Weiss (30) has recently suggested mechanisms by which interreactions can occur between cells or platelets and injured blood vessels under these conditions which he calls "tunneling." Recognition occurs between specific configured positive and negative surface charges such as platelets to collagen uncovered by injury. The structure and configuration of recognition induces the active coagulant factor, in this instance platelets, to deposit on the blood vessel wall and become activated with release of ADP (31).

Thus a number of investigators including Nossel (32), Vroman (33), Baier (34), Lyman (35), Salzman (31), and Sawyer (28) and their co-workers appear each to have contributed one segment of our understanding of the *in vivo* reaction. Massini and Luscher (36) and Nossel (32) suggest that it is the recognition of abnormal or disordered surface charges on the wall that stimulates platelet sticking both to collagen, microfibrilae, basement membrane, and ostensibly to any positively charged surface including an injured blood vessel wall, leading ultimately to the development of thrombus.

Wilner, Nossel, and Leroy have shown, using classic techniques, the interaction between platelets and collagen (Fig. 15) in an aggregometer (37). In their *in vitro* studies, they reduced the negative charges of collagen by acetylation of carbozyl groups or pepsin

treatment of the telo peptides. In a second set of experiments they reduced the positive charges (epsilon amino groups of the lysine) of collagen by deaminating the collagen with nitrous acid or by dinitrofluorobenzene. The investigators were able to show that platelet aggregation was potentiated by highly positively charged collagen but only marginally affected by reduction of the negatively charged groups of collagen.

Baier has used contact angle as a criterion for physicochemical interaction of prosthetic surfaces with blood (38). Dutton and Baier and Petchek have performed additional experiments by measuring coagulation characteristics of blood flowing by a transparent glass slide (39) (Fig. 16a and b). Concomitantly, Vroman has shown that all foreign surfaces adsorb a protein, probably fibrinogen, on exposure to blood (33). The thrombogenic characteristics of a surface appear dependent on subsequent interreactions between the blood proteins and the underlying prosthetic or natural surface. Extreme denaturation of the protein layer initially deposited on surfaces due to high specific activity of the prosthetic surface has been shown to be thrombogenic by Lyman (35).

Electrochemical Reactions of Blood Coagulation Factors—Their Role in Thrombosis

Considerable evidence is now developing to show that thrombosis is catalyzed on conducting prosthetic materials when the potential across the interface exceeds +300 mV/NHE. Thrombus deposition is triggered by a series of reactions involving blood coagulation factors, the last of which is the conversion of fibrinogen to fibrin. Electrochemical studies alone or in combination with optical studies have led to some interesting findings. (*i*) Using cyclic voltametric techniques, it has recently been shown that a number of the blood coagulation factors, such as fibrinogen (40), prothrombin (41), Factors V and VIII (42), and Factor IX, take part in adsorption and electron transfer reactions across metal-solution interfaces (Fig. 17). (*ii*) Electrocapillarity (43), ellipsometric (40), and capacitance (44) methods confirm that these blood coagulation factors show potential-dependent adsorption behavior on metal surfaces. (*iii*) At positive potentials, prothrombin yields a product with thrombinlike activity (41). (*iv*) A combined electrochemical-electron microscopic investigation has shown that fibrinogen is electropolymerized to a fibrinlike substance at anodic potentials. Electron microscopy reveals that fibrin thus formed is very similar morphologically to enzymatically formed fibrin (45) (Fig. 18). (*v*) When a platinum electrode is maintained in a fibrinogen containing solution at negative potentials/NHE, the resultant solution shows long term inhibition of fibrinogen coagulation as revealed by thrombin time determinations (46, 47). (*vi*) Heparin inhibits the adsorption of fibrinogen on freshly cleaved mica surfaces (48).

It appears that thrombosis is encouraged on both prosthetic and biological surfaces by the removal of electrons from blood constituents with a normal blood coagulation cascade at potentials more positive than a critical potential, approximately +400 mV *vs.* NHE, and this occurs with platelet aggregation, whereas thombosis is normally prevented by the opposite phenomena-electron donation to blood from the blood vessel surface if at a critical potential.

Biochemical Reactions at the Interface: Molecular Basis for Platelet Aggregation

Over the past few years, several series of *in vitro* experiments carried out by Jamieson (49), Wolfe and Shulman (50), and others have been reported which illustrate the biochemistry of recognition and, we suggest, facilitated electron exchange during thrombosis formation as described above (49-51). They have shown that enzyme acceptor complexes on platelets, proteins, and other cells interreact with injured blood vessel wall receptor groups (probably underlying collagen that is exposed due to injury) to catalyze platelet adhesion. Salzman and his group, among others, have shown that these reactions are catalyzed and/or inhibited by membrane cyclic AMP (52). Potentiation or increase in intracellular cyclic AMP has been shown to suppress thrombosis and/or platelet aggregation.

Jamieson (49) has related the inhibitory effects of many pharmacologic agents of platelet adhesion to collagen to inhibition of enzyme function of glucosyl transferase present on the surface of platelets (Table III). This enzyme helps in the formation of glucose galactose side chains on collagen by facilitating transfer of glucose from platelet membrane to free galactose side chains of collagen. This may be a possible mechanism of platelet adhesion. The work of Nossel relating the modification of structure of collagen on platelet

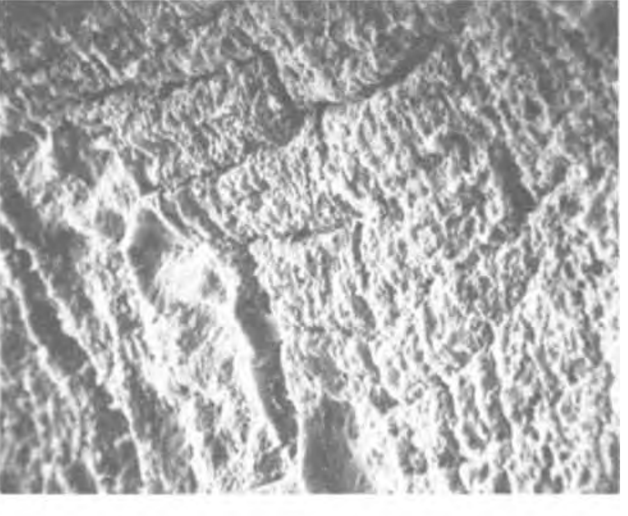
adhesion has been discussed earlier. Other pharmacologic agents like prostaglandin (PGE_1) inhibit release of neucleotides and calcium from platelets during aggregation (50) (Fig. 19).

A confirming group of experiments has been completed by Chesney, Harper, and Coleman (51) relating collagen structure to platelet aggregation (Fig. 20) and also relating the critical role of intact galactose side chains of collagen to platelet aggregation. Here the oxidation of a single bond on the galactose side chains was shown to prevent platelet recognition of collagen, blocking subsequent platelet activation and aggregation in an aggregometer. Shulman has categorized other biochemical characteristics which can be assumed operative in the recognition of abnormal exposed surface charges on the blood vessel wall by the platelets and proteins flowing past a point of injury or which are due to abnormal exposure to underlying microfibrillae, collagen, etc. Epinephrine possibly potentiates an alpha receptor, fibrinogen through thrombin, ADP with a sulfhydril group on a protein, and antibodies through glucoproteins, and destructured glycoproteins. All of these can be assumed to produce thrombosis through an electron transfer or an equivalent physical chemical mechanism.

Luscher's and Massini's (36) experimental evidence shows that cell recognition occurs because of alteration of charges. This provides an environment for platelet recognition and attachment. These in combination with Weiss's concept (30) of "tunneling" provide a rather satisfactory theoretical picture of the biochemistry of platelet attachment.

Anticoagulants—Inhibitory Phenomena in Thrombosis

It is now of interest to show the relevant factors relating to inhibition of these recognition phenomena



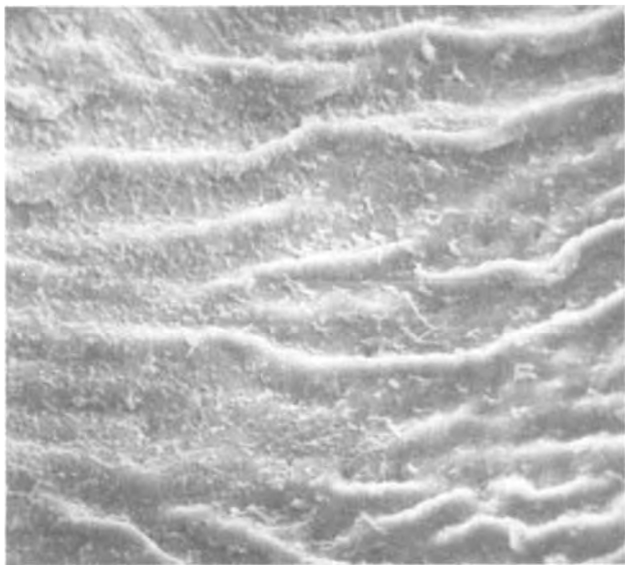


Fig. 14. Effect of heparin perfusion before injury on the nature of thrombus deposit on the artery. Scanning electron microscopic photographs (magnification 1000×) of a (top left), crush injury; b (top right), Fogarty catheter injury; and c (bottom left), electrical injury.

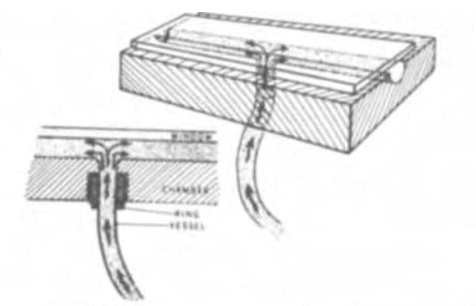
which normally result in thrombosis. The direct acting anticoagulant material, heparin, appears to prevent intravascular thrombosis through a physical chemical mechanism potentiating both the normal structure and density of the negative surface charge at the blood vascular interface. The interface potential of both walls and cells is apparently made both more negative and more stable, thus promoting dispersion of all blood cells.

At a recent symposium, Chien (53), Seaman and Brooks (54), Danon (55), Schmidt-Schoenbein (56), and others have shown a possible mechanism of anticoagulant action of dextran. Dextran produces a blanketing phenomenon on red cells increasing the intercellular distance between red cells rouleaux (Fig. 21). Conventional van der Waals effects may thus become nonoperational, markedly potentiating the dispersing negative charge and increasing the mutual repellancy of cell-cell and cell-wall interactions. Chien has also shown that dextran alters the viscosity of blood and the extent of aggregation. At relatively low concentrations of dextran (of molecular weight 40,000) it produces antiagglutination. The effects of dextran on blood cells varies with the molecular weight of the polysaccharide (Fig. 22). Work from this laboratory has shown the slight, negative, surface charge enhancing effect of dextran (Fig. 23) (19). Animal experiments with perfusion of dextran before injury to the blood vessel wall indicate significant reduction in thrombus formation on



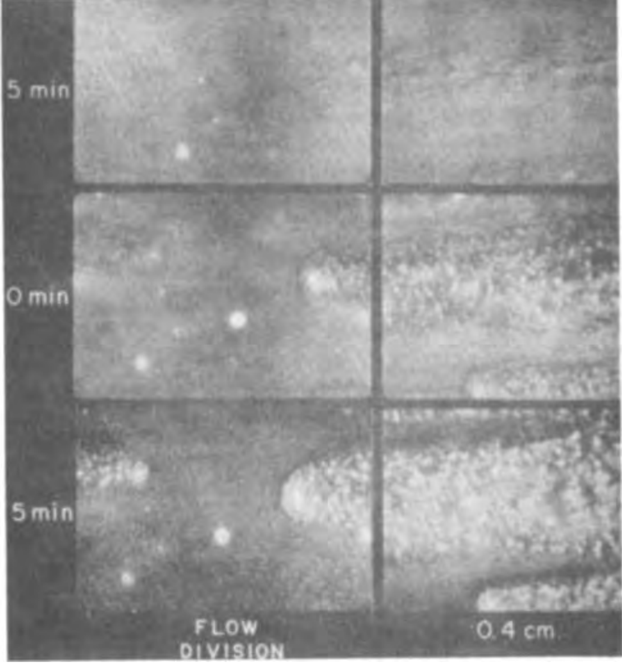


Fig. 16. Baier and Dutton cell (a, top) which allows native blood from a blood vessel to flow through a narrow chamber. The blood flowing beneath the glass cover slip reveals thrombus deposition (b, bottom) at various points on the glass.

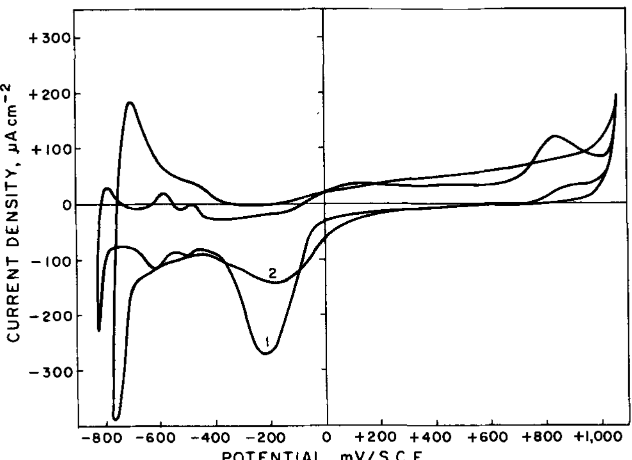

Fig. 17. Cyclic voltammograms of saline (1) and fibrinogen in saline (2) at a concentration of 3 mg/ml with bright platinum electrodes at a scan rate of 50 mV/sec^{-1}.

the injured wall (Fig. 24). Snake venoms appear operative by virtue of their blocking the last stage in thrombus formation, the formation of a fibrin clot, by blocking fibrinogen polypeptide A or B separation (57).

Conclusion

The multiple factors that influence the process of conversion of the colloidal suspension of blood into a gel called thrombus are listed in Table IV. Based on

Table IV

Blood (fluid) ⟶	Thrombus (gel)
Antithrombogenic	Thrombogenic
Blood vessel porosity	Injury to blood vessel
Ion fluxes	Flow
Transverse streaming potentials	Turbulence
pH	Atherosclerosis
Surface charge	Trauma
Antithrombotic drugs	Evulsion intima (mechanical etc. collagen)
Negatively charged dextran-heparin	Exposure, microfibrillae, basal membrane
Fibrinolytic drugs	Decreased porosity, activated platelets + ADP
Snake venoms	ADP (plasma)
Polymerized fibrin	Chemical activators, coagulation system
Antithrombin factor	Platelets
Cyclic AMP	Cardiac output
	Flow/unit mass tissue (localized)
	Dilution coagulation, enzymes hepatic splenic, filtration
	Cell content (polycythemia)
	Viscosity postoperative hyperplasia

the discussions of the findings of various groups of workers, the surface charge approach to this process of coagulation of blood can be summarized as follows.

The normal vascular tree, with its intact endotheleum, and the cellular elements and platelets in blood possess an electric double layer at the solid-solution interface with intense electric field. They all have a net negative surface charge which results in a properly ordered separation of blood cells from one another as well as from the blood vessel wall.

Injury of any sort to the blood vessel wall, including suturing, clamping, destruction of endothelium due to turbulence or chemicals like endo-toxin, and immune response, results in disordering of the negative surface charge density, permitting recognition between platelets and the underlying cell surfaces. This recognition permits attachment of the platelets to underlying collagen, microfibrillae, or injured tissues of any sort which involves disruption of the integrity of the vascular-blood interface change, possibly by a process equivalent to or similar to "tunneling" and "recognition." With attachment of platelets and possibly also leucocytes and erythrocytes, adenine neuclotides, histamine, and other biologically active amines are released from platelets (4). This produces sequential aggregation, with the deposition of thrombus, due to activation of the blood coagulation cascade at multiple levels, producing conversion of prothrombin to thrombin, and fibrinogen to fibrin monomer with polymerization of fibrin monomer to stable fibrin mediated by Factor XIII. The fibrin in its totally polymerized form passivates thrombus formation, so that thrombus deposition may at any time reach sufficient thickness that the disordered charge density may be restructured into normal configuration (58, 59).

Inhibition of thrombosis can be produced by many anticoagulants, such as heparin, which seems to work on the wall and blood cells (by virtue of its negatively charged SO_4^{--} groups) at a physical chemical level by enhancing the net negative surface charge by adsorption and possibly at the biochemical level as well. Dextran operates by a different mechanism displacing charges by adsorption on blood cells and resulting in deaggregation or deagglutination. Other pharmacologic blocking agents such as Arvin or Reptilase prevent polymerization of fibrin, thus preventing the formation of an effective fibrin web, the terminal point in thrombus formation.

Thus, the beginning of an understanding of the physical chemistry of ion transport, and of the reactions that occur at the blood vessel wall-blood interface in the initiation or inhibition of thrombosis, is being developed and it encompasses many disciplines.

Manuscript received Aug. 22, 1973.

GLOSSARY

Anticoagulant. A drug which prevents the formation of a coagulum.

Antithrombotic. A drug which prevents the formation of a thrombus.

Charge transfer or electron transfer reactions. An interfacial reaction where there is transfer of charge across the interface, usually electrons.

Coagulation. The formation of a solid from blood (coagulum).

Interfacial reaction. A reaction that takes place at the junction of two phases; blood vessel <—> blood interface.

Coagulation cascade. Sequential reaction of clotting factors to form a coagulum.

Coagulum. The solid formed from blood via the activation of the coagulation cascade. Composed primarily of polymerized fibrin.

Electrokinetic phenomena. These arise due to relative movement of ions along the shear plane in the electric double layer across an insulator solution interface. Electrophoresis, streaming potential, and electro-osmosis come under this category. Measurement of any of these electrokinetic parameters of blood cells and cellular fragments gives an indication of their surface charge. The measured parameters are related to the zeta-potential.

Hemostasis. The cessation of bleeding.

Platelet aggregation. The specific binding together of platelets in the formation of a "plug" as an early stage in hemostasis.

Platelets. Cell fragments involved in primary hemostasis.

Primary hemostasis. The initial cessation of bleeding due to adhesion and aggregation of platelets at the site of injury.

Prostheses. Something artificial which replaces a body structure or part.

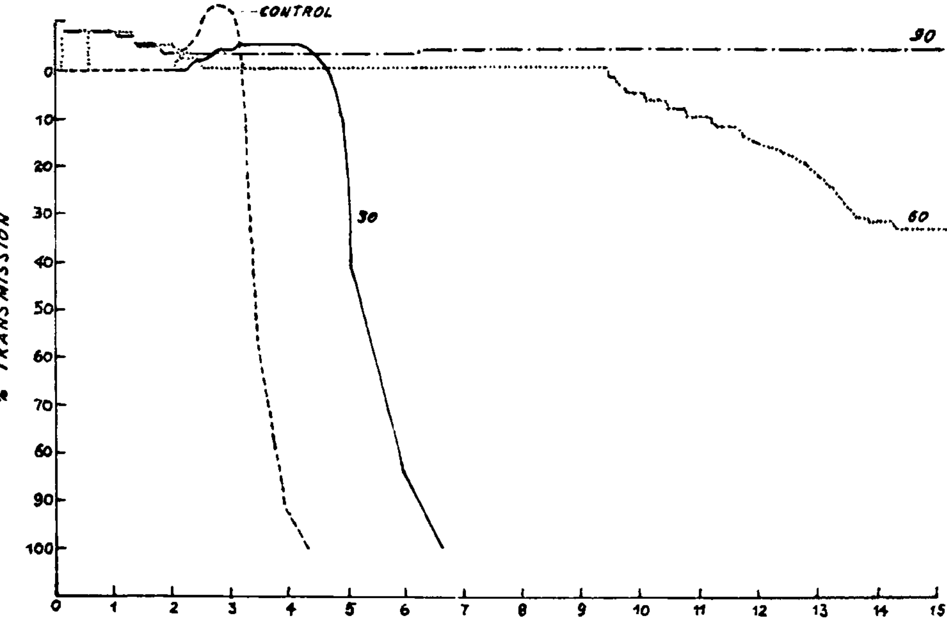

Fig. 20. Effect of sequential destruction of collagen by collagenase on platelet aggregation as shown by per cent transmission time curves (platelet aggregometer study).

Red blood cells. Blood cells that carry hemoglobin and are responsible for O_2 transport. Also called erythrocytes.

Secondary hemostasis. The coagulum formed by activation of blood coagulation cascade resulting in polymerization of fibrinogen to fibrin preventing rebleeding.

Spontaneous potential. The potential difference developed across a conductor solution interface when it is dipped in an ionic solution. It is measured with reference to the normal hydrogen electrode (NHE) which is the arbitrary zero of the potential scale.

Thrombogenesis. The generation of a thrombus or thrombi *in vivo.*

Thrombus. A coagulum within a blood vessel.

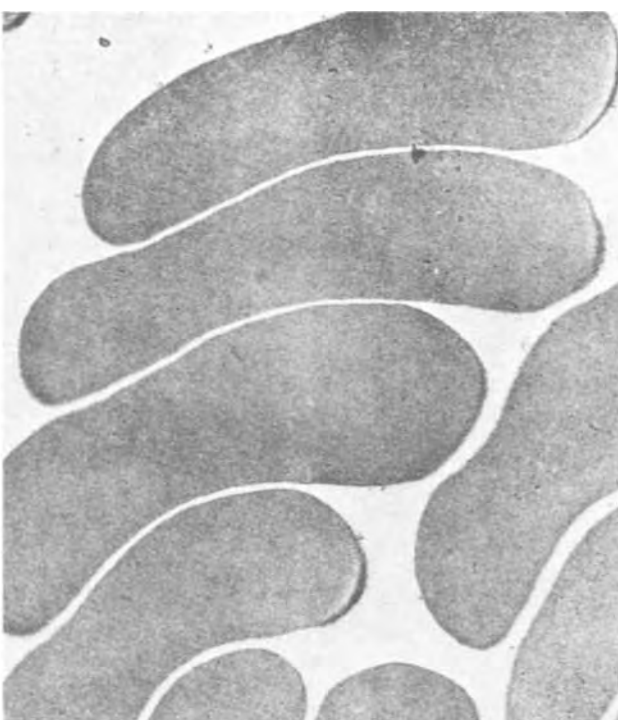

Fig. 21. Effect of dextran on the red cells, electron microscopic study.

White blood cells. Blood cells involved primarily in host defense (leukocytes).

Zeta-potentials. The potential drop across the mobile part of the double layer.

Heat Capacity of an Ordering Fe-16% Si Alloy Measured with a Spherical Adiabatic Calorimeter

Gary M. Crosbie[1]

Department of Metallurgy, The University, Sheffield S1 3JD, United Kingdom

The central matter in the teaching of the subject of alloy steels is the analysis of how various additions affect phase equilibria and transformations of austenite. This face-centered-cubic phase is stable in pure iron only through an intermediate temperature range. At higher and lower temperatures body-centered-cubic phases are stable. Some alloying additions, such as carbon, cause the austenite to be stable over a wider temperature range; others, such as silicon, reduce this temperature range.

Phase diagrams evidence these changes and can be used in the processing of such alloy steels as have been studied. But why is the phase diagram so in each case? And, why is the austenite stable at all? To these questions thermodynamic formalism can provide alternate explanations. The measurements of heat capacity and of heat of transformation are two ways of entering the formalism. For example, it is the lambda-shaped peak in the heat capacity of pure iron, at the Curie point, which raises the Gibbs free energy of the body-centered ferrite above that of the austenite for the intermediate range. Alloy additions which alter the size, shape, and position of this magnetic peak in the heat capacity will, for this reason, alter the range of stability of the austenite.

The group I worked with at the University of Sheffield, Sheffield, United Kingdom, is developing a comprehensive picture of ferrous alloy thermodynamics. Techniques in use include adiabatic calorimetry, isoperibol calorimetry, mass spectrometry, emf methods, and gas equilibrium methods.

Directly, the work of this summer was the final assembly and commissioning of a high temperature adiabatic calorimeter and the use of the apparatus to measure the heat capacity of an Fe-16.1 atomic per cent (a/o) Si alloy. Although the alloy chosen has no stable austenite phase, a knowledge of the magnetic heat capacity will be part of a comparative explanation of why there is no stable austenite. Additionally, since this is an alloy in which atomic ordering occurs, features of the heat capacity curve will relate to the entropy of disordering. This, however, requires a separation of Cp into components by further experimentation before a link to statistical theories can be made.

Design and Construction

Following the design of Sale (1970) (1), the adiabatic calorimeter consists of several spherical shells. The centermost shell, which encloses the specimen, has the same temperature as the specimen before, during, and after the injection of heat. In this way, loss of heat to the specimen surroundings is prevented.

The control is achieved by the use of a pair of thermocouple junctions connected in series: one located in the specimen and one on the outer surface of the first shell. The voltage across this differential couple is controlled to zero by adding heat from a small spherical furnace located next out from the center. Control accuracy is obtained by the use of a three-term solid-state controller.[2] In addition to the proportional term (which alone would make the output signal proportional to the temperature deviation), these are integral and derivative terms to minimize overshoot. Different settings of these terms are determined for each temperature range. Unchanging temperature, before and after the addition of heat is not a sufficient condition for an adiabatic experiment. The error signal must be monitored throughout, to be sure that the adiabatic condition is $\pm 0.01°C$ and about a mean of zero. This is obtained when the controller terms are properly set.

While this delicate balance is maintained in the center, the bulk of the energy to keep the calorimeter at temperature is provided by an outer furnace. Though this, too, is controlled by a differential thermocouple with a three-term controller, the shields here are not adiabatic. Clearly, they cannot be so as the electrical energy dissipated by the inner furnace must pass through these outer shells, if the center is not to rise in temperature. Additionally, conduction of heat through supports and furnace leads is a factor in the setting of the nonzero deviation of the outer furnace. A plot of such settings was generated and used to expedite work.

The temperature is measured with thermocouples embedded in the specimen. All couples in the calorimeter are British Standard 1826 Pt/Pt-13%Rh. Deionized ice and water make up the reference junction at 0°C. A precision decade potentiometer[3] of 0.1 μV accuracy is used with standard cell, lead-acid batteries, and an amplified galvanometer.

The specimen is cylindrical, with a longitudinal central hole for the specimen heater. This coil of platinum wire, wound on a 1.2 mm alumina shaft, is protected from the specimen by another alumina tube. Power is supplied by a d-c, stabilized, constant-current source. The connections for measuring the voltage drop across the heater are just outside the specimen. Moving coil volt and ammeters, tested to an accuracy of 0.1% were used in this initial setup. Manual timing accuracy was also 0.1%, or 1 sec in 1000.

To permit the calorimeter to be used at temperatures in excess of 1400°C, special requirements are placed on materials. The spherical shells are either molybdenum or tantalum. Furnace windings and clips are exclusively tantalum. Electrical insulation is high-grade alumina throughout. The only other materials in the calorimeter spheres are the Pt/Pt-13%Rh thermocouples and the ferrous alloy of the specimen.

The whole assembly of shells is protected from the laboratory environment by a vacuum of $0.5\text{-}1.0 \times 10^{-6}$ Torr. The plinth, on which the spheres rest, is water-cooled, just as is the 316L stainless steel "bell jar." The oil diffusion pump has an automatic timing system for filling its liquid nitrogen cold trap. Multiple reassembly of the vacuum seals, coupled with hydrogen

leak testing, was needed before the desired vacuum was obtained.

Specimen Manufacture and Analysis

An 800g melt for vacuum induction melting was prepared from deoxidized Japanese electrolytic iron and 99.999% silicon. The major impurities of the iron are oxygen at 0.008 a/o ±20% and sulfur and carbon at 0.005 ± 0.001 weight per cent (w/o) each. The deoxidation was done in our laboratory. The melt was preceded by washout melts of the iron with a small quantity of carbon to minimize oxygen contamination from the crucible. The iron-silicon alloy was held just above the solidus temperature for 10 min with 200 Torr argon pressure, then it was teemed into a 25 mm diameter mold. As this alloy was more brittle than the lower silicon alloys in the vacuum melting series, special care was taken in handling.

The analysis showed the alloy to be close to expectations. Wet analysis for silicon indicated 8.80 ± 0.02 w/o Si, or 16.1 a/o Si. Conductimetric analysis of carbon was 0.009 ± 0.001 w/o C. Spectroscopic analysis for eleven metallic impurities found all to be less than 0.02 w/o.

Routine machining was not possible for this alloy. After holding at 1000°C for 2 days and cooling in a vacuum furnace, the specimen diameter was able to be machined with a tungsten carbide tool. However, the holes in the specimen for the heater and thermocouples could not be drilled without pulling out grains. These apertures were obtained by spark erosion, with a cutting speed of 3 mm/hr.

Final heat-treatment in the vacuum furnace consisted of the following: 900°C for 2 days, then cool at an average rate of 7°K/hr, but never more than 15°K/hr, to reach 400°C, then furnace cool. The specimen was then polished and weighed. Total mass was 52.8125g, or 0.989 moles of 16.1 a/o Si alloy.

For calibration of the calorimeter, a second specimen, of zone-refined iron, was machined by ordinary methods. The chief impurities in this specimen were 0.0064 a/o C and 0.0032 a/o Si. This specimen had a mass of 46.524g, or 0.833 moles Fe.

Commissioning

The first specimen placed in the calorimeter was the zone-refined iron. Heat capacities were measured above and below the Curie point and the ferrite-to-austenite transition. These are shown in Table I. Set points were established and controller terms were found for these temperature ranges. Also, the enthalpy of α-γ transformation was measured on heating and cooling as shown in Table II. These data do not supersede previous work, as they suffer from too rapid heat addition (or subtraction) at the time of completions of the transformation. This causes an ambiguity in the termination point.

After completion of this series, the controllers were exchanged to disassociate the controller with greater touch and vibration sensitivity from the delicate center control. This had been a source of instability at temperatures below 600°C.

Table I. Heat capacity of pure Fe

T°C	T°K	Present C_p	Preceding C_p	
638.8	912	40.88	43.25	Joules/mole °K
652.6	926	47.06	44.4	
658.0	931	44.74	44.8

1059.5	1333	33.63	35.0	

Table II. Enthalpy of ferrite-austenite transformation

Heating	1048 joules/mole
Cooling	789 joules/mole
Accepted value	915 joules/mole ±10

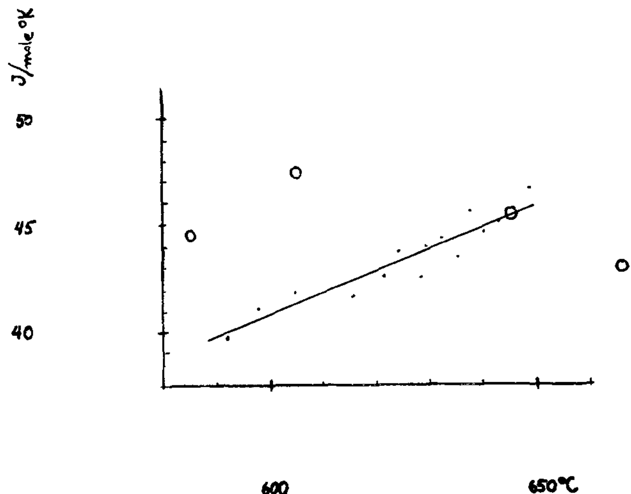

Fig. 1. Heat capacity of Fe-16.1 a/o Si. ○, Data of Ettwig and Pepperhoff (7); ●, present data.

Iron-Silicon Results

The heat capacities are presented in Fig. 1. Only those points for which adiabatic conditions were present before, during, and after the addition of heat are plotted. The temperature of the specimen must not have drifted more than 0.04°K in the 5 min preceding, and the temperature must have leveled in 5 min afterwards. Furthermore, the departure from adiabatic conditions had to be less than 0.02°K throughout, and about a mean of zero.

Other data collected, in the range from 400° to 650°C, are not presented in these results because the above conditions were not met. When a second potentiometer of less accuracy (1.0 μV instead of 0.1 μV) was used, only temperature changes of about 0.1°K could be discerned. Thus, the drift rate before and after may have exceeded the above-stated requirements. Secondly, those measurements taken when the integral term was removed from the inner furnace control have a steady deviation about a nonzero mean during the time the specimen heater was on. During the heating interval, the specimen was hotter than its surroundings. As there was no way to correct for this, these data were deleted.

Those heat capacity measurements which are left are in the temperature range of 600°-650°C, as shown in Fig. 1. Each heat capacity represents a temperature increment of less than 6°K, and each is plotted at its temperature midpoint. A rise from 40.8 to 45.9 joules/mole°K is found for the interval.

Discussion

Since the review of Shunk (1969) (2), discussion of the constitution of ordered Fe-Si ferrites has followed two lines. That set forth by Warlimont (1968) (3-4) suggests the existence of two-phase fields and presents transmission electron micrographs to show such microstructures. The other, of Inden and Pitsch (1971-1972) (5-6) and Ettwig and Pepperhoff (1972) (7), suggests that the transformations are continuous and presents x-ray and heat capacity measures as evidence of such. To the first, the second is based on macroscopic properties, and is true only of a metastable state.

The calorimeter constructed and used in the present experimentation has characteristics which enable it to contribute more reliable data. By virtue of using smaller temperature increments than other calorimeters, the departure from equilibrium is less. The calorimeter can be held at temperature for however long is necessary to reach equilibrium. The special care taken in the final anneal of the specimen before inser-

tion into the calorimeter may or may not have been sufficient.

It is not possible to compare features of heat capacity curves when so short a range has been validly studied. Hence, interpretation with respect to ordering and phase constitution is postponed until a broader range has been studied. The data of Ettwig and Pepperhoff (1972) (7) are superimposed on the present results.

The increase of heat capacity with temperature in this range is what would be expected on approaching the Curie temperature reported by Hansen and Anderko (1958) (8).

It is conjectured that the magnetic peak in the heat capacity is reduced from that of pure iron. For the same temperature difference from the Curie temperature, the slope and the value of heat capacity in this alloy is less than that of Fe. If this peak is substantially reduced from that of pure iron and the austenite is little changed, then an explanation for the instability of austenite in this alloy is provided.

Summary

A spherical, high temperature (1425°C maximum), adiabatic calorimeter was assembled, commissioned, and used to measure the heat capacity of an Fe-16.1% Si alloy from 600° to 650°C. The design and constructions of the instrument are discussed, as well as the means of manufacturing the specimen of this ordered alloy. This work extends the program of research of thermodynamics of ferrous alloys into ordered iron-silicon alloys.

Acknowledgments

I am grateful to Professors B. B. Argent and G. W. Greenwood for their cooperation in the selection of this project and for the provision of laboratory facilities and encouragement for its execution. I wish to thank Dr. A. S. Normanton for the experimental guidance he offered so freely throughout my stay at the University of Sheffield. Of the many other individuals in the Department of Metallurgy who helped, I particularly thank the technicians who spent so many hours assisting in this work.

Finally, I thank the people of The Electrochemical Society and the Union Carbide Corporation for giving me this opportunity to do thermochemical research with the F. M. Becket Award.

Mechanism and Kinetics of Formaldehyde Oxidation Using a New Fuel Cell Catalyst

W. R. Wolfe* and K. B. Keating*

E. I. du Pont de Nemours and Company, Incorporated, Wilmington, Delaware 19898

ABSTRACT

Recently a new class of nonprecious metal anode catalysts has been disclosed. The catalysts are based on the Mo-O-S system and are excellent catalysts for the oxidation of formaldehyde. *IR* free polarization data have been obtained as a function of temperature and formaldehyde concentration and at constant hydrogen ion concentration for formaldehyde in hydrochloric acid electrolyte. The data indicate that the catalyst disassociates the formaldehyde, *i.e.*, $H_2CO \rightleftarrows CO + H_2$ with subsequent oxidation of the carbon monoxide and hydrogen. The adsorption of the formaldehyde on the catalyst appears to be the rate determining step.

The economic incentive for a methanol fuel cell stems from the relatively low cost of this fuel[1] and the simplicity of electrode construction that accrues to a soluble fuel system. However, the high loadings of precious metal catalysts required to electrochemically oxidize this compound have turned investigators increasingly to consideration of formaldehyde as a fuel (2). Certainly the costs are more favorable than hydrazine, another suggested fuel. The general status of fuel cell electrode and catalyst art for many fuels has been compiled in several excellent reviews (3-6) and will not be covered here.

Recently, a new class of nonprecious metal anode catalysts has been disclosed (7). They consist of at least one oxide of molybdenum and at least one sulfurated compound of molybdenum, with the oxide having the formula MoO_x wherein x has a value of 2-2.88 and the O/S ratio is between 36:1 and 1:36. The catalytic activity in this system increases as the average valence of the Mo approaches 2 and the O/S ratio lies between 10:1 and 1:3.

Because of the excellent activity of these catalysts for formaldehyde oxidation, a study of the kinetics of this oxidation on these catalysts was made for the purpose of optimization of the conditions for fuel cell operation. In these studies the catalyst used was made by heating 18.3g sulfur with 98g of ammonium heptamolybdate $[(NH_4)_6Mo_7O_{24} \cdot 4H_2O]$ in an alumina combustion tube at 450°C in hydrogen for 7 hr. A typical chemical analysis of the resultant acid insoluble compound was as follows

Mo: 64.6 weight per cent (w/o);
S: 10.0 w/o; O: 24.0 w/o

Experimental Procedure

All of the experiments were carried out in the apparatus shown in Fig. 1. In this equipment a batch-type experiment was carried out: the experimental anode was immersed in approximately 250 cm^3 of anolyte and driven against a lead dioxide plate in 250 cm^3 10% H_2SO_4. The anode and cathode compartments were separated by an American Machine and Foundry cation exchange membrane (Series C310). A saturated calomel electrode was used to obtain anode reference potential readings. The current was interrupted every 5 sec using a mercury-wet, relay-type interrupter; this enabled determination of the resistance losses in the electrode so that *IR* free performances could be determined. These data were recorded on a Moseley Model 136-A Autograf X-Y recorder.

Two factors led us to consider that this method of abstracting the polarization due to *IR* losses in the electrodes was legitimate in this case:

(*i*) Preliminary experiments using an oscilloscope demonstrated that the decay in polarization, interpreted by us as being due to *IR* loss in the electrode, was always less than 1 μsec, eliminating the possibility of this being due to charge transfer.

(*ii*) For any given electrode configuration, the magnitude of this measured *IR* loss was always directly proportional to the applied current.

Key words: electrocatalysts, molybdenum, sulfur, HCHO, reaction mechanism, kinetics.

[1] For example, in midyear 1974 the price for methanol was approximately 4 ¢/lb; for formaldehyde it was approximately 10 ¢/lb (1). This means a factor of about 4:1 in favor of methanol in terms of cost of generated power.

Results and Discussion

Effect of temperature.—The temperature effect data were taken with an anolyte composition of 9 w/o CH_2O, 7 w/o HCl, and 84 w/o H_2O. The data are for the previously described catalyst material which was fabricated into a 1 in. diameter anode containing 2g catalyst, 1g tantalum wool, and 0.2g Teflon® 7 fluorocarbon resin by pressing at approximately 60,000 psi. The thickness of these electrodes was about 50-60 mils. This is the so-called standard anode which was always soaked overnight in the anolyte before determination of the electrochemical parameters.

The data are shown in Fig. 2 which is a plot of current density in milliamperes per square centimeter *vs.* anode reference potential measured against the saturated calomel electrode (SCE) at the temperature of the experiment.

The temperature effect is quite significant; for example at 15 mA/cm^2 the *IR* free polarization is about 0.2V *vs.* SCE at 65°C and about −0.03V *vs.* SCE at 85°C.

Effect of electrolyte composition.—It was found that the polarization characteristics are very sensitive to electrolyte composition. Forty different anolyte compositions were studied. All of these experiments were performed at 85°C. Standard anodes were used in this study also; they were equilibrated overnight with the solution studied. The same apparatus was used as that used for the temperature studies. It was later found that identical performance to this "equilibrated" performance could be achieved by eliminating the Teflon® 7 fluorocarbon resin and pressing the catalyst materials with tantalum wool and making the run almost immediately.

Figure 3 shows the effect of formaldehyde concentration, keeping the hydrogen ion concentration approximately the same. Concentrations of formaldehyde lower than 4g in 500 cm^3 solution (0.7% by weight) result in unstable performance; the anode polarizes continuously and the current continues to drop. This effect is not eliminated by stirring. It was also determined that the concentration of formaldehyde remains constant in the bulk solution during the course of the experiment so that depletion of the formaldehyde in the bulk is not the cause of this behavior. Data were also taken in the current density region 0.01-1 mA/cm^2. These data, taken at 85°C, are shown in Fig. 4 for an anolyte containing 9.3% CH_2O, 6.2% HCl, 84.4% H_2O.

Large deviations in the hydrogen ion concentration affect the polarization curves markedly; this effect can be conveniently represented on a ternary diagram as in Fig. 5 which shows contour lines of current density at 85°C for *IR* free polarization of 0.1V *vs.* SCE. The numbers on the ternary diagram are current densities at 0.1V polarization for the concentration at that point. A sharply defined optimal region in the neighborhood of 24% CH_2O, 4% HCl, 72% H_2O is evident.

Kinetic analysis of data.—The anode reaction is thought to proceed as follows at the electrode surface

$$CH_2O + H_2O \rightleftarrows CO_2\uparrow + 4H^+ + 4e^- \quad [1]$$

Let us consider the possibility that this reaction occurs in two major steps of the following type

$$A \underset{k_{-1}}{\overset{k_1}{\rightleftarrows}} B \quad [2]$$

$$B \underset{k'_{-2}}{\overset{k'_2}{\rightleftarrows}} C \quad [3]$$

We can now develop the kinetics after Bockris (8) and Christiansen (9) and write the reaction for the net forward velocity

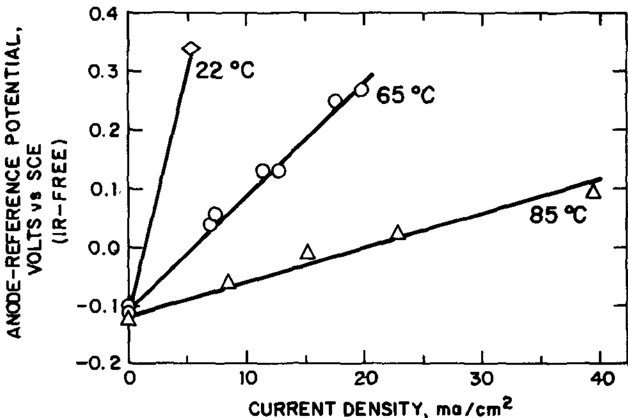

Fig. 2. Effect of temperature on anode performance. Anolyte composition: 9.0% CH_2O; 7.0% HCl; 84.0% H_2O.

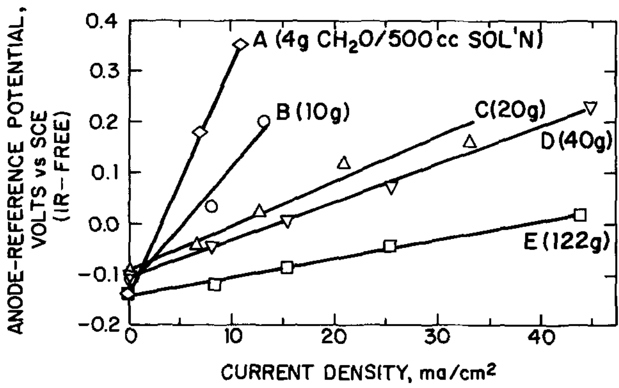

Fig. 3. Effect of concentration on anode performance (temperature, 85°C).

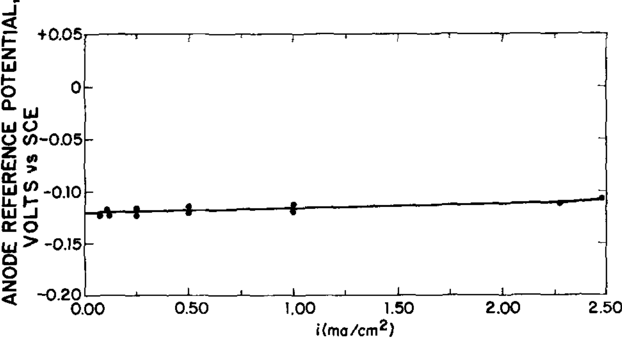

Fig. 4. Plot of E vs. i (low current densities). Temperature, 85°C. Standard anode, standard catalyst. Anolyte concentration: 9.0% CH_2O; 7.0% HCl; 84.0% H_2O.

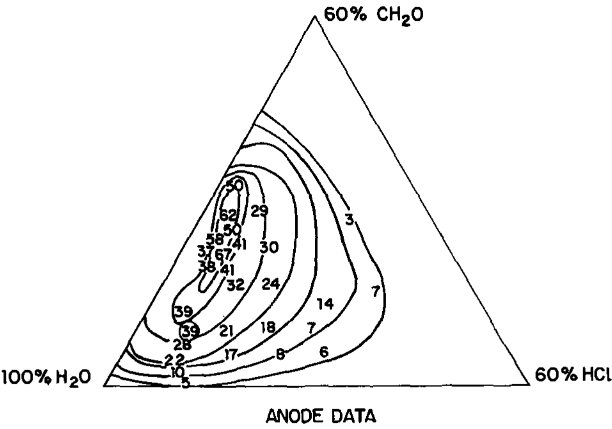

Fig. 5. Ternary diagram of anode. Current density (mA/cm^2) at 0.1V vs. SCE (*IR* free) at 85°C.

$$v_f = \frac{k_1 k'_2 A}{k_{-1} + k'_2} \quad [4]$$

Now, if we consider the oxidation of formaldehyde to take place as a first order, nonelectrochemical reaction followed by an electron transfer reaction involving the intermediate, we can write

$$CH_2O \underset{k_{-1}}{\overset{k_1}{\rightleftarrows}} Z \quad [5]$$

$$Z \underset{k'_{-2}}{\overset{k'_2}{\rightleftarrows}} \text{products} + ne \quad [6]$$

A set of reactions consistent with this form and with the over-all reaction (Eq. [1]) is

$$CH_2O \rightleftarrows CO + H_2 \quad [7]$$

$$[CO + H_2O \rightarrow CO_2 + 2H^+ + 2e^-] \text{ fast, non-rate determining} \quad [8]$$

$$H_2 \rightleftarrows 2H^+ + 2e^- \quad [9]$$

Proceeding as in the simple prototype, we get

$$v_1 = k_1 C_F;\; v_{-1} = k_{-1} C_Z \quad [10]$$

$$v_2 = k'_2 C_Z e^{\beta f E};\; v_{-2} = k'_{-2} C_{prod} e^{-\alpha f E} \quad [11]$$

where we have made the following substitutions: $k'_2 = k_2 e^{\beta f E}$ for the oxidation or forward reaction; $k'_{-2} = k_{-2} e^{-\alpha f E}$ for the reduction or backward reaction.

Here $f = n\mathbf{F}/RT$, E is the anodic polarization, β is the fraction of the potential assisting the forward or oxidation step, and α is the fraction of the potential assisting the backward or reduction step.

It should be pointed out that in Eq. [10] and [11] the reactions are considered to be first order; also k_2 and k_{-2} may be functions of temperature.

Now, resubstituting in Eq. [4], we get, for the current density, i

$$i = \frac{n\mathbf{F} k_1 k_2 C_F e^{\beta f E}}{k_{-1} + k_2 e^{\beta f E}} \quad [12]$$

This equation will represent the total predicted i-E behavior, assuming the back reaction is negligible and the temperature is constant.

We now examine the limiting cases. (*i*) With a small E, then $k_{-1} >> k_2 e^{\beta f E}$. Therefore

$$i = \frac{n\mathbf{F} k_1 k_2 C_F e^{\beta f E}}{k_{-1}} \quad [13]$$

This would predict Tafel-type behavior at low E, for a given formaldehyde concentration, with reaction [9] controlling.

(*ii*) With large E, then $k_{-1} << k_2 e^{\beta f E}$. Now

$$i = n\mathbf{F} k_1 C_F = i_1 \quad [14]$$

or

$$\frac{\partial \log i)_T}{\partial \log C_F)_T} = 1 \quad [15]$$

Thus we get a nondiffusional limiting current (i_1) behavior, independent of E, with reaction [7] rate controlling and a slope of unity for a plot of log i *vs.* log C_F.

Returning to Eq. [12] and [14], we get

$$E = \frac{0.059}{\beta n}\left(\frac{T}{298}\right)\log\frac{k_{-1}}{k_2} - \frac{0.059}{\beta n}\left(\frac{T}{298}\right)\log\left(\frac{i_1 - i}{i}\right) \quad [16]$$

We summarize then the three major predictions of this model:

(*i*) The existence of a limiting current i_1, proportional to the formaldehyde concentration, C_F (Eq. [14].

(*ii*) A linear plot of E *vs.* log $\frac{i_1 - i}{i}$, with a slope of $\frac{0.059}{n}\frac{T}{298}$. (See Eq. [16].)

(*iii*) The current is proportional to the formaldehyde concentration. A plot of log i *vs.* log C_F will have a slope unity (Eq. [15]) at large values of E.

For the purpose of an analysis of the data in terms of this model, let us confine ourselves to data taken on a tieline in the CH_2O-H_2O-HCl ternary diagram at about 4% HCl by weight and between 9 and 32% by weight CH_2O.

Figure 6 shows a plot of E, the anodic polarization, *vs.* log i (on a semilogarithmic plot) for a standard catalyst in anolyte at 85°C containing the formaldehyde concentrations indicated.

Examination of these curves reveals that they do indeed exhibit limiting current behavior as predicted by our model. It is useful at this point to establish that this limiting current behavior is not due to diffusion control. Using the well-known equation for the limiting current in a diffusion controlled process

$$[i_1]_D = \frac{n\mathbf{F}D}{\delta} C_F \quad [17]$$

where: $[i_1]_D$ = diffusion controlled limiting current (A/cm²); n = number of electrons involved in reaction; D = diffusion coefficient of formaldehyde in anolyte (cm²/sec); C_F = concentration of formaldehyde in bulk solution (moles/cm³); δ = thickness of diffusion film (cm); and $\mathbf{F}$ = Faraday's constant (9.65 × 10^4 A-sec/mole). We obtain[2] a limiting current of 200-400 mA/cm² at a concentration of 3.33 × 10^{-3} moles/cm³ (50g in 500 cm³) formaldehyde, using conservative values of D and δ (10^{-5} cm²/sec and 0.03 cm, respectively). This current is far in excess of what any reasonable extrapolation of the data in Fig. 6 would suggest as a limiting current for this concentration. Another experimental indication that diffusion is not controlling the rate of this reaction is that vigorous stirring has no effect on the polarization curves obtained.

Figure 7 shows a plot of E *vs.* $\frac{i_1 - i}{i_1}$, where i_1 is estimated from Fig. 6. As can be seen, all of the data can be represented fairly well by a straight line with a slope of −0.232. This slope provides a value of βn of 0.3, which is reasonable.

Figure 8 shows a plot of log i *vs.* log C_F at constant values of E, the anodic polarization. Statistical anal-

[2] For n = 2, $[i_1]_d$ = 214 mA/cm²; for n = 4, $[i_1]_d$ = 428 mA/cm².

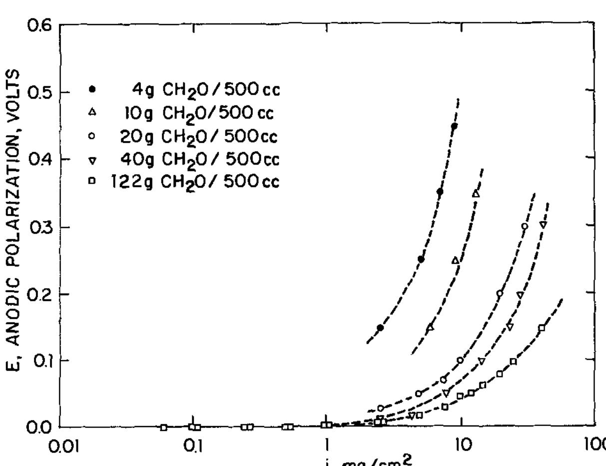

Fig. 6. Plots of E vs. i at 85°C. Standard catalyst, standard anode

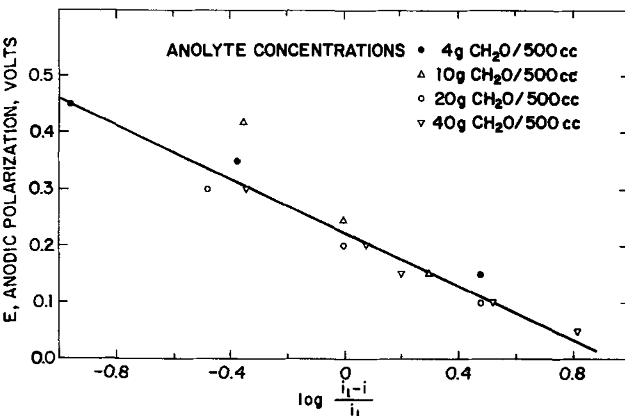

Fig. 7. Plot of E vs. $\log i_l - i/i_l$ at 85°C

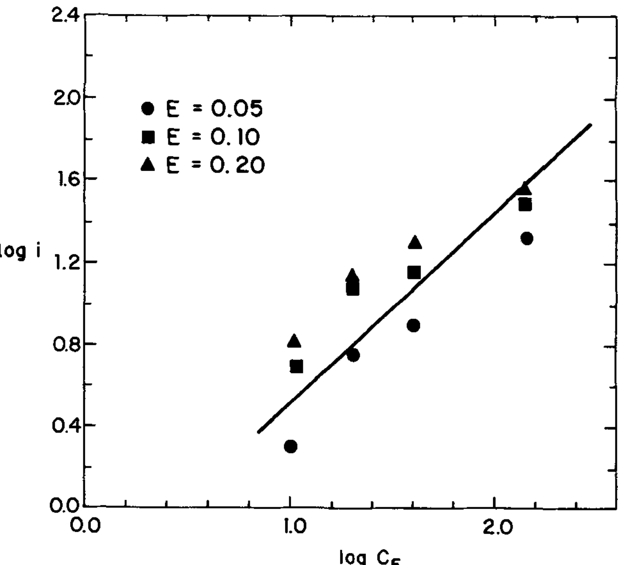

Fig. 8. Plot of $\log i$ vs. $\log C_F$ at 85°C

ysis of the data shows that a line can be drawn through the data with a slope equal to unity at the 95% level of confidence. Such a line is drawn in Fig. 7. This is in very good agreement with the third major prediction of the model developed for the anode reaction.

At very low current densities, the backward reaction will not be negligible and we will then obtain from Eq. [12] the following expression

$$v = \frac{k_1 k_2 C_F e^{\beta f E} - k_{-1} k_{-2} C_{prod} e^{-\alpha f E}}{k_{-1} + k_2 e^{\beta f E}} \quad [18]$$

This equation will be important at small E, therefore $k_{-1} >> k_2 e^{\beta f E}$. Simplifying and introducing the expression for the current, we get

$$\frac{i}{nF} = K_1 k_2 C_F e^{\beta f E} - k_{-2} C_{prod} e^{-\alpha f E} \quad [19]$$

where

$$K_1 = \frac{k_1}{k_{-1}} \quad [20]$$

For small E, we can make the following mathematical substitutions

$$e^{\beta f E} \cong 1 + \beta f E \quad [21]$$

$$e^{-\alpha f E} \cong 1 - \alpha f E \quad [22]$$

Then

$$\frac{i}{nF} = K_1 k_2 C_F (1 + \beta f E) - k_{-2} C_{prod} (1 - \alpha f E) \quad [23]$$

and

$$\frac{i}{nF} = E[\beta f K_1 k_2 C_F + \alpha f k_{-2} C_{prod}] + [K_1 k_2 C_F - k_{-2} C_{prod}] \quad [24]$$

This equation predicts a linear relationship between i and E at low values of E. Figure 9 is such a plot showing this relationship. Above current densities of about 2.5 mA/cm^2 (corresponding to values of E of approximately 10 mV) this linear relationship breaks down, presumably because the backward reaction is now negligible.

Our model still holds if what in fact happens is the following

$$CH_2O \rightarrow CH_2O \text{ (ads)} \quad \text{slow} \quad [25]$$

$$CH_2O \text{ (ads)} \rightarrow CO + H_2 \quad \text{fast} \quad [26]$$

with the rest of the steps following as in Eq. [5] and [6].

An indication that this first slow step may be an adsorption step is the fact that it is necessary to soak the anodes in anolyte overnight before running in order to obtain maximum, reproducible current densities. After 816 hr of soaking a standard electrode in

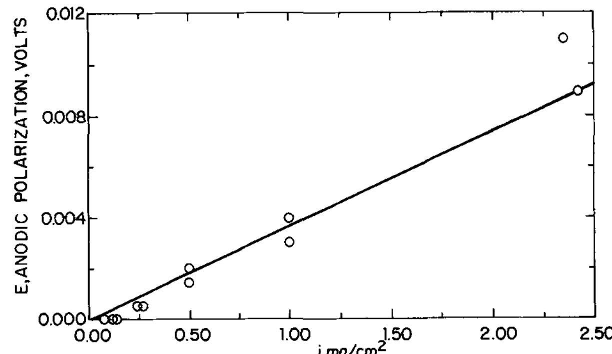

Fig. 9. Plot of E vs. i at 85°C (low current density region). Anolyte concentration: 9.0% CH_2O; 7.0% HCl; 84.0% H_2O.

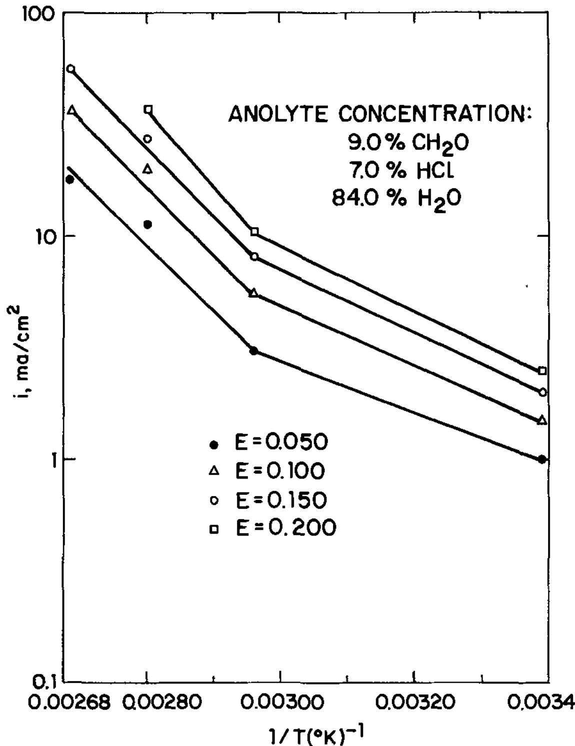

Fig. 10. Plot of i vs. $1/T$ at constant E. Anolyte concentration: 9.0% CH_2O; 7.0% HCl; 84.0% H_2O.

optimized anolyte, it was found that although the formaldehyde concentration had been reduced by about two-thirds, the water concentration (determined by difference, knowing Cl^- and CH_2O concentration) actually increased. This suggests that at open circuit CH_2O does not combine with H_2O to form CO_2. Thus, Eq. [25] and [26] may indicate the correct course of the reaction.

Figure 10 shows a plot of i *vs.* the reciprocal of the absolute temperature ($1/T$) for values of the same polarization. We can immediately discern two separate regimes: the first between 22° and 65°C, in which the heat of adsorption is 4.6 kcal/mole; the second (from 65° to 100°C), in which the heat of adsorption is approximately 13 kcal/mole. These values bracket the value reported for the adsorption of formaldehyde on tungsten carbide, namely 10 kcal/mole (10). In this connection it is interesting to note a report of two adsorbed species for formaldehyde on germania, one very weakly bonded, a second more strongly bonded with a spectrum similar to polyoxymethylene(11). All of these considerations strongly suggest that Eq. [25] is indeed a proper representation of the rate determining step for the oxidation of formadehyde on this catalyst.

Acknowledgment

It is a pleasure to acknowledge the contributions of Dr. J. F. Nestor who synthesized the catalysts, Dr. Allen J. Bard of the University of Texas who aided in the kinetic analysis, and Mr. K. J. P. Karawin who aided in performing many of the experiments.

Manuscript submitted Sept. 21, 1973; revised manuscript received April 26, 1974.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1975 JOURNAL. All discussions for the June 1975 Discussion Section should be submitted by Feb. 1, 1975.

The publication costs of this article have been assisted by E. I. du Pont de Nemours and Company, Incorporated.

ABSTRACT

Pacemakers and biotelemeters are being powered by implantable hybrid cells consisting of sacrificial anodes and cathodes where body oxygen is reduced. A high corrosion rate of anode materials for the hybrid cell is a distinct disadvantage because of the cell's proposed goal as a long term power source. *In vitro* and *in vivo* corrosion studies made on anode materials such as aluminum, zinc, and magnesium alloy AZ31B under different loadings have been correlated histopathologically with the tissue reaction at the implant interface. Magnesium and magnesium alloy AZ31B appear to be unacceptable as an anode material due to their high corrosion rates and poor biocompatibility. *In vivo* corrosion measurements on aluminum over 147 days under different loadings demonstrated that a load current density of the order of 13 $\mu A/cm^2$ produced a low corrosion rate and good biocompatibility. Although aluminum appears to be more biocompatible than zinc further work needs to be undertaken in order to more completely characterize corrosion mechanisms and the biocompatibility of these materials.

Many thousands of patients have received successfully implanted pacemakers and live useful lives. Recent advances in technology have led to more dependable electrodes and generators so that the average functional life of a pacemaker has increased from six to eighteen months with some as high as thirty-six months (1, 2). Ideally an implantable power source should last for ten years, eliminating the necessity of replacing power sources (3). There are a variety of approaches which have been pursued in an attempt to prolong the lifetime of internal power sources (4). The implantable hybrid cell as a long term power source for cardiac pacemakers has been extensively studied (1, 3-5). The hybrid cell consists of a fuel cell cathode where dissolved oxygen in the body fluids is catalytically reduced and a sacrificial anode is galvanically oxidized.

Previous studies indicated that the primary problem was electrode polarization at the cathode resulting in a loss of power (6). The development of porous palladium black cathodes using powder metallurgy techniques resulted in a substantial increase in the *in vivo* power density obtainable from these cells (7). This paper addresses itself to the corrosion of anode mate-

Key words: *in vivo* corrosion, aluminum, zinc, magnesium AZ31B, biocompatibility.

rials. A high corrosion rate for an anode material for the hybrid cell can be a distinct disadvantage because of its proposed goal as a long term power source, the increase in waste products in the host and the possible weakening of the anode with built up corrosion products (8, 9). Weight loss studies are not sufficiently sensitive to adapt to *in vivo* corrosion studies (9, 10) while for *in vitro* they produce an average corrosion rate with time (11, 12).

A technique that can be used for both *in vitro* and *in vivo* corrosion studies of anodes is the linear polarization method developed by Stern (11-13) and used by Greene *et al.* (9, 10) to study corrosion of surgical implants. The hybrid cell draws 25 $\mu A/cm^2$ when driving a commercial pacemaker, thus in order to obtain galvanostatic and potentiostatic anodic and cathodic polarization curves under load conditions anodes were loaded to draw approximately 25 $\mu A/cm^2$. After loading for various periods of time, *i.e.*, for a number of days, polarization, galvanostatic and potentiostatic curves were taken on removal of the load. Besides corrosion rates being determined by linear polarization techniques, rates were estimated similar to Tafel extrapolation by drawing tangents to the polarization curves in the loaded current range. The intersection of these "Tafel" lines with the horizontally drawn line representing $E_{corrosion}$ was taken as $I_{corrosion}$.

Experimental Procedures

Linear polarization technique for determining corrosion rates (9, 14, 29).—This method consists of determining the Tafel slopes; β_a and β_c for both anodic and cathodic processes, and the polarization resistance, R_{pol}, of the corroding electrode under study. The polarization resistance is the slope of the linear portion of the polarization curve obtained by plotting overpotential *vs.* current density for the first 10-20 mV of overpotential of the electrode.

The values of β_a and β_c and R_{pol} are then used to calculate the corrosion rate expressed as a corrosion current I_{corr} from the following equation

$$I_{corr} = \frac{\beta_a\beta_c}{2.3R_{pol}(\beta_a + \beta_c)} \quad [1]$$

A Tacussel PIT 20-2X potentiostat and a polarization cell fabricated according to Greene (14) was used for *in vitro* studies. In determining R_{pol} and for galvanostatic measurements a constant current source, a Keithley Model 225 was used for accurate low currents. A Lauda Circulator Model K-2 kept samples at a body temperature of 37° ± 0.1°C.

In *in vivo* studies the current was passed through a test electrode and a porous palladium black electrode which is implanted with the test electrodes for use as the auxiliary or counterelectrode. The electrical connection to all the electrodes was made by connecting very fine Teflon-coated stainless steel wires to the electrodes and then bringing the other end of the wire out through the skin. The wire connection is insulated by a fluid impermeable neoprene coating covered with Ciba Aradite 6010 epoxy with a final coating of Dow Corning Medical Adhesive Silicon Type A.

The potential of each test electrode was measured with respect to a silver-silver chloride electrode (standard 16 mm Beckman biopotential skin electrode) which was placed on the skin with conductive paste. All samples were 1 or 3 cm^2 in geometric area and were implanted subcutaneously in the lateral abdomen and thorax of dogs.

Histological Examinations

H & H stains were used for histological staining of the tissue capsules surrounding the implants. Hematoxylin, H, colors basophilic material blue or purple, while eosin, E, colors acidophilic material pink or red. Thus collagen stains pink to red (15). Another staining method used to supplement the H & E is the Gomari trichrome stain (16) which differentiates between collagen and muscle. Collagen stains a clear green while smooth muscle stains a deep purplish red and fibrin an orange red. In order to differentiate bacteria in tissue a Brown and Brenn method was used.

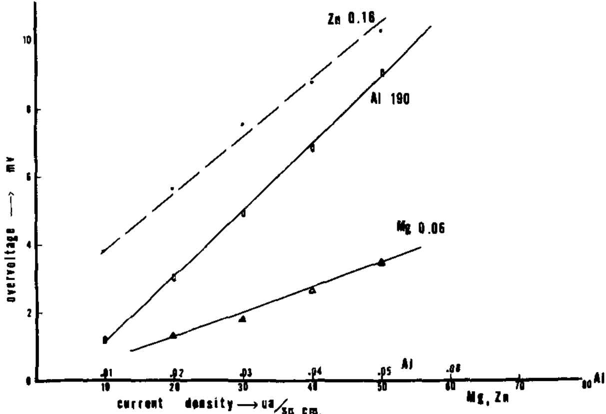

Fig. 1. *In vitro* anodic linear polarization curves under no load used to determine the R_{pol} in kilo ohms per square centimeter for Al, Zn, and Mg alloy AZ31B, in 0.9% aqueous NaCl at 37°C open to atmosphere.

Materials

Solid aluminum and zinc were obtained from A. D. Mackay Company with the following purity: aluminum, 99.99%; zinc, 99.9%. The magnesium alloy, AZ31B consisted of magnesium with 3% aluminum and 1% zinc.

Results and Discussion

In vitro measurements.—Although the anodic and cathodic Tafel slopes varied over a wide range of values the I_{corr} can be shown to be approximated by

$$I_{corr} = \frac{0.026^{(10)}}{R_{pol}} \quad [2]$$

Figure 1 contains plots of linear polarization curves for determining R_{pol} for the various metals under *in vitro* conditions. Table I is a summation of *in vitro* data. It is noted that there is a range of values of R_{pol}. The intersection of the Tafel line with E_{corr} in Fig. 3 is at 0.2 which checks reasonably well with the values obtained from Eq. [2].

It is noted from Table I that the *in vitro* corrosion rates of zinc and magnesium alloy AZ31B are 2 to 3 orders of magnitude greater than aluminum. The unloaded *in vivo* data of Table II demonstrates that *in vivo* corrosion rates are reduced by an order of magnitude over the *in vitro* corrosion although the relative rates between metals remain approximately the same. Table III illustrates that loading the anode with a current density of 25 $\mu A/cm^2$ which has been used for powering present commercially available pacemakers increases the corrosion rate particularly for Al. At this loading the *in vivo* corrosion rates of Al increases with time of implantation as shown in Fig. 2a to arrive at an asymptotic value of I_{corr} which is the same order of magnitude as for zinc.

Table I. Comparison of I_{corr} of anodic materials unler no load conditions 0.9% NaCl, T = 37°C

	In vitro

Solid aluminum	100-330	0.09-0.26	0.1-0.5
Solid zinc	0.14-0.35	52-186	25-45
Solid magnesium alloy AZ31B	0.066-0.242	107-394	35-500

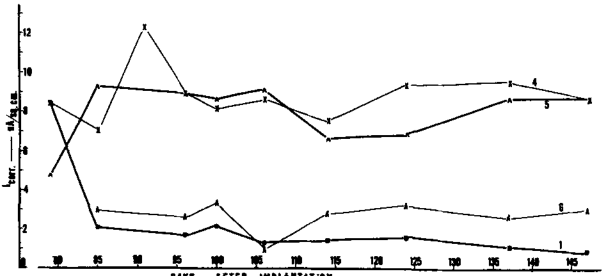

Fig. 2a. Comparison of the time variation of I_{corr} of aluminum anodes implanted in the lateral thorax of dogs under different loadings. Curve 2 is for a 10 kohm or 38 $\mu A/cm^2$ load while curve 3 is for a 20 kohm or 19 $\mu A/cm^2$ load. Implants sterilized with ethylene oxide.

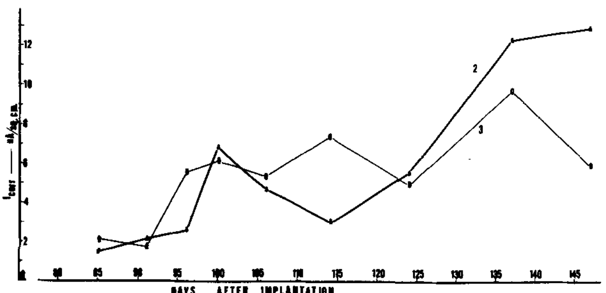

Fig. 2b. Time variation of I_{corr} for aluminum anodes implanted in dogs under different loadings. Curve 1 represents an electrode heavily loaded at 75 $\mu A/cm^2$ for the first 80 days and then open circuited for a no load. Curve 6 is a loading of 13 $\mu A/cm^2$ for 147 days. Curves 4 and 5 have been loaded for 147 days at approximately 18.5 $\mu A/cm^2$.

The *in vitro* electrodes unlike the *in vivo* electrodes were not autoclaved so they did not obtain a heavy oxide film. Attempts to make *in vitro* measurements on autoclaved electrodes produced nonreproducible and unstable data. Autoclaved *in vivo* electrodes under no load demonstrated some instability reflected as variations of potential. However, it was possible to obtain reasonably steady values with time which fell in the range of values presented in Tables II and III. Ethylene oxide gas sterilized electrodes under no load *in vivo* behaved similar to the autoclaved as above. Electrodes which were either sterilized in a "Bard" ethylene-oxide gas sterilizer or autoclaved, produced stable potentials under load conditions.

The above results indicate that the oxide film at the aluminum interface may be partially ruptured under load conditions (17-20), increasing the corrosion rate.

* Indicates cells loaded 79 days after implantation.

When the hybrid cell is coupled to a pacemaker the whole unit is gas sterilized before implantation. Electrodes were therefore sterilized with ethylene-oxide for *in vivo* measurements under load as given in Table IV.

As expected the disturbance to the corrosion rate of passing a current through the aluminum interface due to its more pronounced oxide coating is greater than that of zinc. *In vivo* corrosion rates for various loadings shown in Table IV illustrates that for 18 $\mu A/cm^2$ the I_{corr} is approximately 5-12 $\mu A/cm^2$ while at a loading of 13 $\mu A/cm^2$ is on the average 3 $\mu A/cm^2$. When a sample of solid aluminum was loaded to 25 $\mu A/cm^2$ and then the load removed the I_{corr} after a number of weeks approached its no load value. *In vivo* data on the magnesium alloy under load conditions was unstable, although these results indicate that under load conditions the corrosion rate is of the same order as under no load conditions.

The following paragraphs discuss the polarization curves used to obtain the data of Tables I-IV.

The intersection of the Tafel line of Fig. 3 with the E_{corr} line, which in this case is 1V gave the I_{corr} recorded in Table I.

Figure 4 illustrates the effects of the oxide coating on aluminum with the curve at low current densities being characteristic of the corrosion rate with a substantial oxide coating. The surface appears to be considerably different under loaded current densities of 25 $\mu A/cm^2$.

Curve 2 of Fig. 4 and 5 demonstrate the upward shift in I_{corr} with time. The break in the curves of Fig. 4 appears at about 0.5V which checks with the findings of Zahavi *et al.* Figure 4 representing typical curves for a loaded electrode for 4 days and 36 days illustrates that for a given current density the polarization decreased with increasing corrosion rates of electrodes.

A tangent or "Tafel" line was drawn for the curve in the operating range. The I_{corr} determined from the intersection of the tangent lines with the horizontal E_{corr} line for the anodic and cathodic galvanostatic curves checks closely.

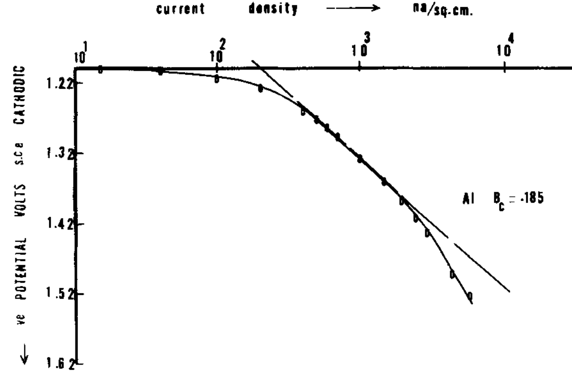

Fig. 3. *In vitro* galvanostatic cathodic polarization curve for solid aluminum in 0.9% aqueous NaCl at 37°C open to atmosphere under no load conditions.

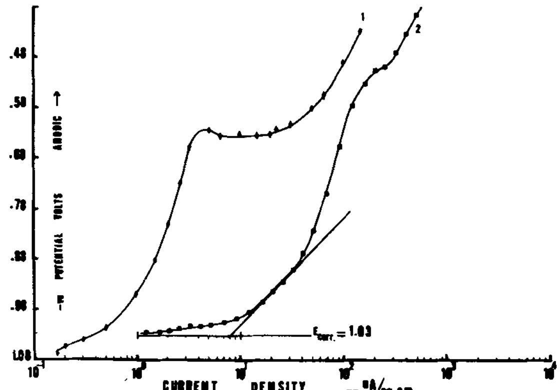

Fig. 4. *In vivo* galvanostatic anodic polarization curves for solid aluminum electrodes implanted in a dog under an approximate loading of 25 $\mu A/cm^2$. The potentials are referenced to a Ag/AgCl skin electrode. Curve 1 was loaded for approximately 4 days and curve 2 for 36 days before measuring the anodic polarization.

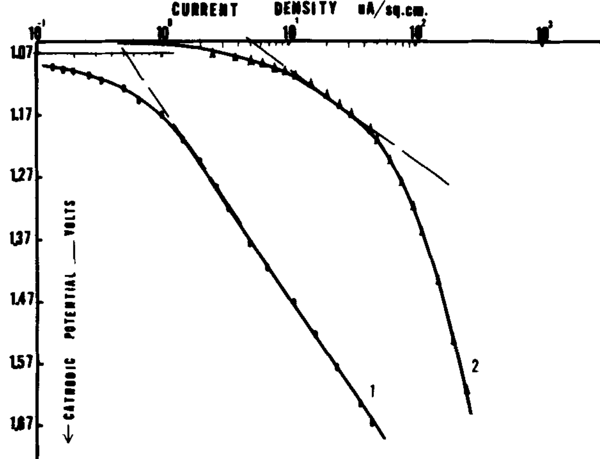

Fig. 5. *In vivo* galvanostatic cathodic polarization curves for solid aluminum curves for solid aluminum electrodes implanted in a dog under an approximate loading of 25 $\mu A/cm^2$. The potentials are referenced to a Ag/AgCl skin electrode. Curve 1 was loaded for approximately 4 days, and curve 2 for 100 days before measuring the cathodic polarization.

Figure 6 is an illustration of linear polarization data under loaded *in vivo* conditions. Although the slopes of the curves vary on a dog, from measurement to measurement and from dog to dog the data points line up well for a given measurement.

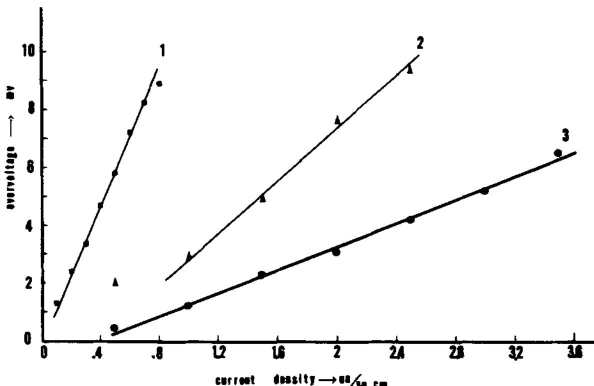

Fig. 6. *In vivo* anodic linear polarization curves of aluminum for determining R_{pol} in kilo ohms per square centimeter for electrodes implanted in dogs with a load of approximately 25 $\mu A/cm^2$. The potentials are referenced to a Ag/AgCl *skin* electrode. Curve 1 represents data taken after 7 days of loading, R_{pol} = 12 kohms; curve 2 is from data after 22 days of loading, R_{pol} = 4.26 kohms; curve 3 is from data after 67 days of loading, R_{pol} = 2 kohms.

The present pacemaker system we are using requires 610 μA continuously when operating from a cell voltage of 0.5V. Over a ten year period the faradaic weight loss in an anode of trivalent Al needed to supply the above current is 17.6g. The weight loss based on I_{corr} measurements under the above load is 7.4g or about 29% of the faradaic loss. Divalent Zn on the other hand because of a 300 mV higher voltage would need a current of about 400 μA or a faradaic weight loss of 40g over a ten year period. The weight loss based on I_{corr} for Zn of an equivalent geometrical area is 11.4-14.7g. Thus for Zn approximately 52g is needed to supply energy over a ten year period, 40g being consumed as useful energy and 12g being lost by way of corrosion, and not converted into usable energy. The efficiency has therefore been defined as the ratio of the faradaic weight loss to the faradaic weight loss plus the weight loss due to corrosion which gives for Zn efficiencies of 73-78% (23). Roy *et al.* (22), in their *in vivo* studies of zinc under various load conditions defined the efficiency as the ratio of the actual life to expected life. They obtained for zinc efficiencies ranging from 73-86%.

Divalent Mg with its 600 mV higher voltage requires a current of approximately 270 μA or a faradaic weight loss of 10.7g. The weight loss based on I_{corr} for Mg of an equivalent geometrical area under no load is 8g or 75% of the faradaic weight loss. The corrosion rate under load, although difficult to measure, is estimated to be the order of 1 g/yr which checks with a reported value of 1.2 g/yr (24). After operating *in vivo* under load the Mg galvanostatic and potentiostatic curves were too unstable for corrosion data.

Histopathological examinations of tissue surrounding the aluminum, zinc, and magnesium implants are discussed in the following paragraphs with the help of microscopic photographs.

It is seen in Fig. 7 that a dense capsule composed of fibrous connective tissue has formed around magnesium implanted for 6 months. It is further noted that at the tissue-metal interface, a moderately heavy inflammatory cell reaction is present consisting of granulation tissue with an infiltrate of neutrophils, lymphocytes, and plasma cells.

Figure 8 shows a fibrous connective tissue capsule with a moderately heavy inflammatory cell infiltrate at the tissue-zinc interface after 6 months of implantation. This reaction is characterized by dilated capillaries, infiltrate of neutrophils, lymphocytes, and plasma cells. The adverse tissue response is contrary to the findings of other investigators (4, 28). Further implantations of zinc will be undertaken by us to gain a greater insight into zinc biocompatibility.

Figure 9 shows that under no load conditions histologic examination revealed a well-formed, relatively thick (550μ) mature fibrous connective tissue capsule which shows only mild aggregates of lymphocytes. No particular matter was observed in the capsule. Under

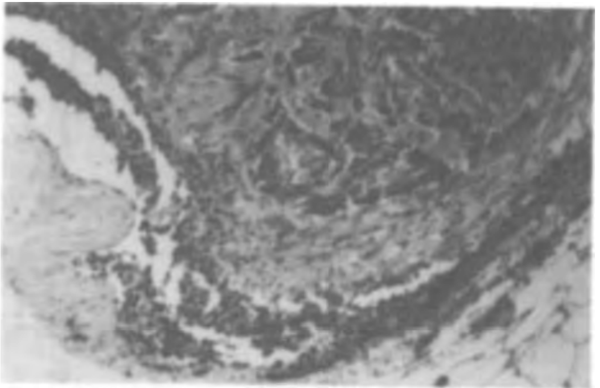

Fig. 7. Tissue surrounding magnesium alloy electrode implanted for 6 months unloaded. Magnification 100×. E and H stain used.

Fig. 8. Tissue surrounding zinc electrode implanted for 6 months unloaded. Magnification 100×. E and H stain used.

Fig. 9. Tissue surrounding aluminum electrode implanted for 6 months unloaded. Magnification 100×. E and H stain used.

load conditions removal of aluminum implants after 147 days revealed that they all were encapsulated with a thick wall formed mature fibrous connective tissue capsule. Cells loaded in the range of 18 $\mu A/cm^2$ showed little inflammatory reaction. Loads greater than 70 $\mu A/cm^2$ produced an open pus drain above the implant. Cells loaded in the 13 $\mu A/cm^2$ range were macroscopically free from inflammation.

Magnesium has been reported by Sawyer and Srinivasan (25) as being not only highly corrosive but markedly toxic, destructive of blood cells, and forming magnesium proteinate. On the other hand aluminum was found by them to be nontoxic on tissue surrounding wounds and to have a minimal destruction on red and white blood cells. Determination of aluminum concentrations in blood samples and surrounding tissue of implants by atomic absorption spectrophotometry (26) illustrated that the aluminum concentrations are within the range of values of aluminum of 0.21-0.94 parts per million reported for man (27).

It was further observed by us, that none of the Pd-black cathodes which were coupled and loaded at the same rate as the anodes, showed any visible signs of tissue reaction.

Conclusions

1. The corrosion rate of aluminum anodes is approximately proportional to the load current density reaching an average steady-state value in 20-30 days after loading.

2. A load current density of 13 $\mu A/cm^2$ or less is desirable for lowering of the tissue reaction and corrosion rate.

3. Histopathological data indicate that aluminum is a more biocompatible anode material than magnesium, magnesium alloy AZ31B, or zinc. Further *in vivo* measurements are being conducted on aluminum and zinc implants in order to more completely characterize the biocompatibility of these anode materials.

4. Magnesium and magnesium alloy AZ31B appear to be unacceptable as an anode material due to their high corrosive rates and poor biocompatibility.

High Power Facility for Testing Electrochemical Power Sources

E. J. Dowgiallo, Jr., J. B. O'Sullivan,* I. R. Snellings, and R. B. Anderson

USAMERDC, Electrochemical Division, Electrotechnology Department, Fort Belvoir, Virginia 22060

ABSTRACT

A 125 kW programmable power supply has been constructed for testing electrochemical propulsion systems and components. This facility has a number of features which are of value to others for use in broader applications. These features are: voltage programmable for both current and voltage levels, change from charge to discharge in a fraction of a second, fast response, low ripple content, and integral load dissipation. Typical applications are: direct control by field generated profiles, simulation of rapidly changing hybrid charge-discharge regimes, and control techniques such as constant power.

Evaluation and characterization of electrochemical propulsion systems and components for the U.S. Army had reached a stage that required a programmable electrical power system for reproduction, modification, and generation of full-scale test duty cycles. A 125 kW thyristor power system with features that satisfied immediate needs and control techniques that will allow for adaptation to a variety of future requirements is described herein.

The program at the U.S. Army Mobility Equipment Research and Development Center, Fort Belvoir, Virginia, requires evaluation of candidate batteries and fuel cells for propulsion and stationary power applications. Propulsion applications involve construction and materials handling equipment. Evaluation and selection of the most applicable battery for a system requires extensive and realistic testing to particular military regimes.

The thyristor power system described here is the third of four test stations designed to meet these needs. To gain a perspective of its purpose relative to the other stations, all their main functions are briefly presented in the order of progression of a candidate electrochemical power source through them. Station (*i*), preliminary check of manufacturer's specifications, acceptance tests, and life cycle tests primarily for single cells. Charges and discharges can be controlled to 10V and 3 kW. Station (*ii*), characterization of systems, load profile tests (25 different preset levels), trial of new test procedures, variable charge/discharge methods, and computer control. Three configurations are available producing maximums of either 8, 16, or 52V, and 14 kW (1). Station (*iii*), the subject of this paper, has the highest power rating of any of the stations and is more oriented toward full scale or prototype testing. It is programmable by actual averaged wave forms obtained from field testing, or by analog voltages from conventional instrumentation. Station (*iv*) (now under development), will have a minimum response time of 20 μsec enabling further examination of fast pulse charging and more detailed load profile simulations. It is also scheduled to be used for special battery studies of dynamic impedance from very low frequencies to about 50 kHz. This station will have a maximum capability of 50V and 6000W.

System Description

The thyristor power system of station (*iii*) was built under contract by Westinghouse Electric Corporation (2). A system was specified that could duplicate the characteristics of conventional chargers and be changed rapidly to extended discharges with an integral dissipation capability. This is, to our knowledge, the first time such a system has been used in this manner. A simplified diagram of the system is shown in Fig. 1. The system may be divided into two main parts: one is a variable regulator, consisting of operational amplifiers, function modules, and referencing and director logic elements; the other is a thyristor power converter, consisting essentially of a thyristor power modulator, a thyristor power transformer, a basic regulator, and converter sequencing and protective elements. The outer controllers, shown in Fig. 1, are initial input shaping networks; while the inner control loop compensates for basic nonlinearities and time delays.

The variable regulator consists of the outer voltage and current limit controllers. They are driven with two programming input voltages: *v* for bus voltage and *I* for output current. These controllers are in parallel and the outputs are connected through a diode switching circuit to a common output terminal. Only one controller is in operation at any one time. The outer voltage controller is in operation as long as the programmed current limit is not reached. The current controller is switched off during this time. When the current limit is reached the current controller takes over and the voltage controller is switched off. Switching in and out of the controllers is accomplished smoothly and quickly due to the characteristics of the operational amplifiers used. A current limit controller is used for each polarity of sensed output current. The maximum current in either direction is limited to 1500A. The gate pulse generator output will be suppressed at 1600A.

The basic regulator includes all the components required to close the inner voltage control loop, to sense bus voltage and current, to sense the demand for and execution of current reversals, and to provide gate pulses to the thyristor power modulator. This regulating loop is used to develop the proper signals for current reversals and it helps to overcome the nonlinearities of the power converter when going through a current reversal. This loop makes it possible to consider the converter system for the outer (variable)

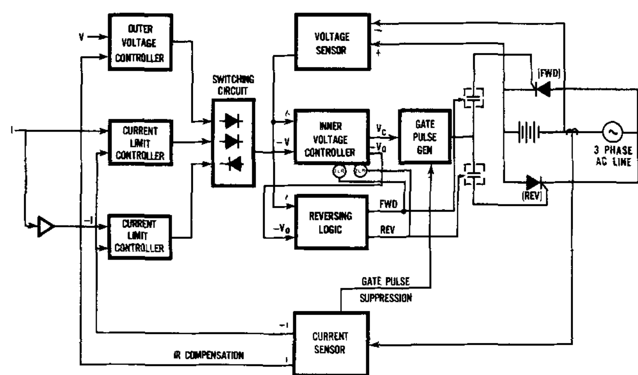

Fig. 1. Regulator system diagram with parallel voltage and current controllers.

* Electrochemical Society Active Member.

Key words: controller, simulator, charger.

regulator loops as a "black box" amplifier with nearly ideal characteristics (3). A brief description of the operation of this inner loop follows. The bus voltage, v, is picked up by the voltage sensor and brought to one input of the inner voltage controller. There it is compared with the reference voltage $-V$ applied at a second input. Depending on the polarity of the difference of the two voltages, the output voltage $-Vo$ will swing negative or positive. By comparing this output voltage $-Vo$ with the bus voltage v, the polarity of converter conduction can be determined. For example, if the bus voltage v is smaller than the reference signal V, forward load current conduction is indicated, and therefore the forward channel of the dual converter should be pulsed. Under this condition, $-Vo$ is negative, and when compared with v at the input of the reversing logic module will result in its output picking up relay 1CR and closing the gate pulse distribution switch to the forward converter. If now the reference V is suddenly reduced to demand reverse current, the opposite sequence of events will take place.

The main power stage, on the right hand of Fig. 1, is a dual type converter which can provide output current in either direction. This consists of an autotransformer in a wye-delta connection, as shown in Fig. 2. The delta transformer drives a thyristor power modulator which converts three-phase, a-c power into voltage adjustable d-c power. The modulator assembly contains 24 thyristors; half for forward (charge) and half for reverse (discharge) operation. The thyristors are connected in a six-phase, double-way circuit. The assembly also has all the necessary voltage protecting networks, current limiting fuses, pulse distribution panel and pulse transformers, and current sensing transformers. The six-phase, double-way converter circuit requires that two legs are conducting simultaneously to complete a current path through the battery. Gating pulses, from the gate pulse generator, occur every 60° and are channeled sequentially to each of the six legs of the converter circuit. This produces six peaks per a-c line cycle for reduced direct voltage ripple and distortion of the alternating current. Figure 2 shows an abbreviated dual converter, antiparallel circuit showing one of the four thyristors in each leg.

The forward (charge) thyristors are labeled with an F and the reverse (discharge) thyristors with an R. Consider the moment when the voltage of V-U is zero and the voltages of U-W and V-W are, respectively, $\sqrt{3/2}$ and $-\sqrt{3/2}$ of their maximum values. At this time 1F and 6F are conducting (rectifying) in the

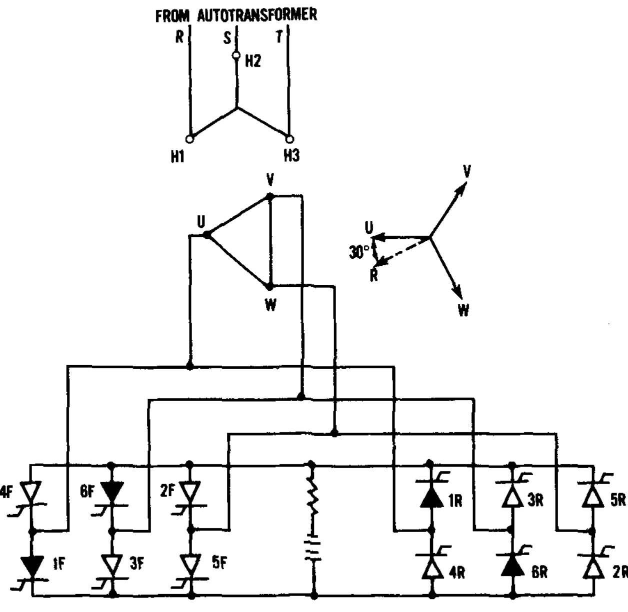

Fig. 2. Dual converter, antiparallel circuit

forward direction thereby charging the battery with a voltage determined by the programming reference voltage. In the discharge mode, the forward (F) thyristors are off, and for the same condition as above but with reverse polarities, 1R and 6R would be gated on. This would effectively reverse the battery current. The system now operates in the inverter mode. It is, in effect, a line controlled inverter with the line and system absorbing the battery current. The gate pulse generator gating angle change, determined by the programmed current demand, causes the average output voltage to be enough below the battery voltage to produce the desired current. The difference is determined by the loop drop. This inverter feature eliminates the need for large banks of load dissipation resistors. The system can be operated continuously up to 125V at 1000A d.c., and, in overload to 1500A for a duration of 30 sec.

System Characteristics

The fluctuation of the d-c voltage about the average value was measured in terms of the root-mean-square (RMS) value. The effect of different autotransformer connections on the ripple was of interest. The results are shown in Table I. The connections were made for 125V d.c. (208V a.c.) and 50V d.c. (83.2V a.c.). A fork lift truck battery was connected at the output and run in the charge mode for the ripple measurements. The per cent change of ripple voltage to the output d-c voltage was improved for the 50V connection to one-tenth of that at the 125V connection. The current ripple was approximately 2A for the 50V connections and 6A for the 125V connections. The inherent ripple in a three-phase, full wave bridge is 4.5% RMS. The system uses an inductive input "L" filter before the output terminals to reduce the ripple. Its unipolar electrolytic capacitors have protective diodes to prevent voltage reversals. A typical battery may have capacitance values in farads at 360 Hz which also reduces the ripple (4).

The output circuit is transformer isolated from the input; either a positive or negative d-c bus can be grounded. Other similar units can be connected in series to 600V. The autotransformer can be wired for 228V a.c., thereby raising the output voltage in the present system to 137V. The system has many protection features. The major ones are a d-c circuit breaker with combined instantaneous magnetic trip and current limiting protection, an overload heater trip, surge suppressors for overvoltage and dV/dt protection, thyristor fuses, and a protection switch for thyristor over temperature; and finally in case of an a-c power failure, the system will draw less than 50 mA from a 36V fork lift battery.

Total drift in output over an 8 hr interval under constant line, load, and ambient temperature following 30 min warm up was 0.03% for a constant voltage of 40V and 0.03% for a constant current of 500A.

The system has an automatic crossover characteristic that changes the method of regulation from constant voltage to constant current (or vice versa) as dictated by varying load conditions. This is often used in charging batteries where a maximum initial current level is held until battery voltage reaches a preset upper limit after which current drops to a leakage level. To evaluate this capability, system current was set for a maximum of 90A. A load was varied from zero current to short circuit. The difference between an initial falloff of current and the short circuit current expressed as a percentage of the maximum set

Table I. Voltage ripple measurements

Maximum voltage connection (V)	Output voltage (V)	Output current (A)	Ripple voltage (True RMS V)	Per cent ripple (%)
125	41.3	291.0	0.418	1.0
50	41.3	291.0	0.045	0.1

Table II. System efficiency

Input a.c. power (kW)	Output d.c. Voltage (V)	Output d.c. Current (A)	Output d.c. Power (kW)	Efficiency (%)	Dissipated power (kW)
120.600	118.5	960	113.760	94	6.840

current was measured at less than 1% for 30V and 90A.

The efficiency of this system is much higher than any other means of conversion, approaching 93% at rated load and rated volts. Efficiency was calculated based on measurements made with a two-element, polyphase wattmeter with two current transformers on the three-phase a-c input and d-c output power based on the product of measured volts and amperes (5). The system input autotransformer taps were connected for 125V d.c. The a-c meter indicates the average impulse (integral of power over a cycle) and corresponds to the true average power, regardless of the power factor, and is true for nonsinusoidal currents and voltages of any wave form (6). The measurements were made using a load bank. The results are given in Table II.

Input-output correspondence was within 1% for any incremental current programming voltage change from 50 to 1500A and for any incremental voltage programming voltage change from 6 to 50V for the 0-50V range.

Remote programming response is shown in Fig. 3. The upper wave form was applied to the programming voltage input. The two levels of -0.4 and -4V correspond to ouput voltages of $+5$ and $+50$V, respectively. The current programming voltage was fixed at -6.67V producing 1000A output. A fork lift battery was connected at the output, the current level changed from $+1000$ to -1000A depending on whether the programmed voltage was above or below the battery voltage. The time to change the full current range was about 0.2 sec.

Applications

To summarize, the system can be viewed as a low frequency, d-c amplifier that can be driven by two 0 to -10V inputs, one for a range of ± 1500A and the other to $+125$V with a response time of less than about 0.1 sec to 1000A. These features can be utilized for simulation of field recorded duty cycles for tests of prototype batteries. Such tests as life cycle and battery system comparisons could be performed at fractions of the field test costs without further costly battery development. An example of the system ability to simulate a field load profile is shown in Fig. 4. The input profile is from a magnetic tape recording of a 4000 lb fork lift truck on a standard military test (7). The current wave form was averaged by a filter prior to recording since the truck current is frequency modulated from about 30 to 150 Hz. The load profile is reproduced with some attenuation of fast spikes due to the previously described response characteristics. In preliminary tests of 6 hr profiles the battery discharged in about the same time as in the field runs. This demonstrated, in a limited way, that smoothing the wave

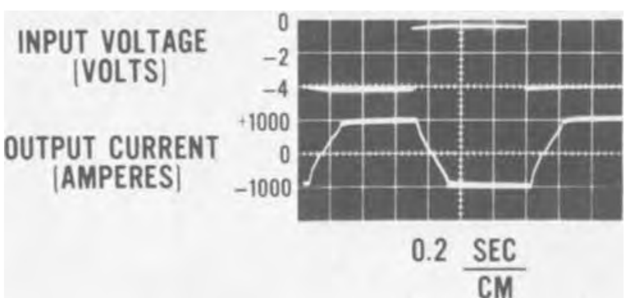

Fig. 3. Remote programming response

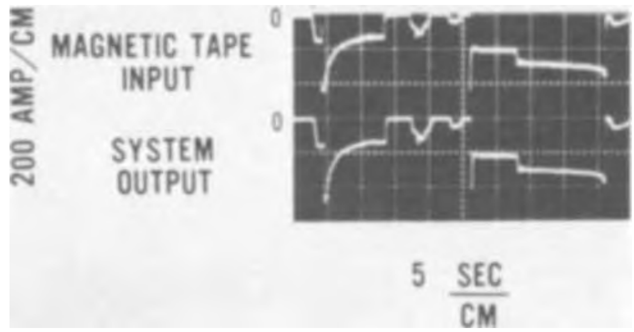

Fig. 4. Fork lift vehicle load profile simulation

form does not significantly effect the simulation of field discharges.

A computer driven digital to analog output channel was also used to produce several precalculated fork lift load profiles which consisted of various voltage levels for durations based on fork lift operations. The profiles were used in both constant current and constant power discharges by driving the system with recordings of the analog outputs. The system can be directly driven by a computer for any desired load profile. An automated control scheme with erasable programmable read only memory chips for making test changes is under development (8).

Testing batteries under constant power discharge conditions is desirable. The energy a battery can produce at constant power accelerations and the number of fixed duration accelerations are conveniently revealed. Horsepower profiles can be easily simulated as input power levels. An external power control circuit that is a modification of one based on voltage-current multiplication incorporated into station (*ii*) is used to control the thyristor power system (9). In this control scheme an analog division circuit is used. The battery voltage is one input and an analog voltage representing power is the other input. The battery voltage is divided into the reference power level (P), and the output voltages (v) is fed to the current programming input (I) of the thyristor power system with its output connected across the battery. The formular $I = P/V$ is thereby implemented. Constant power discharges or charges can be performed to 187.5 kW for 30 sec or continuously at any level below 125 kW. The results of a constant power discharge on a fork lift battery are shown in Table III. The voltage decreased 43% and the current increased 56% while power was held to less than a 3% decrease.

Future Applications

Simulation and other tests requiring rapidly changing wave forms will be performed with four programmable transistorized load banks. The combined dissipation to 50V is 6 kW (10, 11). The step response time is 20 μsec for 0-30A and 1.2 μsec/A above 30A. This will permit simulation of actual wave forms for battery system comparison tests and depolarization pulses for fast charge studies and for hybrid development where the power battery may only be drained on rapidly changing peaks.

A hybrid fuel cell-battery system development is being planned. The fuel cell energy source will be sized for the average power while the battery power source will be sized to provide short duration power when the load is above the average and to accept

Table III. Constant power discharge variation

Elapsed time (hr)	Voltage (V)	Current (A)	Power (W)

1	34.78	184.6	6420
2	33.15	192.6	6385
2.77	22.18	281.6	6246
Per cent change based on avg. of 415 readings	−43%	+56%	−3%

power when the load is below average. This requires a test that will effectively reproduce field recorded wave forms. An investigation is planned to determine if the net difference between a smoothed current and its corresponding actual wave form is significant for fork truck discharges. These tests will be performed on scaled-down fork truck batteries that have power ratings compatible with the transistorized load banks. If significant errors are found, a means of modifying the smoothed programming current for correction will be studied. Preliminary field data indicate that less than 30% of the discharge time is spent under solid-state control during which the current is pulsing. The resistive losses resulting from use of an averaged wave form are in appreciable error only during periods in which the "on time" is a small per cent of the total. Since this occurs only at low average power levels during which the over-all losses are low it is felt that a large percentage error during a time of small loss will not significantly effect the cumulative losses.

Conclusion

The thyristor power system eliminated both the need for switching a contactor to reverse current flow and the large dissipating resistors required for battery discharge with conventional power supplies. The contactors life would be extremely short under fast multiple charge-discharge regimes characteristic of hybrid power sources where current may change direction several times in 1 min. High current and low maintenance requirements exceeded motor generator capabilities. The system has a demonstrated efficiency that is much higher than any other means of conversion. This system makes possible the testing of full size electrical power sources with maximum monitor, accurate control, and fast test change without the necessity for expensive field operation.

The capabilities and applications described here, will, it is hoped, demonstrate what is possible today and serve as a stimulus for the development of new uses by those involved in other areas of electrical power source development.

Passivity and Pitting of Ni-Cu Alloys in NaCl Solutions

T. Koizumi[1] and H. H. Uhlig*

Department of Metallurgy and Materials Science,
Massachusetts Institute of Technology, Cambridge, Massachusetts 02139

ABSTRACT

Passsivity of the Ni-Cu alloy series in NaCl solutions is evaluated by means of potentiostatic polarization curves and by measurements of critical pitting potential. Passivity is observed only in alloys of >40% Ni, the actual critical Ni content depending on Cl^- concentration, sulfate concentration, and pH. Pitting of Ni-Cu alloys is expected and corresponding critical pitting potentials are found only in environments favoring stable passivity.

The passive properties of Ni-Cu alloys in 1*N* H_2SO_4 have previously been studied in detail employing potentiostatic anodic polarization curves (1, 2). According to these studies, passivity is clearly a property of Ni and of the high Ni alloys, but not of Cu or low Ni alloys. The critical Ni composition below which a passive-active transition is no longer observed comes at 30-40% Ni. This critical composition has been related to the approximate filling of the vacant d-band of energy levels in Ni (0.6 vacancy per atom) by electrons supplied by alloyed Cu (1 electron per atom). On this basis, only alloys containing unfilled d-band energy levels have passive properties. In this respect, added solid solution elements contributing more than one electron per atom, *e.g.*, Al, Zn, Ga, shift the critical composition of Ni-Cu alloys to higher Ni values. On

Key words: critical pitting potential, electron configuration theory of passivity, potentiostatic polarization curves.

the other hand, those elements adding electron vacancies, *e.g.*, alloyed Fe, Co, Mn, shift the critical Ni composition to lower values (3-7).

But passive properties are not only a function of alloy composition; the environment also plays a role. Pure Ni, for example, loses its passivity in dilute HCl solutions. Also an increasing neutral NaCl concentration tends to break down passivity of otherwise passive Ni-Cu compositions. The question is: How does the factor of electron configuration applying to the passive properties of Cu-Ni alloys in 1*N* H_2SO_4 explain the behavior of such alloys in NaCl solutions varying both in concentration and *p*H?

North and Pryor (8) studied the behavior in NaCl solutions of Cu-Ni alloys containing up to 40% Ni. Here, as their polarization measurements confirmed, the alloys are not passive; that is a passive current density is not a characteristic of their potentiostatic polarization curves. The small deviations in current density which they observed in the Flade potential region at relatively high sweep rates were probably caused by temporary films of soluble or porous corrosion products accumulating on the alloy surface. With slower sweep rates, such discontinuities disappeared and hence the responsible films were not the same as the passive films which typically persist at low sweep rates. Their studies focused mainly on the nature of thick oxide films, protective in some degree as diffusion barriers on Cu and on the low Ni-Cu alloys, but with only limited influence on anodic polarization characteristics typical of truly passive films as discussed above.

Leckie (9) found that protective films are also formed on pure Cu, *e.g.*, in 1*M* H_2SO_4 at 0°C or in 10*M* H_2SO_4 at 25°C, or in 0.01-1.0*M* NaOH at 25°C which affect anodic polarization characteristics in potentiodynamic measurements. But these environmental conditions favored insoluble surface reaction products, which combined with characteristics of the reported potential decay characteristics, suggest that relatively thick diffusion barrier films were responsible, rather than the much thinner passive films typical of Ni. The diffusion barrier films have passive properties in accord with definition 2 of the Corrosion Handbook (10) (low reaction rates of metals having a pronounced thermodynamic tendency to react) whereas the thin passive films imparting marked anodic polarization characteristics follow definition 1 and its supplement proposed by Wagner (11). Only the latter type films can give rise to passive-active cells of appreciable potential difference responsible for rapid localized corrosion (pitting).

Since deep pitting corrosion is typical of the higher Ni alloys it is of interest to know how the critical pitting potential varies with Cl^- concentration and with temperature. Data of this kind are presently reported. They are useful in applying Ni-Cu alloys to sea water environments, desalination equipment and for condenser tube applications in general, where pitting corrosion can be especially damaging.

Experimental

Alloys were prepared by induction melting in vacuum employing dense pure alumina crucibles. After melting was completed, the furnace was filled with purified argon; ingots were cast by drawing the melt into 7 mm diam Vycor tubes and were water quenched. The ingots were then homogenized in pure argon at 950°C for 20 hr, swaged to 0.42 cm diam, annealed at 750°C for 1 hr, and water quenched. Nickel was carbonyl grade (courtesy of International Nickel Company) and the copper was 99.999% pure. Chemical analyses of the various alloys are given in Table I.

Electrodes were machined to cylinders of about 0.40 cm diam, 1 cm long, then drilled and tapped at one end allowing attachment of a threaded small diameter nickel wire. The nickel wire was enclosed within a glass tube; a water-tight seal was maintained by means of a Teflon gasket between electrode and glass tube held firmly in place by a rubber grommet, washer and nut attached to the nickel wire at the other end. Specimens were polished with emery paper and then pickled in dilute nitric acid to remove any cold-worked surface.

64.7	35.3

The electrolyte for most experiments consisted of various concentrations of NaCl deaerated with purified nitrogen for several hours. Temperature of the air thermostat in which measurements were conducted was 25° ± 0.2°C.

For measuring the critical pitting potential, the procedure was to first polarize the electrodes continuously within the least noble passive region for 30 min in order to achieve steady-state passivity. The potential was then advanced in 40 mV steps, recording the corresponding current after a 5 min wait at each potential. The provisional critical potential was the least noble value at which the current decreased or remained constant in time, whereas just above such a potential the current increased attended by pitting. Additional points were separated at smaller potential intervals in the region of the critical potential. The final value was obtained by polarizing the electrode at a potential just at or below the approximate critical value for a period of several hours and observing the absence of pits employing a low power microscope. No crevice corrosion normally occurred at the Teflon gasket interface; if it occurred, the measurement was repeated.

The critical alloy compositions dividing passive from nonpassive compositions were determined by measuring anodic polarization curves stepwise in deaerated NaCl solutions. The existence of a passive current density smaller in some degree than the critical current density for passivity, and persisting regardless of the time spent at a given potential, defined a passive composition in accord with the definition of passivity proposed by Wagner (11).

Results

The effect of alloy composition on passivity in neutral 0.5*N* NaCl is shown by typical potentiostatic anodic polarization curves in Fig. 1. It is obvious that the 65.8% Ni-Cu alloy is not passive in this solution, whereas all the higher Ni composition alloys exhibit a

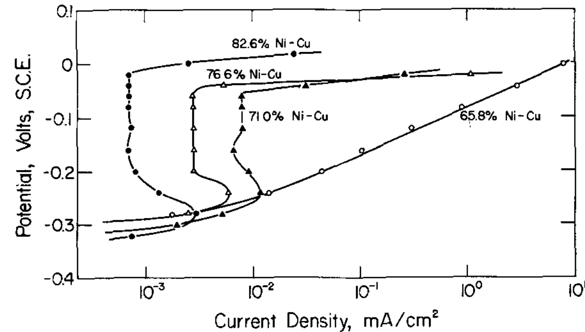

Fig. 1. Potentiostatic anodic polarization curves of Ni-Cu alloys in deaerated 0.5*N* NaCl, 25°C. Stepwise change of potential.

passive region. The sudden upturn of current at specific potentials for the passive compositions corresponds to the onset of pitting corrosion. Pitting initiates at any potential noble to such critical values, but not below.

Figure 2 shows similar typical anodic polarization data for the 82.6% Ni-Cu alloy in various concentrations of NaCl, other than 0.5*N* NaCl shown in Fig. 1. The alloy is passive in 1*N* NaCl and in more dilute solutions, but not in 2.5*N* or 5.0*N* NaCl. A summary of data dividing passive from active compositions as a function of nickel content in a variety of neutral NaCl solutions is shown in Fig. 3. These data plus analogous data obtained at pH 3 and 9 are collected in Fig. 4. At *p*H 3, even spectroscopically pure Ni loses passivity in 1.0*N* NaCl and above, whereas alloys containing less than about 68% Ni lose passivity at and above 0.01*N* NaCl. At *p*H 9, the latter composition alloy retains passivity in 5.0*N* NaCl, showing that pH as well as NaCl concentration is an important factor establishing conditions for passive behavior. Significantly, all alloys lose passivity regardless of *p*H or presence of Cl^- ions below 40% Ni, in agreement with previous results reported by North and Pryor (8). This composition corresponds to the critical composition for passivity established by anodic polarization data in 1*N* H_2SO_4 and which is explained by the electron configuration theory. In other words, chlorides can break down passivity of normally passive alloy compositions, but higher Cl^- concentrations are required the higher the Ni content of the alloy, and less Cl^- ion is required the lower the *p*H of the solution. Furthermore, since the minimum alloy composition for passivity at *p*H 9 remains at 40% Ni, hydroxyl ions exert no special passivating effect on alloys containing less than 40% Ni.

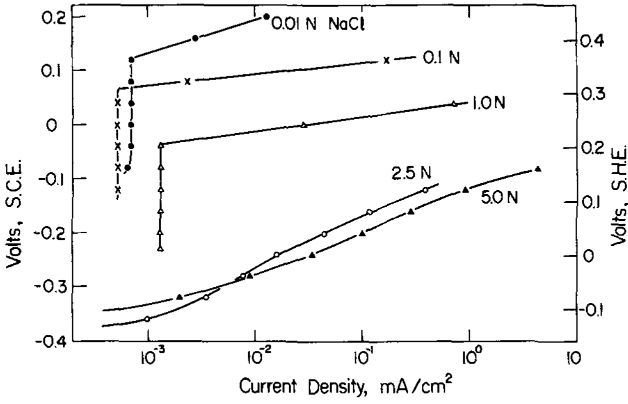

Fig. 2. Potentiostatic anodic polarization curves of 82.6% Ni-Cu alloy in NaCl solutions, 25°C. Stepwise change of potential.

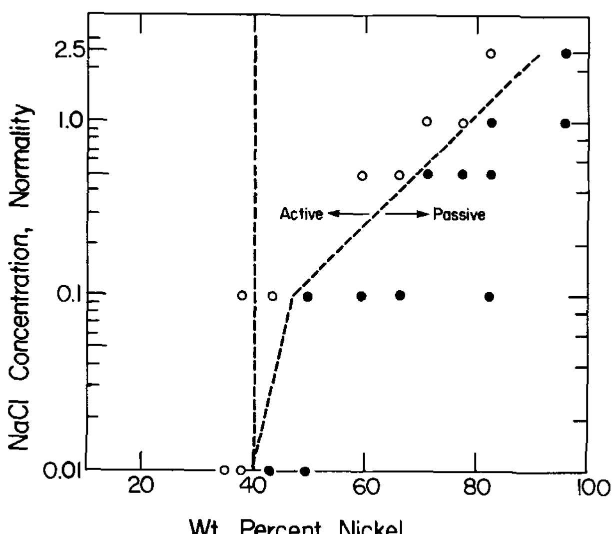

Fig. 3. Effect of NaCl concentration on loss of passivity in Ni-Cu alloys, 25°C.

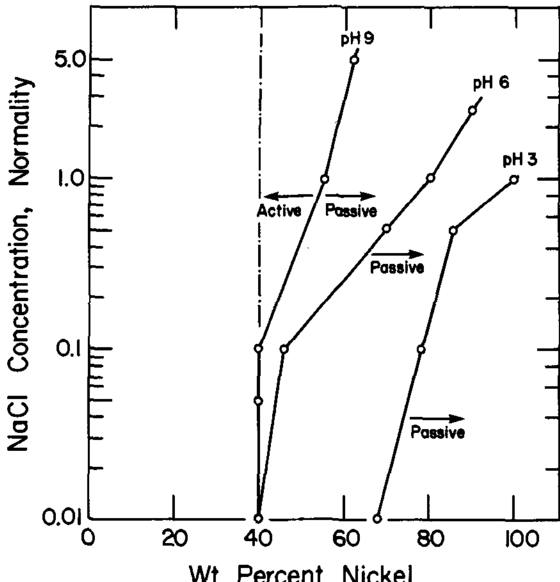

Fig. 4. Effect of NaCl concentration and *p*H on loss of passivity in Ni-Cu alloys, 25°C.

Sulfate ions are not as effective as Cl^- ions in breaking down passivity. If Na_2SO_4 is added to neutral NaCl solutions, the higher the molal ratio of sulfate to chloride the more nearly does the critical alloy composition for passivity approach the minimum value of 40% Ni for all Cl^- concentrations. The effect is appreciable for 1.0*N* NaCl as shown in Fig. 5, but it is small at 0.1*N* NaCl and it disappears entirely at 0.01*N* NaCl. At the latter dilute NaCl concentration, chloride ions alone or in presence of sulfates do not destroy passivity of any of the Ni-Cu alloys.

Zamin and Ives (12) showed from anodic polarization curves that Ni does not become passive at a molal ratio $SO_4^{--}/Cl^- = 0.5$ in 0.5*N* H_2SO_4 indicating, on comparing with data of Fig. 5, that in these solutions as in NaCl solutions (Fig. 4), breakdown of passivity occurs more readily in acid compared to neutral solutions. Similar data of Szklarska-Smialowska (13) also suggest that anodic passivation of Ni is disrupted at a lower concentration of Cl^- in 0.1*N* H_2SO_4 than at 0.1*N* Na_2SO_4.

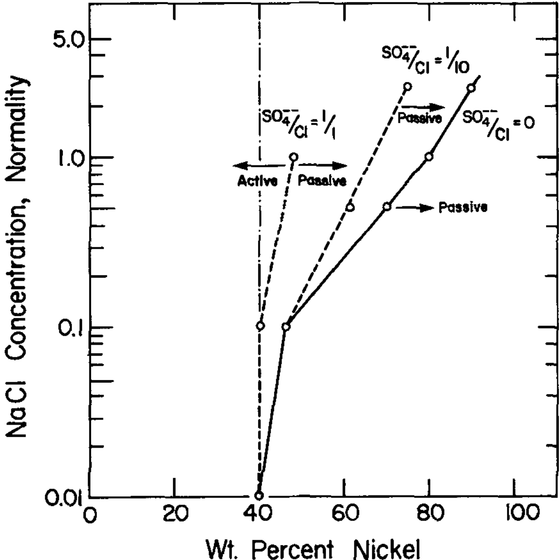

Fig. 5. Effect of sodium sulfate additions to sodium chloride solutions (molal ratios) on loss of passivity in Ni-Cu alloys, 25°C.

Critical Potential for Pitting

Because pitting potentials refer to values at which the passive film is broken down locally by Cl^-, values can be measured only for passive alloy compositions, *i.e.*, > 40% Ni in dilute NaCl solutions (0.01*N*) and > 45% Ni in 0.1*N* NaCl. Steady-state values in 0.1*N* NaCl for passive compositions are plotted in Fig. 6. The maximum potential corresponding to maximum resistance to initiation of pitting corrosion is observed at about 85% Ni. The values for Ni, however, depending on source, are shown to fall between 0.21 and 0.26V (SHE). The upper value lies relatively close to the value of 0.28V reported earlier by Horvath and Uhlig (14). Obviously, the critical potential for Ni is surprisingly sensitive to purity of the metal, and this effect very likely enters values reported for the high Ni alloys as well. For example, the critical potential for a commercial 69% Ni-Cu alloy (Monel) lies 0.05V below the interpolated value for the corresponding laboratory melted 69% Ni-Cu alloy (Fig. 6). The difference is far outside the experimental variations of such measurements and indicates the relative order of deleterious effects on pitting resistance induced by impurities common to the commercial alloy. The nature of the responsible impurities has not been investigated; they probably do not include Al or Fe as was shown by preparing alloys of 69-70% Ni-Cu containing 1.1 and 2.1% Fe and 1.1 and 2.4% Al. The critical pitting potentials of these alloys in 0.1*N* NaCl were all the same within ± 10 mV compared to the 50 mV displacement in the active direction for Monel.

It is not certain that the value for spectroscopically pure nickel should receive greater weight than the value for commercially pure nickel because of the as yet unknown influence of small amounts of nonmetallic impurities present in the spectroscopically pure material. Heat-treatment of spectroscopically pure Ni was not a factor; the critical potential of the electrode water quenched from 1050°C remained at the same value as before heat-treatment.

The effects of NaCl concentration on critical potentials for Ni and two Ni-Cu alloys are shown in Fig. 7. "Active" designates the approximate NaCl concentration above which uniform passivity breaks down. On the average, the potential becomes more active by about 0.075V for a tenfold increase of NaCl concentration. This can be compared with a corresponding 0.085V change in the active direction for 18-8 stainless steel (15).

The effect of lowering the temperature is to increase the critical potential relative to (noble to) the room temperature value. There is less effect at temperatures above room temperature (Fig. 8). Temperature effects are more pronounced for Ni than for the 84.9% Ni-Cu alloy; they are both less than the temperature effects measured for 18-8 stainless steel (15) but they are correspondingly greater than those measured for aluminum (16).

Discussion

Anodic polarization data show that the passive film can be destroyed uniformly by increasing the Cl^-

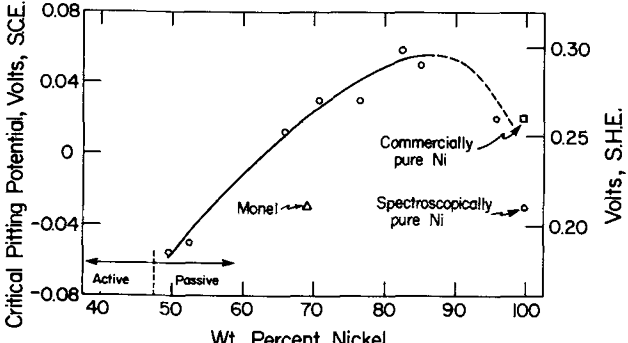

Fig. 6. Critical pitting potentials of Ni-Cu alloys in 0.1*N* NaCl, 25°C

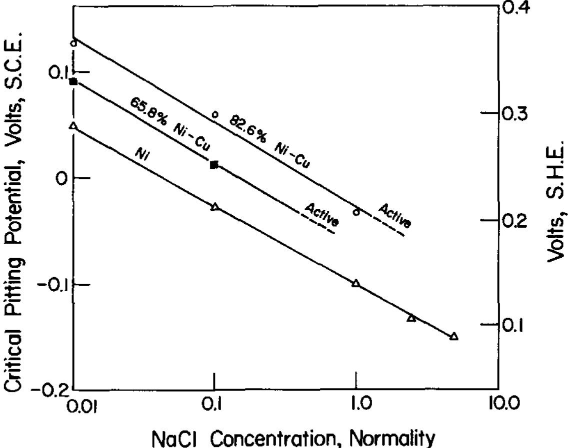

Fig. 7. Effect of NaCl concentration on critical pitting potentials of spectroscopically pure nickel and of Cu-Ni alloys, 25°C.

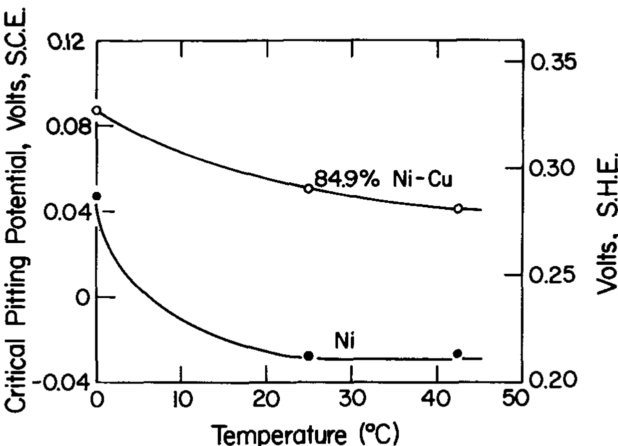

Fig. 8. Effect of temperature on critical pitting potentials of spectroscopically pure Ni and of 84.9% Ni-Cu alloy in 0.1*N* NaCl.

concentration sufficiently, or it can be broken down locally at lower Cl^- concentrations by shifting the applied potential to more noble values. The present data confirm that a passive film as presently defined exists only on alloys containing about 40 or more per cent Ni, whether in sulfuric acid, in acid or alkaline NaCl solutions, or in neutral NaCl plus Na_2SO_4 solutions.

Nickel alloys of > 40% Ni better resist uniform breakdown of passivity in chloride media the higher the Ni content. This behavior is in line with the more active Flade (decay) potentials observed for Ni-Cu alloys as the Ni content increases (2), corresponding to increased stability of the passive film (17). Extraneous anions like sulfate or hydroxyl, which are less effective than chloride ions in breaking down passivity, when added to NaCl solutions decrease the effectiveness of the chloride ion. In this regard, the extraneous anions compete for sites on the passive surface, hence the passive film is stable at lower Ni composition alloys in a mixture of chloride and sulfate or hydroxyl ions, than in chloride ions alone.

The apparent maximum in critical pitting potential at about 85% Ni has no obvious explanation based on passive properties of these alloys. The conclusion is plausible as mentioned earlier that the maximum is probably not real but represents an impurity effect instead. This conclusion, however, should be verified by additional measurements on carefully purified nickel excluding not only spectroscopically identifiable metallic impurities, but also nonmetallic impurities, *e.g.*, carbon. An effect of degree of purity of Ni on passive properties was also noted by Mansfeld and

Uhlig (2) in their reported potential decay curves in 1N H_2SO_4.

The effect of below-room temperature to increase the critical potential to more noble values parallels the situation for 18-8 stainless steel, but with a smaller comparable temperature effect for nickel and for 84.9% Ni-Cu. The effect, as was proposed for 18-8 stainless steel (15), may be one of more pronounced hydration of the passive film at low temperatures. Hydration may serve to stabilize the film against disruption by Cl^- which proceeds by an exchange mechanism between Cl^- and the adsorbed oxygen presumably making up the passive film (18). It is less likely that the passive film, conceived as a supposed thick oxide, becomes a better diffusion barrier at low temperatures, *e.g.*, 0° compared to 25° or 40°C. A thick oxide film is probably a source of improved corrosion resistance only in alloys that are not passive as presently defined, *i.e.*, < 40% Ni.

The present results further emphasize that since pitting corrosion occurs only in presence of a passive film as presently studied, only the Ni-Cu alloys containing > 40% Ni are subject to this type of corrosion. Furthermore, > 40% Ni alloys are susceptible only within ranges of NaCl concentration and *p*H for which the passive film remains intact (Fig. 4). For example, the 70% Ni-Cu alloy would in principle be susceptible to pitting corrosion in aerated 0.01*N* NaCl, *p*H 3 in which it remains passive, but it would not be expected to undergo pitting corrosion in 0.1*N* NaCl or higher concentrations of Cl^- at this same *p*H in which it is active. In aerated neutral NaCl solution it would be subject for the same reasons to pitting damage below 0.5*N* NaCl, but not above.

Conclusions

1. Passivity in NaCl solutions of any concentration is observed only in copper alloys containing > 40% Ni. Breakdown of passivity occurs at increasingly higher Ni compositions the higher the Cl^- concentration and the lower the *p*H.

2. Sulfate and hydroxyl ions added to NaCl solutions shift the alloy composition at which loss of passivity occurs to lower Ni compositions, but not below 40% Ni where the d-band of electronic energy levels is filled.

3. The critical pitting potentials become more noble the higher the Ni content of the alloy. This is in line with more active Flade potentials and increased stability of the passive film as the Ni content increases. The critical pitting potentials for Ni and high Ni-Cu alloys (*e.g.*, Monel) are appreciably sensitive to unknown impurities in the metal.

4. The critical pitting potentials become more active with increasing Cl^- concentration, and for Ni and 84.9% Ni-Cu alloy become more noble at 0°C compared to 25° and 40°C.

The Anodic Polarization Behavior of Nickel in Acidic Chloride Solution

M. Zamin* and M. B. Ives

Institute for Materials Research, McMaster University, Hamilton, Ontario, Canada

ABSTRACT

The effect of grain size and cold work on the anodic polarization behavior of polycrystalline nickel in acidic chloride solution has been investigated using potentiostatic techniques and *in situ* microscopic observations. A variation in grain size from 0.025 to 0.330 mm and cold working to 40% does not affect the critical breakdown potential. It is concluded that the critical breakdown potential is not an adequate measure of the electrochemical conditions required for pitting corrosion of nickel.

It has generally been believed (1-3) that metals undergo pitting corrosion only beyond a certain critical potential (E_c). This potential has served as one of the fundamental electrochemical criteria characterizing the susceptibility of metals to pitting corrosion. It is believed (4) that at more negative potentials than E_c the metal exists in a passive state, while above E_c, active and passive states coexist on the metal surface giving rise to pitting corrosion. Thus, the more positive is E_c, the more resistant is the metal to pitting corrosion.

* Electrochemical Society Student Member.

Key words: anodic polarization behavior, critical breakdown potential, *in-situ* microscopic observations, grain size, cold work.

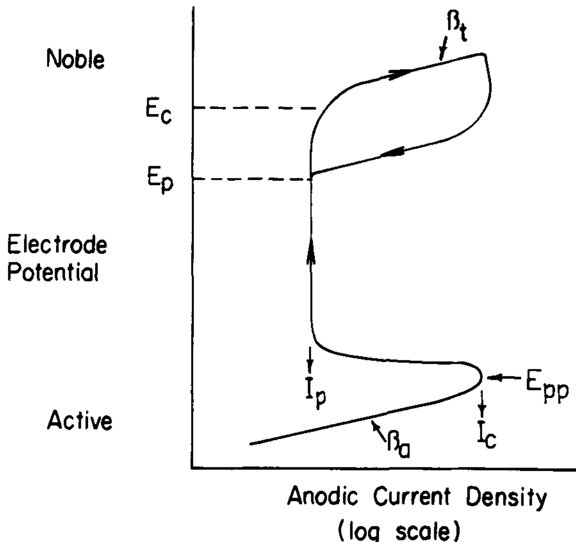

Fig. 1. Schematic representation of the breakdown potential (E_c) and the protection potential (E_p). Other symbols used in the text are also represented.

Pourbaix *et al.* (5) have distinguished two types of critical potentials: breakdown potential (E_c), the potential corresponding to a rapid increase of the current due to pit nucleation, and protection potential (E_p), the potential corresponding to the current drop during the reverse potential sweep, caused by the repassivation of the pits (Fig. 1). According to Pourbaix, within the range E_p to E_c propagation of already existing pits continues, but nucleation of new pits is restrained, occurring only when $E \geqq E_c$. However, Wilde (6) has shown that E_p is not a unique property of a metal and depends on the length of time a pit has been growing.

The effect of cold work on nickel single crystals has been found (7) to increase the passive current density but to decrease the primary passive and critical breakdown potentials. On the other hand, austenitic stainless steels in 3% NaCl solution exhibit no difference in the E_c values of cold-worked and annealed specimens (8). However, on the cold-worked samples, the pits are smaller and more numerous. The invariance of E_c with cold work has also been supported by Smialowska and Czachor (9) on 16 Cr-Fe. In this case, no difference was observed in pit density.

Tomashov *et al.* (10) measured the effect of grain size on the E_c values of Ni-Cr steels. They found that E_c shifted toward more noble potentials when the grain size increased from 0.005 to 0.07 mm; at greater sizes than 0.07 mm, E_c was constant. This behavior was interpreted on the basis that small grain size specimens contained more grain boundaries with "heterogeneous inclusions."

It is shown in this paper that the critical breakdown potential (E_c) does not adequately describe the electrochemical conditions required for pitting corrosion of nickel.

Experimental Procedure

The nickel used in this investigation was "low-oxygen nickel" supplied by Falconbridge Nickel Mines Ltd.[1] The material was received as cold-rolled sheets prepared directly from refined cathode material.

Specimen preparation, corrosion cell, potentiostatic circuit, and polarization procedure have been described elsewhere (11, 12). Specimens of 0.36 cm^2 area were metallographically polished to 1 μm diamond. The polarizing solution containing 2 mliters 1*N* NaCl/100 mliters 1*N* H_2SO_4 was flushed with pure dry nitrogen for an hour before commencement of the experiment and the bubbling of nitrogen was continued throughout the experiment. The temperature of the solution was maintained at 24° ± 1°C. Potentials were measured with reference to a saturated calomel electrode (SCE) using an agar-agar salt bridge and the values reported do not incorporate any corrections for junction potentials.

The equilibrium corrosion potential, E_{corr}, was obtained by allowing the specimen to stand in solution and monitoring the potential until a drift of less than 5 mV in 15 min was obtained.

Two types of metallurgical treatments were adopted: annealing (to modify the grain size) and cold working. Initially, the annealing was done in air. However, for large grain sizes, the results obtained depended on the time period and temperature of anneal. Hence, as a standard procedure, annealing was performed in vacuum. The nickel sheet was cut into strips and sealed in a quartz tube under vacuum (< 10^{-5} Torr) before placing in a crucible furnace. The starting material for grain-growth anneal was 1 mm thick, "as-received," nickel sheet.

Cold working was achieved by rolling. The sheet was cut into strips and rolled to various degrees of cold work, defined as the percentage reduction in thickness.

The measurement of the grain size was performed using the ASTM nonferrous grain size standard (13). The microstructure was revealed by etching for about 5 sec in a 1:1 solution of nitric acid (conc) and acetic acid (ice-cooled).

Results

The anodic polarization curves for eight specimens with grain size ranging from 0.025 to 0.330 mm are shown in Fig. 2. All specimens exhibit an active-passive transition. The anodic dissolution parameters, the anodic Tafel slopes (β_a), and the slopes in the transpassive region (β_t) are summarized in Table I.

It can be seen that the value of the critical breakdown potential (E_c) is the same in every case and, within the limits of calculational error, the values of the other parameters do not change significantly over the grain size range.

A definite trend was observed in the nature of the attack in these specimens. At lower grain sizes (0.025-0.035 mm) pits were formed only along the grain boundaries (Fig. 3a). As the grain size increased to 0.060 mm both grain boundary and grain interior pitting occurred (Fig. 3b). Beyond a grain size of 0.080 mm, pits were formed only within the grains, and their density increased with grain size (Fig. 3c and 3d).

