful Mössbauer experiment to have approximately 0.05g of cathode material which contained about 0.02g of iron. This cell was discharged 43.5% of theoretical assuming one electron/iron atom. After complete discharge of the cell the sodium was removed from the cup by a pipette while still molten, any residual sodium being scraped off in the dry box. A second Mössbauer spectrum shown in Fig. 10 was run in an analogous manner to the initial one. From the spectra, four of the six magnetically split lines due to Fe_2O_3 can be seen which did not go into the spinel block during the cathode synthesis. These lines occur at velocities of −0.805, −0.43, +0.54, and +0.87 cm/sec. The other two peaks of Fe_2O_3 occur at −0.08 and +0.2 cm/sec and were not observable because of one of the Fe^{2+} quadrupole

splittings at −0.105 cm/sec and the intense Fe^{3+} quadrupole splittings at +0.013 and +0.065 cm/sec. It is immediately clear from the spectra that there was an increase in the Fe^{2+} peak at −0.105 cm/sec and a reduction in the Fe^{3+} lines at +0.013 and +0.065 cm/sec after discharge of the cell. The Fe^{2+} peak at −0.105 cm/sec had a contribution from the magnetically split Fe_2O_3 line at −0.08 cm/sec. A reasonable estimate for this contribution would be one-third the area of the peak at −0.805 cm/sec since the magnetically split lines are in the approximate area ratio of 3:2:1. The

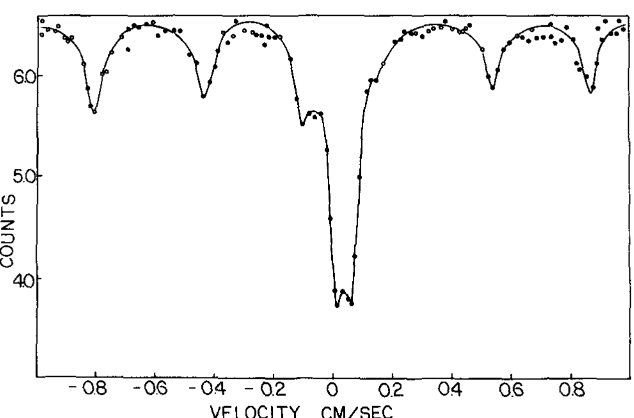

Fig. 10. Mössbauer spectrum of $Na_2O \cdot 11(FeAlO_3)$ cathode material after discharge to zero volts at 0.077 mA/cm².

relative areas of the Fe_2O_3 peak at −0.805 cm/sec before and after discharge were 5.55 and 6.8, respectively, (arbitrary units used) and therefore the areas of the Fe_2O_3 peak at −0.08 cm/sec were estimated at 1.85 before and 2.27 after discharge. Different count rates were used in each Mössbauer experiment.

The area changes taking place in the Mössbauer spectrum before and after discharge can be seen in Table II. These data give a qualitative picture for the reduction process taking place in the cathode. Only 70% of the iron is in the spinel sites of the cathode before discharge. For 70% of the iron atoms active we would expect a maximum charge capacity of 23.3 coulombs assuming a one electron reduction per iron atom. The 14.6 coulombs of charge actually delivered therefore represented 62.5% of theoretical. Over 70% of the total charge was in the low voltage region below 0.9V.

The fact that the increase in the Fe^{2+} peak (4% of 31.6 coulombs = 1.3 coulombs) did not correspond to the expected change on the basis of charge passed (14.6 coulombs total charge of which 4.3 coulombs were in high voltage region and 10.3 coulombs in low voltage region) can be explained by air oxidation of the cathode material during recording of the Mössbauer spectrum. The cell voltage was found to be sensitive to impurities such as oxygen in the dry box and when air was purposely introduced, the cell voltage was found to rise even while being discharged under constant current. This enhanced cathode performance was observed in both the high and low voltage regions.

Cell No. 16 was thermally reactivated by heating to 1500°C, and a further Mössbauer spectrum was taken (Fig. 11). This indicated not only a reduction in the Fe^{2+} peak at −0.105 cm/sec but the incorporation of the majority of the remaining Fe_2O_3 into the Fe^{3+} spinel block sites. The cell was subsequently discharged

Table II. Cell No. 16 Mössbauer spectra peak areas

Line position, cm/sec		Area (arbitrary units) before discharge	Area (arbitrary units) after discharge
Fe_2O_3 −0.805		5.55	6.8
−0.43		3.55	5.22

at 36 μA to 1.0V so as to determine whether the reduction of Fe^{3+} to Fe^{2+} occurred in the high or low voltage region or both. The Mössbauer spectrum after discharge indicated that no apparent reduction of the Fe^{3+} had taken place in the high voltage region. The reduction of the Fe^{3+} must therefore occur only in the low voltage region, and some other electrochemical process must be responsible for the high voltage region.

High electronic and ionic conduction are essential to any efficient cathode system. The presence of electronic conductivity in the cathode material $Na_2O \cdot 11(FeAlO_3)$ was determined by fabricating the cell Au/$Na_2O \cdot 11(FeAlO_3)$/Au and placing a constant d-c voltage across it. Under such conditions, the Au thin film electrodes acted as blocking electrodes to the migration of ionic current through the cell. The current measured through the circuit should therefore be due to the electronic conductivity within the cell. The d-c resistance was 890 ohms at 120°C and did not vary appreciably over a period of several days. From the d-c resistance and the pellet dimensions (1 cm diameter × 0.45 cm thick) the electronic conductivity was estimated to be 6.7×10^{-4} (ohm-cm)$^{-1}$. When a-c measurements were made on the same cell frequency dependency was found indicating that some ionic conduction was also present in the cathode.

Discussion

In this approach we have attempted to substitute Fe^{3+} ions for Al^{3+} ions in the spinel block and use this material as a cathode in which there would be no physical phase boundary between cathode and electrolyte and no phase change in the reduction process. The Fe^{3+} in the spinel block would be reduced to Fe^{2+} and a Na^+ ion would move into the layer-type structure to maintain charge balance. From the Mössbauer spectrum of cell No. 16 it appeared that 70% of the iron resided in the Al^{3+} sites of the spinel block after the synthesis sintering with the rest of the iron being in the reduced Fe^{2+} form or as unincorporated Fe_2O_3. From x-ray diffraction analysis these cathode materials had a spinel-type structure analogous to β-alumina, and the presence of unreacted Fe_2O_3 was detected.

From the discharge curves two voltage regions were observed. The lower one around 0.7V can be explained on the basis of the reaction

$$2Na + Fe_2O_3 \rightarrow Na_2O + 2FeO \quad [1]$$

for which the theoretical voltage is 0.71V based on free energies of formation. Further evidence for this process in the low voltage region comes from the Mössbauer spectra. The cell after discharge to zero volts showed a significant increase in the Fe^{2+} peak together with a corresponding decrease in the Fe^{3+} peak, whereas after being thermally regenerated and then discharged down

to 1.0V no apparent reduction had taken place. The following oxidative process is proposed to take place at the cathode in the presence of air simultaneously with the electrochemical reduction process

$$2Na^+ + \frac{1}{2} O_2 + 2Fe^{2+} \rightarrow Na_2O + 2Fe^{3+}$$

with the Na_2O being formed on the outer surface of the cathode. A white film was observed to form on the surface of the cathode after extensive discharge. Thus, the cell appeared to show some characteristics of a fuel cell in which the over-all reaction is

$$2Na + \frac{1}{2} O_2 \rightarrow Na_2O$$

Here the reductant is Na and the oxidant is O_2 from the atmosphere via the Fe^{3+}/Fe^{2+} couple. This would also explain the thermal regenerative capability of the cathode. The high voltage region is more difficult to explain but there appear to be three possibilities, (*a*) trapped O_2 gas, (*b*) iron in oxidation states greater than plus three, and (c) vacancies in the valence band created by excess O^{2-}. The fact that the cells were sensitive to O_2 leads to the hypothesis that the presence of O_2 gas trapped in the sintered cathode material would exhibit high voltages. This could be present from two sources. The first is the trapping caused during the sintering process of the cathode. High porosity would be expected since the particle sizes before sintering were much larger ($> 50\mu$) than those used in the sintering of the electrolyte (1μ) and shorter sintering times were used with the cathode. The second source of O_2 could come from Fe^{2+} produced during the sintering from the reaction

$$2Fe_2O_3 \rightarrow 4FeO + O_2$$

The presence of O_2 gas would give rise to the electrochemical process

$$2Na \rightarrow 2Na^+ + 2e^-$$

$$2e^- + \frac{1}{2} O_2 \rightarrow \frac{1}{2} O_2^{2-}$$

over-all reaction

$$2Na + \frac{1}{2} O_2 \rightarrow Na_2O$$

The theoretical voltage for this process is 2.17V based on free energy of formation for Na_2O. With the cathode density of about 3.0 and from a consideration of the volume of O_2 required for this high voltage region, we calculate an oxygen pressure in excess of 200 atm (assuming a 10% porosity). When we consider the conditions under which the cathode was synthesized such pressures are not realistic. There is also the related mechanism of slow O_2 migration into the cathode from the traces present in the dry box. However, for this mechanism one would expect the high voltage region charge capacity to be current density dependent. Very little, if any, such dependence was found unlike the low voltage region which was discussed above.

If the oxygen were chemisorbed its pressure need not be 200 atm. A monolayer of chemisorbed oxygen on particles of 10μ radius would constitute a charge of 0.2 coulomb for the 400 mg cathodes used. This is only a fraction of the 5 coulombs observed, but chemisorbed layers are often thicker than one monolayer. On the other hand, after sintering, the particles are no longer 10μ radius, and thus this estimate of charge is probably much too high. Also, if the high voltage region were due only to chemisorbed oxygen the discharge curve should be Nernstian (not the nearly linear decay observed) and should not be iron-dependent as was observed. Chemisorption though may play a part and be the first step in the third hypothesis discussed below.

The possibility of iron in an oxidation state of greater than three although reasonable in view of possible ferrate formation was not indicated in the negative velocity range of the Mössbauer spectra where such an oxidation state would be expected (7). Also, sintered β-alumina cups with no iron-doped cathode and just a thin film metal electrode at the base exhibited potentials in the 2V range. Such cells however had little charge capacity and the potential quickly decayed during a resistance measurement. This suggested that the high voltage region was not due directly to the doped iron but the charge capacity was an indirect function of the iron content or the sintering characteristics of the cathode material or both. The third hypothesis assumes that at the grain boundaries of the polycrystalline material, O^{2-} ions are formed from reduction of chemisorbed O_2 during the sintering process creating simultaneously electron holes in the valence band of the iron-substituted spinel by the following process

$$\frac{1}{2} O_2 + 2e_{vb}^- \rightarrow O^{2-} + 2V_{vb}$$

where e_{vb}^- is an electron in the valence band and V_{vb} is a vacancy in the valence band. That is, highly electronegative oxygen atoms draw electron density from the crystal. For the passage of 4 coulombs in the high voltage region of cell 16, $4/1.6 \times 10^{-19}$ charge carriers, *i.e.*, $1.25 \times 10^{+19}$ O^{2-} species, are required which represents 0.33 mg of O_2 for 50 mg of cathode. The high voltage region can then be explained on the basis of the reaction

$$Na + V_{vb} \rightarrow e_{vb}^- + Na^+$$

A schematic energy level is shown in Fig. 12. As the valence band becomes filled to point B reduction of Fe^{3+} to Fe^{2+} will become the favored process in the low voltage region.

Discharge curves showed almost linear decreases in the higher voltage region (Fig. 4-6, 8) which is consistent with the proposed mechanism. In addition, there is no reason to expect the density of states to be constant throughout the voltage range of 2.5-0.7V. A low density of states above 2V and below 1.3V would result in a discharge curve as exhibited by cell No. 15 (Fig. 4). The density of states could be slightly different for each cathode leading to the subtle differences observed for the various cells. On the other hand, the plateau at 0.7V is much more Nernstian in behavior and is explained more simply by the reduction of iron +3. Iron doping is necessary to create the electron energy level proposed, but since no iron is reduced in the high voltage region, no changes in the Mössbauer spectrum were observed for cells discharged to 1V.

The regeneration of the cathode in the high voltage region in the presence of O_2 can be explained by the following process

$$2Na^+ + \frac{1}{2} O_2 + 2e_{vb}^- \rightarrow Na_2O + 2V_{vb}$$

In this way, the cell is once again able to accept electrons from the anode with potential differences $> 2V$.

The question now remains, can this type of cathode material be incorporated into a practical battery system? The great advantage of this system is its relatively low operating temperature compared to the sodium/sulfur battery in which corrosion and insulation considerations are of major concern.

The current densities that can be drawn from the cell are encouraging, as well as its thermal regenerative capability. The electrochemical reversibility of the cell should be intrinsically long-lived because no phase change takes place in the cathode.

The successful operation of these cells makes β-alumina worthy of serious consideration not only as the electrolyte, but, in the doped form, as the cathode material in electrochemical systems operative much

closer to ambient temperatures than is possible in the sodium/sulfur system.

Polarization Characteristics and Anodic Disintegration of Beryllium in Nonaqueous Solutions

H. Vaidyanathan,* M. E. Straumanis, and W. J. James***

Graduate Center for Materials Research, University of Missouri-Rolla, Rolla, Missouri 65401

ABSTRACT

Anodic polarization of Be in both aqueous and nonaqueous media leads to a spalling or disintegration of the anode. The disintegration product is composed of shiny, metallic, crystalline particles embedded in a white brittle mass [BeO and/or $Be(OH)_2$] as viewed under an optical microscope. Microstructural studies using scanning electron microscopy provide further proof for the nature and identity of the Be particles. Valency determinations from weight loss measurements give values between 0.34 and 1.75. These anomalous values are attributed to the production of Be by anodic disintegration rather than to a disproportionation reaction of monovalent Be. The "apparent" valency appears to be more a function of the nature of the anion than of the solvent. The apparent valency approaches 1.0 in $LiClO_4$/EtOH and KCl/aq and is fractional in LiCl/MeOH. Beryllium is passivated both in aqueous and nonaqueous media containing NO_3^- ions. Beryllium passivated in $NaNO_3$/MeOH has no electronic conduction; the surface when examined optically appears dark with shiny Be crystals on it. Thus anodic disintegration occurs even at potentials where passive oxides predominate on the surface.

The seeming inapplicability of Faraday's law for the anodic dissolution of Be, Zn, Mg, Al, etc. has led to several inquiries into the fundamental aspects of uncommon valency (1-4). The formation of univalent cations as the first stage during anodic dissolution is partly accepted in the case of Al, In, etc. (5, 6). However, the univalent cations react much faster according to

$$M^+ \rightarrow M^{2+} + e \quad [1]$$

$$M^+ + H_2O \rightarrow MOH^+ + H_{ads}(M) \quad [2]$$

than they are formed and as such there is no evidence for the existence of Zn^+, Fe^+, Be^+, Mg^+, etc. in solution. The inapplicability of Faraday's law can also be accounted for without considering the formation of stable univalent cations. Straumanis (7) has proposed the phenomenon of anodic disintegration as responsible for this deviation in several instances where anodic spalling is known to occur. This proposition provides a reasonable rationale for the abnormal valences of Be, Zn, Mg, Ag, etc. and the formation of metallic particles in the anolyte solutions. Anodic disintegration, however, is not limited to aqueous solutions alone. This paper presents a case for Be dissolution and the mechanism of anodic disintegration in such anhydrous media as MeOH, EtOH, and dimethyl formamide (DMF). Anodic disintegration studies in this laboratory were supplemented with microstructural studies using an optical microscope in the past. The present study utilizes a scanning electron microscope also, which has a high resolution and large depth of focus.

Experimental

The Be anodes had a purity greater than 99.00%. Circular disks of Be were machined, polished with emery paper, cleansed in an ultrasonic cleaner, degreased with CCl_4 and acetone, and dried in a desiccator. A specially constructed Teflon holder was used to hold these leak-proof Be disks in the electrolyte. The nonaqueous solvents methanol, ethanol, and dimethyl formamide were 99.9% pure. They were purified further by using Davison Type 4A molecular sieves. Valency determinations were carried out as described earlier (8). Prepurified N_2 provided an inert atmosphere in the electrolysis cell. The water content of the electrolyte was determined at the end of each valency study by Karl-Fisher titrations.

Several potential sweep experiments were carried out. Though a steady-state galvanostatic study is extremely simple the potential sweep method enables the evaluation of current density at all potentials within the range of interest and hence the pursuit of passivation stages in the reaction. A Wenking potentiostat externally modulated by an Elron function generator was used. The cyclic current (i) *vs.* potential (E) curves obtained at different sweep rates were recorded using

Table I. Apparent valency of beryllium in aqueous solutions*

Solution and concentration, moles/liter	Current density, mA/cm^2	Apparent valency, V_I
1M KCl	3.8	1.07
	15.4	1.19
	38.5	1.22
1M KI	20	1.41
0.33M K_2SO_4	20	1.82
0.01M LiCl + 0.33M K_2SO_4	20	1.21

* Data from ref. (18).
Note: In all electrolytes anodic disintegration occurred.

Table II. Apparent valency of polycrystalline Be in some nonaqueous solutions

Solution and concentration, g-mol/liter	Current density, mA/cm^2	Apparent valency, V_I
0.2M LiCl in MeOH	1.71	0.35
	3.15	0.34
	17.1	0.44
0.2M KI in DMF	3.06	1.75
0.2M $NaNO_3$ in MeOH	—	*
0.2M $LiClO_4$ in EtOH	0.613	0.91
	3.06	1.15
	7.66	1.09
	12.25	1.00
	18.40	0.94
	24.5	1.00
	30.6	0.98

* Valency is indeterminable since the electrode becomes nonconducting due to the formation of a black film on the surface.
Note: Anodic disintegration occurred in all electrolytes. Average water content at the end of each valency determination is in LiCl/MeOH = 0.68%, KI/DMF = 0.30%, $NaNO_3$/MeOH = 0.68%, and $LiClO_4$/MeOH = 0.4%.

a Mosley 135 AM X-Y recorder. The function generator was adjusted to deliver a single sweep starting at the rest potential. The reference electrode was a freshly prepared Hg/Hg_2SO_4/methyl alcohol electrode with a potential of 0.56V *vs.* NHE in agreement with the literature value (9).

After each valency study, the polarized electrodes were washed with methanol and dried. These were then used for optical and scanning electron microscopic (SEM) studies. In certain cases the electrodes were metalized with Au and then used for the SEM studies.

All experiments were performed at 24° ± 1°C in an all Pyrex "H" cell the two arms of the cell being used to contain the working Be and auxiliary Pt electrodes.

Results

Valency studies.—The apparent valency of Be is a function of several variables. Tables I and II list the values obtained in different electrolytes. The apparent valency approaches one in $LiClO_4$/EtOH and KCl/aq. In KI/DMF the value is greater than one and in LiCl/MeOH it is much less than one. In $NaNO_3$/MeOH the valency is indeterminable since the electrode loses electronic conductance as the dissolution proceeds. Figure 1 shows the variation of the apparent valency with current density (C.D.). There is a leveling off of the valency at high C.D. Similar behavior was reported earlier by Aida *et al.* (10). Anodic spalling occurs in all cases.

Current-potential relation.—Cyclic potential sweep experiments were performed to study the dissolution at varying sweep rates. Potential sweeps from 10-400 mV/sec made no difference in the over-all nature of the *i-E* curves. Reproducibility of the curves was best only at sweep rates of 100-200 mV/sec in certain electrolytes. Figures 2-5 show the *i-E* behavior in various electrolytes. There is a hysteresis between the anodic (forward) and cathodic (reverse) sweeps in all the curves. Dissolution rates in terms of C.D. are maximum in KCl/aq and least in $NaNO_3$/MeOH.

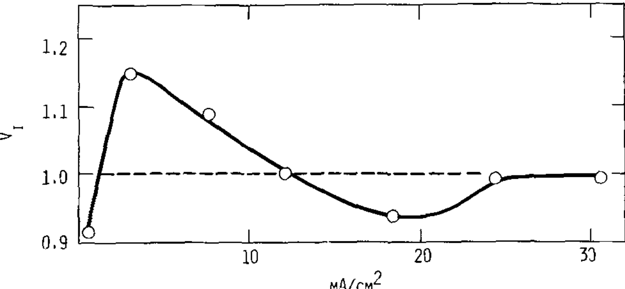

Fig. 1. Apparent valency of Be dissolving anodically in 0.2M $LiClO_4$/EtOH. Water content 0.4% by weight at the end of the experiment.

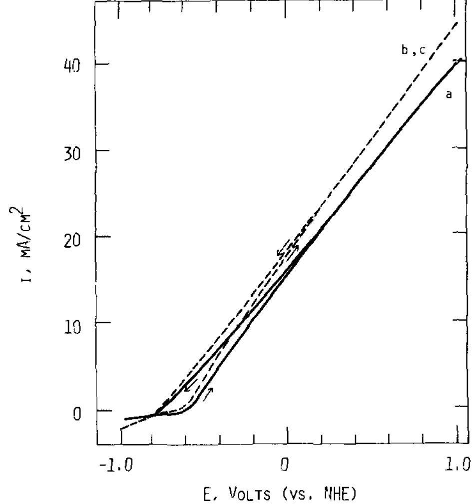

Fig. 2. Cyclic current-potential relations obtained for Be in 0.2M KCl/aq when scanned at 200 mV/sec. Curve a = 1st cycle, curve b = 30th cycle, curve c = 60th cycle.

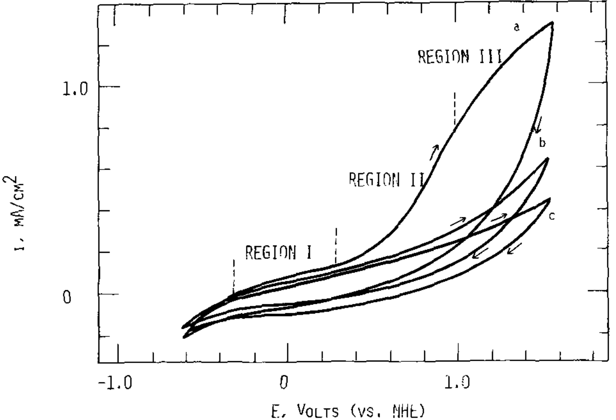

Fig. 3. Cyclic current-potential relation obtained for Be in 0.2M $NaNO_3$/aq when scanned at 200 mV/sec. Curve a = 1st cycle, curve b = 3rd cycle, curve c = 8th cycle.

In KCl(aq) and LiCl/MeOH the *i-E* relation is very similar, C.D. values being greater during the cathodic sweep and appreciable Be dissolution commencing at approximately the same overvoltage. In KCl(aq) the general shape of the *i-E* behavior is unchanged even when scanned 60 times at 200 mV/sec as shown by curves b and c in Fig. 2.

In $NaNO_3$/aq the *i-E* relation has two transition points dividing the curve into three regions. The rate of Be dissolution is very low up to 0.28V (first transition point) beyond which the rate increases very rapidly up to 0.98V (second transition point). Curves b and c show the effect of repetitive cycling and the magnitude of the C.D. decreases with each subsequent scan.

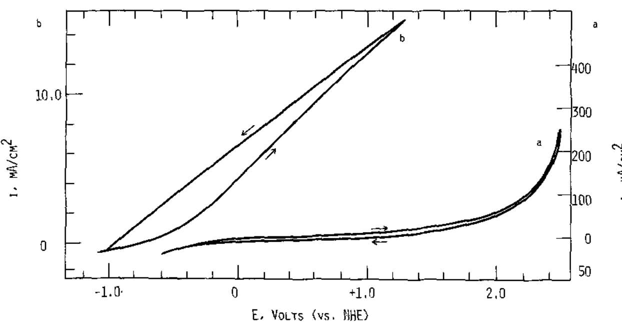

Fig. 4. Cyclic current-potential curves obtained for Be in MeOH when scanned at 200 mV/sec. Curve a = 0.2M $NaNO_3$/MeOH, curve b = 0.2M LiCl/MeOH. H_2O = 0.68% in $NaNO_3$/MeOH and 0.76% in LiCl/MeOH.

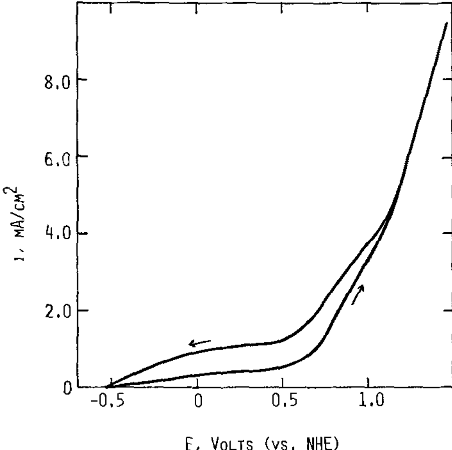

Fig. 5. *i-E* relation obtained for Be in 0.2M KI/DMF at a sweep rate of 10 mV/sec. $H_2O \doteq 0.43\%$.

In $NaNO_3$/MeOH the rate of dissolution is very low even at a potential of 2.0V. Methanol oxidation contributes to the C.D. values beyond 2.0V. The electrode surface turns black on repetitive cycling just as it does on prolonged galvanostatic polarization.

The *i-E* curve in KI/DMF also shows a transition point. Current density values are very low up to $\simeq$0.7V, beyond which they increase at a greater rate. The electrolyte in the immediate vicinity of the Be anode turns reddish brown during the course of a potential cycle beyond $E > 0.6$V. Since I^- ions are believed to be oxidized at these overvoltages, there is contribution to the total C.D. from the anode oxidation of I^- to I_2 and I_3^-. This is reflected in the C.D. values beyond 0.7V. Anodic disintegration occurs regardless of the I_2 reaction.

The *i-E* curves obtained in this study can be used for a comparison of the dissolution rates in the respective media. Current density values at three selected potentials were derived from the *i-E* curves obtained at a fixed sweep rate of 200 mV/sec and were used to compose Table III. The variations of C.D. with repetitive potential sweeps were also determined from the *i-E* curves. The variations are presented in Table IV.

Surface studies.—In all electrolytes studied, large aggregates of black particles appeared in the anolyte. They were filtered, washed, dried, and used for the SEM study. The anode in each experiment was also used for the SEM study. The anodes were heavily pitted. In several instances the anodes were covered with a slime which could be removed only by ultrasonic cleaning. Figure 6 shows the surface structure of a Be anode which has been polarized for 6 hr in 0.2M $NaNO_3$/MeOH. Under an optical microscope the surface appears dark with shiny metallic particles on it. Some of the particles are crystalline when viewed by SEM.

Table III. Electrochemical rates of beryllium dissolution in passivating and nonpassivating media

Solution and concentration	H_2O content as analyzed by KF titration at the end of the expt., %	Reaction rate, *i* 0.30V	(mA/cm²) at potentials 0.68V	1.28V
0.2M $NaNO_3$/MeOH	0.68	0.045	0.12	0.304
0.2M $NaNO_3$/H_2O	—	0.131	0.360	1.1
0.2M KI/DMF	0.43	0.88	1.94*	5.3*
0.2M LiCl/MeOH	0.76	8.7	10.3	14.8
0.2M KCl/H_2O	—	23.8	33.6	—

* These two data do not truly represent the rates of Be dissolution, since electrochemical oxidation of I^- occurs under these potentials.

Table IV. Effect of repetitive potential sweeps at 200 mV/sec on the rate of dissolution of Be at 1.0V (NHE)

Electrolyte (0.2M)	Ordinal number of cycles	C.D., mA/cm²
KCl/aq	1	41.4
	15	42.1
	30	45.8
	60	46.5
$NaNO_3$/aq	1	0.82
	3	0.31
	8	0.24

Figures 7 and 8 show the Be electrode and the anolyte residue when Be is polarized in 0.2M KCl. At the electrode surface, needle-shaped crystals of Be can be recognized readily. Several of the black particles which are in the anolyte appear as hexagonal crystals by SEM.

Figure 9 shows the SEM picture of a Be electrode which has been polarized in 0.2M $LiClO_4$/EtOH at 24.5 mA/cm². The surface of the electrode is covered with black particles approximately hexagonal in shape which can be removed only by ultrasonic cleaning.

Figure 10 shows the SEM picture of the anolyte residue obtained when Be is polarized in 0.2M LiCl/MeOH. Some of the particles in the residue have a distinct hexagonal structure.

Figure 11 shows a Be electrode polarized in 0.2M KI/DMF. The surface is covered with particles which have metallic luster. Grain boundaries on the Be surface are also visible.

Anodically disintegrated Be particles embedded in the oxide film can be clearly seen in Fig. 12, which shows a Be anode polarized in LiCl/MeOH. The oxide does not cover the surface totally.

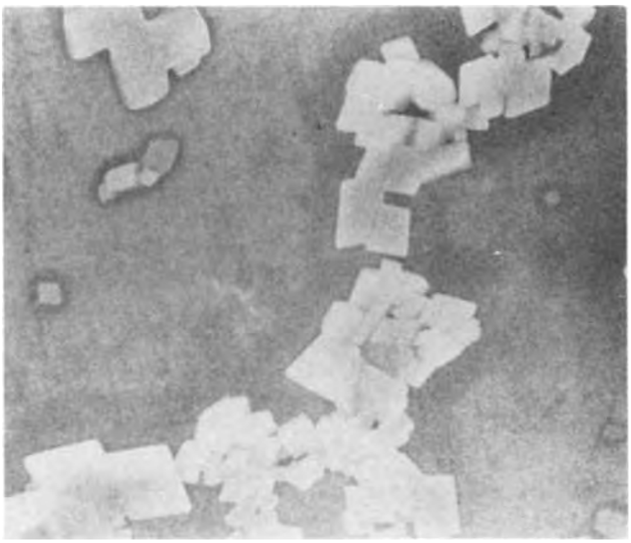

Fig. 6. Be electrode polarized in $NaNO_3$/MeOH, H_2O = 0.68%. Magnification 800X.

Fig. 7. Be electrode surface after polarization in 0.2M KCl/aq. Magnification 800X.

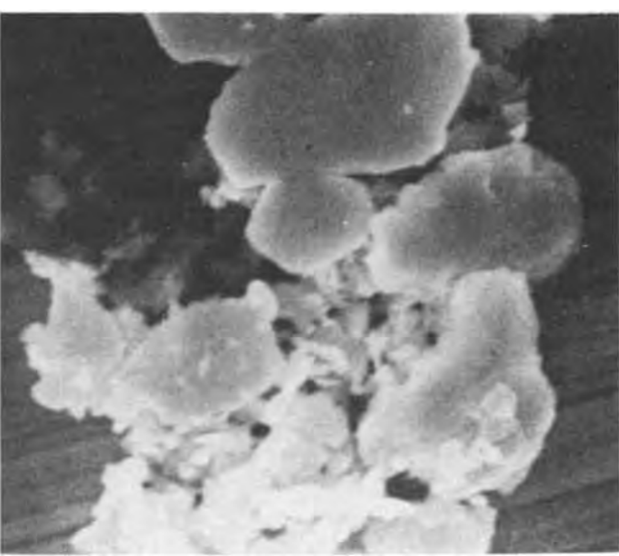

Fig. 10. Anolyte residue obtained when Be is polarized in 0.2M LiCl/MeOH, H_2O = 0.60%, V_i = 0.34. Magnification 2400X.

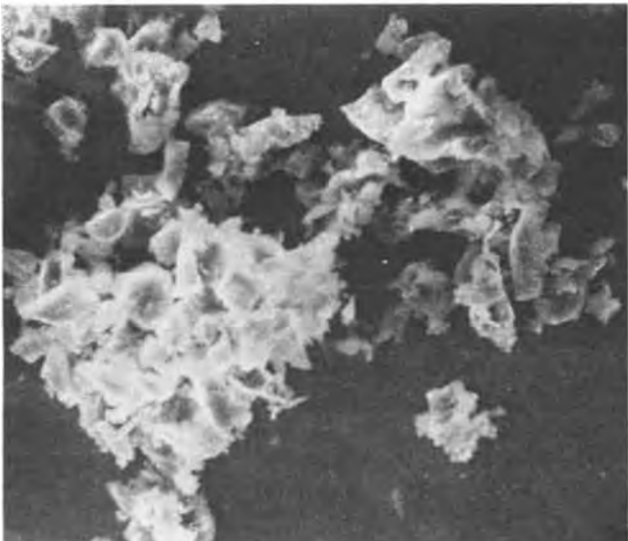

Fig. 8. Anolyte residue obtained when Be is polarized in 0.2M KCl/aq. Magnification 2400X.

Fig. 11. Be electrode surface after polarization in 0.2M KI/DMF, H_2O = 0.3%, V_i = 1.75. Magnification 800X.

Fig. 9. Be anode polarized in 0.2M $LiClO_4$/EtOH at 24.5 mA/cm^2, H_2O = 0.4%, V_i = 1.00. Magnification 2400×.

Fig. 12. Be anode polarized in 0.2M LiCl/MeOH, V_i = 0.34, H_2O = 0.61%. Magnification 2400×.

Large black holes very often occur on the surface. These are not etch pits. They probably arise as a result of detachment of metallic Be leaving a cavity.

Discussion

The experimental values for the valency of Be (Tables I and II) are interpreted by some as evidence for the formation and existence of both Be(I) and Be(II) in solution (10). One indication of the possible formation of Be(I) is the increased current efficiency for the process as well as the difference between the first and second ionization potentials (11). However, the concept of monovalent ions cannot account for the formation of Be particles in the anolyte unless a disproportionation reaction like

$$2Be(I) \rightarrow Be(II) + Be \quad [3]$$

is postulated (10, 12, 13). The source of Be particles, however, in the anolyte has been established clearly as arising from spalling of the electrode as evidenced by the presence of deformation twins on the anode as well as in the anolyte residue (7, 14). In nonaqueous solutions such as methyl alcohol, ethyl alcohol, and dimethyl formamide, the existence of Be^{+} is favored since reaction [2] is believed to take place at a negligible rate. Reaction [2] cannot be totally eliminated since a water content of zero was never obtained at the end of an experiment. If a disproportionation of the type shown in reaction [3] occurs at all, its probability may be the same in aqueous as well as in nonaqueous solution. However, the existence of a long-lived Be^{+}, even in nonaqueous electrolytes, is questionable due to the following facts:

1. Effective valency (V_i) as a rule should increase with increase of anodic potential and attain the normal value (V) 2.0 (15). Indium and In(Hg) show such behavior and the existence of In^{+} under certain conditions is accepted (6) and in certain others not (16). In the case of Be, however, the valency value levels off at 1.0 at high anodic currents and a value of 2.0 is never obtained.

2. If Be^{+} ions are formed at greater rates than they are consumed by reactions [1] or [3] (considering reactions in nonaqueous solutions), they should diffuse into the bulk of the electrolyte. Thus detection of the univalent ion by polarography and/or ESR should be possible as is the case of Bi (15) by the former method. In the present study the cyclic voltammograms obtained for Be in LiCl/MeOH and $NaNO_3$/MeOH do not show peaks corresponding to two oxidation states (Fig. 4).

3. An apparent valency of less than 1.0, *e.g.*, 0.34 obtained for Be in LiCl/MeOH in this study and 0.27 for Mg in NaI/pyridine-nitrobenzene (17), can be explained only by assuming a predominant influence of anodic disintegration and/or local corrosion. In no way can the unusual valency or transitory ion concept account for valences less than unity.

4. The anions seem to have a greater effect on V_i than the medium H_2O, EtOH, MeOH, or DMF. The Cl^{-} ions produce a lower value for V_i in both H_2O and MeOH (Tables I and II). The I^{-} ions do not yield as low a value for V_i as Cl^{-} ions and their values are comparable in H_2O and DMF. In aqueous solutions a small anion, *e.g.*, Cl^{-}, results in a greater lowering of V_i than does a large anion, SO_4^{-2}, PO_4^{-3}, etc. (18). This trend is maintained also in alcoholic solutions: Cl^{-} results in a much lower V_i, 0.34 compared to 1.0 for ClO_4^{-}. The extent of deviation from $V = 2$, approximately corresponds to the degree of disintegration, the lower the V_i the greater the extent of disintegration. Then, the anion effect during disintegration in increasing order is: I^{-}(DMF), I^{-}/aq, ClO_4^{-}/EtOH, Cl^{-}/aq, Cl^{-}/MeOH. Experimental values (Table III) for the rate of Be dissolution increase in the order of NO_3^{-}/MeOH $<$ NO_3^{-}/aq $<$ I^{-}/DMF $<$ Cl^{-}/MeOH $<$ Cl^{-}/aq. This gradation in the reactivity of anions for anodic dissolution and disintegration follows the same order as the aggressiveness of the said anions in rupturing a protective film. The comparative effect of various anions on V_i has been discussed earlier (18). It has been postulated (10) that a total elimination of water from the electrolysis system can stabilize Be(I) thus accounting for values of V_i close to unity. The results described above show that $V_i \sim 1.0$ can be obtained even in aqueous solutions where Be(I) is supposedly unstable, by choosing the proper anion and C.D. Furthermore, in a nonaqueous media, where Be(I) is believed to be more stable, an anion like I^{-} gives rise to a V_i close to two (Table II).

It is clear from the potential-current profile shown in Fig. 3a and Fig. 5 that the anodic polarization of Be takes place in three stages in $NaNO_3$(aq) and KI/DMF. Transition regions in the polarization curve of a metal are generally noticed in active-passive transitions and electropolishing As is evident from the curves, Be does not show active-passive behavior under the present experimental conditions. The *i-E* curve does not show the kind of polarization stages-anodic dissolution region at low overvoltages followed by a limiting current region at intermediate overvoltages and an O_2 evolution region at high overvoltages corresponding to electropolishing. This is further substantiated by visual observation of the polarized electrodes which did not show any polishing effect. The transition point 0.28V, apparently indicates a change in the mechanism of dissolution of Be. Beryllium dissolution may occur with the participation of NO_3^{-} ion up to 0.28V, a type of reaction we proposed earlier for Zn (19), and beyond 0.28V with formation of an oxide or hydroxylated species of Be. Normally such oxide formations lead to a passive region in the *i-E* curve. This is not the case with Be, since Be salt solutions are known to dissolve several molecules of oxide or hydroxide per mole of Be ion present in aqueous solutions (20). The transition point at 0.98 may denote the mass transfer effects in oxide formation.

The passivation of Be is accomplished more easily in NO_3^{-}/MeOH. The electrode turns black and loses its conduction as a result of a porous oxide film formation. A microstructural study using SEM (Fig. 6) reveals particles of Be embedded in this film. This observation of anodically disintegrated metallic particles has some parallelism to the occurrence of Zn and Mg particles in the passive film on a Zn or Mg anode (19, 21, 22).

Breaks in the *i-E* curves for Be in $LiClO_4$/EtOH have been reported by Aida *et al.* (23). They observed a change in the slope at 1.0V *vs.* Ag/Ag^{+} (0.2M) and associated it with the border separating the potential range within which $V_i = 1$ and the surface is bright from the range within which V_i differs from unity and the surface is rough due to spalling and/or local corrosion. Such a view is tantamount to stating that the *i-E* curve can be divided into regions where anodic disintegration occurs and where it does not occur. This is not the case as proved by our experimental observation of spalling at all potentials. Local corrosion, faradaic dissolution, and anodic disintegration occur simultaneously for Be and an assessment of the degree of each process cannot be made from *i-E* curves.

Data in Table III illustrate the decrease in the rate of Be dissolution when NO_3^{-} ions are present in aqueous and nonaqueous media. For the same concentration of NO_3^{-} and Cl^{-}, the rate is much lower in MeOH than in water at all potentials. Thus water molecules do not seem to have a predominant influence in the formation of a passive film on the metallic surface. This is in contrast to the behavior of Ti in MeOH/HCl (24) but similar to Fe and Cu in MeOH/H_2SO_4 (25).

Another aspect of the *i-E* behavior (Fig. 2-5) is that the current values are different for the anodic and cathodic sweeps. Such a behavior is very common for metals like Pt, Pb, etc. (26, 27), and could be due to a mass transfer effect, a film formation reaction or

due to two different types of films, an adsorbed oxide or a hydroxylated species. Repetitive potential scans between −0.62 to 1.56V in NO_3^-/aq (Fig. 2) lead to deactivation of the electrode due to film growth. Repetitive cycling in KCl/aq has no deactivation effect, instead there is a slight acceleration effect (Fig. 2 and Table IV). Repetitive cycling is known to bring about changes in the electrode surface structure leading to greater reactivity (28, 29). In the present case, the slight increase in C.D.'s may be due to removal of electro-oxidative impurities from the surface or to an area effect as a result of disintegration.

Anodic disintegration has been associated at times with a grain boundary type of attack (10, 30). However, in the case of Be this is ruled out on the basis of previous studies using Be single crystals which showed spalling (31). It is also proposed (10) that a uniform and homogeneous dissolution occurs whenever the measured valency is 1.0 and Be(I) formation is favored. This is disputable since the nature of the attack and the appearance of the Be surface depend more on the nature and concentration of the anions than on the measured valency. For example, when Be is polarized in NO_3^-/H_2O or NO_3^-/MeOH, a smooth black surface is obtained. The black coloration is unmistakably due to the presence of minute Be particles. On repolishing it is found that the region underneath has been severely pitted in the case of NO_3^-/MeOH and NO_3^-/aq. In KI/DMF the spalling is not as great as in KCl/aq (compare the valency of 1.75 in DMF to 1.07 in KCl/aq). The surface is not as severely attacked though curiously grain boundaries are still visible. In both cases aggregates of Be particles sticking to the surface can be seen in a microscope (see Fig. 8 and 11). The nature and type of attack of a Be electrode and the appearance of its surface have been reported for various electrolytes (18).

In summary, the results of this study provide direct evidence (optical) for the existence of anodic disintegration during polarization of Be in aqueous and nonaqueous media in accord with Aida *et al.* (10). Cyclic voltammograms obtained for Be in LiCl/MeOH and $NaNO_3$/MeOH do not show peaks corresponding to two oxidation states, although this observation does not rule out the presence of a short-lived univalent ion. Nevertheless while the findings of our study provide no direct evidence for or against the univalent ion mechanism, the apparent valency of less than one obtained for anodic polarization of Be in LiCl/MeOH and the accompanying spalling of the electrode rule out the univalent ion concept in this instance. The work of Aida *et al.* (23) wherein specific potential regions are attributed to the occurrence of disintegration is not borne out by our experimental studies of *i-E* behavior as we observe disintegration at all potentials. Furthermore the variation of valency with potential and the nonattainment of the normal value of two at any potential or C.D. can only underscore our contention that the assumption of the transient univalent state in postulating a mechanism for the anodic dissolution of Be is superfluous.

Some Aspects of Gas Recombination in Lead-Acid Systems

B. K. Mahato,* E. Y. Weissman,* and E. C. Laird*

Globe-Union Inc., Corporate Applied Research Group, Milwaukee, Wisconsin 53201

ABSTRACT

It is shown that in a structurally controlled lead-acid cell the electrodes, in addition to their electrochemical function, also provide evolved gas recombination sites. The reaction kinetics and the transport properties in the acid electrolyte solution are making the process possible at practical rates. Typical recombination rates for oxygen are of the order of 15 mA/cm^2 (C/10). For hydrogen, the observed starting rate of recombination exceeds self-discharge evolution in a lead-calcium system by a factor of at least 30. A review of various operational characteristics is given including half-cell potentials, cell voltages, internal pressures, and hydrogen partial pressures.

Although hermetically sealed alkaline battery systems, such as the nickel-oxide-cadmium variety, have been studied and used extensively (1, 2), the same does not hold true for lead-acid batteries. The literature (mostly patents) deals with a variety of approaches: catalytic recombination of evolved hydrogen and oxygen inside the battery or external to it; oxygen, voltage, or pressure sensors used as overcharge limiting devices; hydrogen permeable materials for the battery case; "third electrodes" for oxygen recombination; bifunctional electrodes used as electrochemical and gas recombination components. It is this last approach which forms the subject of the present paper.

From a thermodynamic standpoint, the internal recombination of battery evolved gases is possible (3). In a lead-acid battery, oxygen could be reduced at the lead electrode and hydrogen oxidized at the lead dioxide electrode. From a rate standpoint, the chemical affinity of oxygen for lead in the presence of moisture is well known (4) while the reactivity of hydrogen with lead dioxide has been considered to be of no consequence.

Structural factors will play an important role, particularly: the state of charge of the electrodes and the nature of the electrode-electrolyte solution and gas-electrolyte solution interfaces. If the recombination rate, primarily of oxygen, is diffusion-limited in the liquid phase, which is very likely, the amount of active nonflooded lead sites will play a determining role in the process. An initial study was reported in this general area, dealing with partially exposed and electrochemically active lead electrodes (5), but otherwise there is no significant literature on the subject.

One notes that, compared to the alkaline KOH systems, the lead-acid battery is at an advantage from the standpoint of the pertinent transport properties. Table I summarizes some solubility and liquid diffusivity data of interest.

On the other hand, there is a fundamental difference between the operation of an alkaline and a lead-acid battery and it affects their performance as sealed systems. In an alkaline system such as the sealed nickel oxide-cadmium battery the aqueous KOH electrolyte is essentially an ion transfer medium, whereas in the lead-acid battery sulfuric acid participates directly in the anode and cathode reactions. In the latter case the minimum amount of electrolyte required for adequate operation, usually results in flooded electrodes, *i.e.*, a system exhibiting high resistance to any kind of dissolved oxygen transfer step. Furthermore, hydrogen is spontaneously evolved in the lead-acid battery, even at open-circuit conditions, and hydrogen and oxygen are evolved during charge and overcharge in nonstoichiometric ratios determined by the design characteristics of the system. This, in turn, makes the use of recombination catalysts (8) and auxiliary recombination electrodes (9) less than effective with the added disadvantage, in the case of catalyst use, of lead electrode contamination followed by increased self-discharge and hydrogen evolution.

Development of an Internal Recombination Lead-Acid System

If the reactivity of lead with oxygen and, to a certain extent, of lead dioxide with hydrogen could be effectively put to use, a reliable and economic sealed lead-acid battery would result. The use of a high hydrogen overvoltage system such as electrodes with lead-calcium current collectors is, of course, a step in the right direction. If the oxygen recombination cycle can be made to prevail in such a battery, the only hydrogen recombination capacity required would be that corresponding to the existing rates of lead electrode self-discharge.

Figure 1 is a schematic representation of the oxygen cycle in a lead-acid battery. The cycle is symbolized in the upper right-hand corner while the rest of the figure is a more detailed representation where each of the chemical species involved in the process appears as both a source and a sink at steady state. We note that, under these conditions, the lead dioxide electrode is fully charged and evolving oxygen. The lead electrode, on the other hand, is at a constant state of partial discharge below the operating potential corresponding to significant hydrogen evolution.

Experimental

In order to evaluate the internal gas recombination capability of a hermetically sealed lead-acid system, use was made of a leak-proof pressure chamber (Fig. 2) containing a variety of test cells. Some hermetically

sealed test cells were subsequently evaluated outside the pressure chamber. The chamber was equipped with pressure and voltage sensors and had ports for gas insertion or evacuation and sampling.

The test cells were normally prepared from selected dry-charged electrodes utilizing lead-calcium grids. Dimensions were generally 3.5 × 3.0 × 0.10 cm for the lead electrodes and 3.5 × 3.0 × 0.15 cm for the lead dioxide electrodes and the total amounts of corresponding lead and lead dioxide active material were roughly equal. The electrolyte was approximately 37 w/o (weight per cent) sulfuric acid containing 22 g/liter of 85 w/o phosphoric acid, and it was maintained in an immobilized state by additions of silica gel or by containment in a porous matrix. In the latter case the matrix was electrolyte-saturated to the extent of 85-90% as determined by established procedures (10) and the electrodes were covered with a liquid film having a calculated average thickness of approximately 10μ. In all cases the cell capacity was electrolyte-limited.

Pressure measurements were carried out with a compound pressure gauge having an accuracy of ± 0.2 psi or ± 0.2 in. Hg (for vacuum measurements). The pressure gauge was also used for control of the initial cell activation procedure which consisted of creating a reserve of partially discharged lead electrodes by the introduction of predetermined amounts of oxygen.

A precision differential manometer, having an accuracy of ± 0.05 mm Hg, was used for determining the hydrogen oxidation capacity of the system. For that purpose, the test cell-containing chamber was evacuated and then filled with hydrogen at 1 atm absolute. Pressure changes, corresponding to hydrogen consumption at the partially wet lead dioxide electrodes, were then monitored and corrected for changes in the ambient conditions and for hydrogen permeation losses by comparison with a control pressure chamber not containing electrode elements.

Gas analyses were carried out with an F&M Research Chromatograph and half-cell potential measurements were taken with a Keithley Electrometer No. 610C with respect to a Hg/Hg_2SO_4 reference electrode.

Results and Discussion

Oxygen recombination.—The internal oxygen recombination in a fully charged cell, as reflected in the corresponding pressure *vs.* time decay curve, is represented in Fig. 3. The initial recombination rate derived therefrom is about 3 cm^3 (STP)/hr/cm^2 of geometric lead electrode area. This is equivalent to a current density of 15 mA/cm^2 which corresponded to approximately 11 times the 20-hr (overcharge) rate for the test cell under evaluation.

Half-cell potential characteristics are represented in Fig. 4 as a function of the extent of charge and discharge, with the rate of charge or discharge as the parameter. So long as the rate is not high enough to cause gas evolution on overcharge also at the lead electrodes, a steady negative potential is achievable. In the particular case under examination the highest tolerable current is somewhere between the 5- and the 10-hr rate.

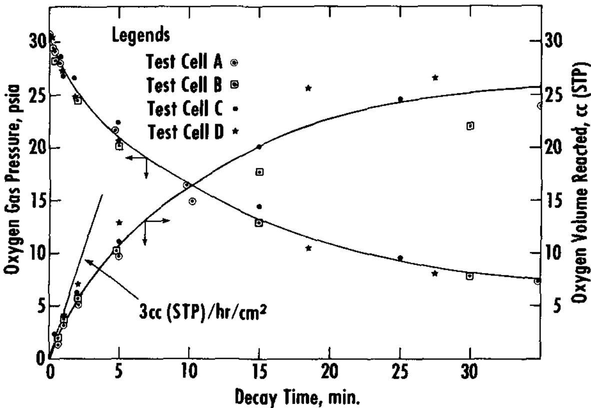

Fig. 3. Oxygen recombination in a hermetically sealed lead-acid cell.

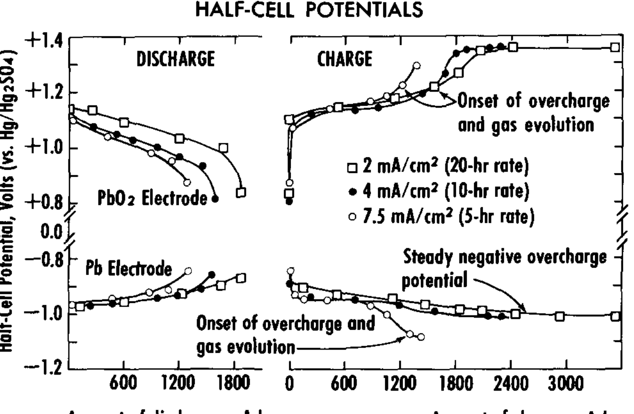

Fig. 4. Half-cell potentials in a hermetically sealed lead-acid cell operating in an oxygen recombination mode.

Hydrogen recombination.—Figure 5 is a representation of internal hydrogen recombination, or hydrogen pressure decay, as a function of time compared to a nonrecombining control test unit. The starting recombination rate amounts in this case to 1.74×10^{-2} cm^3 of H_2 (STP)/hr/cm^2 of lead dioxide electrode geometric area. For the test cell under evaluation this corresponds to approximately 30 times the measured self-discharge rate.

Generally speaking, hydrogen recombination in a sealed storage battery has been of limited practical significance. It proceeds to a negligible extent in alkaline systems, such as the nickel oxide-cadmium battery (1, 11), but should do better in the lead-acid system owing to the higher equilibrium hydrogen concentration in the liquid phase (Table I). Hydrogen oxidation in a lead-acid cell has previously been reported as insignificant (12) but the cases under study apparently involved only flooded lead dioxide electrodes where the liquid phase hydrogen diffusion path would be impractically long.

The exponential shape of the gas recombination curves (Fig. 3 and 5) suggests the possibility of active site inhibition by sulfate ion adsorption (12). Looking at the hydrogen data in particular, the measured oxidation rate would seem to be adequate to handle limited self-discharge in a system such as one using lead-calcium alloys for the grids. Operation based on a hydrogen cycle remains, for the time being, out of the question though it would be interesting to determine the nature of the hydrogen oxidation mechanism (*e.g.*, active oxygen in the PbO_{2-x} structure).

Another way to demonstrate the capacity for limited hydrogen recombination is presented in Fig. 6 where the test cell is compared with a hermetically sealed commercial unit of similar size and structure but operating in a "conventional" mode, *i.e.*, with a higher degree of electrode flooding (the electrolyte is of a paste-type consistency owing to SiO_2 additions).

Operational results: cycling and extensive overcharge.—Figure 7 represents the internal pressure characteristics and hydrogen concentration in the gas space of test units during initial cycling. Gradual attainment of practical steady-state operating conditions is apparent. The effect of overcharge and the subsequent equilibration as the oxygen cycle takes effect are graphically represented in Fig. 8 for two different operation modes. It is to be noted that the 8-hr "discharge" period indicated in the figure always includes a certain time interval of open-circuit stand following attainment of the 1.7V cut-off point. As the system ages the open-circuit intervals become progressively longer.

At the onset of overcharge the lead dioxide electrode attains a constant oxygen evolution potential. Thus the cell voltage excursions measured in this case are representative of changes occurring at the lead electrode. The cathodic shift is probably indicative of adsorbed hydrogen film formation preceding the conditions for hydrogen evolution. The subsequent anodic shift would seem to represent the depolarizing action, probably at least partially electrochemical in nature

(5, 9), of the reacting oxygen. Since these voltage excursions are not accompanied by noticeable changes in internal cell pressure it would appear that the net effects of hydrogen generation and subsequent oxidation are relatively insignificant at the rates of charge used.

Steady state at practical equilibrium pressures is also possible under conditions of continuous constant current overcharge applied over long periods of time. This is evident in Fig. 9 and 10, at various equilibrium cell voltages as a function of the charge rate. The equilibrium pressures and voltages depend on such internal structure parameters as the lead plate morphology, the electrolyte soaked separator-matrix assembly and its interface with the plates. No direct relationship between the steady-state pressure and the overcharge rate is evident. Indeed, at 5 mA a higher pressure has been measured than at 25 mA.

Conclusions

The use of a bifunctional lead electrode in a hermetically sealed lead-acid battery operating in an oxygen cycle mode appears to be possible. The maintaining of a controlled electrode-electrolyte solution interface and a careful selection of the structural parameters are yielding practical oxygen recombination rates. Limited hydrogen recombination at the lead dioxide electrode, at least to the extent required by the self-discharge characteristics of a battery using lead-calcium alloy grids, also appears feasible.

Work in this area is needed for a thorough definition of the structure-dependent rate-limiting steps for both oxygen and hydrogen recombination. An understanding of the chemical and electrochemical mechanisms responsible for the observed behavior of the gas-tight lead-acid system at steady state (*e.g.*, active oxygen sites, sulfate ion inhibition) is a desirable long-range objective.

Oxidation of Silver Electrodes in CsOH Solutions

Charles P. Wales*

Electrochemistry Branch, Naval Research Laboratory, Washington, D. C. 20375

ABSTRACT

Sintered Ag electrodes were cycled under several conditions in aqueous CsOH or KOH solutions. Over a wide range of charge rates the capacity accepted at the Ag/Ag_2O potential plateau increased as electrolyte concentration decreased, but charge acceptance at the Ag_2O/AgO plateau increased as concentration increased and was larger in CsOH than in KOH. Polarization was greater in CsOH than in KOH of the same concentration. Cross sections through electrodes were examined by optical microscopy. The structures that formed in CsOH tended to be similar to those that formed in a more concentrated KOH. After several cycles the average Ag particle size became larger in KOH than was typical in CsOH. Results indicated that concentration gradients were higher in CsOH.

The charge and discharge reactions are well known for the Ag electrode in alkaline solutions. First, Ag is oxidized to Ag_2O and then to AgO during charge. The opposite reactions take place during discharge. The work reported in the literature has been done most often in aqueous KOH solutions and less often in NaOH solutions. The products of charge and discharge are the same in both electrolytes. Nevertheless, electrolyte concentration has a definite effect on the characteristics of Ag electrodes (1-5).

Variations between results in different KOH concentrations may be effects of changes in ionic mobility or in the amount of free water. Dirkse has pointed out the importance of the mobility of OH^- ions and of hydration of the various ions in the electrolyte (2). Comparison of results in different KOH concentrations can indicate the influence of water concentration.

Another factor that may have an influence on the characteristics of Ag electrodes is the particular alkaline metal cation involved. The cation can have a noticeable effect even though it does not enter into an electrode reaction. For example, the capacity obtained when sheet Zn was oxidized in KOH was a little larger than in CsOH or RbOH, an effect probably related to solubility of Zn oxidation products (6).

The use of CsOH instead of KOH should indicate if the cation of the electrolyte has a strong effect on the Ag electrode. The atomic weight of Cs is 3.4 times that of K. CsOH and KOH solutions having the same molar concentration of cation will contain different amounts of water. The ionic radius of Cs (as measured in crystals) is about 1.26 times as large as K, but hydration of the ions decreases this size difference. A recent review points out the considerable disagreement among various workers as to the actual solvation numbers of most ions (7). It seems reasonable, however, to consider the ionic radius of hydrated Cs to be approximately 1.19 times as large as hydrated K. Thus, it is of interest to determine some of the characteristics of Ag electrodes in aqueous CsOH solutions because results may differ significantly from those obtained in KOH solutions of the same concentration. A better understanding of the behavior of Ag electrodes in alkaline solutions can result in improvements in high energy batteries that use this electrode.

Experimental

Electrolyte.—The aqueous CsOH solutions contained OH^- ion concentrations of about 8.4 and 3.6M. This gave solutions that were 61 and 36.6% CsOH by weight. The value 8.4M was chosen for comparison with earlier work in 8.4M (35%) KOH. Spectroscopy of the stock CsOH solution indicated that concentration of the main impurity, Rb^+, was on the order of ten times that of Na^+ or K^+. Concentrations of Rb^+, OH^-, and CO_3^{2-} were determined by chemical analysis. Table I gives the results calculated for the two CsOH solutions and includes the magnitude of Na^+, K^+, and Li^+ as estimated by spectroscopy.

Cells.—Average dimensions of the sintered Ag electrodes were 43.7 ± 0.1 mm wide, 36.0 ± 0.1 mm high, and 0.87 ± 0.01 mm thick. Electrodes contained a grid of expanded sheet Ag. The average weight of sintered Ag in an electrode corresponded to a theoretical capacity of 2.8 A-hr. Electrodes could be removed from the cell in order to cut samples for microscopic examination. Two other sintered Ag electrodes were placed on each side of a test electrode, and served as counterelectrodes. All three electrodes were wrapped with five layers of separator material. Two of the test electrodes that were cycled in CsOH used a cellulosic separator, while the other 12 in CsOH and all electrodes in KOH used a cross-linked polyethylene. Results for the two separators are combined, because electrode characteristics did not differ. Counterelectrodes had the same separator material as the test electrodes. Cells contained an excess of electrolyte. Electrode potentials were measured with respect to a Ag/Ag_2O reference electrode.

Cycling procedure.—Test electrodes were charged (anodic oxidation) at constant current until oxygen evolution occurred. Except where otherwise stated, charge rates were chosen so that a complete charge of a test electrode required 20 hr. Some electrodes were always discharged (reduced) using the 20-hr rate of constant current, and others were always discharged at the 1-hr rate. Discharges at the 20-hr rate were ended when potential reached −300 mV *vs.* the reference electrode. This potential was about 250 mV below the observed Ag/Ag_2O potential plateau during discharge. Discharges at the 1-hr rate took place at a lower potential and were usually continued until potential dropped 200 mV below the observed Ag/Ag_2O potential plateau. (Results obtained during reduction of charged electrodes will be reported in a separate paper.) Temperature was 24° ± 1°C. Samples were

Key words: silver oxides, electrolyte, electrode structure, anodization.

cut from most of the electrodes and were prepared for optical microscopic examination as described earlier (8).

When the effect of charge rate was being studied, a new electrode was first given about five charge-discharge cycles at the 20-hr charge rate, until electrode capacity became steady. After these initial cycles an electrode was charged at another rate for three cycles, with each group of three cycles followed by two to four cycles at the 20-hr charge rate to check for shifts in capacity. The 20-hr discharge rate was always used when the effect of charge rate was being studied.

Results

Effect of charge rate on capacity.—Charge acceptance of the Ag electrodes decreased as charge current increased. The capacity of slow discharges was a good measure of charge acceptance. Charge current and capacity are plotted on relative scales in Fig. 1 taking the 20-hr rate as the standard. Relative scales are preferable to actual current and capacity because the actual current that required a particular length of time for a complete charge varied from electrode to electrode, and changed as an electrode was cycled or when a sample was cut from the electrodes.

The relationship between capacity and charge current was linear on a log-log scale for Ag electrodes in KOH solutions over the current range studied (bottom of Fig. 1). The line for 8.4M KOH is also given on the top section of Fig. 1 for comparison with results in CsOH. A linear relationship was only observed at the higher current densities in CsOH solutions. Individual measured values in 8.4M CsOH had no more than a 3% average deviation from the points shown in Fig. 1, but values in 3.6M CsOH varied by about 10%.

Effect of charge rate on electrode potentials.—Potentials of the Ag electrodes during charges at three rates are given in Fig. 2. The charges lasting approximately 0.8, 4, and 43 hr were done at currents given in Fig. 1 as 16, 4, and 0.5 times the 20-hr rate, respectively. All potentials reported in this paper are given with respect to the Ag/Ag_2O reference electrode in the same electrolyte as the test electrodes.

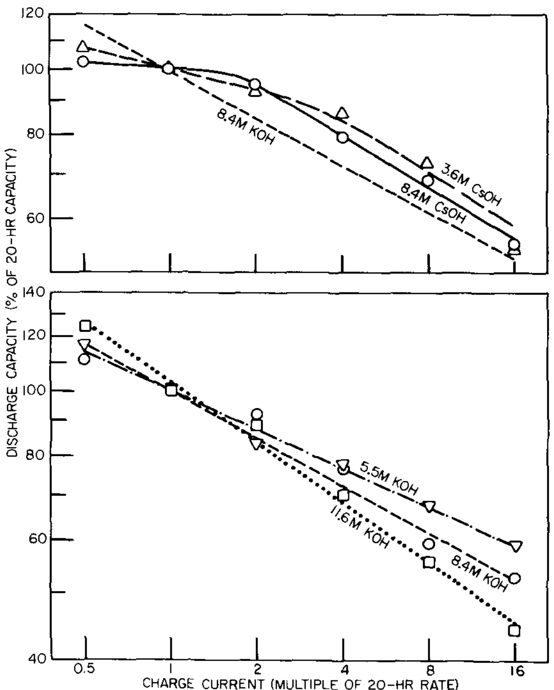

Fig. 1. Log-log relationship between charge current and discharge capacity. Each point is the average of at least three charge-discharge cycles. Straight lines for KOH were fitted by the least squares method.

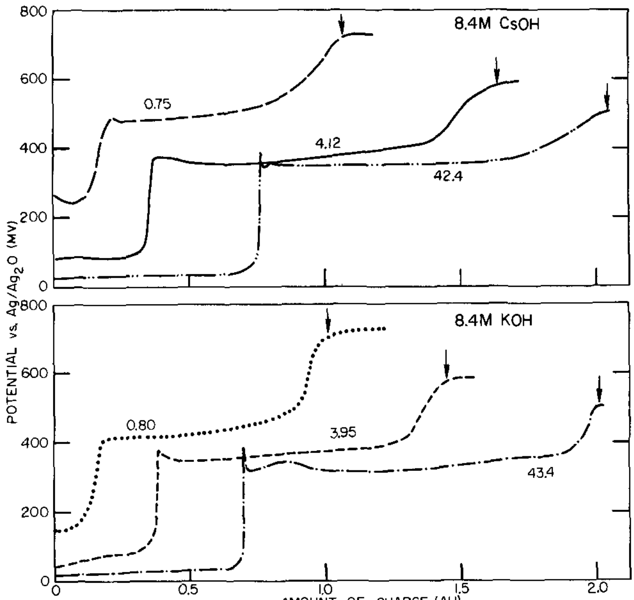

Fig. 2. Charge potentials at various rates of current. Numbers on curves give length of charge in hours. Arrows indicate capacity of following discharge, which was done at the 20-hr rate.

Effect of charge rate on charge acceptance at Ag/Ag_2O potential.—Silver is oxidized to Ag_2O during the first part of a charge, before potential becomes sufficiently high that AgO can also form. It can be seen in Fig. 2 that the first potential plateau shortened as charge time decreased; that is, as current density increased. In addition, this initial potential plateau constituted a smaller proportion of the total charge at the higher current densities. The proportion of a charge that took place at this Ag/Ag_2O potential plateau decreased linearly as log of charge current increased over the range of currents studied (Fig. 3). The line fitted to the points in 8.4M KOH in the lower section of Fig. 3 is repeated in the upper section for ease in comparing KOH with CsOH. Although both Fig. 1 and 3 show linear relationships, note that discharge capacity is plotted on a log scale (Fig. 1) but proportion of charge at the Ag/Ag_2O level is on a linear scale (Fig. 3).

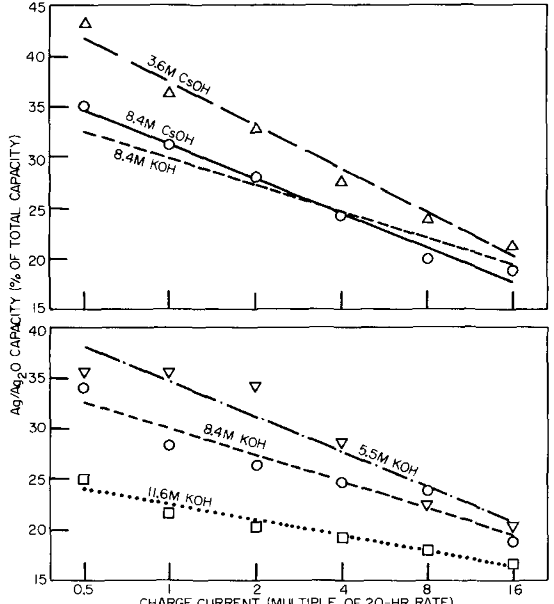

Fig. 3. Dependence of charge acceptance at Ag/Ag_2O potential plateau on the log of charge current. These straight lines were fitted by the least squares method.

Effect of discharge rate on charge potentials.—During the first charge at the 20-hr rate a new sintered Ag electrode always accepted more capacity in 3.6M CsOH solution than in 8.4M CsOH. Charge acceptance of new electrodes at cycle 1 ranged from 2.45 to 2.53 A-hr for four electrodes in 3.6M CsOH, and from 2.10 to 2.44 A-hr for nine electrodes in 8.4M CsOH. Figure 4 includes potentials for the first charges of four previously unused sintered Ag electrodes.

The rate of discharge (reduction) had a strong effect on capacity and on potentials of the following charge. Discharge capacities at the 20-hr discharge rate (arrows in upper section of Fig. 4) were equal to capacity given an electrode up to the point that charge potential became sufficiently high that oxygen evolution occurred. Discharge capacity was smaller at cycle 1 when Ag electrodes were discharged at the 1-hr rate (lower section of Fig. 4). Cycle 1 discharge at the 1-hr rate delivered only 85-90% of the capacity given to an electrode during the charge. Close to 100% capacity was obtained from subsequent cycles at the 1-hr rate.

Potential of the Ag/Ag_2O charge plateau was not affected by the particular electrolyte used. Potential of the Ag_2O/AgO plateau tended to rise during the first three to five cycles. The level rose 5-10 mV when the 20-hr discharge rate had been used in 8.4M CsOH, and twice as much when the 1-hr discharge rate had been used. This plateau was usually an additional 5-20 mV higher in 3.6M CsOH than in 8.4M CsOH.

The amount of charge accepted at the Ag_2O/AgO plateau decreased during the first few cycles (Fig. 4). This decrease corresponded fairly closely to the decrease in discharge capacity between cycle 1 and 3 observed at both rates of discharge. Capacity changes became more gradual beginning about cycle 3, and charge curves at cycle 15 were close to those shown for cycle 4.

The rise to the oxygen evolution potential was more rapid in 3.6M CsOH than in 8.4M CsOH, with 8.4M KOH giving a rise intermediate between the two CsOH concentrations (Fig. 4). At the end of the first charge the potentials at the oxygen evolution plateau averaged 80 mV higher in 3.6M CsOH than in the other electrolytes. The difference between final charge potentials decreased greatly at cycle 2 and had disappeared by cycle 3 or 4.

Effect of discharge rate on charge acceptance at Ag/Ag_2O potential.—It is evident from both sections of Fig. 4 that cycle 1 charge in 8.4M CsOH gave the least charge acceptance at the first potential plateau.

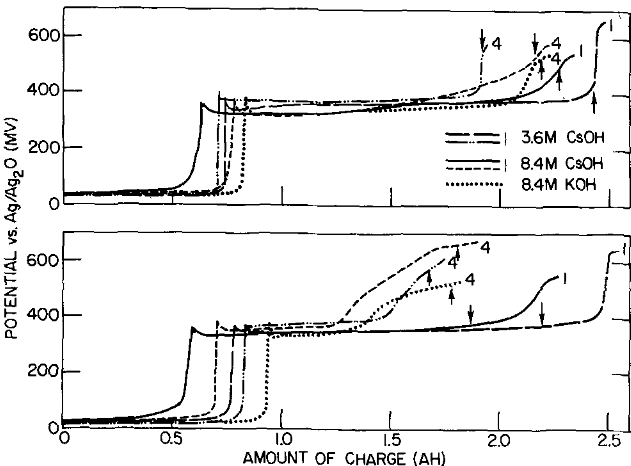

Fig. 4. Charge potentials at the 20-hr rate. Upper half of figure shows the initial charges in two CsOH concentrations, and cycle 4 charges when all discharges had been done at the 20-hr rate. Cycle number is given beside the curves. Lower half shows the results when using the 1-hr discharge rate. Typical cycle 4 charges in 8.4M KOH are included for comparison. Arrows indicate capacity of the following discharges.

The length of this Ag/Ag_2O potential plateau increased during the first few cycles (Fig. 5). For any particular Ag electrode the charge acceptance at the Ag/Ag_2O plateau fluctuated from cycle to cycle, but had the general trend shown in Fig. 5. When the 1-hr discharge rate was used, the length of the Ag/Ag_2O charge plateau was usually less following a stand of two or more days discharged than it was when recharge began a few hours after ending a discharge. Each of the curves given in Fig. 5 is a smoothed composite of measurements from two or three electrodes, except only one electrode was cycled at the 1-hr rate in 3.4M CsOH.

Structural changes during a charge.—Typical changes as Ag was oxidized can be illustrated by a series of samples taken from an electrode during cycle 6 charge in 8.4M CsOH. Figure 6 shows a sample taken from an electrode that was 19% charged, judging by capacity accepted later in the charge. All photographs in this work are of cross sections through the electrode and, therefore, show cross sections through individual particles and crystals. During a discharge at the 1-hr

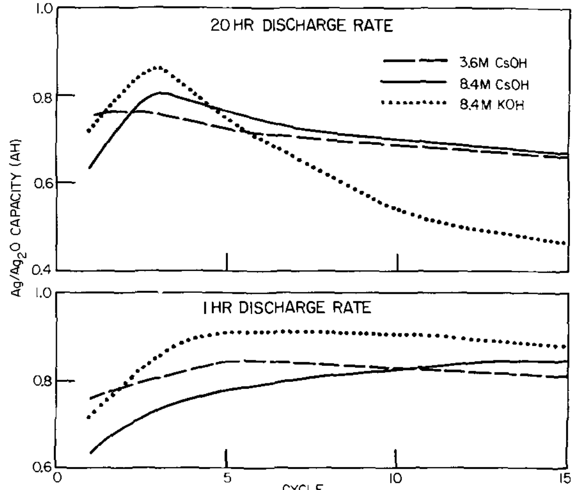

Fig. 5. Charge acceptance at the Ag/Ag_2O potential plateau. All charges were done at the 20-hr rate.

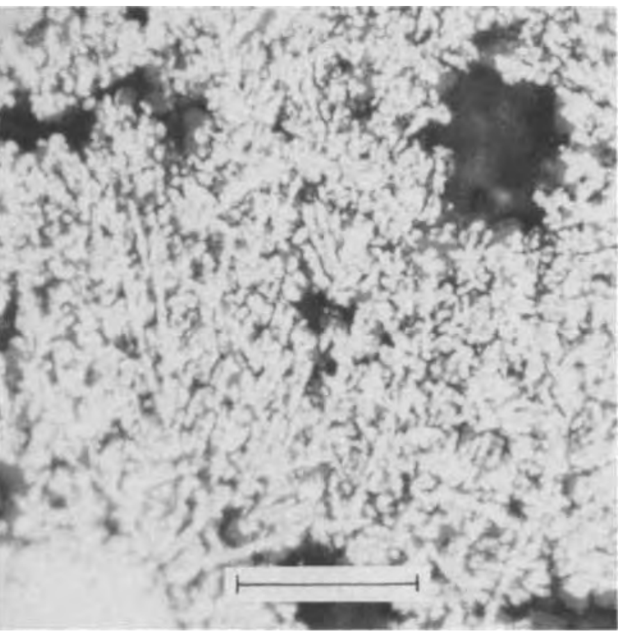

Fig. 6. Silver electrode charged halfway across the Ag/Ag_2O potential plateau at cycle 6 in 8.4M CsOH. In this cross section metallic Ag is white, Ag_2O that formed during the charge is gray, and empty areas (formerly filled with electrolyte) are black. Charge was done at the 20-hr rate. All previous discharges were done at the 1-hr rate. Marker indicates 15 μm.

rate, Ag formed as small particles, often with dendritic shapes and sometimes with planar components. When these flat or planar components were cut by a cross section they looked like skeleton crystals, or like partially oriented needles. Oxidation of the electrode shown in Fig. 6 had not proceeded far enough to obscure the linear shapes of the Ag particles. Another common form of Ag was nonoriented granular particles. The interior of an electrode tended to have more Ag_2O present than had formed near the surface of an electrode.

A sample was also taken from this electrode when potential rose to the peak that separates the Ag/Ag_2O plateau from the Ag_2O/AgO plateau (Fig. 7). At this point the electrode was 38% charged. Comparison of Fig. 6 to Fig. 7 shows that Ag particles had become much smaller. Particles that appeared linear were rare in electrodes charged to the end of the Ag/Ag_2O potential plateau, but suggestions of these particles remained if one looked carfully. In some places the region near the surface of the electrode still had less Ag_2O than the rest of the electrode.

The electrode surface had an off-white color when charged as in Fig. 6, indicating Ag with small amounts of Ag_2O. When the electrode was charged to the end of the Ag/Ag_2O potential plateau the surface color was irregular shades of light gray, indicating Ag with varying amounts of Ag_2O. The outline of the expanded Ag grid showed as black (Ag_2O) at the electrode surface closest to the grid, with only a few signs of the grid visible at the other surface.

An additional sample was cut from this electrode after the charge was 49% complete. Clumps of AgO crystals had formed at many sites (Fig. 8). These AgO sites were usually located within 1 or 2 mm of the grid. Formation of AgO had also taken place near most of the large Ag particles that were present in the active material. Very little AgO had formed near the surface of the electrode. The appearance of the external surface of the electrode had not changed since the potential peak.

The clumps of AgO crystals grew in size as adjacent Ag_2O and small Ag particles were oxidized to AgO. Small Ag particles were much rarer in the AgO clumps than in Ag_2O (Fig. 8). In areas of this sample where AgO had not formed the structure was unchanged from that at the potential peak (Fig 7). This indicated that

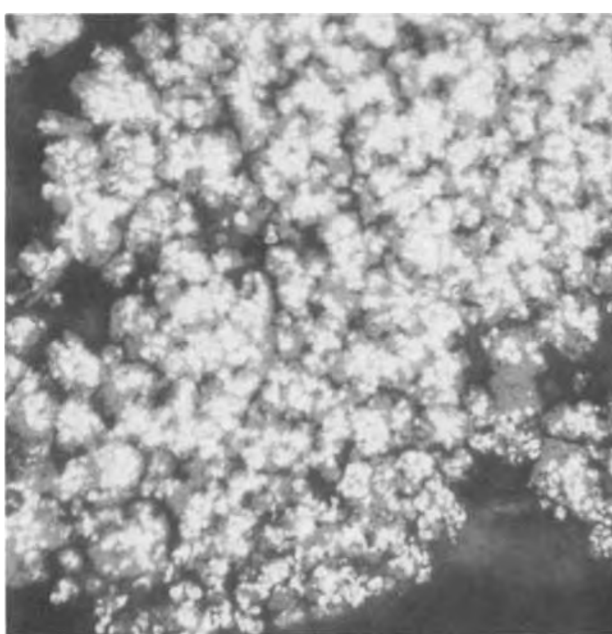

Fig. 7. Another area of the electrode shown in Fig. 6 after being charged until potential rose at the end of the Ag/Ag_2O potential plateau. Both Ag and Ag_2O were present. Same magnification as Fig. 6.

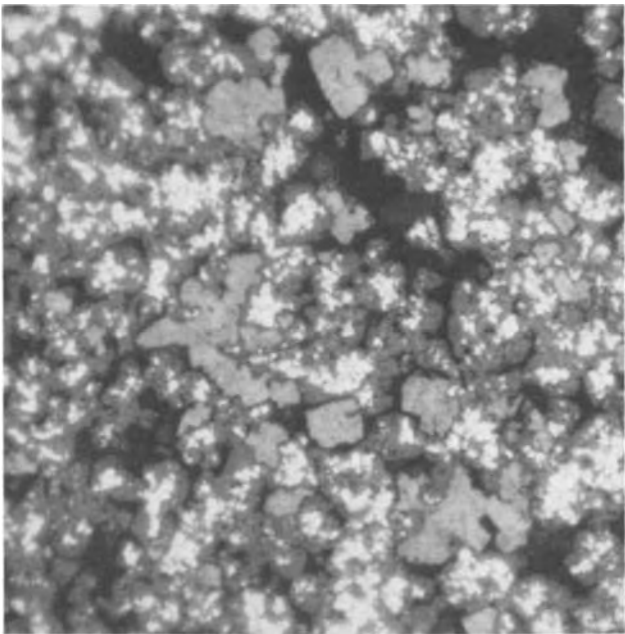

Fig. 8. Typical formation of AgO when the electrode shown in Fig. 6 and 7 was partly charged at Ag_2O/AgO potential. Metallic Ag is white, AgO is light gray, Ag_2O is darker gray, and voids are black. Same magnification as Fig. 6 and 7.

little or no oxidation of Ag had taken place after potential reached the Ag_2O/AgO plateau, except in areas where AgO was forming.

By the end of a charge to oxygen evolution many clumps of AgO had grown together into large masses (Fig. 9). All clumps of AgO were not as large as those in Fig. 9. The active material within approximately 1.2 mm of a grid had mostly been oxidized to AgO but little AgO had formed at a distance greater than 2 mm from the grid. The areas that were largely composed of Ag_2O and Ag were unchanged from their appearance at the potential peak (Fig. 7). A charged electrode contained large amounts of Ag_2O under these

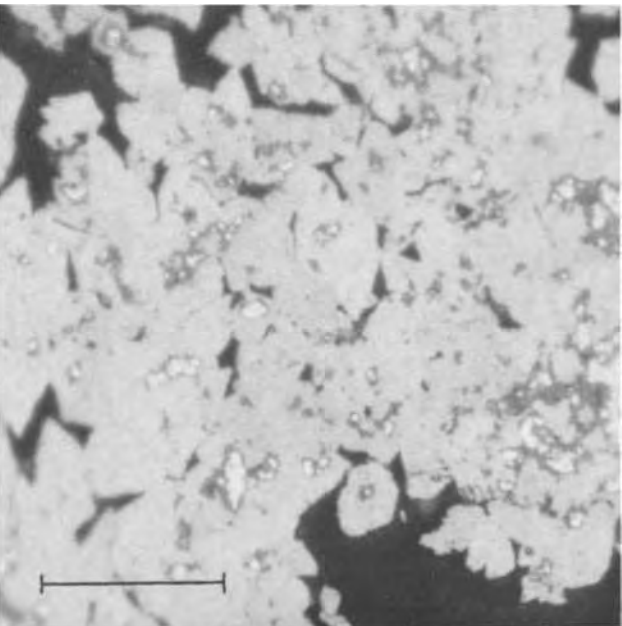

Fig. 9. Silver electrode charged at the 20-hr rate to oxygen evolution in 8.4M CsOH at cycle 6. Most of the Ag had been oxidized to AgO. Remaining Ag was separated from AgO by a thin layer of Ag_2O. Earlier stages of this charge were shown in Fig. 6-8 at the same magnification. Electrode had always been discharged at the 1-hr rate. Marker indicates 15 μm.

conditions. There were fewer voids in the AgO than in areas of Ag_2O and Ag (compare Fig. 9 with Fig. 7). At lower magnification than was used for Fig. 6-9 it was evident that a progressive filling of small voids took place during a charge.

Effect of Ag particle size.—The above description of structural changes refers to an electrode always discharged at the 1-hr rate, a condition that resulted in formation of small Ag particles. Silver formed into larger particles when an electrode was discharged at the slow, 20-hr rate. When electrodes containing large Ag particles were charged until potential rose at the end of the Ag/Ag_2O potential plateau, the most common structure had the form shown in Fig. 10. Again it was found that some regions closest to the surface had thinner Ag_2O layers than were normal for the rest of a partly charged electrode. Electrode surface color was darker when the slower discharges had been used, indicating a greater average thickness of Ag_2O.

Although most Ag had formed as large particles during discharges at the 20-hr rate, groups of small Ag particles had formed in some areas. A greater proportion of the active material had oxidized to Ag_2O in areas where Ag was in small particles. This resulted in structure being irregular when an electrode was charged at the Ag/Ag_2O potential after slow discharges had been used, with some areas like Fig. 7 but most of the electrode like Fig. 10.

The large Ag particles that formed during a slow discharge did not oxidize completely during a charge (Fig. 11). Comparison of Fig. 11 to Fig. 9 (at twice the magnification) gives an idea of the sizes of Ag particles that remained at the end of a charge under the two conditions. In contrast to results when small Ag particles had formed, structure was relatively uniform in the electrodes with larger Ag particles. Most of the active material had oxidized to AgO at the end of a charge. The surface of these electrodes had the gray color of AgO.

Structural changes that occur with cycling.—During the first charge of sintered Ag electrodes the pore distribution was more regular than in later cycles. Figure 12 shows an electrode at the end of cycle 1

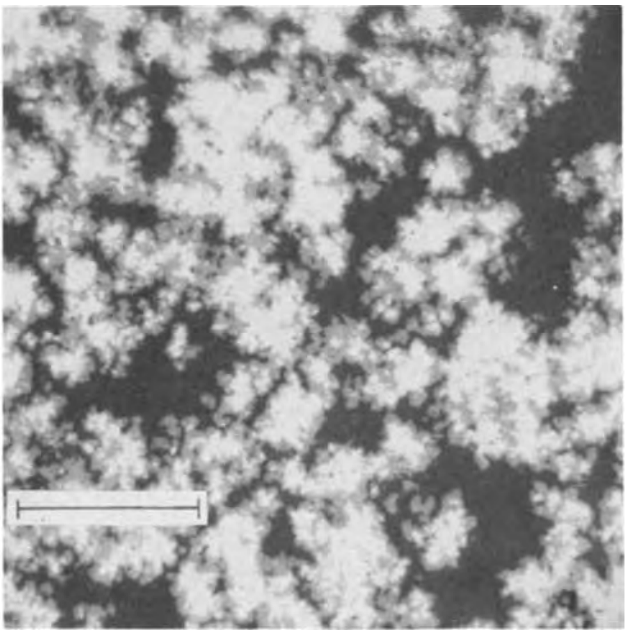

Fig. 10. Electrode charged at the 20-hr rate until potential rose at the end of the Ag/Ag_2O plateau. Both Ag and Ag_2O were present. This sample was taken during cycle 15 charge in 8.4M CsOH of an electrode that always was discharged at the 20-hr rate. Compare this cross section with Fig. 7 (at twice the magnification) to see the effect of discharge rate on particle size. Marker indicates 30 μm.

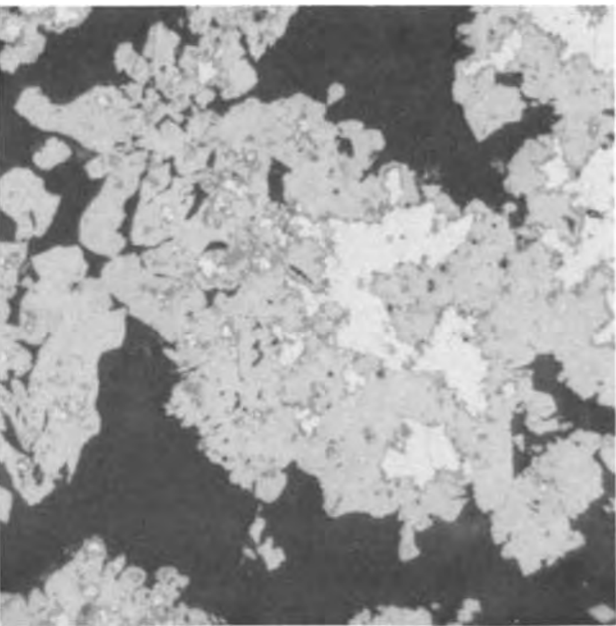

Fig. 11. Electrode charged at the 20-hr rate in 8.4M CsOH until oxygen evolution took place. This is the end of cycle 15 charge of the electrode always discharged at the 20-hr rate shown in Fig. 10. Same magnification as Fig. 10.

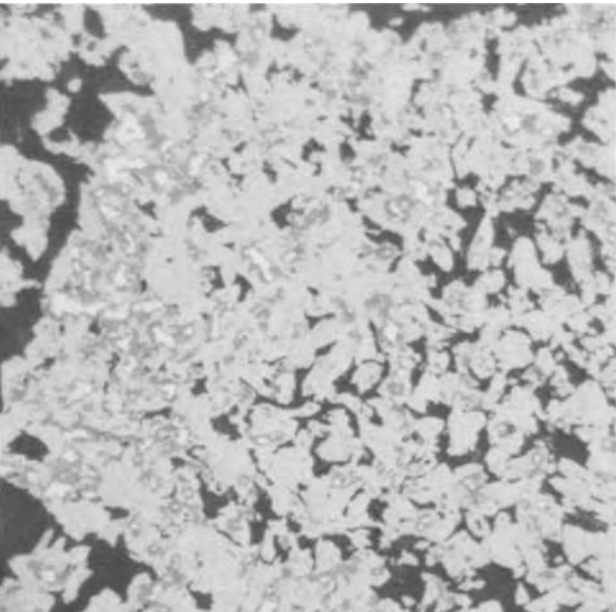

Fig. 12. Appearance of active material at cycle 1 when previously unused sintered Ag electrode was charged to oxygen evolution at the 20-hr rate in 8.4M CsOH. Comparison with Fig. 9 and 11 indicates that active material clumped during the cycling. Same magnification as Fig. 10 and 11.

charge. At cycle 1, AgO was relatively porous but formed into larger masses with fewer pores at later cycles (Fig. 9, 11). Active material gradually clumped into larger masses with cycling. Small voids became less common in these clumps, and large voids gradually formed between clumps. These changes were best seen at low magnification.

An electrode contained a random distribution of small and large particles at cycle 1, but an uneven distribution developed during the next few cycles in CsOH. Silver particles tended to increase in size during the first few cycles when an electrode was given slow discharges, apparently because adjacent particles had grown together. The greatest change took place in the first five cycles, with little additional change between

cycle 6 and 30. Large Ag particles formed in most areas and small particles in a few areas, while intermediate sizes became scarce. Most of the small Ag particles were oxidized completely to AgO during a charge.

The structure of an electrode always discharged at the 1-hr rate changed considerably during cycle 1 discharge, as Ag particles formed that were much smaller than the Ag originally present. A lesser change occurred in the next few cycles. In the first part of a charge, Ag_2O formed throughout these electrodes, but oxidation to AgO was limited to a distance extending 1-2 mm from each grid member. A low magnification view of the border between areas where AgO predominated and areas largely Ag_2O and Ag is given in Fig. 13. The nearest grid was about 1.5 mm from this border. A higher magnification view of the same type of structure in another electrode is shown in Fig. 14. Approximately half of a charged electrode contained little or no AgO under these conditions, despite the fact that oxygen evolution had already taken place. Note that the lower part of Fig. 14 has the same structure as Fig. 7, indicating that oxidation had not taken place here after potential reached the Ag_2O/AgO plateau.

The pattern of the grid was visible as lines of AgO color that were 1.2-2 mm wide on the external surface of these charged electrodes that had formed a high proportion of small Ag particles. The rest of the surface had the colors of Ag_2O and Ag mixtures. Thus, the surface appearance agreed with internal structure. The two types of charged structure shown in Fig. 13 and 14 formed during the first few cycles when using the 1-hr discharge rate. No additional major changes were noted from cycle 6 to 30 except for clumping of active material into larger masses.

The Ag grid in an electrode was slowly attacked. Some pits developed on the surface of a grid during the first charge. Grids in electrodes given fast discharges gradually became thinner with cycling. The grids sometimes lost as much as 25-30% of their original thickness after 30 cycles (Fig. 15). In the charged electrode shown in Fig. 15 the grid was surrounded by a coating of small AgO particles consisting mainly of material that had originally been part of the grid. Coatings around a grid gradually became thicker as cycling progressed. Grids of electrodes given slow discharges had more of a penetrating, irregular attack, with pits gradually reaching deeper into the grid as cycling proceeded. Grids of electrodes given 30 cycles with all discharges at the 20-hr rate had not lost as much of their original thickness as did the grid shown in Fig. 15, and had less of an oxide coating.

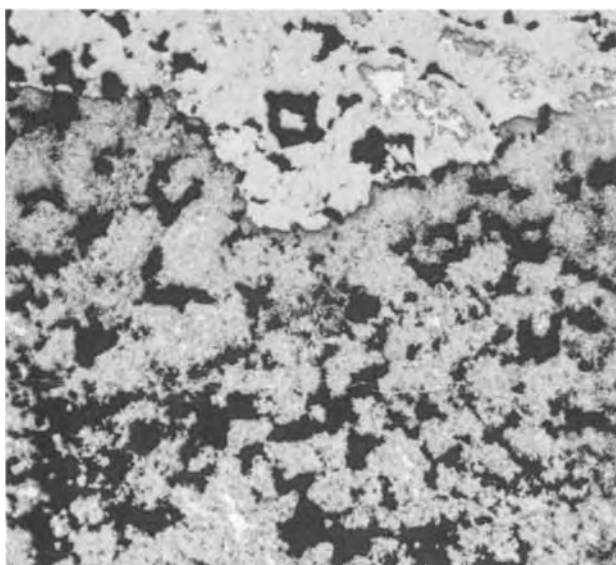

Fig. 13. Cross section through an electrode at the end of cycle 30 charge to oxygen evolution in 8.4M CsOH. All discharges had been done at the 1-hr rate. Areas near the grid were largely oxidized to AgO (top), while more distant areas consisted mainly of Ag_2O and Ag (bottom). Electrode thickness (from left to right in photograph) was 0.87 mm.

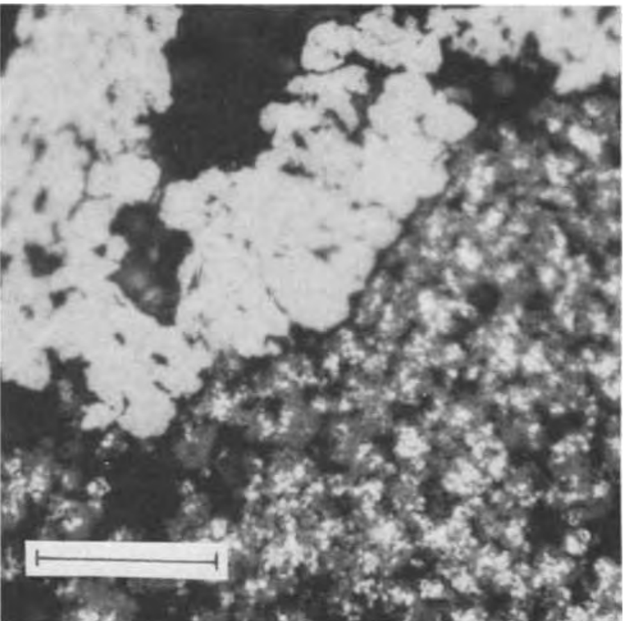

Fig. 14. Electrode charged to oxygen evolution at cycle 16 in 8.4M CsOH. All discharges were done at the 1-hr rate. High magnification view of the type of structure shown in Fig. 13. The AgO is at the top, and the Ag_2O surrounds small Ag particles at the bottom. Marker indicates 15 μm.

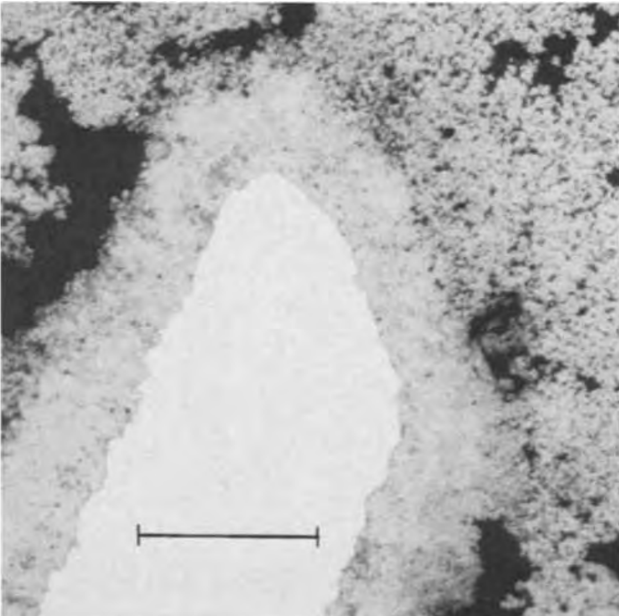

Fig. 15. Structure of AgO at the grid of a charged electrode at cycle 30 in 8.4M CsOH, when all discharges had been done at the 1-hr rate. Cross section through part of the Ag grid shows as white, AgO is light gray, and empty spaces are black. Same charged electrode as Fig. 13. Marker indicates 60 μm.

Effect of electrolyte on electrode structure.—Electrodes cycled in 3.6M CsOH differed from those in 8.4M CsOH in several ways. A cross section through a fully

charged electrode that had been cycled in 3.6M CsOH is shown in Fig. 16 in an area where much of the AgO had formed as elongated or thin shapes. Figure 16 can be compared to Fig. 11, an electrode cycled similarly except for CsOH concentration, but note the higher magnification of Fig. 11. Elongated AgO crystals were less common in 8.4M CsOH but were sometimes found, particularly at the surface of an electrode. Many areas of the electrode shown in Fig. 16 lacked elongated AgO. The AgO crystals were in smaller, more porous clumps in 3.6M CsOH. Limited weight measurements indicated that loss of active material was greatest in 3.6M CsOH.

The grid was attacked a little less in 3.6M CsOH than in 8.4M CsOH, and oxide layers on the grid were quite a bit thinner and more porous. Another difference was that less Ag_2O was present in fully charged electrodes cycled in 3.6M CsOH. Regions that were largely Ag_2O did not remain at the end of a charge in 3.6M CsOH when electrodes had always been discharged at the 1-hr rate as they did in 8.6M CsOH. Larger Ag particles had formed at the surface of electrodes discharged at the 20-hr rate in 3.6M CsOH than elsewhere, and were still evident at the end of a charge.

The only difference noted between structures in 8.4M CsOH and 8.4M KOH during cycle 1 charge of unused sintered Ag electrodes was that a small amount of thin AgO crystals had formed at some places on the surface of the electrode charged in CsOH solution. These thin or elongated AgO crystals were much rarer in 8.4M KOH. Since thin AgO crystals were found more often in 5.5M KOH than in 8.4M KOH and were also more common in 3.6M CsOH than in 8.4M CsOH, it was concluded that formation of thin AgO was inhibited in concentrated hydroxides.

The average particle size of Ag became at least twice as large in KOH as was typical in CsOH, when electrodes were cycled using the 20-hr discharge rate. The Ag particles had grown together in many places. The fact that larger Ag particles had formed in KOH was evident in all stages of a charge following the slow discharges. Differences between results in KOH and CsOH were less when the 1-hr discharge rate had been used, but in the first part of a charge the Ag particle size was noticeably larger in KOH.

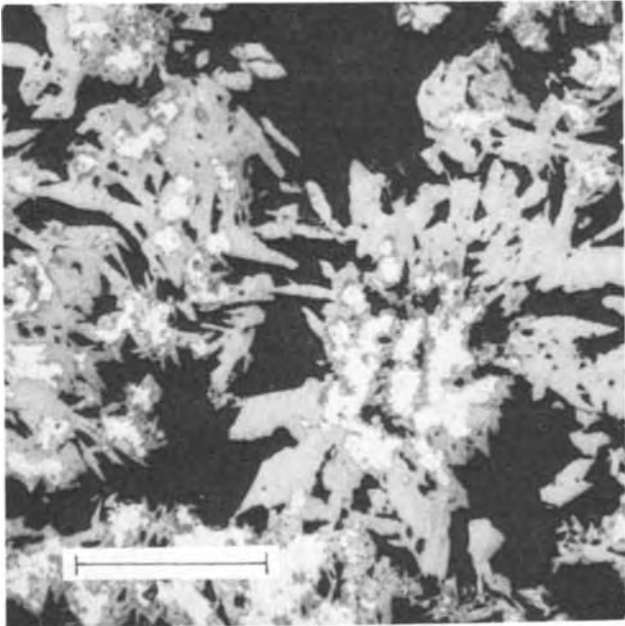

Fig. 16. Active material at the end of cycle 16 charge to oxygen evolution in 3.6M CsOH. All charges and discharges had been done at the 20-hr rate. The AgO had a greater tendency to form as elongated crystals in 3.6M CsOH than in 8.4M CsOH. Marker indicates 50 μm.

Discussion

Oxidation of Ag to Ag_2O.—During the initial part of a charge the Ag_2O forms from a dissolved Ag(I) species. A KOH solution becomes supersaturated with dissolved Ag as Ag_2O is forming (9, 10). The soluble species is usually considered to be $Ag(OH)_2^-$. Dissolution is followed by the precipitation of Ag_2O. Equation [1] gives the over-all reaction for Ag_2O formation by either the dissolution-precipitation mechanism in the initial part of a charge, or the solid-solid transition after Ag is coated with Ag_2O

$$2Ag + 2\,OH^- \cdot xH_2O \rightarrow Ag_2O + (2x + 1)H_2O + 2e \quad [1]$$

The solvation number for the OH^- ion is given as x in this equation. The amount of solvation decreases in concentrated solutions. According to Eq. [1] pH tended to increase in the interior of the electrode during a charge because of the consumption of OH^- ions and the formation of water. High rates of charge gave the greatest concentration gradients.

During the first charge in fresh electrolyte an unusually large part of the $Ag(OH)_2^-$ that formed near the surface of an electrode diffused into the bulk of the electrolyte instead of precipitating within the electrode as Ag_2O, and thus less Ag_2O formed near the surface. An electrode charged at cycle 1 until potential rose to the peak that ends the Ag/Ag_2O plateau had much thinner Ag_2O on Ag particles in the 50-100 μm closest to the surface. The border was fairly sharp between this region where Ag_2O was thin and the rest of the electrode at cycle 1, but less noticeable in later cycles. Less $Ag(OH)_2^-$ diffused from the electrode in subsequent cycles because the electrolyte in a cycled cell contained dissolved Ag. Even if $Ag(OH)_2^-$ had been depleted during a discharge, some oxide usually remained in the electrode to replenish dissolved Ag.

Electrodes cycled in CsOH did not develop as large an average particle size of Ag as developed in KOH. Particle size will be discussed in more detail in a separate paper on reduction of charged electrodes in CsOH. The smaller size of particles gave a larger surface area and this resulted in a larger quantity of Ag_2O forming during a charge in CsOH than in KOH.

The decrease in charge acceptance at the Ag/Ag_2O plateau shown in the upper part of Fig. 5 was the result of a gradual increase in particle size as electrodes were cycled. The largest average particle size had formed in KOH when discharges were always done at the 20-hr rate, and these conditions gave the lowest Ag/Ag_2O charge acceptance before potential increased to the Ag_2O/AgO plateau. Under a given set of conditions passivation occurred after Ag_2O reached a particular thickness, and then potential increased until AgO began to form. The rise to the potential peak that ends the Ag/Ag_2O plateau was slower in 8.4M CsOH than in 8.4M KOH when other conditions were similar (Fig. 2, 4) indicating that oxidation in KOH took place under conditions that were closer to equilibrium.

Oxidation of Ag_2O to AgO.—The reaction for the formation of AgO

$$Ag_2O + 2\,OH^- \cdot xH_2O \rightarrow 2AgO + (2x + 1)H_2O + 2e \quad [2]$$

involves the same loss of hydrated OH^- ions and gain of water as was given in Eq. [1]. Thus concentration gradients continued to be present in the electrolyte, particularly at high rates of charge. An indication of a concentration difference between the surface and the interior of an electrode while charging at the Ag_2O/AgO potential was the fact that thin or elongated AgO crystals formed on the surface of electrodes in 8.4M CsOH. As AgO formed from Ag_2O in 8.4M CsOH (Fig. 8) the active material as a whole looked identical to what had been found earlier in 8.4M KOH (11).

The capacity accepted at the Ag_2O/AgO potential plateau was larger in more concentrated solutions than in dilute solutions over the range of charge currents

that were used. This was opposite to the effect of electrolyte concentration on charge acceptance at the Ag/Ag_2O potential plateau. The thick Ag_2O coatings that formed in dilute solutions hindered oxidation of the remaining active material, probably because Ag_2O has a low conductivity. Total charge acceptance was larger in the more concentrated CsOH or KOH solutions, since the capacity increase at the AgO level was larger than was needed to compensate for the decrease at the Ag/Ag_2O level. Both the capacity accepted at the Ag_2O/AgO plateau and the total charge acceptance were larger in CsOH than in the same concentration of KOH. The smaller particle size of Ag that was present in CsOH when slow discharges were always used allowed a more complete oxidation of Ag.

Development of one type of structure within 1-2 mm of the grid members and another type elsewhere, as shown in Fig. 13 and 14, was found when using the most concentrated solutions of CsOH or KOH, but only when the original sintered Ag electrodes contained a low proportion of large Ag particles. The development of two structures in these electrodes that had relatively few large Ag particles can be attributed to a lowered internal conductivity after a discharge at the 1-hr rate had produced a decrease in average particle size (5). Electrode structure was much more uniform when the original sintered Ag electrodes had a higher proportion of large Ag particles, or when use of slow discharges had produced larger Ag particles.

An increasing internal resistance in the active material can be the cause of higher potentials while charging at the Ag_2O/AgO plateau after using discharges at the 1-hr rate (lower part of Fig. 4) and of a gradual potential increase at the end of this plateau under these conditions. Although potentials were high in the last part of a charge at the Ag_2O/AgO plateau, most of the current was being used to form silver oxides and not in oxygen evolution. Charge-discharge efficiency was high, as indicated by the arrows in the lower part of Fig. 4, except at cycle 1. A fairly constant amount of oxide remained in an electrode at the end of a discharge at the 1-hr rate, so efficiency was close to 100% after the first charge-discharge cycle.

Comparison of CsOH to KOH.—It is of interest to know the water concentration in the solutions used in this work (Table II) since the amount of water present can be an important factor in determining electrode behavior in concentrated electrolytes. The concentrated solutions used in this work did not contain sufficient water to allow the full amount of hydration found in dilute solutions. Measurements of the properties of concentrated CsOH, such as ionic mobility and hydration, are not available. For more dilute solutions various measurements given for the solvation number of the Cs^+ ion range from 0 to 6, and the solvation number of K^+ is generally given as 0.5-2 more positive than Cs^+ (7). The solvation number for the OH^- ion has been given values ranging from 0 to 8, with 3-6 reported most often. Solvation numbers tend to decrease in concentrated solutions when the amount of free water becomes low, and were likely near or equal to 0 in 8.4M CsOH. Concentrated KOH may exist mainly in the form of water-bridged ion pairs (12). If Cs^+ is not hydrated, as some reports of the solvation number indicate, then the Cs^+ ion may be associated directly with the hydroxyl ion. Formation of either type of ion pair decreases ionic mobility and, therefore, decreases conductivity in concentrated solutions.

Table II. Water present in electrolyte

Solution	Moles H_2O/liter	Moles H_2O/mole of CsOH or KOH
3.6M CsOH	51.4	14.4
8.4M CsOH	44.3	5.3
5.5M KOH	51.4	9.3
8.4M KOH	48.3	5.8
11.6M KOH	44.3	3.8

The specific conductances of 3.7-6.5M CsOH and of 3.2-10M KOH solutions were measured by Rubin and Baboian (13). At 25°C the specific conductances reached a maximum in approximately 5.5M CsOH and 6.7M KOH. An extrapolation from 6.5 to 8.4M CsOH is very uncertain, but conductance of 8.4M CsOH might only be two-thirds as much as conductance of 8.4M KOH, although not as low as 8.4M NaOH. The viscosities of 3.7-6.2M CsOH and KOH solutions are close to each other (13). Extrapolation of the values given in (13) suggests that 8.4M CsOH would have a viscosity higher than that of KOH but much less than the viscosity of NaOH.

The lower conductivity of 8.4M CsOH resulted in potentials increasing a greater amount in CsOH than in KOH when charge current was increased (Fig. 2). The higher viscosity of 8.4M CsOH may also be a factor in the higher potentials. These higher charge potentials did not affect capacity more adversely in CsOH than in KOH (Fig. 1). If measurements had been extended to lower charge currents than were used for Fig. 1, the linear relationship on the log-log scale should eventually fail in KOH as it had already done in CsOH. Electrode capacity obviously could not increase indefinitely as charge current decreased.

When discharges were always performed at the 1-hr rate the structures that developed in 8.4M CsOH (Fig. 13 and 14) were like those found in 11.6M KOH (5). At the 20-hr rate of discharge the average size of Ag particle that formed in 8.4M CsOH was only half the size of Ag in 8.4M KOH. Thus, the structures that formed in CsOH tended to be like those found in a more concentrated KOH, or that would be expected in KOH at the same concentration if a higher C.D. had been used.

The differences in potential and structure indicate that concentration gradients were higher in CsOH than in KOH, when electrodes were cycled under the same conditions in electrolytes of the same molar concentration. The different behaviors probably result from mobilities being lower in CsOH because Cs^+ ions are larger than hydrated K^+ ions, and because OH^- ions are directly associated with the Cs^+ ions and somewhat less mobile than are OH^- ions in a KOH solution. It is not known whether there is a difference between the solubility of disoslved Ag in CsOH and KOH, or in the degree of supersaturation that forms. Appreciable differences would be important because the formation of Ag during discharge and part of the Ag_2O formation during charge take place by a dissolution-precipitation mechanism.

When high current densities are used an electrolyte should be chosen that has high conductivity, because ionic mobility can become limiting and polarization will be high. Therefore the most concentrated solutions should be avoided and KOH used if a cell containing Ag electrodes is to be cycled at high rates of charge or discharge. At low currents, however, the somewhat limited ionic mobility found in concentrated electrolytes or in CsOH is desirable because it inhibits growth of large Ag particles during reduction and, therefore, slows or prevents the loss of capacity that occurs with repeated cycling. At decreased temperatures the electrolyte freezing point needs to be considered also, and the low eutectic of CsOH solutions is a desirable feature.

Conclusions

The products of anodic oxidation were the same in aqueous CsOH solutions as in aqueous KOH solutions. First Ag was oxidized to Ag_2O and then to AgO. Charge potentials increased a greater amount in 8.4M CsOH than in 8.4M KOH when charge was done at a higher current, because of the lower conductivity of the CsOH solution. Perhaps the higher viscosity of CsOH was also a factor. Oxidation took place under conditions farther from equilibrium in CsOH than in KOH.

A concentrated CsOH solution was the preferred electrolyte for maximum capacity when using slow discharges, because Ag particle size increased the least in this electrolyte. The rate of discharge (reduction) had a strong effect on electrode structure and, therefore, on capacity and potentials of the following charge in both electrolytes. The capacity decrease observed during the first few cycles corresponded fairly closely to a decrease in charge acceptance at the Ag_2O/AgO potential plateau.

The structures that developed in CsOH resembled those found in a more concentrated KOH at the same current density, or were like those expected in KOH of the same concentration if a higher current density had been used. These results indicated that concentration gradients were higher in CsOH than in KOH of the same molar concentration. The different behaviors probably resulted from ionic mobilities being lower in CsOH than in a KOH solution. Differences in ion hydration were more important than differences in the total amount of water present.

Sintered Ag electrodes should contain small particles so that the electrodes can be charged to a large per cent of theoretical capacity. The electrodes should also contain some large Ag particles for conductivity if discharges are always to be done at a high current density in a concentrated electrolyte, since small Ag particles develop under these conditions and then conductivity becomes poor during a charge.

The Standard Potential of the Single-Crystal Copper Electrode in Aqueous Solutions

Finn Grønlund and Søren Noer

Chemical Laboratory IV, H. C. Ørsted Institute, University of Copenhagen, 2100 Copenhagen Ø, Denmark

ABSTRACT

A cell is described for measuring the equilibrium potential of the $Cu|Cu^{2+}$, H_2O electrode. The cell was vacuum-tight and the water vacuum-distilled in order to eliminate oxygen; the solution was equilibrated with metallic copper before immersion of the electrodes. These were disk-shaped, oriented single crystals made from 99.999% copper and vacuum annealed before use. Pairs of differently oriented crystals showed potential differences smaller than 0.02 mV. The standard potential of such electrodes was determined by measuring the emf of cells of the type Ag, $AgCl|CuCl_2(m_o)$, $H_2O|Cu$ with m_o in the range from $4.8 \cdot 10^{-4}$ to $2.5 \cdot 10^{-3}$M. The resulting value, $e^o_{Cu|Cu^{2+}} = 335.2 \pm 0.4$ mV at 25°C, is significantly lower than those generally accepted, probably beause the accepted values were all obtained from measurements in relatively concentrated cupric sulfate solutions.

Measurements of the $Cu|Cu^{2+}$ electrode potential in aqueous solutions have led to a number of values for the standard potential, some of which are listed in Table I. The scatter of these results is so large as to mask the differences between the various types of electrodes. It is probably due to the neglect of one or more of the following conditions, which we found essential in determining the copper single-crystal electrode potential:

1. The electrode should be made from high purity, strain-free copper single crystals, presenting an oriented, clean, and unperturbed surface.
2. Oxygen must be rigorously excluded.
3. The solution must be equilibrated with metallic copper before the electrode is immersed, and pH should be low enough to prevent formation of Cu_2O.

Key words: equilibrium, crystallographic planes, vacuum cells, chloride medium.

4. The reference electrode should be suitably chosen. In all studies cited above, the reference electrode was Hg, $Hg_2SO_4|SO_4^{2-}$, and the electrolyte $CuSO_4$. As Hg_2SO_4 is relatively soluble, it is not feasible to work at concentrations below $5 \cdot 10^{-3}$M. At this level, the Debye-Hückel law is only beginning to assume validity; what is more, an appreciable fraction of the cupric

Table I. Standard potential measurements of $Cu | Cu^{2+}$ electrode

Electrode	Standard potential, V
Copper sponge, grown electrolytically (1)	0.3469
Copper sponge, grown electrolytically (2)	0.3457
Two-phase copper amalgam (3)	0.3502
Two-phase copper amalgam (4)	0.3454
Amalgamated polycrystalline copper (5)	0.3498
Amalgamated copper single crystal (6)	0.3419
Copper single crystal (5)	0.3475

ions is complexed as $CuSO_4$ (7). This fact, which adds a considerable systematic error, has apparently been overlooked by most investigators.

The measurements described below were made with an evacuated cell with movable electrodes and a solution previously equilibrated with metallic copper. In a preliminary series, potential differences were measured between copper single crystals; when these worked reproducibly, as indicated by values sufficiently close to zero, the potential difference of the cell

$$Ag,AgCl|CuCl_2(m_o), H_2O|Cu$$

was measured as a function of m_o down to $5 \cdot 10^{-4}$M.

Experimental

Electrodes.—The copper single-crystal electrodes were made from cylindrical (17 mm diameter) single crystals, grown in vacuum from 99.999% ASARCO copper by the standard Bridgman method (8) in a high purity graphite mold. The crystal was oriented to within 1° using the Laue back-reflection method, and disk-shaped slices 1 mm thick were cut with an acid saw to avoid introducing strains. The disks were electropolished in a 50-60% phosphoric acid bath for at least 20 mn at a current density of about 0.05 A/cm^2. So prepared, they gave somewhat fluctuating values; satisfactory results were obtained only after a subsequent anneal at 1000°C at 10^{-6} Torr for at least 1 hr.

Silver-silver chloride reference electrodes were prepared as described by Ives and Janz (9): silver oxide deposited on platinum wire is decomposed thermally, and the silver formed is partly chlorinated by electrolysis. To reduce diffusion, the wire was sealed into one end of a glass tube, the other end of which was a capillary 4 mm long and having an internal diameter of 1 mm. More than twenty such electrodes were made, most of which differed by less than 0.1 mV when immersed in cupric chloride solutions more concentrated than $5 \cdot 10^{-4}$M, and remained constant for many days.

Auxiliary copper electrodes were adopted with the purpose of equilibrating the solution before the single-crystal copper electrodes were immersed, as explained below. They were made from 99.999% pure, polycrystalline Johnson-Matthey copper sheet, 0.5 mm thick, cylindrically shaped so as to fit the inside of the glass cell, and with an immersed area of 30-40 cm^2. They were electropolished and vacuum annealed before use as described above.

Chemicals.—In all applications, water was demineralized and twice distilled in a quartz apparatus before use.

$CuSO_4 \cdot 5H_2O$ was Merck, analytical purity; the $CuCl_2$ was Riedel-de Haën, analytical purity; and the $Cu(ClO_4)_2 \cdot 6H_2O$ was prepared from CuO (Riedel-de Haën, pure) and $HClO_4$ (Riedel-de Haën, analytical purity).

All salts were recrystallized twice from aqueous solutions before use.

Electrical equipment.—In all measurements involving new electrodes, a Keithley Model 610 B electrometer (input resistance 10^{13} ohms, input offset current 10^{-14}A) was used. Subsequently a Solartron LM 1420.2 digital voltmeter (input resistance 10^9 ohms, sensitivity 2.5 μV) was connected. In all instances the same reading was obtained, and the DVM with a logging unit was then used to measure and record potential differences.

Cell.—Experiments with a simple cell, flushed with purified nitrogen, showed that the potential difference varied with the bubbling rate and time, and that the copper tarnished. To reduce the amount of oxygen present, a vacuum-tight cell (Fig. 1) was constructed which could be evacuated and which permitted vacuum distillation of the water.

The cell, which is made from Pyrex glass, may be evacuated through a large tap T by means of a rotary pump or an oil diffusion pump. A liquid nitrogen trap is inserted between the cell and the diffusion pump in order to prevent oil contamination. The limiting pressure is well below 10^{-5} Torr, and the air leak rate is less than 10^{-8} Torr·liter·sec^{-1}, or about $5 \cdot 10^{-13}$ moles of air per second. Water vapor may be admitted from the reservoir R through tap t. A cold finger F which may be filled with liquid nitrogen is placed above the demountable measuring cell C. A small water thermostat Th, controlled to within 0.01°C, may be raised so as to surround C; both are equipped with magnetic stirrers. The cell accommodates a total of four electrodes, only one of which (E) is shown. Each is suspended from a guided copper rod, attached by a thin nylon thread to a piece of nickel-plated soft iron I inside the top part of the apparatus; the iron is maintained in place by a strong external magnet, so that the electrode may be raised or lowered independently of the others. A thin, insulated copper wire connects it to one of the four electrical lead-throughs L.

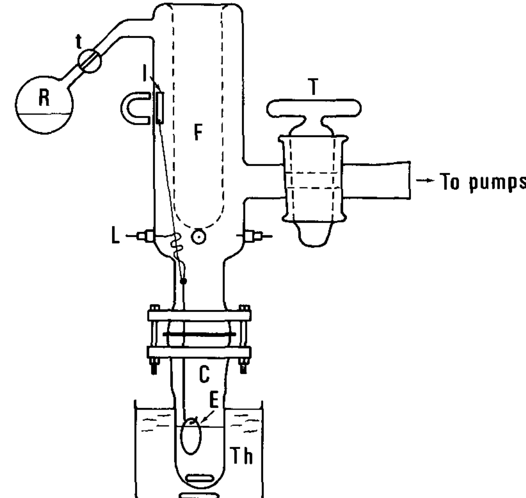

Fig. 1. Cell for emf measurements. E, electrode (only one of four is shown); C, measuring compartment; Th, thermostat; L, electrical lead-through; I, soft iron piece; F, cold finger; R, water reservoir; T and t, taps.

Procedure.—When the electrodes have been prepared, they are suspended in the apparatus, connected electrically, and raised to a high position. A suitable amount of cupric salt is deposited in the bottom of C by pipetting off a small volume of solution of known concentration in the salt; and roughly 25 ml of pure water are introduced into R. The apparatus is assembled and evacuated with a rotary pump, both taps T and t being open in order to remove most of the residual gases, including those dissolved in the water. After a while, the contents of C and R are frozen by cooling from the outside. The diffusion pump is next switched on, and when the pressure is about 10^{-5} Torr, F is filled with liquid nitrogen, while C and R are heated gently. This causes the water frozen in C and R to sublime onto the cold surface of F, whereas residual air in the ice, liberated in the sublimation process, is removed by the pump. When all the water has been carried over, the cell is isolated by closing both taps; and as the liquid nitrogen in F boils off, the ice melts and drips down into C. Stirring and thermostating (to slightly below room temperature, in order to keep all the water down in C) is started, and the electrolyte is now ready to receive the electrodes which may be immersed when convenient. At the end of the experiment, the liquid content of C is determined by weighing the electrolyte so as to permit calculation of the electrolyte concentration with an accuracy of about 0.3%.

Results

Preliminary experiments.—With the cell described, the potential difference was measured between two

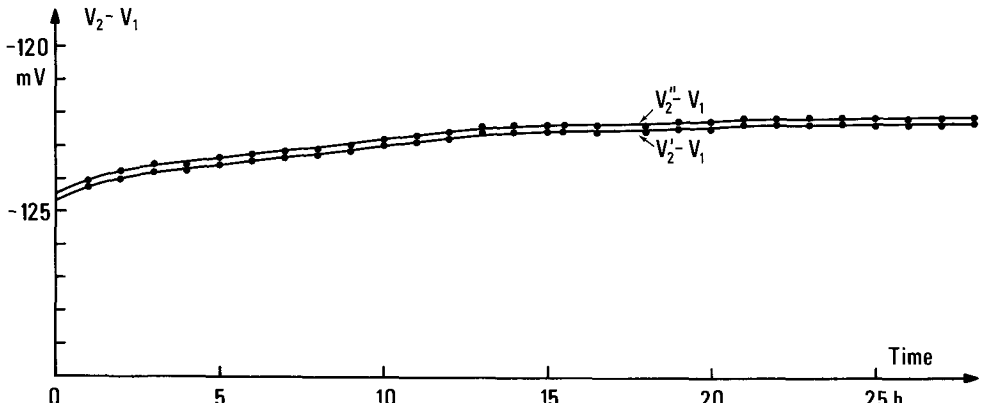

Fig. 2. Behavior of the potential differences between each of two copper single-crystal electrodes and one silver-silver chloride electrode with time. $t = 0$ at the moment of immersion of the former, and $m_o = 1.747 \cdot 10^{-3}$M.

identical unannealed copper single crystals in aqueous, oxygen-free solutions of $CuSO_4$ or $Cu(ClO_4)_2$ in the range $5 \cdot 10^{-3}$ to $5 \cdot 10^{-2}$M. It fluctuated and often changed sign, with peak values decreasing from about 10 to 1 mV over a period of 24 hr; furthermore it was sensitive to light. The electrode surfaces were visibly modified. As pointed out by Jenkins and Bertocci (10), even in the absence of oxygen two reactions may be expected: dissolution of the electrode upon immersion

$$Cu + Cu^{2+} \rightarrow 2Cu^{+} \qquad K_1 \approx 10^{-6}M \qquad [1]$$

until equilibrium, and precipitation of Cu_2O

$$2Cu^{+} + H_2O \rightarrow Cu_2O + 2H^{+} \qquad K_2 \approx 1 \qquad [2]$$

for pH values sufficiently high.

Therefore, the auxiliary copper electrode described above was immersed into the solution in order to equilibrate it with respect to Cu^+ and H^+ prior to measurement. After at least 10 hr it was withdrawn, and only then were the single-crystal electrodes lowered into the solution. Immediately after, the potential difference was about 1 mV, and in 4 hr it decreased to about 0.02 mV where it stayed for days. The electrode surfaces remained perfectly bright throughout this period, and no photosensitivity was detected.

When the copper single crystals were annealed before use, the voltage was found to decrease from an initial value of 0.5 mV to 0.02 mV or less in 1 hr, where it remained for days or even weeks.

The same low value was obtained both when the two single-crystal electrodes were oriented alike and when different orientations were combined from the set of (100), (110), (111), and (311). This result is in complete agreement with the observations of Jenkins and Bertocci (10).

Investigation of the electrode surface with reflection high energy electron diffraction after completion of the measurements showed the presence of a few monolayers of Cu_2O on the copper crystals. Similar patterns were obtained after the experiments described below. The oxide may, however, have formed during transfer of the specimens from one apparatus to the other.

Copper-silver chloride potential difference.—A silver-silver chloride electrode was chosen as a reference for several reasons. It has been thoroughly investigated and is reported to work satisfactorily. The low solubility of silver chloride permits electrolyte concentrations down to 10^{-4}M, a considerable improvement with respect to the mercury-mercurous sulfate electrode. Both Cu^{2+} and Cu^+ form complexes with Cl^-, but calculations based on the available complex formation constants (11) show that the amount of chloro-ligated copper is insignificant for $CuCl_2$ concentrations below $3 \cdot 10^{-3}$M. This value is, incidentally, a limit not to be exceeded if precipitation of CuCl is to be avoided.

The experimental procedure is as described above, with slight modifications: after 3-4 hr of equilibration with the auxiliary electrode, the silver chloride electrode is lowered into the liquid so as to be filled through the capillary (the system is evacuated). After another 6-7 hr of equilibration, the reference electrode is emptied and refilled with electrolyte; the auxiliary electrode is raised; and two copper single-crystal electrodes are immersed.

The cell may be summarized as follows

$$(V_1)\ \mathrm{Ag,AgCl} \mid \mathrm{CuCl_2}(m_o), \mathrm{H_2O} \left| \begin{array}{l} \mathrm{Cu'}\ (V_2') \\ \mathrm{Cu''}\ (V_2'') \end{array} \right.$$

where m_o is the original molality in $CuCl_2$ of the solution before equilibration and the V's designate the potentials of the three electrodes relative to some common reference potential.

The behavior of the potential differences $V_2' - V_1$ and $V_2'' - V_1$ with time from the moment of immersion is shown for a typical experiment in Fig. 2; $m_o = 1.747 \cdot 10^{-3}$M, and $t = 20.30$°C. The ordinate difference between the curves $V_2'' - V_2'$ gives the potential difference between the two single-crystal electrodes. Its constancy and magnitude, of the order of 0.2 mV, indicates that the copper electrodes work reliably. Both curves approach a limiting value which is maintained for many days, and their average, $(V_2' + V_2'')/2 - V_1$, is taken to be the emf of the cell, E.

Nine experiments were performed, in which E was measured at temperatures close to 20°C. The values of m_o were chosen in the range from $4.8 \cdot 10^{-4}$ to $2.5 \cdot 10^{-3}$M, the upper concentration limit being imposed by the solubility of CuCl and complex formation, the lower limit by reaction [1]. In Table II, the first three columns list values of m_o, t, and E, respectively, while the fourth and fifth give the quantities $E^{o\prime}(t)$ and $E^{o\prime}(20°C)$ to be defined below.

Discussion

The cell reaction is

$$2Ag + 2Cl^- + Cu^{2+} \rightarrow 2AgCl + Cu$$

and the emf of the cell

$$E = E^o + \frac{RT}{2F} \ln(a_{Cu^{2+}} a_{Cl^-}{}^2)$$

$$= e^o{}_2 - e^o{}_1 + \frac{RT}{2F} \ln(m_{Cu^{2+}} m_{Cl^-}{}^2 f_{Cu^{2+}} f_{Cl^-}{}^2)$$

where $e^o{}_2$ is the standard potential of the $Cu^{2+}|Cu$ electrode, and $e^o{}_1$ that of the $Cl^-|AgCl,Ag$ electrode.

Table II. EMF values of the cell Ag, AgCl | $CuCl_2$ (m_o) | Cu for various values of m_o

$10^4 m_o$, mol kg^{-1}	t, °C	E, mV meas.	$E^{o\prime}(t)$, mV calc.	$E^{o\prime}$(20°C), mV calc.
4.820	20.05	−167.0	108.7	108.7
6.214	20.10	−157.3	109.2	109.3
6.241	20.10	−157.5	108.9	108.9
7.029	20.10	−153.1	109.0	109.1
9.145	20.20	−143.9	108.9	109.0
9.292	20.20	−144.0	108.2	108.3
15.22	20.05	−127.0	107.7	107.7
17.47	20.30	−122.5	107.6	107.8
25.62	20.30	−110.2	106.7	106.9

Some of the Cu^{2+} ions originally present are transformed into Cu^{+} ions by reaction [1] so that $m_{Cu^{2+}} \approx m_o(1 - (1/2)\sqrt{K_1/m_o})$ where K_1 is the equilibrium constant of [1]. Reaction [2] has been suppressed by using a 10^{-5}M solution of HCl in water for filling the reservoir R. The amount of complexed Cl^- is negligibly small in the concentration range investigated, as already mentioned, so that $m_{Cl^-} \approx 2m_o$.

The activity coefficients may be assumed to follow the modified Debye-Hückel expression $\log_{10} f_i = Az_i^2\sqrt{I} - B_iI$, where $A = 2618T^{-3/2}$, $I \approx 3m_o$, and B_i is an individual constant. When this is introduced, the emf expression becomes

$$E = E^o + \frac{RT}{2\mathbf{F}}\left\{ \ln\left(4m_o^3\left(1 - \frac{1}{2}\sqrt{\frac{K_1}{m_o}}\right)\right) - \ln 10(6A\sqrt{3m_o} + 3Bm_o) \right\}$$

$$\approx E^o + \frac{RT}{2\mathbf{F}}\left\{ \ln(4m_o^3) - \frac{1}{2}\sqrt{\frac{K_1}{m_o}} - 6\sqrt{3}\ln 10A\sqrt{m_o} - 3\ln 10\, Bm_o \right\}$$

Following the standard procedure, a quantity $E^{o\prime}(t)$ may be defined by

$$E^{o\prime}(t) \equiv E - \frac{RT}{2\mathbf{F}}\left\{ \ln(4m_o^3) - \frac{1}{2}\sqrt{\frac{K_1}{m_o}} - 6\sqrt{3}\ln 10A\sqrt{m_o} \right\}$$

$$\approx E^o(t) - \frac{3\ln 10\, RTB}{2\mathbf{F}} m_o$$

Values of $E^{o\prime}(t)$, calculated for the temperature of each experiment, are given in the fourth column of Table II. The corresponding values of $E^{o\prime}$ at 20°C are found in the fifth column; they were obtained by means of the temperature coefficient of the standard potential of the cell

$$\frac{dE^{o\prime}}{dt} \approx \frac{dE^o}{dt} = 0.66 \text{ mV K}^{-1} \quad \text{at } 25°\text{C (12)}$$

In Fig. 3, $E^{o\prime}$ (20°C) is plotted against m_o. Assuming a linear relationship to hold, a straight line was drawn by the method of least squares, with equal statistical weight to all points. Its intercept with the ordinate axis was calculated to be

$$E^o\ (20°\text{C}) = (109.6 \pm 0.2) \text{ mV}$$

At 20°C, $e^o_1 = 225.6$ mV (11). Therefore, the standard potential of the $Cu^{2+}|Cu$ electrode

$$e^o_2 = (335.2 \pm 0.2) \text{ mV at } 20°\text{C}$$

The corresponding values at 25°C may be found using the temperature coefficient of the standard $Cu^{2+}|Cu$ electrode, $de^o_2/dT = 8\cdot 10^{-3}$ mV K^{-1} at 25°C (12)

$$e^o_2 = (335.2 \pm 0.4) \text{ mV at } 25°\text{C}$$

A few remarks may be in place concerning possible errors. The potential difference between two copper electrodes in solutions of Cu_2SO_4 or $Cu(ClO_4)_2$ was repeatedly found to be 0.02 mV or less irrespective of orientation, a factor of 5 to 10 smaller than the values obtained by Jenkins and Bertocci (10) in similar experiments. This is probably due to differences in the technique of oxygen exclusion, since annealing was shown to have no effect on the rest potential, and since the solutions were equilibrated in both cases. In solutions of $CuCl_2$ and in presence of an AgCl,Ag electrode, however, the potential difference between two copper electrodes was found to assume a constant value of about 0.2 mV (see Fig. 2). The reason for this increase is not clear. Tests have shown that it is neither caused by the measuring equipment, nor by temperature nor concentration gradients in the cell. It could be due to silver ions from the reference electrode or impurities from the electrolyte, reacting with or adsorbing on the two copper crystals to different extents, thereby causing either a change in the emf value or an increase in the overvoltage produced by some side reaction, *e.g.*, oxidation from a residual leak.

Taking this possible error in consideration we have stated the accuracy of the value found to be ±0.4 mV.

The value of E^o is based on the effective concentration of free Cu^{2+} ions which equals m_o, determined as mentioned above, and corrected for changes due to chemical reactions. The most important of these is reaction [1], the equilibrium constant K_1 of which is not known accurately. Its value was taken to be 10^{-6}, but it is not critical as calculations show that to $\Delta K_1 = \pm 10^{-6}$ correspond ΔE^o (20°C) $= \pm 0.2$ mV only. Further, the Cu^{2+} ion concentration might be changed significantly if copper compounds precipitated, but electron diffraction has shown that this does not happen on the electrodes, possibly except for insignificant amounts of Cu_2O. Finally, copper ions may complex with chloride ions, in the solution, but a glance at the rectilinear relationship of Fig. 3, which covers a range of 1:5 in m_o, confirms that Cu^{2+} ions are not bound to any measurable extent in a concentration-dependent way.

It will be noted that the value of the copper electrode standard potential found is considerably lower than those determined from previous emf measurements. In our opinion the reason is that in the latter cases, Cu_2SO_4 solutions 10 to 100 times more concentrated than ours were used because of the choice of reference electrode. In such conditions, the Debye-Hückel approximation is not sufficiently good, and association between cupric and sulfate ions reduces the content of free (though of course solvated) cupric ions quite considerably. The latter effect was discussed by

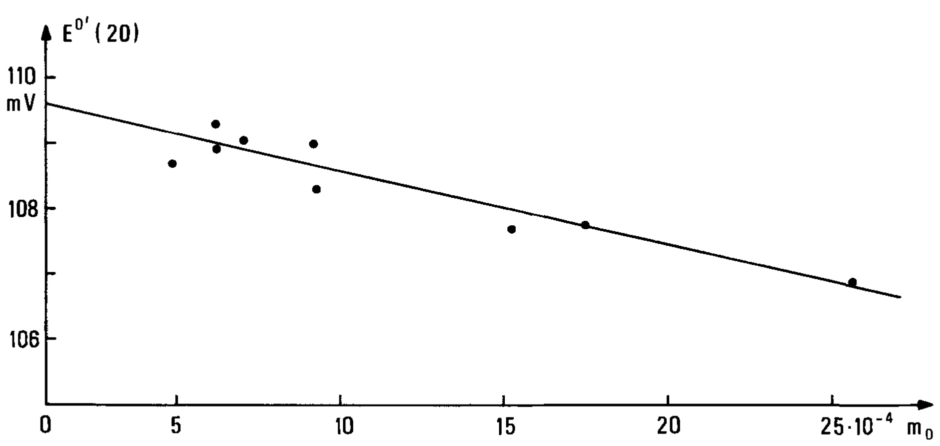

Fig. 3. Plot of $E^{o\prime}$ at 20°C against m_o, the original concentration of $CuCl_2$. The standard potential E^o(20°C) of the cell Ag,AgCl | $CuCl_2(m_o)$ | Cu is found by extrapolating to $m_o = 0$.

Guggenheim years ago (13); we intend to publish in due course a study examining its influence on results reported previously for the $Hg,Hg_2SO_4|CuSO_4|Cu$ cell.

Conclusions

The present study has shown that if all precautions listed at the beginning of this paper are taken, it is possible to obtain potential differences of 0.02 mV or less between two copper single crystals in the same electrolyte.

Second, potential differences between crystals exposing different faces are zero within the limits cited above.

Third, by adopting the silver-silver chloride electrode as a reference, permitting concentrations 10-100 times lower than those used previously, the standard potential of the copper single crystal|cupric ion electrode is found to be 335.2 ± 0.4 mV at 25°C.

Manuscript submitted Feb. 12, 1973; revised manuscript received July 6, 1973.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1974 JOURNAL.

The Undercutting of Organic Lacquers on Steel

O. D. Gonzalez,[1] P. H. Josephic, and R. A. Oriani*

United States Steel Corporation, Research Laboratory, Monroeville, Pennsylvania 15146

ABSTRACT

A mechanism for the undercutting of scratched lacquers on black plate (uncoated low-carbon steel sheet) is proposed. Experimental evidence leading to its postulation and some tests carried out to confirm it are summarized. It is believed that the undercutting at breaks in coatings on black plate is initiated by the electrochemical reduction of the air-formed iron oxide film between metal and lacquer effectively to enlarge the break in the film. The subsequent corrosion of exposed steel results in the final undercutting. The stability to reduction of the chromium oxide in the chrome coating of TFS and the absence of iron oxide therein, are the reasons for the resistance of TFS to undercutting.

One of the usual performance tests for coating systems on food and beverage containers is the immersion of container material with scratched coatings in citric acid-sodium chloride solutions. After some tens of hours of immersion at room temperature, organic lacquers deposited on black plate (uncoated, low-carbon steel sheet) exhibit an undercutting which is characterized by extensive corrosion under the lacquer film extending laterally from the scratch. A similar immersion leaves lacquered TFS (*i.e.*, steel plated with chromium-chromium oxide) unharmed. The objective of the work reported here was to elucidate the mechanism of this undercutting, or, from another viewpoint, to understand how the chrome plate affords protection to TFS.

It is evident from Fig. 1 that of the several layers and interfaces which a scratch exposes to the aqueous medium, any one of them can represent the weak link of the assembly, and thus several physical or chemical processes can be postulated as the primary cause for the undercutting. However, for a mechanism to be acceptable it must take account of three aspects of the undercutting: specifically, the extreme difference of behavior of TFS and black plate toward undercutting, the fact that undercutting always proceeds laterally from the scratch, and the observed rate of spreading. This paper summarizes the experimental evidence leading to the postulation of the autoreduction of iron oxide as the responsible mechanism and describes some tests carried out to check its validity.

In practice a specimen is considered to pass the salt-citrate test when the undercutting shown by the scratched coating after a 5-day immersion extends no more than 0.05 mm from the scratch. Lacquered black

Key words: delamination, lacquer films, chrome coatings, autoreduction.

plate in this time interval shows undercutting of several millimeters. However, the initial evidence of damage to the lacquer on black plate can be detected much earlier than this, in about 15 to 30 min after immersion, as a faint uniform bleaching of the lacquer developing as a band adjacent and parallel to the scratch. This change in color of the lacquer can be seen only under moderate and oblique illumination and at magnifications less than 100X. Except for the slight change in color, the lacquer appears otherwise undamaged. Figure 2, a photograph taken of a specimen after an immersion test, illustrates the effect. We have chosen to call this early change delamination, to differentiate it from the final over-all undercutting which is associated with extensive corrosion and a visible separation of the lacquer from the metal. Detection of the delamination reduces the time for assessment of a particular specimen and/or test solution, and allows for practical rate studies. In this investigation we have limited ourselves to the observation of delamination.

Experimental

The routine salt-citric acid test consists of dipping a scratched lacquered specimen into an aqueous solution of 15 g/liter each of citric acid and of sodium chloride, corresponding to 0.07M citric acid and 0.26M NaCl. The *p*H of this solution is 2.1. The lacquer is scratched at right angles to the rolling direction of the underlying metal and sufficiently deeply to penetrate into the steel. The scratch is kept vertical during immersion. We retained essentially the same methodology in this investigation except for variations in bath composition. Where anaerobic conditions were desired, the test was performed in a cell provided with a fritted gas inlet and a water bubbler outlet. Pure argon gas, bubbled first through a chromous sulfate-Zn amalgam solution, and then through a water trap, was used as the gaseous medium. All solutions were similarly deaerated for 1 hr prior to use in the anaerobic tests. The lacquer employed in most of our studies was a phenol formaldehyde heat-cured resin, but some studies were also carried out with two brush-on or dip-type, air-dried lacquers. No significant difference in delamination behavior was observed among the three lacquers.

Close to a hundred delamination tests were performed in different baths with different acids and in two principal *p*H ranges. In these tests the concentration of the particular acid was kept at 0.07M and NaCl was always added to keep the ionic concentration at 0.26M. The tests were performed both aerobically (*i.e.*, in the ambient laboratory atmosphere) and anaerobically as described above. The results obtained can be grouped together and summarized simply in tabular form, Table I. In this table a positive sign (+) indicates that delamination was observed for the particular system; a negative result (−) indicates that no delamination was detected at 40X magnification after at least 24 hr (the detection limit in this case was 0.02 mm). No significant differences were observed in behavior under aerobic or anaerobic conditions, except in one experiment with sodium citrate at *p*H 8 in which delamination was obtained only under aerobic conditions. The *p*H values used were 2.0 and 4.0 (corresponding to those of soft drinks and beer), except where listed otherwise. The principal information to be drawn from Table I is the difference in delamination behavior between systems containing organic acids and those with inorganic acids: delamination was not observed in any inorganic system at or above *p*H 4.0. Column 3 of Table I lists stability constants, K_s, (or over-all equilibrium constants) for the complexes of ferrous ions[2] with the anions of the particular acid; column 4 lists the ionization constants for the acids. The values of the equilibrium constants for complexation indicate that a correlation can be made between appearance of delamination and the complex-forming ability of the particular system. The case of oxalic acid appears anomalous, but an explanation for this will be given later.

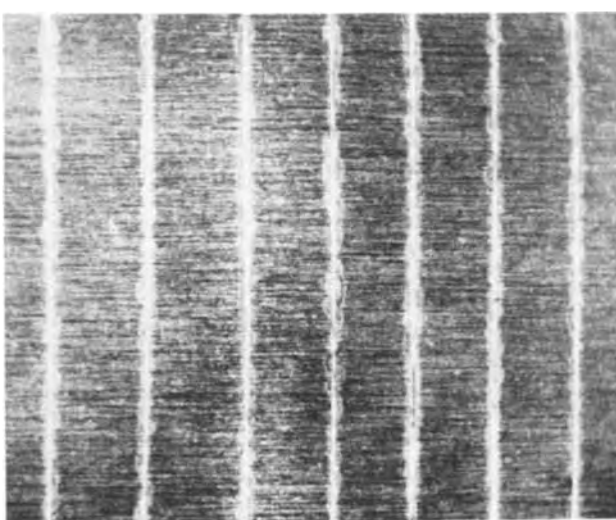

Fig. 2. Photograph of delamination in scratched lacquered black plate after 2 hr in salt-citric acid bath (3.5X). The center white line of the vertical patterns represents the scratch. The contrast has been enhanced in the development of the photograph.

* All acid concentrations 0.07M; ionic strength kept constant at 0.26M with NaCl except for inorganic acids where the salt of the common anion was used. All values of K_s were taken from Ref. (1) except for those for citric and tartaric acids, taken from Ref. (8). The value for the lactate complex was estimated from the values for other divalent cations.

† + indicates occurrence of delamination; − indicates no delamination.

The information in Table I indicates only whether a particular system resulted in delamination or not. In Fig. 3a and b we characterize the delamination further by showing its magnitude and time dependence and also the effect of organic acid concentration and *p*H for a salt-citrate bath. (In these plots the delamination has been measured from the center of the scratch, so that the zero time value includes half the width of the scratch.) Rates of delamination were measured quantitatively only for the systems given in Fig. 3a and b. However, the rates for the other systems producing delamination were of the same order of magnitude.

The effect of changing metal substrate (apart from the use of TFS) was studied by checking the performance of lacquered specimens of stainless steel, low-Cr-Ni alloy (COR-TEN steel), and Cr-phosphated black plate. Of these, only the stainless-steel specimen did not exhibit delamination. The delamination rate for Cr-phosphated steel is shown in Fig. 3b. The difference in behavior between stainless steel and the low-Cr alloy steel would seem to indicate that a minimum

[2] The values for the ferric ion complexes are not included in this table for the sake of simplicity. Ferric ion forms very strong complexes with all these organic anions, with values of stability constants great enough to cause large complexation even at *p*H 2.0. For inorganic anions the values of the stability constants for the ferric complexes are also larger than for the ferrous complexes, and the same general difference in magnitude between the values for organic and inorganic anions is also displayed.

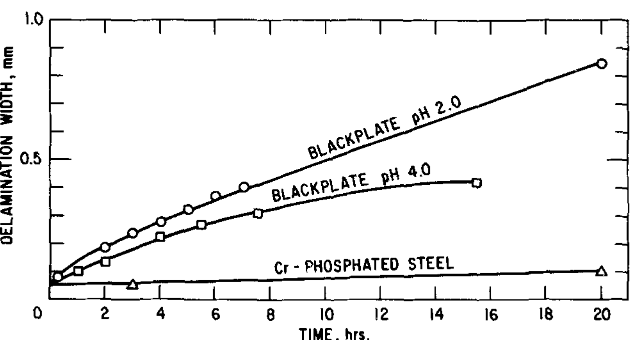

Fig. 3b. Delamination rate of scratched lacquered black plate at longer times. Effect of pH. Delamination rate of Cr-phosphated steel is also shown.

content of Cr in the alloy is necessary to afford protection against delamination.

The use of various etching solutions on black plate prior to lacquering did not significantly change subsequent delamination behavior.

Discussion

The correlation found between the delamination and the complex-forming ability of the acids immediately suggests that delamination could represent the chemical dissolution of the iron oxide film between the lacquer and steel, but enhanced in rate, since the formation of soluble complexes in the aqueous phase will reduce the activity of metal ions and increase the driving force for dissolution, and consequently the rate. Since the rate of formation of Cr^{3+} complexes is known[3] to be several orders of magnitude smaller than for Fe^{3+}, this would explain the lack of delamination in TFS. However, a simple measurement of dissolution rates of the appropriate oxides clearly negates the hypothesis of chemical dissolution. In Table II we list the initial dissolution rates of three forms of oxides determined by us in a solution with and without citric acid. The measurement consisted simply of analyzing for Fe in the aqueous phase of a system of known volume and with a known weight of oxide at appropriate times, and converting the iron concentration to gram-atoms of Fe ions dissolved per square centimeter of surface. (The specific surface area was measured by the BET method.) Although the results show that presence of complexing agents does increase the rate of dissolution by a large

[3] See, for example, Table I of Ref. (2).

* Corresponds to about 0.7 layer of Fe atoms removed per day, or 3A/day.

factor, when the results are converted to a linear basis, the number so obtained (viz., 0.7 atomic layer of Fe ions removed per day) cannot explain the rate of delamination of black plate, which corresponds to about 3×10^5 atomic layers of 50A-thick oxide removed per day.

The simplest mechanism that explains the delamination and is consistent with all the facts is the following: when scratched lacquered black plate is immersed in acidified water, an electrochemical reaction between the metal substrate and the air-formed ferric oxide film occurs which may be written as

$$Fe \rightarrow Fe^{2+} + 2e \quad \text{(anodic reaction)} \quad [1]$$

$$\gamma\text{-}Fe_2O_3 + 6H^+ + 2e \rightarrow 2Fe^{2+} + 3HOH \quad \text{(cathodic reaction)} \quad [2]$$

This process was first invoked by Evans (3), to explain the rapid disappearance of interference colors of oxidized iron surface (a matter of seconds) upon immersion in acid solutions of pH less than 4.0. In contrast, a very slow dissolution occurs (a matter of days) when the same oxide films (removed from the iron substrate by bromine-methanol) are immersed in the same acid solutions. The validity of this mechanism was established by Pryor and Evans in a series of papers (4-6). Pryor and Evans named the reductive dissolution of the iron oxide in contact with iron "autoreduction" to distinguish it from cathodic reduction produced by an external emf. Oswin and Cohen (7) later observed that autoreduction persists up to pH 7.6 if a buffer is present, that is, if an adequate supply of H^+ ions is maintained to allow the cathodic reaction to continue. In delamination, because of the nearly two-dimensional character of the air-formed film, being at most 50A thick, the consumption of hydrogen ions by the cathodic reaction is not easily made up by diffusion, so that a rise of pH occurs. At the right conditions the rise in pH produces the precipitation of ferrous hydroxide locally, strongly inhibiting the cathodic reaction and halting the autoreduction. In the presence of anions which can form soluble complexes with the ferrous ions, the formation of ferrous hydroxide is precluded and the autoreduction persists. It should be noted that in the special case of oxalic acid, the complexing of ferrous ion quickly leads to insoluble ferrous oxalate which also effectively inhibits the cathodic reaction. In fact, ferrous oxalate can be seen deposited at the scratch when scratched lacquered black plate is allowed to remain in contact with oxalic acid solution for periods of 24 hr.

Insight into why delamination in organic acid persists beyond a pH of 4 (whereas it does not in inorganic acids) may be obtained by a calculation of the variation with pH of the fraction of total iron complexed by organic acids. This calculation is summarized in Fig. 4a for the Fe^{2+}-citric acid system. The complexes formed by ferrous ion are ($FeHCit^+$) and ($FeCit^-$) (8); Fig. 4a shows

$$([FeHCit^+] + [FeCit^-])/([Fe^{++}] + [FeHCit^+] + [FeCit^-])$$

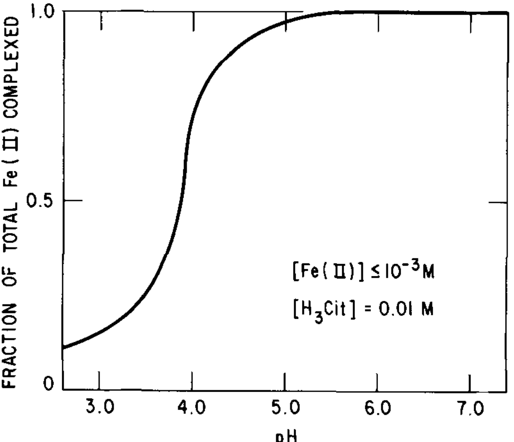

Fig. 4a. Fraction of total iron complexed in ferrous ion-citrate system as a function of pH; values computed from constants determined by Timberlake (8). Note $[Fe(II)] \equiv [Fe^{++}] + [FeHCit^{+}] + [FeCit^{-}]$.

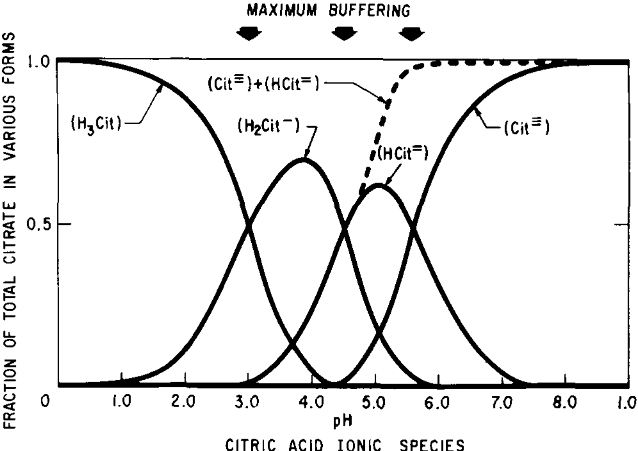

Fig. 4b. Fraction of anionic species present in citric acid as a function of pH. Ionization constants taken from Timberlake (8).

against pH, and one sees that the amount of complexation, and hence of the solubilization of ferrous hydroxide, increases sharply about the pH of 4. In Fig. 4b the fraction of the various anionic species in citric acid is plotted against pH, and the reason for the rapid rise of complexation around pH 4.0 seen in Fig. 4a becomes evident. An inspection of the values for the ionization constants $[pK_a \equiv (-\log K_a)]$ for the organic acids listed in Table I, shows that the same behavior with pH can be expected for all these acids. It should also be noted that for all these acids, the listed values of pK_a also indicate that maximum buffering action can be expected around pH 4.0, a fact which contributes to the persistence of delamination. Moreover, the formation of soluble ferrous complexes at the same time reduces the activity of ferrous ion, and hence increases the driving force of both cathodic and anodic reactions, another contributing factor.

On a thermodynamic basis for the system considered, Cr_2O_3 is not expected to reduce in the presence of H^+ ions at the existing potential. The Nernst potential for the reduction of Cr_2O_3 to Cr^{++} at pH 4.0, and at an activity of Cr^{++} ion of 10^{-6}, is about 0.3V more negative than for the reduction of H^+. This may be checked by referring to the appropriate Pourbaix diagram (9). Caplan and Cohen (10) have proved this to be true kinetically as well, by observing H_2 evolution rather than the reduction of Cr_2O_3 during cathodic reduction under an impressed current at pH 7.6. Thus, the protection against delamination provided by the chrome coating on TFS is imparted by the inherent stability of Cr_2O_3.

The proposed mechanism has been examined by three very simple electrochemical techniques devised to answer three questions:

1. Does the air-formed oxide film in black plate in fact dissolve through a cathodic reduction, and at what rate? This was answered by noting the current obtained upon immersing a specimen of unlacquered black plate into a standard salt-citrate bath electrically connected through a known resistance to a large-area specimen of unlacquered black plate placed in the bath some minutes before. The experimental arrangement is shown schematically in Fig. 5a. The currents observed in this fashion are reproduced in Fig. 6 for two specimens of black plate. The polarity of the currents observed indicated that the electron flow was from the large-area black plate to the specimen, as required by the reduction process (Eq. [2]) of the oxide upon it. The results indicate that the oxide is reduced in about 4 min. The initial current rise can be converted to the number of Fe atoms dissolved per square centimeter per hour, thence to the number of atomic Fe layers removed per hour from the iron oxide, assuming 10^{15} Fe atoms per square centimeter. This number, applied to the lateral dissolution of the 50Å oxide film, gives for a calculated rate of delamination a value of 0.03 mm/hr, which is within the order of magnitude of the delamination actually observed, 0.1 mm/hr. Figure 6 indicates also the very small transient current observed when a specimen of TFS is immersed into the bath, confirming the fact that the oxide film of TFS is not reduced by simple contact with Fe.

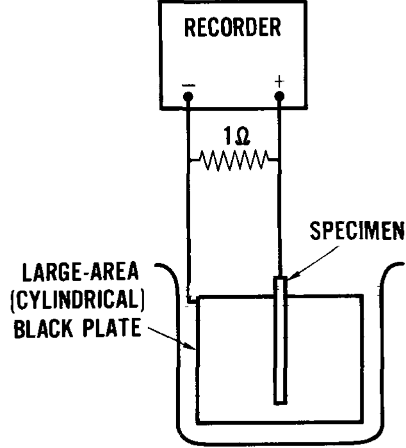

Fig. 5a. Schematic diagram of experimental arrangement for detection of current transients in reductive dissolutions of oxide films on steel.

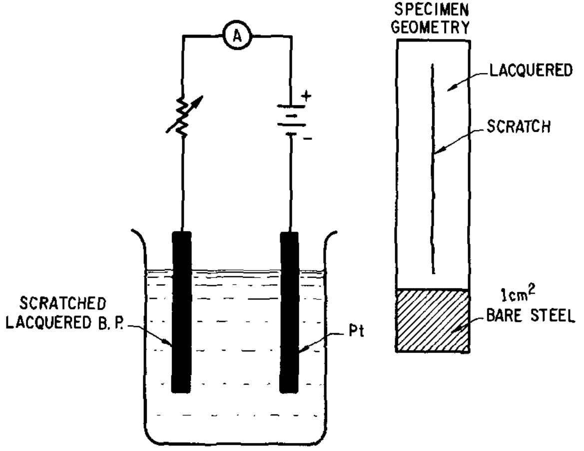

Fig. 5c. Schematic diagram of experimental arrangement used to apply an anodic current to scratched lacquered black-plate specimen.

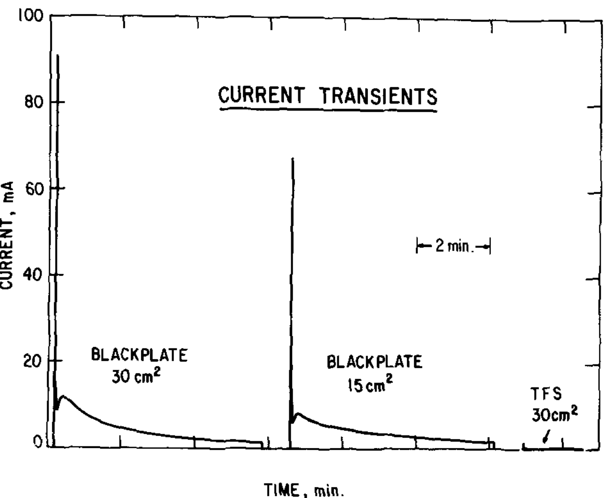

Fig. 6. Current transients observed with black plate and with TFS. The area figures refer to the centrally hung specimen (see Fig. 5a), which is much smaller in area than the surrounding large-area electrode.

2. How will the presence of a more efficient anode affect the delamination? For this test (Fig. 5b) a large-area Zn sheet was short-circuited to a specimen of scratched lacquered black plate, and the two specimens positioned so that the scratch was only 1 mm away from the Zn; the assembly was then immersed in a standard salt-citrate bath. The delamination measured after 2 hr was found to be twice that given by Fig. 3b. (A standard salt-citrate test on a scratched black-plate specimen was simultaneously performed as a control.) Since our experimental scatter in measuring delamination rates was always better than 10%, this result is significant and indicates that delamination is anodically controlled.

3. Can the application of a current to a scratched black-plate specimen stop the delamination? In other words, can the oxide film be made passive? The experimental arrangement used here is shown in Fig. 5c. A current density of 50 mA/cm² was used, this value having been selected from the conversion of the delamination rates observed (Fig. 3a) to a current density, assuming the delamination to occur in a slab of thickness 50Å. (The density of the oxide was assumed to be 4.0 g/cm³.) This large current density, of course, leads to considerable anodic dissolution of the black plate, so that the time of experiment was confined to 1 hr. The current had the effect of widening and deepening the scratch, as was expected, but no evidence of delamination was observed. However, this test is not conclusive since all that can be said is that if delamination occurred it did not stay ahead of the corrosive widening of the scratch.

These tests leave no question as to the electrochemical nature of the delamination and indicate that the proposed mechanism is internally self-consistent.

The proposed mechanism implies that the absence of delamination on TFS means that a layer of iron oxide does not exist between lacquer and metal in TFS. This is not unreasonable, considering the electrochemical method of application of the chrome plate; however, this was independently verified (11) by examining the surface of TFS for Fe^{++} and Fe^{+++} ions using soft x-ray spectroscopy. Negligible amounts of iron ions were detected on TFS. However, iron ions were found on the surface of Cr-phosphated steel which also exhibits delamination although its outer surface is also chromium oxide.

Conclusions

The proposed undercutting mechanism may be summarized as follows with the aid of Fig. 7.

1. *a.* Upon contact of iron and iron oxide with the aqueous medium through a defect such as a scratch in the lacquer film, the oxide dissolves rapidly by the process of reduction (A), exposing more iron surface and, in effect, enlarging the original defect.

b. The exposed iron surface will corrode as usual (B), introducing iron into the aqueous medium. We have found that only a minor fraction of the iron ions in the aqueous phase are attributable to the corrosion of the iron surface of the original scratch.

2. In the presence of complexing buffering agents, e.g., organic acids, the reduction of the oxide film continues because of the formation of soluble ferrous ion complexes and the maintenance of an adequate H^+ concentration.

3. In the absence of complexing buffering agents, the pH at the oxide cathode goes up rapidly because of the depletion of H^+ ions, and $Fe(OH)_2$ precipitates locally, inhibiting the electrochemical process, and effectively stopping the dissolution of the oxide film.

4. TFS resists undercutting because a ferric oxide layer does not exist between the steel and the chromic oxide layer, and the latter is too stable to be reduced by the oxidation of metallic iron.

Composition of Pt Anode Surfaces by Auger Spectroscopy

W. C. Johnson and L. A. Heldt

Department of Metallurgical Engineering, Michigan Technological University, Houghton, Michigan 49931

ABSTRACT

Auger spectroscopy was employed to study platinum surfaces anodized either in $1N$ H_2SO_4 with evolution of oxygen, or in $2N$ NaCl with evolution of chlorine. For the Pt anodized in H_2SO_4, Pt and oxygen interact to form a stable film of PtO stoichiometry. Anodization in NaCl resulted in a less stable film; although relatively large concentrations of oxygen and chlorine are present after anodization, these are removed by electron beam bombardment in the Auger apparatus.

Numerous studies have been concerned with the nature of the surfaces of Pt anodes in electrolytic cells, particularly the oxygen electrode (1). It has been demonstrated conclusively that Pt is not inert but does interact with oxygen in some manner to produce an altered surface. Direct evidence concerning the state of the oxygen associated with the Pt anode has been difficult to obtain because the affected layer on the Pt is no more than a few atomic layers thick.

Indirect evidence for this interaction has been gained through detailed studies of the electrochemical behavior of Pt electrodes during anodizing and during subsequent cathodic stripping of the resultant anodic films. For example, Thacker and Hoare (2) in a recent study concluded that for Pt anodes in H_2SO_4 solutions, no sorption of oxygen occurred below a potential of 800 mV; from 800-1000 mV oxygen was adsorbed (relatively weakly) on the Pt surface; and that above 1000 mV oxygen was absorbed (dermasorbed) in the first one or two layers of Pt. Evidence for the existence of the dermasorbed oxygen is the difficulty with which this anodic layer is removed during cathodic stripping. At higher potentals (>2000 mV) the behavior of the anode is interpreted in terms of the formation of a PtO_2 monolayer which decomposes to a monolayer of adsorbed oxygen (Pt-O) under open-circuit conditions or at potentials below 1.55V. Further evidence was also obtained for the absorption or dissolution of relatively large quantities of oxygen within the bulk of the Pt; this oxygen is then available for replenishing any adsorbed oxygen lost from the surface.

Interpretations of the several electrochemical studies have given rise to considerable controversy, particularly concerning the question of whether bona fide oxides, PtO and PtO_2, form under various conditions.

It is well known that chloride ions inhibit the formation of oxygen or oxide anodic films. Kuhn and Wright (3) studied the anodization of bright Pt under conditions simulating those of a chlor-alkali electrolytic cell with concentrated NaCl solutions of pH approximately 3. The electrochemical characteristics of Pt during anodization and cathodic stripping in these environments were interpreted in terms of the following phenomena occurring with increasing potential: (*i*) adsorption of Cl^- ions on bare Pt, (*ii*) subsequent adsorption of Cl atoms on adsorbed Cl^- ions, (*iii*) successive replacement of chloride ions by adsorbed oxygen atoms, and (*iv*) full coverage achieved with two oxygen atoms per Pt atom.

In view of the thin nature of the anodic layers formed, an extremely sensitive technique is needed to study the surface chemistry. To date the only direct evidence concerning the state of oxygen on Pt anode surfaces is an ESCA study by Kim, Winograd, and Davis (4); this study revealed an electron configuration for the Pt consistent with the formation of chemisorbed oxygen at a potential of 1200 mV in 1M $HClO_4$. Above 1600 mV increasing amounts of PtO_2 are formed and it becomes the predominant specie at 2000 mV. These results are in general agreement with the interpretation of recent electrochemical results (2). Auger electron spectroscopy (AES) is a relatively new technique which has been proven effective for chemical determination of small amounts of impurities on a solid surface (5-7). It was decided, therefore, that a study of Pt surfaces after anodizing, using AES for surface chemical analysis, could be used to determine directly if oxygen is present and if present provide information about its chemical state. Since AES is a relatively new technique, a short description is given below.

AES.—When an electron is removed from an inner level in an atom by an incident electron (or photon), the atom can fill the vacancy with an outer shell (less tightly bound) electron. The excess energy released can be carried away by an x-ray photon or by ejection from the atom of another outer shell electron, an Auger electron.

Figure 1 gives a schematic example of an Auger emission from a hypothetical solid. In this example a K-level electron is removed by the incident electron beam. When an M-level electron fills the vacancy, the excess energy is carried away by an N-level electron. The kinetic energy of this Auger electron is approximately $E_K - E_M - E_N$ and is characteristic of the electron levels that took part in that emission, hence

Key words: platinum, anode, Auger, oxygen, chlorine.

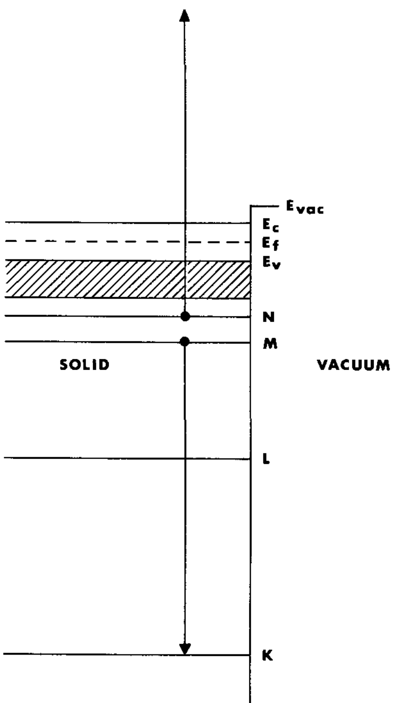

Fig. 1. Schematic energy diagram of an Auger electron emission

of the atom that gives rise to the electron (6). The mechanisms of detection are discussed elsewhere (8-11), but it is important to note that since 50-2000 eV Auger electrons are used for chemical analysis, only the first few atomic layers (3-10Å) can contribute electrons which have not lost energy through scattering. Hence the chemical information obtained using AES applies to the first 1-3 atomic layers of a surface. All AES analysis is done in an ultrahigh vacuum (UHV) system (10^{-9}-10^{-10} Torr).

Experimental

Platinum was cut into 5 mm square foil electrodes for use in the anodizing study. Since analysis of the sample surfaces with AES revealed the presence of carbon, oxygen, sulfur, and other impurity species, a further cleaning technique was required to assure that the anodizing began on a microscopically clean Pt surface. Inert-ion sputtering was used to etch into the Pt samples until the clean Pt surface was exposed. The samples were then removed from the vacuum system and given the anodizing treatment. A control specimen was used to monitor atmospheric effects on the Pt surface chemistry. No contamination due to the atmosphere was noticed on the control specimens; only Pt peaks were observed in the Auger spectrum.

Anodizing procedures.—Two different anodizing treatments were employed to determine the feasibility of applying AES to advantage in studying Pt anode surfaces. Sufficient voltage was provided in both cases to achieve gas evolution.

1. Anodization (16 hr) in 1*N* H_2SO_4 solution with evolution of oxygen. Current density 500 mA/in^2. $T = 26°C$.
2. Anodization (12 hr) in 2*N* NaCl solution, pH 3, with evolution of chlorine. Current density 500 mA/in^2. $T = 26°C$.

After the Pt anodes were removed from the solutions, they were dipped in distilled water to remove any electrolyte adhering to the surfaces and blasted with dry He gas to remove the residual water film. The samples were then transferred quickly to the UHV system and examined with AES after a vacuum in the 10^{-9} Torr range was obtained (10-12 hr). As a qualitative indication of species stability, the electron beam was allowed to bombard the same spot on the samples for various lengths of time and any change in Auger peak height (corresponding to concentration of the given species) noted.

Results

The results of Auger analysis of a surface are usually presented in a spectrum similar to Fig. 2. The peaks superimposed on the relatively smooth background are due to different elements in the first 1-3 atom layers of the surface and are labeled as to species. To obtain a quantitative estimate of the per cent coverage of a particular element, the observed peak is compared to a peak due to a known concentration of that element on a calibrated standard specimen. The calibration for oxygen was obtained from an Al_2O_3 sample; this, in turn, was found to be consistent with results from an MgO sample. In Fig. 2, which represents the Auger spectrum from the surface of the Pt anodized in H_2SO_4, only platinum and oxygen peaks are present. The surface concentration (*i.e.*, atomic per cent coverage in the first few atomic layers) of oxygen on this specimen was approximately 45 a/o (atomic per cent). Figure 3 presents the oxygen concentration as a function of time under electron beam bombardment. It was observed that the oxygen concentration remained constant, with the slight variation due to error in measurement of the O peak.

The spectrum of the Pt anodized in NaCl is presented in Fig. 4. In this case, Cl was observed as well as Pt and O. However, after 20 min of electron beam bombardment, both the O and Cl peaks had decayed to a small

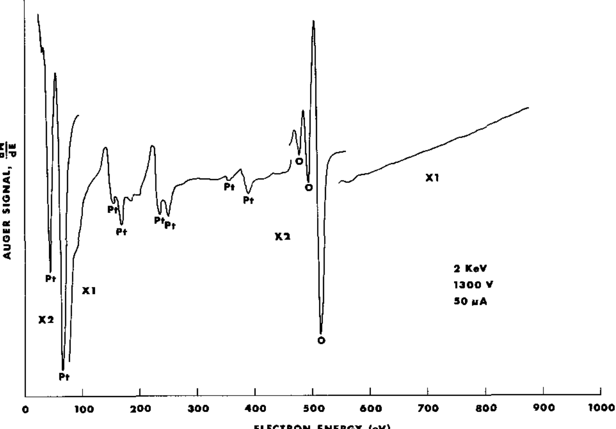

Fig. 2. Auger spectrum of Pt surface anodized in H_2SO_4

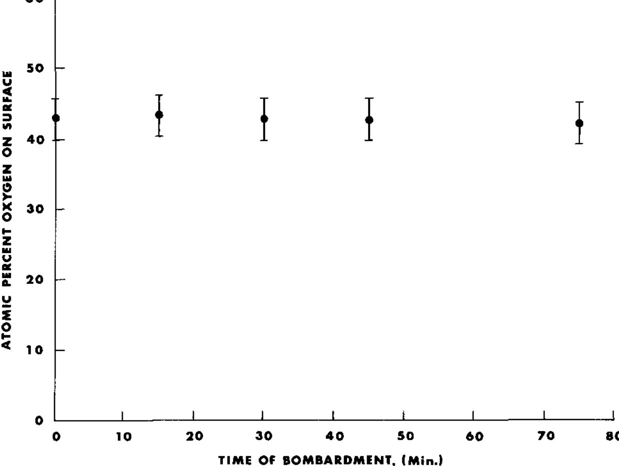

Fig. 3. Effects of electron bombardment on the oxygen concentration of H_2SO_4 anodized Pt surface.

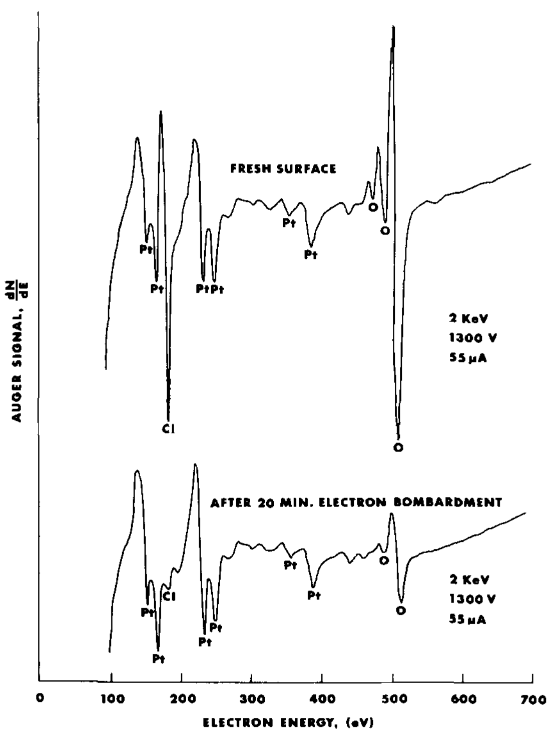

Fig. 4. Auger spectrum of Pt surface anodized in NaCl

fraction of their original size. Since the oxygen and chlorine peaks decayed continuously with time, the initial coverages could not be measured.

Discussion

H_2SO_4 electrode.—Analyses of the Pt anode surfaces by AES have revealed directly the presence of oxygen in an extremely stable state of combination or sorption capable of persisting under electron bombardment at pressures of less than 10^{-9} Torr. The surface contains about 50% oxygen, corresponding to a composition of PtO. The high stability is consistent with the fact that the anodic film is difficult to remove during cathodic stripping (1).

The stoichiometry of the anodic layer does correspond to the oxide, PtO, reported to be stable in vacuum (13). This stoichiometry also corresponds with the interpretation of Thacker and Hoare (2) of their electrochemical data. It is possible that oxygen is adsorbed or dermasorbed strongly enough to be present in this concentration and in this stable a state; if this is the case, the characteristics (stoichiometry and stability) would be difficult to distinguish from an oxide (3).

NaCl electrode.—The AES results in this case indicate the presence of both chlorine and oxygen at the Pt surface. Both persist in the hard vacuum but are removed with time by the electron bombardment. This appears to correspond with the third stage of polarization described by Kuhn and Wright (3), namely, partial replacement of a part of the adsorbed chlorine by adsorbed oxygen. It is apparent that the oxygen is not bound as strongly under these conditions as for the H_2SO_4 electrode.

Conclusion

In summary, AES is capable of detecting anodization products present in thin layers on anodized Pt. Additional studies are warranted in which adsorption and/or combination is measured in conjunction with potentiostatic measurements of potential-current characteristics over a range of potentials.

Anodic Deposition of Ferric Oxy-Hydroxide Films on Platinum from Perchlorate Solutions

Koji Hashimoto[1] **and Morris Cohen***

Division of Chemistry, National Research Council, Ottawa, Ontario, Canada

ABSTRACT

The effect of pH and added anions such as phosphate, acetate, chloride, or sulfate in perchlorate solutions on the anodic deposition of ferric oxy-hydroxide films on platinum was studied. In all cases deposition took place by the oxidation of a ferrous species to a ferric film with 100% current efficiency. The growth rate of the film was dependent on the concentration of $FeOH^+$ ion which was the depositing species in a ferrous perchlorate solution and in the solutions containing acetate, chloride, or sulfate. In the solution containing phosphate, the anodic deposition proceeded by the simultaneous oxidation of $FeOH^+$ and $FeH_2PO_4^+$ ions to γ-FeOOH and $FePO_4 \cdot 2H_2O$.

In previous investigations it was shown that "protective oxide films" could be formed on iron by either direct anodic oxidation of iron (1) or by deposition from aqueous solutions containing dissolved ferrous ion (2, 3). It was also shown that similar films could be deposited on platinum (4). The mechanism of deposition is independent of the substrate metal, but measurements of current efficiency and analysis of the films are less complex using a platinum substrate.

The composition of the films was found to be partially dependent on the anions present in the solution so that films formed in borate (4) or sulfate (5) solutions contain boron or sulfur, respectively. This would indicate that at least part of the film is formed by anodic oxidation of ferrous ion complexes.

In the study reported below the electrolyte was mainly ammonium perchlorate solution containing ferrous ion. The perchlorate ion is usually considered not to form complexes with cations. The effect of other anions on the anodic deposition mechanism and the composition of the film was studied by the addition of phosphate, acetate, chloride, and sulfate to the perchlorate solution. The effect of these results on considerations of the formation and properties of passive film on iron is discussed.

Experimental

The apparatus for the anodic deposition was the same as that reported elsewhere (4). Smooth platinum sheets 5 × 1 cm with small handles were used as specimens. The purification of the platinum surface was carried out as follows. After oxidation of platinum specimens at 900°C and 1 Torr of oxygen for 24 hr, impurities on the surfaces were dissolved in boiling 1*N*-HCl. The specimens were then annealed under high vacuum ($<10^{-7}$ Torr) at 800°C for 24 hr and were reduced by hydrogen at 1 Torr and 800°C for 8 hr.

An aqueous solution of 0.15*N*-NH_4ClO_4 with different concentrations of $Fe(ClO_4)_2$ was used as an electrolyte whose *p*H was adjusted by the addition of 0.15*N*-NH_4OH solution. In some experiments, $NH_4H_2PO_4$, CH_3COONH_4, NH_4Cl, or $(NH_4)_2SO_4$ was added to the solution in the concentration range of 0.2 to 20 × 10^{-6} mole/liter. The solution was deaerated by bubbling a stream of oxygen-free argon for more than 20 hr. The oxygen-free argon was prepared by passing commercial argon (99.996%) through a column of finely dispersed copper on Kieselguhr, heated at 180°C.

The anodic deposition was carried out by means of a potentiostat at a constant potential of +300 mV (*vs.* SCE) and constant temperature of 25° ± 1°C. The solution was deaerated and stirred by a stream of purified argon at a constant flow. The limiting current measurements were carried out by streaming purified argon over the solution instead of stirring. The weight change of the specimen, G_w, was measured by weighing before and after anodic deposition using a microbalance with an accuracy of ±2 μg. The concentration change of ferrous ion during deposition, G_c, was determined by colorimetric analysis using the o-phenanthroline method (6). The quantity of iron deposited, G_a, was calculated from the total amount of charge determined by the graphic integration of the experimental curve of current density *vs.* time. After the anodic deposition the film was dissolved, G_c', and the weight loss of specimen, G_w' was determined. The initial concentration of ferrous ion was colorimetrically determined because it could not be obtained from the weight of hygroscopic ferrous perchlorate. The phosphate content of the film was measured from the concentration change of phosphate during deposition by means of colorimetric determination as molybdenum blue (7).

The deposited film was identified by means of reflection electron diffraction. In some cases the film was cathodically reduced in steps and reflection electron diffraction patterns were taken to identify the composition of the inside of the film.

Results and Discussion

Perchlorate solution.—Platinum specimens were anodically polarized at a constant potential of +300 mV with various concentrations of ferrous ion at different *p*H's. Examples of the change in the anodic current density with time are shown in Fig. 1. The shape of the curves is almost identical with that obtained by the deposition on platinum in borate (4) and sulfate (5) solutions. The changes in quantity of iron deposited as effected by concentration of ferrous ion and *p*H are shown in Table I. All parts of the film, from the outer side to the inner, which were examined after partial cathodic reduction of the film, corresponded to γ-FeOOH as determined by reflection electron diffraction. In Table I, values of G_w and G_w' were obtained from weight changes after anodic deposition and dissolution of the film, respectively, assuming that the film consisted of γ-FeOOH. The value of G_a was calculated by the following Eq. [2] assuming that the total amount of charge passed during deposition was used for reaction [1]

$$Fe^{2+} \rightarrow Fe^{3+} + e^- \quad [1]$$

$$G_a = \frac{1}{\mathbf{F}} \int_0^t i_a dt \quad [2]$$

where i_a is the anodic current density, t the time of deposition, and $\mathbf{F}$ the Faraday. The value of G_c corre-

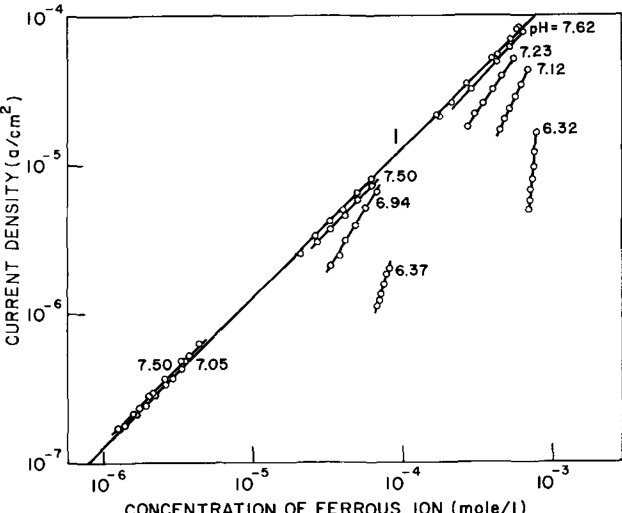

Fig. 2. Relationship between anodic current density and concentration of ferrous ion in 0.15N-NH_4ClO_4 solution.

sponds to the concentration change of ferrous ion during anodic deposition, and the value of G_c' was obtained by dissolving the film in dilute hydrochloric acid. The thickness of the film was calculated from the value of G_a assuming a solid film of γ-FeOOH with a density of 4.07 (8).

As can be seen, the value of G_a is in good agreement with that of G_c, which indicates that the anodic deposition proceeds by the oxidation of the ferrous state to the ferric state with a current efficiency of nearly 100%. The quantity of iron deposited and the thickness of the film should be proportional to the amount of charge passed. Values of G_w and G_w' are always larger than G_a or G_c and changed from day to day because G_w and G_w' were calculated from the weight of film assuming a γ-FeOOH film without water although it did contain some adsorbed water. The water was loosely adsorbed and could be removed by evacuation to 10^{-7} Torr, since vacuum x-ray microanalysis of the film in 10^{-7} Torr showed the atomic ratio of iron and oxygen to be ½ (9).

The concentration of ferrous ion in the solution at any time during the anodic deposition could be calculated from the initial concentration and the total number of coulombs passed up to that time. The relationships between anodic current density and ferrous ion concentration at various pH's are shown plotted on a log-log scale in Fig. 2. At all pH's there is a linear relationship between $[Fe^{++}]$ and current. At high pH's and intermediate or low concentrations of ferrous ion all the results fit a single straight line. At lower pH's the deposition rate (current density) at the same ferrous ion concentration is lower. This would indicate that the depositing species is not simply ferrous ion but is a complex ion the concentration of which is pH dependent and increases with increasing pH. At sufficiently high pH (*e.g.*, 7.5) all of the iron is probably in the complex form.

In that the depositing species is stable at high pH's it is probably $FeOH^+$ formed by the following reaction

$$Fe^{2+} + H_2O \rightarrow FeOH^+ + H^+ \quad [3]$$

and anodic deposition in the perchlorate solutions occurs exclusively by the reaction

$$FeOH^+ + H_2O \rightarrow \gamma\text{-}FeOOH + 2H^+ + e \quad [4]$$

Line 1 in Fig. 6 has a slope of 45° and the data would also give a linear plot on linear coordinates. This indicates that the rate of deposition is probably diffusion controlled and that either the iron in these solutions is mainly present as $FeOH^+$ or that the hydration reaction [3] is very rapid. The fact that the slopes of the other curves shown in Fig. 2 deviate markedly from that of line 1 would indicate that the assumption of an initial high proportion $FeOH^+$ is the more acceptable assumption, although some hydration must obviously take place during the run. However, the initial rate in the steady-state region of deposition (after the sharp initial drop in current due to the formation of the first 30Å of film) is lower at low pH's than high and this is due to a lower $FeOH^+$ concentration.

Table I. The quantity of iron deposited as effected by pH and $[Fe^{++}]$ in 0.15N-NH_4ClO_4 solutions

Experiment No.	pH	Concentration of Fe^{2+} (10^{-5} mole/liter)	Quantity of iron deposited (10^{-7} g-atom/cm²) G_w	G_a	G_c	G_w'	G_c'	Film thickness (A)

Bolzan and Arvia (10) had an average value of log K of −6.74.

Assuming that the current density is directly proportional to the $FeOH^+$ concentration and that the Fe^{++} ion in those solutions following line 1 is mainly present as $FeOH^+$, one can calculate the $FeOH^+$ concentration in those solutions which do not give deposition lines on line 1. This gives the $FeOH^+$ concentration for a range of pH and total Fe^{++} and allows the calculation of a stability constant. The numbers are given in Table II. The average value in the perchlorate solutions is −6.63, which is in good agreement with the value of −6.74 obtained by Bolzan and Arvis (10) using a potential-titration technique. This indicates that the assumption of almost complete hydration to $FeOH^+$ assumed for line 1 is essentially correct. If one takes the value of 6.6 as correct for the stability constant the ratio of $FeOH^+/Fe^{++}$ varies from 25 at pH 8 to 0.25 at pH 6.

The deviation of the slopes of the curves at lower pH's or low Fe^{++} concentration from the slope of line 1 would indicate that the concentration of the depositing species $FeOH^+$ decreases more rapidly than the total concentration of iron in the solution and would indicate that the hydration rate is less than the deposition rate at low pH's and/or Fe^{++} ion concentration.

Perchlorate solution with phosphate.—The platinum specimens were anodically polarized at +300 mV at different pH's in perchlorate solutions containing 8×10^{-5} mole/liter ferrous ion and different quantities of phosphate. An example of the change in anodic current density with time is shown in curve 13, Fig. 1. In Table III are shown the quantities of iron deposited and the phosphate content of the film at various concentrations of phopshate ion and pH after 1 hr deposition. The quantity of iron deposited increased with an increase of pH of the solution at the same concentration of phosphate ion. In solutions with a high concentration of phosphate ion (curve 13, Fig. 1) the quantity of iron deposited was remarkably lower in comparison with that obtained in solutions with a low concentration of phosphate ion and a significantly larger quantity of phosphate ion was contained in the film. Clear electron diffraction patterns corresponding to γ-FeOOH were obtained from the anodic deposition films except for the film in the experiment portrayed by curve 13. A very diffuse diffraction pattern was obtained from the film formed in a solution with 21×10^{-6} mole/liter phosphate ion (curve 13) due to the formation of a fine crystalline or amorphous film. The iron phosphate compound of fine crystalline or amorphous state has been reported to be $FePO_4 \cdot 2H_2O$ (11). If the compound containing phosphate was $FePO_4 \cdot 2H_2O$, the quantity of iron deposited, G_a, can be divided into two portions: one of them corresponds to γ-FeOOH, G_{aFeOOH}, and the other to $FePO_4 \cdot 2H_2O$, G_{aFePO_4}. The latter was estimated from the phosphate content of the film. The thickness of the film was calculated from values of G_{aFeOOH} and G_{aFePO_4} assuming the film to consist of a mixture of γ-FeOOH with a density of 4.07 (10) and of $FePO_4 \cdot 2H_2O$ with a density of 2.87 (12).

As shown in Fig. 3, there were linear relationships between the logs of the anodic current density and ferrous ion concentration. It is, therefore, probable that the rate of deposition in perchlorate-ferrous ion solution with phosphate also depended on the concentration of depositing species. The anodic current density, i_a, can be divided into two parts, that is, current density of γ-FeOOH formation, i_{aFeOOH}, and that of $FePO_4 \cdot 2H_2O$ formation, i_{aFePO_4}. Because the phosphate content of the film increased with decrease of pH (Table III), we assume that the depositing species responsible for the formation of $FePO_4 \cdot 2H_2O$ was $FeH_2PO_4^+$ ion formed by the reaction

$$Fe^{2+} + H_2PO_4^- \rightarrow FeH_2PO_4^+ \quad [5]$$

and that $FePO_4 \cdot 2H_2O$ was formed by the electrode reaction

$$FeH_2PO_4^+ + 2H_2O \rightarrow FePO_4 \cdot 2H_2O + 2H^+ + e^- \quad [6]$$

If we assume that when the concentration of $H_2PO_4^-$ ion was lower than that of ferrous ion, as in the present work, and that the majority of $H_2PO_4^-$ species had formed $FeH_2PO_4^+$ ion before anodic deposition was carried out (*i.e.*, that the reaction [5] is relatively slow), then the concentration of $FeH_2PO_4^+$ ion during anodic deposition can be estimated by subtracting G_{aFePO_4} from the initial concentration of $H_2PO_4^-$ ion. The latter can be estimated at a given pH and using the equilibrium constant of the reaction

Table III. The change in film composition with pH and concentration of phosphate in 0.15N-NH_4ClO_4 solutions

17	6.97-6.90	0.21

$$H_2PO_4^- \rightarrow HPO_4^{2-} + H^+ \quad [7]$$

$$\log K = -7.19 \ (13)$$

In Fig. 4 is shown the change of anodic current density of $FePO_4$ formation, i_{aFePO_4}, as a function of the concentration of $H_2PO_4^-$ ion. If the rate of deposition of $FePO_4 \cdot 2H_2O$ depended only on the concentration of $FeH_2PO_4^+$ ion, the linear relationship should be seen on the figure of i_{aFePO_4} *vs.* concentration of $H_2PO_4^-$ ion. A fairly good linear relationship between anodic current of $FePO_4$ formation and concentration of $H_2PO_4^-$ ion was obtained,[2] although some slight deviation from the ideal gradient of 45° can be seen. It is, therefore, probable that the anodic deposition in perchlorate-ferrous ion solution with phosphate formed the film of γ-FeOOH and $FePO_4 \cdot 2H_2O$ by reactions [4] and [6], and that the rate of deposition depended on the concentration of $FeOH^+$ and $FeH_2PO_4^+$ ions. The lower thickness may be related to the phosphate containing

[2] This current, i_{aFePO_4}, was calculated by subtracting the current due to deposition from the residual iron present as $FeOH^+$ from the total deposition current.

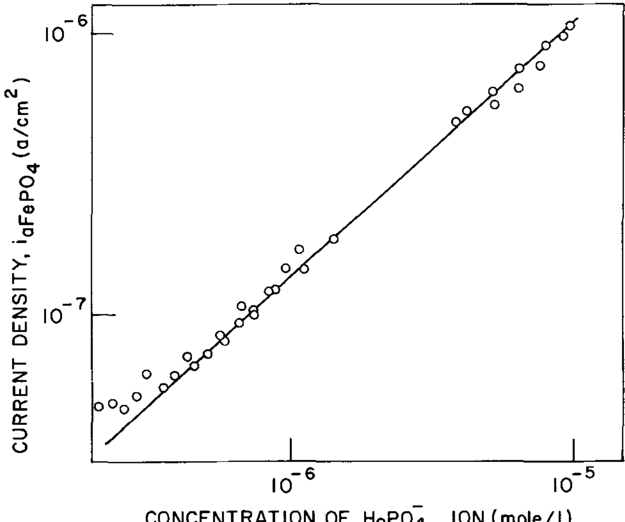

Fig. 4. Change in anodic current density of $FePO_4 \cdot 2H_2O$ formation, i_{aFePO_4}, with concentration of $H_2PO_4^-$ ion.

film having a much higher resistance than γ-FeOOH, thus causing a greater initial current decrease in the first few seconds.

Perchlorate solution with other anions.—The platinum specimens were anodically polarized at +300 mV at pH 7 in perchlorate solutions containing 8 × 10^{-5} mole/liter of ferrous ion plus various concentrations of acetate, chloride, or sulfate ion. An example of the change in current density with time is shown in Fig. 1 (curve 18). The shape of other curves was similar to that of curve 18 although the current density changed slightly with slight changes of initial pH and initial concentration of ferrous ion. All films formed in these solutions were identified as γ-FeOOH and compounds containing acetate, chloride, or sulfate ion were not found in the film by means of electron diffraction or chemical analysis.

The relationship between the quantity of iron deposited and concentration of anions in solutions is shown in Table IV. The value of G_a is again in good agreement with that of G_c, so that the Eq. [1] and [2] are applicable to the anodic deposition in these solutions. The quantity of iron deposited is not remarkably affected by concentration changes of these anions. All the experimental points are very close to one straight line in the relationship between anodic current density and ferrous ion concentration as shown in Fig. 5. The stability constant of the $FeOH^+$ ion in these solutions was estimated as shown in Table II assuming that the anodic deposition proceeded exclusively by the reaction [4]. Although the stability constants showed some variations from those obtained in perchlorate-ferrous

Table IV. The relationship between the quantity of iron deposited and concentration of anions on the anodic deposition for 1 hr in 0.15*N*-NH_4ClO_4 solutions with CH_3COONH_4, NH_4Cl, or $(NH_4)_2SO_4$

Experiment No.	pH	Concentration of Fe^{2+} (10^{-5} mole/liter)	Concentration of anion (10^{-6} mole/liter)	G_w	Quantity of iron deposited (10^{-7} g-atom/cm²) G_a	G_c	G_w'	G_c'	Film Thickness (Å)

23	7.00-6.90	8.42	0.21	2.217	1.903	1.903	2.352	1.920	415
			SO_4^{2-}						
24	7.02-6.97	8.25	21	2.206	1.789	1.787	2.206	1.789	391
25	6.99-6.89	8.14	2.1	2.239	1.785	1.754	2.149	1.783	390
26	7.04-6.94	8.31	0.21	2.048	1.786	1.781	2.104	1.783	390

Methods by which values listed above were obtained are described in Table I. The film thickness was calculated from the value of G_a assuming that the film consists of γ-FeOOH.

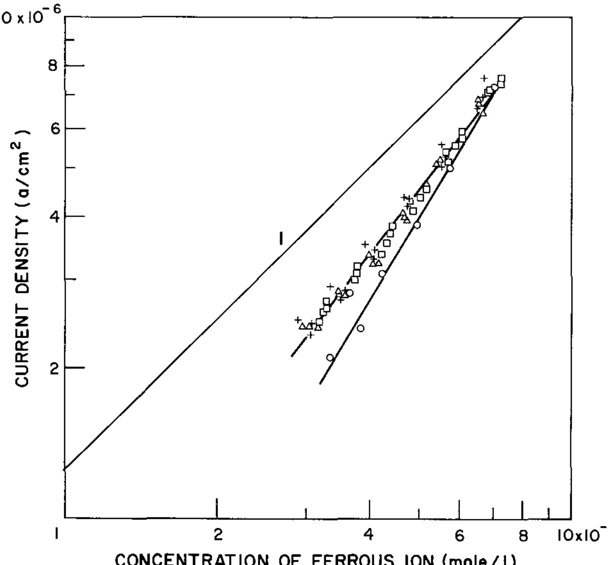

Fig. 5. Relationship between anodic current density and concentration of ferrous ion in 0.15N-NH_4ClO_4 solution with CH_3COO^-, Cl^-, or SO_4^{2-} ion. pH≈7.0-6.9. ○, No addition of other anions; □, CH_3COO^- 20-0.2 x 10^{-6} mole/liter; +, Cl^- 20-0.2 x 10^{-6} mole/liter; △, SO_4^{2-} 20-0.2 x 10^{-6} mole/liter.

ion solution without other anions, it can be said that the anodic deposition in perchlorate-ferrous ion solutions with the addition of acetate, chloride, or sulfate ion proceeded mostly by the reaction [4]. According to Leibenguth and Cohen (5) sulfate was contained in the anodic deposition film formed from Fe^{++} in 0.15N-$(NH_4)_2SO_4$ solution and the sulfate content of the film increased with decrease of pH. Thus $FeHSO_4^+$ ion may play a minor role as one of the depositing species in sulfate-ferrous ion solution.

Diffusion coefficients of depositing species.—In order to obtain the limiting current of oxidation of $FeOH^+$ ion the anodic deposition was carried out in deaerated stagnant perchlorate-ferrous ion solutions without other anions. The results are shown as line 1′ in Fig. 6. In stirred solutions the limiting current as a function of $FeOH^+$ ion concentration was obtained as line 1 in Fig. 2. In solutions with phosphate a linear relationship

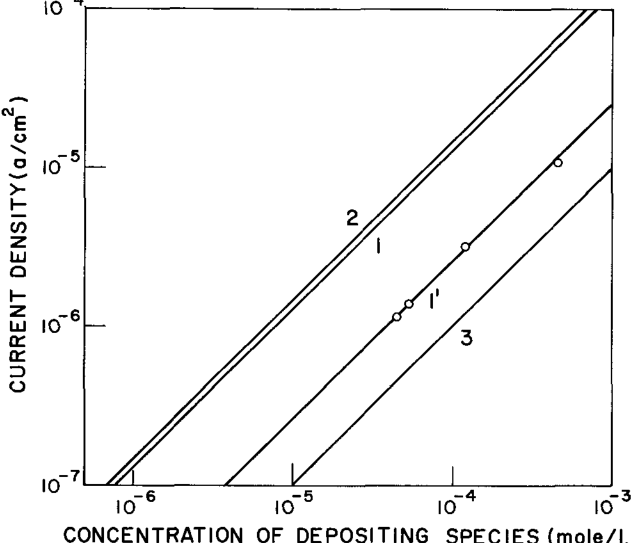

Fig. 6. Effect of concentration of depositing species on the limiting diffusion current of anodic deposition. Curve 1, $FeOH^+$ in ClO_4^- solution with constant stirring; curve 1′, $FeOH^+$ in ClO_4^- solution without stirring; curve 2, $FeH_2PO_4^+$ in ClO_4^- solution with constant stirring; curve 3, in borate-boric acid solution (Nagayama and Cohen).

between anodic current for $FePO_4 \cdot 2H_2O$ formation and concentration of $H_2PO_4^-$ ion was obtained, as seen in Fig. 3, although the gradient of the line is slightly lower than 45°. This has arisen because no account of $FeH_2PO_4^+$ ion formation by reactions [7] and [5] during anodic deposition was taken in calculating the $FeH_2PO_4^+$ ion concentration. If the correction is made to the concentration of $FeH_2PO_4^+$ ion, line 2 in Fig. 6 may be drawn for the anodic current density of $FePO_4 \cdot 2H_2O$ formation *vs.* $FeH_2PO_4^+$ ion concentration in stirred solution. Nagayama and Cohen (2) had obtained line 3 from neutral borate-boric acid solution.

From Fig. 6, diffusion coefficients of depositing species can be estimated by the simple diffusion equation

$$i_a = n\mathbf{F}DC/d \qquad [8]$$

where i_a is the limiting current (A/cm^2) at a concentration of depositing species of C ($mole/cm^3$), $\mathbf{F}$ the Faraday, and d the effective thickness of the diffusion layer which was assumed to be 5×10^{-2} cm in stagnant solution. The diffusion coefficient of $FeOH^+$ ion was approximately 1.3×10^{-5} cm^2 sec^{-1} from the line 1′ in Fig. 6. The effective thickness of the diffusion layer in stirred solution was estimated to be 1×10^{-2} cm assuming the same diffusion coefficient for $FeOH^+$ ion in stagnant solution (line 1′) and stirred solution (line 1). The flow rate of argon for stirring was the same in solutions without phosphate (line 1) and with phosphate (line 2). Therefore, using $d = 1 \times 10^{-2}$ cm in stirred solutions, the diffusion coefficient of $FeH_2PO_4^+$ ion was estimated from line 2 and was approximately 1.5×10^{-5} cm^2 sec^{-1}. The diffusion coefficients seem to be reasonable. The diffusion coefficient of the depositing species in neutral borate-boric acid solution had been reported as 5×10^{-6} cm^2 sec^{-1} (2). This confirms a previous observation (4) that deposition in borate solution is partly via a ferrous borate complex.

Summary

1. The anodic deposition of films on platinum from ferrous ion in perchlorate solutions with and without addition of phosphate, acetate, chloride, and sulfate was studied.

2. In the ferrous solutions containing only perchlorate ion the film was γ-FeOOH and was formed by anodic oxidation of $FeOH^+$ ion. The rate of deposition depended only on the concentration of $FeOH^+$ ion. The stability constant K of the $FeOH^+$ was estimated as log $K = -6.63$.

3. In ferrous-perchlorate solutions containing phosphate ion the film was a mixture of γ-FeOOH and $FePO_4 \cdot H_2O$ and was formed by the simultaneous oxidation of $FeOH^+$ and $FeH_2PO_4^+$ ions. The resistance of the phosphate-containing film is probably higher than that of the other films.

4. In perchlorate-ferrous ion solution with acetate, chloride, or sulfate the anodic deposition proceeded mostly by oxidation of $FeOH^+$ ion to γ-FeOOH film.

5. Diffusion coefficients of $FeOH^+$ and $FeH_2PO_4^+$ ions were estimated as $D_{FeOH^+} = 1.3 \times 10^{-5}$ cm^2 sec^{-1} and $D_{FeH_2PO_4^+} = 1.5 \times 10^{-5}$ cm^2 sec^{-1}.

The Cathodic Reduction of Gamma-FeOOH, Gamma-Fe_2O_3, and Oxide Films on Iron

Morris Cohen* and Koji Hashimoto[1]

National Research Council of Canada, Ottawa, Ontario, Canada

ABSTRACT

A comparison has been made of the galvanostatic reduction of iron oxide films formed by deposition on platinum and by anodic or air oxidation of iron. The major reduction process is that of Fe^{+++} ion to Fe^{++} ion in solution. Some ferrous ion is adsorbed on the unreduced oxide. There is no evidence for reduction to an intermediate solid phase. The results indicate that the two waves observed in the cathodic reduction of anodically formed (or air-formed) films are due to the presence of the two "phases" Fe_3O_4 and γ-Fe_2O_3 in the as-formed films.

Thin iron oxide films of various compositions can be formed in a variety of ways, such as by dry oxidation of iron, direct anodic oxidation of iron, and deposition on either iron or platinum from ferrous ion in solution. In previous work it was shown that films formed in iron by either anodic oxidation (1) or dry oxidation at low temperatures (2) have quite similar cathodic behavior. Cathodic reduction curves in neutral borate solutions showed two waves, one corresponding to the reduction of ferric ion in the outer layer of γ-Fe_2O_3 to give Fe^{++} in solution and the other to the reduction of underlying Fe_3O_4 to give a combination of Fe^{++} in solution and reduced iron. Although two waves are observed, it is not implied that there are two distinct phases with a sharp grain boundary in between in these thin films. The films have a composition varying from Fe_3O_4 near the metal to γ-Fe_2O_3 or even $Fe_{2-x}O_3$ at the outer surface.

In the work reported here this previous cathodic reduction behavior is compared to the cathodic reduction of films deposited on platinum. As was shown in the earlier work, the films deposited from Fe^{++} ion in borate solutions (3) are amorphous and contain borate, while those deposited from Fe^{++} in sulfate (4) or perchlorate (5) solutions are crystalline and gave the electron diffraction pattern of γ-FeOOH. In both cases the iron in the films was almost completely in the ferric state. It was also previously shown (4) that the γ-FeOOH films could be converted to γ-Fe_2O_3 by vacuum heating and exposure to air. This type of γ-Fe_2O_3 was also cathodically reduced and the results compared to those obtained from reduction of both the deposited films and films on anodically oxidized iron.

Experimental

The anodic deposition on previously cleaned platinum was carried out in a borate buffer solution of pH 8.4 (made by mixing equal volumes of 0.3 mole/liter H_3BO_3 and 0.075 mole/liter $Na_2B_4O_7 \cdot 10H_2O$) or 0.15N-NH_4ClO_4, both containing $FeSO_4(NH_4)_2SO_4 \cdot 6H_2O$. The solution used for cathodic reduction was the slightly basic borate solution (pH = 8.4) without ferrous ion. A 1N-HCl-0.55N-H_3PO_4 solution was used for the dissolution of residual films on platinum after cathodic reduction. H_3PO_4 was added to stabilize the ratio of ferrous ion to ferric ion in solution (6). Solutions used for anodic deposition, cathodic reduction, and dissolution of films were deaerated by bubbling oxygen-free argon through the solution via a sintered disk for over 40 hr.

Anodic deposition was carried out on platinum specimens of a total area of 10 cm^2 at a constant potential[2] of +300 mV and a constant temperature of 25° ± 1°C in a solution stirred by bubbling argon at a constant flow. Immediately after anodic deposition, the cell with the specimen was rinsed 3 times by the borate-boric acid solution and then cathodic reduction was carried out at a constant current density of 10 μA/cm^2 at a constant temperature of 25° ± 1°C in stagnant borate-boric acid solution under argon flow. After an appropriate time, cathodic reduction was interrupted and the solution was stirred by bubbling the argon for 1 min and was then drained from the cell to determine the weight of dissolved iron by the o-phenanthroline method. The cell with specimen was then rinsed 3 times with the borate-boric acid solution and deaerated hydrochloric acid-o-phosphoric acid solution transferred into the cell to dissolve the residual film on the platinum. The solutions formed by the dissolution of the residual film were analyzed using the o-phenanthroline (7) for total iron and $\alpha\alpha'$-dipyridyl for ferrous ion.

Anodic deposition takes place with a current efficiency of 100% (2) from ferrous ion to ferric oxide film. Consequently the thickness of the deposited film can be obtained from the graphic integration of current density-time curves of anodic deposition. The deposited film from the perchlorate solution was identified as γ-FeOOH by electron diffraction (5). The deposited film from the borate-boric acid solution was estimated to be $Fe \cdot B_{0.32-0.35}O_{2.0-2.2} \cdot H_x$ using the technique of vacuum x-ray microanalysis (8). Some of the γ-FeOOH films were annealed under vacuum at about 10^{-8} Torr at 180°C until no release of water from the specimens was observed by a mass spectrometer. Then the films

were exposed to air for 5 days and electron diffraction patterns which corresponded to γ-Fe_2O_3 were taken. These films were used for cathodic reduction as specimens of γ-Fe_2O_3.

Results

As had been observed previously with films formed in sulfate solutions (4), the γ-FeOOH films on platinum could not be reduced by a single cathodic reduction step. In Fig. 1 are shown a series of cathodic reduction curves for a specimen originally covered with a film containing 9.55 μg Fe/cm^2 ($\approx$ 400Å). Curve 1 is the initial cathodic reduction curve and shows a long plateau during which iron is being reduced to give Fe^{++} in solution with quite a high current efficiency. However at point A (Fig. 1), at which the second plateau is reached, there is still about 15% of the original iron (1.0 μg Fe/cm^2) left on the platinum. Renewing the deaerated borate buffer solution and re-applying the cathodic current gives a potential curve without a reduction plateau and no further iron is put into solution. If, however, the specimen is first exposed to air before further cathodic treatment, a second reduction wave is observed, as shown in curve 2, Fig. 1, and more iron is put into solution. This can be continued until at about the fourth cycle no further iron goes into solution although a reduction wave is observed. This may indicate that at that point the metal is completely reduced to deposited metallic iron, which oxidized on exposure to moist air. After each cathodic reduction and exposure to air the specimen gave an electron diffraction pattern of γ-FeOOH. No other oxide was identified.

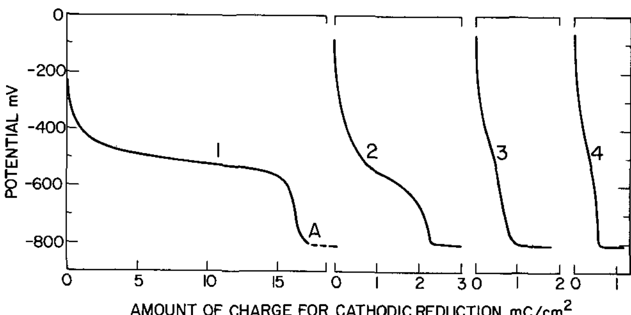

Fig. 1. Successive cathodic reduction curves for γ-FeOOH on platinum. Specimen exposed to air after each reduction cycle. At point A over 80% of the film was reduced.

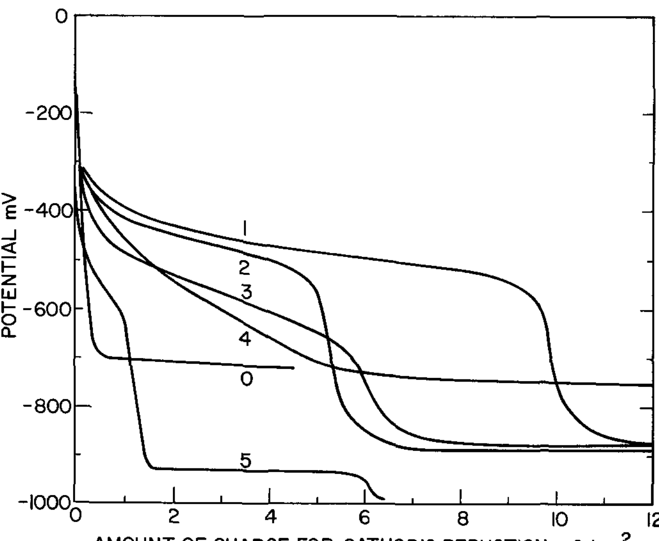

Fig. 2. Cathodic reduction curves for various films. 0—clean platinum. 1. Thick film deposited from borate. 2. Thinner film ($\approx$200Å) from borate. 3. γ-FeOOH film deposited from sulfate. 4. γ-Fe_2O_3 on platinum. 5. Anodically formed oxide film on iron.

The cathodic reduction curves for the various films are shown in Fig. 2. Curves 1-4 are for various deposited films while curve 0 is for platinum and curve 5 for anodically oxidized iron. Tables I-IV contain a summary of the data for each of the deposited specimens with regard to both anodic and cathodic charges in coulombs and the weights of total, ferric and ferrous iron. Analyses of the films were made for total iron and ferrous ion. Ferric ion was obtained by difference. Only ferrous ion was found in solution after cathodic reduction. The weight of residual ferric ion in the deposited

films decreased linearly with time. The calculated current efficiency, based on the current going to the reduction of ferric ion to ferrous ion, was 90+% for the γ-FeOOH films and about 80% for the γ-Fe_2O_3 film on platinum.

Plots of the Fe^{++} in solution after cathodic reduction *vs.* coulombs for films of the same ferric ion content formed in three different ways are shown in Fig. 3. The results for films deposited from borate or perchlorate are almost identical. The apparent current efficiency in the linear portion of the curve is almost 100% for appearance of Fe^{++} in solution. The current efficiency for the film converted to γ-Fe_2O_3 is slightly less than 100%. However, the γ-Fe_2O_3 can be completely reduced to Fe^{++} in solution by one long cathodic reduction treatment. The γ-FeOOH film stops reducing after only about 80% of the Fe^{+++} ion is reduced. At that point the film also contains some ferrous ion, and as pointed out earlier, further reduction is only possible if the specimen is first exposed to air.

Discussion

The cathodic reduction behavior of the films on platinum are quite different depending on whether they are reduced as deposited or after heating in vacuum to convert to γ-Fe_2O_3. They also differ from anodically formed or air-formed oxide films on iron. This over-all difference in behavior is related to both the initial film composition and to the disposition of the ferrous ion formed during the reduction of the ferric oxide film. A sensible interpretation of the cathodic behavior is only possible by a comparison between the various films in relation to both their method of formation and their reduction products.

The basic cathodic reduction reaction is

$$Fe^{+++}{}_{\text{in film}} + e \rightarrow Fe^{++} \quad [1]$$

The ferrous iron can either go into solution or remain in the film as an adsorbed or occluded species. The solubility of $Fe(OH)_2$ in these solutions is sufficient to allow all the ferrous ion to go into solution. Sato *et al.* (9) have suggested that the Fe_2O_3 or FeOOH might reduce to Fe_3O_4. In the experiments reported here some ferrous iron is found in the deposited films both as deposited and as converted to γ-Fe_2O_3 after various stages of cathodic reduction. The amount first goes up and then decreases as the film is further thinned. At the end of the cathodic reduction of the pure γ-FeOOH films formed in perchlorate solution, the Fe^{++}/Fe^{+++} ratio (0.8) is quite far from that for Fe_3O_4 (0.5). An Fe_3O_4 pattern is never observed by diffraction after cathodic reduction. The γ-Fe_2O_3 film is completely reduced and the Fe^{+++}/Fe^{++} ratio of Fe_3O_4 is never observed.

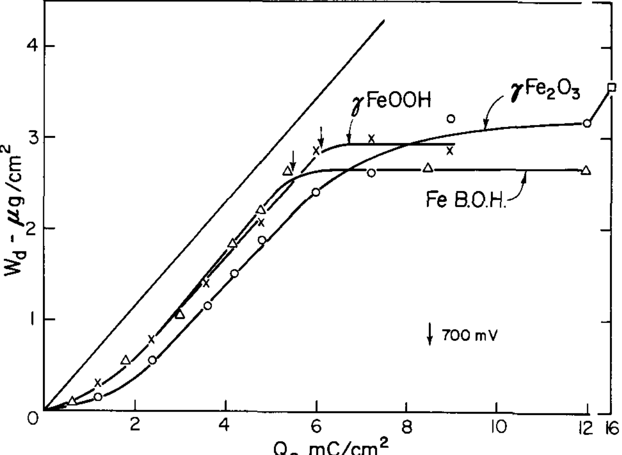

Fig. 3. Amount of ferrous ion (W_d) in solution at various stages (Q_c) of cathodic reduction. The solid line is the theoretical at 100% current efficiency.

These facts indicate that Fe_3O_4 is not formed as an intermediate reduction product for either γ-Fe_2O_3 or FeOOH.

The current efficiency for the cathodic reduction of γ-FeOOH is dependent on how the calculation is made. If we use the amount of Fe^{+++} left in the film the current efficiency based on Eq. [1] for about 80% of the reduction (to a potential of −700 mV) is over 90%. The current efficiency then drops and apparently some of the current is used in the production of both hydrogen and metallic iron. Based on previous work, which showed a very low current efficiency for the reduction of Fe_3O_4, the high current efficiency suggests that Fe_3O_4 is not a major intermediate product. The current efficiency for the reduction of the γ-Fe_2O_3 over the major portion of the curve is somewhat less than this at about 80% (again based on residual Fe^{+++} ion in films), and may be due to the early partial baring of platinum and hence earlier evolution of hydrogen.

If the current efficiency is calculated on the basis of an analysis of Fe^{++} in solution, a different result is obtained. In all cases the current efficiency is initially small and then approaches 1 over the intermediate range. In the case of the deposited films, both from borate and perchlorate, at about −700 mV no further increase of ferrous iron in solution is observed. With γ-Fe_2O_3, although the current efficiency drops after about 80% if the film is dissolved, the Fe^{++} iron concentration continues to increase until the whole film is reduced. With the FeOOH type films further reduction is only possible if the specimen is first exposed to air. These results indicate that the major portion of the film is reduced directly to Fe^{++} in solution with high current efficiency. Some of the Fe^{++} remains in the film as an occluded or adsorbed species. The amount remaining in the film gradually decreases as the film thins, again suggesting an adsorbed species which decreases in amount as the film area and volume decrease. The reduction of the γ-FeOOH ceases before it is completely reduced because it is shielded from the solution by the adsorbed Fe^{++} species, and the alternative reactions to evolve hydrogen and reduce the ferrous species to iron can take place. On exposure to air both the ferrous species and iron are oxidized and allow further cathodic reduction.

The potentials at which the various processes take place are of some interest. The potential for the cathodic reduction of γ-FeOOH on platinum appears to be a little higher than that for γ-Fe_2O_3 on iron. This higher potential for the reduction of γ-FeOOH was also observed by Nagayama (10) for γ-FeOOH formed on top of passive iron. The waves for the reduction of γ-Fe_2O_3 on platinum or iron occur at essentially the same potential. The γ-Fe_2O_3 on platinum shows only a single wave, *i.e.*, a single stage reduction, and the final potential is only slightly less than that for hydrogen evolution on platinum (−710 mV). In contrast to this the final potential for the reduction of γ-FeOOH is much lower than this (−875 mV) and probably corresponds to that for hydrogen evolution on a contaminated (with film and possibly iron) platinum surface. The potentials for the cathodic reduction of magnetite on iron and hydrogen evolution on iron both take place at lower potentials than any of those observed during cathodic reduction of the films on platinum.

The two stage cathodic reduction of oxide films on iron has also been observed with films formed by dry oxidation at both low and medium temperature and always corresponded to the reduction of Fe_2O_3 and then Fe_3O_4. The potential arrests for the reduction of the γ-Fe_2O_3 and Fe_3O_4 were the same as those observed during the reduction of the anodically formed oxide film on iron. If the iron is oxidized at a temperature sufficiently high to form a film composed of α-Fe_2O_3 and Fe_3O_4, two reduction waves are again observed. The wave for the reduction of α-Fe_2O_3 takes place at a more negative potential than that for γ-Fe_2O_3.

Conclusions

The current efficiencies for the reduction to Fe^{++} ion are high for the major portion of all the films which were studied.

Thick films of γ-FeOOH cannot be completely cathodically reduced to Fe^{++} in solution in a single step. This is due to a combination of adsorption of the ferrous species and some complete reduction to metallic iron. There is no evidence for the formation of Fe_3O_4 as an intermediate reduction phase.

Gamma-Fe_2O_3 film can be completely reduced to Fe^{++} ion in solution in a single step.

The two waves observed in the cathodic-reduction of both air-formed and anodically formed films on iron correspond to layers of γ-Fe_2O_3 and Fe_3O_4 in the as-formed films.

Range Profiles for Ions Implanted into Anodic Tantalum Oxide

J. P. S. Pringle*

Chalk River Nuclear Laboratories, Atomic Energy of Canada Limited, Chalk River, Ontario, Canada

ABSTRACT

Radioactive $^{24}Na^+$, $^{42}K^+$, $^{85}Kr^+$, $^{86}Rb^+$, $^{125}Xe^+$, $^{134}Cs^+$, $^{204}Tl^+$, and $^{222}Rn^+$ were implanted at 0.5, 1, 2, 5, 10, 20, 40, 80, and 160 keV into anodic tantalum oxide. A sectioning technique, based on slow dissolution of the oxide in concentrated HF almost saturated with NH_4F, was used to obtain integrated range profiles, and these were analyzed for range parameters by means of a least squares fitting procedure. Range profiles at 5 keV and above could be described, within experimental error, as being normally distributed; the modal ranges and standard deviations increased with energy, and with decreasing mass of the implanting ion. The ratio between modal range and standard deviation was such that a portion of the normal distribution extended beyond the oxide surface; evidence showing that a similar fraction of the ions would fail to implant was discussed. Range profiles below 5 keV were much influenced by the nature of the oxide surface, and could be distinguished experimentally in three parts. The first part was located in the contaminant layer adsorbed on the oxide surface, the second in the immediate surface layer itself, and the third at greater depths in the oxide; this last corresponds to the range profiles observed at higher energy. At 0.5 keV, the profile in the third part could be fitted with an exponential; the change to a normal distribution at 5 keV has been interpreted in terms of Poisson statistics.

In the process of ion implantation, a beam of ions accelerated to high energy impinges on the surface of a solid. Most come to rest a short distance into the solid, but a few fail to implant at all. Two concepts describe the situation: the range profile, which measures the concentration as a function of depth beneath the surface, and the sticking factor, which is that fraction of the incident ions that actually remains, or sticks, in the solid. The present paper describes the use of a highly precise sectioning technique (1, 2) to measure range profiles in anodic tantalum oxide; some measurements on the corresponding sticking factors are also reported. The results are used elsewhere (3, 4) in studying the migration process during the anodic oxidation itself.

Range profiles were first reported from this laboratory by Davies *et al.* (5) for radioactive $^{24}Na^+$, $^{86}Rb^+$, and $^{137}Cs^+$ implanted in polycrystalline aluminum. These profiles were markedly skew, for they consisted of a peak near the surface, followed by an approximately exponential tail extending deep into the metal. In subsequent work, Davies *et al.* (6) showed that the exponential tail was due to channeling of the implanted atoms along preferred directions in the crystal lattice. To eliminate the channeling effect, Domeij *et al.* (7) studied range profiles in amorphous solids such as anodic Al_2O_3 and anodic WO_3, and found that the range profiles were "rather symmetric;" Jespersgard and Davies (8) subsequently described them as being "Gaussian in form." Anodic Ta_2O_5 is also believed to be amorphous (9), and so the range profiles should be similar.

These range profiles had all been measured with the aid of sectioning techniques developed by Davies and his co-workers. Aluminum (10) or tungsten (11) was anodized to produce an oxide film, and the latter dissolved in a reagent that would not attack the underlying metal. By repeating this sequence of operations, thin uniform layers could be removed from the surface of the metal, and the range profile for an implanted species determined; by altering the procedure slightly, it was possible to measure range profiles in the anodic oxides as well (7, 8). The resolution of a sectioning

Key words: tantalum, anodic oxide, ion implantation, range profiles.

technique depends on the limiting thinness with which the layers can be removed (1), and the latter was about 40Å for both oxides.

By contrast, the sectioning technique described in a previous paper (1) of this series allowed the removal of layers as thin as 5Å from the surface of anodic tantalum oxide. The significance for range profile measurements is that whereas half the ions implanted at 5 keV are removed with a 40Å layer, half the ions implanted at 0.5 keV are removed with a 5Å layer; range profiles can therefore be measured to much lower energies than before.

Experimental Measurements

Method.—Tantalum coupons, 3.5 × 1.0 × 0.037 cm, were cut from 0.015 in. sheets supplied by the Fansteel Metallurgical Corporation, and polished electrochemically (1). All anodizations were performed at room temperature and 1 mA/cm^2 with the apparatus devised by Walker (12), using 0.1M H_2SO_4 as the electrolyte. The anodized coupons were wrapped in household aluminum foil leaving the middle 2.0 × 0.4 cm of one face exposed; radioactive ions were implanted into the exposed area by means of the Chalk River isotope separator, whose use for this purpose has been described elsewhere (13). The implantation fluences ranged up to 10^{15} ions/cm^2, but were generally less than 10^{13} ions/cm^2. Except for ^{85}Kr, obtained from Oak Ridge, and ^{222}Rn, obtained from the Radium Chemical Company of New York, the radioactive species were all prepared in the NRX and NRU reactors at Chalk River by (n, γ) reactions on the stable precursors.

Range profiles for the implanted ions were obtained by dissolving a series of thin uniform layers in succession from the oxide surface (1) and counting the activity left after the removal of each layer. The dissolution was accomplished using concentrated HF almost saturated with NH_4F, and the thickness of the remaining oxide was measured spectrophotometrically, with a standard error of 1.8Å (1). All counting was performed with a 2π proportional methane counter, the ^{222}Rn being estimated from the β-activity of its decay products by the method of Bergstrom *et al.* (14). Counts and their statistical errors were corrected for counter dead time, background, and radioactive decay by means of a program written for a PDP-5 computer, and expressed as percentages of the initial count. The resulting experimental data, in the form of percentage counts remaining *vs.* oxide thickness remaining, described the integrated range profile, from which the range parameters could be extracted by means of the mathematical analyses of the next section.

The implanting conditions were always adjusted so that the peak of the range profile occurred about 1760Å from the metal/oxide interface; the higher the energy, therefore, the thicker the oxide into which the ions were implanted. This thickness was chosen as standard because it has an interference minimum in third order near 350 nm, right in the middle of the favored 300-400 nm region for the operation of the spectrophotometer (1); thicknesses up to 350Å on either side of 1760Å could be measured without changing orders. Furthermore, the interference color changes very rapidly about 1760Å, from blue at slightly greater thicknesses to red at slightly smaller thicknesses; this feature was very useful for monitoring the uniformity of the implanted area, and hence the uniformity of the oxide dissolution (2).

General description of results.—The characteristics of the integrated range profiles are illustrated in Fig. 1 for 1 keV $^{134}Cs^+$ and 40 keV $^{134}Cs^+$. Each profile consisted of several parts, namely: (*i*) A portion of the activity that could be washed off the surface without any change in oxide thickness. At low energies, this portion could be substantial, and this is why the 1 keV $^{134}Cs^+$ range profile does not start at 100% in Fig. 1. (*ii*) A range profile characteristic of ions implanted at

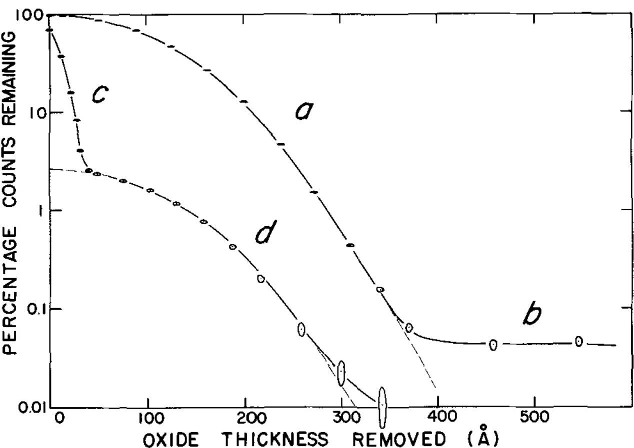

Fig. 1. Integrated range profiles for $^{134}Cs^+$ at 40 keV (a) and 1 keV (c). The fraction of the activity that persists on continued stripping is labeled b, while d represents the neutral tail. Ovals drawn round each point at a radius of twice the standard error indicate the 95% confidence limits; these are ovals rather than ellipses because the plot is semilogarithmic. The abscissa is expressed in terms of oxide thickness removed rather than film thickness remaining to allow comparison of the two samples on a single figure.

the specified energy; these are labeled a and c in Fig. 1. (*iii*) At low energies, such as 1 keV, this profile was succeeded by another, labeled d in Fig. 1. (*iv*) Finally, there was sometimes a very small portion of the activity, labeled b in Fig. 1, that could not be removed even on prolonged stripping.

Removal of activity from the oxide surface.—The status of the oxide surface after implantation will be different from that left after stripping and washing, and so the first point on the range profile will be anomalous. To reduce the anomaly, coupons implanted in the mass separator were washed for 30 sec in distilled water and 15 sec in acetone, according to the procedure described in a previous paper (1). This initial washing had no detectable (0.5%) effect on the counting rate for any noble gas implant, but it did reduce the counting rates for alkali metal implants, as shown in Table I.

Figure 2 shows the effect of repeated washings, 30 sec in distilled water followed by 15 sec in acetone, on foils containing $^{134}Cs^+$ implanted at 0.5 and 1 keV. The activity remaining decreases to the constant values listed in the figure, and the decrease is approximately exponential. To distinguish the effect of acetone from water, the experiment illustrated in Fig. 3 was performed; foils containing 0.5 and 1 keV $^{86}Rb^+$ were

Table I. Fraction of initial activity left after washing with water (alkali metals) or 10% acetic acid (thallium). The standard error in the determination of each figure was 0.002-0.006, but reproducibility measurements (see text) suggest that the real variation could be perhaps ten times as much at the lowest energies.

Projectile energy (keV)	$^{24}Na^+$	$^{42}K^+$	$^{86}Rb^+$	$^{134}Cs^+$	$^{204}Tl^+$
0.5	0.418	0.509	0.517	0.562 0.518	—
1.0	0.765 0.844	0.566	0.746	0.714	0.837
2.0	0.877	0.881	0.844	0.846	0.950
5.0	0.962	0.953	0.908	0.949	0.976
10	0.978	0.965	0.963	0.953 0.969	0.969
20	N.R.	0.980	0.987	0.982	0.985
40	N.R.	0.983	1.005	0.987 0.998	0.998
80	N.R.	0.991	0.993	0.995	0.989

N.R. = Not recorded. The necessity for washing had not been appreciated at the time these specimens were analyzed.

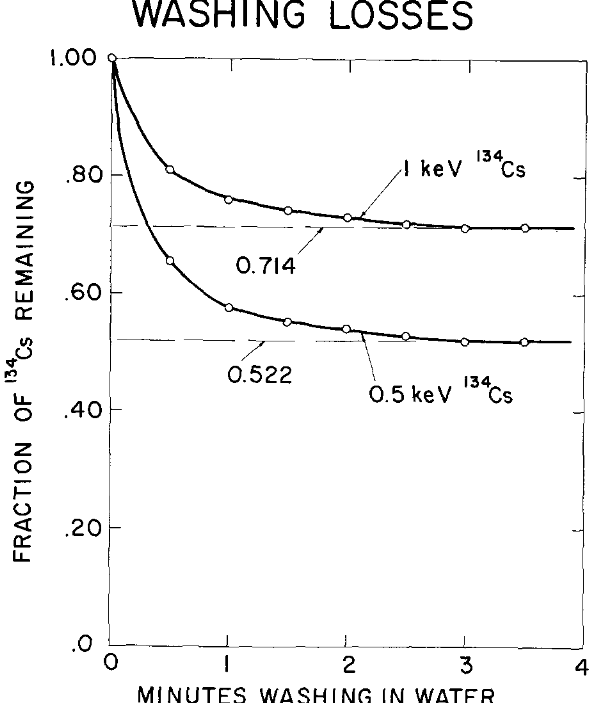

Fig. 2. Loss of ^{134}Cs from implanted targets on washing with water.

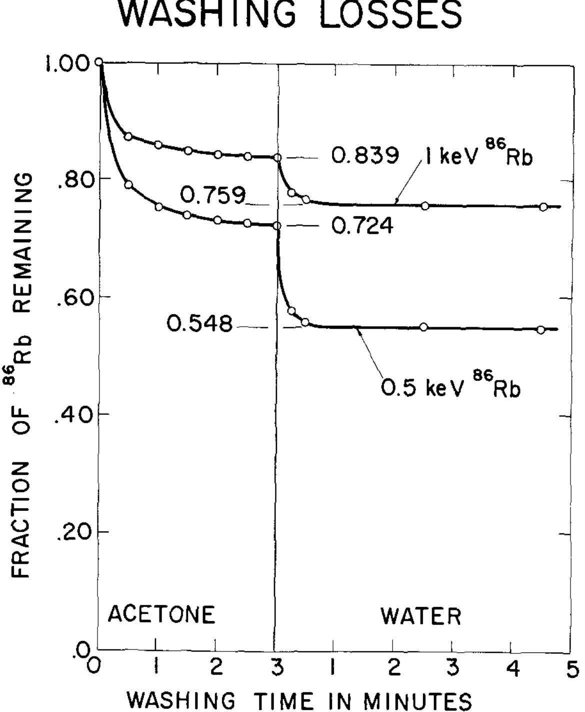

Fig. 3. Loss of ^{86}Rb from implanted targets on washing first with acetone, and then with water.

washed for several 30-sec periods in acetone, and then for varying periods in water followed by 15 sec in acetone. It is apparent that acetone behaves in much the same way as water; the activity decreases in an approximately exponential fashion as before, but to a slowly decreasing rather than a constant value. Washing with water after the acetone reduces the activity very quickly to a new and constant value, characteristic of the water wash alone (c.f. Fig. 2).

The removal of surface activity from the $^{204}Tl^+$ specimens presented some difficulty. Less than 10% of the activity was removed on washing the 0.5 keV sample with water, yet by comparison with 0.5 keV $^{134}Cs^+$, a 50% loss was expected. The sample was therefore washed with saturated NH_4HF_2, which reduced the activity substantially, but also dissolved the tantalum oxide at the rate of about 1 Å/min. In consequence, the distinction between surface and bulk activity was not well defined for this sample. All the other $^{204}Tl^+$ samples, except 1 keV, were washed for 1 min in 10% acetic acid, as thallium acetate is very soluble (15); this reagent did reduce the activity by about the expected amount, and, from thickness measurements, did not dissolve the oxide. The 1 keV sample was washed for 30 sec in saturated NH_4HF_2, which removed about 16% of the activity, followed by 30 sec in acetic acid, which removed another 2%.

The results described so far were obtained in the course of the range profile measurements. To establish the reproducibility of the washing losses, eight anodized foils were implanted with 1 keV $^{24}Na^+$, and on a second occasion, another four were implanted similarly; all twelve were used for experiments of the kind illustrated in Fig. 2 and 3. On washing first in a reagent grade organic liquid and then in distilled water, both for 9 min, it was found that 2/3 to 5/6 of the total washing loss could be removed in acetone, methyl alcohol, or ethyl alcohol; in all cases the rate of loss was much as depicted in Fig. 3. Curiously enough, no detectable activity was lost in the course of 9-min washing in benzene. After the water wash, the fraction of the activity remaining on the first set of eight foils varied from 0.59 to 0.70, while on the second set it varied from 0.75 to 0.79. There thus appears to be a significant difference between the two sets, and between both of them and the results quoted in Table I, even though the implantation conditions were nominally the same in all cases. Subsequent washing in aqua regia or 1*N* NaOH caused almost no additional loss of activity.

Range profiles.—Range profiles were measured for a variety of atomic projectiles from $^{24}Na^+$ to $^{222}Rn^+$, and at energies from 0.5 to 160 keV. The experimental data have been analyzed as described in the next section, with the results listed in Tables II-VI.

Range profiles due to neutral atoms in the implanting beam.—As has long been known (13, 16), the second profile obtained at low energy is an artifact resulting from the operation of the mass separator. Ions generated in the ion source are accelerated to 40 keV, and then separated into isotopic components by means of a magnetic field. The focusing requirements after separation are such that the ions travel another meter or so before striking the anodized tantalum coupons. Separation is best at energies near 40 keV; the other energies were obtained by applying accelerating or retarding voltages to the coupons. Thus an implantation energy of 1 keV was obtained by applying a 39 keV positive (retarding) potential. These accelerating or retarding potentials will only be effective, however, if the atoms are still ionized as they approach the coupons. If they have been neutralized since leaving the magnetic field, they will implant with the full 40 keV.

Figure 1 shows that the range profile for 1 keV $^{134}Cs^+$ is the sum of two separate range profiles. Analysis of the second profile, by the method described in the next section, shows quite clearly that it corresponds to implantation at 40 keV, and similar effects have been observed with all the other ions implanted. This "neutral tail" is distinct only for energies below about 10 keV; at 20 keV it is reduced to a small inflection. The fraction of the incident beam appearing as neutral tail could be substantial, ranging from about 0.5 to 10%; the 3% shown in Fig. 1 appears to be about average. A liquid nitrogen trap in the target chamber would have reduced the neutral tail considerably (13).

Effect of impurities.—As demonstrated in Fig. 1, a very small fraction of the initial activity would some-

times persist even on prolonged stripping. This feature was not always present in the range profiles, but was well defined when it was. The detection limit, set by the ratio of initial to background counting rates, was normally about 0.005%. Persisting fractions were rarely observed in tantalum anodized for the first time, but the same specimens were used repeatedly in the present experiments, being reanodized after each range measurement. After three or four reanodizations, the persisting fraction had risen to about 0.05%, though individual specimens fluctuated considerably about this value. The biggest fraction ever observed was 0.36%.

The effect can be attributed to the presence of inclusions in the oxide film. These could be Ta_2C particles originating in the parent metal (17) or, more probably, fragments of crystalline Ta_2O_5 produced by field crystallization during the anodic oxidation process itself (18, 19). Neither is soluble in hydrofluoric acid, and so the inclusions are not removed by the stripping process. Vermilyea (9) found that the inclusions would persist through several cycles of anodizing and stripping; indeed, the amount even tended to increase as more crystalline oxide was formed in the successive anodizations.

Radioactive ions implant at random on the oxide surface, and so some will come to rest in the inclusions, from which they will not readily be removed by stripping. The persisting fraction was found to increase on reanodization, and attempts to clean the foils showed that the activity could not be removed by successive cycles of anodizing and stripping. In all respects, therefore, the properties of the persisting fraction are consistent with the reported behavior of the crystalline oxide fragments.

Sticking factors.—Relative sticking factors at very low energies were obtained using a method of Brown and Davies (20). Anodized tantalum foils were implanted to the same fluence at various energies, and the activity present in each foil counted. By fixing the sticking factor for one energy at a particular value, sticking factors for all the other energies could be calculated relative to this standard. The basis for choosing the standards and the presentation of the results are discussed later.

Mathematical Analysis of the Profile Data

Least squares fitting procedure.—The purpose of the mathematical analysis was three-fold: (*a*) to find a mathematical function that would adequately describe the experimental profiles, (*b*) to obtain best estimates for the parameters of the function, and (*c*) to calculate standard errors in these estimates.

A least squares fitting procedure was therefore required, but those available proved unsuitable. Their most important defect was that they would account for errors in the dependent variable only, yet experimentally there were errors in both dependent and independent variables; that is, in both the percentage counts remaining and the oxide thickness measurements. Since the errors were of the same relative magnitude, neither could be ignored. The problem of making least squares fits when there are errors in both variables has been little studied, and so the matter was investigated further.

The experimental data consisted of a series $I = 1, 2 \ldots N$ of percentage counts remaining, $Y(I)$, *vs.* thickness remaining, $X(I)$; $EX(I)$ and $EY(I)$ were the observed standard errors in $X(I)$ and $Y(I)$, respectively. A suitable function, F, defined by

$$YFIT(I) = F(C(J); XFIT(I)) \quad [1]$$

and containing M parameters $C(J)$, $J = 1, 2 \ldots M$, was fitted to the $X(I)$, $Y(I)$ array, in such a way that the sum of the squares

$$S^2 = \sum_I [(X(I) - XFIT(I))/EX(I)]^2 + \sum_I [(Y(I) - YFIT(I))/EY(I)]^2 \quad [2]$$

was minimized; this criterion is due to Deming (21). The minimization of S^2 was accomplished by modifying the standard Newton-Raphson method in such a way that the quantities $XFIT(I)$ are treated as adjustable parameters of the fit. The resulting program was run on a CDC G-20 computer and provided best estimates for the parameters, $C(J)$, together with their standard errors $EC(J)$ thus meeting requirements (*b*) and (*c*) above. To meet (*a*), the χ^2 goodness-of-fit test was applied; S^2 was calculated from Eq [2] and compared with the probability, $p(\chi^2)_{N-M}$, of obtaining a value as large or larger from a χ^2 distribution with N-M degrees of freedom. A special routine was written to calculate these probabilities with an accuracy of one part in a thousand.

Application to range profiles.—Following Jespersgard and Davies (8), the range profiles were assumed to be normal distributions, so that they could be described by a function of the form

$$Y_n = (C(1)/\sqrt{(2\pi)}\cdot C(3)) \cdot \exp[-(X - C(2))/\sqrt{2}\cdot C(3))^2] \quad [3]$$

as illustrated in the bottom portion of Fig. 4. The experimental points, however, referred to the integral of this function; that is, to

$$Y = (C(1)/2)\cdot \mathrm{erfc}[-(X - C(2))/\sqrt{2}\cdot C(3)] + C(4) \quad [4]$$

as illustrated in the top portion of Fig. 4. Accordingly, the function actually fitted was

$$YFIT(I) = (C(1)/2)\cdot \mathrm{erfc}[-(XFIT(I) - C(2))/\sqrt{2}\cdot C(3)] + C(4) \quad [5]$$

where $XFIT(I)$ is a best approximation to $X(I)$, the observed oxide thickness remaining after the removal of $(I - 1)$ layers, and $YFIT(I)$ is a best approximation to $Y(I)$, the percentage counts remaining after the removal of $(I - 1)$ layers.

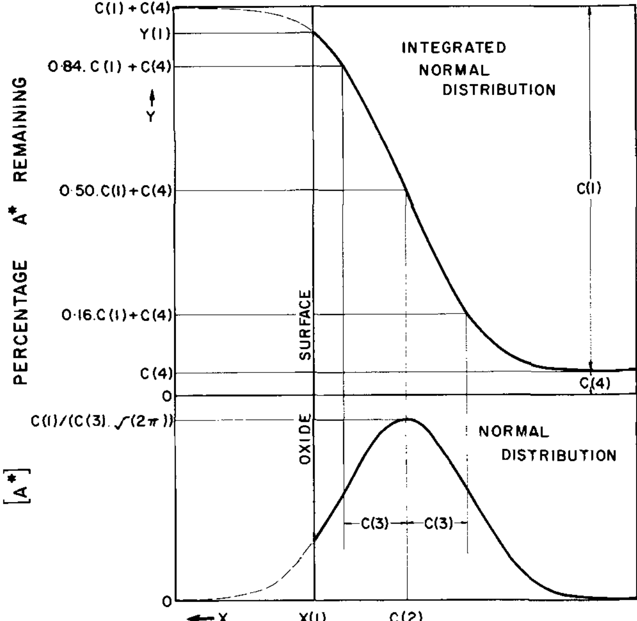

Fig. 4. Relationship between the normal distribution

$$Y = (C(1)/\sqrt{(2\pi)}\cdot C(3))\cdot \exp[-(-(X-C(2))/\sqrt{2}\cdot C(3))^2]$$

and its integral

$$Y = (C(1)/2)\cdot \mathrm{erfc}[-(X-C(2))/\sqrt{2}\cdot C(3)] + C(4)$$

to illustrate the significance of the various parameters used in the least squares fitting. A* represents the implanted radioactive species.

The signficance of the parameters in Eq. [5] is illustrated in Fig. 4, where: $C(1)$ is a normalizing factor, expressed in per cent, proportional to the area under the complete normal distribution fitted; $C(2)$ is the mode of the normal distribution, measured, like $X(I)$, in terms of its distance in angstroms from the metal/oxide interface; $C(3)$ is the standard deviation of the normal distribution, also measured in angstroms; and $C(4)$ is a constant of integration, measured in per cent, which accounts for the fraction of the activity that persists on continued stripping.

The parameter $C(3)$ was of direct interest, but $C(2)$ and $C(1)$ had to be converted to more useful forms. To obtain the modal range, $C(2)$ was subtracted from $X(1)$; the error in the range was then a combination of the separate errors in $C(2)$ and $X(1)$, as indicated in Table II. The proportionality between range and standard deviation was such that the normal distribution extended signficantly beyond the boundaries of the oxide film, as illustrated in Fig. 4, so that the observed range profile is more correctly described as a truncated normal distribution. To find out what fraction of a normal distribution was present, the parameter $C(1)$ was divided into the initial percentage count, $Y(1)$, less the correction, $C(4)$, for the persisting fraction; the result is described as the fitted sticking factor.

Table II. Fit of an integrated normal distribution to the 40 keV $^{134}Cs^+$ sample illustrated in Fig. 1

A. The Experimental Data

Point number I	Oxide thickness remaining (A) $X(I)$	Percentage counts remaining (%) $Y(I)$	Error in thickness (A) $EX(I)$	Error in counts (%) $EY(I)$

Number of parameters fitted, $M = 3$.

D. Results

Σ (Relative error in fits)²	$S^2 = 4.37$
Number of degrees of freedom	$N\text{-}M = 11$
Chi-square probability	$p(\chi^2)_{11} = 0.958$
Modal range	$X(1) - C(2) = 116.5A$
Standard error in range	$[(EX(1))^2 + (EC(2))^2]^{1/2} = 2.0A$
Standard deviation	$C(3) = 72.1A$
Standard error in standard deviation	$EC(3) = 0.4A$
Fitted sticking factor	$(Y(1) - C(4))/C(1) = 0.947$
Error in fitted sticking factor	$\left[\left(\frac{Y(1)-C(4)}{C(1)}\right)^2 \cdot \left(\frac{EC(1)}{C(1)}\right)^2 + \left(\frac{EY(1)}{C(1)}\right)^2\right]^{1/2} = 0.004$

The analysis was a little more complicated in the presence of a neutral tail. An integrated normal distribution was first fitted through the points in the tail only, to establish that this was due to a 40 keV implant. Thus a fit to the tail portion, d, of the 1 keV $^{134}Cs^+$ profile in Fig. 1, excluding the last two points, gave a modal range of 114.2 ± 2.8Å, and a standard deviation of 70.7 ± 1.2Å, parameters in good agreement with those found for 40 keV $^{134}Cs^+$ in Table II. Once the neutral tail had been confirmed as a 40 keV implant, there was no need to reconfirm it in every range study; only enough points, therefore, were taken to establish its intensity, $C_{40}(1)$. Three points sufficed, the fit being made with $X(1)\text{-}C_{40}(2)$ and $C_{40}(3)$ fixed at the appropriate 40 keV values, and $C_{40}(4)$ as 0.05%, which was a good average value for the intensity of the persisting fraction of the activity. With the nature and intensity of the neutral tail known, and the intensity of the persisting fraction defined, both effects could be subtracted from the low energy range profile, and a normal distribution fitted to the remainder.

Few range profiles were analyzed in as great detail or as far as 40 keV $^{134}Cs^+$ and so, for comparative purposes, the range profiles were analyzed in a slightly different fashion from that illustrated in Table II. Profiles without a neutral tail were analyzed with $C(4)$ set at 0.05%, and all points with $Y(I)$ less than 2% were eliminated from the fitting, since many of the analyses were not continued below this figure; the limit was set at 1% after the removal of a neutral tail. With these restrictions, the average number of points fitted was approximately ten, ranging from a maximum of sixteen to a minimum, in several 0.5 keV profiles, of four.

Adequacy of the fitting by the integrated normal distribution.—The prime requirement in the least squares fitting was that the chosen distribution give an adequate fit to the experimental points. An "adequate" fit must therefore be defined, and this involves an arbitrary decision as to the level of significance required. Application of the χ^2 test at the 5% level means that fits with $0.975 > p(\chi^2)_{N\text{-}M} > 0.025$ are considered adequate; those with $1.000 > p(\chi^2)_{N\text{-}M} > 0.975$ are considered too good, and those with $0.025 > p(\chi^2)_{N\text{-}M} > 0.000$ too bad. These remarks apply to individual samples; when fitting to a large number of different samples, it is to be expected that, on the average, one in forty will have $p(\chi^2)_{N\text{-}M} > 0.975$ and another one in forty $p(\chi^2)_{N\text{-}M} < 0.025$.

On applying the χ^2 test to the ninety-six samples listed in Tables III, IV, and V, then, there should be two or three samples with $p(\chi^2)_{N\text{-}M} > 0.975$ and another two or three with $p(\chi^2)_{N\text{-}M} < 0.025$. In fact, it was found that 10 samples had $p(\chi^2)_{N\text{-}M} > 0.975$ and 12 more had $p(\chi^2)_{N\text{-}M} < 0.025$. The additional variation that this expresses can almost certainly be attributed to $EX(I)$, for which an average value of 1.8Å (1) has been assumed; $EX(I)$ would vary from sample to sample, and even from point to point. Accordingly, the general nature of these fitting probabilities may be taken as indicating that 1.8Å is a good average for $EX(I)$, and that an integrated normal distribution does give an adequate fit to the range profiles. However, it must be noted that the very good fits cluster at low energy, and the very poor fits at high energy; possibly, therefore, the range profiles depart somewhat from a normal distribution at the higher energies, but no significant conclusion can be drawn.

Table III. Modal values of the range profiles as determined from the least squares fit of a normal distribution. All values can be corrected for the depletion depth by adding 5 ± 1Å. Results, together with standard error in the fitting, quoted to nearest 0.5Å

Reproducibility of the results.—The six 5 keV $^{125}Xe^+$ profiles in Table VI illustrate the reproducibility obtained. The standard deviation, 2.4Å, about the average modal range, 30.0Å, agrees with the average error 2.0Å in the fitting within the combined statistical error of $\sqrt{(0.8^2 + 0.1^2)}$ Å, and indicates that the error of fit is a reasonable estimate for the variability of individual measurements. The same holds true for both the stan-

dard deviation and the fitted sticking factor. Six samples, however, do not provide a very stringent test because the statistical errors are relatively large, as indicated in the bottom line of Table VI.

Further evidence on the reproducibility is provided by the duplicate experiments listed in Tables III, IV, and V and by comparing the results for projectiles of similar atomic weight; *i.e.*, the $^{85}Kr^+$, $^{86}Rb^+$ and $^{125}Xe^+$, $^{134}Cs^+$ pairs. In general, the agreement is well within the combined experimental errors, particularly for the standard deviations. There are, however, some notable discrepancies, such as the difference between the modal ranges for 40 keV $^{125}Xe^+$ and $^{134}Cs^+$.

The $^{222}Rn^+$ results were somewhat peculiar. The first set of $^{222}Rn^+$ profiles, listed on the upper line in the tables, showed that while the standard deviations were, as expected, slightly less than those for $^{125}Xe^+$ at the same energy, the modal ranges were the same or even greater, whereas they should have been less. This observation was so surprising that the measurements were repeated, but with exactly the same result. Subsequent measurements with $^{204}Tl^+$ gave values more in keeping with those expected, and so $^{222}Rn^+$ appears to be anomalous. The reason for the anomaly is not known, and this, coupled with the generally poor fits at higher energy, means that the $^{222}Rn^+$ results must be regarded as being less reliable than the others.

Implantation Phenomena at Energies above 5 keV

An implanting ion loses energy by both electronic and nuclear collisions with the target atoms, the latter predominating at energies below about 100 keV. Nuclear collisions can be arbitrarily divided into two types, according to the angular deflection they impart to the ion's trajectory. Small angle nuclear collisions occur every time the ion penetrates an atomic layer in the solid, but little energy is lost in each; large angle nuclear collisions are much less frequent, but are responsible for most of the energy loss. Ions normally penetrate several atom layers before undergoing their first large angle collision, and since the cross section for these collisions increases with decreasing energy, the mean free path to the next such collision decreases. Subsequent large angle collisions follow the same pattern, the process ending either with the ion at rest in the solid (implanted), or recrossing the surface with sufficient energy to escape (reflected).

Adequacy of the normal distribution as a description of the range profiles.—The complexity of this energy loss process is such that it is very difficult to predict the size and shape of the range profile. Detailed theoretical calculations by Winterbon, Sigmund, and Sanders (22) suggest that range profiles in amorphous monatomic solids should be close to normal distributions, and very recently Winterbon (23) has given reasons why range profiles in amorphous polyatomic solids should be even closer. Since the greatest departures from normality are expected in the profile tails, the satisfactory fit of the range profiles in Tables III, IV, and V is readily explained. Both tails were cut off; one by the oxide surface, and the other by arbitrarily limiting the fit to points with greater than 2% of the initial count.

Table II, however, shows that an excellent fit can be obtained even when this limitation is lifted. The modal range of the 40 keV $^{134}Cs^+$ was 120 ± 2Å (Table III) with the 2% limit applied, and the standard deviation 72 ± 0.5Å (Table IV); the corresponding figures from Table II are 116.5 ± 2 and 72 ± 0.5Å, respectively, after rounding to the nearest 0.5Å. Since the quoted errors are standard errors, they must be doubled to obtain the 95% confidence limits about each value; it is then obvious that the two sets of parameters do not differ significantly. The present results, therefore, provide no evidence against a normal distribution. Indeed it may be impossible to obtain such evidence from range profile measurements alone, for the thickness errors in the present range measurements are already of the order of one atom layer (1); it is hard to see how they could be reduced significantly in the interests of more exact fitting.

Comparison with previous studies on amorphous oxides.—It will be shown elsewhere (24) that these range profiles in anodic tantalum oxide are effectively identical to those obtained by Domeij *et al.* (7) in anodic tungsten oxide, as might be anticipated from the similar mix of very light and very heavy atoms present. Schiøtt (25) has compared both sets of experimental data with ranges calculated from the theory of atomic collisions and found that the agreement was within about 10%. This is reasonable considering the difficulty of the calculations. He noted that the experimental $^{222}Rn^+$ ranges obtained here seemed consistently higher than those calculated, but, as explained earlier, this appears to be due to some systematic but unknown experimental error. The calculated ranges for $^{204}Tl^+$ would be almost identical to those for $^{222}Rn^+$, and so the agreement between theory and experiment would be much better with this ion. Baroody (26) has calculated the straggling of $^{125}Xe^+$ about its projected range in WO_3 and obtained fair agreement with the experimental results of Domeij *et al.* (7).