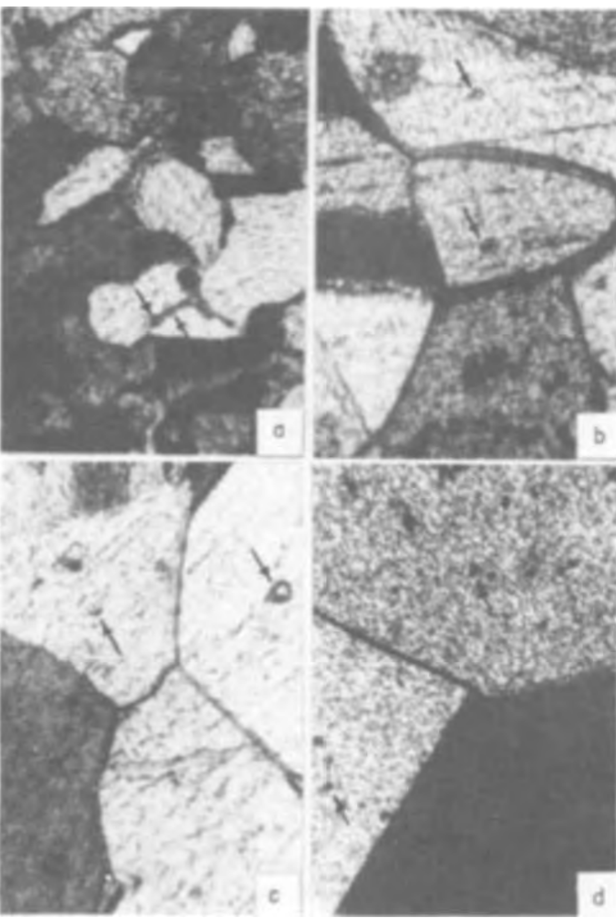

Fig. 3. Nature of attack on polycrystalline nickel with varying grain size in 2 mliters 1N NaCl/100 mliters 1N H_2SO_4 after polarization to +1200 mV (SCE). (a) Grain size = 0.025 mm, 360×. (b) Grain size = 0.060 mm, 360×. (c) Grain size = 0.100 mm, 360×. (d) Grain size = 0.330 mm, 180×. The arrows indicate some regions of localized attack.

In-situ microscopic examination of the specimen surface was performed throughout one polarization run and photomicrographs were taken to record the surface morphology at various stages of polarization. It was found that most of the attack develops in the active region, *i.e.*, before the onset of passivity, and at higher potentials only increases slightly in intensity. This effect will be described in detail elsewhere (14).

The effect of cold work on the critical breakdown potential of nickel was tested for specimens of grain size 0.250 mm. The anodic polarization curves obtained are shown in Fig. 4. The anodic dissolution parameters, along with the anodic Tafel and transpassive slopes, are summarized in Table II. It is evident that cold working has no effect on the value of E_{pp} and E_c and within limits of calculational error on β_a and β_t of nickel.

Microscopic examination of the specimens after removal from the polarization cell revealed pits to be nucleated not only along the grain boundaries, but also within the grains. The number of pits within the grains did not change significantly with cold work but pitting along the grain boundaries tended to become continuous.

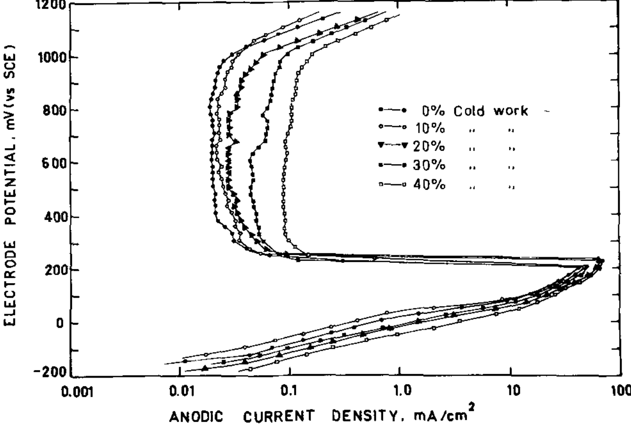

Fig. 4. Anodic polarization curves for polycrystalline nickel of grain size 0.250 mm with varying amount of cold work in 2 mliter 1N NaCl/100 mliters 1N H_2SO_4.

The results on air-annealed specimens were similar to those on vacuum-annealed ones. In general, the values of E_{pp} and β_a were lower, E_{corr} was more active, and β_t was almost the same. The value of E_c remained the same in every case

In order to understand better the significance of the critical potential, specimens of grain sizes 0.025, 0.100, and 0.330 mm were subjected to a passive potential of +400 mV for 28 min (time taken for a normal potentiostatic sweep from −300 to +400 mV) in 1*N* H_2SO_4 followed by the addition of 2 mliters 1*N* NaCl/100 mliters 1*N* H_2SO_4 and polarization continued to +1200 mV. The results are presented in Fig. 5. The anodic current density rises linearly with a change in slope between +950 and +1000 mV. The number of pits decreased with grain size even though pit distribution followed the trend shown in Fig. 3. The surface of every specimen remained bright until the addition of Cl^- ions, after which most of the surface remained in this visual condition (even though pits nucleated) while a small area of the specimen tarnished and by the end of polarization, a faint outline of the grain structure was visible.

Further, a specimen of 0.100 mm grain size was polarized in 1*N* H_2SO_4 from −300 to +1200 mV. The solution was removed and a fresh, previously deaerated 1*N* H_2SO_4 solution was introduced into the corrosion cell. The specimen was subjected to a potential of −300 mV, held at this potential for 30 min, polarized again up to +400 mV, and then Cl^- ions added as 2 mliters 1*N* NaCl/100 mliters 1*N* H_2SO_4 and polarization continued up to +1200 mV. Very few pits were formed, all within the grains and they nucleated in the passive region. The critical breakdown potential in the two cases was almost the same, *viz.*, +1000 mV in the former instance and +950 mV in the latter.

Discussion

In general, the extent of corrosion on a metal surface depends on the active anode/cathode site ratio, being higher if this ratio is large and vice versa. If the sites are fixed with time, localized corrosion is obtained, whereas if they are mobile, general corrosion results. The distribution of the anodic and cathodic sites may be assumed random over the entire specimen surface with both types of sites being present along the grain boundaries as well as within the grains. Which of these sites become activated depends on the conditions existing at the metal/solution interface during polarization. Grain size, cold work, and other aspects of metallurgical condition could all possibly affect the anode/cathode site distribution and, therefore, have a significant effect on the pitting corrosion characteristics of a metal.

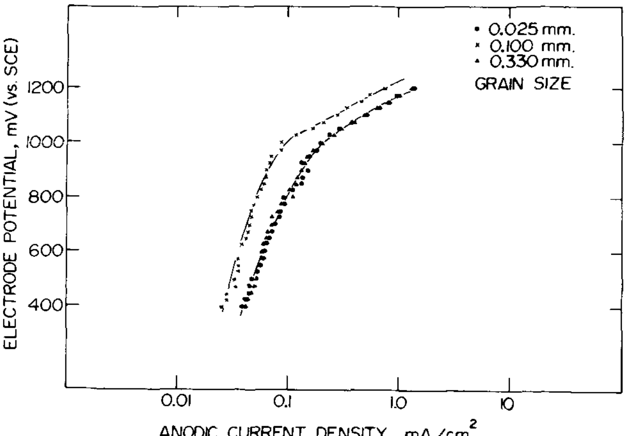

Fig. 5. Potential-current density curves for polycrystalline nickel of varying grain size after being held at +400 mV (SCE) for 28 min followed by addition of Cl^- ions as 2 mliters 1*N* NaCl/100 mliters 1*N* H_2SO_4.

The results presented show that it is inappropriate to suppose the critical breakdown potential, E_c, can be used to predict the pitting corrosion characteristics of nickel in sulfuric acid solutions containing chloride ions. Also, the anodic Tafel slopes show little difference over the entire range of grain size and cold work (Tables I and II). Electrochemically, this fact may be taken to mean that the primary dissolution mechanism, and possibly the characteristics of the passive film, are similar in each case. It is therefore concluded that a variation in grain size from 0.025 to 0.330 mm and cold working up to 40% has no effect on the pitting corrosion characteristics of nickel. The invariance of E_c with cold work as found in the present case is consistent with instances reported in the literature for austenitic steels (8) and Fe-Cr alloys (9).

The value of the primary passive potential, E_{pp}, is higher for vacuum-annealed specimens as compared to air-annealed ones. This is in support of the dissolution-precipitation mechanism of passivity (15). Since the vacuum-annealed specimens show lower reactivity, they need to be polarized to higher potentials before the passive state can set in.

The slopes in the transpassive region do not provide any specific information. They cannot be regarded as a measure of the growth rate of the pits because of the multiple events occurring on the surface. Pits that had nucleated grow, new ones might nucleate, and some of the older ones passivate. However, the transpassive slopes, β_t, do provide an idea of the over-all corrosion of the specimen in that potential range. Within limits of computational error (±10 mV/decade), it may be seen that β_t does not significantly change with either grain size or cold work. This is consistent with the observation that neither variation in grain size nor cold working have any effect on the pitting corrosion characteristics of nickel.

Referring to Fig. 5, if one does consider the point of the change of the slope of the curves to have the same significance as the critical breakdown potential, it is around +950 to +975 mV, even though pit formation is observed to occur much earlier. The transpassive slopes for these curves are much higher (ranging between 215-235 mV/decade) which indicates a lower over-all corrosion rate. This is because the pit density in these cases is much lower than in the instance where the specimen is polarized from the beginning of a Cl^--containing solution.

The formation of pits in the active region is consistent with the concept of a "balance" between film formation and solution as discussed elsewhere (11), but is in direct conflict with the idea that pitting corrosion cannot occur at potentials more active than some critical potential (1-3). The critical potential thus does not adequately describe the electrochemical conditions required for pitting corrosion of nickel in sulfuric acid solutions containing chloride ions. In view of this conclusion on nickel, it is suggested that considerable caution must be exercised in interpreting data based on critical potentials to assess the pitting susceptibility of metals and alloys.

The critical breakdown potential may be dependent on two factors: (*a*) internal factors, such as grain size, cold work, inclusions, and compositional inhomogeneity, and (*b*) external factors, such as the chemistry of either the solution or the passive film. Since E_c is independent of the internal factors, it is inferred that the critical breakdown potential is chemistry controlled. That the chemistry of the solution affects E_c has already been demonstrated (11).

The exact mode by which the aggressive ion causes pitting is still unclear. However, since the discharge potential for Cl is very positive (16) (the exact value depending on the concentration of Cl^- ions) and pitting is observed to occur at negative potentials, as pointed out by Ammar and Darwish (16), the first step leading to the formation of pits is most likely to be associated with Cl^- ions. It is possible that two mecha-

nisms may be operative simultaneously. One, in which the chloride ion reacts with the nickel in the metal lattice and the other, in which the chloride ion reacts with the passive oxide film; both processes eventually leading to the formation of soluble $NiCl_2$. The incorporation of the chloride ion into the passive oxide film may also be via anion vacancies with the chloride not necessarily of charge, -1. The details of this mechanism will be the subject of a future communication.

Conclusions

1. (*i*) Variation of grain size from 0.025 to 0.330 mm, cold working up to 40%, and annealing atmosphere (air or vacuum) do not affect the critical breakdown potential (E_c), and within limits of calculational error, the anodic Tafel slope (β_a) and the transpassive slope (β_t) of nickel.

(*ii*) Cold working up to 40% does not have any significant effect on the primary passive potential (E_{pp}) of nickel, although E_{pp} becomes more positive with increase in grain size from 0.025 to 0.330 mm.

2. At lower grain sizes, pits are formed along the grain boundaries. At larger grain size, the pits are formed within the grains with an increased density.

3. Most of the surface attack and nucleation of pits occurs in the "active" region of the polarization curve. *i.e.*, before the onset of passivity.

4. The critical breakdown potential does not adequately describe the electrochemical conditions required for pitting corrosion of nickel in sulfuric acid solutions containing chloride ions. Considerable caution must be exercised in employing data based on critical potentials to assess the pitting susceptibility of metals and alloys.

Ellipsometric Study of the Formation of Films on Iron in Chromate Solutions

Z. Szklarska-Smialowska[1] and R. W. Staehle*

Department of Metallurgical Engineering, The Ohio State University, Columbus, Ohio 43210

ABSTRACT

Film growth on iron was studied by ellipsometry in aerated or deaerated chromate solutions of different *p*H's at open-circuit potentials and at various anodic potentials. It was found that various films can be formed depending on the experimental conditions. At high anodic potentials iron oxide is chiefly produced with an index of refraction of 2.6(1-0.12*i*). At open-circuit potential the iron and chromium hydroxides with the index of refraction of 1.6-1.7 or a mixture of iron and chromium hydroxides with iron and chromium oxide (with index of refraction of 1.6-1.9 and various absorption coefficients) is formed. The kinetics of the film growth at open-circuit potential is logarithmic, and the kinetics of iron hydroxide formation at constant potentials follow the cubic law.

The aim of this work was to improve the understanding of the mechanism of passivation of iron in chromate solutions. Ellipsometry was used for determining optical parameters and film growth kinetics of the film formed both at open-circuit potential and at anodic potentials. These studies included *p*H's of 3.9, 7, and 12.

Chromates belong to the most efficient oxidizing type of corrosion inhibitors. They are effective both in aerated and deaerated solutions; they are also effective in neutral and alkaline solutions as well as in acid solutions.

The composition and the growth rate of oxide film on iron formed in chromate solutions has been studied by many authors. During passivation chromates undergo reduction with formation of chromium oxide (1-4). The concentration of chromium in the film can be different, depending on the condition of film formation (oxygen concentration in the solution, solution *p*H). The amount of reduced chromates during passivation process was determined by Uhlig and King (5), Powers and Hackerman (6), Cohen and Beck (4), Brasher (3), and others. The concentration of oxygen in the solution has an especially large effect on the composition of the film (2, 7, 8). The chromium concentration in the protective layer is decreased as the oxygen in solution is increased or as the surface is exposed to the atmosphere. Films formed in chromate solutions at the open-circuit potential are composed of γ-Fe_2O_3 + Cr_2O_3 and grow according to a logarithmic law (3).

Kruger (9) who was the first to measure the film growth in chromates using ellipsometry found also that the initially air-formed films grew further when immersed in aerated chromate solutions and followed a logarithmic law.

Experimental

The measurements of polarization curves and ellipsometric measurements of the film growth on iron were performed at 22°C in 0.01*N* Na_2CrO_4 solutions at *p*H 7 and 12 and in 0.01*N* $Na_2Cr_2O_7$ solution at *p*H 3.9.

Polarization curves were performed potentiokinetically at 20 mV/min in deaerated solutions, starting about 300 mV more negative than corrosion potential. Potentials were measured against the saturated calomel electrode and are expressed in this paper on the calomel scale.

The ellipsometric measurements were made at open-circuit potential and at anodic potentials.

The measurements were performed on specimens of 99.99% purity iron having the form of cylindrical disks with an exposed area of 0.32 cm^2; the specimens were prepared and the data taken as before (10-12).

The premature formation of films on the iron surfaces was prevented by holding the specimen at 300 mV more negative than the corrosion potential. Other specimens were studied with the initially air-formed film left intact, and these surfaces were neither electropolished nor cathodically reduced prior to the experiment.

Since the solutions in these experiments had an orange or yellow color, it was necessary, before starting the study of films on the metal substrate, to evaluate optical effects due to color. It was found that the values of *A* (analyzer) and *P* (polarizer) of the film formed in chromate solutions were the same as in borate solutions (0.15*N* H_3BO_3 + 0.15*N* $Na_2B_4O_7$, *p*H 8.8). The comparison was performed by first obtaining values of *A* and *P* in the chromate solution. The chromate solution was then flushed out by the borate solution, and the values of *A* and *P* were again determined and found to be the same as before.

The ellipsometer was Model 436 from Rudolf and Sons, with a mercury arc light source. The vacuum wavelength was 5461Å; the angle of incidence was 70.96°. The optical constants of iron and of the films formed on its surface as well as the film thicknesses were calculated using the Mc Crackin computer program (13) and an IBM 360 computer.

The ellipsometric measurements of the film growth were performed in deaerated chromate of different *p*H at anodic potentials. The readings of the polarizer and analyzer angles were taken for a period of 1 hr.

Measurements of the film growth in chromate soluions at open-circuit potential were performed under the following conditions:

1. The film was cathodically treated in a deaerated solution, the applied potential was removed. and the open-circuit condition obtained; then the solution was exposed to the atmosphere. Here the solution was aerated slowly.

2. The surface was cathodically treated in an aerated solution, the applied potential was removed, and the open-circuit condition obtained. Here the state of aeration was constant.

3. The air-formed film was left on the surface when exposed to the aerated solution, and there was no cathodic pretreatment.

For the first two circumstances the cathodic potential was 300 mV below the corrosion potential. and at this potential there were no differences observed in the index of refraction. After the readings were taken, the

cathodic current was switched off and the changes of A and P and changes of potential with time were noted. The open-circuit potential was monitored at the same time as ellipsometric parameters for films grown in cases 1, 2, and 3.

Results

Polarization curves.—Figure 1 shows anodic polarization curves for the solutions of interest. The polarization curves do not show a transition from the active to the passive state. The current flowing in the passive state does not depend on the pH.

Optical measurements.—The complex index of refraction for the substrate was 2.9(1-1.4*i*). This value is smaller than the values of refraction indices obtained for the same material in borate, tungstate 3.21(1-1.26*i*), and phosphate 3.14(1-1.14*i*) solutions (10-12).

Anodic film.—The results of ΔA *vs.* ΔP are plotted in Fig. 2 and 3. Approximately one third of the measurements taken during the 1 hr experiment are plotted as representative values. Figure 2 gives the dependence between ΔA and ΔP for pH 3.9 and 12. (ΔA and ΔP are the differences between the clean and the oxide-covered surfaces.) The values in Fig. 2 correspond to the same line independent of the potential and pH.

It is not possible to assign an exact value to the complex refractive index for the data of Fig. 2. The range of possible values of index of refraction is 2.4-2.7. Assuming that we choose a value of 2.6 as a likely value, the complex refraction index is 2.6 (1-0.12*i*) in the range of $n = 2.6 \pm 0.15$ and $k = 0.12 \pm 0.015$. This value corresponds to the indices of refraction which are reported in the literature for anodically formed γFe_2O_3 or Fe_3O_4.

The same kind of measurements were performed in pH 7 and the results are given in Fig. 3. Here two curves are plotted, one for the potential of -500 mV (active region of potential) and the second one for the more positive potentials. All values of ΔA *vs.* ΔP obtained at potentials more positive than -300 mV have the same slope as presented in Fig. 2. However, the slope for -500 mV is significantly steeper. At pH 7 the slope of ΔA *vs.* ΔP is the same for -500 and -400 mV as for the corrosion potential.

Films obtained at open-circuit potential.—The formation of films in chromate solutions at open-circuit potential is influenced by the choice of experimental conditions. The results of measurements performed under conditions given above in the experimental section are as follows.

Case 1: The results of the first kind of experiments are presented in Fig. 4 which illustrates the relationship between ΔA and ΔP for several measurements performed in chromate solutions at pH 3.9, 7, and 12 at open-circuit potential, and also for the measurements made at -500 mV in deaerated Na_2CrO_4 solution at pH

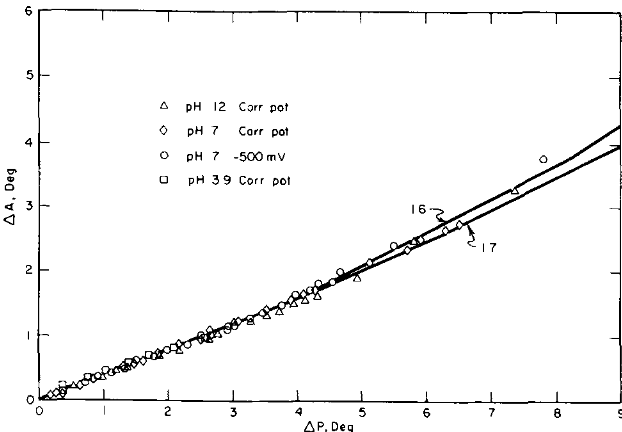

Fig. 4. Relationship between ΔA and ΔP for a film grown at open-circuit potential at different pH.

7. The curve at open-circuit potential is much steeper than the curve representing the same dependence for iron oxide formation during anodic polarization. This film has an index of refraction of 1.6-1.7.

Case 2: In this case the film growth followed two slightly different patterns, and it seemed that both were equally probable and both of these different from Case 1. The existence of these two different growth processes demonstrates the importance of initial conditions. The first growth pattern is shown in Fig. 5. This curve is composed of two linear segments, the first segment with the small slope and the second one with larger slope than the first. This indicates that two layers, one on top of the other, are formed in such conditions. The first layer is very thin (7Å) and is assumed to be iron oxide since the slope corresponds approximately to Fig. 2. The index of refraction of this layer was assumed to be the same as for the anodic film formed in chromate solutions. The most reasonable values of the refractive indices for the second layer are between 1.6 and 1.9 with their assumed imaginary parts as noted in Fig. 5. Values outside this range give improbable values for the imaginary part. This two layer film is obtained when the potential change in the positive direction is more rapid than in Case 1. Still another dependence between A and P is observed; namely a linear dependence between ΔA and ΔP but with smaller slope than in the case when the film with refractive index of 1.6-1.7 is formed. Figure 6 gives an example of such a result obtained in chromate solution of pH 12. Since the changes of both P and A are small, it is difficult to determine precisely the index of refraction of the film. As for Case 1, different values are possible from $1.6(1\text{-}0.02i)$ to $1.9(1\text{-}0.04i)$.

Case 3: Here, immersion of the specimen into chromate solutions of pH 7 and 12 causes the formation of the same oxides as for Case 2. However, in the solution of pH 3.9 the film is similar to that in Case 1 with an index of refraction equal to 1.6-1.7.

Thickness of the films.—The thickness of the anodic film formed in chromate solutions does not exceed 35Å, even for anodic potentials as high as +1000 mV. However, the thicknesses of the films formed at open-circuit potential with index of refraction equal to 1.6-1.7 are of the order of 100-120Å after 1000 min.

Kinetics of the film growth.—Figure 7 shows for Case 1 examples of the thickness *vs.* time of the films formed at open-circuit potentials for various pH's. The growth rates are logarithmic but the growth of the

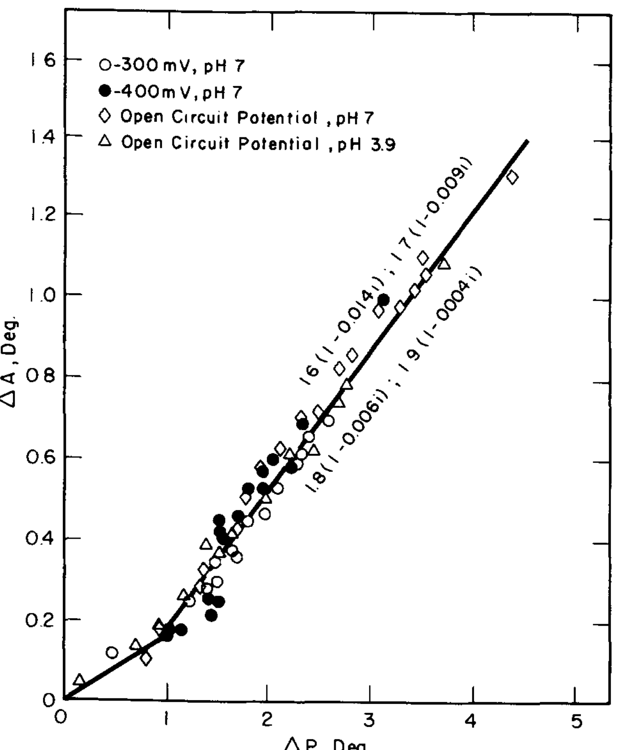

Fig. 5. Relationship between ΔA and ΔP for a film grown at open-circuit potential when two layers are formed.

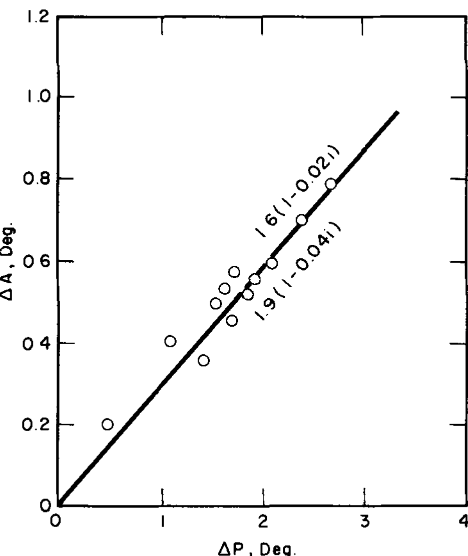

Fig. 6. Relationship between ΔA and ΔP for a film grown at open-circuit potential when one layer is formed with index of refraction of 1.6-1.9.

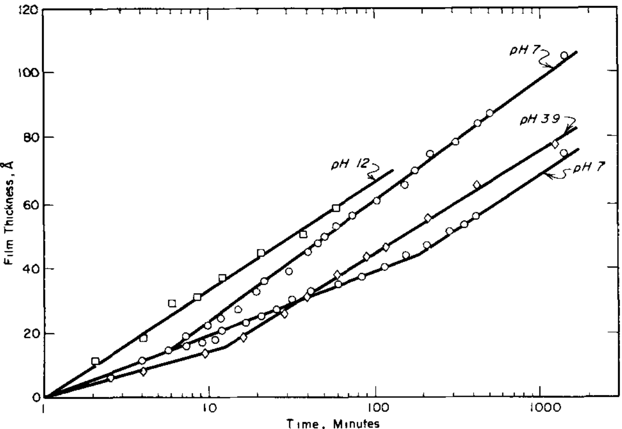

Fig. 7. Film thickness vs. time for the film whose optical constants are given in Fig. 4 (open-circuit potential).

films occurs in two stages. In the initial stage the slope is smaller than in the second stage. The extent and slope of the first stage vary and the reasons for these variations are not presently clear. However, in the second region the slope is the same for all pH's and is about 33 Å/decade.

Figure 8 shows for Case 2, when two layers exist, the thickness *vs.* time relationship for the two experiments shown in Fig. 5, assuming the complex index of refraction 1.7(1-0.004*i*). These films follow the logarithmic law as in Fig. 8. The slope of these curves is 20 Å/decade. There is a somewhat different slope at short times, but the extent of this region is too small to permit assignment of a valid growth law.

The second alternative growth pattern of Case 2 is presented in Fig. 9 showing the relationship between the thickness of the film and time for experiments given in Fig. 6. The two curves in this figure assume indices of refraction of 1.6(1-0.02*i*) and 1.9(1-0.04*i*). The character of the dependence in both cases is the same; the differences are in the film thickness and the slopes. At first the growth of the film is rapid but after 15 min when the film thickness reaches 32Å (curve 1) and 20Å (curve 2), the film grows more slowly; and after 1000 min the film increases only 12Å (curve 1) and 6Å (curve 2) more. Kinetics of the film growth are logarithmic in both of these regions.

While films formed at the corrosion potential grow according to logarithmic kinetics (see Fig. 7-9), the films formed at applied anodic potentials only slightly greater than the corrosion potential grow according to a cubic law. Such films have indices of refraction in the range of 1.6-1.7. Figure 10 illustrates this kind of film growth kinetics for the specimen in deaerated 0.01*N* Na_2CrO_4 solution at *p*H 7 polarized at −500 and −400 mV. Figure 11 gives the current accompanying the growth of the film at −500 mV. After reaching 75Å thickness of the layer, the current decreases remarkably.

Changes of potential during the film growth at open-circuit potential.—Figure 12 shows examples of poten-

tial *vs.* thickness for Case 1 with different *p*H's. These correspond with circumstances for Case 1 shown in Fig. 4 and 7. As the thickness of the film increases, the potential shifts in the positive direction. Three regions can be distinguished: in the initial period of film growth, the potential changes rapidly; in the second region the rate of potential changes slowly with increase in the film thickness; after a certain value of film thickness the rate of change increases again. This third region can be explained by the formation of a more protective film containing iron oxide on the metal surface. A similar circumstance was observed in the phosphate solution (10). However, the amount of iron oxide seems to be small, because the optical properties of the film do not change. This also parallels the phosphate results.

Figure 13 gives the results of potential *vs.* time for Case 2, having two layers already shown in Fig. 5 and 8. Figure 13 assumes an index of refraction of 1.7(1-0.009*i*). The change of potential *vs.* thickness is

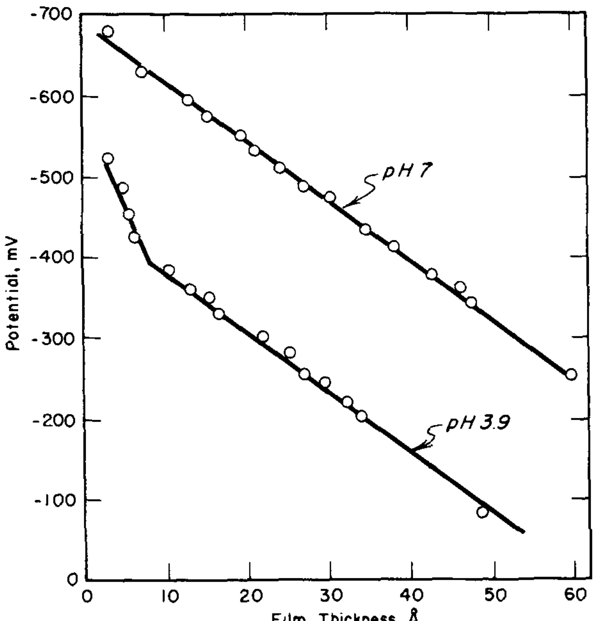

Fig. 13. Potential *vs.* film thickness for the film whose optical constants are given in Fig. 5. The complex index of refraction of the first layer: 2.6(1-0.12*i*); and the second layer: 1.7(1-0.009*i*).

equal to 7.5 mV/Å. The same dependence is shown in Fig. 14 for Case 2 but with only one layer and this corresponds to the experiments presented also in Fig. 6 and 9. For the single layer Case 2, the increase of potential is more rapid than it was for the double layer, and is equal to 17.5 mV/Å (curve 1) and 28 mV/Å (curve 2). Slopes for Fig. 12, 13, and 14 are summarized in Table I.

There is another very important parallel circumstance between the chromate and phosphate experiments. In the phosphate it was observed that above a certain potential the rate of change of potential with film thickness would increase. We hypothesized for the phosphate that this change was preceded by the formation of iron oxide. This hypothesis was checked on

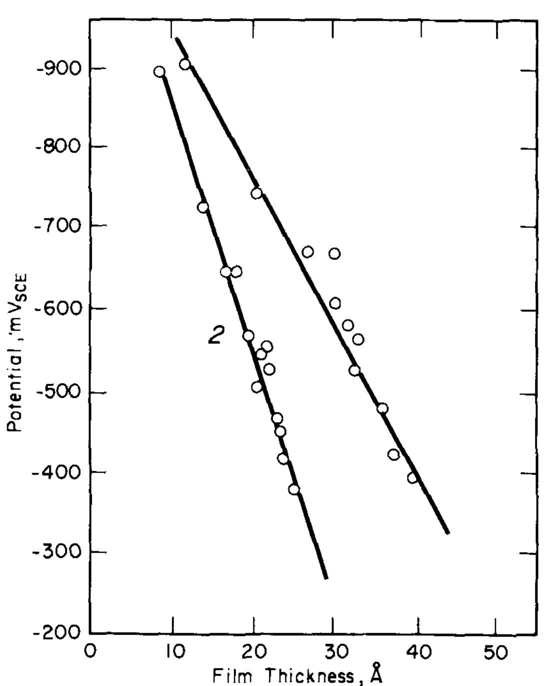

Fig. 14. Potential *vs.* film thickness for the film whose optical constants are given in Fig. 6: curve 1, complex index of refraction 1.6(1-0.02*i*); curve 2, complex index of refraction 1.9(1-0.04*i*).

Table I.

Index of refraction	Change of potential (mV/A)	Rate of film growth A/decade of time (in min)	Change of potential in time mV/decade of time (in min)
	I —	—	
1.6	II 3	33	140
	III —	6-8	
First film

		II 6	

phosphate by allowing the films to grow only at a limited extent followed by applying the higher potential potentiostatically. Since the new iron oxide was a large part of the total, it was then possible to observe a change in optical properties. The same experiment is shown in Fig. 15 for the chromate solution. A film was grown initially at −400 mV; after a short time a potential of +400 mV was applied and at this stage the ΔA *vs.* ΔP changed abruptly.

The change of potential *vs.* time for the Case 1 and 2 films is shown in Fig. 16. These do not provide the same implications as those for potential *vs.* film thickness. For Case 1 the potential changes slowly until it reaches a parting value and then a rapid change is observed. For Case 2 different patterns are observed for the one and the two layer films.

Discussion

Optical parameters and film composition.—Depending on the experimental condition established on the metal surface, different films of different optical constants are found; these different optical constants imply certainly different chemical compositions. The kind of film does not depend on the pH of the chromate solution; it depends on the potential and initial conditions. The films can be approximately divided into two groups: those with an index of refraction of 2.6 and those with an index of refraction of 1.6-1.9.

It is well known that the anodically produced iron oxide films have the index of refraction about 2.6; however, it is not known what composition corresponds

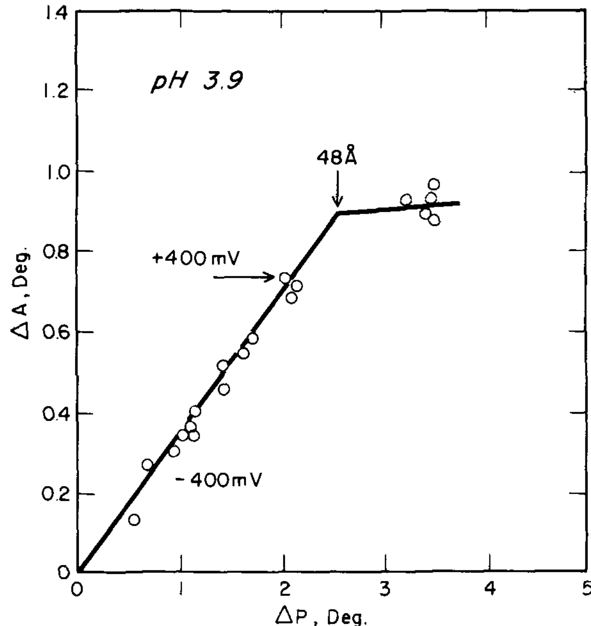

Fig. 15. Effect of anodic polarization on ΔA *vs.* ΔP relationship for a film formed in chromate solution of pH 7.

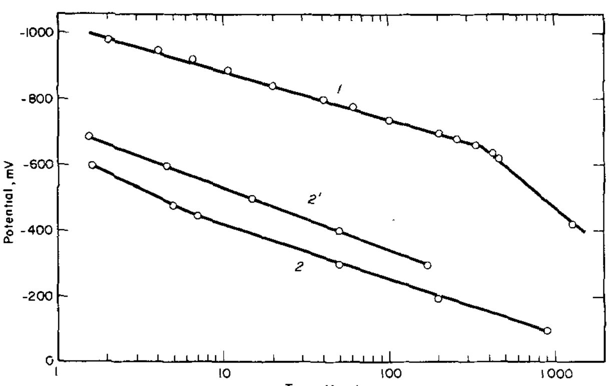

Fig. 16. Potential vs. time for the films of different optical constants produced in chromate solutions: curve 1, 1.6; curve 2, first layer 2.6(1-0.12*i*), second layer 1.7(1-0.009*i*); curve 2', 1.6-1.9 with different imaginary parts.

to a film with the index of refraction 1.6-1.7. $Cr(OH)_3$ has such a low refractive index (1.62) (17). For FeOOH Ord gives the value of 1.7 (16) however, his value differs significantly from those given by other authors (2.2-2.4) (18). Also, the index of refraction of Cr_2O_3 is 2.54 ± 0.4 and that of CrOOH is 2.0 ± 0.1 (17). These also do not correspond to the range of 1.6-1.7 found in the present study.

If the potential-pH equilibrium diagrams of the system chromium-water and iron-water systems are compared, both chromium hydroxide (oxide) and iron hydroxide (oxide) are stable in the region of potential of the present study. Further, $Cr(OH)_3$ is also stable at much more negative potentials than iron oxides. However, to obtain the deposition of $Cr(OH)_3$ on the iron surfaces, chromate anions would have to first be reduced. We found that at potentials more negative than the equilibrium potential for Fe/Fe_2O_3 but in the region of $Cr(OH)_3$ stability, such cathodic reduction occurred very slowly because we observed very slow formation of a film. However, we noticed that the index of refraction of iron is lower than that obtained in different solutions studied previously (10-12). This indicates that the iron surface is covered by adsorbed chromate molecules or by a thin film of chromium hydroxide. It is well established that trivalent chromium is always present in the film produced in chromate solutions; hence it appears that there is a direct relationship between the reduction of chromate and the oxidation of iron. Details of this coupled reaction are discussed later.

We will not speculate at this time on the exact composition and structure of films with the index of refraction 1.6-1.7, because more studies are necessary. But such a low index of refraction shows that the film cannot be composed of γ-Fe_2O_3, Fe_3O_4, and Cr_2O_3. We presume that this film is some combination of iron hydroxide and chromium hydroxide.

Four different kinds of films can be distinguished according to their optical properties:

1. The films formed at high anodic potentials with a complex index of refraction equal to 2.6 (1-0.12i). The film is composed of γ-Fe_2O_3 or Fe_3O_4 with a negligible concentration of Cr_2O_3 (19).

2. The films on the clean surface of iron at open-circuit potentials. During the initial stage of the film growth, high negative potentials occur. The same type of film forms when a constant potential near the open-circuit potential is applied to an initially film-free surface. Such a film is formed also in dichromate solutions on the iron surface having an oxide film formed in the air. The film formed under such conditions has an index of refraction of 1.6-1.7. We suppose that this film is composed of a mixture of iron and chromium hydroxides. After a sufficiently anodic potential is reached, γ-Fe_2O_3 or Fe_3O_4 and Cr_2O_3 is also formed.

3. The films formed at open-circuit potentials, when the potential moves more rapidly in positive direction than it was in Case 2. The formed film is composed of two layers. The first layer (thin) on the metal surface appears to be γ-Fe_2O_3 or Fe_3O_4 which is too thin to be protective; on the top of this oxide layer another layer is formed with an index of refraction in the range of n = 1.7-1.9 and k = 0.16 and 0.04, respectively. It seems that such a layer is composed of iron and chromium hydroxides with a small amount of γ-FeOOH, γ-Fe_2O_3 or Fe_3O_4 and Cr_2O_3. The same kind of film is formed in chromate solutions of pH 7 and 12 having oxide films formed in the air.

4. The films formed at open-circuit potential with only one layer but with index of refraction in the range 1.6-1.9 with k = 0.02 and 0.04, respectively. This film is also one containing iron and chromium hydroxide but probably contains a higher concentration of γ-FeOOH, γ-Fe_2O_3 or Fe_3O_4 and Cr_2O_3 than the film formed in Case 3.

Kinetics of film growth.—Table I summarizes growth rate of films. Both kinds of film (with the index of refraction 2.6 and 1.6) grow according to the logarithmic law at the open-circuit potential. At constant potentials the film with the index of refraction 1.6-1.9 grows according to the cubic law. Logarithmic and cubic kinetics of oxide film growth show that both films have protective properties. However, the growth rates are different for the various films as given in Table I. The film growth is the most rapid when only iron hydroxide is produced (33Å/decade).

Changes of potentials during film growth.—The shift of potential in the noble direction at open-circuit potential during the formation of iron and chromium hydroxide is indicative of the protective properties of iron hydroxide. Table I gives the values of the potential change per Ångstrom of film thickness for films studied in the present work. Some differences exist between the various kinds of films. A higher drop of potential is observed on the mixture of iron and chromium oxide than on the mixture of hydroxide and oxide films.

Mechanism of iron inhibition by chromate.—There exist two opinions concerning the mechanism of inhibition of iron by chromate. This first view is based on the fact that in neutral solutions of chromate containing oxygen the oxygen reduction is more rapid than the reaction of reduction of chromate. Therefore, the oxygen is in fact the passivator, and chromate adsorbed on the metal surface in a nonreduced form acts only by decreasing the critical current of passivation (14, 15). The second point of view is expressed by Cohen and Beck (4). They assume that the corrosion of iron occurs with formation of the hydroxide of bivalent iron which undergoes oxidation in the presence of oxygen. In the presence of chromates the oxidation occurs directly on the metal surface and causes formation of protective layers of iron oxide with some amount of Cr_2O_3. If a protective layer is already present on the metal surface, then the role of the chromate is limited to healing the weak points on the film and thickening of the film.

Our results suggest that formation of protective films in the presence of chromate anions occurs by successive steps:

1. Iron dissolves forming iron hydroxide, $Fe(OH)_2$
2. In the presence of the air or CrO_4^{2-} ions, $Fe(OH)_2$ is oxidized to $Fe(OH)_3$. Even in the absence of air the chromate anions react with $Fe(OH)_2$ producing $Fe(OH)_3$ and $Cr(OH)_3$. This reaction occurs at potentials near the initial corrosion potential thereby extending the range of significant corrosion resistance to lower potentials.
3. At higher anodic potentials iron and chromium hydroxides can probably be dehydrated to produce γ-FeOOH and CrOOH and γ-Fe_2O_3 and Cr_2O_3, corresponding to observations of the higher refractive index.

Summary

1. Anodic passive films in chromate solutions of pH 3.9, 7, and 12 have the same complex refractive index which is 2.6(1-0.12*i*). These films are chiefly composed of γ-Fe_2O_3 or Fe_3O_4.
2. At the open-circuit potential on iron surface various films are formed depending on experimental conditions. They are composed of iron and chromium hydroxide (index of refraction 1.6-1.7) or a mixture of iron and chromium hydroxides with iron and chromium oxides (index of refraction 1.6-1.9, with various adsorption coefficients).
3. The films produced on iron surface with an initially formed oxide in aerated chromate solutions of pH 7 and 12 have the index of refraction of 1.6-1.9 with various adsorption coefficients.
4. The kinetics of iron oxide and iron and chromium hydroxide formation at open-circuit potential is logarithmic, and the kinetics of iron hydroxide formation at constant potential is cubic.
5. All films formed in chromate solution have a protective nature.

Anodic Oxidation of Nickel in Neutral Sulfate Solution

B. MacDougall* and M. Cohen*

Division of Chemistry, National Research Council of Canada, Ottawa, Ontario, Canada

ABSTRACT

The formation and growth of protective oxide films on nickel electrodes was studied in a pH 8.4 Na_2SO_4 solution. A cathodic treatment of 10 min at -1.35V (*vs.* Hg_2SO_4) was sufficient for removal of the oxide film on electropolished nickel and thereby provided a starting point for the oxidation experiments. Anodization of the nickel electrode into the passive potential region produced a 9-12Å oxide film on the surface, this being *ca.* 50% thicker than the oxide film on electropolished nickel. Although both types of oxide inhibited nickel dissolution, their cathodic electrochemical behavior was quite different, with the film on anodized nickel not being susceptible to cathodic reduction. Reflection electron diffraction showed that the lattice parameter of the oxide on anodized nickel was closer to stoichiometric NiO than that on electropolished nickel. Formation of the oxide film on anodized nickel is by a direct electrochemical reaction, while that on electropolished nickel is probably due to the subsequent air exposure. The mechanism by which oxide films passivate nickel dissolution is discussed.

The electrochemical behavior of nickel has been the subject of extensive investigation in both acid and alkaline solutions. The typical potentiostatic i-V profile for the anodic polarization of nickel in an aqueous electrolyte shows that nickel dissolution occurs in the "active" potential region but is inhibited at more anodic potentials (*e.g.*, see Fig. 1). The importance of water, and hence probably an oxide film, in the passivation of nickel dissolution has been noted, passivation being absent in anhydrous acetonitrile solutions (1). The oxide film is believed to inhibit nickel dissolution by forming a physical barrier between the metal and solution, thus preventing bare metal from being in contact with solution (2-5). However, there is some question as to whether the physical presence of the oxide is, by itself, sufficient for passivation since a large potential drop across the oxide film may allow continued dissolution through field-assisted metal cation migration. In the latter case, passivation would occur when the potential gradient across the oxide is too small to allow cation migration and this condition could arise by either a thickening of the oxide or an

* Electrochemical Society Active Member.

Key words: nickel oxide, passivity, anodic oxidation.

increase in its electronic conductivity. It has also been suggested that the essential step in the passivation of nickel is the conversion of a precursor, nonprotective, oxide film into an electronic conductor through the introduction of nonstoichiometry (6, 7).

The two main mechanisms suggested for oxide formation on nickel are: (*i*) dissolution-precipitation (6, 8, 9); (*ii*) direct oxidation of the metal surface (2, 3, 5, 10, 11). In the first case, it is postulated that oxide formation can occur when the solubility of a species such as $Ni(OH)_2$ in solution near the electrode is exceeded, thus resulting in a precipitation of the $Ni(OH)_2$ onto the electrode. Dependence of the induction time for oxide formation on the rate of solution stirring has been used as support for this mechanism of oxide formation (9); however, the observed dependence might also be due to a concentration overvoltage. The second mechanism of oxide film formation would involve a reaction such as: $Ni + H_2O \rightarrow NiO + 2H^+ + 2e^-$, where there is a direct electrochemical reaction between the nickel electrode and water from solution.

The present investigation is a study of the nature of the protective oxide film on nickel and the mechanism for its formation in a neutral Na_2SO_4 solution. Electrochemical methods were complemented with electron diffraction, electron microscopy, and x-ray emission spectroscopy, in an attempt to determine more accurately the composition and structure of the film and to decide between the various possibilities given above for oxide formation and passivation.

Experimental

Specimen preparation.—Zone-refined nickel sheet supplied by Materials Research Corporation was used in this work, spark source mass spectrographic analysis showing it to be 99.996% pure. Electrodes of various surface areas (generally 1 cm by 2.5 cm), were degreased with benzene in a soxhlet extractor and chemically polished (12). They were then electropolished for 2 min at 23°C in a 57% sulfuric acid solution at *ca.* 0.5A cm^{-2} and annealed at 800°C in a vacuum of 10^{-8} Torr. The specimens were always electropolished again immediately before use in an experiment. Electrical contact was made by spot-welding a nickel wire to the top of the narrow handles of the specimen. The spot-weld was always at least 2 cm above the Na_2SO_4 electrolyte during an experiment. A (111) nickel single-crystal disk, the preparation and analysis of which has been described elsewhere (13), was used to obtain detailed information regarding the lattice parameters of the nickel oxides formed under various conditions.

Reference electrode.—All potentials quoted in this paper are referred to the Hg_2SO_4 electrode (+0.665V with respect to the standard reversible hydrogen electrode).

Solutions.—All experiments were conducted at 25°C. A deaerated solution of 0.15*N* Na_2SO_4, its *p*H adjusted to 8.4, was used for both the cathodic reduction and the anodic passivation experiments.

Apparatus.—A Wenking fast-rise potentiostat was used to obtain controlled potentials and the mode of polarization could be changed to galvanostatic by means of a switch in the circuit (14). A high-speed Brush recorder was used to follow the initial rapid decrease of current after the potential step, with the current and charge measurement being switched over to a slower speed recorder and electronic counter after the rate of current decay had decreased. A Wenking current integrator, Model SS1 70, was used to complement this method of charge determination. Potentials were measured on a Beckman Century *p*H meter with high input impedance, and/or a Hewlett-Packard strip chart recorder.

The electrochemical cell had the recording and counterelectrodes in the same compartment, the compartment usually being filled with 50 ml of solution. The counterelectrode consisted of two large sheets of platinum gauze placed in the cell so that they would be parallel to the nickel sheet electrode. The nickel electrodes were on sliding tru-bore ground glass tubes, thus allowing the electrodes to be immersed into or removed from the electrolyte without admitting air to the system.

Electrochemical procedure.—After electropolishing in H_2SO_4, the nickel electrodes were immersed in a deaerated Na_2SO_4 solution of *p*H 8.4 under cathodic polarization at −1.35V for 10 min to remove the prior surface oxide. Potentiostatic polarization curves were obtained by changing the potential in 50 mV steps, the current being measured after 60 sec. Galvanostatic charging curves were obtained on both oxide-free and oxide-covered nickel electrodes. The amount of nickel dissolution was measured at various times and potentials.

The potential step method was used for determining oxide coverage on nickel at various anodic potentials, V_a. The program consisted of a 10 min cathodic reduction of the prior oxide film at −1.35V during which time the current changed from *ca.* 500 to *ca.* 35 $\mu A\ cm^{-2}$. This was followed by 10 min at a constant cathodic current density of 5 $\mu A\ cm^{-2}$ to reduce the concentration of molecular hydrogen, produced at −1.35V, from the solution. The potential was then stepped to V_a for the desired period of time, the change of current and anodic charge being followed during this procedure. The nickel electrode was removed from the solution while still potentiostated at V_a, and the solution was analyzed for nickel. The electrode was immediately rinsed with doubly distilled water and dried in a stream of oil-free compressed air.

The electrochemical behavior of anodized nickel electrodes was studied by two procedures: (*i*) the electrode was examined in the same solution in which it had been anodized, *i.e.*, the circuit was never broken; (*ii*) the electrode was removed from the solution on open-circuit, exposed to air, and the solution changed.

When the behavior of nickel electrodes in alkaline solutions was studied, the cathodic reduction of the prior oxide was carried out at *p*H 8.4 and then the *p*H of the solution was adjusted to its new value by addition of deaerated NaOH solution. The same type of procedure was employed when the effect of nickel ions was under investigation, *i.e.*, the solution of nickel ions was added after the reduction of the prior oxide in a nickel free Na_2SO_4 solution.

Analysis.—The solutions were analyzed for nickel by atomic absorption spectroscopy using a carbon rod analyzer. The lower limit of detection by this method was 0.005 ppm. Reflection high energy electron diffraction was used to investigate the orientation, mean particle size, and lattice parameters of the oxide films on nickel. X-ray emission spectroscopy (15, 16) gave the oxygen content in the oxide films along with the amount of foreign atoms, *e.g.*, carbon and sulfur. Replica electron microscopy with a magnification of 30,000 was used to determine the effect of various electrochemical treatments on the smoothness of the nickel surfaces.

Results and Discussion

Effect of electrode pretreatment on anodic oxidation of nickel.—Figure 1 shows the anodic point-by-point polarization curve obtained on a nickel electrode in a *p*H 8.4 Na_2SO_4 solution. The electrode had been cathodically pretreated at −1.35V to remove the prior oxide film and the potential increment was 50 mV every 60 sec. The rate of active nickel dissolution increases with anodic potential until *ca.* −0.8V, at which point the current begins to decrease with increasing anodic potential. The small current (<2 $\mu A\ cm^{-2}$) which flows between −0.5 and +0.3V is independent of

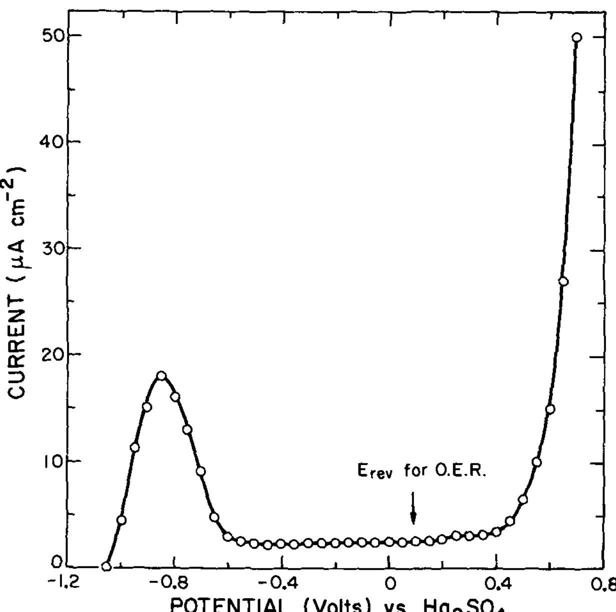

Fig. 1. Anodic potentiostatic current (i)-potential (V) profile for a previously oxide free nickel electrode in pH 8.4 Na_2SO_4 solution with potential increments of 0.05V every 60 sec. Measured current is that registered at the end of 60 sec.

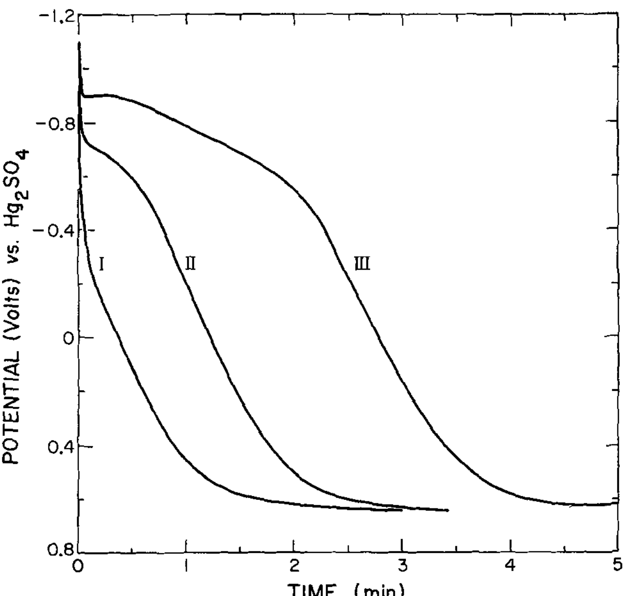

Fig. 3. Anodic galvanostatic charging curves for electropolished nickel in pH 8.4 Na_2SO_4 solution after prior cathodic treatments at different potentials: (I) 10 min at −1.0V; (II) 10 min at −1.1V; (III) 10 min at −1.35V. Anodic current density = 50 μA cm^{-2}.

potential and continues to decrease slowly with time after 60 sec. At potentials above +0.4V the sharp current increase is due to oxygen evolution on nickel.

It was of critical importance in the present study to determine the electrochemical conditions for obtaining an initial oxide free nickel surface from which to start the oxidation experiments. Figure 2 shows the effect of various cathodic pretreatments on the anodic polarization curves for electropolished nickel. The current maximum for nickel dissolution in the active region increases with increasing cathodic pretreatment until 10 min exposure at −1.35V, after which no significant changes are observed even after polarization for 10 min at −1.6V. Figure 3 shows the change of potential with time of an electropolished nickel electrode in pH 8.4 Na_2SO_4 upon application of an anodic current of 50 μA cm^{-2} after various prior cathodic treatments. A cathodic pretreatment of 10 min at −1.35V gives a curve with a significant arrest around −0.8V. In a separate experiment it was found that 90% of the charge associated with this arrest, up to *ca.* −0.55V, could be accounted for by nickel in the electrolyte. This region of active nickel dissolution is absent with a cathodic pretreatment of 10 min at −1.0V and is quite small for 10 min at −1.1V. Figure 4 shows the dependence of the charge associated with the arrest up to −0.55V, *i.e.*, charge for nickel dissolution, on the cathodic pretreatment. These results indicate that a cathodic pretreatment of 10 min at −1.35V in the Na_2SO_4 solution is required to remove the prior oxide on electropolished nickel, further cathodic polarization having no additional effect.

Figure 5 shows the potentiostatic polarization curve for Ni in pH 8.4 Na_2SO_4 solution in both the anodic and cathodic directions, the direction of potential

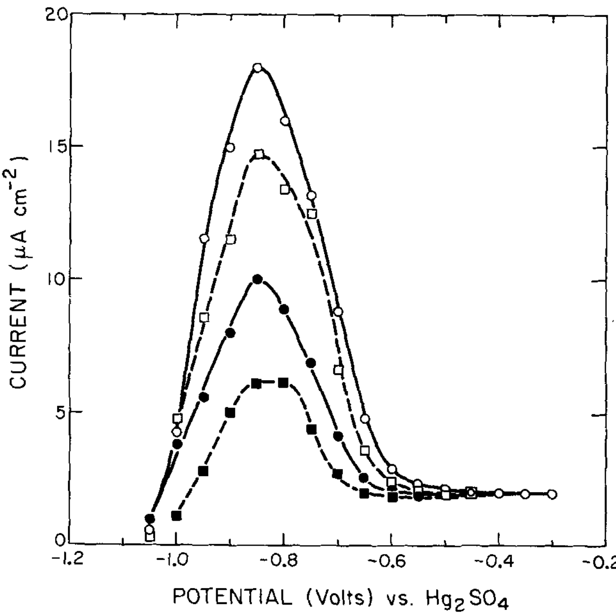

Fig. 2. Anodic potentiostatic *i-V* profiles for electropolished nickel electrodes after different cathodic pretreatments in pH 8.4 Na_2SO_4 solution: (—■—) 1 min at −1.10V; (—●—) 1 min at −1.35V; (—□—) 5 min at −1.35V; (—○—) 10 min at −1.35V. $\Delta V = 0.05$V and $\Delta t = 60$ sec.

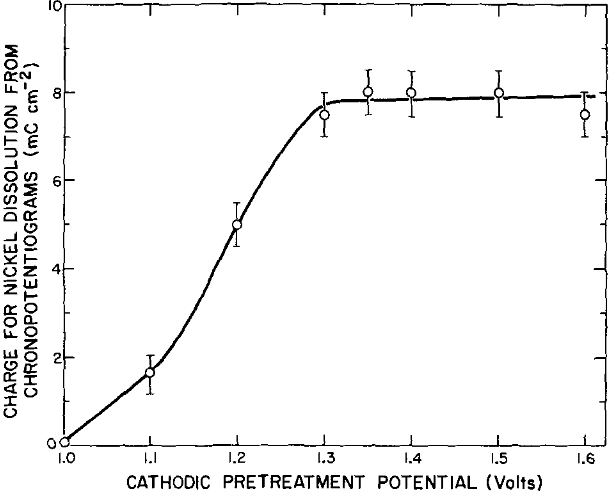

Fig. 4. Dependence of the amount of nickel dissolution as measured by the galvanostatic transient technique of Fig. 3 (and checked my solution analysis) on cathodic pretreatment potential for electropolished nickel in pH 8.4 Na_2SO_4 solution. 1 mc represents 0.30 μg of nickel which is equivalent to *ca.* 2 monolayers of nickel on a 1 cm^2 surface.

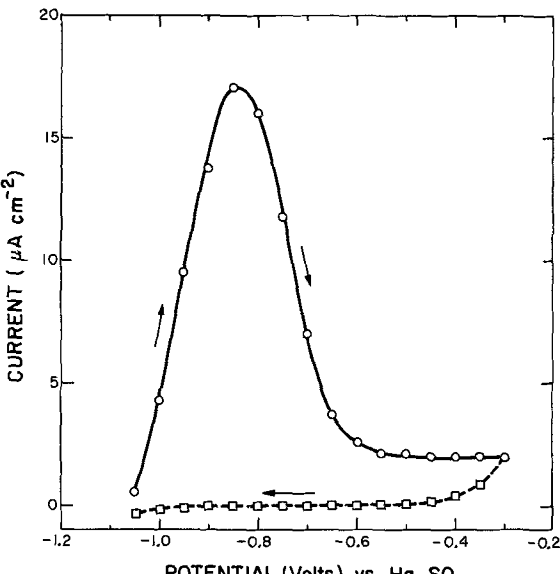

Fig. 5. Potentiostatic *i-V* profile for nickel in *p*H 8.4 Na_2SO_4 solution in both the anodic and cathodic directions, reversal of potential at −0.3V. Oxide film resulting from electropolishing was cathodically reduced at −1.35V for 10 min prior to the anodic sweep. $\Delta V = 0.05V$ and $\Delta t = 60$ sec.

change being reversed in the passive region at −0.3V. No activation of the electrode surface toward nickel dissolution is observed on the cathodic curve. In a separate experiment, an anodic polarization curve was obtained up to −0.3V and then the potential was switched back to −1.35V for 10 min, after which another anodic polarization curve was taken (Fig. 6). The cathodic treatment which removed the oxide film due to electropolishing in H_2SO_4 does not remove, to any significant extent, the oxide film arising from anodic polarization of the nickel electrode to −0.3V in *p*H 8.4 Na_2SO_4. The same result was obtained when, after the anodic polarization to −0.3V, the nickel electrode was removed from the cell and the solution replaced by a fresh Na_2SO_4 solution of *p*H 8.4 before cathodic polarization.

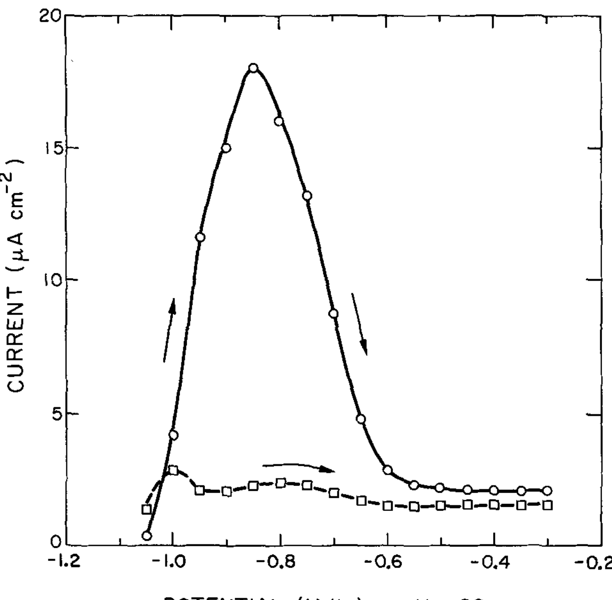

Fig. 6. Anodic potentiostatic *i-V* profiles for nickel in *p*H 8.4 Na_2SO_4 solution: (—○—) after prior cathodic reduction at −1.35V for 10 min of the electropolished nickel electrode; (—□—) after cathodic reduction at −1.35V for 10 min of the nickel electrode which had been anodized to −0.3V in the first part of Fig. 5. $\Delta V = 0.05V$ and $\Delta t = 60$ sec.

The galvanostatic charging technique was also used to investigate the possibility of cathodic reduction of the anodized nickel surface[1] in the Na_2SO_4 solution. It was found that even with a severe cathodic pretreatment, an arrest corresponding to nickel dissolution was not observed on reanodizing a previously oxidized specimen (see Fig. 7). The same result was also obtained with nickel electrodes anodized without removal of the prior film from electropolishing, *i.e.*, although nickel dissolution is markedly reduced by the presence of oxide from electropolishing, formation of the protective oxide occurs whether or not this oxide is present.

Potential step technique and oxide coverage.—In agreement with the electrochemical behavior of anodized nickel surfaces given above, a cathodic galvanostatic transient on an anodized nickel electrode showed no potential arrest corresponding to oxide reduction even at low current densities and hence cathodic coulometry could not be used to determine oxide thickness. The anodic potential step technique was therefore used to determine the amount of oxide on the nickel surface and its dependence on anodization potential. After application of the potential step the initial current was very high (*e.g.*, several hundred mA's at $V_a = 0V$), but fell very rapidly as an oxide film formed on the surface. The quantity of nickel dissolved during the cathodic pretreatment could not be detected (i.e., <0.005 ppm from a 5 cm^2 nickel electrode). Hence the charge for oxide formation, Q_a, is simply the total charge, Q_T, less the calculated charge corresponding to the quantity of nickel in solution, Q_{Ni}, *i.e.*, $Q_a = Q_T - Q_{Ni}$.

If the assumption is made that the oxide stoichiometry is NiO and the charge Q_a converted to oxygen content, the dependence of oxide coverage on anodiza-

[1] In the present work, this term will indicate a nickel electrode whose potential has been taken into the passive region in a *p*H 8.4 Na_2SO_4 solution.

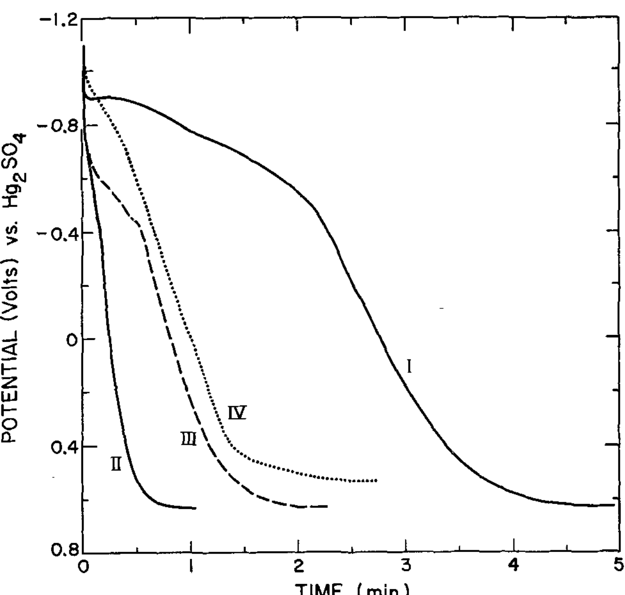

Fig. 7. Anodic galvanostatic charging curves, at 50 μA cm^{-2}, for nickel in various electrochemical states in *p*H 8.4 Na_2SO_4 solution (I to III) and *p*H 9.6 Na_2SO_4 solution (IV): (I) electropolished and then cathodically reduced at −1.35V for 10 min; (II) anodized to 0V for 1 hr in *p*H 8.4 Na_2SO_4 followed by cathodic reduction at −1.35V for 10 min in a fresh *p*H 8.4 Na_2SO_4 solution; (III) anodized to 0V for 1 hr in *p*H 8.4 Na_2SO_4 followed by cathodic reduction at −1.35V for 10 min in a *p*H 3.5 Na_2SO_4 solution; (IV) electropolished and cathodically reduced at −1.35V for 10 min in *p*H 8.4 Na_2SO_4 solution, then the *p*H was adjusted to 9.6 and the galvanostatic transient obtained.

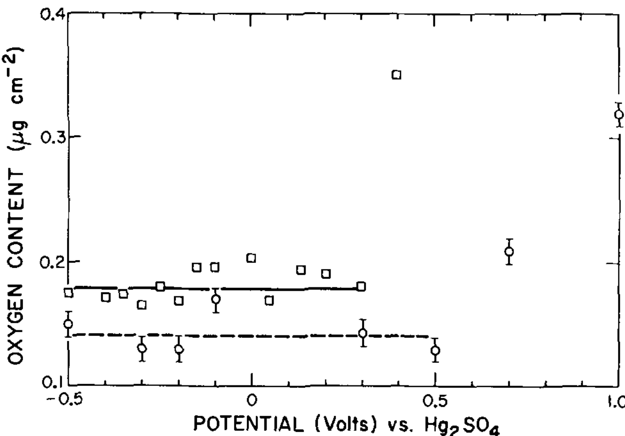

Fig. 8. Dependence of amount of oxygen on nickel on anodization potential, V_a, using the potential step technique, as determined by coulometry (—□—) and x-ray emission analysis (—ϕ—). Time of anodization was 1 hr. 0.1 μg cm^{-2} of oxygen corresponds to 6.9Å of NiO.

tion potential is given in Fig. 8 (see also Table I). The measurements were made 1 hr after initiation of the potential step. Also shown in Fig. 8 are the oxide coverages at different potentials obtained by x-ray emission spectroscopy, also on the basis of an oxide stoichiometry NiO. The oxide thickness agrees to within 20% (Fig. 8 and Table I) with that determined by coulometry, the discrepancy probably being associated with difficulties in preparing accurate nickel standards for the x-ray technique with oxides of less than *ca.* 30Å thickness. The oxide coverage is also seen to be almost independent of V_a until *ca.* +0.4V. At potentials less than +0.4V the residual current after 1 hr of anodic polarization is $<1 \times 10^{-8}$A cm^{-2}, *i.e.*, essentially zero. However, at $V_a \geqq +0.4$V, the residual current is finite and measurable and without doubt associated with oxygen evolution (see Fig. 1). The reasonably good agreement between the two sets of data for those potentials below oxygen evolution and the oxide coverage at +0.5V determined by the x-ray method indicates that the oxide thicknesses at $V_a \geqq +0.4$V calculated from coulometry are incorrect due to oxygen evolution.

The x-ray method gave a thickness of *ca.* 6Å, *i.e.*, 0.09 μg oxygen cm^{-2}, for the oxide film on nickel after electropolishing in H_2SO_4, the film on anodized nickel being *ca.* 50% thicker. Cathodic reduction of the electropolished specimen in *p*H 8.4 Na_2SO_4 and air-exposure of the resulting oxide free nickel electrode also yielded an oxide film of *ca.* 6Å thickness, this oxide displaying the same electrochemical behavior as that on electropolished nickel. The oxide film on both electropolished and anodized nickel contained[2] <0.01 μg cm^{-2} of carbon and <0.005 μg cm^{-2} of sulfur for any potential $V_a \leqq 0.5$V, *i.e.*, there was little if any sulfur incorporation into the film even at high anodic potentials.

At $V_a >$ *ca.* + 0.5V the oxide coverage, as measured by oxygen K_α x-ray emission spectroscopy, increased because of a roughening of the nickel surface. Analysis of the electrolyte after polarization at these potentials shows that large quantities of nickel (*ca.* 500 monolayers) have dissolved and electron micrographs at 18,900× (Fig. 9) of the resulting nickel surface show a substantial increase in roughness. In comparison, the nickel surface is very smooth after electropolishing and remains smooth even after the potential step treatments up to +0.5V, justifying the use of a roughness factor of 1. The substantial increase in the roughness factor at higher anodic potentials means that the calculated quantity of oxygen cm^{-2} of electrode surface, as determined by x-ray emission, will be too high since it is based on a roughness factor of 1.

Bockris *et al.* (6) found that the oxide thickness on nickel in a *p*H 3.0 Na_2SO_4 solution was independent of anodic potential, the quoted thickness being from 60 to 100Å as determined by ellipsometry. This value for oxide thickness is high in comparison with the present 10 to 12Å film and may be due to the experimental technique of the former. Instead of using a potential step treatment, a point by point anodic polarization technique was employed which probably resulted in heavy etching of the surface because of nickel dissolution. This roughening of the surface would lead to

[2] These represent limits of detection.

Table I. Comparison of total quantity of electricity passed, amount of nickel in solution and oxide film thickness associated with anodization for 1 hr to various potentials, V_a, using the potential step technique.

Anodization potential V_a (V)	Total charge passed (mC cm^{-2})	Charge due to nickel dissolution cm^{-2} of electrode (mc)	Amount of oxide from charge (μg cm^{-2})	% of total charge for oxide formation	Amount of oxide from x-ray measurements (μg cm^{-2})

*** Potential step technique employed in a solution of 10 μg ml^{-1} Ni^{2+}.

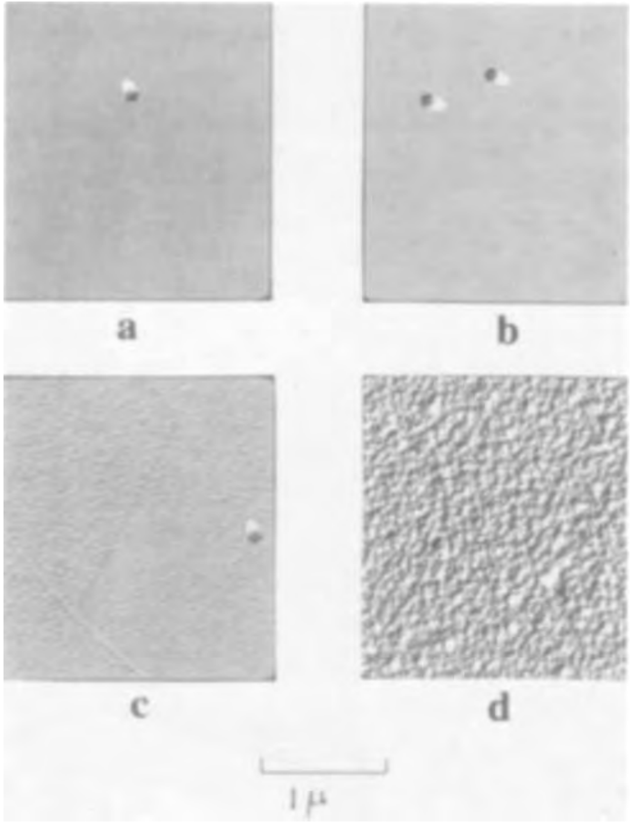

Fig. 9. Electron micrographs at 18,900× of the nickel surface after different electrochemical treatments: (a) electropolished in H_2SO_4; (b) anodized to 0V for 1 hr; (c) as in (b) but with V_a = +0.7V; (d) as in (b) but with V_a = +1.0V. Shadowed spheres are 900Å polystyrene balls.

a large uncertainty in the oxide thickness as measured by the ellipsometric technique (17). The discrepancy in oxide thickness is not associated with the fact that their Na_2SO_4 solution was at a $pH = 3.0$ since the oxide thickness on nickel obtained in this laboratory at $pH = 3.0$ by x-ray spectroscopy, using the potential step technique to $V_a = 0V$, was *ca.* 10Å. Sato *et al.* (18, 19) have recently reported that the oxide thickness on nickel (measured ellipsometrically) in neutral borate buffer solution is dependent on anodic potential in the passive region, the thickness increasing from *ca.* 5 to 15Å with increasing anodic potential. The error limits in the present oxide measurement are ±1.5Å (Fig. 8), and this fact taken along with the x-ray measurements would suggest that the discrepancy between our results and those of Sato *et al.* is quite real. Figure 10a shows the change in oxide coverage with time after a potential step to −0.3V. The oxide grows very quickly, reaching its maximum thickness after ca. 5 min. Correspondingly, the quantity of nickel in the solution after the potential step to −0.3V for various times (Fig. 10b) is found to reach a limit after *ca.* 5 min, with only a small increase thereafter. As the oxide forms and thickens on the surface, nickel dissolution is inhibited, most of the nickel going into solution when the surface is oxide free.

Effect of added nickel and solution stirring on oxide formation.—After a cathodic reduction of the electropolished nickel in pH 8.4 Na_2SO_4 solution at −1.35V and with the potential changed to −1.1V to remove excess H_2, a $NiSO_4$ solution was added to the electrolyte. Enough $NiSO_4$ was added to give a $[Ni^{2+}]$ in solution which was about 50× higher than would normally be found after the galvanostatic transient (Fig. 3). Reflection electron diffraction on a (111) nickel single crystal (see below) showed that addition of the $NiSO_4$ solution during the prior cathodic treatment at −1.1V did not alter the electrode surface. This large quantity of added nickel in the solution does not diminish the potential arrest corresponding to nickel dissolution during an anodic charging experiment at 50 $\mu A\ cm^{-2}$. The potential step technique provided an excellent alternative method for determining the mechanism of oxide formation on nickel. When the potential is stepped to −0.3V or 0V in the presence of a large quantity of added nickel (10 $\mu g\ ml^{-1}\ Ni^{2+}$), the current decays at the same rate as that obtained in an experiment without added nickel.

Identical experiments were carried out, in the absence of added nickel, with and without solution stirring by argon bubbling. The results were independent of solution stirring just as they had been independent of added nickel in the system. These results show that Ni^{2+} ions in solution are not an important factor in the oxide formation reaction on nickel under our experimental conditions, *i.e.*, a dissolution-precipitation mechanism does not apply. The results are more consistent with a direct electrochemical reaction between water and metal to form essentially anhydrons NiO.

Electron diffraction study of the oxides on nickel.—Reflection electron diffraction patterns of an electropolished (111) nickel single crystal are shown in Fig. 11 for both the <112> and <110> zones. Also shown are the diffraction patterns obtained after anodization, by the potential step method, for 1 hr at −0.45, +0.4, and +0.7V. The electropolished surface shows sharp,

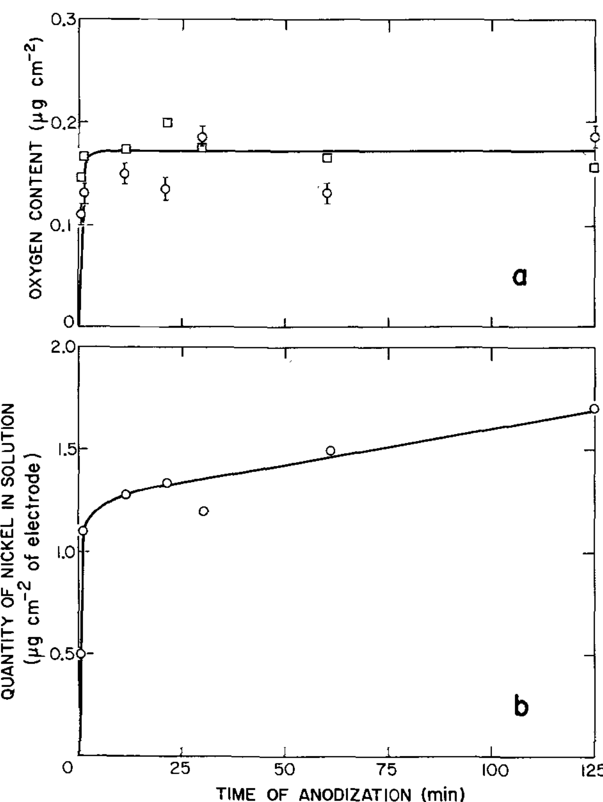

Fig. 10. (a) Variation of oxygen content on nickel with time of anodization after the potential step treatment to −0.3V. (□) Coulometric analysis; (ɸ) x-ray analysis. (b) Variation of the quantity of nickel in solution with time of anodization after the potential step treatment to −0.3V.

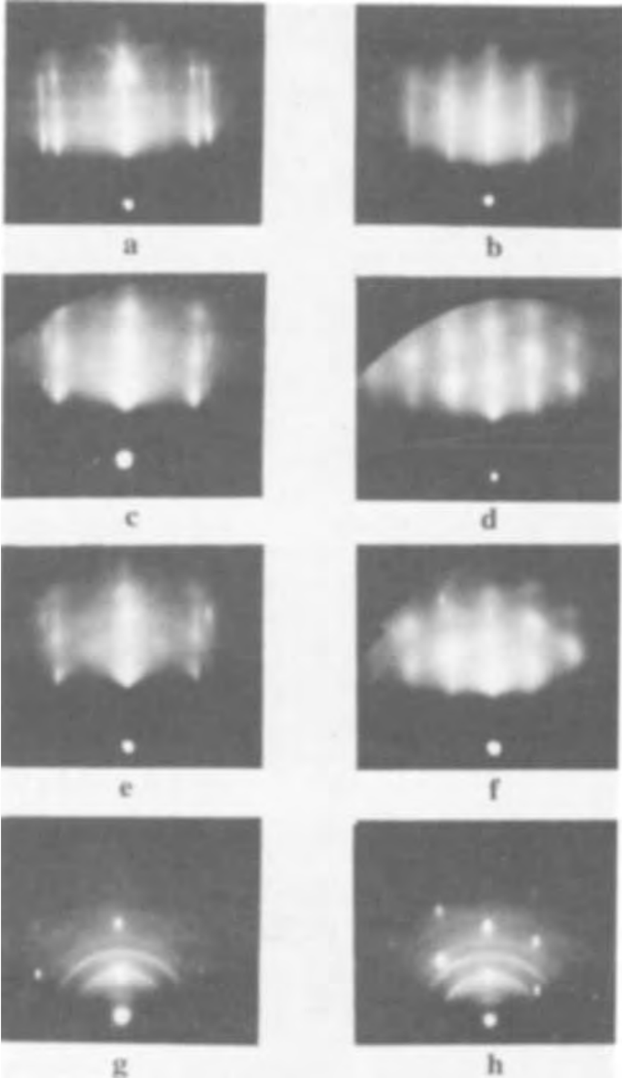

Fig. 11. Reflection electron diffraction patterns from a (111) nickel single crystal, in the <112> and <110> directions, after various electrochemical treatments: (a-b) electropolished in H_2SO_4; (c-d) anodized to −0.45V for 1 hr; (e-f) as in (c-d) but with $V_a = +0.4V$; (g-h) as in (c-d) but with $V_a = +0.7V$.

elongated reflections for both metal and oxide, the indication being that the oxide has a highly oriented mosaic structure with a mean particle size of *ca.* 50Å. The electron diffraction patterns of electropolished specimens which had been cathodically reduced and subsequently air-exposed were similar to those obtained from the electropolished specimens.

Upon anodization in the range -0.45 to $+0.4$V, the sharp nickel reflections were less intense, especially in the <110> zone, and the oxide reflections became somewhat diffuse. This diffuse characteristic may be due to either a smaller oxide particle size or a roughening of the nickel surface (relative to that existing with electropolished nickel). Since the diffuse oxide spots show a distinct refraction displacement (20), the electrode surface is still smooth and hence the oxide has a finer particle size. Measurement of the half-width of the oxide reflections indicate a 25Å particle size for the highly oriented, parallel oxide. Cathodic polarization at -1.35V of these anodized nickel electrodes in pH 8.4 Na_2SO_4 solution did not alter their electron diffraction patterns, another indication that the oxide film on anodized nickel cannot be cathodically removed in our system.

The nickel reflections are still very distinct in the case of the anodized electrode, providing qualitative support for the earlier observation (Fig. 8) that the oxide film resulting from anodization is only about 50% thicker than that due to electropolishing. Indeed, it is known from the dry oxidation of a smooth, electropolished (111) nickel that an oxide of *ca.* 15Å thickness completely obscures the reflections from the underlying nickel surface, this upper limit agreeing very well with the 10-12Å value in Fig. 8. The electron diffraction patterns also suggest that the oxide thickness has not changed considerably between the anodization potentials of -0.45 and $+0.4$V, further support for the x-ray and coulometric measurements in Fig. 8.

After anodization at $+0.7$V for 1 hr, the sharp nickel reflections had become diffuse spots, indicating that the surface was strongly etched (cf. Fig. 9). The oxide now gave a semi-ring pattern corresponding to that expected for polycrystalline NiO. Stepping the potential to $+0.7$V for only 90 sec allows the current to fall to a steady value, associated partly with oxygen evolution. However, electron diffraction on such a specimen gave a pattern very much like that obtained with polarization to -0.45V (Fig. 11), *i.e.*, there was little or no etching of the nickel electrode, and the oxide was highly oriented with a fine grain structure. Etching of the electrode surface and polycrystallinity of the oxide would thus seem to be related.

The diffraction patterns for both the electropolished and anodized nickel electrodes show the presence of the face-centered cubic oxide NiO, reflections from other possible oxides of nickel being absent. The lattice parameter for the nickel oxide formed by electropolishing in a H_2SO_4 solution deviated from that expected for stoichiometric NiO by $+1.9$% and $+2.2$% in the <112> zone and <110> zone, respectively, *i.e.*, the oxide lattice appears to be somewhat expanded over that of stoichiometric NiO. In the case of nickel electrodes, anodized either galvanostatically or by the potential step technique, the lattice parameter deviated from that of stoichiometric NiO by $+0.3$% in both zones, *i.e.*, the oxide formed by anodization has a lattice parameter which is much closer to that expected for stoichiometric NiO than that obtained by electropolishing. The oxide lattice parameter for an anodized specimen is independent of anodization potential or of the path taken to attain that potential. These changes in the oxide lattice parameter and general appearance of the diffraction patterns upon anodization occur even if the electropolished oxide is not removed prior to the anodization.

The lattice parameters cited above are characteristic of the spacing between planes of atoms which are perpendicular to the surface and says nothing about the distance between the two planes parallel to the surface (21). Consequently it is impossible to give the exact oxide stoichiometry; however, the electron diffraction results have shown that the oxides in question are NiO as opposed to $Ni(OH)_2$, βNiOOH, γNiOOH, or NiO_2. There is thus correlation with the coulometry and x-ray measurements where an assumption of NiO as the oxide on anodized nickel gave results which were in reasonably good agreement. Indeed, in the present investigation there was no success at preparing a nickel oxide, other than NiO, by the potential step technique in the systems studied. At $pH = 11.0$ or 13.0, and with a reduction of the prior oxide film, a potential step into the passive region, with $V_a = 0$ or $+0.5$V, gave polycrystalline NiO on the (111) single crystal with a sharp semi-ring diffraction pattern. The random orientation of the oxide in these more alkaline solutions is possibly due to either a faster oxidation rate or a different reaction mechanism (in comparison with the oxidation at $pH = 8.4$). The quantity of nickel dissolved during a potential step in the alkaline solutions was *ca.* 25% of that dissolved at *p*H 8.4, indicating a more rapid oxide formation (cf. Fig. 7), and showing the importance of *p*H in the oxide formation reaction, *i.e.*, $Ni + H_2O \rightarrow NiO + 2H^+ + 2e^-$.

In an attempt to prepare an NiOOH film on nickel, the potential step technique was employed in *p*H 8.4 Na_2SO_4 solutions containing 5 and 10 $\mu g\ ml^{-1}$ nickel. Reflection electron diffraction on the (111) nickel crystal showed that the above procedure gave the passive, highly oriented NiO film on the (111) crystal (cf. Fig. 11) with no sign of any other oxide reflections. It is, however, possible that long term potential cycling of the nickel electrode would have resulted in the appearance of other oxides of nickel.

The results generally reported in the literature suggest that the "passive" film is nonstoichiometric nickel oxide, *e.g.*, $NiO_{1.2}$ or $NiO_{1.7}$ (6, 22) which is electronically conducting. The present electron diffraction results seem to indicate that the oxide film on anodized (111) nickel is closer to stoichiometric NiO than that on electropolished nickel. The oxide films on both electropolished and anodized nickel are similar in that they inhibit nickel dissolution; however, they differ with regard to their thickness, lattice parameters, and cathodic reducibility. The fact that the oxide on electropolished nickel is converted to the stoichiometric[3] NiO upon anodization would indicate that it is the stoichiometric NiO which is the passive oxide on nickel.

Cathodic treatment of the oxide on anodized nickel.—It has been noted above that although the surface oxide on electropolished nickel can be removed by cathodic reduction at -1.35V (Fig. 5), the oxide film formed by anodizing in *p*H 8.4 Na_2SO_4 solution is not removed by such treatment. Upon immersion into the *p*H 8.4 Na_2SO_4 solution at -1.35V, the electropolished nickel displays initial large cathodic currents (*ca.* 500 $\mu A\ cm^{-2}$) which rapidly fall as the prior oxide is removed. On the other hand, previously anodized nickel electrodes do not give any initial large surge of cathodic current upon immersion at -1.35V but adjust almost instantaneously to a steady value for this potential. After 10 min of polarization at -1.35V in *p*H 8.4 Na_2SO_4 solution, the electropolished nickel displays a current of *ca.* 35 $\mu A\ cm^{-2}$ while the same treatment on the anodized nickel electrode gives a current of *ca.* 90 $\mu A\ cm^{-2}$, *i.e.*, 2.5 times larger.[4] Prolonging the cathodic polarization results in only a small decrease in these currents with time; however the 250% difference remains and the prolonged polarization for as much as 2 hr does not affect the subsequent anodic galvanostatic transient. Any attempted cathodic reduction of anodized nickel in the neutral Na_2SO_4 solution is thus

[3] Stoichiometric in the sense that the measured lattice parameters are similar to those obtained with true stoichiometric NiO.

[4] This situation exists over a wide range of potentials; however, because of the neutral, unbuffered nature of the electrolyte, accurate Tafel slope evaluation could not be made.

complicated by the increased rate of hydrogen evolution at −1.35V.

It has been postulated that cathodic polarization induced alkalinity plays a significant role in the reduction of the oxides of zirconium (23). In terms of the present nickel experiments, this theory would suggest that since cathodic polarization gives a high rate of hydrogen evolution from passive nickel, the pH may increase enough in the vicinity of the electrode to make the reaction $NiO + 2H^+ + 2e^- \rightarrow Ni + H_2O$ impossible. A way to test such a theory in the present case is to cathodically polarize the anodized nickel electrodes in an acid solution. It is seen (Fig. 7) that cathodic reduction in a pH 3.5 Na_2SO_4 solution results in only a slight increase in the activity of the anodized nickel electrodes, and this reflects the difficulty in reducing the passive oxide film even in these acidic solutions where induced alkalinity should not play a role.

The question which naturally arises is whether the difference in cathodic electrochemical behavior between the oxide film on electropolished nickel and that on anodized nickel can be explained in terms of the 50% increase in thickness upon anodization. The oxide film on electropolished nickel is very thin (*ca.* 6Å), and it will not likely have the properties of bulk stoichiometric NiO. It is possible that the increase in oxide thickness with anodization gives an oxide which more closely resembles bulk NiO as indicated by reflection electron diffraction. This feature could explain the difference in stability of the two oxide films towards cathodic reduction or further thickening by anodization.

Mechanism of oxide formation on nickel.—The two principle methods for obtaining nickel oxides were electropolishing and anodization. It has already been concluded that a direct electrochemical reaction is the most probable mechanism of oxide formation on nickel anodized in the neutral solutions. In the case of electropolishing, the question is whether the oxide is formed during the polishing or the subsequent air exposure. It was noted in the results that cathodic reduction at −1.35V for 10 min in pH 8.4 Na_2SO_4 solution removes the prior oxide from electropolished nickel. Subsequent air exposure of the cathodically reduced, bare (and wet) nickel surface gives an oxide whose thickness, lattice parameter, and cathodic and anodic electrochemical behavior are identical to those existing on electropolished nickel. This taken in conjunction with the results of others (10), suggests that the oxide obtained by electropolishing in H_2SO_4 solution is a result of the subsequent air exposure of the wet nickel electrode, the electropolishing itself mainly stripping nickel from the surface in a uniform manner and leaving the surface essentially free from oxide.

Both the oxide on electropolished nickel and the wet air-formed oxide are 6-8Å thick nonstoichiometric NiO. The dry air-formed film at room temperature is also 6-8Å in thickness but is basically stoichiometric NiO (13). However, the film formed under anodic conditions is both stoichiometric and somewhat thicker due to the applied potential. The growth rate is approximately logarithmic and could be explained by either a place-exchange mechanism (24, 25) or a Mott-Cabrera type mechanism (26, 27). The electronic conductivity of the film would not suggest a high-field mechanism. A distinction between the various types of mechanism is complicated by the dissolution of nickel during oxide film formation (Fig. 10).

Summary

1. The anodic dissolution behavior of nickel is highly dependent on the extent of coverage with prior surface oxide.

2. Electropolishing of nickel in H_2SO_4 gives a thin (6-8Å) film of NiO which can be removed by cathodic reduction in pH 8.4 Na_2SO_4 solution at −1.35V.

3. Anodization in the pH 8.4 Na_2SO_4 solution gives a thicker NiO film (9-12Å) which cannot be removed by cathodic reduction.

4. The oxide film on anodized nickel is formed by a direct electrochemical reaction.

5. The lattice spacings of the oxide film on electropolished nickel, as determined by reflection electron diffraction, show a 2% expansion while those on anodized nickel correspond to almost stoichiometric NiO.

6. Although the oxide films on both electropolished and anodized nickel inhibit nickel dissolution, they differ with regard to their thickness, lattice parameters, and cathodic reducibility, the film on anodized nickel being the passive oxide.

Acknowledgment

The authors thank Dr. D. Mitchell for the x-ray determination of oxygen content, Mr. G. Ducharme for the A.A. analysis for nickel, Mr. I. Sproule for the replica electron micrographs, and Dr. P. B. Sewell for helpful discussions concerning the electron diffraction results.

On the Origin of the Photocatalytic Deposition of Noble Metals on TiO_2

F. Möllers, H. J. Tolle, and R. Memming

Philips Forschungslaboratorium Hamburg GmbH, 2 Hamburg 54, Germany

ABSTRACT

In connection with studies on the photographic properties of TiO_2 the photocatalytic deposition of palladium and the electrochemical properties of TiO_2 were investigated. In order to study both phenomena simultaneously the experiments were performed with thin, TiO_2 layers deposited on a conducting substrate. It could be shown that the primary step is an anodic photocurrent (O_2 evolution) which catalyzes the cathodic deposition of palladium under open-circuit conditions. Various parameters such as space charge effects, film thickness, and doping were studied and are discussed in detail.

Photocatalytic properties of TiO_2 were reported in 1920 by Renz (1) who observed a darkening of the material by u.v. irradiation. Later on photoreactions with the surrounding medium were also investigated. According to the literature electrons as well as holes produced by light excitation within TiO_2 may be involved in those processes. Obviously the oxidation-reduction behavior of the species in contact with TiO_2 determines whether it will be photoreduced (2) or photo-oxidized (3, 4).

During the last decade the photoreduction of noble metal ions such as, *e.g.*, Ag^+ and Pd^{2+} at TiO_2, found great interest because this reaction can be used as an initial step in a photographic process with TiO_2 (5, 6). In this process the reduced Pd^{2+} ions form metal nuclei on the TiO_2 surface, whereas in a second reaction these nuclei may be intensified using chemical metallization (physical developers) in order to give a visible image.

In the primary step the photocatalytic reduction of Pd^{2+} must be accompanied by a corresponding oxidation. The Pd^{2+} ions need not necessarily be at the surface during the exposure to light but they are also reduced if they are introduced to the solution at the TiO_2 surface immediately afterward. This fact leads to the conclusion that the oxidation must be the initial step and determines the reduction. As proved with TiO_2 powder oxygen is desorbed during illumination. Since the remaining TiO_2 is deficient in oxygen it has become a reducing agent (6, 4).

Information about the primary steps in photocatalytic deposition on TiO_2 can be obtained by studying photographic and electrochemical properties of the same samples. Photographic experiments, however, were only performed with polycrystalline TiO_2 dispersed in organic binders which cannot be used for electrochemical studies. On the other hand, electrochemical experiments were performed with single crystals of TiO_2 which turned out not to be very suitable for photographic experiments. The investigations described in this paper were performed with polycrystalline TiO_2 layers deposited on a substrate. These layers have the advantage of being very transparent and, as far as the photographic properties are concerned, show a higher resolution than the dispersed layers. Electrochemical experiments are easily performed with this type of TiO_2 layers.

Experimental Technique

The TiO_2 layers are produced by chemical vapor deposition. In this process a solution of titanium-acetylacetonate dissolved in isobutanol was sprayed by a carrier gas on a hot substrate ($\sim$ 450°C) on which the titanium salt was oxidized to TiO_2. As a substrate either glass plates (Duran/Schott) covered with a conducting SnO_2 layer or titanium sheet metal were used. According to x-ray measurements the TiO_2 film is polycrystalline, the grain size is not larger than 0.1μ. The properties of TiO_2 layers depend strongly on various process parameters such as substrate temperature, deposition rate, and the type of organic titanium compound.

The electrochemical experiments were performed in $0.1N$ H_2SO_4 under potentiostatic conditions using a calomel electrode as a reference electrode. The space charge capacities were determined from measurements of impedance and phase angle between a-c current and a-c potential. For this purpose a small a-c voltage of 10 mV and 1 kc was superimposed on the externally applied d-c voltage.

The photocurrent measurements were performed using a mercury, high pressure lamp or a 450W xenon lamp as a light source. In some cases the light was chopped (12.5 Hz) and then the photocurrent measured using lock-in technique.

Key words: electrochemistry, semiconductors, photography.

Results and Discussion

Photocurrent measurements.—The anodic oxygen evolution at n-type TiO_2 electrodes only occurs with a large overpotential (see dotted line in Fig. 1). Under illumination (u.v. light), however, it occurs at much lower potentials, as proved by measuring the photocurrent (solid line in Fig. 1). A saturation current was found which is proportional to the light intensity. This curve is similar to that found by Boddy for a rutile single-crystal electrode (7).

Such behavior of a TiO_2 electrode is typical for n-type semiconductor electrodes if the charge transfer occurs via the valence band. In this case the concentration of holes in the valence band controls the reaction rate. In an n-type semiconductor of large bandgap, as in TiO_2, the equilibrium concentration of holes is extremely low and the anodic dark current should be determined by diffusion of holes toward the surface or by some generation process. The strong increase of the dark current above 1.5V is due to a tunneling or to an avalanche process which was not further investigated. On the other hand, an illumination by light absorbed by TiO_2 leads to a generation of electron-hole pairs which are separated by the electric field within the space charge region near the TiO_2 surface. Since in the potential range in which a photocurrent was observed the energy bands are bent upward (proved by capacity measurements, see next section), the photogenerated electrons are forced toward the interior and holes toward the surface where they are consumed for the electrochemical process as shown schematically in Fig. 2.

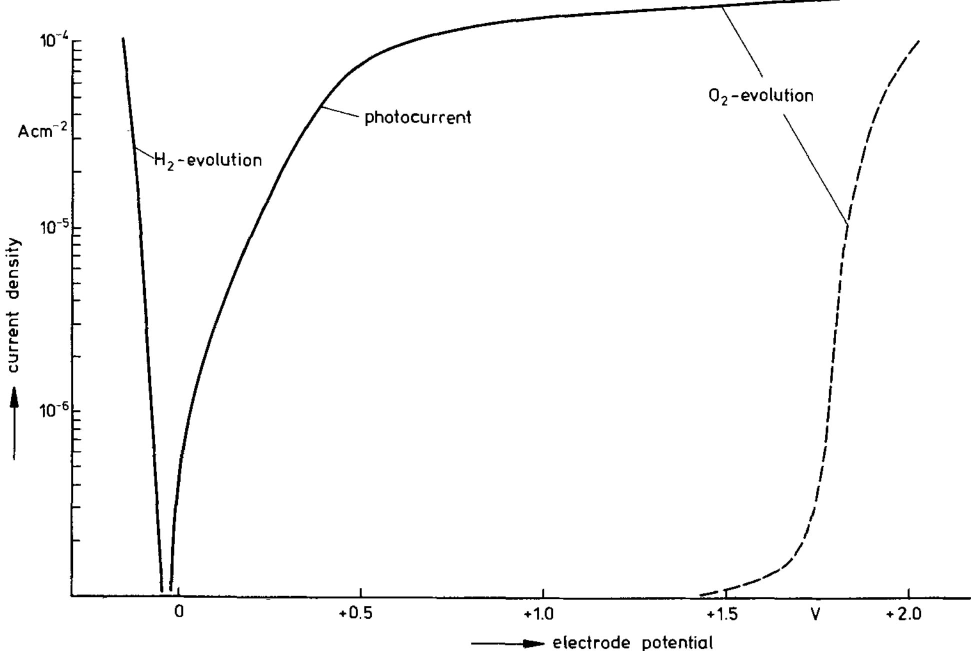

Fig. 1. Dark and photo current vs. electrode potential for TiO_2 layer (deposited on SnO_2) in 0.1*N* H_2SO_4.

In the charge transfer process at the interface, surface states may also be involved. An influence of surface states in photoelectronic processes at TiO_2 has been assumed, *e.g.*, in the investigations of Vohl (6) and of Addis and Wakim (6). These authors have studied the surface photovoltage and the photoconductivity of TiO_2 in an ambient O_2 atmosphere. They concluded that O_2 may trap conduction band electrons in a chemisorption reaction and form surface O^- ions. Under illumination these O^- ions again trap photoholes and O_2 is regenerated.

In aqueous solutions the TiO_2 surface consists of acidic and alkaline Ti-OH groups of equal parts (8). The role of these surface groups in the photoelectrochemical O_2 evolution should be similar to that of O^- on dry surfaces. The first step may be described by

$$\geqq Ti - OH + p^{\oplus} \rightarrow -\dot{T}i^{\bullet\oplus} \cdot \dot{O}H \quad [1]$$

In consecutive reactions with water the OH radical forms molecular O_2 and the TiO_2 surface is renewed (see Fig. 2). The same surface states of course may act as recombination centers.

Besides the occurrence of photocurrents also a shift of the rest potential during illumination was observed. Whereas in the dark the rest potential is not well defined and varies from sample to sample, it is shifted by ~300 mV toward cathodic potentials by illumination. The rest potential at an illuminated TiO_2 electrode is fixed at such a value where either all photocarriers recombine or the anodic reaction of photoholes is just balanced by a cathodic reaction. Since there is a steep increase of the cathodic current which corresponds to the hydrogen evolution, it may be assumed that the rest potential is indeed determined by the photocatalyzed decomposition of water. The origin of the shift of the rest potential under illumination is also due to the existence of the electric field of the space charge. Measuring the rest potential under open-circuit conditions the potential reached its new value after the light has been turned on. This change of the open-circuit potential is the so-called photopotential. The separation of photocarriers in the electrical field reduces this field and consequently the potential drop across the space charge layer. If the surface photoeffect is exclusively caused by a displacement of charges in the TiO_2, the open-circuit potential should return to its dark value instantaneously after having switched off the incident light. In all experiments, however, we found a much slower return to its dark value as shown in Fig. 3. The slow decrease of the open-circuit potential after illumination can be explained by the existence of traps within the space charge layer or by surface states.

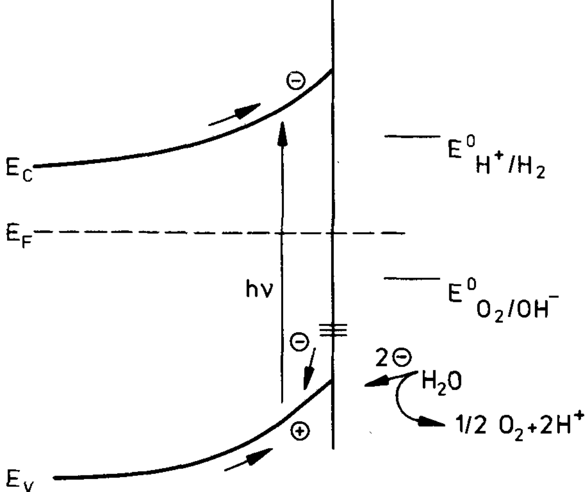

Fig. 2. Schematic diagram of charge transfer process at the TiO_2 electrolyte interface.

These traps may also influence the movement of photoexcited charge carriers as indicated by results obtained from nonstationary photocurrent measurements. Corresponding experiments are performed by illuminating an electrode with chopped light causing a pulsed photocurrent. As shown in Fig. 4 there is a pronounced maximum of this photocurrent on varying the electrode potential. It occurs in a potential range where the stationary photocurrent shows its strongest increase with potential. Moreover, the pulsed photocurrent reaches larger values than in the stationary case whereas in the higher potential range the pulsed and stationary photocurrents are almost identical. A similar difference between fast and slow photoeffects were also observed at germanium electrodes by Boddy and Brattain (9). These authors used a galvanostatic arrangement and detected potential changes during illumination with light pulses. They interpreted the fast potential change by a decrease of the band bending due to the formation of electron hole pairs within the space charge layer. In order to get more insight into the mechanism we illuminated the electrode by single light

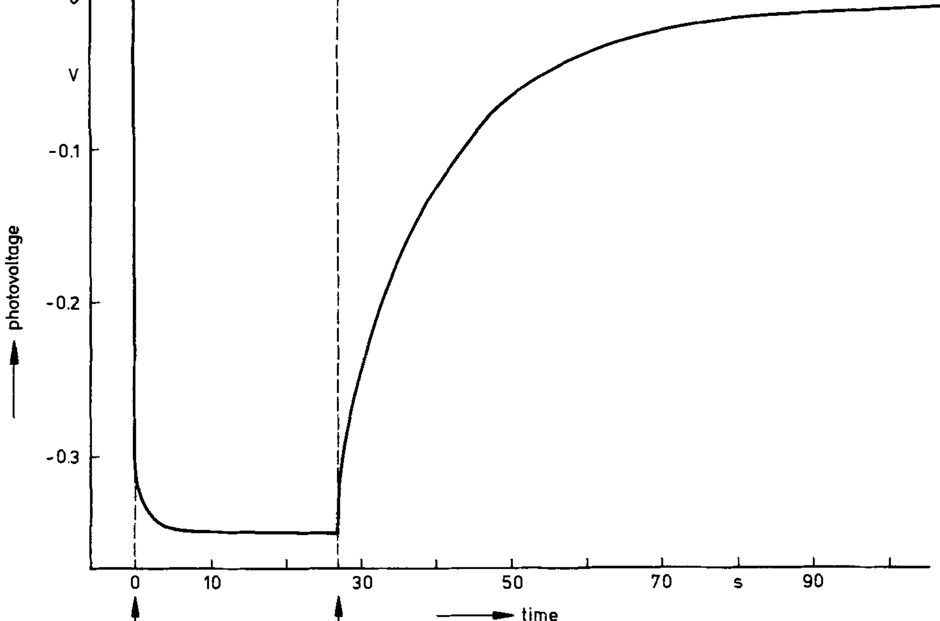

Fig. 3. Photovoltage vs. time for TiO_2 (on SnO_2 substrate) in 1N H_2SO_4 (under open-circuit conditions).

flashes. In the lower potential range the photocurrent rises rapidly immediately after the light has been turned on (curve b in Fig. 5), passes a maximum, and decreases down to a stationary value. It is interesting to note that in the following dark period a negative photocurrent also occurs. In the higher potential range those peaks are not observed (curve c), the photocurrent immediately reaches its stationary value. According to this result it has to be assumed that the pulsed photocurrent is due to a displacement of charges, *i.e.*, some of the excited charge carriers are trapped in certain centers. Since the pulsed current passes a maximum the occupation of traps is variable by changing the electrode potential, *i.e.*, by varying the band bending. Consequently, it has to be assumed that the traps have to be located within the space charge layer or even at the surface.

Accordingly the pulsed photocurrent can be described by two terms

$$\Delta i_{ph} = \Delta i_{st} + \Delta i_D \quad [2]$$

where Δi_{st} corresponds to the stationary photocurrent and Δi_D is due to displacement of charges. The latter current is proportional to the variation of the function f determining the occupation of the traps

$$\Delta i_D \sim \frac{df}{dt} \quad [3]$$

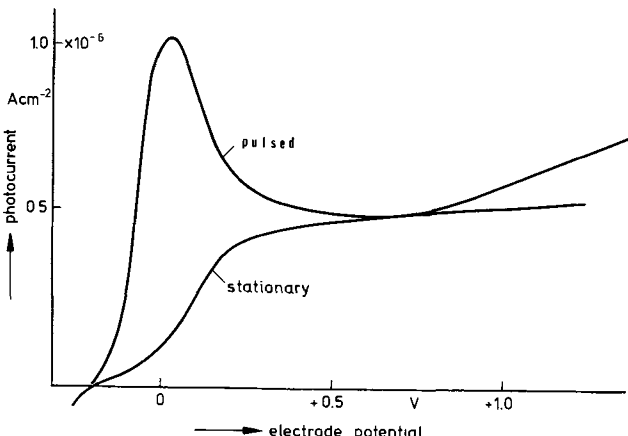

Fig. 4. Potential dependence of photocurrent for TiO_2 (on SnO_2 substrate) in 1N H_2SO_4.

Since the occupation f depends strongly on the band bending ϕ_s the pulsed photocurrent is given by

$$\Delta i_{ph} = \Delta i_{st} + b\,\frac{df(\phi_s)}{d\phi_s}\,\frac{d\phi_s}{dt} \quad [4]$$

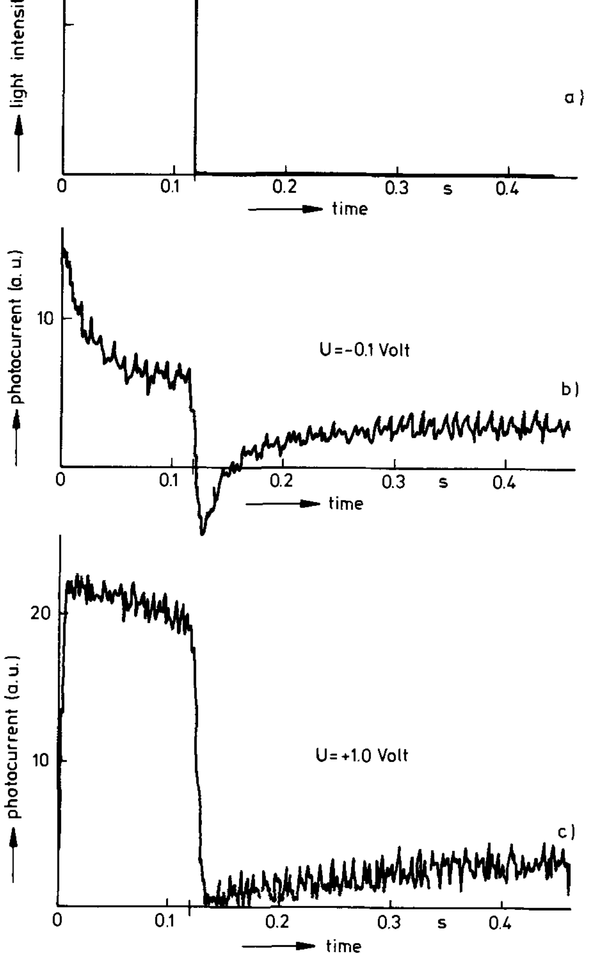

Fig. 5. Photocurrent vs. time for the same electrode as used in Fig. 4.

where b is a constant containing material and trap parameters.

This interpretation includes the assumption, however, that such a displacement of charges followed by a trapping of excited carriers leads to a small modulation of the band bending ($d\phi_s/dt$) although the potential drop across the whole system is kept constant (potentiostatic measurement). Such a variation of the potential drop across the space charge can only be compensated by a corresponding change of the Helmholtz layer.

This model is supported by measurements of the pulsed current performed with TiO_2 layers of different thickness. Since the additional peak in the lower potential range does not occur for a layer of a very small thickness (Fig. 6) but only for thicker layers, surface effects have to be excluded.

Consequently the traps have to be assumed to be in the space charge layer itself. The trapping effect may decrease or even disappear if the thickness of the whole TiO_2 film becomes smaller than the space charge layer, because then more excited electrons and holes may reach the backside contact and the surface, respectively. Since the maximum of the pulsed current is not visible for a layer thickness of 0.1μ the space charge thickness should be larger. This can only be proved by capacity measurements discussed below.

Potential distribution.—As discussed above a photoexcitation of electron hole pairs in TiO_2 causes a change of the potential distribution at least under open-circuit conditions, which are relevant to the photographic process. For a more quantitative understanding of the photoeffect it is important to obtain more knowledge about the potential distribution at the TiO_2 electrolyte interface. Such information is easily obtained from capacity measurements.

The space charge of an n-semiconducting electrode is a depletion layer at strong anodic polarization. Its capacity is described by the well-known Schottky-Mott equation

$$C_{sc} = \left(\frac{\epsilon\,\epsilon_0 Ne}{2}\right)^{1/2}\left(\Delta\phi_{sc} - \frac{kT}{e}\right)^{-1/2} \quad [5]$$

C_{sc} is the space charge capacity, $\Delta\phi_{sc}$ the potential drop across the space charge layer, ϵ and ϵ_0 the dielectric constants of TiO_2 and vacuum, respectively; N is the concentration of donors and e and kT have the usual meaning. Since the space charge capacity becomes smaller with increasing values of $\Delta\phi_{sc}$ and since it is in series with the larger electrolytic double layer capacity ($\approx 20\ \mu F/cm^2$), the total capacity of the TiO_2/electrolyte interface is determined by C_{sc}. In this case

$$C \approx C_{sc} \quad [6]$$

Provided that a change of the electrode potential U only leads to a change in $\Delta\phi_{sc}$ then it may be substituted by

$$\Delta\phi_{sc} = U - U_{fb} \quad [7]$$

U_{fb} is the flatband potential at which $\Delta\phi_{sc}$ is zero. The validity of these two assumptions (Eq. [6] and [7]) is proved if a linear relation is found between experimental values of $1/C^2$ and the electrode potential U. Inserting Eq. [6] and [7] into Eq [5] one obtains

$$1/C^2 = \frac{2}{\epsilon\,\epsilon_0 Ne}\left(U - U_{fb} - \frac{kT}{e}\right) \quad [8]$$

N is readily calculated from the slope of $1/C^2$ *vs.* U lines and the flatband potential by extrapolation of the linear part of the curve to $1/C^2 = 0$. Such a linear relation was observed with TiO_2 over a large potential range using single crystals as electrodes (7). We proved these results with rutile electrodes (single crystal), which were reduced by hydrogen in order to get a smaller resistivity. Varying the frequency of the potential modulation between 100 Hz and 10 kHz, however, lines of different slopes were obtained. This may result from slow surface states and was not further investigated. In this case the flatband potential was found around $-0.3V$ *vs.* SCE at pH = 1.

Performing capacity measurements with TiO_2 layers the $1/C^2$ *vs.* U curves differ from those obtained with single crystals in so far that not a single straight line but bent curves were found (Fig. 7). This result may be interpreted by assuming that these curves consist of two $1/C^2$ lines with a steep slope at lower potentials and a much lower slope at higher anodic potentials. On the other hand, a break in a capacity curve may also occur if the space charge thickness is larger than the film thickness. The thickness of the space charge can be defined as follows:

Rewriting the Schottky-Mott equation [8] one obtains

$$C_{sc} = \frac{\epsilon\,\epsilon_0}{\sqrt{\frac{2\epsilon\,\epsilon_0}{eN}}\cdot\sqrt{U - U_{fb} - \frac{kT}{e}}} \quad [9]$$

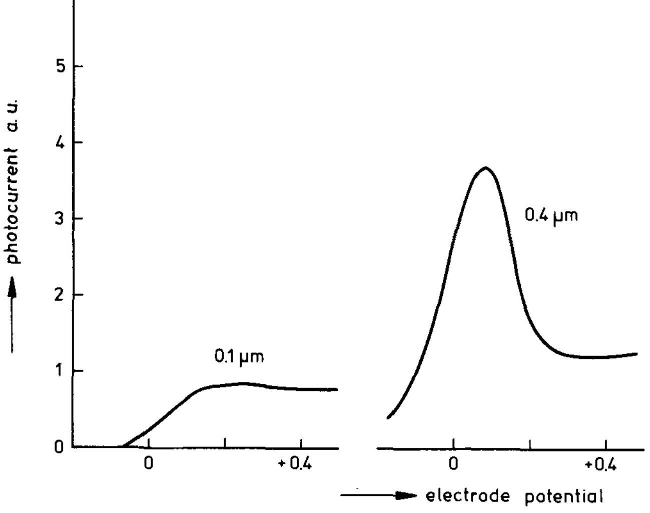
Since the capacity of a normal condenser is given by

$$C = \frac{\epsilon\,\epsilon_0}{d} \quad [10]$$

the thickness of the space charge can be defined as

$$d_{sc} = \sqrt{\frac{2\epsilon\,\epsilon_0}{eN}}\sqrt{U - U_{fb} - \frac{kT}{e}} \quad [11]$$

This thickness depends on the electrode potential. If d_{sc}, however, increases above the film thickness d_f the capacity is not determined by Eq. [9] but only by



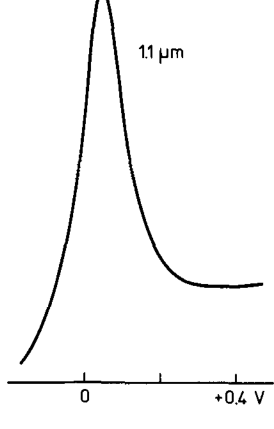


Fig. 6. Alternating photocurrent vs. electrode potential for TiO_2 of different oxide thicknesses in 1N H_2SO_4. Light source: Hg-lamp (361 nm). TiO_2 electrode: TiO_2 deposited on Ti-metal.

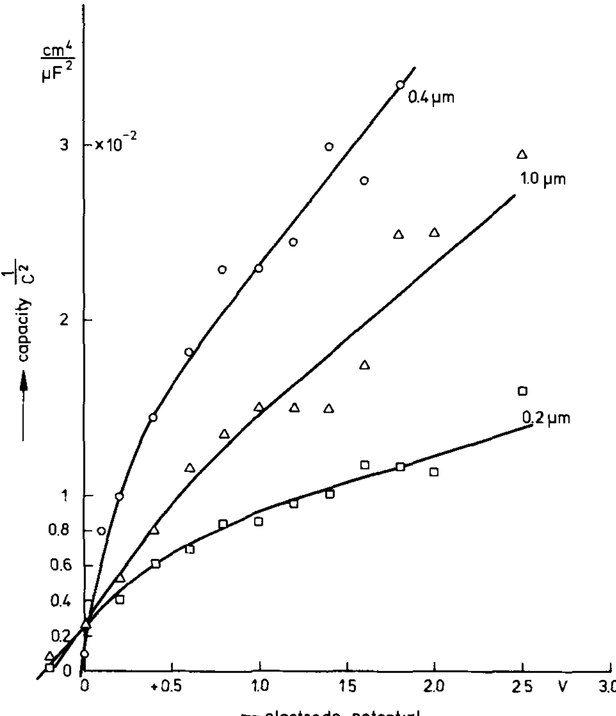

Fig. 7. Schottky-Mott plot of capacity *vs.* electrode potential for TiO_2 on SnO_2 substrate in 1*N* H_2SO_4.

the normal condenser equation, Eq. [10], inserting the film thickness d_f. Then the capacity curve should show a break where $d_{sc} = d_f$ and should be independent of potential above a certain potential. Since the thickness of the space charge layer d_{sc} varies with the square root of the potential, the potential at which the break in the curve occurs should very much depend on the film thickness. The interpretation, however, has to be excluded because the break in the curve appears at about the same potential for all samples of different thickness. It is supported by the fact that the thickness of the space charge layer amounts to $d_{sc} \approx 0.14\mu$ as obtained from the slopes of the capacity curves in the lower potential range. [For the corresponding calculation we used an average value of $\bar{\epsilon} = 120$ (10), where we obtained for the donor density N a value of $N = 1\text{-}2 \cdot 10^{17}\ cm^{-3}$.]

According to Pleskov (11) a break in the capacity curve may also occur if deeper donor levels are present which are not ionized within the bulk. The occupation of these levels may change, however, within the space region increasing the band bending. Assuming only one discrete energy level for such an additional donor of a density N' a Schottky-Mott equation of two linear slopes can be derived: The first one, measured at small band bendings, is only determined by the ionized shallow donors (density N) and the second by the sum of both, the shallow and the deep donor level ($N = N'$).

We assume the latter interpretation to be valid at least for the samples of a film thickness of 0.4 and 1.0μ, although we could not check whether only one or several types of deep donor levels are involved Theoretically, all curves obtained with samples of different thickness should be identical. The difference between the 0.4μ- and 1μ-samples is due to the layer preparation which has a large influence on the density of donor levels. Many measurements have shown, however, that the slope of the capacity curve of a very thin layer ($\leq 0.2\mu$) was always smaller than that of layers of larger thickness. This may be due to the fact that now the film thickness is of the order of the space charge thickness.

Influence of film thickness on the stationary photocurrent.—The photocurrent across the TiO_2 electrolyte interface should increase with increasing layer thickness provided that the penetration depth of light is larger than the film thickness itself. The penetration depth of light is determined by the absorption coefficient α. As shown in Fig. 8, the absorption sets in at about 420 nm which corresponds to an energy gap of 3.2 eV. Since we varied the film thickness up to 1.4μ, the first condition is fulfilled for wavelengths above 355 nm (see Fig. 8).

Corresponding measurements were performed with various layers using an excitation wavelength of 361 nm or white light. We obtained values which indeed increased with increasing film thickness as long as the film thickness was below about 0.6μ. For larger thicknesses mostly lower photocurrents were found. Theoretically the photocurrent should be proportional to the absorbed photons, *i.e.*, it should increase with $(1 - e^{-\alpha d})$. The large deviation cannot be interpreted by any excitation within the SnO_2 substrate because even with white light the photocurrent for SnO_2 is much smaller (12).

More quantitative information about this problem can be obtained from the spectral distribution of the photocurrent as shown in Fig. 9. According to this figure the spectral distribution depends strongly on the film thickness: varying the wavelength of the incident light from higher to shorter wavelengths the photocurrent rises due to the increase of absorption, passes a maximum, and decreases again which is caused by recombination. The TiO_2 layer of the smallest thickness shows the highest photocurrent and its maximum occurs at shorter wavelengths than for the other layers. It should be mentioned that this experiment was performed with a TiO_2 layer deposited on Ti metal and the electrodes were illuminated through the electrolyte. The thickness dependence of the spectral distribution, however, is independent of the substrate. This is demonstrated in Fig. 10a which was obtained

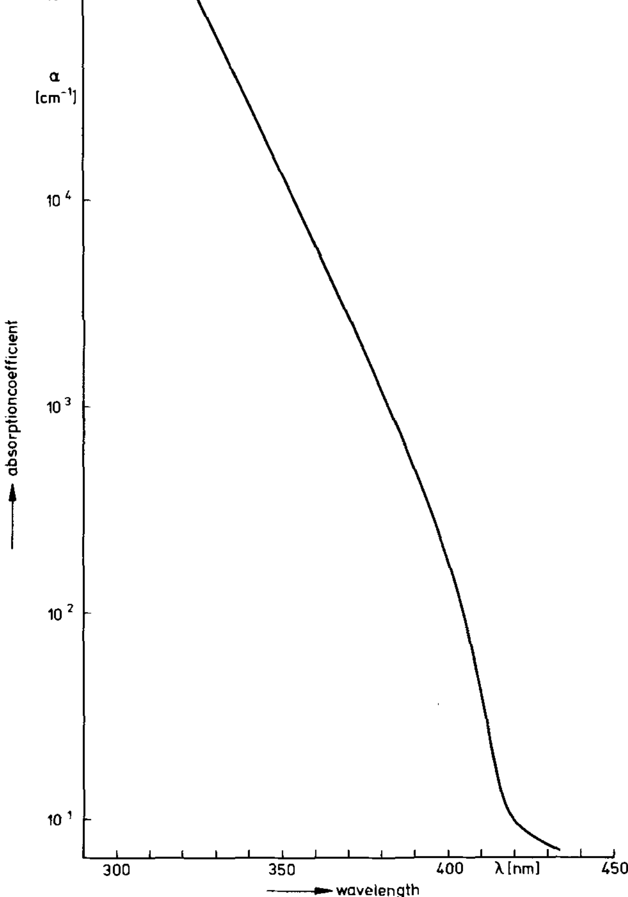

Fig. 8. Absorption coefficient *vs.* wavelength for TiO_2 layers

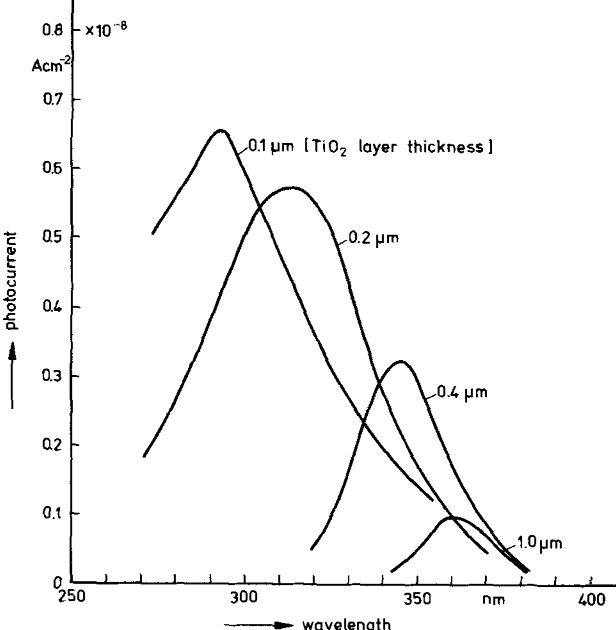

Fig. 9. Spectral distribution of photocurrent for TiO_2 (deposited on titanium, exposure through electrolyte).

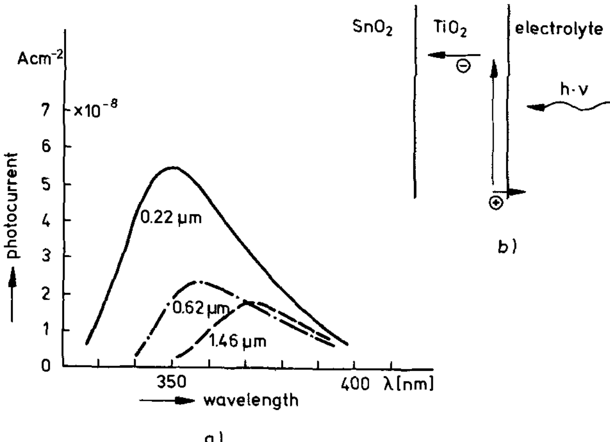

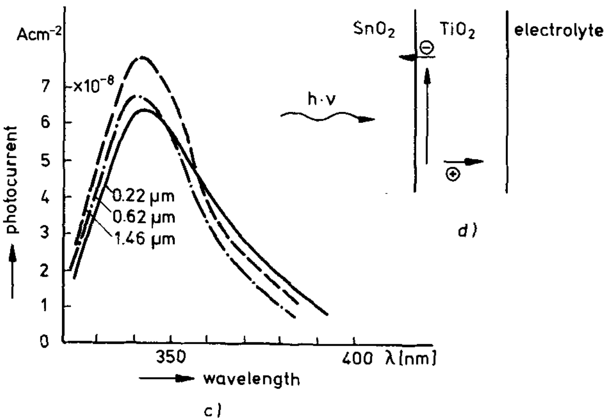

Fig. 10. Spectral distribution of photocurrent for TiO_2 on SnO_2 substrate. (a) Illumination through electrolyte, (c) illumination through SnO_2, (b) and (d) schematic representation of excitation process.

by using SnO_2 instead Ti as a substrate. Since the bandgap of SnO_2 is considerably larger than for TiO_2 this system could also be illuminated from the reverse side, *i.e.*, through the SnO_2 layer (see Fig. 10d). The corresponding spectra were obtained with the same samples as presented in Fig. 10c. In this case the spectral distribution of the photocurrent is independent of the thickness of the TiO_2 layer and its maximum occurs only in the shorter wavelength range.

According to these results it must be concluded that the highest yield for the photocurrent is obtained if the electron-hole pairs are created near the backside contact (Fig. 10d). In this case the electrons produced by light excitations have to move a relatively short distance to the contact, whereas holes have to move all the way through the TiO_2 layer toward the surface where they are consumed in the electrode reaction process. On the other hand, when the electrode is illuminated through the electrolyte, then the electron-hole pairs are created mainly near the TiO_2 electrolyte interface and the electrons have to move across a larger distance, at least in TiO_2 layers of 0.2μ and of greater thickness. Since in this case the photocurrents are small and since their maxima in the spectral distribution depend on the layer thickness we assume that electrons are more readily trapped than holes and therefore determine the recombination process.

It should be mentioned that the recombination rate is strongly influenced by the structure of the TiO_2 layers and need not be homogeneous over the whole layer. According to our experiments it varied with the decomposition temperature, the substrate, and the Ti compound used in the preparation technique of these layers.

Photocatalytic deposition of palladium nuclei.—As already observed with TiO_2 dispersed in polymer binders, palladium is deposited from aqueous solutions on TiO_2 during illumination with ultraviolet light (6). The same effect was observed with TiO_2 layers deposited on SnO_2 by our technique. These experiments were performed with TiO_2 layers on a SnO_2 substrate. It was proved that no palladium was deposited with SnO_2 alone. Following the open-circuit potential of such a TiO_2 electrode in a Pd^{2+} solution during illumination a fast shift toward cathodic potentials was observed. After the potential has passed a minimum at around +100 mV it reached a final value of about +200 mV (curve I in Fig. 11a). For comparison we also plotted the open-circuit potential during illumination of a system free from palladium ions as shown by the dashed line in Fig. 11a. The amount of palladium deposited during illumination was determined by subsequent anodic dissolution of palladium under galvanostatic conditions. From the corresponding potential change with time the electrical equivalent of Pd was calculated.

The nature of the photocatalytic deposition of Pd on TiO_2 can easily be interpreted on the basis of the photovoltaic effect of the semiconducting TiO_2. As discussed in detail above, illumination of TiO_2 electrolyte interface leads to a small rate of the photolysis of water, *i.e.*, holes created by light are consumed for the formation of O_2 and simultaneously an equal amount of electrons for the reduction of H^+ ions. This mechanism can be illustrated by the anodic and cathodic currents involved in this process as shown schematically in Fig. 12. In the dark only a small anodic current (solid line) was observed since almost no holes are available, whereas the cathodic current increases rapidly with increasing cathodic potential (solid line) and hydrogen evolution occurs. Under open-circuit conditions the rest potential U_R is found at that potential at which anodic and cathodic currents are equal. Illumination causes an anodic photocurrent (dotted curve) leading to oxygen evolution. This anodic partial current sets in at flatband potential U_{fb} which is more negative than the rest potential U_R as derived from capacity measurements. Since the cathodic current remains unchanged the new rest potential will occur at $U_{L(H)}$. The potential difference

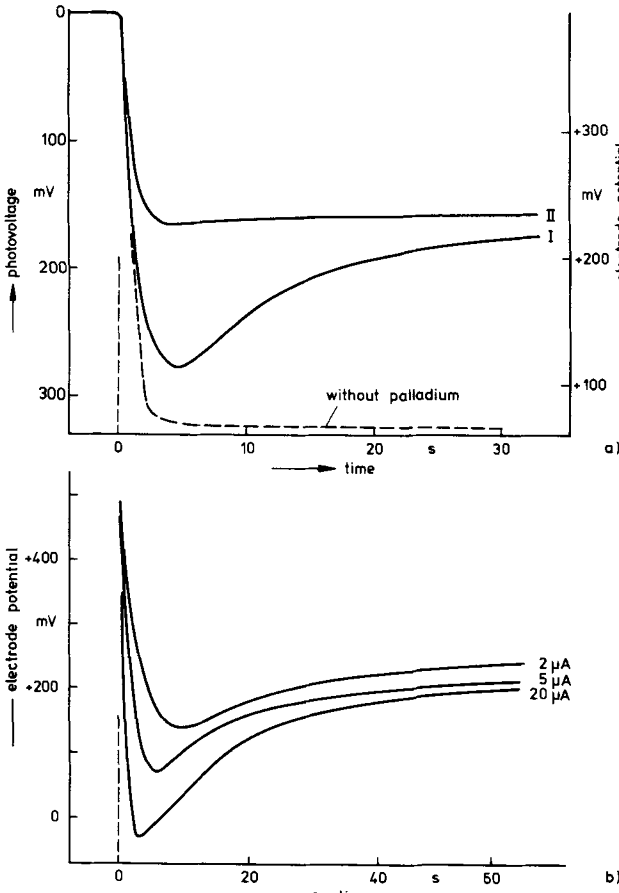

Fig. 11. (a) Photovoltage vs. time for a TiO_2 electrode (on SnO_2 substrate) in 10^{-3}M $PdCl_2$ in 0.1N HCl. Curve I, first run; curve II, second exposure. (b) Electrode potential vs. time without illumination at constant cathodic current as indicated.