Sticking factors.—To be reflected, an ion must acquire a momentum component normal to and away from the oxide surface, and this can occur only after one or more large angle nuclear collisions with target atoms. The probability for reflection depends, therefore, on the angular deflection in each collision; reflection is obviously much more probable if the deflections are likely to be large. From the conservation of momentum, the average angular deflection of a heavy ion colliding with a light atom is less than that of a light ion colliding with a heavy atom, and so a smaller fraction of

the former should be reflected. The sticking factor will therefore be larger.

Brown and Davies (20) have illustrated this point experimentally. They implanted different materials with the same fluence of radioactive noble gas ions, and then, by counting the activity present, determined the relative fraction of the ions that "stuck" in each material. To obtain absolute values, it was necessary to know the absolute sticking factor for one particular combination of ion, target, and energy; special measurement showed that the absolute sticking factor for 40 keV $^{85}Kr^+$ (heavy ion) in ^{27}Al (light atom) was "unity within $\pm$ 2%." With this as base, Brown and Davies were able to measure absolute sticking factors for 40 keV $^{125}Xe^+$ and $^{133}Xe^+$ (light ions) in ^{181}Ta (heavy atom); five determinations gave 0.95 $\pm$ 0.02 (standard error), which is significantly less than unity.

The obvious correlation between a sticking factor and a range profile is that the fraction of the ions failing to implant corresponds to the fraction of the normal distribution extending beyond the oxide surface; indeed, this correlation is implicit in the name, fitted sticking factor, given to the quantity listed in Table V. Absolute sticking factors have not been measured for aluminum and tantalum oxides, but it seems reasonable to suppose that the presence of the light oxygen atoms would tend to increase the values over those for the corresponding metals. Range measurements by Domeij *et al.* (7) in anodic $^{27}Al_2{}^{16}O_3$ have been reanalyzed by the least squares fitting procedure described here, and the fitted sticking factor for 40 keV $^{85}Kr^+$ was found to be 0.998 in excellent agreement with the 1.00 $\pm$ 0.01 (standard error) actually observed for ^{27}Al metal. Similarly, the five 40 keV $^{125}Xe^+$ profiles measured here gave 0.969 $\pm$ 0.004 (standard error), again in good agreement with the 0.95 $\pm$ 0.02 (standard error) observed in ^{181}Ta metal.

Additional support for this correlation is provided by the experiment of Bøttiger *et al.* (27). They measured the fraction of the ions reflected when $^{42}K^+$ was implanted at 60 keV into anodic tungsten oxide and found it was approximately 0.04-0.05; the corresponding sticking factor was therefore 0.96-0.95. Interpolation from Table V will show that the fitted sticking factor for 60 keV $^{42}K^+$ implanting in anodic tantalum oxide would be about 0.94 $\pm$ 0.01, so that the two results are in excellent agreement. All in all, therefore, the normal distribution provides an excellent description for the range profiles at implantation energies above 5 keV.

Implantation Phenomena at Energies below 5 keV

As the implantation energy decreases, the ions penetrate the oxide less and less, until eventually they fail to penetrate even the first atomic layer. At very low energies, then, the nature of the oxide surface is of great importance. One question that immediately arises is: how far must the ions penetrate before they stick? Presumably there must be a minimum of one atom layer above the ions to hold them in place, and so they must penetrate a distance of at least 3Å. A second question concerns the cleanliness of the oxide surface, and the possible presence of adsorbed gases. Since the adsorption process is of great importance for subsequent arguments, it is considered next.

Adsorption at thermal energies (<0.1 eV).—A gaseous atom approaching the surface of a solid is accelerated by the surface binding force in such a way that its kinetic energy perpendicular to the surface is increased, and its trajectory is bent toward the normal. On colliding with the surface, the atom loses energy and is reflected. As it leaves the surface, the binding force acts in reverse, so that the kinetic energy perpendicular to the surface is reduced, and the trajectory is bent away from the normal (28). If the kinetic energy is reduced to zero in the course of this process, the atom will not escape from the surface at all, but will return and be adsorbed. The minimum kinetic energy needed to overcome the binding force is known as the heat of adsorption.

The probability for adsorption therefore depends on the energy of the incoming atom, and on its heat of adsorption. If the incoming energy is small enough, as in the case of low temperature gas, all the atoms must adsorb. When the heat of adsorption is also small, however, the adsorbed atoms may subsequently acquire sufficient thermal energy to overcome it, and they then desorb. Noble gas atoms, for example, are in fact mostly adsorbed on solid surfaces at room temperature, but their heats of adsorption are so low, at about 0.2 eV, that they desorb again in less than a millisecond (29). By contrast, the heat of adsorption for alkali metal atoms is, at about 2 eV (30), so much higher that their residence time on the surface is of the order of centuries (29). Most atomic and molecular species fall somewhere between these two extremes, but some hydrocarbons have very high heats of adsorption (29) so that they too remain firmly adsorbed.

Surface contamination.—This phenomenon of adsorption applies to any gas on any surface, and so the residual gas in the vacuum system of the mass separator will tend to adsorb on the surface of the anodic oxide. The presence of such adsorbed layers can lead to significant effects, as McHugh and Sheffield (31) discovered in experiments very similar to those reported here.

These authors implanted noble gas ions into tantalum at energies from 0.3 to 14 keV and studied the positive ions ejected from the surface with the aid of a mass spectrometer. Positive ions of measurable intensity were detected for "practically all masses through 100" when the tantalum was at room temperature, but these ions were "nonexistent at higher temperatures." Since the residence time for an adsorbed species decreases markedly with temperature (29), this behavior confirms the presence of contaminants at room temperature. The numerous mass peaks suggest the fragmentation of large molecules such as hydrocarbons. The latter would certainly have been present, in the form of vapor from the pump oils used to maintain the vacuum.

Conditions in the mass separator would be very similar, and the presence of adsorbed hydrocarbons is confirmed by the carbonaceous deposits formed during the implantation of hydrogen (2). All implantations performed here, therefore, were implantations into contaminated surfaces, so that the target would consist of a thin layer of very light atoms (mostly carbon and hydrogen), superimposed on a much thicker layer of light atoms (oxygen) and very heavy atoms (tantalum).

Sticking factors for alkali metals.—Most of the measurements reported at very low energies refer to the reflection coefficient, which is the complement of the sticking factor. These measurements show that the considerations determining sticking factors at high energy continue to apply at low energy also. Thus Arifov and Khadzhimukhamedov (32) measured the reflection coefficient for $^{133}Cs^+$ (heavy ion) from a ^{59}Ni surface (light target atom) and found it was practically zero at 0.2 keV; the corresponding sticking factor was therefore unity. By contrast, Brunnee (33) measured the reflection coefficient for $^{39}K^+$ from a ^{96av}Mo surface and found that it was about 0.23 at 0.6 keV; the sticking factor was therefore considerably below unity, as expected for a light ion implanting into a heavy target. Both experiments were performed on surfaces which were believed to be clean.

Brunnee, however, repeated his experiment with a molybdenum surface that had not been cleaned, and then found that the $^{39}K^+$ reflection coefficient dropped to rather less than 0.01 at the same 0.6 keV energy. The obvious interpretation is that the uncleaned mo-

lybdenum was covered with light atom contaminants, so that the $^{39}K^+$ was then behaving as a heavy ion implanting into a light target. Significantly enough, Brunnee cleaned his surfaces by flashing them to high temperature, a process calculated to desorb any contaminants that might be present.

The $^{39}K^+$ ions were implanted into the uncleaned surface at normal incidence, so that they would cross the contaminant layer at right angles and at relatively high energy. Upon reflection from the underlying molybdenum, they would traverse it at all angles and at much lower energy. Since the cross section for large angle nuclear collisions increases with decreasing energy, the probability for colliding with the contaminant atoms and losing still more energy is much increased when the ions are on their way out; furthermore, the trajectory bending discussed in connection with adsorption would tend to hold the $^{39}K^+$ ions within the contaminant layer as they slowed down. The lower the implantation energy, therefore, the less likely are the reflected $^{39}K^+$ ions to break back through the contaminant layer, and hence the reflection coefficient should decrease. Brunnee observed that the reflection coefficient did in fact decrease from about 0.02 at 2 keV to about 0.005 at 0.5 keV.

The sticking factor for an alkali metal implanting at very low energy into a contaminated surface is therefore expected to be almost unity. Since the tantalum oxide surfaces used here certainly were contaminated, the sticking factor for 0.5 keV $^{24}Na^+$ was taken as unity, thus providing a standard against which the sticking factors at 1, 2, and 5 keV could be determined. Within the experimental standard error of about 0.03, the latter are unity as well (Table VII), a result anticipated from the preceding discussion.

Sticking factors for noble gases.—Ions arriving at the contaminated surface suffer one of four fates. (*i*) They can be reflected. If the ions do escape from the surface and its contaminants, they are most unlikely to return, since their mean free path at the pressure, 10^{-6} Torr, inside the mass separator is of the order of a meter. (*ii*) They can come to rest in the outermost layer of the target, which is the contaminant layer. (*iii*) They can come to rest at such shallow depth in the oxide that they are not firmly trapped; *i.e.* within an atom layer or so of the oxide surface. (*iv*) They can come to rest sufficiently far into the oxide that they are firmly trapped; that is, they implant in the usual way.

When the implanting species is an alkali metal, ions suffering fate (*ii*) become strongly adsorbed on the oxide surface, while those suffering fate (*iii*) are adsorbed in the surface. The only ions lost to the system, then, are those suffering fate (*i*), and these form a very small proportion. Noble gas ions are almost certainly neutralized on coming to rest, and their heats of adsorption are so low that ions suffering fates (*ii*) and (*iii*) would rapidly desorb; the only ions that would actually stick in the oxide, then, would be those suffering fate (*iv*). As the implantation energy decreased, the proportion of the ions that penetrated far enough to suffer fate (*iv*) would also decrease, thus accounting for the observed diminution in the sticking factor (Table VII). The xenon sticking factors were therefore standardized by assuming that the fitted sticking factor at 5 keV (Table V) was a good approximation to the experimental value; justification for the equivalence of observed and fitted values at high energy has been given already.

Table VII. The fraction of an alkali metal implant left after washing compared with the observed sticking factors. Data for ^{134}Cs repeated from Table I; the two columns on ^{24}Na describe results obtained with the same samples. The standard error in each figure is of the order of 0.03

Energy in keV	Fraction of $^{134}Cs^+$ activity remaining after washing with H_2O	Observed relative sticking factors for $^{125}Xe^+$ (base 5 keV = 0.93)	Observed relative sticking factors for $^{24}Na^+$ (base 0.5 keV = 1.00)	Fraction of $^{24}Na^+$ activity remaining after washing with H_2O
5	0.95	[0.93]	0.97	0.96
2	0.85	0.79	1.02	0.89
1	0.71	0.66	1.02	0.72
0.5	0.56, 0.52	0.44	[1.00]	0.69

Washing losses.—The reason for the loss of activity on washing is now readily apparent. Alkali metal ions adsorbed on the oxide surface (*ii*) are washed off with organic liquids, while those adsorbed in the surface (*iii*) are washed out only with water (Fig. 3). Noble gas ions coming to rest in or on the oxide surface have already been desorbed, and so no washing losses are observed with these elements. Since the range profile is determined only by the mass and energy of the incident ions, the fraction of an alkali metal implant left after washing (*iv*) should be the same as the fraction of the corresponding noble gas that sticks (*iv*). The comparison between $^{134}Cs^+$ and $^{125}Xe^+$ in Table VII indicates that this is indeed the case.

The superior efficiency of the water wash can be interpreted in several ways. Alkali metal ions are more soluble in polar solvents, and the oxide surface might well hydrate when exposed to water. In this connection, the exchange reaction between the oxygen of the water molecules and that in the immediate surface layer of the oxide (34) is interesting; presumably no such exchange occurs with organic liquids, since these do not act as oxygen sources during anodization (35). The variation in washing loss from experiment to experiment can then be accounted for as differences in the nature and thickness of the contaminant layer.

Form of the range observed profiles.—At low energies, the implanting ions necessarily come to rest after very few collisions with the target atoms. Because the number of collisions is so few, Gaussian statistics cannot apply; the range profiles should not, therefore, be normally distributed. Nevertheless, the range profiles have been adequately described by normal distributions in Tables III and IV, and the fitted sticking factors in Table V are at least in rough agreement with those observed in Table VII. This paradox can be resolved by noting that the least squares fitting procedure lacks power at these low energies to distinguish between alternate descriptions for the profiles; the lack of power is due to the small number of experimental points, and the relatively large error in each.

In view of the small number of collisions, a first assumption would be that some form of Poisson statistics apply, and that the range profiles should therefore resemble a Poisson distribution. When the average number of collisions is very small, the Poisson distribution consists of a peak followed by an exponential tail; as the average number increases, this transforms gradually to a normal distribution, as shown schematically in Fig. 5.

If the energy is low enough, therefore, the peak would occur either in the contaminant layer or in the surface layer of the oxide, so that the measured profile would consist solely of the exponential tail. This suggested that it might be possible to fit an exponential function to the range data at 0.5 keV. If the range profile is described by

$$Y_e = C(1) \cdot \exp\left[\ln(\tfrac{1}{2}) \cdot (X(1) - X)/C(2)\right] \quad [6]$$

the function that must actually be fitted through the experimental points is its integral, namely

$$YFIT(I) = -(C(1) \cdot C(2)/\ln(\tfrac{1}{2})) \cdot \exp\left[\ln(\tfrac{1}{2}) \cdot (XFIT(1) - XFIT(I))/C(2)\right] \quad [7]$$

where, apart from $C(2)$, the symbols have the same significance as in Eq. [3], [4], and [5]. The parameter $C(2)$ is now the distance in angstroms over which the concentration of the implanted ions falls by half. Least

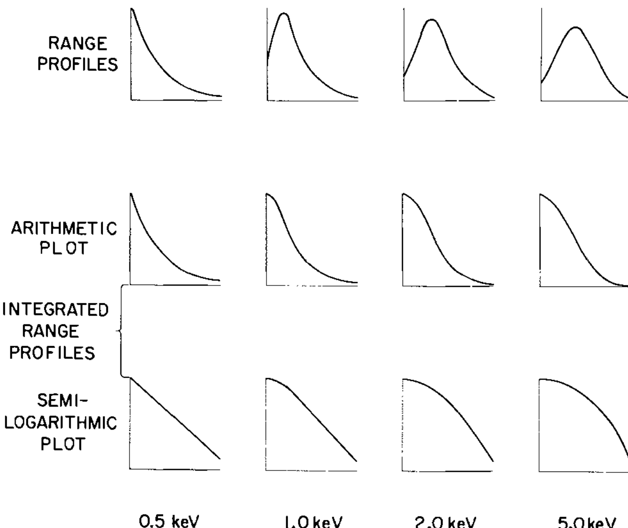

Fig. 5. Schematic diagram to show how the range profiles change from an exponential at 0.5 keV to a normal distribution at 5 keV. Scales arbitrary to emphasize the changes in form; for any particular energy, however, horizontal scales are the same for all three diagrams.

squares fit of the function [7] to the 0.5 keV samples listed in Table III, IV, and V resulted in $p(\chi^2)_{N-2}$ greater than 0.025 for all except $^{222}Rn^+$; $C(2)$ varied from 5.4 ± 0.3Å for $^{24}Na^+$ to 3.4 ± 0.8Å for $^{222}Rn^+$, with an average of about 4.5Å.

The fit of the exponential is therefore just as good as that of the normal distribution, and rather more convincing, since it involves only two adjustable parameters instead of three. Attempts to fit the exponential to the range data at 1 keV were not successful; only one of the twelve samples listed in Tables III, IV, and V gave an acceptable fit, and that one ($^{85}Kr^+$) was barely acceptable ($p(\chi^2)_3 = 0.057$). Examination showed that the largest discrepancy between observed and fitted values was almost invariably associated with the first point, the fitted values being too high; when the first points were eliminated, an exponential could be fitted satisfactorily through the remainder. Range profiles at 1 keV are therefore consistent with a peak followed by an exponential tail (Fig. 5); compared to the 0.5 keV profile, therefore, the peak has moved further into the oxide. As the implantation energy continues to increase, the peak moves still further into the oxide until at 5 keV the range profile is unmistakably close to a normal distribution.

It follows from this analysis that any similarity between the fitted sticking factors in Table V and the observed sticking factors in Table VII is largely fortuitous.

Resolution of the sectioning technique.—As discussed in a previous paper (1), the accuracy with which the range profiles can be measured is limited by the precision of the sectioning technique, and this depends on a number of factors. In particular, the resolution of the technique is governed by the uniformity with which the layers can be removed, since any nonuniformity will tend to increase the width of the observed profiles. This broadening can be interpreted as the folding of a mathematical distribution describing the nonuniformities into another mathematical distribution describing the true range profile. In terms of root mean square deviations, σ, about their respective means, these distributions are related by

$$\sigma_o^2 = \sigma_c^2 + \sigma_h^2 \quad [8]$$

where the subscripts refer to the observed range profiles, the correct range profile, and the nonuniformities left in the oxide thickness, h, remaining after the removal of each layer. The quantity σ_h is liable to vary with the removal of each successive layer; in what follows an average value will be assumed.

Because of the squared dependence, σ_o will be determined mostly by the greater of σ_c or σ_h. At high energies, where $\sigma_c >> \sigma_h$, σ_o will be effectively equal to σ_c; as the implantation energy is decreased, σ_c will also decrease, until eventually it becomes less than σ_h. The observed deviation then approximates to σ_h and will not decrease significantly with further decrease in the implantation energy. Since the root mean square deviation for a normal distribution is just the standard deviation, reference to Table IV will show that σ_o becomes sensibly constant once the implantation energy has fallen below 2 keV. Assuming that the nonuniformities are normally distributed, therefore, σ_h is approximately 10Å, a figure in excellent agreement with those, 8 and 9Å, obtained previously using the reanodization technique (1). Furthermore, all of these figures must be regarded as maximum estimates.

It is rather unlikely, however, that the nonuniformities would be normally distributed. Quantitative analysis (36) of the accelerated stripping effect (2) suggests that the oxide in the immediate vicinity of each implanted ion dissolves faster than usual, and so the removal of such atoms would tend to leave depressions in the oxide surface. Such nonuniformities would approximate the single-tailed exponential better than the double-tailed normal distribution, and this may account for both the nature and similarity of the range profiles at 0.5 keV. Against this, however, it must be noted that differences in mass become less important as the implantation energy decreases. Thus the ratio of the modal ranges for $^{24}Na^+$:$^{204}Tl^+$ decreases from about 4:1 at 80 keV to about 1.7:1 at 5 keV (Table III). The similarity of the profiles, and hence ranges, at 0.5 keV is then but a continuation of this trend. The exact nature of the profiles at 0.5 keV is therefore somewhat uncertain.

Magnitude of penetration.—The dissolution of a thin oxide layer in the HF-NH_4F reagent gives rise to the formation of a new oxide surface. Ions implanted sufficiently close to this new surface will be desorbed (noble gases), or washed out (alkali metals), or even dissolved out by the accelerated stripping effect discussed in the previous paragraph. Whatever the process, the oxide layer immediately beneath the new surface will be depleted in implanted ions, and the remaining profile will therefore begin, not at the oxide surface, but a short distance below it. This phenomenon will not influence the measured form of the range profiles, as long as the depletion distance remains constant; the latter seems probable, in view of the washing experiments. It will, however, affect the measurements of range, since these should be corrected for the depletion distance.

An estimate for this distance may be obtained by assuming that the alkali metal ions washed out only with water are those located in the depletion zone, and that the exponentiality of the range profile at 0.5 keV extends back to the oxide surface. Reference to Fig. 3 will show that 18% of the $^{86}Rb^+$ implanted at 0.5 keV is washed out only with water. Taking the exponential half-distance as 4.5Å, this corresponds to a depletion depth of 2.5Å or about one atom layer (1). As noted earlier, it seems very reasonable that there should be at least one atom layer between an implanted ion and the surface.

The half distance of the exponential is a different parameter from either the mode or standard deviation of a normal distribution, and so an appropriate quantity with which to compare different range profiles is the mean range. For an exponential distribution, the mean range is simply the mean free path, given by $C(2)/\ln 2$. It is therefore about 6.5Å for 0.5 keV $^{125}Xe^+$. Mean ranges for 1 and 2 keV $^{125}Xe^+$ can be estimated as being about 11 and 20Å, respectively, including corrections for the depletion distance. At energies of 5

keV or more, where the range profiles can be regarded as normal distributions truncated at the oxide surface, the mean range is computed to be about 3Å greater than the observed modal range. When the depletion distance is included as well, it is 5.5Å greater.

Best estimates for the observed mean ranges of the 0.5, 1, 2, 5, 10, 20, 40, 80, and 160 keV $^{125}Xe^+$ in anodic tantalum oxide are therefore about 6.5, 11, 20, 36, 53, 78, 136, 206, and 357Å, respectively. Strictly speaking, these ranges refer to implantation energies slightly lower than those indicated, since the xenon atoms lose energy in traversing the contaminant layer on the oxide surface. Nevertheless, the results can be summarized by noting that when the implantation energy doubles, the mean range increases by a factor of approximately 1.6. Other implants behave similarly, but the factor increases with decreasing mass, becoming nearly 2.0 with $^{24}Na^+$.

Conclusions

At energies of 5 keV and above:

1. The range profiles can be described within experimental error as normal distributions truncated at the oxide surface.
2. The observed sticking factor agrees within experimental error with the fraction of the normal distribution present as the range profile.
3. The results are in accord with previous measurements and with theory, in so far as the latter has been developed.

At energies below 5 keV:

4. The ranges are so short that the nature of the oxide surface becomes important. In particular, a layer of adsorbed contaminants, including hydrocarbons, is present when the surface is exposed to an oil pumped vacuum system.
5. The range profiles have been divided, largely on the basis of washing experiments with alkali metal implants, into three parts. The first part is located in the contaminant layer, the second in the immediate surface layer of the oxide, and the third, equivalent to normal implantation, at greater depth in the oxide.
6. The range profile of an ion implanted at 0.5 keV can be fitted to an exponential function, and the gradual change to a normal distribution at 5 keV has been interpreted in terms of Poisson statistics.

Acknowledgments

The author would like to express his gratitude to D. Hall, C. Sitter, J. Tole, and O. Westcott for implantations with the mass separator, to D. Phillips for assistance with the experiments, and to J. A. Davies and K. B. Winterbon for comments on the manuscript.

Some Practical Aspects of Electroless Gold Plating

Y. Okinaka,* R. Sard,** C. Wolowodiuk, W. H. Craft, and T. F. Retajczyk

Bell Laboratories, Murray Hill, New Jersey 07974

ABSTRACT

The electroless gold plating process using potassium borohydride as the reducing agent has been investigated for impurity effects, material compatibility, bath agitation effects, and thickness uniformity and line resolution in selective plating of patterned substrates. Impurities may cause a decrease in plating rate [Ni(II)], bath instability [Ni(II), Co(II), Fe(II)], thickness nonuniformity (polyethylene, organics in deionized water), and nodule formation (some surfactants). Bath agitation is beneficial: it increases plating rate, minimizes porosity of thin deposits, and eliminates nodule formation. Edge build-up generally occurs in selective pattern plating but, with proper selection of bath compositions and agitation conditions, it can be maintained below 10% in the thickness range of 1–12 μm. The rate of lateral growth of electroless gold deposits is about 60% of that of perpendicular growth under optimum plating conditions. Also considered in this paper are certain aspects of the scale-up and waste disposal problems associated with electroless gold plating.

Electroless gold plating has been found to be useful in a variety of applications, especially for selective plating on patterned substrates for electronics applications. Such applications generally require pure soft gold with a thickness in the range of 1-15 μm. A bath developed in this laboratory (1) has been found to be quite suitable for forming such deposits. Previous papers described the general bath characteristics (1), physical properties of deposits (2), bath operation with replenishment (3), reaction mechanism (4), and the nucleation and growth of deposits (5). The purpose of this paper is to describe several other aspects of the process which are important from the practical viewpoint and which have hitherto not been discussed. The topics covered include impurity effects, material compatibility, bath agitation effects, deposit thickness uniformity, and line resolution in selective plating of fine line patterned substrates. General recommendations are made as a guide for users of this process. Specific applications will be described in separate communications.

Solution Preparation and Plating Procedure

Compositions of three electroless gold plating baths used are listed in Table I. Bath A was used often in our earlier studies (1-3) including those of impurity effects and porosity described in this paper. More recently, baths B and C have been used exclusively. These two baths contain less KCN and KBH_4 and, therefore, are more preferable than bath A for practical reasons. Bath B gives the highest deposition rate (5-7 μm/hr at 70°-75°C with vigorous agitation), but deposits with acceptable physical properties can be obtained only when plated with agitation. Bath C is slower plating (2 μm/hr at 70°C with agitation) but gives better thickness uniformity on thin deposits in fine line plating. Details will be described in subsequent sections. It is convenient to prepare the baths by dilution of 5× concentrated stock solutions. These solutions can be stored at room temperature for at least three months without noticeable decrease in plating rate. Since a very small amount of hydrogen gas continues to evolve from the solution due to the hydrolysis of BH_4^-, it is suggested that the cap of the storage bottle have a pressure vent or be only loosely tightened for safety purposes.

Details of various plating procedures used will be described in each section. Generally it is necessary to carry out the plating with controlled agitation in order to obtain deposits with uniform thickness at a fast rate. A plating temperature of 70°-75°C is recommended.

Key words: electroless plating, gold plating, borohydride.

Table I. Composition of electroless gold plating baths used

	Bath A	Bath B	Bath C
$KAu(CN)_2$	0.02M	0.003M	0.02M
KCN	0.2M	0.1M	0.1M
KOH	0.2M	0.2M	0.2M
KBH_4	0.4M	0.2M	0.2M

Impurity Effects and Material Compatibility

Inorganics.—As described earlier (1), the electroless gold deposition takes place on noble metals such as Pd, Pt, Rh, and Au itself as well as on active metals such as Cu, Ni, Co, Fe, and their alloys. The initial reactions, however, are different on these two classes of metals. On noble metals the reaction is catalytic from the very beginning, whereas the gold deposition on the other active metals is initiated by a galvanic displacement reaction. For example, it was found (6) that when a copper substrate is placed in bath A at 70°C, about 100Å of copper dissolves into the solution before the surface is completely coated with pore-free gold deposits. Since such displacement reactions result in accumulation of ions of the substrate metals, it is important to know whether such ions exert any deleterious effects and, if they do, how much of them can be tolerated in the plating solution.

Figure 1 illustrates the effects of Cu(II), Ni(II), Co(II), and Fe(II) ions on plating rate. These ions were added in the form of a sulfate salt. Substrates

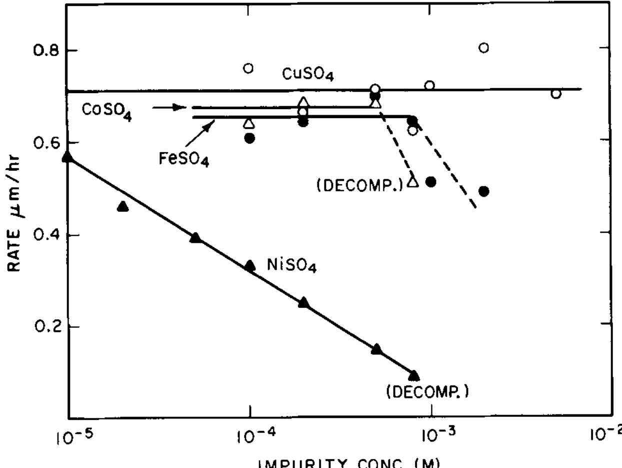

Fig. 1. Effects of metallic ion impurities on plating rate and bath stability. (Bath A, 75°C, no agitation.)

were ½ in. × 1 in. glass plates with evaporated Ti(500Å) and Au(1000Å). The plating was performed in 25 ml of bath A at 75°C without external agitation. It is seen in Fig. 1 that the presence of Cu(II) at least up to 0.01M does not affect the plating rate. The bath remained stable, and there was no effect on the deposit appearance as observed with an optical microscope. It is believed that the borohydride reduces Cu(II) to a Cu(I)-cyanide complex, which owing to its high stability remains unreacted in solution. On the other hand, 10^{-3}M Co(II) or Fe(II) was found to decompose the bath, although at lower concentrations the bath remained stable and the plating rate was unaffected. It was noted, however, that the presence of these ions tended to make the deposit rough and nodular. The effect of Ni(II) is different in that it greatly decreases the plating rate at concentrations lower than 10^{-3}M. The deposit obtained in the presence of Ni(II) is nodular, and at 10^{-3}M or greater bath decomposition takes place. It has been shown (4) that the cause of the decrease in plating rate is the poisoning effect of $Ni(CN)_4^{--}$ on the electrocatalytic activity of gold, which is due to the inhibition of the anodic partial reaction (oxidation of BH_3OH^-)[1] by adsorbed $Ni(CN)_4^{--}$. The observed bath instability may be due to the formation and precipitation of the heavy metal borides (7) and subsequent catalytic deposition of gold on the precipitates. It is evident from these results that substrates with nickel, cobalt, iron, or their alloys are not generally compatible with the electroless gold system. Such substrates should be precoated with a thin layer of a suitable noble metal catalyst [*e.g.*, displacement ("immersion") gold] before electroless gold plating.

Silicon undergoes a displacement reaction in the bath, which deposits loosely adherent gold with simultaneous dissolution of silicon. Consequently, in plating on silicon wafers, the backs and edges must be effectively protected from exposure to solution (8).

Aluminum is vigorously attacked by the solution because of the high alkalinity.

The following metals are stable in the bath and do not initiate gold deposition: Cr, Mo, W, Ta, Ti, Zr.

Organics.—Organic materials and compounds which are stable in the bath include "Teflon," polypropylene, negative photoresists such as KMER and KTFR (Eastman Kodak Company), and perfluoro surfactants.

Polyethylene is not stable in this system because it is attacked by KOH at elevated temperatures. It was found that the exposure of a large area of this material causes a suppression of plating due to its inhibiting effect on the anodic oxidation of BH_3OH^-. The latter effect, which is similar to the effect of $Ni(CN)_4^{--}$, is illustrated by the current-potential curves shown in Fig. 2. These curves were obtained by a potential scan technique using a rotating platinum disk electrode (area 0.465 cm², 1600 rpm) precoated with about 25 μm of electrolytically deposited gold from an alkaline cyanide bath. Curve 1 is due to the anodic oxidation of BH_3OH^- at 75°C in a mixture of 0.2M KOH, 0.1M KCN, and 0.1M KBH_4 before the addition of polyethylene. Curves 2 and 3 were obtained, respectively, 10 and 30 min after addition of 1g pulverized polyethylene (Allied Chemical Company, No. AC-680). The relatively slow decrease in current is attributed to the slow dissolution of polyethylene powder. While these curves show the inhibiting effect of polyethylene (or its degradation product) on the anodic partial reaction, the cathodic partial reaction [reduction of $Au(CN)_2^-$] is not affected by polyethylene (curve 4). The poisoning effect of polyethylene manifests itself in the anomalous thickness uniformity of deposits formed on patterned substrates. Figure 3 shows SEM views and profiles of portions of gold deposits [formed on evaporated Ti(750Å)/Pd(1000Å) patterns on oxidized silicon

[1] BH_3OH^- is an intermediate species formed during the hydrolysis of BH_4^-, and has been identified as the reducing agent in the electroless gold deposition reaction (4).

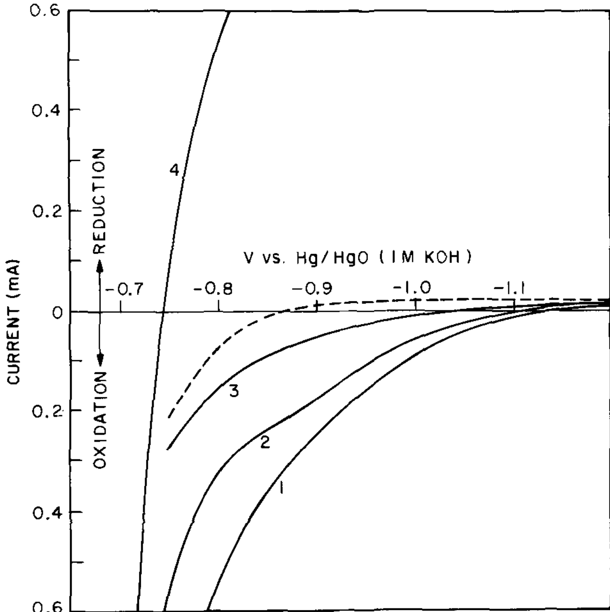

Fig. 2. Effect of polyethylene on anodic oxidation of BH_3OH^- and cathodic reduction of $Au(CN)_2^-$ at rotating platinum disk electrode precoated with gold. (75°C, 1600 rpm, 5.56 mV/sec.) wafers] in solutions uncontaminated (top) and heavily contaminated with polyethylene (bottom). The plating was carried out in bath B (Table I) at 70°C for 110 min using the agitation and rotation method described in the subsequent section. The thickness profiles were obtained using a stylus instrument (Dektak, Sloan Instruments Corporation). It is seen that the thickness uniformity of the deposit formed in the uncontaminated solution is excellent, whereas extreme thickness nonuniformity is apparent on the deposit formed in the contaminated solution. The reason why the deposition is less inhibited at edges than at the center is not obvious, but this phenomenon indicates that there is a mechanism whereby the adsorption of polyethylene (or its degradation product) occurs less at the edges.

Our experience in plating a large number of patterned substrates shows that a similar center suppression effect occurs, though to a much lesser extent, when water used to prepare the plating solution is contaminated with traces of organics. For example, deionized water not treated with active charcoal was found to bring about center suppression amounting to 20-30%, whereas distilled water or charcoal-treated deionized water invariably gave rise to only $\leq$10% thickness nonuniformity.

Positive AZ photoresists (Shipley Company) are unstable in alkaline media and therefore not compatible with the electroless gold process. Other organic compounds tested and found to be incompatible are Triton X-100 (Rohm and Haas Company, a nonionic surfactant) and n-dodecylamine. The addition of these compounds formed nodular, discolored deposits.

Agitation Effects

In addition to the enhanced plating rate which has already been described (1), bath agitation brings about two important beneficial effects: (*i*) it entirely eliminates the tendency for nodule formation, and (*ii*) it facilitates the formation of deposits with lateral growth structure and uniform grain size, which brings about a decrease in porosity. Three typical structures of 2 μm thick electroless gold deposits are illustrated in Fig. 4 by scanning electron micrographs. Figure 4a

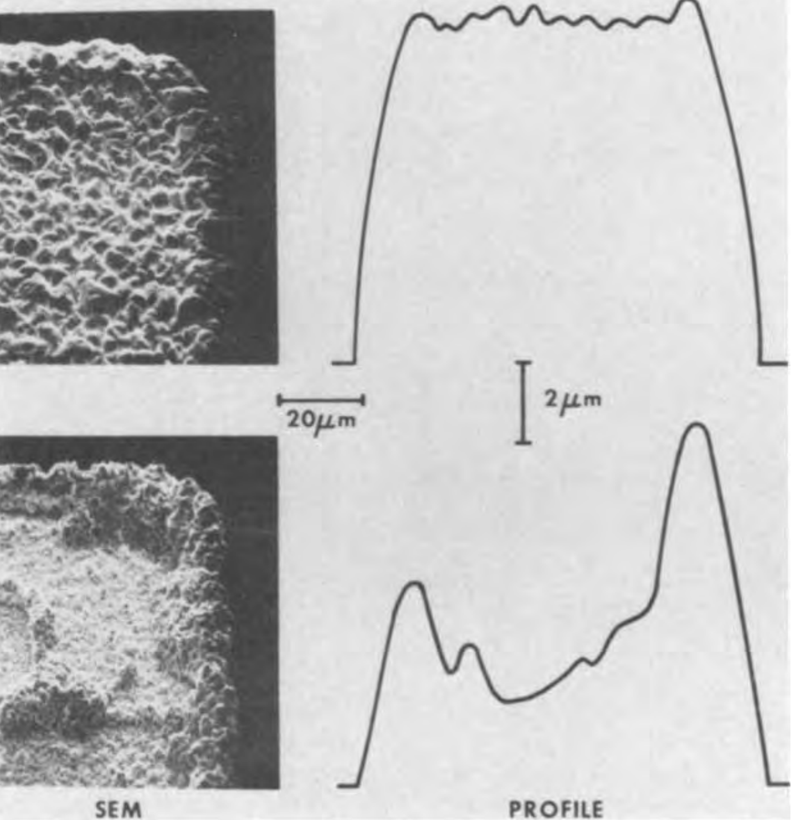

Fig. 3. Scanning electron micrographs and thickness profiles showing effects of contamination with polyethylene. Top, uncontaminated; bottom, heavily contaminated. (Bath B, 70°C, rotational plating.)

shows the morphology of deposits formed without agitation in a solution similar in composition to bath A (Table I) except the concentration of $KAu(CN)_2$ was decreased to 0.0025M. The plating temperature was 75°C. This deposit was brown in color, consisting of particles approximately micron size, and protruding outwards from the surface. Figure 4b shows the deposit formed in bath A [0.02M $KAu(CN)_2$] also with no external stirring. The deposit was smooth and yellow, with a fine structure consisting of a network of web-like features. Figure 4c shows a deposit obtained in the same bath but with vigorous agitation. The dilute bath which yielded photograph (a) gave deposits similar to photograph (c) when operated with agitation. These deposits are characterized by well-developed crystalline facets.

As may be expected from the morphological observations, the deposit formed in the dilute $KAu(CN)_2$ bath without agitation (Fig. 4a) was found to be most porous. The least porous deposit was formed in vigorously agitated baths (Fig. 4c) Porosities of deposits corresponding to Fig. 4b and c are compared in Fig. 5 as a function of the average deposit thickness. The deposits for the porosity determination were formed on ceramic alumina substrates precoated with evaporated titanium and copper. The porosity was determined by the method described previously (2): namely, each plated sample was immersed in 20% HNO_3 and ultrasonically agitated for 5 min at 30°C, and the dissolved copper was determined using atomic absorption spectroscopy. The ratio of the copper concentration determined for each plated substrate to that found with an unplated blank substrate was taken to represent per cent porosity. It is seen from Fig. 5 that the effect of agitation on porosity is especially significant for deposits thinner than 0.5 μm. For thicker deposits the effect is insignificant, and essentially zero porosity is achieved at thicknesses greater than 1 μm.

The electrical resistivity and hardness of deposits were also investigated with and without bath agitation. The results obtained with agitation were identical to those reported previously (2) for deposits obtained without agitation.

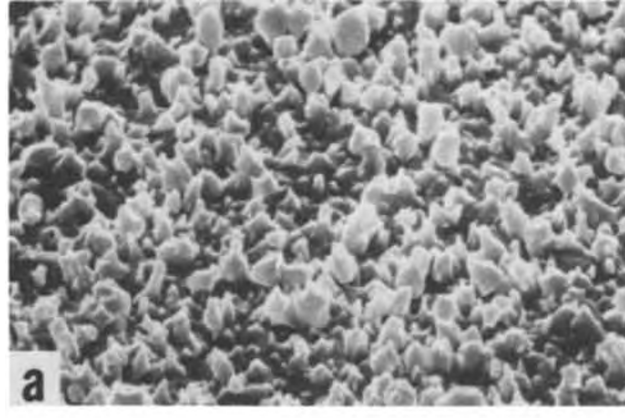
From the known dependence of deposition rate on the speed of bath agitation (1), it is clear that the deposition rate is partly controlled by the rate of transport of reacting species from the bulk of solution to the substrate surface. Therefore, conditions of agitation play an important role in determining the uniformity of deposit thickness on a given substrate. This subject is discussed in the next section.

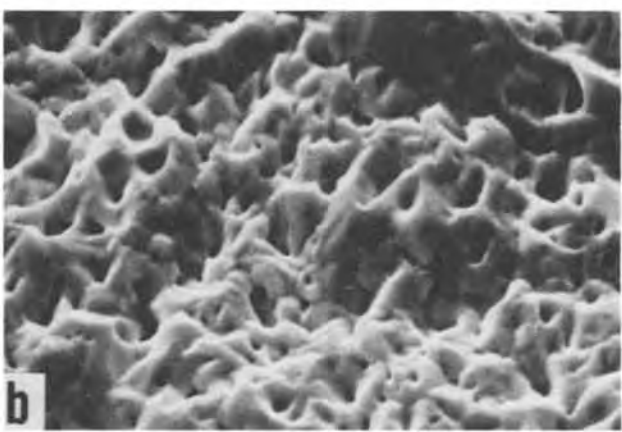
Uniformity of Deposit Thickness

It was found that the use of a simple magnetic stirrer or a stirring blade generally gives unsatisfactory results in regard to thickness uniformity across the substrate surface. For example, when a glass substrate (2.54 × 1.75 cm) precoated with evaporated Ti/Au was plated for 1 hr with motorized stirring rod agitation, a thickness variation of ±15% was observed. Using either of the two methods described below, the thickness variation can be maintained within ±3%.

The first method for providing uniform convection conditions uses a substrate holder of carousel type as shown in Fig. 6. The particular holder shown was constructed for plating silicon wafer substrates 1¼ in. to 1½ in. in diameter. It consists of two Teflon wheels and a Teflon shaft with stainless steel core. Grooves were cut in both wheels to hold the substrates vertically as shown in the figure. Silicon wafers were mounted on suitable supporting plates such as high density alumina or quartz using polypropylene as the mounting material. Blank supporting plates were placed in empty positions in the holder to obtain identical agitation conditions regardless of the number of substrates being plated. The assembled holder was connected to a motor and rotated with periodic reversal to obtain uniform thickness distribution.

The second method is more suitable for plating a larger number of substrates (up to 60) in one run. In this method, substrates are placed vertically in a holder in a radial array, and the holder is connected to a motor





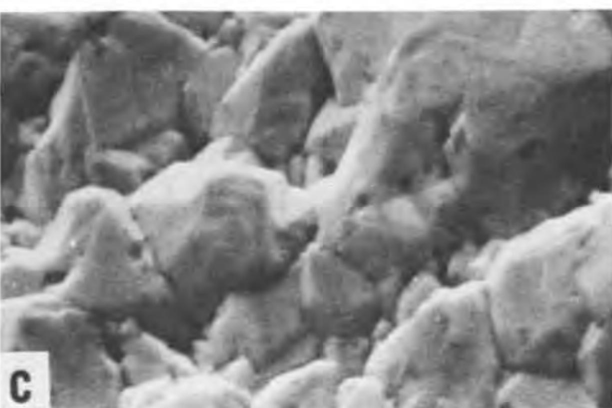


Fig. 4. Morphology of 2 μm thick electroless gold deposits. (Substrate, evaporated Au/Ti/glass.) a, Bath A except 0.0025M $KAu(CN)_2$, no agitation, 75°C. b, Bath A (0.02M $KAu(CN)_2$), no agitation, 75°C. c, Bath A (0.02M $KAu(CN)_2$), vigorous agitation, 75°C.

through a flywheel in such a way that it moves up and down during plating.[2] A photograph of the equipment constructed for plating silicon wafers with diameter up to 2 in. is shown in Fig.7. The substrate holder used in this particular apparatus was a commercially available Fluoroware wafer carrier fitted with a specially constructed Teflon shaft with steel core.

[2] It should be noted that the principle of vertical oscillatory plating is more readily adaptable to the scale-up for plating large area substrates such as ceramics (3¾ in. x 4½ in.).

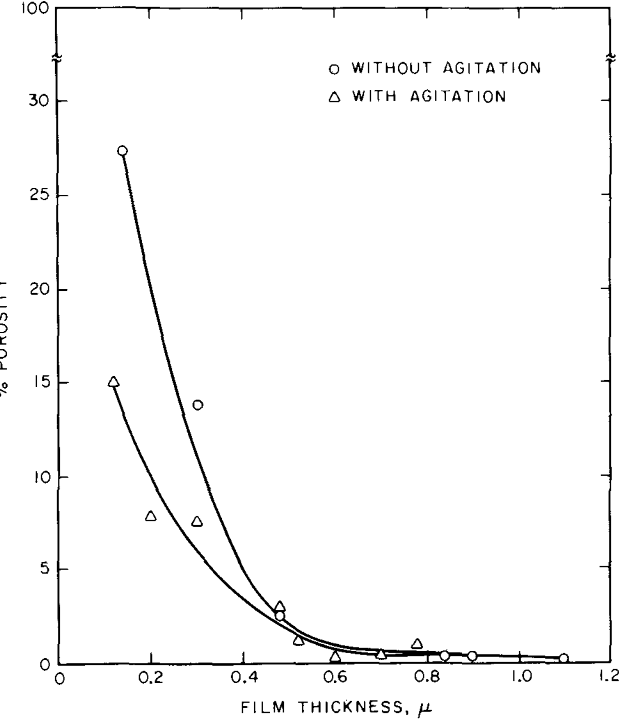

Fig. 5. Effect of agitation on deposit porosity. (Bath A, 75°C, Cu/Ti/alumina substrate).

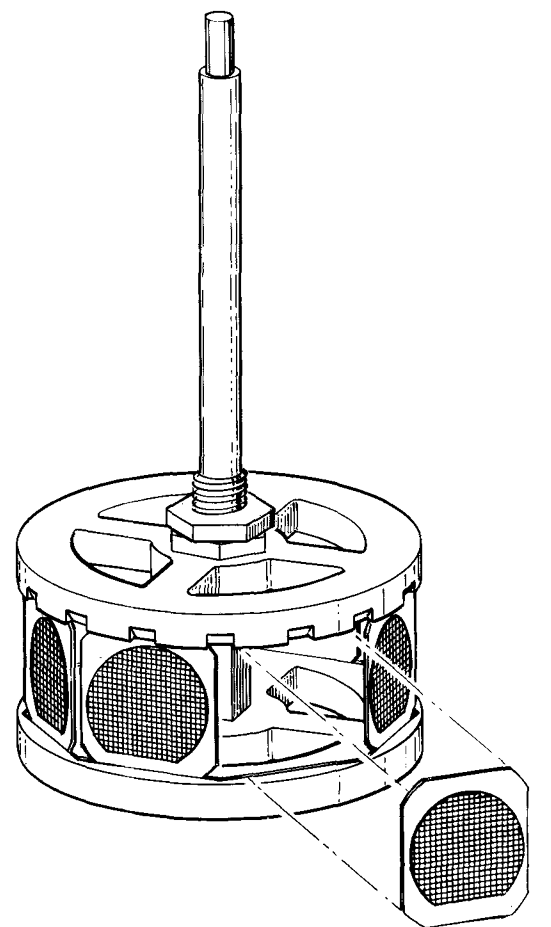

Fig. 6. "Teflon" rotating substrate holder for silicon wafer plating.

Both methods are equally satisfactory for obtaining thick deposits (*i.e.*, >10 μm thick) with no significant thickness variation at different locations on a substrate. However, there is a tendency for some thickness non-uniformity to occur on fine line patterned substrates

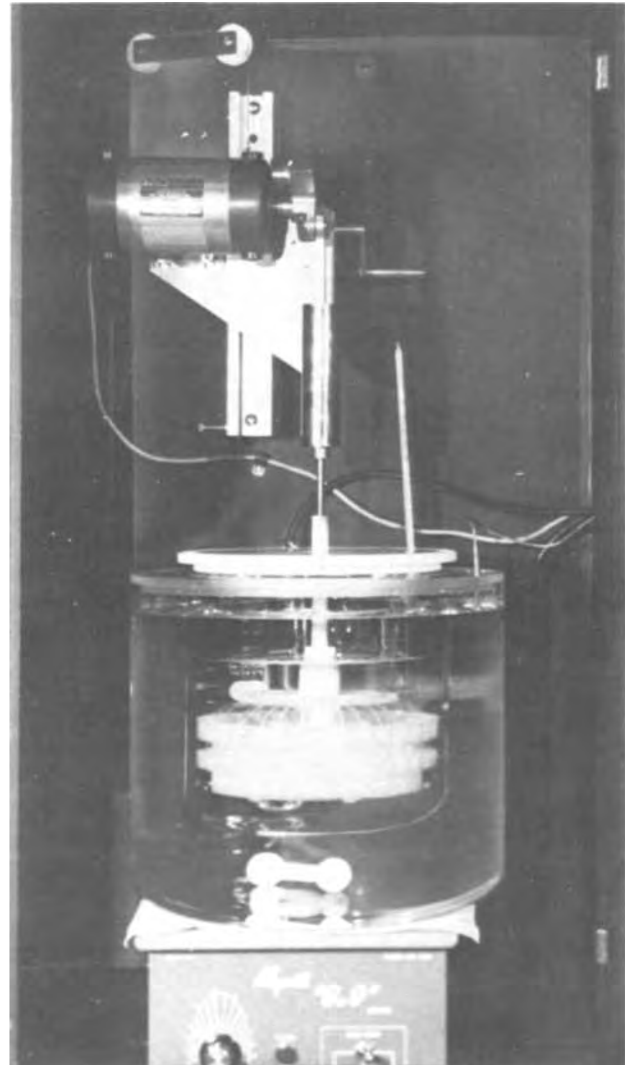

Fig. 7. Front view of vertical oscillatory plating apparatus for silicon wafer plating.

when the plating is carried out to only a few microns in thickness. The substrates used to study this effect were oxidized silicon wafers with suitable patterns of evaporated Ti(750Å)/Pd(1000Å) which were formed either by deposition through a metal shadow mask or by photolithography and etching. The plating was performed in bath B (Table I) at 70°C. Figure 8 shows a plot of deposit thicknesses at the edge and center of 75 μm wide lines against plating time for the vertical oscillatory plating. It is seen that deposits with a center thickness of 10.5-11.5 μm with less than 1 μm high edges are formed in 2 hr. Also noted in this figure is the fact that the edges form in the very early stages of plating, and their height increases only slightly with plating time. Therefore, the edge build-up is relatively more significant for thinner deposits. For example, the edge of 2 μm deposits is 25% higher than the center, whereas this number becomes only 7% for 11 μm deposits. Similar results are obtained with the rotational equipment.

It was found that the thickness uniformity of thin deposits can be greatly improved by plating at a slower rate in a bath containing a larger concentration of $KAu(CN)_2$. The thickness uniformity of deposits plated in bath C (Table I) at 70°C using the rotational equipment is illustrated in Fig. 9. It is seen that at the 2 μm level the edge nonuniformity remains within 10%. It is quite clear also from this figure that the edge build-up to a certain height occurs in the very early stages of deposit growth, and that this height does not change much with plating time. The cause of this phenomenon is not fully understood at the present time, but conceivably it may be related to the effect of geometry on the initial adsorption of reacting species or the recently discovered effect of crystallographic orientation on plating rate (9). The fact that the edge height changes little as the plating proceeds indicates that the mass transport condition is, on the average, quite uniform.

Line Resolution

Information on line resolution is essential in plating substrates with fine line patterns. As long as deposits are not constrained to grow vertically, *i.e.*, by photoresist, they also grow laterally to widen the original lines and narrow the spacing between them. The line resolution was determined using oxidized silicon substrates with Ti/Pd Ealing high resolution test patterns. Bath B and the rotational equipment were used. Plating was carried out for various lengths of time, the deposit thickness was measured with a Dektak instrument, and the set of smallest lines resolved was determined by optical and scanning electron microscopy. The results are tabulated in Table II. A scanning electron micrograph showing the resolution attained at 25 min is shown in Fig. 10. From the resolution data it can be calculated that the lateral growth was only about 60% of the perpendicular growth.

Table II. Line resolution

Plating time (min)	Thickness[a] (μm)	Width and spacing of smallest set of bars resolved (μm)
100-110	11-13	12.6[b]
50	5.2-5.6	6.3[c]
25	1.8-2.2	2.5

[a] Measured at center of 25 μm bars.
[b] 10 μm bars resolved except at ends.
[c] 5 μm bars resolved except at ends.

The slower lateral growth is beneficial in the application of the electroless gold process on substrates with patterns containing narrow spacings. In one application (10) a transistor structure with initial line spacing of 1.3 μm was successfully plated with 7000Å of electroless gold. It should be emphasized, however, that the success of such critical applications is greatly dependent on the cleanliness of substrate surface. For example, if the initial pattern of catalytic metal is generated by photolithography and etching, the areas where the metal is etched off must be completely free of metal and organic residues.

Some Considerations Relevant to Scale-Up and Waste Disposal

The vertical oscillatory plating apparatus described in a previous section (Fig. 7) is capable of handling thirty 2 in. silicon wafers in 2 liters of solution if one wafer is placed into each slot. This capacity can be doubled, of course, by placing two substrates back to back in a slot. With such a large number of substrates a significant decrease in the concentration of bath constituents occurs during plating. For example, a typical 2 in. silicon wafer plated in this laboratory had a plating area of about 1 cm^2 and required a gold thickness of 12 μm. Deposition onto 30 of these wafers requires a total of 0.7g of gold. On the other hand, 2 liters of plating solution (bath B) contains 1.18g gold. Thus, the amount of gold depleted at the end of the plating run is 59%. In order to learn whether such depletion causes any significant change in plating rate, experiments were run with a suitable number of wafers blanket coated with Ti/Pd in addition to one patterned wafer. The depletion percentage was calculated from the weight gain of the wafers and the initial quantity of gold present in the solution. Figure 11 shows a plot of plating rate in μm/hr calculated from the gold thickness achieved in 2 hr on 75 μm wide lines, *vs.* the percentage depletion of gold at the end of the plating time. It is seen that the plating rate at 83% gold depletion is only about 10% less than that at 1.5% depletion. In a separate series of experiments using copper sheet substrates, a sharp drop in plating rate was observed only after 95% of gold had been depleted. The dashed portion of the curve in Fig. 11 was drawn based on this information. The result indicates that under the conditions assumed for this evaluation, it would be possible to plate up to 45 wafers without a significant decrease in plating rate. For plating a larger number of substrates or a larger plating area, it would be necessary to increase the gold concentration or solution volume in order to avoid the depletion effects. An alternative method would be to replenish the bath with $KAu(CN)_2$ solution either continuously or periodically during plating.

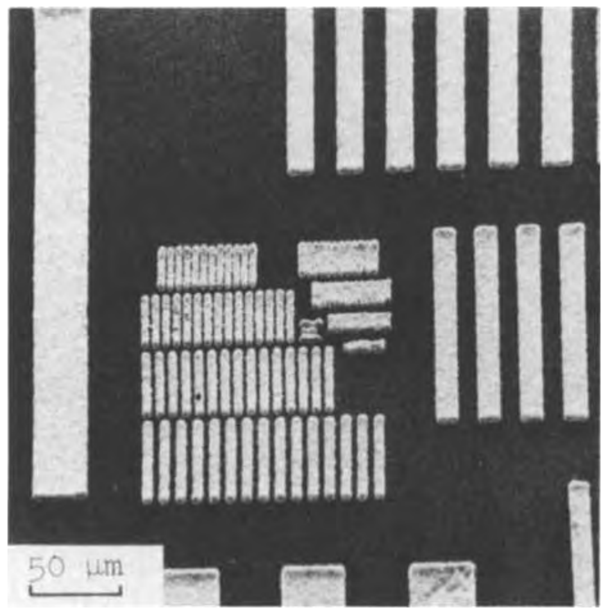

Fig. 10. Scanning electron micrograph showing line resolution after 25 min of plating. (Bath B, 75°C, rotational plating, gold thickness 2 μm.)

As far as the depletion of borohydride is concerned, it has already been shown (3) that the amount of borohydride consumed for the plating reaction is negligible as compared to the large excess borohydride present in the bath, and that the loss of borohydride can be regarded as being entirely due to hydrolysis (4). The possibility of operating the bath with periodic replenishment of KBH_4 has been discussed in the previous paper (3).

Waste disposal of spent solutions must be considered before the process is used on a large production scale. Gold can be recovered readily as metal by one of the three methods: (*i*) precipitation of spongy gold powder by heating to a temperature above 90°C followed by filtration; (*ii*) continuing electroless deposition on a large area substrate until all gold is plated out; (*iii*) electroplating gold. Addition of KBH_4 may be required to carry out method (*i*) or (*ii*). Method (*ii*) is recommended for treating solutions containing relatively small concentrations of gold. Method (*iii*) (electrolytic method) is suitable for recovering gold from more concentrated solutions because the deposition rate can be increased to a much higher level. The solution left after gold recovery can be treated by the standard alkaline chlorination process for destruction of cyanide ions to CO_2 and N_2. This process also oxidizes BH_4^- to borates. In order to keep the boron content of the final waste sufficiently low, dilution will be necessary before disposal.

Summary and Conclusions

1. Two bath formulations are recommended for obtaining deposits with optimal properties: bath B (Table I) for fast plating of thick (>5 μm) deposits, and bath C for forming thin (1-3 μm), uniform deposits. Both baths can be stored as 5× concentrated stock solutions at room temperature. These baths yield pure gold deposits at rates of 5 and 2 μm/hr, respectively, at 70°C with agitation.

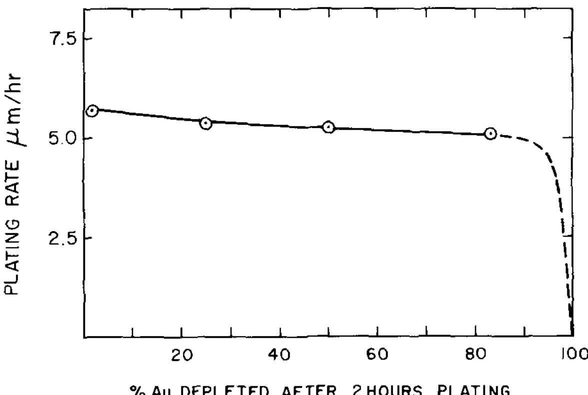

Fig. 11. Effect of gold depletion on plating rate. (Bath B, 70°C, vertical oscillatory plating.)

2. Nickel, cobalt, and ferrous ions cause bath instability and/or a decrease in plating rate; therefore, they should not be present. Copper does not show such effects.
3. Polyethylene is not compatible with the bath due to a chemical instability and can impair the quality of the deposit, whereas polypropylene is stable.
4. Water used to prepare the plating solution should be free of organic impurities when thickness uniformity is important on fine line patterns.
5. Bath agitation is beneficial. It increases plating rate, decreases porosity of deposits <1 μm thick, and eliminates nodule formation. Hardness and electrical resistivity are not affected by agitation.
6. Two methods of agitation suitable for obtaining uniform deposits are: rotational method with periodic reversal and vertical oscillatory method. Both methods give equally uniform deposits at essentially the same rate, but the vertical oscillatory method is more suitable for large scale operations. Under optimal conditions the thickness nonuniformity across a substrate can be maintained within 3%. On patterned substrates these conditions will maintain any edge build-up on fine lines within 10% over the thickness range of 1-12 μm.
7. The rate of lateral growth of electroless gold deposit is about 60% of the rate of perpendicular growth.
8. Gold recovery and disposal of spent solution are simple and straightforward.

Various practical and fundamental aspects of the electroless gold plating process are now believed to be sufficiently characterized and understood. The process has found a number of applications in this laboratory, and they will be described elsewhere.

Electroless Gold Beam Lead Plating

R. Sard,* Y. Okinaka,** and H. A. Waggener

Bell Laboratories, Murray Hill, New Jersey 07974

ABSTRACT

The electroless gold plating process developed in this laboratory has been successfully applied to the fabrication of beam leads on silicon integrated circuits. This unique plating process selectively plates gold onto discrete patterned regions of a substrate at 6 μm/hr with ≤10% thickness nonuniformity for thicknesses of 10-12 μm. Beam lead patterns were formed either by vacuum evaporation of titanium followed by palladium through a metal shadow mask or by photolithography and etching. The compatibility of this processing with a number of other materials present on Si devices has been established. Beam lead structures have been characterized with respect to mechanical properties and found to meet or exceed system requirements. This process is shown to be capable of high yields and is an attractive alternative to conventional methods of fabricating beam leads.

Gold beam leads (1) on silicon integrated circuits are conventionally formed by electroplating through a photoresist pattern onto a base metal such as Ti/Pd or Ti/Pt. As shown schematically in Fig. 1A, a minimum of six basic processing steps are involved: (*i*) titanium and palladium (or platinum) evaporation, (*ii*) photoresist application, exposure and development, (*iii*) gold plating, (*iv*) photoresist removal, (*v*) palladium etching, and (*vi*) titanium etching. Many variations of this processing have evolved, such as etching the palladium before plating then using a second photoresist application to define the beams, or by using back sputtering techniques in place of etching to remove the unwanted metals. All such variations are inevitably more complex than the scheme depicted in Fig. 1A, although they have in some instances (2) been shown to yield improved results.

Key words: electroless gold plating, beam lead, silicon integrated circuit.

A program was undertaken to develop a simpler procedure based on the electroless gold process developed in this laboratory (3). This process is known to produce gold deposits with satisfactory properties (4) (*i.e.*, conductivity, hardness, structure and thermocompression bondability) for device applications. Moreover, this process will only deposit gold on catalytic regions of a substrate and is therefore compatible with all-additive processing (*i.e.*, no metal etching is required). In its simplest form, such a beam lead process consists of the following steps (which are illustrated schematically in Fig. 1B): (*i*) alignment of a metal shadow mask with apertures corresponding to the regions where beam leads are desired, (*ii*) Ti/Pd (or Ti/Pt) evaporation, and (*iii*) electroless gold plating.

In addition to the obvious reduction in the number of processing steps, the electroless gold process entirely eliminates the possibility of gold "underplating" or other complications associated with plating through a

patterned photoresist. It does, however, require that the regions of the substrate which are not to be plated, *i.e.*, the intrachip area and the regions between the beams, be covered with a suitable material such as a dielectric.[1]

Fabrication of electroless gold beam leads by this procedure is well suited to the structure shown schematically in Fig. 2. In a sealed structure of this type, the contact metallization, M, is covered by a top dielectric, D, and is accessed through via windows. Test structures of this type were fabricated using oxidized (4000Å SiO_2) wafers that received two main processing steps prior to beam leads: (*i*) contact metal deposition (sputtered tungsten was used primarily in this work) and patterning by photolithography and etching and (*ii*) dielectric deposition and pattern definition of contact windows. The choice of this fabrication method follows directly from the properties of the metals, tungsten and gold. Tungsten cannot be gold plated directly and, from a corrosion standpoint, this combination is relatively poor (5). Hence these metals are not exposed to the same environment (Fig. 2).

After a brief description of the plating method used, the compatibility of various materials (dielectrics and metals) with this processing will be discussed. The final sections of this paper will present specific results relating to beam lead geometry and the physical and mechanical properties of electroless gold beam leads, both for the test vehicle described above and for random access memory devices (6) to which this processing has been applied.

[1] An alternative to this procedure, which more closely resembles Fig. 1A, is to deposit Ti/Pd everywhere then pattern and etch Pd only, leaving the Ti as a mask since it is inert in the plating solution. Two important requirements for high yield processing in this case will be (*i*) residue-free Pd etching and (*ii*) pinhole free Ti. This approach is feasible but will not be discussed further in this paper.

Beam Lead Processing

The first step of the beam lead processing scheme outlined in Fig. 1B is the evaporation of titanium and palladium through a metal shadow mask which was previously mounted in a fixture (Fig. 3), aligned, and held in place against the wafer.[2] The mask material used, most often, was molybdenum, fabricated from 0.0005 in. or 0.001 in. thick material. This assembly (Fig. 3) was placed in a conventional vacuum station, either e-gun or filament, pumped $<10^{-6}$ Torr and then coated with 750Å Ti and 1000Å Pd. After removing from the holders, the patterned wafers were mounted on quartz carrier plates with polypropylene and placed in a carousel-type apparatus using the procedures outlined in Ref. (7).

The electroless gold solution formulation was as follows:

$KAu(CN)_2$	0.003M
KCN	0.1M
KOH	0.2M
KBH_4	0.2M

The plating rate of this solution is 6 μm/hr at 70°C with forced convection provided by rotating the carousel at 150 rpm with a periodic reversal every 10 sec (7). All plating runs were of the batch type. The amount of gold which would be plated out due to beam lead processing of eight wafers is estimated to be less than 40% of that in solution. Separate experiments have shown that the plating rate and deposit structure are unaffected by this amount of depletion for the conditions reported.

Compatibility of Materials

A number of materials, both metals and dielectrics, that might be used in SIC's were investigated from the standpoint of their compatibility with electroless gold processing.

Metals.—Previous studies (3, 7) have reported on the three qualitatively different types of behavior exhibited by metals in electroless gold solution: (*i*) the directly catalytic noble metals, (*ii*) the marginal transition metals which begin plating by displacement, and (*iii*) the inert refractory metals. The reason for using a binary combination (*e.g.*, Ti/Pd) is because the directly catalytic noble metals have rather poor adhesion to dielectric surfaces, whereas the inert metals in category (*iii*) adhere strongly to such substrates.

Dielectrics.—The stability of various dielectrics was determined by making thickness measurements on

[2] Alternatively, beam lead patterns were defined by blanket evaporation of Ti/Pd followed by standard photolithography and etching procedures. This approach gave similar results, but was not used as often because of its greater complexity.

Al_2O_3	<50

patterned wafers with a stylus instrument (Dektak, Sloan Instrument Company) before and after exposure to the electroless gold plating conditions. The films used and results obtained are listed in Table I. It is evident from these data that the dissolution rate of the films investigated ranges from a negligible value of <50 Å/hr for Si_3N_4 deposited at 875°C and Al_2O_3, to a considerable value of 2000 Å/hr for a low temperature P-glass (SiO_2 + 4% P_2O_5 glass deposited at 350°C).

The optimum choice of dielectric depends mainly on the specific structure being fabricated. Refractory contact metallizations such as tungsten can withstand high temperature processing. Silicon nitride was used primarily in this work. The Si_3N_4 was patterned using the oxide etch mask technique (8), and, more often than not, the SiO_2 cap was left in place during the subsequent beam lead plating operations.

Silicon.—Exposure of bare Si to an alkaline solution containing $KAu(CN)_2$ is known (9) to result in the deposition of gold by displacement

$$Si + 2KAu(CN)_2 + 4KOH \rightarrow 2Au + H_2 + K_2SiO_3 + 4KCN + H_2O \quad [1]$$

This fact requires proper masking of Si on the backs of wafers by an appropriate mounting technique (7), otherwise, the high negative potential of the displacement reaction will cause an abnormally fast deposition rate on those beams electrically connected to the silicon bulk. The effects of potential on electroless gold plating are discussed in more detail below.

Beam Lead Geometry

Neither electroless gold nor any other autocatalytic system for metal deposition has yet been used for an application comparable to the present one which requires uniform plating (within ±0.0001 in. or 2.5 μm) on all of the ~6000 discrete regions which must be plated on each substrate. Consequently, it was believed necessary to thoroughly evaluate the final geometry of electroless gold beam leads. The techniques used in this evaluation were optical and scanning electron microscopy and thickness profile measurements.

Lateral spreading.—The proper design of beam leads should make allowance for lateral spreading in order to prevent shorts between adjacent beams. It was previously shown with patterned substrates formed by photolithography that lateral growth is about two-thirds of the thickness (7). This result was confirmed in the present study.

Thickness uniformity.—The thickness uniformity of electroless gold beam leads was found to be typically, within ±10% for all variations, *i.e.*, for edge build-up on a given beam, beam-to-beam and wafer-to-wafer variations. To obtain this degree of uniformity, it is necessary to eliminate those organic impurities from the system which can adversely affect plating uniformity as discussed in Ref. (7).

Potential effects.—If sources of biasing potentials exist on a substrate being plated, then the thickness uniformity quoted above will not be obtained. The reason for this is that the electroless gold deposition reaction occurs at a mixed potential governed by the cathodic reduction of $Au(CN)_2^-$ and the anodic oxidation of BH_3OH^- (an intermediate species formed during hydrolysis of KBH_4) (10). Thus, anything that alters the potential of the surface is expected to affect the rate of deposition. The dependence of deposition rate on potential can be estimated from the current-potential curves shown in Fig. 4. These curves were obtained with a rotating platinum disk electrode plated with electroless gold using a solution of slightly different composition to the one described above. The result, however, is quite general. Curve 1 was obtained by slowly scanning the potential (0.56 mV/sec) in the anodic direction while the current was being recorded. The electrode was rotated at 1600 rpm. This speed was chosen because previous results indicated that under these plating conditions a deposition rate of about 6 μm/hr is observed which is equal to the rate obtained for beam lead plating in the carousel apparatus. In Fig. 4 the electroless deposition occurs at the potential where curve 1 intersects the abscissa (−0.80V). The rate of electroless deposition corresponds to the current measured at this potential on curve 2, which was obtained in the absence of borohydride (broken line). If the potential of the surface at which gold deposition is taking place is altered for some reason, the deposition rate should vary according to curve 2. The current-potential relationship in the range shown is essentially linear with a slope 0.0258 mA · cm^{-2} · mV^{-1}, which corresponds to a rate variation of 0.97 μm/hr for a potential change of 10 mV.

As mentioned earlier, significant potential shift can be brought about if bare silicon is exposed to the solution and the region being plated is connected to the silicon bulk. A large thickness variation attributable to this cause was observed in one instance. On this test wafer most of the beams were 10-11 μm thick, but there were several very thick (~25 μm) beams. Such thick beams always occurred in pairs: namely, they were interconnected by conductor metallization. An electrical probe test revealed that the thick beams were all in direct electrical contact with the silicon, indicating that the dielectric material had suffered breakdown under the thick beams or interconnecting tungsten films. It was further found that portions of the back of this wafer were covered with loosely adherent gold deposits which appeared to have formed by the displacement reaction between exposed silicon and

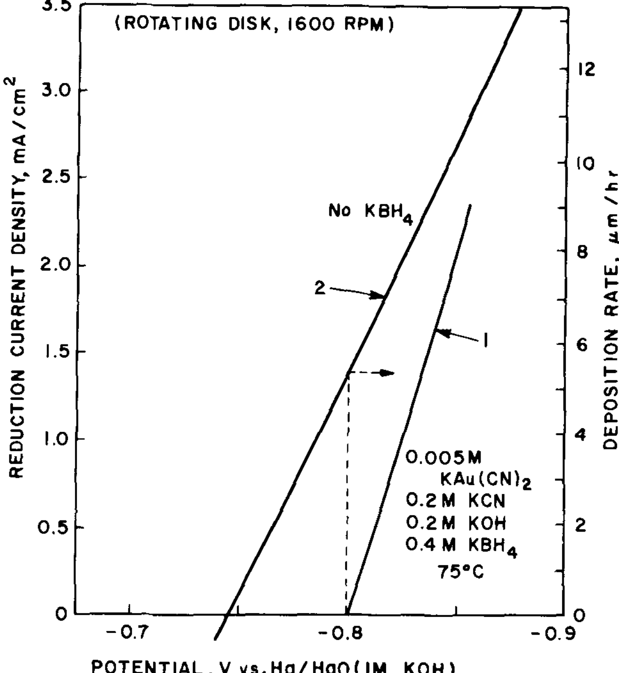

Fig. 4. Current-potential relationship for electroless gold system, obtained at rotating disk electrode.

$Au(CN)_2^-$ (reaction [1]). In view of the high reactivity of Si in alkali [$SiO_3^{--} + 3H_2O + 4e^- = Si + 6\,OH^-$, $E^\circ = -1.7V$ (11), $H_2 + SiO_3^{--} + H_2O + 2e^- = Si + 4\,OH^-$, $E^\circ = -2.6V$] and the deposition potential of electroless gold (-0.6 to $-0.9V$ *vs.* NHE) (10), it follows that if beams are in direct contact with silicon and the back side of the wafer has silicon directly exposed to the solution, the deposition potential of such beams must be more negative than that on beams electrically isolated from the silicon. From Fig. 4 it can be deduced that a 72 mV negative shift is sufficient to cause the anomalously high deposition rate observed. It should be noted that beams in actual integrated circuits are not electrically isolated from silicon; therefore, it is important that the back of the wafer be protected from the direct exposure of silicon to the plating solution. This also applies to edges of the silicon. As mentioned previously, and discussed more fully in Ref. (7), the method used to mount the wafers is adequate for this purpose.

As another source of potential, which is extremely important on S.I.C.'s is the photovoltaic effect across a p-n junction. The effect of photovoltage on gold deposition by displacement on silicon has already been described by Silverman and Benn (12). The difference in plating rate of electroless nickel on p- and n-type surfaces of silicon at p-n junctions under strong illumination is also known (13). The magnitude of photovoltage is, of course, dependent upon the conversion efficiency of the particular p-n junction and lighting conditions. The potential across a p-n junction during plating can be much less than the open-circuit value because of the low impedance of the electrochemical process. On the basis of the current-potential curves of Fig. 4, it can generally be stated that if the photovoltage causes a potential shift at the Ti/Pd pads in solution of about 6 mV, the difference in plating rate across the p-n junction will be about 10%. An illustration of how this effect can influence device results is shown in Fig. 5 where the white leads (No. 4, 5) make contact to regions of an IGFET test structure that were positively biased during plating in ordinary room light. Additional evidence for this effect is the fact that the negatively biased beam (No. 8) was plated at a rate of about 12 μm/hr, which is twice as fast as the normal rate for beams not biased by the substrate (No. 1-3, 6, 7). The effect can, of course, be eliminated should it occur for a particular device simply by plating in the dark.

Process Yields

A pilot line operation has been set up to implement the processing of electroless gold beam leads on silicon integrated circuits such as a random access memory (6). The factors discussed above which can affect processing yield have been brought under control. It can be stated that this process gives reproducible results with essentially no yield loss except for that due to the shadow mask which is nearly zero. Experience with this process has shown that typical mask defect densities are about 0.1 cm^{-2}. An example showing a portion of the beam leads on a finished memory chip is shown in Fig. 6.

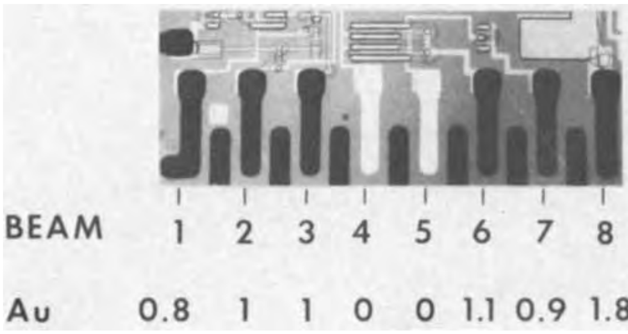

Fig. 5. Photomicrograph of electroless gold beam leads on one side of an IGFET test chip. Beams 4 and 5 are unplated due to positive bias from light incident on p-n junctions. The thickness data shown were normalized based on the standard plating rate. Beam 8 was negatively biased and plated twice as thick as unbiased beams.

Physical Characteristics of Electroless Gold Beam Leads

Deposit appearance and morphology.—The appearance of electroless gold deposits has previously been shown (4, 13) to depend on the morphology of surface features on the scale of approximately 1 μm. The nature of these features is determined by the deposition conditions and they have been classified on the basis of scanning electron microscopic studies as follows: (*i*) outward growth type; (*ii*) lateral growth type with weblike features, or (*iii*) lateral growth type with faceted structure. The beam leads plated under the conditions described above have the characteristic faceted structure illustrated in Fig. 7. This scanning electron micrograph indicates that the deposit surface has a roughness of approximately 1 μm due to the grain structure. This result is in agreement with the fine detail in the profile traces used to obtain thickness data.

Thermocompression bonding, hardness, and related properties.—Thin electroless gold deposits are known to be highly suitable for thermocompression (T/C) bonding (4) and relatively high in purity (3) (>99.9% Au). Furthermore, they exhibit bulk conductivity and have been classified as being "soft gold" deposits (3, 4).

Although none of these properties is expected to change under the conditions used to plate beam leads,

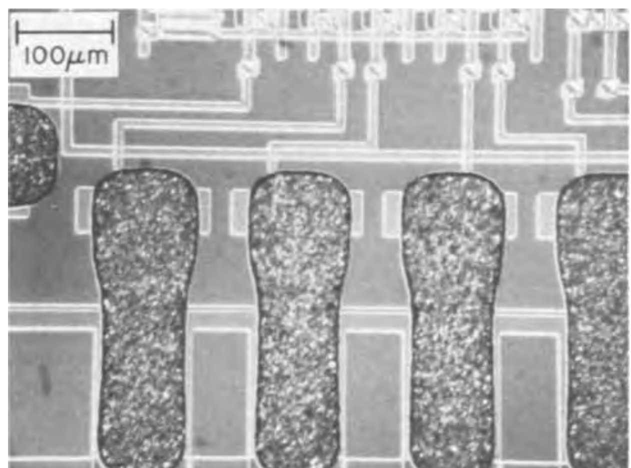

Fig. 6. Photomicrograph of electroless gold beam leads on random access memory chip.

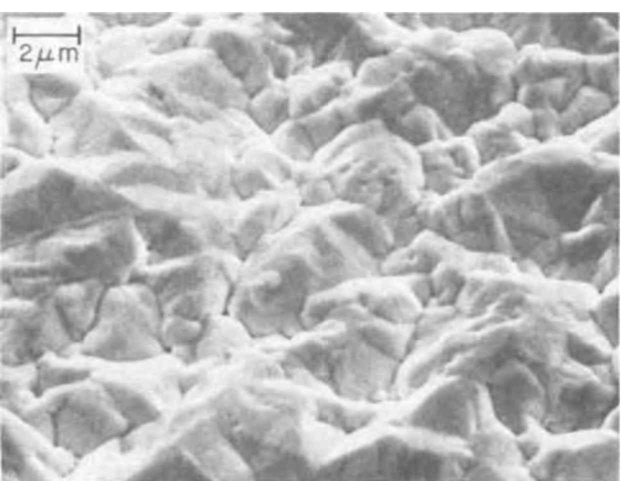

Fig. 7. Scanning electron micrograph showing surface topography of electroless gold beam lead.

it was possible to evaluate the most important ones from a device standpoint simply by processing the slices through a chip separation procedure consisting of mounting the wafer face down, thinning the silicon, back aligning a photoresist pattern, and Si etching to open up the grid areas between chips and expose the ends of the beam leads. Separated chips were T/C bonded to patterned ceramics for electrical, mechanical, and environmental tests. To date, no bonding failures have been observed for these chips. Furthermore, blow tests, which subject bonded chips to pulsed air blasts have shown that these chips can withstand a large number of cycles, typically 50-100 without failure. Standard beam leaded devices are required to pass 3 cycles without failure in this test.

Indentation hardness measurements were carried out on the underside of beams (*i.e.*, in the grid area) of etched apart chips that were still supported by sapphire and imbedded in mounting material. Such measurements approximate the techniques used previously for thinner, larger area deposits (4). Typical Knoop hardness values of 50-60 were obtained at 5g load, which agrees well with earlier results and is consistent with the good ductility implied by the T/C bonding and blow test results.

Peel tests of electroless gold beam leads.—A detailed study is now underway (15) to characterize the mechanical behavior of beam lead structures of the type shown in Fig. 2 using the 90° peel test. In this test the beams are bent up and pulled, one at a time, at 90° to the chip. It has been found that beams which fail this test, *i.e.*, those with fail values below 2-3g, may cause device failures during subsequent packaging, life testing, or in service. Some preliminary results with electroless gold beam leads on memory chips are shown in Fig. 8. These data, which are plotted as a fail strength distribution, indicate that the mechanical integrity of the structure is satisfactory for device purposes. A more comprehensive report dealing with the effects of processing and design variables on the mechanical properties of this structure is presently being completed.

Summary

Electroless gold plating can be used to selectively plate discrete geometries to any thickness required for device processing. This unique capability has led to the development of a new method for fabricating beam leads. The main advantage of this method is its relative simplicity which results from the elimination of the photoresist and etching operations used in conventional processing.

The vehicle used to demonstrate this new approach was a dielectric encapsulated, tungsten metalized tester chip with beam lead patterns formed by vacuum evaporation of Ti/Pd through a shadow mask. These procedures have also been applied to the plating of beam leads on random access memory chips in a pilot line operation.

Some specific results of this work are as follows:

1. Beam leads are plated at 6 μm/hr with a thickness uniformity of ± 1 μm at the 12 μm level.
2. The yield of the beam lead processing is mask limited with typical defect densities $\sim$0.1 cm^{-2}. Ti/Pd metalization evaporated through a shadow mask proved to be a highly satisfactory technique for beam pattern definition on S.I.C.'s.
3. The compatibility of this processing with a number of metals and dielectrics has been established.
4. The effect of biasing potential on deposition rate is given. Two sources of potential which can lead to nonuniform plating of beams, namely, the photovoltaic effect and Si displacement are shown not to cause problems provided plating is carried out in the dark and the substrate does not have Si exposed to the solution.
5. The mechanical properties and T/C bonding of beam leaded chips are satisfactory for device applications.

Method for Forming a Printed Circuit by Photolysis of Silver Salt of Organic Acid

Hisao Tabei, Shigeo Nara, and Kentaro Matsuyama

Ibaraki Electrical Communication Laboratory, Nippon Telegram and Telephone Public Corporation, Tokai, Ibaraki, Japan

ABSTRACT

A method for forming a printed circuit was carried out. The method comprises coating the surface of an insulating substrate with a solution of silver salts of organic acids in a mixed solvent consisting of alcohol, water, and ammonia to form a photosensitive layer thereon, exposing the layer to uv-light so as to deposit the metal silver on a pattern of a desired circuit, and carrying out the electroless plating on the pattern, whereby the deposited metal silver functions as the nuclei for the plating.

Printed circuit boards, heretofore, have been made by the so-called photoetching process which comprises forming a photoresist layer mainly comprising photosensitive resin on the surface of an insulating substrate with a copper foil top, laying a negative of a desired circuit pattern thereon, exposing the layer by the negative to light, processing the photoresist layer to develop the pattern and to remove the unexposed regions, and etching the copper foil so as to remove the regions of the copper foil corresponding to the unexposed regions. For this, the material loss is great since most of the copper foil is removed by dissolution, only required circuit regions being left. Also this method involves extremely complicated steps such as through-hole plating which effects connection of the circuit patterns on both surfaces, that is, the sensitizing, activating, and plating treatments of the through-hole wall are required for connecting. Therefore, this method requires much time and many processes and incurs low yield and high cost.

We investigated an entirely new method for forming a printed circuit utilizing a photochemical reaction, which is intended to eliminate the above-explained disadvantages of the prior art method.

Certain metal salts of organic acids liberate metal ions when irradiated with uv-light, and liberated metal ions turn to metal atoms as the result of reduction, and the formed metal atoms agglomerate (1-3). This result suggested to us a new method for forming the electrically conductive pattern on insulating substrates.

We investigated the new method which comprises coating the surface of an insulating substrate with silver salts of organic acids, exposing the layer to uv-light so as to deposit silver metal on a pattern of the desired circuit, and carrying out the electroless plating on the pattern, whereby the deposited silver metal functions as the nuclei for plating.

Most of our experiments have been made with the compound silver glutamate. In addition, a more limited experiment of the compound silver acrylate is discussed.

Experimental

Materials and effect of uv-light exposure.—Silver glutamate and silver acrylate were prepared by the usual procedures. Each solution containing 25 ml of 0.02M monosodium L-glutamate or sodium acrylate was mixed with 25 ml of 0.02M $AgNO_3$ solution. The precipitates were filtered and air-dried at room temperature in the dark. Then 1.5g of silver glutamate was dissolved in 30 ml ammonia-ethanol solution (concentrated ammonia water: ethanol: water = 1:6:3 volume). Similarly 1g of silver acrylate was dissolved in 30 ml ammonia-ethanol solution. These solutions were preserved in polyethylene bottles in a refrigerator.

Key words: Silver salt of organic acid, photolysis, printed circuit pattern, electroless plating, silver glutamate.

Coatings on quartz slides were made by the following method. A few drops of the solution containing silver salt were placed on the quartz. After drying at 60°C, the solid adhered to the quartz strongly enough for the quartz to be handled without loss of solid. The coatings contained about 3 mg/cm^2 of silver glutamate and 2 mg/cm^2 of silver acrylate.

The uv spectra were obtained with a Hitachi spectrophotometer Type 124, and the Sakura densitometer Type PDA-60 was used for measuring transmission densities. The amount of silver metal was analyzed by the EDTA chelate titration technique (4). One milliliter of solution containing silver glutamate was pipetted in a dish with flat bottom and dried at 60°C. After exposure to uv-light with 251 nm wavelength, exposed silver glutamate was dissolved in aqueous ammonia (about 3% solution) and filtered. Then $K_2Ni(CN)_4$ and MX indicator (Murexide) were added to the filtrate and titrated with 0.01M EDTA solution. Furthermore, 1 ml of solution containing silver glutamate was titrated without the procedures of drying, exposing, and dissolving. The ratio of both amounts of EDTA solution is the proportion of photolysis silver glutamate.

The irradiation source employed was the Nihon Bunko CRM-FA spectro irradiator.

The dark reaction of silver glutamate was examined using a vacuum oven.

Forming the printed circuit.—The steps in forming the printed circuit pattern are explained with reference to Fig. 1.

(A) Substrate preparation: The surface of an insulating substrate was cleaned and roughened as required to produce a clean and wettable surface.

(B) Sensitization: A solution layer containing silver salt of organic acid was painted on the surface and the substrate was dried at 60°C. A photosensitive layer was formed on the insulating substrate.

(C) Print (photo-image reaction): A circuit pattern negative was laid in contact with the substrate and it was uv-light exposed in air. Exposed regions of the photosensitive layer were blackened by photolysis, while the unexposed regions remained unchanged.

(D) Fix: On immersion into a mixed solution of sodium hydroxide and ammonium hydroxide (NaOH 40g. conc NH_4OH 50 ml, water 950 ml), the unexposed regions of the photosensitive layer were dissolved and in the exposed regions, agglomerate silver metal remained insoluble.

(E) Metalization: The exposed regions were metalized by immersion in an appropriate electroless plating bath.

The irradiation source employed was a 250W high pressure mercury lamp (Ushio Uniark 250D). The distance between the sensitive layer and irradiation source was 15 cm.

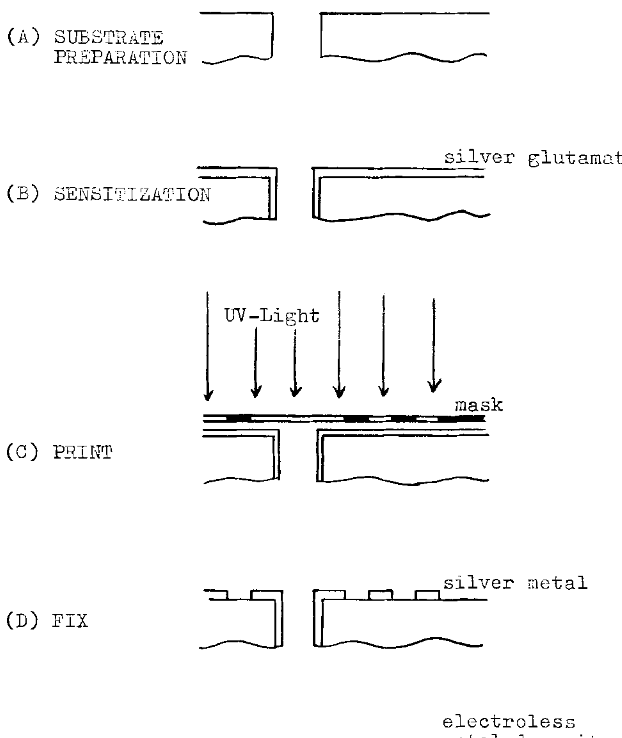

Fig. 1. Steps of method for forming printed circuit

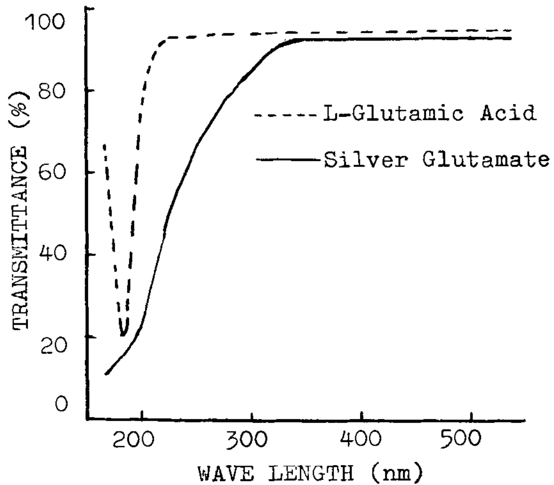

Fig. 2. UV-V spectra of L-glutamic acid and its silver salt

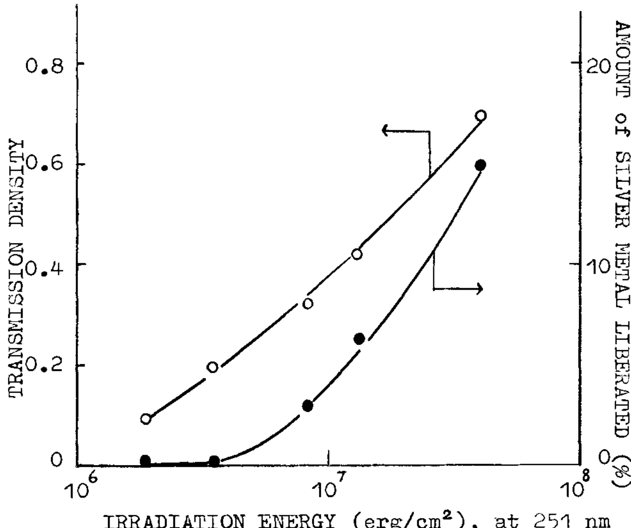

Fig. 3. Relations among exposure energy, transmission density, and amount of silver metal liberated.

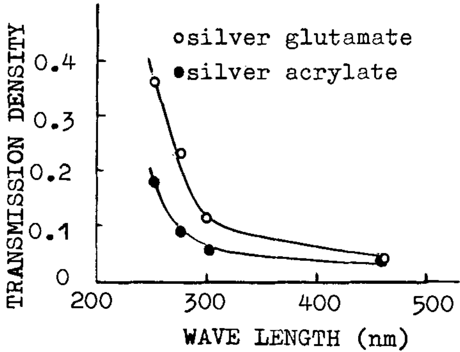

Fig. 4. Sensitivity curves of silver salts

Results and Discussion

Materials.—In Fig. 2 is shown uv spectra of L-glutamic acid and its silver salt (HOOCCH(NH_2) (CH_2)$_2$ COOAg). The L-glutamic acid shows peaking at about 190 nm, while its silver salt shows the absorption band at about 220 nm. Further, the spectra of acrylic acid and its silver salt were similar to that described above, that is, the absorption bands of silver salts are shifted to long wavelength. In general carboxylic acids show peaking at about 200 nm and it is considered that the absorption corresponds to carbonyl group. It can therefore be presumed that —COOH turns to —COOAg.

In Fig. 3 are shown the relations among exposure energy, transmission densities, and the amount of silver metal liberated by photolysis. Liberated silver metal increases according to the increase of exposure energy and transmission density increases too.

The sensitivity curves of silver salts are shown in Fig. 4. When exposed with light of wavelength longer than 300 nm, transmission densities are small, and therefore, photolytic deposition of silver metal is poor. The concentrations of silver salts in each film are equal in mole per cent and therefore, in comparison of transmission densities, it is considered that the sensitivity of silver glutamate is greater than that of silver acrylate.

In Fig. 5 is shown the dark reaction of silver glutamate. The decomposition of silver glutamate scarcely proceeds below 80°C within 15 min.

Forming a printed circuit.—The surface of the insulating substrates are cleaned and roughened. These

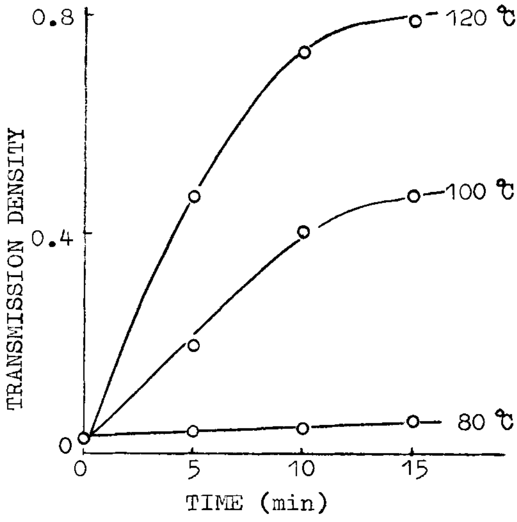

Fig. 5. Dark reaction of silver glutamate

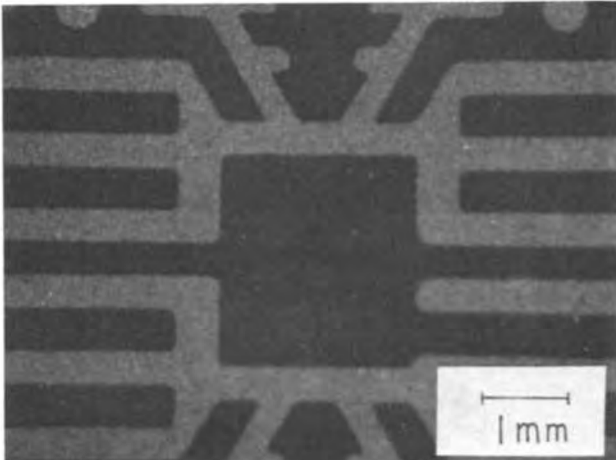

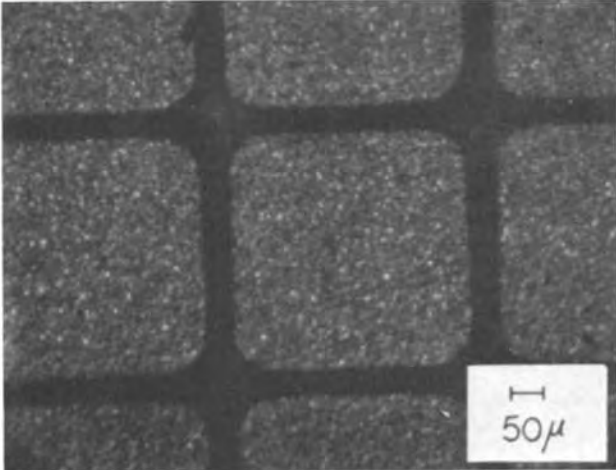

Fig. 6. Examples of circuit patterns obtained

procedures are required to obtain homogeneous sensitive layers and good adhesion between substrates and silver atoms liberated by photolysis. In order to obtain epoxy resin laminates with an active surface, we performed liquid honing with aluminum oxide powder and chemical etching with a solution of potassium dichromate and sulfuric acid ($K_2Cr_2O_7$ 150g, conc H_2SO_4 1000 ml, water 500 ml) at 60°C for 5 min. The surface of the ceramic substrates was polished with diamond powder, and the surface was roughened. As a flexible substrate, polyester tracing film was used.

When the substrates coated with silver salts are exposed to uv-light in air through a mask, exposed regions blacken and deposit colloidal silver atoms. A high pressure mercury lamp is used as a uv-light source and silver glutamate is employed for its high sensitivity. The sensitive layers need to be exposed for 10 min to form stable nuclei for electroless plating. In the fix step, the role of sodium hydroxide is to fix colloidal silver atoms. When sodium hydroxide is not contained in the fix solution, the colloidal silver atoms are liable to be dissolved. That means the decrease of nuclei for electroless plating, and adhesion for electroless plating is labilized. The unexposed regions can be washed away easily with the NaOH + NH_4OH solution.

The substrate having the pattern of silver particles is then immersed in an ordinary electroless copper plating solution (5), comprising 14.6g copper sulfate ($CuSO_4 \cdot 5H_2O$), 7.5g sodium hydroxide, 7.5g Rochelle salt, and 43.8g, 37% aqueous formaldehyde solution in water to make 1 liter, without employing any activating pretreatment. In 15-20 min, a copper circuit pattern 1-2μ in thickness is formed.

Examples of the obtained patterns are shown in Fig. 6. From this figure, it is observed that fine patterns can be obtained by deposition of metal particles.

Conclusion

We have shown that printed circuits can be formed on insulating substrates utilizing the photolysis of silver salts of organic acids. This is a simple process to form printed circuits and the process can be applied to other fields such as photographic material, inlaid work, and photomask.

At present, basic studies of the important process steps are being carried out and will be reported in the near future.

Mutual Effect of Current Density, pH, Temperature, and Hydrodynamic Factors on Current Efficiency in the Chlorate Cell Process

Milan M. Jaksic*

Electrochemistry Department, Institute for Chemistry, Technology, and Metallurgy, Belgrade, Yugoslavia

ABSTRACT

The simultaneous mutual effect of pH, temperature, current density, and hydrodynamic factors on current efficiency in the chlorate cell process has been investigated and considered. Certain practical considerations of the process optimization are also given. Some contributions to the scale-up of chlorate cells have also been introduced. It has been pointed out that by adjusting all other parameters at their optimal values (temperature, pH, and the linear velocity of flow), the current density is then the main factor providing high current yields.

The basic electrode process in electrochemical chlorate production is anodic chloride ion oxidation, accompanied by immediate hydrolysis of the resulting elemental chlorine, that yields as a further intermediate product hypochlorous species or available chlorine.[1] Two simultaneous parallel ways remain for active chlorine to reach the final state of chlorate formation. The first and the useful one (t_1) would be its direct chemical conversion

$$2HClO + ClO^- + 2H_2O \xrightarrow{k_r} ClO_3^- + 2H_3O^+ + 2Cl^- \quad [1]$$

well known as the Foerster reaction of chemical chlorate formation (1).

The second and unavoidable path represents another Foerster reaction of further anodic hypochlorite oxidation to the final state

$$6ClO^- + 9H_2O \xrightarrow{6e} 2ClO_3^- + 6H_3O^+ + 4Cl^- + 3/2\,O_2 \quad [2]$$

also known as the reaction of electrochemical chlorate formation (1), which represents an unnecessary loss of current (t_2).

For the sake of Faradaic balance treatment, it is much more convenient to present the reaction of electrochemical chlorate formation in a form of total anodic oxidation process from chloride ion to the final species

$$2Cl^- + 18\,OH^- \xrightarrow{18e} 2ClO_3^- + 9H_2O + 3/2\,O_2 \quad [3]$$

In the chlorate cell process one practically neglects anodic chlorine evolution and defines as efficient (t_1) the electrode path in which the electrochemical oxidation goes to the hypochlorous species only, with chlorate as further final product of the pure chemical conversion. Considering the total anodic chloride oxidation to the final state (reaction [3]) as unavoidable anodic current losses (t_2), it can easily be shown that the over-all current efficiency (t) of the whole electrolytic process is the same as that of the first stage chloride anion oxidation (t_1), or in another words, that $t_1 + t_2 = 1$.

Both reactions (Eq. [1] and [3]) are dependent on each other and hence both depend on pH, temperature, current density, electrolyte volume ratios, and their active chlorine contents, as well as on the hydrodynamic conditions inside the cells.

A chlorate production system mainly consists of the cells and the holding volume usually in a closed loop. The cell has often been considered primarily as a generator of active chlorine, and the holding volume as a reactor for its further conversion to the final product. (2).

Faradaic stoichiometry and material balance consideration have been leading to the derivation of an equation which relates the over-all current efficiency (t_1) of chlorate production to the operational parameters of the process including all partial volume contributions of active chlorine conversion (see Appendix I) throughout the system (2)

$$t_1 = \frac{2}{3} + \frac{2f_c^2 \cdot k_{r,c} \cdot V_c \cdot \mathbf{F}}{I} \cdot \frac{K^*_c \cdot (a_{H_3O^+})_c^2 \cdot C_{sc}^3}{[K^*_c + (a_{H_3O^+})_c]^3} + \frac{2}{3}\mathbf{F}\left(\frac{q}{I}\right) \cdot (C_{sc} - C_{sh}) - \frac{2}{3}(t_3 + t_4) \quad [4]$$

or otherwise (2)

$$t_1 = \frac{2}{3} + \frac{2f_c^2 \cdot k_{r,c} \cdot V_c \cdot \mathbf{F}}{I} \cdot \frac{K^*_c \cdot (a_{H_3O^+})_c^2 \cdot C_{sc}^3}{[K^*_c + (a_{H_3O^+})_c]^3} + \frac{2f_h^2 \cdot k_{r,h} \cdot V_h \cdot \mathbf{F}}{I} \cdot \frac{K^*_h \cdot (a_{H_3O^+})_h^2 \cdot C_{sh}^3}{[K^*_h + (a_{H_3O^+})_h]^3} - \frac{2}{3}(t_3 + t_4) \quad [5]$$

where I denotes the total current or the cell load; k_r is the rate constant for the reaction [1]; q, the flow rate; V, the electrolyte volume; $\mathbf{F}$, the Faraday constant; f, the activity coefficient of hypochlorous acid; K^*, the rearranged dissociation constant of hypochlorous acid (see below); $a_{H_3O^+}$, the hydronium ion activity; C_s, the active chlorine concentration; and t_3 and t_4, possible current losses for chlorine evaporation and cathodic hypochlorite reduction, respectively. The last two terms could be neglected in common practice of the chlorate production, that means $t_1 + t_2 + t_3 + t_4 \approx t_1 + t_2 = 1$. Subscripts c and h shall refer, throughout, to the quantities corresponding to the cells and to the holding volume, respectively. In the above equations f^2 approximately represents the Brönsted's kinetic coefficient (3, 4) for the reaction of chemical chlorate formation (Eq. [1]).

* Electrochemical Society Active Member.

Key words: active chlorine, hypochlorous species, steady-state current yields, back-mix-flow reactor, plug-flow reactor, instantaneous current efficiency.

[1] "Available chlorine" comprises the sum of concentrations of hypochlorous acid, hypochlorite ion, and dissolved elemental chlorine. However, at the pH of usual electrolytic chlorate production the latter can be neglected, so that the more convenient term active chlorine will be used henceforth for hypochlorous entities only.

The first term in Eq. [4] and [5] defines current yields under conditions such that all electrolytically produced active chlorine simultaneously undergoes the further electrochemical oxidation to chlorate according to Eq. [3]. The next two terms represent contributions to the over-all current efficiency of the chemical conversion of hypochlorous species taking place inside the cells and the holding volume, respectively.

The pH Effect of the Whole Chlorate System

One could immediately draw some general conclusions considering Eq. [4] and [5] by quite a simple analysis. Firstly, in very acid solutions, when hypochlorous species decompose and tend to negligible concentration, chlorine evolution approaches its maximal current yields ($t_3 \rightarrow 1$), chlorate current efficiency takes small values, and the whole cell operates as a chlorine producing unit. On the contrary, in alkaline solutions ($a_{H_3O^+} \rightarrow 0$), hypochlorous acid approaches zero concentration, and all active chlorine builds up its concentration and exists in the form of hypochlorite ions. This reduces chemical conversion of available chlorine to negligible rates, so that the final effect represents chlorate production taking place from total anodic oxidation only (Eq. [3]). Therefore, one has to seek an intermediate pH range providing the optimal operating conditions and yielding the maximal current efficiencies. In the two limiting cases, just discussed, neither the temperatures and the current density, nor any other operating variable and parameter could bring about any improvement of the chlorate cell efficiency. Hence, a certain mutual effect of variable optimization must exist somewhere in between these two limiting cases.

The pH Effect of the Holding Volume

Partial differentiation with respect to ($a_{H_3O^+}$) of both terms relating over-all current efficiency in Eq. [5] to the contributions of hypochlorous species conversion inside the two volumes, V_c and V_h, reveals the optimal pH region providing maximal current yields to be

$$pH_M = pK^* - \log 2 \qquad [6]$$

The rearranged dissociation constant (5), as well as its corresponding thermodynamic value, represents a quantity dependent on temperature.

It has previously been shown elsewhere (5) that the relevant equilibrium constant for calculating the actual hypochlorous species contents at the ionic strengths of the chlorate cell brine and for evaluating the over-all current efficiency according to Eq. [5], is

$$K^* = \frac{a_{H_3O^+} \cdot C_{ClO^-}}{C_{HClO}} = K_a \frac{f \cdot a_{H_2O}}{f_{ClO^-}} \approx 10 \cdot K_a \qquad [7]$$

where K_a stands for its thermodynamic value, and other signs have the usual meaning.

Caramazza (6) revealed the functional temperature dependence of the thermodynamic dissociation constant of the hypochlorous acid to obey the equation

$$pK_a = \frac{800}{T} + 4.892 \qquad [8]$$

However, Morris (7) has recently presented somewhat more reliable data expressed by the following relation

$$pK_a = \frac{3000.00}{T} - 10.0686 + 0.0253 \cdot T \qquad [9]$$

which was asserted to be valid up to 45°C (7).

Thus, combining Eq. [8] and [9] with [6] and [7], one obtains the temperature dependence of the optimal pH range (pH_M) for the chlorate cell process. Some experimental and calculated values are shown in Fig. 1. One easily observes that the higher the temperature, the lower is the optimal pH value which provides maximal current yields in the electrolytic chlorate production [*cf.* (5)]. This matter has been discussed in more detail elsewhere (5).

The pH Effect of the Chlorate Cell

The pH effect of the chlorate cell itself on the overall current yield was investigated as a function of the holding volume temperature at constant current density (Fig. 2). It has again been experimentally confirmed that the optimal pH range given above provides maximal current efficiencies. However, one could accept as much more important the optimal pH value to be maintained inside the holding volume, whose content and retention time are of incomparably higher values. Due to the chemical conversion of available chlorine, as well as the reaction proceeding (Eq. [1]) the electrolyte tends to be more acid. Hence, one needs a somewhat higher pH value of the brine leaving the cell and entering the holding volume, in order to maintain optimal acidity inside the latter. Of course, this also depends on the buffer content (hydrochromic acid) in the brine. At the same time one tends to reduce and maintain an optimal dichromate concentration for many important reasons. First, of all, the latter is partially lost during the crystallization of the final product. Also, although dichromate enables the cathodic hypochlorite reduction to be effectively suppressed, and

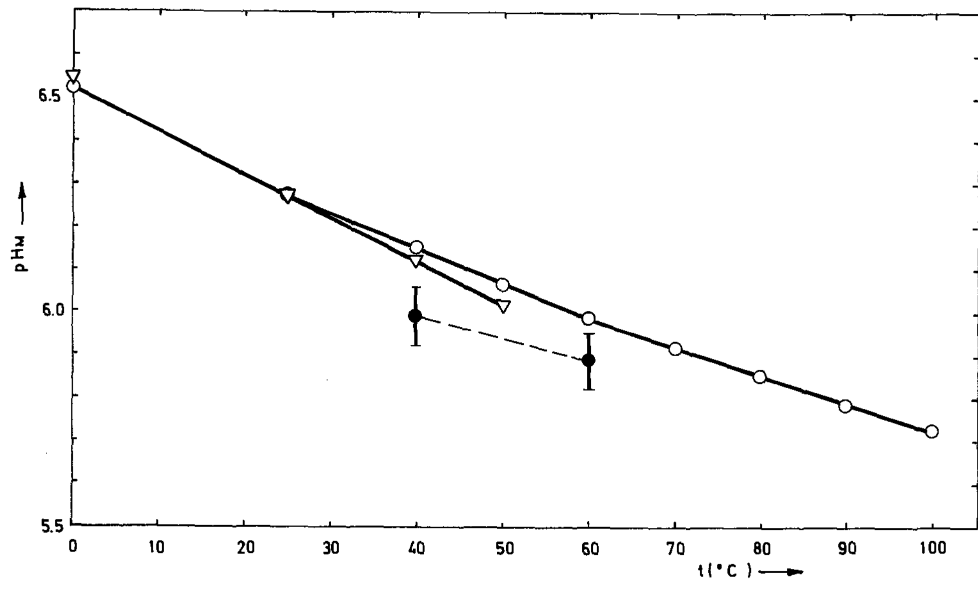

Fig. 1. Theoretical (○, ▽) and experimental (●) temperature dependence of the optimal pH value (pH_M) providing maximal active chlorine conversion rates into chlorate inside the holding volume [○ and ▽ according to Caramazza (6) and Morris (7), respectively].

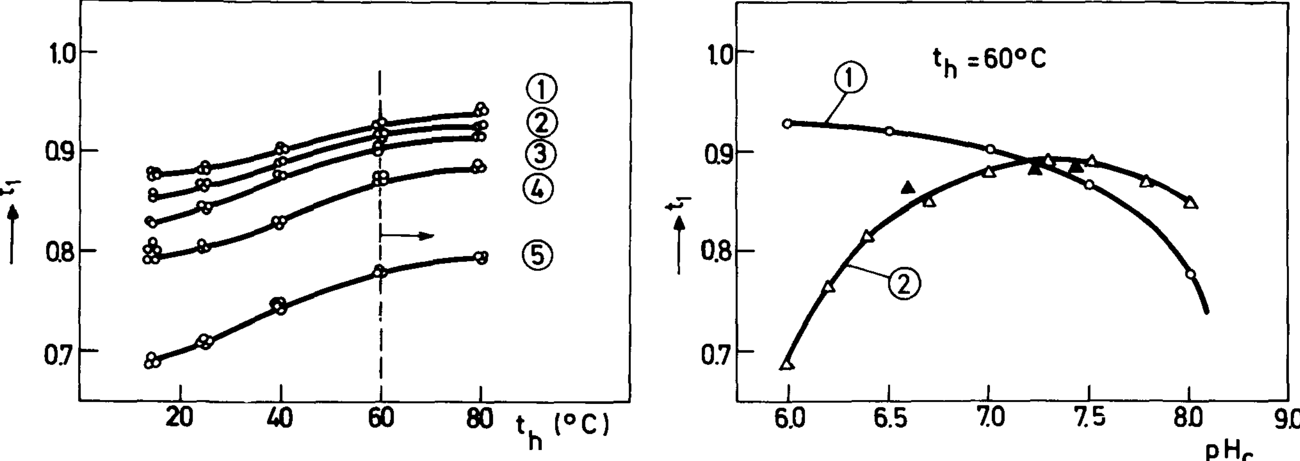

Fig. 2. Mutual effect of the cell pH (pH_c) and the holding vessel temperature (t_h) on the current efficiency (t_1) in the electrolytic chlorate process. ○, experimental data (pH_c: 1—6.0; 2—6.5; 3—7.0; 4—7.5, and 5—8.0); other operating parameters being maintained constant, I, i, q, V_c, V_h, and t_c; △ and ▲, theoretical and experimental values, respectively, according to Claus (12) [cf. (33)].

enables useful buffering of the brine, chromate ions simultaneously exhibit an undue effect on the anodic cell process (8). On the other hand, however, chromate ions represent an efficient inhibitor of corrosion for precious metals deposited on titanium anodes and hence, one may need to increase their brine content (9) for this reason.

The Over-All Temperature Effect of the Chlorate System

The temperature effect of the chlorate producing system is confined by a certain number of kinetic parameters encompassed by the relationships for current efficiency given above, *i.e.*, k_r, K^* and, as will be seen below, over the rate constant for chlorine hydrolysis. In addition the simultaneous effect of increasing temperature on cell voltage decrease is well known, thus providing for power consumption to be efficiently decreased as well. One tends, therefore, to increase the temperature throughout the whole system. However, the temperature exhibits a negative effect on anode consumption. Thus, economical considerations define a rather limited level of temperature inside the chlorate cells.

One of the most important temperature effects for the process would be to increase the rate of the chemical conversion of active chlorine (Eq. [1]), which otherwise represents a slow reaction. Hence, an economical compromise is found for cells with graphite anodes in temperature range of about 40°C. Nevertheless, to increase chemical chlorate formation inside the whole system, it has been suggested that the retention volume of the reactor should be elevated to a relatively higher temperature level (2).

Due to platinum metal coating corrosion, one also chooses, as well suited from an economical point of view, a rather compromised temperature range of about 60°C for chlorate cells with titanium (DSA) anodes (9). This higher temperature increases current yield and reduces the over-all power consumption.

There exists another important reason for limiting the temperature of the chlorate producing system. It appears because of the thermal decomposition of the hypochlorous species resulting in oxygen evolution and reverting active chlorine to its initial state of chloride ions (10, 11). Therefore, an exact derivation of the relationships given before the over-all current efficiency (Eq. [4] and [5]) requires that the thermal decomposition rate of active chlorine should also be included in the whole material balance treatment of the system [cf. (12)].

All the above considered reasons have resulted in a temperature range for actual chlorate systems of about 60°C.

This region has also been confirmed experimentally and assessed as the optimal and efficient one (Fig. 2 and 3). Namely, mainly due to the relatively low active chlorine concentration inside the optimal pH region for chlorate production, a rather asymptotic leveling effect of temperature on the current efficiency appears above 60°C. This is much more pronounced at lower current densities as could be noted in Fig. 4. Therefore, it could be concluded that the heating effect of the holding volume (2) is efficient enough indeed, and of practical importance only for chlorate cells running at low current densities (unipolar cells with graphite anodes).

The over-all current efficiency (t_1) dependence on the holding vessel temperature is evidently not a straightforward one. One should consider that, in addition to kinetic parameters $k_{r,h}$ and K^*_h, the effect of active chlorine content (C_{sh}) in Eq. [4] and [5] is also temperature dependent in a quite complex manner. This could be comprehended as follows. Both relationships (Eq. [4] and [5]) reflect primarily the Faradaic stoichiometry which states that, the larger the current efficiency, the higher should be the accumulation of the active chlorine inside the cell ($C_{sc} - C_{sh}$) or the lower the hypochlorous species content leaving the holding volume ($C_{sh} \rightarrow 0$). However, a quite converse require-

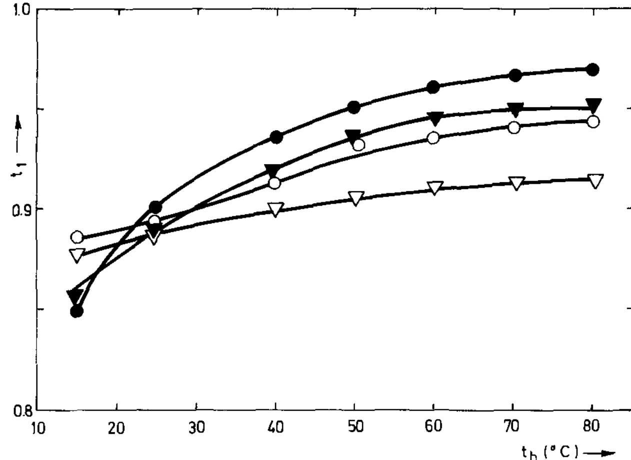

Fig. 3. Mutual effect of the temperature (t_h) and the pH inside the holding volume (pH_h) on the current efficiency (t_1) in the chlorate cell process: ● and ▼ experimental data at pH_h 6.0 and 6.5, respectively; other operating parameters being maintained constant: I, i, q, V_c, V_h, and t_c · ○ and ▽ denote calculated values according to Eq. [10] for experimental values of the C_{sc} at the pH_h 6.0 and 6.5, respectively.

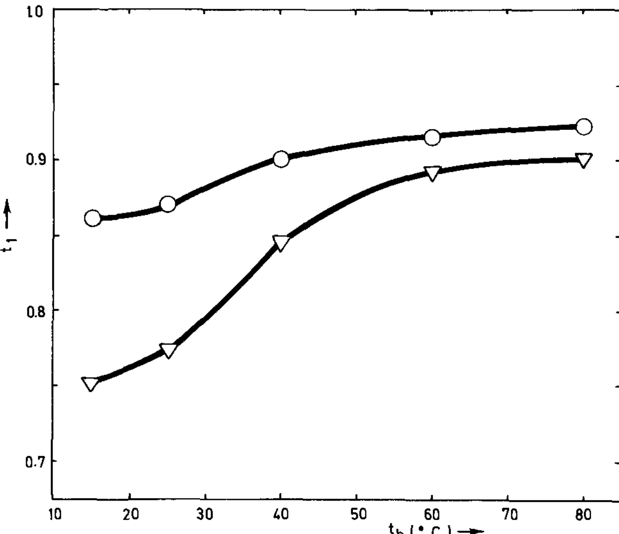

Fig. 4. Mutual effect of the current density (*i*) and the holding vessel temperature (t_h) on the current efficiency (t_1) at a constant pH of the cell (pH_c—6.0). ○ and ▽ denote experimental data at current densities 6.67 and 1.8 A/sq. dm., respectively. Other operating parameters of the system being maintained constant are q, V_c, V_h, and t_c.

ment arises from hydrodynamic considerations (see below), because the increase of the C_{sc} leads consequently to proportional current losses due to increased direct anodic oxidation.

Therefore, although the concentration difference ($C_{sc} - C_{sh}$) is needed as large as possible, one should at the same time also try to maintain the C_{sc} as low as possible. This fact is in itself a practical reason causing the existence of an optimal holding vessel to cell volume ratio (V_c and V_h), previously often considered in terms of current concentration. This is also the reason why active chlorine concentration (C_{sh}) entering the cell is never negligible compared to the one leaving it or why the former does not tend to zero or negligible values at all, as required by Eq. [4], to approach the maximal current efficiencies. Therefore, the increase in the rate of active chlorine conversion into chlorate with temperature must exhibit an asymptotic tendency to a certain maximal value, in spite of the fact that the rate constant is increasing, because the concentration factor in the rate expression (Eq. [5]) decreases with the third power (Fig. 3). Hence, both values of active chlorine content, entering and leaving the cell, under practical operating conditions of chlorate production are usually of the same order.

Considering Eq. [4], it could be easily found that the higher the flow rate (q), the smaller the difference of the two active chlorine contents ($C_{sc} \rightarrow C_{sh}$) and the whole term reflecting the holding volume contribution to the over-all current efficiency of the system asymptotically tends to its limiting value.

Quite a simple analysis would lead to the conclusion that, just due to the small active chlorine contents throughout the system, the plug-flow type of reactor (V_h), for the same volume, provides higher degrees of conversion to chlorate and higher current yields, than does the back-mix flow one (26).

The Contributions of Hydrodynamic Factors to Over-All Current Yield

There has been an old general acceptance in the chlorate cell process that the motion of the electrolyte inside the cell should be reduced in order to provide concentration polarization for the anodic oxidation of the active chlorine. However, Ibl and Landolt (13) were the ones to show an interesting and complex nature of its anodic diffusion layer. Namely, due to the subsequent chlorine hydrolysis, which prevalently takes place within the diffusion layer, hypochlorous species diffuse in both directions from and toward the generating electrode, thus creating a certain concentration maximum inside the diffusion layer (13).

Hence, in order to really provide the concentration polarization, the diffusion layer should be cut down from the solution side by increasing the linear velocity of brine flow increasing thereby the fraction of hypochlorous species, which then avoids a further anodic oxidation.

The concentration profile, the resulting active chlorine flux and the concentration gradient at the anode surface, were also analytically given by Ibl and Landolt (13). Equating the Ibl-Landolt equation for the flux with the fraction of the current used for further active chlorine anodic oxidation, Despic *et al.* (14) were able to derive a quantitative expression relating the over-all current efficiency to the hydrodynamic, operational, and kinetic parameters of the process

$$t_1 = \frac{1 - \dfrac{D_2 \cdot \mathbf{F}}{i \cdot \delta} \cdot f_{sc} \cdot C_{sc}}{\dfrac{3}{2} - \dfrac{1 - \exp\left(-\delta\sqrt{k_1/D_1}\right)}{2\delta \cdot \sqrt{k_1/D_1}}} \qquad [10]$$

where δ is the anodic diffusion layer thickness; k_1, the rate constant for the reaction of chlorine hydrolysis; i, the current density; D_1 and D_2 are the diffusion coefficients of the elemental chlorine and the active chlorine, respectively; while f_{sc} represents the formal activity coefficient of both hypochlorous species taken together as active chlorine. This relationship differs from the original flux equation [cf. (13)] by the correction introduced to extend its application to concentrated solutions. In other words, instead of the concentration, one relates the flux and thereby the current efficiency to the activity of active chlorine (14). Namely, one could easily find it much more convenient to use the chemical potential as the driving force of diffusion in concentrated solutions and, hence, to relate fluxes of the considered species to their individual activities in the first approximation. In general this is a better approximation anyway compared to the application of their concentrations in the Fick's equation (18). Some ions, however (and particularly the hydronium ion is usually the most important among them in aqueous solutions) undergo considerable, but regular activity changes in concentrated solutions of some neutral salts (19). The same conclusion is found to be valid for the hypochlorite ion, and in concentrated solutions of neutral salts also for both hypochlorous species taken formally together in the form of active chlorine (18).

Certain individual activities have recently appeared as experimentally attainable values in the first approximation at least (19, 20). It will be shown at another instance that these activities obey the diffusion relationships much better than their corresponding concentrations (18).

One should not overlook the fact that the concentration of active chlorine, C_{sc}, does not represent an independent value, but a variable of a very complex nature. Therefore, Eq. [10] is valid for its steady-state values only (2, 14).

Of course, Eq. [10] could be combined with relations [4] and [5], as well as with the one expressing material balance of the holding vessel, in order to eliminate or to introduce the steady-state C_{sc} and C_{sh} values in resulting relationship [cf. (14) and (21)].

According to Eq. [10], the over-all current efficiency exhibits a region of maximal values as function of the anode diffusion layer thickness (Fig. 5). This range is defined by the following transcendental function

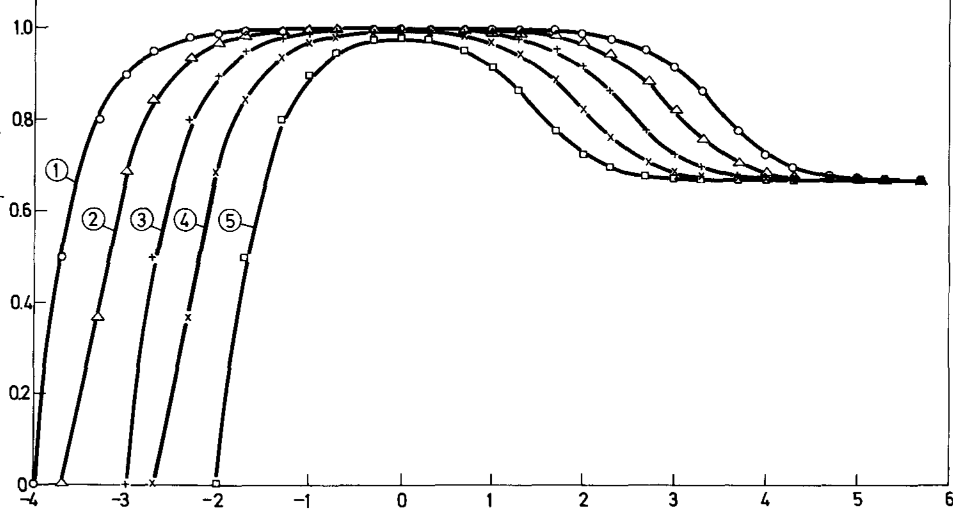

Fig. 5. The current efficiency (t_1) of the chlorate cell as a function of the anode diffusion layer thickness (δ) for various C_{sc}/i ratios taken as parameter at 25°C (see Appendix II). Calculated values according to Eq. [10].

$$i - D_2\mathbf{F} \cdot f_{sc} \cdot C_{sc}\sqrt{\frac{k_1}{D_1}} + i\sqrt{\frac{k_1}{D_1}} \cdot \delta_M$$

$$= \left(i - 3D_2\mathbf{F}f_{sc} \cdot C_{sc} \cdot \sqrt{\frac{k_1}{D_1}} \right) \cdot \exp\left(\delta_m \sqrt{\frac{k_1}{D_1}} \right) \quad [11]$$

or approximately by the relation

$$\delta_M \approx 2\sqrt{\frac{D_2 \cdot \mathbf{F} \cdot f_{sc} \cdot C_{sc}}{i} \cdot \sqrt{\frac{D_1}{k_1}}} \quad [12]$$

It would be worthwhile to point out that the current yields always reach their maximal values for $\delta_M > 0$. Such a conclusion results from the consideration of Eq. [11]. Namely, its left-hand side represents a straight line, while its right-hand side defines an exponential function of the diffusion layer thickness. Both lines, however, always cross each other for $\delta_M > 0$. Moreover, under practical operating conditions this represents an easily attainable required condition.

It is also worthwhile to note that the current efficiency, according to Eq. [10] could reach values lower than 2/3 only for unsteady-state active chlorine contents. In such a case, t_1 does not represent the steady-state yield, but the instantaneous one, which changes successively with time and with the active chlorine consumption. It asymptotically approaches both C_{sc} and t_1, the final steady values. Moreover, the chlorate cell anode represents in itself a self-adjusting system. That means, the larger the diffusion layer thickness the lower is the instantaneous current efficiency (see Eq. [10]), but it also means the more intensive is oxygen evolution. On the other hand, gas evolution represents an efficient short-circuiting of the diffusion layer [cf. (15, 16, and 31)] and hence, the latter begins to decrease in accordance with oxygen evolution rate, resulting in a gradual increase of the current efficiency with time.

As one could easily note, current losses ($1 - t_1$) now do not represent a direct, but a very complex function of the active chlorine concentration [cf. (3)]. This results from quite an unusual diffusion layer structure and the very complex active chlorine profile, the latter being quite different from the Nernst linear distribution.

Equation [10] has been experimentally found well suited in the chlorate cell process (14) (Fig. 3). In conclusion, it could also be emphasized that the hydrodynamic operating parameters and conditions of the cell represent essential factors (Fig. 5) for the process inside the latter because of the occurrence of quite unusual and specific events taking place inside the anode diffusion layer.

The Effect of Current Density

The main characteristic of the two parallel anodic reactions taking place simultaneously in the chlorate cells represents the fact that, in common industrial practice at least, chloride oxidation abounds in the ions present (usually the steady-state concentration is about 2 moles/liter), while the reaction of hypochlorous species, being rather concentration polarized, is suppressed (C_{sc} is usually of the order $3 - 5 \cdot 10^{-2}$ moles/liter). Therefore, the most efficient and intrinsic parameter of the chlorate cell process providing higher current efficiencies is the current density itself (cf. below Fig. 9). However, in order to effectively use these common conclusions regarding concentration polarization and to adjust the anodic process, a suitable anode material is needed.

Figure 6 shows the current efficiency dependence on the current density. Experimental data are compared with data predicted by Eq. [10] as well as with other values appearing from another theory (12) for environmental (25°C) temperatures and common active chlorine concentrations.

For more than eighty years graphite has been the unique anode material in electrolytic chlorate production. Mainly due to its relatively poor polarization characteristics for the anode reaction of chlorine evolution, and also because of its relatively high resistance, one has had to reduce the current density to between 2.5 and 5.0 A/dm² for the industrial cell process.

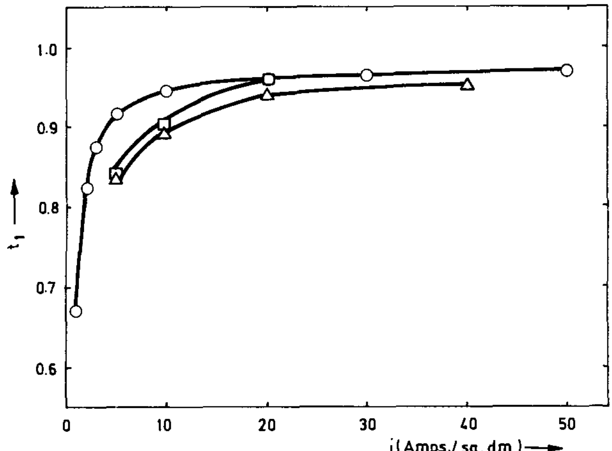

Fig. 6. The current efficiency (t_1) of the chlorate cell as a function of the current density (i). ○, theoretical values according to Eq. [10] for the common active chlorine concentration ($C_{sc} = 4.0 \cdot 10^{-2}$ mol/liter); δ, $8.2 \cdot 10^{-4}$ cm; f_{sc}, 0.1; and t_c, 25°C; □, experimental data; and △, values according to Claus (12).

At the same time, one had to reduce the cell temperature to maintain the graphite wear to economical conditions of consumption. The graphite wear, however, also represents, besides other factors, an anodic property depending on its potential and thereby on the current density (22). Therefore, both the concentration polarization for the active chlorine oxidation at the anode and its chemical conversion to the final state, have been inconveniently restricted. The resulting current efficiencies, for chlorate cells with unipolar graphite electrodes, at least, are thereby in practice usually rather limited to values of about 0.8 (see Fig. 6). In accordance with relationships [4] and [5], in order to increase the current efficiency, even in the case of cells using graphite anodes, some suggestions have been given (2) consisting of an independent increase of the holding volume temperature, while maintaining the reasonably low temperature of the cell. This provides further intensification of chemical conversion inside the former and, thereby its further contribution to the over-all current yields (30).

Recently, however, metallic electrodes of dimensionally stable behavior and with greatly advanced polarization characteristics (DSA-electrodes) (23) finally appeared.

The higher the current density, the more economical is the consumption of precious metals. However, the *IR*-drop severely increases linearly with the current density and, moreover, very soon the limiting current is reached for the anode oxidation of chloride ions. Therefore, besides the quite advanced polarization properties of DSA-electrodes which results in a higher asymptotic effect of the current density on the current efficiency (Fig. 6), a range of about 30 A/dm^2 has been chosen as a compromise and accepted as the most convenient. Of course, this requires an optimal pH region of the brine to be maintained, too, because out of it, not only the current density, but also all other process parameters are practically of no effect. The cell operates either as a chlorine producer in the acid region, or produces chlorate as the final product of total electrochemical oxidation in the alkaline region thus yielding the lower steady-state value of the current efficiency ($t_l \rightarrow 2/3$).

Some Scale-Up Considerations of the Chlorate Cells

Equation [10] relates the current efficiency to the average value of the actual steady-state active chlorine concentration (C_{sc}) for chlorate cells operating as back-mix-flow reactors. A different situation arises in the more frequent case of plug-flow cells. In the latter case one must first integrate a material balance equation (2, 17, 24) for an element of the cell volume along the anode (Fig. 7)

$$\frac{dC_{sc}}{dl} = \frac{i}{2\mathbf{F}q}\,(3\,t_{l(l)} - 2) \qquad [13]$$

where $t_{l(l)}$ denotes the local current yield depending on the anode length (l). The $t_{l(l)}$ from Eq. [10] may be substituted in relationship [13], on the assumption that the former relates the local current efficiency for any element of the anode length to its particular active chlorine concentration ($C_{s(l)}$). Integrating from entering hypochlorous species content of the cell (C_{sh}, l = 0), to the leaving one (C_{sc}, l = L), one easily comes to the distribution relation for the active chlorine concentration along the anode (17). Now, again, the over-all current efficiency of chlorate cells running in plug-flow is obtained as an average of the local current yields (17), *i.e.*

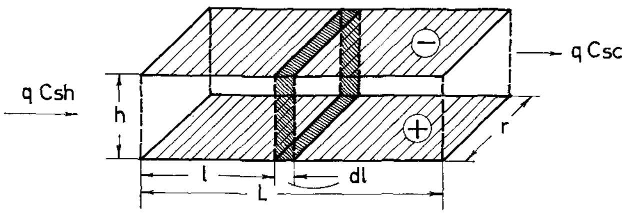

Fig. 7. Elemental cross section of the chlorate cell plug-flow running.

$$t_l = \frac{1}{L}\int_0^L t_{l(l)}\,dl \qquad [14]$$

or, finally

$$t_l = \frac{2}{3} + \frac{2}{3}\cdot\frac{\mathbf{F}q}{irL}\left[\frac{i(1-\exp(-\delta\sqrt{k_1/D_1}))}{3D_2\mathbf{F}f_{sc}\sqrt{k_1/D_1}} - C_{sh}\right] \cdot\left\{1-\exp\left\{-\frac{3}{2}\cdot\frac{irL}{\mathbf{F}q}\cdot\frac{\dfrac{D_2\mathbf{F}f_{sc}}{i\delta}}{\dfrac{3}{2}-\dfrac{1-\exp(-\delta\sqrt{k_1/D_1})}{2\delta\sqrt{k_1/D_1}}}\right\}\right\} \qquad [15]$$

where *r* denotes the anode width. This relationship, as well as the intermediate ones, have also been experimentally tested in a ribbon type of cell and found to well obey the process (17, 24).

The final equation [15] was examined by analogue computer analysis in order to relate the current yields to the anode diffusion layer thickness and cell dimensions (Fig. 8). It could easily be found that the relationship [15] reflects in essence the previous relation (Eq. [10]), which already has been discussed, and which is also implicitly encompassed by the former. In other words, by increasing the linear brine velocity of flow along the anode, the current yields first also increase, and after some maximum, decrease again. At relatively fast flow rates, the anode length exhibits a more pronounced effect, but in its optimal range, the longitudinal cell dimension has practically no further effect on the yields within very wide limits. However, because of an intrinsic effect of gas bubble collection at the upper part of the cell (25), the anode length should be reduced. At the same time the flow rate along it optimized, thus providing the diffusion layer thickness maintained within the optimal range. The latter requirement is, of course, easily attainable by the cell's own gas-lifting effect, known under the term of the natural brine recirculation (32).

Equation [15] was tested experimentally and found well suited (17) (Fig. 9). As one could expect from the theory (cf. Eq. [10]), the current efficiency exhibits its maximum range as a function of the diffusion layer thickness or of the linear flow velocity along the anode.

It should also be noted that all the presented equations relating the current efficiency to the hydrodynamic parameters (δ) are based on the Ibl and Landolt (13) relation for the active chlorine gradient at the anode. However, the authors neglected the chemical conversion of hypochlorous species within the anode diffusion layer. This is correct only for their operating conditions of high pH values and low temperatures. Hence, a more complete diffusion relation would be [cf. (13) and (24)]

$$D_2\left(\frac{d^2a_s}{dx^2}\right) + k_1\cdot a_{Cl_2(x)} - 3f_c^2\cdot k_{r,c} \cdot\frac{K^*(a_{H_3O^+})^2_{(x)}}{[K^* + (a_{H_3O^+})_{(x)}]^3}\cdot C^3_{s(x)} = 0 \qquad [16]$$

The latter, however, could not be easily analytically solved. It would not lead to a simple analytic form of

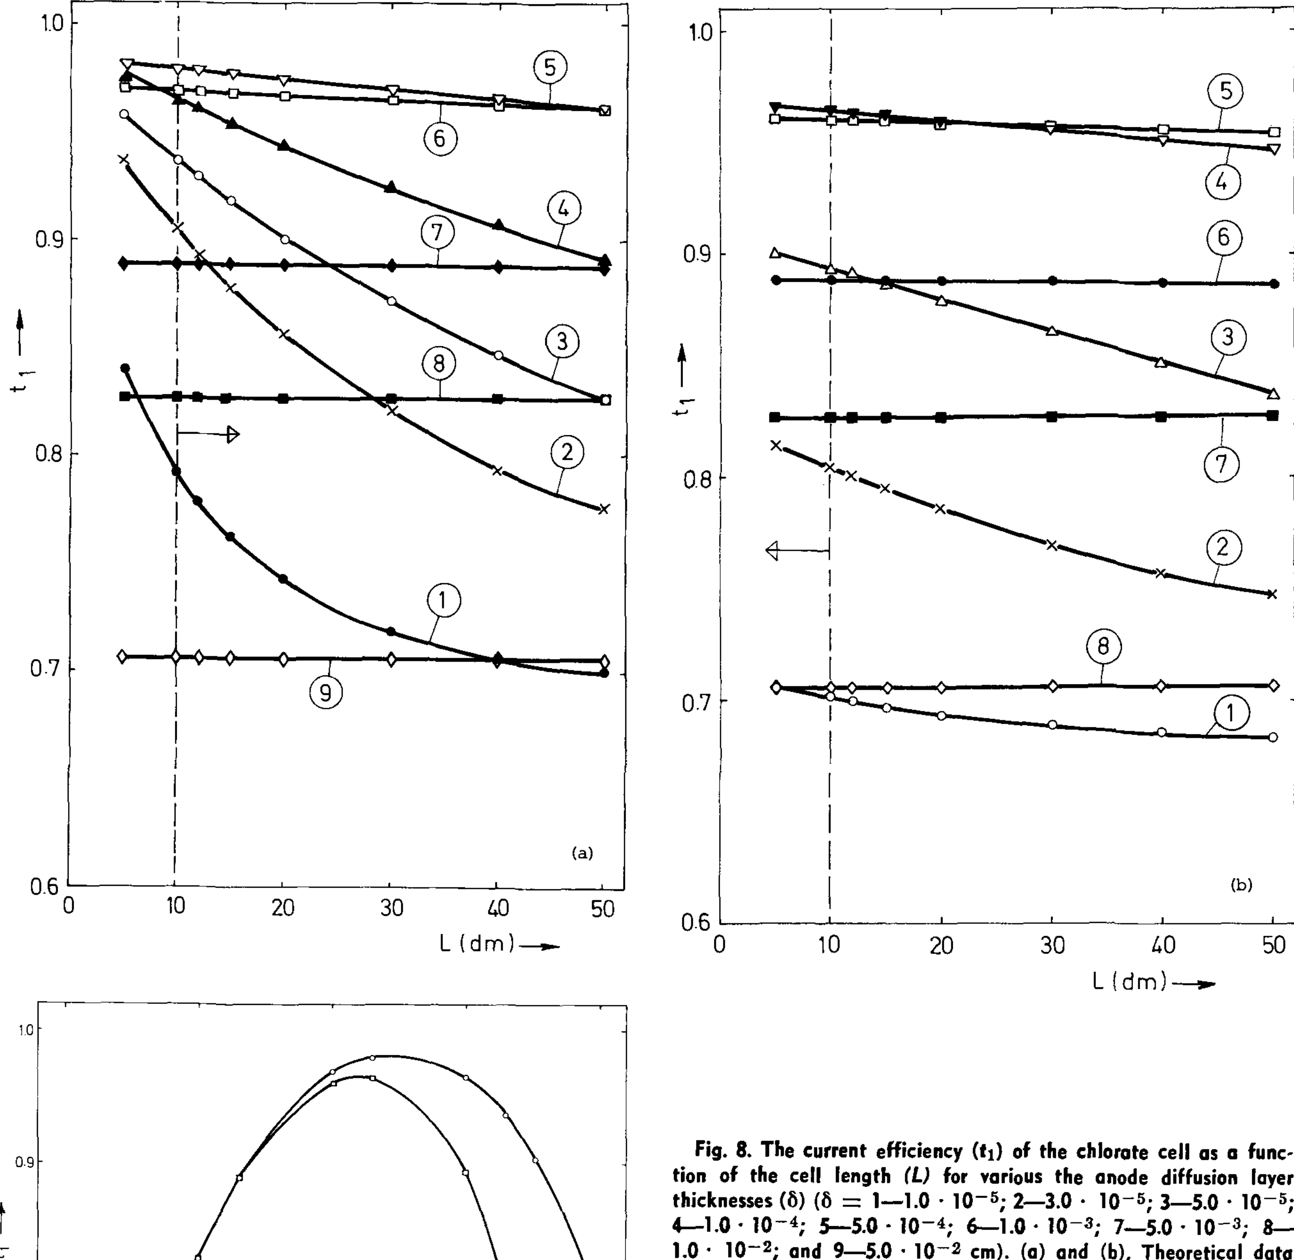

Fig. 8. The current efficiency (t_1) of the chlorate cell as a function of the cell length *(L)* for various the anode diffusion layer thicknesses (δ) (δ = 1—1.0 · 10^{-5}; 2—3.0 · 10^{-5}; 3—5.0 · 10^{-5}; 4—1.0 · 10^{-4}; 5—5.0 · 10^{-4}; 6—1.0 · 10^{-3}; 7—5.0 · 10^{-3}; 8—1.0 · 10^{-2}; and 9—5.0 · 10^{-2} cm). (a) and (b), Theoretical data according to Eq. [15] for the current density 30.0 and 3.0 A/sq. dm., respectively. (c), The current efficiency (t_1) as a function of the anode diffusion layer thickness (δ). Theoretical data according to Eq. [15] for the anode length *(L)* 10 dm. and the current density (○, □) 30.0 and 3.0 A/sq. dm., respectively. Other parameters used in calculation were as follows: *r*, 4.0 dm.; *q*, 0.26 liter/sec; and C_{sh}, 4.0 · 10^{-3} mol/liter.

equation, due to the third power of concentration dependence. Also, the hydrogen ion distribution within the diffusion layer is of rather a complex nature. Thus, it is necessary to solve simultaneously several rather complicated differential equations, encompassing all equilibria, all diffusion fluxes, and also all the electrode reactions at the anode. This advanced and more complex matter will be reported at a latter instance (27).

It should also be noted that, in a view of the fact that active chlorine exhibits the appearance of a maximum concentration within the diffusion layer, which exceeds that in the bulk (13), its further chemical conversion must not be neglected for higher operating temperatures at least. However, such temperatures just lately characterize up-to-date chlorate cell industrial practice.

The above treatment might be usefully applied as the one leading to the limiting optimal conditions. This implies that, just as the thermodynamic method usually gives the lower limits for the considered processes to be able to proceed at all, the present treatment also provides operational and dimensional limiting conditions for optimal cell current yields. Namely, providing the above-defined optimal cell parameters and main-

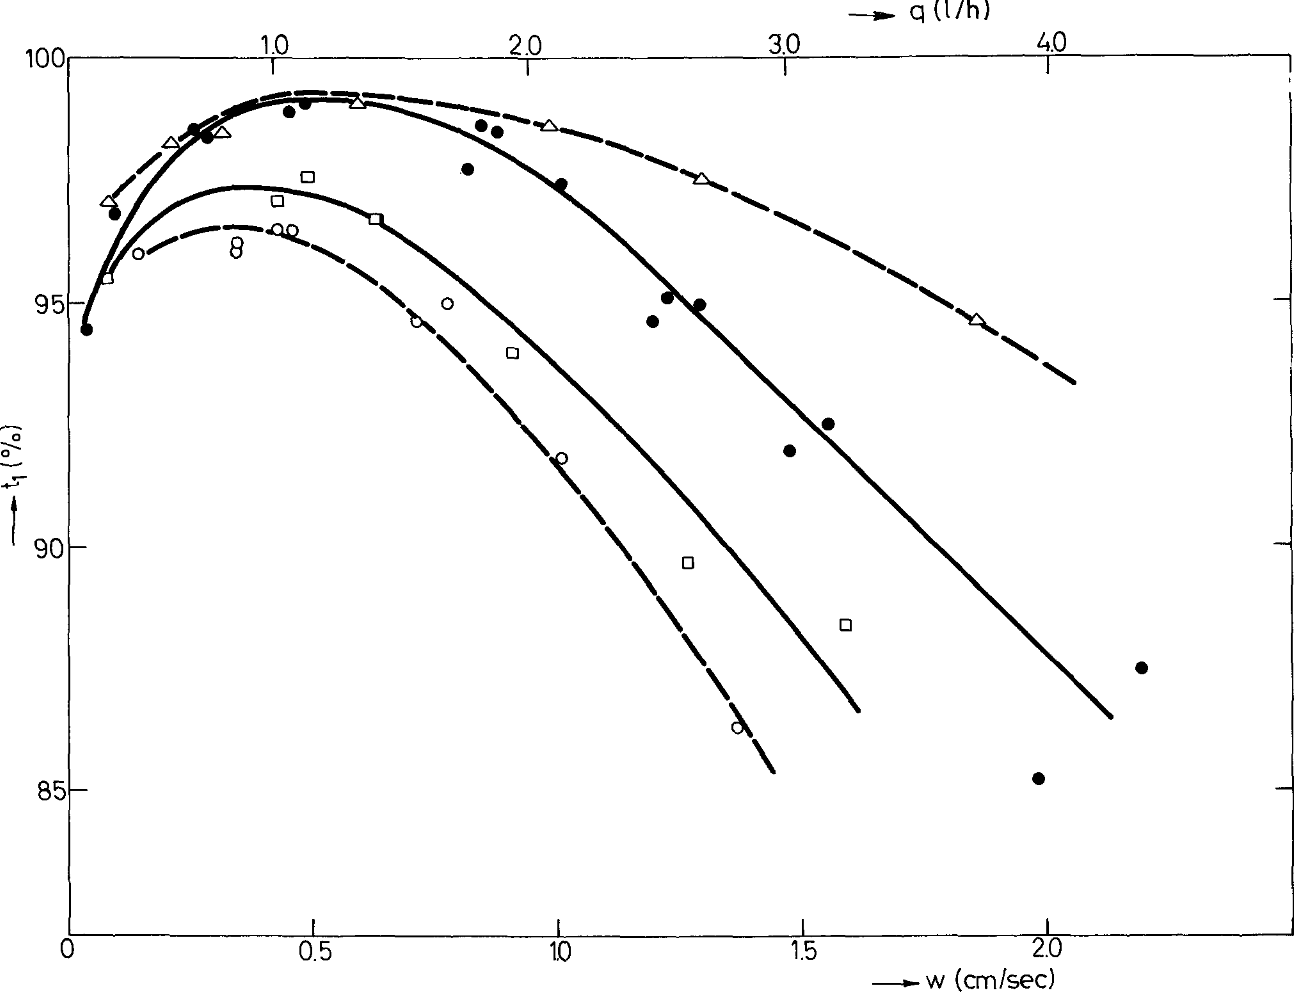

Fig. 9. The effect of the linear velocity of the brine flow on the over-all current efficiency in the chlorate cell plug-flow running. Experimental data for the ribbon type of the cell. ●, □, and ○, values for pH_c—6.5, 7.6, and 8.1, respectively, and at the current density 1.97 A/sq. dm.; △, values for pH_c—6.5 and i = 3.61 A/sq. dm.

taining their mutual effect, *i.e.*, the linear velocity of the brine flow, current density, pH, and temperature (just because of the effect of the latter on the decrease of the C_{sc} through its further chemical conversion to chlorate which was neglected in all the equations based on diffusion layer analysis); one could doubtlessly expect better results only, than those predicted by the above equations and consideration (cf. Fig. 5). It should also be noted that both relations which comprise the hydrodynamic factors (Eq. [10] and [15]), exhibit a very pronounced sensitivity on the active chlorine concentration (C_s). Hence, the higher the temperature, the lower should be the active chlorine content, and thereby the higher the current efficiency.

The above consideration represents a certain scale-up and optimization guide for the chlorate cell process based on the Faradaic efficiency. Another side of the medal is represented by its voltage and power optimization. The latter has recently been developed and thoroughly carried out by Rousar *et al.* (25), particularly in examination of the cell dimensions and the gas bubble cell effects. Both methods, the mentioned one (25) and the one presented here, of course, lead to the mutual optimal point at which two independent schemes cross each other and thus define the most suitable operating conditions for the whole electrolytic process.

Experimental Guide

The experimental data presented in this paper were prevalently obtained by means of the same apparatus as that described elsewhere (2). The setup consisted of an electrolytic cell 0.6 liter in volume and a holding vessel of 2.2 liters connected in a loop so as to provide a constant recirculation of brine at a given flow rate (q = 8.2 × 10^{-4} liters/sec). The pH in the cell was maintained constant to within ± 0.1 pH unit by means of a pH-stat. The electrolyte was stirred both in the cell and in the holding volume so that they operated as back-mix-flow reactors. The stirring in the cell was intensified by the cathodic evolution of hydrogen and homogenized by an appropriate positioning of both the platinum gauze anode and the wire cathode.

The cell load was maintained at 4.5A, and with the electrode surface area A = 67.5 cm^2, this implied an anodic current density of 6.67 A/dm^2.

The cell temperature was maintained at 25°C, while that of the holding volume varied between 15° and 80°C.

In the described setup and under the given hydrodynamic conditions, the diffusion layer thickness was experimentally estimated to be 8.2 × 10^{-4} cm by measuring the steady-state limiting diffusion current of the ferrous-cyanide oxidation from a usual and appropriate electrolyte composition [cf. (13)].

Other details of the apparatus and of the determination of the current efficiency may be found elsewhere (2).

The value of the rate constant of chlorine hydrolysis (k_1 = 0.17 sec^{-1}) was obtained by extrapolation of Spalding's data (28) for the actually existing ionic strength of the chlorate cell brine [cf. (14) and (18)]. The diffusion constants of elemental (D_1 = 6.7 × 10^{-6} cm^2/sec) and active chlorine (D_2 = 1.2 × 10^{-5}

cm^2/sec) represents Chao's data (29) corrected for viscosity of solution at the given ionic strength of chlorate production [cf. (14)].

The activity coefficient of hypochlorous acid was taken from data of Imagawa (4) to be about 2.0. The corresponding value for hypochlorite ion, and for active chlorine as well, was estimated to be about 0.1 [cf. (14) and (18)]. Activity of water was approximately taken to be 0.8 (3). The rate constants for the active chlorine chemical conversion to chlorate as function of temperature were taken from data of De Valera (3).

The electrolyte consisted of 300 g/liter of NaCl and about 4.0 g/liter of sodium dichromate. The electrolysis was carried out to 30 g/liter of sodium chlorate, whereupon the electrolyte was renewed.

The apparatus with a ribbon type of cell and the plug-flow circulation was also described elsewhere (17, 24). The entire setup was very similar to the one described elsewhere (2) and partly here, the only difference being that all the dimensions of the apparatus were enlarged. The anode was DSA-electrode supplied by Oronzio de Nora, Milano, Italy (L = 70 dm, r = 4.5 cm). The current densities were i = 3.61 and 1.97 A/sq.dm., and temperature (t_c) was at 14°C.

Acknowledgments

Thanks are due to Dr. S. Bingulac for numerical computations. The author gratefully acknowledges the important personal help of Dr. Oronzio De Nora, Milano, Italy and his Company in supplying DSA electrodes for investigations and application in the Institute's cell and its chlorate process.

Manuscript submitted Sept. 8, 1972; revised manuscript received *ca.* July 30, 1973. This paper was presented at the Houston, Texas, Meeting of the Society, May 7-11, 1972.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1974 JOURNAL.

APPENDIX I

It should be noted that, in deriving Faradaic stoichiometry and mass balance equations, one has been considering (2) both hypochlorous species as potentially equal entities able to take part in both Foerster's reactions of the chemical conversion and the anode oxidation. Hence, both species are together summationally expressed in a certain mutual and more suitable unique form of the active chlorine (C_s). Therefore, for Eq. [1], it could be written

$$-\frac{d[ClO^-]}{dt} = -\frac{1}{2}\cdot\frac{d[HClO]}{dt} = \frac{d[ClO_3^-]}{dt} \quad \text{[A-1]}$$

or, otherwise

$$-\frac{dC_s}{dt} = -\frac{d([HClO] + [ClO^-])}{dt} \cong -3\frac{d[ClO^-]}{dt} \quad \text{[A-2]}$$

Further, introducing Foerster's kinetic law for the chemical conversion in concentrated solutions or, in other words, recognizing Brönsted's kinetic theory (1, 4), it could be written

$$-\frac{dC_s}{dt} = 3\cdot f^2\cdot k_r[HClO]^2\cdot[ClO^-] \quad \text{[A-3]}$$

As it is already descriptively said, one implies that the active chlorine represents the sum of both hypochlorous species, or otherwise

$$C_s = [HClO] + [ClO^-] \quad \text{[A-4]}$$

Two last relations could finally be combined with Eq. [7] that leads to the more suitable form of the kinetic law for the chemical chlorate formation (2, 5)

$$-\frac{dC_s}{dt} = 3\cdot f^2\cdot k_r\cdot\frac{K^*\cdot(a_{H_3O^+})^2}{[K^* + (a_{H_3O^+})]^3}\cdot C_s^3 \quad \text{[A-5]}$$

Namely, considering that both species reversibly interchange their states between each other over an extremely fast reaction of proton exchange [cf. (13)], the active chlorine might be imagined as an instantaneous mutual hibride form similar to an active complex in the transition state. Such a conclusion seems probable for the transition pH range at least, where both hypochlorous species exist in comparable contents.

APPENDIX II

Explanation of Fig. 5

Equation [10] could be presented in a somewhat more convenient form for further computer analysis. Hence, one firstly introduces another parameter (A) being

$$A = D_2\cdot\mathbf{F}\cdot f_{sc}\cdot\frac{C_{sc}}{i\cdot\delta_M} \quad \text{[B-1]}$$

or in combination with Eq. [12] the latter leads to the relation

$$A = \frac{1}{2}\sqrt{\frac{D_2\cdot\mathbf{F}\cdot f_{sc}\cdot C_{sc}}{i}\sqrt{\frac{k_1}{D_1}}} \quad \text{[B-2]}$$

Finally, one more parameter (X) can be introduced

$$X = \frac{\delta}{\delta_M} \quad \text{[B-3]}$$

Replacing Eq. [B-2] and [B-3] into Eq. [10], one obtains its other form

$$t_1 = \frac{1 - A/X}{\frac{3}{2} - \frac{1}{2}\,\frac{1-\exp(-4AX)}{4AX}} \quad \text{[B-4]}$$

Thus, the parameter X in Fig. 5 represents in essence the variable δ in a somewhat different and more suitable form. Hence, the various curves in Fig. 5 represent the basic relationship (Eq. [10]), expressed in a more convenient form (Eq. [B-4]), for different ratios C_{sc}/i used as parameter. This is reflected here over different A values (1-10^{-4}, 2-3.3 · 10^{-4}, 3-10^{-3}, 4-3.3 · 10^{-3}, and 5-10^{-2}).

Standard Electrode Potential Measurements of $Pb/PbCl_2/HCl$ and $Tl/TlCl/HCl$ Half Cells in Dimethylformamide at 30°C

Frank Leslie Bates[1] **and Yeu Tsang Nee**[2]

Department of Chemistry, The University of Detroit, Detroit, Michigan 48221

ABSTRACT

The potentials of electrodes consisting of metal, solid metal chloride, and a solution of a soluble chloride (anhydrous HCl) in dimethylformamide (DMF) have been measured *vs.* a hydrogen electrode as the reference electrode. Half cells $Pb/PbCl_2/HCl$ and Tl/TlCl/HCl were prepared by contacting pure metal with its associated chloride after forming the solid phase in a glass tube. Elaborate and scrupulous procedure is important for preparing the hydrogen electrode to attain reliable and reproducible measurements in DMF. Standard electrode potentials of −0.3368 and −0.5994V *vs.* SHE in DMF, at 30°C, were attained in DMF for the lead chloride and thallium chloride electrodes, respectively, at 30°C.

Measurements of electrode potentials in nonaqueous solvents have shown complications since 1909, even though some of them were found to be a natural and straightforward extension of the corresponding measurements in aqueous solutions. Pavlopoulous and Strehlow (1) measured the standard potentials of some heavy metals in the solvent formamide, but were unsuccessful in using the Ag/AgCl electrode in the same solvent. The Ag/AgCl electrode in formamide was used for measurements without much difficulty by Mandel and Decroly (2).

Since the unsubstituted amides (with the exception of formamide) are all crystalline solids at room temperature, N,N-dimethylformamide was chosen, which is a powerful solvent for both polar and nonpolar compounds. It has not been investigated as a nonaqueous solvent (3) for the measurement of electrode potentials. It was employed in this paper for the measurement of the standard potential of electrodes of the metal-insoluble salt type *vs.* the hydrogen electrode.

Discussion

In Pavlopoulous and Strehlow's paper (1) the hydrogen electrode was used without adequate description of operational detail. The literature indicates that the level of accuracy of most potentiometric measurements in anhydrous solutions has been insufficient to warrant any distinct choice between alternative methods of preparing the hydrogen electrode. The attainment of a truly reproducible hydrogen electrode actually holds the key to the successful performance in its role as the reference electrode (4) in anhydrous DMF solutions.

A typical laboratory procedure for preparing the platinized hydrogen electrode in aqueous solutions includes cleaning the Pt plate with aqua regia, testing the cleanliness in a 10% solution of H_2SO_4, then electrolyzing it as the cathode in dilute NaOH and H_2SO_4 solutions after electrolyzing it as the cathode for 5 min in a 3% solution of chloroplatinic acid containing 0.5 ml of 0.1*N* lead acetate in 100 ml solution.

The portion of the procedure most likely to cause a difference in behavior of the hydrogen electrode in aqueous and nonaqueous solutions is the process of platinization. Lead acetate is added to the platinizing solution as an impurity. Purified chloroplatinic acid solutions give only bright Pt deposits upon the platinum plate, which as an electrode can be initially active but decays in activity rather rapidly. Hence the lead acetate has to be retained in the platinizing solution (5). The second factor with prominent importance

[1] Deceased.
[2] Present address: No. 58, Tung Hai Road, Tung Hai University, Tai-Chung, Taiwan, The Republic of China.
Key words: electrode potentials, metals in DMF.

is the thickness of the coating of the Pt black hiding the sheen of the metal base. The actual thickness of the Pt black does not matter at all in water solutions. The thicker the film, the more likely will the electrode give constant results. In 1922, Clark (6) made use of a thin deposit of Pt black to avoid reduction of the metal ion upon the hydrogen electrode. Confirmed by Draves and Tartar (7) in 1925, the reduction on the surface of the Pt plate was due to the use of a thickly coated electrode in nonaqueous solutions. Walter (8) in 1926 renewed platinized hydrogen electrodes after three or four measurements. Kanning and Bowman (9) in 1946 attempted to lengthen the usual short life of hydrogen electrodes in methanol beyond 60 min. Moore and Felsing (10) pointed out that the electrodes which were least platinized gave the highest potential values and approached a near steady state most rapidly. Then in 1956 Oiwa (11) mentioned in a paper dealing with activity coefficients of HCl in methanol-water mixtures that the hydrogen electrodes used were plated with Pt black as thin as possible. It is evident that Pt black is necessary, but only the minimum thickness required to obscure the surface luster should be used.

In view of all the difficulties with the hydrogen electrode in anhydrous solvents, all of which indicating some irreversible change in the condition of the electrode, the only hope of finding the reversible potential is to get it before the irreversible change in the hydrogen electrode occurs, namely at zero time. The spontaneous, irreversible electrochemical process reduces the potential from the hypothetical reversible value given by the cell as it is initially constituted. Mandel and Decroly (2) extrapolated the drifting potential back to zero time, that is to the time the cell was assembled as a complete unit. By soaking the metal electrode in the cell solution for some time and washing the hydrogen electrode with the cell solution before use, all the possible, purely chemical (as distinct from electrochemical) changes are allowed to occur before the circuit is actually completed.

Experimental Preparation

Cell.—The cell is an H-cell with two limbs. The first limb had a diameter of about 1 cm. There was a neck (constriction) made close to the lower end with the purpose of keeping the metal chloride from being stirred up. The second limb had a diameter of 4 cm. Into this limb the hydrogen electrode was placed. Clean glass wool was used in the connecting arm to minimize the diffusion of metal salt onto the platinum plate resulting in the poisoning of the hydrogen electrode.

Metals electrodes.—Pure metal in its molten state was sucked into a glass tube through a small nozzle (Fig. 1). The molten metal gradually solidified from the side to the center of the tube.

Hydrogen electrode.—The Pt plate was thinly platinized with Pt black so as just to hide the sheen. The electrodes were cleaned before each platinization by electrolyzing in concentrated HCl day and night; sometimes a week or more was required. The hydrogen gas was maintained at 1 atm pressure.

Metal chlorides.—Metal chlorides were dried for a sufficient period of time at an appropriate temperature to remove the water of crystallization.

Hydrogen gas.—Commercial tank hydrogen purified by passing through a train consisting of basic pyrogallol, sulfuric acid, and anhydrous calcium chloride was used.

Formamide.—The formamide used was prepared by Eastman Organic Chemicals, and had a refractive index 1.4457 at 26°C.

N,N-dimethylformamide.—The reagent grade DMF purchased from Fischer Scientific Company was purified by shaking it with BaO powder (technical grade, Code 1422), decanted, and distilled at 15-20 mm Hg pressure and the middle fraction of the distillate retained. The distillate had a refractive index of 1.4280 at 26°C.

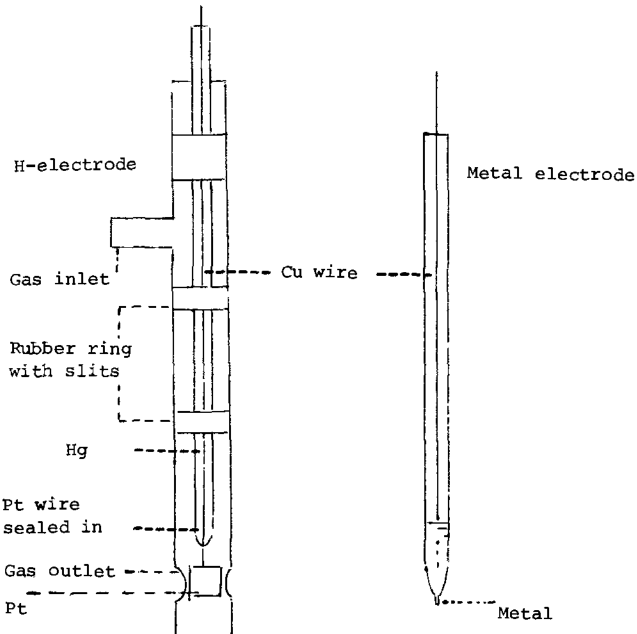

Fig. 1. Form of the electrodes

HCl-amide solution.—Dry gaseous tank HCl was passed into the amide one day before measuring. This process could be carried out in a 125 ml Erlenmeyer flask. Care must be exercised to keep the solution dry and away from getting contact with the rubber stopper. It would be much safer to use a glass stopper to fit the flask. The solution was then poured into the cell in which the dry metal salt and clean glass wool were placed beforehand. Subsequently, the metal electrode was introduced into the left cell and allowed to stand with the salt in the HCl-amide solution. After the metal and the metal salt stood in contact with the solution for 10-12 hr indicating that the metal had become coated with metal chloride, the half cell was able to reach a steady and reproducible voltage when coupled with the hydrogen electrode.

The sample of the HCl-amide solution to be analyzed for chloride ion concentration was withdrawn from the bulk of the solution before it was poured into the cell. It was not permissible to prepare a stock volume of HCl-amide solution, enough to be used over a longer period of time, because of the suspected decomposition resulting from hydrolysis of amide by very small traces of water and catalyzed by HCl.

The determination of the HCl concentration in the solvent amide.—A 2 or 5 ml sample was treated with enough NaOH to make it basic plus a little excess and evaporated until the residue was only slightly damp. The amide in the form of a light yellow residue was decomposed on the addition of about 1 ml of 15*N* NaOH and a few milliliters of 3% H_2O_2, just enough to react with all the amide. After the foaming ceased, water was then added to dissolve the reaction mixture and to make the total volume about 50 ml. The solution was acidified with $HClO_4$ and titrated with 0.1*N* $AgNO_3$ using potassium chromate as the indicator. Two porcelain crucibles were used in order to catch the end point accurately, since the addition of chromate would give the solution to be titrated a color between orange and light red in a presence of organic amine. As the end point was approached, which can be easily detected in the process of titration, the precipitate was allowed to settle. The liquid was decanted into the second crucible. The color of the precipitate would stay white or nearly so before the end point. At the end point there would be a red precipitate appearing in the

AgCl precipitate like a mass of cottage cheese studded with red crystals. Once the end point was overpassed the whole body of precipitate would turn to clearer red tint. Some of the results from titration were further tested by gravimetric precipitation of silver chloride.

EMF measurements.—After the metal electrode stood in the cell with the metal chloride and HCl-amide solution for about 10-20 hr, H_2 gas was bubbled through the cell solution in the larger compartment for 2 hr. Simultaneously, the temperature of the thermostat was adjusted to the desired value. The upper part of the tube containing the hydrogen electrode was dried by passing dry N_2 or H_2 gas through the tube for 2 hr. At the end of the 2 hr, the hydrogen electrode was rinsed several times with the cell solution before it was introduced into the cell. A Leeds and Northrup Type K-2 potentiometer was used to measure the cell potentials at intervals over a period of time. The potential values which changed slightly (not more than a few mV) with time were extrapolated to zero time to obtain the initial value of the cell potential E.

Treatment of data.—The cells studied were

$$(-)\mathrm{Pb/PbCl_2(c), HCl(in\ DMF), H_2(g, 1\ atm)/Pt}(+) \qquad [A]$$

$$(-)\mathrm{Tl/TlCl(c), HCl(in\ DMF), H_2(g, 1\ atm)/Pt}(+) \qquad [B]$$

at 30°C. For the conventional cell reactions

$$\mathrm{Pb + 2H^+ + 2Cl^- = PbCl_2 + H_2} \qquad [A1]$$

$$\mathrm{2Tl + 2H^+ + 2Cl^- = 2TlCl + H_2} \qquad [B1]$$

the standard cell potential $E°$ is related to the actual cell potential E and to the activity of the acid electrolyte by the Nernst equation

$$E = E° + (RT/\mathbf{F})\ln(a_H + a_{Cl^-}) \qquad [1]$$

At a given molar concentration of acid, the approximate value of $E°$, indicated by E', can be calculated from the concentration and the experimental E by the equations

$$E' = E - 0.1183 \log C_{HCl}, \text{ at } 25°C \qquad [2a]$$

$$E' + E - 0.1203 \log C_{HCl}, \text{ at } 30°C \qquad [2b]$$

Equation [1] is valid at unit fugacity (1 atm) of hydrogen gas.

The measured potential values were followed as a function of time. The drift from the "true" cell emf (at zero time) does not appear to exceed a few thousandths of a volt in any case after 30 min.

The correct value of $E°$ for cells [A] and [B] can be found by plotting the E' values obtained with various concentrations of HCl via Eq. [2b] against $\sqrt{C}$. By the method of least squares, the standard potential $E°$ of cells [A] and [B] is obtained as the intercept of the $E' - \sqrt{C}$ curve, extrapolated to the limit $\sqrt{C} \to 0$.

The numerical data for cells [A] and [B] with two different hydrogen electrodes are summarized in Tables I and II, respectively. These tables list the observed cell potentials E in volts, the values of E' calculated via Eq. [2b], and the concentrations C in moles of HCl per liter of solution in dimethylformamide. The tables also give the least squares equations for E' *vs.* $\sqrt{C}$ for two separate hydrogen electrodes with each cell, and give an estimate of $E°$ with its standard deviation for each of the four sets of data. For each cell, the two values of $E°$ are consistent within the experimental error, despite the discrepancy in the observed slopes for the two separate hydrogen electrodes (see below).

The cell $E°$ values reported in Tables I and II for cells [A] and [B] can be equated to what Latimer (13) called the oxidation potentials of the $Pb/PbCl_2$ and Tl/TlCl redox couples in DMF at 30°C, respectively. Following the conventions adopted by the International Union of Pure and Applied Chemistry (12) at Stockholm in 1953, cell potentials with the SHE at the right-hand terminal should not be called electrode potentials. Rather, the standard potentials of the $Pb/PbCl_2$ and Tl/TlCl electrodes in DMF may be equated to the cell $E°$ values of the reversed forms of cells [A] and [B]. Therefore, the electrode potentials reported here are equal in value but opposite in sign to the cell $E°$ values. The standard electrode potentials $E°$ are negative for both electrodes, corresponding to the (−) d-c polarity exhibited experimentally by both electrodes in cells [A] and [B] (Tables I and II, bottom line).

Conclusion

The procedure for the determination of the standard potentials of anion responsive electrodes of the Ag/AgCl type in nonaqueous solvents was checked by measuring the potential of the cell

$$\mathrm{Cd/CdCl_2(c), HCl(in\ formamide, H_2(g, 1\ atm))/Pt} \qquad [C]$$

at 25°C. The equation for E' was obtained as $E' = -0.0308\sqrt{C} + 0.6158$ giving the standard potential of the electrode: $Cd/CdCl_2$/HCl(in formamide), $E° = -0.6158 \pm 0.0068$V at 25°C [as compared to the value of -0.617 ± 0.004 given by Pavlopoulous and Strehlow (1)].

Table I. Potential data for cell [A] at 30°C

Data observed with:	1st hydrogen electrode				2nd hydrogen electrode			
Cell potential E, V (extrapolated to zero time)	0.3689	0.3630	0.3038	0.2365	0.2389	0.2788	0.3075	0.1982
E', V	0.3748	0.3743	0.3595	0.3518	0.3289	0.3263	0.3271	0.3327
C, moles/liter	0.8926	0.8060	0.3437	0.1101	0.1785	0.4030	0.6785	0.0760
Equation of the E' *vs.* $\sqrt{C}$ line	$E' = 0.03953\sqrt{C} + 0.3378$				$E' = -0.01091\sqrt{C} + 0.3358$			
Standard potential of cell [A]	$E° = 0.3378 \pm 0.0011$				$E° = 0.3358 \pm 0.0020$			

Standard potential of $Pb/PbCl_2$/HCl electrode in DMF, *vs.* SME in DMF, at 30°C.
$E°(Pb/PbCl_2 \text{ in DMF}) = -0.3368 \pm 0.0015$V

Table II. Potential data for cell [B] at 30°C

Data observed with:	1st hydrogen electrode				2nd hydrogen electrode			
Cell potential E, V (extrapolated to zero time)	0.6018	0.7153	0.5900	0.7000	0.5874	0.5776	0.6760	0.5430
E', V	0.6761	0.7323	0.6703	0.7230	0.6617	0.6579	0.6990	0.6467
C, moles/liter	0.2410	0.7220	0.2148	0.6443	0.2410	0.2148	0.6443	0.1374
Equation of the E' *vs.* $\sqrt{C}$ line	$E' = 0.1554\sqrt{C} + 0.5994$				$E' = 0.1241\sqrt{C} + 0.5994$			
Standard potential of cell [B]	$E° = 0.5994 \pm 0.0010$				$E° = 0.5994 \pm 0.0012$			

Standard potential of Tl/TlCl/HCl electrode in DMF, *vs.* SHE in DMF, at 30°.
$E°(\text{Tl/TlCl in DMF}) = -0.5994 \pm 0.0011$V

Upon consideration of the solubility of metal chlorides in dimethylformamide, the standard potentials of the $Pb/PbCl_2/HCl$ and $Tl/TlCl/HCl$ electrodes have been determined in this study in DMF. The E' values revealed an interesting point. From the two hydrogen electrodes, two sets of E' values for different concentrations of HCl in the solvent DMF converge to an identical standard potential $E°$ value. This phenomenon probably results from the difference in thickness of the Pt black plated upon the two hydrogen electrodes. It supports the hypothesis that Pt black made as thin as possible is effective in improving the reproducibility of voltages obtained in anhydrous DMF.

The standard electrode potentials in DMF at 30°C are obtained from the present study as follows

$HCl(in\ DMF)/PbCl_2/Pb$

$$PbCl_2 + 2e^- \rightleftharpoons Pb + 2Cl^- \quad E° = -0.3368V \pm 0.0015V \quad [3]$$

$HCl(in\ DMF)/TlCl/Tl$

$$TlCl + e^- = Tl + Cl^- \quad E° = -0.5994V \pm 0.0011V \quad [4]$$

The individual standard electrode potentials are referred to that of the standard hydrogen electrode in the same solvent, and the algebraic sign conforms to that adopted by the International Union of Pure and Applied Chemistry (12) in expressing the electrode potential.

It appears that not only does the hydrogen electrode respond differently in nonaqueous solvents than it does in water, but also problems are encountered peculiar to the particular solvent employed. The conception we have had for the electrochemical response of the hydrogen electrode in water is not equally applicable to anhydrous nonaqueous solvents. The prolonged usage of the platinized hydrogen electrode in nonaqueous solvents continually for two or more hours is harmful to its proper functioning. Between measurements a procedure of soaking the hydrogen electrode in concentrated HNO_3 for about 3 hr, followed by subsequent electrolysis in NaOH and H_2SO_4 is a satisfactory way to prevent the deposition of metal ions on the surface of the electrode and to prolong its life. Where the possibility of reduction of metal ion is negligible, the HNO_3 treatment could be omitted. The poisoning of the electrode is indicated by a decrease in potential which may even result in a reversal of polarity. It is conceivable that there is a corresponding span of catalytic life for each thickness of Pt black for its usage in a particular solvent, although it was not possible to determine any real difference between the two solvents used.

The experimental results indicate that the hydrogen electrodes were functioning satisfactorily during most of the runs generally showing only slow drifts in potential with no erratic behavior. The proper thickness of the platinum black proved to be the critical factor in the use of the platinized hydrogen electrode in the anhydrous nonaqueous solvents: formamide and dimethylformamide.

Manuscript submitted July 24, 1972; revised manuscript received July 11, 1973.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1974 JOURNAL.

LIST OF SYMBOLS

E	cell potential extrapolated at zero time from the measured potentials, V
$E°$	standard cell potential, V. Also, the electrode potential (IUPAC)
E'	approximate value of $E°$ at a given concentration of acid electrolyte, V
R	ideal gas constant
T	absolute temperature, Kelvins
F	Faraday constant, 96487 coulombs/equiv
C	molar concentration, moles/liter of solution

On the Transference Number for Li^+ Ion in Propylene Carbonate Solutions from EMF Measurements

James P. Hoare* and Charles R. Wiese

Electrochemistry Department, Research Laboratories, General Motors Corporation, Warren, Michigan 48090

ABSTRACT

The rest potential of a Li/Li^+ electrode was determined with respect to a Li/Li^+, 1M reference electrode in propylene carbonate solutions of $LiClO_4$ as a function of the Li^+ ion concentration and of the H_2O concentration. The transference number for Li^+ ion was determined from these data and found to be 0.32. This value is virtually independent of the amount of H_2O present in the PC solution. For low water content, the electrode is one of the first kind and the potential is determined by the Li/Li^+ reaction. At high water content, the electrode becomes one of the second kind and the potential is determined by the Li/LiOH reaction. The transition from one reaction to the other takes place where, on the average, one H_2O molecule replaces one PC molecule in the solvation sheath of each Li^+ ion.

To investigate the electrochemical properties of the light, highly reactive metal electrode systems, it is desirable to use an aprotic nonaqueous electrolyte. In the search for a suitable reference electrode for the study of such a system, the possibility of employing the Li/Li^+ couple in propylene carbonate (PC) was considered since this couple has been reported (1) to be reversible and well behaved. From chronopotentiometric and cyclic voltammetric studies (2, 3), it appears that the presence of water in this system may play (3) a complex role. Keller and associates (4) report that the mobility of the Li^+ ion in PC is very low ($t_+ \sim 0.25$) as determined from conductance measurements. Solvation of the Li^+ ion may account for the low value of the transference number, t_+.

Using a reference electrode composed of a Li rod in 1M $LiClO_4$ in PC, the potential of a concentration cell, Li/$LiClO_4$ ($C = x$), PC ¦ PC, $LiClO_4$ (1M)/Li, was investigated as a function of the Li^+ ion and H_2O concentration. Some information about the effect of H_2O on the ionic mobilities and on the potential-determining reactions at the Li electrode can be obtained from these studies. This report describes the results of such an investigation since to these authors' knowledge this information is not available in the reviewed literature.

Experimental

All experiments were carried out in a glove box in an argon atmosphere in which the oxygen, nitrogen, and water content are maintained below 1 ppm. The PC was vacuum (2 Torr) distilled in a still with a Podbilniak column and the first 30% of the still pot charge was discarded. The next 60% of the pot charge was used in the experiments. Ultrapure $LiClO_4$ certified to contain less than 20 ppm H_2O was used to make up a stock solution of 1M $LiClO_4$ in PC. Further traces of H_2O were removed from these solutions by gettering with scraped Li foil until no water was detected by a Karl Fischer titration (<5 ppm H_2O). Such treated solutions will be referred to as dry solutions.

After investigating a number of designs for the envelope of our reference electrode including cracked glass, wetted ground glass, and asbestos fiber junctions, the best performance was obtained with glass frits. A glass tube (13.5 cm long sealed at one end by a glass frit 1 cm thick and 0.5 cm in diameter with a pore diameter of 4-8 μm) was filled with the dry 1M $LiClO_4$-PC reference solution. After a Li wire (0.3 cm in diameter) was placed in the solution, the top of the tube was sealed with an epoxy plug so that electrical connection to the protruding Li wire could be made. When not in use, these electrodes were immersed in the dry 1M $LiClO_4$-PC solution in an auxiliary vessel.

The test electrodes were made from pure Li wire (0.3 cm in diameter) and from a cast rod (1.5 cm in diameter). These electrodes were cast in an epoxy resin and the ends of the electrodes were polished flush with the epoxy cast. From long term compatibility studies, it was found that the epoxy resin did not interact with the electrolyte nor with the Li metal. These electrodes were clamped by a holder in the cell (a glass crystallizing dish 6 cm in diameter and 3 cm deep) filled with the electrolyte to be studied. The reference electrode was clamped in position in the cell only when measurements were being made. Before each run, the faces of the electrode were scraped with a stainless steel spatula.

In a typical run the rest potential of the Li electrode was recorded with a Keithley 600A electrometer after the potential *vs.* the Li/Li^+ (1M $LiClO_4$-PC) reference electrode had come to a steady value (usually within 30 min). The solution was stirred continuously with bubbling argon. Afterwards, a sample of the electrolyte was removed for the determination of its H_2O content by a Karl Fischer titration. The temperature of these experiments was 24° ± 1°C. Water was added to the electrolyte with a microsyringe and the concentration of Li^+ ion was changed by dilution with pure dry PC.

Results and Discussion

In Fig. 1 is plotted the rest potential of a Li/Li^+ electrode *vs.* Li/Li^+, (1M) for six solutions of $LiClO_4$ ranging from 1 to 0.001M as a function of the water content of the solution. Each point on these curves is the average value of nine independent readings using three different reference electrodes and three different test electrodes with two different areas (0.28 and 7.1 cm^2). For those data points where the potential decreases with increasing H_2O content, the data were reproducible within ±1 mV (for low H_2O content and high Li^+ ion content, within ±0.5 mV). In the cases where the water content is high and the Li^+ ion content is low, the rest potential increases rapidly with water content and there is a spread of potential values between electrodes of different areas ranging as much as 20 mV. At very high H_2O content (above 6000 ppm H_2O in the 0.01M $LiClO_4$-PC solution), this area effect disappears and the data can be reproduced within ± 1.5 mV.

The test electrode and reference electrode constitute a concentration cell whose potential is

$$E = E_1 - E_2 + Ej = \frac{RT}{nF} \ln \left(\frac{a_1}{a_2} \right) + Ej \qquad [1]$$

* Electrochemical Society Active Member.

Key words: lithium, propylene carbonate, transference number.

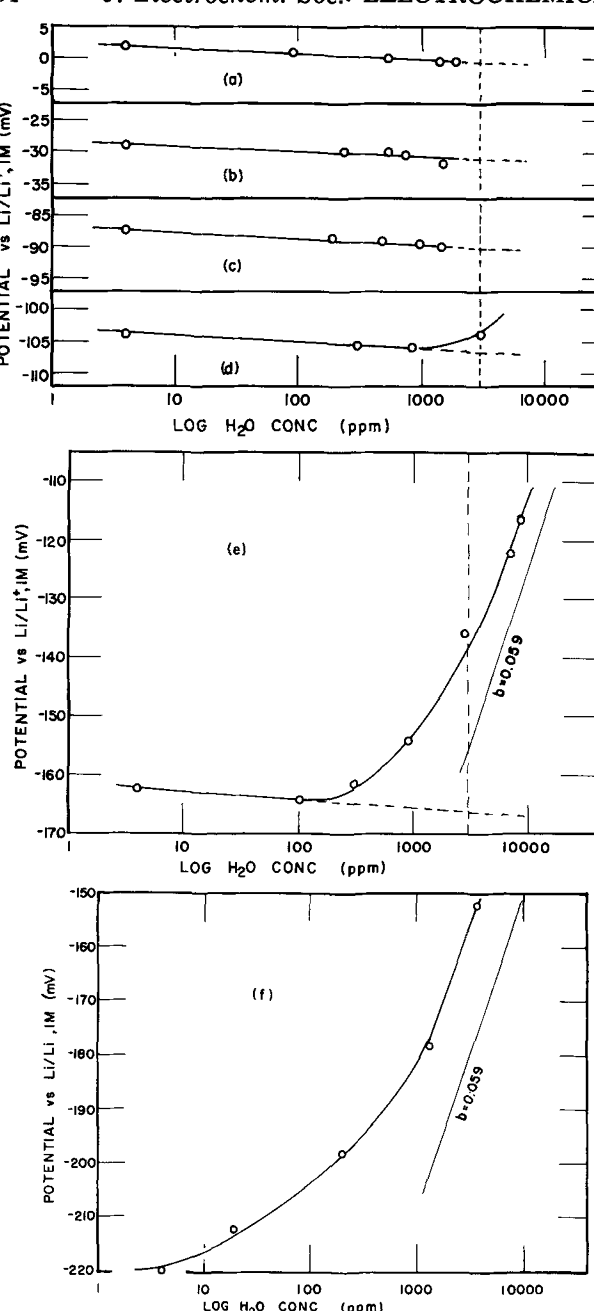

Fig. 1. Plots of the rest potential of a Li/Li$^+$ electrode as a function of the H_2O content of the PC solutions of 1M (a), 0.5M (b), 0.1M (c), 0.05M (d), 0.01M (e), and 0.001M (f) $LiClO_4$. The vertical dashed line appears at 3000 ppm H_2O and the lines are extrapolated to this point in (a-e) to obtain the data (triangles) in Fig. 2. A line with a slope of 0.059 is given in (e, f) for the sake of comparison.

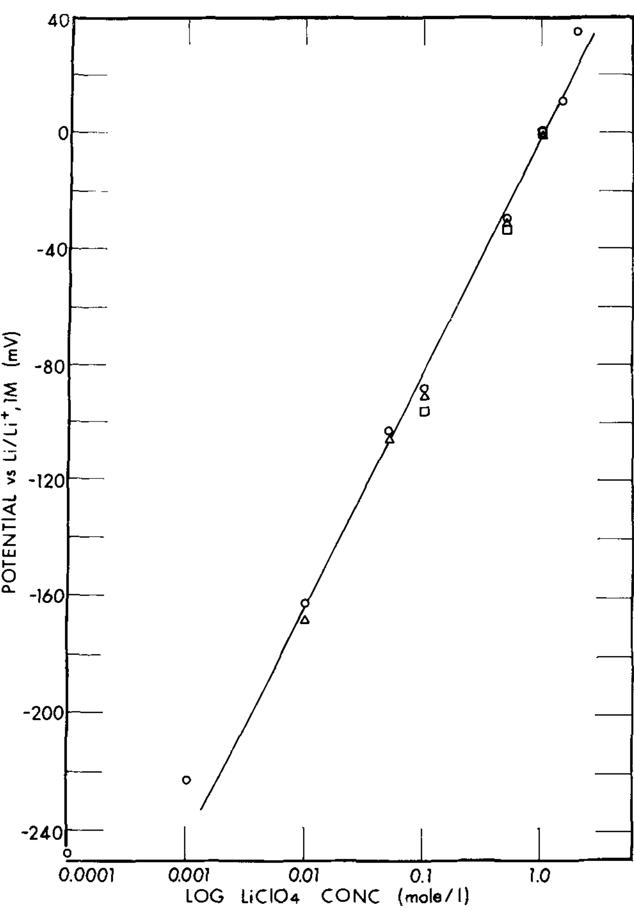

Fig. 2. A plot of the rest potential of a Li/Li$^+$ electrode with respect to a Li/Li$^+$, 1M reference electrode as a function of the $LiClO_4$ concentration for dry (○) and wet (containing 3000 ppm H_2O) (△) PC solutions. Data from Meibuhr (6) is also plotted (□). Deviation from straight line at low $LiClO_4$ concentrations is an activity coefficient effect.

where a_1 and a_2 are the activities of the reversible ion on each side of the liquid junction and Ej is the junction potential which is a function of the activities and transference numbers of all the ions present. It can be shown [*e.g.*, (5)] that for a one-one salt

$$E = \frac{2RT}{\mathbf{F}} (t_-) \ln \frac{(a_+)_1}{(a_+)_2} \qquad [2]$$

Note that the transference number, t_-, involved in Eq. [2] refers to the ion (in this case, the anion) which is not the reversible ion (in this case the cation).

A plot of the rest potential as a function of the log of the Li$^+$ ion concentration is given in Fig. 2 (circles) for dry solutions of $LiClO_4$ in PC. Here a_2 is always 1M and it is assumed that the activity coefficients are the same for both the test and the reference solution. From the slope of this line, a value of t_- can be obtained and a least squares analysis of the data provides a value of 0.68 for the transport number of ClO_4^- ion, t_- from which one calculates for Li$^+$ ion a value of 0.32 for t_+. Keller and co-workers (4) report a value of 0.28 for t_+ in PC at 25°C which was determined from conductivity measurements. If the few measurements reported by Meibuhr (6) on a concentration cell are treated (7) similarly (see squares in Fig. 2) at t_+ value of 0.21 is obtained.[1]

This low value for the t_+ of Li$^+$ ion can be accounted for by solvation of the Li$^+$ ion. Using conductivity data, the ionic radius r of the Li$^+$ ion was determined by Keller *et al.* (4) from Stokes law and was compared with the crystal ionic radius, r_c. Since $r >> r_c$, the number of solvent molecules, n, associated at a given instant with a Li$^+$ ion in the solvation sheath can be determined from the volume of the sheath and the volume of the solvent molecules. They record a value of 2.8 PC molecules per Li$^+$ ion for n. For Li$^+$ ions in DMSO, Yao and Bennion (8) reported a value of 4.8 for n using conductivity data and an empirically modified Stokes equation (9) which in effect takes into account (10, 11) dielectric relaxation effects. It is generally known (12) that lithium has a coordination number of 4. With these results in mind, it is reasonable to assume that each Li$^+$ ion at any instant is coordinated with four PC molecules. Because of the hindering effect of these coordinated PC molecules, the solvated Li$^+$

[1] One of the reviewers brought the work of Mukherjee *et al.* (14) to our attention where t_+ for Li$^+$ ion in PC was determined in a concentration cell using Li-amalgam electrodes. Their t_+ values not only vary from 0.18 to 0.24 with the Li$^+$ ion concentration but also do not agree with this work nor with the conductivity results (4).

ions carry only about 30% of the current while the ClO_4^- ions which are virtually unsolvated (4, 8) carry about 70% of the current.

When water is added to a PC solution of $LiClO_4$, the rest potential of the Li electrode (*vs.* Li/Li^+, 1M) decreases slowly with the log of the H_2O concentration as noted in Fig. 1. If these straight lines are extrapolated to a water concenrtation of 3000 ppm, a plot of the extrapolated potential as a function of the log of the Li^+ ion concentration for solutions containing 3000 ppm H_2O is shown in Fig. 2 (triangles). A least squares analysis of these data gives a value of 0.31 for t_+. The data of Fig. 2 indicate that the presence of H_2O in PC does not affect the mobility of the Li^+ ion appreciably. Such an observation is understandable if a water molecule replaces only one PC in the solvation sheath

$$[Li(PC)_4]^+ + H_2O \rightleftarrows [Li(PC)_3 \cdot H_2O]^+ + PC \quad [3]$$

Because of the large size of the PC molecule, the mobility of the $[Li(PC)_3 \cdot H_2O]^+$ ion would be about the same as the $[Li(PC)_4]^+$ ion.

Since the transference number is not affected by the presence of H_2O in the PC solution, the low slope of the E-log H_2O concentration plots in Fig. 1 may be accounted for by a small change in the value of the junction potential, Ej, of Eq. [1]. The H_2O concentration of the reference electrode compartment is maintained at a very low level. It is not possible to calculate the Ej for the different values of the H_2O concentration across the junction because the H_2O molecule is not an ion. The effect is not large, however, since the Ej in a 1M solution of $LiClO_4$ in PC containing 3000 ppm H_2O is only 2.5 mV less noble than that in the dry solution according to the data in Fig. 1.

As noted in Fig. 1 when the concentration ratio, K, in ppm of Li^+ ions to H_2O molecules reaches a value of about 5 (0.01M Li $\sim$ 1000 ppm), the potential no longer decreases with the log of the concentration of H_2O but rises rapidly to more noble potentials with further additions of H_2O. In the region where $K < 1$ the plot approaches a slope of 0.059. This behavior indicates that the electrode reaction has changed from one in which H_2O is not a potential-determining species to one in which it is.

In the range where K is large (>5), water is tied up in the solvation sheath of the Li^+ ions as $[Li(PC)_4 \cdot H_2O]^+$ ions. Here, the potential-determining reaction is

$$Li^+ + e \rightleftarrows Li \quad [4]$$

as noted in Fig. 2 where the straight line plot of E *vs.* the log of the Li^+ ion concentration passes through zero for 1M Li^+ ion, and the presence of water does not seriously affect the electrode potential. When K reaches a value of 5, the mole ratio of $LiClO_4$ to H_2O is unity (1000/106/200/18 $\sim$ 1). At this point there is, on the average, one molecule of H_2O associated in the solvation sheath with each Li^+ ion present in solution and the system may be saturated with respect to its ability for tying up water.

When water is first added to a dry solution of $LiClO_4$ in PC, the water molecules are quickly tied up in the solvation sheath of the Li^+ ions. In this region where K is large, H_2O does not react with the Li metal and the electrode surface remains bright. After enough water is added so that $5 > K > 2$, H_2O can react with Li metal according to

$$Li + H_2O \rightarrow LiOH + \tfrac{1}{2}H_2 \quad [5]$$

and one observes a slow tarnishing of the electrode surface as a film of LiOH is built up. It is in this region that the Li electrode potential becomes strongly dependent on the H_2O concentration (Fig. 1) and large area effects are detected between electrodes of small and large areas. In the presence of a large amount of H_2O where $K < 1$, the Li surface becomes dark with a thick film of LiOH, the area effects disappear, and $\partial E / \partial \log H_2O = 0.059$. The data in Fig. 1 indicate that the potential-determining reaction must be a one-electron process involving H_2O. A reaction consistent with these data is Eq. [6] since LiOH is very insoluble in PC (3)

$$Li + H_2O \rightarrow LiOH + H^+ + e \quad [6]$$

If the activity of Li and LiOH is taken as unity, then

$$E = E_o - 0.059 \log C_{H^+} + 0.059 \log C_{H_2O} \quad [7]$$

From this viewpoint, the Li electrode immersed in a PC solution of $LiClO_4$ changes from an electrode of the first kind (Eq. [4]) to one of the second kind (Eq. [6]) as the H_2O content of the solution increases. The transition takes place where the mole ratio of H_2O to $LiClO_4$ is unity.

It is known (13) that PC is unstable in the presence of small amounts of acids or bases, and a discoloration of the PC takes place. When H_2O or $LiClO_4$ or both are added to the distilled PC, the solution remains clear and colorless; but when small amounts of $HClO_4$ are added (solution 10^{-4}M in H^+), the solution becomes yellowish. This coloration deepens to a dark brown as the H^+ concentration is increased. If Li metal is placed in contact with wet ($K < 5$) PC solutions of $LiClO_4$, the solution also develops a light yellow coloration. This coloration develops more quickly and becomes deeper as the H_2O content of the solution is increased. According to Eq. [6], H^+ ions would be generated and some decomposition of PC could take place. It has been reported by others that wet PC solutions become yellow when coming in contact with alkali metals (13).

When enough $HClO_4$ (72%) was added to a PC solution of 0.01M $LiClO_4$ containing about 7400 ppm H_2O to make it 0.001M in H^+ ions, the potential of the Li electrode (*vs.* Li/Li^+, 1M) became less noble initially as required by Eq. [7]. However, the potential drifted to more noble values, as the solution became yellow with time.

These data support the conclusion that the potential of a Li electrode in wet PC solutions of $LiClO_4$ is determined by the Li/LiOH reaction (Eq. [6]).

It appears that the presence of H^+ ions brings about the decomposition of PC with a formation of $CO_3^=$ ions and propylene residues which probably polymerize to form the colored material. This colored compound was not identified in the literature (13) nor in this work. In the very wet PC solutions, the film on the Li electrode was copious and black. This film was scraped off for analysis and became white when dried. The presence of Li_2CO_3 was detected in this material as determined from a wet chemical microanalysis of the film scrapings.

ABSTRACT

Electrochemical studies of U(IV) in molten LiF-NaF-KF (46.5-11.5-42.0 mole per cent) at 500°C reveal a two-step reduction process at a platinum electrode. The first step is complicated by disproportionation of U(III) to regenerate U(IV); the second step involves formation of uranium metal. Standard electrode potentials with respect to a unit mole fraction Ni(II)/Ni electrode are estimated for the U(IV)/U(III) and U(III)/U couples as −1.41 and −1.81V, respectively. These values must be considered tentative because of complications in the electrode processes. The voltammetric oxidation of U(IV) at platinum and pyrolytic graphite electrodes in LiF-NaF-KF occurs at ~ +1.3V *vs.* a Ni(II)(saturated)/Ni reference electrode. The results point to the disproportionation of electrochemically generated U(V). In voltammetric studies of Th(IV) in molten LiF-NaF-KF at 500°C, a reduction wave is obtained at nickel and tungsten electrodes, with a peak potential of −2.02V (*vs.* a Ni(II)(saturated)/Ni reference electrode). Analysis indicated that Th(IV) is reversibly reduced to the metal with alloy formation between the deposited thorium and the nickel. A standard electrode potential for the Th(IV)/Th couple in this melt is calculated to be −2.13V *vs.* a unit mole fraction Ni(II)/Ni electrode.

In this paper we describe electrochemical studies of uranium(IV) and thorium(IV) in a basic fluoride solvent LiF-NaF-KF [46.5-11.5-42.0 m/o (mole per cent)] at 500°C. Electrochemical studies of uranium in other molten fluorides have been described (1-4) and the results of these investigations have been summarized by one of us (5). The U(IV) reduction in the more acidic LiF-BeF_2-ZrF_4 (65.6-29.4-5.0 m/o) at 500°C was shown (1, 2) to be a reversible, one-electron process occurring at ~ −1.5V (*vs.* the unit mole fraction Ni(II)/Ni couple). No voltammetric reduction wave for U(III) was observed at platinum prior to the cathodic limit of the melt. Electrochemical oxidation of U(IV) produced unstable U(V) (4).

The only emf data available for the Th(IV)/Th couple in molten fluorides are the values of standard electrode potential calculated from thermodynamic data for pure thorium fluoride (6) and for ThF_4 solutions in molten LiF-BeF_2 (67-33 m/o) (7). The E° value (−2.332*V* *vs.* a unit mole fraction Ni(II)/Ni electrode) in LiF-BeF_2 at 500°C (7) is indicative of the great thermodynamic stability of the fluoro complexes of thorium(IV).

Experimental

The eutectic mixture of LiF-NaF-KF (46.5-11.5-42.0 m/o) used as the solvent and the solutes of LiF-UF_4 (73-27 m/o) and LiF-ThF_4 (73-27 m/o) were obtained from the Reactor Chemistry Division of the Oak Ridge National Laboratory. They were prepared from analytical reagent grade salts and purified by treatment of the molten mixtures with anhydrous HF and hydrogen (8).

The electrolytic cell assembly and the instrumentation employed for this work was the same as that used in a previous study (9). The Ni(II)/Ni reference electrode contained in a lanthanum trifluoride compartment has been described (10, 11). The background voltammograms for the melt employed in this work have been reported previously (9).

The details of the experimental procedures are presented elsewhere (12).

Results and Discussion

Voltammetric and chronopotentiometric reduction of U(IV).—The voltammetric reduction of U(IV) was investigated in molten LiF-NaF-KF contained in a platinum crucible at 500°C. Platinum indicator and counter-electrodes were employed, and potentials were measured with respect to a nickel(II) (saturated)/nickel reference electrode (LaF_3 membrane-type). The solute material was LiF-UF_4.

A typical linear sweep voltammogram for the reduction of U(IV) in molten LiF-NaF-KF at platinum is shown in Fig. 1. The broken-line curve in this figure is the reverse half-cycle obtained on switching the direction of potential scan at a given point between the two

* Electrochemical Society Active Member.
Key words: molten fluorides, uranium, thorium, linear sweep voltammetry, chronopotentiometry.

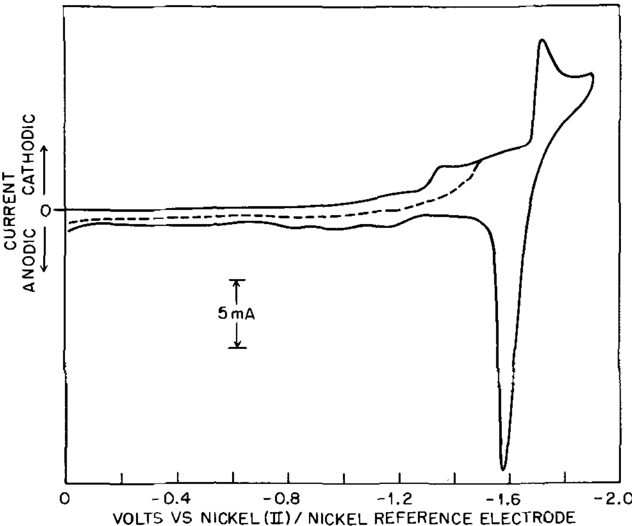

Fig. 1. Linear sweep voltammogram for the reduction of U(IV) in molten LiF-NaF-KF at 500°C at platinum electrode. Scan rate, 0.1 V/sec; U(IV) concentration, 0.220M; electrode area, 0.10 cm^2.

reduction waves. The first reduction wave at ~ −1.3V *vs.* the Ni(II) (saturated)/Ni reference electrode (LaF_3 membrane-type) apparently corresponds to U(IV) + e → U(III). Reduction of U(IV) to U(III) in LiF-BeF_2-ZrF_4 at 500°C occurs at about −1.5V *vs.* a unit mole fraction Ni(II)/Ni reference electrode (2). On the basis of emf data relating the potential of the saturated Ni(II)/Ni electrode in LiF-NaF-KF to a unit mole fraction Ni(II)/Ni electrode (10), the reduction of U(IV) in LiF-NaF-KF occurs at ~ −1.4V *vs.* a unit mole fraction Ni(II)/Ni reference electrode.

In contrast with the behavior of the U(IV) → U(III) reduction in LiF-BeF_2-ZrF_4, this first reduction wave for U(IV) in LiF-NaF-KF does not behave as a simple one-electron reversible wave. This is demonstrated by the data of Table I. The half-peak to peak potential separation (13) for the wave corresponds to noninteger n values of 1.5 to 1.6 and is relatively independent of scan rate up to 10 V/sec. In addition, plots of log $(i_p - i)/i$ *vs.* potential (14) resulted in slopes corresponding to n values between 1.4 and 1.7. The variation of $i_p/v^{1/2}$ with scan rate for the reduction of U(IV) at a platinum electrode is shown in Fig. 2. This variation is not indicative of simple reversible charge transfer but resembles that predicted for a reversible charge transfer followed by a catalytic regeneration of the reactant (13).

Table I. Peak potentials, half-peak to peak potential separation (theoretical values[a] in parentheses), and i_p/C for the processes U(IV) + e → U(III) and U(III) + 3e → U at platinum electrode in molten LiF-NaF-KF at 500°C; scan rate: 1.0 V/sec

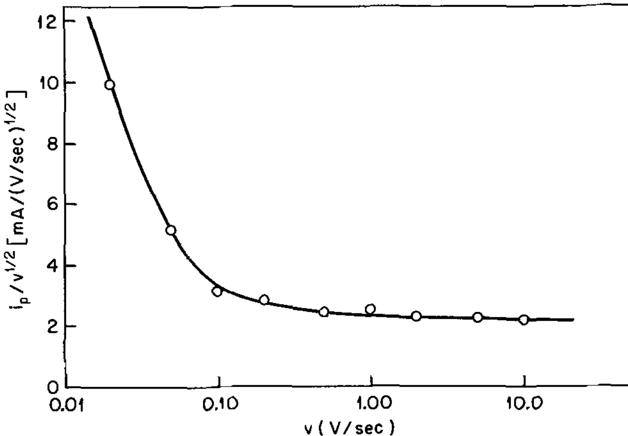

Fig. 2. Variation of $i_p/v^{1/2}$ with scan rate v for the U(IV) → U(III) reduction wave in molten LiF-NaF-KF at 500°C. U(IV) concentration, 0.111M; Pt electrode area, 0.10 cm^2.

A possible reaction scheme which could explain the experimental observations is

$$U(IV) + e \rightarrow U(III) \quad [1]$$

$$4U(III) \rightarrow 3U(IV) + U \quad [2]$$

The disproportionation of U(III) is at least a second-order chemical reaction which should be favored by the removal of one of the reaction products, uranium metal, by the reaction with potassium ions of the solvent in the following manner

$$U + 4K^+ \rightleftarrows U(IV) + 4K\uparrow \quad [3]$$

The volatilization of potassium (vapor pressure ~ 40 Torr at 500°C) (15) from the melt to the cooler region of the cell would be a driving force shifting the above equilibrium to the right even though the reverse reaction would be slightly favored on a thermochemical basis (6).

The theory of linear sweep voltammetry for an electrochemical reaction followed by a second-order disproportionation reaction has been worked out for linear (16) and spherical (17) diffusion. The theory provides certain diagnostic criteria for testing an unknown system, such as the effect of concentration and scan rate on peak current and peak potential. The influence on peak current is more significant than on peak potential in the case of disproportionation of the electron-transfer product (16). For such a reaction, the peak current is no longer directly proportional to the concentration; instead, a markedly larger increase occurs. Also the parameter $i_p/v^{1/2}$ is much larger at slow scan rates than the value corresponding to the transfer of n electrons under pure diffusion control but decreases with increasing scan rate, approaching a constant value at higher scan rates. This type of variation of $i_p/v^{1/2}$ with scan rate was observed for the U(IV) reduction in LiF-NaF-KF (Fig. 2). The peak current variation with concentration of U(IV) at the scan rate of 0.1 V/sec is shown in Table II. It is seen that the i_p/C ratio increases with concentration of U(IV), providing additional evidence that disproportionation of U(III) takes place under our experimental conditions.

Table II. Variation of peak current with concentration for the reduction of U(IV) to U(III) in LiF-NaF-KF at 500°C; platinum electrode area: 0.10 cm^2; scan rate: 0.10 V/sec

U(IV) concentration (moles/liter)	Peak current, i_p (mA)	i_p/C ratio (mA · liter/mole)
5.16×10^{-2}	0.49	9.5
1.11×10^{-1}	1.15	10.4
2.20×10^{-1}	2.50	11.4

Further support for U(III) disproportionation is provided by another diagnostic criterion, namely, the variation of the peak potential E_p with scan rate. For an uncomplicated charge transfer process, E_p should be independent of scan rate but should shift in the cathodic direction with increasing scan rate in the case of disproportionation of the electron-transfer product (16). For the first U(IV) reduction wave, E_p shifts in the cathodic direction by 100 mV as the scan rate is increased from 0.1 to 5 V/sec.

It is also interesting to note that E_p for the first wave shifts in the anodic direction by 110 mV when the concentration of U(IV) is increased from 0.11 to 0.22M; such a shift is to be expected from the theoretical treatment of Saveant and co-workers [see Fig. 14 in Ref. (16)]. This shift is accompanied by a small increase in the function i_p/C (see Table I).

Attempts were made to study the reduction of U(IV) by means of chronopotentiometry and chronoamperometry. The chronopotentiograms at platinum for the reduction of U(IV) to U(III) were poorly defined, particularly at lower current densities (long transition times). Reasonably well-defined chronopotentiograms were obtained at high current densities (transition times of 0.08-0.26 sec) yielding $i\tau^{1/2}$ values ranging from 2.00 to 2.16 mA·(sec)$^{1/2}$. Using the average $i\tau^{1/2}$ value of 2.06 mA·(sec)$^{1/2}$ and an $i_p/v^{1/2}$ value of 5.20 mA·(sec)$^{1/2}$·V$^{-1/2}$ obtained from voltammetry ($v = 1.0$ V/sec) under exactly the same experimental conditions ($A = 0.10$ cm^2; $C = 0.220$M), an n value of 1.13 was determined from the ratio of $i_p/v^{1/2}$ to $i\tau^{1/2}$. Theoretically, this ratio is equivalent to 1.96 $n^{1/2}$ V$^{-1/2}$ at 500°C, assuming a diffusion-controlled, reversible charge transfer yielding a soluble product (18).

Application of a potential step that corresponded to the peak potential of the U(IV) reduction to U(III) [~ −1.35V *vs.* the Ni(II) (saturated)/Ni reference electrode] resulted in a current that decreased only very slowly with time. The current obtained after a given time was erratic from one experiment to another.

The second reduction wave corresponding to uranium metal deposition was a steep, well-defined curve showing far greater reproducibility than the preceding wave. On reverse scans, the stripping curve revealed no inflection upon passing through the point of zero current; this behavior suggests that the deposited metal is reversibly oxidized.

Evidence for reversible metal deposition is provided by the half-peak to peak potential separation for the wave (see Table I) and by the results obtained from a log ($i_p - i$) *vs.* potential plot (14) which is shown in Fig. 3. The data for Fig. 3 were obtained from a voltammogram at 0.1 V/sec and a U(IV) concentration of 0.220M. The theoretical slopes (2.2 nF/RT) (14) for $n = 3$ and $n = 4$ differ by only about 33 V^{-1}. Lines corresponding to both slopes were drawn through the data points of Fig. 3. Since the theoretical slope (14) is applicable in the current range 0.5-0.9 i_p as indicated by the dashed lines of Fig. 3, an n value of 3 is favored from this type of log plot. A plot of log ($i_p - i$)/i *vs.* potential using the same data as in Fig. 3 gave an unrealistic $n \approx 6$. The inapplicability of this type of log plot suggests that a soluble product is not involved in the uranium deposition at platinum, in agreement with other experimental observations. A small shift in the anodic direction for E_p of the second step was also observed as predicted for a diffusion-controlled reversible deposition of an insoluble product (18) (see Table I). Although U-Pt alloys are known (19), diffusion of uranium into the electrode may be so slow that uranium metal at essentially unit activity remains as a monolayer to be oxidized on the reverse scan. A plot of i_p *vs.* $v^{1/2}$ for the uranium deposition wave is linear for the scan rates 0.1-2 V/sec.

Voltammetric studies of the oxidation of uranium(IV).—A voltammetric study was made on the

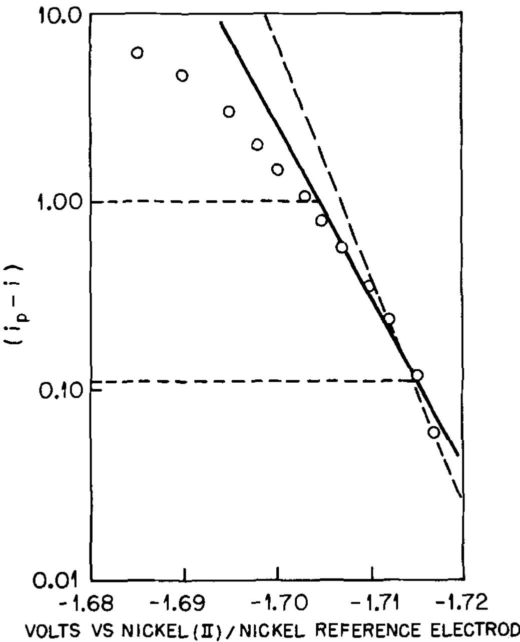

Fig. 3. Plot of log ($i_p - i$) *vs.* potential for the reduction of U(III) to U at platinum electrode in molten LiF-NaF-KF at 500°C. Solid line, theoretical slope corresponding to $n = 3$; dashed line, slope for $n = 4$.

oxidation of U(IV) at unsheathed platinum and PG electrodes in molten LiF-NaF-KF at 500°C. A series of voltammograms at different scan rates for the oxidation of U(IV) at platinum is shown in Fig. 4. Essentially identical voltammograms were obtained at a PG electrode. The oxidation of U(IV) occurs at ~ +1.3V *vs.* a Ni(II)(saturated)/Ni reference electrode. The following points should be noted with regard to these voltammograms: (*i*) no current is observed for the re-reduction process at the slower scan rates (0.2 V/sec and less), (*ii*) the current for the oxidation of U(IV) at high scan rates (≧ 1.0 V/sec) is about the same as that for the reduction of U(IV) to U(III); the i_p/C value of 25.0 at 1.0 V/sec compares well with the i_p/C values for U(IV) reduction given in Table I, and (*iii*) $i_p/v^{1/2}$ *vs.* v plot is very similar to that shown in Fig. 2. These results are essentially the same as those obtained for the oxidation of U(IV) in molten $LiF\text{-}BeF_2\text{-}ZrF_4$ where a catalytic regeneration of U(IV) from U(V) was suggested based on the following reactions

$$U(IV) \rightarrow U(V) + e \quad [4]$$

$$2U(V) \rightarrow U(IV) + U(VI) \quad [5]$$

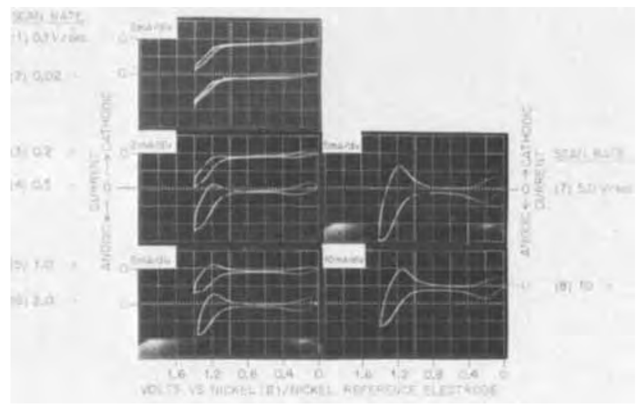

Fig. 4. Linear sweep voltammograms for the oxidation of U(IV) at platinum electrode in molten LiF-NaF-KF at 500°C. U(IV) concentration, 0.220M; electrode area, 0.10 cm^2.

The small wave near +0.2V in Fig. 4 is believed to be due to the presence of adsorbed H_2 produced electrochemically from traces of H_2O or HF.

In the previous work (4) chronopotentiometric and chronoamperometric results were obtained which also pointed to the disproportionation of the electrochemically produced U(V). An attempt to study the oxidation of U(IV) in LiF-NaF-KF by chronopotentiometry proved futile due to very poor definition and reproducibility of the chronopotentiograms at both Pt and PG electrodes. These adverse effects are presumably caused by the attack of the working electrode by UF_6 produced in the disproportionation reaction. The attack might be expected to be more severe in molten LiF-NaF-KF than in LiF-BeF_2-ZrF_4 since the highly volatile UF_6 can be more readily complexed in the former melt and thus may be retained in that melt longer.

Electrode potentials of the uranium(IV)/uranium(III) and uranium(III)/uranium couples.—The half-wave potential $E_{1/2}$ for the process U(IV) + $e \rightleftarrows$ U(III) in LiF-NaF-KF at 500°C was used to estimate the standard electrode potential of the U(IV)/U(III) couple in this melt. Assuming an uncomplicated charge transfer, the half-wave potential for the U(IV) + $e \rightarrow$ U(III) process was determined from the 0.85 i_p point on the wave (13). An average of $E_{1/2}$ values obtained at three different U(IV) concentrations (scan rate = 1.0 V/sec) gave an $E_{1/2}$ of −1.27V *vs.* a Ni(II) (saturated)/Ni reference electrode. Since the potential of the Ni(II) (saturated)/Ni reference electrode is about 0.14V more cathodic than the potential of the unit mole fraction Ni(II)/Ni couple (10), $E°$ for the U(IV)/U(III) couple in LiF-NaF-KF is estimated as −1.41V *vs.* a unit mole fraction Ni(II)/Ni reference electrode. This value is less negative than the value obtained in LiF-BeF_2-ZrF_4 (2). Since an opposite trend was expected from qualitative acid-base considerations (9), the $E°$ value obtained remains suspect. This is not surprising since the estimate of $E°$ was based on the assumption that the U(IV) + e = U(III) reaction is a simple reversible process, which is certainly not the case at lower scan rates and higher concentrations of U(IV).

The electrode potential of the U(III)/U couple will depend on the concentration of U(III). Since the reduction of U(III) at platinum has been tentatively shown to be a reversible deposition of uranium metal at essentially unit activity, the voltammetric E_p will depend on concentration as given by the following expression (18)

$$E_p = E° + \frac{RT}{n\mathbf{F}} \ln fC - 0.854 \frac{RT}{n\mathbf{F}} \quad [6]$$

An approximate value for $E°$ was calculated from Eq. [6] using the experimental E_p of −1.74V at a concentration of 0.111M and assuming the activity coefficient of U(III) to be unity. The value for $E°$ determined in this manner is −1.67V *vs.* the Ni(II) (saturated)/Ni reference electrode. Applying the correction given above, the standard potential for the U(III)/U couple is estimated as −1.81V *vs.* a unit mole fraction Ni(II)/Ni reference electrode. This value may be compared with the $E°$ of −1.838V for the U(III)/U couple determined by Baes (7) in LiF-BeF_2 (67-33 m/o) at 500°C.

Voltammetric studies of Th(IV) in molten LiF-NaF-KF at 500°C.—The voltammograms obtained at platinum for Th(IV) solutions in molten LiF-NaF-KF at 500°C showed a barely distinguishable shoulder just preceding the onset of the cathodic melt limit at −2.00V *vs.* a Ni(II) (saturated)/Ni reference electrode. On the reverse scan, only a single large stripping wave was observed which was obviously due to reoxidation of deposited alkali metal; no separate stripping peak for the thorium metal was detected. A nickel working electrode was then employed in an effort to better resolve the thorium(IV) wave. In this case, the cathodic melt limit shifted in the cathodic direction by about 50 mV, and a much better defined reduction wave due to Th(IV) was obtained. A typical voltammogram for Th(IV) at a nickel electrode is shown in Fig. 5. The peak potential was estimated as −2.02V. On the reverse scan, the corresponding stripping wave displays a sharp peak at −1.83V. Upon scanning to −2.05V, the Th(IV) reduction was followed by the onset of the cathodic limit, and two separate stripping peaks were observed on the reverse scan at −2.00 and −1.83V, corresponding to reoxidation of alkali metal and thorium metal, respectively. Similar voltammograms were obtained at a tungsten working electrode, but the definition was better at the nickel electrode. The differences in behavior between the platinum and nickel electrodes (tungsten, as well) are likely due to different tendencies toward alloy formation. The ready formation of alkali metal-platinum alloys near 500°C (19) is probably responsible for the occurrence of a less cathodic melt limit at platinum than at either nickel or tungsten; nickel and tungsten are more resistant than platinum to alloy formation with the alkali metals at 500°C (19).

A plot of peak current *vs.* the square root of the scan rate was linear for the rates studied; this is evidence for a simple diffusion-controlled process. A plot of log $(i_p - i)/i$ *vs.* potential for the Th(IV) reduction wave is shown in Fig. 6. The data points display a good fit to a straight line of theoretical slope (14) corresponding to an n of 4. In comparison, a log $(i_p - i)$ *vs.* potential plot was linear in the region 0.5-0.9 i_p but yielded a slope corresponding to an n of 1. The results obtained from the slopes of the log plots point to the formation of a soluble product in the case of Th(IV) reduction at nickel. This would require the dissolution of thorium metal in the nickel electrode; the existence of five compounds in the Ni-Th system has been shown (19). The behavior of the anodic stripping curve (Fig. 5) also supports alloy formation since the curve shows an inflection on passing through zero current not expected for reversible stripping of metal at unit activity; also the stripping peak is separated from the reduction peak by about 0.2V, which is greater than that expected for reversible deposition of metal at unit activity.

The half-peak to peak potential separation ΔE for the Th(IV) reduction wave shown in Fig. 5 is 40 ± 5 mV, in good agreement with the predicted value (37 mV) for a reversible charge transfer process yielding

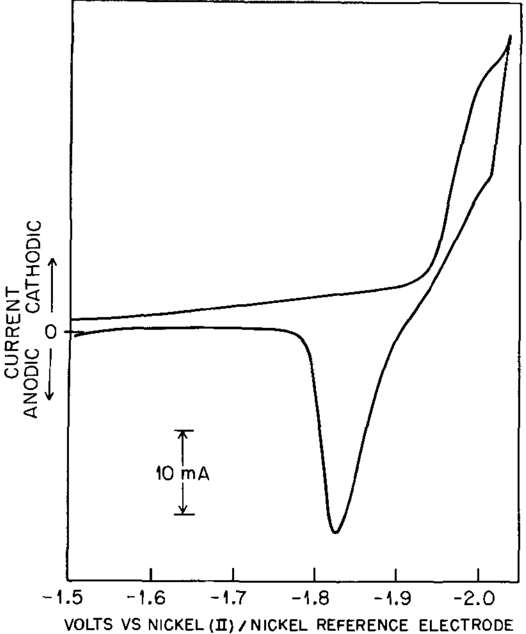

Fig. 5. Linear sweep voltammogram for the reduction of Th(IV) at nickel electrode in LiF-NaF-KF at 500°C. Scan rate, 0.20 V/sec; electrode area, 0.10 cm²; Th(IV) concentration, 0.254M.

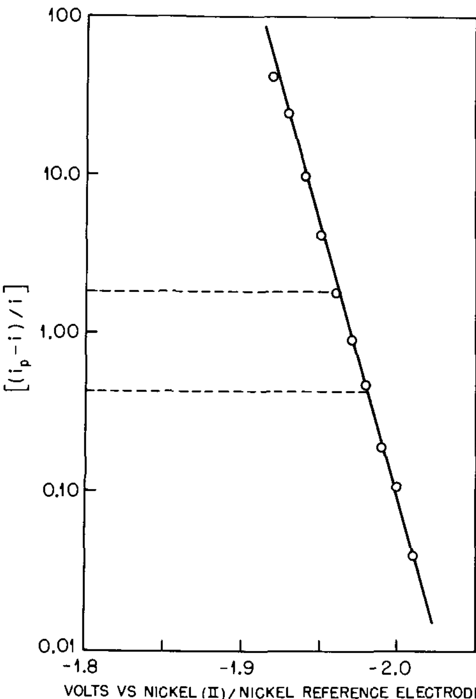

Fig. 6. Plot of log (i_p — i) *vs.* potential for the reduction of Th(IV) in molten LiF-NaF-KF at 500°C.

a soluble product (13). A much lower value (13 mV) is expected in the case of reversible deposition of an insoluble product (14). A diffusion coefficient of $1.8 \pm 0.3 \times 10^{-6}$ cm²/sec was calculated from the Randles-Sevcik equation (18) using the slope of the i_p *vs.* $v^{1/2}$ plot.

Standard electrode potential of the thorium(IV)/ thorium couple in molten LiF-NaF-KF.—The standard electrode potential for the Th(IV)/Th couple in molten LiF-NaF-KF at 500°C can be estimated from the half-wave potential $E_{1/2}$ for the Th(IV) reduction wave assuming solubility of thorium metal in the nickel electrode. In this case, $E_{1/2}$ for a reversible process is equivalent to the standard electrode potential $E°$, assuming that the activity coefficients and diffusion coefficients for the reactants and products are equal (13). Also $E_{1/2}$ is related to the half-peak potential $E_{p/2}$ by the following equation (13)

$$E_{p/2} = E_{1/2} + 1.09 \frac{RT}{nF} \quad [7]$$

Using the more conveniently measured $E_{p/2}$ of −1.975V, $E_{1/2}$ for the Th(IV) reduction wave was calculated to be −1.993V *vs.* the Ni(II)(saturated)/Ni reference electrode. This particular reference was previously shown to be 0.138V more cathodic than a unit mole fraction Ni(II)/Ni couple (10). Thus, the standard electrode potential $E°$ for the Th(IV)/Th couple in molten LiF-KF-NaF at 500°C is estimated as −2.13V *vs.* a unit mole fraction Ni(II)/Ni reference electrode.

Conductances of Protonic and Lewis Acids in N,N-Dimethylformamide (DMF)

A. K. Mishra and K. N. Tandon

Department of Chemistry, University of Rajasthan, Jaipur-4, India

ABSTRACT

Paul and Sreenathan reported abnormally high values of limiting equivalent conductances for several protonic and Lewis acids in DMF and suggested a proton-jump mechanism (similar to that which is known to exist in water) to explain these data. However, it has been found that these abnormally high values are grossly in error. The error, apparently is made by a uniformly constant factor and seems to have manifested itself in one set of their measurements; it cannot be attributed to be due to a difference in the extrapolation of Λ *vs.* $\sqrt{c}$ plots. A careful repetition of their work has revealed values which support the earlier work of Thomas and Rochow and Sears *et al.*, and excludes abnormal proton conductance in DMF. The conductance data have been treated with Shedlovsky's equation and the values of K have been calculated from the slopes of the plots of $1/\Lambda s$ *vs.* $C\Lambda s f_{\pm}^2$.

The conductances of a number of organic and inorganic electrolytes have been determined in DMF (1-21). Contradictory and controversial conductometric data exist in the literature for acids in DMF. Dawson and co-workers reported the limiting equivalent conductance (Λ_0) of hydrogen chloride to be 70 ohm^{-1} cm^{2}eq^{-1} at 25°C. Thomas and Rochow (4) determined the value in a highly purified solvent to be 79.3 ohm^{-1} cm^2 eq^{-1} at 20°C. The lower conductance value reported by Dawson was explained due to the presence of impurities especially water in his solvent. Since the triethylammonium chloride was found to be more conducting than hydrogen chloride, it was presumed (18) that the abnormal proton conductance was absent in this solvent. This was, further supported by the work of Sears *et al.* (5) who found hydrogen bromide to be relatively strong acid in DMF($K_{HBr} = 1.7 \times 10^{-2}$ at 25°C) with a Λ_0 value of 88.7 ohm^{-1} cm^2 eq^{-1} at 25°C, which excludes abnormal proton conductance. In contrast to these results, Paul and co-workers (14-16) have reported Λ_0 values for hydrogen chloride of 290 (14) and 280 (16) ohm^{-1} cm^2 eq^{-1} at 25°C, and similarly high values for several other protonic and Lewis acids (Table I). Our experimental results reported here show that the abnormally high Λ_0 values reported by Paul and Sreenathan are grossly in error, and thus the major conclusions drawn by them on the basis of these erroneous data need reconsideration. An attempt has been made to ascertain the nature of the error in the reported data of Paul and Sreenathan.

Experimental

Purification of solvent.—Dimethylformamide (BDH) was fractionally distilled at reduced pressure, the distillate was mixed with about 12% by volume of dry benzene (dried over sodium wire) and the benzene distilled at atmospheric pressure at about 80°. After removing the benzene-water azeotrope, the DMF was again distilled at reduced pressure and benzene free DMF was obtained. The benzene-free DMF was then shaken with pre-ignited, anhydrous alumina powder (BDH chromatographic grade). The solvent was decanted off, distilled, and the middle fraction boiling at 55° ± 1°C and 35 Torr pressure was collected and stored in blackened, stoppered Pyrex flasks. The specific conductivity of the solvent was found to be 0.5-1.5 $\times 10^{-7}$ ohm^{-1} cm^{-1} at 25°C.

Preparation and purification of protonic and Lewis acids.—One hundred per cent sulfuric acid was prepared by adding the calculated quantity of sulfur trioxide to sulfuric acid (AR). p-Toluene sulfonic acid (Riedel) was crystallized from acetic acid and dried in vacuum desiccator. It melted at 159.5° ± 1°. Fluorosulfuric acid was prepared by adding required quantity of potassium bifluoride in small lots at a time, into ice-cold, fuming sulfuric acid. It was then distilled and the fraction boiling at 160°-61° was collected. The fraction was redistilled in an atmosphere of dry nitrogen. Hydrogen chloride was prepared by dropping sulfuric acid (AR) on solid ammonium chloride (AR) and dried by passing through phosphorus pentoxide towers; it was then immediately absorbed in the purified DMF.

Anhydrous acetic acid was obtained by the process described by Bruckenstein (24). Monochloroacetic acid was purified by simple fractional distillation (bp 182.5°). Dichloroacetic acid was distilled under reduced pressure, and the fraction boiling at 102°/20 mm was collected (bp 193° ± 1°). Trichloroacetic acid was recrystallized from hot benzene and dried under reduced pressure.

Tin tetrachloride (BDH) was distilled in an atmosphere of dry nitrogen. The middle fraction was collected which boiled at 113.5° ± 1°. Tin tetrabromide was prepared by slowly mixing liquid bromine with tin metal (AR). It was purified by redistillation. The middle fraction was collected which boiled at 201.5° ± 1°. Sulfur trioxide was prepared by distillation of a mixture of phosphorus pentoxide and sulfuric acid (AR) and was led directly into the solvent to avoid moisture. Antimony trichloride was purified by distillation under reduced pressure (bp 220°). Bismuth trichloride (Riedel) was purified by sublimation under reduced pressure. Antimony pentachloride (BDH) was used as received. Pyrosulfuric acid was prepared by adding one calculated quantity of sulfur trioxide to 100% sulfuric acid.

Solutions of protonic and Lewis acids in DMF.—Solutions of protonic and Lewis acids in DMF were prepared by dissolving the requisite quantity of the acids in DMF and made up to 50 ml. The solutions of protonic acids were standardized by titrating with 0.1M sodium methoxide in benzene-methanol mixture using thymol blue as indicator (26, 27). The solutions of Lewis acids were standardized by gravimetrical estimation of the metal and the nonmetal in a known volume of the solution. Allowance for the density of DMF (D = 0.944 g/ml) was made for calculating the molarities of the solutions. Solutions of the desired molarities were then obtained by suitably diluting the above solutions with DMF. Freshly prepared solutions were always used.

Key words: acids, conductivity, dissociation, formamide, N,N-dimethyl.

Table I. Conductances in DMF

(A comparison of the values of Λ measured by the present authors with those of Paul and Sreenathan)

(a) Values of Λ deduced from the curves of Λ *vs.* $\sqrt{c}$ plots published by Paul and Sreenathan.
(b) Measured values of Λ by the present authors.

Conductivity measurements.—The conductivity bridge and cell were the same as used in the earlier investigation (22). Conductivity measurements were carried out at a constant temperature of 25° ± 0.5° using an oil bath. Twenty grams of DMF was taken in the conductance cell and then installment of the acid solution was added, stirred, and kept for 10 min before measuring the conductance. About 10-12 readings were taken for each acid.[1]

Results and Discussion

The molar conductivities at infinite dilution (Λ_{M_0}) at 25° of a number of protonic and Lewis acids in DMF have been determined by the extrapolation of Λ_M *vs.* $\sqrt{c}$ curves (Fig. 1). Abnormally high values of the conductances of hydrogen chloride, fluorosulfuric acid, p-toluene sulfonic acid, sulfuric and pyrosulfuric acids, and antimony pentachloride, tin tetrabromide, tin tetrachloride, and sulfurtrioxide in DMF as reported by Paul and Sreenathan (14-16) could not be verified by us, even after repeated experiments and utmost care and due precautions during experimental procedures. Their data of equivalent conductances in tabular form are not available, but they have published the curves of Λ *vs.* $\sqrt{c}$. We have deduced their values of equivalent conductances at some arbitrarily chosen concentrations, from the plots of Λ *vs.* $\sqrt{c}$ published by them and compared them with those determined experimentally by us (Table I). Their values of equivalent conductances (*a*) do not agree with those of ours (*b*), but differ in such a way that the ratio (*a/b*) is almost a constant factor ($a/b \approx 3.4$). Their values of the limiting equivalent conductances also differ with those of ours (determined by a common method, *i.e.*, extrapolation of Λ *vs.* $\sqrt{c}$) by almost the same constant factor. This indicates that the variation in our values from those of theirs is not due to the variation in the extrapolation of the curves. Clearly, the error in their data lies in the determination of the equivalent conductances and the mistake is uniform by a constant factor. This error appears to be present in one set of their measurements. The values of Λ_0 for various protonic acids reported by them in their paper (16) can be sharply divided into two sets *viz.* (*i*) high values 125-490 and (*ii*) low values 2.5-42.0. The values in the first set are in error, whereas the values of the second set agree with our determined values within the range of the experimental error. For instance they have quoted Λ_0 values for monochloroacetic acid and acetic acid as 28.6 and 20.0 ohm^{-1} cm^{-1}, respectively, which are in agreement with the values determined by us, *i.e.*, 28.0 and 20.0 ohm^{-1} cm^2eq^{-1}, respectively.

The errors in the values determined by Paul and Sreenathan are also reflected in the following:

1. The limiting equivalent conductance data of acetic acid ($\Lambda_0 = 20.0$) and monochloroacetic acid ($\Lambda_0 = 28.6$) and dichloroacetic acid ($\Lambda_0 = 125.0$) at 25° reported by them do not fit in logically with the well-known principle of gradation. The difference between the values of Λ_0 of acetic acid and monochloroacetic acid is only 8.6 ohm^{-1} cm^2 eq^{-1} whereas between mono- and dichloroacetic acid it is 96.4.

2. The pK ($-\log_{10}K$) values of several organic and inorganic acids calculated from conductance data by Paul and Sreenathan (16) do not correlate the limiting conductance data of these acids in DMF determined by the same workers. For example, it can be easily seen from their data that dichloroacetic acid is stronger acid (smaller pK) than sulfuric acid but the value of dichloroacetic acid is much smaller. Similarly, monochloroacetic acid is slightly stronger than pyrosulfuric acid in DMF, whereas the limiting conductance of

[1] An estimate of the errors in our data of the values of molar conductances has been made with the help of four independent measurements carried out in several replicate sets. These measurements were found to agree within ±1%.

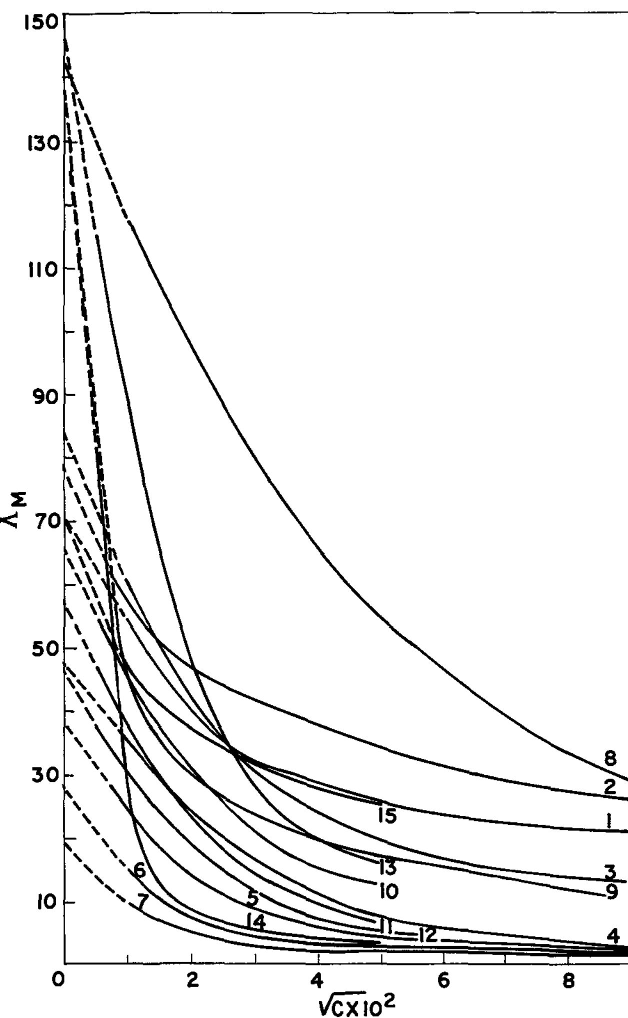

Fig. 1. Plots of Λ_M vs. $\sqrt{c}$. 1, p-Toluene sulfonic acid; 2, fluorosulfuric acid; 3, hydrochloric acid; 4, trichloroacetic acid; 5, dichloroacetic acid; 6, monochloroacetic acid; 7, acetic acid; 8, pyrosulfuric acid; 9, sulfuric acid; 10, antimony pentachloride; 11, bismuth trichloride; 12, antimony trichloride; 13, tin tetrabromide; 14, tin tetrachloride; and 15, sulfur trioxide. All in DMF.

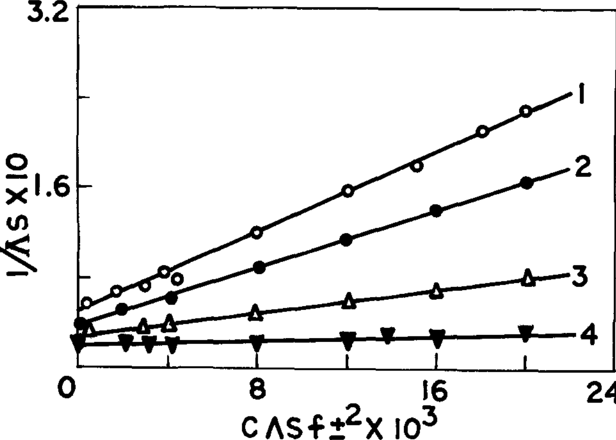

Fig. 2. Plots of $1/\Lambda s$ vs. $c\Lambda s f_{\pm}^2$. 1, CH_3COOH; 2, $CH_2ClCOOH$; 3, $CHCl_2COOH$; 4, CCl_3COOH.

pyrosulfuric acid (Λ_o = 490.0) is very much larger than that of monochloroacetic acid (Λ_o = 28.6).

3. In their paper (14) Paul *et al.* have mentioned "The values of equivalent conductivity at infinite dilution for sulfuric acid and pyrosulfuric acid respectively are much higher than those of fluorosulfuric acid, p-toluene sulfonic acid, and hydrochloric acid. Sulfuric acid and pyrosulfuric acid are dibasic acids and at the very low concentrations involved capable of releasing both the protons while the rest of the acids are monobasic and can release only one proton. . . ."

This explanation would be valid if one considers molar conductivity rather than equivalent conductivity but to analyze the data of equivalent conductivity in the above light is fundamentally wrong.

4. In order to explain the abnormally high values of conductances of protonic and Lewis acids in DMF, they suggested abnormal proton conductance in DMF and "proton jump" or "charge transfer" mechanism for the high mobility of proton similar to that suggested for water. However, a fundamental difference exists in the mechanisms suggested for water and DMF. In the case of water system, the actual migration of proton does not occur but the solvated proton may be obtained on the other side of the chain (see Fig. 3), when an electric field is applied, due to the internal rearrangement of electrons inside the chain causing the hydrogen bonds to change into covalent bonds and vice versa, *i.e.*, through tunneling effect. During this process, no change in the structure of water molecules results. But, in the case of DMF system, if the internal rearrangement of electrons be made and the hydrogen bonds be changed to covalent bonds and the required covalent bonds be changed to hydrogen bonds, the structure of DMF molecules are drastically changed. If on the other hand, the solvated proton be obtained on the other side of the chain without causing a change in the structure of the DMF molecules, the migration of proton from position (a) to (b) (see Fig. 3) becomes inevitable which would amount to actual migration and not through the tunneling effect. Consequently, a normal (non-Grothus type) proton conductance would be expected.

5. In order to explain the abnormally high values of the conductances of Lewis acids such as antimony pentachloride, tin tetrachloride, and bromide, in DMF they suggested the protonic nature of the complexes of Lewis acids and DMF. The mechanism suggested by them involves the following ionization process

$$H{-}C{=}\overset{\oplus}{N}(CH_3)_2 \; (\text{with } {:}\ddot{O}{:}{-}L^{\ominus} \text{ on } C) + HCON(CH_3)_2 \rightarrow \{H_2CON(CH_3)_2\}^+ + \left\{ \begin{matrix} C{-}\ddot{N}(CH_3)_2 \\ | \\ {:}\ddot{O}{:} \\ | \\ L \end{matrix} \right\}^- \rightarrow \{H_2CON(CH_3)_2\}^+ + \left\{ \begin{matrix} {:}C{=}\overset{\oplus}{N}(CH_3)_2 \\ | \\ {:}\ddot{O}{:} \\ | \\ L^{\ominus} \end{matrix} \right\}^- \quad [1]$$

The above ionization process will occur only when the Lewis acid-DMF complex is dissolved in DMF, but this mechanism does not afford any explanation for the conductance of the complexes in the molten state where no extra DMF molecule is available to facilitate the above ionization.

Further, according to the above mechanism, antimony pentachloride should form 1:2 complex and tin tetrahalides 1:4 complexes with DMF, but the actual formation of 1:1 complex with antimony pentachloride and 1:2 complexes with tin tetrahalides can hardly be explained.

On the other hand, the values of conductances determined by us support the earlier work of Thomas and Rochow (4) and Sears *et al.* (5) and exclude abnormal proton conductance in DMF. Our values appear to be coherent and in correlation with the values of *K* (Table

Fig. 3. Proton mobility in DMF

II) determined by the extrapolation of the Shedlovsky plots (Fig. 2). The rationality of our values is reflected in the gradation which exists among acetic, monochloroacetic, dichloroacetic, and trichloroacetic acids, *i.e.*, 20.0, 28.0, 38.0, and 48.0, respectively. The polar nature of the Lewis acid-DMF complexes may be explained better by the ideas suggested by Drago and Purcell (28) who evolved a coordination model for the nonaqueous solvent behavior, rather than the mechanism suggested by Paul and Sreenathan (15). In a recent communication (22) it was shown that bismuth trichloride in DMF ionizes in the following way

$$2[BiCl_3 \cdot DMF] \rightleftharpoons [BiCl_2 \cdot 2DMF]^+ + [BiCl_4]^- \quad [2]$$

Analogous work on antimony trichloride and antimony pentachloride (23) in DMF medium have supported the existence of the following equilibria

$$2[SbCl_3 \cdot DMF] \rightleftharpoons [SbCl_2 \cdot 2DMF]^+ + [SbCl_4]^- \quad [3]$$

$$2[SbCl_5 \cdot DMF] \rightleftharpoons [SbCl_4 \cdot 2DMF]^+ + [SbCl_6]^- \quad [4]$$

The plots of Λ_M *vs.* $\sqrt{c}$ are not linear and the experimental Onsager slopes calculated from the limiting slopes of the curves are found to be more negative than the theoretically calculated Onsager slopes computed from the following equation

$$\alpha = (A + B\Lambda_0) = \frac{82}{\eta(DT)^{1/2}} + \frac{8.2 \times 10^5}{(DT)^{3/2}}\Lambda_0 \quad [5]$$

where D is the dielectric constant, η is the viscosity of the solvent, T is the absolute temperature, and A and B are Onsager constants. The experimental and theoretical Onsager slopes are given in Table II. The deviations of the experimental slopes from the theoretical slopes indicate incomplete dissociation or ion pair formation of the solutes in solution. (The value of A for DMF is 98.5 at 25° and, therefore, the computed value of α would always be greater than 98.5. It is, however, not understandable, how Paul and Sreenathan (16) have mentioned the theoretical Onsager slopes of acetic, propionic, monochloroacetic, dichloroacetic, acids and phenol to be 24.05, 21.7, 30.17, 98.81, and 11.6, respectively, in Table III of their paper.)

The conductance data have been further treated by Shedlovsky's equation (25) which may be written as

$$\frac{1}{\Lambda s} = \frac{1}{\Lambda_0} + \frac{C\Lambda s f_\pm^2}{K\Lambda_0^2} \quad [6]$$

where Λ is equivalent conductivity at concentration C,[2] Λ_0 is equivalent conductivity at zero concentration,[2] $f_\pm$ is mean activity coefficient, K is thermodynamic dissociation constant, and s is a function of z and is equal to

$$s = \left[z/2 + \sqrt{1 + (z/2)^2}\right]^2 \quad [7]$$

and z is defined by

$$z = \alpha\Lambda_0^{-3/2}\sqrt{c\Lambda} \quad [8]$$

where α is the Onsager coefficient determined by the limiting slopes from the Λ_M *vs.* $\sqrt{c}$ plots.

The mean activity coefficient $f_\pm$ is computed from

$$-\log f_\pm = \beta\sqrt{cs\Lambda/\Lambda_0} \quad [9]$$

where β is the Debye Huckel's A constant whose value for DMF is equal to

$$\frac{1.812 \times 10^6}{(DT)^{3/2}} = 1.573$$

A plot of $1/\Lambda s$ *vs.* $c\Lambda\ sf_\pm^2$ is a straight line at low concentrations which on extrapolation gives an intercept of $1/\Lambda_0$ and slope of $1/K\Lambda_0^2$ (Fig. 2) (only some samples are given). With the help of such plots the values of Λ_0 and K of monobasic protonic acids have been calculated. These are also described in Table II.

In the equilibria represented by Eq. [2], [3], and [4], two univalent ions are produced from two molecules of the Lewis acid-DMF complex and in this form, the Shedlovsky equation cannot be applied. However, if the two molecules on the left-hand side in these equations are reckoned as one molecule (this can be done by treating the concentration equal to half the molar

[2] For 1-1 electrolyte the equivalent conductivity is the same as the molar conductivity and since the Shedlovsky equation is applicable in the case of 1-1 electrolytes only, no attempt has been made to distinguish molar conductivity from equivalent conductivity here and separate symbols for representing the two conductivities have not been used.

concentration of Lewis acid-DMF adduct), then the Shedlovsky equation would be applicable to these systems. Such an assumption would make little difference as the neutral molecules of the Lewis acid-DMF complex do not contribute towards the conductance of the solution. The Shedlovsky equation has been applied utilizing the above assumption in these systems and the values of K have been calculated (Table II). The values of K would correspond to the following mass law equation

$$K = [(BiCl_2 \cdot 2DMF)^+][(BiCl_4)^-]/[Bi_2Cl_6 \cdot 2DMF] \quad [10]$$

The actual value of K (say K') should correspond to

$$K' = [(BiCl_2 \cdot 2DMF)^+][(BiCl_4)^-]/[BiCl_3 \cdot DMF]^2 \quad [11]$$

so that

$$\frac{K'}{K} = K'' = [Bi_2Cl_6 \cdot 2DMF]/[BiCl_3 \cdot DMF]^2 \quad [12]$$

However, it is difficult to calculate the exact value of K from the existing data.

Two-Dimensional Current Distribution Within a Packed-Bed Electrochemical Flow Reactor

Richard Alkire* and Patrick K. Ng**

Department of Chemical Engineering, University of Illinois, Urbana, Illinois 61801

ABSTRACT

An analysis is presented for describing behavior of a packed-bed electrode confined within a thin cylindrical porous separator and surrounded by a concentric counterelectrode. Electrolytic solution, containing reactive species, flows axially in plug flow through the packed-bed electrode while the peripheral surface of the packed bed is held under a constant applied potential. Results are obtained for two types of porous separators, (*i*) permeable to all solute species and (*ii*) impermeable to the reactive solute species. For each case, the two-dimensional (radial and axial) concentration, potential, and current distributions are calculated by a finite difference method. The results clarify over-all reactor performance and, in particular, predict the relation between the volumetric reaction rate and the residence time for a wide range of system parameters.

The appealing advantage of electrochemical synthesis processes is that electrical current is inexpensive in comparison with the price of chemical oxidizing or reducing agents. Carrying out electrochemical synthesis operations at high rates, however, can be difficult owing to the heterogeneous nature of electrochemical reactions. The volumetric reaction rates of typical elec-

Key words: current distribution, porous electrode, copper removal, reactor design.

trolysis cells are low in comparison with volumetric reaction rates of chemical reactors, especially those for homogeneous chemical reactions. In order to compete favorably, electrochemical reactors can often be designed with porous electrodes which exhibit very large surface areas for reaction.

The voltage applied to an electrolysis cell is consumed by various means which include ohmic resistance of the electrolyte, diffusional resistance, and hindrance associated with the reactions occurring at the electrode surface. Whereas porous electrodes can substantially relieve charge-transfer hindrances by their very large surface area, they introduce still additional ohmic and diffusional resistances in the electrolyte within the porous region. One way to relieve diffusional resistance is to force electrolyte through the porous electrode. Although flow-through porous electrodes can exhibit moderately high volumetric reaction rates, their design is complex because the potential, reaction rate, and concentration of reacting species will vary with position within the electrode. Knowledge of the reaction rate distribution, however, is exceedingly helpful for a rational analysis, preliminary design, and economic evaluation of the reactor.

Among various possible reactor configurations, two offer particular advantages of simplicity as indicated in Fig. 1. In Geometry A, the counterelectrode is positioned upstream or downstream of the porous reactor electrode. In this configuration, flow of electrolyte and of electrical current take place essentially along the same spatial direction. In order to avoid appreciable mixing of anolyte and catholyte, a porous separator is usually placed between the respective cell compartments. In Geometry B, the porous separator consists of a cylindrical tube within which the porous electrode is placed. In Geometry B, the counterelectrode surrounds the packed-bed electrode with the result that flow of electrolyte and of electrical current take place in different directions. On the basis of a unit volume of packed bed, Geometry B exposes a larger surface area to the counterelectrode than Geometry A.

No theoretical analyses are known to be available for Geometry B. A small number of experimental studies of Geometry B are available; these employed the electrode as a potentiostatic chromatograph (1), for elution voltammetry (2), and for removal of heavy metal ions and radioisotope separation (3). On the other hand, a substantial number of experimental investigations have also been conducted in Geometry A (4-6) owing, in part, to the relatively simpler (one-dimensional) basis for theoretical calculations (4, 7-9). Based on model predictions, economic feasibility studies have been carried out for one reactor designed to remove copper from very dilute solutions (10). Other common industrial problems include reclaiming of metals, treatment of chromic acid, cyanide, and acid-mine wastes, and detoxification of refractory organics (11). However, the large-scale usage of such electrochemical methods for waste treatment and synthesis awaits the development of carefully engineered cells. One important task is to predict how current-voltage behavior of a cell depends, for example, on conductivity, flow rates, concentrations, cell geometry, and reaction rate constants. The following study has been undertaken in order to, on the one hand, clarify behavior of an important class of reactors and, on the other hand, to illustrate how predictions of behavior may be compiled for use in cell design.

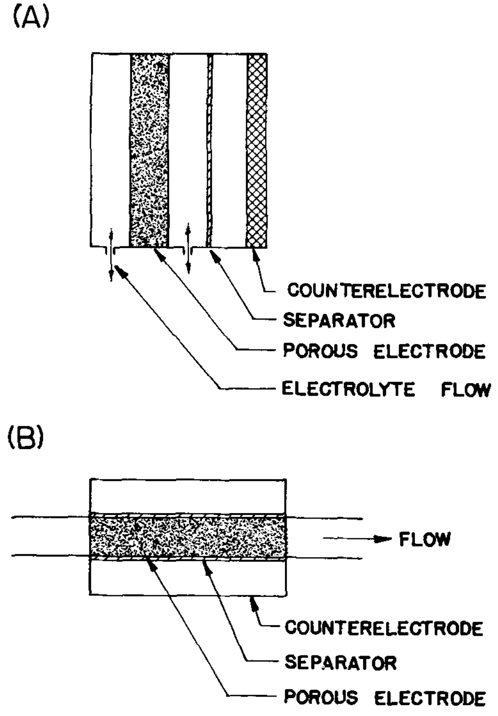

Fig. 1. Schematic diagrams of two flow-through porous electrode configurations: (A) electrolyte flows essentially parallel to current flow, (B) electrolyte flows essentially perpendicular to current flow.