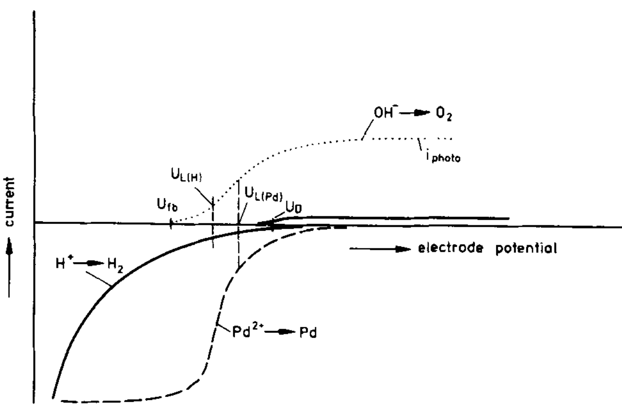

Fig. 12. Schematic current-potential diagram. Symbols are given in text

$U_{L(H)} - U_D$ is the actually observed photovoltage under open-circuit conditions. In the presence of Pd ions an additional cathodic current is possible which appears at less cathodic potentials (dashed curve) than for the hydrogen evolution since the normal potential of Pd/Pd^{2+} is positive. As may be seen from Fig. 12 under illumination the rest potential will now occur at $U_{L(Pd)}$, a potential at which the anodic photocurrent and the cathodic deposition current are equal. In this case the corresponding photovoltage is smaller and given by $U_{L(Pd)} - U_D$. It should be emphasized that the primary effect is the production of holes by light excitation leading to oxygen evolution represented by an anodic photocurrent. Under open-circuit conditions a cathodic current of the same magnitude is induced. This current may be either hydrogen evolution or palladium deposition depending on the composition of the electrolyte. This mechanism, which also was principally observed with other semiconductor electrodes, can only work, however, if the flatband potential is more cathodic than the normal hydrogen potential or the normal Pd^{2+}/Pd potential. This condition is, *e.g.*, not fulfilled for SnO_2, which explains the fact that no photodeposition of palladium on SnO_2 was observed.

It is interesting to note that the open-circuit potential in the presence of Pd ions does not immediately reach its final value after light had been turned on but passes a minimum (see Fig. 11a). Repeating this experiment with the same electrode on which palladium was already deposited during the first run, this minimum does not occur again (curve II in Fig. 11a). Obviously an overpotential of more than 100 mV is required for the deposition of the first palladium nuclei. This is a rather large value for the formation of nuclei. We proved this process by depositing palladium by polarizing the electrode with a constant cathodic current. The corresponding potential-time curves also show a pronounced potential minimum due to the formation of palladium nuclei (Fig. 11b). We did not study the nucleation process in detail. It would be interesting to investigate it also at TiO_2 single crystals since crystal faces and grain boundaries will be of importance.

We only studied the problem of how far the amount of palladium deposited photocatalytically depends on the layer thickness. According to Fig. 13 a considerable increase of the deposited palladium occurs in the range between 0.2 and 0.5μ, whereas above 0.5μ it only rises very weakly. As shown in this figure a large amount of scatter is observed in the experimental values. Therefore we could not obtain a reliable spectral distribution of this effect so that a comparison with the thickness dependence of the photocurrent was not possible. Nevertheless, the thickness dependence of the palladium deposition should be determined by two factors: (*i*) The number of deposited palladium atoms should increase in the thickness range below a value which corresponds to the penetration depth of light (penetration depth $\delta = 1.5\mu$ at $\lambda = 361$ nm). (*ii*) Since the film thickness is of the order of or even smaller than the thickness of the space charge layer for $d < 0.4\mu$ the effective photovoltage may be smaller leading to a lower deposition rate.

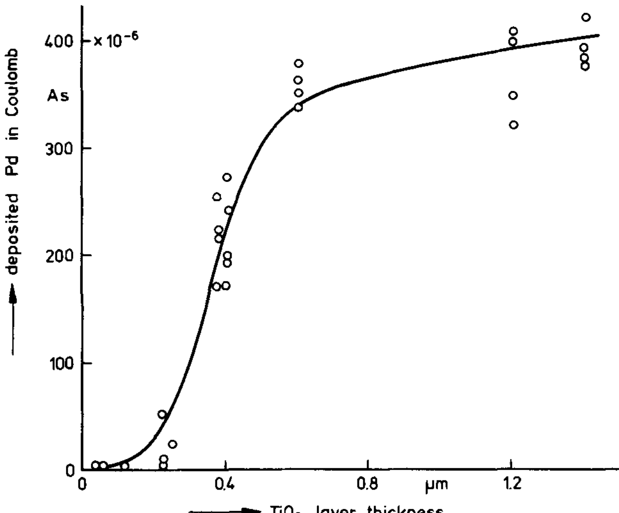

Fig. 13. Amounts of deposited palladium for various film thicknesses after constant exposure for TiO_2 on SnO_2 substrate in 10^{-3}M $PdCl_2$ in 0.1N HCl.

The Formation of Monolayer Metal Films on Electrodes

W. J. Lorenz,* H. D. Hermann, N. Wüthrich, and F. Hilbert

Institute of Physical Chemistry and Electrochemistry, Univeristy of Karlsruhe, Karlsruhe, Germany

ABSTRACT

The two- and three-dimensional nucleation and the metal ion adsorption process are discussed as initial steps for electrocrystallization on the same or on a foreign substrate. The metal ion adsorption takes place in the underpotential range, which is more positive than the equilibrium potential of the nucleated metal/metal ion electrode. Thermodynamic considerations show that an overlapping of disturbing processes in the underpotential range can be characterized by a factor Z_E, which is called charge-coverage coefficient or electrosorption valency. It is a function of different independent variables. The metal monolayer model is satisfied only in the simplest case for $Z_E = z$ (valency of metal ions in solution).

The different experimental methods for determining the thermodynamics, kinetics, and structure of metal ion adsorbates are critically discussed. The most reliable thermodynamic results are obtained by the twin-electrode thin-layer technique. Kinetic data can be obtained by pulse measurements under potentiostatic-galvanostatic conditions. The structure of metal films can be determined by combining different methods including optical investigations.

Results are given for different systems. In the systems Au/Ag^+, Au/Tl^+, and Au/Pb^{++} the metal monolayer model is practically valid. In the case of Cu^{++} ion adsorption on Au the redox reaction forming Cu^+ ions acts as a disturbing process. A cosorption of anions takes place in the system Ag/Pb^{++}. The formation of alloys in the underpotential range was observed in the systems Pt/Pb^{++} and Bi/Pb^{++}.

The structure of metal ion adsorbates must be in correlation with the nucleation phenomena at more negative potentials. In many systems no three-dimensional nucleation overvoltage is observed by using a quasi-steady-state experimental technique. The density of the crystal imperfections and the crystallographic orientation of the surface planes influence the metal ion adsorption process and the structure of films. The results obtained in the systems Ag (poly- and monocrystalline)/Tl^+ can be explained by assuming the formation of superlattices on the electrode surface.

Kinetic investigations in the systems Au/Ag^+, Au/Tl^+, and Au/Pb^{++} show relatively high exchange current densities for the metal ion adsorption process. In these cases the experimental results can be explained by assuming surface diffusion of adions as the rate determining step in the adsorption process. In the system Au/Cu^{++}, a charge transfer step is rate determining, which probably forms precedingly Cu^+ ions.

Crystallization phenomena play an important role in the case of cathodic metal deposition. They include different steps after the metal ion has passed through the electrochemical double layer and is still partially solvated. The final state can be described as the incorporation of the discharged metal atom into the bulk of the metal lattice. The following crystallization steps can occur: surface diffusion of metal adatoms or partially charged metal adions, the formation of two- or three-dimensional nuclei, and the growth of formed nuclei and steps. A hindrance of these crystallization steps leads to a crystallization overvoltage, which can be measured experimentally. In most cases this crys-

* Electrochemical Society Active Member.

Key words: metal ion adsorption, electrocrystallization, thermodynamics, kinetics, structure, experimental methods.

tallization overvoltage is superimposed upon other kinds of overvoltages, especially charge transfer and diffusion overvoltage.

The hindrance of crystallization steps influences the kinetics of the over-all reaction, *i.e.*, the reaction rate and the mechanism. Moreover, the structure of the deposited metal depends on the kinetics. Therefore many mechanical, physical, and electrical properties of the deposited metal are determined by the deposition conditions which are directly connected with the kinetics.

The processes of cathodic metal deposition are practically important in the fields of galvanotechnique and electrometallurgy. On the other hand, the inverse process of metal dissolution is of great interest for metal corrosion and etching.

The important question is, what are the initial steps in electrocrystallization processes? First one has to distinguish between electrodeposition on the same or on a foreign substrate.

In the first case the crystallization steps are a function of the substructure of the substrate. If the density of crystal imperfections is relatively high and a great number of growth sites exist at the surface, then the deposition reaction takes place practically without crystallization overvoltage. Under this condition the charge transfer step takes place directly on these growth sites, *e.g.*, kinks, screw dislocations, and steps. However, if the density of crystal imperfection is relatively low or zero, the formation of two-dimensional nuclei is the rate determining step at low overvoltages and can be considered as the initial step. This was shown impressively by Budevski and co-workers (1, 2) in the case of silver deposition on monocrystalline silver electrodes which were free of dislocations. Similar results were obtained by Fischer and co-workers (3, 4) in the case of Cu^{++} deposition on monocrystalline copper substrates and also on polycrystalline copper substrates in the presence of inhibitors in the electrolyte solution.

In the case of metal deposition on a foreign substrate the formation of three-dimensional nuclei had been considered as the initial step for a long time. The theoretical treatment of nucleation phenomena in electrochemistry was already given by Erdey-Gruz and Volmer (5). According to this theory, the three-dimensional nucleation rate is a function of supersaturation and therefore depends on the crystallization overvoltage η_k

$$J = A \cdot \exp\left(-\frac{\Delta G_{crit}}{k \cdot T}\right) = A \cdot \exp\left(-\frac{S}{|\eta_k|^2}\right) \quad [1]$$

with

$$S = \frac{8\pi \cdot \gamma_{N-V}^3 \cdot V_M^2}{3kTz^2 \cdot \mathbf{F}^2}$$

whereby γ_{N-V} = specific free surface energy of the interphase between nucleus and electrolyte phase, differing for different crystal faces of the nucleus; V_M = mole volume of nuclei. The other symbols have their usual significance.

This theoretical equation could be confirmed experimentally only in the last decade. Mainly Kaischev and co-workers (6) studied the three-dimensional nucleation phenomena. They investigated the deposition of Fe^{++}, Ag^+, Pb^{++}, and Hg^+ ions on monocrystalline platinum substrates using a potentiostatic pulse technique. They observed high crystallization overvoltages up to more than 100 mV in order to form three-dimensional nuclei. These findings could be confirmed also by Schottky and Mierke (7) in the case of Ag^+ ion deposition on polycrystalline and monocrystalline platinum substrates, as well as by Fischer and co-workers (8) in the case of Cu^{++} ion deposition on a polycrystalline copper substrate in the presence of inhibitors in acidic aqueous solutions.

However, platinum seems to be not the regular case, presumably because of its relatively high adsorption capacity for hydrogen and oxygen. Adsorption of inhibitors has probably the same effect (8).

During the last decade the specific adsorption of metal ions on foreign substrates was observed in so many systems using different experimental techniques, that this reaction step and the following formation of metal films can now be considered as the regular initial step of electrodeposition on foreign substrates. This conclusion applies for deposition onto bare metallic surfaces in solutions which are free from surface active substances.

The investigations on the metal ion adsorption phenomena are connected with the work of Schmidt and co-workers. They developed new experimental techniques in order to determine exactly the thermodynamics of metal ion adsorption processes and the formation of metal films. On the basis of the earlier findings of Rogers and co-workers (9-17), the adsorption of metal ions on foreign substrates was studied experimentally and theoretically in many systems by Schmidt and co-workers in the last decade (18-40). At present the following groups are mainly dealing with this subject using different experimental techniques: Bruckenstein and co-workers (41-48), Vetter and Schultze (49-53), Bowles (54-59), and Lorenz and co-workers (60-64).

Moreover, metal ion adsorption processes and film formation were also described by some other authors (65-82). Optical investigations of these adsorption phenomena were done by Yeager and co-workers (83) and by Kolb (84, 85). But only very recently have there been some attempts to correlate the adsorption phenomena with electrocrystallization steps (64, 75, 86). Investigations on the metal ion adsorption on semiconductor surfaces are only at the beginning (85). These investigations have great importance for understanding and improving the metallization steps in IC silicon technology and other related semiconductor device applications.

Metal Ion Adsorption

Phenomenological considerations.—The specific adsorption of metal ions on foreign substrates takes place in the so-called "underpotential range," which is more positive than the equilibrium potential of the deposited metal/metal ion electrode

$$\epsilon \geqq \epsilon_{0,Me/Me^{z+}} = E_{0,Me/Me^{z+}} + \frac{RT}{z\mathbf{F}} \ln \frac{a_{Me^{z+}}}{a_{Me}} \quad [2]$$

This underpotential range extends over several hundred millivolts, however, it depends on the kind of system being investigated.

In order to determine exactly such metal ion adsorption processes cathodically or the reverse desorption processes anodically, it is necessary to measure the corresponding adsorption or desorption currents, respectively, of the corresponding charge amounts.

In the simplest case one can assume that the substrate electrode is ideally polarizable in the underpotential range and no other faradaic or sorption processes occur simultaneously. Here the measured charge amounts correspond exactly to the adsorption or desorption processes of metal ions. In the absence of metal ions in the electrolyte solutions in such systems only capacity current is flowing in order to change the structure of the electrochemical double layer.

However, such ideal conditions are not often realizable. In many systems there is a superposition of disturbing processes, namely faradaic or other sorption processes, *e.g.*, the coverage of the electrode surface with hydrogen or oxygen, the specific adsorption or desorption of other ions, the formation of alloys or intermediate compounds between the substrate and the adsorbed metal ion species, parallel redox reactions, corrosion of the substrate, etc. Under these circumstances the experimental conditions have to be chosen in such a way that these disturbing reactions can be

eliminated or separated either experimentally or by calculations.

Thermodynamics.—In the simplest case of an ideally polarizable substrate electrode and no disturbing processes, the metal ion adsorbate can be described by the so-called metal monolayer model. Here the behavior of the adsorbate follows a pseudo-Nernst equation

$$\epsilon = \epsilon_{0,Me/Me^{z+}} + \frac{RT}{z\mathbf{F}} \ln \frac{a_{Me^{z+}}}{a_{ads}(\Gamma)} \quad [3]$$

In this equation $a_{ads}(\Gamma)$ is the activity of the adsorbed species on the surface at the given surface excess Γ.

Stoichiometric charge measurements show that an equivalent charge amount flows in order to form the adsorbate

$$Me^{z+} + z \cdot e^- \rightleftharpoons Me_{ads} \quad [4]$$

The charge amount, integrated over a certain part of the underpotential range, is given by (see Eq. [14])

$$\int_{t_i}^{t_e} i(t)\,dt = \int_{\epsilon_i >> \epsilon_e, \Gamma_i = 0}^{\epsilon_e, \Gamma_e} \left[\left(\frac{\partial q}{\partial \epsilon} \right)_\Gamma d\epsilon + \left(\frac{\partial q}{\partial \Gamma} \right)_\epsilon d\Gamma \right] \quad [5]$$

$$= q(\epsilon_e, \Gamma_e) - q(\epsilon_i, \Gamma_i = 0) \quad [6]$$

ϵ_i is the equilibrium starting potential at time t_i, and ϵ_e is the equilibrium end potential at time t_e of single sweep respectively cyclic voltammetry as well as potentiostatic step methods.

The metal ion adsorbate disappears for $a_{Me^{z+}} \rightarrow 0$, *i.e.*, $\mu_{Me^{z+}} \rightarrow -\infty$. In other words, in the electrolyte, which is free of metal ions, there flows only a capacity current. The integral over the same underpotential range is given by

$$\lim_{\mu_{Me^{z+}} \rightarrow -\infty} \int_{t_i}^{t_e} i(t)\,dt = \int_{t_i'}^{t_e} i_C(t)\,dt = q(\epsilon_e, \Gamma_e = 0) - q(\epsilon_i, \Gamma_i = 0) \quad [7]$$

Subtraction of Eq. [7] from Eq. [6] leads to

$$\int_{t_i}^{t_e} [i(t) - i_C(t)]dt = q(\epsilon_e, \Gamma_e) - q(\epsilon_e, \Gamma_e = 0) = \Delta q(\epsilon_e, \Gamma_e) = \int_{\Gamma=0}^{\Gamma} \left(\frac{\partial q}{\partial \Gamma} \right)_{\epsilon_e} d\Gamma \quad [8]$$

The limiting value of such charge amounts integrated over the total underpotential range up to the equilibrium potential can be written

$$\lim_{\epsilon_e \rightarrow \epsilon_{0,Me/Me^{z+}}} \Delta q(\epsilon, \Gamma) = \Delta q_{max} \quad [9]$$

The measurable Δq_{max} values are in the magnitude of a complete metal monolayer, *e.g.*, for $z = 1$

$$\Delta q_{max} = 220 \pm 10 \ \mu\text{coulombs} \cdot \text{cm}^{-2}$$

This corresponds to a maximal coverage Γ_{max}

$$\Gamma_{max} = \frac{\Delta q_{max}}{z \cdot \mathbf{F}} \simeq 2.2 \cdot 10^{-9} \ \text{mole} \cdot \text{cm}^{-2}$$

For divalent ions $z = 2$ and therefore Δq_{max} is twice, etc.

The saturation coverage Γ_{max} has been confirmed experimentally in many systems and can be calculated also by taking into consideration an epitaxial adsorption of metal ions on the closest packed lattice plane of the substrate, *e.g.*, the (111) plane in the case of a face-centered cubic lattice. The surface of a polycrystalline substrate is formed by different crystal planes, *e.g.*, (100) and (110) planes in the above-mentioned case. These other planes adsorb a little bit lower Γ_{max} values as can be seen by calculation. On the other hand, the limiting coverage will be increased somewhat by the roughness factor of the electrode surface. Therefore the experimental data for Γ_{max} or Δq_{max} vary somewhat according to the pretreatment of the polycrystalline or monocrystalline electrode surfaces.

If disturbing processes occur simultaneously in the underpotential range, the measurement of Δq values on the working electrode becomes more complex, *i.e.*, the measured $q_{\mu\epsilon}$ isotherm is different from the $q_{\Gamma\epsilon}$ isotherm

$$\Delta q \neq z\mathbf{F}\Gamma \quad [10]$$

Generally, for the interphase between the substrate electrode and the electrolyte the following thermodynamic considerations must be taken into account:

The surface free energy, σ, is a function of the chemical potentials of all species μ_i, which are in the solution, and of the electrode potential ϵ. In the presence of an excess of inert electrolyte and with only one common anion the chemical potentials of the supporting electrolyte as well as that of the anion can be assumed as constant. Therefore at p, T, μ_j $(j \neq Me^{z+}) =$ const

$$\sigma = \sigma(\mu_{Me^{z+}}, \epsilon) \quad [11]$$

With the definitions

$$q = \left(\frac{\partial \sigma}{\partial \epsilon} \right)_{p,T,\mu_{Me^{z+}},\mu_j} = q(\mu_{Me^{z+}}, \epsilon) \quad [12]$$

and

$$\Gamma = -\left(\frac{\partial \sigma}{\partial \mu_{Me^{z+}}} \right)_{p,T,\epsilon,\mu_j} = \Gamma(\mu_{Me^{z+}}, \epsilon) \quad [13]$$

it follows

$$q = q(\Gamma, \epsilon) \quad [14]$$

The partial derivative leads to the so-called charge coverage coefficient Z_E

$$\left(\frac{\partial q}{\partial \Gamma} \right)_\epsilon = Z_E \cdot \mathbf{F} \quad [15]$$

Generally, this coefficient is a function of Γ and ϵ

$$Z_E = Z_E(\Gamma, \epsilon) \quad [16]$$

There exist three limiting cases:

(*i*) $Z_E = z =$ constant, whereby z is the charge number of the metal ion Me^{z+}. In this simplest case the metal monolayer model is valid as above mentioned.

(*ii*) $Z_E = Z_E(\Gamma)$

(*iii*) $Z_E = Z_E(\epsilon)$

In the second and third case it is necessary to measure $\Gamma_{\mu_{Me^{z+}}\epsilon}$ isotherms in an independent way of that used for $q_{\mu_{Me^{z+}}\epsilon}$ isotherms in order to determine the metal ion adsorption process exactly. Naturally, the same statement is valid if Z_E is a mixed function. If such measurements are possible, then the deviations between the two isotherms can be correlated to Z_E and can be explained by disturbing processes, which take place simultaneously in the underpotential range. Schmidt and co-workers (27-29, 32, 33, 35-37, 39) have given the theoretical treatment as well as the experimental confirmation of the thermodynamic predictions using the newly developed twin-electrode thin-layer technique. Some examples will be demonstrated under Results below.

This twin-electrode thin-layer technique is the only one at present which allows us to determine independently $\Gamma_{\mu_{Me^{z+}}\epsilon}$ isotherms in a relatively simple manner. Other suitable methods might be radiotracer measurements and in some cases rotating ring disk techniques.

A more detailed interpretation of the deviation of Z_E from z is given by Vetter and Schultze (50-52) taking into consideration a geometrical factor for the adsorbed species, a partial charge transfer coefficient,

dipole factors, and a capacitive term. Instead of Z_E Vetter and Schultze use the symbol γ and call it "electrosorption valency." The disadvantage of this theory is the difficulty of an experimental separation of the different components by electrochemical measurements. Moreover, Vetter and Schultze give a thermodynamic treatment of cosorption processes in order to determine electrosorption valencies for mixed interphase reactions (53). It seems that only optical investigations could be applied in order to decide in which charge state exist the adsorbed metal species.

Experimental Techniques

At present the following electrochemical measurement methods are applied in the field of metal ion adsorption.

Twin-electrode thin-layer technique.—This method was developed by Schmidt and co-workers in the last 5 years. In principle the thin-layer cell contains four electrodes; the working or indicator electrode, the generator electrode, and the usual reference and counterelectrodes. The first two are situated parallel at a distance of about 50μ from each other. The small electrolyte volume between them constitutes the thin layer. This thin layer is separated by small capillaries from the other part of the electrolyte, which contains both the other electrodes. The generator must be a reversible electrode for the ion species being adsorbed on the indicator, *e.g.*, in the case of metal ion adsorption a reversible metal/metal ion electrode. Both, indicator and generator are polarized potentiostatically at different potentials.

The indicator potential is varied cyclic voltammetrically between defined start and end potentials, ϵ_i and ϵ_e, using scanning rates of about 1 mV · sec^{-1} and waiting for equilibrium adjusting at these potentials. Integration of current-time transients in the indicator circuit gives changes in q, as can be seen from Eq. [6].

According to the Nernst equation the fixed generator potential, ϵ_G,[1] maintains a certain chemical potential $\mu_{Me^{z+}}$ of metal ions in the thin layer. Therefore, any concentration changes within the thin layer due to metal ion adsorption or desorption on the indicator are compensated by the generator. The integration of the current-time transients in the generator circuit corresponds directly to Γ changes on the indicator.

The advantages of the two-electrode thin-layer technique are: (*i*) exact thermodynamic results, especially the possibility to measure $\Gamma_{\mu\epsilon}$ isotherms independently; (*ii*) simple diffusion conditions in the steady state according to Ficks first law; (*iii*) the possibility to purify the thin-layer electrolyte to a very great extent by pre-electrolysis. Moreover, this method is not sensitive against electrolyte impurities, because the ratio between electrode surface and electrolyte volume is very high;[2] (*iv*) the possibility to put in so-called grid electrodes between indicator and generator and to measure potentiostatically the fluxes of different ionic species (39).

The disadvantages are: (*i*) reversible generator electrodes exist only for a few systems; (*ii*) pulse measurements are not possible, because the system has too high impedance; (*iii*) kinetic results cannot be obtained, because the system must be always in quasi equilibrium or in the steady state in order to make possible the mathematical treatment of the findings; (*iv*) the metal ion concentration in the thin-layer electrolyte is limited by the noise and the stability of the operation amplifiers used in the potentiostatic circuits to about 10^{-3} mole · l^{-1} or less as an upper limit.

A scheme of the arrangement of the two-electrode thin-layer technique is demonstrated in Fig. 1.

Rotating electrode systems.—Rotating disk or ring disk electrodes were used in order to simplify the flux

[1] $\epsilon_G = \epsilon_{0,Me/Me^{z+}}$ in Eq. [2] for $a_{Me} = 1$.
[2] Assuming that the components of the thin-layer compartment are initially clean. Otherwise this ratio becomes a disadvantage.

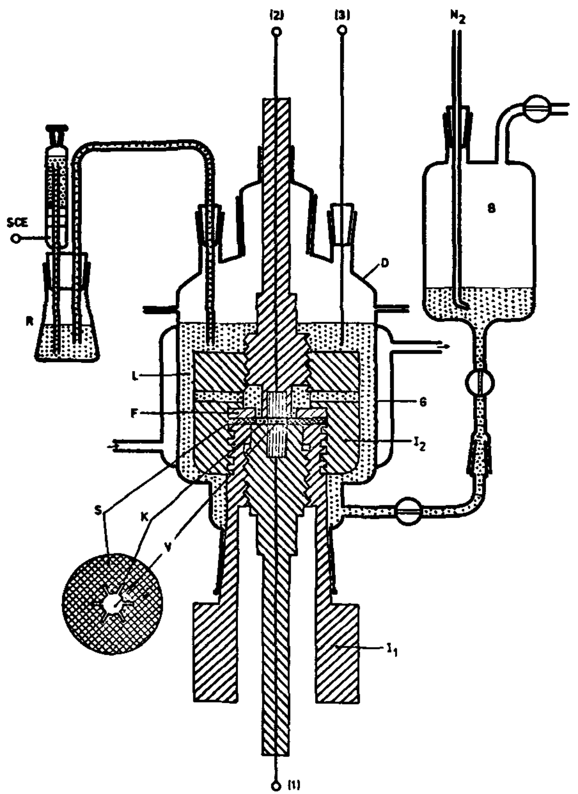

Fig. 1. Twin-electrode thin-layer cell. 1 and 2, Working or indicator electrode and generator electrode, respectively (metal rods, fitted in insulating holders, *e.g.*, Teflon); 3, counterelectrode. I_1, I_2, support of insulating material; F, ring of insulating material; K, capillaries cut out of an insulating spacer S; V, thin layer volume cut out of an insulating spacer S; S, spacer of 50μ thickness; B, electrolyte container; D, glass cover; G, glass cell; L, electrolyte; N_2, nitrogen; R, container for the reference electrode (SCE).

conditions for the metal ion species and to measure ring currents in the case of anodically stripping experiments. The disadvantage of this and the following methods is the high sensitivity against impurities, because the ratio between electrode surface and electrolyte volume is very small. Moreover, when using this technique it is not so easy to measure independently $\Gamma_{\mu\epsilon}$ isotherms on the ring as in the case of the thin-layer technique. Rotating electrode systems are applied mainly by Bruckenstein and co-workers (41-48).

Cyclic or linear sweep voltammetry under semi-infinite diffusion conditions.—These well-known methods give very rapidly useful thermodynamic and kinetic results. The following disadvantages must be taken into account for the interpretation of the results: (*i*) The obtained thermodynamical data can be correlated only to the simple metal monolayer model, because the $\Gamma_{\mu\epsilon}$ isotherms are not measurable independently. (*ii*) An exact interpretation of kinetic data in the underpotential range is relatively difficult, because the mathematical treatment of the current-density potential curves is complicated by the additional parameter $a_{ads}(\Gamma)$ and has not been solved generally up to date.

These methods are used by Harrison and Thirsk (75) and by Lorenz and co-workers (60-64) in the field of metal ion adsorption processes.

Galvanostatic or potentiostatic rectangular pulse measurements under semi-infinite diffusion conditions.—Both methods give only limited thermodynamic data as mentioned above. However, the great advantage of nonsteady-state pulse measurements is the possibility to study the kinetics of metal ion adsorption processes. Both methods require pulse techniques with rise times of maximum 10^{-6} sec. Usual potentiostats are not able to follow in such time constants under load.

Therefore, Lorenz and co-workers (87) are applying multichannel pulse galvanostats, which are very rapid and have a rise time of about 6.10^{-8} sec (88).[3] In addition, this technique also requires an electronic voltage-to-current converter with the same switching time constant in order to change instantaneously from potentiostatically fixed equilibrium conditions to non-steady-state galvanostatic ones (88).

Earlier Schultze (49) had used galvanostatic pulse measurements in order to determine thermodynamics as well as kinetics of the Cu^{++} ion adsorption process on polycrystalline platinum substrate. It should be mentioned that the obtained results are problematic due to disturbing processes on platinum electrodes, *e.g.*, adsorption of hydrogen and oxygen. Moreover, no evidence could be given for the adsorption step to be rate determining instead of the reduction of Cu^{++} ions to Cu^{+} ions.

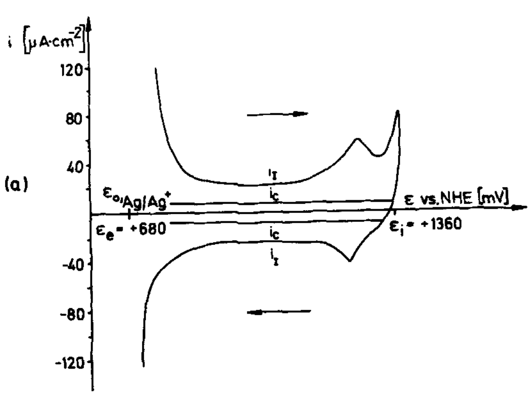
Optical methods.—In order to determine the formation of metal films on foreign substrates as well as their structures, reflection spectroscopy was applied by Yeager and co-workers (83) and by Kolb (84, 85). The metal ion adsorption changes the reflectivity in a definite way. But the correlation between this change and the structure of the adsorbate seems to be relatively uncertain at present, because of the simplifying assumptions incorporated in the theoretical interpretation of the data.

Results

Au/Ag⁺ and Au/Tl⁺ systems.—Figure 2 shows the Ag^{+} ion adsorption on polycrystalline and monocrystalline gold electrodes from sulfuric acid solutions using cyclic voltammetry. The monocrystalline electrode surface has a defined crystallographical orientation of (111) plane. Both kinds of electrodes were mechanically and electrolytically polished and preactivated by polarization. In the first approximation this system follows the metal monolayer model. The integrated Δq_{max} values are about 400 μcoulombs · cm^{-2} for the polycrystalline and monocrystalline electrode surfaces, respectively. These results are in a good agreement with the theoretical Δq_{max} value taking into consideration a roughness factor of about 1.5, which could be verified experimentally by measuring the double layer capacity. Moreover, from Fig. 2 it can be seen clearly that the nucleation of metallic silver takes place without any three-dimensional nucleation overvoltage. The $q_{\mu\varepsilon}$ isotherm is represented in Fig. 3.

The system with polycrystalline gold as a substrate and Tl^{+} ions has a quite similar behavior. Figure 4

[3] The apparatus are produced by Mega-Physik Limited, D 7550 Rastatt, Germany.



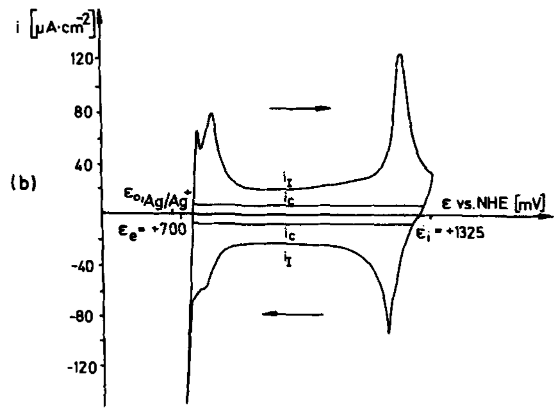


Fig. 2. Au/0.5M H_2SO_4 + 3.9 × 10^{-2}M Ag^{+} system. $\left|\frac{d\varepsilon}{dt}\right|$ = 50 mV · sec^{-1}; T = 298°K; i_I = current of the working electrode; i_C = capacity current at c_{Ag^+} = 0. a, Polycrystalline Au; b, monocrystalline Au (111).

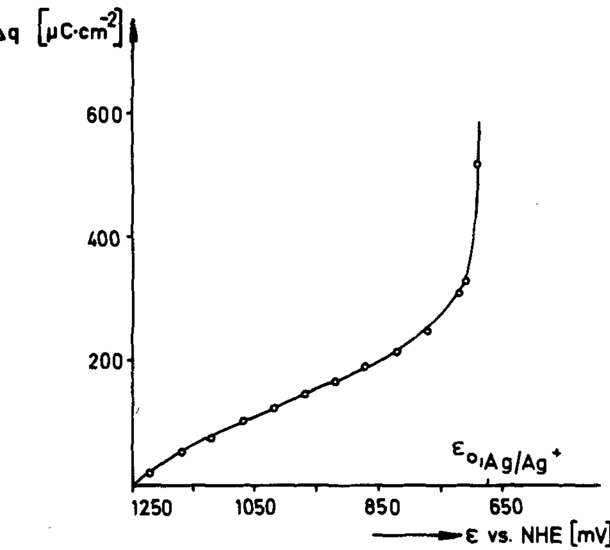

Fig. 3. Au (polycrystalline)/0.5M H_2SO_4 + 3.9 × 10^{-2}M Ag^{+} system. $q_{\mu\varepsilon}$ isotherm determined by potentiostatic step measurements under steady-state conditions. T = 298°K.

demonstrates cyclic voltammetric measurements in chloride media with and without Tl^+ ions in the electrolyte. The metal ion adsorption occurs mainly at the peak potentials IIa and IIb. In this experiment the end potential was chosen more negative than the equilibrium potential of the Tl/Tl^+ electrode. It can be seen also that the nucleation of metallic thallium happens practically without any crystallization overvoltage.

Au/Cu++ system.—The Cu^{++} ion adsorption on polycrystalline gold electrodes is shown in Fig. 5 for cyclic voltammetric measurements. In this system the single peak in the underpotential range does not only correspond to the adsorption process cathodically and the desorption process anodically, but it contains also the disturbing faradaic redox process

$$Cu^{++} + e^- \rightleftharpoons Cu^+ \quad [17]$$

This follows from the measured Δq_{max} values, which are much higher than the theoretical ones and are dependent on the Cu^{++} ion concentration in the electrolyte as well as on the scanning rate (61, 62, 89). Investigations in the same system using the twin-electrode thin-layer technique are in a good agreement with the cyclic voltammetrical results (34, 62). A mathematical treatment of the experimental results obtained by cyclic voltammetry under semi-infinite diffusion conditions (relatively high Cu^{++} ion concentrations in the electrolyte and low scanning rates) showed that the diffusion of Cu^+ ions from the electrode surface into the bulk of the solution can be considered as the rate determining step (89).

Au/Pb++ system.—Figure 6 shows the Pb^{++} ion adsorption on polycrystalline gold electrodes using the twin-electrode thin-layer technique given by Schmidt and Wüthrich (35). It can be seen that the currents of the indicator and generator electrodes are about the same in the opposite direction. In other words, this system follows the metal monolayer model. This was verified by considering the $q\Gamma\epsilon$ isotherms, which are given in Fig. 7. The measured integrals are situated on the theoretical line for $Z_E = z = +2$. In this case the $\Gamma\mu\epsilon$ isotherms, plotted in the special form $\theta = \theta(\epsilon_G, \epsilon_G - \epsilon)$, are all situated on the same curve, which

shows the current potential curves for the indicator and generator electrodes. Obviously in this case there are deviations between them. The $q\Gamma\epsilon$ isotherms, which are represented in Fig. 10, show that in the lower underpotential range $Z_E = Z_E(\Gamma) > 2$ and in the higher one $Z_E = Z_E(\Gamma,\epsilon) < 2$. These deviations were explained by codesorption and coadsorption processes, respectively, of Cl^- ions. In this case the special $\Gamma\mu\epsilon$ isotherms $\theta = \theta(\epsilon_G, \epsilon_G - \epsilon)$ are different curves for each ϵ_G, as it is shown in Fig. 11. The horizontal shift of these curves is correlated to the deviation of Z_E from $z = +2$.

Pt/Pb^{++} and Bi/Pb^{++} systems.—In these systems Schmidt and Wüthrich (37, 90) found the formation of alloys in the underpotential range. Moreover, the sorption process on the platinum electrode is not reversible. Consequently, thermodynamic treatment could not be applied in these cases.

Structure of Metal Films

At present the structure of adsorbed metal ions in the underpotential range is an open question. This problem is not solved because the interpretation of the Δq_{max} or Γ_{max} values as the formation of complete metal monolayers on the substrate is only an assumption. The measurable Δq or Γ values are only integrals. They cannot predict anything about the arrange-

ment of the adsorbed species. The formation of multiatomar metal layers or multiatomar islands in the underpotential range was supposed by Schultze (49), Thirsk (75), Breiter (73, 74), Wüthrich (35, 37, 90), and Kolb (85). The formation of such instable prenuclei would be very interesting in considering the nucleation phenomena of the compact metal at potentials which are more negative than the equilibrium potential $\epsilon_{0,Me/Me^{z+}}$. However, a strong argument for the monolayer theory is the fact that in many cases the Δq_{max} respective Γ_{max} values correspond just to a monolayer. This constancy could hardly be explained by island formation, which would be much more dependent on pretreatment of electrodes and purity grade of solutions.

In many systems no crystallization overvoltage can be determined using voltammetric techniques under quasi-steady-state conditions, starting from the underpotential range and polarizing to nucleation potentials, which are more negative than the equilibrium potential $\epsilon_{0,Me/Me^{z+}}$. In other systems the observed amount of it is only several millivolts and indicates more a two-dimensional rather than a three-dimensional nucleation. In other words, under quasi-steady-state conditions the formation of three-dimensional nuclei as the initial process of electrocrystallization on foreign substrates is improbable in many investigated systems. However, the three-dimensional nucleation could be a kinetic phenomenon. In the case of nonsteady-state pulse experiments the formation of three-dimensional nuclei may occur if the relaxation time is relatively high for the formation of a metal monolayer or instable prenuclei in the underpotential range. On the contrary, under quasi-equilibrium conditions using voltammetry there might be a direct nucleation or growth process starting from the metal adsorbate in the underpotential range.

Another very important problem is the influence of the substructure of the substrate on thermodynamics, kinetics, and structure of metal ion adsorption in the underpotential range. Polycrystalline material as a substrate has a certain density of crystal imperfections, *e.g.*, different kinds of dislocations, lattice deformations, etc. However, the density of crystal imperfections in monocrystalline material is generally lower by several orders of magnitude. Furthermore, the polycrystalline surface consists of different crystal grains belonging to different lattice planes. These grains are separated by large angle boundaries. Each crystal grain consists of subgrains separated by low angle boundaries, which are built up by penetration points of edge dislocations. Monocrystalline material consists also of subgrains. However, the density of subgrain boundaries is much lower than in the case of polycrystalline material.

Consequently two parameters of the substrate have to be taken into account in metal ion adsorption processes: (*i*) the density of crystal imperfections and (*ii*) the kind of crystallographic orientation of the surface. Accordingly, Lorenz and co-workers (63, 64) investigated the influence of these two parameters in the case of Tl^+ ion adsorption on silver electrodes. Polycrystalline as well as monocrystalline silver electrodes were used as substrates. The monocrystalline electrode had definite crystallographic surface orientation of (100), (110), and (111) planes and a much lower density of crystal imperfections than the polycrystalline electrodes. Three different electrolyte systems were investigated. The pretreatment of the electrode surfaces was either only mechanical polishing or mechanical polishing followed by electrolytical polishing as carried out by Budevski (91-93). Cyclic voltammograms of mechanical polished electrodes are represented in Fig. 12-14. The obtained results were surprisingly independent of the kind of electrode pretreatment. q values were determined by integrating only the peak currents, therefore $q \leq \Delta q_{max}$. Two important results could be observed:

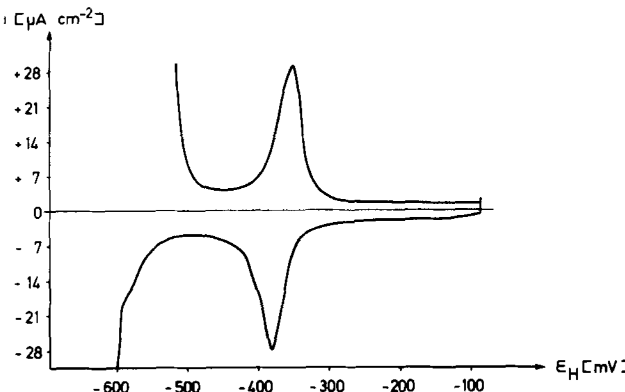

Fig. 12. Ag (polycrystalline)/0.5M KCl + 3.75×10^{-4}M Tl^+ system. $\left|\frac{d\epsilon}{dt}\right| = 6.1$ mV · sec^{-1}; $T = 298$°K.

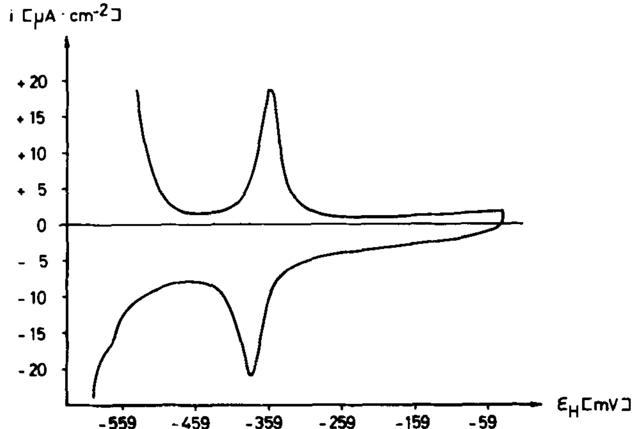

Fig. 13. Ag (110)/0.5M KCl + 3.75×10^{-4}M Tl^+ system. $\left|\frac{d\epsilon}{dt}\right| = 6.1$ mV · sec^{-1}; $T = 298$°K.

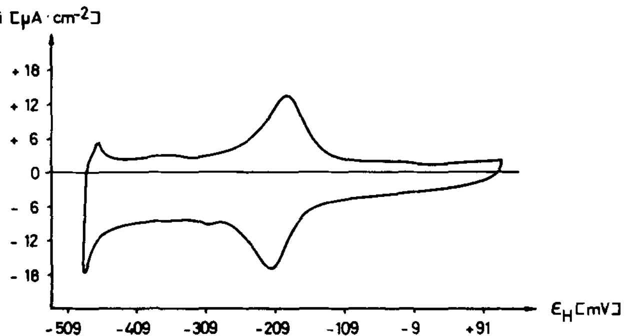

Fig. 14. Ag (100)/0.5M $NaClO_4$ + 0.01M $HClO_4$ + 4×10^{-3}M Tl^+ system. $\left|\frac{d\epsilon}{dt}\right| = 6.1$ mV · sec^{-1}; $T = 298$°K.

(*i*) The single current peak, recorded in the underpotential range, corresponds to the Tl^+ ion adsorption and its potential value is not influenced markedly by the kind of substrate. This means that the free energy of adsorption will not mainly depend on the surface orientation. Furthermore, it may be tentatively concluded that this free energy hardly depends on the density of crystal imperfections. This second conclusion depends on how much of the surface deformation caused by mechanical work remains after the last polishing. It is known from the investigations of Samuels and co-workers (94-96) that this remaining surface deformation can be kept quite low. Even without electrochemical polishing it can be kept below the

Table I. Adsorption of Tl^+ ions on polycrystalline and monocrystalline Ag substrates depending on the surface pretreatment, electrolyte system, and scanning rate of cyclic voltammograms ($T = 298°K$)

detection limit of electron diffraction measurements, if the procedures worked out by this author are carefully followed, as it was done during the present investigations. A further argument for the validity of both conclusions are LEED investigations (97), in which the free energy for CO adsorption on poly- and monocrystalline palladium surfaces was found to be independent of the kind of substrate.

(*ii*) The measured q values correspond approximately to the formation of a metal monolayer in the case of polycrystalline substrate. However, in the case of monocrystalline electrodes the q values depend on the kind of crystallographic orientation. This is illustrated in Table I. Surprisingly the q values decrease in the following sequence:

$$q(100) > q(110) > q(111)$$

This means that the closest packed lattice plane (111) of the face-centered cubic lattice of silver adsorbs the lowest amount of Tl^+ ions. This can be explained by assuming that the adsorption of Tl^+ ions takes place on interstitial sites between the surface silver atoms and leads to the formation of a superlattice. Such superlattices are well known from LEED investigations dealing with adsorption phenomena from the gas phase. Using this model, the above-mentionad sequence can be calculated. The experimental results are higher than the calculated data. These deviations can be attributed to the influences of crystal imperfections, formation of multilayers or islands, and of the roughness factor. According to the superlattice model, the coverage of the polycrystalline substrate should be placed between the coverages of the (100) and (110) planes, if one does not take into account any influence of the density of crystal imperfections. In two of the three investigated electrolyte systems this statement could be confirmed as Table I indicates. The third system contains Cl^- ions and here coadsorption or codesorption processes cannot be excluded. A true to scale representation of such superlattices is given in Fig. 15-17 using $r_{Tl} = 1.70Å$ and $r_{Ag} = 1.44Å$.

Kinetics of Metal Ion Adsorption

Up to date only one paper dealt with the subject of the kinetics of metal ion adsorption. Schultze (49) investigated the kinetics of Cu^{++} ion adsorption on polycrystalline platinum electrodes using galvanostatic pulse measurements after potentiostatically adjusted equilibria. He calculated exchange current densities for the adsorption process in the underpotential range which are higher than those for the corresponding Cu/Cu^{++} electrode. Naturally, the evaluated values depend on the degree of coverage as well as on the Cu^{++} ion concentration in the solution. However, the results of Schultze are not without doubt as already mentioned.

Presently a study of adsorption kinetics is being carried out for the systems Au/Ag^+, Au/Cu^{2+}, Au/Pb^{2+}, and Au/Tl^+ with (111) orientated monocrystalline and polycrystalline substrates utilizing potentiostatic-galvanostatic pulse techniques (87). The potentiostatically fixed initial states in the underpotential region in this method are equilibrium states, which are characterized by ϵ^*, Γ^*, and $C_{DL}(\epsilon^*)$, whereby C_{DL} represents the double layer capacity. The following galvanostatic pulse width depends on the applied pulse amplitude i and is chosen in such a way that the change of Δq does not exceed 1 μcoulomb · cm^{-2} and the potential deviations from ϵ^* are a few millivolts at most. Under these experimental conditions the $\Gamma_{\mu\epsilon}$ isotherm can be linearized in the vicinity of the initial state, and therefore potential time transients can be calculated for $\eta << RT/z\mathbf{F}$ to fit the experimental curves, assuming simple adsorption kinetics.

Furthermore, the concentrations of metal ions in the electrolyte are chosen high enough to neglect bulk

diffusion polarization within the experimental time scale. Under this additional condition two extreme cases of adsorption models were tested.

(*i*) A charge transfer step is rate determining. Assuming kinetic simple steps of metal ion transfer, one is able to show that the working electrode behaves like the equivalent circuit of Fig. 18. Then the potential-time transient is described by the following equation

$$\eta(t) = \epsilon(t) - \epsilon^* = \frac{iR_{ads}C_{ads}^2}{(C_{DL} + C_{ads})^2} \cdot \left[1 - \exp\left(-\frac{C_{DL} + C_{ads}}{R_{ads}C_{ads}C_{DL}}t\right)\right] + \frac{i}{C_{DL} + C_{ads}} \cdot t \quad [18]$$

whereby

$$R_{ads} = \frac{RT}{z\mathbf{F}} \cdot \frac{1}{i_{0,ads}}$$

with $i_{0,ads}$ = exchange-current density of adsorption, and

$$C_{ads} = \frac{z^2\mathbf{F}^2}{RT} a_{\Gamma^*} \cdot \left(\frac{da_\Gamma}{d\Gamma}\right)^{-1}$$

$$C_{DL} = C_{DL}(\epsilon^*)$$

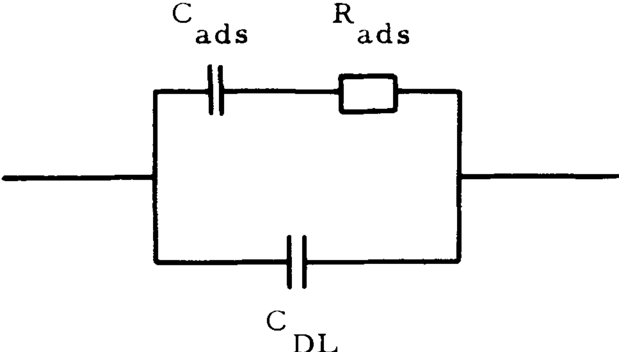

Fig. 18. Equivalent circuit for the kinetics of metal ion adsorption according to the metal monolayer model. C_{DL} = double layer capacity; C_{ads} = adsorption capacity; R_{ads} = adsorption resistance.

(*ii*) A surface-diffusion step is rate determining. The same well-known linear geometry of an electrode surface as in the adatom model of electrocrystallization was assumed [see Ref. (98) and literature cited there], *i.e.*, the surface was considered to consist of parallel step lines in a distance of 2 *l*. Moreover, the following assumptions were made: In equilibrium the adsorbate is distributed homogeneously; adsorptive charge transfer only occurs at the step lines; within short measuring times (<100 μsec), a semi-infinite linear approximation of the diffusion problem is valid. The potential-time transient then may be described by the following equation

$$\eta(t) = \epsilon(t) - \epsilon^* = -\frac{iC_{DL}}{C_{ads}^2} \cdot \frac{l^2}{D} + \frac{2i}{\sqrt{\pi}C_{ads}} \cdot \frac{l}{\sqrt{D}} \cdot \sqrt{t} + \frac{iC_{DL}}{C_{ads}^2}\frac{l^2}{D} \cdot \exp\left(\frac{C_{ads}^2}{C_{DL}^2} \cdot \frac{D}{l^2} \cdot t\right) \operatorname{erfc}\left(\frac{C_{ads}}{C_{DL}} \cdot \frac{\sqrt{D}}{l} \cdot \sqrt{t}\right) \quad [19]$$

whereby *D* is the surface diffusion coefficient (other symbols see above). In both cases, C_{ads} has to be identical to the thermodynamic adsorption capacity $-z\mathbf{F}(\partial\Gamma^*/\partial\epsilon)_\mu$ which can be evaluated by differentiating $\Gamma_{\mu\epsilon}$ isotherms, whereas C_{DL} can be taken from the initial slope of the potential time transient.

In the cases of adsorption of Ag^+, Pb^{2+}, and Tl^+ on gold electrodes, the potential time transients can only be fitted within experimental errors by Eq. [19]. Therefore a surface diffusion step seems to be rate determining. The ratio $\sqrt{D}/l$, which is the only experimentally detectable parameter in this case, depends on the surface conditions. As expected this ratio is higher for polycrystalline than for monocrystalline electrode surfaces in the Au/Pb^{++} system.

The applicability of Eq. [19] implies a neglectable charge transfer polarization. This means that the exchange current densities of the adsorption processes are relatively high. This could be confirmed by fitting the experimental transients using a program which takes into consideration charge transfer as well as surface diffusion. In the systems Au/0.04M Ag^+, Au/0.1M Pb^{++}, and Au/0.1M Tl^+ one obtains lower limits of $i_{0,ads}$ of 6.3 and 20 A · cm^{-2} respectively (87, 99).

Only in the case of Cu^{2+} adsorption on gold is a charge transfer step rate determining according to Eq. [18]. At a coverage of θ = 0.6 the exchange current density in the system Au/0.1M Cu^{2+} is found to be 10^{-3} A · cm^{-2}. This value is of the same magnitude as the exchange current density of the Cu/Cu^{2+} electrode which is known to be determined by the preceding redox reaction

$$Cu^{2+} \rightleftharpoons Cu^+ + e^-$$

Therefore it could be supposed that the rate of Cu^{2+} adsorption is also determined by this step.

Manuscript submitted Feb. 18, 1974; revised manuscript received May 13, 1974.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1975 JOURNAL. All discussions for the June 1975 Discussion Section should be submitted by Feb. 1, 1975.

Analytical Aspects of Energy-Deficient Electrogenerated Chemiluminescence

Terry M. Huret[1] **and J. T. Maloy***

Department of Chemistry, West Virginia University, Morgantown, West Virginia 26506

ABSTRACT

A potential scan method has been developed for analytical studies of energy-deficient electrogenerated chemiluminescence (ECL) in mixed systems. This method involves the use of an unsymmetrical alternating potential, one portion of which is held at a fixed negative potential, while the other is scanned over a linearly increasing positive potential. This alternating potential program has been used to monitor the intensity of the ECL from 9,10-diphenylanthracene as a measure of the concentration of N,N,N',N'-tetramethyl-*p*-phenylenediamine, N,N-dimethyl-*p*-phenylenediamine, and 10-methylphenothiazine in solution. This ECL intensity was found to be linear with concentration for these compounds for concentrations less than 0.1 mM. Because this method allows the recording of ECL intensity as a function of potential it represents the stationary electrode ECL equivalent of polarography.

Electrogenerated aromatic radical cations and anions can undergo an electron-transfer reaction in an aprotic solvent to produce electrogenerated chemiluminescence (ECL). The radical cation and the radical anion can be formed from the same parent compound, as in the cases of 9,10-diphenylanthracene (DPA) or rubrene, or from different parent compounds, as in the case of the mixed system of N,N,N',N'-tetramethyl-*p*-phenylenediamine (WBP) and DPA. The end result of the electron transfer, or any other subsequent reaction which ensues, is the production of first excited singlet-state molecules of one or both of the compounds. Because ECL arises from first excited singlet-state emission it is usually similar to the fluorescence of the parent compound.

Two main pathways have been proposed for the production of excited singlet-state molecules of the compounds involved in the electron-transfer reaction. The first is an energy-sufficient pathway where the electron-transfer reaction produces enough energy to directly populate the first excited singlet state

$$R + e^- \rightarrow R^{\overline{\cdot}} \qquad [1]$$

$$R' - e^- \rightarrow R'^{\overset{+}{\cdot}} \qquad [2]$$

$$R^{\overline{\cdot}} + R'^{\overset{+}{\cdot}} \rightarrow {}^1R^* + R' \text{ or } {}^1R'^* + R \qquad [3]$$

$${}^1R^* \rightarrow R + h\nu \text{ or } {}^1R'^* \rightarrow R' + h\nu' \qquad [4]$$

where R and R' can be the same compound or different compounds. It has been postulated that the neutral molecule formed in its excited singlet state is that having the lower energy level for its first excited singlet state (1).

The second pathway by which neutral molecules are produced in the first excited singlet state is an energy-deficient process. Here, the electron-transfer reaction between the electrogenerated reductant and the electrogenerated oxidant does not provide enough energy to produce neutral product molecules in their first excited singlet state, but sufficient energy is available to form the lowest triplet state of the product molecules of one or both of the reactants. Two triplets may then undergo triplet-triplet annihilation to produce a molecule in its first excited singlet state

$$R + e^- \rightarrow R^{\overline{\cdot}} \qquad [5]$$

$$R' - e^- \rightarrow R'^{\overset{+}{\cdot}} \qquad [6]$$

$$R^{\overline{\cdot}} + R'^{\overset{+}{\cdot}} \rightarrow {}^3R^* + R' \text{ or } {}^3R'^* + R \qquad [7]$$

$${}^3R^* + {}^3R^* \rightarrow {}^1R^* + R \text{ or } {}^3R'^* + {}^3R'^* \rightarrow {}^1R'^* + R' \qquad [8]$$

$${}^1R^* \rightarrow R + h\nu \text{ or } {}^1R'^* \rightarrow R' + h\nu' \qquad [9]$$

If the electron-transfer reaction energy is sufficient to form either triplet state, it has been postulated that the parent compound with the lower triplet energy will be formed when the electron transfer occurs (2). For the triplet-triplet annihilation reaction to produce molecules to their first excited singlet state, it has also been postulated that the triplet energy of the compound must be at least equal to one-half of its first excited singlet energy (3).

Much experimental work has been done in the characterization of energy-sufficient and energy-deficient reaction schemes (4-6). Some concentration studies have also been performed. Cruser and Bard (7) studied ECL intensity as a function of concentration for single-component, energy-sufficient systems. Fleet, Kirkbright, and Pickford (8) did a quantitative determination of certain fused-ring aromatic hydrocarbons using ECL. Maloy and Bard (9) have used a rotating ring-disk electrode (RRDE) to show that the ECL intensity and efficiency of the energy-deficient WBP-DPA system decreases at high concentrations of the WBP.

In most of the ECL studies performed so far, the cation radicals and the anion radicals have been alternately generated at a single working electrode. Sinusoidal, triangular, and square-wave potential programs have been used. None of these methods involving the alternate formation of the ion radicals at a single working electrode can be used to produce a steady-state ion-annihilation ECL. Therefore, they are difficult to use for the study of the potential dependence of ECL intensity. Nevertheless, Hercules and his coworkers (10) have investigated the potential dependence of ECL by using triangular wave cyclic voltammetry. Zweig *et al.* (11) examined the potential dependence of ECL by manually switching between the required positive or negative potentials and measuring the intensity of the ECL. This method was not only time-consuming, but no steady-state ECL intensity was obtained.

Potential scan ECL experiments have been performed with the RRDE (9, 12). In these experiments the ring potential was maintained in the diffusion-limited region for the generation of one of the radical

Key words: nonaqueous solvents, luminescence, voltammetry, chemiluminescence, electroanalysis.

ions, while the potential of the disk was scanned through regions where the other reactant was generated. Steady-state ECL intensities of one-component, energy-sufficient systems and two-component, energy-deficient systems were produced using this method. This method is difficult to employ generally however, due to the complexity of the RRDE apparatus.

Because no detailed experiments have been done on concentration effects on energy-deficient ECL using two-component systems, and because no simple method of doing easily reproducible potential scan experiments on ECL have been proposed, this present work was undertaken. Its objectives were twofold. The first was to devise a technique that would use a stationary working electrode to approximate the steady-state ECL signal obtained with the RRDE in potential dependence studies on two-component, energy-deficient systems, and thereby avoid some of the experimental difficulties of the RRDE. The second objective was to study, for two-component, energy-deficient systems, the effect of changing the bulk concentration of the parent compound of the electrogenerated oxidant on the intensity of the ECL.

The electrogenerated radical anion of DPA was the reductant used in these studies. It was selected as the reductant because DPA has a high quantum efficiency for fluorescence, a low triplet energy for electron transfer, and is known to produce ECL with a variety of oxidants (2). In an attempt to achieve reproducible conditions regardless of oxidant, the DPA concentration was maintained in at least tenfold excess of the concentration of the parent compound of the electrogenerated oxidant. The three oxidants used in these studies were the radical cations of WBP, WRP (Wurster's Red Parent or N,N-dimethyl-*p*-phenyleneamine), and 10 MP (10-methylphenothiazine). These systems were chosen because they had been studied previously (4, 9), and their energy-deficient ECL, produced by the electron-transfer reactions and subsequent triplet-triplet annihilation reactions, was known to be emitted from the first excited singlet state of DPA (2). Also, it had been shown that for one of the mixed systems (WBP-DPA), both the intensity and ECL efficiency decreased with increasing concentration of WBP at a RRDE when the concentration of WBP was greater than 1 mM (9). This study was undertaken to determine if there was a concentration range over which the ECL intensity increased linearly with concentration. Since this concentration range was expected to be below the 1 mM level, the development of a new chemiluminescent method for trace analysis was an indirect objective of this study. The possibilities for a trace analysis method seemed particularly appealing because ion-annihilation ECL results from electron-transfer reactions in the diffusion layer around the electrode; therefore, all ECL of this type must result from faradaic processes, and no correction for nonfaradaic background processes as in conventional voltammetry was anticipated. It was hoped that this would permit the detection of lower concentration levels of the parent compound of the electrogenerated oxidant than conventional electrochemical techniques.

To meet the two objectives of this work, an electrochemical cell and an electronic circuit were designed which allowed concentration and potential scan studies to be carried out concurrently. The specially constructed electrochemical cell employed a stationary working electrode and was equipped with a burette for adding known amounts of the parent compounds of the electrogenerated oxidants used in this study. The electronic circuit was designed to generate an unsymmetrical alternating potential. One portion of this alternating potential was a square wave held at a fixed negative potential. The other portion was a slowly increasing, linear, positive potential ramp. With this circuit, the fixed negative potential of the unsymmetrical square wave was set at the cyclic voltammetric peak potential for the formation of the electrogenerated oxidant. Thus, on alternate half-cycles, a slowly varying oxidative potential was applied to the working electrode. The recording of the intensity of the approximate steady-state ECL signal obtained in this manner *vs.* the positive ramp potential provided the ECL equivalent of polarography. Thus, while the magnitude of the maximum ECL signal produced measured the quantity of electrogenerated oxidant present, the ramp potential at which this signal was observed was a characteristic of the parent compound of the oxidant. One of the main results of this study was the investigation and exploitation of the polarographic nature of this analytical technique.

Experimental

Electrochemical cell.—The cell used for these studies is shown in Fig. 1. The cell was a three electrode design with a 5.5 mm 22 gauge platinum wire working electrode, a coiled, platinum counterelectrode, and a coiled, platinum quasi-reference electrode (QRE). The working electrode was made by silver soldering a short piece of platinum wire to a long piece of 20 gauge silver wire which was in turn silver soldered to a short length of nickel-tungsten-nickel alloy sealed into a 10/30 standard taper inner joint. All the wire, except the 5.5 mm of platinum used for the working electrode, was sealed liquid tight in a thin, hollow glass tube which was joined to the 10/30 standard taper inner joint. A small hole in this thin glass tube near the joint allowed the pressure inside and outside

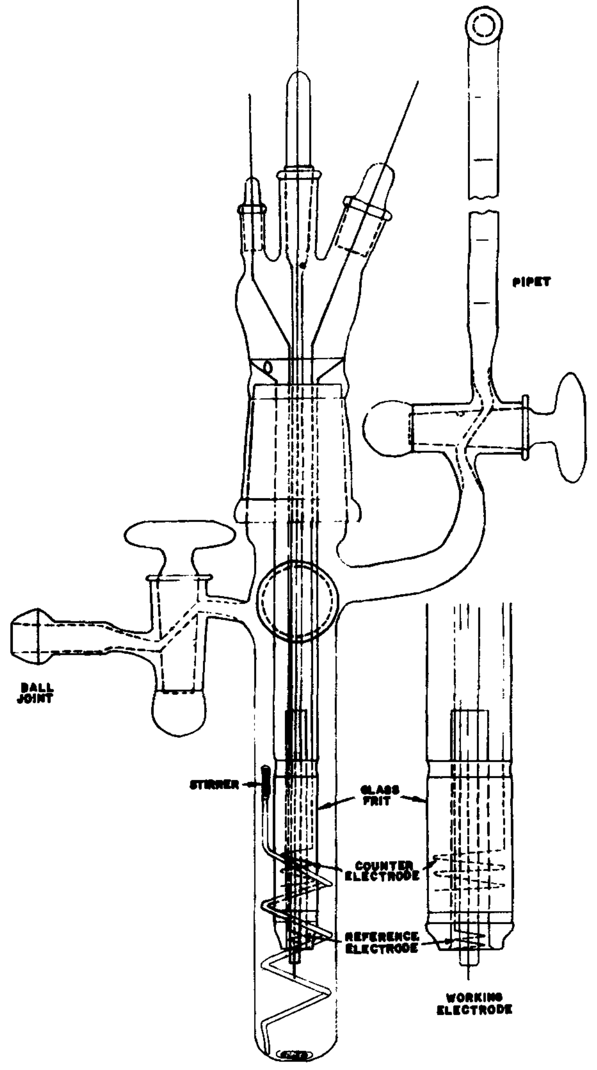

Fig. 1. Electrochemical cell

of this tube to equilibrate. The counterelectrode was a long piece of platinum wire silver soldered to a short length of nickel-tungsten-nickel alloy which was sealed into a 12/18 standard taper inner joint. The quasi-reference electrode was made the same way as the counterelectrode except the coil was smaller, and the alloy connector was sealed into a 7/15 standard taper inner joint. The electrodes were made with joints so that they could easily be removed from the electrochemical cell cap in order to be cleaned between experiments.

The cap of the electrochemical cell was designed to hold all the electrodes in a concentric configuration. In addition, it supported a fritted glass auxiliary compartment. The cap consisted of a 34/45 standard taper outer joint fitted with three outer joints corresponding to the inner joints of the the three electrodes. Sealed inside the cap, above the ground surface of the joint, was a flared glass tube with an outer diameter of 15 mm. This tube extended vertically 9 cm below the bottom of the 34/45 standard taper outer joint to a point at which a 6 cm portion of cylindrical, fritted filter tube of identical diameter was attached. Sealed in the Pyrex bottom of the fritted filter tube was a smaller tube of an inner diameter of 5 mm which extended up into the cap assembly 2.4 cm above the end of the fritted glass to a point above the normal solution levels in the cell. The coil of the counterelectrode was large enough to fit over this inner glass tube, and the counterelectrode was long enough so that when it was seated into the cell cap, its coil was positioned between the fritted glass and the inner glass tube. This formed a cylindrical auxiliary electrode compartment to keep any products formed at the counterelectrode during an experiment from mixing with the rest of the solution in the cell. The coiled reference electrode and the wire working electrode, when seated in the cell cap, both extended down through the inner glass tube. The coil of the reference electrode was large enough to slip over the glass tube in which the working electrode was sealed. The tip of the working electrode extended 1 cm below the end of the auxiliary electrode compartment. The reference electrode was *ca.* 1.5 cm above the working electrode and was just inside the inner glass tube of the cell cap. The electrodes were placed in the cell cap assembly before the cap was placed on the 34/45 standard taper inner joint attached to the main body of the electrochemical cell.

The main body of the electrochemical cell consisted of an electrode chamber, a cold finger, a cap, a calibrated burette connected to the cell through a high-vacuum stopcock, and a ball joint connected to the cell through a high-vacuum stopcock. The electrode chamber was made from glass tubing with an inner diameter of approximately 25 mm and was positioned vertically beneath the electrolysis cell cap. The electrode chamber housed both the glass tube and electrodes which extended downward from the cell cap and the coiled glass stirrer. The electrode chamber extended 2.7 cm below the tip of the working electrode in order to provide an undistorted optical path for the ECL generated at the working electrode. The coiled stirrer was made from thin, hollow glass tubing and contained a small magnet sealed in its top. A horseshoe magnet was used to move this stirrer up and down from outside of the cell to facilitate the mixing of solutions added from the burette. The cold finger, which extended at a right angle to the electrode chamber (coming out of the plane of the paper in Fig.1) was made of the same inner diameter tubing as the electrode chamber and was about the same length. The cap, which was on the opposite side of the cell as the cold finger, was made from a 24/40 standard taper outer joint. It was attached to the cell by means of a 24/40 standard taper inner joint sealed onto the main body of the cell. This cap allowed entry into the cell when the cell was completely assembled. The burette used for the ECL concentration studies was made from a 10 mliter, calibrated Mohr pipette connected to the cell with a 2 mm high-vacuum stopcock. On top of this burette was a 10 mliter capped bulb (perpendicular to the plane of the paper in Fig. 1). The cap of the burette bulb was made from a 10/30 standard taper outer joint. The whole electrolysis cell could be attached to a vacuum line with the 18/9 ball joint connected to the cell with a 2 mm, high-vacuum stopcock. This electrolysis cell was capable of being evacuated to less than 10^{-5} Torr.

Instruments.—Potentials between the working electrode and quasi-reference electrode were controlled by a Wenking Model 68FR0.5 potentiostat modified to have a built-in variable offset of ± 2.0V. The potential programs used were supplied by a Wavetek Model 114 Sweep/Trigger Variable Current Generator (VCG). Potentials between the working electrode and quasi-reference electrode were set with and monitored by a Systron Donner Model 7050 digital voltmeter. Cyclic voltammograms, relative ECL intensity *vs.* ramp potential graphs, and ECL spectra were recorded on a Hewlett-Packard Model 7005B x-y recorder. The ECL was monitored using an 1P21 photomultiplier tube supplied by Hamamatsu, a Model 4-8402 grating monochromator, and a Model 10-267 photomultiplier microphotometer, both of which were supplied by the American Instrument Company.

Electronic circuit.—Shown in Fig. 2 is the electronic circuitry used in the ECL studies. The unsymmetrical, alternating potential program which was applied to the working electrode was generated by circuits A and B and the Wavetek VCG and fed through a Model HGS 3074 modified relay (R) to the potentiostat (POT). The square wave of known frequency was generated by the Wavetek VCG, which also, along with the 6V battery (B3), drove the relay which had a switching threshold potential of 8.27V with R5 set at 560 ohms. Circuit A supplied the fixed voltage value of the unsymmetrical square wave. The ten-turn, 100 kohms potentiometer was used to regulate the voltage supplied by the two 1.35V Hg batteries. The linearly ramping portion of the unsymmetrical square wave was produced by circuit B which was a voltage integrator circuit built around a Burr-Brown 3292/14 chopper-stabilized operational amplifier (OA) and a Burr-Brown Model 524 power supply. With the resistors and capacitor shown in Fig. 2, ramp rates of 0.021, 0.0089, 0.0053, and 0.0045 V/sec, were obtained. The unsymmetrical, square wave potential generated by the circuits A and B shown in Fig. 2 was used as the voltage input to the potentiostat. The negative cell potential was alternately fixed at the cyclic voltammetric peak potential for DPA reduction, while the positive cell potential was ramped from 0.00V in a positive direction. The ramp rates were such that the potential of the ramp voltage changed very little

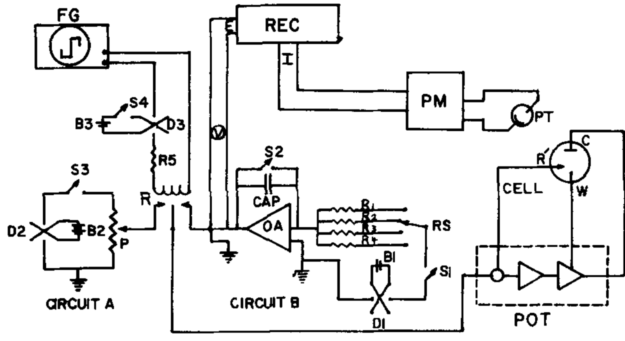

Fig. 2. Electronic circuit. In this figure R1 = 6 Mohms, R2 = 13.6 Mohms, R3 = 22 Mohms, R4 = 25.6 Mohms, R5 = 560 ohms, B1 = 1.35V, B2 = 2.7V, B3 = 6.0V, CAP = 10 μf, and P = 100 kohms (ten turn).

during one cycle of the square wave. For instance, at a frequency of 20 Hz and a ramp rate of 0.0089 V/sec, the potential of the ramp changed less than 0.5 mV during one cycle of the square wave.

The voltage output of this circuit is shown in Fig. 3; this potential program is similar to one developed independently by Keszthelyi (13) using somewhat different electronics. Shown also in this figure is a conceptual representation of the ECL signal obtained with this potential program. Two observations are to be inferred from this representation of the ECL output:

1. Because DPA is present in great excess, very little ECL would be expected during the half-cycles when $DPA^{\cdot -}$ is being generated; only very small amounts of electrogenerated oxidant would remain in the diffusion layer from the previous oxidation, and when this was depleted, chemiluminescence would cease. On the other hand, during oxidation, the supply of WBP is catalytically regenerated in the diffusion layer by the reaction of $WBP^{\cdot +}$ with excess $DPA^{\cdot -}$; this regenerated WBP is then available for reoxidation at the electrode to produce more $WBP^{\cdot +}$ which results in more ECL, so long as the previously generated supply of $DPA^{\cdot -}$ is not exhausted. Thus, larger ECL signals would intuitively be expected on the oxidation half-cycles if the concentration of oxidant is small with respect to that of DPA.

2. Because the electronics of the photomultiplier-recorder combination effectively served to average the instantaneous ECL signal, the signal recorded using this potential program should be proportional only to the average ECL output and in no way should it represent a true steady-state signal. Indeed, this was deemed an advantage analytically. This averaged ECL signal is illustrated in Fig. 3, also. Previous authors have used a similar potential program but performed it manually and have found "averaged" plateaus (14).

Cell holder.—The cell holder was a block of wood bolted to the face of the monochromator. Drilled into its top was a hole slightly larger than the electrode chamber of the electrochemical cell; another hole, perpendicular to the first, was drilled through the block in line with the entrance slit of the monochromator. When the electrode chamber of the electrochemical cell was placed in this block, the working electrode of the cell was reproducibly positioned in front of the monochromator entrance slit.

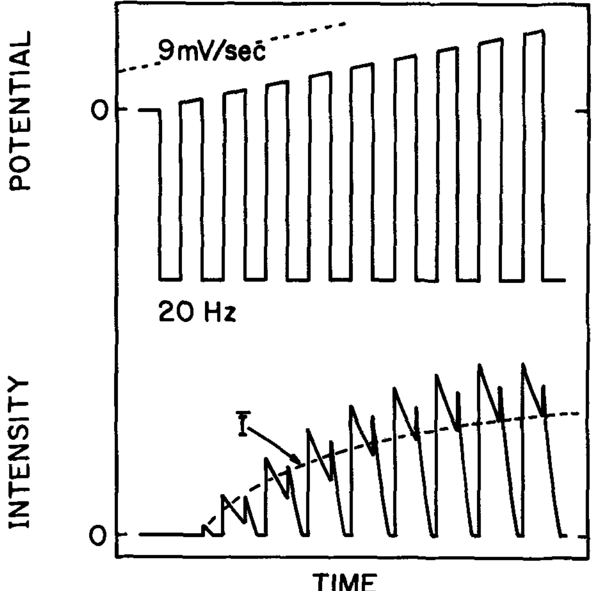

Fig. 3. Potential program and corresponding ECL output. The "averaged" ECL signal obtained using this technique is illustrated by the dashed line.

Reagents.—Spectroquality N,N-dimethylformamide (DMF) was supplied by Fisher Scientific Company; it was double distilled according to the method of Faulkner and Bard (15) and stored under vacuum in a special flask designed for this purpose. Polarographic grade tetrabutylammonium perchlorate (TBAP) was supplied by Southwestern Analytical Chemicals, Inc. for use as the supporting electrolyte. The compound was dried in a vacuum oven at 90°C for at least 48 hr and stored under vacuum over anhydrous P_2O_5. The 9,10-diphenylanthracene (DPA) used in this study was supplied by City Chemical Corporation and was used as received. N,N,N',N'-Tetramethyl-p-phenylenediamine or Wurster's Blue Parent (WBP) was furnished as the dihydrochloride by Eastman Organic Chemicals. Approximately 2g of the dihydrochloride compound were dissolved in 25 mliters of distilled water and then were neutralized using an excess of a 0.5M solution of sodium carbonate. The WBP was then extracted into benzene. This benzene solution was passed through a column of activated alumina using benzene as the eluting solvent. The fraction of the eluent containing the WBP was collected, and the benzene was evaporated off by passing a stream of dry nitrogen over the WBP solution. The crystals which formed after evaporating away the benzene were purified by vacuum sublimation. N,N-Dimethyl-p-phenylenediamine or Wurster's Red Parent (WRP) was supplied as the dihydrochloride by Eastman Organic Chemicals. It was purified using the same procedure as used for the WBP, with the exception that the eluting solvent used on the activated alumina column was a 1 to 1 mixture of heptane and n-propanol instead of benzene. 10-Methylphenothiazine (10 MP) was obtained from Eastman Organic; it was recrystallized three times from benzene. The prepurified nitrogen and the 99.995% pure helium were supplied by Air Products and Chemicals, Inc. The helium was used as received, but the nitrogen was passed through a column of activated molecular sieves to remove any moisture present.

Procedure.—Two methods of preparing the solutions for the studies of the effect of the concentration of the parent compound of the electrogenerated oxidant on the DPA ECL were used, depending on what concentration range of the parent compound was desired. For a solution having a final concentration greater than 0.5 mM of the parent compound the stock solution of the parent compound was prepared directly in the burette of the cell. For a solution having a final concentration of less than 0.5 mM, the stock solution was prepared outside the cell in a glove bag and then transferred into the burette.

In a typical experiment the cell was evacuated and weighed so that solution volumes could be determined gravimetrically. The amount of the parent compound of the electrogenerated oxidant needed to give the final desired concentration in the electrode chamber of the cell was transferred quantitatively into the bulb on top of the burette attached to the cell. The cell was evacuated to a pressure of 10^{-5} Torr with the burette stopcock closed. Then the stopcock of the burette was opened, and the burette and burette bulb were evacuated rapidly to a pressure of about 10^{-5} Torr. The stopcock of the burette was again closed to minimize any chance for sublimation of the parent compound of the electrogenerated oxidant. The cell was removed from the vacuum line, and enough DPA to make approximately a 10 mM solution and enough TBAP to make approximately a 0.2M solution when mixed with *ca.* 50 mliters of solvent were weighed out and placed in the cold finger of the electrochemical cell through the 24/40 standard taper joint above the cold finger. The cell was reassembled and the main body of the cell was evacuated to approximately 10^{-5} Torr and

was outgassed for about an hour to dry the TBAP and DPA completely. After the cell had been sealed, it was removed from the vacuum line and attached to the DMF storage flask. The connecting tubes were evacuated through the storage flask; then DMF was introduced into the cell under helium pressure, and the cell was sealed, removed from the flask, and reconnected to the vacuum line so that the solution could be outgassed by repeated freeze-pump-thaw cycles. After the final freeze-pump-thaw cycle, and the temperature of the cell reached room temperature, the cell was weighed so that the solution volume could be determined. Finally, the stopcock of the burette was opened to allow a measurable volume of the TBAP-DPA solution to enter the burette so that a solution of the parent compound of the electrogenerated oxidant of known concentration could be prepared in the burette.

A second method of preparing the stock solution of the parent compound was used when the amount of the parent compound needed to make up the stock solution was too little to be weighed accurately. The cell was evacuated and filled with solvent, and the solution was outgassed as described above. It was removed from the vacuum line and placed in a glove bag which was flushed with dried, prepurified nitrogen. The cell was opened in the glove bag and sufficient solution was removed to prepare by dilution 10 mliters of solution in which the concentration of the parent of the electrogenerated oxidant was less than 1 mM. This solution was then sealed in the burette and the cell was removed from the glove bag.

After the solutions had been prepared and placed in the cell, the cell was clamped into its holder so that electrochemical experiments could be performed. All electrochemical experiments were conducted with the cell clamped in place so that reproducible ECL signals could be obtained. To avoid any problem of stray radiation, experiments were conducted in a darkroom; this permitted visual and instrumental observation of the ECL produced.

Before any ECL experiments were performed and after every addition of parent compound from the burette into the electrode chamber, both wide and narrow sweep cyclic voltammograms were recorded. Wide sweep voltammetry was conducted over a potential range that included both the one-electron oxidation and reduction of DPA. Narrow sweep voltammograms excluded these redox processes, but included the potential range where the parent compound oxidized; these were recorded at ten or thirty times the current sensitivity as the wide sweep voltammograms. These experiments were performed both to measure the concentration of the parent compound voltammetrically (wherever possible) and to determine the potentials of electrode processes. This was necessary because the potentials of the quasi-reference electrode tended to drift positively a few hundredths of a volt as the experiment progressed. Peak to peak voltages for the reactants stayed the same, however; all potentials cited herein, therefore, were measured against the cyclic voltammetric peak potential for the reduction of DPA.

After the cyclic voltammograms of the solution in the electrode chamber had been obtained, the ECL of the solution was obtained as a function of ramp potential with the circuit shown in Fig. 2. With the Wavetek frequency set at 20 Hz, the constant negative potential portion of the unsymmetrical square wave was set at the peak potential for the formation of the DPA radical anion. The range switch used for the selection of the ramp rate was turned to the desired resistance value; usually a ramp rate of 0.0089 V/sec was used. The monochromator wavelength was set at 433 nm, the wavelength of maximum emission for DPA ECL produced in DMF.

With the lights in the darkroom turned off, the shutter of the photomultiplier tube housing was opened and the function switch of the potentiostat was turned to the current mode. The capacitor discharge switch of the ramp circuit was opened and the ECL intensity as a function of ramp potential was recorded. The ramp potential was alternately applied to the working electrode until the ECL reached a steady-state value, went through a maximum, or became too great to be recorded at that sensitivity. The solution in the electrode chamber was stirred and at least two more ECL intensity *vs.* ramp potential measurements were taken for a solution of a given concentration of the parent compound of the electrogenerated oxidant. Sometimes more measurements were taken to assure reproducibility. After the ECL measurements were taken, more of the parent compound of the electrogenerated oxidant was added to the electrode chamber from the pipette, and the solution was again stirred. Then the cyclic voltammetry-ECL measurement cycle was repeated.

Results and Discussion

Typical results are shown in Fig. 4; here, curve A shows the cyclic voltammetry for both radical ions of 9.1 mM DPA in DMF. The cyclic voltammetric peak-to-peak potential for the formation of the DPA radical anion and the DPA radical cation in such a solution was generally found to be 3.32V. Faulkner, Tachikawa, and Bard (4) have reported a peak-to-peak voltage of 3.24V using a saturated calomel reference electrode. Because of the slight instability of the QRE, all potentials have been referenced to the reduction peak potential for DPA.

Curve B shows the background linear sweep voltammetry of the same solution in the potential region where WBP is oxidized; no WBP has been added, however, and the current sensitivity is ten times that which was used to record curve A. Curve D shows the linear sweep voltammetry in the same potential region under identical conditions after a small amount of WBP had been added from the burette to make the bulk concentration of WBP 0.013 mM. Even though the current sensitivity was high, it is clear from this figure that this concentration of WBP lies close to the limit of detectability for linear sweep voltammetry because the current attributable to faradaic processes is not much greater than the background current. In addition, identification of the species undergoing oxidation through its peak potential is virtually impossible; no peak potential for the formation of $WBP^{+\cdot}$ can be discerned easily, if at all.

Curve C shows the ECL *vs.* ramp potential behavior obtained from the solution of DPA (uncontaminated with WBP) using the potential programming circuit shown in Fig. 2. The stepping frequency was 20 Hz while the ramp rate was 0.0089 V/sec. This curve shows that some ECL does occur in solutions containing no known oxidizable species. This low level ECL

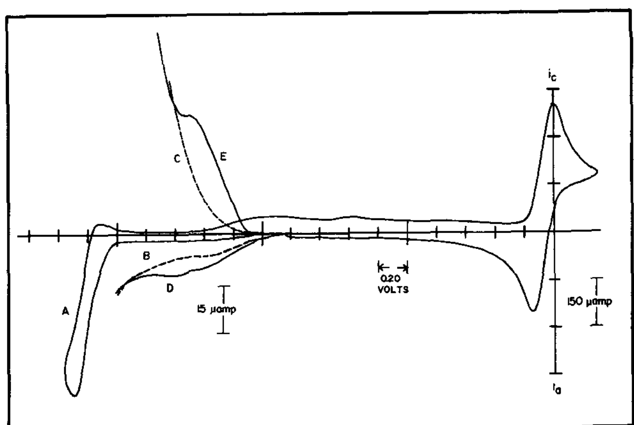

Fig. 4. Typical experimental results. Cyclic voltammetry (A) is for 9.1 mM DPA; high sensitivity linear sweep voltammetry is shown in the absence (B) and presence (D) of 0.013 mM WBP; corresponding ECL behavior is shown in C and E.

is the object of some experiments presented below; at this point it is sufficient to note that a background ECL signal is obtained even in the absence of WBP. Thus, contrary to expectation, all ECL signals obtained from solutions containing WBP had to be corrected for background emission.

That a measurable ECL signal is obtained from solutions containing WBP may be seen in curve E. Here, ECL *vs.* potential is shown for the solution 0.013 mM in WBP; other experimental conditions are identical to those used to record curve C. Even this small amount of WBP produces an ECL signal significantly larger than background emission. In addition, a potential-dependent maximum in the ECL plot is observed; no such peak may be detected in the corresponding voltammetry.

In an attempt to characterize the potential dependence of the ECL process, a new parameter, $E_{I\max/2}$, was defined. Like the polarographic half-wave potential, this value is the potential at which half of the maximum ECL intensity due to the presence of the parent compound of the electrogenerated oxidant has been emitted. This potential was determined by finding the potential at which the ECL is one-half its maximum intensity (corrected for background); for curve E in Fig. 4, $E_{I\max/2}$ of the WBP is 2.25V *vs.* E_p (DPA/$DPA^{\bar{\cdot}}$).

The effect of incremental additions of WBP to a 10 mM DPA solution is shown in Fig. 5. Here, curves A through E show the changes in linear sweep voltammetry as the bulk concentration of WBP is increased from 2.57×10^{-5} to 7.21×10^{-5}M. (Curve F shows the cyclic voltammetry for the oxidation of DPA.) Noteworthy is the observation that linear sweep voltammetry would be of little use for analysis in this concentration range: it is difficult to detect a change in current with a change in concentration. This may be contrasted with the behavior of ECL intensity for the same solutions when the working electrode is subjected to the potential program described above. Curves a through e demonstrate that analysis by this method is feasible: ECL intensity at all potentials increases regularly with increasing WBP concentration, and in this concentration range this intensity greatly exceeds that attributable to background processes; in addition, $E_{I\max/2}$ is useful in identifying WBP throughout, even at low concentrations. The ECL intensity curves shown in Fig. 5 were independent of ramp rate at rates less than 0.0098 V/sec.

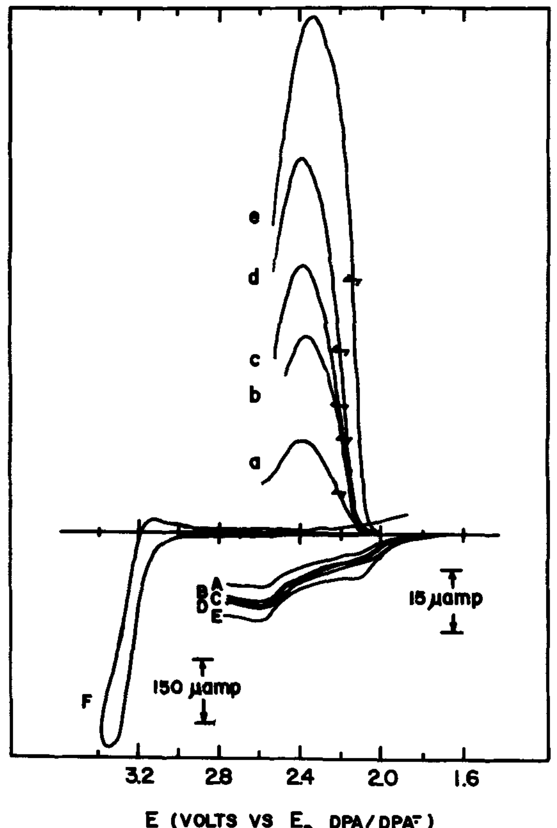

Fig. 5. Concentration effects. Curves A-E show high sensitivity linear sweep voltammetry for solutions containing 2.57, 3.82, 4.93, 6.00, and 7.21 × 10^{-5}M WBP, respectively; curves a-e show ECL intensity behavior for the same solutions. $E_{I\max/2}$ is indicated on each ECL curve. Curve F shows low sensitivity cyclic voltammetry of DPA.

While $E_{I\max/2}$ is generally only 0.10V more positive than E_p, $E_{I\max}$ itself is usually 0.25V more positive than the corresponding voltammetric oxidation peak. Thus, if $E_{I\max}$ is taken as a measure of the potential at which diffusion-limiting conditions are obtained, considerable uncompensated *IR* losses must be present in the ECL experiment. This seems reasonable because fairly high current levels are achieved in the alternating potential ECL experiment. That the ECL intensity goes through a maximum rather than reaching a plateau is probably due to two effects. First, any conversion of $WBP^{\dot{+}}$ to electroinactive product (either by reaction with $DPA^{\bar{\cdot}}$ or by a side reaction) will diminish the amount of WBP available during subsequent cycles; this could result in lower levels of ECL emission as the scan progresses. Second, at potentials where WBP^{++} is formed, one would expect a change in ECL output as WBP^{++} becomes available to react with $DPA^{\bar{\cdot}}$. The ECL maximum obtained by this method is fairly broad; the ECL output 0.15V beyond $E_{I\max}$ (0.40V positive of E_p) is still 90% of $I_{\max}$. Thus, significant amounts of WBP^{++} (peak potential 0.50V positive of E_p) are probably being electrogenerated in the potential region where the ECL decreases.

It is of interest to note that the ECL intensity decreases rapidly as the ramp potential approaches that sufficient to form WBP^{++}, regardless of concentration and ramp rate. This observation implies that WBP^{++} does not produce ECL when it reacts with $DPA^{\bar{\cdot}}$; this is in apparent disagreement with a result reported previously for RRDE studies of the same system (9). In these studies, the ECL intensity at the ring (where $DPA^{\bar{\cdot}}$ was being generated) increased when the disk potential was changed to produce WBP^{++} instead of $WBP^{\dot{+}}$ to be swept into the reaction zone beneath the ring. This apparent discrepancy may be resolved by considering the concentration profiles in each experiment. In the stationary electrode case, WBP^{++} can react with $DPA^{\bar{\cdot}}$ only in a region where small amounts of WBP are present; thus, there is little chance for the reaction

$$WBP^{++} + WBP \rightarrow 2WBP^{\dot{+}} \quad [10]$$

to produce $WBP^{\dot{+}}$ to react secondarily with $DPA^{\bar{\cdot}}$. On the other hand, in the RRDE experiment, WBP^{++} is swept into a region where there is a high relative concentration of WBP, so that in this case, the formation of $WBP^{\dot{+}}$ is more likely. Thus, the ECL observed upon generating WBP^{++} in the RRDE experiment may be attributed only indirectly to the WBP dication.

While extensive studies were conducted with WBP to test the specific applicability of this method to that compound, some experiments were performed with WRP and 10 MP also. Typical experimental results are shown in Table I. These results show that at concentrations less than 0.1 mM, both $I_{\max}$ and $E_{I\max/2}$ may be

determined more readily than their linear sweep voltammetry counterparts for all three compounds selected. While $E_{I_{max}/2}$ does not correspond to E_p for any of the compounds studied, it is generally reproducible within 20 mV at concentrations less than 0.10 mM. In this concentration range there is also a linear relationship between I_{max} and bulk parent concentration; this may be seen also in the calibration curves presented in Fig. 6. At higher bulk parent concentrations, I_{max} no longer increases with increasing concentrations and $E_{I_{max}/2}$ is no longer reproducible. This occurs at a concentration level where linear sweep voltammetry begins to be analytically effective, however, Thus, in this sense, the two methods are complimentary; each is effective at concentration levels where the other is not.

The calibration curves presented in Fig. 6 for multiple runs of each compound give some indication of the reproducibility of the determination from run to run. Different runs (*i.e.*, different DPA solutions) are shown by different symbols. Since most determinations were conducted with WBP, overwhelming evidence of reproducibility is available only for that compound. Indications are good, however, that the behavior of WRP and 10 MP is similarly reproducible. Two of the WBP points show considerable negative deviation from the calibration curve shown. These points were obtained at the end of a run when a considerable amount of electrolysis had taken place at the working electrode. Generally reproducible ECL behavior was obtainable only from relatively fresh solutions.

Because I_{max} is shown on the same relative intensity scale for all compounds, it is apparent that 10 MP is most efficient at producing ECL upon reacting with DPA$^{\cdot-}$, while WRP appears to be least efficient. This concentration efficiency (the slope of the linear portions of the calibration curves) exaggerates the differences in actual current efficiency (photons emitted/electron transferred) for these compounds. Analysis of the linear sweep voltammetry data in Table I reveals that the relative diffusion coefficients of these three compounds increases in the same order as the concentration efficiency; thus, much of the apparent differences in the efficiency of ECL production for these compounds may be attributed to higher average oxidation currents in the order 10 MP > WBP > WRP.

The calibration curves also show that I_{max} increases linearly with parent concentration only up to 0.10 mM; thereafter, increases in parent concentration bring about no further increases in ECL intensity. This trend,

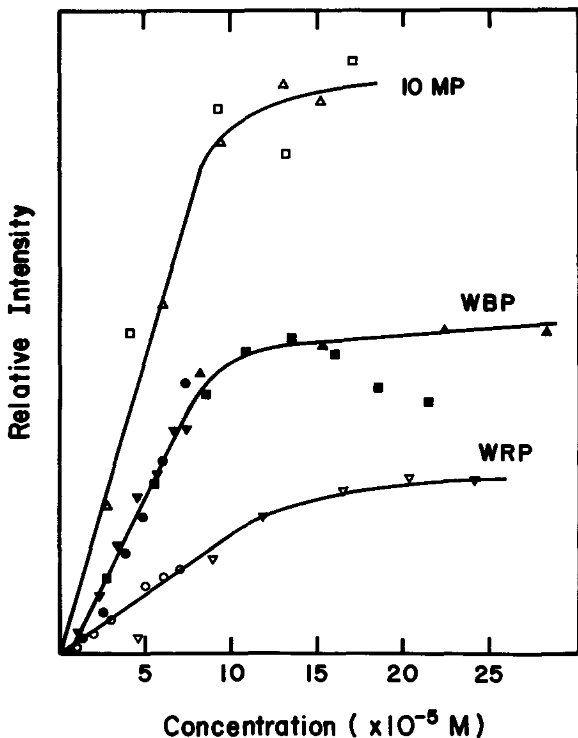

Fig. 6. Calibration curves. Different symbols are used to designate different runs having slightly different concentrations of DPA. For each parent concentration, I_{max} is shown on the same relative intensity scale.

independent of compound, suggests that the energy deficient ECL from DPA$^{\cdot-}$ is limited when the concentration of the radical ion oxidant or its precursor is approximately 1% of the DPA concentration. This could be due to a quenching effect attributable to either the radical cation or its parent hydrocarbon.

Because background ECL was not anticipated at the outset of this work, experiments were conducted to determine its probable cause. The actual intensity of this background ECL was quite low. This may be seen in Fig. 7 where background ECL (curve a) was recorded at 100 times the sensitivity of the energy-sufficient ECL (curve b) resulting from the reaction of the

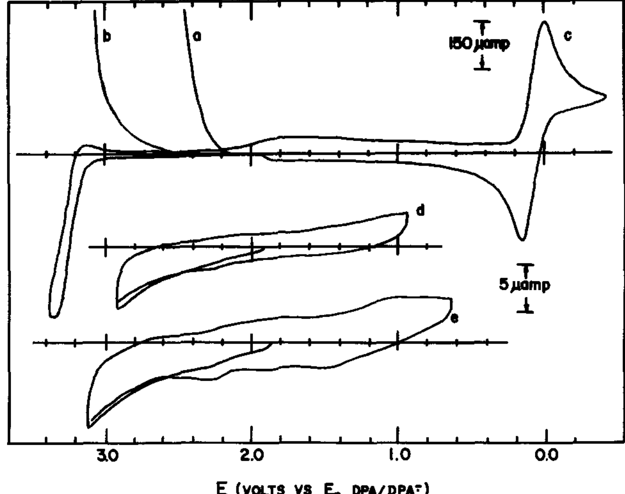

Fig. 7. Background ECL effects. Curve a shows typical high sensitivity background ECL from 10 mM DPA in DMF-TBAI; curve b shows low sensitivity (0.01 times that in curve a) ECL from the same solution. Curve c shows low sensitivity cyclic voltammetry of DPA; curves d and e show high sensitivity cyclic voltammetry of 0.10M TBAP in DMF in the absence of DPA.

radical ions of DPA itself. Since ECL of greater intensity had been detected for solutions containing a known amount of parent compound that was only marginally detectable electroanalytically, it was reasonable to attribute this background ECL to a trace amount of oxidizable species present in the solvent system. High-sensitivity cyclic voltammetry was performed on the DMF-TBAP solvent system (in the absence of DPA) in an attempt to detect this trace amount of oxidizable compound. This is shown by curves d and e in Fig. 7. Admittedly, since no DPA was present in these solutions, the assignment of potentials depends on the agreement of the rest potential of the QRE in the presence and the absence of DPA. If such agreement is assumed for fresh solutions, the high-sensitivity cyclic voltammetry in curves d and e shows that an oxidizable species is generated on the positive potential scan, even though the upper limit of this scan is less than that regarded as sufficient for DPA oxidation. Present at low concentration and detectable only on the second positive potential scan, the oxidizable species found has its peak potential at 2.3V *vs.* E_p DPA/$\overline{\text{DPA}\cdot}$; this corresponds well with the potential onset of background ECL. Since only trace amounts are necessary for ECL production, this species could be present residually from previous positive scans or might be generated in sufficient quantity from any positive scan; it is detectable electroanalytically following a scan to 2.9V *vs.* E_p DPA/$\overline{\text{DPA}\cdot}$. This species seems reasonable as the source of background ECL observed.

Conclusion

The method described herein has been shown to be suitable for the analysis of WBP, WRP, and 10 MP at concentration levels not suitable for ordinary electroanalysis; thus it may find use in trace analysis as the stationary electrode ECL equivalent of polarography. Its use, of course, is limited by the ability of the electrogenerated oxidant to produce ECL upon reaction with $\overline{\text{DPA}\cdot}$. Recent studies (16) indicate that halides electrogenerated from their ions will produce ECL when reacted with $\overline{\text{DPA}\cdot}$. Therefore, there is reason to suspect that the method may be more universal than indicated by this work. Indeed, all that may be necessary is that the electrogenerated oxidant be formed at potentials sufficiently positive to produce triplet DPA when reacted with $\overline{\text{DPA}\cdot}$. Work is presently underway to determine the limitations of the method.

In addition to introducing a simple method to employ ECL analytically, this work provides information about the concentration dependence of the ECL energy-deficient process that was hitherto unavailable. The fact that ECL may be observed from solutions containing a known amount of parent compound that is not detectable electroanalytically supports the contention that only trace amounts of electrogenerated oxidant are necessary to produce ECL upon reaction with $\overline{\text{DPA}\cdot}$.

Effect of the Thickness of Anodic Oxide Films on the Rate of the Oxygen Evolution Reaction at Pt in H_2SO_4 Solution

I. Growth at Constant Current

A. Damjanovic, A. T. Ward,* and M. O'Jea

Xerox Corporation, Rochester Research Center, Webster, New York 14580

ABSTRACT

Ellipsometry and standard electrochemical techniques are used to determine whether, and if so, how the thickness of an anodic oxide film affects the catalysis of the oxygen evolution reaction at platinum. A prereduced electrode is first polarized in sulfuric acid solution with a constant current density, i_p for a given time and then the thickness, d, of the anodic film and the electrode potential, V, are determined for various current densities $i \leq i_p$. It is found that the thickness of the oxide film affects the catalytic activity in an exponential way, *i.e.*

$$i = A \exp(-\delta d/2) \exp(\mathbf{F}V/2RT)$$

where A and δ are constants. For the same time of polarization both the oxide thickness and the electrode potential increase with the logarithm of the polarization current density, i_p. The potential dependence is $dV/d(\log i_p) \simeq 170$ mV. This is in contrast with the value of about 115 mV usually reported for the oxygen evolution reaction. The latter value can be obtained only when the electrode is anodically treated at a current density, i_p, and the i-V relationship is subsequently determined at current densities $i < i_p$. Ellipsometry shows that under these conditions the anodic film thickness remains essentially constant at the value achieved during the initial polarization at a higher current density.

It has been shown that the catalytic activity for the oxygen evolution reaction at platinum in acid solutions is greatly affected by the electrode pretreatment (1). Only after an electrode was kept at a high potential (*e.g.*, 1.7-2.0V), or was subjected to a high anodic current density (*e.g.*, 10^{-4} to 10^{-2} A/cm²) for some time (>10-20 min) was it possible to obtain V-log i relationships which were linear over several decades of current density (2-5) and had slopes of 2.3 $(2RT/\mathbf{F})$, and then only if the potentials or current densities in the subsequent process of measurement were lower than those used in the electrode pretreatment. No linear V-log i relationship could be obtained in a first "run-up" experiment with electrodes that were not so pretreated. In the latter case, the $dV/d(\log i)$ slopes at any point of current density were higher (1, 6) than 2.3 $(2RT/\mathbf{F})$. Higher current density or electrode potential and longer time of initial polarization were found to lower the activity. The observed changes in activity were attributed to differences in the thickness of the anodic oxide films that formed during the various electrode pretreatments. The surface oxide film was assumed to act as a barrier to charge transfer, the barrier increasing with increasing thickness of the oxide film. The oxide barrier is in series with the double layer barrier and with it controls the rate of the oxygen evolution reaction.

The experiments of the present study have been designed to verify the assumption that the thickness of the surface oxide film affects the kinetics of the oxygen evolution reaction and to show that an analytical expression can be obtained relating the rate of the reaction to the thickness of the surface film. To achieve this ellipsometry has been combined with a standard electrochemical (galvanostatic) technique and current densities have been determined as a function of the thickness of the oxide film and electrode potential.

* Electrochemical Society Active Member.

Key words: anodic films, platinum anodes, catalysis of O_2 evolution.

Experimental

The procedure involved:

1. Galvanostatic anodic polarization of a highly polished platinum disk electrode in 0.1N H_2SO_4 for a fixed time. (P.A.R. Model 173 potentiostat in a galvanostatic mode).
2. Measurement of the electrode potential *vs.* a reversible hydrogen electrode in the same solution (H.E.). (Keithley Model 600 A electrometer).
3. Simultaneous determination of the change in azimuth and ellipticity of monochromatic light reflected from the electrode. (Automated recording ellipsometer, Rudolf Research Incorporated).

The Teflon cell used in the present work was similar to those already described (7). The cell was equipped with a large platinum gauze auxiliary electrode, a Luggin capillary that approached the edge of the disk electrode, and an oxygen gas inlet and outlet. The stream of gas from the inlet served not only to oxygenate the solution prior to polarization but also when necessary, to stir the solution and to displace oxygen bubbles attached to the anode. Except at the highest current densities ($i > 3.10^{-4}$ A/cm²) reliable ellipsometric data could be obtained by displacing these bubbles immediately prior to making a measurement.

The working electrode was a 99.9% pure platinum disk, 1.13 cm² in geometrical area, welded to a stainless steel rod. The rod with the disk was enclosed in a shrinkable Teflon sleeve. The face of the disk was polished to a mirror finish, the final polishing being with 0.05μ alumina. The electrode was washed with alcohol, alkaline solutions, sulfuric acid, and triply distilled water. Finally. both the electrode and the cell were washed *in situ* with triply distilled water and then acid solution of the same concentration as used in subsequent experiments. Solutions used in this work were prepared from Baker "Analyzed" grade sulfuric acid and triply distilled water. No further purification of the

solution was made. This is because the oxygen evolution reaction at current densities greater than 10^{-7}-10^{-6} A/cm^2 is apparently not affected by trace amounts of impurities. Before measurements, the electrode was subjected to a few high (10^{-3} A/cm^2) anodic and cathodic pulses ending with a cathodic pulse. After this pretreatment the solution was replaced and the electrode was kept at 0.5V for 5 min. The electrode surface at this potential was then used as the reference state.

The changes in azimuth and ellipticity associated with the change in the electrode surface from the initial, freshly reduced film-free state[1] to the final anodically oxidized state were used to calculate the change $(\Delta_o - \Delta)$ in the relative phase retardation, Δ, between components of the light polarized perpendicular and parallel to the plane of incidence, respectively. This change was then used to calculate the mean film thickness, d, using Drude's (8) equation,[2] $[d = \text{constant } (\Delta_o - \Delta)]$, a relationship valid for films thin compared with the wavelength of light.

The optical constants ($n_1 = 2.80$; $n_2 = 1.94$; $K_2 = 4.36$) used here to calculate thickness were taken from the work of Kim, Paik, and Bockris (9) who determined these parameters entirely from ellipsometric data. Here n_1 is the refractive index of the film and n_2 and K_2 are the refractive index and absorption constant, respectively, of the platinum substrate. Other workers have obtained similar values for n and K using a combination of optical (ellipsometric, immersion refractive index) and electrical (coulometric) techniques (10, 11). With the experimental angle of incidence corrected for refraction through the cell windows, $\phi = 75°$, and wavelength, $\lambda = 5460$Å, the constant term in Drude's equation is calculated as 3.80 Å/deg. The resulting film thicknesses are then typically less than 10Å so that the use of Drude's equation appears justified.

Results

In Fig. 1 the phase retardation change, $\Delta_o - \Delta$, observed after a specified time for polarization (125, 750, or 1800 sec) is plotted against the constant current density (C.D.), i_p, to which a freshly prereduced electrode was subjected. The calculated ellipsometric thickness is also shown in the same figure. Likewise, Fig. 2 shows the respective electrode potentials plotted *vs.* i_p.

In the examined region of current densities both the thickness and electrode potential change linearly, or very nearly so, with the logarithm of the C.D., i_p, with which the electrode was anodically prepolarized. For all times of polarization the $dV/d(\log i_p)$ slopes are close to 170 mV/decade of C.D., and the $dd/d(\log i_p)$ slopes are close to 1.0 Å/dec. of C.D.

[1] The film-free condition was assumed to exist under potentiostatic conditions at 0.5V H.E. At 0.98V, the rest potential in the oxygen-saturated system, the phase retardation was somewhat lower reflecting the presence of adsorbed species on the electrode.

[2] The assumption implicit in Drude's equation is that the refractive index of the film is independent of thickness. Since the adsorbed layer and the film ultimately formed may not have the same refractive index the Drude assumption will lead to a small but constant error in the calculated value of thickness.

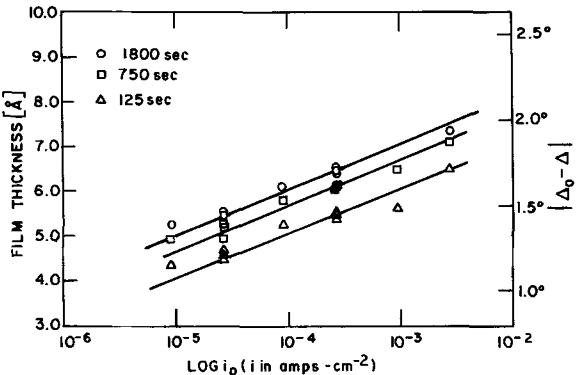

Fig. 1. Plot of anodic film thickness after 125, 750, and 1800 sec *vs.* log current density of polarization.

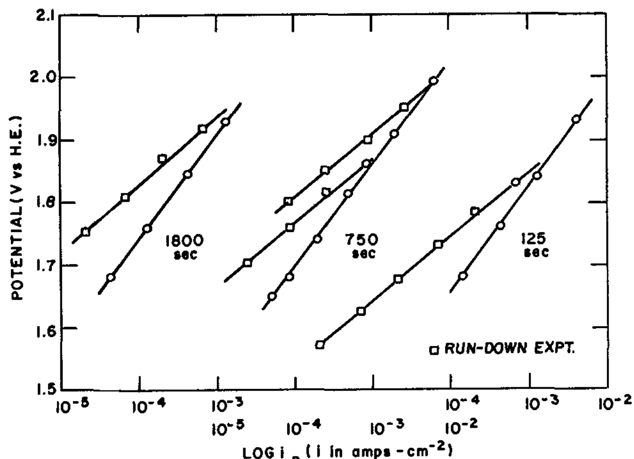

Fig. 2. Plot of electrode potential (H.E.) after 125, 750, and 1800 sec (circles) *vs.* log current density of polarization. Squares represent subsequent potential-current density relationships for decreasing current densities.

After an electrode has been polarized for 750 sec with a constant C.D., i_p, and the current density, i, is decreased in steps, no change in thickness, d, is observed (from A to B in Fig. 3). In contrast to this, the potential, V, decreases as the C.D., i, is decreased (Fig. 2). The $dV/d(\log i)$ slope is now close to 115 mV/decade of C.D., or to 2.3 $(2RT/\mathbf{F})$. The same is observed after the electrode has been prepolarized for 125 or 1800 sec as shown in Fig. 2. (The corresponding thickness data is omitted from Fig. 1 and 3 in order to preserve clarity.)

Analysis of Data

The important features of the results may be summarized as follows:

1. For the same time of polarization at a constant current density, i_p, both electrode potential and ellipsometric thickness increase with the logarithm of the applied current density. At any applied current density, for a constant time of polarization, the ellipsometric thickness therefore changes, to a good approximation, linearly with electrode potential. This is illustrated in Fig. 4 which is composed from Fig. 1 and 2. Linear V-d relationships have been observed also in potentiostatic studies both by ellipsometric (10-12) and coulometric (4, 13-15) techniques. Apparently no attempt was made in this earlier work to relate the rate of the oxygen evolution reaction to the thickness of the surface oxide film.

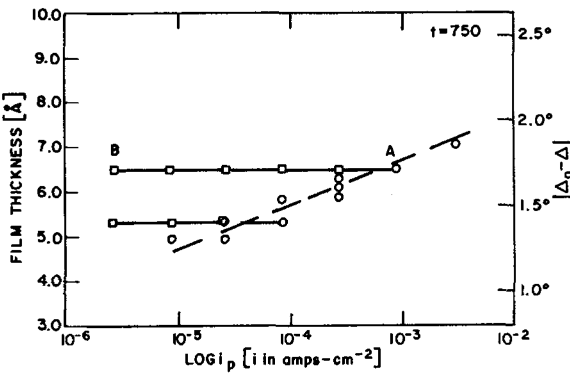

Fig. 3. Plot of anodic film thickness after 750 sec (circles) *vs.* log current density of polarization. Squares represent subsequent film thickness-current density relationships for decreasing current densities.

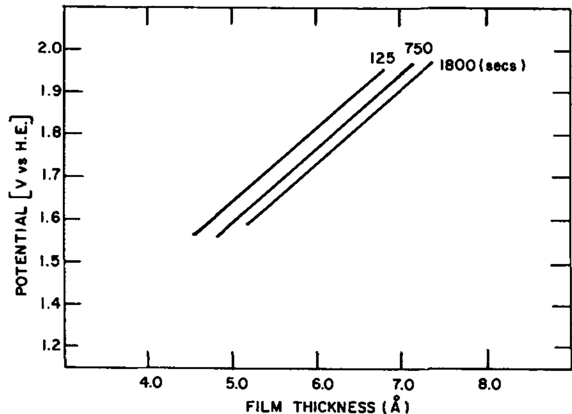

Fig. 4. Plot of electrode potential (H.E.) vs. film thickness after polarization for 125, 750, and 1800 sec at various current densities.

2. An arrest in further growth of the oxide film occurs when, after the initial polarization of a prereduced electrode with a constant applied current density, the current density is decreased. Such "hysteresis" has been reported previously in coulometric studies of surface coverages in the potential region lower than that of the present work (13, 14).

3. A V-log i relationship which is linear over several orders of magnitude[3] with slope close to $\partial V/\partial \ln i = 2RT/\mathbf{F}$ is obtained under the condition of nearly constant thickness of the surface oxide film. This is self-evident from the comparison of Fig. 2 and 3: in the process of lowering current density, say from point A to B, the thickness represented by point A did not change, *i.e.*,

$$\left(\frac{\partial V}{\partial \ln i}\right)_d = \frac{2RT}{\mathbf{F}} \text{ and } \left(\frac{\partial V}{\partial \ln i}\right)_d \neq f(V,d,i) \quad [1]$$

4. The catalytic activity for the oxygen evolution reaction decreases with increasing thickness of the surface oxide film. This is evident from the change of the electrode potential at the same current density with the thickness of the film as illustrated in Fig. 5. In this figure the potentials from Fig. 1 and 2 are plotted *vs.* thickness, d, for two current densities (rather than for a constant time of polarization at different applied current densities as in the case of Fig. 4). As the thickness increases, the potential at the same current density increases linearly, *i.e.*, the catalytic activity decreases. Were the catalytic activity expressed in terms of exchange current densities then it would decrease exponentially with the thickness of the oxide film, *i.e.*

$$\log i_o = \text{constant } (-d) \quad [2]$$

as will be shown later in this work.

[3] See also Ref. (2) and (3).

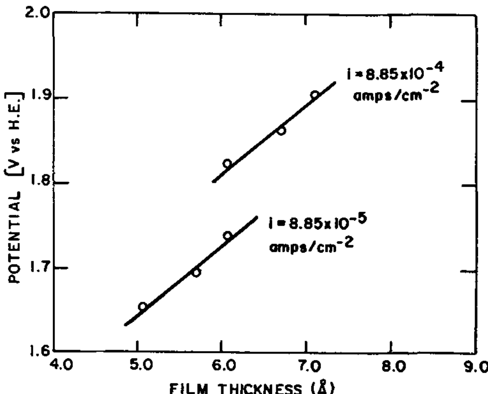

Fig. 5. Plot of electrode potential (H.E.) vs. film thickness after polarization at constant current density for various times.

5. To a fair approximation the slopes of the V *vs.* d lines in Fig. 5 are constant and equal for both current densities, *i.e.*

$$\left(\frac{\partial V}{\partial d}\right)_i = 0.085 \text{ V/Å and } \left(\frac{\partial V}{\partial d}\right)_i \neq f(V,i,d) \quad [3]$$

The difference may be noted at this point between the $\partial V/\partial d$ slopes of Fig. 4, that refer to a constant time of polarization, and those of Fig. 5, that refer to constant current density. This demonstrates the importance of defining the conditions under which the V *vs.* d relationship is obtained.

6. The mechanism of the oxygen evolution reaction is apparently unaltered with the change in the thickness of the oxide film. This is indicated by the fact that the $dV/d(\ln i)$ slopes remain the same over the entire, though limited, range of thicknesses of the oxide films examined in the present study. This is in accord with a previous report that the slopes are nearly the same irrespective of the conditions of the anodic pretreatment of the electrodes (1). Also, most of the workers in the field have reported slopes close to $2RT/\mathbf{F}$ although the pretreatments of their electrodes[4] certainly were not identical (2-6, 13, 16-20).

7. Finally, to a good approximation, in the region of current densities and oxide film thicknesses examined here, log i is linearly related to both V and d, *i.e.*, the function

$$f(V,d,\log i) = \text{constant} \quad [4]$$

represents a plane surface in three dimensions. This follows from the fact that, as illustrated in Fig. 6, the projections of the straight line AB[5] on two perpendicular planes are parallel to the corresponding projections of the straight line A'B' (or A"B") while intersecting the projection of the third straight line AD. All these lines lie in the plane $f(V, \log i, d)$ = constant.

How well the function $f(V, \log i, d)$ = constant approximates a plane surface depends on: (i) how well the $dV/d(\log i)$ slopes can be taken as independent of the thickness of the surface oxide film [their independence of potential or current density being well established over several decades of current density (2, 3)], and (ii) whether $(\partial V/\partial \ln i_p)t$ is constant. Now, as already shown, the present experiments as well as the literature give $dV/d(\log i)$ close to 2.3. ($2RT/\mathbf{F}$) irrespective of the conditions of anodic pretreatment of the electrode and, therefore, irrespective of the surface film thickness. Furthermore, it is evident

[4] It is uncertain whether the purity of the platinum metal itself will affect the rate of oxide growth, the thickness of the oxide film or the catalysis mechanism of the oxygen evolution reaction.
[5] The line AB is not parallel to either of the axes V, log i or d.

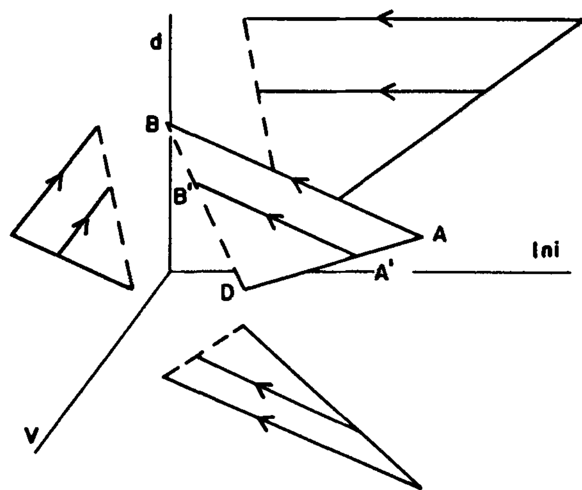

Fig. 6. Representation of the plane $f(V, \ln i, d)$ = constant in three dimensions.

from Fig. 2 that V does indeed depend nearly linearly on log i_p.

The Rate Equation and the Catalytic Activity for the Reaction

The analytical solution to the expression $f(V, \log i, d)$ = constant is given in the Appendix. It is

$$\epsilon V - \left(\frac{2RT\epsilon}{\mathbf{F}}\right)\ln i + \left(1 - \frac{\kappa \mathbf{F}}{2RT}\right) d = \text{constant} \quad [5]$$

where

$$\epsilon = \left[\frac{dd}{d(\ln i_p)}\right]_t \quad [6]$$

is obtained from the data in Fig. 1. It is equal to 1.0 Å/decade of C.D. Constant κ is given by

$$\kappa = \left(\frac{dV}{d \ln i_p}\right)_t \quad [7]$$

which, from Fig. 2, is equivalent to 0.170 V/decade.

Now with

$$\frac{2RT - \kappa}{\epsilon RT} = \delta \quad [8]$$

Eq. [5] transforms to

$$i = A \exp\left(\frac{-\delta d}{2}\right) \exp\left(\frac{\mathbf{F}V}{2RT}\right) \quad [9]$$

This equation gives the dependence of the rate of the oxygen evolution reaction on both the electrode potential and the thickness of the surface oxide film. For a constant thickness the equation reduces to the well-known rate equation for the oxygen evolution reaction in an acid solution of a given pH

$$i = i_o \exp\left(\frac{\mathbf{F}V}{2RT}\right) \quad [10]$$

It follows from Eq. [9] and [10] that the catalytic activity, expressed as i_o, decreases exponentially with the thickness of the oxide film

$$i_o = A \exp\left(-\frac{\delta d}{2}\right) \quad [11]$$

where constant A contains, among other terms, those which involve the concentration dependence. Differences in the reported catalytic activities can now easily be accounted for in terms of the different thicknesses of the surface oxide films produced in different experiments.

Vetter and Schultze (15) have reported that the coulometric thickness of the surface oxide film at electrodes kept at a constant potential in the region from about 1.0 to 2.0V increases logarithmically with time. From this observation and from Eq. [11] it follows that, at constant potential, current density should decrease with time according to

$$\log (i/i_o) = \beta \log t \quad [12]$$

where constant β has a negative value. Such a dependence has indeed been found by Schultze (21). No relevant data could be traced in the literature that would allow a check of the validity of Eq. [11] under galvanostatic conditions. Bockris and Huq (2) have reported that, at a constant current density, potential increases logarithmically with time of polarization. This would require, according to Eq. [11], that again, under galvanostatic conditions, the thickness of the oxide film increases with time according to a direct logarithmic law. Apparently, no such law for platinum oxide growth has been reported in the literature. Makrides (22), however, reports that at gold anodes, under galvanostatic conditions, oxide films grow according to a direct logarithmic law. The same law of growth[6] has been found for other metal electrodes (23, 24). The logarithmic law should be expected for platinum anodes under galvanostatic polarization conditions also. Further study of this question appears desirable and is currently in progress in this laboratory.

[6] Vetter and Schultze (15) report for galvanostatic polarization, a linear increase of surface coverage with time. This linear dependence holds only for the initial growth of surface oxides (for, say, less than 10 sec, depending on current density).

The Rate Equation for the Current Density Across the Surface Oxide Film

The exponential dependence of the catalytic activity for the oxygen evolution reaction upon film thickness is apparently related to the mechanism of electron transfer from a species in solution or at the electrode surface (*e.g.*, adsorbed water molecules), across the oxide film to the metal itself. As will be discussed in a subsequent paper, the charge transfer occurs by a quantum mechanical tunneling process rather than by electron or hole conduction in the oxide film. This requires the existence of a substantial electric field across the oxide film and also requires that the field change with current density (at a constant surface oxide film thickness). Consequently, the potential difference, V_t, between the metal itself and the outer Helmholtz plane (in the solution) should be divided into the potential difference across the oxide film, V_{of}, and the potential difference across the double layer, V_{dl}. In previous work (1) such a division was introduced in order to account for the observed kinetic parameters for the oxygen evolution reaction in sulfuric acid solutions of different pH. With this division, since the current density across the oxide film, i_{of}, is equal to the current density for the oxygen evolution reaction across the double layer, it was argued that[7]

$$i = i_{of} = X \exp\left[\frac{\mathbf{F}\Delta V_{of}}{RT}\right] = A \exp\left[\frac{\mathbf{F}\Delta V_{dl}}{RT}\right] \quad [13]$$

In this work, X contained the dependence of the catalytic activity on the thickness of the oxide film. X was assumed constant only for a given, strictly controlled pretreatment of the electrodes and only when the V-i measurements were made at current densities or potentials lower than those at which the electrode was anodically pretreated. It was contended that the observed current density $i = i_{of} = i_{dl}$ should be given in terms of the total potential difference, V_t, by the following equation

$$i = (AX)^{1/2} \exp\left[\frac{\mathbf{F}\Delta V_t}{2RT}\right] \quad [14]$$

Now, from this equation and from Eq. [9] of the present work it becomes possible to express X in terms of the thickness of the oxide film

$$X = X_o \exp(-\delta d) \quad [15]$$

and thus, the expression for the current density across the oxide film can be written as

$$i_{of} = X_o \exp(-\delta d) \exp\left[\frac{\mathbf{F}\Delta V_{of}}{RT}\right] \quad [16]$$

This rate expression represents a basis for the study of the mechanism of electron transfer through the surface oxide film. Such study is in progress and will be reported in subsequent publications.

Acknowledgment

The authors are grateful to Dr. M. L. Hair for valuable discussions of various topics in this paper. The assistance of E. Gray in making some of the ellipsometric measurements is also gratefully acknowledged.

Manuscript received Dec. 3, 1973. This was Paper 326 presented at the San Francisco, California, Meeting of the Society, May 12-17, 1974.

[7] In this expression X replaces A of Ref. (1) and A replaces Bc^{-1} of Ref. (1) since pH dependence of the reaction is not considered in the present work.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1975 JOURNAL. All discussions for the June 1975 Discussion Section should be submitted by Feb. 1, 1975.

The publication costs of this article have been assisted by the Xerox Corporation.

APPENDIX

Equation [5] is obtained by solving the determinant of the coordinates of three points in the plane $f(V, \ln i, d)$ = constant. The determinant includes the coordinates (V, ln i, d) of point A in Fig. 6 (at the intersection of lines AB, AD) and the coordinates of a point in AB and a point in AD each removed from point A by one ln unit of current density, *i.e.*

$$\begin{vmatrix} V & \ln i & d \\ V - \dfrac{2RT}{\mathbf{F}} & \ln i - 1 & d \\ V - \kappa & \ln i - 1 & d - \epsilon \end{vmatrix} = \text{constant}$$

This transforms to

$$\epsilon V = \frac{2RT\epsilon}{\mathbf{F}} \ln i + \left(1 - \frac{\kappa \mathbf{F}}{2RT}\right) d = \text{constant}$$

Technical Notes

Morphology of Transgranular Stress Corrosion Crack in Type 304 Stainless Steel Tested in pH 2.5 H_2SO_4 at 289°C

David A. Vermilyea*

Corporate Research and Development, General Electric Company, Schenectady, New York 12301

In a previous paper (1) it was reported that annealed as well as cold-worked Type 304 stainless steel was susceptible to transgranular stress corrosion cracking in pH 2.5 H_2SO_4 at 289°C. The purpose of this note is to present and discuss some unique fractographs which have been obtained from similar tests.

The material used contained 18.3 Cr, 9.3 Ni, 0.045 C, 0.5 Mn, 0.018 P, 0.006 S, 0.43 Si, 0.15 Mo, 0.32 Cu, and 0.088 Co, in weight per cent. Before testing the 0.050 in. wire was electropolished and then notched (30° angle, 0.001 in. root radius, 0.020 in. deep). The test was conducted at a constant crosshead speed of 10^{-5} in./min using the apparatus previously described (1), with a potential controlled at zero volts *vs.* a standard hydrogen electrode. The fracture load was about half the value obtained in a test in air. Test details may be found in the earlier paper (1).

Figures 1-5 show scanning electron micrographs of a typical fracture at several magnifications. In all figures the direction of crack propagation is from the bottom to the top of the photograph. The fan-shaped areas containing marks roughly parallel to the crack propagation direction are reminiscent of similar features on fractographs produced in boiling $MgCl_2$ or in H_2SO_4-NaCl solutions (2). The unique feature of these fractographs is the pronounced set of striations roughly perpendicular to the crack propagation direction. (The small particles thinly spread over the surface are iron oxide produced by oxidation of ferrous ions in solution.)

In a recent discussion of these photographs Professor Pugh of the University of Illinois pointed out that the marks which run roughly parallel to the crack propagation direction differ from cleavage steps in being very jagged. It can be seen that the irregularities in these marks frequently occur at places where the striations cross them.

It is believed that the striations represent positions at which the crack stopped temporarily during its propagation. Crack propagation is believed to occur by a film rupture mechanism (3, 4), with repeated periods of rapid corrosion and repassivation. Corrosion may leave surfaces which are bounded by certain crystallo-

Fig. 1. SEM fractograph of the sample at low magnification; the lower half shows the notch surface.

Fig. 2. Area about half-way from notch to outer edge

graphic planes. The marks parallel to the crack propagation direction may then be formed by tearing of material at steps between the crystallographically corroding surfaces, in a manner similar to the way cleavage steps are produced. During crack arrest the striations may be produced by crack blunting due to creep or by continued localized corrosion accompanying the full development of the passive film.

Fig. 3. Same as Fig. 2

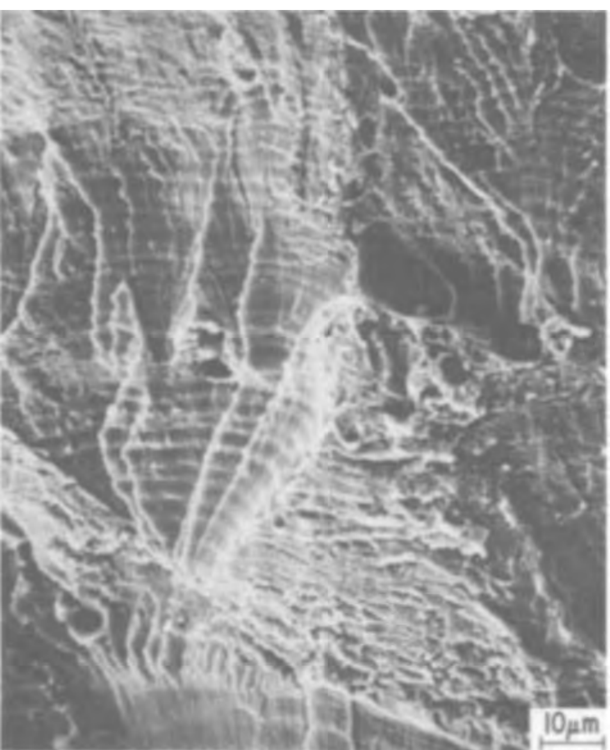

Fig. 4. Area near the outer edge

Support for such an interpretation of the fractographs can be obtained from a consideration of the striation spacing. Figure 5 shows that the finest striations are separated by only about 1-2 $\times$ 10^{-5} cm. In a recent paper Vermilyea and Diegle (4) show that the ratio of metal corrosion rate ($\dot{l}$) to the strain rate ($\dot{\epsilon}$) of material being corroded while being continuously strained is roughly equal to the crack advance per film rupture event. This ratio of $\dot{l}/\dot{\epsilon}$ was measured under the conditions of this test using a smooth specimen and a crosshead speed of 0.05 in./min, and was found to

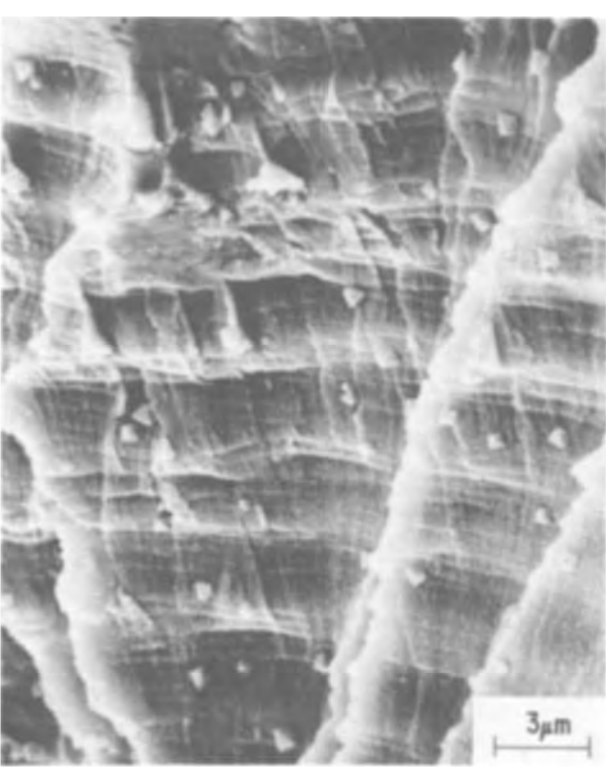

Fig. 5. Same as Fig. 4

be 2.6 × 10^{-5} cm, in reasonable agreement with the striation spacing.

Pitting Resistance of 18% Cr Ferritic Stainless Steels Containing Molybdenum

R. J. Brigham and E. W. Tozer

Endako Mines Limited, Molybdenum Research, Ottawa, Ontario, Canada

The pitting resistance of ferritic stainless steel and the effect of Mo content on pitting characteristics at various temperatures have been discussed recently in terms of pitting potentials (1). An alternative approach using temperature as a pitting criterion has been successfully applied to Mo-bearing 18% Cr austenitic stainless steels (2, 3) and appears to be applicable in clarifying the behavior of 18% Cr ferritic stainless steels as well.

It has been shown for austenitic stainless steel that there exists a temperature, which we have called the critical pitting temperature (CPT), below which a steel will not pit when exposed to oxidizing acid chloride solution such as 10% $FeCl_3$. An exposure time of 24 hr in this solution has been shown to be sufficient for pit initiation if pitting is to occur at that temperature. For example, an austenitic steel with a CPT of 40°C has been exposed at room temperature varying between 20° and 36°C for more than 600 days and has not initiated pits in that time. The initiation and growth of pits in 10% $FeCl_3$ solution at a fixed temperature must occur on the flat surface parallel to the rolling plane well removed from the edges of the coupon for the test results to be valid. Crevice, edge, or end-grain attack which may occur at temperatures below CPT are disregarded in judging whether attack by pitting has occurred after exposure at a particular temperature. The test temperature is increased in 2.5°C steps every 24 hr until pitting occurs.

Key words: pitting, corrosion, temperature.

In tests below room temperature, care is taken to prechill samples before exposure to avoid spurious results.

The series of commercial (AISI 430 and Alloy X) and experimental alloys (Alloys Q, R, S, and T) listed in Table I in order of increasing Mo content have been tested. The experimental alloys were made by a split heat technique, rolled to sheet, annealed for 1 hr at 840°C and furnace cooled. The commercial alloys were tested in the as-received annealed condition. Surface preparation consisted of abrading with 120 grit SiC paper as in the previous studies on austenitic steels (2, 3). The results are plotted in Fig. 1 as CPT *vs.* per cent Mo using error bars. For each alloy, pitting was not observed at the temperature indicated by the left-hand side of the bar while the right-hand side indicates that temperature (2.5°C higher) at which pitting was observed. The data can be described em-

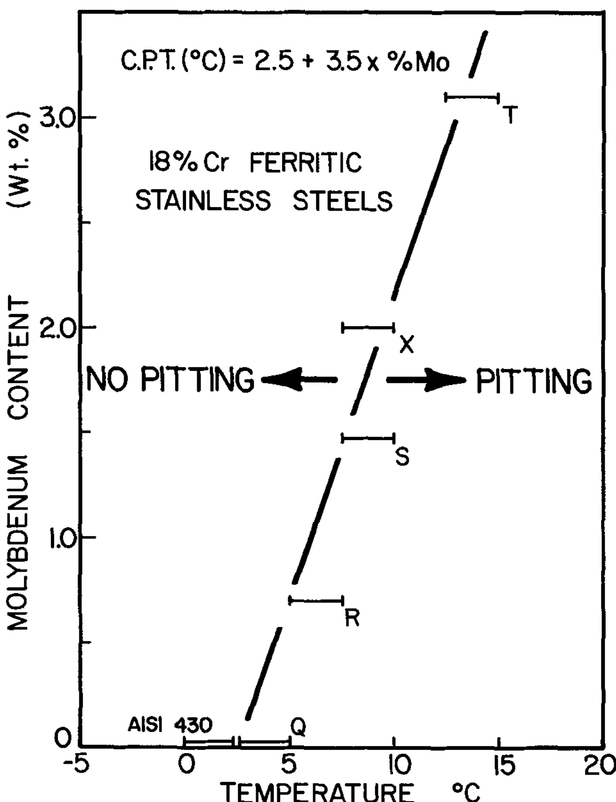

Fig. 1. Critical pitting temperature as a function of Mo content for a series of commercial and experimental 18% Cr ferritic stainless steels.

pirically by

$$\text{CPT } (^\circ\text{C}) = 2.5 + 3.5 \times \%\text{ Mo}$$

It can be seen that the pitting resistance increases continuously with increasing Mo content over the range nil to 3% Mo.

The Mo response of these 18% Cr ferritic alloys is only approximately ½ that for a comparable family of 18% Cr austenitic steels (3) for which

$$\text{CPT } (^\circ\text{C}) = 5 + 7 \times \%\text{ Mo}$$

but is entirely consistent with the reduced thermodynamic activity of Mo in ferritic phases. A measure of this lower Mo activity in the ferritic phase is given by the high-temperature partition of Mo between phases to achieve equal thermodynamic activities at equilibrium. A ferritic/austenitic partition ratio of approximately 2 has been observed for molybdenum in duplex stainless steels (4, 5).

Acknowledgments

The cooperation of the Physical Metallurgy Division, Department of Energy, Mines and Resources in making their facilities available and helpful discussions with Dr. G. J. Biefer (Head) and Dr. J. B. Gilmour (Research Scientist) of the Corrosion Section, Physical Metallurgy Division, are gratefully acknowledged. The experimental ferritic alloys were supplied through the good offices of Dr. Biefer.

Manuscript submitted Feb. 1, 1974; revised manuscript received May 3, 1974.

Erratum

In the paper "Activities of Organic Compounds in Aqueous Electrolyte Solutions" by D. M. Mohilner, L. M. Bowman, S. J. Freeland, and H. Nakadomari which appeared on pp. 1658-1662 in the December 1973 JOURNAL, Vol. 120, No. 12, there were three errors in the drawing of the circuit diagram (Fig. 4, p. 1660). One of these errors was major and would render the circuit as drawn inoperable. This major error is that operational amplifier OA7 was shown connected as an inverting amplifier. OA7 is actually connected as a noninverting amplifier just as is OA6. The other two errors in the drawing are as follows: (*i*) There should be a 10K resistor connected between the output of OA2 and the terminal labeled integrator out. (*ii*) The resistor labeled 100 SL on the drawing is actually a 100 ohm resistor. A corrected version of Fig. 4 is shown below.

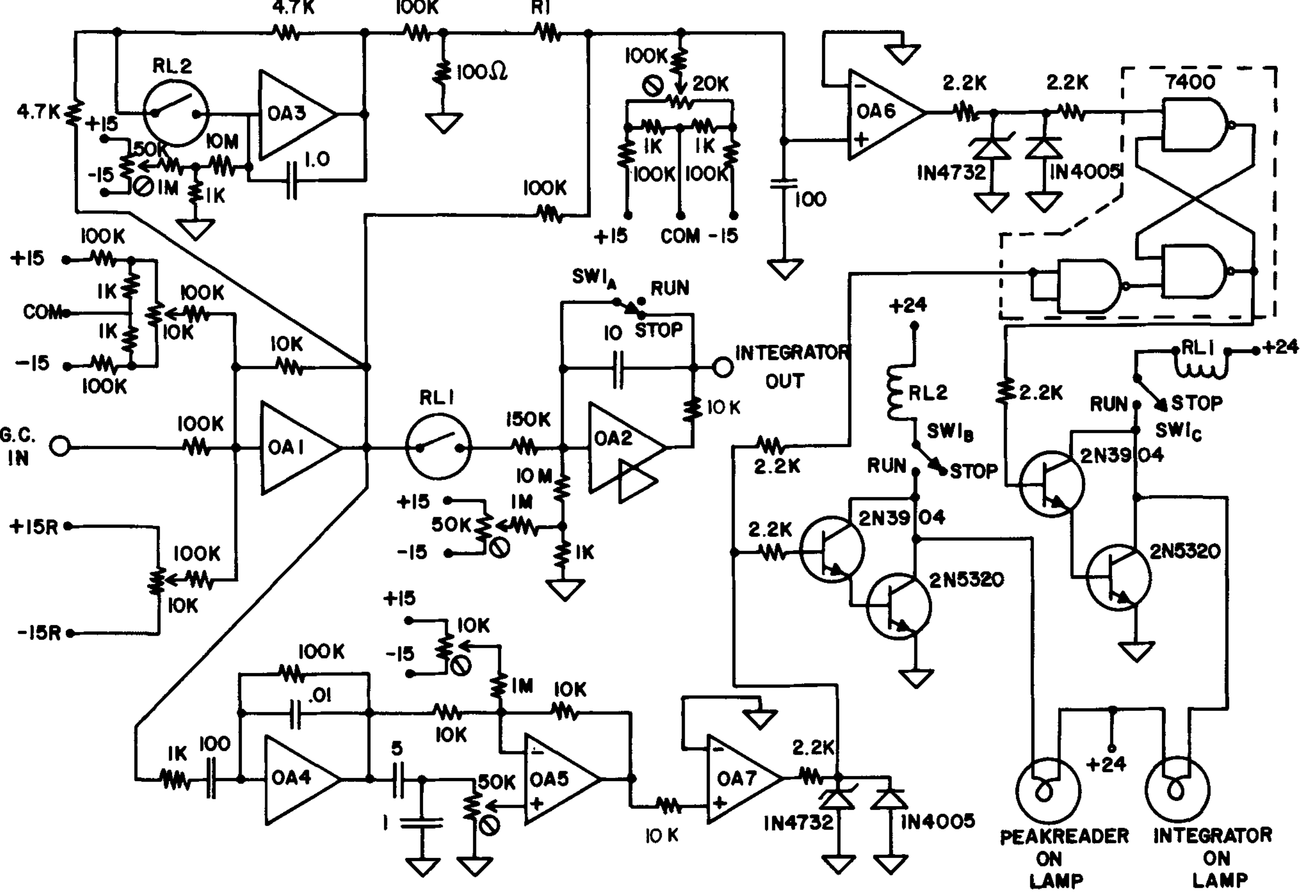

Fig. 4. Circuit diagram of integrator control circuit. The operational amplifiers used are: OA1, Philbrick 1020; OA2, Philbrick 1700, chopper stabilized; OA3, Philbrick 1023; OA4 and OA5, Philbrick Sq10A and OA7, Model 741.

Sodium-Induced Barrier-Height Lowering and Dielectric Breakdown on SiO_2 Films on Silicon

C. M. Osburn* and D. W. Ormond*

IBM Thomas J. Watson Research Center, Yorktown, Heights, New York 10598

ABSTRACT

Electrical conduction measurements in SiO_2 films showed that the injecting barrier height was uniformly reduced by a small amount (<1 eV) in proportion to the level of Na contamination. However, at high contamination levels (>10^{13} Na^+/cm^2) after bias-temperature stressing, a very substantial (≈3 eV), localized barrier lowering was observed. Since this second type of lowering was eliminated after exposure of the film to moisture (in air) and was also seen in uncontaminated samples, it was not attributed to sodium. Accelerated dielectric breakdown measurements at low fields (<2 MV/cm) showed that even a monolayer of Na did not appreciably decrease the wear-out time. Moderately contaminated samples (5 × 10^{12} Na^+/cm^2) had the same limiting failure times as controls over the temperature range 100°-400°C.

It has been recognized (1) for some time that mobile ions in MOSFET structures lead to threshold voltage shifts. Recently Raider (2) and Osburn and Raider (3) have shown that mobile ions can also lead to a time-dependent dielectric breakdown of a thermally grown SiO_2 film. The electric field due to the charged ions adds to the applied field and causes premature failure. Internal photoemission measurements of DiStefano (4, 5) have revealed another possible breakdown mechanism due to mobile ions: lowering of the height of the injecting barrier resulting in distinctively high conduction levels. But electrical measurements (6) of sodium-free (<$10^{10}/cm^2$) SiO_2 films prior to breakdown have also shown a large, localized barrier-height lowering. The purpose of this work was to more fully determine the extent of barrier-height lowering due to sodium ions and the effect, with regard to dielectric breakdown, of mobile charge on long term reliability.

Electrical conduction data showing two different types of barrier-height lowering are presented. One component occurred uniformly, was relatively small ($\lesssim$ 1 eV), and can be attributed to dipole lowering due to sodium; the second component was large (≈3 eV), localized (~25Å channels), and is not believed to be due to sodium. This second type of lowering was the same as that seen earlier (6) in uncontaminated samples where it was believed responsible for dielectric breakdown. Measurements of the time interval before breakdown of Na-contaminated examples are also given which do not support the contention that barrier lowering caused by Na ions is responsible for breakdown. Indeed, at typical FET operating fields (2 MV/cm) tests showed that even a monolayer of sodium did not accelerate wear-out.

Experimental Procedure

Metal-oxide-semiconductor capacitors were fabricated on 2 ohm-cm, n-type, <100>-oriented silicon wafers as previously described (3). The silicon dioxide growth was at 1000°C in dry oxygen. Contamination was introduced by evaporating a small amount of NaCl onto the freshly oxidized surface. Aluminum capacitor dots were then evaporated through metal masks. Contamination levels were measured with either the capacitance-voltage flatband shift (1) or the charge-time (Q-t) technique (7). Uncontaminated samples typically had less than 10^{10} mobile ions/cm^2 as measured by the triangular voltage sweep (TVS) technique (8).

Both the time to breakdown at constant field and the time dependence of the conduction were determined for contamination levels from less than 10^{10} Na^+/cm^2 to greater than $10^{15}/cm^2$. Because large prebreakdown currents were often seen, the main criterion for the occurrence of dielectric breakdown was an irreversible, step jump in current. A special high-temperature measuring cell, filled with dry nitrogen, was used to insure against stray leakage. The metal was biased positively in all cases in order to drive the sodium to the Si|SiO_2 interface and also to inject electrons from the silicon into the SiO_2. The electric fields used in this work were low enough so that field enhancement breakdown did not occur (3). Barrier heights were inferred from room-temperature conduction measurements assuming Fowler-Nordheim emission (9). In cases where the calculated barrier height was low, it was recalculated assuming Schottky emission.

Results and Discussion

Conduction and barrier-height lowering.—The conduction current as a function of time for several different temperatures is given in Fig. 1. At room temperature when a bias voltage is applied, the current increased with time until a maximum was obtained, and then decreased (3). This maximum has been explained in terms of the sodium being at an optimal distance (≈30Å) from the Si|SiO_2 interface (10). As the ions moved closer to the silicon, the tunneling distance would increase and hence the current decreased.

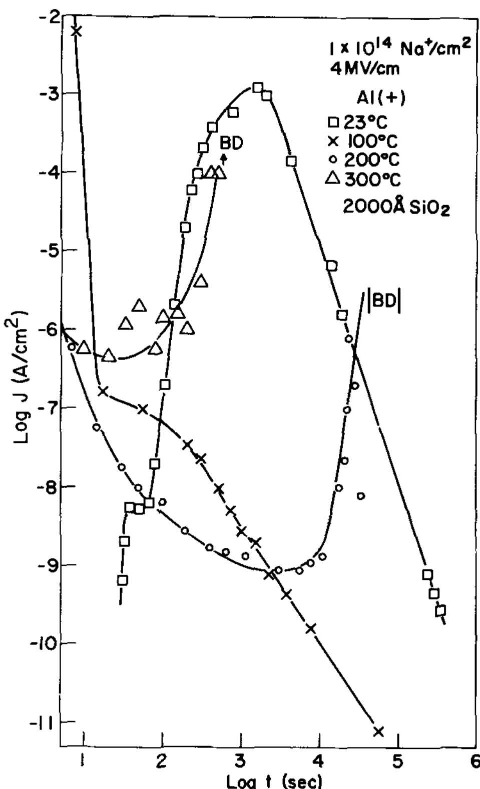

Fig. 1. Current at a fixed electric field as a function of time for several different temperatures.

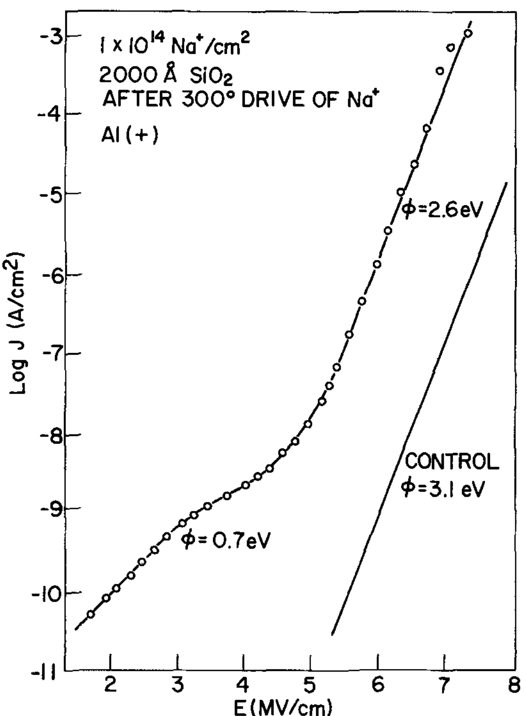

Fig. 2. Room-temperature *I-V* characteristics after current enhancement.

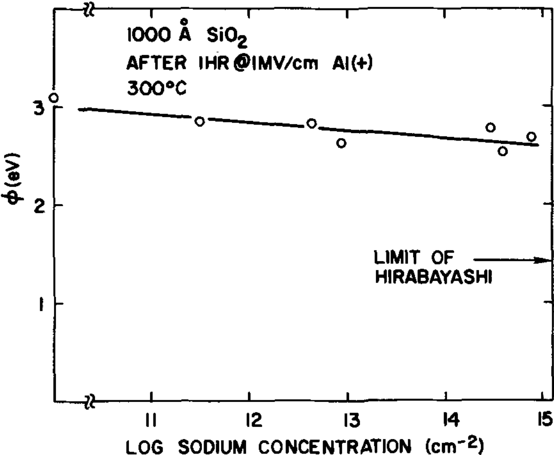

Fig. 3. Barrier height as a function of sodium concentration after bias-temperature stressing.

A minor peak was seen in the current after a very short time and can probably be attributed to the sodium ionic current. At 100°C the ionic decay largely occurred in the first 10 sec (under the conditions of Fig. 1), and the maximum (corresponding to the sodium being about 30Å from the silicon) is seen only as a slope change. At 200° and 300°C a new effect, associated with barrier-height lowering, was seen: after the usual decay, the current increased with time until breakdown occurred. This enhanced current was usually quite erratic, as previously seen with noncontaminated samples (6). The time for the current enhancement to occur increased dramatically with decreasing electric field.

Room-temperature current-voltage characteristics of a capacitor after enhancement are given in Fig. 2. Characteristics of an uncontaminated sample are also shown for reference. Two components of barrier-height lowering are evident: At high fields the barrier was reduced from 3.1 to 2.6 eV and at lower fields the slope of a Fowler-Nordheim plot gave a 0.7 eV barrier. Values of barrier height were calculated from both the slope of the *I-V* curve and the magnitude of the current. Self-consistent barrier heights as low as 2.5 eV were observed. This compares with a theoretical limit (12) of 1.63 eV and a previously measured (4) value of 1.8 eV (which was not determined to be the absolute minimum obtainable). For barriers less than 2.5 eV, the data suggested that the lowering was localized.

The magnitude of the high-field uniform component of the barrier height after the sodium has been driven to the Si|SiO_2 interface is presented in Fig. 3 as a function of sodium concentration. A 1 MV/cm field was applied for 1 hr at 300°C, at which conditions charge-time measurements confirmed that the sodium drift was very nearly complete. That is, tests showed that the barrier lowering after 20 hr was not substantially greater than that after 1 hr at 300°C at 1 MV/cm. It should be noted, however, that *C-V* or *Q-t* measurements could not resolve the position of the sodium ions better than 10-20Å and therefore could not insure that all the sodium was close enough to the silicon to contribute to barrier lowering.

An alternate analysis of the low-field data in terms of the Schottky conduction model also resulted in a low barrier height. The current density associated with this low barrier (~10 A/cm^2 at 2 MV/cm) is much higher than the average current density that was measured. This discrepancy in current densities could be resolved by (*a*) inferring that the low-field conduction was localized (25Å diameter channels) or (*b*) determining that neither the Fowler-Nordheim nor the Schottky mechanism provides a valid description of the conduction. All evidence to date, including data on uncontaminated samples (6), favors the localization model: (*a*) after enhancement the conduction was dependent on both polarity and electrode material as would be expected of either Fowler-Nordheim or Schottky conductor, (*b*) the temperature dependence of the conduction was not exponentially activated and was very similar to that seen with Fowler-Nordheim conduction in good SiO_2 films (9), and (*c*) scanning internal photoemission measurements of DiStefano (4) showed a localized barrier lowering.

The localized component of the barrier lowering is important since the very high current density (>1 A/cm^2) through this region is of the order of that required for thermal runaway (11) and breakdown. After the conduction enhancement has occurred at elevated temperature, contaminated samples exhibit the same kind of sensitivity to moisture as do uncontaminated samples (6). For example, exposure of the capacitor to room air for a few seconds resulted in a decrease of the current and an increase in the barrier height (often by as much as 2 eV). Locally low barrier heights and sensitivity to atmosphere are not unique to Na-contaminated capacitors but also occur in the purest films available. In uncontaminated samples, the barrier lowering cannot be removed by a reverse bias and hence is not attributed to a mobile species. Likewise, even though a reverse bias moved the sodium away from the $Si\text{-}SiO_2$ interface, measurements showed that the localized lowering remained present and thus was not due to the sodium.

At low measuring fields and higher sodium concentrations, barrier heights were often quite variable from one capacitor to another, and the values did not correlate well with the sodium concentration. It is apparent however that increasing the sodium concentration lowers the barrier and that above 10^{13} Na^+/cm^2 localization is likely. It also should be noted that barrier heights considerably lower than the 1.63 eV theoretical minimum (12) were observed. Such low barrier heights were also routinely seen (6) in uncontaminated samples and suggest a process more complex than simple barrier lowering due to sodium, *e.g.*, crystallization.

Dielectric breakdown.—In order to assess the effect of sodium ions on dielectric integrity of SiO_2 films, breakdown times were obtained as a function of electric field for capacitors having up to 10^{15} Na^+/cm^2 (see Fig. 4). Breakdown times, of course, are statistical variables since defects in the dielectric cause premature failure (3, 6). The maximum time to breakdown (t_{max}) of a sampling (10-20 samplings) of MOS capacitors was chosen for close examination since it was associated with the breakdown time of defect-free SiO_2. At high electric fields, as Fig. 4 shows, high sodium contamination shortened the life of the capacitors. This is expected because of the field-enhancement from the sodium and is not necessarily related to any barrier-height lowering. At lower fields, like those normally encountered in FET operation, where breakdown might occur induced by barrier lowering, it is seen that even a monolayer of sodium did not shorten the lifetime by more than half an order of magnitude. This effect probably could also be attributed to the increased electric field in the oxide. Flatband voltage measurements (13) as a function of time, made on MOS capacitors having 10^{12} Na^+/cm^2, have failed to detect any large scale, lateral, ion motion or neutralization of the sodium and thus eliminate these as mechanisms for improving the life of the contaminated samples.

The temperature dependence of the maximum time to failure (Fig. 5) shows that the wear-out process in SiO_2 films contaminated with 5×10^{12} Na/cm^2 had a 1.4 ± 0.2 eV thermal activation energy from 100° to 400°C. The activation energy is identical to that reported for wear-out (6) and for interface state generation (14) in uncontaminated films. The sodium did not accelerate dielectric wear-out in these films.

Two different breakdown mechanisms have been postulated (6, 9) for uncontaminated SiO_2 films depending on the measuring conditions. Normally, the breakdown in SiO_2 films is electronic in nature: electrons gain energy from the high applied field and then ionize centers in the dielectric (9). In this mode, the applied field and the trap ionization energy are important but the current density is secondary. Magnesium and gold injecting electrodes having barrier heights of 1.7 and >5 eV, respectively, and showing at least a 10-decade difference in conduction, give the same MOS dielectric strength (9). After accelerated bias-temperature stressing, breakdown is believed to be thermal in nature (6). The generation of interface states at the injecting electrode lowers the barrier height enough so that an exceedingly high current flow

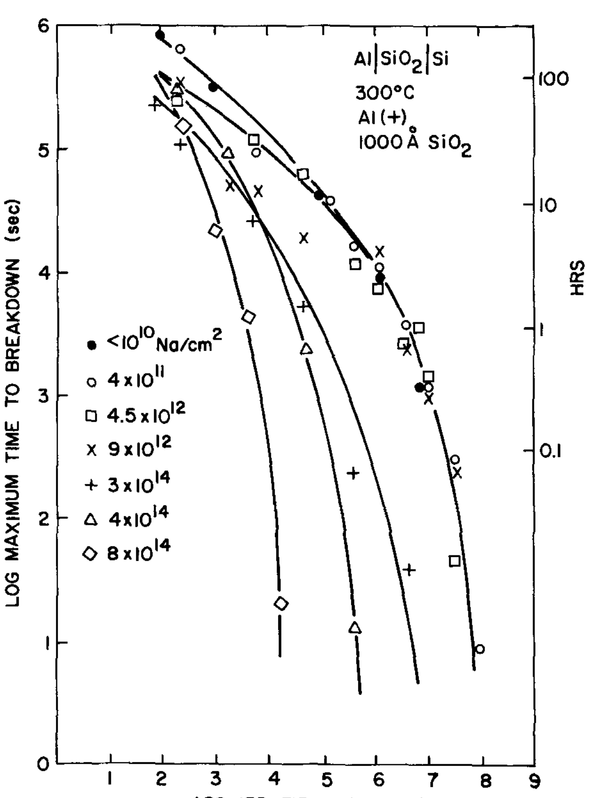

Fig. 4. Breakdown time as a function of electric field for different levels of mobile charge.

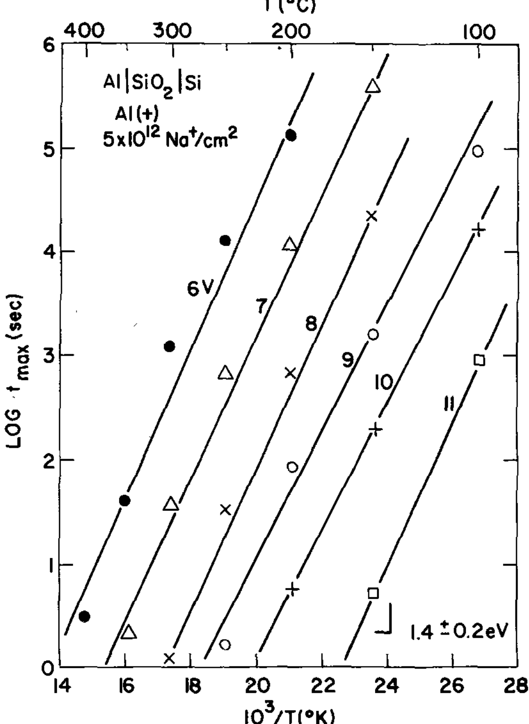

Fig. 5. Temperature dependence of maximum time to breakdown in a 175Å SiO_2 film contaminated with 5×10^{12} Na^+/cm^2 for various applied voltages.

(>>1 A/cm^2) can initiate thermal runaway. Localized barriers of about 0.5 eV have been frequently observed in uncontaminated films prior to breakdown (6); certainly a barrier height of less than 1 eV would be required to achieve such high current at low fields.

For sodium-related barrier-height lowering to initiate dielectric breakdown at low electric fields (<3 MV/cm), the barrier must be lowered by at least 2 eV. Such a large change has not been observed to occur uniformly even with a monolayer of sodium. Based on this consideration, it is argued that Na-induced barrier-height lowering alone does not enhance uniform wear-out of SiO_2 films.

The localized effects of sodium cannot be ignored since the Na is not uniformly distributed (4, 5, 15) but presumably accumulates at some defect. Although locations of maximum barrier-height lowering and of dielectric breakdown have been correlated (5), the barrier lowering itself may not be the cause of the breakdown. Other mechanisms, notably crystallization (16) or field enhancement (2, 3) due to Na trapped at oxide defects could equally well explain the observed correlation.

Summary

Electrical conduction measurements in SiO_2 films have confirmed scanning internal photoemission findings (4, 5) that the Si-SiO_2 barrier height can be lowered (often locally) by the presence of sodium ions. With the low electric fields typically encountered in FET device operation, a monolayer of Na^+ contamination did not appreciably reduce the maximum time to failure. In addition, moderately contaminated (5×10^{12} Na^+/cm^2) and clean ($<10^{10}$ Na^+/cm^2) oxides had the same maximum failure times over the 100°-400°C range and for oxide thicknesses from 175 to 1000Å. When the barrier lowering was uniform, its magnitude was less than 1 eV and well within the range observed by DiStefano (4, 5) and predicted by Hirabayashi (12), but yet was still too small to initiate high current and thermal runaway. In view of these findings, the causative relationship between localized barrier lowering and localized breakdown are questioned. Both field enhancement (2, 3) from Na trapped at oxide defects and Na-induced crystallization (16) provide alternative explanations, but these were not tested in the present experiments.

Acknowledgments

The authors would like to thank Drs. S. Raider, N. Chou, J. Eldridge, and T. DiStefano for helpful and stimulating discussions during the course of this work.

The Temperature and Oxygen Pressure Dependence of the Ionic Transference Number of Nonstoichiometric CeO_{2-x}

G. J. VanHandel and R. N. Blumenthal

Metallurgy and Materials Science, College of Engineering, Marquette University, Milwaukee, Wisconsin 53233

ABSTRACT

An electrochemical cell technique was used to measure the ionic transference number of sintered specimens of nonstoichiometric CeO_{2-x} as a function of temperature (590°-1000°C) and oxygen partial pressure (1-10^{-22} atm). The results were described in terms of a high and low oxygen pressure region. The ionic transference number is controlled by impurities in the high oxygen pressure region. In this region the electronic conductivity was p-type at lower temperature and n-type at higher temperatures. In the low oxygen pressure region the ionic transference number is small (*e.g.*, above 700°C, $t_i < 0.08$). The electrical conduction in this region is controlled by the nonstoichiometric defects and is predominantly electronic. Using the value of $t_i \simeq 0.05$, an estimate of the diffusion coefficient for doubly ionized oxygen vacancies, $D_{V_O^{\cdot\cdot}} \simeq 3.5 \times 10^{-5}$ cm^2/sec at 1000°C was calculated by combining recently obtained thermodynamic and conductivity data with the Nernst-Einstein relation.

Nonstoichiometric cerium dioxide, CeO_{2-x}, has been the subject of several x-ray (1-4), thermodynamic (5-8), and electrical conductivity (9-16) investigations. Based on these experimental observations, CeO_{2-x} may be classified as a metal-excess, n-type semiconductor. In a recent thermodynamic study (8) the nonstoichiometric defect structure has been characterized in terms of defect model involving doubly ionized

Key words: ionic conductivity, ionic transference number, diffusion coefficient.

oxygen vacancies, $V_o^{\cdot\cdot}$, and electrons localized on normal cerium atoms, Ce_{Ce}'. Although the electrical conduction at lower oxygen pressures has generally been assumed to be predominantly electronic (10, 14-16) there has not been any ionic transference measurements to verify this assumption.

The objective of this study was (*i*) to measure the ionic transference, t_i, of CeO_{2-x} as a function of oxygen partial pressure and temperature and (*ii*) to combine this data with electrical conductivity and thermodynamic data to obtain information about the oxygen vacancy diffusion coefficient, $D_{V_o^{\cdot\cdot}}$, in "pure" CeO_{2-x} and to compare these results with the recently reported values of $D_{V_o^{\cdot\cdot}}$ for CaO-doped cerium dioxide (17).

Theory

An oxygen concentration cell of the type

$$P_{O_2},Pt \mid CeO_2\text{-}CaO \mid Pt,P_{O_2}'$$

was used in this investigation to obtain ionic transference numbers of CeO_2 as a function of P_{O_2} and temperature. The open-circuit emf of this cell for $P_{O_2} \neq P_{O_2}'$ is given by the well-known expression

$$E_{meas} = (RT/n\mathbf{F})t_i \ln(P_{O_2}'/P_{O_2}) \quad [1]$$

where R is the universal gas constant, T the absolute temperature, n the number of electrical equivalents, $\mathbf{F}$ Faraday's constant, and t_i the ionic transference number. The subscript on E indicates that this is the measured emf. The theoretical or thermodynamic emf of a similar cell with a totally ionic electrolyte ($t_i = 1$) is given by

$$E_{theo} = (RT/n\mathbf{F}) \ln(P_{O_2}'/P_{O_2}) \quad [2]$$

If the ionic transference number does vary too much across the electrolyte then t_i is given by

$$t_i = E_{meas}/E_{theo} \quad [3]$$

The use of Eq. [3] requires that the electrodes act reversibly.

The diffusion coefficient of a nonstoichiometric defect may be determined by combining transport numbers data with the appropriate composition and electrical conductivity data. For example, in nonstoichiometric CeO_{2-x} the predominate defects are $V_o^{\cdot\cdot}$ and Ce_{Ce}' (8). Thus the ionic conductivity, σ_i, may be represented by

$$\sigma_i = n_{V_o^{\cdot\cdot}} 2e\mu_{V_o^{\cdot\cdot}} \quad [4]$$

where $n_{V_o^{\cdot\cdot}}$ is the concentration of oxygen vacancies per cubic centimeter, e the charge of an electron, and $\mu_{V_o^{\cdot\cdot}}$ the mobility of a doubly ionized oxygen vacancy.

According to the Nernst-Einstein relation

$$D_{V_o^{\cdot\cdot}} = \frac{\mu_{V_o^{\cdot\cdot}} kT}{2e} \quad [5]$$

Combining Eq. [4] and [5] we obtain

$$\sigma_i = n_{V_o^{\cdot\cdot}} 4e^2 \frac{D_{V_o^{\cdot\cdot}}}{kT} \quad [6]$$

Since cerium dioxide exhibits a fluorite structure with eight oxygen and four cerium sites per unit cell, the concentration of oxygen vacancies may be related to the deviation from stoichiometry, x, in CeO_{2-x} by the expression

$$n_{V_o^{\cdot\cdot}} = \frac{4x}{a_o^3} \quad [7]$$

where a_o is the lattice parameter of CeO_{2-x}

$$\sigma_i = \left(\frac{16e^2}{a_o^3}\right) \frac{xD_{V_o^{\cdot\cdot}}}{kT} \quad [8]$$

The conductivity may be calculated from the relation

$$\sigma_i = \sigma_T t_i \quad [9]$$

Combining Eq. [8] and [9] we obtain the following expression for the diffusion coefficient for oxygen vacancies

$$D_{V_o^{\cdot\cdot}} = \left(\frac{a_o^3}{16e^2}\right) \frac{kT}{x} \sigma_T t_i \quad [10]$$

Thus, if the transference number data is combined with the appropriate conductivity and composition data, $D_{V_o^{\cdot\cdot}}$ may be calculated from Eq. [10].

Experimental

Sintered polycrystalline disks were used for the electrolytes in the electrochemical cells. The "pure" cerium dioxide powder was obtained from the Trona Division of American Potash Corporation and was 99.99% pure with respect to other rare earths. The chemical analyses of the CeO_2 powder are given in a previous publication (17). Disks were formed by cold pressing the CeO_2 powder in a ¾ in. diam steel die at approximately 32,000 psi. The green specimens were lightly scraped to remove material deposited on the specimens from the die walls. The disks were fired in flowing argon for 3 hr at 1600°C. Oxygen was introduced at 1300°C during cooling of the sintering furnace. The sintered bulk densities ranged from 80 to 90% of theoretical. The disks were ground to a final size of 13 mm diam by ~3.2 mm thick using 180 grit silicon carbide polishing paper.

Pyrex rings were used to seal each electrolyte disk to the end of a ½ in. OD alumina tube. The rings which were approximately 1.5 mm thick were cut from ½ in. OD Pyrex tubing. Rubber cement which later burned off was used to hold the electrolyte disk and Pyrex ring in place for insertion into the cell assembly. The electrolyte disk, Pyrex ring, tube assembly was then heated to 1000°C *in situ*. The Pyrex ring softened sufficiently to produce a seal between the tube and disk such that the inside of the tube could be used as one of the electrode chambers.

The cell as used in this investigation is shown schematically in Fig. 1 and 2. The alumina tube with the electrolyte pellet was held in place by the large brass head and rested on a platinum mesh contact. This contact in turn rested on the flat bottom of a quartz support tube. The support tube was cemented to the large brass head. An O-ring compression fitting in the brass head formed a gas seal at the point where the electrolyte tube entered the head.

The electrode-gas atmosphere for the outer electrode was supplied through the brass head which also provided an exhaust exit. Gas atmospheres entering at the

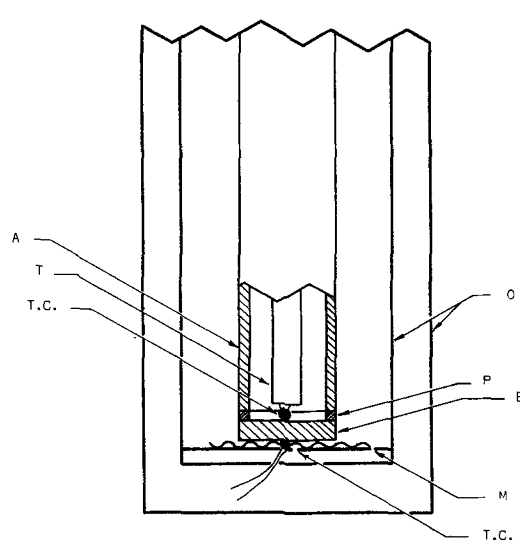

Fig. 1. Schematic detail of cell electrolyte area. A, alumina electrolyte tube; E, electrolyte; M, platinum mesh contact; P, Pyrex seal; Q, quartz tube; T, thermocouple insulator; T.C., Pt/Pt-13% Rh thermocouple.

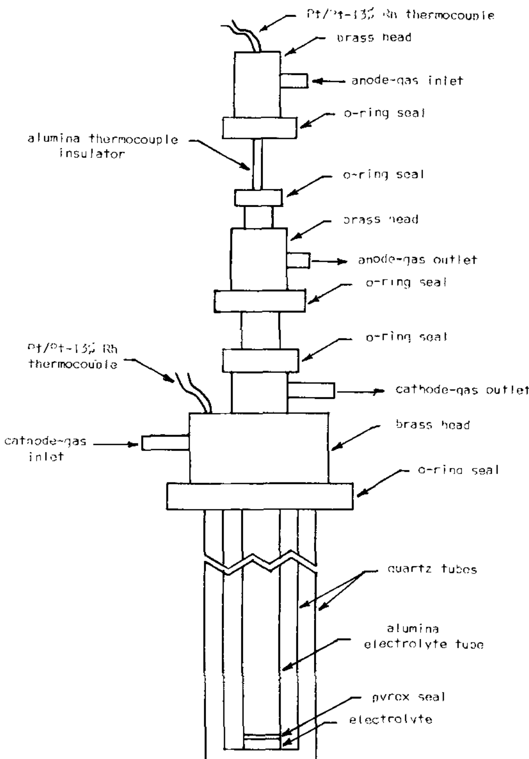

Fig. 2. Schematic of the electrochemical cell assembly

head passed down into the cell and around the outer surface of the electrolyte via a hole in the flat bottom of the quartz support tube.

A Pt/Pt-13% Rh thermocouple was used to measure the temperature at the outer electrode. The leads of this thermocouple passed through a two-hole Kovar seal in the large head. The platinum mesh contact was connected to the platinum lead of this thermocouple which served as the outer potential lead.

A smaller brass head, connected to the ½ in. alumina tube by means of another O-ring fitting, provided the gas exhaust for the inner electrode chamber and accepted a thermocouple insulator tube.

A third brass fitting on the inner thermocouple insulator was used to supply gas to the inner electrode chamber through the thermocouple insulator. The thermocouple leads exited through a 2-hole Kovar seal in this fitting with platinum lead of this Pt/Pt-13% Rh thermocouple serving as the potential lead for the inner electrode.

Both of the smaller brass fittings were spring-loaded to provide good physical contact between the thermocouple and electrolyte and between the platinum mesh and the electrolyte at all times during heating and cooling of the cell.

Mixtures of O_2-Ar and CO-CO_2 supplied prepurified, premixed, and analyzed by the Matheson Company were used for the electrode atmospheres. The O_2-Ar mixtures which ranged from 104 ppm O_2 to pure O_2 were checked with an oxygen gauge using a calcia-stabilized zirconia electrolyte. The oxygen contents as determined from use of the oxygen gauge were used in calculating experimental values of the ionic transference fractions. The CO-CO_2 mixtures ranged from 1000 ppm CO to 97% CO. The Matheson analyses were used in calculations involving these mixtures.

The gas flow rates were controlled by Matheson No. 602 rotometers. Systems of two 3-way glass stopcocks were used to route the gases to the inner and outer chambers as desired. A flow rate of approximately 280 cm^3/min was used in both chambers.

The cells were heated in a Kanthal resistance furnace to a maximum temperature of 1000°C. The temperature was controlled to ±1°C with Barber Coleman Model 477 Capacitrol controllers and Barber Coleman Model 621 power controllers.

The cell emf's were measured with a Keithley Model 630 potentiometric electrometer. The negative lead to the electrometer was maintained at ground potential. All electrical grounds originated at this negative potential lead which was grounded through the electrometer. An electrically grounded Nichrome screen was used to shield the cell from electrical pickup from the furnace windings.

Several experimental observations led to the final cell design. Earlier designs used a gas inlet tube which was separate from the thermocouple insulator in the inner electrode chamber. The cell emf was observed to be a function of the anode-gas flow rate. This effect was more pronounced with the anode gas in the inner chamber. Negligible variations in the emf were observed when the cathode-gas flow rate was varied. This was independent of the chamber used as the cathode.

The emf variations with anode-gas flow rate could not be interpreted as a thermoelectric effect arising from cooling of the electrolyte surface because the change in magnitude of the emf was not consistent with the observed polarity of the thermoelectric power coefficient. Polarization due to insufficient removal rates of oxygen evolved at the anode was suspected as the source of the variations in the emf. To aid in oxygen removal the thermocouple insulator in the inner chamber was used to direct the incoming gas to the point of electrical contact. This procedure appeared to eliminate variations in the emf with gas flow which could not be explained on the basis of surface cooling at the anode. All subsequent measurements were performed with the anode gas in the inner electrode chamber. In addition, gas mixtures differing in oxygen pressure by 1 atm or less were used for any given determination to avoid polarization due to internal currents.

Results

The ionic transference numbers of sintered specimens of CeO_{2-x} were measured isothermally at 100°C intervals between 590°-1000°C and from 1 to 10^{-22} atm of oxygen. The results of the transference measurements are shown in Fig. 3: The set of two points at a given value of t_i corresponds to the two different oxygen pressures of the gas mixtures used to obtain that value of t_i. A smooth curve was drawn through the center of each set of points.

There are two oxygen pressure regions separated by a gap which widens with decreasing temperature. The data at higher oxygen pressures were obtained with O_2-Ar mixtures while those at lower oxygen pressures were obtained with CO-CO_2 mixtures. Oxygen pressures in the gap are unobtainable with these gas mixtures at a total pressure of 1 atm. Dashed lines have been drawn in Fig. 3 in an attempt to show how the transition in t_i from high to low oxygen pressures might look.

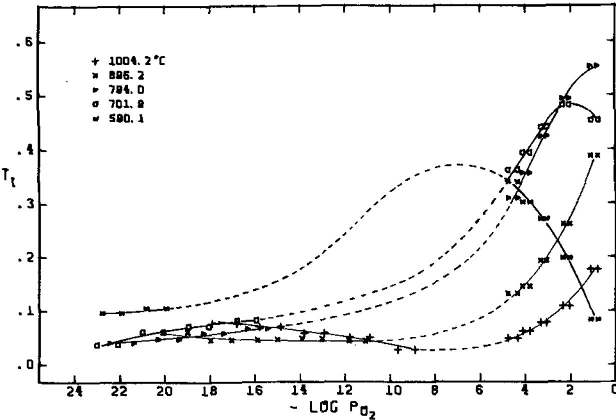

Fig. 3. Isothermal t_i *vs.* log P_{O_2} for pure CeO_2

For purposes of discussion the P_{O_2} dependence of t_i may be described in terms of two oxygen pressure regions.

Region 1: At high oxygen partial pressure (*i.e.*, 1-10^{-4} atm obtained with O_2-Ar mixtures) the electrical conductivity has been reported to be influenced by the impurities present in "pure" CeO_2 (14, 15). In this region the deviation from stoichiometry is $x < 10^{-4}$ which is of the same order of magnitude as the major impurity (*e.g.*, Ca) (8, 15). Thus it appears that in this region t_i is probably controlled by defects created by Ca ion impurities. The presence of foreign Ca ion has been shown to produce oxygen vacancies in CeO_{2-x} (17). In similar oxide fluorite structures (*e.g.*, ThO_2) it is believed that near stoichiometry, oxygen vacancies produced by y^{+3} ions result in the formation of holes according to the following defect reaction (18)

$$V_o^{\cdot\cdot} + \frac{1}{2} O_2(g) = O_o^x + 2h^{\cdot} \qquad [12]$$

It is interesting to note that in Fig. 3 the shapes of the isotherms at 590°, 702°, and 794°C suggest possible maxima in t_i which shift to lower oxygen pressures with decreasing temperature. The observed maxima might correspond to a p to n transition where the electronic conductivity is a minimum. The ionic transference number would decrease from its maximum with increasing oxygen pressure because of the increasing importance of hole conductivity with increasing oxygen pressure (*e.g.*, applying Le Chatelier's principle to Eq. [12]).

To determine the effect of temperature on t_i at higher oxygen pressures a plot of t_i *vs.* $1/T$ at several isobars was made as shown in Fig. 4. This figure shows a maximum in t_i which shifts to higher temperatures with increasing oxygen pressure. Below ~610°C, t_i is increasing with decreasing oxygen pressure while the reverse behavior is observed above ~717°C. This behavior is in accord with electronic conductivity which is predominantly p-type at lower temperatures and higher oxygen pressures, and n-type at higher temperatures and lower oxygen pressures where the deviation from stoichiometry is larger (8).

Region 2: In the low oxygen pressure region the ionic transference number is small (*e.g.*, above 700°C, $t_i < 0.08$), thus electrical conduction in this region is predominately electronic. Recent thermodynamic and electrical conductivity studies have shown the predominant defects in this region of P_{O_2} and temperature are doubly ionized oxygen vacancies and electrons localized on normal cerium sites (8). The electronic conductivity has been shown to be a "hopping" type process where the electrons localized at normal cerium sites move to adjacent cerium sites under the influence of an electric field (19).

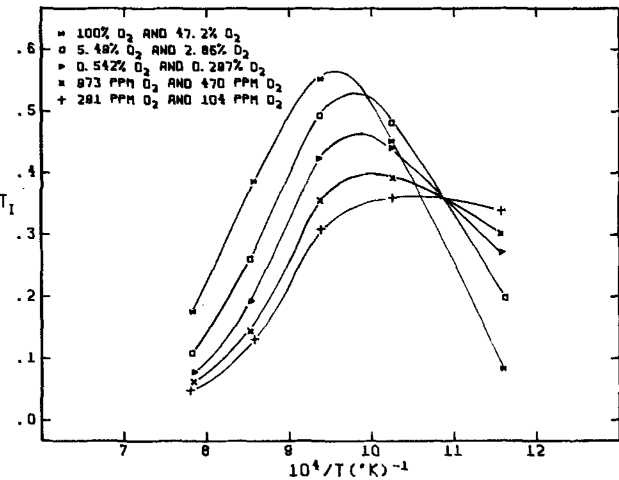

Fig. 4. Isobaric t_i *vs.* $10^4/T$ for pure CeO_2

To determine the effect of the deviation from stoichiometry, x, on t_i thermodynamic data (8) [*i.e.*, $x = f(T,P_{O_2})$] was combined with the t_i data shown in Fig. 3. The combined data are limited to the temperature region 800°-1000°C and composition region $x > 10^{-3}$ where the error in x is less than 4% (8). The results of these calculations are represented by isothermal plots of t_i *vs.* log x as shown in Fig. 5. In the composition region $10^{-3} < x < 10^{-2}$, where the electronic (16) and ionic mobilities should be relatively independent of x, $t_i \approx 0.05$ is relatively constant with the exception of the data points at $x \sim 10^{-3}$ where $t_i \sim 0.066$ at 800°C and at 900°C where $t_i \sim 0.028$. At larger deviations from stoichiometry ($x > 5 \times 10^{-2}$) t_i appears to increase slightly with x at 900° and 1000°C. Because of the possibility of relatively large absolute errors in t_i (*i.e.*, approximately 50% in the low oxygen pressure region) it is difficult to ascribe any particular significance to the apparent variation in t_i with x and temperature at this time. It is interesting to note, however, that Floyd and Steele (20) have reported the activation energies for diffusion of oxygen in CeO_{2-x} is about 4 kcal/mole when $x \sim 0.2$ whereas in the near stoichiometric state, $Q \simeq 23$ kcal/mole.

Using the value of $t_i \sim 0.05$ an estimate of the diffusion coefficient for doubly ionized oxygen vacancies, $D_{V_o^{\cdot\cdot}} \simeq 3.5 \times 10^{-5}$ cm²/sec at 1000°C was calculated by combining recently obtained thermodynamic (8) [$x = x(T,P_{O_2})$] and conductivity data (21) [*i.e.*, $\sigma_T = \sigma(T,P_{O_2})$] with Eq. [10]. This value of $D_{V_o^{\cdot\cdot}}$ appears to be independent of x in the region $10^{-3} < x < 10^{-2}$. No attempt was made to determine the temperature dependence of $D_{V_o^{\cdot\cdot}}$ because of the uncertainty in t_i with temperature.

It is interesting to compare the above value of $D_{V_o^{\cdot\cdot}}$ for "pure" CeO_{2-x} with $D_{V_o^{\cdot\cdot}} \simeq 1.1 \times 10^{-5}$ cm²/sec calculated at 1000°C from the expression for $D_{V_o^{\cdot\cdot}}$ obtained from a recent electrical conductivity study on CaO-doped CeO_2 (17). Within experimental error the two calculated values of $D_{V_o^{\cdot\cdot}}$ are in relatively good agreement. Since the above expression for $D_{V_o^{\cdot\cdot}}$ was obtained for CaO contents between 1 and 8 mole per cent (m/o), it appears that the presence of CaO at least up to 8 m/o does not have any significant effect on the magnitude of $D_{V_o^{\cdot\cdot}}$.

Microstructural Observations on Gallium Nitride Light-Emitting Diodes

H. P. Maruska,*[1] L. J. Anderson, and D. A. Stevenson*

Department of Materials Science, Stanford University, Stanford, California 94305

ABSTRACT

Microstructural observations, utilizing optical microscopy, scanning electron microscopy, and transmission electron microscopy, were made on gallium nitride (GaN) metal/insulator/n-type semiconductor (m-i-n) light-emitting diodes. The GaN films from which the diodes were fabricated were grown by heteroepitaxial chemical vapor deposition on sapphire substrates, and consisted of an undoped n-layer and a Mg-doped i-layer; a metal contact was subsequently placed on the surface of the i-layer forming an m-i and an n-i junction. Significant observations include the following: optical microscopy and scanning electron microscopy show a faceted surface of the layers and the existence of cell boundaries; the cell boundaries result from the coalescence of the individual crystallites formed on the substrate in the early stages of growth; x-ray Laue patterns consist of spots that are slightly diffuse, indicating that the cells are only slightly misoriented with respect to their adjoining cells; light emission occurs as a pattern of small discrete spots and this pattern of spots correlates with the faceted structure of the film; the light emanates from the cathode regions (the i-n junction with forward bias and the m-i junction with reverse bias); steep electrical potential gradients ($\sim 10^5$ V/cm), measured using line scan techniques in the scanning electron microscope, occur at the m-i and the n-i junctions. The observations are consistent with an impact ionization model for light emission.

There is considerable interest in the phenomenon of electroluminescence in the III-V compound gallium nitride (GaN) as evidenced by several recent publications (1-6). Light-emitting diodes (LED's) have been fabricated which emit red and yellow (2), green (3), blue (4), and violet light (5, 6). In all of these cases, the basic device is an m-i-n structure, consisting of a layer of n-type GaN, a layer of insulating (i) GaN, and a metal contact to the i-GaN layer. Although numerous emission spectra, current-voltage characteristics, and efficiency characteristics have been published for these diodes, the actual mechanisms responsible for the operation of GaN m-i-n diodes remain nuclear. In this paper we present observations made on GaN m-i-n diodes in the optical, scanning electron, and transmission electron microscopes concerning important structural features of these devices. These observations provide valuable insight concerning the processes that contribute to the operation of the device.

Experimental Techniques

Films of GaN were grown by heteroepitaxial chemical vapor deposition with the n-i junction structures produced by sequential chemical vapor deposition of first GaN, and then GaN:Mg, on sapphire substrates. Details of the growth process are described elsewhere (5). The devices were made by placing a metal contact over the surface i-layer either by evaporation, painting liquid In-Ga, or by an amalgam technique (6); thus an m-i-n diode structure is formed.

An Advanced Metals Research Model 900 scanning electron microscope (SEM) was used to study the surface characteristics of samples. The SEM is particu-

Key words: junction structure, light emission pattern, voltage profile, voltage contrast.

larly suited for observations and measurements of junction and space-charge regions in the 1μ size range. Since an electric field either enhances or retards the emission of secondary electrons, there is a relation between the brightness of the local image and the internal electric field (7). This phenomenon is known as voltage contrast. The voltage contrast may result from an internal electric field in the material due to a concentration gradient of an electrically active species, such as with an n-p junction or an i-n junction, or to an electric field imposed on a device due to an applied bias. A representation of the potential distribution in a sample may be obtained with a line scan. The primary beam is set to sweep one line across the sample and the secondary electron current signal *vs.* distance is displayed on a screen. By taking two of these line scans at the same position across a sample, one with and one without bias, a representation of the potential distribution across the diode can be obtained.

Precipitates and dislocations have been observed in several III-V compounds and have been suggested as potential carrier recombination centers (8). Since the precipitates could be smaller than 500Å in diameter, transmission electron microscopy (TEM) provides the only method for definitive examination. Dislocations are also readily observable in single crystalline materials by TEM because the lattice discontinuity they create leads to localized changes in diffraction conditions and consequent contrast in the transmitted image.

A 10 μm thick, Mg-doped, GaN layer on a 70 μm thick, n-type layer, that had separated from the sapphire substrate during postgrowth cooling, was ultrasonically cut into 3 mm diameter disks for TEM examination. Low angle ion-milling was used to smooth the faceted surface of the i-layer, and then the n-layer and some of the i-layer were removed in a region near the center of the disk during a 65-hr bombardment on the n-layer side with 10 kV Ar ions in a Commonwealth Scientific Ion Milling Machine. The sample provided an area larger than 500 μm^2 that was thin enough (<3000Å) for detailed TEM examination.

Optical microscopic studies of the light emission from the diodes were carried out with a Leitz Panphot microscope which allowed focusing at magnifications up to 500X.

Experimental Results

Electroluminescence.—As reported earlier (6), electroluminescence was obtained from Mg-doped GaN m-i-n diodes both with forward (m biased positive with respect to n) and reverse bias. Light emission under forward bias was obtained in the region of 2.86-2.98 eV, with 400 meV half width, and the external quantum efficiency was about 0.005%. Diodes operated in reverse bias exhibited a major emission peak at 4820Å (2.57 eV), which is light-blue in color, and another less intense peak at 6000Å (2.07 eV) in the yellow-orange; the diodes appear green in reverse bias due to the eye's sensitivity. Photoluminescence in Mg-doped GaN showed an emission spectrum similar to the forward bias electroluminescence spectrum, with a peak at 2.92 eV (independent of temperature) (6). The luminous intensity varies linearly with diode current and superlinearly with applied voltage.

Growth and surface morphology of GaN.—The growth and surface morphology of the GaN epitaxial films were studied in order to obtain a better understanding of the processes which control the operation of the LED devices. Gallium nitride crystallizes with the hexagonal wurtzite structure. It was found that a large number of GaN nuclei are formed on the sapphire substrate during the chemical vapor deposition (open-flow vapor phase growth) process. This is reasonable since the deposition temperature used was several hundred degrees below the equilibrium temperature for the chemical reaction. These nuclei grow to form separate hexagonal islands of GaN. An example of these islands is shown in Fig. 1, taken at

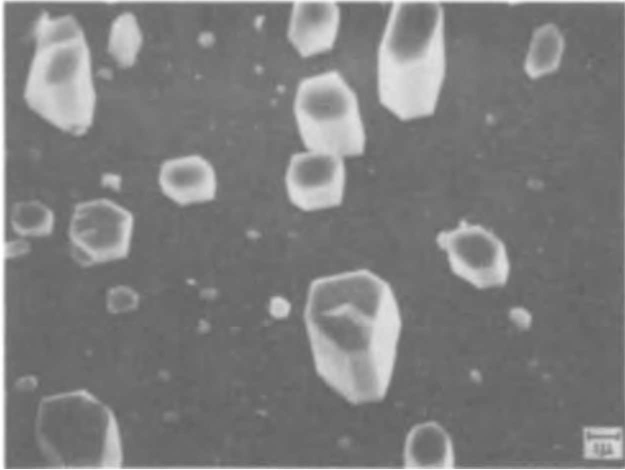

Fig. 1. Hexagonal islands of GaN nucleated on (0001)-sapphire

5000X magnification in the scanning electron microscope. The deposition occurred on an (0001)-oriented sapphire substrate, and the GaN islands have this same orientation. Notice that the individual islands have the form of hexagonal columns, with the respective sides of each column parallel to those of all the other columns. Given sufficient time, all of these islands grow together. This is clearly shown in Fig. 2, where separate islands are still visible on the right side of the micrograph (2000X magnification) while a continuous film has formed on the left side. However, the original island pattern is still visible in the continuous films, which exhibits a faceted surface. This suggests that the various islands may not be exactly aligned. Figure 3 shows the type of GaN surface which occurs for films grown on $(1\bar{1}02)$-oriented sapphire substrates. The GaN films have a $(11\bar{2}0)$ orientation when grown on $(1\bar{1}02)$ sapphire substrates and the GaN c axis is then parallel to the substrate surface. The size of the facets is directly related to the position of the substrate in the growth tube; the facet size decreases with distance downstream from the ammonia inlet tube, as shown in Fig. 4 for growth on a 5-in. long quartz plate. The thickness of the deposit shows a marked decrease with distance downstream probably due to a small temperature gradient.

A Laue pattern for the faceted $(11\bar{2}0)$ GaN films, consists only of spots, indicative of a single crystal. There are no rings which would indicate a polycrystalline sample. Therefore, even though many nuclei are involved in the formation of a GaN film, the resulting

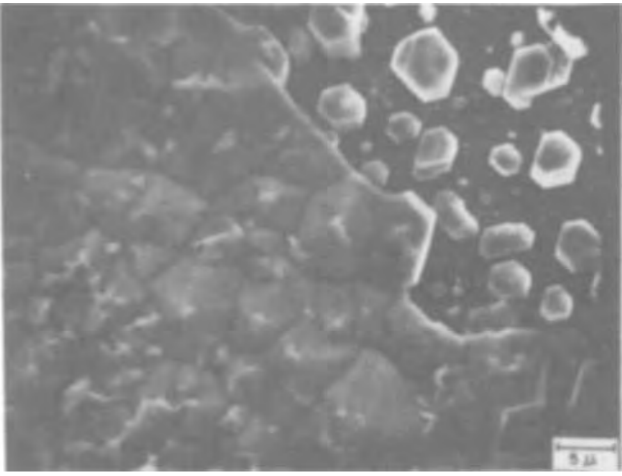

Fig. 2. Hexagonal islands of GaN, which have grown together to form a continuous film on the left side of the picture.

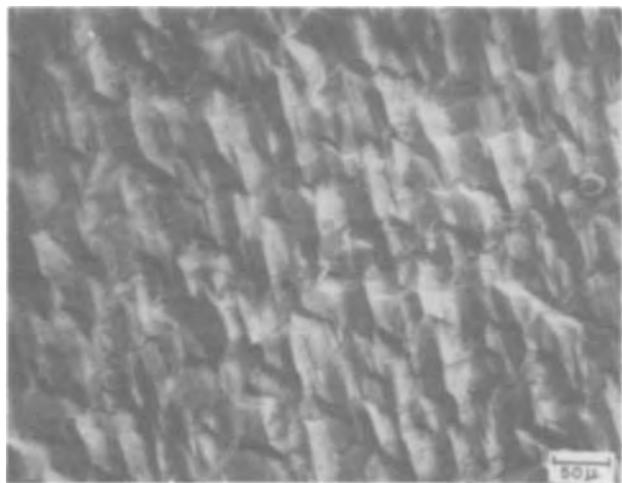

Fig. 3. Typical faceted surface developed in GaN grown on $(\bar{1}102)$-sapphire.

film gives x-ray evidence of single crystallinity. However, the Laue pattern spots are not pinpoints but instead show a little smearing, characteristic of slight crystalline misalignment. Thus there are probably subgrain boundaries between the coalescing islands.

Pattern of light emission.—It is thus clear that GaN films on sapphire substrates consist of microscopic islands which have coalesced to form a continuous, single-crystalline epitaxial layer with a faceted surface. The microscopic study was extended to actual operating LED's in order to discover how the light emission is correlated with the structure of the crystals.

Chips which separate from the sapphire substrate upon cooling are especially suited for emission pattern observations, since it is possible to directly focus the optical microscope onto the light pattern at magnifications as high as 200X without any dispersion of light due to an intervening sapphire layer. The light emission does not occur uniformly throughout the material but rather takes the form of small discrete spots. The pattern of light spots occurring with forward bias

at 200X magnification is shown in Fig. 5a. The spots appear larger on the film than they actually are due to the exposure time of 6 min. Visual observations of the spots in the microscope indicate that they are less than 10μ in diameter.

The same region of the LED of Fig. 5a is shown externally illuminated in Fig. 5b, with the light spot pattern of Fig. 5a superimposed. It can be seen that the light spots can be correlated with the crystal facets; no more than one spot occurs in any facet, and most facets are without spots. For comparison, the facets can be seen more clearly in the scanning electron micrograph shown in Fig. 3. A spotty light emission pattern is also observed with reverse bias, although most of the spot positions are different from the ones seen when a diode is forward biased.

It has been observed that the light spots turn on in a definite, reproducible order as the applied voltage is increased above a threshold voltage of about 8V. Once all the spots are lighted, they just become brighter as the voltage is further increased. As the voltage is decreased, the spots go out in reverse order. The brighter devices have large numbers of closely spaced light spots, all of which turn on over a short range of voltage increase (about 2-3V). Some diodes only had one or two light spots which increased in brightness with increasing voltage but which burned through before other spots turned on. Any GaN LED will burn through and become a short circuit if the applied voltage is continuously increased sufficiently. In all cases the position of the brightest light spot overheats and burns through leaving a tiny black dot. The device can be salvaged by simply altering the metal contact so that it does not touch this black dot.

It is of interest to determine where the light is actually created inside the device; possible regions are at the m-i junction, the i-n junction, throughout the bulk of the i-layer, or within the n-layer. A sample was mounted perpendicular to a glass slide, so that the various regions (m, i, and n) were visible. Figure 6 is a scanning electron micrograph of the sample and shows, on the right, the sapphire substrate, in the center the GaN n- and i-layers (which are indistinguishable in this picture), and on the left the metal contact to the i-layer. This sample is shown with forward bias applied (and without external illumination) at a magnification of 500X in the optical micrograph of Fig. 7; light spots which were particularly close to the top edge of the chip are clearly seen. They occur about one-eighth of the way from the metal contact on the i-layer to the sapphire substrate. In the next section it is shown that this is the exact position of the i-n junction.

Reverse bias light proved more difficult to study. The size of the reverse bias light spots, when viewed through the n-layer, was the same as the forward bias spots; however, none could be clearly seen and photographed from the edge of the sample. The metal-GaN:Mg interface appeared to glow and there were no signs of light spots anywhere within the i- or the n- regions, thus the reverse-bias light appears to come from the m-i junction.

Characteristics of the insulating (Mg-doped) region.—It was appropriate to make a more detailed study of the insulating Mg-doped GaN layer in the diodes. The Mg concentration in the doped material

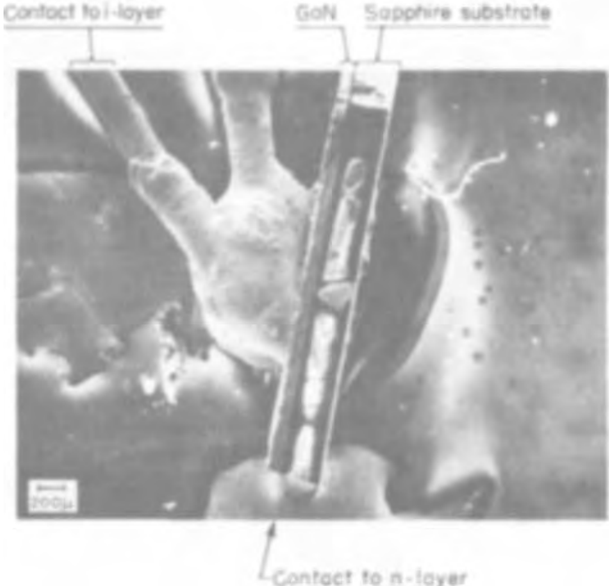

Fig. 6. Perpendicular view of diodes as seen in the scanning electron microscope. The entire device (including the sapphire substrate) and the two metal contacts (to the n- and i-layers) are visible. Magnification 25×.

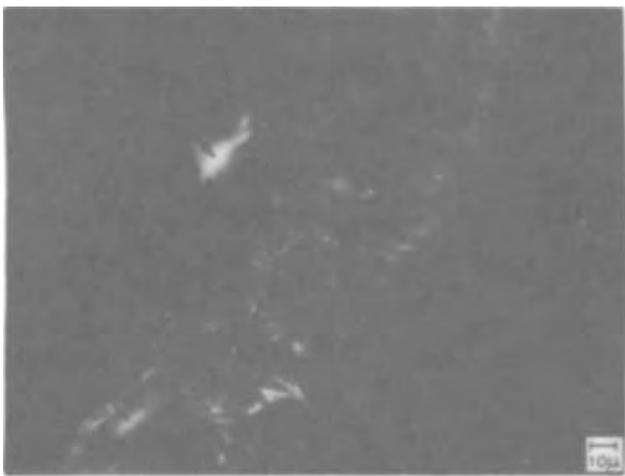

Fig. 7. Light spots observed when diode shown in Fig. 6 was forward biased. The light spots occur within the GaN region. Magnification 500×.

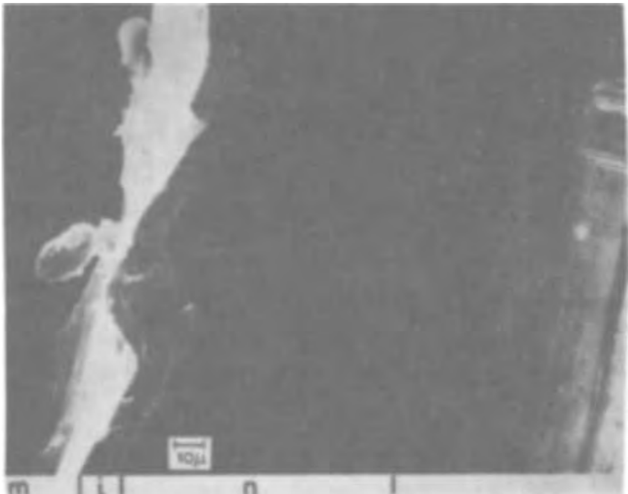

Fig. 8. Scanning electron micrograph of diode at 500× magnification with reverse bias. The insulating (Mg-doped) GaN layer can be clearly distinguished.

was determined by electron microprobe analysis, and dopant concentrations of 2-6 $\times$ 10^{20} atoms/cm^3 were found; however, it is not known what percentage of the dopant is electrically active. The addition of a large quantity of dopant affects the lattice parameters of GaN. Table I presents the lattice parameter measurements of a number of investigations (including the present one) for undoped GaN and for Mg-doped GaN (from the present study). The a and c values for the doped material were found to increase by 0.14 and 0.21%, respectively, over the average values for undoped material. This is not surprising, since the tetrahedral radius of Mg is larger than that of Ga.

Further studies of the insulating region in the diodes were made with the SEM. Diodes were suitably mounted onto glass slides to expose the two junctions (see Fig. 6). Figure 8 shows a device at 500X magnification and with reverse bias. The faceted nature of the GaN surface is apparent, and the extent of the insulating region may be distinguished due to voltage contrast. The i-layer is light gray, the n-layer is dark gray, and the very white region is the front surface of the i-layer which is visible because the metal contact does not come all the way up to the edge and the sample is slightly tilted. Over most of its extent, the i-layer is 10μ wide, although the width varies up to 25μ in sections due to different growth rates of the facet planes. The m-i junction and the i-n junction are parallel, and both have a jagged appearance (conforming to the facets), with the i-n junction one-eighth of the way from the front face to the sapphire substrate. Thus the light spots seen in Fig. 7 were generated at the i-n junction.

Table I. Lattice parameters of undoped and Mg-doped GaN

	a, A	c, A	Data source
GaN	3.189	5.185	Maruska and Tietjen, 1969 (9)
GaN	3.190	5.17	Faulkner, *et al.*, 1970 (10)
GaN	3.189	5.185	Ilegems and Montgomery, 1973 (11)
GaN	3.190	5.184	Present study
GaN:Mg	3.194	5.192	Present study

The n-GaN was grown for one-half hour and the i-GaN for one-quarter hour in the diode shown in Fig. 7 and 8; however, the n-layer is eight times as thick as the i-layer. Therefore the presence of Mg in the vapor during the growth of GaN appears to reduce the growth rate to about one-fourth that of undoped material.

Detailed examination of Mg-doped GaN in the transmission electron microscope revealed no evidence of precipitates or dislocations. Grain boundaries were not observed because of the small size of the thinned area as compared to the known grain size. Selected area diffraction yielded a distinct, single-crystalline GaN pattern. It can be concluded that the i-layer is precipitate-free and that the dislocation density is less than 10^5 cm^{-2} in the interior regions of the crystallites. (It is undoubtedly high in the vicinity of the crystallite boundaries.)

Electrical potential distribution.—A representative line scan trace across a diode is displayed in Fig. 9, taken at 1000X magnification at the same position across the sample, with and without forward bias. These traces are superimposed on a standard secondary electron image of the same region. Since for a topographically and compositionally uniform sample, as is the cross section of the sample shown in Fig. 9, the number of secondary electrons emitted from any point on the sample depends on the voltage at that point (7), and since the height of the line scan trace is directly proportional to the number of secondary electrons collected, it is possible to display the voltage profile across the diode for an applied bias (Fig. 10). In a similar manner, voltage profiles were obtained for reverse bias (Fig. 11). In either case, gradients in potential occur only at both the m-i and the i-n junctions, and electric field strengths of about 10^5 V/cm are encountered. Because of a geometrical step in the vicinity of the metal contact, there are spurious peaks in the line scan in this region, which are disregarded in Fig. 10 and 11. The diode electrical and electroluminescent properties are not appreciably influenced by changes

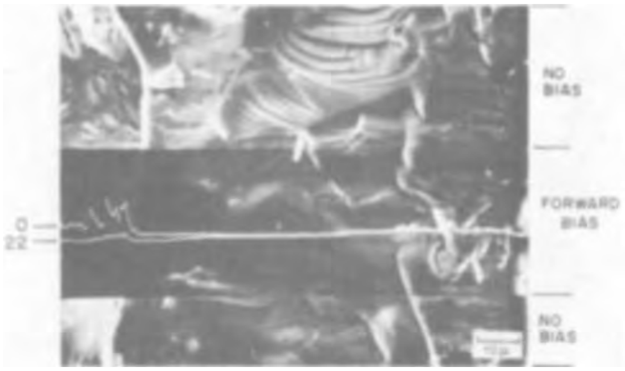

Fig. 9. Superimposed zero bias and forward bias line scan traces and SEM photograph of a gallium nitride light-emitting diode. Magnification 1000×.

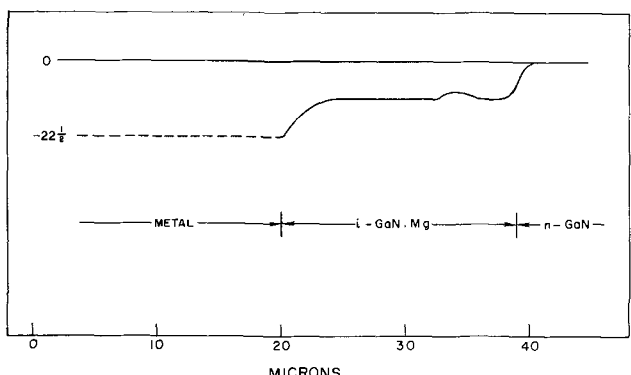

Fig. 11. Electric potential distribution across a gallium nitride light-emitting diode when reverse bias is applied.

in the thickness of the i-layer; diodes grown at the same position in the furnace but with i-layers differing in thickness by an order of magnitude showed virtually no difference in current passed or light emitted at a fixed voltage.

Summary

The important structural features of GaN m-i-n light-emitting diodes are summarized below.

1. Light-emitting diodes made from GaN:Mg m-i-n structures exhibit violet electroluminescence. Forward bias results in a broad spectrum (400 meV half-width) which peaks at 2.9 eV, with a similar spectrum for photoluminescence.
2. The light emission occurs as a pattern of small, discrete spots, which can be correlated with the GaN crystal facets.
3. The light is emitted at the cathode (i-n junction) with forward bias, and apparently also at the cathode (m-i junction) with reverse bias.
4. Laue patterns indicate that the GaN is single crystalline, but the surface shows a strongly faceted structure. For this reason, the m-i and the i-n junctions are not planar, but follow the faceted nature of the growth.
5. When a bias is applied, steep potential gradients and electric fields of about 10^5 V/cm appear at both the m-i and the i-n junctions in the diodes, but not over the bulk of the insulating (i) region.
6. The diode characteristics are not substantially influenced by variations in the i-layer thickness.

The observations of light emission generated at the cathode in the form of small, discrete spots, a high electric field in the depletion region at the negative electrode, a threshold voltage for light emission greater than the bandgap, and brightness proportional to the current are suggestive of an impact ionization mechanism for electroluminescence.

ABSTRACT

Liquid phase epitaxy by conventional tipping technique has been employed for the growth of high purity InP epitaxial layers. The layers were grown at 720°-560°C on (100) and (111) oriented InP substrates. Characteristic surface structures for the substrate orientations as a function of the growth temperature were observed. The layers were characterized by Hall data and photoluminescence measurements at low temperatures. The simultaneous observation of the band-acceptor and donor-acceptor pair transition due to the main acceptor in our LPE-layers is reported. The binding energy of this acceptor is determined to $E_{A1} = 41.0$ meV (± 1 meV).

During the last years there has been an increasing interest in high purity epitaxial layers of InP, for instance for Gunn effect applications (1). So far, high purity epitaxial layers were grown by vapor phase epitaxy in particular by the Effer method (2, 3). Net electron concentrations of $n = 4 \cdot 10^{14}$ cm^{-3} and mobilities of $\mu_{77K} = 87{,}000$ cm^2 V^{-1} sec^{-1} were obtained. In the case of GaAs liquid phase epitaxy (LPE) has been very successful in the preparation of high purity epitaxial layers (4-8). One should therefore expect similar good results for the case of InP. In this paper the growth of high purity InP layers is described in connection with Hall data and photoluminescence measurements at low temperatures. Previous works on InP LPE were done by several authors (9-11). The best values for the LPE-layers with $N_D - N_A = 2 \cdot 10^{15}$ cm^{-3} and $\mu_{77K} = 49{,}000$ cm^2 V^{-1} sec^{-1} were reached by Wood *et al.* (11). Recently Astles *et al.* (12) have reported on the growth of InP by LPE from solutions saturated with P from PH_3. Values of $N_D - N_A = 3 \cdot 10^{15}$ cm^{-3} and $\mu_{77} = 27{,}000$ cm^2 V^{-1} sec^{-1} have been reported.

LPE—Apparatus and Experimental Procedure

The experience from LPE growth of high purity GaAs has been that the growth results are strongly influenced by the way in which the growth process is performed (13, 14). Important steps are: (*i*) heating of In-InP solution, (*ii*) preparation of the single-crystal substrate, (*iii*) equilibration and homogenization of the solution, and (*iv*) tipping the solution on the substrate. In the following we describe the corresponding conditions for InP-LPE. For the growth experiments we used a tipping system (14) (schematically shown in Fig. 1). The reaction tube was made of suprasil quartz, the boat for the In-InP solution of high purity graphite. The tube and boat were locked together and could be rotated around the long axis for immersion and withdrawal of the substrate from the solution. To avoid air leaks we used a Pyrex spiral which allowed the rotation of the tube without moving joints. The furnace was transparent (15) in order to observe substrate and solution. The graphite boat was heated at $T = 1600$°C under a vacuum of 10^{-6} Torr for 3 hr. After that, the boat was loaded with 6*N* In (Johnson Matthey Limited, England) and baked at $T = 730$°C in the reaction tube for 10 hr under a Pd-diffused H_2 gas flow. At the end of this procedure the boat was cooled down to room temperature and the In was removed. We believe that residual impurities on the crucible walls were dissolved in the In. The boat was then loaded again with 10g 6*N* In and 370 mg 6*N* InP (MCP, England). Prior to the experiment this In-InP-solution was baked at $T = 730$°C for 15 hr and with a H_2 flow rate of 15 liters/hr. During this time the phosphorous content of the solution decreases due to phosphorous evaporation.

The amount of P loss during this baking process is very difficult to calculate because it depends on several factors. The concentration of P in the solution is determined by the evaporation of P at the surface and the diffusion in the solution. The diffusion equation involves the diffusion coefficient of P in liquid In, which is not yet known. For this reason the amount of P loss during this baking process and the temperature T_S at which the solution is saturated cannot be calculated. The tipping temperature T_K at which the solution was tipped on the substrate was therefore estimated experimentally by observing the temperature at which solid InP appears on the surface of the solution. By this method of determining the starting temperature, the solution was slightly supercooled at T_K. The temperature was measured near the graphite boat and was controlled within $\Delta T = \pm 0.5$°C. There was no temperature gradient across the tipping zone, the temperature gradient normal to the substrate was negligible.

Under the conditions described above, we have grown single-crystal layers on (111)A, (111)B, and (100) Cr-doped, semi-insulating InP substrates (RRE, England; $\rho = 1 \cdot 10^3$ ohm-cm). The substrates which were available were cut 2° off orientation and were etched in a solution of 1% bromine in methanol for 10 min. Prior to use, the substrates were rinsed with 18 megohms water. The In-InP-solution was heated up very quickly (within 20 min) to 40°C above T_K in order to reduce the evaporation of phosphorous. The boat was agitated in order to equilibrate and homogenize the solution. The solution was tipped over the substrate at T_K. In the different experimental runs, T_K was varied between 720° and 560°C. The growth time was 2 or 3 hr. The cooling rate was 4°-52°C/hr, however in most cases 6°C/hr. After termination of the experiment, the solution was removed from the substrate by rotation of the crucible.

Growth Results

Figure 2 shows the growth rate as a function of the tipping temperature T_K for two different cooling rates. For a cooling rate of 6°/hr a large scatter of data was observed. This is due to differences in the starting

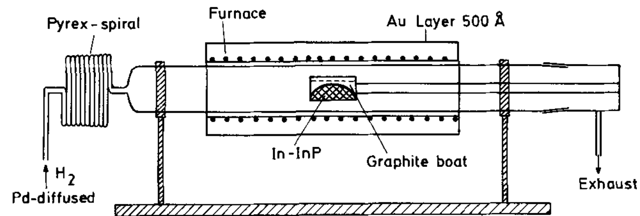

Fig. 1. Schematic drawing of the LPE-apparatus

Key words: InP, liquid phase expitaxy, photoluminescence.

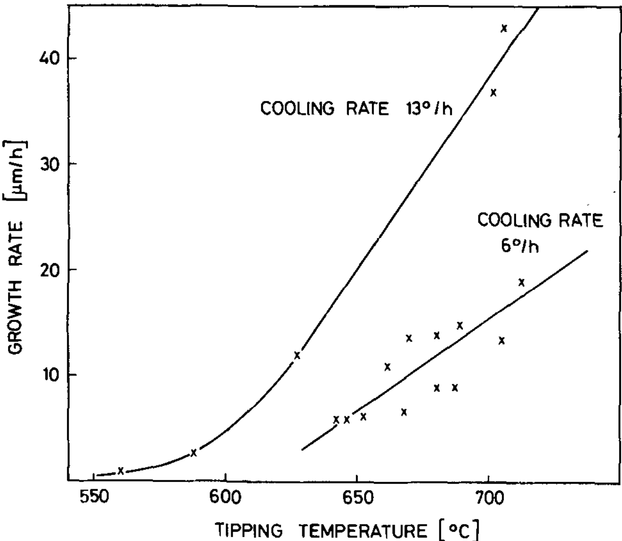

Fig. 2. Growth rate as a function of the tipping temperature for two different cooling rates.

growth conditions. For both cooling rates the growth rate decreases with decreasing tipping temperature.

We have grown epitaxial layers with thicknesses between 5 and 120 μm. Thicknesses were determined either by etching a cleavage plane or by means of a micrometer. The layers grown on (100) and (111) substrates show two types of surface structure: a shed structure of the layers which were grown at tipping temperature $T > \sim 650°C$ (Fig. 3a) and a terrace-structure of the layers with $T_K < \sim 650°C$ (Fig. 3b) was observed in general. No significant differences for the layer structures between (100), (111)A, and (111)B faces were noticed. These structures are due to misorientation of the substrates (16, 17).

The net electron concentrations and the mobilities of our layers were measured by the method of van der Pauw. The best values we have reached were $N_D - N_A = 5 \cdot 10^{14}$ cm^{-3} and $\mu = 4800$ cm^2 V^{-1} sec^{-1} ($T = 300°K$), $N_D - N_A = 3.4 \cdot 10^{14}$ cm^{-3} and $\mu = 26{,}000$ cm^2 V^{-1} sec^{-1} ($T = 77°K$). Some samples contain deep impurity levels, as seen in luminescence (Fig. 4), which reduce low temperature mobility.

The effect of the baking time of the In-InP-solution is shown in Table I. Layer No. 25 for instance was grown from an In-InP-solution without any baking time, *i.e.*, immediately after its preparation. Layer No. 26 was grown from the same solution after heating it at 730°C in H_2 gas flow for 25 hr. One can notice a considerable decrease of the electron concentration and an increase of the mobility for the "baked" sample. Similar effects which are due to evaporation of impurities have been reported for GaAs (13).

Table I. Influence of baking of the In-InP solution onto epilayer impurity concentrations and mobilities

Sample	300K Electron conc (cm^{-3})	300K Mobility (cm^2 V^{-1} sec^{-1})	77K Electron conc (cm^{-3})	77K Mobility (cm^2 V^{-1} sec^{-1})
25	$2.7 \cdot 10^{16}$	3200	$2.0 \cdot 10^{15}$	8,800
Baking of In-InP solution at 730°C in H_2 gas flow for 25 hr				
26	$1.0 \cdot 10^{15}$	3500	$9.0 \cdot 10^{14}$	22,500

Table II. Growth conditions of various samples used for photoluminescence measurements

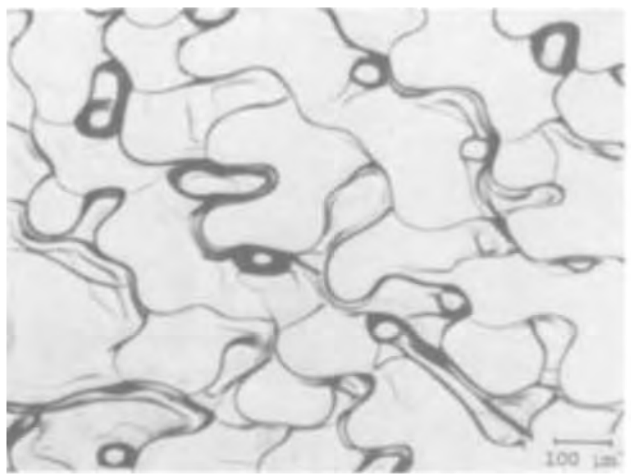
Sample	Substrate orientation	Growth temperature (°C)	Cooling rate (deg. hr^{-1})	Growth time (hr)	Layer thickness (μm)
31	(100)	688-670	6	3	27
32	(100)	655-635	6	3	19
33	(100)	627-588	13	3	35
34	(100)	587-548	13	3	11
35	(100)	560-521	13	3	4

Photoluminescence Measurements

The quality of the LPE layers was characterized by low temperature (1.8°K and 77°K) photoluminescence. The crystals were excited by a Kr^+ laser ($\lambda = 647$ nm) which was focused to a spot of ~ 100 μm diameter. The maximal light density was $I_o = 400$ mW/cm^2. The intensity of the light could be varied by neutral density filters. A 1m Type 1704 Spex monochromator was used in connection with a RCA 7102 S 1 photomultiplier and conventional lock-in technique.

The growth conditions of the various samples discussed in this section are listed in Table II.

The main features of the observed photoluminescence spectra of high purity InP layers ($N_D - N_A = 5 \cdot 10^{14}$ cm^{-3}) are shown in Fig. 4. Emission spectra of two epitaxial layers (No. 31 and 34) grown at different temperatures are compared in this figure. The near gap luminescence (energy range 1.42 eV to 1.41 eV) can be attributed predominantly to the radiative decay of free and bound excitons. In the energy range 1.39-1.36 eV InP usually exhibits one or several pair bands and/or band-to-acceptor transitions (18-25) Some spectra show very sharp lines at 1.3866 eV (half width 0.1 meV) (sample 34 at 1.3876 eV) and at 1.3773 eV (half width 0.4 meV). Their intensity decreases rapidly



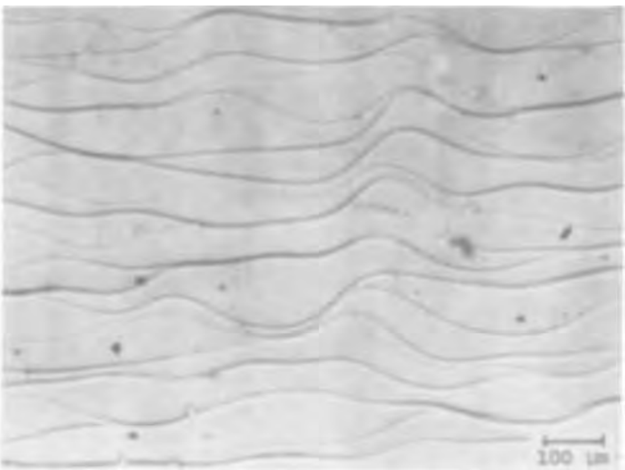


Fig. 3. Characteristic surfaces: (a, left) shed structure for growth temperature $T > \sim 650°C$ and (b, right) terrace structure for growth temperatures $T < \sim 650°C$.

with decreasing excitation intensity. They are assumed to contribute to the decay of excitons bound to deep impurities. The concentration of different impurities is monitored by the relative luminescence intensity of the impurity-induced transitions. For quantitative comparison, all spectra are normalized with respect to the peak intensity of a donor-induced near edge emission, labeled (D^oX) in Fig. 4.

Near Gap Emission

Figure 5 shows the near gap luminescence of the two layers for low excitation density at high resolution and in an expanded energy scale. Up to 11 different emission lines (or shoulders) can be observed. The peak at 1.4184 eV has been identified as the free exciton-polariton emission (22, 26). Two weak lines are observed at 1.4181 eV (not previously reported) and at 1.4179 eV, which have not been explained so far. In all our samples the three sharp lines at 1.4174, 1.4172, and 1.4169 eV are the strongest emission. The half widths of these lines are 0.1 meV or less. Such a half width is characteristic for the decay of bound excitons. These transitions appear in the energy range expected for excitons bound to neutral donors (D^oX) (22, 26).

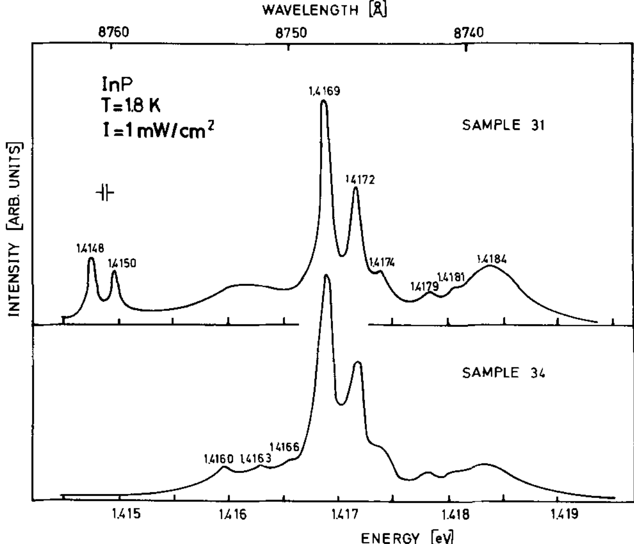

Fig. 5. Near gap luminescence of samples 31 and 34 at low excitation intensities.

The spectra of most layers show a broad emission at 1.416 eV. For layer No. 34 this band can be resolved into three lines at 1.4166, 1.4163, and 1.4160 eV. It is believed that they are associated with the recombination of free holes to neutral donors.[2]

Some layers, *e.g.*, No. 31 (Fig. 5 upper curve), show a doublet centered at 1.4149 eV with spacing ~0.22 meV (the half width is 0.1 meV). This doublet is associated with the recombination of bound excitons at neutral shallow acceptors (22). It always appears together with the emission lines at 1.3832 and 1.3803 eV (Fig. 4). These lines are identified as band-acceptor (BA) and donor acceptor (DA) pair transitions, respectively, which is discussed in detail below. The simultaneous appearance of (A_1^oX), (BA_1), and (DA_1) transitions suggests that one common acceptor element A_1 is involved.

White *et al.* (24) have identified similar doublets and the corresponding (BA) and (DA) lines for the elements Zn and Cd. The energetic positions of the (A^oX)-doublets vary hardly at all, but the comparison of the (BA) and (DA) emission peak energies shows that A_1 is not identical with Zn or Cd (see Table III). Possible candidates for such a shallow acceptor are C, Si, and Mg. The following considerations may narrow the list of these elements. Astles *et al.* (12) have done LPE doping experiments with Si which yielded to n-type material. There was no evidence for Si-acceptors. Zschauer (28) and Dean *et al.* (29) find that LPE GaAs is dominantly contaminated by C-acceptors, and this element is attributed to the shallowest acceptor in GaAs. Therefore we believe that the shallow acceptor A_1 in our LPE-InP layers is C.

Pair Bands and Band-Acceptor Transitions

The band-acceptor transitions and pair bands, we have found in the LPE layers are listed in Table II. The transitions at 1.3775 eV (BA_2) and 1.3735 eV (DA_2) are attributed to Zn (24), those at 1.369 eV (BA_3) and 1.365 eV (DA_3) to Cd (24). The acceptor ionization energy is $E_{A2} = 47.3$ meV for Zn (24) and $E_{A3} = 56.3$ meV for Cd (24). Several authors (18-20) have reported an emission band at 1.38 eV. Possibly this emission is caused by the acceptor A_1, associated with the lines at 1.3832 eV (BA_1) and at 1.3790 eV (DA_1)[3] in our samples.

The following arguments lead to the identification of the 1.3790 eV line as a donor-acceptor transition. Figure 6 depicts the intensity dependence of the emission spectra in the energy range around 1.38 eV at constant temperature (1.8°K). At lowest intensities, one line at 1.3790 eV can be observed. This peak shifts to 1.3803 eV as the intensity is increased. The peak energy of this transition depends on the impurity concentration. Samples with high net donor concentration show this line at higher energies. This is typical for a donor-acceptor pair transition.

The emission line at 1.3832 eV is due to a (BA)-transition for the following reasons. At lowest intensities only the line at 1.3790 eV can be observed, as above mentioned. With increasing excitation intensity a new line emerges at 1.3832 eV. This line becomes the strongest emission at highest excitation levels. The peak energy does not change with excitation intensity

[2] Taking $E_D = 7.65$ meV, reported by Chamberlain *et al.* (27) and $E_G = 1.4234$ eV (26) the (h,D°)-transition is expected at 1.4158 eV.
[3] DA_1 transition at low excitation density.

Table III. (BA) and (DA) transitions of three shallow acceptors

Photonenergy (eV)	Transi-tion	Acceptor element
1.3832	BA_1	? (A_1)
1.3790	DA_1	? (A_1)
1.3775	BA_2	Zn (A_2)
1.3735	DA_2	Zn (A_2)
1.369	BA_3	Cd (A_3)
1.365	DA_3	Cd (A_3)

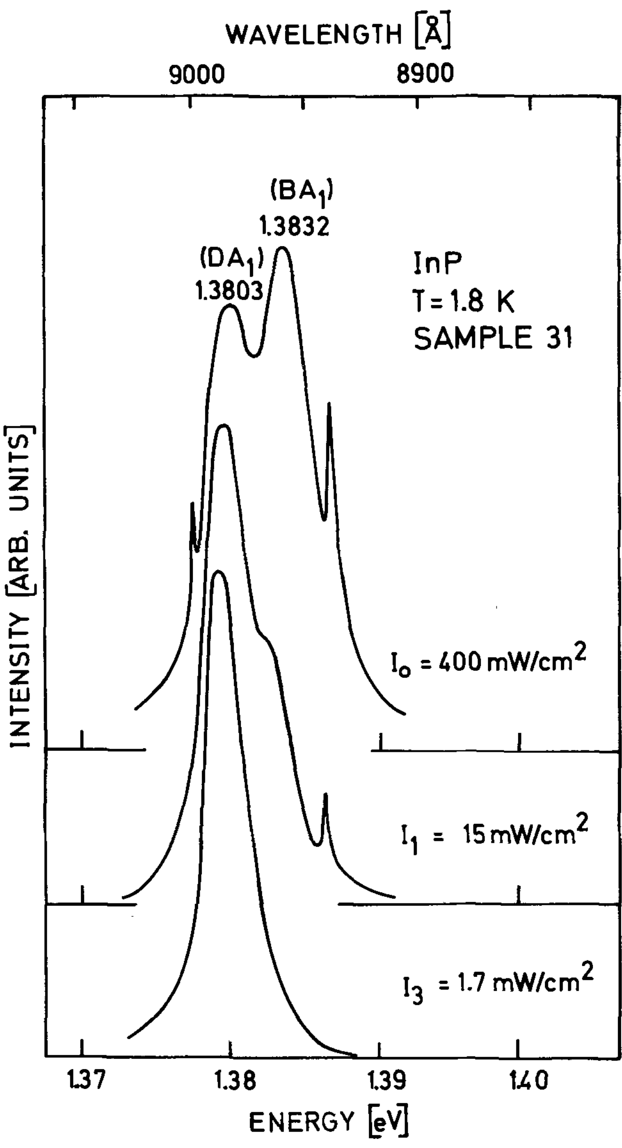

Fig. 6. Intensity dependence of emission spectra in the energy range around 1.38 eV at constant temperature (1.8°K).

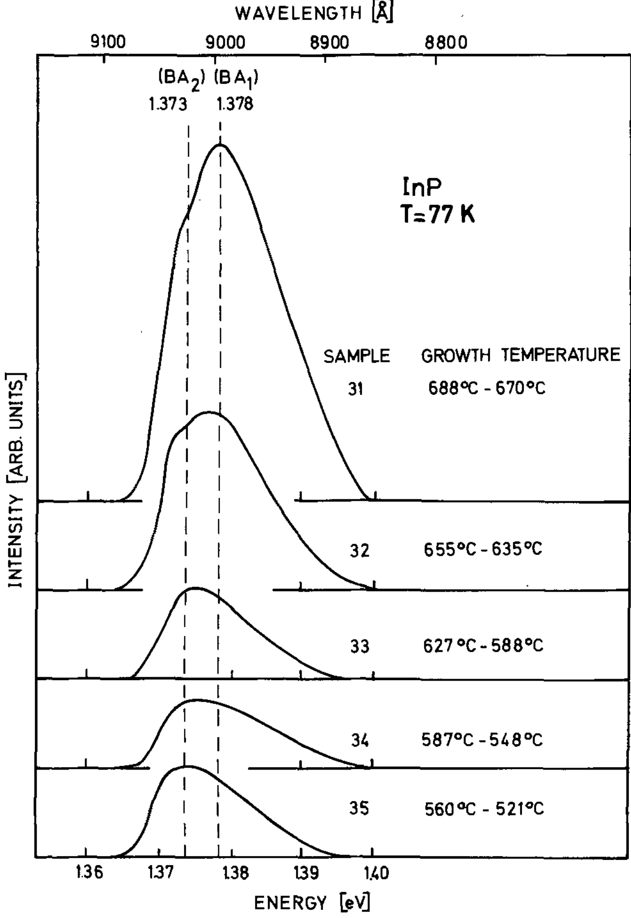

Fig. 7. The 77°K spectra of the layers No. 31-35 and the corresponding growth temperatures. The background of near gap luminescence was eliminated.

as long as the electron temperature remains constant. This is expected for a BA transition. The high energy side of the BA transition has an exponential slope according to the theory of Eagles (30). Using this theory and a bandgap value of $E_G = 1.4234$ eV the binding energy of the acceptor A_1 becomes $E_{A1} = 41.0$ meV ($\pm$ 1 meV).

Finally, the influence of growth temperature on the incorporation of the acceptor A_1 is pointed out. Figure 7 shows the 77°K spectra of the layers No. 31-35 which were grown at different temperatures. It may be noticed that the (BA_1) transition at 1.378 eV is relatively strong in layers No. 31 and No. 32 (high growth temperatures). The band is relatively weak in samples No. 33-35 (low growth temperatures); therefore, in these layers the (BA_2) transition dominates. We attribute this effect in the following way to the growth temperature: the acceptor A_1 will be incorporated much stronger at higher temperatures than at lower ones. The change of the incorporation probability rate is especially strong in the temperature range of 600°C.

Effect of Semiconductor Inhomogeneities on Carrier Mobilities Measured by the van der Pauw Method

R. D. Westbrook

Solid State Division, Oak Ridge National Laboratory, Oak Ridge, Tennessee 37830

ABSTRACT

Carrier mobility is often used to evaluate semiconductor material. A low value of mobility is generally construed to imply the presence of impurities or defects that adversely affect carrier transport. It is shown theoretically that low mobility values will also be obtained by van der Pauw measurements on samples containing certain types of radial inhomogeneities in the distribution of ionized impurities. The theoretical predictions have been confirmed by experiments on germanium slices cut from Czochralski-grown crystals.

The purpose of this work is to show that the apparent charge carrier mobility in a slice of semiconductor material, as measured by the van der Pauw method (1), will be anomalously low if certain types of ionized impurity gradients are present. Crystals grown by the Czochralski method for our high-purity germanium program sometimes contain both p- and n-type regions, as illustrated by the schematic longitudinal section shown in Fig. 1. A slice taken normal to the growth direction at A shows little if any radial gradient in net acceptor concentration. At B, near the point on the axis where the core becomes n-type, the net acceptor concentration is higher at the perimeter of the slice than at the center. At C, there is a radial n-p junction, and the net acceptor concentration increases from the junction to the perimeter. In this case the junction may be considered as a very steep gradient where the net acceptor concentration changes from negative to positive. Similar radial variations in donor and acceptor concentrations in high-purity germanium crystals have been observed at other laboratories, and the effects of these variations on various properties of high-purity germanium photon detectors have been reported (2, 3).

The van der Pauw method (1) is useful in characterizing semiconductor crystals because it permits measurements of the Hall coefficient and resistivity to be made on whole slices taken from a crystal, rather than being limited to measurements on bar-shaped samples taken from each slice. One therefore obtains some average value of the carrier concentration and mobility in the slice according to the relationships

Key words: impurity distribution, radial gradient, Hall mobility, anomalous mobility.

$$n = \frac{1}{eR}$$

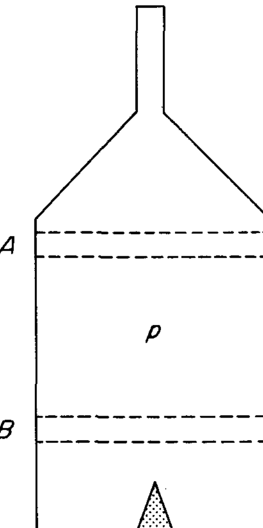
$$\mu = R/\rho$$

where n is the carrier concentration, e the electronic charge, R the Hall coefficient, μ the mobility, and ρ the resistivity. In van der Pauw measurements on crystals of the type shown in Fig. 1, it was found that the apparent mobility decreased for slices cut at intervals between A and C. This observation led us to investigate the consequences of positive radial gradients in the carrier concentration on the results of van der Pauw measurements and to determine the degree to which such gradients influence the apparent mobility. (We designate a radial gradient as positive when the carrier concentration increases from the center of a slice to the perimeter.)

Theory

Radial n-p junction.—Wolfe, Stillman, and Rossi (4), (WSR), have developed a general model of apparent mobility in a cylindrically symmetrical semiconductor slice of radius a, containing an outer region of resistivity ρ and mobility μ and a central region of radius b, resistivity ρ_0, and mobility μ_0 (Fig. 2). They show that van der Pauw measurements will lead to anomalously high values of mobility when $\rho_0 << \rho$ and $\mu B << 1$ (electrostatic units), where B is the magnetic field ($\mu B << 10^8$ when μ is in square centimeters/volt-second and B is in gauss).

By applying the WSR model to the case where $\rho_0 >> \rho$, which approximates a sample containing a radial n-p junction, it can readily be shown that the apparent Hall coefficient, R_{app}, is the same as the Hall coefficient,



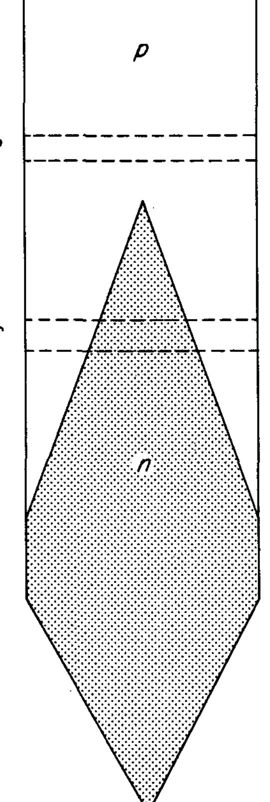


Fig. 1. Location of p- and n-type regions in high-purity germanium crystal grown by the Czochralski method. The positions of three representative slices are indicated by dashed lines.

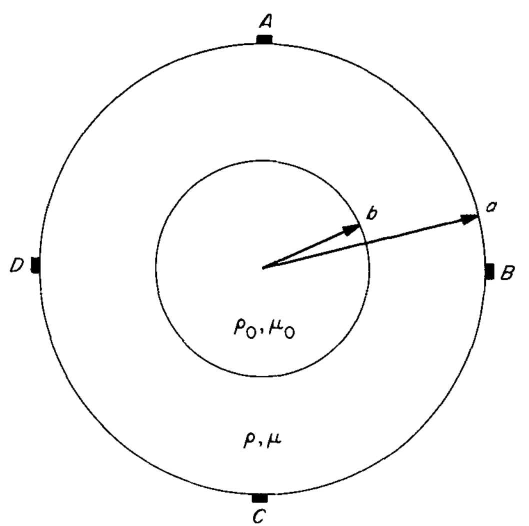

Fig. 2. Sample geometry used in this work. Electrical contacts A, B, C, D at 90° intervals. By the van der Pauw method $R = R$ (V_{BD}/I_{AC}) and $\rho = \rho$ (V_{AB}/I_{CD}).

R, for a uniform disk with the same carrier concentration as the outer region, while the apparent resistivity, ρ_{app}, is larger than ρ by a factor depending upon $\alpha = b/a$. Apparent mobilities, therefore, are smaller than the values for the outer region. These results are similar to those of Juretschke, Landauer, and Swanson (5), (JLS), who studied Hall effect and resistivity in porous material. For samples containing one or more hollow cylinders of arbitrary cross section parallel to the magnetic field and normal to the electric field, they also predict $R_{app} = R$, but obtain a somewhat different functional dependence of ρ_{app} on b/a.

The relations ρ_{app}/ρ *vs.* $(1 - \alpha)$ for both models are shown as solid lines in Fig. 3. For the WSR model

$$\frac{\rho_{app}}{\rho} = \frac{1}{\ln 2} \sum_{n=1}^{\infty} \frac{(1 + \alpha^{2n})^2 + 2\alpha^{2n}}{(1 - \alpha^{4n})} \cdot \frac{(-1)^{n+1}}{n}$$

for the JLS model

$$\frac{\rho_{app}}{\rho} = \frac{1 + \alpha^2}{1 - \alpha^2}$$

Since $\mu = R/\rho$ and $R_{app} = R$, the ratio of aparent mobility to the mobility in the outer region, μ_{app}/μ, is given by $(\rho_{app}/\rho)^{-1}$.

Ionized impurity gradient.—If there is a negative radial gradient in the net ionized impurity concentration, WSR show that μ_{app}/μ is expected to be greater than unity. By analogy we expect a positive radial gradient to result in μ_{app}/μ less than unity. This conclusion should apply to the case of a continuous gradient only, as at B in Fig. 1, and also to the case of a step function and a continuous gradient in the outer region as at C in Fig. 1.

Experimental Procedure

Radial n-p junction.—As it was necessary to make van der Pauw measurements under extrinsic condi-

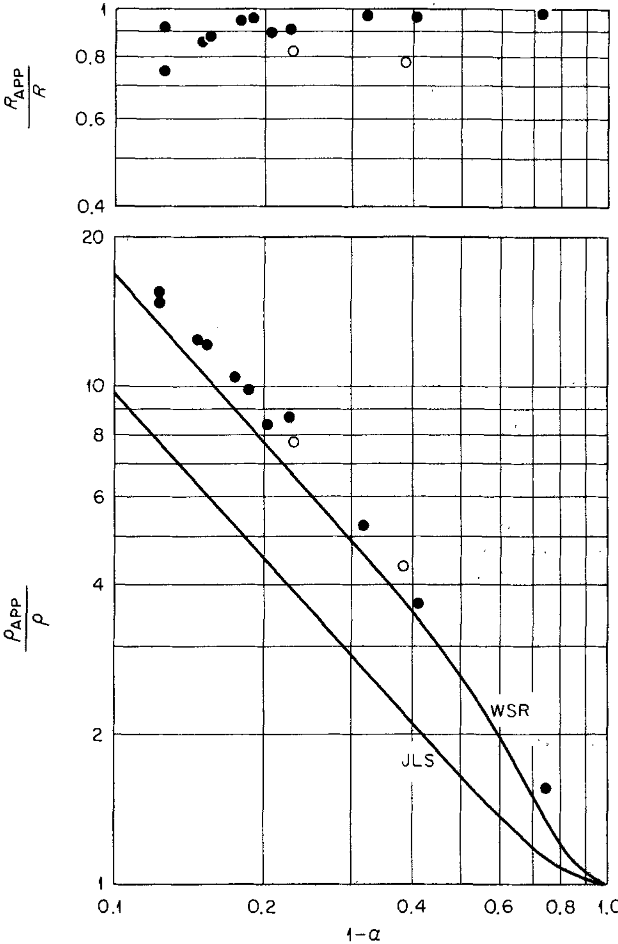

Fig. 3. Relative Hall coefficient and resistivity as a function of $(1 - \alpha)$ for cored samples, ●, and samples containing radial n-p junctions, ○. Solid lines are theoretical curves from Wolfe, Stillman, and Rossi (WSR), and from Juretschke, Landauer, and Swanson (JLS).

tions, and as our high-purity crystals were intrinsic at room temperature, we worked at 77°K. To be consistent, the doped samples were also measured at that temperature.

Several slices of p-type germanium were cut from a crystal pulled in the <100> direction. The material was 20-30 ohm-cm p-type, with a radial variation in resistivity of not more than 5-10% as determined by four-point-probe measurements. Etch pit concentrations were 2000-4000 cm^{-2}, and there was no evidence of strain, lineage, or slip. A disk of 3.75 cm diameter was cut from each slice to eliminate any possible skin effects and to provide a uniform sample size. After making van der Pauw measurements on a whole disk to determine R and ρ, core drills of various diameters were used to cut one or more successively larger concentric holes in the sample to simulate the presence of an n-p junction. The samples were carefully etched before each measurement to minimize surface effects and also as a sensitive test to reveal any cracks that might have occurred during the core-drilling operation. Each cut was followed by a set of electrical measurements to determine R_{app} and ρ_{app}.

Two similar disks were diffused with lithium to form concentric n-type cores while retaining a uniform outer p-type region.

Ionized impurity gradient.—Slices containing radial ionized impurity gradients were cut from high-purity germanium crystals with impurity distributions of the type shown in Fig. 1. Several specimens were taken at intervals above and below the onset of the n-p junction. If a junction was present, it was located by immersing the sample into liquid nitrogen containing a suspension of barium titanate, and applying a high reverse bias voltage. Other methods of locating the junction, such as using thermal, electrical, or optical probes, proved to be less satisfactory.

Results and Discussion

Cored and diffused samples.—Most of the experimental work to determine the effects of radial n-p junctions on the Hall coefficient and resistivity was performed on cored samples. A cored sample was assumed to be the approximate electrical equivalent of a disk containing a radial n-p junction and an outer, uniform p-type portion, under the condition that current flowing in the outer portion of the disk is large compared to the junction saturation current. The validity of this assumption was shown by measurements made on the two p-type samples into which n-type centers had been diffused. At 77°K the saturation current was much less than the sample currents of 10-100 μA used in the van der Pauw measurements. The data points for the apparent resistivities of the diffused samples fell on the experimental curve for the cored samples; however the Hall coefficients of the diffused samples were slightly lower than expected, possibly because of the junction current.

Figure 3 shows the experimental results for R_{app}/R and ρ_{app}/ρ as functions of $(1 - \alpha)$. Representative values of R and ρ at 77°K for uniform uncored samples were 4.5-6.0 $\times$ 10^4 cm^3/coulomb and 1.4-1.0 ohm-cm, respectively. The resistivity data agree rather well with the WSR model; the experimental values are generally a few per cent higher than the theoretical curve. Since $R_{app}/R \approx 1$, the apparent mobility ratio, μ_{app}/μ, is essentially the same as $(\rho_{app}/\rho)^{-1}$ and therefore is not plotted in Fig. 3, but is shown in Fig. 4.

Continuous concentration gradients.—For these experiments we chose crystals with the radial characteristics illustrated in Fig. 1. For those slices that contained an n-p junction, as well as a positive radial gradient in net acceptor concentration from the junction to the perimeter, the measured quantities were influenced by both the diameter of the n-type core and the magnitude of the gradient. Values of R and ρ could not be assigned to these samples as was possible in the case of the cored and diffused samples, which initially were of uniform concentration. The apparent mobility measured for each slice was therefore compared to the mobility measured for uniformly doped samples cut from the top of the crystal.

At some point along each crystal, μ_{app}/μ began to decrease from unity. Beginning at this point the slices were probed for the existence of a radial n-p junction by the barium titanate decoration method. The junctions were not always well defined and occasionally deviated from a circular pattern, so that values of α often had to be estimated.

The data for μ_{app}/μ in the high-purity germanium samples are presented in Fig. 4, which includes those for the cored and diffused samples for comparison. In slices taken above the junction, represented in the figure by points along the $(1 - \alpha) = 1$ axis, μ_{app}/μ ranges from unity to about 0.4-0.5, showing that the apparent mobility decreases as the radial ionized impurity gradient increases. As the junction appears and its radius increases, μ_{app}/μ continues to decrease with a slope similar to that for samples containing an n-p junction but no gradient. Therefore, it appears that the contribution of the radial gradient to the decrease in apparent mobility remains essentially constant as a function of length for all the crystals studied.

Summary

The van der Pauw method of evaluating semiconductor slices will yield erroneously high values of resistivity, and hence erroneously low values of apparent mobility, if the sample contains either a radial n-p junction (and the sample current is large compared to the junction saturation current) or a positive

radial gradient in carrier concentration. If both a junction and a positive gradient in the outer region are present, the effects are additive.

A Chemical Etchant for the Selective Removal of GaAs Through SiO_2 Masks

J. J. Gannon and C. J. Nuese

RCA Laboratories, Princeton, New Jersey 08540

ABSTRACT

An $NH_4OH:H_2O_2$ etchant has been developed for etching selected regions of GaAs through windows in an SiO_2 mask. This etchant has been found to provide flat etching profiles across the unmasked regions of the GaAs, and has considerably reduced undercutting commonly caused by attack of the SiO_2. The chemical etching rates have been evaluated and have been found to depend strongly on the concentration of the etching solution and on the crystal orientation of the GaAs. The utility of the $NH_4OH:H_2O_2$ for GaAs device preparation has been demonstrated by its application to the fabrication of interdigitated GaAs bipolar transistors with 5 μm base-emitter separation.

During the years, as the technology of GaAs crystal growth has advanced to the point where it is useful and occasionally unique in device fabrication, many chemical etches have been developed. The most useful of these are Caro's (1), bromine-methanol (2), sodium-hypochlorite, and more recently, a mixture of NH_4OH: H_2O_2 (3) used as a chemical-mechanical polishing etch. Each of these etches has its advantages for some applications. Each too has its drawbacks: the acid etches cannot be used in the presence of most metal contacts, while the alkaline etches tend to attack SiO_2 masks commonly used in device technology. A more serious disadvantage common to most of the etches mentioned above is a tendency toward an enhanced etch rate near the edges of an SiO_2 mask (4), presumably due to migration of adsorbed etchant molecules along the mask.

In a previous publication (4), Shaw described a $NaOH:H_2O_2$ solution that provided a flat GaAs etching profile over the area of a "window" in an SiO_2 protective surface mask. We found this characteristic attractive when selectively etching through portions of a three-layered GaAs transistor structure to expose a thin inner (base) layer for subsequent contacting (5). For the simple, large-area stripe geometry used in these early prototype transistors, resolution was of little concern.

In subsequent work, we found it necessary to fabricate more sophisticated GaAs bipolar transistors with a closely spaced ($\sim$5 μm) interdigitated base-emitter geometry (6). For the fabrication of these devices, the attack of the SiO_2 mask by the $NaOH:H_2O_2$ was undesirable, since it provided poor resolution due to undercutting. An alternative chemical etch, described in this paper, led to a major reduction in the attack of the SiO_2, resulting in well-defined, closely spaced transistor patterns with highly polished surfaces, free of imperfections. As we will show below, the new etch, a mixture of NH_4OH and H_2O_2, also provides relatively low etching rates for both n- and p-type <100> GaAs, and a flat etching plane over the entirety of the areas defined by the SiO_2 mask. Hence, this etch should be of general value to GaAs device technology.

Key words: selective etching, GaAs, bipolar transistors.

Experimental Procedure

The "standard" $NH_4OH:H_2O_2$ etchant described in this paper was prepared by mixing 20 mliters of NH_4OH, 7 mliters of 30% H_2O_2 (stabilized), and 973 mliters of H_2O to form a 0.3N NH_4OH:0.1N H_2O_2 solution. The etchant was always used at room temperature and was freshly mixed prior to each experiment. The SiO_2 masks used in conjunction with this etchant were approximately 3000Å thick and were prepared by reacting silane and oxygen at 350°C (7). The desired geometries (in this case, emitter or base transistor patterns) were defined by standard photoresist techniques using KTFR. Most of the GaAs used in the etching experiments was oriented in the <100> crystallographic direction or 3° off the <100> and was prepared by a vapor-phase growth technique described previously (8). A few experiments were performed on <111>-oriented GaAs to delineate the effects of crystal orientation on etching rates.

Results and Discussion

Undercutting.—A comparison of the undercutting for the $NH_4OH:H_2O_2$ etch and the previous $NaOH:H_2O_2$ etch was made by masking an n-type GaAs epitaxial layer with SiO_2 and defining a "finger"-type transis-

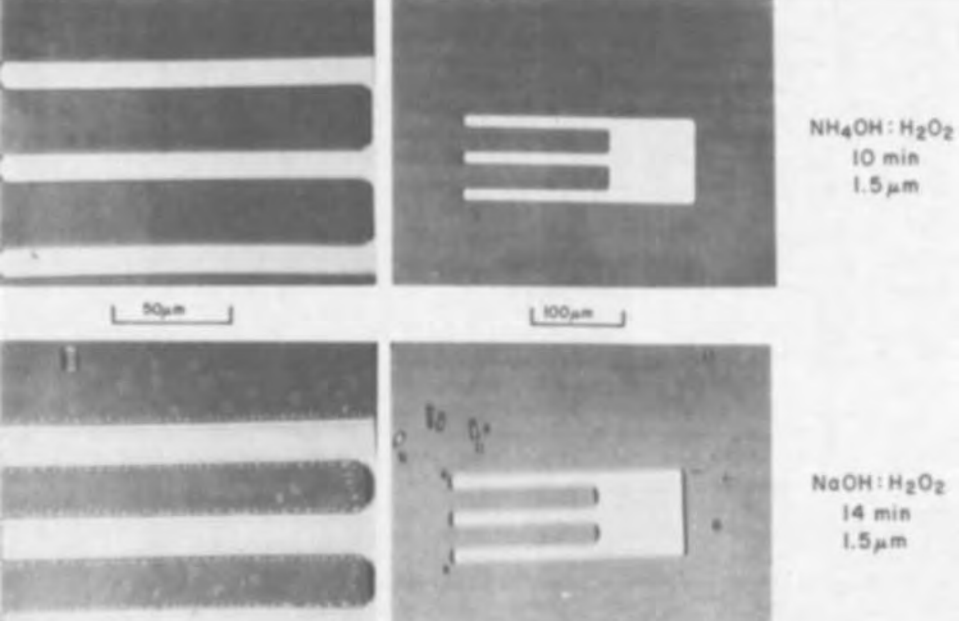

Fig. 1. Comparison of undercutting and attack of SiO_2 mask due to chemical etching with $NH_4OH:H_2O_2$, and $NaOH:H_2O_2$.

tor pattern with KTFR. Different pieces of this wafer were then exposed to the two etches for a time sufficient to etch about 1.5 μm into the GaAs (10 min for the $NH_4OH:H_2O_2$; 14 min for the $NaOH:H_2O_2$). The results of this experiment are shown in Fig. 1, where the attack of the SiO_2 by the $NaOH:H_2O_2$ is readily apparent in the lower photomicrographs. The crystallographic shape of many of the defects here is probably due to preferential etching of the GaAs beneath pinholes and weak spots in the SiO_2, which become enlarged during the etching process by dissolution of the SiO_2 from both sides of the mask. In contrast, the upper photomicrographs illustrate that the $NH_4OH:H_2O_2$ does not give rise to such defects, since it does not attack the SiO_2 perceptibly.[1] In the lower left-hand photo of Fig. 1, the attack of the SiO_2 by the $NaOH:H_2O_2$ is further demonstrated by the significant widening of each of the fingers of the pattern. Here, the finger width was measured to be 17.4 μm, in contrast to a value of 12.3 μm for the pattern etched with $NH_4OH:H_2O_2$. Since the width of the original photoresist mask was 12.0 μm, the finger width after etching represents the amount of lateral etching or undercutting for the two etchants (about 0.15 μm per edge for $NH_4OH:H_2O_2$ and about 2.7 μm per edge for $NaOH:H_2O_2$). We should add that the slight widening that occurs for the $NH_4OH:H_2O_2$ is thought to arise from enhanced lateral etching rates at the GaAs-SiO_2 interface rather than to dissolution of the SiO_2 mask. This statement is supported by occasional observations of SiO_2 layers that extend a small distance (<1 μm) over the etched region of the GaAs after a lengthy etching process.

Etching rates.—The etching rate for the "standard" 0.3*N* NH_4OH:0.1*N* H_2O_2 solution was determined for a series of two n-type and two p-type GaAs Czochralski-grown <100>-oriented wafers that previously had been polished chemically (in Caro's etch) to remove any work damage. As shown in Fig. 2, the etching distance was found to have a slightly sublinear dependence on etching time, probably due to a gradual dissociation of the H_2O_2 after times on the order of 15-30 min. The maximum etching rate (for 0-10 min) was found to be about 0.18-0.2 μm/min for n-type GaAs and 0.12-0.14 μm/min for p-type GaAs. Although the dependence of etching rate on doping concentration has not been evaluated in detail, both the n- and p-type wafers in Fig. 2 yielded somewhat higher etching rates for the more heavily doped sample.

For our applications, where etching distances on the order of 1-2 μm were usually required, the slow etching rates demonstrated in Fig. 2 were highly desirable. However, for other applications, the rate could be increased significantly by simply increasing the concentration of the aqueous solution, as shown in Fig. 3. Here, for a concentration 10 times larger than the "standard" 0.3*N* NH_4OH:0.1*N* H_2O_2 solution, an etching rate of about 1.4 μm/min was obtained for the particular wafer used in Fig. 3. This is about 5.5 times larger than the rate obtained for the more dilute "standard" solution. In addition, the highly polished surface appearance of the GaAs was maintained after etching with each of the $NH_4OH:H_2O_2$ mixtures used in Fig. 3. Although it would be interesting to explore the $NH_4OH:H_2O_2:H_2O$ family of solutions over a much broader range of ratios and concentrations, the etching rates between about 0.12 and 1.4 μm/min illustrated in Fig. 2 and 3 have been sufficient for most GaAs applications encountered to date.

The $NH_4OH:H_2O_2$ etchant described in this paper has been mostly used for <100>-oriented GaAs sur-

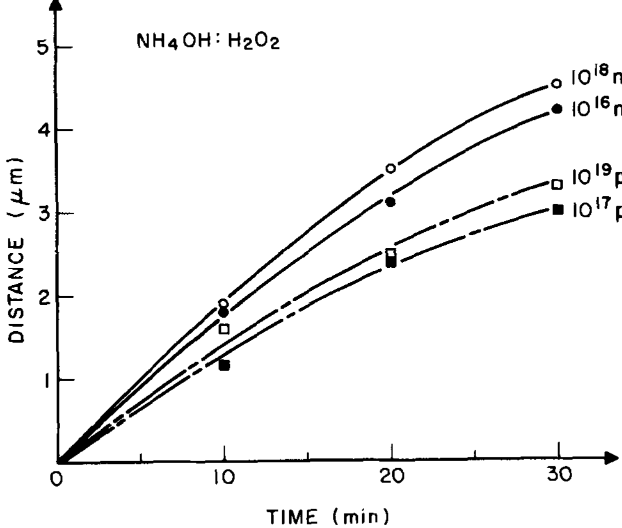

Fig. 2. Etching rates for n- and p-type GaAs in 0.3*N* NH_4OH: 0.1*N* H_2O_2 at room temperature. The crystal orientation is <100>.

[1] In an attempt to determine the extent of dissolution of a deposited SiO_2 layer in $NH_4OH:H_2O_2$, a GaAs wafer covered with 3000A of SiO_2 was placed in 3*N* NH_4OH:1*N* H_2O_2 for 8 hr. (The solution was changed every hour.) At the end of this time, no perceptible change in the SiO_2 could be observed.

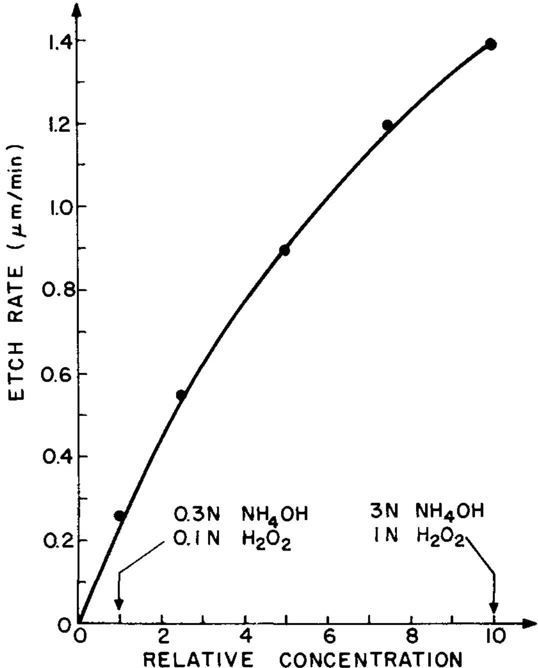

Fig. 3. Dependence of etch rate (in micrometers per minute) on the relative concentration of the $NH_4OH:H_2O_2$ etchant for <100>-oriented GaAs.

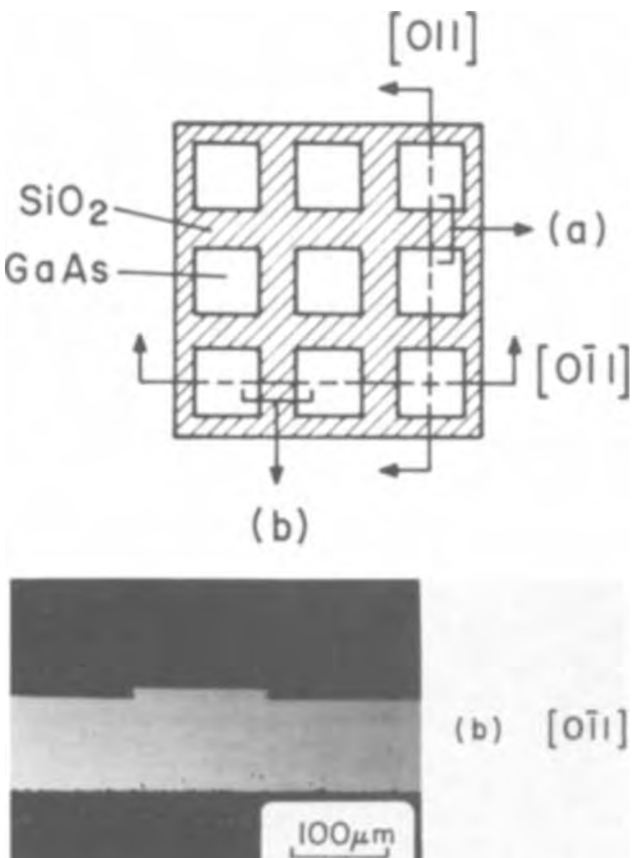
faces. However, it has been evaluated a few times on {111} surfaces. For these experiments, n-type GaAs wafers oriented in the <111>A, <111>B, and <100> crystallographic directions were simultaneously etched in the "standard" $NH_4OH:H_2O_2$ solution for 30 min. The etching distances for these orientations are listed in Table I. Immediately evident here is the enhanced etching rate for the {111}B surface and the retarded rate for the {111}A. Similar effects have been previously observed for GaAs etched with Br_2-CH_3OH (9)

Table I. Effect of crystal orientation on the etch rate of $NH_4OH:H_2O_2$

Orientation	Etching distance (μm)	Average etching rate (μm/min)
<111>B	6.0	0.20
<100>	3.7	0.12
<111>A	1.1	0.037

and $H_2SO_4:H_2O_2$ (10). The enhanced etch rate for the {111}B surface is thought to arise from the unshared electron pairs of each surface atom, while the passive chemical nature of the {111}A surface is due to the absence of unshared bonds (11, 12).

Preferential etching.—The preferential etch rates discussed above also were apparent from an observed incline of the edges of the etching pattern, as shown in Fig. 4. Here, a rectangular grid was defined with SiO_2 on the {100} surface of GaAs, after which the exposed regions of the GaAs were etched with a standard solution of $NH_4OH:H_2O_2$. The etching profile was then examined by cleaving the wafer in orthogonal directions along the (011) and ($0\bar{1}1$) planes. As shown in Fig. 4, the edges of the pattern deviated appreciably from a direction normal to the (100) surface, in one case sloping downward toward the SiO_2 [Fig. 4(b)], and in the other, sloping downward away from the SiO_2 mask [Fig. 4(a)]. This type of etching profile is thought to occur due to the very slow etching rate for the {111}A planes, as we have illustrated previously in Table I. The fact that the direction of incline changes for the two cleavage planes in Fig. 4 merely reflects the change in polarity of the chemical bonds associated with the {111}A planes in zincblende structures upon a 90° crystallographic rotation about the <100> axis. Tarui and co-workers (9) have observed similar etching patterns in <100>-oriented GaAs etched with bromide-methanol, which also has a very slow etch rate for the (111)A planes. We should mention that the angle of incline observed in our present



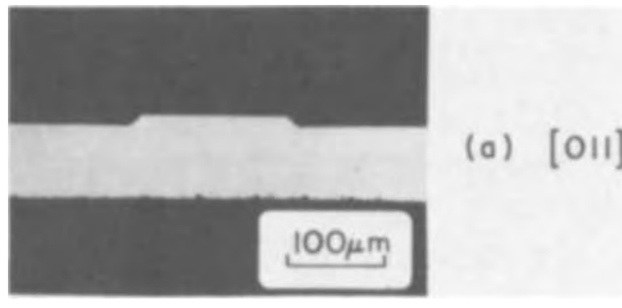


Fig. 4. Etching profile for a square pattern defined by an SiO_2 mask on GaAs. The etched region was cross sectioned in orthogonal <110> directions by cleaving. Note the change in the slope of the edges produced by the 90° crystallographic rotation about the {100} growth axis.

work varied from crystal to crystal in the range of 15°-40° from normal. However, these angles have little physical meaning due to the slight lateral etching near the surface discussed previously.

Device Application

The $NH_4OH:H_2O_2$ etchant whose characteristics were described above has been used extensively for the fabrication of three-layered GaAs bipolar transistors (6). In this final section of our paper, we describe the manner in which the $NH_4OH:H_2O_2$ was used for this purpose, since it illustrates the utility of the etchant for general GaAs device fabrication.

For our transistor fabrication, an interdigitated array of emitter and base "fingers" was desired, with a separation of about 5 μm. To obtain this, an emitter contact was first evaporated to the outermost GaAs layer through a SiO_2 pattern, and sintered to ensure good adhesion [see Fig. 5(a)]. The inner base layer was then exposed for contacting by evaporating SiO_2 over the emitter, defining a pattern in the SiO_2 with standard photoresist technology, and etching through the emitter layer (1-2 μm thick) with the $NH_4OH:H_2O_2$ etchant [see Fig. 5(b)]. A flat etching profile was essential here to avoid penetrating the base layer, which was only 1 μm thick. The ohmic contact to the base [Fig. 5(c)] was then obtained by using a third SiO_2 pattern slightly smaller than that used for etching. The utility of the $NH_4OH:H_2O_2$ etchant for this fabrication procedure is demonstrated by the sharpness of the edges and by the smoothness of the metallization in Fig. 5(a)-5(c).

A cross-sectional view of a GaAs transistor prepared as described above is illustrated in Fig. 6(a), where a {110} cleavage plane has been used to bisect one of the interdigitated base-emitter patterns. The flatness of the etching front and its position just beneath the emitter-base p-n junction is clearly evident. The p-n junctions for this transistor were delineated by an electrolytic etch after cleaving. The base-collector junction is difficult to accent by this technique because of the light doping in the base and collector layers (1×10^{17} and 1×10^{16} cm^{-3}, respectively), however, the approximate position of the base-collector junction is indicated by the line drawn at the side of the photomicrograph. We should stress that if we had used one of the common GaAs etches that provide enhanced etching rates near the edges of an SiO_2 mask, the base would have been penetrated in these locations, thereby shorting the emitter to the collector during the subsequent base metallization.

The *I-V* characteristics of a GaAs transistor fabricated with the $NH_4OH:H_2O_2$ etchant is illustrated in Fig. 6(b). Here, a current gain of approximately 10 was obtained, which is about the value expected for GaAs n-p-n transistors with a base width of 1-2 μm (5).

The success of the fabrication procedure described above relies heavily on an etchant that provides a flat etching front and a slow etching rate. In addition, the chemical makeup of the etchant must be such that SiO_2 masks are not appreciably attacked by the etchant. Clearly, the $NH_4OH:H_2O_2$ etchant described in this paper meets these requirements, and should find general usefulness for the fabrication of GaAs devices.

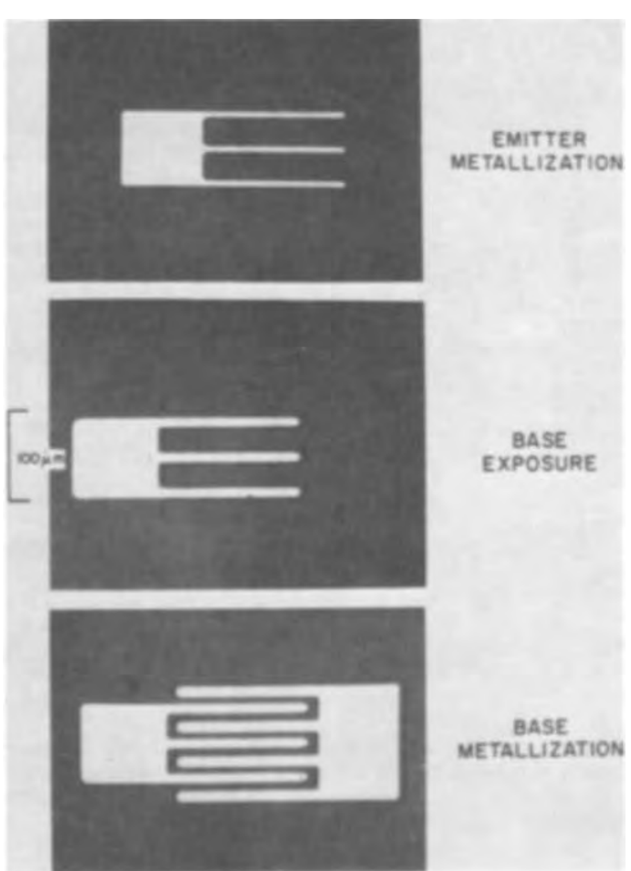

Fig. 5. Photomicrographs of GaAs bipolar transistor fabrication: (top) evaporated emitter metallization, (center) exposure of inner base layer in selected areas by etching with $NH_4OH:H_2O_2$, (bottom) completed base-emitter transistor array following evaporation of base metallization in etched regions.