Theoretical Aspects

The packed-bed reactor under consideration is of radius r_o, and is of uniform porosity and specific surface area throughout. Electrolyte of uniform composition enters at the upstream end of the reactor ($z = 0$) and proceeds axially downstream along its length. Several restrictions have been adopted in order to simplify calculations: (*i*) isothermal operation occurs in the steady-state; (*ii*) a single, reversible electrode reaction occurs; (*iii*) the potential along the exterior surface of the reactor (at $r = r_o$) is constant; (*iv*) the motion of solute species in the electrolyte is described by transport equations for dilute solutions with constant coefficients; (*v*) electrolyte motion occurs within the reactor in plug flow, and the porous separator is impermeable to flow, although diffusion may occur across it; and (*vi*) axial diffusion and migration are negligible in comparison with radial diffusion and migration. Some of the foregoing assumptions are necessary for conduct of analysis by the methods employed, while other assumptions are chosen somewhat arbitrarily and could easily be replaced by other choices for particular situations.

The electrochemical reaction under study is represented by the general form

$$\sum_i \nu_i M_i^{z_i} = ne^- \quad [1]$$

The reaction rate expression for reaction [1] could have a wide variety of forms depending on the system; the present study directs attention toward "reversible" electrodeposition of a metal ion in accord with the Butler-Volmer equation

$$j = i_o \left\{ e^{-\frac{\alpha nF}{\mathcal{R}T}(\phi - \phi_e)} - \frac{c_i}{c_i^b} e^{\frac{(1-\alpha)nF}{\mathcal{R}T}(\phi - \phi_e)} \right\} \quad [2]$$

Movement of solute species in the electrolyte occurs by diffusion, migration, and convection; in addition, electroactive species are consumed or generated by reaction. Under steady-state operating conditions, an equation for the conservation of species i therefore has the form

$$D_i \nabla^2 c_i + \frac{z_i D_i F}{\mathcal{R}T} \nabla \cdot (c_i \nabla \phi) - \nabla \cdot (v c_i) = \frac{a \nu_i}{nF} j \quad [3]$$

In accord with the assumptions listed previously, Eq. [3] may be written in circular cylindrical coordinates

$$v_o \frac{\partial c_i}{\partial z} = D_i \frac{\partial^2 c_i}{\partial r^2} + \frac{D_i}{r}\frac{\partial c_i}{\partial r} + \frac{z_i D_i \mathbf{F}}{\mathcal{R}T}\left(c_i \frac{\partial^2 \phi}{\partial r^2} + \frac{c_i}{r}\frac{\partial \phi}{\partial r} + \frac{\partial \phi}{\partial r}\frac{\partial c_i}{\partial r}\right) - \frac{a\nu_i i_o}{n\mathbf{F}}\left[e^{-\frac{\alpha n \mathbf{F}}{\mathcal{R}T}(\phi - \phi_e)} - \frac{c_i}{c_i^b} e^{\frac{(1-\alpha)n\mathbf{F}}{\mathcal{R}T}(\phi - \phi_e)}\right] \quad [4]$$

Equation [4] has (i + 1) unknowns: the i concentrations and the potential. Relations having the form of Eq. [4] may be written for each of the i solute species in solution; the remaining relationship is provided by the equation of electrical neutrality

$$\sum_i z_i c_i = 0 \quad [5]$$

Two sets of boundary and initial conditions have been chosen for study which correspond to two different types of porous separator membranes. The first set characterizes sieve-type membranes which obstruct passage of reactant species but which allow free passage of smaller species. For the acidified copper sulfate system chosen for study, outlined below, the boundary conditions are

$$\begin{aligned} z = 0 \qquad & c_i = c_i^b \\ r = 0 \qquad & \frac{\partial c_i}{\partial r} = 0 \\ & \frac{\partial \phi}{\partial r} = 0 \\ r = r_o \qquad & \phi = \phi_a \\ & c_{H^+} = c_{H^+}^b \\ & \frac{\partial c_{Cu^{+2}}}{\partial r} = 0 \end{aligned} \quad [6]$$

The second set of conditions characterizes membranes which permit free passage of all solute species

$$\begin{aligned} z = 0 \qquad & c_i = c_i^b \\ r = 0 \qquad & \frac{\partial c_i}{\partial r} = 0 \\ & \frac{\partial \phi}{\partial r} = 0 \\ r = r_o \qquad & \phi = \phi_a \\ & c_i = c_i^b \end{aligned} \quad [7]$$

Equations [4] and [5] along with side conditions [6] or [7] permit calculation of the concentration and potential distribution throughout the packed-bed reactor. The local reaction rate distribution throughout the reactor can subsequently be determined from Eq. [2]. In turn, the current density distribution along the porous separator, denoted $i^*(z)$, is found by integration of Eq. [2]

$$i^* = \frac{a}{r_o}\int_o^{r_o} j r dr \quad [8]$$

Finally, Eq. [8] may be integrated along the length of the reactor to yield the volumetric reaction rate, i_v, having units amperes per cubic centimeter of reactor volume

$$i_v = \frac{2}{r_o z}\int_o^z i^* dz \quad [9]$$

In order to reduce the number of independent parameters which influence the system, it is convenient to introduce dimensionless variables

$$R = \frac{r}{r_o} \qquad \theta = \frac{D_r z}{r_o^2 v_o} \qquad C_i = \frac{c_i}{c_r}$$

$$\Phi = \frac{\mathbf{F}}{\mathcal{R}T}(\phi - \phi_e) \qquad J = \frac{a r_o}{i^*} j \quad [10]$$

The equations and side conditions which conform to the model then have the form

$$\sum_i z_i C_i = 0 \quad [11]$$

and

$$\frac{1}{\pi_i}\frac{\partial C_i}{\partial \theta} = \frac{\partial^2 C_i}{\partial R^2} + \frac{1}{R}\frac{\partial C_i}{\partial R} + z_i\left[\frac{\partial}{\partial R}\left(C_i \frac{\partial \Phi}{\partial R}\right) + \frac{C_i}{R}\frac{\partial \Phi}{\partial R}\right] - \frac{\xi \nu_i}{\pi_i}\left[e^{-\alpha n \Phi} - \frac{C_i}{\gamma_i} e^{-(\alpha - 1)n\Phi}\right] \quad [12]$$

with either

$$\begin{aligned} \theta = 0 \qquad & C_i = \gamma_i \\ R = 0 \qquad & \frac{\partial C_i}{\partial R} = \frac{\partial \Phi}{\partial R} = 0 \\ R = 1 \qquad & C_{H^+} = \gamma_{H^+} \\ & \frac{\partial C_{Cu^{+2}}}{\partial R} = 0 \\ & \Phi = \Phi_a \end{aligned} \quad [13]$$

or

$$\begin{aligned} \theta = 0 \qquad & C_i = \gamma_i \\ R = 0 \qquad & \frac{\partial C_i}{\partial R} = \frac{\partial \Phi}{\partial R} = 0 \\ R = 1 \qquad & C_i = \gamma_i \\ & \Phi = \Phi_a \end{aligned} \quad [14]$$

The dimensionless parameters which appear in the foregoing model are

$$\pi_i = \frac{D_i}{D_r} \qquad \gamma_i = \frac{c_i^b}{c_r} \qquad \xi = \frac{a r_o^2 i_o}{n\mathbf{F} c_r D_r} \quad [15]$$

The dimensionless forms of Eq. [2] and [8] which are subsequently employed are, respectively

$$\beta J = \xi\left[e^{-\alpha n \Phi} - \frac{C_i}{\gamma_i} e^{(1-\alpha)n\Phi}\right] \quad [16]$$

$$\beta = \xi \int_o^1 \left[e^{-\alpha n \Phi} - \frac{C_i}{\gamma_i} e^{(1-\alpha)n\Phi}\right] R dR \quad [17]$$

where

$$\beta = \frac{i^* r_o}{n\mathbf{F} c_r D_r} \quad [18]$$

Equations [16] and [17] imply that

$$\int_o^1 J R dR = 1 \quad [19]$$

Finally Eq. [9] will be used to determine the average volumetric reaction rate between reactor inlet and position θ in accord with the integral

$$I = \frac{\int_o^\theta \beta d\theta}{\theta} \quad [20]$$

Before passing to a discussion of the model, it would be useful to pause for a moment to gain a better physical feeling for the dimensionless groupings which

have arisen. The quantity θ is a dimensionless distance and may also be interpreted as the dimensionless time period during which a fluid packet has been in contact with the packed bed. That is, since the fluid moves in plug flow, all fluid packets having contact time θ_1, would be located at the same distance from the reactor entrance. The quantity J is the local reaction rate which varies with both radial and axial position within the electrode. For a given value of θ, the current density flowing through the porous separator is β, given by Eq. [17]. The current distribution, embodied in J and β, is related to the potential and concentration distributions by the parameter ξ, as indicated by Eq. [16]. According to its definition, ξ is a ratio of diffusion resistance to charge-transfer resistance insofar as it contains the ratio i_o/D_r. A detailed treatment of these quantities is given below.

Method of Solution

The solution of the set of equations and side conditions derived above was accomplished by a numerical procedure which employed finite difference equations. Equation [11] is parabolic in the sense that the only θ-dependence which enters into the equation is in the derivative on the left side. Therefore integration over the two-dimensional volume can proceed in a step-wise manner beginning at the upstream end of the reactor, at $\theta = 0$. At each subsequent step in the axial direction, the θ-derivative was placed into finite difference representation in accord with the Crank-Nicolson symmetric form (12). Owing to the plug flow assumption, the quantity θ corresponds to the residence time of electrolyte within the reactor; the solution of the model is similar to the analysis of unsteady-state behavior in porous battery electrodes (13).

At each step along the θ-direction, the radial dependence of potential and concentrations was determined by linearizing Eq. [10] and [11] about a trial solution and then setting them into finite difference form. The trial matrix was then inverted (14), and the solution of the nonlinear equation was gained by iteration with successive correction of the trial solution. The criterion chosen for convergence was that the potential anywhere within the electrode should change by less than 0.01% upon successive iterations. A typical individual θ-step calculation was found to take 2 sec and involved three iterations.

The results presented below were calculated with use of 100 R-increments; the initial size of the θ-increment was so chosen that the maximum solute concentration change was 2% of the bulk value. Smaller increments did not improve the numerical results to any appreciable degree. Between successive θ-steps, the θ-increment was increased by a factor of 1.1 in order to conserve computer time.

Results and Discussion

The theoretical model developed above was employed to predict behavior during electrodeposition of copper from acidified sulfate solution. This system has been chosen since it lends itself nicely to an experimental program of investigation; values of the system parameters are given in Table I. The results chosen for presentation below are intended both to elucidate details of electrode behavior and to provide a compilation of results. Before proceeding to details of two-dimensional behavior, the results for two limiting cases are presented.

Table I. Properties of the acid copper sulfate system chosen for calculations

Species	z_i	γ_i	π_i	ν_i
H^+	+1	4.0	9.312	0
$SO_4^=$	−2	2.1	1.065	0
Cu^{++}	+2	0.1	0.7188	−1

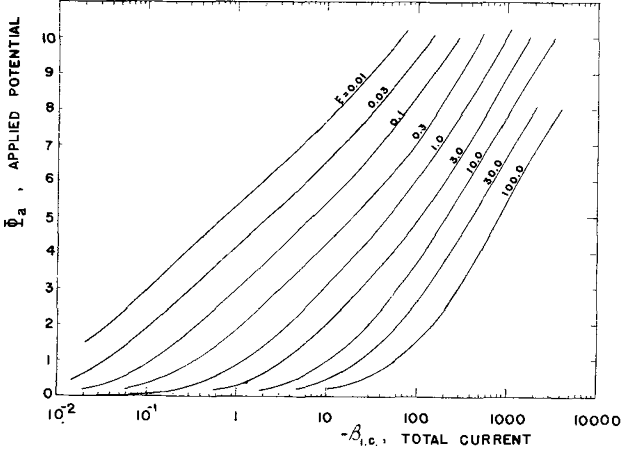
$n = 2.$
$\alpha = 0.5.$

Behavior upon initial contact.—If electrolyte passes through the reactor without appreciable mass transfer limitations, then the solute concentrations will be constant everywhere and the set of Eq. [10] and [11] may be simplified to a single ordinary differential equation

$$\frac{d^2\Phi}{dR^2} + \frac{1}{R}\frac{d\Phi}{dR} = \frac{n\xi}{\sum_i z_i^2\pi_i\gamma_i}\left[e^{-\alpha n\Phi} - e^{(1-\alpha)n\Phi}\right] \quad [21]$$

For a given applied potential, Eq. [21] can be used to determine the uppermost current which may be achieved for a system of known exchange current density, conductivity, and electrode geometry. The potential distribution gained by solving Eq. [21] for a given applied potential may be substituted into Eq. [17] to generate the corresponding total current flowing to the electrode. Figure 2A provides the current-potential curves predicted for various values of the parameter ξ. It is reasonable to anticipate that the results depicted in Fig. 2A would also apply in the upstream regions of the packed-bed reactor, during initial contact, whether or not concentration variations eventually develop downstream.

Behavior far downstream.—Far downstream from the reactor entrance, behavior will depend on which of the aforementioned boundary conditions prevail. When the porous separator is impermeable to reactive species (Eq. [13]), electrochemical reaction will eventually deplete reactants insofar as the applied potential permits. In this situation, the region far downstream is not reactive with the consequence that an optimum reactor length will exist which balances fabrication and maintenance costs against volumetric productivity.



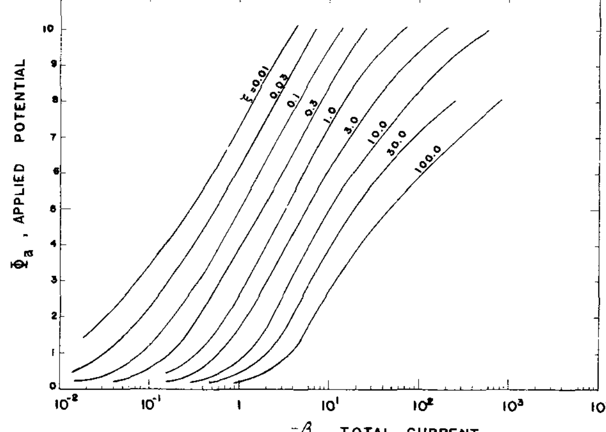


Fig. 2. Current/potential diagrams for two limiting cases of reactor behavior: (A) initial contact, *i.e.*, uniform concentration, (B) well-developed region far downstream.

On the other hand, when the porous separator is permeable to all species (Eq. [14]), the reactor will exhibit quite different behavior far downstream from the entrance. In this case, after a sufficient distance downstream, the reactor will achieve a "well-developed" configuration in which the concentration and potential distributions within the packed-bed will vary with radial, but not axial, position. Since there are no concentration variations along the θ-direction in this well-developed region, the left side of Eq. [12] becomes zero and one obtains an ordinary differential equation for each solute species i. For the copper system under study, integration of the set of equations provides the current/potential curves shown in Fig. 2B. Comparison of Fig. 2A and B indicates that the concentration overpotential inherent in the "well-developed" region serves to reduce the reactivity of the electrode in comparison with the initial contact value. For systems having low values of ξ, differences in behavior are noticeable only at larger values of applied potential. For systems of large ξ, however, significant differences between initial contact and far downstream are evident even at low applied potentials. In many instances, interdiffusion of reactive anolyte and catholyte species can lower the current efficiency and be disadvantageous. Therefore permeable separator reactors of excessive length are not attractive with the result that an optimum reactor length needs to be determined.

Intermediate behavior.—Between the two limiting cases outlined above lies the region in which reactor behavior is more complex to predict owing to the existence of both axial and radial variations of concentration and potential. Knowledge of this region, however, is of special value for the understanding of reactor behavior.

Figure 3a shows the distribution of copper ion concentration along the radial direction for several locations downstream from the reactor entrance when the porous separator is impermeable to reactants. It is seen that the concentration of cupric ions is initially uniform but decreases with distance downstream. The rate of decrease is initially most rapid near the periphery where the reaction rate is highest. The radial concentration gradient at the periphery is zero throughout the reactor in accord with the boundary conditions [13]. Once reactants near the periphery become substantially depleted, radial diffusion of reactants takes place from regions of higher concentration, along the axis of the reactor, toward peripheral regions. Eventually, the reactants become depleted throughout the reactor and the copper ion concentration approaches the minimum possible value given by the Nernst equation.

Continuing with the impermeable separator case, Fig. 3b shows the radial distribution of reaction rate for various axial positions downstream from the entrance. It is seen that the initial contact current distribution is nonuniform owing to the large values of Φ_a and ξ chosen for the example. The reaction rate is highest at the periphery, near the counterelectrode. The reactivity of the periphery, however, decreases rapidly with distance downstream owing to the depletion of reactive species as already indicated in Fig. 3a. At intermediate positions along the reactor, the most reactive portion of the reactor is far enough from the periphery that reactants are available, but not so far that the ohmic resistance of the electrolyte consumes the applied potential. With sufficient distance downstream, even the central portion of the packed-bed becomes reactive.

In contrast to Fig. 3, Fig. 4 shows concentration and reaction rate distributions predicted for permeable porous separators. From Fig. 4a, it is seen that the concentration of cupric ions remains constant at the periphery of the reactor along its entire length, in accord with the boundary conditions. For large values of ξ, for which the current distribution upon initial

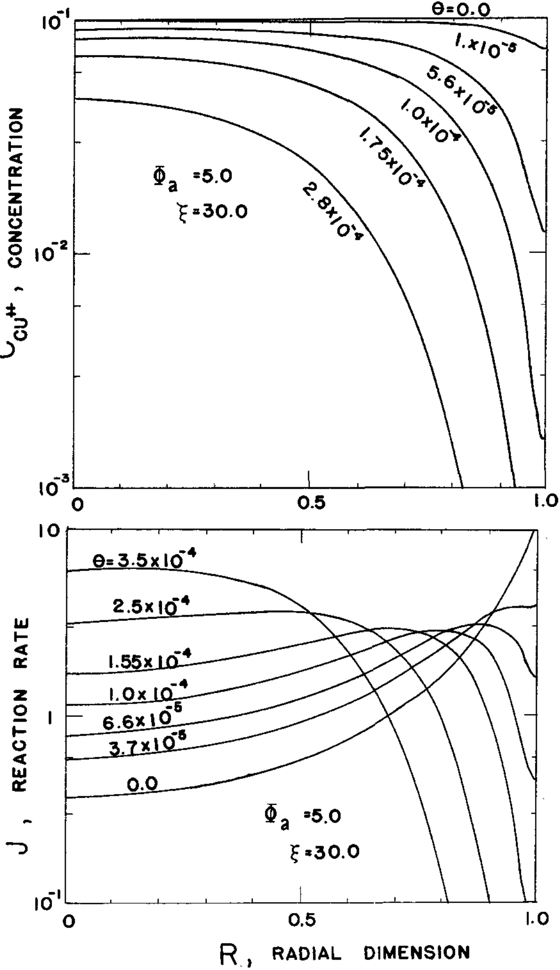

Fig. 3. Dependence of radial distributions on residence time within plug-flow reactor with porous separator impermeable to copper ions ($\Phi_a = 5$, $\xi = 30$): (a, upper) copper ion concentration during cathodic deposition, (b, lower) local reaction rate.

contact is highly nonuniform, the results shown in Fig. 4 are typical. Reactants near the central region are not consumed near the reactor entrance owing to low reactivity of these regions. Although the periphery is highly reactive, the copper ions are easily replenished by diffusion through the permeable separator. The depletion of reactants therefore proceeds most rapidly at intermediate locations, and a minimum in the reactant concentration appears. As the electrolyte flows through the reactor, the minimum shifts toward the center of the reactor; when the minimum reaches the centerline, the reactor is said to be "well-developed."

Figure 4b provides the radial current distributions at various axial distances downstream for the same conditions as in Fig. 4a. It is seen that the reactivity of the peripheral region remains high along the length of the reactor, but that a minimum in reactivity may be located at the regions which are depleted of reactive species. The interior of the reactor (near $R = 0$) becomes relatively more and more reactive with distance downstream until reactant depletion near the axis occurs to a sufficient extent. Far downstream, a well-developed reaction distribution is found for which the peripheral regions alone are reactive by virtue of reactant supply through the porous separator.

Calculations have also been performed in order to determine the current density passing through the porous separator. The radial potential distribution was integrated at each θ-increment in accord with Eq. [17]. Because of depletion of reactive species, the current passing the separator decreases with distance downstream from the inlet. For an impermeable separator, Fig. 5 indicates the axial distribution of current for $\xi = 0.1$ and several values of applied potential. The

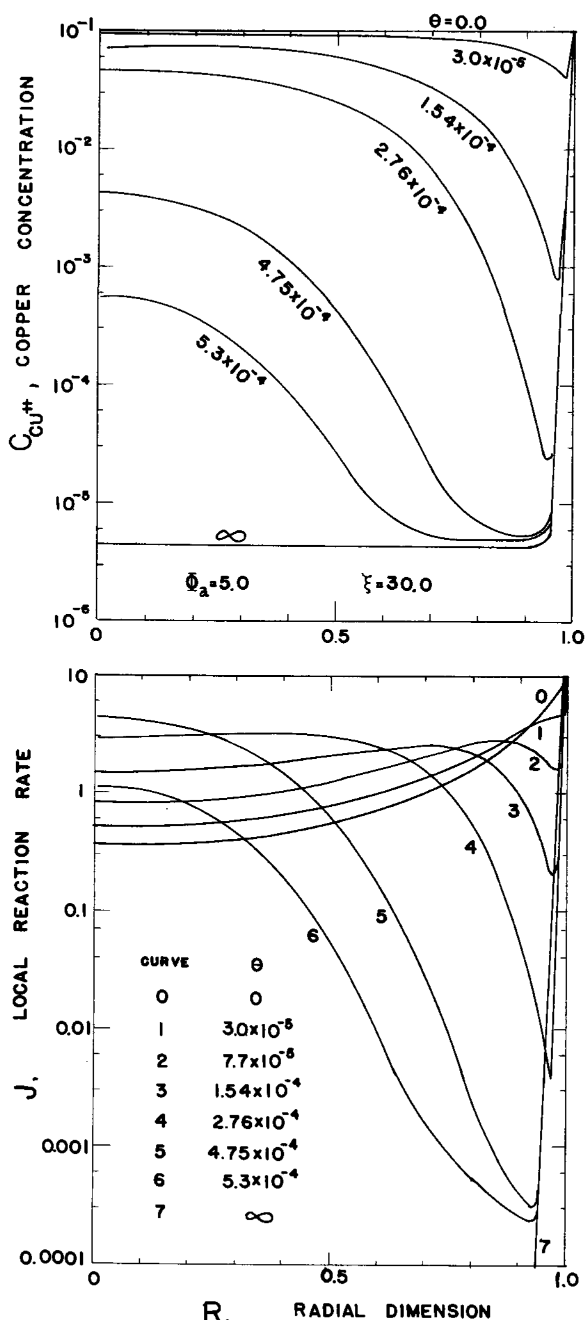

Fig. 4. Dependence of radial distributions on residence time within plug-flow reactor for a porous separator permeable to all solute species ($\Phi_a = 5$, $\xi = 30$): (a, upper) copper ion concentration during cathodic deposition, (b, lower) local reaction rate.

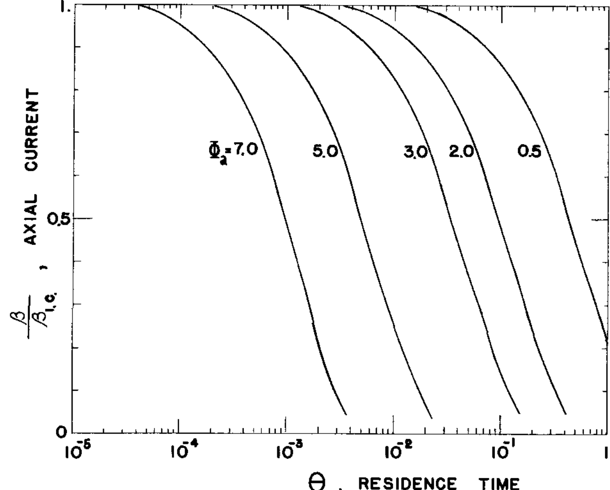

Fig. 5. Axial variation of current flowing through porous separator for various applied potentials and $\xi = 0.1$ (separator impermeable to copper ions).

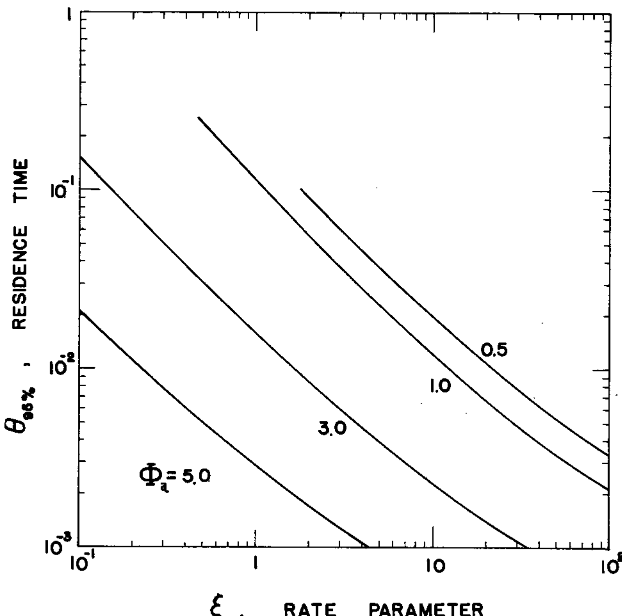

Fig. 6. Dependence of residence time (95% criteria) on system parameters (separator impermeable to copper ions).

ordinate is normalized by the current density which flows upon initial contact (see Fig. 2a). Although the shapes of the curves are similar, the residence times for onset of depletion at $\Phi_a = 2.0$ and 7.0 differ by a factor of 100. The residence time at which the local current density has decreased to within 5% of the initial contact value is denoted $\theta_{95\%}$. Figure 6 illustrates how $\theta_{95\%}$ varies with ξ for several values of applied potential. It is seen that the residence time for attainment of $\theta_{95\%}$ decreases with an increase in either ξ or Φ_a. For a given value of ξ and Φ_a, Fig. 6 indicates the maximum useful ratio of reactor length to flow velocity; reactors having residence times in excess of $\theta_{95\%}$ will have downstream regions which are essentially unreactive. The 95% criterion is of course an arbitrary choice which may not be well suited for some applications.

The axial current distribution depicted in Fig. 5 has been integrated in accord with Eq. [20] to yield the average current density passing between the packed-bed reactor and counterelectrode, shown in Fig. 7. It is seen that the average volumetric reaction rate increases with both ξ and Φ_a. The results shown in Fig. 7 correspond to reaction rates averaged over the reactor between the entrance and $\theta = \theta_{95\%}$. Since the 95% criterion may be ill-suited for certain applications, Table II provides additional information for other criteria and for various values of ξ and Φ_a. Two numbers appear for each row and column entry in the table. The upper number gives the average volumetric reaction rate while the lower number indicates the corresponding residence time, θ_x. The residence time θ_x is defined as the residence time at which the local current density, $\beta(\theta)$, has decreased by x% of the initial contact current density (Fig. 2a). It is seen that the average reaction rate increases strongly upon an increase of either ξ or Φ_a, regardless of the value of x chosen as criteria. For given values of ξ and Φ_a, the average volumetric reaction rate can vary by severalfold according to the choice of x.

Similar calculations have been conducted for the situation where the porous separator is permeable to all solute species. The current which passes through the separator varies with axial position and is largest at

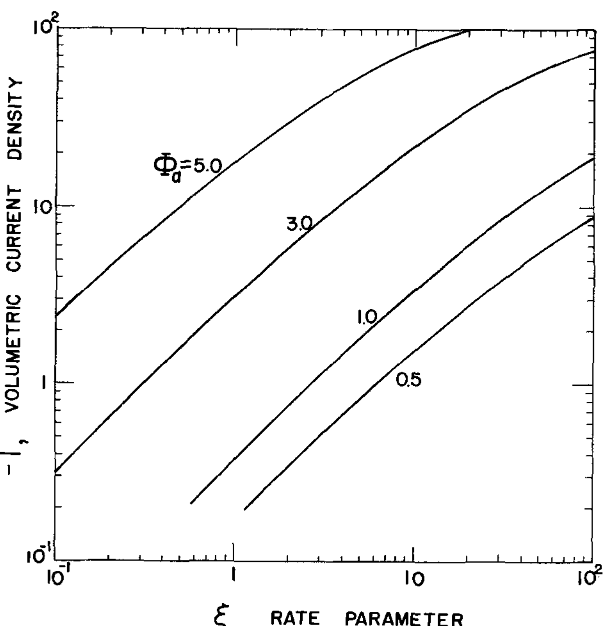

Fig. 7. Dependence of volumetric reaction rate (95% criteria) on system parameters (separator impermeable to copper ions).

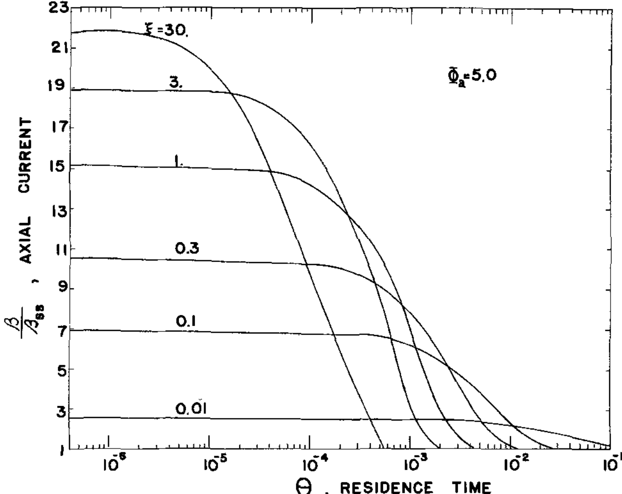

Fig. 8. Axial variation of current flowing through porous separator for $\Phi_a = 5.0$ and various values of ξ (separator permeable to all species).

the reactor entrance region. Figure 8 indicates how the current varies between the initial contact value and the well-developed (or steady-state) value achieved far downstream for $\Phi_a = 5.0$ and several values of ξ. As was already seen from Fig. 2, small values of ξ lead to negligible concentration differences so that the initial contact and well-developed reaction rates are nearly the same. Larger values of ξ indicate that significant concentration effects will develop during residence so that the reactivity of the reactor will vary a great deal along its length. Since the initial local reactivity is proportional to ξ, the residence time (or reactor length) necessary for attainment of the well-developed configuration decreases with an increase of ξ as shown in Fig. 9.

The residence time at which the local reactivity has decreased by 95% of the difference ($\beta_{i.c.} - \beta_{s.s.}$) is denoted $\theta_{95\%}$ in Fig. 9. Comparison of Fig. 9 with Fig. 6 indicates that they are nearly identical. That is, even though the nature of the porous separator leads to significant differences in localized behavior, the over-all behavior (as normalized on the basis of Fig. 6 and 9) is not appreciably different.

The total current passing between reactor and counterelectrode is provided in Table III for various criteria. As in Table II, each row and column entry provides two numbers: the upper value gives the average volumetric reaction rate while the lower indicates the corresponding residence time, θ_x. The quantity θ_x is defined as the residence time at which the local current density, $\beta(\theta)$, has decreased by $x\%$ of the difference ($\beta_{i.c.} - \beta_{s.s.}$) as determined from Fig. 2. Comparison of Tables II and III indicates that corresponding entries

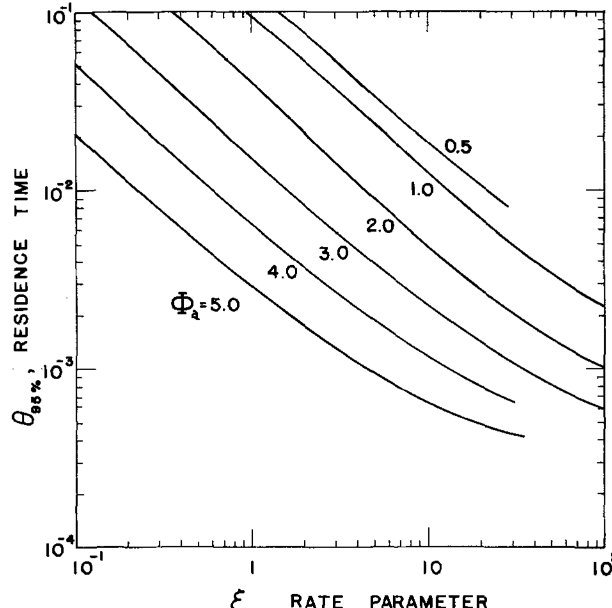

Fig. 9. Dependence of residence time (95% criteria) on system parameters (separator permeable to all species).

have very nearly the same values throughout most of the tables. It is important to recognize, however, that the information contained in the two tables is normalized in very different ways owing to the influence of the porous separator. Figure 10 displays the volumetric reaction rate data for the 95% criterion.

Let us conclude discussion with a numerical example to illustrate usage of the foregoing results. Consider cathodic deposition of copper from 0.1M $CuSO_4$ and 2.0M H_2SO_4 having the properties already listed in Table I. The reaction is assumed to proceed with $i_o = 10^{-3}$, in a reactor 1 cm in diameter packed with spherical particles of diameter 0.5 mm; for closest packing of spheres, $a = 220$ cm^2/cm^3 void volume. For the foregoing values, ξ has the value 27.5. Operation at 130 mV corresponds to $\Phi_a = 5$. To illustrate results with the permeable separator and the 95% criterion, one obtains from Fig. 9 and 10 the values $\theta_{95\%} = 0.00044$ and $I = 120$, respectively. According to the definition of I, given in the notation, the average volumetric reaction rate is found to be $i_v = 2nFIc_rD_r/r_o^2 = 1.92$ A/cm^3. According to the definition of θ, the reactor length is related to the fluid velocity by $L = \theta r_o^2 v_o/D_r = 11\ v_o$. In order to determine the reactor length, one may choose a flow velocity which will avoid both high pumping costs and excessive radial flow through the porous separator membrane. For the present example, a pressure drop of 0.1 atm along the reactor length is chosen. The superficial velocity of fluid outside the reactor is obtained in the laminar region from the Blake-Kozeny equation (15)

$$v_o = \frac{\Delta p}{L} \frac{D_p^2}{150\mu} \frac{\epsilon^3}{(1-\epsilon)^2} \qquad [22]$$

With a void fraction of $\epsilon = 0.3$, $D_p = 0.05$ cm, and $\mu = 0.01$ g/cm-sec, one finds the relation $v_oL = 9.2$. By combining the above two relations between v_o and L, one obtains the results $L = 10.1$ cm and $v_o = 0.92$ cm/sec.

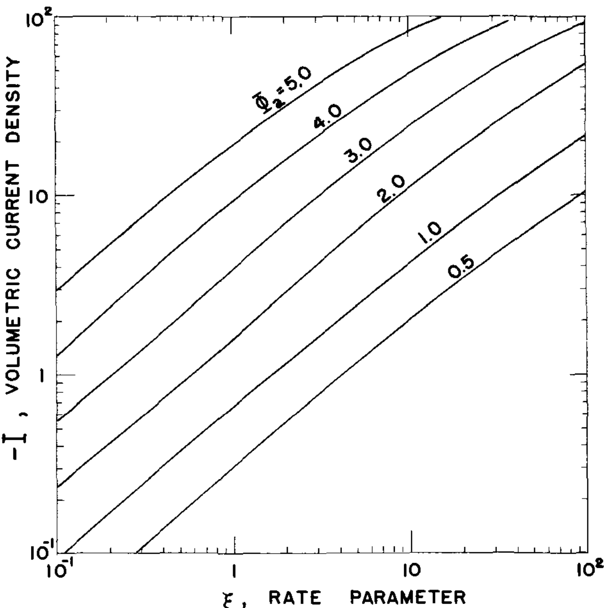

Fig. 10. Dependence of volumetric reaction rate (95% criteria) on system parameters (separator permeable to all species).

Conclusions

The steady-state operation of electrochemical reactors at high volumetric production rates is difficult to sustain owing, in part, to competing requirements of large surface area, rapid mass transfer, low ohmic resistance, and ready accessibility to the counterelectrode. Porous flow-through reactors can offer high volumetric rates, but are difficult to design without knowledge of the current distribution. The foregoing simple theoretical model may be used in conducting preliminary design steps for one type of flow reactor. The theoretical analysis indicates how the relationship between volumetric reaction rate and residence time depends on the kinetic, mass transfer, ohmic, and geometric parameters of the system. On the basis of these results, economic design and operation of flow reactors with porous electrodes can be accomplished with added confidence.

The predicted results of the model are based on several assumptions which ease computational difficulties. Although extensive use of the plug flow simplification has been made in previous studies, the assumption is known to be invalid in some flow systems having the geometry indicated by Fig. 1A; in the system under study, Fig. 1B, the fluid flows in a perpendicular direction to the electrical current so that the effect of dispersion would be less pronounced. The assumption that axial diffusion and migration are negligible in comparison with radial diffusion and migration may be evaluated by examining the computed results. In general, the assumption is very good near the periphery of the reactor and in the downstream regions; for example, with $\xi = 1.0$ and $\Phi_a = 0.5$, the radial diffusion and migration are 10^3 times larger than axial components near the periphery. At large values of ξ, however, the assumption breaks down in the upstream interior regions of the reactor; on the other hand, the upstream interior region of the reactor does not contribute to electrochemical conversion, as indicated clearly in Fig. 3 and 4, so that breakdown of the assumption is not expected to affect significantly the predicted results. The two assumptions indicated here are, as noted, of limited validity; on the other hand, they are essential for simplifying mathematical treatment of reactor behavior. A more correct two-dimensional analysis would be exceedingly difficult.

The other assumptions placed on the calculations could be relieved in favor of equivalent conditions. In particular, several aspects of the model could be extended in order to investigate more complex systems. Analyses of multiple electrode reactions, or of electrode reactions coupled with homogeneous chemical (scavenger) reactions would be of value. In addition, study of double-porosity reactor structures would be profitable.

Other boundary conditions could be chosen for study. For example, Eq. [14] for the permeable separator indicates that the reactant concentration along the separator is the same as the reactant concentration in the catholyte flowing into the reactor. Entirely different behavior would be encountered if the concentration

along the separator were zero. For large values of ξ, however, it may be expected that the proposed boundary conditions would lead to behavior very similar to that encountered with reactant-impermeable separators.

The foregoing results may be applied to nonflow porous electrode systems by interpreting the residence time as the time following application of a constant applied potential. The results may therefore be applied directly to the unsteady-state behavior of cylindrical porous electrode systems as, for example, encountered in batteries.

Even the simple model presented above, however, contains several parameters so that portraying results can be awkward. Nevertheless, over-all reactor behavior for one type of electrode reaction has been portrayed on the basis of a limited number of graphs which were based on a large number of calculations. Behavior involving other reaction sequences may perhaps differ in detailed aspects, but would be expected to exhibit similar over-all trends upon variation of system parameters.

Acknowledgments

Portions of this study constituted partial fulfillment of requirements for a Master of Science degree in the Department of Chemical Engineering, University of Illinois, Urbana-Champaign. Acknowledgment is made to the donors of The Petroleum Research Fund, administered by the American Chemical Society, for partial support of this research. The University of Illinois Research Board sustained the computer costs associated with this study.

Thermodynamic Properties of Molten Mixtures of Nickel Chloride with Cesium Chloride at 700° and 800°C

Drannan C. Hamby and A. Roger Hohimer

Linfield Research Institute, Linfield College, McMinnville, Oregon 97128

Reversible emf's of the cell

$$Ni \mid NiCl_2\ (N),\quad CsCl\ (1 - N) \mid graphite,\quad Cl_2 \quad [1]$$

where N, the mole fraction of solute, is

$$N = \text{moles } NiCl_2/(\text{moles } NiCl_2 + \text{moles } CsCl) \quad [2]$$

have been measured over a range of concentration from $N \cong 10^{-3}$ to 4×10^{-1} for temperatures ranging from 650°-875°C. Supplementary thermochemical data from the literature have been utilized to calculate the activity coefficient and the partial molar Gibbs energy, enthalpy, and entropy of mixing for the solute $NiCl_2$ in the solvent CsCl. In an earlier paper similar data and calculated functions were presented for $NiCl_2$ in the solvents KCl, NaCl, 1:1 NaCl-KCl, and LiCl (1).

Experimental

Chemicals.—Gases.—The chlorine, argon, and HCl gases were Matheson Company "high purity." The HCl and chlorine gases were passed over $Mg(ClO_4)_2$ and hot (500°C) porous graphite (National Carbon Company, grade 60) before entering the cell. The argon was passed over $Mg(ClO_4)_2$ and then over hot Cu at 500°C; the Cu was in the form of pellets formed by reduction of CuO with H_2. The gas delivery system was glass except for a few inches of rubber tubing near the cell top.

Reagent grade $NiCl_2 \cdot 6H_2O$ was dried under flowing argon at reduced pressure in a vacuum oven at 140°C for two days. The salt was then ground to a fine powder in a porcelain morter, placed in a Pyrex tube, and dried at least 4 hr under anhydrous HCl at 400°C. Transfer of the salt to weighing bottles was carried out in a dry box under argon and the bottles were then stored in a dessicator until used. Transfer to the cell involved brief exposure to the atmosphere.

CsCl, 99.90%, was obtained from Cooper Chemical Company. The salt was dried in the cell crucible under flowing argon at reduced pressure in a vacuum oven at 100°C for 24 hr. The crucible was then placed inside the cell envelope and drying was continued under flowing anhydrous HCl over a 24 hr period while the cell temperature was gradually brought to the melting point. After solvent fusion, the chlorine electrodes were inserted and chlorination of the melt in the presence of carbon provided further guarantee of melt dehydration (3).

AgCl-CsCl mixtures for use in a Ag | AgCl, CsCl || reference electrode were prepared from reagent grade AgCl and the Cooper Chemical Company CsCl. The salts were weighed out in the desired proportions, fused under HCl, and chlorinated in the presence of carbon for 1 hr. The solutions were dilute in AgCl, approximately 10^{-2} mole fraction, and were melted and chlorinated near the melting point of CsCl, 646°C. After chlorination the salt was drawn into and sealed in clean, dry, Vycor tubes until used to make up the reference electrode.

Key words: nickel chloride, cesium chloride, molten salts (fused salts), formation cells, nickel electrode, thermodynamics.

Apparatus and procedure.—Several experimental details have been described previously (1, 2). These include temperature measurement; measurement of thermoelectric emf's developed by electrode pairs; analytical methods for nickel mole fraction determination; polarization tests for establishment of electrode reversibility; methods of solute, $NiCl_2$, addition; pretreatment of chlorine electrodes; method of preparation of the Ag | AgCl, CsCl || reference electrode; source and treatment of metal electrodes; metal electrode housing design; and method of melt sampling. The cell envelope was similar in design to that described previously (2) but was larger in diameter, 78 mm, which permitted insertion of an additional nickel electrode. Thus, when assembled, the cell contained two chlorine electrodes, one Ag | AgCl, CsCl || reference, two nickel electrodes, and a Vycor sheathed Chromel-Alumel thermocouple; an additional opening was available in the cell top for melt sampling. Adequate salt was initially placed in the cell crucible to insure a melt depth of at least 4 cm.

Chlorine electrode design is illustrated in Fig. 1. The graphite rod was 1/4 in. diameter Ultra Carbon Company grade UF-4-S. In earlier studies several chlorine electrode designs were tested and found to perform equally well; therefore, the simplest, most easily constructed electrode was chosen for this work (1, 4). Chlorine gas pressure was ambient atmospheric pressure. Uncertainty in cell emf's due to uncertainty in chlorine pressure have been discussed previously (2).

The Ag | AgCl, CsCl || reference electrode was used in this work as before to provide a continuous record of chlorine electrode behavior with time (1, 2).

The furnace was a noninductively wound Marshall Company, Model 1057, tube furnace, 3-1/2 in. diameter, 24 in. long. Power and temperature control for the furnace were furnished by a Marshall Model 4042 current proportioning control.

Emf measurements were made with a Keithley 660A differential voltmeter. This instrument was checked against a laboratory standard Eppley cell.

Cell emf's were measured as a function of temperature at eleven mole fractions of the solute, $NiCl_2$; usually four or five emf measurements and at least three melt samples were taken at each mole fraction.

Results

The data for cell [1] are illustrated in Fig. 2 where cell emf's E, are plotted as a function of temperature. All emf's have been corrected for thermoelectric effects. At each mole fraction, the relationship of cell

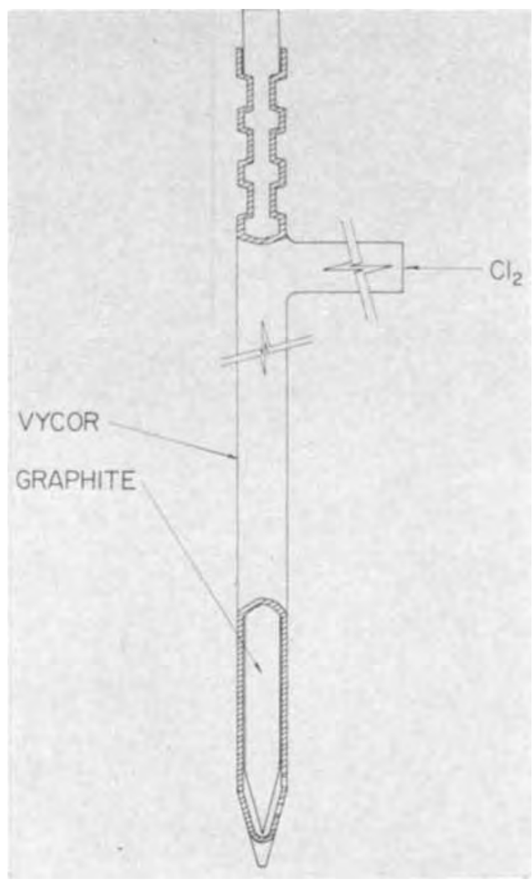

Fig. 1. Chlorine electrode design

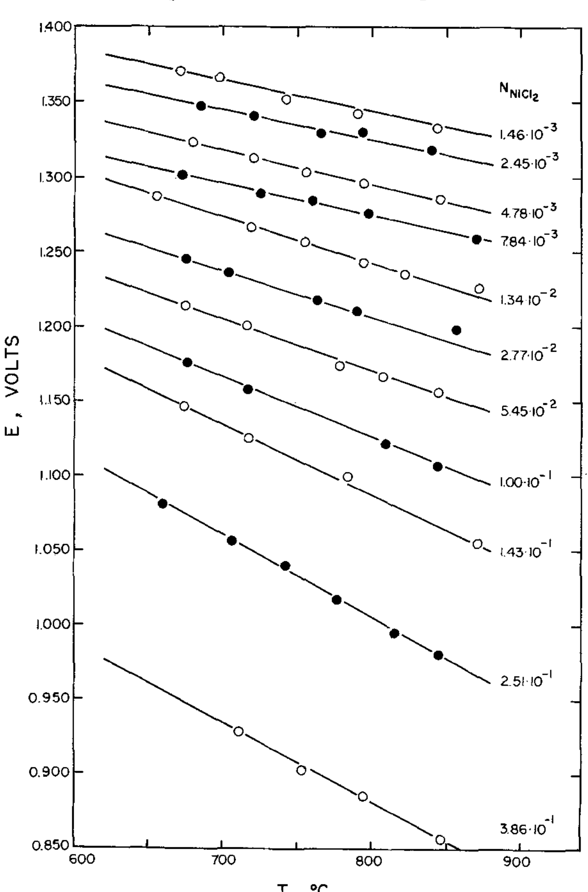

Fig. 2. Primary cell data. CsCl solvent; $NiCl_2$ solute. Cell emf's, E, are plotted as a function of temperature for eleven concentrations. $NiCl_2$ mole fractions are indicated beside the corresponding emf data.

emf to temperature was assumed to be linear. From Fig. 2 cell emf's were read at 700° and 800°C and plotted as functions of log N_{NiCl_2} in CsCl in Fig. 3. Also shown in Fig. 3 for comparison are emf *vs.* log N curves for other solvents as reported previously (1).

Below $N = 2 \times 10^{-2}$, E at constant temperature for the solvent CsCl may be represented by

$$E = d - b \log N \quad [3]$$

where

$$b = 2.303\ RT/2F \quad [4]$$

The lines in Fig. 3 for CsCl were drawn with the Nernst slopes b below $N = 2 \times 10^{-2}$. The intercept d was chosen to give the best fit with the data points for $N < 2 \times 10^{-2}$; at 700°C d = 1.094V, at 800°C d =

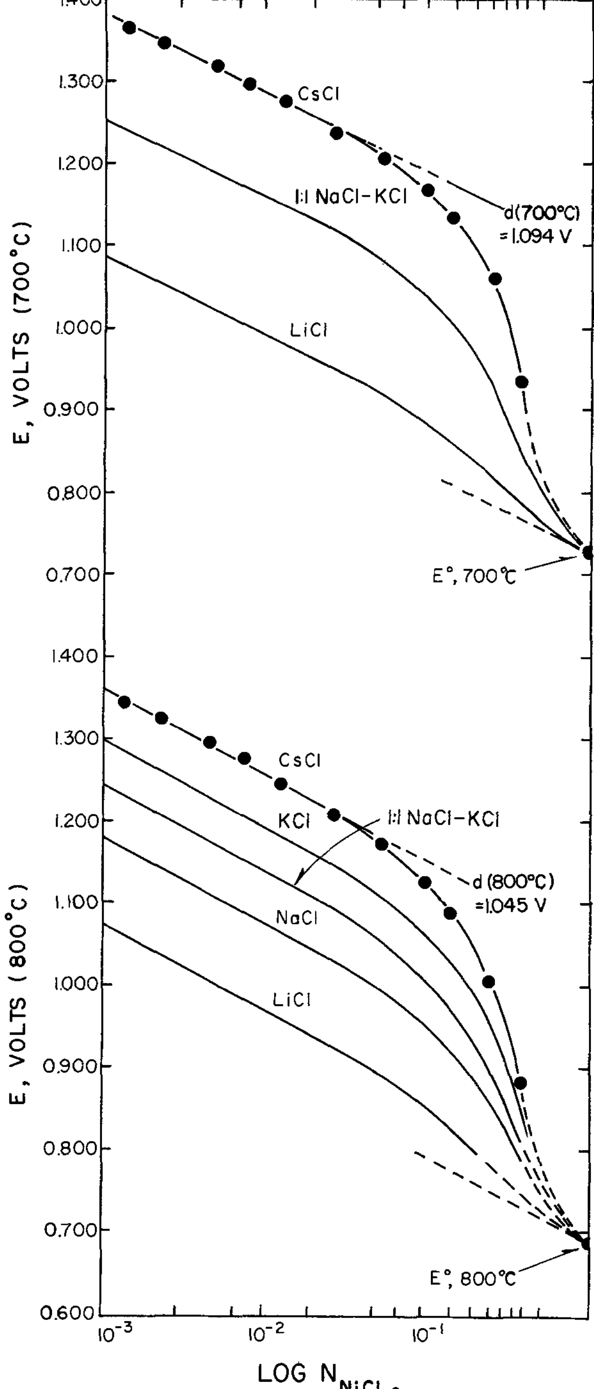

Fig. 3. Cell emf, E, vs. log N_{NiCl_2} at 700° and 800°C. Solvents are indicated beside the corresponding data (1). ● Data for CsCl solvent reported in this paper. Values of $E°$ are calculated values as described in the text.

1.045V. The calculated least-squares slopes for the five low concentration data points are -0.096 at 700°C and -0.104 at 800°C which may be compared with the corresponding Nernst values of b, 0.097 and 0.106. Average deviations of the six low concentration data points from the lines as drawn in Fig. 3 are 2.3 mV and 3.5 mV at 700° and 800°C, respectively.

The thermodynamic functions for the cell reaction

$$Ni(c) + Cl_2(g) \rightarrow NiCl_2 \text{ (in liq soln at conc N)} \quad [5]$$

have been calculated on the basis of the Nernst equation and the following definitions and equations

$$\lim_{N \to 1} a/N = 1 \quad [6]$$

$$a = N\gamma \quad [7]$$

where a and γ refer to the activity and activity coefficient of the solute, $NiCl_2$. The standard and reference states of the solute are the pure liquid with the properties of the pure liquid at the temperature of the experiment. The partial molar Gibbs energy of mixing and the partial molar enthalpy and entropy of mixing are given by

$$\overline{G} = -n\mathbf{F}E - \Delta G^\circ \quad [8]$$

$$\overline{H} = \Delta H - \Delta H^\circ \quad [9]$$

$$\overline{S} = n\mathbf{F}\,(\partial E/\partial T)_p - \Delta S^\circ \quad [10]$$

where ΔG°, ΔH°, and ΔS° are the standard changes for reaction [5]. The excess Gibbs energy of mixing, $\overline{G}^E$, is given by

$$\overline{G}^E = \overline{G} - RT \ln N = RT \ln \gamma \quad [11]$$

Equations describing the temperature dependence of ΔG°, ΔH°, and ΔS°, calculated from the tables of Wicks and Block (6) and Kubaschewsky and Evans (7) were reported previously (1) and have been used here.

The curves of Fig. 3 have been extrapolated to $N = 1$, to give a value of E°, by using the calculated values of ΔG° at 700° and 800°C, -33.6 kcal and -31.6 kcal, respectively, and by utilizing Raoult's law to predict a limiting slope as $N \rightarrow 1$. Values for $\Delta S = n\mathbf{F}\,(\partial E/\partial T)_p$ for reaction [5] were calculated from the slopes of the lines shown in Fig. 2 and, therefore, represent average values over the temperature range from 650° to 850°C. The uncertainty involved in the determination of the slopes is estimated to be 5×10^{-5} V/K.

Emf values were read at selected concentrations from the curves for CsCl solvent, Fig. 3, and used to calculate the functions given in Table I. Values of $\overline{S}$ and $\overline{H}$ in the table were calculated from smoothed values of ΔS based on graphs of ΔS *vs.* $\log N$ and the values of ΔS° and ΔH° mentioned above; scatter of the data for ΔS indicating an uncertainty of at least ± 2 cal/K in this quantity is in agreement with the estimated uncertainty in the values of the slopes $(\partial E/\partial T)_p$ from Fig. 1. Values of $\overline{S}$ and $\overline{H}$ were not included in the table for concentrations above $N = 0.15$ because the experimental values of ΔS as determined from the slopes of the lines of Fig. 2 were larger in magnitude than ΔS°.

Discussion

Because γ is observed to be independent of N at low N over a range of temperatures it follows from the Nernst equation that the partial molar entropy of mixing, $\overline{S}$, will follow

$$\overline{S} = \Delta S - \Delta S^\circ = -R \ln N + \text{constant} \quad [12]$$

at low values of N. At higher values of N the variation of $\overline{S}$ with concentration may be predicted on the basis of various microstate models of the liquid (1, 2); however, the present data are insufficiently accurate to make useful comparisons between observed and calculated values.

Combining Eq. [8] and [11], one obtains

$$\overline{G}^E = -n\mathbf{F}E - \Delta G^\circ - RT \ln N \quad [13]$$

from which one may calculate $\overline{G}^E$. Utilizing Eq. [13] one may deduce the order of variation of the magnitude of $\overline{G}^E$ for $NiCl_2$ with solvent cation at constant N from Fig. 3. The observed order CsCl > KCl > NaCl – KCl > NaCl > LiCl follows the well-established pattern which is commonly explained on the basis of competition for anions between solute and solvent cations (8). However, the observed magnitude of the change in $\overline{G}^E$ in going from KCl to CsCl is smaller than one might have predicted on the basis of the linear relationship which exists in the Henry's law region between $\overline{G}^E$ and the hexicoordinate radii (5) of solvent cations in LiCl, NaCl, and KCl.

It is interesting to note that the color of the solid resulting from solidification of the CsCl-$NiCl_2$ melt is quite different from that observed for $NiCl_2$ in the other alkali halides. At $N \cong 0.1$ the solidified mixtures with LiCl, NaCl, and KCl are brown to reddish brown whereas with CsCl the solid is a light blue.

Molten Alkali Treatment of Alumina Surfaces for Bonding to Electroless Copper

G. V. Elmore* and R. F. Hershberger

System Products Division, IBM Corporation, Endicott, New York 13760

The plating of copper upon a sintered Al_2O_3 ceramic substrate is a process of considerable usefulness to the printed circuit industry. Copper plating can be accomplished by covering the Al_2O_3 with electroless copper and electroplating to the desired thickness. However, the resulting bond of the copper to the untreated Al_2O_3 is weak. The use of boiling acids, such as orthophosphoric has been advocated by Stalnecker (1) to improve the bond. Hydrofluoric acid has also been used in ceramics containing silica for improved adhesion (2). This investigation was undertaken to develop a satisfactory method of achieving an improved bond over that previously attained. A comparison of the molten alkali treatment with various other treatments has been made by Ameen, McBride, and Philips (3).

Test Procedures

A pull test was used as a method of measuring the bond between the copper and alumina. The treated alumina was sensitized with $SnCl_2$ solution, activated with $PdCl_2$ solution, plated with electroless copper, and plated to 1.3 mils of copper with copper pyrophosphate plating solution. A 150 mil-diameter copper dot was etched upon the surface using photoresist techniques. To this dot was soldered a 150 mil-diameter brass stud. The stud was first immersed in molten solder and placed upon the fluxed Cu dot while the Al_2O_3 substrate was heated above the solder melting point. After cooling, this was then placed in a special fixture designed to assure a direct vertical pull. The setup was placed in an Instron tester, and the stud was pulled until a fracture occurred.

Experimental Procedure

The alumina used for most of the experiments was a 96% Al_2O_3 with 4% glass binder, commercially obtained. The treatment process consists of etching the Al_2O_3 surface with molten alkali which attacks the glass binder and the Al_2O_3. Of the three common alkali hydroxides (KOH, NaOH, and LiOH), NaOH has the lowest melting point (328°C) and was chosen for investigation. The Al_2O_3 modules were first cleaned by treatment in an alkaline solution, rinsed, and then dipped in a concentrated solution of NaOH in water. The modules were placed on a stainless steel screen, and dried. Then, the alkali was melted by placing the modules, while on a stainless steel screen, in an oven at 450°C for 15 min. After cooling, the modules were rinsed with water, dipped in sulfuric acid solution, rinsed, and dried. The modules were placed on a screen during melting to prevent modules from sticking together. The modules were then sensitized, activated, plated, and a 150 mil diameter dot etched on the surface.

Results

Pull tests were performed on 17 modules treated according to the above procedure. The pull on the 150 mil dots etched in the copper, varied from 43 to 88 lb with an average value of 68 lb. These results can be compared with pull values of 20 to 25 lb on an untreated module.

In addition, other tests were performed at lower temperatures. For these experiments a eutectic mixture of 60% KOH and 40% NaOH was used; this mixture melts at 167°C. Nine modules were precleaned then dipped in a solution consisting of 330g KOH, 200g NaOH, and 400 ml of water. The modules were heated at 170°C for 15 min, rinsed treated with sulfuric acid solution, rinsed, and dried. Pull test on 150 mil dots varied from 23 to 57 lb, with an average value of 38 lb.

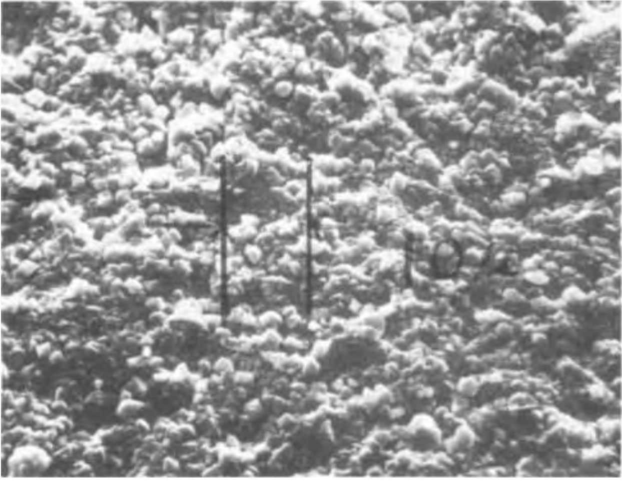

Fig. 4. Treated surface of the sintered Al_2O_3 (1200X)

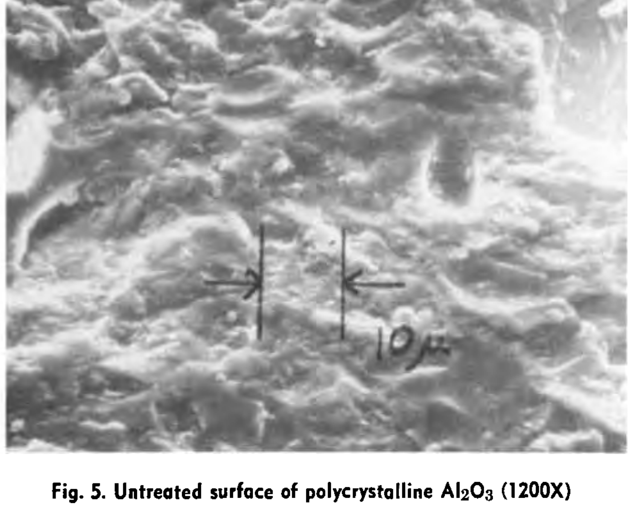

Fig. 5. Untreated surface of polycrystalline Al_2O_3 (1200X)

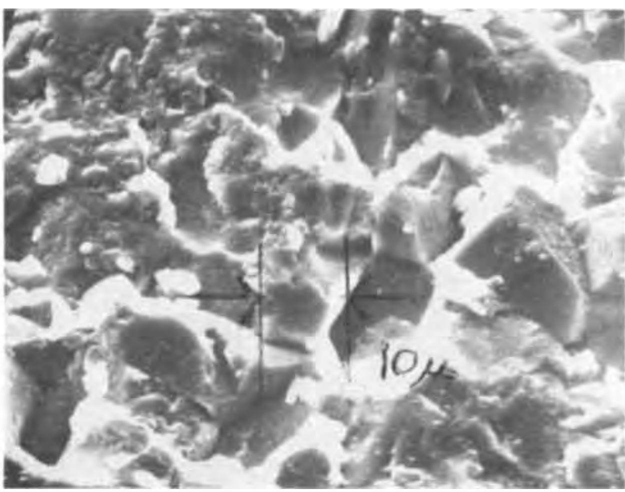

Fig. 6. Treated surface of polycrystalline Al_2O_3 (1200X)

Scanning electron microscope (SEM) photographs were taken of the Al_2O_3 surfaces before and after treatment at 450°C. Figure 1 shows the untreated surface at 2400X while Fig. 2 shows the treated surface at 2400X. The micropits caused by the molten NaOH are quite evident in Fig. 2. Figure 3 shows the untreated surface of 96% Al_2O_3, 4% binder from a different source at 1200X, and the treated surface at 1200X is shown in Fig. 4. A sample of polycrystalline Al_2O_3 is shown before treatment in Fig. 5 at 1200X and the treated surface at 1200X is shown in Fig. 6. The attack on the polycrystalline material indicates that the Al_2O_3 itself is the material whose etching causes the bondable surface formation.

Conclusions

All the Al_2O_3 samples indicate the molten NaOH at 450°C attacks the Al_2O_3 surface creating a pitted surface which greatly improves the mechanical interlocking of the electroless copper to the Al_2O_3 surface. The treatment at 450°C using NaOH proved to be better than treatment at lower temperatures using a eutectic mixture of NaOH and KOH.

Green Direct Current Electroluminescence from Lead-Doped Zinc Sulfide Powder Phosphors

M. S. Waite and A. Vecht*

School of Materials Science and Physics, Thames Polytechnic, London, England

ABSTRACT

Green emission (500 nm) under d-c field excitation has been observed with lead-doped ZnS powder phosphor layers, about 100 microns thick, at external applied voltages of 100V and current densities up to 10 mA cm^{-2}. The conditions found to favor this emission are a high residual lead concentration, preferably greater than 10^{-4} g-atoms per mole ZnS, and absence of copper and chlorine from the bulk of the crystal. The maximum power efficiency obtained so far is about 10^{-5} at room temperature, increasing to 10^{-3} at 77°K, the room temperature efficiency of ZnS:Mn,Cu phosphors. The origin of the green emission was sought from the luminescent spectra of undoped, copper-doped, and lead-doped zinc sulfide under d-c, a-c, and 365 nm (Hg) excitation at both room temperature and 77°K. Although copper centers may be introduced during the "forming" process the spectral evidence suggests that the DCEL emission at 500 nm is from divalent lead adjacent to substitutional oxygen in the ZnS lattice.

The practical applications of direct current electroluminescence (DCEL) in II-VI powder phosphors are at present restricted to the properties of ZnS:Mn, Cu phosphors, which emit broad band yellow light with a power efficiency up to 10^{-3} (1,2). In an attempt to extend the range of emission colors substitution for Mn by various dopants is being investigated, and in connection with this program the effect of incorporating rare earth ions has already been reported (2,3). It was found that blue, green, and orange emission could be obtained from the appropriate rare earth ion dopant but with a low efficiency under d-c excitation of 10^{-6}-10^{-5}. This means that under practical operating conditions the brightness of each of these devices would be less than 5 ft-L. The lower efficiency of rare earth-doped phosphors compared with manganese-doped phosphors may be partly due to the limited solubility of rare earth ions in zinc sulfide (4). Consequently other classes of dopants have been tested, including some elements which have been used in a-c electroluminescent phosphors. In particular we have re-examined lead-doped phosphors, preparing d-c electroluminescent phosphors and devices by the methods previously established for manganese and rare earth-doped phosphors.

Lead, with copper and chlorine, has been used in the preparation of blue and green a-c phosphors, where it was added in small amounts to improve the emission from the copper centers (5,6). However, the quantity of lead remaining after firing was reported to be less than 10^{-4} g-atoms per mole ZnS, and it does not seem to have been used as the principal or sole activator in practical electroluminescent systems although it is known to give green photoluminescence in zinc sulfide (7-11). The green emission is centered at 490-505 nm, dependent on the crystal structure, and has been interpreted by Uehara as due to a localized transition between excited and ground states of divalent lead at zinc lattice sites. By analogy with excitation processes in ZnS:Mn phosphors there is a possibility that green-emitting DCEL phosphors can be made from lead-doped zinc sulfide since in the methods developed for Mn-doped phosphors deliberate addition of copper is not essential, unlike the case for a-c electroluminescence.

Phosphors have therefore been prepared with a wide range of lead concentrations, and at the higher concentrations, greater than 10^{-4} g-atoms per mole ZnS, green DCEL emission was found. Both the spectral distribution and efficiency of the emission are dependent on the lead concentration as will be shown below and the nature of the emission process is discussed as far as the present results allow.

Experimental

Phosphor preparation.—Halogen free zinc sulfide was used to prepare the phosphors, which were doped with lead by firing with lead carbonate in air or nitrogen at 850°-1000°C. Copper and chlorine were incorporated where needed by slurrying with cupric and sodium chloride solutions, respectively. After firing surface oxides were removed by treatment with hot, concentrated acetic acid. Table I indicates the formu-

Table I. Formulation and firing conditions of lead-doped phosphors

Phosphor	Preparative conditions	Lead concentration (g-atoms per mole ZnS)
ZnS:Pb (10^{-3})	Fired in N_2 at 850°C, 12%, w/w, NaCl	10^{-5}
ZnS:Pb (5×10^{-3})	Fired in N_2 at 850°C, 12%, w/w, NaCl	8×10^{-5}
ZnS:Pb (1.5×10^{-2})	Fired in N_2 at 850°C, no flux	1.3×10^{-5}
ZnS:Pb (4×10^{-2})	Fired in N_2 at 850°C, no flux	4.7×10^{-3}
ZnS:Pb (4×10^{-2})	Fired in N_2 at 850°C, 3%, w/w, NaCl	8×10^{-4}
ZnS:Pb (6×10^{-2})	Fired in N_2 at 900°C, no flux	2×10^{-4}
ZnS:Pb (6×10^{-2})	Fired in air at 950°C, no flux	10^{-2}

* Electrochemical Society Active Member.

Key words: direct current electroluminescence, lead doped ZnS, powder cells.

lation and typical firing conditions used for the principal phosphors examined.

The residual lead concentration of several phosphors with different initial lead levels was estimated by dissolving the powder in 6M HCl and measuring the absorbance of the chloro-lead complex at 270 nm (12). A reproducibility generally better than 5% was found with this simple method and although interference from cuprous ions is possible there was no spectroscopic evidence for the presence of these ions (Table I).

Preparation of electroluminescent panels.—The phosphors were made into electroluminescent devices ("panels") by the methods already evolved for Mn-doped phosphors. This procedure has already been described in detail (1,2) and involves the following stages. Firstly, the phosphor particles are coated with a conducting copper-rich phase, and then, with the aid of an organic binder, spread as a thin layer (approximately 100μ thick) on a conducting glass surface. This surface provides the positive electrode, while the negative electrode is obtained by evaporating an aluminum film onto the phosphor layer. The cells are then encapsulated with a desiccant. In the final stage, the "forming" process, a gradually increasing d-c field is applied. The current through the cell rises with the voltage until, at about 20 to 30V, the current drops sharply and light emission begins. Earlier work established that diffusion of copper from the copper-rich surface to the bulk of the phosphor particle takes place during forming and operation, and therefore copper centers may be present even in those phosphors prepared without deliberate addition of copper (2).

Copper-coated ZnS:Pb phosphors show a similiar forming behavior to that of ZnS:Mn phosphors, but when silver sulfide was tried as a surface coating no forming process and no light emission could be obtained. Consequently it was not possible to eliminate copper centers arising from the copper coating.

Evaluation of spectra and brightness.—Photo and electroluminescent spectra were analyzed with a Hilger and Watts D330 monochromator, equipped with a Bausch and Lomb 600 lines per mm grating operated in second order, and a EMI 9558 photomultiplier. A similiar photomultiplier was used for the photometric determinations.

Results and Discussion

Visible emission was obtained from all the phosphors listed in Table I but with considerable variation in spectral distribution and brightness, a variation that is related to the lead concentration.

Spectra.—The spectra and brightness both show a definite, if irregular, trend towards increased green emission with increase in lead concentration. This can be seen on comparing Fig. 1 and 2 and Tables I and III.

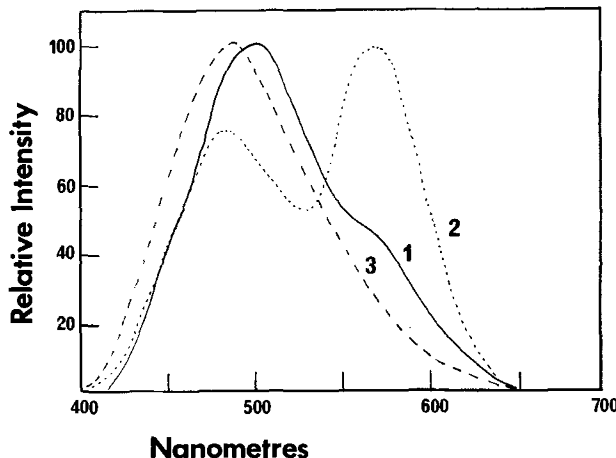

Fig. 2. DCEL spectra at room temperature. Curve 1, ZnS:Pb (4×10^{-2}); curve 2, ZnS:Pb (4×10^{-2}), 3%, w/w, NaCl flux; curve 3, ZnS:Pb (6×10^{-2}).

The electroluminescent spectra of phosphors with low concentrations of lead are illustrated in Fig. 1 and the spectra of heavily doped phosphors in Fig. 2. When the lead concentration is low, the most prominent emission band is at 575 nm with minor, indistinct bands in the blue-green region. The over-all emission is weak and in several cases a voltage greater than 150V had to be applied to obtain spectra. It was noticed that the blue-green bands showed a greater increase in intensity with voltage than did the band at 575 nm. Thus over the range 80-180V at least the spectral emission is slightly voltage dependent. Since the level of lead in these phosphors is very low it is interesting to compare the electroluminescent spectra with those of undoped but copper-coated zinc sulfide and zinc sulfide doped with copper (Fig. 3 and 4). At room temperature the DCEL emission of undoped zinc sulfide (Fig. 3) is very similiar to the spectra in Fig. 1. This suggests that at low lead concentrations, below approximately 10^{-4} g-atoms per mole ZnS, the presence of lead does not affect the spectral distribution of the emission which may be associated with copper, oxygen, or defect centers (13) in the material or may be due to Mn contamination. If undoped ZnS is fired in an atmosphere of H_2S, the resulting DCEL spectrum is identical to that of ZnS fired in N_2 or air, *i.e.*, the major emission band is at 575 nm, although one would expect either a difference in the relative intensities of the different bands or a change in total intensity if oxygen centers are involved. Doping zinc sulfide with copper (5×10^{-4} to 10^{-3} g-atoms per mole) or copper and chlorine yields phosphors with the main DCEL emission bands in the blue-green region (Fig. 4), not

at 575 nm, suggesting that the blue-green bands seen in Fig. 1 are due to copper diffusing from the copper coating or to that copper deliberately added with lead. The 575 nm band appears consistently in phosphors with a low dopant level but is reduced in absolute and relative intensity by the presence of copper and if Mn contamination was responsible for this peak one would expect it even in the presence of copper. The band at 575 nm cannot therefore be readily explained on the present evidence but the origin may lie with a suggestion made recently by one of us (13) that this band is due to a transition involving one or more defect centers.

As the proportion of lead is increased a band at about 500 nm becomes the major feature in the electroluminescent spectra, (Fig. 2). It is reduced in intensity compared to the 575 nm band by the addition of sodium chloride flux which was therefore avoided during the preparation of the more heavily doped phosphors in order to produce a predominantly green emission. These phosphors, with an initial Pb concentration of 6 $\times$ 10^{-2} g-atoms per mole ZnS, gave relatively bright green electroluminescence with only a minor band at 575 nm, if at all. Firing in air seemed to give better results, *i.e.*, higher brightness, than firing in N_2 and this was adopted as standard practice.

There is an apparent similarity between the electroluminescent spectra of the heavily doped lead-doped phosphors and those of ZnS: Cu phosphors. At room temperature the latter have emission bands at 490-520 nm and this obviously raises the possibility that the green emission from the ZnS: Pb phosphors is due to the copper centers introduced from the copper coating and that this process is somehow facilitated by the presence of lead. However the addition of copper to green-emitting ZnS: Pb phosphors reduces the EL output and raises the current density to the point where the panel may burn out, about 80-100 mA cm^{-2}. A further test of the similarity between lead- and copper-doped phosphors was made by obtaining DCEL spectra at 77°K and the ACEL and photoluminescent spectra at both room temperature and 77°K (Fig. 3-6). The similarity shown by the room temperature DCEL spectra of ZnS: Pb and ZnS: Cu disappears at 77°K. For lead-doped phosphors the spectrum changes little between room temperature and 77°K, but in the case of ZnS: Cu phosphors the single peak seen at 510 nm at 300°K is resolved into two bands, at 455 nm and 510 nm. For both types of phosphor the ACEL spectra resemble the DCEL spectra, showing similar changes with temperature (Fig. 4 and 5). Finally the photoluminescent spectra of ZnS: Pb phosphors have been obtained under 365 nm Hg excitation and can be compared to the DCEL spectra. The peak maxima under uv excitation are close to the range of those found under d-c excitation and those found by pre-

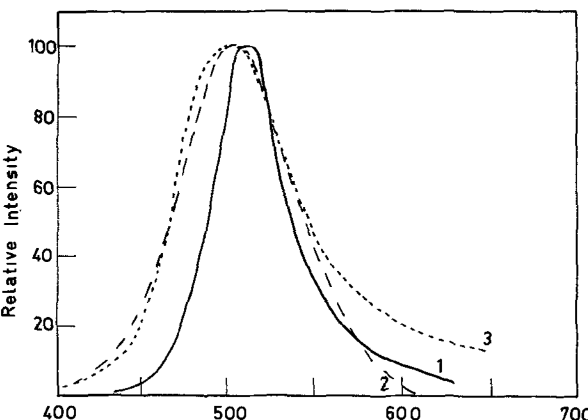

Fig. 6. 365 nm excitation. Curve 1, ZnS:Pb (6 x 10^{-2}), at 77°K; curve 2, ZnS:Pb (6 x 10^{-2}), at room temperature; curve 3, ZnS:Pb (5 x 10^{-2}), at room temperature, Uehara (11).

vious investigations of the ZnS: Pb system (7-11). In Table II the mean wavelengths of the peak maxima are listed for the various methods of excitation.

Brightness and efficiency.—The brightness of the band at 500 nm has been estimated for the lead-doped phosphors from the net photometric response and the spectral distribution, and can be found in Table III. At room temperature the brightness of the most efficient phosphor does not exceed 4 ft-L and the power efficiency is less than 10^{-5}. This is less by two orders of magnitude than the brightness of ZnS: Mn,Cu phosphors. However while measurements were being taken of the variation of brightness with voltage and current it was found that some of the lead-doped phosphors showed efficiencies at 77°K equal to that of the ZnS: Mn,Cu system at room temperature.

Variation of brightness with voltage and current.—The relationship between brightness and voltage for cells made as described above have been found to be of the following form for Mn-doped phosphors (2)

Table II. Peak maxima of luminescence for ZnS:Pb (6 x 10^{-2}) phosphors under various excitations

Excitation	Peak maxima, nm	
	Room temperature	77°K
d-c field	497 ± 7	497 ± 2
a-c field	497 ± 13	507 ± 3
365 nm (Hg)	501 ± 2 494 [Uehara (11) for ZnS:Pb (5 x 10^{-2}) phosphor] 490 [Fonda (7) ZnS:Pb,Cl] 485 (8)	504 ± 6

Table III.

Phosphor	Total brightness at 100V (ft-L)	Brightness of green band (ft-L)	Energy efficiency for green emission
$ZnS:Pb$ (10^{-3})	4×10^{-2}	5×10^{-3}	10^{-6}
$ZnS:Pb$ (5×10^{-3})	5×10^{-2}	10^{-2}	2×10^{-6}
$ZnS:Pb$ (1.5×10^{-2})	10^{-2}	10^{-3}	10^{-7}
$ZnS:Pb$ (4×10^{-2})	8×10^{-1}	7.5×10^{-1}	3×10^{-6}
$ZnS:Pb$ (4×10^{-2}) 3% w/w, NaCl	2.5×10^{-1}	6×10^{-2}	4×10^{-7}
$ZnS:Pb$ (6×10^{-2}) fired in N_2	1.5 to 2	1.5 to 2	8×10^{-6}
$ZnS:Pb$ (6×10^{-2}) fired in air	1 to 4	1 to 4	6 to 8×10^{-6}

$$B \simeq A \exp(-bV^{-1/2})$$

where B is the luminance, V is the applied voltage, and A and b are constants.

A similar relationship has been looked for in Fig. 7 for green-emitting ZnS:Pb phosphors where the brightness is plotted on a logarithmic scale against $V^{-1/2}$. A fairly linear plot can be seen in the samples shown in Fig. 7 which were all encapsulated panels operated at room temperature. For comparison manganese- and rare earth-doped phosphors are also plotted. Linear plots are also found for the 575 nm band of undoped zinc sulfide (not included on the figure). The slope of such plots has, in the case of a-c electroluminescence, been related to the energy of excitation of the center responsible for the emission in various phosphors (14) and it is interesting to note therefore that although the slope is different for each type of phosphor in Fig. 7, it does not seem to be related to the emission energy, Table IVa. In the case of Mn-doped phosphors two intersecting straight lines could be drawn, in agreement with as yet unpublished observations on many examples of this type of phosphor (15).

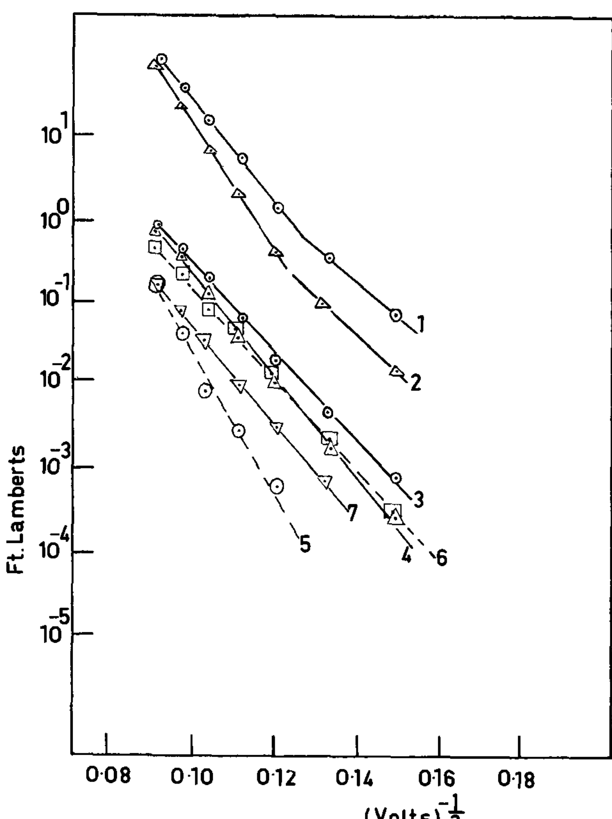

Fig. 7. Brightness vs. voltage of encapsulated panels at room temperature. Curve 1, ZnS:Mn,Cu; curve 2, ZnS:Mn; curve 3, ZnS:Pb, (6×10^{-2}), fired in air; curve 4, ZnS:Pb, (6×10^{-2}), fired in N_2; curve 5, ZnS:Cu; curve 6, ZnS:Er,Li; curve 7, ZnS:Nd,Na.

Table IV. Numerical values of brightness/voltage constants, b

a. Encapsulated panels at room temperature

Phosphor	b ($\mathrm{Volts}^{1/2}$)	eV corresponding to emission band
ZnS:Mn,Cu (1)*	145 ± 5 (55V)	2.16
ZnS:Mn (2)	175 ± 5 (60V)	2.16
ZnS:Cu (5)	177 ± 5	2.45 ± 0.05
ZnS:Pb (6×10^{-2}) (3)	137 ± 10	2.5 ± 0.1
ZnS:Er,Li (6)	134 ± 10	2.32
ZnS:Nd,Na (7)	130 ± 10	2.0

b. Unencapsulated panels

Phosphor	b ($\mathrm{Volts}^{1/2}$) 300°K	b ($\mathrm{Volts}^{1/2}$) 70°K	Ratio of efficiencies 77°K / 300°K
ZnS:Mn,Cu	89	118 ± 10	1 to 10
ZnS:Mn	107 ± 7	150 ± 10	
ZnS:Cu	182	177 ± 10	1.5
ZnS:Pb (6×10^{-2})	104 ± 10	185 ± 30	10 to 500

* Number in parentheses refers to the numbered plot in Fig. 7.

The brightness was also measured for unencapsulated panels before and after immersion in liquid nitrogen, and b values are given in Table IVb. Unencapsulated panels seem to have different b values from encapsulated panels but the most significant feature is the change in brightness and efficiency of the different phosphors with change in temperature. Whilst the brightness was lower at 77°K in the case of Mn-doped phosphors an increase was found for several lead panels made from ZnS:Pb (6×10^{-2}) phosphors. The difference in behavior of the two types of phosphor was even more marked on measuring the power efficiencies at room temperature and 77°K. The ratio of efficiencies at 77°K and room temperature (290°-300°K) is given in Table IVb and although a wide range of values was found, there is a clear difference between manganese- and lead-doped panels. The efficiency of several lead panels increased by two orders of magnitude on reducing the ambient temperature to 77°K and they became comparable in efficiency and brightness to ZnS:Mn,Cu phosphors at that temperature, and one sample of a ZnS:Pb phosphor was as efficient at 77°K as the manganese-doped phosphors at room temperature (10^{-3}).

Current densities at room temperature for the lead-doped panels are very similar to those of Mn-doped panels made by the same technique, that is of the order 10^{-1} to 10 mA cm^{-2} at 100V. The current density falls to the range 10^{-4} to 10^{-2} mA cm^{-2} at 77°K and a similar decrease was also noted for Mn-doped phosphors. Thus the difference in the temperature dependence of the efficiencies of Mn- and Pb-doped phosphors may be due to greater thermal quenching of the active centers in the latter case.

Origin of the green emission.—In order to improve the room temperature efficiency of the green emission of the lead phosphors it would be useful to identify the active radiating centers involved. A connection between these centers and the amount of lead present is clear from the dependence of the brightness on the level of residual lead (Table III). Furthermore the spectral evidence suggests that the centers responsible for both a-c and d-c electroluminescence are also responsible for the photoluminescence, so that the conclusions of previous investigations on the photoluminescence of lead-doped zinc sulfide are pertinent.

The most comprehensive investigation to date is that of Uehara (11) which followed the earlier work of, particularly, Fonda (7), Smit and Kroger (8), and Voev (9). The relevant conclusions are that: (*i*) green emission is found for lead phosphors prepared in the presence of oxygen or halogen, (*ii*) the solubility of Pb in ZnS is 5×10^{-5} g-atoms per mole (9), and (*iii*) the emission band is centered at 490 nm in wurtzite and 500 nm in zinc blende and is attributed by Uehara

to the transition $^3P_2$-$^1S_0$ of Pb^2 at zinc sites with oxygen or chlorine substituting for sulfur in adjacent sites.

Thus the EL brightness of ZnS:Pb phosphors should be increased by increasing the effective concentration of these centers, but a limit may have been reached already with an initial lead concentration of 6×10^{-2} g-atoms per mole ZnS since this was found to correspond to a residual lead concentration of about 10^{-2} under the firing conditions used and this level is far greater than the limit of dissolved Pb in ZnS as found by Voev (9). Separate PbS and PbO phases must therefore be present and it was found that increasing the initial lead concentration beyond the level stated above results in a dark colored and rather sintered powder with low DCEL efficiency.

In ZnS:Mn,Cu phosphors an efficiency of 10^{-3} has proved adequate for practical use in electroluminescent displays, and this level can be reached by ZnS:Pb phosphors at 77°K. Since the behavior of the current density at low temperatures is, qualitatively, similar in both types of phosphor then either the excitation efficiency of the Pb center is more temperature sensitive or the radiationless transitions are greater in the case of the lead-doped phosphors. The evidence gathered does not yet indicate which is the temperature sensitive step or steps.

Acknowledgments

We would like to thank all our colleagues for their help, particularly R. Ellis and Miss R. Hayes in the preparative work and N.J. Werring for making available equipment for photometric and electrical measurements. We acknowledge the support of the Ministry of Defence and are grateful for their permission to publish this work.

Oxidation of $GaAs_{1-x}P_x$ Surface by Oxygen Plasma and Properties of Oxide Film

Takuo Sugano and Yoshifumi Mori

Department of Electronic Engineering, University of Tokyo, 7-3-1 Hongo, Bunkyo-ku, Tokyo 113, Japan

ABSTRACT

This paper presents a new technology for oxidizing a $GaAs_{1-x}P_x$ ($x = 0 \sim 1$) surface by oxygen plasma, produced by high-frequency discharge in oxygen, whose pressure is of the order of about 0.1 ~ 1.0 Torr. Growth rate of the oxide film is remarkably high, and can be controlled by the oxygen gas pressure and the high-frequency field over a range of 50 Å/sec to 1 μ/sec. The plasma-oxidized fims have complex composition, including polycrystalline β-Ga_2O_3, $GaAsO_4$, and $GaPO_4$. The refractive index of these fims measured by ellipsometry reveals a dependence on the substrate material and on film thickness, and also distribution in the film, so that the refractive index changes from a value, corresponding to β-Ga_2O_3 at the top surface, to the value approximately equal to that of the substrate material at the oxide-substrate interface. Such distribution of the refractive index is useful for attaining optical isolation in monolithic optical integrated circuits. Furthermore, this technique has various applications, such as the surface passivation of $GaAs_{1-x}P_x$ devices and dielectric isolation in GaAs integrated circuits, fabricated on a semi-insulating substrate.

To attain surface passivation of compound semiconductor devices and fabrication of insulated gate field effect transistors using a compound semiconductor, insulator-compound semiconductor systems offer practical interest. However III-V compound semiconductors such as GaAs have a high equilibrium vapor pressure and are easily decomposed at high temperature, which is common to thermal oxidation or chemical vapor deposition, rendering poor results (1-4) and recognizing the necessity for low-temperature processes. Low-temperature chemical vapor deposition, deposition by glow discharge, and sputtering are examples of anticipated low-temperature processes; however, successful results have not yet been obtained. This paper presents a new technique for forming an insulating film on $GaAs_{1-x}P_x$ ($x = 0 \sim 1$) wafers. That is, oxidation by plasma, produced by high-frequency discharge in low-pressure oxygen gas. Characteristics of this tech-

Key words: oxide, gallium arsenide phosphide, plasma, surface passivation.

nique, properties of oxide films, and application are described herein.

Oxidation

Plasma oxidation apparatus.—Oxygen plasma was generated in the apparatus shown in Fig. 1, a commercial pumping station with slight modifications. A fused quartz cap (diameter 6.0 cm and length 30.0 cm) is placed on the top of a bell jar (diameter 30.0 cm). Oxygen was supplied through a needle valve from a bottle. A 420 kHz, high-frequency field was applied through the 9-turn coil, surrounding the cap. $GaAs_{1-x}P_x$ substrate, supported by an alumina or fused quartz rod, was inserted into the middle of the plasma, electrically isolating the substrate from the earth.

Oxidation rate.—The oxidation rate was strongly dependent on the plasma condition. Figure 2 indicates the relation of output of an Alumel-Chromel thermocouple inserted into the plasma at the pressure of oxygen gas, measured by a Pirani gauge and the anode voltage of the high-frequency oscillator, whose maximum output was rated at 15 kW. By raising the anode voltage, glow discharge (whose temperature measured by the thermocouple was between 150° and 200°C) started initially. The glow discharge produced no appreciable oxide film on the substrates. However, in the bright discharge which we called oxygen plasma, very rapid oxidation occurred. Examples of the oxidation rate are shown in Fig. 3(a), (b), and (c), showing the initial delay of oxidation, perhaps due to delay of the substrate temperature, and the saturation tendency with time. In rather high-pressure plasma, the oxidation rate is extremely high, reaching 1 μ/sec, but in low-pressure plasma, it is moderate, at 50 Å/sec. It was determined from these results that the oxidation rate can be controlled by adjusting the oxygen gas pressure and the anode voltage of the high-frequency oscillator. For dependence of the oxidation rate on surface orientation of the substrates, no appreciable difference is evident except for an extremely thin film.

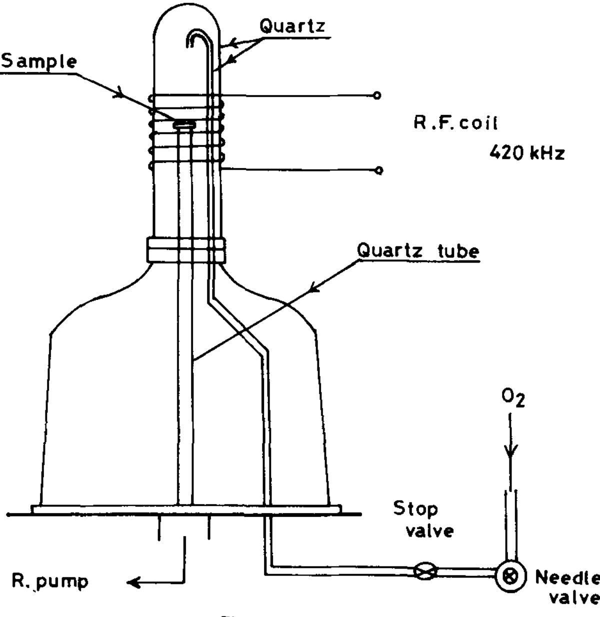

Fig. 1. Apparatus

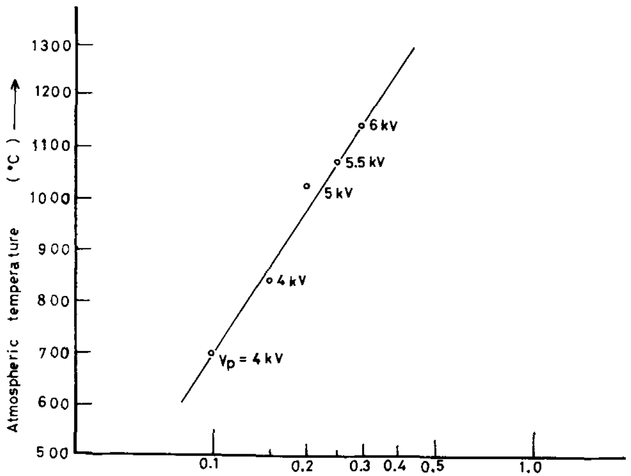

Fig. 2. Atmospheric temperature by thermocouple measurement

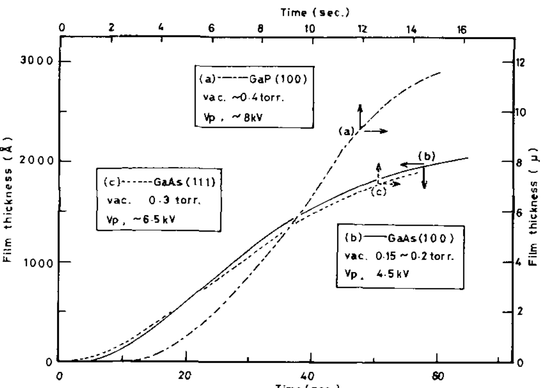

Fig. 3. Oxidation rate

Masking by Al film.—Evaporated Al film thicker than 5000Å was effective in preventing oxidation, rendering it useful as a mask for selective oxidation. Effect of the window opening of the Al mask on oxide thickness is illustrated in Fig. 4. For a window whose opening is 10μ, the oxide thickness is decreased by about 10%.

Properties of Oxide Films

Chemical properties.—Oxide films grown on GaAs substrates are quite stable and practically insoluble in various acids and alkalis. Boiling in HCl acid etched them at the rate of 50 ~ 80 Å/min. On the other hand, oxide films grown on $GaAs_{0.6}P_{0.4}$ and GaP were easily soluble in acids and alkalis. The etch rate in 5% HF was 500 ~ 1000 Å/min.

Electrical properties.—Electrical properties of oxide films were evaluated by the current-voltage characteristics of MOS structures. A typical I-V characteristic of a GaAs MOS diode possessing oxide film (3.5μ thick) and an Al electrode (1 mm diameter) is shown in Fig. 5. Region (1) in Fig. 5 can be explained by the Poole-Frenkel mechanism, assuming the dielectric constant of the oxide as 4; region (2) can be attributed to Schottky emission, assuming the dielectric constant as 5.2.

Roughly speaking, resistivity of the oxides ranged from 10^8 to 10^{10} ohm-cm.

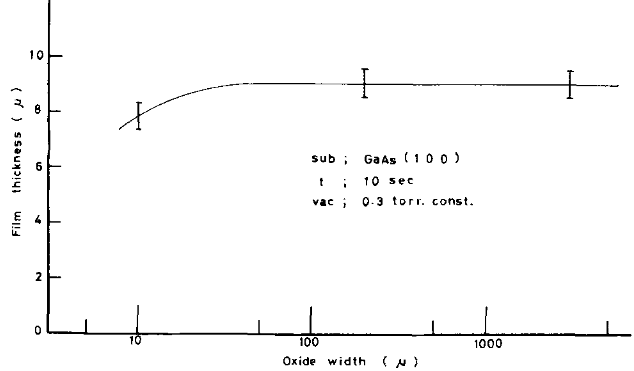

Fig. 4. Effect of window opening of Al mask on oxide thickness

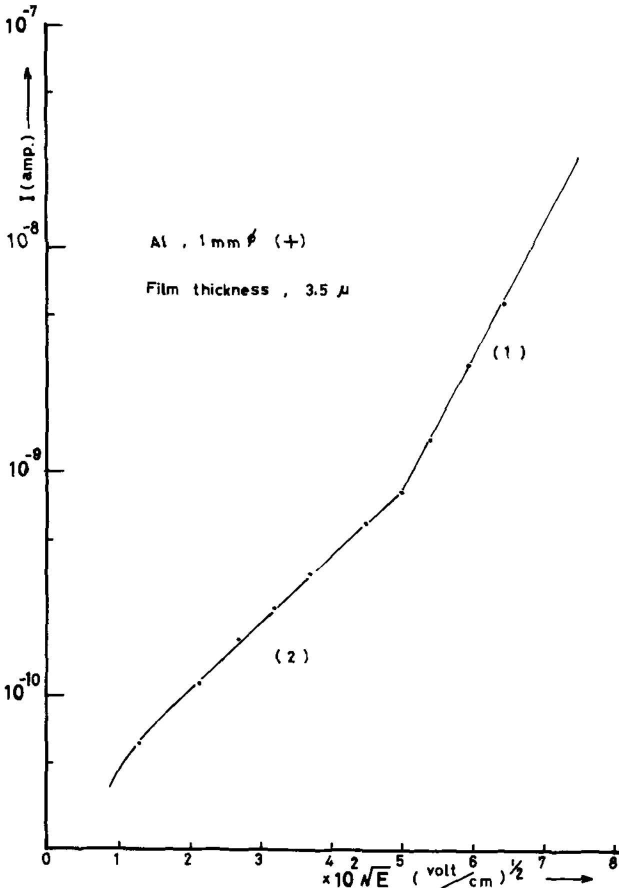

Fig. 5. Typical I-V characteristics of GaAs MOS diode

Optical properties.—The average refractive index of the oxide films was measured by split-beam ellipsometry, using a monochromatic light source of 5461Å wavelength with the angle of incidence maintained constant at 70°. Optical constants of GaAs, $GaAs_{0.6}P_{0.4}$, and GaP at λ = 5461Å, assumed for calculation of the ellipsometric chart, are (5) (6)

$n_{GaAs} = 3.923$, $k_{GaAs} = 0.304$
$n_{GaAs0.6P0.4} = 3.840$, $k_{GaAs0.6P0.4} = 0.100$
$n_{GaP} = 3.565$, $k_{GaP} = 0.000069$

As shown in Fig. 6, oxide films with different thicknesses have a different average refractive index. Curve A in Fig. 6 shows the refractive index for the films on GaAs. Curve B shows that of $GaAs_{0.6}P_{0.4}$, and curve C shows that of GaP. The average refractive index of oxide films on GaAs and $GaAs_{0.6}P_{0.4}$, indicated by the

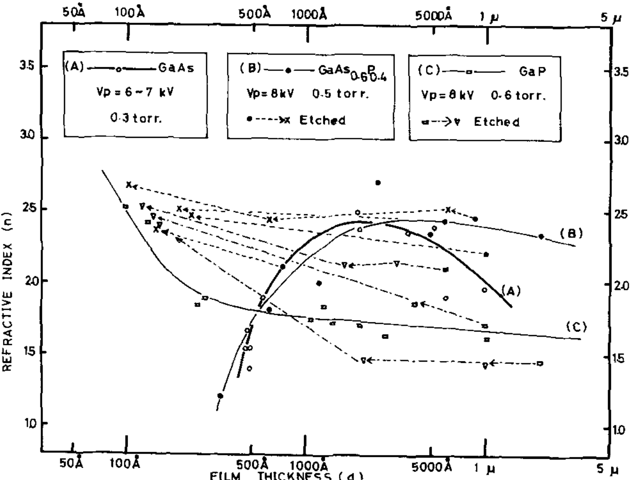

Fig. 6. Ellipsometric investigation of oxide films on $GaAs_{1-x}P_x$

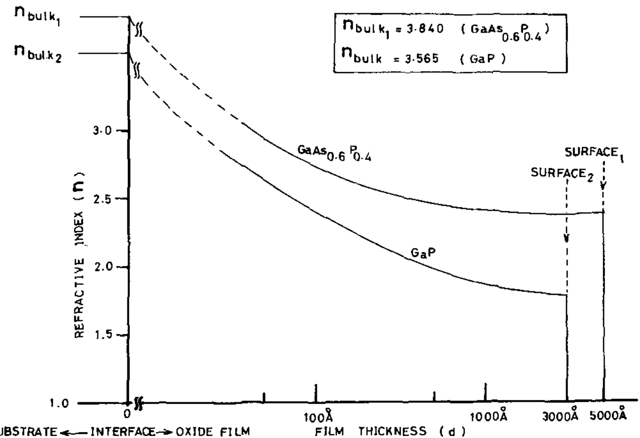

Fig. 7. Estimated distribution of refractive index through oxide films.

thick, solid-line curve, has a peak value of about 2.5, whereas that of GaP does not.

These results imply that the oxide films lack uniform composition, and the difference of these relations of the substrate material seems to be due to the varying vapor pressure of arsenic and phosphor. To determine distribution of the refractive index perpendicular to the surface of films on $GaAs_{0.6}P_{0.4}$ and on GaP, the oxide was step-etched by 5% HF acid. After each etching, the average refractive index of the remaining film was measured by ellipsometry. The results are indicated by the broken-line curves in Fig. 6.

Based on the above results, distribution of refractive index through the oxide films on $GaAs_{0.6}P_{0.4}$ and GaP can be estimated as shown in Fig. 7.

Structural properties.—Electron beam diffraction patterns also reveal the complex structure of those oxide films.

A few of the electron diffraction patterns are shown in Fig. 8.

Table I summarizes the results obtained for some of the oxide films, which can be related to the optical properties.

In the first stage of oxidation corresponding to a film thickness less than about 1000Å, the oxide films on GaAs and $GaAs_{0.6}P_{0.4}$ are mostly composed of polycrystalline β-Ga_2O_3. This suggests that arsenic is almost completely vaporized from the GaAs and $GaAs_{0.6}P_{0.4}$ surface during oxidation.

The thicker the oxide film becomes, the less the arsenic becomes vaporized. This results in an increase of the average refractive index with the oxide thickness. The thin oxide film on GaP is mostly composed of polycrystalline β-Ga_2O_3; however, the 1000Å-thick film on GaP includes more $GaPO_4$ than $GaAsO_4$ included on GaAs. The refractive index decreases with oxide thickness. This implies that an accumulation of phosphor occurs at the interface, even during the early stage of oxidation, caused by the vapor pressure of phosphor being lower than that of arsenic.

For the second stage of oxidation, corresponding to a film thickness ranging from about 1000Å to 1μ, composition of the oxide films on GaAs and $GaAs_{0.6}P_{0.4}$ are a mixture of polycrystalline β-Ga_2O_3 and $GaAsO_4$ or $GaPO_4$. The average refractive index becomes maximum at a thickness in this region. This suggests that less arsenic is vaporized in this oxidation stage, caused by a masking effect of the previously formed β-Ga_2O_3 film. The oxide film on GaP thicker than 2000Å is composed of polycrystalline $GaPO_4$, and the average refractive index also approaches the value of bulk $GaPO_4$.

For the final stage of oxidation, corresponding to film thickness beyond 1μ, composition of the oxide on

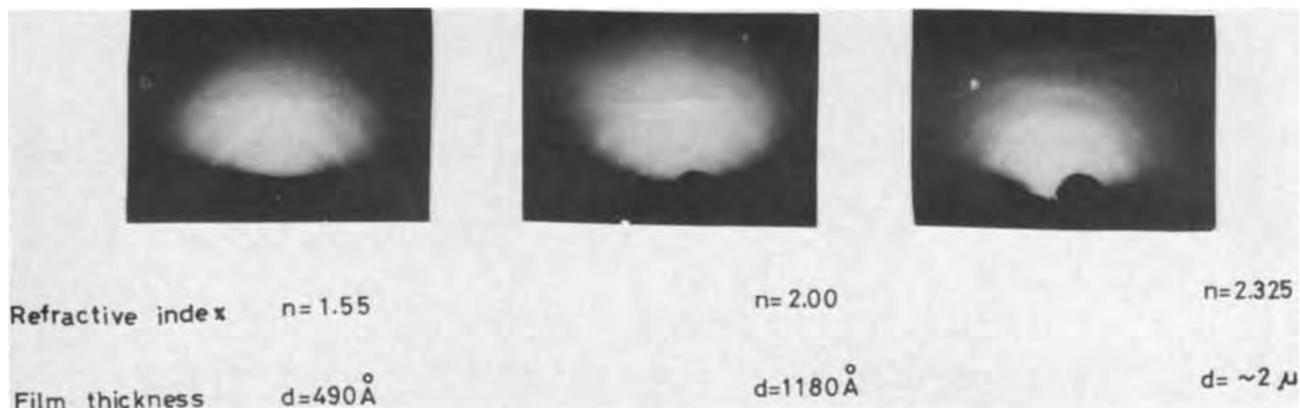

Fig. 8. Electron diffraction patterns of $GaAs_{0.6}P_{0.4}$

GaAs and $GaAs_{0.6}P_{0.4}$ is orientated polycrystalline $GaAsO_4$ and a mixture of $GaAsO_4$ and $GaPO_4$, respectively. In the case of GaAs oxidation, a change of composition of the oxide as a function of time and a distribution of composition as a function of depth is schematically indicated in Fig. 9. Chemical stability of the oxide films on GaAs is much better than that of $GaAs_{0.6}P_{0.4}$ and GaP. This is also related to the structural properties of each oxide film, based on the fact that oxide on GaAs includes much β-Ga_2O_3 which is chemically stable.

In any case, annealing at 300°C for 60 min in oxygen renders the oxide structure amorphous, decreases the film thickness by about 5%, and increases the average refractive index by about 0.1.

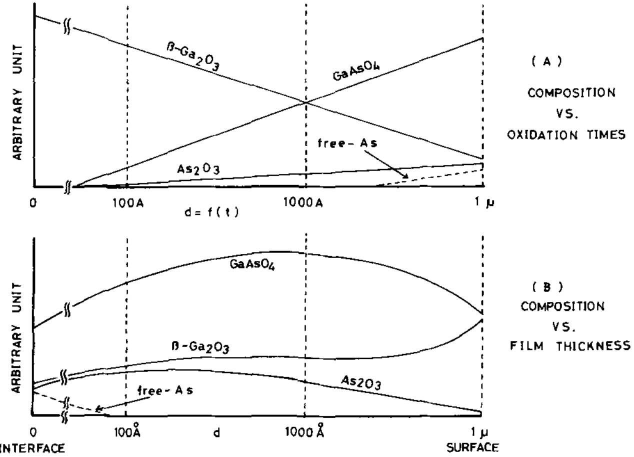

Fig. 9. Model of plasma oxidation process and profiles of GaAs substrate.

Applications

Dielectric isolation in GaAs monolithic integrated circuits.—Cross-sectional views of the GaAs wafers in each process of dielectric isolation in a GaAs monolithic integrated circuit are schematically shown in Fig. 10. An active GaAs layer is epitaxially grown on a semi-insulating GaAs substrate, and Al film is evaporated on it and photolithographically etched to form a mask for selective oxidation. Then the wafer is oxidized by oxygen plasma. The oxide penetrates through the epitaxial layer, reaches the semi-insulating substrate, and forms islands of epitaxial GaAs, isolated by the oxide and the semi-insulating substrate. The Al mask is etched away by HF acid finally.

The isolation property was evaluated by the current-voltage characteristics between two islands, as shown in Fig. 11. In much the same way as in the above isolation process, prefabricated pn junctions were isolated as shown in Fig. 12. The pn junction was slightly damaged during the oxidation process as indicated by the broken curves in Fig. 12 in comparison with the solid-line curves, which indicated I-V characteristics of the pn junction obtained by mesa-etching for monitoring. However, in both cases, the epitaxial layer and pn junction were not seriously damaged during the oxidation process.

Surface passivation of light-emitting diodes.—Surface passivation of light-emitting diodes by this technique is accompanied by an improvement of their external efficiency of light emission. Extensive studies on the reliability of passivated devices by this oxide film have not yet been completed, although a small degree of improvement in the external efficiency of $GaAs_{0.6}P_{0.4}$ light-emitting diodes was evident. Distribution of the refractive index through the film can be conceived as that shown in Fig. 7; consequently, improved optical matching between the light-emitting medium and the oxide film is expected.

Optical isolation in optical integrated circuits.—$GaAs_{0.6}P_{0.4}$ with a pn junction on GaAs substrate was used as a wafer. The wafer was oxidized selectively until the oxide reached the GaAs substrate, forming a strip of $GaAs_{0.6}P_{0.4}$ layer that was isolated electrically.

Table I. Structure of oxide films

Substrate	Film thickness	Refractive index	Structure	Composition
Undoped GaAs (100)	590A	1.87	Polycrystalline	β-Ga_2O_3

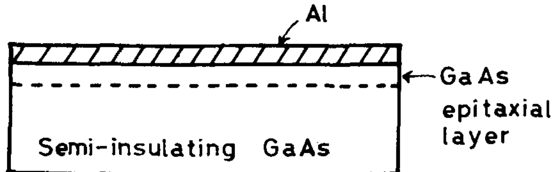

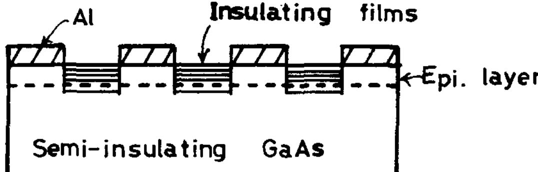

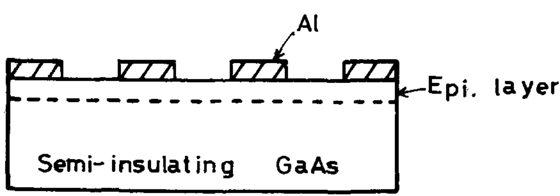

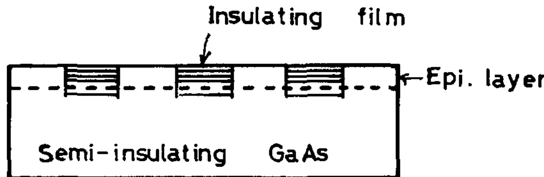

Fig. 10. Cross-sectional views

When light is emitted from a part of the strip, the light passes through the $GaAs_{0.6}P_{0.4}$ layer, which possesses a self-focusing characteristic because of distribution of the refractive index in the oxide film, as shown in Fig. 7. A preliminary experiment revealed a 3 db improvement of the attenuation constant of a $GaAs_{0.6}P_{0.4}$ strip about 550μ wide in comparison with the air-isolated $GaAs_{0.6}P_{0.4}$ strip.

Conclusion

It has been found that plasma oxidation has an extremely high oxidation rate on the surface of $GaAs_{1-x}P_x$ substrate, and the rate can be controlled from 50 Å/sec to 1 μ/sec by oxygen gas pressure and anode voltage of the oscillator. 0.5μ thick Al film functions well as a mask for selective oxidation and assists this technique in becoming compatible with the photolithic process.

Structural and optical properties of the oxides are not uniform throughout the film. The oxides include β-Ga_2O_3, $GaAsO_4$, and $GaPO_4$, and the composition ratio varies in depth. The average refractive index measured by split-beam ellipsometry also changes with film thickness, and it is estimated that the refractive index is distributed from the oxide-substrate interface (where it has a value very close to that of the substrate) to the surface of the oxide (where it has the value corresponding to that of β-Ga_2O_3).

Such distribution of the refractive index is expected to be useful in the optical integrated circuits of light-emitting diodes, an improvement of the optical characteristics of those devices, and for surface passivation. A flow of Schottky emission current and Poole-Frenkel current through the oxide film has been observed, whereby resistivity of the oxide ranged from 10^8 ohm-cm to 10^{10} ohm-cm, sufficient to cause dielectric isolation in GaAs monolithic integrated circuits. Physical mechanisms of the rapid oxidation of $GaAs_{1-x}P_x$ by oxygen plasma are not yet known, neither have exten-

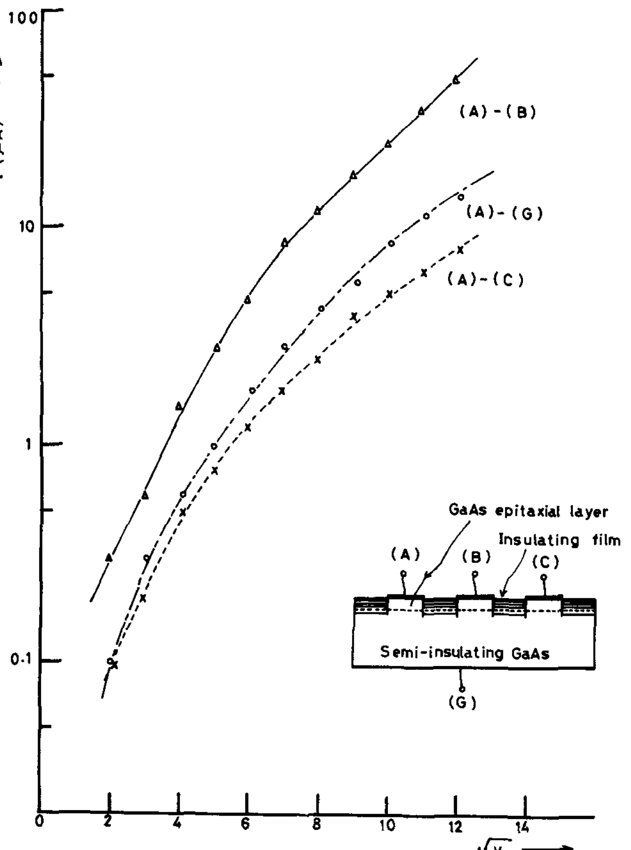

Fig. 11. Current-voltage characteristics between two islands

Oxidation Characteristics of Some Nickel Alloy Films in Air and Water Vapor

K. Gupta, J. P. Marton, and J. Shewchun

Department of Engineering Physics and Institute for Materials Research, McMaster University, Hamilton, Ontario, Canada

ABSTRACT

Ellipsometric techniques were used to study the oxidation of Ni, Ni-Cr, and Ni-P deposits. Oxidation was carried out at temperatures ranging from 100° to 500°C in different ambients including air, saturated water vapor, and gas mixtures containing oxygen at 0.05 and 0.5 atm, respectively. The optical constants n and k of fresh deposits were found to undergo change on heating. Typically, n decreased and k increased, both saturating at longer times. The oxidation of Ni, Ni-Cr, and Ni-P was found to be a three stage process. At temperatures below 300°C, mainly oxygen is absorbed; while above this temperature a surface oxide layer is formed. The third stage occurs at 400°C, and for long times where the films become anisotropic or inhomogeneous. The optical constants of the oxide layers formed on all three metals were found to be nearly the same, and their values to be close to those of NiO. The oxidation in different oxygen pressures indicated that water vapor plays a role in the oxidation process. The oxidation in water vapor could not be accounted for by the oxygen normally present in water as a dissolved gas.

The structure of freshly deposited Ni-P films has been reported (1) to be of a polycrystalline island type. On heating it undergoes a chemical phase transition, the final products (2) being Ni and Ni_3P. Marton and Chan (3) have determined the optical constants of Ni-P films annealed in hydrogen to be $n = 2.15$, $k = 2.75$. The oxidation of Ni-P films has also been studied (3, 4). It was found than an oxide film grows only above 280°C and that it is a two phase mixture of NiO and P_2O_5. The optical constants of the oxide were found to depend on thickness of oxide film and the saturated values were determined to be $n = 1.3$, $k = 0.15$. The effect of water vapor on the oxidation process and on the oxide layer has not been studied before.

The oxidation of bulk Ni (5-7) and Ni-Cr at high temperatures (8-10) has been shown to follow Wagner's parabolic law. Very little is known, however, about the behavior of films of these metals at temperatures below 500°C. Oxidation of Ni in water vapor has been studied by some investigators (11, 12). Although the mechanism of oxidation in water vapor is not clearly understood, it is known (10) that the rate of oxidation in water vapor is lower than that in air by a factor of three. Rhamel (13) studied the oxidation of Ni at 1000°C in oxygen alone and with 43% water vapor. His results indicated that the presence of water vapor does not alter the rate of oxidation. Roberts (14) and Meyerson (15) have determined the optical constants of bulk Ni from reflectance studies to be $n = 1.66$, $k = 3.39$. Roberts (14) also found these constants to change with temperature. Optical constants of Ni-Cr have not been reported in the literature.

In the present investigation, we have determined optical constants for films of Ni, Ni-Cr, and Ni-P in the thickness range of 1000-1500Å and studied their variation with temperature. We also studied the oxidation of these films in the temperature range of 100°-400°C in different ambients including air, water vapor, and gas mixtures in which the partial pressure of oxygen was 0.05 and 0.5 atm, respectively. The thickness of the oxide film and its optical constants were calculated in each case. Finally, we investigated the effect of water vapor on the oxide layer formed on Ni, Ni-Cr, and Ni-P films. The information found enabled us to construct working models of the oxidation process of these metals. The results also indicated that the oxide film on the three types of film studied consists mainly of NiO.

Key words: ellipsometry, nickel alloy films, oxidation, effect of moisture.

Experimental

Sample preparation.—Nickel and nichrome films were made by thermal evaporation of these metals in

vacuum ($\sim$4 $\times$ 10^{-6} Torr) on Pyrex glass substrates, 1 in. square and ¼ in. thick. An NRC 3116 vacuum coater, with an alumina-coated tungsten boat as source, was used for evaporation. Deposition was carried out at room temperature at the rate of about 200Å/min. The thickness of the deposit was continuously monitored by a Sloan-Omni II deposit control master. Films were grown to 1200-1500Å thickness. Nickel phosphorous films were made by electroless deposition of the metal on Pyrex glass substrates. For cleaning and activation of the substrates and deposition of the metal, we followed accepted procedures (1). Thickness of the deposit as measured by the Angstrom-meter was in the range of 1200-1500Å and the composition was maintained at 16 atomic per cent (a/o) phosphorous. The Ni-P was removed from one side of the glass substrate by rubbing the surface with aqua regia. This was necessary in order to enable ellipsometric measurements to be made at the glass metal interface by second surface reflection.

Thermal oxidation of samples.—The specimens were subjected to heat-treatment at temperatures ranging from 100° to 500°C for times ranging from 10 to 1000 min. This was done in different ambients including air, saturated water vapor, and two oxygen-nitrogen mixtures containing oxygen at 0.05 and 0.5 atm, respectively. The experimental arrangement consisted of a quartz tube, 3 in. in diameter, placed in a three-zone low-temperature furnace. A quartz boat was used to introduce the sample. The temperature gradient along the length of the boat was determined to be less than 1°. After the sample had been heated in the desired atmosphere for the required period, it was withdrawn from the furnace and allowed to cool in air at room temperature.

Ellipsometric measurements.—Measurements were made on freshly deposited samples and after each period of heating. All measurements were carried out in air at room temperature using a Rudolph thin film ellipsometer Model 43603-200E in a conventional manner. The parameters Δ and Ψ were measured at both the air and the glass surface of the metal. The latter were used to calculate optical constants, n and k of the metal by second surface reflection (16). Optical constants of the metal were also determined by the multiple-angle of incidence method (17). The results obtained from the two methods agreed only when the oxide was nonabsorbing or very slightly absorbing ($k \approx 0.05$). When the oxide was more absorbing the results varied by 20-25%. In such cases, the optical constants obtained from second surface measurements were taken.

The second surface ellipsometric measurements were carried out at two different angles of incidence between 65° and 75° in all four zones. One of the criteria used for computer iteration was that the oxide film thickness be independent of angle of incidence. The results discussed below are averages of 8 readings for each sample in each state of oxidation. In all measurements the ellipsometer was operated at $\lambda = 5461$Å

Analysis of the Data

The interpretation of ellipsometric data in terms of the optical constants and thickness of the oxide film is based on the Fresnel and Drude equations. An iterative computer program, similar to McCrackin and Colson (18) was used for the actual calculations. This program is designed to calculate optical constants of the oxide film and its thickness if the optical constants of the substrate are known. An expected range is specified for the optical constants of the oxide film. The final values for optical constants and film thickness are obtained by iterating the program for best possible convergence.

Interpretation of the ellipsometric data in terms of a surface oxide film is possible only if the oxide film is of uniform thickness, isotropic, and homogeneous. It was found that ellipsometric data on samples heated at lower temperatures, *i.e.*, 100°-250°C did not yield a satisfactory and acceptable solution in terms of a surface oxide film. This could be due either to the absence of a surface oxide or to extreme inhomogeneities in the initial stages of oxide growth. Since the measurements were not made *in situ* under ultra high vacuum conditions, it is also possible that a thin oxide layer could have been masked by the adsorbed gas on the surface. As the oxide thickness would grow, the effect of the adsorbed gases would be less pronounced. Engell, Hauffe, and Ilschner have reported (19) oxide film thickness of the order of 700Å at 400°C for bulk nickel. They have measured volumetrically the amount of oxygen consumed. However, there is no direct measurement of the thickness of the oxide layer either on bulk nickel or on deposited Ni film.

Although the data for low temperatures of heating could not be interpreted in terms of a homogeneous oxide layer, meaningful results were obtained with the help of Maxwell-Garnett theory (20). The changes in the optical properties of the surface were interpreted as caused by absorption or desorption of gases. For temperatures of heat-treatment at and above 300°C, the observed Δ and Ψ could be interpreted in terms of a surface oxide film. Again when nickel and nickel phosphorous were heated in air at 400°C for longer periods ($\sim$200 min or more) or at higher temperatures, the observed data failed to give a satisfactory solution in terms of thickness of oxide film.

Results and Discussion

Ellipsometer readings Δ and Ψ measured at 70° angle of incidence for some samples of Ni, Ni-Cr, and Ni-P are plotted in Fig. 1. The samples were heated in air at temperatures of 300° and 400°C for various times. In the figure, the oxidation time progresses from right to left. Results of the various interpretations of the ellipsometric data are presented below.

Optical constants of the metals.—Optical constants of freshly deposited Ni films were determined to be $n = 1.9 \pm 0.1$ and $k = 3.5 \pm 0.1$. When they were heated in air and water vapor, both n and k showed a decrease, saturating at $n \approx 1.7$ and $k \approx 3.4$. For Ni-P films, the optical constants were found to be $n = 2.6 \pm 0.1$, $k = 2.6 \pm 0.1$. On heating, n decreased and k increased, both saturating at long times. The saturation values of the optical constants ($n = 2.15$, $k = 2.78$) are also in close agreement with those reported by Marton and Chan (3) for Ni-P films annealed in hydrogen.

Optical constants of Ni-Cr (Ni 80%, Cr 20%) have not been reported in the literature before. For freshly deposited nichrome films (1000-1500Å), we determined the optical constants to be $n = 2.5 \pm 0.1$, $k = 3.4 \pm 0.1$. The changes in the optical constants on heating were similar to those for Ni-P. The saturation values of the optical constants were found to be $n \approx 2.25$, $k \approx 3.48$.

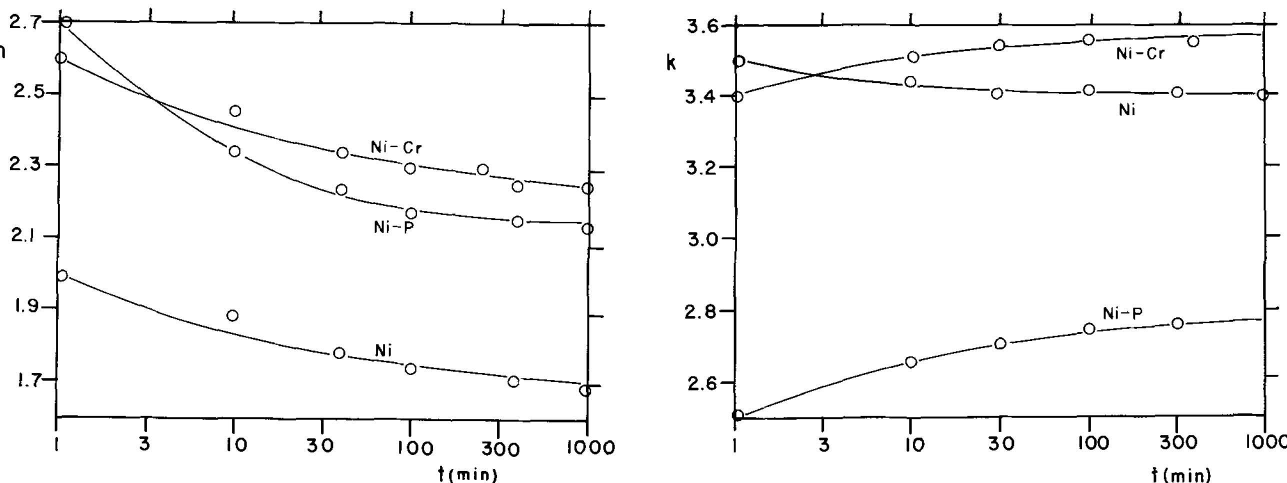

Fig. 2. Variations of n and k of metal films of Ni, Ni-Cr, and Ni-P with time of heating at 400°C. (a, left) Changes of n, (b, right) changes of k.

Figures 2a and 2b show the variation of n and k for Ni, Ni-Cr, and Ni-P at 400°C.

Ni-P films are known to undergo compositional and crystalline changes during heating. Pai and Marton (4) have found that initially the Ni-P film is a fine grain polycrystalline material. Upon heating, the film is transformed into a two phase mixture of Ni and Ni_3P. These changes may also account for the observed variation in optical constants. Roberts (14) and Nag (21) also have reported a temperature dependence of optical properties of nickel. Adams and Rao (22) have suggested that part of the changes in the optical constants of thin films on heating may be due to annealing of defects. It is reasonable to assume that the changes in the optical constants of our films are caused by some of the above processes.

Growth of oxide in air and water vapor.—Parameters Δ and Ψ measured on samples that were heated between 300° and 400°C were interpretable in terms of a surface oxide film. Analysis of Δ and Ψ yielded the thickness of the oxide film and optical constants of the oxide. The growth of oxide film appears to be monotonous for temperatures above 300°C. When the samples were heated in water vapor, the rate of oxide growth was found to be considerably less than that in air. The optical constants of the oxide are found to be thickness dependent in all the three materials. Figure 3 illustrates the growth of oxide film on Ni, Ni-Cr, and Ni-P in air and water vapor at 400°C. Figures 4a and 4b show the variation of optical constants of oxide films with thickness in these materials.

On inspection of Fig. 3 and 4 we see that the rate of oxidation in the time interval observed, is highest for Ni and lowest for Ni-Cr, and that the saturation values of n of the oxide formed in all three cases are very close. The common value is approximately 1.4. The k values do not show the same trend, but for all three oxides they have a low value. The comparison of these values with those of bulk NiO ($n = 2.36$, $k = 0.05$) reported by Powell and Spicer (23) is not favorable. Recently, however, Blondeau *et al.* (24) determined the optical constants of NiO in thin-film form, which compare well with our results. They used ellipsometric techniques for an *in situ* study of anodic oxidation of nickel, and found the optical constants to be $n = 1.34$, $k = 0.04$.

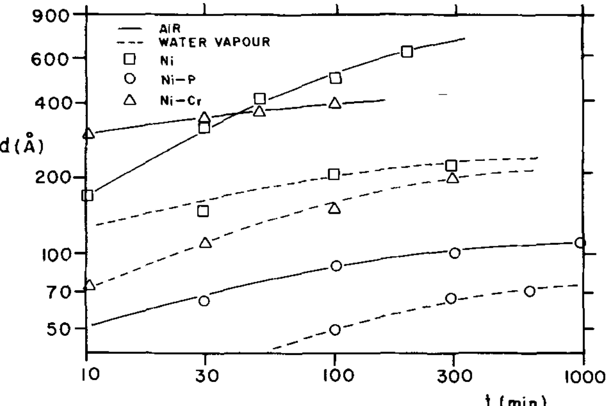

Fig. 3. The thickness of oxide films on Ni, Ni-Cr, and Ni-P at 400°C with time, grown in air and water vapor.

Oxidation at different oxygen pressures.—It is apparent from Fig. 3 that the rate of oxidation for all three metals in water vapor is less than that in air. To gain a better understanding of the mechanism of oxidation in water vapor, we carried out oxidation of the three metals at two different oxygen pressures. We mixed oxygen and nitrogen at different pressures to achieve 0.05 and 0.5 atm pressures of oxygen. Samples of Ni, Ni-Cr, and Ni-P were heated at 300° and 400°C in these two gas mixtures separately for various lengths of time. The thickness of the oxide film was calculated from Δ and Ψ for each period of heating. The result of these measurements for Ni are shown in Fig. 5 where the thickness of oxide film has been plotted *vs.* oxygen partial pressure. The oxide film thicknesses at 300°C are shown for 100 and 200 min of heating time. Thickness values corresponding to 0.05, 0.21, and 0.5 atm are found to lie on a straight line. The thickness of the oxide which forms in water vapor does not lie on this line. This deviation cannot be accounted for by experimental errors. These results seem to indicate that the observed rate of oxidation in water vapor is higher than is to be expected on the basis of oxygen dissolved in water. The mechanism of oxidation in water vapor is not clearly understood. It is possible that water vapor might act as a catalyst in this process. Figure 6 shows the results of measurements for Ni, Ni-Cr, and Ni-P. The samples were heated at 400°C for 100 min at various oxygen pressures. From Fig. 6 we see that the conclusions drawn for nickel from Fig. 5 also apply to Ni-Cr and Ni-P.

Effect of water vapor on the oxide layer.—We also studied the effect of water vapor on the oxide formed on the three metals. Samples of Ni, Ni-Cr, and Ni-P with a sufficiently thick oxide layer (≈500Å) were subjected to heating in water vapor at 100° and 200°C for periods up to 1000 min. In the case of the Ni-P samples, we found the oxide thickness to decrease by 13-15%. The decrease in the thickness of oxide film is of the same order as the phosphorous content of the Ni-P film. This suggests that the decrease is caused by removal of phosphorous from the surface by the water vapor. Pai and Marton (4) have

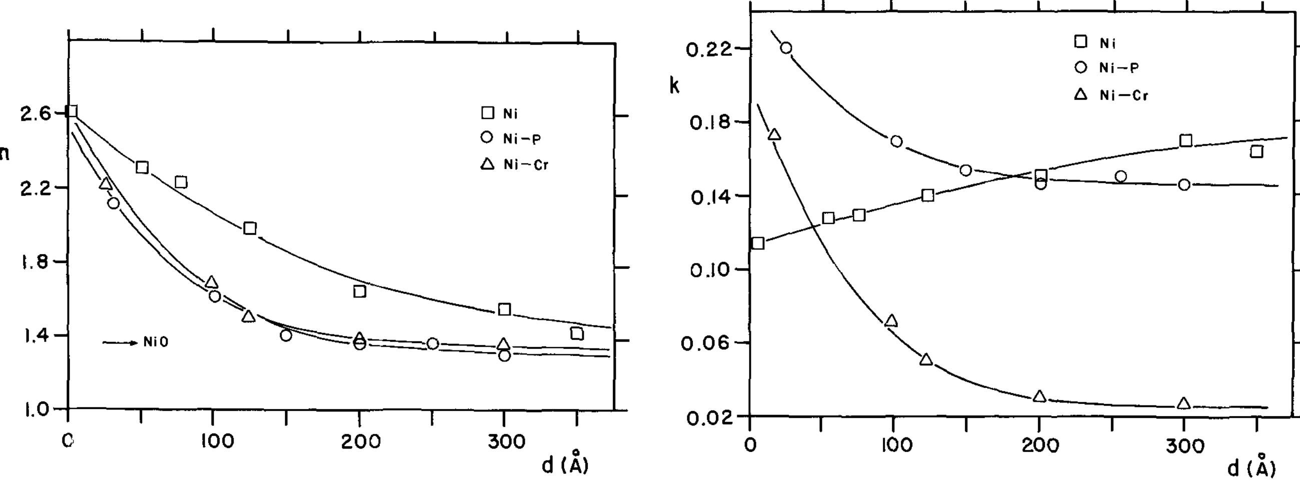

Fig. 4. Variation of n and k of the oxide films on Ni, Ni-Cr, and Ni-P with film thickness. (a, left) Variation of n, (b, right) variation of k. Note that n approaches the NiO value for large thicknesses.

found that NiO and P_2O_5 are present in the oxide layer on Ni-P film, thus it may be P_2O_5 that is dissolved and is removed from the surface. In the case of Ni and Ni-Cr, no significant change in the thickness of oxide film was observed.

Maxwell-Garnett interpretation.—It was mentioned above that the ellipsometric data on samples heated below 300°C and the data on samples heated at 400°C for long periods could not be interpreted in terms of a surface oxide film. The failure to interpret the low temperature data may be understood if we adopt the ideas of Lederick and Bellina (25), Marton and Chan (3), and Pai and Marton (4) who visualized the low temperature oxidation process as a selective oxygen absorption on the surface, rather than the formation of a uniform oxide layer. The optical properties would then be described in terms of the Maxwell-Garnett (20) theory. The theory gives a connection between the complex index of the metal $\tilde{N}$ and the effective, measured index $\tilde{N}_e$ in terms of the volume fraction q of the metal in the surface as

$$\frac{\tilde{N}_e^2 - 1}{\tilde{N}_e^2 + 2} = q\,\frac{\tilde{N}^2 - 1}{\tilde{N}^2 + 2}$$

We attempted to interpret the ellipsometric data obtained on the free surfaces in terms of $\tilde{N}_e$ and those from the back surfaces (metal-glass interface) in terms of $\tilde{N}$. The value of q was calculated for each measurement and was plotted as function of heating time. An example for Ni-P is given in Fig. 7. An increase in q is interpreted as gas desorption from the surface, and a decrease is interpreted as gas absorption. Both trends are apparent from the figure. The increase at 100°C is thought to be due to the desorption of H_2 from the film (H is a by-product in the deposition of Ni-P films) and the decreasing portion of the q curve at 300°C is thought to be due to oxygen absorption.

The failure to interpret the high-temperature data obtained at long times cannot be explained satisfactorily. It is possible that the oxide film develops anisotropies and inhomogeneities, in the form of blemishes or cracks. In such situations the assumptions of homogeneity and isotropy of the surface, used in the deriva-

tion of the ellipsometric equations would not apply. Interpretations would yield film thicknesses with either complex values, or angle of incidence dependent real values, which are not accepted as solutions by our computer program.

Conclusions

The oxidation of Ni, Ni-Cr, and Ni-P films appears to be a three stage process. First, at low temperatures gaseous impurities desorb and oxygen is absorbed in the surface. At temperatures at and above 300°C a surface oxide forms, which at temperatures above 400°C develops optically anisotropic or inhomogeneous features. Quantitative interpretation of ellipsometric data was found possible only in the middle temperature range.

The optical properties of oxide films grown on all three metals in the middle temperature range were found to be similar to those of pure NiO films. This is an indication that the product of oxidation in our case is predominantly NiO. In the case of Ni-P deposits, the experiments also indicated that the oxide contained approximately the same P content as the metal. The P may have been in the form of P_2O_5 as reported by others.

The study of oxidation rates at various oxygen pressures, though interesting, turned out to be inconclusive. The measured rate of oxidation was found to be higher than that which would be expected on the basis of partial pressure of oxygen in water vapor. Water vapor could be acting as a catalyst in the process.

High-Temperature Dielectric Behavior of Ca-Doped CeO_2

M. A. Seitz and T. B. Holliday

Metallurgy and Materials Science, College of Engineering, Marquette University, Milwaukee, Wisconsin 53233

ABSTRACT

The dielectric behavior of cerium dioxide with calcium concentrations ranging up to 8 mole per cent (m/o) were investigated as a function of frequency, from 50 Hz to 600 kHz, and temperature, over the interval from room temperature to 1000°C. At temperatures less than 500°C and calcium concentrations less than 1.0 m/o, barrier layer polarization seemed responsible for the observed dielectric behavior. At larger calcium concentrations and higher temperatures, where ionic conduction predominated, the dielectric behavior was rationalized on the basis of a space charge polarization model involving mobile ionic point defects, which were blocked or partially blocked at the specimen electrodes, and electronic carriers, which were able to freely pass through the electrodes. The effective dielectric constant was found to increase exponentially with temperature with an activation energy of approximately 0.74 eV.

The electrical behavior of CaO-doped nonstoichiometric cerium dioxide has been the topic of a number of investigations in recent years (1-5). X-ray diffraction studies indicate that CeO_2 has a cubic fluorite crystal structure and the solubility of CaO in CeO_2 ranges to 15 mole per cent (6). The calcium impurity substitutes for cerium atoms in the structure leading to the formation of oxygen ion vacancies. This results in a significant increase in the ionic conduction occurring in this material.

Electrochemical cell experiments in the temperature range 600°-1000°C have shown that the ionic transport number for CaO-doped CeO_2 ranges between 0.8 and 1.0 for calcium concentrations greater than about 2 m/o (7). For reducing atmospheres, $P_{O_2} < 10^{-5}$ atm, or temperature less than 600°C, the conduction was

predominately electronic in nature. Tracer diffusion studies indicate that the energy for motion of O^{18} in yttria-doped CeO_2 is 0.87 eV (8). Energies of motion for oxygen vacancies ranging between 0.71 and 0.76 eV have been obtained by combining conductivity and transport number data (7). Lay and Whitmore, measuring dielectric and mechanical losses in the temperature range 25°-200°C, have found an energy for reorientation of an oxygen vacancy–Ca^{+2} dipole of 0.86 eV for calcium concentrations up to 2.5 m/o (9).

In this study, dielectric measurements were performed on CaO-doped CeO_2 over the frequency interval 50 Hz to 6 × 10^5 Hz and at temperatures ranging from room temperature to 1000°C, using a previously developed technique (10). Specimens having calcium concentrations from 0.5 to 8.0 m/o were investigated in order to determine the influence of calcium doping on the dielectric behavior of ceria.

Experimental Procedure

In early attempts to measure the high-temperature dielectric behavior of calcia-doped CeO_2, it was noted that the specimen conductance, G_{sp}, was often greater than the capacitive susceptance, ωC_{sp}. This results in dissipation factors which were fairly large, $0.1 < \tan\delta < 10^2$. Therefore, a special technique had to be used to perform dielectric measurements. A substitution technique, where corrections are made for parasitic capacitances and inductances associated with the system, was the subject of a previous paper (10). With this technique the capacitance of specimen having a total resistance of greater than 100 ohms and a dissipation factor less than 10^4 can be measured to within ± 15%. For mid-range frequencies (1-50 kHz) the error is less than ± 5%.

Polycrystalline specimens were prepared using pressing and sintering techniques with 99.999% pure CeO_2 obtained from American Potash and Chemical Company and "Specpure" $CaCO_3$ obtained from Johnson-Matthey Chemicals Limited. The final disk-shaped specimens had a thickness of 0.5 cm and plane parallel surface areas of 2 cm^2. Doped polycrystalline specimens were produced by mixing the appropriate amounts of $CaCO_3$ with powdered CeO_2. The powdered material was heated to 1000°C for 3 hr, to drive off the CO_2 gas resulting from the decomposition of $CaCO_3$. The material was then homogenized at 1500°C for 3 hr. After these procedures the material was ground and pressed in the form of a disk at 20,000 psi. Sintering, at 1500°C for 3-6 hr, resulted in specimens having a density approximately 75-80% of the theoretical density. All lines on x-ray powder diffraction patterns could be assigned to the fluorite crystal structure, confirming the completeness of the CaO-CeO_2 reaction. Electrical contact to the specimens was made on their plane parallel surfaces, using Engelhard No. 05 platinum paste. Thick platinum coatings were obtained by repeated applications of platinum paste.

The specimens were loaded into the measurement system. Before performing a measurement, the specimens were allowed to equilibrate at temperature and in various partial presures of oxygen provided by oxygen-argon tank mixtures. Equilibrium was assumed when the capacitance and resistance changes over a several hour period were less than those due to the variation in temperature. Measurements of capacitance and resistance were made at selected frequencies in the range 50 Hz to 600 kHz. The specimen temperature was increased or decreased at approximately 100°C intervals and the above procedures repeated. The effective dielectric constants were calculated from the data using a parallel equivalent circuit representation of the specimen.

Results and Discussion

The dielectric behavior of calcium-doped cerium dioxide has been investigated from 10^2 to 6 × 10^5 Hz and over the temperature range from room temperature to 1000°C. In these studies, inert and impervious platinum electrodes were used. The variations of the apparent dielectric constant, K', with frequency; the a-c and d-c conductivities with temperature; and $\tan\delta$ with frequency are shown in Fig. 1 for CeO_2 doped with 0.5 m/o calcium. The variation of the effective dielectric

constant, K', with frequency for a specimen doped with 8.0 m/o calcium is shown in Fig. 2, while the temperature variation at 1 kHz for specimens having 1.0, 2.0, and 8.0 m/o calcium dopings is shown in Fig. 3.

The low-frequency dielectric behavior of CeO_2 doped with 0.5 m/o calcium in the temperature range from 500°-800°K is best explained by a model involving a static space charge or barrier layer within the specimen. These thin barrier layers have a resistivity greater than that of the bulk material. In this range of temperature and composition principally electronic conduction has been shown to exist in CeO_2 (7). Volger (11) has shown for such a situation where the conductivity, σ_1, of the barrier layer or layers is much less than that of the bulk material, σ_2, the effective low frequency relative dielectric constant, K'_s, is given by

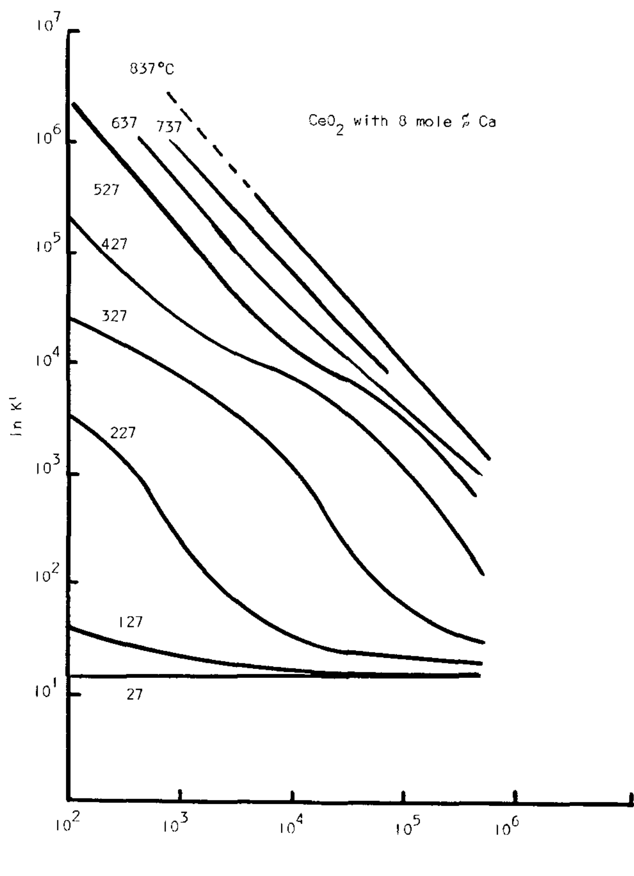

Fig. 2. K' vs. frequency for CeO_2 doped with 8.0 m/o Ca over the range 27°-837°C at $P_{O_2} = 1$ atm.

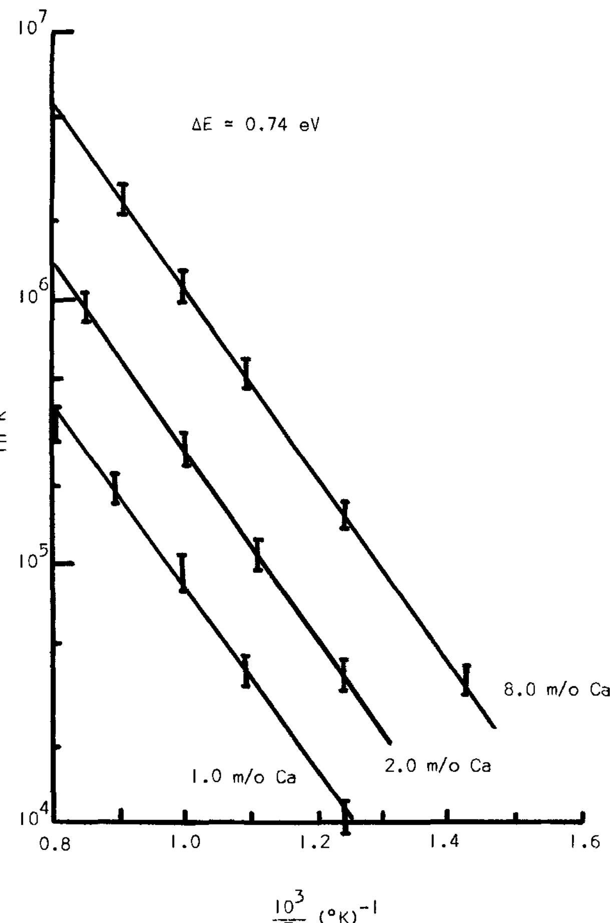

Fig. 3. The logarithm of K' vs. $1/T$ for CeO_2 doped with 1.0, 2.0, and 8.0 m/o Ca and at $P_{O_2} = 1$ atm.

$$K'_s = \frac{d_2}{d_1} K'_\infty \qquad [1]$$

Here, K'_∞ is the high frequency value of the relative dielectric constant, while d_1 and d_2 are the total thicknesses of the barrier layer or layers and the bulk material, respectively. The effective low frequency conductivity, σ_s, was shown to be

$$\sigma_s = \frac{d_1}{d_2} \sigma_1 \qquad [2]$$

while the high frequency value, σ_∞, was given as

$$\sigma_\infty = \sigma_2 \qquad [3]$$

Between the low- and high-frequency limits, K' and σ_{AC} follow the relationships

$$K' = \frac{K'_s + K'_\infty \tau^2\omega^2}{1 + \tau^2\omega^2} \qquad [4]$$

and

$$\sigma_{AC} = \frac{\sigma_s + \sigma_\infty \tau^2\omega^2}{1 + \tau^2\omega^2} \qquad [5]$$

In these expressions, τ is a dielectric relaxation time and ω is the frequency in radians per second. The dissipation factor, tan δ, was also designated as

$$\tan\delta = \sqrt{\frac{d_2}{d_1}} \frac{\tau\omega}{1 + \tau^2\omega^2} \qquad [6]$$

The dielectric behavior observed in Fig. 1 for CeO_2 doped with 0.5 m/o calcium reasonably fulfills the prediction of Eq. [1]-[6] at temperatures less than 500°C. The values of K' follow a Debye type dispersion as predicted by Eq. [4]. From Eq. [1] the ratio of K'_s to

K'_∞ indicates that the thickness of the barrier layer is about 1% of the thickness of the specimen. This is further substantiated by the variation of tan δ in Fig. 1c which follows the prediction of Eq. [6] up to about 500°C. Equation [6] further predicts that the maximum value of tan δ is given by $\frac{1}{2}\sqrt{\frac{d_2}{d_1}}$, which again indicates that barrier layers occupy about 1% of the specimen thickness. The nature of the barrier layers or where they exist, although not known at this time, might be the results of air gaps (12), or Schottky barriers (13, 14).

At temperatures greater than about 500°C, the predictions set forth by Eq. [1]-[6] for the aforementioned barrier layer model are not fulfilled as well as they were at lower temperatures. The a-c and d-c conductivities approach one another and there appears to be a further anomalous increase of K' at low frequencies as the temperature is increased. It is noted that although the general behavior observed for CeO_2 with 0.5 m/o calcium was also observed for pure ceria, the anomalous increase of K' at low frequency and high temperature ($T > 500°C$) was not seen. This suggests that the calcium doping was in some way responsible for the low-frequency high-temperature dielectric behavior observed for calcium-doped CeO_2. Upon increasing the concentration of calcium, the anomalous increase of K' at high temperatures also increased in magnitude (see Fig. 2 and 3).

It is known that the addition of calcium to CeO_2 results in the formation of oxygen ion vacancies in the ceria lattice (1-9). These vacancies, which become mobile or semimobile at elevated temperatures, can lead to space charge polarization at elevated temperatures. The high-temperature dielectric behavior of CeO_2 doped with calcium is best rationalized on the basis of a two carrier space charge polarization model involving mobile oxygen vacancies, which are blocked at the specimen electrodes, and electrons, which are free to pass through the specimen electrodes (15-17).

Several authors have dealt with two carrier space charge polarization models, where charge carriers of one polarity are completely blocked while those of the opposite polarity are able to freely pass through the electrodes (15-17). These authors, however, generally assume that the positively and negatively charged species are in equal concentration, *e.g.*, Schottky or Frenkel defects. These models indicate that the capacitance and/or apparent dielectric constant would vary with frequency as ω^{-n} and would show an exponential dependence on temperature. The value of n is found to be about 3/2. The exponential temperature dependence arises from the variation of the concentration and diffusion coefficient of the mobile species with temperature.

For calcium-doped polycrystalline ceria the negative charge carrying species would be electrons, while the positive charge carrying species would be oxygen ion vacancies. It should be noted that these would not necessarily be of equal concentrations as is set forth by the aforementioned space charge polarization models. An electroneutrality condition of the type $n + [Ca''_{Ce}] \rightleftarrows 2[V_o^{\cdot\cdot}]^{NS} + [V_o^{\cdot\cdot}]^{Ca}$ would exist for this material (18, 19). Here, electrons result from the ionization of oxygen ion vacancies that are due to nonstoichiometry, $[V_o]^{NS}$. The positive mobile ionic species would be oxygen ion vacancies, which predominately arise from the calcium doping, *i.e.*, $[V_o^{\cdot\cdot}] \sim [Ca''_{Ce}]$. For $P_{O_2} \simeq 1$ atm it would be expected that $n << [V_o^{\cdot\cdot}]$.

If the platinum contacts were reasonably ohmic at elevated temperature, the electrons would be free to pass through them. Thus, the electrons, which are highly mobile when compared to oxygen ion vacancies, would contribute significantly to the conduction current (8, 20). The inert and impervious platinum electrodes would not be expected to chemically react with oxygen ion vacancies or allow the transport of oxygen through them (21, 22). Oxygen ion vacancies, which cannot be annihilated at the Pt/CeO_2 interface, would be blocked at the Pt/CeO_2 interface and lead to a polarization.

The data of Fig. 2 and 3 follow many of the qualitative predictions of the aforementioned two carrier space charge polarization models at temperatures greater than 400°C. The value of K' at constant temperature decreases as ω^{-n}, although the value of n is between 1.1 and 1.2 rather than being equal to 1.5 as predicted by existing models. The temperature dependence of K' at constant frequency should be mainly related to variation in the concentration and diffusion coefficient of the blocked species. In this study the concentration of defects was set by the calcium doping and, thus, would not contribute to the temperature dependence of K'.

The high-temperature dielectric behavior of K', as shown in Fig. 3, should essentially contain information regarding the energy of motion of mobile ionic point defects in calcium-doped ceria. Blumenthal and Panlener, combining electrical conductivity and thermogravimetric data, have shown that the electron mobility in ceria increases exponentially with temperature with an activation energy of about 0.13 eV (19). Steele and Floyd (8) have reported an energy of motion of about 0.87 eV for O^{18} self-diffusion in yttria-doped ceria in the temperature range 850°-1150°C. Van Handel (7), combining conductivity and transport number data, in the temperature range 700°-1000°C, has observed an activation energy for oxygen vacancy diffusion in calcium-doped ceria of 0.71 and 0.76 eV for 2 and 5 m/o calcium, respectively. The activation energy of approximately 0.74 eV observed for the exponential increase of K' with temperature in Fig. 3 seems to be consistent with the previously reported energies of motion for oxygen in Ca-doped CeO_2.

Several other factors support a model involving space charge polarization due to the motion of oxygen ion vacancies in ceria. First, measurements have indicated that the ionic transport number is of the order of 0.9 or greater in the temperature range where space charge polarization is observed (7, 19). Where the ionic transport number was less than 0.5, the previously discussed barrier layer polarization dominated the dielectric behavior. Secondly, the magnitude of K' in this temperature and frequency range is directly proportional to the calcium concentration for concentrations greater than about 1 m/o. Van Handel found that the ionic conductivity was directly proportional to the concentration of calcium in CeO_2 up to approximately 8 m/o (7).

A more quantitative interpretation of the data must await the development of two carrier space charge polarization models where the concentration of oppositely charged species may differ. Macdonald (23) is presently involved in setting up such a model which will be available at some future date. Added complications arise in the interpretation due to the porosity of the material resulting from its polycrystalline nature, and the fact that an oxygen ion vacancy has a charge of $2|e|$ rather than $1|e|$ as assumed in previous modeling.

Conclusion

In summary it would seem that barrier layer polarization was responsible for the observed dielectric behavior of Ca-doped CeO_2 at lower temperatures and small calcium concentrations, where electronic conduction was predominate. At higher calcium concentrations and temperature, where ionic conduction is significant, space charge polarization was thought to result. These data were rationalized on the basis of a space charge polarization model involving mobile ionic point defects, which were blocked or partially blocked at the specimen electrodes, and electronic carriers, which were able to pass through the electrodes. The

effective dielectric constant, K', increased exponentially with temperature with an activation energy of approximately 0.74 eV. This activation energy, which was principally associated with the motion of oxygen vacancies, seemed to be consistent with previously reported energies of motion of oxygen in Ca-doped CeO_2.

The Temperature and Compositional Dependence of the Electrical Conductivity of Nonstoichiometric CeO_{2-x}

R. N. Blumenthal and R. L. Hofmaier

Metallurgy and Materials Science, College of Engineering, Marquette University, Milwaukee, Wisconsin 53223

ABSTRACT

The electrical conductivity of sintered specimens of nonstoichiometric CeO_{2-x} was measured as a function of temperature from 1000°-300°C and composition from $0.00424 \leq x \leq 0.178$. These results are described in terms of a high temperature and low temperature region. In both temperature regions the conductivity for fixed values of x exhibits an exponential dependence on temperature, $\sigma = \sigma_0 e^{-Q/kT}$.

The temperature of the intersection between the high and low temperature regions for each composition agrees closely with the composition-temperature dependence of the miscibility gap reported by Brauer and Gingerich. The compositional and temperature dependence of the conductivity in the high temperature region, which corresponds to a single-phase region, may be represented by the expression $\sigma \propto xe^{-Q/kT}$ where Q is a function of x. This expression is rationalized in terms of simple relations for the electron carrier concentration, $[Ce'_{Ce}] \propto x$, and the electron mobility, $\mu = \mu_0 e^{-Q/kT}$, where μ_0 is independent of x. For log x between -3.0 and -1.8, Q is constant at 0.22 eV, but increases to 0.37 eV at log $x = -0.7$. In the low temperature region the activation energy, 0.61 ± 0.03 eV, was found to be independent of x.

Nonstoichiometric cerium dioxide, CeO_{2-x}, has been the subject of several x-ray (1-3), thermodynamic (4-6), and electrical conductivity investigations (7-13). Based on these experimental observations, CeO_{2-x} may be classified as a metal-excess, n-type semiconductor.

Brauer and Gingerich (3, 4) studied the influence of temperature on the phase relations in the cerium-oxygen system by measuring the oxygen dissociation pressure in the region CeO_2-$CeO_{1.5}$, from 600° to 1000°C, and by x-ray powder-diffraction analysis in the region CeO_2-$CeO_{1.78}$ over the temperature range 20°-1050°C. They reported a miscibility gap which has the boundaries CeO_2 and $CeO_{1.81}$ at room temperature, contracts with rising temperatures, and closes with a composition of approximately $CeO_{1.92}$ at 685°C. Above 800°C they report that a homogeneous single-phase region extends from CeO_2 to about $CeO_{1.67}$.

Bevan and Kordis (6) also studied the oxygen dissociation pressures of the cerium-oxygen system from 636° to 1169°C. Based on their results they constructed a cerium-oxygen phase diagram at these temperatures between the composition CeO_2 and $CeO_{1.5}$. The results of their study were similar to those of Brauer and Gingerich except that they report a two-phase region between $CeO_{1.72}$ and $CeO_{1.70}$. They also report a miscibility gap which appears to have a similar composi-

Key words: electrical conductivity, cerium dioxide, electron mobility, nonstoichiometry.

tional dependence on temperature as reported by Brauer and Gingerich (3, 4).

The defect structure responsible for the metal excess behavior of CeO_{2-x} has been inferred from the analysis of thermodynamic electrical conductivity, and oxygen self-diffusion studies (7-18). Although defect models involving either oxygen vacancies or cerium interstitials have been proposed, the recent investigations of oxygen self-diffusion (15-17) in nonstoichiometric CeO_2 and $Ce_{1-2y}Y_{2y}O_{2-y}$ and the electrical conductivity (18) of CaO-doped CeO_2 over a wide range of temperature, oxygen pressures, and CaO content appear to be consistent with an oxygen vacancy model.

The electron mobility in nonstoichiometric CeO_{2-x} was also calculated as a function of temperature by combining electrical conductivity and thermogravimetric data for the temperature and oxygen pressure region where the atomic defect predominates in one state of ionization (19). The mobility was characterized by an expression of the form.

$$\mu = \mu_0 e^{-E/kT} \quad [1]$$

where the activation energy, E, was equal to 0.14 eV. These results are consistent with a hopping-type conduction mechanism where the electrons localized at normal cerium sites move to adjacent cerium sites.

The purpose of the present study was to measure the electrical conductivity of cerium dioxide as a function of temperature and nonstoichiometry and to relate these data to the temperature and compositional dependence of the electronic mobility in the single-phase region above the miscibility gap and to investigate the behavior of the conductivity of the cerium-oxygen system below the miscibility gap.

Theory

Information about the defect structure and electronic mobility of CeO_{2-x} can be obtained from measurements of the electrical conductivity as a function of temperature at constant oxygen composition (*i.e.*, fixed values of x in CeO_{2-x}). For example, since $x = f(T,P_{O_2})$, the composition of a specimen may be controlled by fixing the temperature and oxygen partial pressure. If a reduced specimen of CeO_{2-x} is then placed in an inert atmosphere, which allows the oxygen composition to be maintained, the observed temperature dependence of the electrical conductivity may then be attributed to changes in the concentration of charge carriers and/or a change in the carrier mobility with temperature.

Electron transport in nonstoichiometric CeO_2 has been interpreted in terms of a hopping-type process, whereby the electrons localized on a cerium ion, Ce'_{Ce}, may be exchanged with adjacent normal cerium ions Ce^x_{Ce} (19). For simple, limiting, case defect models the concentration of electron carriers, $[Ce'_{Ce}]$, may be simply related to the departure from stoichiometry in cerium dioxide provided the concentration of defects arising from impurities is negligibly small compared to those produced by the nonstoichiometric defects. For example, if each nonstoichiometric atomic defect contributes the same number of electronic carriers over the whole temperature range, then

$$x \propto [Ce'_{Ce}] \quad [2]$$

and the temperature dependence of σ for conditions of constant x must be the same as for the electronic mobility μ.

However, for the case where the nonstoichiometric defects exhibit multiple states of ionization, $[Ce'_{Ce}]$ is a more complicated nonlinear function of x and σ will exhibit a nonlinear dependence on x, even if $\mu = f(T)$ only (13).

Experimental

The conductivity specimens were prepared by cold pressing and sintering CeO_2 powder obtained from the American Potash and Chemical Company (12, 13). The results of a mass spectrographic analysis of a sintered specimen are shown in Table I.

A standard four-probe d-c technique was employed for the electrical conductivity measurements. An Altair Model C2 constant current source with a continuously variable range from 1 μA to 50 mA was used to supply the current. The voltage across the potential probes was recorded on a Sargent Model DSR two-channel recorder. The second channel was used to record the thermocouple emf. Measurements of the temperature dependence of the electrical conductivity under conditions of constant oxygen composition were made using the following procedure. A specimen of ceria was reduced in a known CO-CO_2 mixture at 1000°C. The oxygen partial pressure was calculated as a function of temperature from the well-known reaction

$$CO_2 \rightleftarrows CO + 1/2O_2 \quad [3]$$

When equilibrium was obtained, the specimen had a fixed oxygen composition which was determined from data on the composition of CeO_{2-x} as a function of P_{O_2} obtained in this laboratory (21). The CO-CO_2 mixture was then purged with purified helium. As explained in the next section, this effectively prevents the loss or gain of oxygen from the specimen over the time intervals necessary to make the conductivity measurements. The helium was purified by passing it over a mixture of TiO_2-Ti_2O_3 powder at approximately 950°C (20). This procedure reduced the oxygen partial pressure in the helium to approximately 10^{-16} atm as measured by an oxygen gauge. Usually 10 min were used to purge the system of CO-CO_2. The conductivity remained essentially constant during this time for the nonstoichiometric compositions investigated (*i.e.*, $0.00424 \leq x \leq 0.178$). The temperature was then lowered to about 300°C at a rate decreasing from about 150° to 50°C per minute and then reheated at a much lower heating rate while recording the temperature and voltage across the potential leads.

Results and Discussion

The electrical conductivity of sintered specimens of nonstoichiometric CeO_{2-x} was measured as a function of temperature from 300° to 1000°C, as well as a function of composition over the range $0.00424 \leq x \leq 0.178$. The upper limit of x was fixed by the largest CO/CO_2

ratio, 97.3%, used in this investigation. As discussed below, the lower limit of x was determined by the experimental technique since for compositions close to stoichiometry a fixed oxygen composition could not be maintained in the specimen.

Typical results of the electrical conductivity measured as a function of temperature for two different oxygen compositions, $x = 0.00424$ and $x = 0.040$, are shown in Fig. 1 as a plot of log σ *vs.* $1/T$. As illustrated in Fig. 1, the conductivity for the cooling and heating curves are in good agreement for the case where $x = 0.040$. However, for the case $x = 0.00424$ the conductivity for the heating cycle is slightly lower than the cooling cycle. Thus in this composition range, and for the conditions of the experiment, it is established that any loss or gain of oxygen from the specimens is small enough as to exert a negligible effect on the conductivity. Strictly speaking, in order to maintain a constant value of x under equilibrium conditions the chemical potential of oxygen in the gas phase would have to be equal to that of the reduced ceria sample. Since $x = f(T, P_{O_2})$, (*e.g.*, with $x = 10^{-3}$, $P_{O_2} \cong 10^{-8}$ atm at 1000°C, and $P_{O_2} \cong 10^{-20}$ atm at 700°C) (21) the composition of the gas phase would have to be altered at every temperature in order to maintain a fixed temperature-independent composition. From an experimental point of view these conditions would be practically impossible to obtain. As discussed above, the procedure used in this study, however, was to minimize the exchange of oxygen between the conductivity sample and the ambient gas phase by (*i*) employing a purified helium atmosphere and (*ii*) by limiting the amount of time that the sample is in contact with the "inert" atmosphere during the conductivity measurements. The success of this technique can be understood on the basis of the following simple considerations. If the partial pressure of the impurities containing oxygen (such as CO_2, H_2O, etc.) are of the order of 10^{-6} atm, then for a flow rate of 400 cm^3/min the maximum amount of oxygen which can be furnished to the sample in a period of 1 hr is about 32 μg which for a 1g sample would correspond to a negligible decrease in x of about 3×10^{-4}. Similarly, if the equilibrium P_{O_2} of the reduced ceria specimen is taken as 10^{-6} atm, well above the actual equilibrium pressure for the compositions studied, and the inert gas is absolutely pure, then the maximum amount of oxygen which could be lost from the specimen for the same flow rate and time as above would result in a negligible increase in the value of x of approximately 3×10^{-4}.

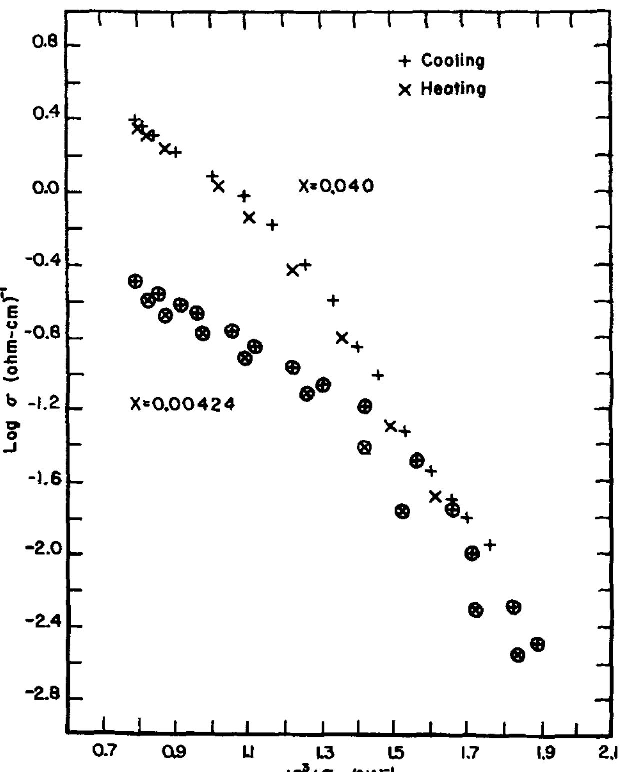

Fig. 1. A plot of log σ *vs.* $1/T$ for cooling and heating under conditions designed to maintain constant values of x in CeO_{2-x}.

Since the effective P_{O_2} of the purified helium gas was approximately 10^{-16} atm as determined by an oxygen gauge at 1000°C, the P_{O_2} of the gas is probably controlled by the water gas reaction and the amount of CO, CO_2, H_2, and H_2O present as impurities. Because the concentration of these impurities is of the order of parts per millions the "buffering" capacity (*i.e.*, the amount of oxygen that can be exchanged with the gas without changing P_{O_2}) is extremely small. Thus the actual amount of oxygen exchanged with the sample would be less than the amount given in the above calculations because it would be limited to a great extent by the "buffering capacity" of the gas. On the basis of the above considerations it would be expected that the change in the oxygen composition of the specimen during a conductivity run will be negligibly small except for samples with compositions near stoichiometry (*i.e.*, $x < 10^{-3}$). In this study the conductivity data obtained on cooling was considered to be more accurate because the amount of time the specimen was in contact with the inert atmosphere at elevated temperatures (*e.g.*, 1000°-600°C) was much less than the corresponding time required for heating.

The conductivity data obtained on cooling from 1000°C is shown in Fig. 2a and 2b as a composite plot of the log of the electrical conductivity as a function of the reciprocal temperature for several different values of x. The straight lines shown in Fig. 2a and 2b are obtained from a least square curve fit of the conductivity data for sintered specimens which were normalized for porosity using the expression (22)

$$\sigma_{norm} = \sigma_{meas} \frac{\rho_{theor}}{\rho_{meas}} \quad [4]$$

where ρ_{meas} is the density of the sintered specimen. These results may be described conveniently in terms of a high temperature and a low temperature region. Since in both of these temperature regions the conductivity exhibits an exponential dependence on temperature, the conductivity in each region may be characterized by an Arrhenius type expression

$$\sigma = \sigma_0 e^{-Q/kT} \quad [5]$$

The parameters σ_0 and Q which characterize the lines shown in Fig. 2a and 2b and the corresponding compositions are tabulated in Table II. In the high temperature region the activation energy, Q, increases with increasing departure from stoichiometry. The magnitude of the electrical conductivity is also very dependent on the value of x between $x = 0.00424$ and $x = 0.0855$. For values of $x > 0.0855$ the conductivity is less dependent on x. However, in the low temperature region, with the exception of the largest value of x, the activation energy does not appear to be a function of x and the magnitude of σ increases only slightly with increasing x. Another interesting observation is that the temperature at which the lines in the high and

low temperature region intersect, increases with increasing values of x up to about $x = 0.0855$. For larger values of x the temperature at which the intersection occurs decreases with increasing x.

The temperature of the intersection for each composition and the composition-temperature dependence of the miscibility gap reported by Brauer and Gingerich are shown in Fig. 3 for purposes of comparison. The error bars shown for the x-ray study were estimated on the basis of the precision of their lattice parameter measurements and the dependence of the lattice parameter on composition which they report. The error bars shown for the data determined in this study were calculated from a least square analysis assuming a 95% confidence limit and from the reproducibility of the data. With the exception of two points all of the data from this study are within the experimental error of the results obtained by Brauer and Gingerich (4). It should be noted, however, that most of the data points obtained in this study lie slightly below the reported miscibility gap.

It thus appears that the sharp break in the slope of log σ as the temperature is decreased is due to the transition from a single phase to a low temperature, two-phase mixture. The conductivity in the low temperature region is only weakly dependent, and the activation energy, Q, independent of x. Thus one conduction mechanism appears to predominate but the conductivity cannot be accounted for on the basis of a simple phase mixture rule. An interesting question that cannot be explained from the conductivity data in this study is the following. Why is the activation energy for the low temperature conductivity larger than for the high temperature conductivity? Is it because the mobility exhibits a larger temperature dependence or because the concentration of charge carrier varies more rapidly, or both? Hall mobility measurements in this temperature region would help provide an explanation for this question.

In the high temperature region of this study, the compositions of the CeO_{2-x} specimens correspond to a single-phase region. As discussed in the theory section, the nonstoichiometric atomic defects may be found

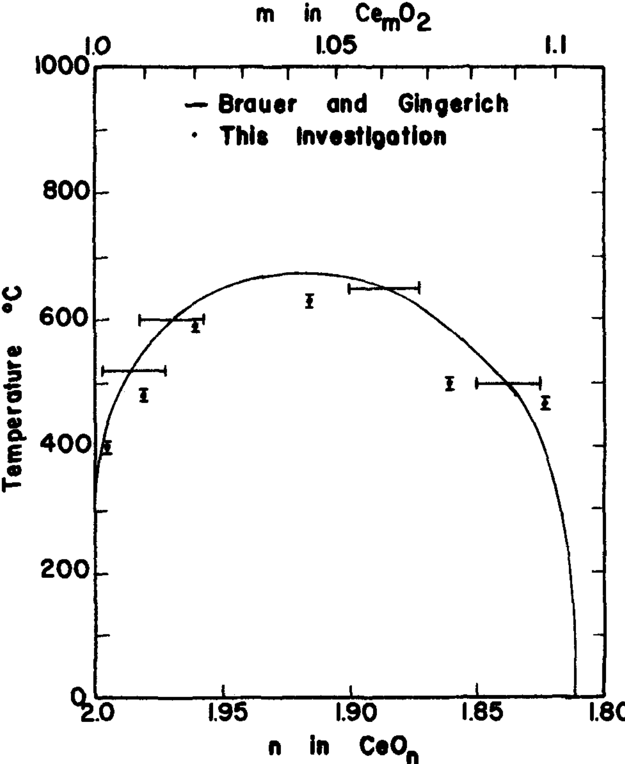

Fig. 3. Phase diagram of the cerium oxide system in the composition region CeO_2-$CeO_{1.8}$.

predominantly in one state of ionization or they may exhibit multiple states of ionization. In order to test which of these cases is more likely to occur in CeO_{2-x}, an isothermal plot of log σ *vs.* log x was made as shown by the solid line in Fig. 4. This plot was constructed using data from two recent equilibrium studies in this laboratory (21, 23). In one study log σ *vs.* log P_{O_2} at 1000°C was determined; in the other thermogravimetric study log x *vs.* log P_{O_2} at 1000°C was determined. Smooth curves through the data points of each study were used to obtain the desired log σ-log x relationship. For purposes of convenience, the dependence of σ on x will be described below in terms of two composition regions.

In the composition region, $-3.0 < \log x < -1.8$, the slope of log σ *vs.* log x is equal to 1. Since $\sigma \propto x$, it appears that the limiting case given by Eq. [2] is valid (*i.e.*, $[Ce'_{Ce}] \propto x$). For this case, (*i*) the nonstoichiometric atomic defect exists in one predominant state of ionization and (*ii*) the temperature dependence of σ, for the fixed values of x is equal to the temperature dependence of the electron mobility (*i.e.*, Q obtained from the relation $\sigma = \sigma_0 e^{-Q/kT}$ is equal to E from the expression $\mu = \mu_0 e^{-E/kT}$). To illustrate how Q varies with x, a plot of Q *vs.* log x was made as shown in Fig. 5. From this plot it appears that Q is relatively insensitive to x in this composition region. The following expression

$$\mu = \mu_0 e^{-0.22/kT} \qquad (-3.0 < \log x < -1.8) \qquad [6]$$

for the electron mobility was calculated from Eq. [1], [2], and [5] and the above conductivity data. The previously reported activation energy for the electron mobility was 0.14 eV (19). This value was obtained by combining composition (*i.e.*, $x = f(T, P_{O_2})$ and conductivity (*i.e.*, $\sigma = f(T, P_{O_2})$ data in the composition region near stoichiometry (*i.e.*, $x \simeq 10^{-3}$) where the nonstoichiometric defect was assumed to exist in predominately one state of ionization. It is interesting to note that Panlener (21) has recently repeated this analysis using more accurate thermodynamic data. He calculated an activation energy of 0.23 eV for the composition $CeO_{1.998}$ and the temperature range 700°-1300°C. This value is in excellent agreement with the results of this study.

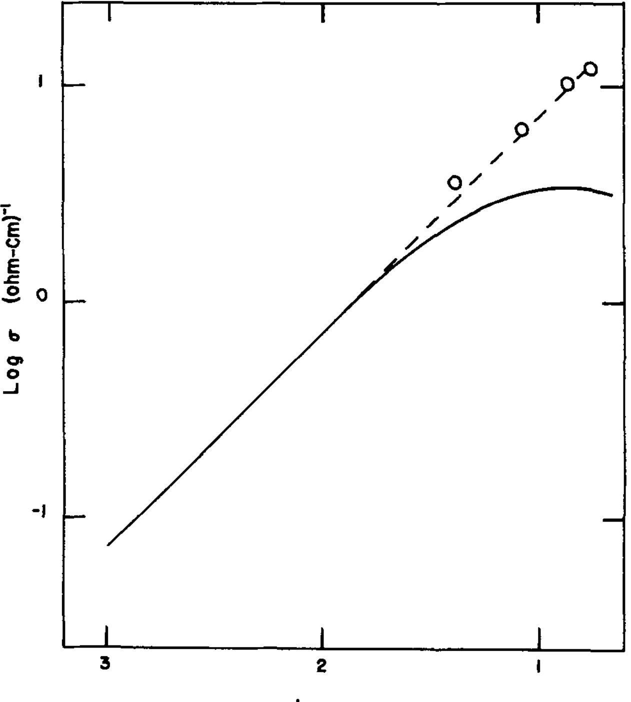

Fig. 4. An isothermal plot of log σ vs. log x at 1000°C for CeO_{2-x} obtained by combining the data from a conductivity and thermodynamic study.

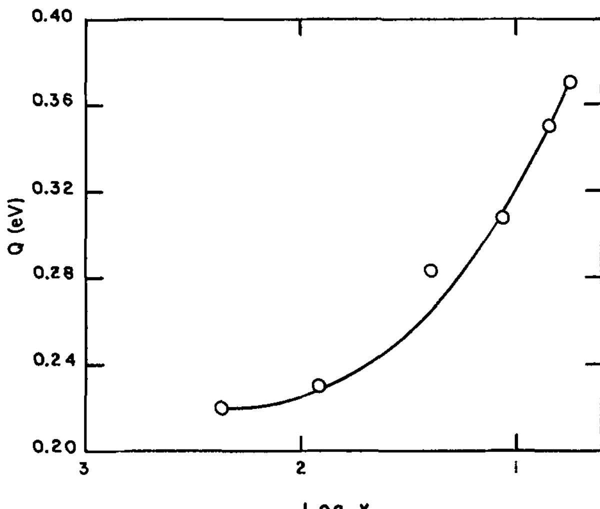

Fig. 5. A plot of the experimental activation energy, Q, obtained from the relation $\sigma = \sigma_0 e^{-Q/kT}$, under conditions of constant composition, as a function of log x.

At larger departures from stoichiometry, $-1.8 < \log x < -0.7$, the experimental activation energy, Q, increases with increasing x. In this composition region σ is no longer proportional to x. As shown in Fig. 4 the dependence of σ on x decreases with increasing x, until $\log x \simeq -0.8$ where a maximum in σ is obtained. For larger values of x, σ decreases with increasing x. The nonlinear dependence of σ on x in this composition region may be attributed to either of the following limiting case situations: (*i*) the dependence of the electron mobility on x; or (*ii*) the dependence of the $[Ce'_{Ce}]$ on x. In case (*i*) the electron carrier concentration is assumed to be proportional to x, whereas, in case (*ii*) the electron mobility is assumed to be independent of x.

Assuming case (*i*) predominates, then the experimental activation energy, Q, is equal to E and the electron mobility may be represented by the expression

$$\mu = \mu_0 e^{-Q/kT} \qquad [7]$$

In addition, if μ_0 is assumed to be independent of x, then the ratio of the mobility, μ, in the region where σ is nonlinear in x to the mobility, μ', in the composition region $\sigma \propto x$, is given by the following expression

$$\ln \frac{\mu}{\mu'} = -\left[\frac{Q - 0.22}{kT}\right] \qquad [8]$$

The ratios of μ/μ' for different values of x were calculated from the corresponding values of Q given in Table II. The results of this calculation at 1000°C are shown in Fig. 6 where log μ/μ' is plotted as a function of log x. The interesting result to observe from Fig. 6 is that the nonlinear behavior of log μ/μ' with log x is similar to the nonlinear behavior of log σ *vs.* log x. In order to determine if the nonlinear behavior in Fig. 4 and 6 is caused by the mobility, the calculated dependence of the mobility on x was adjusted for by adding the corresponding value of $|\log \mu/\mu'|$ to log σ for a given value of x. These "normalized" values of σ are shown in Fig. 4. The most striking observation in this figure is that a single line with a slope of one may be drawn through both the actual values of σ (*i.e.*, $-3.0 < \log x < -1.8$) and the "normalized" values of σ (*i.e.*, $-1.8 < \log x < -0.7$).

The following conclusions may be drawn from the above results:

1. The compositional and temperature dependence of the electrical conductivity of nonstoichiometric CeO_{2-x} may be represented by the following expression

$$\sigma \propto x e^{-Q/kT}$$

where Q is a function of x.

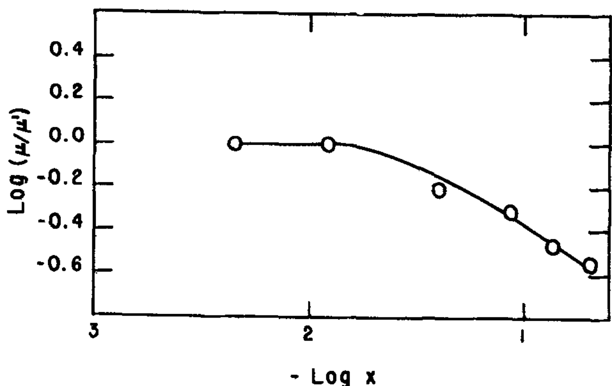

Fig. 6. An isothermal plot of log μ/μ' vs. log x at 1000°C where μ is the electron mobility in the composition region, where σ is nonlinear in x, and where μ' corresponds to the region where $\sigma \propto x$.

2. This expression may be rationalized in terms of the following simple relations for the electron carrier concentration

$$[Ce'_{Ce}] \propto x$$

and the electron mobility

$$\mu = \mu_0 e^{-Q/kT}$$

where μ_0 is independent of x; Q is independent of x in the region $-3.0 < \log x < -1.8$; and Q is a function of x between $-1.8 < \log x < -0.7$.

3. The relation $[Ce'_{Ce}] \propto x$ implies the same nonstoichiometric atomic defect exists in predominately one state of ionization over the entire composition region (*i.e.* $-3.0 < \log x < -0.7$).

It should be noted that the results of an earlier study (13) of the electrical conductivity of CeO_{2-x} as a function of P_{O_2} and T were rationalized utilizing the law of mass action in terms of a defect model involving cerium interstitials in two states of ionization. The relation $[Ce'_{Ce}] \propto x$ obtained from the analysis of the conductivity data in this study is inconsistent with the earlier interpretation (13) involving a nonstoichiometric atomic defect with multiple states of ionization. The most likely explanation for this discrepancy is that the earlier analyses (13) are probably incorrect because the law of mass action was used in regions where the departure from stoichiometry is large.

It should also be noted that although the analysis used in this study circumvents the problem of consideration of the type of the nonstoichiometric defect and its distribution in the fluorite lattice, it does provide a very important characteristic of the nonstoichiometric defect (*i.e.*, $[Ce'_{Ce}] \propto x$) which should be considered in any detailed analysis of the defect structure of CeO_{2-x}. The nature of the nonstoichiometric defect and its state of ionization will be discussed later in a paper based on a thermodynamic study of CeO_{2-x} (21, 24).

The following question also arises from this study. Why is Q a function of x? A current study in this laboratory (25) of the dependence of the lattice parameter as a function of nonstoichiometry at elevated temperatures (800°-1000°C) shows that the lattice parameter increases with increasing x. Since the "hopping-type process" for electron conduction involves an activation energy. it appears likely that the increase in E with x is associated with the increase in the size of the unit cell.

Acknowledgment

The authors wish to thank Dr. R. J. Panlener for providing the thermodynamic data for the analysis and Dr. R. F. Brebrick for useful comments. The authors gratefully acknowledge the financial support provided by the U. S. Atomic Energy Commission, Division of Research. This is AEC Report COO-1441-17.

This paper is based in part on a thesis submitted by one of the authors (R. L. H.) in partial fulfillment of the requirements for the M.S. degree, Marquette University, Milwaukee, Wisconsin, December 1971.

Manuscript submitted Oct. 12, 1972; revised manuscript received Aug. 3, 1973.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1974 JOURNAL.

Low Phosphorus Concentrations in Si by Diffusion from Doped Oxide Layers

J. Middelhoek and J. Holleman

Twente University of Technology, Enschede, The Netherlands

ABSTRACT

The diffusion of phosphorus into silicon from doped oxide layers, deposited at low temperatures, has been studied in order to achieve reproducible impurity distributions with surface concentrations varying from 5×10^{15} to 10^{18} atoms/cm^3. Special attention has been given to the differences arising from indiffusion in an N_2 or in an O_2 ambient. The dependence on the temperature of the diffusion coefficients of phosphorus in silicon and in silicon dioxide is determined at a surface concentration of 5×10^{16} atoms/cm^3.

Doped and undoped oxide layers, which are formed by the oxidation with O_2 of the hydrides of Si, P, B, and other elements at the surface of a slice of monocrystalline silicon at a characteristic temperature of 400°C have valuable applications in the manufacture of integrated circuits (1-4).

The application as a diffusion source is particularly interesting, because an independent control of the surface concentration over several orders of magnitude is made possible.

The purpose of this research is to find the practical lower limit of the phosphorus concentration, which can be obtained by indiffusion. Our research forms an extension of the work of Barry *et al.* (5-7). He reported surface concentrations of phosphorus varying from 6×10^{17} to 2×10^{20} atoms/cm^3. Moreover we also studied the differences which arise when the indiffusion takes place either in an N_2 or in an O_2 ambient. In particular the indiffusion in an O_2 atmosphere has important applications in integrated circuit technology.

Usually a thin layer of undoped oxide is already present on the surface of the substrate before deposition of the oxide. This is caused by air oxidation or due to a cleaning step in nitric acid. The influence of this barrier layer on the result of the diffusion has been carefully observed.

The temperature dependence of the diffusion coefficients of P on Si and SiO_2 has been studied in view of process control. Activation energy values of importance from a theoretical point of view might be expected due to the method of diffusion and on account of the low concentrations.

Theory

Barry and Olofsen (5) have given a detailed mathematical description of a model for the evaluation of the diffusion from a doped oxide layer. We shall use the same model and notation. Figure 1 shows a schematic representation of the different layers together with the diffusion parameters.

The expected impurity distribution after indiffusion from an infinitely thick source layer and without a barrier layer present, is

$$C_2(x,t) = C_o[m\sqrt{D_1}/(m\sqrt{D_2} + \sqrt{D_1})] \text{ erfc } x/2\sqrt{D_2t} \quad [1]$$

The segregation constant m is defined by the equation $m = C_2(0,t)/C_1(0,t)$. Throughout this paper we will use the approximation

$$m\sqrt{D_1}/(m\sqrt{D_2} + \sqrt{D_1}) = \sqrt{D_1}/\sqrt{D_2} \quad [2]$$

because in the case of phosphorus, the data from literature (7, 9) indicate that $\sqrt{D_2} >> \sqrt{D_1}$ and $m >> 1$.

When a first correction term for a finite thickness of the source layer x_o is added we arrive at

$$C_2(x,t) = C_o\sqrt{D_1}/\sqrt{D_2}[\text{erfc } x/2\sqrt{D_2t} - 2 \text{ erfc } (x/2\sqrt{D_2t} + x_o/2\sqrt{D_1t})] \quad [3]$$

The decrease of the total amount of indiffused atoms due to a finite thickness is less than 1% if $x_o > 4\sqrt{D_1t}$. It is useful to express x_o in this inequality as a fraction of the desired junction depth x_j. Using the approximation $x_j \simeq 4\sqrt{D_2t}$, we find as a general rule

$$x_o > x_j\sqrt{D_1/D_2} \quad [4]$$

Using Barry's results (7), we find that in the case of phosphorus no decrease is apparent when

$$x_o > 0.05x_j. \quad [5]$$

When a thin, undoped oxide layer is present between the silicon slice and the doped source layer, caused, for instance, by a cleaning procedure, the distribution in the silicon may still be described as a complementary error-function.

$$C_2(x,t) = C_o\sqrt{D_1/D_2} \text{ erfc } (x + x_B\sqrt{D_2/D_1})/(2\sqrt{D_2t}) \quad [6]$$

Contrary to expression [1] the surface concentration is now time-dependent

$$C_2(0,t) = C_o\sqrt{D_1/D_2} \text{ erfc } x_B/2\sqrt{D_1t} \quad [7]$$

The distribution in the silicon is equal to the profile arrived at when, from a pure complementary error-function profile, a top layer with a thickness of $x_B\sqrt{D_2/D_1}$ has been removed by a sectioning technique. Irvin (8) has composed a set of graphs which can be used for the evaluation of profiles obtained by sectioning. These graphs are also applicable in the case of the presence of an undoped barrier layer, provided that $x_B\sqrt{D_2/D_1}$ is known.

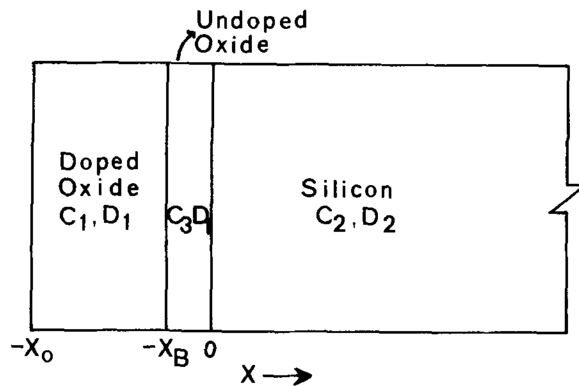

Fig. 1. Diffusion from a deposited doped oxide through a barrier oxide into a semiconductor substrate.

Key words: impurity distribution, low surface concentration, chemical vapor deposition, MOS channels, IC fabrication.

The above solutions are applicable for diffusion in the presence of constant barrier thickness. However, in an oxidizing ambient, an undoped oxide layer grows between the deposited layer of doped oxide and the silicon slice. What occurs can be physically clarified without a thorough mathematical explanation.

The rate of the barrier growth can be derived from the well-known parabolic law for thermal oxidation (9) when the thickness x_o of the deposited layer is also taken into account

$$(x_o + x_B)^2 = B(t_i + t), \text{ where } (x_o + x_{Bo})^2 = Bt_i$$

The parabolic rate constant B is proportional to the diffusion constant of the oxidizing species. By approximation

$$x_B = x_{Bo} + Bt/2x_o \quad [8]$$

The progress of the diffusion in the SiO_2 barrier is difficult to characterize precisely. We take $2\sqrt{D_1t}$ as the distance covered, which is a reasonable assumption as $x_B > \sqrt{D_1t}$. In Fig. 2 we plotted x_B and $2\sqrt{D_1t}$ in one graph as function of the time. What occurs can be clearly seen. Initially the diffusion progresses more quickly than the barrier increases, but after some time the barrier growth overtakes the diffusion of the dopant. At the moment that the processes have the same velocity, the indiffusion into the silicon ceases. The total amount of indiffused impurity remains constant and by further high temperature treatment the distribution begins to approach a Gaussian profile.

Experimental Details

Standard Monsanto silicon slices, doped with boron to a specific resistivity of about 10 ohm-cm plane direction (100), with one side polished and the other side lapped, were used in this research. The specific resistivity of each slice was determined before the experiments and the dopant concentration was derived from literature data (9).

The pretreatment of the slices comprised treatments in fuming nitric acid and in boiling nitric acid (65%), rinsing and centrifuging until dry. Directly afterwards, the deposition in the reactor was carried out.

The depositions were performed in a home-made, one-slice reactor at a slice temperature of 325° ± 2°C. The reactor was cylindrical with a height of 20 cm and a diameter of 8 cm. Before the deposition the reactor was purged with N_2 and the slice preheated for 2 min. The gas flows were argon: 7 liter/min; O_2: 35 ml/min; SiH_4 (net): 7 ml/min. The gas flow of PH_3 varied. The dilution in the cylinder used was 6 ppm. The dilution of SiH_4 in A was 1%.

At first a uniform phosphorus-doped oxide layer of 4000Å was deposited at a rate of 1000 Å/min. Thereafter a densification step (10) followed during 10 min at 650°C in N_2, wetted by leading the gas flow through a washing-bottle containing water at room temperature. This step has been proved to be essential for achieving good diode characteristics in the fabrication of MOS transistors.

Finally, the phosphorus-doped layer was covered by another deposited layer of 4000Å. This layer configuration is also applied in the fabrication of MOS transistors.

After diffusion the oxide was etched away and the sheet resistance was determined with a four point probe. The junction was made visible (12) by grinding a circular groove with a steel ball and by staining one of the layers with $AgNO_3$ or Fuller and Ditzenberger's etching fluid (12). The junction depth was determined with the measuring ocular of a light-microscope.

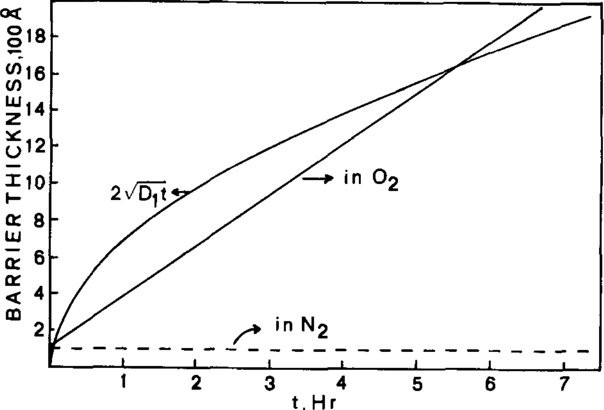

Fig. 2. The increase of the barrier thickness and of the diffusion length of phosphorus in oxide vs. time.

Evaluation Method

The theoretical conditions for an evaluation of the indiffusion based on the combined measurement of junction depths and sheet conductivities, assuming an erfc distribution, are excellent. The background as well as the diffusant concentrations are in this research always much smaller than the intrinsic carrier concentrations at the diffusion temperatures. Complications (14-16) due to an internal field and variation of the vacancy concentration do not occur.

For the justification of the diffusion model it is not only necessary to investigate the variation of x_j and R_s^{-1} with diffusion time, but also the variation with the concentration of dopant in the oxide. It is essential that the surface concentration is proportional to the initial dopant concentration in the source layer (1).

The expression for the junction depth, as derived from [6], is

$$x_j = -x_B\sqrt{D_2/D_1} + 2\sqrt{D_2t} \text{ argerfc } C_B\sqrt{D_2}/C_o\sqrt{D_1} \quad [9]$$

The value, x_B, of the thickness of the thin oxide barrier in this research is not determined separately. It has an estimated value (2, 5) between 15 and 50Å. The expected intercept with the ordinate of the curve x_j *vs.* $\sqrt{t}$ is, according to the diffusivity values reported by Barry (7), very small, about 1000Å. The determination of this intercept cannot be done accurately because systematic errors in the junction depth measurement are of the same order of magnitude. However the determination of $x_B\sqrt{D_2/D_1}$ is made possible by comparing the systematic difference of two series of measurements of x_j *vs.* C_o. The wafers of one series were dipped in a SiO_2 etchant just before the deposition of the doped oxide layer. The wafers of the other series are covered with the thin oxide layer normally found after a cleaning step with HNO_3.

The total amount (6, 9) of indiffused atoms Q is in the case of a complementary error function distribution

$$Q(t,C_o) = 2\pi^{-1/2}C_s\sqrt{D_2t} = 2\pi^{-1/2}C_o\sqrt{D_1t} \quad [10]$$

For very low concentrations compared with the background concentration, three corrections have to be made. First the integral may not be extended to infinity. For finite thickness of x_j the expression for Q can be completed with a factor (11) (Fig. 3)

$$F = (1 - \sqrt{\pi} \text{ ierfc } x_j/2\sqrt{D_2t}) \quad [11]$$

Secondly an amount x_jC_B must be subtracted for the compensation of the background concentration. Thirdly when an undoped barrier layer is present, an amount x_BC_o must also be subtracted because this thin undoped barrier layer acts to a first approximation as a source for a Gaussian distribution, but then in a negative sense.

Thus, the amount of indiffused atoms, which can be determined by sheet conductivity measurements is

$$Q = 2\pi^{-1/2}C_oF\sqrt{D_1t} - x_jC_B - x_BC_o \quad [12]$$

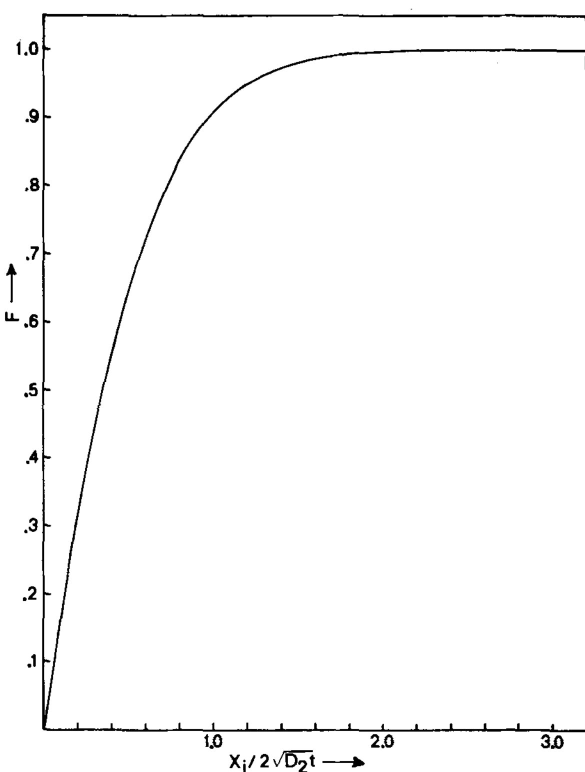

Fig. 3. The factor F, which accounts for the indiffused atoms beyond the metallurgical junction, vs. $x_j/2\sqrt{D_2t}$.

The sheet conductivity R_s^{-1} would be a linear function of Q, if the mobility of the charge carriers, in this case electrons, was independent of the concentration. This problem is usually circumvented by using Irvin's graphs (8) for the evaluation in which this mobility variation is taken into account. But it is however, interesting to check how this mobility variation influences the evaluation. The sheet conductivity as well as the surface concentration determined with Irvin's graphs will therefore be plotted *vs.* the dopant concentration in the oxide. Thereby we shall assume that in our reactor system the following relation is valid for small PH_3/SiH_4 ratios

$$C_o = (PH_3/SiH_4)\,K2 \cdot 3 \times 10^{22}\ \text{atoms/cm}^3 \quad [13]$$

K is a reactor constant. Therefore we evaluate according to

$$R_s^{-1} = K^*\sqrt{D_1t}\,(PH_3/SiH_4) \quad [14]$$

Results and Discussion

In Fig. 4 and 5 the experimentally found junction depth x_j and the sheet conductivity $(R_s)^{-1}$ are both represented as functions of the square root of the time. The graphs show straight lines for diffusion in N_2 as expected according to Eq. [9] and [14] for diffusions in an inert atmosphere.

The intercept of the curve x_j *vs.* $\sqrt{t}$ is smaller than 1000Å and can not be accurately determined from these experiments.

When the diffusion was performed in an oxygen ambient, the junction depths for longer times are somewhat smaller than the values found in N_2. This is obviously an indication that the amount of indiffused phosphorus atoms is smaller. This is even more evident from the sheet conductivity plot (Fig. 5). By diffusion after a certain time in O_2 the sheet conductivity remains constant. This is a result of the cut-off of further influx caused by the growth of an undoped barrier as explained in the theoretical section (Fig. 2).

The sheet conductivity after indiffusion in N_2 for longer times also remains below the value predicted by theory. This may be due partly to exhaustion of the source layer, because x_o = 4000Å and x_j = 10μ and, according to [5], exhaustion should lead to a small decrease of the sheet conductivity.

The average specific conductivity of the layers $(R_sx_j)^{-1}$ is equal to the quotient of the slopes of the

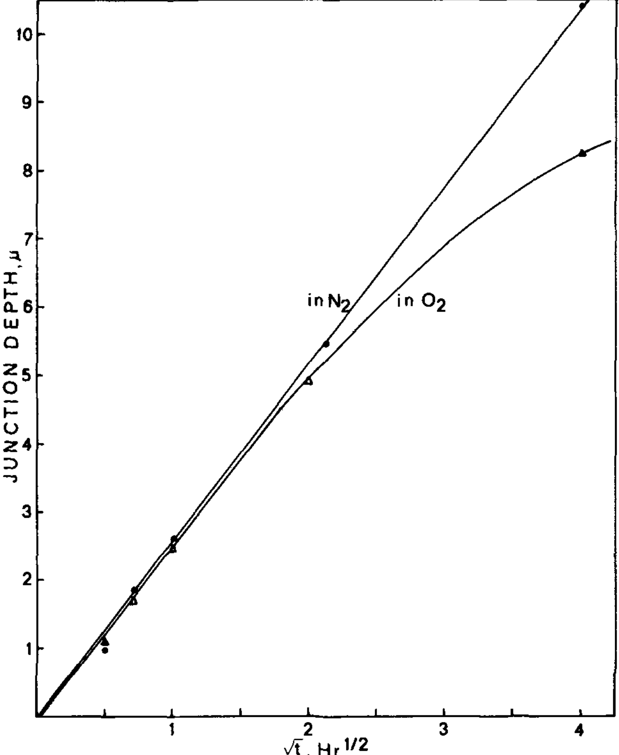

Fig. 4. Junction depths resulting from P diffusion into Si from deposited oxides at 1200°C in an N_2 or in an O_2 ambient, vs. time. $PH_3/SiH_4 = 2.34 \times 10^{-4}$. $C_s = 4.8 \times 10^{17}$ atoms/cm³.

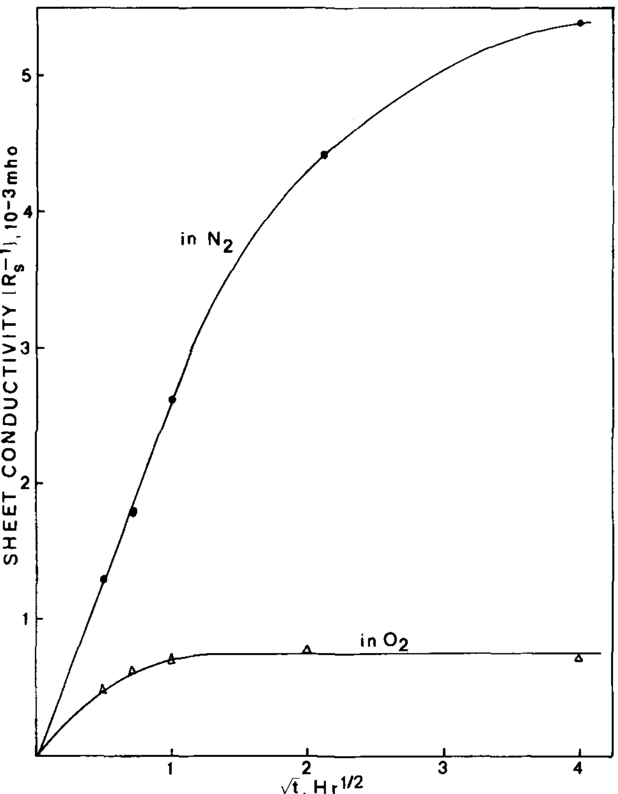

Fig. 5. Sheet conductivities resulting from P diffusion into Si from deposited oxides at 1200°C in an N_2 or in an O_2 ambient, vs. time. $PH_3/SiH_4 = 2.34 \times 10^{-4}$. C_s 4.8 x 10^{17} atoms/cm³.

respective curves. It is a constant for the layers diffused in N_2 as would be expected for a complementary error-function profile. With the help of Irvin's graphs (8) the surface concentration for the diffusion experiments in N_2, represented in Fig. 4 and 5, is found to be 4.8 $\times$ 10^{17} atoms/cm^3. The diffusivity of phosphorus in silicon at 1200° $\pm$ 1°C was calculated from the slope of the plot x_j *vs.* t and the found surface concentration. $\sqrt{D_2} = 0.60$ μ/hr$^{1/2}$.

Figures 6 and 7 show the result of comparable experiments, but with a much smaller phosphorus concentration C_o in the oxide. A pronounced difference occurs, when the slice before deposition, is either dipped or not dipped in an SiO_2 etchant. This was not the case with the above discussed concentration of 4.8 $\times$ 10^{17} atoms/cm^3. Evaluation of the surface concentration gives 3.0 $\times$ 10^{16} atoms/cm^3 when dipping is included and 8.5 $\times$ 10^{15} atoms/cm^3 without dipping. The diffusivities were respectively 0.52 and 0.56 μ/hr$^{1/2}$. The concentration of PH_3 in the deposition gas was 8 times smaller for the experiments of Fig. 6 and 7, than for the experiments of Fig. 4 and 5. The resulting surface concentration was however 16 times smaller with dipping and 57 times smaller without dipping. This means that for this low concentration more than half of the amount of phosphorus is lost during the operation in the reactor system.

Diffusion in an oxygen ambient leads to irreproducible results at this low concentration.

The results of the experiments concerning the temperature dependence of the diffusivities are represented in Fig. 8 and Table I. From the slope of the curve ln $D_2^{1/2}$ *vs.* T^{-1} an activation energy of 5.00 $\pm$ 0.10 eV was calculated at a surface concentration of 5 $\times$ 10^{16} atoms/cm^3. Compared with other values from the literature (7, 13) such as 2.45 eV(2 $\times$ 10^{20}/cm^3); 3.78 eV(5 $\times$ 20^{18}/cm^3); 2.4 eV(9.5 $\times$ 10^{20}/cm^3; and 3.4 eV(3 $\times$ 10^{18}/cm^3) the value now found is much larger. The calculation of the activation energy depends mainly on the values found for the junction depth. The assumption of a systematic error in the junction depth of 0.45μ is necessary to bring the value for the activation energy into agreement with the values reported thus far in the literature for phosphorus diffusion.

The graph of ln R_s^{-1} *vs.* T^{-1} makes it possible, according to [14], to calculate the activation energy of the diffusion coefficient of phosphorus in the oxide. We found 2.04 $\pm$ 0.20 eV. It was assumed that the effective average mobility at 5 $\times$ 10^{16} atoms/cm^3 did not change very much. Literature data indicate a variation of less than 10% and the results, represented in Fig. 10, give reason to believe that the variation is even less. Barry (7) found 4 eV, but this value is not very accurate, as he states in his article, because it is calculated with the help of the barrier thickness x_B.

Barry (7) also found by independent measurements of C_o and C_s that the ratio $C_o/C_s = \sqrt{D_2/D_1}$ is independent of the temperature, but dependent on the concentration of the diffusant. This result is incompatible with his diffusion model. We found, however, in Table I that C_s decreases at a constant C_o and an increasing temperature, because D_2 has a greater increase with a rise in temperature than D_1.

Figures 9, 10, and 11 show the results of diffusion experiments at a constant diffusion time and temperature with varying concentrations of PH_3 in the deposi-

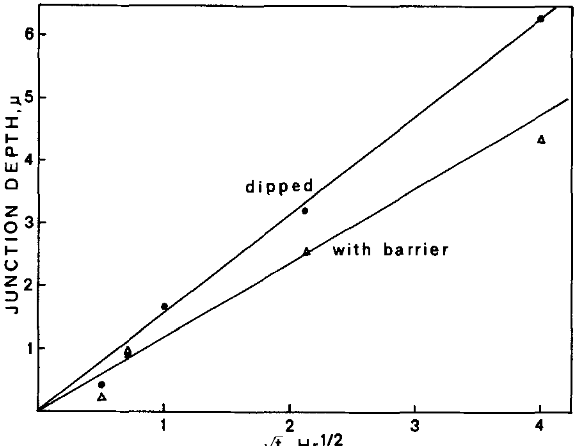

Fig. 6. Junction depths resulting from P diffusion into Si from deposited oxides at 1200°C in an N_2 ambient, vs. time. PH_3/SiH_4 = 3 x 10^{-5}. After a cleaning step in HNO_3 the wafers of one series are dipped in an HF solution before the deposition of the doped oxide.

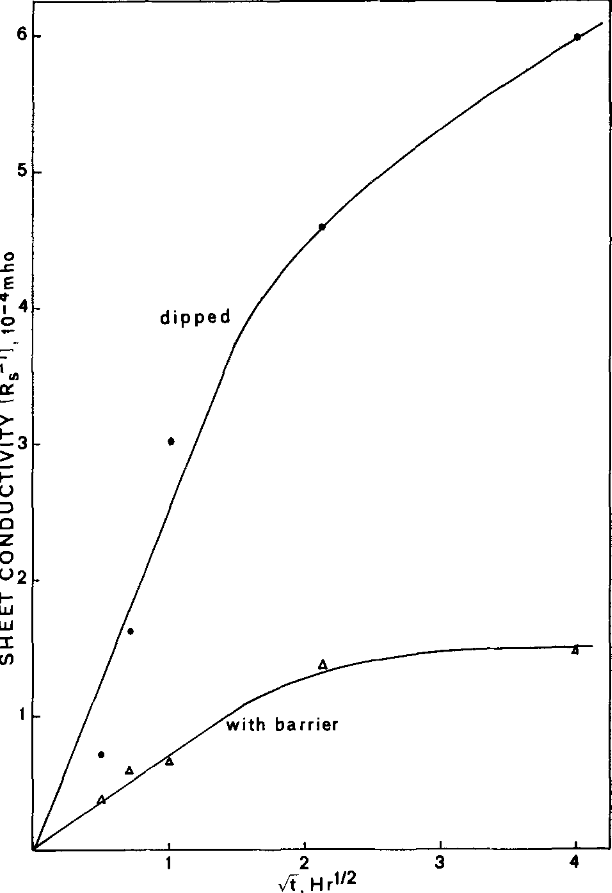

Fig. 7. Sheet conductivities resulting from P diffusion into Si from deposited oxide at 1200°C in an N_2 ambient, vs. time PH_3/SiH_4 = 3 x 10^{-5}. After a cleaning step in HNO_3 the wafers of one series are dipped in an HF solution before the deposition of the doped oxide.

1250	4.34	6.18	1.42	2.5	1.037

tion gas. It was supposed that the concentration C_o was a linear function of the ratio PH_3/SiH_4 in the deposition gas (13). That this supposition was correct, is demonstrated in Fig. 10. According to the theory a linear relation is predicted between $(R_S)^{-1}$ and C_o, and a linear relation between $(R_S)^{-1}$ and (PH_3/SiH_4) is found.

At the highest concentrations a deviation occurs. This may be due to a smaller mobility at these concentrations. But this is not probable, because a similar deviation occurs by diffusion in an oxygen ambient, while the concentration is in a range, where no deviation occurs in the results obtained in an N_2 atmosphere. An error in the control of the PH_3 flow is more probable. The graph of the surface concentration *vs.* (PH_3/SiH_4) (Fig. 11) is not as straight as the graph $(R_S)^{-1}$ *vs.* (PH_3/SiH_4) (Fig. 10). It would appear that the dependence of the mobility on the concentration, such as taken into account by Irvin in his graphs (8) is exaggerated in the range of 10^{17}-10^{18} atoms/cm³.

The systematic difference in junction depth between slices with etching and those without etching is obvious. This difference must correspond with $x_B\sqrt{D_2/D_1}$ (9). The series in N_2 show a difference of about 800Å

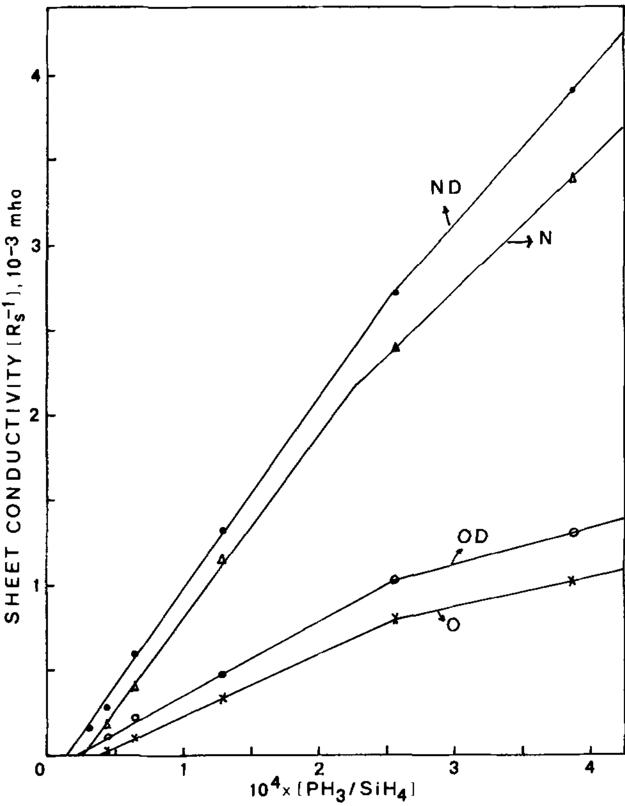

Fig. 10. Sheet conductivities, resulting from P diffusion into Si from deposited oxides during 43 min at 1200°C, vs. the PH_3/SiH_4 ratio in the deposition gas. For symbol definition see Fig. 9.

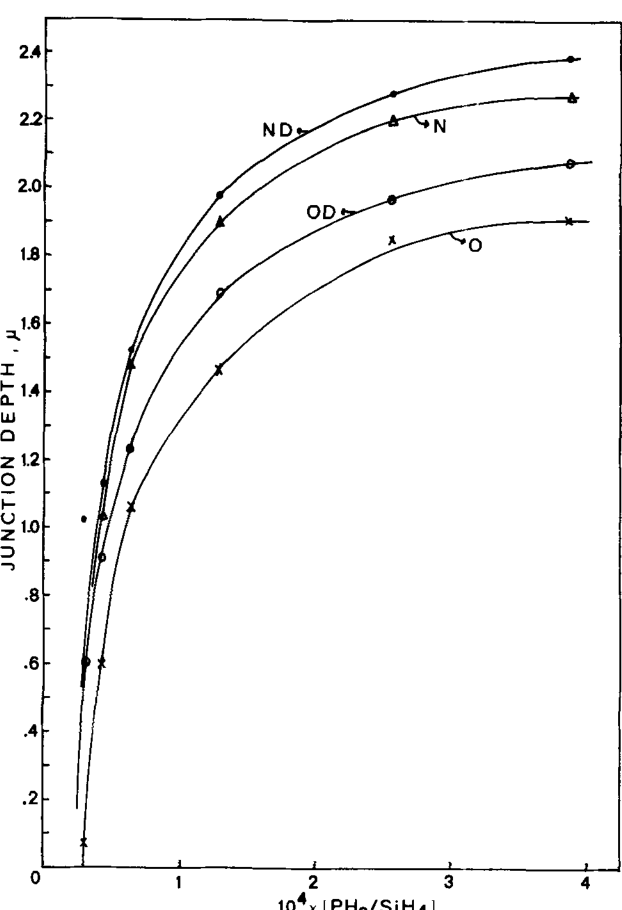

Fig. 9. Junction depths, resulting from P diffusion into Si from deposited oxides during 43 min at 1200°C, vs. the PH_3/SiH_4 ratio in the deposited gas. N: diffusion in an N_2 ambient. O: diffusion in an O_2 ambient. D: dipped in an HF solution before deposition.

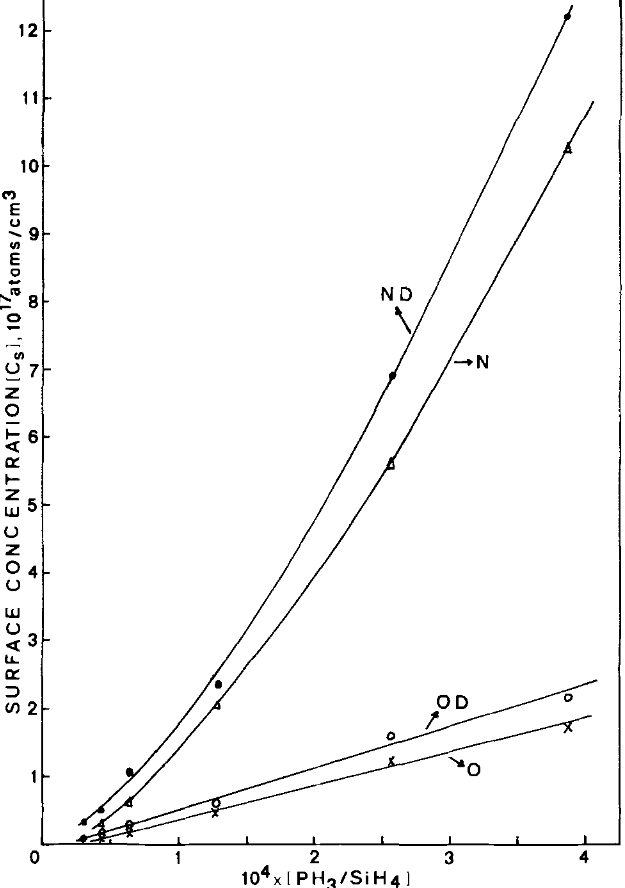

Fig. 11. Surface concentration, derived by means of Irvin's graphs from junction depth and sheet conductivity data, vs. the PH_3/SiH_4 ratio in the deposition gas. See Fig. 9 and 10.

and those in O_2 of about 1700Å. If we assume that the ratio P/Si in the oxide is the same as in the deposition gas, then $C_o/C_s = \sqrt{D_2/D_1}$ at 1200°C can be calculated. A value between 11 and 13 is found. Then in the case of N_2, x_B would be 67Å. This value is fairly large, as we expected (2, 5) a value of about 30Å. It may therefore be concluded that at 325°C relatively more P is deposited than according to the ratio PH_3/SiH_4.

We expected to find a larger value of the effective x_B in the case of an O_2 ambient during the drive-in but the theory is lacking for further analysis.

The difference between $(R_s)^{-1}$ in N_2 with or without a barrier corresponds, according to the theory, with $q\mu C_s x_B \sqrt{D_2/D_1}$. From this result we also derived a value for $x_B\sqrt{D_2/D_1}$. It was 900Å. This value agrees with the 800Å derived from the junction depth measurements. These values show that the theory gives a consistent description of the diffusion process. An application of these diffusion sources with low dopant concentration is shown in Fig. 12. To prevent (13) parasitic channels in p-channel MOS integrated circuits the active regions are surrounded by an area where the surface concentration of the substrate is increased by a diffusion from a phosphorus-doped layer.

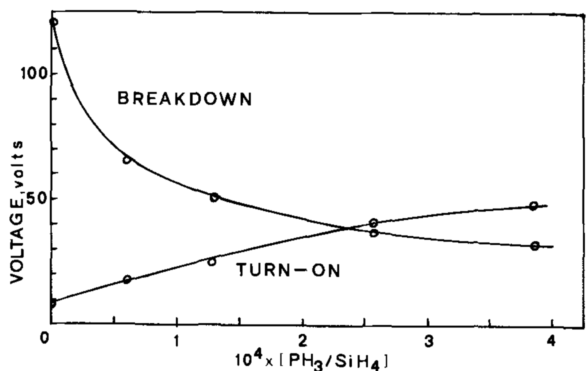

Fig. 12. Breakdown voltage of the drain of a MOS transistor and the parasitic turn-on voltage vs. the PH_3/SiH_4 ratio in the deposition gas for the doped oxide from which a diffusion takes place during the thermal growth of the gate oxide at 1200°C. Field oxide thickness: 8000Å.

The result is that the parasitic turn-on voltage increases. An adverse effect is that the breakdown voltage of the diffused areas decreases. A compromise is found when according to Fig. 12, the turn-on voltage and the breakdown voltage are both 40V. It is interesting to note that measurements of the turn-on voltage or C-V plots give an independent method of determining the surface concentrations. The values may be compared with those obtained by means of Irvin's graphs (8). In our experience the agreement is satisfactory but we do not consider these methods more accurate than Irvin's evaluation.

Manuscript submitted March 5, 1973; revised manuscript received Sept. 18, 1973.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1974 JOURNAL.

The Synthesis and Photoluminescence of $M^{II}M_2^{III}(S,Se)_4$

P. C. Donohue and J. E. Hanlon[1]

Central Research Department, E. I. du Pont de Nemours and Company, Experimental Station, Wilmington, Delaware 19898

ABSTRACT

The compositions $M^{II}M_2^{III}(S,Se)_4$ where M^{II} = Eu, Yb, Ca, Sr, Ba and M^{III} = Al, Ga, In were prepared by reaction of the elements in evacuated silica tubes with iodine as a mineralizer. All members except $Ba(Ga,Al)_2S_4$, which is cubic, exhibit the pseudo-orthorhombic $PbGa_2Se_4$ type structure. They are high resistivity p-type semiconductors; they exhibit Eu^{+2}-activated fluorescence which varies from red to blue as the electropositive character of the cations increase. Fluorescence activated by Yb^{+2} is seen at low temperature. Studies were made of the fluorescence decay lifetimes, temperature dependence, excitation spectra, and optical adsorption of $SrGa_2S_4$:Eu in order to relate the Eu^{+2}-activated fluorescence to the host bandgap. It is concluded that the most efficient phosphors are those in which the Eu^{+2} excited states lie farthest from the fundamental edge.

Sulfides and selenides of general formula $M^{II}M_2^{III}(S,Se)_4$ where M^{II} and M^{III} are divalent and trivalent cations, respectively, form a variety of structures (1,2). The most common are the Ag_2HgI_4 type, spinel type, Th_3P_4 type, and $CaFe_2O_4$ type. The spinel type is favored by smaller cations while the Th_3P_4 and $CaFe_2O_4$

[1] Deceased.

Key words: Eu^{+2} and Yb^{+2} activated photoluminescence of $M^{II}(Al,Ga,In)_2(S,Se)_4$.

types are favored by larger electropositive cations such as the rare earths. The Ag_2HgI_4 type, in which all cations are tetrahedrally coordinated, is favored by the more covalent cations, *e.g.*, the $HgGa_2S_4$-type series (3).

Until recently, with the exception of $MgGa_2S_4$ (4) and $BaIn_2S_4$ and $SrIn_2S_4$ (5), very little work had been reported on compounds combining the larger ionic divalent cations with the more covalent trivalent cations. Eholie and co-workers reported $PbGa_2Se_4$ (6) to exhibit a new orthorhombic structure. In a later paper (7) they reported lattice constants and paramagnetism of $EuM_2^{III}(S,Se)_4$, $SrM_2^{III}(S,Se)_4$, and $PbAl_2(S,Se)_4$ where M^{III} = Al, Ga. The phases exhibit an orthorhombic sublattice with the simultaneous presence of twinning and superlattice.

The luminescence and structural properties of Ce^{+3} and Eu^{+2} activated $M^{II}Ga_2S_4$ where M^{II} = Ca, Sr, Ba, Pb, Eu (Na, La), and (Na, Ce) were reported by Peter and Baglio (8). Their structural data are in agreement with Eholie *et al.*, and they report $BaGa_2S_4$ to be cubic. The alkali earth thiogallates were shown to be efficient hosts for Eu^{+2} luminescence. The peak emission was shown to vary from the blue-green to yellow depending on the host.

We here report the extension of the series to include $Yb(Ga,Al)_2(S,Se)_4$, $M^{II}In_2(S,Se)_4$, $BaAl_2S_4$, and $(Ca,Ba)Ga_2Se_4$. We also measured the Eu^{+2} and Yb^{+2} activated luminescence, electrical resistivity, and optical absorption on several compositions.

Sample preparation.—Compositions were prepared by reactions in evacuated silica tubes using a small quantity of iodine as a mineralizing agent. EuS and EuSe were prepared by starting with ingots of 99.9 pure Eu obtained from Kerr McGee Company, and 99.999 pure S and Se obtained from ROC/RIC. All other reactants were used in elemental form; 99.9999 pure Ga obtained from Alcoa, 99.999+ pure In obtained from Asarco, and 99.999 pure Al wire obtained from ESPI. Ca, Sr, and Ba were obtained 99.5% pure from ROC/RIC. Sr and Ba were cut from bars and weighed in a N_2-filled dry box. The reactants, in stoichiometric proportions, were placed in dried silica tubes. About 5 mg I_2/cm^3 was added and the tubes were evacuated and sealed at a length of about 6 in.

Reactions were carried out in natural gradient tube furnaces with the ends of the tubes containing the metals in the hot center and the chalcogen at the cooler outer edges of the furnaces. The temperature of the centers was raised to about 500°C and held for 24-48 hr. The cooler ends of the tubes were at ~300°C to keep the vapor pressure of the chalcogen low. During this treatment, $M^{II}S,Se$ formed without reaction of the M^{II} metal with the silica. The temperature of the center was then raised to about 800°C and after about 24 hr most of the chalcogen was taken up. The tubes were removed and shaken to better mix the reagents or opened, the products reground, resealed in silica. They were reheated at between 800° and 1000°C for 24-48 hr. When using Al wire, several shakings were required since a hard sulfide crust forms preventing further reaction.

Solid solutions and doped compositions were prepared by starting with the desired ratio of reactants and proceeding as described or grinding together preprepared material, sealing in evacuated silica tubing, and heating at between 800° and 1000°C.

The products generally formed in the hotter ends of the tubes as sintered crystalline masses. In some cases crystals were transported to the cool zone.

Boules of several compositions were grown in either graphite or Al_2O_3 crucibles, sealed under vacuum in silica tubes, and cooled from about 50°C above the melting point at 5°C/hr. The crystalline habit was typically lamellar, and bubbles were seen in the sulfides indicating a high S vapor pressure at the melting point.

The melting points of $EuGa_2S_4$, $EuGa_2Se_4$, $EuIn_2Se_4$, $BaGa_2S_4$, and $SrGa_2S_4$ were determined by DTA and are given in Table I. All appear to melt congruently and freeze with supercooling of between 50° and 100°C. $BaGa_2S_4$ formed a glass.

Results and Discussion

Crystal chemistry.—Table I summarizes the results of the syntheses, cell refinements, and resistivity measurements. Debye-Scherrer x-ray powder patterns were refined by a computerized least squares technique and standard deviations in the cell parameters are typically 0.003Å.

Two structure types are exhibited by this series, the $PbGa_2Se_4$ type and the cubic $BaGa_2S_4$ type. The orthorhombic cell, although it could not account for all diffraction lines, was used to compare relative cell sizes of the $PbGa_2Se_4$ type compounds and for phase identification.

Several crystals of various samples of the $PbGa_2S_4$ type were examined by Buerger precession camera techniques and our results are consistent with those reported (7, 8). In all cases a large orthorhombic superlattice was indicated; however, extinctions inconsistent with any orthorhombic space group were observed suggesting the presence of twinning and that the true symmetry is lower than orthorhombic.

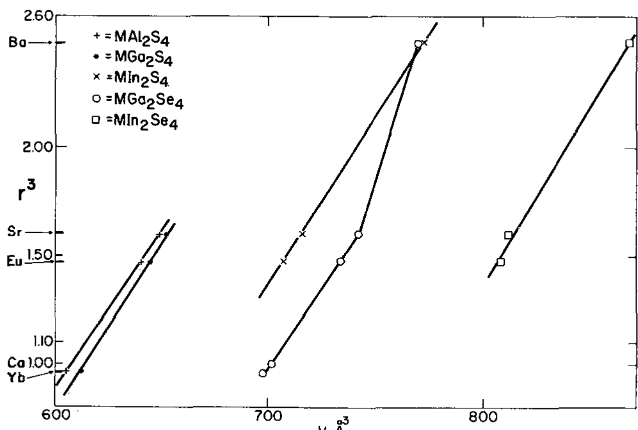

Fig. 1. Size relationships of the orthorhombic $PbGa_2Se_4$ type cells

In a study of a crystal of $EuIn_2Se_4$, a triclinic cell was derived by sorting out untwinned reflections. The dimensions are $a = 6.42Å$, $b = 12.840Å$, $c = 15.424Å$, $\alpha = 127°$, $\beta = 52.8°$, $\gamma = 116.6°$.

Figure 1 shows the size relationships. It is a plot of the radii cubed (r^3) of the divalent cations *vs.* the volume of the orthorhombic cells. The radii of the divalent cations were obtained by taking half the cell edge of the rock salt sulfides $M^{II}S$ and subtracting the ionic radius of S (1.84Å).

The figure suggests that relative cation size is an important factor in the formation of the $PbGa_2Se_4$-type structure. When M^{II} = Ca or Yb, only combinations with M^{III} = Al, Ga show this structure. When M^{II} is Ba, the structure forms only in combination with the large M^{III} cation, In; with M^{III} = Al,Ga, a cubic structure forms for the sulfides.

$BaGa_2Se_4$ exhibits the orthorhombic $PbGa_2Se_4$-type powder pattern but with an anomalous cell volume. A study of the system $BaGa_2S_{4-x}Se_x$ showed the $BaGa_2S_4$ type present for $x = 3.6$ but a rhombohedral distortion was seen.

Electrical properties.—Room temperature resistivities (Table I) and Seebeck coefficients measured on single crystals indicate high resistance, p-type semiconduction. Many attempts were made to dope these materials but resistivities could not be appreciably lowered.

$EuIn_2Se_4$ exhibited photoconductivity with ρ dark $> 10^{14}$ ohm-cm; when exposed to light (4000-6000Å), $\rho = 2 \times 10^9$ ohm-cm.

Photoluminescence: Eu^{+2}.—The Eu^{+2} photoluminescence emission spectra of $M^{II}M_2^{III}(S,Se)_4$ phosphors excited by 253.7 nm Hg light were measured on powders between 300 and 750 nm using a 1/2 meter Bausch and Lomb monochromator fitted with an EMI extended S-20 response photomultiplier tube detector. The monochromator-detector system was calibrated against an Eppley quartz-iodine standard lamp. As a further check, the spectra obtained on NBS reference phosphors were compared with those obtained by Shelton (9).

Consistent with the findings of Peters and Baglio (8), we found the emission of Eu^{+2} in $M^{II}M_2^{III}Se_4$:Eu to consist of narrow bands which peaked, depending on the host, in the blue through red region of the spectrum. We extended studies of the fluorescent properties of Eu^{+2} in these materials to include cases where M^{III} = Al, In, selenides and $EuM_2^{III}(S,Se)_4$.

The emission band peak positions, peak half widths, and quantum efficiencies are given in Table II.

The photoluminescence quantum efficiencies were estimated by comparing the integrated emission intensities of the $M^{II}M_2^{III}(S,Se)_4$:Eu, Yb samples with the integrated intensities of the National Bureau of Standards reference phosphors NBS 1026, 1027, and 1028. The 254 nm excited photoluminescent quantum efficiencies of the reference phosphors were measured by Bril and Hoekstra (10), Kingsley and Ludwig (11), and Shelton (9). For most work, NBS 1026 was the comparison phosphor and was assumed to have a quantum efficiency of 77% under 254 nm excitation.

The $M^{II}In_2(S,Se)_4$:Eu compositions are not luminescent at room temperature; 80°K luminescence properties are given in Table II.

From Table II it can be seen that the emission peak position is shifted to the blue region of the spectrum for $Ba_{0.999}Al_2S_4$:0.006 Eu. It may be stated that, as the electropositive character of the cations of the host increases, the emission shifts in color from red to blue. In the same way the optical bandgap would be expected to increase since the ionic character of the host would increase.

It can also be seen in Table II that the emissions from $EuGa_2S_4$ and $EuAl_2S_4$ are quite strong.

In order to understand the fluorescences of Eu^{+2} in these materials as a function of host bandgap, we studied the lifetimes, thermal properties, optical absorption, and excitation spectra of selected compositions. We hoped to gain an understanding of the relationship of the band levels of the fluorescent levels for the possibility of achieving injection electroluminescence.

Decay lifetimes.—The fluorescence decay lifetimes of several Eu^{+2} activated $M^{II}M_2^{III}(S,Se)_4$ phosphors are listed in Table III. The decay lifetimes fall into three groups: (*i*) $EuM_2^{III}S_4 \approx 0.2$ μsec, (*ii*) $M^{II}M_2^{III}S_4$: (dilute Eu) $\approx$ 0.3-0.5 μsec, and (*iii*) $M^{II}M_2^{III}Se_4$: (dilute Eu) $\approx$ 1-2 μsec. The 0.3-0.5 μsec range is believed to be representative of Eu^{+2} in the $M^{II}M_2^{III}S_4$ environment. The oscillator strength estimated from the 0.42 μsec lifetime of $SrGa_2S_4$:Eu is 5×10^{-3}, consistent in order of magnitude with previously reported values

(12). The shorter lifetimes of the $EuM_2^{III}S_4$ sample is believed to be a manifestation of concentration quenching: the observed lifetimes are shortened by nonradiative depopulation of the Eu^{+2} excited states.

The longer emission lifetimes of the selenides compared to the sulfides may be caused by greater mixing of the $4f^65d$ or $4f^66s$ Eu^{+2} excited states with Se^{-2} excited states than occurs with the S^{-2} excited states. In other words, the Eu^{+2} excited states may be delocalized in the selenides and lie within or above the conduction band. This is consistent with the emission data (Table II) which shows the selenides $EuGa_2Se_4$ and $Ca_{0.9}Ga_2Se_4$:0.1 Eu to emit at energies higher than or nearly the same as the analogous sulfides. Since the bandgaps of the selenides would be expected to be narrower than the sulfides, the Eu^{+2} excited states may be within the conduction band. The selenides have very low photoluminescent efficiencies only slightly increased by cooling to 80°K.

Although most of the photoluminescence of Eu-activated $M^{II}M_2^{III}(S,Se)_4$ decays very rapidly, in a few μsec or less, a small amount of the photoluminescence, typically 1-5% of the total intensity, decays much more slowly, over intervals of 10 msec or longer. The long decay duration emission or phosphorescence is most prominent in the $BaM_2^{III}S_4$ compositions, for which as much as 10% of the photoluminescence is phosphorescence. Under electron excitation, the phosphorescence of the $BaM_2^{III}S_4$ phosphors lasts several seconds for samples with the lowest Eu concentrations (~100 ppm). The phosphorescence and fluorescence emission spectra are the same. The more phosphorescent $M^{II}M_2^{III}(S,Se)_4$:Eu compositions can also be excited by *IR* light after exposure to uv. We conclude that the phosphorescence is caused by trapped electrons which are thermally ionized over a period of time.

Temperature dependence of the photoluminescence.—The temperature dependence of $M^{II}M_2^{III}S_4$:Eu phosphors is sensitive to Eu concentration. The temperature dependence of $EuGa_2S_4$ and $SrGa_2S_4$:Eu is shown in Fig. 2. The photoluminescence efficiency of Eu^{+2} in $EuGa_2S_4$ decreases with temperature and is a factor of 100 greater at 100°K than at 500°K. On the other hand, the photoluminescence of $SrGa_2S_4$ doped with 100 ppm Eu or less is almost temperature independent.

Excitation spectra and optical absorption.—The photoluminescence excitation and emission spectra of $EuGa_2S_4$ are shown in Fig. 3: 254 nm light is 60% as efficient in exciting luminescence as is 450 nm light. However, according to the data of Peters and Baglio (8), 254 nm light is only ~10% as efficient as 450 nm light in exciting luminescence in $Sr_{0.98}Ga_2S_4$:0.02 Eu. Thus as the Eu concentration increases in the system $SrGa_2S_4$:Eu, the increased relative utility of 254 nm light partially cancels the deleterious effect of concentration quenching.

The optical absorption of $SrGa_2S_4$ and $Sr_{0.98}Ga_2S_4$:0.02 Eu crystals are shown in Fig. 4. The absorption was determined by measuring the transmission of ~2×10^{-3} cm thick samples in a Cary 14. $SrGa_2S_4$ has an absorption edge at 380 nm and little or no absorption between this edge and the infrared. $Sr_{0.98}Ga_2S_4$:0.02 Eu has additional absorption between 360 and 510 nm which we associate with Eu^{+2} $4f^7 \rightarrow 4f^65d$ or $4f^66s$ transitions. The oscillator strength determined by integrating the Eu^{+2} part of the absorption in $Sr_{0.98}Ga_2S_4$:0.02 Eu is 4×10^{-3}, in satisfactory agreement with the 5×10^{-3} value derived from fluorescence decay lifetime data and quite reasonable for a parity allowed transition in a multielectron transition metal ion. The Eu^{+2} absorption has also been measured in $Sr_{0.995}Al_2S_4$:0.005 Eu. In this compound the Eu absorption peaks at 380 nm compared with 393 nm in $Sr_{0.98}Ga_2S_4$:0.02 Eu.

Discussion.—The Eu luminescence is excited relatively efficiently in the wavelength region where Eu^{+2} absorption is dominant. At excitation wavelengths shorter than the host fundamental edge, the Eu^{+2}

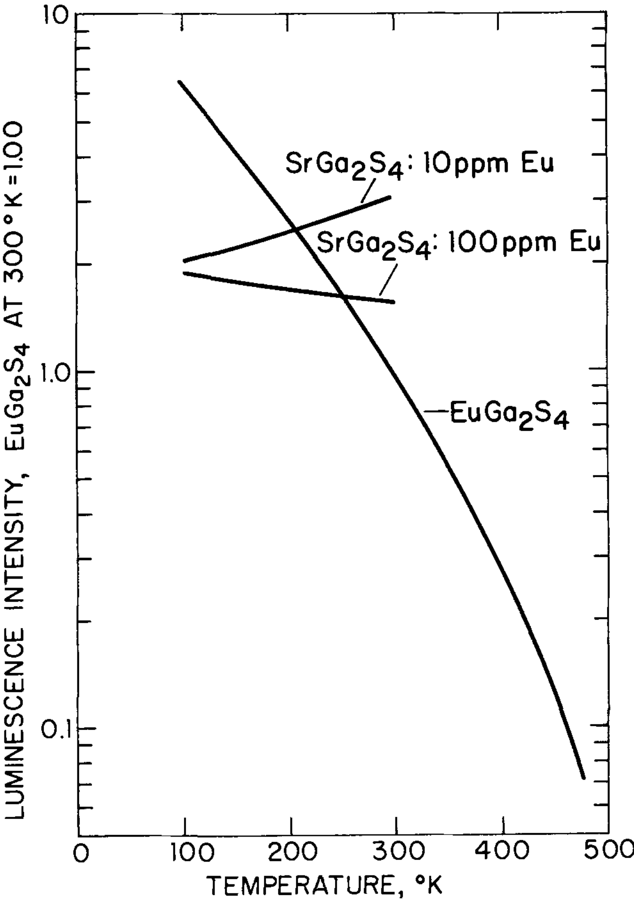

Fig. 2. Temperature dependence of the photoluminescence of $EuGa_2S_4$ and $SrGa_2S_4$:Eu.

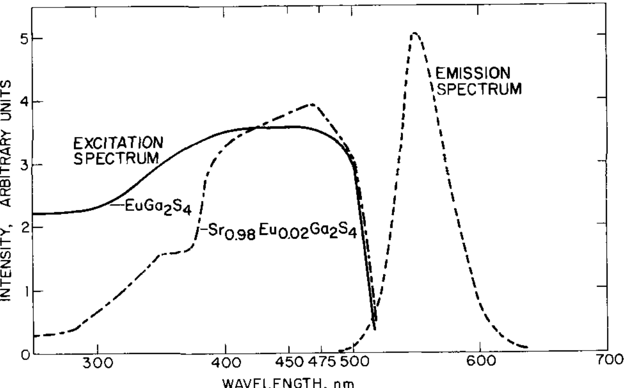

Fig. 3. Photoluminescence excitation and emission spectra of $EuGa_2S_4$ and $Sr_{0.98}Eu_{0.02}Ga_2S_4$. The data on $Sr_{0.98}Eu_{0.02}Ga_2S_4$ were taken from Peters and Baglio (8).

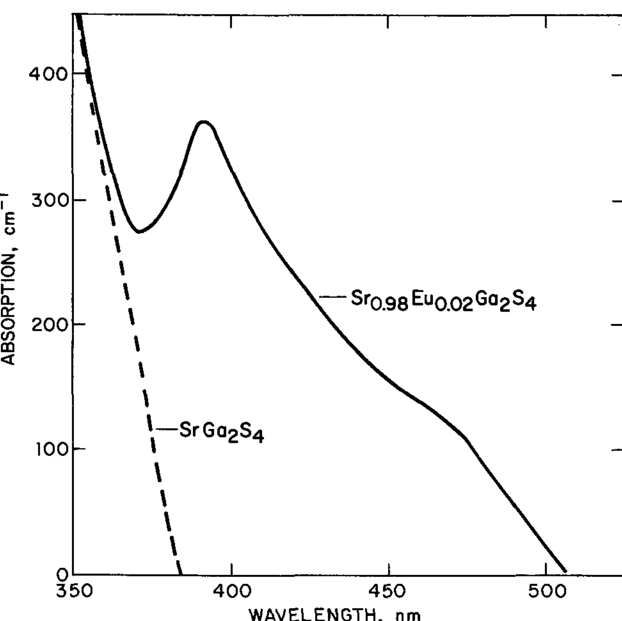

Fig. 4. Optical absorption of $SrGa_2S_4$ and $Sr_{0.98}Eu_{0.02}Ga_2S_4$

luminescence efficiency drops sharply in dilutely doped samples (compare Fig. 3 and 4). We conclude that the host absorption mechanism is able to excite the Eu^{+2} luminescence only weakly or not at all. Consequently the relative Eu^{+2} photoluminescence efficiency at any exciting wavelength scales with the ratio of the Eu absorption to the host absorption.

The values of the efficiencies quoted in Table II are therefore insufficient measures of the true efficiencies because the 254 nm excitation is very poor for stimulating fluorescence.

Many of the features noted in these studies may be correlated in terms of the observation that fluorescence is produced more efficiently by excitation directly into the Eu^{+2} excited states.

When the bandgap or host absorption energy levels are only slightly higher than the Eu^{+2} excited states, energy may be lost from the Eu^{+2} excited states to the host where nonradiative processes predominate by thermal excitation. The much greater efficiency of the luminescence of $EuGa_2S_4$ at low temperature may be interpreted as due to less of this type of thermal excitation. The more isolated Eu^{+2} levels in the very dilute $SrGa_2S_4$:Eu compositions may not receive thermal energy from the host in the same way as in the more concentrated composition. Their different behavior may be related to such an effect.

The low fluorescence efficiency of the selenides and In composition is probably also due to mixing of the Eu^{+2} levels with the fundamental edge since the bandgaps of these compounds would be expected to be narrower than the sulfides and GaAl compositions. The most efficient phosphors should then be those with the widest bandgaps where interaction between the Eu^{+2} excited states and fundamental edge is minimal, *e.g.*, $BaAl_2S_4$:Eu.

Photoluminescence: Yb^{+2}.—The photoluminescence of Yb^{+2} has been observed and measured in a few $M^{II}M_2^{III}S_4$ hosts, but is bright only at low temperatures (Table II). The color of the Yb^{+2} emission is yellow or orange. At 80°K, the quantum efficiencies of $YbGa_2S_4$ and $Ca_{0.99}Ga_2S_4$:0.1 Yb are 0.1 and 3%, respectively. The Yb^{+2} emission intensity is completely quenched at ~200°K. It is not known why the Yb^{+2} emission is quenched at room temperature, but we speculate that the excitation energy may be degraded by the presence of a small concentration of Yb^{+3}. In $YbGa_2S_4$, the intensity of the 0.97μ Yb^{+3} absorption band suggests that about 5% of the Yb in the sample is trivalent.

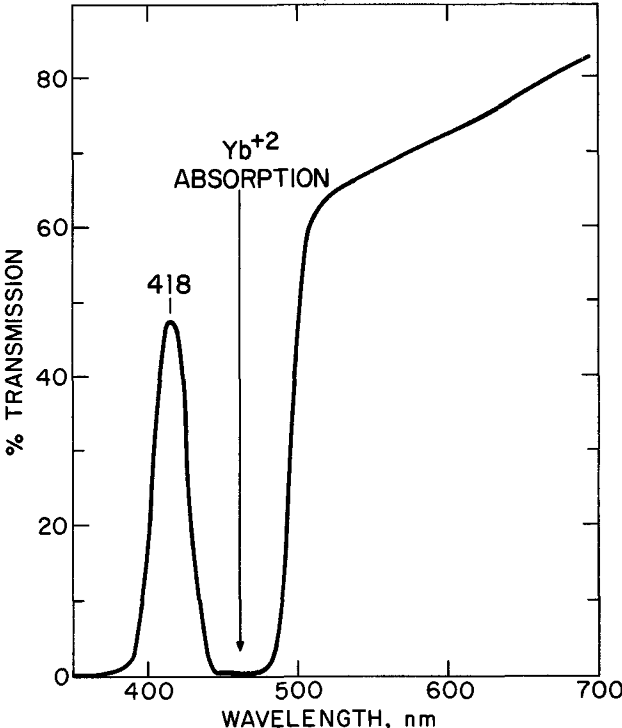

Fig. 5. Optical transmission of $YbAl_2S_4$

Optical absorption, Yb^{+2}.—The optical absorption of $M^{II}M_2^{III}S_4$:Yb is qualitatively similar to $M^{II}M_2^{III}S_4$:Eu. There is a long wavelength Yb absorption band which overlaps the fundamental edge of the host to some extent. The overlap is smaller for Yb than for Eu. For example in $YbAl_2S_4$, there is a window between the Yb absorption band and the fundamental edge. This may be seen in the optical transmission data for a 2×10^{-3} cm thick crystal illustrated in Fig. 5.

Acknowledgment

Dr. J. D. Bierlein is especially thanked for helpful suggestions and discovering the infrared stimulable fluorescence. Drs. H. S. Jarrett and D. B. Rogers contributed helpful discussion. Dr. W. Jeitschko contributed to the x-ray work. Dr. P. E. Bierstedt and Mr. J. L. Gillson performed electrical measurements. The equipment for measurement of fluorescent lifetime was designed and built by Mr. P. C. Hoell. Many of the photoluminescence emission spectra were measured on equipment developed by Mr. R. P. Schwenker. Mr. D. J. Jones and Mr. D. W. Reutter assisted in sample preparation and testing.

Manuscript submitted June 18, 1973; revised manuscript received Aug. 3, 1973.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1974 JOURNAL.

Candoluminescence in Transition-Ion-Activated Oxide Phosphors

John W. Hess, Jr.,[1] John R. Sweet, and William B. White*[,1]

Materials Research Laboratory, The Pennsylvania State University, University Park, Pennsylvania 16802

ABSTRACT

Flame-excited luminescence (candoluminescence) has been measured for transition-ion-activated phosphors Zn_2SiO_4:Mn, $LaAlO_3$:Cr, and $Zn_3(PO_4)_2$:Mn. Willemite and the Cr-activated phosphors exhibit candoluminescent spectra similar to emission spectra obtained by other excitations. The emission spectra of $Zn_3(PO_4)_2$ is profoundly different. Certain other common phosphors $Sr_2P_2O_7$:Sn, $CaCO_3$:Mn, Pb, and $CaWO_4$ do not luminesce under flame excitation. All emitting phosphors require a temperature of several hundred degrees centrigrade for most efficient emission.

Candoluminescence is defined as a process of light emission from solids under flame excitation, in excess of thermal radiation. The phenomenon was once a subject of great interest in connection with the operation of gas mantles and received extensive, although mainly qualitative, investigation in the first quarter of this century (1). There has been a minor but continuing interest in the Russian literature, for example a series of papers by Sokolov (2-5). There have been a number of investigations of the radical recombination mechanism that excites the luminescence (6-9) and at least one attempt to apply candoluminescence to a practical device (10). A report by Mason (11) summarized an investigation of many of the rare earth oxides and numerous commercial phosphors.

The candoluminescent phosphors can be divided into two categories of materials: low- and high-temperature emitters. The latter type luminesce at or near red heat, while the former emit from room temperature up to a few hundred degrees C. The low-temperature emitters can be further subdivided into rare-earth doped phosphors which give a spectrum of many narrow lines, and transition-ion doped phosphors which show a very broad-band spectral energy distribution. Our concern in this paper is with low-temperature emitters activated by transition metal ions.

Experimental

Rare-earth doped candoluminescent phosphors have been investigated in some detail (12, 13), and the experimental apparatus and procedures used in the present work are identical with those described previously. Briefly, candoluminescence measurements were made by playing a hydrogen diffusion flame on a layer of powder phosphor coated on a Kanthal rod. Spectra were measured with a 3/4-meter grating spectrograph and are shown here as densitometer traces from the photographic plates. Temperature-dependence measurements were made using a Cary 14 spectrophotometer held at a fixed wavelength, while the sample temperature was cycled up and down.

Some phosphors examined were commercial products contributed by Sylvania Electric Company, others were synthesized by dry firing the corresponding oxides or carbonates at 1200°C in an air atmosphere. Table I summarizes the phosphors examined and the activator concentration. The structure and phase purity of all synthetic phosphors were determined by x-ray diffraction.

Spectral Measurements and Discussion

Mn^{2+}-activated phosphors.—Mn^{2+}-doped willemite, Zn_2SiO_4:Mn^{2+}, is a commercial green-emitting photophosphor obtained in several Mn^{2+} concentrations from Sylvania Electric Products, Incorporated. Figure 1 shows spectra typical of this material, measured from Type 103-F plates without compensation for spectral sensitivity. Both the candoluminescence spectrum (solid line) and the 254 nm Hg-excited photoluminescence spectrum (dashed line) were taken at about 170°C. The emphasis in this figure is on the similarities, rather than the differences between the spectra. The candoluminescence spectrum was a slightly lower exposure, resulting in a lower peak height, and has a slightly denser background due to the flame. Note that the bandwidth and peak frequency are essentially the same for both excitations. The true bandwidth at half-peak height cannot be directly determined, since the intensity scale is nonlinear. The small peak at 625 nm is probably not significant.

Candoluminescent phosphors generally exhibit a temperature dependence of maximum emission intensity characteristic of the activator-host combination. For most of the rare-earth phosphors, the intensity-temperature curve is reproducible over several cycles of heating and cooling (13). A typical response for willemite is shown in Fig. 2. As long as the temperature was held below 200°-250°C the uppermost curve was reproduced. Once the temperature was raised to 360°C, the intensity followed the middle curve, which was again reproducible as long as the temperature was held below 200°-250°C. When the temperature was again raised to 360°C and allowed to cool, the lowest curve was obtained. Once the intensity was degraded by the flame, it did not recover its former value. The phosphor was quite stable to flame heating at low temperature but is rapidly rendered nonemitting by repeated heating at higher temperatures.

The candoluminescence spectrum of willemite, therefore, is not measurably different from the photoluminescence. Gorban' *et al.* (5) reported different decay

Table I. Summary of phosphors examined

Host	Activator	Luminescence: 254 nm Photo-	Luminescence: Cando-	Source
Zn_2SiO_4	0.022 Mn^{2+}	Bright green	Bright green	Sylvania 161
Zn_2SiO_4	0.048 Mn^{2+}	Bright green	Bright green	Sylvania (?)
Zn_2SiO_4	0.093 Mn^{2+}	Bright green	Bright green	Sylvania 2282
$Zn_3(PO_4)_2$	(?) Mn^{2+}	Very weak red	Bright yellow-orange	Sylvania 151
$LaAlO_3$	0.0048 Cr^{3+}	None	Weak red	National Lead Co.
Al_2O_3	0.002 Cr^{3+}	None	Weak red	Synthesized
	0.01 Cr^{3+}	None	Weak red	Synthesized
	0.02 Cr^{3+}	None	Weak red	Synthesized
$MgAl_2O_4$	0.01 Cr^{3+}	None	Weak red	Synthesized
$MgGa_2O_4$	0.01 Cr^{3+}	None	Weak red	Synthesized
$Sr_2P_2O_7$	(?) Sn^{2+}	Bright blue	None	Sylvania 243
$CaCO_3$	0.01 Mn^{2+} 0.01 Pb^{2+}	Bright pink	None	Synthesized
$CaWO_4$	None	Medium blue	None	Reagent grade

times for the two excitation mechanisms. The critical temperature for optimum brightness in Fig. 2 ranges from 220° to 190°C and is distinctly lower than the ~260°C reported by Thorington (10).

$Zn_3(PO_4)_2$:Mn^{2+} Sylvania Type 151, is listed as a red cathode-ray-tube phosphor with peak wavelength at 639 nm and bandwidth at half-peak height of 90 nm. It was found to weakly photoluminesce at the same wavelength under 254 nm excitation. Its flame-excited emission, however, was a very intense yellow-orange, which is shown in Fig. 3, as measured from a Type 103-F plate. There appear to be two peaks which are barely resolved, one at ~640 nm, the same as cathodo- and photoexcitation, and another at 600 nm which is not observed with other excitation mechanisms. The candoluminescent emission of $Zn_3(PO_4)_2$ is different from cathodo-excited emission. X-ray diffraction shows this commercial phosphor to consist of β-$Zn_3(PO_4)_2$ which emits in the red at 638 nm (14). One could imagine a phase change to the low temperature α-$Zn_3(PO_4)_2$ in the hydrogen flame, but α-$Zn_3(PO_4)_2$ is known to emit in the green at 551 nm (14), in clear disagreement with Fig. 3. This is an important result that will be discussed in more detail later.

The emission intensity of zinc phosphate exhibits a temperature dependence similar to that of willemite. The optimum efficiency occurs at 225°C (Fig. 4). This phosphor can be heated to at least 350°C and can be cycled up and down in temperature indefinitely without loss of brightness.

Cr^{3+}-activated phosphors.—Phosphors activated by Cr^{3+} typically exhibit an emission in the far red near 690 nm from the ^2E, $^2T_2 \rightarrow {}^4A_2$ transition. It is a narrow band emission at low temperatures, gradually broadening as the temperature is increased. Four different oxide hosts activated by Cr^{3+} were examined for flame-activated emission.

A sample of $LaAl_{0.9952}Cr_{0.0048}O_3$ obtained from National Lead Company was found to candoluminesce with a very broad band emission in the red (Fig. 5). The emission is quite weak relative to the other phosphors such that very long exposures were needed to produce even the faintest usable images on a plate. The spectrum shown was taken from an ~8 hr exposure on a Type IV-N plate, the sensitivity of which extends to almost 900 nm. The temperature of maximum intensity for this phosphor is higher than for others studied, being approximately 375°C on the first cooling-heating cycle, shown in Fig. 6. A behavior similar to that for Zn_2SiO_4:Mn^{2+} (Fig. 2) was observed with repeated cycles. These measurements were made at 600 nm on the short wavelength shoulder of the emission peak, rather than on the peak itself, due to the rapidly failing sensitivity of the 1P28 photomultiplier with increasing wavelength and the low intensity of the emission. This wavelength provided optimum instrumental parameters. The broad emission with

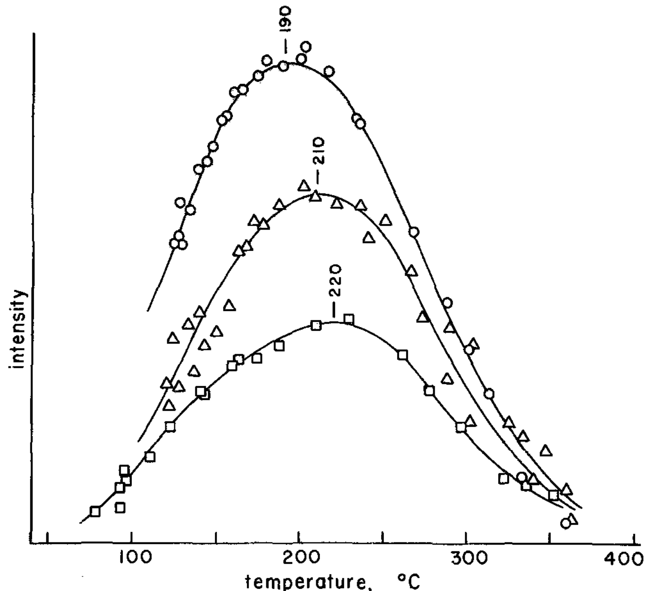

Fig. 2. Temperature dependence of the candoluminescent intensity of Zn_2SiO_4: Mn^{2+} measured at 530 nm with a 2 mm slit width (spectral band width ~7 nm). First cooling-heating cycle ○, second cycle △, third cycle □.

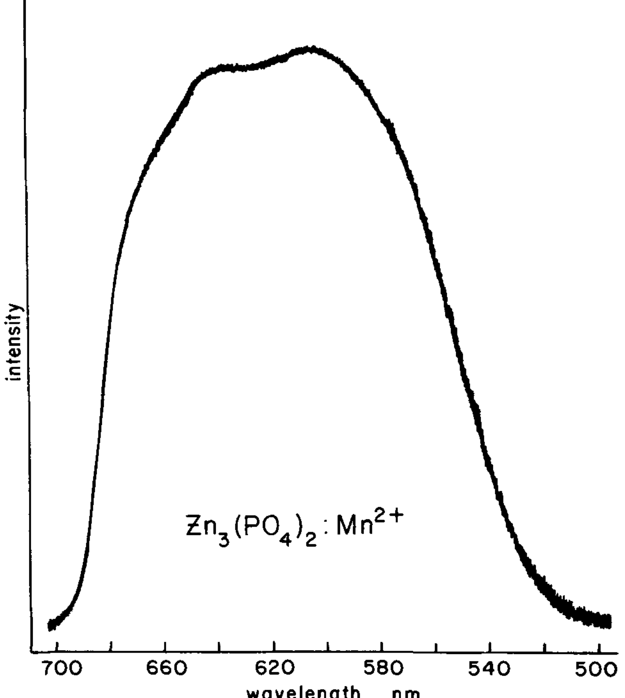

Fig. 3. Candoluminescence spectrum of $Zn_3(PO_4)_2:Mn^{2+}$, Sylvania phosphor Type 151. The rapid plunge in intensity above 680 nm is attributable in part to the spectral sensitivity of the 103-F plate, which begins to fall sharply at this wavelength.

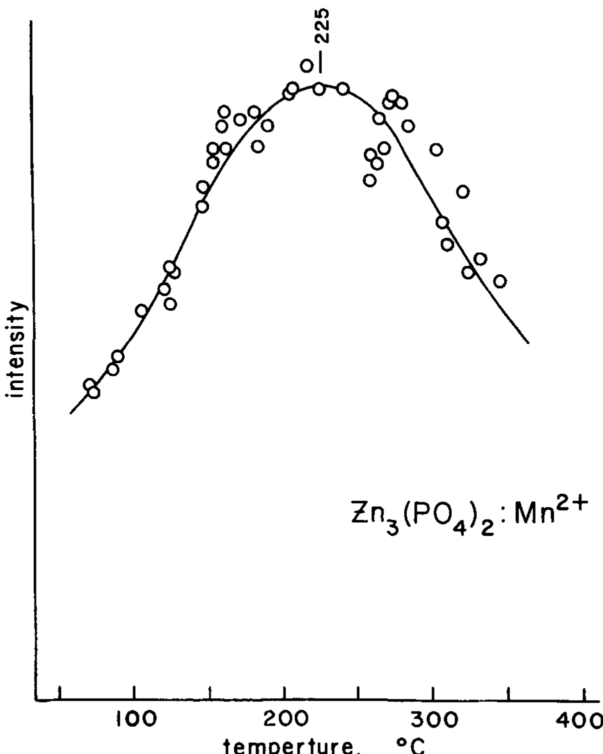

Fig. 4. Temperature dependence of the candoluminescent intensity of $Zn_3(PO_4)_2:Mn^{2+}$ measured at 600 nm with a 3 mm slit width (spectral bandwidth ~10 nm).

poorly resolved features obtained from $LaAlO_3:Cr^{3+}$ is about as expected at the temperature of measurement, 300°C. Cr^{3+} is a line-emitter at low temperatures but at higher temperatures and moderate chromium concentrations phonon processes and Cr-pair interactions generate a great complexity of spectral bands which gradually fuse into a single broad emission (15). The spectrum shown in Fig. 5, taken at

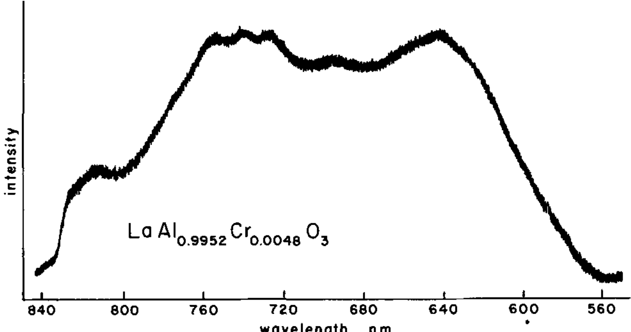

Fig. 5. Candoluminescence spectrum of $LaAlO_3:Cr^{3+}$ measured at roughly 300°C.

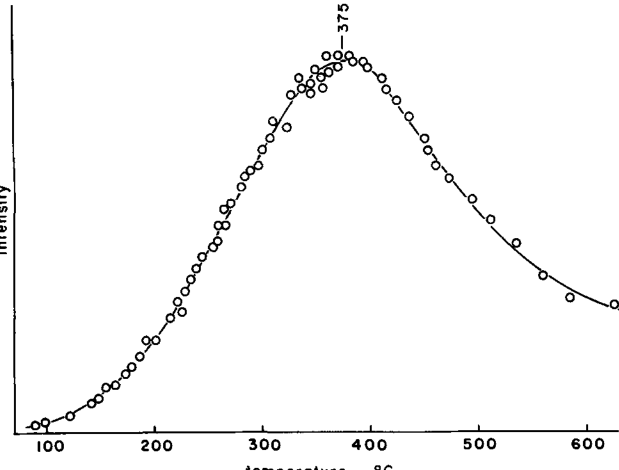

Fig. 6. Temperature dependence of the candoluminescent intensity of $LaAlO_3:Cr^{3+}$ measured at 600 nm with a 3 mm slit width (spectral bandwidth ~10 nm).

roughly 570°K, is similar to published $Al_2O_3:Cr^{3+}$ spectra obtained at similar temperatures (15).

Several other chromium-doped materials were investigated, among them $Al_{2-x}Cr_xO_3$ with $x = 0.002$, 0.01, 0.02; $MgAl_{1.99}Cr_{0.01}O_4$; and $MgGa_{1.99}Cr_{0.01}O_4$. All were observed to emit a faint red candoluminescence at temperatures of a few hundred degrees C. In addition, a faint yellowish-green emission appears as a transient phenomenon at lower temperatures. Neither emission was strong enough for satisfactory spectral measurements. Visual observations seem to indicate a slightly higher efficiency for the $Al_{1.99}Cr_{0.01}O_3$ than for either the higher or lower chromium fraction. None of the samples was strongly photoluminescent (254 nm excitation), but all emit in the red under cathodo-excitation.

Other phosphors.—The commercial phosphor $Sr_2P_2O_7:Sn^{2+}$ is a strong blue emitter under 254 nm excitation. This phosphor shows no fluorescence at all under hydrogen flame excitation. The phosphor exposed to the flame retains its strong photo-emission so degradation of the phosphor by reaction in the flame does not seem to be the explanation for the absence of candoluminescence.

$CaWO_4$, the usual example of a self-activated phosphor with a strong cathodo-emission in the blue, is inert under the hydrogen flame. No emission was observed at temperatures up to red heat.

$CaCO_3$ coactivated with 0.01 Mn^{2+} and 0.01 Pb^{2+} was prepared by coprecipitation from solution. The dried phosphor emits a bright pink under 254 nm excitation. This material likewise did not luminesce in the hydrogen flame.

Experimentation with several Mn^{4+}-activated phosphors, β-Al_2O_3, $SrAl_{12}O_{19}$, and $CaAl_{12}O_{19}$ produced no

luminescence. No special significance can be assigned to this result because Mn^{4+} may have been reduced in the hydrogen flame.

General Discussion and Conclusions

In a recent summary of the extensive Soviet effort on radical recombination luminescence, Volkenstein *et al.* (16) make a very firm statement that, "It should be observed that the same centers give rise to both photo- and candoluminescence . . . the position of the luminescence bands in the spectrum is independent of the nature of the excitation of the crystallophosphor." In spite of a very considerable effort on the part of workers cited previously, relatively few phosphor activator:host combinations have been examined in detail. As a result of the brief survey reported here, we can show that the candoluminescence process must be more complicated than the statement quoted above would imply.

The survey of the spectral emission characteristics of a set of transition-metal-ion-activated phosphors can be summarized as follows: (*i*) Two phosphors, willemite, and Cr^{3+}-activated oxides do indeed exhibit the same spectrum under flame excitation as under u.v. or electron excitation. (*ii*) Three phosphors, $Sr_2P_2O_7$:Sn^{2+}, $CaWO_4$, and $CaCO_3$:Mn, Pb are not candoluminescent although they emit brightly under u.v. excitation and show no evidence for damage in the flame. (*iii*) One phosphor, β-$Zn_3(PO_4)_2$ exhibits a flame-excited emission spectrum of two overlapping broad bands giving a yellow-orange color, whereas the same phosphor under u.v. or cathode-ray excitation emits only in the red band.

Result (*iii*) is deemed of most importance because it is a form of candoluminescent behavior apparently not observed by any of the previous workers. Since this work was completed, a second such case has been found in $CaSO_4$:Mn in which the usual green emission gives way to a deep yellow as the temperature is increased (17). The crystal structure of β-$Zn_3(PO_4)_2$ contains three distinct cation sites on which the Mn^{2+} activator could substitute (18). Zn(I) is four-fold coordinated and Zn(II) and Zn(III) are five-fold coordinated with nearly the same mean Zn-O bond lengths. However, Zn(2) has an additional long Zn-O distance which changes the local geometry and almost certainly the local crystal field. Although EPR results show that the Mn^{2+} activator is distributed over all three sites, it is not known which site is responsible for the characteristic red emission. It does not seem impossible, however, that the flame may excite the activator on both 5-coordinated sites and the u.v. and electron induced red emission may be due to only one of them. A similar situation seems to prevail in the $CaSO_4$:Mn phosphor noted above.

Two additional lines of evidence have evolved from the examination of other phosphor systems (12, 13) that indicate that candoluminescence is more complicated than just a novel method of excitation. The most characteristic feature of candoluminescence is the strongly peaked response of the intensity to temperature. The explanation offered by Hanle and Niermann (8) is that the rising wing represents the evaporation of adsorbed gases exposing more phosphor surface to the recombination process. The decaying wing represents the thermal quenching of the luminescence. Although this explanation might be appropriate to the phosphors described in this paper, the maxima for the rare earth-activated phosphors occur in the range of 50°-250°C, over which range the thermal quenching is not detectable. Secondly, the lack of much enthusiasm for possible application of candoluminescence in devices is due in large part to Sommermeyer's (6) estimation of the quantum efficiency at 10^{-5}. These calculations were based on measurements of the radical recombination process in nitrogen gas. However, experiments with a microwave discharge cavity (12) showed that activated species from nitrogen or hydrogen gas only, used by many previous investigators, were very ineffective in exciting luminescence whereas radicals obtained from the microwave dissociation of water vapor produced bright luminescence. The efficiency, it appears, is very sensitive to particular excited species and there is no reason to believe that Sommermeyer's 10^{-5} quantum efficiency represents any sort of upper limit.

We conclude from this and our previous studies that the energy transfer process in flame-excited luminescence is by no means fully elucidated and that new mechanisms must be devised.

ABSTRACT

Material contrasts which were dependent on the doping were seen on integrated circuits during examination with the photoemission electron microscope (PEEM). Surface studies using the PEEM, Auger electron spectroscopy (AES), and secondary ion mass spectroscopy (SIMS) showed that these material contrasts can be traced to doping dependent coverage of the silicon surface by hydrocarbons.

Strong material and relief contrasts were observed during photoemission electron microscopic (PEEM) examinations of integrated circuits from different manufacturers after removal of aluminum and silicon dioxide from the samples (Fig. 1). After a short etch with argon ions the relief contrasts only were seen (Fig. 4). Wegmann (1) proposed that such material contrasts were at least partly produced by contamination layers. This paper is a study on this hypothesis and the possible correlations between material contrasts and the doping of diffused areas in integrated circuits.

One of the possibilities for direct imaging of surfaces is given by the use of photo electrons in an electron microscope (2). It can be assumed that information is gathered up to a depth of a few monolayers in a PEEM picture (3, 4). Ultraviolet radiation (2968 ± 100Å) is directed on the object to be observed from which the electrons, released by the photo effect, are accelerated by an electric field between sample and anode and guided via the anode diaphragm into a three stage electromagnetic electron microscope. The magnified emission pattern can be viewed on a screen or can be used to expose a photo plate.

The three types of contrasts are: (*i*) relief contrast, formed somewhat similarly to contrasts in the scanning electron microscope (1); (*ii*) material contrast, due to different values of the work function for different substances present within the sample surface; and (*iii*) orientational contrast, due to different crystallographic orientations of grains of one and the same substance.

Since our investigated integrated circuits are made using 111 single crystal silicon wafers, no orientational contrasts can be expected.

Surface analysis with auger electron spectroscopy (AES) (5) reveals which elements are present in surface layers by means of measuring the energies of Auger electrons emitted from the sample during electron bombardment.

Information on the type of chemical bonding can be gained by secondary ion mass spectrometry (SIMS). In this method, argon ions bombard the sample and secondary ions emitted from the uppermost monolayer of the sample are analyzed by a mass spectrometer (6).

Sample Preparation

The following is a description of the manufacturing procedure of the integrated circuits studied in these investigations.

Starting from dislocation-free silicon single crystal wafers which had surfaces on the 111 plane, 38 mm diameter, 250μ thickness and doping of 10^{15} atoms/cm^3 of boron, phosphorous-doped epitaxial layers with resistivities of 1-10 ohm·cm were grown at 1200°C using $SiCl_4$. Oxidations were carried out at 1200°C using oxygen saturated with water at 90°C. Boron was deposited at 975°C using a BBr_3 source. Phosphorus was deposited at 1000°C using a $POCl_3$ source. Aluminum was deposited at 10^{-6} Torr using electron bombardment heating and 5*N* aluminum.

Cleaning of the wafers was done in a 1:1 mixture of sulfuric acid and nitric acid at 90°C. The wafers were then rinsed in deionized water with resistivity greater

than 14 megohm and spun dry. Photoresist processing was done using negative resist from Hunt or Kodak, the recommended developers, and isopropanol for rinsing. Chemical etching of oxides was done in HF buffered with NH_4F except when oxides were removed just before being studied. In this case concentrated HF was used. Etching of aluminum was done in a mixture of phosphoric, nitric, and acetic acids. Removal of photoresist was done in fuming nitric acid.

All of the above-mentioned chemicals, with the exception of the photoresists and resist developers, were electronic grade chemicals.

Experimental Results

Figure 1 shows the material contrast of an integrated circuit observed in the PEEM. The diffused

regions and their respective surface concentrations are specified in Fig. 2. As shown in Fig. 3 and 4, the material contrast disappeared after short argon ion etching. (I beam = 10^{-10} A, 4 kV, beam area at the target = 3 mm^2, etching time 5 respective 10 sec.) During etching the argon ions not only cause material to be sputtered away, but are also implanted into the silicon, thus destroying the crystal structure in the surface region.

In order to show that the material contrast was due to some sort of contamination layer, and that the etching off of this layer and not the creation of an amorphous layer was responsible for removing the contrast, an integrated circuit was heated at 10^{-6} Torr to 1000°C in the PEEM. A residual gas analysis showed that no significant amount of hydrocarbons originating from the vacuum system was present at this pressure. As a cross experiment another circuit was heated in a furnace with oxygen atmosphere to 1000°C. After both treatments, only relief contrast could be observed during examination in the PEEM. It can therefore be assumed that a volatile contamination layer was present which could evaporate at a temperature below 1000°C, or be etched off.

A further circuit was analyzed by AES. The only contaminants that were found were oxygen and carbon, and the concentration of these contaminants was drastically reduced after a similar short argon ion etch.

Since the diameter of the primary electron beam was 25μ it was not possible to analyze single homogeneous areas of the circuit which showed minimal dimensions of about 10μ. For this reason we manufactured a single junction in silicon wafer which allowed AES studies of each region separately without interference by the others. The primary beam spot was continuously moved from the P to the N side.

As shown in Fig. 5, the concentration of carbon is higher on the N-doped than on the P-doped surface. Measurements showed no difference in oxygen content.

The small peak beside the carbon signal in Fig. 5 was never observed in the complete spectrum of the surface but only in the repetitive sweep mode. Therefore we will attach no importance to it.

Simultaneous PEEM observations of separated P respectively N homogeneously doped samples with widely varying doping levels were made.

No material contrasts were seen. Also the concentration of carbon determined by Auger spectroscopy was the same in the two separated P-doped and N-doped surfaces.

In order to determine the forms of the carbon contamination on the surface we have used the SIMS method.

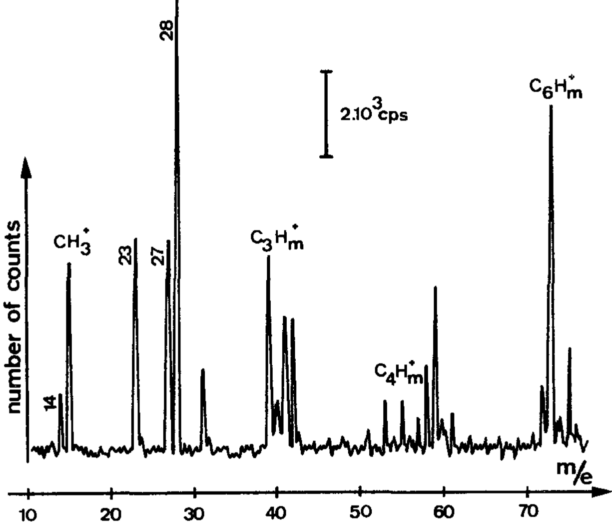
Figure 6 shows the spectrum of the first monolayer of an integrated circuit. For such an analysis we used a primary ion beam of 10^{-10}A under a partial argon pressure of about 10^{-7} Torr. This spectrum presents the characteristic $C_nH_m^+$ groups. After removing the first monolayer all the hydrocarbons disappeared.

Table I shows, besides the previously mentioned compounds, the other elements present on the surface. The presence of aluminum can be explained by the fact that previously the circuits had conducting paths, which were etched off according to the described procedure.

Discussion

The presence of a volatile contamination layer on the surface of silicon was also demonstrated by Chang (7). He found that adsorbed hydrocarbons are desorbed from the silicon surface at temperatures lower than 1000°C. It has also been shown (8, 9) that oxygen is removed from the surface as silicon monoxide (SiO) at 900°-1000°C, while hydrocarbons disappear from the surface in the same temperature range by oxidation through CO or CO_2 or by diffusing into the silicon (>1100°C).

As shown in the experiments the contamination layer on the surface consists of hydrocarbon compounds which are localized in one monolayer. The



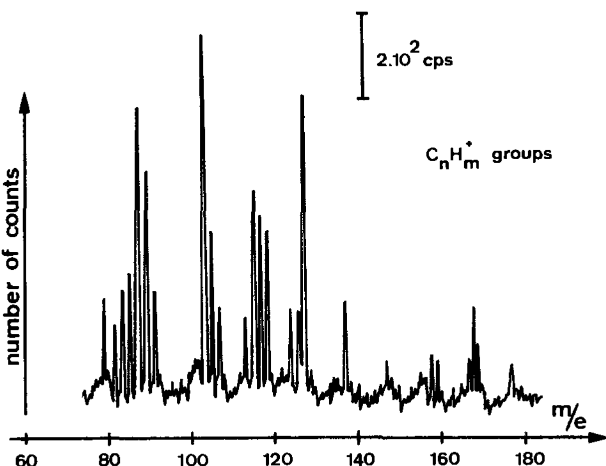


Fig. 6. Positive secondary ion mass spectrum of the first monolayer of the integrated circuit.

coverage of the surface with adsorbates can be quantitatively described by a degree of coverage θ, where $\theta = 1$ represents the case when all possible adsorption sites on the surface are filled, that is to say a complete monolayer is formed. An adsorbed impurity atom generally changes the charge distribution on the surface.

For smaller degrees of coverage, the change in the work function ΔW is a linear function of θ. With larger degrees of coverage, the interaction between adsorbed particles causes a decrease in the variation of ΔW (Fig. 7). The fact that no contrast difference and variation of carbon concentration in AES were seen from the two separated N-doped and P-doped silicon wafers indicates that the same degree of coverage is present on their surface, that means $\theta_N = \theta_P$. Hendersen *et al.* (11) observed that the adsorbed carbon concentration on the surface of homogeneous silicon wafers was independent of the type and amount of doping, crystal orientation, dislocation density, and method of crystal

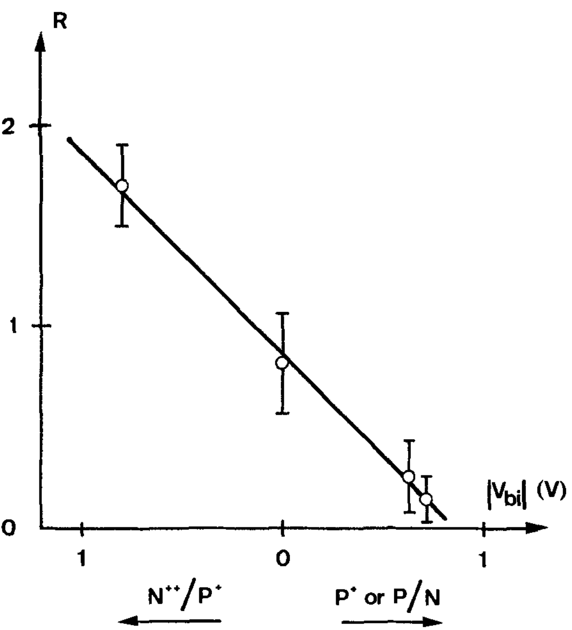

Fig. 10. Relationship between the built-in voltage and the reflection density.

growth. These results are consistent with our observations.

The peak-to-peak amplitudes from the Auger transition are a linear function of the amounts of material present in the first monolayer (10). Since in Fig. 5 we observe a variation of the peak-to-peak amplitude of the carbon, the degree of coverage of each diffused region must be different. All experiments proved that

$$\theta_N > \theta_P$$

Figure 8 demonstrates the found situation.

This last inequation leads to the fact that the work function (W) of each diffused region must also be different

$$W_N > W_P$$

This explains the observed contrast of integrated circuits in the PEEM.

From our experiments we can therefore affirm that a diffused junction has an influence on the degree of coverage by hydrocarbons. Figure 9 shows a schematic cross section through an integrated circuit as well as the position of the Fermi level and the variation of the reflection density based on the Kodak gray tones scale.

By recording the reflection density as a function of the built-in voltage of the junction, a monotonous relation (Fig. 10) is obtained. This means that the degree of the contamination layer directly depends on the surface potential. The change of the potential on the surface takes place only in the depletion layer. These have widths of 0.01-0.5μ, so that, compared with the geometry of the diffused regions, sharp contrasts are shown in a PEEM picture.

After removing the contamination layer ($\theta = 0$), no contrast remained and therefore we can conclude that the work function is practically independent of the doping of silicon. Different authors found the same (12).

Conclusions

It has been shown that the material contrasts, as seen in the PEEM, are dependent on the built-in voltages of the doped regions, and are produced by hydrocarbon contaminations. The degree of coverage of hydrocarbons is practically constant for regions which have the same doping, but varies as a function of the built-in voltage when regions with different doping are present. No dependence of the work function on the doping was found after removal of the contamination layer.

In the course of our experiments it was not possible to find the sources of contamination, but such contamination was also found on circuits made by other manufacturers. It is probable that they come from the manufacturing and the cleaning processes.

Acknowledgments

The Influence of the Phase Shift on Thickness Measurements of Silicon Epitaxial Layers with a Fourier Transform Spectrometer

P. J. Severin

Philips Research Laboratories, Eindhoven, Netherlands

ABSTRACT

The thickness of a silicon epitaxial layer can most easily be measured with Fourier transform spectroscopy. The influence of the phase shift at the substrate-epitaxial layer interface has not been taken into account in earlier treatments and in the available instruments. Under simplified conditions the effect of the phase shift on the interferogram is derived, yielding an instrumental correction to be applied to the position of the side burst maximum. To this result then also a physical correction should be applied as derived earlier from multiple interference measurements in order to finally yield the metallurgical thickness.

Recently Flournoy *et al.* (1) described a thin-layer thickness measuring instrument based on the use of Fourier transform spectroscopy. Referring to the thickness d of a transparent coating of refractive index n on an opaque or transparent substrate they state that the distance between two side bursts equals $2\,dn$, ignoring any phase shift. Such an instrument is commercially available and marketed for the main purpose of measuring silicon epitaxial layer thickness by Digilab, Incorporated.[1]

For several years the phase shift δ at the substrate-epitaxial layer interface has been subject of discussion. Neglecting this phase shift in the interpretation of the data would cause an error and two different approaches have been followed to obtain the correct results. Schumann *et al.* (2, 3) calculated with classical theory the phase shift δ as a function of wave number k and substrate resistivity ρ from a model based on an abrupt junction, both for dope and charge carriers, free of stress, characterized by bulk properties. It was found that $\delta\ (k)$ decreases with substrate resistivity ρ, equals π at $k = 0$ and vanishes at large k for all ρ. These data were introduced into a standard procedure (4) for the analysis of an infrared multiple interference (IMI) spectrum. The author (5) followed a different approach, based on experimental evidence. The phase shift δ was deduced directly from IMI data, and it was found that the spectra could be described by a constant phase shift δ_0. It was shown then (6) that over the limited wave number range used a function $\delta(k)$ can be approximated by a linear expression in which δ_0 only plays a formal role. It has no relation whatsoever to the part of Schumann's curves where δ is a constant. In Schumann's evaluation procedure the orders of the extrema are corrected with the appropriate $\delta(k)$ and the ensuing values of the thickness are averaged. In our approach the uncorrected data yield d_s and δ_0. Eversteyn and van den Heuvel (7) recently described a method by which from the thickness of the layer actually deposited, the metallurgical thickness d_m, can be determined. Using these methods on a large number of epitaxial N on N^+ and N on N^{++} structures δ_0, d_s, and d_m were determined and definite correlation was found (8) between $\Delta d = d_s - d_m$ and δ_0 for both kinds of structures. Using these data as a calibration for a given production process, δ_0 determines the value of Δd to be subtracted from d_s to obtain d_m. The correction Δd is called a physical correction here because it should be applied wherever $2d\,nk - \delta(k)$ occurs, *i.e.*, both to the conventional IMI spectrophotometer results and to the data obtained with Fourier transform spectroscopy.

In the following sections the Fourier spectrum is calculated assuming a phase shift at the substrate-layer interface, carefully stating the assumptions without

Key words: silicon, epitaxial layer thickness, Fourier transform spectroscopy, interferogram, phase shift.

[1] Digilab, Incorporated, subsidiary of Block Engineering Incorporated, Cambridge, Massachusetts 02139.

going into any technical detail. It will be shown that when the phase shifts at the top layer and at the interface are neglected, the distance between the two side burst maxima equals 2 dn, but that due to the phase shift the position and shape of the side bursts are modified. Because all samples show phase shifts in one way or another, the distance between the two side burst maxima which the instrument reads simply as 2 dn, should be corrected. This correction, which should be applied in addition to the physical correction discussed above, is typical of the Fourier spectrometer and therefore called an instrumental correction. Dielectric structures should also be corrected in this way.

Both corrections are indispensable for accurate results and increasingly important with decreasing thickness and increasing need for accuracy for advanced applications of epitaxial layers. With an epitaxial layer grown on an N^{++} substrate the error due to the neglect of the physical phase shift correction may amount up to 0.5 μm (8). The error due to the neglect of the instrumental correction can be of the same order as will be shown in the last section.

Instrumental Correction Due to Top Layer and Interface Phase Shift

The interferometer layout is shown in Fig. 1. The phase of ray Y due to topside reflection equals π and that of ray X due to interface reflection equals $\delta + 4\pi nd/\lambda$, both apart from an arbitrary but equal constant, upon entering the interferometer.

Calling the position of the movable mirror at which the central burst occurs $z = 0$ and the departure from that position z, positive or negative, the signals impinging on the detector are

$$E_{y1} = E^o_{y1} \cos(\omega t + \pi)$$
$$E_{y2} = E^o_{y2} \cos(\omega t - 2\,kz + \pi)$$
$$E_{x1} = E^o_{x1} \cos(\omega t - 2\,k\,dn + \delta)$$
$$E_{x2} = E^o_{x2} \cos(\omega t - 2\,kz - 2\,k\,dn + \delta) \quad [1]$$

with ω, the frequency and $k = 2\,\pi/\lambda$, the wave number. The detected signal $V = AE^2$ equals, with A unity, after averaging over t and dropping the constant terms

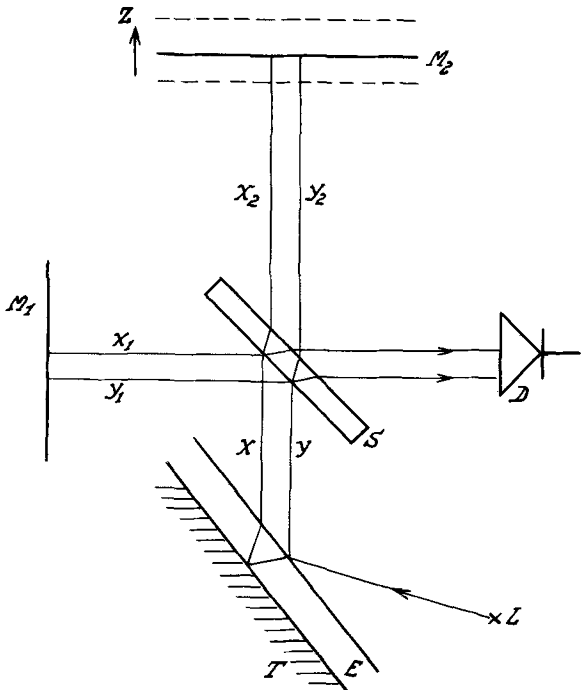

Fig. 1. The principle of operation, with light source L, mirrors M_1 and M_2, detector D, semitransparent plate S, epitaxial layer E, and substrate T.

$$V = (E^o_{y1}E^o_{y2} + E^o_{x1}E^o_{x2}) \cos 2\,kz + E^o_{y1}E^o_{x2} \cos[2k(dn + z) + \pi - \delta] + E^o_{x1}E^o_{y2} \cos[2k(dn - z) + \pi - \delta] \quad [2]$$

Assuming a white spectrum between zero and k_1, of unit total intensity, these noncoherent waves should be added quadratically. This, after integration, yields a k-dependent part

$$V = (E^o_{y1}E^o_{y2} + E^o_{x1}E^o_{x2}) \frac{\sin 2\,k_1 z}{2z} + E^o_{y1}E^o_{x2} \frac{\sin[k_1\,2(dn + z) + \pi - \delta] - \sin(\pi - \delta)}{2(dn + z)} + E^o_{y2}E^o_{x1} \frac{\sin[k_1\,2(dn - z) + \pi - \delta] - \sin(\pi - \delta)}{2(dn - z)} \quad [3]$$

provided δ, n, and the amplitudes E^o do not depend on k. It is a key point of this paper that this condition can be relaxed with respect to δ. Writing δ in Eq. [2] as a linear relation to k and the last term as

$$E^o_{x1}E^o_{y2}k_1 \frac{\sin \alpha}{\alpha} \cos(\alpha + \pi - \delta) \quad [4]$$

with $\alpha = k_1(dn - z)$, it is clear that δ can also be linearly related to k without complicating the mathematics. This will be discussed in the next section. The second and third terms are related by simply changing the sign of z and Eq. [3] is functionally symmetric with respect to $z = 0$. The first term is called the center burst, the second and third terms are the side bursts. In Fig. 2 the shape of the $z > 0$ side burst is presented with $\delta/2\pi$ as a parameter, varying between 0 and 0.5. The shape of the center burst is identical to the curve labeled $\delta = \pi$, that is to say with vanishing top layer and interface phase shifts, with the z-axis shifted by dn.

It is clear from Fig. 2 that the distance read between the two extreme values of the two side bursts depends on the value of $\delta/2\pi$. At $\delta/2\pi = 0.25$ the extreme values of both side bursts change sign. In Fig. 3 the positive and negative deviations α_p and α_n from the position $\alpha = 0$ are shown for the nearest positive and negative extrema as a function of $\delta/2\pi$. The correction to be applied to the distance read between the two peaks follows from this calculated error, the details being dependent on the peak determination procedure chosen.

In real life, of course, δ is not known and should be processed from the Fourier spectrum. From Fig. 2 it is evident that the ratio r between the heights V_p and V_n of the positive and negative peaks nearest to $\alpha = 0$ could provide a good criterion. This ratio r has also been shown in Fig. 3 as a function of $\delta/2\pi$. The sequence: measurement of r, determination of $\delta/2\pi$, and correction to side bursts distance can easily be built into the instruments. The amplitude of the positive peak which is either the maximum itself of the side burst or the positive maximum most near the negative maximum can also serve this purpose.

Physical Correction Due to Interface Phase Shift

It has been shown earlier (6) and repeated briefly in the introductory remarks that from IMI spectra follows a k-dependent phase shift, with $k = 2\pi/\lambda$, according to

$$\delta = \delta_o - 2\,n\,k\,\Delta d \quad [5]$$

Any higher order approximation to the $\delta(k)$ curve is beyond experimental precision for an infrared spectrophotometer. Also the ASTM corrections (4) admit this approximation in a limited wave number range, but the author did not find the correlation between the values of δ_o, Δd, and ρ implied in these curves. An empirical relation has been discovered (8) relating δ_o and $\Delta d = d_s - d_m$ by comparing the thickness d_s

Fig. 2. Interferogram of the side maximum due to interference of rays X and Y plotted with normalized V as a function of α and $\delta/2\pi$ as a parameter.

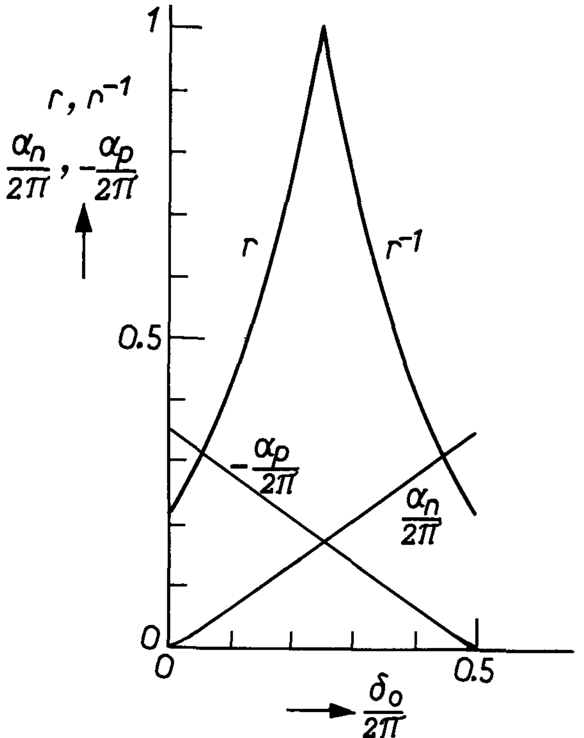

Fig. 3. The phase shift $\delta/2\pi$ as a function of the ratio r of the heights of the positive and negative peaks nearest to $\alpha = 0$ and the ensuing distances α_p and α_n of the positive and negative extrema from the point $\alpha = 0$.

found from the IMI spectrum (5) and the metallurgical thickness d_m measured otherwise (7). Introducing Eq. [5] into Eq. [2] it is clear that in Eq. [3] and [4] $d + \Delta d$ figures instead of d, and δ_o instead of δ. This means that the instrumental correction described previously should be followed by a physical correction consisting of subtraction of an amount Δd, determined by $\delta_o/2\pi$. The second, physical part of the correction procedure is identical to the procedure to be followed with an IMI spectrum.

When the instrument is used in connection with a single production process of epitaxial slices, the relations $\Delta d(\delta_o/2\pi)$, different for N^+ and N^{++} substrates, can also be built into the instrument.

Discussion

The thickness of the epitaxial layer has been measured on a Digilab FTG^R-12 and the thickness d_D found with two sets of thirty slices satisfies the following relationships to d_m, measured as described by Eversteyn and van der Heuvel (7)

$$d_D = 0.983\ d_m - 0.06\ \mu m \text{ for } N^{++} \text{ substrates} \quad [6a]$$

and

$$d_D = 0.983\ d_m + 0.52\ \mu m \text{ for } N^{+} \text{ substrates} \quad [6b]$$

with correlation coefficients equal to 0.99991 and 0.99978, respectively. The data points are shown in Fig. 4 and the difference between the two sets is obvious.

Neither the instrumental nor any physical correction has been made to these data. However, the manufacturer (9) has indicated that a correction mechanism has been built into the instrument, empirically determined to match the data obtained otherwise, that is

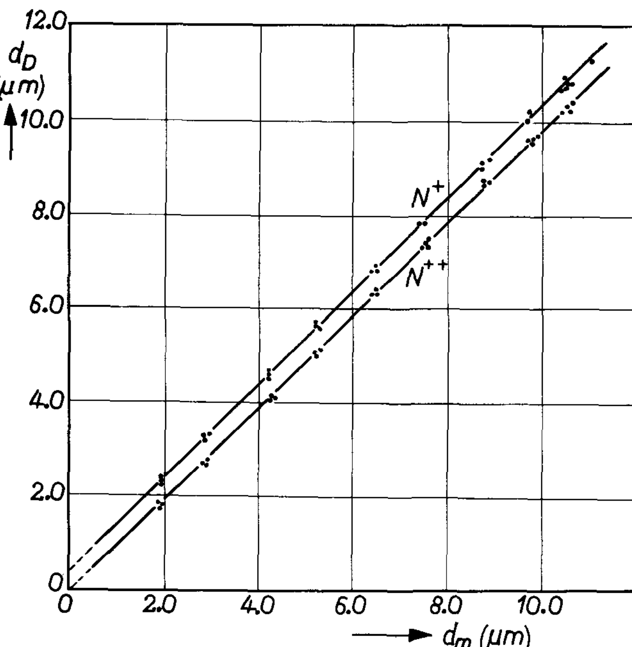

Fig. 4. The Digilab measured thickness d_D vs. metallurgical thickness d_m. The layers with resistivities of about 1 ohm-cm were grown in silane at 1050°C corrected temperature, on Sb-doped N^+ substrates and on As-doped N^{++} substrates.

to say the ASTM-corrected IMI spectra results. Hence no conclusions on the theory and necessary corrections can be drawn from the actual results.

The description given above applied to an idealized version of the instrument which may be realistic only to a limited extent. The spectrum emitted from the light source is not white, and E^o will always be a function of k due to wavelength dependence of optical components. Furthermore, the integral (Eq. [3]) will have to be limited between k_1 and k_2 and the detector efficiency A (k) should be taken into account. This would imply performing the integration Eq. [3] with a weight function for the k-dependent light intensity and detector efficiency yielding curves different from those shown in Fig. 2 and 3. Then the correction $\Delta\alpha$ can be read, if $\delta_0/2\pi$ is known from r or from an IMI spectrum, and the correction $\Delta\alpha$ can be translated into a correction Δd. At this stage, however, this cannot safely be done.

In summary, the Digilab FTG produces precise and reproducible results rapidly in an easy way, but the accuracy can be obtained only by calibration, as shown in Eq. [6a] and [6b].

Determination of the Solidus and Gallium and Phosphorus Vacancy Concentrations in GaP

A. S. Jordan, A. R. Von Neida, R. Caruso, and C. K. Kim

Bell Laboratories, Murray Hill, New Jersey 07974

ABSTRACT

The Ga concentration in GaP crystals prepared by a variety of techniques (pulled by the liquid encapsulation Czochralski technique from stoichiometric or nonstoichiometric melts, solution grown, and annealed) has been determined by precision coulometric titration, yielding the experimental solidus boundary which exhibits an excess of Ga along the Ga-rich liquidus. Based on a thermodynamic model, assuming that neutral Ga and P vacancies are the predominant native defects, the analysis of the solidus data permitted the evaluation of the vacancy concentrations over a wide temperature range. At the melting point of GaP (1465°C) there are 8×10^{18} and 1.3×10^{19} cm^{-3} Ga and P vacancies, respectively, in the crystal. The calculated solidus curve well represents the totality of experimental data and shows retrograde temperatures at 1375° and 1400°C on the Ga- and P-rich sides, respectively. The enthalpies and entropies associated with vacancy formation are given and discussed. It is shown that the data provide strong additional support to the previous identification of Ga vacancies with killer centers in GaP.

The successful commercial realization of GaP red and green light-emitting diodes (LED's) is based on the extensive scientific and technological accomplishments of the past decade. In order to obtain device quality material of improved and controlled optical properties a considerable effort has been devoted to the study of the physicochemical aspects of the growth and characterization of undoped and doped GaP crystals. In particular, the thermodynamic properties, liquidus curve, and pressure-temperature boundary of GaP have been critically evaluated (1). In addition, by means of experimental and/or theoretical investigations of the ternary liquidus surface (2-5) and solid solubilities (6-10), a satisfactory understanding of impurity incorporation in GaP has been achieved for such electrically important impurities as Zn (6, 7), Te (8), O

Key words: defect chemistry, crystal growth, light-emitting diodes, thermodynamics.

(5, 8, 9), and N (10). However, on account of experimental difficulties, the departure from stoichiometry of GaP represented by the solidus curve and the closely related absolute phosphorus and gallium vacancy (V_P and V_{Ga}) concentrations have not yet been determined. Nevertheless, there is increasing interest in a knowledge of absolute vacancy concentrations in GaP motivated by the accumulating evidence from optical measurements that Ga vacancies or associated complexes may strongly influence the photoluminescence and electroluminescence properties.

A rapid increase in the red photoluminescent efficiency (accompanied by a rise in the shunt path or "killer center" lifetime, τ_n) with decreasing growth temperature has been observed in Zn, O-doped GaP pulled by the liquid-encapsulation Czochralski (LEC) technique from stoichiometric and nonstoichiometric melts and grown from solution (SG) (11). At the same time, a linear correlation was shown to exist between $1/\tau_n$ and the relative V_{Ga} concentration for these different crystals. Further studies have also shown that by annealing at 1280° and 1350°C the originally large τ_n of SG platelets was drastically decreased to values in good accord with this correlation (12). In contrast, with annealing at 1200°C the small τ_n of stoichiometric LEC crystals was significantly increased (13).

Very recently Ladany and Kressel (14) have suggested that V_{Ga} and/or related complexes are important centers in reducing the green luminescent efficiency of n-type GaP. Furthermore, some evidence for the existence of the V_{Ga}-O_P complex (orange luminescence at 2.125 eV) has been given by Dean (15) and Bhargava *et al.* (16). Obviously, a more complete understanding of nonradiative or radiative processes attributed to vacancies or associated complexes is impossible in the absence of absolute vacancy concentrations.

The major objective of this paper is to determine the solidus and V_P and V_{Ga} concentrations in GaP over a wide temperature range. First, we describe the experimental data obtained by high precision coulometric titration of Ga in undoped and doped GaP crystals prepared by a variety of techniques (pulled by LEC from stoichiometric and nonstoichiometric melts, SG, annealed LEC). Second, the atom fraction of Ga, x^s_{Ga}, in these samples is deduced to yield the experimental solidus points. Third, by means of a thermodynamic model applied to the data on undoped seed-end crystals, assuming the presence of single neutral vacancies only, the concentrations of V_P and V_{Ga} are evaluated. Finally, the full solidus curve is calculated and the results are discussed and compared with those for some other semiconducting compounds.

Experimental Procedure and the Evaluation of the Solidus Points

Thermodynamic considerations for a binary system at a constant temperature and pressure lead to the conclusion that in equilibrium, the composition of the liquid (Ga + P liquid solution) and solid (crystalline GaP) phases is fixed. Usually the published phase diagrams for Group III-V and II-VI compounds (17) only present the variation of the liquid composition with temperature. *i.e.*, the liquidus curve. Meanwhile, the corresponding solidus curve, describing the variation of solid composition with temperature, is given by a vertical temperature invariant line at the stoichiometric composition ($x^s_{Ga} = 0.50$) because the departures from stoichiometry for the solid phase, although generally not known, are expected to be very much smaller than for the liquid phase. Any experimental determination of the solidus boundary requires crystalline samples either grown or annealed in equilibrium with the liquid phase at a set temperature and a high precision analytical technique to determine minute compositional variations in the solid.

Crystal growth.—In Table I, the samples analyzed in this study are characterized with respect to origin, growth or preparatory technique, growth or heat-treatment temperature, and doping level. Most crystals were pulled by LEC from stoichiometric melts (atom fraction of phosphorus in the melt, $x^l_P = 0.5$) at 1465°C or from nonstoichiometric melts ($0.20 \leq x^l_P \leq 0.42$) at appropriate liquidus temperatures (1). As in previous work (11, 18), pulled crystals from nonstoichiometric melts provided the crucial bridge, intermediate in growth temperatures and solution compositions, between crystals obtained by standard stoichiometric LEC pulling and SG. Both doped and undoped crystals were available and the net carrier concentrations, $|N_D - N_A|$, were determined either by the Schottky barrier capacitance technique (MH crystals) or by Hall measurements (RD crystals).

The SG platelets were prepared in the usual manner by the slow cooling from ~1150° to 900°C of a ~ 6 atomic per cent (a/o) P solution in Ga. In addition, the tail end of a stoichiometric LEC crystal was annealed for 19 hr at 1300°C and held for 120 hr at 1200°C while immersed in B_2O_3 liquid. Minute droplets of Ga were observed on the annealed slice assuring solid-liquid equilibrium.

Analytical procedure.—The GaP samples, weighing between ~0.3 and 2.0g, were analyzed for Ga by high precision coulometric titration, a technique described in detail elsewhere (19) and only briefly reviewed here. The samples were etched in HNO_3 to remove traces of free Ga, weighed on a microbalance, dissolved in aqua regia and, after adjusting the *p*H to 3, an exactly weighed amount of EDTA (H_4Y = ethylene diamine tetracetic acid) was added to the solution in excess to consume all the Ga by reacting stoichiometrically according to

$$Ga^{+++} + H_4Y \rightarrow GaHY + 3H^+ \quad [1]$$

The excess EDTA was complexed with coulometrically generated Hg^{++} and the end point of this reaction (appearance of free Hg^{++} ions) was accurately detected by a potentiometric method. Although EDTA of very

* Annealing temperature.

high nominal purity[2] was used, several calibration experiments were also performed on the basis of 99.9999+% Ga metal as the primary standard to establish the actual purity of EDTA and thus to obtain analytical results independent of contamination. The high precision of the data is further assured by the fact that at the pH employed, the magnitude of the stability constant for Eq. [1] (20.3) allows only a completely negligible fraction of the Ga complexes to dissociate even in the presence of Hg^{++} ions.

The analytical data provided a direct measurement of the number of moles of Ga, n_{Ga}, contained in each sample as the difference between the total number of moles of EDTA added to the solution and the number of moles of Hg^{++} complexed with the excess EDTA. The total estimated uncertainty by this coulometric technique is 10 ppm, as found by the usual combination of errors.

To remove Ga occlusions, crystals grown at lower temperatures ($x^l_P < 0.3$) were powdered to a maximum particle size of about 100 mesh under an argon atmosphere to avoid the formation of PH_3 from moisture in the air, and then treated as described above. The mesh size used was sufficient to obtain reproducible results without causing undue handling problems.

Powdering has only a minute effect on the Ga analysis of crystals grown at a higher growth temperature as shown by an experiment in which the seed end of a boule grown at 1465°C (MH-143) was divided and subsequently processed as both a powder and a single piece.

Evaluation of the solidus points.—Since presently there is no reliable technique to perform an independent phosphorus analysis of our samples, x^s_{Ga} was calculated from n_{Ga} and the weight of GaP, w. The definition of x^s_{Ga} gives

$$x^s_{Ga} = n_{Ga}/(n_{Ga} + n_P) \quad [2]$$

where n_P is the number of moles of P.

Assuming that the sample is pure GaP, we find

$$n_P = \frac{w - n_{Ga}A_{Ga}}{A_P} \quad [3]$$

where A_i is the atomic weight of the subscripted species. Substituting Eq. [3] into Eq. [2] yields[3]

$$x^s_{Ga} = \frac{1}{1 + (w - n_{Ga}A_{Ga})/A_P n_{Ga}} \quad [4]$$

Since A_{Ga} is only known to four significant figures, (69.72) and A_P to six (30.9738) (22), additional significant figures, consistent with the chemical analysis, were determined by the coulometric titration of 99.99999% Ga, yielding $A_{Ga} = 69.7219$. Values of x^s_{Ga} for each sample were calculated from Eq. [4] and are tabulated in Table I. In Fig. 1 we present the experimental solidus data plotted as growth[4] or annealing temperature *vs.* x^s_{Ga}.

The experimental solidus data exhibit the following important features:

(*i*) There is a systematic functional relationship between temperature and x^s_{Ga} and all the crystals prepared along the Ga-rich liquidus contain an excess of Ga.

(*ii*) Different LEC growth systems (MH and RD crystals were grown using Arthur D. Little and Materials Research Corporation pullers, respectively) lead to similar results.

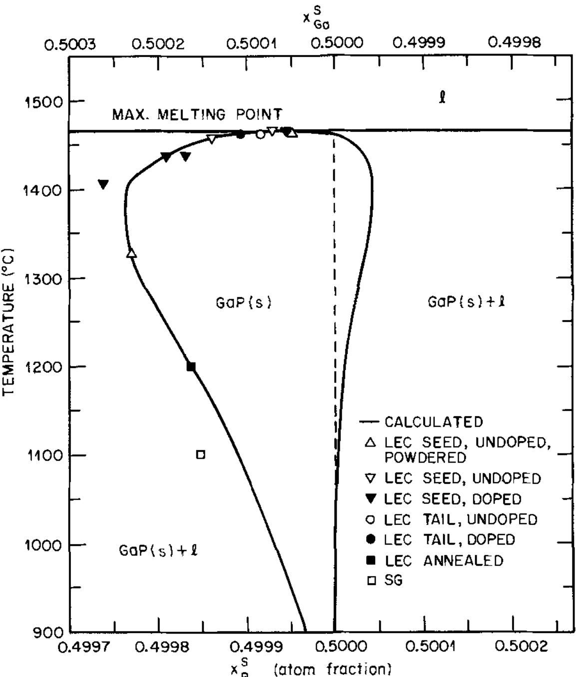

Fig. 1. The solidus of GaP. The data represent the growth or annealing temperature of GaP crystals *vs.* the Ga concentration (Eq. [4]) found by coulometric analysis. Note that 1100°C was taken as the average growth temperature of SG crystals.

(*iii*) Near the melting point of GaP the solidus is relatively flat and the tail end of boules always shows a greater departure from stoichiometry than the seed end.

(*iv*) The solidus is retrograde, as is the case for many other semiconductor systems (23-25), with a maximum departure from stoichiometry near 1400°C.

(*v*) There is no strong influence on the data resulting from the variation in doping levels; indeed, no combination of inadvertent or intentional impurities can be responsible for the large retrograde maximum in x^s_{Ga}.

(*vi*) By annealing an LEC tail-end crystal (RD-164), a change in the stoichiometry is induced.

These observations support the view that the values of x^s_{Ga} directly evaluated from the chemical analysis accurately represent the solidus boundary. In the next sections below we give a detailed thermodynamic analysis of the solidus data.

Thermodynamic Analysis and Discussion

Relationship between the solidus and vacancy concentrations.—We shall assume that the predominant point defects in the pure GaP lattice are single neutral Ga and P vacancies and consider the concentrations of charged vacancies and vacancy clusters to be negligible. It is convenient to express the concentrations of V_{Ga} and V_P in terms of the site fractions, with v_{Ga} and v_P, respectively, defined by

$$v_{Ga} = \frac{[V_{Ga}]}{[Ga_{Ga}] + [V_{Ga}]} \quad [5]$$

and

$$v_P = \frac{[V_P]}{[P_P] + [V_P]} \quad [6]$$

where the bracket $[A_i]$ denotes the total number of lattice constituent A on i-type sites.

Likewise, x^s_{Ga} and x^s_P can be expressed in terms of the atomic lattice constituent P as

[2] J. T. Baker, "ULTREX" grade, all determinations from same batch of 99.99+% purity.

[3] A complete analysis of Eq. [2] through [4], taking into account contributions to w from impurities, would show a small contribution to the x^s_{Ga}. As our samples were not analyzed for residual impurities, their influence could only be indirectly ascertained. However, for typical undoped GaP, using measured impurity levels (20, 21) the calculation yields a maximum possible correction of $+8 \times 10^{-6}$ (atom fraction) to the computed value of x^s_{Ga}. For mid -10^{17} cm^{-3} of Zn or Te, the corrections are likewise small, being -6×10^{-6} and $+20 \times 10^{-6}$, respectively.

[4] A minor adjustment of -2°C was applied to the growth temperature of the tail end of LEC pulled crystals, to take into account the decrease in melting point accompanying the slight phosphorus loss in the melt during the growth cycle.

$$x^s_{Ga} = \frac{[Ga_{Ga}]}{[Ga_{Ga}] + [P_P]} \quad [7]$$

and

$$x^s_P = \frac{[P_P]}{[Ga_{Ga}] + [P_P]} \quad [8]$$

To express x^s_{Ga} in terms of v_{Ga} and v_P let us add $[V_{Ga}] - [V_{Ga}]$ to the numerator and denominator of Eq. [7] and divide both by $[Ga_{Ga}] + [V_{Ga}]$. Then, we find with the aid of Eq. [5] that

$$x^s_{Ga} = \frac{1 - v_{Ga}}{1 - v_{Ga} + [P_P]/\{[Ga_{Ga}] + [V_{Ga}]\}} \quad [9]$$

But by the equality of Ga and P sites, $[P_P] = [Ga_{Ga}] + [V_{Ga}] - [V_P]$ which in combination with Eq. [6] transforms Eq. [9] into

$$x^s_{Ga} = \frac{1 - v_{Ga}}{2 - v_{Ga} - v_P} \quad [10]$$

By a similar procedure we also have

$$x^s_P = \frac{1 - v_P}{2 - v_{Ga} - v_P} \quad [11]$$

For further calculations the use of the difference, δ, between Eq. [10] and [11] is very convenient because it reduces to

$$\delta = x^s_{Ga} - x^s_P = 2x^s_{Ga} - 1 = \frac{v_P - v_{Ga}}{2 - v_P - v_{Ga}}$$

Since $|v_P - v_{Ga}| << 2$, the expression sought to relate the experimental x^s_{Ga} or δ to v_P and v_{Ga} becomes

$$\delta = 2x^s_{Ga} - 1 = \frac{v_P - v_{Ga}}{2} \quad [12]$$

Thermodynamic equations for the vacancy concentrations.—At any temperature, T, where solid GaP is in equilibrium with the Ga-P liquid solution, v_P and v_{Ga} are fixed. The incorporation of V_{Ga} and V_P at T along the liquidus curve can be expressed by the following chemical defect equilibria[5]

$$Ga(l) = Ga_{Ga} + V_P$$

$$K_P = \frac{v_P}{a_{Ga}} \times \frac{[Ga_{Ga}]}{[Ga_{Ga}] + [V_{Ga}]} \quad [13]$$

and

$$P(l) = P_P + V_{Ga}$$

$$K_{Ga} = \frac{v_{Ga}}{a_P} \times \frac{[P_P]}{[P_P] + [V_P]} \quad [14]$$

In Eq. [13] and [14] the site fractions of Ga and P atoms on their own sites (≈ 1) can be incorporated in the respective equilibrium constants K_P and K_{Ga} without error. The functions a_P and a_{Ga} are the conventional thermodynamic activities of the subscripted species along the liquidus curve.[6]

As usual, we resolve K_P and K_{Ga} in terms of the enthalpies (ΔH_P and ΔH_{Ga}) and entropies (ΔS_P and ΔS_{Ga}) of incorporation, assuming that these quantities are independent of T in the range of interest. Then, we find from Eq. [13] and [14] for v_P and v_{Ga} that

$$v_P = e^{\Delta S_P/R} e^{-\Delta H_P/RT} a_{Ga} \quad [15]$$

and

$$v_{Ga} = e^{\Delta S_{Ga}/R} e^{-\Delta H_{Ga}/RT} a_P \quad [16]$$

It should be noted that ΔH_{Ga} is related to ΔH_P through the heat of formation of GaP, ΔH°_f, according to the reaction

$$Ga(l) + P(l) = Ga_{Ga} + P_P \quad [17]$$

[5] Note that the concentrations of the lattice constituents in subsequent equations appear as site fractions.
[6] By definition $a_i = x^l_i \gamma^l_i$, where x^l_i and γ^l_i are the atom fraction and activity coefficient of component i in the liquid phase, respectively.

and the Schottky enthalpy, H_S, for the defect reaction

$$0 = V_P + V_{Ga} \quad [18]$$

For it can be seen that by adding Eq. [17] and [18] and subtracting Eq. [13], we obtain Eq. [14]. Hence

$$\Delta H_{Ga} = \Delta H^\circ_f + H_S - \Delta H_P \quad [19]$$

Finally, substituting Eq. [19] into Eq. [16] and subsequently introducing Eq. [15] and [16] into Eq. [12] yields

$$2\delta = e^{\Delta S_P/R} e^{-\Delta H_P/RT} a_{Ga} - e^{\Delta S_{Ga}/R} e^{-(\Delta H^\circ_f + H_S - \Delta H_P)/RT} a_P \quad [20]$$

Enthalpies and entropies of vacancy formation.—According to Eq. [20], at any T the experimental x^s_{Ga} or $\delta (= 2x^s_{Ga} - 1)$ is related to well-defined thermodynamic quantities. All required values in Eq. [20] except ΔS_P, ΔS_{Ga}, and ΔH_P can be obtained from previous work. Therefore, a knowledge of δ at three temperatures is necessary to determine these entropies and enthalpy. These quantities were evaluated from a set of three simultaneous transcendental equations which were generated by writing Eq. [20] for three different temperatures with the appropriate values of the activities and experimental δ.

The experimental data selected for this calculation were taken from the analysis of undoped seed-end crystals, grown at 1465° (MH-143-powdered), 1457° (MH-134), and 1327°C (MH-70-powdered). The activities a_P and a_{Ga} at these temperatures were derived from the published liquidus and activity coefficient curves (1). A value of $\Delta H^\circ_f = -30.9$ kcal at 1400°C (the average growth temperature of samples used in the calculation) was derived from a combination of the heat of formation of GaP from the solid elements at 25°C (1) with the enthalpy changes (including the heats of fusion of Ga and P) associated with heating Ga (26), P (27), and GaP (1) to 1400°C. The Schottky enthalpy was previously estimated (7) to be 88.6 kcal (3.84 eV) which was based on Kroger's rule (28) stating that the ratios of the heat of atomization to H_S are relatively constant values for covalent semiconductors.

Due to the complexity of solving the transcendental equations for ΔS_P, ΔS_{Ga}, and ΔH_P, a brief outline of the computational procedure is in order. As the equations are linear in $e^{\Delta S_P/R}$ and $e^{\Delta S_{Ga}/R}$, these quantities were expressed explicitly in terms of ΔH_P by applying Kramer's rule to a pair of equations. Then, substituting $e^{\Delta S_P/R}$ and $e^{\Delta S_{Ga}/R}$ as a function of ΔH_P into the third equation, an implicit transcendental equation in one unknown was obtained which was solved for ΔH_P by a numerical method. Finally, knowing ΔH_P, $e^{\Delta S_P/R}$ and $e^{\Delta S_{Ga}/R}$ were calculated by Kramer's rule.

The results can be summarized in the following manner. For Eq. [13]

$$\Delta H_P = 16.5 \text{ kcal } (0.71 \text{ eV}), \quad \Delta S_P = -3.38 \text{ cal/deg}$$

For Eq. [14] (using Eq. [19])

$$\Delta H_{Ga} = 41.2 \text{ kcal } (1.79 \text{ eV}), \quad \Delta S_{Ga} = 9.11 \text{ cal/deg}$$

Calculations of the vacancy concentrations and of the solidus.—Using the above values of the entropies and enthalpies in combination with a_{Ga} and a_P, the site fractions v_P and v_{Ga} were readily calculated over a wide temperature range from Eq. [15] and [16], respectively. Multiplication of the fractional concentrations by 2.47×10^{22} yields the absolute vacancy concentrations in the customary vacancies/cm^3 units; these are presented in Fig. 2 as a function of reciprocal temperature.

It follows from the observation that $x^s_{Ga} > 0.5$ in Table I that along the Ga-rich liquidus v_P is always greater than v_{Ga}, as shown in Fig. 2. In particular, at the melting point of GaP there are, respectively, 8×10^{18} and 1.3×10^{19} cm^{-3} Ga and P vacancies in the

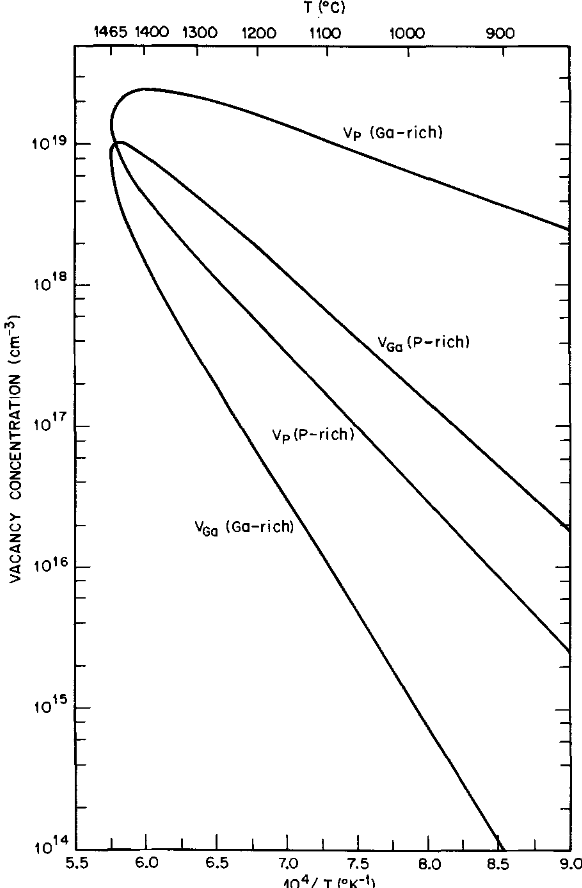

Fig. 2. The calculated Ga and P vacancy concentrations for GaP crystals in equilibrium with liquid solutions along the Ga- and P-rich branches of the liquidus curve.

crystal. However, along the P-rich liquidus, v_{Ga} is always greater than v_P.

Having evaluated v_P and v_{Ga}, the entire solidus boundary was calculated from Eq. [12] and superimposed over the experimental solidus data in Fig. 1. The calculated solidus is retrograde with a large excess of Ga in equilibrium with the Ga-rich liquid solution and with a much smaller excess of P along the P-rich liquidus. The retrograde maximums are at ~1375° (in the vicinity of the v_P maximum) and ~1400°C on the Ga and P-rich sides, respectively.

Discussion.—It can be seen in Fig. 2 that along the Ga-rich branch of the liquidus curve, v_{Ga} drops much more drastically with decreasing temperature than v_P. Consequently, in view of the maximum along the v_P curve, v_P is within a factor of 2 for crystals pulled by LEC at 1465°C and grown from solution (assuming that the average growth temperature of SG is ~1100°C); whereas, v_{Ga} decreases by a factor of ~1000. This observation bears significantly on the interpretation of electrical and optical measurements. If crystals are grown or heat-treated at different temperatures near or at the Ga-rich liquidus, then subsequent electrical or optical measurements are much more likely to reveal effects associated with the changes in v_{Ga} rather than v_P.

Previously, a linear correlation was established between $1/\tau_n$ and relative Ga vacancy concentration for SG crystals and crystals pulled by LEC from stoichiometric and nonstoichiometric melts (11). The relative insensitivity of v_P to crystal growth or heat-treating temperature provides additional evidence supporting the interpretation that the dominant nonradiative centers are related to V_{Ga} and not to V_P. Moreover, an independent value of ΔH_{Ga} was obtained by a reanalysis of the $1/\tau_n$ data (11). If $1/\tau_n = C_1 v_{Ga}$, where C_1 is a constant of proportionality, then according to Eq. [16]

$$\log 1/\tau_n = \log C_1 + \Delta S_{Ga}/R - \Delta H_{Ga}/RT + \log a_P$$

Combining the temperature-independent terms in a new constant, C_2, we find that

$$\log 1/(\tau_n a_P) = \log C_2 - \Delta H_{Ga}/RT$$

Since this equation is linear in $1/T$ and the left-hand side consists of known quantities, the method of least-squares yields $\Delta H_{Ga} = 1.73 \pm 0.36$ eV.[7] The good agreement found between the above ΔH_{Ga}, derived from optical measurements, and that obtained from the thermodynamic analysis of the solidus data (1.79 eV) gives additional strong support to the identification of Ga vacancies with killer centers.

The effect of varying H_S on ΔH_P and ΔH_{Ga} was determined by repeating the initial calculation based on Eq. [20]. It was found that ΔH_P is relatively insensitive to changes in H_S. In particular, varying H_S, by ±10%,[8] effects ΔH_P by less than ~±0.5%, while ΔH_{Ga} changes by ~±20% (as seen from Eq. [19]) which is comparable in magnitude to the error in the optical ΔH_{Ga}.

The calculated solidus curve, shown in Fig. 1, is in good accord with all the experimental solidus data. Indeed, the solidus data obtained for SG, doped LEC pulled, and annealed crystals, none of which were used in the calculations, by their agreement with the solidus curve, corroborates the consistency of the thermodynamic treatment. In view of the relatively large observed deviations from stoichiometry, precision x-ray and density measurements on nonstoichiometric LEC pulled crystals could provide further confirmation of the analysis.

Recently, Logan and Hurle (23) estimated the solidus curve of GaAs by a detailed analysis of the annealing results of Potts and Pearson (29), Munoz *et al.* (31), and others. The shape of the solidus curve for GaAs is similar to the one obtained for GaP. In essence, the solidus is retrograde and the departures from stoichiometry are much more pronounced along the Ga-rich branch of the solidus than along the As-rich one.

In addition, it is interesting to compare the values of the Schottky entropy and enthalpy (H_S and S_S) for GaAs and GaP. According to Logan and Hurle (23), $H_S = 4$ eV for GaAs which should be compared with the value of 3.84 eV used in this study. For GaP, S_S was found by adding the derived values of ΔS_P and ΔS_{Ga} for Eq. [13] and [14], respectively, and subtracting the 1400°C value of $\Delta S°_f$ for Eq. [17]. An application of the third law method to the thermodynamic data for Ga(l) (26), P(l) (27), and GaP (l) yielded $\Delta S°_f = 14.24$ cal/deg. Thus $S_S \approx 20$ cal/deg for GaP which is similar in magnitude to the value (18.6 cal/deg) determined by Logan and Hurle (23) for GaAs. The important enthalpy and entropy values for GaP are summarized in Table II.

According to the principles of defect chemistry (28) S_S is a measurable thermodynamic property not ex-

[7] In the previous work (11) which showed the linear correlation, $\Delta H_{Ga} = 1.71$ eV was estimated for Eq. [14] from the sum of H_S (3.84 eV) and the enthalpy for the reaction $P(l) + V_P = P_P$, ΔH_V, obtained (7) by a simple generalization of the results of Potts and Pearson for GaAs (29). However, since recently Logan and Hurle (23) showed that the annealing data of Potts and Pearson (29) were not along the liquidus, the estimated ΔH_V was not used here.

[8] Note that the selected upper limit for H_S approaches the sum of the recently estimated values (30) for the vacancy formation energies of Ge (1.9 eV) and Si (2.38 eV).

Table II. Defect entropies and enthalpies for GaP

† From solidus data.
* From optical data.

perimentally separable into the entropies of individual defects $s(V_P)$ and $s(V_{Ga})$, interrelated by $S_S = s(V_P) + s(V_{Ga})$. But a rough estimate of these virtual thermodynamic quantities from the data was possible. Writing out in detail the entropy changes implied by Eq. [13] and [14], we find for $s(V_P)$ and $s(V_{Ga})$, respectively

$$s(V_P) = \Delta S_P + S^\circ(\text{Ga(l)}) - s(\text{Ga}_{Ga}) \quad [21]$$

and

$$s(V_{Ga}) = \Delta S_{Ga} + S^\circ(\text{P(l)}) - s(\text{P}_P) \quad [22]$$

Assuming that

$$s(\text{Ga}_{Ga}) = S^\circ(\text{Ge(c)})$$

and

$$s(\text{P}_P) = S^\circ(\text{Si(c)})$$

and using tabulated thermodynamic data for crystalline Ge (26), Si (27), Ga(l) (26), and P(l) (27), at 1400°C in combination with ΔS_P and ΔS_{Ga} from Table II, Eq. [21] and [22] yield the virtual vacancy entropies with respect to the atomic sublattice constituents Ga and P as $s(V_P) \approx 4$ cal/deg and $s(V_{Ga}) \approx 16$ cal/deg.

Finally, we can estimate the effect of V_P on the local vibrational frequency of the adjacent Ga atoms and V_{Ga} on that of the P atoms. If the crystal as a whole has a frequency ν and the number of nearest neighbors is 4 then (28)

$$s(V_{Ga}) = k \ln \left(\frac{\nu}{\nu'_P}\right)^4 \quad [23]$$

and

$$s(V_P) = k \ln \left(\frac{\nu}{\nu'_{Ga}}\right)^4 \quad [24]$$

where ν'_P and ν'_{Ga} are the average vibrational frequencies near V_{Ga} and V_P, respectively. Solving for ν/ν'_P and ν/ν'_{Ga} we find

$$\nu/\nu'_{Ga} = 1.65,\ \nu/\nu'_P = 7.48,\ \text{and}\ \nu'_{Ga}/\nu'_P = 4.5$$

Thus the wavelengths of local vibrational modes due to vacancies lie above the lattice modes. This suggests that local mode identification in the far infrared may be aided by these thermodynamic results.

Crystal Growth and Characterization of Gallium Nitride

T. L. Chu,* K. Ito, R. K. Smeltzer,*,[1] and Shirley S. C. Chu

Electronic Sciences Center, Southern Methodist University, Dallas, Texas 75275

ABSTRACT

The crystal growth of gallium nitride has been investigated by using the ammonolysis of gallium suboxide, the sublimation of gallium nitride or gallium oxide in an ammonia atmosphere, and the ammonolysis of gallium monochloride at 1150° ± 20°C in gas flow systems. The first two techniques have produced only low resistivity gallium nitride crystals of millimeter size. The ammonolysis of gallium monochloride is most promising; single crystals of gallium nitride as large as 25 × 15 × 5 mm, heretofore unknown, have been obtained by using sapphire platelets with main faces of $(1\bar{1}02)$ orientation as substrates. The single crystallinity of these crystals was verified by chemical etching and optical microscopy and x-ray diffraction techniques. These crystals, with an electron concentration of about 10^{19} cm^{-3} and Hall mobilities of about 150 cm^2 V^{-1} sec^{-1} at room temperature, have been used as substrates for the growth of large gallium nitride crystals of improved structural perfection.

Gallium nitride crystallizes in the wurtzite structure and has a direct energy gap of about 3.5 eV at 2°K (1). It is, therefore, a potentially important optoelectronic material. However, gallium nitride has a high melting point, above 1600°C (2), and is thermally unstable with respect to decomposition into its elements. Early work has reported that gallium nitride undergoes slow dissociation at temperatures as low as 600°C (3). The available vapor pressure data on gallium nitride have recently been reviewed and found tc be consistent with the equilibrium pressure of nitrogen over gallium nitride and liquid gallium calculated from thermodynamic functions (4). For example, the vapor pressure of nitrogen is in the range of 1-100 atm at 1000°C and 700-40,000 atm at 1600°C. These results indicate the severe problems involved in the preparation of large gallium nitride crystals. Also, gallium nitride is essentially insoluble in gallium at temperatures below 1100°C. Thus, a vapor growth technique with a growth rate of gallium nitride considerably higher than its decomposition rate is best suited for the crystal growth of gallium nitride.

Single crystals of gallium nitride have been prepared in the form of needles with hexagonal symmetry by heating gallium nitride at 1150° to 1200°C in an ammonia flow (5). However, major efforts have been directed to the epitaxial growth of thin layers of gallium nitride on foreign substrates by physical and chemical vapor growth techniques. The former included the evaporation of gallium in a nitrogen discharge (6) and the rf sputtering of gallium nitride (7), and the latter included the ammonolysis of gallium monochloride (8-10), the thermal decomposition of a gallium tribromide-ammonia complex (11), and the ammonolysis of trimethylgallium (12). The ammonolysis of gallium monochloride on sapphire substrates has been most widely used. In most cases, however, the grown layer exhibited high donor concentrations, due presumably to a native defect such as nitrogen vacancies, and p-type layers have not been produced. Also, sapphire is structurally not an ideal substrate for the epitaxial growth of gallium nitride because of their differences in lattice parameters (a = 4.76Å and c = 12.99Å for sapphire; a = 3.18Å and c = 5.16Å for gallium nitride) and thermal expansion coefficients (9.2 × 10^{-6} $°K^{-1}$ for sapphire in the a and c directions, range 0°-1200°C; 5.6 × 10^{-6} $°K^{-1}$ and 7.75 × 10^{-6} $°K^{-1}$ for gallium nitride in the a and c directions, 700°-900°K. Homoepitaxial growth of gallium nitride, which is inherently capable of yielding better quality layers, has not been investigated because of the lack of bulk crystals of gallium nitride.

In the present work, three chemical vapor growth techniques were investigated for the growth of bulk gallium nitride crystals. They included the ammonolysis of gallium suboxide, the sublimation of gallium nitride or gallium trioxide in an ammonia atmosphere, and the ammonolysis of gallium monochloride in gas flow systems. The third technique has produced gallium nitride single crystals up to 25 × 15 × 5 mm in size, heretofore unknown. The experimental procedures of the vapor growth processes and the characterization of grown crystals are discussed in this paper.

Ammonolysis of Gallium Suboxide

Gallium nitride can, in general, be prepared by the reaction between ammonia and a gaseous gallium compound. Gallium suboxide, Ga_2O, with an appreciable vapor pressure at temperatures near 1000°C, is suitable for the preparation of gallium nitride as indicated by the thermochemistry of the reaction

$$Ga_2O(g) + 2NH_3(g) \rightarrow 2GaN(s) + H_2O(g) + 2H_2(g)$$

Using the free energies of formation of gallium suboxide (13), ammonia (14), gallium nitride (4), and water (14), the standard free energy changes of this reaction have been calculated to be −35.7, −35.2, −27.5, and −15.1 kcal/mole at 1100°, 1200°, 1300°, and 1400°K, respectively, indicating that the reaction is thermochemically feasible in the temperature range under consideration. Gallium suboxide can be readily prepared by the reaction of gallium and gallium trioxide according to the reaction

$$4Ga(1) + Ga_2O_3(s) \rightarrow 3Ga_2O(g)$$

The equilibrium vapor pressure of gallium suboxide over a 4:1 molar mixture of gallium and gallium trioxide has been reported to be approximately 0.2 Torr at 800°C and 10 Torr at 1000°C (15).

The ammonolysis of gallium suboxide was carried out with the apparatus shown in Fig. 1. Gallium suboxide was produced in the quartz boat containing a mixture of gallium and gallium trioxide, and the nitrogen flow was used to carry the suboxide vapor into the reaction

Key words: ammonolysis, gallium monochloride, sapphire, semiconductor.

tube. The suboxide then reacted with the ammonia to produce gallium nitride. The experiments were carried out with the quartz boat in the temperature range 900°-1050°C and the reaction zone in the temperature range 1000°-1200°C. The flow rate of ammonia was 400 ml/min. The suboxide formation temperature was found to be not critical; however, gallium nitride crystals were obtained only for a reaction zone temperature of 1150° ± 10°C. Needle-like crystals, dark green in color and up to 1 mm in size, were found near the ammonia outlet. Dendritic crystals with dimensions up to 3 mm were sometimes found also. X-ray techniques showed the crystals to be single crystalline gallium nitride with the long axis in the c direction. The limited success of this method for the crystal growth of gallium nitride may be due to the disproportionation of gallium suboxide in the reaction zone, as indicated by the free gallium and powdery material found near the reaction zone.

Sublimation of Gallium Nitride or Gallium Oxide in Ammonia

It has been reported that small needle-like nitride crystals were obtained by heating powdered gallium nitride in ammonia at 1150°-1200°C (5). Attempts were made to improve upon this result by using different source materials. The apparatus for the sublimation method consisted of a single-zone furnace with an alumina or a fused silica reaction tube. The source material was placed in an alumina boat in the maximum temperature region of the reaction tube, and ammonia or an ammonia-nitrogen mixture was introduced at various flow rates. The reaction tube could be maintained at pressures up to 5 atm. Six types of source material were used: (*i*) gallium trioxide powder, (*ii*) gallium nitride powder, (*iii*) a mixture of gallium and gallium trioxide, (*iv*) a mixture of gallium and gallium nitride, (*v*) pressed pellets of gallium and gallium trioxide, and (*vi*) pressed pellets of gallium and gallium nitride. The pellets weighed about 1g and were made with a Parr Model 2811 pellet press.

The initial experiments were carried out with loosely packed powder of gallium trioxide or gallium nitride. A source temperature of 1170° ± 10°C was necessary to achieve growth of gallium nitride crystals. Typically, after three days of reaction time, very small crystals of gallium nitride were found in the boat. With a fifteen day growth period, crystals were found at two locations. Dark green, slightly transparent, n-type, needle-shaped crystals up to 2 mm long by 0.2 mm thick were found on the wall downstream from the source material; the dark color is due apparently to the thermal decomposition of gallium nitride. Light green transparent crystals of about 0.4 × 0.04 mm dimensions were found in the boat. These results were not affected by changing the flow rate of ammonia, by diluting the ammonia with nitrogen, or by using ammonia pressures up to 5 atm. Similar results were obtained by using loose mixtures of gallium-gallium trioxide and gallium-gallium nitride as the source material except that there was a tendency for larger gallium nitride crystals to form in the boat.

When the pressed pellets of gallium-gallium trioxide and gallium-gallium nitride were used as the source material, source temperatures in the range 1160°-1180°C and ammonia flow rates in the range 50-500 ml/min were used. The experiments were carried out for periods up to 20 days. Two types of needle-like crystals, both with dimensions up to 3 mm long by 0.5 mm thick, were obtained. Light colored crystals were found growing inward from what was the surface of the pellets, and dark green crystals were found on the wall of the reaction tube downstream from the pellets. Usually one type or the other predominated in a particular experiments, but the exact reason for this was not established. Figure 2 shows examples of the two types of gallium nitride crystals; these crystals have a hexagonal cross section and were shown to be single crystalline by the x-ray diffraction

Fig. 2. Gallium nitride crystals grown on the wall of the silica tube (upper) and in the alumina boat (lower) by the sublimation technique.

technique. Chemical etching of these crystals with a 40% sodium hydroxide solution for 30 min revealed no significant structural defects. Using indium as ohmic contacts, the electrical resistivity of these n-type crystals were measured to be essentially independent of temperature in the range 160°-330°K. The darker crystals have a resistivity of about 3×10^{-3} ohm-cm, and the lighter ones about 3×10^{-2} ohm-cm.

Ammonolysis of Gallium Monochloride

The ammonolysis of gallium monochloride has been used for the epitaxial growth of gallium nitride on the basal plane of sapphire at 850°-1050°C, and the growth rates were up to about 1 μm/min (8-10). This process involves two steps: the formation of gallium monochloride by the reaction of gallium with hydrogen chloride, and the reaction of gallium monochloride with ammonia to form gallium nitride. The chemical reactions are (16)

$$2Ga(l) + 2HCl(g) \rightarrow 2GaCl(g) + H_2(g)$$

$$GaCl(g) + NH_3(g) \rightarrow GaN(s) + HCl(g) + H_2(g)$$

The ammonolysis of gallium monochloride was also used in this work, and gallium nitride was deposited on sapphire substrates of $(1\bar{1}02)$ orientation at high rates, 10 μm/min for example. The high deposition rate was achieved by the use of high hydrogen chloride concentrations in the reactant mixture, a particular substrate orientation, and a closely spaced geometrical arrangement in the reaction tube. Single crystals of gallium nitride as large as 25 × 15 × 5 mm have been obtained.

The apparatus used in this work is shown schematically in Fig. 3. It consists of a fused silica reaction

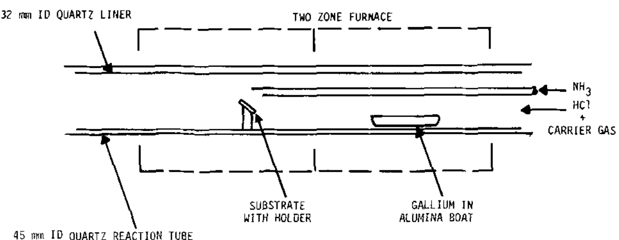

Fig. 3. Schematic of the apparatus for the growth of bulk gallium nitride crystals by the ammonolysis of gallium monochloride.

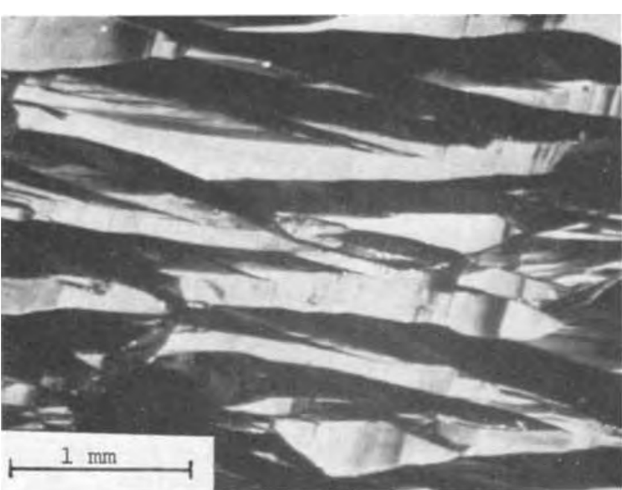

Fig. 4. The as-grown surface of a gallium nitride crystal on a sapphire substrate of $(\bar{1}\bar{1}02)$ orientation.

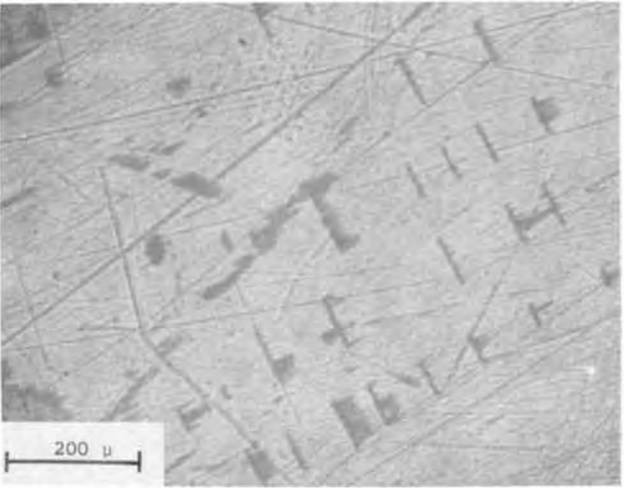
tube, 45 mm ID with a 32 mm ID liner and 90 cm long, situated in a two-zone resistance-heated furnace. The ends of the reaction tube are provided with standard taper joints. The end cap on the gas inlet side has provisions for introducing hydrogen chloride mixed with a diluent, helium or hydrogen, and for introducing ammonia to the reaction zone. Gallium was placed in an alumina boat and heated in one zone of the furnace, and sapphire substrates were located in the second zone of the furnace. The parameters in this process include the composition and flow rate of the reactant mixture, the temperatures of the gallium source and the substrate, and the position of the substrate with respect to the ammonia outlet tube. A large NH_3/HCl molar ratio is necessary to minimize the formation of free gallium. The concentration and flow rate of hydrogen chloride in the reactant mixture determine the rate of formation of gallium monochloride and therefore that of gallium nitride. Also, the reaction between gallium monochloride and ammonia should take place predominately on the substrate surface to minimize homogeneous nucleation through gas phase reactions. The gas phase reaction is more pronounced at high substrate temperatures and can be minimized by using a small separation between the substrate and the ammonia outlet tube.

Both hydrogen and helium were used as the diluent gas. Under optimum temperature and flow rate conditions, the use of helium was found to produce about a 20% higher yield than that of hydrogen, qualitatively in agreement with a previous report (16). Typical flow rates of helium, hydrogen chloride, and ammonia were 2, 0.02, and 1 liter/min, respectively. The gallium source was held at about 900°C, and the substrate was maintained at about 1050°C. The substrate, 5 mm × 25 mm in area, was located within 1 cm from the ammonia outlet and was tilted at about 30°. After a 6 hr experiment, the single crystal deposit on a $(1\bar{1}02)$ oriented sapphire substrate was usually 2-5 mm thick, weighing up to 4g. The deposition of gallium nitride on the basal plane of sapphire yielded crystals more than one order of magnitude smaller in volume that the crystals on $(1\bar{1}02)$ substrates.

The grown crystals range from colorless to dark green in color, and their surfaces always exhibit many growth ridges, as shown in Fig. 4. The faces consist of three orientations at approximately 120° angles to each other. Back-reflection Laue x-ray technique indicated that these faces, each of which has a twofold symmetry, are of $(\bar{2}110)$, $(1\bar{2}10)$, and $(11\bar{2}0)$ orientations. These orientations are symmetry related, and the orientation relation $(\bar{2}110)_{GaN}$ || $(1\bar{1}02)_{Al_2O_3}$ is in agreement with an early work (12). In addition to a reasonable match in lattice parameters, the development of the $\{\bar{2}110\}$ faces presumably arises from the fact that the $\{\bar{2}110\}$ planes are the most densely packed, and therefore the lowest energy planes in gallium nitride. Planes of other crystallographic orientations developed during the growth process will eventually grow out.

Gallium nitride crystals grown on sapphire substrates have high concentrations of structural defects. Defects in gallium nitride may be revealed by etching with a 40% sodium hydroxide solution at about 100°C for 30 min. Figure 5 shows typical defects observed in gallium nitride crystals. The etch figures on a mechanically polished surface (Fig. 5a) consist of many parallel lines and are stacking fault traces, *i.e.*, the intersections of stacking fault planes with the surface of the crystal. The transmission micrograph of the same area (Fig. 5b) shows the projection of stacking fault planes on the surface of the crystal, mostly in the form of isosceles triangles of the same orientation, indicating that all faulting planes are parallel and make the same angle with the grown surface. The stacking fault plane is presumably a $\{\bar{2}110\}$ plane, the most densely packed plane, which makes an angle of 60° with the grown surface, intersecting along a <0001> direction. Thus, the stacking faults usually commence at certain points and develop along a $\{\bar{2}110\}$ plane with a rapid increase in area, similar to the formation of stacking faults in epitaxial silicon (17, 18).



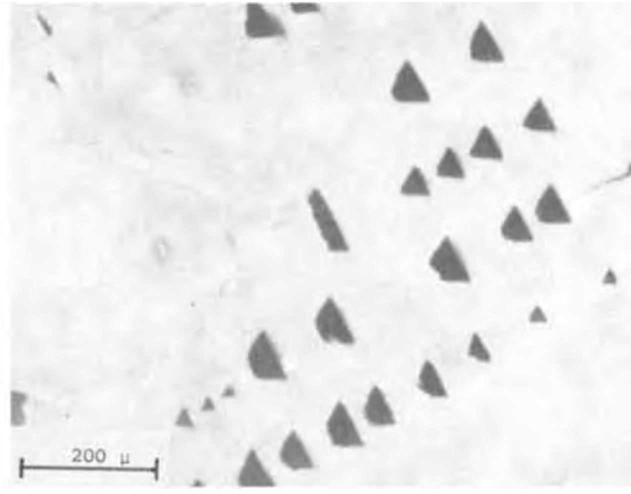


Fig. 5. Stacking faults in vapor-grown gallium nitride crystals. (a, left) Etch figures on a polished grown surface. (b, right) Transmission micrograph of the same area shown in (a).

The sapphire substrate on the grown crystal can be readily removed by mechanical lapping. Hall measurements were made on the bulk gallium nitride crystals at 77° and 300°K by the van der Pauw technique (19). At room temperature, the bulk crystals were n-type, and had an electron concentration of approximately 10^{19} cm^{-3} and carrier mobilities in the range of 120-180 cm^2 V^{-1} sec^{-1}. The carrier concentration was essentially the same at 77°K; however, the mobilities decreased by about 25%, due presumably to the ionized impurity scattering.

The large gallium nitride crystals have also been used as substrates for crystal growth. They were first mechanically polished with an alumina abrasive and etched *in situ* with a hydrogen-hydrogen chloride mixture at 850°C just prior to the deposition process. Single crystals of gallium nitride on gallium nitride substrates with dimensions similar to those on sapphire substrates were obtained. Figure 6 shows two typical gallium nitride crystals grown on a sapphire substrate of $(1\bar{1}02)$ orientation and a gallium nitride substrate. Figure 7 shows the angle-lapped and chemically etched surface of a gallium nitride crystal deposited on a gallium nitride substrate. As expected, the grown crystal has considerably better structural perfection than the substrate as indicated by the relatively heavy attack of the substrate by the sodium hydroxide solution.

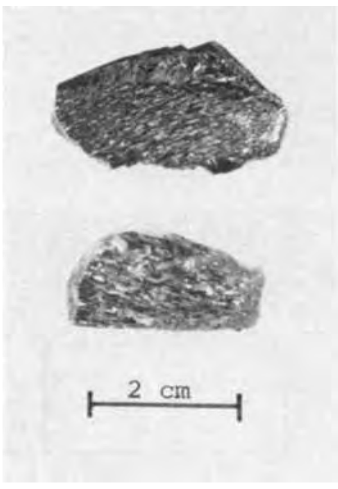

Fig. 6. Gallium nitride crystals obtained by the ammonolysis of gallium monochloride. The upper crystal was grown on a sapphire substrate of $(1\bar{1}02)$ orientation, and the lower crystal was grown on a gallium nitride substrate.

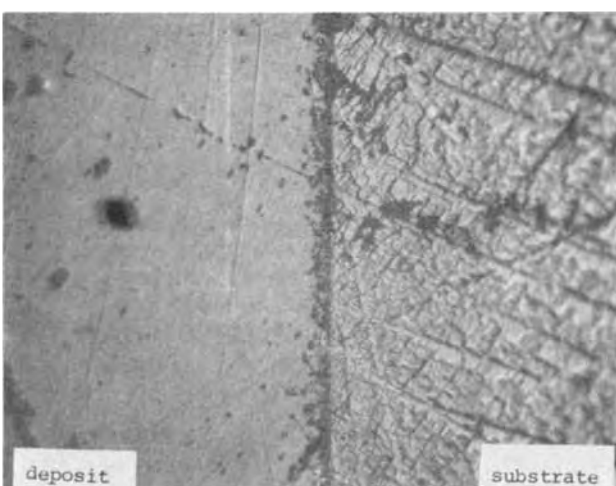

Fig. 7. The angle-lapped and chemically etched surface of a gallium nitride crystal deposited on a gallium nitride substrate. Etchant: 40% sodium hydroxide solution at 100°C for 30 min.

Summary and Conclusions

Three chemical vapor growth techniques have been used for the preparation of gallium nitride crystals at 1150° ± 20°C. The ammonolysis of gallium suboxide and the sublimation of gallium nitride or gallium trioxide in an ammonia atmosphere have produced only gallium nitride crystals of millimeter size. They were n-type and had low electrical resistivities. The ammonolysis of gallium monochloride on sapphire substrates of $(1\bar{1}02)$ orientation at 1050°C has produced single crystals of gallium nitride with dimensions up to 25 × 15 × 5 mm. Gallium nitride crystals grown in this manner had electron concentrations on the order of 10^{19} cm^{-3} and electron mobilities of about 150 cm^2 V^{-1} sec^{-1} at room temperature. Using these crystals as substrates, large gallium nitride crystals with better structural perfection have also been obtained. The growth of large gallium nitride crystals reported in this work, due largely to the use of a relatively high flow rate of hydrogen chloride, the closely spaced reaction tube geometry, and the $(1\bar{1}02)$ oriented substrates, represents a significant contribution to the state of the art technology.

High-Temperature Dielectric Behavior of Polycrystalline ZnO

M. A. Seitz and T. O. Sokoly

Metallurgy and Materials Science, College of Engineering, Marquette University, Milwaukee, Wisconsin 53233

ABSTRACT

The dielectric behavior of undoped, lithium-doped, and sodium-doped polycrystalline ZnO was investigated as a function of frequency, from 100 Hz to 600 kHz, and temperature, over the interval from room temperature to 900°K. Barrier layer polarization seemed responsible for capacitance dispersion for undoped polycrystalline ZnO. These barrier layers appeared to occur at the surfaces of the individual polycrystalline grains and seemed to be the result of the chemisorption of oxygen. The data for lithium- and sodium-doped ZnO was rationalized on the basis of a space charge polarization model involving mobile ionic point defects, which were blocked or partially blocked at the specimen electrodes, and electronic carriers, which were able to freely pass through the electrodes. The effective dielectric constant for the doped specimens varied exponentially with temperature. The activation energies of 0.6 eV for Li-doped ZnO and 1.1 eV for Na-doped ZnO were attributed to the energy of motion of the interstitial defect.

In the last two decades zinc oxide has been the subject of numerous investigations. Excellent reviews of much of this work have been presented by several authors (1-3). Zinc oxide has been found attractive for a diversity of applications which include dental cements, catalysts, photoconductive devices, luminescent phosphors, ultrasonic amplifiers, varistors, and field-effect transistors.

Zinc oxide crystallizes in the hexagonal wurtzite crystal structure and has lattice constants $a = 3.24$Å and $c = 5.19$Å. Due to the great difference in size of the zinc and oxygen ions, the atomic packing factor is only 0.44. Relatively large (0.95Å radius) open spaces exist in the lattice and play an important role in the electrical, physical, and chemical behavior of this material. Azaroff has demonstrated the role of crystal structure on atomistic diffusion in ZnO (4, 5). The results of other diffusion studies on this material are also to be found in the literature (6-12).

Optical absorption studies have shown that the bandgap energy of ZnO ranges from 3.4 eV at liquid helium temperature to 2.4 eV at 1360°K. The commonly accepted room temperature value is 3.2 eV. The electrical conductivity of ZnO has been found to be n-type and to vary from 10^{-18} to 10^3 (ohm-cm)$^{-1}$ depending on the temperature of measurement and the materials previous history (6-12). Hall effect studies have confirmed the n-type behavior of ZnO (13, 14).

A number of investigations of the dielectric behavior of ZnO have been conducted (15-23). These studies, however, have been conducted at relatively low temperatures (room temperature and below) and high frequencies (100 kHz and above). The high frequency relative dielectric constant in the a direction was found to be 8.5 ± 0.2, while that in the c direction was found to be 10.0 ± 0.2.

Heretofore, the high conductivity of nonstoichiometric ZnO has made it difficult to perform dielectric measurements at lower frequencies and/or higher temperatures. In this study, measurements were performed over the frequency interval 10^2 to 6×10^5 Hz and at temperatures ranging from room temperature to 900°K, using a previously developed technique (24).

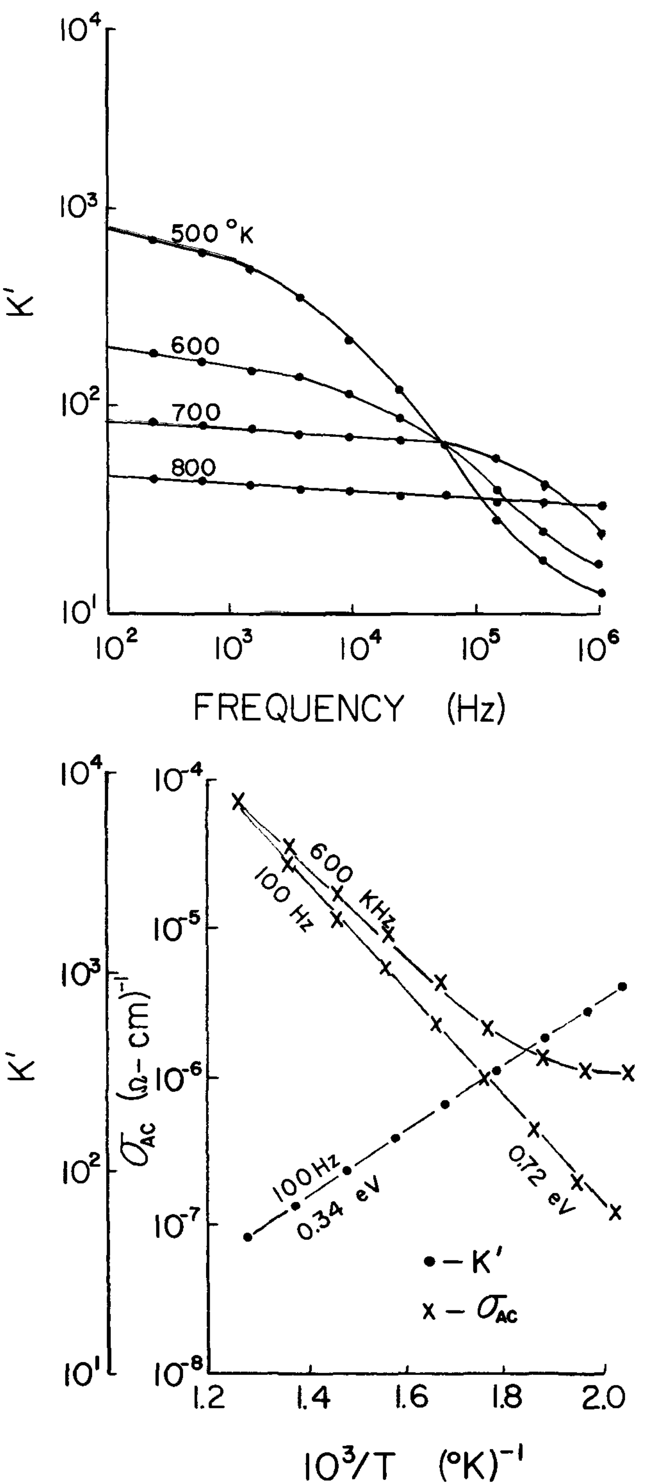
Experimental Procedure

In our early attempts to measure the high-temperature dielectric behavior of ZnO, it was noted that the specimen conductance, G_{sp}, was always greater than the capacitive susceptance, wC_{sp}. This results in dissipation factors which were quite large, $1.0 < \tan \delta < 10^5$. Therefore, a special technique had to be used to perform dielectric measurements. A substitution technique, where corrections are made for parasitic capacitances and inductances associated with the system, was the subject of a previous paper (24). With this technique the capacitance of specimens having a total resistance of greater than 100 ohms and a dissipation factor less than 10^4 can be measured to $\pm 15\%$. For midrange frequencies (1-50 kHz) the error is less than $\pm 5\%$.

Polycrystalline specimens were prepared using pressing and sintering techniques with Johnson Matthey "specpure" ZnO powder (99.999% pure), which had an average grain size of about 5μ. The final disk-shaped specimens had a thickness of 0.5 cm and plane parallel surface areas of 2 cm^2. Doped polycrystalline specimens were produced by mixing the appropriate amounts of the hydroxides, LiOH or NaOH, with powdered ZnO (8, 14). The powdered material was then heated to 600°C for 12 hr, during which time the hydroxides were converted to the oxide and homogenization occurred by interstitial diffusion. The powdered material was then pressed and sintered at 650°C for a second 12 hr period of time. The relatively low temperature heat-treatments were chosen in an attempt to have most of the added impurity remain in interstitial lattice positions. Electrical contact to the specimens were made, on their plane parallel surfaces, using either fluxed platinum paste (Engelhard No. 05), fluxed gold paste (Engelhard 601-FM), or silver paint (GC Electronics Silver Print). Approximately three coatings were used in each case. Between each application the sample was baked at 600°C for about 6-8 hr. When the resistance between any pair of points across the electrode contact had been reduced to less than 0.1 ohm, the procedure was terminated. In all cases investigated it was attempted to have a slight amount of diffusion of the electrode material into the sample surface to insure an intimate contact with the specimen. Although intergradular diffusion, to a depth of approximately 0.5-1 mil, could be observed under microscopic examination, no convenient technique was available to determine the degree of penetration into the grains themselves.

The specimens were loaded into the measurement system. Before performing a measurement, the specimens were allowed to equilibrate at temperature and in various partial pressures of oxygen provided by oxygen-argon tank mixtures. Equilibrium was assumed when the capacitance and resistance changes over a several hour period were less than those due to

Key words: zinc oxide, chemisorption, dielectric, diffusion.



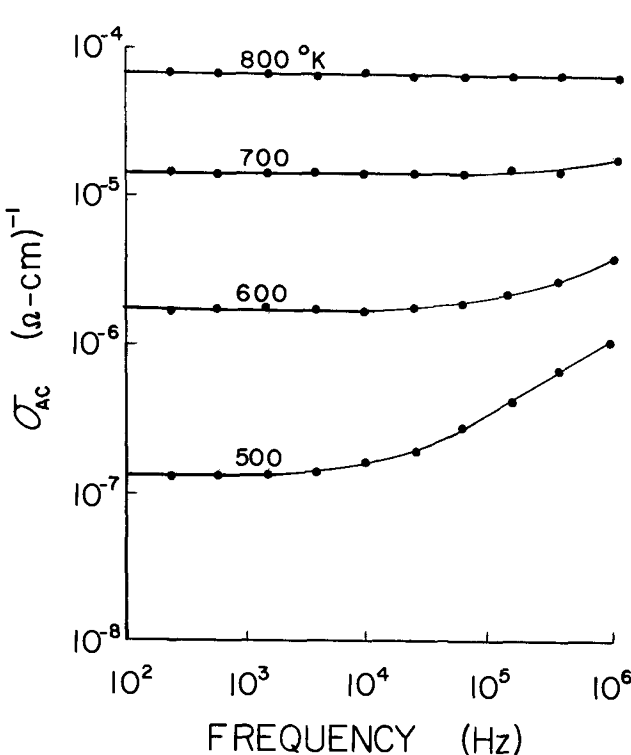


Fig. 1. (a, above left) K', and (b, above right) σ_{ac} vs. frequency; and (c, left) K' and σ_{ac} vs. $1/T$ for an undoped polycrystalline specimen of ZnO with Au contacts at $P_{O_2} = 1$ atm.

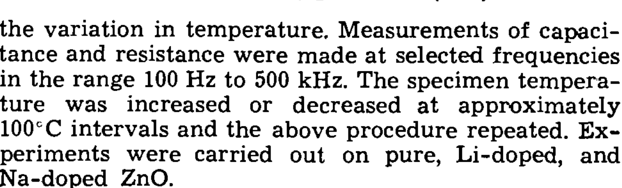

the variation in temperature. Measurements of capacitance and resistance were made at selected frequencies in the range 100 Hz to 500 kHz. The specimen temperature was increased or decreased at approximately 100°C intervals and the above procedure repeated. Experiments were carried out on pure, Li-doped, and Na-doped ZnO.

Results and Discussion

Dielectric behavior of undoped polycrystalline ZnO.—The dielectric behavior of undoped (99.999% pure) polycrystalline ZnO with gold electrodes has been investigated from 10^2 Hz to 6×10^5 Hz and over the temperature range from room temperature to 800°K. The variations of the apparent dielectric constant, K', and a-c conductivity, σ_{ac}, are shown as functions of frequency and reciprocal temperature for an oxygen partial pressure of 1 atm in Fig. 1. The dispersion of K' and σ_{ac} with frequency disappear as the temperature is increased. Upon decreasing the partial pressure of oxygen to less than about 10^{-5} atm it was found that the low frequency values of K' decreased and σ_{ac} increased until no dispersions with frequency were noted for either K' or σ_{ac}. This behavior was found to be relatively independent of the electrode materials used, *i.e*, Pt, Au, or Ag.

The aforementioned behavior was distinctly different from that observed for undoped (99.999% pure) single crystal specimens of ZnO that were obtained from the 3M Company. Here, the dispersions in K' and σ_{ac} increased with increasing temperature. This behavior was strongly dependent on the electrode material being used and was relatively independent of the partial pressure of oxygen surrounding the sample. This seems to suggest that dielectric behavior observed for single crystal specimens was controlled by nonohmic be-

havior of the metal-semiconductor contact, *i.e.*, high-resistance space charge layers at the specimen-electrode interface (25-26).

The low frequency-low temperature behavior of K' observed for undoped polycrystalline ZnO also suggests the existence of space-charge layers within the sample. These data, however, were independent of the electrode material used, which might indicate that these space-charge layers exist at the surfaces of the grains rather than the electrode interface (27-32). This was further evidenced by the fact that little difference was noted in 2 and 4 probe d-c conductivity of similar samples. The large effective surface area of the metal-semiconductor contact probably yielded a better ohmic contact than the single crystal specimens (33). The space-charge layers seemed to disappear with decreasing partial pressure of oxygen or increasing temperature. This suggests that the space layers are the result of the chemisorption of oxygen at the grain surfaces.

A number of investigations have suggested that when oxygen is chemisorbed on the surface of ZnO it leads to surface acceptors (1, 34-38). These acceptors, which capture conduction electrons from the surface region of ZnO, yield a space-charge or depleted layer having a high resistance. A reduction of surface conductivity has been observed in single crystal and thin layer specimens of ZnO due to oxygen chemisorption (34-36). Powdered samples of ZnO consisting of very small particles have become excellent insulators as the result of the chemisorption of oxygen [$\sigma \simeq 10^{-17}$ (ohm-cm)$^{-1}$] (37). The above observations are consistent with the adsorption studies of oxygen on ZnO by Morrison and Miller (38).

Volger has considered the influence of space charge or barrier layers on the dielectric behavior of materials (27). The situations he considered of interest here are those where the conductivity of the surface layer, σ_1, is much less than that of the bulk material, σ_2. Two cases can result, in the first case the thickness of the barrier layer, d_1, is of sufficient magnitude compared to that of the bulk material, d_2, such that the resistance of the surface layer is greater than that of the bulk material. The low frequency effective dielectric constant, K_s', would be given by

$$K'_s = \frac{d_1}{d_2} K'_\infty \qquad [1]$$

where K'_∞ is the high-frequency value of the dielectric constant. The effective low-frequency conductivity, σ_s, would be

$$\sigma_s \; \frac{d_2}{d_1} \sigma_1 \qquad [2]$$

while the high-frequency values, σ_∞, would be

$$\sigma_\infty = \sigma_2 \qquad [3]$$

In the second case the barrier layer thickness, d_1, is sufficiently small compared to that of the bulk material, d_2, such that the resistance of the surface layer is less than that of the bulk material. Here, K'_s is given by

$$K'_s = \frac{d_1}{d_2} \left[\frac{\sigma_2}{\sigma_1}\right] K_\infty \qquad [4]$$

while

$$\sigma_s = \sigma_\infty = \sigma_2 \qquad [5]$$

Between the high- and low-frequency limits, K' and σ_{ac} follow a Debye type dispersion, *i.e.*

$$K' = \frac{K'_s + K'_\infty \tau^2\omega^2}{1 + \tau^2\omega^2} \qquad [6]$$

and

$$\sigma = \frac{\sigma_s + \sigma_\infty \tau^2\omega^2}{1 + \tau^2\omega^2} \qquad [7]$$

Here, τ is a dielectric relaxation time and ω the frequency in radians per second.

The variation of the energy band picture across a grain of ZnO on which oxygen is chemisorbed can be depicted as shown in Fig. 2 (2, 38-40). Here, chemisorbed oxygen molecules take up an electron from the surface and lead to a space charge double layer. The potential, $\Delta\phi$, developed at the surface has been proposed to vary exponentially with distance from the surface with a characteristic length, L_D, *i.e.*, (39)

$$\Delta\phi = \zeta \exp\left(\frac{-x}{L_D}\right) \qquad [8]$$

where ζ is a characteristic value for the diffuse double layer. The values of ζ and L_D would decrease as the surface concentration of chemisorbed species, Q_s, decreases and/or as the density of free electrons in the bulk material increases. The space charge at the surface would lead to a barrier layer which has an effective thickness, d_1, proportional to L_D. The resistivity, which would vary with distance from the surface, and effective resistance of this barrier layer would also vary with the concentration of chemisorbed species and free electrons in the bulk material.

The competitive processes of adsorption-desorption should cause the concentration of chemisorbed species, Q_s, to decrease exponentially with increasing temperature (39, 40). If the chemisorbed species were oxygen, then the concentration, Q_s, would also be expected to decrease with decreasing partial pressure of oxygen.

The lowest temperature data of Fig. 1 is best explained on the basis of a thin space-charge layer or barrier layer whose resistivity and resistance are greater than the bulk material. In this case both K' and σ should show a dispersion with frequency (see Eq. [1]-[3]). However, as the temperature is increased the dispersions in σ_{ac} disappear and K' decreases exponentially with increasing temperature according to a relationship of the type: $K' = K'_0 \exp\left(+\frac{0.34\text{eV}}{kT}\right)$. This behavior best fulfills the predictions of a model based on a space charge layer which has a resistivity greater than, but a resistance less than the bulk material (see Eq. [4] and [5]). Here the value of $d_1 \propto L_D$ would decrease exponentially with temperature as the surface charge, Q_s, decreases and/or as the concentration of free electrons in the bulk material increases. The effective value of the conductivity of the surface layer, σ_1, would also increase exponentially with temperature more rapidly than the conductivity of the bulk material, σ_2. Thus, the 0.34 eV activation energy observed for the decrease of K' with increasing temperature would be related to both the decrease in the surface concentration of chemisorbed oxygen, Q_s, and the increase in the concentration of free electrons in the bulk material of the ZnO grain. The change of σ_{ac} with temperature, similarly, contains information related to both the decrease of surface charge, Q_s, and the

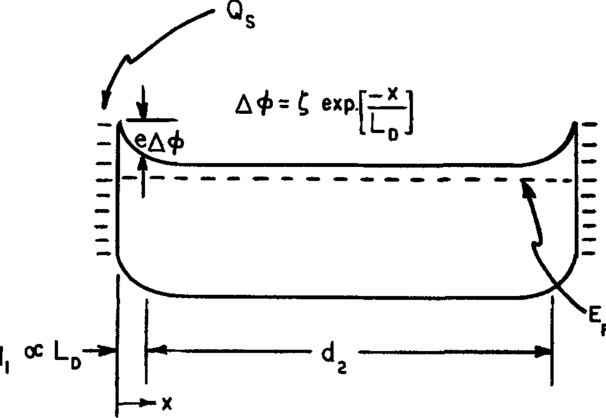

Fig. 2. Band picture representation of a particle of ZnO with surface chemisorbed oxygen.

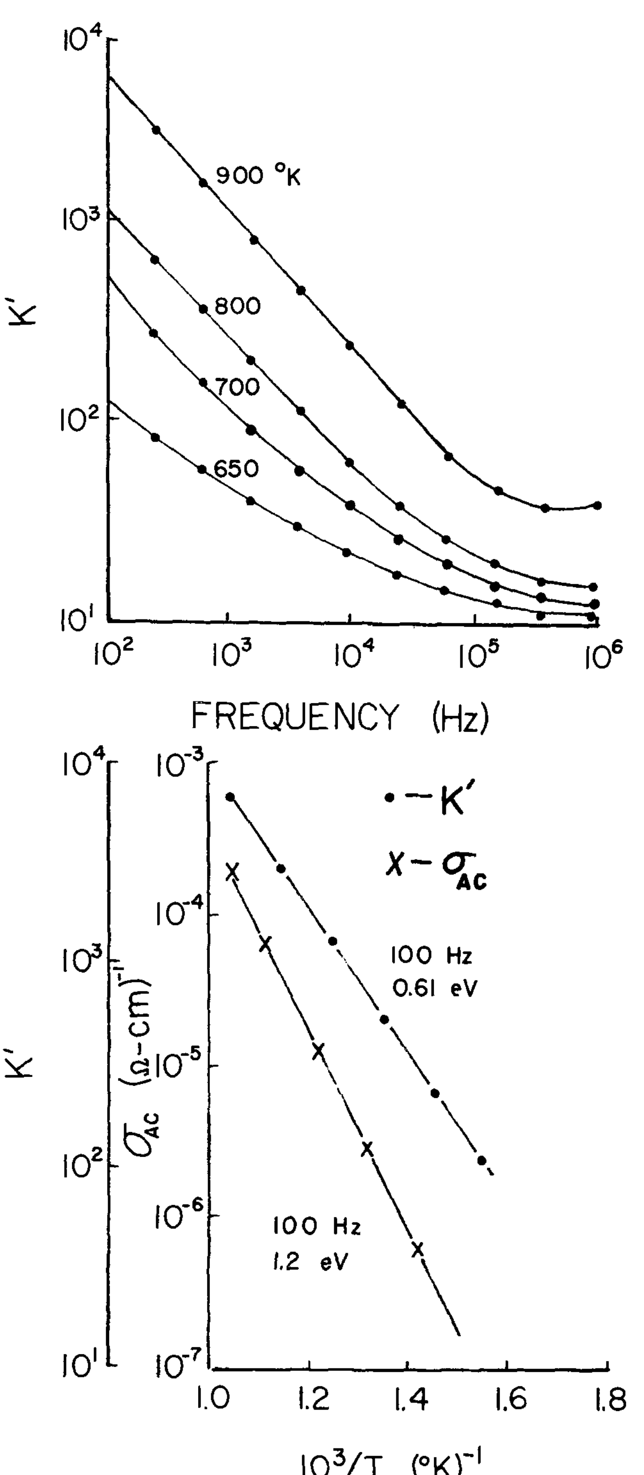

Fig. 3. (a, above left) K' and (b, above right) σ_{ac} vs. frequency; and (c, left) K' and σ_{ac} vs. $1/T$ for a polycrystalline specimen of ZnO, doped with 0.1 m/o Li, with Au electrodes at $P_{O_2} = 10^{-4}$ atm.

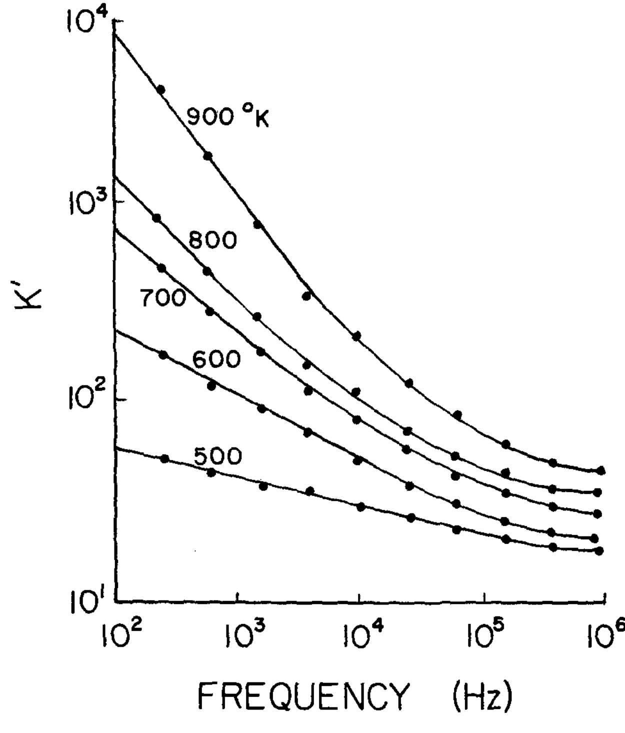
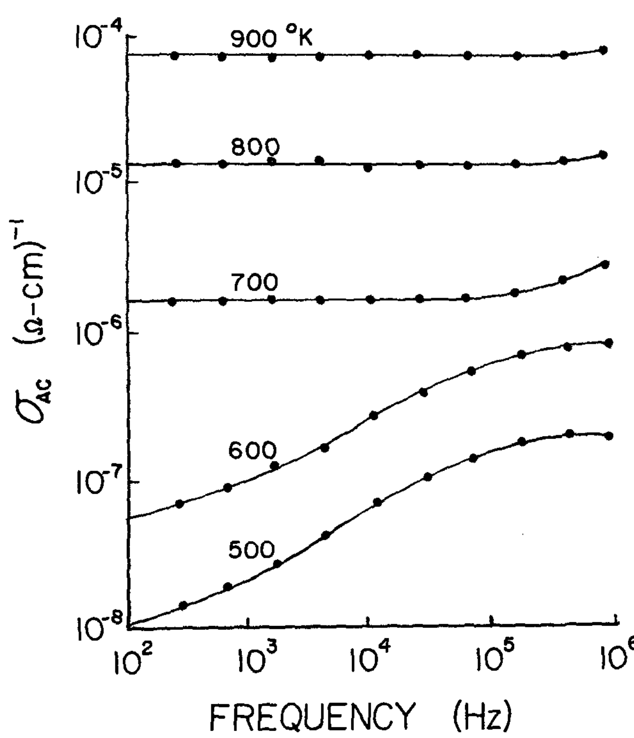
increase in the free electron concentration within the bulk of the grain. Further studies are required to quantitatively define the relative roles played by the chemisorption process as compared to the increase in free electron concentration in determining the dielectric behavior of this material.

Dielectric behavior of Li- and Na-doped ZnO.—It was observed for polycrystalline ZnO that the influence of the barrier layer on the values of K' disappeared as the temperature increased. Therefore, if a polycrystalline sample were doped with an appropriate impurity of small atomic radius, one might observe space-charge polarization due to interstitial diffusion and/or grain-boundary diffusion of the impurity. Interstices in the lattice of ZnO are as large as 0.95Å. Thus, Li^+, which has an ionic radius of 0.6Å, and Na^+, which has an ionic radius of 0.95Å, where chosen as dopants in the hope that they might be able to diffuse interstitially in the ZnO lattice (41, 42).

Samples of polycrystalline ZnO were prepared having Li concentrations of 0.1 and 0.3 mole per cent (m/o), and a Na concentration of 0.3 m/o. In each case the hydroxide of the alkali metal was converted to the oxide when mixed with ZnO powder. These impurities were introduced by low temperature diffusion ($T <$ 950°K) for relatively long periods of time ($\sim$ 1 day) to keep the majority of the impurity atoms in interstitial sites. The dielectric behavior observed for these specimens with inert gold electrodes is shown in Fig. 3-5.

These data do not seem to fulfill the conditions set forth by Volger for barrier layer polarization, in that the major dispersion in K' appears at a temperature above that for which the dispersion occurs in σ. The value of K' increased with increasing temperature, which is also opposite from what one would expect from Eq. [4] where, from the previously discussed behavior, one would expect K'_s to decrease with increas-





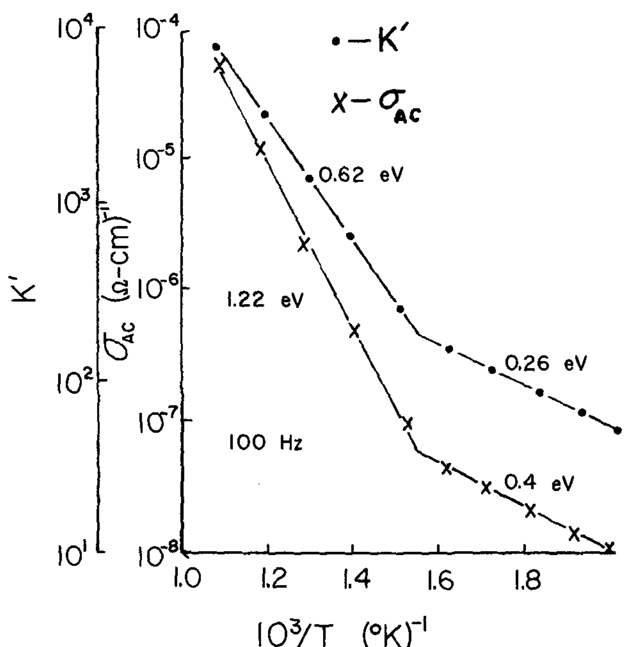


Fig. 4. (a, above left) K', and (b, above right) σ_{ac} vs. frequency; and (c, left) K' and σ_{ac} vs. $1/T$ for a polycrystalline specimen of ZnO, doped with 0.3 m/o Li, with Au electrodes at $P_{O_2} = 10^{-4}$ atm.

ing temperature. A space charge polarization model, where mobile electrons are able to freely pass through the electrodes, while mobile ions are blocked at the electrodes seems to best fulfill the conditions observed at elevated temperature (43-45).

Several authors have dealt with two-carrier space-charge polarization models, where charge carriers of one sign are completely blocked while those of the opposite sign are able to freely pass through the electrodes (43-45). These authors, however, generally assume that the positively and negatively charged species are in equal concentration, *e.g.*, Schottky and Frenkel defects. Existing models indicate that the capacitance or effective dielectric constant would vary with frequency as ω^{-n} and would show an exponential dependence on temperature. The value of n is found to be about 3/2. The exponential temperature dependence arises from the variations of the concentration and diffusion coefficient of the mobile species with temperature.

For lithium- or sodium-doped ZnO the negative charge carrying species would be electrons, while the positive charge carrying species would be the ionized interstitial dopant. It is noted that these would not necessarily be of equal concentration as set forth by the aforementioned space charge polarization models. Electroneutrality conditions of the type $[Zn^+_i] + [Li^+_i] = [Li_s^-] + n$, or $[Zn^+_i] + [Na^+_i] = [Na_s^-] + n$ would be expected for the materials investigated. Thus, electrons result from the ionization of interstitial zinc and impurity atoms. A portion of these would, however, be trapped by impurities occupying substitutional cation positions in the lattice.

If the gold contacts were reasonably ohmic, the electrons would be free to pass through the electrodes. Thus, electrons, which are highly mobile when compared to the ionized interstitial impurity, would contribute significantly to the conduction current. The inert and impervious gold electrodes would, however, block impurity ions from passing through them and lead to a space charge polarization.

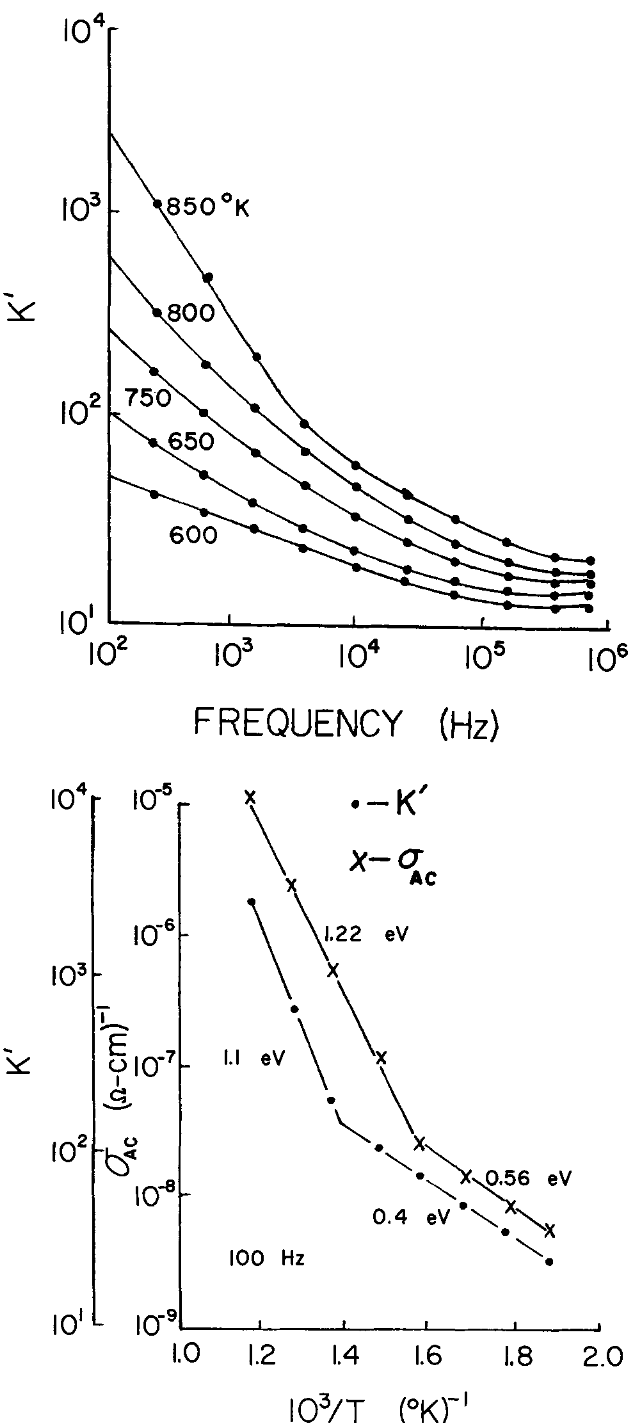

Fig. 5. (a, above left) K', and (b, above right) σ_{ac} vs. frequency; and (c, left) K' and σ_{ac} vs. $1/T$ for a polycrystalline specimen of ZnO, doped with 0.3 m/o Na, with Au electrodes at $P_{O_2} = 10^{-4}$ atm.

The effective dielectric constant data of Fig. 3-5 follow many of the qualitative predictions of the aforementioned two carrier space charge polarization models in the higher temperature region. The values of K' at constant temperature decrease as ω^{-n}, although the value of n is between 0.7 and 0.8 for the Li-doped material and about 1.0 for the Na-doped material, rather than being equal to 1.5 as predicted by existing models. The temperature dependence of K', at constant frequency, should be mainly related to the variation in the concentration and diffusion coefficient of the blocked species. In this study, the concentration of interstitial impurities was set by doping and, thus, concentration variations would not be expected to contribute to the temperature dependence of K'. Thus, the activation energy of approximately 0.6 eV from Fig. 3c and 4c, and 1.1 eV from Fig. 5, should essentially contain information regarding the energy of motion of the mobile ionic point defects. The higher value found for Na^+ as compared to Li^+ would seem reasonable in light of its larger ionic radius. Lander (8) has found that the energy of motion of substitutional Li^+ was of the order of 0.98 eV, but he states that the energy of motion would be less for the interstitial impurity. The fact that the doping levels 0.1 and 0.3 m/o Li^{+1} lead to essentially the same magnitude of K' and σ suggests that some of the Li^{+1} is going into substitutional positions at the higher doping level. The experiment, however, would still only be sensitive to the motions of interstitial Li^{+1}.

At lower temperatures, where there is a dispersion in σ, a barrier-layer mechanism might be responsible for the variations of K' with frequency and temperature. The above is further evidenced by the ln σ *vs.* $1/T$ plots, where for both impurity dopings, the activation energy for conduction is always about 1.2 eV at high temperature where space-charge processes are operative, but varies from sample to sample at lower temperatures where barrier-layer processes are suspected.

A more quantitative interpretation of the data must await the development of two carrier space charge polarization models where the concentration of oppositely charged species may differ. Macdonald is presently involved in setting up such a model which will be available at some future date (46). Added complications arise in the interpretation due to the porosity of the material resulting from its polycrystalline nature.

Conclusion

In summary it would seem that the single crystalline samples of ZnO led to barrier layer polarization, where the barrier layer was formed at the electrode-specimen interface. For the undoped polycrystalline samples, barrier-layer polarization was again observed. However, in this situation the barrier layer was found to occur at the surface of the individual grains and is thought to be the result of the surface chemisorption of oxygen. The influence of this barrier layer on the dielectric behavior became negligible with increasing temperature.

Upon doping polycrystalline samples with Li^+ or Na^+, space-charge polarization was thought to result due to the interstitial or grain-boundary motion of various point defects. These data were rationalized on the basis of a space-charge polarization model involving mobile ionic point defects, which were blocked or partially blocked at the electrodes, and electronic carriers, which were able to pass through the electrodes. The activation energies for the exponential temperature dependence of the effective dielectric constant were believed to be associated with the energy of motion of the interstitial impurities. An energy of about 0.6 eV was found for the Li-doped ZnO while that for the Na-doped material was about 1.1 eV. The relative magnitudes of the activation energies are consistent with the size differences of the Li^+ and Na^+ ions.

Technical Note

Crystallographic Assignment of the Domains in Single Crystals of Gadolinium Molybdate (GMO)

A. S. Bhalla[1]

Materials Research Laboratory, The Pennsylvania State University, University Park, Pennsylvania 16802

The structure of gadolinium molybdate (GMO), which exhibits strongly coupled ferroelectric and ferroelastic behavior (1, 2) has been studied in detail in recent papers (3, 4). In the ferroelectric phase below 159°C the point symmetry is 2 mm with the polar axis parallel to c. The existence of a polar axis in a structure may affect the etching behavior of the surfaces perpendicular to the polar direction (5, 6). Also one should assign these surfaces crystallographically in relation to the nature of the chemical attack. In the present paper the behavior of some chemical etchants is studied on the surfaces of the single domain crystals of GMO. Subsequently the surfaces were assigned crystallographically by the pyroelectric measurements and the x-ray studies.

Crystals were cut in the shape of a rectangular prism and with the edges parallel to the orthorhombic a, b, c axes. The faces were polished with 0.3μ alumina powder. The two c-faces (after removing the damaged layer by warm diluted NaOH) of this prism were coated with evaporated silver film (rectangular shape with edges parallel to [110]). Crystals were poled by applying d-c field along the c-axis. A number of etchants (Table I) were tried (after removing Ag-film) to study the etch-pit behavior of the two surfaces at room temperature. One surface showed the well-defined, point-bottomed pits whereas the other showed the

Table I. Chemical etchants, etching time and other features observed in the chemical etching of GMO

Etchant	Etching time	Remarks
A. HNO_3	40-60 sec	HNO_3 (reagent grade) and H_2O solution in 2:3 proportion. (001) face etched faster than (001). Pits were produced on {100} (Fig. 5), {010}, and {001} faces (Fig. 1a and 1b). Pits on (001) face were oriented by 90° about the c-axis from the pits on the $(00\bar{1})$ face, i.e., on $(00\bar{1})$ the longer edge was parallel to 'a' whereas on (001) it was parallel to 'b' direction. {010} and {100} did not show these features.
B. HCl	10-20 sec	25% water solution of reagent grade HCl. (5-30% solution produced the well-defined pits.) Other features were similar as in case A. $(00\bar{1})$ *showed the point-bottomed pits* (Fig. 3).
C. HF	5-10 sec	20% HF (48%) solution in water. $(00\bar{1})$ showed the conical pits (Fig. 2). No sharp features on (001) face.
D. H_2SO_4	4-7 min	Mixture of reagent grade H_2SO_4 and H_2O (1:3). Pits on {001} faces were elongated along the domain direction. $(00\bar{1})$ showed deep and sharp-bottomed pits (Fig. 4). The pits on the two opposite c-faces were rotated from each other by 90° about the c-axis.

Fig. 1 (a). Etch pits produced on the (001) face of the $Gd_2(MoO_4)_3$ by 40% HNO_3 (45 sec of etching time). This face developed the positive electrostatic charge on heating (×400).

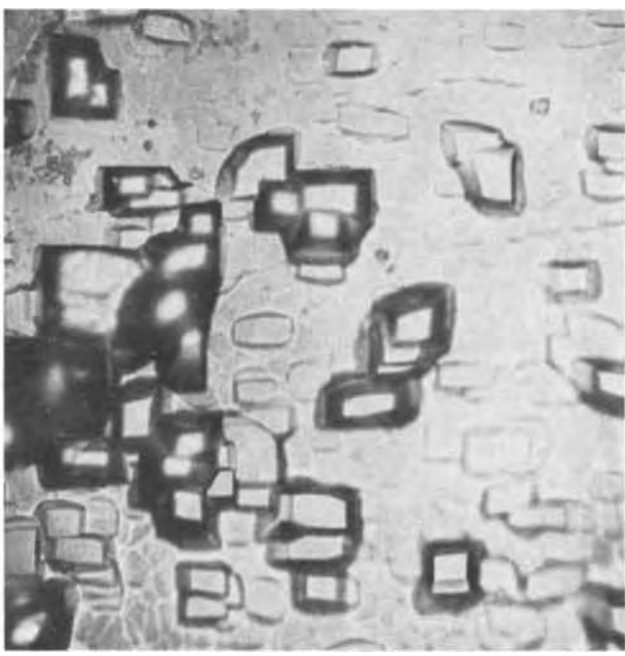

Fig. 1 (b). Etch pits produced on the (001) face of the same crystal. Pits are oriented by 90° from the pits in Fig. 1(a). This face developed the negative electrostatic charge on heating (×400).

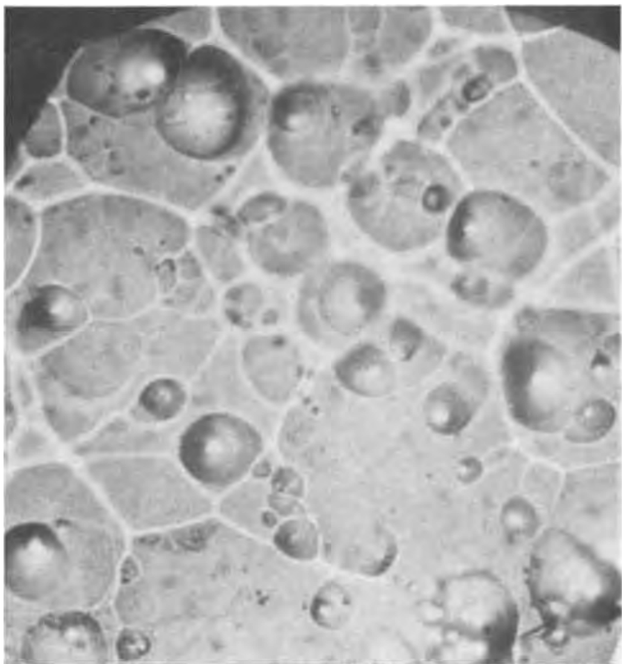

Fig. 2. Conical pits produced by $HF:H_2O$ (1:3) on $(00\bar{1})$ face; etching time 7 sec (×400).

Fig. 3. Pits produced on $(00\bar{1})$ c-face by 25% water solution of HCl, with 15 sec of etching time (×400).

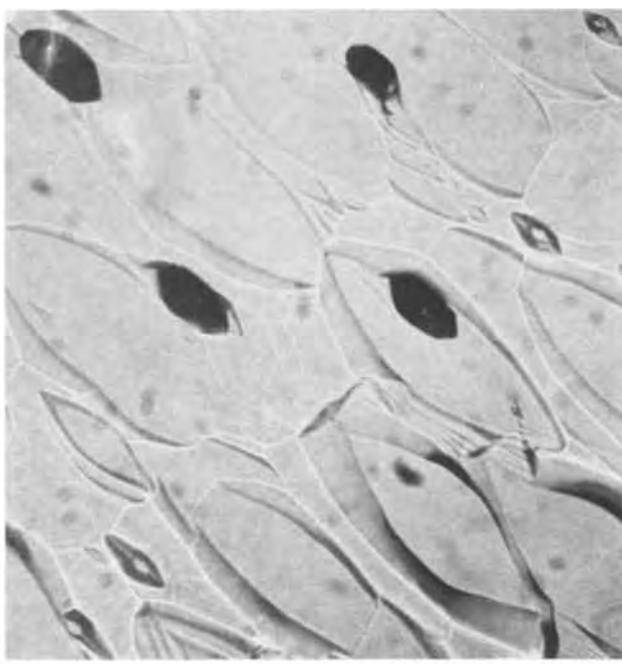

Fig. 4. Point-bottomed and deep pits produced along [110] direction on $(00\bar{1})$ face by mixture of H_2SO_4 and H_2O (1:3); etched for 5 min.

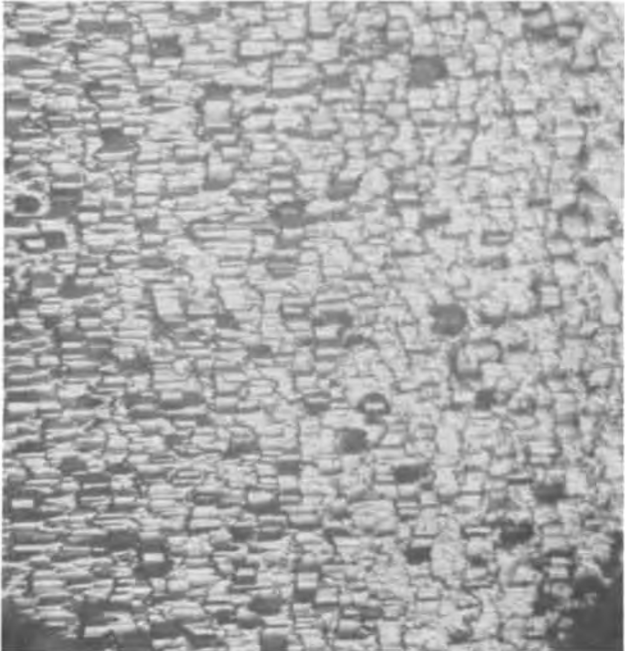

Fig. 5. Pits produced on a-face of the same crystal of Fig. 1 (×400).

flat-bottomed pits. Various dilutions of the etchants were tried for obtaining the well-defined features. The proper range of concentration, the etching time, and the other features are described in Table I.

In order to identify the (001) and (001) surfaces the pyroelectric measurements were made on the samples after chemical etching. The set up used for the study has been described earlier by Fable and Henisch (7). Two c-faces of the crystal were silver electroded, and the sample was heated through 100°C (much below the Curie temperature). The pyroelectric voltage was measured. It was noticed that the surface with the point-bottomed pits had developed the positive charge whereas the surface with the flat-bottomed pits the negative charge in all the cases. In GMO the sense of the pyroelectric axis is just opposite to the positive crystallographic axis (3). Thus the surface which etched slower, showed point-bottomed pits and developed positive charge on heating was assigned crystallographically, in the present studies, as $(00\bar{1})$ and the one which etched faster, showed flat-bottomed pits and developed the negative charge on heating as the (001).

Unfortunately, the exact nature of the dislocations in GMO is not known, so that the detailed mechanism of the chemical attack and etching is also questionable. The present studies do, however, reveal the importance of changing anions in the sequence of acids used and identify the positive and negative ends of the single domain crystals.

Brief Communication

High Sensitivity Detection of Solution Contaminants by MeV Ion Scattering

Ronald L. Meek*

Bell Laboratories, Murray Hill, New Jersey 07974

Rutherford ion backscattering (1-3) of MeV He ions has been established as a very sensitive technique for detecting surface impurities heavier than the atoms of the substrate. A typical sensitivity (3) for the intermediate to heavy mass surface atoms is 10^{12} atoms cm^{-2}. Suppose that one places 0.1 cm^3 of a solution on an otherwise clean substrate, allows it to spread to cover $\sim$1 cm^2 of the substrate and evaporate to dryness. Since one-tenth cm^3 of water contains about 10^{22} atoms, the detection of 10^{12} atoms cm^{-2} on the surface of the solid is equivalent to detecting impurities at levels of 1 part in 10^{10}, atomic. It is emphasized that the ion scattering technique both qualitatively identifies the species present, by the energy of the backscattered ions, and quantitatively determines their number, through the number of scattered ions. Thus standards or references of known impurity concentration are not needed. Usually the detection solid angle is not actually measured, but rather the sensitivity factor is determined through the scattering yield from the substrate, in this case silicon, of known atomic density, and of course the Rutherford cross section.

It has been shown elsewhere (3) that it is possible to obtain silicon surfaces free of surface impurities heavier than chlorine. Such clean silicon substrates have been used for the work reported here. Clearly, clean carbon substrates would allow for analysis of some interesting lower mass contaminants. In order to demonstrate this method, approximately 0.1 cm^3 of a number of reagents commonly used in semiconductor device processing were transferred directly from a previously unopened bottle onto the surface of a clean silicon wafer. The area of the wafer over which the solution spreads is about 1 cm^2. The volume was determined by comparing the droplet size to that of a droplet of a known volume of water transferred to the wafer with a micropipet. Clearly more exact procedures could be developed to determine the volume and area accurately, but here the primary concern has been to avoid contamination during the transferal. After the reagent had evaporated in a clean hood at room temperature, the surface was examined by ion scattering. The details of the scattering experiments have been described elsewhere (3). It is emphasized that the pile-up system used, combined with channeling, can reduce pile up counts to a point where only $\sim$10 counts are found in the $\sim$100 channels beyond the silicon edge after He ion fluence $\sim 10^{16}$ cm^{-2}. The energy or mass resolution, however, is limited. For example ^{39}K and ^{40}Ca are separated by 14 keV which is about the resolution of the detector so that they can be distinguished; Br and Se, on the other hand, are separated by only 4 keV so that they cannot be unambiguously identified by this technique.

Figure 1 is the spectrum (scattered ion yield as counts per channel *vs.* scattered ion energy) from a surface on which concentrated HCl had been placed. On the clean wafer only a few isolated counts are present at energies greater than that corresponding to ions scattered from surface Cl after the same incident ion fluence. On the clean surface chlorine was present at 10^{13} cm^{-2}; here we see it has increased to $4(10)^{13}$ cm^{-2}. Also Ca, Fe and Br or Se are present. Concentrations were determined by scanning across the wafer area on which the reagent had been placed. Typical variations of a factor of two were found and the area not contacted by liquid was found to remain free of contamination.

Key words: semiconductor processing, ion scattering, surface analysis.

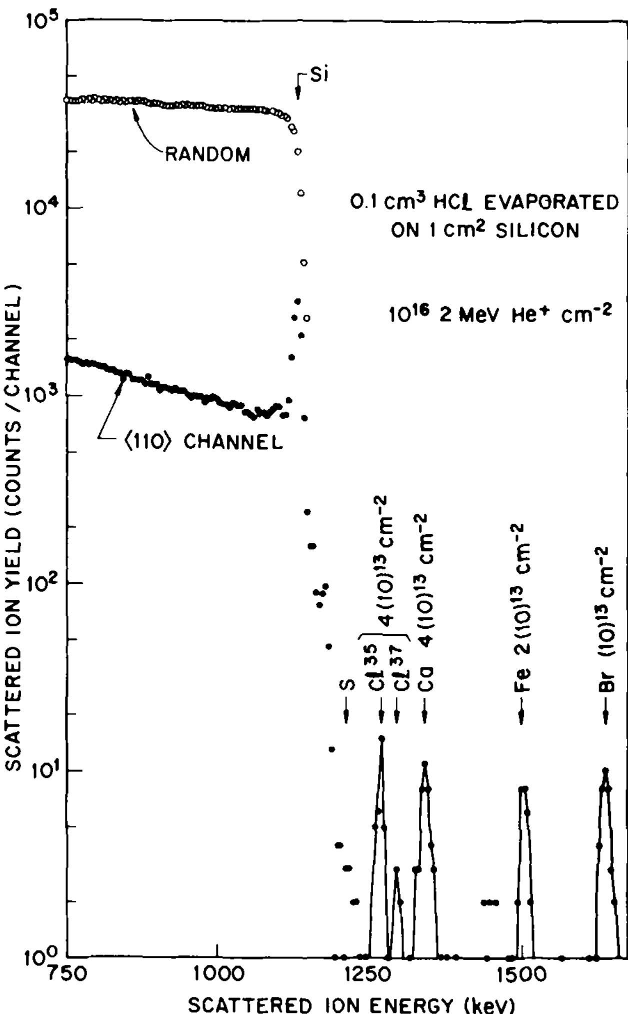

Fig. 1. Scattered ion spectrum from a Si surface on which HCl had been placed.

The surface contaminants found, converted to parts per billion (10^9) atomic in the original solution, for HCl and other reagents examined are tabulated in Table I. It is interesting to note that the HCl is contaminated with Fe (2 ppba) which perhaps explains the previous observation (3) that a HCl dip of a wafer previously showing no Fe gave 10^{12} cm^{-2} (10^{-3} monolayer) of Fe. Others (4-6) have shown that for transition metals in acid solutions $n \sim C$ where n is the adsorbed surface contamination in monolayers from a solution containing the species at concentration C in parts per million. Thus, parts per billion in solution should lead to $\sim 10^{-3}$ absorbed monolayers as observed in the previous work (3).

Table I. Principal contaminants in some semiconductor processing reagents

Reagents	Contaminant	Contaminant level (ppba)
HCl	Ca	4
	Fe	2
	Br or Se	1
HNO_3	Ca	30
	Ti	50
	Fe	5
	Zn	6
	I or Te	2
	Pt to Pb	1
HAc	Fe	20
	Cu	20
HF	None detected	—
NH_4OH	Ca	10
H_2O_2	Zn	10
	Sn or Sb	2
Methanol	None detected	—
Acetone	None detected	—
Trichloroethylene	Fe	2

Nitric acid proved to be the most contaminated reagent containing Ca, Ti, Fe, Zn, I, or Te and some member of the group Pt, Au, Hg, Tl, or Pb. The observation that HNO_3 is contaminated with a Pt-Pb species (1 ppba) is interesting in light of previous work (3) which showed that cleaning procedures using HNO_3 and HF appeared to introduce a surface impurity (10^{-3}-10^{-4} monolayer) in the Pt-Pb mass range. Acetic acid was found to contain 20 ppba of the fast diffusing (in silicon) transition metals Fe and Cu. Results for several other reagents are listed in Table I. No impurities were detected in the commonly used organic solvents methanol and acetone nor in HF, while a small amount of Fe was found in trichloroethylene.

Manuscript submitted June 1, 1973; revised manuscript received Sept. 14, 1973.

Computer-Controlled Battery Pulse Charging

John P. Elder*,[1]
ESB Incorporated, C. F. Norberg Technology Center, Yardley, Pennsylvania 19067

ABSTRACT

A Fortran language program system has been developed for computer-controlled, square wave, constant current battery pulse charging. It provides complete experimental control and rapid, accurate data acquisition for a set of test cells with or without *in situ* reference electrodes. It incorporates automatic charge termination and individual cell cut-out features, which may be brought into play for a variety of reasons. Multicell operational data is readily available for cell to cell comparison and interpretation. Examples of the use of the program for charging secondary alkaline battery systems are presented. Information regarding the charging behavior of the limiting mercury-silver substrate positive electrode in the secondary mercury-cadmium cell, not readily available when using conventional pulse charging techniques, has been obtained.

A variety of techniques have been employed to charge secondary cells, particularly for the several alkaline systems (1). Essentially, all attempt by various means to maximize the charge acceptance efficiency. Many applications also require that the charging time be minimized. In attempting to achieve these purposes, certain hazards may be encountered. Some may lead to a potentially physically dangerous situation for the battery user, while others only deleteriously affect the subsequent discharge characteristics of the cell, and the over-all cycle life of the system. For example, while certain battery systems are routinely overcharged, excessive overcharging can be potentially dangerous. Thus, the pressure build-up, observed when nickel-cadmium cells are overcharged (2), can increase rapidly when the cells are charged at a high rate. Furthermore, the oxygen recombination at the negative plate, which acts as an internal pressure relief valve, is dependent upon the state-of-charge of this electrode (3). Heat generation can also be a problem in this system when undergoing high rate charging (2). This is an even more appreciable problem in nickel-zinc batteries (4). If zinc electrodes are too highly polarized on charge, dendritic growth can result with subsequent catastrophic failure, due to internal short circuiting, in cells containing such electrodes.

Secondary mercury cells often incorporate a more noble metal, usually silver, in the mercuric oxide positive, acting as an immobilizing substrate for the discharged state of this electrode. Such electrodes can exhibit large polarization on charge. When charged at moderate to low rates, the electrode potential rises to a value indicative of silver oxidation well before all the available mercury has been oxidized. Catherino and Carson (5) indicate that, in order to achieve full charge acceptance in mercury-cadmium cells, it is necessary to charge well beyond the onset of silver substrate oxidation. If this is pursued on a continuing basis, it could prove detrimental to the system, leading to mechanical degradation of the positive plate and a concomitant deterioration in its charge acceptance efficiency and cycle life. It has been found possible to approach 100% charge acceptance efficiency of the mercury-silver electrode prior to the onset of silver oxidation by constant current charging at very low rates (6).

In recent years, a limited number of workers have investigated the use of pulse charging techniques to improve charging efficiency. Boyd (7) has recently indicated that the cycle life of nickel-cadmium batteries is increased when they are pulse charged. Wales (8) has found that an a-c pulse superimposed on d-c charging markedly enhances the positive electrode charge acceptance efficiency in silver-zinc cells. Toni (9) has indicated that the response of a mercury electrode to a current pulse is dependent upon its state-of-charge, and has reported briefly on the possible efficacy of square wave, galvanostatic pulse charging in cell systems using this electrode. Recent work in this laboratory on mercury-cadmium cells has shown that charging times may be significantly reduced, without any large detrimental effect on charge acceptance efficiency by using a millisecond regime, square wave, constant current pulse technique (10).

Kordesch has long espoused the viewpoint that one should terminate charging any cell when the equilibrium voltage or potential of the limiting electrode, with respect to a suitable reference, attains a prescribed value. He and his co-workers have successfully accomplished this end by using both square (11a) and sine (11b) wave pulse techniques incorporating the interrupter concept, whereby the *IR*-free cell voltage or electrode potential may be monitored oscilloscopically during the interruption period.

If multicell pulse charge testing of secondary cells is envisaged, one is limited, when using conventional laboratory instrumentation, in the amount of pertinent data which can be recorded. This is particularly so when rapid perturbations in the millisecond range are employed, and if reference electrodes are incorporated into the cells. Zinder (12) has discussed circuitry which allows the monitoring of the cell response during the off-current phase in a 60 Hz sine wave charger used for the sealed nickel-cadmium system. If one is interested in following variations in both the

Key words: computer-controlled experiments, pulse charging, charge acceptance, Ni-Cd cell, Hg-Cd cell.

cell internal resistance, and the open-circuit voltage at the end of the off-current phase, one should attempt to monitor responses as close as possible to the interruption points (13, 14). When the monitored parameter attains a prescribed value, it should be used to activate the appropriate cell cut-out relay. In the absence of a specific device to effect these purposes, oscilloscopic monitoring of the total response of the system to the perturbation serves as a valuable guide. However, the test requires constant attention and is very tedious. Furthermore, the separation of the average voltage data for a group of cells over the entire charging period, monitored on a multipoint recorder, is a time-consuming task.

The disadvantages and limitations of the conventional method may be obviated by using an on-line digital computer. When used in conjunction with a programmable galvanostat, high speed D/A and A/D converters, and the requisite relays, a completely automatic, real-time, experimental control and data acquisition system is possible. Frazer (15) has indicated that it is preferable to employ machine language programming for real-time control and data acquisition in closed loop experiments. A number of computer-controlled electrochemical studies, primarily in the analytical field, have utilized this form of programming throughout (16-19). However, there is no *a priori* reason why a higher level language should not be used, and in many instances it may prove the easier route.

A program system has been developed which fulfils all the requirements for rapid pulse charging of secondary batteries, and the necessary data acquisition. With the exception of five assembly language coded subroutines, which control the operation of the D/A and A/D converters and the cell relays, and the recording of data on magnetic tape, the entire system has been written in Fortran IV. The operation of the program system is discussed in outline, with further details in the Appendix,[2] and some examples of its use with nickel-cadmium and mercury-cadmium cells are presented.

System Hardware

An E.A.I. 640 computer (Electronics Associates, Incorporated, West Long Branch, New Jersey, 07764) was used in developing and running this program. It is a 16 bit machine with a 1.65 μsec memory access cycle time and 16K words of core memory. The SRC Astroverter 3900, rated at 100 kHz, was used for both D/A and A/D converters (Moxon Incorporated, SRC Division, Newport Beach, California). They utilize an eleven plus sign bit pattern, and have a maximum voltage capability of $\pm$10.024V. A binary number bit pattern is transferred from the central processing unit to the D/A converter, and converted into a voltage level, which is held continuously until another bit pattern is transferred. Transfer and conversion is complete within less than 5 μsec. The output of the D/A converter is connected to the programmable galvanostat. The A/D converter together with a number of preamplifiers and a multiplexer comprises the analog measuring system, with a total input impedance of 10 megohm. The A/D converter samples an incoming voltage signal and holds till conversion is complete. The sample and hold "window" is open for less than 1 μsec, but the total sampling and conversion time is 10 μsec.

The programmable galvanostat employed was the LCT 16-365.[3] This module is powered by a 36V regulated power supply. Up to sixteen cells may be connected in series to this unit. Each cell connection is paralleled with a bypass relay, which may be actuated manually or remotely by computer command. The relay switching time is 40 msec. The input impedance of the galvanostat is 167 kohm, and the operational loop rise time, no load to full load, is less than 10 μsec. This module produces a constant current output, range 15 mA to 5A, proportional to the voltage level output of the D/A converter. The test cells, located in the laboratory, were connected to both the galvanostat and the analog measuring system with shielded, twisted pair cabling. No effects, due to cable reactance, were observed. Continual noise problems were not encountered while acquiring data. Occasionally, when the output level of the D/A converter changed, a spike voltage passed through the narrow window in the A/D converter. The program recognizes the spurious voltage and takes appropriate action.

Time was continually monitored with an EECO 915A digital clock (Electronics Engineering Company of California, Santa Ana, California). It incorporates a 1 MHz crystal-controlled oscillator timing system, with a 3×10^{-8} sec/day stability. Four output pulses, of frequency 1 kHz, 100, 10, and 1 Hz, were continually counted in four memory locations in the central processing unit. These "internal clocks" were used for pulse and time synchronization during program operation. Each could be independently reset to zero at any time by the appropriate software command.

All pertinent cell information and data was recorded on magnetic tape in such a manner (see below) that the amount and rate of data acquisition was independent of the speed of the tape unit.

Main Program

The main, on-line, real-time program controls the square wave, galvanostatic pulse charging of secondary battery systems. It provides an accurate and precise control of the pulse regime, irrespective of whether data is being acquired, modified, compared with previously acquired data, or being recorded on tape. This control is maintained even when a cell cut-out relay is being actuated and its status checked. At prescribed charge input level increments, the cell voltage is monitored at certain time intervals within the pulse period and, if desired, recorded permanently. When reference electrodes are incorporated in the cells, the positive electrode potential is also monitored. All cells remaining on charge are monitored in sequence. Negative electrode potential data are computed by difference.

Charge termination may be effected if: (*i*) The cell voltage or either electrode potential at the end of the off-current phase of the pulse regime attains or exceeds a predefined limit. (*ii*) There is a continual significant increase in either the internal resistance or the polarization exclusive of the resistive contribution; or in the contribution of either electrode system to the total parameter. It has been arbitrarily stipulated that if ten consecutive significant increases are observed in any of these parameters, then this is sufficient cause to initiate the cell cut-out command. A build-up in the internal resistance within a cell could prove detrimental to its continuing operation. An increase in polarization could indicate a possibly malfunctioning electrode. (*iii*) The charge input level attains a prescribed limiting value.

When charge termination for any cell is requested for reasons (*i*) or (*ii*), the appropriate relay is deactivated, causing current flow to bypass the cell. When all cells have been cut out, or the charge input level limit is attained, an end-of-file mark is recorded on the magnetic tape, the D/A converter output level set to zero, and the program stops.

In Fig. 1. is shown a simplified flow diagram of the program system which, due to the functions it performs, is nonsequential. A detailed outline of the operation of the program is given in the Appendix. During the running of the experiment, the charge input level, Q, in mA-hr, is continually incremented by an amount Q_{inc} per pulse period, where $Q_{inc} = PA \times PL/3.6$ mA-hr. PA and PL are the pulse amplitude (amperes) and length (seconds), respectively. Data is acquired at predefined mA-hr increments of the charge input level. Two types of data are monitored at speci-

[2] Detailed flow diagrams and program listings are available to interested parties.
[3] ESB Incorporated, Technology Center Bulletin 70-81-02.

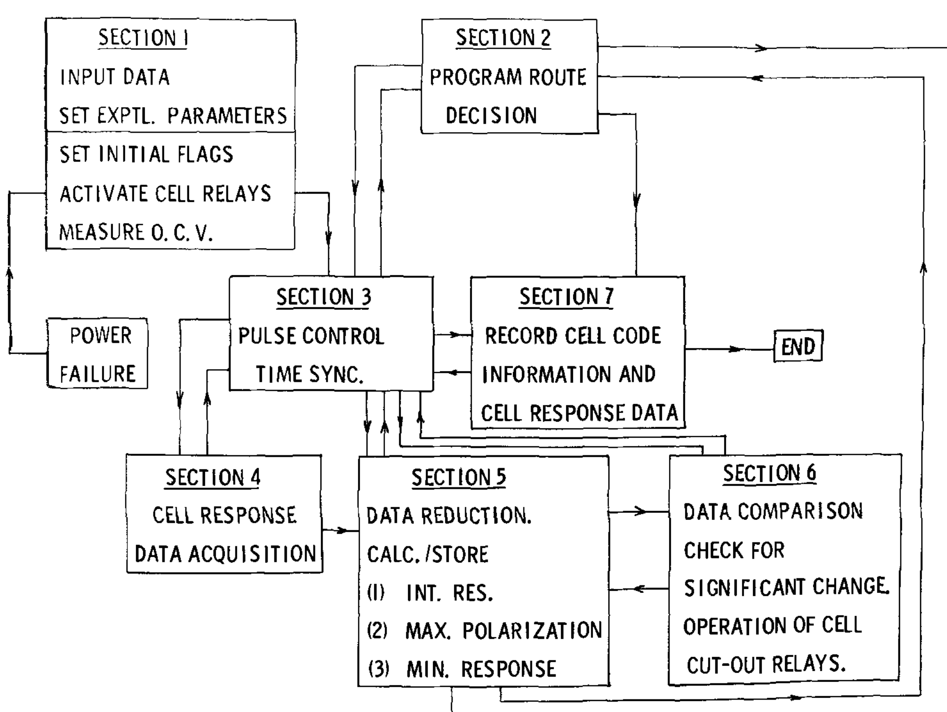

Fig. 1. Simplified flow diagram, main program.

fied intervals throughout the pulse regime, the so-called "complete response" and "partial response" data.

Maximum and minimum levels.—It is impossible to maintain correct pulse regime time synchronization during the data acquisition sequences if one attempts to monitor the actual maximum and minimum data points immediately prior to turning the pulse off and on, respectively. The pulse regime is so chosen that the cell voltage and electrode potential values 1 msec prior to turning the pulse off and on show a minimal deviation from the actual maximum and minimum values, as viewed oscilloscopically. Data taken at these time intervals are considered the maximum and minimum values, and are used as such in all decision making.

Time profile.—This term refers to the time intervals, in multiples of 1 msec, during the entire pulse regime, at which cell voltage and positive electrode potential data are to be monitored.

Complete response.—A request for a "complete response" indicates that data is to be monitored at every interval specified in the time profile. When such a request is made, the data are always recorded permanently.

Partial response.—This term indicates that data is to be monitored only at the maximum and minimum levels, as defined above. When "partial response" data is requested, it is recorded permanently, only if a significant change from the previous sequence, whether "complete or partial," is observed.

The charge input levels, at which the two types of "response" are to be monitored, are computed in section 2 of the Appendix from initial and incremental values given as test parameter information. "Complete response" data is usually requested at certain large increments in the charge input level, *e.g.*, at levels corresponding to 10% increments of the theoretical capacity of the cell. At much closer intervals, *e.g.*, corresponding to 1% increments, "partial response" data is requested.

Information and data storage.—Throughout the running of the program, information relating to the condition of each cell is stored in coded form in the NCODE array, the structure of which is shown in Table I. When cell data are to be recorded permanently, it is always preceded by an up-to-date record of this array. The secondary program (see below) utilizes this information in separating and decoding the succeeding block of data. Three sets of data are stored in the IDATA array in the following order: (*i*) Cell voltage or positive electrode potential or calculated negative electrode potential data for each interval requested in the time profile. (*ii*) The "*IR* drop" data or contribution from each electrode-separator interface. (*iii*) The characteristic and mantissa of the charge input level at which data was monitored for the particular cell.

For each cell, $N + 3$ locations in the IDATA array are required. For "complete response," N is given by the number of intervals in the time profile. For "partial response," $N = 2$. If the cells incorporate reference electrodes, three blocks of the appropriate size are required to accommodate all the data, *i.e.*, the monitored cell voltage and positive electrode potential, and the calculated negative electrode potential data. All pertinent data for each cell remaining on charge in sequence is thereby packed into one contiguous block of the IDATA array.

Data processing time.—A measure of the total time required to process the numerous program instructions

Table I. Cell condition code—NCODE(M)

M	Information	Value
1	Data record number	Variable
2	"Complete response" data monitored	1
2	"Partial Response" data monitored	2
2	Final information	0
3	Number of cells remaining on charge	Variable
4	"Partial response" data not recorded permanently	1
4	"Partial response" data recorded permanently	2
4	Charge input level limit attained—end program	3
4	Individual cell cut-out	4
4	All cells cut-out—end program	5
I	Cell number [I = 3 × (Cell No. − 1) + 5]	1-16
I + 1	Significant increase in minimum cell voltage	1
I + 1	Significant increase in minimum positive electrode potential	4
I + 1	Significant increase in minimum negative electrode potential	7
I + 1	Significant increase in internal resistance	
	Total cell	2
	Positive electrode contribution	5
	Negative electrode contribution	8

	Total cell	3
	Positive electrode	6
	Negative electrode	9
I + 2	Cell NCODE(4) value	Variable

in sections 2-6 of the Appendix may be obtained by monitoring the difference in the charge input levels at which the data acquisition sequence is initiated for the first and last cells in a series. By monitoring this value throughout the entire experiment, an average value per cell may be calculated. For example, a number of cells without incorporated reference electrodes were subjected to a 240 mA amplitude pulse of length 5 msec and period 15 msec. "Complete response" data was taken at 1 msec intervals throughout the pulse regime. The average value for the charge input level difference per cell was 1.6 μA-hr. At this current level, this difference corresponds to a time of 72 msec, *i.e.*, approximately 5 pulse periods. For pulse regimes of this order of magnitude, for sixteen cells without reference electrodes, the total data acquisition, processing, and recording time was between 1 and 2 sec. When reference electrodes are incorporated into the cells, this time is approximately doubled. For the particular pulse regime referred to above, 1 mA-hr of charge is injected into each cell in 45 sec. Thus, one can acquire data for each cell in a series at the desired charge input levels with reasonable precision, and thus compare cell to cell and cycle to cycle behavior.

Experimental procedure.—The cells to be tested are connected in series to the galvanostat. Following section 1 initiation, the starting time of day is noted and pulse charging initiated. Immediately, *i.e.*, at zero charge input level a "complete response" data acquisition sequence is initiated. The program flow then continues as outlined in the Appendix until termination is indicated. Throughout the running of the program, the length of tape used to record permanent information and data is noted. At the conclusion of the test, the time of day is again monitored, and the total experiment run time calculated. For convenience, since most of the tests were scheduled for overnight running, these two pieces of information together with a record of the final open-circuit cell voltages, and positive electrode potentials, if available, were typed out on the teletype. The cells are now disconnected from the galvanostat. They are then discharged at constant current with conventional laboratory instrumentation, in order to measure the charge acceptance efficiency, and in preparation for the next pulse charging cycle.

Secondary Program

This program is run off-line at the conclusion of the pulse charging experiment, using the main program tape output as input information. The program is much shorter and more simple than the main program, and will not be discussed in any detail. The fixed length NCODE record is first scanned and decoded. The resulting information describes the type, "complete or partial response," and the amount of data, and to which cells they pertain, in the ensuing IDATA record. The requisite calculations are performed and the output, in suitable tabulated format, is printed on the line printer. This procedure is repeated until the final information record is recognized. A copy of some typical records, in the original output format, are shown in Table IV.

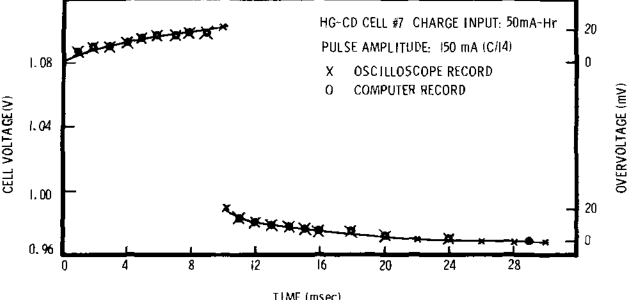

Fig. 2. Comparison of computer and oscilloscopic record of mercury-cadmium cell voltage response to pulse charging.

For the most part it should be self-explanatory. Records 13 and 108 refer to "partial response" data, and indicate that although the data was recorded because of an observed significant change in the positive and negative electrode potentials, respectively, (see Table I) the cells still remain IN circuit.

Results

General program operation.—During the development of the main program, the accuracy of the pulse regime time synchronization and rapid data acquisition was tested in the following manner. A waveform generator (Microdot, Incorporated, Model F23OB) was connected to the input of the analog measuring system. A 10 msec period, 0-2V triangular voltage function was triggered by the change in level of the D/A converter. The resulting voltage was monitored at 1 msec intervals and compared with the correct waveform values. With the successful development of the time synchronization, agreement to within less than 1 mV was obtained on continued cycling. In Fig. 2 is shown a comparison of the oscilloscopic and computer record of the cell voltage of a 600 mA-hr mercury-cadmium button cell responding to a 150 mA pulse of 30 msec period and 10 msec length at room temperature. As can be seen, the agreement is excellent.

Application to a nickel-cadmium multicell system.—As part of a general pacemaker battery study operative at the Technology Center, six Varta 225 DKH nickel-cadmium button cells were pulse charged at 37°C at the nominal 5 hr rate, *viz.*, 144 mA amplitude, 30 msec period, and 10 msec length. Since these cells do not contain reference electrodes, it was arbitrarily decided to effect cell cut-out when the off-current phase minimum cell voltage attained the value 1.500V. In Fig. 3A and 3B are shown cell No. 6 voltages at 1 msec intervals at charge input levels of 20 and 220 mA-hr, respectively. These curves are typical of the entire set. As charging proceeds, the character of the curves changes gradually from that shown in A to that in B. The pertinent parameters, indicative of the over-all behavior of these cells, are summarized in Table II. Generally, the maximum polarization and the internal resistance remain fairly constant during charging, tending to increase when the cells attain the fully charged state.

(C, D) Hg-Cd cell, room temperature, 0.480A, 15 msec period, 5 msec length. (C) 70% Hg-30% Ag electrode potential response. (D) Cd electrode potential response, curve 1, 0.1 A-hr; curve 2, 0.88 A-hr.

Operational behavior of the mercury-cadmium cell.—Previous experimental investigations in this laboratory (6) indicated that efficient d-c charging of two-electrode mercury-cadmium button cells can only be attained at very low rates, in excess of the 100 hr rate, if oxidation of the positive electrode silver substrate is to be avoided. It has also been shown that a 70% mercury-30% silver pressed powder positive may be pulse charged with high-charge acceptance efficiency at effectively the 15 hr rate or less without excessive silver oxidation (10). An optimization study indicated that, for this particular cell system and geometry, the preferred regime was a pulse of length in the range 5-10 msec, with an on/off ratio of at least 1:2.

In order to study the charging behavior of this cell system more completely, a cell containing an *in situ* reference electrode was employed. It consisted of a 70% mercury-30% silver pressed powder, rectangular positive plate, 1.5 in. × 1.4 in. × 0.037 in., placed between two pressed powder cadmium negative plates, 1.5 in. × 1.4 in. × 0.047 in. A smaller positive plate, acting as a mercury-mercuric oxide reference electrode, was positioned orthogonally to the sandwich. Both positive plates were wrapped in untreated Permion 2291, an irradiated, cross-linked polyethylene with an acrylic graft (R.A.I. Research Corporation) acting as a barrier. They were then contained in a sleeve of nonwoven polypropylene, FT 2140 (Pellon Corporation), acting as an electrolyte absorber. The electrodes were placed in a rectangular Lucite container, and filled with 31% potassium hydroxide. The cell, of 1 A-hr nominal capacity, was positive limited on both charge and discharge. All tests were performed at room temperature. Following the initial discharge of the as-formed charged cell, and prior to performing pulse charge-d-c discharge cycling, the positive electrode was conditioned. The negative electrode behaved normally throughout. Conditioning involved a sequence of short charge-overdischarge cycles, and was completed when, on charging, the positive electrode potential initially did not rise above *ca.* 0.035V, *i.e.*, for this system the cell voltage did not rise above 1.0V. It should be noted that for this type of cell, up to ten conditioning cycles may be required before normal cell operation ensues.

The cell was subjected to a series of high rate, 33.3% duty cycle pulse charge tests, *viz.*, 0.48A amplitude, 15 msec period, and 5 msec length. Charge termination was to be implemented if the minimum potential of the electrodes with respect to the reference at the end of the off-current phase attained or exceeded the values, indicative of the onset of silver oxidation at the positive and hydrogen evolution at the negative, *viz.*, 0.244V (20) and −1.100V, respectively. "Complete and partial response" data was monitored at charge input level increments of 20 and 2 mA-hr, respectively. "Partial response" data was recorded permanently if any of the following conditions were met:

1. The minimum potential at the end of the off-current phase of the positive and negative electrodes changed by 5 and 10 mV, respectively, from any immediately prior value.
2. The maximum polarization, exclusive of the resistive contribution, increased by 5 mV over the previously monitored value.
3. The contribution of either working electrode-electrolyte interface to the internal resistance changed by 25 milliohms or greater.

Initially, the charging curve of the cell and the positive electrode exhibited two distinct regions, as indicated by Catherino and Carson (5). On continued cycling the following effects were observed:

1. The initial, low plateau, positive electrode rest potential and cell voltage (minimum at the end of the off-current phase) tended to decrease, ultimately leveling at the values 0.035 and 0.955V, respectively.
2. The charge acceptance in this first plateau region increased, finally attaining a steady value of 43% of the total charge accepted, as shown in Table III.

Table III. Charge acceptance behavior of the mercury-cadmium cell

	Charge input level (A-hr)

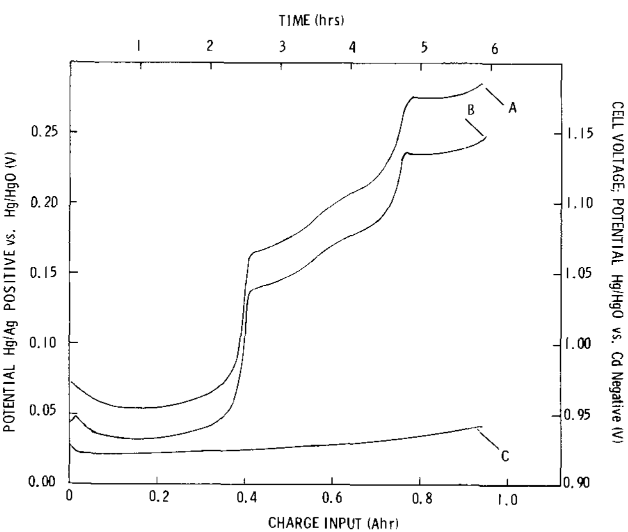

Fig. 4. Mercury-cadmium cell, off-current phase minimum response vs. charge input, room temperature, 0.48A, 15 msec period, 5 msec length. Curve A, cell voltage; curve B, positive electrode potential; curve C, negative electrode potential.

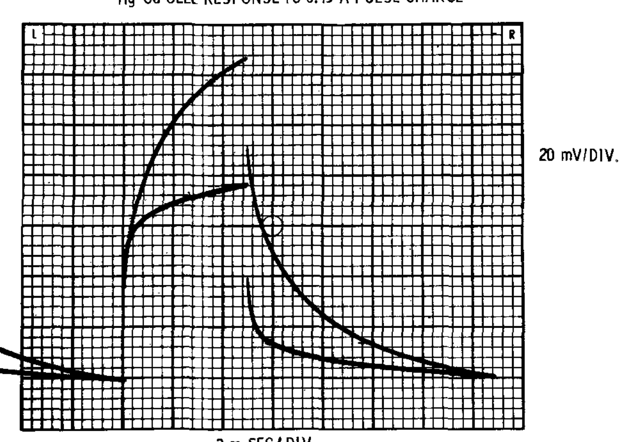

Fig. 5. Comparison of response of a mercury-cadmium cell to pulse prior to and after the onset of silver oxidation. Room temperature, 0.15A, 15 msec period, 5 msec length.

3. The positive electrode potential and cell voltage in the second region commenced to develop a more definite four-step character.
4. Total charge acceptance increased, finally leveling at a value of 0.94 A-hr.

The sequence of cycling tests was terminated after cycle 22. The fully developed minimum data values at the end of the off-current phase for cycle 21 are shown in Fig. 4. There is every reason to believe that this system can exhibit an extensive cycle life. The constancy of the charging data over the final six cycles (see Table III) confirms that it is possible to develop a well-behaved, nondeteriorating mercury-cadmium cell capable of being fully charged without the possible debilitating effect of silver substrate oxidation in the positive electrode. Furthermore, Permion 2291 is seen to be an effective barrier to the transport of mercury to the cadmium cathode during charging, a known cause of capacity losses in this cell system (21). The "complete response" potentials of the mercury-silver positive at a charge input level of 100 mA-hr are shown in Fig. 3C. The character of this curve remained the same throughout the entire charging period. The indicated minimal polarization is not in agreement with the findings of Toni (9). In Fig. 5 is shown an oscilloscopic record of the "complete response" voltage of the mercury-cadmium cell prior to and after the onset of silver substrate oxidation. The curve slowly changes in character from the lower to the upper trace as the off-current phase minimum potential of the positive commences to rise from the fourth plateau at 0.235V (see Fig. 4). In Fig. 3D are shown the "complete response" potential data for the cadmium negative at charge input levels of 100 and 880 mA-hr, curves 1 and 2, respectively. Small polarization effects are in evidence, the magnitude diminishing with increase in charge input. Some examples of the computer output of the secondary program are shown in Table IV. As can be seen, the resistive drop through the cell is equally divided between the positive and negative electrodes, remaining essentially constant at 256 $\pm$ 6 milliohms throughout the entire experiment. The "partial response" data shown indicating that the cell is still in circuit, was recorded permanently because a significant change in the positive and negative electrode potentials respectively at the end of the off-current phase was observed.

Although further extensive work is necessary to characterize the behavior of the mercury-silver electrode unequivocally, a tentative explanation is proposed for the characteristic curve B in Fig. 4. From a consideration of the phase diagram reported for the mercury-silver system (22), in agreement with Catherino and Carson (5), it appears that the low potential, initial plateau is characteristic of the oxidation of a solid solution of mercury in silver. The fourth, well-defined wave at 0.235V appear to be indicative of the oxidation of mercury from the silver-rich α-phase. Regarding the two shallow, but distinct waves in the 0.163-0.235V potential region, it is hypothesized that these characterize the oxidation of small quantities of mercury present in the $\beta(\epsilon)$ and γ intermediate phases, which may develop on continued cycling.

Summary

Computer-controlled, square wave, galvanostatic battery pulse charging is a successful, viable technique, which affords many advantages over the conventional method, with its limitations, especially when multicell studies are required. It affords an accurate means of monitoring the response of the cell or individual electrodes to the perturbing signal, and separating the contributions due to polarization, the resistive drop and the equilibrium voltage or potentials. Charge termination may be effected for any individual cell in a multicell stack, for a variety of reasons, an extremely difficult task with the conventional method. Multicell data is readily available for cell to cell, and cycle to cycle comparison and interpretation. The application of the technique to the study of the operational behavior of the mercury-cadmium cell has proved very successful, resulting in information not readily available when using conventional charging techniques. Information gleaned in this manner can be of great utility in formulating optimum charging conditions, and as a guideline for designing simple, field operated pulse charging equipment.

sign adhered to the following rules: (*i*) Wherever possible, integer arithmetic was used throughout. (*ii*) All cell condition information, in coded format, and voltage data were stored in integer form in linear arrays. (*iii*) Wherever possible, logical variables and logical decision making were used (*i.e.*, the logical "if" was preferred over the arithmetic "if"). (*iv*) All nonsequential routing through the various sections was under the control of the "assigned go to" rather than the slower operating "computed go to" statement.

Section 1.—This section deals with program initiation and is separated into five subdivisions.

(*i*) Reading of necessary input information, which falls into four categories.

A. General experimental information according to the requirements of the investigator, *e.g.*, cell description, charging cycle number, environmental test conditions, number of cells on test, presence or absence of reference electrodes in test cells.
B. Specific test information, *i.e.*, pulse amplitude, period and length; charge input limit, if required; off-current phase cell voltage or electrode potential cut-out limits; magnitude of the increase which will be considered significant in: (a) cell voltage or electrode potentials at the end of the off-current phase of the pulse regime. (b) internal resistance. (c) polarization less resistive contribution.
C. Time profile information.
D. The increments in the charge input level at which "complete response" and "partial response" data are to be monitored.

(*ii*) Setting the values of a number of permanent program parameters.

(*iii*) Initialization of a number of program counters, the NCODE array, and a number of "significant increase" counting arrays used in section 6.

(*iv*) Assignment of the initial values of program route flags used in sections 2 and 3.

(*v*) Activation and status checking of the cell relays, monitoring of the initial open-circuit cell voltages and positive electrode potentials as a final check on all hardware connections.

Section 2.—In the program routing section, the decision is made as to the next charge input level at which a data acquisition sequence is to be initiated, and whether "complete or partial response" data is to be monitored. In order to effect this decision, three charge input level counters are employed. Two of the counters, *QC* pertaining to "complete response" and *QP*, pertaining to "partial response," whose initial values are set in section 1, are increased by the increments given as input information. The third counter, *QI*, initially set equal to −1, is continually incremented by 1 mA-hr, and compared with both *QC* and *QP* until an equality is observed. The equality indicates the type of response, and the value of *QI* sets the charge input level at which the next data acquisition sequence will be initiated. (If $QI = QC = QP$, "complete response" data will be monitored.) The appropriate routing flags for the necessary program flow through sections 4-6 are set. The specific locations in the IDATA array are selected. The number indicative of the type of response is placed in NCODE(2) (see Table I), and the entry point into the data acquisition section 4 is assigned.

The experimental charge input level, *Q*, is continually compared with *QI*, with frequent interruptive excursions to and return from section 3 for the necessary pulse control. When equality is observed, the characteristic and mantissa of *Q* are inserted into the assigned locations in the IDATA array, and the selected data acquisition sequence for those cells remaining on charge will commence after the initiation of the next pulse regime.

Section 3.—This section is concerned with pulse control, which is effected by means of the following time synchronization sequence. The location in core memory, which is continually counting the 1 kHz output pulses from the digital clock, is used as a millisecond clock. This count is continually compared with the pulse on and off times, calculated in section 1 from the desired pulse period and length. Approximately 1 msec prior to the time at which the pulse is to be turned on or off the count is set equal to zero. When this count is incremented by unity by an incoming pulse from the digital clock, the count is again set equal to zero and immediately the command to change the output level of the D/A converter is given. In approximately 10 μsec the output of the galvanostat

changes. The parameters for the next D/A converter output are set. Once per pulse regime, the charge input level is incremented. The program then proceeds to the assigned entry point in the appropriate section. Each of these sections is so designed that there is a continual return to section 3 in order to check on the necessity to resynchronize the millisecond clock and process the next pulse on or off command. In this manner, it is possible to maintain sharply defined, constant current pulse charging.

Section 4.—In this the data acquisition section, the millisecond clock time is continually compared with the selected data acquisition times according to the type of response requested. The A/D converter monitors the data as an integer number of millivolts at the appropriate intervals throughout the pulse regime, and stores them in the specific locations in the IDATA array. Following the acquisition of the maximum and minimum data points, 1 msec prior to the pulse on and off times, the program returns to section 3 for pulse control. If the cells contain reference electrodes, a second pass through this section is required to monitor the positive electrode potential data. Following the acquisition of data, whether complete or partial, the "*IR*-drop" in the cell or the contribution from the positive plate-separator interface, is monitored in the following manner. One millisecond after acquiring the minimum voltage level data point in the off-current phase of the pulse regime, the pulse is turned on. Immediately, the cell voltage or electrode potential level is monitored. The difference between this value and the just acquired minimum value is later used as a measure of the "*IR*-drop." Theoretically, the "*IR*-drop" should be monitored as soon as the perturbation is applied. Practically, there is a finite interval, whose value is governed by the operational speed of the A/D converter, and the time required for the requisite program instructions to be processed. In this system the interval is about 80 μsec. Although by no means correct, it does give a meaure of the "*IR*-drop" as exact as that obtained oscilloscopically.

Section 5.—The purpose of this section is (*i*) to calculate and store in the appropriate locations in the IDATA array the negative electrode potential data, if required; (*ii*) to calculate the internal resistance and maximum polarization less the resistive contribution, which, together with the minimum data point, are stored in comparison arrays for later use in section 6. When "complete response" data has been acquired, the program returns to that part of section 2 where the IDATA array locations are selected. The updated value of the experimental charge input level is stored and the entire program flow through sections 3, 4, and 5 is repeated for the next cell in the series. This continues until all the cells remaining on charge have been scanned. The program now enters section 7. When "partial response" data has been acquired, the program first enters section 6 prior to returning to section 2.

Section 6.—In this section, which is only employed when "partial response" data has been requested, the parameters calculated in section 5 and stored in the comparison arrays are compared with those measured in the previous data acquisition sequence. If significant differences are encountered in any one of the three parameters listed in section 1, [see (*i*)-B-(a), (b), or (c)], then the data just acquired will be permanently recorded. The reason is noted in the NCODE array by assigning the appropriate code number (see Table I). For each cell, a count is made for each parameter of the number of times it has shown a consecutive significant increase. If any of the counts attain the value 10 or if the minimum cell voltage or either electrode potential has attained or exceeded the prescribed limit, the cell is cut out of the galvanostat by actuating the appropriate relay. The status of the relay position is checked before continuing. The number of cells remaining on charge is decremented by unity. These facts are noted in the appropriate locations in the NCODE array. The program now returns to section 2 and proceeds as described in section 5 above.

Section 7.—This section is concerned with the permanent recording of information and data on magnetic tape. This is performed by means of a special core dump routine, which requires that the size of the block of contiguous data to be transferred be specified exactly. Although the size of the NCODE array is fixed, that of the IDATA array varies according to the number of cells remaining on charge, whether electrode potential as well as cell voltage data has been acquired, and whether "complete or partial response" data has been monitored. Furthermore, the speed of the tape unit is limited. Thus, the total data transfer time can be relatively long in comparison with the period and length of the pulse regimes which may be used. The data transfer subroutine incorporates a controllable interrupt and operates in the following manner. Upon being called, data transfer commences. When an excursion to section 3 for pulse control is necessitated, the transfer is interrupted. It continues at the point it left off when the program returns from section 3. This process of interrupted data transfer continues until the specified block of data has been dumped from core. The NCODE array is first recorded followed by the IDATA array. When experiment termination is indicated, either when all cells have been cut out or when the charge input level limit has been attained, the necessary indicative information in the NCODE array is recorded in the final core dump.

Differential Aeration Corrosion of a Passivating Metal under a Moist Film of Locally Variable Thickness

Richard Alkire* and George Nicolaides**

Department of Chemical Engineering, University of Illinois, Urbana, Illinois 61801

ABSTRACT

A theoretical model is developed to predict the current distribution along a metal surface which exhibits passivity during differential aeration corrosion. The process is modeled by assuming that oxygen diffuses through a moist film of variable thickness to the corroding surface whereupon cathodic reaction proceeds in accordance with a Tafel rate expression which includes oxygen concentration dependence. The anodic dissolution rate depends solely upon the potential difference across the electrolyte-metal interface, behavior characteristic of active-passive metals. The model consists of a second-order nonlinear ordinary differential equation which was solved numerically. The influence of the system parameters upon the corrosion process was investigated. The results indicate that multiple steady-state solutions may exist for a single set of system parameters. It is usually found that current is conducted along the moist film between net anodic and net cathodic regions of the corroding surface. It is shown that in certain regions of parameter space the anodic dissolution rate can became highly localized.

Whereas electrochemical corrosion involves two distinct reactions which occur simultaneously, it is not necessary that the two reactions proceed at identical rates everywhere along the corroding surface. The problem of determining the local rate of corrosion reactions corresponds, in part, to determining the details of the current flow between localized anodic and cathodic regions. That is, one needs to know the current distribution. The present study illustrates one method of calculating the current distribution in a simple system which has many features which are characteristic of an active-passive metal undergoing differential aeration corrosion.

Under conditions of uniform attack, corrosion rates may be estimated with use of mixed-potential theory (1) as indicated in Fig. 1 for a situation of aeration corrosion (2). The anodic curve is typical of metals which undergo passivity, while the three cathodic curves correspond to three different oxygen limiting currents. For high rates of oxygen transport (curve A), passivity is attained. For lower rates of oxygen transport (curves B and C), active corrosion may occur to one extent or another.

When two corrodable metal pieces of identical composition are placed in connected solutions of different oxygen concentration, the metals proceed to corrode at different rates. When the two metal pieces are connected by a wire, it is observed that electrons move toward the corroding metal in the more oxygenated compartment (3). That is, the more oxygenated metal becomes cathodic with respect to the other piece. However, merely observing the direction of current flow does not give any information about which metal piece is corroding more rapidly. Kaesche showed (4) that if both metal pieces corrode in the active region (curves B and C in Fig. 1), then the "cathodic" metal corrodes more rapidly. On the other hand, if the "cathodic" compartment contains sufficient oxygen that the metal becomes passivated (curves A and C in Fig. 1), then the "anodic" metal corrodes more rapidly.

A similar situation arises during differential aeration corrosion of a metal surface. While one might expect the local corrosion rate to be higher where the oxygen concentration is higher, the possibility of metal passivation in the more aerated region makes the problem more complex since passivation of the entire surface may not necessarily occur. For example, one possible type of behavior would be for the metal to be passive in highly aerated regions, inactive in the oxygen deficient regions, and highly reactive in the intermediate regions. Naturally, the question arises as to the specific conditions under which the anodic reaction rate distribution might be highly localized. The problem is complex because the oxygen concentration along the surface, the anodic and cathodic reaction rates, the net current, and the potential in the solution along the surface are all interdependent. Furthermore, in contrast to uniform attack, these quantities can all vary with position along the corroding surface. As a consequence of differential aeration corrosion, one may thus expect certain conditions under which some regions of the metal surface will be anodic while adjacent regions of the same surface will be cathodic. In order to investigate the conditions under which local current flows lead to localized corrosion, it is therefore necessary to combine mixed-potential theory with the concepts of current distribution phenomena.

Electrochemical current distribution problems originated in attempts to predict the over-all current-voltage behavior of electrolysis cells (5). Several such

Key words: corrosion, differential aeration, current distribution.

studies have also been conducted on corrosion-like configurations of fixed anode/cathode geometry. Waber *et al.* (6) calculated the primary and secondary current distributions in "local cells" having two-dimensional adjacent coplanar cathodic and anodic strips of fixed size. This method of calculation has been recently extended to other geometries including coplanar concentric rectangles (7) and circular strips (8). Wagner (9) included the role of mass transport limitations on local cell action for cases where the cathodic reaction was diffusion limited. Along somewhat different lines, Levich (10) employed a convective diffusion model to predict the rate of dissolution of inclusions of known size in both horizontal and vertical surfaces. A discussion of several of the foregoing aspects may be found in the book by Vetter (11). All of the foregoing studies assumed, however, that the anodic and/or cathodic regions were of known shape and size. One cannot make such assumptions and, at the same time, ask for the conditions under which the anodic corrosion region is extremely localized. Only a limited number of current distribution studies have been conducted on systems where localized anodic and cathodic regions coexist on adjacent regions of a single bipolar conductive surface. These studies consider bipolar resistive wires (12), bipolar porous diaphragms (13), and corroding iron disks (14). The last-mentioned study is particularly noteworthy, since it examines the consequence of differential aeration caused by nonuniform rates of oxygen transport to a corrodable surface.

By expanding upon these studies of bipolar current distribution phenomena, the following investigation arrives at a simple model for elucidating corrosion behavior of a passivating surface undergoing differential aeration corrosion. To be sure, the theoretical model does not take sufficient account of many complexities which may arise during an actual corrosion situation. For example, the effect of pH and of accelerator ions (such as Cl^-) upon the passivation kinetics has not been included. However, the model does contain many of the most important salient features of differential aeration corrosion and can thereby serve as a basis both for developing more sophisticated studies, as well as for refining one's intuitive grasp of a complex situation.

Derivation of the Mathematical Model

A metal surface may experience differential aeration from a wide variety of causes. A stationary meniscus, or stagnant pools and droplets of liquids in idle equipment, for example, can lead to attack. Uneven electrolyte agitation or local temperature differences may be the cause. Uneven aeration may also arise owing to the presence of a scale deposit, a block of wood lying on a tank bottom, a crevice formed by improper gasket fitting, or within a porous metal such as used for bone implants. The following theoretical model confines itself to a rather simple moist film configuration which may be thought of as akin to the region in the vicinity of a meniscus. Figure 2 illustrates the geometry of the system under investigation. The metal is covered by an electrolyte-moistened film of locally variable thickness. Oxygen diffuses from the atmosphere through the moist film to the metal surface where it is reduced. Simultaneously, the metal corrodes anodically. Electrical current flows in the moist film between the anodic and cathodic regions along the metal surface. The driving force behind the localized corrosion process under study is the difference in oxygen concentration at various positions along the metal surface. The moist film, which leads to the onset of corrosion, may eventually accumulate corrosion products and thereby change its form and nature. The following model does not account for such transient structural variations, either within the moist film or in the corroding metal surface. The applicability of the model lies in clarifying conditions under which the onset of localized corrosion is likely to occur.

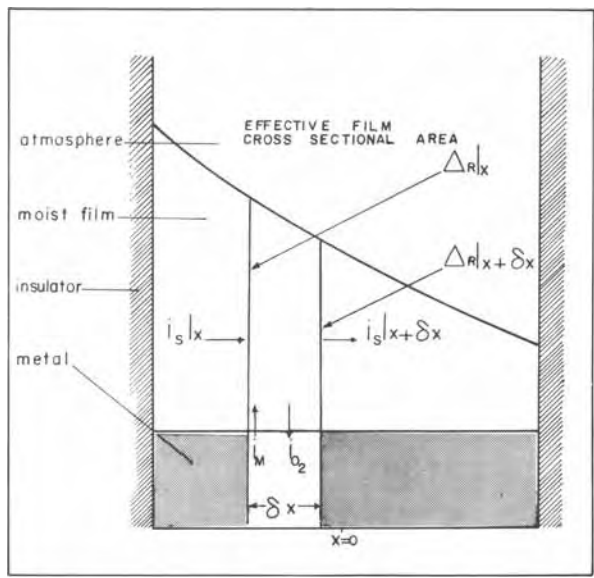

Fig. 2. System configuration for differential aeration corrosion study.

Because rigorous calculations are not necessary for a useful preliminary analysis, several simplifying assumptions have been introduced: (*i*) The corroding system is confined by two insulating planes as shown in Fig. 2. (*ii*) The potential within the corroding metal is uniform owing to the high conductivity of the metal phase. (*iii*) Current flows in the moist film parallel to the corroding surface. (*iv*) Oxygen diffuses through the moist film along paths which are perpendicular to the surface. (*v*) The film thickness varies with position in an exponential manner. (*vi*) The concentration of ionic species is uniform. Although these assumptions restrict somewhat the range of validity of the model, they do not obviate many essential features of behavior which are of interest.

The partial reactions which occur during corrosion proceed at rates which depend upon the local potential difference across the metal-film interface. Over the range of potential of interest, the current-potential behavior typical of many active-passive metals can be modeled by the function

$$i_M(x) = a\left\{\frac{1-\beta}{e^{\frac{[(V-\phi_s(x))-V_R]^2}{s}}}+\beta\right\} \quad [1]$$

The quantity, a, gives the maximum current density in the active region; β is the fraction of the maximum active current density which is exhibited in the passive plateau; s is related to the width of the hump which appears in the active region. Other nomenclature are compiled at the end of the text. Oxygen reduction has been modeled by a Tafel equation which includes consideration of mass transport limitations

$$i_{O_2}(x) = k\cdot\frac{c(x)}{c^o}\cdot\exp\left\{\frac{-\alpha\mathbf{F}}{RT}[V-\phi_s(x)]\right\} \quad [2]$$

The steady-state concentration of oxygen along the metal surface, $c(x)$, can be eliminated from Eq. [2] with use of Fick's first law of diffusion written locally along the film

$$i_{O_2}(x) = -\frac{4\mathbf{F}D[c^o - c(x)]}{\Delta_m(x)} \quad [3]$$

The local thickness of the film through which oxygen must diffuse, $\Delta_m(x)$, has been chosen to have the form

$$\Delta_m(x) = \delta_m \exp\left(-\frac{x}{l}\right) \quad [4]$$

Owing to local imbalances in anodic and cathodic rates, a net current may flow along the film. The current passing along the film obeys Ohm's law

$$i_s(x) = -\kappa \frac{d\phi_s(x)}{dx} \quad [5]$$

The current density flowing in the film, $i_s(x)$, may vary with position along the metal surface for several reasons. Figure 2 illustrates a differential slice of film having width Δx. Within this region, the current density flowing in the film changes owing to the change in cross-sectional area, as well as to a local imbalance of anodic and cathodic reactions. In differential form, the situation corresponds to a conservation of charge equation

$$\frac{d[i_s(x) \cdot \Delta_R(x)]}{dx} = i_{O_2}(x) + i_M(x) \quad [6]$$

The function $\Delta_R(x)$ represents the effective cross-sectional area through which current flows. The one-dimensional flow of current, however, would not be a good approximation if the film is very thick in some regions. It should be recognized that the two-dimensional current lines, which might actually prevail, would be most dense near the corroding surface where the distance between anodic and cathodic regions is small. In view of these considerations, the function Δ_R has been chosen to have the form

$$\Delta_R(x) = \delta_R\left[1 - \tanh\left(\frac{x}{l}\right)\right] \quad [7]$$

That is, the choice of the hyperbolic tangent function represents a way of confining the lines of current flow to the region near the electrode surface, even when the film may be quite thick. An exponential function for Δ_R would perhaps be more consistent with Eq. [4], but would be less realistic in view of the two-dimensional nature of current flow which may occur under thicker portions of the film.

In order to reduce the number of independent parameters, it is convenient to introduce dimensionless variables

$$X = \frac{x}{l}$$

$$\Phi = (V - \phi_s)\frac{\mathbf{F}}{RT}$$

$$C = \frac{c}{c^o}$$

$$\sigma = \left(\frac{\mathbf{F}}{\mathrm{RT}}\right)^2 s$$

$$\Phi_R = \frac{V_R \mathbf{F}}{RT} \quad [8]$$

The model may then be rendered highly compact by combining Eq. [1]-[8] to obtain the dimensionless relation

$$\frac{d^2\Phi}{dX^2} - (1 + \tanh X)\frac{d\Phi}{dX} = \frac{\xi}{(1 - \tanh X)} \left\{\left[\frac{1-\beta}{e^{\frac{(\Phi - \Phi_R)^2}{\sigma}}} + \beta\right] - \left[\frac{\zeta e^{-\alpha\Phi}}{\zeta\Gamma e^{-X} e^{-\alpha\Phi} + 1}\right]\right\} \quad [9]$$

The dimensionless parameters which thereby appear in Eq. [9] are

$$\Gamma = \frac{a\delta_m}{4\mathbf{F}Dc^o}$$

$$\xi = \frac{\mathbf{F}l^2 a}{RT\kappa\delta_R}$$

$$\zeta = \frac{k}{a} \quad [10]$$

The term on the right side of Eq. [9] is the net reaction rate which, for conditions of uniform corrosion, would have the value of zero everywhere along the surface. On physical grounds, Eq. [9] indicates that current flows into the film in the net anodic regions, flows along the moist film while suffering ohmic resistance and cross-sectional strictions, and flows out of the film into the net cathodic regions of the surface. A detailed treatment of the physical significance of the important parameters, Eq. [10], will be provided in the Results and Discussion Section which follows.

The only unknown quantity in Eq. [9] is $\Phi(X)$, the potential distribution along the metal surface. Since the differential equation is of second order, two boundary conditions must be specified; in accord with the arrangement depicted in Fig. 2, these are

$$\frac{d\Phi}{dX} = 0 \quad \text{at} \quad X = -\lambda$$

$$\frac{d\Phi}{dX} = 0 \quad \text{at} \quad X = +\lambda \quad [11]$$

Equation [11] also defines the parameter λ. To be consistent with Eq. [8], the characteristic length l must be defined as

$$l = \frac{L}{\lambda} \quad [12]$$

where L is the dimensional length of the corroding surface. Effectively, the value of λ determines how sharply the functions Δ_m and Δ_R vary from one end of the interval to the other.

Once the potential distribution is found from Eq. [9] and [11], one may return to calculate the local reaction rates from Eq. [1] and [2], and the oxygen concentration distribution from Eq. [3]. In dimensionless form, the quantities are given by

$$\frac{i_M}{a} = \frac{1-\beta}{e^{\frac{(\Phi - \Phi_R)^2}{\sigma}}} + \beta \quad [13]$$

$$\frac{i_{O_2}}{a} = \frac{\zeta e^{-\alpha\Phi}}{\zeta\Gamma e^{-X} e^{-\alpha\Phi} + 1} \quad [14]$$

$$\frac{c}{c^o} = \frac{1}{\zeta\Gamma e^{-X} e^{-\alpha\Phi} + 1} \quad [15]$$

The theoretical model outlined above has extended previous current distribution studies to include multiple reactions occurring at bipolar electrode surfaces. The model does not require *a priori* specification of where the anodic and cathodic regions exist. In clear contrast to previous current distribution studies on corroding systems, the foregoing model allows the basic parameters of the corroding system to define the location of anodic and cathodic regions along the metal surface. As a consequence, the model is capable of predicting the conditions under which the anodic corrosion rate may be very localized.

Method of Solution

Equation [9], along with its boundary conditions, was solved numerically with use of an IBM 1800 digital computer. The equation was linearized about a trial solution and then set into finite difference form. The

trial distribution matrix was inverted (15), and the solution of the nonlinear equation was gained by iteration with successive correction of the trial distribution. The criterion for testing convergence was that values of the solution at the beginning, middle, and end of the spatial interval should not change by more than 0.001% of their absolute values upon successive iterations. It was found that the final solutions obtained were not noticeably affected by the mesh size when between 80 and 160 points were used, depending upon parameter values. Convergence was usually achieved smoothly within about five iterations.

In certain regions of parameter space, it was found that the choice of the first trial distribution was crucial in determining whether successful convergence would be achieved. Also, as will be discussed below, multiple solutions were obtained in certain regions of parameter space. The first trial distribution usually determined to which solution the program would converge for a given set of parameters. Convergence within such delicate regions was achieved by first obtaining a converged solution with "nearby" values of the system parameters. The values of the system parameters were then changed slightly; the "nearby" converged solution was then used as a first trial in attaining convergence at the newest set of parameters. By making only slight changes in the parameter values, and by obtaining a converged solution with every change, it was possible to explore large regions of parameter space.

The method used in this study for attaining convergence enjoys both advantages and disadvantages. During iterative steps, the trial potential distribution homes into a correct solution in a manner which, in some respects, is reminiscent of the physical response the system might have following an upset in operating conditions. As a consequence, the procedure used here usually converges onto stable solutions (16). On the other hand, the method has the disadvantage that one cannot know how many such solutions exist, except by finding them.

Results and Discussion

Calculations based on the preceding theoretical model have been conducted in order to evaluate the computational method and in order to gain an understanding of characteristic features of differential aeration corrosion systems. Since the model contains a large number of system properties, and because the investigation is preliminary in nature, it would be cumbersome to report detailed parameter studies for every possible case. Only a few aspects which appear to be of special interest have been chosen for discussion. Table I gives the values used for those dimensionless parameters which were not varied in this investigation.

Under conditions of uniform corrosion, the local anodic and cathodic currents are in balance and the right-hand side of Eq. [9] equals zero everywhere along the surface. Up to three roots of the algebraic equation are possible, as illustrated qualitatively in Fig. 1 by curves B or C. If three roots exist, then the middle root, on the descending side of the polarization curve (*i.e.*, having negative charge-transfer resistance), is unstable and will usually not be observed in actual systems. It is important to make a clear distinction between the number of algebraic roots of the right side of Eq. [9], and the number of solutions to the differential equation. Although up to three algebraic roots may be found from the right side, such information bears no direct relation to the number of solutions which the differential equation may exhibit.

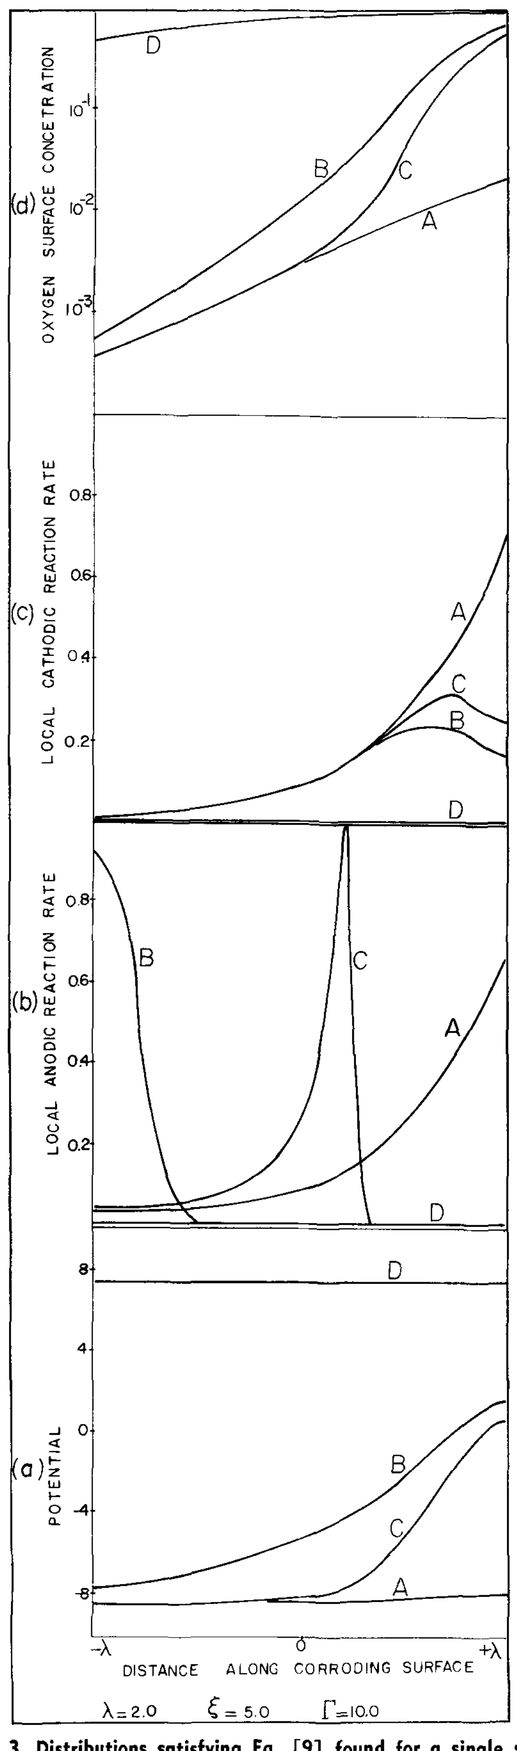

Fig. 3. Distributions satisfying Eq. [9] found for a single set of parameters. (a) Potential of the metal relative to the solution, (b) anodic dissolution rate, (c) cathodic reduction rate, (d) oxygen concentration at the surface.

The occurrence of multiple solutions.—In certain regions of parameter space, as many as four independent solutions of Eq. [9] have been found for a single

set of system parameters. For example, in Fig. 3, four sets of potential, current, and concentration distributions are shown for the parameter values $\lambda = 2.0$, $\xi = 5.0$, and $\Gamma = 10.0$. The quantities whch are plotted are given by Eq. [13], [14], and [15]. The right side of Fig. 2 ($X = +\lambda$) corresponds to the thinner edge of the moist film, consistent with Fig. 1. The four potential distributions shown in Fig. 3a illustrate, in accord with introductory remarks, that the most cathodic region of the metal surface is at the more oxygenated end on the right side. The range of the potential distribution over the metal surface is seen to vary markedly from one solution to another. As a consequence, it is to be expected that the current distributions associated with each solution may be very different from each other. Figure 3b shows the four different anodic dissolution rate distributions which correspond to the four solutions. For solution A, the metal is in the active potential range everywhere and, accordingly, the local anodic dissolution rate increases with decreasing film thickness. Solution D corresponds to a fully passive situation at a very positive potential. Solutions B and C correspond to intermediate cases where one portion of the surface is passive while another portion is reactive. Solution B lies entirely on the decreasing branch of the anodic polarization curve and so is monotonic with distance. For some metals, the decreasing branch may be ill-defined so that a B-type solution may not exist. Solution C, on the other hand, varies all the way from the mildly active region to the passive region and thereby exhibits a strong maximum. Naturally, solution C is especially interesting since it indicates an obvious possibility for highly localized corrosion at intermediate positions under the moist film. It should be mentioned that, for certain parameter values, solutions A and B can also exhibit highly nonuniform dissolution rates, but the location of the maximum rate is always at or very near the extremities of the film. The average corrosion rate is related to the area under the anodic current distribution. Continuing to Fig. 3c, the cathodic reaction rate also varies with position owing in part to the potential variation and, in part, to the oxygen concentration along the surface. The cathodic current distributions given by solutions B and C are particularly noteworthy since they exhibit maxima owing to the competing effects of oxygen accessibility and distance from the net anodic region. The oxygen concentration distributions, shown in Fig. 3d, are consistent with the aforementioned behavior. Oxygen depletion does not occur to any large extent for the passive solution (D), whereas marked depletion occurs for the active solution (A). Solutions B and C are characterized by intermediate behavior.

The current flowing along the moist film is sustained by a net imbalance of local anodic and cathodic rates. As may be seen by subtracting the respective distributions in Fig. 3b and 3c, the net anodic region is always under the thick side of the film, where the oxygen concentration is the lowest. The current flowing through the film will be small for both solutions A and D, whereas it will be large for intermediate solutions B and C.

The role of oxygen diffusion.—Now let us turn to the influence of variations of system parameters upon the distributed variables, beginning with the parameter

$$\Gamma = \frac{a\delta_M}{4\mathbf{F}Dc^o}$$

From its definition, it may be expected that very small values of Γ correspond to rapid diffusion of oxygen so that the surface concentration would be essentially uniform, near the saturated value. One may see the situation by referring to the rightmost bracketed term of Eq. [9] in which Γ appears in the denominator. As the value of Γ approaches zero, the oxygen reaction rate depends solely upon the potential, not concentration. In this limiting case, only "uniform" corrosion would be found, since the *raison d'être* for differential aeration no longer exists. For the value $\xi = 0.5$ used in this study, only the passive root exists when $\Gamma = 0$, as shown schematically by curve A of Fig. 1.

On the other hand, for very large values of Γ, the sluggish diffusion of oxygen renders the surface concentration very low so that the surface may be active everywhere, but the corrosion rate would nevertheless be low because of the limited rate of supply of oxygen. Referring once again to the rightmost bracketed term of Eq. [9] illustrates the point. As Γ increases, the average cathodic rate decreases since Γ appears in the denominator. In the limit, the rightmost term behaves as $1/\Gamma e^{-X}$ so that differential aeration exists, but the average corrosion rate would be exceedingly small owing to the paucity of oxygen.

Only over intermediate values of Γ will situations be found which correspond to appreciable rates of localized corrosion. Figure 4 illustrates the effect of Γ upon the anodic current distributions of solutions A, B, and C. By examining the areas under the curves, it is observed that the act of increasing Γ has the effect of lowering the average corrosion rate since the surface concentration of oxygen is also lowered. Solution A, which lies entirely in the active region of the metal polarization curve, responds by approaching the "rest potential" of the metal and becoming very inactive. Solution B lies primarily on the descending branch and passive region of the metal polarization curve. Solution B has the characteristic that the maximum anodic rate is always at or near the left (thick) side of the film, while the maximum cathodic rate is at or near the right (thin) side. Because the distance between anodic and cathodic regions thus remains essentially constant, and because increasing the parameter Γ has the effect of reducing the average anodic current, then the potential gradients along the surface become smaller. As a consequence of increasing Γ, the anodic current distribution becomes more uniform and the area under the distribution becomes less. One unusual characteristic of the B solution is that when Γ is increased, the potential in the solution shifts to more positive values under the thick part of the film and to more negative values under the thin part. This behavior is different from the other three solutions. Solution C has the characteristic of a very wide range of potential which passes through the potential of maximum anodic dissolution rate. Therefore solution C always exhibits a maximum in its anodic current distribution. Thus, since an increase in Γ reduces the average corrosion current, the effect on the anodic distribution is to render it more and more highly localized.

The role of film resistivity.—The parameter ξ characterizes the resistivity of the moist film

$$\xi = \frac{\mathbf{F}\, l^2 a}{RT\, \kappa\, \delta_R}$$

and thus is an indication of the ease with which current flows between net anodic and net cathodic regions. A very small value of ξ corresponds to a film of very high conductivity. As a consequence, the potential drop along the film tends to be very small, and the metal thus corrodes "uniformly" at a local rate determined only by oxygen accessibility. That is, the high conductivity counteracts the potential driving force made available by differential aeration. On the other hand, a very large value of ξ corresponds to a film of very low conductivity. In this case, in spite of the possibility of a large range of potential along the film (owing to differential aeration) the film is not capable of carrying appreciable current between local anodic and cathodic sites. For intermediate values of ξ, the existence of highly nonuniform anodic attack is possible, and the potential distribution takes on values which

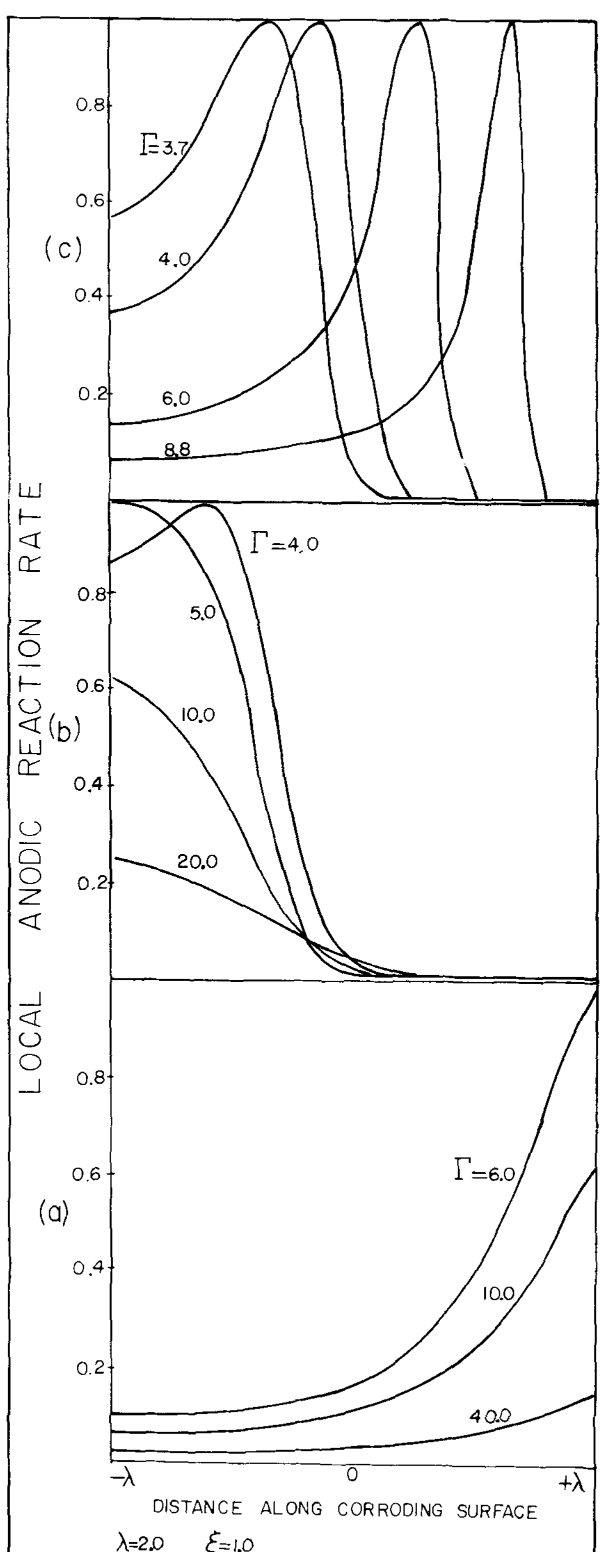

Fig. 4. The effect of Γ on the anodic dissolution rate distributions associated with solutions (a) A, (b) B, (c) C.

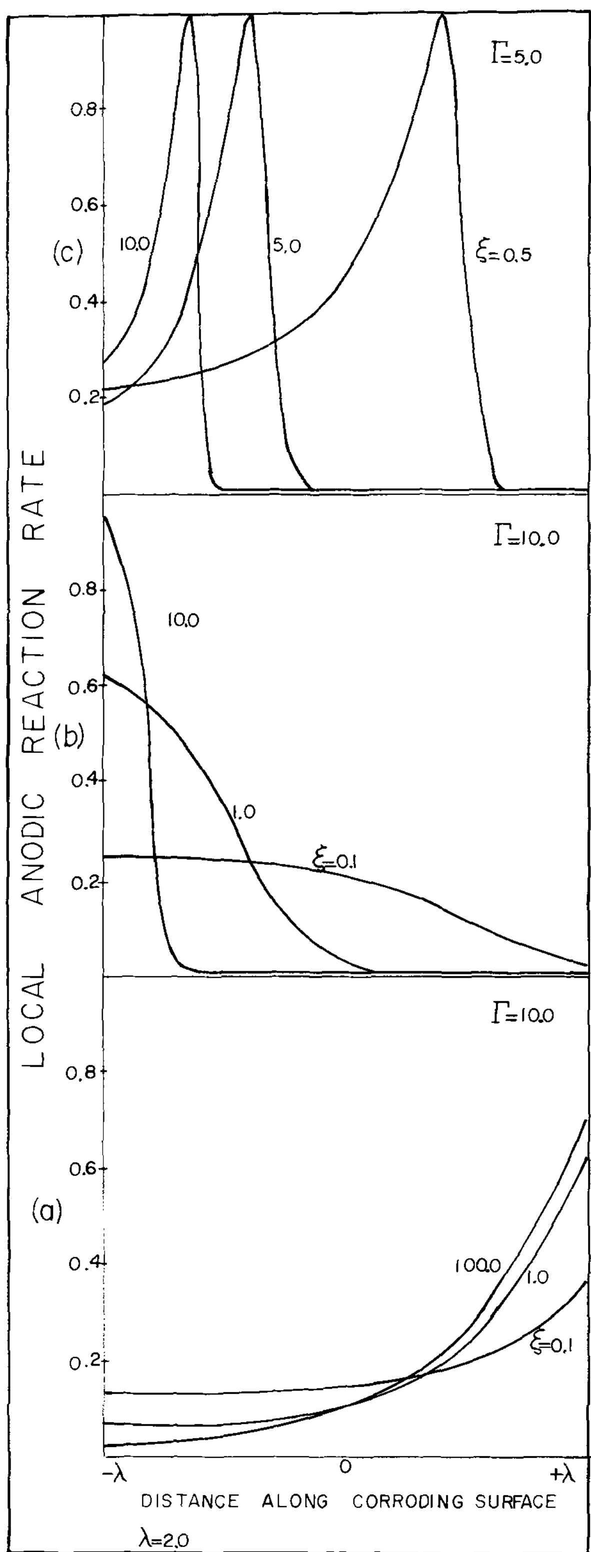

Fig. 5. The effect of ξ on the anodic dissolution rate distributions associated with solutions (a) A, (b) B, (c) C.

are intermediate between the potential distributions for $\xi \rightarrow 0$ and $\xi \rightarrow \infty$ (11).

Figure 5 illustrates the effect of parameter ξ on the anodic current distribution given by solutions A, B, and C. As ξ increases, current flow in the film becomes more difficult so that the potential gradients increase. Thus, smaller portions of the metal surface remain in the highly active anodic state. That is, for all three solutions the current distributions tend to be more localized for large values of ξ than for small values. In addition large values of ξ correspond to a wide range of potential from one end of the film to the other. In other words, an increase in ξ acts to impede the system's ability to corrode at high rates, as evidenced by examining the areas under the anodic distributions of Fig. 5. Because, for large ξ, the system cannot pass current along the film, the potential energy made available by differential aeration is stored within the system. For example, at large ξ, solutions A and B both exhibit more localized dissolution (large potential gradients) as well as large maximum dissolution rates (large potential range). Solution C, on the other hand,

cannot increase its maximum dissolution rate any further, and so responds by increasing the distance between anode and cathode.

Because the corrosion model is highly nonlinear, changes in values of one parameter affect the influence of the other parameters. Figure 6a provides an example when ξ is small; "C" solutions are found only over a small range of Γ. However, for larger values of ξ, as in Fig. 6b, solutions were found over a larger range of Γ values.

The role of differential aeration.—A measure of the difference in oxygen availability between one end of the electrode surface and the other end is embodied in the parameter

$$\lambda = \frac{L}{l}$$

which appears in the boundary conditions, Eq. [11]. A large value of λ corresponds to a large differential aeration and thereby enhances tendencies toward localized corrosion. For the value $\lambda = 3$ and $\xi = 1.0$, Fig. 7 provides the anodic current distributions for solutions A and C for several values of Γ. These results may be compared to the distributions given in Fig. 4, for $\lambda = 2$, $\xi = 1.0$. The comparison illustrates that when λ is increased, localized corrosion situations may be expected to occur over wider ranges of the other system parameters.

Conclusions

The investigation has shown that a relatively simple model of differential aearation corrosion may be use-

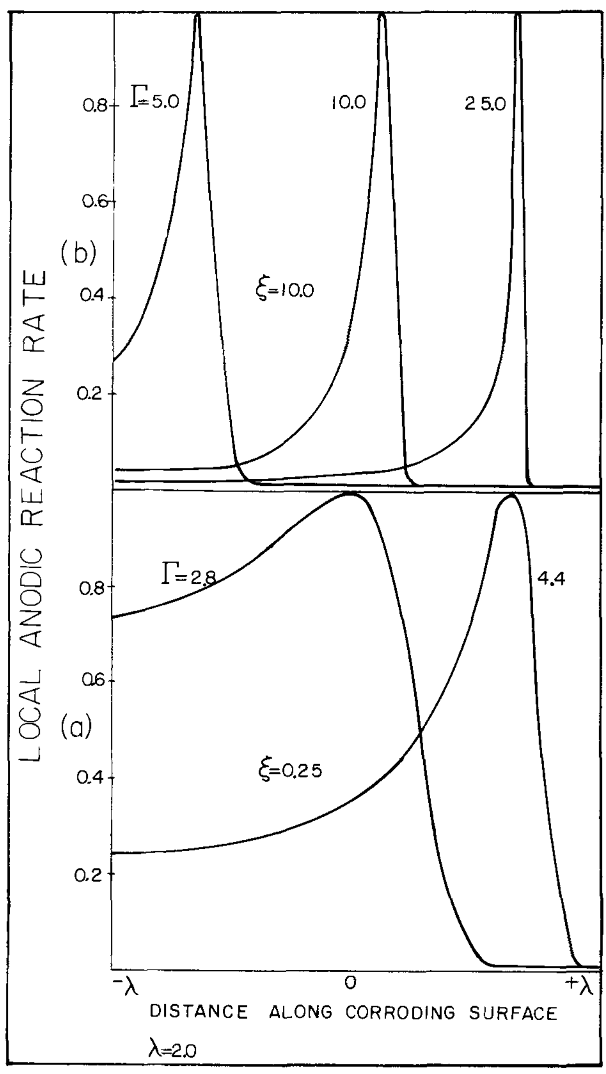

Fig. 6. The effect of Γ on the anodic dissolution rate distributions associated with solution C at (a) low ξ (b) high ξ.

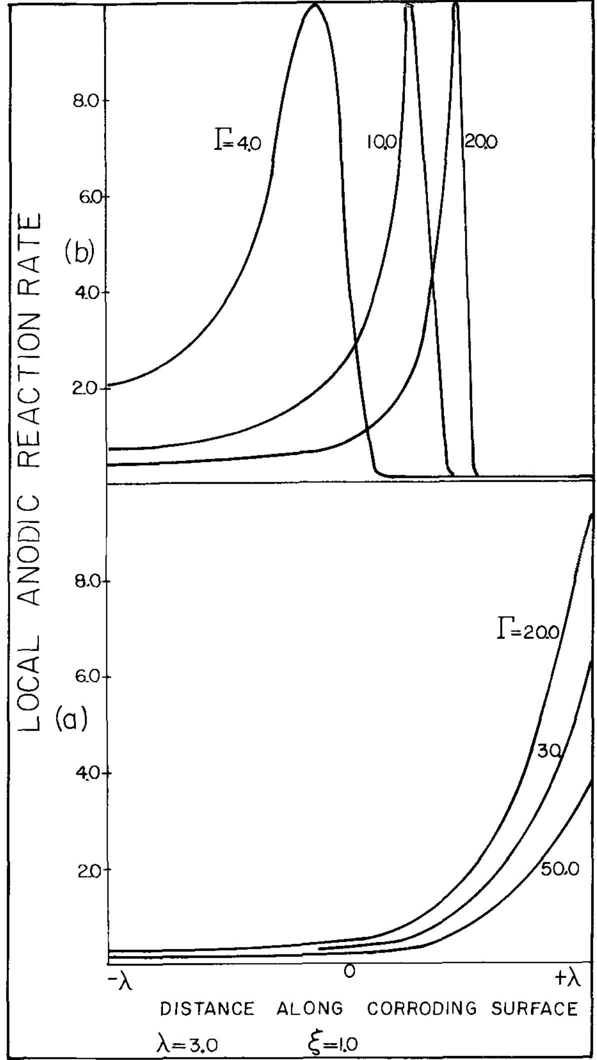

Fig. 7. Anodic dissolution rate distributions for λ = 3 associated with solutions (a) A, (b) C.

ful for elucidating conditions under which localized attack may be expected; the model indicates both the location and the local rate of corrosive attack. The response of the model to changes in system parameters is in agreement with intuitive expectations. The reasonable behavior of the model supports the expectation that the solutions reported above are stable solutions. Unstable solutions generally behave opposite to one's intuition owing, in essence, to the negative-resistance aspect which is the source of their instability. However, as noted above, solution B is perhaps suspect because of its potential response upon variation of Γ, and because its potential range lies primarily on the descending branch of the anodic polarization curve, a region of negative charge-transfer resistance.

The central purpose of the foregoing study was to organize several important aspects of differential aeration corrosion systems in order to improve intuitive understanding of this complex phenomenon. Therefore, it is important to emphasize the assumptions upon which the model rests. A considerable flexibility is available for adjusting the specific details involved in the anodic rate equation, the cathodic rate equation, the shape, and cross-sectional area of the moist film. However, a major omission of the model is that it does not include consideration of concentration variations of several important constituents, particularly pH and Cl^- effects. It would be possible, in principle, to modify existing theoretical models of porous electrodes in order to investigate pH and Cl^- effects during corrosion of porous metals, flanges, and slotted regions. On

the other hand, such studies would involve eighth order systems of coupled nonlinear differential equations having, perhaps, multiple solutions. Another significant omission is that the model does not take account of the effect the substrate may have on passivation kinetics. For example, grain boundary regions may exhibit a different passivation current than other regions of the surface.

The foregoing analysis has arranged the corrosion system parameters into a small number of dimensionless groups and has illustrated how over-all system behavior is affected upon variation of these groups. Under certain regions of parameter space, at least four multiple solutions are possible. The characteristic behavior of the solutions differ from each other because each solution exhibits a different range of potential along the surface. Solution A always has potentials which are on the active branch of the metal polarization curve. The qualitative behavior of solution A is therefore expected to resemble that of nonpassivating metals undergoing differential aeration corrosion.

One of the four solutions (C) is particularly striking since it exhibits a strong maximum in the anodic current distribution. In attempting to avoid localized corrosion, one is not so much concerned with the over-all corrosion rate as with the current distribution over the surface. Therefore, it seems important to develop computational methods for ascertaining the regions of parameter space over which highly nonuniform current distributions are possible. The iterative method used in the present study is not particularly convenient since convergence upon the desired solution often depends upon one's skill in providing an initial guess of the desired solution; that is, one is not assured that a certain type of solution does not exist simply because one cannot converge upon it. Alternative solution-seeking methods are available, however, which generally find all possible solutions. Additional methods are also available for investigating the stability of the solutions.

One finds repeated comments throughout the experimental literature which emphasize the importance of establishing a definite order of operations for conducting corrosion experiments in order to obtain reproducible and consistent results. On the basis of the present investigation of one type of corroding system, it should be recognized that, if multiple steady-state situations exist, then the particular steady solution which is arrived at depends upon the start-up conditions which precede attainment of steady state. Therefore, with respect to differential aeration corrosion, ominous implications may exist for experimental procedures aimed at corrosion testing and at scale-up of corrosion tests to field situations. Not only would the corrosive test environment need to be similar to the field situation, but the events leading to establishment of the corrosion conditions would also need to be simulated. Once again, the conclusion seems clear that a method should be developed for elucidating parameter regions where highly localized attack is possible. With such information at hand, a corrosion engineer would have a better criterion for evaluating prospective designs so as to avoid altogether those potentially hazardous corrosion conditions.

Anodic Behavior of Mild Steel in $NaClO_3$ at High Current Densities

Kao-Wen Mao* and Der-Tau Chin*

Electrochemistry Department, Research Laboratories, General Motors Corporation, Warren, Michigan 48090

ABSTRACT

The *IR*-free anode potential and the current efficiency were studied for the electrochemical machining of mild steel in $NaClO_3$. The results show that an electronically conductive oxide film is present in the low current density region where the current is consumed in oxygen generation. With increasing current density, the film begins to break up with the formation of pits in the film. The film finally disappears in the high current density region where the metal dissolution takes place with a current efficiency greater than 100% and the metal surface is polished due to the presence of a precipitated salt layer with high ionic conductivity.

In order to compete with conventional methods of metal removal, it is important for an electrochemical machining (ECM) process to provide the workpiece with good dimensional control and surface finish. For ECM of steels, $NaClO_3$ has been found to be superior to the commonly used NaCl solution (1). It has been suggested that the excellent dimensional control and surface finish obtained with steel in $NaClO_3$ are associated with anodic passivation (2, 3). Recently, it also has been pointed out that dimensional control in a passivating ECM electrolyte is related to the metal dissolution efficiency (4, 5).

In the present work, the anodic polarization and the current efficiency for ECM of mild steel in $NaClO_3$ were studied by carrying out the experiments in flow-channel cells. The results of this work should provide further information for future improvement of the ECM process.

Experimental

Anodic polarization measurements.—The experiments for studying the anodic polarization of mild steel[1] in $NaClO_3$ were carried out in flow cell I previously described (6). A current interruption technique was employed to measure the *IR*-free anode potential. The current was interrupted after machining 0.6-3 sec (at constant current) depending upon the current density.[2] The experimental techniques and procedures are identical to those previously described (6, 7).

The $NaClO_3$ used had a NaCl content less than 0.04%. Distilled water was used to prepare the electrolyte. Experiments were conducted at 26° ± 2°C under the following conditions: Re = 16,000[3] (flow velocity, U = 2000 cm/sec) and 4000 (U = 500 cm/sec) in 4M $NaClO_3$; Re = 19,500 (U = 2000 cm/sec) and 4000 (U = 410 cm/sec) in 2M $NaClO_3$.

Anodic current efficiency measurements.—The current efficiency measurements were conducted in flow cell II, previously described (5). The details of the experimental procedures and techniques have been given elsewhere (5, 7).

Two kinds of mild steel were used for the study.[4] Mild Steel II was richer in carbon and phosphorus than Mild Steel I. The anodes were machined at a constant current and the dissolution time was varied from 5 sec at 100 A/cm² to 120 sec at 2 A/cm². The electrolytes used were 1-4M $NaClO_3$; the flow rate was kept at Re = 7000 (or U = 1000 cm/sec). All the runs were made at 21° ± 1°C. The anode was weighed before and after the dissolution test to determine the amount of metal removal, and the current efficiency was calculated on the basis of ferrous ion as the dissolution product.

Results

Anodic polarization.—The oscillogram of the anodic potential decay was enlarged 10 times for the determination of the initial slope of the decay trace. The initial slope was used for a linear extrapolation of the trace to zero time to determine the *IR* potential drop.

The *IR*-free anode potentials as a function of current density are given in Fig. 1. The data in the figure represent the average values of two or more runs. The difference between the results of replicate runs is less than 5%. The results represented by open symbols were obtained in 4M $NaClO_3$ at Re = 16,000 and in 2M $NaClO_3$ at Re = 19,500. It was found that the rate of

electrolyte flow had no significant effect on polarization when the current density was lower than 60 A/cm². However, for current densities greater than 60 A/cm², the anodic potentials at Reynolds numbers less than 4000 became significantly lower as shown by the filled symbols in Fig. 1.

Figure 2 shows the anodic potential decay traces and the machined surfaces obtained in 4M $NaClO_3$ at Re = 16,000. In Fig. 2Aa and 2B1, the anodic potential decay shows two arrests: the first arrest starts at 1.6V *vs.* SCE, and the second arrest starts at about 0.5V *vs.* SCE, corresponding to the reduction potential of Fe_2O_3 to Fe^{++} (8). Such a wave plateau was always observed at current densities between 2.5-17.5 A/cm² (the second arrest is not shown in Fig. 2A1 because of the large time scale used). At the present time, there is no reasonable explanation why the first arrest starts at 1.6V *vs.* SCE. Since this arrest potential was also observed in $NaNO_3$ (7) over a range of current densities where oxygen was generated on the electrode surface, it is probably caused by absorbed oxygen on the anode surface.

Figure 2A2 shows that the machined surface obtained at 10 A/cm² was covered with a layer of oxide film with localized pits occurring randomly in the film. It should be noted that pitting in the film was not observed until the current density reached about 5 A/cm². As the current density was increased, more pits appeared, and the film started to break up as shown in Fig. 2B2. At this time the wave plateau in the potential decay curve became significantly shorter (Fig. 2B1). When the current density was further increased to 25 A/cm², the oxide film was completely broken up (Fig. 2C2) and no arrest was observed (Fig. 2C1). The surface at this stage was polished and brightened.

Current efficiency.—The current efficiencies for ECM of Mild Steel I in 1, 2, and 4M $NaClO_3$ solutions at different current densities are given in Fig. 3. The results clearly show that the current efficiency increased with the concentration and with the current density. For each curve, iron was not dissolved until the current density reached a value indicated by point a in the figure. This value varied from 1.5 A/cm² for 4M $NaClO_3$ to 3 A/cm² for 1M $NaClO_3$. Then, there was a rapid increase in current efficiency as the current density was increased. As the current density reached point b on the curves (approximately 15 A/cm² for 4M and 30 A/cm² for 1M solutions), the efficiency became greater than 100%. These results were obtained at Re = 7000, with a linear flow velocity of 1000 cm/sec. Experiments carried out at a lower flow rate indicate

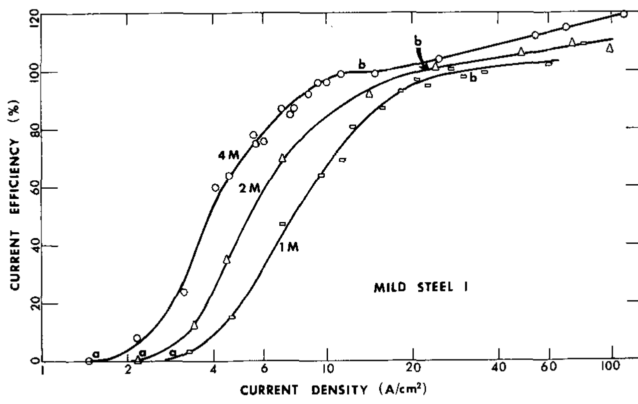

Fig. 3. Current efficiency *vs.* current density for Mild Steel I. Three reaction stages can be seen on each curve. The region to the left of point a is the oxygen generation stage; the region between points a and b is the transition region; and the region to the right of point b is the metal dissolution stage.

that the flow rate has little effect on the current efficiency (5).

Figure 4 presents the current efficiency results obtained with Mild Steel II in 1M and 4M $NaClO_3$. These current efficiencies tend to be lower than those found for Mild Steel I (Fig. 3). The main difference between the two steels employed is that Mild Steel II has higher contents of carbon and phosphorus (see footnote 4). This is in agreement with the results of Freer and his co-workers (9). They found that in NaCl solution, the current efficiency became lower as the carbon content increased.

Photomicrographs of the machined surfaces obtained in the current efficiency study are presented in Fig. 5; this shows that the surfaces obtained at equal current efficiencies are very much alike despite the differences in the concentration and the current density. The surfaces obtained at 70% current efficiency are pitted (Fig. 5A, D). As the efficiency increases the surfaces start to become polished (Fig. 5B, E). Finally, the surfaces are highly polished when the current efficiency is greater than 100% (Fig. 5C, F).

It is interesting to note that in Fig. 5C and F, flow streaks are observed on the anode surface. The appearance of the flow streaks is due to recession of the anode surface from the electrically inert flow-channel wall during metal dissolution (10). In the case of low current efficiencies, flow streaks are not observed because of oxygen generation which provides the solution with "micro" agitation.

Discussion

Based on the results of this current efficiency study, the transpassive region for mild steel dissolution in $NaClO_3$ can be divided into three stages: (*i*) oxygen generation; (*ii*) transition; and (*iii*) metal dissolution stages.

Oxygen generation stage.—The oxygen generation stage for current densities below point a on the current efficiency curves: According to Fig. 3, this stage occurred at current densities lower than 2-3 A/cm², depending on the concentration. In this stage the metal is not dissolved and current is expended for oxygen generation (11) on the surface of a protective oxide film. This oxide film is probably a layer of γ-Fe_2O_3 (12). Since the current is consumed by the discharge of H_2O

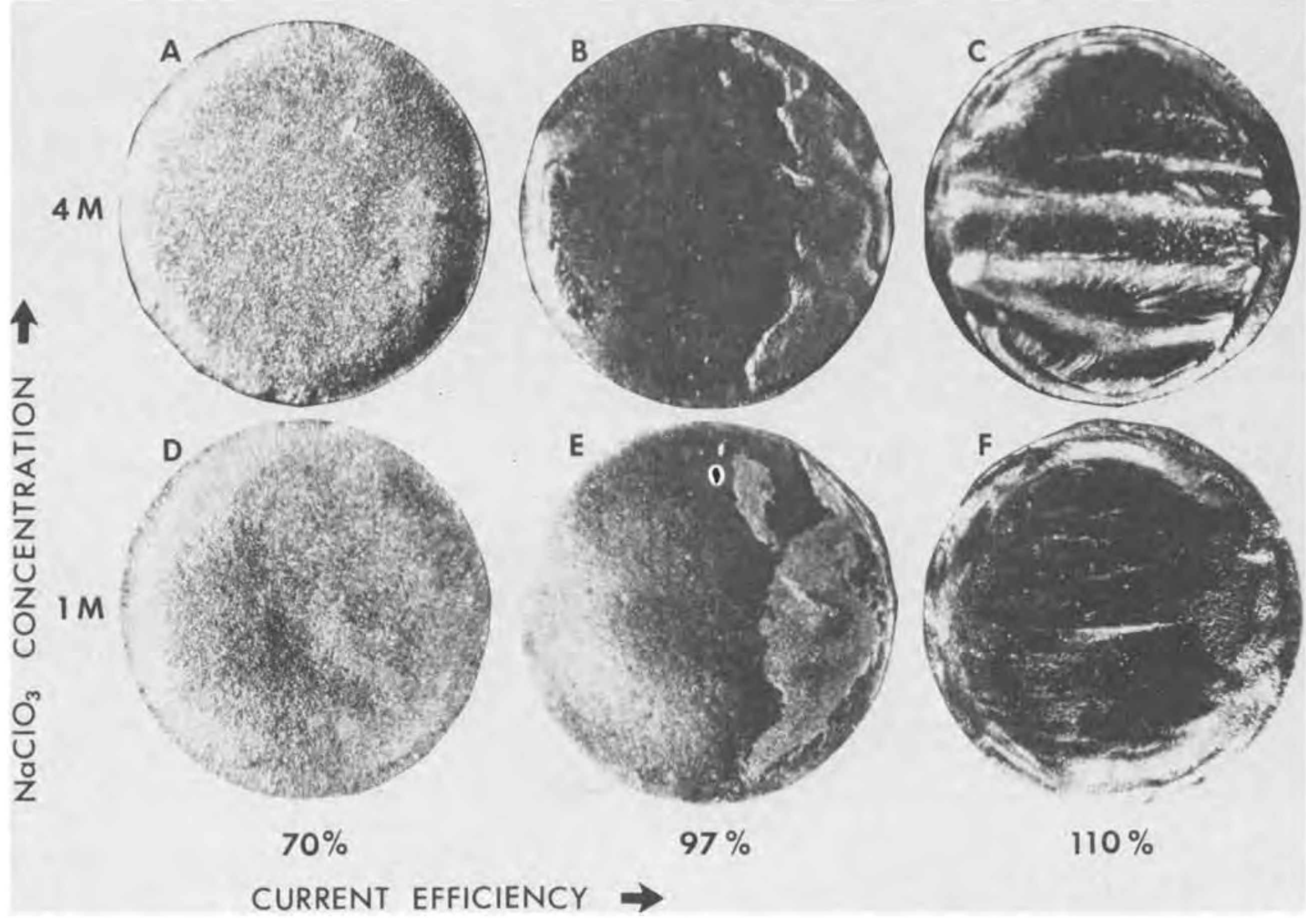

Fig. 5. ECM machined surfaces of Mild Steel I: the effect of current efficiency and $NaClO_3$ concentration. The current densities for the surfaces shown are: A, 4.6 A/cm²; B, 9.4 A/cm²; C, 54 A/cm²; D, 11 A/cm²; E, 21 A/cm²; and F, 80 A/cm².

to O_2, the film has to be electronically conductive. In $NaNO_3$ an electronically conductive film was also found, which was thought to be Fe_3O_4 (7, 13).

Transition stage.—The transition stage for current densities between points a and b on the current efficiency curves: This stage corresponds to the region in Fig. 3 and 4 where the current efficiency increases from nearly 0 to 100% as the current density increases.

It was found in a previous mass balance study (11) that the total current efficiency for metal dissolution plus oxygen generation is 100%. The increase in the metal removal efficiency results from the breakup of the oxide film which starts with the formation of localized pits in the porous film (14).

At present, there are three models given in the literature to explain how the anodic oxide film is broken up in the transpassive region. They are the penetration (15), the mechanical mechanism (16), and the ion exchange (13) models. In this report no attempt is made to discuss these models. However, it is interesting to note that all three models suggest that the breakup of the anodic oxide film has to be initiated by the process of anion adsorption. Thus, the degree of the breakdown is proportional to the anion concentration and the anode potential (or current density), in agreement with the results of this current efficiency study. Here, due to breakdown of the film, the current efficiency increases with not only the anode potential (or current density) but also with the $NaClO_3$ concentration. Similar phenomena were also observed during ECM of mild steel in $NaNO_3$ (7).

Metal dissolution stage.—The metal dissolution stage for current densities above point b on the current efficiency curves: In this stage, the anode surface is highly polished, the current efficiency is greater than 100%, and no oxygen is formed. The absence of oxygen formation in this stage is also supported by the absence of a potential plateau at 1.6V (*vs.* SCE) (Fig. 2C1). At the present time there is no evidence on which to base an explanation of why the current efficiency is greater than 100%. There are two possible reasons: one is due to severe grain boundary attacks and the other is metal dissolution by chemical oxidation. However, grain boundary attack may be unlikely since a bright, polished surface is obtained.

For electropolishing, Hoar and his co-workers (15) have suggested that brightness results from the presence of a thin "contaminated" anodic layer which is ionically conductive and, thus, provides an even attack on differently oriented grains. Based on this electropolishing theory, the bright surface obtained in the metal dissolution stage of the transpassive region can be attributed to the presence of an anodic layer with high ionic conductivity. This layer, which is different from the previously mentioned electronically conductive oxide film, is probably formed by salt precipitation from a saturated solution (5, 14).

The nearly parallel relationship between the polarization curves for 2 and 4M $NaClO_3$ in the metal dissolution stage indicates that the rate of iron dissolution is proportional to the chlorate concentration. The decrease in anode potential when Re was reduced to 4000 (Fig. 1) can be associated with an increase in the acidity of the solution near the anode (17). The H^+ concentration can influence the solubility of the salt and, thus, the layer structure. However, such a change does not affect the ECM performance significantly because there are no apparent changes in the surface finish or in the current efficiency on reducing the flow rate.

Conclusions

From the results of this study, it may be concluded that the transpassive dissolution of mild steel in $NaClO_3$ takes place in three reaction stages depending on current density (applied potential). In the first stage, at low current densities, the mild steel surface is covered with an electronically conductive oxide film, and the current is consumed in oxygen evolution. In the second stage, at higher current densities, the oxide film is broken apart and the metal starts to dissolve into the electrolyte. The breakdown of the oxide film is started by the formation of localized pits in the film. In the third stage at still higher current densities, the oxide film has completely disappeared, and the high-rate metal dissolution takes place with a current efficiency greater than 100%. The metal surface after dissolution in this final stage is found to be highly polished probably due to the presence of a precipitated salt layer on the anode.