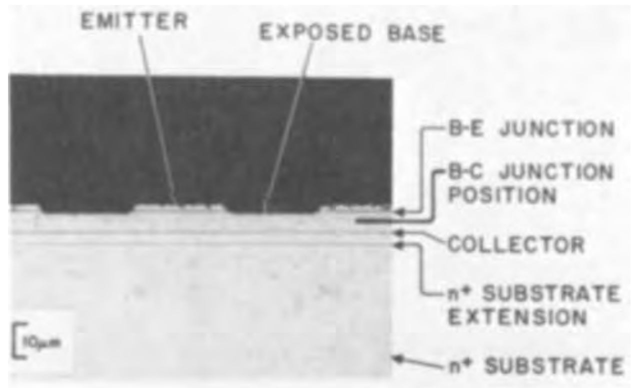

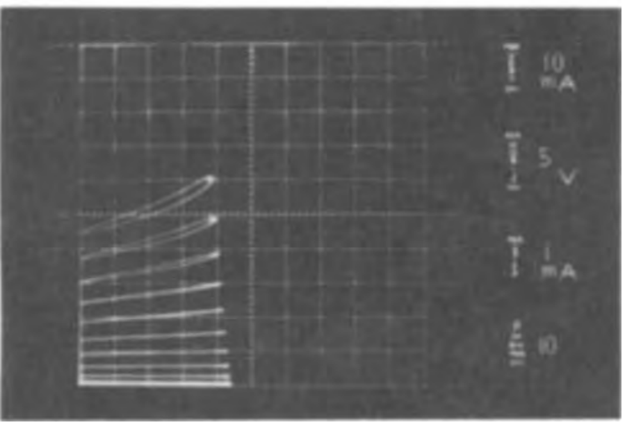

Fig. 6. (Top) {110} cleavage plane of GaAs n-p-n transistor structure after exposing base in selected areas with $NH_4OH:H_2O_2$ etch. Note flatness of etching front and its location just below base-emitter junction. Base-collector junction was difficult to stain, but was located approximately where indicated. (Bottom) *I-V* characteristics of GaAs bipolar transistor after complete fabrication. Current gain is approximately 10.

Summary

An $NH_4OH:H_2O_2$ chemical etch for GaAs has been developed that provides a flat etching front when used for selective etching through holes in an SiO_2 mask. Furthermore, this etchant does not attack SiO_2 per-

ceptibly, thereby providing improved resolution and definition for fine photoresist patterns.

The etching rate of dilute $NH_4OH:H_2O_2$ solutions is on the order of 0.1-0.2 μm/min (for {100} GaAs) and increases to values greater than 1 μm/min with increasing solution concentration. The rate depends strongly on crystal orientation, decreasing as the orientation is changed from {111}B to {100} to {111}A. The slow etching rate for the {111}A planes results in inclined etching fronts at the edges of an SiO_2 mask, similar to those found previously with bromine-methanol solutions (9).

The characteristics mentioned above, as well as the shiny, unblemished surfaces provided by this etchant, make the $NH_4OH:H_2O_2$ attractive for a variety of GaAs device applications. As an example, bipolar GaAs transistors with current gains greater than 10 have been routinely fabricated from three-layered n-p-n structures by etching into the inner base layer with $NH_4OH:H_2O_2$.

Acknowledgments

The authors wish to thank R. H. Dean and G. H. Olsen for their valuable comments concerning the preferential nature of the etching profile. We also would like to thank J. Alexander for his extensive efforts in the areas of SiO_2 deposition and photoresist masking, and N. Goldsmith for critical review of this manuscript. This research was supported in part by the National Aeronautics and Space Administration, Huntsville, Alabama, and by RCA Laboratories, Princeton, New Jersey.

A Simplified Method of Measuring Lifetime Using Steady-State Back Illumination of an MOS Capacitor

C. St. L. Rhodes and C. A. T. Salama*

Department of Electrical Engineering, University of Toronto, Toronto, Ontario, Canada

ABSTRACT

The semiconductor minority carrier lifetime in an MOS capacitor can be determined from measurements of back-illumination induced increases in both the steady-state, high frequency, inversion region capacitance and the rate of recovery following deep depletion. The theory of the method is discussed and its application is illustrated by means of experimental results obtained from MOS capacitors fabricated on a silicon substrate. Unlike other MOS deep depletion techniques, this method of minority carrier lifetime determination is not subject to errors due to either peripheral surface-state generation or the assumption of a dominant midgap trap. The over-all simplicity, accuracy, and speed of implementation of this method make it suitable for material specification and process control applications.

Previous authors (1-4) have shown that both surface-state generation effects and the assumption of a midgap trap level in the semiconductor can lead to substantial errors in minority carrier lifetime measurements by standard MOS deep depletion techniques. Rhodes and Salama (4) discussed the response of an MOS capacitor to back illumination under both deep depletion and steady-state conditions, and suggested the possibility of measuring the minority carrier lifetime using this method. This paper describes a simplified procedure for implementing the back-illumination technique, and illustrates a method for rapid reduction of the data, enabling the lifetime to be found readily without graphical analysis using only simple calculations. The method is particularly useful in device applications where exact specification of the minority carrier diffusion length is important. For example, in the case of charge-coupled imaging devices and photodiode arrays scanned by MOS shift registers, the lifetime affects the integration or storage time of the array and is a very critical parameter in determining the over-all usefulness of these devices as optical sensors in television camera applications.

The method involves application of steady-state back illumination to an MOS capacitor, and measurement of the small signal, high frequency,[1] heavy inversion region capacitance and the recovery of the MOS capacitor from a deeply depleted condition, as illustrated in Fig. 1 and 2. The minority carrier lifetime can be cal-

* Electrochemical Society Active Member.
Key words: silicon, diffusion length, deep depletion.

[1] Throughout this paper the measurement frequency is assumed to be sufficiently high that light-induced conductance effects in the depletion region are negligible (5).

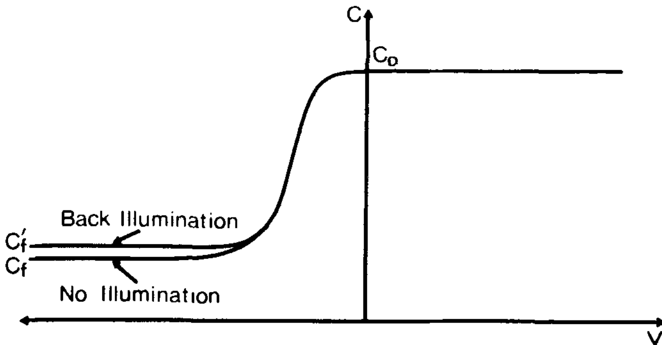

Fig. 1. Effect of back illumination on the steady-state, high frequency, heavy inversion region capacitance of an MOS capacitor on n-type silicon.

culated from the excess minority carrier density obtained from Fig. 1 and the minority carrier diffusion flux obtained from Fig. 2.

Theory

Zerbst (6) showed that the rate of change of the high frequency capacitance C of an MOS structure is related to the generation rate per unit area g by

$$\frac{d}{dt}\left(\frac{C}{C_o}\right) = \frac{K_o}{K_s X_o N}\left(\frac{C}{C_o}\right)^3 g \qquad [1]$$

where K_o, X_o, and C_o are the relative dielectric constant, thickness, and capacitance of the oxide, respectively, K_s is the relative dielectric constant of the semiconductor, and N the effective doping density.[2] The generation rate components consist of bulk, surface, and peripheral generation, and a component due to diffusion (1-4, 7).

Under deep depletion conditions with sufficient back illumination,[3] the only non-negligible component of g is g_d', that component due to diffusion from the bulk (3, 4) Since this component is time independent it is easily evaluated by integrating [1] to get

$$g_d' = \frac{K_s X_o N}{2K_o(t_2 - t_1)}\left[\left(\frac{C_o}{C_1}\right)^2 - \left(\frac{C_o}{C_2}\right)^2\right] \qquad [2]$$

where C_1, t_1 and C_2, t_2 are coordinates of a pair of arbitrarily chosen points on the C-t recovery curve shown in Fig. 2.

In steady state, with the MOS capacitor biased into the heavy inversion region, band bending causes the recombination rate per unit volume to be much greater in the depletion region than elsewhere. The total recombination rate per unit area, obtained by integrating the recombination rate per unit volume R over the space charge region width X_d, is equal to the available flux of minority carriers. Under sufficient back illumination, this flux is approximately equal to the diffusion flux g_d' giving

$$g_d' = \int_0^{X_d} R dx \qquad [3]$$

Provided the minority carrier diffusion length is greater than X_d, evaluation of Eq. [3] using Shockley-Read recombination theory and the depletion approximation (4) gives

$$g_d' = \frac{\pi}{2\tau}\left[\frac{K_s\epsilon_o r k T}{q^2 \ln\left(\frac{N}{p_o + r}\right)}\right]^{1/2} \qquad [4]$$

where ϵ_o is the permittivity of free space, q the electronic charge, τ the minority carrier lifetime, p_o the thermal equilibrium minority carrier (hole) density in the neutral bulk, k the Boltzmann constant, T the absolute temperature, and r the excess minority carrier density at the edge of the space charge region under steady-state conditions.

The value of r required to solve Eq. [4] can be obtained from the illumination-induced shift in the high frequency, heavy inversion region capacitance. This shift from C_f to C_f' (see Fig. 1) can be related to the parameter $\eta = (p_o + r)/p_o$ by the following equation (4)

$$\ln \eta = \frac{N}{\xi}\left(\frac{C_o}{C_f'} + \frac{C_o}{C_f} - 2\right)\left(\frac{C_o}{C_f} - \frac{C_o}{C_f'}\right) \qquad [5]$$

where ξ is defined by

$$\xi = \frac{2K_o^2\epsilon_o kT}{q^2 K_s X_o^2} \qquad [6]$$

Substituting n_i^2/N for p_o, where n_i is the intrinsic carrier density, and solving Eq. [4] for τ in terms of η gives

$$\tau = \frac{\pi n_i}{2g_d'}\left[\frac{K_s\epsilon_o(\eta - 1)kT}{q^2 N \ln\left(\frac{N^2}{\eta n_i^2}\right)}\right]^{1/2} \qquad [7]$$

Thus the procedure for finding the lifetime τ involves the determination[4] of N from C_o and C_f, the calculation of η from C_f' using Eq. [5] and [6], and finally the determination of τ from Eq. [7] using the value of g_d' given by Eq. [2]. With sufficient illumination the diffusion flux dominates all other components of g, so the lifetime obtained in the above manner is not subject to errors due to either surface-state or bulk trap thermal generation effects.

Experimental Procedure

To determine the minority carrier lifetime the apparatus illustrated in Fig. 3 is used for slice probing with back illumination. The associated measurement setup is illustrated in Fig. 4. In practice, the light levels required to make Eq. [2] valid are sufficiently large that the corresponding transient C-t curve is too fast for most mechanical X-Y recorders to follow; requiring the use of a storage oscilloscope or an analog data memory (Biomation Model 610).

The shift in the steady-state inversion region capacitance from C_f to C_f' is typically a few per cent of C_o at these light levels. To facilitate rapid and accurate recording of the steady-state capacitance data, the

[2] For simplicity, this analysis will be restricted to n-type silicon.

[3] The back illumination is sufficient if the recovery time under illumination is less than one-tenth of the recovery time without illumination. Typically an incident photon flux of 2.5×10^{15} cm^{-2} sec^{-1} is sufficient.

[4] The depletion approximation (9) gives the relation

$$N = \frac{2\xi}{\left(\frac{C_o}{C_f} - 1\right)^2}\ln\left(\frac{N}{n_i}\right)$$

which may be iteratively solved for N using Putley and Mitchell's (10) relation for n_i

$$n_i = 3.10 \times 10^{16} T^{3/2} \exp\left(\frac{-0.603}{kT}\right) \text{ cm}^{-3}$$

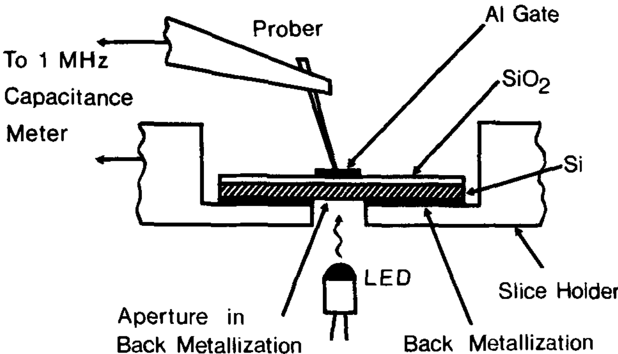

Fig. 3. Apparatus used for slice probing with back illumination

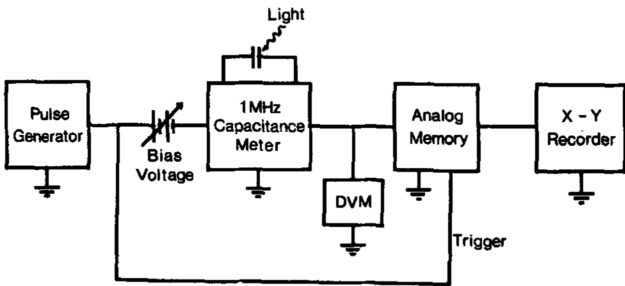

Fig. 4. Minority carrier lifetime measurement setup

capacitance meter output was fed into a digital voltmeter (DVM). Capacitances C_f and C_f' were measured at a fixed bias voltage.

The light-emitting diode (LED) used was a Monsanto ME2A, which is a diffused planar gallium arsenide diode with a noncollimating lens. At a current of 1.0A this LED has a minimum total external radiated power of 7.5 mW centered in wavelength at 9000Å, with a spectral half width of 500Å. The measurements described in this paper were conducted at an LED current of 0.75A, resulting in a photon intensity of approximately 2.5×10^{15} cm^{-2} sec^{-1} incident on the slice.

Since Eq. [7] has an explicit n_i dependence it is essential that both the steady-state *C-V* and the transient *C-t* measurements be made at the same temperature. Errors due to *C-t* transient end effects and quantization within the analog memory were minimized by choosing the points (C_1, t_1) and (C_2, t_2) at about ¼ and ¾ of the way along the deep depletion *C-t* recovery curve with back illumination.

The SiO_2 thickness was measured using a Talystep, and the value so obtained was cross-checked using a measurement of the oxide capacitance per unit area. Once the oxide thickness was determined the MOS dots were characterized using only capacitance ratios, thus avoiding precise measurements of their individual areas or absolute capacitances.

To demonstrate the usefulness and practicality of the method, mappings were made of the minority carrier lifetime and doping as a function of position over a portion of a typical n-type (100) orientation silicon slice. This slice was 250μ thick, 3.2 cm in diameter, and had a nominal resistivity of 10 ohm-cm. A 950Å thick thermal oxide was grown in dry oxygen on the polished surface of the slice and was annealed in N_2 at 1100°C.

Using a metal mask, a square array of 0.076 cm diameter aluminum dots with a center to center spacing of 0.125 cm were evaporated onto the oxide. An aluminum back contact with an aperture opposite the portion of the slice to be mapped was also deposited by evaporation.

The numerical work involved in analyzing the data was minimized by using a simple computer program.[5] This program, with data inputs of T, C_f/C_o, C_f'/C_o, C_1/C_f', C_2/C_f', and $t_2 - t_1$ for each dot and X_o for the slice, prints out the values of n_i, ξ, N, η, g_d', and τ associated with each set of MOS capacitor measurements.

The area of the slice which was mapped is shown cross-hatched in Fig. 5(a) and the resulting doping and minority carrier lifetime values at room temperature, are shown in Fig. 5(b) and (c). In these figures, *X*'s indicate dots which on probing were found to be defective. Figure 5(b) indicates that the doping is reasonably constant across the slice, exhibiting an average value of 0.621×10^{15} cm^{-3} and a root mean square deviation of 0.0462×10^{15} cm^{-3}. Figure 5(c) indicates that the minority carrier lifetime varies widely within 0.5 cm (four rows of dots) of the edge of the slice, but is fairly uniform near the center of the slice. For the four rows of dots nearest the edge of the slice the average minority carrier lifetime is 0.121×10^{-6} sec and the root mean square deviation is 0.0617×10^{-6} sec. For the remaining dots the average minority carrier lifetime is 0.173×10^{-6} sec and the root mean square deviation is 0.0159×10^{-6} sec. The dots away from the edge of the slice exhibited a much more uniform lifetime distribution than that observed by Schroder and Guldberg (2) using the deep depletion method without back illumination. The high failure rate and wide variations in lifetime exhibited by dots near the edge of the slice seems to indicate that the silicon ingot or the slice preparation is inferior near the slice rim.

[5] Available on request.

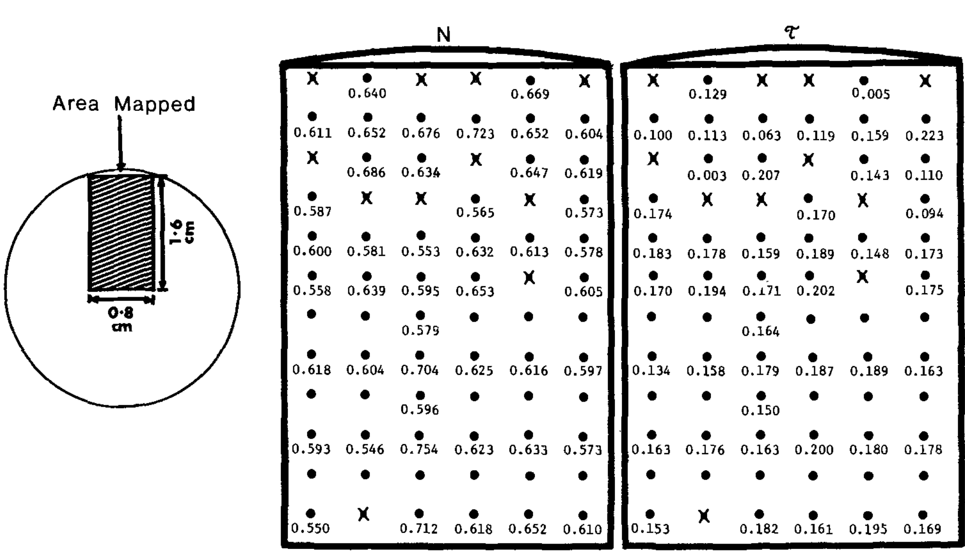

Fig. 5. (a) Plan view of slice showing area mapped. (b) Doping map in units of 10^{15} cm^{-3}. (c) Minority carrier lifetime map in microseconds.

For a typical dot near the center of the slice (the one in the lower, left-hand corner of the map) characterized by the data: $T = 298°K$, $X_o = 950Å$, $C_f/C_o = 0.202$, $C_f'/C_o = 0.223$, $C_1/C_f' = 0.373$, $C_2/C_f' = 0.879$, and $t_2 - t_1 = 0.20$ sec, the preceding analysis gave values of: $N = 5.50 \times 10^{14}$ cm^{-3}, $\eta = 1.15 \times 10^2$, and yielded $\tau = 0.153 \times 10^{-6}$ sec.

Conclusion

A simple technique using back illumination of an MOS capacitor to measure minority carrier lifetime has been presented. The technique involves measurements which can be analyzed quickly and results in values which are not subject to errors present in other methods of minority carrier lifetime measurements. By using this technique in conjunction with an on-line minicomputer, it is possible to monitor minority carrier lifetime at production rates and to perform slice surveys for doping and minority carrier lifetime.

Preparation of High-Resistivity Silicon by Vacuum Float Zoning

T. G. Digges, Jr.[1] **and C. L. Yaws**

Texas Instruments Incorporated, Dallas, Texas 75222

ABSTRACT

A successful, vacuum float-zone process was developed for the preparation of ultra high-resistivity polysilicon crystals. The high-resistivity polysilicon crystals were then converted to dislocation-free single crystals in an inert atmosphere by the usual Dash float-zone technique. The vacuum float-zone process is based on a semiquantitative purification technique for prediction of silicon bar resistivity after each float-zone pass. Purification is attained by multiple vacuum float zoning on lightly compensated silicon (<0.10 ppb boron). Impurity removal is achieved by a combination of zone refining and evaporation, with evaporation the dominant mode. Equations are derived which permit vacuum float-zone speeds to be determined quantitatively for resistivity targeting. The versatile production process is applicable to a broad product range of single-crystal material: 200-30,000 ohm-cm n-type and 2,000-30,000 ohm-cm p-type silicon.

Dislocation-free silicon crystals up to 1 in. in diameter and 20 in. in length with resistivities greater than 9000 ohm-cm p-type are being grown in our production float-zone facility as a source of wafers for photon detectors. One apparent way to produce high-resistivity silicon is by vacuum float zoning. This paper describes a successful vacuum float-zone technique

[1] Present address: Spectrolab, Division of Textron Inc., Sylmar, California 91342.

Key words: single-crystal silicon, production process, polydeposition process, polycrystalline silicon.

based on semiquantitative purification for prediction of silicon bar resistivity after each pass and presents additional information on purification rates of the impurity species. The versatile production process is applicable to a broad product range of single-crystal material: 200-30,000 ohm-cm n-type and 2,000-30,000 ohm-cm p-type silicon.

Theory

The concentration of impurity in a crystal, grown by the float-zone process, when both evaporation and segregation of impurity are occurring, is according to Ziegler (1)

$$\frac{C_f}{C_o} = \left(k - \frac{k}{u}\right) \exp \frac{-ux}{l} + \frac{k}{u} \quad [1]$$

where C_f is the impurity concentration in the solid, C_o the initial impurity concentration in the solid, k the segregation coefficient, x the distance solidified, l the zone length, and

$$u = k + \alpha \frac{l}{v} \quad [2]$$

where v is the growth rate and α is the evaporation time constant dependent on the impurity species. Assumptions of a cylindrically shaped zone, no diffusion in the solid, uniform concentration in the liquid, and constant k are made for Eq. [1] and [2].

It is also assumed that the molten zone is instantaneously formed initially. If the evaporation term, $\alpha(l/v)$, is zero, Eq. [1] reduces to Pfann's equation (2) for zone melting.

Bradshaw and Mlavsky (3) have derived the vacuum purification equations for normal freezing and give the proportional time constants E^{-1} for the evaporation of several different impurities. Their E^{-1} factor is related to α by

$$\alpha l = \frac{2E}{\rho} \quad [3]$$

where ρ is the specific density of the melt.

From Eq. [1] and [2], it is seen that the maximum purification that can occur for one pass is (k/u). For n passes the ultimate purification is $(k/u)^n$ at constant zone speed.

The theoretical purification profiles for individual species are given in Fig. 1. It is noticed that the flat portion of the (C_f/C_o) *vs.* (x/l) occurs after three effective zone lengths for all impurities except aluminum. Most aluminum initially present in the polysilicon will be quickly removed by liquid-solid purification (reduced by a minimum factor of 95% per pass). The presence of aluminum can be implied by a failure to reach a flat (C_f/C_o) *vs.* (x/l) curve after one vacuum pass at $x/l > 10$. The ultimate purification analysis to be given considers impurities for $x/l > 3$, but is valid for any impurity which has a flat portion of (C_f/C_o) *vs.* (x/l) curve.

From the knowledge of k and u (a function of α), one can in theory predict the purification rate required to attain any resistivity if the impurity species is known. However, in practice there are several factors that make the attainment of high-resistivity silicon (>3000 ohm-cm p-type) difficult. The first is that the starting p-level must be kept below 0.10 ppb to prevent compensation from becoming dominant. The second important factor is to identify and control the n-type impurities that are initially present in the vapor deposited polycrystalline rod.

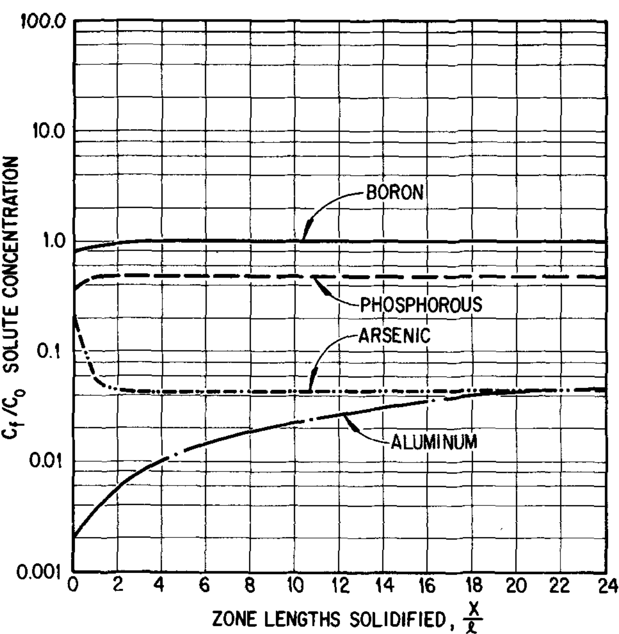

Fig. 1. Vacuum purification profiles for major impurities in silicon (pull rate, 3 in./hr).

Experimental

Polycrystalline deposition.—A material flow diagram for the process is given in Fig. 2. The flow diagram shows the starting point in the process with polycrystalline silicon, the various intermediate processing-testing operations, and the ending point for the high-resistivity silicon crystal which is sliced into wafers for device fabrication.

The polycrystalline silicon was produced from specially purified trichlorosilane, palladium-diffused, purified hydrogen with nondetectible impurities, and high-purity silicon filaments. The equipment was fabricated from materials of construction which were compatible with the hydrogen-chlorine-silicon system. In predeposition, the filaments were selectively etched to remove trace surface contamination. The polydeposition on the filament was next initiated from the pre-

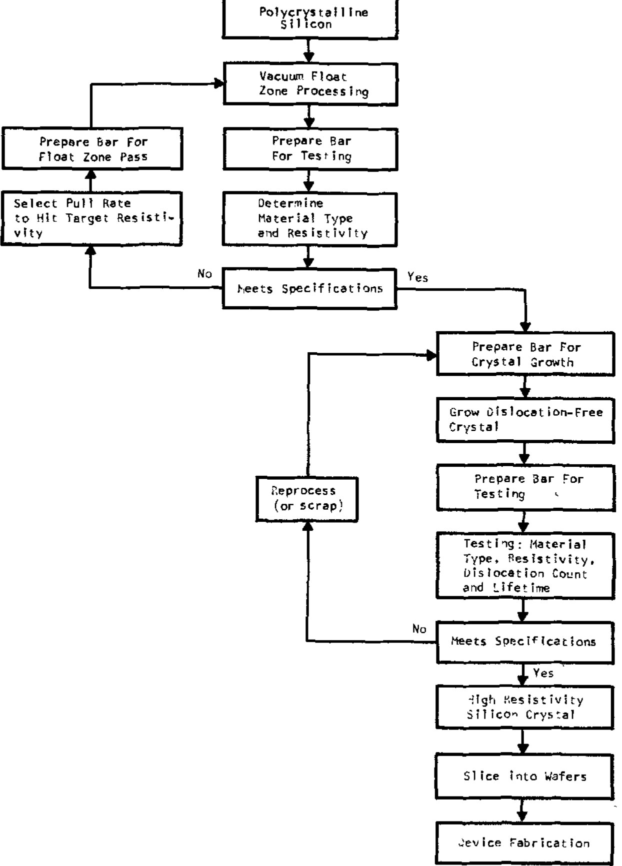

Fig. 2. Process flow diagram for high resistivity silicon

mium quality trichlorosilane and purified hydrogen. Deposition was continued until the rod of desired size (normally 1 to 1¼ in. diam) was attained. During deposition, process parameters such as reactant concentrations, deposition temperature, and various process temperatures were carefully monitored and controlled. By careful control of the process parameters, trace contamination from several sources such as gas phase components in the reactant feed and the process equipment was minimized. Polycrystalline silicon of very high quality with less than 0.1 ppb p-type impurity (boron) was produced.

Polycrystalline silicon was produced from two different reactors in the process. The initial reactor (single hairpin) produced rods in which arsenic was the major n-type impurity as determined by neutron activation analysis as well as data deduced from the rate of evaporation. The next reactor (double hairpin) produced rods in which phosphorus was the major n-type impurity.

Vacuum float-zone purification.—The polycrystalline silicon was purified in vacuum float-zone chambers which were specially designed and fabricated by Texas Instruments. The zone was held molten by use of a four-turn robber coil with one reverse turn. The effective molten zone length was determined to be 0.60 ± 0.06 in. The zone length was measured by two separate techniques. The first consisted of using a calibrated telescope to measure the length when purifying. The second method was by metallographic examination after purifying. Metallographic examination revealed that the solid-liquid interface was concave downward at the upper interface and concave upward at the bottom interface. Likewise, the assumed cylindrical portion was concave toward the center, but with an order of magnitude larger radius than the top and bottom portions. Simple calculation revealed that the total volume could be approximated by a cylinder with the diameter (95%) of the largest lateral dimension and the fill coming from the concave portions on the top and bottom. The effective zone length was then determined to be the length of this hypothetical cylinder.

The vacuum was attained with a Model 3103 turbomolecular pump, with a pumping speed of 260 liters/sec, manufactured by the Welch Scientific Company of Skokie, Illinois. This pump was selected primarily because of its unique design which minimizes backstreaming. The vacuum pressure of approximately 2×10^{-4} Torr during zone melting was monitored by Norton gauges (Models 507 and 831). The pull rate of the zoner was controlled by a Leeds and Northrup Electromax II. A Trendrack recorder equipped with a digital output display was utilized to preset or change pull rate during vacuum float zoning.

Concentration of impurities.—The initial concentrations of the n- and p-type impurities were essentially the same in each polycrystalline rod produced by vapor deposition in a given reactor.

The concentration of total impurities was experimentally determined in a control rod by the procedure described below. The initial step was to make one float-zone pass in argon to find the net n-type level. Next, the control rod was vacuum purified five or six passes at a slow pull rate (3 in./hr) to insure impurity removal. The resistivity was then plotted *vs.* zone length for each pass. When there is no further change in resistivity after a subsequent vacuum float-zone pass, the existing resistivity is due to the concentration of the p-type impurity (boron) level in the silicon bar. The concentration of the n-type impurity is then determined from knowledge of the net n-type and the total p-type level.

In silicon, the usual p-type impurities are aluminum and boron. The relative amounts of boron and aluminum can be approximated in several ways. After the control rod has had one or more vacuum passes to produce a flat resistivity profile (at $x/l > 3$ if boron is the principal impurity or at $x/l > 20$ if aluminum is the principal impurity), the rod is melted-in in this flat profile portion under inert atmosphere and a pass made to the end. From the shape of the x/l curve *vs.* resistivity an accurate approximation can now be made on the relative amounts of boron and aluminum by knowing the segregation coefficients. In the present work, boron was the predominant p-type impurity.

The n-type impurities can be determined from the change in concentration in the flat portion of the curve from vacuum passes one through six or seven. From the evaporation constants of the different species it is possible to determine the principal n-type impurity. In theory, neutron activation analysis can be employed to identify the n-type contaminants, but the evaporation technique is more amenable for production application. The prominent n-type impurities were determined to be arsenic and phosphorus.

A control rod was processed weekly to ensure that the contaminants did not appreciably change. The consistency in polyquality was accomplished by running the facilities continuously to minimize contamination.

Results and Discussion

Theoretical technique.—Typical results obtained from the purification of over 100 polycrystalline rods, each receiving multiple passes, are illustrated in Fig. 3. The purification chart was constructed by plotting log (total n-type impurity concentration) *vs.* time that a given section of the silicon rod was molten at each pass. The concentration of impurity plotted after vacuum float zoning was measured in that flat profile portion of the bar where $x/l > 3$ (see Fig. 1).

There are two curves plotted in Fig. 3. Curve A with the steeper slope is for polycrystalline silicon grown in the initial 2-bar (single hairpin) reactor. Curve B with the less steep slope in Fig. 3 is for polycrystalline silicon deposited in a subsequent 4-bar (double hairpin) reactor.

From data such as found in Fig. 3 estimates have been made of the evaporation constants of phosphorus and arsenic. The evaporation constant α_P for phosphorus is in general agreement with the value of Bradshaw and Mlavsky. The result is higher than Ziegler's, possibly arising from the float-zone rods here being four times larger than those used by Ziegler. For arsenic, our measured evaporation constant α_{As} is an order of magnitude less than that reported by Bradshaw and Mlavsky. A comparison of the experimental results is given in Table I.

Peizulaev (4) has derived equations describing evaporation and segregation for purification during

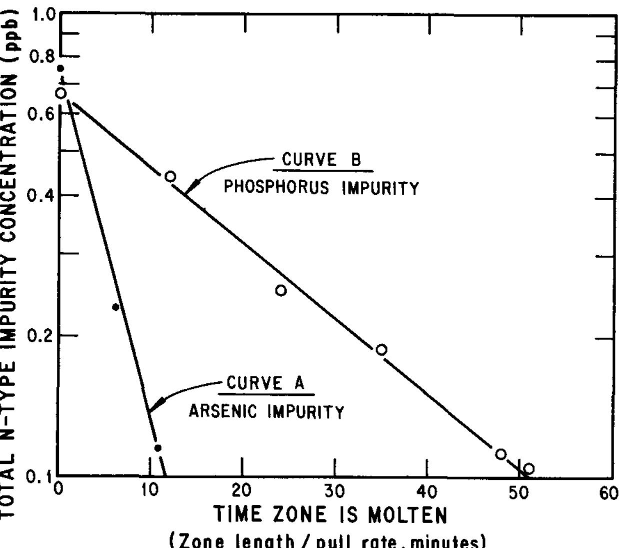

Fig. 3. Typical concentration vs. time plot showing n-type impurity removal.

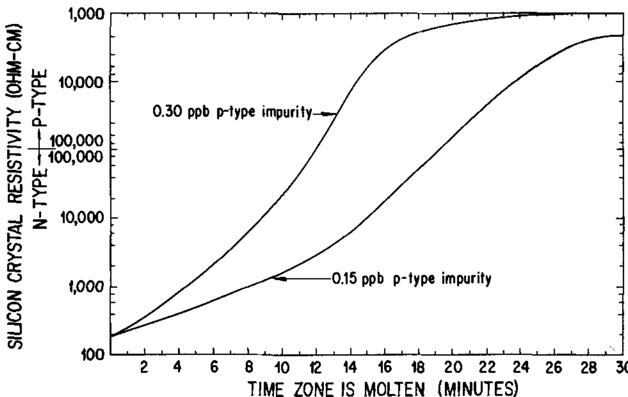

Fig. 4. Effect of p-type impurity on targeting resistivity. Both curves have same n-type contaminant.

multiple zone vacuum passes. His equations pertain to one solute component and may be extended to cover multiple solute components.

For example, to determine, n, the number of passes and the zone speeds required to attain resistivity X, analytical techniques can be employed. Assume that the polycrystalline silicon originally contains known amounts of phosphorus and arsenic as impurities. The resistivity is related to the concentration of these impurity components by the relation

$$\frac{1}{X} = (C_{As} + C_P)_n(e\mu_e) \qquad [4]$$

where C_{As} is the concentration of arsenic after n vacuum passes are made; C_P, the concentration of phosphorus after n vacuum passes are made; e, the charge of electron; μ_e, the mobility of electron; and n, the number of vacuum passes.

Table I. Evaporation constant α according to different investigations

Impurity species	Evaporation constant α		
	This work	Ziegler (1)	Bradshaw & Mivasky (3)
As	2×10^{-3}	—	1×10^{-2}
P	6×10^{-4}	7×10^{-3}	3×10^{-4}

The number of passes, n, required to obtain $1/X$ (Eq. [4]) can be analytically determined by the iterative process from the following equation

$$(C_{As} + C_P)_n = \left(\frac{k_{As}}{u_{As}}\right)^{n-1}\left(\frac{k_{As}}{u'_{As}}\right)C_{As}^{\circ} + \left(\frac{k_P}{u_P}\right)^{n-1}\left(\frac{k_P}{u'_P}\right)C_P^{\circ} \qquad [5]$$

where C_{As}° is the initial concentration of arsenic and, C_P° the initial concentration of phosphorus, u_{As} and u_P are applicable for float-zone passes up to $n - 1$ (defined by Eq. [2]), u'_{As} and u'_P are applicable for the last float-zone pass (nth pass) (defined by Eq. [2], u_{As} and u_P determine the constant pull rate up to the $n - 1$ pass, whereas u'_{As} and u'_P determine the variable pull rate required for the nth pass.

The technique to iterate Eq. [5] is given in the Appendix.

The experimental concentration *vs.* time profile for polycrystalline silicon containing both arsenic and

Fig. 5. High resistivity n-type silicon from semiempirical purification technique

phosphorus would lie between curves A and B in Fig. 3 and in general would not be a straight line. This relationship has often been experimentally observed for impurities in silicon. The above theoretical equations can be extended to cover three or more impurity constituents in the polycrystalline silicon.

The above calculations have neglected the effect of compensation. But, if known, then compensation can be directly entered in Eq. [4] by calculating the excess C_{As} and C_P required to attain a specific resistivity. The effect of p-type impurity in the starting material on purification is vividly illustrated in Fig. 4. For low-resistivity material, compensation is a minor effect. But as can be seen from the steep slope of the resistivity *vs.* time curve, for high-resistivity targeting, compensation is a highly damaging effect.

Semiempirical purification technique.—The semiempirical purification technique was found to be most valuable for the production of high-resistivity silicon in the process.

The purification technique is based on a knowledge of starting material quality (n- and p-type levels) and construction of a purification chart. The purification chart was constructed by plotting log (total n-type impurity concentration) *vs.* time the zone was held molten for the applicable section of the bar (flat profile section, $x/l > 3$). The time axis is determined by dividing the zone length by the pull rate. The material quality (n-type level) is plotted at time zero, after the first pass vacuum, and after each of the ensuing vacuum passes. After three or more points are experimentally determined, the general shape of the purification curve can be ascertained. It then becomes possible to semiquantitatively predict the resistivity of the silicon bar after the next vacuum pass. Or conversely, after several passes, it is possible to achieve the targeted resistivity by making the final vacuum pass at a predetermined pull rate based on the semiempirical purification chart.

Use of the technique to produce 5000 ohm-cm n-type silicon is illustrated in Fig. 5. The following data points for the material quality of a particular rod are initially plotted: *Start 0.52 ppb at $t = 0$; *Pass 1 0.30 ppb at $t = t_1 = 6$ min; *Pass 2 0.215 ppb at $t = t_1 + t_2 = 6 + 4.5 = 10.5$ min. The purification curve is then constructed through the data points and extended into the prediction region.

The purification curve is extended until it intercepts the target n-type resistivity line (horizontal line at 5000 ohm-cm). The intercept point occurs at that time required to achieve target resistivity material. Determination of the time (t_3) for the next pass (Pass 3) is made from the intercept point in the figure as follows

$$t_3 = 15 \text{ (from figure)} - (t_1 + t_2)$$
$$= 15 - 10.5$$
$$= 4.5 \text{ min}$$

Recalling that

$$t_3 = \frac{\text{zone length}}{\text{pull rate for Pass 3}}$$

and solving for pull rate

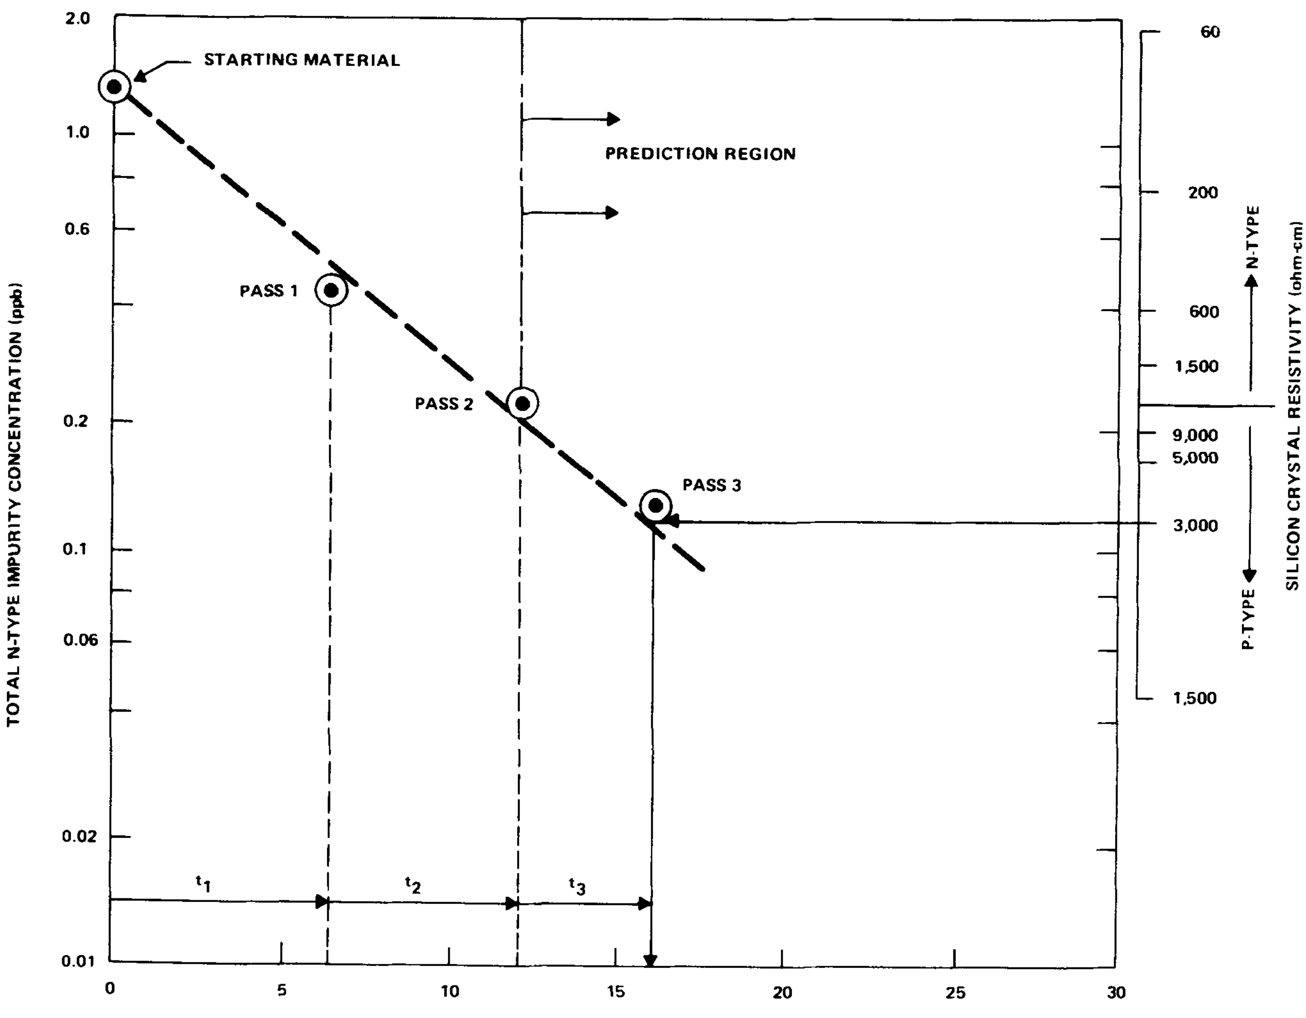

Fig. 6. High resistivity p-type silicon from semiempirical purification technique

Table II. Dislocation-free silicon crystals grown with vacuum float-zone process

Resistivity range (ohm-cm)	Type	Minority carrier lifetime range (μsec)	Quantity of crystals growth
10,000-30,000	p	500-10,000	>10
5,000-10,000	p	750-9,500	>10
2,000-5,000	p	750-7,500	>10
30,000-70,000	n	2,000-4,000	>5
10,000-30,000	n	1,500-6,000	>5
5,000-10,000	n	1,500-6,000	>5
2,000-5,000	n	1,500-6,000	>5
200-2,000	n	1,500-6,000	>5

$$\text{Pull rate for Pass 3} = \frac{\text{zone length}}{t_3} = \frac{0.6 \text{ in.}}{4.5 \text{ min}} = 8 \text{ in./hr}$$

Thus the pull rate for the next vacuum pass (Pass 3) is 8 in./hr to hit the target resistivity of 5000 ohm-cm, n-type material. The next vacuum pass was conducted at this pull rate. Material of 4800-5200 ohm-cm, n-type resistivity (average 5000) was obtained as shown by the data point for Pass 3 in the figure.

Application of the semiempirical purification technique for the production of high-resistivity p-type silicon (3000 ohm-cm) is illustrated in Fig. 6.

Following attainment of the target high-resistivity silicon (n- or p-type) through use of the semiempirical purification technique, dislocation-free single crystals were grown in an inert argon atmosphere. In general, the high resistivity did not change at this step of the process.

Large quantities of n- and p-type, high-resistivity, silicon single crystals were reproducibly prepared in the vacuum float-zone production process with the purification technique. The targeted resistivities varied from 2000-30,000 ohm-cm for p-type material and from 200 to 70,000 ohm-cm for n-type material. Minority carrier lifetime varied from 500-10,000 μsec for p-type and 1500-6000 μsec for n-type. Crystal orientation was <111>.

Resistivities and lifetimes for dislocation-free silicon crystals produced by the process are summarized in Table II.

Summary and Conclusions

The preparation of ultra high-resistivity silicon single crystals was attained in the vacuum float-zone process. The versatile production process is applicable to a broad product range of single-crystal material: 200-30,000 ohm-cm n-type and 2000-30,000 ohm-cm p-type silicon.

A semiempirical purification technique was successfully used in the process to produce the high-resistivity silicon. With the technique, it is possible to semiquantitatively predict silicon bar resistivity after each float-zone pass. Or conversely, after several passes, it is possible to achieve the target resistivity by making the final vacuum pass at a predetermined pull rate.

Theoretical equations which encompass impurity removal by a combination of zone refining and evaporation are presented for the determination of vacuum float-zone speed to attain target high resistivity. The equations are applicable for silicon with single or multicomponent impurities.

Evaporation coefficients, calculated from the data, for phosphorus and arsenic are reported.

APPENDIX

Method for Solving Number of Passes and Zone Speed

$$(C_{As} + C_P)_n = \left(\frac{k_{As}}{u_{As}}\right)^{n-1}\left(\frac{k_{As}}{u'_{As}}\right)C_{As}^{\circ} + \left(\frac{k_P}{u_P}\right)^{n-1}\left(\frac{k_P}{u'_P}\right)C_P^{\circ} \quad [5]$$

First assume a constant pull rate and calculate u_{As} and u_P from Eq. [2]. Next let $n = 1$, assume for calculation purposes $u_{As} = u'_{As}$ and $u_P = u'_P$ and apply these values to Eq. [5]. If the right-hand side of Eq. [5] is greater than the left-hand side, assume $n = 2$, $u_{As} = u'_{As}$, and $u_P = u'_P$ and recalculate. Whenever the right-hand side becomes less than the left-hand side for positive integral value of n assuming $u_{As} = u'_{As}$ and $u_P = u'_P$ the value of n is then determined. Once n has been determined, the final pull rate required to define u'_{As} and u'_P can be calculated to satisfy Eq. [5].

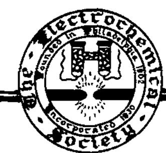
Technical Notes



Formation of Silicon Whiskers by Aluminum-Quartz Interaction

P. Rai-Choudhury* and W. J. Takei

Westinghouse Research Laboratories, Pittsburgh, Pennsylvania 15235

Aluminum diffusion in silicon is normally carried out in a sealed quartz tube under vacuum using elemental aluminum as the dopant source (1). For deep junctions, diffusion temperatures as high as 1200°C are often used. When large diameter wafers (~50-75 mm) are processed at such high temperatures it becomes necessary to back fill the quartz tube with a suitable gas which prevents the tube from collapsing. Back filling with argon consistently results in a nonuniform diffusion with very low surface concentration. If the sealed tube is maintained relatively free from moisture and oxygen, then the source Al remains uncoated with Al_2O_3, and an equilibrium Al vapor pressure is maintained throughout the diffusion time. Under these conditions, silicon whiskers grow from the walls of the Al_2O_3 crucible containing the Al melt. The purpose of this note is to discuss the thermodynamic and kinetic factors which favor the growth of silicon whiskers.

Experimental Results

Under vacuum conditions ($p_{Al} \approx 3 \times 10^{-4}$ mm) the evaporated Al molecules leaving the Al_2O_3 crucible could travel considerable distances without undergoing any collisions. The mean free path of Al is of the order of 180 cm, which, being considerably larger than the diameter of any quartz tube normally used for the diffusion, most collisions occur at the tube wall. An x-ray diffraction analysis of the deposits from the quartz wall indicates that the wall is coated with a mixture of silicon and aluminum oxide. When the entire surface of the quartz is coated with Si and Al_2O_3, the interaction between the Al and SiO_2 ceases, and the equilibrium Al vapor pressure present acts only as the diffusion source.

When the quartz tube is filled with argon to provide about one atmosphere pressure at the diffusion temperature, the mean free path of the evaporated Al molecules is reduced to about 1 μm. Thus, the Al molecules suffer numerous collisions in the gas phase and with the Al_2O_3 crucible walls. Interaction with the quartz walls is only possible by Al transport through molecular diffusion. Assuming a sufficient partial pressure of SiO (see Discussion) in equilibrium with the quartz, silicon could be formed at the inner walls of the Al_2O_3 crucible by interacting with the Al vapor. Growth of numerous silicon whiskers nucleating at the inner walls of the crucible is observed as shown in Fig. 1.

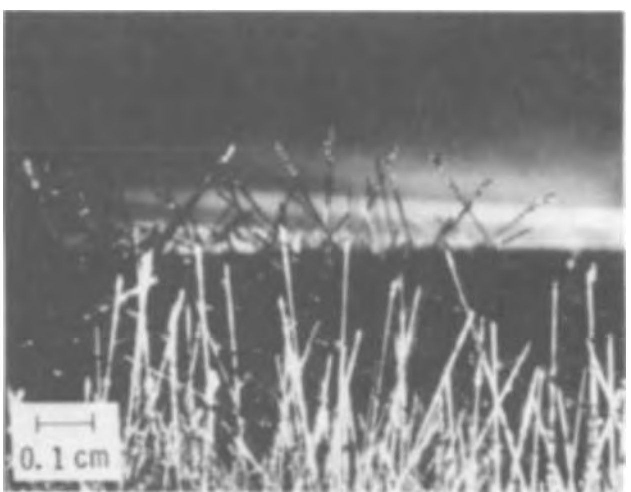


Fig. 1. Silicon whiskers growing from the inner walls of the alumina crucible at 1050°C in argon atmosphere.

The majority of the whiskers were 30-40 μm in diameter and approximately 1 cm long with trigonal faceting at the tip as shown in Fig. 2. Analysis by x-ray Weissenberg techniques showed that they had a [111] axis terminated by $\{11\bar{1}\}$ facets. This is in agreement with the orientation previously reported (2) for Si whiskers grown by other techniques. Other whiskers had approximately the same dimensions but with very rough sides, as shown in Fig. 3, and were found to be polycrystalline, giving a spotty ring x-ray pattern. This clearly shows that the development of whisker growth results, not from crystallographic orientation effects, but from the peculiar growth conditions found in this system. A few other whiskers had an appear-

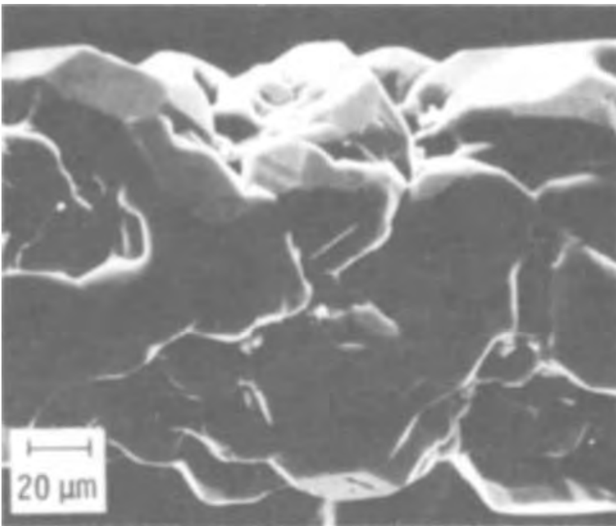

Fig. 3. The stem of a whisker showing rough growth of polycrystalline silicon.

ance different from those described and examination showed them to possess different growth axes. These were found to be, in decreasing order of occurrence, [112], *i.e.*, the same as Si dendrites and web, [113], and one whisker of [110]. This is not to imply that a more thorough examination may not have revealed other orientations but those that were found and their appearance are summarized in Table I.

Discussion

For the growth of silicon whiskers two factors need to be considered, namely, the transport of the reactants to the alumina crucible, and the reaction or reactions by which silicon is produced. Before silicon can be transported SiO_2 (*i.e.*, quartz) must be reduced to SiO. The thermal reduction of SiO_2 as represented by

$$SiO_2(s) = SiO(g) + \frac{1}{2}O_2(g)$$

has a reaction free energy of 105.496 kcal at 1400°K, and the equilibrium partial pressure of SiO is negligible. On the other hand, reaction with aluminum vapor

$$SiO_2(s) + 2Al(g) = SiO(g) + Al_2O(g)$$

has a standard free energy of −22.869 kcal at 1400°K, and is therefore a likely reaction by which SiO is produced.

Table I. Description of whiskers found, listed in order of their occurrence

Axis	Appearance	Cross section
[111]	Smooth and rough sides	Approximately equiaxed ~40 µm
Poly	Very rough sides	Equiaxed ~40 µm
[112]	Smooth	Thin rectangle 20 µm × 100µm
[113]	Smooth	Very flat rhombohedron 20 µm × 200 µm
[110]	Smooth tapering	Approximately equiaxed 50 µm × 50 µm

An examination of various reactions by which silicon whiskers could grow indicates the likely reaction to be

$$SiO(g) + 2Al(g) = Si(s) + Al_2O(g)$$

This reaction has a standard free energy of −75.874 kcal and has no solid reaction by-product. Although the reaction

$$3SiO(g) + 2Al(g) = 3Si(s) + Al_2O_3(\delta)$$

is thermodynamically favored ($\Delta F° = -207.227$ kcal) is probably not taking place, because no Al_2O_3 could be detected in the whiskers. Also the partial pressures of SiO and Al are probably too low for this reaction to proceed.

Summary

The physical conditions under which silicon whiskers can be grown by Al-SiO_2 interaction are described. The most probable reactions are the reduction of SiO_2 to SiO by Al vapor, and a further reduction of SiO to Si in regions of high Al activity. The practical implications of the Al-SiO_2 interaction are that, for successful diffusion of Al in silicon, either the quartz tube should be passivated (*e.g.*, coated with a layer of Al_2O_3 or silicon), or the oxygen activity reduced in the system.

The Effect of Silicon Wafer Imperfections on Minority Carrier Generation and Dielectric Breakdown in MOS Structures

C. M. Osburn* and D. W. Ormond*

IBM Thomas J. Watson Research Center, Yorktown Heights, New York 10598

A very large amount of work has been done to determine the effect of silicon wafer imperfections on device characteristics or yield (1-26). Although many individual studies (particularly recent ones) have successfully correlated device failure with substrate damage, considerable ambiguity remains in this area for several reasons. In the first place, processing induced damage effects (1-9, 13) often exceed those due to defects in the starting materials. Furthermore, device fabrication at high temperatures leads to thermal stresses whose effects are quite dependent on the initial

* Electrochemical Society Active Member.
Key words: silicon wafer damage, silicon etching, minority carrier generation, dielectric breakdown.

wafer condition [particularly the back side (2)]. Starting with zero dislocation density wafers gives no assurance of obtaining high device yields because float-zone silicon (~100/cm^2) has not generally been proven to be superior to (~10^3-10^4/cm^2) dislocation density Czochralski material (8). Metallic contaminants (especially those with states near the middle of the Si forbidden band) contribute to the ambiguity by promoting minority carrier generation and diode leakage. Such impurities (3-9, 11, 12, 14, 15, 17, 18, 24, 27) precipitate at locations of Si damage, vacancy clusters, or at oxygen inclusions. Gettering (15-17, 28-31) of metallic impurities reduces the minority carrier generation rate without lowering the defect concentration.

Although many questions are still unresolved, poor device performance has been repeatedly related to silicon imperfection sites. Chynoweth and Pearson (10) found that light was emitted at dislocation sites (as revealed by etching) during p-n junction breakdown. Queisser and Goetzberger (11) observed microplasma breakdown and soft p-n junctions at stacking faults. Soft junctions and diffusion pipes (or shorts) from emitter to collector have been associated with dislocation loops induced by processing (12, 13). Transmission electron micrographs (14) have found that stacking faults at the surface or in an epitaxial layer degrade junctions. Lawrence (5) attributed excessive recombination currents to lattice strain and dislocations as a result of impurity diffusion, and he distinguished between stable, unstable, and impurity-precipitated dislocations (9). High concentrations of stable dislocations had only minor effects on leakage, transistor gain, and storage time; unstable dislocations, *i.e.*, those that move during device fabrication, were somewhat more detrimental. Impurity precipitation caused large p-n junction reverse currents, emitter to collector shorts, and wide variations in transistor gain. Using scanning oscillator topography, Schwuttke has correlated yield with processing induced dislocations (3) and attributed poor MOS storage times to microsplits (19).

This study represents another attempt to interrelate silicon wafer damage with device properties. Metal-oxide-semiconductor capacitor structures were chosen as the test vehicle since only one high temperature step is required for fabrication and there are no oxide steps, diffusions, or photoresist operations which might serve to confuse the interpretation of the results. Some samples were gettered with HCl during oxidation in order to assess the influence of metallic impurities. Two different electrical measurements were made: minority carrier generation, which provides a measure of the number of generation centers in the region just below (~1μ) the Si surface, and dielectric breakdown of a thin (400Å) SiO_2 layer, which is very sensitive to oxide and silicon defects. Chemical etching or polishing (32-36) of as-received, chemically and mechanically polished silicon was used to reduce silicon damage to a minimum.

Experimental

The silicon wafers were 2 ohm-cm, n-type (phosphorus doped), <100> single crystal with only the front side polished by a silica gel, chemical-mechanical technique. A series of wafers having a cupric ion polish was also tested for comparison. Initial thicknesses of the 1¼ in. diameter wafers varied from 8 to 10 mils.

Wafers were cleaned both prior to etching and prior to oxidation in solutions of NH_4OH-H_2O_2, HCl-H_2O_2, and HF with a final deionized water rinse. Chemical etching was done with a mixture of nitric (70%), acetic, and hydrofluoric (49%) acids (24-28) in the ratio 7:2:1. The etch rate observed here was 11μ/min or about one-third that reported by Robbins and Schwartz (32, 33) in freshly sawed (and hence highly damaged) Si; apparently the etch rate is quite sensitive to damage. Etching times of 50 and 500 sec were standardly used to remove 5 and 47μ from each side of the wafer. Another etchant variation used here was a nitric acid to hydrofluoric acid mixture in a ratio of 250:1 ("reactive etch"). This solution dissolved 400-500Å Si/min and was used for total time of 5 min.

The clean, dry 1¼ in. wafers were placed polished side up in 2¾ in. ID Teflon cups. The cup was then filled with 60 ml of etchant and rotated (~60 rpm) while tilted about 40° from the horizontal plane. The rotational speed and the tilt angle were such that the wafer rotated as a wheel inside the cup, producing adequate shearing and mixing of the etchant layer in contact with the wafer (36). A sudden addition of 500 ml of conc. nitric acid (35) followed by 3 liters of deionized water was used to halt the etching process. This procedure was quite critical since uneven quenching resulted in swirl patterns or hazy residues on the surface. The nitric acid addition greatly diminished this problem.

Two ambients were used to grow the 400Å SiO_2 films at 1000°C: high purity oxygen and 97 volume per cent (v/o) O_2-3 v/o HCl (99.99% purity). To complete the MOS structures, one hundred 32 mil diameter aluminum electrodes were vacuum deposited through a mask onto each wafer using an electron beam heated source. The wafers were then annealed in nitrogen at 500°C for 5 min to remove interface states.

Dislocation densities were measured by counting Sirtl decorated etch pits (37, 38). This etchant is prepared by dissolving 100g chromium trioxide in 200g H_2O and mixing four parts of this acid with five parts hydrofluoric acid. Thirty milliliters of etchant were added to a clean wafer, placed in a rotating (60 rpm), 1⅞ in. Teflon cup tilted ~40° from the horizon. Etching time of 15 sec removed 1.5μ (average thickness) of Si to reveal surface damage.

Minority carrier generation was measured (30, 39-41) on fifty MOS capacitors per wafer. Basically, a depleting voltage pulse was applied and the time required to reach a steady-state inversion capacitance was recorded. Dielectric breakdown was measured by applying a ramp voltage to obtain the voltage of the first breakdown event for each capacitor. Care was taken to detect the first breakdown whether or not it was shorting or nonshorting (self-healing) since these events can be interpreted in terms of insulator defects (42). One hundred capacitors were measured on each wafer.

Results and Discussion

Wafer damage.—Chemical etching of silicon wafers was effective in reducing defect levels, as shown by the decrease in Sirtl etch mound density with etching time in Fig. 1. As can also be seen, a longer Sirtl etching time (300 *vs.* 15 sec) reveals a higher etch pit density. The photomicrographs in Fig. 2 show the improvement for both surfaces, when 5 and 47μ of Si are removed.

Silicon oxidation greatly increases damage, as can be seen by the photomicrographs in Fig. 3 obtained by growing a 2000Å SiO_2 film at 1000°C on previously etched wafers. Clearly, the amount of damage present after oxidation depends strongly on the degree of perfection of the unoxidized material. Dumin and Henry (2) have noted this earlier: *i.e.*, oxidation induced damage can be markedly reduced by starting with damage-free wafers. Furthermore, Porter *et al.* (26) were able to reduce oxidation induced damage by etching the starting wafers. Both sides of the wafer after oxidation had more nearly equal dislocation densities, suggesting that the back surface dominates the defect growth. It is unfortunate that the quality of the back surface has usually been relegated to secondary importance because the authors have almost invariably found that the backs of wafers, from a half dozen vendors, show visible saw marks and at least 10^5 Sirtl etch pits/cm^2. This point is demonstrated in Table I. It can also be seen that when the initial back side dislocation density is low, the etch pit density after

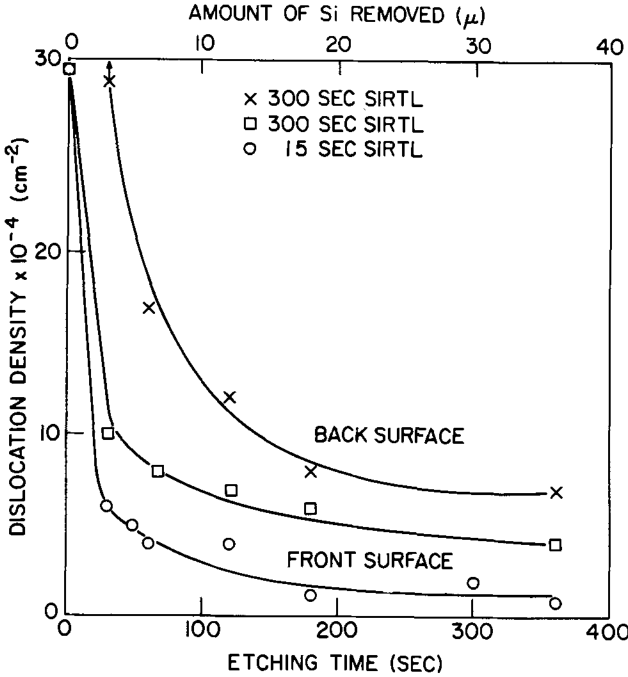

Fig. 1. Dislocation etch mound density for wafer front surface (○, □) and back surface (×) as a function of etching time in HNO_3-HF-$NC_2H_3O_2$. Top scale gives amount of silicon removed from each wafer surface. Sirtl etching times of 15 or 300 sec were employed.

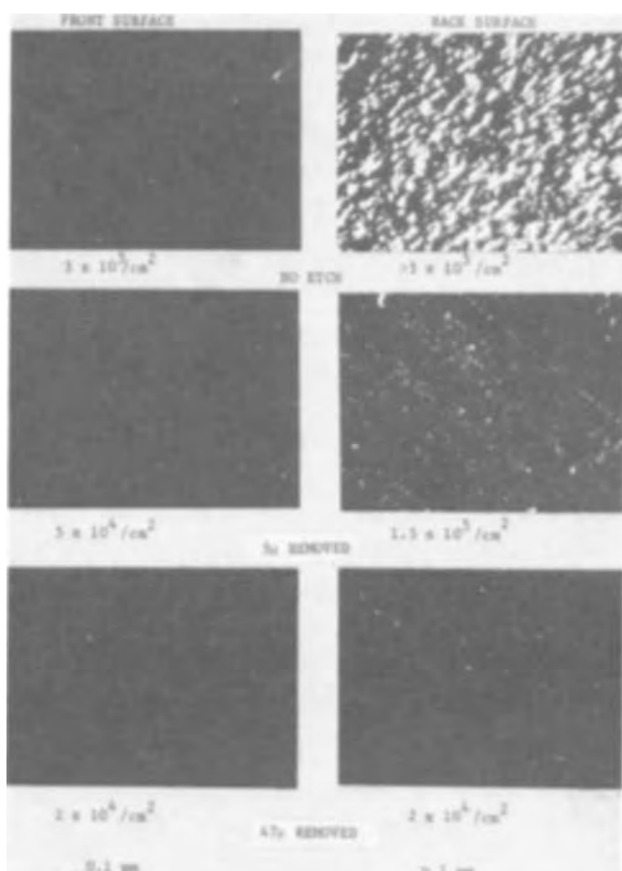

Fig. 2. Effect of silicon removal on wafer damage before oxidation. Wafers were Sirtl etched for 15 sec.

oxidation is also low. Likewise the advantage of using low dislocation density float-zone wafers having heavily damaged back surfaces is eliminated during the oxidation step.

In addition to higher pit counts, the oxidized wafers also show line defects (see Fig. 3, unetched front

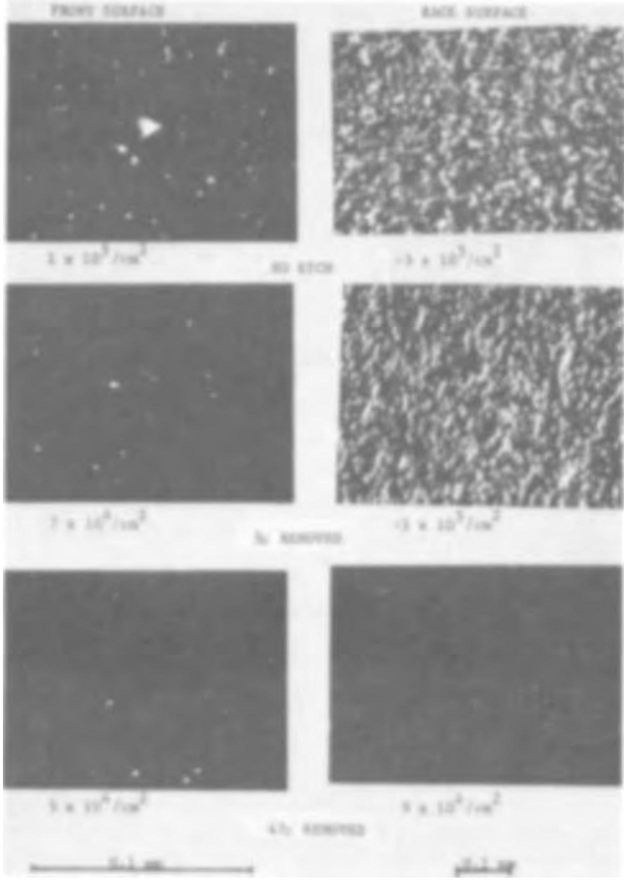

Fig. 3. Effect of silicon removal on wafer damage after oxidation. Wafers were Sirtl etched for 15 sec.

surface). These line defects, in the <110> direction, can be up to 10μ long and generally terminate at dislocations which appear as large bright spots under dark field illumination after Sirtl etching; the dislocation pair is often visible while the line defect cannot be seen. Schwuttke (19) interprets similar line defects in the <110> direction as microsplits with stacking faults at the end. Striation patterns are also revealed by 300 sec Sirtl etching of oxidized wafers. Pre-etching with HNO_3-HF-$HC_2H_3O_2$ had no effect on the striation pattern. Such patterns were not seen without oxidation and are another (1, 18) example of processing induced changes.

Electrical properties.—The results of pulsed capacitance measurements of minority carrier lifetime are summarized in Table II, where the average capacitance relaxation (or inversion) times are given as a function of processing conditions in four different runs. Schroder and Guldberg (41) have found that the relaxation time is directly proportional to minority carrier lifetime in the absence of significant surface generation. Each tabulated value represents the average of 300 capacitors on six wafers in three oxidation runs,

* Average standard deviation in parenthesis.

with the exception of the cupric ion polish Si in which 100 capacitors on one wafer were evaluated. Unfortunately, most of the time, the averages of the two identically processed wafers were not statistically identical at the 95% significance level. Chi-squared tests (41) on the statistical distributions of relaxation times further confirmed that more than half of the simultaneously and identically processed wafer pairs were not statistically equal, even at the 99% confidence level. This lack of reproducibility meant that subtle differences due to processing could not be resolved. The variability of the impurity content of the starting wafers presumably accounts for the poor wafer-to-wafer reproducibility. The standard deviation, σ (averaged over the three oxidation runs), is also included in Table II; no substantial variations were discerned.

Despite the serious reproducibility problem, the statistical inversion time distributions revealed several trends. Of the 3000 capacitors tested, those having the longest inversion times were invariably made with etched silicon. Inspection of Table II shows that in five cases out of six, Si etching enhances the relaxation time by 10-70%. It was also observed that the etched samples had a higher than average incidence of very short relaxation time capacitors, possibly as a result of residual surface haze from etching. Wafers having a cupric ion polish (run 4, Table II) showed a dramatic increase in lifetime after even a reactive etch, *e.g.*, more than a thousandfold with standard oxidation. In all cases, the cupric ion polished samples did not have as long a lifetime as did the silica gel polished samples (21, 31). Very likely the improvement seen in these reactively etched samples resulted from removal of a Cu contaminated layer rather than removal of Si imperfections.

Dielectric breakdown characteristics were more reproducible from wafer to wafer than were minority carrier lifetimes (see Table III). In wafers receiving a control oxidation, Si etching rather consistently improved average breakdown strength. It should be emphasized that each entry represents data from 700 capacitors and hence has a very small statistical error. Oxidation in HCl, on the other hand, was seen to degrade reactively etched specimens and to obscure any effect of 50 or 500 sec of etching. The spread of the statistical distribution, as measured by the standard deviation, was not influenced by etching.

The data base generated by these experiments was sufficient to attempt a correlation between minority carrier generation and dielectric breakdown. Both properties were measured on 50 capacitors on a wafer

Table III. Average dielectric breakdown field in the oxide as a function of processing (MV/cm)

	Control	0.25μ Si removed	5μ Si removed	47μ Si removed
Control oxidation	7.3 (0.16)*	7.7 (0.12)	8.1 (0.10)	8.5 (0.11)
HCl oxidation	8.7 (0.12)	6.4 (0.14)	8.5 (0.25)	8.8 (0.09)

* Average standard deviation in parenthesis.

and the correlation coefficient (43) computed; ten wafers were thus tested. Indeed some wafers did show a high correlation (up to 0.25), but other wafers had a negative coefficient. The average correlation coefficient was about +0.05 while its standard deviation was 0.10. Hence it must be concluded that any relationship between the two properties is very tenuous. Minority carrier generation is a property of the silicon, while dielectric breakdown is a property of the silicon dioxide film.

Summary

Chemical etching of silicon using the HNO_3-HF-$HC_2H_3O_2$ etchant system was found to reduce the density of silicon defects, as revealed by Sirtl etching. Improvements were seen with removal of over 50μ per side. Thermal oxidation increased the defect density, making the front and back surfaces more alike. The amount of oxidation induced damage depended on the quality of the starting wafer. The wafer back surface was judged to be particularly important since it contained most of the damage. Sirtl etching of oxidized wafers revealed striation patterns that were not visible before oxidation.

Pulsed capacitance, minority carrier generation measurements showed that removal of 0.25, 5, and 47μ of damaged silicon extended the high lifetime end of the statistical distribution and also slightly increased the average lifetime. Wafer-to-wafer reproducibility was exceedingly difficult to attain, presumably because the impurity content of the starting wafers was uncontrolled. On the other hand, Si etching also degraded the lifetime of other samples; this degradation may be attributed to etching residue contaminants. Wafers polished with cupric ions improved dramatically with even a 2500Å Si etch, probably due to removal of residual copper. Etching of the underlying silicon increased the average dielectric breakdown strength of SiO_2 films by as much as 16% when the oxide was grown in pure O_2. Oxide growth in HCl + O_2 lowered the breakdown strength of oxide over lightly etched Si, and longer etches did not result in any improvement.

Acknowledgments

The authors are indebted to E. Alley for painstaking measurements of the capacitance relaxation time and also etch pit densities. The careful manuscript review of J. Eldridge is greatly appreciated. They are also grateful for many helpful discussions during the course of this work to Y. J. van der Meulen, C. E. Hallas, Jr., and C. Hauerwas.

In Situ Monitoring of Film Deposition Using He-Ne Laser System

I. Measurements of CVD Insulating Film at 6328Å

Katsuro Sugawara,* Takeo Yoshimi, Hiroaki Okuyama, and Tatsumi Shirasu

Semiconductor and Integrated Circuits Division, Hitachi, Limited, Kodaira, Tokyo, Japan

Chemical vapor deposition (CVD) technology for semiconductor device fabrication has been widely applied to the formation of semiconductor film and insulating films. For these applications, uniformity of both the film thickness and film composition is required to decrease variations of electrical characteristics and to increase the capability of fine photoetching. Consequently, the method of "in-process" monitoring has been strongly in demand. Dumin (1) first devised a technique for "in-process" monitoring of the thickness of heteroepitaxial silicon film grown on sapphire (SOS), utilizing the interference caused by infrared emission radiated from the substrate. This method was subsequently developed into an *in situ* thickness monitor for polycrystalline silicon deposition on SiO_2-Si substrates by Kamins and Dell'Oca (2) and for alumina deposition by Roberts, Clark, and Dumbri (3). Another method, using an illuminator and a photocell with a filter and a polarizer, was reported by Davidse and Maissel (4) for monitoring the thickness of sputtered SiO_2 films.

To increase control accuracy caused by a coherent single beam and to detect thickness variations even at small, localized spots, a new monitor of CVD film thickness using a laser system was devised. In this paper the experimental method and the results are presented.

Figure 1 shows the layout of the monitoring system using the visible 6328Å He-Ne laser during CVD SiO_2 deposition. A vertical reactor was of the rf heated type with a SiC-coated graphite susceptor. In this reactor, CVD SiO_2 films produced by the SiH_4-O_2 system were deposited on three different substrates—silicon wafers, thermally grown SiO_2 films formed on silicon substrates, and aluminum films evaporated on silicon. During deposition, the He-Ne laser beam, (wavelength 6328Å, ouput power 1 mW, and diameter of beam spot 1 mm) was directed onto the specimens from outside of a quartz reactor chamber of 250 mm inner diameter. As the film was deposited on the substrate, the laser beam was partially reflected at the surface of the deposited SiO_2 film and partially at the interface between the CVD SiO_2 and the silicon substrate, after being transmitted through the CVD SiO_2. These reflected beams were received by a selenium photocell (maximum sensitivity: 6000Å in wavelength), amplified, and recorded as an interference wave. Since this wave corresponds to the film thickness, the thickness

Table I. Standard deposition condition of CVD SiO_2 and PSG films

Condition		CVD SiO_2
Flow rate	SiH_4	56 cm^3/min
	O_2	1120 cm^3/min
	N_2	20 liters/min
Deposition temperature		450°C

can be determined from the obtained pattern while the film is being subjected to deposit. The standard deposition condition was tabulated as listed in Table I. After deposition, the SiO_2 films were partially removed by etching and the film thickness was measured with a "Talystep."

Figure 2 shows the relation between reaction time and reflective intensity, when the CVD SiO_2 film was deposited on the silicon substrate. The axis of abscissa reveals both reaction time and film thickness measured by the "Talystep;" one cycle of the interference wave is approximately 2900Å. In this figure, the solid line (a) is an observed value and the line of dashes (b) represents the calculated value (5) where the refractive index is taken as 1.44, determined by an ellipsometer. The calculated pattern (b), when 1.44 was used, approximately coincides with the experimental pattern.

When the CVD films were deposited on the silicon substrate, thermally grown SiO_2, and aluminum film, each interference pattern is drawn on the same chart in Fig. 3. The pattern observed on the silicon substrate is similar to that on the thermally grown SiO_2, but the pattern on the evaporated aluminum differs from these two. It is considered that this fact was effected by the large extinction coefficient of aluminum, 6.6 at 6500Å in wavelength (6).

The result is reported on applying the visible He-Ne laser to Si_3N_4 film formation. The Si_3N_4 film was deposited at 800°C and NH_3/SiH_4 = 18, in the SiH_4-NH_3-N_2 system, the latter parameter was adapted to prevent the formation of excess silicon (7). The interference patterns are shown in Fig. 4, depositing on the oxidized silicon substrate with 1.0 μm thickness. As is evident in Fig. 4, the observed curve (a) practically coincides with the calculated one (b), applied as 2.0 in the refractive index of Si_3N_4 film (8). The curve (c) shows the obtained one by the infrared radiation system. The laser system is superior in control accuracy; the thickness of one cycle in the interference wave is 1500Å for monitoring by the laser system, while 3200Å for the infrared radiation.

Precise control of CVD film thickness has been required from the standpoints of stable electric properties and accurate photoetching. As one of the countermeasures to meet these demands, a new monitoring method by applying the laser system was devised. This

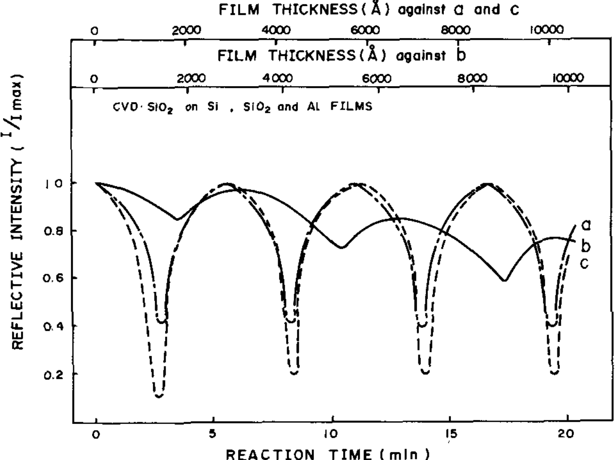

Fig. 3. Observed patterns of interference during CVD SiO_2 deposition on various substrates. a, On silicon substrate. b, On aluminum film evaporated on a silicon substrate. Thickness of aluminum film, 1 μm. c, On thermally grown SiO_2 film formed on silicon substrate. Thickness of thermally grown SiO_2, 9000Å.

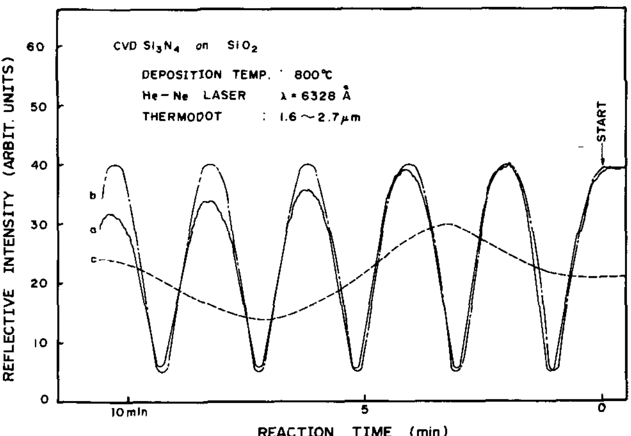

Fig. 4. Observed patterns of interference when CVD Si_3N_4 film was formed on thermally oxidized silicon wafer. Thickness of SiO_2 film, 1.0 μm. a, Observed pattern by visible He-Ne laser system. b, Calculated pattern as n = 2.0 by laser system. c, Observed pattern by infrared radiation system.

method has several merits: it is precise even at small spots and is widely applicable even to low temperature deposition. The He-Ne visible laser of 6328Å wavelength was adapted for monitoring of insulating films. For CVD SiO_2 film, one cycle of the interference wave was 2900Å; control accuracy was ±100Å at the minima, ±250Å at the maxima, and ±200Å at the remaining parts of the interference patterns. Tendency of the deposition rates of PSG (phosphosilicate glass) films in relation to $O_2/SiH_4 + PH_3$ and $PH_3/SiH_4 + PH_3$ mole fractions during PSG film formation (9) was confirmed by this monitoring. For Si_3N_4 film in a higher temperature deposition, it is obvious upon comparing the laser and the infrared radiation system that the control accuracy of film thickness in the former system is improved three times, as a result of shorter wavelength of the laser beam.

Acknowledgments

The authors express their deep appreciation to Mr. S. Nishida for his helpful discussions and encouragement during this experiment, to Mr. T. Nohara for ellipsometric measurements, and to Mr. K. Akiba for assistance in fabrication of the experimental equipment.

In Situ Monitoring of Film Deposition Using He-Ne Laser System

II. Measurements of Polycrystalline Silicon Film in the Infrared

Katsuro Sugawara,* Takeo Yoshimi, and Hiroaki Okuyama

Semiconductor and Integrated Circuits Division, Hitachi, Limited, Kodaira, Tokyo, Japan

and Yoshio Homma

Central Research Laboratory, Hitachi, Limited, Kokubunji, Tokyo, Japan

In the previous paper (1), the monitoring method was reported applying a visible He-Ne laser for insulating films SiO_2 and Si_3N_4. Monitoring by the laser system was further developed, and a new method using an infrared He-Ne laser was attempted for polycrystalline silicon film. In this work, the monitoring system was compared with the infrared radiation method (2) and the effect of the deposition condition on monitoring by the laser system was investigated.

A schematic diagram of the monitoring apparatus is shown in Fig. 1. A vertical reactor was of the rf heated type with a SiC-coated graphite susceptor. In this reactor, polycrystalline silicon film was deposited on thermally grown SiO_2 films formed on silicon substrates by the SiH_4-N_2 and SiH_4-B_2H_6-N_2 systems. Standard thickness of the SiO_2 films was about 9000Å. The apparatus is similar to that used for CVD SiO_2 film formation (1) except for the laser and its detector. In this system, an infrared He-Ne laser (wavelength, 1.15 μm; output power, 3 mW; and diameter of beam spot, 1.4 mm) was adapted. The detector was a silicon solar cell with maximum sensitivity of 7700Å. Besides the laser system, a PbS infrared pyrometer (sensitive to radiation with wavelength between 1.6 and 2.7 μm) was positioned to detect interference caused by the abovementioned infrared radiation. Reading the wafer temperature with the infrared pyrometer, emissivity was corrected according to Allen's data (3). The standard deposition conditions are listed in Table I.

* Electrochemical Society Active Member.
Key words: polycrystalline silicon film, 1.15 μm He-Ne laser, infrared radiation, control of film thickness.

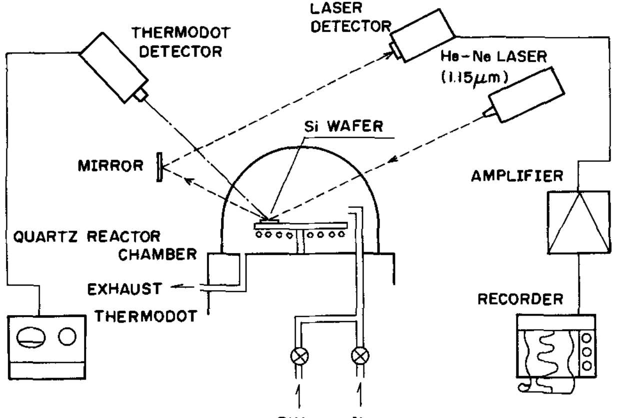

Fig. 1. Layout of monitoring apparatus using the infrared He-Ne laser with 1.15 μm during polycrystalline silicon deposition.

The visible He-Ne laser with 6328Å was tested for the deposition of polycrystalline silicon film. As is evident from Fig. 2, when thickness of the deposited film exceeded 4000Å, variation of the reflective intensity was difficult to recognize, because of absorption through the silicon film.

The infrared He-Ne laser beam with 1.5 μm is less absorbed in silicon than the 6328Å beam. The interference pattern obtained by the 1.15 μm beam is shown in Fig. 3. The solid line (a) represents the observed pattern by the laser system, appearing sharp and clear; while the chain line (c) shows interference produced by infrared radiation recorded by the infrared pyrometer. A large difference of film thickness between adjacent maxima, and weak interference can be seen in the interference pattern by the infrared radiation. In this figure, also recorded is the calculated pattern (b) (4), where 3.42, value of the refractive index for the single crystal silicon (5-6) was taken for that of the polycrystalline silicon. Coincidence between the observed (a) and the calculated (b) patterns was good.

Table I. Standard deposition conditions of polycrystalline silicon films without and with B_2H_6 doping

Conditions		Poly. Si without doping	Poly. Si with doping
Flow rate	SiH_4	56 cm³/min	56 cm³/min
	B_2H_6	—	0.5 cm³/min
	N_2	20 liters/min	20 liters/min
Deposition temperature		650°C	650°C

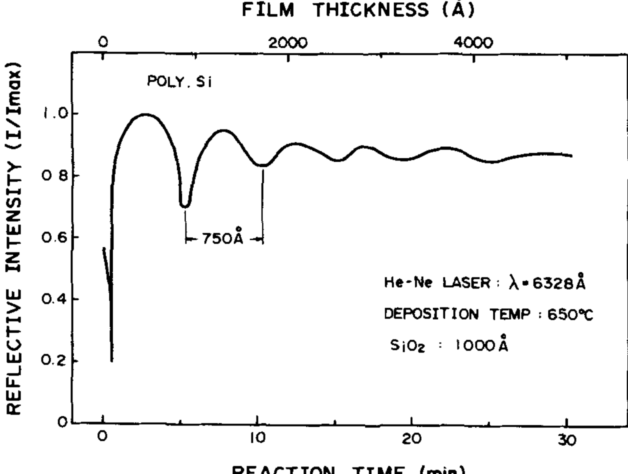

Fig. 2. Observed pattern of interference when the visible He-Ne laser with 6328Å was used during polycrystalline silicon deposition.

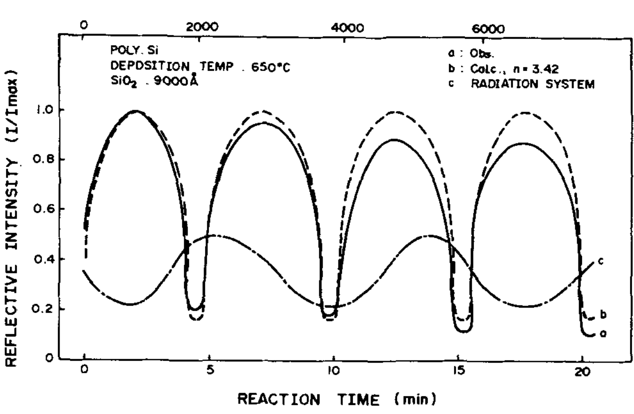

Fig. 3. Comparison between patterns of interference by the infrared laser system and by the infrared radiation system during polycrystalline film deposition. a, Observed pattern by infrared laser system. b, Calculated pattern with infrared laser monitoring as $n = 3.42$. c, Observed pattern by infrared radiation system.

Table II. Comparison between laser and infrared radiation systems

Method	Feature	Problem
Laser system	1. More accurate monitoring 2. Applicable even to low temp. deposition 3. Applicable to thin and thick film	1. Maintenance of alignment 2. Sensitivity and area of detector
Infrared radiation system	1. Simple in construction 2. Simple to apply	1. Inapplicable to low temp. deposition 2. Dispersion 3. Large infrared wavelength

Figure 4 shows the result of a rotating specimen on which the polycrystalline silicon film was deposited, initially without doping and subsequently with B_2H_6 doping of 0.5 cm^3/min at 650°C. From the moment of doping, the peak-to-peak distance in the interference pattern became shorter, causing an increase of the deposition rate to be noticed. B_2H_6 doping created an increase of the deposition rate while increasing the flow rate, as Eversteyn and his co-worker already pointed out (7). They observed a two-time increase when boron was introduced by more than an atomic fraction B/Si $= 0.0025$, and the result of this experiment shows approximately the same order; the deposition rates without and with B_2H_6 doping were 900 and 1500 Å/min, respectively.

Although the infrared radiation method is simple to apply, it presents problems of precision and minimum specimen temperature, dispersion of radiation beams, and intensity of infrared radiation; while the laser system can be accurately applied to more CVD reactions, based on the single wavelength and injection from outside of the reactor. This method, however, requires more mechanical accuracy for the CVD reactor mechanism—such as that of susceptor rotation—to prevent variations of laser beam reflection. Features and problems of both systems are compared in Table II.

For monitoring the thickness of polycrystalline silicon films, a new method using a He-Ne laser at 1.15 μm wavelength (much less absorbed than the visible He-Ne laser at 6328Å) was devised. For the infrared radiation system and the laser system, one cycle of the interference wave was 5900 and 3700Å, and control

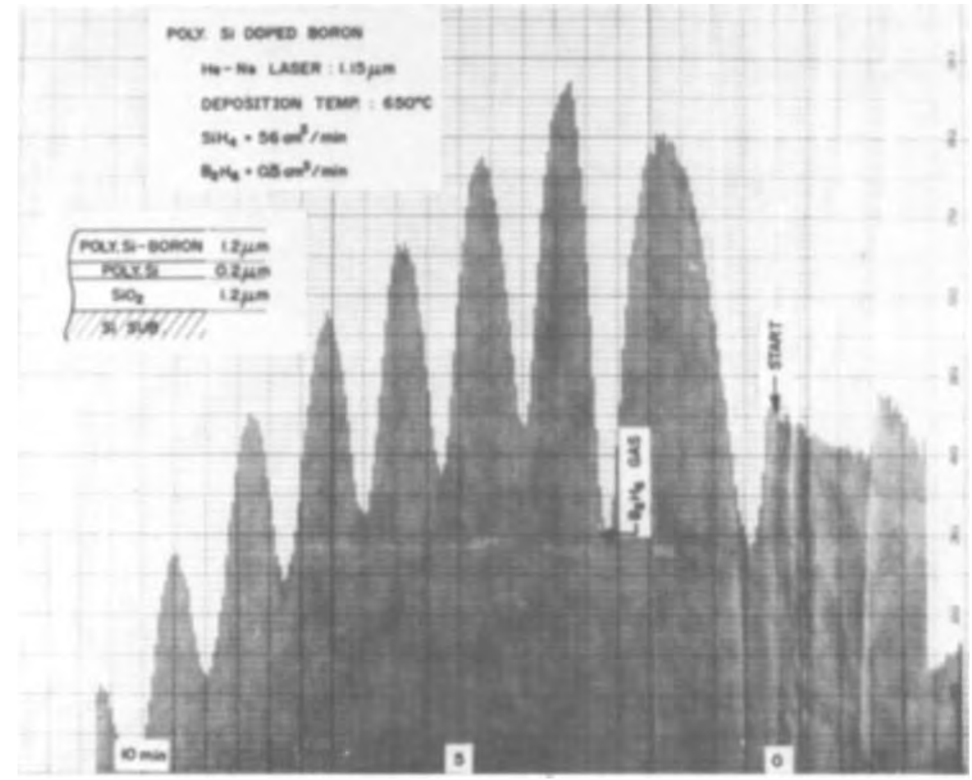

Fig. 4. Interference pattern by infrared laser beam during polycrystalline silicon deposition without and with B_2H_6 doping. At the beginning of deposition, the film was formed without doping, and after 3 min with B_2H_6 doping while the specimen was rotated on the susceptor.

accuracy was ± 400 and ± 200Å, respectively. Further, the influence of B_2H_6 doping was investigated and the deposition rate increment was determined by this monitoring.

Acknowledgment

Germanium-Doped GaAs for P-Type Ohmic Contacts

D. R. Ketchow

Bell Laboratories, Murray Hill, New Jersey 07974

Ohmic contacts to epitaxial p-type GaAs, such as those used on double heterostructure lasers, are usually fabricated by deposition of a metal layer on a Zn-diffused ($p \approx 10^{20}$ cm^{-3}) GaAs layer. Contact to the p-type layer without a Zn diffusion has not been feasible because the hole concentration in the layer was not sufficient for ohmic contact. Previous reports of Ge as a p-type dopant in GaAs used a method not applicable for multilayer growth (1, 2) or did not achieve the level of free carriers necessary for a nonalloyed ohmic contact without a zinc diffusion (3, 4). Carrier concentrations as high as 8×10^{19} cm^{-3} were attained in the work reported here. A nonalloyed ohmic contact, with resistance equal to that measured on layers having a Zn diffusion, was achieved without a Zn diffusion.

Single epitaxial GaAs layers were grown on <111> B and <100> oriented GaAs substrates. Cr-doped substrates were used for carrier concentration experiments. Zn-doped p-type ($p \approx 10^{18}$ cm^{-3}) substrates were used for contact resistance experiments. The Ge-doped single layers were grown in a graphite slider by the source-seed technique for LPE growth of GaAs-$Ga_{1-x}Al_xAs$ double heterostructures as described by Dawson (5).

Experimental

Hall measurements.—Hall measurements were done at room temperature in a magnetic field of 5250 Gauss. The results are shown in Table I. Duplication of sample numbers indicates that growth occurred simultaneously on two different substrates from the same Ga-Ge-As solution.

Key words: epitaxy, crystal growth, semiconductor.

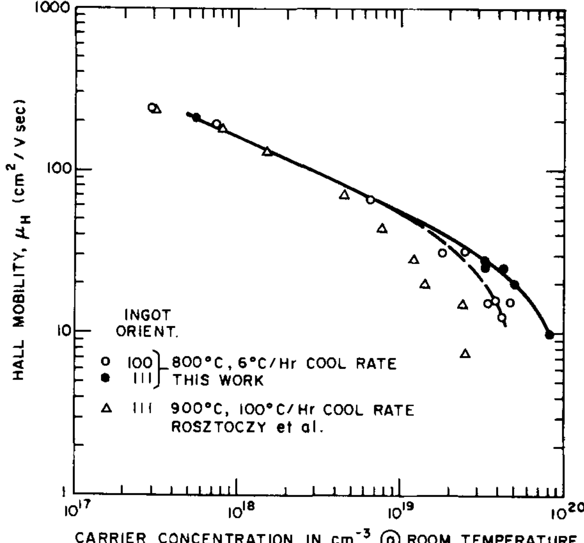

Fig. 2. Hall mobility *vs.* carrier concentration at room temperature.

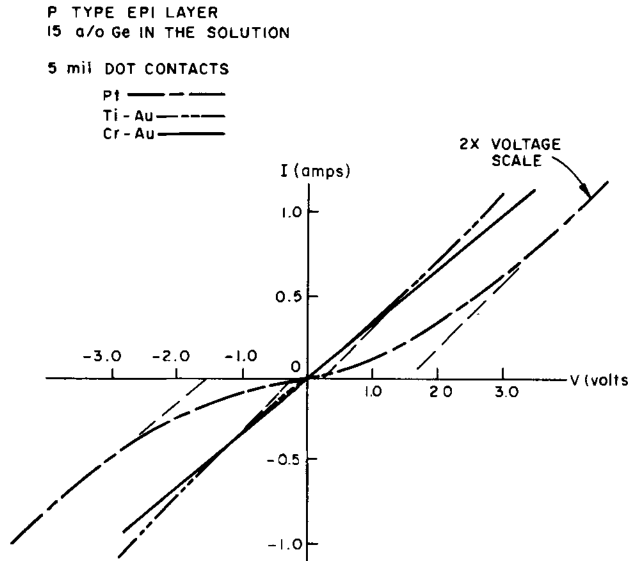

Fig. 3. Typical *I/V* curves of the contact resistance of three types of metal contacts to epi-layers grown from 15 a/o Ge concentration solutions.

tration in the grown layers. On the log-log scale the carrier concentration of layers grown on the <111> oriented substrates increases with a slope of one for growth solutions containing 0.2-44.5 atomic per cent (a/o) Ge. Included also are the data reported by Rosztoczy *et al.* (3, 4), on their work using only <111> oriented substrates. All of their data are lower than ours (<111> and <100>), and they have a departure from unit slope at ~4 a/o Ge ($p \approx 6.5 \times 10^{18}$ cm^{-3}) which we do not observe in our <111> data. The reason for their lower carrier concentration might be their higher average growth temperature (900°-875°C) which could result in lower Ge concentration in the layer and a lower hole concentration for the same Ge concentration. Comparing our data on <111> oriented substrates with that on our <100> substrates we find a departure from unit slope at ~6 a/o Ge ($p \approx 1 \times 10^{19}$ cm^{-3}) for the latter orientation.

Figure 2 is a plot of the room temperature Hall mobility *vs.* carrier concentration. The data for our <100> and <111> oriented substrates part agreement again at $p \approx 1 \times 10^{19}$ cm^{-3} with a decrease in the mobility data for the <100> oriented substrates. The higher mobility presented here indicates the layers grown at the lower temperatures are less compensated for the same carrier concentration than those grown by Rosztoczy *et al.* at the higher temperature.

Contact resistance measurements.—The contact resistance measurements were made across pairs of evaporated metal dots on the grown layers. As may be seen in Table II, the contacts were varied in size from 5 to 10 mils in diameter and were of 3 different metals: (*i*) 3000Å Pt, (*ii*) 300Å Cr-5000Å Au, and (*iii*) 250Å Ti-2400Å Au. They were not alloyed or sintered after evaporation. The a/o Ge concentration in the solutions used to grow the layer ranged from 1.0 a/o ($p \approx 2.3 \times 10^{18}$ cm^{-3}) to 44.5 a/o ($p \approx 8.2 \times 10^{19}$ cm^{-3}). Layers with the lower Ge concentrations did not show ohmic behavior. Pt contacts to these layers exhibited blocking voltages three to four times higher than the Cr-Au or the Ti-Au contacts. At 15 a/o Ge concentration in the solution ($p \approx 2.49 \times 10^{18}$ cm^{-3}) the Pt contracts showed an average of 0.6V blocking voltage while the Ti-Au contacts averaged 0.13V blocking voltage. The Cr-Au contacts showed no blocking voltages on layers grown at this Ge concentration in the solution nor did they show any on layers grown from higher Ge concentration solutions. Figure 3 shows typical *I vs. V* curves of the three different types of contacts made to layers grown from the 15 a/o Ge solutions. The voltage scale for the Pt contact has been compressed in order for it to fit on the scale of the figure.

The higher Ge concentration samples were used to determine the contact resistance of the grown layers with and without a Zn-diffusion. The three samples were each cleaved into two parts. One part of each was zinc diffused prior to the evaporation of Cr-Au contacts

on both parts as one unit. There was no significant difference in the contact resistance between the parts to indicate the presence or absence of the zinc diffusion. These results have been confirmed in measurements made on double heterostructure lasers.

Conclusions

The work presented here shows ohmic contact can be made to p-type Ge-doped layers with carrier concentrations of 4-8 $\times$ 10^{19} cm^{-3} without a diffused zinc contact layer. The carrier concentration varies linearly with the amount of Ge in the solution used to grow the layers at 800°-790°C. A comparison of the contact resistance of these layers with and without a zinc diffusion showed little or no difference. The zinc diffusion, therefore, was not the major factor in achieving good ohmic contact. A comparison between types of metal contacts showed the metal species are a factor in achieving good contact. The three types of contacts, Ti-Au, Cr-Au, and Pt used in these comparisons were not alloyed. They were selected because of their availability. No intensive work was done to search for or develop a low contact metal. The Pt contacts showed three times as much resistance and displayed as much as one volt greater blocking voltage than the Ti-Au or Cr-Au contacts. The origin of this discrepancy was not investigated.

Acknowledgments

Acknowledgment is made to F. Ermanis for some of the Hall effect measurements, G. Barnosky and his co-workers for their patience and skill in evaporating the metal contacts, R. H. Peaker for the use of the pulsed I/V equipment and his cheerful assistance in measuring the contact resistance, and L. R. Dawson and D. L. Rode for their helpful discussions.

The Vapor Pressure of Solid Aluminum Bromide

K. G. P. Sulzmann

Department of Applied Mechanics and Engineering Sciences and Institute for Pure and Applied Physical Sciences, University of California, San Diego, La Jolla, California 92037

Vapor pressure measurements for aluminum bromide have been performed in the past by Fischer *et al.* (1) only for the phase equilibrium between the liquid and the vapor at temperatures between about 390° and 523°K. These investigators have shown that the vapor is a dimer of the form $(AlBr_3)_2$ for which the degree of dissociation is less than 1% even at the boiling point near 536°K. They also established the heat of fusion at the melting point so that Kelley (2) was able to deduce theoretical data for the phase equilibrium between the solid and the vapor. Over the temperature range between about 320° and 355°K, these data can be fitted by the expression

$$[\log_{10} p(\text{mm Hg})]_{\text{th}} = -4651.16°\text{K}/T + 13.13674 \quad [1]$$

which corresponds to a heat of vaporization for the solid of $\Delta H = 21.270$ kcal/mole. In the course of absolute infrared band-intensity measurements on AlO produced by shock-heating trace amounts of $(AlBr_3)_2$ in argon-oxygen mixtures, we required accurate vapor pressure data between about 315° and 330°K. Therefore, we have made measurements on the purified solid bromide at temperatures between 300° and 335°K, which allowed us to verify the theoretically deduced data.

Experimental Procedure

The equilibrium vapor pressure of $(AlBr_3)_2$ was measured by using a precision capacitance micromanometer (MKS Baratron gauge, Type 145AHS-10) which has a minimum resolution of 1 $\times$ 10^{-4} Torr and a measurement error of less than $\pm$ 0.5% of the pressure reading for the pressure range of interest. The gauge was connected to a glass sample reservoir and to a high vacuum pumping station by an all glass system. Backstreaming of diffusion-pump oil was prevented by a glass trap at liquid nitrogen temperature, which was separated from the system during pressure measurements in order to avoid condensation of the aluminum bromide vapor. The entire measurement apparatus was kept at a temperature above the condensation temperature of the bromide by heating tapes. The system was evacuated routinely to pressures below about 5 $\times$ 10^{-6} Torr at a leak rate of less than 10^{-6} Torr/min which was achieved by prolonged outgassing procedures and was adequate for our purposes. The gauge was kept at a regulated temperature of about 49°C for measurements at temperatures of up to about 45°C of the sample reservoir, and at a nonregulated temperature of about 71°C for measurements between about 48° and 62°C. The entire system was outgassed after each measurement by heating the gauge to 71°C and by vacuum pumping with the remainder of the measurement portion of the system above about 75°C.

The aluminum bromide used for the vapor pressure measurements was obtained by purifying certified anhydrous samples of an assayed purity of better than 99.98% (Fischer Scientific Corporation). The test sample was pulverized and transferred into the sample reservoir in a dry nitrogen environment in order to prevent oxidation by atmospheric oxygen and water vapor. The measurement apparatus was evacuated, filled and flushed with dry nitrogen before introducing about 20 cm^3 of bromide powder. After filling, the glass reservoir was closed by melting off its filling stud, leaving only one glass stopcock in the system when the diffusion pump with its associated liquid nitrogen trap was separate from the measurement portion of the arrangement. A separate and removable liquid nitrogen glass-trap at the pump-side of the glass valve was used for condensing the aluminum bromide vapors generated while fractionally distilling to waste portions of the sample for further purification. Decomposition of the bromide sample by photon absorption was

Key words: aluminum bromide, vapor pressure.

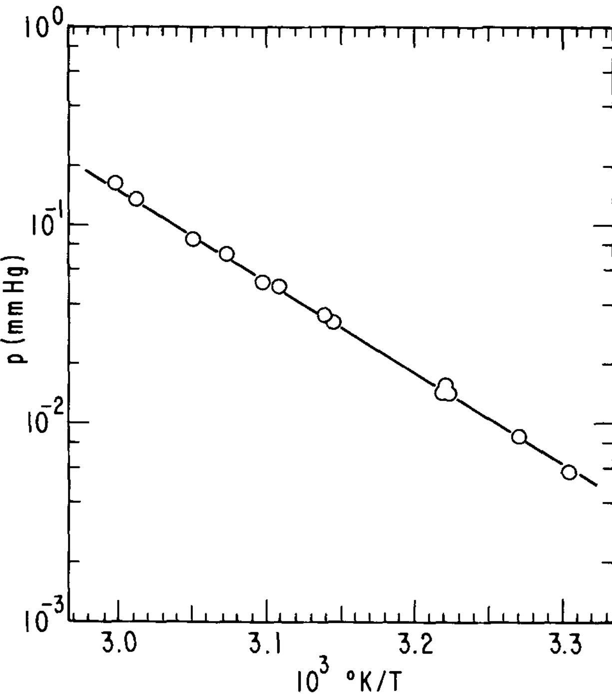

Fig. 1. Measured vapor pressure of $(AlBr_3)_2$ for the solid-vapor phase equilibrium (⨀). Least squares fit to the experimental data (———).

avoided by shielding the entire apparatus against room light.

After filling and sealing the sample reservoir, the bromide was brought to liquid nitrogen temperature and the whole system was evacuated to pressures of less than 5×10^{-6} Torr. Then the sample was heated to about 75°C and partly distilled to waste into a separate liquid nitrogen trap by vacuum pumping for at least 2 hr at pressures of less than about 10^{-5} Torr. After purification, the sample was cooled in a water bath to 0°C, and the system was evacuated to below 5×10^{-6} Torr for half an hour before measurements were conducted at different bath temperatures. Uniform temperature of the water bath was assured by continuous stirring; the bath temperature was measured with an iron-constantan thermocouple gauge within 0.1°C. Vapor pressure measurements were obtained between about 29° and 62°C.

Results

The experimental data obtained are shown in Table I and are plotted in Fig. 1. The results can be represented by an Arrhenius-plot of the form

$$4.573\,(\log_{10} p) = -\Delta H/T + B \qquad [2]$$

Table I. Vapor pressures of solid aluminum bromide

for the equilibrium between the solid and the vapor phase over our limited range of temperatures. A least squares fit to the data is shown in Fig. 1 and results in the experimental relation

$$[\log_{10} p\,(\text{mm Hg})]_{exp} = -4610.82°\text{K}/T + 13.0080 \qquad [3]$$

From Eq. [2] and [3] we obtain for the heat of vaporization of the solid bromide, $\Delta H = (21.085 \pm 0.250)$ kcal/mole. These results may be compared with the theoretically derived expression, Eq. [1], which has not been plotted in Fig. 1, since it agrees with our relation [3] within +1.2% and −1.8% over the range of temperatures used. We consider the experimental and theoretical data in excellent agreement with each other, and we conclude that the theoretically derived results for the phase equilibrium between the solid and the vapor of aluminum bromide have been verified experimentally.

Surface Preparation of Ceramic Oxide Crystals: Work Damage and Microhardness

Michael F. Ehman*

Rockwell International, Incorporated, Electronics Research Division, Anaheim, California 92083

The use of single crystalline materials in solid-state devices frequently requires the preparation of surfaces that are strain free and chemically representative of the bulk material. A highly strained surface results whenever materials are cut by abrasive action. This surface strain is referred to as a damaged layer. The depth of the damaged layer depends on several factors, including hardness of the material, orientation of the surface, abrasive particle size and type, and pressure applied during processing. The primary concern about the depth of damage to date has been in the semiconductor industry where the characteristic elec-

trical properties of the materials can be realized only after removal of the damage. Depths of damage have been reported for Ge and Si (1) and Si (2), and several III-V intermetallic compounds (3). The more recent use of ceramic oxide crystals as substrates for epitaxially deposited thin films has required the preparation of surfaces of similar quality, *i.e.*, flat, clean, damage free, and chemically representative of the bulk material.

Some of these ceramic crystals include: $Gd_3Ga_5O_{12}$ (GGG), the primary substrate for magnetic oxide films used in magnetic bubble domain memories, and BeO, α-Al_2O_3, and $MgAl_2O_4$ which are the most common materials used as substrates for microelectronic devices.

This paper reports the relationship between the penetration of damage and the hardness (bulk and micro-) of different crystal compositions, and the crystallographic orientations within the crystals.

Experimental

Crystals.—The wafers utilized in this study were cut from single crystalline boules grown by the Czochralski technique in the case of GGG,[1] α-Al_2O_3,[2] and $MgAl_2O_4$.[3] The BeO crystals were grown from an alkali molybdate flux by a continuous dissolution-precipitation process.[1]

The dislocation densities of the crystals were in the following ranges (d/cm^2): GGG, <10, BeO, 10^3-10^5; $MgAl_2O_4$, 10^5; α-Al_2O_3, 10^6.

The crystals were oriented to within 1° of the desired orientation by the x-ray Laue back-reflection technique and sliced such that the major surface was at last 20 times larger than the sides to minimize edge contributions to the weight losses (described later).

Mechanical preparation techniques.—The crystals were first wafered on an inside-diameter (I.D.) tensioned membrane diamond saw; the blades were 0.015 in. thick with 340 mesh diamond. Typical cutting rates were 0.1 cm/min; with blade speeds of 2000 rpm; the as-sawed wafers were then individually hand-lapped on both sides to produce flat surfaces for subsequent mounting on appropriate individual polishing fixtures.

After the thoroughly cleaned wafers were properly mounted on the polishing fixture with a wax, the wafers are subjected to a machine-lapping step employing a vibratory polisher[4] with a cast-iron lapping plate and a 12 μm silicon carbide/ethyleneglycol slurry. The final polishing steps for the crystals were performed on vibratory polishing apparatus with the following abrasives and cloths: GGG, 0.2 μm Syton[5] on nylon; BeO, 0.05 μm Cabosil[6] on perforated Pellon[7] cloth; $MgAl_2O_4$, 0.05 μm Al_2O_3 [8] on nylon; and α-Al_2O_3, 0.25 μm top-diamond on perforated Pellon cloth. Thus slicing and lapping steps were identical for all crystals but the polishing step differed in that harder abrasives were used for harder crystals. Both sides of each wafer were given the same surface treatments.

Throughout the lapping steps 350 g/cm^2 loads were used on the lapping and polishing fixtures. The loadings were decreased to 300 g/cm^2 during polishing steps.

The epitaxial surfaces were free of scratches and polishing pits visible at 100X using Nomarski interference contrast. X-ray topographic analysis of the samples revealed a few scratches only on the $MgAl_2O_4$ surfaces (<0.1% of surface area).

[8] Linde C, a Product of Union Carbide Corporation, San Diego, California 92123.

Constancy of etch rate technique.—The constancy of etch rate technique (1) was used to evaluate the depth of damage; the technique is based on the observation that highly strained material etches more rapidly than that with reduced strain. Initially, a chemical etchant attacks a damaged layer vigorously; thus the initial rate is high. As the disturbed layer is removed, the strain decreases and the etch rate decreases accordingly, approaching a constant value which represents that of the bulk material. The point at which the etch rate becomes constant represents that level in the crystal where the damage ends. From the total material loss during removal of the damaged layer, the depth of damage can be determined. Typical etch rate *vs.* etch time plots are shown in Fig. 1; this example shows the plots for the (111) surface of GGG after sawing, lapping, and polishing.

Etchants.—The etchants used in this study are primarily chemical polishes, *i.e.*, they leave a relatively flat, unpitted surface (4). The H_3PO_4 used on the GGG is an effective dislocation etchant at 200°C (5); however, since the total dislocation count was <10 in a 1 in. diameter wafer, it was decided that the effects of pitting would contribute negligible error to weight loss measurements. The BeO was etched in hot (120°C) HCl (6). A mixture of H_3PO_4/H_2SO_4 in a 1:1 volume ratio developed by Reissman *et al.* (7) was utilized at 200°C for both the α-Al_2O_3 and $MgAl_2O_4$.

Platinum wire mesh baskets were used to hold the samples in the acid. The etchants were magnetically stirred (~100 rpm) in constant temperature baths controlled to ±0.5°C. The surface areas are the apparent surface areas measured by micrometers. The weight losses were measured on a microbalance to ±2 μg.

Results

The depth-of-damage values (in microns) determined for each crystal as a function of surface orientation and type of surface preparation are shown in Table I. The data are average values of the damaged layer measured on four wafers, each with identical surface preparations, of each orientation. The crystals have been arranged in order of increasing bulk (Mohs) hardness. It should be noted that the depth of damage incurred during a given type of surface preparation decreases as the hardness of the material increases. This general relationship also holds when the microhardness (knoop) of a given orientation is compared to the damage incurred by that orientation. The only exception to this general relationship is that the epitaxially polished $MgAl_2O_4$ has a deeper depth of damage than that measured on epitaxially polished BeO. This discrepancy can be accounted for though by two factors: one, the $MgAl_2O_4$ was polished using 0.05 μm Al_2O_3 which is significantly harder than the 0.05 μm Cabosil used on BeO: the second factor is that the $MgAl_2O_4$ surfaces contained numerous scratches and polishing

* Note that this hardness is dependent on orientation, the average values are reported.

pits during the initial etchings, which would tend to distort the initial weight loss measurements and hence the depth of damage.

Figure 2 shows a plot of the depth of damage penetration into surfaces of various orientation after ID saw wafering *vs.* the knoop microhardness of the crystal orientation. Similar plots of depth of damage penetration *vs.* knoop microhardness are shown for surfaces prepared with a 12 μm SiC lap finish and final polish in Fig. 3 and 4. The orientation of each surface has been identified only in Fig. 2 for brevity; the points for a given orientation occur in the same sequences in Fig. 3 and 4. It is interesting to note that within a given crystal, there is a linear relationship between the microhardness and the depth of damage incurred during a given type of preparation, with the exception of the 12 μm SiC lap surface.

If the depth of damage penetration was only a function of the microhardness of the material, then we would expect all of the points, irrespective of crystal type, should fall on a common line. They do not. Not only do they not have such a relation, but the depth values overlap for BeO and spinel.

The tailing off of the curves of 12 μm SiC lap of BeO and spinel are presently unexplained. The curves have been reproduced in three sets of runs, utilizing four wafers per run.

As a check on the accuracy of the values determined above, x-ray rocking curves were made on GGG and

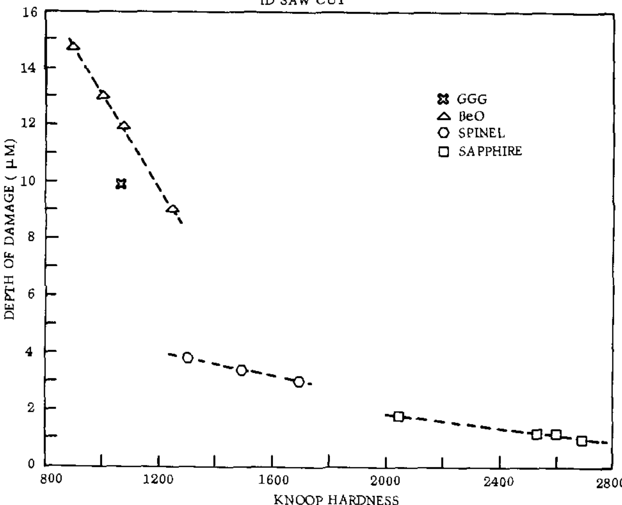

Fig. 2. Plot of depth of damage incurred by surfaces prepared by I.D. saw wafering *vs.* knoop microhardness of the crystal orientation.

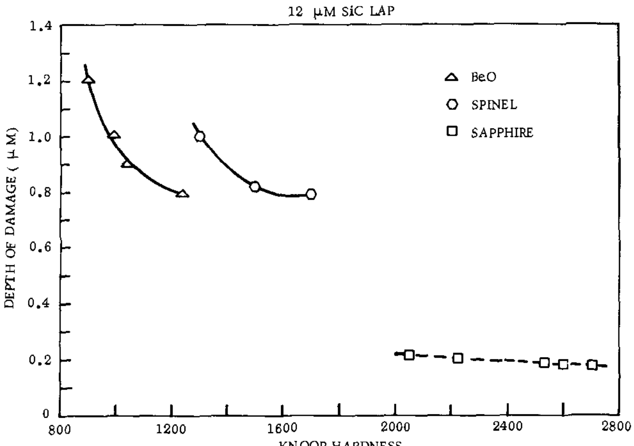

Fig. 3. Plot of depth of damage incurred by surfaces lapped with 12 μm SiC abrasive *vs.* knoop microhardness of the crystal orientation.

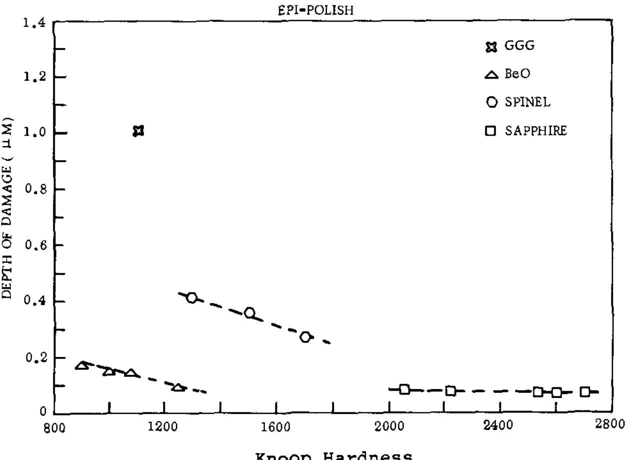

Fig. 4. Plot of depth of damage incurred by epitaxially polished surfaces *vs.* knoop microhardness of the crystal orientation.

$MgAl_2O_4$ samples which had received the same surface treatments. The values for saw-cut and lapped surfaces agreed within 10%. The x-ray analysis was unable to detect any damage on the polished wafers due to the penetration depth of the beam. There was no buildup of dislocations at the epitaxially polished surfaces observable either by dislocation etchants or x-ray techniques.

Conclusions

The depth of damage incurred by selected ceramic oxide crystals under various types of mechanical surface preparations were measured, showing a linear relationship between the damage penetration and the knoop microhardness of the specific orientation.

It must be concluded that there is a general linear relationship between the damage and hardness within a crystal type, but that other, still unrecognized factors exist between the deformation strain mechanisms of different crystal types.

High Pressure Effects on the EMF of Seawater Battery Electrodes in Chloride Electrolyte

E. M. L. Valeriote* and L. D. Gallop

Defence Research Establishment Ottawa, Ottawa, Ontario, Canada K1A OZ4

ABSTRACT

Reference electrodes, suitable for use at high pressures in chloride or hydrogen containing solutions, were applied to the study of various buffer equilibria at pressures from 0 to 2.5 kbar. Partial molal volumes of reaction obtained are compared and interpreted in terms of their effects on the solvent structure. Results obtained with anodes of magnesium alloys (AZ 61 and AP 65), aluminum alloys (GB 420 and GB 80S) and pure aluminum, in phosphate and borate buffered and unbuffered chloride solutions, are presented and discussed. Anode potentials were found to be simultaneously controlled by more than one oxidation reaction. In the case of the magnesium anodes, the relative contributions of the three oxidation reactions were clearly determined by both the alloy composition and the ambient pressure. In the case of aluminum this was also true, but the actual reactions taking place were more difficult to identify.

Although a large amount of work has been done on the effect of high pressure on electrolyte systems (1), only little has been directed toward an understanding of electrochemistry or electrode mechanisms at high pressures. These assume particular importance when one considers the operation of seawater batteries at great ocean depths for such purposes as undersea monitoring equipment for military or scientific investigations or for life support systems for bathyscapes or underwater habitats. The present work was intended to explore such pressure effects, particularly as they are related toward the magnesium- or aluminum-silver chloride seawater batteries. The first phase of the work concentrated on the choice of suitable reference electrodes and the second on the effects of pressure on the electrolyte and buffer systems required to simulate seawater conditions. Experiments were then extended to open-circuit measurements for magnesium and aluminum anodes.

The expression for the Gibbs free energy in differential form

$$dG = -SdT + VdP \quad [1]$$

may be expressed suitably for electrochemical systems in terms of the electrochemical potential of species i, $\bar{\mu}_i \equiv (\partial G_i/\partial n_i)$, and the partial molar quantities $\bar{S}_i$ and $\bar{V}_i$

$$d\bar{\mu}_i = -\bar{S}_i dT + \bar{V}_i dP \quad [2]$$

Thus

$$\bar{V}_i = (\partial\bar{\mu}_i/\partial P)_{T,\mu_{j\neq i}} \quad [3]$$

at constant temperature and constant chemical potential of all other species, j. If this equation is applied separately to each of the products and reactants of a chemical reaction and algebraically summed, one obtains

$$\overline{\Delta V} = \sum_i \bar{V}_i = \sum_i (\partial\bar{\mu}_i/\partial P)_{T,\mu_{j\neq i}} \quad [4]$$

but

$$\sum_i \bar{\mu}_i = \Delta G = -n\mathbf{F}E \quad [5]$$

and hence

$$\overline{\Delta V} = -n\mathbf{F}(\partial E/\partial P)_{T,\mu} \quad [6]$$

where a partial molar volume change $\overline{\Delta V}$ accompanies the passage of n faradays/mole through the cell at the reversible potential difference E. Thus $\overline{\Delta V}$ can be obtained from the slope of the emf *vs.* pressure relationship. Since

$$\bar{\mu}_i = \bar{\mu}_i^0 + RT \ln a_i \quad [7]$$

it is also possible to write

$$-n\mathbf{F}(\partial E/\partial P)_{T,\mu} = (\partial\Delta\bar{\mu}^0/\partial P)_{T,\mu} + RT(\partial \ln \prod_i a_i^{\nu_i}/\partial P)_{T,\mu} \quad [8]$$

where $\prod_i a_i^{\nu_i}$ is the product of the activities of the reaction products raised to their stoichiometric numbers ν_i (negative power for reactants) corresponding to a transfer of n electrons for the over-all cell reaction. Choice of a standard state at unit pressure makes the first term in Eq. [8] zero by definition, and the second term represents the rate of variation of the activities of the potential determining species with pressure. At 25°C Eq. [8] can be integrated to give

$$E_1 - E_p = \frac{59.16}{n} \log \prod_i a_i^{\nu_i} \text{ mV} \quad [9]$$

For cells of the type

$$Pt/H_2(aq),MCl(aq)/AgCl/Ag$$

studied in these experiments, the cell reaction is

$$AgCl(s) + \tfrac{1}{2}H_2(aq) = Ag(s) + H^+(aq) + Cl^-(aq)$$

* Electrochemical Society Active Member.

Key words: reference electrodes, magnesium, aluminum, reaction volume, buffer.

Equation [9] thus becomes

$$E_1 - E_p = 59.16 \log \frac{[a_{H^+(p)} a_{Cl^-(p)} a_{H_2(p)}{}^{-1/2}]}{[a_{H^+(1)} a_{Cl^-(1)} a_{H_2(1)}{}^{-1/2}]} \quad [10]$$

and

$$\overline{\Delta V} = V_{Ag} - V_{AgCl} + \overline{V}_{HCl(MCl)} - \tfrac{1}{2}\overline{V}_{H_2} \quad [11]$$

Some simplification of Eq. [10] is possible.

Since activity coefficients used for electrolytes refer to molal quantities, concentration changes due to compressive effects are reflected in the values of $\gamma_\pm$, the mean ionic activity coefficients. Therefore concentration changes with pressure need not be considered explicitly. The variation of activity coefficients, due to changes in partial molal volumes with pressure, can be calculated (2) using the equation

$$\log \gamma_\pm = (\log \gamma_\pm)_{p=1} + 0.888 \times 10^{-5} \left(\frac{3}{2} S_v\right)(P-1)\sqrt{c} - 0.444 \times 10^{-5} \left(\frac{3}{2} S_k\right)(P-1)^2\sqrt{c} \quad [12]$$

where S_v and S_k are experimental slopes of linear fits of apparent molal volume and compressibility, respectively, to the square root of the molal concentration, c.

For 0.5M NaCl solutions at 25°C, $S_v = 2.153$, $S_k = 11.4 \times 10^{-4}$ (7) and $\gamma_\pm = 0.681$ (3) at $P = 1$. When the calculations were done using Eq. [12] the potential variation of the Ag/AgCl electrode, ΔE_γ, was found to reach a maximum of 1.13 mV[1] at about 1.9 kbar.

If a calculation was made using an extended Debye-Huckel model for the electrolyte and interpreting the variations in $\gamma_\pm$ as a consequence of variation of dielectric constant (2) with pressure, close agreement at the maximum, and agreement within 0.3 mV over the entire pressure range was obtained. Data for the calculation were taken from measurements of the dependence of the dielectric constant of water on pressure (4, 5) and published $\mathring{a}$ and B Debye-Huckel parameters (2).

Similar calculations for dilute HCl (<0.05M) in 0.5M NaCl, and for 0.1M KCl solutions, indicated that the pressure variation of $\gamma_\pm$ of the HCl, and those of both HCl and KCl in 0.1M KCl, were negligible.

These calculations have been concerned with estimating changes in activity coefficients for H^+ and Cl^- ions. They have not, however, dealt with changes in H^+ concentration due to the dissociation of water in unbuffered solutions or the buffering agent in buffered solutions. This will be discussed later, after treatment of the last term in Eq. [10], the variation of the molecular hydrogen activity coefficient with pressure, which is far larger than those of the ionic species already discussed.

The activity of a gas, or its fugacity f_p, relative to the standard state of unit pressure, can be calculated from compressibility data by considering the deviation of molar volume from ideality, as given by

$$\alpha \equiv RT/P - \overline{V}_p \quad [13]$$

For a gas at constant temperature from Eq. [2]

$$d\mu = RT \ln f_p = \overline{V}_p dp \quad [14]$$

Combining Eq. [13] and [14] gives

$$RT \ln f_p = RTd \ln P - \alpha \, dP \quad [15]$$

Integrating from $P = 0$ to p gives

$$f_p = p \exp\left[-1/RT \int_0^p \alpha \, dP\right] \quad [16]$$

Using published compressibility data for hydrogen (6, 7), values of f_p and

$$\Delta E_f = 29.58 \log \gamma_{H_2} = 29.58 \log (f_p/f_1 p) \text{mV} \quad [17]$$

were calculated. Equation [10] can now be rewritten including the calculated corrections to read

$$(E_1 - E_p) - \Delta E_f - \Delta E_\gamma = 59.16 \log [a_{H^+(p)}/a_{H^+(1)}] \quad [18]$$

For a neutral unbuffered solution the dependence on pressure of the dissociation equilibrium of water must be considered. Thus

$$\frac{a_{H^+(p)}}{a_{H^+(1)}} = \frac{K_p}{K_1} \cdot \frac{a_{OH^-(1)}}{a_{OH^-(p)}}$$

but

$$a_{OH^-} = a_{H^+}$$

hence

$$\frac{a_{H^+(p)}}{a_{H^+(1)}} = \left[\frac{K_{w(p)}}{K_{w(1)}}\right]^{1/2} \quad [19]$$

Therefore Eq. [18] becomes

$$(E_1 - E_p) - \Delta E_f - \Delta E_\gamma = 29.58 \log K_{w(p)}/K_{w(1)} \quad [20]$$

A similar equation replacing K_w by K_a can be derived for solutions containing weak acids at low concentration.

For acid-buffer solutions the equilibrium

$$HA = H^+ + A^- \qquad K_a = \frac{[H^+][A^-]}{[HA]} \quad [21]$$

must be considered. In this case

$$\frac{a_{H^+(p)}}{a_{H^+(1)}} = \frac{K_{a(p)}}{K_{a(1)}} \cdot \frac{a_{HA(p)}}{a_{HA(1)}} \cdot \frac{a_{A^-(1)}}{a_{A^-(p)}} \quad [22]$$

For most of the buffer concentrations used in these experiments, the concentrations of buffer acid and salt anions do not change appreciably with pressure and the variation of activity coefficients can be shown to be negligible by means of calculations similar to those discussed earlier using Eq. [12]. Hence for buffered solutions Eq. [18] reduces to

$$(E_1 - E_p) - \Delta E_f - \Delta E_\gamma = 59.16 \log K_{a(p)}/K_{a(1)} \quad [23]$$

Neglect of the terms discussed is estimated to give rise to errors of no more than 0.2 mV in the left hand side of Eq. [20] and [23] at all the pressures investigated. From Eq. [6], setting

$$E = E_p + \Delta E_f + E_\gamma$$

one then obtains

$$\overline{\Delta V} = -n\mathbf{F}\, \partial(E_p - E_1 + \Delta E_f + \Delta E_\gamma)/\partial P \quad [24]$$

Experimental

Electrochemical cells and pressure vessel.—Electrochemical cells of two basic designs were used for the measurement of electrode potentials.

A glass cell (Fig. 1a) was used for most of the work described below but some measurements were made using plastic machined cells (Fig. 1b) made of Lexan® (polycarbonate), Teflon®, or nylon. The plastic cells had advantages in ease of fabrication but were difficult to make leak proof at high pressures. Six platinum electrical leads were sealed with epoxy into holes through the screw-type head. However, leakage of hydrogen from the cell, as measured by hysteresis of the hydrogen electrodes in buffered solutions at 1 atm pressure between the beginning and end of a run, was appreciable using the plastic cells, even with the O-ring seal incorporated later in the work. Under similar conditions hydrogen electrodes in the glass cells, with the ground glass joint sealed with a minimum of high vacuum stop-cock grease, remained constant within about 1 mV at 1 atm over the 10-12 hr required for a complete run; in the plastic cells shifts

[1] Values of S_v, up to 14% smaller than that used here have been reported recently (33, 45). Use of the lower values would give a maximum ΔE_γ of about 1.0 mV.