The Effect of Ion Implantation upon the Dissolution of Anodic Tantalum Oxide in Buffered Hydrogen Fluoride

J. P. S. Pringle*

Chalk River Nuclear Laboratories, Atomic Energy of Canada Limited, Chalk River, Ontario, Canada

ABSTRACT

A very precise sectioning technique for measuring concentration profiles in anodic tantalum oxide is based on the slow dissolution of the oxide in HF almost saturated with NH_4F. Since many of the profiles to be measured were for radioactive isotopes incorporated by ion implantation, it was necessary to establish whether ion implantation had any effect on the technique. To this end, several stable isotopes were implanted at fluences up to 10^{17} ions/cm^2. It was found that heavy ions gave rise to sputtering and accelerated the stripping of the oxide; by contrast, hydrogen ions gave no sputtering and decelerated the stripping. The accelerated stripping was attributed to the physical presence of the implanted ions, while the decelerated stripping may be due to the formation of hydrogen bonds between neighboring oxygen atoms in the oxide. When 10^{17} ions/cm^2 of hydrogen were implanted, a carbonaceous deposit formed on the oxide surface due to the radiative polymerization of adsorbed pump oil molecules; this deposit prevented the oxide from dissolving at all. Implantations involving radioactive species were usually much less than 10^{15} ions/cm^2, and the accelerated stripping was often negligible; when present, it had no effect on the profile measurements.

A fundamental problem in metal oxidation is the nature of the atomic movements leading to the formation of an oxide film. To study these movements, tracer species must be incorporated, and their concentration profiles determined before and after the oxidation event. In the present series of experiments, the tracer species are usually incorporated in anodic tantalum oxide by ion implantation, and the profiles measured by means of the highly precise sectioning technique described previously (1). Range profiles for implanted ions have been surveyed elsewhere (2), and these constitute the initial profiles for the tracers. By studying the changes that occur on further anodization, information on the tantalum and oxygen movements has been obtained (3, 4).

The sectioning technique is based on slow dissolution of the oxide in HF almost saturated with NH_4F and depends for its success on the uniformity of the dissolution (1). Etching processes are, however, notoriously sensitive to the experimental conditions, as Vermilyea (5) has demonstrated for the anodic oxide itself. He annealed samples at different temperatures for varying times and found that the etching rate decreased with both increasing temperature and increased time at a particular temperature. These studies were performed with concentrated HF as etchant, but similar results have been obtained here using the HF-NH_4F reagent. Hill (6) has implanted 15 keV electrons and observed that the dissolution rate in HF-NH_4F decreased. Ion implantation was therefore very likely to have an effect, and because the extreme precision of the technique was important for subsequent work, it became necessary to find out what it was.

Effects due to implantation were readily apparent in the course of the range profile measurements reported elsewhere (2). These measurements were made with radioactive isotopes, and so the implantation fluences were relatively small ($< 10^{15}$ ions/cm^2). Nevertheless, an image of the implanted area would frequently develop on sectioning, due to the formation of different interference colors on the implanted and nonimplanted areas. Since the interference color is determined by film thickness, the oxide on the implanted area was dissolving at a different rate; from the character of the interference colors, this dissolution could be either faster or slower.

To study the process under more favorable conditions, the anodic oxide was implanted with stable isotopes to much higher fluences (10^{16}-10^{17} ions/cm^2). This greatly enhanced the effects and allowed their nature to be elucidated. At the same time, another phenomenon became apparent, for an image of the implanted area would now appear solely as the result of implantation. Comparison of the interference colors showed that the apparent thickness of the implanted oxide could again be either greater or less than that of the surrounding nonimplanted oxide. Several different effects therefore occurred as a result of implantation.

The present paper examines these effects with particular reference to their influence on the sectioning procedure.

Experimental Methods

Preparation, anodization, and sectioning of experimental samples.—Tantalum coupons, 3.5 × 1.0 cm^2, were cut from 0.015 in. (0.037 cm) sheet supplied by the Fansteel Metallurgical Corporation, and chemically polished as described previously (1). Anodizations were normally performed at a constant current density of 1 mA/cm^2 in 0.1M H_2SO_4 maintained within 0.2°C of 25°C by means of a water bath. When oxides thicker than 3500A were required, the electrolyte was changed to 0.01M butyric acid. The anodic films were sectioned by dissolving successive layers in concentrated HF almost saturated with NH_4F. Full details have been presented elsewhere (1).

Film thickness measurement.—Oxide thicknesses were measured by means of the spectrophotometric method due to Young (7). The wavelength, λ, for the nth order interference minimum was measured and related to the oxide thickness, h, by

$$\lambda = 2\eta \cdot \cos\phi \cdot (h - X)/(n - ½) \qquad [1]$$

where η is the refractive index of the oxide, ϕ the angle of refraction in the oxide, while X accounts

* Electrochemical Society Active Member.

Key words: tantalum, anodic oxidation, oxide dissolution, ion implantation, concentration profiles.

for the phase changes on reflection at the metal/oxide and oxide/air interfaces. Both η and X are functions of λ, and so the variation of h with λ had to be calibrated (7, 1). This meant, in effect, that the variation of η and X with λ had to be calibrated, and the success of the calibration showed that these variations were effectively independent of the oxide thickness. The calibration could be strictly applied, of course, only to oxide films formed under the same conditions; in this case, 1 mA/cm^2 in 0.1M H_2SO_4 at 25°C (1). It was assumed, however, that the films formed in 0.01M butyric acid would be similar, and indeed there was no reason to think otherwise.

Masing, Orme, and Young (8) have shown that the refractive index varies slightly with temperature and current density when the anodization is performed in 0.1M H_2SO_4, and Dell'Oca and Young (9) have shown that it decreases when phosphorus is incorporated from 0.23*N* H_3PO_4 electrolyte. It seemed very probable, therefore, that insertion of the foreign atoms by ion implantation would also change the optical properties of the oxide, and ellipsometric measurements with J. Ord at the University of Waterloo showed that this was indeed so.

Anodized tantalum coupons were implanted with 3.8×10^{16} to 2.5×10^{17} $^{40}Ar^+/cm^2$ at 39 keV so that thicknesses measured spectrophotometrically could be compared with those measured ellipsometrically. The agreement was within experimental error for the nonimplanted areas, but the ellipsometric measurements on the implanted area were abnormal; this clearly showed that the optical properties of the oxide had been changed by the implantation. The abnormality decreased with decreasing implantation fluence, and extrapolation of the results suggested that it would disappear at a fluence of about 10^{16} Ar^+/cm^2. Since most of the implantations reported here were made with fluences at or below this figure, the use of the spectrophotometric method to measure oxide thicknesses on the implanted areas should generally be satisfactory. When a specimen implanted to 5.6×10^{16} $^{40}Ar^+/cm^2$ was reanodized, however, the abnormality was much increased; considerations of time and distance precluded a more detailed investigation.

Thickness errors quoted in the present paper are standard errors, calculated according to the second procedure described in the previous paper (1).

Testing for the uniformity of the effects due to ion implantation.—The interference color developed by an anodic film on tantalum is very intense, and its hue is proportional to the film thickness. Near 420, 1760, and 3180Å, the hue changes very rapidly as the first, second, and third order interference minima traverse the middle region of the visible spectrum. These rapid changes, from brown (420Å) or red at thicknesses below the specified thicknesses to blue just above, proved very useful for monitoring the uniformity of the thickness on the implanted area, and hence for monitoring the uniformity of the effects associated with ion implantation. Thickness differences as small as 10Å could readily be detected in these favored regions; gross differences could of course be detected at any thickness.

Implantation method.—Ion implantation by means of the mass separator at Chalk River has been discussed in previous papers from this laboratory (10, 11). Positive ions are accelerated electrostatically to 40 keV and then passed through a magnetic field which separates them into their isotopic components. The latter were focused into lines 4 cm high $\times$ 0.1 cm wide on a fluorescent screen (12) in front of the target; a hole in this screen allowed the desired isotope to strike the target.

Since it was very important that the stable isotopes be implanted at uniform intensity over the specified area, the following procedure was adopted. Rutherford scattering experiments by Bellavance (13), using ^{209}Bi implanted in Si, had shown that the intensity of the isotopic beams varied along their 4 cm height, reaching a plateau-like crest between 2 and 2.5 cm from the top. The hole in the fluorescent screen was therefore stopped down to this 0.5 cm in height, and to 0.8 cm in width. By modulating the magnet current, it was possible to sweep the beam horizontally across this width every 30 sec, thus obtaining a uniform dose over an area of 0.5×0.8 cm^2. This was just enough for the spectrophotometric method of measuring oxide thickness, which requires an area of 0.2×0.8 cm^2 (1). Except as noted in the individual experiments, the interference colors on the implanted areas were just as uniform as those on the nonimplanted areas.

The total charge deposited in the target was used as a measure of the implantation fluence. For this purpose, the targets were mounted at the bottom of Faraday cups, 2 cm deep, behind a grid made of 0.0005 in. tungsten wire; the grid was maintained at -90V to suppress the emission of secondary electrons. Difficulties connected with the measurement of heavy ion beam currents are notorious; in estimating the fluence, it was necessary to assume that the beam consisted entirely of singly charged positive ions, and that the Faraday cups were 100% efficient. The first assumption is approximately correct, at least for radioactive species, since the range profile measurements in the next paper (2) show that less than 10% of the nuclei implant as neutral atoms. The efficiency of the Faraday cups was, however, in considerable doubt.

The insulation of the cups was not sufficient to permit retarding potentials on the target holder, and so really low implantation energies were unattainable (10). By varying the accelerating voltage, however, implantations were performed at 25, 40, and 55 keV. The maximum fluence that could be implanted in an hour, using the most abundant isotope, 99.6% ^{40}Ar, was about 10^{17} ions/cm^2; the minimum fluence obtained with a stable isotope was 10^{11} ions/cm^2, using the 0.090% abundant ^{126}Xe.

The reproducibility of the results was found to depend markedly on the way in which the implantations were performed. Normally, several specimens at a time were mounted in the mass separator and implanted in succession. Such specimens gave excellent reproducibility amongst themselves, but the results could differ by as much as 50% from similar implantations on other occasions. This suggested a lack of consistency in measuring the beam currents, but its origin was uncertain. When making comparisons, therefore, it is necessary to specify whether the results were obtained in the same series of implantations or in different series.

Presentation of the results.—A special format has been used to present the results. The independent variable is the change in oxide thickness on the nonimplanted area as a consequence of further treatment; thinning by dissolution in the HF-NH_4F reagent or thickening by anodizing. The dependent variable is the implantation differential, which is defined as the oxide thickness on the implanted area less that on the nonimplanted area. A positive implantation differential, therefore, shows that the implanted area exists as a mesa in the surrounding nonimplanted area, while a negative differential indicates that it is present as a depression.

In sectioning experiments, this format provides an integral record of the difference between the stripping rates on the implanted and nonimplanted areas, so that the difference itself is proportional to the slope of the record. Since the stripping rate of the nonimplanted oxide is constant (1), any changes in the slope are due to changes in the stripping rate on the implanted area. A downward slope shows that the implanted oxide is dissolving faster; in what follows, this situation is described as accelerated stripping. By analogy, an upward slope is described as decelerated stripping. Three other terms are used. The initial implantation differential is the differential observed as the result of implantation alone, while the final implantation differential refers

to the constant value obtained at the end of an experiment. The magnitude of the accelerated or decelerated stripping is then defined as the difference between these two differentials.

Ellipses drawn around each experimental point define the 95% confidence limits; the major and minor radii are equal to twice the appropriate standard errors. The latter are somewhat larger than those recorded elsewhere in these experiments (2-4), since they correspond to errors in the differences between two thickness measurements, not to errors in the thickness measurements themselves.

Experimental Results

Implantations with xenon.—The general features of the results obtained with heavy ions are illustrated in Fig. 1. When $^{136}Xe^+$ ions were implanted at 40 keV to a total fluence of $10^{16}/cm^2$, the initial implantation differential was found to be −68Å. This thickness of oxide had therefore been removed, obviously by sputtering. On sectioning the oxide, the implanted area began by dissolving faster, so that accelerated stripping (downward slope) was observed. After a small amount of decelerated stripping (upward slope), which may not be a real effect since it was only observed on two occasions, the implantation differential reached its constant final value of −138Å.

The sputtering and accelerated stripping are obviously a function of the implantation fluence, since no such effects were observed in the sample implanted with 10^{12} $^{126}Xe^+/cm^2$ at 40 keV. Additional experiments showed that accelerated stripping would only become noticeable (final implantation differential ~ −10Å) at 10^{14} ions/cm², and sputtering (initial implantation differential ~ −10Å) only at 10^{15} ions/cm².

Implantations with krypton.—A more detailed examination of these effects was performed with krypton, since this could be labeled conveniently with the long-lived radioisotope, ^{85}Kr. Samples of this fission product were obtained from Oak Ridge, and because the volume of gas was insufficient for the operation of the separator, they had to be diluted with stable gas. By diluting with xenon, the $^{85}Kr^+$ could be implanted in almost carrier-free form, with an implantation fluence of 10^{13} ions/cm² or less. To obtain higher fluences, the ^{85}Kr sample was diluted with stable krypton; by sweeping the mass 84 and mass 85 beams over the surface of the target, $^{84}Kr^+$ (natural abundance 56.90%) and $^{85}Kr^+$ could be implanted together. Under these conditions, of course, the vast majority of the implanted ions were ^{84}Kr, the ^{85}Kr merely acting as a tracer.

Figure 2 shows the results obtained when 10^{16} ions/cm² of $^{84}Kr^+$ and $^{85}Kr^+$ were implanted together at 40 keV. The initial implantation differential was −78Å, very similar to that observed with xenon at the same fluence. Like the latter, therefore, it was attributed to sputtering. To show that material really had been removed from the specimen, an oxide film was implanted with 40 keV $^{85}Kr^+$ only, and the activity counted; 10^{16} $^{84}Kr^+/cm^2$ were then implanted into exactly the same area, and the ^{85}Kr activity recounted. Two such specimens gave identical results; only 68% of the original ^{85}Kr activity remained after the ^{84}Kr implantation.

The experiment in Fig. 2 also showed that accelerated stripping would cease when all the krypton had been removed, since the fraction of the ^{85}Kr activity remaining at the last two points in the figure was 1.2 and 0.2%. A fraction of 1.2% is equivalent to approximately 10^{14} ions/cm², which is just about the detection limit for accelerated stripping as determined from the xenon experiments. Once the krypton had been removed, the oxide remaining on the implanted area was oxide that had not been implanted at all, and so its stripping rate should be the same as that on the nonimplanted area. The constancy of the final implantation differential, as illustrated in Fig. 1, showed that this was indeed the case.

Accelerated stripping is thus related to the presence of the implanted ions and can be interpreted in two ways. It could be a radiation damage effect, in which the breaking of the tantalum-oxygen bonds leads to more rapid dissolution of the individual atoms; effects of this type have been reported in semiconductors (14). Alternatively, it could be due to the physical presence of the implanted atoms themselves. Three experiments were performed to distinguish between these possibilities.

The first experiment was to reanodize a specimen implanted with krypton. Both tantalum and oxygen migrate during the reanodization (3), and all the oxygen atoms take part in this process (4); it may reasonably be inferred that all the tantalum atoms would behave likewise (3). On reanodization, then, all

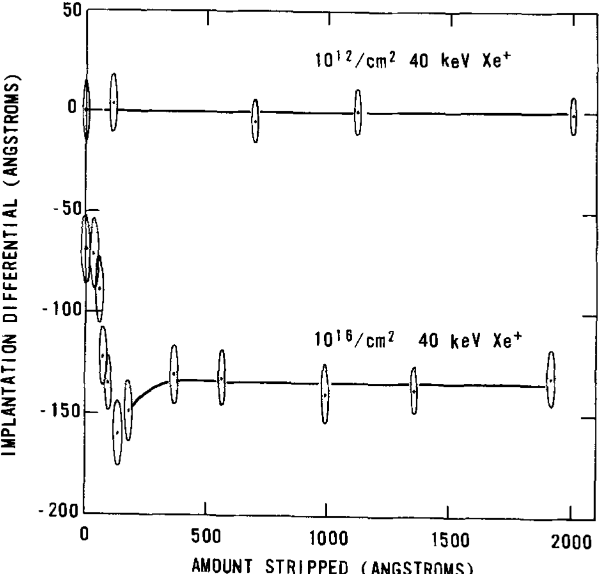

Fig. 1. Implantation differentials observed with xenon to illustrate the form of the results obtained. The amount stripped is the thickness of oxide dissolved from the nonimplanted portion of the specimen; the implantation differential is the thickness of oxide remaining on the implanted area less that remaining on the nonimplanted area. Error ellipses have been drawn at twice the standard errors round each point to indicate the 95% confidence limits. Same series of implantations.

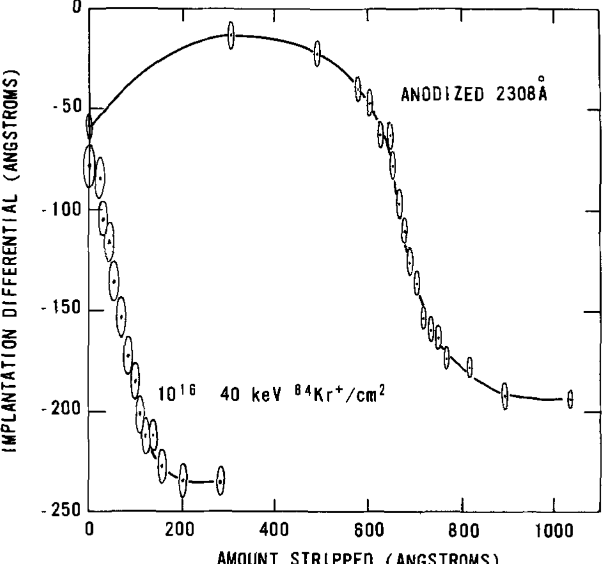

Fig. 2. Implantation differentials with krypton to illustrate the effect of reanodization on an implanted noble gas. Different series of implantations.

the atoms in the oxide rearrange to new positions, and so any structural damage should anneal out. If, therefore, the accelerated stripping is due to radiation damage, it should quickly disappear on further anodization. If, on the other hand, it is related to the physical presence of the implanted krypton atoms, it will still be associated with them after reanodization.

Another specimen was implanted with 40 keV $^{84}Kr^+$ and $^{85}Kr^+$ to 10^{16} ions/cm² and then reanodized so that the oxide was thickened by 2308Å. On sectioning, most of the ^{85}Kr label was lost as between 600 and 700Å of oxide was being removed from the nonimplanted area. Reference to Fig. 2 will show that this is just the region in which accelerated stripping was found. The latter is therefore still present after reanodization, to much the same extent as before, and still associated with the krypton atoms.

This argument is not quite conclusive, however, because it could be argued that the radiation damage gives rise to "dead" oxide; that is, oxide which does not take part in the rearrangement process. Such dead oxide would presumably approximate rather well to an inert immobile marker on further anodization, and since krypton behaves similarly (3), they would both fortuitously finish up at the same place in the final oxide. To resolve this ambiguity, the experiment was repeated with an implant known to migrate out of the oxide entirely on reanodization.

Implantations with copper.—The element chosen was copper, and two samples were implanted with 40 keV $^{63}Cu^+$ and $^{64}Cu^+$ by sweeping over both mass numbers as before. The stable $^{63}Cu^+$, natural abundance 69.09%, provided the implantation fluence of 10^{16} ions/cm², while the radioactive $^{64}Cu^+$, prepared by (n,γ) reaction in the NRX reactor, acted as the tracer. One sample had an initial implantation differential of −62Å, and was sectioned to establish that accelerated stripping would indeed occur with copper implants. Figure 3 shows that it did, the final implantation differential being −129Å. The other sample, with an initial implantation differential of −63Å, was then reanodized to thicken the oxide by 1360Å. No copper remained after this treatment, as demonstrated by the complete absence of ^{64}Cu activity. On sectioning, no definite evidence for accelerated stripping was obtained either (Fig. 3). The accelerated stripping must therefore be due to the physical presence of the implanted ions.

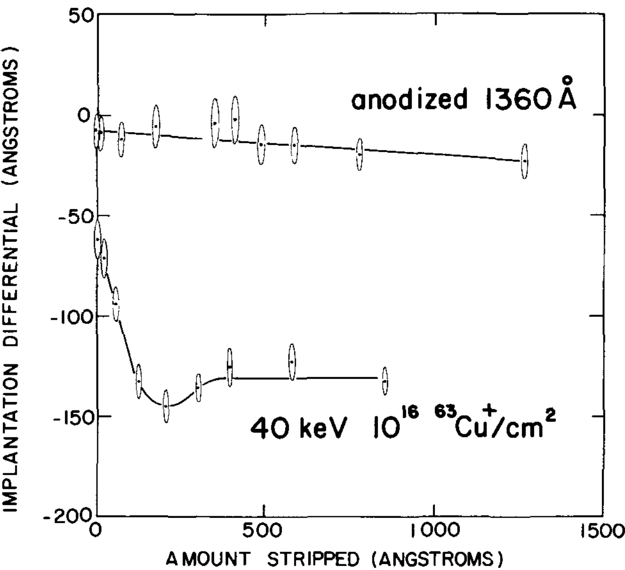

Fig. 3. Implantation differentials with copper to illustrate the effect of reanodization when the implanted species migrates out of the oxide. Same series of implantations.

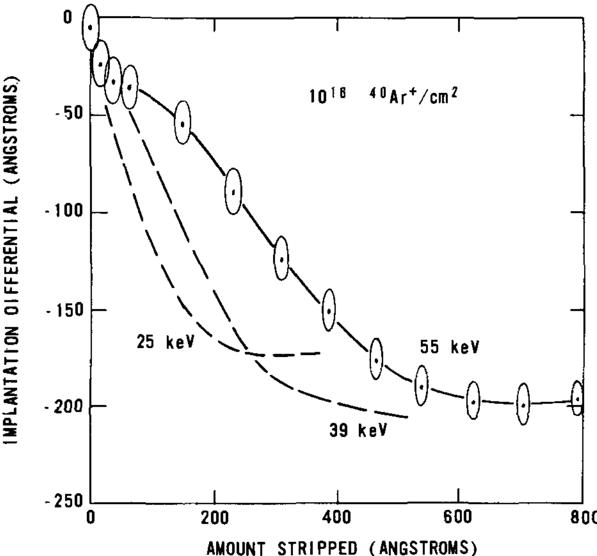

Fig. 4. Implantation differentials with argon to demonstrate the effect of varying the implantation energy. To avoid confusion, a trend line only has been drawn for the results at 25 and 39 keV. Same series of implantations.

Implantations with argon.—The third experiment was to implant to the same fluence at different energies, and to different fluences at the same energy. If accelerated stripping is due to radiation damage, its magnitude should depend not only on the number of atoms implanted, but also on their energy; if, however, it is merely due to their physical presence, it should depend on number only. Since comparisons are involved, it is first necessary to establish the reproducibility of the results obtained in the same series of implantations under the same conditions. Three samples were implanted with 10^{16} $^{40}Ar^+$/cm² at 39 keV, whereupon the initial implantation differentials were found to vary from −14 to −18Å, and the final differentials from −213 to −220Å; these results are therefore identical within the experimental standard error of 3Å. Figure 4 then indicates that the magnitude of the accelerated stripping is independent of energy, while Fig. 5 shows that there most certainly is a dependence on number. The hypothesis that the accelerated stripping is due to the physical presence of the implanted atoms is therefore confirmed.

One further test for the nature of the accelerated stripping was to heat the oxide. Radiation damage frequently anneals on heating, and Kelly and Brown (15) have shown that no significant amounts of implanted noble gas are lost from the anodic oxide below 600°C. An oxide film implanted with 10^{16} $^{40}Ar^+$/cm² at 39 keV was therefore heated to 250° for one day, with the results illustrated in Fig. 6. Accelerated stripping is present and is even more pronounced than for an unheated specimen; the final implantation differential is in fact about twice as great and is reached after the removal of only about half the usual amount of oxide. As Vermilyea (5) has shown, heating to 250°C for one day causes the nonimplanted oxide to dissolve at half its normal rate. The observed results can then be interpreted by assuming that the oxide on the implanted area continues to dissolve at the same rate as before, so that heating has no effect on the acceleration in the stripping. This is certainly consistent with the continued presence of the implanted atoms, but not conclusive evidence against radiation damage because the rate at which the latter would anneal out is impossible to predict.

If the accelerated stripping is due to the physical presence of the implanted atoms, it should be possible to demonstrate a relationship with their concentration profile. This is possible and will be discussed in a later paper (16).

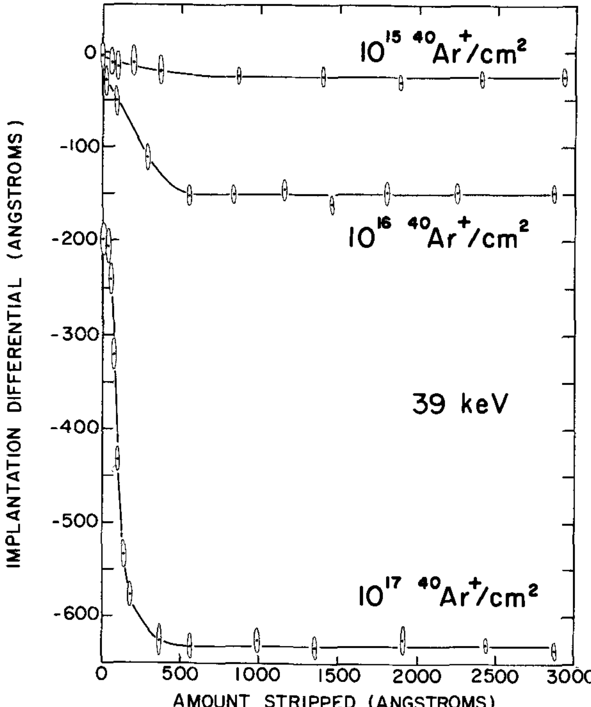

Fig. 5. Implantation differentials with argon to demonstrate the effect of implantation fluence. Same series of implantations.

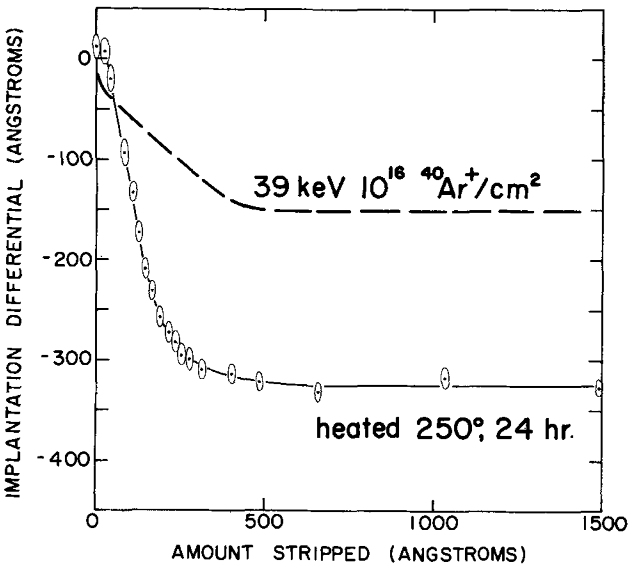

Fig. 6. Implantation differentials with argon to illustrate the effect of heating an implanted sample. Different series of implanted samples.

The initial implantation differentials in Fig. 5 were effectively 0, −10, and −195Å for the 10^{15}, 10^{16}, and 10^{17} $^{40}Ar^+/cm^2$ implantations, respectively. Sputtering was therefore negligible at 10^{15} $^{40}Ar^+/cm^2$ and barely detectable at 10^{16} $^{40}Ar^+/cm^2$, in marked contrast to the results with $^{63}Cu^+$, $^{84}Kr^+$. and $^{136}Xe^+$ at the same fluence. This observation is much as expected, since the sputtering efficiency is known to decrease with decreasing mass (17). At 10^{17} $^{40}Ar^+/cm^2$, the effect of the sputtering was clear and unmistakable; some preliminary experiments indicated that it was probably not proportional to fluence, at least between 10^{16} and 10^{17} ions/cm².

Argon-40 ions were implanted at 39 keV rather than 40 keV for a trivial reason connected with the operation of the mass separator.

Implantation with carbon.—Accelerated stripping has been observed thus far with a metallic implant, copper, and with several noble gases. The chemical nature of the implant therefore appeared of small importance, and additional confirmation was obtained by implanting the nonmetal carbon. Accelerated stripping of the usual magnitude was observed with this species also.

Implantation with hydrogen.—Hydrogen implantations were performed with $^1H_2^+$ instead of $^1H^+$, owing to its greater beam current in the mass separator. Unlike all the other species investigated, hydrogen implants decelerated the stripping.

When 10^{17} $^1H_2^+/cm^2$ were implanted at 40 keV, the initial implantation differential was found to be +99Å, as shown in Fig. 7. On sectioning, the implanted area failed to dissolve at all, and so the implantation differential increased by the rate at which oxide was being removed from the nonimplanted area. The positive differential at the start, coupled with this failure to dissolve, suggested that the oxide surface was covered with a layer of contaminant, and that this inhibited the dissolution in the HF-NH_4F reagent. As sectioning proceeded, however, the oxide on the implanted area did eventually start to dissolve, but the dissolution was slow and very nonuniform, as demonstrated by the interference colors of the remaining oxide. So nonuniform did these become, in fact, that further thickness measurements were impossible.

Very similar effects were observed in the reanodization experiment depicted in Fig. 8. Though implanted to the same nominal 10^{17} ions/cm² dose as before, the initial implantation differential was only +53Å; this illustrates the reproducibility between different series of implantations. When the oxide thickness on the nonimplanted area was reanodized by 10Å, the implantation differential jumped to +143Å; such a large increase must be attributed to a change in the optical properties of the contaminant layer.

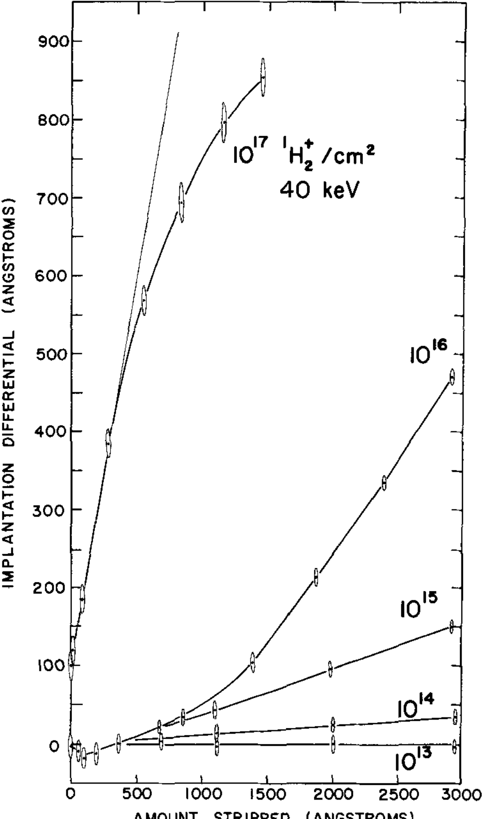

Fig. 7. Implantation differentials observed with hydrogen to demonstrate the effect of implantation fluence. The straight line tangent to the curve at 10^{17} $^1H_2^+/cm^2$ indicates zero stripping on the implanted area. Same series of implantations.

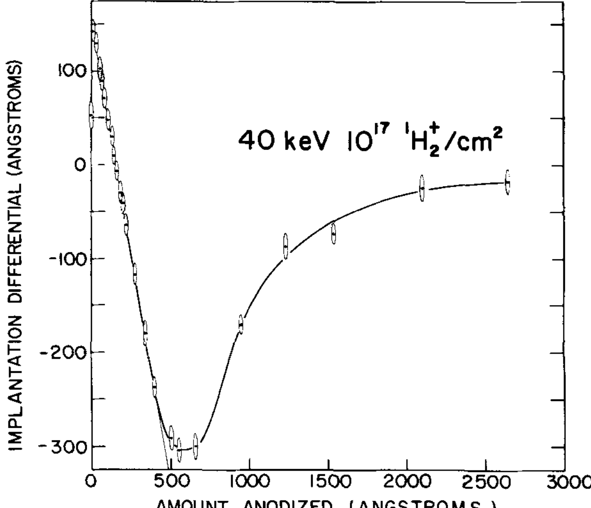

Fig. 8. Implantation differentials with hydrogen to illustrate the effect of reanodization. The abscissa is the thickness increase on the nonimplanted area.

Thereafter, the implantation differential decreased as fast as the oxide thickness on the nonimplanted area increased, until it became strongly negative. As in the initial stages of stripping, the oxide on the implanted area had been protected against further anodization by the contaminant layer; its thickness therefore remained constant, and its interference color unchanged. On continued anodizing, however, the protection again broke down at certain places, so that the resulting thickness variations gave rise to a nonuniform interference color on the implanted area. As the breakdown became more general, these thickness variations disappeared owing to the self-healing properties of the anodization process (1); the interference color was then again uniform, and the same as that on the nonimplanted area.

Sewell kindly verified the presence of carbon in the contaminant by detecting the characteristic K x-ray emitted during bombardment with 1800 eV electrons (18). An anodized tantalum specimen was implanted with 5×10^{16}, 10^{17}, and 2×10^{17} $^1H_2^+/cm^2$ on different areas of the surface, and Sewell found the carbon deposited in each area to be 0.40, 0.56, and 0.96 mg/cm^2, respectively; the standard error in these figures is relatively large, at about 25%, owing to the difficulty of obtaining accurate standards for calibration. If the fractional density of the carbon in the contaminant layer is assumed unity, the thickness of the layers will be 40, 56, and 96Å, respectively. The figure of 56Å for 10^{17} $^1H_2^+/cm^2$ agrees rather well with the 99 and 53Å recorded by the spectrophotometric technique, but the agreement is fortuitous.

Almost certainly, therefore, the contaminant was a polymer produced by the radiation decomposition of adsorbed hydrocarbons (2); the latter would be present in the atmosphere of the mass separator as vapor from the pump oils used to maintain the vacuum. The polymer would not itself be attacked by the hydrofluoric acid, but would probably contain weak spots through which the acid could penetrate to dissolve the oxide, and through which the current could start flowing on reanodization. Polymer formation would also occur during the implantation of heavy ions, but in this case, typified by the 10^{17} 39 keV $^{40}Ar^+/cm^2$ sample of Fig. 5, the contaminant layer would be removed by sputtering as fast as it was formed.

At implantation fluences of 10^{16} $^1H_2^+/cm^2$ or less, the situation was entirely different. The initial implantation differential was essentially zero, and no decelerated stripping occurred immediately; the effect developed only as sectioning was prolonged. Furthermore, the interference color on the implanted area was always uniform. This decelerated stripping cannot, therefore be due to the presence of a contaminant layer, but must be related in some way to the presence of the hydrogen itself. The mean range for 20 keV $^1H^+$ ($\equiv$ 40 keV $^1H_2^+$) can be estimated from data in the literature (19) as being about 3000Å. Up to this point, therefore, the hydrogen concentration will increase, and any effect associated with its presence should likewise increase, as observed in Fig. 7.

When the implantation energy was reduced to 25 keV, the range of the hydrogen ions decreased, and a more complete record of the decelerated stripping effect could be obtained. The result (Fig. 9) appears to be an S-shaped curve similar to those observed with accelerated stripping. Furthermore, comparison of Fig. 4 and 9 will show that the effect of varying the implantation energy seems much the same for both types of stripping, always provided that due allowance is made for the much greater range of the hydrogen ions. Despite the incompleteness of the evidence, therefore, it seems reasonable to conclude that the magnitude of the decelerated stripping effect is independent of the implantation energy, while Fig. 7 shows that there is once again a most definite dependence on the implantation fluence.

This form of decelerated stripping can therefore be interpreted in the same two ways as accelerated stripping, and the same arguments apply. The independence of implantation energy suggests that it is the physical presence of the hydrogen ions rather than radiation damage that is responsible; confirmatory evidence from reanodization or heating experiments unfortunately cannot be obtained, because the behavior of the implanted hydrogen ions under these conditions is not known. Since decelerated stripping is not observed with any of the other species, it must be related to some special property of the hydrogen itself. Presumably this is the ability to form hydrogen bonds between nearest neighbor oxygen atoms.

Implantations with hydrogen and argon.—To find out whether there was any interaction between accelerated and decelerated stripping, 10^{16} $^1H_2^+/cm^2$ were implanted at 40 keV, followed by 10^{16} $^{40}Ar^+/cm^2$ at

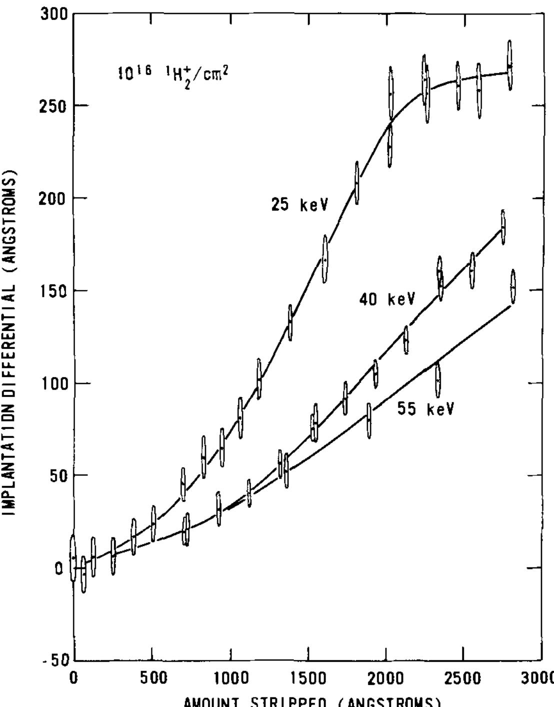

Fig. 9. Implantation differentials with hydrogen to demonstrate the effect of varying the implantation energy. Same series of implantations.

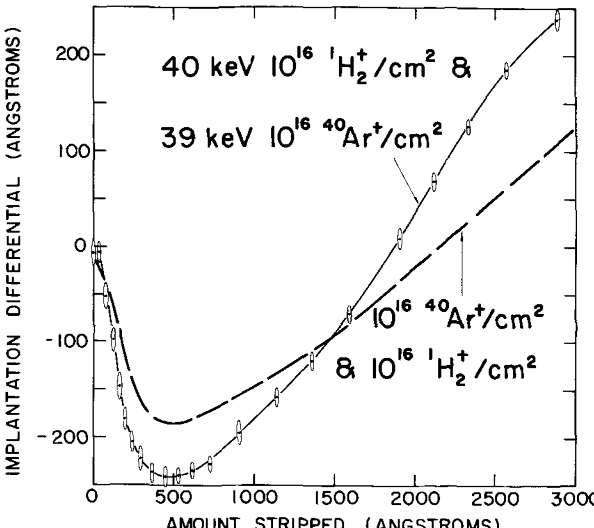

Fig. 10. Implantation differentials observed with both argon and hydrogen to demonstrate the absence of an interaction between the accelerated and decelerated stripping. Different series of implantations.

39 keV into exactly the same area; in a second experiment the implantation order was reversed. The reproducibility of the results in Fig. 10 is rather poor, but characteristic of implantations made during different series; compare, for instance the 10^{16} 39 keV $^{40}Ar^+/cm^2$ samples in Fig. 4 and 5, and the 10^{16} 40 keV $^{1}H_2^+/cm^2$ samples in Fig. 7 and 9. Within the experimental uncertainty, therefore, the effects are independent of one another, a conclusion consistent with their proposed natures.

Implantation with radioactive isotopes.—The range profile measurements reported elsewhere (2) were performed with radioactive isotopes, and these were normally prepared by (n,γ) reactions on the stable precursors. The radioactive atoms had, therefore, to be separated from a very much larger number of stable atoms. Previous experience with the mass separator had shown that the separation was by no means complete (11) and that the vast majority of the ions implanting at the radioisotope focus were in fact defocused stable isotopes (20). The fluences of these stable isotopes could be gauged from the measured beam currents, their isotopic abundances, and the known beam profiles (11), and were on occasion as much as 10^{15} ion/cm². Accelerated stripping effects could therefore be expected, and were indeed observed; their incidence and magnitude were in excellent accord with the previous observations of this paper. Two exceptional results were however obtained, both with krypton.

The first attempt to measure 0.5-2.0 keV range profiles with radioactive ^{85}Kr was performed with a total (stable ^{84}Kr) fluence of about 10^{15} ions/cm². Implantation differentials of about + 7Å were observed on receipt from the separator, and though accelerated stripping was observed, it was so nonuniform that no meaningful profiles could be obtained; indeed, it appeared from the interference colors as though some portions of the implanted area had not stripped at all. These results can be interpreted as accelerated stripping due to the presence of the krypton, combined with the presence of a carbonaceous polymer protecting the oxide against dissolution; the latter might well be present at very low energies only where the sputtering efficiency of the krypton markedly decreases. When the total implantation fluence was reduced to about 10^{13} ions/cm², these effects disappeared, and satisfactory range profiles were obtained.

The other exceptional result was observed in the specimen implanted with 160 keV $^{85}Kr^+$. To obtain this energy, a −40 kV accelerating voltage was applied to the target holder, so that the total accelerating voltage was 80 kV; by using the $^{85}Kr^{++}$ beam, the implantation energy was doubled. The intensity of the $^{85}Kr^{++}$ beams was, from the implanted activity, about an order of magnitude less than that for $^{85}Kr^+$ and no accelerated stripping was observed. When some 1800Å of oxide had been removed, however, an implantation differential of + 20Å was obtained. Since the interference color on the implanted area was uniform, this decelerated stripping would appear to be similar to that observed with hydrogen implants. It is in fact quite possible that some hydrogen was present, for krypton hydride beams have been observed in the mass separator; the most common species, $^{84}KrH^{++}$, would of course implant at the mass 85 position.

The most important question for the present investigations (2-4) was whether these variations in stripping rate would affect the measurement of range profiles. The experimental data for the latter consisted of a series of counts remaining *vs.* oxide thickness left on the implanted area, and so any variations in the overall magnitude of the stripping rate were of no consequence; what did matter was that the variation should be the same all over the 2.0 × 0.4 cm area implanted. From the behavior of the interference colors, this was certainly not true for the $^{85}Kr^+$ implanted at very low energy and high fluence, but it did appear to be true for the accelerated stripping. This was confirmed by comparing range profiles for $^{134}Cs^+$, obtained in the presence of about 15Å of accelerated stripping, with those for $^{125}Xe^+$ obtained in its absence. Since xenon and cesium have almost the same atomic mass, the range profiles are expected to be almost identical; the results reported elsewhere (2) will show that they were.

Comparison with Related Studies

The sputtering of anodic tantalum oxide leads to a decrease in the film thickness, and hence to a change in the interference color. This property can be used to establish the geometry of a sputtering beam, as Nielsen and Shepherd (21) have suggested; the sensitivity of the technique could be much enhanced by making use of the accelerated or decelerated stripping effect as well. Nghi and Kelly (22) have investigated the sputtering process by comparing changes in interference color with a standard color gauge; the magnitude of the effect they observed is consistent with that reported here.

Hill (6) bombarded anodic tantalum oxide with 15 keV electrons, and observed decelerated stripping in the HF-NH_4F reagent. His irradiations were conducted in an oil-pumped vacuum system at 5 × 10^{-6} Torr, with the sample surrounded by a cold finger at liquid nitrogen temperature; the latter was intended to prevent the adsorption of pump oil molecules on the specimen surface. A similar cold finger was present in the target chamber of the oil-pumped mass separator used in the present experiments and the pressure approached 1 × 10^{-6} Torr; nevertheless, decelerated stripping due to a carbonaceous polymer was still observed in the absence of sputtering. Since Hill noted that his etching was somewhat uneven, his decelerated stripping can definitely be attributed to the presence of a carbonaceous contaminant.

Conclusions

The effect of ion implantation on anodic tantalum oxide has been examined with the following results.

1. Implantation with heavy ions led to sputtering. The effect decreased with decreasing ion mass and implantation fluence, and was not observed with hydrogen.

2. On sectioning a specimen implanted with heavy ions, the implanted area was found to dissolve more rapidly in the HF-NH_4F reagent. This accelerated stripping has been attributed to the physical presence of the implanted ions.

3. When $^1H_2^+$ was implanted to a fluence of 10^{17} ions/cm^2, a carbonaceous contaminant, some 50-100Å thick, was formed on the oxide surface, due to the radiative decomposition of adsorbed pump oil molecules. The resulting polymer protected the oxide against further anodization and against dissolution in HF-NH_4F.

4. When $^1H_2^+$ was implanted to fluences between about 10^{13} and 10^{16} ions/cm^2, the implanted area dissolved more slowly. This decelerated stripping was attributed to the presence of the hydrogen itself, possibly by forming hydrogen bonds between neighboring oxygen atoms.

5. No accelerated or decelerated stripping was observed with fluences of 10^{13} ions/cm^2 or less.

6. Implantations with radioisotopes showed that accelerated stripping had no effect on the sectioning procedure, at least for implantation fluences below 10^{15} ions/cm^2.

Acknowledgments

The author expresses his thanks to O. Westcott for the ion implantations and to D. Phillips for sectioning the oxides. He is grateful to J. Ord at the University of Waterloo, Waterloo, Canada, for the ellipsometric measurements, and to P. B. Sewell of the National Research Council, Ottawa, Canada, for using his x-ray technique to detect the carbon in the contaminant. J. A. Davies and D. Santry read the manuscript, and made valuable suggestions for improvement.

Manuscript submitted March 19, 1973; revised manuscript received Aug. 10, 1973.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1974 JOURNAL.

Nucleation of Copper Electrodeposits on Thin (111) Films of Evaporated Copper

Yasusada Ueno, Nobuyuki Kidokoro, and Masayasu Tsuiki*

Department of Industrial Chemistry, Gifu University, Kagamihara, Gifu, Japan

ABSTRACT

Electrodeposited nuclei and defect structures on thin (111) films of evaporated copper were studied by means of electron and optical microscopes and electron diffraction, as a part of an investigation of copper nucleation from sulfate baths. The roles of noncoherent twin boundaries on the films were of limited significance in the nucleation. Macroscopic defects such as notches and macrosteps on the surface with mirror luster were preferential nucleation sites. The rate of nucleation in the initial stage was evaluated under various overpotentials.

In studies of nucleation of copper electrodeposits, it is necessary to determine whether defect structures on the cathode surface are responsible for nucleation or not. The single-crystal film of evaporated copper would be suitable as cathode substrates for this purpose because the deposited nuclei and defect structures on the film can be observed simultaneously by transmission electron microscope. Fundamental studies on the preparation of the epitaxial film of evaporated copper under high vacuum and on the electrodeposition of copper on the film have been carried out (1-3). Electrocrystallization of copper from sulfate solution on the thin (111) film of evaporated copper, which contains noncoherent twin boundaries and macrosteps as well as mechanical notches, is described in this paper. Distribution of nuclei in the vicinity of these defects were observed by electron and optical microscopes. The number of deposited nuclei on the cathode, which did not contain macroscopic defects, was counted with time during potentiostatic cathodic polarization. Distribution of nuclei near twin boundaries and the effects of surface defects on nucleation and its rate are also discussed.

Key words: electrocrystallization, copper single-crystal film, nucleation.

Experimental

The vacuum apparatus for the preparation of copper (111) film was the same as the one in the previous report (1). Thin film of 500-1000Å was prepared for transmission electron microscopy so as to facilitate penetration of an electron beam. On the other hand, thick film was made use of in other experiments. The surface of the epitaxial (111) films was optically mirror-smooth except for cleaved steps, when the films were prepared on a freshly cleaved mica substrate held at about 200°C under 1×10^{-5} Torr of residual gas pressure and with an evaporation rate of the order of about 10 Å/sec. The (100) films were also pre-

pared on a cleaved surface of potassium bromide by the same procedure, if necessary. Presence of noncoherent twin boundaries in the films was ascertained by transmission electron micrographs and diffraction patterns of the sample removed from the substrate.

Epitaxial copper films of about 1.5 × 1.5 cm^2 area were cut with a mica base and were used as the cathode. Specimens were cleaned with trichloroethylene under ultrasonic vibration for 2 min, rinsed in a stream of alcohol, and finally with triply distilled water prior to experiment. The surface still kept a mirror luster. The cathode assembly and the plating cell used are shown in Fig. 1. The specimen was placed at least 3 mm from the cell bottom so as to keep uniform current distribution. Observation of nucleation was also carried out simultaneously. A potentiostat (Hokuto Model P.S. 1000) was used as the power source. The cathode was polarized in the range of 20-90 mV *vs.* the static potential of a pure copper electrode immersed in a solution of the same composition as that of the plating solution. The current with time was recorded during electrolysis (with a Rikendenshi Model 42 X-Y recorder).

In order to avoid dissolution of electrodeposited nuclei and cathode films, a neutral solution containing only 200 g/liter copper sulfate was prepared. Then, the solution was treated with active carbon, and its pH was adjusted to about 2 by pre-electrolysis with a platinum anode. The solution was stored in contact with a piece of metallic copper. Nevertheless, Cu_2O deposition from this electrolyte was hardly possible at the initial stage of electrolysis. Color change of cathodic surface based on Cu_2O deposition is easily detectable by *in situ* optical observation. The unexpected results obtained from such oxidized specimens were entirely excluded. But a trace amount of nondetectable codeposition of Cu_2O may be ignored.

The electrodeposited layer for transmission electron microscopy was washed immediately with water, dried in air, and then coated with an acetone solution of cellulose acetate. Since the copper layer adhered strongly to the coated layer, it could be stripped off the mica substrate by pulling one end of the coated layer. After the dissolution of the coated layer in acetone, the residual copper film was held on a sheet mesh and examined by electron microscope (Nihondenshi Model JEM T-7).

Results and Discussion

Electrodeposited nuclei on very thin films.—Noncoherent twin boundaries parallel to the <110> direction on the (111) plane of the fcc lattice is observed only when the electron beam is perpendicularly incident on the film surface. Observation is not always possible due to nonuniformity of the fine structure. A typical example of the thin (111) film of evaporated copper, about 500Å thick, is shown in Fig. 2. A selected area diffraction pattern in this region is shown in Fig. 3. In this figure, extra diffraction spots of n/3{$\bar{4}$22} type were recognized in the positions not expected from the perfect fcc lattice. Such extra spots had already been explained as an evidence of noncoherent twin boundaries in silver films by Allpress and Sanders (4). Similar explanations in copper films are also possible, and extra spots found in Fig. 3 are attributable to the diffraction from the three sets of the boundaries, which are parallel to the {211} plane; these planes are normal to the film surface and mutually inclined by 120°. It is, therefore concluded that noncoherent twin boundaries in Fig. 2 arise from the mutual contact of copper nuclei which occupied a double position (5) on a mica substrate during evaporation. Since the atomic arrangement on such a disturbed region is different from that of the perfect fcc structure, vacancies or interstitials must appear from mismatching between boundaries and bulk parts. This atomic configuration of boundaries is described by constructing a marble ball model as shown in Fig. 4. The dislocation density in the vicinity of such boundaries is much larger than that in other parts, and hence, the boundary region would become an active site of nucleation for electrocrystallization. An example supporting this concept had been demonstrated as a result of preferential

nucleation of silver deposits on twin or high angle grain boundaries of annealed silver surfaces by Kilner and Plumtree (6). On the electrodeposition of copper on a (100) film of evaporated copper, Sard and Weil (7) suggested correlation between the twin density of the substrate and the extended pyramidal growth. Therefore, electrocrystallization of copper was performed in our experiment to explore the role of a noncoherent twin boundary in the nucleation of the deposits.

Figure 5 shows an electron micrograph of nuclei electrodeposited at 25°C with polarization of 70 mV on a surface region containing noncoherent twin boundaries. Some other experiments were carried out under 20-70 mV, and similar results were obtained. The electrodeposited nuclei on the film surface were widely distributed in nature, and aggregation of deposits along the noncoherent twin boundaries was not necessarily observed in this case.

When the cathodic overpotential decreases, noncoherent twin boundaries are expected to become more sensitive nucleation sites. A typical photomicrograph at 25 mV of polarization is shown in Fig. 6. The percentage of the number of nuclei in contact with noncoherent twin boundaries in the total number of nuclei can be determined from Fig. 6 and other photomicrographs obtained at the same overpotential. In this instance, the nuclei smaller than 0.05 μm in diameter are liable to be confused with faults, so such small nuclei are not counted. The percentage is shown by open circles in Fig. 7 as a function of twin boundary density. It is noticed that these values do not exceed 16%.

On the other hand if we assume that nucleation sites are independent of the presence of noncoherent twin boundaries, then the percentage of the number of nuclei in contact with noncoherent twin boundaries on

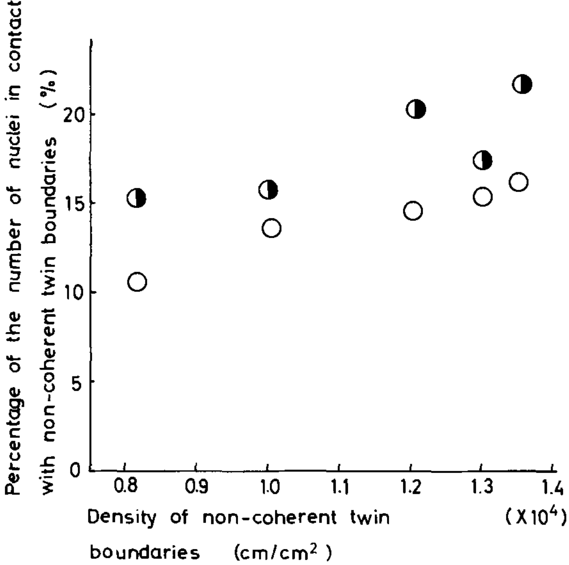

Fig. 7. Ratio of nuclei in contact with noncoherent twin boundaries to the total number of nuclei per unit area. Overpotential, 25 mV. Charge passed, 0.033 coulomb/cm^2. ○, Observed value; ◑, calculated value.

the electrodeposited surface can be evaluated by Eq. [1]

$$Nc/Nt = (L\overline{D} + n\pi\overline{D}^2/4)/\text{cm}^2 \quad [1]$$

where the size of the nuclei is constant and the distribution of the nuclei is homogeneous. Nc and Nt are the number of nuclei in contact with twin boundaries and the total number of nuclei per unit area, respectively. L and n are the total length and the number of intersection lines between a twinning plane and the film surface, respectively, in the observed area. $\overline{D}$ is the average diameter of deposited nuclei. Percentages estimated from Eq. [1] are represented by the semifilled circles in Fig. 7. Although these estimated values are somewhat higher than the values determined from the photomicrographs, the difference between the two sets of data is within 35%. In addition, the observed number of nuclei in contact with twin boundaries was always less than that expected from Eq. [1]. Consequently, it seems that the noncoherent twin boundary is less sensitive as a nucleation site than other active sites such as a step with screw dislocation.

On the contrary, Sard and Weil have shown that coherent twin boundaries on thin (100) films of evaporated copper played important roles for pyramidal or rooftop growth under galvanostatic conditions. A further experiment was made on copper electrodeposition on the (100) films with coherent twin boundaries

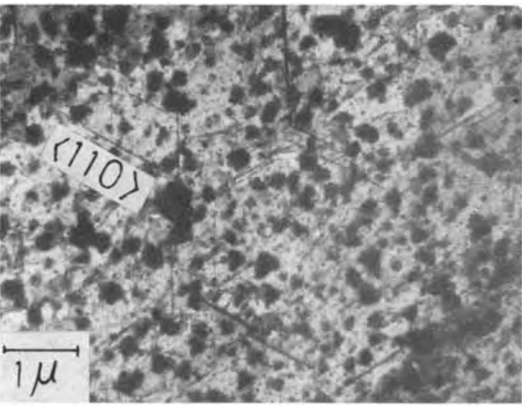

Fig. 5. Electrodeposited nuclei on the region containing noncoherent twin boundaries. Overpotential: 70 mV, (111) surface. Charge passed, 0.06 coulomb/cm^2.

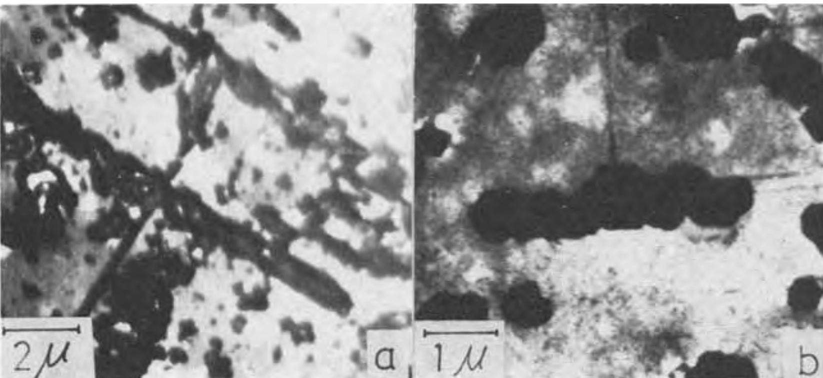

Fig. 8. Electrodeposited nuclei on (100) films of evaporated copper. Overpotential: a, 70 mV; b, 20 mV.

under potentiostatic conditions. The results obtained at 70 and 20 mV are shown in Fig. 8a and b. It can be seen that nucleation occurs on the coherent twin boundaries in the <110> direction and in the vicinity of canals, which arise during the evaporation of the film. Thus the contribution of twin boundaries is much more evident on a (100) plane than on a (111) plane. Although the comparison of roles as nucleation sites of twin boundaries on the (111) plane with that on the (100) plane is interesting, it is difficult to interpret the role of twin boundaries themselves in the above results because the film contains other defect structures such as narrow canals between island structures, at the film thickness, which permitted the observation of twin boundaries. It is, however estimated that the nucleation rate on the (111) planes in a fcc lattice is larger than that on the (100) planes (8) and the nucleation energy of a two dimensional nucleus with (111) preferred orientation at lower overpotential is lower than that of the (100) preferred orientation (9). Thus it is presumed that the contribution of microscopic defects to preferential nucleation is of limited significance on the (111) planes, where nucleation occurs easily.

Effects of macroscopic defects on preferential nucleation.—Macroscopic defects on (111) films of evaporated copper, such as mechanical notches and macrosteps which depend on cleavage steps of the mica substrate, will also be regarded as preferential nucleation sites for electrodeposition. For this observation, highly perfect films, more than 5000Å thick, were used as substrates to avoid fracture of the film due to notched lines or macrosteps. Electrodeposits on such a surface consist of relatively few nuclei with larger size than those on very thin films, whereby optical microscopy is available for observation of deposits.

Figure 9 shows an optical micrograph of deposits along mechanical notches scratched by a knife edge. It was found that preferential nucleation occurred in the distorted region on the notches. Similar results were obtained by the observation of electrodeposits on the specimen containing macrosteps, which conformed to the cleaved step of a substrate as shown in Fig. 10. From these photographs, it was revealed for preferential nucleation of electrodeposits that the effect of macroscopic defects is larger than that of microscopic defects such as twin boundaries on (111) films of copper.

Now, for the investigation of nucleation rate, it is necessary to perform the electrodeposition on the surface, which is free from mechanical notches or macrosteps. Noncoherent twin boundaries presumably do not affect the preferential nucleation in this case. But the forms of nuclei were affected strongly by the topography of film surfaces. Isolated nuclei with geometrical forms emerged from the film with a mirror-smooth surface as shown in Fig. 11, but the number of nuclei on an uneven film was no longer countable in the photomicrograph. On such a surface, layer growth developed after a long time deposition, as shown in Fig. 12. Therefore, former types of evaporated films

were selected as cathode specimens in the observation of the nucleation process. In this case, electrodeposited nuclei were distributed uniformly on the film surface.

Nucleation process at the initial stage of electrodeposition.—Figure 13 shows the density of electrodeposited nuclei as a function of deposition time in a 200 g/liter (0.8M) copper sulfate solution. The data in a dilute solution (0.27M) is shown in Fig. 14. The number of nuclei rapidly increased in the initial stage of deposition and then gradually decreased via a maximum value due to coalescence of growing nuclei. After the nucleation was completed at the initial overpotential, increasing the overpotential abruptly caused nucleation of the second stage. Then the nucleation continued until nucleation sites were saturated at the higher potential. It is noticed that the number of effective nucleation sites is held constant at an applied potential. However, the maximum values of effective nucleation sites differ from one substrate to another due to nonuniformity of the fine structure, even at the same condition. Therefore, the data presented above were those obtained by the measurement on a set of specimens which were cut off from the substrate with an epitaxial copper piece of mirror-smooth surface topography. If we assume that the nucleation process obeys the first order kinetics, the reaction rate is as follows

$$\frac{dN}{dt} = A(No - N) \quad [2]$$

$$N = No(1 - e^{-At}) \quad [3]$$

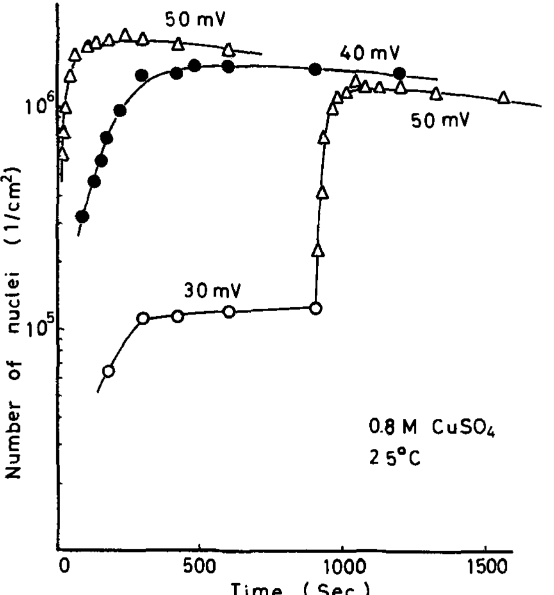

Fig. 13. Number of nuclei as a function of depositing time

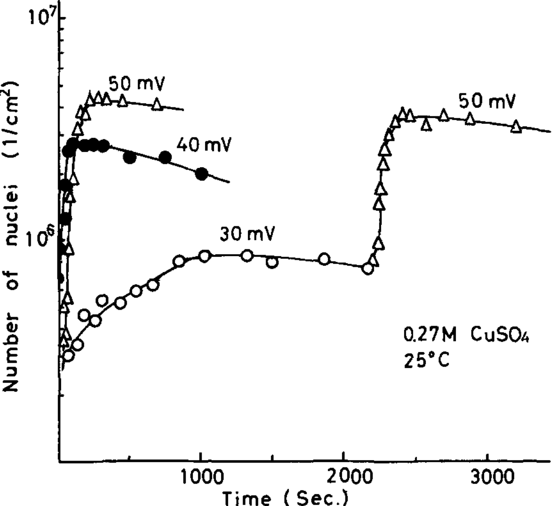

Fig. 14. Number of nuclei as a function of depositing time

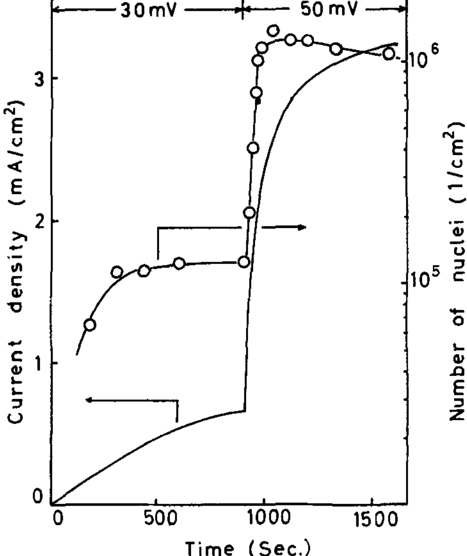

Fig. 15. Current density and number of nuclei vs. depositing time (overpotential was changed abruptly in the course of deposition).

or

$$A = \frac{1}{t} \ln \frac{No}{No - N} \quad [4]$$

where N is the number of deposited nuclei at time t, and No the maximum number of nuclei evaluated from the figure. The rate constant, A, from Eq. [4] is summarized in Table I. These values are useful for calculation of the number of nuclei over the rapid nucleation processes. Therefore, it is roughly assumed that multiplication of depositing nuclei on the cathode film with mirror-smooth surface obeys the first order process. From Table I, it is noted that the nucleation process is enhanced by the increase of the overpotential and the decrease in the metal ion concentration in the electrolyte. Finally, Fig. 15 shows an example of vari-

Table I. Rate constants of nucleation A (1/sec)

50	0.020	0.065
50*	0.021	0.10

* Values obtained after the applied overpotential changed from 30 to 50 mV.

ation of current density and number of nuclei with depositing time. Since the deposition current is sensitive to the change in the number of nuclei, it is likely that the step propagation process or layer growth scarcely occurred and the formation or the growth of nuclei was dominant.

Summary

1. Deposited nuclei and noncoherent twin boundaries on thin (111) films of evaporated copper were simultaneously observed by transmission electron microscopy under limited conditions.

2. Number of nuclei in contact with noncoherent twin boundaries was less than 16% of that of the total deposited nuclei at 25 mV of overpotential.

3. Mechanical notches and macrosteps on the film provide the nucleation sites for preferential deposition.

4. Nucleation rate obeys the first order kinetics in the initial stage.

Mechanism of Electrocrystallization

T. Vitanov, A. Popov, and E. Budevski

Division of Electrochemical Power Sources, Bulgarian Academy of Sciences, Sofia, Bulgaria

ABSTRACT

The mechanism of silver deposition on electrodes representing a cubic plane of silver single crystal with known surface topography was investigated. The exchange current densities on dislocation-free intact planes and on stepped planes with exactly known step density were obtained by impedance measurements at high frequencies. It has been found that the exchange current density $i_{o,st}$ of the charge transfer reaction

ion in solution ⇄ atom on a step

is about three orders of magnitude higher than the exchange current density $i_{o,ad}$ of the reaction

ion in solution ⇄ adion on a close packed plane

The comparison between experimental and calculated values of both the rate of propagation of monolayers and the slope of current-square overvoltage relation has shown that the direct transfer mechanism plays a predominant role in metal deposition. The contribution of surface diffusion is negligible.

Two possible ways of ion incorporation into the crystal lattice can be considered in the process of metal deposition: (*i*) ions are discharged at any site of the crystal surface and are transported afterwards by surface diffusion to the sites of growth where they are incorporated, this is what we call the surface diffusion mechanism; (*ii*) ions are directly discharged on a growth step or on a growth site with simultaneous incorporation, this we call the direct transfer mechanism.

Although the question which of these two possible paths prevails in metal deposition is of crucial interest for the understanding of the process, no answer to the problem can be considered adequate as yet. In earlier theoretical treatments the second path has been shown to be connected with prohibitively high activation energy (1) and was completely disregarded. Inspired by some experimental results of the authors of this paper a new approach to the problem was recently made by Despic (2) who showed that the second path is by no means negligible. Anyway, the theoretical treatment appears to be rather complicated and uncertain.

The experimental investigation of the process also failed to give a clear answer to the problem. This is mainly due to the fact that the crystallographic character of the electrode surface under normal experimental conditions is completely unknown not to mention the detailed surface topography.

Theoretical Background

The idea that surface diffusion can be considered as rate controlling in electrochemical metal deposition was suggested by Brandes (3) as early as 1929. The first quantitative treatment was given by Lorenz (4) who adapted the theory of Burton, Cabrerra, and Frank (5) to the case of metal deposition. Later, the problem was treated by Vermilyea (6), Fleischmann and Thirsk (7), Damjanovic and Bockris (8), and Schnittler (9), who brought the theory of surface diffusion mechanism to its present state.

The equation which describes the overvoltage dependence of the current at steady-state conditions has

Key words: electrodeposition, silver, dislocation-free plane, crystal growth, exchange current.

generally the form

$$i = i_{o,ad} \left[e^{\frac{\alpha z F}{RT} \eta} - e^{-(1-\alpha)\frac{zF}{RT}\eta} \right] \frac{\lambda_o}{x_o} \tanh \frac{x_o}{\lambda_o} \quad [1]$$

where

$$\lambda_o = (zF\, D_s\, C^o_{ad}/i_{o,ad})^{1/2}\, e^{-\frac{\alpha z F}{2RT}\eta}$$

is the surface diffusion penetration, D_s is the surface diffusion coefficient, C^o_{ad} the equilibrium concentration of adions. $i_{o,ad}$ the exchange current density of ions in solution with adions and $2x_o$ the average step distance. The latter can be expressed also by the step density (number of steps per unit length in cm^{-1}) or the equivalent quantity L, the total length of growth steps per unit area in cm/cm^2: $2x_o = 1/L$.

Two limiting cases can be distinguished:

(*i*) The surface diffusion penetration is greater than the average step distance ($\lambda_o >> x_o$). For that case Eq. [1] gives the Butler-Volmer relation, *i.e.*, the charge transfer dominates the process.

(*ii*) The surface diffusion penetration is smaller than the average step distance ($\lambda_o << x_o$). For that case we obtain from [1]

$$i = i_{o,ad} \left[e^{\frac{\alpha z F}{RT}\eta} - e^{-(1-\alpha)\frac{zF}{RT}\eta} \right] \frac{\lambda_o}{x_o} \quad [2]$$

The surface diffusion has a predominant role. The current is strongly influenced by the step density.

The direct transfer mechanism was suggested for the first time by Volmer (10) and was discussed later in the works of Lorenz (4), Fleischmann and Thirsk (7), Gerischer (11), Mott and Watts-Tobin (12), and others. A quantitative expression for this case can be derived in a very simple way and can be found, *e.g.*, in (13). Denoting with $i_{o,st}$ the exchange current density of ions in solution with atoms on a step (or kink) the current density is given by

$$i = i_{o,st}\, 2r_o\, L \left[e^{\frac{\alpha z F}{RT}\eta} - e^{-(1-\alpha)\frac{zF}{RT}\eta} \right] \quad [3]$$

where r_o is the atomic radius in the crystal lattice.

It can be easily seen that no clear distinction between the two mechanisms can be obtained using steady-state measurements only. In both cases the over-all exchange current density obtained from the slope of the current-overvoltage relation for small overvoltage

$$i_o = \frac{RT}{zF} \left(\frac{di}{d\eta} \right) \quad [4]$$

contains the step length L. In the case of surface diffusion

$$i_o = i_{o,ad}\, 2L\, \lambda_o \tanh \frac{1}{2L\, \lambda_o} \quad [5]$$

and in the case of direct transfer

$$i_o = i_{o,st}\, 2r_o L \quad [6]$$

In the second case i_o is proportional to L regardless of step density. In the first case a proportionality exists only for small densities ($2L\,\lambda_o < 1$). For higher step densities i_o becomes independent of L and the process is purely charge transfer controlled. It is clear that in the case where the surface diffusion is manifested, no distinction between the two mechanisms can be made.

Transient and high frequency impedance measurements can give additional information in that respect. The frequency dependence of impedance in the case of electrocrystallization was treated first by Lorenz (4) and later by other authors (7, 14, 15). At high frequencies the equivalent circuit of the charge transfer reaction can be represented by a resistance parallel to the double layer capacitance. It can readily be shown [c.f. Vetter (13)] that in the case of surface diffusion this resistance is given by

$$R_{F,SD\,(\omega \to \infty)} = \frac{RT}{zF} \cdot \frac{1}{i_{o,ad}} \quad [7]$$

At high frequencies the surface diffusion penetration becomes negligible in comparison to the step distance and the contribution of the surface diffusion to the impedance can be neglected; the exchange current density does not depend on step density.

Contrary to this the parallel resistance R_F in the case of direct transfer will be given by

$$R_{F,DT\,(\omega \to \infty)} = \frac{RT}{zF} \cdot \frac{1}{i_{o,st} \cdot 2r_o L} \quad [8]$$

and should depend on the step density. This gives a possibility to distinguish between the two mechanisms, and with a known value of L to obtain the exchange current density $i_{o,st}$ of ions on a step or kink site.

Experimental Technique

The experimental technique for the preparation of electrodes representing a single-crystal plane only (16-19) offers the possibility for a very detailed investigation of the mechanism of electrocrystallization. The most remarkable advantage of these electrodes is that they can be prepared with an exactly known surface topography and number of screw dislocations, or even without screw dislocations. Three very important surface configurations can be obtained: (*i*) Dislocation-free plane with atomically smooth surface (18, 19). (*ii*) Dislocation-free plane with a monoatomic step of known length; on a dislocation-free plane a new monoatomic step can be produced by nucleation and growth of a new lattice net (18-20). The propagation of the monolayer can be stopped at any desired position by switching off the current. (*iii*) Stepped plane with a known uniform step density: a plane with few screw dislocations (low dislocation density) can be grown at a constant overvoltage until a regular pyramidal growth pattern is obtained.

According to Frank's theory the distance between successive turns of the spiral is inversely proportional to the overvoltage. For a polygonal spiral growth from simple geometrical reasoning one obtains the relation (5b, 21)

$$2x_o = \frac{1}{L} = \frac{\gamma\, \epsilon\, V_m}{zFh\, \eta} \quad [9]$$

where V_m is the molar volume, ϵ the specific edge energy, γ a coefficient depending on the spiral geometry, and h the step height. From the experiments described in (18, 19), it follows that the current is proportional to the length L of the growing step and the overpotential

$$i = K\, L\, \eta \quad [10]$$

In the case of a spiral growth the total step length per unit area L, *i.e.*, the step density, can be given by $\frac{1}{2x_o}$, so that for the current density from [9] and [10] we obtain

$$i = K \frac{zFh}{\gamma\, \epsilon\, V_m} \eta^2 \quad [11]$$

This equation was experimentally verified in the case of silver deposition from aqueous solutions and melts of silver nitrate on cubic and octahedral planes of silver single crystals (22, 23).

Mechanism of Metal Deposition

Information obtained from dislocation-free planes.—A dislocation-free intact plane behaves as an ideally polarizable electrode in the region between 0 and 10 mV cathodic overvoltage. Double layer capacity is

easily determined by impedance or galvanostatic transient measurements. A typical value of

$$C_{DL} = 30\ \mu F \cdot cm^{-2}$$

was found for the cubic plane of silver in 6*N* silver nitrate solution.

Impedance measurements at high frequencies allow one to estimate the resistance of the charge transfer reaction

ion in solution ⇄ adion on a close packed plane

For this resistance which is parallel to the double layer capacity a value of 0.45 ohm-cm² was found. From this value the corresponding exchange current density

$$i_{o,ad} = 0.060 \pm 0.001\ A\ cm^{-2}$$

of the charge transfer reaction of adions on a perfect cubic plane of silver in 6M silver nitrate solution was obtained (25, 26).

The frequency dependence of the impedance and galvanostatic transients could be used to estimate the adsorption capacity and the adion concentration, respectively. The frequency dependence of impedance and the transients are however far too complex to permit an easy interpretation (26).

A very rough estimation of the adion concentration from galvanostatic transients can be made as follows: the time constant for double layer charging calculated from double layer capacity and the resistance of the charge transfer reaction is approximately 13 μsec. The slope of the galvanostatic transient (Fig. 1) at twice that time gives a capacity of *ca.* 40-50 $\mu F\ cm^{-2}$, leaving for the adsorption capacity a maximum value of 10-20 $\mu F\ cm^{-2}$. This corresponds to an adion concentration $C^o_{ad} = (2\text{-}5) \times 10^{-12}$ mol cm^{-2}.

Information obtained from stepped planes.—Impedance measurements on stepped planes have shown that the charge transfer resistance depends strongly on step density. It can be therefore assumed that two parallel charge transfer reactions are taking place

(*i*) ion in solution ⇄ adion on a close packed plane

(*ii*) ion in solution ⇄ atom on a step

with exchange C.D. $i_{o,ad}$ and $i_{o,st}$, respectively. The over-all exchange current density is then the sum of both.

The results of two sets of measurements performed on a cubic plane of a silver single crystal in 6M $AgNO_3$ at 45°C are shown in Table I. The first two columns in Table I present the preparation conditions of the plane.

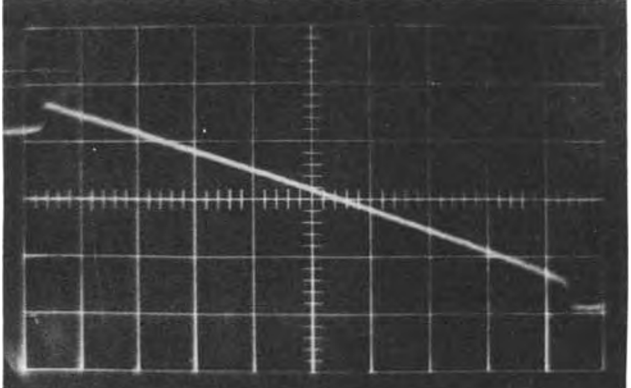

Fig. 1. Overvoltage transient on a dislocation-free cubic plane. $i = 2.7 \times 10^{-2}$ A cm^{-2}; vertical sensitivity: 5 mV/cm; time base: 2 μsec/cm.

The third column gives the overvoltage corrected for the ohmic drop and concentration polarization. The correction is made on the assumption (22) that for low η values both terms depend linearly on current density, while according to Eq. [11] the discharge overpotential term is proportional to $\sqrt{i}$. Plotting $\frac{\Delta E}{i}$ as function of $\frac{1}{\sqrt{i}}$ one obtains a straight line, where the slope is equal to $\left(K \frac{zFh}{\gamma \epsilon V_m}\right)^{-1/2}$ and the intercept contains the coefficients of the linear terms. The additional terms connected with the semicylindrical configuration of the mass transport to the steps is negligible as can be calculated from equations given by Gerischer (11) having in mind the small step distance ($2x_o < 10^{-4}$ cm) in this case. The fourth column gives the over-all exchange current densities i_o measured immediately after switching off the growth current.[1]

[1] It is assumed that the step density does not change after switching off the growth current and during the measurements. This assumption for (100) plane is backed by the constancy of the surface topography and the impedance values during 30 min after switching off the cathodic current. Similar observations on the (111) plane show a visible flattening of the pyramids' tops accompanied by a strong change of the impedance with time. Therefore it was not possible to measure the dependence of i_o on *L* on the (111) plane.

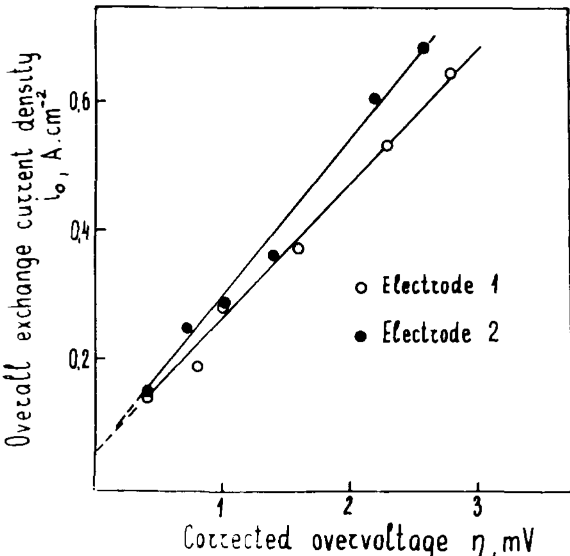

Fig. 2. Dependence of the exchange current density on a stepped cubic plane on the preparation conditions.

It is clearly seen (Fig. 2) that there is a linear dependence between the over-all exchange current density and the overvoltage at which the plane was prepared. The limiting value of i_o, determined by the intercept of the i_o/η relation is numerically equal to the value of $i_{o,ad}$, measured on a dislocation-free atomically smooth plane. The fifth column gives the difference Δi_o between the over-all exchange current density and $i_{o,ad}$ and the next one, the ratio $\frac{\Delta i_o}{\eta}$, which is constant over the entire range of overvoltages studied.

Since according to Frank's theory the step density L is proportional to η (Eq. [9]), the constancy of $\frac{\Delta i_o}{\eta}$ shows that a magnitude characteristic for the steps has been obtained. This magnitude can be expressed as exchange current per unit step length

$$i^*_{o,st} \equiv \frac{\Delta i_o}{L}\ [\mathrm{A \cdot cm^{-1}}]$$

From [9]

$$i^*_{o,st} = \frac{\Delta i_o}{L} = \frac{\Delta i_o}{\eta}\frac{\gamma \epsilon V_m}{z\mathbf{F}h} \quad [12]$$

The term $\frac{\gamma \epsilon V_m}{z\mathbf{F}h}$ can be eliminated using Eq. [11] so that $i^*_{o,st}$ can be determined from

$$i^*_{o,st} = K\,\Delta i_o \frac{\eta}{i} \quad [13]$$

The constant K in Eq. [13] was obtained by measuring the dependence of the propagation rate θ of steps from overvoltage according to (23) (Fig. 3), while

$$\theta = K\frac{V_m \eta}{z\mathbf{F}h}\ [\mathrm{cm \cdot sec^{-1}}] \quad [14]$$

A value of 1.77×10^{-4} ohm^{-1} cm^{-1} was found for K.

The values of $i^*_{o,st}$ at different preparation conditions are represented in column 6. It is clearly seen that $i^*_{o,st}$ is a constant which does not depend on the preparation conditions. This quantity is related to the exchange current density $i_{o,st}$ of the direct transfer reaction. Assuming that the ion exchange takes place at a distance from the step edge not exceeding the thickness of one atomic row added to the step, the current density of the direct charge transfer reaction can be obtained by dividing $i^*_{o,st}$ with this thickness, which

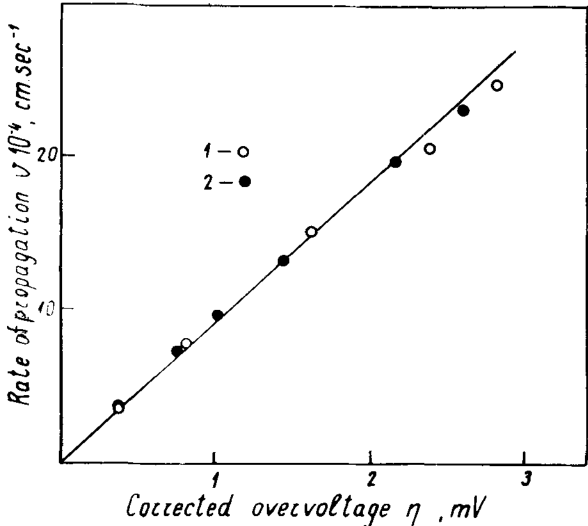

Fig. 3. Overvoltage dependence of the propagation rate of spiral steps on a cubic plane.

for the cubic plane is equal to the diameter of the silver atom in the crystal lattice $2r_o = 2.88 \cdot 10^{-8}$ cm, *i.e.*

$$i_{o,st} = 180 \pm 24\ \mathrm{A\,cm^{-2}}$$

This value is about three orders of magnitude higher than the $i_{o,ad}$ value for adions. This fact might be considered as contradicting the theoretical calculations of Conway and Bockris (1). However considering the case of ion discharge on the edge of a growth step, Despic (2) showed recently that the discharge on a step can proceed almost barrierless.

Steady-state deposition mechanism.—We can now return to the case of a steady state, to discuss which of the two mechanisms is prevailing in metal deposition: (*i*) the surface diffusion mechanism or (*ii*) the direct transfer mechanism.

The experimental current-square overvoltage dependence on a plane with screw dislocations has shown that the current is proportional to the step length. This fact is consistent with mechanism (*ii*), but agrees also with mechanism (*i*) under the condition that the surface diffusion penetration λ_o is smaller than the minimum value of the half distance of the steps over the entire range of experimental conditions, where the validity of the current-square overvoltage law was confirmed, *i.e.*

$$\lambda_o < x_{o,min} = \frac{\gamma \epsilon V_m}{2z\mathbf{F}h\,\eta_{max}} \quad [15]$$

In order to distinguish between the two mechanisms, it is necessary to know not only the value of $i_{o,ad}$ and $i_{o,st}$, but also that of λ_o. The estimation of the latter is however impossible since the value of D_s is unaccessible. An evaluation of the maximal value of λ_o nevertheless is feasible with the aid of the relation

$$x_{o,min} = \frac{K}{2\left(\frac{di}{d\eta^2}\right)}\frac{1}{\eta_{max}} \quad [16]$$

which is obtained from Eq. [9] and [11]. With $\frac{di}{d\eta^2} = 7.2 \times 10^3$ AV^{-2} cm^{-2} (Fig. 4), $K = 1.77 \times 10^{-4}$ ohm^{-1} cm^{-1}, and $\eta_{max} = 3$ mV, one obtains $\lambda_o < 4 \times 10^{-6}$ cm.

We can now compare the contributions of the surface diffusion and that of direct transfer to the deposition process using experimental and calculated values of the propagation rate of monosteps. From the measurements of the kinetics of advance of monolayers (24) and the rate of propagation of spiral steps (Fig. 3)

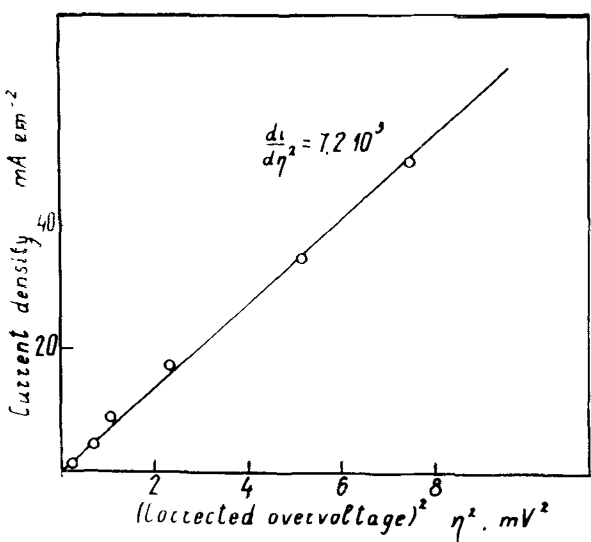

Fig. 4. Current-square overvoltage plot obtained on a cubic plane

a value $\theta_{exp} = (0.92 \text{ to } 1.04)\ x\eta$ cm · sec^{-1} (η in volts) was found.[2]

The rate of propagation can be calculated from the current density i and step density L according to

$$\theta = \frac{iV_m}{z\mathbf{F}hL}$$

in the case of direct transfer and surface diffusion using the theoretical i/η relations [2] and [3].

For small η values in the case of surface diffusion we have

$$\theta_{SD} = \frac{i_{o,ad}V_m 2\lambda_o}{RTh}\eta \quad [17a]$$

and in the case of direct transfer

$$\theta_{DT} = \frac{i_{o,st}V_m 2r_o}{RTh}\eta \quad [17b]$$

A comparison between calculated and experimental results can also be made in terms of the current-square overvoltage law

$$i = B\eta^2$$

The experimental value of B is 7.2×10^3 AV^{-2} cm^{-2} (Fig. 4). The constant B can be calculated for both mechanisms using the values of $i_{o,ad}$ and $\Delta i_o/\eta$, determined by impedance measurements.

In the case of surface diffusion after linearization for low η values and having in mind relation [15], Eq. [2] yields

$$i < \frac{i_{o,ad}}{\eta_{max}}\frac{z\mathbf{F}}{RT}\eta^2 \quad [18a]$$

For direct transfer the constant B can be estimated from the relation

$$i = \frac{\Delta i_o}{\eta}\frac{z\mathbf{F}}{RT}\eta^2 \quad [18b]$$

which is derived from Eq. [3] after linearization at low η values and taking into account that $i_{o,st} = \Delta i_o/2r_oL$.

Calculated and experimental values of the propagation rate constant $d\theta/d\eta$ and the current-square overvoltage relation constant $B = di/d\eta^2$ are given in Table II.

It can readily be seen that the direct transfer in our case plays a predominant role and is sufficiently rapid

[2] The similarity in the propagation rates for both monolayers and spiral steps gives reason to suggest that the latter are also monoatomic.

Table II. Calculated and experimental values of the propagation rate constant $\frac{d\theta}{d\eta}$ and the current-square overvoltage relation constant B for the cubic plane of silver in 6M $AgNO_3$ (45°C)

* $i_{o,ad} = 0.060 \pm 0.001$ A cm^{-2}; $i_{o,st} = 180 \pm 24$ A cm^{-2}; $\lambda_o < 4 \times 10^{-6}$ cm; $\frac{\Delta i_o}{\eta} = (0.21 \pm 0.01) \times 10^3$ AV^{-1} cm^{-2}; $\eta_{max} = 3$ mV.

to supply ions for the rate of advance as found experimentally.

It appears that, at least in the case of silver deposition from concentrated silver nitrate solutions, the contribution of the surface diffusion mechanism is negligibly small.

Manuscript submitted Dec. 19, 1972; revised manuscript received June 14, 1973. This was Paper 119 presented at the Cleveland, Ohio, Meeting of the Society, Oct. 3-7, 1971.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1974 JOURNAL.

Electrochemical Studies on Ag, Fe, and Cu Species in $AlCl_3$-NaCl Melts

L. G. Boxall,* H. L. Jones, and R. A. Osteryoung*

Department of Chemistry, Colorado State University, Fort Collins, Colorado 80521

ABSTRACT

The electrochemical behavior of the Ag/Ag^+, Fe/Fe^{2+}, Fe^{2+}/Fe^{3+}, and Cu/Cu^+, Cu^+/Cu^{2+} systems in the equimolar region of $AlCl_3$-NaCl melts has been investigated using potentiometry, pulse polarography, cyclic voltammetry, chronoamperometry, and chronopotentiometry. In contrast to the Al electrode, the emf of the Ag^+/Ag electrode was found to be virtually independent of the melt composition. The Ag^+ was found to undergo reversible deposition at a tungsten electrode. However, in cyclic voltammetric experiments, the stripping process showed a marked dependence on Ag^+ concentration, temperature, and sweep rate. Possible explanations for this dependence are presented. The diffusion coefficient for Ag^+ at 175°C was found to be 3.01×10^{-6} $cm^2\ sec^{-1}$. The Fe^{3+}/Fe^{2+} couple was found to be reversible while the Fe^{2+}/Fe couple showed typical deposition-stripping behavior. Above an initial $FeCl_3$ concentration of 5 mM the deposition process became concentration independent while the stripping process was found to involve two different electrode reactions. This behavior was consistent with the low solubility of $FeCl_2$ in the equimolar region. Nernst plots for the anodization of Cu gave low n-values in Cl-rich melts, while n-values of 1 were obtained in $AlCl_3$-rich melts. These results are best explained by introducing the following equilibrium reaction

$$Cu^+ + 2Cl^- \rightleftarrows CuCl_2^- \qquad K_{Cu}$$

for which a value of 6.5×10^4 was calculated for K_{Cu}. The two Cu couples were well behaved electrochemically.

Electrochemical studies of metal/metal ion systems in molten $AlCl_3$-alkali halides have received considerable attention in recent years (1-10). These studies have been carried out almost exclusively in $AlCl_3$-rich melts where, in several cases (11-14), unusually low oxidation states are stabilized because of the high acidity of the solvent. To our knowledge studies of metal/metal ion systems in NaCl-rich or equimolar chloroaluminate melts, where the greatest change in acidity occurs, have gone unreported.

In the present investigation we have studied the electrochemical behavior of the Ag/Ag^+, Fe/Fe^{2+}, Fe^{2+}/Fe^{3+}, and Cu/Cu^+, Cu^+/Cu^{2+} systems in the equimolar region of $AlCl_3$-NaCl melts. The recently devised aluminum titration technique has allowed us to adjust the acidity of the melt to any desired value (16). The marked dependency of the Al reference electrode on the composition of the melt led us to look at the Ag/Ag^+ and Cu/Cu^+, Cu^+/Cu^{2+} systems while the possibility of iron impurities in these melts led us to study the Fe/Fe^{2+}, Fe^{2+}/Fe^{3+} system. The electrochemistry of these melts is characterized by the use of cyclic voltammetry, pulse polarography, chronoamperometry, and chronopotentiometry.

Experimental

All of the experimental work was carried out in a nitrogen-filled dry box (Vacuum Atmosphere, Inc.) to protect the melts from moisture and oxygen. All of the glassware was heated to 500°C for several hours and then allowed to cool in the evacuated antechamber of the dry box.

* Electrochemical Society Active Member.

Key words: fused salts, $AlCl_3$-NaCl melt, metal/metal ion systems, pulse polarography, cyclic voltammetry.

To facilitate the ease and rate at which an individual experiment could be carried out, a special electrochemical cell (Fig. 1) incorporating a glass bottom and a tight fitting Teflon top was constructed. Several holes were drilled in the Teflon top and various sizes of ground joints were press-fitted in these holes. The typical cell top contained a 6 mm hole for a thermocouple well, a ₸ 10/18 joint for a counterelectrode, a ₸ 14/20 joint for the reference electrode compartment, and a 25 mm hole with an O-ring groove around the top for the working electrode compartment. Together with a standard tube furnace, small ring furnaces were built to fit around the Teflon tops. By maintaining the temperature of the tops between 175° and 200°C, the build-up of $AlCl_3$ in the cooler portions of the cell was eliminated. This feature is of utmost importance when measurements are made in the $AlCl_3$-rich melts.

Temperature controllers (Thermo Electric Model 32422) were used to control the temperatures of the melts to within ±0.5°C. The temperature was measured using a Chromel-Alumel Pyrex-sheathed thermocouple and a Leeds & Northrup Student Potentiometer. The precision of the potentiometer was better than ±0.1 mV compared to a precision voltage source.

All electrochemical measurements were made with a multipurpose instrument (15) interfaced to a Digital Equipment Corporation PDP-12 computer. Read-out of the data was by either a Hewlett-Packard Model 7004-B X-Y recorder, a Hewlett-Packard Model 7030-AM X-Y recorder with point plotting capabilities, or a Tektronics Model 564 oscilloscope with a Type 3A3 and Type 2A63 plug-ins. A Sargent Model IV coulometric current source was used for all of the anodization of the metals in the melt. The purity of all the metals was better than 99.99%

Melt purification.—Chemical analysis of the Fluka (A.G., anhydrous iron free) aluminum chloride and the Fluka (A.G.) sodium chloride found their purity to be better than 99.5%. The fusion of Fluka (A.G., anhydrous, iron free) aluminum chloride and Fluka (A.G.) sodium chloride usually produced a faintly yellow-colored melt which would slowly turn gray in color on standing for a period of several days. Rather than use a pair of Pt electrodes for purification electrolysis (where Cl_2 is produced at the anode during electrolysis), a pair of aluminum electrodes was used. The net result during the electrolysis, thus, is either the replacement of impurities in the melt with the aluminum ion or the transfer of Al from one electrode to the other. The simple displacement of the impurities using Al metal failed due to the coating of the metal surface by a film formed by the displaced metal impurities which effectively stopped further displacement. The transfer of Al metal in the electrolysis procedure continually replenishes the Al surface and prevents the passivation of the aluminum. The normal procedure is to electrolyze the melt in the temperature range 225°-250°C for at least 24 hr at a current density of 1.5 mA cm^{-2}.

In carrying out the work described below, the normal procedure was to prepare a 150 mliter melt in a cell placed in a furnace containing a window so that the bottom of the cell could be seen. After purification, the 7 mm fine-porosity sintered-glass fritted reference electrode compartment was placed into the melt. The aluminum reference electrode consisted of a spiral of aluminum wire connected to a short piece of tungsten wire sealed in the glass plug in the top of the reference compartment. The counterelectrode consisted of a large tungsten wire spiral sealed into a ₮ 10/18 glass plug. The working electrode compartment consisted of a 20 mm medium-porosity sintered glass frit at one end, a 25 mm piece of glass tubing in the middle, and a ₮ 14/20 ground joint at the top. A tightly fitting O-ring around the 25 mm glass barrel of the compartment both supported and sealed it in the Teflon top. Teflon adapters were used to seal the electrodes into the compartment as well as adjust the level of the electrode in the compartment. The working electrode compartmnt was filled to approximately 10 mliters either by flow through the frit from the bulk of the melt, or by transferring melt from a second furnace by means of a preheated pipette. All of the compartments were adjusted so that all of the melt levels in the cell were equal. It was necessary to blow a small hole 5-7 cm above the melt level in each of the cell compartments to equalize any differences in the vapor pressures above the various melts.

Pretreatment of the micro tungsten indicator electrodes.—If the tungsten wire was found to be very splintery due to longitudinal holes in the wire, or to contain excessive amounts of gas, it was not used in the manufacture of the electrodes. The wire was sealed into 6 mm Pyrex glass tubing using a bead of uranium glass. The button electrodes were ground flat on an emery wheel and then polished with 600 grit silicon carbide powder. All the tungsten electrodes were then electrolyzed for 15 sec at 4-5V a.c. in a 25% sodium hydroxide solution. After rinsing with water, the electrodes were dried under vacuum at 110°C for several hours. It was necessary to cycle the electrode from +0.5 to +1.5V in the melt for several minutes to remove the final traces of the oxide film on the metal electrode surface. This electrolysis procedure produced a reasonably reproducible indicator electrode.

Reference electrode.—The potential of the aluminum electrode in the fritted reference compartment *vs.* Al in an equimolar $AlCl_3$-NaCl melt was determined by the aluminum titration technique (16). The potential of this arbitrary, but stable, reference electrode system was normally about 170 mV negative of the Al electrode in the 1:1 melt.[1] A variation of less than ±2 mV was observed for a given reference electrode over a period of 2 months.

Aluminum anodization was used to adjust the acidity of the melt in the working electrode compartment to any desired value. This enabled us to determine the acid dependency of each electrode system being studied.

Results and Discussion

All of the potentials are reported with respect to an aluminum reference electrode in an equimolar $AlCl_3$-NaCl melt.

Cyclic voltammetry was used to determine the current-voltage characteristics of the melt before (Fig. 2a) and after (Fig. 2b) purification. The final melt was completely colorless and exhibited no irregularities in the current-voltage curves using either a tungsten button or a hanging mercury drop indicator electrode.

[1] Throughout this paper the expression "1:1 melt" refers to a melt consisting of 50:50 m/o (mole per cent) $AlCl_3$:NaCl while a 2:1 melt refers to 66.34 m/o $AlCl_3$:NaCl.

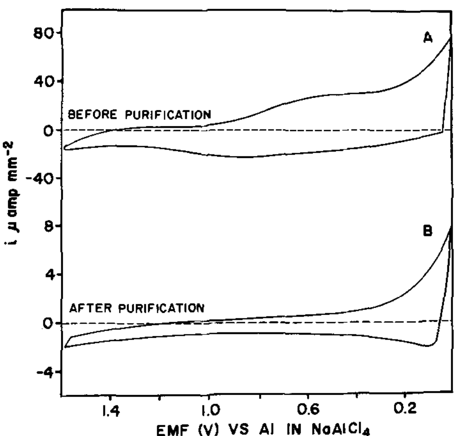

Fig. 2. Cyclic voltammetry of $NaAlCl_4$ background on tungsten, 175°C, ν = 0.5 V/sec.

After a week's storage of the melt, open to the atmosphere in the dry box, no detectable changes were observed. Under similar experimental conditions the background current reported by Torsi and Mamantov (13) is about ten times larger than what we have observed. Unfortunately, most of the other workers have not published their background currents; hence, many of the discrepancies in the literature may be due to impure melts.

Most of the experimental measurements were made using either tungsten button or wire indicator electrodes. The useful potential range of these electrodes was from 0.3 to 1.5V. On carrying out voltammetric experiments beyond this range, it appeared as if the electrode increased in area resulting in a background current of about four to five times the magnitude of the original values. No significant changes were observed in the shape of these enhanced voltammograms except for the increase in magnitude by a constant factor.

An apparent differential capacity, C_d, for the indicator electrode in a pure melt was determined from the slope of a plot of current *vs.* sweep rate at a given potential. The plots for the tungsten electrodes at sweep rates greater than 1.0 $V\text{-sec}^{-1}$ gave consistent C_d values with respect to sweep rate; however, the C_d values increased as the applied potential decreased. The C_d values increased from 50-80 $\mu F\ cm^{-2}$ at 0.8V to 160-200 $\mu F\ cm^{-2}$ at 0.1V. Slow sweep rates (0.05-0.5 $V\text{-sec}^{-1}$) produced capacitances which were abnormally high and very dependent on the preparation of the electrode. At slow sweep rates any faradaic reaction, such as filming or alloying, could make an appreciable contribution to the observed current. The degree of roughness of the solid electrode will change the effective capacitance area of the tungsten electrodes and, hence, the calculated C_d value.

The background cyclic voltammogram using a platinum button electrode exhibited two anodic and two cathodic waves between +0.3 and +1.1V; however, at potentials more anodic than +1.1V, the electrode appeared to be well behaved. Continued cyclic sweeps caused the anodic and cathodic peaks for one couple to grow and the peaks for the other couple to decrease in height. As the sweep rate was increased, the growth phenomenon shifted from the couple at 0.9V to the one at 0.6V. The fact that stirring had no effect on the voltammogram and that none of the other electrode materials exhibited peaks in this region suggested one of two things: (*i*) the peaks may arise from some surface reaction involving a platinum chloride film, or (*ii*) some impurity is strongly adsorbed and the reaction is catalyzed on the platinum surface. For these reasons the platinum electrode received only limited use as an indicator electrode in the chloroaluminate melts.

Cyclic voltammograms in which the sweep rate varied from 0.05 to 100 $V\text{-sec}^{-1}$ exhibited a useful working range from +0.1 to +1.0V for a hanging mercury drop electrode. Shifting the cathodic limit from +0.10 to +0.05V produced an anodic peak at +0.55V which disappeared as soon as the cathodic limit was returned to +0.10V. The shift in the useful working range for the mercury electrode with increasing melt acidity is identical to that observed for the aluminum reference electrode. Plots of current, measured at various potentials, *vs.* the sweep rate (0.05-100 $V\text{-sec}^{-1}$) gave consistent capacitance values of ~14 $\mu F\ cm^{-2}$ for the mercury electrode in the $NaAlCl_4$ melt at 175°C. The main disadvantages of this electrode are the mechanical problems and the fact that most of the metals of interest are electroactive at potentials in excess of 1.0V. The advantages are the use of a nonsolid electrode and the fact that observed capacitance is about one-tenth that of the tungsten electrodes.

Silver.—Silver(I) was generated coulometrically in the chloroaluminate melts with 100% current efficiency at current densities from 1 to 30 mA cm^{-2}. All of the Ag^+ solutions were clear and colorless under all experimental conditions. The polarization of the silver wire never exceeded 200 mV during any of the electrolysis. An average value for n of 0.99 ± 0.02 was obtained either from Nernst plots (Fig. 3) or chemical analysis for silver in the melt. The E^0_M (molarity scale obtained by extrapolation of Nernst plots) values for silver in the 1:1 and 2:1 melts at 175°C *vs.* Al in the 1:1 melt are 1.086 ± 0.010 and 1.106 ± 0.010V, respectively. The major portion of the 10 mV uncertainty in these values is due to the errors in determining the actual potential of the experimental Al reference electrode with respect to an Al electrode in an exact 1:1 melt. A plot of E^0_M *vs.* temperature (175°-250°C) for silver in a 1:1 melt showed no hysteresis and gave a value for dE^0_M/dt of −0.63 ± 0.05 mV deg^{-1}. This value is to be compared with the value of −0.44 mV deg^{-1} reported for silver in the ternary [66:20:14 m/o (mole per cent) $AlCl_3$:NaCl:KCl] melt (6).

Good agreement was found between our E^0_M (1.106V) value for silver in a 2:1 melt at 175°C and the value of 1.132V derived from Plambeck and co-workers (6) who reported E^0_M values of 0.695 and 0.714V in the ternary melt at 135° and 150°C, respectively. This conversion was accomplished using the authors' dE^0_M/dt value, and the assumption that the potential of the Al electrode in ternary melt is equivalent to the Al electrode in the 2.1 ($AlCl_3$:NaCl) melt (*i.e.,* 455 mV *vs.* Al in the 1:1 melt). The 26 mV difference may be easily attributed to the effect of changing the cations in the melt from just sodium to a mixture of sodium and potassium ions. This effect has been observed in other melts as well (17).

The response of the potential of the silver electrode to a change in the composition of the melt at 175°C was determined using the cell

$$Al/NaAlCl_4//(x)AlCl_3,\ (100 - x)NaCl,\ Ag^+/Ag \quad [1]$$

and is shown in Fig. 4. The response of an Al electrode is included for comparison. The mole per cent $AlCl_3$ was varied from 66 to 49.7% by the addition of known aliquots of NaCl to the 2:1 melt. The E^0_M values determined from Nernst plots in which the $AlCl_3$ content had been adjusted by the anodization of an aluminum wire are in accord with the values in Fig. 4.

The difference of 20 mV in the E^0_M values for silver in the two melts is almost negligible compared to the 455 mV observed for the aluminum electrode. The indifference of the silver electrode potential to the 4.5 orders of magnitude of change in the chloride ion concentration indicates that the silver ion is a much weaker acid than the $AlCl_3$ in these chloroaluminate melts. It is evident that the silver electrode would be a much better reference electrode for these melts than is the aluminum electrode.

Typical pulse polarograms and cyclic voltammograms for the deposition of Ag^+ at a tungsten electrode

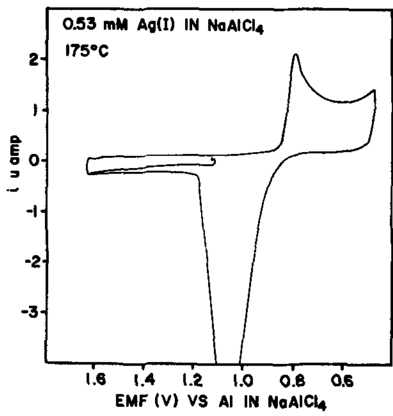

Fig. 6. Cyclic voltammogram of Ag^+ in $NaAlCl_4$. Area of tungsten indicator electrode = 0.785 mm². ν = 0.5 V/sec.

are shown in Fig. 5 and 6, respectively. Plots of the observed currents *vs.* pulse width (Fig. 7), and Ag^+ concentration (Fig. 8) were linear (18). Values for $i_p/\nu^{1/2}$ and E_p remained constant when the cyclic voltammetric sweep rate was varied from 0.01 to 100 V-sec^{-1}. The experimental pulse polarogram is most closely approximated by the theoretical plot (Fig. 5) for the deposition of an insoluble product. A value for the diffusion coefficient of 3.01×10^{-6} cm² sec^{-1} was calculated from the pulse polarographic data using the Cottrell equation.

Although the shape of the cathodic peak for Ag^+ reduction in the observed cyclic voltammograms was unaffected by changes in temperature and/or concentration, marked differences occurred in the anodic portion. A second sharp anodic stripping peak positive to the main stripping peak was observed as a result of increased Ag^+ concentrations or lowered temperatures (Fig. 9). At 175°C this peak does not appear during a single continuous cycle until the Ag^+ concentration exceeds ≈ 1 mM. If the sweep is held momentarily at 0.5V, the second anodic peak can be observed at lower Ag^+ concentrations. Regardless of the Ag^+ concentration, the second anodic peak could not be observed without first sweeping through the region of silver deposition and dissolution. The position of this peak shifts anodically with a decrease in temperature and to a lesser degree with an increase in the Ag^+ concentration. At temperatures of 200°C and above, this peak collapses completely to form a single broad stripping

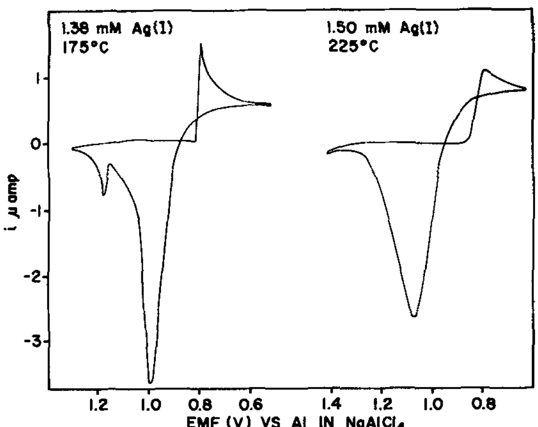

Fig. 9. Cyclic voltammograms of Ag^+ in $NaAlCl_4$. ν = 0.05 V/sec. Area of tungsten indicator electrode = 0.785 mm².

peak. Cyclic voltacoulograms show that the area under the small anodic peak corresponds to the quantity of silver on the electrode surface ranging from less than half a monolayer to that stripped off in the first peak. The size of the peak is directly proportional to the amount of silver being stripped off the electrode. Cyclic voltammograms in the 2:1 melt exhibit only the single large anodic stripping peak regardless of the Ag^+ concentrations or switching potential. The charge under the small anodic peak is directly proportional to the amount of silver being stripped off the electrode. Also, the ratio of the areas of the second peak to that of the first stripping peak increases with both Ag^+ concentration and sweep rate.

This anodic behavior suggests that there may be two different electrode reactions by which the silver metal is stripped from the indicator electrode. The first reaction is not diffusion limited when only small amounts of silver are anodized; however, at a higher rate of silver anodization, the local concentration of the anionic species is depleted and the electrode reaction shifts to the more anodic reaction. The product from the second reaction then reacts in the solution to form a single dominant silver species in solution, hence a single deposition peak. The Nernst data indicates that the Ag^+ ion is not complexed with the Cl^- ion leaving only the $AlCl_4^-$ and/or the $Al_2Cl_7^-$ anions to take part in the electrode reaction. It does not appear likely that the $AlCl_4^-$ anion would be diffusion limited due to its high concentration in the melt. The $Al_2Cl_7^-$ concentration is low enough in the 1:1 melt to exhibit this diffusion-limiting effect. The increase in the $Al_2Cl_7^-$ concentration in the $AlCl_3$-rich melts and the increase in its diffusion coefficient would produce changes in the stripping peak consistent with the experimental data. A temperature increase from 175° to 250°C will also triple the $Al_2Cl_7^-$ concentration in the melt (16).

The second stripping peak may be the formation of the uncomplexed Ag^+ ion or an $Ag(AlCl_4)_n{}^{1-n}$ complex. The ratio of the area under the second peak to that under the first stripping peak increases with both sweep rate and the silver concentration. This is consistent with the premise that the first peak may become diffusion limited. The small cathodic wave at about 1.15V in Fig. 9 (175°C) becomes more prevalent at higher sweep rates, higher Ag^+ concentrations, and when the anodic switching potential is moved closer to that of the second stripping peak. If the anodic switching potential is moved cathodic of the second peak, this small cathodic wave disappears completely.

No explanation is available at the present which will satisfy all of the experimental data.

Iron.—A number of methods were tried to introduce an iron species into a 1:1 melt. Ferrous chloride was found to be virtually insoluble and anodization of an iron wire at current densities as low as 2 mA cm^{-1} polarized the electrode to such an extent ($\simeq$ 2V) that chlorine evolution occurred. However, ferric chloride was found to be readily soluble. Also, a steady current of 500 μA could be realized by potentiostating the iron wire at +1.6V *vs.* the aluminum reference electrode. None of the above problems were encountered when adding iron to a 2:1 melt. The inability to anodize an iron wire appeared to be caused by filming of the electrode (insoluble $FeCl_2$). The insolubility of the lower oxidation states of other metals has been noted before when the chloroaluminate melts were of low acidity (7).

In a 2:1 melt a Nernst plot for the Fe^{2+}/Fe system gave a value of 0.98V for E^0_M. The slope was 0.042V compared to the theoretical value of 0.044V for a two-electron process. A temperature coefficient of −0.77 mV deg^{-1} over a range of 175°-225°C was found. Our E^0_M value of 0.95V at 218°C is in good agreement with the published value (2) of 0.97V.

A normal pulse polarogram for the reduction of $FeCl_3$ in a 1:1 melt is shown in Fig. 10. The height of the wave attributed to the Fe^{2+}/Fe couple ($E_{1/2}$ = 0.509 ± 0.005V) is twice that for the Fe^{3+}/Fe^{2+} couple ($E_{1/2}$ = 1.406 ± 0.005V). Linear plots of diffusion current *vs.* concentration gave a slope for the Fe^{2+}/Fe couple which was twice that for the Fe^{3+}/Fe^{2+} couple.

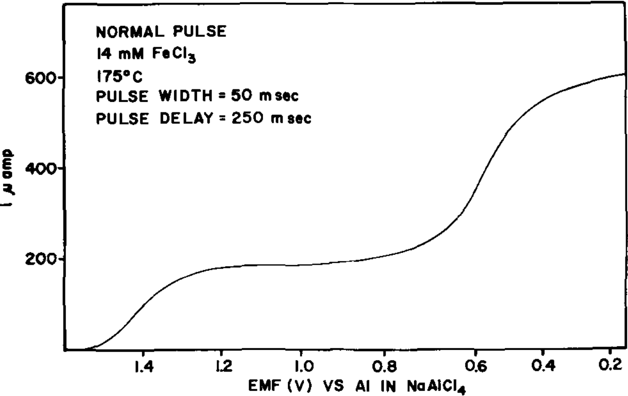

Fig. 10. Normal pulse polarogram of Fe^{3+} in $NaAlCl_4$. Area of tungsten indicator electrode = 1.79 mm^2.

The cathodic and reverse anodic scans from double potential step pulse polarography (19) for the Fe^{3+}/Fe^{2+} couple are presented in Fig. 11. In this technique a generating pulse is applied causing the *in situ* reduction of Fe^{3+} to Fe^{2+}. Each generating pulse is followed by a normal pulse polarographic analysis pulse with a pulse width of one-tenth or less that of the generating pulse, thus insuring that the concentration profile of the generated material may be considered flat within the diffusion layer region established by the analysis pulse. The cathodic and anodic $E_{1/2}$'s differ by only 9 mV and the average $i_d{}^c/i_d{}^a$ ratio over a range of concentrations is 0.91 where the theoretical values for completely reversible systems are 0 and 0.962 mV, respectively. The good fit of the experimental polarogram to the theoretical polarogram in Fig. 11 further indicates a high degree of reversibility in the Fe^{3+}/Fe^{2+} couple.

A typical cyclic voltammogram (sweep rate 0.05 $V\text{-}sec^{-1}$) of $FeCl_3$ in a 1:1 melt is shown in Fig. 12. The Fe^{3+}/Fe^{2+} couple at $E_{1/2}$ = 1.40V appears to be reversible while Fe^{2+}/Fe couple with E^0_M = 0.62V shows typical deposition-stripping behavior. The peak currents for the Fe^{3+}/Fe^{2+} couple were concentration dependent over the range of 0.5-2.0 mM while they were not for the Fe^{2+}/Fe couple above an initial $FeCl_3$ concentration of 5 mM. The peak separation of 100 mV for the Fe^{3+}/Fe^{2+} couple is slightly greater than the

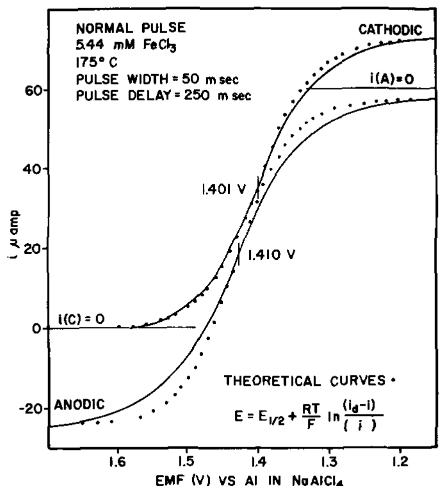

Fig. 11. Normal pulse polarograms of Fe^{3+} in $NaAlCl_4$. Anodic polarogram using double pulse polarography. Area of tungsten indicator electrode = 1.79 mm^2.

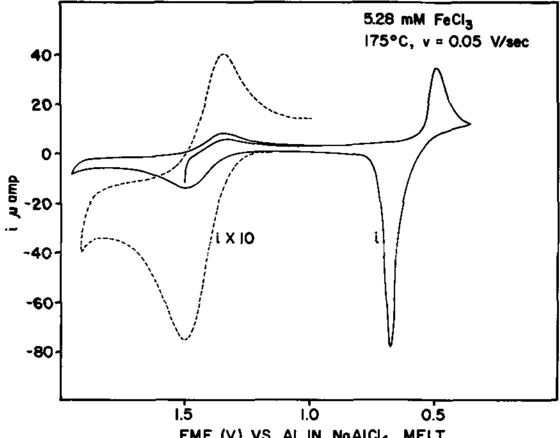

Fig. 12. Cyclic voltammogram of Fe^{3+} in $NaAlCl_4$, dashed curve-scale expanded by 10. Area of tungsten indicator electrode = 1.79 mm^2.

theoretical value of 84 mV for a one-electron reversible system at 175°C. As the sweep rate was increased, the anodic stripping peak split into two peaks (see Fig. 13) at 0.690 and 0.730V with their relative heights becoming reversed. The second peak at 0.730V became more predominant with increasing $FeCl_3$ concentration or more cathodic switching potentials. At $FeCl_3$ concentrations below 5 mM only a single anodic stripping peak was observed. This behavior is similar to that exhibited by silver.

The above observations indicate that the stripping process involves two different electrode reactions. The reaction occurring at 0.690V is well behaved as long as the concentration of iron on the electrode surface is not too high. We attribute this reaction to the oxidation of Fe to $FeCl_2$. When the rate of production of Fe^{2+} reaches a certain value, the reaction producing $FeCl_2$ becomes limited possibly due to the depletion of Cl^- in the vicinity of the electrode. Consequently, the second reaction at 0.730V takes place. We believe that this process involves the oxidation of Fe to Fe^{2+} which diffuses out into solution. Furthermore, as only one deposition peak is observed, the two anodic processes must give rise to a single species in solution. It is very likely that the predominant Fe(II) species in these melts are chloroaluminate complexes $(Fe(AlCl_4)_m{}^{2-m}$ or $Fe(Al_2Cl_7)_m{}^{2-m})$ and when $FeCl_2$ is added it must give a similar complex. A likely reaction for the process is

$$FeCl_2 + 2Al_2Cl_7^- \rightleftarrows Fe(AlCl_4)_2 + 2AlCl_4^- \quad [2]$$

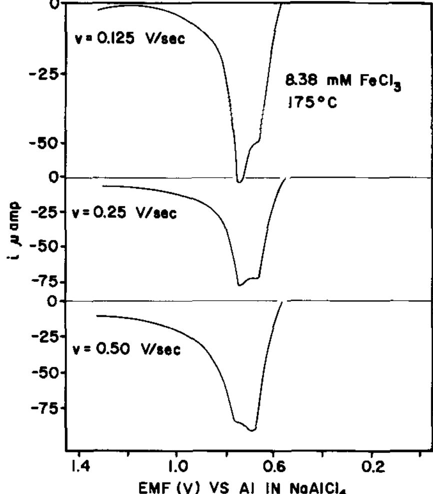

Fig. 13. Partial cyclic voltammograms for the dissolution of Fe from a tungsten electrode. Area of tungsten electrode = 1.79 mm^2. Potential program 1.7 → 0.3 → 1.7V *vs.* Al.

which is also consistent with the solubility behavior of $FeCl_2$ (in 1:1 melt low concentration of $Al_2Cl_7^-$, low solubility of $FeCl_2$; in 2:1 melt high concentration of $Al_2Cl_7^-$, high solubility of $FeCl_2$).

The Fe^{2+} species was found to be soluble in the 2:1 melt at 175°C and an overpotential of only 150 mV resulted when the iron wire was anodized at a current density of 5 mA cm^{-2}. The separation between the two anodic stripping peaks (0.76 and 0.93V) is considerably greater in the 2:1 melt than in the 1:1 melt (Fig. 14). No peaks corresponding to the Fe^{3+}/Fe^{2+} couple were observed for potentials cathodic of +2.2V. The small anodic peak at +1.14V and the cathodic prewave at ≈ +1V are present in the background sweeps and are not due to the iron in the melt. The distortion of the reduction peak is due in part to other small pre-aluminum deposition waves which can be observed in the background.

The Nernst plot for the Fe^{2+}/Fe couple had a slope of 0.0371V compared to the theoretical value of 0.0444V for a two-electron process. The $E^0{}_M$ for Fe^{2+}/Fe at 175°C in the 2:1 melt is 1.04V with a temperature coefficient of −0.77 mV deg^{-1} over a temperature range of 175°-225°C.

Several reverse current chronopotentiograms were recorded in an attempt to confirm our results. The irreproducibility of the data obtained did not warrant interpretation except that there is an apparent couple between 0.4 and 0.3V. This may be due to a codeposition of iron and aluminum on the electrode which is in keeping with the results of Yntema *et al.* (2).

An average diffusion coefficient of 9.1 ± 0.9 × 10^{-6} cm^2 sec^{-1} for Fe^{3+} in a 1:1 melt at 175°C was calculated from chronoamperometric and pulse polarographic data. This is in good agreement with a value of 2.2 × 10^{-5} cm^2 sec^{-1} at 250°C (10) (2% change in D per degree change in T).

Copper.—Copper(I) was most conveniently introduced into the 1:1 chloroaluminate melts by anodization of a copper wire. A current density of 10 mA cm^{-2} polarized the wire about 200 mV anodic of its equilibrium potential. Although CuCl dissolved very slowly, electrochemical results identical to those for the coulometric generation of Cu^+ were obtained. While $CuBr_2$ was completely insoluble, $CuCl_2$ was soluble to an extent of 5 mM in a 1:1 melt at 175°C. In $AlCl_3$-rich melts no solubility problems were encountered.

The Nernst plots for duplicate sets of Cu^+/Cu emf measurements made in both a Cl^--rich melt (49.87 m/o $AlCl_3$) and an $AlCl_3$-rich melt (50.25 m/o $AlCl_3$) are shown in Fig. 15. While an n-value of 0.98 ± 0.02 was obtained for the couple in the $AlCl_3$-rich melt, an approximate n-value of only 0.8 was obtained in the Cl^--rich melt. The low n-value in effect means

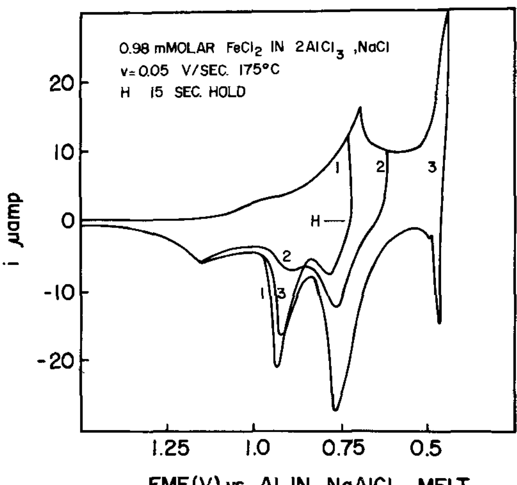

Fig. 14. Cyclic voltammogram of 0.98 mM $FeCl_2$ in a 2:1 $AlCl_3$-NaCl melt. Area of tungsten indicator electrode = 1.79 mm^2.

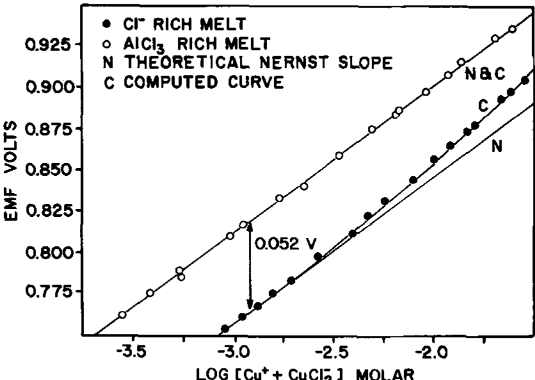

Fig. 15. Nernst plots for Cu^+ in $NaAlCl_4$ melts at 175°C. Reference electrode is Al in a 1:1 $AlCl_3$-NaCl melt.

that the observed electrode potential changed too rapidly, *i.e.*, the apparent concentration of Cu^+ in the vicinity of the electrode is too high. An explanation for this is presented below.

As Cu^+ is added to the melt, a certain amount of chloride ion will be tied up according to the following equation

$$Cu^+ + m\,Cl^- \rightleftarrows CuCl_m{}^{1-m}\ (K_{Cu}) \quad [3]$$

As the Cl^- concentration decreases, reaction [3] shifts to the left producing more Cu^+ with respect to the amount expected from anodization of the copper electrode and, therefore, a higher potential. Using an iterative technique (where K_{Cu} and m are varied) similar to that previously developed for determining the acid base properties of these melts (16), we have calculated the shift in the over-all melt composition and the concentration of the individual species in the melt after each addition of Cu^+. At fixed values of m the value for K_{Cu} was varied until a minimum deviation between the calculated and experimental emf values was obtained. The best fit was obtained for $K_{Cu} = 6.5 \times 10^4$ with a value for m equal to 2. A partial list of the calculated species concentrations and electrode potentials are given in Table I and plotted in Fig. 16.

The copper concentration at which the deviation occurs is dependent on the initial composition of the melt. Above 49.99 m/o $AlCl_3$ no deviation will be observed as illustrated by the $AlCl_3$-rich Nernst plot in Fig. 15. As the melt becomes richer in NaCl, the greater is the quantity of copper required to change the composition of the melt into the range where the Nernst deviation occurs (49.89 to 49.99 m/o $AlCl_3$). The deviation from the Nernst slope in this region is equivalent to an increase of 42 mV in the calculated E^0_M for the Cl^--rich region to that for the $AlCl_3$-rich melts. The computed E^0_M from the Cl^--rich region ($n = 1$) is 1.027 + 0.042 = 1.069V compared to the 1.077V calculated from the $AlCl_3$-rich Nernst slope data.

A cyclic voltammogram for CuCl in a chloride-rich $NaAlCl_4$ melt at 175°C is shown in Fig. 17. At low CuCl concentrations (< 2 mM) the Cu^{2+}/Cu^+ couple is obscured by the evolution of chlorine. An increase in the CuCl concentration shifts the chlorine evolution to

more anodic potentials as a result of the decrease in chloride ion concentration. The Cu^{2+}/Cu^+ redox couple appears to be a reversible electrode process with no insoluble species. At CuCl concentrations in excess of 5 mM, the peak for the reduction of the cupric species becomes enhanced and resembles the shape of a stripping peak. Integration of the cyclic voltammogram shows that the amount of reduction products and oxidation products at the Cu^+/Cu couple are equal while there is about 6% excess of oxidation products at the Cu^{2+}/Cu^+ couple on each cycle. This is probably the result of the somewhat irreversible oxidation of Cl^-.

The cathodic peak current for the Cu^+/Cu couple is linear with Cu^+ concentration and the $i_p/v^{1/2}$ at a given concentration was found to be constant over the sweep rate range 0.05-1.0 V-sec^{-1}. The shift in the E_p peak of copper deposition is 0.087V per decade change in concentration compared to the theoretical value of 0.089V for a one-electron process at 175°C.

Evolution of Cl_2 distorts the anodic peak for the oxidation of Cu^+ and makes measurement of the anodic peak potential somewhat arbitrary; however, the peak separation of 100 mV is still in reasonable agreement with the theoretical value (20) of 84 mV for a reversible one-electron process. The cathodic peak potential shifts from 1.75 to 1.67V when the solubility of the $CuCl_2$ is exceeded. At Cu^+ concentrations less than 5 mM, the cathodic E_p for the Cu^{2+}/Cu^+ couple is independent of sweep rate over the range 0.05-1.0 V-sec^{-1}. The peak currents for the deposition of Cu^+ and for the oxidation of Cu^+ were of equal magnitude.

The observed pulse polarograms for the reduction of Cu^+ in 1:1 melts gave linear plots for i_p *vs.* $[Cu^+]$ and i_p *vs.* (pulse width)$^{-1/2}$. The shift in $E_{1/2}$ for the Cu^+ reduction wave with increasing copper concentration obeyed the expected Nernstian behavior for a one-

Effects of the Active Chlorine and the pH on Consumption of Graphite Anode in Chlor-Alkali Cells

F. Hine,* M. Yasuda, I. Sugiura,[1] and T. Noda

Nagoya Institute of Technology, Nagoya 466, Japan

ABSTRACT

Corrosion tests of graphite anodes in saturated NaCl solution at 40°C have been carried out at 100 A/dm². The corrosion rate was a small function of the pH between 2 and 9, but affected by the active chlorine. Electrochemical formation of chlorate is a side reaction and is limited by slow diffusion of HClO and/or ClO^-. While chlorate does not affect degradation of graphite anode either electrochemically or chemically, the carbon surface oxide, which forms during electrochemical formation of chlorate from hypochlorite, is the largest factor in consumption of graphite anode in chlor-alkali cells.

It has been pointed out that the graphite anode is largely consumed by chemical oxidation with physical degradation when it is electrolyzed in alkali chloride solution containing hypochlorite ions (1, 2). A part of the chlorine dissolved in the anolyte may convert into HClO and ClO^-, depending on the pH, due to the chemical equilibrium shown by reactions [A] and [B]

$$Cl_2(aq) + H_2O \rightleftarrows HClO + H^+ + Cl^- \quad [A]$$

$$K_1 = 4.66 \times 10^{-4} \text{ at } 25°C \ (3)$$

and

$$HClO \rightleftarrows H^+ + ClO^- \quad [B]$$

$$K_2 = 3.2 \times 10^{-8} \text{ at } 25°C \ (3)$$

where K_1 and K_2 are the dissociation constants for reactions [A] and [B], respectively.

Since graphite has many micropores, the charge-transfer reaction of Cl^- in the pore might be controlled by diffusion because of low concentration of Cl^- in comparison with the bulk solution. It causes formation of HClO due to hydrolysis of Cl_2, and oxidation of carbon or graphite occurs

$$C + HClO = CO + HCl \quad [C\text{-}1]$$

and

$$C + 2HClO = CO_2 + 2HCl \quad [C\text{-}2]$$

Kokhanov *et al.* studied the electrochemical consumption of graphite anodes of chlorine and chlorate cells (pH 3.3-7), and they considered that the effect of the active chlorine (sum of Cl_2 dissolved, HClO, and ClO^-) was negligible (4, 5). They also found that corrosion of graphite in the brine without electrolysis was affected by the active chlorine, but was almost independent of the pH. Therefore, they concluded that the electrochemical consumption of graphite was caused by discharge of H_2O.

Since the H^+ concentration of solution in the graphite pore reached 0.1-0.12*N* in the chlorate cell (6), it was considered that the graphite anode was oxidized by ClO_2 instead of HClO

$$ClO_3^- + 2HClO = ClO_2 + \tfrac{1}{2} Cl_2 + H_2O + Cl^- \quad [D]$$

and

$$C + ClO_2 = CO_2 + \tfrac{1}{2} Cl_2 \quad [E]$$

Influence of the pH on degradation of graphite anodes has been studied by many authors (7-11), but they have not been attentive to the active chlorine.

The active chlorine is being maintained naturally in a chlorate cell as an important factor for cell reaction (12, 13). From these experimental works and practical experience, it is known that the corrosion rate of graphite anodes attains a maximum in neutral solutions, although the mechanism of consumption is still unclear.

Laboratory testing of corrosion of the graphite anodes in concentrated NaCl solutions has been carried out for many years. The influence of pH and active chlorine are described.

Experimental Procedure

The flowsheet of the system used is shown in Fig. 1. The pH (controlled within ±0.2), the temperature (usually 40°C), and the concentration of active chlorine are controlled in the brine reservoir (50 liters) located at about 1m below the cell level, then the brine is pumped up to the level tank at about 1.5m above the cell. A part of the brine is supplied to the anode compartment of the test cell by gravity, then sent back to the reservoir with the chlorine, where chlorine gas is separated from the brine. The gas is carried away by vacuum. Since the flow rate is more than 1 liter/min, change of the NaCl concentration by electrolysis is negligible (less than 1% decomposition). A part of the anolyte permeates to the cathode compartment through a porcelain diaphragm. The difference of the level of the anolyte-to-catholyte was about 2 cm. The catholyte and hydrogen are swept out by vacuum. Back migration of alkali causes difficulty of control of the concentration of active chlorine in the anode compartment.

[1] Present address: Yamanashi Plant, Nippon Carbon Company, Yamanashi 405, Japan.

Key words: graphite anode, consumption of graphite anode, graphite corrosion testing, carbon surface oxide.

The pH was varied between 2 and 9, and the concentration of active chlorine was from 10^{-3} to 10^{-2}M. The chlorine content was titrated and controlled every 30 min, whereas the pH was recorded continuously. Addition of NaClO solution and dechlorination were carried out if necessary.

There are some papers on the effects of oxyacid ions such as ClO_3^- on corrosion behavior of graphite anodes (14). However, results of our preliminary experiments showed no effect of ClO_3^- on the corrosion rate.

The test cell made of titanium is illustrated in Fig. 2. A titanium cathode is located at the center within a porcelain diaphragm. Three anode assemblies are arranged around the cathode. The anode lead rod, also of titanium, as shown in Fig. 3A, is able to contact three to four graphite specimens (Fig. 3C). A commercial graphite (specific gravity, 1.71; resistivity, 55 × 10^{-5} ohm·cm; vanadium content, 3 ppm; ash less than 0.1%) was machined: 12 mm outer diameter and 10 mm long, and it had a center hole of 5 mm diam for fitting (Fig. 3B).

The corrosion rate is evaluated from the slope of the weight loss *vs.* time curve such as Fig. 5. Generally, electrolysis was carried out for 50 hr, and the corrosion rate was evaluated by the method of least squares. Desalting of a graphite specimen is the most important and time-consuming work prior to weighing. Immersion and washing with hot water at about 80°C for 3-4 days was needed for complete removal of Cl^-. The sample was dried at 110°C for 2 hr and cooled in a desiccator. Since some deviations of weight loss were determined, experiments under the same conditions were repeated at least three times.

Most experiments were carried out in saturated NaCl solutions at 40°C, and the current density was constant at 100 A/dm^2. Operating temperature, current density, and brine composition are all important factors affecting the graphite anode.

The steady-state polarization curves of a graphite anode have been obtained under various conditions of the brine composition. The *IR* drop between the working electrode and the Luggin probe was calibrated by the current interruption technique. To minimize the bubble effect, a small rotating cylinder was used as the working anode (1 cm^2 area). A saturated calomel electrode was used as reference.

Results

Table I summarizes the corrosion rate with respect to operating conditions such as the concentration of active chlorine and the pH. The standard deviation of the concentration of active chlorine is also given.

Figure 4 shows an example of the variation of the concentration of active chlorine during electrolysis. Control at the 10^{-2}M level is relatively easy in comparison with lower levels such as 10^{-3}M. Generally, deviation of the concentration of active chlorine is large in a solution at high pH ranges containing dilute active chlorine. An example of the weight loss *vs.* time

Table I. Corrosion rate of a graphite anode in saturated NaCl at 40°C and 100 A/dm^2

Exp. No.	pH	Average corrosion rate (mg/A-hr)	Average concentration of active chlorine (mM)	Standard deviation (mM)
1	2	0.12	0.62	—

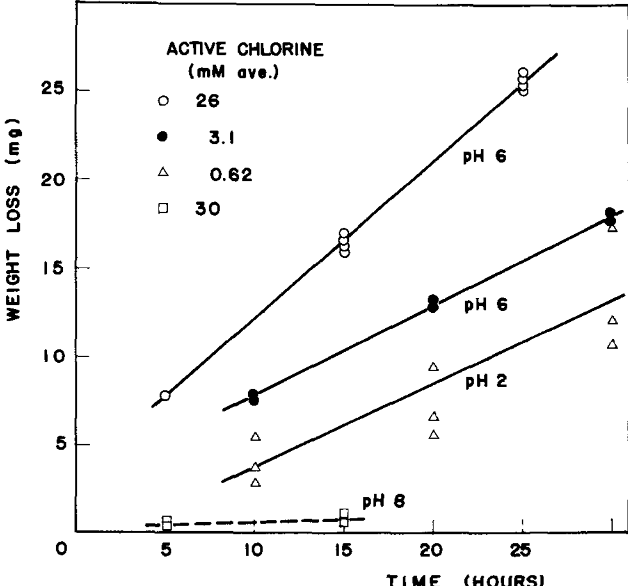

Fig. 5. Weight loss vs. time curves in saturated NaCl at 40°C. Current density, 100 A/dm^2; surface area of specimen, 3.8 cm^2. Broken line shows the data without electrolysis.

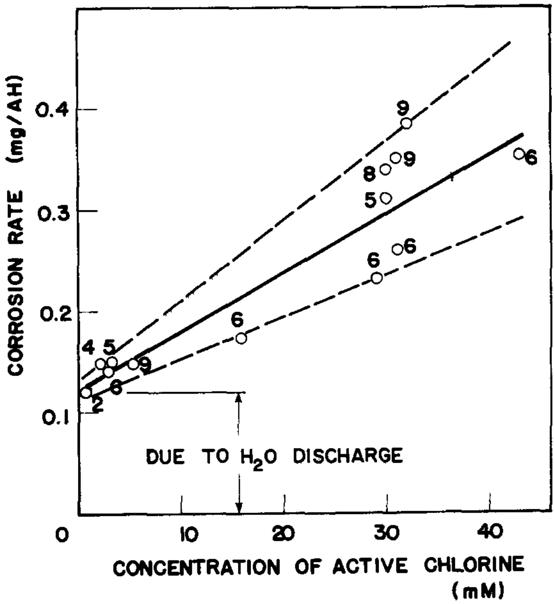

Fig. 7. Corrosion rate vs. concentration of active chlorine at 100 A/dm^2. Label shows the brine pH.

curve is shown in Fig. 5. The weight loss is almost linear with time except the first stage, probably due to physical loss of fine powders from the anode surface.

The corrosion rate depends on the concentration of active chlorine and is a weak function of the pH. A broken line in the figure shows the data of consumption due to chemical oxidation in the brine containing 30 mM of active chlorine at pH 8.

Another experiment for chemical oxidation of graphite was carried out in which fine graphite powder (less than 60 mesh) was immersed in 0.1M NaClO (pH 4.2 and 9.7) at 50°C for 5 hr. The weight loss was recorded to be only 0.4-0.6% or less. It was, therefore, concluded that the chemical oxidation is negligible compared to the electrochemical consumption.

Figure 6 shows the corrosion rate *vs.* the ClO_3^- concentration. The corrosion rate is almost independent of ClO_3^- but is affected by active chlorine.

The corrosion rate as a function of the concentration of active chlorine is shown in Fig. 7. Most data have been obtained in the solution of pH 6. The corrosion rate is about linear with the concentration of chlorine. The data obtained in the solution containing a relatively high level of chlorine deviates because of the fluctuation of the chlorine concentration.

Figure 8 shows the corrosion rate *vs.* pH curves. The labels in the figure show the concentration of active chlorine on the order of 10^{-2}M (closed points) or 10^{-3}M (open points). It is clear that the corrosion rate is almost independent of the pH over a relatively wide range.

The steady-state polarization curves of the rotating graphite cylinder anode after corrosion tests are shown in Fig. 9 and 10. There is no effect of ClO_3^- (Fig. 9), and hence ClO_3^- would not discharge on the graphite anode. On the other hand, the potential

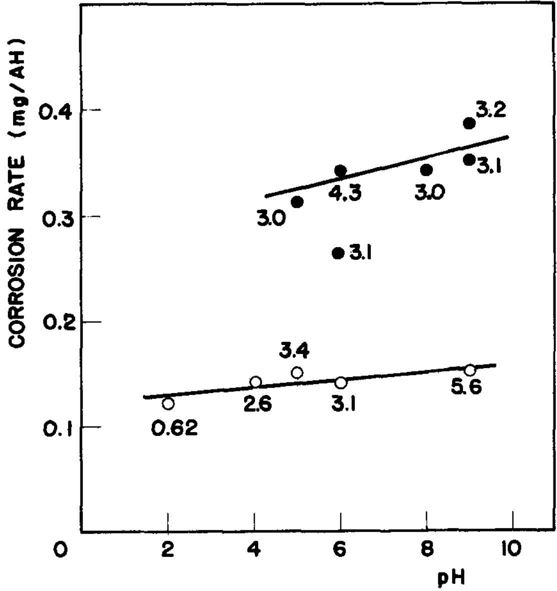

Fig. 8. Corrosion rate vs. brine pH under given concentration of active chlorine. Current density, 100 A/dm^2 at 40°C. Label shows the concentration of active chlorine. The values in the labels are to be multiplied by 10^{-2}M (closed points) and 10^{-3}M (open points).

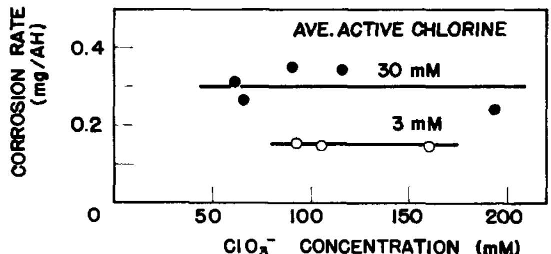

Fig. 6. Corrosion rate vs. ClO_3^- concentration

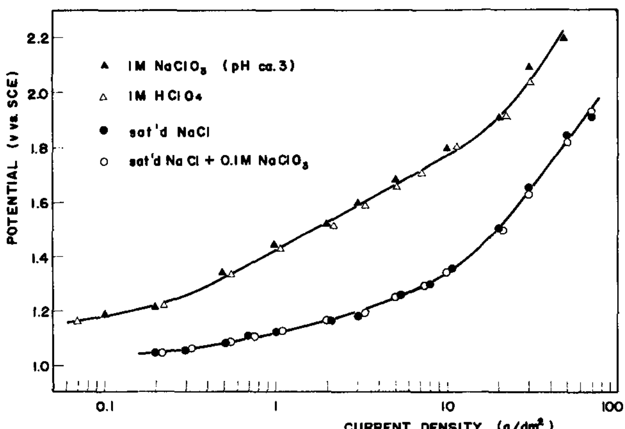

Fig. 9. Steady-state polarization curves of a rotating graphite anode.

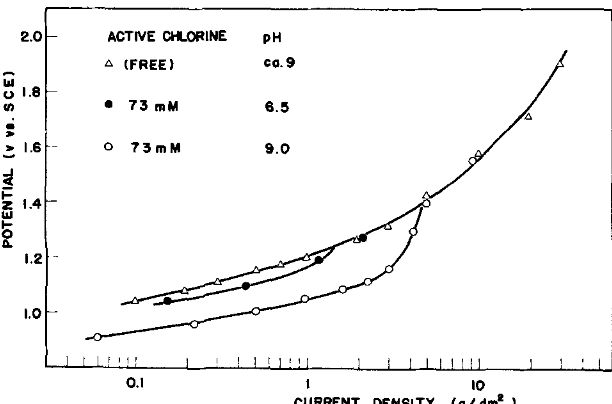

Fig. 10. Steady-state polarization curves of a rotating graphite anode.

is quite sensitive to addition of chlorine (Fig. 10) and also depends on the pH and the rotating speed.

Discussion

A part of the chlorine generated from the graphite anode by electrolysis dissolves into the solution and forms HClO and ClO^- by hydrolysis as shown by reactions [A] and [B]. The distributions of Cl_2 dissolved, HClO, and ClO^- in the saturated NaCl at 25°C as functions of the pH are shown in Fig. 11. Since the ordinate is the mole fractions of these species, it is only a function of the brine pH, but is independent of the total concentration of active chlorine. The experiment has been carried out under given concentrations of active chlorine over a wide range of pH, or with much less than 1 atm of Cl_2 pressure. It is recognized the necessity of this at higher pH's but at pH 1-3, as occurs in chlorine cells, it could have been possible to saturate the anolyte with chlorine. The distribution between Cl_2 dissolved and HClO under 1 atm of Cl_2 partial pressure in the low pH range has been calculated by Barr (31). The HClO concentration increases with the pH but the Cl_2 concentration remains almost constant up to pH 3. A careful study in this pH range of 1-4 would have been most applicable to chlorine cells. The range 6-8 would be applicable to chlorate cells but the active chlorine is unstable in this range, going either to chlorate or oxygen, or both. The condition at the electrode must be different from the bulk of electrolyte under these unstable conditions. From Fig. 11, at about 2.5 of the pH, half of the active chlorine converts into HClO. In a range of pH 5-6, almost all chlorine dissolves as HClO, whereas ClO^- is stable

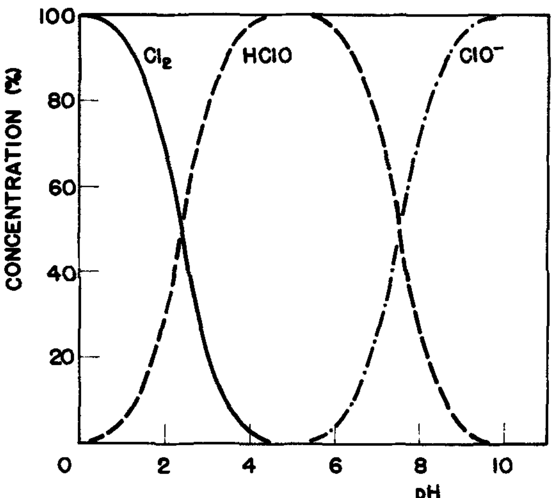

Fig. 11. Concentration ratio of three components of active chlorine in the brine as a function of the pH at 25°C.

at high pH ranges. It agrees well with the results by Cowley *et al.* (32), who have obtained the polarization curves of a graphite cathode in a solution 5M NaCl + 10^{-2}M HCl saturated with chlorine. The diffusion limiting current density of Cl_2 dissolved is about the same as that of HClO.

As shown in Fig. 8, the corrosion rate is almost constant across a wide range of pH if the concentration of active chlorine is kept constant. Therefore, during electrolysis, the graphite anodes seem to be corroded by active chlorine in the bulk solution, but the species in the vicinity of the anode are unknown. However, it is well known that the graphite anode is durable in concentrated HCl solution, also the current efficiency for the Cl_2 formation at the graphite anode in concentrated and acidified (pH *ca.* 2) NaCl solution is more than 99% over wide ranges of the current density (16). The graphite anode must be corroded by HClO and/or ClO^-, and not by Cl_2.

It is well known that the graphite anode is oxidized into carbon surface oxide (as an intermediate) with CO and CO_2 in the electrolytic solution free from Cl^- The process is believed to be due to charge-transfer of H_2O and OH^- in acidic and alkaline solutions, respectively (17-22). Formation of CO and CO_2 depends on the operating conditions of electrolysis (23-25). The oxygen electrode reaction is in competition with the chlorine formation depending on the Cl^- concentration and is important for corrosion of the graphite anodes. The oxygen electrode process on the graphite anodes and the carbon surface oxides will be discussed in detail in the separate papers by the same authors (23-25).

Vaaler has studied the effect of the pH on the consumption of graphite anodes in the range of pH 3-4.2 (10). He pointed out that the amount of the CO_2 formation increased with the pH. Wallen studied the mixed solution of 50 g/liter NaCl and 300 g/liter $NaClO_3$ in the pH range of 2-10, but he did not pay attention to the concentration of active chlorine (11, 26).

Kokhanov *et al.* proposed the discharge of H_2O (to form CO and CO_2 with the O_2 formation) as a cause of graphite corrosion from the experimental results, *i.e.*, that the electrochemical weight loss minus the chemical loss was independent of the pH in the range of 3.3-7 (5). Others showed the "critical potential," at which the graphite consumption was minimized (27-29). The critical potential depends on the temperature: 1.63V *vs.* SHE at 25°C, 1.57V at 40°C, and 1.52V at 60°C. It is important that it agrees well with the potential at which the higher oxide, designated as ($C\text{-}O_H$) by the author of this paper, would form on the graphite anode (23).

Since Cl_2 formation is the main reaction in concentrated NaCl at high current densities, the rate of discharge of H_2O is relatively small. By projection of the line in Fig. 7 to zero concentration of active chlorine, the corrosion rate owing to discharge of H_2O is estimated to be about 0.12 mg/A-hr under the conditions of 100 A/dm² at 40°C.

Formation of chlorate from hypochlorite takes place both chemically and electrochemically depending on operating conditions such as temperature, pH, and the electrode potential (12, 13).

The operating conditions of the corrosion test under discussion here (also in practical chlorine cells) are feasible for chlorate formation as a side reaction. Deviation of the polarization curve at relatively low current densities with addition of chlorine in the electrolyte is, therefore, reasonable as shown in Fig. 10. The diffusion limiting current density depends on the pH and the chlorine concentration which agrees with the results of Filippov and Ibl who have studied the anodic oxidation of hypochlorite with Pt and graphite (12, 13, 30).

Because the electrode potential was high enough during our corrosion tests, the formation of the car-

bon surface oxide as an intermediate is quite possible with formation of chlorate and evolution of oxygen.

Weight loss of graphite immersed in NaCl solution saturated with chlorine is negligible. The weight loss of the graphite during electrolysis at high current density (100 A/dm^2) depends on the chlorine concentration and is a relatively small function of the *p*H. The effect of chlorate on graphite corrosion is also negligible. It is, therefore, concluded that the carbon oxide as an intermediate for electrochemical formation of chlorate from HClO and/or ClO^- is the largest factor in consumption of a graphite anode, while some electrochemical oxidation of the graphite anode with discharge of H_2O or OH^- may also take place.

The corrosion rate described in this paper (*e.g.*, Table I) is relatively low (0.1-0.3 kg/ton-Cl_2) in comparison with in the practical cells (2-3 kg/ton), because the corrosion test was carried out in the saturated brine free from SO_4^{2-} at low temperature (40°C).

While chlorate does not affect degradation of graphite anode, the carbon surface oxide forms simultaneously with electrochemical formation of chlorate from hypochlorite and is the largest factor of consumption of graphite anode in chlor-alkali cells.

Vaaler has reviewed the data in this paper and has worked out a regression analysis by computer. With the data of Table I, he has obtained the results shown in Table II and in Fig. 12 and 13. Although the regression coefficient b_2 associated with *p*H is not defined very accurately, the *F* ratio shows that *p*H has a definite effect on corrosion rate. The plots in Fig. 12 show that scatter around the regression line is moderate and that the effect of *p*H, considered from a practical standpoint, is not large (33).

The authors have no doubts about his conclusion. However, the polarization measurements show that diffusion of HClO, ClO^-, and OH^- are limited under operating conditions of the practical chlorine cells, and the main reaction is formation of Cl_2. The brine *p*H also has an effect on the corrosion rate of graphite anodes, while the slope of the corrosion rate *vs.* *p*H curves (Fig. 8) is small.

In conclusion, the effect of the active chlorine on corrosion of graphite anodes has been emphasized in this paper because the effect is large in comparison with the *p*H effect both during experimental work as well as in practical cells.

Acknowledgment

This work has been directed with the support of Olin Research Center, New Haven, Connecticut. Graphite samples were supplied by Nippon Carbon Company, Tokyo. Titanium equipment was given by Kobe Steel Works, Kobe. The authors also wish to express many thanks to Dr. W. C. Gardiner and Dr. L. E. Vaaler for their kind suggestions and advice for preparation of this report. The Ph.D. thesis of M. Y. at Kyoto University (1972) involves a part of this work.

Hydrogen Evolution Reaction on Vanadium, Chromium, Manganese, Cobalt

A. Bélanger*

and Ashok K. Vijh**

Hydro-Quebec Institute of Research, Varennes, Province of Quebec, Canada

ABSTRACT

The electrolytic hydrogen evolution reaction (HER) has been studied on V, Cr, Mn, and Co in sulfuric acid-sulfate solutions. The data consist of Tafel slopes, exchange current densities, apparent heats of activation, corrosion rates, corrosion potentials, and, in some cases, reaction order derivatives. Attempts were also made to obtain information on the electrode coverage by transient techniques. The presence of corrosion, however, makes the possible electrode coverage by adsorbed hydrogen inaccessible. By combining these electrode kinetic data with the gas-phase hydrogen adsorption behavior of these metals, it is suggested that the HER proceeds by means of the initial discharge mechanism on V and Mn whereas on Cr and Co, the radical-ion mechanism has been concluded.

In a previous theoretical study (1) of the electrocatalysis of the hydrogen evolution reaction (HER) by the metals of the periodic table of elements, it was found that reliable electrode kinetic data for the hydrogen evolution reaction on V, Cr, Mn, and Co were rather scarce in the literature. It was decided to obtain these values and the results of these investigations are presented here.

Experimental

The HER was investigated on V, Cr, Mn, and Co in a three-compartment all-Pyrex cell containing suitable gas inlets and outlets. The hydrogen bubbled in the working and reference compartments and the helium in the counter compartment were purified by the purification trains described previously (2) and were led into the cell by means of glass-to-glass connections. The gas outlets from the cell had water-filled bubblers in order to eliminate the diffusion of atmospheric oxygen into the cell. The stopcocks separating the three compartments of the cell had long necks and were solution-sealed. The cell was thoroughly cleaned in chromic acid with subsequent several washings and soakings in conductivity water. The conductivity water was obtained by eliminating first the ionic and organic impurities of the tap water by passage over suitable commercial cartridges and then by distilling twice over alkaline $KMnO_4$ in two consecutive all-Pyrex stills. The electrolyte solutions were prepared, from H_2SO_4 (Ultrex, J. T. Baker Chemical Corporation) and Na_2SO_4 (Fischer A.C.S.), by adding various quantities of H_2SO_4 (to fix the pH) to Na_2SO_4, the sodium sulfate acting as the supporting electrolyte to maintain a high conductivity. Buffers, which necessitate the use of weak acids such as acetic, formic, phosphoric, etc. for the preparation of acidic solutions, were avoided in order not to introduce traces of contaminants (either in the acid to start with, or produced in the counter compartment during electrolysis with the consequent migration to the working compartment even if the compartments are isolated by means of closed solution-sealed stopcock) or ions which might undergo contact adsorption. Throughout the experiments, solutions were agitated by bubbling hydrogen gas in the working compartment. When limiting currents were to be studied (*e.g.*, proton discharge at low acidic concentrations), the agitation was however stopped in the corresponding region. Solutions were subjected to a cathodic pre-electrolysis on a sacrificial electrode (area $\simeq$ 1 cm^2) of the same material as the working electrode. This pre-electrolysis was conducted first at a low current density (*ca.* 0.1 mA cm^{-2}) for 10-12 hr to remove any organics followed by a second one at around 100 mA cm^{-2} for 2 hr. The electrode was then pulled out of the solution when still under po-

Key words: hydrogen evolution reaction, transition metals, corrosion, active dissolution.

larization. The second pre-electrolysis at 100 mA cm^{-2} was first tried for 12-hr periods. It was noticed that it yielded Tafel lines identical with those obtained by pre-electrolysis for 2 hr. This longer pre-electrolysis was thus avoided because it resulted in change of pH in solutions of higher (from 1.9 →4) pH values. The working electrodes were fabricated from spectroscopically pure metals obtained from A. D. Mackay, Inc., New York, and were mounted into heat-shrinkable Teflon as described previously (3). The working electrodes were polished either mechanically (Mn, Cr) or chemically (Co, V) and were thoroughly and repeatedly cleaned, the final cleaning being in boiling trichloroethylene. Hydrogen reference electrodes and iridium counterelectrodes were employed. Routine potentiostatic and potentiodynamic procedures (4) were used, and in some runs, an automatic steady-state polarization method was employed (5). The circuits used in the measurement of charging curves and open-circuit decays were as described previously (2).

The various potentiostatic plots have been corrected for the *IR* drop. This ohmic drop has been determined by the oscillographic method (6, 7). Checks were made to establish that this *IR* drop was a linear function of the current density.

Results

The electrode kinetic parameters for the HER obtained on the four metals, together with some other related information, have been presented in Tables I-IV. Since the relevant data are contained in these tables, it is unnecessary to present these results in details in various figures. It would appear sufficient, therefore, to show here some representative figures only, as follows:

In Fig. 1, steady-state potentiostatic Tafel lines on vanadium at different temperatures are shown. An examination of these data shows that the Tafel slope is generally around $2.3 \times 2RT/F$ at each temperature, although showing some scatter around this value. The curvature at higher current densities, exhibited by

Table I. HER on vanadium: kinetic parameters and some other characteristics

	Parameter	Value	Comments

1.	Tafel slope (25°C)	120 mV/decade	For both ascending and descending directions of potentials in solution of pH = 0.7
2.	Exchange current density (25°C)	5.0×10^{-8} A · cm^{-2}	Extrapolation of the Tafel plot to $\eta = 0$
3.	Apparent heat of activation	(*a*) 9.8 kcal · $mole^{-1}$	(*a*) Obtained between 21° and 70°C from the plot of $(-\log i)_{\eta=-0.62V}$ *vs.* 1/*T*
		(*b*) 10.2 kcal · $mole^{-1}$	(*b*) Obtained from the relation $\left(\frac{\partial E_{corr}}{\partial 1/T}\right) = \left(\frac{\partial (E_{HER})}{\partial 1/T}\right)$
4.	Reaction order derivative	—	No reaction order for the proton discharge is available because of chromium corrosion
5.	Corrosion potential (25°C)	−500 mV	At pH = 0.7, in 1*N* H_2SO_4 + 2*N* Na_2SO_4 solution
6.	Corrosion current (25°C)	1 mA · cm^{-2}	As determined by the Stern-Geary analysis (26)
7.	Electrode coverage by hydrogen	No clear evidence	General masking of any information concerning the hydrogen adsorption
8.	Hydrogen adsorption in gas phase	$\Delta H_{ads \cdot H} = 74$ kcal · $mole^{-1}$	As given in ref. (25).

Table III. HER on manganese: kinetic parameters and some other characteristics

	Parameter	Value	Comments
1.	Tafel slope (25°C)	140 mV/decade	This value is obtained for H_2O discharge in 0.1*N* H_2SO_4 + 2*N* Na_2SO_4 solution (pH = 1.9)
2.	Exchange current density (25°C)	3.98×10^{-12} A · cm^{-2}	Also for water discharge
3.	Apparent heat of activation	8.1 kcal · $mole^{-1}$	Calculated from the plot of $(-\log i)_{\eta=-1.4V}$ *vs.* 1/*T*
4.	Reaction order derivative	—	No reaction order for the proton discharge because of corrosion
5.	Corrosion potential (25°C)	−1.04V	In a solution of 0.1*N* H_2SO_4 + 2*N* Na_2SO_4 (pH = 1.9)
6.	Corrosion current (25°C)	17 mA · cm^{-2}	Determined by the chemical analysis of dissolved Mn^{2+} in the working compartment
7.	Electrode coverage by hydrogen	—	The corrosion of Mn leads to a general masking of any information on the coverage by H
8.	Hydrogen adsorption in gas phase	$\Delta H_{ads \cdot H} < 52$ kcal · $mole^{-1}$	Not detectable by calorimetric methods (25)

Table IV. HER on cobalt: kinetic parameters and some other characteristics

	Parameter	Value	Comments
1.	Tafel slope (25°C)	115 mV/decade	In the descending direction of potentials (high → low current densities) in 1*N* H_2SO_4 + 2*N* Na_2SO_4 (pH = 0.7)
2.	Exchange current density (25°C)	6.25×10^{-7} A · cm^{-2}	For proton discharge from the extrapolation of the Tafel plot at $\eta = 0$
3.	Apparent heat of activation	14.8 kcal · $mole^{-1}$	Obtained from the plot of $(-\log i_o)$ *vs.* 1/*T*
4.	Reaction order derivative	—	No Tafel behavior in acidic solutions. For water discharge the reaction order is near 0 (see text)
5.	Corrosion potential (25°C)	−114 mV	Open-circuit potential in 1*N* H_2SO_4 + 2*N* Na_2SO_4 (pH = 0.7)
6.	Corrosion current (25°C)	5.4×10^{-6} A · cm^{-2}	By the use of Stern-Geary equation (26)
7.	Electrode coverage by hydrogen	No positive evidence	Masking by the concomitant corrosion reaction
8.	Hydrogen adsorption in gas phase	$\Delta H_{ads \cdot H} = 64$ kcal · $mole^{-1}$	Ref. (25)

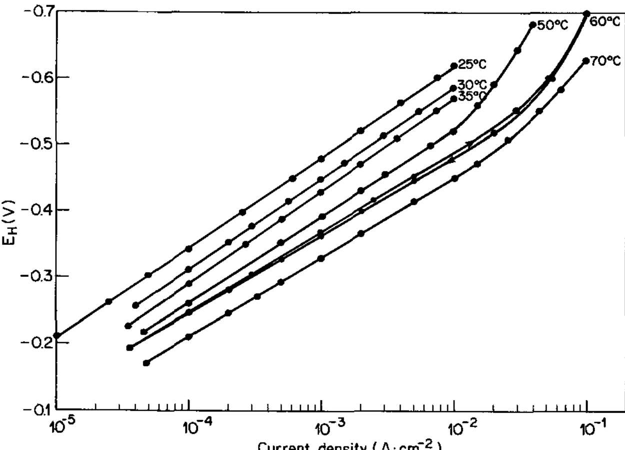

Fig. 1. Tafel relations for the HER on vanadium in 1*N* H_2SO_4 + 2*N* Na_2SO_4 (pH = 0.70) at different temperatures. All Tafel plots taken in the descending direction of the potential. Ascending and descending lines shown for one typical temperature, however.

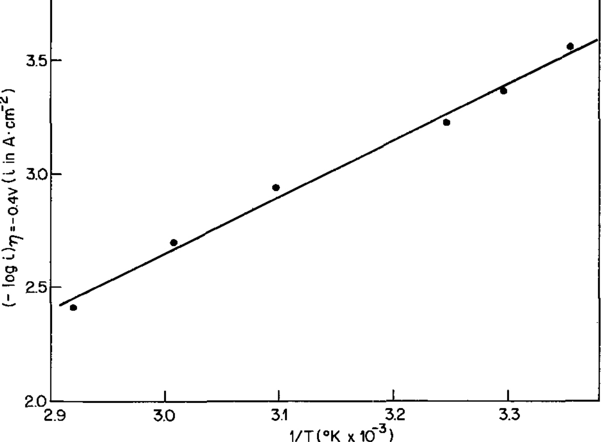

Fig. 2. Plot of $(-\log i)_{\eta=-0.4V}$ vs. 1/*T* for obtaining the derivative $\left(\frac{\partial(-\log i)_{\eta=-0.4V}}{\partial(1/T)}\right)$ for the HER on vanadium in 1*N* H_2SO_4 + 2*N* Na_2SO_4. Data used are taken from Fig. 1. The value of ΔH^* thus obtained is 11.6 kcal·mole^{-1}.

some lines in Fig. 1, does not arise from the *IR* effects nor does it appear to be a limiting current. It is probably associated with the formation of some surface hydride phase. This curvature was also noticed by Kudryashov (8) (at $i > 10^{-2}$ A·cm^{-2}) in a study intended to show the influence of crystal structure of vanadium on Tafel plots for the HER in 1*N* H_2SO_4. Our results, on the polycrystalline samples are comparable to those observed on the (1,1,0) face by Kudryashov, *i.e.*, b = 140 mV and $i_o = 5.8 \times 10^{-6}$ A·cm^{-2}.

For obtaining apparent heat of activation for the HER on V, an attempt has been made to plot the logarithm of the exchange current density ($-\log i_o$) values against 1/*T*, where *T* is the absolute temperature. These data showed an enormous scatter and the ΔH^* value corresponding to the line drawn is incredibly low, viz., 2 kcal · mole^{-1}. The origin of this spurious value for an activation-controlled reaction lies in the fact that the Tafel lines in Fig. 1 are not parallel, and the long extrapolations involved in obtaining the i_o values yield a convergence at the reversible potential owing to different b values associated with the lines in Fig. 1. To circumvent this problem it was decided to extract a representative ΔH^* value from Fig. 1 by plotting the logarithm of the current density at a typical potential (actually at -0.4V, which corresponds, roughly, to the center of the Tafel lines) against the 1/*T* values (Fig. 2). The ΔH^* thus obtained is 11.6 kcal · mole^{-1}, which is quite consistent with the values usually associated with the activation-controlled electrode reactions (9).

Figure 3 contains steady-state potential-log current density relationships on chromium at various temperatures. Linear Tafel regions are obtained only at more cathodic potentials whereas at less cathodic potentials, vanishingly small polarization values are observed, owing to appreciable participation of the corrosion (dissolution) reaction. The experimental Tafel slope decreases with the increasing temperature contrary to theoretical expectations for the variation of $2.3 \times RT/\beta\mathbf{F}$ with the value of $\beta = 0.5$. One possible way to explain this would be to suppose that at low temperatures, high b values are observed because of the presence of a surface oxide on Cr; at higher temperatures, this oxide probably becomes hydrated and thus "short-circuited" as far as its kinetic participation in the charge transfer events is concerned, leading thereby to small slopes. This explanation, however, is highly speculative. The HER on chromium has also been studied previously (10-13). Our results shown in Table II may be compared at room temperature to the ones obtained by the following authors: Slope of 107

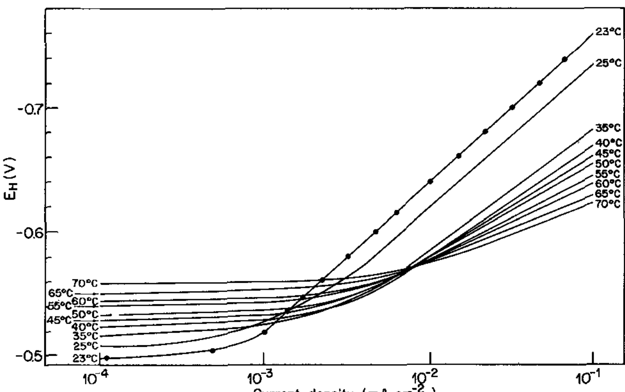

Fig. 3. Tafel relationships for the HER on chromium in 1*N* H_2SO_4 + 2*N* Na_2SO_4 (pH = 0.7) solution at different temperatures. The curves shown represent the ascending and descending directions of both the potential and temperature. Data were recorded at 20 mV intervals in most cases. These curves are used to evaluate the apparent heat of activation of the reaction. Typical experimental points have been shown at one curve.

mV was observed in 1*N* H_2SO_4 with $i_o = 3.5 \times 10^{-8}$ A·cm^{-2} by Ho Nhok Ba *et al.* (11). De Becdelièvre *et al.* (12) obtained a slope of 123 mV and $i_o = 5.9 \times 10^{-7}$ A·cm^{-2} for the face (1,0,0) of chromium in 1*N* H_2SO_4, and finally a slope of 126 mV and $i_o = 4 \times 10^{-7}$ A·cm^{-2} for active chromium in 1*N* H_2SO_4 by Wilde and Hodge (13). From the plot of log i (at $\eta = -0.62$V) *vs.* 1/*T* we obtained a value of 9.8 kcal·mole^{-1} for the apparent heat of activation (Table II).

It is of interest in the present context to examine the plot of the open-circuit mixed corrosion potentials *vs.* 1/*T* values as taken from Fig. 3. One may estimate the ΔH^* value from this plot by assuming, as in a previous publication (14), that the mixed corrosion potential is determined almost entirely by the cathodic conjugate partial reaction (*i.e.*, the HER). With this assumption, $\left(\frac{\partial E_{corr}}{\partial(1/T)}\right)$ value is 129 mV (and roughly equal to 120 mV at room temperature, *i.e.*, equal to *ca.* $2.3 \times 2RT/\mathbf{F}$) and that this change in E_{corr} corresponds roughly to 1 decade change in the current density, one may estimate a ΔH^* value from these data as equal to 10.2 kcal·mole^{-1}. This value agrees well with the one calculated from log i *vs.* 1/*T*, the plot as obtained above. On "active" chromium, Wilde and Hodge (13) got a much higher value

from their Arrhenius plot, *i.e.*, 38.4 kcal·mole^{-1} in 1*N* H_2SO_4 while they obtained 11 kcal·mole^{-1} for their passive chromium in the same solution. From the magnitudes of our corrosion potential and the corrosion current density and of those observed by Wilde and Hodge (13), it is clear that our data for the HER refer to a nonpassivated chromium surface. The values of ΔH^* observed by Wilde and Hodge (13) for the active chromium are, however, enormously higher than those obtained by us; the magnitude of their ΔH^* values for this case (38.4 kcal·mole^{-1}) appears much too high in comparison with the ΔH^* values generally observed for the HER on various metals.

In Fig. 4, steady-state potentiostatic Tafel plots for the HER on Mn in 0.1*N* H_2SO_4 + 1*N* Na_2SO_4 (pH = 1.9), at the shown temperatures, are presented. At the lower cathodic potentials, no Tafel plot is obtained because of the vigorous open-circuit corrosion reaction. Around 10^{-2} A·cm^{-2}, a limiting current density for the discharge of H_3O^+ is reached, as also noted in some previous work (15), folowed by a long Tafel region, at all temperatures, associated with the evolution of hydrogen by the discharge of H_2O. The Tafel slopes for these lines are *ca.* 140 mV/decade and may hence be roughly assumed to be 2.3 × 2*RT*/**F**. An attempt was made to obtain the apparent heat of activation ΔH^*, from these Tafel lines by plotting the current density values at −1.4V vs. 1/T. It was observed the $\left(\frac{\partial \log i}{\partial\, 1/T}\right)_{\eta=-1.4V}$ is 8.1 kcal·mole^{-1}. Melendez and Brenet (16) have reported a Tafel slope of 152 mV in buffered phosphate solutions (*p*H = 7.6) which also corresponds to water discharge. Hurlen and Valand (17) obtained a slope of 117 mV in sulfuric acid-potassium sulfate solutions but these experiments (17) were conducted in a single compartment cell which would make them of questionable validity due to the possible contamination by oxygen formed at the anode. In 0.1*N* H_2SO_4, Gamali and Stender (18) obtained a slope of 120 mV with an exchange current density of 1.8×10^{-12} A·cm^{-2}.

In Fig. 5 steady-state potentiostatic Tafel plots for the HER on Co are presented. They cover a range of temperatures and were taken in 1*N* H_2SO_4 + 1*N* Na_2SO_4 (*p*H = 0.7) solutions. Reproducible Tafel lines over several decades of current densities are obtained only if one prepolarizes the electrode for about 30 min at the highest current density and traces the Tafel slopes in the descending (more cathodic → less cathodic) direction of potentials. Even under these conditions, the marginal "second" Tafel region at higher cathodic potentials is not very reproducible and will not be discussed further here. It should be emphasized that this lack of reproducibility in the upper Tafel

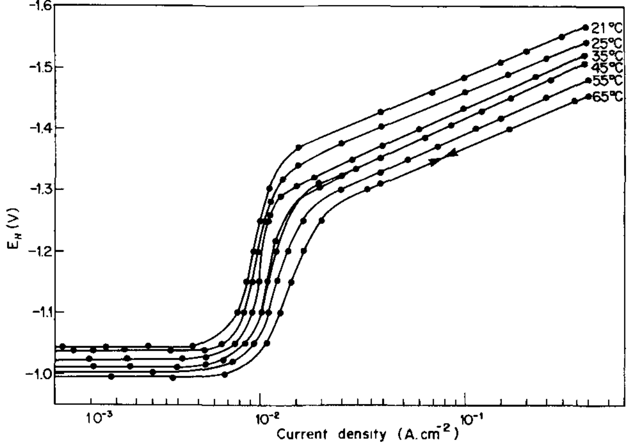

Fig. 4. Tafel relationships for the HER on manganese in 0.1*N* H_2SO_4 + 2*N* Na_2SO_4 (*p*H = 1.9) at different temperatures. These curves were used to calculate the apparent heat of activation.

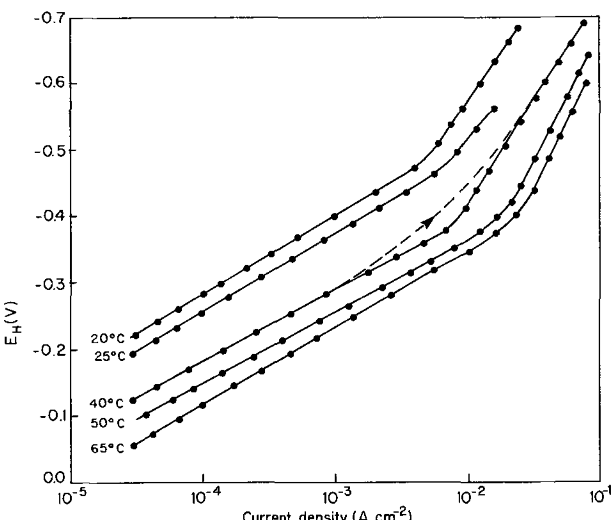

Fig. 5. Tafel relationships for the HER on cobalt in 1*N* H_2SO_4 + 2*N* Na_2SO_4 (*p*H = 0.70) at different temperatures. All Tafel plots are in the descending direction of the potential but a typical ascending curve is shown (in dashes) for one temperature (40°C). Data are: b_{20} = 117 mV; b_{25} = 115 mV; b_{40} = 106 mV; b_{50} = 105 mV; b_{65} = 115 mV.

region is not due to the impurities in the solution since good Tafel lines are obtained in the potential range, −0.05 to −0.5V at all temperatures. It appears that cathodic polarization leads to some profound change in the cobalt surface which results in their stability, and hence reproducibility after the prepolarization. The hysteresis between the ascending and descending Tafel plots (on the conditioned electrodes, of course) is shown only for 40°C in Fig. 5; it is least pronounced for 65°C and assumes higher magnitudes for lower temperatures.

An attempt has been made to deduce the apparent heat of activation, ΔH^*, by plotting $-\log i_o$ values against the corresponding 1/*T* value. The parent data for this plot are extracted from Fig. 5. The ΔH^* obtained is 14.8 kcal·mole^{-1}. All the results presented here and summarized in Table IV may be compared with the following ones. Iofa *et al.* (19) obtained a slope of 147 mV and an i_o of 1.9×10^{-5} A·cm^{-2} in 0.1*N* H_2SO_4; Mottern and Myers (21) give a value of 125 mV for the cathodic Tafel slope and 1.3×10^{-5} A·cm^{-2} for the exchange curent density with E_{corr} being −0.31V (SCE) in 1*N* H_2SO_4.

A typical determination of the chemically significant reaction order derivative, $\left(\frac{\partial \log i}{\partial\, pH}\right)_{\phi=-0.7V,\Psi,T}$ is depicted in Fig. 6, for the case of V; here ϕ refers to the electrode potential against standard hydrogen electrode (also see Table IV), and Ψ is the potential drop across the diffuse double layer.

Potentiodynamic and transient studies.—A complete study of the behavior of the four metals under dynamic variation of potential was carried out. The techniques used were the following: (*i*) potentiodynamic profiles for various sweep rates, temperatures, and *p*H values; (*ii*) open-circuit decay of the electrode potential; (*iii*) galvanostatic cathodic charging curves from the open-circuit potential; and (*iv*) galvanostatic forced decay (22) curves at high anodic or cathodic current densities. These experiments were conducted with a view to obtain some information on the coverage of the electrodes by chemisorbed hydrogen. In general, very high pseudo-capacitance values characteristic of a significant corrosion reaction were observed in all cases. The studies could not bring out, therefore, any evidence of the chemisorption (or lack of it) of atomic hydrogen on these electrodes during the HER.

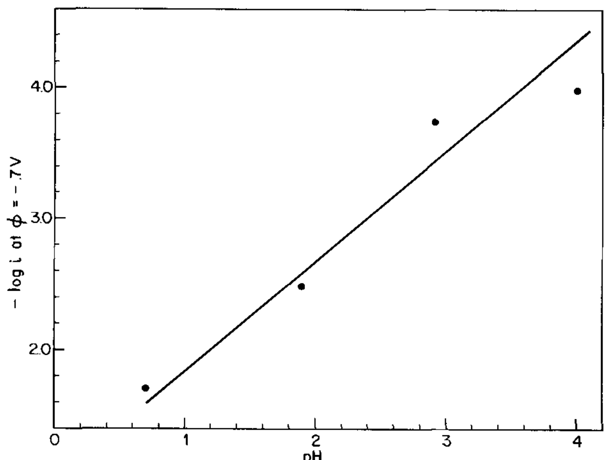

Fig. 6. Plot of $-\log i$ at $\phi = -0.7V$ vs. pH for the vanadium electrode in $xH_2SO_4 + 2N\ Na_2SO_4$ solutions ($1N > x > 10^{-4}N$); ϕ is the value of the electrode potential against standard hydrogen electrode (SHE).

Discussion

For V, Cr, and Co the corrosion rates in the highly acidic ($pH = 0.7$) solutions are not high enough to prohibit the measurement of Tafel regions for the HER proceeding by the discharge of H_3O^+ (Fig. 1, 3, and 5). For the case of Mn, however, the corrosion rate is of very high magnitude so that a Tafel line for the HER by proton discharge is not obtained even in solutions with $pH = 1.9$ (Fig. 4). In this case, a limiting current for the H_3O^+ discharge is obtained around 10^{-2} $A \cdot cm^{-2}$, which is followed by a Tafel region for the HER by water discharge at higher cathodic potentials (Fig. 4).

The evolution of hydrogen on V, Cr, and Co, from the acidic solutions can involve the following elementary steps (14, 23, 24)

$$H_3O^+ + e^- + M \rightarrow M - H + H_2O \qquad [1]$$

followed by

$$H_3O^+ + e^- + M - H \rightarrow M + H_2 + H_2O \qquad [2]$$

or

$$2M - H \rightarrow 2M + H_2 \qquad [3]$$

The values of the Tafel slope for these three metals (Table I, II, and IV) exclude the possibility of step [3] as the rate-determining step (rds). The experimental values observed (*ca.* $2.3 \times 2RT/\mathbf{F}$) would indicate either step [1] (with electrode coverage $\theta \rightarrow 0$) or step [2] (with electrode coverage $\theta \rightarrow 1$) as the rds. Since direct evidence on the electrode coverage by electrochemical transient studies cannot be obtained for these metals because of the interference by metal dissolution and oxide formation (or reduction) etc., it is difficult to distinguish between the choice of step [1] or step [2] as the rds. Some light may be thrown on this point, however, by the behavior of these metals toward the adsorption of H_2 in the gas phase (Tables I, II, and IV), as discussed previously in the theoretical considerations of the HER (1, 23, 24). Since Cr (Table II) and Co (Table IV) are good catalysts for adsorbing hydrogen (25), it is likely that the HER proceeds on an electrode covered by adsorbed hydrogen. This fact would indicate step [2] as the rds for Co and Cr. It is found, however, that vanadium does not adsorb hydrogen from the gas phase (Table I). It is likely that because of its rather noncatalytic nature in the gas phase (25), the vanadium electrode is not covered by chemisorbed hydrogen during the HER; this would suggest step [1] as the rds for V.

For the case of Mn, the Tafel line is observed only for the discharge of H_2O for the solutions examined (Fig. 4). The steps involved in the HER on Mn would then be

$$M + H_2O + e^- \rightarrow M - H + OH^- \qquad [4]$$

followed by

$$M - H + H_2O + e^- \rightarrow M - H + H_2 + OH^- \qquad [5]$$

or

$$2M - H \rightarrow 2M + H_2 \qquad [3]$$

The value of Tafel slope (Table III) would exclude, again, step [3] as the rds. The direct knowledge on the electrode coverage by adsorbed H, during the HER, is again not accessible. However poor adsorbent properties of Mn for the H_2 in the gas phase (Table III) would lead one to suggest that the electrode coverage during the HER is probably not significant. One would thus tend to conclude step [4] as the rds on Mn in the Tafel region in Fig. 4.

The relevance of other experimental data (Tables I to IV) to the proposed mechanisms may now be examined. The value of i_o for V is rather high (9, 23) for the suggested initial discharge mechanism whereas the magnitudes of reaction order and the heat of activation are not incompatible with it (Table I). For the case of chromium, the i_o and ΔH^* values are not inconsistent with the proposed mechanism (14, 23). The attempts to measure reaction order on Cr by examining the current-potential relations at pH values of 0.7, 1.9, 3, and 4 were not successful; this arises because at higher pH values (1.9, 3, and 4), the Tafel line (obtained between the open-circuit corrosion potential and the potential for the change-over to H_2O discharge) for the H_3O^+ discharge is too small to be significant.

For the case of Mn (Table III) the exchange current density value observed clearly confirms the suggested mechanism (14, 23, 24), although the ΔH^* is rather low though not inconsistent (4) with the proposed mechanism. Here the reaction order could not be determined since the Tafel lines are obtained for the discharge of water only (Fig. 4).

The exchange current density for Co (Table IV) is of the same magnitude as is generally observed for metals proceeding with step [2] as the rds (1, 14, 23, 24). The heat of activation is not so high as would militate against the proposed mechanism. The reaction order could not be determined owing to the reasons very similar to those mentioned for chromium above.

In conclusion, it is suggested that HER on V and Mn proceeds with steps [1] and [4] as the rds, respectively. For the case of Co and Cr, step [2] appears to be the likely rds.

Hydrogen and Nitrogen Evolution Reactions in Acid Liquid Ammonia

M. H. Miles* and C. A. Yates

Department of Chemistry, Middle Tennessee State University, Murfreesboro, Tennessee 37130

ABSTRACT

The hydrogen and nitrogen evolution reactions were investigated on various electrode surfaces in acid (NH_4NO_3) liquid ammonia solutions at temperatures ranging from 20° to −60°C. Tafel slopes, transfer coefficients, and exchange currents were determined from the potential-current measurements. The relative rates of the hydrogen evolution reaction on various surfaces in liquid ammonia is in the order Pt, Ir >> Ni_2B, Au > Mo, Cr, W >> Ta, similar to the relative reactivities found in aqueous solutions. The Tafel slopes for the cathodic reaction are also similar to Tafel slopes determined in aqueous solutions at comparable temperatures. However, the apparent cathodic transfer coefficients tend to decrease significantly at low temperatures. On platinum surfaces, the slow step appears to change from the chemical recombination of adsorbed hydrogen atoms to an electrochemical process as the temperature decreases. Studies of the nitrogen evolution reaction are complicated by possible interfering anodic reactions. However, the results indicate that there is an extremely high overvoltage associated with the nitrogen evolution reaction, and that electrochemical process rather than chemical recombination steps control the reaction rate.

Investigations of the hydrogen evolution reaction (h.e.r.) in liquid ammonia solutions (1-3) have been surprisingly few, especially when compared with the numerous studies of the h.e.r. in aqueous solutions (4, 5). The literature indicates that the Tafel parameters for the h.e.r. in liquid ammonia solutions have been determined only for nickel and platinum electrodes (1, 3). The only detailed study reported of the nitrogen evolution reaction (n.e.r.) in liquid ammonia was made using a platinum electrode in several acid salt solutions at −50°C (6). In our study, Tafel parameters were determined for the h.e.r. on various electrodes in NH_4NO_3 solutions in liquid ammonia at temperatures of 20°, 0°, and −60°C. The nitrogen evolution reaction on several electrodes was also investigated at 0°C.

Experimental

The liquid ammonia solutions were prepared from anhydrous ammonia (99.99%) and vacuum-dried, reagent grade NH_4NO_3 using methods similar to those described previously (2, 7). At 0° and 20°C, the mole ratio of NH_3 to NH_4NO_3 is about 1.5 in the ammoniate of this salt (8). At −60°C, approximately 5M solutions of NH_4NO_3 were used. A dry ice-chloroform bath was used for measurements at −60°C to provide temperature control of ±1°C. Recent work has verified that the lead-saturated lead nitrate (SLN) reference electrode used works well in liquid ammonia solutions (9).

All potential-current measurements were made using a Beckman Electroscan 30 instrument. Prior to each run, the electrode received a pretreatment by sweeping the potential in the positive direction until nitrogen evolution occurred, then in the negative direction until hydrogen evolution appeared. This procedure was repeated several times, always allowing hydrogen to be evolved before the actual run started. In each run, the potential was swept in the direction of interest at a rate of 0.5 mV/sec.

Results

The linear regions of the log i *vs.* potential plots suggested by Tafel's equation

$$|\eta| = |E - E_o| = a + b \log |i| \quad [1]$$

for all electrodes studied is shown in Fig. 1 for the hydrogen evolution reaction

$$NH_4^+ + e^- \rightleftharpoons NH_3 + \tfrac{1}{2} H_2 \quad [2]$$

* Electrochemical Society Active Member.

Key words: exchange current, Tafel slopes, transfer coefficients, overvoltage.

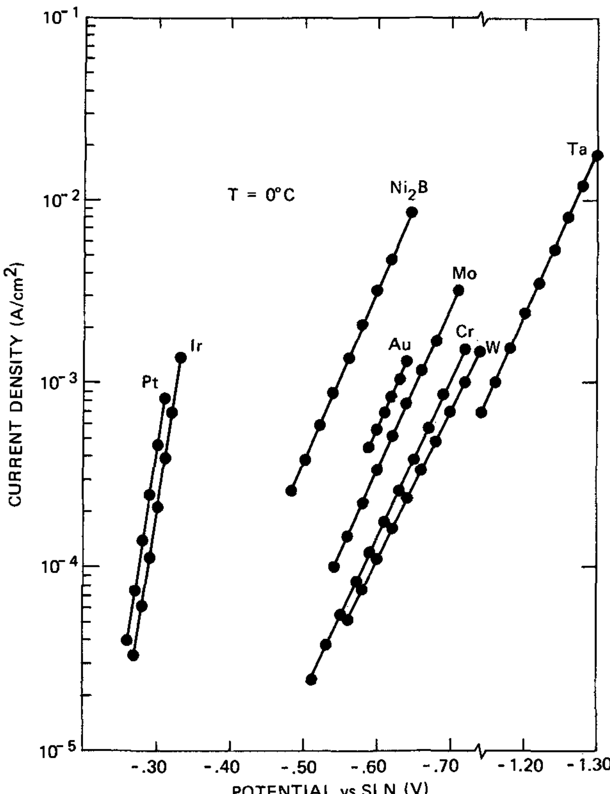

Fig. 1. Linear Tafel regions for the hydrogen evolution reaction on various electrode surfaces in acid (NH_4NO_3) liquid ammonia solutions at 0°C.

in NH_4NO_3 solutions in liquid ammonia at 0°C. The current density, i, was determined using the geometrical area of the electrode. Except for platinum and iridium, the slopes of these plots are about the same for each electrode material. However, the overvoltage, η, required for a given current density varies greatly with the metal used. This indicates that the ranking of these electrodes as electrocatalysts for the above reaction is in the order Pt $>$ Ir $>>$ Ni_2B $>$ Au $>$ Mo $>$ Cr $>$ W $>>$ Ta, with Pt being the best electrocatalyst. The Tafel parameter, b, and the apparent cathodic transfer coefficient, β, can be determined from Fig. 1 using the relationships

$$b = \frac{d|\eta|}{d \log |i|} = \frac{2.303RT}{\beta \mathbf{F}} \quad [3]$$

Knowledge of the equilibrium potential, E_o, for reaction [2] is required before the determination of the Tafel parameter, a, can be made. Due to indicated difficulties with the hydrogen reference electrode in liquid ammonia (9) involving rather long initial settling down periods (10), no attempt was made to measure the equilibrium potential directly for our solutions. However, the equilibrium potential can be estimated to be about -0.25V *vs.* SLN for the solutions at 0°C, based upon the current-potential measurements using the platinum electrode. Using this estimated value for E_o, both the Tafel parameter, a, and the apparent exchange current, i_o, can be determined for the h.e.r. in liquid ammonia. These results are given in Table I for the various electrodes used. Using the apparent exchange currents gives almost the same ranking as above for the electrodes as electrocatalysts for reaction [2].

Figure 2 shows Tafel plots at 20°, 0°, and -60°C for the hydrogen evolution reaction on molybdenum in acid liquid ammonia solutions. Similar studies at these three temperatures were made using platinum, gold, and tungsten electrodes. Values for the apparent cathodic transfer coefficients, β, for the h.e.r. were calculated from the Tafel slopes using Eq. [3]. The results given in Table II show that the values for β vary with the temperature. For Au, Mo, and W electrodes, the values for β range from about 0.5 at 20°C to about 0.3 at -60°C. For Pt, β ranges from about 2 at 20°C to about 0.5 at -60°C.

Table I. Tafel parameters for the hydrogen evolution reaction at various electrodes in NH_3-NH_4NO_3 solutions at 0°C

Electrode material	a (Volts)	b (Volts)	i_o (A/cm²)
Pt	0.15	0.031	2×10^{-5}
Ir	0.16	0.032	10^{-5}
Ni_2B	0.59	0.10	10^{-6}
Au	0.71	0.12	10^{-6}
Mo	0.71	0.11	4×10^{-7}
W	0.81	0.12	2×10^{-7}
Cr	0.79	0.11	10^{-7}
Ta	1.21	0.10	10^{-12}

Table II. Apparent cathodic transfer coefficients for the hydrogen evolution reaction in NH_3-NH_4NO_3 solutions at 20°, 0°, and -60°C

Electrode material	β (20°C)	β (0°C)	β (-60°C)
Pt	2.15	1.75	0.47
Au	0.58	0.48	0.26
Mo	0.45	0.52	0.32
W	0.45	0.46	0.28

Figure 3 shows Tafel plots at 0°C for the anodic or nitrogen evolution reaction on various electrodes in acid liquid ammonia solutions. Although formation of gas bubbles is directly visible on all the electrodes at the higher current densities, it is also possible that the anodic current includes components due to direct oxidation of the electrode itself or due to formation of interstitial nitrides of the metal. Gessler and Pleskov (6) have demonstrated that in acid salt solutions in liquid ammonia at -50°C, about 6% of a constant current density of 10^{-5} A/cm² is consumed by dissolution of the platinum anode, assuming platinum is trans-

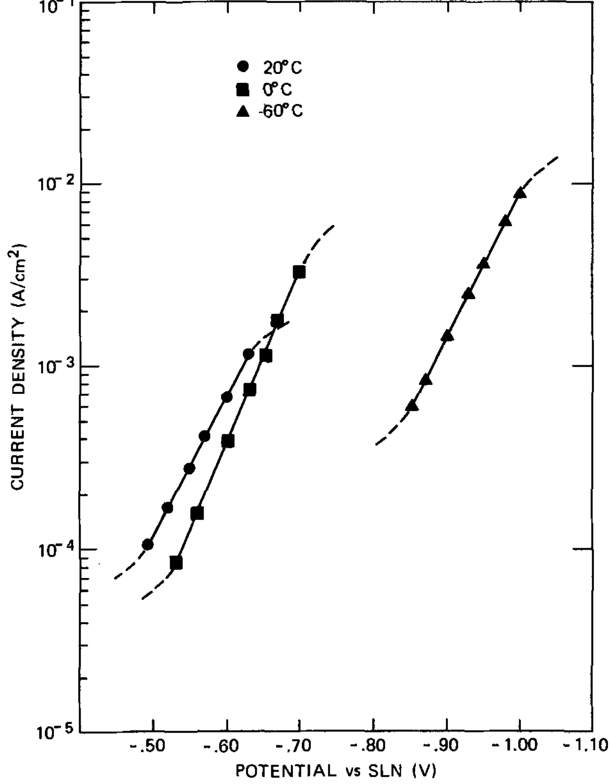

Fig. 2. Linear Tafel regions for the hydrogen evolution reaction on molybdenum in acid (NH_4NO_3) liquid ammonia solutions at 20°, 0°, and -60°C.

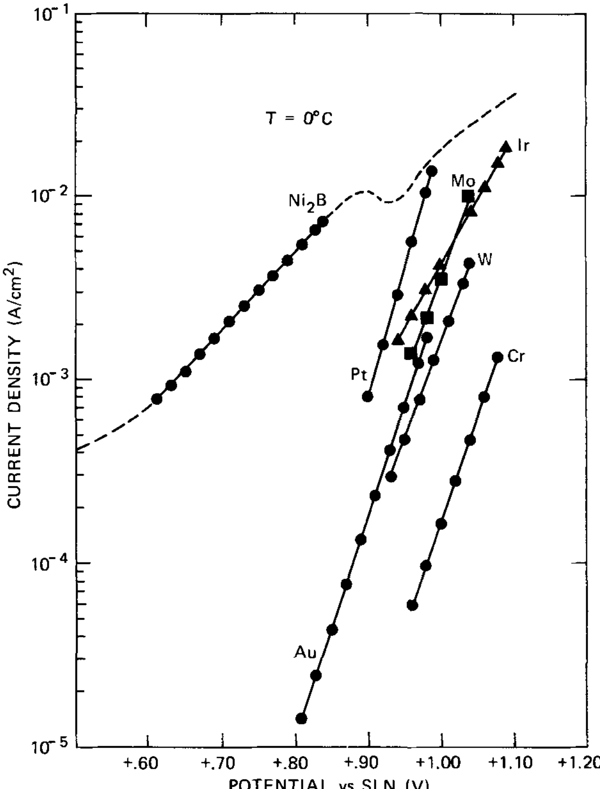

Fig. 3. Linear Tafel regions for the anodic or nitrogen evolution reaction on various electrode surfaces in acid (NH_4NO_3) liquid ammonia solutions at 0°C.

ferred to the solution in the form of tetravalent ions. Such dissolution would likely be larger for the less-noble metals. The apparent anodic transfer coefficient calculated from the Tafel slopes in Fig. 3 are 0.2 for Ni_2B, 0.4 for Ir, 0.6 for Mo, W, and Cr, and 0.7 for Au and Pt. The Tafel slopes reported by Gessler and Pleskov (6) indicate an apparent anodic transfer coefficient of 0.5 for the n.e.r. on platinum at −50°C.

Discussion

At normal temperatures, the hydrogen evolution reaction in acid liquid ammonia appears to be kinetically similar to the h.e.r. in acid aqueous solutions. The reaction steps to be considered in the mechanism of reaction [2] are likely

$$NH_4^+ + e^- \rightarrow H_{ads} + NH_3 \quad [4]$$

$$NH_4^+ + H_{ads} + e^- \rightarrow H_2 + NH_3 \quad [5]$$

$$H_{ads} + H_{ads} \rightarrow H_2 \quad [6]$$

For most transition metals, the h.e.r. proceeds with significant steady-state adsorption of hydrogen (11, 12), hence either reaction [5] or [6] would probably be rate-determining. Judging from the Tafel slopes (Tables I and II), reaction [6] appears to be rate-determining on Pt and Ir surfaces at temperatures 0°C or above ($\beta \approx 2$), while reaction [5] is likely rate-determining on the other surfaces. The unusually large decrease in β with decreasing temperature to a value of about 0.5 at −60°C suggests that reaction [5] becomes rate-determining on Pt at extremely low temperatures.

The reactivity scale for the h.e.r. on various metals appears to be about the same in acid ammonia solutions as observed in acid aqueous solutions. Trasatti (12) has indicated that the solvent would not interfere substantially with the h.e.r., except for shifting the absolute scale of reactivity. Studies of the results for the h.e.r. in aqueous solutions suggest that there is a linear correlation between log i_o and the heat of adsorption of hydrogen on the electrode, ΔH_{ads} (12, 13). Omitting Ta, the measured exchange currents in acid liquid ammonia show a linear relationship between log i_o and ΔH_{ads} with $d \log i_o / d\, \Delta H_{ads} \approx 0.3$, while a slope of 0.6 was found for aqueous solutions (13). Although the measured exchange currents in acid ammonia solutions generally tend to increase with increasing work function of the metal, the relationship between log i_o and the work function is not clearly linear as suggested by Trasatti (12). The possibility of producing persistent interstitial nitrides during the electrode pretreatment might account for the lack of linearity. It should also be noted, however, that Kuhn *et al.* (13) question proposed correlations between the rate of the h.e.r. and the work function.

A temperature dependence of β similar to that shown in Table II has been observed in other studies of the h.e.r. at low temperatures (14-16). It has been proposed that either β is a function of temperature, or

$$b = C - \frac{2.303RT}{\beta \mathbf{F}} \quad [7]$$

where C and β are constants, to account for observed increases in b with decreasing temperature (16). This anomalous temperature dependence of b can be rationalized in terms of specific adsorption of anions, presence of surface films, solvent structure effects in the double layer, or by proton tunneling at low temperatures (16, 17). It is interesting to note that a proton tunneling mechanism predicts a Tafel slope corresponding to $\beta \approx 0.25$ (17), which is close to the experimental values at −60°C (Table II) for the h.e.r. on W, Mo, and Au. Lamarre and Vijh (3) observed a similar Tafel slope for the h.e.r. on Pt at −73°C in liquid ammonia and suggested the possibility of a proton tunneling mechanism. However, detailed studies of the h.e.r. in methanolic and ethanolic acid solutions at low temperatures give very little evidence for a proton tunneling mechanism (14-16).

The calculated thermodynamic dissociation voltage of liquid ammonia corresponding to evolution of hydrogen at the cathode and nitrogen at the anode is only 0.04V at 25°C (2, 6). Using this to estimate an equilibrium potential of −0.2V *vs.* SLN for the n.e.r., the data in Fig. 3 indicate that the kinetics are very slow for the nitrogen evolution reaction in liquid ammonia. The exchange current density for the n.e.r. on platinum is calculated to be only about 10^{-19} A/cm² at 0°C in acid liquid ammonia solutions. Gessler and Pleskov (6) have also shown that a high nitrogen overvoltage exists for the n.e.r. on platinum in liquid ammonia.

Possible steps in the reaction mechanism for the n.e.r. in liquid ammonia include

$$NH_{x\,ads} \rightarrow NH_{y\,ads} + (x-y)H^+ + (x-y)e^- \quad [8]$$

$$NH_{x\,ads} + NH_{y\,ads} \rightarrow N_2H_{z\,ads} \quad [9]$$

$$N_2H_{z\,ads} \rightarrow N_2 + zH^+ + ze^- \quad [10]$$

where x and y are integers ranging from 0 to 3 with $x \geqq y$ and $0 \leqq z \leqq 4$. Simple kinetic considerations predict an anodic transfer coefficient value of $\alpha = 2$ when processes involving chemical recombination of adsorbed species are rate determining. If interfering anodic reactions can be neglected, then the experimental values for α, which range from 0.2 to 0.7, suggest that neither reaction [9] nor the recombination of adsorbed nitrogen atoms is rate determining. Since the electrochemical oxidation of hydrazine occurs readily in liquid ammonia (7), it seems unlikely that reaction [10] would be rate determining. Therefore, the rate-determining step for the n.e.r. in liquid ammonia must be some electrochemical process represented by Eq. [8]. Similar conclusions were reached by Gessler and Pleskov (6) in their studies in liquid ammonia, and by Gerischer and Mauerer (18) in their investigations in aqueous KOH solutions. In basic aqueous solutions, the participation of adsorbed OH-radicals promotes the electrochemical oxidation of ammonia. In both aque-

ous and liquid ammonia acid solutions, where OH^- species are rare or absent, the electrochemical oxidation of ammonia is extremely slow.

Conclusions

The Tafel slopes, reaction mechanisms, and relative reactivities for the h.e.r. on various electrodes in acid liquid ammonia show expected similarities to the h.e.r. in acid aqueous solutions at comparable temperatures. However, the apparent cathodic transfer coefficients tend to decrease at low temperatures, and on platinum there is evidence that a change in the rate-determining stop occurs at low temperatures.

There is an extremely high overvoltage associated with the nitrogen evolution reaction in acid liquid ammonia solutions. The Tafel slopes suggest that an electrochemical step rather than a chemical recombination step is rate determining for the anodic reaction.

A Radiometric Study of Carbon Dioxide Adsorption on Platinum

H. B. Urbach,* L. G. Adams, and R. E. Smith

Naval Ship Research and Development Center, Annapolis, Maryland 21402

ABSTRACT

The adsorption of CO_2 on platinum covered with adsorbed hydrogen atoms gives rise to an adsorbate called "reduced CO_2," written $(CO_2)_r$. The steady-state adsorption of $(CO_2)_r$ (the isoconcs) and its initial adsorption kinetics (Tafel plots) were studied by radiometric methods employing C^{14}-labeled CO_2. Radiometric results and selected reported electrochemical results appear to be compatible provided the adsorbate $(CO_2)_r$, is assumed to be a carbonyl species that is bridged on two adjacent platinum sites. Isoconcs (coverage *vs.* potential relation) reveal a gaussian curve with a steady-state adsorption peak between 0.00 and 0.10V (RHE). Both the steady-state adsorption and kinetic rates increase with pH. No current is observed during the formation of $(CO_2)_r$. The character of the isoconcs and the initial kinetic rates are predicted by a reaction scheme based on cathodic reduction of carbon dioxide and anodic oxidation of adsorbed hydrogen atoms in equal amounts.

The reaction of CO_2 with chemisorbed hydrogen on platinum electrodes was first studied by Giner (1). He concluded that he was observing a redox reaction and called the final adsorbed product "reduced CO_2" [henceforth referred to as $(CO_2)_r$]. His studies, conducted at room temperature in an acidic electrolyte, indicated that CO_2 adsorbs below 0.25V with the resultant adsorbate oxidizing above 0.5V during linear potential sweeps. In subsequent studies of the adsorption of organic materials and saturated hydrocarbons (3) he reported $(CO_2)_r$ as part of the partially oxidized residue of these reactants.

Further studies by Niedrach *et al.* (4) indicated the presence of $(CO_2)_r$ on platinum fuel-cell electrodes exposed to low molecular weight hydrocarbons, implicating $(CO_2)_r$ as a detrimental factor (4) affecting fuel-cell operation. Additional experiments were subsequently undertaken by other researchers (5-27) to further the characterization of reactions producing CO_2 and its adsorbate. Each of these experiments has provided further insight into the basic properties of $(CO_2)_r$ using purely electrochemical means.

Concern for the detrimental effects of $(CO_2)_r$ on the behavior of fuel-cell anodes using carbonaceous fuels (4, 7) has prompted this radiometric investigation of the adsorption phenomenon to gain thereby further understanding of the conditions causing fuel-cell impairment. This report describes and reinterprets previously reported data in the light of these independent nonelectrochemical methods. The experiments described herein are a continuation of radiometric studies involving C^{14}-tagged formic acid (report in preparation) undertaken at this laboratory. The radiometric

techniques are modifications of methods described by Bockris and co-workers (28, 29).

Experimental

The definition of the surface coverage parameter, θ, employed herein is an experimental quantity equal to the ratio of the charge obtained by oxidation of the organic adsorbate divided by the charge associated with the oxidation of a clean layer (supposedly a saturated layer) of adsorbed hydrogen on the surface in question. The oxidation charge of the organic adsorbate is derived from measurement of the radioactivity of radioactive molecules of the adsorbate. The definition is simplistic and, as discussed below, subject to much error. However, the critical feature of the computation of θ in this paper is the radiometric method which as will be seen, makes rigorous, clear-cut demands on the adsorbate model.

Radiometric methods.—Details of the experimental cell and the working (window) electrode were described previously (12). The experimental cell was a typical three-electrode cell of all glass and Teflon components. Both the counterelectrode and the reference electrode [a dynamic hydrogen electrode (30)] consisted of isolated platinized platinum grids. The working electrode was a thin, platinized, gold-polyester electrode, prepared by evaporative vacuum-deposition of a thin layer of gold on a polyester film, and subsequent electrodeposition of platinum. (The reverse side also received a very thin gold layer to eliminate static charge build-up). The resultant thin electrodes have a high transmission efficiency ($\approx$ 5%) for the β-radiation emanating from the radiolabeled adsorbate, providing the basis for the radiometric procedure described below. The detection efficiency was established at the end of each experiment by using a standard radiation source (31). Standard electrolytes of 1.0*N* $HClO_4$ and 0.1*N* $HClO_4$ with 0.9*N* $NaClO_4$ were used with approximate *p*H values of 0 and 1, respectively. Sodium perchlorate was introduced in the latter electrolyte to maintain constant ionic strength. When the platinized side of the electrode was placed in contact with the electrolyte, it performed the simultaneous functions of an electrode and radiation counter "window" to monitor radioisotope-tagged species adsorbed at the electrode-electrolyte interface. Predetermined quantities of C^{14}-tagged Na_2CO_3 were injected through an isolated septum into the electrolyte cell. The desired CO_2 concentration was varied from test to test from approximately 10^{-7} to 10^{-3} molar in the standard electrolytes. However, a decrease in CO_2 concentration occurred during each test due to a slow exchange between radiolabeled CO_2 in the cell and inert CO_2 diffusing into the cell. Therefore the concentration was evaluated and recorded at 15-60 min intervals during the course of the experiment by assaying 100-μliter aliquots of the electrolyte with a liquid scintillation spectrometer. Implicit in some previous studies and in this work is the assumption of virtually complete (although sometimes slow) conversion of the H_2CO_3 to CO_2 (32, 33).

The potential of the working electrode was applied and maintained at a constant value by a fast-rise Wenking potentiostat, which was in turn controlled by a programmable potential stepping device (PPSD). The working electrode potential was measured with respect to the reversible hydrogen electrode (RHE).

Injection of the Na_2CO_3 solution was executed at 0.9V, a potential determined from preliminary work to be sufficiently high that no adsorption occurs. The background count, β-radiation from the bulk solution, was thus established. Adsorption of the tagged CO_2 was then monitored at potentials and for periods of time programmed into the PPSD.

Two different adsorption procedures were used for these experiments. The first procedure involved stepping sequentially from 0.8 to -0.1V in 0.1V decrements. Adsorption at each potential was independent of that at any previous potential because a "precleaning" potential sequence was applied prior to establishing the adsorption potential.

In the second procedure no "precleaning" sequence was applied prior to adsorption at each potential so that measurements represented an accumulative adsorption.

The roughness factor of the electrode was determined before and after a particular experiment from analysis of galvanostatic charging curves (34) at 100 mA. A linear relation between roughness factor and time was assumed between these measurements when variation was observed. From a measurement of the roughness factor and known geometric area the effective surface area of the electrode was calculated (12).

Electrochemical methods.—Experiments were conducted to detect net charge transfer resulting from the introduction of CO_2 into the electrolyte at the adsorption potential. The apparatus used for this measurement was a typical three-electrode cell of glass and Teflon components. The working electrode was a perforated platinized platinum electrode of large geometric surface area ($\sim$ 20 cm^2). A gas inlet was connected to a CO_2 and He manifold. A bubble-off and valve served to regulate gas release from the cell.

With the potential of the cell maintained at 0.8V where reactants are inactive, helium was bubbled through the electrolyte to remove CO_2 and O_2. When the cell current reached a low, steady-state value, the potential was stepped to 0.1V where the cell current was permitted, again, to approach a steady value. Then, after appropriate flushing of lines to remove impurities. CO_2 was admitted into the cell while the cell current was continually recorded on a Speedomax strip-chart recorder.

Results

As stated above, the adsorption of CO_2 on precleaned platinum in acid media yields an adsorbate referred to as "reduced CO_2." Coverage of this adsorbate, θ, is plotted in Fig. 1a and b as a function of electrode potential for different bulk concentrations of CO_2. The adsorption time at each potential was 10 min. The electrolytes were the standard solutions 1.0*N* $HClO_4$ and 0.1*N* $HClO_4$, 0.9*N* $NaClO_4$ mentioned previously (henceforth referred to as 1.0*N* $HClO_4$ and 0.1*N* $HClO_4$). Gaussian-shaped curves are similar at each *p*H with an apparent peak of adsorption between 0.05 and 0.10V. Coverage increases as the concentration is increased, for the same adsorption time and potential. At corresponding values of potential and concentration, a higher degree of coverage is observed at the higher *p*H.

An attempt was made to duplicate concentrations at several points. This was not possible because the concentration of CO_2 was under constant flux due to gas evolution on the electrodes and loss of CO_2 by diffusion through the liquid seal. However, in one case (see Fig. 1b) the concentrations 8.5 and 8.0 $\times$ 10^{-4}M CO_2 were sufficiently approximate to permit an estimate of the standard deviation from four sets of duplicate points. The relative standard deviation is 25% for the experiments in Fig. 1b and this value is assumed for other measurements.

Cumulative adsorption behavior (adsorbates were not removed by precleaning the electrode) is shown in Fig. 2a and b for 1.0 and 0.1*N* $HClO_4$ electrolytes, respectively. Adsorption time was again 10 min. The direction of the voltage stepping sequence is indicated by the arrows. No adsorption was observed at 0.3V or higher in the cathodic portion of the voltage sequence for either *p*H. Coverage was first observed at 0.2V, but because of the restricted time allowed for adsorption at each potential, full coverage was not achieved at 0.2V. The coverage continues to increase during the remainder of the cathodic portion and during the

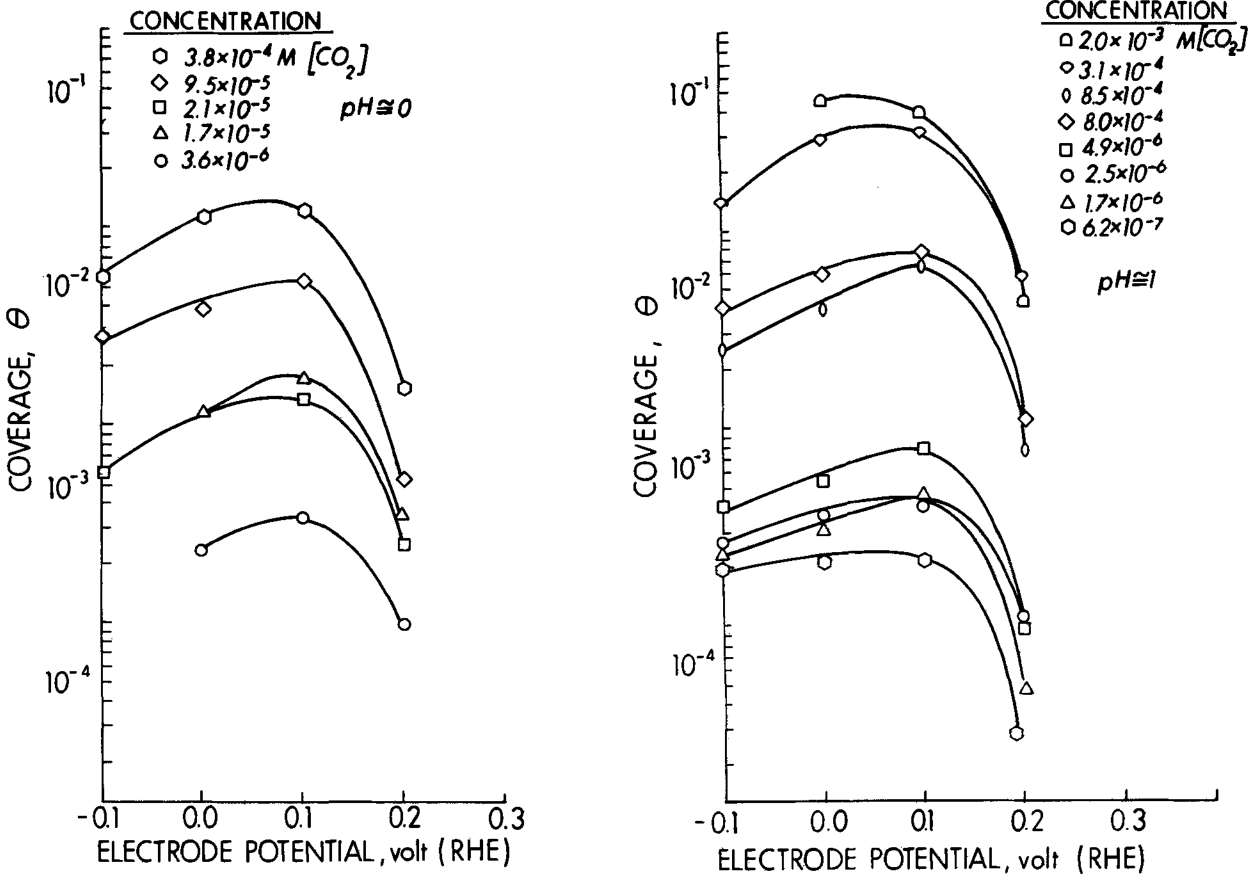

Fig. 1. Electrode coverage as a function of potential at constant CO_2 concentration; adsorption time at each potential is 10 min. Electrolytes are: (a, left) 1.0N $HClO_4$; (b, right) 0.1N $HClO_4$ with 0.9N $NaClO_4$.

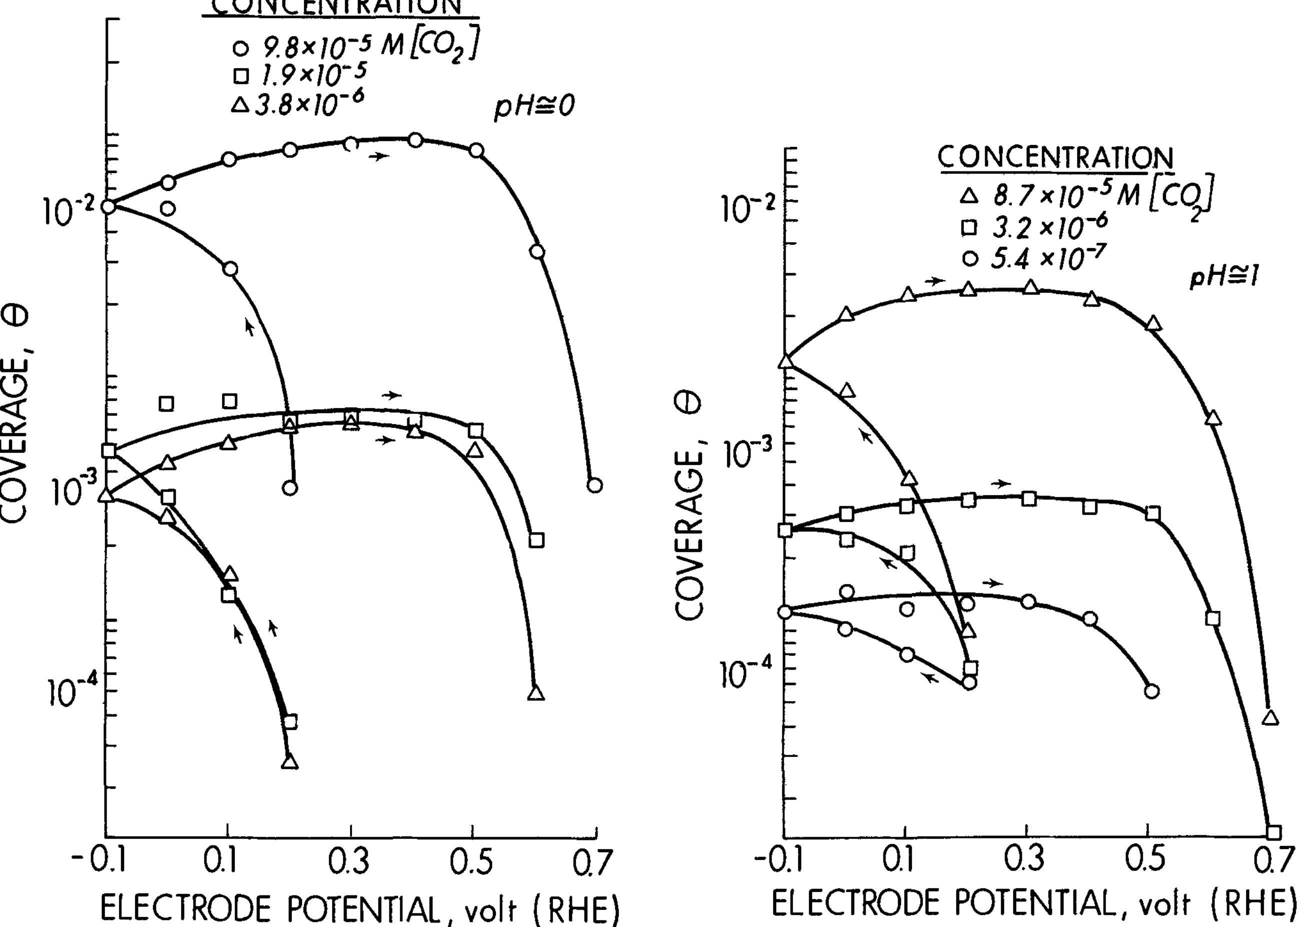

Fig. 2. Cumulative coverage as a function of potential at constant CO_2 concentration. Adsorption time at each potential is 10 min without precleaning. Electrolytes are: (a, left) 1.0N $HClO_4$; (b, right) 0.1N $HClO_4$ with 0.9N $NaClO_4$.

anodic portion to 0.2V. The coverage remains relatively flat from 0.2 to 0.5V and then it decreases.

The decrease in coverage increases exponentially with potential so that desorption is essentially complete after 10 min at 0.8V in all observed cases. Thus, the curves exhibit a "hysteresis" in the anodic and cathodic isoconcs. The cumulative anodic curves are similar to cumulative anodic isoconcs obtained with methanol (11). Also, coverage increases with concentration as was observed above in Fig. 1a and b. In this respect there is evidence of scatter in the 1.0N $HClO_4$ data.

The effect of adsorption time is shown in Fig. 3a and b for comparably high ($\sim 10^{-3}$ molar) CO_2 concentrations. For 1.0 and 0.1N $HClO_4$, respectively, the coverage increases with time approaching a steady-state coverage at each potential. The peak of adsorption may shift from the apparent peak near 0.1V to a value which is closer to 0.0V.

Figures 4a and b indicate more clearly how coverage varies with concentration for the 1.0 and 0.1N $HClO_4$ electrolytes, respectively. The semilogarithmic relations (Langmuir plots) are given for fixed potentials from -0.1 to 0.2V. The coverage increases slowly at first, but increases rapidly above a coverage of 0.02. Finally, at the highest experimental concentration (in the 0.1N $HClO_4$) a negative curvature indicates possible approach to saturation coverage. The Langmuir plots of Fig. 4b and 5 show the effect of different adsorption times of 10 and 40 min, respectively. Again, a slight negative curvature indicates a trend toward saturation for the 40-min case. However, in the 40-min case, a more pronounced negative curvature is expected but not observed.

Values of the calculated Tempkin factor, f, were obtained from the linear portions of the Langmuir plots of Fig. 4b and 5. Values for the 10-min (Fig. 4b) and 40-min (Fig. 5) adsorption times, 1.9 and 2.2, respectively, show reasonable agreement (considering experimental scatter).

Figure 6 shows the build-up of the adsorbate with time at 0.0 and 0.1V for 2.0×10^{-3}M CO_2. The coverage appears to approach a steady-state value. (Lack of reversibility with respect to activity and potential indicates a nonequilibrium condition.) The existence of the steady-state coverage was verified by measuring the increments in coverage, $\Delta\theta$, for each two-fold increase in time. For each doubling of adsorption time $\Delta\theta$ decreased geometrically. Thus, series summation for coverage at 0.0V yielded the asymptotic θ value 0.62 represented in Fig. 6 by the dashed line.

Figure 7 shows the initial adsorption rate (in monolayers per second) as a function of the potential, concentration, and pH. These curves indicate an increasing rate from -0.1V to a maximum below 0.1V and then a decrease above 0.1V. The rate appears to be higher in the 0.1N $HClO_4$ electrolyte, the less acid case, when other parameters are comparable. The ascending and descending portions of the kinetic curves form linear Tafel plots according to the electrochemical results (7). If these slopes are assumed to be Tafel slopes, the radiometric data yield ascending slopes of 400 $\pm$ 80 mV and descending slopes of 85 $\pm$ 10 mV.

An electrochemical experiment was performed to determine whether the formation of $(CO_2)_r$ obtained from the reaction of CO_2 with hydrogen adsorbed on platinum was associated with a cathodic current. A very small steady-state diffusion current, probably caused by O_2 reduction, did not change significantly (either cathodically or anodically) upon admission of CO_2 to the platinum electrode. (It is also possible that a small hydrogen ion reduction current may occur to replace adsorbed H.) Thus, it is evident that formation of $(CO_2)_r$ involves no net faradaic charge transfer.

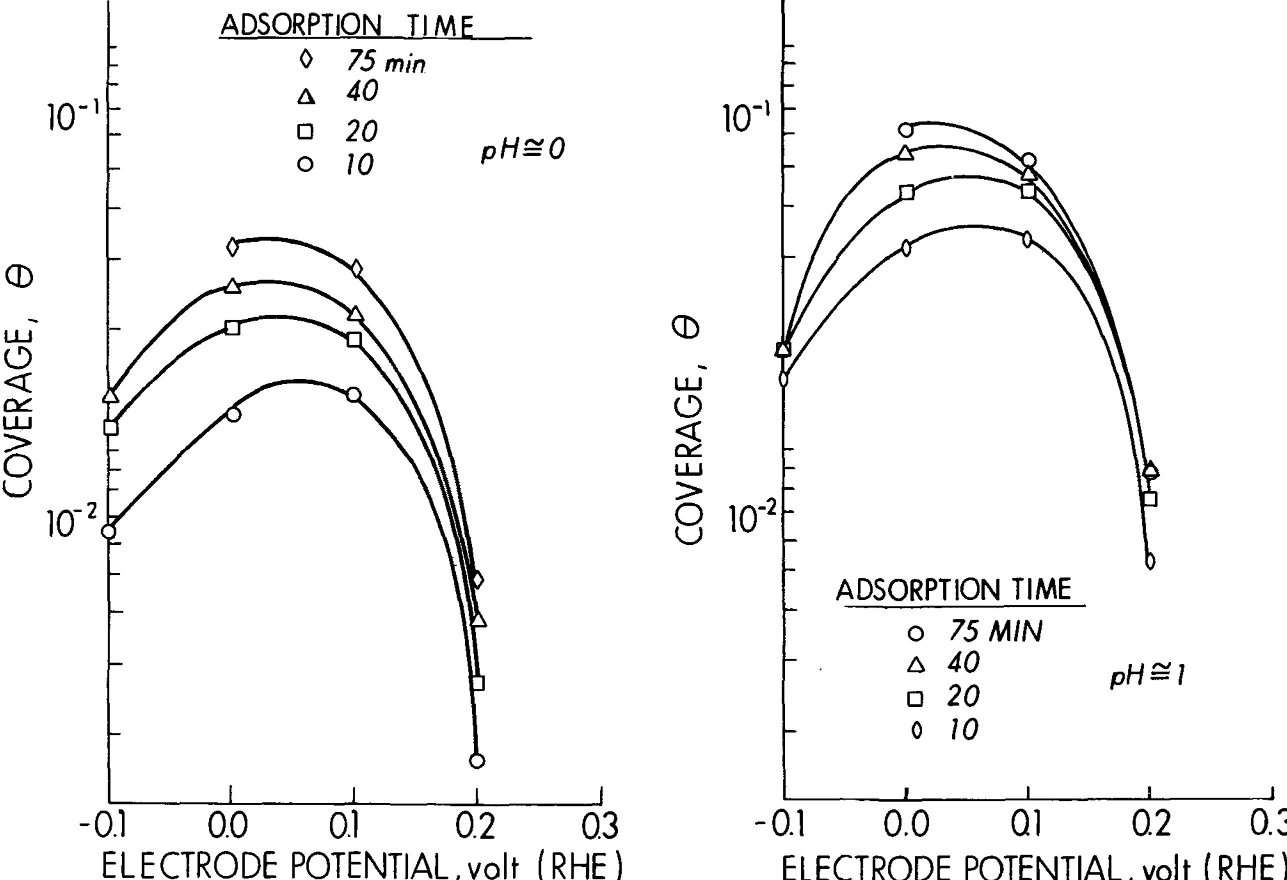

Fig. 3. Coverage-time dependence; electrode coverage as a function of potential at varying adsorption times. Bulk CO_2 concentrations are: (a, left) 3.8×10^{-4}M; (b, right) 3.1×10^{-4}M. Electrolytes are: a, 1.0N $HClO_4$; b, 0.1N $HClO_4$ with 0.9N $NaClO_4$.

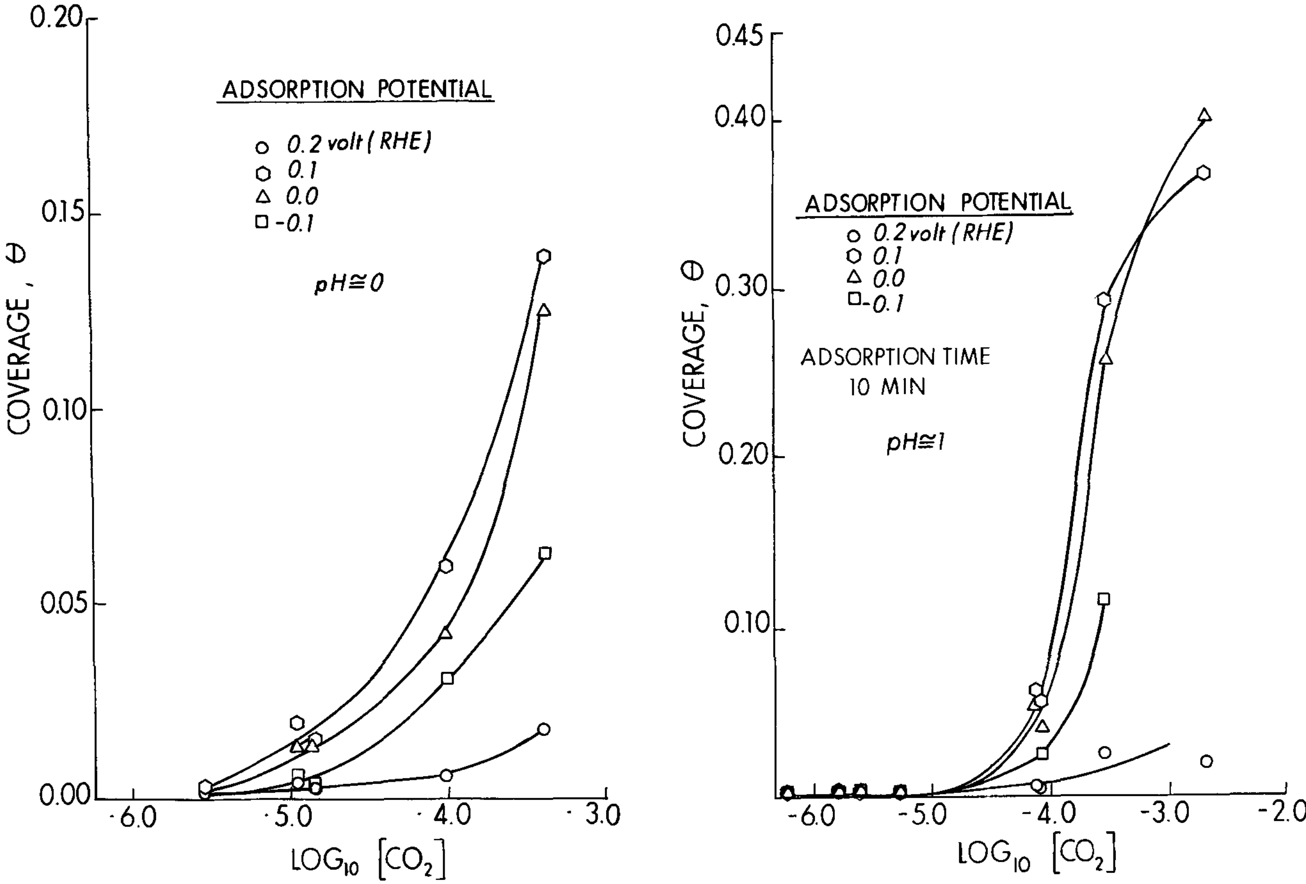

Fig. 4. Effect of CO_2 concentration at constant adsorption potential. Adsorption time is 10 min. Electrolytes are: (a, left) 1.0*N* $HClO_4$; (b, right) 0.1*N* $HClO_4$ with 0.9*N* $NaClO_4$.

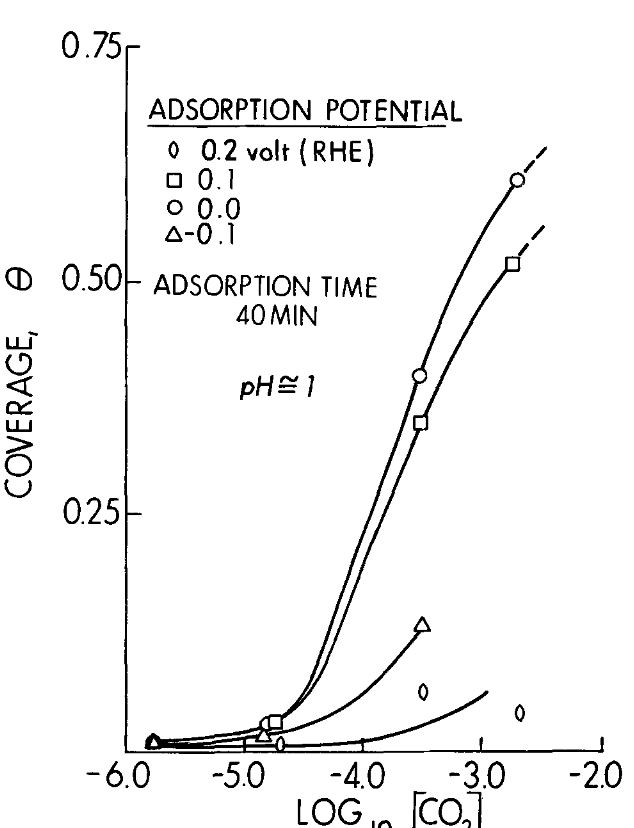

Fig. 5. Langmuir plot for 40-min adsorption time at constant adsorption potential. Electrolyte is 0.1*N* $HClO_4$ with 0.9*N* $NaClO_4$.

To verify adsorption of the CO_2, a galvanostatic charging curve was obtained at a current of 100 mA. The resultant curve, when compared with that of a "clean" electrode, displayed an arrest characteristic of the oxidation of the adsorbate, $(CO_2)_r$.

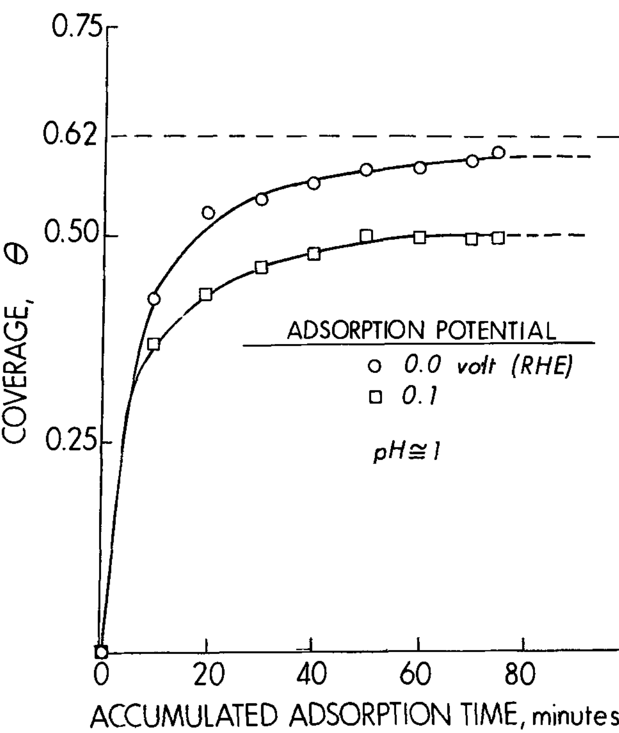

Fig. 6. Coverage as a function of time at maximum experimental concentration, $(CO_2) = 2.0 \times 10^{-3}M$.

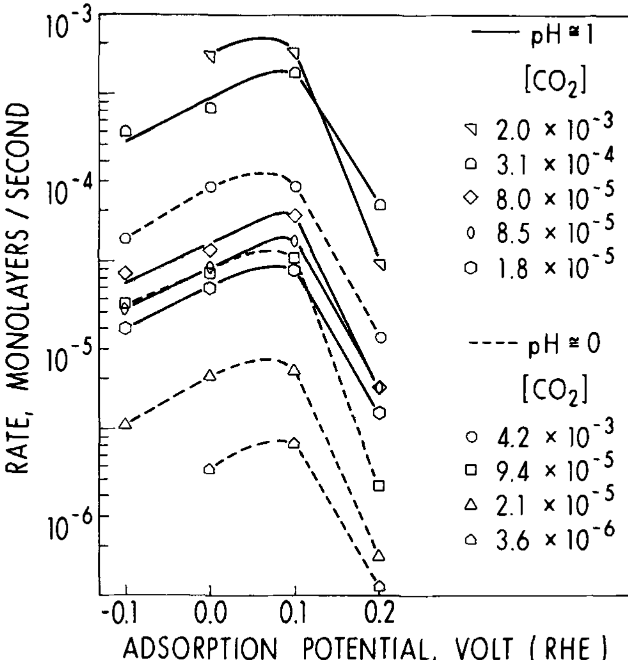

Fig. 7. Initial adsorption rate as a function of potential at constant CO_2 concentration. Adsorption time is 10 min.

Discussion

A particularly desirable objective of this study would be the achievement of a theoretical and experimental consistency between the radiometric and electrochemical adsorption data and kinetic interpretations. A total harmony between the methodologies has not existed in the past (35, 36). Fortunately, several correlations and anomalies of the experimental data of the two methods appear amenable to analysis. The following discussion is concerned with significant generalizations involving controversial aspects of adsorbed CO_2. These include the nature of the adsorbate, a comparison of radiometric and electrochemical data, and kinetic behavior. A plausible hypothesis on the structure of the adsorbate makes possible an evaluation of the coverage of the adsorbate species. Since this number is essential to the radiometric determination of the coverages, the nature of the adsorbate is discussed first.

Nature of the adsorbate.—Published experimental results on the characteristics and behavior of reduced CO_2 are voluminous. They impose a highly restrictive set of conditions with which any hypothetical adsorbate structure must conform. For example, Breiter (6) has determined by means of a chromatographic technique employed in conjunction with anodic stripping that the average number of electrons per carbon atom is 2.1 ± 0.2. Piersma, Warner, and Schuldiner (5) reported the anodic charge associated with the stripping of adsorbate to be 260 ± 35 $\mu C/cm^2$ while Brummer and Cahill (7) reported that this charge is 220 ± 10 $\mu C/cm^2$. Brummer *et al.* (7) reported 1.05 electrons per site which is sensibly equal to unity for the adsorbate and a saturation coverage of 0.68 (cathodic hydrogen coverage was 0.32, since $\theta_{CO_2} = 1 - \theta_H$ in Brummer's calculations). Such numbers give rise to conclusions that there are 2.0 sites per carbon.

One may propose surface structures which incorporate many of the above constraints. These include several configurations employing the carbonyl group which has been popular with several authors (6, 7, 17, 22). The simple bridged carbonyl form $Pt_2 = CO$ would normally yield a platinum-site, carbon ratio of two. However, one logical difficulty arises. The saturation limit of 0.68 is difficult to explain since there is no factor other than repulsive neighbor-neighbor interactions restricting total saturation of the surface with carbonyl groups. Such neighbor-neighbor interactions are possible though not evident from the calculated f factors. (The f factor may be a measure of this interaction only if the adsorption data represents equilibrium.) It is assumed here that as far as $(CO_2)_r$ is concerned there are no restricted sites and two sites per carbon are available. The resultant average valence state of each platinum site would, therefore, normally be equivalent to 1.0 electron per site even when summed over $(CO_2)_r$ and hydrogen. A reduction in site occupancy produced by steric factors could result in a third of bare sites coverable by hydrogen atoms and would yield 1.0 electron per site and a carbon-hydrogen ratio of 1.5. Moreover, the hydrogen coverage would be 70 $\mu C/cm^2$ in good agreement with the reported hydrogen coverage of 0.32 and in agreement with the conclusions of Brummer [see footnote on p. 467 of ref. (7)]. Experimental results yielding a high total carbon and hydrogen charge of 280 $\mu C/cm^2$ may be explained on the basis of low values of area determination (7, 27).

The model suggested above is based on the empirical result that the adsorption energy of $(CO_2)_r$ is large in comparison with the adsorption energy of hydrogen. [This assumption appears well supported by the irreversibility of the adsorption (12) and the high anodic potential (>0.5V) required to oxidize $(CO_2)_r$.] A second assumption is that the adsorption energy for hydrogen atoms be relatively small in the neighborhood of the $(CO_2)_r$ adsorbate. Also the adsorption energy is overcome when steric factors make their appearance at large ($\theta > 0.52$) values of $(CO_2)_r$ coverage (37-42).

The nature of the potential arrest observed during anodic galvanostatic stripping of reduced CO_2 would suggest that only one species is predominately present [Brummer and Cahill consider only the predominant type I adsorbate (7)] or that several species of similar oxidation energy are present. The proposal that hydrated as well as unhydrated forms of the carbonyl species, *i.e.*, $Pt_2 = CO$ and $Pt_2 = C(OH)_2$, occupy the surface simultaneously might be in conflict with the above conclusion. This is particularly true if the oxidation energy of the carbon-platinum bonds were modified in the hydrated form. The relative stability of monomeric formaldehyde in dilute aqueous solution indicates that the hydrated formaldehyde species is formed without appreciable energy change. A similar behavior might be expected in $(CO_2)_r$.

A brief remark about the order of the adsorbed molecular configurations is appropriate. Several models of a random nature could be exhibited. They differ only in the choice of pairs of platinum atoms employed as substrate for the organic adsorbate. Since the more disordered array of pairs would have the greater entropic energy contribution, the disordered array should be preferred unless ordering forces are present. The appearance of Tempkin effects in the adsorption energy of the carbon bond would suggest that ordering forces are in fact absent. The disordered state of adsorption would account for the large surface fraction which apparently remains uncovered by $(CO_2)_r$.

The utility of the radiometric method is strongly dependent on a valid estimate of the number of carbon-containing species formed from the reduction of CO_2. Any estimate must yield values of saturation and coverages consistent with those produced by electrochemical methods. The number of carbon species used in the radiometric calculations, 6.55×10^{14} atoms/cm^2, is consistent with the assumption of two sites per carbon-containing adsorbate, one carbon per adsorbate, and 1.31×10^{15} effective sites/cm^2 ±20% (from 210 $\mu C/cm^2$ for hydrogen coverage). Having once assumed two sites per carbon, the requirement for a bridged molecular adsorbate follows.

Comparison with previous work.—*Saturation effects.*—The behavior of the coverage-time curves in Fig. 6 suggests that asymptotic steady-state values of coverage may be attained. [In the nonelectrochemical

sense that ultimately mass and energy gradients vanish, a quasi-equilibrium between $(CO_2)_r$ and CO_2 is possible. Reversibility with respect to electrode potential does not exist of course.] Stationary steady-state values imply a steady-state oxidation of $(CO_2)_r$. That the asymptotic values (in Fig. 6) are indeed physical is deduced from the convergence of the sum of terms representing the coverage increment with each doubling of adsorption time (the incremental terms form a convergent geometric series). An examination of the electrochemically observed time-dependent coverages indicates that the reaction rates of Brummer and Cahill (7) were favored with a small boundary layer (good stirring) as well as a ten-fold higher concentration of CO_2. Thus, the electrochemically derived data (7) exhibited evidence of saturation in the form of well-defined adsorption plateaus after less than 10 min.

The radiochemically determined values of coverage based on 6.55×10^{14} carbon atoms/cm^2 (two sites per carbon) show little evidence of saturation at values in the neighborhood of 0.62. The coverage-time plots of Fig. 6 show at 0.0 and 0.1V a consistent difference of 0.13 [compared with a total range of 0.063 in the scatter of coverage values in Fig. 2 of ref. (7)]. If, indeed, saturation coverage were established in the data of Fig. 6, the long-time values of coverage would approximate each other.

Evidence of saturation is positively provided by the appearance of a negative curvature in Langmuir plots such as Fig. 4b and 5. The Langmuir plot at 0.1V (see Fig. 4b) for adsorption times of 10 min suggests, because of the crossover of the plots, that a degree of negative curvature exists. However, Fig. 5, where adsorption time was 40 min, shows no crossover in the plots with only a slight negative curvature indicative of the fact that saturation is far from complete even at a θ value in the neighborhood of 0.60. It is evident that the arbitrary use of a number based on three sites per carbon atom would force the θ values dangerously close to unity but the negative curvatures of Fig. 4b and 5 would not be enhanced. Such behavior in the radiometric model represents confirmation of the proposed two sites per carbon model of the adsorbate.

Shape of the isoconcs.—Evidence of saturation may be inferred from the appearance of plateau-like isoconcs (7). In Fig. 3b no evidence of a plateau is observed, although the θ-value at 75 min surpasses 0.5. The curves exhibit peaks with the maximum lying between 0.0 and 0.1V. Electrochemical data (7) for adsorption periods less than 25 sec show peaks between 0.10 and 0.15V in agreement wtih the radiometric results of Fig. 4b and 5. No such agreement can be claimed for similar measurements in ref. (5). The data in these figures indicate in the crossover of the curves, that the potential of maximum adsorption shifts toward lower values as reaction time increases. However, the data are too scattered for certainty.

Since no plateau is evident, θ values of 0.62 do not appear to be representative of saturation in the radiometric results in contrast with the electrochemical results.

Kinetic data.—The electrochemical measurements of Brummer and Cahill (7) yield initial adsorption rates which are a maximum at about 0.1V. The radiometric data of Fig. 7 indicate kinetic maxima between 0.04 and 0.1V in fair agreement with the electrochemical data considering the smaller number of radiometric measurements.

Some electrochemical data (7) exhibit well-defined Tafel slopes of 80 mV/decade above 0.1V. The radiometric Tafel slopes between 0.1 and 0.2V are based on only two points one of which is located near the peak so that the slopes must be somewhat on the low side. Moreover, some of the points show considerable scatter. Ignoring two CO_2 concentrations, 9.4×10^{-5} and 2×10^{-3}M, where scatter is obvious, the slopes appear to lie between 75 and 95 mV (closer to the low end) in fair agreement with the electrochemical slopes of 80 mV (7). Corrected for variation in θ_H the Tafel slopes are 120 mV by both methods.

There is considerable deviation, however, in the slopes of the left-hand side of the peaks in Fig. 7 which are of the order of 400 mV. The electrochemical slopes are of the order of 180 mV. Disagreement may be due to failure to correct ohmic errors in potential.

Kinetic mechanism.—Hypothetical mechanisms invoked to explain the observed kinetics must be consistent with the experimental observation of this study that net charge transfer does not occur during the formation of $(CO_2)_r$. Based on the ad hoc-requirement of 2.1 oxidation electrons per carbon (6), it is essential that two adsorbed hydrogen atoms per CO_2 be consumed in the over-all reaction. According to Fig. 8, the reaction expression should be first order in CO_2. Finally, it should be first order in adsorbed hydrogen (7). The following proposed reaction scheme fulfills these requirements

$$PtH + CO_2 + e^- \underset{k_{-c}}{\overset{k_c}{\rightleftarrows}} PtCO_2\bar{H}\cdot \quad [1a, b]$$

$$PtCO_2\bar{H}\cdot + PtH \xrightarrow{k_a} Pt_2C(OH)_2 + e^- \quad [2]$$

The adsorbed atomic hydrogen, PtH, is represented by θ_H, the activated ion-radical complex, $PtCO_2\bar{H}\cdot$, is represented by θ_c, and the k's are the specific electrochemical reaction rate constants associated with each reaction. Reaction [1a] will be recognized as the cathodic reaction proposed previously by Brummer and Cahill (7). Reaction [1b] indicates a degree of reversibility not indicated for reaction [2] which is highly irreversible. Under some conditions the concentration of the ion radical may thus be described by a quasi-equilibrium. According to the arguments above $Pt_2C(OH)_2$ is closely related to $(CO_2)_r$ or is one of the hydrated forms of $(CO_2)_r$.

The imposition of the condition of zero-charge transfer is obeyed by reactions [1] and [2] provided the over-all sum of the anodic and cathodic rate proc-

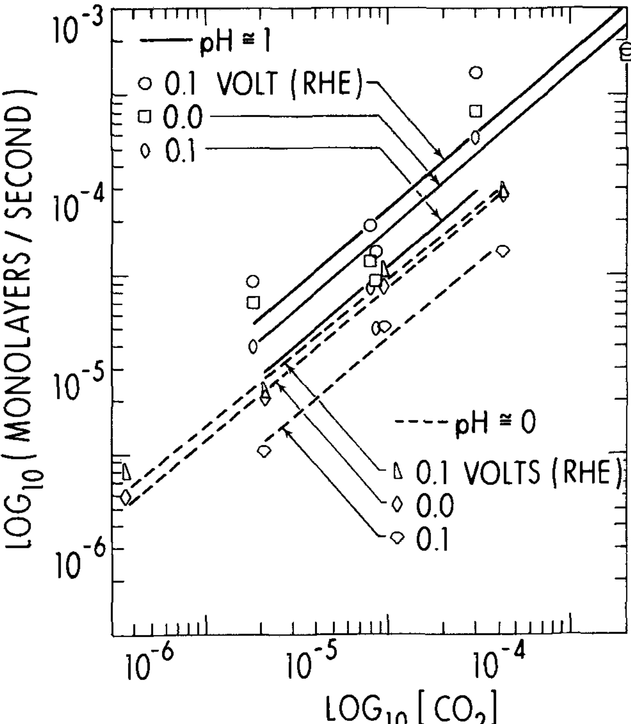

Fig. 8. Determination of the stochiometric factor for CO_2; initial adsorption rate as a function of concentration.

esses vanishes. Imposing this condition there is obtained

$$0 = \frac{d\theta_c}{dt} = k_c\theta_H(CO_2)\exp(-\alpha_c\mathbf{F}E/RT) - k_{-c}\theta_c\exp(f_c\theta_c)\exp[(1-\alpha_c)\mathbf{F}E/RT] - k_a\theta_H\theta_c\exp(\alpha_a\mathbf{F}E/RT) \quad [3]$$

where t is the time, α_c and α_a are the transfer coefficients associated with the reactions indicated in the subscript, $\mathbf{F}$ is Faraday's constant, E is the potential at which adsorption occurs, R is the gas constant, T is the temperature, and f_c is the Temkin f-factor for the activated ion-radical complex. Equation [3] also represents the condition that the concentration of the activated complex be invariant. Tempkin f-factor terms are included only in the second term of the right-hand member because [1b] is nonactivated (43); *i.e.*, the Tempkin symmetry factor, α, is unity [see Conway (43) for discussion of activation]. The implication of the unit α-factor is that the activation energy on the adsorption side of the reaction barrier is potential independent. Only the desorption involves a large potential and coverage dependent energy.

Equation [3] may be rearranged to facilitate deduction of the behavior of the activated complex, θ_c, with respect to potential

$$\theta_c\exp(f_c\theta_c) = \frac{k_c\theta_H(CO_2)\exp(-\alpha_c\mathbf{F}E/RT)}{k_{-c}\exp((1-\alpha_c)\mathbf{F}E/RT) + k_a\theta_H\exp(\alpha_a\mathbf{F}E/RT)\exp(-f_c\theta_c)} \quad [4]$$

The dominant term in the denominator will depend on the exponential θ_c-factor. Whichever term predominates, θ_c is seen to increase as E decreases. For qualitative reasoning we can approximate the $\theta_c - E$ relation by the expression $\theta_c \cong b - ME$, where b and M are constants and M is positive. Thus, at high potential the factor $\exp(-f_c\theta_c) \cong \exp(-f_cb + Mf_cE)$ causes the second term in the denominator to predominate if Mf_c is large. Thus

$$\theta_c \cong (k_c/k_a)(CO_2)\exp(-(\alpha_c+\alpha_a)\mathbf{F}E/RT) \quad [5]$$

and log θ_c is seen to decrease exponentially with E with slope of −59 mV [assuming that α_a as well as α_c (7) is 0.5]. The pattern of behavior of θ_c is thus qualitatively similar to the behavior of θ_H.

The rate of product formation is given by

$$\frac{d\theta}{dt} = k_a\theta_H\theta_c\exp(\alpha_a\mathbf{F}E/RT) \quad [6]$$

Equation [6] does not contain the Tempkin f-factor in accordance with the above logic. Equation [5] may be used to eliminate the surface concentration θ_c, whence

$$\frac{d\theta}{dt} = k_c\theta_H(CO_2)\exp(-\alpha_c\mathbf{F}E/RT) \quad [7]$$

Equation [7] is seen to be identical with the kinetic expression of Brummer and Cahill (7) which may be regarded as a special extremum of the more general reactions [1] and [2]. The kinetic equation is first order in CO_2 and in adsorbed hydrogen as required. That Eq. [7] is in excellent agreement with the experimental data has been adequately demonstrated (7) (provided correction is made for varying θ_H).

At low potentials the first term in the denominator of [4] predominates and the expression for θ_c becomes

$$\theta_c \cong K\theta_H(CO_2)\exp(-f_c\theta_c)\exp(-\mathbf{F}E/RT) \quad [8]$$

where K is the equilibrium constant for Eq. [1] so that θ_c is approximated by a quasi-equilibrium expression. Thus, as the potential decreases, the exponential rise in θ_c becomes linear in E with some slope $-M'$ (M' is not necessarily equal to M). At low potentials, the kinetic rate expression is given by

$$\frac{d\theta}{dt} = k_aK(CO_2)\theta_H^2\exp(-f_c\theta_c)\exp[(\alpha_a-1)\mathbf{F}E/RT] \quad [9]$$

after substitution of Eq. [8] for θ_c in [6]. Now for potentials less than 0.07V, $0.97 > \theta_H > 0.91$, θ_H^2 may be assumed constant (43) with respect to exponential potential terms below 0.07V. The exponential f-factor becomes $\exp(-bf_c + M'f_cE)$ whence taking the logarithm of Eq. [9] there is obtained

$$\log\frac{d\theta}{dt} = K_o + \frac{1}{2.303}((\alpha_a-1)\mathbf{F}/RT + M'f_c)E \quad [10]$$

where K_o is $\log k_aK(CO_2)\theta_H^2 - bf_c$. With $M'f_c$ equal to 25, the Tafel slope of [9] and [10] is +400 mV in agreement with the experimental range of slopes.

According to Fig. 7 and 8 the rates of reaction are a half-order of magnitude faster at high pH. The higher rate of reaction is reflected in the higher coverages in the isoconcs at high pH values. These facts explain in part why better performance of carbonaceous fuel electrodes is achieved in strongly acid media. It is possible to explain the effect of pH in both the steady-state coverage and the kinetics by noting that Eq. [1a] represents a complex reaction which could be written more fundamentally as

$$Pt + CO_2 + e^- \rightleftarrows PtCO_2^- \quad [11a, b]$$

$$PtCO_2^- + PtH \rightarrow PtCO_2H^{\overline{\cdot}} + Pt \quad [12]$$

Equations [11] and [12] give rise to the over-all reaction indicated by [1a].

Formation of the ion-radical $PtCO_2H^{\overline{\cdot}}$ could be prevented by competing reactions, *i.e.*

$$PtCO_2^- + H^+ \rightarrow PtCO_2H \quad [13]$$

Since the singly bonded species $PtCO_2H$ is apparently less stable, we expect decomposition to the reactants

$$PtCO_2H \rightarrow Pt + CO_2 + H^+ + e \quad [14]$$

In essence it is proposed that formation of the ion radical via reaction with adsorbed hydrogen in [12] is contraverted by reaction with hydrogen ions according to [13]. Thus, hydrogen ions would be expected to exhibit a kinetic stoichiometry which is dependent on the relative rates of reactions in [12] and [13]. The dependence of the rate would therefore not be first order in the hydrogen ion concentration as is confirmed in Fig. 8.

The close similarity between the shape of the isoconcs and the Tafel plots warrants consideration. The obvious correlation between the steady-state adsorption behavior in Fig. 1a and b and the kinetic rates in Fig. 7 suggests that the rate of oxidation or removal of $(CO_2)_r$ is roughly independent of potential below 0.3V. Certainly above 0.4V the data of Piersma, Warner, and Schuldiner (5) demonstrate a clear exponential dependence of the adsorbate oxidation on potential. However, below 0.3V no information on the oxidation (or removal) rate of the adsorbate is known except what can be inferred from the argument here.

Summary

The adsorption of CO_2 on platinum covered with adsorbed hydrogen atoms gives rise to an adsorbate called "reduced CO_2" or $(CO_2)_r$. The steady-state adsorption of $(CO_2)_r$ (the isoconcs) and its initial adsorption kinetics (Tafel plots) were studied by radiometric methods employing C^{14}-labeled CO_2. The isoconcs of $(CO_2)_r$ are roughly gaussian in form with a

peak between 0.05 and 0.10V. The initial adsorption kinetics are similar in form to the isoconcs. For example, the initial adsorption rate is maximum between 0.05 and 0.10V. Both the adsorption and rates increase with pH.

The radiometric isoconcs exhibit no evidence of saturation even at coverage values of 0.62. The radiometric results and selected electrochemical reports appear to be compatible provided the adsorbate, $(CO_2)_r$, is assumed to be a carbonyl species that is bridged to two adjacent sites each of which is capable of forming an additional half bond with adsorbed hydrogen.

No current is observed during the conversion of CO_2 to $(CO_2)_r$. The character is the isoconcs and the kinetics are predicted by a reaction scheme based on cathodic reduction of CO_2 and anodic oxidation of adsorbed hydrogen atoms in equal amounts.

Current Distribution on a Rotating Sphere below the Limiting Current

Kemal Nisancioğlu* and John Newman**

Inorganic Materials Research Division, Lawrence Berkeley Laboratory, and Department of Chemical Engineering, University of California, Berkeley, California 94720

ABSTRACT

The current distribution on a rotating spherical electrode is calculated at appreciable fractions of the limiting current. Numerical results are given for Tafel kinetics and for high rotation speeds. The current distribution depends only on the specified current level and becomes uniform when this level is set below 68% of the limiting current at high rotation speeds. In general, the results disclose a number of complementary aspects of the spherical electrode alongside the disk electrode in electroanalytical applications.

The sphere has been employed in the past as an important electrode geometry in electrochemical research such as the investigation of the double-layer structure on mercury drops (1) and the study of the overpotential and reaction kinetics on copper electrodes by transient methods (2). The effects of diffusion were either eliminated or ignored in that work. The rotating sphere has been proposed anew as a potential tool in studies of mass transfer and reaction kinetics in electrochemical systems (3, 4). The convective diffusion equation for a thin diffusion layer at limiting current conditions has been solved recently (3, 5, 6) and compared successfully with experimental data (7).

Key words: current distribution, mass transfer, electrode kinetics.

The present interest in the rotating sphere arises from the fact that the mass transfer and current distribution characteristics of the disk and the sphere turn out to be rather complementary in some respects. For instance, the rotating disk exhibits a uniform limiting current distribution (8), which makes it attractive for mass transfer work. The disk electrode, however, has a highly nonuniform primary distribution (9), and consequently serious errors may result in the assessment of exchange current densities in investigations of reaction kinetics (10). The spherical electrode does not have the same drawback, owing to its uniform primary distribution. The disk electrode can be polished very easily, but the surface preparation for the spherical electrode does not seem to be just as straightforward without deforming its shape. On the other hand, in high-rate metal deposition or dissolution studies the spherical electrode maintains its geometry, whereas the disk rapidly forms a step between the insulating surface and the metal, thereby altering seriously the hydrodynamic conditions prevailing at its surface (3). Below the limiting current, the current distribution on a rotating disk is nonuniform (11, 12). It is possible, in principle, to attain a uniform distribution of current on a rotating sphere below the limiting current even in the presence of concentration variations at the surface as will be shown in this paper.

The mathematical treatment of thin diffusion layers with the complicating effect of nonuniform current distribution has become possible in the last decade. The underlying theory has been discussed in detail (13-16) and applied to a number of electrode geometries (11, 12, 17-20). The same theory and numerical techniques are employed here to investigate mass transfer and current distribution on a rotating spherical electrode at appreciable fractions of the limiting current. The following assumptions are made:

(*i*) The rotating sphere is suspended and allowed to rotate with respect to a fixed axis in an otherwise stagnant electrolyte. The analysis also applies to a hemispherical cap on an insulating plane (3).

(*ii*) Dilute solution theory is applicable with constant transport and thermodynamic properties.

(*iii*) For simplicity, the analysis is restricted to metal deposition from a single salt solution and electrode reactions with an excess of supporting electrolyte. Migration is not accounted for explicitly. Results can be obtained for more complex systems, and corrections can be made for migration effects, if necessary, with added numerical effort (15).

(*iv*) The fluid flow around the sphere is laminar, and the hydrodynamic boundary layer is thin (high Reynolds numbers), so that the boundary layer solution of the Navier-Stokes equations (21) is an adequate description of the hydrodynamic conditions near the surface. The dimensionless shear-stress distribution is given by (5)

$$B(\theta) = \beta_0 \nu^{1/2}/r_0\Omega^{3/2} = 0.51023\,\theta - 0.1808819\,\theta^3 - 0.040408\sin^3\theta \quad [1]$$

where β_0 is the velocity derivative $\partial v_x/\partial y$ at the surface. The boundary layer approximation is known to break down at a region near the equator (22) with the magnitude 0(1/Re), but the size of this region can be rendered small by increasing the Reynolds number.

(*v*) Diffusion in the direction parallel to the electrode surface can be neglected whenever the diffusion layer is thin compared to the size of the sphere. It is further assumed that the diffusion layer is thin compared to the hydrodynamic boundary layer (high Schmidt numbers), so that the fluid velocity inside the diffusion layer can be approximated by

$$v_x = \beta_0 y,\; v_y = -\frac{1}{2}y^2\frac{1}{\mathcal{R}}\frac{d\mathcal{R}\beta_0}{dx} \quad [2]$$

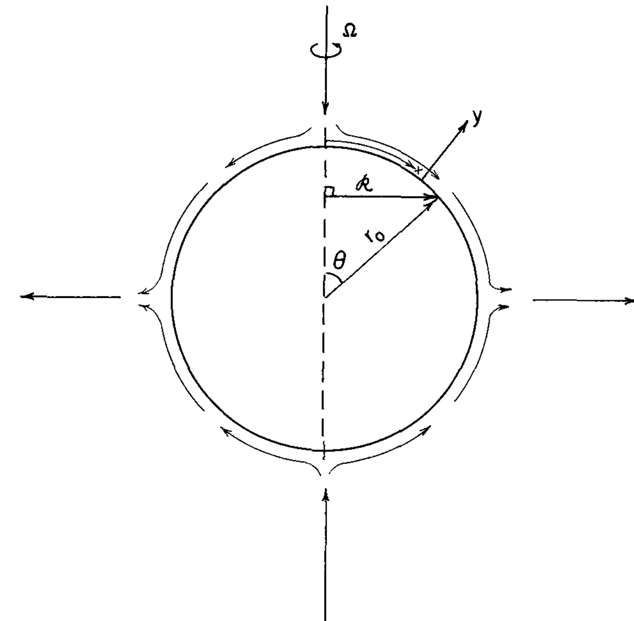

Fig. 1. The rotating sphere

where x is the distance along the electrode from its upstream end, y is the perpendicular distance from the electrode surface, and $\mathcal{R}$ is the distance of the axisymmetric surface from the axis of symmetry (see Fig. 1).

Mathematical Fomulation

In light of the above assumptions, the convective diffusion equation can be written in the form

$$y\beta_0\frac{\partial c}{\partial x} - \frac{1}{2}y^2\frac{1}{\mathcal{R}}\frac{d\mathcal{R}\beta_0}{dx}\frac{\partial c}{\partial y} = D\frac{\partial^2 c}{\partial y^2} \quad [3]$$

where c is the concentration of the reactant. The boundary conditions are

$$\left.\begin{array}{l} c = c_\infty \text{ as } y \to \infty \\ \partial c/\partial x = 0 \text{ at } x = 0 \end{array}\right\} \quad [4]$$

$$i = \frac{n\mathbf{F}D}{1-t}\frac{\partial c}{\partial y} \text{ at } y = 0 \quad [5]$$

where i is the normal current density at the electrode surface, n is the number of electrons produced when a reactant ion or molecule reacts, and t is the transference number. The solution satisfying the first set of boundary conditions (Eq. [4]) can be expressed as an integral equation for the concentration at the surface (15, 16, 19)

$$\left.\frac{\partial c}{\partial y}\right|_{y=0} = -\frac{\sqrt{\mathcal{R}\beta_0}}{\Gamma\left(\frac{4}{3}\right)}\int_0^x \left.\frac{dc_0}{dx}\right|_{x=x'} \frac{dx'}{\left[9D\int_{x'}^x \mathcal{R}\sqrt{\mathcal{R}\beta_0}\,dx\right]^{1/3}} \quad [6]$$

or equivalently

$$c_0(x) - c_\infty = -\frac{(D/3)^{1/3}}{\Gamma\left(\frac{2}{3}\right)}\int_0^x \left.\frac{\partial c}{\partial y}\right|_{\substack{y=0\\x=x'}} \frac{\mathcal{R}dx'}{\left[\int_{x'}^x \mathcal{R}\sqrt{\mathcal{R}\beta_0}\,dx\right]^{2/3}} \quad [7]$$

The current density is assumed to be related to the surface overpotential by the Butler-Volmer expression

$$i = i_o \left(\frac{c_o}{c_\infty} \right)^\gamma \left[\exp\left\{ \frac{\alpha z F}{RT} \eta_s \right\} - \exp\left\{ -\frac{\beta Z F}{RT} \eta_s \right\} \right] \quad [8]$$

where i_o is the exchange current density at the bulk concentration, and α, β, and γ are kinetic parameters. The surface overpotential is in turn related to the electrode potential by

$$\eta_s = V - \Phi_o - \eta_c \quad [9]$$

where Φ_o is the potential in the solution just outside the diffusion layer, and η_c is the concentration overpotential given by

$$\eta_c = \frac{RT}{ZF} \left[\ln\left(\frac{c_o}{c_\infty} \right) + t\left(1 - \frac{c_o}{c_\infty} \right) \right] \quad [10]$$

The parameter Z is equal to $-z_+z_-/(z_+ - z_-)$ for a single salt and $-n$ with supporting electrolyte. The transference number t is zero if excess supporting electrolyte is present.

The potential in the solution satisfies Laplace's equation

$$\nabla^2\Phi = 0 \quad [11]$$

and the boundary conditions are

$$\left.\begin{array}{l} \Phi = 0 \text{ as } y \to \infty \\ \partial\Phi/\partial\theta = 0 \text{ at } \theta = 0, \pi/2 \\ -\kappa\, \partial\Phi/\partial y = i \text{ at } y = 0 \end{array}\right\} \quad [12]$$

where κ is the conductivity of the bulk solution. At $y = 0$, the solution can be expressed as

$$\Phi_o = \frac{RT}{ZF} \sum_{m=0}^{\infty} B_m P_{2m}(\cos\theta) \quad [13]$$

where P_{2m} $(\cos\theta)$ is the Legendre polynomial of order $2m$. The coefficients B_m are given by

$$B_m = \frac{ZFr_o}{\kappa RT} \frac{4m+1}{2m+1} \int_0^1 i\, P_{2m}(\cos\theta)\, d(\cos\theta) \quad [14]$$

Equations [5], [6], [8], [9], [10], [13], and [14] are solved numerically for the unknowns c_o, $(\partial c/\partial y)_{y=0}$, i, η_s, η_c, Φ_o, and B_m. One has the freedom to specify the electrode potential V or the current level $i/(i_{lim})_{avg}$. Equivalently, one can instead fix the concentration or the current density at a given point on the sphere, such as the pole. This last choice avoids an additional iteration loop in the numerical procedure.

Results for Tafel Kinetics

A scaling of all parameters which appear in the problem suggests that the results can be best presented in terms of the dimensionless quantities

$$J = \frac{i_o r_o Z F}{RT\kappa} \quad [15]$$

$$N = -\frac{nZF^2Dc_\infty}{RT\kappa(1-t)} \sqrt{\frac{r_o^2\Omega}{\nu}} \left(\frac{\nu}{9D} \right)^{1/3} \quad [16]$$

in addition to the kinetic parameters α, β, and γ, and the transference number t. Since the primary distribution is uniform, the secondary current distribution, which is obtained by ignoring the concentration polarization, is also uniform regardless of the reaction kinetics. Unless there are concentration gradients, there is no reason for the current density to be different at different parts of the sphere. As a consequence, the results do not depend strongly upon the dimensionless exchange current density J even when concentration polarization is present. Our numerical calculations for different J values, although not shown here, confirm this conclusion. Current and concentration distributions thus largely depend on N, which can be regarded as a dimensionless limiting current, and on the specified current level with respect to the average limiting current. In view of these observations, and because mass transfer effects are important at high current densities, we have chosen to report results for Tafel kinetics, thus, for the parameter J tending toward zero.

Figures 2 and 3 show the current and concentration distributions, respectively, for various current levels at $N = 10$. All other parameters are arbitrarily set at 0.5. The current becomes more nonuniform as the limiting current is approached whereas the concentration shows marked deviations from its average value at intermediate current levels. Figures 4 and 5 show the effect of increasing N (or increasing rotation speed) on the current and concentration distributions for a fixed concentration ($c_o = 0.5\ c_\infty$) at the pole. The

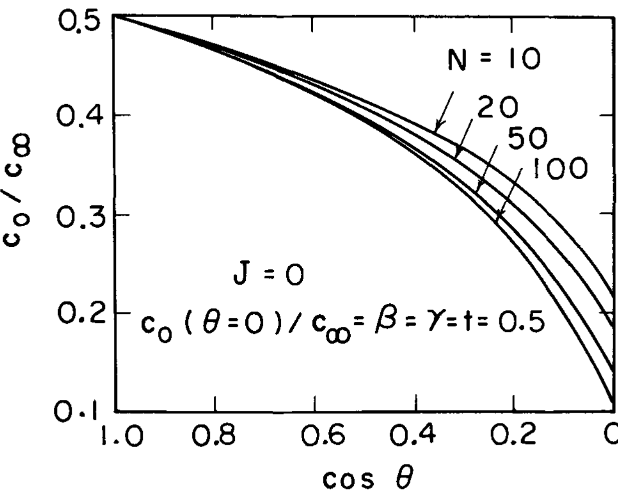

Fig. 5. The effect of rotation speed on the concentration distribution for Tafel kinetics.

current density exceeds the limiting current locally close to the equator. This can also be observed in Fig. 2 for large enough current levels. The same phenomenon has been reported for other geometries under similar conditions (11, 17, 18). With increasing N, the concentration distribution becomes slightly more nonuniform and appears to be approaching an asymptotic profile. Meanwhile, the current distribution becomes more uniform, and the current level tends toward a limiting value different from the limiting current distribution. This represents a contrast to what has been observed for the disk (11) and plane electrodes (17, 18), where the diffusion layer is completely depleted of the reactant near the trailing edges for large enough flow rates, thereby limiting the local current density. The present results suggest the possibility of attaining a uniform current distribution for large N on a rotating sphere in the presence of appreciable concentration polarization. Further investigation is in order below.

Conditions at High Rotation Speeds

If a constant-flux situation prevails on the surface of the sphere, the concentration derivative inside the integral in Eq. [7] is constant and related to the uniform current density by Eq. [5]. After scaling the current with respect to the average limiting current density (5), Eq. [7] reduces to

$$1 - c_o/c_\infty = 0.230825\, \mathbf{F}(\theta)\, i/(i_{\mathrm{lim}})_{\mathrm{avg}} \qquad [17]$$

where

$$\mathbf{F}(\theta) = \int_0^\theta \frac{\sin\theta' d\theta'}{[\int_{\theta'}^\theta \sin\theta \sqrt{B\sin\theta}\, d\theta]^{2/3}} \qquad [18]$$

This function $\mathbf{F}(\theta)$ increases from the value 3.14768 at $\theta = 0$ (the pole) to the value 6.36850 at $\theta = \pi/2$ (the equator). Since the surface concentration is always positive or zero, Eq. [17] can be satisfied over the entire surface if and only if

$$i/(i_{\mathrm{lim}})_{\mathrm{avg}} \leq 0.680267 \qquad [19]$$

It also follows from Eq. [17] that for currents restricted by condition [19] the concentration at the pole will be given by

$$c_o(0)/c_\infty \geq 0.505742 \qquad [20]$$

Equation [19] or [20] is the condition, therefore, for which a uniform distribution of current is possible on the sphere. The corresponding concentration distribution is given by Eq. [17].

If condition [19] or [20] is not met, the concentration becomes zero at a certain angle θ^*, which can be determined from Eq. [17] by setting $c_o = 0$. The current becomes limited for $\theta > \theta^*$ due to this zero concentration distribution and is expected to be nonuniform. Hence Eq. [17] is no more applicable in this region. Under these circumstances, the current density can be calculated from Eq. [6]. After combining with Eq. [5] and [17] and some rearrangement, this becomes

$$\frac{i(\theta)}{(i_{\mathrm{lim}})_{\mathrm{avg}}} = 0.379408\, [1 - c_o(0)/c_\infty]\sqrt{B\sin\theta} \times \int_0^{\theta^*} \frac{d\mathbf{F}}{d\theta}\bigg|_{\theta=\theta'} \frac{d\theta'}{[\int_{\theta'}^\theta \sin\theta\sqrt{B\sin\theta}\, d\theta]^{1/3}} \quad (\theta > \theta^*) \qquad [21]$$

Numerical calculations for various current levels yield the interesting results depicted in Fig. 6 and 7.

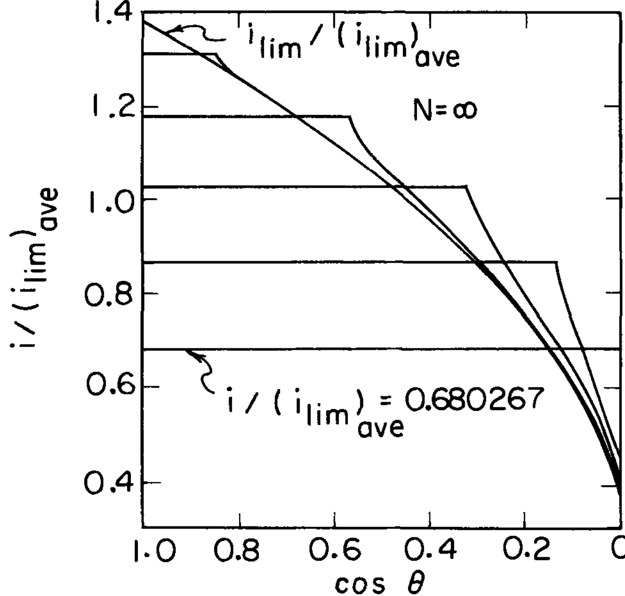

Fig. 6. Current distribution at high rotation speeds

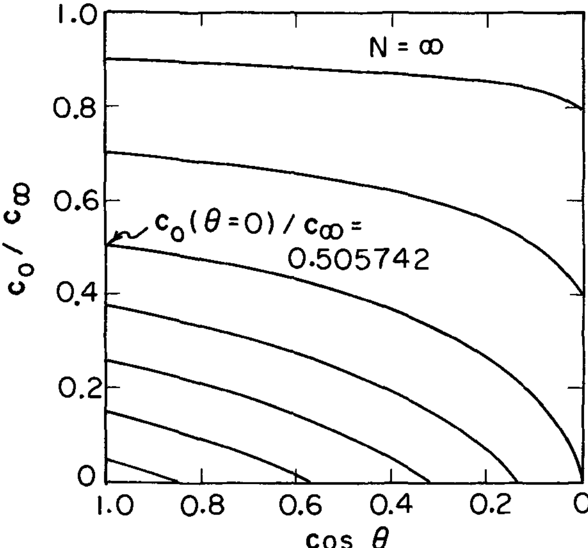

Fig. 7. Concentration distribution at high rotation speeds

Note that Eq. [17] and [21] do not depend on any of the kinetic parameters or the exchange current density; the current and concentration distributions are determined only by the specified current level for a galvanostatic process. The reaction parameters are necessary, however, to calculate the overpotential, or conversely, to calculate the current level if the electrode potential is fixed (potentiostatic process). These remarks are also true for the secondary distribution. In fact, the results of this section map out the transition from the secondary current distribution, which is uniform, to the limiting current distribution, which is nonuniform.

At low current levels ($|i| << i_{\rm lim}$), the secondary distribution prevails, and the surface concentration is equal to the bulk concentration. As a result, the concentration overpotential is negligible, and the electrode potential is due to the surface overpotential and the ohmic drop in the solution, the latter being given by

$$\Phi = \frac{I}{4\pi\kappa r} \qquad [22]$$

where I is the total applied current. As the current level increases, the ohmic drop rises linearly with I according to Eq. [22], and the surface overpotential increases as ln I according to the Tafel expression. If there are no mass transfer limitations, the concentration overpotential does not vary significantly. Therefore, the current distribution is controlled by the large ohmic drop, which remains uniform at the surface in the absence of mass transfer limitations, and the current distribution is also uniform. The concentration becomes zero at the equator once a critical current level is reached as specified by Eq. [19]. With increasing current, the depleted portion of the diffusion layer grows from near the equator toward the poles, and correspondingly the region of uniform current density shrinks in the same direction. Finally, the limiting current distribution is attained.

The present results are significant, first of all, in high rate dissolution or deposition studies because the spherical electrode maintains its geometry, especially when the current level is kept below 0.68 $(i_{\rm lim})_{\rm avg}$, and high rotation speeds are applied. Secondly, the placement of the reference electrode is not as crucial as for the disk (9, 10) because the potential distribution is uniform if constant flux prevails at the surface. If the reference electrode is close to the surface, a correction for radial position is required. This consists of a simple extrapolation to infinity since the primary distribution (Eq. [22]) is a function of radial displacement only. Under these conditions, the assessment of the ohmic drop by the interrupter technique, which measures the value corresponding to the primary distribution (23), is also much more straightforward (2) in comparison to the disk electrode (10, 24).

Ohmic effects due to a nonuniform potential distribution near the surface of an electrode may become important in electroanalytical work. A nonuniform ohmic drop can result in a loss of control of the electrode potential in potentiostatic applications (25, 26), cause waste of current due to hydrogen evolution during the cathodic protection of metals against corrosion, or render difficult the anodic protection of metals with active-passive kinetics (27, 28). The potential variations near the surface of a sphere are at a maximum level at the limiting current (Fig. 8). The maximum potential difference between the pole and the equator is

$$\Delta\Phi_0 = 0.546\, r_0 i_{\rm avg}/\kappa \qquad [23]$$

This formula should be helpful in design calculations to determine the permissible values of r_0, $i_{\rm avg}$, and κ for a maximum allowable potential variation near a spherical electrode. Problems due to a nonuniform potential distribution can of course be eliminated by operating close to the conditions which guarantee a uniform current and at the same time a uniform potential distribution on the sphere as discussed in this section.

Conclusions

The current and concentration distributions below the limiting current have been calculated for a rotating spherical electrode employing a general theoretical and numerical approach applied earlier to the disk and plane electrodes. Mass transfer is assumed to be restricted to a thin diffusion layer near the electrode surface so that the potential distribution can be obtained by solution of Laplace's equation in the bulk and convective diffusion equation in the diffusion layer.

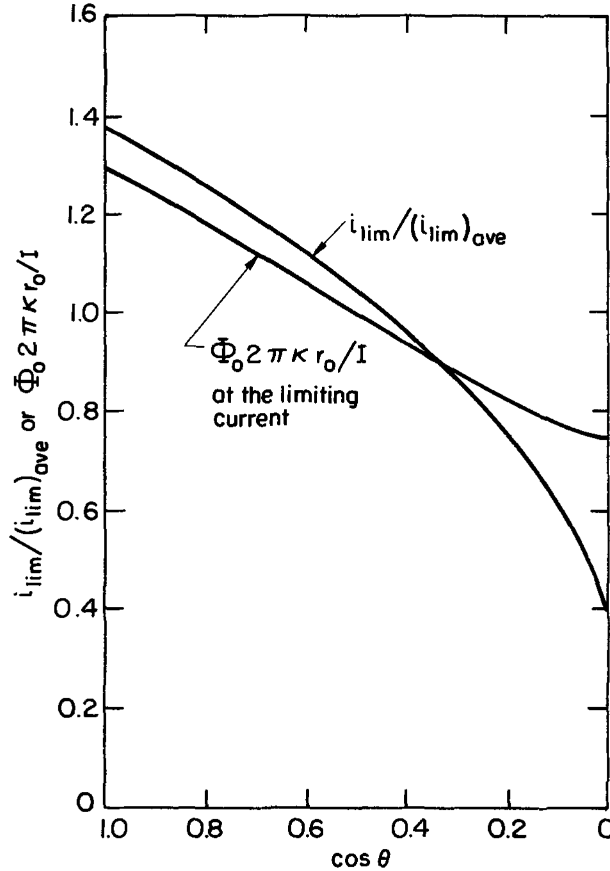

Fig. 8. Current and potential distributions at the limiting current on a spherical electrode.

The two solutions are matched according to the conditions at the electrode surface including complex electrode kinetics.

Numerical results indicate that the current distribution becomes more nonuniform with increasing mass transfer limitations, and that the exchange current density is not an important parameter, in contrast to the previous results obtained for the disk and planar geometries. Furthermore, the current density is shown to reach a uniform distribution below a certain current level, suggesting the possibility of operating at uniform flux below the limiting current even if the concentration distribution may be nonuniform.

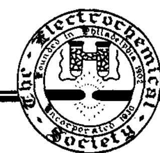
Technical Notes



Lithium-Bismuth Alloy Electrodes for Thermodynamic Investigation of Molten LiF-BeF$_2$ Mixtures

D. D. Sood[1] and J. Braunstein

Reactor Chemistry Division, Oak Ridge National Laboratory, Oak Ridge, Tennessee 37830

We wish to report here Nernst response of dilute Li-Bi alloy electrodes and their applicability for studies of thermodynamic and transport properties of molten LiF-BeF$_2$ mixtures employing emf cells with and without transference (1-3). Such electrodes have the advantage that: by controlling the alloy composition, the electrode may be made more noble than, say, a Be electrode; they are simpler to employ than gas electrodes such as H$_2$, HF; they may avoid possible solubility difficulties with recently developed LaF$_3$ membrane electrodes (4).

We wish also to report a new calculation of the limiting excess chemical potential of Li in Bi. Previous evaluations of this thermodynamic quantity have been based on measurements in chlorides or chloride-fluoride mixtures where Li metal is soluble, and furthermore Nernst behavior has not been previously experimentally demonstrated for the dilute alloy electrodes. An independent re-evaluation was therefore desirable.

We employed the cell

$$\text{Be} \mid \underset{1-x\quad x}{\text{LiF-BeF}_2} \mid \underset{y}{\text{Li, Bi}} \qquad [A]$$

in which the second electrode was metallic Be.

It is almost an axiom of electrochemistry that a cell with metal electrodes reversible to two different ions cannot be stable, since the more active metal will reduce the ion of the more noble one. For example, pure molten Li would reduce Be^{2+} to Be and there could be no stable emf. However the activity coefficient of Li in dilute solutions in molten Bi is of the order of 10^{-5} (5), and the activity may thus be reduced sufficiently by dissolution that Li in Bi is more noble than pure Be. Furthermore Be is insoluble in Bi and remains at unit activity. With the Li in Bi more noble than Be, it is thermodynamically possible for Be to reduce Li^+ to Li in Bi. (It cannot reduce Li^+ to liquid Li, the latter being more active.) If a pathway for this process existed, *e.g.*, via dissolution of Li°, Be°, or Be^+ in the salt, followed by diffusion to the Bi anode, it would act as a chemical short circuit of the cell, with the Li content in Bi increasing until the cell emf approached zero. We find, however, that the emf of cell [A] is stable (for periods of observation up to 24 hr), which suggests that the solubility of reduced species in the melt in contact with metallic Be must be extremely low.

Experimental

The experimental arrangement of the cell is indicated in Fig. 1. A stainless steel envelope which can be evacuated or provided with an inert gas blanket contains a Mo cup in which the molten salt floats on a layer of molten Bi. Be electrodes are inserted through Teflon packed Swagelok[2] fittings in the risers. The purpose of the Mo tubular (reference) compartment is to trap salt of fixed composition; on subsequently changing the salt composition in the bulk compartment, constancy of the alloy composition can be ascertained by constancy of the emf measured between the Be electrode in the reference compartment and the Mo tube in contact with the Li-Bi alloy.

Bi of 69 grade from Cominco American is employed (about 500g in a cell) without further purification. BeF$_2$ is purified by sublimation. Single-crystal LiF is fused and treated with HF in a nickel vessel, sparged with H$_2$ and then He. Purity of the materials is essential to avoid corrosion of the Be electrodes. A typical impurity analysis is, in ppm: O$_2$, 120; K, 7; Na, 70; Al, 70; Mg, 30; Cr, 10; Ti, 5; Fe $<$ 1.

After several attempts to prepare Li-Bi alloys of known composition, or to analyze samples of the alloy after Li had been added, it was found that only by forming the alloy electrolytically *in situ* and determining the concentration by coulometry could sufficient precision be obtained to test adherence to the Nernst equation for cell [A] at a fixed salt composition. The electrolysis was carried out by connecting leads from the Be and Bi electrodes to the terminals of a twenty ohm resistor, across which the potential drop was recorded as a function of time and integrated to determine the quantity of electricity passed and of Li de-

posited in the Bi. Even without stirring the alloy, a steady emf was obtained within about a minute and remained constant (within several tenths of a millivolt) for periods of observation up to a day. Since Li has a very low activity in dilute solution in Bi, the alloy pool apparently provides an effective sink for the Li.

Results and Discussion

The emf of the alloy concentration cell with fixed salt composition varies, with changing alloy composition, as

$$\Delta E = \frac{RT}{\mathbf{F}} \ln \frac{a_{\text{Li}}(y)}{a_{\text{Li}}(y + \Delta y)}$$

Figure 2 shows the emf of the cell in a typical experiment as a function of mole fraction of Li in Bi, together with the calculated Nernst slope. (From measurements of the emf at different salt compositions, a small correction was applied for the virtually negligible change of salt composition resulting from the electrolysis.)

The fit of the Nernst equation in the Li mole fraction demonstrates that the activity coefficient of Li is constant in this concentration range, and that therefore the solution of Li in Bi follows Henry's law. Previously reported values of the excess chemical potential of Li at infinite dilution in Bi were based on extrapolation of measurements of two separate cells with higher concentrations of Li (5) ($\geq$5%), and Nernst behavior of the electrode at low Li composition was not demonstrated experimentally. The present measurements, together with activity coefficients in LiF-BeF_2 mixtures (2), provide an independent estimate of the limiting excess chemical potential of Li in Bi with the aid of the cycle shown in Table I. In Table I $\mu_{\text{Li}}^{\text{E}}$ is the excess chemical potential of Li in Bi, γ_{Li} is the activity coefficient, $\mu_{\text{Li}}^{\text{E}} = RT \ln \gamma_{\text{Li}}$, the γ being referred to pure liquid lithium. x is the mole fraction of BeF_2 in the melt used for the investigation. T is the temperature at which the emf is measured (819°K). x' is the mole fraction of BeF_2 at the LiF liquidus composition, and x'' is the mole fraction of BeF_2 at the BeF_2 liquidus composition at the same temperature. At these compositions, the chemical potential of LiF in the melt is equal to that of pure crystalline LiF and the chemical potential of BeF_2 in the melt is equal to that of crystalline BeF_2. These relations are indicated in Fig. 3 for the particular value $x = 1/3$.

$x' = 0.2935$	
$x'' = 0.975$	$E(y = 10^{-3}) = 0.378\text{V}$

[a] Free energies of formation from Ref. (6).
[b] Phase data from Ref. (3).
[c] Activity coefficients from Ref. (2).

The resulting value $\mu^{\text{E}}_{\text{Li(Bi)}} = -16.82$ kcal/mole is in agreement with the value -16.96 kcal/mole calculated from the results of Foster, Wood, and Crouthamel (5). The difference of 0.14 kcal corresponds to an emf discrepancy of only 3 mV, which is remarkably good since the uncertainty of 1 kcal/mole in $\Delta Gf°(BeF_2)$ (6) would correspond to an emf error of 20 mV.

Figure 4 shows an emf isotherm taken from measurements at a series of LiF-BeF_2 compositions and a fixed alloy composition, compared with previously reported results of emf measurements with transference cells.

The emf equation for the isotherm of cell [A] is

$$2\mathbf{F} \frac{dE}{dx} = \frac{1 + x}{1 - x} \frac{d\mu_{\text{BeF}_2}}{dx}$$

while that for the transference cell is

$$2\mathbf{F} \frac{dE}{dx} = t_{\text{Li}} \frac{1 + x}{1 - x} \frac{d\mu_{\text{BeF}_2}}{dx}$$

The equivalence of the emf results from the two cells confirms that the transference number of Be^{2+} is zero, and that the Be electrode transference concentration cell may be used in this region to determine solution thermodynamic properties.

Conclusions

The response of the Li-Bi electrode suggests its potential usefulness for a sensitive test of the unicationic (electrical) conduction mechanism in alkali fluoride-beryllium fluoride mixtures. A knowledge of the extent of the concentration range in which this mechanism is valid is important for the interpretation of anodic chronopotentiometry at a Be microelectrode in alkali fluoride-beryllium fluoride melts (7). The emf of

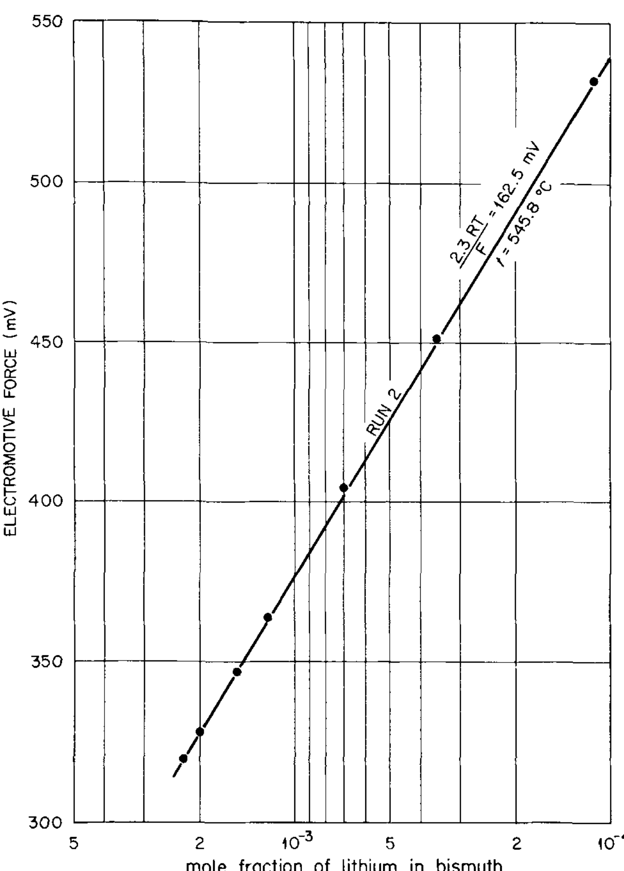

Fig. 2. Electromotive force and Nernst slopes of the cell Be | LiF,BeF₂ | Li, Bi at fixed salt composition, $x_{\text{BeF}_2} = 0.3275$.

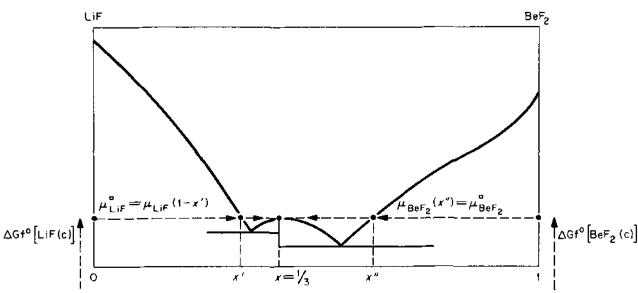

Fig. 3. Relations among free energies of formation and phase data

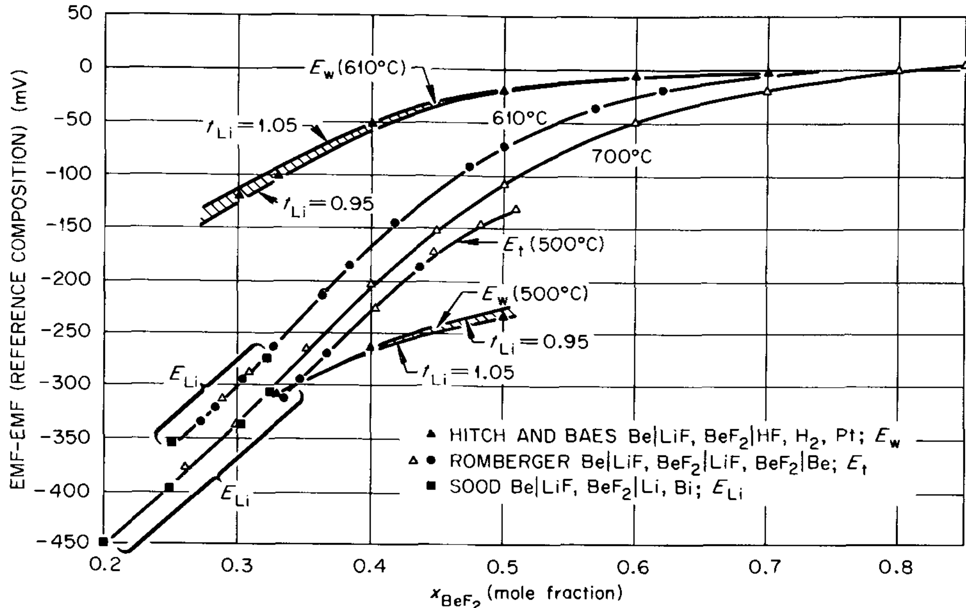

Fig. 4. Electromotive force of LiF-BeF2 concentration cells.

a transference cell with an M-Bi alloy electrode in melts of varying concentrations of BeF_2

$$M(Bi)|MF\text{-}BeF_2 \ \ x'(\text{reference}) \ \vdots \ MF\text{-}BeF_2|M(Bi) \ \ x \qquad [B]$$

would be given by

$$\frac{dE}{dx} = t_{Be}\frac{1+x}{1-x}\frac{d\mu_{BeF_2}}{dx}$$

Thus the emf of such a cell should be zero, and hence the cell would provide a sensitive indication of deviations from unicationic conduction; a negative slope would indicate anionic transport of beryllium ion relative to fluoride.

The Nernst response of the dilute Li-Bi alloy electrode, agreement with an independent value of the excess chemical potential of Li in Bi at infinite dilution, and agreement with transference cell measurements with Be electrodes, taken together, demonstrate that this electrode may be used with confidence for thermodynamic measurements.

Potentiostatic Anodic Synthesis of Ferrate(VI)

A. S. Venkatadri,[1] H. H. Bauer,* and W. F. Wagner

Department of Chemistry, University of Kentucky, Lexington, Kentucky 40506

Ferrate(VI) production by electrolysis at iron anodes was observed as early as 1841 by Poggendorf (1). Since that time, ferrate has been used as a strong oxidizing agent in certain situations (2, 3), and electrochemical preparation has been a standard procedure. However, the preparation has been empirically developed and the electrode potential was not controlled (2, 4). It seemed worthwhile, therefore, to study the

* Electrochemical Society Active Member.

Key words: ferrate synthesis, iron(VI) synthesis, anodic dissolution, electrochemical synthesis.

yield of ferrate obtainable under potentiostatic conditions.

Comparatively recently, the influence of a number of experimental variables was studied by Tousek (5) with controlled currents: ferrate production was found to be greatest in 40% sodium hydroxide solution, at 20°-25°C, and at a current density of about 5 mA/cm^2. At lower current densities, iron(III) was the main product, while at higher current densities oxygen was increasingly produced. In that work, the electrode potential varied appreciably over the course of the electrolysis. In the present communication, results are reported concerning the current efficiency for ferrate formation in relation to the electrode potential.

Experimental

Controlled-potential electrolysis was carried out with a Princeton Applied Research Corporation (P.A.R.) Model 170 Electrochemistry System. The same instrument was used to determine ferrate concentration by voltammetry at a rotating iron disk electrode (6).

For ferrate synthesis, the anode consisted of four iron rods (99.7%, A. D. Mackay Inc.), ½ in. diameter immersed to a depth of 2 in. For determination of ferrate, an iron disk electrode (¼ in. diameter) fitted to a Beckman Rotating Electrode Assembly was used. The counterelectrode in both cases was a platinum gauze, and the reference electrode was Hg/HgO/10.5M KOH.

The electrolyte was 10.5M KOH; "Baker Analyzed" potassium hydroxide was treated to remove oxidizable impurities as previously described (6). Controlled potential electrolysis was carried out in a water-jacketed cell for temperature control, and the solution was stirred with a magnetic stirrer. The amount of ferrate formed was calculated from the volume of the solution and from the ferrate concentration determined voltammetrically as previously described (6). The total charge passed during electrolysis was obtained directly with the P.A.R. instrument in the integrated readout mode.

Results

Ferrate decomposes spontaneously. Electrolyses carried out over periods of 10-15 hr showed a decrease with time in the apparent current efficiency for ferrate production. This decrease is due at least in part to decomposition of the synthesized ferrate; however, the results of Tousek (5) indicate that passivation of the anode may also contribute to this effect under certain conditions.

Some studies were made of the kinetics of decomposition of ferrate, but the process is a complicated one; the decomposition is influenced by the presence of iron(III), and it did not appear that corrections for decomposition of ferrate during electrolysis could be made reliably over lengthy electrolysis times. Therefore the data reported here refer only to ferrate synthesis at electrolysis times up to 1 hr; during that period, spontaneous decomposition of ferrate was not sufficiently great as to influence the results appreciably (in more dilute KOH, however, the rate of decomposition of ferrate is greater, and corrections would have to be made).

Results are shown in Fig. 1. It is evident that maximum production of ferrate is observed in a quite narrow range of potentials (<50 mV). Moreover, the maximum coulombic efficiency (62 ± 4%) is significantly less than 100%, indicating that competing electrode reactions are occurring throughout the potential range where ferrate is formed. Tousek (5) had observed concurrent formation of iron(III) and of oxygen in his constant-current investigations; the present studies show that these processes cannot be effectively prevented by control of the electrode potential to produce exclusively ferrate. The formation of bubbles of oxygen at the anode was seen in the present work at potentials about 70 mV less anodic than the potentials at which ferrate production was maximal.

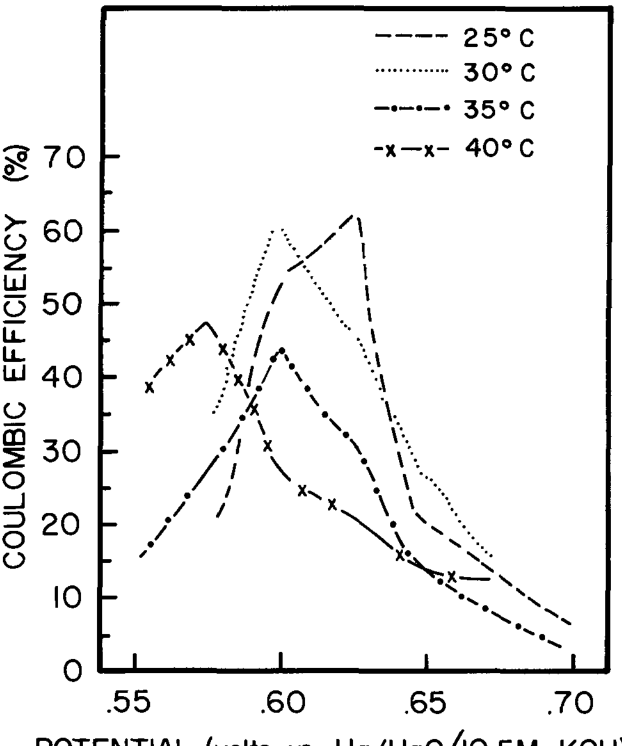

Fig. 1. Effect of potential on efficiency of ferrate (VI) production

Figure 1 indicates that the potential for maximal ferrate formation becomes less anodic as the temperature increases from 25° to 40°C, but the maximum coulombic efficiency decreases above 30°C. [These results are in good agreement with those of Tousek (5) who obtained a maximum coulombic efficiency of 60-70%, at 20°-25°C.]

Automatic, Sparkless Gas Pump for Gas Electrodes

Leonard F. Silvester and Peter A. Rock

Department of Chemistry, University of California, Davis, California 95616

A variety of pumps suitable for use with gas electrodes, in which recirculation of the gas is necessary, have been described (1-5). Gas recirculation may be required for several reasons, among which are: (*i*) the gas is expensive (*e.g.*, D_2) and cannot be continuously discarded; (*ii*) the cell must be operated under strictly anhydrous, controlled atmosphere conditions; or (*iii*) the cell is being studied on a vacuum line.

A very brief description of each of the gas pumps designed for use with gas electrodes follows.

The Bollen pump (1) is a clever stirring device based on the Bernoulli principle that sucks gas into the solution from the vapor space above the solution as the stirrer operates. The pump can be used with a small volume of gas, but it is not suited for use where vacuum operation is necessary or where organic vapors are present, or where high speed stirring is undesirable.

The Harned-Scholes pump (2) consists of two mercury-filled cylinders activated by a plunger that is driven by an electric motor through a series of pulleys, gears, and cams in such a way that when one cylinder fills with mercury the other cylinder is emptying. In principle, the pump should circulate gas at a constant pressure; in practice, condensation of solvent vapor usually occurs because of the large volume change within each cylinder. The pump is not designed for vacuum-line applications.

The Curry-Hugus gas pump (3) is a simple, inexpensive device specifically designed for use with the hydrogen electrode in aqueous solutions. The pump can be made quite small and placed in a thermostat, except for the upper gas loop which must be maintained at a higher temperature than the pumping mechanism in order to prevent solvent condensation. The heart (and weakness) of the pump is a Bunsen valve made from a rubber medicine dropper. Adjustments to this valve are made on a trial and error basis. Becaues of the numerous rubber connections, the pump is not suited for vacuum applications, or for use with most organic solvents.

The Schuldiner-Hoare gas pump (4) is a stainless steel, aquarium-type circulating pump. The pump is protected from acid spray on the outlet and inlet by fritted glass disks. The design on this pump prevents its use on a vacuum line or with organic vapors that will damage the diaphragms on the pump.

The Johnson-Glover pump (5) consists of two Toepler pumps connected in parallel and operating one-half cycle apart to provide for continuous gas delivery at constant pressure. The pump employs electrical contacts in the stream of circulating gas. The pump employs eight check valves and six electrical contacts which must all function with the proper phasing to maintain correct pump operation. The pump may be used for vacuum operation, but it is difficult to adjust and maintain in operation with the proper phasing.

The gas pump described in this work is a Toepler-type pump in basic design that incorporates several novel and useful features. These features are: automatic operation, small displacement, continuous delivery of gas, wide-range working pressures, compactness, ease of adaptability, and the absence of an upper electrical contact (this feature reduces the chance of a spark-initiated explosion in a gas mixture). The pump is constructed from Pyrex glass and Teflon-core valves (stopcocks); it can be used in conjunction with a vacuum line and its operation is unaffected by organic vapors and most inorganic vapors.

Key words: pump, hydrogen, gas electrode.

Figure 1 shows the pump layout. The parts and their functions are described below.

A is the pump vessel; it consists of a 300 ml spherical flask that serves as the mercury reservoir. The vessel has four openings. The bottom one for mercury delivery to the check valves (F); an opening (C) for the working gas used to pump the mercury; and two openings (B and D) for electrical contacts.

B is the lower contact, whose height is adjustable to compensate for various mercury levels that result from varying pressures of the pumped gas.

B is shown in an enlarged view as follows: a is an 8-32 NFT brass screw; b is a ½ in. diameter hexagonal brass bar tapped for an 8-32 thread and drilled to receive a 7 mm glass tube at the other end; c is an "O" ring seal to prevent escape of working gas during a pump-up cycle; d is a 7 mm gas support tube attached to the mercury storage vessel and cemented with Torr-

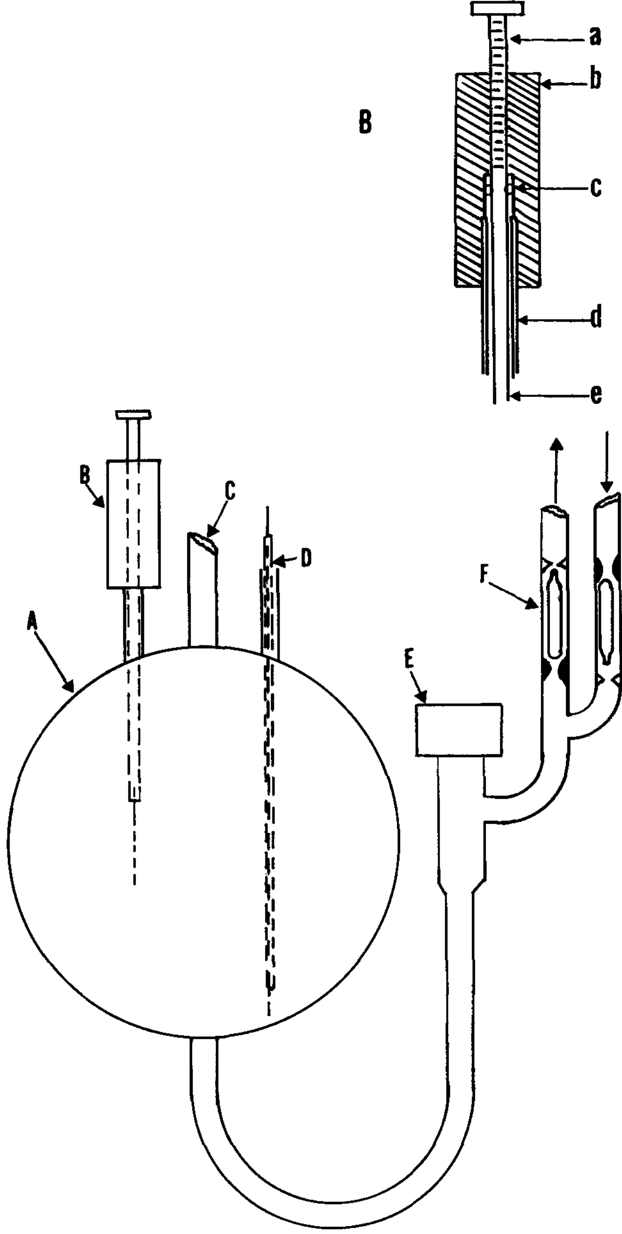

Fig. 1. Pump layout

Seal to B; and e is a ⅛ in. diameter nickel-plate-brass tube soldered to the adjusting screw with a tungsten metal contact to mercury soldered in the lower end.

C is the inlet-outlet tube for the working gas. C is connected either to vacuum for low gas pressure or to pressurized gas (*e.g.*, tank nitrogen) for high gas pressure.

D is the common contact; it is a nonadjustable contact made by sealing tungsten wire in a 3 mm Pyrex tube and cementing the upper end with Torr-Seal to the associated support tube. (This connection could be placed near the bottom of the vessel exciting with a glass-to-metal seal.)

E is a Kontes 0-4 mm Teflon valve. This valve may be used to control the rate of rise and fall of mercury in the valving part of the pump. It has been used, however, in the present work as an isolating valve so that the entire gas recirculating system may be evacuated.

F is the check valve assembly. These valves control the direction of gas flow, as indicated by the arrows in Fig. 1. On the present pump the jackets are approximately 9 mm in diameter, with an orifice of approximately 4 mm. The exhaust valve plungers are one-half filled with mercury which acts as a weight to seal the valve during the intake cycle. (The mercury may be replaced with an iron bar so that the valve may be held open with a magnet.) The intake plungers float free; they are not mercury filled. The plunger head and valve seat are ground one upon the other to form a matched unit that provides an effective seal.

For automatic operation an electrical switching circuit is needed. This is outlined along with the working gas control system in Fig. 2. The parts and their functions are listed below.

A is the control box. This is a separate unit with banana-plug-type outlets for connection to the pump, and a Cinch-Jones connector from the control box to the Timer, B. Power is 115V, ~ 60 cps, a.c. The electrical power connection, P, for the control box plugs into an electrical junction box which plugs directly into the timer unit, B. (Connection of the junction box is into the red outlet on the timer. The control box and timer could be conveniently placed in one unit.) a is a 1A fuse, connected to a double-pole, single-throw switch and a neon on-off indicator lamp; b is a single-pole single-throw relay.

B is the timer unit: a Time-Lite, Model M-59 automatic reset darkroom timer modified to start by remote signal. c is a solenoid whose plunger activates the timer start switch via a lever; d is the timer motor and automatic switching and reset mechanism of the timer (not modified), where there is a connection to the solenoid via a Cinch-Jones two-prong connector from the control box.

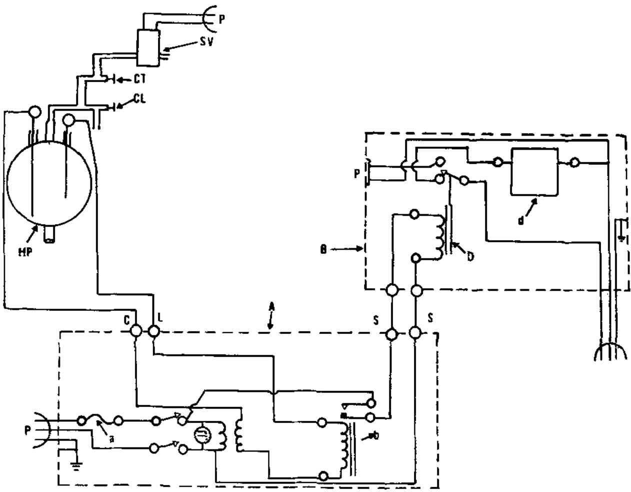

Fig. 2. Electrical switching circuit

CT, CL are the working gas control valves, Fisher-Porter 0-4 mm Teflon needle valves, for control of the incoming and outgoing flow rates. CL connects to a source of working gas.

SV is the electrical valve for the exhaust of the working gas to the atmosphere, and connection to plug P on timer unit B via a junction box.

For operating a pressures greater than atmospheric no modifications are necessary. Only the valve CT controlling the exhaust flow of the working gas through the electric valve SV need be adjusted such that the mercury falls slowly. This will prevent the gas from bubbling out of the pump through the mercury delivery tube before the working gas can come to the operating pressure.

For operations less than atmospheric pressure, *i.e.*, 700 mm and less, solenoid SV is replaced with a three way valve; one to the pump, one to vacuum, the other to air or tank gas. The value CL, as shown in Fig. 2, which connects to the working gas, is eliminated, while the other valve, CT, is placed on the air inlet of the electric valve to control the rate of rise of mercury (another valve may be placed on the vacuum outlet if the rate of fall of mercury is to be controlled).

The operation of the pump for automatic cycling is as follows. Suppose the pump-exhaust cycle has been completed and that the mercury is falling. Mercury continues to fall; this causes the level to rise in the vessel, A, until contact is made with the lower contact, B. Upon making contact, relay b is closed and this activates solenoid c, closing the timer-start switch. This deactivates the electric valve, SV, and the control unit, A, redirecting the working gas flow to vessel A, causing mercury to rise in the valve section, F. Mercury continues to rise at a rate set by the intake control valve and for a period of time that is preset on the timer. After the preset time, the timer action resets and in so doing activates the electric valve SV, and control unit A, exhausting the working gas to the atmosphere. Mercury falls until contact with B is again made to restart the cycle. Though the pump is presently used for recirculating gas, it may be used in the conventional manner for pumping gas into a collection flask by merely attaching the assembly to the pump exhaust port.

As noted earlier, the pump has no upper contact, and as such eliminates any possibility of electrical sparks resulting from mercury making and breaking contact during a pumping cycle, as happens with standard Toepler pumps on automatic mode employing the upper contact.

Because of this feature, explosive gaseous mixtures, or those subject to chemical reactions initiated by electrical spark discharge, or possibly contaminated by some such reaction initiated by electrical spark discharge, may be safely handled. Also the pumping system, because of the relatively simple design, is amenable to custom fabrication for the volume and rate of gas flow in question.

On automatic control, because the rate of rise of mercury in the pump (and its fall) and the period of duration of this rise are easily controlled, the volume of gas per pump cycle and the pumping cycle with periods of 2 sec to 1 min are easily selected (longer periods are possible by choice of a suitable timer).

Continuous flow is obtained by short pump-cycle times and because the volume of mercury displaced is small, surging effects and pressure fluctuations are very low. This permits gas-phase chemical reactions to be studied using the pump to supply a continuous flow of one of the reactants.

Two working models of the pump exist and have been in trouble-free operation for nearly 2 years. The pumps have run on automatic mode continuously for periods of up to 1 week without any failures or missing of pumping cycles.

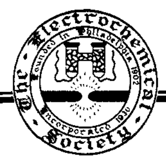
Brief Communication



Variable Composition of Basic Lead Sulfates

R. F. Dapo*,[1]

Gould Incorporated, Gould Laboratories, Energy Technology, Mendota Heights, Minnesota 55118

During the study of the compounds in the cured pastes of the lead-acid battery, procedures were developed for the preparation of pure basic lead sulfates. These methods were based on using the calculated stoichiometric ratio of sulfuric acid to lead monoxide for a given basic lead sulfate and obtaining a product having only the x-ray diffraction lines reported for that basic sulfate.

The method of preparing tetrabasic lead sulfate ($PbSO_4 \cdot 4PbO$) is as follows: 250g of Baker Analyzed yellow lead monoxide was suspended in 1.0 liter of deionized water by means of rapid stirring. To this was added 31.0 ml of 1.400 sulfuric acid from a burette. The suspension was stirred and heated at 80°C for 4 hr. The solid was separated by filtration, washed and dried at 110°C. This intermediate solid, A, was ground and transferred to a nickel crucible. The solid was heated at 550°C for 4 hr to obtain the product.

The x-ray diffraction pattern of the resulting product showed only the lines of tetrabasic lead sulfate (1). Chemical analyses were also performed: total lead as PbO, 92.94 weight per cent (w/o); SO_3, 6.58 w/o; and H_2O, 0.32 w/o. Thus the total weight accounted for was 99.84 w/o. A number of preparations using this method were made, the product was always found to be only tetrabasic lead sulfate. The true density of the tetrabasic lead sulfate was measured by means of an air pycnometer. A density of 8.04 ± 0.06 g/cm^3 was found. This compares to a literature value (2) of 8.15 g/cm^3. No peaks were found on the differential thermal analysis curve except the melting point near 895°C. This melting point of 895°C agrees with the literature value of 897°C. However, this is claimed in Figure 1139 of Phase Diagrams for Ceramist to be the tribasic lead sulfate rather than the tetrabasic lead sulfate. Thus Figure 1139 is in error.

In the above method of preparation, the question was raised as to the purpose of the heating period at 550°C as no comparable heating has been required in reported preparations (3, 4). The intermediate solid, A, obtained after the digestion and before the heat-treatment at 550°C should be pure tetrabasic lead sulfate. X-ray examinations showed that the intermediate solid was always a mixture of tri- and tetrabasic lead sulfates. The amount of tribasic lead sulfate was estimated to be as much as 60 w/o of the total sample. As tribasic lead sulfate was present in large amounts, lead monoxide or monobasic lead sulfate should be present to satisfy the stoichiometry. As neither lead monoxide nor monobasic lead sulfate could be identified in the intermediate solid, the possibility of biased x-ray results was considered. The x-ray results could be biased due to large particle size of the sample along with a poor x-ray penetration, or the results could be biased due to an amorphous form of either lead monoxide or monobasic lead sulfate.

In order to see if large particles having tri- or tetrabasic lead sulfates covering lead monoxide or monobasic lead sulfate might be responsible for the x-ray results, microscopic examination was used. Average size of the particles was estimated as 3μ. The x-ray penetration of the copper K_a radiation was calculated to be 20μ (90% critical depth). Thus the x-ray diffraction results were not biased due to large particle size.

The possibility of an amorphous component of either lead monoxide or monobasic lead sulfate was considered unlikely because of the low specific surface area of the intermediate solid, 0.48 m^2/g. For lead compounds, a specific surface area of greater than 20 m^2/g appears necessary for the loss of intensity of x-ray diffraction lines. Thus the x-ray data was considered valid and a different explanation of the data was sought.

It was found that when a weighed sample of the intermediate solid was heated at 550°C, cooled, and reweighed, a weight loss occurred. Such a weight loss could be due to the loss of the water of hydration of the tribasic lead sulfate. However, chemical analysis showed that a large fraction of the weight loss on heating at 550°C consisted of carbon dioxide. Thus a reasonable explanation of the data was considered; the possibility existed that carbonate ion in the intermediate was obtained from atmospheric carbon dioxide. This carbonate ion replaced, in part, the sulfate ions in the basic lead sulfate lattice structure. As x-ray diffraction indicates the crystal lattice structure, carbonate ion might replace some sulfate ion in the lattice, hence causing the apparent violation of the stoichiometric calculations based only on the amount of sulfate. Such a substitution of one ion by another without a change in the lattice structure of a crystal is not unknown, a classical case is that of alums.

This possible explanation was investigated by the addition of ammonium carbonate to the usual preparation of tetrabasic lead sulfate, in an amount such that if carbonate replaced sulfate in the basic lead

* Electrochemical Society Active Member.
[1] Present address: General Electric Company, Columbia, South Carolina 29202.
Key words: lead sulfates, lead carbonates, lead oxide reactions.

sulfate lattice, only the tribasic lattice would be evident by x-ray diffraction. Thus upon decomposition of this material at 550°C, water and carbon dioxide would be lost leaving chemically pure tetrabasic lead sulfate. In contrast to such behavior, chemically pure tribasic lead sulfate forms a 1:2 mixture of mono- and tetrabasic lead sulfates when heated at 550°C.

The procedure used follows: 250g lead monoxide, Baker Analyzed reagent, yellow powder was suspended in 2 liters of deionized water. To this was added 31.0 ml of 1.400 sulfuric acid with rapid stirring to effect suspension. The mixture was heated to 80°C. Sixteen grams of ammonium carbonate were added and the mixture allowed to digest at 80°C for 4 hr. The solid was separated by filtering, washed, and dried at 110°C. The following chemical analysis was found for this material:

	Weight per cent	Mole Ratio
PbO	88.4	4.00
SO_3	6.27	0.791
CO_2	2.76	0.632
H_2O	2.53	1.42

The data indicate that a sufficient amount of CO_2 is present for the formation of the tribasic lead sulfate crystal lattice. The x-ray diffraction pattern of this material showed only the lines of tribasic lead sulfate (5).

When this material was heated at 550°C there was a weight loss of 5.29 w/o. This loss of weight corresponds to the loss of water and CO_2. The heated solid was analyzed. The amount of CO_2 remaining was determined as 0.11 w/o. Neglecting this amount of CO_2, the mole ratio of PbO:SO_3 was calculated to be 5:1. The resulting material showed only the x-ray diffraction pattern of tetrabasic lead sulfate. This proves that carbonate ion substitutes for sulfate ion in the tribasic lead sulfate crystal lattice.

The possible role of carbonate ion in the tetrabasic lead sulfate crystal structure was next considered. The same procedure as described above was used, but different amounts; 20.0 ml 1.400 acid, 9.29g ammonium carbonate. These amounts were calculated such that only a tetrabasic crystal structure in which about 40% substitution of carbonate ion for sulfate ion could occur.

The x-ray diffraction pattern of the product showed only the pattern of tetrabasic lead sulfate. For a synthetic mixture of pure tetrabasic lead sulfate and 15 w/o of basic lead carbonate, basic lead carbonate lines were present in the x-ray pattern. The true density of the product was measured as 8.04 g/cm^3 by an air pycnometer. This corresponds to the true density of pure tetrabasic lead sulfate, 8.04 ± 0.06 g/cm^3. This value of the true density rules out the possibility of small amounts of basic lead carbonate ($d = 7.55$ g/cm^3) as an impurity. The chemical composition was determined and the results are listed below with the calculated mole ratios:

	Weight per cent	Mole Ratio
PbO	92.2	5.00
SO_3	4.21	0.637
CO_2	1.44	0.395
H_2O	0.595	0.400

The composition indicated by these analytical results and having the tetrabasic lead sulfate lattice structure might be written as

$$(PbSO_4)_{1-x} \cdot (PbCO_3 \cdot H_2O)_x \cdot 4PbO$$

where x is the degree of substitution, 0.4 in this case.

When this material was heated at 550°C, 2.04 w/o was lost. The x-ray diffraction pattern of this heated material showed only tetrabasic lead sulfate and lead monoxide in the amounts expected. The heated material, when analyzed, contained only 0.20 w/o carbon dioxide. In contrast to this behavior, pure tetrabasic lead sulfate would be stable at 550°C. Thus the carbonate substitution for sulfate ion in the tetrabasic lead sulfate crystal lattice was proven.

Additional preparations were performed to establish the possible range of carbonate substitution for sulfate (x, above) in the tetrabasic lead sulfate crystal lattice. Above $x = 0.4$, basic lead carbonate appears in the x-ray diffraction patterns of the resulting products. Although the ion sizes may be close, enough stress is apparently induced in the lattice with increasing amounts of carbonate, such that the more stable basic lead carbonate is formed. Preliminary experiments have shown that other anions, such as sulfite and oxalate, behave in the same fashion as carbonate in the basic lead sulfate lattice structures.

Note that the amounts of carbon dioxide in the analysis of these compounds is small when in terms of weight per cent. However, when the amounts of either carbon dioxide or water is expressed in terms of mole per cent, the magnitude assumes its appropriate importance. As pointed out above, a 1.44 w/o of carbon dioxide in a sample represented about 40 m/o of the anionic material other than oxide in the sample. Small amounts of carbon dioxide have been found in cured pastes. This is reasonable because a wet paste is basic, and may be flashed dried by an open flame. Vinal (6) asserts that carbon dioxide may be important to the hardness and strength of the cured pastes. What role these compounds might play in terms of physical or electrochemical properties is yet to be assessed.

Ionic and Electronic Conductivity in Y_2O_3-Doped Monoclinic ZrO_2

M. M. Nasrallah*,[1] and D. L. Douglass

School of Engineering, University of California, Los Angeles, California 90024

ABSTRACT

The electronic and ionic conductivities of ZrO_2 were determined as a function of temperature, oxygen partial pressure, and trivalent dopant content. The experimental observations were in reasonable agreement with the proposed defect structure model. Ionic conductivity for undoped zirconia was attributed to doubly ionized oxygen interstitials at high oxygen pressures and to doubly ionized oxygen vacancies at the lower extreme of the oxygen partial pressure. Doped zirconia, contrary to the undoped sample, showed maximum ionic transport at intermediate oxygen pressures. The ionic conductivity, due to extrinsic dopant effects, increased by increasing the amount of dopant and its range extended over a wider oxygen partial pressure. The observed decrease in activation energy for ionic conductivity upon doping was attributed to the formation of anion vacancies whose concentration is directly proportional to the dopant content. The 1 mole per cent (m/o) Y_2O_3 sample showed predominant ionic transport.

According to the Wagner-Schottky-Hauffe semiconductor valence approach (1), appropriate additions of foreign ions[2] will alter the defect concentration in an oxide. The addition of higher valent cations to an n-type oxide causes a decrease in the ionic defect concentration whereas, the electron concentration is increased. Similar additions to a p-type oxide cause an increase in the ionic defect concentration and a decrease in the electron hole concentration. The opposite effect occurs in each oxide type for lower valent dopants. This approach may in principle be applied to the oxidation of metals which form n- or p-type oxide scales. The theory involving this behavior was first given by Wagner (2) and has been verified experimentally for numerous pure metals.

Previous work on ZrO_2 showed that its defect structure varies across the scale depending on the oxygen pressure. Mallett and Albrecht (3) detected a negative thermoelectric power on oxide films formed on Zr-Sn alloys and suggested that zirconia is an n-type semiconductor. However, from electrical conductivity data as a function of oxygen partial pressure, Rudolph (4) found a positive pressure dependence on the conductivity over the range 10^{-3} to 10^{3} mm Hg. This p-type conductivity was also confirmed by his thermoelectric power measurements. Vest, Tallan, and Tripp (5) measured the electrical conductivity as a function of oxygen pressure from 1 to 10^{-23} atm and concluded that zirconia is an amphoteric oxide with the transition from n-type to p-type conductivity occurring at about 10^{-16} atm. They observed a 1/5 slope at high oxygen partial pressure and attributed it to completely ionized zirconium vacancies. Kofstad (6) stated that the presence of zirconium vacancies is inconsistent with the phase diagram considerations and suggested an alternative interpretation in which the oxide predominantly contains oxygen vacancies which under the experimental conditions are determined by substitutionally dissolved cations of lower valence. Kofstad and Ruzika (7) also observed p- and n-type conductivity at different oxygen partial pressures and suggested an ionic conduction mechanism in which both anion vacancies and interstitials exist.

From partial electrical conductivity data, Poulton and Smeltzer (8) reported that at 990°C hot-pressed monoclinic zirconia is an n-type electronic conductor at oxygen partial pressures below 10^{-18} atm and a p-type electronic conductor at pressures above 10^{-10} atm oxygen. Oxygen ion transport predominates at intermediate pressures. Kumar *et al.* (9) measured the transference numbers and electrical conductivity as a function of oxygen pressure and temperature and suggested that the defect structure of monoclinic zirconia in the temperature range of 700°-1000°C involves doubly ionized oxygen vacancies at pressures below 10^{-19} atm, and singly ionized oxygen interstitials at pressures above 10^{-9} atm.

Kröger (10) further discussed the results of Vest *et al.* (5) and suggested a Schottky-type model involving both isolated oxygen vacancies and zirconium vacancies singly associated with oxygen vacancies. A detailed analysis was given by Douglass and Wagner (11) who proposed an anti-Frenkel model based on the assumption that the ionic defect structure of zirconia is similar to that of CaF_2. These models (10, 11) have been found (12) to be mathematically equivalent if the doubly ionized oxygen interstitial of the anti-Frenkel model is replaced by a doubly ionized pair of zirconium and oxygen vacancies.

The fact that ZrO_2 is n-type at low oxygen pressures and is p-type at high oxygen pressures, means that a p-n junction exists within the scale, which junc-

Key words: defect structures, anion vacancies, interstitial oxygen, anti-Frenkel disorder.

[2] Foreign ions are assumed to dissolve substitutionally in the parent oxide.

tion would obviously affect the transport of electrons and ions across the scale. Therefore, Wagner's theory involving the change in defect concentration with dopant cannot be applied to an amphoteric oxide as zirconia. The inconsistencies in all these results can be accounted for if one considers the different materials, oxidant purity, methods of specimen preparation, and the techniques involved by various investigators. The presence of foreign cations, either in the form of impurities or intentionally added, may significantly alter the concentration of native defects. It was the objective of this work to determine the ionic and electronic conductivities of dense monoclinic zirconia containing small additions of yttria.

Proposed Defect Structure

Assuming that anti-Frenkel type disorder prevails in monoclinic zirconia, the predominant type of defects at high oxygen partial pressure will be oxygen interstitials and electron holes. Furthermore, for simplicity, only doubly ionized defects will be considered, hence

$$\frac{1}{2} O_2 \overset{K_1}{\rightleftarrows} O_i'' + 2e^+ \qquad [1]$$

by applying the law of mass action and the electroneutrality condition that $[e^+] = 2[O_i'']$. The concentration of doubly ionized oxygen interstitials or electron holes will have a 1/6 power dependence on oxygen partial pressure.

If one assumes that, upon doping, the Y^{+3} enters the ZrO_2 lattice substitutionally for Zr^{+4} according to the equation

$$Y_2O_3 = 2Y'_{Zr} + V_O^{\cdot\cdot} + 3\,O_O \qquad [2]$$

The dopant cation will have one effective negative charge. Thus, Y_2O_3 additions will cause an increase in the anion vacancy concentration which, even in the high oxygen partial pressure region, will be greater than the concentration of oxygen interstitials. Following Lasker's and Rapp's (13) analysis on Y_2O_3-doped ThO_2, expressions for the partial conductivities can be obtained, where

$$\kappa_{e^+} = \text{const}\, P_{O_2}{}^{1/4}[Y_2O_3]^{1/2} \qquad [3]$$

and

$$\kappa_i = 2|e|\mu_v[Y_2O_3] \qquad [4]$$

From Eq. [3] and [4] the dependence of Y_2O_3 content and P_{O_2} on the ionic transference number is given by

$$\tau_i = \frac{1}{1 + \text{const}\, P_{O_2}{}^{1/4}[Y_2O_3]^{-1/2}} \qquad [5]$$

Similarly, in the low oxygen partial pressure region, the predominant defects in undoped ZrO_2 will be doubly ionized oxygen vacancies and free electrons according to

$$O_O \overset{K_2}{\rightleftarrows} V_O^{\cdot\cdot} + 2\,e^- + 1/2\,O_2 \qquad [6]$$

the concentration of defects will then have a $-1/6$ power dependence on oxygen partial pressure. Upon Y_2O_3 additions the free electron conductivity and ionic transference number will be expressed by

$$\kappa_{e^-} = \text{const}\, P_{O_2}{}^{-1/4}\,[Y_2O_3]^{-1/2} \qquad [7]$$

and

$$\tau_i = \frac{1}{1 + \text{const}\, P_{O_2}{}^{-1/4}\,[Y_2O_3]^{-3/2}}$$

This shows that the addition of Y_2O_3 might affect the native defect equilibrium (extrinsic region), hence the ionic conductivity will be proportional to the dopant content and is independent of the oxygen partial pressure, Eq. [4]. Whereas the electron hole and free electron conductivities will have a $+1/4$ and $-1/4$ dependence on oxygen partial pressure according to Eq. [3] and [4], respectively. However, if the foreign cations do not affect the native defect equilibrium, (intrinsic region), the dependence of the concentration of electronic and ionic defects on oxygen partial pressure will be represented by Eq. [1] and [6].

Experimental Procedures

Sample preparation.—The starting materials were Wah Chang Zirconia Powder [compositional analysis given in Ref. (9)] and Y_2O_3 99.99% pure. Batches of 100g of undoped zirconia and zirconia containing 0.5 mole per cent (m/o) Y_2O_3 and 1 m/o Y_2O_3 were prepared. To insure homogeneity, the doped powders were thoroughly mixed in a blender for 24 hr. Isostatic compaction of the powders was performed at 60,000 psi for 5 min in glycerine. Slices, about 1.3 cm in diameter and 0.5 cm thick, were cut off the pressed samples. The disks were vacuum-sintered, in an NRC vacuum resistance furnace, at 10^{-5} Torr and 2300°C for 3 hr. Zirconia powder sintered at 2250°C, was used as a spacer between the disks and the furnace base plate to prevent contamination and sticking of the disks to the tungsten base plate. The furnace temperature was measured by a disappearing filament optical pyrometer. The sintered, black, oxygen-deficient disks were embedded in zirconia powder and oxidized in air at 850°C for 3 days. The disks were polished on fine SiC paper. The density of the undoped zirconia sample was determined by measuring dimensions and by the water displacement methods, values ranging from 5.53 to 5.67 g/cm^3 were obtained. These values correspond to 96-98% of the theoretical x-ray computed density (5.77 g/cm^3).

X-ray diffraction (with filtered Cu-K_α radiation) and metallographic analyses were performed on all samples before and after conductivity measurements to check the structure and morphology of the samples. X-ray analysis revealed the monoclinic structure whereas metallographic examination showed a single phase with no evidence of microcracks.

Electron vapor-deposition techniques were used to apply thin platinum film electrodes to the disk faces. The samples were heated during deposition at 850°C in vacuum (2×10^{-5} Torr). High-temperature vapor deposition was essential to obtain optimum contact between the platinum film and the zirconia samples. Films deposited were 0.5 cm in diameter and about 15μ thick.

Electrical conductivity and transference number assembly.—The a-c electrical conductivity *vs.* temperature measurements were performed at a test frequency of 1000 Hz using a General Radio Model 1608A impedance bridge. The samples were maintained in compression by means of spring-loaded platinum electrode assemblies which gave optimum contact through the deposited platinum thin films on the samples.

Two-probe conductivity measurements were employed. As a check on the two-probe technique Strickler and Carlson (14) measured the conductivity of several M_2O_3-ZrO_2 systems using both the two- and four-probe techniques, their results for both techniques agreeing within experimental error. Similarly, Mittoff (15) did not observe any substantial difference between both techniques from his conductivity measurements on MgO single crystal.

The sample holder was designed to completely isolate the two chambers on each face of the sample. By this setup it was possible to conduct both total electrical conductivity and galvanic cell transport measurements at different oxygen pressures and temperature on the same sample *in situ* prior to its replacement. Interruption of measurements might give inconsistent results and rupture the platinum thin film. The resistance of the platinum leads was found to be negligible. The sample was isolated from the furnace heating elements by means of a quartz tube, the furnace was kept at low impedance to ground. A

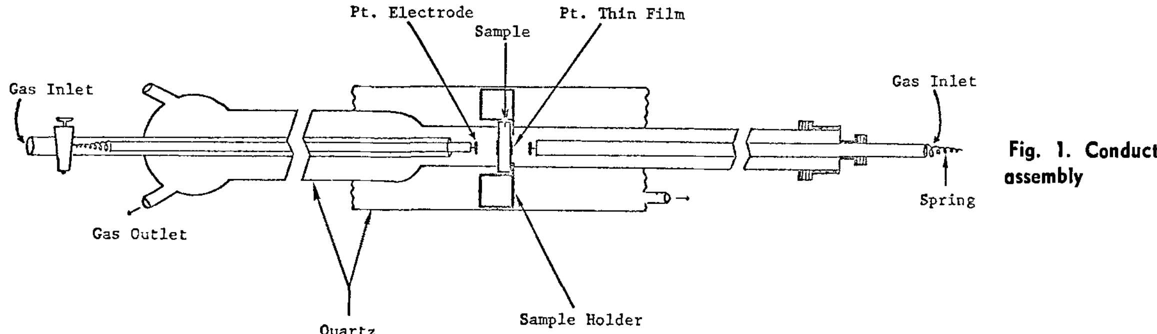

Fig. 1. Conductivity and emf assembly

schematic representation of the apparatus is shown in Fig. 1.

Transference number measurements were performed by maintaining a difference in oxygen pressure on both sides of the sample. This has been achieved by the use of gas trains which have been described elsewhere (9). Gas mixtures and their corresponding oxygen partial pressure within the temperature range of this investigation have been previously reported (16). The emf generated was measured by an L&N K-3 potentiometer. The potentiometer was also used to eliminate thermoelectric effects by reversing the polarity. The furnace had a 1.5 in. constant temperature zone at the center where the sample was located, the average temperature gradient within 2 in. from each face of the sample was 2°C; the temperature was measured by a Pt-Pt-10Rh thermocouple. A 0-100 mV chart recorder was connected from the output of the potentiometer and used to facilitate the prompt detection of steady-state conditions.

All samples were heated at 900°C for 48 hr after insertion into the apparatus and prior to the measurements.

The electrochemical cell is $P_{O_2}{}^{I}$, Pt|ZrO_2|Pt, $P_{O_2}{}^{II}$ or $P_{O_2}{}^{I}$, Pt|ZrO_2-Y_2O_3|Pt, $P_{O_2}{}^{II}$. Such cells may be employed to discriminate between ionic and electronic conductivity in solids as described by Wagner (1).

The principle is to establish different oxygen activities at opposite sides of the oxide. The potential developed is measured with a potentiometer when no current is supplied to or drawn from the cell. Provided the electrodes are completely reversible and the two sides of the sample are in equilibrium with the corresponding partial pressure of oxygen, then the measured potential across the oxide, E_e, is given by

$$E_e = \tau_i \frac{kT}{4e} \ln \frac{P_{O_2}{}^{I}}{P_{O_2}{}^{II}} \quad [9]$$

where τ_i represents the average ionic transport number for the ionic conductivity between the limits II and I and is evaluated from the values of E_e, $P_{O_2}{}^{II}$, and $P_{O_2}{}^{I}$. When the oxide is an electronic conductor the cell is short-circuited and $E_e = 0$. By using Pt electrodes, only the potential difference due to separation of ionic charges is measured. The maximum value of $\tau_i = 1$, in which case Eq. [9] becomes

$$E = \frac{kT}{4e} \ln \frac{P_{O_2}{}^{I}}{P_{O_2}{}^{II}} \quad [10]$$

The difference in oxygen partial pressure ($P_{O_2}{}^{I}$ and $P_{O_2}{}^{II}$) on both sides of the sample was maintained at about one order of magnitude.

By combining Eq. [9] and [10]

$$\tau_i = \frac{E_e}{E} \quad [11]$$

accordingly, the average ionic transference number could be obtained from knowledge of the experimentally determined potential and that theoretically calculated for purely ionic conductor.

From total electrical conductivity and transference number data, the partial ionic and electronic conductivities can be determined according to

$$\kappa_i = \tau_i \sigma_T \quad [12]$$

and

$$\kappa_e = \sigma_T - \tau_i \quad [13]$$

Conductivity and open circuit emf measurements were conducted at various oxygen partial pressures ranging from 10^{-25} to 1 atm and at temperatures between 600°-900°C.

Results and Discussion

The electronic and ionic conductivities for all three samples at both temperature extremes of this investigation are shown in Fig. 2, 3, and 4. With the exception of the high P_{O_2} region (0.21-1 atm) and at lower temperatures, the conductivity of the undoped sample was mainly due to electrons. This has been reported previously by Vest and Tallan (5) and by Kumar *et al.* (9). The ionic, pressure-independent region for the undoped sample at 600°C is attributed to equal concentrations of doubly ionized oxygen vacancies and interstitials as predicted from Eq. [1] and [6]. The decrease in electronic conductivity with increasing oxygen pressure from 0.21-1 atm at 600°C, has been previously observed (9). This observation is difficult to rationalize. A possible explanation is that zirconium dioxide has a tendency to lose oxygen, as verified experimentally from the volumetric measurements (16). Thus, an appreciable amount of oxygen deficiency may occur initially which results in the formation of anion vacancies or free electrons, but long exposure times will be required at low temperatures before equilibrium is attained. Furthermore, since the undoped sample was predominantly electronically conducting, it is expected that this inherent behavior was attributed to the initial free-electron conductivity giving rise to the observed n-type behavior. This is further supported by the fact that the initial n-type conductivity does not appear in the electronic plot at 900°C, a temperature that is high

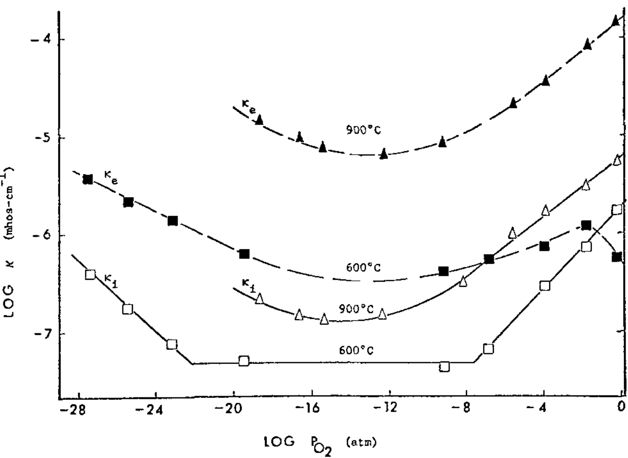

Fig. 2. Ionic and electronic conductivities of undoped ZrO_2

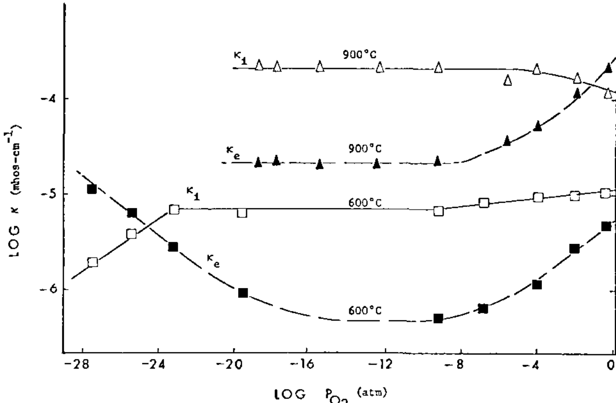

Fig. 4. Ionic and electronic conductivities of ZrO_2 + 1 m/o Y_2O_3

enough to attain equilibrium after short exposure times yielding the p-type effect directly. At 900°C the electronic conductivity decreases with decreasing P_{O_2} with a 1/6 slope, the conductivity in this region is attributed to electron holes as indicated in Eq. [1], the plot achieves a minimum at about 10^{-14} atm followed by an increase in electronic conductivity with further decrease in P_{O_2} which is attributed to free electron conductivity according to Eq. [6]. The 0.5 m/o Y_2O_3 sample showed predominant ionic conductivity at 600°C and at oxygen partial pressures above 10^{-20} atm. At lower oxygen pressures, however, the reverse was observed; this predominant electronic conductivity had been observed also at 900°C (Fig. 3). Apparently the amount of trivalent additive was insufficient at higher temperatures to produce predominantly ionic conductivity. Thus, inherent electronic conductivity was observed. The 1 m/o Y_2O_3 sample showed mainly ionic conductivity at oxygen pressures down to 10^{-24} atm at 600°C, and at oxygen pressures between 10^{-20}-10^{-4} atm at 900°C as shown in Fig. 4. The predominant ionic conductivity which prevailed upon doping was attributed to the extrinsic effect of trivalent additives as predicted from the defect-structure model. The pressure-independent range for the electronic conductivity of doped zirconia at high temperature was attributed to equal concentrations of free electrons and electron holes. The 1/4 oxygen pressure dependence on electron-hole conductivity for doped samples, as predicted from Eq. [3], is clearly shown for the 0.5 m/o Y_2O_3 sample (Fig. 3), whereas, this effect is not clearly identified for the 1 m/o Y_2O_3 sample. The increase in electronic conductivity with decreasing oxygen partial pressure below 10^{-16} atm for the doped samples was attributed to free electron conductivity and seems to be consistent with the theoretical prediction at 600°C, yet the exact determination of the slope was difficult to verify. At higher temperature, the negative pressure dependency on the electronic conductivity was not observed probably due to the extension of the P_{O_2}-independent region beyond our experimental limits.

The observed decrease in ionic conductivity with decreasing oxygen partial pressure upon doping in the low-pressure region and at lower temperatures is inconsistent with the theoretical predictions from which an increase in anion vacancy concentration is expected upon the addition of Y_2O_3. This behavior has been previously observed by Keneshea and Douglass for undoped ZrO_2 (12). A possible explanation is that the high concentration of anion vacancies causes clustering (14) or vacancy-impurity interaction (17) which could cause an appreciable decrease in the anion-vacancy mobility. Although the concentration of interstitial anions is expected to be low in this region, their mobility may be higher than that for anion vacancies, resulting in the observed interstitial-controlled oxygen ion conductivity at the lower extreme of oxygen pressure.

This positive pressure dependence of ionic conductivity on oxygen partial pressure can also be interpreted in terms of interstitial Y^{3+} cations in the ZrO_2 lattice at low oxygen partial pressures, the defect equation is given by

$$Y_2O_3 = 2\,Y_i^{\cdots} + 6\,e^- + 3/2\,O_2$$

This equation predicts an increase in the free-electron concentration and a decrease in the anion vacancy concentration. Accordingly, the concentration of oxygen interstitials will be expected to increase giving rise to the observed behavior at very low oxygen pressure.

The oxygen pressure dependence of the ionic conductivity of undoped monoclinic zirconia is shown for several temperatures in Fig. 5. Two pressure-dependent regions can be observed at high and low oxygen pressures, representing interstitial and vacancy-controlled oxygen ion conductivity, respectively. The ionic conductivity in the high-pressure range (10^{-8}-1 atm) follows a 1/6 dependence to a good approximation, particularly at higher temperatures, and may be attributed to doubly ionized oxygen interstitials. Similarly, in the very low pressure range ($P_{O_2} \cong 10^{-23}$ atm) the conductivity seems to follow a $-1/6$ dependence on oxygen pressure at 600°C which might be due to doubly ionized oxygen vacancies; however, the lack of sufficient experimental points in the low-pressure range makes it difficult to determine exactly the type of pressure dependence. A pressure-independent plateau is clearly identified at lower temperatures and gradually disappears as the temperature is increased. This plateau may be attributed to either equal concentrations of cationic and anionic defects or to aliovalent impurity effects. The disappearance of the pressure-independent region at 900°C, as op-

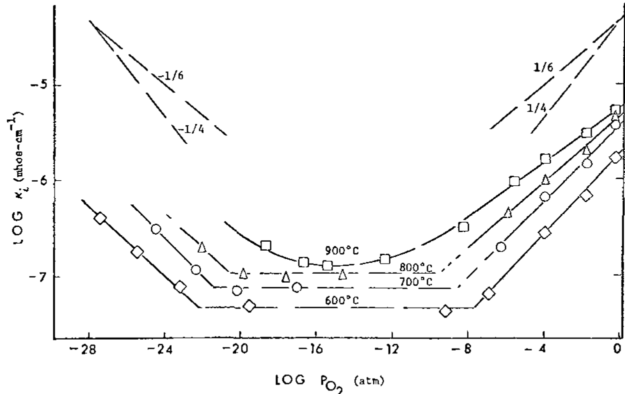

Fig. 5. Ionic conductivity for undoped zirconia

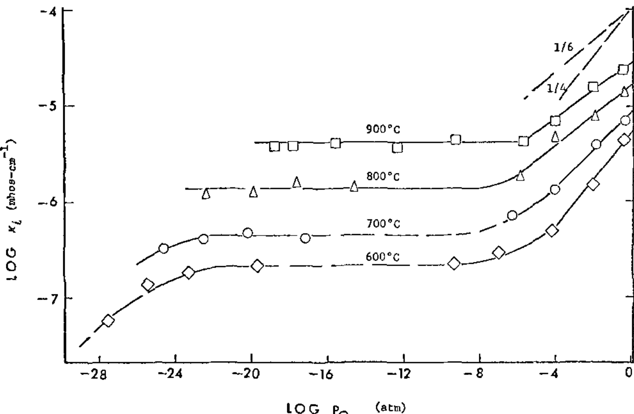

Fig. 6. Dependence of ionic conductivity on P_{O_2} and temperature for ZrO_2 + 0.5 m/o Y_2O_3.

posed to earlier work (9), might be due to the lower impurity level achieved in this work during the sintering operation.

The 0.5 m/o Y_2O_3 sample showed an initial decrease in ionic conductivity with decreasing oxygen pressure over the range of 1 to about 10^{-6} atm, indicating anion interstitial-controlled conductivity as shown in Fig. 6. The slope in this region seems to fit a 1/4 dependence on oxygen pressure at lower temperatures however, as the temperature is increased, the slope deviates from the 1/4 dependency and seems to follow 1/6 dependency at 900°C. The p-type region is followed by a pressure-independent region which seems to spread over a wider P_{O_2} range as the temperature is increased from 600°-900°C. A decrease in ionic conductivity was observed below 10^{-24} atm, indicative of p-type conductivity. This behavior was not observed at temperatures above 700°C, probably due to the extension of the pressure-independent region beyond the lower P_{O_2} limit of this work. Although the experimental points are insufficient to determine the slope exactly, it seems, however, that the slope is approximated best by a 1/4 dependence.

Doping with 1 m/o Y_2O_3 caused a barely detectable, if any, change in ionic conductivity at temperatures between 700°-900°C and throughout the entire range of oxygen pressure, except in the region between 10^{-2} and 1 atm, where a slight decrease in conductivity with increasing oxygen pressure was detected as shown in Fig. 7. At 600°C there was a slight increase in ionic conductivity with increasing oxygen pressure from 10^{-7} to 1 atm, and at P_{O_2} below 10^{-23} atm the ionic conductivity decreased with P_{O_2}.

An Arrhenius plot of log ($\kappa_i T$) *vs.* reciprocal temperature for the zirconia sample doped with 1 m/o Y_2O_3 is shown in Fig. 8. The isobar chosen is at an

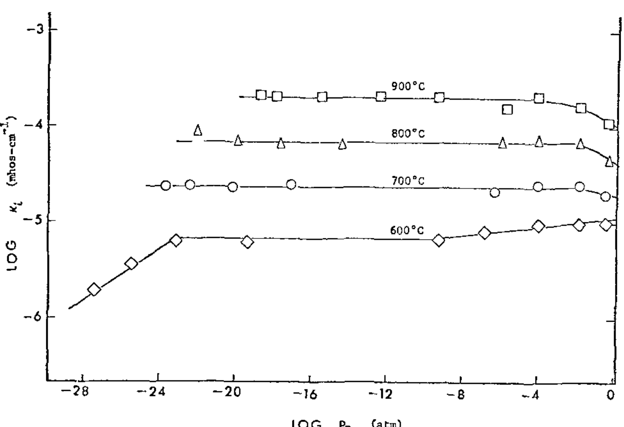

Fig. 7. Dependence of ionic conductivity on P_{O_2} and temperature for ZrO_2 + 1 m/o Y_2O_3.

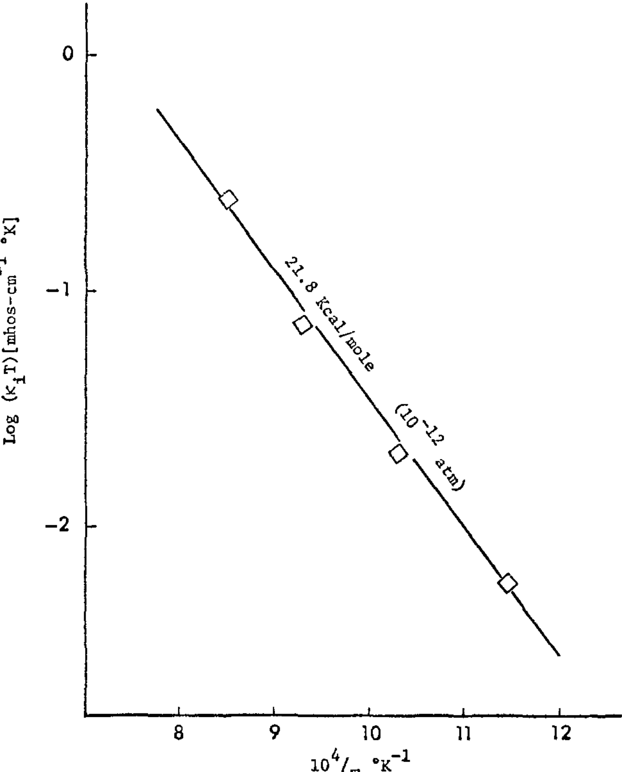

Fig. 8. Arrhenius plot for ZrO_2 + 1 m/o Y_2O_3 at 10^{-12} atm

intermediate oxygen pressure, because ionic conductivity values at both extremes of oxygen pressure cannot be derived with high accuracy from Fig. 7, and consequently, their corresponding Arrhenius plots might be misleading. From Fig. 8, a continuous increase in ionic conductivity with increasing temperature can be observed. The data fit a straight-line relationship with an activation energy of 21.8 kcal/mole, which is lower than most of the reported values for undoped ZrO_2. Hussey and Smeltzer (21) reported an activation energy value of 31.9 kcal/mole from their Arrhenius plot of log parabolic rate constant Kp *vs.* $1/T$ at temperatures between 400° and 850°C, Gulbransen and Andrew (22) obtained a value of 28.6 kcal/mole. This is attributed to the increase in ionic defects as predicted from Eq. [2].

By comparing Fig. 5, 6, and 7, one can observe the effect of dopant on the ionic conductivity of monoclinic zirconia. The ionic conductivity increased with increasing dopant concentration which behavior is consistent with Eq. [4]. Doping with 0.5 m/o Y_2O_3 resulted in a change of slope from 1/6 to 1/4 in the p-type region at high oxygen partial pressure and at lower temperatures. The undoped sample showed an increase in ionic conductivity with decreasing oxygen pressure below 10^{-23} atm, whereas, the Y_2O_3-containing samples exhibited a decrease in ionic conductivity with decreasing oxygen pressure; this behavior has been discussed previously.

Increasing temperature resulted in a decrease in the pressure-independent range for the undoped sample, whereas, the opposite was observed for the doped specimens. Furthermore, the pressure-independent region extended over a wider range as the amount of dopant increased. This interesting observation identifies the role of trivalent additives. The low-temperature behavior at intermediate oxygen partial pressures for undoped zirconia can be attributed to either extrinsic factors or to equal concentrations of doubly ionized oxygen vacancies and interstitials. The disappearance of this plateau at high temperatures suggests that the intrinsic, thermally generated defects dominate as the temperature is increased.

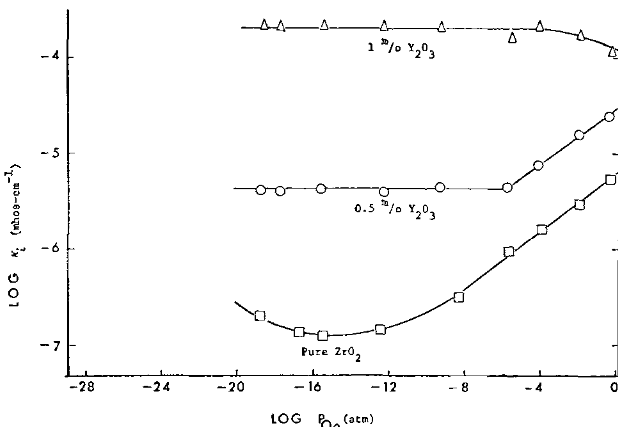

Fig. 9. Ionic conductivity as a function of dopant content and P_{O_2} at 900°C.

A cross plot for all three samples at 900°C is shown in Fig. 9. The ionic conductivity for undoped ZrO_2 is due primarily to intrinsic ionic equilibria for which oxygen interstitials predominate at high P_{O_2} and to oxygen vacancies at low P_{O_2}, as shown by Eq. [1] and [6], respectively. The theoretical derivation predicts that the pressure-independent plateau is due primarily to dopant effects. The stoichiometric composition for undoped ZrO_2 will yield a pressure-independent region; however, this plateau was not observed in the case of undoped ZrO_2 at high temperatures where a minimum in the conductivity curve at about 10^{-14} atm, was observed indicating a transition from predominant oxygen interstitials to oxygen vacancy conductivity as the P_{O_2} is lowered. Alternatively, Y_2O_3-containing samples had a pressure-independent plateau for ionic conductivity as predicted from Eq. [4]. The shift of the pressure-independent plateau towards higher oxygen pressures, and consequently the extension of the pressure-independent region over a wider P_{O_2}-range, is in agreement with Lasker's and Rapp's (13) results on Y_2O_3-doped ThO_2. The addition of 1 m/o Y_2O_3 to ZrO_2 is sufficient to produce essentially ionic conductivity over the pressure range studied. Burke and co-workers (22) predicted that the ionic conductivity for thoria doped with 10 m/o Y_2O_3, in the temperature range of 900°-1100°C, should be independent of oxygen pressure from 10^{-25}-1 atm. Similar behavior was reported (23) for ZrO_2 doped with 16.5 m/o CaO at 1000°C. Patterson *et al.* (24) found that the ionic conduction for $Zr_{0.85}Ca_{0.15}O_{1.85}$ was pressure-independent over the range of 10^{-27}-1 atm oxygen at 800°-1000°C

The change in ionic transference number with temperature as a function of dopant content is represented in Fig. 10. Figure 10A shows the ionic transference number data obtained at oxygen pressures between 10^{-3} and 0.21 atm. An increase in ionic transference number with increasing dopant content was observed in agreement with Eq. [5]. As the temperature was increased, the ionic transference number decreased, however, this became less pronounced as the amount of Y_2O_3 increased. Undoped ZrO_2 exhibited exclusive electronic conductivity at 900°C as reported earlier by Kumar *et al.* (9); however, zirconia doped with 1 m/o Y_2O_3 was primarily an ionic conductor at the same temperature and at intermediate oxygen partial pressures. The change in transference number with temperature in the pressure-independent region (10^{-12} atm) is shown in Fig. 10B. Generally, the ionic transference number values are lower than those obtained in the higher pressure region for the undoped sample, whereas, the opposite effect was observed for the Y_2O_3-containing samples. The ionic transference number for the undoped zirconia was about 0.1 at 600°C with a slight decrease as the temperature increased from 600°-900°C. Accordingly, electronic transport prevails at intermediate oxygen partial pressures, and the conductivity is primarily due to equal concentrations of free electrons and electron holes. A wide variation in transference number was observed for the sample doped with 0.5 m/o Y_2O_3. The latter had a value of 0.5 at 600°C and decreased to about 0.2 at 900°C. The observed mixed conductivity suggests that the amount of dopant was insufficient to produce the expected ionic transport and that temperature was the rate-controlling factor. Doping with 1 m/o Y_2O_3 increased the ionic transference number to about 0.92 at 600°C.

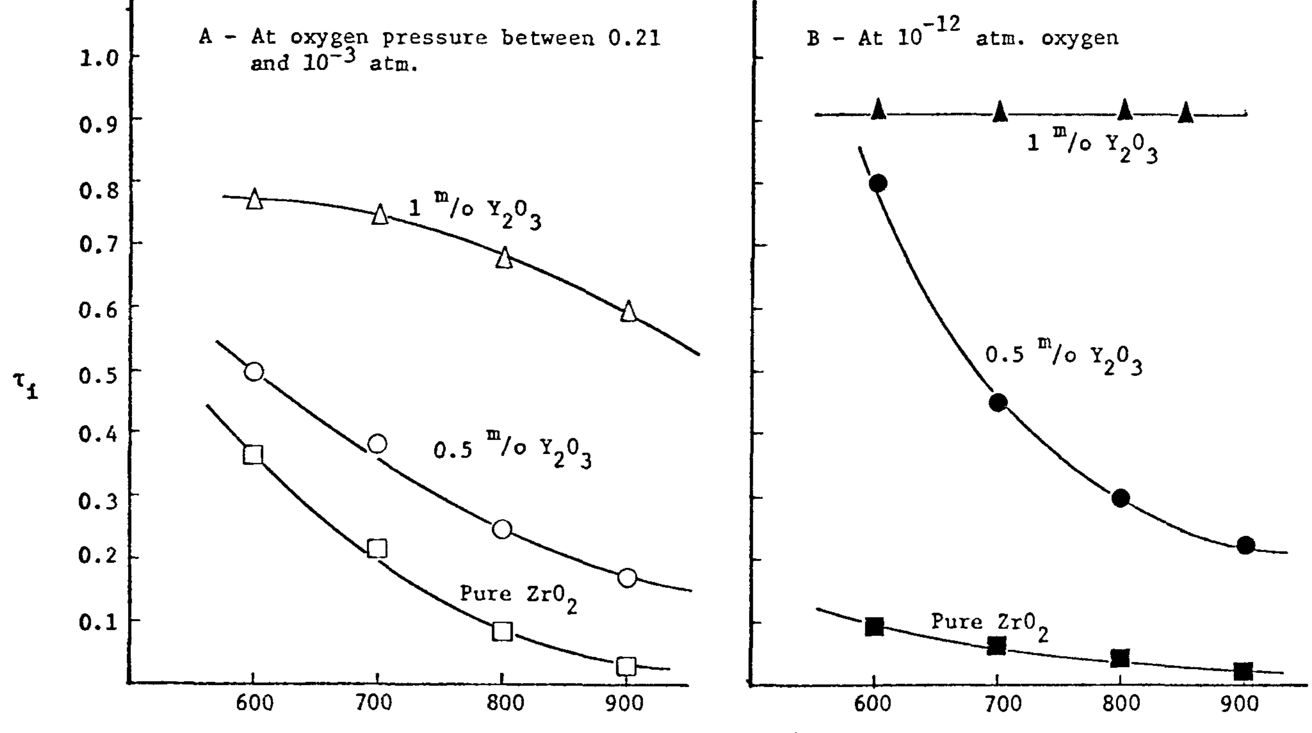

Fig. 10. Ionic transfer number as a function of temperature and Y_2O_3 content

This value remained virtually unchanged over the entire temperature range of this investigation.

The dependence of ionic transference number on oxygen pressure at 600°C is shown in Fig. 11. The ionic transference number for pure zirconia increased from 0.1 to 0.8 as the oxygen pressure increased from 10^{-8}-1 atm. The transference number remained almost unchanged at pressures between 10^{-23} and 10^{-18} atm. Below 10^{-23} atm a slight increase in transference number was observed with decreasing oxygen pressure. The sample doped with 0.5 m/o Y_2O_3 showed an increase in ionic transference number from about 0.2 to 0.85 with decreasing oxygen pressure from 1-10^{-7} atm. A further decrease in oxygen pressure resulted in a slight plateau of constant transference number between 10^{-7}-10^{-10} atm, followed by a rapid decrease in ionic transference number. For the 1 m/o Y_2O_3 sample, the ionic transference number initially increased from 0.6 to 0.9 between 1 and 10^{-5} atm. This was followed by a pressure-independent region between 10^{-5}-10^{-19} atm. A further decrease in oxygen pressure resulted in a decrease in the ionic transference number. Figure 11 shows that the range of constant ionic transference number in the higher oxygen pressure region shifted towards higher oxygen pressure as the amount of dopant increased. The relationship between ionic transport and dopant concentration is predicted from Eq. [5] and [8] at the higher and lower limits of the oxygen partial pressure, respectively. In the intermediate pressure range, the ionic conductivity is due primarily to anion vacancies whose concentration is directly proportional to the amount of trivalent dopant. This extrinsic effect should be pressure-independent for a fixed dopant content.

The agreement between the model and experimental observations is visualized from Fig. 12 which shows the change in ionic transference number as a function

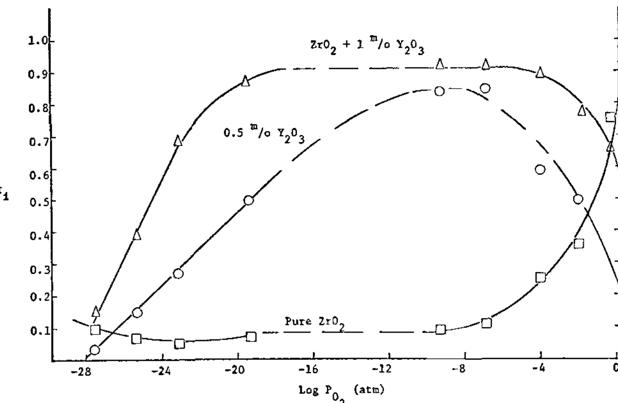

Fig. 11. Dependence of ionic transfer number on P_{O_2} and Y_2O_3 content at 600°C.

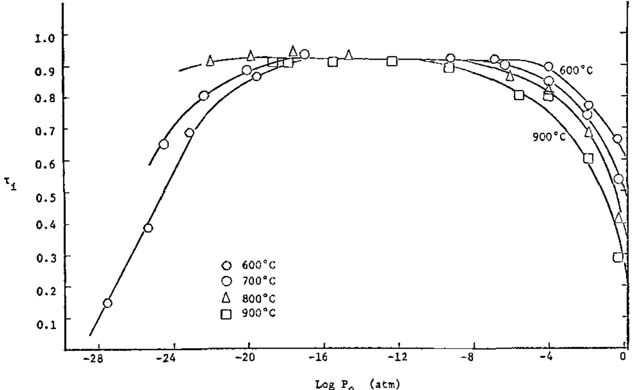

Fig. 12. Transfer number dependence of P_{O_2} and temperature for ZrO_2 + 1 m/o Y_2O_3.

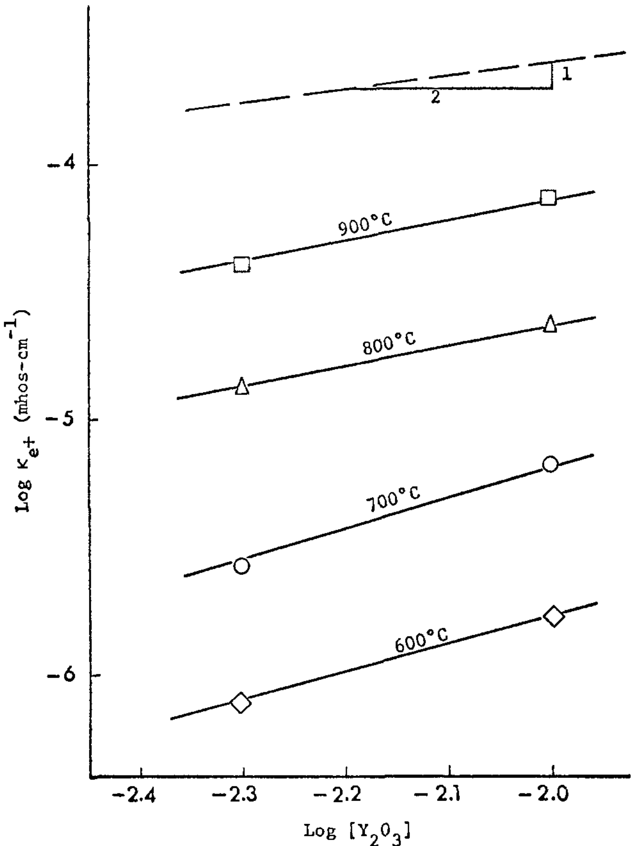

Fig. 13. Electron hole conduction as a function of Y_2O_3 content and temperature at 10^{-3} atm.

of oxygen pressure and temperature for zirconia doped with 1 m/o Y_2O_3. The figure clearly shows that doping with 1 m/o Y_2O_3 results in predominant ionic transport in the intermediate oxygen pressure range, which is independent of both oxygen pressure and temperature. A theoretical prediction, of an increase in ionic transport with decreasing oxygen pressure at high P_{O_2} and a decrease in ionic transport with further decrease in P_{O_2} at low oxygen pressure, was experimentally verified in Fig. 12. The figure also shows that the ionic transport at both oxygen pressure extremes decreased with increasing temperature.

From Eq. [3] it is predicted that the electron hole conductivity should obey a 1/2 dependence on Y_2O_3 content. A plot of log κ_{e^+} *vs.* log $[Y_2O_3]$ for several isotherms of 0.5 and 1 m/o Y_2O_3 containing samples is shown in Fig. 13. Although this work was limited to only two dopant compositions, a verification of the above dependence was observed, and the electron hole conduction mechanism is in reasonable agreement with the theoretical model.

Conclusions

A model of the defect structure of zirconia was proposed. The model predicts the dependence of ionic and electronic conductivities on oxygen pressure and dopant content.

Undoped zirconia showed predominant electronic transport over the entire temperature range except at 600°C in the high P_{O_2} region. The ionic transport number decreased with decreasing oxygen pressure, achieves a minimum and then remains essentially constant upon further decrease in P_{O_2}, at the same temperature. Conductivity at high oxygen pressure was attributed to doubly ionized oxygen interstitials and electron holes, whereas, at low oxygen pressure, conductivity was due to doubly ionized oxygen vacancies and free electrons. The stoichiometric composition, detected by a pressure-independent plateau for undoped zirconia, occurred at intermediate oxygen pressures.

The absence of a plateau at high temperatures was attributed to the decrease in impurity content of the ZrO_2 powder by the sintering operation.

The Y_2O_3-doped zirconia samples showed an increase in ionic transference number with decreasing oxygen pressure in the high oxygen pressure region and a decrease in ionic transference with further decrease in oxygen pressure at the lower extreme of the oxygen pressure range. Increasing the dopant content caused an increase in ionic transference number and extended its range over a wider oxygen pressure. The 1 m/o Y_2O_3 sample showed mostly ionic transport, *i.e.*, 90%, which was independent of temperature at intermediate oxygen pressures. These observations were in good agreement with the proposed model.

Ionic conductivity, due to the extrinsic dopant effect, was found to be independent of oxygen pressure, increased with increasing the amount of dopant and extended over a wider oxygen pressure range as the amount of dopant increased. This was attributed to anion vacancy formation and was in good agreement with the proposed model.

The interstitial-controlled oxygen ion conductivity for the Y_2O_3-doped specimens at low temperatures and oxygen partial pressures was attributed to either vacancy clustering and vacancy-dopant interaction or to the presence of dopant cations in interstitial sites. This behavior was not observed at higher temperatures probably due to the extension of P_{O_2}-independent region beyond the lower limits of this work.

The observed activation energy for oxygen diffusion in the doped sample was lower than the published values for undoped ZrO_2; this is in agreement with the theoretical predictions. The theoretical model was qualitatively verified for the ionic transport at various oxygen partial pressures and dopant content, moreover, the model was in good agreement with the observed relation between electron-hole conductivity and dopant content.

Acknowledgment

This work is based on a portion of the dissertation of one of the authors (M.M.N.) in partial fulfillment of the requirements for the degree of Doctor of Philosophy in Engineering, University of California, Los Angeles, 1972.

Manuscript submitted Feb. 6, 1973; revised manuscript received Sept. 11, 1973.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1974 JOURNAL.

Ellipsometric Study of the Plasma Oxidation of Tantalum

ABSTRACT

We have shown that it is possible to grow a uniform Ta oxide film up to a thickness of 1500Å by plasma oxidation. The average speed of growth was 0.1 Å/sec, which is comparable to earlier studies. Our experiments show that there is no significant contamination of the oxide due to sputtering from the cathode and that there is no evidence of sputter etching of the sample oxide due to the sample facing the cathode. These results are in opposition to the reports of earlier investigators. We find that our ellipsometric measurements on the oxide growth indicate that the Ta oxide being formed is a single, uniform layer with an index of refraction of 2.21. This result is in contrast to the earlier work of Lee *et al.*, who fitted their ellipsometric measurements on plasma-grown Ta oxide with a two-layer model with layer indices of 1.89 and 2.22.

In this paper we would like to report on an ellipsometric study of the plasma oxidation of tantalum. Since the pioneering work of Miles and Smith (1) on the formation of oxides in an oxygen glow discharge there have been several studies of the plasma oxidation of tantalum (2-4). One of the main problems with these earlier studies has been the technique used to measure the oxide thickness. Capacitance measurements (2, 3) require a value of the dielectric constant to be assumed, and just as for optical-step measurements (2), the growth of the oxide has to be stopped at particular points and the thickness of the oxide determined in a separate measurement. Ellipsometry (5) allows *in situ* optical measurements to be made during the growth of the oxide, which can later be analyzed to yield a thickness calibration and a value of the index of refraction of the oxide. However, the previous *in situ* ellipsometric study of the plasma oxidation of Ta by Lee *et al.* (4) may have suffered from the fact that a manual ellipsometer was used. Since it requires an appreciable time, perhaps 2-3 min, to take a reading on a manual instrument, it is necessary to stop the oxidation at particular points in the growth so that oxide thickness data can be taken. If ellipsometric measurements are made while the film is growing, the long nulling time of a manual instrument will cause significant errors in the optical data, particularly in those regions where the optical data are changing rapidly with time.

The instrument used in the present study is an automated ellipsometer (6) that is capable of taking a reading every second. This allowed optical data to be taken continually during the growth of the oxide. Consequently this has led us to some observations on better ways to grow these oxides which are at variance with the recommendations of previous experimenters, and has allowed us to collect enough optical data during the growth of the oxide to be able to get a value of the index of refraction of the oxide that fits the experimental data very well.

Experimental Procedures

Figure 1 shows schematically the experimental arrangement. The light source, L, is a He-Ne laser ($\lambda = 6328Å$) with Brewster windows. The first quarter-wave plate, Q_1, is just to convert the linearly polarized laser light to circularly polarized. The polarizer, P, and the analyzer, A, are Glan-Thompson prisms mounted so that they can be rotated around the optic axis by stepping motors. The output signal from the photomultiplier, PM, controls a special purpose digital computer which drives the P and A stepping motors in a sequence which finds and displays digitally the angular position of P and A for a null condition at PM. The optical alignment is done via pinholes. The sample, S, is mounted on a sample holder, SM, which can rotate from the vertical position shown to a horizontal position. The latter is used when it is desired to prepare a thin-film sample by using a source that evaporates vertically upward through a hole in the baseplate of the vacuum chamber, C. The orientation of the sample with respect to the optic axis is defined by pressing the sample holder, SM, in the vertical position against three alignment screws. The angle of incidence, θ_i, was measured to be 59.5°. The laser light enters and leaves the vacuum chamber, C, via two glass windows mounted on bellows so that they can be aligned appropriately with respect to the optic axis.

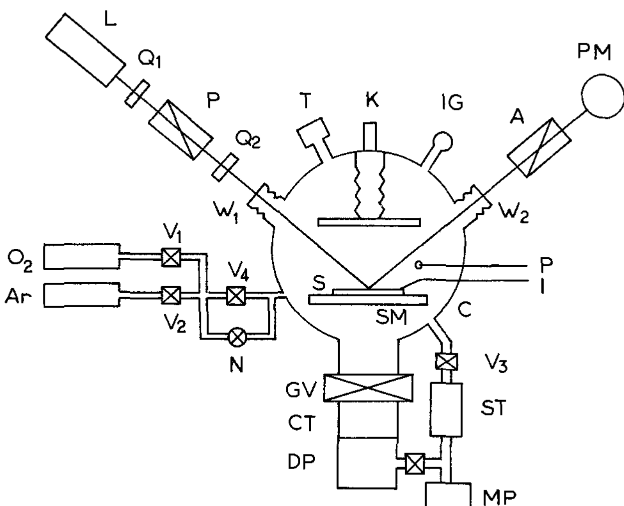

Fig. 1. Schematic diagram of the experimental arrangement. The components are: laser (L), two quarter-wave plates (Q_1, Q_2), polarizer (P), analyzer (A), photomultiplier (PM), sample (S), sample mount (SM), windows (W), drive current wire (I), voltage probe (P), vacuum chamber (C), valves (V), needle valve (N), gate valve (GV), sorption trap (ST), liquid nitrogen cold trap (CT), mechanical pump (MP), diffusion pump (DP), thermocouple gauge (T), ionization gauge (IG), and the glow discharge cathode (K).

[1] Present address: Department of Physics, University of Waterloo, Waterloo, Ontario, Canada.

Key words: ellipsometry, tantalum, oxidation, plasma.

The vacuum chamber, C, can be evacuated to 10^{-3} Torr by a mechanical pump, MP, connected through a sorption trap, ST, to eliminate the possibility of hydrocarbon contamination, and the valve, V3. To attain pressures of 10^{-7} Torr, *e.g.*, for evaporation of a thin-film sample, the chamber, C, can be pumped by a diffusion pump, DP, through a liquid nitrogen cooled cold trap, CT, and a gate valve, GV. Pressures higher than 10^{-3} Torr are measured with a thermocouple gauge, T, and pressures lower than 10^{-3} Torr are measured with an ionization gauge, IG. Oxygen or argon gas can be leaked into the vacuum chamber while being pumped out through valve V3 via the mechanical pump so that a constant pressure in the 10^{-3}-10^{-1} Torr range can be maintained dynamically under flow conditions.

The cathode, K, for the glow discharge is mounted on a high voltage feed-through and consists of an aluminum plate, 10 by 4 by 0.5 cm covered with a 0.1 mm tantalum foil, with the 40 cm^2 face of the plate facing the sample which is 8 cm away. The cathode is normally operated at between -600 and -1000V during plasma oxidation. A wire, I, which is insulated throughout its length as it passes through the vacuum space from a feed-through to the sample where it makes contact, is used to supply current to the sample and to measure its voltage during plasma oxidation. A Au probe, P, located close to the sample was used to measure the voltage of the plasma adjacent to the sample. The intent was to use the voltage measured with the wire I and the voltage measured with the probe P to arrive at the voltage across the oxide, but this is not too reliable a procedure, since one cannot be sure that the voltage measured with the probe P is really the voltage at the oxide-plasma interface.

One of the main differences in experimental technique between the present measurements and those of previous investigators besides the use of an automated ellipsometer, concerns the location of the glow discharge electrode, K, relative to the sample, S. In the pioneering work of Miles and Smith (1), the glow discharge electrode was an aluminum wire circular loop located so that the front face of the sample was facing away from the source of the plasma. Initially we tried an electrode arrangement similar to that of Miles and Smith. However, we found that the resulting glow discharge was very weak and nonuniform, so that the growth of the oxide, which could be observed directly with the ellipsometer, was very slow. If the cathode voltage was increased sufficiently, the plasma density increased and the plasma oxidation process speeded up, but the whole vacuum system, and in particular the cathode, became hot and the glow discharge changed color suggesting that impurities were being released. The P,A readings of the oxide being grown, by comparison with later results, confirmed that the oxide was being contaminated with impurities. We decided to try a cathode with a flat plate geometry located directly in front of the sample, and this certainly produced a strong uniform plasma between the cathode and the sample as was expected. Initially we tried a cathode consisting of an aluminum plate 10 by 4 by 0.5 cm thick.

The objections in the literature to the sample seeing the source of the plasma are, first, that material sputtered directly or reactively from the cathode will contaminate the oxide being grown (7), and second, that ion bombardment from the cathode will sputter etch the anodic oxide being formed and limit the maximum oxide thickness attainable (8). With *in situ* measurements with an automated ellipsometer it was possible to test for both these effects.

To investigate the cathode sputtering proposal we evaporated a Au film onto a glass slide mounted on the sample mount and then tipped it up into the vertical position to make the optical measurements. We took P,A readings of the freshly prepared Au surface, and then we proceeded to observe the P,A readings of the Au surface in an oxygen plasma produced by applying -1000V to the Al cathode. If Al was being sputtered off the cathode and reaching the gold film, then we would expect to see a gradual change in the P,A readings corresponding to a Au surface moving towards the P,A readings characteristic of an Al surface. If Al from the cathode were reaching the sample as an aluminum oxide layer due to reactive sputtering, then we should see the P,A readings trace out a loop as an aluminum oxide layer is deposited on the Au substrate. The result of this test was that, even when the Au sample was left in an oxygen glow discharge for several hours, we could detect no change in the initial P,A readings within the experimental error of a few steps of 0.01° in P and A. This corresponds to less than 1Å of aluminum oxide on the Au surface in the 15,000 sec needed to grow 1500Å of tantalum oxide in our actual experiment. We thus concluded that under our experimental operating conditions, sputtering from the cathode was not a problem as regards contamination of the growing oxide film.

In contrast, O'Hanlon (7) states that, with a sample a few centimeters from and facing the cathode he observed sputtering deposition rates of 2.5 Å/min and higher in the case of an Al cathode. He does not give details of how these deposition rates were measured or about the voltage of the cathode.

Although the Al cathode worked quite well, occasionally we saw a little flickering of the plasma at the surface of the cathode. We found that covering the aluminum cathode with a sheet of 0.1 mm Ta foil, so that no Al could be seen by the plasma, eliminated this flickering. Since Ta has an even lower sputtering rate than Al (8), we were reducing even further the possibility of any problem from sputtering. The ellipsometry test for cathode sputtering onto a Au surface was repeated with the Al cathode covered with the Ta foil, and the same results were obtained as for the bare Al cathode. The use of a thin Ta foil as the active cathode over the Al plate allowed us to make another check on the possibility of cathode sputtering.

After operating the cathode for a total running time of more than 2000 hr over a period of 9 months, during which the plasma oxidation of Ta and a number of other materials were studied, we measured the thickness of a part of the Ta foil exposed to the plasma. We compared it with the thickness of a part of the same Ta foil that was folded under so that it did not see the plasma, and with the thickness of a piece of Ta foil from the same roll. Within experimental accuracy of 1%, the thicknesses were all the same. In contrast, if the Ta were being removed from the foil at the rate of 2.5 Å/min as found by O'Hanlon for an Al cathode, we would have expected to find a 30% change in the foil thickness in 2000 hr. Naturally, weighing the foil before and after would have been an even more sensitive test, but unfortunately we did not weigh the foil before mounting it. However, we feel that this result together with the result of our ellipsometer test strongly support our conclusion that cathode sputtering and resultant oxide contamination is negligible with our experimental conditions.

Subsequent to the previously described tests, a neutron activation analysis has been carried out by R. Henkelmann, Institut Max Von Laue-Paul Langevin, in order to detect whether any Ta is sputtered from the cathode and incorporated into the growing oxide in our plasma oxidation experiments. We produced a 2000Å aluminum oxide film on a piece of bulk Al (Johnson-Matthey, 99.999% pure) in our experimental apparatus using the Al cathode covered with the sheet of 0.1 mm Ta foil. The neutron activation analysis was carried out on this Al + 2000Å aluminum oxide sample and a pure Al sample for comparison. The results indicate that the Ta concentration in the plasma grown aluminum oxide layer is below the level of detection, which is 0.1 atomic per cent (a/o) of the alu-

minum oxide, under the special circumstances of this measurement.

As mentioned earlier, the other problem supposedly connected with the sample seeing the cathode is the sputter etching of the anodic oxide due to energetic neutrals and/or negative ions emanating from the cathode striking the sample surface (9). To test the importance of this effect in our experimental arrangement, we applied a driving current to a sample, *e.g.*, a Ta foil, and grew an oxide up to some particular thickness, as measured by the P,A readings of our ellipsometer. Then the driving current was reduced to zero, but the sample was left exposed to the oxygen plasma, while the ellipsometer took readings. If the oxide were being sputter etched, we would have expected to see the P,A readings head towards the bare surface values as oxide was being removed. Although the sample was left for 1 hr in this condition there was no change in the P,A readings. Even when the sample was biased positively, but at a voltage less than that to which it had been grown, there was still no change in the P,A readings with time. A change of 0.01° in the P reading would have indicated a change of 0.2Å in the oxide thickness. The same type of experiments were performed on an aluminum oxide layer grown on an evaporated Al sample, with the same negative results. Of course, while our sample sees the cathode, the particular geometry may have helped to minimize this effect, since O'Hanlon (9) states that the sputtering yield is greatest for obliquely incident particles, and most of the ions coming from the cathode would be striking the sample approximately vertically. While this effect may be important for materials which are sputtered easily, with our geometry we have not observed the effect even for aluminum oxide in contrast to what has been reported in the literature (10).

The sample for the plasma oxidation study of Ta was a piece of 0.1 mm thick capacitor grade Ta sheet obtained from Metallwerke Plansee, Austria. The sample, with the drive current wire, I, spotwelded to it, was insulated from the sample holder by one sheet of mica and held in place with a covering sheet of mica. This top mica sheet has a rectangular hole, 9 by 18 mm, which defined the active area of the sample on which the oxide was grown. The mica sheets also shielded the edges of the sample from the plasma.

With the ellipsometer it was possible to test various treatments of the surface of the sample to find the one that gave the cleanest surface possible prior to growth of the plasma oxide. The criterion used was that the best surface treatment should produce the highest P reading possible and a stable A reading, because if the initial surface is pictured as a perfectly clean surface covered by a thin layer of oxide or dirt, the presence of this thin layer would act primarily to lower the P reading from its true "clean" value and shift the A value by a much smaller amount, either up or down depending on whether the layer was nonabsorbing or absorbing, respectively. A number of different surface treatments were tried, including mechanical polishing followed by electropolishing, but the best treatment was found to be heating the sample, without any prior surface treatment, to a white heat in a 10^{-7} Torr vacuum. This was done by mounting a piece of the Ta foil in the evaporator section of the apparatus and passing a large current through the sample after the chamber had been pumped down to the low pressure. The sample was then cut out of this piece of cleaned Ta foil and mounted. P,A readings were taken before and after the system was pumped down. Then argon gas was admitted to a pressure of 0.05 Torr and a short glow cleaning was employed by putting −600V on the glow discharge cathode K. This glow cleaning did not change the P,A readings much but was just to ensure that no water or dust particles were on the sample. Typically, the initial heat-treatment gave P,A readings of 24.0° and 31.0°, respectively, and the final Ar glow cleaning changed these values by a further 0.1°. After this cleaning technique, we certainly still had a thin oxide on the sample, because we saw no spontaneous oxidation when the oxygen was admitted to the cleaned sample (something that we saw in measurements on freshly evaporated Al films), but this cleaning process was very reproducible and we were able to allow for the still present thin oxide layer (probably not more than 20Å) in our ellipsometer fit.

Once the surface had been cleaned, the argon was pumped out of the chamber. The chamber was then flushed several times with oxygen to ensure that all the argon was removed. Finally, a dynamic equilibrium was established with oxygen flowing into the chamber through the needle valve, N, and being pumped out with the mechanical pump, MP. The oxygen gas used was Air Liquide Grade N 48. During all this process, the automatic ellipsometer was taking readings that indicated that the state of the surface was not changing. Once the state of dynamic equilibrium of pressure was reached, the voltage was applied to the cathode and the constant drive current was injected into the sample to initiate the plasma oxidation.

Several runs were made with pressures in the range 0.05-0.07 Torr, cathode voltages between −800 and −1000V, and drive currents between 5 and 15 mA. The data that we are presenting here were obtained with a pressure of 0.055 Torr, a cathode voltage of −900V, and a drive current of 10 mA. The automatic ellipsometer displayed the P,A readings digitally and these digital readings were recorded. In addition, digital to analog converters were used to convert the digital P,A readings to voltages proportional to the digital readings so that the curve in the P,A plane could be plotted directly on an X-Y recorder during the experimental run. The voltage of the sample and the voltage of the nearby probe in the plasma were measured and recorded during a run. The output of a digital clock, together with the constant value of the drive current being supplied to the sample, allowed the total charge, q, passed through the sample to be measured. Normally P,A readings were taken for a period of 15,000 sec to grow 1500Å of oxide, and with a time of approximately 5 sec to take a P and A reading we ended up with 3000 P,A points to characterize a run. At the end of a run, after the glow discharge and drive current had been stopped, final P,A readings were taken. Then the oxygen pressure was brought up to the atmospheric, and P,A readings were taken again and were found to be identical within experimental error.

Results and Discussion

Figure 2 shows typical P,A data on the plasma oxidation of Ta as it appears on our X-Y recorder. The folding back of the P,A curve at P = 0 is just the result of the fact that our digital to analog converters plot the absolute value of P or A, and so when P goes negative, the positive value −P is plotted. The steps

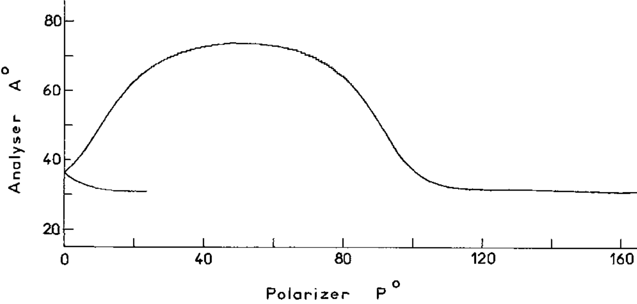

Fig. 2. Typical P,A data on the plasma oxidation of Ta as it appears on the X-Y recorder.

in the plot, which are most apparent at high A values, are just the result of the sequential way in which the P null value is updated and then the A null value is updated, with the X-Y recorder pen always in contact with the paper. The reproducibility of the data is so good that data from different runs can be superimposed on each other within the envelope given by the step structure. Indeed, if the step structure is removed by drawing a smooth curve through the midpoints of the steps, the smooth curves obtained from different runs fall almost exactly on top of each other.

To get the best fit to our experimental P,A data on the plasma oxidation of Ta shown in Fig. 2, we had to shift our bare surface P value from the experimentally measured value of 24.0° to 25.6° while leaving our bare surface A value at the experimentally measured value of 31.3°. This shift in the bare surface P value by 1.6° corresponds to the assumption that our surface treatment of the Ta sample left a 20Å layer of Ta oxide on the surface. This is certainly consistent with our observation that there was no spontaneous oxidation of the Ta surface when the oxygen was first admitted to the chamber after the final cleaning stage with the Ar glow discharge. Using initial P,A values of 25.6° and 31.3°, respectively, the index of refraction of Ta at 6328Å is found to be 2.3 $-i$ 2.6. The angle of incidence was 59.5°.

The P,A data of Fig. 2 could be fitted with an oxide of a constant, real, index of refraction of 2.21 growing on the bare Ta surface with initial P,A values of 25.6° and 31.3°, respectively. This fit was obtained initially by varying the index of refraction of the oxide in a standard ellipsometer program (5) while keeping all other parameters fixed, and determining the fit visually by superimposing the theoretical P,A curve plotted on one sheet of paper on the experimental P,A curve plotted on another sheet of paper. Doing this, we discovered the need to shift the initial value of P, representing the "true bare surface," by 1.6° otherwise the theoretical and experimental P,A curves were always displaced slightly from each other by a small amount in P. The fit obtained visually was checked later by an automatic nonlinear least squares fitting ellipsometer program which obtained the best fit between the experimental and theoretical curves by adjusting the real and imaginary parts of the index of refraction of the oxide film to minimize the least squares deviation between the experimental and theoretical values of P and A for a selected set of points on the experimental curve. Using this program, we found almost the same index of refraction for the Ta oxide film, *i.e.*, $n = n_r - ik$, with $n_r = 2.215 \pm 0.015$ and $k = 0.003 \pm 0.003$. Since the error in k is as large as its value, we suggest that it is as valid to take k to be zero within experimental error.

Because a number of people presenting ellipsometer curves do so only in the form of Δ and ψ, we have replotted our experimental data and the theoretical fit in this form and presented them in Fig. 3. In this form we can compare our results more directly with those of Lee *et al.* (4), who have made the only other ellipsometric study of the plasma oxidation of Ta. Our Fig. 3 should be compared with Fig. 3 of Lee *et al.* Their experimental data consist of 10 points that were taken with a manual ellipsometer, operating at 5461Å and at an angle of incidence of 65°, and the experimental points were probably taken by stopping the oxidation process at particular points to make ellipsometric measurements, although this is not stated. Our experimental data were obtained with an automated ellipsometer, operating at 6328Å and at an angle of incidence of 59.5°, that took data points at least every 5 sec while the oxidation process was proceeding at a constant sample driving current. Our experimental data are presented as a solid line through the approximately 3000 data points defining our curve.

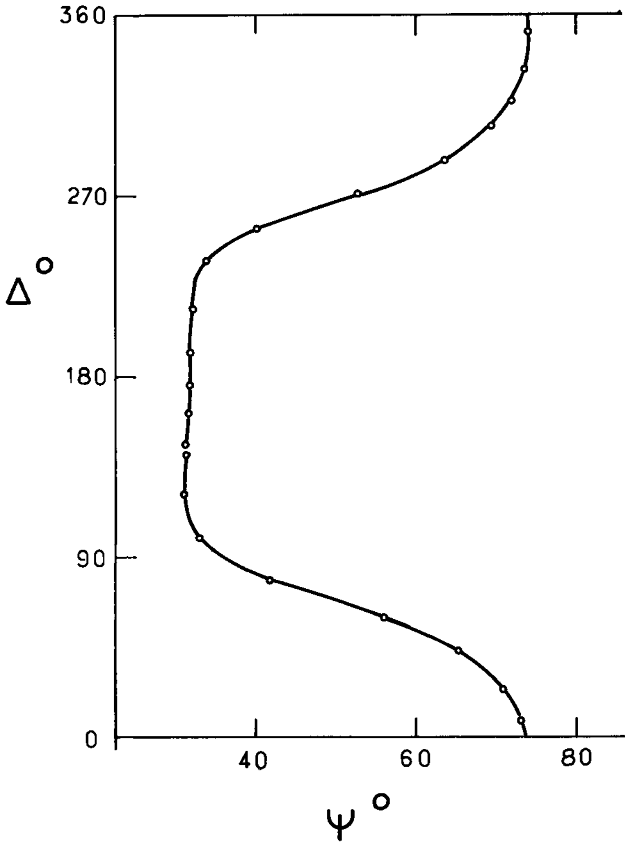

Fig. 3. Ellipsometric results for the plasma oxidation of Ta. The solid curve represents the experimental results and the open circles denote the theoretical fit obtained using a refractive index of 2.21 for the Ta oxide. Experimental conditions: sample area 162 mm², constant drive current 10 mA, oxygen pressure 0.055 Torr, cathode voltage −900V, wavelength 6328Å, and angle of incidence 59.5°.

Lee *et al.* fitted their data with a model consisting of two layers: an outer layer with an index of 1.89 and an inner layer with an index of 2.22, with the outer layer comprising 43% of the total thickness of the two layers at any stage of the growth. Their fit is presented as a solid curve with the experimental data as superimposed points. As discussed earlier, we have been able to fit our ellipsometer data by a single uniform Ta oxide layer of index 2.21. For clarity, our theoretical fit is presented in Fig. 3 as a series of theoretical points superimposed on our solid experimental curve. In comparing the fit between our experimental curve and theoretical points with the fit between the theoretical curve and experimental points of Lee *et al.*, it is perhaps most revealing to note that in the regions where ψ is varying most rapidly, *i.e.*, $60° \geqq \Delta \geqq 0°$ and $360° \geqq \Delta \geqq 280°$, Lee *et al.* in their Fig. 3 have only three experimental points and their theoretical fit passes through only two of them. From their theoretical fit it would appear that Lee *et al.* had a residual oxide layer of 80Å on their Ta sample after electropolishing, which is in agreement with our observations that electropolishing did not give as clean an initial surface as heating out the sample in a vacuum which left a residual oxide layer of only 20Å.

In Fig. 4 we present our electrical measurements during the growth of the plasma oxide on Ta in the form of plots of time, total charge passed, q, and sample voltage, V, *vs.* oxide thickness. As can be seen in Fig. 4 the time or q *vs.* oxide thickness plot is well represented by a straight line passing almost through the starting point (20Å of residual oxide at $t = 0$). The current efficiency, η, was calculated from Eq. [1] of Dell'Oca *et al.* (11), assuming that the oxide being formed is Ta_2O_5 with a molecular weight of 442 and a density of 8.7 g/cm³. A value of $\eta = 0.4\%$ was found

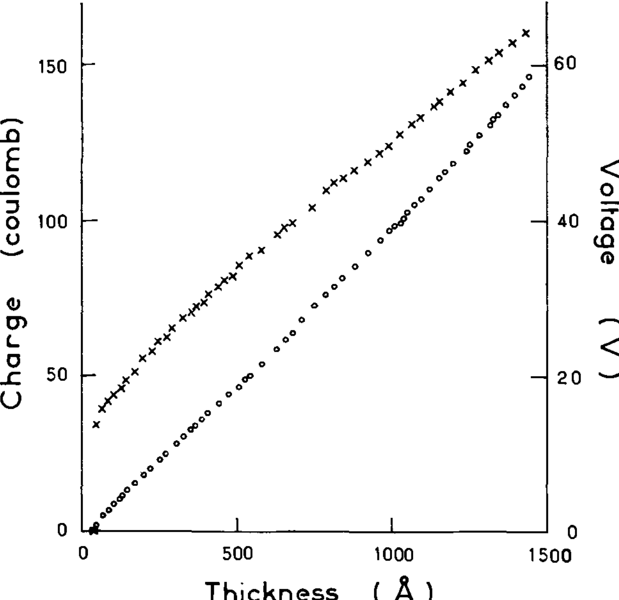

Fig. 4. Electrical measurements for the plasma oxidation of Ta. The open circles denote the total charge passed through the sample vs. the oxide thickness. The crosses denote the voltage of the sample with respect to a Au probe nearby in the plasma vs. the oxide thickness.

and this is consistent with the value of 0.5% found by Lee *et al.* The voltage V of the sample with respect to a Au probe nearby in the plasma can be seen in Fig. 4 to increase fairly quickly to a certain value at low thicknesses and then increase linearly with thickness thereafter. The interpretation of these voltage readings is complicated by the fact that it is not certain exactly what voltage is being measured by the probe in the plasma. Therefore it is difficult in Fig. 4 to separate the voltage across the oxide from the voltage drop in the plasma between the probe and the oxide-plasma interface. Since the voltage measured is so sensitive to the pressure, and this is apparently the cause of the scatter of the voltage readings in Fig. 4, we feel that the voltage drop in the plasma is a significant effect, and consequently it is dangerous to attempt to use such voltage measurements to obtain the voltage across the oxide layer.

We have not attempted to fit a model of oxide growth to our ellipsometric and electrical measurements. Since the current efficiency is so low, the ionic current, which is connected with oxide growth, is much smaller than the electron current, whose effect on oxide growth is unknown. The voltage measurements are affected by voltage drop in the plasma and also the electron current passing through the oxide, so it is difficult to determine what is the effective electric field in the oxide producing growth. We feel that at the present time with so many important quantities unknown, it would be meaningless to attempt to fit a model of oxide growth to our data. Perhaps in the future it will be possible to improve the present techniques and supplement them with some other types of experiments to yield information on the unknown quantities, and thus make it fruitful to analyze plasma oxidation results in terms of a growth model.

In conclusion, we have shown that it is possible to grow a uniform Ta oxide layer, up to 1500Å in thickness, on a Ta foil by plasma oxidation with the sample facing the cathode. Our experimental results show that there is no significant contamination of the oxide due to sputtering from the cathode, as has been suggested by earlier investigators. Also, we find that there is no evidence for sputter etching of the oxide due to the cathode facing the sample. We have been able to fit our Ta oxide film with a single index of refraction of 2.21, in contrast to the work of Lee *et al.* who fitted their ellipsometric data with a double layer model, consisting of an outer layer of index 1.89 and an inner layer of index 2.22, with the outer layer comprising 43% of the total thickness of the two layers at any stage of the growth. Our electrical measurements, in conjunction with our ellipsometric results, show that the oxide grows at a constant rate and with a constant current efficiency of 0.4%. The sample voltage V also shows a linear dependence on thickness or time, after an initial jump.

Acknowledgments

The authors would like to thank Dr. R. Henkelmann of I.L.L. for carrying out the neutron activation analysis of the Al samples. One of the authors (J. D. L.) would like to thank M. Lacaze, Directeur C.R.T.B.T., for the financial assistance in bringing the author's equipment with him on his sabbatical leave, and all the members of the laboratory for their hospitality.

Manuscript submitted May 2, 1973; revised manuscript received July 16, 1973.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1974 JOURNAL.

Effect of Chloride on Growth of an Anodic Film

J. Zahavi* and M. Metzger*

Department of Metallurgy and Mining Engineering and Materials Research Laboratory, University of Illinois at Urbana-Champaign, Urbana, Illinois 61801

ABSTRACT

Al was anodized in 2.4M H_2SO_4 at 5 mA/cm^2 and electronmicroscopic studies made of breakdown and formation of pits beneath the film after various surface treatments or after additions of up to 0.05M Cl^- to the acid and selection of those specimens which had remained in the film-growth stage before stable pits grew. An electron-opacity technique was developed for studying film growth. Even in the absence of Cl^-, there was a continued incidence of breakdown and a substantial time-dependent direct-dissolution current. With Cl^-, cell voltage tended to be lower. Film formation efficiency and geometrical structure were correlated directly with average cell voltage and not directly with Cl^- concentration. Cl^- was interpreted as having only an indirect effect on film growth by stabilizing concurrent pit growth, which reduced the film-forming current. Possible modes of pitting beneath the film are discussed.

In a recent paper (1), the authors presented electronmicroscopic evidence that during galvanostatic anodizing of aluminum in sulfuric acid many small breakdown-repair (B-R) or breakdown-pitting-repair (B-P-R) events occurred at the base of the film concurrently with porous film growth and that these events were not generally associated with substrate lattice defects or impurity clusters. As part of a program concerned with the mechanism of pit initiation, this was followed in the present work by studies of: (*i*) the possible influence of the surface preparation on the incidence of breakdown and (*ii*) the effects of Cl^- additions to the anodizing bath. The previous results and those of Part (*i*) directed attention not to the production by Cl^- of breakdown, which occurred in its absence, but to its reduction of the effectiveness of repair. This might be due to an effect of Cl^- on film growth rate or structure. Conditions favorable for examining this question were obtained by adjusting the Cl^- concentration in the bath to the highest level at which film growth would not be immediately short-circuited by growth of optically visible stable pits. Observations had been made identifying the transition in behavior with increasing Cl^- concentration (2).

The surface treatment before anodizing was of concern specifically because with the perchloric acid-ethanol electropolishing bath employed a residual film was known to be present after rinsing and this film presumably contained Cl, which has been detected by Auger analysis on surfaces polished in this bath (3). Such surfaces have been reported to yield films of low ionic resistance after forming (4).

The processes occurring in this system were such that the microtopographic features most accessible to observation were not those of growing pits but those of repair zones in the film and of the pore structure at various stages of growth. Comparisons were effectively made by examining the film after anodizing times at which it contained evidence of the previous occurrence of a high density of small (~ 0.1 μm) B-P-R or B-R "events," and the nature of the geometry deduced is illustrated schematically in Fig. 1 for one type of B-P-R (no implication is intended concerning the mechanism of pit initiation). The events occurred at the base of the film and were not evident in external-surface replicas. The projecting regions of repair film seen in film-underside replicas were prominent for recent events, but the ones which had occurred substantially before the time of observation had become shallower in the course of continuing general film growth although tending to remain visible in transmission because of the alteration of the local pore structure. In addition to these events, the film showed a much lower density of larger open repaired pits usually 1/2-1 μm across.

In the present work, the apparent effect of Cl^- was not to alter the basic character of the processes occurring but to increase the portion of the charge passed going to metal dissolution rather than film growth. The magnitude of the direct dissolution current associated with pitting in B-P-R events and growing pits could not be readily determined through microscopy, but over-all formation efficiency was investigated by measuring the electron opacities of the films, which give a measure of their relative mass-thicknesses. Opacity techniques have been employed effectively for studying amorphous-film growth (4) as well as for other purposes such as measurement of gas pressure in an environmental chamber (5).

Experimental

As in a previous paper (1), coarse-grained sheet specimens of 99.999% Al (Lot III-A) were anodized for 10-900 sec at 5 mA/cm^2 in 2.4M H_2SO_4 at 25.0° ± 0.2°C in a stirred bath with a Pt cathode. NaCl was added up to 0.1M.

Surface preparation.—The reference procedure as used previously (1) included etching off the oxide film from annealing in 10% HF, electropolishing at 0.1 A/cm^2 in 20 volume per cent (v/o) 70% $HClO_4$ in ethanol at −10° to −15°C and rinsing with a jet of ethanol (treatment A). This provided a featureless or almost featureless surface which facilitated observation of B-R, B-P-R, or stable pitting events and of any possible associations with structural features of the substrate such as grain boundaries (1, 2); it had been used earlier in examining the structure-related free-corrosion behavior of this material (6). $HClO_4$ electropolishing baths have also been used in several major studies of the classical pore structure (7, 8). To investigate whether ClO_4^- or other ions containing Cl present in the residual film influence subsequent film formation, two approaches were made. The first was to remove the electropolishing film by either (B) a 2 min etch in 10% HF at 24°C or (C) use of the film stripping solution containing 35 ml 85% H_3PO_4 and 20g CrO_3 per liter at 80°C for 4.5 min. The second was to avoid exposure to ClO_4^- or F^- by giving no treatment other than (D) a chemical polish at 85°C for 3 min in a solution containing 150 ml of 96% H_2SO_4, 800 ml of 85% H_3PO_4, and 50 ml of 70% HNO_3 or (E) an etch in 1M NaOH for 35 min at 25°C and a 1 sec dip in 50%

HNO_3 at 70°C [(E) is based on a recommended alternative to electropolishing (4) but was modified to ensure removal of the annealing film]. The final step in each case was a distilled water rinse. A change in surface treatment necessarily introduces the possibility of surface contamination by ions other than ClO_4^-, even with reagent grade chemicals. (B) and (D) (and the distilled water supply) had been evaluated and found acceptable earlier in corrosion studies sensitive to metallic ion contamination (6, 9). A recent note on some Auger studies did not report contamination from NaOH or HNO_3 treatments [as in (E)] but indicated that (C), while removing most or all of the Cl, leaves detectable amounts of P and Cr (3).

Electron microscopy.—Several samples were taken from each specimen to permit observations in different grains. Certain B-P-R events occurring in films formed for $t > 25$ sec were displayed strongly in transmission of the detached film, which normally remained thin enough up to approximately 150 sec, and this mode of observation was especially suited to making comparisons. Carbon replicas, preshadowed lightly with Pt at 35°-45°, were taken of film external surface, of film underside, and of the metal surface exposed by removing the anodic film with the H_3PO_4-CrO_3 solution used in treatment (C). Because even a slight attack on the metal by this solution could have produced significant extraneous features, the metal-film interface was examined mainly on the film underside. High magnification transmission studies of pore structure were made with special attention to defining focus (to avoid phase-contrast effects) in a series of through-focus photographs. At the time of examination, the films appeared "amorphous" by electron diffraction. Thus any crystals of precipitate, such as $Al_2(SO_4)_3$, which were still trapped in a repaired pit at the termination of anodizing had been dissolved during the thorough washing.

Electron opacity.—This can be measured in the electron microscope in several ways, the empirical coefficient which relates it to the mass-thickness of amorphous film depending on the method and instrumental factors. The opacity α is $\ln(I_o/I_c)$, where I_o is the incident current and I_c is that part of the emergent current collected by the technique employed. One method makes use of a Faraday cage below the specimen (4) and this collects the undeviated beam plus the beam scattered within the aperture of the cage. What was measured in the present work was the current absorbed by the specimen, I_{ab}. In this case I_c is obtained by difference as $I_o - I_{ab}$ and is the total emergent current. Measurements were made with a HU-11A microscope at 100 kV by substituting in the specimen chamber a current measuring specimen holder (CMSH) built by R. J. Anderson. This was insulated from the column and grounded through an electrometer, which read I_{ab}. The geometry of the CMSH was such that it effectively functioned as a Faraday cage when the beam was intercepted by an opaque object, such as an anodized 500 μm aluminum disk or a crossbar of the grid on which the specimen film was mounted. Either of these gave the same beam current I_o as was read when a conventional Faraday cage was substituted for the CMSH. It was essential to combine the measurements with microscopy of the film to provide assurance that the opacity was being determined in a region of the film free from folds, cracks, or other defects. This was done as follows. A suitable area of film (≈ 7 μm diam) having been selected after scanning the neighborhood, the objective aperture was retracted (to avoid electron backscatter to the CMSH) and the second condenser current adjusted to the setting giving the beam C.D. (≈ 50 mA/cm^2) used for opacity measurements. I_{ab} was then read, the CMSH immediately displaced so that the beam intercepted a grid bar, and I_o read at several positions. This allowed the I_o corresponding to each reading of I_{ab} to be determined without being influenced by drift in the instrument and with greater precision than could be achieved merely from a predetermined calibration of I_o *vs.* second condenser current. The procedure was then repeated in different regions of the film. The opacity technique reveals variations in local mass-thickness not indicated by other methods of measuring thickness, *e.g.*, weighing. The instrument's anticontamination devices were found adequate to prevent buildup of significant contamination layers in the irradiated area.

With the opacity calculated from

$$\alpha = \ln[I_o/(I_o - I_{ab})] \qquad [1]$$

the fractional error is

$$\Delta\alpha/\alpha = [-(\Delta I_o/I_o) + (\Delta I_{ab}/I_{ab})]\, I_{ab}/(I_o - I_{ab})\,\alpha \quad [2]$$

and is lowest at low opacity. In the low opacity approximation, $\alpha \approx I_{ab}/I_o << 1$, Eq. [2] simplifies to

$$\Delta\alpha/\alpha \approx -(\Delta I_o/I_o) + (\Delta I_{ab}/I_{ab}) \quad [3]$$

and this expression can be used up to the highest opacity measured, 0.28, at which it differs from the exact expression by only 15%. The short-time stability of I_o and I_{ab} was good and the Keithley 610B electrometer (accuracy 2%) could be read to better than 1%, so that from Eq. [3] the measurement of α had precision 2% and accuracy 4% independent of α over the range covered.

In the Appendix, the significance of the technique is discussed further and an analysis presented for the opacity of a porous film.

Results and Discussion

Surface preparation.—Cell voltage-time curves for specimens subjected to the different surface treatments are given in Fig. 2a and b. Except for treatment (C), most differences in the curves fell within the range of variation of replicate runs with the same treatment and systematic differences worthy of comment were not apparent. The steady-state voltages at $t > 50$ sec exhibited in >50 runs with (A) ranged from 6.5 to 7.6V, and the values for (B), (D), and (E) fell within this range. In the case of (C), there was more variation from run to run. The plateau voltage tended to be lower and ranged from 7.6 to 4.9V. The initial voltage rise was usually distinctly faster, as in Fig. 2b, although sometimes the same.

The thickness and the structure of the film varied with surface treatment to a minor degree at most, and these aspects are discussed later together with the observations on films formed in acid containing Cl^-. In this section, consideration is given to the specific question whether B-P-R events occur with the same frequency, intensity, and apparent character after treatments (B)-(E) as after (A). The evidence pertinent to this question is illustrated concisely in low magnification transmission micrographs, where recent "events" appear as dark patches. Some examples for films formed in 2.4M H_2SO_4 after different surface treatments are given in Fig. 3a, c, d (25 sec anodizing), Fig. 4a, b, c (84 sec), and Fig. 5a, b (150 sec) (the average plateau voltage, $\overline{V}$, has been given in these figures for later reference). These figures illustrate the result that for all treatments the events began only after about 25 sec and varied with time in a rather similar manner. The widely scattered holes in the film, as shown for (A) in Fig. 3a, represented the positions of some

transient ~ 1/2 μm pits formed during anodizing and were found with all treatments.

The typical appearance of the events for the several surfaces may have been slightly different, to about the degree illustrated in Fig. 3a, c, d; Fig. 4a, b, c; and Fig. 5a, b. Any such differences were never much greater than those in any one specimen from one grain to an-

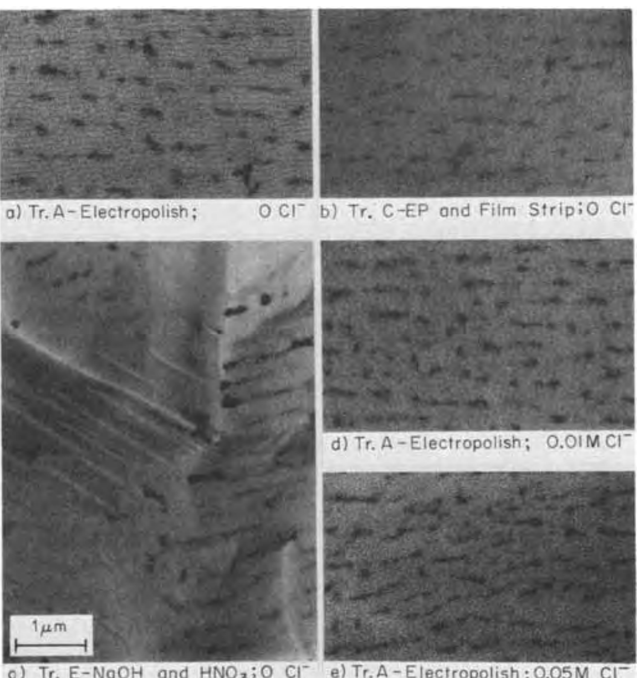

Fig. 4. Similarity of events in transmission micrographs of 84 sec films formed at relatively high plateau voltages under various conditions. $\overline{V}$ was (a) 7.1V, (b) 6.7V, (c) 6.6V, (d) 5.9V, (e) 6.8V.

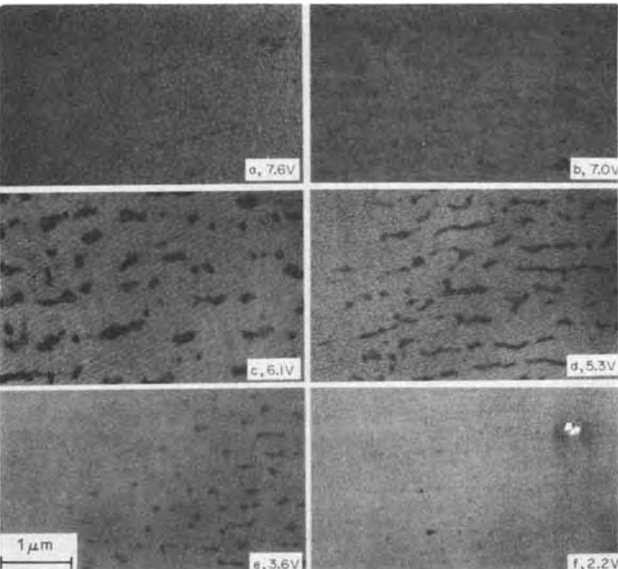

Fig. 5. Appearance of events in 150 sec films as a function of average plateau voltage, $\overline{V}$. (a) and (b), 0 Cl^-; (c)-(f), 0.01M Cl^-. Treatment A was used except for (b) which was given treatment (B).

other. In replica studies, no substantial differences were noted. It was concluded that events of the same general character occurred with roughly the same frequency for all surface treatments examined and thus that the high incidence of breakdown originally noted with treatment (A) (1) was not the result of special conditioning of the surface by this treatment but was an intrinsic characteristic of film growth under the present conditions.

Apart from the events, the anodic film replicated the original surface. The granular or furrow structure (dimensions ~ 0.1 μm) characteristically produced by $HClO_4$ electropolishing baths (10) was visible to a varying degree, *e.g.*, Fig. 4a, and this was not altered by stripping the electropolishing film with treatment (C), Fig. 3d and 4b. This treatment tended to produce some shallow pits $\lesssim 0.3$ μm across, as replicated in Fig. 3d. The granular structure was no longer visible after the HF etch employed in (B), Figs. 3c and 5b, because this etch removes $\lesssim 1$ μm of metal (it also produces scattered shallow pits which do not appear in these fields) (11).

Treatment (E) was the only one yielding a surface with asperities sufficient to examine their possible influence on breakdown (12, 13). In this surface, the NaOH etch had produced craters with large smooth areas on which some geometric etching was superimposed, as replicated by the anodic film in Fig. 4c. It can be seen in this figure that most of the events were associated with smooth areas of the surface, and that most of the asperities, such as edges or corners of intersecting facets, had not given rise to events. Thus any influence of asperities on breakdown here appeared small in comparison with the breakdown tendencies intrinsic to flat surfaces.

Effects of Cl^- additions.—Simple electropolishing, treatment (A), was employed for further studies because it yielded a surface with a minimum of geometrical features and facilitated the observation of pits formed during anodizing.

The effect of adding Cl^- to the 2.4M H_2SO_4 first became pronounced at 0.01M. At this level, pits did not grow to macroscopic size immediately but there was an initial period of film growth varying in duration from a few minutes to almost an hour. In this film-growth stage, the cell voltage varied considerably from one test to another and usually showed severe short- and long-period fluctuations in the course of the test. Several examples are given in Fig. 6a. In comparison with the behavior without Cl^- additions (curve 1), the cell voltage often ran for a time in a similar manner at a slightly lower level (curve 2a) but more frequently ran from the start at a substantially lower level in a fluctuating fashion (curves 2b and 2c). Sometimes, a curve such as 2b would, after fluctuating severely in the 3-5V range during the first few minutes, drift upward and run with only mild fluctuations in the 5-6V range for a considerable period. A considerable voltage drop below 2V, as at the end of curve 2c, marked the growth of stable pits. With 0.05M Cl^-, an occasional specimen ran for a minute or two with a curve like 2b or 2a, but typically at 0.05M and 0.1M there was little or no film-growth stage, curve 3.

For studying the effect of Cl^- on film growth and structure, to obtain the highest concentration at which film growth was not immediately short-circuited by stable pitting, the Cl^- was set at 0.01M (to a limited extent 0.03M), many specimens were run various times, and from the *V-t* curves a selection was made of those which had remained in the film-growth stage throughout the anodizing. This normally included only curves which had not fallen, such as 2a and 2b in Fig. 6a, but two specimens with curves such as 2c, where the voltage had fallen at the very end of the run, were included to provide films formed at lower average voltages than were otherwise obtained.

An appropriate parameter for over-all characterization of the *V-t* curve was the average plateau voltage, $\overline{V}$. This was determined starting from the time of the voltage maximum (which provided the only suitable reference point near the plateau level) as indicated in Fig. 6b. Averaging cell voltage from $t = 0$ would have given a misleading time-dependent index having lower values for short times just beyond the maximum even when the plateau was relatively flat. It is to be noted that although cell voltage eventually became constant for $\overline{V} \gtrsim 6V$, this was achieved only after 40-50 sec anodizing, well beyond the voltage maximum at 7-13 sec (curves 1 and 2a of Fig. 6a, also Fig. 2).

Rate of film growth by electron opacity.—Large differences in opacity were found for films from different specimens formed for the same time with 0.01M Cl^- additions. Additional sampling and checking showed differences in opacity to be related consistently to differences in average plateau voltage, $\overline{V}$, during forming, and additional specimens anodized with various Cl^- concentrations or surface treatments were chosen to

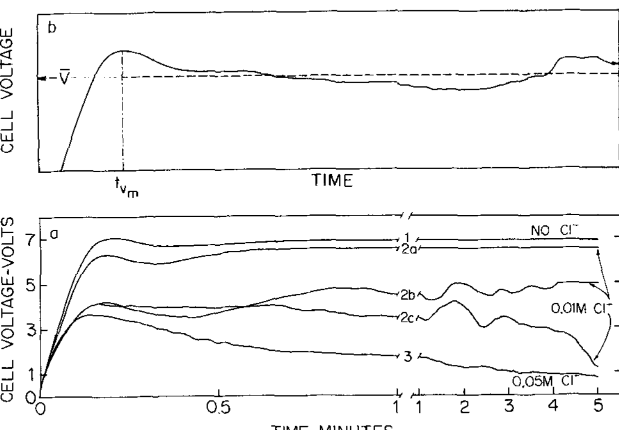

Fig. 6. (a) Cell voltage time in 2.4M H_2SO_4 at 5 mA/cm² showing typical behavior without Cl^- (curve 1) and at 0.05M Cl^- (curve 3) and range of behavior exhibited at 0.01M Cl^- (curves 2a, 2b, 2c). (b) Schematic showing method of defining average plateau voltage, $\overline{V}$.

permit determination of opacity-time curves at various $\overline{V}$.

In any opacity measurement, the region of film sampled never included holes (as in Fig. 3a or b) or large ($\gtrsim$ 1/2 μm) repaired pits, but the small B-P-R events (Fig. 4 and 5) were closely spaced so that the 7 μm diameter beam necessarily included many of them, and the opacity was a measure of mass-thickness averaged over the main body of the film and the events in that region. The average opacity was typically determined from readings in ten regions in two grids with film patches taken from different parts of the specimen. The range of values in one grid overlapped that in others. The range in the sample of ten was as high as 16% of the average, and it was considered likely that the mean opacity determined here from a necessarily limited sample could deviate from the ideal mean opacity averaged over the whole area of the film by 10% or more.

Opacity *vs.* $\overline{V}$ was studied primarily at 150, 300, and 900 sec and the data are given in Fig. 7. This plot was populated by first taking at each time electropolished specimens [treatment (A)] anodized either in acid without Cl^- additions at $\overline{V}$ near 7V (open circles) or in acid with 0.01M Cl^- (half-filled circles) at various lower $\overline{V}$, the range of which was covered by anodizing many specimens and selecting appropriate ones for opacity measurement. For anodizing at other than 0.01M Cl^-, it was not possible to check the whole range of $\overline{V}$ effectively, but individual examples could be run to find whether or not the films showed the same dependence of opacity on $\overline{V}$. These examples included one for 0.003M Cl^- (one-quarter filled circle), at which $\overline{V}$ was always $\gtrsim$ 6V, two for 0.03M Cl^- (filled circles), at which $\overline{V}$ varied but specimens rarely remained in the film-growth stage for times of interest, and several films formed in acid without Cl^- additions for 300 sec after treatments (B-E) (triangles, square, and diamond) and for 150 and 900 sec after treatment (B) (erect triangle). It can be seen in Fig. 7 that at each anodizing time the data for all conditions scatter around a single relation between opacity and $\overline{V}$. Thus, for example, in the 300 sec data opacities obtained with treatment (A) and 0.01M Cl^- at 3, 4-1/2, and 6-1/2V are close to opacities obtained near these $\overline{V}$ with different surface treatments and/or different Cl^- levels. When all data were averaged, the relation between opacity and $\overline{V}$ appeared to be linear and is so represented in Fig. 7. For $V > 3V$, the deviations of the points from the lines in Fig. 7 correspond to differences in opacity of less than 10% except for one difference of 13% and one of 15%. Most of this scatter was attributed to the sampling problem discussed above. This scatter completely overshadowed any differences which might have existed between specimens given different surface treatments and thus initially bearing films of different thickness. In the case of the electropolishing film (which was too fragile for a direct measurement), the opacity could be estimated from an extrapolation in Fig. A-1 of the Appendix as only $\approx$0.002, so that any extra opacity in anodized treatment (A) specimens due to the persistence of the electropolishing film would not have been detectable in Fig. 7.

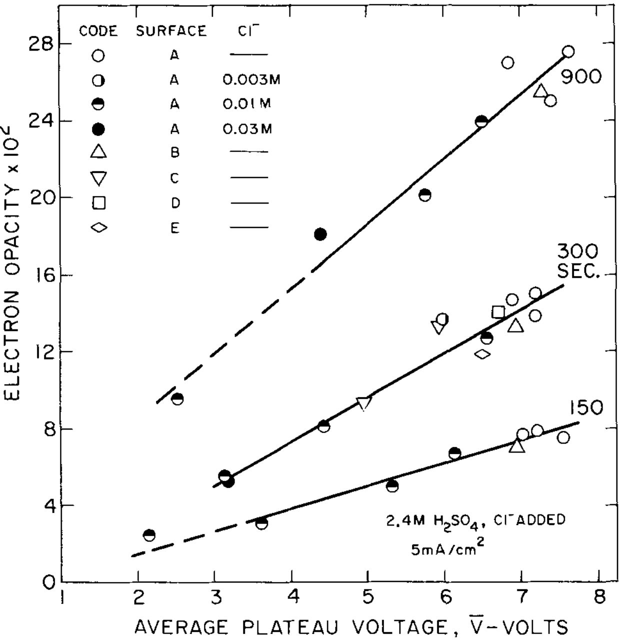

Fig. 7. Electron opacity *vs.* average plateau voltage for films formed 150, 300, and 900 sec under various conditions.

Opacity-time curves for various $\overline{V}$ were constructed from values taken from the lines fitted to the data of Fig. 7 at 150, 300, and 900 sec and from some additional values at $\overline{V}$ near 6 or 7V measured in specimens anodized 25 and 84 sec, Fig. 8. The behavior in unmodified H_2SO_4, which can be compared with other studies, is shown in the 7V data, and the formation efficiency *vs.* time was analyzed for these as discussed below.

Film-formation efficiency.—Cherki and Siejka (14) have most recently considered how the current (or charge) per unit area passed through the cell, I_{tot} (or Q_{tot}), is partitioned, and their notation is used here. If the quantity of porous film present corresponds to charge Q_{ox}, then all losses are grouped as $Q_{diss} = Q_{tot} - Q_{ox}$. The electronic current can be assumed negligible in cases of interest here [so that Q_{diss} is determinable from the Al^{3+} in the acid and is the quantity measured by certain workers (15, 16)]. Q_{diss} includes Q_{dec} which formed the oxide previously in pores and which was electrochemically decomposed ["field-assisted dissolution" at pore bases (17)] in the course of pore growth, Q_{ch} from the oxide subsequently lost by purely chemical dissolution from pore walls and film external surface, and Q_{Al} the charge associated with direct transport of cations into solution (this never went to form oxide). Cherki and Siejka used nuclear microanalysis techniques to study films formed on Al at 10V in 1.5M H_2SO_4 at 15°C. For the constant current stage of their anodizing, they found that I_{diss} was 0.47 I_{tot} and was not time-dependent. I_{ch} having been found to be negligible for $t \leq 600$ sec, and I_{dec} having been calculated from previous measurements of pore dimensions, I_{Al} was found by difference to be $\approx$0.38 I_{tot}. The presence of a substantial direct-dissolution current had been pointed out earlier by Nagayama, Tamura, and Takahashi (16) under the name, "extra-dissolution (electrochemical) at the pore base."

An exact treatment of these questions is not obtained from the opacity data, but certain conclusions of interest can be drawn from the 7V data in Fig. 8 with the aid of the formalism described in the Appendix relating opacity to the geometrical parameters of a classical porous film. The calculations are described in the Appendix and their applications noted here. It was convenient to use as a reference the calculated α-t curve of a film which continued to thicken, at its initial rate, by simple pore lengthening (allowance for Q_{dec} thus being built into the model). The initial thickening rate was derived from the early part of the experimental 7V curve and a hypothetical α-t curve calculated for continued pore lengthening at this rate. This curve was insensitive to reasonable variations in the values of the parameters employed in the fit, and it is shown in Fig. 8. That the experimental curve fell increasingly below this calculated curve after about 84 sec indicated that losses from Q_{ch} and/or Q_{Al} became relatively important at longer times. The uncertainties

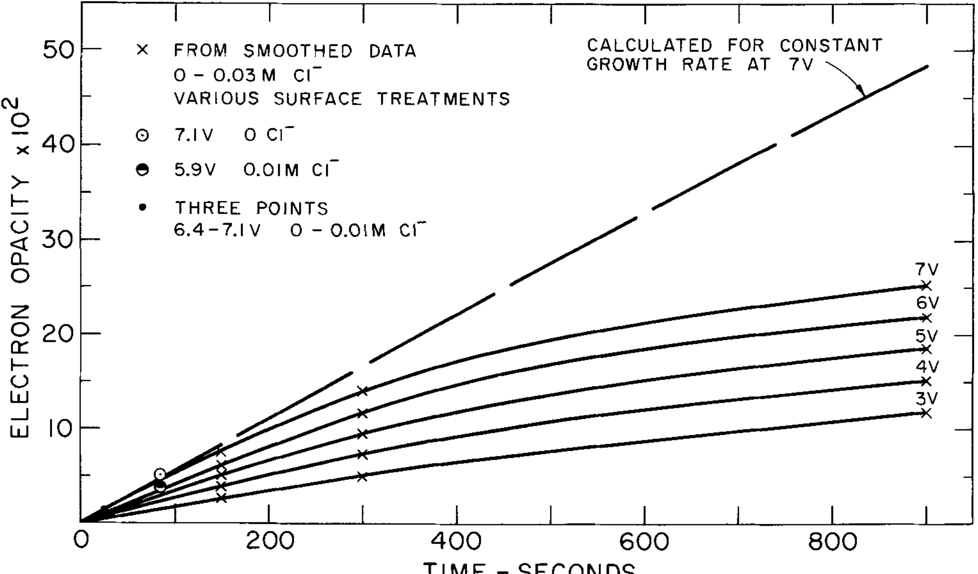

Fig. 8. Opacity time at several mean plateau voltages. The opacity of any film present at $t = 0$ would not be visible on this scale. The dashed curve is a calculated curve for a 7V film which continued to grow at its initial rate.

of the present treatment are regarded as insufficient to place this conclusion in doubt. In particular, a nonclassical distribution of pores should not have a major influence on the calculated opacity because in the low opacity range this depends only on mass-thickness, *i.e.*, on thickness and void volume fraction but not on void distribution (see Appendix).

At 900 sec, the measured 7V opacity in Fig. 8 was 48% of the calculated constant-thickening-rate value. The increasing difference between these curves may have been due to chemical dissolution, which always has negligible influence initially and becomes more important with time, and/or direct dissolution, which conceivably became more important at longer times in these experiments. For chemical dissolution, recent measurements have given linear dissolution rates from 0.75 Å/min (1M H_2SO_4, 27°C) (15) to 0.2 Å/min (1.5M, 15°C) (14) and 1 Å/min was taken as an upper limit for both pore-wall and external-surface dissolution. From the changes in film thickness and average pore area produced by this dissolution rate, the hypothetical 7V constant growth-rate opacity curve was recalculated to include the effect of chemical dissolution. Its effect was found to be small at times of interest, the hypothetical opacity being reduced at most by 2.2% at 300 sec and 8.4% at 900 sec. The major part of the 48% difference at 900 sec then had to be attributed to direct-dissolution processes, $Q_{Al}(t)$, which became relatively more important with time.

For films formed in solutions containing Cl^- at $\bar{V} < 6V$, the lower opacities cannot be attributed to an increased chemical-dissolution rate in view of results of Diggle *et al.* showing this rate to be comparable in SO_4^{2-} and Cl^- solutions at low *p*H (18). That the lower opacities of such films did not include a substantial loss from oxygen evolution in pits was indicated qualitatively by optical microscope observations of bubble evolution during anodizing (these also ruled out any substantial contribution to Q_{tot} from the hydrogen evolution possible in a pit beneath the film where the potential was momentarily low enough). Thus the lower opacities could be attributed only to a larger direct-dissolution loss, Q_{Al}/Q_{tot}.

The analysis cannot at present be extended with confidence from a relative to an absolute basis to yield values of the ratio Q_{Al}/Q_{tot} at various times. The early rate of porous film growth at 7V could be estimated from the data as 25 Å/sec by making use of the linear scattering coefficient determined for a compact film formed in borate solution, but the film formed in sulfuric acid differs in incorporating substantial quantities of SO_4^{2-} (14, 19) and may also differ in degree of hydration. Calculated formation rates for porous films are subject to uncertainties related to their SO_4^{2-} content as discussed by Cherki and Siejka (14). It is sufficient here to point out that if the film were Al_2O_3 of density 3.17 g/cm³ forming at 5 mA/cm² at the highest possible efficiency ($I_{Al} = I_{ch} = 0$) it would thicken at 27.2 Å/sec, so that the estimated 25 Å/sec is of acceptable magnitude.

The 7V opacity results indicated that Q_{Al}/Q_{tot} underwent a transition from some constant value to larger values after roughly 84 sec anodizing and that this ratio had a substantial value at 900 sec; there were too few points for analysis of its time dependence after the transition. Other evidence of a transition near this time was shown by the *V*-*t* curves, in which the cell voltage became constant after 40-50 sec, and by the electron microscopy, which revealed events occurring with high frequency in the period $25 < t < 65$ sec and with much lower frequency thereafter. This transition did not represent pore initiation, which started as early as 5 sec and produced a well-developed pore structure no later than 15 sec.

The reason Cherki and Siejka (14) did not observe a transition in formation efficiency may have been that their analysis started only after 30 sec when the current became constant. Extensive studies of formation efficiency were made some years ago over ranges of C.D. (usually >5 mA/cm²) temperature and H_2SO_4 concentration (usually 1.5M) from the changes in specimen weight on forming and on stripping the film, the efficiency usually being given as the "coating ratio" (20-22). Because this ratio averages efficiency from the start of anodizing and because the first ratios obtained in these studies represented $t \geqq 1$ min, an early transition could not have been displayed distinctly in their plots. However, the plots did show coating ratios decreasing with time at relatively short times under conditions for which chemical-dissolution effects would be minimal and thus were broadly consistent with a time-dependent Q_{Al}/Q_{tot} as found here.

The previous workers (14, 16) were concerned to establish the existence of a substantial I_{Al} but did not examine its nature. Now I_{Al} conceivably originates in (*i*) a uniform direct-dissolution current, I_{Al-u}, across the intact barrier layer at the base of every pore (this current coexists with the currents in this layer producing growth) and/or (*ii*) a pitting current, I_{Al-p}. The latter is the average over the surface of the instantaneous rate of charge input to scattered transient or stable pits growing beneath the film through individual channels or cracks in the barrier layer providing paths of electrolyte extending to the metal (*e.g.*, as in Fig. 1). In principle, pit size and density hence total pit volume can be examined by microscopy. However,

pit dimensions and geometry in the present specimens did not permit determination of the extent to which pitting was responsible for low film formation efficiencies, as discussed below.

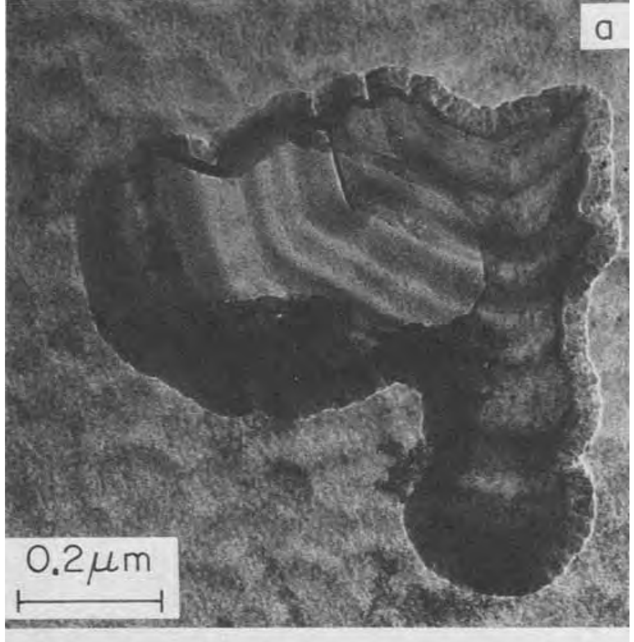
Microscopic evidence of pitting.—In the film-growth stage of anodizing, evidence was found for three categories of pits beneath the main film, as follows [the stable pits accompanying a fall in cell voltage in solutions containing Cl^- (2) are not dealt with here]:

1. Repaired open partly geometric pits mainly 1/2-1 μm across, some of which were visible relatively early in the anodizing (25 sec).
2. "Events" mainly $\sim$0.1 μm across visible in the transmission micrographs (Fig. 4 and 5) thought to represent repaired shallow geometric and nongeometric pits beneath the film, many of which formed between 25 and 65 sec for $\overline{V} \gtrsim 6V$.
3. Smooth broad and shallow pits beneath the film, apparently triggered by type 1 or 2 pits, which did not soon repair and which were generally not visible in the film structure or even prominent in the metal-surface topography.

The pitting here was time-dependent and complex and the processes in initiation, growth, and repair have not been established. Only the type 3 pits appeared able to persist long enough to account for a substantial direct-dissolution current, I_{Al-p}. The evidence discussed below pertains mainly to films formed at $\overline{V} \gtrsim$ 6V, for which many samples were available. Evidence pertaining to the film-substrate interface was preferably obtained from film-underside replicas because the CrO_3-H_3PO_4 solution used to expose the metal surface for replication could introduce some shallow pits, as noted above and as has been mentioned by previous workers (23).

Type 1.—Figure 9a shows an external-surface replica of a 900 sec film in which the geometrically etched pit surface was visible. Here a patch of the pre-existing overlying film had been lost thus permitting direct replication of part of the pit surface, and the remainder of the pre-existing film had collapsed into the pit and conformed to the contours of the terraced pit surface thus permitting indirect replication of these contours. That the pit surface bore a repair film could be deduced from evidence of the pore mouths on the uncovered part of this surface similar to those on the main area of the external surface. Underside replicas, even for short anodizing times, showed the convex undersides of the repair film over pits, as in the region of a 25 sec film containing several repaired 1/2 μm pits shown in Fig. 9b, indicating that pit growth was of short duration. The film overlying type 1 pits is thought generally to have cracked during anodizing (as in Fig. 9a) leaving the pit at least partly open. This is consistent with observations in transmission on detached films. In transmission, there was the possibility that additional damage to the film had occurred during detaching and washing. Thus, in 25 sec films usually only holes in the film were left, as in Fig. 3a and b. Apparently at this time the repair film was still too thin and fragile to survive the treatments used.

Note that Fig. 9a and b and 3a and b represent fields illustrating type 1 pits and are not typical fields. The density of these pits was perhaps $\sim 10^2$ per cm^2 for sulfuric acid anodizing and was not much greater when Cl^- had been added, and it is estimated that their formation had consumed a negligible fraction of Q_{tot}. This type of repaired pit was at least in part strongly geometric (Fig. 9a and b), which suggested an active dissolution mode. The low metal-surface potential required for this dissolution mode would not have been possible without large *IR* drops in the electrolyte. Even with a high local transient pitting current, *IR* drops of the magnitude required would be possible only if the pit had been fed initially through an extremely fine channel or crack in the barrier layer. This situation would be unlikely to persist, the channel becoming enlarged or the overlying film becoming grossly cracked by one of several processes possible as the pit grew. The size of the *IR* drop would then have fallen sharply, thus returning the metal surface to a high potential and leading to repair (dispersion of the electrolyte in the pit may also have been important). This scheme would account for the transient nature of this mode of pitting.



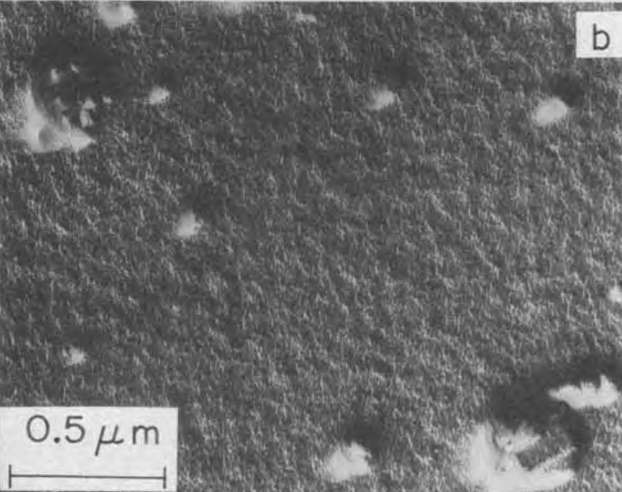


Fig. 9. Examples of type 1 pits ($\sim$1/2 μm across) in specimens formed with 0.01M Cl^- additions. (a) External-surface replica showing partly open repaired pit in 900 sec film. $\overline{V}$ = 6.2V. (b) Film-underside replica of a region in a 25 sec film (shadowed with Au-Pd). $\overline{V}$ = 5.7V.

Type 2.—The numerous "events" prominent in Fig. 4 and 5 were part of a sequence of phenomena which began after $\gtrsim$ 25 sec anodizing (for $\overline{V} \gtrsim$ 6V), these events themselves occurring with lower frequency for $t > 65$ sec. There were also much smaller events, as discussed in the previous paper (1) in relation to individual pore appearance at high magnification in 25 sec films and diagnosed as B-R, but these are not discernible in the present micrographs and are not considered further here. Distinction between forms of B-R and of B-P-R, uncertain in earlier observations (1), now appears possible and an interpretation of the breakdown processes occurring and of the characteris-

tic arrangement of the events of Fig. 4 and 5 in stringers or streamers will be attempted in a later paper. An interpretation of the repaired geometric pitting aspect of these events is given in Fig. 1. This differs from type 1 pitting in that the pit was smaller and shallower and the overlying film was apparently intact except for a narrow path in the barrier layer assumed to be present although it was not identifiable in the electron micrographs. For example the external surface replica of a 900 sec film in Fig. 10 shows the undulant topography from the original electropolished surface and evidence of pore mouths but no indication of the processes which had occurred at the base of the film except for occasional patches of slightly different appearance (as at the upper center of Fig. 10), which may have represented part of the film overhanging a pit. Attention is directed below to the two kinds of evidence that the events in Fig. 4 and 5 were associated at least in part with pitting-repair:

1. The events as seen on the film underside tended to exhibit some angular or geometric character and no process appears capable of yielding this except repair of small geometric pits somewhat as represented in Fig. 1. Some examples from 300 sec film underside replicas are given in Fig. 11. For all conditions of anodizing (including various surface treatments, Fig. 11a and b, or anodizing in acid containing Cl^-, Fig. 11c) certain events had considerable angular or geometric character, and their outlines tended to lie in parallel directions as though they formed in the same substrate grain and had geometries related to the same crystal orientation. It is to be noted that although geometric character in an event is taken as evidence of pitting preceding repair, its absence does not establish that no pitting was involved.

2. The events were arranged in streaks running preferentially in certain directions, as in Fig. 4, and these were related to substrate orientation and changed direction at a grain boundary. Studies in progress in single crystals indicate that more than one factor is involved in the streaking, but one is a tendency for the streak to extend parallel to the surface trace of a {100} plane. Trenches growing along the surface in these directions have been observed during pitting of aluminum in HCl solutions (24, 25). One also recalls the tunnel pits, in chloride solutions or tap water, growing in <100> directions (26, 27).

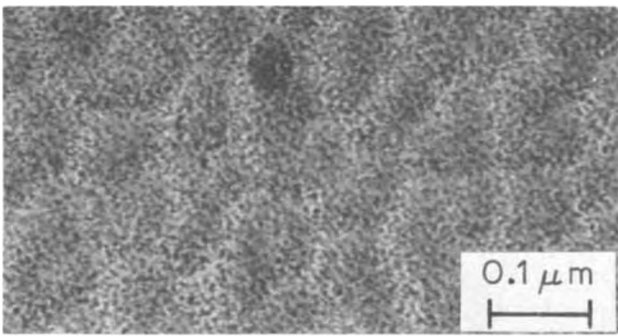

Fig. 10. External surface replica of a 900 sec film formed with 0.01M Cl^- addition. $\overline{V} = 6.2V$ Cf. Fig. 5b of Ref. (1).

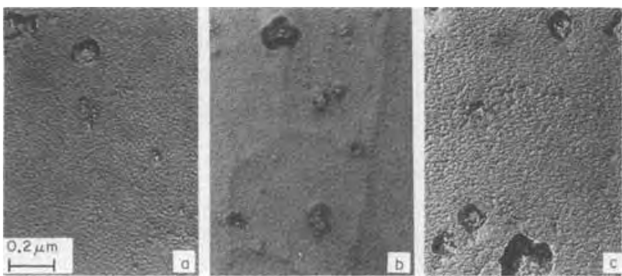

Fig. 11. Appearance of events in underside replicas of 300 sec films. (a) NaOH-HNO_3 treatment (E), 0 Cl^-, 6.5V. (b) Chemical polish (D), 0 Cl^-, 6.7V. (c) Electropolish (A), 0.01M Cl^-, 6.4V.

The period of pit growth in the active dissolution mode implied by the geometric aspects of the events would have tended to be short because the severe constriction in the electrolyte path required for the large *IR* drop would be unlikely to persist, as discussed above for type 1 pits. It is also possible pit growth was interrupted by the inability of the acid to flow through the constriction at a sufficient rate. The pitting may have ceased through repair, or it may have continued in some other mode. There is evidence (for $\overline{V} < 6V$) that some of the events were followed by a type 3 pitting not apparent in these micrographs, as discussed below. A feature of type 2 pits which may have been important was that the overlying film did not crack and the strongly occluded pit geometry (which permits an electrolyte of different character to develop within the pit) was retained. The basic character of type 2 and type 1 pits shown by microscopy did not appear altered by the presence of Cl^-.

Estimation of the charge consumed by type 2 pitting from the apparent volume of the shallow events was subject to considerable uncertainty, as seen from the interpretation of pitting-repair geometry in Fig. 1. After rapid growth to a certain size (Fig. 1a) there is reanodization of the pit surface, this occurring by constant-voltage anodizing while the system is on the plateau of the *V-t* curve. If this anodizing is tentatively idealized following Hoar and Yahalom (28), there is initially a rapid formation of a compact film of limiting thickness (Fig. 1b) followed by a stage of slow growth and pore formation associated with the minimum in the current-time curve (28). In this stage, continuing film growth at the bases of the other pores tends to level the film underside profile (Fig. 1c). A little later, film growth is again occurring over the whole front (Fig. 1d). At this point the event may not be prominent as a perturbation in the film underside or metal surface profile but may still be visible in transmission as a darker patch because of the nonalignment of old and new pores, the local pores having smaller apparent sizes or showing lower contrast. Thus, while occurrence of the event was readily detected and its lateral dimensions could be estimated, there was no way of establishing how much its depth had been reduced by film growth around it (Fig. 1b *vs.* 1d).

The most generous estimate possible of the total pit volume in visible events (using maximum depths observed in shadows on underside replicas) gave $Q_{Al} \leq 0.1\ Q_{tot}$ at 84 sec (just after the frequency of events declined) and a smaller fraction of Q_{tot} at longer times, so that the visible events themselves could not have been responsible for the substantial Q_{Al}/Q_{tot} at 900 sec indicated by the analysis of the opacity data.

Type 3.—A simplified geometry for a type of possibly more persistent pitting under the anodic film labeled type 3 is shown schematically in Fig. 12. It is assumed that this unrepaired pit is stabilized by what may be classified as an electropolishing film and that this is lost during film detaching or washing operations and is

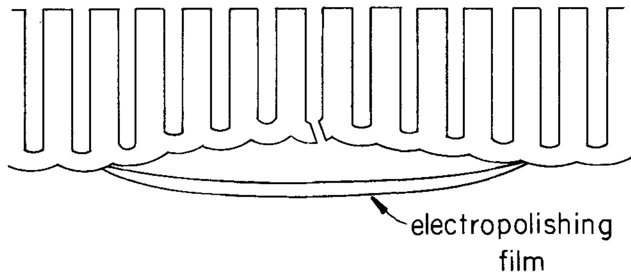

Fig. 12. Schematic geometry for a smooth pit spreading under the anodic film (type 3).

thus not detected in the electron micrographs. The distinctive features envisioned here are the smooth growth front and the spreading relatively slow growth. A shallow tapered depression is left in the anodic film underside through the progressive cessation of film growth as the pit spreads (this differs from Fig. 1a where pit growth in the active geometric mode is idealized as occurring so rapidly that there is negligible film growth in the interval). An unrepaired pit of the shape shown in Fig. 12 would be difficult to identify and characterize through replicas of metal surface and film underside because the topographic features are gently sloped, and the only feature favorable for observation is the tapering of the overlying film, which if sufficient could give rise to substantial contrast when the detached film was examined in transmission. Unambiguous evidence of this feature was not found in films formed at 7V for 300 or 900 sec, but Fig. 13 shows, in a film formed at 2.5V, a $\sim$5 μm diameter area with the contrast expected. A number of such areas were visible in the films formed at lower $\overline{V}$, usually with a weaker photographic density gradient than the one in Fig. 13 indicative of a more gradual film thickness variation. In metal surface replicas some smooth craters consistent with Fig. 12 were noted but a positive characterization of all shallow surface features was not achieved. Evidence for the presence of unrepaired pits of significant extent was provided by testing for film adherence with replica tape, and it was found that patches of film could be removed, in accordance with Fig. 12. Repaired shallow type 3 pits could have been present incorporated into the film structure (analogous to Fig. 1) and not have been identifiable because with the pit shape visualized the patch of repair film would not at any stage appear as a prominent projection on the film underside. The question to what extent the charge Q_{Al-p} consumed in such pitting processes could have been responsible for the lower film formation efficiency for longer anodizing times at 7V or all anodizing times at lower $\overline{V}$ cannot be answered directly from these observations.

The proposed type 3 is visualized as a possibly persistent mode of pitting which can be triggered by incompletely repaired type 1 or 2 pitting (not shown in Fig. 12) and which does not require a severely constricted electrolyte path and large *IR* drop. This is consistent with evidence such as that in Fig. 13 where the light area includes 1/2 μm type 1 "repaired" pit which has a 0.2 μm gap in the repair film at the bottom of the pit (not visible in this print). A type 3 pit conceivably grows in a transpassive "bright pitting" or electrobrightening mode (29) [as occurs, for example, in electrochemical machining of Fe (30, 31)], the electropolishing film being stable in the special environment within the occluded pit. The change from crystallographic to brightened pits with increasing potential has been noted for Al in KCl solution (32).

Effect of Cl^- on film growth and structure.—The results of adding 0.01M Cl^- to the anodizing bath were variable in that cell voltage tended to fluctuate with time and that $\overline{V}$ and opacity varied from one run to another, and this behavior cannot be plausibly attributed to changes in a uniform direct-dissolution current. Therefore, the behavior with Cl^- is attributed to a greater persistence of the pitting processes concurrent with film growth, which are inherently variable, even though it was not possible to demonstrate this directly. It could not be concluded that Cl^- caused more persistent pitting by affecting film growth so as to inhibit repair, *i.e.*, reanodization, of pits in view of the observation that films could grow at $\overline{V} > 6V$ yielding opacities similar to those of films grown at 0 Cl^- and geometrical structures which were indistinguishable, as noted in the following paragraph. The action of Cl^- was therefore interpreted as a tendency to stabilize pit growth (type 3). Its effect on film growth was then an indirect one resulting from an increased fraction of the total current consumed by pitting leaving less available for film growth. Thus in specimens anodized with 0.01M Cl^- at a nominal 5 mA/cm^2 with $\overline{V} = 2.5V$ the effective film-forming current was much lower, $<$2 mA/cm^2 to judge from the relation observed between C.D. and plateau voltage for films formed without Cl^-.

It was possible to examine the question whether Cl^- had a direct effect visible in the geometrical structure of the film by selecting, for comparison with previously described films formed without Cl^- additions at 6.5 to 7.6V (1), those which had grown in the presence of 0.01M Cl^- at $\overline{V} > 6V$ and thus had reached comparable thickness at a given anodizing time. At higher magnification in transmission, the pore structures of 84 and 150 sec films (Fig. 14) were nonclassical and similar to those previously described, *i.e.*, the pores did not appear round, of uniform size and arranged in a hexagonal pattern but they had irregular shapes, a range of sizes and they sometimes ran in strings. Their appearance is attributed to the numerous B-P-R (and B-R) events which had occurred a little earlier and had become incorporated into the film (*e.g.*, as suggested in Fig. 1) with the result that pores were jogged and had sloping segments, the net appearance in transmission at this time then varying from one pore to another according to the details of its geometry. Structures visible at high magnification after 15 or 25 sec

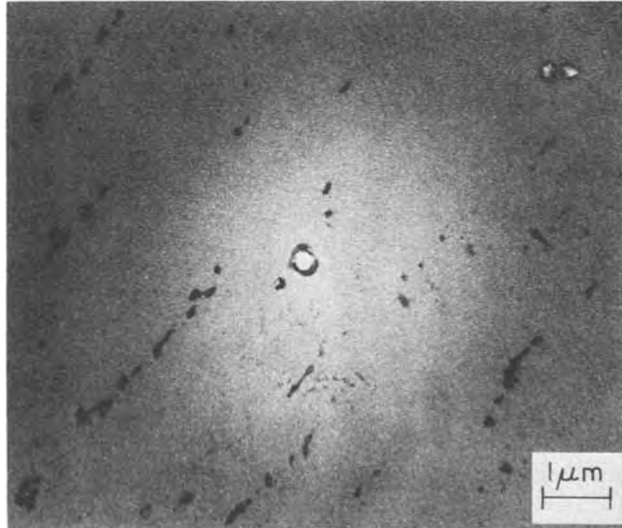

Fig. 13. Region of tapering film thickness in a film formed 900 sec in acid containing 0.01M Cl^-. $\overline{V} = 2.5V$.

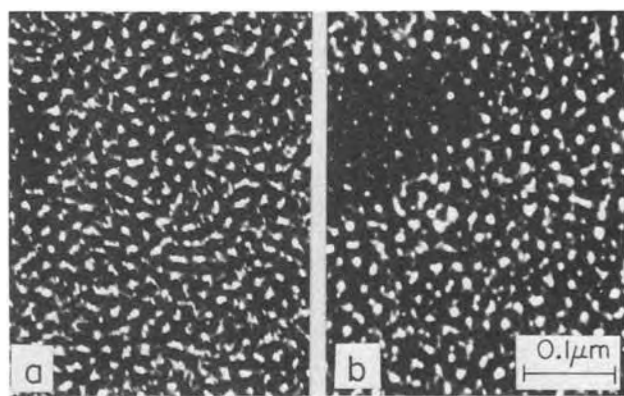

Fig. 14. Nonclassical appearance of pores in transmission micrographs of films formed with 0.01M Cl^- addition for (a) 84 sec ($\overline{V} = 6.3V$) and (b) 150 sec ($\overline{V} = 6.1V$). Cf. Fig. 4c and d of Ref. (1).

anodizing (not shown) before the onset of the prominent events were also much the same as those previously described (1) as were the external surface structures (Fig. 10). In addition to these 0.01M Cl^- films, a few samples grown at higher Cl^- levels were available such as the 0.05M Cl^-, 6.8V film of Fig. 4e, which showed events and pores of appearance similar to those of the 0 Cl^-, 7.1V film of Fig. 4a.

These comparisons could be extended to films grown with 0.01M Cl^- at low $\overline{V}$ by making them not at the same anodizing time but at the same electron opacity. On this basis, the scale of the pore structure decreased with decreasing $\overline{V}$ as expected from the relationships established at higher cell voltages (7), but the appearance and distribution of the events in film formed with and without Cl^- was similar. Figure 5 shows events in 150 sec films at various $\overline{V}$. For $\overline{V} < 7V$, the 150 sec films were similar to those in 7V films formed for shorter times. Thus for the 5.3V-150 sec film in Fig. 5d the opacity and events were close to those of the $\approx$7V-84 sec films in Fig. 4, the 3.6V-150 sec film in Fig. 5e was comparable with a 7V-45 sec film (not shown) where prominent events had occurred over only part of the surface, and the 2.2V-150 sec film in Fig. 5f had an opacity only slightly higher than that of a 7V-25 sec film and was similar in relative freedom from events to the 25 sec films of Fig. 3. The comparisons of this type suggested that the sequence of events contributing to the evolution of film structure was much the same whether films were formed with or without Cl^- additions. Thus none of the microscopic observations revealed evidence that the Cl^- had a direct effect on film structure.

Further Discussion

These results represent initial steps in examining and interpreting questions of film stability and pit initiation through observations of geometrical fine structure, and the resolution of many of the questions raised awaits further study. There are nonetheless certain implications of general interest. One is that film growth and forms of pitting on a fine scale may be concurrent and mutually interacting processes which must be considered simultaneously even if this involves a wide and unwieldy range of phenomena, as in this paper. The need for microscopy to accompany film-growth studies is satisfied within one experimental technique whenever the latter can be followed by electron opacity. A few comments on the relation of the present results to other studies are given below.

Pore structure.—The classical model of a porous film proposed by Keller *et al.* (33) was generally confirmed and further refined by Wood and O'Sullivan (7, 8) who showed among other observations, sections of thick films with arrays of long straight pores of roughly circular section, as for 45 μm films in Fig. 4 of Ref. (7). It is not inconsistent with this that the present work, in transmission micrographs of much thinner films, emphasized the events and consequent nonclassical aspects of apparent pore shape, size, and distribution in 7V 84 and 150 sec films (Fig. 14). After longer anodizing times, the layers of the film perturbed by the high density of events which had occurred at $25 < t < 65$ sec occupied a smaller fraction of its total thickness and further events occurred at much lower frequency, so that in 300 sec films, which could still be examined in transmission despite fogging of the background, the general pore appearance was much closer to that expected from the classical model. Films formed at 25 mA/cm^2 were also examined in transmission and the pore appearance was found to pass through similar stages although on a coarser scale corresponding to the higher cell voltage. A comparison could be made at the same Q_{tot}, *i.e.*, the progression from nonclassical to near classical appearance occurring at 17, 30, and 60 sec at 25 mA/cm^2 corresponded to that at 84, 150, and 300 sec at 5 mA/cm^2.

Thus previous workers (7, 34) investigating the pore structure (of films formed at 20°C in H_2SO_4 of the same or slightly lower concentration) at C.D. $\geq$ 10 mA/cm^2 would not have seen a distinctly nonclassical pore appearance except at short anodizing times. Their 30 or 45 sec transmission micrographs (prepared for making pore-density counts) actually did show some nonclassical pore appearance consistent with the present results, Fig. 7 of Ref. (7) and Fig. 6 of Ref. (34).

Pitting.—The present work was designed to examine film-growth questions relating to pitting phenomena. Although the experimental conditions differ from those in the main body of Al pitting studies, which involve electrochemical measurements and low-magnification (by present standards) microscopy in near-neutral Cl^- solutions usually at $\sim -1/2V$ *vs.* S.H.E. [see the recent review by Kaesche (35)], some of the present conclusions are thought likely to have rather general pertinence to pitting of Al. That "micropitting phenomena" occurred concurrent with film growth for various initial surfaces and in the absence of Cl^- indicates attention should be directed not to breakdown but to pit growth *vs.* repair. That Cl^- did not exert a detectable direct effect on film growth or structure directs attention to its role in stabilizing pit growth. These conclusions are consistent with those of Richardson and Wood (32) noted below, but they are not reconcilable with notions involving degradation of the electrical or mechanical properties of the film above the "breakthrough potential" from some form of Cl^- penetration (29).

The details of micropitting phenomena will depend on the experimental conditions. The view given for the film-growth stage in this paper is that at the cell voltages prevailing any low-potential pitting in an active mode was of very short duration and any persistent pitting had to be of a high-potential transpassive type. An attempt to interpret the pitting and repair processes in more detail is not made here, but it may be pointed out that the very small size and severely occluded geometry of the pits visualized in Fig. 1 and 12 give rise to certain constraints not present with larger pits.

Richardson and Wood (32) studied by scanning microscopy pit growth beneath a pre-existing film for Al in 1M KCl at pH 6. They concluded that the film was not destroyed by Cl^- but was relatively inert. Pits would grow without delay from pre-existing "mechanical-" or "residual-flaws" in the film (conceived as resulting from film growth at scratches, impurity-rich regions, bubbles, etc.) whenever electrochemical conditions were favorable, so that the basic question was not one of pit initiation but of pit growth. The conclusions of the present work are consistent with theirs but would argue further that knowledge of film growth is also required for understanding why pit growth occurs instead of repair and the origin and nature of the flaws.

APPENDIX

Significance of the Electron Opacity

For a homogeneous compact amorphous film, the electron opacity is proportional to mass-thickness w if the single scattering treatment may be used and the collected current follows the exponential law

$$I_c = I_o \exp(-S_c w) \qquad [A-1]$$

Here I_c is the part of the emergent current collected and S_c is the total empirical cross section (cm^2/g) for scattering out of the aperture of the collector. The electron opacity, $\alpha = \ln(I_o/I_c)$, is then $S_c w$ or, in terms of film thickness h and linear scattering coefficient μ_c, is $\mu_c h$ (μ_c being S_c times film mass-density). A discussion of the exponential law and certain scattering parameters was given by Hall in connection with image formation (36).

The significance of the opacity is not different with the method of measurement used here even though I_c is obtained by difference from the current I_{ab} absorbed in the specimen and the opacity is calculated as $\ln[I_o/(I_o - I_{ab})]$. The method is distinctive in that the effective collector aperture is large and $I_o - I_{ab}$ is the total emergent current so that only a small fraction of the scattering events in the film are sensed, S_c representing the cross section for scattering above a minimum angle near 90°. This should make the technique less sensitive to short-range crystallinity in "amorphous" films. As a check on the validity of the exponential law, Eq. [A-1], for these conditions, compact films were formed on electropolished specimens by anodizing in a $Na_2B_4O_7$ solution at 2 mA/cm^2 to several voltages without current decay. These films appeared compact in transmission microscopy and a special examination of 60V films at high magnification did not reveal incipient pores or cell structure. The opacity was found to be linear in cell voltage (Fig. A-1) with a small intercept at the value corresponding to equilibrium attributed to the persistence of a residual (noncompact) layer from the electropolishing. Figure A-1 is qualitatively similar to the results of Beck *et al.* (4) for opacities of compact alumina films measured at 75 kV with a Faraday cage below the specimen, but their line yields a linear scattering coefficient two orders of magnitude larger, the difference reflecting the smaller collector aperture of their technique.

Although the linearity in Fig. A-1 represents a check of the exponential law to the extent compact film thickness may be taken as proportional to formation voltage, the scattering parameters are not determinable precisely because of uncertainties in the values of one or more of the quantities required, *e.g.*, h/V at a given C.D. or film density. The values of the parameters in the growth law for compact films were considered recently by Siejka, Nadai, and Amsel (37) and from their figures for polished Al samples, the h/V for the present film was taken to be approximately 12 Å/V. From Fig. A-1, one then obtains $\mu_c = 2.5 \times 10^3$ cm^{-1} (4 μm per unit opacity).

Opacity of a Porous Amorphous Film

The general case of a void, assumed disk shaped, is reviewed first. If the void occupies a fraction f_i of the area sampled by the beam and its height is a fraction g_i of the film thickness, h, the opacity will depend on the shape or orientation of the void (although not on its location in the film) in the general case. However, in the low opacity range, the opacity can be written

$$\alpha \approx \mu_c h\,(1 - f_i g_i), \qquad \mu_c h << 1 \qquad [A\text{-}2]$$

and for a given film thickness it depends only on the void volume fraction, *i.e.*, it is proportional to mass-thickness.

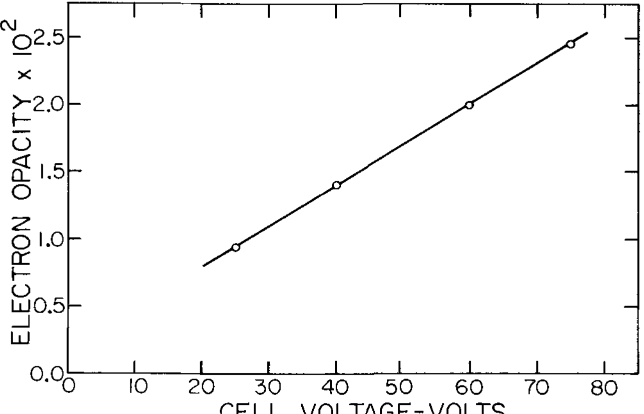

Fig. A-1. Test of the exponential law for compact anodic films formed in 1% $Na_2B_4O_7$ at 2 mA/cm^2.

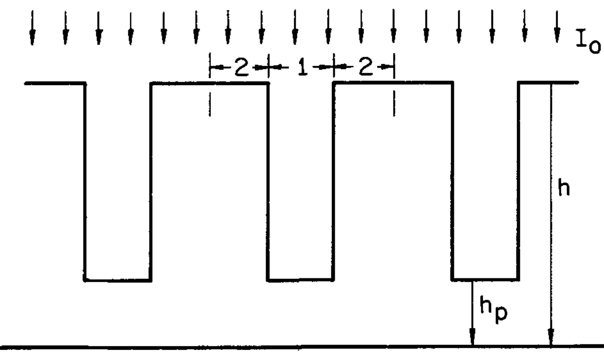

Fig. A-2. Idealization of the classical pore structure for calculation of electron opacity *vs.* film thickness.

In films growing through pores, the fractional porosity changes with time and it is convenient to set the problem in the specific geometry of the classical pore structure as idealized in Fig. A-2. The linear scattering coefficient of the film material is assumed the same for cell walls and barrier layer. If f_p is the fraction of area presented to the beam as pores (region 1) and the barrier layer at the bases of pores has thickness h_p, the contribution to the "collected" beam from electrons passing down the pores is $I_o f_p \exp(-\mu_c h_p)$ and from the electrons traversing the main body of the film (region 2) is $I_o(1 - f_p)\exp(-\mu_c h)$, and the opacity is then, for $h \geq h_p$

$$\alpha = \ln\,[f_p \exp(-\mu_c h_p) + (1 - f_p)\exp(-\mu_c h)] \qquad [A\text{-}3]$$

In the low opacity range, this becomes

$$\alpha \approx \mu_c\,[f_p h_p + (1 - f_p)h], \qquad \mu_c h << 1 \quad [A\text{-}3a]$$

These expressions are useful for analysis of film thickening at constant voltage (as on the plateau of the cell voltage-time curve) where according to the classical model h_p, which is scaled to the voltage (7, 8), remains constant. f_p is constant if pore tapering by chemical dissolution of its walls is assumed, for the moment, negligible, so that only h increases with time. f_p is taken as 0.12 from the recent measurements of Wood and O'Sullivan (7) and h_p/V as 10 Å/V from their data for films formed in H_3PO_4 (8), no microscopic measurement being available for H_2SO_4. The form of the α-h relation given by Eq. [A-3] is shown in Fig. A-3 by plotting α *vs.* h/h_p for $\mu_c h_p = 1 \times 10^{-3}$, a level appropriate to the present experiments, and for 1×10^{-2}. The opacity-thickness relation is initially linear, as seen from Eq. [A-3a], and then curves slightly. The α-t curve would have the same shape for constant dh/dt.

Application to 7V Opacity Data

Although the microscopy emphasized that the pore structure had distinctly nonclassical features during the early stages of anodizing, this did not prohibit application of the opacity analysis based on the classical model because the measured opacities were low and thus, as noted above, were substantially uninfluenced by the distribution of porosity, the opacity being determined by film mass-thickness whether pores were straight, sloped, or jogged. Because μ_c has not been measured directly for the porous film, there was minimum uncertainty in applying Eq. [A-3] when a curve-fitting procedure was employed to show how film growth-rate changed with time.

In the 7V α-t data in Fig. 8, the early linear region extending up to about 84 sec can be fitted with a theoretical curve for thickening at a constant rate by pore growth. A period of nonporous growth for a few seconds at the start of anodizing would not have introduced nonlinearity detectable here. From the microscopy, it was known that the pore structure required $\leq$15 sec to become fully developed and was present for the bulk of the linear period. It was also known that many "events" involving in part type 2 pitting-repair processes occurred at $25 < t < 65$ sec. However, despite their prominence in transmission micrographs these were shallow and could have consumed at most

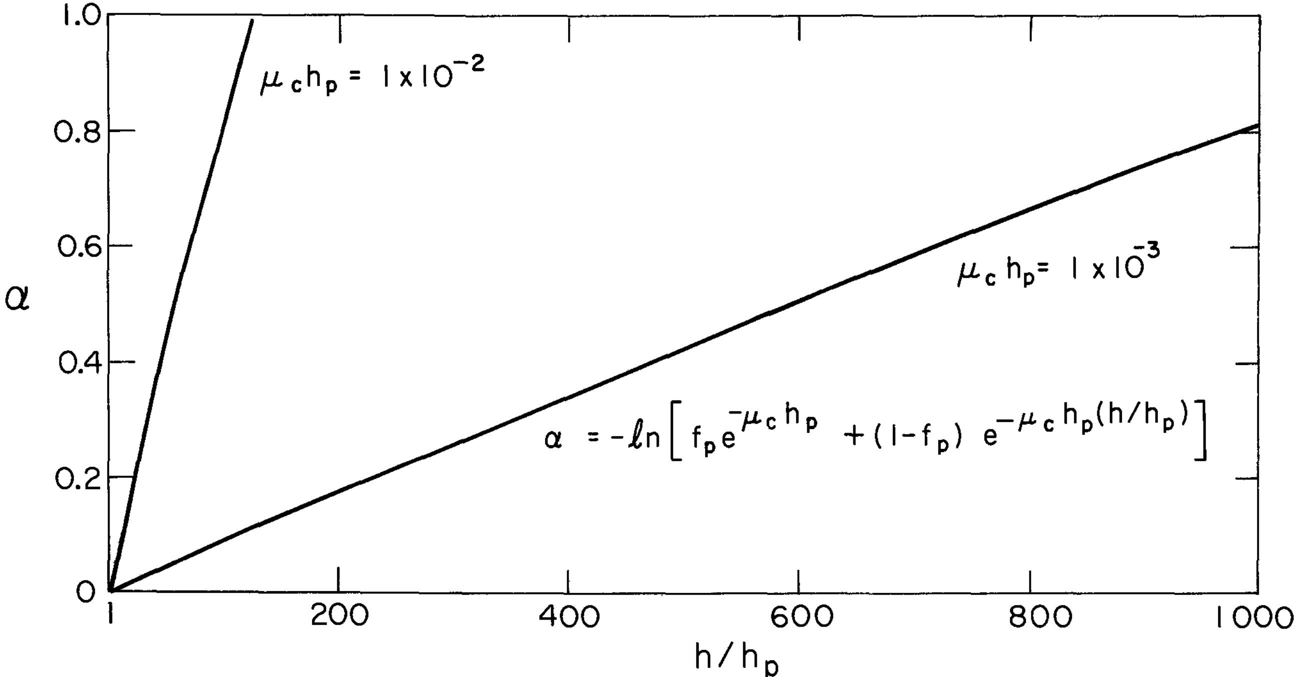

Fig. A-3. Electron opacity vs. thickness of a porous film calculated for two values of parameter $\mu_c h_p$.

a small fraction of the charge passed (see text), so that their presence did not contradict the supposition of an approximately constant rate of thickening by pore growth up to about 84 sec.

The initial slope of the α-t curve given by Eq. [A-3] is

$$(d\alpha/dt)_i = \mu_c(1 - f_p)(dh/dt)_i \qquad \text{[A-4]}$$

The initial slope of the experimental 7V curve in Fig. 8, was used to calculate the product $\mu_c(dh/dt)_i$. For continued thickening at the initial rate, this was integrated to yield $\mu_c h(t)$ (plus a constant of integration which could be neglected according to a fit of the data). For the other product, $\mu_c h_p$, required in Eq. [A-3], the μ_c determined above for a compact alumina film was employed and h_p was taken from the cell voltage as 70Å. The α-t curve for constant thickening rate at 7V so calculated from Eq. [A-3] is shown dashed in Fig. 8. This curve is insensitive to the choice of values of μ_c or f_p, *e.g.*, doubling μ_c would change the calculated opacity at 900 sec by 0.1%. The $(dh/dt)_i$ derived included in principle the chemical dissolution effect on the external surface, but this was negligible here.

In the low opacity range, the effect of chemical dissolution of film external surface (at rate v_2) and pore walls (at rate v_1) during anodizing can be treated within the formalism of Eq. [A-3] by modifying the parameters h and f_p. The $h(t)$ calculated from the growth rate assumed is reduced by v_2t. The effective f_p is increased by an enlargement of pore diameter varying linearly from $2v_1t$ at the external surface to zero at the pore base, and the sectional area of the pore is averaged to yield $\bar{f}_p(t)$ as a product of the original value, 0.12, and a function of v_1t.

IBM System Products Division, East Fishkill Facility, Hopewell Junction, New York 12533

ABSTRACT

Examining transistors which were anodically decorated in HF solution to reveal pipes, we found that large differences in emitter-collector leakage currents are mainly due to the different number of leakage paths in each transistor. Resistance associated with each leakage path was in the 12,000-20,000 ohm range; different resistances were detected both electrically and by electrochemical etching behavior in the n^+ region. From their behavior during electrochemical etching, it was determined that the leakage paths seemed to consist of narrow regions of n^+ material extending from the emitter through the base into the collector. The leakage paths occurred both in and at the edge of the emitter (at the vertical emitter-base junction). No direct relation between pipes and crystallographic defects could be made, but it is shown that not all crystallographic defects cause serious junction leakages.

Several techniques have recently been developed which use electrochemical reactions to delineate devices with electrical defects (1). A silicon wafer is placed in an electrochemical cell and anodically biased. Cell conditions are adjusted so that a reaction product develops only on devices with particular electrical characteristics. Thus, a wafer can be electrically mapped for an electrical defect by examining the decorated wafer optically. This technique allows the testing of very small devices which could not be probed electrically. Considerable data can also be obtained in a relatively short time on the distribution of electrical defects, both within a wafer and on a wafer-to-wafer basis.

Our purpose was to investigate the structure of npn transistors which were shown to contain collector-to-emitter electrical leakage by anodic decoration in HF electrolyte (1). After removing the reaction product, the surface features of the decorated transistors were observed in the SEM; the defect structure within the transistors was studied using a high-voltage (1 MV) TEM.

Experimental Procedure

Transistors of two different geometries were produced in phosphorus-doped n^- epitaxial silicon on p^- substrates with arsenic-doped subcollector diffusions. The base region was obtained through a boron diffusion; the phosphorus-diffused emitters were embedded in the base regions. For electrical measurements and SEM observation, emitter diffusions approximately 9 mil^2 were made in slightly larger base areas. The TEM observations were made mainly on devices which had rows of 1 mil^2 emitters embedded in a common base. Contact windows were etched in the surface oxide to expose silicon in the emitter, base, and collector contact areas. Electrical contact was established by affixing a copper plate to the back surface of the silicon wafer. After coating the wafer with wax (Fig. 1), it was made an anode in an electrolytic cell, using a 5% HF solution as the electrolyte. In the case of an n-p-n transistor under these conditions, the collector-base junction is reverse biased, so that if the cell voltage is lower than the collector-base breakdown voltage, the current density at the base and emitter regions is essentially zero, and no reaction deposits (brown amorphous Si) will develop. However, if there is an emitter-collector leakage (pipe), or if the collector-base junction has a premature breakdown, current will flow across the junction and an electrochemical reaction takes place at the device surface. Thus, a reaction product at the device surface will identify those devices with an electrical defect.

The voltage across the cell was adjusted well below collector-base breakdown so that no reaction occurred within the emitter and base contacts. Within the n^+ diffusion windows in the collector region, however, the current density was sufficient to produce a reaction product within a few minutes. Under these conditions, it has been shown that emitters with emitter-collector leakages will be decorated (1).

After anodic decoration, the devices were examined by optical microscopy to determine the location of the decorated transistors. The dark brown product deposited on n^+ emitter regions was removed by dipping the sample momentarily in a 3:2:1 mixture of acetic, nitric, and hydrofluoric acids, and the transistor surfaces beneath the deposits were examined in the SEM for details.

TEM samples were prepared from these wafers using an electrochemical technique (2) to provide large thinned areas. The p^- substrate and the p^+ isolation areas were selectively removed by anodic dissolution, leaving the n^- epitaxial layer containing the device junctions (Fig. 2). Final sample thinning was performed by chemically etching the sample in a 3:3:5 mixture of acetic, hydrofluoric, and nitric acids. The transistor array was thinned from the substrate side

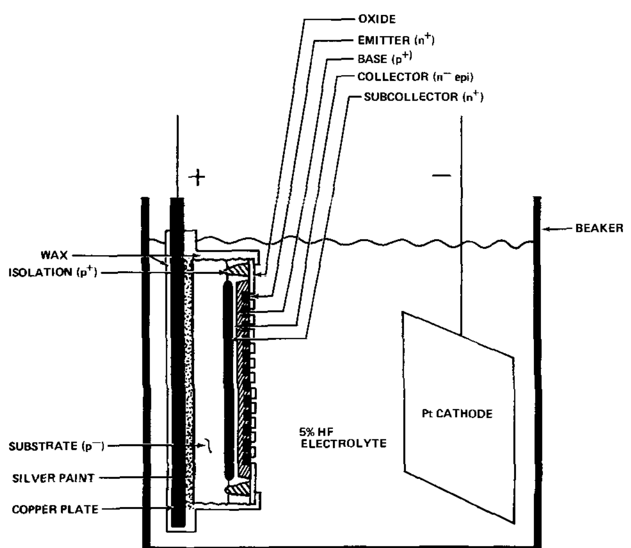

Fig. 1. Anodic decoration of transistor array. Electrical contact is made to the substrate of the wafer using a copper plate. When the sample is anodically biased, the collector-base junction is reverse-biased and no reaction product develops on the emitter. If a pipe (emitter-collector leakage) is present, current flows to the emitter and a reaction product forms on the surface.

to approximately 2-3 μm and examined at 1 MV; thus the TEM sample contained the entire emitter and base regions, and part of the collector. During thinning the top side was protected to insure no further etching of the emitter areas.

SEM Examination of Decorated Emitter Surfaces

After 5 min of anodic decoration, the emitter areas containing a collector-emitter electrical leakage (pipe) developed a brownish surface deposit (Fig. 3); the correspondence between decorated transistors and transistors with collector-emitter electrical leakage has been previously demonstrated (1). In the case of transistors with collector to emitter leakage, the brown deposit is formed as a result of the electrochemical conversion of n^+ emitter silicon to amorphous silicon. This deposit of amorphous silicon is then removed by etching for a few seconds with 3:2:1 acid mixture described previously. The transistors with no emitter to collector leakage did not have any amorphous silicon deposit on n^+ emitters. The etching did not cause any significant removal of n^+ silicon on these undecorated emitters. Within the decorated emitter areas, a noticeable amount of material was removed as a result of electrochemical reaction. Of 61 emitters with pipes, 58 emitters contained small square etched areas (Fig. 4). The $\approx$ 4 μm^2 etched areas occurred both within the emitters and at the emitter-base junction. In some transistors, two etched areas were present (Fig. 4b). No detail in the etched areas could be resolved in the SEM. In the three other emitters with pipes which did not contain distinct etched areas there was evidence of substantial etching around the emitter-base junction. None of the emitters without pipes contained etched areas, nor was there any visible etching at the emitter-base junction (Fig. 5).

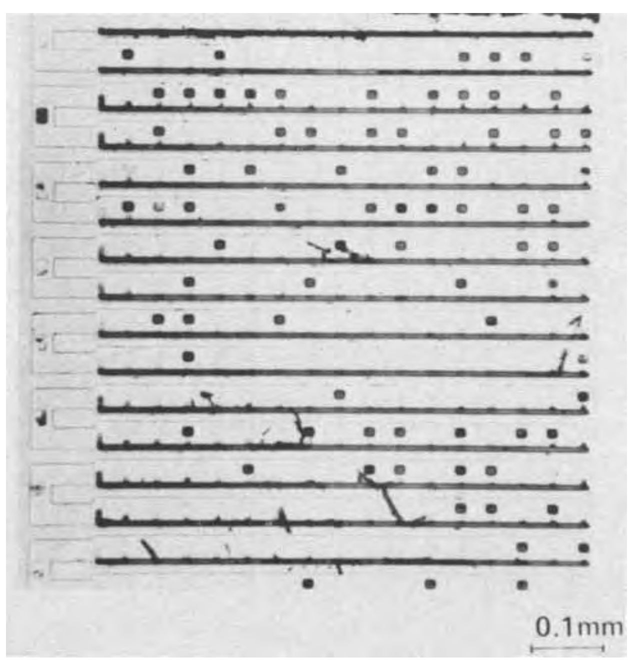

Fig. 3. Decorated transistor array. In each row the emitters are embedded in a common base. The dark emitters have been anodically decorated showing that they each contain a pipe.

By anodically decorating large (9 mil^2) emitter transistors in which the leakage currents were measured electrically, it was shown that each of the etched areas in the emitter region was associated with a leakage current through the transistor (cf. Table I and Fig. 6). For transistors with emitter-collector leakages in the 0-10 μA range, at 3V reverse bias, no decoration was observed in the emitter areas. From 10-43 μA the emitters were decorated, but no localized etched areas were present. Above 150 μA, approximately 4 μm^2 etched areas were observed on the transistors; the number of etched areas increased with leakage current. From Table I it can be seen that many of the etched areas corresponded to a leakage current of approximately 150-250 μA. In the transistor with 1650 μA leakage currents (Fig. 6), some of the etched areas were substantially smaller than the typical 4 μm^2 area (cf. Fig. 5), indicating less leakage was associated with those particular leakage paths. In general, however, the number of parallel leakage paths within a transistor is a major influence on the total leakage current, especially in the high leakage range.

TEM Examination of Decorated Transistors

After thinning to approximately 3 μm, the transistor array was examined at 1 MV. At the surface the etched areas form squares, with the sides along <110> directions (Fig. 7). Stereomicrographs show that the etched areas are square only near the top surface, becoming roughly conical with increasing depth. The shape of the etched area can also be obtained from the thickness contours visible in the larger etched area in Fig. 7. The alternating light and dark fringes are a result of thickness variations in the sample; each fringe represents an area of constant thickness. If a 1 sec Sirtl etch is used to remove anodization product rather than the 3:2:1 etchant solution, the etched area is roughly circular. Thus no conclusions can be drawn about the

geometry of the etch pits in the anodically decorated emitters.

Two-dimensional defects were observed within several emitter areas (Fig. 8); similar defects were also observed outside the emitter areas. These defects were identified by Booker and Tunstall (3) as extrinsic stacking faults which grew from the top surface into the silicon wafer during oxidation. A curved Frank partial dislocation forms the boundary between the stacking fault and the nonfaulted matrix. If the TEM sample is sufficiently thin, the stacking fault will intersect the bottom surface as in this case. Recognizing the flat shape of the stacking fault at the bottom surface (lower right edge), the sample thickness can be calculated from the projected width of the stacking fault.

The amount of material removed from an emitter with a pipe can be estimated from the stacking fault shown in Fig. 7, which terminates at the upper right edge of the emitter. Assuming the stacking fault originally extended laterally into the emitter region, the thickness of material removed from the emitter is at least as great as the depth of penetration of the stacking fault into the wafer. The distance from the top surface to the bottom of the stacking fault is

$$d = w \tan \theta$$

where w is the projected width and θ is the angle between the surface plane and the fault plane, which is always a (111) plane. For a (100) surface and the (111) fault plane, $\theta = 54.7°$. For the stacking fault in

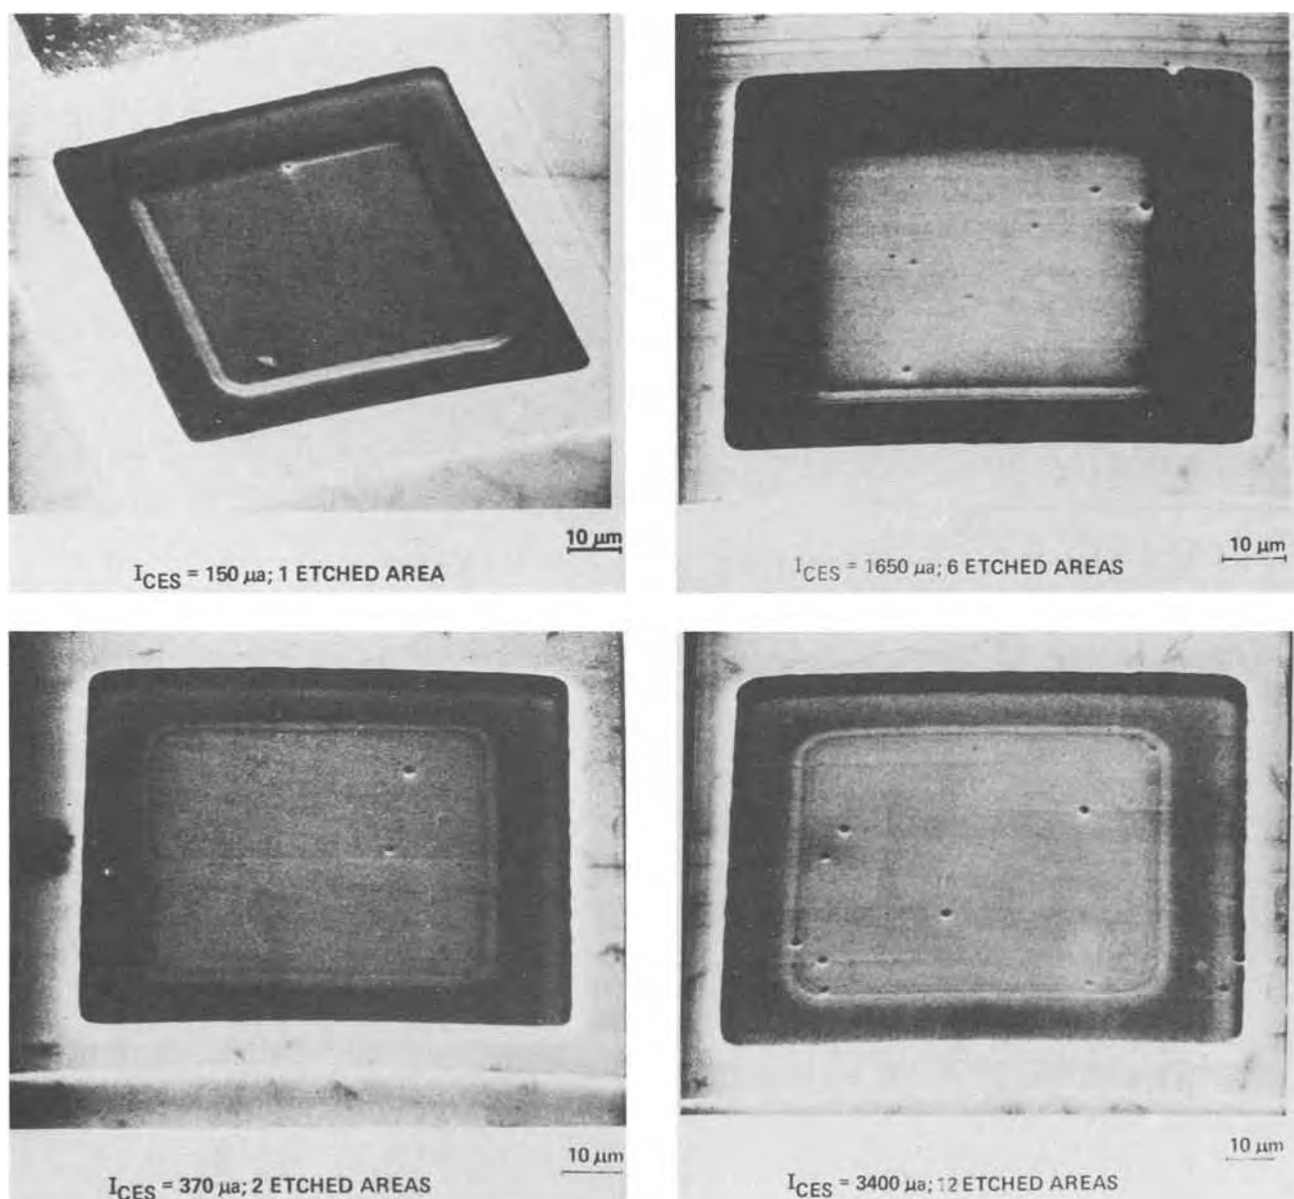

Fig. 6. Scanning electron micrographs of large-kerf transistors which had been electrically probed prior to anodic decoration. The number of etched areas within the emitter increases with increasing emitter-collector leakage.

Fig. 7, $w = 1.25$ μm, so $d = 1.75$ μm. Since the emitter-base junction depth is 1.7 μm, it is reasonable to conclude that the n^+ silicon from the entire emitter region of the transistor was converted to amorphous silicon during anodic decoration. This explains why transistors with a leakage current larger than 150 μA cannot be redecorated after removing the initial decoration with an acid mixture (Table I).

The thickness contours at the edge of the etched area could be used to approximate the depth to which the etched area extended into the device. Assuming a two-beam condition, the extinction distance for the (220) reflection at 1 MV is approximately 0.13 μm (4). The ten thickness fringes within the etched area show the etched area extends 1.3 μm below the surface. We have previously shown that during anodic decoration the amount of n^+ material converted was at least as great as the entire depth of the emitter region for transistors with etch pits in the emitter. We expect that conversion of n^+ material to amorphous silicon should stop when the active donor concentration decreases below a certain level (see next paragraph), so that none of the material below the junction is expected to be removed during anodic decoration. Therefore, the top of the etched area is at the emitter-base junction, and the etched area extends through the base and well into the collector region. (The base width is 0.4 μm.)

The fact that the anodic decoration caused etching in the collector shows that localized, high n^+ donor concentrations extend into the n^- collector. M. J. J. Theunissen *et al.* (5) have shown that in the range between 3×10^{18} and 2×10^{16} donors/cm^3 (0.01-0.3 ohm-cm), only partial dissolution of the n^- silicon occurred at a cell voltage of 10V and the rate of anodic dissolution decreased at the lower concentrations. The n^- epitaxial silicon in the collector region of our devices had a donor concentration of 1×10^{17} donors/cm^3 (0.09 ohm-cm). As stated above, the electron microscope samples from these device wafers were prepared by selective anodic etching of p material at 10V; the n^- epitaxy regions did not substantially dissolve even at cell voltages of 10V. In our present work, we have also noticed that the n^- collector regions did not etch when exposed to the electrolyte during the anodic decoration. However, the depth measurements of the etched areas have shown that in the region of the pipe the collectors are electrochemically etched. The presence of the etched areas in the n^- collector indicates dopant concentrations higher than the epitaxial dopant concentration. Thus, the enhanced donor

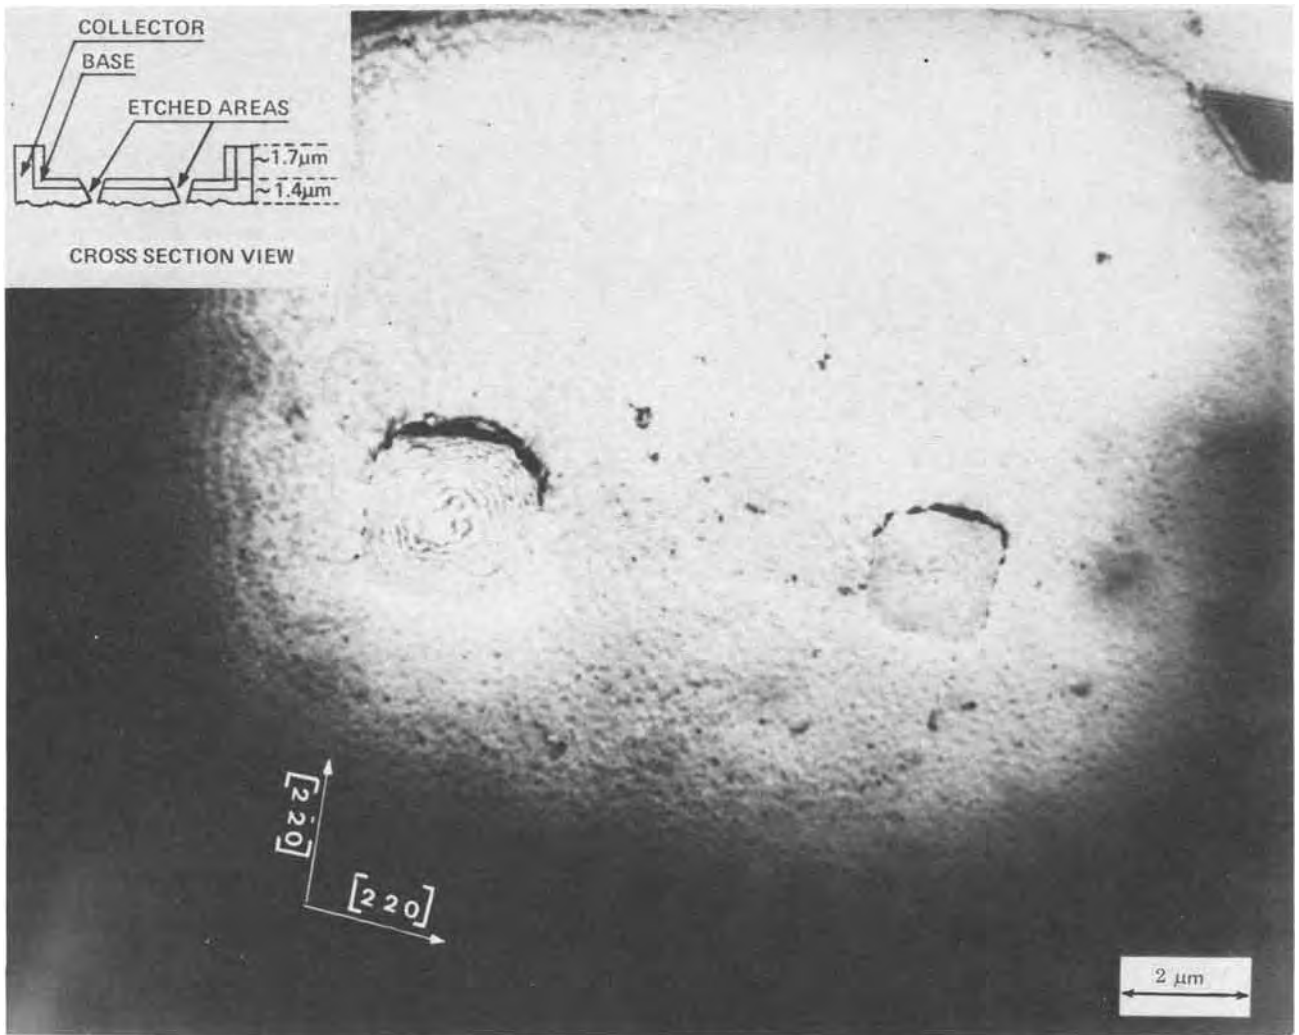

Fig. 7. Transmission electron micrograph of the device in Fig. 4b. Thickness fringes are visible both within the etched areas and at the edge of the device. The emitter has been removed during anodic decoration. An oxidation-induced stacking fault terminates at the edge of the device.

concentration, shown by Barson *et al.* (6) to be associated with the pipe in the base region, is also present in the n^- collector.

The calculation of thickness using thickness fringes could contain substantial errors due to uncertainty in deviation from the true Bragg condition (4). However, if one used the thickness contours at the edge of the emitter area to calculate the relative thickness of the base and emitter regions, a difference in thickness of 1.2 μm is obtained, which is reasonably close to the value of 1.7 μm obtained using the projected width of the stacking fault. Thus, it is clear that the above calculation on the depth of the etched area is sufficiently accurate to conclude that the etched area does extend from the emitter to collector, and corresponds to the actual location of the pipe.

The fact that not all crystallographic defects which cross junctions cause significant electrical problems is well illustrated by the transistor containing two oxidation-induced stacking faults (Fig. 8). From the lack of anodic decoration it is known that the emitter-collector leakage current is less than 10 μA which is equivalent to a pipe resistance $\geqq$ 330 kohm. The offset of the top fringe of the stacking fault as it crosses the emitter-base junction shows the emitter surface is 0.54 μm below the surface of the adjacent base. Of this value, approximately 0.05 μm of silicon was consumed during the formation of phosphosilicate glass during the emitter diffusion cycle. Therefore, the remaining 0.5 μm of n^+ silicon was removed during the anodic decoration, showing that an electrochemical reaction occurred at the emitter surface, but was not strong enough to produce visible decoration.

From the projected width of the stacking fault within the emitter region, we calculated that the larger stacking fault extends at least 3 μm into the device. Since the emitter-base and collector-base junctions are 1.7 and 2.1 μm deep, respectively, the stacking fault and the bounding Frank partial dislocation extend from the emitter region through the base and into the collector region without causing a significant leakage current. Further, from the shape of the etched areas in decorated transistors, it is reasonable to conclude that they were not produced at the ends of oxidation-induced stacking faults. If the etched areas had been produced at stacking faults, one would expect the etched areas to follow the direction of the bounding Frank partial dislocation, which, in the base and collector region, tends to become parallel to the wafer surface. However, the etched area is roughly conical with the long axis approximately normal to the wafer surface and thus, does not seem to have been generated by an oxidation-induced stacking fault.

Thus, the oxidation-induced stacking faults in these devices caused no substantial leakage currents across the junctions. Obviously, no conclusions about the presence or absence of other crystallographic defects within the devices can be drawn since the leakage path was removed during decoration.

The presence of the stacking faults in devices with no appreciable leakage currents is in agreement with the hypothesis that crystalline defects degrade device

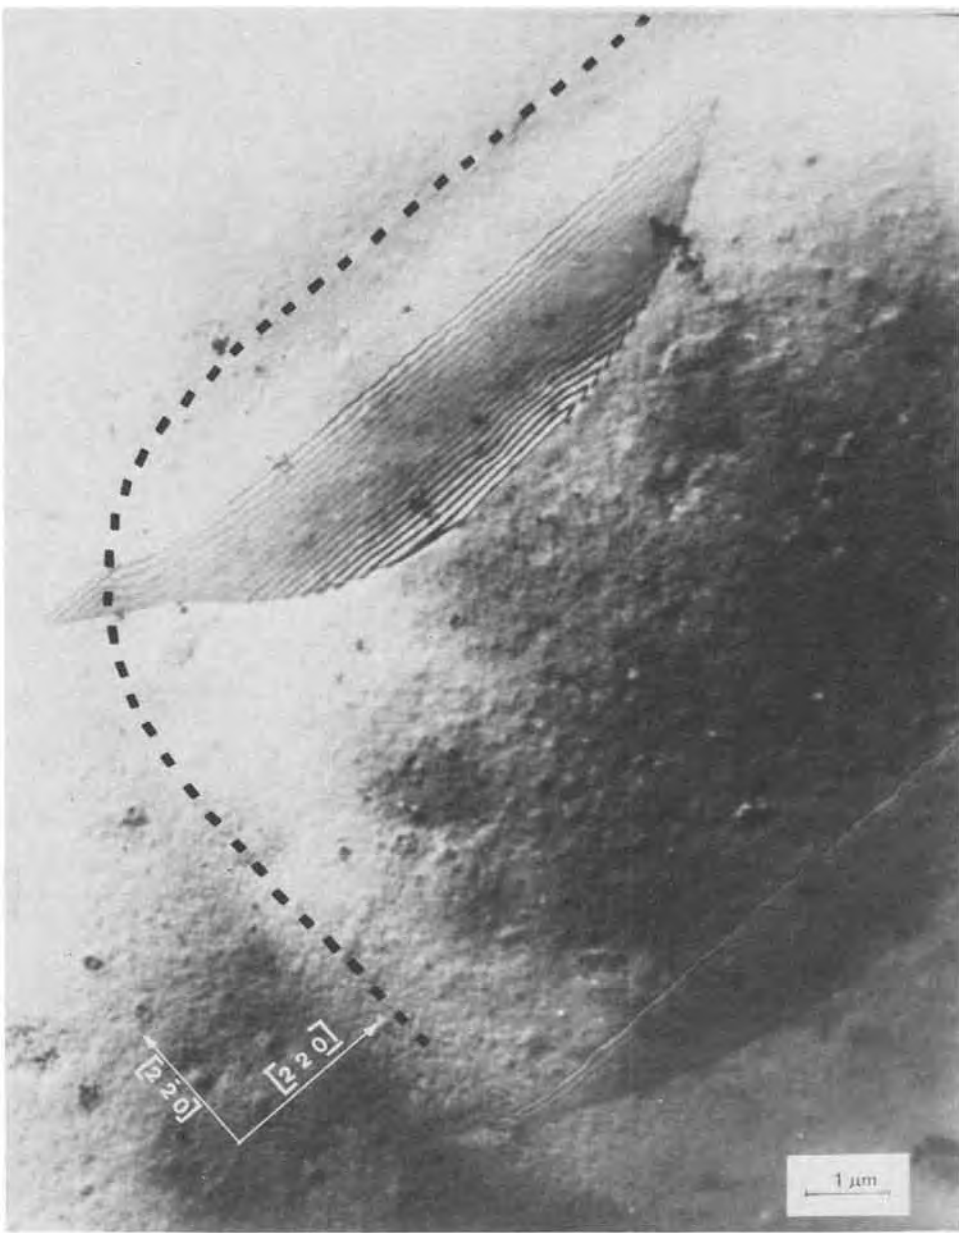

Fig. 8. Transmission electron micrograph of a transistor with a leakage current less than 10 μA. The dotted line delineates the emitter area. The upper oxidation-induced stacking fault extends through the emitter and base regions and into the collector; the smaller stacking fault is in the lower right corner of the emitter.

properties only when there is an impurity present at the defect. Studies by Barson (6) showed that individual pipes, identified by microsectioning and staining, were often associated with stacking faults nucleated in the epi-substrate interface. Since not all stacking faults caused pipes and since the number of pipes increased if a gold diffusion was included, they concluded that a defect-impurity interaction was responsible for pipe formation. Parekh (7) also observed that increased densities of dislocations and stacking faults only caused increased pipe densities when a gold diffusion step was included.

Summary and Conclusions

By examining transistors which had been anodically decorated in HF solution to reveal the presence of pipes, we found that large differences in the magnitude of the emitter-collector leakage current are mainly due to the different number of leakage paths existing in each transistor. The resistance associated with each leakage path was in the 12,000-20,000 ohm range; differences in resistance were detected both by electrical testing and by electrochemical etching behavior of the n^+ region. From their behavior during electrochemical etching, the leakage paths have been shown to consist of narrow regions of n^+ material extending from the emitter through the base into the collector. The leakage paths occurred both at the edge of the emitter region (at the vertical emitter-base junction) and within the emitter region.

Since electrochemical decoration removed the material in the immediate area of a pipe, no direct relation between a pipe and crystallographic defects could be made. Oxidation-induced stacking faults were observed crossing the emitter-base and collector-base junctions of a transistor. The emitter-collector leakage current of the transistor was very low, equivalent to a pipe resistance $\geqq$ 330,000 ohms, illustrating that not all crystallographic defects cause serious junction leakages.