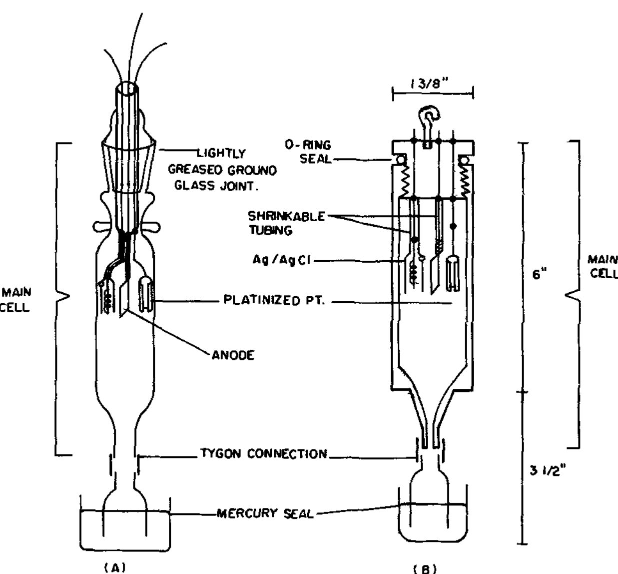

Fig. 1. Electrochemical cells of glass (A) and plastic (B) used to measure the pressure coefficients of cell emf.

of several millivolts toward more positive potentials were observed. Accordingly the plastic cells could only be used when changes of hydrogen concentration due to leakage during the course of a run were unimportant as, for example, when Mg anodes were present in the cell. To prevent leakage from the glass cells, tungsten leads were sealed through the Pyrex head and platinum was welded to the tungsten with a spot welder. Except for the platinized platinum electrodes the electrode leads were insulated from the solution by means of shrinkable polyolefin tubing. Only four or five electrodes could conveniently be incorporated into the glass cells.

The pressure vessel (8) (cavity dimensions 1½ in. diameter by 11½ in.) was manufactured by Pressure Products Incorporated, Hatboro, Pennsylvania. Six insulated electrical connections of nichrome wire were sealed into holes in the head using epoxy. After soldering connections to the electrochemical cell, the pressure vessel could be sealed and pressure increased by a hydraulic pump, which compressed the oil in the pressure chamber. Control valves were used for fine adjustments and for decreasing the pressure, which was measured with a 16 in. Bourdon gauge (Heise Bourdon Tube Company, Newport, Connecticut) accurate to ± 2.5 bars. Pressure was transmitted to the interior of the cell by means of a mercury seal (Fig. 1) which isolated oil from electrolyte. The pressure chamber was immersed in a high thermal conductivity oil bath maintained at 25.0°C for all experiments.

Reference electrodes—Silver-silver chloride reference electrodes were prepared by sealing 0.020 in. platinum wire into sleeves 2-3 cm long made from 7 mm OD glass tubing to protect the electrodes. The sleeves were open at the bottom, and there was a small hole near the top seal to admit solution freely. The platinum was silver-plated in freshly prepared $KAg(CN)_2$ solution at 0.5 mA/cm^2 for 6 hr according to the standard procedures (9) after cleaning in aqua regia and anodizing in concentrated nitric acid. Following soaking in NH_4OH for several hours and thorough rinsing in water (1-3 days), the electrodes were then chloridized in 0.1M HCl for 30-60 min at 0.8 mA/cm^2, rinsed and stored in 0.01M KCl.

Platinum foils ($\sim$1 cm^2) for hydrogen reference electrodes were cleaned by immersion in hot aqua regia, hot concentrated nitric acid and thorough rinsing. This was followed by hydrogen flaming to red heat and cathodic cleaning in 1% sulfuric acid so that very small bubbles were evolved uniformly over the surface. Platinization was then carried out by cathodizing at 100 mA/cm^2 for 3 min in a solution of 2% chloroplatinic acid containing 0.02% lead acetate.

Both types of reference electrodes were checked against each other and against saturated calomel electrodes and found very stable. Differences between hydrogen electrodes remained constant within a few hundredths of a millivolt and between Ag/AgCl electrodes within a few tenths of a millivolt after equilibration. Differences of 1-3 mV occurred following large changes in pressure or electrolyte concentration before reequilibration.

Chemicals.—Chloride solutions were prepared from reagent grade salts without additional recrystallization. Phosphate buffered solutions were made up from Fisher Certified pH 7.0 Buffer, borate buffered solutions from Fisher Certified sodium borax and 2*N* volumetric hydrochloric acid, and acetate buffered solutions from reagent glacial acetic acid and Fisher Certified volumetric 0.1*N* sodium hydroxide.

The solvent used was high purity conductivity water (maximum 0.5μ mho cm^{-1}) obtained by a pyrodistillation process (10). Mercury was distilled twice under vacuum with an air leak and twice under high vacuum.

Magnesium alloy anodes were cut from 0.030 in. AZ 61 (6% Al, 1% Zn; Dow Corning, Midland, Michigan) or AP 65 (6% Al, 5% Pb; Magnesium Elektron, London, United Kingdom) into 1 cm^2 foils. Platinum leads were crimped on one edge of the *Mg* foil and the joint was then sealed with Silastic® (Dow Corning, Midland, Michigan) 731 RTV adhesive sealant. The leads were then protected from solution with shrinkable polyolefin tubing.

Before each run Mg electrodes were briefly immersed several times alternately in 5-10% HNO_3 and 1-2% HCl solutions and rinsed in water.

Aluminum anodes were similarly constructed from Alcan GB 80S Al alloy (0.45% Sn, 0.05% Ga) and GB 420 ternary (4.5% Zn, 0.15% Sn) alloy (11) (Alcan Research and Development, Kingston, Ontario, Canada). Cleaning of the aluminum was carried out by means of 20-40 sec alternate immersions in 1M NaOH and 33% HNO_3 solution rinsing with water after each immersion.

Method and results.—Initial experimental work was concentrated on the development of reference electrodes suitable for use in seawater related electrolytes. Since seawater is a moderately buffered chloride electrolyte, silver-silver chloride was selected as the chloride reversible electrode and a hydrogen electrode as the pH sensitive electrode. Other possibilities were considered in the event that these were to prove unsuitable. A specially constructed glass electrode has been described (12) for use at pressures up to 1500 kg/cm^2.[2]

A three-electrode reference system generating hydrogen *in situ* has been reported by Conway after poor performance had been obtained using a Giner-type system (13). The glass and Giner-type system cannot give thermodynamically meaningful potentials except by calibration using standard systems. Furthermore, the three electrodes and Giner systems would have been undesirable because of the limitation of the cell to 5 or 6 electrical connections. Specially constructed calomel reference electrodes have been used at pressures up to 1000 atm (14).

In order to extend measurements up to 2500 bar and retain the possibility of monitoring hydrogen pressure, as well as pH, in later experiments involving anode materials (and for various other considerations, some of which have been cited) these other possibilities were excluded in selection of the reference electrodes of first choice.

Since the hydrogen electrode is controlled not only by the hydrogen ion activity, but also by the fugacity

[2] 1 standard atmosphere = 1.013 bar = 1.013 × 10^5 nm^{-2} = 1.033 kg/cm^2.

of the molecular hydrogen in solution, it was essential to maintain the hydrogen pressure as constant as possible during the course of a run. At atmospheric pressures this is usually accomplished by bubbling hydrogen gas over a platinized platinum surface. Except by using *in situ* electrolytic hydrogen generation, this is difficult at high pressures. Accordingly in these experiments solutions, presaturated with hydrogen, were sealed before each run and the hydrogen allowed to exert its own near atmospheric pressure within the cell.

After welding of the electrical leads, sealing all but those for the hydrogen electrodes in shrinkable polyolefin tubing and filling the cell with electrolyte, the main section of the cell was inverted and hydrogen gas was bubbled through the solution using a fine capillary in both the main section and the section including the mercury seal for 30-60 min. The two sections were then joined with a short piece of tygon tubing in such a way as to eliminate any visible gas bubbles or void spaces from the cell, and sealed into the pressure vessel. After each change of pressure, 25-50 min were permitted for thermal and mechanical equilibrium to be reestablished, as indicated by constancy of electrode potentials. Replicate (at least four) measurements of potential were then made at 5 min intervals, and the cycle was repeated for both increasing and decreasing pressure. Pressure increments were usually 500 bars between each set of measurements. Intermediate values of pressure were applied during the decompression period. Atmospheric pressure readings were taken at the beginning and end of every run as a check against hysteresis effects due to H_2 leakage or electrode failure. Thus a complete run up to 2.5 kbars normally included 12 experimental points, half obtained during the compression period.

The first experiments were intended to test the constancy of potential as a function of pressure for cells of the type

$$Pt/H_2(aq, 1\ bar), MCl(aq)/AgCl/Ag$$

where M is a soluble cation.

Unbuffered systems.—Measurements of emf were made in unbuffered 0.5M NaCl and in synthetic seawater (0.46M NaCl, 0.02M $MgSO_4$, 0.12M $MgCl_2 \cdot 6H_2O$) solutions using a DVM accurate to $\pm 2\ \mu V$. (In some of the work on other systems discussed below a DVM accurate to 0.2% was used but the accuracy of either DVM was always better than the precision of the measurements being taken.) These experiments in unbuffered solutions (see Fig. 2a) did not conclusively establish the pressure independence of the electrodes because of time-dependent effects caused either by pH variation or hydrogen loss. Accordingly measurements were then carried out in acidic chloride solutions in order to eliminate any possible pH effects and the glass cells were tightly sealed with high pressure stopcock grease to avoid any loss of hydrogen. The results are displayed in Fig. 2(b-d). The solid lines were calculated from compressibility data for hydrogen, using Eq. [16] and include the correction for variation of activity coefficient of the chloride ion (negligible in the case of the 0.1M HCl solution). The points are experimentally determined and are accurately fitted by a quadratic equation (broken curves) giving a standard error comparable to the mean deviation of the three hydrogen electrodes from their average. Individual hydrogen electrodes were constant to within 0.02 mV during the 20 min of measurements. A linear least squares fit gave a standard error two or three times as large as the quadratic whereas no significant improvement was obtained using a cubic equation (see Table Ib).

At the lower pressures (<800 bars) agreement between experimental and calculated potential differences are excellent. However, at higher pressures the apparent fugacity becomes less than that calculated using compressibility data for dry hydrogen gas. A similar but slightly larger discrepancy was observed for the hydrogen-calomel system (14) and was attributed to the influence of increased hydrogen solubility on the partial molal volume of hydrochloric acid. This interpretation was refuted recently (41) but a residual discrepancy remained of about the same magnitude as in the present work. It is thought that the remaining deviation is due to neglecting the effect of water vapor on the hydrogen fugacity, *i.e.*, compressibility data for hydrogen gas, saturated with water vapor, would have been more appropriate for the present calculations than the data for dry hydrogen which were used. It has also been suggested (42) that some hydrogen loss may occur due to diffusion into the elec-

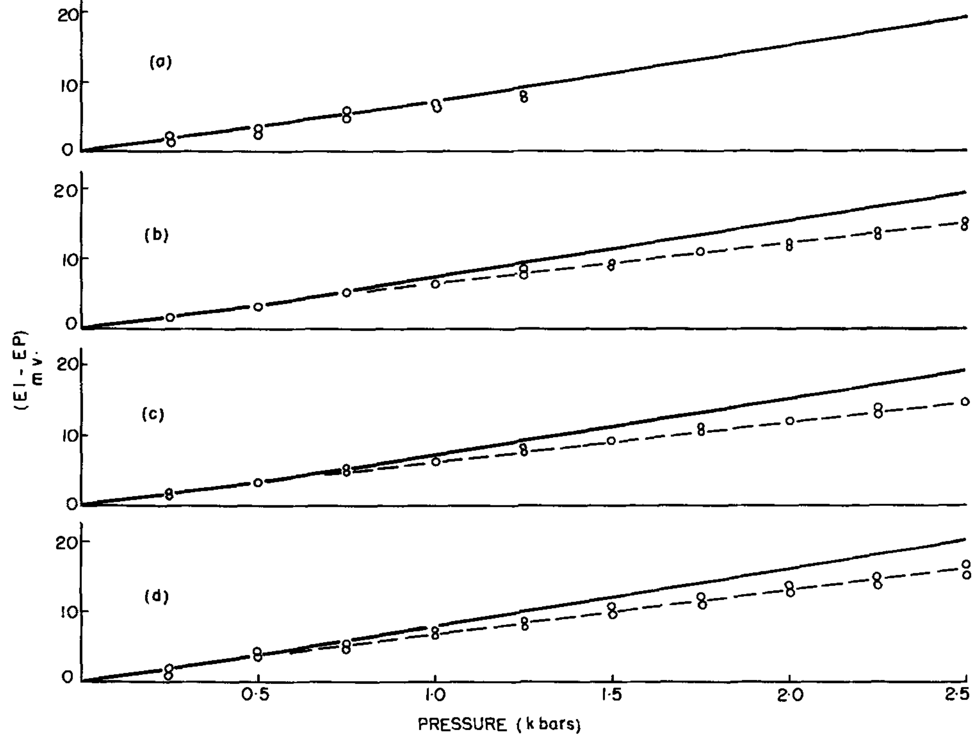

Fig. 2. Increase of hydrogen electrode potential relative to the Ag/AgCl electrode as a function of pressure. Broken curves are fitted to experimental points using a quadratic equation. Solid curves are calculated using compressibility data for hydrogen gas to determine hydrogen fugacity. (a), 0.5M NaCl; (b), 0.5M NaCl + 0.01M HCl; (c), 0.5M NaCl + 0.1M HCl; (d), 0.1M HCl.

trode materials or shrinkable tubing. If this does not occur, then the data of Fig. 2 can be used to determine the fugacity of hydrogen saturated with water vapor. In any case, the cause of the apparent change of fugacity is unimportant to the present work; only its magnitude need be known. Hence in the rest of this paper, the "empirical" fugacity correction, determined from the data (broken lines) of Fig. 2, is applied to the hydrogen electrode potential results in other systems.

Runs were also carried out in 0.5M NaCl solutions saturated with $Mg(OH)_2$ and $Al(OH)_3$. The solutions were prepared by allowing excess Mg or Al to corrode in the salt solutions for a sufficient period of time to assure saturation. Although these electrolytes are buffered by means of the hydroxide equilibria at *p*H values near 10 and 6, respectively, they have been included in Table I under unbuffered solutions to emphasize the fact that no foreign buffering agent is present.

Buffered systems.—Experiments were carried out in the following buffered solutions: (*i*) 0.1M KCl +0.2M acetate buffer, *p*H 4.7; (*ii*) 0.5M NaCl + 0.01M phosphate buffer, *p*H 6.6; (*iii*) 0.5M NaCl + 0.05M phosphate buffer, *p*H 6.6; (*iv*) 0.5M NaCl + 0.025M borate buffer, *p*H 8.1. The results are tabulated in Table I, giving the slope of the linear least squares fit of potential to pressure, the standard error of the linear least squares fit, the standard error of a quadratic least squares fit, and the experimentally attained precision of the emf measurements. As can be seen from the table the data fit a linear equation quite well. However a better fit, giving a standard error in closer agreement with experimental precision, is obtained using a quadratic equation.

Magnesium and aluminum anodes.—Buffered systems.—Runs were carried out using the following anodes in borate and phosphate buffered solutions of 0.5M NaCl. Potentials were measured relative to a hydrogen and a Ag/AgCl electrode in the same solution.

Mg(AZ 61): 6% Al, 1% Zn
Mg(AP 65): 6% Al, 1% Pb
Al(GB 80S)[3]: 0.5% Sn, 0.05% Ga
Al(GB 420)[3]: 5% Zn, 0.2% Sn

Gas evolution occurs during the course of a run and the hydrogen electrode potentials became sufficiently more negative to indicate that the gas was hydrogen in every case. The magnesium anodes caused an increase of *p*H and the Al anodes a slight decrease, since the solutions were only partially buffered.

[3] Alcan designation.

Table I.

Buffered solutions (a)	pH	Number of electrodes averaged	Linear E/P fit: Slope mV/kbar	Linear E/P fit: Standard error (mV)	Quadratic E/P fit Standard error (mV)	Experiment precision (mV)
(i)	4.7	3	−0.36	0.32	0.15	0.1
(ii)	6.6	1	−13.6	0.37	0.13	<0.1
		1	−13.5	0.45	0.16	<0.1
(iii)	6.6	1	−14.2	0.52	0.23	0.3
		1	−14.2	0.59	0.37	0.4
(iv)	8.1	2	−20.4	0.83	0.38	0.4

Unbuffered solutions (b)	Standard error of fit: Linear	Quadratic	Cubic	Experimental precision (mV)
0.1M HCl	0.38	0.29	0.28	<0.1
0.5M NaCl + 0.1M HCl	0.24	0.11	0.11	0.3
0.5M NaCl + 0.01M HCl	0.22	0.12	0.11	0.2
0.5M NaCl: Sat'd $Mg(OH)_2$	1.32	1.26	1.24	0.4 (1.1)
0.5M NaCl: Sat'd $Al(OH)_3$	4.01	2.64	2.10	0.6 (5)

Standard errors decreased only by about 10% in most cases when the data were fitted to a quadratic equation, in comparison with the linear equation. However rather large standard errors, in comparison to the slopes, were obtained in the corroding systems, particularly in 0.05M phosphate buffers and for Al GB 420 and Mg AP 65 anodes. Reasonably good consistency was observed for AZ 61 in 0.01M phosphate and 0.025M borate buffers and fairly reliable results were obtained for Al GB 80S anodes. In the former cases standard errors were comparable to experimental precision and in the latter the standard error was less than the potential change caused by a 500 bar change in pressure.

Some further observations on the behavior of the anode materials will be useful before discussing the various $\overline{\Delta V}$ values obtained. The Mg AZ 61 anodes tarnished to a black color and pitted during the course of a run in phosphate solutions, evolving substantial quantities of gas, enough to force more than half of the electrolyte out of the cell upon decompression to atmospheric pressure. In borate solutions less hydrogen was evolved and the anodes remained bright although small tarnish spots appeared particularly near the edges (approximately 15 ml of gas was evolved by 4 cm^2 of magnesium surface over a period of 12 hr). The Mg AP 65 in both buffers blackened and tended to crumble into small black pieces which fell free of the anode as corrosion progressed. A gelatinous grayish-white product also formed in each case, and gas evolution was high (only 15-20 ml of solution remained of the 65 ml cell capacity). The increase in *p*H, observed for both magnesium alloys, was appreciably greater for AP 65 than for AZ 61 under similar conditions (see Table II).

For the aluminum alloys, the rate of gassing was greater for GB 80S than for GB 420, but both were very low (<5 ml) in comparison to Mg. The GB 80S tarnished only slightly and some white voluminous product formed whereas the GB 420 remained bright with no visible indication of deterioration and only slight amounts of white product formed on it. *p*H decreased very slightly during a run.

Unbuffered systems.—Similar experiments were then carried out in unbuffered (*i.e.*, self-buffered) solutions, made up by adding excess Mg or Al to the 0.5M NaCl to presaturate the electrolyte with the respective hydroxide.

The measured potentials were much more reliably stable and reproducible in these cases and the experimental precision was typically as good or better than that in most of the buffered systems studied. Significant improvement in standard error was obtained when the emf data were fitted to a quadratic equation in comparison to a linear equation. Table II compares experimental errors and standard errors for polynomials of order 2, 3, and 4 for the five anodes investigated. The reproducibility of a single electrode is given in column six and the mean deviation between electrodes is given in column seven (with the number of electrodes in brackets). In the case of the Al GB 420 alloy, two stable ranges of potential were observed

Table II.

Anode	pH	Standard error of fit of emf *vs.* P for order (mV): $n = 2$	$n = 3$	$n = 4$	Experimental precision at each pressure (mV)	Mean deviation between electrodes (mV)
Mg (AZ 61)	9.9-10.8	1.5	1.1	1.0	0.3	2-5 (2)
Mg (AP 65)	—	4.6	4.5		1	3-6 (4)
Al (99.999%)	6.3-6.3	5.7 (21.4)	5.3 (21.4)		4	20 (2)
Al (GB 420)	5.6-6.3					
Low potentials		5.0	4.1		3	5 (4)
High potentials		5.8	5.7		1	5
Al (GB 80S)	5.6-7.9	6.8	6.7		3	20 (5)
Low potentials		(2.5)	(1.9)			

depending on the pressure and history of the sample. At low pressures a high potential region (−1.12 to −1.15V *vs.* Ag/AgCl) having a small pressure dependence was obtained. Upon compression the potential dropped to a low potential region (−1.03 to −1.10V) very suddenly. At lower pressures the electrode potential sometimes recovered to the higher region during the half-hour waiting period between measurements, but at some point it remained low until later decompression, and then returned to the high potential region with some hysteresis observed. The lower potential region was apparently the stable value at high pressures but the exact transition pressure varied from sample to sample. Accordingly in Table II these two cases are given separately. There was some indication that a similar phenomenon occurred for the Al(GB 80S) alloy. However the high potential region was observed only sporadically at atmospheric pressure and only with one sample at pressures greater than 250 bars.

Inspection of the table indicates that only a small further improvement in the fit is obtained for $n > 2$ except in the cases of Mg (AZ 61) and the low potential region of Al (GB 420).

Gassing of the aluminum anodes was less and that of the magnesium the same or greater than was the case in the buffered solutions. During the course of a run 0.1 ml of gas was evolved from pure Al and Al (GB 420); 2-5 ml from Al (GB 80S) and 12 ml from Mg (AZ 61). The Mg (AP 65) gassed so vigorously that all of the solution was forced out of the cell. So little magnesium metal was left six or seven hours following immersion that potentials were no longer stable and dropped considerably. Accordingly there was no solution remaining with which to measure pH following the run. The run had to be repeated in order to build up enough points to assure their reliability and points obtained after electrode failure were not included in the data analysis.

Much more rapid precipitate formation was observed for AP 65 than for AZ 61.

Derived results and discussion.—Derived results: buffered systems.—Typical values of $(E_p - E_1 + \Delta E_f + \Delta E_\gamma)$, derived from the experimental data are shown in Fig. 3 for the buffer systems studied. The solid lines, 1 and 2, were calculated from values of $K_{a(p)}/K_{a(1)}$, using Eq. [23] from compressibility data (15) and conductance data (16), respectively.

The error bars shown on line 1 are from the emf data of Distèche (12). Lines 3 and 4 are also experimental emf data (12) but for different concentrations of phosphate buffer and chloride electrolyte than used in the experimental work reported here. The experimental points shown were corrected using the fugacity values, empirically determined in the acidified chloride solutions, except that points corrected using the fugacity determined from dry hydrogen compressibility are also shown for the acetate buffered system for comparison.

Excellent agreement was obtained with conductance data for acetic acid (line 2) but a large difference with density data (line 1) can be seen. It is likely that the density data shown are in error, in spite of agreement with Distèche's emf results. Hamann and Lim (19, 32) have reported density measurements in much closer agreement with the conductance data than those of line 1.

The $\overline{\Delta V}$ values obtained by other workers and methods can also be used as a basis of comparison and as a measure of the validity of our experimental data.

Figure 4 gives values of $-\overline{\Delta V}$ obtained by fitting the experimental emf values to a quadratic equation using a least squares method and calculating the analytical slope. (The standard error of the quadratic fit is given in Table Ia.) $\overline{\Delta V}$ values for formic acid (line 1), phosphoric acid—1st dissociation (lines 2 and 3), bicarbonate buffer (line 4), and carbonic acid (line 5) from other work (17, 31) are included for comparison. Values of $-\overline{\Delta V}_1^0$ ($-\overline{\Delta V}$ at 1 atm and infinite dilution), obtained by Distèche (17) using a glass electrode and those obtained by other methods are compared with the present work in Table III.

It may be noted, that except for the low value of $-\overline{\Delta V}_1^0$ of 9.2 for acetic acid from density measurements, the results of this work are in as good or better agreement with the results of other methods than those obtained using the glass electrode.

Magnesium and aluminum anodes.—Figure 5 gives derived $\overline{\Delta V}$ values obtained from the data for self-buf-

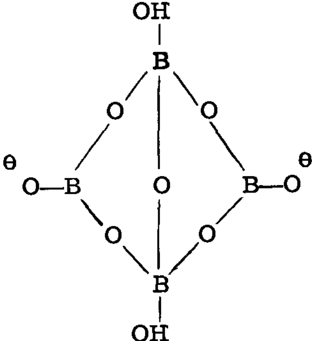
fered solutions. The solid curves represent the average values of $\overline{\Delta V}$ from the quadratic and cubic fits. The error bars are conservative in that they give the difference between the two orders of fit or the mean deviation between electrodes, whichever is the larger. Included in Fig. 5 are similar average values calculated from the results in buffered systems. These are the unconnected points and error estimates are not shown but are usually larger than those for the self-buffered systems. In spite of the differences in reproducibility, the results are generally in fairly good semiquantitative agreement.

For the purposes of the discussion in the following section, the $\overline{\Delta V}$ values for the Mg and Al saturated solutions, derived from the dependence of the hydrogen electrode potential on pressure have also been included in Fig. 5. Again the averages of the cubic and quadratic fits are plotted.

Discussion: buffered systems.— The significance of the variation of $\overline{\Delta V}$ with pressure for buffered systems (Fig. 4) can readily be seen in terms of the dissociation equilibrium of the weak acid of the buffer system (Eq. [21]). Thus an increase in applied pressure shifts the equilibrium toward the production of more ions which electrostrict the water structure in their vicinity and thereby reduce the stress in the solution. The negative $\overline{\Delta V}$ values thus arise principally from the increases in local water density caused by the presence of the orienting fields of the ions produced. In the borate system, the equilibria are complicated by the tendency of polyboric acid formation to occur.

The anion formed $B_4O_5(OH)_4^{=}$ consists of a ring structure (18) of two trigonal planar borate BO_3 groups and two tetrahedral BO_4 groups (structure A) which may hydrolyze in solution to form $B(OH)_3$ monomer (structures B) or other complex borates such as $B_3O_3(OH)_5^{=}$ (structure C) or chains of linked tetrahedra and triangles (20).



Structure A

Structure B

Structure C

In crystalline boric acid, layers of $B(OH)_3$ molecules are held together by hydrogen bonds (20) and it would be expected that in aqueous solution similar hydrogen bonding would occur.

Table III.

Acid or buffer	Present work emf	Glass electrode (17) emf	Density measurements	Conductivity measurements
(a) Values of $-\overline{\Delta V}_1^0$ (cm³/mol) at unit pressure				
Acetic acid or acetate buffer	11.6	11.5 10.8	9.2 (15), 11.5 (18) 12.5 (19, 32)	12.2 (16, 19, 31)
Phosphate buffer	23.2 (0.01M) 24.4 (0.05M)	23.0	24.1 (17) 28.1 (17)	—
Borate buffer	31.8	—	—	—
(b) Values of $-\overline{\Delta V}$ at 1 kbar pressure				
Acetic acid or acetate buffer	10.0	10.8 10.3	12.2 (16, 19)	9.8-10.6* (16, 19, 31)
Phosphate buffer	20.2 (0.01M) 21.0 (0.05M)	23.0		
Borate buffer	27.1

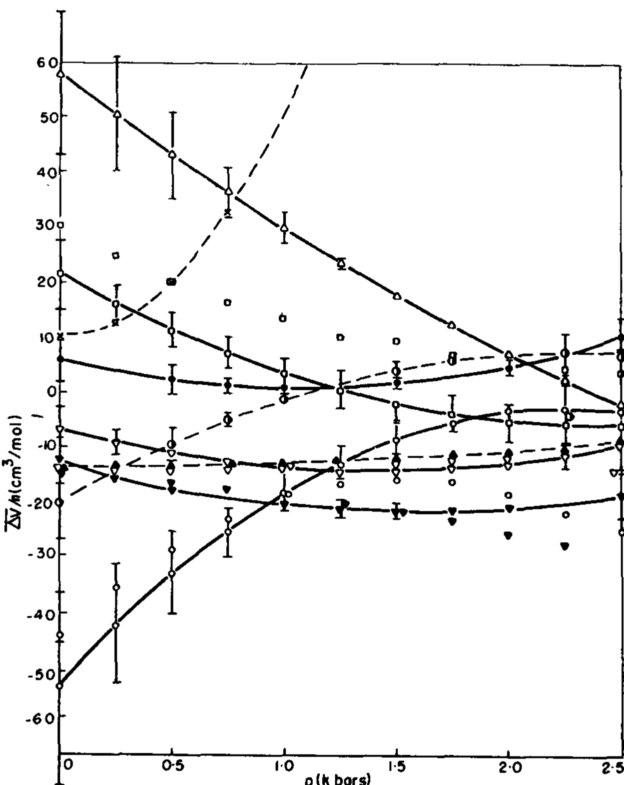

Fig. 5. $\overline{\Delta V}/n$ for magnesium and aluminum alloys in self-buffered solutions of 0.5M NaCl. Average $\overline{\Delta V}/n$ of quadratic and cubic fits. Points not falling on the curves are from data of buffered systems. Error bars are conservative (see text). △, Al (99.999% purity); ○, Al (GB 420) low potential region; ●, Al (GB 420) high potential region; □, Al (GB 80S); ×, Al (GB 80S) possible high potential region; ▽, Mg (AZ 61); ▼, Mg (AP 65). $\overline{\Delta V}/n$ values for the reactions: ▲, $Mg(OH)_2 + H_2\ (aq) = Mg^{++} + 2H_2O + 2e^-$; ○, $Al(OH)_3 + 3/2\ H_2\ (aq) = Al^{+++} + 3H_2O + 3e^-$ obtained from the dependence of hydrogen electrode potential on pressure.

As are the borate structures, the acetate ion and phosphate ions are also oxygen acids containing resonance stabilized anions with favorable structures for hydrogen bonding; note for example, hydrogen bonded dimeric acetic acid, with hydrogen bond energies of 1.8 kJ mol^{-1} (21). Similar comments apply to the four other systems, formic acid, phosphoric acid—1st dissociation, carbonic acid and bicarbonate buffer, included in Fig. 3 for comparison. A large discrepancy exists in the experimental results for bicarbonate between the emf data of line 3 and those obtained by compressibility data (15); this has been speculatively attributed (12) to unknown effects of pressure on the $NaHCO_3$ equilibrium or to complications of hydrolysis reactions. However the author (12) did not explain why such complications would not also be reflected in compressibility or conductivity results; hence the $\overline{\Delta V}$ values for line 3 may be incorrect. Other values of $\overline{\Delta V}$ reported for the bicarbonate equilibrium are −24.9 (17) and −27.8 (15).

The magnitudes and pressure dependence of the derived $\overline{\Delta V}$ values can be rationalized in the following manner: Values of the standard entropy of ionization of the systems of Fig. 3 were calculated from published data (2, 22, 23) and are listed in Table IV.

Comparison of these values of ΔS_i^0 with the $\overline{\Delta V}$ values shows an interesting (if imperfect) correlation, in that larger $-\overline{\Delta V}$ values appear to be associated with larger $-\Delta S_i^0$ values. This is not surprising when one recalls that volume decreases are caused partially by electrostriction of the water structure, resulting in local ordering of the water dipoles. However, account

Table IV. Values of ΔS_i^0 and $\overline{\Delta V}$ (1 atm) for various equilibria

Equilibrium	ΔS_i^0 (cal K^{-1} mol^{-1})	$\overline{\Delta V}$ (cm^3/mol)
$HCOOH = HCOO^- + H^+$	−17.4	−9.1
$CH_3COOH = CH_3COO^- + H^+$	−22.1	−11.5
$H_2CO_3 = HCO_3^- + H^+$	−23.3	−30.0
$H_3PO_4 = H_2PO_4^- + H^+$	−15.7	−16.5 ± 1
$H_2PO_4^- = HPO_4^= + H^+$	−30.3	−23.7 ± 0.6
$HCO_3^- = CO_3^= + H^+$	−35.3	−22.7
$H_3BO_3 = H_2BO_3^- + H^+$	−31.1	−31.9

must also be taken of size effects and structure-breaking entropy (24, 25). For most singly charged anions, there is a considerable increase of disorder and volume. Thus the net entropies in Table IV are due to a difference of ordering and disordering terms. The highly ordered structure around the ion will decrease the volume of the solvent, and the effects of disordering may increase it. However, the differences between molecular and/or ionic sizes also contribute to the $\overline{\Delta V}$ term whereas their effect on ΔS_i^0 is less direct. The correlation between the two quantities is therefore not completely straightforward, particularly in a solvent with such an abnormally open structure as water.

In inspecting Table IV there is an anomaly, in the case of phosphoric acid, among the reactions producing singly charged anions by dissociation of the neutral molecular species. On the basis of the $\overline{\Delta V}$ values one might expect the entropy change for the first dissociation step to be more negative. A possible explanation for this may be that the tetrahedral phosphate group fits better into the water structure than the trigonal carboxyl or bicarbonate groups. Hence the bulk water structure is better preserved with phosphate whereas the other groups cause greater short range ordering effects.

A cage of water molecules forming a clathrate-type structure may act as a transition region between the ion and the bulk water structure.

The equilibria producing doubly charged ions have more negative ΔS_i^0 and $\overline{\Delta V}$ values, as expected, due to the greater orienting and compressive effect of the higher ionic fields. However the boric-borate values are far too negative to correspond to the equilibrium as written in the table. They would be far more consistent with the formation of one of the doubly charged borate ions discussed earlier.

The slopes of the $\overline{\Delta V}$/pressure plots calculated from the present data are in the ratio of 3.0:2.0:0.94 for the borate, phosphate, and acetate equilibria, respectively. This may indicate that the borate equilibria involve reversible formation of both singly and doubly charged species simultaneously.

Magnesium and aluminum electrodes.—Magnesium and aluminum ions are strong structure makers with large negative ΔS_i values. Large negative $\overline{\Delta V}$ values would be expected if the potential of these anodes were controlled by dissolution of Mg^{++} and Al^{+++} ions.

The results of Fig. 5 show that this cannot always be the case for aluninum but may be so for magnesium.

Stability constants for complex metal ions (27) indicate that Mg goes into solution in neutral or basic solutions predominantly as hydrated Mg^{++} ion and $MgOH^+$ ion and that there are no stable complex chloride ions.

For aluminum the picture is much more complicated. Evidence exists (27) for a large number of hydroxyl complex ions such as $Al_n(OH)_{3n+1}^-$, $Al_n(OH)_n^{2n+}$, $Al_n(OH)_{2n}^{n+}$ and $Al_{2n}(OH)_{5n}^{n+}$ where n = 1, 2, or 3. The existence of $Al(H_2O)_6Cl_3$ [as well as $Mg(H_2O)_6Cl_2$] in crystals (28) suggests the likelihood of hexahydrated $Al(H_2O)_6^{+++}$ [and $Mg(H_2O)_6^{++}$] in concentrated chloride solutions. Furthermore there is now

strong, n.m.r. spectroscopic evidence (30) in support of an integral six waters of hydration for Al^{+++} and Mg^{++} giving stable solvation complexes in aqueous solutions.

The alloying metals contained in the anodes used are sufficiently noble to be retained in the metallic phase and so have not been considered.

In order to interpret the values of $\overline{\Delta V}/n$ obtained experimentally, all of the electrochemical reactions controlling the electrode potential must be considered. If these reactions are sufficiently reversible that the present analysis can be applied, the discrepancy between the observed and thermodynamically calculated (29) electrode potentials must be due to mixed potential control.

Magnesium.—In the case of magnesium, a corrosion potential is measured which must be controlled by the magnesium oxidation reaction(s) and by the hydrogen evolution reaction. Since there is no external current these oxidation and reduction reactions must proceed at equal rates, so that the $\overline{\Delta V}/n$ value determined will be the sum of the two (or more) processes

$$Mg = \text{oxidized product(s)} + ne$$

and

$$nH^+ + ne = \frac{n}{2} H_2 \text{ (aq)}$$

In order to derive a value of $\overline{\Delta V}$ for the oxidation reaction(s) only, an estimate of $\overline{\Delta V}/n$ for the hydrogen evolution reaction is required. The most probable value of $\overline{V}$, the partial molal volume of a hydrogen ion in aqueous solution at 25°C, is -5.0 cm^3/mol (33), although there remains some argument in favor of a slightly more positive value (33, 34). The partial volume of solvation of the hydrogen molecule should be small and positive since it probably can be accommodated in the void spaces of the water structure with negligible distortion [cf. Ne, Ar (23)]. $\overline{\Delta V}$ values for the reaction

$$H^+ + e^- = \tfrac{1}{2} H_2 \text{ (aq)}$$

can be obtained from the data of Fig. 2. For the 0.1M HCl and the acidified 0.5M NaCl solutions the value of $\overline{\Delta V}/n$ obtained at atmospheric pressure is $+7.5 \pm 0.2$ cm^3/equivalent. Since it is $\overline{\Delta V}$ for the over-all reaction which is required, it is not important whether the expansions due to hydrogen ion extraction and molecular hydrogen inclusion are 5.0 and 5.0 cm^3/mole, respectively, or 0 and 15 cm^3/mole, respectively (or something in between). However the former values appear the more likely.

Accordingly a partial molal volume of -5.0 cm^3/mole for the hydrogen ion has been assumed for the calculations of $\overline{\Delta V}$ to follow. From this value and published values of partial molal volumes of electrolytes (33), $\overline{\Delta V}$ values of $+22.8$, -31.2, and -57.2 cm^3 mol^{-1} are obtained for Cl^-, Mg^{++}, and Al^{+++} ions, respectively. From published density data (22) and a $\overline{\Delta V}$ value of -23.4 cm^3/mole (2) for the water dissociation reaction, volumes of solid phases could be determined, and a partial molal volume of -0.3 cm^3/mole for OH^- ion was calculated. These values were then used to calculate $\overline{\Delta V}$ for the electrode reactions considered below. The magnesium results at atmospheric pressure will be discussed first.

The magnesium oxidation reactions considered and their calculated values of $\overline{\Delta V}/n$ were as follows

Reaction	$\overline{\Delta V}/n$ (cm^3/mol)	
$Mg + 6H_2O = Mg(H_2O)_6{}^{++} + 2e^-$	-21.4	[I]
$Mg + 2H_2O = Mg(OH)_2 + 2H^+ + 2e^-$	-17.7	[II]
$Mg + H_2O = MgO + 2H^+ + 2e^-$	-15.4	[III]
$Mg + OH^- = MgO + H^+ + 2e^-$	-3.7	[IV]
$Mg + 2OH^- = Mg(OH)_2 + 2e^-$	$+5.7$	[V]

In addition the following reactions were considered, in which calculated $\overline{\Delta V}$ values are approximate since density data were unavailable for MgO_2 and partial molal volumes for the ions had to be inferred from other ions of similar size and charge

Reaction	$\overline{\Delta V}/n$	
$Mg + OH^- = MgOH^+ + 2e$	$\sim +3$	[VI]
$Mg + H_2O = MgOH^+ + H^+ + 2e^-$	~ -8.5	[VII]
$Mg = Mg^+ + e^-$	~ -20	[VIII]
$Mg + 2H_2O = MgO_2 + 4H^+ + 4e^-$	~ -12.5	[IX]
$Mg + 2OH^- = MgO_2 + 2H^+ + 4e^-$	~ -1	[X]

In order to make a comparison with the experimental values of $\overline{\Delta V}/n$, correction for the contribution of the hydrogen evolution reaction is required. Table V gives the corrected values with maximum probable experimental error for the various anodes studied. Comparison of the table with the calculated values for magnesium eliminates all of the reactions in which OH^- is a reactant species or in which $Mg\ OH^+$ is a product. For AZ 61 and AP 65, the formation of Mg^+ and MgO_2, respectively, can also be eliminated except as possible minor parallel reactions. These reactions have been suggested by other workers (29, 35, 36).

The experimental data are consistent with production of Mg^+ from the AP 65 alloy and MgO_2 for the magnesium AZ 61. However, at present, scant other evidence exists to support these reactions. Accordingly, having noted these as possibilities, reactions [I]-[III] will be discussed in more detail. The experimental data favor reaction [I] as the oxidation mechanism for AP 65 and reaction [III] for AZ 61. Reaction [II] lies within the experimental error for both alloys however and therefore cannot be ignored. Immersion of these alloys in 0.5M NaCl gives rise to the following phenomena. The AP 65 corrodes rapidly with vigorous gassing and production of grayish-white voluminous precipitate near the surface. In a short time the electrode completely corrodes away and only a white precipitate and

Table V. Corrected experimental $\overline{\Delta V}/n$ values for the metal oxidation reaction

Anode	$\overline{\Delta V}/n$ (cm^3/equivalent)	Error
Mg AZ 61	-14	± 4
Mg AP 65	-19.5	± 4
Al (99.999%)	50	± 15
Al (GB 80S)	14	± 6
Al (GB 420)		
High potentials	-1.5	± 3.5
Low potentials	-60	± 17

fine black particles remain (presumably from the lead which should not corrode at pH 8-12). The AZ 61 corrodes much less rapidly however and eventually builds up an incomplete black film which retards the rate of corrosion even further.

These observations, in conjunction with the experimental $\overline{\Delta V}/n$ values, lead to the conclusion that AP 65 corrodes according to reaction [I] by direct dissolution to hexahydrated Mg^{++} ions (or by reaction [VIII] to Mg^{+} ions) followed by solution phase chemical formation of $Mg(OH)_2$.

For AZ 61, reaction [III] results in formation of a passivating layer of MgO on the surface (or MgO_2 by reaction [IX]) which may then be slowly hydrated.

Direct formation of $Mg(OH)_2$ by reaction [II] cannot be dismissed completely on the basis of the present evidence. However the mechanisms of the two alloys appear to be so different that it cannot occur, as more than a minor parallel reaction, for both alloys. If it were to occur for AP 65, for example, that would strongly point to reaction [III] for AZ 61. Conversely reaction [I] would be indicated for AP 65 if [II] were accepted for AZ 61. This latter possibility seems unlikely if the errors cited are as conservative as is thought.

Accordingly it is concluded that at atmospheric pressure reaction [I] is the most likely potential controlling oxidation reaction for AP 65 with a possible major parallel contribution by reaction [II]. For AZ 61, the most favored interpretation is that reaction [III] is the principal oxidation process with a possible minor contribution by reaction [II].

In buffered solutions the $\overline{\Delta V}$ values tended to be somewhat more negative at lower pressures, particularly for AZ 61. Whether this is experimentally significant for AP 65 or not is open to question. However if it is a real effect, it suggests that the buffering agents tend to inhibit oxide formation and possibly dissolution as well. Ion pairing and insoluble salt formation are known to occur between magnesium and phosphate ions in solution and phosphate adsorption on the surface would not be surprising. Furthermore borax is a widely used rust inhibitor. The presence of these agents may very well shift the oxidation reaction path for AZ 61, enhancing the contribution of reaction [II] and reducing that of reaction [III].

The AP 65 corroded more quickly in the unbuffered than in the buffered solutions even though the pH was higher in the former, also suggesting some shift toward reaction [II] in the presence of phosphate or borate. Differences in corrosion rate were much less for AZ 61, consistent with a shift from reaction [III] to reaction [II] which would have identical pH dependencies.

At higher pressures, both magnesium alloys reacted with more negative $\overline{\Delta V}$ values than at atmospheric pressure. This would not be expected if a single electrode reaction were occurring at either anode and suggests a shift of mechanism at higher pressures toward the more negative $\overline{\Delta V}$ reactions. Further evidence that this is occurring for AZ 61 was obtained by the observation that, although AZ 61 did not produce any visible precipitate at atmospheric pressure for several days, a fine white suspension was observed in solution after the alloy had completed an experimental cycle taking it to 2.5 kbars and back to atmospheric pressure again.

These facts suggest that at higher pressures the mechanism shifts from reaction [III] toward [II] or even [I] for AZ 61 and that reaction [II] is inhibited for AP 65.

Finally at very high pressures $\overline{\Delta V}$ values begin approaching zero as would be expected when the reaction products can no longer aid in compressing the solvent structure or in reducing the system volume further.

Included in Fig. 5, are values of $\overline{\Delta V}/n$, obtained by measuring the hydrogen electrode potentials *vs.* Ag/AgCl in solutions saturated with $Mg(OH)_2$ or $Al(OH)_3$. The over-all reaction controlling the electrode potential in the case of $Mg(OH)_2$ is actually the sum of three reactions

Reaction		$\overline{\Delta V}$ ($cm^3\,mol^{-1}$)
$Mg(OH)_2$	$= Mg^{++} + 2\,OH^-$	−56.5
$2H^+ + 2\,OH^-$	$= 2H_2O$	+46.8
$H_2(aq)$	$= 2H^+ + 2e^-$	−15.0
$Mg(OH)_2 + H_2(aq)$	$= Mg^{++} + 2H_2O + 2e^-$	−24.7

The calculated values of $\overline{\Delta V}$ at 1 atm are shown. The measured value of $\overline{\Delta V}/n = -13.2 \pm 1.0$ cm^3/equivalent is in good agreement with the calculated value of −12.4, indicating that the reactions controlling electrode potential in the magnesium system are all reversible. The very small pressure dependence observed suggests that no changes of mechanism occur at higher pressures.

Aluminum.—The reason for the rather large experimental scatter of $\overline{\Delta V}$ values for the aluminum anodes in buffered solutions became more comprehensible when the results for the self-buffered solutions were analyzed. The more evident separation of Al (GB 420) into two distinct potential regions, and the sporadic experimental results, suggesting the same phenomenon was possible (though less favored) for Al (GB 80S), led to the conclusion that at least two potential controlling reactions were important. Furthermore, the hysteresis observed indicated slow attainment of equilibrium between competing species. No high potential region was unambiguously detected in buffered solutions except in the borate buffered system and then at only 1 and 50 bars pressure. Hence the results in buffered systems are in much closer agreement with the low potential self-buffered data than with the high potential results. In the case of aluminum, addition of the buffering agent to the solution raises the pH, the opposite of its effect in the magnesium system. Yet less gassing was observed in the absence of buffering agents, suggesting inhibition either by adsorption of the oxyanion or by a pH effect. In order to interpret the aluminum results, the following reactions were first considered and the $\overline{\Delta V}/n$ values calculated from published data

Reaction		$\overline{\Delta V}/n$	
$2Al + 6H_2O$	$= Al_2O_3 \cdot 3H_2O + 6H^+ + 6e^-$	−15.9	[XI]
$2Al + 4H_2O$	$= Al_2O_3 \cdot H_2O + 6H^+ + 6e^-$	−13.7	[XII]
$2Al + 3H_2O$	$= Al_2O_3 + 6H^+ + 6e^-$	−13.1	[XIII]
$Al + 3H_2O$	$= Al(OH)_3 + 3H^+ + 3e^-$	−15.6	[XIV]
$2Al + 3\,OH^-$	$= Al_2O_3 + 3H^+ + 6e^-$	− 1.7	[XV]
$2Al + 4\,OH^-$	$= Al_2O_3 \cdot H_2O + 2H^+ + 6e^-$	1.9	[XVI]

$2Al + 6\,OH^- = Al_2O_3 \cdot 3H_2O + 6e^-$ 7.4 [XVII]

$Al + 3\,OH^- = Al(OH)_3 + 3e^-$ 7.7 [XVIII]

$Al + 6H_2O = Al(H_2O)_6^{+++} + 3e^-$ −22.3 [XIX]

$Al + 2H_2O = AlO(OH) + 3H^+ + 3e^-$ −14.1 [XX]

$Al + 2\,OH^- = AlO(OH) + H^+ + 3e^-$ + 1.5 [XXI]

$Al + Al(H_2O)_6^{+++} = Al_2O_3 \cdot 3H_2O + 6H^+ + 3e^-$ − 9.5 [XXII]

$Al + Al(OH)_3 = Al_2O_3 + 3H^+ + 3e^-$ −10.5 [XXIII]

$Al + Al(OH)_3 + H_2O = Al_2O_3 \cdot H_2O + 3H^+ + 3e^-$ −11.8 [XXIV]

$Al + Al(OH)_3 + 3H_2O = Al_2O_3 \cdot 3H_2O + 3H^+ + 3e^-$ −16.1 [XXV]

Other combinations of the above reactions have also been considered.

For pure aluminum, for Al (GB 80S), and for the low potential region of Al (GB 420) at atmospheric pressure, none of the above reactions has values of $\overline{\Delta V}/n$ within the error limits of the experimental values, although reaction [XVIII] lies just outside these limits for Al (GB 80S). For the high potential data of Al (GB 420), only reactions [XV], [XVI], and [XXI] are possible. All of these reactions involve the consumption of hydroxyl ions and production of hydrogen ions and a surface oxide. When the simultaneous hydrogen evolution reaction is added, all would predict no pH dependence.

Estimates of $\overline{\Delta V}/n$ based on size and charge considerations for reactions producing AlO^+, $AlOH^{++}$, AlO_2^-, $Al(OH)_4^-$, and $Al(H_2O)_5OH^{++}$ were also inconsistent with experimental values with some exceptions for the high potential Al (GB 420) results. The partial molal volumes for these species were taken to be approximately +20, −7, +27, +50, and −30 cm^3/mol, respectively.

Clearly, either irreversible electrode processes are occurring, or other reactions than those considered above are controlling the electrode potentials.

The analysis of the aluminum results has so far carried the tacit assumption that the potential controlling oxidation reaction involves formation of trivalent aluminum from metallic aluminum. Since no reactions have been found to justify this assumption, other oxidation states of aluminum must be considered. This requires estimated $\overline{\Delta V}/n$ based on approximations, since no density or partial molal volume data exist for such species.

When such estimates were made for reactions in which metallic aluminum is oxidized to the univalent aluminum species Al^+, AlOH, or $Al(OH)_2^-$ no values of $\overline{\Delta V}$ calculated were consistent with experimental values. In considering oxidations from metallic aluminum to divalent aluminum by formation of $Al(OH)_2$, $Al_2O_2 \cdot 3H_2O$, AlO, or $Al(OH)_3^-$ only two reactions were found consistent with any of the data. These were

$Al + 2\,OH^- = Al(OH)_2 + 2e^-$ $\overline{\Delta V}/n \approx +12$ [XXVI]

$Al + 3\,OH^- = Al(OH)_3^- + 2e^-$ $\overline{\Delta V}/n \approx 20$ [XXVII]

which were only consistent with the Al(GB 80S) $\overline{\Delta V}/n$ values.

Similarly consideration of oxidations from univalent to trivalent aluminum led to only two possible reactions

$Al^+ + 3\,OH^- = Al(OH)_3 + 2e^-$ $\overline{\Delta V}/n \sim 9$ [XXVIII]

$Al(OH)_2^- + OH^- = Al(OH)_3 + 2e^-$ $\overline{\Delta V}/n \sim -1.3$ [XXIX]

These both would involve the anode, only as a heterogeneous catalyst, and are consistent only with the Al(GB 80S) and Al(GB 420) high potential $\overline{\Delta V}/n$ values.

Oxidation from divalent to trivalent aluminum is the *only* remaining case having a stable reactant or product species. The oxygen deficiency of the anodic aluminum barrier layer (adjacent to the solution) has been established (37) and gives rise to an n-type defect structure. The existence of Al(II) has been suggested (38) and infrared absorption studies of barrier layer oxides have been interpreted (39) as indicative of an alumina layer containing divalent aluminum. The structure proposed (39) contained a trivalent cyclic polymeric aluminum oxide trihydrate layer with oxygen deficient terminal groups containing divalent aluminum, at which oxidation and depolymerization could occur to form porous alumina.

The following reactions were considered for oxidation from divalent to trivalent aluminum. It was assumed that divalent solid aluminum phases had the same density as the corresponding trivalent solid phases and estimates of partial molal volumes of ions were made, as before, based on size and charge comparisons.

$\overline{\Delta V}/n$ (approximate)

$Al(OH)_2 + 6H_2O = Al(H_2O)_6^{+++} + 2\,OH^- + e^-$ −196 [XXX]

$Al_2O_2 \cdot 3H_2O + 11H_2O = 2Al(H_2O)_6^{+++} + 4\,OH^- + 2e^-$ −189 [XXXI]

$Al(OH)_2 + 4H_2O + 2H^+ = Al(H_2O)_6^{+++} + e^-$ −151 [XXXII]

$Al_2O_2 \cdot 3H_2O + 5H_2O = Al(H_2O)_6^{+++} + Al(OH)_3 + OH^- + 2e^-$ − 90 [XXXIII]

$Al(OH)_2 + H_2O = Al(OH)_3 + H^+ + e^-$ − 23 [XXXIV]

$Al(OH)_2 + Al(OH)_3 + H_2O = Al_2O_3 \cdot 3H_2O + H^+ + e^-$ − 23 [XXXV]

$Al_2O_2 \cdot 3H_2O + H_2O = Al_2O_3 \cdot 3H_2O + 2H^+ + 2e^-$ − 14 [XXXVI]

$Al(OH)_2 + OH^- = Al(OH)_3 + e^-$ 0 [XXXVII]

$Al(OH)_2 + Al(OH)_3 + OH^- = Al_2O_3 \cdot 3H_2O + e^-$ 0 [XXXVIII]

$Al_2O_2 \cdot 3H_2O + 2\,OH^-$
$= Al_2O_3 \cdot 3H_2O + H_2O + 2e^-$ 9 [XXXIX]

$Al_2O_2 \cdot 3H_2O + 3\,OH^-$
$= 2Al(OH)_4^- + H^+ + 2e^-$ 16 [XL]

$Al(OH)_2 + 2\,OH^-$
$= Al(OH)_4^- + e^-$ 18 [XLI]

Reactions [XXX]-[XXXIII] in which divalent aluminum is oxidized to hexahydrated aluminum ion have negative values of $\overline{\Delta V}/n$ larger than those obtained from the low potential Al (GB 420) data. By themselves they could not explain the experimental results unless another reaction with a more positive $\overline{\Delta V}/n$ were occurring simultaneously.

Such a reaction could be any or several of the others already discussed. The most probable are [XI], [XVII], or [XIX] in which metallic aluminum is oxidized to a trivalent solid phase or solution phase species. However the other oxidation reactions cannot be eliminated. It would also be possible to rationalize the other aluminum alloy results in terms of combinations of the reactions cited. However no rationalization of the large positive $\overline{\Delta V}/n$ values for pure aluminum would be possible from the above reaction schemes.

Aluminum oxide is known to form a negatively charged colloidal sol and it has been suggested (40) that this is of the form $[Al_2O_3 \cdot x\,H_2O]\,AlO_2^- \,\vdots\, Na^+$. No data are available, and it is difficult to estimate the partial molal volume of such a species. If a structure for $Al_2O_3 \cdot 3H_2O$ of the form suggested by Dorsey (39) is accepted, a crude estimate of 100-120 cm^3/mol can be made. This is based on values for singly charged substituted benzene rings, for which $\overline{V}^0$ values of about 75-85 cm^3/mol/phenyl group have been obtained (33) and on an estimated value of $\overline{V}^0$ for AlO_2^- of about 30 cm^3/mole. Such a value could give an order of magnitude for $\overline{\Delta V}/n$ consistent with the experimental results for Al (GB 80S) if oxidation from a divalent state took place. However the $\overline{\Delta V}/n$ values calculated would still be too small to explain the results for pure aluminum.

There remain two other possibilities which will be discussed here. First, if the hydrogen evolved is not adsorbed on the alumina surface in such a way as to dissolve in solution reversibly, and therefore forms gas phase hydrogen, a very large positive $\overline{\Delta V}$ contribution would appear. Second, if a porous alumina layer is formed by depolymerization according to the model of Dorsey (39), there would be larger positive $\overline{\Delta V}$ values than those calculated. Unfortunately since the model does not include a detailed geometry for porous layer formation, it is impossible at present to estimate values of $\overline{\Delta V}$ without entering even more deeply into an area of extreme speculation.

Measurements of the hydrogen electrode potential, in solutions of 0.5M NaCl, in which an excess of Al (GB 80S) was permitted to corrode for several days, were much less reproducible than in $Mg(OH)_2$ saturated solutions.

The reactions considered and the calculated $\overline{\Delta V}$ values at 1 atm are

		$\overline{\Delta V}$
$Al(OH)_3$	$= Al^{+++} + 3\,OH^-$	−90.3
$3H^+ + 3\,OH^-$	$= 3H_2O$	+70.2
$3/2H_2(aq)$	$= 3H^+ + 3e$	−22.5
$Al(OH)_3 + 3/2H_2(aq)$	$= Al^{+++} + 3H_2O + 3e^-$	−42.6

The calculated value of $\overline{\Delta V}/n = -14.2$ is in agreement with the experimental value of -20 ± 6 cm^3/equivalent. However the strong dependence on pressure and large experimental uncertainty suggest that irreversible processes are occurring and/or there may be other reactions exerting some control on electrode potential.

If the first reaction considered above were

$$Al_2O_3 \cdot 3H_2O = 2Al^{+++} + 6\,OH^-$$

the calculated $\overline{\Delta V}/n$ for the over-all reaction would be $+7.0$ cm^3/equivalent, in close agreement with the observed high pressure values of $+7.4 \pm 4$. Hence there could be a change from one mechanism to another as pressure is increased. Other reactions could also be considered, but the comparatively imprecise experimental results for this system do not warrant a high enough degree of confidence to lead to definite conclusions without further evidence.

The aluminum results cannot be definitively explained by the present data. There are many reactions which may be simultaneously occurring to cause this state of affairs, some of which may be irreversible. However the simplest and most likely model which emerges, consistent with the cited facts may be the following.

For Al (GB 420) there are at least two oxidizing reactions occurring: one in which surface alumina containing divalent aluminum is oxidized to hexahydrated aluminum ions (possible reactions [XXX]-[XXXIII]); a second in which metallic aluminum is oxidized to a surface oxide or hydroxide by reaction with hydroxyl ions (possible reactions [XVII], [XVIII], [XIX], [XXVI], [XXVII]); the second reaction might instead involve formation of colloidal or porous alumina.

At atmospheric or low pressures, the second reaction(s) occurs preferentially along cracks or pores in the oxide layer. If the cracks heal or are sealed by the application of pressure, the second reaction is blocked or inhibited and the first becomes favored giving large negative $\overline{\Delta V}$ values. These mechanisms appear to be consistent with conclusions based on O^{18} tracer techniques (43) if the structure proposed by Dorsey (38) and substantiated by electron micrographs (44) is accepted.

For Al (GB 80S), the first reaction does not apparently occur, which suggests that the pores do not seal. A single oxidation reaction might control the electrode potential if divalent aluminum is formed reversibly by reactions [XXVI] or [XXVII]; this seems unlikely. Reactions [XXXIX]-[XLI] are also possible but are not expected to be energetically probable except on a surface without pores. This means that it is also necessary to consider two simultaneous oxidation reactions controlling this alloy's potential. If one reaction is the large positive $\overline{\Delta V}$ process involving formation of porous or colloidal alumina or gaseous hydrogen, it is impossible to state definitely which of the other 28 reactions, having values of $\overline{\Delta V}/n$ less than 14, is the second, although some can be eliminated on various grounds.

For pure aluminum, the same unknown reaction(s) as for Al (GB 80S) are possible although a large positive $\overline{\Delta V}$ process of porous alumina formation or gaseous hydrogen evolution appears to be potential controlling. The latter process would not likely be reversible.

Conclusion

Practical significance.—Pressures much in excess of 1 kbar would not be encountered even at the greatest ocean depths. Hence the present work demonstrates that pressure effects on the electrodes themselves would cause only small changes in most seawater battery voltages.

The elucidation of the electrode mechanisms involved using the present technique should be of some

value in choosing the appropriate alloy for a particular application and in understanding the criteria for such a choice. For example AZ 61 is a superior alloy where sludging in a stagnant electrolyte cannot be tolerated because of the formation of a surface oxide, or in cases where a reduction of corrosion rate during open-circuit periods is essential, as is the case of the personal beacon battery. For a high rate, high voltage, short life application, where circulation of electrolyte is maintained, as in a torpedo battery, AP 65 would be preferred but greater interelectrode spacing would be beneficial.

The reduction of open-circuit emf at high pressures would have to be considered for batteries employing aluminum GB 420 for very deep ocean applications. The increase in open-circuit emf for pure aluminum is of little practical benefit in a battery because of excessive polarization. However an Al (GB 80S) anode coupled with a silver chloride cathode would give a stable voltage independent of depth with only a small increase of OCV with pressure and a low corrosion rate.

Summary

Reference electrodes, for use at high pressures in chloride or hydrogen containing solutions, were tested in various chloride media, both acidified and buffered. The electrodes were silver chloride, and platinized platinum in hydrogen saturated electrolyte. The results in unbuffered solutions indicated that the very small ($\lesssim$ 1 mV over the 2.5 kbar range) pressure dependence of the AgCl electrode could be quantitatively attributed to variation of chloride ion activity with pressure. The larger variation of the hydrogen electrodes were caused by the dependence of hydrogen fugacity on pressure and could be accurately estimated.

The reference electrodes were applied to the study of various buffer equilibria at pressures from 0 to 2.5 kbar. Partial volumes of reaction obtained were linear in pressure to a good approximation. However, there was a slight but definite quadratic dependence which was only detectable due to the high precision of the measurements. The volumes are compared with each other and those obtained by other methods and are interpreted qualitatively in terms of their effect on the solvent structure.

The open-circuit potentials of two magnesium alloy anodes (AZ 61 and AP 65) and three aluminum anodes (99.999% Al, GB 420[4] and GB 80S[4]) were measured relative to AgCl, using hydrogen electrodes to monitor hydrogen evolution. Experiments were done in phosphate and borate buffered sodium chloride solutions, and in 0.5M NaCl, buffered only by the solubility equilibrium of the appropriate metal hydroxide. The partial molal volumes derived for unbuffered (self-buffered) systems were negative for the magnesium alloys (-10 to -20 cm^3/mol) and were not strongly dependent on pressure. They were positive and strongly dependent on pressure for the pure aluminum (60-0 cm^3/mol). One of the Al alloys (GB 80S—0.5% Sn, 0.05% Ga) had a positive ΔV over most of the pressure range (30 to -5 cm^3/mol). The other alloy (GB 420—5% Zn, 0.2% Sn) exhibited two stable potentials at certain pressures. The higher (more negative) potential was easier to reproduce at lower pressures, whereas the lower potential often appeared by a rather sudden transition following increase of pressure. It usually remained at the lower values, returning with some hysteresis upon decompression.

The ΔV values, associated with the low potentials, were large and negative and more dependent on pressure than the near zero ΔV values of the high potential region.

The signs and orders of magnitude of ΔV were similar in both the buffered and unbuffered solutions. However, reproducibility was poorer in the former, possibly as a consequence of adsorption, ion pairing or precipitation caused by phosphate or borate reaction with the metal ion at the electrode surface.

Of the two magnesium anodes investigated, the data indicated that Mg (AZ 61) reacted to produce predominantly a surface oxide, with some hydroxide formation possible, at atmospheric pressure. The Mg (AP 65) produced predominantly hexahydrated magnesium ions and some surface hydroxide. At higher pressures the reactions shifted toward more hydroxide and possibly ion formation for Mg (AZ 61) and less hydroxide and more ion formation for Mg(AP 65).

All aluminum anode potentials also appeared to be controlled by more than one oxidation mechanism. For Al (GB 420), metallic aluminum appeared to be oxidized to a surface oxide by reaction with hydroxyl ions along pores or cracks in the oxide layer at atmospheric pressure. At higher pressures or as the pores healed, the contribution of a reaction involving oxidation of divalent aluminum oxide to hexahydrated aluminum ions, increased in importance.

For Al (GB 80S) and for pure aluminum the interpretation of the data was more equivocal. The formation of porous or colloidal alumina combined with some other oxidation reaction was indicated if the potential controlling processes are reversible. Otherwise the formation of gaseous hydrogen or some other irreversible process controls the potential, rendering the present analysis invalid in such a case.

Additive Ternary Molten Salt Systems—Calculation of Phase Diagrams from Thermodynamic Data of Lower Order Systems

ABSTRACT

Calculations of the liquidus temperatures of additive ternary molten salt systems are carried out from the conformal ionic solution theory (up to second order terms). The comparison between measured and calculated phase diagrams is made for five systems [(Li,Na,K)F; (Li,Na,Cs)F; (Na,K,Cs)NO_3; (Li,K,Tl)NO_3; and Na(F,Cl,I)] chosen according to different types of liquidus and different values of the binary interaction coefficients. For most cases, and in particular when solid solutions are not reported, the agreement between measurements and calculations is found to be very good. In the search for low melting electrolytes for electrochemical applications, these equations should prove useful in predicting the range of compositions where low liquidus temperatures are most likely.

The thermodynamic study of multicomponent molten salt systems has been focused largely on experimental measurements. However, since measurements are generally expensive and time consuming, it is of interest to be able to predict thermodynamic properties of multicomponent systems from known theories by using available data for lower order systems. If this can be achieved with a satisfactory degree of accuracy, general properties of multicomponent systems, unmeasured or inaccessible to conventional measurements, are then *a priori* calculable. As multicomponent molten salt systems appear to be important as low melting stable electrolytes in many electrochemical applications, calculations such as ours should ultimately prove useful in choosing low melting mixtures for particular applications.

[1] Present address: Argonne National Laboratory, Argonne, Illinois 60439.
Key words: conformal ionic solution theory, multicomponent systems, liquidus temperatures, thermodynamic properties, fused salts.

Recently, the conformal ionic solution (CIS) theory (1) has been successfully used to calculate the liquidus temperatures (2, 3) and the liquid-liquid miscibility gaps (4) for ternary reciprocal molten salt systems utilizing thermodynamic data for the four pure salts and the four constituent binaries.

In this paper, we shall focus on another class of ternary molten salt systems, the additive ternary systems for which few theoretical investigations (5) have been published. Our main purpose is to apply the conformal ionic solution theory to the additive ternary systems and compare calculated and experimental data.

First, we shall derive by a statistical mechanical treatment a set of equations relating the thermodynamic properties of ternary mixtures to those of the three pure salts and the three constituent binaries; the equations were derived up to second-order terms. Second, the liquidus temperatures are then calculated for

the five systems: (Li,Na,K)F; (Li,Na,Cs)F; (Na,K,Cs)NO_3; (Li,K,Tl)NO_3; and Na(F,Cl,I) for which published measurements are available. These calculations for the ternary systems were made utilizing only liquidus phase diagram data from the three binary subsystems. Although simplifications in the calculations are used, these simplifications do not greatly influence our results.

Finally, a comparison between the experimental and calculated phase diagrams is carried out with regard to the different types and strengths of interactions of the constituent binaries. For all the cases, the agreement is good. The second-order equations appear to be accurate enough to be used for predicting the general topological behavior of such systems and for determining the compositions of low melting eutectics.

Conformal Ionic Solution Theory—Extension to Ternary Additive Salt Solutions

Ternary additive molten salt systems are those containing three different anions (or cations) and one common cation (or anion). In this paper, we shall deal with the $(A^+,B^+,C^+)X^-$ ternary mixture composed of uni-univalent salts AX (component 1), BX (component 2), and CX (component 3). It should be pointed out that the calculations are strictly the same for the $A^+(X^-,Y^-,Z^-)$ ternary mixture composed of the AX, AY, and AZ salts; the calculations can also be easily extended to other additive systems containing mixtures of salts of multivalent charges (6) and to solutions containing more than three different anions (or cations) but one common cation (or anion). Following the perturbation method of Reiss *et al.* (7), we shall define for each salt i, a size parameter d_i (equal to the characteristic sum of the cation and anion radii) and a dimensionless parameter

$$g_i = \frac{d_o}{d_i}$$

where d_o is the size parameter for a "test" salt A_oX, having, in this case, X^- as an anion.

In order to calculate the thermodynamic functions for a mixture consisting of n_A moles of A^+, n_B moles of B^+, n_C moles of C^+, and $n = (n_A + n_B + n_C)$ moles of X^-, four separate perturbation calculations must be carried out. At first, in three separate samples, the components are conveniently produced: the size of the cations of the "test" salt varies so that d_o is changed to d_i (i = 1, 2, 3). Finally, the ternary mixture is obtained by allowing a fraction, x_A, of the cations of the "test" salt to vary so that d_o is changed to d_1, a fraction x_B to vary so that d_o is changed to d_2 and a fraction ($x_C = 1 - x_B - x_A$) to vary so that d_o is changed to d_3. The fractions x_i are the ionic fractions

$$x_A = \frac{n_A}{n_A + n_B + n_C} = \frac{n_{AX}}{n}$$

$$x_B = \frac{n_B}{n_A + n_B + n_C} = \frac{n_{BX}}{n}$$

$$x_C = \frac{n_C}{n_A + n_B + n_C} = \frac{n_{CX}}{n} \quad [1]$$

where n_{AX}, n_{BX}, and n_{CX} are the number of moles of the subscript components.

The perturbations and their effect on the potential energy, *U*, the configurational integral, *Z*, and the Helmholtz free energy, *A*, can be summarized in the following scheme

(*i*)	$d_o \to d_1$	$U_o \to U_1$	$Z_o \to Z_1$	$A_o \to A_1$
(*ii*)	$d_o \to d_2$	$U_o \to U_2$	$Z_o \to Z_2$	$A_o \to A_2$
(*iii*)	$d_o \to d_3$	$U_o \to U_3$	$Z_o \to Z_3$	$A_o \to A_3$
(*iv*)	$x_A d_o \to d_1$; $x_B d_o \to d_2$; $x_C d_o \to d_3$	$U_o \to U_m$	$Z_o \to Z_m$	$A_o \to A_m$ [2]

According to the definition of the conformal ionic solution (7), the potential energy U_i for a salt i in a particular configuration is expressed by

$$U_i = \sum_c^n \sum_a^n g_i f_{ca}(g_i r) + \sum_c^n \sum_a^n h_{ca}(r) + \sum_{a<a'}^n \sum^n u_{aa'} + \sum_{c<c'}^n \sum^n u_{cc'} \quad [3]$$

where c and a refer to a cation and an anion, respectively. The configurational integral, Z_i, is expressed by

$$Z_i = \frac{1}{(n!)^2} \int \ldots \int \exp(-U_i/kT)(d\tau)^{2n} \quad [4]$$

and the Helmholtz free energy A_i by

$$A_i = -kT \ln Z_i \quad [5]$$

Similarly, for the mixture $(A^+, B^+, C^+)X^-$

$$U_m = \sum_c^{n_A} \sum_a^n g_1 f_{ca}(g_1 r) + \sum_c^{n_B} \sum_a^n g_2 f_{ca}(g_2 r) + \sum_c^{n_C} \sum_a^n g_3 f_{ca}(g_3 r) + \sum_c^n \sum_a^n h_{ca}(r) + \sum_{a<a'}^n \sum^n u_{aa'} + \sum_{c<c'}^n \sum^n u_{cc'} \quad [6]$$

$$Z_m = \frac{1}{n_A! n_B! n_C! n!} \int \ldots \int \exp(-U_m/kT)(d\tau)^{2n} \quad [7]$$

and

$$A_m = -kT \ln Z_m \quad [8]$$

One mole of the ternary solution can be considered as consisting of x_A mole of AX, x_B mole of BX, and x_C mole of CX; then the excess Helmholtz free energy of mixing is expressed by

$$\Delta A_m^{xs} = A_m - x_A A_1 - x_B A_2 - x_C A_3 - RT(x_A \ln x_A + x_B \ln x_B + x_C \ln x_C) \quad [9]$$

In order to calculate ΔA_m^{xs}, the functions A_i and A_m are expanded about the values of the "test" salt up to the second order as follows

$$-\frac{A_i}{kT} = \ln Z_i = \ln Z_o + (g_i - 1)\left(\frac{\partial \ln Z_i}{\partial g_i}\right)_{(g_i=1)} + \frac{1}{2}(g_i - 1)^2 \left(\frac{\partial^2 \ln Z_i}{\partial g_i^2}\right)_{(g_i=1)} + \ldots\ldots \quad [10]$$

$$-\frac{A_m}{kT} = \ln Z_m = \ln Z_o + \sum_{i=1}^3 (g_i - 1)\left(\frac{\partial \ln Z_m}{\partial g_i}\right)_{(g=1)} + \tfrac{1}{2}\sum_{i=1}^3 \sum_{j=1}^3 (g_i - 1)(g_j - 1)\left(\frac{\partial^2 \ln Z_m}{\partial g_i \partial g_j}\right)_{(g=1)} + \ldots\ldots \quad [11]$$

where Z_o refers to the configurational integral of the "test" salt and the symbol $g = 1$ designates the limit as g_1, g_2, and g_3 approach unity. The calculations are identical to those given by Blander (8) for the binary systems; by keeping the same notation, the results for the excess Helmholtz free energy of mixing lead to the following second-order equation

$$\Delta A_m^{xs} = \Delta A_{12}^{xs} + \Delta A_{13}^{xs} + \Delta A_{23}^{xs} \quad [12]$$

where

$$\Delta A_{12}^{xs} = \Gamma(T, V)(g_1 - g_2)^2 x_A x_B$$

$$\Delta A_{13}^{xs} = \Gamma(T, V)(g_1 - g_3)^2 x_A x_C$$

$$\Delta A_{23}^{xs} = \Gamma(T, V)(g_2 - g_3)^2 x_B x_C \quad [13]$$

$\Gamma(T, V)$ is a combination of integrals depending only on the properties of the "test" salt and is a constant quantity for binary ionic conformal mixtures having X^- as a common anion. It should be noted that the terms of the first-order development cancel exactly as for binary mixtures.

The difference between the Helmholtz free energy A and the Gibbs free energy G can be considered as negligible in the second-order theory; then, the expression for the total excess free energy of mixing, ΔG_m^{xs}, of the ternary mixture is deduced from Eq. [12]

$$\Delta G_m^{xs} = \Delta G_{12}^{xs} + \Delta G_{13}^{xs} + \Delta G_{23}^{xs} \quad [14]$$

In order to be self-consistent we shall include only second-order terms so that

$$\Delta G_{12}^{xs} = \lambda_{12} x_A x_B$$
$$\Delta G_{13}^{xs} = \lambda_{13} x_A x_C \text{ etc.} \quad [15]$$

λ_{ij} being an energy coefficient which can be determined experimentally in the case of common ion systems. For one mole of ternary solution, the excess free energy of mixing is then expressed by

$$\Delta G_m^{xs} = x_A x_B \lambda_{12} + x_A x_C \lambda_{13} + x_B x_C \lambda_{23} \quad [16]$$

Assuming that the ternary mixture is regular and the heat of mixing of each of the constituent binaries is a symmetrical parabolic function of composition, Lumsden (9) has previously suggested that the heat of mixing of the ternary solution may be represented by the equation

$$\Delta H_m = x_A x_B \lambda_{12} + x_A x_C \lambda_{13} + x_B x_C \lambda_{23} \quad [16a]$$

The right hand side of this equation is identical to Eq. [16]. Lumsden applied Eq. [16a] to calculate the excess free energy for silver chloride in the LiCl-KCl eutectic melt; the agreement between his calculation and the experimental results is within the limits of the error in estimating the coefficients, λ_{ij}.

Finally, it should be pointed out that the higher order terms in Eq. [10]-[11] do not cancel. Blander and Hagemark (10) using the quasi-chemical theory gave a higher order equation for the excess free energy of mixing for ternary mixtures, taking into account terms which correspond to some of the third-order terms of the CIS. Because of limitations in the quasi-chemical theory, all the third-order terms cannot be obtained. In any case, these terms appear to be small in the systems we studied; using the equation of Blander and Hagemark (10), we have numerically estimated the third-order terms for our systems and in the most extreme cases, the correction was negligibly small.

Calculations of Ternary Phase Diagrams—Discussion

Method of calculation.—The activity coefficient, γ_{ij}, of any component can be calculated from Eq. [16] with the aid of the following relation

$$RT \ln \gamma_{ij} = \frac{\partial (n \Delta G_m^{xs})}{\partial n_{ij}} = \frac{\partial (n \Delta G_m^{xs})}{\partial n_i} \quad [17]$$

the number of moles n_{ij} of any component being, in this case, equal to the number of moles of the cations, n_i. For example, for the AX compoent, one obtains

$$RT \ln \gamma_{AX} = x_B(1 - x_A)\lambda_{12} + x_C(1 - x_A)\lambda_{13} - x_B x_C \lambda_{23} \quad [18]$$

Similar equations can be derived for the other components by changes in the subscripts in Eq. [18] as follows

for BX change A → B B → A 1 → 2 and 2 → 1
for CX change A → C C → A 1 → 3 and 3 → 1

The ternary liquidus temperatures may be calculated from expressions as

$$R \ln a_1 = R \ln \gamma_1 x_A = -\Delta H_f \left(\frac{1}{T} - \frac{1}{T_f} \right) \quad [19]$$

where the enthalpy of fusion ΔH_f has been assumed to be temperature independent; this assumption does not have any significant effect on our conclusions.

Indeed, if one takes into consideration the variation of the heat of fusion ΔH_f with the temperature, ΔH_f is then expressed by

$$\Delta H_f(T) = \Delta H_f(T_f) - \int_T^{T_f} \Delta C_p dT$$

where $\Delta H_f(T)$ and $\Delta H_f(T_f)$ are the enthalpies of fusion at T and T_f, respectively, and $\Delta C_p = C_p(\text{liq}) - C_p(\text{s})$. If ΔC_p is expressed by

$$\Delta C_p = \Delta a + T\Delta b + T^{-2}\Delta C$$

one obtains

$$R \ln a_1 = -\Delta H_f(T_f) \left(\frac{1}{T} - \frac{1}{T_f} \right) + \Delta a \left(\frac{T_f}{T} 1 - \ln \frac{T_f}{T} \right) + \frac{\Delta b}{2} \left(\frac{T_f^2}{T} - 2T_f + T \right) + \frac{\Delta c}{2} \left(\frac{1}{T} - \frac{1}{T_f} \right)^2 \quad [19a]$$

The terms containing the correction for the variation of ΔH_f with the temperature have a very small contribution, in the range of temperatures considered in this paper. For example, for $\Delta T = T_f - T = 540°$ which corresponds to the case of NaF, the error in a_1 would be about 4.6%. However, Eq. [19] will also be used to obtain the coefficients λ_{ij} from binary phase diagrams. This self-consistent procedure considerably reduces the uncertainties inherent in the use of Eq. [19] (rather than Eq. [19a]) for the calculation of the ternary liquidus temperatures.

Table I lists the values of ΔH_f and T_f used; the values of the melting points of the pure salts T_f are those given in the published phase diagrams, our main purpose being the comparison of calculated and measured ternary liquidus temperatures.

Values of the λ_{ij} coefficients are calculated from known binary phase diagrams in a manner described previously (1,2). Combining Eq. [19] with the following simplified relations

$$RT \ln \gamma_i = \lambda_{ij} x_j^2 \text{ and } RT \ln \gamma_j = \lambda_{ij}(1 - x_j)^2 \quad [20]$$

one obtains

$$T(\text{eutectic}) = [\lambda_{ij}(1 - x_j)^2 + \Delta H_{f,i}] / [(\Delta H_{f,j}/T_{f,j}) - R \ln x_j]$$
$$= [\lambda_{ij} x_j^2 + \Delta H_{f,j}] / [(\Delta H_{f,i}/T_{f,i}) - R \ln (1 - x_j)] \quad [21]$$

Table I. Values of enthalpies of fusion and melting points used in calculations

Salt	ΔH_f[a,b] (kcal mole^{-1})	T[c] (°K)

[e] The eutectic temperatures are taken from phase diagrams for which the calculations are made. Parentheses indicate extrapolated values for the binaries where solid solutions or some intermediate compounds are reported.

From the eutectic temperature and from Eq. (21), unique values for the energy coefficient λ_{ij} and the eutectic composition x_j may then be numerically calculated.

This procedure applies for simple binary systems where neither solid solutions nor binary compounds are reported. The calculated values obtained for λ_{ij} and x_j are given in Table II and are in reasonable agreement with the experimental values within experimental uncertainties. Our procedure constrains our calculations so as to include the binary eutectic point in the calculated phase diagram.

When solid solutions or binary compounds are known to exist, Eq. [20] and [21] if applied, would lead to higher values of λ_{ij}. In this case, we estimate a eutectic which would occur in the absence of solid solutions or binary compounds such that the calculated values of λ_{ij} are then consistent with available calorimetric or emf data (Table II). This procedure leads to a better representation of the thermodynamic properties at most compositions not close to the binary in question.

Comparison of Measured and Calculated Ternary Liquidus Temperatures

Experimental data for some ternary additive molten salt systems are available (10). The phase diagram is plotted in an equilateral triangle; each composition of the solution fixed by a point is defined by the corresponding triangular coordinates.

In order to adopt a uniform method to represent the calculated phase diagrams, the isotherms are drawn in each phase field for intervals of 50°C. For consistency, the binary data (*i.e.*, the eutectic temperatures) we use in the present calculations are those given by the same workers who made the ternary measurements, rather than values given in more recent work; for some binary systems included in more than one ternary phase diagram and measured by different authors, there are some discrepancies in the eutectic temperatures; in these cases, we use the value of T(eutectic) given in the corresponding ternary.

For the present purpose of comparing measured values with those calculated from lower order systems using the above equations, five systems have been examined; four of these are systems composed of salts containing a common anion and are characterized by relatively large negative binary interaction coefficients; the last is a system composed of salts containing a common cation and is characterized by small positive binary interaction coefficients ($\lesssim 1$ kcal mole^{-1}).

Figures 1-5 give both measured and calculated phase diagrams for several types of ternary additive systems. The range of applicability of the theory and the approximations used can then be discussed.

For the simplest ternary systems (*i.e.*, those in which the binary subsidiary solutions have eutectics and a ternary eutectic is reported) such as the (Li,Na,K)F and Na(F,Cl,I) systems (11), the differences between the measured and calculated phase diagrams are small and reflect, in part, uncertainties in the measured phase diagram (Fig. 1 and 5). For example, differences in the location and shape of some iso-

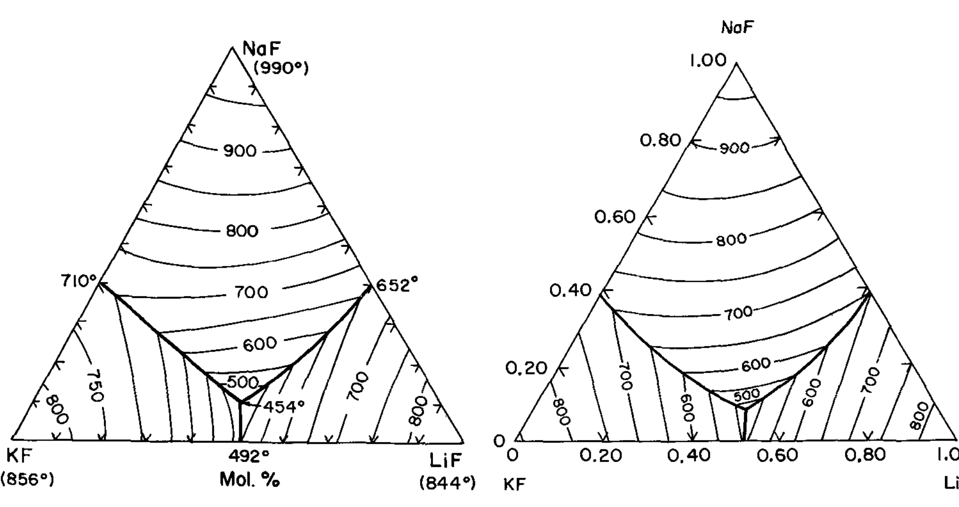

Fig. 1. Phase diagrams of the (Li,Na,K)F system. a (left), Measured [Ref. (11)]; b (right), calculated.

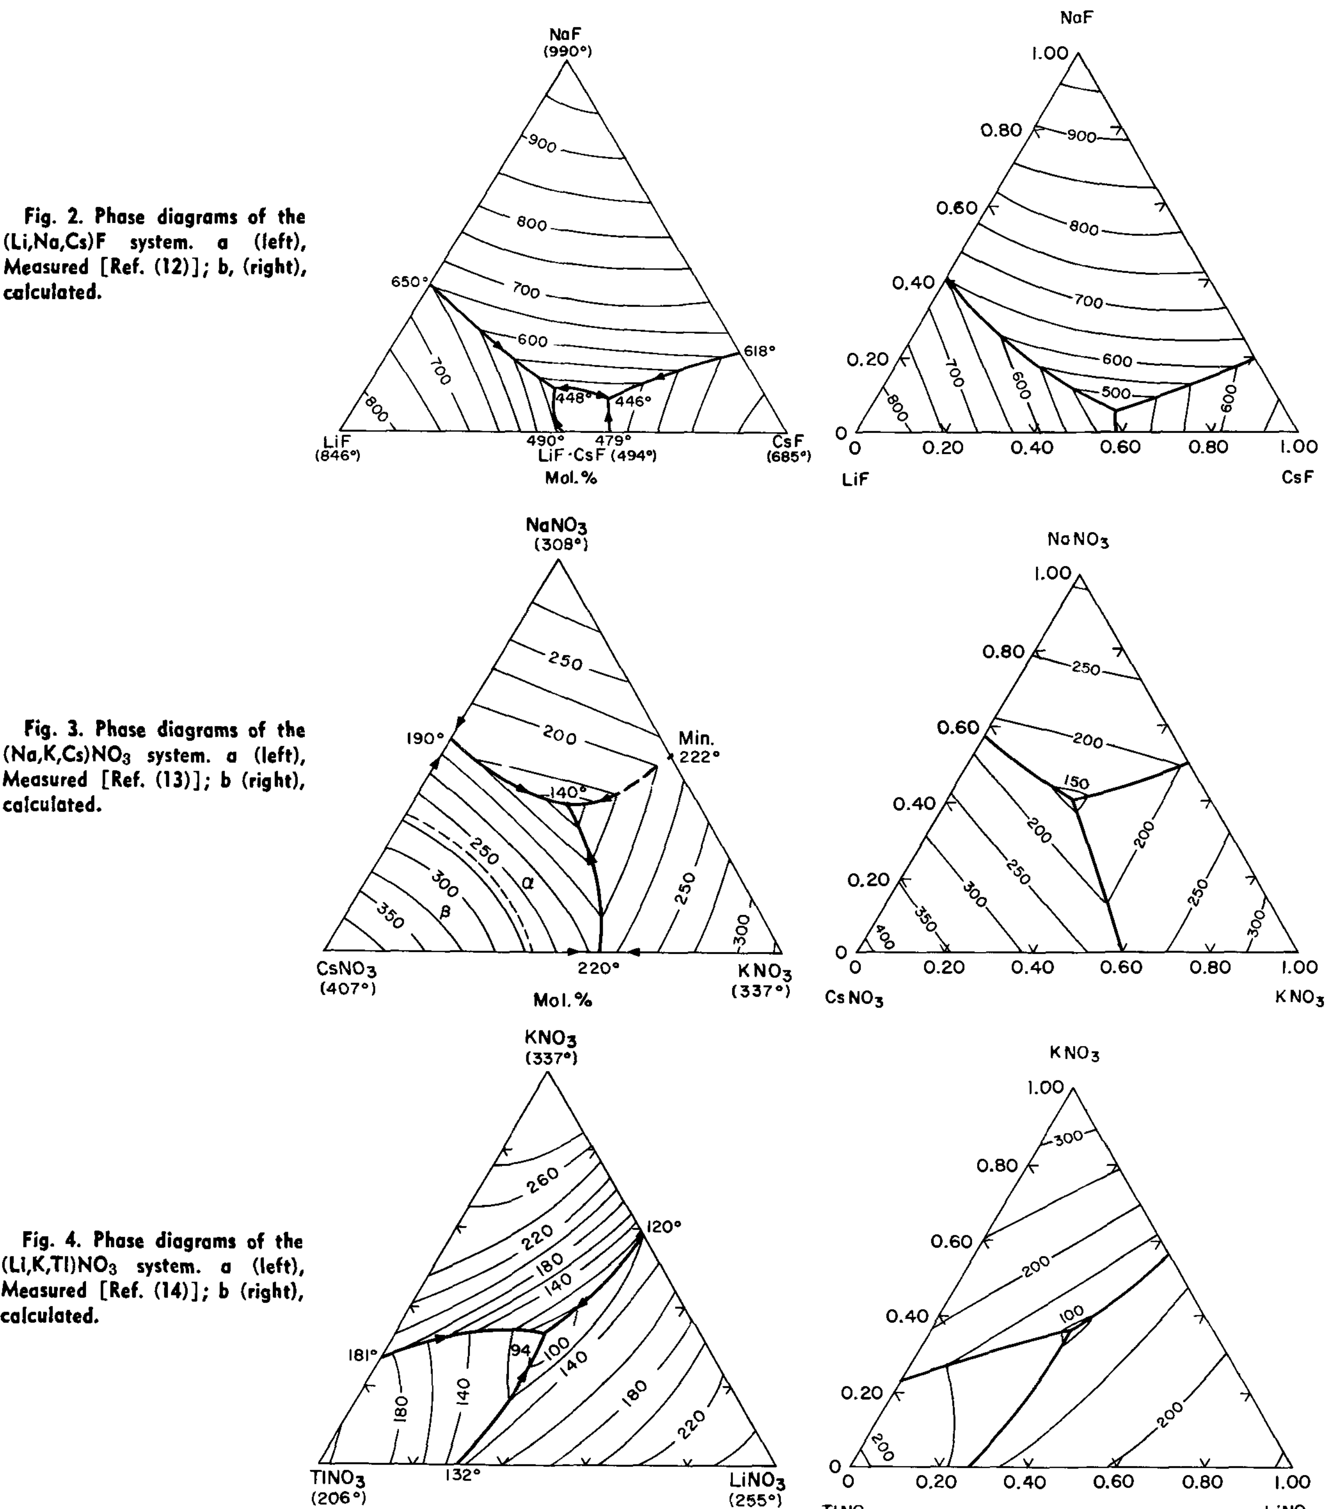

Fig. 2. Phase diagrams of the (Li,Na,Cs)F system. a (left), Measured [Ref. (12)]; b, (right), calculated.

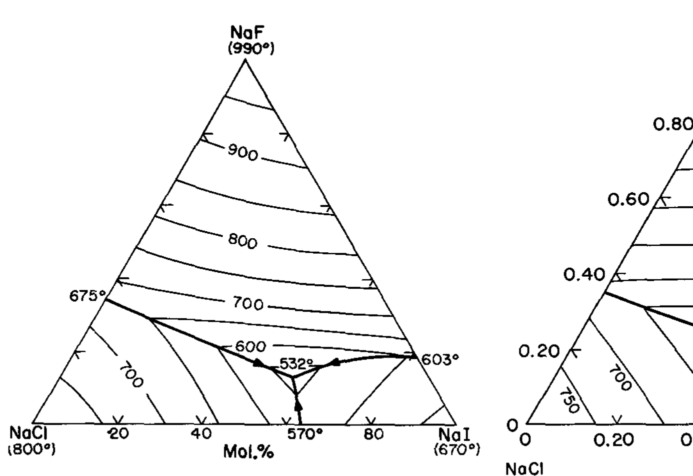
Fig. 3. Phase diagrams of the (Na,K,Cs)NO_3 system. a (left), Measured [Ref. (13)]; b (right), calculated.

Fig. 4. Phase diagrams of the (Li,K,Tl)NO_3 system. a (left), Measured [Ref. (14)]; b (right), calculated.

therms (*i.e.*, in Fig. 1, the 900 and 800 isotherms in the phase field of NaF and 750 isotherm in the phase field of KF, and in Fig. 5 the isotherms in the phase field of NaF) are within the experimental uncertainties and the limits of error in calculating the interaction coefficients.

Two ternary invariants are reported in the (Li,Na,Cs)F system (12) (Fig. 2a). For the binary LiF-CsF where the compound LiF · CsF exists, we have estimated a single hypothetical eutectic temperature by extrapolation from the phase fields of the pure components LiF and CsF. From the hypothetical eutectic temperature (lower by 32° than the experimental eutectic temperature) and from Eq. [20] and [21], the calculated value of λ_{ij} is in agreement with both the measured calorimetric data and the value calculated using the dilute branches of the binary liquidus (Table II). The calculated phase diagram (Fig. 2b) accurately reproduces the measured phase diagram except in the small area subtended by the phase field of the compound LiF · CsF.

For ternary systems where solid solutions are known to exist as in the systems (Na,K,Cs)NO_3 (13), (Li,K,Tl)NO_3 (14), the calculated phase diagrams (Fig. 3b and 4b) are in good agreement with measurements (Fig. 3a and 4a). The same approximative procedure is used to calculate the interaction coefficients λ_{ij} and the eutectic compositions x_{ij} for the binaries $NaNO_3$-KNO_3, KNO_3-$TlNO_3$. The hypothetical eutectic temperatures are found to be about 20° lower than the lowest measured temperatures; this procedure allows us to obtain a better fit between calculated and mea-



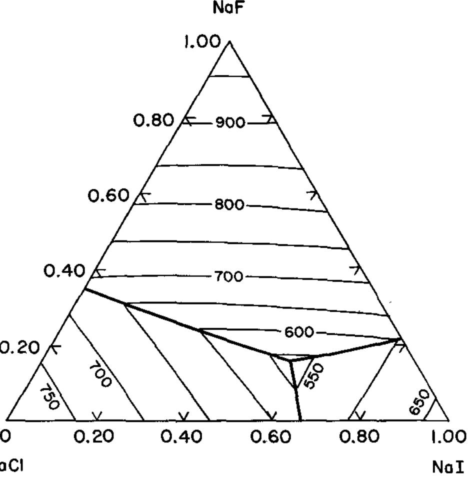


Fig. 5. Phase diagrams of the Na(F,Cl,I) system. a (left), Measured [Ref. (11)]; b (right), calculated.

sured interaction coefficients (Table II). Although the general topology is not affected by these approximations, some discrepancies result.

For example, because the hypothetical eutectic temperatures used for the binaries $NaNO_3$-KNO_3 and KNO_3-$TlNO_3$ is lower than the reported minimum temperatures, the phase fields of $NaNO_3$ and $TlNO_3$ occupy a slightly smaller area in Fig. 3b and 4b than in Fig. 3a and 4a, respectively. In addition, the calculated eutectic valley separating the phase fields of the pure components has a curvature different from the measurements; for example in Fig. 3 and 4 compare the curvature of the eutectic valley separating the phase fields of $CsNO_3$ and KNO_3 and of KNO_3 and $TlNO_3$, respectively. Again, this difference results from the fact that solid solutions do form and are not taken into account in our calculations.

However, the correspondence between measurements and calculations is good in the region of the phase diagrams where solid solutions do not form and where Eq. [20]-[22] are rigorously applicable.

It should be pointed out that the magnitude of the binary interaction coefficients does not have a large effect on the applicability of the calculations. The calculated phase diagrams are consistent with measurements in ternary systems which have different values of the three binary interaction coefficients. The λ_{ij}'s are strongly negative for systems as (Li,Na,K)F, (Li,Na,Cs)F and positive for the system Na(F,Cl,I).

Finally, the phase diagrams of three other systems (15, 16, 11), (Li,Na,Cs)NO_3, (Li,Na,Rb)F, and K(F,Cl,I), were also calculated. We do not report them here since they do not have any special significance.

Conclusion

The prediction of the liquidus temperatures of ternary systems from the phase diagrams of the subsidiary binaries using the equations given in this paper is good. An empirical approximation may be successfully used for slightly more complex cases where solid solutions or intermediate compounds exist; the correspondence between the calculations and the experiments can be improved if solid solutions or intermediate compounds are taken into account. It must finally be emphasized that the results of this present study are promising since the prediction *a priori* of ternary liquidus temperatures is possible without ternary experimental data; modifications, such as including higher order terms, have to be considered in order to study a broader range of systems.

Surface-Catalyzed Anodes for Hydrazine Fuel Cells

I. Preparation of the Substrate

S. G. Meibuhr*

Electrochemistry Department, Research Laboratories, General Motors Corporation, Warren, Michigan 48090

ABSTRACT

Surface-catalyzed anodes for the electrochemical oxidation of N_2H_4 were prepared by first codepositing a porous layer of Mond Ni powder with Ni on an electroformed Ni sheet substrate and then catalyzing by chemically precipitating nickel boride into the porous Ni layer. The parameters associated with the codeposition step were studied for their effect on (*i*) the structure and texture of the resultant deposit, and (*ii*) the electrochemical performance of the subsequently catalyzed electrode. Scanning electron micrographs were made after the Mond Ni was codeposited. The catalyzed electrodes were operated at 2 kA/m² (200 mA/cm²) and the anode *vs.* reference potential was monitored. The most influential parameters was the total number of coulombs used during the codeposition process. When 1200 coulombs on 48 cm² were exceeded, the rough texture of the Mond Ni was destroyed and the Ni_2B catalyst was quickly shed during the electrochemical test.

Numerous catalysts have been examined for their activity toward the electrochemical oxidation of hydrazine (1-3). The over-all anodic reaction is decribed by

$$N_2H_4 + 4OH^- \rightarrow N_2\uparrow + 4H_2O + 4e^-$$

The most widely used catalysts have included Ru metal (3), Pd metal (3-7), and the borides of Ni and Co (8-10). Open-circuit potentials of about −1.10V referred to the Hg/HgO reference electrode) were achieved with the best catalysts. The best catalysts also gave anodes that polarized less than 80 mV at the highest density of 1 kA/m² (100 mA/cm²). However, there have been few published data on the performance of hydrazine anode catalysts operating at current densities greater than 1 kA/m², nor have there been many data on the performance of surface catalyzed, nonporous substrates when used as hydrazine anodes (11).

Early work at the laboratories showed that hydrazine anodes yielding 1.5 kA/m² at an *iR*-free potential of −0.95V could be prepared by using surface-catalyzed, nonporous substrates. These anodes were prepared by chemically depositing nickel boride (Ni_2B) onto a nonporous substrate. However, because of the N_2 gas evolution during the anodic oxidation of hydrazine, the Ni_2B catalyst quickly shed from the substrate in all instances except one (12). This latter substrate was prepared by codepositing[1] Mond 255 Ni powder[2] (13) with electroplated Ni onto an electroformed, scrobiculated Ni sheet. This paper describes the optimized preparation of this substrate.

Experimental

The steps involved in the preparation of surface catalyzed, nonporous electrodes for hydrazine fuel cells were: (*i*) electroform the Ni sheet; (*ii*) codeposit the Mond Ni powder with Ni; (*iii*) catalyze with Ni_2B.

Electroformation of the sheets.—Scrobiculated Ni sheets (0.05 mm thick) were electroformed on a Cr-plated stainless steel mandrel from an 18 liter Ni sulfamate/chloride bath. The geometric area of the scrobiculated portion was 48 cm². The nominal bath composition and the operating conditions for the electroforming process are listed in Table I, column A. Two types of scrobiculated sheets were made. Initially, a dimpled design was utilized; however, in the latter stages of this work, a corrugated design was used to better meet the engineering requirements of the project. No differences resulted from this design change.

Codeposition of the Mond powder.—The codeposition of Mond Ni powder with Ni was performed in the three-piece plastic half-box cell shown in Fig. 1. The top section fitted inside the middle section which was bolted to the base to hold in position the electroformed Ni sheet. The steps in the codeposition process were:

1. Separate the electroformed scrobiculated Ni sheet from the mandrel.
2. Position the Ni sheet on the base and bolt the middle piece to the base forming the half-box cell.
3. Add the 500 ml of sulfamate/chloride Ni plating solution maintained at 50°C.
4. Position the top section of the cell so that the counterelectrode (Ni anode) is located 62 mm from the Ni sheet (cathode). This distance is fixed by the cell design.
5. Position the stirrer above the anode.
6. Add 0.5g of Mond powder, turn on the stirrer, and apply current to the cell for the appropriate time to codeposit the Mond Ni powder with the electrodeposited Ni on the scrobiculated portion of the Ni sheet (see Fig. 2). Turn off the stirrer after an appropriate time.

The exact procedure in step 6 was varied so that the following codeposition parameters could be studied: speed of the impeller (1,000-10,000 rpm measured under no-load), duration of stirring (0.5-10 min), solution *p*H, plating time, cell voltage and current, bath composition, and particle size of Mond powder. A high-stress Ni-plating bath was also used in one ex-

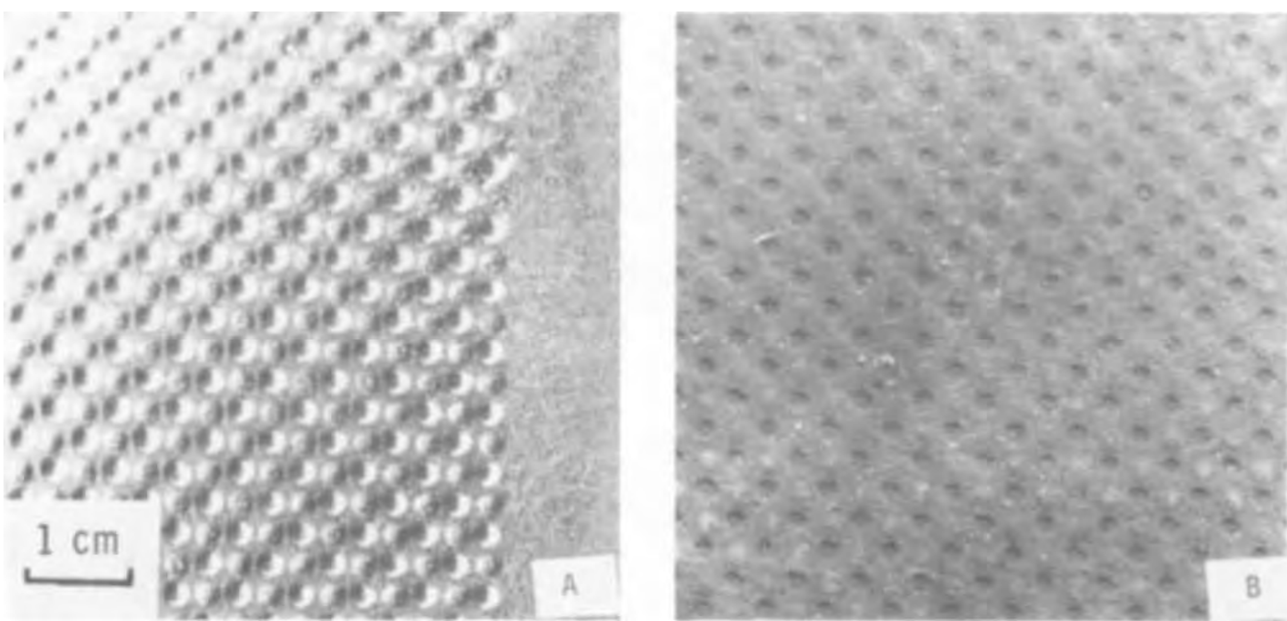

Fig. 2. Dimpled surfaces of the electroformed sheet. A, Before the codeposition of Mond Ni powder; B, the Mond surfaces. Both are at 1.4X magnification.

periment to codeposit the Mond powder. The composition of this bath is also given in Table I, column B (14).

Duplicate substrates were made at each experimental condition. One substrate was chemically catalyzed with Ni_2B and was tested as an anode in a hydrazine half-cell. The other substrate was cut to yield samples for use in the scanning electron microscope (SEM); cross section and top view samples were taken for each substrate, both before and after chemical catalyzation. Consequently, both microscopic and electrochemical data were taken on substrates for every experimental condition of the codeposition process.

Chemical catalyzation.—Approximately 3 mg/cm^2 of Ni_2B catalyst was chemically deposited onto the substrate surface by thrice alternately dipping the substrate into a 5% nickel acetate solution and a 10% $NaBH_4$ solution, just long enough for the initial, violent reaction to subside. Excess solution was drained from the electrode before it was inserted into the other solution. The substrates were positioned hori-

zontally in these solutions. The electrodes were tested immediately after a final rinse.

Electrochemical test procedure.—The catalyzed anodes (48 cm^2 active area) were operated in 5.7M (33%) KOH containing 1M (3.2%) N_2H_4 at a constant current density of 2 kA/m^2 for about 2 hr before the initial resistance-free polarization data were taken. The electrolyte temperature was $31° \pm 1°C$; the electrolyte flow rate was about 16 times stoichiometric for a current density of 2 kA/m^2. Subsequent polarization data were taken regularly and the anode was operated at 2 kA/m^2 between polarization runs.

Results

Scanning electron micrographs.—As a frame of reference, the SEM micrographs are displayed in Fig. 3 for the two Mond Ni powders used in this study: Mond 255 and Mond 128. These photos confirm the particle sizes to be approximately 3 and 8 μm (13) for the 255 and 128 powders, respectively.

The effect of varying the stirring impeller speed from 1,000 to 10,000 rpm on the codeposition of Mond 255 powder from the sulfamate/chloride Ni bath is seen in Fig. 4. The top row of micrographs is at 10,000X magnification and the bottom row is at 5,000X. Figure 4 (A-D) correspond to 1,000, 4,000, 7,100, and 10,000 rpm, respectively. As these micrographs show, there is little effect of stirring impeller speed on the surface structure and texture of these substrates. Hence, substrates were subsequently prepared at 7100 rpm.

The effect of stirring time (0.5-10 min) during codeposition demonstrated that whereas there was no obvious difference in the surface texture as seen by the SEM, there was a difference in the structure as seen by the unaided eye. The stirring time that gave reproducibly the most uniform substrate was 1 min. Consequently, the preparation of substrates was standardized using an impeller speed of 7100 rpm to stir the bath for only the first minute of the total 10 min during which current flowed.

Although the SEM micrographs presented in Fig. 4 represent substrates prepared by codeposition from a bath at $pH=4$, they also could represent substrates codeposited from a bath of $pH=2$. No differences were evident in the surface texture, nor in the subsequent electrochemical performance of catalyzed substrates. Consequently, the *pH* value of the codeposition bath was maintained in the range of 2.8-4.

Variation in the length of the plating time (at 2A) produced striking changes in the appearance of the substrate. These micrographs are displayed in Fig. 5 where (A-E) represent plating times of 30, 20, 10, 5, and 2 min, respectively (3600, 2400, 1200, 600, and 240 coulombs). It is evident that at plating times of only 5 min, there is some loss in surface area (compare

with Fig. 3). However, the electrochemical performance of the subsequently catalyzed substrates did not show the earlier problem of shedding until the plating time exceeded 10 min. The micrographs (A) and (B) of Fig. 5 clearly demonstrate the significant loss in surface area; fuel cell anodes prepared from these two substrates showed the original problem of catalyst shedding after only 1-2 hr under current load. In contrast, the shedding problem was absent with anodes prepared using plating times of 10 min or less at 2A.

Parts D and E of Fig. 5 show a surface texture that is very desirable as a substrate for the anode catalyst. The texture is rough, and the true surface area appears to approach that of the powder. However, in Fig. 5E, the plating time of only 2 min was used, and there was only 3 min allowed for the preparation: 1 min stirring and 2 min plating. Under these conditions, there is insufficient time to permit the Mond powder to settle. These latter two substrates have poor coverage and distribution of the Mond powder. Because these times, as represented by Fig. 5D and E, are too short to permit adequate disposition of the powder, some modification to these two preparation methods may yield better coverage and distribution, and still produce a substrate with a surface texture as represented by Fig. 5D and E. Two possibilities are immediately evident.

1. Adjust the current to a lower value so that the total number of coulombs does not exceed that represented by Fig. 5C (1200 coulombs). Continue the plating throughout the total preparation time. Under these conditions (1A for 20 min = 1200 coulombs), a substrate was produced that had uniform coverage of the Mond powder. The SEM micrographs for this substrate are shown in Fig. 6A and B at 5,000X and 10,000X magnification, respectively. The resultant surface texture approximates that represented by Fig. 5D (2A for 5 min). These SEM micrographs indicate that the substrate of Fig. 6 should yield an anode that would not shed its catalyst, although no electrochemical test was performed. No further work with this codeposition condition (1A for 20 min) was performed because it was desirable to minimize the time involved in the codeposition process and no significant improvement resulted over that achieved by using the standard procedure.

2. Maintain the present standard current value (2A) but adjust the plating sequence to include a settling time, for example, 1 min stirring, 8 min settling (no stirring and no plating), 2 min plating (total coulombs = 240) or 10 min plating (total coulombs = 1200). Using the condition of only 2 min plating time, the resultant substrate was neither uniformly nor densely covered with the Mond powder. A large portion of the powder remained suspended in solution. The micrograph of this sample showed a rough surface texture similar to that shown in Fig. 5E. This substrate was unsuitable for testing because of the sparse, nonuniform coverage by the Mond powder. Using the condition of 10 min plating time, however, the resultant substrate was uniformly and densely covered with the Mond powder. The SEM micrograph taken from this sample showed a surface texture similar to that shown in Fig. 5C. Although the surface texture was considered to be good, no further testing of this modification was employed, because no improvement was achieved over that obtained by using the standard procedure of 1 min stirring, and no current followed by 10 min plating at 2A with no stirring.

All of the previously described substrates were prepared from the low-stress sulfamate/chloride Ni plating bath. The Mond 255 powder was also codeposited at standard conditions from a high-stress, Ni plating bath whose composition is given in Table I. The resultant surface texture was similar to that shown in Fig. 5C and D. Hence, no further work was performed using this bath.

In two separate codeposition experiments with Mond 255, the interelectrode distance was increased from 62 to 140 mm. In one experiment, the cell voltage was maintained at the usual value of 6V; the resulting current was only 0.8A. In the other experiment, the current was maintained at the usual value of 2A; the

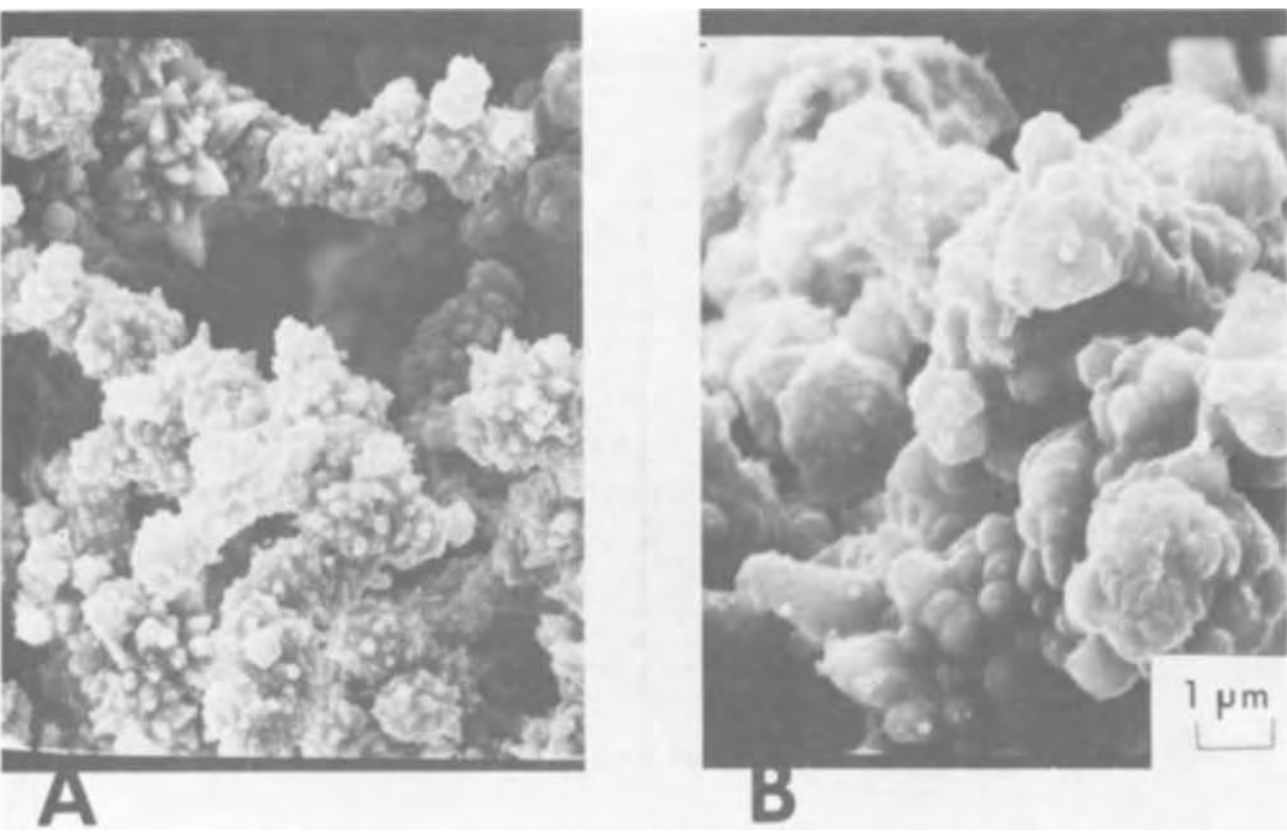

Fig. 6. The effect of a lower current (1A, 20 min) during codeposition of Mond 255 powder

resulting voltage was about 10V. In neither case was the rough surface texture altered significantly from the standard shown in Fig. 5. However, in the former of these two experiments, the resultant substrate was poorly covered with the Mond powder. No further work was performed using either of these procedures.

Heating the codeposited Mond substrate.—The prime function of the codeposited Ni is to act as "glue" to bond the Mond Ni to the substrate without destroying the rough surface texture required for the adhesion of a catalyst. This electrochemical preparation method is superior to a thermal diffusion bonding method. For example, when the codeposited Ni powder was heated at 800°C (a temperature commonly used to anneal Ni) for 2 hr in a reducing atmosphere, the original rough surface texture was destroyed. The micrograph of Fig. 7 shows this loss in texture. When this substrate was catalyzed and tested as an hydrazine anode, the Ni_2B catalyst quickly shed.

In a separate experiment, a sample of the codeposited Mond Ni substrate was mounted in the hot-stage of a SEM and the temperature was increased. Figure 8A shows the Mond surface unchanged at temperatures to 400°C; Fig. 8B shows the surface at temperatures above 600°C up to about 1000°C. An important area to note is area 1, consisting of a chain of 6 or 7 spheres. In Fig. 8B, the spheres have fused and are no longer distinct. Note also the area marked 2. The rough surface texture evident in Fig. 8A has been destroyed by heating. It is clearly evident that the Mond 255 Ni substrate begins to lose its desirable characteristic surface features at some temperature between 400° and 600°C.

Polarization data.—Electrodes prepared from substrates for which more than 1200 coulombs (at 2A) were used during the codeposition process resulted in the catalyst being shed from the substrate even before the initial polarization data could be taken. The black catalyst particles were observed floating in the KOH electrolyte. However, with electrodes prepared from substrates for which less than 1200 coulombs (at 2A)

were used to codeposit the Mond 255 powder, no shedding of the catalyst was evident. Typical initial polarization data for these latter electrodes are given in Fig. 9. Duplicate runs, while not giving exactly the same potential values, did fall within the shaded area. The use of Mond 128 Ni powder yielded substrates which when catalyzed gave anodes that had polarization data represented by the same curve. There was no detectable difference in polarization.

Discussion

Although inclusion plating (the incorporation of metallic or nonmetallic particles into an electrodeposit) is well documented (15-18), this is the first known application of this approach to the formation of fuel cell electrodes. The usual applications of electrodeposited composite coatings (ECC) obtained by inclusion plating involve improving some characteristic of the electroplate itself, such as wear resistance, frictional behavior, or electrical contacts. In each instance, the value of the desirable property of the ECC begins to decrease when the included portion of the coating increases to about 40 weight per cent (w/o). For the fuel cell application, the desirable property of surface roughness begins to decrease when the included portion of the coating (the Mond Ni powder) drops below about 60 w/o. This value corresponds to the 10 min plating time at 2A (Fig. 5C). The amount

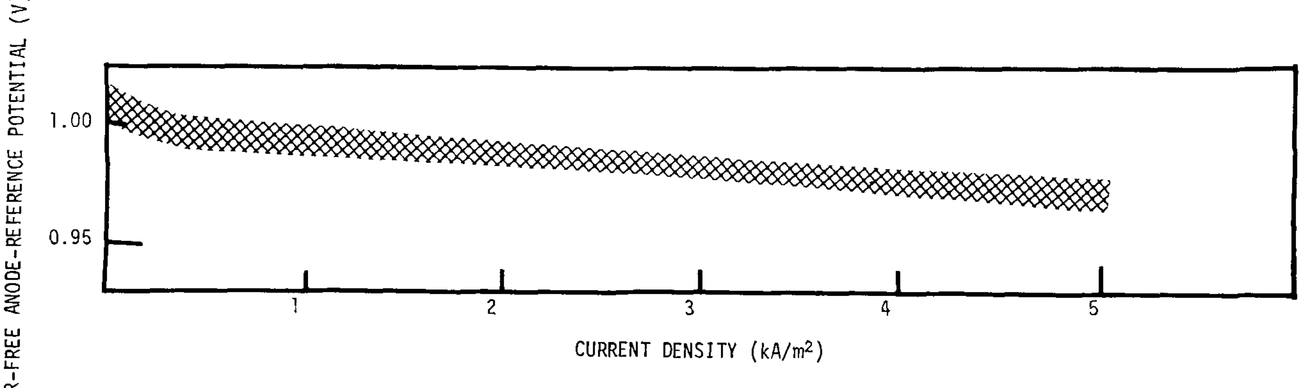

Fig. 9. Current density-*iR* free potential data at operating time (Δt), 2 hr

of Mond Ni can approach 87 w/o (Fig. 5E) and still yield a suitable substrate, although this latter substrate is sparsely coated with the Mond powder and as such is less desirable than a substrate that is more densely coated.

In general, the results of this study showed that there were two parameters that affected the quality of codeposited Mond Ni powder and the subsequent electrochemical performance of the catalyzed-codeposited surface: (*i*) the duration of stirring, and (*ii*) the number of coulombs used in the codeposition process, although this parameter is not unequivocal because of limited data at different plating currents.

If stirring continued beyond about 10% of the time for codeposition, the resultant substrate was nonuniformly and sparsely coated with the Mond powder. The extended stirring was sufficient to maintain the powder in suspension. When a substrate had both nonuniform and sparse distribution of Mond, there was insufficient amount of the powder to retain the Ni_2B catalyst. If the number of coulombs exceeded 1200/48 cm^2, corresponding to 10 min plating time at 2A, the resultant Mond surface texture was too smooth to provide enough adhesion sites for the catalyst. However, catalyst shedding during the oxidation of hydrazine would probably not be a problem if there were no phase change involved in the electrochemical reaction.

Acknowledgments

Anodic Behavior of Aluminum Straining and a Mechanism for Pitting

S. B. de Wexler and J. R. Galvele

Comision Nacional de Energia Atomica, Departamento de Metalurgia, Buenos Aires, Argentina

ABSTRACT

The anodic behavior of pure aluminum during straining at a constant potential in various electrolytes was studied. In sodium sulfate solutions, up to 1.84V, and both in sodium chloride solutions and in sodium nitrate solutions below the pitting potential, the exposure of bare metal to the solution leads to repassivation. At potentials higher than the pitting potential, pitting localization depends on the rate of pitting nucleation. Under conditions of fast pitting nucleation generalized pitting was observed, while under conditions of slow pitting, pits nucleated preferentially on the slip lines and might eventually have led to transgranular stress corrosion cracking. Pitting is the result of localized acidification on the metal-solution interphase due to metal dissolution and hydrolysis of the metal ions. To maintain such acidification, compensation for the loss of protons by hydrogen evolution and by diffusion to the bulk of the solution is necessary. Such compensation will occur if the electrode potential of the metal is higher than its corrosion potential in the locally acidified solution. No pitting will propagate at or below that corrosion potential, which is, for aluminum in chloride solutions, -0.64V.

The study of anodic behavior of straining metals has been widely applied to the investigation of the mechanism for stress corrosion cracking (SCC) (1-4). In the present work, the same technique has been used to study the mechanism for the pitting of aluminum. It was found that the exposure of bare metal to a solution, at a potential lower than the pitting potential, leads to the repassivation of the metal. It is only at potentials higher than the pitting potential that the reaction changes from repassivation to anodic dissolution. The change in behavior is correlated to the type of anodic and cathodic reactions occurring on the bare metal.

The above results have also been used to propose a mechanism for transgranular SCC initiation. In many cases the SCC of a metal starts at the pitting potential (5). The reason for this correlation is clear for high strength steels (5, 6) and for aluminum alloys (5), but it is not so in cases where transgranular SCC is observed as is the case with stainless steels in hot chloride solutions.

Experimental

The straining experiments were made with aluminum wires. "Analar" 99.9% aluminum wires, 0.6 mm diameter, and "Leico" 99.999% aluminum wires, 1 mm, diameter, were used. The specimens were about 10 cm long. The wires were previously annealed for 20 min at 400°C in an argon atmosphere, and water quenched. Before the straining experiments the wires were electropolished in a solution of Butilcellosolve, 10% $HClO_4$, at 0°C and 25V. The cell used for the straining experiments was described in a previous publication (5).

Static experiments were performed on 99.99% aluminum coupons of 10 $\times$ 30 mm. The heat-treatment of these specimens was the same as for the wires. The edges and the surface of the specimens were covered with a cured-epoxy resin, leaving an uncovered area of about 1 cm^2. These specimens were electropolished in the same way as the wires.

The solutions were prepared with analytical grade reagents and were deaerated with purified N_2 (7). A saturated calomel reference electrode was used for the experiments in NaCl solutions, and a mercurous sulfate reference electrode in $NaNO_3$ and in Na_2SO_4 solutions. All the potentials are reported on the normal hydrogen electrode (NHE) scale. The straining experiments were done at room temperature (20° $\pm$ 2°C) and at constant potentials, the current changes were recorded during the experiments.

Polarization of aluminum specimens was controlled by a Tacussel PRT 20-2X potentiostat, and the potential was measured with a Tacussel Aries 10000 electronic millivoltmeter. The current was recorded on a Tacussel EPL2 multirange recorder.

The straining of the wires was done with a motor-driven Hounsfield Tensometer at constant rate of cross head displacement, using initial strain rates of 1.6, 5, 21, and 90%/min. Before straining the wires, they were prestressed below the yield stress and kept at a desired passive potential until a constant current was attained. For the experiments at higher than the pitting potential the specimens were kept for 10 min at a constant potential below the pitting potential, and switched to the working potential simultaneously with the straining machine.

Results

Straining aluminum in neutral 1.0 NaCl solution.—The anodic current was observed to increase significantly when 99.9% aluminum was strained in 1.0M NaCl solution at a constant potential. As soon as the plastic deformation of the wire started, the current began to increase but attained a steady-state value after about 5% elongation. Over a wide range of potentials the steady-state current density observed during deformation was independent of the potential but varied with the strain rate. Figure 1 shows typical results obtained with wires yielding at a constant strain rate of 90%/min with potentials ranging from -0.80 to -0.56V. The mean value of the steady-state current density observed at this strain rate was 2.5 ($\pm$0.5) $\times$ 10^{-5} A/cm^2. Wide scattering of the steady-state current density was found in experiments at -0.53V (Fig. 2). The current density measured at this potential was 5 ($\pm$2) $\times$ 10^{-5} A/cm^2. At potentials higher than -0.53V the steady-state current density became potential dependent, and a potential increase of 20 mV produced a 100 times increase in the current density. The potential at which steady-state current density became potential dependent was the same for all the strain rates tested, and was equal (8) to the pitting potential of aluminum in the test solution (Fig. 3).

Below the pitting potential, the steady-state current density during straining depended on the strain rate

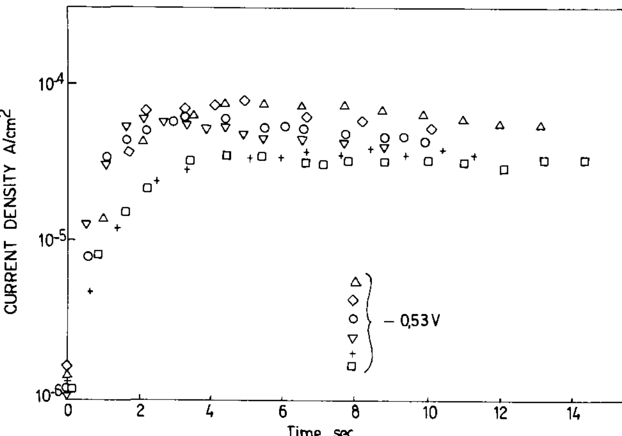

Fig. 2. Potentiostatic current density/time curves near the pitting potential for aluminum straining at 90%/min in 1M NaCl solution.

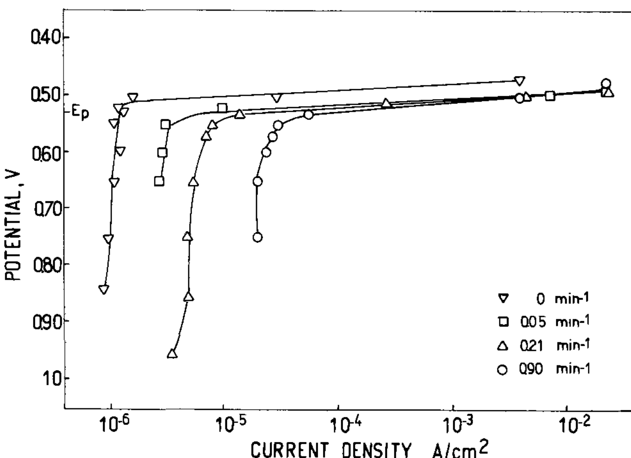

Fig. 3. Steady-state current densities for aluminum during straining in 1M NaCl solution at different potentials and at different strain rates.

(Fig. 4). Above the pitting potential this current was practically independent of the strain rate (Fig. 3).

At potentials lower than the pitting potential, interruption of straining caused a drop in the current density which after a couple of seconds reached the value observed before straining. At the pitting potential and above, interruption of straining also caused a drop in the current, but the drop was less severe than in the previous case. At potentials 100 mV higher than the

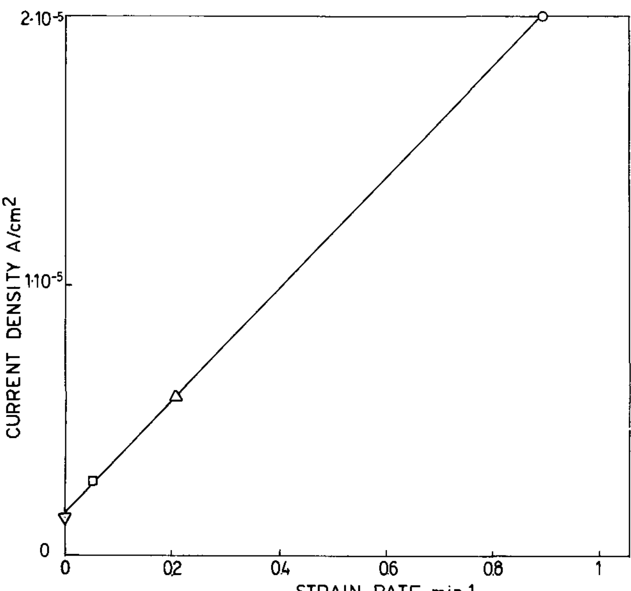

Fig. 4. Relation between steady-state current density and strain rate for aluminum straining in 1M NaCl solution.

pitting potential no current drop was observed after interruption of straining.

After the tests all the wires were examined under both an optical and a scanning electron microscope. No evidence of corrosion was observed on wires strained below the pitting potential. On the other hand, extensive pitting was found on wires which were potentiostated above the pitting potential. The density of the pitting observed was much higher than usually observed on nonstrained or static specimens, but the pits were smaller. Pitting on aluminum in NaCl solutions is known to nucleate very easily without showing any induction time (8). The straining of the metal does not introduce any change in the type of attack except that it offers more sites for pit nucleation, leading to higher density of pits.

Straining aluminum in neutral 0.5M Na_2SO_4 solution.—Figure 5 shows the typical results of the anodic behavior of straining 99.9% aluminum in 0.5M Na_2SO_4 solution. Up to a potential of above 0.9V the steady-state current density was independent of the potential and of the same order of magnitude as that found during straining in 1M NaCl solution below the pitting potential (Fig. 1). At higher potentials a slight potential dependence was observed probably due to

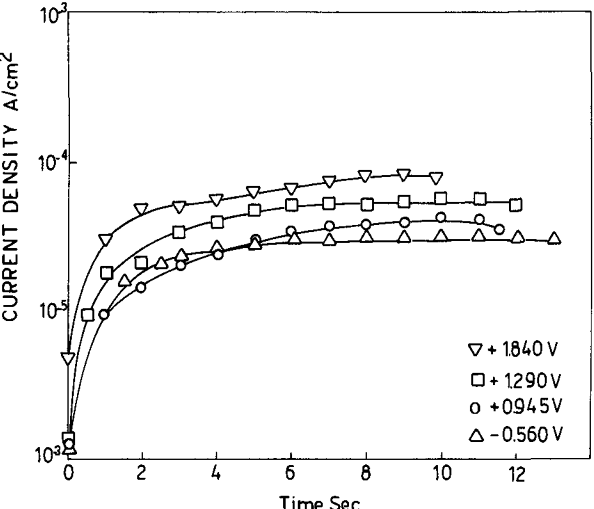

Fig. 5. Potentiostatic current density/time curves at various potentials for aluminum straining at 90%/min in 0.5M Na_2SO_4 solution.

oxygen evolution on the bare metal. The strained wires did not show any sign of corrosion, and no passivity breakdown was detected at potentials up to 1.84V.

Straining aluminum in 0.9M Na_2SO_4 plus 0.1M NaCl solution.—The anodic behavior of 99.9% aluminum during straining at constant potentials was studied in a mixture containing 0.9M Na_2SO_4 plus 0.1M NaCl. The results were similar to those found in 1M NaCl solution, with a potential independent region and a potential dependent region. The transition potential, −0.35V, coincided with the pitting potential reported for aluminum in the same solution (9).

Straining aluminum in 1.0M $NaNO_3$ solution.—The anodic behavior during straining at a constant potential in deaerated 1.0M $NaNO_3$ solution was studied with 99.9% aluminum and 99.999% aluminum wires. Similar results were obtained with both grades of purity.

Below the pitting potential of aluminum in nitrates, E_p =1.70V, the current density after about 5% elongation reached a steady-state value, as found in the previous solutions (Fig. 6.). The values of current density, however, are slightly higher than those found in chloride or in sulfate solutions. The steady-state current density was also observed to be slightly dependent on the applied potential. No traces of corrosion were to be found on the strained wires below the pitting potential. Interruption of straining at those potentials caused a rapid drop in the current, which in a couple of seconds reached the same value observed before straining.

When aluminum was strained in nitrate solutions, at potentials higher than 1.70V, the current did not reach a steady value, but kept increasing all through the experiment. The rate of current increase was a function of the potential, and it became higher as the potential increased. No pitting was observed on the strained metal up to potentials 100 mV higher than the pitting potential, provided that the exposure time was not too long. However white corrosion products covering the slip lines could be observed under a microscope.

As described in a recent paper (5), the rate of current increase for aluminum straining in nitrate solutions at potentials higher than the pitting potential followed a square root law (Fig. 7). It was then explained that such a law was the result of pitting nucleation on the slip lines. Recent electron microscopy done in our laboratory confirmed that semicylindrical channels are formed on the slip lines under conditions of the square root law behavior (10).

The rates of current increase for static aluminum and for straining aluminum in nitrate solutions at constant potential are shown in Fig. 8 and 9. It was ob-

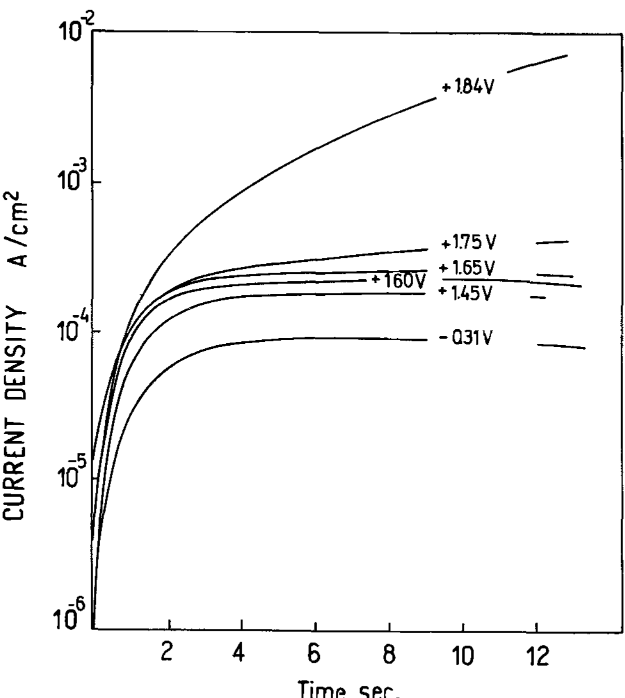

Fig. 6. Potentiostatic current density/time curves at various potentials for aluminum straining at 90%/min in 1M $NaNO_3$ solution.