Diffusion in Thin Silicon Films Formed by Electrochemical Etching

T. I. Kamins

Research and Development Laboratory, Fairchild Camera and Instrument Corporation, Palo Alto, California 94304

ABSTRACT

The diffusion of dopant atoms into thin silicon films formed by an electrochemical-etching technique has been investigated. Dopant atoms have been diffused from boron- and phosphorus-doped, vapor-deposited oxides into both thin-film samples of the opposite conductivity type and into bulk control wafers. The diffusion characteristics of the impurity atoms are generally similar in the thin films and in bulk wafers. Second-order effects include slightly higher sheet conductances in the thin films than in the bulk control wafers and slightly shallower diffusion of phosphorus into p-type films than into bulk wafers. The oxidation rate of the thin films is the same as that of bulk silicon.

Thin silicon films on insulating substrates have received considerable attention recently because of the reduced d-c and a-c interactions between adjacent devices fabricated in the films. Most interest has been focused on silicon layers heteroepitaxially deposited on sapphire or spinel (1, 2), although the low minority-carrier lifetimes found in these films have limited their application to majority-carrier MOS transistors. One alternative to this approach is to form the thin silicon film from a thick, epitaxial, single-crystal silicon wafer by an electrochemical-etching process which terminates at a well-defined, epi-substrate interface (3). A thick, insulated layer of polycrystalline silicon, added by chemical vapor deposition before the electrochemical-thinning process, serves as a mechanical support for the single-crystal silicon film (Fig. 1). Since this system is not limited by the inherent mismatches of a heteroepitaxial deposition, the minority-carrier lifetime is significantly greater than in the silicon-on-sapphire system. Films of a quality suitable for bipolar, as well as MOS, integrated circuits can readily be fabricated (4).

A series of experiments was conducted in order to determine if the diffusion of dopant impurities into the thin, single-crystal silicon films formed by the electrochemical-etching process differs from that in bulk wafers. Diffusion of both boron and phosphorus was considered. The oxidation rate of the thin films was also examined. Unlike the cases of polycrystalline-silicon films (5) or silicon on sapphire, no gross differences were expected between the thin-film wafers and bulk samples because of the high crystal quality of these thin films.

Experimental Method

After the appropriate conducting and insulating layers were added to the starting wafers, the films were formed by electrochemical etching (3) so that the final structure appeared as shown in Fig. 1. Then approximately 2 μm of silicon was removed from each sample by vapor etching in order to avoid possible effects of a surface region with a different dopant concentration than the remainder of the film. The final thickness of each silicon film was approximately 6-7 μm.

Impurities were diffused into the (111)-oriented silicon films and into similarly doped (111)-oriented, bulk control wafers from doped, vapor-deposited, silicon-dioxide films. The use of these doped oxides allowed direct comparison of diffusion into the thin films and into the bulk control wafers since the amount of dopant which entered the silicon from the doped oxide was primarily controlled by diffusion in the oxide while the diffusion depth was controlled by the diffusivity of the dopant in the silicon (6). The doped oxide films were deposited by the oxidation of silane and either diborane or phosphine at a substrate temperature of approximately 400°C and were about 1 μm thick. The diffusions were performed in a dry nitrogen ambient, with each thin-film sample being placed in the diffusion furnace between two similarly doped, bulk control samples of approximately the same size. A diffusion temperature of 1100°C was used since diffusion at this temperature is generally more reproducible than diffusion at lower temperatures.

Surface concentrations of the dopant atoms were calculated by reference to previous work on diffusion from boron-doped oxides (6) and phosphorus-doped oxides (7). The boron-doped oxide contained about 5% B_2O_3 or 2×10^{21} cm^{-3} boron atoms, which should produce a surface concentration of about 5×10^{19}

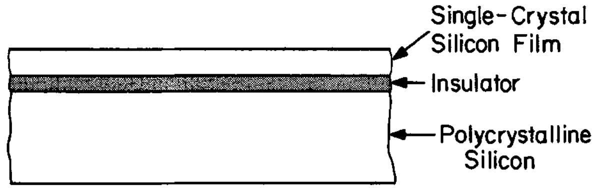

Fig. 1. Cross section of composite substrate after electrochemical etching.

Key words: silicon films, thin films, diffusion.

cm^{-3} boron atoms in the silicon. The phosphorus-doped oxide contained about 10% P_2O_5 or 2 × 10^{21} cm^{-3} phosphorus atoms so that the surface concentration in the silicon was about 8 × 10^{19} cm^{-3}.

The diffusion times were chosen so that the sheet conductance and the junction depth of the diffused layer could be plotted as functions of the square root of the diffusion time for both the single-crystal films and the control samples. As discussed by Barry and Olofsen (6), this method of presentation allows ready calculation of the diffusivity of the dopant impurity.

After diffusion the sheet resistivity was measured with a four-point probe in several spots on each sample. Junction depths were measured by optical interferometric techniques after delineation by grooving and staining with a nitric-hydrofluoric acid solution (70% HNO_3:49% HF:H_2O = 1:500:500 by volume).

Experimental Results

The sheet conductances measured after the diffusions were approximately linearly proportional to the square root of the diffusion times, although the agreement was better for phosphorus diffusion into p-type samples than for boron into n-type samples. The deviation from a linear relationship seen in the latter case may be similar to that observed by Barry and Olofsen at high boron surface concentrations ($C_s > 10^{20}$ cm^{-3}). Figures 2(a) and 2(b) are plots of the sheet conductances in the thin films as functions of the sheet conductances in the simultaneously diffused bulk samples. In both cases the data points lie above a line with unity slope, indicating a consistent tendency for somewhat higher sheet conductances in the thin films than in the bulk samples. In some cases the value in the thin film was the same as that in the bulk samples, but in no case was the value in the thin film less than that in the corresponding bulk samples. The dashed lines in Fig. 2 indicate that the sheet conductances were approximately 10% higher in the thin films for boron diffusion and about 6% higher for phosphorus diffusion.

The measured values of junction depth were also plotted as functions of the square root of the diffusion time with reasonable fit to a linear relationship. Clear, well-defined junctions were obtained in the case of phosphorus diffusion into p-type films while difficulty was occasionally encountered obtaining clear stain lines on some of the n-type films after boron diffusion.

Figures 3(a) and 3(b) show the junction depths in the thin films as functions of those in the bulk samples. In both cases the junction depths were the same in the thin films and in the bulk samples for shallower diffusions ($x_j < 4$ μm). For the longer phosphorus diffusions, however, the junction depths in the thin films became appreciably less than those in the bulk samples. This trend was seen in three separate series of diffusions and is probably not a statistical error. The dashed line in Fig. 3(b) indicates that the junction depths were approximately 8% less in the thin films than in the bulk control samples after prolonged phosphorus diffusion.

In order to find any difference in the oxidation rate of the thin films from that of bulk silicon wafers, films were oxidized together with bulk control samples. The oxides were formed under conditions controlled by the surface reaction rate rather than by the diffusion of oxygen through the already formed oxide, since any differences caused by the thin-film structure would be most easily observed in the former case. Wafers were oxidized at 920°C in both dry oxygen

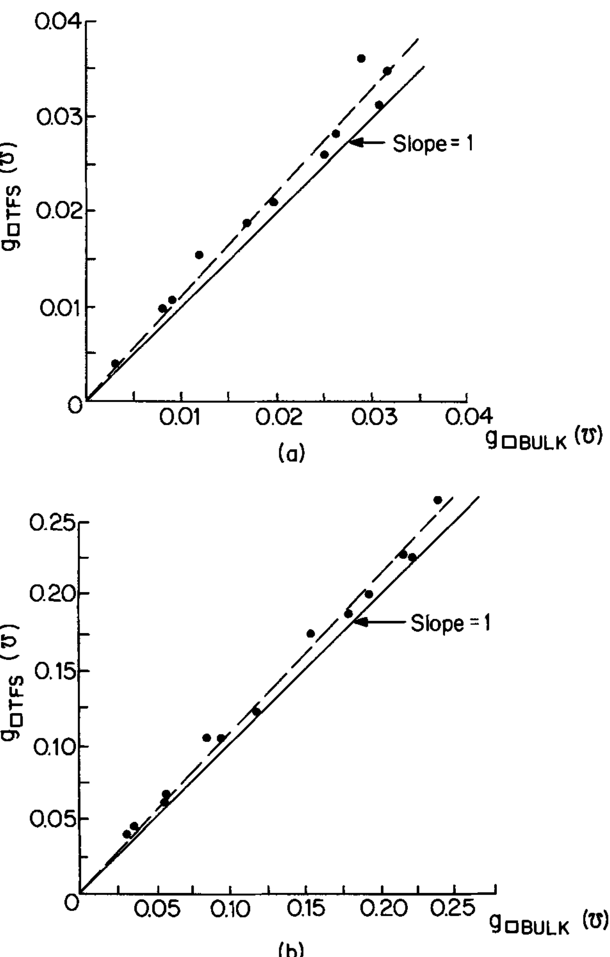

Fig. 2. Sheet conductance in thin films after diffusion as a function of sheet conductance in corresponding bulk wafers: (a) boron diffusion into n-type samples; (b) phosphorus diffusion into p-type samples.

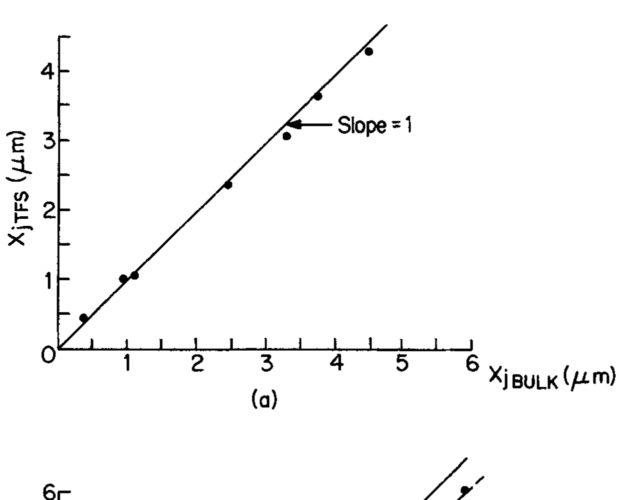

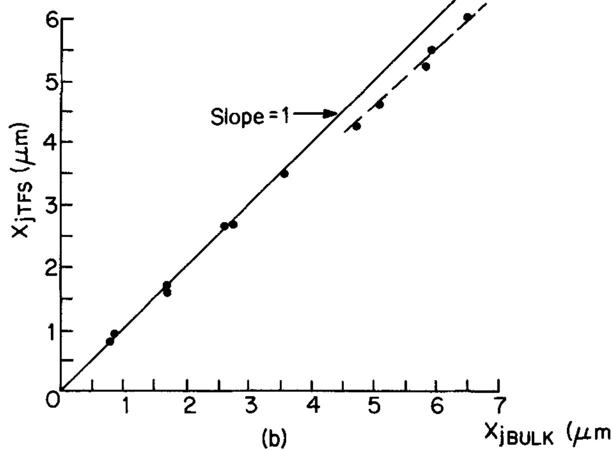

Fig. 3. Junction depth in thin films after diffusion as a function of junction depth in corresponding bulk wafers: (a) boron diffusion into n-type samples; (b) phosphorus diffusion into p-type samples.

and "stream"[1] ambients. The oxide thicknesses were measured with an ellipsometer at the center of each sample. Unoxidized thin-film samples were also measured with the ellipsometer to confirm that the light ($\lambda = 6328$Å) did not penetrate through the silicon film to the underlying oxide layer and invalidate the results of the ellipsometer measurements. In most cases the oxide thickness on the thin-film sample was within 1% of that on the bulk samples, indicating that the oxidation rate of the thin films does not differ to any significant degree from the oxidation rate of bulk silicon wafers.

Discussion

The data obtained from these experiments may be interpreted on the basis of the theory developed by Barry and Olofsen (6), which relates the diffusivity D and the segregation coefficient m of the dopant in the silicon to the measured sheet conductances and junction depths. Figures 3(a) and 3(b) indicate that the diffusivities of both phosphorus and boron are the same in the thin films and in bulk wafers, at least for the shallower diffusions. From the x_j *vs.* $\sqrt{t}$ data, $\sqrt{D}$ in the silicon film was calculated to be 0.22 μm/hr$^{1/2}$ for boron diffusion and 0.30 μm/hr$^{1/2}$ for the shallower phosphorus diffusions, in good agreement with the values previously obtained under similar conditions in bulk silicon (6, 7).

Possible causes of the shallower junction depths measured in the thin-film samples than in bulk wafers after the longer phosphorus diffusions should be briefly considered. Since the phosphorus atoms only have a finite thickness of silicon into which to diffuse, the boundary condition of the diffusion equation will be different from that usually encountered. As the junction depth approaches the film thickness, the impurity atoms will start to pile up near the bottom surface. The solution to the diffusion equation for the case of a finite film thickness and a constant surface dopant concentration is given by (8)

$$\frac{C}{C_s} = \sum_{n=0}^{\infty} (-1)^n \left[\text{erfc}\frac{2n\,x_f + x}{2\sqrt{Dt}} + \text{erfc}\frac{2(n+1)\,x_f - x}{2\sqrt{Dt}} \right] \quad [1]$$

where x is the distance from the top surface of the silicon film and x_f is the film thickness. As a worst case we find that the concentration 1 μm from the back of a 7 μm-thick film is approximately 0.1% higher than the value found for the semi-infinite case. Consequently, the finite thickness of the silicon film cannot lead to the shallower junction depths observed in the thin films. In fact, the pile-up of impurity atoms near the back of the film should eventually lead to deeper junction depths in the thin films since the concentration at a given depth into the film will be increased above its value for the semi-infinite case. The shallower phosphorus junction depths may be related to the properties of the silicon film near the bottom surface, including the possibility of a stressed layer near the Si-SiO_2 interface or the precipitation of impurities. Subtle differences in the staining behavior may also influence the measured junction depth.

The differences in sheet conductance between the thin films and the bulk samples (Fig. 2) must arise from either a greater mobility or a larger number of charge carriers in the thin films. Consideration of mobility changes expected from stress effects (9-11) indicates that the change should be in the opposite direction and markedly less in n-type diffused layers than in p-type diffused layers while the experimental behavior shows that the difference in sheet conductance is about the same for n-type and p-type diffused layers. In addition, stress measurements (12) indicate an upper bound of about 5×10^8 dynes/cm^2 on the stress in the films. The corresponding maximum change in conductance should be less than about 1.5% in the boron diffused layers and less than about 0.2% in the phosphorus diffused layers—much less than the experimentally observed differences. Consequently, the differences in sheet conductance between the thin films and the bulk wafers cannot result solely from straightforward stress effects. Since Eq. [1] indicates that the finite film thickness should not significantly affect the dopant distribution for any case considered, a larger number of charge carriers in the thin film most likely results from a higher surface concentration and, hence, a greater segregation coefficient. (Further measurements on bulk samples which were either vapor etched or mechanically polished before phosphorus diffusion from doped oxides did not indicate any significant differences; therefore, any difference in segregation coefficient between the thin films and the bulk samples cannot be related solely to the vapor etch treatment given the electrochemically etched films.)

[1] Oxygen bubbled through 97°C water.

Conclusions

From these measurements we may conclude that, to first order, the diffusion characteristics of dopant impurities are similar in the electrochemically etched thin films and in bulk wafers. Possible second-order effects include slightly higher sheet conductances in the thin films than in bulk control wafers and slightly shallower diffusion of phosphorus into p-type thin films than into bulk control wafers. The oxidation rate of the thin films is the same as that of bulk silicon.

Investigation of Imperfections in Silicon Substrates Using Copper Displacement Technique

M. J. Grieco*,[1]

IBM Components Division, East Fishkill Facility, Hopewell Junction, New York 12533

ABSTRACT

A copper displacement etching system (1) has been used as an effective and sensitive technique for the delineation and evaluation of crystal imperfections in polished silicon substrates. X-ray topographs of the substrate prior to and after epitaxial deposition show a relationship between subsurface damage and/or contamination and defects in the epitaxial film.

Clean surfaces are essential in the fabrication of semiconductor devices. Any contaminants in the surface or subsurface could affect subsequent processing steps and thus influence the performance, yield, reliability, and quality of the semiconductor devices. Epitaxial spikes and/or mounds, for instance, on the surface would impact the subsequent photolithographic and masking operations resulting in device yield loss.

A technique is described to reveal damaged semiconductor material and to remove embedded material and surface contaminants to produce a clean surface.

Experimental

For all experiments, vendor material and IBM Chem-Mech polished p-type, <111> 10-20 ohm-cm were used (2). Prior to delineation of subsurface damage with the copper displacement reaction,[2] the wafers were degreased in trichloroethylene, rinsed in acetone, deionized water, and heated in nitric acid (HNO_3). The wafers were then rinsed in distilled water, rinsed in methanol, and blown dry with filtered N_2. The copper displacement process is performed at room temperature in a Teflon or polyethylene beaker. All photomicrographs were taken using Nomarski interference contrast.

In order to minimize artifacts produced during the copper displacement process and to remove controlled amounts of silicon, a 10 or 20 times dilution of the stock solution with distilled water is used. A 10:1 and

20:1 dilution removes approximately 800 and 400 Å/min of silicon, respectively. Unless otherwise noted, all wafers were copper displaced for 1 min using the 10:1 dilution system. The copper plating is stopped by quenching the wafers with water. The copper film is then removed by dissolving in concentrated nitric acid (HNO_3) and rinsing in distilled water. Adequate care must be taken to insure that all copper plating solution is removed prior to removal of the copper film with HNO_3. If this is not done, continued etching of the surface will occur due to the HNO_3-HF mixture. This will cause anomalous results and interpretation of data will be difficult due to a leveling of imperfection sites revealed by the copper displacement reaction.

The dissolution of silicon and the simultaneous plating of copper takes place according to the following reactions

$$2Cu^{+2} + Si^{0} \rightarrow 2Cu^{0} + Si^{+4} \quad [1]$$

$$Si^{+4} + 6F^{-} \rightarrow SiF_{6}^{=} \quad [2]$$

The displacement process involves an oxidation-reduction reaction, in which the copper ions are reduced to copper and the silicon is oxidized (Eq. [1]). The oxidized silicon is brought into solution by a suitable complexing agent such as fluoride ions (Eq. [2]).

Results and Discussion

Figure 1 shows a schematic representation of the mechanism involved in the copper displacement of silicon surfaces for the delineation of subsurface damage, crystallographic imperfections, and removal of surface contaminants. Figure 1(a) represents a wafer containing subsurface damage, embedded material, and surface contamination. During the copper displacement process [Fig. 1(b)], copper plates the entire platable silicon surface. However, there is an enhanced displacement of silicon under and around the nonplatable material and a copper layer is formed between the silicon surface and the subsurface or surface contaminants. There is also an enhanced displacement of silicon at crystallographic imperfections and regions where there is surface damage. This enhanced displacement is caused by small changes in surface energy and subsequent higher etch rates in these regions. When the copper layer is removed by a suitable reagent, the surface contaminants are removed and surface imperfections are delineated [Fig. 1(c)]. In the regions where particulate matter was present, small craters were revealed.

After delineation with the copper displacement technique, the types of surfaces obtained can be grouped into three types: (*i*) embedded or occluded material, (*ii*) crystallographic defects such as imperfections and twinning, and (*iii*) work damage caused by the sawing or lapping operation prior to polishing the silicon substrate. Figure 2 shows a photomicrograph of a silicon surface prior to and after copper displacement in which the embedded material in the subsurface has been delineated. These particles are 10-12 μm in diameter. An attempt was made to identify these embedded particles with an electron microprobe. Aluminum well above the background level was found in these areas. The embedded particles were also observed in the scanning electron microscope (SEM), to "pop out" of the surface due to electrostatic charge up of the dielectric. This evidence indicates that the particles in question are most probably Al_3O_3 (5), a material used in the wafer shaping operation having a typical size of 10-12 μm in diameter.

Figure 3 shows a photomicrograph of a silicon surface which contains crystallographic defects. Imperfections and twinning can be seen in Fig. 3(b) and 3(c), respectively, after copper displacement of the original silicon surface.

During the wafer shaping operation, if sufficient material is not removed during the lapping or polishing operation, work damage will still be present in the silicon crystal [Fig. 4(b, c)]. Figure 4(b) shows a photomicrograph of a silicon surface containing work damage after copper displacement. After removing a total of 1 μm from this surface [Fig. 4(c)], additional work damage is delineated that was present in the silicon crystal and not removed during the polishing operation.

As a final step in the silicon wafer shaping operation, some silicon wafer vendors "buff" their wafers on a polishing cloth. Although this removes any sur-

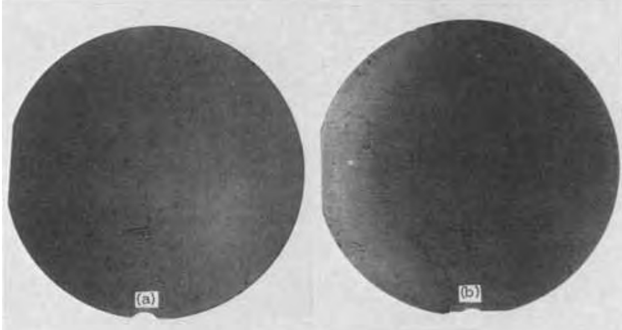

Fig. 6. X-ray topographs of: a, as-received silicon substrate; and b, after deposition of 7 μm epitaxial film.

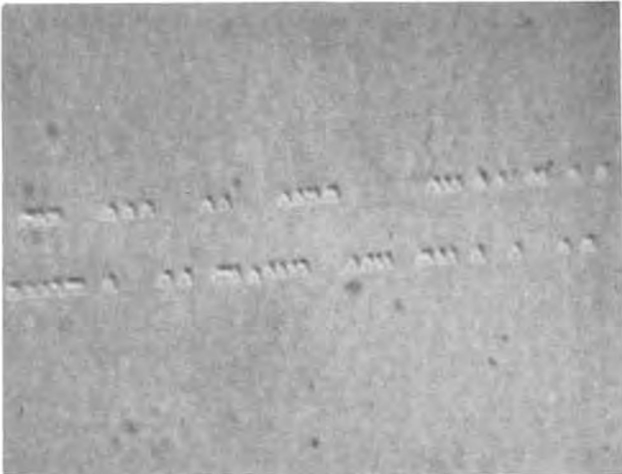

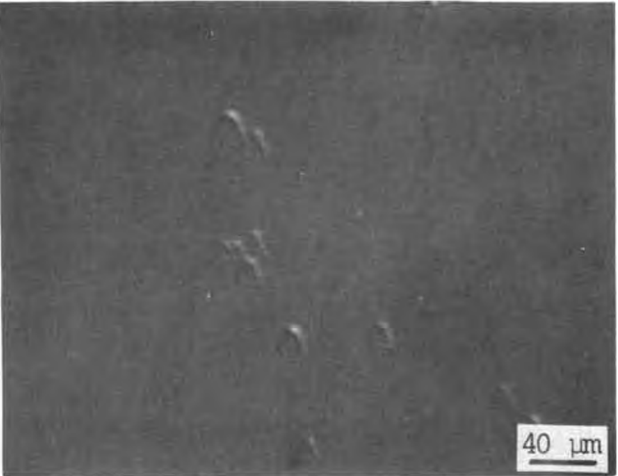

Fig. 7. Photomicrograph of film quality obtained after deposition of 7 μm epitaxial film shown in Fig. 6

face particulate contamination, this process produces "wipe marks." It is felt that the "wipe marks" are caused by a smearing of a chemically removable residue that is present in the polishing cloth. This is evidenced by the fact that wafers from the same vendor not receiving the "buffing" step did not exhibit "wipe marks." The copper displacement technique was used to evaluate different surface cleaning techniques and their effect on surface quality and the removal of "wipe marks." Wafers known to contain "wipe marks" each received a different cleaning technique. After a copper displacement, the surface quality was evaluated.

Wafers received a solvent clean of trichloroethylene for 10 min at 60°C. Also used was the trichloroethylene/acetone/alcohol sequence (this sequence for water miscibility), and in all cases "wipe marks" were present after copper displacement [Fig. 5(a)]. When trichloroethylene (60°C, 10 min) plus sulfuric/nitric acid (sulfuric/nitric was used for the removal of organic contaminants) (100°C, 10 min) was used, the surface produced after copper displacement had a substantial reduction in the amount of "wipe marks" [Fig. 5(b)]. A combination cleaning of trichloroethylene (60°C, 10 min), sulfuric acid (100°C, 10 min), plus concentrated hydrofluoric acid (*RT*, 10 min) produced a featureless surface as seen in Fig. 5(c).

X-ray topographs [scanning oscillating technique, (SOT)] (3, 4) were performed on silicon wafers to determine by another technique if there was any crystal imperfections, subsurface damage, and embedded material in the silicon substrates. This x-ray technique scans across the wafer and reveals local variations in crystal perfection and orientation. The beam size used in this study was ≈ 0.5 mm in diameter.

Figure 6(a) shows an x-ray topograph of an as received wafer in which subsurface damage and contaminants present in the wafer are revealed. A 7 μm epitaxial film was deposited and Fig. 6(b) shows a SOT in which the damage and contamination from Fig. 6(a) have propagated and are revealed in greater detail.

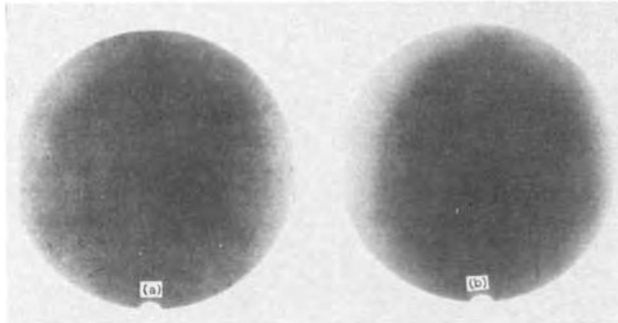

Fig. 8. X-ray topograph of a wafer prior to and after copper displacement technique. a, As-received silicon substrate; b, after 2 μm material removed.

Figure 7 is a photomicrograph of the wafer shown in Fig. 6 after deposition of a 7 μm epitaxial film. Stacking faults and imperfections were revealed in the epitaxial film and most defects in the epitaxial film could be correlated to defects/contaminants seen in the x-ray topograph prior to epitaxial deposition.

Contaminants on wafer surfaces were plotted prior to epitaxial growth. After epitaxial growth, the same regions were replotted and, in 65% of the cases, spikes/mounds were found.

X-ray topographs were also used to determine the extent of removal of embedded particles and surface contaminants when using the copper displacement technique. X-ray topographs were taken of the substrate prior to copper displacement. The contaminants revealed by the x-ray topograph can be seen in Fig. 8(a). Approximately 2 μm of material was then removed from this surface by the copper displacement technique and x-ray topographs were taken of the resulting surface. As can be seen in Fig. 8(b), there is freedom from contaminants as seen in the silicon substrate prior to copper displacement.

Conclusions

The copper displacement technique is a sensitive and suitable method for the delineation of subsurface damage and crystallographic imperfections in polished silicon substrates. This technique can also be used as a rapid method for evaluating and determining the crystalline quality of silicon substrates. X-ray topographs of the substrates prior to and after the copper displacement technique have shown that this technique does remove unwanted contaminants and that these contaminants do affect the quality of epitaxial films.

Acknowledgments

I would like to thank D. L. Klein for helpful discussions and W. A. Westdorp for the performance and interpretation of the x-ray topographs.

Gas-Phase Etching of Sapphire

III. Chlorotrifluoromethane

H. M. Manasevit*

Rockwell International Electronics Group, Electronics Research Division, Anaheim, California 92803

ABSTRACT

The ever increasing interest in the use of sapphire (α-Al_2O_3) as a substrate for the heteroepitaxial growth of various materials has prompted a re-examination of gas-phase etching as an effective means for improving the surface of Al_2O_3. Based on a previous investigation (1) in which several fluorinated hydrocarbons were found effective as etchants for Al_2O_3, chlorotrifluoromethane was selected for further study for several Al_2O_3 orientations. It was found to be a good etch-polish agent for $(01\bar{1}2)$, (0001), and $\sim(11\bar{2}0)Al_2O_3$.

The ever increasing interest in the use of sapphire (α-Al_2O_3) for the heteroepitaxial growth of various materials has prompted a re-examination of gas-phase etching as a means for removal of work damage from the surfaces of several Al_2O_3 orientations that show promise for the epitaxial growth of Si. Several years ago we described the use of sulfur fluorides (2) and fluorinated hydrocarbons (3) for the etch-polishing of α-Al_2O_3. Since then several other reports have appeared which have described chemical polishing methods involving molten salt (4-6) and liquid phase etchants (7-8). Reisman and co-workers (8) recently described their success in using air annealing combined with chemical polishing with H_2SO_4-H_3PO_4 mixtures to effect scratch-free Al_2O_3 and MgAl spinel surfaces. Their results are encouraging; yet, the simplicity afforded by a gas-phase method which is compatible with the epitaxial growth system should not be overlooked.

We chose to investigate more in depth the effect of etching mechanically polished Verneuil and Czochralski-grown α-Al_2O_3 with chlorotrifluoromethane, $CClF_3$ (Freon-13), which from our previous studies (3) seemed to be less orientation dependent in its etch-polishing ability than most of the other fluorinated hydrocarbons superficially examined. In the studies to be described, particular attention was given to the etching characteristics of $(01\bar{1}2)Al_2O_3$, which controls (100) Si growth, and $(10\bar{1}4)$, (0001), and

~(11$\bar{2}$0) Al_2O_3, which control (111) Si growth. Cuts were made several degrees off of the (11$\bar{2}$0) plane in order to provide a surface orientation which would assure the growth of approximately (111) Si rather than (110) Si (9). The other Al_2O_3 orientations were within 2 degrees of their designated planes.

Experimental

Studies were performed in a vertical reactor system similar to that previously used (3). It includes a tank of inert carrier gas, such as helium, upstream from a tank of the "etchant" to be studied. These are connected via Matheson No. 607 and No. 600 flowmeters, respectively, to a stainless steel manifold joined to the quartz reactor by a Teflon connector. Carrier gas flow rates were set at 6 liters/min. The gases were passed over substrates resting on an Al_2O_3 spacer covering a carbon pedestal inductively heated to the etching temperature. The spacer seemed to help provide a more even temperature distribution and to reduce reaction between the Freon-13 and the carbon pedestal. Pedestal temperatures were measured with an optical pyrometer, and uncorrected values are reported. The actual substrate temperature is estimated to be 50-100° lower than the observed 1400°-1550°C etching temperature used to establish the etch-polishing ability of Freon-13. The photomicrographs shown in the figures were made using a Nomarski interference objective on the microscope.

Etch-rate data for α-Al_2O_3 as a function of the flow rate of Freon-13 gas are recorded in Fig. 1-3 for uncorrected pedestal temperatures of 1400°, 1450°, and 1500°C. These preliminary data indicate that (01$\bar{1}$2) Al_2O_3, etches at a greater rate than (10$\bar{1}$4) Al_2O_3, the rate ratio being ~4:1 at 1400°C and 1450°C but ~ 2:1 at 1500°C. The spread in the data points is mostly due to the fact that the etch rate was calculated from the weight loss of a 15 mil thick slice, and 0.1 mg error can represent a considerable error in the etch rate, particularly when the measured weight loss was normally less than 2 mg for a sample weighing about 225 mg. (No correction was made for the weight loss from the edges and sides of the substrate or from the outer edge of the underside of the wafer, which normally is reached by the gas stream).

Etch temperature, substrate orientation, and etch rate were found to have an effect on surface quality, particularly on (01$\bar{1}$2) Al_2O_3. The condition of the etched surface indicated that 1500°C is preferred to either 1400° or 1450°C for etch-polishing (01$\bar{1}$2) Al_2O_3 at Freon flows of ~13 ml/min, even though the etch rate is approximately the same for the three temperatures. Structural defects appeared on the samples etched at 1400° and 1450°C, but only faint scratches were evident on the substrate etched at ~1500°C. If these scratches were not propagated by the etching, then work damage was present even after 9 μm of the thickness had been removed. Greater Freon flows, such as 20 ml/min and 40 ml/min, caused selective etching rather than polishing of the (01$\bar{1}$2)-oriented surface.

Etching was also sensitive to the quality of the crystals. Different etch patterns were often obtained on opposite sides of grain boundaries, as revealed

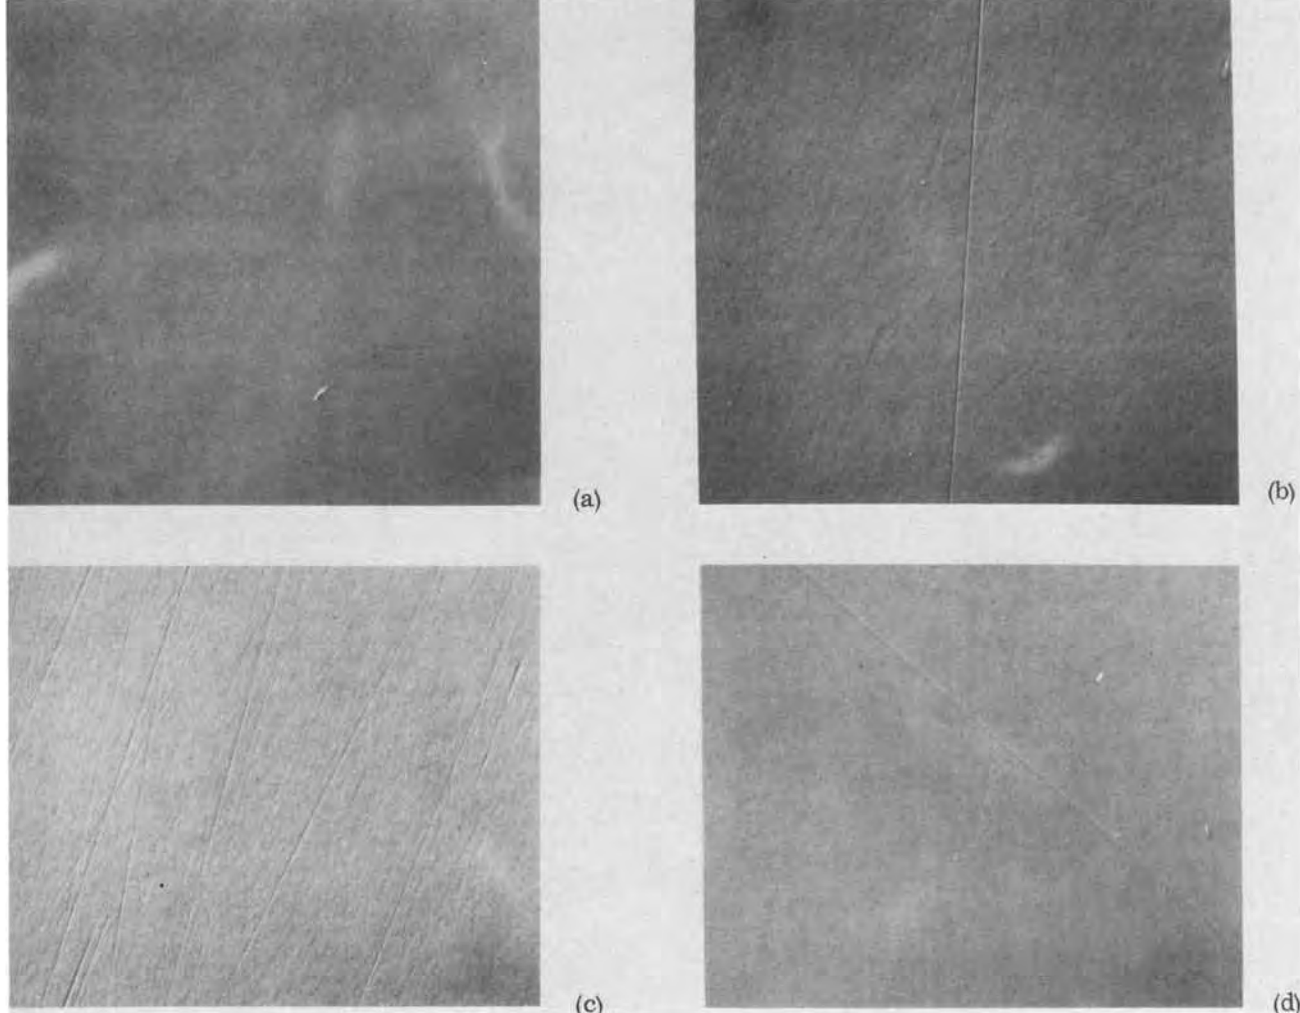

Fig. 6. The surface of different substrates of Verneuil-grown ~(1$\bar{1}$20)Al_2O_3 after etching at 1500°C with Freon at a flow rate of 13 ccpm for (a) 25 min, (b) 50 min, (c) 75 min, and (d) 100 min.

in Fig. 4 for a $(01\bar{1}2)$-oriented slice of Verneuil Al_2O_3 from which ~8 μm of thickness has been removed. The etch rate of Czochralski-grown Al_2O_3 also appeared to be somewhat slower than that of Verneuil-grown Al_2O_3, for the same substrate orientation.

Figure 5 shows that gas-phase etching of Czochralski-grown $(01\bar{1}2)Al_2O_3$ can also produce considerable etching of the crystal planes, but the etch pattern is relatively uniformly distributed. Etching to a ~20 μm depth led to a smoother surface, which may have resulted either from the removal of surface work damage or the exposure of a plane of Al_2O_3, oriented slightly different from the original plane, that is more susceptible to gas-phase polishing than to etching.

Etching of good quality Verneuil Al_2O_3 oriented to ~$(11\bar{2}0)$ (Fig. 6) seems to reveal primarily the work damage produced by mechanical polishing; however, some areas of the Verneuil-grown substrate did possess a relatively high density of diamond-shaped etch pits (not shown in the figure). Czochralski-grown Al_2O_3 oriented near $(11\bar{2}0)$ seemed to polish well with Freon-13 except when the work damage in the vendor-polished slices was very deep. In some cases the removal of ~5 μm of surface seemed sufficient; for other substrates, the removal of at least 12 μm was still insufficient to remove obvious work damage. These results suggest that close control of the sawing and mechanical polishing processes used in earlier stages of substrate preparation is necessary.

Si films, 2 μm-thick, were grown simultaneously on the various substrate surfaces shown in Fig. 5 and 6 and on unetched $(01\bar{1}2)Al_2O_3$. Essentially identical carrier mobilities were found, suggesting that the Si overgrowth is able to "overcome" much of the substrate imperfection during its growth, with the actual mobility-limiting factor being the stress-producing thermal contraction and/or lattice mismatch between the two substrates.

The same set of etch-polish conditions proved to be helpful in preparing smooth surfaces on $(0001)Al_2O_3$, shown in Fig. 7. After 25 min of etching, scratches were still visible. After 50 min the scratches were essentially gone, and the surface remained smooth after 75 and 100 min of etching. However, a number of hexagonal etch pits are evident. These may be characteristic of defects in the substrate or caused by reaction with the substrate of impurities in the etchant and/or those that may have been introduced into the etching atmosphere by reaction of the Freon with the carbon pedestal. Figure 7c is included to show the selectivity of the gas-phase process to certain types of defect structure present in these substrates cut from Verneuil-grown Al_2O_3.

As was the experience of Reisman *et al.* (8), $(10\bar{1}4)Al_2O_3$ did not lend itself readily to gas-phase polishing, for a pit-free surface was not obtained under any of the experimental conditions used. Figure 8 indicates the effect of temperature on $(10\bar{1}4)$-oriented surfaces after removal of ~3 μm of material. The substrate as received from the vendor appeared to be essentially featureless but, after removal of 2-3 μm or less of material, the scratch density was revealed. A majority of these scratches can be removed; light scratches seem to be removable, but major ones are either propagated by the etching or are so deep

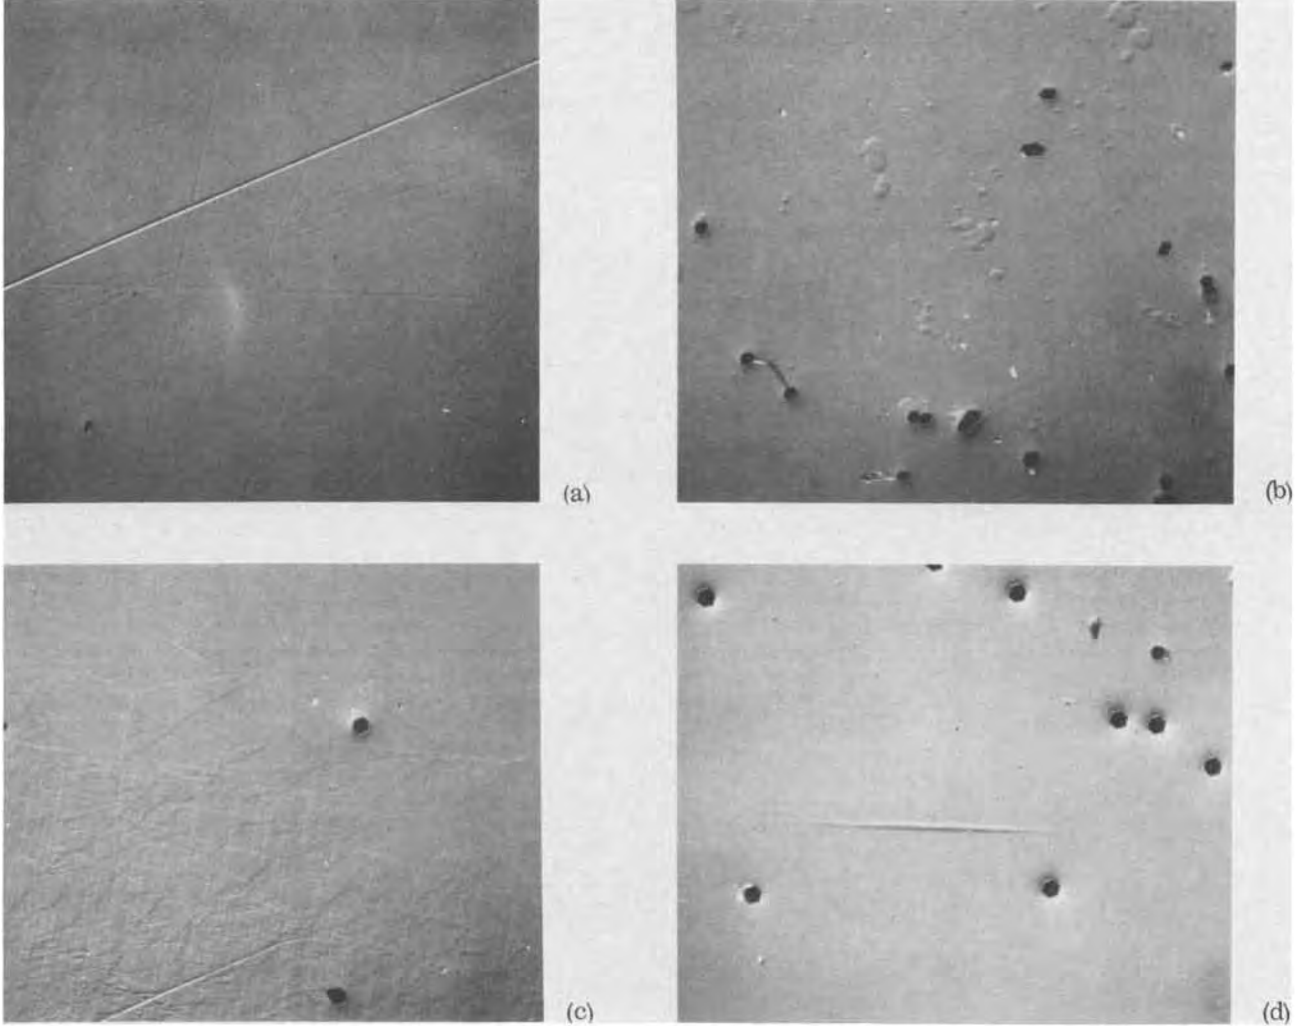

Fig. 7. The surface of $(0001)Al_2O_3$ after etching at 1500°C with Freon at a flow rate of 13 ccpm for (a) 25 min, (b) 50 min, (c) 75 min, and (d) 100 min.

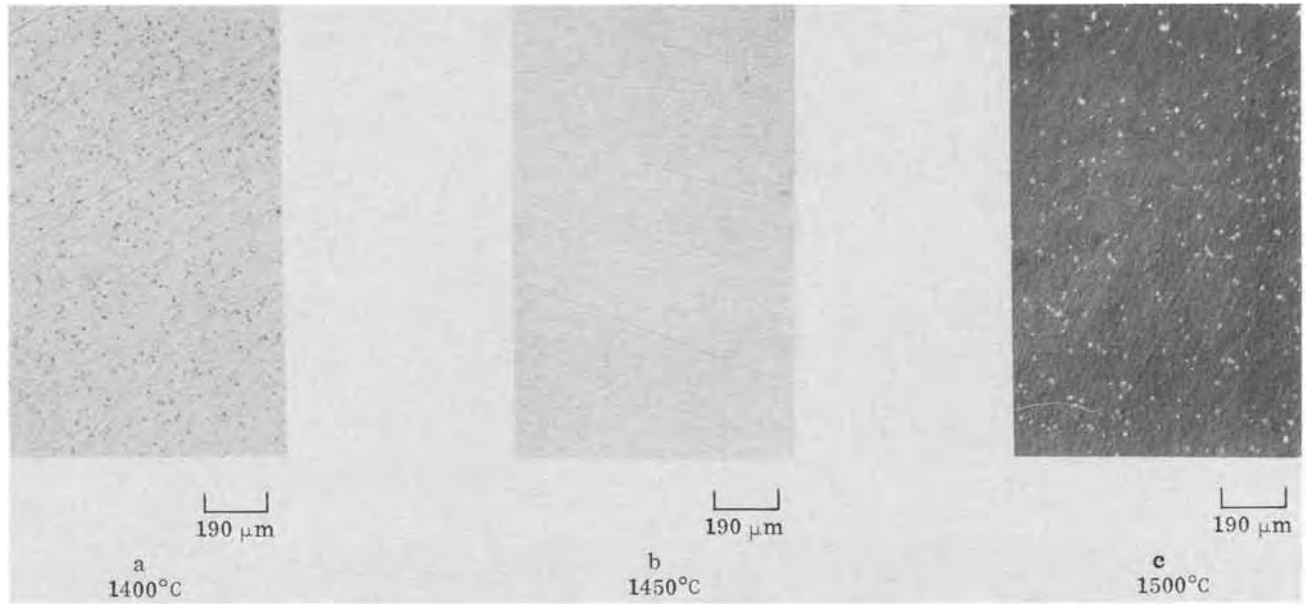

Fig. 8. $(10\bar{1}4)Al_2O_3$ surface after etch-polishing with Freon at flow rate of 13 ml/min at various temperatures. Approximately 3 μm of surface removed from each substrate.

as to require removal of major quantities of the substrate surface. This, in turn, usually causes deep pitting of the surfaces. However, even though Freon-13 has not been effective in providing an etch pit-free surface on $(10\bar{1}4)\,Al_2O_3$, it has been useful as a means for helping evaluate mechanical polishing techniques for this orientation and others. The low etch rates possible with Freon-13 permit very good control of surface removal in order to correlate studies of polishing with the formation and presence of work damage.

Conclusion

Freon-13 appears to be a good etch-polish agent for $(01\bar{1}2)$, $\sim(11\bar{2}0)$, and $(0001)\,Al_2O_3$ and useful for removing work damage from $(10\bar{1}4)\,Al_2O_3$. A combination of slow etch rate and high etch temperature seems to provide the best surfaces for the above Al_2O_3 orientations. A work-damage free surface, however, does not necessarily lead to Si films with improved mobilities.

Chemically Vapor Deposited Tungsten for Semiconductor Metallizations

C. M. Melliar-Smith, A. C. Adams,* R. H. Kaiser, and R. A. Kushner

Bell Laboratories, Murray Hill, New Jersey 07974

ABSTRACT

The properties of CVD tungsten films, produced by the hydrogen reduction of WF_6 or WCl_6, have been investigated to determine the suitability of the films for use as silicon integrated circuit metallizations. Both low pressure and atmospheric pressure flow system have been investigated.

The tungsten films show excellent adhesion to silicon substrates, have resistivities between 6 and 15 μohm-cm depending on thickness, and are easily etched into submicron patterns. In addition, data on the contact resistance to silicon and MOS properties of tungsten films from both deposition reactions have been measured.

The use of chemical vapor deposition (CVD) to deposit thin tungsten films for integrated circuit metallizations has been investigated for several years (1, 2). Usually the tungsten is deposited using the hydrogen reduction of tungsten hexafluoride at temperatures between 600° and 800°C. The process is easily controlled and produces excellent tungsten films which are suitable for some integrated circuit applications (2).

However, the corrosive nature of the reactants and products tends to degrade the thermally oxidized silicon wafers used for the integrated circuits. This fact has generated additional interest in the use of tungsten hexachloride, which is less corrosive toward SiO_2, and has been used to deposit tungsten films in a similar manner to the hexafluoride (3, 4) although less information is available on their subsequent use for integrated circuit metallizations.

Consequently we have compared the two reactions for application to silicon integrated circuits, extending previous studies to include the use of CVD tungsten as a gate metallization for unipolar devices.

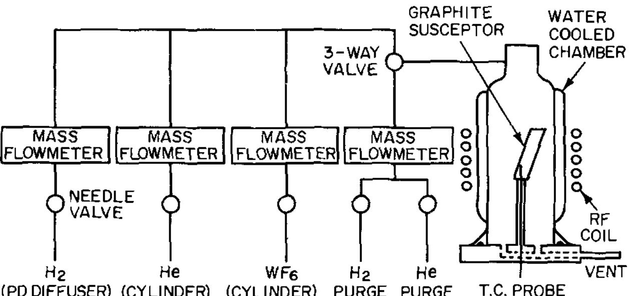
Experimental

Tungsten films were deposited in both atmospheric and low pressure (1-10 Torr) flow systems from the hexafluoride and at atmospheric pressure from the hexachloride. Schematic diagrams of the deposition systems are shown in Fig. 1 and 2. The systems were rf heated using graphite or molybdenum susceptors. The temperature was controlled by a thermocouple embedded in the susceptor. The low pressure system proved somewhat unsatisfactory for two reasons. Firstly, at low pressure good thermal contact between the susceptor and the substrate is difficult to achieve and an inevitable uncertainty exists as to the substrate surface temperature in a fast flow system. Secondly, the use of rf heating at low pressure resulted in a plasma in the deposition chamber, the effect of which could result in ion bombardment damage to sensitive substrates.

The tungsten hexachloride saturator and the gas lines leading from the saturator to the reaction chamber were heated to 150° ± 5°C. Chemicals used were: hydrogen, purified using a palladium diffuser; argon, purified using a titanium chip furnace; helium (99.9999%); hydrogen chloride (99.99%); tungsten hexafluoride (99.5%); and tungsten hexachloride (99%). The major impurity in the tungsten hexachloride was tungsten oxychloride ($WOCl_4$) which was removed by sublimation at 100°C. The thickness of the deposited tungsten was measured by the β-backscatter technique.

Results and Discussion

Deposition.—Typical deposition conditions are shown in Table I. The deposition temperature was varied from



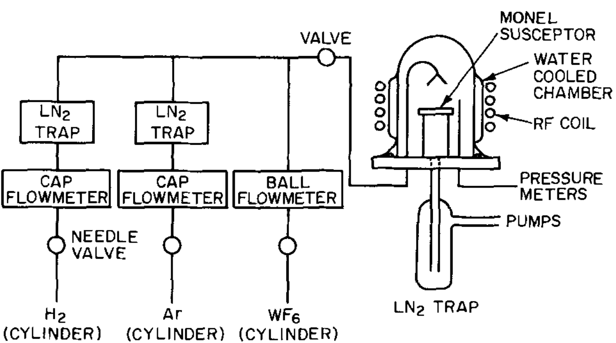


Fig. 1. Apparatus used for the chemical vapor deposition of tungsten from tungsten hexafluoride.

420° to 800°C for the hexafluoride reaction, and from 550° to 950°C for the hexachloride process. The effect of substrate temperature on the deposition rate is shown in Fig. 3 for the hexachloride reaction. At deposition temperatures below 600°C the rate falls off rapidly, rises to a maximum between 700° and 900°C and subsequently falls off again above 900°C. The results are similar to those published by Mehalchick and MacInnis (4) who found a maximum deposition rate at 600°C. The temperature dependence of the deposition

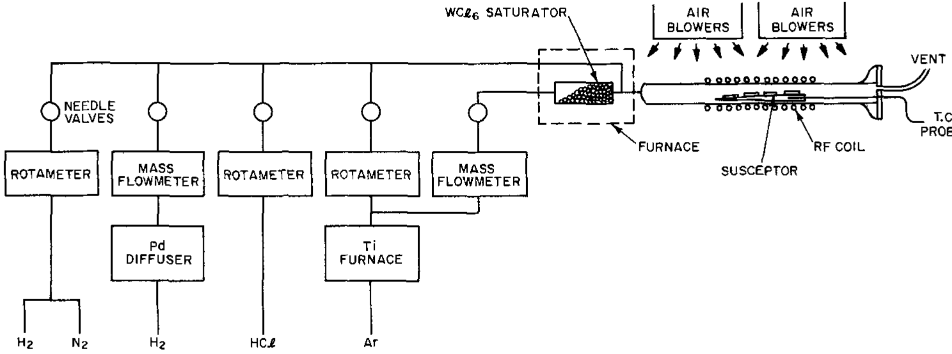

Fig. 2. Apparatus used for the chemical vapor deposition of tungsten from tungsten hexachloride.

rate can be rationalized as follows: at low temperatures the reaction behaves as a normal, thermally dependent, surface reaction. As the substrate temperature is raised, the deposition rate becomes more and more limited by gas-phase diffusion of the reactants to the surface, and consequently approaches a region of temperature independence. A further increase in temperature results in a drop in the deposition rate as measured by the thickness of the substrate. This is a result of the combined effects of the onset of a homogeneous gas-phase reaction and deposition on the walls of the reaction chamber.

For both chemical reactions, the deposition rate could be varied between 200 and 3000 Å/min by changing the concentration of the tungsten hexafluoride or tungsten hexachloride. The thickness of the tungsten films ranged up to 3 μm.

Tungsten films can be deposited selectively at a silicon surface by reducing tungsten hexafluoride with silicon in an inert atmosphere (1, 2). The reaction proceeds until a limiting tungsten thickness of 300 to 400Å is reached. The selective deposition of tungsten onto silicon from hexachloride proved very slow, and useful films cannot be produced unless hydrogen is used as the reducing agent.

Film structure and analysis.—CVD tungsten from the hydrogen reduction of tungsten hexachloride deposits on SiO_2 with a bcc structure and a slight <110> orientation as shown by pole figure x-ray measurements. The preferred orientation is enhanced if the

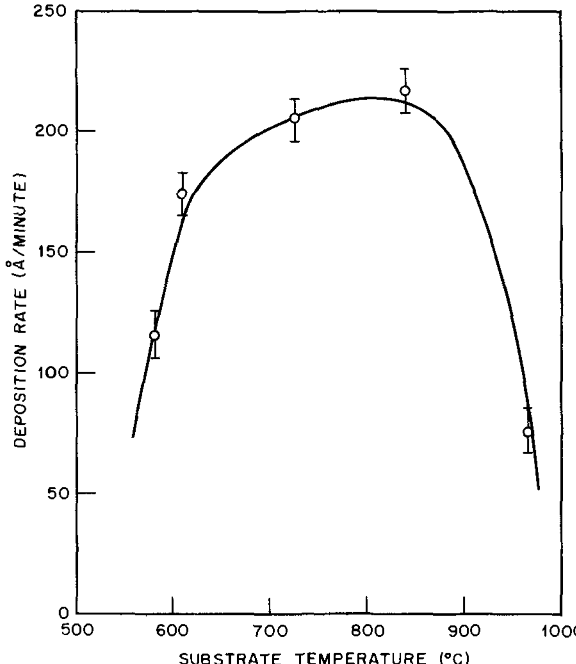

Fig. 3. Deposition rate as a function of substrate temperature using tungsten hexachloride.

samples are annealed in vacuum at 900°C for 60 min. The <100> texture is observed in films deposited by the tungsten hexafluoride reaction. X-ray diffraction and transmission electron diffraction show no evidence for the presence of the β-phase in tungsten produced by either reaction.

The grain size of the films has been measured by transmission and replica electron microscopy. The surface grain size increases with increasing thickness as shown in Fig. 4. In addition, thicker films appear to have much larger individual crystals growing on the surface, some as large as 1μ in a 3200Å film.

Stress measurements in films of CVD tungsten deposited on SiO_2 have been made by both x-ray and substrate bending techniques. All films have low residual stress levels, less than 1×10^{10} dynes/cm^2. Films deposited from tungsten hexafluoride tended to be in compression, while films from tungsten hexachloride had tensile stress. Grain size and stress data are summarized in Table II.

No impurities were detected in the tungsten films by electron microprobe analysis, but spark mass spectrometry showed the presence of a number of trace elements, the major impurity being fluorine or chlorine (0.05-0.1%) from the fluoride and chloride reduction reactions, respectively.

Film adhesion.—Adherent tungsten films, 160-30,000Å thick, have been deposited on silicon, silicon dioxide, and sapphire. More than 300 films were deposited from tungsten hexachloride and none showed evidence of poor adherence. Eleven samples were subjected to a 5 min boiling water treatment and to rapid thermal cycling from boiling water to liquid nitrogen. None of the samples failed these tests. Samples annealed in vacuum at 1000°C for 60 min showed no loss in adherence to silicon dioxide or sapphire; however, adhesion to silicon was lost due to tungsten silicide formation.

Tungsten films deposited on silicon from tungsten hexafluoride at atmospheric pressure were initially found to be nonadherent due to the formation of a thin (~20Å) black film. The film was analyzed by electron diffraction and found to be polycrystalline silicon which is produced when the hydrogen fluoride byproduct reacts with the native oxide film on the silicon surface

$$Si + SiO_2 + 4HF \rightarrow 2SiF_2 + 2H_2O \quad [1]$$

$$2SiF_2 \rightarrow Si + SiF_4 \quad [2]$$

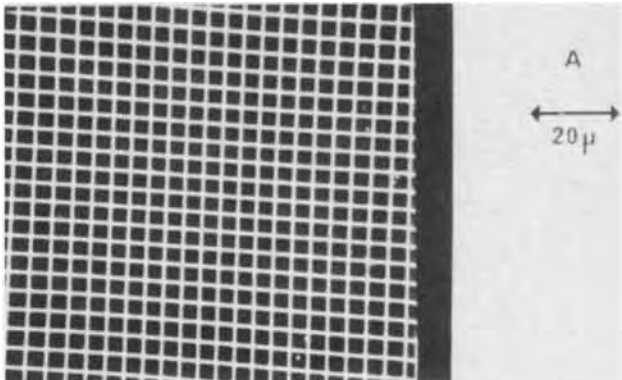
This reaction scheme is supported by several observations. The polycrystalline silicon forms only at the Si-W interface and not at the SiO_2-W interface. This indicates that the silicon is required in the reactions. The polycrystalline silicon does not form when WF_6 in helium reacts with silicon; however, it does form when the WF_6 is reduced by hydrogen. The polycrystalline silicon has also been produced by passing dilute (0.01%) hydrogen fluoride in helium over a tungsten-coated silicon sample at 700°C. These observations indicate that the hydrogen fluoride diffuses through the tungsten to react at the Si-W interface. Finally, where silicon samples are coated with sputtered tungsten after removal of the native oxide by backsputtering and the samples exposed to WF_6 in hydrogen at 750°C, the polycrystalline silicon is not formed. However, the polycrystalline silicon is formed when the experiment is repeated using silicon samples coated by atmospheric pressure CVD or E-gun evaporation techniques, where the native oxide film is not removed. These observations are consistent with reactions [1] and [2] in which silicon reacts with an oxidizing agent in the presence of hydrogen fluoride to form SiF_2 which disproportionates to form SiF_4 and polycrystalline silicon.

The formation of the polycrystalline silicon can be prevented by using high flow rates where the hydrogen fluoride is removed before it can react at the interface, or by using an *in situ* HCl etch which removes the native oxide.

The polycrystalline silicon does not form when tungsten hexachloride is used as the source of tungsten.

Etching and step coverage.—CVD tungsten may be delineated into high resolution patterns by standard lithography and etching techniques. Submicron lines have been produced using electron beam lithography and a buffered $KOH/K_3Fe(CN)_6$ etch. The finest lines otained were 2500Å wide. Figure 5a shows a grid pattern of 5000Å wide tungsten lines.

Step coverage was measured by depositing 2000Å of tungsten over 10 μm wide stripes etched into a 6000Å thick thermal oxide. The tungsten was delineated into 5 μm wide stripes perpendicular to the oxide bars. Step coverage was checked by measuring electrical continuity or by viewing with a scanning electron micro-



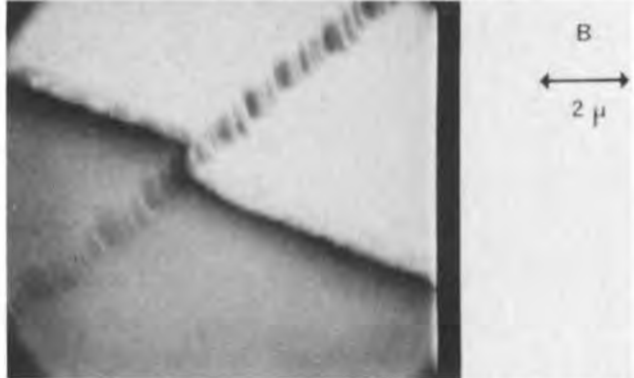


Fig. 5. A, Scanning electron micrographs of 5000Å wide grid pattern in 1400Å of CVD tungsten; B, scanning electron micrograph of 5 μm wide tungsten line passing over a 6000Å high oxide step.

scope (Fig. 5b). No failures in step coverage were observed.

Resistivity.—The resistivity of the tungsten films was found to be dependent on the thickness of the film, as shown in Fig. 6. The resistivity ranged from about three times the bulk value for films less than 1000Å thick to the bulk value (5.4 ohm-cm) for film thicknesses greater than 1 μm. No difference in resistivity was observed between films deposited from tungsten hexafluoride and from tungsten hexachloride. Annealing tungsten films on SiO_2 at 1000°C in vacuum for 60 min produced no detectable change in the resistivity.

A very similar dependence of resistivity on film thickness for polycrystalline CVD tungsten has been observed by Mayadas *et al.* (5) which they attribute to grain size effects. The work of Sheng *et al.* (6) on sputtered tungsten films (2500Å thick), however, suggests that the presence of vacancies and interstitial impurities is an additional cause of the residual resistivity above the bulk value.

Contact resistance.—The contact resistance of W-Si structures has been investigated by depositing tungsten on highly doped silicon through 11 × 14 μm holes in a 2000Å thick oxide film. The tungsten is then delineated into pads around each contact window and the I-V characteristics obtained from pad to pad measurements. The values for the contact resistance are dependent on the silicon doping concentration as shown

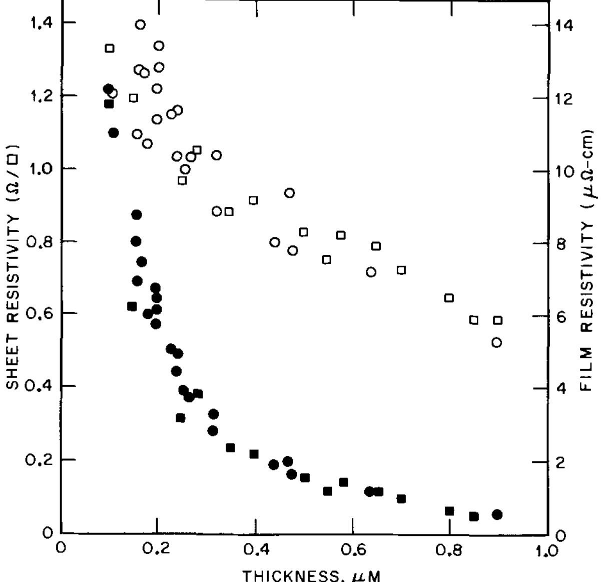

Fig. 6. Sheet and film resistivity curves as a function of film thickness for CVD tungsten. (Film resistivity points: ○, WCl_6; □, WF_6. Sheet resistivity points: ●, WCl_6; ■, WF_6.)

in Table III. In this table, the contribution from the spreading resistance has not been subtracted from the experimental values, so the true contact resistance is smaller than the values reported.

The contact resistance is independent of deposition temperature for films deposited from tungsten hexafluoride; however, the contact resistance is strongly dependent on deposition temperature when tungsten hexachloride is used as the source material. Samples deposited from tungsten hexachloride between 600° and 800°C are characterized by a high, nonohmic contact resistance; as the deposition temperature increases in this range, the I-V characteristics of the contacts become more nearly ohmic and the contact resistance decreases. Samples deposited at 850°C are ohmic with a low contact resistance (Table III). The temperature dependence suggests the presence of a detrimental interfacial layer between the tungsten and the silicon. This layer may be a native oxide film present on the silicon surface before deposition, or an oxide layer may be formed in the deposition chamber by the reaction of silicon with impurities in the tungsten hexachloride or in the carrier gas. Where tungsten is deposited at 850°C, the oxide layer may not prevent contact formation due to rapid diffusion of tungsten and/or silicon through the thin oxide. However, at 850°C the formation of tungsten silicide is rapid which may result in nonadherent films.

The contact resistance is markedly affected by subsequent heat-treatment. Tungsten as deposited on silicon shows evidence for only a very small amount of tungsten silicide and little change is observed in the contact resistance on annealing up to 800°C. Annealing above 800°C, however, causes silicide formation to proceed rapidly (7, 8) and 30 min at 900°C is sufficient to cause considerable deterioration in the contact resistance. The failure mechanism appears to be due to excessive tungsten silicide formation in the contact region. This compound formation results in a volume change in the contact metallization leading to severe mechanical stresses which can cause cracks to develop at the base of the contact window.

Forward bias measurements on n-type, 1-10 ohm-cm Schottky diode structures using tungsten deposited from tungsten hexafluoride give values of 0.66 eV for

Table III. Contact resistance for CVD tungsten

Substrate	R_c experimental (ohm-cm²)	R_c theoretical (9) (ohm-cm²)
WF_6 at 700°C		
2×10^{19} p-type	3×10^{-5}	1×10^{-6}

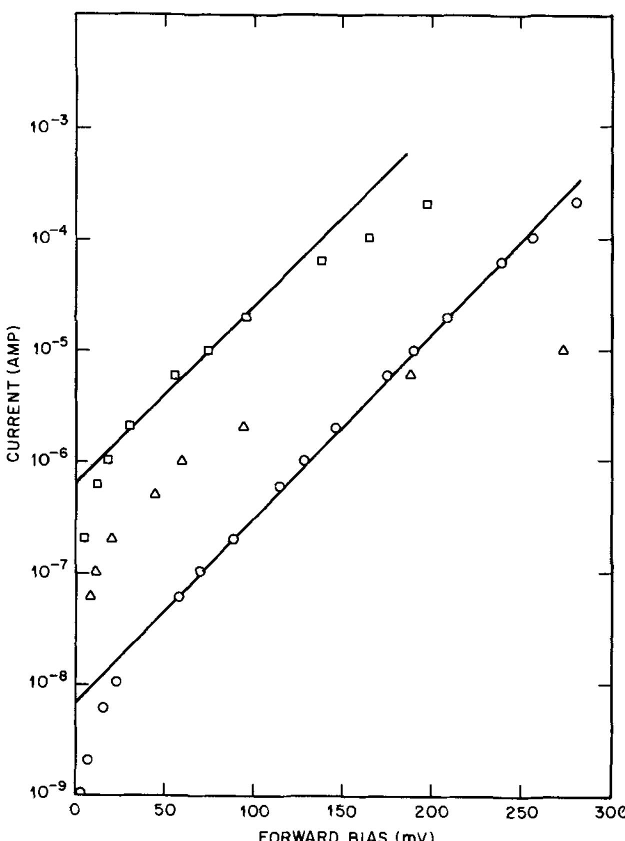

Fig. 7. Forward current as a function of applied voltage for CVD tungsten-silicon diode. ○: WF_6 at 575°C, 3 mil diode, $N = 1.02$, $\phi = 0.66$ eV. □: WCl_6 at 700°C, 10 mil diode, $N = 1.07$, $\phi = 0.59$ eV. △: WCl_6 at 600°C, 3 mil diode.

the barrier height and 1.02 for n (Fig. 7). Both values are in good agreement with data in the literature (1). If the tungsten is deposited from tungsten hexachloride, the forward bias measurement depends on the deposition temperature. Structures deposited at 850°C have I-V characteristics identical to those for the hexafluoride films ($n = 1.03$, $\phi = 0.65$ eV); for deposition at 700°C, $n = 1.07$ and $\phi = 0.59$ eV. For depositions at 600°C, the I-V characteristics become too nonlinear for n and ϕ to be determined (Fig. 7).

MOS properties.—The MOS characteristics of $W/SiO_2/Si$ structures have been established by (*i*) 1 MHz C-V measurements; (*ii*) quasistatic C-V measurements with a 50 mV/sec sweep rate and ± 10V sweep range; (*iii*) triangular voltage ramp ionic drift measurements with a 45 mV/sec sweep rate and ± 6V sweep range at a temperature of 300°C; and (*iv*) bias-temperature stressing at 300°C for 5-15 min, with ± 10V on the field plate and cooling the sample under bias. The samples had 1200Å of dry oxide grown in oxygen containing 1% hydrogen chloride on <100>, 0.5 ohm-cm, n-type substrates. Prior to tungsten deposition, 200Å of oxide was removed by etching in dilute hydrofluoric acid. The MOS capacitors were 20 or 25 mils in diameter and were formed by standard photolithography and etching techniques. Evaporated aluminum was used as the back contact. None of the samples were annealed.

The MOS characteristics are summarized in Table IV. MOS dots formed from tungsten hexafluoride were usually shorted or very leaky. This resulted from attack of the oxide by the tungsten hexafluoride during the metal deposition. Decoration of the MOS oxide after removing the tungsten showed pinhole densities as great as $10^7/cm^2$. Because of the large number of pinholes, the tungsten hexafluoride reaction is not suitable for gate metallizations over SiO_2.

Shorted and leaky dots do not form when tungsten is deposited from tungsten hexachloride, and the MOS

Table IV. MOS properties of CVD tungsten

Property	Source material	
	WF_6	WCl_6
% shorts	50-75%	0
Flatband voltage, V_{FB}	−0.5 to +0.1V	+0.2 to +0.5V
ΔV_{FB} after B-T stress	—	−0.1V
Fixed charge, Q_{ss}	2-3 × 10^{10} cm^{-2}	1-3 × 10^{10} cm^{-2}
Mobile charge, N_a	2-3 × 10^{11} cm^{-2}	1-5 × 10^{10} cm^{-2}
Fast-state density, N_{ss} (Midgap)	8-10 × 10^9 cm^{-2} eV^{-1}	2-4 × 10^{10} cm^{-2} eV^{-1}

properties of the $W/SiO_2/Si$ structures are nearly ideal. The flatband voltage is 0.2-0.5V; this implies that the fixed charge, Q_{SS}, is very low (1-3 × 10^{10} cm^{-2}). The fast-state density distribution, shown in Fig. 8, is independent of the deposition temperature. There are no unusual or irregular peaks across the bandgap, and at midgap the fast-state density is 2-4 × 10^{10} cm^{-2} eV^{-1} for all the samples. The mobile charge, which ranged from 1 × 10^{10} to 5 × 10^{12} cm^{-2}, is very dependent on deposition conditions. However, consistent values of 1-5 × 10^{10} cm^{-2} were obtained by adding 0.1% hydrogen chloride to the carrier gas during deposition. The addition of hydrogen chloride had no effect on the other properties of the tungsten films.

Summary

Tungsten films have been deposited by hydrogen reduction of tungsten hexafluoride or tungsten hexachloride, and the two systems have been compared for applications for silicon integrated circuits. Films with thicknesses as great as 30,000Å have been deposited from both chemical sources at rates up to 3000 Å/min. The films from both sources have low residual stress,

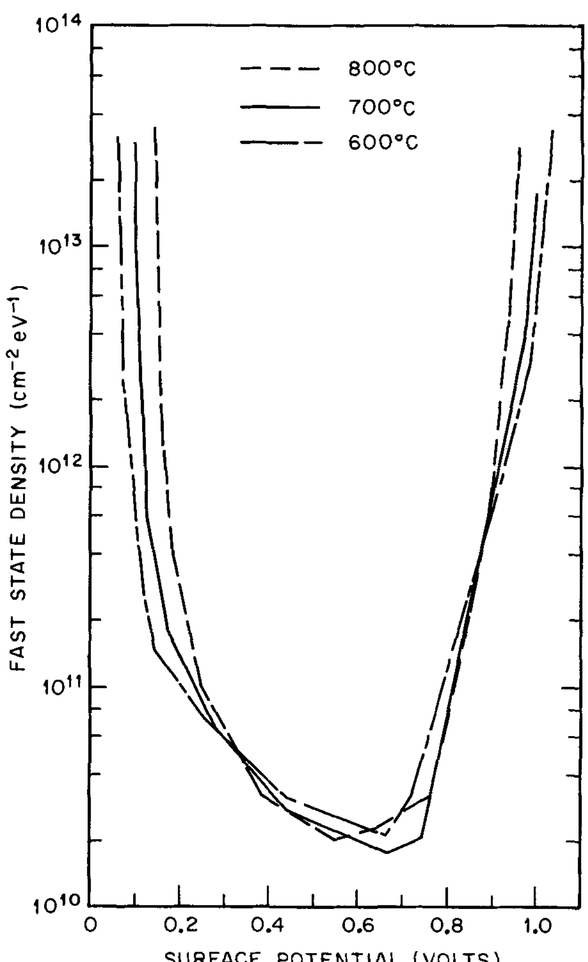

Fig. 8. Fast-state density distribution as a function of substrate temperature during deposition (600°-800°C) for the WCl_6 reaction.

good step coverage, are easily etched into fine resolution patterns, and have resistivities between one and three times the bulk value. Films deposited from tungsten hexafluoride have excellent W-Si contacts; however, tungsten hexafluoride attacks SiO_2 which results in shorted or leaky MOS structures. Consequently, tungsten hexafluoride cannot be used for a gate metallization on SiO_2. In contrast, films deposited from tungsten hexachloride have nearly ideal MOS properties; however, the W-Si contacts are poor unless the metal is deposited at high temperatures (850°C). At high temperatures, the formation of tungsten silicide is rapid and the films frequently develop cracks due to the volume change associated with the silicide formation. Consequently, tungsten hexachloride has not been used in metallizations that require the formation of a W-Si contact.

Technical Notes

Luminescence of Mn^{2+} in Alpha-$LiAlSiO_4$

K. R. Laud, T. Y. Tien,[1] E. F. Gibbons, and H. L. Stadler

Scientific Research Staff, Ford Motor Company, Dearborn, Michigan 48121

Synthetic lithium aluminum orthosilicate, $LiAlSiO_4$, exists in two crystallographic forms (1, 2). The high temperature β-form has a β-quartz type structure and transforms to the low temperature α-form under hydrothermal conditions. The α-form is found in nature as α-eucryptite and has a phenacite (Be_2SiO_4) structure (2, 3). The $\alpha \rightleftarrows \beta$ inversion temperature at atmospheric pressure is reported as 848°C (2).

The objective of the work reported here is to synthesize α-$LiAlSiO_4$:Mn^{2+} phosphor. Since this phosphor can be prepared only under hydrothermal conditions, a wide variation of pressure and temperature is possible in the phosphor preparation.

Experimental

Chemically pure lithium carbonate, aluminum hydroxide, silicic acid, and manganous carbonate were used as starting materials. The batch was formulated as $LiAlSiO_4$:Mn^{2+} where the Mn^{2+} concentration was maintained at as low as 0.005 atom per cent (a/o) (*i.e.*, 2 Mn replacing 'Li + Al').

The weighted batch was wet mixed in acetone, dried, and slowly calcined to 800°C for 18 hr. The calcined mixture was melted in a platinum crucible at 1400°C for 20 min and was eventually quenched to obtain glass for use in hydrothermal experiments. The glass was crushed and passed through a 325 mesh screen. Approximately 1.5g of glass powder was packed in a gold tube (3/8 in. I.D., 1 in. long) which was placed in a hydrothermal pressure vessel. The hydrothermal apparatus is described elsewhere (4). The phosphor specimens were prepared in the entire α-eucryptite region of the P-T diagram shown in Fig. 1. Holding times at 14,000, 7,500, and 2,000 psi pressure were 48, 84, and 120 hr, respectively.

The cathodoluminescence (C.L.) data were obtained in a demountable electron beam gun system operated at 3 kV. Samples were mounted at the focal point of an optical system which then refocused the emitted light on the entrance slit of a 3/4m Czerny-Turner spectrometer. The output from a photomultiplier (P.M.) tube, located at the exit slit of the spectrometer, was amplified by means of a synchronous detector and displayed on an x-y recorder. The required periodic signal for the P.M. tube was obtained by applying a 13 Hz square wave to the horizontal deflection plates of the electron beam gun, thus providing a 50% excitation duty cycle on the sample. The same square-wave generator provided the reference signal for the synchronous detector.

The excitation and emission spectra were taken in a system using a xenon light source focused through a monochrometer with a mechanical light chopper after the exit slit. The phosphor emission was focused on the entrance slit of a 3/4m Czerny-Turner spectrometer and again the output of a P.M. tube located at the exit slit was amplified by means of a syn-

chronous detector and displayed on an x-y recorder. For excitation spectra, the spectrometer was set at the desired emission peak and the monochrometer was scanned over the appropriate range, while for emission spectra, the desired excitation wavelength was chosen by the monochrometer and the spectrometer was scanned over the emission band. Appropriate filters were used in front of and behind the phosphor sample.

Results

In all, ten phosphors were prepared in the α-$LiAlSiO_4$ area of the P-T diagram (Fig. 1). The x-ray diffraction patterns indicated all the phosphors to be composed entirely of α-$LiAlSiO_4$:Mn.

Figure 2 shows the C.L. emission spectra for three phosphors prepared under different hydrothermal conditions. In nine phosphors, two C.L. emission bands appear with peak positions at 5230Å in the green region and 6900Å in the red region of the spectrum. In only one phosphor, prepared at 2000 psi and 850°C, a 5230Å band predominates. The ratio of the peak intensities of green to red bands decreases with increasing pressure but increases with increase in temperature. This indicates that low pressure and high temperature conditions favor the green band but high pressure and low temperature are suitable for the red band to appear.

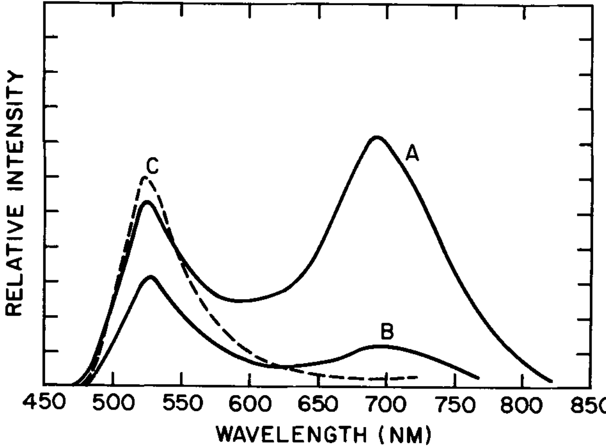

Fig. 2. C.L. emission spectra for α-$LiAlSiO_4$:Mn^{2+} phosphors prepared under hydrothermal conditions. A, 14,000 psi, 700°C, 48 hr; B, 7,500 psi, 800°C, 84 hr; and C, 2,000 psi, 850°C, 120 hr.

For a phosphor, prepared at low pressure and high temperature, the excitation and photoluminescence spectra are shown in Fig. 3 and 4, respectively. The excitation peak positions are at 2750Å and 3750Å for the 6900Å and 5230Å emission settings of the spectrometer, respectively. In the photoluminescence spectrum two bands appear. For the 3750Å excitation wavelength, an emission peak appears at 5230Å and for the 2750Å excitation wavelength, an emission peak is located at 6900Å. The excitation and photoluminescence spectra for a phosphor prepared at high pressure and low temperature were identical to those shown in Fig. 3 and 4 except in peak intensities.

The excitation and photoluminescence spectra (Fig. 3 and 4) suggest that the emission occurs from two separate systems. In one system, the excitation is at the 3750Å level and emission occurs in a band whose peak is at 5230Å. In the other system, the excitation is at the 2750Å level and emission is from the 6900Å

level. However, there is no evidence of energy transfer occurring between these two systems.

YVO_4:Eu,Tb—An Efficient High Pressure Mercury Vapor Lamp Phosphor

S. Faria* and E. J. Mehalchick

GTE Sylvania Incorporated, Chemical and Metallurgical Division, Towanda, Pennsylvania 18848

Enhancement of Eu^{3+} emission by relatively high concentrations of Tb^{3+} was reported by Van Uitert *et al.* (1) in the alkali rare earth tungstates and by Ropp (2) in yttrium oxide. The increase in Eu^{3+} emission was described as a resonance transfer of energy absorbed by the Tb^{3+} center. Using relatively low concentrations of Tb^{3+} Mehalchick *et al.* (3) showed a significant increase in the cathode ray brightness of YVO_4:Eu. This work shows that moderate amounts of Tb^{3+} are also effective in enhancing the Eu^{3+} emission of YVO_4:Eu, when the phosphor is used as a color corrector in high pressure mercury vapor (HPMV) lamps (4). The improvement is most readily observed at the high operating temperature of the HPMV lamps, thus indicating that the energy transfer from Tb^{3+} to Eu^{3+} is thermally activated (5).

Experiments and Results

Series of YVO_4:Eu and YVO_4:Eu,Tb phosphors were prepared by the usual solid-state reaction described in a previous paper (6). All the phosphors were evaluated in HPMV lamps operating at 400W. The red emission was measured using a Corning red filter number 2418 (CS-2-62) and is expressed in per cent relative to the control sample. Unless otherwise stated, the Eu concentration was maintained at 5 mole per cent (m/o), although other concentrations were also evaluated (4).

Tb^{3+} Concentration

In Table I we report the lumens per watt (LPW) and the per cent red for 0 and 100 hr of lamp operation as a function of Tb^{3+} concentration. Note that increasing the Tb^{3+} appreciably affects the per cent red as well as the LPW. The optimum Tb^{3+} concentration varied between 50 and 750 ppm by weight and depended on the purity of the yttrium oxide lots. The spectral energy distribution at 0 hours of samples 1 and 2 are shown in Fig. 1.

Further investigation on the effect of Tb^{3+} on Eu^{3+} was evaluated by using a high purity lot of yttrium oxide. The results shown in Table II were obtained by adding 250 ppm and 300 ppm Tb^{3+} to a 99.999% pure yttrium oxide lot.

The increase in the red output was again observed in a yttrium oxide lot containing 25 ppm Tb as an impurity. When we added 250 ppm Tb, an increase from 112% to 150% was obtained. The large differences in per cent red output shown in Tables I, II, and III are mainly due to the variation in Y_2O_3 lots and their impurity contents.

Table I. Terbium variation

Sample No.	Tb, ppm	0 hr LPW	0 hr % Red	100 hr LPW	100 hr % Red
1	0	100	100	100	100
2	50	104	115	103	107
3	250	105	119	102	103
4	500	105	119.5	99	108
5	750	105	119.5	102	109
6	1000	105	115.0	100	103

Table II. Terbium addition to high purity Y_2O_3

Control	No Tb	100% Red at 0 hr
Test A	250 ppm Tb	140% Red at 0 hr
Test B	300 ppm Tb	153% Red at 0 hr

Effect of Dysprosium

Many of the tested yttrium oxide lots contain Dy as well as other rare earth impurities. In many instances, the Dy content was determined to be as high as 400 ppm. To establish the effect of Dy on the overall performance of the HPMV lamps, various Dy concentrations were evaluated with or without Tb.

Table III shows the results obtained without Tb, with Tb, with Dy, and with Tb + Dy. The results indicate that levels of Dy equal to or lower than Tb do not appreciably affect the total lumen output or the per cent red.

YVO_4:Eu,Tb phosphor prepared from lots containing relatively high Dy as an impurity were almost as efficient as those prepared from low Dy.

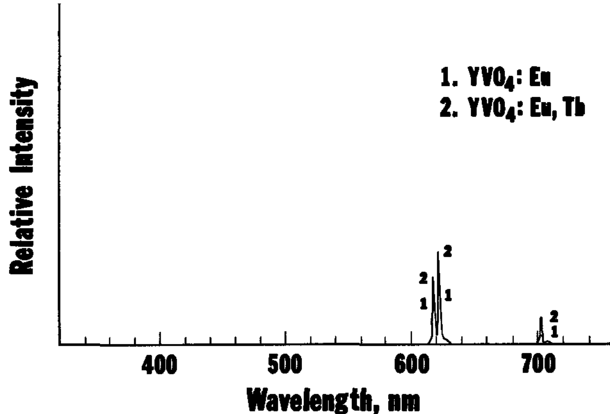

Fig. 1. Spectral energy distribution of YVO_4:Eu,(1) and YVO_4:Eu,Tb(2) in 400W HPMV lamps.

Key words: energy transfer, rare earth phosphors.

Table III. Effect of Dy and Dy + Tb on % red and LPW

Description	LPW	% Red
Control test	100	100
Test + 150 ppm Tb	108	138
Test + 300 ppm Tb	104	149
Test + 150 ppm Dy	100	100
Test + 150 ppm Dy + 150 ppm Tb	105	128
Test + 150 ppm Dy + 300 ppm Tb	106	143
Test + 300 ppm Dy	100	97.0

The particle size was also taken into consideration when optimizing the system for HPMV lamp application. Best output in lumens and per cent red were obtained when the particle size ranged between 6 and 10μ as measured by the Fisher Sub-Sieve-Sizer (FSSS). In general, the small particle size phosphor always showed a slight gain in red output, but at a slight loss in LPW.

Discussion

Blasse (7) and Palilla (8) have described the very strong optical absorption of YVO_4 for both short and long ultraviolet radiation. Incorporation of Eu^{3+} in this matrix results in luminescence through a rather efficient host transfer mechanism. The efficient Eu emission arises from the large overlap between the visible matrix emission band and Eu visible absorption levels. These Eu absorption lines are clearly shown in Fig. 2.

Although we do not know the actual mechanism for the Eu enhancement, it would appear that when Tb is also incorporated in the matrix, a similar energy interaction between Tb emission and Eu absorption levels could exist. In Fig. 3, we show the visible emission lines of Tb in YPO_4 since Tb emission does not occur in YVO_4 (9), even though both YVO_4 and YPO_4 have similar structures (both matrices being tetragonal-xenotime). Figure 4 shows the possible energy overlap that would exist for Eu absorption in YVO_4 and Tb emission as it appears in YPO_4.

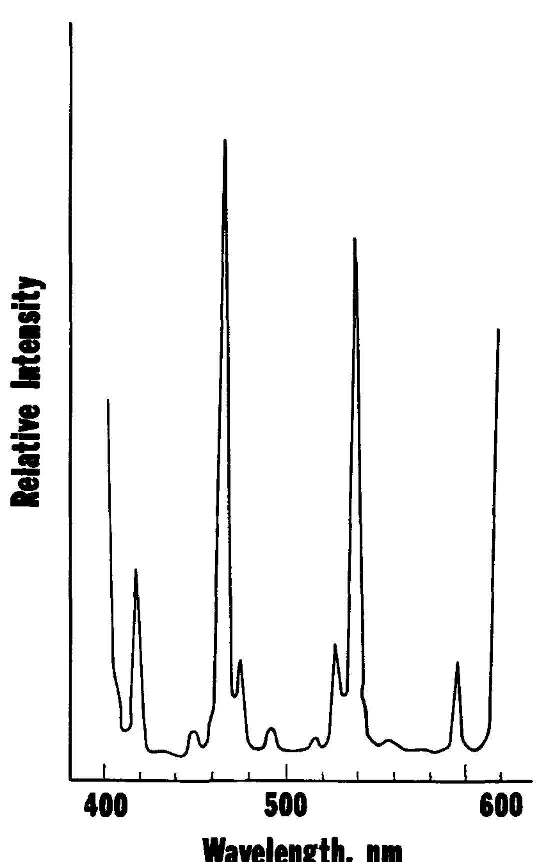

Fig. 2. Excitation spectrum of Eu in YVO_4

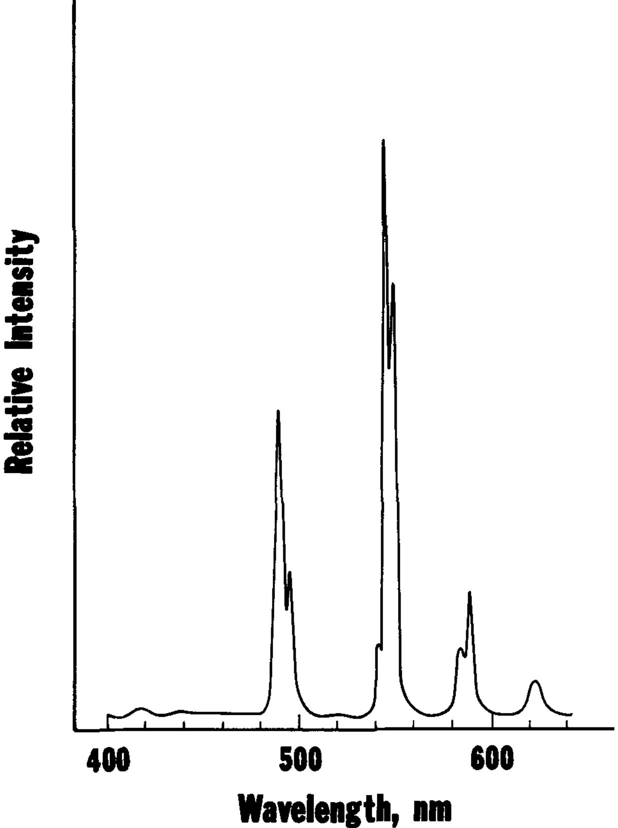

Fig. 3. Spectral energy distribution of YPO_4:Tb showing characteristic Tb emission.

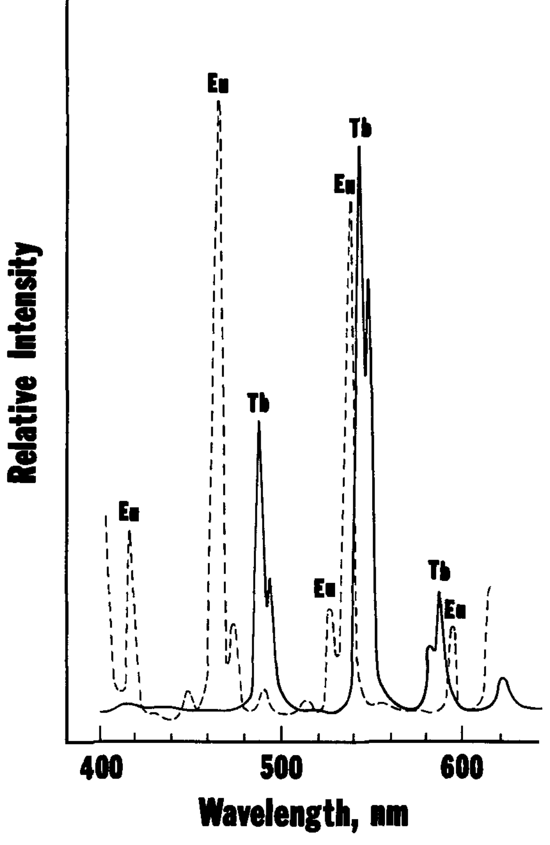

Fig. 4. Combined excitation spectrum of Eu in YVO_4 and the emission spectrum of Tb in YPO_4.

The enhancement of Eu^{3+} emission in YVO_4 by Tb^{3+} has been described. We believe that the same energy

transfer mechanism may apply here as suggested by Ropp for Tb^{3+} and Eu^{3+} in Y_2O_3.

A Scanning Electron Microscope Investigation of Glass Flow in MOS Integrated Circuit Fabrication

W. E. Armstrong and D. L. Tolliver*

Motorola Semiconductor Products Division, Phoenix, Arizona 85008

A formidable problem in the fabrication of multilayer metal bipolar integrated circuits and MOS circuits has been the discontinuity in metal interconnections over steep or even retrograde steps (1-3). These steps result from three primary sources: (*i*) metal or poly silicon interconnects which lie under an insulating oxide; (*ii*) thick oxide steps; and (*iii*) oxide windows or contact holes which have been etched open to allow connection between metal and an underlying surface. In a study of multilayer metallization problems, Santoro and Tolliver (4) outlined techniques for reducing step problems associated with deposited oxides over aluminum metal layers. One of the points presented in that work was "step profiling can result in ideal (metal) coverage even with non-ideal (oxide) deposition control." When profiles involve deposited oxides over steps other than etched aluminum metallization, new degrees of profiling steps are attainable. A method for controlling the profile steps resulting from deposition of oxide on MOS poly silicon interconnections was discussed in a recent work by C. T. Nabor (5). The profile control of oxide over poly silicon steps or etched oxide steps is achieved by doping the oxide to lower its softening point and annealing at a temperature above that point. This work reports on a study of related conditions that can be used to control oxide profiles in MOS integrated circuits. The effects of impurity concentration in the glass, time and temperature of the anneal, and annealing ambient on the step profile are investigated. The application of the technique to "contact window" steps as well as poly silicon steps is discussed.

Effects of Impurity Concentration

It has long been known that phosphorous oxide doping of vapor deposited glass films changes important chemical and physical properties. Among these properties are etch rate, thermal coefficient of expansion, and viscosity-temperature characteristics. The measurement of phosphorous concentration in this work is referenced to a diffusion technique, and utilizes a typical 10^{16} background p-type wafer. A minimum 6000Å phosphorous doped glass film is deposited on the surface. The wafer is then diffused for a sufficient time at 1100°-1200°C to achieve an easily measured junction depth in the order of 3-4μ. Using Irvin's curves (6), the surface concentration of the wafer is then calculated. Figure 1 is a set of scanning electron micrographs of the step formed when an 8000Å phosphosilicate glass film (6×10^{20} atom/cm^3) which corresponds to approximately 7 weight per cent (w/o) phosphorus is deposited over a 5000Å poly silicon step and subsequently annealed in nitrogen at 1050°C for times from 0 to 120 min. The flow becomes apparent first as a smoothing and restructuring of the oxide surface and eventually creates a new profile of the oxide step. In Fig. 2-5, the 8000Å phosphosilicate glass was deposited on a steep, recessed, 1μ oxide step. Note that very high phosphorous concentration (2.2×10^{21}) has such a low viscosity that it loses physical stability. In the last micrograph of each anneal time, the heavily phosphorous enriched layers have vigorously boiled off, so as to completely alter the pattern and partly vaporize it along with the highly volatile phosphorous oxide. There are, of course, many other problems with the use of such a film. These include: (*i*) The formation of strong acid due to the hydroscopic nature of heavily doped phosphosilicate glass. This phosphoric acid formed from low level moisture in room ambient with high glass phosphorous concentrations can attack aluminum metallization or cause photoresist layers to lift and make subsequent processing impossible. (*ii*) Solubility or corrosion in "cleaning acids" (*e.g.*, chromic or nitric acid) or even in water. The phosphorous concentration must be properly controlled to avoid attack by frequent immersions in integrated circuit cleaning and rinsing agents. (*iii*) Polarization under temperature-bias stress. Polarization of high concentration films under temperature bias stress can result in circuit failures caused by changing characteristics of parasitic devices. Fortunately, with proper stoichiometric control good step profiles can still be obtained by annealing lower concentration glass films.

Effects of Ambient and Temperature

The effects of different ambients are demonstrated in Fig. 6 and 7. Glass was deposited on a steep, 1μ oxide step and annealed at 1050°C. A comparison of these figures with Fig. 1 shows that for the given temperature, the viscosity is lowest for a steam ambient ("highest flow") and greatest for a nitrogen ambient ("lowest flow") with oxygen falling somewhere between the two. In Fig. 8, the same glass/step system was used to demonstrate the effect of annealing at lower temperature (1000°C). A comparison of Fig. 8 (1000°C) with Fig. 6 (1050°C) shows that the same profile can be achieved at lower temperature, but at the expense of a longer anneal time.

* Electrochemical Society Active Member.

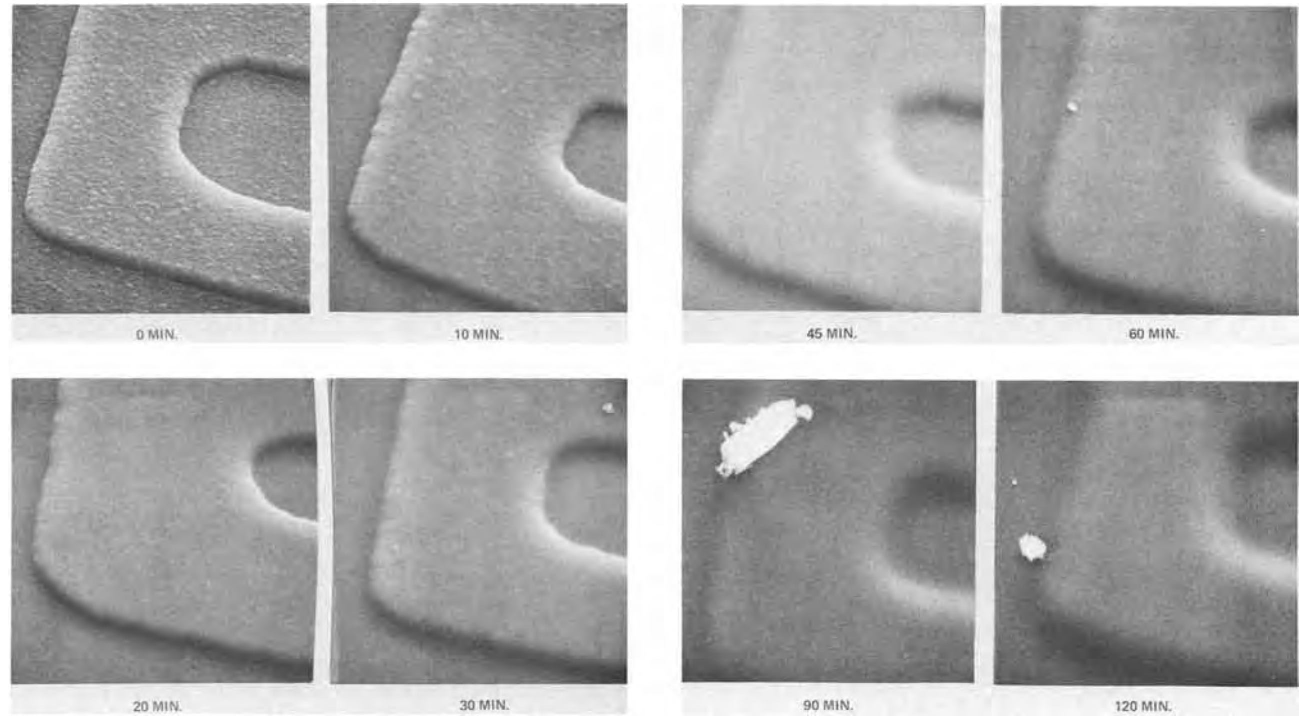

Fig. 1. 1050°C N_2 anneal of an 8000Å phosphosilicate glass film deposited over a 5000Å poly silicon step

Discussion

Figure 9 is a photomicrograph of a "contact window" etched in a 8000Å, phosphosilicate glass. With conventional metal evaporation, this step is typically steep enough to cause the microcracks shown in Fig. 9b. If the oxide window is annealed after the window is opened as in Fig. 9c, the step will be reprofiled and the microcracks will not appear. There are, of course, photoresist or deposition techniques which will cause the profile of the oxide to be improved as it is etched; but the profile is generally not as reproducible. However, these less reproducible techniques may still be more effective in cases where the anneal may cause other problems. For example, if the contact window opens into a P^+ diffused area, the area may be converted by phosphorous autodoping during the anneal.

Figure 9d shows the metal coverage achieveable when the glass film which isolates poly silicon from metal is profiled with a steam anneal. If this anneal were done after the contact windows were opened as just discussed, the steam anneal would grow an oxide in the windows. This oxide would then have to be etched out before metal could be evaporated. Even if the anneal is performed before the contact windows are opened, there are still several other

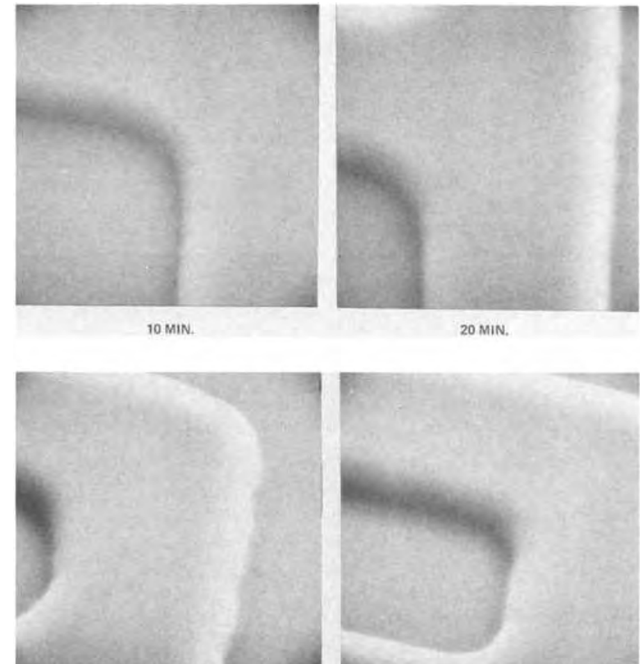

Fig. 6. 1050°C anneal of an 8000Å phosphosilicate glass film deposited over a steep, 1μ oxide step.

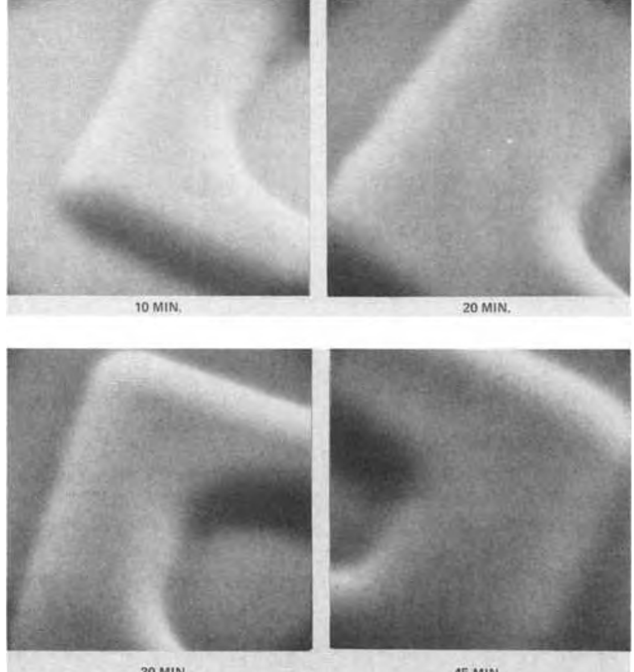

Fig. 7. 1050°C steam anneal of an 8000Å phosphosilicate glass film deposited over a steep, 1μ oxide step.

problems which must be considered: (*i*) the additional diffusion time (regardless of the ambient) will change the effective source-drain space as well as the space between unrelated diffusions; (*ii*) ambients such as steam or oxygen will change surface conditions and affect device or even parasitic thresholds; (*iii*) if the time required to achieve a given profile is shortened by increasing the phosphorous content of the glass, photoresist adhesion or film stability may suffer; and (*iv*) steam annealing of p-channel devices will result in hydrogen-aided boron diffusion through the gate oxide (thus reducing the threshold below desirable limits). In spite of these disadvantages, the technique is probably more widely used than might be expected from the amount of relevant information available in the literature. In many cases the authors believe advantageous profiles will be obtained during processing without direct intent to create them, by using deposited oxide films in conventional processing sequences.

Conclusions

It has been shown that an increase in the concentration of phosphorous in a vapor-deposited oxide can change the viscosity-temperature characteristics of the film to cause "flow" at temperatures as low as 1000°C. In addition, this oxide flow can be further enhanced by annealing the glass in oxygen or steam ambients rather than in inert gases. Finally, the technique was shown to improve step profiles as it was applied to (*i*) steps from poly silicon lying under the

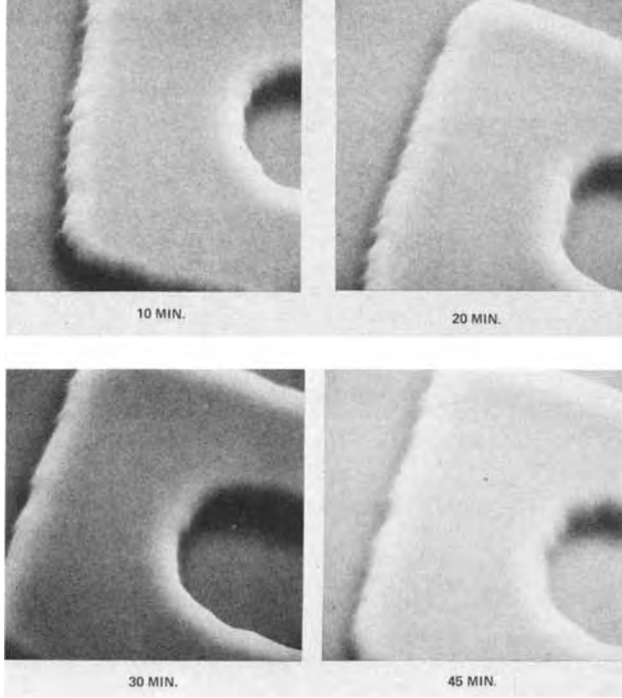

Fig. 8. 1000°C O_2 anneal of 8000Å phosphosilicate glass film deposited over a steep, 1μ oxide step.

phosphosilicate glass film, (*ii*) thick oxide steps, and (*iii*) "contact window" openings.

Germanium Surface Cleaning—An Auger Analysis

D. A. Kiewit,*,[1] I. J. D'Haenens, and J. A. Roth

Hughes Research Laboratories, Malibu, California 90265

A variety of methods have been used to clean germanium surfaces in order to insure the removal of lifetime killing impurities (*e.g.*, Cu) prior to high temperature processing. Much of the older literature recommends the use of cyanide solutions or chelating agents in the cleaning process, while more recent studies have suggested the use of basic and acidic peroxide solutions (1). We have used Auger electron spectroscopy to study several methods embodying both approaches, and have also measured the etch rates associated with some of these cleaning agents in order to assess their suitability for use with partially processed wafers containing thin doped regions For all the experiments reported here we used chemically polished, (111) oriented, 10 ohm-cm n-type germanium wafers.

Etch rates were measured on germanium wafers that were partially masked with Apiezon W wax, exposed to the cleaning solution for 10 min, stripped of the mask, and examined interferometrically to measure the etch step, if any. The results of these measurements appear in Table I and indicate a substantial etch rate for many of these cleaners. The data for the acidic peroxide solutions in particular, are in good agreement with etch rate studies made by Primak *et al.* (2) on germanium surfaces exposed to peroxide solutions of varying pH.

Most of the samples that were used in the subsequent cleaning studies were given an initial standard preclean consisting of boiling in xylene; washing in trichloroethylene, acetone, methanol, and deionized water; and cleaning first in $NH_4OH{:}H_2O_2{:}H_2O$ (1:1:5) and then in $HCl{:}H_2O_2{:}H_2O$ (1:1:5), for 1 min at 24°C. These samples were then rinsed in deionized water and blown dry with nitrogen. Following the preclean, each of these samples was subjected, for 1 min, to a variable cleaning step which is listed in Table I. With the exception of the sample cleaned with acetone (MA) which was blown dry immediately, all of these samples were subsequently rinsed in ten changes of deionized water and then blown dry with nitrogen. One other sample (FL) was not subjected to the standard preclean sequence, but was cleaned with trichloroethylene. acetone, methanol, and deionized water, soaked in HF,

rinsed in deionized water, and then blown dry. No intentionally contaminated samples were employed.

The organic solvents, HF, and disodium ethylenediamine-tetracetic acid (Na_2EDTA) were either reagent or electronic grade. The deionized water used for rinsing had a resistivity of at least 18 Mohm and was passed through both activated carbon and 0.22 μm particle filters prior to use. Pyrex labware, which has been previously noted as a source of boron contamination on silicon wafers (3), was used in all wet steps not employing HF. HF rinses were done in polypropylene beakers.

Within 2 hr after cleaning, the samples were loaded into a Physical Electronics Industries LEED/Auger system and pumped down to 10^{-8} Torr without bakeout. Auger derivative spectra were taken from each sample and plotted out automatically. These data are summarized in Table I, and representative Auger derivative spectra for samples STD, SC, and MA are shown in the figure.

The total list of elements present at detectable levels (*i.e.*, in excess of 10^{11}-10^{12} cm^{-2})[2] were: Ge, O, N, C, Ca, F, and P, although the last three named were seen only on some of the samples, as indicated in Table I. It should be noted that none of the common lifetime killers, such as copper, were found.

A fluorine contamination on the order of 10^{11}-10^{12} cm^{-2} was seen only on the samples that were washed in HF prior to water rinses. Kern (4), who used radiochemical tracer methods to study semiconductor cleaning methods, reported a fluorine contaminant level on germanium of about 10^{17} cm^{-2} immediately after HF immersion and about 10^{15} after a water rinse. The discrepancy of three orders of magnitude between our results and his may be due to differences in the final washing procedures, faster desorption of the residual fluorine *in vacuo*, or to electron desorption of the fluorine by the Auger primary beam. [Chou *et al.* (5), for example, have recently reported electron desorption of halides during Auger studies.] Sample MA, which was washed with methanol and acetone after an immersion in HF, did not show a detectable level of fluorine contamination. This agrees with Kern's observation that acetone is very effective in desorbing fluorine.

Calcium was noted only on samples STD and SC for which the variable cleaning step employed an acidic peroxide solution, and phosphorus was found only on sample MA which had a final acetone rinse. The Auger spectra from these three samples are given in Fig. 1. Both the phosphorous and calcium impurities are believed to be due to reagent contamination.

The use of chelating agents and cyanide leads to changes in the amounts of carbon and oxygen that

[2] Estimated on the basis of an Auger sensitivity of ~1% of a monolayer.

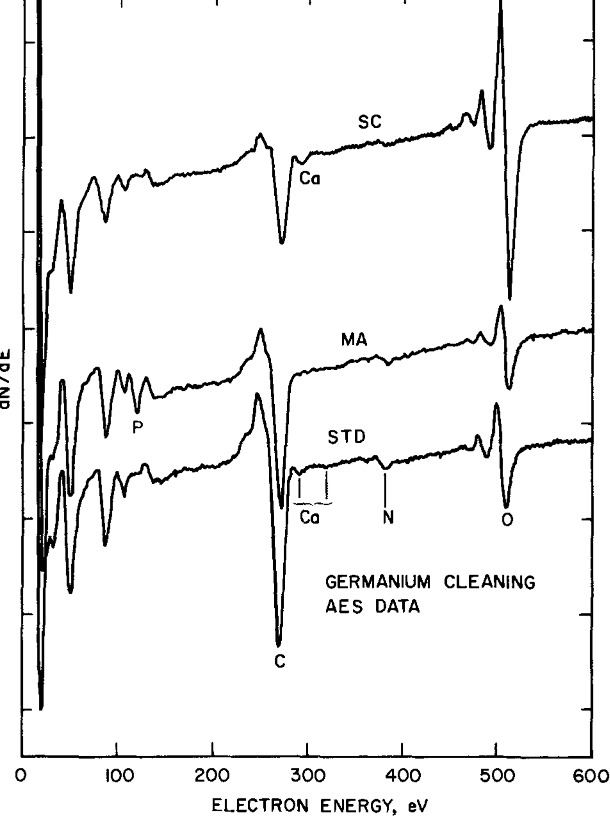

Fig. 1. Auger derivative spectra for Ge samples STD, SC, and MA

were observed on the surfaces. These treatments decreased the carbon level by about 1/2 and/or increased the oxygen concentration to about 3 or 4 times the value otherwise observed, as may be seen from Fig. 1 by comparing the spectrum from sample SC with those from samples STD and MA. These effects could be due to the formation of an oxide film, to increased water adsorption, or to decreased hydrocarbon contamination.

We conclude that for many applications, such as the in-process cleaning of germanium devices containing thin doped regions, germanium cleaning methods that employ either concentrated cyanide solutions or acidic peroxides are of limited utility due to concomitant etching. The recommended procedure, when etching is to be avoided, is to employ organic solvents to remove gross contaminations such as wax residues, and to then use a chelating agent such as EDTA.

Brief Communications

Comments on the Article "On the Theory of Thermal Quenching of Luminescence" by H. Payen de la Garanderie and D. Curie

R. Pappalardo

GTE Laboratories Incorporated, Waltham, Massachusetts 02154

Fluorescence, as the radiative deactivation of an excited species (atom or molecule) is one of several deactivation paths. Other decay processes involve instead of atom-photon interactions the coupling of the excited species with the phonon field (nonradiative deactivation). The increase in system temperature, by enhancing the phonon field favors in general the nonradiative relaxation to the expense of the radiative process. This adverse effect of temperature on the fluorescence properties of an emitting species can be quite important to the design of new gas lasers (1) and high-temperature phosphors.

In the case of vapors of "complex" aromatic molecules, the operating temperature (150°-250°C) of the envelope of the discharge tube is expected to favor intersystem crossing (2), by comparison with the situation existing at room temperature in dye-solution lasers. For longer lived emitting species in solid matrices, the temperature increase raises the probability of multiphonon relaxation and of potential-curve crossing.

In view of the commonly adverse effect of temperature on fluorescence, it was of considerable interest to find in the literature statements to the effect that the fluorescence intensity can be enhanced by temperature increases.

Payen de la Garanderie and Curie (3) consider a common, simplified model of an activator center as characterized by potential curves for the ground and excited electronic state and conclude, within the framework of the model used, that the radiative intensity I_r is not a constant quantity, but that on the contrary "it increases with increasing temperature." The physical reason for this effect is identified as follows: "the effective number of states leading to a light transition increases with temperature."

The conclusion that I_r increases with temperature would be quite pertinent to the area of high-temperature phosphors. Our contention is that the conclusions reached by the two authors are erroneous, as it will be shown in what follows.

The model for the activator center used by Payen de la Garanderie and Curie is now briefly summarized. The ground and excited electronic states are described by potential curves with vibrational levels characterized in the excited electronic state by a regular energy spacing $h\nu_e$. Excitation from the ground state is assumed to lead to the j_o vibrational level of the excited state, located at $E_{j_o} = j_o h\nu_e$ above the corresponding potential minimum. The over-all pumping intensity to j_o is characterized by a constant term q.

Single-phonon processes in the excited electronic state are responsible for a fast redistribution of the population among the vibrational levels, in times that are much shorter than the radiative deactivation. A quasi-Boltzmann distribution of population over the vibrational levels ensues. The radiative transition probability p is assumed constant for all vibrational levels j. A very fast radiationless deactivation occurs at energy $j_1 h\nu_e >> j_o h\nu_e$.

The authors then proceed to calculate the over-all intensity of radiative emission I_r, assuming a Boltzmann distribution for the vibrational levels of the excited state, and they find

$$I_r = pn_o \frac{1 - e^{-j_1 h\nu_e/kT}}{1 - e^{-h\nu_e/kT}} \sim pn_o \frac{1}{1 - e^{-h\nu_e/kT}} \quad [1]$$

n_o being the population of the lowest vibrational level of the excited electronic state. The factor multiplied by pn_o reflects a population summation carried over the levels not affected by radiationless deactivation, using the condition that $j_1 h\nu_e >> kT$. The authors point out that on increasing T the value of I_r increases, in particular at the Debye temperature $kT = h\nu_e$ one has $I_r = 1.58\ pn_o$.

Our criticism is as follows. Given a constant pump intensity q and a radiative transition probability p which is constant over the vibrational levels considered, I_r should not be affected by the vibrational distribution of the population. The only conceivable effect resulting from a temperature increase is an enhanced contribution of the radiationless deactivation, resulting in a decrease of I_r.

The authors assume implicitly in the expression for I_r shown above, that n_o will remain constant with variations of the temperature. This is of course physically meaningless. Equation [1] cannot be used because its derivation is based on a wrong normalization constant. The vibrational-level populations n_j have in effect been expressed in terms of n_o, the population of the lowest vibrational level in the excited manifold. An expression of this type is only appropriate when ratios of population are considered. As soon as absolute values of population come into play, the normalization constant should contain the total population, which in this case is expressed by the constant pump term q. If the vibrational level populations are expressed as

$$n_j = \frac{q}{\sum_{j=0}^{j_1} e^{-jh\nu_e/kT}} e^{-jh\nu_e/kT} \quad [2]$$

instead of Eq. [1], one finds

$$I_r = pq \quad [3]$$

as intuitively anticipated. The conclusion that I_r increases with temperature is unacceptable.

Key words: luminescence, temperature dependence, theory.

A Flux Step Boundary Condition Solution to the Diffusion Equation Corresponding to the Error Function Complement Profile

M. A. Fullenwider*,[1]

B-B Laboratory, Carlisle, Pennsylvania 17013

One of the solutions of the diffusion equation

$$\frac{\partial C}{\partial t} = D\frac{\partial^2 C}{\partial x^2} \qquad [1]$$

which is basic to semiconductor diffusion is the error function complement profile (1)

$$\frac{C(x,t)}{C_o} = \text{erfc}\,\frac{x}{2(Dt)^{1/2}} \qquad [2]$$

where x is the distance into a semi-infinite specimen, t is the time of diffusion, $C(x, t)$ is the concentration at x and t, C_o is the maximum concentration within the specimen, constant in Eq. [2], and D is the diffusion coefficient. This solution is based on the simple boundary conditions for the diffusion equation

$$C(x,t) = 0, \qquad x \to \infty \qquad [3]$$

$$C(x,t) = 0, \qquad t = 0 \qquad [4]$$

$$C(0,t) = C_o, \qquad t > 0 \qquad [5]$$

Now Eq. [5] which corresponds to a step function in concentration at $x = 0$ and for times greater than zero is a carry-over from the theory of heat conduction where no other condition would be reasonable under these circumstances.

In the flux of matter (diffusion), however, there is the possibility of another condition which will replace Eq. [5]. It is that of a flux step at $x = 0$

$$-D\left(\frac{\partial C}{\partial x}\right)_{x=0} = j, \qquad t > 0 \qquad [6]$$

where j is the time constant flux at the surface due to kinetic control of a chemical nature, and where it has been assumed that the quantity of diffusing substance available to the surface is constant.

It is the purpose of this paper to show that this boundary condition and solutions resulting from it, different from Eq. [2], will produce concentration profiles which, with the exception of the value of the diffusion coefficient and behavior as a function of time, are very similar to Eq. [2].

Recent work (2) with the hydrogen-palladium system has shown that Eq. [6] obtains for diffusion through thin membranes as according to the analysis of Schmidt and Siegenthaler (3). This was a new and previously unsuspected result for the system. Rate limited diffusion of impurities into semiconductors has been reported previously (4-6) for the case of rate limitation due to a physical barrier at the surface. Of the two cases, physical and chemical rate limitation, the first is probably the more general since it may be applied to such nonchemical situations as, for example, diffusion through an impeding film into a substrate. However, expressions derived from considerations on the second case (where it applies) are simpler and involve fewer parameters, and where both might apply, it can be difficult to distinguish between them experimentally.

From Eq. [1], [3], [4], and [6] with the method of the Laplace transformation we obtain

$$C(x,t) = 2j\left(\frac{t}{\pi D}\right)^{1/2} e^{-x^2/4Dt} - j\frac{x}{D}\,\text{erfc}\,\frac{x}{2(Dt)^{1/2}} \qquad [7]$$

or

$$C(x,t) = 2j\left(\frac{t}{D}\right)^{1/2} i\,\text{erfc}\frac{x}{2(Dt)^{1/2}} \qquad [8]$$

and since

$$C(0,t) = C_o = 2j\left(\frac{t}{\pi D}\right)^{1/2} \qquad [9]$$

we have

$$\frac{C(x,t)}{C_o} = e^{-x^2/4Dt} - \frac{x}{2}\left(\frac{\pi}{Dt}\right)^{1/2} \text{erfc}\,\frac{x}{2(Dt)^{1/2}} \qquad [10]$$

Figures 1 and 2 show plots of Eq. [2] and [10], respectively, for identical times and diffusion coefficients. The curves of Fig. 2 can be seen to lie well below those of Fig. 1. However, simply dividing the diffusion coefficient of Eq. [2] by a factor of 1.7 results in curves which are very similar (see Fig. 3). Thus the mistaken use of Eq. [2] where Eq. [10] applies will result in an error in the estimation of the diffusion coefficient of a factor of 1.7.

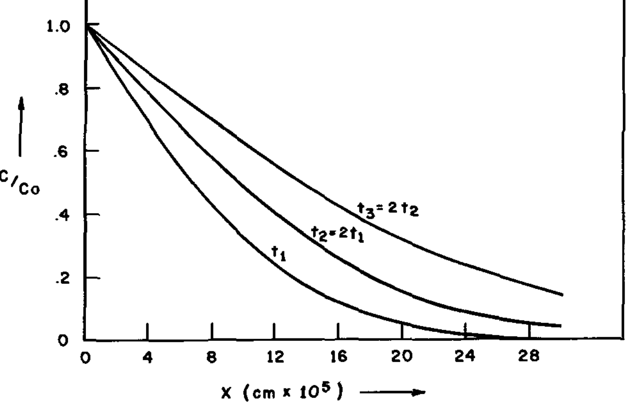

Fig. 1. $C(x,t) = C_o\,\text{erfc}\,\frac{x}{2(Dt)^{1/2}}$

[1] Present address: 2970 MacArthur Road, Whitehall, Pennsylvania 18052.

Key words: error function complement profile, flux step boundary condition, concentration dependent diffusion, semiconductor diffusion.

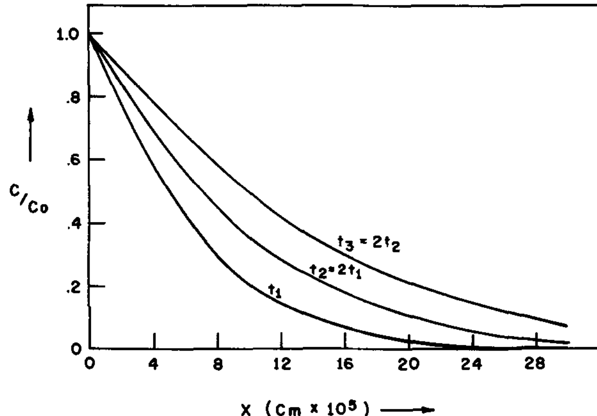

Fig. 2. $C(x, t) = C_o\left[e^{-x^2/4Dt} - \frac{x}{2}\left(\frac{\pi}{Dt}\right)^{1/2} \text{erfc}\,\frac{x}{2(Dt)^{1/2}}\right]$

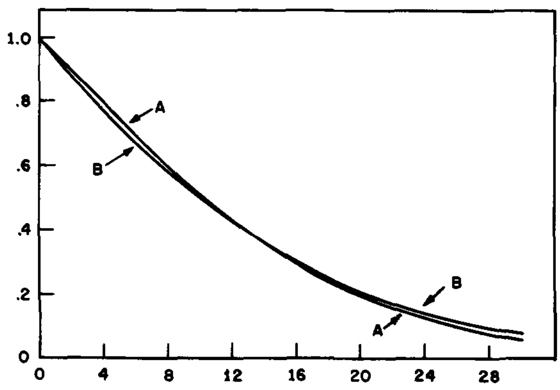

Fig. 3. A, $C(x,t) = C_o \text{ erfc } \frac{x}{2\left(\frac{D}{1.7}t\right)^{1/2}}$. B, $C(x,t) = C_o\left[e^{-x^2/4Dt} - \frac{x}{2}\left(\frac{\pi}{Dt}\right)^{1/2} \text{erfc}\,\frac{x}{2(Dt)^{1/2}}\right]$.

Experimentally the two cases can be distinguished simply by comparing profiles for the same system at different values of t, since the C_o of Eq. [10] should have the time functionality of Eq. [9], if it applies. A diffusion coefficient should never be assigned to a system from analysis of a single profile.

Another point is that eventually equilibrium must be established at the interface, since C_o of Eq. [9] cannot, of course, go to infinity. At equilibrium, Eq. [5] will apply. At small times for a system Eq. [6] will always apply, and the rate at which equilibrium is established will depend upon the magnitude of j. If the time to equilibrium is finite, however, the system will have obeyed Eq. [10] during this time interval, and the final result will not be Eq. [2], but a combination of Eq. [10] and [2]. This behavior could easily be mistaken for concentration dependent diffusion, *i.e.*, if Eq. [2] were to be used for all times D would appear to increase with time after equilibrium had been established.

It is of interest to compare these expressions with those for physical rate limitation. The expression similar to Eq. [9] is (5)

$$\frac{C_o}{C_e} = 1 - e^{K^2t/D} \text{erfc } K\left(\frac{t}{D}\right)^{1/2} \quad [11]$$

where C_e is the equilibrium concentration within the substrate, a constant, and K is a rate constant defined in terms of transport across a physical barrier. Also for the concentration profile (5)

$$\frac{C(x,t)}{C_e} = \text{erfc}\,\frac{x}{2(Dt)^{1/2}} - e^{(Kx+K^2t)/D}\,\text{erfc}\left[\frac{x}{2(Dt)^{1/2}} + K\left(\frac{t}{D}\right)^{1/2}\right] \quad [12]$$

Nonaqueous Lithium-Bromine Secondary Galvanic Cell

J. L. Weininger* and F. W. Secor

General Electric Corporate Research and Development, Schenectady, New York 12301

ABSTRACT

A nonaqueous secondary cell consists of a negative lithium electrode and a positive bromine electrode. This combination is made possible by the use of an ultrafine, porous polyethylene separator. It reduces the diffusion of bromine to the lithium electrode to tolerable levels. The cell was tested with 90 min charge-discharge cycles. Based on the utilization of lithium deposited on the anode, the current efficiency was 90% for the first 100 cycles, 70% up to cycle 300, and above 30% for the duration of the cell life of 1785 cycles. Self-discharge was sufficiently slow so that an open-circuit stand up to 2 hr did not show appreciable loss of charge. The over-all cell mechanism is complex. It consists of the interaction of the electrode reactions, the propylene carbonate solution properties, and the effect of the porous separator. Within this framework a bromine shuttle mechanism has been identified which explains the long life of the cell in spite of a small but measurable self-discharge.

In recent years many attempts have been made to extend battery technology to nonaqueous solvents in order to take advantage of the high-energy density inherent in the use of alkali and alkaline earth metals (1). Lithium is generally recognized as the most satisfactory material for the negative electrode (anode on discharge) in a nonaqueous cell. Although there remain some problems in its use, the phenomenology, if not the state-of-the-art, of a lithium electrode is equivalent to that of other metal electrodes in aqueous systems; for example, zinc in alkaline solution. Until now, however, there has not been a satisfactory material for the positive electrode (cathode on discharge) which is to be paired with the lithium electrode in a rechargeable cell.

The difficulties encountered with cathode materials are lack of complete and repeated utilization of conventional electrodes as well as lack of chemical compatibility and their increased electrical resistivity in the organic environment.

Halogens have been frequently proposed as cathode materials in fuel cells and galvanic cells. Their application failed because of their chemical reactivity with materials of construction (for example, the separator) and with the counterelectrode, resulting in self-discharge. Homogeneous ion-exchange membranes can be used, but failed in nonaqueous solvents because of their greatly increased resistivity.

We have set as our goal the application of a halogen electrode to the lithium nonaqueous system, and we now describe below the mechanism, design, and performance of a lithium-bromine cell.

Mechanism of the Cell

Figure 1 is a schematic diagram of the cell. The negative electrode is an inert nickel substrate on which lithium is alternately deposited and discharged while bromine undergoes the electrode reactions at a positive porous carbon electrode. The tribromide ion is much more stable in the organic solvent, propylene carbonate (PC), than in water. Lithium bromide and lithium perchlorate are added as solutes, as shown in the diagram.

During operation of the cell, the lithium couple Li/Li^+ undergoes reversible electrode reactions with fairly high exchange currents. The four reactions in which the bromide species participate involve only relatively small overvoltages so that very large cell voltages can be obtained from the electrode reactions

$$Li^+ + e \rightleftharpoons Li \qquad E^\circ\ (vs.\ Ag/AgBr) = -2.67V \qquad [1]$$

$$Br_2^- + 2e \rightleftharpoons 3Br^- \qquad E^\circ\ (vs.\ Ag/AgBr) = +1.15V\ (approx.) \qquad [2]$$

$$3/2Br_2 + e \rightleftharpoons 2Br_3^- \qquad E^\circ\ (vs.\ Ag/AgBr) \doteq +1.38V \qquad [3]$$

Combination of reactions [1] and [2] gives a cell voltage of 3.82V and a theoretical energy density of 320

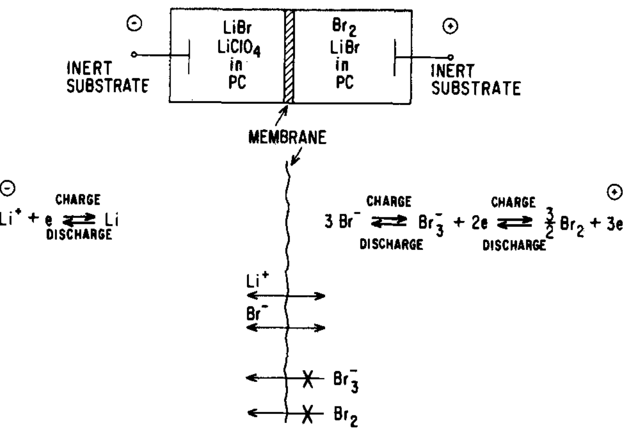

Fig. 1. Schematic of lithium-bromine cell

Key words: electrochemistry, nonaqueous batteries, lithium anodes, halogen electrodes, propylene carbonate solvent.

Whr/lb; combination of reactions [1] and [3] increases the initial open-circuit voltage to 4.05V and the theoretical energy density to 504 Whr/lb. In practical use, voltages close to the theoretical values are obtained on open circuit and during discharge. As for the energy density, only a small fraction of the theoretical value is realized in the present cell which is designed for developmental purposes and not for maximizing energy density.

The use of bromine at the positive electrode takes advantage of favorable electrode potentials and kinetics. The control of the rate of the electrode reaction is changed from ionic diffusion in a solid, as in AgCl/Ag or CuF_2/Cu electrodes, to diffusion control in the solution. The greater solubility of bromine in the organic solvent is important in two respects: it increases the available electroactive material in dissolved form, and it also reduces the chemical attack of bromine on the materials of cell construction. The single, most important disadvantage in the use of bromine is its reaction with lithium. As indicated in Fig. 1, the self-discharge of the cell by the tarnishing reaction must be avoided; the oxidized bromine species, Br_2 and Br_3^-, may not enter the negative electrode chamber.

The early part of this study was therefore concerned with a search for a barrier for dissolved and solvated bromine molecules. When a porous Vycor glass disk with pore diameters of 60Å was used as a separator in a lithium-bromine cell (2) diffusion of Br_2 or Br_3^- was prevented. This was attributed to the relatively large size of the solvated complexes of Br_2 and Br_3^- with propylene carbonate. The literature contains information on a variety of stable molecular complexes of the alkali metal salts of polyhalide anions, *e.g.*, in benzonitrile $KI_3 \cdot 2C_6H_5CN$ and $LiI_3 \cdot 4C_6H_5CN$ (3). The bromine species were therefore expected to complex in propylene carbonate, but the extent to which this would retard bromine diffusion remained to be seen.

The present cell has an ultrafine, porous polyethylene membrane (4) which prevents most of the bromine diffusion. It has about 50% porosity and an average pore size of 40-120Å. The limited migration of Br_2 and Br_3^- can be tolerated, provided the cell is not required to stand on open charge for more than a few hours. This is predicated on a shuttle mechanism similar to those occurring in aqueous battery systems. The tarnishing of the lithium electrode is controlled by the diffusion of the bromine species to the lithium. This results in self-discharge with LiBr as the product, identical to the product of the galvanic cell reaction. Therefore, as the LiBr concentration increases in the solution contained in the negative electrode compartment, it saturates that solution. The chemical concentration gradient with respect to the positive compartment (bromine electrode) produces the back diffusion of bromide ions. This completes the shuttle. In the present cell, the process is slow enough so as not to decrease unduly the current efficiency of the cell.

Cell Composition

Different cell designs and variations in the concentration of the cell components have been tested. Preliminary experiments were performed with small cells having 2.54 cm diameter electrodes. Life tests were performed on larger cells, for which only one of twelve tests is reported here. The following cell was used $\ominus$ Li(Ni foam)/0.2M LiBr + 0.8M $LiClO_4$ in PC/UF polyethylene membrane/1.5M Br_2 + 1.6M LiBr in PC/porous C $\oplus$

Electrodes.—Figure 2 is a sketch of the external view and cross section of the cell. Nickel and carbon were used as inert electrodes. The anode was Foametal® nickel, a 95% porous metal structure, prepared by the Metallurgical Products Department, General Electric Company. The porous carbon cathode was made of material supplied by the Pure Carbon Company. It was a fuel cell grade (FC-22) carbon with 60% porosity, a surface area of 600 m^2/g, and a median pore diameter of 11 μm.

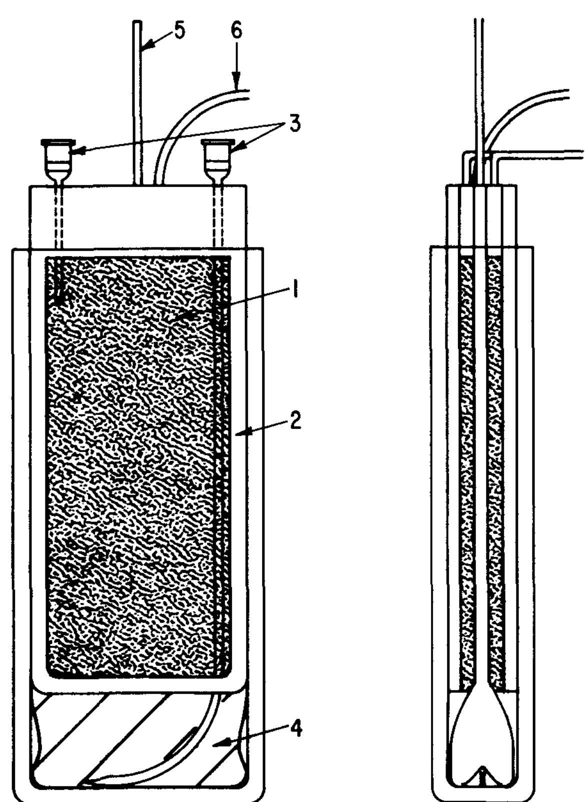

Fig. 2. External and cross-sectional view of lithium-bromine cell. 1, Porous carbon cathode; 2, PTFE cathode frame; 3, PTFE syringes for filling and venting; 4, UF polymer separator bag; 5, anode; 6, Ag/AgBr reference electrode.

A brominated silver wire was immersed in the anode chamber as a reference electrode. This gives a potential sufficiently stable to determine the polarization of the respective electrodes. However, the Ag/AgBr couple is not stable in the solution containing bromine (cathode chamber) because AgBr is slightly soluble due to the formation of the $AgBr_2^-$ complex.

Solvent.—The distillation of propylene carbonate is run continuously for about 80 hr in a glass column packed with 1 in. diameter stainless steel helices at a pressure of 26.5 mm and boiling point of 120°C. During the first stage the column is on total reflux for 1 hr. Then the first 10% cut, approximately 300 cm^3, is discarded. This is followed by the sample collection. After each cut the material is poured directly from the still into a molecular sieve (Linde 5A) column. It is then allowed to stay for more than 16 hr over the molecular sieve until it is placed in the oven-dried receiver at 50 drops. Before use, the molecular sieve is heated to 220°C for 36 hr under nitrogen flow and cooled with nitrogen. It is used for two consecutive distillations before it is discarded. This procedure yielded solvent free of water at the limit of detection of vapor phase chromatography (less than 10 ppm).

Solute.—Lithium bromide and lithium perchlorate were recrystallized and vacuum dried. The active cathode material, bromine, was used as-received. The concentrations were chosen for convenience and not for maximum conductivity. In the anode chamber, $LiClO_4$ was added to the solution to bring the Li^+ ion concentration up to 1M. In the cathode chamber the bromine concentration was less than that of LiBr so as to have almost all of Br_2 complexed as the tribromide. This increased the chemical stability of the system.

The conductivity could be increased, first of all, by addition of other solutes such as $LiBF_4$. For the given system LiBr + Br_2 in PC the conductivity and solu-

bility of the electrolyte are illustrated in Fig. 3. One curve represents the conductivity of the solution, saturated with LiBr, as a function of Br_2 concentration. The numbers of the data points of the curve represent the molarity of saturated LiBr corresponding to the given Br_2 concentration. Thus at the maximum conductivity of 0.0083 mho/cm the concentrations are 2.23*N* (1.115M) Br_2 and 1.17M LiBr. For the solution used in the cathode compartment the conductivity is 0.0067 mho/cm. In the absence of bromine the solubility of LiBr in PC is limited to 0.203M. Other and larger values reported in the literature can be attributed to the probable presence of water in those systems. If bromine is added to the 0.2M LiBr solution without further addition of LiBr the lower conductivity curve of Fig. 3 is obtained.

During the lifetime of the cell, the initial concentrations will undergo substantial changes in the two compartments. Except for the presence of bromine in the cathode chamber and the existence of the bromine-bromide shuttle, described above, the supporting electrolyte will tend to equalize in the two compartments. Because of the shuttle, the anode chamber will be saturated with LiBr and provisions must be made to accommodate some precipitated LiBr in that compartment.

Separator.—The porous 0.01 cm thick polyethylene was heat-sealed to form a bag containing the lithium electrode. This membrane material was characterized by a porosity of 43%, a flow rate of nitrogen per cm^2 at 5.6 and 65.6 psi of 1.2 and 4.0 ml/min/cm^2, and a conductivity of 0.76×10^{-3} mho/cm when filled with 1M KCl in water.

Cell Performance

The cell was tested in 90 min cycles with charge-discharge times divided into 60:30, 42:48, and 48:42 min half cycles. Constant current levels of 30-100 mA were used, which corresponded to charge transfer of 252-360 coulombs on charge and 108-324 coulombs on discharge (the electrode dimensions were 10.4×4.2 cm, resulting in a current density of 1.15 mA/cm^2 equivalent to 100 mA). Occasionally steady-state current voltage measurements were made. These were carried out at different points in the cycle and reflected the relative state of charge of the cell. Simultaneous measurements of the individual electrode potentials with respect to a Ag/AgBr reference electrode indicated the sources of overpotential.

Figure 4 shows several current-voltage curves. Symbols C and D indicate whether these steady-state measurements, which include both charging and discharging conditions, were actually made at a time when the cell was nearly fully charged or discharged. Curves C53 and D67 are typical polarization curves for about the first hundred cycles when there was little polarization due to activation and diffusion control. The slope of about 5 ohms was indicative of the electrolyte and membrane impedance. This is also reflected

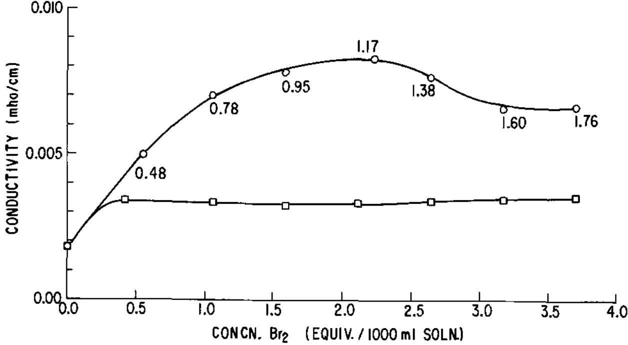

Fig. 3. Conductivity of bromine-containing solution of propylene carbonate as a function of bromine and lithium bromide concentration. □, 0.2M LiBr solution; ○, solution saturated with LiBr.

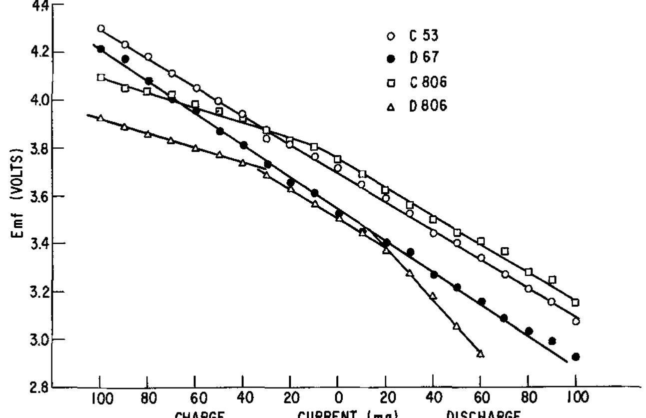

Fig. 4. Current-voltage curves for lithium-bromine cell. C53 at end of charge, cycle 53; D67 at end of discharge, cycle 67; C806 and D806 at end of charge and discharge of cycle 806.

in the constant-current cycling discussed below. At cycle 806, curve C806 indicates an equally good cell capability at end of charge (start of discharge). The reason for the change in slope (to 3 ohms) for the charging part of the *i-E* curve is not known. It may be due to the presence of nickel ions in solution, lowering the potential of the lithium electrode, or to a change in the electrolyte concentration in either the anode compartment or in the membrane due to the operation of the bromine shuttle. On the other hand, D806 shows considerable polarization during discharge of a nearly discharged cell. Here both electrodes are under diffusion and activation control, resulting in a slope for the *i-E* curve of about 12 ohms. This is brought out more clearly in Fig. 5 where the individual cell potentials are shown for comparable conditions during cycle 1017.

Constant-current cycling of the cell was followed by observing the cell voltage as a function of time at various stages in the life of the cell, during charge and discharge cycles, and with different current levels and ratios of time at charge and discharge. Consequently, the depths of discharge were also varied.

Originally there was no bulk lithium present and all of the lithium deposited in one cycle on the inert nickel foam substrate could be discharged in the same cycle, subject only to aging and deterioration of the cell. With incomplete discharge, the active electrode mate-

Approx. % utilization	90	70	30

rials, lithium and bromine, are not completely used up and create activation and diffusion barriers in subsequent charge. The actual utilization of lithium, which was in limited supply, given as the percentage of charge recovered on discharge, was a function of cycle life. Approximate values which depend on the lithium electrode, are shown in Table I.

Deep discharge cycles, or even current reversal, had no deleterious effects on the cell. Cycle 917 showed complete discharge of the lithium electrode. Cycle 918 even reversed polarity. Significantly, this improved the charge acceptance and discharge of the following cycle.

The effect of open-circuit stand on the cell was also tested. The cycling regime was changed for cycles 222-230 to a 60 min, 90 mA charge half-cycle and a 30 min 90 mA discharge half-cycle. The discharge was interrupted after 15 min and the cell was left on open circuit for various times: 10, 30, 60 min, 2 hr, and overnight (8 hr and 40 min). Only in the last case was there a noticeable effect due to open-circuit stand. On other occasions the cell was left on open circuit for several days, in which case the cell self-discharged but readily accepted a fresh charge and showed good subsequent performance.

After a final open-circuit stand of 6 days after cycle 1785 the cell failed to accept reasonable charge. Its life, therefore, was 1785 cycles, in almost continuous operation over a period of 4 months.

Conclusions

A lithium-bromine cell can be repeatedly charged when an ultrafine, porous separator is used. The separator retards the diffusion of bromine to the lithium electrode, thereby allowing a short open-circuit stand in the charge condition.

The mechanism of the cell is understood in general terms. The long cell life could only be achieved because of the bromine shuttle. However, the individual electrode reactions have not yet been elucidated nor is the cell mechanism completely understood in terms of the presently found cell polarization.

The cell design is convenient for testing lithium anodes with nickel metal foam substrates, UF membranes as separators, and porous carbon cathodes. It made no pretention at achieving high-energy density. The latter will require a careful balance of active materials and inert electrode substrates. In the present case bromine was kept in excess so that the utilization or current efficiency reported above refers to the lithium electrode. This is justified by the smaller chemical stability of the lithium electrode in spite of its higher rates of electrode reactions, as compared with the lower rates and less reversible kinetics of the bromine electrode. In fact, after 4 months of operation, the bromine electrode was still completely serviceable, whereas the lithium electrode in the form of a deposit on the nickel metal foam had partly disintegrated.

Redox Couple Behavior on Lithiated Nickel Oxide Electrodes

Dennis M. Tench*,[1] and Ernest Yeager*

Chemistry Department, Case Western Reserve University, Cleveland, Ohio 44106

ABSTRACT

The rotating electrode technique has been used to study the kinetics of various redox couples [$Fe(CN)_6^{4-}/Fe(CN)_6^{3-}$, Fe^{2+}/Fe^{3+}, Cr^{2+}/Cr^{3+}, and quinone/hydroquinone] on mosaic lithiated nickel oxide electrodes in sulfate solutions. At potentials cathodic to the flatband potential, the redox reactions are very inhibited. At potentials anodic to the flatband potential, the oxidation of the ferrocyanide ion exhibits a transfer coefficient of $\alpha = 1/2$ with an apparent standard rate constant approximately two orders of magnitude smaller than on Pt. The other couples exhibit abnormal transfer coefficients under these conditions, probably because of specific adsorption on the oxide electrode surface.

The kinetics of various redox reactions have been examined on lithiated mosaic nickel oxide electrodes with the objective of comparing the behavior of these couples on this compound semiconductor with that on metals. With NiO(Li) electrodes, the heterogeneous electron transfer is expected to involve rather localized valency states within the electrode phase [*i.e.*, $Ni^{2+}(3d^8)$ and $Ni^{3+}(3d^7)$] rather than the wide bands involved with metal and some other semiconductor electrodes.

The electronic properties of NiO(Li) have been discussed by various authors [see, *e.g.*, Ref. (1) and (2)]. Although the conduction process appears to involve a narrow valence band carrier mechanism, the band width may still be sufficiently narrow that the electron transfer across the interface can be reasonably well approximated as involving localized valency states within the electrode phase.

Information concerning the potential distribution at the semiconductor-electrolytic solution interface is a

Key words: nickel oxide electrodes, semiconductor electrochemistry, redox couples, electrode kinetics.

prerequisite to redox kinetic studies at such interfaces. In earlier work (3) the charge and potential distributions at the NiO(Li)-sulfate electrolyte interface were examined using a-c impedance measurements. At potentials more than ~0.5V cathodic to the voltammetry peak at 1.00-0.059 pH volts re SHE [designated as peak I in Ref. (3)], linear Mott-Schottky plots (see Appendix) were obtained, indicating that virtually all of any change in electrode potential occurs across the space charge region within the semiconductor. Peak I is attributed to the Ni^{2+}-Ni^{3+} surface reaction and hence is attended by a large change in surface charge. As the potential becomes more anodic, an increasing fraction of any electrode potential change occurs across the Helmholtz region. At potentials anodic to peak I virtually all of the potential change occurs across this region. Under these circumstances the redox kinetics would be expected to approach those on metal electrodes except for possible differences in the free energies of activation arising from the involvement of localized valency states in the electrode phase.

Earlier workers (4, 5) have examined the kinetic behavior of redox couples on NiO(Li). Rouse and Weininger (4), using chronopotentiometry, reported apparent Tafel slopes for the ferro-ferricyanide couple on mosaic NiO(Li) which varied between 69 and 153 mV/decade for Li concentrations of 0.21-2.74 cation % Li in sulfate solutions of pH ~ 3 even at potentials where electrode potential changes should be almost entirely across the Helmholtz region. Yohe *et al.* (5), using the rotating disk technique, found values of the Tafel slope for this couple which increased with rotation rate (*e.g.*, for $5 \cdot 10^{-3}$M $Fe(CN)_6^{3-}$-$5 \cdot 10^{-3}$M $Fe(CN)_6^{4-}$ in 0.5M K_2SO_4, the anodic Tafel slope increased from 90 mV/decade at 64 rpm to 220 mV/decade at 6400 rpm). This effect was attributed by Yohe *et al.* to the series contribution of the potential drop associated with the back electrical contact to the NiO(Li). As the rotation rate increased and the current becames higher, more of the potential drop occurred at the back junction of the crystal, rather than just at the semiconductor-solution interface, and the Tafel slope increased. The electrical contacts used in the earlier work of Yohe *et al.* and also that of Rouse and Weininger (cured Ag epoxy resin) appear to be unsatisfactory for measurements of this kind with NiO(Li) electrodes.

The fused Ag electrical contact used in the present work has eliminated this problem. With this contact the Tafel slopes did not vary with rotation rate, when ohmic losses within the NiO(Li) electrodes were negligible and the kinetics were principally under charge transfer control at potentials anodic to voltammetry peak I.

For a redox reaction involving surface p carriers (p_s)

$$A + p_s \rightleftarrows C$$

the kinetics may be represented as follows (6)

$$i = i_o \cdot \left[\frac{i_a - i}{i_a} \exp f(\alpha \Delta\phi_H + \Delta\phi_S) - \frac{i_c + i}{i_c} \exp - f\beta\Delta\phi_H \right] \quad [1]$$

where α and β are the anodic and cathodic transfer coefficients, $\Delta\phi_H$ and $\Delta\phi_S$ are the contributions to the overpotential from the potential drops across the Helmholtz layer and semiconductor space charge region, respectively; i_a and i_c are the anodic and cathodic diffusion limiting current densities; i_o is the exchange current density (uncorrected for ionic double layer effects); and $f = \mathbf{F}/RT$. Equation [1] involves the assumption that only p-carriers are involved in the redox reactions and that the p-carrier surface concentrations can be described by a simple Boltzmann distribution. Equation [1] can also be expressed in the form

$$\eta = \frac{RT/\mathbf{F}}{1 - (1 - \alpha)\gamma} \cdot \ln \left\{ \frac{i}{i_o} \Big/ \left[\left(1 - \frac{i}{i_a} \right) - \left(1 + \frac{i}{i_c} \right) \exp - f\eta \right] \right\} \quad [2]$$

where η is the overpotential, ($\eta = \Delta\phi_H + \Delta\phi_S$), $\gamma = \Delta\phi_H/\eta$, and $\alpha + \beta = 1$. At potentials cathodic to voltammetry peak I, $\gamma \rightarrow 0$ and the Tafel slope approaches $RT/\mathbf{F}$; at potentials in the vicinity of this peak and anodic to it, $\gamma \cong 1$ and the Tafel slope is $RT/(\alpha\mathbf{F})$.

Very high carrier concentration are involved with the NiO(Li) electrodes used in the present study (~10^{20} carriers/cm^3). This, together with the high concentration of surface states expected as voltammetry peak I is approached, makes it unlikely that Eq. [1] will be followed except when $\gamma \rightarrow 1$.

Experimental Procedures

Procedures used in preparing the mosaic NiO(Li) electrodes and the electrolytes (except alkaline solution) have been described previously (3). The redox couple solutions were prepared using recrystallized reagent grade chemicals. The alkaline electrolyte (0.497M K_2SO_4 + 0.01M NaOH) was purified by *in situ* pre-electrolysis of 100 ml of solution for 16 hr using passivated Ni electrodes having areas of ~4 cm^2 each at potentials of about −0.40 and 0.83V re SHE. Platinum pre-electrolysis electrodes are not acceptable because of possible Pt contamination of the NiO(Li) electrode surface. All electrolytes were saturated with helium which was passed through hot copper turnings to remove O_2 and traps containing Linde molecular sieves (3A and 13X) at liquid N_2 temperatures to remove other contaminants.

The NiO(Li) electrodes were prepared as described previously (3) and compression molded into Kel-F cylindrical holders for use with the rotating disk method. The exposed NiO(Li) surface was near square shaped (~0.1 cm^2) rather than circular because of fabrication problems. Earlier studies (5) with metal electrodes have shown that the use of square rather than circular electrodes does not lead to appreciable errors in kinetic studies with the rotating disk method. The lithium concentrations in the NiO(Li) electrodes listed in this paper were obtained from the slopes of the Mott-Schottky plots. These values have been shown to be essentially the same as those from flame photometric analyses (3).

The Pyrex cell (Fig. 1) consisted of a main compartment containing the NiO(Li) working electrode and separate compartments for the reference and platinum counterelectrode. Temperature control was achieved through the circulation of thermostated water through a jacket surrounding the bottom of the main compartment. A Teflon gasket was used between the ground surfaces of the lid and body of the cell with a screw clamp to apply pressure.

The potential of the NiO(Li) electrode was controlled with a Wenking potentiostat in conjunction with a slow linear potential sweep scanner and a Hewlett Packard/Moseley 7030A x-y plotter to record the current-potential data.

The reference electrode was $Hg|HgSO_4$ in acid and neutral solutions and $Hg|HgO$ in basic solutions with the same electrolyte as used for the supporting electrolyte in the main compartment, with the exception of the measurements in neutral solution. For the 0.50M K_2SO_4 redox solutions the reference compartment contained 0.495M K_2SO_4 + 0.005M H_2SO_4. All potentials reported have been converted to the standard hydrogen electrode (SHE) scale.

Results and Discussion

The results presented in this paper are representative of those found for electrodes containing 0.2-0.5 cation % Li. Electrodes which were less highly doped

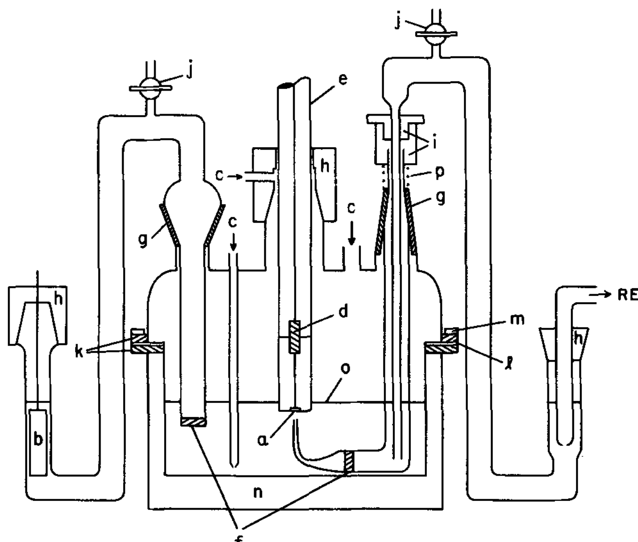

Fig. 1. Electrochemical cell for use with rotating electrode assembly. a, NiO(Li) electrode (WE); b, Pt foil (external CE); c, helium gas inlets; d, spring-cap electrical contact; e, rotating shaft (Teflon sleeve); f, sintered glass plugs; g, standard taper glass joints; h, Teflon plug fittings to standard taper joints; i, Teflon plugs (press-fit); j, Teflon-glass stopcocks; k, ground glass lips or rims; l, Teflon gasket; m, brass ring; n, water jacket; o, electrolyte level; p, spring.

($<$0.1 cation % Li) generally exhibited Tafel slopes which were considerably higher and dependent on rotation rate and at high current densities also on potential. These effects are attributed to errors in the measured electrode potential due to ohmic losses within the bulk of the electrode. This conclusion is in accord with the a-c impedance results which yielded values for the bulk electrode resistance as high as 1000 ohms at 1 kHz corresponding to a resistivity of $\sim 10^4$ ohm-cm for 0.05 cation % Li. While results are presented only for rather highly doped electrodes, the Tafel slopes obtained for the less highly doped samples generally agree with those for the more heavily doped electrodes within 10-20% if a correction is applied for bulk resistivity as an adjustable parameter.

The dissolution rates of mosaic NiO(Li) are very slow even in concentrated acid solutions. For a potential of 1.0V re SHE in 1*N* H_2SO_4 at 95°C, Lee and Yeager (7) report the dissolution rate of NiO (0.88 cation % Li) to be $\sim 10^{-5}$ g/cm²-hr. On the basis of the temperature dependence found in this work, the dissolution rates would be expected to be several orders of magnitude slower at room temperature (*i.e.*, $\sim 10^{-8}$ g/cm²-hr). Taking into account the potential dependence of the dissolution rate observed by Lee and Yeager, the amount of NiO lost through dissolution even in the most acid solution involved in the present work (1*N* H_2SO_4) would not be expected to exceed 10^{-7} g/cm² (the equivalent of approximately 1 monolayer) over the times (5-10 min) required to record the current-potential curves, scanning in any one direction.

Ferro-ferricyanide couple.—This couple was chosen for the majority of the study because the reactants are moderately stable over a wide pH range, the salts are easily recrystallized for purification purposes, and the couple has a reversible potential near the flatband potential for NiO(Li), thus affording an opportunity to examine the effects of changes in the space charge within the semiconductor on the kinetics. This couple has been found to be relatively fast on various metals in sulfate solutions at various pH (8), with the rate increasing as the hydrogen ion is replaced by alkali metal cations such as Na^+ or K^+.

The current-potential behavior of the ferro-ferricyanide reaction on NiO(Li) electrodes at various rotation rates is illustrated in Fig. 2-5 for sulfate solutions at pH from 0.5 to 12.0. Appreciable hysteresis was observed in the voltammetry curves for the ferro-ferricyanide reaction only in neutral solution (see Fig. 4) and this may be due to pH changes at the interface and/or the specific adsorption of some solution species. Unless otherwise indicated, only the current-potential curves obtained with sweeps in the cathodic direction are shown in the graphs.

For the strongly acidic medium, the cathodic branch is very inhibited but becomes progressively less inhibited at higher pH. The anodic branch also is somewhat inhibited at low overpotentials in acidic solutions but this effect becomes less pronounced at higher pH. The inhibition of the cathodic reaction arises because the depletion of charge carriers in the vicinity of the electrode surface leads to a small value of γ in Eq. [2], *i.e.*, a large potential drop across the space charge region. Studies on a-c impedance have shown that protons on the electrode surface strongly affect the potential distribution [see Ref. (3)] and that the depletion of charge carriers becomes less severe as the pH is increased. At more anodic potentials, protons are desorbed from the surface and hence the depletion of charge carriers is less with the result that the anodic reaction proceeds faster.

In acid solutions the cathodic currents are independent of the rotation rate (Fig. 2 and 3) but this is not the case at higher pH values (Fig. 4 and 5). Even at pH 12.0, however, the cathodic limiting currents at 0.264V re SHE are not completely diffusion controlled as is evident from the plot of $1/i_L$ *vs.* $1/(\omega)^{1/2}$ in Fig. 6. For a diffusion controlled reaction this curve should pass through the origin.

The limiting currents for the anodic branches are not very clearly defined, especially at the higher rotation rates and lower pH values. A possible cause for this effect may be that, with the near square rather than circular exposed electrode surfaces used in this work, the current distribution on the rotating electrode may not be uniform even at the diffusion limiting current. Yohe *et al.* (5), however, have shown experimentally that rotating near-square electrodes yield electrochemical results for redox reactions which do not differ significantly from those obtained on rotating

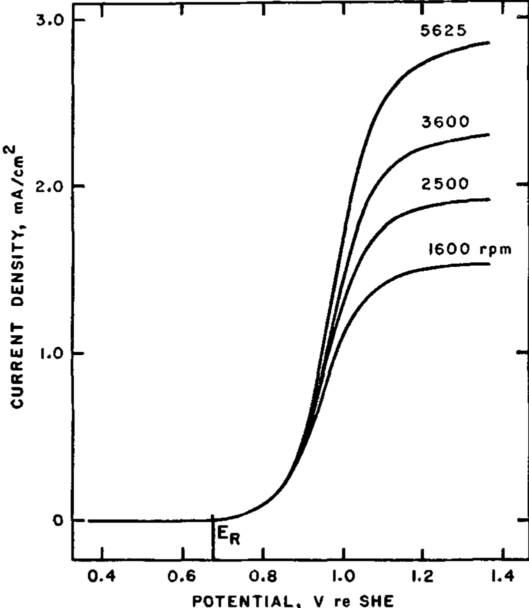

Fig. 2. Current-potential curves at various rotation rates for mosaic NiO(0.36 cation % Li) in He-saturated 1.0N H_2SO_4 [2.5 mM $K_4Fe(CN)_6$ and 2.5 mM $K_3Fe(CN)_6$] at 25°C. Electrode area, 0.128 cm²; sweep rate, 2 V/min; E_R = 0.672V re SHE.

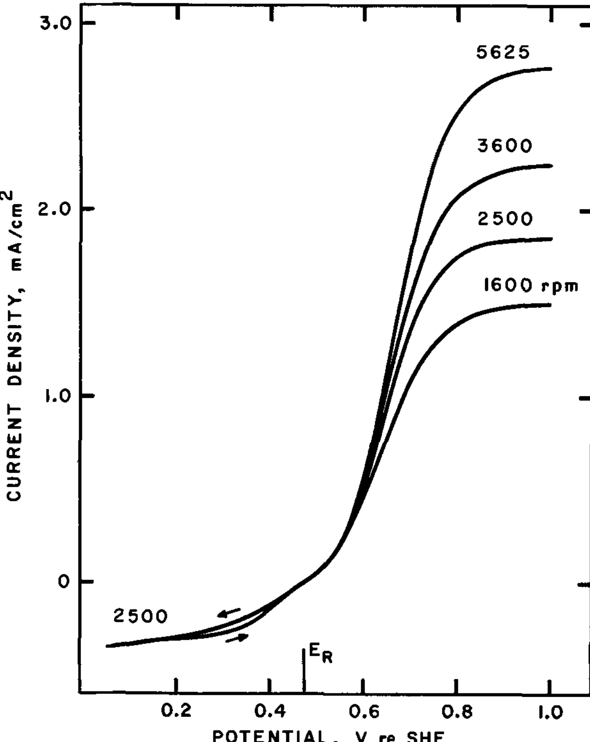

Fig. 3. Current-potential curves at various rotation rates for mosaic NiO(0.36 cation % Li) in He-saturated 0.495M K_2SO_4 + 0.005M H_2SO_4 [2.5 mM $K_4Fe(CN)_6$ and 2.5 mM $K_3Fe(CN)_6$] at 25°C. Electrode area, 0.128 cm^2; sweep rate, 1 V/min; E_R = 0.470V re SHE.

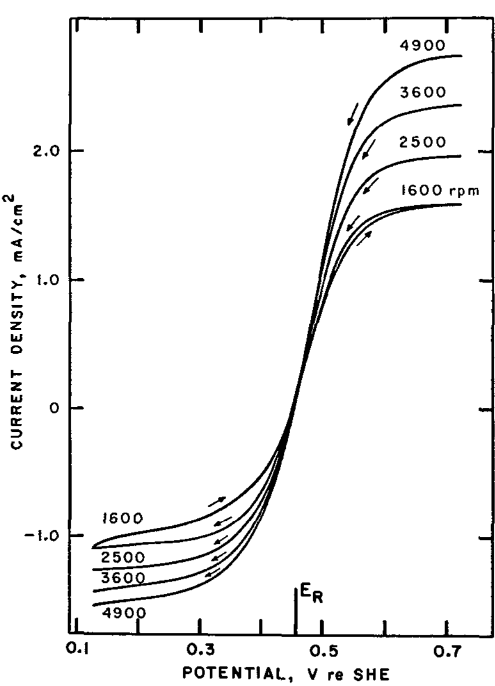

Fig. 4. Current-potential curves at various rotation rates for mosaic NiO(0.36 cation % Li) in He-saturated 0.50M K_2SO_4 [2.5 mM $K_4Fe(CN)_6$ and 2.5 mM $K_3Fe(CN)_6$] at 25°C. Electrode area, 0.128 cm^2; sweep rate, 4 V/min; E_R = 0.460V re SHE.

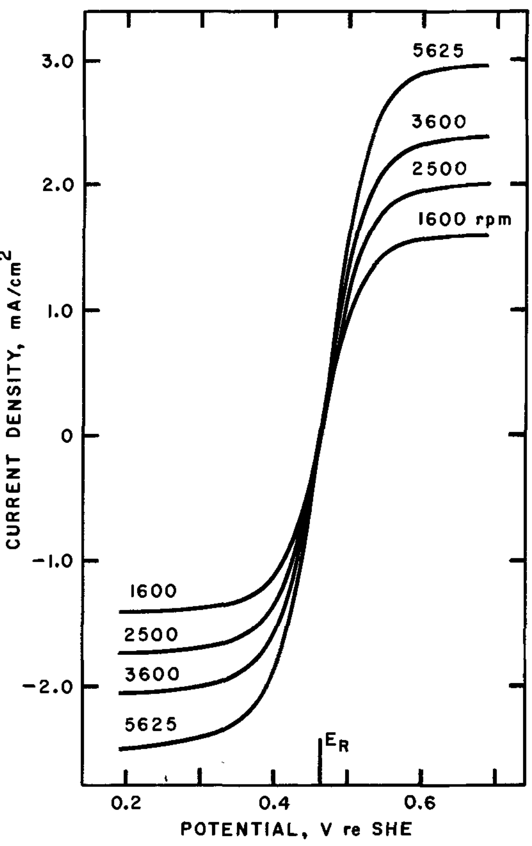

Fig. 5. Current-potential curves at various rotation rates for mosaic NiO(0.48 cation % Li) in He-saturated, pre-electrolyzed 0.497M K_2SO_4 + 0.01M NaOH [2.5 mM $K_4Fe(CN)_6$ and 2.5 mM $K_3Fe(CN)_6$] at 25°C. Electrode area, 0.0416 cm^2; sweep rate, 1 V/min; E_R = 0.461V re SHE.

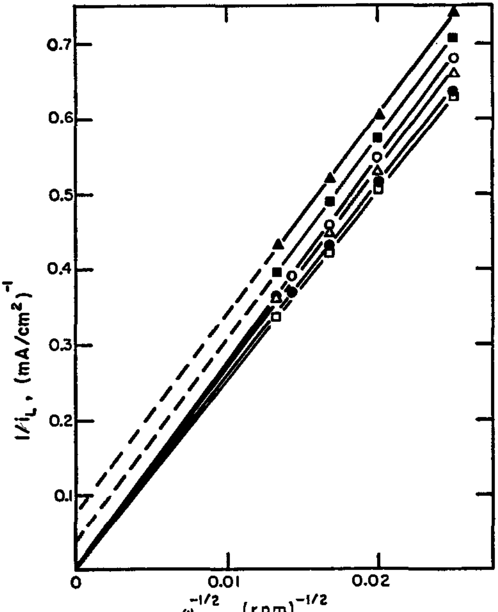

Fig. 6. Plots of $1/i_L$ vs. $\omega^{-1/2}$ for the ferro-ferricyanide couple on mosaic NiO(0.36 cation % Li) in He-saturated sulfate solutions [2.5 mM $K_3Fe(CN)_6$ and 2.5 mM $K_3Fe(CN)_6$] for various pH at 25°C. △, ▲ = 1.0N H_2SO_4; oxidation at 1.22 and 1.07V re SHE, respectively; pH:0.5. ○ = 0.495M K_2SO_4 + 0.005M H_2SO_4; oxidation at 0.92V; pH:2.9. ● = 0.50M K_2SO_4; oxidation at 0.70V. □, ■ = 0.497M K_2SO_4 + 0.01M NaOH; oxidation at 0.664V and reduction at 0.264V, respectively; pH:12.0.

disk electrodes. Furthermore, there is no reason to believe that current distribution effects at the diffusion limiting current density should be markedly dependent on the pH of the solution. A more likely explanation for the ill-defined anodic limiting currents is interference from the surface reaction associated with voltammetry peak I [see Fig. 1 in Ref. (1)]. The potential of peak I lies near that for the anodic limiting

currents (see Table I) in acid but not neutral and alkaline solutions.

In spite of difficulties encountered in determining the anodic limiting current densities exactly, Fig. 6 verifies that the experimental values chosen for each rotation rate at a given potential for each solution are essentially the diffusion limiting current densities.[2] The potentials at which the diffusion limiting currents were determined are given in the legend to this figure. For comparison, a plot for the solution of $pH = 0.5$ is also given in Fig. 6 at a fixed potential of 1.07V re SHE, corresponding to a region well below the limiting current.

Anodic plots of $\ln[i/(i_a - i)]$ *vs.* potential are shown in Fig. 7 for various rotation rates for the 1.0*N* H_2SO_4 solution. Linearity is to be expected when the back reaction is negligible and γ is constant or negligible (see Eq. [2]). Above 0.8V the plots of $\ln[i/(i_a - i)]$ *vs.* E are linear with a constant slope of 120 mV/decade at all rotation rates. The slope of these plots indicates that in this potential region all of the change in electrode potential is across the Helmholtz region with no appreciable space charge effects within the semiconductor and also no appreciable ionic double layer effects despite the relatively high charge of the species undergoing oxidation. This is the kind of behavior usually observed for a redox couple on a metal electrode with the reaction under combined kinetic and diffusion control with $\alpha = ½$.

At potentials cathodic to 0.8V, the anodic Tafel plots deviate from linearity. These deviations are almost certainly related to a change in the potential distribution at the interface with an appreciable fraction of the change in electrode potential occurring across the space charge region within the semiconductor. The intercept of the Mott-Schottky plot for this electrode at 1 kHz in 1.0*N* H_2SO_4 is at ~1.1V with $1/C_{sc}^2$ becoming appreciable at ~0.8V (C_{sc} = space charge capacitance; see Appendix, Fig. A-1).

[2] The points on this and subsequent graphs in this paper correspond to the particular values calculated using arbitrarily chosen specific points from the continuously recorded current-potential curves.

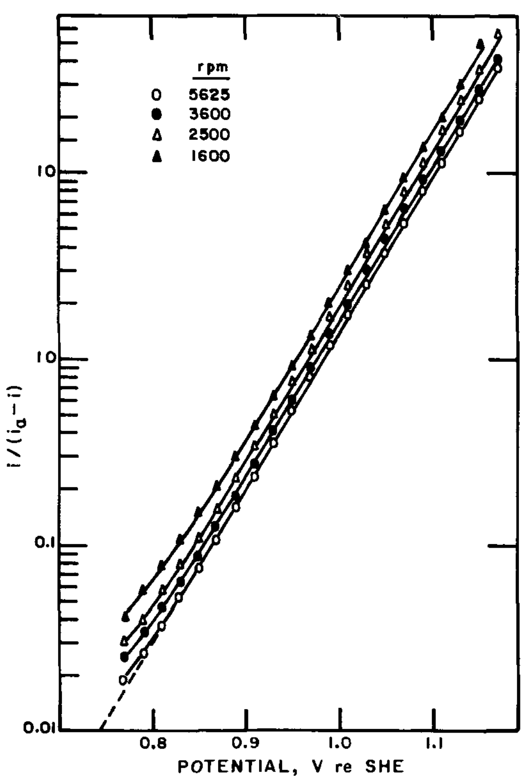

Fig. 7. Tafel plots for oxidation of ferrocyanide on mosaic NiO(0.36 cation % Li) in He-saturated 1.0*N* H_2SO_4 [2.5 mM $K_4Fe(CN)_6$ and 2.5 mM $K_3Fe(CN)_6$] at 25°C. $E_R = 0.672$V re SHE; $b = 120$ mV/decade (all rotation rates).

Extrapolation of the linear portions of the Tafel plots to the reversible potential ($E_R = 0.672$V re SHE) yields a value for the apparent exchange current density of 6.6 ± 0.1 $\mu A/cm^2$. If all of the potential drop occurs in the space charge region of a p-type semiconductor, the cathodic current should reach a limiting value which corresponds to i_o, the exchange current density. Although the cathodic current actually increases slowly at more cathodic potentials, there is a sharp "leveling off" which should yield an approximate value for the exchange current density. For comparison, the value of i_o determined in this way is about 8.6 $\mu A/cm^2$.

In solutions of higher pH, the back reaction term in Eq. [2] cannot be neglected. In Fig. 8, a typical plot according to Eq. [2] is shown for the oxidation of ferrocyanide on NiO(Li) in 0.495M K_2SO_4 + 0.005M H_2SO_4. The cathodic diffusion limiting current density i_c has been assumed to be equal to the anodic value i_a in making this plot. At potentials cathodic to 0.75V, the points on the graph for different rotation rates superimpose. The slight divergence at more anodic potentials is probably due to the inaccuracy inherent in this type of plot at current densities approaching i_a, coupled with the uncertainty involved in determining the i_a value. The linear portion of this plot has a slope of 120 mV/decade which indicates that $\alpha = 0.5$ and that all of the potential change occurs across the Helmholtz layer. At potentials cathodic to about 0.6V, the points deviate from linearity. This is probably because an appreciable potential change occurs across the space charge region.

Extrapolation of the linear portion of the Tafel plot to the reversible potential [$E_R = 0.470$V re SHE] for the 0.495M K_2SO_4 + 0.005M H_2SO_4 solution yields a value for the exchange current density of 64 $\mu A/cm^2$. This is considerably larger than the value observed in 1.0*N* H_2SO_4 (6.6 $\mu A/cm^2$). The rate of reaction would be expected to be faster at higher pH because the electrode surface is less protonated and the depletion of p-carriers near the surface does not become pronounced until more cathodic potentials. The kinetics of the ferro-ferricyanide couple also are highly de-

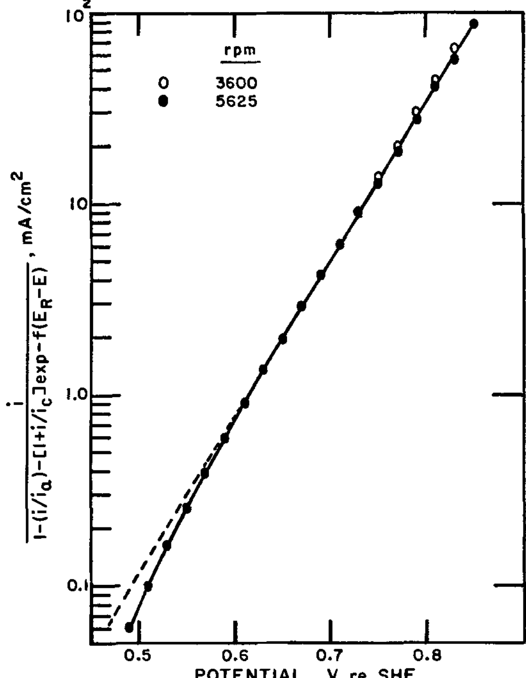

Fig. 8. Tafel plots for oxidation of ferrocyanide on mosaic NiO(0.36 cation % Li) in He-saturated 0.495M K_2SO_4 + 0.005M H_2SO_4 [2.5 mM $K_4Fe(CN)_6$ and 2.5 mM $K_3Fe(CN)_6$] at 25°C. $E_R = 0.470$V re SHE; $b = 120$ mV/decade.

pendent on the pH and the cations. The rates are very fast with polarizable cations such as Cs^+ and relatively slow with less polarizable cations such as Li^+ or H^+ as the principal cations on metal electrodes such as gold (9). A similar cation effect has also been observed on the homogeneous rate constants for this couple (10). Both effects are probably a consequence of the association of the cations with the anions of the couple, particularly the ferrocyanide ion with its charge otherwise of -4 (11, 12). Polarizable cations may facilitate the electron transfer through some type of outer sphere, bridged activation complex between couples or to the surface. The replacement of the H^+ or Li^+ ions associated with the $Fe(CN)_6^{4-}$ by more polarizable cations may also reduce the outer sphere contribution to the free energy of activation within the framework of the Marcus-Hush (13) and Levich-Dogonadze (14) theories of electron transfer. In the present work, ion association alone, however, cannot explain the pH dependence of the exchange current density since the dependence of the apparent rate constant continues to be great outside the range where proton association with the ferrocyanide is predominant (see Table I).

In Fig. 9 are plots based on Eq. [2] for near neutral solutions (pH = 6.5) with 0.5M K_2SO_4 as the supporting electrolyte. The cathodic diffusion limiting current densities have been taken as equal to the anodic values since the space charge effects interfere with the direct determination of the cathodic values from Fig. 4. From Fig. 9, it is evident that the plots are no longer linear and the slopes are dependent on the concentration of the redox couple as well as the rotation rate at higher anodic current densities. Thus at the higher ferro- and ferricyanide concentrations (5×10^{-3}M) and the highest rotation rate (5625 rpm) in Fig. 9, the slope is 105 mV/decade whereas at 2.5×10^{-3}M and 1600 rpm, the slope is ~70 mV/decade at higher anodic potentials.

Theoretically, Eq. [2] is applicable regardless of whether the electrochemical reaction rate is controlled by electron transfer, diffusion, or both. When the reaction rate approaches pure diffusion control ($i_o > i_a$ or i_c) however, practical application of Eq. [2] becomes tenuous. Because of the magnitude of i_o, small errors in the value of i_a or i_c become very significant

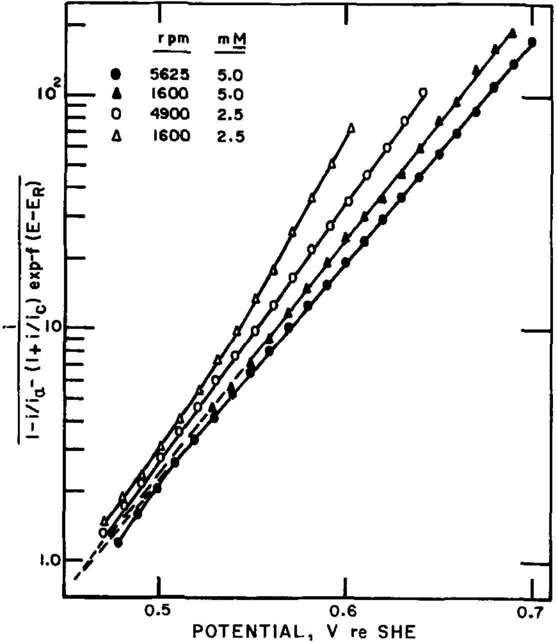

Fig. 9. Tafel plots for oxidation of ferrocyanide on mosaic NiO(0.36 cation % Li) in He-saturated 0.50M K_2SO_4 [2.5 and 5.0 mM $K_4Fe(CN)_6$ and $K_3Fe(CN)_6$] at 25°C. pH = 6.5; E_R = 0.460V re SHE.

and deviations can occur in plots of the type given in Fig. 9. This is the probable explanation for the deviations at more anodic potentials in this figure. In the near neutral solutions, even the minute amount of NiO which dissolves under these conditions may result in an appreciable pH change adjacent to the electrode surface. Such changes in pH could change the state of protonation of the electrode surface and hence also change the exchange current density for the redox couple, thus disturbing the apparent Tafel slope in Fig. 9.

Only at the higher redox couple concentrations (5×10^{-3}M) and highest rotation rate (5625 rpm) is the plot in Fig. 9 sufficiently linear to permit extrapolation to the reversible potential (E_R = 0.461V) to obtain an estimated exchange density of $i_o \cong 0.9$ mA/cm^2.

In more alkaline solutions (*i.e.*, pH = 12) the kinetics have become sufficiently fast that the oxidation and reduction are under almost pure diffusion control and quantitative values for the exchange current densities and Tafel slopes could not be obtained with the rotating disk technique.

The apparent exchange current densities, Tafel slopes, and diffusion coefficients evaluated from the present study are listed in Table I. The diffusion coefficient determined from the anodic limiting current density for the ferrocyanide is in reasonably good agreement with the value of 7.2×10^{-6} cm^2/sec reported by Jahn and Vielstich (16) on Pt in 0.5M K_2SO_4 at 25°C. The rest potentials were always the same (±2 mV) as the values observed on platinum and agree quite well with the literature (15).

The apparent standard rate constants for the ferro-ferricyanide couple on NiO(Li) are considerably slower than on metals such as platinum and gold even at low pH values where protonation of the ferrocyanide leads to less reversibility [see *e.g.*, (17-23)]. Using a-c methods, Randles and Sommerton (20) obtained an apparent standard rate constant of 1.3×10^{-1} cm/sec in 0.5M K_2SO_4 at 20°C. The apparent k_o value for this reaction on NiO(Li) at 25°C is 1.9×10^{-3} cm/sec or approximately two orders of magnitude less.

Fe^{2+}-Fe^{3+} couple.—Typical voltammetry curves at various rotation rates are shown in Fig. 10 for the Fe^{2+}-Fe^{3+} couple on NiO(Li) in 0.495M K_2SO_4 + 0.005M H_2SO_4 (pH = 2.9). Pronounced inhibition is evident for the cathodic branch and also for the anodic branch at low overvoltages. At more anodic potentials the current increases to a limiting value, which is rotation dependent. At about 1.6V re SHE, the current again increases, due to the onset of oxygen evolution. Values of i_L determined at 1.50V are diffusion limited, as shown in Fig. 11. For comparison, current densities at 1.27V are also plotted in this figure. Tafel plots with corrections for diffusion of reactants using i_L evaluated at 1.50V are shown in Fig. 12. These plots are linear over at least two decades of current with a slope of

200 mV/decade, independent of rotation rate. The dependence of the intercept on rotation rate is that anticipated for this type of plot according to Eq. [2].

The Tafel slope of 200 mV/decade is considerably higher than found for this couple on metals such as

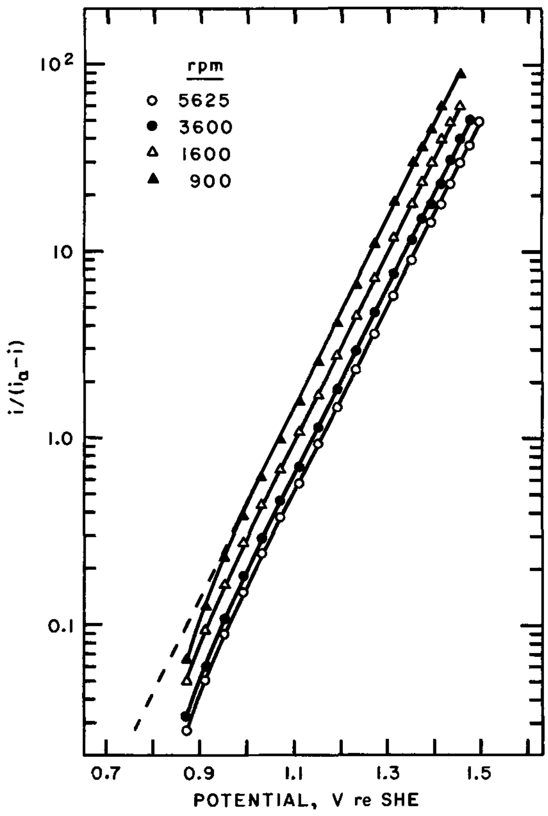

Fig. 12. Tafel plots for oxidation of ferrous ion on mosaic NiO(0.36 cation % Li) in He-saturated 0.495M K_2SO_4 + 0.005M H_2SO_4 [2.5 mM $FeSO_4$ and 2.5 mM $Fe_2(SO_4)_3$] at 25°C. E_R = 0.706V re SHE; b = 200 mV/decade (all rotation rates).

platinum. Gerischer (24) has reported an apparent anodic transfer coefficient of 0.42 corresponding to a Tafel slope of 143 mV/decade and an apparent standard rate constant of 3×10^{-3} cm/sec for this couple in 1M H_2SO_4 on platinum. Other workers have confirmed these results (8). The apparent standard rate constant evaluated from the plots in Fig. 12 is 8.3×10^{-5} cm/sec or approximately two orders of magnitude smaller than the value on platinum. Note, however, that the supporting electrolytes and pH are not the same.

The lack of any appreciable current for the reduction of ferric ion on NiO(Li) and evidence of inhibition at low anodic overpotentials are somewhat surprising since the reversible potential for the ferrous-ferric couple is 0.706V re SHE and more anodic than that for the ferro-ferricyanide couple. On the basis of the a-c impedance studies in the same supporting electrolyte (3), the onset of the exhaustive depletion region would not have been expected at potentials less cathodic than 0.5V re SHE.

Both the slope of 200 mV/decade and the pronounced cathodic inhibition for this system may be explained by considering specific adsorption of Fe ions. The interaction of Fe ions with the electrode surface may involve sharing of an H_2O from the inner coordination sphere of Fe with a Ni ion on the surface or replacement of an H_2O in the inner coordination sphere of iron by surface $O^=$ or OH^- ions. The adsorption of either Fe^{+2} or Fe^{+3} ions will modify the potential distribution and Ni^{3+} concentration at the surface. The depletion of p-carriers produced by the adsorption of Fe^{2+} or Fe^{3+} ions will lead to a relatively large potential drop across the space charge region at electrode potential considerably less cathodic than otherwise would be necessary for such a depletion effect.

Much of the anodic branch occurs at potentials more positive than the voltammetry peak I where a substantial fraction of the surface nickel ions appear to be

converted to the +3 valency state. In the anodic branch, therefore, most of the potential drop should be across the Helmholtz region and hence available to drive the electrochemical oxidation. Consequently the p-carrier surface concentration would not be expected to depend strongly on the electrode potential in this region. Under these circumstances the behavior of the Fe^{+2}-Fe^{+3} couple should approach that on a metal. The higher than usual anodic slope of 200 mV/decade may reflect the specific adsorption of Fe^{+2} and/or Fe^{+3} ions (even at potentials anodic to voltammetry peak I).

Hydroquinone-quinone couple.—The current-potential curves for 1.0×10^3M quinhydrone were examined in He-saturated 1.0*N* H_2SO_4 on an NiO(0.48 cation % Li) electrode at various rotation rates (1600-5625 rpm). The rest potential was unsteady, although the expected value of 0.67V re SHE was obtained on Pt electrodes in these solutions. The cathodic branch on the NiO(Li) electrode was very inhibited. No current was evident from −0.7 to 0.9V re SHE but at more anodic potentials the current increased reproducibly to a well-defined diffusion limited value at 1.6V. Plots of log $i/(i_a - i)$ *vs.* E were linear over two decades of current with a slope of 170 mV/decade, independent of rotation rate.

Assuming that all of the potential drop occurs in the Helmholtz region at anodic potentials, the corresponding anodic transfer coefficient is 0.35 for a rate-determining step involving only one electron change. The values agree quite well with the limiting value for α of 0.37 obtained by Vetter (8) above *p*H 5 for this electrode reaction on platinum.

Cr^{2+}-Cr^{3+} couple.—The behavior of the Cr^{2+}-Cr^{3+} couple was examined on the NiO(Li) electrodes in perchlorate solutions using slow linear sweep voltammetry. The reversible potential ($E^\circ = -0.41$V re SHE) of this couple is very cathodic compared to the flatband potential or potentials where the capacitance contribution from the space charge region in the semiconductor first becomes appreciable. In a 0.5M $NaClO_4$ solution containing 0.02M Cr^{2+} and 0.02M Cr^{3+} plus sufficient $HClO_4$ to adjust the *p*H to 1.2, the slow sweep voltammetry curves (4 V/min) were the same as in the absence of the Cr^{2+}-Cr^{3+} couple over the voltage range −0.8 to +1.5V re SHE. Oxidation or reduction current densities of even a few $\mu A/cm^2$ would have been detectable.

In the absence of halide ions the Cr^{2+}-Cr^{3+} couple is quite irreversible even on metals such as Hg and Pt. None the less at overpotentials of several tenths of a volt, currents in the mA/cm^2 range are observed [see *e.g.* Ref. (25)]. The much more pronounced irreversibility of the Cr^{2+}-Cr^{3+} couple in NiO(Li), therefore, must be attributed to the electrode.

The introduction of halide anions into the perchlorate solution greatly increases the reversibility of the oxidation of Cr^{2+} and also the reduction of Cr^{3+} on metal electrodes if the halide anion is present in the inner coordination sphere of the Cr^{3+} (25). The halide is believed to facilitate the charge transfer through anion bridging. With the NiO(Li) electrode, the introduction of 10^{-3}M NaCl into the $NaClO_4$-$HClO_4$ solution resulted in a substantial oxidation current, for the Cr^{2+}-Cr^{3+} couple at potentials anodic to 0.75V re SHE where the depletion layer is not involved. Quantitative steady-state data for the kinetics of the oxidation are not available in the presence of the Cl^- but the behavior appears similar to that on metal electrodes at anodic potentials.

Comparison of Redox Behavior on NiO(Li) and Metal Electrodes

The rates of the various redox couples examined in this work are substantially slower on the NiO(Li) electrode than on metals such as Pt and Au. Factors which may be responsible for the difference in rates include: (*a*) semiconductor effects, (*b*) ionic double layer effects, (*c*) differences in surface roughness, and (*d*) contribution of the electrode phase directly to the free energy of activation for the charge transfer.

At potentials appreciably cathodic to the flatband potential, most of the potential drop is across a depletion layer within the NiO(Li). Under such circumstances, pronounced inhibition of cathodic and anodic processes is to be expected. This has been observed not only for the couples already cited, but also a number of other processes including the oxidation of CO and organic acids (26). At potentials anodic to the flatband potential, all the couples studied in the present work were still slower even in the anodic branch than on metals such as Pt. For the ferro-ferricyanide couple, the ratio of the standard rate constants on NiO(Li) and Pt electrodes in 0.5M K_2SO_4 is 1.5×10^{-2}. For the Fe^{2+}-Fe^{3+} couple this ratio is 2.7×10^{-2} although the comparison is not fully valid since the electrolyte used with the NiO(Li) electrode was 0.5M K_2SO_4 + 0.005M H_2SO_4, whereas that for the Pt was 1M H_2SO_4 (24).

Differences in the ionic double layers on the two electrodes would be expected to cause some difference in the apparent rate constants but it is doubtful whether ionic double layer effects would cause differences of $\sim$ 2 orders of magnitude. Further the double layer effects would act in opposite directions for the ferro-ferricyanide and ferrous-ferric couples because of the differences in the charge of the reacting ions. The constancy of the Tafel slopes and in the instance of the ferro-ferricyanide couple the finding of a transfer coefficient of 0.5 are further arguments against large ionic double layer effects.

For surface roughness to be the major factor responsible for the two orders of magnitude difference in rate constants on NiO(Li) and Pt would require a roughness factor of $\sim 10^2$ for the Pt used by such workers as Randles and Sommerton (20) and Gerischer (24). This seems unlikely with bright platinum electrodes of the type used by these authors.

The most probable explanation for the two orders of magnitude difference in rate constants at potentials anodic to the flatband potential is that the electrode phase contributes significantly to the free energy of activation for the charge transfer process. According to the Marcus-Hush theory (13) of heterogeneous electron transfer the true standard first order rate constant $(k_o)_t$ (corrected for double layer effects) is given by

$$(k_o)_t = A \exp - \frac{\Delta F^*}{RT} = \kappa Z \exp - \frac{\Delta F^*}{RT} \quad [3]$$

where κ is the transmission coefficient (taken as unity by Marcus), ΔF^* is the free energy of activation, and Z is the collision frequency factor. Assuming all sites on the electrode surface equally accessible, Z is given[3] by Marcus as

$$Z = [kT/(2\pi m^*)]^{1/2} \quad [4]$$

where m^* is the effective mass of the reactant. For a species such as $Fe(CN)_6^{4-}$, $Z \cong 4 \times 10^4$ cm/sec.

The activation free energy for a redox couple on a metal is as follows

$$\Delta F^* = \Delta F^*_i + \Delta F^*_o + \Delta F^*_e \quad [5]$$

where ΔF^*_i is the contribution from rearrangement (prestressing) of the inner sphere ligands, ΔF^*_o is the contribution from the outer sphere and more remote ion-solvent environment, and ΔF^*_e is any electronic quantum mechanical contribution. For a metal, ΔF^*_e is usually taken to be zero but with a semiconductor, particularly involving rather localized electronic states ΔF^*_e may not be zero because of possible spin inversion attending the electron transfer.

[3] The validity of this expression given by Marcus for Z has been challenged by Bockris (27). At the best, the term is probably not more accurate than to an order of magnitude. In the present discussion, only the ratio of the values between the NiO(Li) electrode and metal electrodes such as Pt is important.

With semiconductor electrodes, the pre-exponential term A in Eq. [3] (or alternatively the exponential term ΔF^*) must be modified to take into account the carrier concentration in the electrode surface. At potentials anodic to peak I in the voltammetry curve (3, 5), however, the surface concentration of Ni^{3+} is estimated to be ~ 1/4 of that of the atoms on the surface of a metal such as Pt. This estimate is based on the number of coulombs/square centimeter associated with voltammetry peak I. Since the rate constants on the NiO(Li) electrodes are principally based on kinetic data at potentials anodic to this peak, the pre-exponential term A in Eq. [3] would not be expected to differ from that on Pt by more than four-fold, assuming that κ is still ~1 for the NiO(Li) electrode. Redox species such as the ferrocyanide anions are expected to undergo electron transfer with distances of 7-10Å between their centers and those of the Ni^{3+} on the electrode surface. Consequently the electron transfer probably should not require the aligning of the redox species with sites on the electrode surface and hence the difference in A may be much smaller than a factor of 4.

If the pre-exponential terms A for NiO(Li) and Pt are assumed to be the same, ΔF^* must be ~3 kcal/mole larger for the NiO(Li) electrodes than for the platinum electrodes. Possible sources for such an additional activation free energy are (i) contributions to ΔF^*_i and ΔF^*_o for the electrode phase and (ii) spin problems resulting in an appreciable value for ΔF^*_e. The latter seems unlikely since spin inversion would probably produce a much larger contribution to ΔF^*_e than just a few kcal/mole. Significant contributions to ΔF^*_i and ΔF^*_o from the prestressing of the enviroment of the Ni^{3+} states at the electrode surface appear more likely.

On the other hand, dielectric loss measurements in NiO(Li) as well as resistivity, Hall, and Seebeck coefficient measurements have indicated that any activation energy for Ni^{3+} hole mobility in NiO(Li) is less than 200 cal/mole [see Ref. (2) for a summary of the evidence]. The conductivity has an activation energy which is much larger but this activation energy corresponds to the dissociation of Li^+-Ni^{3+} or Ni^{3+}-cation vacancy pairs to yield highly mobile p-carriers. The lack of any appreciable activation energy for the free p-carriers in NiO is probably the result of Ni^{3+}-O^{2-}-Ni^{2+} interactions which facilitate electron transfer from a Ni^{2+} e_g orbital to an Ni^{3+} e_g orbital of parallel spin (2); *i.e.*, the equivalent of the anion bridge mechanism for redox species in solution. For charge transfer across the interface between Ni^{3+} in the electrode phase and a redox species, the situation would be substantially different and such strong interactions between orbitals of Ni^{3+} and those of the redox species would not be expected, particularly with redox species such as ferro-ferricyanide which have stable inner coordination spheres and which are probably not specifically adsorbed. Thus a contribution of several kcal/mole to ΔF^* from prestressing of the environment of the surface Ni^{3+} ions is quite possible.

If such is the situation, then the charge transfer between the Ni^{3+} states in NiO(Li) and a redox species in the electrolyte is rather analogous to charge transfer between two different redox couples in solution. Such a model has been considered for this system by the authors (28) using the Marcus theory (13) for homogeneous rates of redox reaction. Calculations with this model, however, are limited by the lack of adequate data for use in calculating ΔF^*_i and ΔF^*_o for the surface Ni^{3+} ions as well as difficulties in evaluating the coulombic interactions.

APPENDIX

Helmholtz Capacitance Correction in A-C Impedance Studies of NiO(Li)

In the a-c impedance measurements reported earlier (1), no correction was made for the Helmholtz layer capacitance in the calculation of the space charge capacitance for the NiO(Li) electrodes. Unfortunately information is lacking as to the value of the Helmholtz capacitance. Since the observed capacitance was much smaller than the normal Helmholtz capacitance, the assumption was made that the series Helmholtz capacitance could be neglected for purposes of preparing Mott-Schottky plots with only a minor error.

The omission of the correction for the Helmholtz layer capacitance, however, may lead to a substantial error in the intercepts in the Mott-Schottky plot for highly doped NiO(Li) electrodes. If the value of this capacitance is taken to be ~ 20 μf/cm² at potentials cathodic to the apparent flatband potential, the intercept is shifted to more cathodic potentials by ~ 0.35V for the 0.36 and 0.48 cation % Li electrodes in both the acid and near neutral sulfate electrolytes used in the earlier work (3), see Fig. A-1. The slopes also are slightly decreased numerically by ~ 15% and the linear region slightly extended.

With this correction, the intercepts coincide approximately with the potentials of the first peak in the voltammetry curves corresponding to the Ni^{2+}-Ni^{3+} potential.

Cell Dimensions and Electrical Properties of the Solid Solutions: $1-xZnS/xCuAlS_2$ and $1-xZnSe/xCuAlSe_2$ where $x = 0$ to 0.33

P. C. Donohue and P. E. Bierstedt

ABSTRACT

Sphalerite-type solid solutions were prepared in the systems $1 - x$ZnS/xCuAlS$_2$ and $1 - x$ZnSe/xCuAlSe$_2$ for $x = 0$ to 0.33. The cell dimensions initially increase with x between $x = 0$ and $\sim x = 0.01$ followed by a decrease with further increase in x. The resistivities are high at low values of x and decrease with increasing x. Seebeck coefficients indicate that p-type conduction occurs with x as low as 0.05 for the sulfides and 0.1 for the selenides.

Attempts to prepare light-emitting diodes from the sphalerite-type II-VI compounds have been frustrated by the inability to achieve good p-type conductivity. It has recently been reported that chalcopyrite-type $CuAlS_2$ and $CuAlSe_2$ are p-type conductors (1, 2). Since the chalcopyrite and sphalerite structures are similar, we decided to investigate the properties of solid solutions in these systems. Of special interest was the amount of chalcopyrite needed to impart p-type conduction to the usually n-type sphalerite compounds. Solid solutions in the $1 - x$ZnS/xCuAlS$_2$ system have been recently reported (3); however, their electrical properties were not reported, and the region between $x = 0$ and 0.2 was not investigated.

Experimental

Compositions were prepared starting with high-purity ZnS or ZnSe, Cu, Al, and S or Se which were weighed in stoichiometric proportions and sealed in evacuated silica tubes with about 5 mg I_2/cm^3.

The tubes were heated in a natural gradient tube furnace, and the temperature was increased gradually over a period of several days until all the chalcogen reacted. The tubes were then cooled and opened; the products were reground and then sealed in evacuated silica tubes. These products were reheated for several days in a gradient of about 1000°-800°C, and in most cases, millimeter size crystals were transported to the cooler region. To obtain single compositions, the products were reground, sealed in silica, and heated at 1000°C with no gradient.

The products were characterized by Debye-Scherrer x-ray powder diffraction, and the cell dimensions were refined by a computerized least squares analysis of the data. The standard deviations are 0.001Å or less.

Electrical resistivities (ρ) and Seebeck coefficients (α) were measured on individual crystals using a two-probe method. Small copper probes attached to two micromanipulators were positioned at opposite ends of the crystal being investigated. A heating element was wound around one of these probes and both probes were attached by a differential copper-constantan thermocouple (electrically isolated but thermally linked to the probes). Passing a current through the heating element resulted in thermal voltages being developed by both the sample and the thermocouple, and these voltages were displayed on the axes of an X-Y recorder. The Seebeck coefficients were calculated from the slope of the resulting Seebeck voltage *vs.* temperature difference plot. This technique is similar to that described by Berglund and Beairsto (4).

The electrical resistivities were measured using a Keithley 610A electrometer, operating in the resistance mode, with the copper probes used in the Seebeck co-

efficient serving as the current probes. Air dry silver paint was used to improve and strengthen the contact with the copper probes. All manipulations were performed with the aid of a microscope, and with irregular shaped crystals the use of silver paint was necessary to insure stability.

Results and Discussion

The cell dimensions and some pertinent electrical parameters for compositions in the systems $1 - xZnS/xCuAlS_2$ and $1 - xZnSe/xCuAlSe_2$ are given in Table I. Graphs of a *vs.* x for both systems are shown in Fig. 1. The compositions marked with an asterisk in Table I were used to construct the graph for the sulfides and were those heated at constant temperature to obtain single-phase material. In spite of the lack of a gradient in these cases, the products tended to transport and form a range of compositions. Thus the points on the graph are not precisely defined in x. Crystals used for electrical characterization were picked from transported crystalline aggregates. The compositions of the sulfide crystals were derived from the graph and not from the ratio of starting materials. In the case of the selenides, the compositions were assumed to be the same as the starting ratio. The general trends and conclusions, however, are not influenced by this assumption.

The cell dimensions in both systems show a small rise with increasing x for values of $x \simeq 0.01$. This is followed by the expected decrease in a with further increase in x. At $x = 0.33$, a symmetry change to tetragonal was observed in the sulfide system.

The sample impedances at low values of x were too high to obtain Seebeck coefficients with our present apparatus. Above $x \simeq 0.05$ in the sulfides and $\simeq 0.1$ in the selenides, the resistivities were low enough to measure Seebeck coefficients and positive α values were obtained. With further increase in x, the resistivities became progressively lower and the α values became more positive. In our experience, two-probe resistivity measurements indicate values about an order of magnitude higher than four-probe measurements made on crystals with soldered indium contacts.

The sulfides were black, probably because of iron impurities since the black color of $CuAlS_2$ has been found to be due to iron (5). As we found with $CuAlS_2$ (5), the color of these compositions can be removed by annealing in the presence of excess Al or preparing the phases with excess Al (see Table I).

Thus we have found that small quantities of $CuAlS_2$ in ZnS and $CuAlSe_2$ in ZnSe can yield relatively low resistivity p-type compositions. Because of the similarity in lattice constants, these p-type solid solutions may be used in combination with the n-type end members for the preparation of pn junctions.

Acknowledgments

Mr. D. W. Reutter assisted in sample preparation and Mr. B. F. Gordon assisted in electrical measurements. Dr. J. F. Whitney and his staff in their x-ray diffraction department are thanked for their help in obtaining powder patterns and carrying out refinements of lattice constants. Critical Overpotential and Induction Time of Dendritic Growth

A. R. Despić and M. M. Purenović

Faculty of Technology and Metallurgy, University of Beograd and Institute for Chemistry, Technology and Metallurgy, Beograd, Yugoslavia

ABSTRACT

Relationships developed earlier (1) for the dependence of the rate of appearance and propagation of dendrites on the properties of the system and overpotential, have been used to develop a quantitative theory of induction period and critical overpotential of dendritic growth. It has been shown that the thermodynamic concept of critical overpotential is applicable to metals of high exchange current density only. The limitations in the appearance of dendrites in metals of low exchange current density are of kinetic character and can be represented by a kinetically defined critical overpotential. The theory has been verified experimentally by following the yield of dendritic deposit of zinc from alkaline zincate solutions as a function of concentration of depositing ions, of overpotential, and of time of deposition.

For some time now it has been known that metallic dendrites appear in electrochemical deposition of metals only if a certain current density and overpotential of deposition are surpassed. Even then, some time is known to pass from the beginning of deposition till the first dendrites can be observed. Wranglen (2) introduced the concept of critical current density. On the other side, Barton and Bockris (3) in a comprehensive theory of dendritic growth introduced the concept of critical overpotential maintaining this to be the basic factor governing the appearance of dendrites, because of being associated with the energy needed to start the dendritic growth (nucleate the crystal or start turning a screw-dislocation). They found this to be of the order of 3 mV for the deposition of silver from nitrate melts. They also noted the increase in dendrite length to be linear with time over the period in which it could be observed and defined the induction period as the time at which the dendrite length extrapolates to zero.

More recently, Despić, Diggle, and Bockris (1, 4) as well as Diggle and Damjanović (5) investigated dendritic growth of zinc from alkaline zincate solution and found the critical overpotential in that system to be about 60-80 mV, while Tajima and Ogata (6) investigating the appearance of dendrites in deposition of nickel, cobalt, and iron found the necessary cell voltage to be of the order of several volts.

The thermodynamic concept of critical overpotential could be criticized on two grounds. First, energy is needed to start any crystal growth other than that occurring by continuation of already established crystal layers (layer growth). Hence, growth of compact deposits should as well require a certain minimum overpotential under the same conditions.

One could maintain here that nuclei required for the development of dendritic crystal are different than those for compact growth and requiring increased overpotential to raise the probability of their appearance. Indeed, Justinijanović and Despić (7) have found zinc dendrites to grow always along the $\langle 11\bar{2}0 \rangle$ axis while compact zinc exhibited close to the substrate always $\langle 0001 \rangle$ oriented texture. The work of Pangarov *et al.* (8) has shown that two-dimensional nucleation of the $(11\bar{2}0)$ nuclei requires a higher degree of supersaturation by adatoms than the (0001) nuclei, *i.e.*, higher crystallization overpotential. Hence, in such cases the thermodynamic concept of critical overpotential seems to be fully justified.

The second criticism, however, seemed more difficult to counteract: no difference in crystal properties (lattice energies etc.) between, *e.g.*, silver, zinc, and nickel, could account for the large differences in critical overpotential as observed in experiments. Moreover, the fact that those are in the same sequence as the exchange current densities for the deposition of those metals, indicated that some kinetic factors may also be responsible for the phenomenon of critical overpotential. Indeed, one of us (A.D.) has presented (9) a quantitative kinetic concept of that property based on the theory of dendritic growth of metals with relatively slow electron exchange reaction of Despić, Diggle, and Bockris outlined in their work on dendritic growth of zinc (1, 4) [cf. also Despić and Popov (10)].

It is the purpose of this communication to give the details of the derivation of the kinetic definition of the critical overpotential, to show how it superimposes on the thermodynamic one, and to report about its verification by the results of a study of the yield of dendritic zinc in the electrochemical deposition from alkaline zincate soltuions.

Experimental

Zinc has been deposited onto a stainless steel circular electrode which was a base of a cylinder imbedded in Teflon, 0.2 cm^2 in surface area. The cell used is shown in Fig. 1. Vertical position of the cathode allowed a free escape of codeposited hydrogen, provided a fairly reproducible diffusion layer thickness and also made it possible to shave off any disperse deposit into a mercury pool at the bottom of the cell by a Teflon blade. The yield of dendritic deposit has been determined much in the same way as in the experiments of Romanov (11). The amount of zinc in the pool as well as that of compact zinc remaining on the steel cathode have been determined coulometrically by anodic stripping, and the yield obtained as the ratio of the former to the sum of both.

Key words: kinetic definition of critical overpotential, theory of (equations for) induction time, yield of dendritic deposit of zinc, function of zincate concentration, function of overpotential, overpotential of zero dendrite yield.

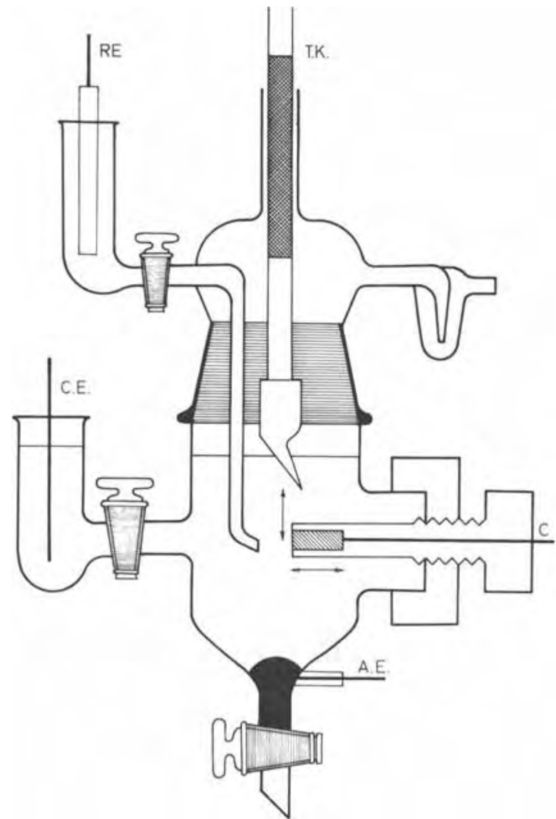

Fig. 1. Cell for determining the yield of disperse deposit. C, cathode; A.E., auxiliary electrode; CE, counterelectrode; RE, reference electrode; T.K., Teflon knife.

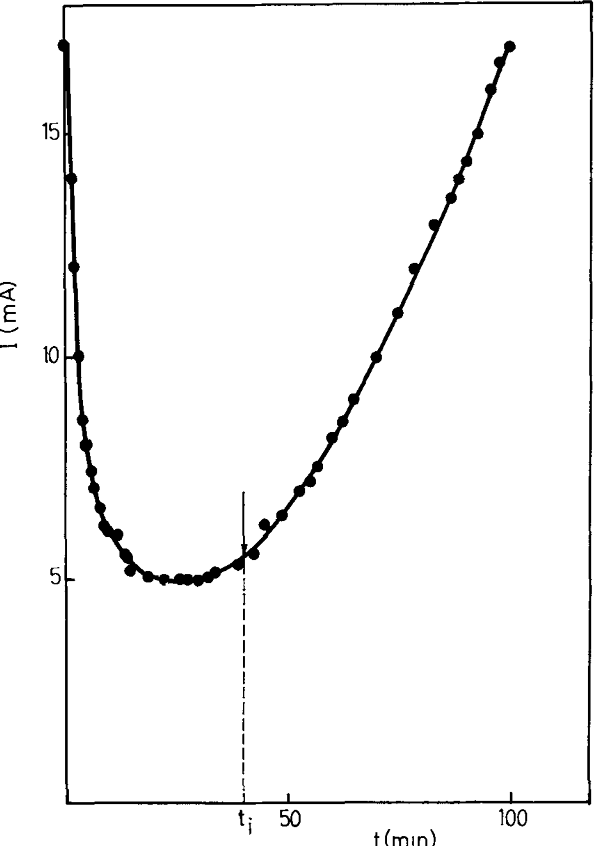

Fig. 2. Typical current-time relationship during the deposition of dendritic deposit at a constant overpotential (100 mV). t_i-induction time recorded at the 10% increase in current.

Solution of KOH (5*N*) has been used as the electrolyte, and varying amounts of zinc oxide have been dissolved in it to make solutions range from 0.025 to 0.5M in zincate. Analytical grade reagents have been used and no additional purification has been carried out after Diggle and Damjanović (5) have shown this to have no effect on the deposition in the investigated system. It was then confirmed in our experiments, as well, that the morphology of the deposit remains the same, whether it is obtained from a fresh electrolyte or from one which has been subjected to prolonged electrolysis.

The experiments consisted of setting the electrode at a constant potential negative to the reversible potential of zinc, by means of a Wenking potentiostat, for a chosen period of time. The development of a disperse deposit could be observed visually. The electrode has then been disconnected for a brief period of time to shave the deposit off, and then submitted to an anodic potential rendering suitable anodic dissolution current which has been followed as a function of time till falling to zero. The same has been done then with the mercury pool at the bottom of the cell.

Results

Current-time relationships.—As already noted and discussed by some authors (1, 5, 12) current-time relationships are known to reflect the establishment of a fixed diffusion layer and the development of a disperse deposit. A typical relationship is shown in Fig. 2. The initial fall in current indicated that the selected potential provided for the appearance of appreciable difficulties in transport of depositing ions, while the ascending part is due to the contribution of the growing crystals penetrating through the diffusion layer. The rather irregular nature of the increase in current past the minimum reflects the properties of the dendrite growth function: for each individual dendrite the latter consists of an initial exponential part and a subsequent linear one (10). Since, the current is determined by the sum of growth rates of all the dendrites at different stages of growth and the appearance of each one is an accidental event, the fluctuations in the increase in the value of the current are not unexpected. Also, it is quite possible that hydrogen evolution (bubble formation and departure) makes its own contribution to such irregularity. For all these reasons the curves are not amenable to quantitative theoretical interpretation for obtaining the time constants of dendritic growth. Instead, they were used to note the time at which the amount of dendrites at the surface becomes so large as to make a noticeable contribution to the current over that used for compact deposition. A 10% increase in current is used as a criterion for recording this type of initiation time. The result is shown in Fig. 7 as a function of overpotential.

Current-potential relationships.—These have been extracted from the current-time curves by plotting the current minima as functions of potential for different concentrations of zincate ions. A plot is shown in Fig. 3. The dispersion of points is indicative of a fair degree of reproducibility of the diffusion layer thickness.

The absence of limiting currents indicates that all the investigated potentials remained in the region of mixed activation and diffusion control.

Dendrite yield as a function of time.—This is shown in Fig. 4 for different constant overpotentials at a constant zincate concentration of 0.5M, and in Fig. 5 for different zincate concentrations at a constant cathodic overpotential of 100 mV. Linear extrapolation of these functions to zero yield rendered the initiation time of dendritic growth. This extrapolation rests on the assumption that even at the shortest time of observations the majority of dendrites is already in the phase of constant rate of growth.

Dendrite yield as a function of overpotential.—For a given time of observation the yield of dendrites was

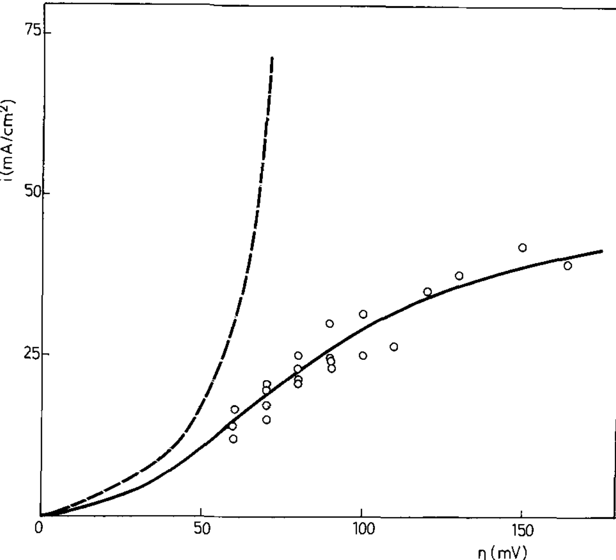

Fig. 3. Current density overpotential relationship for the deposition of zinc from 0.5M alkaline zincate solution. Dashed line-expected relationship in the absence of concentration polarization.

traced as a function of overpotential. The resulting dependence is shown in Fig. 6 for the zincate concentration of 0.5M. The decrease of the functions to zero yield defines the overpotentials of zero yield below which compact deposition should be taking place.

Induction times and overpotentials of zero yield.— The induction times extracted from the results of Fig. 4 and 5 are shown in Fig. 7 and 8 as functions of

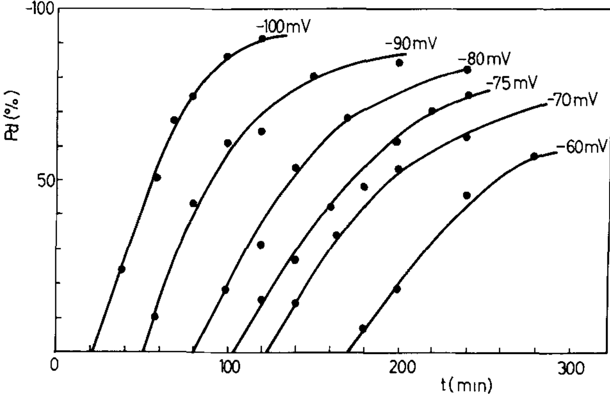

Fig. 4. Yield of dendrites as a function of time at different constant overpotentials at a zincate concentration of 0.5M.

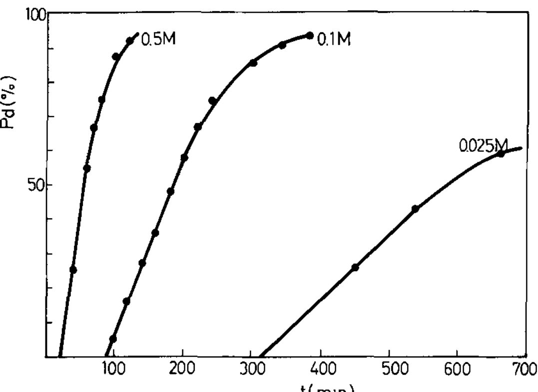

Fig. 5. Yield of dendrites as a function of time at different alkaline zincate concentrations at a constant overpotential of 100 mV.

overpotential (at zincate ion concentration of 0.6M) and of zincate ion concentration (at $\eta = 100$ mV), respectively.

Figure 7 shows also the overpotential of zero yield as obtained from Fig. 6 as a function of the time of observation, as well as the induction times obtained from current minima (cf. Fig. 2).

Discussion

The plot of Fig. 7 justifies once more the contention that the current increase is indicative of the appearance of dendritic deposit, for the times of 10% current increase practically coincide with the induction times obtained from the zero yield.

More significant, however, is the finding indicated by the same plot, that the induction period function of overpotential coincides with the zero yield overpotential as a function of the time of observation. It seems justified to identify the zero yield overpotential with the known critical overpotential of dendritic growth for it is the overpotential below which dendrites do not appear within the time of experiment. However, the fact that the critical overpotential should depend on the time of observation, does not seem to be in accordance with the concept of the critical overpotential used so far and obviously calls for a more detailed analysis of the problem.

This can be made in terms of the theory of dendritic growth as set by Barton and Bockris (3) and developed by Despić, Diggle, and Bockris (14).

That theory has rendered equations for the rate of growth of dendrites (tip current density) under mixed activation and diffusion control as a function of concentration of depositing ions, C_0, diffusion layer thickness, δ, and overpotenital, η, [cf. Despić and Popov

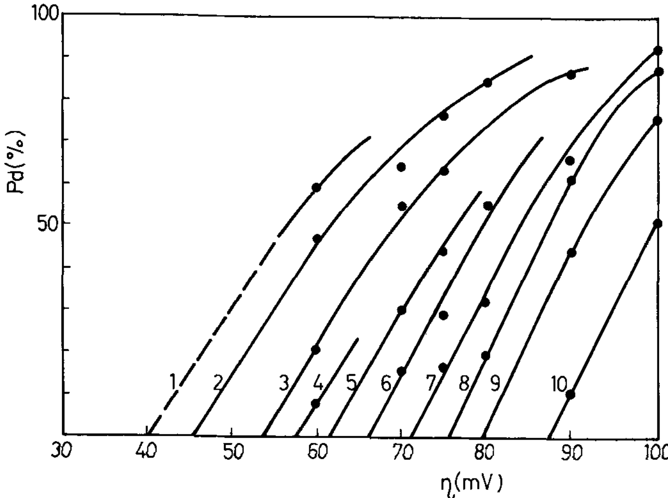

Fig. 6. Yield of dendrites as a function of overpotential for different times of observation (zincate concentration 0.5M).

(10)]. From those, taking the case of divalent metal ion discharge one could derive a complete equation (without some simplifying assumptions made in the original work) for the relationship between dendrite height , h, and time, t.

$$\frac{n\mathbf{F}}{V}\frac{r}{i_L}(1+\beta)\frac{[(1-f_{ac})+(1-f_{ac}K(r))\beta+f_{ac}(1-K(r))]}{[(1-f_{ac}K(r))\beta+f_{ac}(1-K(r))]^2}\left\{\ln\frac{h-h_c}{h_o-h_c}+\frac{h-h_o}{h_c-r\beta}\right\}=t \quad [1]$$

where

$$\beta=\frac{i_of_c(\eta)}{i_L} \quad [2]$$

$$f_{ac}=\frac{f_a(\eta)}{f_c(\eta)} \quad [3]$$

$$h_c=\frac{r\beta(1-f_{ac})}{(1-f_{ac}K(r))\beta+f_{ac}(1-K(r))} \quad [4]$$

and

$$f_c(\eta)=\exp\left[-\frac{\alpha_c\mathbf{F}}{RT}\eta\right] \quad [5]$$

$$f_a(\eta)=\exp\left[\frac{\alpha_a\mathbf{F}}{RT}\eta\right] \quad [6]$$

$$K(r)=\exp\left[\frac{2\sigma V}{RT\rho/2}\right] \quad [7]$$

Here h_o is the height of the dendrite precursor, while r is a quantity reflecting the tip radius. If one approximated the situation by a paraboloidal diffusion law, this would be

$$r=\frac{\rho/2}{\nabla f'} \quad [8]$$

where ρ is the radius of curvature of the paraboloid at the tip of $\nabla f'$ is a function [cf. Ref. (10), Fig. 19] of depositing ion concentration. In fact, $\nabla f'$ is not too sensitive to the latter and in the concentration range which may be encountered in practice, taking a constant value of 0.1 would be a fairly good approximation. i_o is the exchange current density and α_c and α_a the transfer coefficients of the electrochemical reaction; i_L is the diffusion limiting current density for linear diffusion through limited diffusion layer thickness, δ; $K(r)$ is the Kelvin-effect term where σ is the surface tension of the metal.

A typical dependence arising from this relationship is shown in Fig. 9. This demonstrates the physical meaning of the following quantities, which may be determined by experiment:

(i) The time constant of growth, τ_s, is the constant of the exponential part of the growth and could be ob-

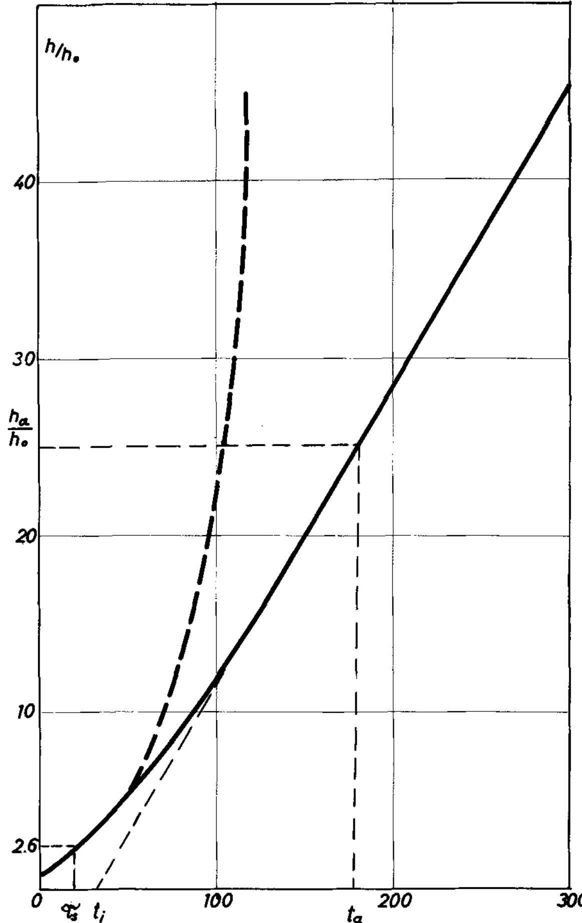

Fig. 9. Time dependence of a dendrite height. h_o, initial height; τ_s, time constant of the exponential growth; t_i, induction time; t_a, time of appearance.

tained in principle from the slope of the plot of log height *vs.* time if that phase of growth could be found experimentally.

(*ii*) The induction period, t_i, is obtained by extrapolation of the linear phase of growth to zero height.

(*iii*) The time of appearance, t_a, is the time in which a dendrite reaches a height, h_a, detectable by the method used.

Simple relationships exist between the three quantities.

Equation [1] reveals directly the factors determining τ_s, *i.e.*

$$\tau_s = \frac{n\mathbf{F}}{V}\frac{r}{i_L}(1+\beta)\frac{[(1-f_{ac})+(1-f_{ac}K(r))\beta+f_{ac}(1-K(r))]}{[(1-f_{ac}K(r))\beta+f_{ac}(1-K(r))]^2} \quad [9]$$

The initiation time, t_i, can be obtained from the following reasoning. It was shown earlier (2) that, as an experimental quantity, it is found by extrapolation of the linear growth function to zero dendrite height. This function could be derived theoretically for the growth of dendrite outside the diffusion layer boundary on the basis of the tip current density [cf. Ref. (10)] as

$$h = \frac{V}{n\mathbf{F}} i(\text{tip})(t-t_i) = \frac{V}{n\mathbf{F}}\frac{i_L i_o[f_c(\eta)-K(r)f_a(\eta)]}{i_L+\frac{r}{\delta}i_o f_c(\eta)}(t-t_i) \quad [10]$$

At the very exit from the linear diffusion layer ($h = \delta$) this function must coincide with the function presented above (Eq. [1]) for the growth of the dendrite from the start up to the diffusion layer boundary. Equating the two, one can eliminate t and solve the equation for t_i. The result is

$$t_i = \tau_s\left\{\ln\frac{\delta-h_c}{h_o-h_c}-\frac{h_o}{h_c+r\beta} + \frac{\delta}{h_c+r\beta}\left[1+\frac{r\beta}{h_c}\cdot\frac{\left(1+\frac{r}{\delta}\beta\right)}{(1+\beta)}\right]\right\} \quad [11]$$

The time of appearance, t_a, is directly given by Eq. [1] when h is replaced by h_a.

It is of interest now to analyze any one of these quantities for its dependence on the operational parameter η, for different values of the basic properties of the system as are the i_o and the concentration of depositing ions. One could assume certain values of the diffusion coefficient of depositing ions ($D = 10^{-5}$ cm^2 sec^{-1}) and the diffusion layer thickness ($\delta = 10^{-3}$ cm) determining the diffusion limiting current density i_L as well as of the height of the dendrite precursor ($h_o = 10^{-4}$ cm) and the radius of the dendrite tip ($r = 10^{-5}$ cm). The cathodic transfer coefficient α_c is known to be about 0.5 and the anodic one α_a about 1.5 for most divalent metal deposition reactions. With the r value taken, the Kelvin effect, as given by Eq. [7] is negligible, *i.e.*, the factor $K(r)$ sufficiently close to unity. This simplifies considerably Eq. [11] for computational purposes. Hence, the dependence of the induction time on overpotential was obtained using the simplified Eq. [11] with the above set of parameters. This is shown in Fig. 10 on a log-log scale, for a number of different i_o values ranging from 1 to 10^{-8} A/cm^2 and in Fig. 11 for concentrations ranging from 1 to 10^{-4}M. In Fig. 12 two values of the tip radius have been taken differing by a power of ten.

Several characteristics features should be noted:

(*i*) In the high overpotential region all the curves for different i_o values and the same concentration of depositing ions converge to a single one, with an asymptotic tendency to a level inversely dependent on concentration. This is obviously the region of prevailing diffusion control.

The limiting value of the induction time is obtained from [11] as

$$t_{i,1} = \frac{n\mathbf{F}}{V}\cdot\frac{r}{i_L}\ln\left(\frac{\delta-r}{h_o-r}\right) = \left[\frac{\delta}{VD}\ln\left(\frac{\delta-r}{h_o-r}\right)\right]\frac{r}{C_o} \quad [12]$$

(*ii*) In the low overpotential region linear functions with the slope of -1 are obtained, indicating the first order relationship between inverse induction time and overpotential. This is the region of prevailing activation control.

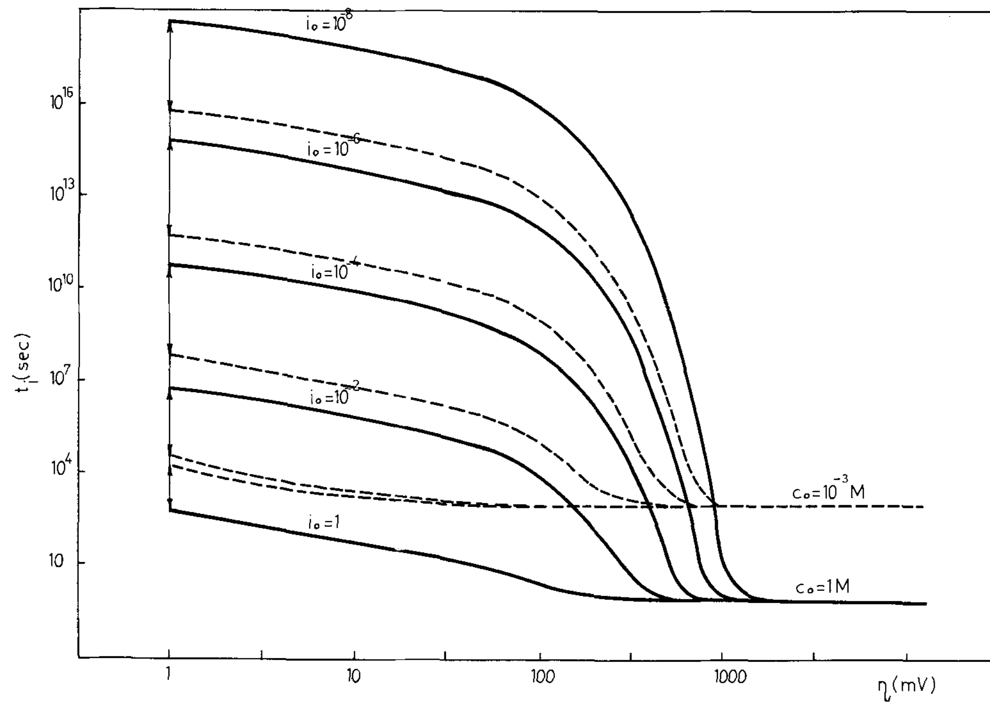

Fig. 10. The induction time as a function of overpotential (theoretical relationship, Eq. [11]) for different constant i_o and zincate concentrations.

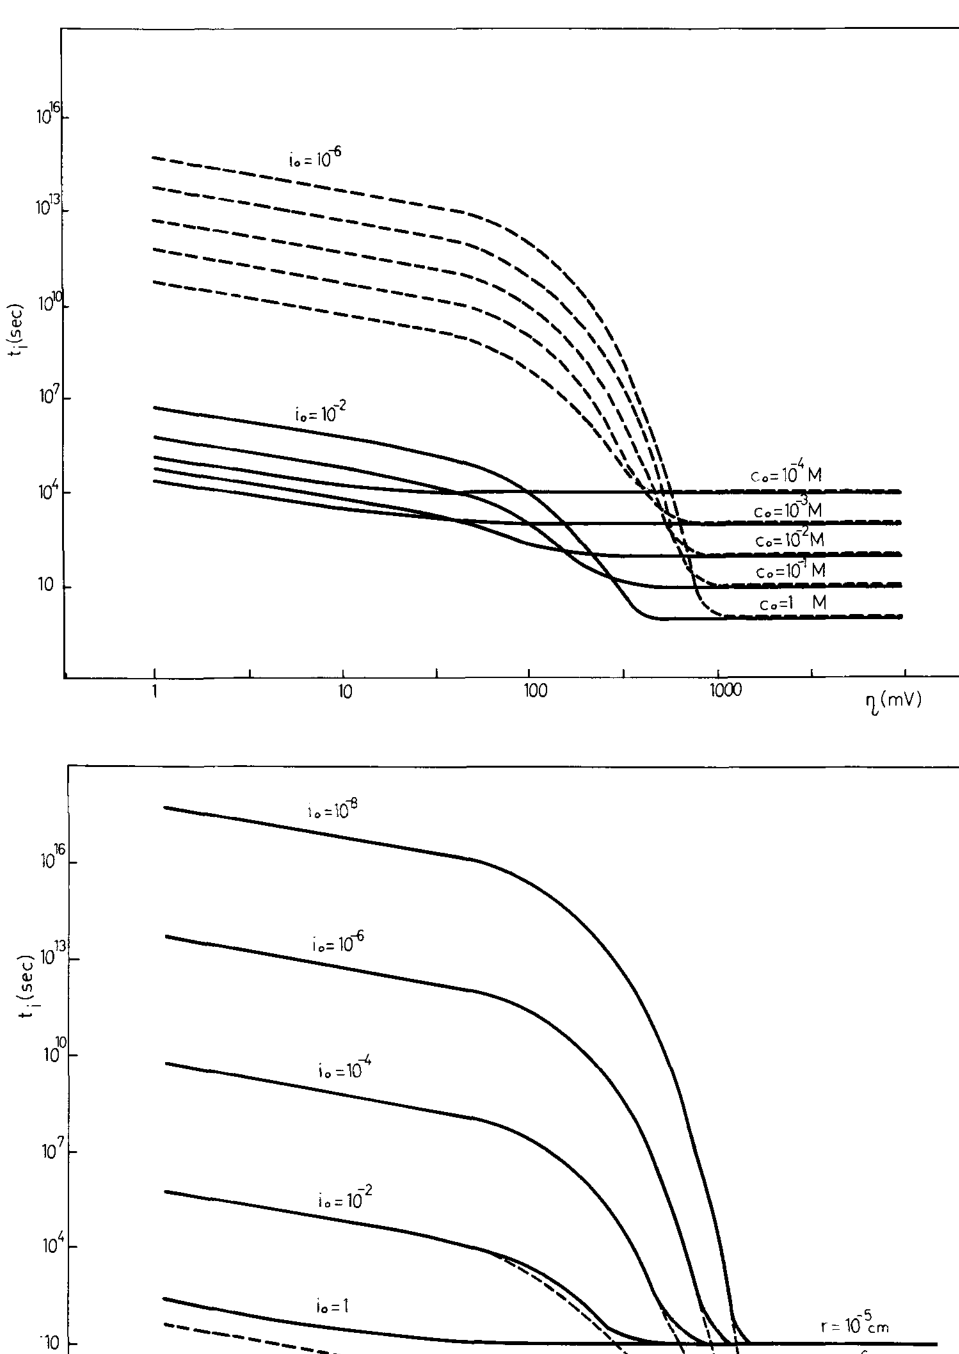

Fig. 11. The induction time as a function of overpotential (theoretical relationship, Eq. [11]), for different constant zincate ion concentrations and i_o values of 10^{-2} A/cm² (full line) and 10^{-6}A/cm² (dashed line).

Fig. 12. The induction time as a function of overpotential for two different values of the dendrite tip radius ($C_o = 10^{-1}$M).

(*iii*) The tip radius has no effect in the activation controlled region, while the limiting induction time level at high potentials is directly proportional to it.

(*iv*) There is a transition region in which the change in the induction time with overpotential can be very sharp. It is sharper the lower the i_o value and the higher the concentration.

(*v*) In the transition region, in systems of low i_o value and at high concentration of depositing ions, decreasing the overpotential in a relatively narrow range can result in a change of the induction time by so many powers of ten as to bring it to values unattainable under normal experimental conditions (10^8 to 10^{10} sec).

In view of these findings one should consider the problem of the critical overpotential. In systems of high i_o values and at high concentrations of depositing ions the induction time does not increase much with decreasing overpotential and it should always be possible to extend the experimental observation to times far outside the possible induction time limits. Hence, if no dendrites appear in such time intervals one could maintain to have carried out the deposition at the overpotential below the true, *i.e.*, thermodynamic critical overpotential value. The proper way to ascertain the latter would be to establish the dependence of the inverse of induction time on overpotential. In the absence of critical overpotential with decreasing overpotential this should extrapolate to zero. Any critical overpotential should show as a non-zero intersection with the abscissa.

In the case of systems with high i_o values, however, when operating at ever decreasing overpotentials one is likely to enter the region of sharp change in induction time. At still lower overpotentials one would record no dendrites within reasonable time and the over-

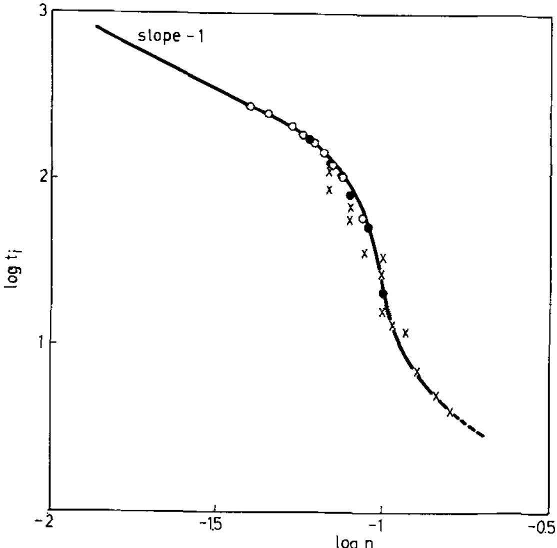

Fig. 13. The induction time as a function of overpotential-experimental relationship based on data of Fig. 7.

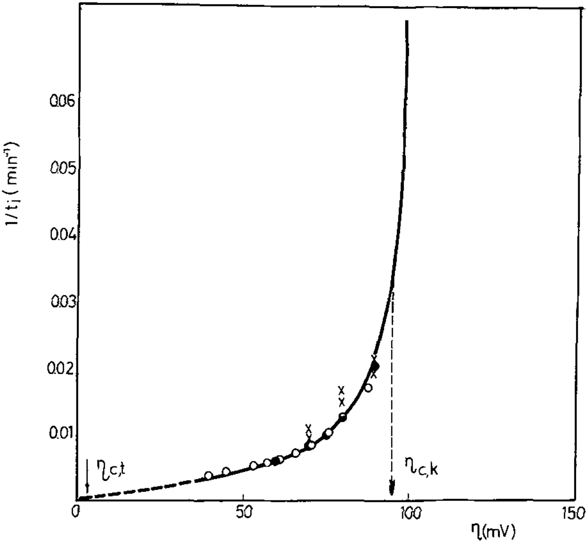

Fig. 14. Inverse induction time as a function of overpotential: $\eta_{c,t}$, thermodynamic critical overpotential; $\eta_{c,k}$, kinetic critical overpotential.

potential at which that transition takes place would have the character of a critical overpotential. Obviously, extending the existing definition of the critical overpotential is indicated. Beside the true thermodynamic critical overpotential, one should define also an apparent or kinetic critical overpotential as the overpotential at which the induction time sharply rises to high values unattainable under normal conditions of experiment.

If one takes as the kinetic critical overpotential that overpotential at which the induction time becomes x-fold (*e.g.*, 100 times) larger than the limiting induction time value, $t_{i,L}$, one can derive by contrasting Eq. [11] and [12], that for reasonably high r values

$$-\eta_{c,k} = \frac{2.3\,RT}{\alpha_c \mathbf{F}} \log \frac{n\mathbf{F}D}{\delta\,(x^{1/2}-1)} + \frac{2.3\,RT}{\alpha_c \mathbf{F}} \log \frac{C_o}{i_o} \quad [13]$$

In view of these conclusions one should consider the results of the present experimental investigations. The data of Fig. 7 are replotted in Fig. 13, to match the presentation of the theoretically derived functions. The similarity is evident. This plot indicates that the critical overpotential of dendritic growth of zinc from zincate solution reported in the literature to be between 60 and 80 mV, is a kinetic critical overpotential. It is interesting to note that this system is on the limit at which the thermodynamic critical overpotential could also be determined from the same plot but from the low overpotential region. It is seen that the last few points indicate a linear dependence with the theoretically predicted slope of -1. Hence, a graph of $1/t_i$ *vs.* η is constructed, as shown in Fig. 14, and the extrapolation to $1/t_i = 0$ is made. The precision of such an extrapolation is necessarily rather poor. Nevertheless, one could maintain with a fair degree of certainty that the thermodynamic critical overpotential, if any, is not larger than 10 mV.

At the end one should note that the above theory should also be applicable to other transport controlled phenomena in metal deposition and in particular to the phenomenon of the amplification of surface roughness (13).

In that context it was possible to show that the above analysis could be carried out with respect to current density of deposition rather than to overpotential, which for many a practical purpose is a more easily controllable operational parameter. It was shown that the concept of critical current density can also be given a kinetic background similar to that derived above for the critical overpotential.

Amalgam Decomposition

I. Theoretical Relations for Decomposition Kinetics of Sodium Amalgam in Tower Decomposer

I. Roušar,* S. Rajasekaran,[1] and V. Cezner

Department of Inorganic Technology, Institute of Chemical Technology, Prague, Czechoslovakia

ABSTRACT

Relationships between the amalgam decomposition rate in a tower decomposer, concentration of sodium in the amalgam, and mass flow of the amalgam through the tower were derived. The dependence of the reaction rate on the rate of flow exhibits a maximum.

Problems of the kinetics of amalgam decomposition in tower decomposers were studied by Hine and coworkers (1-7) who derived equations for calculation of the local and average decomposition rate in a tower with the use of several simplifying assumptions. Their equations are in good agreement with experimental data only at low or medium rates of flow of the amalgam (8). Hine's experimental data (7) indicate that the amalgam decomposition rate decreases when a certain "optimum" flow rate is exceeded. However, Hine's theory (7) ceases to be satisfactory at amalgam flow rates beyond optimum, because it still would predict an increase of amalgam decomposition rates. We therefore attempted to describe the amalgam decomposition in a tower completely and to derive theoretically the dependence of the decomposition rate on the rate of flow, which would satisfy the experimental data in a broader range of flow rates than Hine's theory. Nevertheless, the presented theory is restricted to systems where amalgam drops are formed and therefore is not valid for flooded systems (with water in the dispersed phase).

Basic Assumptions

During decomposition, the amalgam is brought into contact with graphite and a sodium hydroxide solution. Thus, a local hydrogen-amalgam cell is formed, where the amalgam functions as anode and graphite as cathode. A positive electric current flows from the amalgam to the electrolyte, passes through the latter, enters into the graphite and through the graphite-amalgam interface returns into the amalgam. Along every closed line of current, the reversible voltage of the amalgam-hydrogen cell (${}_rU$) is compensated by anodic and cathodic overvoltages and by ohmic losses in the electrolyte, amalgam, graphite, and contact resistance between the amalgam and graphite.

The anodic overvoltage (η_A) during dissolution of the sodium amalgam is due to an insufficiently rapid transport of sodium from the bulk to the amalgam-electrolyte interface (9-11)

$$\eta_A = (RT/\mathbf{F}) \ln (a_{Na}^o/a_{Na}^s) \qquad [1]$$

Here a_{Na}^o and a_{Na}^s denote activities of sodium in the bulk of the amalgam and at the interface, respectively. The flux of sodium to the interface is given by undirectional diffusion

$$\bar{i}/\mathbf{F} = -N_{Na} D_{Na} d \ln a_{Na}/dz \qquad [2]$$

where $\bar{i}$ denotes average current density on the drop surface (A/cm²), N_{Na} bulk concentration of sodium (mol/cm³), D_{Na} its diffusion coefficient (cm²/sec), and z distance perpendicular to the amalgam surface (cm). In further calculations, we shall express N_{Na} and a_{Na} by molar fraction of sodium in the amalgam, X_{Na}; because η_A reaches significant values if $X_{Na}^o \rightarrow 0$ we shall use the assumption $X_{Na} \rightarrow 0$. Then

$$N_{Na} = X_{Na}/V_{AM}M_{Hg} \qquad [3]$$

where M_{Hg} is the molecular weight of mercury and V_{AM} denotes specific volume of the amalgam (cm³/mol), which can be expressed (12) as a function of X_{Na}; for $X_{Na} \rightarrow 0$

$$V_{AM} = V_{Hg} \qquad [4]$$

Here V_{Hg} denotes specific volume of mercury (cm³/mol) at the given temperature. On introducing Eq. [4] into [3], we obtain

$$N_{Na} = X_{Na}/V_{Hg}M_{Hg} \qquad [5]$$

The activity of sodium in the amalgam is given by (13)

$$a_{Na} = X_{Na} \exp (A + BX_{Na} + CX_{Na}^2) \qquad [6]$$

and for $X_{Na} \rightarrow 0$ we obtain from Eq. [6]

$$a_{Na} = X_{Na} \exp (A) \qquad [7]$$

where $A = 9505.4 \ln 10/T^{1.16}$, $B = 214.3 \ln 10/T^{0.46}$, and $C = (14.7 - 0.027T) \ln 10$. On introducing Eq. [5] and [7] into [2] and rearranging we obtain

$$(\bar{i}/\mathbf{F})\, dz = -(D_{Na}/V_{Hg}M_{Hg})\, dX_{Na} \qquad [8]$$

Integration of this equation from X_{Na}^s ($z = 0$) to X_{Na}^o ($z = \delta$) yields

$$(\bar{i}/\mathbf{F})(\delta V_{Hg}M_{Hg}/D_{Na}) = -(X_{Na}^s - X_{Na}^o) \qquad [9]$$

(X_{Na}^s denotes mean molar fraction of sodium in amalgam on the drop surface and δ thickness of Nernst layer for sodium diffusion to the interface). Rearranging Eq. [9] and using Eq. [7] we obtain

$$a_{Na}^s/a_{Na}^o = 1 - (\bar{i}\delta V_{Hg}M_{Hg}/D_{Na}FX_{Na}^o) \qquad [10]$$

The value of (a_{Na}^s/a_{Na}^o) thus found enables one to calculate η_A (Eq. [1]). The overvoltage during hydrogen evolution, η_K, on a graphite cathode is given by the Tafel equation

$$\eta_K = a_K - b_K \ln i, \qquad \eta_K < 0 \qquad [11]$$

where i denotes current density, a_K and b_K Tafel constants (V) to be determined experimentally (14) for the given sort of graphite, concentration, and temperature of electrolyte.

The ohmic voltage drop in the electrolyte between the anode and cathode is given by the specific resistance of the mixture of hydrogen bubbles and electrolyte in the space between the electrodes and by the geometry of this space. If the specific resistance is constant the Laplace equation applies

$$\nabla^2\phi = 0 \qquad [12]$$

with suitable boundary conditions on the interfaces. However, the solution of this equation is rendered impossible by insufficient knowledge of the distribution

of amalgam flow in the bed. We therefore used for a quantitative description of the processes during amalgam decomposition the drop model described below.

Drop Model for Amalgam Decomposition

We assume that the amalgam flows down through the graphite bed in the form of half-sphere-shaped droplets of radius r_o independent of the rate of flow. The droplets are distributed evenly in the bed at a density of N_1 droplets per unit height of the bed; a circular area of graphite of radius r_f corresponds to every drop. The situation during decomposition of an amalgam drop in contact with graphite is illustrated in Fig. 1 showing a closed line of current which passes the ohmic resistances and interfaces. The voltage balance for this line of current is

$$(f_1 L_E \rho_E + f_2 L_{EL} \rho_E + L_G \rho_G + L_{AM} \rho_{AM}) i + 2\rho_{SL} L_{SL} \bar{i} + \epsilon_A - \epsilon_K = 0 \quad [13]$$

Here L_E, L_{EL}, L_G, L_{AM}, and L_{SL} (cm) denote lengths of the current line in the bulk of electrolyte, in the layer of electrolyte-bubble mixture at the graphite surface, in the graphite, in the amalgam, and in the amalgam-graphite interface, respectively; ρ_E, ρ_G, ρ_{AM}, and ρ_{SL} (ohm · cm) specific resistances of the pure electrolyte (without bubbles), graphite, amalgam, and amalgam-graphite interface, respectively; i (A/cm^2), anodic current density on the given point of the amalgam surface; ϵ_A, ϵ_K (V), local anodic and cathodic potentials; f_1, ratio of the specific resistance of the electrolyte-bubble mixture in the bulk of electrolyte to that of the pure electrolyte; and f_2 the same ratio for the electrolyte-bubble mixture at the graphite surface. The term $2L_{SL}\rho_{SL}\bar{i}$ represents the voltage loss on the contact resistance between amalgam and graphite. The factor of 2 follows from the assumption that the amalgam drops have a hemispherical shape during contact with graphite; the contact area is then πr_o^2 whereas the surface area to which the anodic current is referred is $2\pi r_o^2$. As illustrated in Fig. 1. and Eq. [13], we assume that the only surface on which the evolution of hydrogen can occur is the free surface area of graphite. In fact a small fraction of hydrogen also evolves under the amalgam drop because the graphite surface is covered with a thin layer of caustic. Hydrogen evolution in this contact area leads to an increase of resistance under the amalgam drop. Therefore it is necessary that the voltage balance be extended by a term taking account of this effect, *i.e.*, the term $2L_{SL}\rho_{SL}\bar{i}$.