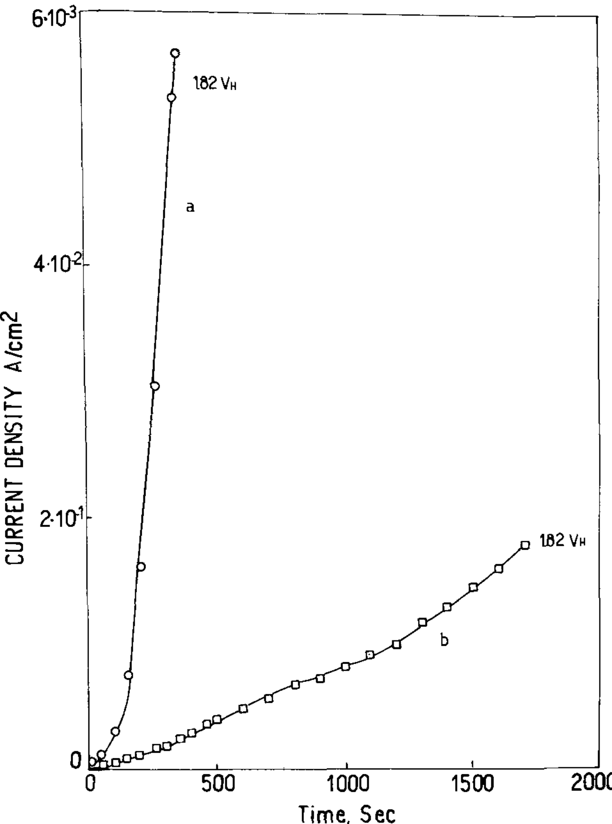

Fig. 9. Potentiostatic current density/time curves for aluminum in 1M $NaNO_3$ solution at a potential 120 mV higher than the pitting potential. a, Specimen straining at 1.6%/min; b, static specimen.

served that there was a great difference between the anodic behavior of the static metal and that of the straining metal. A slow strain rate of 1.6%/min was used to minimize the contribution of the repassivation process, as described above (Fig. 4). The straining metal showed a much faster current increase than the static metal. The difference in behavior was more pronounced at potentials slightly higher than the pitting potential. At 1.75V the current density for the static metal, after an exposure of several hours, is only a small fraction of that obtained after a few minutes of straining. The rate of current rise for the static metal increased with the potential, and at 1.82V the current density for the static metal became significant. If the current density for the static metal corresponds to hemispherical pitting, and that for the straining metal to the corrosion on slip lines, assuming that both processes do not interfere with each other, Fig. 8 shows that compared to corrosion at slip steps, very little pitting should be expected on the metal at fracture time. On the other hand, at 1.82V, the strained metal should have corrosion on slip lines and also hemispherical pits on the surface at fracture time (Fig. 9).

Discussion

Mechanism of the pitting of aluminum.—After a comparison of the several mechanisms proposed for the pitting initiation on aluminum, the most conflicting point appears to be the role assigned to the oxide film. In one line of thought, supported mainly by Pryor *et al.* (11-16), it is considered that a very important step for pit initiation is the contamination of the oxide film by chloride ions. This contamination increases the conductivity of the oxide film leading to enhanced localized dissolution (pitting). While these authors do not elaborate on the effect of the potential, Hoar *et al.* (17, 18) suggest that the migration of the chloride ions should start at the pitting potential. On the other hand, Wood and Richardson (19, 20), taking into consideration observations with the scanning electron microscope, suggest that the oxide film acts mainly as an inert barrier, with no effect on the mechanism of pitting. According to them the pits will start in flaws always present in the oxide film. The existence of such flaws has been questioned by Pryor (15, 16).

The straining method, as used in the present work, avoids discussion of the existence of flaws in the oxide film, since these flaws are continually produced during straining. Before straining, the aluminum wire carries an air-formed oxide film of the order of 30Å (15). The plastic deformation of the aluminum produces slip displacements of the order of 600Å (21). As the aluminum oxide film is very fragile (22) in deformation the film breaks easily, and the bare metal is exposed to the solution.

In the potentiostatic straining experiments it was observed that there is a range of potentials at which the anodic behavior of aluminum is independent of the electrolyte used. The current density observed during straining in Na_2SO_4 solution (Fig. 5) was similar to that found below the pitting potential in NaCl solution (Fig. 1) and in a mixture of aqueous NaCl plus Na_2SO_4 solution. Similar values were obtained by Bubar and Vermilyea (22) for straining aluminum at −0.06V in ammonium borate solutions. The similarity of anodic behavior in the different electrolytes, as well as the absence of any sign of corrosion on the slip steps, suggest that the exposure of bare metal to a NaCl solution, below the pitting potential, leads to the reformation of an oxide film as the only reaction. The linear relation between the steady-state current density and the strain rate, in Fig. 4, as expected from the straining of passive metals (4), confirms this supposition. These results suggest that if there are flaws in the oxide film below the pitting potential, they will not last long, since the bare metal will quickly repassivate.

The straining experiments show that the behavior of aluminum in NaCl solution is similar to that in a $NaNO_3$ solution. In both cases repassivation occurs below the pitting potential, and the attack of the metal starts only at the pitting potential. In the case of nitrates, because of its large size, it is doubtful whether the nitrate ion could migrate through the aluminum oxide film. The migration of chloride ions in the aluminum oxide film, as found by Pryor, could produce weak points in the film which would account for the ease at which the pitting in NaCl solutions starts.

As for the changes in behavior observed at the pitting potential, they are visualized as follows. When an oxide-free metal is exposed to the solution a rapid dissolution of the metal will occur

$$Al = Al^{3+} + 3e \quad [1]$$

In solutions of weak acid salts, like ammonium borate, the solubility point of the aluminum hydroxide will be quickly exceeded, and it will precipitate on the bare metal inhibiting further dissolution.

In the presence of a strong acid salt, like NaCl, a localized acidification will occur as the result of hydrolysis of the metal salt, which allows further dissolution

$$Al^{3+} + 3H_2O = Al(OH)_3 + 3H^+ \quad [2]$$

The existence of local acidity will be favored if the rate of metal dissolution is increased.

Two other important processes occurring in the acidified zone will be hydrogen evolution and proton diffusion to the bulk of the solution

$$2H^+ + 2e = H_2 \quad [3]$$

$$H^+ \text{(Me-sol. interface)} \xrightarrow{\text{dif.}} H^+ \text{(Bulk sol.)} \quad [4]$$

These two processes will oppose the existence of the localized acidity. The rate of metal dissolution, and hence acidity production, has to be high enough to

compensate the loss of protons by diffusion and by reaction.

Reactions [1] plus [3] will give aluminum a certain corrosion potential, or mixed potential. If the potentiostatically controlled potential of the specimen is higher than the corrosion potential of the metal in the acidified solution, the anodic dissolution of the metal will lead to localized corrosion, reactions [1] plus [2]. On the other hand, if the potential of the specimen is maintained below the corrosion potential the reaction of hydrogen evolution, reaction [3], will predominate. In addition there will be no localized acidity, and the oxide film will precipitate on the bare metal. According to this, the pitting potential of aluminum in sodium chloride solutions should be higher than the corrosion potential of aluminum in $AlCl_3$ solutions, so that reactions [1] and [2] might maintain the localized acidity in spite of [3] and [4]. The corrosion potential of aluminum in saturated $AlCl_3$ solutions was found to be $-0.640V$ (23), and the pitting potential in 1M NaCl solution was reported as $-0.530V$ (8). The same relation between corrosion potentials and pitting potentials was found for several aluminum binary alloys (24).

The high pitting potential of aluminum in nitrate solutions is attributed to the interference by a cathodic reaction with the localized acidification process, *i.e.*, reduction of the nitrate ions. Gas evolution was observed during the pitting of aluminum in sodium nitrate solutions. Analysis by explosion showed that this gas was neither hydrogen nor oxygen. Preliminary results of gas chromatography suggested that the main component of this gas was nitrogen. Such a cathodic reaction will produce a high consumption of protons, thus preventing the formation of localized acidity

$$2NO_3^- + 12H^+ + 10e = N_2 + 6H_2O \qquad [5]$$

In this case the anodic reaction will predominate only at potentials at which the nitrate reduction becomes negligible. According to Pourbaix diagrams (25), in an acidic solution the nitrate ion will become stable at potentials higher than 1.0-1.2V. It is only at such high potentials that the current density during straining in nitrate solutions becomes potential dependent (Fig. 6) indicating an increasing contribution of the anodic reaction.

Basically the pitting mechanism described above is similar to the "autocatalytic" process for localized corrosion proposed by Edeleanu and Evans in 1950 (26). The main difference is that these authors did not make any reference to the electrode potential. In the present work an explanation for the existence of a pitting potential is given.

Anodic behavior of straining metals.—The above-described results show that the anodic behavior of a straining metal varies substantially with the composition of the media and with the electrode potential. The differences in behavior can be classified into three different categories: (*i*) repassivation of the metal, (*ii*) fast pitting nucleation, and (*iii*) slow pitting nucleation. When repassivation of the metal is the dominant reaction, straining will have little effect on the anodic behavior of the metal. An increase in the anodic current density will be observed as a result of the rupture and reformation of the oxide film, but no localized corrosion will be detected. This is the case for aluminum in sodium sulfate solutions from -0.56 to $+1.8V$, in ammonium borate solutions at $-0.06V$ (22), or at potentials lower than the pitting potential in solutions containing NaCl or $NaNO_3$. This type of behavior was also observed by Muratta and Staehle for nickel in sulfuric acid solutions (4).

The second type of behavior corresponds to those cases where pitting nucleation occurs very easily. In such cases the straining of the metal will have little effect on the anodic attack, and pitting will be observed over the whole surface on the metal. An example of this behavior is that of aluminum in NaCl solutions above pitting potential as observed in the present work. Another example of this behavior is the one reported by Muratta and Staehle for stainless steel in KCl plus H_2SO_4 solutions at potentials much higher than the pitting potential. This type of behavior is also observed when straining aluminum in nitrate solutions at potentials much higher than the pitting potential.

The third type of behavior corresponds to the conditions of difficult pitting nucleation. In the present work it was found that aluminum in nitrates, at potentials slightly higher than the pitting potential, is one of those cases. Another very well-known instance of difficult pitting nucleation is stainless steel in chloride solutions. This case is well documented in the literature and leads to different pitting potentials under different conditions of measurement (27-29). In these cases straining produces a high increase in the current density. The oxide film acts as an inert barrier, but anodic dissolution on the bare metal exposed at slip steps leads to pitting. When the metal is strained at the pitting potential, pitting will start at the slip steps thus creating conditions that will eventually lead to transgranular SCC initiation.

Electrodissolution Kinetics of Iron in Chloride Solutions

V. Neutral Solutions Containing Benzotriazole

S. Asakura, C. C. Lu, and Ken Nobe*

School of Engineering and Applied Science, University of California, Los Angeles, California 90024

ABSTRACT

The anodic transient and steady-state behavior of iron in neutral chloride solutions containing benzotriazole (BTA) was examined by a potential pulse technique. The results suggest the formation of a resistive film on iron at open circuit. The electrical resistance of the film (R_{sf}) was dependent on the BTA concentration, and decreased with the duration of anodic polarization and the magnitude of the current. Where i_a is the anodic current at steady state, log ($R_{sf}i_a$) varied linearly with the anodic potential with a slope of 80 mV/decade, and the plot was independent of the concentration of BTA. A porous film model is proposed to interpret the electrochemical behavior. The Bockris reaction mechanism is shown to be valid for both the anodic and cathodic reactions.

In a previous investigation (1), the mechanism of iron dissolution in neutral chloride solutions has been described. The present paper extends that work to determine the effect of benzotriazole (BTA) on the kinetics and mechanism of iron dissolution in neutral chloride solutions. Recent work (2, 3) has shown that BTA inhibits the rate of hydrogen evolution on iron in acidic solutions but does not change the mechanism. On the other hand, the effect of BTA on the mechanism of iron dissolution has not been examined, although it has been shown that BTA reduces the rate of anodic dissolution of iron in acidic solutions (3, 4).

Experimental

The solutions were prepared by adding the benzotriazole to 1*N* KCl. Two concentrations of BTA, 2.3 mM and 15.5 mM were used. Deaeration of the solution by prepurified nitrogen was performed for at least 4 hr before a run. The preparation of the iron electrodes has been described previously (1). Potentiostatic pulses were generated by combining a potentiostatic (1 μsec rise time) with a pulse generator. The interval between pulses was always greater than 200 times the pulse duration. The temperature was maintained at 25° ± 1°C.

Results

Anodic potential pulse polarization.—The open-circuit potential, E_o, of inhibited iron was -660 and -640 mV *vs.* SCE for 2.3 and 15.5 millimolar (mM) BTA, respectively. For uninhibited iron, $E_o = -780$ mV. The anodic potential pulse, ΔE_a, was imposed at open circuit as shown schematically in Fig. 1. The pulse is imposed at $t = 0$ and terminated at $t = \tau$. The current immediately after $t = 0$ is expressed by i_{ap}, and the currents immediately before $t = \tau$ and immediately after $t = \tau$ are designated as i_{as} and i_{cp}, respectively. Figure 2 is a plot of i_{ap} *vs.* ΔE_a. A linear relationship was obtained and the slope of the line changed with the concentration of BTA.

The current drop at the termination of the pulse, $i_{as} + |i_{cp}|$, is plotted against the pulse potential, ΔE_a, in Fig. 3 and compared with the i_{ap} *vs.* ΔE_a plot. When the magnitude of the potential pulse was small enough, the i_{ap} and ($i_{as} + |i_{cp}|$) plots were superimposed. However, as ΔE_a increased, the plot of ($i_{as} + |i_{cp}|$) deviated from that of i_{ap}.

The current transients are analyzed utilizing the equivalent circuit shown in Fig. 4. C_{dl}, R_r, R_{sf}, and R_s represent the double layer capacitance, charge transfer resistance, the resistance due to the surface film, and the solution resistance, respectively. R_s is a constant and independent of the polarization current and polarization time. However, R_{sf} may change with polarization since the nature of the surface film may change during the electrode reaction. The parameters

* Electrochemical Society Active Member.

Key words: anodic dissolution, corrosion inhibition.

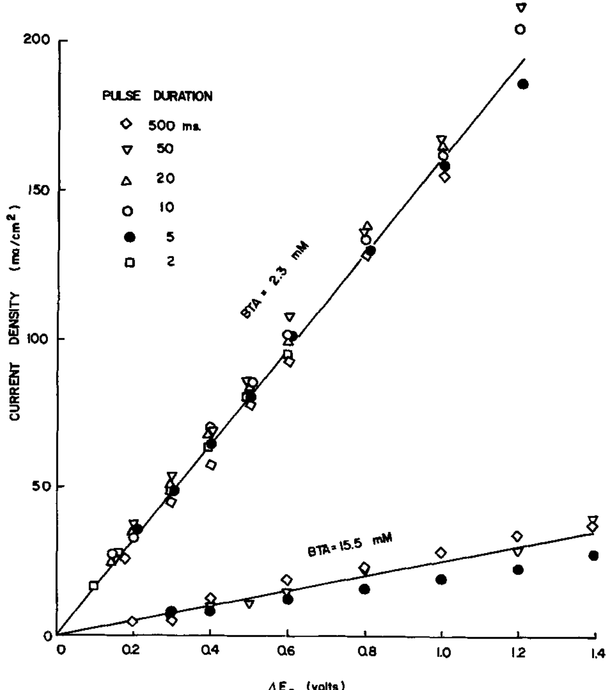

Fig. 2. Plot of i_{ap} vs. ΔE_a

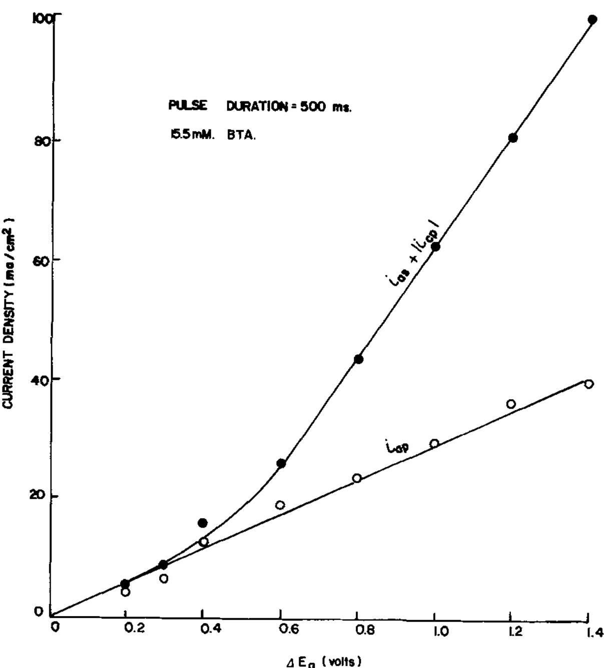

Fig. 3. Comparison of i_{ap} and $i_{as} + |i_{cp}|$ plots vs. ΔE_a

shown in Fig. 4 can be obtained by the experimental procedures described (1).

During the potential pulse, ΔE_a is equal to the sum of the potential difference, e_1, and ohmic potential drop, e_2, *i.e.*

$$\Delta E_a = e_1 + e_2, \quad 0 < t < \tau \qquad [1]$$

Immediately after the potential pulse is initiated, e_1 is zero due to the double layer capacitance. Thus

$$(e_2)_{t=0+} = \Delta E_a \qquad [2]$$

Consequently

$$R_s + R_{sf,0} = \Delta E_a / i_{ap} \qquad [3]$$

where $R_{sf,0}$ is the surface film resistance at open circuit. The slopes of the lines in Fig. 2 are equal to $1/[R_s + R_{sf,0}]$ according to Eq. [3]. This means that the film resistance at open circuit was dependent on

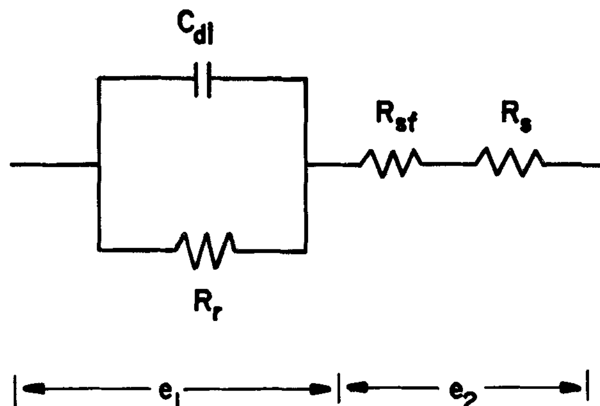

Fig. 4. Equivalent electrical circuit for the electrode system

the concentration of BTA. The solution resistance, R_s, was determined by applying the same procedure to the system without BTA. If it is assumed that the addition of BTA did not change the solution conductivity, $R_{sf,0}$ can be calculated by subtracting R_s from $[R_s + R_{sf,0}]$. The surface resistance at open circuit, $R_{sf,0}$, was about 40 and 1.0 ohm-cm^2 for 15.5 and 2.3 mM BTA, respectively, and was independent of the anodic pulse duration as shown in Fig. 5. These results indicate that the surface returned to *the initial* open-circuit condition before the next pulse was imposed. Since significant differences in $R_{sf,0}$ with concentration of BTA were observed, it seems reasonable that the resistive surface film was formed at the open circuit by the reaction of iron with BTA.

Immediately before the pulse is terminated, the potential drop across the double layer is $(e_1)_{t=\tau-}$. Thus

$$(e_1)_{t=\tau-} = \phi_a - E_o \qquad [4]$$

where ϕ_a is the electrode potential during the potential pulse. Also

$$(e_2)_{t=\tau-} = i_{as}[R_s + R_{sf,\tau}] \qquad [5]$$

Immediately after the current is terminated

$$(e_1)_{t=\tau+} + (e_2)_{t=\tau+} = 0 \qquad [6]$$

and

$$(e_2)_{t=\tau+} = [R_s + R_{sf,\tau}]\, i_{cp} \qquad [7]$$

At this instant, the potential difference across the double layer is given by Eq. [4] since

$$(e_1)_{t=\tau+} = (e_1)_{t=\tau-} \qquad [8]$$

By combining Eq. [1], [5], [6], [7], and [8]

$$R_s + R_{sf,\tau} = \Delta E_a / (i_{as} + |i_{cp}|) \qquad [9]$$

The film resistance at $t = \tau$, $R_{sf,\tau}$, can be determined from Eq. [9] and R_s which was obtained experimentally as described above. A comparison of Eq. [3]

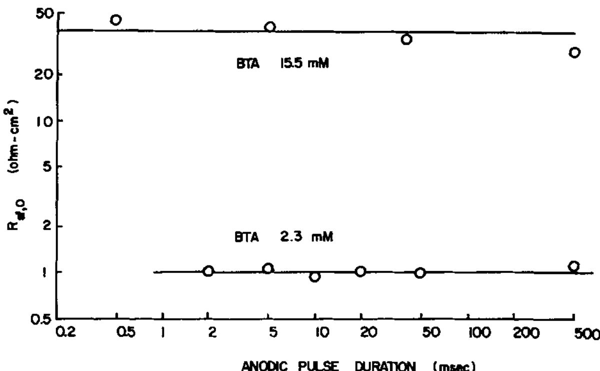

Fig. 5. Surface film resistance, $R_{sf,0}$, vs. the anodic potential pulse duration.

and [9] indicates that the deviation between the lines in Fig. 3 is due to the difference in the film resistance. These results show that the surface state of iron in neutral chloride solutions containing benzotriazole changed with pulse anodic polarization for the larger ΔE_a values. Furthermore, Fig. 6 shows that $R_{sf,\tau}$ increased and approached $R_{sf,0}$ as i_{as} and the pulse duration decreased.

Cathodic potential pulses during steady-state anodic polarization.—Five milliseconds cathodic potential pulses were imposed on iron during steady-state anodic polarization. The interval between pulses was about 1 sec. The cathodic potential pulses were selected to be short enough so as not to perturb appreciably the anodic process. The cathodic current (i_c) transient during the cathodic potential pulse is shown in Fig. 7. An instant after the cathodic pulse is initiated a maximum negative current, i_{ci}, is observed. Then the initial sharp decay which corresponds to charging of the double layer is followed by a slower decay region. Subsequently, log $|i_c|$ decreased linearly with time. This slow current decrease is ascribed to a change in surface state. The extrapolation of this linear portion of the curve to $t = 0$ gives the cathodic current, i_{cx}, corresponding to the surface state during steady-state anodic polarization. The effect of double layer charging on i_{cx} can be neglected.

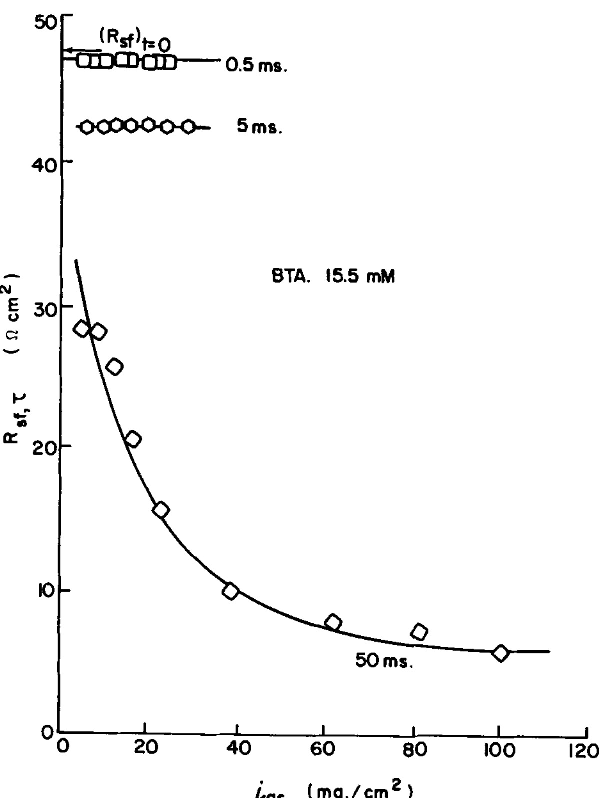

Fig. 6. Surface film resistance, $R_{sf,\tau}$, *vs.* i_{as}

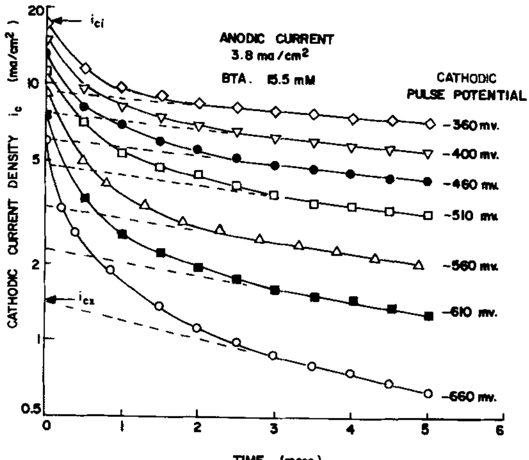

Fig. 7. Cathodic current transient during cathodic potential pulse

The maximum negative current, i_{ci}, is plotted *vs.* the cathodic pulse potential for 15.5 mM BTA in Fig. 8. By applying the previous analysis (1) to the equivalent circuit in Fig. 4. i_{ci}, is related to the cathodic pulse potential, E_c, and the anodic electrode potential, ϕ_a, which is corrected for the ohmic potential drop, as given in Eq. [10]

$$i_{ci} = (E_c - \phi_a)/(R_s + R_{sf}) \quad [10]$$

Equation [10] and Fig. 8 show that for iron in solutions containing BTA, the resistive component, $R_s + R_{sf}$, varied with the steady-state anodic current, i_a, and was much larger than the solution resistance. Therefore, it seems reasonable to assume the existence of a resistive surface film on iron in accord with the above results. R_s was determined by applying the cathodic pulse to iron in BTA-free solutions. The surface film conductance, k_{sf} ($= 1/R_{sf}$), obtained is plotted against the steady-state anodic current in Fig. 9.

According to Eq. [10], the anodic electrode potential, ϕ_a, can be deduced by extrapolating the plot in Fig. 8 to $i_{ci} = 0$. The potential, ϕ_a, and log i_a is plotted in Fig. 10. In the presence of 15.5 mM BTA, an inversion in the current-potential plot at high current densities is observed.

A plot of log $|i_{cx}|$ *vs.* the cathodic electrode potential, ϕ_c, is shown in Fig. 11, where ϕ_c has been corrected for the ohmic potential drop. For both concentrations of BTA, 15.5 and 2.3 mM, these plots give straight lines with slopes of -120 mV/decade, *i.e.*

$$\left(\frac{\partial \phi_c}{\partial \log |i_{cx}|}\right)_{i_a} = -120 \text{ mV/decade} \quad [11]$$

The dependence of the cathodic current, i_{cx}, on the steady-state anodic current for $\phi_c = -670$ mV *vs.* SCE is shown in Fig. 12. Log $|i_{cx}|$ is linearly related to log i_a with a slope of 1/2

$$\left(\frac{\partial \log |i_{cx}|}{\partial \log i_a}\right)_{\phi_c} = 1/2 \quad [12]$$

It is shown that this plot is independent of the con-

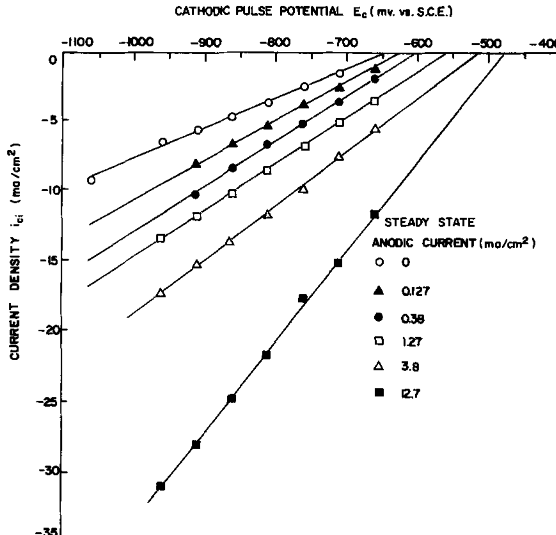

Fig. 8. Cathodic pulse potential, E_c, *vs.* cathodic current, i_{ci}, at the instant the reducing pulse is imposed during steady-state anodic polarization. 15.5 mM BTA.

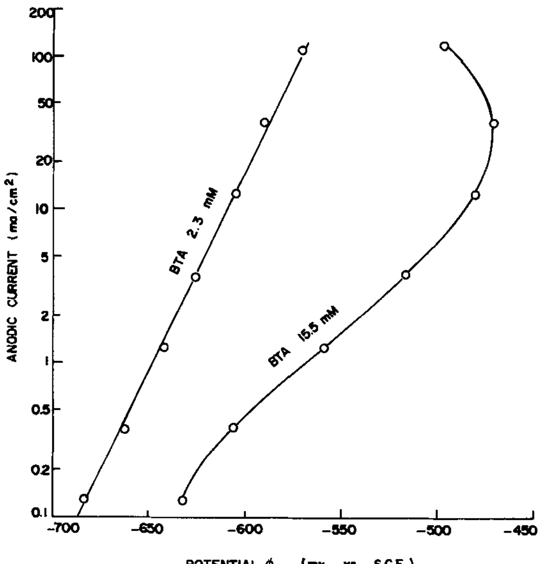

Fig. 10. Steady-state anodic current vs. anodic potential (corrected for ohmic potential drop), ϕ_a.

centration of BTA. Thus, i_{cx} can be expressed as a function of i_a and ϕ_c

$$i_{cx} = -k_1 \sqrt{i_a} \exp\left(-\frac{F}{2RT}\phi_c\right) \quad [13]$$

where k_1 is independent of the concentration of BTA.

Discussion

As shown in Fig. 9, the surface film conductance during steady-state anodic polarization, k_{sf}, increases with anodic current and decreases with concentration of BTA. These results are consistent with the pulse anodic polarization experiments. The inversion in the current-potential plot for 15.5 mM BTA in Fig. 10 is similar to the results obtained by Sathianandhan *et al.* (3). They attributed this phenomenon to a change in the dissolution mechanism.

Correlation between k_{sf} and the potential-current behavior can be obtained by a plot of log (i_a/k_{sf}) *vs.* ϕ_a as in Fig. 13. A linear relation was obtained with a slope of 80 mV/decade, *i.e.*

$$\frac{\partial \phi_a}{\partial \log (i_a/k_{sf})} = 80 \text{ mV/decade} \quad [14]$$

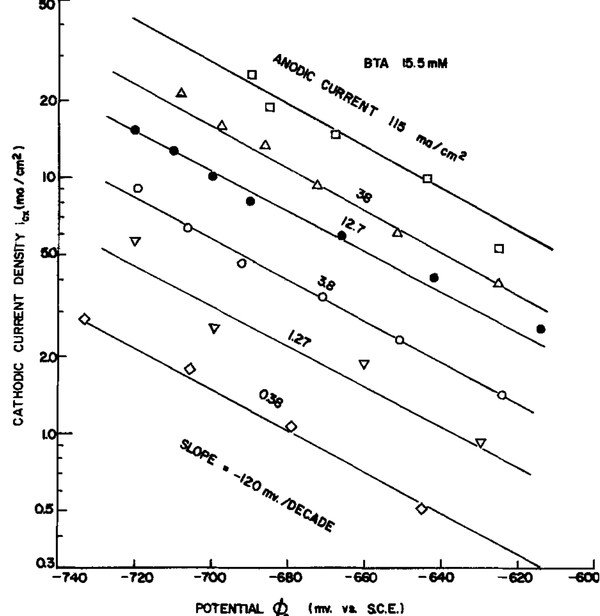

Fig. 11. Cathodic Tafel plots of i_{cx} vs. ϕ_c at various steady-state anodic currents.

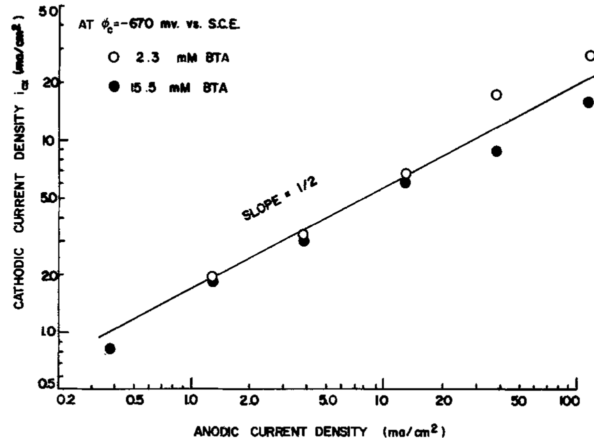

Fig. 12. Cathodic current, i_{cx}, vs. steady-state anodic current

This plot is shown to be independent of the concentration of BTA. The empirical relationship

$$i_a = k_2 \, k_{sf} \exp\left(\frac{3F}{4RT}\phi_a\right) \quad [15]$$

is obtained from Fig. 13 where k_2 is a constant and independent of the BTA concentration.

Based on the experimental results the following model of the iron surface is proposed. As seen in Fig. 14, the surface is covered with an electrical resistive film C and an adsorbed layer B. The surface film C is surmised to be an organo-iron complex consisting of OH^-, Cl^-, and Fe(II) and BTA. Pores exist in the surface film C through which diffusion of dissolved substances can occur. Thus, the electrolyte can penetrate film C and make electrical contact with the electrode surface. Layer B represents a thin adsorbed complex which has a negligible ohmic resistivity.

For the simple pore structure shown in Fig. 14, electrical conductivity of layer C can be given as

$$k_{sf} = \frac{k}{l}\gamma \quad [16]$$

where k, l, and γ are the conductivity of the electro-

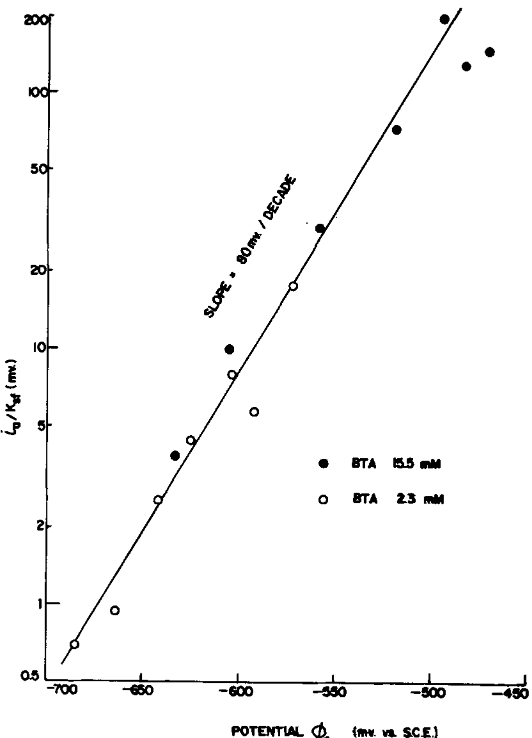

Fig. 13. Plot of log (i_a/k_{sf}) vs. anodic potential, ϕ_a

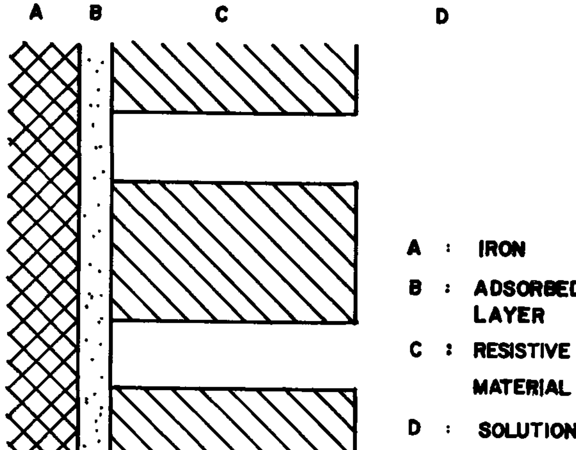

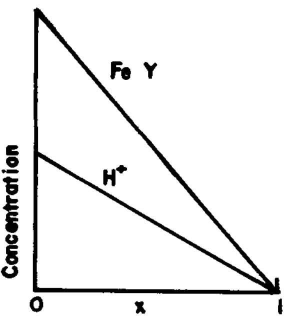

Fig. 14. Porous film model

lyte, thickness of layer C, and the ratio of the pore area to the apparent total area, respectively. The effective current density, i_{eff}, can then be expressed as

$$i_{eff} = i_a/\gamma \quad [17]$$

Thus

$$i_a = \left(\frac{l}{k}\right) k_{sf}\, i_{eff} \quad [18]$$

If i_{eff} follows the expression

$$i_{eff} = k_3 \exp\left(\frac{3F}{4RT}\phi_a\right) \quad [19]$$

and is independent of the concentration of BTA, Eq. [15] can be obtained by substituting $k_3 = (k/l)k_2$ and Eq. [16] and [17] into Eq. [19]. Thus, the Tafel slope for the plot of i_{eff} vs. ϕ_a is 80 mV/decade in accord with that obtained for uninhibited iron in neutral chloride solutions (1) and indicates that, although the rate is decreased, the mechanism of anodic dissolution is not affected by the presence of BTA.

The anodic Tafel slope of 80 mV/decade can be obtained by assuming the Bockris mechanism for electrodissolution of iron (5) and a pH change at the electrode-solution interface due to formation of a hydroxochloro-iron complex (1). The reaction steps in the electrodissolution of iron (5) can be given as

$$Fe + OH^- = Fe(OH)_{ads} + e \quad [20a]$$

$$Fe(OH)_{ads} \xrightarrow{RDS} FeOH^+ + e \quad [20b]$$

$$FeOH^+ = Fe^{++} + OH^- \quad [20c]$$

where Eq. [20b] is the rate-determining step. The over-all reaction for the formation of the organo-iron complex can be expressed by

$$nFe + m\,OH^- + pCl^- + qBTA = FeY + 2ne \quad [21]$$

where $m \neq 0$ and FeY is given the general formula $[Fe_n(OH^-)_m\ (Cl^-)_p(BTA)_q]$. The independence of k_3 in Eq. [19] with respect to the concentration of BTA indicates that the adsorbed layer B is not a function of BTA concentration when it is 2.3 mM or greater and suggests that the electrode surface during anodic dissolution is already saturated with BTA at this concentration.

The cathodic Tafel slope of Eq. [11] obtained from the cathodic pulse potential experiments during steady-state anodic polarization indicates that Eq. [20b] is also the rate-determining step in the cathodic deposition reaction. The details of the analysis have been given previously (1).

Mobility of Metallic Foreign Atoms during the Anodic Oxidation of Aluminum

W. D. Mackintosh, F. Brown,* and H. H. Plattner

Chalk River Nuclear Laboratories, Atomic Energy of Canada Limited, Chalk River, Ontario, Canada

ABSTRACT

Metallic foreign atoms introduced into the surface layers of aluminum specimens are shown to be mobile during anodic oxidation. The direction of motion depends on whether the initial distribution of the foreign atoms is located in aluminum metal under the natural air-formed oxide or entirely contained within a thin preformed surface film of anodic oxide. For a number of the fifteen elements studied, the rate of motion relative to aluminum ions was determined. The results of these experiments are of intrinsic interest in the eventual understanding of the processes involved and have immediate practical consequences for sectioning techniques which involve anodizing and stripping.

In a previous paper (1) it was shown that the energy spectra of He ions backscattered from aluminum, recorded before and after anodic oxidation, could be interpreted to give the thickness of the oxide films and the final position of foreign atoms introduced into the surface layers of the metal before oxidation. Noble gas, halogen, or alkali metal atoms were introduced into the surface layer by implantation with an isotope separator capable of accelerating a chosen ion to energies of a few tens of kilovolts (2). As they are immobile (3), the positions of noble gas atoms were used to deduce the transport number of metal and oxygen. The alkali metals and the halogens were found to be mobile during anodization, the former moving toward the oxide/electrolyte interface, the latter toward the metal/oxide interface. The alkali metals, K, Rb, and Cs, were less mobile than Al; the halogens, Cl, Br, and I, were less mobile than oxygen. In both series the mobility decreased with increasing atom size. Further, there was no significant difference in the behavior between atoms introduced initially into metal and those introduced initially into a preformed anodic oxide film $\sim$ 11 $\mu g/cm^2$ thick.

Using the same techniques of ion implantation and analysis by Rutherford scattering we have extended these studies. The previous work had encompassed only species likely to be singly charged. In order to compare their mobility with species likely to be doubly charged we selected the series Ca, Ba, and Sr. We also chose to investigate Ga, In, and Tl because they are in the same group of the periodic table as Al. During the course of these latter experiments we discovered that, unlike the alkali metals and alkaline earths, the behavior of Ga, In, and Tl depended on the location of the implanted material (*i.e.*, whether in metal or preformed oxide film). To explore the extent of this phenomenon, we eventually included metals representing as many groups of the periodic table as we could within the capabilities of our mass separator. The elements investigated were: Cu, Ag; Hg; V; Cr; Mn; Fe, Co, and Ni.

Experimental

The aluminum specimens were 0.9 cm diameter disks 0.5 mm thick. Surfaces were first prepared by mechanical and vibratory polishing (4). This was followed by four cycles in which the specimen was anodized and then stripped of oxide with a solution of phosphoric and chromic acids at 95°. This particular stripping contaminates the specimen with chromium and phosphorus. Therefore, when studying the elements Co, Fe, and Mn whose masses are close to chromium we used a final cleaning with phosphoric acid only. This solution is corrosive to aluminum metal, hence the exposure was kept to a minimum. Some samples were then exposed to the air at room temperature for a few hours, some were anodized to an oxide thickness of 30V or 11 $\mu g/cm^2$.

The foreign atoms were implanted into these specimens at energies of 20-40 keV. Within this energy range the greater part of the implanted atoms were located in the metal of those specimens covered only with the air-formed oxide and entirely located within the oxide layer of those specimens covered with the preformed oxide. This can be inferred from a knowl-

edge of the ion ranges (2, 5) and the thickness of the oxides. The thickness of the preformed anodic oxides is known from a previous calibration (1) of thickness *vs.* voltage. We measured the thickness of air-formed oxide by using Rutherford scattering and working with single-crystal aluminum, following the principles described by Meyer *et al.* (6). The values obtained in two experiments were 0.5 and 0.7 $\mu g/cm^2$. A few experiments were made using higher energy implants; these are designated in the appropriate sections below and any experiment not specially designated refers to implants at energies of 20-40 keV. The number of ions implanted was commensurate with the sensitivity of the Rutherford scattering method for each species; they were in the range 10^{14}-10^{15} ions/cm^2.

All anodization was done in a saturated solution (~5%) of ammonium pentaborate in water at a temperature of 23°C. The current was kept constant at 2 mA/cm^2. The desired oxide thickness was achieved by terminating the oxidation at a voltage corresponding to the desired thickness obtained from a previously prepared calibration curve and was checked by the subsequent Rutherford backscattering analysis.

The experimental arrangement for obtaining the spectra of backscattered He ion was identical with that described in Ref. (1). Briefly it consists of a Van de Graaff accelerator delivering a beam of 2 MeV He ions, a target chamber, and a surface barrier detector (resolution 17 keV FWHM), placed to observe ions scattered through 150°, together with the usual electronics and pulse height analyzer.

The basis of the Rutherford scattering technique for surface analysis, for film thickness measurements, and for locating the position of foreign atoms has been described extensively [(7) and references therein]. The application of the technique to the particular problem of anodic oxide films on Al and the behavior of implanted foreign atoms is described in detail in Ref. (1). The essence of the method is that, if a He ion of known energy (in this case 2 MeV) is scattered from a surface atom, the resultant energy loss can be calculated from the kinematics of the system. Any additional energy loss observed is due to the fact that the struck atom is not on the surface and therefore the He ion suffers energy loss in both its ingoing and outgoing trajectories. This loss can be interpreted to give the depth of the atom.

The area of the peak obtained by backscattering from implanted ions is dependent on the number of implanted atoms present. It is possible to obtain the absolute amounts (7) but for these experiments it was sufficient to compare areas after normalization to the same integrated beam current (*i.e.*, same number of incident particles) to observe any changes in the relative amount of implant occurring during anodization.

The details of how the spectra are interpreted are, again, given in Ref. (1). We present a very brief illustration by means of Fig. 1 and 2. The former was obtained from a specimen of Al in which the implanted Ag is located in the metal underlying an air-formed oxide film, the latter was obtained from the same specimen after the oxide had been thickened anodically to 100 $\mu g/cm^2$. In both spectra the peak to the right is derived from scattering from the Ag. The continuum to the left of the spectrum of Fig. 1 is derived from scattering by the Al atoms of the substrate.

The continuum in Fig. 2 has a marked step. The portion at the right-hand side, in which the height is reduced, comes from scattering of He by Al atoms in the oxide. The higher level portion at the left comes from scattering by Al atoms in the underlying metal. The width of the step is a measure of the oxide and this can be calculated as described in Ref. (1).

The position of the Ag peak on the energy scale of Fig. 1 corresponds to Ag atoms at a depth of 6 $\mu g/cm^2$ (the implant depth). The Ag peak position in Fig. 2 is shown displaced to one of lower energy. This indicates the Ag atoms were buried beneath the surface during oxidation. The change in depth of the Ag is calculated from this energy shift. The area of the Ag peak in Fig. 2 is 90% of the area in Fig. 1 so that 10% of the Ag is no longer within the boundaries of the principle distribution.

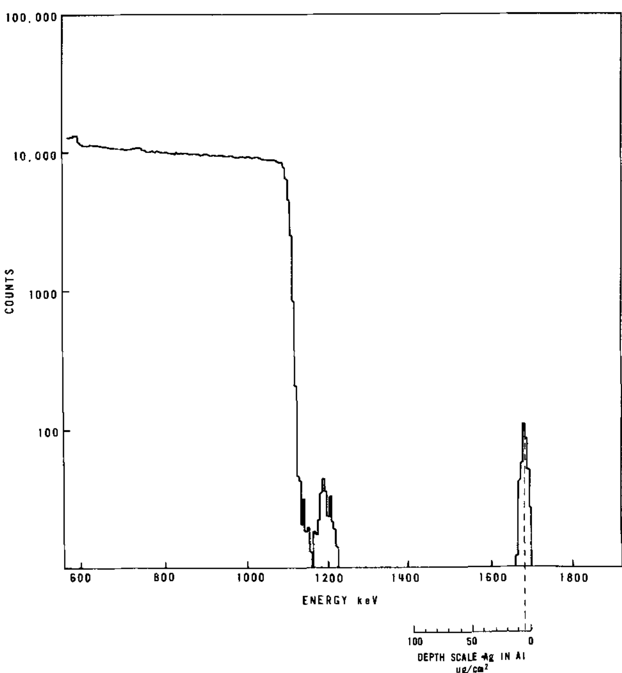

Fig. 1. Spectrum from 2 × 10^{14} Ag atoms implanted in Al. The incident energy of the He$^+$ was 1965 keV.

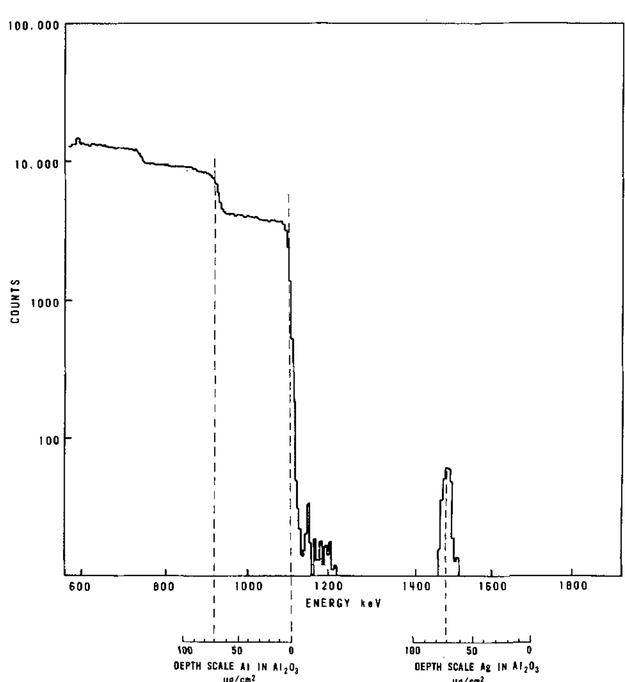

Fig. 2. Spectrum from 2 × 10^{14} Ag atoms buried beneath an oxide layer (70 $\mu g/cm^2$ thick) on the surface of Al. The incident energy of the He$^+$ was 1965 keV.

The depth resolution of the technique is ~2 $\mu g/cm^2$ and is essentially constant over the range of depths involved in the work. It is set mainly by the detector resolution. The resolution sets a limit to precision when one is attempting to measure the depth at which atoms are located. The precision obviously depends on the magnitude of the distance one is measuring in each particular case. It is not possible to tell the difference between atoms on top of the substrate surface or within the first 2-3 $\mu g/cm^2$ of the substrate. In Ref. (1) we found the relative standard deviation at a

depth of 35 $\mu g/cm^2$ to be 6.0%. Likewise, the measurements of oxide thickness have limited precision. In Ref. (1) we found a relative standard deviation of 2.0% for four thickness measurements made on the same oxide, which had a thickness of 93 $\mu g/cm^2$. Thus, the position of foreign atoms relative to the metal/ oxide interface is somewhat imprecise, subject to both the error in depth measurement and the error in oxide thickness measurement. It is not possible to assert from the Rutherford scattering data alone whether foreign atoms close to the interface lie within the metal or within the oxide.

On occasion and as a matter of convenience, the Rutherford scattering experiments were supplemented by experiments in which radioactive ^{204}Tl tracer and conventional radio-assay methods were employed. These are indicated in the relevant section under Results.

Results

Implants in preformed oxides.—In this section we describe the behavior of ions, implanted into preformed oxide, when the oxide film is subsequently thickened by a number of anodic oxidation steps. The preformed oxide thickness is $t = 11$ $\mu g/cm^2$ and the thickness at each successive stage is designated T. In Fig. 3 we illustrate qualitatively, the various phenomena observed. For convenience we consider the results in three groups, as follows:

(*a*) When $T \approx 25$ $\mu g/cm^2$ all the implanted Ba ions were found in the oxide, close to but not at the outer (oxide-electrolyte) interface. Since 4/10 of the new oxide is formed outside the original surface by outward movement of Al [Ref. (1)] the Ba must also move outward, but not quite as fast as the Al. The same behavior was observed on further thickening the oxide ($T_2 = 60$), Fig. 3B, and ($T_{3\text{-}4} = 75$ and 95 $\mu g/cm^2$). The Ba ion mobility can be described in terms of a migration number which we defined in Ref. (1) as the ratio of the distance moved by the implanted atoms to the total thickness of the oxide grown after implantation. The value for Ba averaged 0.39.

(*b*) The group, Ag, Co, Cr, Hg, Ni, and V, on the other hand, disappeared from the solid when $T \approx 25$ $\mu g/cm^2$, leaving, at most, a just detectable trace on the surface of the oxide. They also must move outward, but at a faster rate than Al atoms. No migration number can be assigned, except that it must exceed the Al value (0.4).

(*c*) The remaining group, as shown in Fig. 3A, Cu, Ca, Fe, Ga, In, Mn, Sr, and Tl implants, also move outward; but display a behavior intermediate between groups (*a*) and (*b*). That is, a portion is lost to the electrolyte while the remainder is found close to the outer surface. The fraction remaining at the surface layer varies from species to species, and is not reproducible from specimen to specimen of the same species. For Ca, Cu, Ga, and Sr the amount retained at $T = 25$ $\mu g/cm^2$ was $< 50\%$ and at $T = 50$ $\mu g/cm^2$ they had entirely disappeared (Fig. 3B). Essentially then, these ions move faster than Al. In the case of Fe, In, Mn, and Tl the amount remaining at $T = 25$ $\mu g/cm^2$ was $> 75\%$ and when $T = 100$ $\mu g/cm^2$ (the maximum available), appreciable quantities remained, always located close to the outer surface. These then, move more rapidly than Al and only slowly dissolve in the electrolyte, or, they move at much the same rate as Al and are reduced by dissolution of the alumina matrix or by some other process. Loss of any species to the electrolyte not only involves movement through the oxide but dissolution into the electrolyte and possibly dissolution of the alumina surface layers [2% of the Al converted to Al_2O_3 is known to dissolve (8)]. Thus once an implanted ion reaches the surface layers its rate of egress will depend on factors other than the rate of movement through the oxide. These factors were not investigated in the present work. Some such studies have been carried out with Ta_2O_5 (9).

In order to distinguish between movement within the oxide and these rather complex surface effects, we carried out another experiment. We preformed oxide films 43 $\mu g/cm^2$ thick and sent the specimens to the University of Aarhus, Denmark, where they were implanted with indium to a depth of 34 $\mu g/cm^2$ and with thallium to a depth of 20 $\mu g/cm^2$ (Fig. 4A) using the 600 keV heavy ion accelerator. In this way we substantially increased the path length over which the ions would have to move before they could reach the

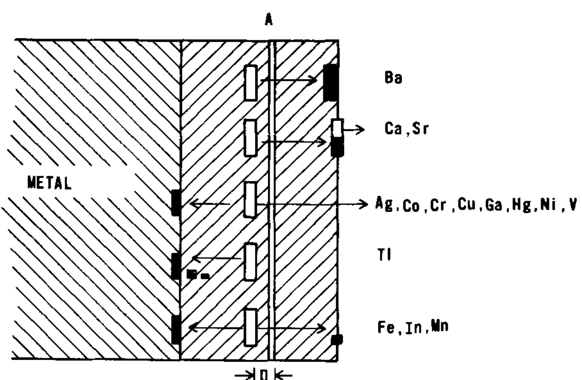
surface. After thickening the oxide ($T_1 = 74$ μg/cm², Fig. 4B) we found all the implanted material within the oxide film and could therefore obtain migration numbers. They were 0.83 and 0.34 for the In and Tl, respectively. On further thickening ($T_3 = 102$ μg/cm², Fig. 3C) the In was located close to the surface, while the Tl was still well within the oxide. For both species the values of the respective migration numbers were the same as before. Thus In moves faster than Al and its presence at the surface in the earlier experiments where it reached the surface quickly must have been due to preference for remaining in the surface rather than dissolving in the electrolyte. The Tl moves at much the same rate as Al. The gradual decrease in amount in the earlier experiments must have been due to alumina dissolution or possibly to the fact that if Tl moves at about the same rate as Al and also suffers any broadening of its distribution, then a small fraction will in fact move faster than the Al; a small degree of broadening is difficult to observe due to the detector resolution.

Such experiments involving deeper implants have not been carried out with Fe and Mn. It is therefore not known whether these move faster than Al and remain on the surface because they are subject to some surface effect or whether they move at the same rate as Al.

Implants into aluminum metal.—The positions of species, implanted into metal under an air-formed oxide film, after the specimens had been anodized are shown in Fig. 5A.

Barium behaved exactly as it did when implanted into preformed oxides, *i.e.*, all of it moved outward to



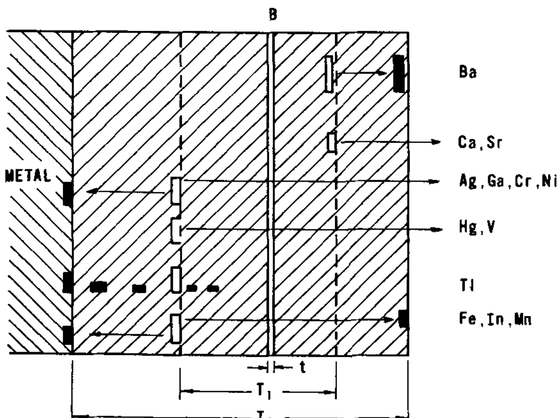


Fig. 5. The position of ions implanted into metal under the air-formed oxide after thickening by anodic oxidation. A, first oxidation; B, second oxidation. T_1 and T_2 are the thicknesses of the 1st and 2nd oxides, respectively, *t* the thickness of the air-formed oxide, and *D* the depth of the implant (in metal) before thickening. ▯ is the position before thickening, ▮ after thickening. ▯ indicates part of implant retained, part moving farther. The height of the latter two rectangles corresponds approximately to the fraction of the implanted material in the position indicated.

a location just below the surface. When $T_1 = 28$ μg/cm², the migration number obtained was 0.38 which agrees with the previously obtained value. Further thickening of T to successively 44, 64, 83, and 104 μg/cm² gave values which averaged 0.39.

Also, as before, a part of both Ca and Sr was located at the surface when the first film was grown ($T_1 = 50$ μg/cm², Fig. 5A) and disappeared during further growth ($T_2 = 100$ μg/cm², Fig. 5B).

By contrast the behavior of all other elements (Fig. 5A) was strikingly different from that observed for implants into preformed oxide. After anodizing, a large fraction of the implanted material was found in a sharp peak corresponding to a depth, within the experimental resolution, that is equal to the oxide thickness, *i.e.*, at the metal/oxide interface. By stripping off the oxide and analyzing again it was found that the implant was, in fact, in the metal and is, within the limit of resolution, at the metal surface. Since it has been shown that the anodic oxidation of Al proceeds, in part, by inward movement of oxygen, the implanted ions retained in the metal must have retreated before the advancing oxide front, moving in a direction opposite to that observed in the preformed oxide experiments.

The amount of implant found at the interface does not fully account for the original amount; Table I shows that fractions were retained at the interface at the end of the first oxidation step. The fractions of Ag, Co, Cr, Cu, Hg, Ga, Ni, and V not retained at the interface were not observed elsewhere in the spectra. They either passed into the electrolyte or the small amounts of material involved were dispersed throughout the oxide too sparsely to be detected. The first alternative seems likely in the case of Hg because a relatively larger amount is missing from the interface region (Table I) and Hg, being heavy, is easily detected in very small amounts. Such behavior would be consistent with that of Hg ions implanted into preformed oxide films where Hg disappeared quickly from the solid system. The Tl not retained at the interface was dispersed in oxide in a concentration gradient decreasing from the oxide/metal interface outward as indicated on Fig. 5B. This too is consistent with previous experiments where Tl was found to move in the oxide at much the same rate as Al. Some Fe, In, and Mn were observed at the outer surface. This too, is the same as the behavior of these species implanted in preformed oxide.

As the oxides were thickened the fraction remaining of Ag, Ga, Cr, and Ni at the metal/oxide interface decreased; Co and Cu did not. For Hg and V the loss was 100% after forming 100 μg/cm² of oxide, the other species lost amounts varying in the range 10-50%. Again, except for Fe, In, Mn, and Tl, the material not at the interface could not be located. Thallium was found in the oxide, decreasing in concentration from the metal/oxide interface outward. In the case of Fe, In, and Mn, the fraction leaving the interface was at the outer surface.

Table I. Fractions located at oxide/metal interface

Implanted species	Oxide thickness (μg/cm²)	Fraction at interface* (% of implanted amount)
Ag	27	56
Co	27	92
Cr	50	84
Cu	28	100
Fe	52	75
Ga	48	100
Hg	35	62
In	28	89
Mn	53	72
Ni	27	92
Tl	31	90
V	26	100

* This fraction varied as much as 15% from one experiment to the next.

The rate at which Tl leaves the metal as the oxide film is thickened was determined by experiments using radioactive ^{204}Tl. Specimens of aluminum metal were implanted with ^{204}Tl and also with stable Tl to bring the dose up to 2×10^{14} ions/cm^2. The activity was measured by β-counting. The specimens were then anodized, the oxide stripped off, and the residual activity measured. This procedure was then repeated many times so that the gradual disappearance of Tl could be followed. The amount lost on the first step was variable, but thereafter the rate of loss showed first-order dependence on the amount of Tl remaining, Fig. 6. The amount lost in a given step is also proportional to the thickness of oxide grown, *i.e.*, to the time of anodizing at constant current. Thus the amount removed by forming a thick oxide will be the same as that removed in successive small steps of total thickness equaling the large one.

Conclusion

These experiments have shown that the behavior of implanted ions depends on the location of the implant. All metal ions implanted in a preformed oxide move outward. However most metal species implanted into Al metal under the natural air-formed oxide exhibit the opposite effect, remaining in the metal and moving inward with the advancing oxide front.

The migration numbers for In and Tl, measured by using deep implants, show that In moves faster than Al whereas Tl moves at about the same speed. A large number of other species clearly move more quickly than Al because they are lost to the electrolyte during anodizing. These are Ag, Co, Cr, Cu, Ga, Hg, Ni, and V. Migration numbers for these species can only be determined by deep implants in thicker oxides as were done for In and Tl. At present, we cannot do this without help from an outside laboratory but equipment now being assembled will shortly remedy this situation.

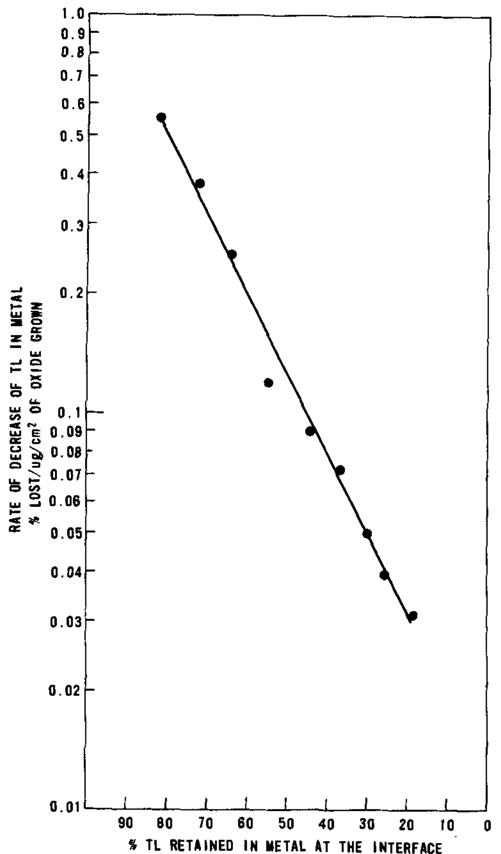

Fig. 6. The rate of decrease of Tl in the metal substrate at the interface as a function of the concentration of the Tl in the metal. The concentration shown is the average for each oxidation-dissolution step.

Only one of the species, Ba, moved more slowly than Al. The other two alkali earths Ca and Sr are more mobile than K, Rb, and Cs (1). If it is assumed that these species move as ions, one can attribute the greater mobility of Ca, Sr, and Ba to the double charge on their ions. It was found in Ref. (1) that mobility decreased in the sequence K, Rb, Cs. Although Ca and Sr move faster than Ba, suggesting the same pattern obtains, the relative mobility of Ca and Sr can only be unambiguously determined with deep implants. However, Sr was retained in greater amounts at the surface than was Ca. In both cases, whether oxide or metal, they should be soluble in the aqueous electrolyte and thus it is not implausible that the greater amount of Sr is due to slower migration, *i.e.*, mobility decreases in the sequence Ca, Sr, Ba. In both sequences this appears to be an effect of size rather than electropositivity (which increases rather than decreases in the two sequences).

The results of the deep implant experiments with In and Tl also exhibit the apparent dependence on size as the mobility of indium is considerably greater than that of thallium.

One further fact emerges from these experiments; all ions which clearly move more slowly than Al, viz., K, Rb, Cs, and Ba, are appreciably greater in size than those which clearly move faster, Ag, Co, Cr, Cu, Ga, Hg, In, Ni, and V.

The most striking feature of the present work is that many metallic species, when implanted into aluminum metal, are retained to a large extent in the aluminum when the specimen is anodized. The over-all pattern fits with normal electrochemical behavior. Species with lower oxidation potentials than aluminum (K, Rb, Cs, Ca, Sr, and Ba) are oxidized and incorporated into the Al_2O_3. Species with higher oxidation potentials than aluminum (all the remaining metallic species studied) are not oxidized and remain in the metal, although the fraction so retained does vary considerably between different species. The anodic oxidation of aluminum proceeds, in part, by inward movement of oxygen. Hence if an implanted atom is retained in the metal it must, in effect retreat before the advancing oxide front. This implies that the implanted atoms must have a high degree of mobility in the aluminum metal close to the metal-oxide interface due to a high concentration of vacancies in this region.

The phenomenon appears to be similar to that observed in thermal oxidation of alloys where oxides containing only one of the components can be found. In these cases the component with the lower heat of formation remains in the metal [see for example Ref. (10)].

When the oxide front moves through the implant region it does not sweep every atom of the implanted species before it. The amounts vary from species to species. Further as the front moves inward, *i.e.*, beyond the implant region into a hitherto undisturbed region, it continuously loses a fraction of the atoms that had been moved inward from the original position. In the more detailed studies with Tl it was shown that the amounts transferred across the interface into the oxide is dependent on the concentration of the Tl atoms at the interface. Atoms not swept along by the oxide front as it passes through the implant region and thus transferring into the oxide evidently behave in the same fashion as the particular species involved does when implanted into preformed oxides.

In addition to the intrinsic interest in formulating a plausible mechanism for the process, this phenomenon has some significant practical consequences. Anodic oxidation and stripping has been used as means of "sectioning" aluminum to determine range profiles and to study diffusion. These procedures are subject to error, or could be totally useless, if the foreign atoms in question do not pass into the oxide (11). Anodizing-stripping cycles and also electrochemical polishing are useful techniques for preparing good surfaces. However, we have found that if they are applied to alu-

minum alloys they will perturb the concentration of additive in the surface region (11). Furthermore, with due consideration of the oxidation potentials involved, similar effects could well be observed with matrix metals other than aluminum.

Acknowledgments

We are indebted to Professor E. Bögh, Aarhus University, for implants of In and Tl in thick oxide. The assistance of O. Westcott, C. Sitter, G. Sims, and J. Lori in operation of the mass separator and Van de Graaff is gratefully acknowledged.

The Effect of Brine Level on the Voltage of Mercury-Type Chlor-Alkali Cells

Peter A. Danna[*,1]

Olin Corporation, Stamford, Connecticut 06904

ABSTRACT

One of the neglected variables affecting the operating voltage of mercury-type chlor-alkali cells is the level of the cell brine relative to the tops of the graphite anodes within the cell. Laboratory data have been analyzed and scaled up to predict the magnitude of this effect in a typical commercial mercury cell.

It is well known that varying the slot and hole configuration of graphite anodes can reduce the cell voltage of a mercury-type chlor-alkali cell (1, 2). The voltage decrease is the result of improved brine circulation rates which in turn result in more rapid chlorine bubble detachment from the graphite as well as minimization of localized depletion of the brine. Brine circulation rates depend on hydrodynamic forces commonly known as the "gas lift pump" principle. In the present application, one critical variable affecting the rate of circulation via the gas lift pump principle is the difference in hydrostatic head which results between the brine-bubble mixture within an operating anode and the relatively bubble-free mixture of the bulk electrolyte in the cell. The relationship of this variable to cell brine level can be understood as follows.

Figure 1 shows a cross section of a portion of a typical graphite anode. Bubbles of chlorine are formed in the anode-cathode gap by the oxidation of chloride ions in the brine solution. These bubbles then rise up through the slotted lower section of the anode (h_2) and enter the upper drilled section of the anode (h_1). As these bubbles rise and fill the slot and hole volume a bubble-brine mixture of density ρM is created. The brine around the outside of the anode is relatively bubble free due to gas disengagement when the bubble-brine mixture emerges from the top of the anode. Thus the brine outside the anode is of density ρB. Due to void fraction of the mixture within the anode ρB is greater than ρM. In this way circulation of brine and removal of the bubbles from the reaction zone result from the driving force caused by the difference in hydrostatic head between the outside bubble-free brine and the bubble-brine mixture within the anode.

As shown in Fig. 2, brine circulation around a typical anode in commercial use takes place not only down through the interelectrode gap (path A), but also through the ends of the anode slots (path B). Since the primary benefit to voltage reduction is obtained when chlorine bubbles are rapidly swept out of the anode-cathode gap, path A circulation is by far the

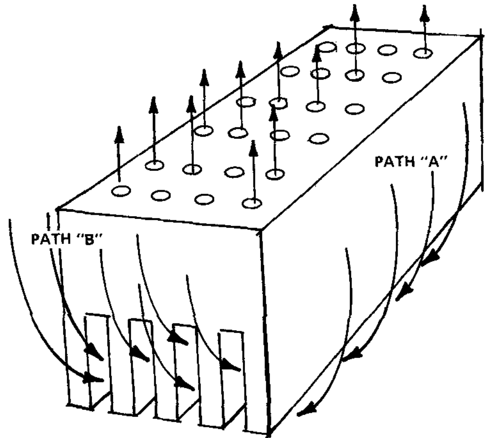

Fig. 2. Typical brine circulation paths

most important to achieving low operating voltages. A patent has been issued to Olin Corporation wherein all brine circulation is forced to also be gap circulation by using several novel anode designs (3).

Experimental

In the present series of studies the experimental anode was 610 mm long × 229 mm wide × 152 mm high. This is one-half the length of a commercial Olin E-510 cell anode. The test apparatus consisted of a brine feed system, mercury pumping system, and a steel bottomed Lucite cell large enough to accommodate the anode and provide clearances around the anode equivalent to those commercially used. Flow rates for brine and amalgam as well as cell temperature were consistent with industrial operating conditions.

Results and Conclusions

For the purpose of isolating the brine level effect in this analysis we will assume that all other cell variables which are a function of anode position in the cell do not interact with brine level effects and remain constant. Actual experimental data showed that only minor errors are introduced by this assumption.

Neglecting dynamic head effects, the brine level relative to the bottom of the graphite anode plane is a straight line function of the slope. If the cell brine inlet level is at 45 mm above the bottom plane of the anodes, and using the dimensions shown in Fig. 3, we can derive the equation

$$(BL)_N = 45\text{ mm} + \left[6\frac{\text{mm}}{\text{m}} \times \frac{0.612\text{m}}{\text{anode}} \times (N - 1) \right] \quad [1]$$

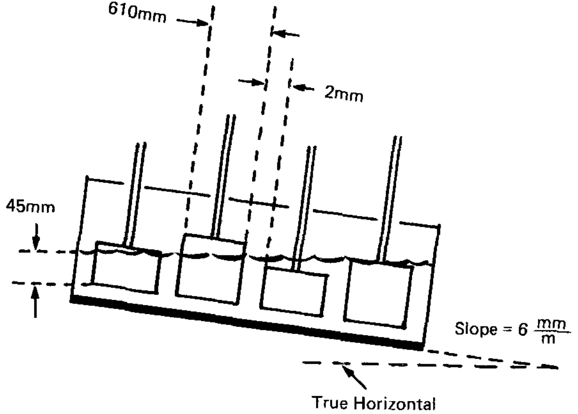

Fig. 3. Brine level vs. anode position

where $(BL)_N$ is the brine level at the leading edge of an anode in position N; and $1 \leq N \leq 20$. Note that for this example N and bus bar number are identical since we are assuming only one post per anode and a bus bar for each post.

Figure 4 graphically depicts the method of numbering and assumed cell arrangement used in this example. For simplicity of electrical circuit analysis we assume our commercial cell room consists of 250 cells, each 1 anode wide and 20 anodes long. As is usual in mercury cell plants, anodes in any cell are electrically in parallel while anodes in the same position from cell to cell are electrically in series.

The anode age distribution for any given bus number is linear. For example, suppose one measures all anodes in position 5 from cell No. 1 through No. 250 inclusive. If the oldest (thinnest) anode is then called No. 1 and the newest (thickest) called No. 250 a straight line age distribution will result from new to "throw away" (or stub loss) thickness. The anodes in this example are 152 mm thick when new. If 100 mm of the anode is used and 52 mm is stub loss, the anodes along any bus in the cell room are linearly distributed in thickness from 52 to 152 mm. The solid black line of Fig. 5 depicts this relationship. From Eq. [1], the brine level at any row position can also be calculated. Typical values are shown as horizontal dotted lines in Fig. 5. The fraction of anodes F_S submerged at row N can then be calculated. For any given row, the number of anodes submerged is given by the intersection of the brine level in that row with the age distribution line of Fig. 5. The fraction of anodes submerged (F_S) is simply the anode number of the intersection point divided by the total number of anodes (250 in this case).

The average circuit voltage drop along any bus is given by the weighted average voltage drop at that bus position for each cell. This results in the general equation

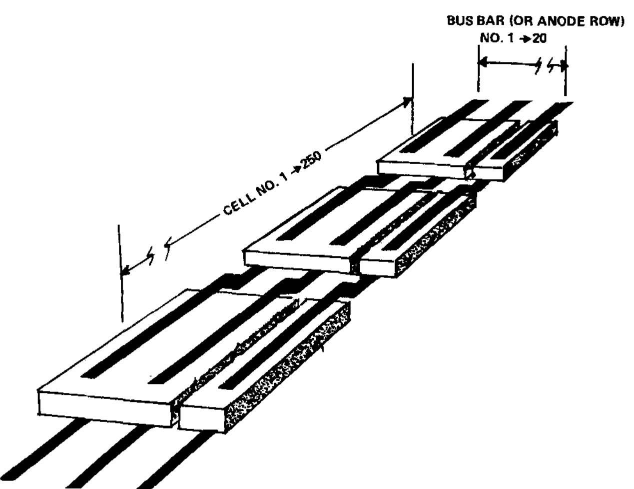

Fig. 4. Schematic of cell and anode positions

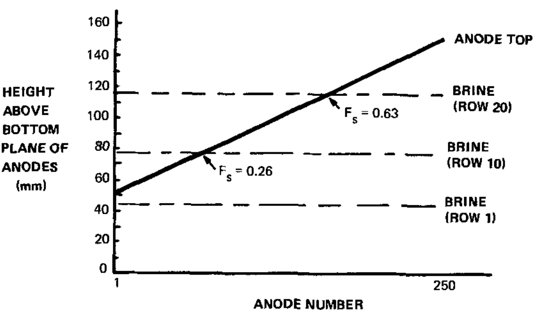

Fig. 5. Relation between brine level and anode age

$$V_N = F_S V_S + (1 - F_S) V_U \quad [2]$$

where V_N = circuit voltage along a given bus bar
F_S = fraction of anodes submerged along bus bar N
V_S = experimentally determined voltage of submerged anode at given current density
V_U = experimentally determined average voltage of unsubmerged anodes over the range of nonsubmergence

For any given anode design, V_U as well as V_S must be determined experimentally. Figure 6 gives the shape of typical experimental data obtained in this study. Note that increasing the brine level above the top of the anode does not result in additional voltage improvement. However, decreasing brine level below the top of the anode at any current density results in considerable worsening of the voltage. This effect is more noticeable as the current density increases. This is probably due to the critical need for increased circulation rates at higher current densities and indicates that anodes should be designed according to the current density at which they are to operate.

With the experimental data represented by Fig. 6, the average voltage (V_U) for those anodes which are unsubmerged in any particular row as well as the voltage for submerged anodes can then be substituted into Eq. [2]. Thus, the cell room voltage at a given current density along any particular bus can be predicted.

Figure 7 gives experimentally determined data obtained for one particular graphite anode design investigated in this study.

Note that the typically shaped qualitative curve described in Fig. 6 again reappears quantitatively in Fig. 7. Upon examination of Fig. 7, the importance of the gas lift pump principle to low voltage operation can be further appreciated.

At brine levels between 0 mm and about −50 mm an increase in current density produced an increase in voltage as shown. However, at brine levels which were lower than about −70 mm relative to the top of the anode a much greater increase in voltage was experienced for a given current density increase. The point of inflection occurring between about −50 and −70 mm represents a change of hydrodynamic mechanism.

The anode used for the data of Fig. 7 was the typical slot and hole design shown in Fig. 2. The top of the slot started 51 mm below the top of the anode. Thus, one can explain the more severe voltage increases at low brine levels by realizing that once the brine level dropped below the top of the slot, gas lift pump or percolation-type circulation was no longer possible and circulation reverted to the mechanism of free convective lift due to bubble buoyancy. The smaller vertical separation of current density lines to the left of the −50 mm level of Fig. 7 is direct evidence of the voltage advantage due to the rapid brine circulation and bubble detachment provided by the gas lift pump principle.

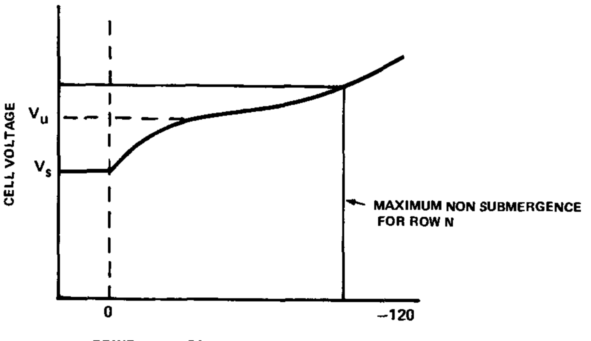

Fig. 6. Typical functional relation between anode voltage and brine level.

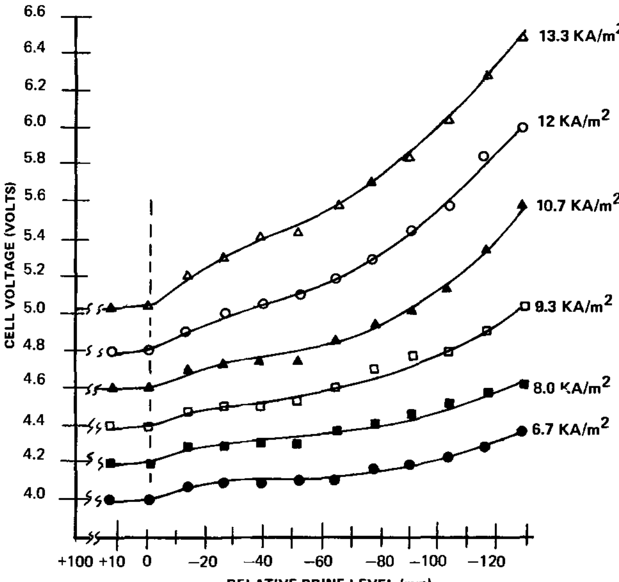

Fig. 7. Cell voltage as a function of brine level relative to the top of a graphite anode.

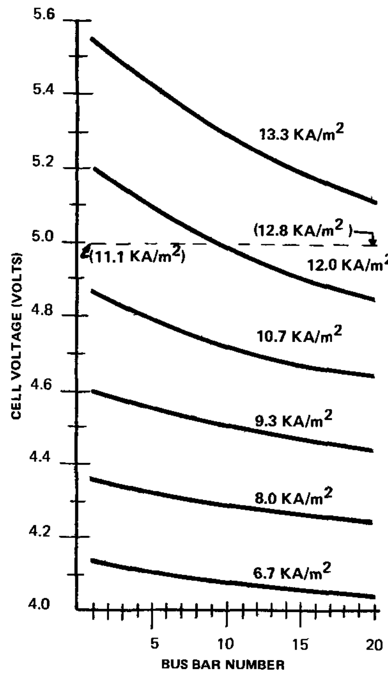

Fig. 8. Cell voltage profile at various current densities as a function of bus bar number.

Using the data of Fig. 7 and Eq. [2] one can plot the cell voltage at any bus bar position with current density as a parameter. The result is given in Fig. 8.

Two points of significant importance should be noted from Fig. 8. Firstly, let us suppose that the cell room is operated under a condition of uniform current density; *i.e.*, the current in each bus bar is equal. Under this condition, due to the brine level effect alone, the average circuit voltage from bus to bus along the length of a given cell will decrease and the control panel rectifier voltage will indicate some value of an average cell voltage.

Secondly, if the cell room anodes are adjusted to a given voltage (say 5V as indicated in Fig. 8) then the current density at the inlet bus position is significantly different from the current at the outlet bus. In this example the brine level effect results in a more

than 10% increase in current density from the inlet to the outlet end of the cell.

Summary

It has been shown that brine level is an important variable affecting the operating voltage of graphite anodes in mercury-type chlor-alkali cells. In addition, a method of analyzing laboratory data has been presented which enables one to predict the effect of this variable on the operating voltage and current distribution in a commercial cell room.

Studies on the Mechanism of the Chlorine Electrode Process

Fumio Hine* and Masaki Yasuda

Nagoya Institute of Technology, Nagoya 466, Japan

ABSTRACT

The chlorine electrode process on the graphite anode under real conditions of chlor-alkali cells has been studied. In relatively low potential range up to 1.25V *vs.* SCE, two consecutive charge-transfer reactions occur, and the second is rate determining

$$Cl^- \rightleftharpoons Cl_{ad} + e$$
$$Cl_{ad} + Cl^- \xrightarrow{A} Cl_2 + e$$

The potential deviates from the Tafel line at high current densities, where the carbon oxide ($C\text{-}O_H$) forms on the electrode surface, and the active sites for the chlorine electrode process diminish.

Substantial development of both science and engineering has taken place in the chlor-alkali industry during the past 20 years. Reduction of the cell voltage at high current densities is a most important goal in practical cell operation. The chlorine overvoltage and the *IR* drop near the graphite anode are major factors in the voltage balance of the amalgam-type cell (1). Even in the diaphragm cell, the situation is essentially the same.

The chlorine electrode in molten salts has been studied by some authors (2-8), but relatively few studies have been made in aqueous solutions (8-11). Electrode behavior in aqueous solutions is complicated by the formation of an oxide layer on the surface of graphite anode during electrolysis of chloride solution because of discharge of H_2O and/or OH^- with chlorine. Thus the effect of the carbon oxide layer on the chlorine evolution reaction should be considered (12, 13). Formation of the higher oxide [designated as ($C\text{-}O_H$) hereafter] becomes a major factor in the electrochemical consumption of graphite anodes; furthermore, the oxide causes an increase in chlorine overvoltage due to occupation of the active sites on the working electrode (13).

The mechanism of the chlorine electrode process will be discussed with respect to results obtained using rotating-disk and rotating-cylinder graphite electrodes in acidified NaCl solutions. A large Tafel slope rather than the theoretical value ($2.3 \times 2RT/F$) at high current densities will also be discussed with assumption of formation of ($C\text{-}O_H$) on the electrode.

Experimental Procedure

Rotating-disk and rotating-cylinder graphite electrodes were used. Properties of the specimen were as follows: specific gravity, 1.71; specific resistance, 55×10^{-5} ohm·cm; vanadium content, 3 ppm; ash, less than 0.1%. A graphite rotating disk of 11 mm diam (*ca.* 0.95 cm^2 working area) and 25 mm long was screwed at the end of the Ti-shaft with a Teflon sleeve. A graphite cylinder, 12 mm diam and 10 mm long, was mounted to the Ti-shaft, and graphite surface was covered with chlorine-resistant plastic resin except for a small part (*ca.* 0.2 cm^2) as working surface. These electrodes were treated in 6*N* HCl at 40-50 A/dm^2 for at least one month. The electrode was placed at the center of the measurement cell of *ca.* 1 liter in capacity having a Pt counterelectrode which was separated by a sintered glass diaphragm. Preelectrolysis of the electrode was carried out at 5 A/dm^2 for an hour prior to measurement.

A calomel electrode in contact with 3.3*N* KCl was used as reference, and a very small liquid junction potential was found. The current interruption method was employed to eliminate a large *IR* drop near the working electrode due to bubbles.

Although preelectrolysis of the solution was not necessary according to Yokoyama and Enyo (14), pretreatment with graphite anode and Pt cathode was sometimes made. Results obtained were not affected. Moisture and temperature of chlorine or mixture of Cl_2 and N_2 were brought to equilibrium before sending to the cell. Temperature was 50°C.

Results and Discussion

Preelectrolysis of the working electrode shown above is most important for reproducibility of the polarization measurement. The surface roughness of graphite was not determined, but the specimen was not degraded during experiment. The graphite anode in practical chlor-caustic cell becomes rough (9), but graphite is resistive toward roughening in HCl (12). The chlorine overvoltage decreased gradually, then stabilized after eight weeks. Penetration of solution would be one reason (15), but it could also be due to slow conversion of the carbon oxide on the working surface into adatoms of chlorine (13). After the sur-

* Electrochemical Society Active Member.

Key words: chlorine electrode, graphite anode, carbon oxide layer, coverage on graphite anode.

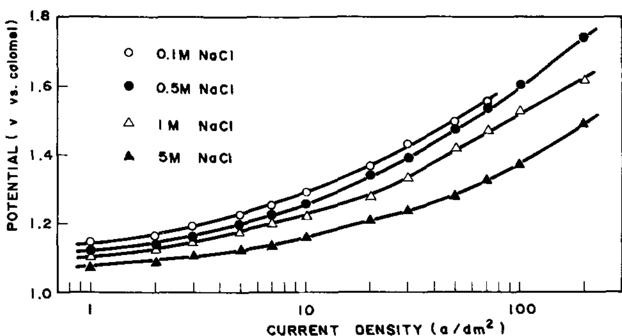

Fig. 1. Polarization curves of graphite anode in acidic NaCl solution (0.1M HCl) at 50°C.

face is stabilized, the chlorine electrode process takes place mostly at the surface, while micropores would also be working. But it was confirmed that the polarization curve was no longer affected by the micropores.

The anodic polarization is a function of the NaCl concentration as shown in Fig. 1. It is independent of the rotating speed, and hence no slow mass transfer step is involved. The Tafel slope at $E < 1.25$V is 120-130 mV/decade, but the potential rises quickly with current density thereafter. Full logarithm plot of the current density *vs.* Cl^- activity has a slope of 0.6 as shown in Fig. 2. The activity coefficient of Cl^- was estimated to be 0.8 in 5.1M NaCl at 50°C (16). The electrochemical reaction order for Cl^- is represented as follows (17)

$$z_{Cl^-} = \left(\frac{\partial \log i}{\partial \log a_{Cl^-}} \right)_{E,\, a_{Cl_2}} \cong 0.6 \quad [1]$$

The reaction order z_{Cl^-} in the previous paper (13) was unity because the process consisted of the chlorine electrode reaction only. On the other hand, the process under discussion here took the effects of the carbon oxide on the anode, and hence a small value of z_{Cl^-} was obtained.

The anodic polarization curves in chlorine saturated and chlorine-free solutions are shown in Fig. 3. Ionization of Cl_2 occurs at $E < 1.15$V in chlorine saturated solution. In chlorine-free solution, the reversible potential is very low, and no backward reaction takes place even at less than 1.1V with the slope of 40 mV/decade.

The cathodic polarization in Fig. 4 is affected by the Cl_2 concentration at a given rotating speed. It also depends on the rotating speed. The cathodic reaction is, therefore, controlled by diffusion of Cl_2.

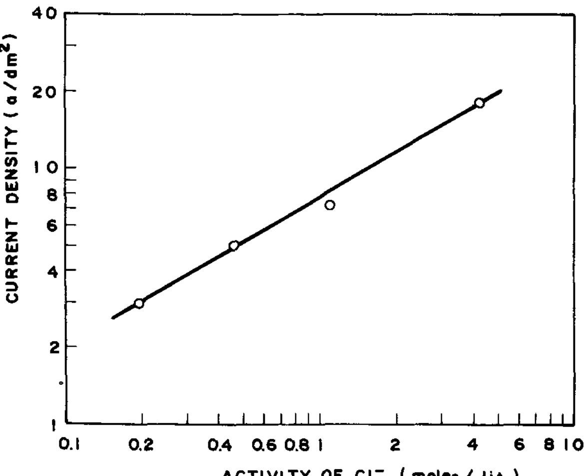

Fig. 2. Current density vs. Cl^- activity curve (logarithmic scale) at constant potential (1.2V vs. calomel).

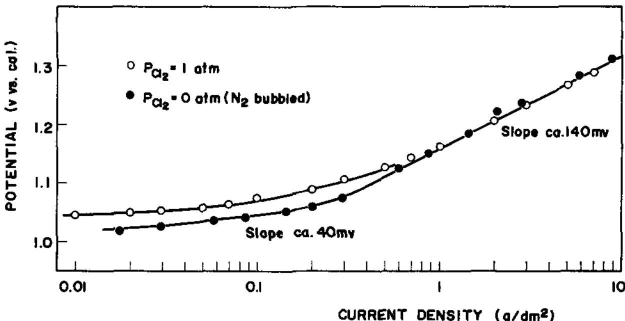

Fig. 3. Polarization curves of graphite anode in saturated NaCl (pH *ca.* 1.0) at 50°C. $E_{eq} = 1.044$V *vs.* calomel.

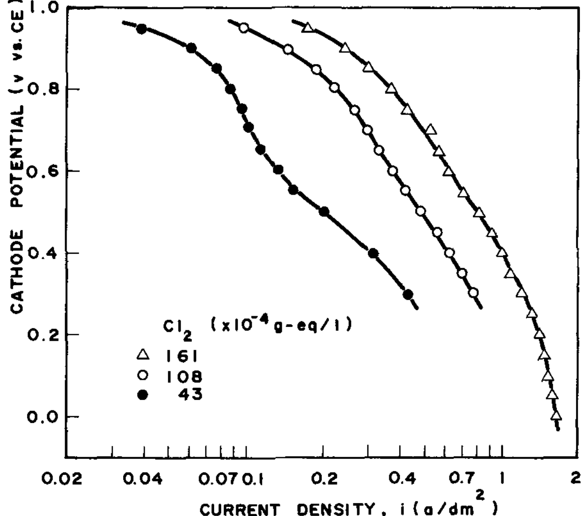

Fig. 4. Polarization curves of graphite cathode in saturated NaCl containing chlorine at 50°C. Rotating speed, 2130 rpm; pH, *ca.* 0.5.

The current density, i, controlled by diffusion of Cl_2 at a rotating speed, m, is as follows (18)

$$i = A([Cl_2] - [Cl_2]_s)\sqrt{m} \quad [2]$$

where A is a constant, and $[Cl_2]$ and $[Cl_2]_s$ are the Cl_2 concentration in the bulk of solution and at the electrode surface, respectively. Also, the diffusion limiting current density, i_d, is represented by

$$i_d = A[Cl_2]\sqrt{m} \quad [3]$$

At the overvoltage more than 70 mV, the backward reaction is negligible, and hence

$$i = k[Cl_2]_s^{z_{Cl_2}} \quad [4]$$

where k is the electrochemical rate constant, and z_{Cl_2} is the reaction order for Cl_2. From Eq. [2]-[4]

$$\log i = \log k + z_{Cl_2} \log\left(1 - \frac{i}{i_d}\right) [Cl_2] \quad [5]$$

The reaction order, z_{Cl_2}, is unity as shown in Fig. 5, and hence, Eq. 5 becomes simply

$$i = k[Cl_2]\left(1 - \frac{i}{i_d}\right) \quad [6]$$

or

$$\frac{1}{i} = \frac{1}{i_r} + \frac{1}{A[Cl_2]\sqrt{m}} \quad [7]$$

where $i_r = k[Cl_2]$, and can be evaluated by projection of the $1/i$ *vs.* $1/\sqrt{m}$. The intercept obtained from this extrapolation is very limited in accuracy since the rotation dependence has only been plotted over a small range. Coefficient A can be calculated by the equation

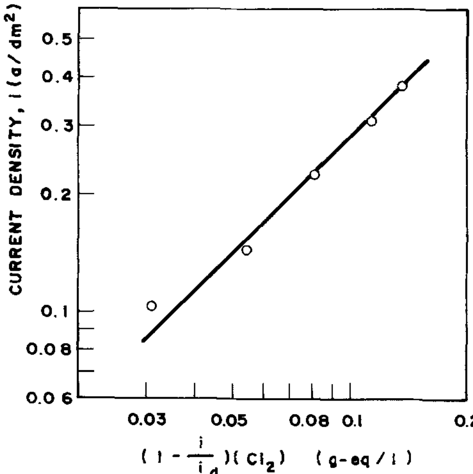

Fig. 5. Current density *vs.* Cl_2 concentration curve in saturated NaCl (pH *ca.* 0.1) at 50°C. Rotating speed, 2150 rpm. *i* and i_d were measured at 900 mV *vs.* calomel and 0V, respectively.

$$A = 0.62\, nFD^{2/3} \left(\frac{\mu}{\rho}\right)^{-1/6} [Cl_2]\,(2\pi m)^{1/2}$$

But reliable data for the diffusion coefficient, *D*, of Cl_2 were not available. Experiments were repeated and the potential was set in several stages. From these data, *A* was computed by the method of least squares.

The potential *vs.* logarithm of i_r with the slope of 120 mV/decade is independent of the Cl^- concentration as shown in Fig. 6, therefore, the reaction order with respect to Cl^- is zero.

The exchange current density of the chlorine electrode process on a graphite electrode in a saturated NaCl (pH 0.5) is *ca.* 0.12 A/dm² (Fig. 7).

The overvoltage *vs.* current density curve in the range of very low overvoltage ($|\eta| < 20$ mV) is exactly straight (Fig. 8), and hence the two directions of the chlorine electrode process are symmetrical. The polarization resistance is 0.15 ohm · dm².

The stoichiometric number, ν, is represented as follows

$$\nu = \frac{nF}{RT}\,(i_o)\left(\frac{\partial \eta}{\partial i}\right)_{\eta=0} = 1.2 \qquad [8]$$

where *n* is the number of charge transfer for the over-all reaction. Those experiments have been carried out in the range of low overvoltage as described above, and it has been confirmed that the cathode process has not been controlled by diffusion.

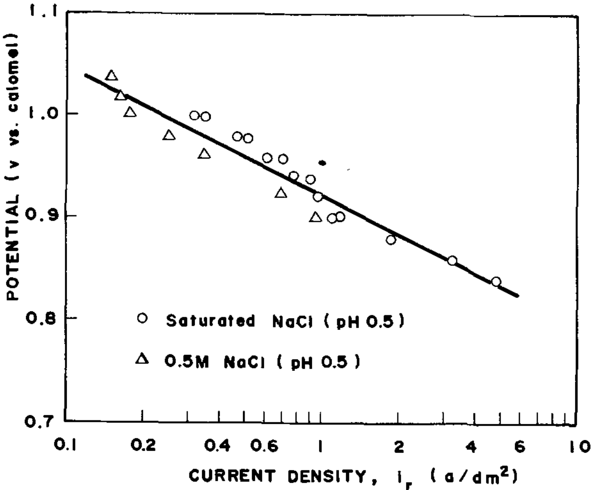

Fig. 6. Polarization curve of graphite cathode in NaCl at 50°C. $p_{Cl_2} = 1$ atm.

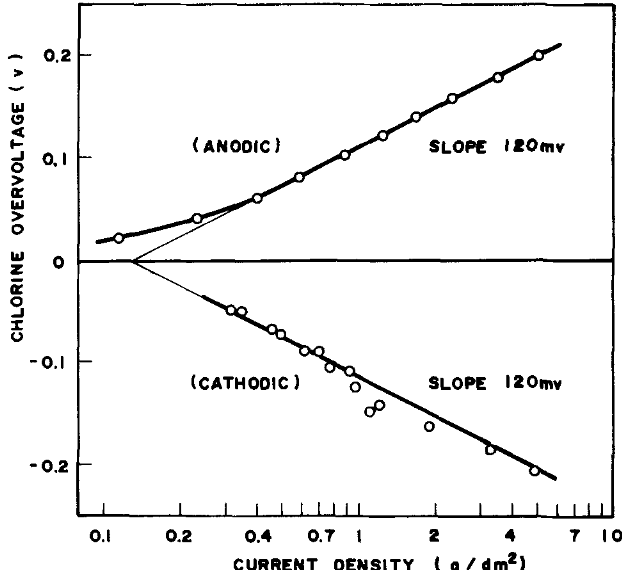

Fig. 7. Anodic and cathodic polarization curves of graphite in saturated NaCl solution (pH *ca.* 0.5) at 50°C. p_{Cl_2} = *ca.* 1 atm.

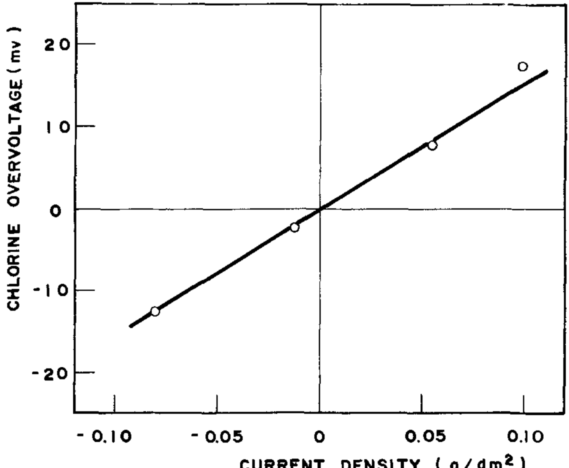

Fig. 8. Overvoltage *vs.* current density curve at low current densities. Saturated NaCl (pH *ca.* 0.8) at 50°C. p_{Cl_2} = *ca.* 1 atm.

Various parameters evaluated from the experimental results are shown in Table I. z_{Cl^-} for anodic process in this table is 1 instead of 0.6 in Fig. 2. The results obtained by the galvanostatic anodic transient method is unity (13). Deviation of z_{Cl^-} might be due to disturbance of ($C\text{-}O_H$) on the working electrode.

The over-all reaction of the chlorine/chloride system is

$$2Cl^- = Cl_2 + 2e \qquad [I]$$

But the elementary reactions involved are as follows (7)

Mechanism I: $Cl^- = Cl_{ad} + e$ [II]

$2Cl_{ad} = Cl_2$ [III]

Mechanism II: $Cl^- = Cl_{ad} + e$ [II]

$Cl_{ad} + Cl^- = Cl_2 + e$ [IV]

The parameters on the electrode kinetics corresponding to these mechanisms are listed in Table II, where the Langmuir-type isotherm is proposed for adsorption of Cl with the coverage θ_{Cl}.

In the potential range up to 1.25V, the Tafel slope under $p_{Cl_2} = 1$ atm is about 120 mV/decade. On the other hand, the slope is about 40 mV/decade at low current densities with $p_{Cl_2} = 0$ (N_2 bubbled solution)

Table I. Parameters for the chlorine electrode process (experimental)

	Stoichiometric number, ν	Tafel slope (mV/decade)	Reaction order		Exchange current density, i_o (A/dm^2)
			z_{Cl^-}	z_{Cl_2}

Table II. Parameters for the chlorine electrode process (theoretical)*

Mechanism		Rate-determining step	ν	Tafel slope**		z_{Cl^-}		z_{Cl_2}	
				$\theta_{Cl} \to 0$	$\theta_{Cl} \to 1$	$\theta_{Cl} \to 0$	$\theta_{Cl} \to 1$	$\theta_{Cl} \to 0$	$\theta_{Cl} \to 1$
Anodic	I	$Cl^- = Cl_{ad} + e$	2	$2RT/F$	$2RT/F$	1	1	0	0
		$2Cl_{ad} = Cl_2$	1	RT/F	∞	2	0	0	0
	II	$Cl^- = Cl_{ad} + e$	1	$2RT/F$	—	1	—	0	—
		$Cl_{ad} + Cl^- = Cl_2 + e$	1	$2RT/3F$	$2RT/F$	2	1	0	0
Cathodic	I	$Cl_2 = 2Cl_{ad}$	1	$-\infty$	—	0	—	1	—
		$Cl_{ad} + e = Cl^-$	2	$-2RT/F$	$-2RT/F$	0	0	½	0
	II	$Cl_2 + e = Cl_{ad} + Cl^-$	1	$-2RT/F$	—	0	—	1	—
		$Cl_{ad} + e = Cl^-$	1	$-2RT/3F$	$-2RT/F$	−1	0	1	0

* Langmuir-type isotherm was adopted for adsorption of Cl_{ad}.
** When $\alpha = 0.5$.

as shown in Fig. 3. The rate of the cathodic process [I] is negligible in this case. The Tafel slope for the anodic process of Mechanism II should be $2.3 \times 2RT/\mathbf{F}$ (=120 mV) at $\theta_{Cl} = 1$ and $2.3 \times 2RT/3\mathbf{F}$ (=40 mV) at $\theta_{Cl} = 0$, and is in agreement with the experimental results. Thus, it is concluded that Mechanism II is appreciable, and reaction [IV] is rate determining.

Results of a previous paper (13) show that formation of the carbon oxide on PG- and GC-anodes in 1M $HClO_4$ increases with the anode potential, *i.e.*, all of the surface oxide tend to the "higher oxide ($C\text{-}O_H$)" at the potential range over *ca.* 1.3V. ($C\text{-}O_H$) may form even in chloride solution, of course, the amount of formation decreases with increase in the Cl^- concentration. The exchange between oxide (or adatom of oxygen) and chlorine depends on the potential and is significantly irreversible.

It is evident that the graphite anode is consumed by a considerable amount if it is preelectrolyzed at very high current densities such as 250 A/dm^2. The rough surface after corrosion resembles the surface of the anode polarized in $HClO_4$ at high current densities where the oxygen electrode reaction may take place.

The polarization curves of the graphite anode preelectrolyzed in a saturated NaCl (*p*H *ca.* 2) at 250 A/dm^2 for about 6 hr is shown in Fig. 9. The chlorine current efficiency (volume ratio of chlorine to total gas) is also shown. At high current densities over 10 A/dm^2, the potential deviates from the Tafel line, and

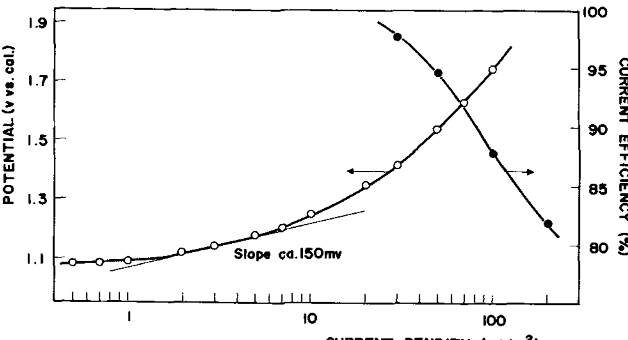

Fig. 9. Polarization curve and current efficiency for chlorine evolution reaction with graphite anode having rough, or corroded, surface in saturated NaCl (*p*H 2.3) at 50°C.

the chlorine current efficiency decreases with increase in current density. It is considered that the effect of the oxide layer on the anode is a major reason for deviation from the Tafel line at high current densities, and also the oxygen electrode process is not negligible even in a saturated NaCl solution at low *p*H such as 2 in the potential range over 1.7V.

In conclusion, Mechanism II is acceptable for the chlorine electrode process at relatively low current densities or at the potential range up to 1.25V, and reaction [IV] is rate determining.

Since the backward reaction is negligible at high potential ranges, Eq. [9] is obtained

$$i = k_D[Cl^-]\,\theta_{Cl} \exp(\alpha \mathbf{F} E/RT) \qquad [9]$$

where k_D is the reaction rate for the anodic direction of reaction [IV], and α is the transfer coefficient (= *ca.* 0.5). θ_{Cl} is the coverage of adatom of chlorine, and is assumed to be about unity. θ_{Cl} decreases with formation of ($C\text{-}O_H$), at high potential over 1.3V. In a small range of potential (*ca.* 1.25-1.5V), it can be assumed that the amount of the oxide is proportional to the potential, therefore, θ_{Cl} decreases with potential

$$\theta_{Cl} = 1 - \theta_O \qquad (E > ca.\ 1.25V) \qquad [10]$$

where θ_O is the coverage of carbon oxide. Thus, we have

$$i' = k_D[Cl^-](1 - \theta_O) \exp(\alpha \mathbf{F} E/RT) \exp[-(1-\alpha) f\theta_O] \qquad [11]$$

where fRT is Temkin's parameter, and hence, the last term will show the factor of increase in the apparent activation energy for the chlorine electrode reaction due to existence of the oxide layer on the surface of the working electrode (19). From Eq. [9] and [11]

$$\frac{i'}{i} = (1 - \theta_O) \exp(-f\theta_O/2) \qquad [12]$$

The straight line with the slope of $2.3 \times 2RT/\mathbf{F}$ in Fig. 10 is represented by Eq. [9], whereas the curve labeled i' follows Eq. [11]. Figure 11 represents the relationship between E *vs.* (i'/i) obtained from the polarization data such as Fig. 1. The chlorine current efficiency obtained by gas analysis was quite high at high current densities such as 250 A/dm^2 (Fig. 12). Therefore, the oxygen evolution reaction is negligible during experiment shown in Fig. 1. θ_O is approximately proportional to the potential in a small range of potential (13).

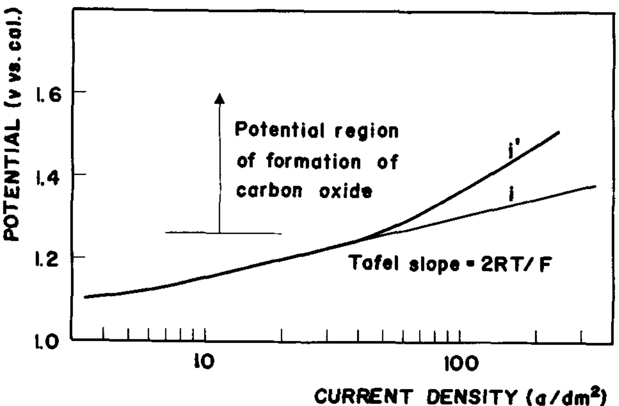

Fig. 10. Polarization curve of graphite in NaCl solution. *i*, Polarization curve represented by Eq. [9]; *i'*, polarization curve represented by Eq. [11].

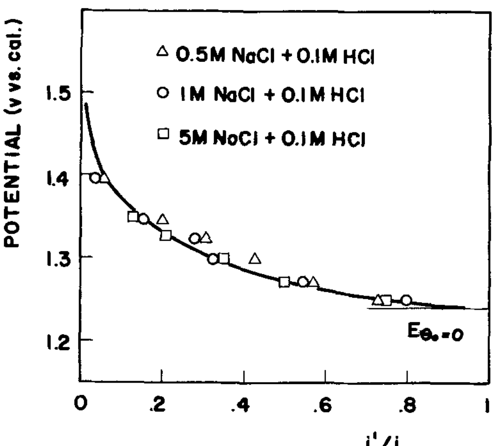

Fig. 11. Potential vs. (*i'*/*i*) curve

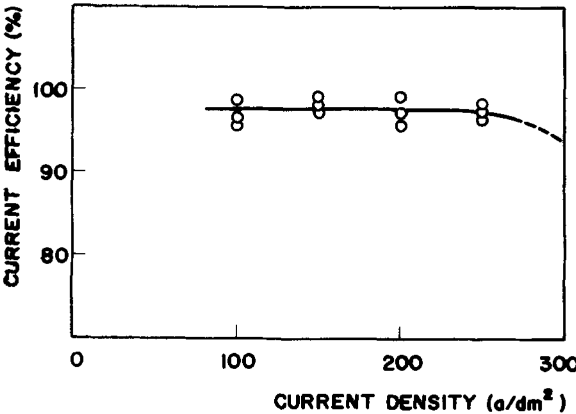

Fig. 12. Chlorine current efficiency vs. current density curve. The graphite anode was preelectrolyzed enough. Solution, saturated NaCl (pH 0.6-1.5) at 50°C.

Since the surface of graphite anode is rough, the oxygen electrode process might not be detected unless the current density is extremely high. It is therefore difficult to explain the exact relationship between θ_O and E, but the relationship between θ_O and $(1 - \theta_O)$ $\exp(-f\theta_O/2)$ in Fig. 13, which was obtained with PG and GC electrodes (13), resembles Fig. 11. The potential $E_{\theta_O=0}$ can be estimated to be *ca.* 1.25V, while $E_{\theta_O=1}$ is not obtained from Fig. 11. The active sites for the chlorine electrode process decrease with disturbance of adatom of oxygen and/or oxide layer, and the activation energy for the chlorine electrode may increase with increase in θ_O.

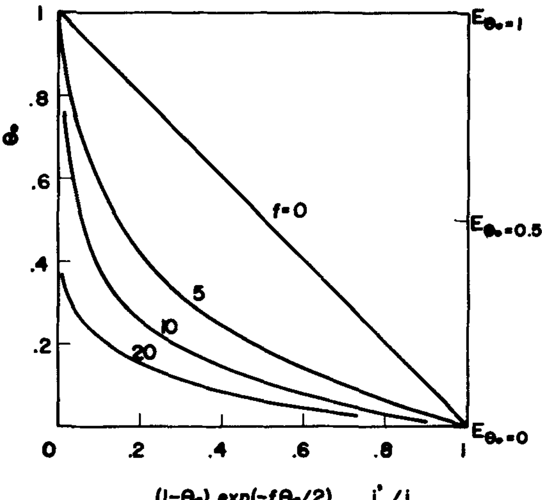

Fig. 13. θ_O vs. $(1 - \theta_O) \exp(-f\theta_O/2)$ curves under the assumption of $\theta_O \sim E_{\theta_O}$.

It has been considered that the surface oxide affects the chlorine current efficiency, graphite consumption, and the overvoltage as well. The chlorine evolution reaction may not take place on the carbon-oxide layer. The "over-all oxygen electrode reaction," which involves formation of O_2, CO, and CO_2, may take place on the graphite anode at high current densities even in concentrated chloride solutions, and the graphite anode might be corroded in this potential range.

Conclusion

The mechanism of the chlorine electrode process on the graphite anode under real conditions of chlor-alkali cells has been discussed. The electrochemical reaction takes place mostly at the surface of graphite anode, while very small current would pass through micropores of several millimeters deep of graphite. In the potential range less than 1.25V, the consecutive charge transfer reactions occur

$$Cl^- = Cl_{ad} + e$$
$$Cl_{ad} + Cl^- \rightarrow Cl_2 + e$$

and the second step is rate determining.

At higher potential ranges, the anode surface is covered by the carbon oxide, and the potential becomes high due to decrease of the active sites for the chlorine electrode process.

Electroinitiated Polymerization of Tetrahydrofuran

A. N. Dey* and E. J. Rudd

P. R. Mallory & Company, Incorporated, Laboratory for Physical Science, Burlington, Massachusetts 01803

ABSTRACT

Electroinitiated polymerization of tetrahydrofuran (THF) was accomplished in 1M $LiClO_4$-THF organic electrolyte solutions by anodic electrolysis on platinum electrodes in a three-compartment cell. THF was found to polymerize to form a viscose gel at 25°C. The rate of polymerization was followed by measuring the electrical resistance of the organic electrolyte solution as a function of time after the electroinitiation. The rate of polymerization was found to increase with the increase in the anodic charge passed. The average molecular weight of the polymer was determined to be 2×10^5 by viscometry. The polymer was found to be "living" in nature. Electrochemical evidence was presented to show that the initiation occurred as a result of the electro-oxidation of THF rather than the ClO_4^- anion.

The chemical polymerization of THF has been studied extensively (1). It has been established that the polymerization occurs strictly by a cationic mechanism and the catalysts are of the strong acid or Lewis acid type or of salts derived from them. Electroinitiated polymerization of THF has also been reported (2-4). The mechanism proposed (3) for the electroinitiation involved the oxidation of the anion, *e.g.* ClO_4^- rather than the THF itself. In this paper we wish to present evidence which indicates that electroinitiation occurs as a result of the electro-oxidation of THF itself. The results reported here have also a direct bearing on the high energy density organic electrolyte lithium batteries (5-8) with THF as a solvent.

Experimental

Materials.—Tetrahydrofuran (Eastman Kodak practical grade) was purified by pretreating with lithium aluminum hydride and subsequent distillation under argon atmosphere. Anhydrous lithium perchlorate (G. Frederick Smith Chemical Company) was dried under vacuum at 120°-140°C for 48 hr. Lithium foil (Foote Mineral Company) was used as received.

$LiClO_4$ solutions in THF were prepared in an argon-filled dry box. The water content of the solutions was determined by gas chromatography (Perkin Elmer Model No. 801, hot wire detector) using a 15 × 0.25 in. column of Porapak Q at 125°C with a helium gas flow of 20 cm^3/min. The moisture contents of the solutions were typically 0.01% or less.

Electrodes.—The working electrode was made of a smooth platinum wire sealed through a glass tube. The geometric surface area of the exposed portion of the platinum wire was approximately 0.3 cm^2. The reference and the counterelectrodes were made by pressing lithium foil on expanded stainless steel current collector.

Cells.—A three-compartment glass cell was used for both the electroinitiated polymerization and the voltammetric measurements. The central compartment contained the working electrode, the counterelectrode compartment was connected to the central compartment via a fritted glass disk of medium porosity, and the reference electrode compartment was connected by a Luggin capillary which was placed close to the working electrode. For the electroinitiated polymerization experiments, the working electrode compartment was modified to allow the insertion of two platinized platinum electrodes used for the measurement of electrical resistance of the solution. This was measured at 1 kc employing an impedance bridge (General Radio Company, Type No. 1650-A).

Polymerization.—Electroinitiated polymerization experiments were carried out by anodically electrolyzing the solution in the working electrode (Pt) compartment at constant currents of 0.2 and 1 mA corresponding to current densities of 0.67 and 3.3 mA/cm^2, respectively. After a certain time the electrolysis was stopped and two platinized platinum electrodes (from a conductivity cell) were inserted in the cell in order to measure the electrical resistance of the solution. The solution became progressively viscose with time as a result of the polymerization of THF and the electrical resistance of the solution increased accordingly. The rate of polymerization of THF was followed by measuring the resistance (instead of the viscosity) of the solution as a function of time at 25°C. There was no polymerization of THF in either the reference or the counterelectrode compartments. Presence of either the Li metal or the moisture (0.5% or more) in the working electrode compartment inhibited the polymerization. Electroinitiation occurred on both Pt and graphite electrodes.

* Electrochemical Society Active Member.

Key words: polytetrahydrofuran, electroinitiation, organic electrolytes, polymerization, living polymer, lithium perchlorate, tetrahydrofuran, lithium batteries, high energy density batteries, organic electrolyte batteries.

The THF polymers were isolated by terminating the reaction with addition of excess distilled water to the solution of the working electrode compartment, and filtering the precipitated polymer. The polymer was purified by successive (three times) dissolution in pure THF and reprecipitation in distilled water. The material was finally dried under vacuum to remove excess monomeric THF and was weighed to determine the conversion. Equilibrium conversions of 30-40% were realized at 25°C.

Molecular weight.—The average molecular weights of the polymers were determined by viscometry in benzene at 30°C in a Cannon Fenske viscometer. Molecular weights were computed from the relation (9)

$$[\eta] = 1.31 \times 10^{-3} \overline{M}_v^{0.60}$$

where $\overline{M}_v$ is the average molecular weight. The intrinsic viscosity $[\eta]$ was determined by extrapolating the linear plots of η_{sp}/C vs. C where the concentration (C) of polymer was expressed in grams/100 mliters. Specific viscosity (η_{sp}) was calculated from the measured relative viscosity (η_r) according to the relations (9)

$$\eta_{sp} = \eta_{r-1}$$
$$\eta_r = t_{solution}/t_{solvent}$$

where $t_{solution}$ is the flow time of the polymer solutions and $t_{solvent}$ is the flow time of the pure solvent (benzene).

Electrochemical measurements.—Cyclic voltammetric and the steady-state measurements were carried out on Pt wire electrodes in 1M $LiClO_4$-THF solutions in the regions of potential anodic to Li/Li^+ potential using a Wenking potentiostat (6354-TR), a Wavetek function generator, and a x-y recorder.

Results and Discussion

Rate of polymerization.—The electroinitiation of the polymerization of THF was carried out at constant currents of 1 and 0.2 mA. The durations of electrolysis were 1 and 4 hr at 1 mA, and 20 hr at 0.2 mA, corresponding to total charges of 3.6 coulombs, and 14.4 coulombs, respectively. The rates of polymerization as reflected from the plots of the electrical resistance of the solution after electroinitiation at 1 mA for 1 hr increased with time for approximately 130 hr and, thereafter, it leveled off indicating that the polymerization reaction reached an equilibrium. The viscosity of the solution increased progressively and the final material had the appearance of a clear viscose gel. There was no evidence of salting out of $LiClO_4$ electrolyte salt. The rate of polymerization, as determined from the slopes of the plots shown in Fig. 1, was found to increase drastically with the increase in the total anodic charge (Q) passed during electroinitiation. Assuming that the electroinitiation of the THF polymer occurs as a result of electrochemical generation of the initiating species, the increase in the polymerization rate with the anodic charge is expected (10), assuming that the current efficiency of electroinitiation remains unchanged.

Molecular weight.—The average molecular weights of the polymer as determined from viscometry are shown in Table I. Although the data are insufficient to draw any conclusions in regard to the dependence

Table I. Average molecular weight of the electroinitiated THF polymer as determined from viscometry (9) in benzene at 30°C

Electroinitiating conditions			
Current (mA)	Time of anodic electrolysis (hr)	Intrinsic viscosity	Average molecular weight, M_v
0.2	20	2.04	2.1×10^5
1.0	4	2.40	2.7×10^5
1.0	1	1.73	1.6×10^5

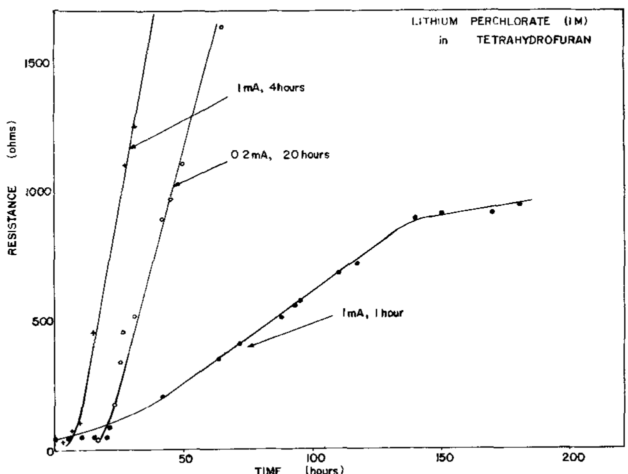

Fig. 1. Change in electrical resistance of the 1M $LiClO_4$-THF solution with time after electroinitiation at 1 mA for 1 hr, 0.2 mA for 20 hr, and 1 mA for 4 hr.

of the molecular weight on the initiating condition, it is clear that a true polymer with molecular weights[1] in the range of 2×10^5 is formed by anodic electrolysis of 1M $LiClO_4$-THF organic electrolyte. The dried polymer had the appearance of a stiff white solid very much like polyethylene or polypropylene.

"Living" polymer.—The "living" nature of the electroinitiated THF polymer was established by studying the change in the electrical resistance of 1M $LiClO_4$-THF solutions (which was initiated at 4 mA for 1.2 hr) with time of equilibration at different temperatures and is shown in Fig. 2. In a "living" polymer system the polymer molecules establish an equilibrium with the monomer units at any given temperature by either depolymerizing (with increasing temperature) or polymerizing (with decreasing temperature). This is reflected in Fig. 2, It is seen that at 25°C the resistance increases steadily with time, indicating the process of polymerization. On increasing the temperature to 54°C, the resistance drops; first sharply (indicating the effect of temperature on the resistance), and then steadily for 25 hr indicating the process of depolymerization. On decreasing the temperature to 40°C, the resistance increases again and on further decrease to 14°C, there is again a sharp rise followed by a steady rise in resistance for 50 hr and

[1] One reviewer suggests that discrepancy in the dependence of the molecular weights on the total charge may be explained in terms of current efficiency of initiation.

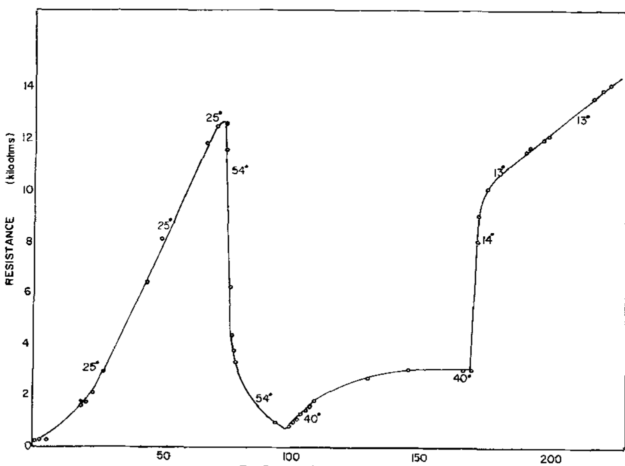

Fig. 2. Change in electrical resistance of 1M $LiClO_4$-THF solution with time at different temperatures of equilibration after electroinitiation at 4 mA for 1.2 hr.

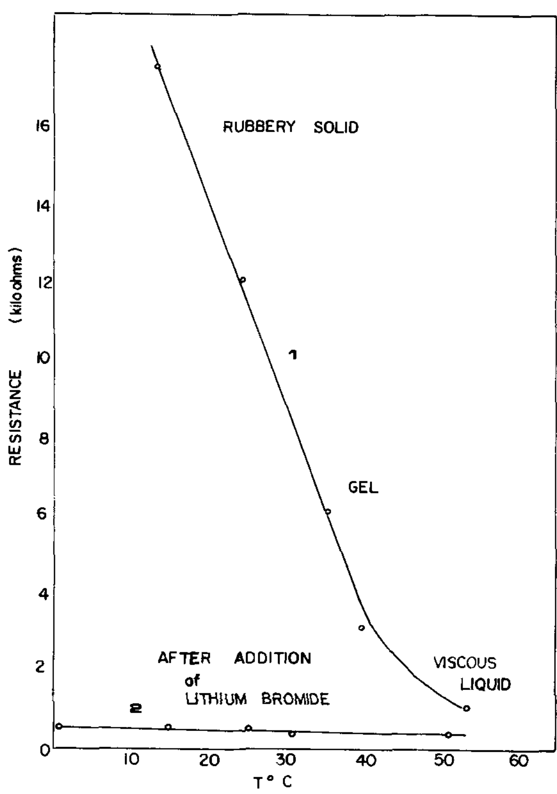

Fig. 3. Equilibrium electrical resistance of 1M $LiClO_4$-THF polymer solutions as a function of temperature, curve 1 before and curve 2 after addition of excess LiBr (termination).

more. The initial sharp rise in resistance is due to the temperature effect and the sustained rise in resistance over 50 hr is due to the process of repolymerization at low temperature.

The "living" nature of the polymer was further demonstrated by comparing the equilibrium resistance of the solution as a function of temperature, before and after the termination of the 'living" polymer, and is shown in Fig. 3. Curve 1 represents the behavior of the "living" polymer before the termination. The consistency of the solution at the various regions of temperature is shown on the curve itself. At 54°C the solution assumes the consistency of a viscose liquid. To this liquid, a saturated solution of anhydrous LiBr in THF was added to terminate (11) the THF polymer so that they lose their "living" nature. The behavior of the "terminated" polymer solution is shown in curve 2. The resistance as well as the consistency of the terminated solution remain relatively unchanged with change in temperature compared to the "living" system.

Electrochemical studies.—Voltammetric studies were carried out in an attempt to understand the electrochemical reactions involved in the process of electroinitiation of the THF polymers. The steady-state current potential curves obtained on a smooth platinum electrode in 1M $LiClO_4$-THF solution are shown in Fig. 4, curve b. Significantly large anodic currents are evident at potentials of 4.0V *vs.* Li/Li^+ from the ascending portion of the curve b. The process appears to be partially inhibited (region BC of curve b) and in this region the formation of a black film on the electrode surface was observed. This film remained on the surface during the descending portion of the curve and the inhibiting effect is reflected in the hysteresis. This film is most likely due to the rapid initiation of the polymerization of THF in the vicinity of the electrode where the initiating species are formed. The hysteresis may be due to the impedance of the polymer film. Prolonged electrolysis at 4.0V *vs.* Li/Li^+ led to an extensive polymerization of THF. The steady-state current potential curve was also obtained in a nonpolymerizing medium, viz., 1M $LiClO_4$ in propylene carbonate (PC) and is shown in Fig. 4, curve a. It is seen that no significant oxidation occurs below the potential of 5.0V *vs.* Li/Li^+ reference and there was no formation of a passive film on the Pt surface. Since the only difference between the two mediums is the solvent, it is reasonable to conclude that the large anodic current at 4.0V *vs.* Li/Li^+ reference obtained in 1M $LiClO_4$-THF medium is due to the oxidation of the solvent THF.

The current-potential curves were also obtained by triangular sweep voltammetry in 1M $LiClO_4$-THF and 1M $LiClO_4$-PC and are shown in Fig. 5 (i) and (ii), respectively. Again, the oxidation occurs at markedly less anodic potential in 1M $LiClO_4$-THF than in 1M $LiClO_4$-PC. The cathodic profile of the curves may correspond to the reduction of the oxidized species. Voltammograms were also obtained in 1M $LiPF_6$-THF and in 1M $LiBF_4$-THF and were identical to

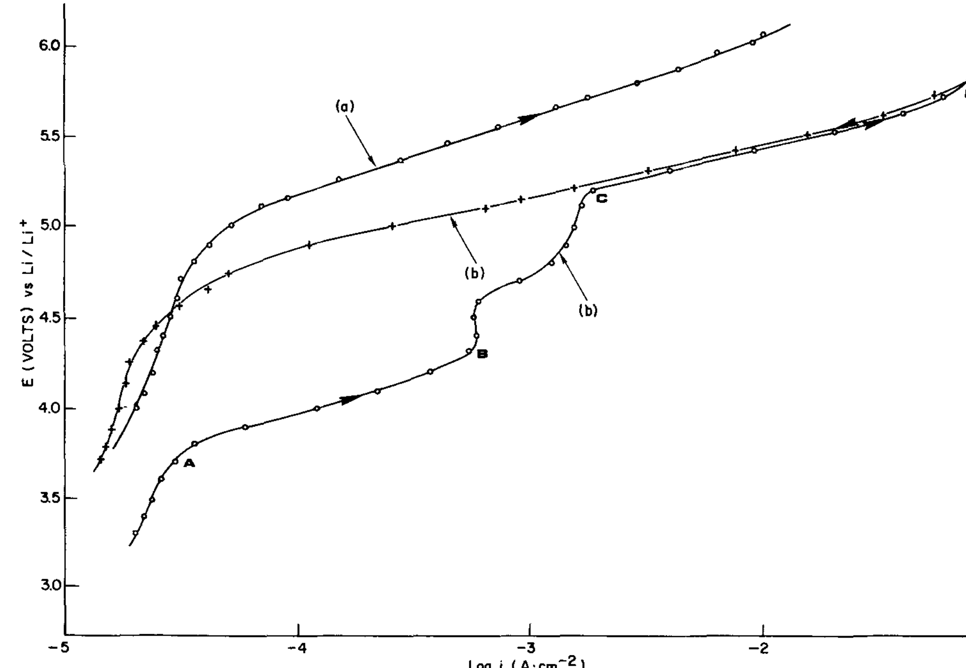

Fig. 4. Steady-state current-potential behavior in (curve a) 1M $LiClO_4$-PC and (curves b) 1M $LiClO_4$-THF solutions on smooth Pt electrodes.

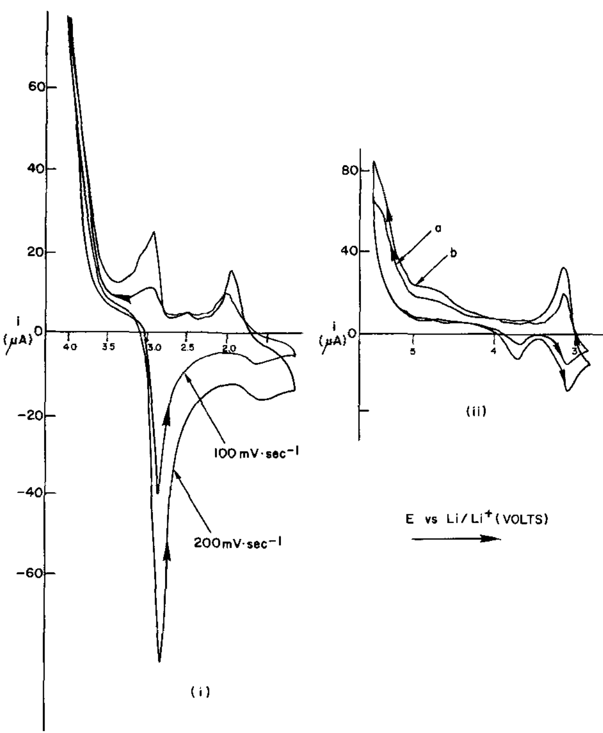

Fig. 5. Cyclic voltammograms of (i) 1M $LiClO_4$-THF and (ii) 1M $LiClO_4$-PC solutions at Pt electrode; (a) Scan rate 100 mV sec^{-1}, (b) scan rate 200 mV sec^{-1}.

those in 1M $LiClO_4$-THF, indicating the oxidation of the solvent rather than the anion. Electroinitiated polymerization occurred with $LiPF_6$ and $LiBF_4$ salts as well.

It may be argued that the comparison of cyclic voltammograms of the two solvent systems, viz.. THF and PC, and the salts, viz., $LiClO_4$, $LiBF_4$, and $LiPF_6$. is not valid because of the possible change in the potential of the Li/Li^+ reference electrode. This was checked by measuring the potential of the following cells with liquid junctions

$$Li/1M\ LiClO_4\text{-}THF//1M\ LiClO_4\text{-}PC/Li \qquad [a]$$

$$Li/1M\ LiClO_4\text{-}THF//1M\ LiBF_4\text{-}THF/Li \qquad [b]$$

The potential differences of cells [*a*] and [*b*] were 0.085 and 0.022V, respectively. The above potential differences include the liquid junction potential. Therefore, the change in the Li/Li^+ reference potential from THF to PC is insignificant compared to the difference in oxidation potentials of approximately 1.5V observed between the two systems in the potentiostatic and cyclic voltammetric measurements shown in Fig. 4 and 5, respectively.