The voltage balance can be rewritten with the use of the equations

$$_rU = {_r\epsilon_A} - {_r\epsilon_K} \quad [14]$$

$$\eta_A = \epsilon_A - {_r\epsilon_A} \quad [15]$$

$$\eta_K = \epsilon_K - {_r\epsilon_K} \quad [16]$$

where the index r refers to the equilibrium state; η_A, η_K (V) local anodic and cathodic overpotentials; and $_rU$ reversible voltage of the amalgam-hydrogen cell. Thus, Eq. [13] gives

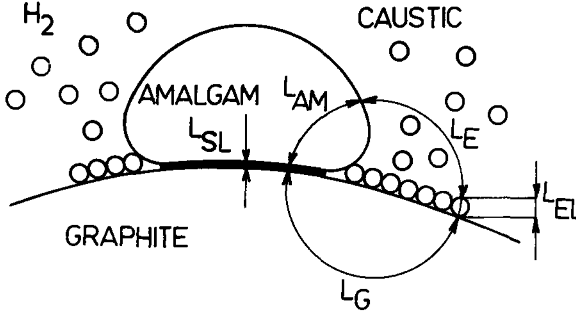

Fig. 1. Drop model (course of a current line)

$$-{_rU} = f_1 L_E \rho_E i + f_2 L_{EL} \rho_E i + L_G \rho_G i + 2L_{SL}\rho_{SL}\bar{i} + L_{AM}\rho_{AM} i + \eta_A - \eta_K \quad [17]$$

Here we can neglect the terms corresponding to the voltage drop in the graphite and amalgam since ρ_G and ρ_{AM} are by about three orders of magnitude smaller than ρ_E. We assume that the length of the lines of current in the electrolyte is given as

$$L_E = r - r_o \quad [18]$$

where r denotes distance from the center of the drop measured along the graphite surface. This simplifying assumption is important since the true value of L_E can be computed only after solving Eq. [12] for a given geometry and boundary conditions. Thus, the assumption that L_E is known implies that the solution of the Laplace equation for the given system is also known. Equation [17] can be rearranged as follows

$$-{_rU} + a_K - (RT/\mathbf{F}) \ln (a_{Na}^o/a_{Na}^s) - 2\rho_{SL}L_{SL}\bar{i} = f_1\rho_E (r - r_o) i + f_2\rho_{EL} L_{EL} i + b_k \ln i \quad [19]$$

The terms that are independent of coordinates are on the left side, those which depend on position (on the drop surface and its proximity) are on the right side.

The current density on the graphite surface attains its maximum value, $i = i_{max}$, for $r = r_o$, which can be found from Eq. [19]

$$-{_rU} + a_K - (RT/\mathbf{F}) \ln (a_{Na}^o/a_{Na}^s) - 2\rho_{SL}L_{SL}\bar{i} = f_2\rho_E L_{EL} i_{max} + b_K \ln i_{max} \quad [20]$$

By subtracting Eq. [20] from [19] we obtain

$$f_i\rho_E (r - r_o) i + f_2\rho_E L_{EL} (i - i_{max}) + b_K \ln (i/i_{max}) = 0 \quad [21]$$

We now define the following dimensionless criteria and simplexes

$$K_D = f_1\rho_E r_o i_{max}/b_K \quad [22]$$

$$K_{SL} = f_2\rho_E L_{EL} i_{max}/b_K \quad [23]$$

$$i_R = i/i_{max} \quad [24]$$

$$r_R = r/r_o \quad [25]$$

The term ln (i/i_{max}) in Eq. [21] can be expanded in series for $i \approx i_{max}$ and the terms of higher order can be neglected

$$\ln (i/i_{max}) = \ln (1 + (i - i_{max})/i_{max}) \doteq ((i - i_{max})/i_{max}) - \tfrac{1}{2} ((i - i_{max})/i_{max})^2 \quad [26]$$

On introducing Eq. [22]-[26] into [21] we obtain

$$K_D(r_R - 1) i_R + K_{SL}(i_R - 1) + (i_R - 1) - (\tfrac{1}{2})(i_R^2 - 2i_R + 1) = 0 \quad [27]$$

and after rearranging the dependence of i_R on r_R is found as

$$i_R = 2 + K_D(r_R - 1) + K_{SL} - [(2 + K_D(r_R - 1) + K_{SL})^2 - 3 - 2K_{SL}]^{1/2} \quad [28]$$

This equation gives the local current density on the graphite surface. The average current density on the amalgam surface, $\bar{i}$, and that on the graphite surface, i_p, is found by integrating over the free graphite surface as

$$\bar{i} 2\pi r_o^2 = i_p \pi (r_f^2 - r_o^2) = 2\pi r_o^2 i_{max} \int_1^{r_f/r_o} i_R r_R dr_R \quad [29]$$

whence follows the relation

$$\bar{i} = 0.5 i_p [(r_f/r_o)^2 - 1] = i_{max} \int_1^{r_f/r_o} i_R r_R dr_R = i_{max} P_1 \quad [30]$$

where

$$P_1 = \int_1^{r_f/r_o} i_R r_R dr_R \quad [31]$$

After introducing i_R from Eq. [28] into [31] we obtain

$$P_1 = \int_1^{r_f/r_o} (2 + K_D r_R - K_D + K_{SL}) r_R dr_R - \int_1^{r_f/r_o} (ar_R^2 + br_R + c)^{1/2} r_R dr_R \quad [32]$$

where

$$a = K_D^2 \quad [33a]$$

$$b = 4K_D - 2K_D^2 + 2K_D K_{SL} \quad [33b]$$

$$c = K_D^2 - 2K_D K_{SL} + K_{SL}^2 - 4K_D + 2K_{SL} + 1 \quad [33c]$$

$$a + b + c = (K_{SL} + 1)^2 \quad [33d]$$

The integrals in Eq. [32] can be evaluated as

$$\int_1^{r_f/r_o} (2 + K_D r_R - K_D + K_{SL}) r_R dr_R = 0.5(K_{SL} - K_D + 2)[(r_f/r_o)^2 - 1] + (K_D/3)[(r_f/r_o)^3 - 1] \quad [34]$$

$$\int_1^{r_f/r_o} (ar_R^2 + br_R + c)^{1/2} r_R dr_R = (1/3a)(a(r_f/r_o)^2 + b(r_f/r_o) + c)^{3/2} - K_{SL} + 1)^3 - (b/8a^2)\{[(2a(r_f/r_o) + b)\, a(r_f/r_o)^2 + b(r_f/r_o) + c]^{1/2} - (2a + b)(K_{SL} + 1)\} - (b(4ac - b^2))/(16a^{5/2}) \cdot \ln \left\{ \frac{2a^{1/2}(a(r_f/r_o)^2 + b(r_f/r_o) + c)^{1/2} + 2a(r_f/r_o) + b}{2a^{1/2}(K_{SL} + 1) + 2a + b} \right\} \quad [35]$$

The final equation for P_1 is

$$P_1 = a_1 - b_1 + c_1 - d_1 \quad [36]$$

where a_1 denotes right side of Eq. [34], b_1, c_1, and d_1 the three terms in Eq. [35]; the average current density on the free graphite surface (not covered with amalgam drops) is

$$i_p = 2P_1 i_{max}/[(r_f/r_o)^2 - 1] \quad [37]$$

The current referred to unit height of tower, I (A/cm) depends on i_p as follows

$$I = i_p \pi (r_f^2 - r_o^2) N_1 \quad [38]$$

where N_1 denotes number of amalgam drops in unit tower height (cm^{-1}). The latter value can be calculated from the balance of the surface on which the amalgam decomposition proceeds

$$N_1 \pi r_f^2 = S_T (S_G/V_T) f_S \quad [39]$$

where S_T denotes inner cross section of tower (cm^2), S_G/V_T total surface area of the graphite bed in unit volume of tower (cm^2/cm^3), f_S a factor proportional to utilization of the graphite surface in the amalgam decomposition (supposing, that the lower part of the graphite spheres is ineffective $f_S \approx 0.6$).

The rate of amalgam decomposition, r_{Na} [mol Na/(cm$^3 \cdot$ sec)] at a given height of tower is given by

$$r_{Na} = I/(\mathbf{F} \cdot S_T) \quad [40]$$

where $\mathbf{F}$ is 96,496 coulombs.

After introducing I from Eq. [38] and N_1 from [39] we obtain

$$r_{Na} = (i_{max}/\mathbf{F})(r_o/r_f)^2 (S_G/V_T) f_S 2P_1 \quad [41]$$

This equation can be directly used in calculating the tower height, H (cm) (assuming homogeneous, piston flow of amalgam through the tower)

$$H \cdot S_T/M = -\int_{Y_1}^{Y_2} dY/r_{Na} \quad [42]$$

Here M denotes rate of flow of mercury (mol Hg/sec), Y concentration of sodium in the amalgam (mol Na/mol Hg), Y_1 and Y_2 values of Y at the inlet and outlet, respectively.

To calculate the ratio r_f/r_o in Eq. [41], the volume balance for the amalgam is expressed as

$$N_1 (2/3) r_o^3 w_{Hg} = M(\overline{V}_{Hg} + Y\overline{V}_{Na}) \quad [43]$$

where w_{Hg} (cm/sec) denotes apparent velocity of fall of amalgam drops through the tower referred to the motion along z axis; $\overline{V}_{Hg}$ and $\overline{V}_{Na}$ partial molar volumes of mercury and sodium in the amalgam (cm^3/mol). The velocity w_{Hg} involves also the exchange effect of amalgam between drops flowing down through the bed and those forming a stationary portion held up in the bed; w_{Hg} is, therefore, smaller than the measured velocity of amalgam drops in the tower. By eliminating N_1 from Eq. [39] and [43] we obtain

$$r_f/r_o = [(2/3) r_o w_{Hg} (S_G/V_T) f_S] / [(M/S_T)(\overline{V}_{Hg} + Y\overline{V}_{Na})]^{1/2} \quad [44]$$

With increasing rate of flow of the amalgam, the free surface area of graphite on which the amalgam decomposition can proceed decreases gradually until a certain rate of flow (which can be denoted as maximum from the point of view of amalgam decomposition) the total available surface of the graphite is flooded with the amalgam.[2] We denote this rate of flow as $(M/S_T)_{max}$; for this case is $r_o = r_f$ and Eq. [44] gives

$$(M/S_T)_{max} = [(2/3) r_o w_{Hg} (S_G/V_T) f_S]^2 / (\overline{V}_{Hg} + Y\overline{V}_{Na}) \quad [45]$$

We introduce relative rate of flow, $(M/S_T)_{rel}$, defined as

$$(M/S_T)_{rel} = (M/S_T)/(M/S_T)_{max} \quad [46]$$

and from Eq. [44]-[46] follows the expression

$$r_f/r_o = 1/(M/S_T)_{rel}^{1/2} = [(M/S_T)_{max}/(M/S_T)]^{1/2} \quad [47]$$

which can be introduced into Eq. [41] to give the expression for the reaction rate in the form suitable for calculation

$$r_{Na} = (i_{max}/\mathbf{F})(M/S_T)_{rel} (S_G/V_T) f_S 2P_1 \quad [48]$$

Equation [48] was verified by measurement of the dependence of the decomposition rate on amalgam concentration at constant rate of flow of the amalgam through the tower as well as by measurement of the decomposition rate on the rate of flow at constant amalgam concentration (15).

Discussion of Results

We shall use the following values of the constants in calculating the rate of amalgam decomposition: $f_S = 0.6$; $(M/S_T)_{max} = 0.025$ mol Hg/(cm$^2 \cdot$ sec); $f_1 r_o = 0.4$ cm; $\delta = 4.23 \times 10^{-4}$ cm. For a reactor containing 40% NaOH at 80°C we calculated the dependences shown in Fig. 2 and 3 with $a_K = -0.604$V, $\alpha = 0.411$, $f_2 L_{EL} = 0.35$ cm, $\rho_{SL} L_{SL} = 0.35$ ohm $\cdot$ cm^2 ($b_K = RT/(1 - \alpha)\mathbf{F}$ and $\beta = 1 - \alpha$).

[2] The reaction rate calculation ought to include a term representing amalgam decomposition at the amalgam-graphite contact area. This term is small for systems where the free surface area of graphite is comparable with the contact area. For systems with small free surface area of graphite (the so-called flooded systems) this new term predominates and represents practically the whole reaction rate of amalgam decomposition. Since our analysis is restricted to the former systems, we neglected this additional term in calculating the reaction rate. Nevertheless, we still use the expression "reaction rate for flooded system," meaning only that fraction of the reaction rate due to hydrogen evolution on the free surface area of graphite, rather than the whole reaction rate.

The dependence of the rate of amalgam decomposition on the concentration of sodium for $M/S_T = 0.01$ mol Hg/(cm^2 · sec) is shown in Fig. 2. Its slope in bilogarithmic coordinates at higher sodium concentrations is close to 0.2; at concentrations <0.05 weight per cent (w/o) Na the slope increases and approaches 1.0 at 0.001%. The value of 0.2 can be attributed to the influence of the resistances of the bubble layer and interelectrode space—without these effects the slope should be about 0.5 (for $\alpha = 0.5$). At low sodium concentrations in the amalgam the rate determining step is diffusion of sodium toward the drop surface, hence the reaction rate becomes linearly dependent on the sodium concentration.

The dependence of the rate of amalgam decomposition on the mass flow of the amalgam (M/S_T) at a sodium concentration of 0.1915 w/o is shown in Fig. 3. It exerts a flat maximum at about 0.012 mol Hg/(cm^2 · sec), which can be attributed to the fact that with increasing number of drops per volume unit of tower (with increasing wetting) the surface area of the bed available for hydrogen evolution diminishes. For high values of M/S_T the drop model fails; the reaction rate in this region is therefore represented by the dashed portion of the curve in Fig. 3.

The influence of a change of hydrogen overvoltage, a_T, from −0.604V to −0.469V and a simultaneous change of α from 0.411 to 0.517 is illustrated in Fig. 4. As a result, the reaction rate increases by about 40% (in the maximum). Thus, materials with a lower hydrogen overvoltage enable one to obtain higher reaction rates.

Figure 5 shows the influence of a change of the quantity $\rho_{SL}L_{SL}$ from 0.35 to 0.01 ohm-cm^2 (curves 1 and 2) and f_2L_{EL} from 0.35 to 0.01 cm (curves 1 and 3). It is seen that the decrease of the resistance at the interface (*i.e.*, the contact resistance on the graphite surface and the surface coverage with evolved gas) causes a marked increase of the reaction rate. A good material of the bed should have a low resistance in contact with the amalgam and the gas bubbles should be easily removable from it.

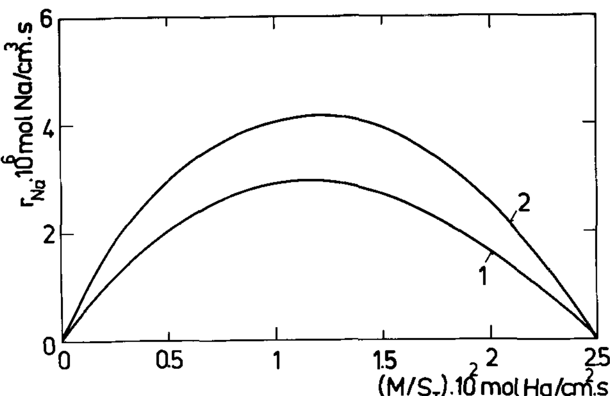

Fig. 4. Influence of hydrogen overvoltage on graphite changing from $a_T = -0.604$V (curve 1) to $a_T = -0.469$V (curve 2).

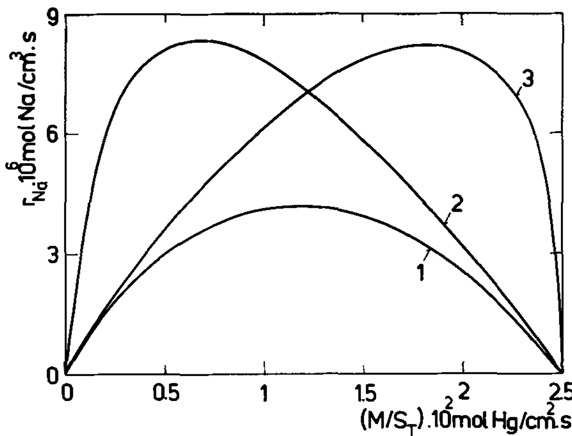

Fig. 5. Influence of $\rho_{SL}L_{SL}$ changing from 0.35 to 0.01 ohm-cm^2 (curves 1 and 2) and f_2L_{EL} changing from 0.35 to 0.01 cm (curves 1 and 3) for $a_T = -0.469$V, $\alpha = 0.517$.

Use of the Theory in Calculating the Tower Height

It is advantageous that the dependence of log r_{Na} on log c_{Na} can be in the technically interesting region replaced by two straight lines. The resulting dependence has therefore the form

$$r_{Na} = kc_{Na}{}^n \text{ or } r_{Na} = k_1Y^n \qquad [49a, b]$$

Both k and n depend on the rate of flow of the amalgam and other factors used in the calculation. Their values were found from the dependence in Fig. 2 to be

$$k = 3.452 \times 10^{-6},\ n = 0.21308 \text{ for } 0.02 \leq c_{Na} \leq 0.2 \qquad [50a]$$

$$k = 1.479 \times 10^{-5},\ n = 0.58496 \text{ for } 0.01 \leq c_{Na} \leq 0.02 \qquad [50b]$$

The relation between c_{Na} and Y is

$$Y \approx (c_{Na}/100)(M_{Hg}/M_{Na}) = c_{Na} \cdot 0.087251 \qquad [51]$$

hence

$$dY = 0.087251 \cdot dc_{Na} \qquad [52]$$

where c_{Na} denotes weight concentration of sodium in the amalgam. If Eq. [52] is introduced in [42] the following expression for the tower height results

$$H = -\frac{M}{S_T}\, 0.087251 \int_{c_1}^{c_2} \frac{dc_{Na}}{k \cdot c_{Na}{}^n}$$

$$= \frac{M}{S_T}\frac{0.087251}{k}\frac{1}{1-n}\,[c_1{}^{1-n} - c_2{}^{1-n}] \qquad [53]$$

Hence, the tower height for the given parameters ($c_{Na,1} = 0.2$; $c_{Na,2} = 0.01$) is equal to 82.2 cm in good accord with the experiment (15). It follows that the parameters used in the calculation will be close to those obtained from experimental data.

Amalgam Decomposition

II. Measurement of Amalgam Decomposition Rate in Tower Decomposer

S. Rajasekaran,[1] I. Roušar,* and V. Cezner

Department of Inorganic Technology, Institute of Chemical Technology, Prague, Czechoslovakia

ABSTRACT

The rate of amalgam decomposition in a laboratory tower decomposer with 40% NaOH was measured at 80°C in dependence on concentration and rate of flow of the amalgam. The dependence of the reaction rate on the rate of flow shows a maximum, which was explained theoretically and the constants in the equation for the rate of decomposition were evaluated. The bed material consists of graphite balls.

The object of present work was to verify the theoretical relations for the rate of decomposition derived previously (4). The independent variables are temperature, concentrations of amalgam and of the alkali hydroxide, and rate of flow of the amalgam. We preferred the measurement of the dependence of the decomposition rate on concentration and rate of flow of the amalgam. The tower was filled with graphite balls (Tohoku Kyowa Carbon Corporation, Japan) of a diameter of 1.1 cm and composition: carbon 97-98%, ash 1.2-2.5%, volatile compounds 0.5%, vanadium 20-50 ppm, manganese 20-50 ppm. The graphite was activated with $FeCl_3$ by the manufacturer.

Experimental

Apparatus.—The apparatus used in measuring the decomposition rate is shown schematically in Fig. 1. It consists of two circuits, one for the amalgam, the other for alkali hydroxide. The amalgam was pumped from reservoir, 1, by centrifugal pump, 2, into overflow vessel, 3. A part of the amalgam from this vessel was returned into the reservoir through conduit, 4, filled with Raschig rings, which retarded the flowing amalgam and thus functioned as a shock absorber. The main portion of the amalgam was led from vessel, 3, through heat exchanger, 5, (a steel tube heated electrically) and thermometer, 8, to the inlet of decomposition tower, 10. The flow of the amalgam was controlled by stopcock, 6, and measured so that the amalgam was for a given time led through three-way stopcock, 7, into a calibrated vessel. Samples of the amalgam were taken at the inlet and outlet of the tower in places 9 and 14. The temperature of the amalgam at the outlet was measured by thermometer, 13.

The cylindrical part of the decomposition tower (10.2 cm ID) was made of organic glass and its ends were closed with steel fittings. A Teflon disk provided with holes was placed at the bottom to support the bed. The height of the active graphite bed was only 4.1 cm so that the decomposer functioned as a differential one. The remaining volume of the tower was filled up with glass balls. The amalgam was distributed over the bed by means of a steel dish provided with 104 openings 1.5 mm in diameter and 9 mm in distance from one another. The amalgam flowed from the tower to electrolyzer, 12, in the form of a horizontal Plexiglas channel of dimensions 60 × 6 × 3 cm. The amalgam functioned as a cathode, the anode was a platinum sheet. Thus, the amalgam which had been partly decomposed in the tower was enriched again. The current lead to the amalgam was a sheet of steel fastened in the bottom of the electrolyzer so as to be wholly covered by the flowing amalgam. The passage of the steel through the electrolyzer wall was cemented with a solution of Plexiglas in chloroform. The current source was a rectifier of the type CKD 30 V/600 A. The maximum possible current that could be safely used was 300A.

The alkali hydroxide solution was circulated by means of air lift, 16, (Fig. 1) where the supporting gas was electrolytic hydrogen which passed through water cooler, 18, into the atmosphere. The electrolyte was pumped from reservoir, 15, into overflow vessel, 17, and flowed through regulation stopcock, 19, rotameter, 20, and heat exchanger, 21 (of same type as 5), into the decomposer. The temperature of the electrolyte at the inlet was measured by thermometer, 22, and

Key words: amalgam decomposition rate, tower decomposer.

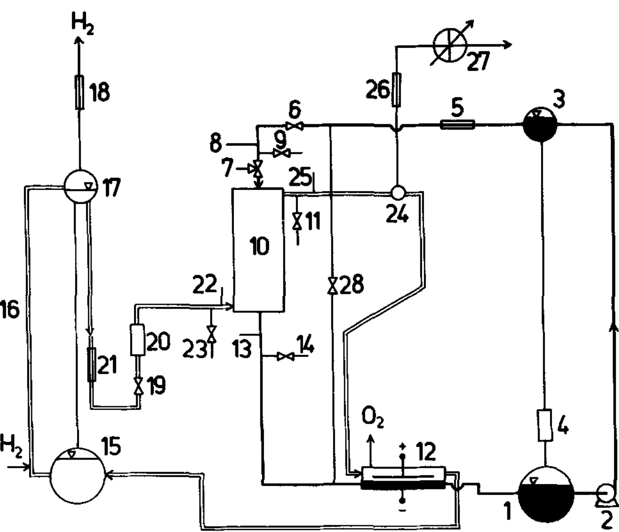

Fig. 1. Scheme of the apparatus for measuring decomposition rates. 1, Amalgam reservoir; 2, centrifugal pump; 3, overflow of amalgam; 4, bed of Raschig rings (shock absorber); 5 and 21, electric heating; 6, stopcock to regulate amalgam flow; 7, three-way stopcock to enable measurement of amalgam flow; 8, 13, 22, and 25, thermometers; 9, 11, 14, and 23, outlets for taking samples of amalgam and electrolyte; 10, decomposition tower; 12, electrolyzer; 15, electrolyte reservoir; 16, air lift; 17, overflow of electrolyte; 18, 26, cooling of hydrogen; 19, electrolyte flow controller; 20, rotameter; 24, hydrogen separator; 27, gasmeter.

electrolyte samples were taken at 23. The alkali hydroxide solution passed through the tower countercurrently with respect to the amalgam; its outlet temperature was measured by thermometer, 25, and outlet solution samples were taken at 11. The hydrogen formed during decomposition of the amalgam was collected in separator, 24, and the electrolyte was led into the electrolyzer. The level heights of the amalgam and electrolyte in the electrolyzer and decomposer were controlled by means of the overflow vessels, 3 and 17. The rate of amalgam decomposition was determined from the rate of hydrogen evolution in the tower. The hydrogen was led from the separator, 24, through water cooler, 26, into gasmeter, 27.

Method of measurement.—The apparatus was filled with distilled mercury and 38-42% NaOH from an electrolysis plant (Spolana, Neratovice, Czechoslovakia: the solution was taken from a conduit leading from the decomposer to the reservoir); the same solution was used also in measuring the hydrogen overvoltage. After the circulation of the mercury and electrolyte started, the amalgam was electrolytically prepared and the temperature in the apparatus was raised gradually to 80°C. When a chosen concentration of the amalgam was attained, the current in the electrolyzer was controlled so as to maintain the amalgam concentration constant, *i.e.*, to compensate for the decomposition of the amalgam in the tower as well as for its spontaneous decomposition elsewhere. The flow rate and temperature of the caustic were also maintained constant (3.26 ml/sec and 80°C). The measurement proper concerned the rate of hydrogen evolution in the decomposer (gasmeter, 27, Fig. 1). When this rate attained a constant value, samples of the amalgam and electrolyte at the inlet and outlet were taken. The concentration of the amalgam was determined by measuring the voltage of the cell NaHg | NaOH 40% | HgO, Hg on the one hand and by dissolving in 0.1*N* HCl and retitrating with 0.1*N* NaOH with use of methyl orange on the other hand. The concentration of NaOH was determined (after the carbonate had been precipitated with 0.5*N* $BaCl_2$) by titration of a diluted sample with 0.1*N* HCl with the use of phenolphthalein as indicator. The molar rate of flow of mercury (mol/cm² sec) was

calculated as

$$M/S_T = 13.15\, Q_{am}/200.47\, S_T \qquad [1]$$

where Q_{am} means measured rate of flow of the amalgam (cm³/sec). We assumed that the density of the amalgam is constant (13.15 g/cm³) since it was dilute. The rate of decomposition, r_{Na} (mol/cm³ sec), was calculated from the rate of hydrogen evolution in the tower, Q_{H_2} (cm³/sec)

$$r_{Na} = Q_{H_2}\, 273.16\, (p_{tot} - p_{H_2O})/(11{,}214\, THS_T) \qquad [2]$$

Here H denotes height of active layer of the bed (cm), p_{tot} total pressure in the gasmeter, and p_{H_2O} tension of water vapor over the NaOH solution (atm) calculated from the equations used previously (4).

Results and discussion.—Experimental data and some calculated values (using Eq. [48], Part I, p. 338)are shown in Table I and in diagrams, Fig. 2 and 3. The dependence of the rate of decomposition on amalgam concentration c_{Na} (weight per cent) for $c_{Na} > 0.05\%$ and M/S_T = const. can be also expressed by the em-

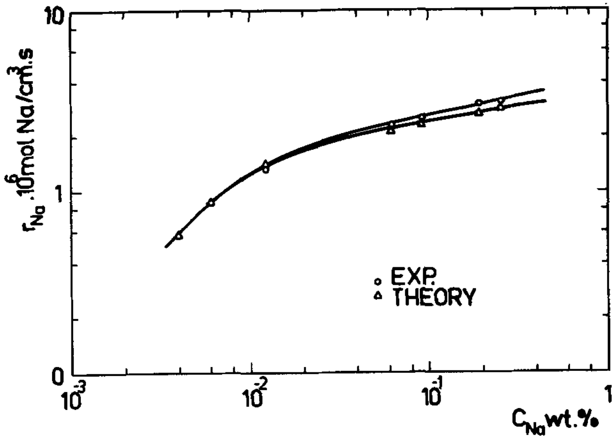

Fig. 2. Dependence of decomposition rate on amalgam concentration. Temperature 79.5° ± 1°C, caustic conc. 37.4 ± 1 w/o, rate of amalgam flow 12.68 × 10^{-3} mol/cm² sec; △, theory; ○, experiments.

pirical equation

$$r_{Na} = kc_{Na}^n \quad [3]$$

The value of n is in the range 0.18-0.23. The values of r_{Na} for less than 0.05% were measured only in several cases. It is seen from Fig. 2 that in this concentration region the value of n increases with decreasing amalgam concentration until it reaches the value of 1.0, *i.e.*, the transport of sodium from the bulk of the amalgam to the interface becomes rate-controlling.

Figure 3 shows the dependence of the decomposition rate on the rate of flow of the amalgam at an average concentration of 0.22% Na. The rate of decomposition shows a maximum at a certain rate of flow, which is optimum with respect to the amalgam decomposition.

The experimental data were used in evaluating the following unknown parameters occurring in the theoretical equations for the rate of decomposition derived previously (4): rate of flow of the amalgam at which the tower becomes flooded, $(M/S_T)_{max}$; the factor of utilization of the graphite surface, f_S; correction for the influence of bubbles in the electrolyte, f_1r_o, and at the graphite surface, f_2L_{EL}; contact resistance between the amalgam and graphite, $\rho_{SL}L_{SL}$; thickness of the diffusion layer for transport of sodium in the amalgam, δ.

The best agreement between experimental and theoretical decomposition rates (with an average deviation of 8.7%) was obtained for the following values of the parameters: $(M/S_T)_{max} = 0.025$ mol/cm² sec, $f_S = 0.6$, $f_1r_o = 0.4$ cm, $f_2L_{EL} = 0.35$ cm, $\rho_{SL}L_{SL} = 0.35$ ohm cm², $\delta = 4.23 \times 10^{-4}$ cm. The values of the rates of decomposition calculated on the basis of these constants are in Table I together with other quantities (see also Fig. 2 and 3). The calculations involved the experimentally (5) found dependence of hydrogen overvoltage on current density, concentration of NaOH, and temperature; the average value of β was set equal to 0.589.

The conductivity of NaOH solution as a function of temperature and concentration was calculated from data in Ref. (1).

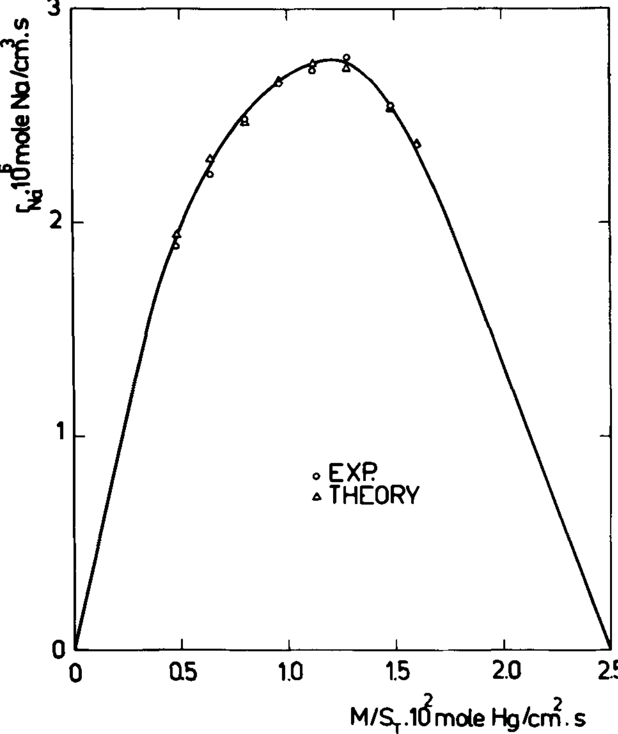

Fig. 3. Dependence of decomposition rate on amalgam flow. Temperature 79.5° ± 1°C, caustic conc. 37.4 ± 1 w/o, amalgam concentration 0.22% Na; △, theory; ○, experiments.

The agreement between experimental and theoretical values was especially good for the dependence of the decomposition rate on the rate of amalgam flow (average deviation 1.69%) (Fig. 3).

The indicated parameter values are plausible from the physical point of view or comparable with literature data. The value of $(M/S_T)_{max} = 0.025$ mol/cm² sec was taken from Hine (2) and at the same time was found by extrapolation of the decomposition rate function of M/S_T to zero. Also the value of $f_S = 0.6$ is acceptable since the lower parts of the graphite balls are probably not utilized in the reaction. The value of $f_1r_o = 0.4$ cm can be accepted since the radius of the amalgam drops was in the range 0.1-0.3 cm, and the ratio of the gas emulsion resistance to the electrolyte resistance could be about 2 (*e.g.*, if the relative volume of gas in the mixture $g = 0.4$, then according to the Meredith-Tobias equation

$$\rho_M/\rho_E = (4 + g)(4 - g)/8(2 - g)(1 - g) \quad [4]$$

the specific resistance of the mixture $\rho_M = 1.93\ \rho_E$). Further, if we assume that the length of the line current in the bubble layer at the graphite surface $L_{EL} \approx$ 0.02-0.05 cm (approximately equal to the bubble diameter), then from the found value of $f_2L_{EL} = 0.35$ cm it follows that $f_2 \approx$ 7-15.5, *i.e.*, after Eq. [6] the relative volume of the gas in the layer $g =$ 0.75-0.90. The value of $\rho_{SL}L_{SL}$ gives the contact resistance between the amalgam and graphite referred to unit contact surface area and is not known as yet. Finally, the thickness of the diffusion layer $\delta = 4.23 \times 10^{-4}$ cm corresponds to common values of δ under the conditions of a turbulent flow (3).

The values of reaction rates in Table I were obtained after one and a half-year operation of the decomposer and were on the average by 15-20% lower than those obtained after a one-month operation.

Fitting of measured data by an empirical equation.— For practical purposes, the dependence of the reaction rate of amalgam concentration is conveniently expressed by Eq. [3] where k and n are empirical parameters. The measured data for different rates of flow were evaluated by the least squares method except for the points for concentrations below 0.05 w/o Na, which were dropped. The results are shown in Table II. It is seen that the value n for concentrations above 0.05 w/o Na does not depend significantly on the rate of flow, the deviations from the average being random in character.

From the data also used in Fig. 3, values of the rate constant k were calculated assuming $n = 0.2$ (see Table III). The value of k depends obviously on the

Amalgam Decomposition

III. Comparison of Different Sorts of Graphite Bed for Decomposition of Amalgam in Tower Decomposer

I. Roušar,* V. Cezner, M. Krajča,[1] and K. Kolařík

Department of Inorganic Technology, Institute of Chemical Technology, Prague, Czechoslovakia

ABSTRACT

Four sorts of graphite bed in a laboratory tower reactor for amalgam decomposition were compared. Measurements were performed at 80°C, concentration of NaOH 40%, rate of flow of amalgam 0.0125 mol/cm² sec, and concentration of sodium in amalgam 0.03-0.7 weight per cent; decomposition of the amalgam was maximum with crushed graphite of the firm Sigri (West Germany).

In preceding communications (1, 2), the problem of calculating the decomposition rate of sodium amalgam in a tower reactor filled with graphite balls was treated. It followed that the reaction rate is directly proportional to the specific surface area of the bed (in cm²/cm³ of bed). The object of the present work was to substantiate this dependence experimentally by measurements on beds with different specific surface areas.

Theoretical

The dependence of the rate of amalgam decomposition on the concentration of sodium in the amalgam was evaluated from the following empirical equation

$$r_{Na} = k\, c_{Na}^{n} \qquad [1]$$

where k and n are empirical parameters; c_{Na}, concentration of sodium in weight per cent w/o; and r_{Na}, rate of decomposition. The values of k and n were calculated by the least squares method for every sort of graphite and Eq. [1] was used in calculating the tower height according to

$$H = -(M/S_T) \int_{Y_1}^{Y_2} r_{Na}^{-1}\, dY \qquad [2]$$

where M/S_T denotes flow of amalgam in mol Hg/cm² sec and Y its concentration in mol Na/mol Hg, which can be expressed as

$$Y = 0.08725\, c_{Na} \qquad [3]$$

By introducing Eq. [1] and [3] into [2] and integrating we obtain the final relation

$$H = \frac{0.08725\, M}{k(1-n) S_T} (c_{Na,1}^{1-n} - c_{Na,2}^{1-n}) \qquad [4]$$

where $c_{Na,1}$ and $c_{Na,2}$ denote inlet and outlet concentration of the amalgam flowing into or out from the tower.

Experimental

The apparatus and measurement of parameters were described in the preceding work (2). All measurements were made after 14 days of operation of apparatus. Three sorts of graphite were used: Sigri (West Germany), ZEW Raciborz (Poland), and Tohoku Kyowa (Japan), the specifications of which are as follows:

1. Crushed Sigri graphite, marked EHK, particle size 9-16 mm, vanadium content less than 2.5 ppm, porosity 14%, apparent density 1.73 g/cm³ (given by the manufacturer), specific surface area about 5-6 cm²/cm³ of bed.
2. ZEW Raciborz graphite cylinders (a) hollow, 10.2 mm in height, 9.6 mm outer diameter, diameter of hole of irregular shape 3.6-4.6 mm, bulk density 0.814 g/cm³, specific surface area 4.41 cm²/cm³ of bed; (b) solid, 10 mm in height, 9.8 mm in diameter, bulk density 1.042 g/cm³, specific surface area 3.695 cm²/cm³ of bed.
3. Tohoku Kyowa Carbon balls containing C 98-99%, ash 0.5-1%, V 10-20 ppm, Mn 20-30 ppm; diameter 10.7 mm, bulk density 0.916 g/cm³, specific surface area 2.876 cm²/cm³ of bed.

The diameter of the bed in the decomposition tower was 102 mm and its height 40 mm; its lid was provided with 104 openings of a diameter of 1.5 mm. The amalgam was circulated by a centrifugal pump. The electrolyte was electrolytic 40% sodium hydroxide solution (Spolana Neratovice, CSSR). Mercury was purified by distillation before use. The temperature of the tower was 80°C unless otherwise indicated.

Results of Measurements

Experimentally found values are presented in Fig. 1 and 2 for the different graphite sorts along with theoretical values corresponding to Eq. [1]. The values of

k and n are given in Table I and were used in calculating the tower height on the assumption that the inlet and outlet concentrations of sodium in the amalgam were 0.2 or 0.4 and 0.01%, respectively. The results given in Table II indicate that the specific surface area (for different sorts of graphite) is not inversely proportional to the tower height, as it should be according

Table I. Values of k and n for different beds

Table II. Height of tower decomposer for different graphite sorts and outlet concentration of amalgam 0.01% Na, temperature 80°C, caustic concentration 40 w/o

Graphite sort	$10^2 M/S_T$ (mol/cm^2 sec)	Tower height (cm) for inlet amalgam conc (0.2 w/o)	(0.4 w/o)
Raciborz, solid cylinders	1.25	134	240
Sigri, crushed	1.25	79	135
Tohoku Kyowa, balls	1.25	90	151
Raciborz, hollow cylinders	1.25	85	150
Raciborz, hollow cylinders	1.50	77	142

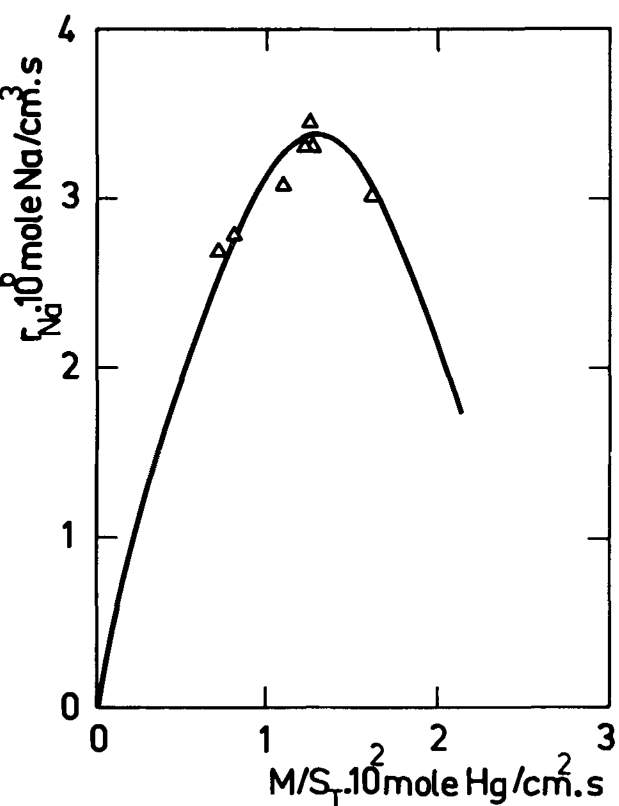

Fig. 3. The dependence of reaction rate on amalgam flow for Tohoku Kyowa graphite for 0.2 w/o Na, 80°C and 40 w/o NaOH.

to the theory (1). It means that also the content of heavy metals, such as Mo, V, Co, Fe, etc., in graphite exerts an important effect on the rate of decomposition. Nevertheless, for one sort of graphite (see Fig. 2, curves 1 and 2) the measured dependence is not far from theoretical predictions. Indeed, Table II shows that for ZEW Raciborz graphite, the ratio of tower heights for solid and hollow cylinders is 1.35/0.85 = 1.58 and the ratio of specific surfaces is 4.41/3.7 = 1.19. The difference between these values can be explained by the fact that the amalgam hold-up is higher for hollow than for solid cylinders.

The dependence of the reaction rate on amalgam flow through the tower was measured on the Tohoku Kyowa graphite ball bed. The dependence $r_{Na} = f(M/S_T)$ is shown in Fig. 3.

Conclusions

It follows from the comparison of the tower heights at a rate of flow of 1.25×10^{-2} mol Hg/cm^2 sec that the most suitable material for the bed is crushed graphite of the Sigri firm, then comes the ZEW Raciborz graphite (hollow cylinders), and finally Tohoku Kyowa graphite (balls). The least suitable were the solid graphite cylinders of ZEW Raciborz. A comparison of graphites of the same sort but with different geometry (ZEW Raciborz) suggests that the reaction rate increases with increasing specific surface area of the bed (S_G/V_T).

Nicotinamide and N'-Methylnicotinamide: Electrochemical Redox Pattern

Behavior of Free Radical, Dimeric, and Dihydropyridine Species

Conrad O. Schmakel,[1] K. S. V. Santhanam,[2] and Philip J. Elving*

The University of Michigan, Ann Arbor, Michigan 48104

ABSTRACT

The mechanisms for the electrochemical reduction of nicotinamide (3-carbamoylpyridine) and N'-methylnicotinamide [3-(N-methylcarbamoyl)-pyridine] in aqueous media, as well as those for reduction and oxidation of intermediate and final products, have been investigated. Both compounds involve the same redox pattern of two successive one-electron additions. The initial step involves simultaneous addition of an electron and a proton to form a free radical (only an electron in the pH range where the compound is protonated), which rapidly dimerizes to an apparent 6,6' species; oxidation of the free radical can be seen at pH 9. At more negative potential, the nicotinamide is reduced to an apparent 1,6-dihydropyridine species (the dimer is stable to reduction in the available potential range); the two polarographic waves begin to merge above pH 8 and are completely merged by pH 12. $E_{1/2}$ for both electron-transfer processes becomes more negative with increasing pH between pH 4 and 9. The rate constants for dimerization of the initially produced free radicals are 1.8×10^6 and 4.9×10^6 liter mol^{-1} sec^{-1} for nicotinamide and N'-methylnicotinamide, respectively, at 30° and pH 9. Adsorption of both compounds and their reduction products at the mercury-solution interface is negligible. Both dimer and dihydropyridine species are oxidized to the original nicotinamide but at considerably more positive potentials than those necessary for their formation.

Nicotinamide (3-carbamoylpyridine) (Fig. 1) is widely distributed in plant and animal tissues and is an essential dietary factor for nearly all mammalian systems. Its absence, along with that of nicotinic acid and other members of the B complex, results in pellegra. The essential role of nicotinamide undoubtedly stems from its importance in the production of certain types of pyridine nucleotides,[3] *e.g.*, NAD^+ and NMN^+, under physiological conditions. The function of such nucleotides in biological systems, *e.g.*, the role of NAD^+ as a coenzyme, generally involves oxidation-reduction of the pyridine ring. For this reason, redox processes involving nicotinamide and its derivatives are of obvious interest.

Nicotinamide itself differs from the pyridine nucleotides in having a ring nitrogen, which is basic due to the presence of the lone electron pair. Consequently, its redox behavior would be expected to show a *p*H-dependence differing from those of the pyridine nucleotides except in the *p*H region where the ring nitrogen is protonated.

The polarography of nicotinamide has been previously studied (1-4). Essentially, nicotinamide is reported to yield in acidic media two rather ill-defined polarographic waves having half-wave potentials, $E_{1/2}$, close to one another, which have been ascribed (5, 6) to the protonated and neutral species, presumably in an acid-base equilibrium of a type frequently seen in polarography. Others (7) observed nearly the same behavior except that the double wave was not noted. Above *p*H 8, a single well-defined wave was reported (5-7), whose $E_{1/2}$ became 40 mV more negative per *p*H unit. These and related results were considered to indicate that the wave was an irreversible two-electron (2*e*) process (number of electrons apparently estimated from diffusion current constant, *I*) with at least one proton taking part in the electrode reaction (two in the total reduction). The product has been postulated to be either a 2,3- or 3,4-dihydropyridine species (5-8). The polarographic assay of nicotinamide (niacinamide) in pharmaceutical preparations has been described (9).

In general, the polarography of nicotinamide was primarily investigated (5, 6, 10-13) from the viewpoint of the catalytic hydrogen current[4] which it produces; its fundamental behavior has been only meagerly interpreted and the reduction mechanism has not been fully understood. Consequently, the electrochemical reduction of nicotinamide and N'-methylnicotinamide [3-(N-methylcarbamoyl)pyridine] in aqueous medium, as well as the nature, reduction, and oxidation of intermediate and final products, *e.g.*, free radical,

[4] A catalytic hydrogen evolution reaction occurs when a compound is present whose protonated adduct under the experimental conditions is more easily reducible, *i.e.*, has a lower activation energy in respect to net addition of an electron to the proton, than the uncomplexed proton itself.

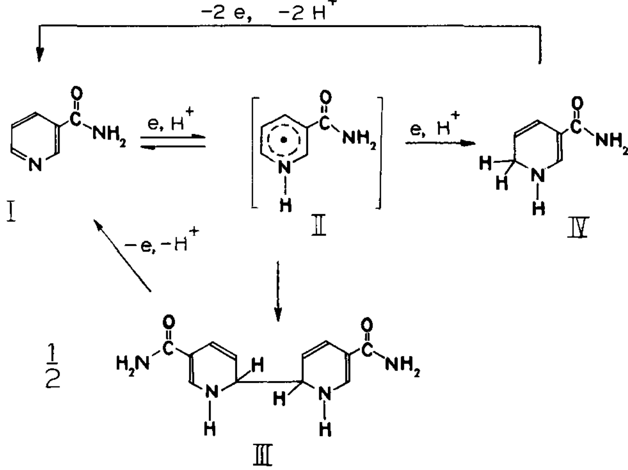

Fig. 1. Reaction paths for the electrochemical behavior of nicotinamide and its reduction products.

[3] NAD^+ represents nicotinamide-adenine-dinucleotide, which is also referred to as diphosphopyridine nucleotide (DPN^+) or coenzyme I; NMN^+ represents nicotinamide mononucleotide.

Key words: dihydropyridines, dimerization, free radicals, N'-methylnicotinamide, nicotinamide.

dimer, and dihydropyridine species, has been investigated by a variety of electrochemical techniques. These included controlled-potential electrolysis to provide solutions of products suitable for chemical, electrochemical, and spectrophotometric examination, and rapid perturbation techniques such as cyclic voltammetry and phase-selective a-c polarography to investigate chemical steps intervening in the redox process, *e.g.*, free radical formation and dimerization.

The choice of N'-methylnicotinamide is based partially on the expectation that its basic pK_a would be similar to that of nicotinamide and partially on the behavior of NAD^+ and $NADP^+$ (1, 4). If a nicotinamide free radical produced in the initial one-electron (1*e*) process dimerizes similarly to NAD^+, the site for dimerization would be expected to be at the 4 or 6 position. Molecular models of the free radicals indicate dimerization at the 4 position in N'-methylnicotinamide to be sterically hindered due to free rotation of the methyl group.

Experimental Procedure

Chemicals.—The reported analytical data and spectrophotometric assay indicated sufficient purity of the nicotinamide and N'-methylnicotinamide (Sigma) for polarographic study. Neither spectrophotometry nor polarography revealed any impurities.

Buffer solutions (Table I) were prepared from analytical reagent grade chemicals. Nitrogen used for deoxygenating was purified and equilibrated by bubbling it successively through acidic (HCl) V(II) kept over heavily amalgamated zinc, saturated CaO, and distilled water.

Apparatus.—Current-voltage and current-time curves were recorded with three-electrode potentiostats and Moseley Model 7001A(S) and 7005B X-Y recorders.

The potentiostats were multipurpose instruments (14-16), based on solid-state operational amplifiers, with only certain functions being used in any given mode; details of construction, operation, and performance are given elsewhere (17). A conventional arrangement was employed for d-c polarography; for phase-selective a-c polarography, a Princeton Applied Research Model 122 lock-in amplifier was incorporated. Automatic compensation for series resistance was achieved by positive feedback (18, 19). Rapidly occurring events were recorded with a Tektronix Type 502 oscilloscope and C-12 camera system; the oscilloscope was also utilized as a general purpose monitoring device. Potentials were accurately monitored with a Hewlett-Packard Model 3430A digital voltmeter.

Voltammetric measurements were made in a water-jacketed three-compartment cell (20), kept at 25.0° ± 0.1°C unless otherwise stated. Agar salt bridges were inserted on the counter and reference sides of the medium porosity glass frits separating the compartments. The reference compartment contained a saturated calomel reference electrode (SCE); the counter compartment contained a platinum mesh electrode immersed in saturated KCl solution. The DME capillaries (marine barometer tubing) had drop-times, measured

at potentials of interest, between 3 and 6 sec, and *m* values of 1.2 to 2.4 mg/sec (open circuit). Sargent S-2931-30 and home-made hanging mercury drop electrodes (HMDE) were employed in the stationary electrode studies.

Coulometry and macroscale electrolysis used a mercury pool electrode (3 or 5 cm^2) at 25.0° ± 0.1°C in a water-jacketed cell (25 mliter capacity), fitted with a Teflon cap, which allowed introduction of sample, salt bridges, and deaeration tubing. Reference and counter-electrodes were thermostated and identical to those used for voltammetry except that they were connected to the cell via saturated KCl salt bridges prepared from polyethylene tubes (2.5 mm ID) fitted at the cell end with 5-mm lengths of Vycor glass rod (Corning Code 7930 porous glass). The number of coulombs passed during electrolysis was found by measuring the area of the current-time curve with a Gelman Model 39231 compensating polar planimeter.

Ultraviolet spectra were obtained with Beckman Model DB and DU spectrophotometers. All *p*H measurements were made with a Beckman Model G *p*H meter.

Voltammetric procedures.—Test solutions were prepared by diluting known volumes of stock solutions in volumetric flasks with the desired buffer. About 10 mliters of test solution were transferred to the cell, purged with N_2 for 15 min, and then examined electrochemically with N_2 passing over the solution. The test solution *p*H was measured after voltammetry. Except where indicated, the background current, obtained on an identically treated buffer solution, was subtracted algebraically from the total current.

A natural drop-time was employed for d-c polarography; $E_{1/2}$ and i_d were determined graphically, utilizing the average recorder trace. For a-c polarography, the instantaneous a-c current amplitude at the end of a controlled 3-sec drop-life was recorded; in the frequency variation studies, a natural drop-time and a 10 mV peak amplitude were used. For single sweep and cyclic runs at the HMDE, one or two drops of Hg were collected from the DME and hung on the hanging drop assembly; the HMDE (0.030 cm^2) was allowed to equilibrate for 15 sec before the voltammetric scan was begun. Scan rates ranged from 0.1 to 32 V/sec.

Macroscale electrolysis procedures.—Twenty milliliters of buffer solution were added to the cell and deoxygenated for 20 min; Hg was then introduced and the stirred solution electrolyzed at a potential identical to that at which the electrolysis was to be run, until the current fell to a minimum value (0.01-0.03 mA). The potential was then shifted to −0.6V and a 5-ml aliquot of stock solutions containing only the electroactive species added; N_2 was again vigorously bubbled through the solution until the current level dropped to zero (5 min); the electrolysis was then switched to the desired potential. Nitrogen was continuously passed through the cell during electrolysis. Current was automatically recorded as a function of time; suitable correction was made for background current.

Immediately before and after each electrolysis, an aliquot of the electrolysis solution was examined spectrophotometrically after dilution with the buffer used for electrolysis; Et_4NCl/carbonate solutions were diluted with carbonate buffer. An identical concentration of buffer was used in the reference cell.

Results

Since the observed electrochemical behavior patterns of nicotinamide and N'-methylnicotinamide are generally similar, the discussion is focused on nicotinamide with reference being made to N'-methylnicotinamide only where significant factors are involved.

D-C polarography.—In acidic media, nicotinamide yields two closely adjacent waves (Table II; Fig. 2); wave II, which is less well-defined than wave I, occurs just prior to a catalytic wave.[4] In *p*H 5.0 acetate buffer,

[a] Wave slope calculated as $(E_{1/4} - E_{3/4})$.
[b] Both nicotinamide waves are ill-defined and are not necessarily diffusion controlled due to the presence of a catalytic hydrogen wave at slightly more negative potential; diffusion current constant ($I = i_l/Cm^{2/3}t^{1/6}$) values have been calculated for comparison with the wave in alkaline solution. It is especially difficult to measure wave II.
[c] Nicotinamide concentration: 0.35 m*M*. Roman numerals refer to the two waves.
[d] Wave is treated as a single wave; actually two closely adjacent electron-transfer steps are involved.
[e] N'-methylnicotinamide concentration: 0.49 to 2.58; concentrations used at pH 5.0: 1.63 and 0.58 m*M*. Wave I is generally well-defined; wave II is always poorly defined.

background discharge (at the 2-μA level) occurs 0.26V more positive than for background electrolyte alone, *i.e.*, the rising portion of the catalytic wave serves as discharge. All three waves have been noted previously (5, 6), but only the catalytic wave has been adequately studied; consequently, it will not be further considered in the present study.

$E_{1/2}$ for wave I (Table II; Fig. 3) is nearly *p*H-independent below *p*H 4 and above *p*H 9, and varies linearly with *p*H between *p*H 4 and 9 (following is based on Table II, *p*H 3.7 and 7.0)

$$E_{1/2} = -0.73 - 0.079\,p\text{H} \quad [1]$$

N'-methylnicotinamide shows an identical pattern (Fig. 3).

Between *p*H 3 and 7, the height of wave II varies between 1 and 2.5 times the height of wave I (this variation may result from uncertain knowledge of the base current due to the close proximity of the catalytic wave to wave II); $E_{1/2}$ for both waves becomes more negative with a constant separation of about 0.1-0.2V. The catalytic wave disappears between *p*H 7 and 8. The apparently single 2*e* wave observed at *p*H 8.0 at low nicotinamide concentration shows an inflection about half way up the wave, *i.e.*, it appears to consist of two merging 1*e* waves; the wave height is slightly less than the sum of the two waves at *p*H 7. With increasing *p*H (*p*H 8-12 in the absence of tetraethylammonium salts), the inflection disappears, $E_{1/2}$ becomes slightly more negative, the wave slope ($E_{1/4} - E_{3/4}$) approaches a more reversible value, and the diffusion current constant (*I*) remains constant.

The nearly merged wave (Fig. 4) is markedly altered on addition of a tetraalkylammonium cation (Fig. 5); addition of Et_4NCl to *p*H 9.4 carbonate buffer shifts $E_{1/4}$ ($E_{1/2}$ of wave I) more positive (−1.57 to −1.55V) and $E_{3/4}$ ($E_{1/2}$ of wave II) more negative (−1.64 to 1.68V) so that two waves of equal height are formed. The wave split is much more pronounced at 1.27 than at 0.13 m*M*. The total current in Et_4NCl solution is diffusion controlled (i_l proportional to $h^{1/2}$) and proportional to concentration (0.13-1.25 m*M*); the slightly lower *I* of 3.44 is due to a viscosity effect. Despite some uncertainty due to the small potential separation, the slopes of both waves at 1.27 m*M* nicotinamide are the same as that expected for reversible electron-transfer steps.

Cyclic voltammetry.—The behavior of nicotinamide is consistent with the DME pattern. In acidic media, the initial sweep to more negative potential produces peaks Ic and IIc (Table III; Fig. 6); these are ill-defined, appearing as shoulders or inflections on the side of background discharge which occurs at more positive potential than for background electrolyte alone. Small differences in E_p between Table III and Fig. 6 are due to differences in nicotinamide concentration; the wave separation seems to increase with concentration (cf. previous paragraph).

The magnitude of the peak IIc current compared to that of peak Ic suggests that the over-all wave Ic product is not further reduced, *i.e.*, most of the nicotinamide in the vicinity of the electrode has been converted to the 1*e* product by the time the potential for formation of the 2*e* product is reached, and that peak

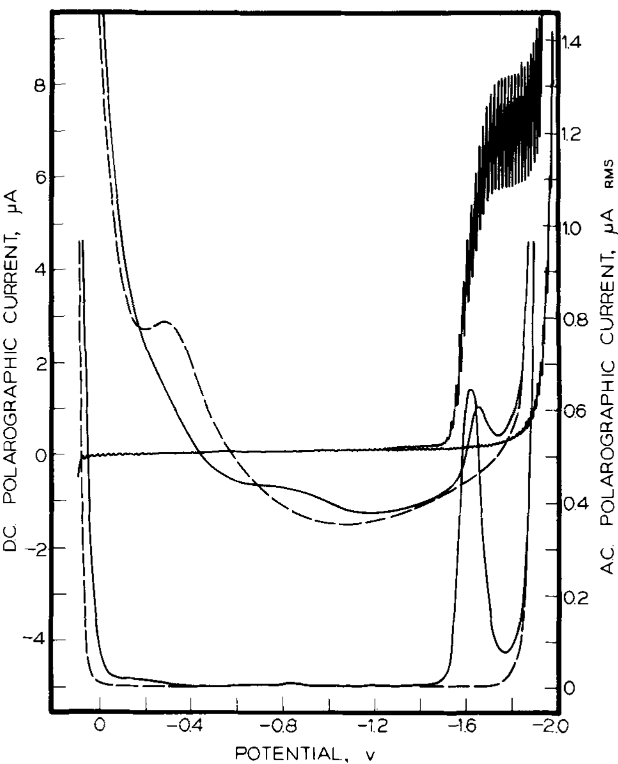

Fig. 4. D-C and a-c polarograms of nicotinamide (1.27 mM) in carbonate buffer (pH 9.4). The upper pair of curves result from d-c polarography (test and background solutions). The intermediate pair of curves represent the quadrature a-c component; the lowest pair of curves the in-phase a-c component; dashed lines are for background solution alone.

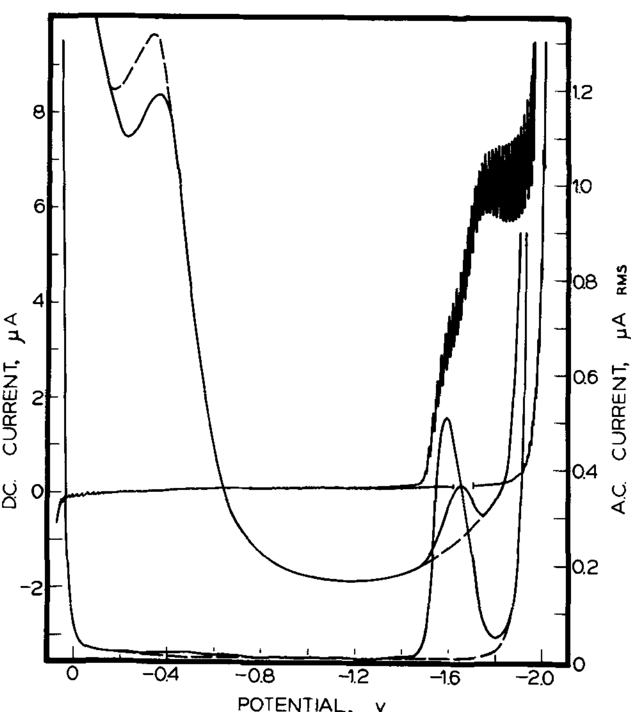

Fig. 5. D-C and a-c polarograms of nicotinamide (1.27 mM) in Et_4NCl/carbonate buffer (pH 9.4) (see Fig. 4 caption for curve identification).

IIc then results from two successive 1*e* reductions of nicotinamide in the partially depleted layer at the interface.

Both peak potentials become more negative with increasing pH. Since the pH-dependence of peak Ic is greater than that of IIc (Eq. [2]), the two peaks

[c] Concentration: 1.63 m*M*.

begin to merge at *ca.* pH 7, although the merging into a single peak is not complete until pH 12. Above pH 8, the cathodic peak current increases to a maximum at pH 12, where it is about twice that of peak Ic in acid solution.

$$\text{Peak IIc: } E_p = -1.02 - 0.065\,\text{pH} \qquad [2]$$

The pattern obtained on the reverse sweep to more positive potential depends on the pH. If the sweep at pH 12 is reversed after the single cathodic peak ($E_p = -1.72$V), a single anodic peak IIa occurs at -0.21V, which is due to oxidation of the 2*e* reduction product. At pH 9.4, sweep reversal immediately following the apparently single cathodic peak produces two anodic peaks (Fig. 7). Peak IIa represents the 2*e* oxidation just discussed; peak Ia represents oxidation of the 1*e* reduction product; both oxidation steps produce nicotinamide. Repetitive scanning (12 V/sec) around the single cathodic peak and either peak Ia at pH 9.4 or peak IIa at pH 12 establishes a relatively high steady-state nicotinamide concentration at the

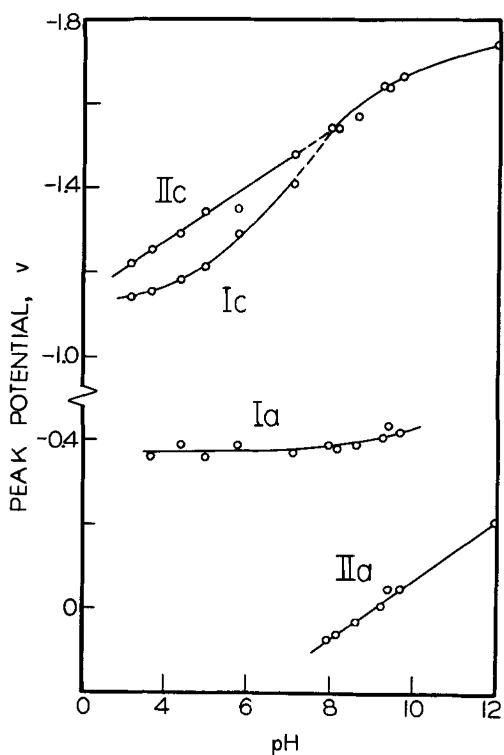

Fig. 6. Variation of peak potentials with pH for nicotinamide (0.35 mM) on cyclic voltammetry at the HMDE. Roman numerals refer to waves, a to anodic, and c to cathodic. Scan rate is 100 mV/sec.

interface; however, the cathodic peak decreases if the anodic peak is excluded from the repetitive cycle.

The formation of two anodic peaks from an apparently single cathodic peak process is obviously due to the latter actually being the fusion of two processes. The fact that the first wave (1*e*) reduction product is mainly formed at potentials on the rising portion of the cathodic peak and the second wave (2*e*) reduction products at more negative potential, is illustrated in Fig. 7. If the first sweep to more negative potential is reversed before the peak potential is reached, only peak Ia appears; if the second sweep is reversed past the cathodic peak, both Ia and IIa are seen. Consistent with the DME results, the two processes separate in the presence of Et_4NCl to yield two closely spaced cathodic peaks (Fig. 8).

The oxidation processes producing peaks Ia and IIa yield a proton or protons during electron transfer, since the peak potentials become more positive with decreasing *p*H (Fig. 6). The *p*H-dependence of peak potential Ia is nonlinear and much less pronounced than that for IIa

$$\text{Peak IIa: } E_p = 0.62 - 0.07\,p\text{H} \quad [3]$$

In neutral or acidic solution, reversing the potential sweep after either peak Ic or IIc yields only peak Ia; peak IIa is masked by mercury discharge, *e.g.*, Eq. [3] predicts E_p for the IIa process to be 0.13V at *p*H 7.1, but mercury discharge occurs at 0.10V at *p*H 7.1.

Magnitudes of the two anodic peak currents depend to some extent on the potential of sweep reversal and are poorly reproducible. However, definite trends are established with change in *p*H. The peak IIa current increases with increasing *p*H, since the 2*e* reduction process is then favored. The peak Ia current reaches a maximum at *p*H 7-8; the decrease at higher *p*H is due to the decreased 1*e* reduction process and at lower *p*H to instability of the 1*e* reduction product.

A similar pattern involving two cathodic peaks is observed for N'-methylnicotinamide; peak II is obscured by background discharge below *p*H 5 (Table III).

Detection of radical intermediate.—In order to confirm formation of the radical intermediate during the first 1*e* step, repetitive fast-scan cyclic voltammetry was employed.

In *p*H 9.0 carbonate buffer, an anodic peak ($E_{pa} = -1.65$V) (Fig. 9) was seen for nicotinamide at v between 14 and 32 V/sec, which was complementary to the cathodic peak ($E_{pc} = -1.71$V) in involving formation of a free radical on reduction and oxidation of the latter back to the original species; the 60-mV difference in the cathodic-anodic peak potentials is characteristic of a 1*e* reversible redox couple. A similar redox couple was observed for N'-methylnicotinamide between 8 and 25 V/sec ($E_{pc} = -1.66$V; $E_{pa} = -1.60$V) (Fig. 9).

The dimerization rate of the free radical was determined from Nicholson's (21) curves relating the i_{pc}/i_{pa} ratio to the kinetic term $k_dC°\tau$, where k_d is the rate constant for a dimerization reaction following an electron-transfer process, $C°$ is the bulk concentration of the original electroactive species, and τ is the switching time, *i.e.*, the time necessary to scan from $E°$ for the

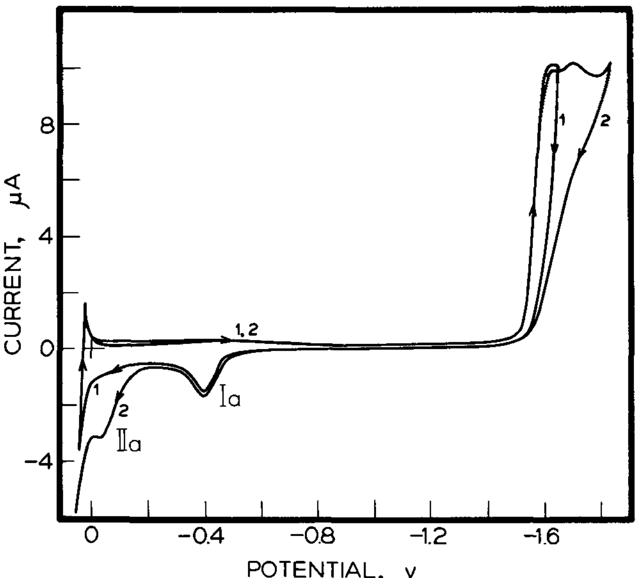

Fig. 8. Cyclic voltammogram of nicotinamide (1.27 mM) in pH 9.4 Et_4NCl/carbonate buffer at the HMDE. Roman numerals refer to waves; Arabic numerals to sweep. Scan rate is 100 mV/sec.

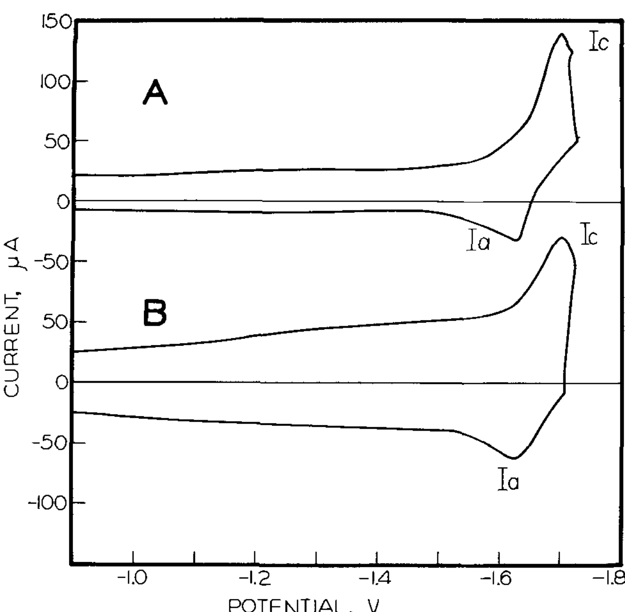

Fig. 9. Cyclic voltammograms of (A) nicotinamide (scan rate = 23 V/sec) and (B) N'-methylnicotinamide (scan rate = 18 V/sec) in pH 9.0 carbonate buffer, showing the reversible cathodic-anodic peak couple for the first electron-transfer process present at high sweep rates.

initial electrode process to the switching potential (E° is assumed to be close to $E_{1/2}$).

At 30°, k_d is $(1.8 \pm 1.1) \times 10^6$ liter mol^{-1} sec^{-1} (mean and standard deviation for five measurements) for nicotinamide, and $(4.9 \pm 1.2) \times 10^6$ liter mol^{-1} sec^{-1} (six measurements) for N'-methylnicotinamide. Measurement of k_d between 15° and 50° gave Arrhenius plots of log k_d *vs.* T^{-1}, whose slopes corresponded to activation energies of 24 kcal mol^{-1} for nicotinamide and 14 kcal mol^{-1} for N'-methylnicotinamide.

Controlled potential electrolysis and coulometry.—Electrolyses were primarily carried out on pH 10 solutions (1.25 m*M* nicotinamide; 0.4*M* Et_4NCl; 0.1*M* carbonate buffer).

Wave I process.—In accord with the indication that the over-all wave I process would be irreversible, electrolysis at a potential (−1.60V) slightly more negative than $E_{1/2}$ of wave I in order to minimize formation of wave II product, went to completion for a faradaic *n* of 1.09. A greenish-yellow color appeared and reached maximum intensity when the electrolysis was about two-thirds complete; the completely electrolyzed solution was clear and only faintly yellow. The transient color is not due to the free radical (based on indication of a rather short half-life); it may be due to formation of an unstable by-product. When electrolysis was complete, shift of the potential to −1.8V produced no additional current flow other than background, confirming that the final wave I product is not an intermediate in the formation of wave II.

A polarogram of the electrolyzed solution revealed the absence of the two nicotinamide cathodic waves and the presence of two anodic waves, one of which ($E_{1/2} = -0.45$V) had a limiting current about three times that of the other ($E_{1/2} = -0.11$V); these correspond to the cyclic voltammetric anodic peaks. Thus, due to the small potential separation of the two reduction processes, some 2*e* reduction product is obtained; this is consistent with the *n* value.

The initial solution had a single absorption maximum at 261 nm ($\epsilon = 2980$). The completely electrolyzed solution had maxima at 266 and 346 nm (Fig. 10); on dilution with McIlvaine buffer (final pH = 7.4), the two maxima slowly disappeared and a new band appeared at 280 nm.

On exposure of the electrolyzed solution to air, the 346-nm band decreased by 11% after 1 hr. After 24 hr, the 261-nm nicotinamide band reappeared; a small shoulder at about 280 nm suggested presence of some decomposition product similar to that formed in McIlvaine buffer. Polarographic examination of the 24-hr solution revealed disappearance of the two anodic waves, regeneration of nicotinamide at about 91% of its original height, and presence of a broad wave characteristic of hydrogen peroxide.

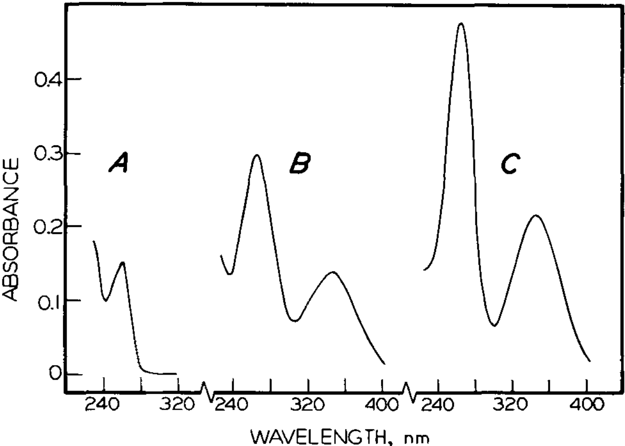

Fig. 10. Absorption spectra obtained on electrolysis of nicotinamide (1.25 mM) in pH 10 Et_4NCl/carbonate buffer. Spectra obtained by a 1/25 dilution of electrolysis solutions with pH 10 carbonate buffer: A, before electrolysis; B, after electrolysis at −1.60V; C, after electrolysis at −1.80V.

Wave II process.—Electrolysis at −1.80V (limiting portion of wave II) gave an *n* of 1.82; no transient color was observed. The colorless electrolyzed solution had absorption maxima at 265 and 346 nm (Fig. 10) and exhibited the two anodic waves seen after electrolysis at the wave I $E_{1/2}$; however, since the first wave height was only about 6% that of the second, mostly the 2*e* reduction product was obtained.

Exposure of the electrolyzed solution to air (room temperature; 24 hr) caused a 95% decrease in 346-nm absorption and appearance of a 272-nm band; this can best be explained by assuming disappearance of the 2*e* reduction product via two paths, similar to the 1*e* reduction product, *i.e.*, the 272-nm band is a combination of bands due to nicotinamide ($\lambda_{max} = 261$ nm) and a decomposition product ($\lambda_{max} = 280$ nm). Polarography revealed absence of the anodic waves, 51% regeneration of nicotinamide, and a broad H_2O_2 wave.

Reoxidation of the freshly electrolyzed solution at 0.0V, which corresponds to the 2*e* anodic wave limiting portion, gave a faradaic *n* of 1.69 based on the original nicotinamide content; the nicotinamide wave reappeared at 91% of its original height.

Electrolysis at pH 9.—Electrolysis of 1.80 m*M* nicotinamide in pH 9.0 carbonate buffer gave results comparable to those obtained at pH 10.0.

Electrolysis at −1.60 gave a faradaic *n* of one. Electrolysis at −1.72V gave an *n* of 1.80 and a solution with absorption maxima at 260 and 340 nm, and an anodic wave at −0.06V, whose height was 91% of the combined cathodic wave I and II heights before electrolysis. Oxidation of the latter solution gave an *n* of 1.90 and a solution with the characteristic nicotinamide polarographic and spectrophotometric patterns.

Electrolysis of N'-methylnicotinamide.—Electrolysis of 0.58 m*M* N'-methylnicotinamide in pH 5.0 acetate buffer at −1.35V gave an *n* of one and a solution with absorption maxima at 270 and 350 nm, and a polarographic pattern which lacked the features of the original compound but had an anodic wave at −0.01V. Oxidation of the latter solution regenerated the orginal compound; coulometry indicated that about half of the reduction product had decomposed chemically.

Electrolysis of 0.91 m*M* N'-methylnicotinamide in pH 9.0 carbonate buffer at a wave I potential (−1.63V) gave an *n* of 1.10; a yellow color appeared and reached maximum intensity when electrolysis was about three-fourths complete. Shifting of the potential to −1.8V on completion of electrolysis gave only background current flow. A polarogram of the electrolyzed solution revealed the absence of both cathodic waves and the presence of two anodic waves, one of which ($E_{1/2} = -0.57$V) was about three times as large as the other ($E_{1/2} = -0.15$V). The original solution had an absorption maximum at 260 nm; the electrolyzed solutions had maxima at 265 and 346 nm.

Oxidation of the reduced solution at −0.40V gave an *n* of 0.92 per original N'-methylnicotinamide molecule and a solution with the polarographic and spectrophotometric patterns characteristic of N'-methylnicotinamide.

A-C polarography.—The in-phase and quadrature components of the alternating current in the presence and absence of nicotinamide and of Et_4NCl at pH 9.4 are shown in Fig. 4 and 5; the presence of Et_4NCl has only minor effect. A single faradaic peak (in-phase component) occurs at −1.62V (at −1.59V in presence of Et_4NCl); the corresponding quadrature components occur at −1.66V.

Table IV. A-C polarography of nicotinamide and N′-methylnicotinamide: faradaic peaks[a]

Compound	Frequency, Hz	Peak I		Peak II

N′-methylnicotinamide (1.63 m*M*)	50	1.25	0.43	—	—
	100	1.25	0.31	—	—

[a] In-phase current component response for pH 5.0 acetate buffer solutions.

Nicotinamide is only slightly surface-active even at relatively high concentration (1.27 m*M*), *i.e.*, the differential double layer (DL) capacity in the potential region immediately prior to the first reduction wave is identical in both systems to that for the corresponding background electrolyte alone, showing an absence of adsorption phenomena involving nicotinamide.[5] The absence or presence of adsorption phenomena involving its reduction products cannot be ascertained with certainty due, for example, to the close proximity of the waves to background discharge in carbonate buffer. The quadrature current component in this potential region shows no capacitance depressions or anomalous peaks which might be attributed to adsorption-desorption (tensammetric) phenomena.

In Et_4NCl/carbonate buffer (Fig. 5), both components of the a-c faradaic response are likely to be primarily due to the first 1*e* step, although a small inflection or shoulder on the more negative potential side of the in-phase component is probably due to the second 1*e* faradaic process. This interpretation is consistent with the fact that Et_4NCl addition shifts both $E_{1/2}$ and E_s (peak potential of the total alternating faradaic current) of wave I to more positive potential and $E_{1/2}$ of wave II to more negative potential, and that the total a-c faradaic response occurs in a potential region more clearly associated with wave I than wave II, *e.g.*, the absolute difference $E_s - E_{1/2}$ is only 34 mV for wave I, but 95 mV for wave II. [Interestingly, E_p for wave I is not markedly shifted on Et_4NCl addition (Fig. 7 and 8).]

The a-c polarographic results for nicotinamide are in contrast to the reported positive shift of the electrocapillary maximum (ecm) in pH 6 solutions of nicotinamide (5, 6).

The a-c polarographic behavior of N′-methylnicotinamide is essentially similar to that of nicotinamide, *e.g.*, in showing only slight surface activity. Thus, at pH 5.0, both compounds show faradaic peak I at −1.25V (Table IV). The faradaic current for nicotinamide at first increases with increasing a-c frequency and then decreases, reflecting behavior common to systems where the initial electrochemical product is involved in a rapid chemical reaction. That of N′-methylnicotinamide starts to decrease at a lower frequency, reflecting the difference in rates of the follow-up chemical reaction at pH 5.

Nicotinamide shows a second faradaic peak at −1.40V at pH 5.0; that for N′-methylnicotinamide is obscured by background discharge.

Discussion

Redox pattern.—The potential separation of the two electron-transfer reactions for the electrochemical reduction of 3-carbamoylpyridine (nicotinamide) in aqueous media never exceeds *ca.* 0.12V; that for 3-(N-methylcarbamoyl)pyridine (N′-methylnicotinamide) is difficult to evaluate due to obscuring of its wave II by background discharge but it may be as large as 0.2V in alkaline solution. The two nicotinamide polarographic waves evident in acidic solution shift to more negative potential with increasing pH and start to merge above pH 8; however, the merging process is not entirely complete until pH 12 or 13. Thus, while an apparently single 2*e* wave is observed at pH 9.4 (Fig. 4), the process occurring on the initial rising portion of the wave leads to the dimeric 1*e* reduction product; Et_4NCl addition separates the two processes and two waves of equal height are seen (Fig. 5). The reason for the separation, which results from a shift in potential of both waves, is unclear. The surface-activity of Et_4N^+ is probably a factor, but its role does not appear to be related to adsorption phenomena involving any of the electrode reaction participants. The waves may be shifted by Et_4N^+ through its effect on the rate of the dimerization reaction.

Redox mechanism.—The reaction scheme outlined in Fig. 1 seems to fit best the electrochemical, chemical, and spectral data for nicotinamide (I) and N′-methylnicotinamide.

At pH above the pK_a of nicotinamide [3.3 at 20° (22)], the initial reduction can be regarded as uptake of an electron and a proton to form a neutral free radical (II) (source of polarographic wave I). This is followed by irreversible dimerization to an apparent 6,6′ dimer (III). At the potential of wave II, nicotinamide is reduced to an apparent 1,6-dihydropyridine species (IV), which is equivalent to a further 1*e* reduction of the free radical; the dimer is not further reduced at this potential. At a potential considerably more positive than that of reduction wave I, the dimer is oxidized to nicotinamide. At still more positive potential, the dihydropyridine species is also oxidized to nicotinamide.

The pH-dependencies of the two electrochemical reductions and the two electrochemical oxidations are compatible with the proposed mechanistic scheme. Below pH 4 (Fig. 3), the wave I reduction process should show only slight pH-dependence because most of the nicotinamide will be protonated at N(1) and the unprotonated compound will rapidly protonate as the protonated form is reduced. Under the conditions of cyclic voltammetry (Fig. 6), peak potential Ic does not become less pH-dependent as the pH is lowered. The essential reactions in the wave I process are, consequently, as follows, where R represents nicotinamide

$$R + H^+ \rightleftarrows RH^+ \quad [4]$$

$$RH^+ + e \rightleftarrows \dot{R}H \quad [5]$$

$$2\dot{R}H \rightarrow (RH)_2 \quad [6]$$

The assumption that protonation is essentially complete before electron transfer is supported by the relatively slight pH-dependence of $E_{1/2}$ and by the closeness of $E_{1/2}$ for nicotinamide (−1.11V) and N′-methylnicotinamide (−1.08V) to that for 1-methyl-3-carbamoylpyridium ion (−1.03V) (23), where the nitrogen lone pair is not available and the electroactive species exists as a cation.

The wave II process involves the previous reactions plus reduction of the free radical (the following may proceed stepwise)

$$\dot{R}H + H^+ + e \rightarrow RH_2 \quad [7]$$

Above pH 4, the energy-controlling step in the reduction involves simultaneous addition of an electron entering the ring electronic system and of a proton localizing itself on N(I)

O C NH2 e N H+

[8]

[5] In potential regions where there is no a-c faradaic process, the quadrature a-c current component is proportional to the differential double layer capacity at the solution-electrode interface, which would reflect adsorption of nicotinamide at the interface.

The distribution of electron density in the nicotinamide ring based on resonance structures supports this model (24). In the slightly acidic to slightly alkaline region (Fig. 3), the protonation is sufficiently rapid that it is not a limiting factor. The essential steps in the wave I process are, accordingly

$$R + H^+ + e \rightleftarrows \dot{R}H \quad [9]$$

$$2\dot{R}H \rightarrow (RH)_2 \quad [10]$$

The pH-dependence of 79 mV/pH unit for $E_{1/2}$ of wave I between pH 4 and 9 (60 mV expected for an uncoupled reversible 1e reaction) probably results from the rapid follow-up reaction as well as possible protonation subsequent to electron transfer (cf. reversibility).

Dimerization of the neutral free radical produced in acidic to slightly alkaline media must be exceedingly rapid since an anodic peak corresponding to its oxidation is not seen even at high scan rates on cyclic voltammetry.

Since oxidation of the free radical is seen at pH 9 and above (Fig. 9), the latter process probably involves the negatively charged radical anion, whose dimerization would be slowed down due to electrostatic repulsion. Protonation would be expected to be a slow process. However, the radical, once formed, is essentially more easily reduced than the original electroactive species as indicated by the behavior at pH 12 where the two electrons add almost simultaneously, producing a polarographic wave which has a slope only slightly less than that expected for a reversible 2e wave. The following reactions are, accordingly, involved

$$R + e \rightleftarrows \dot{R}^- \quad [11]$$

$$2\dot{R} \rightarrow (R_2)^= \quad [12]$$

$$(R_2)^= + 2H^+ \rightarrow R_2H_2 \quad [13]$$

$$\dot{R}^- + e \rightarrow (R:)^= \quad [14]$$

$$(R:)^= + 2H^+ \rightarrow RH_2 \quad [15]$$

The rate constants for the dimerization of the radical anions in aqueous alkaline solution (1.8×10^6 and 4.9×10^6 liter mol^{-1} sec^{-1} for nicotinamide and N′-methylnicotinamide, respectively, at 30°) are comparable to that observed for the pyrimidine radical anion in acetonitrile [8×10^5 liter mol^{-1} sec^{-1} at 25° (25)].

Reversibility.—Evaluation of the reversibility of the electron-transfer processes involved in the nicotinamide redox patterns is complicated by rapid follow-up chemical reactions, which result in the over-all irreversibility of the electrode process. A claim of reversibility can be made for the first 1e addition to nicotinamide, based on wave slope and reversible oxidation of the radical intermediate. Observation for the first faradaic process of less than 3% of the alternating current theoretically expected for a reversible 1e process, is accounted for by the period of the alternating voltage used (20 msec) being much greater than the half-life of the nicotinamide radical, which is considerably less than 1 msec; thus, most of the radicals dimerize before they can be reoxidized.

Similar claims can be made for the first N′-methylnicotinamide wave. For example, cyclic voltammetric peak I shows a difference of 42-44 mV in peak to half-peak potentials, compared to the 39 mV theoretically expected for a dimerization reaction following reversible 1e transfer (21). Similarly, polarographic wave I has a slope ($E_{1/4} - E_{3/4}$) of *ca.* 44 mV compared to the theoretically expected 46 mV for reversible 1e transfer followed by dimerization (26).

The fact that, at any pH, nicotinamide wave I becomes increasingly more evident with increasing concentration is in agreement with theory for an irreversible chemical reaction following a reversible charge transfer, *i.e.*, as the nicotinamide concentration is increased, the rate of the dimerization reaction increases, altering the ratio of concentrations of oxidized and reduced species at the electrode surface and thus causing the wave to shift to more positive potential.

Characterization of the reduction products.—Identification of the stable products of the 1e and 2e processes is based on ultraviolet absorption spectra, chemical behavior, and electrochemical oxidation, as previously described, *e.g.*, postulation of the 6,6′ dimer and the 1,6-dihydropyridine species is based on the absorption bands observed in the 240-400 nm region. Before reduction, 1-substituted 3-carbamoylpyridinium species generally show a single absorption band at about 265 nm; the dihydropyridine reduction products show single bands at about 410 nm for the 1,2 species and 350 for the 1,4 species, and two bands at about 265 and 360 nm for the 1,6 product; similarly, the 4,4′ dimers absorb at about 350 nm and the 6,6′ dimers at about 265 and 360 nm (27-33). These patterns have also been theoretically predicted (30).

Although the 1,6 isomers appear to be the major products, it is not inconceivable that other isomers might also be present, since the final electrolyzed solutions were not examined for product homogeneity. In the case of the 2e product, for example, the 1,4 isomer cannot be readily excluded because it would be expected to exhibit a single absorption band at about the same wavelength as the long wavelength band of the 1,6 isomer. The 1,2 isomer can probably be excluded, because the electrolyzed solution was colorless. In the case of the 1e product, at least six different dimeric structures are possible but, because of the two asymmetric carbons at the point of dimerization, as many as 21 stereoisomers may exist (3 *meso* forms and 9 *dl*-pairs). Furthermore, the validity of using the same spectral arguments for assigning the position of dimerization in partially reduced pyridines has not been thoroughly tested. Using the above criteria, structures have been readily assigned (32) to dimers of nicotinamide model compounds prepared by zinc reduction, but others have suggested caution (34). Nevertheless, in view of the available evidence, it is felt that the 1,6 isomers are the major products of the electrochemical reduction of nicotinamide.

The two reduction products of each compound undergo acid-catalyzed decomposition even in solutions as alkaline as pH 10. With decreasing pH, the rate of decomposition increases; at any given pH, the dimer is less stable than the dihydropyridine species. The decomposition involves hydrolysis of the 4,5 double bond and can be regarded as an instance of enamine nucleophilicity (35, 36)

[16]

Thus, the two nicotinamide products decompose in the presence of a proton donor such as $H_2PO_4^-$ at pH 7.4 to give a single absorption band at 280 nm; the same reaction occurs more slowly in pH 10 Et_4NCl/carbonate buffers. The hydrolytic reaction of Eq. [16] accounts for loss of the 266- and 346-nm bands and for the concomitant increase in 280-nm absorption due to the $HN—C=C—C=O$ chromophore (37).

Hydrolysis of the 5,6 double bond of a 1,4 reduced pyridine species would also be expected to lead to the same chromophore (28, 35), but hydrolysis of a 1,2 reduced pyridine species produces no new increase in absorption (28).

During decomposition, the anodic voltammetric waves characteristic of each reduction product are lost.

Since in alkaline solution the two reduction products of each compound are directly oxidized by molecular oxygen to the original species, two decomposition pathways are possible on exposure to air. For the species derived from nicotinamide, both pathways appear to be equally important for the dihydropyridine species since only half of the original nicotinamide is recovered; the dimer, on the other hand, is more easily oxidized by oxygen than the dihydropyridine species, which is consistent with their electrochemical oxidation potentials, and most of the original nicotinamide is recovered.

The Control of Oxygen Activities in Argon-Oxygen Mixtures by Coulometric Titration

Yogesh K. Agrawal, David W. Short, Roger Gruenke, and Robert A. Rapp*

Department of Metallurgical Engineering, The Ohio State University, Columbus, Ohio 43210

ABSTRACT

High-temperature electrochemical cells based on stabilized zirconia as a solid electrolyte with porous platinum electrodes may be used either to monitor oxygen activities by open-circuit measurements or else to pump oxygen into or out of stationary or streaming gas mixtures. In this work, a feed-back control unit (potentiostat) in combination with a zirconia-base solid electrolyte tube was used to simultaneously control and measure the oxygen partial pressure in a flowing inert carrier gas (argon). The oxygen activity of "tank" argon was controlled to desired levels between 2×10^{-2} and 10^{-16} atm oxygen. A four-electrode double cell arrangement is shown to be superior to a three-electrode arrangement.

The ZrO_2-base electrolytes exhibit a P_{O_2}-independent predominant oxygen ion conduction over a range of oxygen pressures from above 1 atm to about 10^{-25} atm (depending on temperature). The oxygen ion conducting electrolytes may be used in combination with two separated metallic (generally platinum) electrodes, which are at equilibrium with different oxygen partial pressures to form a high-temperature galvanic cell as follows

$$P_{O_2}', \mathrm{Pt} \;\left|\; \begin{array}{c}\text{solid}\\ \text{oxygen ion conducting}\\ \text{electrolyte}\end{array} \;\right|\; \mathrm{Pt}, P_{O_2}'' \qquad [\mathrm{I}]$$

where P_{O_2}' and P_{O_2}'' represent the oxygen partial pressures at the cathode and anode, respectively, with $P_{O_2}' < P_{O_2}''$.

At open circuit, the voltage of this cell indicates the ratio in oxygen chemical potentials at the electrodes according to the equation

$$E_{\mathrm{O.C.}} = \frac{RT}{4\mathbf{F}} \ln \frac{P_{O_2}''}{P_{O_2}'} \qquad [1]$$

if the electrolyte exhibits exclusive ionic conduction ($t_{\mathrm{ion}} > 0.99$) over the oxygen pressure range between the two electrodes. If P_{O_2}'' is considered to be a time-independent and known reference electrode (*e.g.*, air with $P_{O_2} = 0.21$ atm), then the galvanic cell can indicate the unknown or variable P_{O_2}' with high accuracy.

Within the P_{O_2}-range of predominant ionic conduction, essentially all of the current passed through cell [I] should correspond to the transport of oxygen ions through the solid electrolyte from the cathode (at negative polarity) to the anode. At the anode and cathode, respectively, the loss or gain of electrons from the external circuit accomplishes the formation or dissociation of oxygen molecules according to the reaction[1]

$$\frac{1}{2} O_2(g) + 2e' + V_O^{\cdot\cdot} \underset{\text{anode}}{\overset{\text{cathode}}{\rightleftharpoons}} O_O$$

If a voltage (V) is externally superimposed onto the open-circuit, "chemical" voltage of Eq. [1], then oxygen may be passed from the reversible reference electrode at P_{O_2}'' into the phase of variable P_{O_2}', or, alternatively in the opposite direction, depending on the sign and magnitude of the net voltage across the electrolyte. The rate at which oxygen is locally transferred would depend on the ionic conductivity and geometry or cell constant (length/area) of the electrolyte, the local open-circuit cell voltage, the voltage applied across the electrolyte, and any voltage losses through polarization (η)

$$V - E_{\mathrm{O.C.}} - \eta = I_{\mathrm{ion}}\Omega_{\mathrm{ion}} \qquad [2]$$

in which equation the polarity of the applied voltage is denoted as positive when it opposes $E_{\mathrm{O.C.}}$; Ω_{ion} is the ionic resistance of the electrolyte and I_{ion} the ionic current.

At temperatures between 530° and 800°C, Yuan and Kröger (2) have used a stabilized zirconia tube to pump residual oxygen from a streaming mixture of nitrogen plus oxygen. Downstream open-circuit gauges on the same tube indicated the extent of the pumping. In some cases, pumping voltages (V) far in excess of the decomposition voltage of zirconia were used; the buffering effects of H_2O and CO_2 molecules were studied. In the current study, a different electrode arrangement is used and subsequently compared to that of Yuan and Kröger.

Kleitz *et al.* (3, 4) have previously reported on the use of a series combination of an oxygen pump and an oxygen meter whereby each of these elements consisted of separate closed-end stabilized zirconia tubes. The application of a voltage to the upstream pump effected a change in the oxygen content of an inert carrier gas which was measured by the downstream oxygen gauge. However, the pump and meter were not otherwise connected by a device to effect automatic control.

Beekmans and Heyne (5, 6) have introduced a feedback control circuit between an oxygen pump and meter on a single zirconia electrolyte tube to effect the automatic control of oxygen in flowing gas streams. Except for work at very low P_{O_2}, the authors used a three-electrode arrangement whereby the elctrodes for the pump and the meter within the tube were common. The control of the temperature of the system was accomplished by an auxiliary monitoring of the electrical resistance of a section of the electrolyte tube. The direct current-voltage characteristics of the device were not described.

Spacil *et al.* (7, 8) have also introduced a feed-back control unit between an oxygen pump and gauge on a single zirconia tube. Their specific application for this device was the determination of the composition of the gaseous products of combustion reactions.

Key words: oxygen control, zirconia, potentiostat, coulometric titration, solid-state electrochemistry.

[1] The defect notation of Kröger and Vink (1) has been used.

Hickam and Witkowski (9) have recently described an apparatus for the control of oxygen in flowing fluids. Some pumping characteristics of their system were presented.

Many authors (10-14) have previously reported on the direct current-voltage characteristics and the associated polarization behavior of stabilized zirconia cells with porous platinum electrodes. These previous mechanistic studies have employed electrode arrangements and experimental procedures which were better suited to fundamental interpretation than the relatively long pumping cells used here. While the electrode polarization behavior observed in this work is qualitatively similar to that previously reported, we have not attempted to interpret these results in terms of the fundamental mechanisms involved.

Based on the previously described characteristics of zirconia electrolyte cells to function as an oxygen pump and gauge, we have in this work built and tested an electrochemical system and an associated feed-back control device for the simultaneous measurement and control of oxygen activities (partial pressures) in stagnant and flowing gaseous environments at high temperatures (600°-1200°C) (15). This electrochemical system is based on the calcia-doped zirconia electrolyte with two sets of porous Pt electrodes, together with electronic circuitry in closed loop, which was used to regulate the oxygen partial pressures in flowing Ar-O_2 gas mixtures. A special component was introduced to allow the control of oxygen activity independent of temperature fluctuations in the electrochemical system.

Experimental Apparatus and Procedure

Oxide electrolyte cells.—Fully stabilized [7½ w/o (weight per cent) calcia] and partially stabilized (3-4 w/o calcia) zirconia electrolyte tubes purchased from Zircoa (Solon, Ohio) were used. The composite cell system is shown schematically in Fig. 1. A pair of short (1 cm) porous Pt electrodes (III and IV) formed a downstream, open-circuit cell to monitor continuously the oxygen activity of the exiting gas mixture. A pair of longer (22 cm) porous Pt electrodes (I and II) served as an upstream pumping cell. This electrode configuration is different from that of Yuan and Kröger (2) who used three electrodes (a common inner electrode) instead of four while working with N_2-O_2 mixtures at lower temperatures.

The open-circuit measuring cell of electrodes III and IV was used as a sensor for the control system. Platinum wires were wrapped around electrodes I and III, and platinum wires were laid loosely inside the tube to form the electrical leads for electrodes II and IV. The zirconia tube was sealed to soft glass at both ends and further to Pyrex through graded glass seals. A Pt/Pt-10% Rh thermocouple was placed inside the tube to measure the gas temperature at the measuring cell. The thermocouple and the Pt leads to the inner electrodes were sealed through the soft glass tubes at the two ends.

To insure that the oxygen activity measured by the inner electrode of the downstream sensor cell was indeed the average P_{O_2}' of the gas mixture, and not some steady-state P_{O_2}' resulting from laminar flow in the tube and the presence of a stagnant gas film at the wall, a constriction was placed inside the tube between the pumping and the measuring or reference cell. This ceramic constriction (mixer) was a hollow cylinder approximately 10 mm long and 3 mm ID, which fitted snugly into the 12 mm ID CaO-stabilized zirconia electrolyte tube and was positioned between electrodes II and IV as indicated in Fig. 1. This constriction was assumed to create sufficient turbulence in the gas stream so that the downstream cell indicated the average P_{O_2}' of the gas phase after coulometric pumping by the upstream cell. In fact, during the course of the work, the use of this constriction was found to be unnecessary because of the rapid interdiffusion in the flowing gas. This result agrees with the calculation provided by Yuan and Kröger (2).

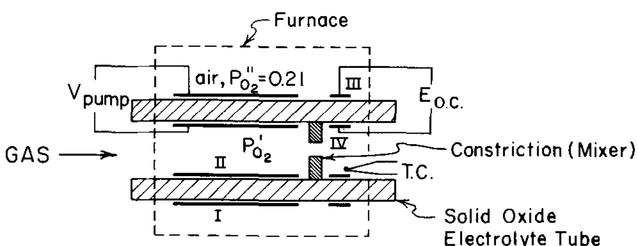

Fig. 1. Four-electrode zirconia electrolyte system for control of oxygen activity in flowing gases.

Closed-loop control system.—The detailed circuit diagrams of different blocks of the system as represented in Fig. 2 are shown in Fig. 3-5. Figure 3 indicates the cell amplifier and the thermocouple amplifier. Figure 4 consists of the divider circuit, set points, summing junction, and amplifier/integrator circuit. Figure 5 shows the power amplifier and limiter circuitry.

As is clear from Eq. [1], the open-circuit emf $E_{O.C.}$ is proportional to the absolute temperature, T(°K), as

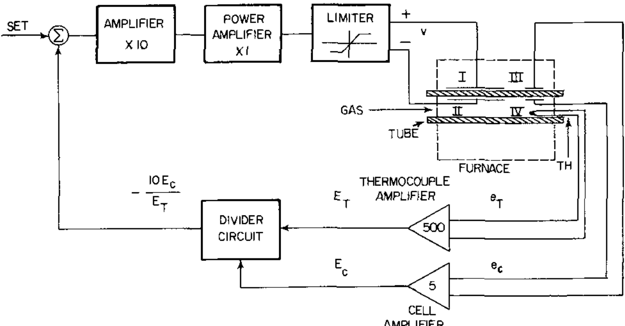

Fig. 2. Block diagram of closed-loop, feed-back control unit for oxygen activity in gases.

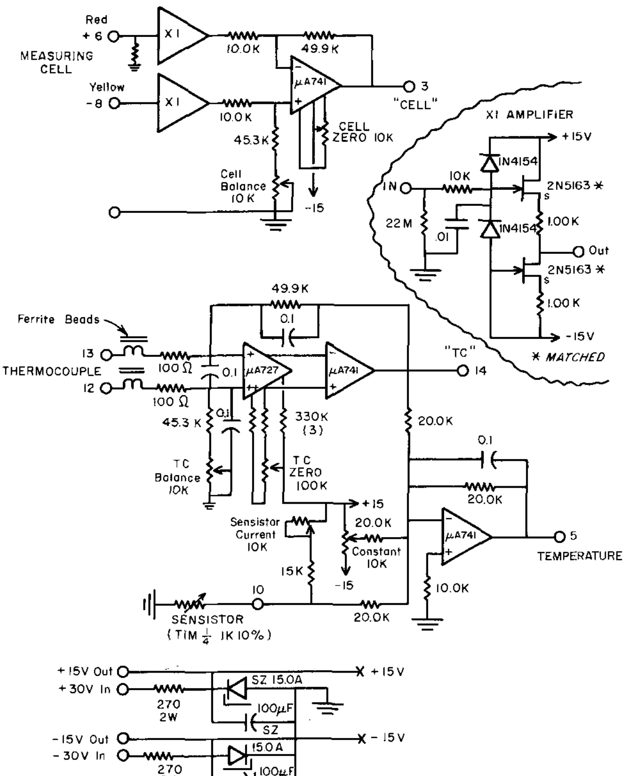

Fig. 3. Cell amplifier and thermocouple amplifier of control unit

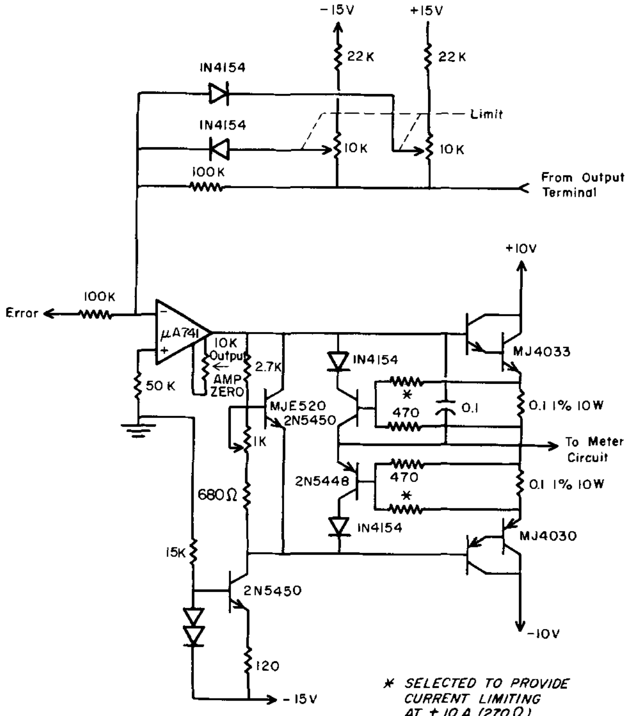

Fig. 5. Power amplifier and limiter circuitry of control unit

well as log P_{O_2}'. To remove the undesirable effect of variation in furnace temperature, the parameter E/T, which is only dependent on P_{O_2}', was chosen as the control variable. The thermocouple output was used to compensate for incremental variations in furnace temperature during operation. The signal to the thermocouple amplifier includes a room temperature cold-junction correction by means of a "sensistor" as shown in Fig. 3. Also, since T of Eq. [1] is the absolute temperature in degrees Kelvin, an additional emf correction corresponding to an additive 273° was built into the thermocouple amplifier such that the output was proportional to T(°K). The two compensations to the thermocouple signal were accomplished by assuming linear E *vs.* T behavior for the thermocouple about the temperature of expected use (850°C), and the extrapolation of this behavior to zero °K. The high gain of the thermocouple amplifier (500X) makes the system quite sensitive to variation in the furnace temperature.

As is seen in Fig. 2, the open-circuit emf between electrodes III and IV is amplified and subsequently divided by the compensated and amplified thermocouple emf. The divider circuit has a built-in gain of 10. The output of the divider circuit is compared with the set value of E/T to produce an error signal, which in turn, is amplified and applied to the pumping cell (electrodes I and II). The amplification of a steady-state error classifies this device as a "type zero" control system. The polarity of the voltage applied to the pumping cell is automatically selected and the gain in the amplification of the error signal is manually chosen so that the error signal is minimized, *i.e.*, so that the desired P_{O_2}' is essentially achieved downstream. By controlling the quantity $E/T = R/4\mathbf{F} \ln P_{O_2}''/P_{O_2}'$ of Eq. [1], the desired oxygen activity P_{O_2}' is achieved and the dependence on cell temperature is removed over a wide temperature range (as long as the thermocouple output is essentially linear with T).

As used in our work, the limiter circuit (Fig. 5) allowed a maximum of only ± 2.0V to be applied to the electrolyte tube, which, however, could be changed to ± 5V by adjusting potentiometers shown by "Limit" in Fig. 5. This limiter was introduced to restrict the voltage applied to the pumping cell to a value beyond which the tube would be expected to pass excessive electronic current and perhaps otherwise degrade by partial reduction or electrolysis.

Argon-O_2 mixtures were dried of water vapor with magnesium perchlorate and passed through the electrolyte tube. Because of the temperature gradient in the furnace, the middle of the pump was at a temperature of 910°C and the measuring cell at 800°C. This temperature difference represented a steady-state condition with gas flowing at a rate of 2 cm^3/sec. Only a few centimeters past the measuring cell, the electrolyte tube was cooled through a steep gradient to ambient temperature. The results for our four-electrode system were compared with that of a three-electrode cell by shorting the inner electrodes II and IV externally.

Results

The Ar-O_2 mixture was passed through the electrolyte tube at a flow rate of 2 cm^3/sec and a steady-state open-circuit emf at the measuring cell was measured. From this emf and Eq. [1] the oxygen content in the gas mixture was calculated. Prior to the testing of the control unit, the characteristics (interrelation of V_{pump}, $E_{\text{O.C.}}$, and I) of the four-electrode arrangement were established for a given flow rate of Ar-O_2 mixture and a given temperature. From a constant voltage supply, different voltages were applied at the pump electrodes, and the current passing through the pump, as well as the open-circuit emf resulting at the measuring cell, were measured. Thus, by initially using the pumping voltage, V_{pump}, as the independent variable, values for I_{pump} and $E_{\text{O.C.}}$ were determined experimentally. Plots of I_{pump} and $E_{\text{O.C.}}$ (or $-$ log P_{O_2}') *vs.* V_{pump} are presented as Fig. 6-8.

Experiments were conducted to demonstrate that the pumping and measuring cells were electrically independent, *i.e.*, that the application of a voltage to the pumping cell did not result in an electrical (voltage) input to the measuring cell. Upon the application of one volt to the downstream (measuring) cell, no change in the open-circuit voltage of the upstream cell was observed. The flow of gas was also reversed and the same observation was made. Thus, the two cells

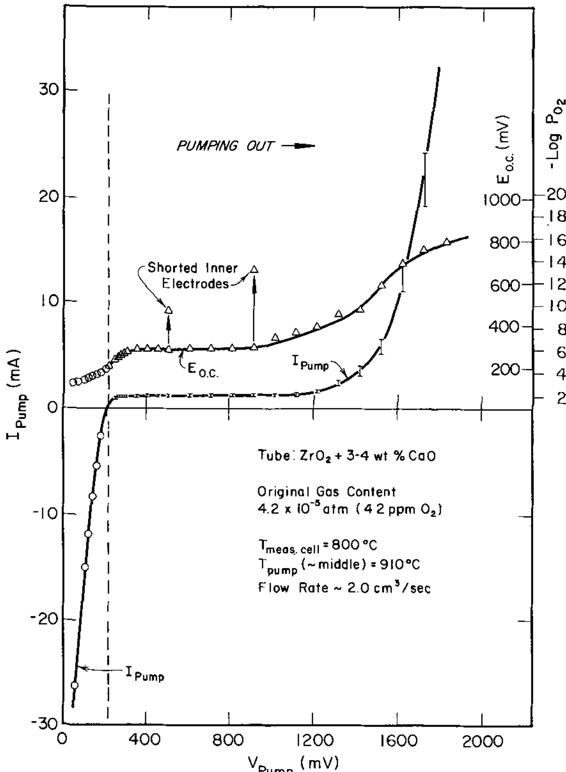

Fig. 6. Electrical characteristics of four-electrode cell arrangement using V_{pump} as independent variable.

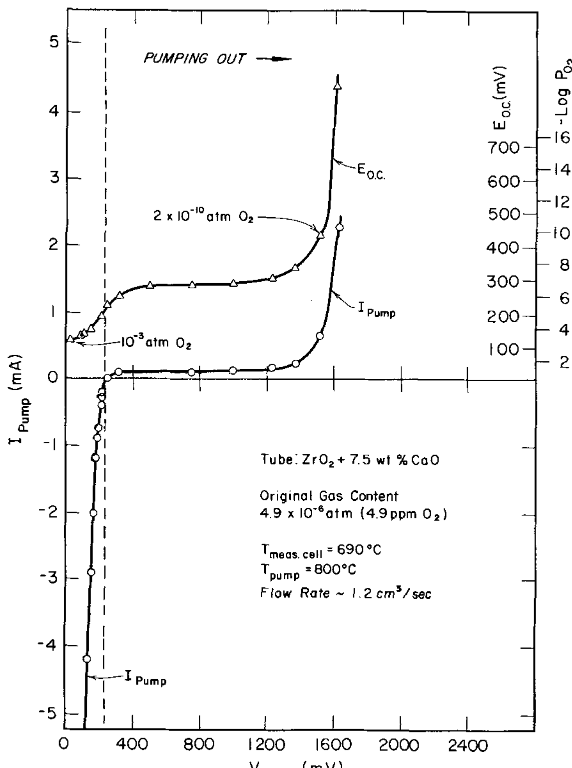

Fig. 7. Electrical characteristics of four-electrode cell arrangement using V_{pump} as independent variable.

were electrically independent. Furthermore, upon shorting the inner electrodes to form a three-electrode cell, the electrical characterization tests resulted in significant voltage changes in the open-circuit cell. Upon shorting the inner electrodes II and IV, the emf of the measuring cell rose almost instantaneously. Examples of this effect are shown in Fig. 6 and 8.

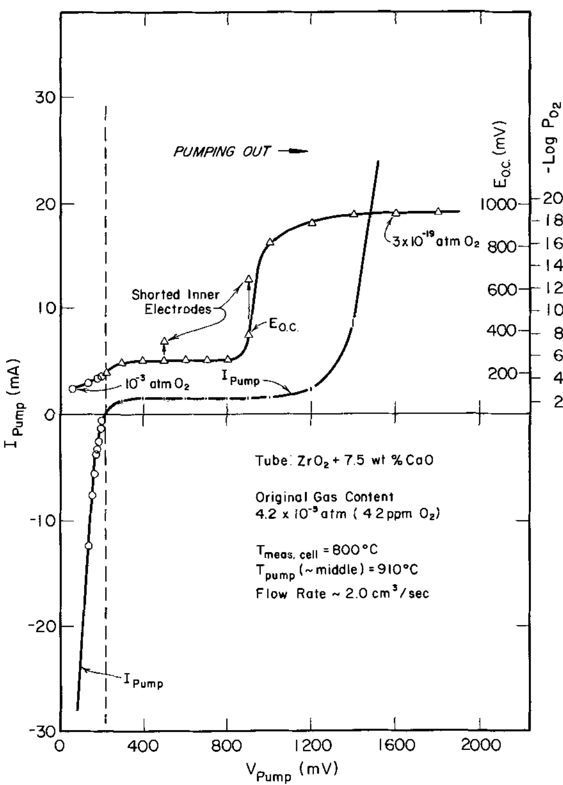

Fig. 8. Electrical characteristics of four-electrode cell arrangement using V_{pump} as independent variable.

After the electrical characteristics of the system had been established using V_{pump} as the independent variable, the previously described feed-back control device was inserted between the measuring and pumping cells. This "potentiostat for gases" automatically applied a variable voltage to the upstream pumping cell in proportion to an error signal corresponding to the difference between the actual signal (E/T) of the downstream open-circuit measuring cell and a desired value which is selected and read into the device. This type-zero control unit was used to reproduce the cell characteristics previously obtained and already presented as Fig. 6-8. In contrast to the characterization experiments, the use of the control unit involves the use of $E_{O.C.}$ as the independent variable with V_{pump} and I_{pump} as the dependent variables. An example of the excellent agreement found is shown in Fig. 9 where the data points resulting from the use of the control unit are compared with the results from Fig. 8 which are given as dotted lines. In Fig. 9, values for I_{pump} are shown by brackets because some fluctuation in these values was observed. The agreement of the two sets of data of Fig. 8 and 9, and similar agreement for the test conditions of Fig. 6 and 7, demonstrates that the potentiostat operated effectively. Thus, in the closed-loop, type-zero, mode of operation, the system effected the automatic control of oxygen activity in flowing argon.

To check further the accuracy of the P_{O_2} achieved by the potentiostat as indicated by the measuring cell, the P_{O_2} was independently measured by another ZrO_2-CaO probe far downstream in another furnace. For $10^{-9} < P_{O_2} < 10^{-3}$ the values observed at this probe were essentially the same as those indicated at the measuring cell. Hence, the gas composition as indicated by the emf of the measuring cell is real and there is no electrical coupling between the electrodes of the pumping cell and those of the measuring cell.

In a few experiments involving the "potentiostat," the inner electrodes II and IV were again shorted to simulate a three-electrode cell. As shown in Fig. 9, anomalous results, equivalent to those previously ob-

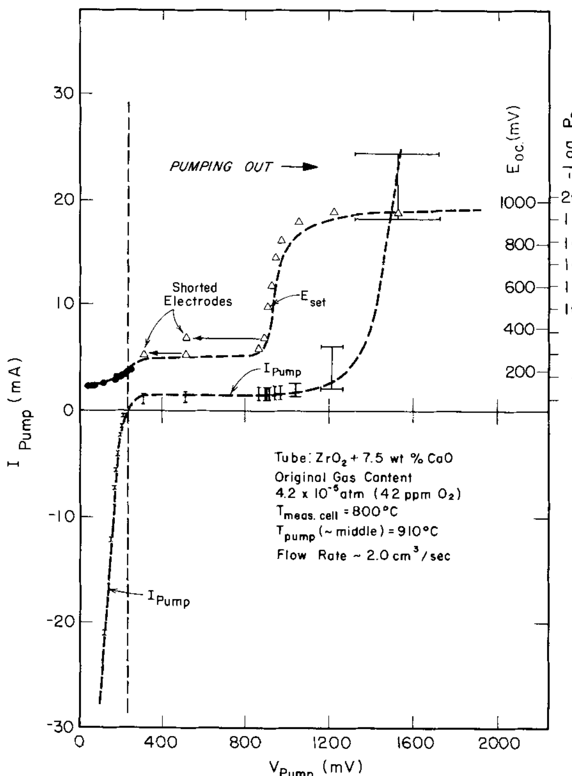

Fig. 9. Response of four-electrode cell arrangement to closed-circuit control unit (results from previous characterization experiments are indicated by dashed lines).

served in the characterization experiments, were again observed.

Discussion

The polarization behavior indicated in Fig. 6-8 is similar to that reported previously (3, 10-14). However, the values of I_{pump} reported here (as a function of V_{pump}) are "integrated" values over a long electrode, along which there exists a gradient in P_{O_2}. Such data (2) are not ideally suited for an interpretation of the electrochemical mechanisms. Moreover, in this work, fluxed platinum electrodes were used (because of their superior tenacity to the electrolyte), and such electrodes are known to exhibit higher polarization than nonfluxed porous platinum or sputtered Pt films (13). As previously observed, in attempting to pump residual oxygen out of the inert gas, plateaus in both pumping current and $E_{\text{O.C.}}$ are experienced until substantial external voltage ($V_{\text{pump}} \approx 1$ volt at our temperatures of study) has been applied to the pumping cell. As shown in Fig. 6-8, the realization of log $P_{O_2} < -6$ is achieved only upon the introduction of significant electronic conduction (rapid rise in I_{pump} with V_{pump}) into the electrolyte. The accepted "high-voltage model," that oxygen is reduced and inserted directly into highly reduced zirconia at points adjacent to the otherwise effective triple-points of Pt-zirconia-gas, seems to be a consistent explanation (11, 12).

The ultimate realization of very low P_{O_2} on the order of 10^{-20} atm is only possible through the presence of a small content of a buffering gaseous constituent like H_2 or CO. In fact, to improve the buffer capacity of the gas at very low P_{O_2}, a few parts per million or more of residual hydrogen or water vapor could be admitted to the pump in the inert carrier gas (2). Obviously, the high proportion of electronic conduction in the "high-voltage" range provides a low Faradaic pumping efficiency.

In high-temperature service, many electrolyte tubes, especially those "partially stabilized" by 3-4 w/o CaO, have been found to leak molecular oxygen at reproducible rates which are quite temperature dependent. In our system, the electrolyte tube was cooled immediately downstream from the measuring cell, thereby eliminating any oxygen leak after the meter.

Upon the addition of oxygen to the argon gas, some polarization is exhibited for small net voltages, $0 > (V_{\text{pump}} - E_{\text{O.C.}}) > -50$ mV. However, for greater net voltages, the oxygen pump exhibited ohmic behavior. By the use of large negative values of V, higher than those shown in Fig. 6-8, the oxygen content in the argon was driven up to as high as $P_{O_2} = 0.02$ atm.

For the tube geometry and temperatures of our study, the necessity to use separate internal electrodes for the pump and gauge was proven. The electrical "crosstalk" between the pump and gauge should become less important for cells at lower temperature and for gases with oxygen O_2 contents exceeding $\sim 10^{-5}$ atm. Nevertheless, the use of four electrodes is generally advisable. We believe that the interference in the performance of the gauge when it shares an electrode common to the pump is a result of polarization. When these electrodes are common, the pumping voltage draws a small current (oxygen flux) from or to the gauge electrode, despite a very disadvantageous cell geometry. For measurements in the range of $P_{O_2} \sim 10^{-6}$, polarization can result in a large error in the value of oxygen activity reported by the gauge cell. For this reason, the extremely low values of P_{O_2} reported by Yuan and Kröger (2) for a three-electrode arrangement must be considered suspect.

The closed-loop system of Fig. 2 could be schematically represented as in Fig. 10(A). The transfer function for the solid electrolyte tube was determined to first-order approximation to be

$$G(s) = \frac{e_c}{e_p} = \frac{0.167\ (40s + 1)}{(160s + 1)\ (2.5s + 1)} = 0.167\, G_1(s)$$

where s is the Laplace Transform operator d/dt, e_p the input signal (input to pump), e_c is the output signal (reference cell output), and in Fig. 10A., ξ_{ss} is the steady-state error signal.

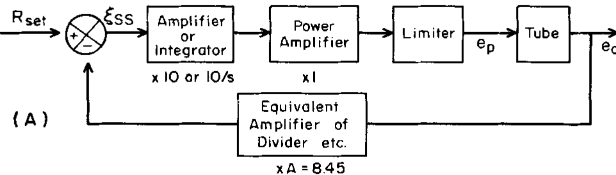
The system of Fig. 10(A) can be more simply represented as a unity feed-back system as in Fig. 10(B), where $G'(s) = KG_1(s)$ and K is the gain including that of amplifier, power amplifier, tube, and divider circuit. Thus

$$\frac{C}{R_{\text{set}}} = \frac{G'(s)}{1 + G'(s)};\ C = Ae_c$$

where the gain of the amplifier is ten, the equivalent gain of the divider circuit is A, the gain of the limiter is unity, and the gain of the tube is 0.167. In general $G'(s)$ has the form as below

$$G'(s) = \frac{K(z_1 s + 1)\,(z_2 s + 1)}{s^j (p_1 s + 1)\,(p_2 s + 1)\,(p_3 s + 1)}$$

where z's and p's are constants, and $j = 0, 1, 2,$ and so on, and the system is referred to as type zero, type one, type two, and so on, respectively. The steady-state



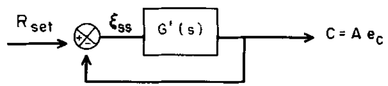


Fig. 10. (A) Schematic representation of closed-loop, type-zero control system. (B) Simplified schematic diagram of control system.

error, ε_{ss}, for an input of R_{set}, defined as a step function of magnitude R, is given by the following for a unity feedback system as shown in Fig. 10(B)

$j = 0$	type zero	$\varepsilon_{ss} = \frac{R}{1+K}$
$j = 1$	type one	$\varepsilon_{ss} = 0$
$j = 2$	type two	$\varepsilon_{ss} = 0$

$\varepsilon_{ss} = 0$ for higher order systems.

Potentiostat circuitry can provide a factor $1/s$ which is simply an integrator in the forward path so that

$$G'(s) = K\frac{G_1(s)}{s}$$

which is a type-one system and, therefore $\varepsilon_{ss} = 0$ for step inputs.

In general, it is desirable to use a control system having a type-one mode of operation, but the possibility of instabilities (overshoot, undamped oscillations, unbound output for a bounded input) in the network increases markedly with an increase in the value of j, the mode designation number. In our research, we have investigated both type-zero and type-one control systems. The following example calculation computes the steady-state error in the measuring cell for type-zero operation.

At 800°C, the thermocouple emf is 7.328 mV and 4.513 mV is added for the correction to Kelvin degrees. Hence, the thermocouple amplifier output is 5.9205V $(7.328 + 4.513) \times 500$. For incremental variations around the quiescent point in the inputs to the divider, the equivalent amplifier of the cell, as shown in Fig. 3 and 4, has a gain of $10 \times 5/5.92 = 8.45$. With a gain of 10 in the amplifier of the forward path, the loop gain K is $8.45 \times 10 \times 0.167 = 14.1$. For $R_{set} = (10E_c/E_t)$ of 2.392V the emf of the open-circuit cell should be 0.2832V for $P_{O_2}' = 10^{-6}$ atm. However $\varepsilon_{ss} = R_{set}/(1 + K) = 2.392/15.10 = 0.1584$V and therefore, the cell voltage $= 0.1584 \times 10 \times 0.167 = 0.2645$V. The corresponding steady-state error of the measuring cell is therefore 18.6 mV. However, with a previous knowledge of the expected steady-state error, it is a simple matter to adjust the set point to compensate for the small error in $E_{O.C.}$

In an attempt to eliminate the ε_{ss}, a type-one system was also investigated. This system featured an integrator instead of an amplifier in the forward path. However, the closed-loop, type-one system was found to be unstable; it could perhaps be made stable by circuit compensation but this further work was not thought to be worthwhile. For a given electrolyte tube the type-zero potentiostat could be calibrated with little difficulty and then be used for controlling the oxygen activities.

While the electrical characteristics and polarization behavior of zirconia-Pt-O_2 cells are of fundamental interest, in fact, the effective use of the feed-back control unit described here to establish oxygen activities in flowing argon does not depend on the details of the electrical characteristics of the pump, nor on the current efficiency of the pumping. If the flowing gas arriving at the downstream meter should deviate in oxygen activity from the desired level, a voltage as high as that allowed by the limiter is automatically applied to the pump until the error signal is minimized. Obviously, it is possible by the use of high flow rates, low cell temperatures, and highly buffered gas mixtures (CO/CO_2 and H_2/H_2O) to exceed the operational range of the system, *i.e.*, the combination of electrolyte resistance and polarization can be too great to accomplish a desired oxygen activity from a given starting activity. Therefore, the utility of the instrument and the system will be realized only within a certain range of operating conditions. However, because the system is specific to oxygen activity, in principle, the unit could be used alternately for establishing the oxygen activity in any sort of inert gas, or in buffered gas mixtures like CO/CO_2 or H_2/H_2O, etc., so long as excessively large pumping currents are not required to accomplish the desired activities.

In our laboratory, we have used the described system in several geometries to support several sorts of high-temperature investigations. In a study of tracer diffusion in oxides, the specimens were enclosed in a closed-end zirconia tube which was initially filled with a partial atmosphere of argon. The oxygen activity within the closed tube was controlled over many days at either 10^{-2} or 10^{-5} atm by use of the four-electrode system. A similar "enclosure" arrangement was used to control the oxygen activity and prevent oxidation in a high-temperature study of the creep of nickel wires. In an "open" flowing system, the evaporation of ZnO crystals was studied as a function of P_{O_2} in an inert carrier gas whose oxygen activity was established in the manner described here.

Potentially, the kinetics of oxygen addition or removal from an enclosed system at known and fixed oxygen activity could be measured by the recording of the current passed through the pumping cell. However, for this application, extreme care must be exercised that the pumping ability of the system is adequate, and that the Faradaic current efficiency is unity. Furthermore, the unavoidable molecular leakage of oxygen through the tube and the seals may contribute in only a minor way compared to the current passed in the pumping cell. The electrochemical semipermeability of oxygen ions resulting from electronic conduction in the electrolyte should not lead to inaccurate gauge readings. Finally, rapid desorption of oxygen from the pump and adequate mixing of gas in the enclosure are required to eliminate gradients within the chamber. The development of "perfect" high-temperature seals has proven difficult, and the use of a low-temperature seal for the enclosure requires the complication of a nonisothermal system. In short, the use of the control unit to measure kinetics will require a reaction of the proper rate, the careful design of a tight high-temperature enclosure, and an experimental demonstration that only oxygen ions are passed through the electrolyte.

A Dissolution-Redeposition Mechanism for the Roughening of Platinum Electrodes by Cyclic Potential Programs

D. F. Untereker*,[1] and S. Bruckenstein*

Chemistry Department, State University of New York at Buffalo, Buffalo, New York 14214

ABSTRACT

Rotating platinum disk-gold ring and platinum disk-platinum ring electrodes were used to study the roughening of platinum produced by a triangular wave potential program. The rate of roughening was found to decrease with increasing rotation speed and/or decreasing potential scan rate. The amount of soluble platinum collected on the gold ring electrode during the roughening process increased with angular velocity. The data obtained are consistent with a mechanism in which soluble platinum produced during both the anodic and cathodic disk potential scans is redeposited on the electrode surface at cathodic potentials.

Much has recently been published about the roughening of platinum electrodes caused by potential cycling (1-7). Although this phenomenon has been known for a number of years [see (1)], its mechanism has never been conclusively established. Gilman (4) assumed that the roughening mechanism involves the making and breaking of Pt-O bonds because both the oxidation and reduction of platinum had been reported in nearly all experiments that increase the electrode roughness. The roughening process was thought to be related to the migration of platinum species on the electrode surface. The activation energy for this migration process was said to arise as a result of the simultaneous reduction of a large amount of platinum oxide. Hoare (3), however, reported that roughening of platinum electrodes occurs only when the electrode potential went into the hydrogen evolution region and attributed this result to a mechanism involving hydrogen embrittlement.

Biegler (7) gave a very complete discussion of platinum electrode roughening and characterized the process in considerable detail. He concluded that (*a*) the roughening rate increased with the anodic limit of the potential scan; (*b*) hydrogen adsorption had little, or a negative, effect on the electrode roughening rate; (*c*) only potential programs which involved rapid reduction of platinum oxide caused roughening, and, in fact, those which did not caused smoothing; (*d*) the roughening rate decreased when the solution was stirred; and (*e*) dissolved platinum was observed in the solution after prolonged roughening of a platinum electrode. The last two observations are not explained by the previously proposed roughening mechanisms.

Since soluble platinum species have been detected along with electrode roughening (7), it seemed probable to us that a link between the two existed. Biegler rejected dissolution and redeposition of platinum as a possible mechanism because he found that platinum particles were not removed from the electrode when he made electron micrograph replicas of the surface. He reasoned that a mechanism involving deposition of soluble platinum would form an epitaxial layer, which would be readily removed from the electrode surface. Evidence, presented below, however, shows conclusively that the roughening mechanism does involve the soluble platinum species *via* a solution/redeposition mechanism.

Rotating disk and ring-disk electrodes seemed to be excellent experimental tools to study the details of the roughening of platinum and were used in the experiments described below.

Experimental

Equipment.—A conventional four electrode potentiostat, cell, and rotator were used. The electrode rotator was supplied by the Pine Instrument Company, of Grove City, Pennsylvania. An EAI XYY' Variplotter was used to record the experimental data.

A platinum disk-gold ring electrode (PDGRE) and platinum disk-platinum ring electrode (PDPRE), both made in our laboratory, were used in the experiments reported below.

All potentials are reported *vs.* the saturated calomel electrode (SCE).

Solutions.—The supporting electrolyte was 1*M* H_2SO_4.

Solutions were deoxygenated by bubbling N_2 gas through them for 20 min preceding the start of experiments. The supporting electrolyte was also bubbled with N_2 during cyclic potential scanning and anodic potential halt experiments in order to remove oxygen generated at anodic potentials. Data were recorded with N_2 passing over, not through, the solution.

Solutions were prepared from triply distilled water and Baker reagent grade sulfuric acid.

Electrode pretreatment.—The electrode pretreatment consisted of polishing the electrode with a slurry of 0.05μ alumina and water before introducing it into the cell, then potential cycling it several times between −0.2 and 1.6V at 2500 rpm. This procedure yielded reproducible *i-E* curves, and was used between each experimental determination of disk electrode roughness.

Measurement of surface area.—The roughness factor of the platinum disk of the PDGRE, pretreated as

* Electrochemical Society Active Member.
[1] Present address: Chemistry Department, University of North Carolina, Chapel Hill, North Carolina 27514.
Key words: platinum roughening, platinum dissolution, platinum redeposition, ring disk.

described above, was always about 1.8 as measured by the hydrogen desorption charge.

The data reported in Fig. 1 were calculated as follows. After the cyclic potential program had been applied for the required time, the total disk electrode anodic charge, obtained on a linear potential sweep between −0.27 and 0.4V, was determined. This value was then divided by the analogous charge obtained at the start of the experiment. This calculated ratio, the "roughness ratio," is an accurate measure of any change in the surface area of the disk electrode produced by potential cycling it.

Results and Discussion

Effect of angular velocity on electrode roughening.— A platinum disk electrode was roughened in 1*M* H_2SO_4 by applying a repetitive triangular sweep voltage program for various times at four selected rotation speeds. The electrode was cycled between 0.0 and 1.8V *vs.* SCE at 25 Hz, *i.e.,* at 90 V/sec.

Figure 1 shows the plot of the roughness ratio, R/R_o, as a function of cycling time for angular velocities of 400, 900, 1600, and 2500 rpm. (The roughness ratio of the electrode is defined in Experimental.) The maximum absolute roughness shown in Fig. 1 is about 3.2

The rate of roughening increases with decreasing angular velocity. Although not shown in Fig. 1, the rate of roughening also increases with cycling rate and anodic disk potential limit.

Our polished electrode, with its initial roughness factor of 1.8 was mirror-like. However, after the electrode roughened about 50%, its surface became slightly dull. This dulling increased until, at values of R/R_o greater than 2, the surface had a hazy appearance. The haze was easily removed from the electrode surface by hand polishing with 0.05μ alumina, provided the electrode was still wet, but it required considerable effort to remove the haze after the electrode surface had dried. This observation may explain why Biegler (7) found no platinum particles on his electron micrograph replicas.

Biegler also mentions that his data were not very reproducible (7), not only for different electrodes, but also for repetitive experiments using the same electrode. Similar behavior was also found by us. When data were obtained during an experiment, such as reported in Fig. 1, the roughness ratio sometimes changed randomly. This phenomenom was usually observed for R/R_o values larger than those shown in Fig. 1. In such situations, if a mirror was placed under the cell in order to observe the rotating electrode surface while the roughening process was occurring, the surface would become hazy and dark, and then golden in appearance. The golden color slowly intensified, provided electrode potential cycling was continued, but quickly

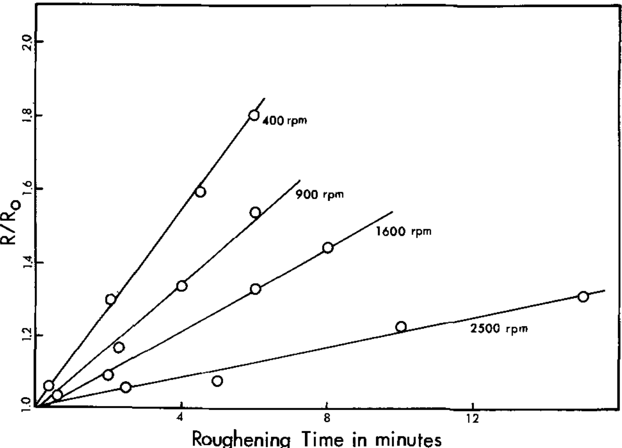

Fig. 1. Relative rates of roughening of platinum disk electrode as a function of time at selected angular velocities. 1M H_2SO_4. Potential cycled between 0.0 and 1.8V at 25 Hz. $R_o \simeq 1.8$ at $t = 0$ for each angular velocity.

(in about 1 sec) changed to a gray deposit when the cycling was stopped at 0.0V. If the electrode potential was cycled for a long period of time, the golden deposit became orange and had the electrochemical properties attributed to phase platinum oxide (8). Data resulting from experiments where phase platinum oxide was formed were not used, since the roughening phenomena of concern to us did not involve phase oxide formation.

Proposed mechanism of roughening.—The rate of roughening, as determined from Fig. 1, depends on angular velocity. Therefore, a soluble species must be involved in the rate-determining step for the roughening process. If only surface rearrangements of platinum atoms occurred, as had been previously postulated, no such angular velocity dependence would be observed.

Since the only soluble species produced during cyclic potential scans in 1*M* H_2SO_4 at platinum electrodes are hydrogen, oxygen, Pt(II) (9), and Pt(IV) (10), the angular velocity dependence would have to be associated with the production of one or more of these species.

From Gilman's (4) and Biegler's (7) results, and confirmed by our data, hydrogen evolution need not occur to roughen a platinum electrode, contrary to Hoare's views (3).

It also seems unlikely that oxygen is involved in the actual roughening process since evolving oxygen at a platinum electrode for long periods of time caused no appreciable roughening. Also, there would seem to be little connection between oxygen evolution and the observation that the rate of roughening depends on the cathodic potential scan program (4, 7).

Finally, although hydrogen need not be evolved to roughen a platinum electrode, the cathodic potential limit must reach about 0.3V, or no roughening occurs.

These observations can only be rationalized if at least one soluble platinum species is taking part in the roughening process.

Two different processes, involving soluble platinum, could lead to roughening. Either platinum dissolves from the electrode surface (forming pits), or it dissolves and redeposits on the electrode surface (forming hills and pits). Figure 1 is not consistent with the first possibility since more soluble platinum would be carried away from the disk electrode surface at higher angular velocities than at low ones, and thus, Fig. 1 would show higher roughening rates at higher, not lower angular velocities. Also, the previously reported dependence of roughening on the potential scan program (4,7) is not consistent with a mechanism solely involving dissolution. Experimental results (4, 7), in fact, show that under conditions where only dissolution of platinum would occur (slow cathodic scans), smoothing of the platinum surface results. Finally, the roughened surface could not be wiped off an electrode if only pits were formed.

A mechanism involving both platinum dissolution and redeposition at cathodic potentials is consistent with Fig. 1 and the other data. This mechanism also predicts that the increased rate of roughening found by Biegler (7), as the anodic potential scan limit is made more anodic, must result from a larger quantity of soluble platinum species being produced.

Probably both Pt(II) and Pt (IV) species are involved in the roughening process. The relative contribution from each species is dependent on convective-diffusion and the potential cycling program, *i.e.,* the amount of platinum that can be redeposited at the electrode depends on the amount of soluble platinum species in the diffusion layer when the electrode potential becomes sufficiently negative to reduce the platinum to Pt(0). The contribution of the Pt(II) species to roughening should be somewhat larger than that from the Pt(IV) species since the Pt(II) is produced on the cathodic potential scan (9), much nearer to the redeposition potential.

For this reason, the quantity of soluble Pt(II) produced during reduction of the platinum oxide (9) that was formed at increasing anodic potentials was determined.

Effect of anodic scan potential limit on Pt(II) formation.—The disk of a platinum disk-platinum ring electrode was oxidized for 60 sec at several anodic potentials, E_a, in 1*M* H_2SO_4. After the oxidation, the disk potential was linearly scanned at 100 mV/sec from E_a to 0.0V at 2500 rpm, while the ring electrode was held at 1.2V. At this ring potential any Pt(II) produced by the disk electrode will be oxidized to Pt(IV) (9). The ring electrode current-disk potential curves recorded during the linear cathodic voltage sweep of the disk electrode were integrated and the resulting charge plotted *vs.* E_a. Figure 2 shows the experimental results obtained on the two consecutive days. The data in this figure support a dissolution-redeposition mechanism since, as predicted, the amount of soluble Pt(II) produced increases with increasing anodic potential scan limit.

Rate of electrode area increase.—Further evidence supporting the dissolution-redeposition mechanism was obtained by quantitatively correlating the amount of soluble platinum produced during the roughening with the increase in electrode surface area. In this experiment the amount of platinum dissolved was determined using the gold ring of a gold ring-platinum disk electrode (PDGRE). The gold ring electrode was held at 0.0V while the disk electrode was potential cycled under the conditions in Fig. 1. The amount of platinum dissolved from the disk electrode at each rotation speed was calculated from the collection efficiency of the ring-disk electrode and the amount of platinum oxide formed by oxidizing the gold ring electrode at 1.3V (12). It was assumed that all platinum deposited on the gold was available for oxidation.

At 3600 rpm, 8×10^{-7} mg/cycle of platinum dissolved. A negligible change in the area of disk electrode was observed.

At 400 rpm much less soluble platinum was collected on the gold ring, *i.e.*, only about 1.2×10^{-7} mg/cycle dissolved from the disk. However, the rate of surface area increase of the disk was significant, *i.e.*, 9.2×10^{-5} cm²/cycle.

The difference between the amount of soluble platinum leaving the disk electrode at 3600 and at 400 rpm corresponds to the extra amount of soluble platinum redeposited at 400 rpm as compared to 3600 rpm. This difference, 6.8×10^{-7} mg Pt/cycle, divided into the difference in rates of area change between 400 and 3600 rpm, 9.2×10^{-5} cm²/cycle, gives the surface area increase per milligram of platinum involved in roughening, $\sim 1.4 \times 10^2$ cm²/mg.

Feltham and Spiro (12) recently investigated the deposition of platinum under a variety of electrochemical conditions. Their Table I indicates that a surface area increase of about 100 ± 25 cm²/mg of platinum deposited would be typical. Our result of $\sim 1.4 \times 10^2$ cm²/mg, based on the dissolution-redeposition hypothesis for roughening of platinum, agrees well with their values.

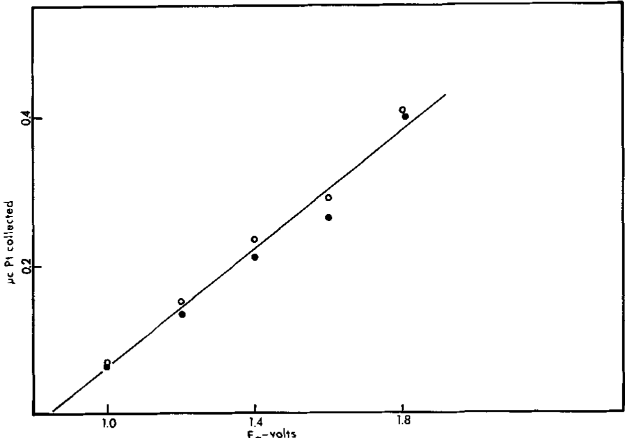

Fig. 2. Amount of soluble Pt(II) collected at ring electrode during reduction of platinum oxide formed at various anodic potentials (E_a). Filled and unfilled circles represent data obtained on two consecutive days. Oxidation time is 60 sec at each E_a. Supporting electrolyte is 1*M* H_2SO_4.

Thus, not only does the dissolution-redeposition mechanism for roughening qualitatively describe all aspects of roughening of platinum electrodes by potential cycling, but it also gives quantitative agreement with other literature concerned with platinum deposition.

A Chalcogenide Glass Electrode Sensitive to Cupric Ions

Raymond Jasinski,* Isaac Trachtenberg,* and Gary Rice

Texas Instruments Incorporated, Dallas, Texas 75222

ABSTRACT

Electrodes formed from the chalcogenide glass, Cu-As_2S_3, are selective to cupric copper in concentrated solutions of chloride, bromide, nitrate, and acetate over the concentration range of 10^{-1} to at least 10^{-6}M copper. Nernstian slopes of approximately 30 mV/decade concentration changes were observed in nitrate and acetate solutions; slopes of 50 mV/decade were observed in 1M chloride and bromide electrolytes. A slope of 40 mV/decade was observed in 0.1M chloride solution. The active phase in the electrode material appears to be "sinnerite" ($Cu_6As_4S_9$); data on the sensing mechanism are presented.

The development of ion-selective electrodes is an active area of analytical electrochemistry (1-3). One of the more technologically important measurements amenable to this technique is that for copper in process streams and waste waters. A variety of sensor electrodes have been suggested (4-9); a few are available commercially (10). All are based on cuprous or cupric sulfide and differ primarily according to the specific technique used to achieve a reasonable electronic conductivity within the sensor element and the technique used to form the active element.

The present paper discusses the preparation, performance, and properties of a copper sensitive chalcogenide glass electrode prepared from copper and arsenic trisulfide. Information will also be presented relative to the cupric ion sensing mechanism for this electrode.

Experimental

Arsenic trisulfide was prepared by heating the elements (99.9999 pure) in a sealed quartz ampul at 525°C for about 90 hr. The resulting glass was deep red and, in 50 mil slices, was transparent. The infrared spectrum of the material prepared as described agreed with that published for arsenic trisulfide. Glasses prepared from commercial arsenic trisulfide were often opaque to the infrared and led to erratic copper sensors. Both effects were ascribed to residual impurities in the starting chemicals.

To prepare the sensor material, the crushed glass was mixed with the appropriate amount of copper metal, cupric oxide, or cupric sulfide, placed in a quartz ampul which was evacuated, sealed, and placed in a furnace for 70 hr at 700°C. The temperature was then reduced to 400°C for 1 hr and the ampul was air quenched to room temperature.

Electrodes were formed in the manner described previously (11). The majority of the Cu^{+2} concentration measurements were taken with an ohmic contact made directly to the sensor glass slice. Entirely equivalent data were obtained when the membrane configuration was used, *i.e.*, when the glass slice was used to separate the solution being studied from an internal solution of constant composition; electrical contact was then made via a commercial reference electrode placed in the internal solution.

Potentials were also measured as previously described (11). An Orion Ag/AgCl reference electrode was used in the double junction mode to minimize contamination of some test solutions; 10% KNO_3, was used as the outer filling solution. Standard copper solutions were prepared by dissolving the appropriate copper salt in the following supporting electrolytes:

(*i*) 1M KCl, pH 2
(*ii*) 3M KCl, pH 2
(*iii*) 1M KCl + 1M HCl
(*iv*) 1M NaBr, pH 2
(*v*) 0.1M KNO_3, pH 2
(*vi*) 1M sodium acetate, pH 4
(*vii*) 0.1M sodium acetate + 0.9M $NaNO_3$, pH 4

No attempt was made to remove residual copper contamination from the supporting electrolytes; it was not necessary to deaerate the solutions.

Three test electrodes were monitored simultaneously in order to sort out spurious electrode effects and spurious solution effects; for simplicity of presentation, the data from only one electrode in each set will be presented here.

Unless otherwise indicated, all measurements were taken in stirred solutions, which was accomplished with a paddle stirrer (275 rpm). The consequences of stirring will be discussed.

In order to obtain a reproducible surface before each series of measurements, the electrodes were etched with 10% KOH, rinsed with the appropriate electrolyte, re-etched, and rerinsed. The electrode was then equilibrated before use in 10^{-1}M cupric ion solution for 1 hr. The chemistry involved in this important activation step will be discussed.

Measurements were also taken with two commercially available copper sensitive electrodes, the Coleman "Copper Ion-Sensitive Electrode," No. 3-804, and the Orion Model 94-29A. The purpose here was not to criticize or evaluate commercial electrodes *per se*, but to determine if significant differences in performance existed relative to the copper-arsenic trisulfide electrodes.

Results and Discussion

Electrode composition.—Visual observation of the glasses indicated a heterogeneous multiphase system with crystalline material distributed randomly throughout an amorphous matrix.

The strongest lines in all x-ray diffraction patterns were those ascribable to "sinnerite," a recently reported mineral (12, 14). In no case was it possible to confirm the presence of copper metal, cupric sulfide, cuprous sulfide, or the oxides, even when the initial source of copper was cupric sulfide or cupric oxide.

Sinnerite is reported to exist in two crystalline modifications, cubic $Cu_6As_4S_9$ ($3Cu_2S \cdot As_2S_3$) and triclinic $Cu_{6.3}As_4S_9$. Both modifications were found in the melt containing 0.25 mole fraction added copper. At lower concentrations of copper, the phase found depended on the age of the sample. This was correlatable with the preparative conditions, according to the following argument. The initial precipitate which formed on quenching the melt was the cubic phase, and was metastable at room temperature. On standing, copper slowly diffused through the glass forming the more stable triclinic distorted material near the

Key words: arsenic trisulfide, sinnerite, copper sulfide, potentiostatic activation, electrodes, ion selective.

$Cu_{6.3}As_4S_9$ composition. Indeed the triclinic lines were visible primarily in the diffraction patterns of the oldest samples and in the slow-cooled samples. The optical micrographs were consistent with such a crystal growth mechanism, in that a long (> 18 hr) reaction time at 550°C gave needle-like dendritic growth while the slow-cooled sample gave large crystals.

Resistivity measurements (d-c) were taken as described previously (11), *i.e.*, with 1 to 2 mm thick slices onto which gold had been evaporated. As shown in Table I, resistivity decreased with increasing additions of copper; the same effect was obtained regardless of the form of the initially added copper. This is consistent with the x-ray data in that the conductive crystalline material formed in the melt was independent of the starting copper compound.

The primary conclusion to be drawn from the data of Table I is that the conductivity of the high copper-content glasses is sufficient in itself for stable electrochemical operation and that the addition of conductive binders such as Ag_2S or graphite is not necessary.

The spread in the data represent the spread in resistivities measured for different slices taken from the same melt. Obviously the slices are also heterogeneous along the length of the melt as well as along the surface of a slice. However this variation in resistivity decreased as the copper content of the melt was increased above mole fraction 0.2, as would be expected if the conductivity were due primarily to the crystalline phase.

A rigorous correlation of electrode performance with electrode composition, crystalline phase, or physical properties was not attempted. It was generally observed however that electrodes containing a mole fraction of copper at or less than 0.2 were less sensitive to changes in Cu^{++} concentration below 10^{-4}M than electrodes containing larger amounts of copper. Unless otherwise noted, all data presented in this paper were taken with electrodes containing 0.25 mole per cent (m/o) copper.

Since electrode performance depended significantly upon the type of supporting electrolyte the experimental results will be grouped according to this parameter.

Performance in nitrate and acetate solutions.—The first series of electrochemical measurements to be described are those taken with 0.1M KNO_3 as the supporting electrolyte; complex ion formation is minimal (13), and soluble cuprous species are unstable.

Shown in Fig. 1 are the potential-concentration relationships for an electrode operated in the following manner. The electrode was first etched and then placed directly into 10^{-6}M cupric nitrate, followed by solutions of increasing copper ion concentration. Data were recorded when potential drift was less than 2 mV/min. After exposure to 10^{-2}M Cu^{++}, the electrode was exposed to decreasing concentrations of copper (in order of magnitude changes) to 10^{-6}M, and then to concentrations increasing to 10^{-1}M. After 30 min at this concentration, the copper content was decreased incrementally to 10^{-6}M and increased incrementally to 10^{-1}M.

The slope of the first of these potential-concentration curves is "super-Nernstian," *i.e.*, with a slope greater than 30 mV/decade; the return to lower concentrations gave a slope of less than 30 mV/decade. On subsequently increasing concentration, Nerstian

Table I. Resistivities of copper-arsenic trisulfide glasses

Mole fraction copper	Resistivity (ohm-cm) CuO added	Resistivity (ohm-cm) Cu added
0.05	3×10^8 to 6×10^{10}	2×10^7 to 4.3×10^7
0.10	3×10^6 to 3×10^8	4.1×10 to 4×10^4
0.15	4×10^3 to 1×10^6	4×10^2 to 3×10^3
0.20	1×10^2 to 8×10^3	4×10^2 to 3×10^3
0.25	46 to 50	64 to 69
0.30	—	36 to 37

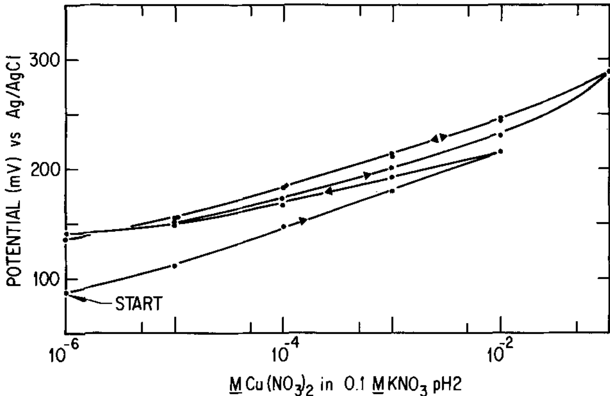

Fig. 1. Performance of a freshly etched, not activated copper-arsenic trisulfide electrode.

behavior was observed from 10^{-4} to 10^{-2}M; the potential at 10^{-2}M showed a slow but real drift to more positive values; the potential change between 10^{-2} and 10^{-1} was 60 mV. The next cycle between 10^{-1} and 10^{-6}M Cu^{++} showed no hysteresis of the type described and showed Nernstian behavior from 10^{-2} and 10^{-5}M copper. Such measurements formed the basis for the activation procedure described, *i.e.*, to obtain a stable, reproducible, and reversible sensor, the freshly etched electrode first had to be exposed to high concentrations of cupric ion.

The time for activation in 10^{-1}M cupric nitrate (in 0.1M KNO_3) was evaluated by measuring the potential-concentration dependencies after the electrodes were etched and exposed to the solution for periods of 45 min, 1 hr, 2.5 hr, and overnight. There was little difference in the slopes of the response curves and the sensitivity to low Cu^{+2} concentrations, although, as exposure time was increased, the curves were always displaced to higher potentials. There was also considerable hysteresis, after the electrode had been equilibrated in 10^{-1} cupric nitrate for more than 2.5 hr, between the first exposures of the electrode from 10^{-1} to 10^{-6}M cupric nitrate relative to subsequent cycles in concentration between these limits.

Shown in Fig. 2 are the concentration-potential relationships determined in nitrate solutions for a properly activated electrode; included for comparison are the performances of the commercial electrodes. Below 10^{-2}M copper, the Orion electrode and the copper-arsenic sulfide electrodes were essentially identical in performance, with Nernstian slopes of 31 and 27 mV/decade, respectively. Above 10^{-2}M copper, the copper-arsenic trisulfide electrode showed a slight super-Nernstian response. Below 10^{-4}M copper, this particular Coleman electrode showed little sensitivity

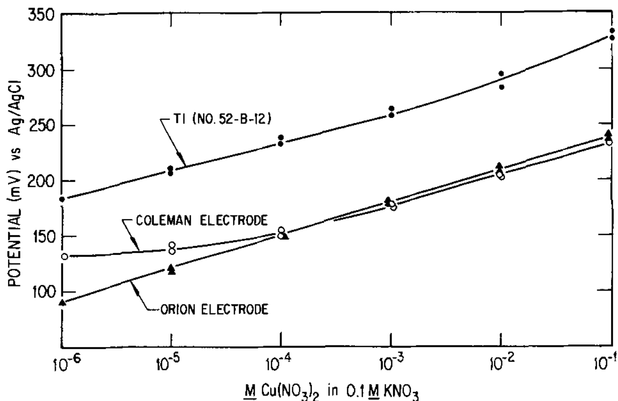

Fig. 2. Steady-state responses of a copper arsenic trisulfide electrode, and two commercial electrodes, to varying copper ion concentrations in a supporting electrolyte of 0.1M KNO_3.

to changing copper ion concentration; above 10^{-4}M copper the two commercial electrodes were essentially identical in response.

Response times for all electrodes were good, *e.g.*, at 10^{-4}M copper, steady state was achieved within 1-3 min; here steady state is defined as a potential stable to less than 1 mV drift in 3 min.

The three electrodes showed little dependence on stirring. For example, 2 min after stirring of the 10^{-2}M copper solution was terminated, the potentials of the Cu-As_2S_3, Orion, and the Coleman electrodes decreased by 1.9, 1.8, and 0.2 mV, respectively.

The effect of *p*H on sensor response in nitrate solution is shown in Fig. 3. In the absence of Cu^{++}, the electrode is *p*H sensitive, probably due to some absorption or reaction of the surface with hydroxyl ion. However in the presence of cupric ion, the electrode response is independent of *p*H until cupric hydroxide begins to precipitate. Even as this takes place, the electrode potential followed the remaining copper in solution until the detection limit of the electrode was reached. The data shown were for an electrode prepared from CuO; identical results were obtained for an electrode prepared from copper metal, as would be expected in view of the x-ray studies described above.

Responses of the Cu-As_2S_3 electrodes in the acetate solutions are summarized in Fig. 4; included for comparison is a response curve for the electrode in 0.1 nitrate solution. Prior to each run the electrode was etched and activated to remove possible complications from prior history.

At and below 10^{-3}M added copper, the slopes of the curves were basically identical, with slopes of approximately 30 mV/decade. The curves did shift to lower potentials with increasing acetate concentration at a fixed added concentration of copper. Qualitatively this is consistent with the argument that the electrode responds to uncomplexed cupric ion which decreases in concentration as acetate increases (13). A rigorous calculation of the shifts in potential with changing acetate concentration was not done due to shifts in E_o of the electrodes by virtue of the re-etching procedure

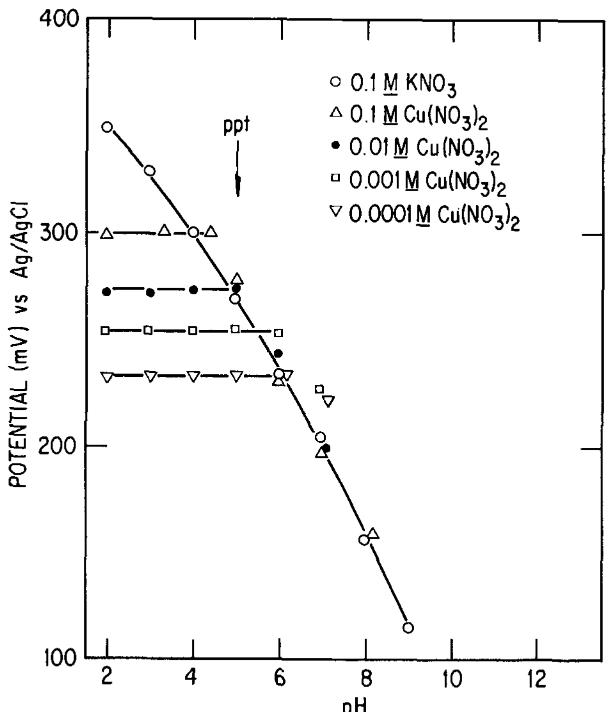

Fig. 3. Response of a $(CuO)_{0.15}(As_2S_3)_{0.85}$ electrode, in the membrane configuration, to varying cupric ion concentration as a function of *p*H. All solutions were 0.1M KNO_3.

followed between each series of concentration measurements.

Performance in chloride and bromide solutions.—Copper-arsenic trisulfide electrodes operated in these solutions also required the activation step before stable Nernstian response could be obtained. There was little difference between electrodes equilibrated in 10^{-1}M cupric chloride solutions (1M KCl, *p*H 2) for 1 hr and those equilibrated for 5 hr. Electrodes equilibrated overnight were less sensitive to changes in cupric ion concentration at and below 10^{-5}M. After a 40 hr exposure to 10^{-1}M $CuCl_2$, all electrodes showed a significant loss in activity below 10^{-4}M copper, *i.e.*, a lowering in sensitivity to changes in cupric ion concentration.

Shown in Fig. 5 are the steady-state responses to varying cupric ion concentrations in 1M KCl for a copper-arsenic trisulfide electrode and, for comparison, an Orion and a Coleman electrode. The copper-arsenic trisulfide electrode showed Nernstian behavior over the range of 10^{-5} to 10^{-2}M copper, but with a slope of 49 ± 2 mV/ decade, rather than ~30 mV/decade. The Nernstian slope for the Coleman electrode was 55 mV/ decade from 10^{-4} to 10^{-1}M cupric ion; the potentials oscillated ± 2 mV at steady state. The Orion electrode demonstrated a saturation effect at high copper concentrations in this high chloride containing solution. This was predicted by the operations manual supplied with the electrode and is apparently due to the reaction (17)

$$Ag_2S + Cu^{++} + 2Cl^- = 2AgCl + CuS$$

The film of AgCl would cover the active surface of the electrode, giving sensitivity to Cl^- rather than Cu^{+2}. Between 10^{-6} and 10^{-4}M copper, the potential change of the Orion electrode gave slopes in the 35-50 mV range. Thus the performance of these electrodes at high chloride ion and low Cu^{+2} concentrations are more complicated than predicted from the standard solubility product mechanism.

All copper-arsenic sulfide electrodes showed a stirring dependence when operated in 1M KCl and 1M NaBr solutions. The most sensitive copper arsenic trisulfide electrodes generally showed a drop in potential of 30 mV 2 min after stirring was stopped in the 10^{-1}M copper chloride solution; smaller changes were observed at the lower copper containing solutions, *e.g.*, 15 mV at 10^{-4} cupric ion. This stirring dependence also varied from electrode to electrode, in the best case being only 10 mV/2 min at 10^{-1}M cupric and 3.3 mV/2 min at 10^{-3}M. However these electrodes were less sensitive to changes in cupric ion concentration at low levels of copper (*e.g.*, 10^{-5}M). A tentative explanation for this stirring dependence will be given below. A correlation of potential with stirring rate was not made.

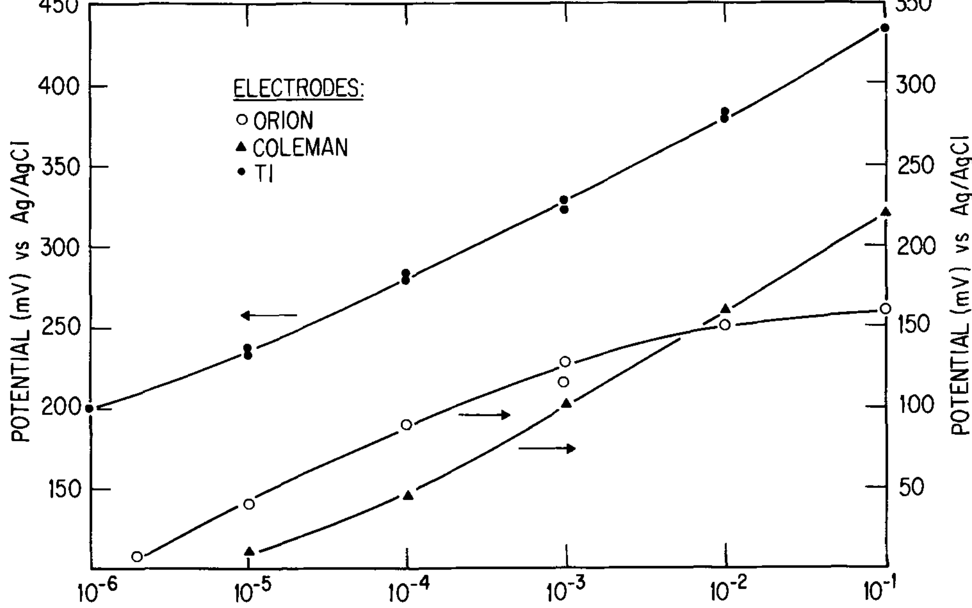

Fig. 5. Steady-state potential-concentration responses of a copper arsenic trisulfide electrode, and two commercial electrodes, in 1M KCl, pH 2. The arrows indicate the appropriate potential scales.

The Coleman electrode showed a stirring effect of the same magnitude but in the opposite direction, *i.e.*, the potential increased after the stirring was shut-off. For one Orion electrode a potential increase of 2 mV was observed 2 min after stirring was terminated in 10^{-5}M cupric chloride. However, two other electrodes showed stirring dependencies similar to those found with the Coleman electrode.

Since the slopes observed in 1M chloride were higher than those observed in nitrate and in acetate, a study was made on the effect of chloride ion concentration on electrode response. Accordingly, electrodes were exposed to varying copper concentrations in supporting electrolytes of 3M KCl, 1M KCl, 0.1M KCl + 0.9M KNO_3, and 0.1M NaCl; *p*H was maintained at 2 in all cases.

Within the accuracy of the experiments the Nernstian slopes in the 3M and the 1M KCl were identical. In all cases the slopes for the 0.1M KCl solution was lower, approximately 40 mV/decade. The actual potentials measured in the 3M KCl were about 50 mV higher than those measured in 1M KCl. Some of these data, together with the performance in zero chloride ion concentration (0.1*N* KNO_3) are shown in Fig. 6.

An evaluation was made of the electrode properties in bromide solution, which has a different distribution of complex ions with cupric ion (13) and in which cuprous ions are still stable (15). The electrodes were etched, stored overnight in 10^{-1}M cupric nitrate solution, and exposed to varying cupric ion concentrations in 1M NaBr and in 1M KCl. In all cases the slope of the potential-concentration dependence appeared to be higher in bromide than in chloride by about 2 mV, however this is well within the accuracy of the data. Stirring dependencies were also observed in bromide electrolytes, and these were slightly greater than in chloride solutions of the same added copper concentration. In all cases the actual potentials of the bromide solutions were higher than those in the chloride solutions. According to Ref. (13) the copper-bromide complexes are weaker than the copper-chloride complexes so that at any given total added copper the available cupric ion concentration will be greater in bromide and could, at least in part, account for the differences observed in the actual potentials (assuming that the electrode responds only to uncomplexed cupric ion).

Electrode selectivity.—The response of the copper-arsenic trisulfide electrode to other soluble ionic species was evaluated. Univalent ions such as Na^+, K^+, and H^+ do not give a response in the presence of cupric ion other than via ionic strength effects. Some interference does result when excessive amounts of ferric ion are present. This is illustrated in Fig. 7. Each plot represents the response of a Cu-As_2S_3 electrode immersed in solutions of constant ferric ion concentration but with varying cupric ion concentrations. These curves indicate that the ferric ion must be at least ten times greater than the cupric ion concentration before significant interference is observed.

The response of the sensor to other ions is shown in Fig. 8. Varying amounts of calcium, nickel, and

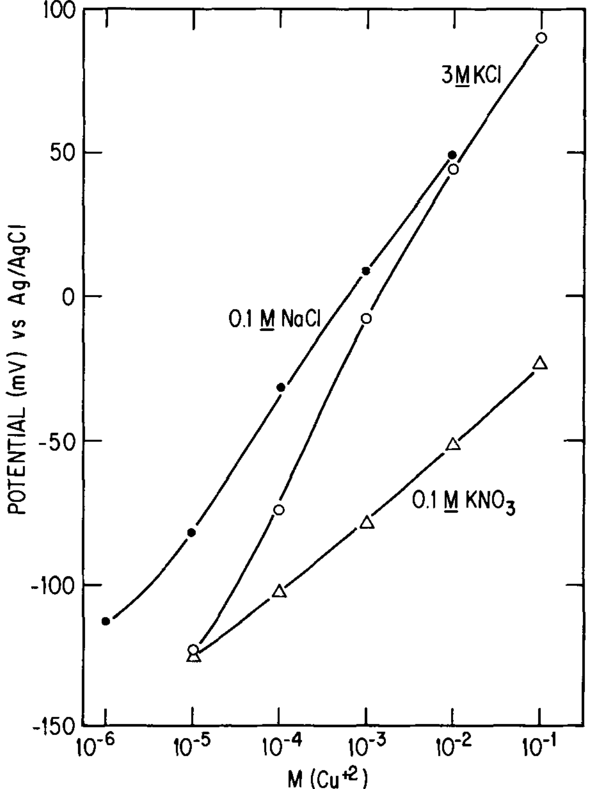

Fig. 6. Potential-log copper concentration relationships shown by a CuO-As_2S_3 electrode in 3M KCl, 0.1M NaCl, and zero molar chloride (0.1M KNO_3).

ferrous ion were added to a 10^{-3}M cupric nitrate solution. The results indicate no interference due to either calcium or nickel. The effect of ferrous ion suggests a titration curve, whereby cupric ion is reduced and ferric ion is generated. There are also no interferences from Pb^{+2}, Mn^{+2}, or Zn^{+2}. Interference was found with silver ion.

Sensing mechanism.—It is apparent that the behavior characteristics of these electrodes are not consistent with the usual solubility product type of ion sensing formalism. A series of experiments were carried out in the hope of clarifying the mechanism operating for the copper-arsenic trisulfide electrodes.

The first feature considered then was the electrode activating mechanism, *i.e.*, whereby a freshly etched electrode surface must first be exposed to high concentrations of cupric ion before stable Nernstian responses can be obtained. Exposures of the electrode to 10^{-1}M Cu^{++} solutions obviously present the electrode with a high concentration of cupric ion, but this also presents the electrode with a high positive potential, which can possibly oxidize the electrode surface.

In order to sort out the relative importance of these two factors, the following experiment was carried out. Electrodes were freshly etched and then potentiostated at the potential of 10^{-1} $CuCl_2$, but in the absence of cupric ion; all other components of the solution were identical to those used in the chemical activation procedure, *i.e.*, 1M KCl, *p*H 2. An anodic current, independent of stirring, was observed, so that chemical oxidation of the electrode surface must take place during the activation procedure. After the anodic current had decreased to less than 1 μA, the electrode was exposed to 10^{-6}M cupric chloride and to incrementally increasing copper concentrations in the usual manner used to test the electrodes. The nature of the response was similar to that shown in Fig. 1, *i.e.*, super-Nernstian responses until high cupric ion concentrations were reached. Thus a high potential alone is not sufficient to activate the electrode surface.

It is not difficult to understand a chemical oxidation-activation mechanism occurring in chloride solution where cuprous ion, the necessary soluble product of the surface oxidation reaction, is chemically stable. However the same chemical activation process takes place in nitrate solution where cuprous ion is unstable according to the reaction

$$2Cu^+ = Cu + Cu^{++}$$

However, according to the equilibrium constant for the above disproportionation reaction the concentration of cuprous ion is 2.5×10^{-4}M in the solutions used. Approximately 2.5 Asec of charge would pass before this concentration was exceeded and copper metal was formed. Since this is in excess of the total charge passed during the potentiostatic oxidation of the electrode, it is possible, even in nitrate solution, for the cupric ion to oxidize the electrode and produce a small amount of cuprous ion in solution.

The potentiostatically oxidized surface still demonstrated super-Nernstian behavior which is indicative of more than a one or two electron process, *i.e.*, indicative of further interaction of the copper sensing surface. This interaction between cupric ion and the electrode surface could take a variety of forms, such as compound formation to generate the active sites, or irreversible reaction with strongly adsorbing sites, or both. In any event, this final surface then comes into reversible equilibrium with the cupric ion content of the electrolytes, providing stable Nernstian slopes to changing Cu^{+2} concentration.

A fundamental difference in this sensing mechanism must exist between halide solutions, and nitrate solutions, since the Nernstian slopes in halide are a nominal 50 mV/decade and are a nominal 30 mV/decade in nitrate. Furthermore there is some dependence of slope on the halide concentration. A major difference in the chemistry of these solutions is the increased stability of cuprous ion in halide electrolytes.

The response of the electrode to cuprous ion was therefore considered. Electrodes were etched and activated as described. Activity was confirmed by exposure to solutions of varying cupric ion concentration

in 1M KCl. The electrodes were then washed with supporting electrolyte and exposed to solutions of cuprous chloride in the same electrolyte. Electrode potential readings were somewhat erratic but always less than that expected from 10^{-6}M cupric chloride. It must therefore be concluded, particularly when considering the difficulties in preventing cuprous chloride from air oxidizing to cupric chloride, that the response of the electrode to Cu^{+1} species is minor.

This then precludes any "solubility product" sensing mechanism involving the participation of sulfide ion in solution. Cuprous sulfide, like silver sulfide is highly insoluble and should have given rise to a potential shift equivalent to a high cupric ion concentration (low sulfide ion).

The electrode was then washed with supporting electrolyte and exposed to 10^{-4}M $CuCl_2$ in 1M KCl. Increments of cuprous chloride were added to determine whether the electrode does respond to the cupric/cuprous couple. As potentials were recorded there was some drift upwards as, apparently, the cuprous ion was slowly oxidized by air. The data obtained are shown in Table II; similar results were obtained when the starting cupric ion concentration was 10^{-3}M.

Obviously cuprous ion suppressed the potential normally generated by a fixed amount of cupric ion; the depression increased as cuprous ion concentration increased, but not in a well-defined manner and not to the extent expected from the cuprous/cupric couple (60 mV/decade).

This depression may afford a pragmatic explanation for the stirring dependencies observed with the copper-arsenic trisulfide electrodes in halide solution. It can be argued that a reduced material, presumably cuprous ion, dissolves slowly off the electrode surface and reacts with cupric ion, thus depressing the amount of cupric ion in the vicinity of the electrode and hence depressing the electrode potential. (If cupric ion dissolved off the electrode potential would have increased.) On stirring, the cuprous copper is swept away from the electrode vicinity and the potential takes on a value more characteristic of the cupric ion in solution. The amounts of cuprous ion are sufficiently small however to prevent any easily detectable increase in total copper ion concentration in the test solution. Consistent with this dissolution mechanism then is the observation that those electrodes demonstrating the most pronounced stirring dependence were also the most pitted after prolonged use.

It is necessary, in using this explanation, to account for the chemistry of a reaction between cuprous and cupric copper in solution. It has been shown by optical absorption spectroscopy (16) that a weak but well-defined complex exists in solution between cuprous and cupric chlorides in the range of chloride concentration used in the electrode studies. Thus cuprous ion may well dissolve off the electrode, complex the cupric copper in the vicinity of the electrode, and thus lower the available concentration of cupric copper at the electrode surface. As a result, potential falls.

More direct evidence for dissolution of a reduced species from electrodes in halide solution was obtained as follows. A copper arsenic trisulfide electrode was etched, activated in 10^{-1}M cupric nitrate and transferred to a deaerated solution of 10^{-3}M cupric chloride; a platinum screen electrode was placed about the copper electrode. In the absence of the copper

Table II. Potential response vs. cuprous chloride concentration (Original solution: 100 ml $CuCl_2$ + 1M KCl)

Molar ratio (Cu^{++}/Cu^{+})	Electrode potential (mV)
∞	287.8
100/1	278.9
10/1	248.1
0.9/1	230.8

Table III. Arsenic contents of equilibration solutions

Solution	Arsenic concentration (ppb)
10^{-1}M KNO_3	<10
10^{-1}M KNO_3 + 10^{-2}M Cu^{++}	<10
1M KCl	35
1M KCl + 10^{-4}M Cu^{++}	35
1M KCl + 10^{-2}M Cu^{++}	65

electrode the potential of the platinum electrode was relatively stable at about +430 mV. After insertion of the copper electrode the potentials of the platinum electrode were well poised, *i.e.*, showing no oscillations, and continuously drifted to more negative values. The drift rate at steady state (after 60 min) was 4.3 mV/hr. Thus, a reduced species, presumably cuprous ion, is indeed dissolving off the electrode surface. The solution was then changed to 10^{-5}M cupric chloride; the final drift rate of the platinum electrode was 1.8 mV/hr. Thus, the cuprous ion dissolution rate is inversely proportional to the cupric ion concentration. (Identifying the "reduced species" as cuprous ion is based on the difference in electrode performance between halide and nitrate solutions, and the stability of Cu^{+1} in halide solutions.)

This proportionality was checked by direct chemical analysis of the solution. Since the copper concentrations involved are small and hence difficult to detect in the presence of the higher ambient concentrations, analysis was made for arsenic. The results are shown in Table III.

Thus there can be little doubt that the electrodes are more soluble in chloride than in nitrate, and that the solubility is higher in the presence of high cupric ion concentrations. All of this is consistent with the stirring dependences discussed above.

The next question is whether this soluble reduced material (presumably cuprous ion) is involved in the cupric ion sensing mechanism, or whether this dissolution reaction is merely incidental. Accordingly, freshly etched electrodes were potentiostated at increasingly positive potentials (in 1M NaBr, *p*H 2) to more completely oxidize the electrodes surface, then equilibrated in 10^{-1}M cupric nitrate (0.1M $NaNO_3$), and exposed to solutions of 1M NaBr, *p*H 2 varying in cupric ion content. The results are shown in Fig. 9; included for comparison are the responses of a chemically activated electrode.

The behavior of the chemically activated electrode and the electrode potentiostated at +600 mV are essentially identical. The effect of higher potentials is obvious, *i.e.*, as potential is made more positive, the subsequent sensitivity of the electrode to change in copper concentration below 10^{-4}M decreases. It was

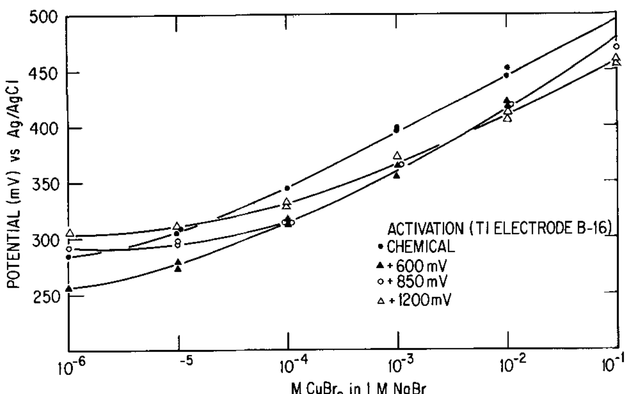

Fig. 9. Steady-state responses of a copper arsenic trisulfide electrode to varying concentrations of cupric bromide after chemical activation and after potentiostatic treatment at the potentials shown.

also observed that electrodes exposed to +1200 mV would oscillate ±4 mV when subsequently equilibrated with copper halide solutions. The stirring dependences decreased with increasing potential applied to the electrode. Note however that sensitivity to low levels of copper concentration decreases at the same time. This is similar to observations made earlier that electrodes which had the lower stirring dependencies also had the lower sensitivities. Application of high potential to such electrodes completely deactivated the electrode. It is thus apparent that the "reduced material" is indeed involved in the potential sensing mechanism.

As indicated previously, the electrode is at least a two-phase system, *i.e.*, crystalline sinnerite imbedded in an amorphous phase. The participation of the amorphous phase in the sensing process was evaluated by comparing the performances of pure sinnerite electrodes with those of $Cu_{0.25}(As_2S_3)$ electrodes.

Accordingly samples of sinnerite material were compounded by mixing Cu_2S and As_2S_3 in a mole ratio of 3:2. The mixture was placed in ampul, evacuated, sealed, and heated to 700C for 1 hr. The temperature was then lowered to 500° for 1 hr and finally raised to 550°C and maintained at this latter temperature for 90 hr. The resulting sample was then air quenched to room temperature. Resistivity as measured on two slices was 3.04 and 3.22 ohm-cm indicating that the sinnerite is indeed a conducting material. Three sinnerite electrodes were prepared from this material. The electrodes were etched, stored overnight in 10^{-3}M cupric nitrate, and exposed first to cupric nitrate solutions over the range of 10^{-3} to 10^{-6}M. A Nernstian slope of 30 mV/decade was obtained. The experiment was repeated in 1M KCl over the range 10^{-1} to 10^{-6}M $CuCl_2$. A Nernstian slope of approximately 55 mV/decade was obtained between 10^{-1} and 10^{-3}M cupric chloride. However between 10^{-4}M and 10^{-6}M $CuCl_2$, the response was super-Nernstian of the order of 100 mV/decade. The electrodes also showed a greater stirring dependence at and below 10^{-4}M.

These responses in nitrate (between 10^{-3} and 10^{-6}M) and in chloride solutions (at and above 10^{-3}M $CuCl_2$) are equivalent to those for the two phase system so that it can be concluded that either the amorphous phase is not involved in the potential sensing *per se* or that its role is entirely equivalent to that of the sinnerite. This is consistent with the observations that all the copper-arsenic trisulfide electrodes behaved in an equivalent manner, regardless of the initial chemical form of the copper put into the melt. Since the crystalline phase was always sinnerite, the amorphous phase must have differed in composition. If it were involved then it would have been expected that the electrode behavior would also have varied with the form of the initial copper.

The abnormal behavior of the sinnerite electrodes at low concentrations of cupric chloride was similar in form to that obtained for $Cu_{0.25}(As_2S_3)_{0.75}$ electrodes exposed to varying Cu^{++}/Cu^{+} ratios. This performance then can be rationalized in terms of the sinnerite electrode depositing abnormally high concentrations of cuprous ion in the vicinity of the electrode and reaching concentration ratios where the cuprous ion exerts a significant effect on observed electrode potential. Furthermore, the pronounced higher stirring dependence for the sinnerite electrodes is what would be expected from the dissolution of greater quantities of cuprous ion.

The conclusions of these semiquantitative mechanistic studies can be summarized by the following formalism. The active electrode material ($Cu_6As_4S_9$) is first oxidized by cupric ions (potentiostated sinnerite developed a high initial anodic current), *i.e.*

$$Cu_6As_4S_9 + Cu^{++} \rightarrow (OxS) + Cu^{+} \quad [1]$$

This oxidized surface, (OxS), then reacts with cupric ion to form the active sites (ActS) which come into equilibrium with the cupric ion concentration of the test solutions, *i.e.*

$$(OxS) + Cu^{++} \rightarrow (ActS) \quad [2]$$

and

$$(ActS) + Cu^{++} \rightleftarrows (ActS)\ (Cu)_{ads} + 2e^{-} \quad [3]$$

A second and irreversible process such as reaction [2] is required to account for the super-Nernstian slope observed only initially with oxidized electrodes. It is envisioned that as the sites are formed they then interact with cupric ion according to reaction [3]. It is postulated that this active copper site with adsorbed copper dissolves in halide solution to inject cuprous ion (or some other reduced specie which can remove Cu^{+2} ions) into the electrolyte. Participation of this site is indicated by virtue of the proportionality between cupric ion concentration and electrode solubility. Also formed during this dissolution process is a soluble arsenic species, a sulfur-arsenic residue and some fresh sinnerite surface

$$(ActS)\ (Cu)_{ads} + Cl^{-} \rightarrow (CuCl)sol + (As_2S_3)residue + Cu_6As_4S_9 + \text{soluble arsenic} \quad [4]$$

The involvement of chloride ion in this reaction, due to its stabilizing influence on cuprous ion, accounts for the dependence of the Nernstian slope on the chloride ion concentration. The sinnerite so exposed can then proceed through the reactions illustrated by Eq. [1] and [2]. Since at least one of these involves electron transfer, a slope greater than 30 mV/decade is obtained. The extent of this reaction is dependent upon cupric ion concentration via the participation of the adsorbed copper sites in reaction [4], so that the over-all response of the electrode is dependent upon cupric ion concentration of the solution. Reaction [4] should lead to an eventual deactivation of the electrode in chloride solutions via the accumulation of the residue, and a deactivation is observed. Furthermore this deactivation should be less important in nitrate solution due to the lower solubility; this is also observed. By the law of mass action it would be expected, from Eq. [3], that deactivation should take the form of lowering sensitivity to low concentrations of cupric ion, and this is also observed.

Summary

Fusing arsenic trisulfide with copper, cupric oxide, or cupric sulfide generates an electronically conductive glass which is sensitive to changes in cupric ion concentration over the ranges of at least 10^{-1} to 10^{-6}M copper in molar solutions of chloride, bromide, nitrate, and acetate. The electrochemically active component of the glass is apparently "sinnerite" ($Cu_6As_4S_9$). Stable, Nernstian responses were obtained only after the electrode surface was etched in caustic and equilibrated with high ($>10^{-3}$M) concentrations of cupric ion; excessive oxidation of the surface ($> +600$ mV *vs.* Ag/AgCl) decreased electrode sensitvity to low levels of copper ion concentration.

In the presence of cupric ions, the electrode response was independent of hydrogen ion concentration from pH 2 to a value at which copper hydroxide precipitation takes place. Even as copper precipitated the electrode potential followed the remaining copper in solution until the limit of detection of the electrode was reached.

In nitrate and acetate solutions the slopes of the potential-log concentration plots were 27 mV/decade; for the 1,2, and 3M chloride and bromide solutions the slopes were 50 mV/decade; the slope in 0.1M KCl was 40 mV/decade. The commercial electrodes studied also showed differences in slope between the nitrate and chloride solutions.

The response of the copper-arsenic trisulfide electrodes were independent of stirring in the nitrate and

acetate electrolytes. However in chloride and in bromide solutions, stirring led to an increase in electrode potential. Stirring dependencies were also found for the commercial electrodes studied but in the opposite direction.

The copper-arsenic trisulfide electrodes did not respond to cuprous ion *per se*, or to the Cu^{++}/Cu^{+} couple. No interference was found from Ca^{++}, Pb^{++}, Zn^{++}, Ni^{++}, or Mn^{++}. Ferric ion, when present in a ten fold excess, interferes; Ag^{+} also interferes.

Qualitative studies of the electrode activation process indicated that direct oxidation of the surface by cupric ion takes place followed by two or more chemical reactions between cupric ion in solution and this oxidized surface. It is this final surface configuration which is involved in cupric ion sensing.

Interferometric Study of the $Zn/ZnSO_4/Zn$ System

II. Concentration Gradients under Convectionless Transport

ABSTRACT

The Laplace transform solution of the unsteady state diffusion equation which describes the concentration gradients in a convectionless system has been compared to experimentally obtained values. The experimental values were obtained as multiple beam Fizeau-type fringes from an electrolysis cell which was also a Fabry-Perot interferometer using a laser as the light source. The electrochemical system was $Zn/ZnSO_4/Zn$, at 0.5-0.05M concentration at room temperature at constant currents ranging from 1.0 to 0.1 mA cm^{-2}. At the middle ranges of times and current densities quite good agreement is found. In general the calculated and experimental values differed more than the expected experimental error. A "passivated" set of electrodes was used and gave much lower concentration changes for similar current densities than the normal electrodes.

In Part I the effect of natural convection on concentration gradients and the potential required for a constant current density was evaluated (1). It was shown that for vertical electrodes natural convection limited the diffusion layer to values of about 0.01-0.03 cm. In the anode over cathode horizontal electrode configuration convection was evident within 15 sec for the lowest current densities (0.37 mA/cm^2). Again with horizontal electrodes the diffusion layer constantly increased in depth with time since no limiting process was present. Interferometry was demonstrated to be efficacious in detecting concentration gradients and the effect of convection. In this part the convectionless system is considered.

Measurements of concentration gradients at working electrodes have become reasonably common (2-4). In general, quite good agreement has been found between the concentration calculated from the solution of the

* Electrochemical Society Active Member.
Key words: Zn anode, Zn cathode, convectionless transport, interferometry.

differential equation of Fick's second law due to Rosebrugh and Miller (5) or variations of it (2) and the experimentally determined values. Some anomalous results have been reported (6): in particular there seemed to be an abrupt discontinuity at 0.07 cm electrode separation of a plot of voltage to maintain a constant current density at a given electrode separation for all electrode arrangements with and without convection. The first complete calculation of a concentration gradient under convectionless conditions (3) was for the system $Cu/CuSO_4/Cu$ and the agreement between calculated and observed values was good at short times (*i.e.*, ~15 sec). At longer times (~150 sec) the order of magnitude was correct but use of the accepted transport number for the sulfate ion required that a diffusion constant lower than the accepted one be used. The diffusion constant derived from old electrochemical methods (Sand's data) without allowance made for ion-pair formation gave the best agreement.

In the present work on the $Zn/ZnSO_4/Zn$ system some anomalies were anticipated because of the expected *p*H changes [as calculated by Wagner (7) and observed by Polukarpov (8)] at the electrodes and the amphoteric behavior of zinc ion on either side of *p*H 7.

In Part III anomalous results obtained for low Zn^{++} (metal ion) concentration will be presented. In this part experimental results for both anode and cathode are presented, but only calculations for the cathode are discussed. The experimental concentration changes are found not to be symmetrical at the two electrodes, whereas calculated results based on constant transport parameters are. The differences between the two electrodes are more marked at lower concentration and hence will be discussed more fully in Part III. In Part III anomalous results obtained for low $ZnSO_4$ concentration will be presented.

Experimental Arrangements

The $ZnSO_4$ stock solution was made from Analar grade material and water (four times distilled), then titrated with EDTA and diluted to the required concentration, and used at its natural *p*H. Concentrations were checked once per week for several weeks until it became obvious that no change occurs in stoppered volumetric flasks kept in the dark. Zinc 99.99% pure was donated by Cominco, Trail, British Columbia. The temperature was 25° ± 0.3°C.

The cell used was a modification (4, 9) of that used in Part I, the distance between electrodes, $2l$, being 0.3 cm which was the same as the thickness of electrode. The cell represented a modified Fabry-Perot interferometer which contained the solid Zn electrodes and the electrolyte. The cathode was in horizontal position above the horizontal anode. The light source was a He-Ne 1 mW laser, of 632.8 nm wavelength. Refractive indices of the solutions at other wavelengths and *p*H's have been published (10). Those at 632.8 nm were obtained using the laser and a precision Abbé refractometer (Table I) by a technique recently published (11).

A constant current was provided by a 6V lead acid battery at 5/8th charge with an external variable resistance in series with the cell whose resistance was always less than 200 ohms. The current was monitored by a voltmeter with 10^7 ohms/V input resistance across a calibrated standard resistance of 100 ohms also in series in the circuit. Current densities from 0.1 to 1 mA/cm^2 in steps of 0.1 mA were investigated at both 0.5 and 0.05M. Interferograms were recorded with a 35 mm camera. These were then projected onto a plotting table and hand drawn on large-size millimeter graph paper at 50 and 100 times magnification. Fringe perturbations were converted to concentration contours by the method previously outlined (4).

Theory

The theory of electrolyte concentration near working electrodes was worked out by Rosebrugh and Miller in 1910 (5) using Fourier analysis methods. O'Brien published data on the $Cu/CuSO_4/Cu$ system obtained interferometrically (3) and compared these with the values obtained using an expression based on a Laplace transform solution.

A modified form of the solution which is easier to analyze by inspection and is more complete will now be presented.

Following the review of Tobias, Eisenberg, and Wilke (12), the rate of transfer of ions in the x direction taken perpendicular to the working surface of a planar, horizontal electrode is

$$N_t = CU\frac{\partial \Psi}{\partial x} - D\frac{\partial C}{\partial x} + VC \qquad [1]$$

where N_t is the total rate of transfer, gram ions cm^{-2} sec^{-1}; C is gram ions cm^{-3}; U is mobility, cm^2 sec^{-1} V^{-1}; Ψ = potential, V; x is distance in direction of transfer, cm; D is the diffusion constant for the salt derived from conductivity measurement, cm^2 sec^{-1}; and V = velocity for the steady-state conditions, cm sec^{-1}. We eliminate the third term by ensuring experimentally that $V = 0$ (exactly horizontal electrodes, cathode above) and the first term by multiplying the second term by the transport number of the anion following Newman (13), resulting in a single term expression corresponding to Fick's first law, or the steady-state concentration gradient. For semi-infinite diffusion (as contrasted to limited diffusion) the achievement of the steady state requires very long times. Accordingly, all experiments can be regarded as being transient (or unsteady state and Fick's second law applies) thus the solution of the equation

$$\frac{\partial C}{\partial t} = D\frac{\partial^2 C}{\partial x^2} \qquad [2]$$

is sought with the initial condition that at $t = 0$, $C = C_0$ at all x from 0 to l where $2l$ is the distance between the two electrodes and the boundary conditions that $\Delta C = 0$, $x = l$, $t > 0$, and $\partial \Delta C/\partial t$ = constant at $x = 0$, $t > 0$.

The electrochemical form of the solution by Laplace transform method is for cathode concentration changes

$$\Delta C_{(x,t)} = \frac{2It_-}{n\mathbf{F}\sqrt{D}}\sqrt{t}\left[\text{ierfc}\left(\frac{(2l-x)}{2\sqrt{DT}}\right) - \text{ierfc}\left(\frac{x}{2\sqrt{DT}}\right)\right] \qquad [3a]$$

which for short times (> 180 sec) reduces to

$$\Delta C_{(x,t)} = \frac{-2It_-}{n\mathbf{F}}\sqrt{t/D}\,\text{ierfc}\frac{x}{2\sqrt{Dt}} \qquad [3b]$$

in which I is the current density, A/cm^{-2}; n the charge on the ion; $\mathbf{F}$ the Faraday, coulombs; t the time in seconds; t_- the transport number of the anion; Δl the change in concentration ($M\ cm^{-3}$); and ierfc the complement of the integrated error function tabulated by Carslaw and Yaeger as 2 ierfc. The previously published equation had typographical errors and should

have been identical to [3b] after algebraic simplification.

For a given starting or bulk concentration C_o, providing the current density is not too high or the time of electrolysis not too long, both D and t_- will be effectively constant. These are really the initial assumptions made in the solution of Eq. [2]. At constant times, the expression then becomes the difference of the two ierfc terms. Under the experimental conditions used, the first ierfc term is negligible at all times [the four place table in Carslaw and Yaeger (14) gives zero] while for the second term it varies from 0.5643 to zero. The value of l is 0.15 cm and obviously must be at least an order of magnitude smaller to affect terms containing it and hence change the results significantly (D is of the order of 10^{-6} and $t \sim 180$ and x is always small relative to l under these conditions).

In the previous calculation of concentration gradients in the $Cu/CuSO_4/Cu$ system it was shown that if the accepted transport numbers were used, a value of the diffusion constant derived from electrochemical measurements without the usual allowances for activity gave the best fit. Accordingly the values derived from conductivities measured by Harned and Hudson (15) using the well-known expression

$$D = \frac{RT\Lambda}{\mathbf{F}^2} \quad [5]$$

rather than the values calculated by them allowing for ion-pair (15) formation were used. A test of the fit with the larger values obtained when ion-pairs are allowed for confirmed the suitability of the choice as would be expected.

Since the variation in temperature between runs was only ±0.3°C (except for the passivated run and the one in Fig. 4) no allowance was made in the diffusion constant, transport number, or refractive index.

Results and Discussion

A very large number of runs were done. A selection of results only is presented. Obviously with a motion picture camera running at 16 fps vastly more data than are presented were obtained, in fact about 10 frames/100 ft or one in 4000 was analyzed. Most of the results presented are those in which the electrodes were assembled quickly into the cell and the electrolysis begun immediately. If this was not done a type of passivation occurred which will be dealt with later.

Data were originally taken from interferograms of the type shown in Fig. 1-3 and compared in tables against calculated values. Both sets of values were then plotted as log ΔC *vs.* x in Fig. 4. Figure 1 is for 0.5M $ZnSO_4$ pH 5.6 electrolyzed at 25.3°C at a current density of 0.5 mA/cm^{-2}, $2l = 0.3$ cm. The optical anomalies reported by Ibl (16) and treated in detail by Beach (17) resulting from unequal refraction of the light in a concentration gradient would cause only about 1% error for the most severe experimental conditions used or for most cases they are smaller than other experimental errors. Figure 2 is taken from Fig. 1 and shows the 120-sec concentration contour. The calculated points are also plotted to show that the agreement is quite good. Figure 3 is the 90-sec concentration contour at 0.5M and 1 mA/cm^{-2} current density and calculated points showing poor agreement, the point at $x = 0.01$ cm being only about one-half the experimental value, and the $x = 0.04$ cm value is also about one-half the experimentally observed one.

In Fig. 4-8, the calculated values appear as a curve since the error function is only partly exponential in nature. Figure 4 in which the experimental results at 27°C, 0.1 mA/cm^2, 5×10^{-2}M at 30, 90, and 120 sec are compared with the calculated values, the best fit of experimental points is two straight lines, which also appears to be the case in Fig. 5, but not in Fig. 6-8 where the concentration is higher. At 0.1 mA/cm^2 the long time value is always above the calculated, at 90

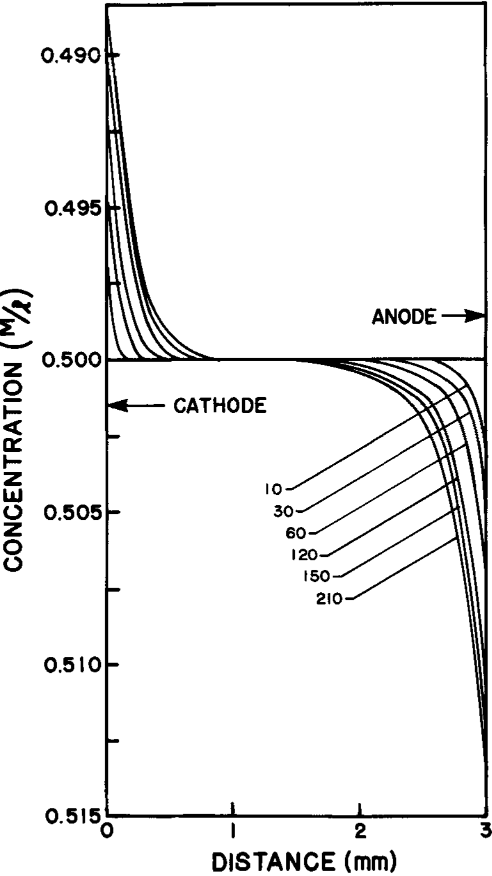

Fig. 1. Concentration contours at various times redrawn from interferograms of 0.5M $ZnSO_4$ solution at pH 5.6 electrolyzed at 25.3°C at 0.5 mA/cm^{-2}.

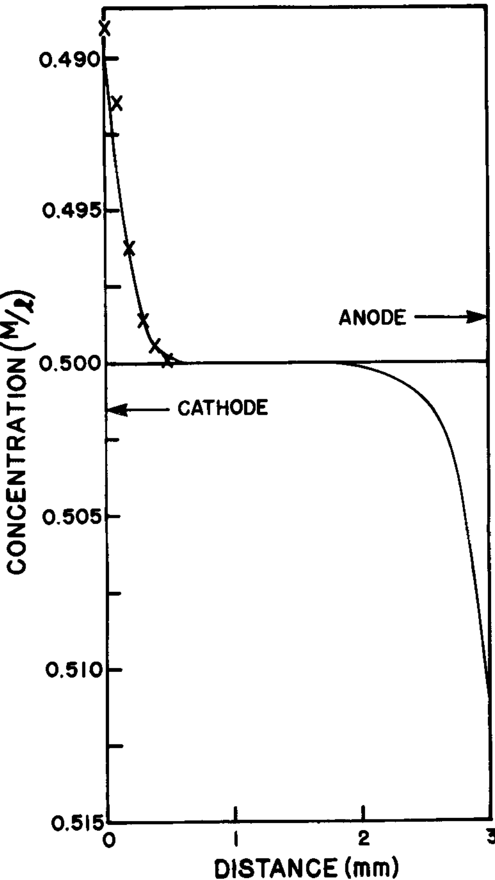

Fig. 2. The 120-sec concentration contour from Fig. 1. The points are calculated from Eq. [3].

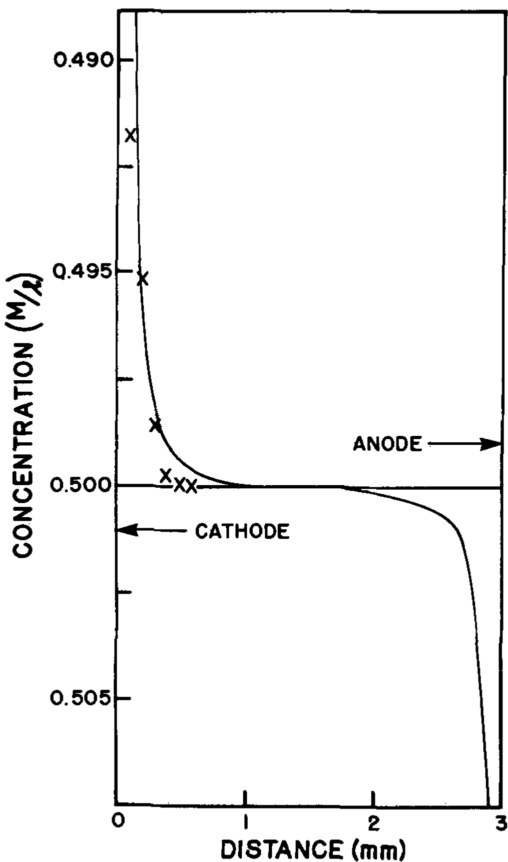

Fig. 3. The 90-sec concentration contour in 0.5M $ZnSO_4$ at 24.7°C electrolyzed at 1 mA/cm^{-2}.

sec they are almost equal and at 30 sec the experimental values are considerably less. At the larger current density (0.5 mA/cm^2, Fig. 5) the 30-sec values are nearly equal, the 90-sec values cross at about one-half way through the diffusion layer (calculated being higher at the electrode), and at 150 sec the calculated values are everywhere higher.

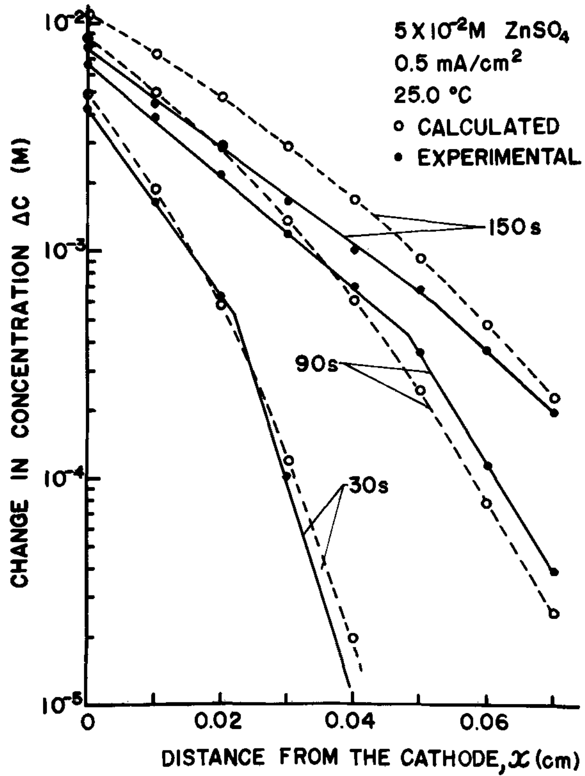

Fig. 5. The logarithm of the concentration change at the cathode in 0.05M $ZnSO_4$ at 24.7°C and 0.5 mA/cm^2 at various times.

In Fig. 6-8, the higher concentration solution (0.5M), the results have a more general pattern. At all short times (10 and 15 sec) the agreement between calculated and experimental values is quite good. At the longer times (30 and 90 sec) and higher current densi-

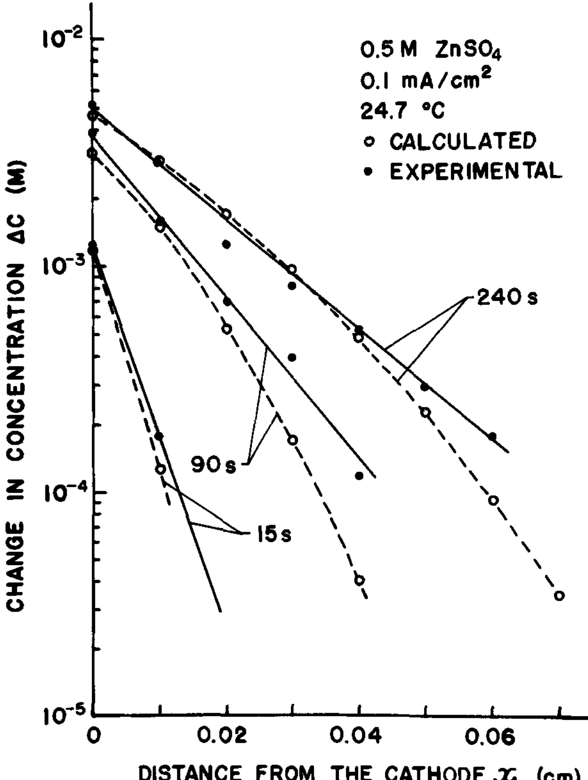

Fig. 6. The logarithm of the concentration change at the cathode in 0.5M $ZnSO_4$ at 24.7°C and 0.1 mA/cm^2 at various times.

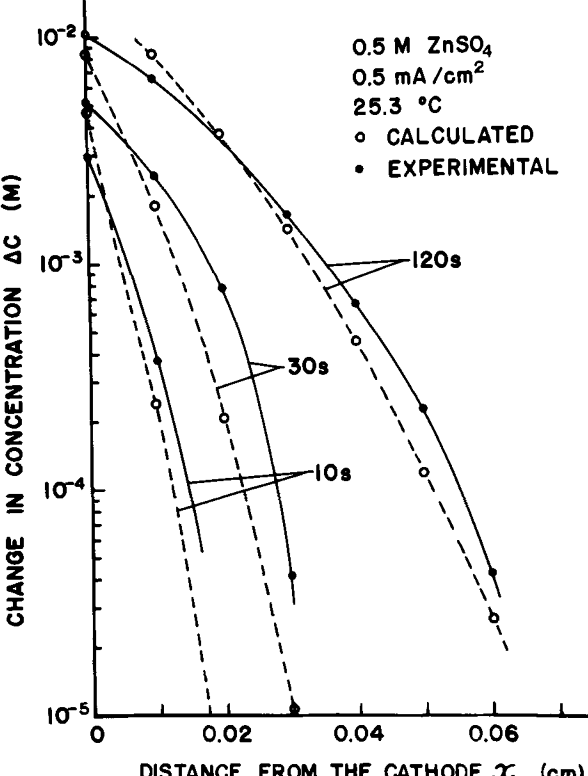

Fig. 7. The logarithm of the concentration change at the cathode in 0.5 mA/cm^2 at 25.3°C at various times.

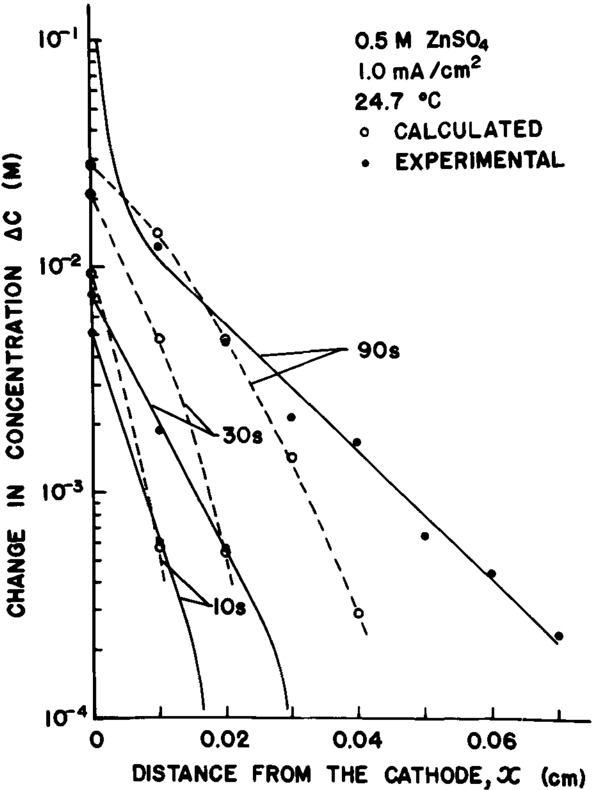

Fig. 8. The logarithm of the concentration change at the cathode in 0.5M $ZnSO_4$ at 24.7°C and 1.0 mA/cm^2 at various times.

ties the agreement deteriorates, but usually there is agreement at some distance, the plots either crossing (0.5 and 1.0 mA/cm^2) or approaching closely (0.1 mA/cm^2). At the longest times shown (120 and 240 sec) this condition still holds for the lower C.D.'s even up to 240 sec for 0.1 mA/cm^2 but the 120-sec experimental value at $x = 0$ was unmeasureable and $> 10^{-2}$M and shows that the depletion of the innermost layer is now proceeding at a higher rate (and well above the calculated rate) than in the outer parts of the diffusion layer.

In general at lower concentrations, at low current densities, and at short times of electrolysis near the electrode, the agreement is good, *i.e.*, in the range of 5-10%. This is greater than the experimental error expected which is estimated to be less than 3% at the electrode in all but the lowest current densities at the shortest times where it may reach 10% at 0.1 mA/cm^{-2} at less than 30 sec. Large per cent deviations at greater distances arise because the limit of detection experimentally is often reached before ierfc goes to zero in the four place table. The limits of detection are typically in the range of 10^{-5}M, varying with the fringe spacing which is controlled by the wedge angle between the interferometer's flats.

Figure 9 shows the concentrations observed when an electrode and the electrolyte were in contact for about 2 hr before the run began. The solution was 0.05M, pH 5.6 electrolyzed at 0.8 mA/cm^{-2} at 26°C. The concentration gradients are much less steep and much less intensive. If the assumption is made that $Zn(OH)_2$ was deposited on both electrodes by the reaction

$$Zn + 2H_2O \rightarrow Zn(OH)_2 + H_2$$

and that the anode reaction during electrolysis was $\overset{o}{Zn} + 2\ OH^- \rightarrow 2e + Zn(OH)_2$, and the cathode reaction was $Zn(OH)_2 + 2e \rightarrow \overset{o}{Zn} + 2\ OH^-$, and if one further assumes only OH^- diffuses, that its transport number is about 0.80, and that its diffusion constant is about 2.6×10^{-5} cm^2 sec^{-1} (OH^- single ion refractive index is about 5.15 compared to $\frac{1}{2}Zn^{2+}$ at 0.305 which would decrease the refractive index slightly at the pH's expected), then at $x = 0$, $t = 90$ sec, $\Delta C_{calc} = 1.72 \times 10^{-3}$, and $\Delta C_{exp} = 1.66 \times 10^{-3}$M in reasonable agreement. The anode arm of the concentration gradient begins to increase markedly between 600 and 1200 sec of electrolysis. The pH would be expected to increase at the anode and the $Zn(OH)_2$ go into solution as the hydroxide complex as previously observed (18). The cathode meanwhile still shows a low concentration change. If the suggested reaction is correct then for there to be still some $Zn(OH)_2$ on the surface the

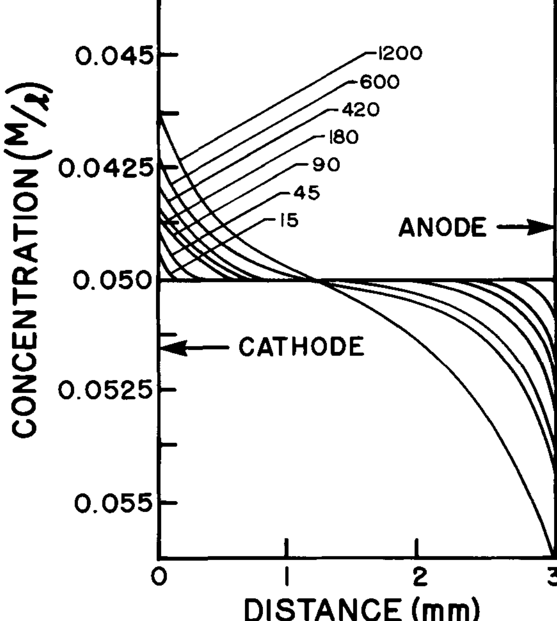

Fig. 9. The "passivation" of electrodes left in contact with the solution for 2 hr before electrolysis began, 0.05M at 26°C and 0.8 mA/cm^2.

thickness at the beginning of electrolysis must have been at least 1000 molecular diameters thick.

Conclusions

Even in a system exhibiting amphoterism the Laplace transform (and Fourier transform) solution obviously fits the experimentally observed concentration gradients. An unexplained but previously observed (19, 20) sudden change in agreement with predicted values occurs often at about 0.03 cm distant from the electrode at longer times. An electrode, assumed passivated by long times of immersion (by for example a slow, film producing, corrosion reaction) in the electrolyte before electrolysis began has much lower concentration gradients and gives reasonable agreement with calculated values if $Zn(OH)_2$ is assumed to be one of the reacting substances at each electrode.

Technical Notes

The Use of D-C Resistance and A-C Impedance Measurements on Discharged and Undischarged Cathodes as a Measure of the Relative Electronic and Ionic Conductance

M. L. Kronenberg*

Union Carbide Corporation, Battery Products Division, Cleveland, Ohio 44101

Dry cell cathodes are normally compacted mixes containing electronically conducting powders (*i.e.*, acetylene black and graphite plus MnO_2) and ionically conducting solutions (*i.e.*, solutions of NH_4Cl-$ZnCl_2$ or KOH). In attempting to understand the mode of discharge of cathodes, it is helpful to know how the conductivity of this mixture is shared by the electronically and ionically conducting phases in fresh and in discharged cells. In this investigation a method was devised to distinguish between ionic and electronic conductivity. The system was regarded as an electronically conducting matrix (MnO_2 + acetylene black and/or graphite) permeated by an ionically conducting phase (solutions of $ZnCl_2 + NH_4Cl$ or KOH). The two types of conductivity were considered to be in parallel. A simple, electrical model of a cathode, therefore, could be approximated by a platinum wire immersed in a conducting solution. The d-c resistance of the wire would be independent of whether or not the wire was immersed in electrolyte as long as no Faradaic reaction takes place. Total resistance (ionic + electronic), as measured by an a-c bridge, depends on whether an ionic path is in parallel with the electronic one, *i.e.*, whether the wire is immersed or not. In the work reported here, measurements were made on fresh and discharged cathodes, not on complete cells. These were obtained from commercial "D" size Leclanché, alkaline MnO_2, and mercuric oxide cells.

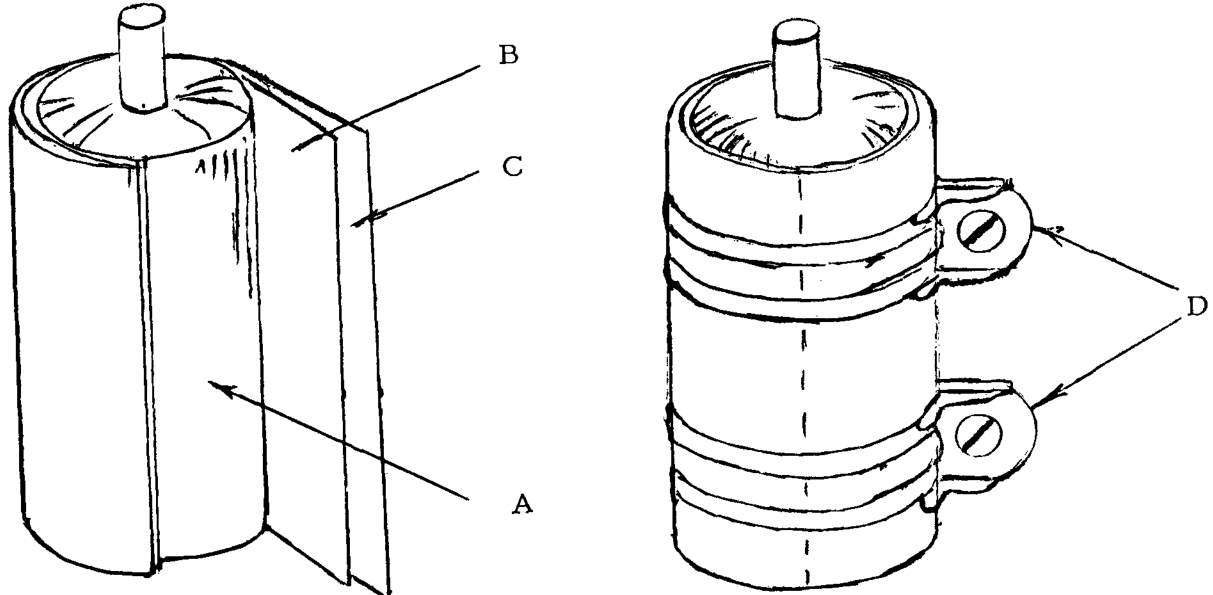

Fig. 1. Experimental arrangement for resistance measurements for Leclanché cell cathodes. A, Bobbin; B, graphite cloth; C, platinum foil; D, adjustable clamps.

Experimental

Cathode resistance was always measured across the thickness of the cathode. For a Leclanché cell bobbin (see Fig. 1, point A), this was between the center carbon rod and graphite cloth (point B) held under pressure by platinum foil (point C). The platinum foil was clamped with adjustable ring clamp (point D). This procedure was evolved after trying many others that were not satisfactory because too much contact resistance was included in the measurement.

The components used for electrical measurements on alkaline MnO_2 and mercuric oxide cells are illustrated in Fig. 2. For these cells, graphite cloth (Fig. 2, point C) was pressed into the inside cathode surface (point D) by a uniformly expanding sleeve (point B) and tapered mandrel (point A). The sleeve had to be gold plated because steel wool and platinum, which were tried first, showed a large frequencey dependence when resistance was measured with an a-c bridge. Virtually no frequency dependence is noted with this present procedure.

Cells referred to as discharged Leclanché and alkaline MnO_2 were discharged at a high rate in excess of their rated capacities to below 0.7V. Leclanché cathodes were discharged continuously through a 20 ohm resistor for 73 hr (231 A-min). Alkaline MnO_2 cells were discharged through a 10 ohm resistor for 115 hr (680 A-min). Mercuric oxide cells were discharged through a 2 ohm resistor to about 1.08V for 5¼ hr which corresponds to about 25-30% of their rated capacity (120 A-min). Mercuric oxide cells were not completely discharged because excessive mercury product would be lost from the discharge site, and anode removal becomes difficult with complete discharge.

The total resistance (R_T) was measured using a Wheatstone resistance bridge. A schematic of this bridge is shown in Fig. 3. The a-c signal input to the bridge was normally 100 mV or lower and resistance

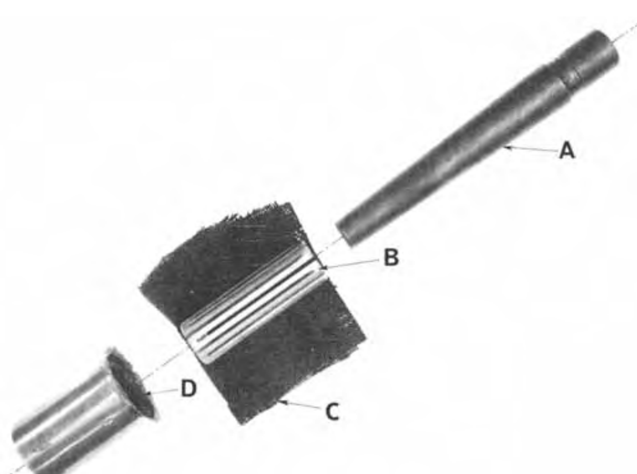

Fig. 2. Experimental arrangement for resistance measurements on alkaline MnO_2 and mercuric oxide cell cathodes. A, Tapered mandrel; B, expanding sleeve; C, graphite cloth; D, inside cathode surface.

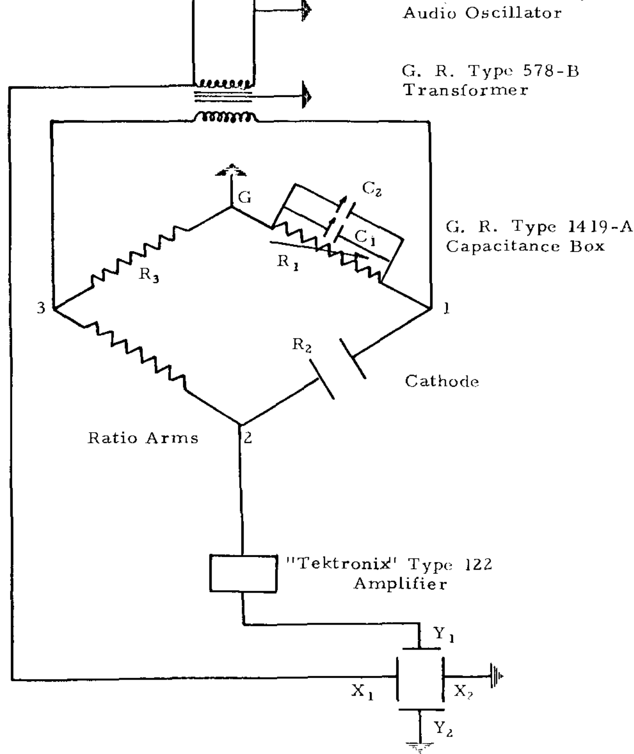

Fig. 3. Bridge circuit used for measurement of total resistance (R_T).

measurements were obtained at frequencies ranging from 1 to 10 kHz. Frequency independence was used to reassure the experimenter that no unexpected changes had taken place along the collector-cathode interface, such as openings developing in the gold-plated platinum which would have led to frequency dependence as was previously noted.

Electronic resistance (R_e) was obtained from the voltage-current slope (E/i) in a potential sweep below the Faradaic range (no appreciable reaction, 0-100 mV). The slope was constant, retraceable up and down, and independent of sweep rate over the range 1-50 mV/sec. A Physical Dynamics Corporation potentiostat and auxiliary voltage scanning unit were used for the potential sweep. The results were recorded on a Honeywell 520 XY recorder. A typical sweep used to obtain R_e on a Leclanché cathode is shown in Fig. 4.

Ionic resistance, R_i, was calculated from R_T and R_e using a parallel circuit analysis as follows

$$\frac{1}{R_i} = \frac{1}{R_T} - \frac{1}{R_e} \quad [1]$$

or

$$R_i = R_e R_T/(R_e - R_T)$$

The ratio of electronic conductance to ionic conductance (κ_e/κ_i) is equal to R_i/R_e.

Experimental Results

Preliminary experiments were conducted with a platinum wire immersed in 9*N* KOH and in $ZnCl_2$-NH_4Cl solutions to test the model. The electrical equivalent of an MnO_2 bobbin was approximated by this technique before beginning work on cathodes from the three different types of cells.

To provide an example of the way in which the data were tabulated, results of resistance measurements on fresh and discharged alkaline MnO_2 cathodes are summarized in Tables I and II, respectively. In Table III, the average values for R_e, R_i, and κ_e/κ_i expressed to the 95% confidence limit are summarized for six different categories of fresh and discharged cathodes.

Fresh Leclanché cathodes have an electronic-to-ionic conductance ratio of 3.37; whereas, discharged Leclanché cathodes have a value close to unity for this same ratio. Electronic resistance increased by a factor of 3-4 upon heavy discharge, while ionic resistance did not change significantly.

Table III. Electronic and ionic conductance measurements on Leclanché, alkaline MnO_2, and mercuric oxide cathodes

Description	R_e, ohms	R_i, ohms	$R_i/R_e = \kappa_e/\kappa_i$
Leclanché, fresh	0.233 ± 0.014	0.786 ± 0.141	3.37 ± 0.85
Leclanché, completely discharged	0.890 ± 0.151	0.830 ± 0.165	0.932 ± 0.317
Alkaline MnO_2, fresh	0.0845 ± 0.014	0.126 ± 0.019	1.49 ± 0.14
Alkaline MnO_2, completely discharged	1.471 ± 0.319	0.309 ± 0.025	0.210 ± 0.056
Mercuric oxide, fresh	0.138 ± 0.019	0.069 ± 0.010	0.527 ± 0.119
Mercuric oxide, partially discharged	0.087 ± 0.023	0.119 ± 0.026	1.367 ± 0.052

Alkaline MnO_2 cathodes have an electronic-to-ionic conductance ratio of 1.49 before discharge and a ratio of 0.2 after heavy discharge. While there was some change in ionic conductance, it is seen that the electronic resistance increases by more than one order of magnitude upon heavy discharge.

Fresh mercuric oxide cells had an electronic-to-ionic conductance ratio of 0.527. With partially discharged cells this ratio increased to 1.367.

Discussion of Results

The sharp increase in electronic resistance upon discharge for both alkaline MnO_2 and Leclanché cells is in agreement with the well-known fact that the resistivity of manganese oxides increases as reduction proceeds. Results in this current work suggest that electronically conducting powder (*i.e.*, acetylene black and graphite) in the cathode mix do not form continuous paths across the width of the cathode in parallel with MnO_2 but that most of their conductance occurs in series with MnO_2 particles. Otherwise the increase in manganese oxide resistance upon discharge would not change the over-all electronic resistance.

The decrease in electronic resistance for mercuric oxide cathodes upon discharge is due to formation of a higher conductivity reduction product (Hg). Similar results would probably be characteristic of silver oxide cathodes but these have not yet been tried.

Electrochemical Oxidation of Secondary Amines

S. Wawzonek* and S. M. Heilmann

Department of Chemistry, The University of Iowa, Iowa City, Iowa 52242

The similarity in intermediates [I] postulated in the electrolytic oxidation of aliphatic amines (1) and in the Hofmann-Loeffler reaction of N-haloamines (2, 3) suggested the present investigation of the electrolytic oxidation of dibutylamine and methylisohexylamine as a possible method of preparing intermediates which could be converted into pyrrolidines

$$\underset{[I]}{(C_4H_9)_2\dot{N}H^+} \rightarrow \underset{[II]}{C_4H_9\overset{+}{N}H_2CH_2CH_2CH_2CH_2\cdot}$$

$$\rightarrow \underset{[III]}{C_4H_9\overset{+}{N}H_2CH_2CH_2CH_2CH_2X}$$

Differences between the electrolytic method and the Hofmann-Loeffler reaction would occur in the third step of the reactions; the radical formed by rearrangement of [I] would require an external reagent in the electrolysis to produce a species [III] which could be converted to a pyrrolidine by base. Electrolyses were therefore studied in methanol at a carbon anode and in the presence of bromotrichloromethane. The former conditions were investigated to determine whether the radical [II], if formed, would be converted to a carbonium ion that would react with methanol and form a methyl ether. Cleavage of this product with hydrogen bromide would give [III] (X = Br). Electrolysis in the presence of bromotrichloromethane would lead to this product ([III], X = Br) directly by an abstraction of a bromine atom from this compound by [II].

Secondary amines (1) studied electrolytically thus far contained alkyl groups which were unsuitable sterically (4) for the hydrogen abstraction step necessary for this series of reactions.

Experimental

Voltammetric studies were carried out with a Beckman Electroscan 30 using a rotating microplatinum electrode or a stationary 10H pencil. The cathode was a platinum wire mesh cylinder and the reference electrode was a silver wire in a 0.1*M* solution of silver nitrate in 90% methanol. Irreversible oxidation waves were found for dibutylamine at 0.70V ($Ag|Ag^+$) at platinum and 0.72V ($Ag|Ag^+$) at graphite, and for methylisohexylamine at 0.62V ($Ag|Ag^+$) at graphite.

Large scale electrolyses were carried out in two types of cells. A 600 ml Berzelius beaker was fitted with a stirrer, platinum cathode (foil cylinder, 1.5 in. high and 1 in. in diameter), platinum wire screen (2 in. high, 0.5 in. in diameter) anode, or graphite rod (5.5 in. high and 1 in. in diameter) anode, and a $Ag|Ag^+$ (0.1*M*) reference cell in the appropriate solvent. The reference cell was separated from the cell by a sintered glass disk. No diaphragm was employed between the anode and cathode.

The second cell was similar to the flow-through cell used by Rüetschi and Trümpler (5) with the following modification. A graphite fiber cylindrical anode (0.8 in. high, 1.2 in. in diameter) was placed on the sintered glass disk and the platinum cathode (disk, 0.8 in. in diameter) was positioned above the anode.

Electrolytic Oxidation of Dibutylamine

(*i*) A solution of dibutylamine (10 ml, 0.059 mole) in methanol-water (90:10) (400 ml) containing benzyltrimethylammonium tetrafluoroborate (19.0g, 0.08 mole) was electrolyzed in the first cell at a platinum anode and at a constant potential of +0.9V using a PAR Model 173 automatic potentiostat. The initial current of 0.9A decreased to 0.75A after 5 hr of electrolysis. A plot of current *vs.* time corresponded to the utilization of 2.5 electrons per molecule of dibutylamine. The resulting solution was acidified with dilute hydrobromic acid and the methanol was removed. The residue was refluxed with concentrated hydrobromic acid for 6 hr and then made basic with concentrated sodium hydroxide. The resulting solution was steam distilled until the distillate was neutral. The distillate was acidified with 12*N* hydrochloric acid, evaporated to dryness, and the amines were liberated with 10% sodium hydroxide and treated with p-toluenesulfonyl chloride, and then dilute acid. Extraction of the sulfonamides with ether was followed by removal of the ether and chromatography on silica gel using benzene and benzene-ethyl acetate mixtures as eluants. The following p-toluenesulfonamides were isolated and characterized by thin layer chromatography (tlc) migration times and comparison of infrared spectra with authentic samples: N-butyl(bis)p-toluenesulfonamide (0.25g, 1.7%), N,N-dibutyl-p-toluenesulfonamide (8.8g, 52.5%), N-butyl-p-toluenesulfonamide (2.88g, 22.6%), N-methyl-p-toluenesulfonamide (0.29g, 3.4%), p-toluenesulfonamide (0.44g, 5.1.%).

The hydrochloric acid solution upon basification and extraction with pentane gave a mixture of tertiary amines (0.27g). Examination by vapor phase chromatography (vpc) using a 6 ft × ⅛ in. column packed with 15% Carbowax 4000 on 100-120 mesh Chromosorb P indicated the presence of only trace amounts of benzyldimethylamine and dibutylmethylamine. Identification was made by comparison of migration times with those of known samples. No 1-butylpyrrolidine was present.

The residue from the steam distillation was extracted with ether and gave a brown oil (0.04g) which by vpc and tlc analyses was shown to be a mixture and was not investigated further because of the small amount present.

Electrolysis of a similar solution at a carbon anode gave identical products. The tertiary amine mixture (0.38g) contained dibutylmethylamine and benzyldimethylamine in a ratio of 60:40.

(*ii*) A solution of dibutylamine (10 ml, 0.059 mole) and bromotrichloromethane (10 ml) in 90% methanol (100 ml) containing tetrabutylammonium tetrafluoroborate (6.58g, 0.02 mole) was passed through a flow-through cell at uncontrolled potential. The current observed was 0.6A at an externally applied potential of 30V. The products obtained were similar to those given in (*i*) above. The tertiary amines (0.2g) contained traces of dibutylmethylamine and tributylamine.

The use of methylene chloride as a solvent in this electrolysis gave similar products. This electrolysis had to be interrupted twice to remove a black substance which coated the cathode.

Electrolytic Oxidation of N-Isohexyl-N-methylamine

Isohexylmethylamine (6) (7.4g) was oxidized at a carbon anode in 90% methanol-water (400 ml) containing 0.2*M* benzyltrimethylammonium tetrafluoroborate at a constant potential of +0.80V in a cell similar to that used in part (*i*) above for dibutylamine. The initial current of 0.66A decreased to 0.05A after 21 hr. A plot of current *vs.* times corresponded to the use of

* Electrochemical Society Active Member.
Key words: cation radicals, Hofmann-Loeffler reaction, disproportionation.

slightly more than one electron for each molecule of amine. The resulting solution was treated in a similar fashion to that given in part (*i*) above for dibutlyamine. The mixture of amines obtained was extracted with pentane. Removal of the pentane gave a yellow liquid (5.10g), which, when examined by gas chromatography, did not contain any of the desired pyrrolidine. Distillation of the oil gave 2.5g of a clear liquid which was subjected to a Hinsberg separation; no tertiary amines were present. Two toluenesulfonamides were isolated and identified as isohexyl(*bis*)toluenesulfonamide (0.95g) and N-methyl-N-isohexyltoluenesulfonamide (3.22 g).

Isohexyl(*bis*)toluenesulfonamide was a white solid which melted at 91.5°-92.5°C after crystallization from hexane; infrared(Nujol) 8.60μ (SO_2); nmr($CDCl_3$) δ 0.80(d, 6H, $C(CH_3)_2$, $J = 6$ cps), 0.90-1.90(m, 5H, $CHCH_2CH_2$), 2.42(s, 6H, $ArCH_3$), 3.68(t, 2H, NCH_2, $J = 8$ cps), 7.33(d, 4H, C_6H_2, $J = 8$ cps), 7.94(d, 4H, C_6H_2, $J = 8$ cps); mass spectrum m/e 338 ($M-C_5H_{11}$); 254 ($M-CH_3C_6H_4SO_2$).

Analysis.—Calculated for $C_{20}H_{27}NS_2O_4$: C, 58.65; H, 6.65; N, 3.42. Found: C, 58.68; H, 6.66; N, 3.44.

N-Methyl-N-isohexyltoluenesulfonamide was a colorless viscous oil; infrared(neat) 8.72μ(SO_2); nmr ($CDCl_3$) δ 0.86(d, 6H, $C(CH_3)_2$, $J = 6$ cps), 1.00-1.70(m, 5H, $CHCH_2CH_2$), 2.40(s, 3H, $ArCH_3$), 2.70(s, 3H, NCH_3), 2.97(t, 2H, NCH_2, $J = 6$ cps), 7.34 (d, 2H, C_6H_2, $J = 8$ cps), 7.70(d, 2H, C_6H_2, $J = 8$ cps); mass spectrum m/e 269(M).

Analysis.—Calculated for $C_{14}H_{23}NSO_2$: C, 62.41; H, 8.60; N, 5.20. Found: C, 62.66; H, 8.52; N, 5.25.

Benzyltrimethylammonium tetrafluoroborate.—A solution of 40% benzyltrimethylammonium hydroxide in methanol (208g) was treated with 48% fluoroboric acid (92g) and the resulting solution was evaporated to dryness using reduced pressure. The addition of 400 ml of benzene followed by distillation to remove water gave a solution which upon cooling gave yellowish crystals (120g). Recrystallization from 1:1 ethanol-ethyl acetate gave white needles melting at 132°-133°C.

Analysis.—Calculated for $C_{10}H_{16}NBF_4$: C, 50.66; H, 6.80; N, 5.91. Found: 50.53; H, 6.70; N, 5.95.

Results and Discussion

Electrolysis of dibutylamine in 90% methanol at platinum and graphite at controlled and uncontrolled potentials in an undivided conventional cell using benzyltrimethylammonium tetrafluoroborate as the supporting electrolyte gave butylamine, methylamine, and ammonia with traces of methyldibutylamine and benzyldimethylamine as products. The oxidation of methylisohexylamine, which would form a cation radical more susceptible to rearrangement because of the tertiary hydrogen present, gave mainly isohexylamine at a graphite anode.

These results indicated that the cation radical [I] was reacting with the parent amine, or with the methanol before it could rearrange, and forming the dibutylamino free radical [IV]

$$\underset{[IV]}{2(C_4H_9)_2N\cdot} \rightarrow (C_4H_9)_2NH + \underset{[V]}{CH_3CH_2CH_2CH{=}NC_4H_9}$$

This radical [IV] undergoes a bimolecular disproportionation to dibutylamine and the Schiff's base [V] (7). Hydrolysis of the Schiff's base [V] would form butylamine which by a similar sequence of reactions would form ammonia. This type of disproportionation occurs only to a slight extent in the Hofmann-Loeffler reaction because of the strong acids used as solvents.

The use of an undivided cell did not complicate the products obtained at the anode. Reduction of the supporting electrolyte at the cathode would produce trimethylamine and toluene as the main products with benzyldimethylamine and methane as side products. The oxidation of these tertiary amines occurs at approximately the same point as that of dibutylamine and at more positive potentials than that of isohexylmethylamine. The coulometric analysis for the oxidation of dibutylamine was therefore high and that for isohexylmethylamine corresponded to the use of one electron per molecule of amine.

The source of the trace amounts of methylamine and methyldibutylamine isolated is not actually known; participation of methanol or its conjugated acid as a methylating agent is implied.

In order to minimize the effect of the amine on the oxidation product [I], the electrolysis was carried out in a modified flow-through cell (5) using a graphite fiber anode and a platinum cathode placed above the anode. The products from dibutylamine in this cell were again butylamine, ammonia, and traces of dibutylmethylamine indicating that the methanol was basic enough to convert [I] to [IV]. Substitution of methylene chloride for the methanol did not aid in the stabilization of the cation radical [I] and butylamine was again the main product.

Oscillatory Interface Instability During Czochralski Growth of Heavily Doped Germanium

R. Singh,*,[1] A. F. Witt,** and H. C. Gatos**

Department of Metallurgy and Materials Science, Massachusetts Institute of Technology, Cambridge, Massachusetts 02139

ABSTRACT

Oscillatory interface instability associated with constitutional supercooling was established during growth of germanium single crystals from gallium-doped melts by the Czochralski technique. The wavelength and phase velocity of the instability were determined and found to be consistent with theory. The effects of pulling and rotation rates on oscillatory instability were quantitatively correlated with the interface stability theory. It was shown that during rotational pulling under conditions leading to constitutional supercooling, the destabilizing effects of rotation dominate its stabilizing effects for moderate rates of rotation in the presence of thermal asymmetry.

During crystal pulling from a doped melt, the region ahead of the growth interface may become constitutionally supercooled if the distribution coefficient of the solute differs from one. The original criterion for constitutional supercooling of Rutter and Chalmers (1) and Tiller *et al.* (2) was derived from static considerations. Constitutional supercooling during crystal growth from stirred melts was first investigated by Hurle (3). Dynamic theories for small perturbations were subsequently developed in the linear approximation by Mullins and Sekerka (4) and by Voronkov (5). Calculations of the conditions leading to instability of solid-liquid interfaces have recently received considerable attention (6-13). In these investigations the melt was considered to be stationary with diffusion being the only means of mass transport; convection effects were excluded. Hurle (13) considered the effects of convective mixing of solute in the melt (expressed in terms of boundary layer thickness) and concluded that the spatial frequency of the first appearing instability is a function of convective mixing. Delves (14, 15), in a recent analysis of interface stability during growth from stirred melts, has predicted oscillatory behavior of the growth interface for convection controlled solute transport encountered in Czochralski growth. Some experimental results consistent with this theoretical treatment have been reported (16).

In the present paper a detailed analysis of an experimental investigation on interface instability during Czochralski growth is reported and discussed in the light of the prevailing theoretical models.

Experimental Procedure

Single crystals of germanium were grown in the <111> direction by the Czochralski technique from gallium-doped melts. The pulling rate, the rotation rate, and the dopant concentration in the melt were adjusted so that the growth interface came to the verge of instability at some point during growth. The diameter of the crystals was maintained between 1.5 and 2 cm over a length of 4-6 cm. The effects of pulling rate and rotation rate were studied in the range of 2.9-6 cm/hr and 13-70 rpm, respectively. The crystals were cut along the growth axis; the sections were polished (0.06 μm particle size alumina) and chemically etched (1.5 min in 1 part HF, 1 part H_2O_2, and 2.5 parts water, by volume) to reveal impurity heterogeneities which were studied with interference contrast microscopy.

Theory

The theory of interface instability for a two-component system solidfying with planar front under conditions of constitutional supercooling has been developed by a number of investigators. If $\Phi(x, t)$ describes the shape of the perturbed interface, it can be expressed by a Fourier integral (12)

$$\phi(x,t) = \frac{1}{2\pi}\int_{-\infty}^{\infty} e^{i\omega x}\, \Phi_0(\omega)\, e^{tf(\omega)}\, d\omega \qquad [1]$$

and

$$\frac{\dot{\Phi}}{\Phi} \equiv \left(\frac{d\Phi}{dt} \Big/ \Phi\right) = f(\omega) \qquad [2]$$

where $\Phi_0(\omega)$ is the Fourier transform of the initially perturbed shape of the interface, Φ is the Fourier transform of ϕ, and ω is the spatial frequency associated with the perturbation; $f(\omega)$ is not strongly time dependent, provided the system is just on the verge of instability (12).

A stability criterion can be established based on the values of $f(\omega)$; it can be positive, negative, or complex corresponding to enhancement, decay, or oscillation of a perturbation, respectively. On the basis of this analysis the stability criterion derived for systems with rotational stirring takes the form (15)

Key words: interface instability, germanium, constitutional supercooling, crystal growth.

$$\frac{K_l G_l + K_s G_s}{(K_l + K_s) G_l} > S \left(-\frac{D}{\nu}\right)^{1/3} 0.75 \qquad [3]$$

where K_l and K_s are the thermal conductivities of the liquid and the solid, respectively; G_l and G_s are the thermal gradients near the interface in the liquid and the solid; ν is the kinematic viscosity of the melt; D is the diffusion coefficient of the solute in the melt; and S is the constitutional supercooling parameter defined as

$$S = \frac{C_l - C_s}{\frac{D}{V} G_l} \left| \frac{dT}{dC} \right| \equiv \frac{mG_c}{G_l}$$

$$= \frac{-m(1-k)VC_o}{G_l D[k + (1-k)\exp - \delta V/D]} \qquad [4]$$

where C_l and C_s are the impurity concentrations in the liquid and the solid, respectively, near the interface; V is the instantaneous microscopic growth rate; m is the slope of the liquidus in the phase diagram; k is the equilibrium distribution coefficient; C_o is the impurity concentration in the bulk of the melt; and δ is the thickness of the boundary layer. G_c is the concentration gradient in the liquid just ahead of the advancing interface given by

$$G_c = \frac{-(1-k)VC_o}{D[k + (1-k)\exp -\delta V/D]} \qquad [5]$$

Thus, the stability criterion becomes

$$\frac{-m(1-k)VC_o}{D[k + (1-k)e^{-\delta V/D}]} \left| \frac{D}{\nu} \right|^{1/3} 0.75 < \frac{K_l G_l + K_s G_s}{(K_l + K_s)} \qquad [6]$$

If the pulling rate V_o, and the impurity concentration, C_o, in the melt are adjusted so that the system is at the verge of instability (*i.e.*, left-hand side of inequality (Eq. [6]) just exceeds the righ-hand side), then during rotational pulling the instantaneous microscopic growth velocity (17), V, is given by

$$V = V_o(1 - \alpha \cos 2\pi Rt) + \frac{d\phi}{dt} \qquad [7]$$

where $\alpha = 2\pi R \Delta T / G_l V_o$; ΔT is the temperature variation for a given point at the growth interface over the rotational cycle; and R is the rotational rate. The first term (Eq. [7]) represents the growth rate fluctuations associated with the rotational pulling in a thermally asymmetric system;[2] the second term is the derivative of the perturbation (Eq. [1]) which arises from the instability due to constitutional supercooling. This second term is relatively small and associated with a spatial frequency.

Growth interface shape in time and space.—For a perturbation of constant spatial frequency, by integrating Eq. [1] and employing a delta function, one obtains

$$\phi(x,t) = \frac{1}{2\pi} \Phi_o(\omega) e^{i\omega x} e^{f(\omega)t} \qquad [8]$$

If $f(\omega)$ is complex, say, $f(\omega) = p_j(\omega) = Re[p_j(\omega)] + iIm[p_j(\omega)]$, then the shape of the growth interface is given by either the real or imaginary parts of Eq. [9]

$$\phi(x,t) = \Phi_o(\omega) e^{Re[p_j(\omega)]t} \sin\{\omega x + Im[p_j(\omega)]t\} \qquad [9]$$

where $\phi_o(\omega) = \Phi_o(\omega)/2\pi$. [The notation adopted here is used by Delves (15).] If the growth rate is constant and the system is on the verge of instability (*i.e.*, inequality, Eq. [6], is just reversed and $Re[p_j(\omega)]$ is small or zero) the general equation representing the one-dimensional growth interface moving in the z direction can be found by integrating Eq. [7] with respect to t

$$z = V_o t + \Phi_o(\omega) \sin\{\omega x + Im[p_j(\omega)]t\} \qquad [10]$$

This equation describes the dynamics of the growth interface with oscillatory instabilities of a wavelength $2\pi/\omega$ and phase velocity $Im[p_j(\omega)]/\omega$. On the basis of Delves's theory (15), the onset of oscillatory instability in Ge for the present experimental conditions should be associated with $\lambda = 80\text{-}90$ μm and $Im[p_j(\omega)] = 0.5\text{-}1.0$ sec^{-1}. If the growth interface, during rotational pulling, advances with periodically varying velocity, V, the general equation representing a one-dimensional growth interface moving in the z direction assumes the form

$$z = V_o t - \frac{\alpha V_o}{2\pi R} \sin 2\pi Rt + \Phi_o(\omega) e^{Re[p_j(\omega)]t} \sin\{\omega x + Im[p_j(\omega)]t\} \qquad [11]$$

Results

During crystal pulling by the Czochralski technique the onset of constitutional supercooling in melts with moderately high doping levels can be delayed by seed rotation since boundary layer thickness is decreased. In the absence of constitutional supercooling, the growth interface remains stable and the microscopic growth rate in the z direction varies in a quasisinusoidal mode within each rotational cycle because of unavoidable thermal asymmetry (first term of Eq. [7]). In the presence of pronounced thermal asymmetry, partial remelting takes place during passage of the interface through the hottest region in the system and "remelt" rotational striations are formed which appear as "smooth" parallel lines delineating the shape of the growth interface at the moment of their formation. During crystal pulling from melts doped to very high levels, constitutional supercooling cannot be suppressed by rotation, for any appreciable growth period, and the interface becomes unstable.

Based on the preceding theoretical considerations, constitutional supercooling depends strongly on the microscopic growth rate (Eq. [4]); thus, sinusoidal growth rate variations associated with rotation may bring the system, within each rotation, periodically to the verge of constitutional supercooling; as a result, oscillatory instability can be brought about and be sustained for prolonged periods of growth.

Oscillatory instability.—The behavior discussed above was experimentally observed as seen in Fig. 1, which depicts an outer region of the grown crystals. The rotational striations, normally "smooth" parallel lines, appear here as "wavy" lines, indicating oscillatory instability without interface breakdown. Since the rotational striations are of the remelt type, the observed amplitude of the elevations and depressions is, of course, less than the maximum amplitude encountered during growth. As is seen in Fig. 1, protrusions of the interface into the melt (maxima) on one striation develop (during growth associated with a 360° rotation) into depressions (minima) on the next striation, while the minima develop into maxima.

This behavior might be interpreted as a "stationary" oscillatory instability with the sinusoidal growth rate variations (resulting from seed rotation) being modulated by an oscillatory instability component. However, examination of the instability as observed in Fig. 2-4 indicates that the behavior observed in Fig. 1 is not typical. The growth direction being normal to the striations, these figures show that the maxima on one striation are displaced laterally on the subsequent striation; the extent of such displacement varies depending on the growth conditions. Such lateral displacement of the oscillatory instability is also consistent with the nonperpendicular alignment of the segregation inhomogeneities within successive striations (see, for example, Fig. 2). These periodic segrega-

[2] The effect of sinusoidal temperature fluctuations on the microscopic growth rate has been independently derived by Hurle et al. (18).

tion inhomogeneities reflect the periodic development and decay of the instability resulting from the sinusoidal growth rate variations within each rotational cycle. Accordingly, it is concluded that the observed oscillatory instability is of a "traveling wave" nature with a characteristic phase velocity (15) and not stationary as could be assumed from Fig. 1.

Using the cylindrical coordinates system, the oscillatory perturbation can be resolved into two oscillatory components, in the radial and tangential directions, with wavelengths λ_r and λ_θ, respectively. The wavelengths of the oscillations in the radial direction (λ_r) were determined on planes exposed by cutting the crystal along the rotational axis. The wavelengths in the tangential direction (λ_θ) were obtained from cuts perpendicular to the above; since there is an inherent uncertainty in obtaining cuts precisely through the axis of rotation, the measured λ_r and λ_θ values do not necessarily represent the pure radial and tangential components. The phase velocity of the oscillations was determined from the horizontal displacements of the segregation inhomogeneities between successive striations (see Fig. 2) and the rotational rates. It can alternatively be obtained from the displacement of the maxima or minima between successive striations. The values of the experimental data are summarized in Table I.

A direct application of the theory to the present experiments could not be made because not all experimental variables controlling the constitutional supercooling parameter, S, Eq. [4] could be determined. However, since the numerical values assumed in Ref. (15) are sufficiently close to those encountered in the present experiments a comparison between theory and the experimental results is considered reasonable. Thus, the theoretically predicted values of λ_θ given in Table I were obtained from Fig. 3 in Ref. (15), assuming that the fluid velocity in the tangential direction is approximately equal to the macroscopic fluid velocity $2\pi rR$ (19) (a reasonable approximation for the distances from the rotational axis at which λ was measured). It is seen that the experimentally determined values of λ_θ are in reasonable agreement with those predicted from theory for the onset of oscillatory in-

stability. A similar comparison of λ_r could not be made since a parabolic velocity distribution (assumed in theory) is not applicable for the radial fluid flow.

Effects of pulling rate and seed rotation on oscillatory instability.—The effects of the pulling rate were investigated in crystals grown at fixed seed rotation (25 rpm) with pulling rates ranging from 2.9 to 6.0 cm/hr. The effects of seed rotation were studied in crystals pulled at rates of 2.9 and 3.38 cm/hr with seed rotation ranging from 20-41 and 13-70 rpm, respectively. Since the experimental conditions necessary for the onset of oscillatory instability cannot be arrived at directly from theoretical considerations, the gallium dopant levels were adjusted by trial and error so that the system reached the verge of instability at some time during growth. Amounts of melt several times larger than those corresponding to the size of the crystals pulled were used to insure the occurrence of sustained instability.

The effect of increasing the rate of rotation on the growth process is clearly seen in Fig. 3. Here the depicted upper and lower segments were rotated at 15 and 20 rpm, respectively. While oscillatory instability prevails throughout both segments, the complexity of the segregation inhomogeneities (reflecting the degree of instability) is noticeably reduced in the region grown at the higher rate of rotation. This stabilizing effect reflects a decrease of the average value of the constitutional supercooling parameter, S, due to enhanced stirring. The characteristics of the instability during rotational and nonrotational pulling are compared below.

The effect of the pulling rate on interface instability is shown in Fig. 4. From the spacing of the rotational striations it can be seen that the pulling rate was increased by a factor of about two in the segment of the crystal depicted in the lower part of the figure. This increase in pulling rate clearly resulted in further developed dopant inhomogeneities. It should be noted that the rate of development of the inhomogeneities following each rotational striation is the same in the upper and lower segments of the crystal. The relationship between the observed inhomogeneities and the amplitude of the perturbation is not known in the present case. In view of the pronounced dependence of interface stability on the microscopic growth rate, the behavior observed in Fig. 4 implies that the increase in the pulling rate by a factor of two did not result in a corresponding increase in the microscopic rate of growth during the initial stages of growth following remelting.

Discussion

Theoretical considerations.—The applicability of the interface stability theory to the presently observed oscillatory instability is tested on the basis of typical experimental data employing Eq. [11]. The effects of thermal asymmetry are examined taking $\alpha = 0$ (no thermal asymmetry); $\alpha = 0.9$ (thermal asymmetry, no backmelting); and $\alpha = 1.1$ (backmelting). The growth interface behavior is graphically presented and discussed on the basis of experimental observations. The experimental values employed are: pulling rate, $V_o = 12.5$ μm/sec; rate of rotation, $R = 25$ rpm; distance of instability from rotational axis = 0.6 cm.

When growth takes place in a thermally symmetric environment, $\alpha = 0$, then Eq. [11] reduces to

$$z = 12.5t + 5 \sin \left[\left(\frac{2\pi x}{70} \right) + 1.2t \right] \quad [12]$$

A graphic representation of Eq. [12] depicting the dynamics of the growth interface, at time intervals of 0.28 sec, is shown in Fig. 5. It is seen that the traveling wave nature of the oscillation (lateral displacement component) modulates the microscopic growth rates thus resulting in periodic regions of decreased and increased growth rates which appear as narrow and wide bands inclined to the advancing growth interface (z direction). The angle of inclination is controlled by the phase velocity of the perturbation. The growth behavior, as shown in Fig. 5, corresponding to