Mechanism.—On a first approximation the electro-oxidation of THF may be represented by an ECE mechanism, *i.e.*, electron transfer step-chemical step-electron transfer step, as has been used to describe the electro-oxidation of related compounds (12-15)

$$\text{(THF)} \rightarrow \text{(THF)}\cdot + H^+ + e \quad (E,C) \qquad [1]$$

I

$$\text{(THF)}\cdot \rightarrow \text{(THF)}\oplus + e \quad (E) \qquad [2]$$

II

It has been established (1) that the initiation requires the formation in some manner of a THF Oxonium ion $\left(R - O\langle + \right)$ in order for the propagation reaction to take place. It was shown (16) that the chemical polymerization of THF with catalysts such as $Ph_3C^+SbCl_6^-$ was initiated by the transfer of a hydride ion from THF to the carbonium ion salt catalyst

$$\text{(THF)} + Ph_3C^+\ SbCl_6^- \rightarrow \text{(THF)}\oplus\ SbCl_6^- + PH_3CH \qquad [3]$$

III IV

The formation of Ph_3CH (IV) was demonstrated by NMR spectroscopy. The THF cation (III) formed as a result of the hydride ion abstraction from the α-carbon atom of THF, reacts (17) with another molecule of THF to form the Oxonium ion (V) which starts the propagation (1)

$$\text{(THF)}\oplus\ SbCl_6^- + O\langle\ \rightarrow \text{(THF)}—O\langle\oplus\ SbCl_6^- \qquad [4]$$

V

The end group is an acetal. The electrochemically formed THF cation (II) is expected to initiate polymerization reaction in a similar manner. The counterion for the THF cation in this case will be ClO_4^- instead of $SbCl_6^-$. The proton formed in the electrochemical reaction [1] may also initiate polymerization (18) by forming the THF Oxonium salt

$$\text{(THF)} + H^+\ ClO_4^- \rightarrow \text{(THF}\oplus\text{)}\!-\!H\ ClO_4^- \qquad [5]$$

$$\text{(THF}\oplus\text{)}\!-\!H\ ClO_4^- + O\langle\ \rightarrow HOCH_2CH_2CH_2CH_2 - O\langle\oplus\ ClO_4^- \qquad [6]$$

The end group in this case is a hydroxyl. No end group analysis was carried out to distinguish the polymerization reactions. However, Nakahama *et al.* (3) carried out the end group analysis of THF polymers made by electroinitiation at 0°C employing Bu_4NClO_4 salt, and determined that end groups were primarily hydroxyl. Nakahama *et al.* (3) suggested that the electroinitiation occurred as a result of the oxidation of ClO_4^- anion rather than the oxidation of THF itself. We have shown by cyclic voltammetry as well as by steady-state current potential measurements that in solutions of $LiClO_4$, $LiBF_4$, or $LiPF_6$ in THF the major oxidation peak occurs at a potential of 3.5V anodic to the Li/Li^+ reference electrode irrespective of the anion. whereas in solution of $LiClO_4$ in propylene carbonate the major oxidation peak occurs at approximately 5.0V anodic to the Li/Li^+ reference elec-

trode. This is a strong evidence in favor of our hypothesis that the electroinitiation step involves the oxidation of THF itself rather than the anion as suggested by Nakahama *et al.*

Electrical Conductivities and Molar Volumes in the Binary Systems $MnCl_2$-LiCl, $MnCl_2$-NaCl, $MnCl_2$-KCl, $MnCl_2$-RbCl, $MnCl_2$-CsCl

A. S. Kucharski and S. N. Flengas*

Department of Metallurgy and Materials Science, University of Toronto, Toronto, Ontario, Canada

ABSTRACT

The densities and the electrical conductivities of the five binary $MnCl_2$-ACl systems, where A = Li, Na, K, Rb, and Cs, have been measured. The molar volumes exhibit increasing positive deviations from additivity, as the size of the alkali metal cation in ACl is increased from Li^+ to Cs^+, and have a maximum positive deviation at approximately $X_{MnCl_2} = 1/3$. The molar conductances exhibit an increasing negative deviation from ideality, with a minimum occurring approximately at $X_{MnCl_2} = 1/3$. The concentration dependence of the molar volumes and of the electrical conductivities in these systems is interpreted in terms of a complex ion model (1) proposed previously for the purpose of interpreting their thermodynamic properties. According to this model the solutions of $MnCl_2$ with alkali chlorides are characterized by the presence of the $MnCl_4^{2-}$ complex anions. The difference between a "free" chloride anion and a chloride anion bonded within a complex configuration, lies in differences in the strength of the anion-to-cation bonds in these two configurations. In this respect, the continuity of the quasilattice structure of a molten salt is not disrupted by the presence of complex species and the latter are not expected to occupy single "lattice" sites within the liquid, as local electrical neutrality is always maintained. Good agreement is obtained between the experimental and the theoretical values for the electrical conductivities and the molar volumes in the systems $MnCl_2$-KCl, $MnCl_2$-RbCl, and $MnCl_2$-CsCl. The deviations from ideal behavior are small in the systems $MnCl_2$-LiCl and $MnCl_2$-NaCl. The coefficients for thermal expansion and the activation energies for specific and molar conductances were also calculated from the experimental results and their concentration dependences are also indicative of complex formation.

There have been few density and electrical conductivity measurements on transition metal chlorides and their mixtures with alkali chlorides. However, extensive investigations on other fused salt systems have been made, and these have been compiled by Janz (2). Klemm (3), and Sundheim (4).

* Electrochemical Society Active Member.

Key words: manganous chloride, densities, conductances, alkali chorides, melt.

In examining the literature, the molar volumes and electrical conductivities of these divalent metal chloride-alkali metal chloride systems indicate certain general trends. In the presence of small alkali metal cations which create strong polarizing fields, such as Li^+ or Na^+, the molar volumes exhibit an additive concentration dependence or indicate slight positive deviations from additive behavior. However, as the polarizing power of the larger alkali metal cation

such as, K^+, Rb^+, or Cs^+ becomes weaker, larger positive deviations from additivity occur. For example, the systems $PbCl_2$-ACl (5) (A = Na, Rb, Cs); $CdCl_2$-ACl (5) (A = Rb, Cs); $BaCl_2$-ACl (6) (A = Li, Na, K, Cs); $CaCl_2$-NaCl (7), $CaCl_2$-KCl (8); and $MgCl_2$-KCl (9), $MgCl_2$-LiCl (10) support this general trend.

The molar electrical conductivities of the solutions show slight negative deviations with cations like Li^+ and Na^+ and progressively larger deviations as the size of the alkali metal cation becomes larger. The $CdCl_2$-ACl (11), $PbCl_2$-ACl (11, 12), $MgCl_2$-ACl (10, 13, 14) systems illustrate this behavior.

These deviations have been ascribed to the formation of "complex" species (15) but specific complexes have not been established conclusively. In the present study the densities and electrical conductivities of the $MnCl_2$-ACl solutions where A = Li, Na, K, Rb, Cs have been determined. Only the conductivities and densities of the $MnCl_2$-KCl system (16) are reported to date in the literature. The present study along with the previously reported emf measurements (17) was conducted to ascertain the relationship between the structure of the molten salts and the corresponding thermodynamic and electrical properties.

Experimental

The densities were measured using the Archimedean method as shown by Fig. 1. The apparatus is similar to that used previously in this laboratory (18, 19) and had the advantage of creating a totally closed system. The technique involved the measurement of the weight change of a quartz sinker filled with platinum, using a quartz-spring type balance. The quartz spring could take a maximum static load of 5g and the spring extension could be measured with an accuracy of ±0.005 cm on the cathetometer's vernier scale. With a spring constant of 0.0742 g cm^{-1}, the absolute accuracy of the weight measurement was ±0.0036g. The lower half of the density cell was made narrower than the melt-containing cavity to minimize the volatization of salt and subsequent condensation on the connecting suspension fiber. The effectiveness of this design was verified by conducting a separate experiment in which only the connecting fiber was suspended over pure molten $MnCl_2$. For convenience and accuracy all measurements and calibrations were made with respect to a reference quartz fiber which was suspended parallel to the spring.

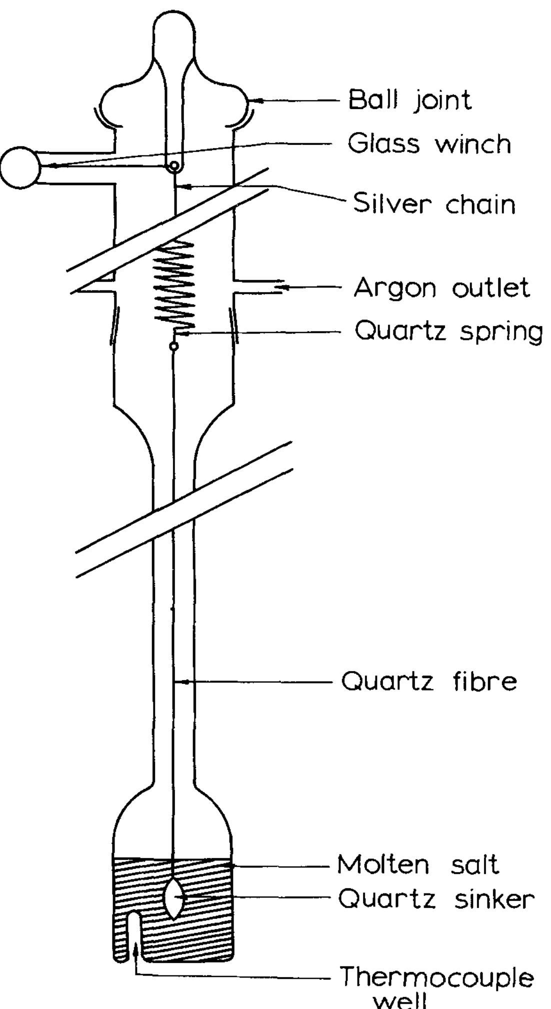

Fig. 1. Apparatus for measuring densities

The electrical conductivity measurements were determined using a U-tube conductivity cell of the type described previously (18, 19) from this laboratory. The cell constant was obtained by calibrating the cell with 1.0 demal KCl solution (20). For this calibration, the cell was at a constant temperature using an oil bath kept at 25° ± 0.01°C. The capillary U-tube section of the cell was about 10 cm in length and represented cell constants ranging from 500 to 700 cm^{-1}.

The electrodes were constructed from 10 mm diameter platinum disks spot welded to platinum wires. All measured resistivities were corrected for lead resistance. No correction was applied for the change of the cell constant with temperature, as quartz expands very little on heating (21).

To establish a constant temperature zone of at least 10 cm long and also for electrical shielding, the conductivity cells were contained in graphite cylinders, 20 cm long by 5 cm in diameter packed with alumina fibrefrax insulation. A quartz tube 8 mm in diameter containing the thermocouple was placed along with the cell into the hole drilled in the graphite.

Initially, conductivities were measured with an a-c resistance bridge at frequencies of 2500, 3500, and 4500 Hz, and there was less than 0.1% difference between the measurements. Subsequently, all resistance readings were taken at a frequency of 3500 Hz. The quartz cell was not attacked by the melts except with the $MnCl_2$-LiCl solutions at high temperatures. Conductivity cells were individually calibrated for each composition.

The molar volumes of a binary system can be calculated from the density data using the equation

$$V_M = \overline{M}/\rho \qquad [1]$$

where. ρ is the density of the solution and $\overline{M}$ the average molecular weight of the binary system given by

$$\overline{M} = X_1 M_1 + X_2 M_2 \qquad [2]$$

where, M's are molecular weights and X's are the mole fractions of the components. The molar conductance in units ohm^{-1} cm^2 $mole^{-1}$ can be calculated from

$$\Lambda = V_M \kappa \qquad [3]$$

where κ is the specific conductance, and V_M is the molar volume.

Density Results

The density results for the five binary systems can be represented by linear equations of the type

$$\rho = a + bt \qquad [4]$$

The experimental data were fitted to this equation by the least squares method and the resulting constants are shown in Table I, along with the standard and maximum deviations.

Errors in density measurements have been discussed by Bloom *et al.* (5) and Mellors and Senderoff (22). For a suspension fiber 0.043 cm in diameter Bloom ascribed a surface tension error of 0.1-0.2%. The use of a fine quartz suspending fiber (0.012 cm in diameter)

in this study diminishes the surface tension errors and accordingly corrections may be neglected. Considering this error and others such as parallax and weighing errors, the total error of 0.3% would be a fair assessment of the present results. The reproducibility of the results would also lie in the same uncertainty range.

Densities of Pure $MnCl_2$ and ACl

The densities of pure alkali halides have been compiled and critically appraised by Janz *et al.* (2). The density results of this investigation are shown in Table II, along with the values taken from Janz (2).

The compilation by Janz *et al.* (2) for the density of the alkali chlorides are taken mainly from the precise work by Yaffe and Van Artsdalen (23, 24). The uncertainties in these results for LiCl, NaCl, KCl, RbCl, and CsCl are given by Janz as 0.2, 0.2, 0.5. 0.4. and 0.1%, respectively. The maximum departure of the present work from the Janz compilation is: 0.2% for LiCl, 0.2% for NaCl, 0.1% for KCl, 0.2% for RbCl, and 0.3% for CsCl.

Due to the poor description of the available density experiments on $MnCl_2$, Janz did not attempt to evaluate the accuracy. The maximum differences between the present results for $MnCl_2$ and those reported by Murgulescu and Zuca (16) is 0.6%.

Electrical Conductivity Results

Pure salts.—The conductivities of the five pure alkali chlorides and of pure $MnCl_2$ were measured. The data were fitted by the method of least squares to equations of the form

$$\kappa = a + bT + cT^2 \text{ (ohm}^{-1}\text{ cm}^{-1}) \quad [5]$$

The coefficients a, b, and c are tabulated in Table III. The specific conductance results for pure LiCl agree within 2% of the values reported by Yaffe and Van Artsdalen (23, 24). The agreement is much better at lower temperatures (better than 1%) where the corrosive effect of LiCl is not as pronounced. Yaffe and Van Artsdalen also reported that considerable corrosion occurred at high temperatures. Similar corrosion of the cells was experienced in the present work in spite of the care used to remove the last traces of water from LiCl. The specific conductance of pure LiCl obtained in this work also agrees to within 1% of the conductance reported by Smirnov *et al.* (25).

The specific conductances of NaCl and KCl agree to within 2 and 1%, respectively, with the above reference. The uncertainty in the specific conductance of pure NaCl and KCl ascribed by Janz *et al.*(2) to the results reported by Yaffe and Van Artsdalen is 0.8 and 2.6% for NaCl and KCl, respectively. The results obtained in this work for NaCl and KCl are slightly outside this uncertainty limit, with the uncertainty for NaCl being the greatest. However, at lower temperatures the specific conductances for NaCl are within the uncertainty of the data reported by Yaffe and Van Artsdalen (23, 24).

The specific conductances obtained in this investigation for RbCl are within the uncertainty limits given to the data of Yaffe and Van Artsdalen (23). The uncertainty limit for RbCl given by Janz (2) is 3.5% and the present results are within this limit. The specific conductances of CsCl obtained in this study are slightly outside the 5.0% uncertainty limit imposed by Janz and co-workers. However, the specific conductances for CsCl measured by Smirnov *et al.* (25) are in good agreement (less than 1%) with the present results. The conductances found by Klemm (26) for RbCl and CsCl are also in good agreement with the present measurements.

There have been two previous determinations of the specific conductances of $MnCl_2$ to date. Murgulescu and Zuca (16) have determined the conductance of pure $MnCl_2$ from 923° to 1123°K. However, the conductance as determined by Winterhager and Werner (27) has maximum departure of 27% from the former data. The present determination supports the data of Murgulescu and Zuca (16) to within 1%.

$MnCl_2$-ACl binary solutions.—The conductivity of five binary solutions have been determined, namely:

$MnCl_2$-LiCl, $MnCl_2$-NaCl, $MnCl_2$-KCl, $MnCl_2$-RbCl, and $MnCl_2$-CsCl. To define the concentration dependence in the simple $MnCl_2$-LiCl binary system only six compositions were studied. In each of the other four systems at least eleven compositions were studied to ascertain the concentration dependence of the conductivities.

The data were fitted to Eq. [5] to determine the three coefficients in the conductivity-temperature equation. The results of this least squares analysis are shown in Table III, along with the data for the pure salts.

Table III shows that there are somewhat greater deviations in the LiCl system, the greater scatter in the data being due to the corrosive nature of LiCl. However, this scatter is partially compensated by the fact that the specific conductances in this system are much higher than in the other alkali halide systems and hence become less important.

The remaining systems are well represented by the equations given, since 90% of the compositions studied have standard deviations of less than 0.006 $ohm^{-1}cm^{-1}$. Assessment of errors in the conductivity measurements is difficult, but a total error of 2% would be a fair estimate. The reproducibility of the results lies in the same error range.

Discussion of Results

In previous publications from this laboratory (1, 17) it has been shown that the formation of a tetrahedrally coordinated complex species of the type A_2MnCl_4 accounts for the unusual concentration behavior of the enthalpy and entropy of mixing in the $MnCl_2$-ACl systems. Similarly, the present results indicate that the concentration dependence of the molar volumes, of the molar conductances of the coefficients of thermal expansion, and of the activation energies for conduction in the $MnCl_2$-ACl type solutions, are directly related to the presence of the complex species in the fused salt solutions.

The concept of complexes in fused salts was based upon the following postulates (1):

1. The fused salt is a continuous and highly electrified medium, and as a result interlocking anionic and cationic quasilattices exist to preserve local electrical neutrality.

2. A nonionic solvent, such as water which is capable of separating ionic species is not present.

3. The differences between a complexed and a noncomplexed state, involving a cation M^{+2} and an anion X^-, is simply defined by a characteristic "shorter" bond distance M-X* for the complexed state as compared to the M-X bond distance for the noncomplexed state.

4. Complexed ionic species must still belong to their respective quasilattices and not disrupt the continuity of the molten structure. Hence the ligands X* in a complex MX^*_n interact with the surrounding A^+ cations in the sequence

```
                        X*
                        |
X⁻ - - - A⁺ - - - X* - M - X* - - - A⁺ - - - X⁻
                        |
                        X*
```

whereby an anion X is always a cation "bridging" specie.

5. Under such restrictions, the complex represents a coordinated configuration of the type MX^*_n which may be treated as a statistical entity.

6. The formation of a complex is initiated by the presence of foreign cations which "compete" with the central cations M^{+2} for the same ligands X^-. Accordingly, the size of the foreign cation is related to its capability of promoting or preventing the formation of complexes.

7. The coordination number of a given monovalent cation is taken to be one-half of that of a divalent cation, with respect to a monovalent anion ligand. The coordination number of a solution containing both mono- and divalent cations is taken to be the ion-fraction average of that of the two cations.

Regarding the preferred coordination of complex ions in fused salts, the accumulated experimental evidence indicates that such coordinations are relatively simple. Thus, mixtures of monovalent cations appear to prefer the 2-ligand configuration representing a linear array or angular structure as in $Ag(CN)_2^-$ (28). Mixtures of mono- with divalent cations appear to follow the tetrahedral coordination as in $MgCl_4^{2-}$ (1) and $MnCl_4^{2-}$ (17). Finally, mixtures of mono- and tetravalent cations as in $ZrCl_4$, $TiCl_4$, and $HfCl_4$ with alkali chlorides, prefer to form octahedrally coordinated complexes of the type $ZrCl_6^{2-}$, $TiCl_6^{2-}$, and $HfCl_6^{2-}$ (29). From the previous discussion it follows that complex species in fused salts are not expected to dissociate in the same manner as their counterparts in aqueous solutions. The formation of the new type M-X* bond is initiated by the presence of the A^+ cations in solution, and each added A^+ cation as AX is expected to disturb the M-X bonds in MX and the "complex" should form stoichiometrically.

[a] Constant over the temperature range indicated by the density measurements in Table I.
[b] Extrapolated from measurements taken at higher temperatures to below the melting points.

Molar Volumes and Thermal Expansivities

The molar volumes can be calculated from Eq. [1] and the data given in Table I. The results of these calculations for the temperature of 700°C are shown in Table IV and are plotted in Fig. 2a to 2e. For the $MnCl_2$-ACl system (where A = Li, Na, K, Rb, and Cs), the molar volumes follow the trends indicated in the literature survey for all the solutions containing divalent metal chlorides and alkali metal chloride. They illustrate the general behavior in that in the LiCl and NaCl binary systems the molar volumes of the solutions are additive and that increasing positive deviations from additivity are observed beginning with the KCl binary system through to CsCl. The most pronounced positive deviations appear to occur at approximately $X_{MnCl_2} = 1/3$. In the $MnCl_2$-NaCl system there is some indication for a positive departure from ideality. This observation is in disagreement with the data of Murgulescu and Zuca (16) for $MnCl_2$-rich concentrations in the $MnCl_2$-KCl system. It should be mentioned that these authors used a density apparatus open to the atmosphere and only few unspecified measurements were taken under a stream of HCl gas. In the present work it was found necessary to handle $MnCl_2$ with extreme caution in order to avoid the formation of oxides or oxychlorides by reaction with atmospheric moisture and oxygen.

The concentration dependence of the molar volumes in the systems $MnCl_2$-KCl, $MnCl_2$-RbCl, and $MnCl_2$-CsCl may be understood in terms of the formation of the $MnCl_4^{2-}$ complex configuration.

For the calculation of finite partial molar volume $\overline{V}_C$ shall be assigned to the $MnCl_4^{2-}$ complex ion. Similarly, the simple "free" ions Mn^{2+}, A^+, and Cl^- shall be assigned finite partial molar volumes, $\overline{V}_{Mn^{2+}}$, $\overline{V}_A$, and $\overline{V}_{Cl^-}$, respectively. The molar volume of a $MnCl_2$-ACl solution can be estimated from a simple model if it is assumed that each ion contributes a volume element proportional to its concentration and the volume of the solution is the sum of the volume contribution from all ions present. The partial molar volumes of the constituent species in solution shall be assumed to be independent of concentration and have the same values as for the pure components.

Considering the complex forming reaction

$$MnCl_2 + 2ACl \rightarrow A_2MnCl_4$$

a solution containing the mole fractions X_{MnCl_2} and X_{ACl}, may be represented by the ionic concentrations given in Table V. The corresponding ionic contributions to the total volume are also included in this table. In the concentration range $1.0 > X_{MnCl_2} > 0.333$, the total volume of the solution is

$$V_{total} = (0.5X_{ACl})\overline{V}_C + (X_{MnCl_2} - 0.5X_{ACl})\overline{V}_{Mn^{2+}} + (2X_{MnCl_2} - X_{ACl})\overline{V}_{Cl^-} + (X_{ACl})\overline{V}_{A^+} \quad [6]$$

and in the concentration range $0.333 > X_{MnCl_2} > 0$

$$V_{total} = (X_{MnCl_2})\overline{V}_C + (1 - 3X_{MnCl_2})\overline{V}_{Cl^-} + (X_{ACl})\overline{V}_{A^+} \quad [7]$$

The ideal or additive molar volume based on the noncomplexed components $MnCl_2$ and ACl may be written as

$$V^{ideal} = X_{MnCl_2}(\overline{V}_{Mn^{2+}} + 2\overline{V}_{Cl^-}) + X_{ACl}(\overline{V}_{A^+} + \overline{V}_{Cl^-}) \quad [8]$$

The excess volume can be obtained

$$\Delta V^{xs} = V_{total} - V^{ideal} \quad [9]$$

For $1.0 > X_{MnCl_2} > 0.333$

$$\Delta V^{xs} = 0.5X_{ACl}(\overline{V}_C - \overline{V}_{Mn^{2+}} - 4\overline{V}_{Cl^-}) = 0.5X_{ACl}\delta \quad [10]$$

where $\delta = \overline{V}_C - \overline{V}_{Mn^{2+}} - 4\overline{V}_{Cl^-}$, given in cm^3 $mole^{-1}$ and for $0.333 > X_{MnCl_2} > 0$

$$\Delta V^{xs} = X_{MnCl_2}(\overline{V}_C - \overline{V}_{Mn^{2+}} - 4\overline{V}_{Cl^-}) = X_{MnCl_2}\delta \quad [11]$$

Experimentally the excess molar volume is obtained by subtracting the additive volume of the pure components from the measured molar volume of a solution. The results of the calculations are shown in Fig. 3. The solid lines represent excess molar volumes determined experimentally and the dashed lines represent the values calculated from the model. The value for δ was obtained for each system by substituting for ΔV^{xs} in a solution rich in alkali chloride where the model is expected to hold best. The values for δ found in this manner are positive and increase beginning with the $MnCl_2$-NaCl through the $MnCl_2$-CsCl systems. The positive deviations from additivity are indicative

n_{Cl^-}	$= X_{ACl} - 2X_{MnCl_2}$	$(1 - 3X_{MnCl_2})\overline{V}_{Cl^-}$
$n_{MnCl_4^{2-}}$	$= X_{MnCl_2}$	$(X_{MnCl_2})\overline{V}_C$

X indicates the original mole fractions in the solution which is prepared by mixing the components ACl and MCl_2.
n_i indicates the moles of a component i after the reaction has taken place.

of inefficient ionic packing within the liquid structure which is usually attributed to complex formation.

This simple model should hold the best in the ACl-rich concentrations and especially for large alkali metal cations in the presence of which the complex species have been shown to be most stable.

In solutions rich in alkali chloride the excess molar volumes in the systems $MnCl_2$-KCl, $MnCl_2$-RbCl, and $MnCl_2$-CsCl are approximately the same and indicate a linear dependence on concentration. This behavior is consistent with Eq. [11], which is applicable to the alkali chloride rich concentration.

It is also probable that the specific accommodation requirements of the various alkali metal cations in the liquid structure depend upon ionic size and bonding and are not strictly an additive property. For example, pure LiCl has a molar volume which is about one half of that for $MnCl_2$, indicating that the volume of the solution is determined mainly by the anions. With large cations like Cs^+, which occupy by themselves about twenty times the volume of a Li^+ ion, the alkali metal cation size should also become a factor determining the total volume of the solution.

The approximate partial molar volumes of $MnCl_2$ in this region were calculated graphically from the molar volume isotherm at 800°C. The results are shown in Fig. 4, and support this interpretation. The partial molar volumes of $MnCl_2$ are almost constant in the rich $MnCl_2$ compositions, and deviate at higher ACl compositions. Poor packing of $MnCl_2$ in the $MnCl_4^{2-}$ species in excess KCl, RbCl, and CsCl is shown by the high partial molar volumes of 60-70 cm^3, respectively.

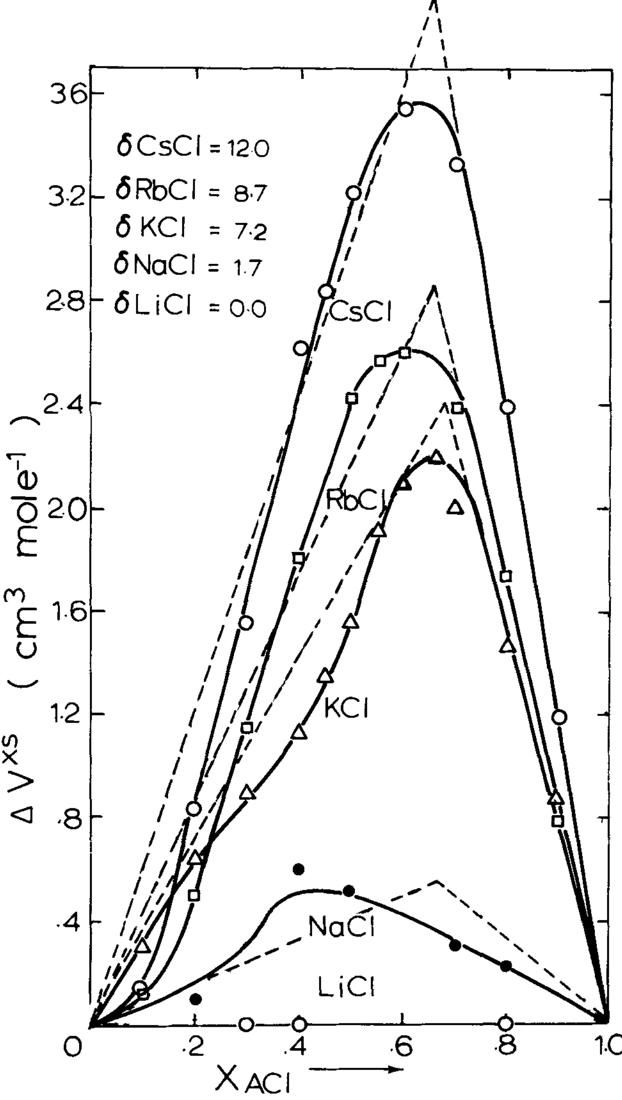

Fig. 3. Excess molar volumes in the $MnCl_2$-ACl systems, where, A = Li, Na, K, Rb, and Cs, plotted vs. X_{ACl} for the temperature of 800°C. ——— Experimental and - - - - - model.

It can be seen from Fig. 3 that the model presented here holds reasonably well in the ACl-rich concentrations but in the $MnCl_2$-rich concentrations some deviations occur.

The coefficients for thermal expansion at constant pressure α_p may be calculated from the temperature dependence of the molar volumes using the expression

$$\alpha_p = (1/V)(\partial V/\partial T)_P = (\partial \ln V/\partial T)_P \quad [12]$$

The plots of ln V *vs.* T for all systems are strictly linear, indicating that the coefficients α_p are temperature independent over the temperature ranges indicated in Table I.

The coefficients for thermal expansion calculated from Eq. [12] are also given in Table IV and their concentration dependence is shown in Fig. 2.

If the thermal expansion of a solution is considered to represent an activated process, then

$$(\partial \ln V/\partial T)_P = \Delta E^*_V/RT^2 \quad [13]$$

where, ΔE^*_V, is the activation energy for thermal expansion. Combining Eq. [12] and [13] it follows that

$$\Delta E^*_V = \alpha_p RT^2 \quad [14]$$

Activation energies for thermal expansion calculated at 700°C are also included in Table IV.

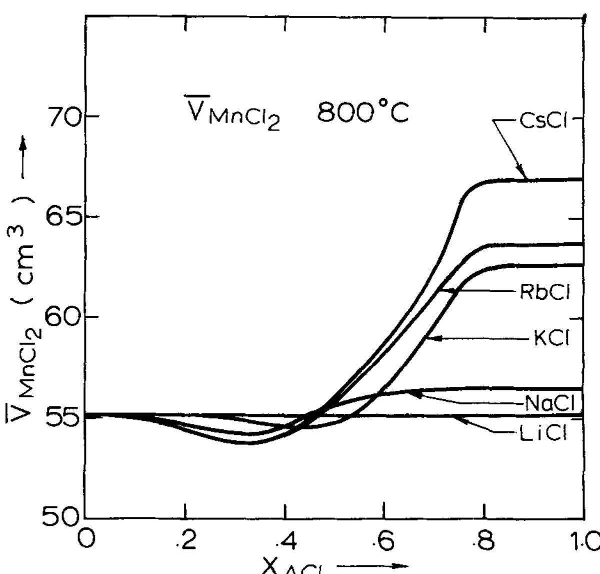

Fig. 4. Partial molar volumes of the $MnCl_2$ solutions plotted vs. X_{ACl} at a temperature of 800°C.

The concentration dependence of the coefficients for thermal expansion in the five $MnCl_2$-ACl systems indicate the following trends.

For the highly complexed systems, $MnCl_2$-RbCl and $MnCl_2$-CsCl, the coefficients for thermal expansion for the alkali chlorides decrease upon addition of $MnCl_2$ and reach a minimum at about 33 mole per cent (m/o) $MnCl_2$, at a point corresponding to the maximum in the curves representing the dependence of molar volumes upon concentration. This composition represents approximately the stoichiometric ratio for ACl/$MnCl_2$ required for the formation of the complex $MnCl_4^{2-}$ species. At higher $MnCl_2$ concentrations the molar volumes of the solutions decrease continuously while the thermal expansivity coefficients increase up to about a $MnCl_2$ content of 70-80 m/o, after which they decrease continuously to the value representing the thermal expansion coefficient for pure molten $MnCl_2$.

The minimum in the thermal expansivity curves should be associated with the availability of "free" volume indicated by the maximum in the molar volume curves. This "free" volume is attributed to poor packing arrangements of the complex $MnCl_4^{2-}$ configurations within the liquid structure. Upon heating this "free" volume is apparently capable of accommodating the thermally expanding liquid structure so that the over-all thermal expansion coefficient for a solution reaches a minimum. At concentrations higher than 33 m/o, the excess $MnCl_2$ added appears to enter the solution by filling the "free" volume present in the A_2MnCl_4 structure. Accordingly, the molar volume of the solution decreases from its maximum value and the thermal expansivity increases in the more densely populated structure to a maximum representing a concentration of 70-80 m/o $MnCl_2$.

It is of interest to note that in this composition range which is at the midpoint between "pure" A_2MnCl_4 and pure $MnCl_2$, the filling of "free" volume may be assigned to the following exchange reaction

$$A_2(MnCl_4) + MnCl_2 \rightarrow Mn(MnCl_4) + 2ACl \quad [15]$$

If the electrostatic interactions between the large monovalent cations, like K^+, Rb^+, or Cs^+, and bonded Cl* specie in a $MnCl_4^{2-}$ type complex, are compared with those of the much smaller Mn^{2+} "free" cations, it is evident that the interatomic distance between Mn and bonded chlorine in the A_2MnCl_4 configuration should also be smaller than that in the $Mn(MnCl_4)$ configuration. Therefore the addition of excess $MnCl_2$ in the ACl-$MnCl_2$ melts of composition beyond 33 m/o $MnCl_2$ is expected to result in a relaxation of the Mn-Cl* type of bonds in the $MnCl_4^{2-}$ complex configurations existing in A_2MnCl_4, followed by more efficiently packed ionic arrangements.

The "activation energies" for thermal expansion are also given in Fig. 2 and in Table IV. These activation energies are rather small and do not indicate any unusual trends.

Molar Conductances

Molar conductances were calculated from the specific conductance results and the density results, using Eq. [3]. In some instances it was found necessary to interpolate the molar volume isotherm to obtain the molar volume for the compositions corresponding to the conductivity data.

The isotherms of the molar conductances as a function of melt composition at 700°C are given in Fig. 2. It is seen that molar conductances exhibit increasing negative departures from additivity to the extent of −8% in LiCl, −6% in NaCl, −23% in KCl, −32% in RbCl, and −39% in CsCl, at $X_{ACl} = 2/3$.

For the $MnCl_2$-KCl system molar conductance data reported by Murgulescu and Zuca (16) agree reasonably well with the present results, except for the $MnCl_2$-rich solutions probably due to the uncertainties in the molar volumes determined by these workers.

The concentration dependence of the molar conductances in the KCl-$MnCl_2$, RbCl-$MnCl_2$, and CsCl-$MnCl_2$ systems, may also be explained by the complex anion model.

If the concentration range, $1.0 > X_{MnCl_2} > 0.333$, the solution consists of unreacted $MnCl_2$ and the complex A_2MnCl_4. The conducting species in this range are the ions Mn^{2+}, A^+, Cl^- (free), and the $MnCl_4^{2-}$ coordinated complex. The molar conductances may be obtained from the general expression

$$\Lambda_M = \mathbf{F} \sum_i e_i z_i b_{ij} \quad [16]$$

where, $\mathbf{F}$ is the Faraday constant, e_i is the number of carriers of type i present in one mole of solution, Z_i is the valence and b_{ij} is the relative mobility of the i carrier with respect to another ion j as the frame of reference (3).

For solutions having the ionic compositions given in Table V, the molar conductance is obtained from Eq. [16] by referring all mobilities to the "free" chloride ions Cl^- as the frame of reference.

These equations are shown below. For the concentration range $1.0 > X_{MnCl_2} > 0.333$

$$\Lambda_{total} = \mathbf{F}[(2X_{MnCl_2} - X_{ACl})b_{14} + X_{ACl}b_{34} + X_{ACl}b_{24} + (2X_{MnCl_2} - X_{ACl})b_{44}] \quad [17]$$

and for $0.333 > X_{MnCl_2} > 0$

$$\Lambda_{total} = \mathbf{F}[X_{ACl}b_{24} + 2X_{MnCl_2}b_{34} + (X_{ACl} - 2X_{MnCl_2})b_{44}] \quad [18]$$

The quantities b_{14}, b_{24}, b_{34}, and b_{44} are the relative mobilities of the ions Mn^{+2}, A^+, $MnCl_4^{2-}$, and Cl^-, respectively, where $b_{44} = 0$.

It should be noted that according to the proposed complex ion model, the $MnCl_4^{2-}$ specie should not be considered as an independent carrier. It seems likely that both the Mn^{2+} and Cl^- species, which are present in $MnCl_4^{2-}$ are independent carriers each having mobilities which are different from those of "free" Mn^{2+} and "free" Cl^- ions. It is also to be expected that the shielding of the Mn^{2+} specie in the $[MnCl_4^{2-}]$ configuration by the chloride ligands should make the mobility of the "bonded" Mn^{2+} lower than that of the "free" Mn^{2+} in solution. Irrespective of the individual behavior of each of the manganese and chloride species bonded within the complex $MnCl_4^{2-}$, the relative mobility b_{34} should be taken as representing a combination of these two contributions. Assuming that the mobilities are concentration independent and have the

same values in pure component as in the solutions, Eq. [17] and [18] reduce to

$$\Lambda_{total} = (X_{MnCl_2} - 0.5X_{ACl})\Lambda^\circ_{MnCl_2} + 0.5X_{ACl}\Lambda^\circ_{A_2MnCl_4} \quad [17a]$$

and

$$\Lambda_{total} = X_{ACl}\Lambda^\circ_{ACl} + 2X_{MnCl_2}(b_{34} - b_{44})\mathbf{F} \quad [18a]$$

where

$$\Lambda^\circ_{ACl} = \mathbf{F}(b_{24} + b_{44}) \quad [19]$$

$$\Lambda^\circ_{MnCl_2} = 2\mathbf{F}(b_{14} + b_{44}) \quad [20]$$

and

$$\Lambda^\circ_{A_2MnCl_4} = 2\mathbf{F}(b_{24} + b_{34}) \quad [21]$$

are the molar conductances of the pure molten compounds ACl, $MnCl_2$, and A_2MnCl_4, respectively.

At the stoichiometric composition for the formation of the complex compound A_2MnCl_4, $X_{MnCl_2} = 0.333$, and Eq. [17a] yields

$$\Lambda_{total} = X_{ACl}(b_{24} + b_{34})\mathbf{F} = 0.5X_{ACl}\Lambda^\circ_{A_2MnCl_4} \quad [22]$$

Equation [18a] predicts that at $X_{MnCl_2} = 0.333$, the total conductance should reduce to 2/3 Λ°_{ACl}, if the mobilities of the $MnCl_4^{2-}$ and Cl^- species are not significant. As seen in Fig. 2d and 2e, in the highly complexed systems like $MnCl_2$-RbCl and $MnCl_2$-CsCl the total molar conductance at $X_{MnCl_2} = 0.333$ is approximately equal to two-thirds of the total conductance of the pure alkali chloride.

In the binary systems, $MnCl_2$-KCl, $MnCl_2$-NaCl, and $MnCl_2$-LiCl, the Mn^{+2} ions are not able to form a strong complex anion and the total conductance at $X_{MnCl_2} = 0.333$ is higher than 2/3 Λ°_{ACl}. For the "ideal" solution the molar conductance is given as

$$\Lambda_{ideal} = X_{ACl}\Lambda^\circ_{ACl} + X_{MnCl_2}\Lambda^\circ_{MnCl_2} \quad [23]$$

where Λ°_{ACl} and $\Lambda^\circ_{MnCl_2}$ are the conductances of the pure ACl and $MnCl_2$, respectively. In terms of mobilities this equation takes the form

$$\Lambda_{ideal} = \mathbf{F}[(b_{24} + b_{44})X_{ACl} + 2X_{MnCl_2}(b_{14} + b_{44})] \quad [24]$$

Excess conductances are obtained by subtracting Eq. [24] from Eq. [17] and [18], respectively. Hence at $1.0 > X_{MnCl_2} > 0.333$

$$\Delta\Lambda^{xs} = 0.5X_{ACl}(2b_{34} - 2b_{14} - 4b_{44})\mathbf{F} = 0.5X_{ACl} \cdot \Delta m \quad [25]$$

where

$$\Delta m = (2b_{34} - 2b_{14} - 4b_{44})\mathbf{F} \quad [25a]$$

and at $0.333 > X_{MnCl_2} > 0$

$$\Delta\Lambda^{xs} = X_{MnCl_2} \cdot \Delta m \quad [26]$$

The quantity Δm is expected to be negative for low b_{34} values. Accordingly, excess conductances are expected to be negative and be proportional to X_{MnCl_2} or X_{ACl}. The model should be applicable to systems having the least polarizing alkali cations like Cs^+ and Rb^+ which also form strong complex anions (1, 17).

The excess conductances for the five binary systems calculated from the specific conductance data at the temperature of 800°C are presented in Fig. 5. The values for Δm are obtained by substituting an experimental value of the molar conductance into Eq. [25] or [26], respectively. From the Δm values, the expected excess molar conductances are calculated over the entire concentration range and compared with the experimental results. In Fig. 5 the solid curves are experimental and the dashed curves are calculated from the model. The model is best applicable to the ACl-rich compositions. In the $MnCl_2$-rich side the model deviates by about 12% from the experimental data. In the $MnCl_2$-NaCl, $MnCl_2$-LiCl systems the model does not appear to be applicable as the conductivity behavior of the solution is almost ideal.

Activation energies for the specific conductances ΔE^*_S were also calculated from the data presented in Table III.

From the temperature dependence of the specific conductance κ given as

$$\kappa = a + bT + cT^2$$

the activation energies at any given temperature may be calculated through the transformation

$$d \ln \kappa/dT = (1/\kappa)(d\kappa/dT) = \Delta E^*_S/RT^2 \quad [27]$$

or

$$\Delta E^*_S = RT^2(b + 2cT)/(a + bT + cT^2) \quad [28]$$

Similarly, the activation energy for molar conductance ΔE^*_M is calculated at any temperature from Eq. [3], [13], [27], and [28], as

$$\Delta E^*_M = \Delta E^*_S + \alpha_p RT^2 \quad [29]$$

where α_p, represents the coefficient for thermal expansion.

The quantities ΔE^*_S and ΔE^*_M were calculated at the common temperature of 700°C and the results are presented in Table IV. The molar activation energies for conductance are also plotted in Fig. 2.

The molar activation energies for KCl, RbCl, and CsCl have much higher values than that for $MnCl_2$, probably due to a smaller temperature effect on the mobilities of the large alkali metal cations.

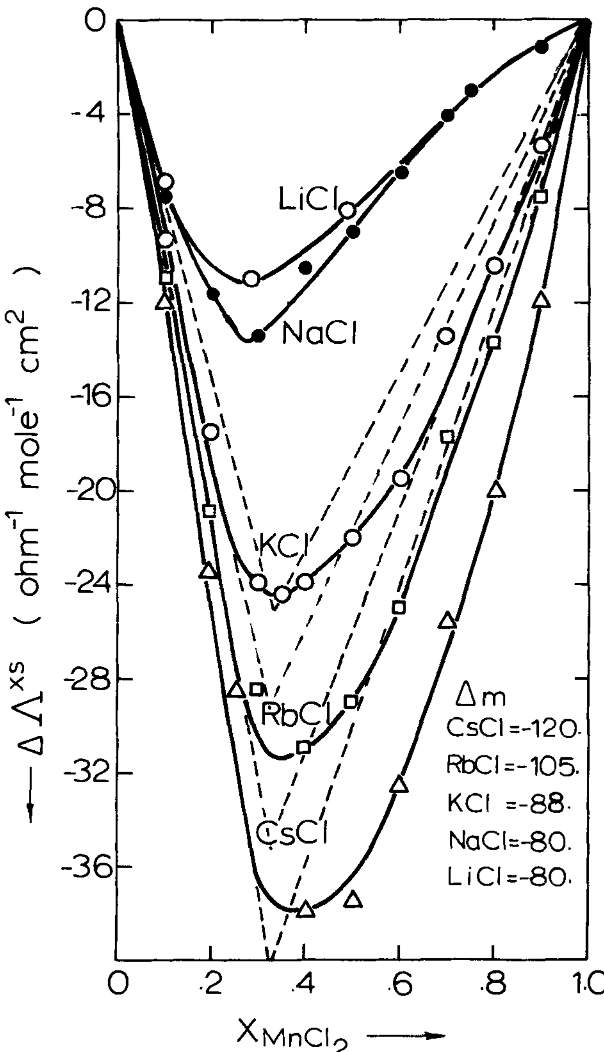

Fig. 5. Excess molar conductances in the $MnCl_2$-ACl systems, where, A = Li, Na, K, Rb, and Cs, plotted vs. X_{MnCl_2} at a temperature of 800°C. ———— Experimental and - - - - - - - model.

Table VI. Comparison between thermodynamic and structural properties in the $MnCl_2$-ACl solutions

System	b_R (17) (cal/mol) (a)	ΔV^{xs} at X_{MnCl_2} = 0.333 (cm^3 mol^{-1})	δ (cm^3 mol^{-1})	Δm (ohm^{-1} cm^2mol^{-1})	r_{A^+} (A°)
LiCl	−1,100	0	0	(−80)	0.60
NaCl	−4,950	0.5	1.7	−80	0.95
KCl	−10,680	2.2	7.2	−88	1.33
RbCl	−13,500	2.6	8.7	−105	1.48
CsCl	−15,720	3.5	12.0	−120	1.69

(a) b_R represents the enthalpy of formation of the complex compounds A_2MnCl_4 according to the reaction

$$2ACl_{liquid} + MnCl_{2\,liquid} \rightarrow A_2MnCl_{4\,liquid}$$

Upon the addition of $MnCl_2$ to either NaCl, KCl, RbCl, or CsCl, the activation energies for molar conductance of the solutions indicate significant maximum values in the concentration ranges in which the A_2-$MnCl_4$ and Mn-$MnCl_4$ complex configurations appear to predominate. In general, however, the concentration dependence of the activation energy curves is not as simple as that of the molar conductances.

From Fig. 2d and 2e, it is of interest to note that the molar conductance and the thermal expansivity curves in the systems $MnCl_2$-RbCl and $MnCl_2$-CsCl indicate a minimum at approximately the same composition for which the molar volume curves indicate their maximum. This characteristic concentration corresponds to the stoichiometric composition required by the formation of a $MnCl_4^{2-}$ complex specie.

If the activation energy for the conductivity process is thought to be related to the energy of dissociating the complex species present in solution, then at $X_{MnCl_2} = 1/3$ the activation energies should be directly related to the enthalpy of formation of the various A_2MnCl_4 compounds.

In Fig. 6, the reaction parameters b_R, which represent the heats of mixing (17) in the various $MnCl_2$-ACl system at a mole ratio of ACl/$MnCl_2$ = 2, are plotted *vs.* the corresponding activation energies ΔE^*_M. The exact linearity of this plot demonstrates clearly the relationship. Table VI represents a summary of the various structural and thermodynamic parameters determined in the course of our investigations. It should also be noted that the effects of the exchange reactions [15] on the thermodynamic behavior of the systems, were also taken into account in our previous treatment on enthalpies of mixing (17).

Accordingly, it may be concluded that the simple quasichemical complex ion model presents a reasonable interpretation for both thermodynamic and structural properties.

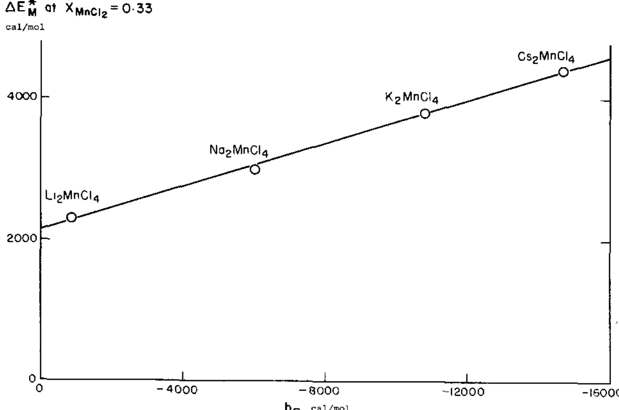

Fig. 6. Plot of activation energy for molar conductances at $X_{MnCl_2} = 1/3$ vs. b_R, where b_R represents the enthalpy of formation of the compounds A_2MnCl_4 according to the reaction

$$(MnCl_2)_{liq} + 2(ACl)_{liq} \rightarrow (A_2MnCl_4)_{liq}$$

Electrochemical Behavior of the Fluorographite Electrode in Nonaqueous Media

William Tiedemann*

Corporate Applied Research Group, Globe-Union Incorporated, Milwaukee, Wisconsin 53201

ABSTRACT

The open-circuit voltage of the fluorographite, $(CF)_n$, electrode can be interpreted as a mixed potential resulting from the anodic reaction of the solvent in question coupled with the cathodic reaction of fluorographite, $(CF)_n$. The Tafel slope was found to be relatively constant as a function of solution composition and discharge state of the $(CF)_n$. An exchange current of 10^{-21} A/cm^2 was estimated based on a thermodynamically predicted open-circuit voltage of the $(CF)_n$ electrode. An average charge transfer coefficient of 0.4 was calculated for the $(CF)_n$ reaction.

Organic electrolyte systems have been studied for a relatively long time because of their potential capabilities of providing a high specific energy, high specific power, wide temperature range battery. Recently (1-5) there has been an interest in the use of lamellar-type compounds of graphite as cathode materials. The technical feasibility of an organic electrolyte battery comprising a lithium anode and a fluorographite cathode, $(CF)_n$, (a lamellar type compound) has been demonstrated (1, 3-5).

Little information exists on the fundamental electrochemical behavior of the $(CF)_n$ electrode and little is known concerning its limiting performance characteristics. Electrochemical investigations of $(CF)_n$ are complicated by the following facts: (*i*) $(CF)_n$ is a nonconductor and must be supported on an electrically conductive phase which is in intimate contact with the electrolyte solution; (*ii*) the reaction products (C and LiF) are insoluble and tend to cover the available surface; and (*iii*) a very small electrochemical reaction rate of $(CF)_n$ necessitates the use of large effective surface areas in order that currents obtained may be measured accurately. These conditions necessitate the use of a test electrode which has a relatively large active surface area, is electronically conducting, and is porous. Porous electrodes tend to complicate the analysis of the polarization results; however, it will be shown below that certain test conditions exist which greatly reduce the complexity of the analysis.

Experimental

Chemicals.—Propylene carbonate (PC), dimethyl sulfite (DMSI), and dimethoxyethane (DME) were obtained in reagent grade form, dried over 4A molecular sieves, and vacuum distilled twice, the middle fraction being retained in each instance. Each solvent was stored in vacuum sealed glass vials until used.

Ultrapure $LiClO_4$ was obtained from Anderson Physics Laboratory and used without further treatment.

One molar solutions of $LiClO_4$ were prepared from combinations of PC/DMSI in a ratio of 30% PC to 70% DMSI by volume, and PC/DME in a ratio of 30% PC to 70% DME by volume. These solutions were stored in vacuum sealed glass vials until used.

$(CF_x)_n$ was obtained from three sources ((*i*) Ozark-Mahoning Company, Tulsa, Oklahoma, $x = 0.96 \pm 0.05$; (*ii*), Air Products and Chemicals, Allentown, Pennsylvania, $x = 1.04 \pm 0.05$; (*iii*), MarChem, Incorporated Houston, Texas, $x = 1.06 \pm 0.04$) and used without further treatment. Conductex SC (Columbian Carbon Company) powder was selected as the conductive diluent and Teflon molding powder as the binder. These three materials were vacuum dried at 250°F for 50 hr.

Electrode preparation.—The porous $(CF)_n$ electrode was prepared from a mixture of $(CF)_n$, Conductex SC carbon, and Teflon molding powder (1:0.2:0.2 ratio by weight) by pressing the resulting powder onto an expanded nickel grid at 200°C and 4000 psi. Prismatic electrodes measuring $5.38 \times 5.38 \times 0.132$ cm had theoretical capacities of 1.8 A-hr, an effective matrix conductivity of 0.2 mho/cm, a porosity of 0.56, and a specific interfacial surface area of 10^6 cm^2/cm^3.

The lithium electrodes were prepared by Foote Mineral Company (Exton, Pennsylvania) by pressing lithium metal onto expanded nickel foil. They were used as received without further treatment.

Cell design.—Experiments were performed on a cell comprising one $(CF)_n$ electrode sandwiched between two lithium electrodes with a solid lithium reference electrode positioned adjacent to the $(CF)_n$ electrode. A 0.0025 cm thick microporous polypropylene separator was inserted between the Li and $(CF)_n$ electrodes. The resulting electrode stack was sealed into an aluminum laminated polypropylene bag and placed in a testing fixture which prevented expansion of the electrode stack. Electrical connections were taken out through seals in the laminate.

Experimental procedure.—The test cell was filled with solution, placed in a vacuum to remove trapped gas, sealed, and placed in a vise-type testing fixture.

* Electrochemical Society Active Member.

Key words: porous electrodes, mixed potential, double layer charging.

Approximately 4 ml of solution were used in each cell. This operation was performed in a vacuum dry box with an argon atmosphere and equipped with N_2, O_2, and H_2O recirculating dry trains. The temperature of the dry box was maintained at 28° ± 1°C. Polarization studies were performed both inside and outside the dry box; however, all assembly, filling, and sealing operations occurred in the dry box.

A Wenking potentiostat was employed for the constant potential polarization studies. Prior to each polarization study the fresh $(CF)_n$ was placed on a 0.035 mA/cm^2 constant current discharge for 9 hr. Approximately 0.05% of the electrode coulombic capacity was removed in this period. The electrode was then allowed to stand at open circuit for a minimum of 24 hr before testing was continued. Current, as a function of time, was recorded on an Esterline Angus chart recorder. Polarization of the electrode was terminated when the current density reached approximately 3 mA/cm^2. All potentials mentioned below are measured with respect to a lithium reference electrode. The maximum *IR* included in these measurements was less than 1 mV.

Treatment of Polarization Data

The reaction which is postulated to occur at the $(CF)_n$ electrode is (1)

$$(CF)_n + nLi^+ + ne^- \rightarrow nC + nLiF \quad [1]$$

The reversibility of this reaction will be discussed below. Analysis of the system is somewhat complicated by the fact that the $(CF)_n$ electrode is porous which suggests the possibility of nonuniform current distribution within the electrode. An equation applicable to this situation is

$$\frac{di_{(x)}}{dx} = A_a i_{o,a} \exp\left[\frac{\alpha_a \mathbf{F}}{RT}\eta_{s(x)}\right] - A_c i_{o,c} \exp\left[-\frac{\alpha_c \mathbf{F}}{RT}\eta_{s(x)}\right] \quad [2]$$

where uniform concentrations have been assumed. Uniformity of current distribution in a porous electrode over the so-called Tafel region can be estimated in terms of the parameter

$$\delta = L|i|(1-\alpha c)(n\mathbf{F}/RT)(1/\kappa + 1/\sigma) \quad [3]$$

For $\delta \approx 0.1$, the current distribution in a porous electrode is nearly uniform (6). The system presently being examined yields $\delta \approx 0.1$. Analysis of the $(CF)_n$ electrode is therefore simplified and Eq. [2] reduces to

$$i = A_a L i_{o,a} \exp\left(\frac{\alpha_a \mathbf{F}}{RT}\eta_s\right) - A_c L i_{o,c} \exp\left(-\frac{\alpha_c \mathbf{F}}{RT}\eta_s\right) \quad [4]$$

In effect Eq. [4] states that a uniform current distribution exists throughout the depth of the electrode and the subsequent behavior can be equated to that of a flat electrode with a surface area (*LA*) times greater.

Results and Discussion

Potentiostatic measurements on the $(CF)_n$ electrode are made difficult by the relatively large surface area of a porous electrode. While the steady-state current related to the $(CF)_n$ reaction might be 10^{-4}A for a 2 mV overpotential, the initial current associated with charging the double layer of the porous electrode was of the order of 10^{-2}A. Subsequent variations in the controlled potential of less than 10 μV produced current oscillations of $\sim 10^{-4}$A. Approaching a steady-state current reading is further complicated by a large time constant of double layer charging of the porous electrode. Due to these complications, linear polarization data of the $(CF)_n$ electrode could not be obtained. As the electrode became more discharged, the amount of carbon increased, and therefore the double layer charging area increased. Double layer charging will be discussed below as it relates to the observed behavior of the $(CF)_n$ electrode.

Figure 1 contains a typical polarization curve of a porous $(CF)_n$ electrode. The large uncertainty limits at low overpotentials are associated with current oscillations resulting from charging of the double layer. A reasonable Tafel region (linear dependence of η_s *vs.* log i) is observed for both solutions examined, and similar Tafel behavior is shown in Fig. 2 for $(CF)_n$ at different states of charge. The Tafel slopes of these four curves were found to be nearly equal. An average value of α_c was calculated to be 0.4. As the current approaches $3 \cdot 10^{-2}$A, the assumptions of constant concentration and uniform current distribution are no longer valid. Nonuniform current distribution is a subject beyond the scope of the present investigation.

Initial open-circuit voltages (O.C.V.) of the $(CF)_n$ electrode in 1M $LiClO_4$-PC/DMSI and -PC/DME solution were 3.20 and 3.35V (*vs.* a lithium reference electrode), respectively. The reversible O.C.V. of $(CF)_n$ has been calculated (7) to be approximately 4.5V (*vs.* lithium) based on free energy of formation data. Figure 3 shows that the O.C.V. of the $(CF)_n$ electrode decreases as the discharge state of the electrode increases. The most rapid decrease in the O.C.V. is observed in the first 10-15% of the discharge followed by a moderate decline of the electrode potential until

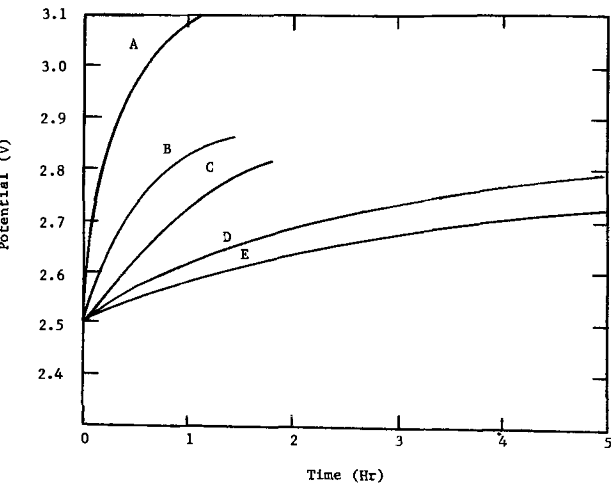

Fig. 4. Voltage recovery of a porous $(CF)_n$ electrode as a function of its discharge state. A = 0%; B = 5%; C = 10%; D = 30%; E = 50%.

about 90-95% of the discharge is reached. The O.C.V. of a completely discharged $(CF)_n$ electrode is approximately 2.5V (*vs.* a lithium reference electrode).

The observed behavior of the O.C.V. of $(CF)_n$ can possibly be attributed to a mixed potential resulting from the anodic decomposition of the solvent(s) coupled with the cathodic reaction of $(CF)_n$. Most solvents, including the ones studied here, undergo some degree of oxidation at potentials greater than 3V. The degree of oxidation is subject to the nature of the catalytic surface (in this case, carbon) and to the total accessible surface area. As $(CF)_n$ is discharged according to Eq. [1], electronically conductive carbon is generated, and one can expect the oxidation of the solvent(s) to increase due to the increase in reactive carbon area. At the same time the cathodic reaction of $(CF)_n$ must increase resulting in a decrease of the O.C.V. This implies that the intercept of the Tafel slope with the O.C.V. gives an estimate of the corrosion (or self-discharge) current and can be used to predict the activated shelf life of the $(CF)_n$ electrode as a function solvent(s). One would expect self-discharge to increase with increasing discharge of $(CF)_n$.

Using 4.57V as the true O.C.V. of the (CF_n) electrode and extrapolating the Tafel slope in Fig. 1 to this value, a value of the exchange current density of $\sim 10^{-21}$ A/cm^2 is calculated. This implies that recharging the $(CF)_n$ electrode in a reasonable length of time would require over 6V (*vs.* a lithium reference electrode). There are virtually no solvents which are stable at this voltage. All attempts to recharge the $(CF)_n$ electrode have been unsuccessful; only decomposition of the solvents was observed.

The discharge behavior of the $(CF)_n$ electrode suggests that the reaction mechanism does not involve a soluble $(CF)_n$ intermediate since the electronically conductive carbon surface area increases by more than an order of magnitude during the time when the rate capability of the $(CF)_n$ electrode is decreasing (Fig. 2). The decrease in rate capability corresponds directly to the decrease in the active area of the $(CF)_n$.

As the electrode becomes more discharged, the time required for the electrode potential to reach its open-circuit value, after polarization has been terminated, increases markedly (Fig. 4). The slow recovery time appears to be linked to the small value of i_o, the decrease in the electrochemically active surface area, and the increasing value of the electronically conducting carbon surface area. These effects are coupled through charging or discharging the double layer capacity of the electrode. An estimation of the relaxation time can be given by

$$\tau = \frac{RTCA_a}{Fi_oA_c} \quad [5]$$

For a 6% discharged electrode we obtain $\tau \cong 10^4$ sec. Therefore, as the end of the discharge is approached, the recovery of the electrode potential (after the cell is open circuited) can take as long as 50 hr. Conversely, in the initial stages of discharge, the electrode potential can recover in a matter of seconds. Time required to charge the double layer can also affect the polarization readings at small currents.

Conclusions

The open-circuit voltage of the $(CF)_n$ electrode is a mixed potential resulting from the anodic reaction of the solvent(s) with the cathodic reaction of $(CF)_n$. The intercept of the Tafel slope with the O.C.V. can be interpreted as a corrosion or self-discharge current and represents an estimate of the activated shelf life of the $(CF)_n$ electrode.

It should be noted that larger O.C.V.'s do not imply higher energy densities for the $(CF)_n$ electrode, since useful currents are obtained only when the $(CF)_n$ electrode has been cathodically polarized to 2.7V (*vs.* a lithium reference electrode).

Double layer charging of the carbon surface of the porous $(CF)_n$ coupled with the small exchange current density of the $(CF)_n$ reaction results in slow attainment of steady-state polarization readings.

Technical Note

The Influence of Electrolyte Impurities on Mercury Losses in the Electrolysis of Aqueous NaCl Solutions

I. T. Rodeanu

Str. Dr. Ratiu 24, bloc 8, ap. 18, Turda, Romania

Experimental work undertaken in laboratories and in industrial installations has shown that impurities in the electrolyte, such as calcium, magnesium, aluminum, iron, and silica compounds, can influence the electrolysis of aqueous sodium chloride in mercury cells. Several papers (1-5) have investigated how metal salts (vanadium, chromium, nickel, barium, magnesium, iron, copper, and arsenic) may intensify amalgam decomposition within the electrolyzer, resulting in unwanted hydrogen evolution.

The object of this paper is to examine and to determine the dependency of mercury losses on electrolyte purification procedures and on the soluble and insoluble constituents which contaminate the electrolyte.

Experimental Procedures and Results

Experiments were undertaken in an industrial electrolysis installation of aqueous sodium chloride solution in a mercury cell. The impurities contained in eight samples of raw electrolyte material are given in Table I. The samples were taken at twenty-day intervals from the salt introduced in the saturator.

In addition, daily measurements were made of the impurities in the electrolytic solution. Table II gives mean values for each working day over a four-week period.

Key words: mercury losses, mercury cell, impurity effects, industrial processing, sodium chloride electrolysis.

Experiments were carried out with use of electrolyte which had been pretreated by one of three different methods: (*a*) "Imposed" working conditions: remove chlorites and hypochlorites with hydrochloric acid, remove calcium ions with sodium carbonate, remove sulfate ions with barium chloride, remove magnesium and ferric ions with sodium hydroxide. (*b*) "Normal working conditions: incomplete purification of electrolyte consisting only of treatment with sodium hydroxide and hydrochloric acid. (*c*) "Uncontrolled" working conditions; no prepurification. In this condition, the electrolyte contained a suspension of NaCl crystals and insoluble impurities which were carried from the settler and were not retained by the filters.

With use of electrolyte prepared by these three methods, measurements were made of the hydrogen content in the chlorine gas leaving the electrolysis cell. Table III gives typical comparative data for how the hydrogen content varies with impurity constituents in the electrolyte. Under imposed working conditions, less than 1.05% hydrogen was found; under normal conditions, between 1.05 and 1.44% hydrogen was found; over 1.44% was found for uncontrolled conditions.

Table I. Impurity content of the NaCl

Impurities determined	Content, %

Mercury losses under normal and uncontrolled conditions were determined simultaneously by sampling the electrolyte at four locations in the electrolyte flow circuit. Samples were taken at the electrolyzer outlet, at the inlet to the precipitation tank, at the outlet of the settling tank, and at the electrolyzer inlet. Mercury in the electrolyte was determined by the dithizone (6) method, which is suitable over the range of 1-55 mg Hg/liter. The presence of Fe, Co, Ni, Bi, Pb, and Mn does not interfere with the determination provided that their concentrations are less than 10^{-2} mol/liter. Results are shown in Fig. 1 for a number of successive experiments.

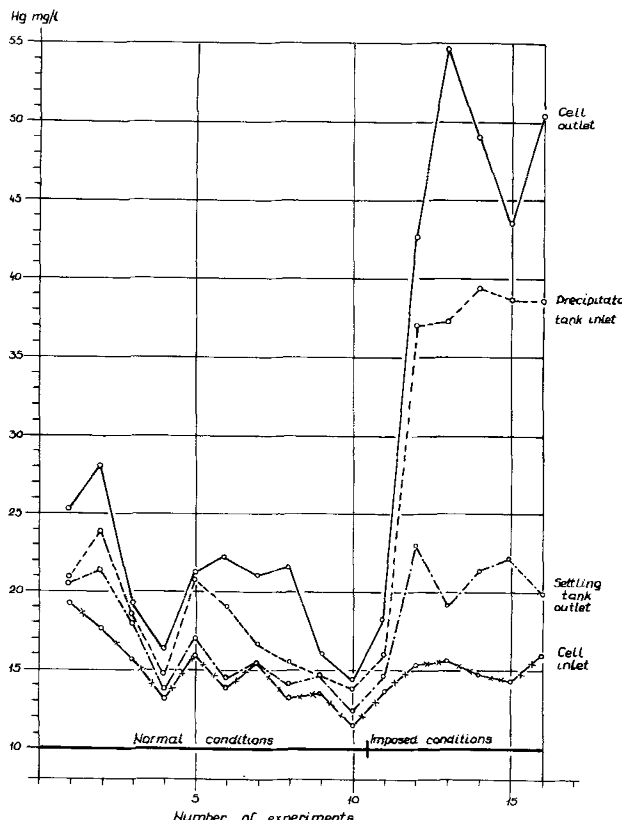

Fig. 1. Results obtained at the determination of the mercury losses in normal and uncontrolled working conditions.

During uncontrolled conditions, *i.e.*, in the absence of electrolyte prepurification, a suspension of sodium chloride crystals and impurity precipitation products was carried from the settling tank and was not retained in the filtering system. Several samples of electrolyte containing such suspensions were withdrawn and examined under a microscope. Typical observations are shown in Fig. 2, 3, and 4. The suspensions, of unknown structure, surround and become attached to the sodium chloride crystals. Microscopic observations during fouling of fresh NaCl crystals were also

Fig. 2. Sample taken in uncontrolled working conditions from the level flask.

Fig. 3. Sample taken in uncontrolled working conditions from the level flask.

Fig. 4. Sample taken in uncontrolled working conditions from the level flask.

carried out. Figure 5 illustrates several fresh crystals which, after fouling, eventually take the forms shown in Fig. 6. Figure 7 shows the region in the vicinity of a fouled NaCl crystal after it has been perturbed by stirring during microscopic observation.

Interpretation of Results

The data in Table III indicate a quantitative relation between the content of soluble impurities in the electrolyte and the hydrogen content in the chlorine gas. The Ca^{+2} and Mg^{+2} do not bring about the decomposition of the amalgam, especially in acid media. Their presence, in addition to other impurities, contributes to increasing the hydrogen content in the chlorine gas from only 0.6-0.8 to 1.05-1.44%. These results confirm the studies undertaken by Hauck (4) and Balej (5). These results are clearly important in

Fig. 5. Experiment carried out by microscopic observation.

Fig. 6. Experiment carried out by microscopic observation and fouled on purpose with impurities coming from the decantor.

Fig. 7. Sample fouled and disturbed on purpose

selecting an optimum purification procedure. Under uncontrolled conditions, the presence of suspensions in the electrolytic solution brings about an abrupt additional increase of hydrogen in the chlorine gas, to values in the range 4.9-6.2%.

Mercury losses vary usually between 7.3 mg Hg/liter under normal purification conditions to 33.55 mg Hg/liter for uncontrolled conditions. In Fig. 1 it is seen that the mercury content various with position in the plant. Under normal conditions, the mean values at the four locations are: at cell outlet, 22.15 mg Hg/liter; in the saturator, 19.2; at the outlet of the settling tank, 16.4; and at the cell inlet, 14. Under controlled conditions, the mercury losses at the same locations were: at the cell outlet, 42.6-54.7 mg Hg/liter; in the saturator, 37.0-39.4; at the outlet of the settling tank, 19.1-23.0; and at the cell inlet, 14.3-15.9.

The lost mercury was found in the mud in the saturator, in the precipitates deposited in the filters which were periodically purged to the waste-dump, and in the sludge of the settling tank. These results establish that part of the mercury contained by the electrolyte remains bound and deposits with precipitates and settled sludge. These events take place both in the acid medium in which saturation is achieved and in the alkaline medium in which precipitation, decantation, and filtration of impurities take place.

Although the mercury losses are greater under uncontrolled working conditions, the mean mercury content of electrolyte by the time it is recycled to the cell is not much different from that observed under normal conditions of purification. This observation seems to indicate the existence of a minimum solubility threshold of mercury in the electrolyte. It also appears that mercury losses depend on the presence of soluble and insoluble impurities and on the processes which occur within the electrolyzer under their influence.

From Fig. 2, 3, 4, one ascertains a close physical association between the insoluble impurities and the newly formed NaCl crystals which leave the electrolyzer and are carried by the sludge. Attachment of impurities to NaCl crystals is achieved at the junction points, on the edges, and at the less order overlapping of the edges with adjacent planes.

This mechanism of attachment is confirmed by the observations of Fig. 5, 6, and 7. The mechanism does not, as was initially expected, permit a chaotic or homogeneous distribution of impurities in the bulk of the electrolyte. Rather, it is seen that electrolyte purification processes should be designed in such a manner as to create voluminous associations between NaCl and impurities which then could be decanted in a shorter time. By comparing the data in Table III and Fig. 1 with the observations of Fig. 2-7, it is seen that both the increase of hydrogen content in the chlorine gas and the increase of mercury losses under uncontrolled conditions are due to the presence of insoluble impurities in the electrolyte phase. These im-

purities exist as calcium sulfates, magnesium and iron hydrates, aluminum oxide, silica, etc., which are attached to NaCl crystals. It appears that the insoluble materials form active decomposition centers on the surface of the amalgam, and that the cathodic hydrogen overvoltage on the remainder of the mercury surface is not decreased. In this manner, the execessive increase of hydrogen content simultaneously with the increase of mercury losses in the electrolyte may be explained.

Conclusions

During the electrolysis of aqueous NaCl solutions in mercury cells, the mercury losses into the electrolyte phase, which are subsequently deposited at various positions throughout the flowsheet, were found to increase with an increase in the soluble and insoluble impurity constituents in the electrolyte. Excessive amounts of hydrogen in the chlorine gas are correlated with large mercury losses when the electrolyte is not prepurified. These occurrences result from the presence in the electrolyte of insoluble impurities which have the structure of impurities attached to the NaCl crystals which form. Thus one has proof of the existence of impurity agglomeration centers which, during normal conditions of electrolyte purification, might bring about a more rapid formation of bulky precipitation products which would have a higher settling speed.

Brief Communications

Measurement of Beta-Alumina Impedance with Constant Current Pulses

G. C. Farrington*

General Electric Company, Research and Development Center, Schenectady, New York 12301

The ionic impedance of a polycrystalline solid electrolyte arises in two regions: within its constituent individual grains and at the boundaries between those grains. Since the intergrain impedance is dominant in a typical polycrystalline beta-alumina ceramic, its separation and characterization from its intragrain counterpart is essential for guiding the optimization of ceramic properties. While such separation can be effected with multifrequency a-c measurements (1), a d-c constant current pulse technique described here yields the same data over an effective frequency range of d.c. to *ca.* 60 MHz with relative simplicity. Results are presented for a tube of polycrystalline beta-alumina.

The gross electrical response of polycrystalline beta-alumina resembles that of the circuit shown in Fig. 1 in which R_1 and R_2C_2 represent intragranular and intergranular impedances, respectively. This simplified model neglects intragrain capacitance and lumps all intergrain impedances into one RC combination. The voltage rise as a function of time occurring across this circuit during passage of a pulse of constant current of magnitude I is related to R_1, R_2, and C_2 by the following expression in which t is the elapsed time since pulse initiation (time into pulse) (2)

$$V = I[R_1 + R_2(1 - e^{-t/R_2C_2})]$$

Since C_2 shunts R_2, for a short time after pulse initiation Z is essentially R_1. If the pulse is of sufficient duration, C_2 gradually charges and Z rises exponentially to the sum of $R_1 + R_2$. C_2 can be determined from the characteristics of the transition region between these two extremes. Clearly, as the product RC decreases, definition of the circuit parameters requires pulses of shorter and shorter risetimes.

To illustrate this behavior, the model circuit shown in Fig. 1 was assembled with $R_1 = 200$ ohms, $R_2 = 2000$ ohms, and $C_2 = 0.0092$ μF. A small constant current pulser was constructed using a 2N3564 transistor as the current switch. The pulser was triggered either with a PAR Model 175 Universal Programmer or a Tektronix 114 Pulse Generator. A typical output pulse rose in 7×10^{-9} sec (10-90%) overshooting its ultimate value, which was attained after *ca.* 10^{-7} sec, by 30%. The behavior of the model circuit was consistent enough, as was that of a beta-alumina tube, that repetitive identical pulses, separated by pauses

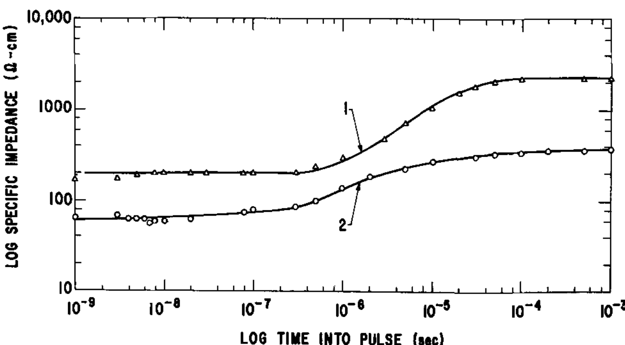

Fig. 2. Log specific impedance vs. log time into pulse plot for model circuit (curve 1) and polycrystalline beta-alumina tube (curve 2).

equal to the pulse width, could be used for measurement, obviating any need for capturing single-shot events.

A repetitive train of constant current pulses of known magnitude (50-1000 μA) and 10^{-7}-10^{-3} sec in duration was applied to the model circuit while the potential buildup across the circuit was monitored as a function of time with a Tektronix 7A11 Probe/Amplifier and 7704A Mainframe (170 MHz bandwidth). Useful potential data could be obtained at times as short as 1×10^{-9} sec after pulse initiation, defined as that time the pulse had risen 10%, by computerized interpolation of points along the rising edge.

Figure 2, curve 1 details the log impedance *vs.* log time into pulse behavior of the model circuit. From these data, R_1, R_2, and C_2 were determined to be 199 ± 4 ohm-cm, 2027 ± 40 ohm-cm, and 0.0088 ± 0.002 μF, respectively. These results compare favorably with the individual component values cited previously which were measured singly at 1 kHz with a General Radio 1650A Impedance Bridge.

Similar measurements were made on a polycrystalline beta-alumina tube of 6 cm length, 1.1 cm OD, and 0.8 cm ID. Four contacts were made along the tube with loops of Pt wire. A saturated solution of $NaClO_4$ in propylene carbonate was used to wet the contact interfaces. Repetitive, identical constant current pulses were applied to the outer two contacts while the voltage rise as a function of time at the inner electrodes was recorded during each pulse. From these data the net impedance rise between the two inner electrodes was calculated as a function of time and corrected for any current inconstancy observed across a 500 ohm resistor in series with the sample.

Figure 2, curve 2 details the results. At short times, an intragranular impedance of 63 ± 5 ohm-cm is observed, consistent with the single crystal impedance of 71 ohm-cm reported by Whittingham and Huggins (3). Z increases to 365 ± 5 ohm-cm after 10^{-4} sec. At the midpoint of the impedance rise $C_2 = 0.012$ μF-cm. The more indistinct slope of the beta-alumina transition region compared to that of the model circuit verifies, as expected, that the intergranular impedance of a real ceramic cannot be modelled by a single *RC* circuit but, rather, is the sum of many such *RC* combinations.

The Electro-Oxidation of Carbon Monoxide on Platinum

K. F. Blurton* and J. M. Sedlak*

Energetics Science, Incorporated, Elmsford, New York 10523

Recently an instrument for the measurement of carbon monoxide in ambient air based on electrochemical principles was developed and described (1-3). During the development of this instrument a study was made of the relationship between the CO oxidation current and the potential of a Pt electrode, and the results of these experiments are reported here.

Previous studies of CO electro-oxidation on smooth Pt electrodes by cyclic voltammetry (4-6) showed that in the anodic sweep (0.4-1.6V) there was no oxidation current from 0.4 to 0.9V, the current sharply increased at 0.91V and thereafter decreased linearly with increasing potential. In the cathodic sweep (*i.e,* 1.6-0.4V) the current was less than on the anodic sweep in the range 1.6-0.9V, it was slightly greater in the range 0.9-0.7V and zero from 0.7 to 0.4V.

In the present work steady-state currents for CO oxidation were determined at a potentiostatically controlled Pt electrode. By making these measurements the electrode is closer to steady-state condition, and hence the influence of the surface Pt oxide on CO oxidation current can be determined. These results, coupled with recent studies (7-10) of oxide formation on Pt electrodes, demonstrate that PtOH is the most active electrocatalytic species for CO electro-oxidation.

Experimental

The electrochemical cell was similar to that used in the CO monitor and it was described previously (2). Essentially it consisted of a three electrode electrochemical cell with 3.4M H_2SO_4 solution as electrolyte. The anode (sensing) and counterelectrodes were Pt-catalyzed, Teflon-bonded diffusion electrodes (11), and the reference electrode was a mercury/mercury sulfate electrode. The geometric area of the sensing electrode was 5 cm^2 and the effective area measured electrochemically (12) was 1.2 m^2. All potentials refer to the standard hydrogen electrode potential.

The potentiostat was designed and constructed in-house (3). The current due to the electro-oxidation of CO was measured by determining the potential drop across a standard resistor with a recorder (Hewlett-Packard Company, Model 680). In order to conform to the experimental conditions of air pollution analysis, the CO oxidation currents were determined in a CO/air mixture. CO/air mixtures (48.5 ppm CO and 84.0 ppm) and UHP grade air were obtained from Matheson Gas Products Company.

Results and Discussion

Figure 1 shows the CO oxidation current *vs.* the potential of the Pt electrode. These results were obtained by initially potentiostating the cell at 0.8V for 24 hr. Then the oxidation currents were determined when UHP air and the CO/air mixtures were introduced into the cell. The sensing electrode potential was increased stepwise to 1.5V and the corresponding oxidation currents were determined after potentiostating for 24 hr at each potential (Fig. 1, curve a). Subsequently, the electrode potential was decreased stepwise from 1.5 to 0.8V (Fig. 1, curve b), and finally it was increased to 1.1V (Fig. 1, curve c). These results show that the shape of the current/potential curve would probably differ if the electrode was potentiostated at another potential prior to taking the measurements at 0.8V.

At each potential there was a small current (approximately 10 μA) when no gas and when UHP air was passed into the sensor, and this was subtracted from the value determined when CO was introduced into the cell. The potential range was restricted to 0.8-1.5V since the currents due to oxygen reduction and to oxygen evolution were negligible. The values of the current/ppm of CO agreed within 3% for the two CO concentrations, and this is within the precision of the CO analysis.

The mechanism of CO electro-oxidation involves the reaction of adsorbed CO with platinum oxide (4-6). The observed variation of CO oxidation current with potential (Fig. 1) occurs as a result of changes in the oxidation state of the Pt electrode surface. This variation may be explained from recent studies of the surface state of the Pt electrodes in this potential region (7-9).

A mechanism for the oxidation of Pt electrodes has recently been proposed (7-9) and it can be summarized as follows.

Stage I: Reversible electrosorption of OH species on Pt

$$\mathrm{Pt} \rightarrow \mathrm{PtOH} \qquad 0.72\mathrm{V} \leq E \leq 0.9\mathrm{V} \qquad [1]$$

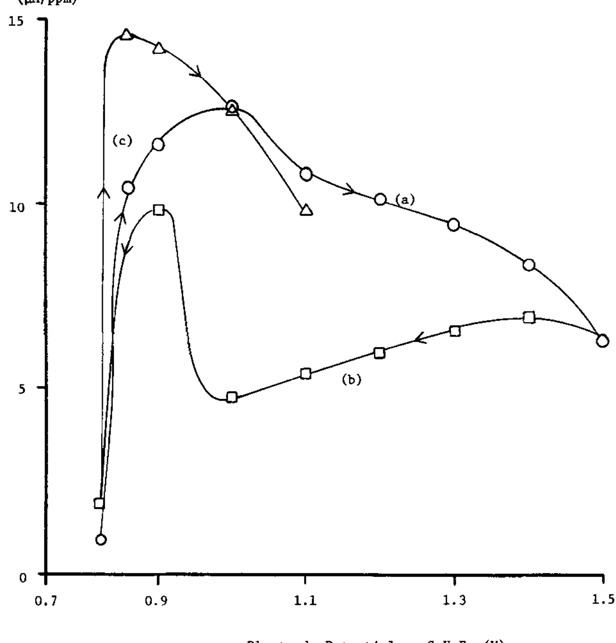

Fig. 1. CO oxidation current as a function of Pt electrode potential. ○, Potential increased from 0.8 to 1.5V; □, potential decreased from 1.5 to 0.8V; △, potential increased from 0.8 to 1.1V.

Stage II: Rearrangement of surface PtOH species

$$\mathrm{PtOH} \rightarrow \mathrm{OHPt} \qquad 0.90\mathrm{V} < E \leq 1.1\mathrm{V} \qquad [2]$$

Stage III: Conversion of PtOH species to PtO

$$\mathrm{PtOH} \rightarrow \mathrm{PtO} \qquad 1.1\mathrm{V} < E \leq 1.5\mathrm{V} \qquad [3]$$

As the surface is oxidized at successively higher potentials or is held for longer times at a given potential, the irreversibility of the reaction for the reduction of rearranged OHPt and the PtO species is increased.

The increase in CO oxidation current in the range 0.8-1.0V (Fig. 1, curve a) parallels the increase in reversibly bound OH species on the Pt surface (Eq. [1]. Between 1.0 and 1.1V there is a sharp decrease in current (Fig. 1, curve a) corresponding to the rearrangement in the surface layer (Eq. [2]). At more anodic potentials the continuing decrease in current with increasing potential is in accordance with the diminished availability of surface PtOH groups (Eq. [3]).

On decreasing the potential from 1.4 to 1.0V (Fig. 1, curve b) the current decreased linearly with potential, due to the retention of PtO which was formed at 1.5V together with the decreasing overvoltage for the reaction. At 0.9V the current increased sharply, and this corresponds to the reforming of electrosorbed PtOH (Eq. [1]). On the further decrease of the potential to 0.8V the CO oxidation current decreased to a small value in accordance with the decrease of surface PtOH concentration.

On the subsequent increase of potential (Fig. 1, curve c) very high currents were observed at 0.85 and 0.90V which are attributed to extensive surface coverage with PtOH. On increasing the potential beyond the reversible PtOH formation region (Eq. [1]) the CO oxidation current decreased markedly due to the rearrangement of electrosorbed OH (Eq. [2]). The CO oxidation current at 1.1V at the end of these experiments (Fig. 1, curve c) was only about 10% lower than the current observed at that potential on the first anodic sequence (Fig. 1, curve a). The final electrochemical area of the Pt electrode was the same as the initial area (*i.e.*, 1.2 m^2).

An estimate of the time involved before the attainment of steady state at the Pt surface was obtained by measuring the CO oxidation current at 1.2V as a function of time. This was done with 20 electrodes and with each the current decreased to a steady value of about 15% lower than the initial value after 35 $\pm$10 days. This was confirmed to be associated with the change in state of the Pt electrode surface since the current did not decay when the sensor remained on open circuit and only potentiostated for the short period required to measure the CO oxidation current.

The measurement of the CO oxidation rate has been shown to be a useful tool for the study of Pt surfaces. The results demonstrate that: (*i*) oxidized Pt electrodes are more electroactive for CO electro-oxidation than unoxidized Pt, (*ii*) PtOH is the preferred catalytic sites and PtO is catalytically active to a lesser extent, (*iii*) the oxidation of the Pt surface in the potential range 0.8-1.0V is reversible while that in the range 1.0-1.5V is irreversible, and (*iv*) the Pt electrode does not attain a steady state at 1.2V until it has been under potentiostatic control for 35 days.

A Study of Low Temperature Diffusion of Copper in Single Crystalline Gold Using a CuCl Solid Electrolyte

J. Goldman[1] and J. B. Wagner, Jr.

Department of Materials Science, Northwestern University, Evanston, Illinois 60201

ABSTRACT

A galvanic cell of Cu|CuCl|Au was used to measure the diffusion coefficient of copper in single crystalline gold in the temperature range of 355°-400°C. Results are in good agreement with tracer data extrapolated to the lower temperatures. Using polarization measurements, electronic conductivity of single crystalline CuCl and the double layer capacitance at the CuCl|Au interface were determined.

The principle of measuring diffusivities by electrochemical methods is well established. Recently, Ramanarayanan *et al.* (1) studied oxygen diffusion in liquid tin and solid silver using a stabilized zirconia electrolyte. Chu *et al.* (2) also used stabilized zirconia to study oxygen diffusion in wustite. They also measured silver diffusion in silver sulfide using AgI as the electrolyte. Oxygen diffusion in silver was measured by Rickert and Steiner (3) using stabilized zirconia. Takahashi *et al.* (4) obtained values for the diffusion of silver in Ag_2Se and Ag_2Te using a $RbAg_4I_5$ electrolyte. Raleigh and Crowe (5) used a polarization cell of the type Ag|AgBr|Au(Ag) to study silver diffusion in gold alloys. They applied a negative potential to the left-hand electrode, thus fixing the silver activity at the AgBr|Au interface. They reported the presence of a low level electronic leakage current which, until very long times, was small relative to the current due to the silver flux. The electronic carriers in AgBr are n-type, and, therefore, application of higher potentials will cause the electronic leakage current to reach a saturation value (6).

Joshi (7) and Wagner (8) have discussed the problems in using a p-type electrolyte for diffusion and other transient measurements. The electronic leakage current in a p-type electrolyte does not saturate on application of higher potentials (6), but continues to increase exponentially. The purpose of the present study was to test the use of a p-type electrolyte, in this case CuCl, as a medium for solid-state titration into an electronic conductor, in this example single crystalline gold. In addition, this investigation was conducted to evaluate effects of electronic leakage through single crystalline CuCl and double layer capacitance at the CuCl-gold interface.

Cu-Au, which is a well-documented system, was chosen for study because of the uncertainty in assessing the effect of a large electronic leakage current through CuCl on the ability to see the diffusion process. Diffusion data for copper in pure gold has been reported (9), as have two different electrochemical investigations of the thermodynamics of the copper-gold system (10, 11).

[1] Present address: Motorola, Inc., Phoenix, Arizona 85008.

Key words: CuCl solid electrolyte, Cu-Au diffusion, electronic leakage, double layer capacitance.

A polarization cell of the type, Cu|CuCl|Au was used. As pointed out by Hebb (12) and Wagner (13), a given copper activity, a, may be fixed at the CuCl|Au surface by applying a potential to the cell with the copper electrode negative. The value of the activity is

$$a = e^{-EF/RT} \quad [1]$$

where E is the applied potential, $\mathbf{F}$ the Faraday constant, R is the gas constant, and T the absolute temperature. If the potential is suddenly changed to a new value, a time dependent current will flow through the external circuit. At least three different phenomena make contributions to this current. First, diffusion of copper into the gold electrode requires the electrochemical transport of copper through the CuCl to maintain the copper activity at the gold interface, and there will be a corresponding current through the external circuit. The second contribution comes from the re-equilibration of electron holes within the electrolyte. The third contribution results from an inherent double layer capacitance which is present at the CuCl|Au interface (7). When the potential is changed, the capacitor charges or discharges, giving rise to an external current. There are also faradaic processes at the electrodes, which in this experiment are assumed not to be rate determining. Mathematical expressions for the first three contributions will be given below.

Consider first the diffusion of copper into the gold. Treating the gold as a semi-infinite solid, and given the boundary conditions

$$C(t=0) = C_0 \qquad 0 \leq x < \infty$$
$$C(0,t) = C_1$$

the flux of copper, J, at the CuCl|Au interface is (12)

$$J = \frac{-(C_1 - C_0)}{63.5}\sqrt{\frac{D}{\pi t}} \quad [2]$$

where D is the diffusion coefficient for copper in gold and t is time. The concentrations are expressed in grams/cubic centimeter and the flux is in equivalents/square centimeter-second. The atomic weight of copper, 63.5, is inserted in Eq. [2] to convert the flux from grams/square centimeter-second to equivalents/square centimeter-second. These boundary conditions per-

tain to an experiment in which a potential corresponding to a copper concentration of C_0 at the CuCl|Au interface is applied to the cell, and held until the concentration is effectively uniform through the Au. This is $t = 0$. During the next instant the potential is changed to a new value corresponding to a concentration, C_1, at the CuCl|Au interface. Faraday's law relates the electrochemical transport in the cell to the diffusion contribution to the external current, I_D, as

$$I_D = JA\mathbf{F}$$

where A is the area in square centimeters. Substituting Eq. [2] into Eq. [3] gives

$$I_D = \frac{-(C_1 - C_0)A\mathbf{F}}{63.5}\sqrt{\frac{D}{\pi t}} \qquad [4]$$

At infinite time, the diffusion ceases and I_D ceases. This equation does require a correction for phase boundary motion (14), which is negligible for small concentration steps.

The concentrations are determined experimentally by measuring the potential difference across a cell using a set of standard copper-gold alloys. Such experiments have been carried out by Chiche (10) and by Weibke *et al.* (11). The diffusion coefficient may be determined by obtaining an experimental slope of Eq. [4], $dI_D/d(1\sqrt{t}) = S$, and rearranging to solve for D

$$D = \left(\frac{S\,63.5\sqrt{\pi}}{(C_1 - C_0)A\mathbf{F}}\right)^2 \qquad [5]$$

Next, the current due to rearrangement of electron holes in the CuCl on applying a potential step will be considered. As discussed above, CuCl exhibits p-type behavior. The hole concentration at the CuCl|Au interface is give by

$$c_{\oplus} = c_{\oplus}^{\,0} \exp\{E\mathbf{F}/RT\} \qquad [6]$$

where $c_{\oplus}^{\,0}$ is the electron hole concentration in coulombs/cubic centimeter at the reversible electrode, the Cu|ClCl interface. When a potential step is applied to the cell the concentration of electron holes changes within the CuCl. The boundary conditions for the hole concentrations in CuCl are

$$c(x, 0) = c_{\oplus}^{\,0} + (c_{\oplus}^{\,1} - C_{\oplus}^{\,0})\frac{x}{L} \qquad [7]$$

and

$$c(x, \infty) = c_{\oplus}^{\,0} + (c_{\oplus}^{\,2} - c_{\oplus}^{\,0})\frac{x}{L} \qquad [8]$$

$c_{\oplus}^{\,1}$ and $c_{\oplus}^{\,2}$ are the initial and final hole concentrations at the gold electrode given by the initial and final potentials E_1 and E_2, respectively, and can be calculated using Eq. [6]. L is the length of the CuCl pellet. The flux of electron holes measured at L is (15)

$$J_{\oplus} = -\frac{D_{\oplus}(c_{\oplus}^{\,2} - c_{\oplus}^{\,0})}{L} + \frac{2D_{\oplus}}{L}(c_{\oplus}^{\,1} - c_{\oplus}^{\,2})\sum_{n=0}^{\infty} \exp(-n^2\pi^2 D_{\oplus} t/L^2) \qquad [9]$$

The flux, $J_{\oplus}$, in amperes/square centimeter can be converted to a current simply by multiplying by A. Doing this, expressing the concentrations in terms of Eq. [6], and recalling that $\sigma_{\oplus}^{\,0}$, the CuCl hole conductivity, is $c_{\oplus}^{\,0}D_{\oplus}\mathbf{F}/RT$ yields

$$I_{\oplus} = \frac{-RTA}{L\mathbf{F}}\sigma_{\oplus}^{\,0}(e^{E_2\mathbf{F}/RT} - 1) + \frac{2RTA}{L\mathbf{F}}\sigma_{\oplus}^{\,0}(e^{E_1\mathbf{F}/RT} - e^{E_2\mathbf{F}/RT}) \sum_{n=0}^{\infty} \exp\left[-\frac{n^2\pi^2 D_{\oplus} t}{L^2}\right] \qquad [10]$$

The current in Eq. [10] approaches a steady-state value as the summation term goes to zero at long times. The resulting well-known expression for the steady-state electron hole leakage current, $I_{\oplus_{ss}}$, through the cell is (13)

$$I_{\oplus_{ss}} = \frac{RTA}{L\mathbf{F}}\sigma_{\oplus}^{\,0}(e^{E_2\mathbf{F}/RT} - 1) \qquad [11]$$

The current due to charging a double layer capacitance is the third contribution on applying a potential step. The equation for the current through a series RC circuit is

$$I_c = \frac{\Delta E}{R}\exp(-t/RC)$$

where C is the capacitance, $\Delta E/R$ is the applied potential divided by the AC resistance of the electrolyte, and is equal to the initial value of the current, I_0.

Experimental

In the present work, a single-crystal CuCl pellet was used, which was obtained from Dr. F. Okabe of Shizuoka University. He has described his method of preparation (16). The pellet length was 0.12 cm, and the diameter, 0.85 cm. The gold single crystal was grown from five-nines purity material by the Bridgeman method, and electron channeling patterns obtained on a Cambridge S4 scanning electron microscope showed the gold to be single crystalline. A 0.78 cm diameter by 0.3 cm disk was cut from a single crystal, mechanically polished by conventional metallographic techniques, then electropolished in a cyanide solution (17). Electron channeling patterns made after the surface preparation revealed no surface damage. The cell was springloaded into a glass tube, through which dry argon was passed. The entire apparatus was placed in a resistance furnace and heated using a d-c power supply. Potential steps were applied using a Keithley No. 260 nanovolt source and a specially designed circuit which stores two potential values, and produces a low-noise, rapid potential step. Measurements of current *vs.* time to determine the capacitive effects were carried out at 228°C. Contributions from diffusion, and hole conduction should be small at this temperature. The current was measured using a Tektronix oscilloscope to measure the voltage across 100 ohms, which is about two orders of magnitude less than the electron hole resistance of the sample at the highest temperatures of this study. Therefore, IR drop across the measuring resistor is not significant. Plots of the log I *vs.* time for various voltage steps are shown in Fig. 1.

Figure 2 shows a plot of I_0, the initial value of the current *vs.* ΔE. The slope yields a value for the AC resistance of the CuCl pellet of 2.23×10^3 ohm-cm. The AC resistivity, determined from the resistance and the sample dimensions is 10.6×10^3 ohm-cm, which is in reasonably good agreement with the published value 7.7×10^3 ohm-cm (18, 19).

The capacitance, determined from the slopes of the curves in Fig. 1 has a value of 3.7×10^{-4} farads. These calculations assume that the only contribution to the current comes from interface charging.

One other point that should be mentioned is that some electronic leakage current was apparently present, as can be seen by noting that the log I *vs.* time curves in Fig. 1 are not quite linear. All curves ap-

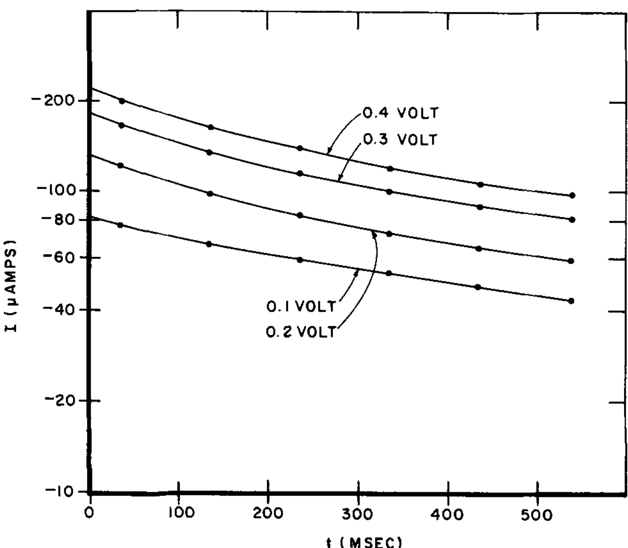

Fig. 1. Plot of log I_c against time at 228°C. Slope indicates time constant, RC, and intercept is $\Delta E/R$.

proach a constant slope, equal to $1/2.3RC$, very quickly, indicating that the electron hole current dies out very fast.

Diffusion experiments were conducted at 355°, 370°, 385°, and 400°C. The procedure was to apply a potential, of about 0.2V, wait 3 hr, instantaneously lower the potential by 3 mV, and monitor the current for one-half hour, apply another potential, wait three more hours, and so on. It was found experimentally that a 3-hr wait between potential steps was sufficient to allow the current from previous steps to decay to a point where it would not make a contribution to the current from a new potential step. Longer waits produced identical current-time characteristics. While 3 hr is obviously not long enough to completely equilibrate the gold sample at a particular activity, it is long enough to permit the current to decay to a level below the resolution of the measuring technique. The current was measured on a Doric digital voltmeter across 100 ohms. The results of the experiments carried out at 370°C are shown in Fig. 3. The experimental currents are linear with $1/\sqrt{t}$. The mean copper mole fractions for each of the curves are from top to bottom: 0.05, 0.175, 0.225, 0.275, and 0.325, corresponding to potentials of 0.25, 0.22, 0.20, 0.18, and 0.105, respectively. Results for other temperatures are similar. The diffusion coefficients were calculated from the ex-

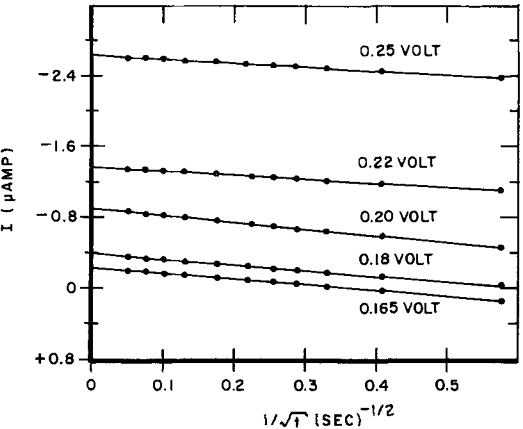

Fig. 3. Experimental current vs. $1/\sqrt{t}$ at 370°C. Slope is linear indicating that the observed time variation is due to chemical diffusion of copper into gold. Residual current at infinite time is due to electronic leakage.

perimental slopes, such as those in Fig. 3, and Eq. [5]. The values of D, corresponding to a potential step of 0.220-0.217V for the four temperatures are shown in Fig. 4. All applied potentials were below the decomposition voltage of CuCl (7).

Values for the hole conductivity in CuCl have also been obtained. The steady-state current obtained when $1/\sqrt{t} = 0$ was plotted against exp $\{EF/RT\}$. According to Eq. [11], this plot should be linear with a slope proportional to the conductivity, as long as the exponential term is much greater than unity. Figure 5 shows that the relation is indeed linear, and that the slope increases with increasing temperature. Figure 6 shows the hole conductivity as a function of reciprocal temperature plotted along with the data obtained by Joshi (7). Joshi's ionic conductivity data are also shown.

Discussion

It has been demonstrated that solid electrolytes in which the minority charge carriers are electron holes are useful in studying low temperature diffusion in solids. Copper diffusion in gold, using a cuprous

chloride solid electrolyte was the particular system studied. The cell arrangement was Cu|CuCl|Au, where the gold electrode was held at a positive potential. As described earlier in this paper, a potential step was applied which produced a step in the copper activity at the CuCl|Au interface. The external current was measured and, through Eq. [3], related to the flux of copper atoms into the gold. It was necessary to take account of all possible contributions to the external current to be certain that the measured current was only due to copper diffusion.

On application of a 3 mV potential step, in addition to the diffusion current, there is a transient, Eq. [10], due to electron hole rearrangement in the CuCl. There is also a transient, given by Eq. [12], from the discharging of the double layer capacitance at the CuCl|Au interface. After these transients have relaxed, there remains a steady-state leakage of electron holes, Eq. [11]. It will be shown that these transients relax very quickly, provided the CuCl pellet is sufficiently thin, and that the external current is only the sum of the diffusion current and the steady-state electron-hole leakage.

Using Eq. [10] and Joshi's (7) conductivity values we see that at 400°C, the transient current due to the rearrangement of electron holes decays in 3 sec to less than 1% of the steady-state leakage current. Because the first data point was taken 3 sec after applying a potential step, neglecting the transient hole current is justified at this temperature. An identical conclusion may be reached by making the calculation at other temperatures.

If the electrolyte sample were, say, 1 cm long instead of 0.12 cm, this conclusion would not be justified. For example, if a measurement of the current were made 10 sec after applying a potential step the transient electron hole current would still be almost 20% away from the steady-state value, and would be making a substantial contribution to the experimental current transient. It is probably possible to separate the diffusional current from that due to the electron hole transient by computational methods, but the entire problem may be eliminated by using a sufficiently thin electrolyte, as has been done in this investigation.

In evaluating the double layer capacitance transient, account must be taken of the time constant, *RC*, in Eq. [12]. *RC* is the time for the double layer current to decay to $1/e$ of its initial value. Beyond a time equivalent to ten times the value of the time constant, it is assumed that the contribution due to double layer charging or discharging is negligible. At 400°C, 10 times *RC* is about 13 msec, and at 355°C, it is about 45 msec, both well under the 3 sec which elapse before the initial data point is taken.

Another consideration is the effect of current transients on the sharpness of the concentration step. The activity change at the Au electrode as predicted by Eq. [1] is valid only if there is no appreciable *IR* drop in the circuit. This is unavoidable immediately after applying the potential step, because of the large initial value of the current. When *IR* drop effects are appreciable, the potential, which fixes the copper activity at the Au electrode will be time dependent. Since it has been shown that the I_c and $I_{\oplus}$ transients decay quickly, relative to the time at which the taking of diffusion data is begun, it is felt that the concentration step is sufficiently sharp.

The fact that the current transient at 228°C was represented fairly well by a series *RC* circuit model supports the assumption that faradaic effects are probably small. The good agreement between the literature and measured values for the *AC* resistivity further supports this assumption.

The only unsteady current left is due to diffusion. Figure 3 shows that the experimental current is indeed linear with $1/\sqrt{t}$ as predicted by Eq. [10], the expression for the diffusion current. Equation [10] also predicts that the diffusion current goes to zero at infinite time ($1/\sqrt{t}=0$). In Fig. 3 it is apparent that there is still a current flowing at infinite time, and that the magnitude of the current increases with increasing applied potential. Since it has been shown that all the transients decay well before the first data point is taken, this offset can only be due to the steady-state electron hole leakage through the cell. The steady-state current was therefore plotted against exp $\{EF/RT\}$ in Fig. 5, and, as predicted by Eq. [11], the slope is constant. The hole conductivities were obtained from the slopes in Fig. 5 and compared with the values obtained by Joshi (7), Fig. 6. The agreement is excellent, confirming that the steady-state current is due to the leakage of electron holes. Joshi's total conductivity data, σ_T, are also shown.

Unlike the n-type electrolytes, in which the application of higher potentials produces a saturation electronic leakage, in p-type electrolytes higher potentials result in larger leakage currents. As long as the sample is thin, however, for a given applied potential, the diffusional current is displaced along the current axis a constant amount by the steady-state electronic leakage.

It is seen in Fig. 3 that the slopes of the current $-1/\sqrt{t}$ lines decrease with increasing applied potential. This is because a larger concentration step for a given potential step is being applied at lower voltages. This is expected for solutions which are ideal, or show negative departures from ideality,[2] and is consistent

[2] For an ideal solution, $E = -(RT/F) \ln X$ so that $\Delta E/\Delta X = RT/FX$. For a given ΔE, ΔX is larger as X is larger (E is smaller). A similar argument applies for solutions showing negative departures from ideality.

with Chiche's data. Weibke's E vs. X data are essentially linear and thus do not predict the behavior seen in Fig. 3. Therefore, it is felt that new emf-concentration measurements would be needed to correctly interpret the concentration dependence from the data in Fig. 3. At a constant mole fraction of Cu of 0.175 the use of Weibke's data in conjunction with the present results yields values of D shown in Fig. 4. The dotted curve is the extrapolated data of Vignes *et al.* (9) for copper diffusion in pure gold. The agreement is excellent considering that Vignes' data was extrapolated over several hundred degrees. While not a great deal of significance should be attached to the fact that actual low temperature data fall slightly below the extrapolated curve, it may be a real effect. It is expected that copper diffusion in an alloy would be slower than in pure gold (20).

It has been demonstrated that the determination of Cu diffusion coefficients down to almost 10^{-16} cm^2/sec may be accomplished by this method. While gold was chosen for this study, any material which is not reactive with CuCl may be substituted, provided thermodynamic data are available for the analysis of the data. The presence of a large steady-state leakage current does not hamper the technique in any way.

The Growth of Hydrous Oxide Films on Aluminum

Robert S. Alwitt[*,1]

Sprague Electric Company, North Adams, Massachusetts 02147

ABSTRACT

The weight gains of Al specimens immersed for short times in water at 50°-70°C were measured. An analysis of these data and published results at other temperatures indicated that the kinetics of pseudoboehmite film growth in the temperature range 50°-100°C is determined initially by the nucleation and growth of hydrolysis sites on the amorphous oxide surface, and subsequently by solid-state diffusion through the pseudoboehmite layer. At 40°C, pseudoboehmite and bayerite were observed to grow simultaneously at first, with bayerite crystallization eventually becoming the dominant process. The two oxide phases occupied completely separate layers.

Aluminum reacts readily with water to form a hydrous oxide film. The initial product is pseudoboehmite, a poorly crystallized oxyhydroxide that is similar to boehmite (AlOOH) but contains excess water (1, 2). Pseudoboehmite has a lamellar structure (2) and in the film the lamellae are oriented approximately perpendicular to the substrate surface (3); this layer has a substantial void fraction and high specific area (4). Electron micrographs have shown that while the outer surface is highly porous there is an absence of porosity at the metal interface, and it seems likely that a thin amorphous barrier oxide layer exists between the metal and the hydrous oxide (1). Pseudoboehmite may be the sole reaction product at higher temperatures, but moderate temperatures or longer reaction times promote the growth of bayerite crystal ($Al(OH)_3$) on the pseudoboehmite surface (3).

The essential steps of the aluminum + water reaction appear to be (*i*) formation of amorphous oxide, (*ii*) dissolution of this oxide, and (*iii*) precipitation of the dissolved species as hydrous oxide (1).

In step (*i*), the amorphous oxide is continuously replenished by an electrochemical process in which barrier film growth is the anodic half-cell reaction, coupled with the cathodic reduction of water. In step (*ii*), the exact nature of the oxide dissolution process is not known, but it must involve a surface hydrolysis reaction. The particular hydrolyzed aluminum species

Key words: bayerite, pseudoboehmite, surface hydrolysis, surface nucleation.

found in solution depends on temperature, pH, and aluminum concentration. In dilute solutions at 25°C, the major aluminum monomer species varies with pH in this fashion: Al^{+3} for pH <3, $Al(OH)^{+2}$ for pH 4-5, $Al(OH)_2^+$ for pH 5-6, and $Al(OH)_4^-$ for pH > 6.5 (5-7). The hydrolyzed species could be produced by these surface reactions

$$Al_2O_3 + 3H_2O \rightarrow 2Al(OH)^{+2} + 4\ OH^- \quad [1]$$

$$Al_2O_3 + 3H_2O \rightarrow 2Al(OH)_2^+ + 2\ OH^- \quad [2]$$

$$Al_2O_3 + 5H_2O \rightarrow 2Al(OH)_4^- + 2H^+ \quad [3]$$

The formation of aluminate anion at lower pH is favored by increasing temperature. For example, at 25°C gibbsite is in equilibrium with 10^{-4}M $Al(OH)_4^-$ at about pH 10, but at 100°C this same equilibrium is achieved at about pH 7 (6). Thus, with increasing temperature and pH the most likely surface hydrolysis shifts from reaction [1] to [2] to [3].

At higher aluminum concentrations and elevated temperatures, hydrolyzed aluminum readily forms polynuclear complexes. These appear to be transitory species that eventually coalesce to form a solid phase (7). Complex cations as large as $[Al_{14}(OH)_{34}]^{+8}$ have been identified (8) and it has been suggested that this species is the precursor of boehmite precipitation under hydrothermal conditions (9). It has not been demonstrated that such complexes are involved in step (*iii*), precipitation leading to film growth, but this is certainly a possibility.

Vedder and Vermilyea (1) have proposed that the rate-controlling step for film growth is the transport of dissolved aluminum species to deposition sites on the hydrous oxide. According to their model, transport is by diffusion in the liquid phase within the interstices of the film. However, recent radiotracer experiments in our laboratory (10) have shown, at least for films grown in boiling water, that there is an inner region of the pseudoboehmite layer that is impermeable to phosphate anions, and presumably other solvated species. Film growth has been found to continue even after this region is established, so ionic diffusion across this layer must eventually be the rate-limiting process, rather than transport in solution.

A characteristic of the aluminum + water reaction is the occurrence of an initial induction period during which there is no weight change, or other sign that a reaction has occurred (11, 12). The length of this period decreases with increasing temperature and depends, among other things, on surface preparation (11). In the Vedder and Vermilyea model the induction period is due to the development of a saturated surface layer that stifles further dissolution until film deposition occurs (1), presumably through localized critical supersaturation. However, one of the experiments reported here demonstrates that the induction period is controlled by events on the surface and not in the solution phase.

Thus, in several respects the existing model for film growth and structure seemed deficient, but it was not possible to synthesize a new explanation without more information about the kinetics at short reaction times. Such results are presented here, and a new model for film growth is discussed.

During the course of this work, some experiments were performed at conditions where pseudoboehmite growth was accompanied by bayerite crystallization. Some preliminary observations of this sequence have already been reported (13), and further details are presented here.

Procedure

Coupons of 99.99% aluminum foil were electropolished in a perchloric acid-acetic anhydride bath and stored in dry air prior to use. In an earlier study (4) it had been found that the weight gain in boiling water of samples prepared in this way was the same as for evaporated aluminum films, suggesting the absence of interfering surface films from electropolishing. Specimens were hung vertically in distilled water in an unstirred jacketed Pyrex beaker for the required reaction time. The reaction temperatures were in the range 40°-80°C and each temperature was maintained to ±0.1°C. After immersion, the specimen was rinsed in acetone and air dried. Sample weight, before and after immersion, was measured with an accuracy of about ±0.5 $\mu g/cm^2$.

Specimens were prepared for scanning electron microscopy by evaporation of a thin aluminum film over the sample surface. Bayerite crystal surface density and size distribution were measured by examining SEM photographs of low temperature films in a Quantimet Image Analyzer (14). To do this, use was made of the ability of the image analyzer to determine the maximum chord length, in the horizontal direction, of each particle in the field of view. Moreover, it is possible to preselect a chord length so that the number of particles with a maximum chord length greater than the preselected value are counted. For the particular photographs being examined, chord lengths less than about 0.23 μm could not be readily distinguished from background noise. The number of bayerite crystals was taken to be the number of particles with maximum chord length greater than 0.23 μm. This number was not significantly different from that obtained by using the image analyzer in the full-feature mode (14). Successive countings with preselections of increasing longest chord gave the particle size distribution function. Subtracting these values from each other yielded the distribution density.

Results

Induction period.—The induction times found in these experiments, as well as those reported by other investigators, are shown in Fig. 1 for temperatures ranging from 40° to 100°C. There was excellent agreement between the present results and the times reported for evaporated aluminum films (1), which is further evidence for the absence of a significant polishing film from the perchloric acid-acetic anhydride bath.

An activation energy of 18.7 kcal/mole was calculated from the slope of the line in Fig. 1. There appeared to be a sharp increase in activation energy at

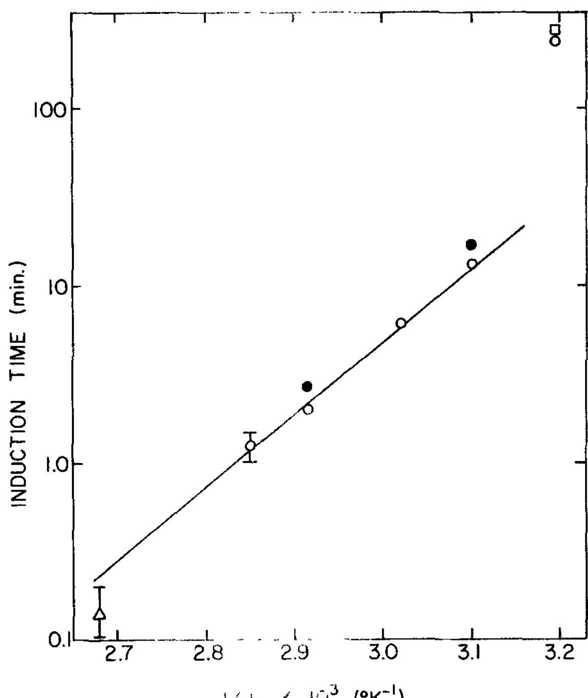

Fig. 1. Temperature dependence of the induction period for film growth on electropolished foil in distilled water. The data are from Ref. (1), ●; Ref. (3) □; Ref. (10), △; and this work, ○.

40°C; Hart (3) also found a 4-hr induction period at 40°C, in agreement with the long time observed here.

The pH dependence of the induction time (t_o) was examined at 78°C in 0.01N sodium nitrate, adjusted with NaOH or HNO_3 to the desired pH. The value of t_o was found to remain between 1 and 1½ min while the pH was varied between 4 and 10. This is consistent with an observation that the early rate of film growth at 100°C was independent of pH over this same range (1).

In order to establish whether t_o is due to events on the solid surface or in solution, an experiment was performed in which specimens were given a series of successive immersions, each one for a time less than t_o, but with a total reaction time greater than t_o. Between immersions, the specimens were rinsed in water at room temperature. If t_o depended on reaching a certain condition in the solution adjacent to the surface, then no weight change would be expected for these specimens. The particular conditions were a reaction temperature of 70°C, and a series of seven immersions each for 1 min. At 70°C, the induction time is 2 min. It was found that there were weight gains of 20 and 22 $\mu g/cm^2$ for two specimens, which can be compared with an expected weight gain of 19 $\mu g/cm^2$ for an uninterrupted immersion of 7 min. This difference is within the observed reproducibility and is not significant. The induction period must be a property of a process occurring on the solid surface.

Reaction rate.—The weight gains found in these experiments at 50°, 60°, and 70°C are shown in Fig. 2 as a function of $(t-t_o)$; data reported by other investigators at 70° and 100°C are also included. At the lowest temperatures, 40° and 50°C, very irreproducible results were obtained at the shortest reaction times, up to times of about $2t_o$; these data are not presented here. This problem was particularly acute when chemically polished foil was used in some preliminary work suggesting that it may have been due to some surface contamination. The data collected at longer times at 50°C and at higher temperatures seemed sufficient for our purposes so this phenomenon was not pursued. At 40°C bayerite crystals, as well as pseudoboehmite, deposited on the surface so the weight gain of these samples could not be used to examine pseudoboehmite growth kinetics. The results obtained at this temperature are treated in a separate section.

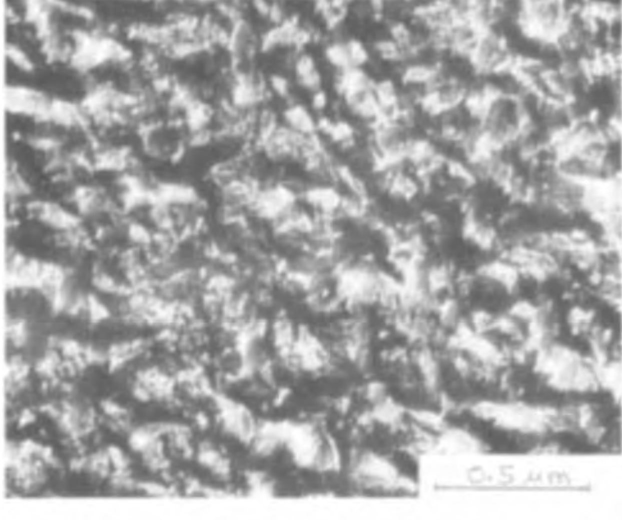
As noted by others (1, 12), at each temperature there appeared to be two reaction periods: an initial period during which the rate was constant or increasing with time, and then a period in which the rate steadily decreased. The lines drawn in Fig. 1 through the data of the initial period have slopes of 1 for 70° and 100°C, 3/2 for 60°C, and 3 for 50°C. At the higher temperatures the lines provide a very good fit for the data; at 50° and 60°C there is more scatter, but it is apparent that a power law is a good approximation and that the exponent increases with decreasing temperature. From the rates at 70° and 100°C an activation energy of 16.3 kcal/mole was found, which is only slightly less than that for the induction period.

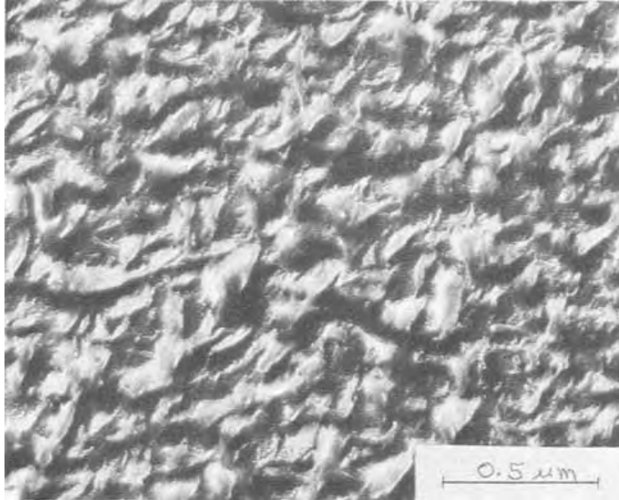
At each temperature there was a relatively sharp transition to the next stage, a period of slow growth. This period was best defined at 100°C where, over more than two decades of time, the weight gain was proportional to $(t-t_o)^{1/3}$. This relationship appeared to be followed at lower temperatures, too, although the 50°C results might be as well described by an exponent of ½. A remarkable feature, noted by previous investigators (1), is that the weight gain not only showed very little dependence on reaction temperature, but sometimes more film was found at lower temperatures. This is illustrated in Fig. 2, where the two lines labeled 50°C and 100°C delineate the narrow band of observed weight gains for a 50° range of reaction temperatures.

Films grown at 40°C.—After about 4 hr, a duplex surface film developed consisting of a uniform, finely textured layer covered with relatively large crystals (13). Although Hart (3) reported that the uniform layer gave the electron diffraction pattern of boehmite (presumably pseudoboehmite), our attempts to obtain a diffraction pattern were not successful, indicating a noncrystalline film. On the other hand, the film had the platelet structure expected of pseudoboehmite (13), and replicas of the surface had the appearance of the pseudoboehmite film produced in boiling water, albeit with coarser detail (Fig. 3). Perhaps the uniform layer can be described as retaining the pseudoboehmite structure, but much more poorly crystallized than films grown at higher temperatures.

Small areas of the film sometimes spalled during preparation for microscopy, revealing the film cross section and the metal substrate, as shown in Fig. 4a. Pits in the metal substrate were sometimes associated with these regions, suggesting that stress due to localized corrosion was a cause for film separation. Except for these occasional pits, the metal surface appeared structureless up to about 12,000X magnification. Film thicknesses were estimated from these cross sections, as well as from an occasional "head-on" view of a lifted film, as in Fig. 4b. After 8 and 16 hr immersions, the pseudoboehmite film was 1.2 and 1.8 μm thick, based on single measurements. Between 24 and 98 hr, film thicknesses were 2.5 ± 0.4 μm, with no trend to greater thicknesses evident.

The crystals resting on the pseudoboehmite layer gave a diffraction pattern for bayerite, as found also by previous investigators (3, 15). The number of crystals increased with immersion time as $(t - t_o)^2$, as shown in Fig. 5. For times up to 24 hr, there was sufficient separation between crystals to get a size distribution in terms of the chord length measured on the image analyzer. The distributions for two typical fields are shown in Fig. 6. The chord length interval was about 0.45 μm and the points in Fig. 6 are placed at the midpoint of each interval. The limit of resolution of 0.23 μm determined the lower cut-off point of the distribution. With the crude assumption that each crystal was a cube with sides equal to chord length, the volume and hence the weight gain due to bayerite growth was calculated. Although the smallest particles were most numerous, they contributed relatively little to the calculated weight. These calculated points are shown in Fig. 7, along with the





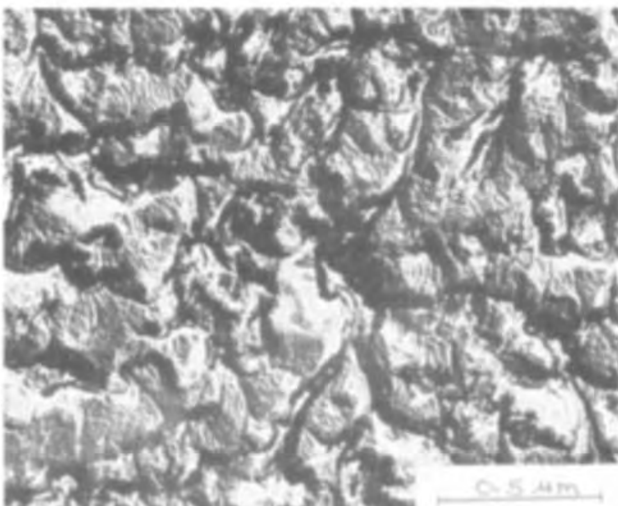


Fig. 3. Transmission electron micrograhs of negative replicas of film surface shadowed with Au-Pd at 45°. Reaction conditions were: a (above left), 4 hr at 40°C; b (below left), 8 hr at 40°C; and c (above right), 5 min at 100°C.

observed total weight gain. The weight of pseudoboehmite, taken as the difference, was found to be unchanged between 16 and 24 hr. The constant film thickness at longer times suggests that no further pseudoboehmite growth occurred beyond 24 hr, and that all the weight gain at these times was due to bayerite growth. The dotted lines in Fig. 7 have been drawn according to this interpretation. From the thickness and weight it is estimated that the pseudoboehmite film had a porosity of about 50%.

A puzzling feature of this duplex film is that the two layers always remained quite separate, even when both were undergoing growth. For example, between 8 and 16 hr the number of bayerite crystals increased fourfold (see Fig. 5) while the pseudoboehmite layer increased in thickness by about 0.6 μm. Yet at 16 hr, or at any other time, no bayerite crystals were found embedded in the bottom layer or surrounded by pseudoboehmite. The crystals always appeared to be simply sitting on the surface.

Discussion

An induction period is frequently observed during the formation of a new phase, as in precipitation or crystallization (15, 16). The induction period arises from the need to achieve a minimum size before a particle of the new phase can sustain its identity. Particles smaller than this "critical nucleus" tend to revert back to starting material, whereas the free energy of the system is reduced by the growth of critical nuclei into still larger particles (15). These events occur at the submicroscopic level; for example, a critical nucleus typical of precipitation of a crystalline solid from aqueous solution might have a diameter on the order of 100Å (15). The induction period is just the time required to produce a sufficient number of critical nuclei to cause an observable change in the system.

The induction period found in the system under investigation suggests that initially the hydrolysis reaction takes place at surface sites that must achieve a critical size in order to sustain the reaction. The mechanism of the reaction is not known, but it very likely involves diffusion of water, perhaps as protons and hydroxyl groups, into the amorphous oxide surface. It may be that sufficient water must enter an oxide region so that thermal fluctuations of the distorted lattice will produce a localized configuration suitable for release of a hydrolyzed monomer. Such regions would constitute the critical nuclei.

The observation that t_0 was independent of pH is consistent with the idea that diffusion of water into the oxide lattice is the rate-determining step. The activation energy for the induction period was found to be 18.7 kcal/mole. The activation energy for a nucleation process should exceed that for the corresponding diffusion process by an amount equal to the maximum free energy for nucleus formation (17). Values of the activation energy for H_2O diffusion in amorphous Al_2O_3 have not been reported; the closest available figures are for D_2O diffusion in boehmite, given as 12.8 (18) and 15.7 (19) kcal/mole. The free energy for nucleus formation would be expected to be relatively small, perhaps on the order of the hydrogen bond energy between water and the oxide which would be several kcal/mole. Thus, the observed activation energy is reasonable for the process that has been postulated.

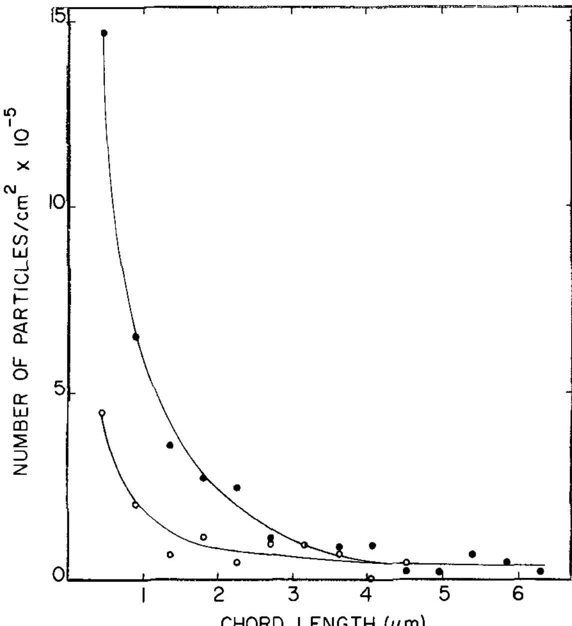

Fig. 6. Size distribution of bayerite crystals after 16 hr (○) and 24 hr (●) at 40°C.

The initial growth rate at 100°C has also been found to be independent of pH (1) and is reported here to have about the same activation energy as for t_o. This suggests that nucleation and growth of hydrolysis sites in the amorphous oxide continues to be rate controlling after the induction period has ended. Of course, as the amorphous oxide is dissolved, new amorphous barrier oxide would be produced by an electrochemical reaction governed by the emf between anodic and cathodic surface sites.

The aluminum oxides are so sparingly soluble (20) that once surface hydrolysis is proceeding at a significant rate, *i.e.*, at the end of t_o, the critical supersaturation would be quickly reached adjacent to the surface and hydrous oxide would be precipitated on low energy surface sites. The pseudoboehmite platelets are exceedingly thin and are attached to the substrate only along an edge (1). For some time then, the deposited material would occupy only a small fraction of the surface and probably would not interfere with the dissolution reaction.

According to the rate equations developed by Jacobs and Tompkins (21), the kinetics during the initial growth period best fit a process consisting of nucleation followed by two-dimensional growth. On a crystalline surface two-dimensional growth might arise from dissolution occurring at steps spreading over the surface, but it is not clear what surface structure supports this growth on an amorphous surface Slow random nucleation followed by normal two-dimensional growth can give rise to $\Delta W \ \alpha (t - t_o)^3$, as ob-

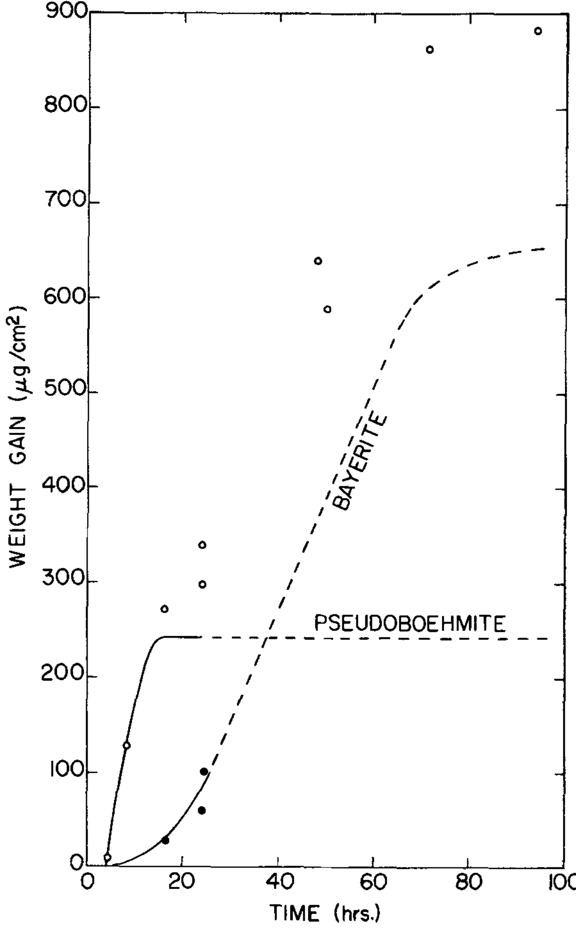

Fig. 7. Weight gain of Al specimens at 40°C. From the total weight gain (○) has been subtracted the calculated weight of bayerite (●) to give the pseudoboehmite component.

served at 50°C. More rapid nucleation reduces the value of the exponent of $(t - t_o)$, until extremely rapid nucleation followed by rapid growth can give rise to a linear dependency for a short initial period, as seen at 70° and 100°C.

The platelets would increase in number and thickness as the reaction proceeded until they impinged upon each other. Finally, the platelet layer would become sufficiently dense so as to block the movement of solvated species, as observed for the case of film produced in a 5-min reaction at 100°C (10), and further growth must occur by solid-state diffusion through the film. The most likely diffusing species is water, diffusing inward perhaps as H^+ and OH^- (18). One would expect growth to now obey a $t^{1/2}$ relationship and this may be the case at 50°C, but at 100°C the weight gain is clearly proportional to $t^{1/3}$.

There is a complete parallel between the kinetics observed during this reaction stage and those observed for the oxidation of Cu_2O to CuO in the 800°-1000°C range (22). In this latter case, the weight increased as $t^{1/3}$ and was not very dependent on reaction temperature. The results were explained as being due to an aging effect that decreased the permeability of the oxide with increasing time and temperature and thus opposed the normal temperature dependence. A similar argument could certainly be applied to pseudoboehmite films since they have been found to exhibit other aging effects, such as a decrease in specific surface area and changes in dielectric properties (4).

The growth process at 40°C differed substantially from that at higher temperatures, the most obvious change being the presence of a second oxide phase. Hart (3) reported that bayerite did not appear until the (pseudo)boehmite film was well established, but we found that the induction time was about the same for both oxide phases. It is likely that his method of detection was not sensitive enough to identify bayerite when only a relatively few crystals were on the surface. The total weight gains shown in Fig. 7 are in excellent agreement with those reported by Hart, whose representation of the data suggests the two-stage growth process we have found [see Fig. 2 in Ref. (3)]. The observed t^2 dependency for bayerite nucleation implies that either two successive events are required to form a stable nucleus, or that nucleation involves a reaction between a surface site and an active intermediary formed in solution at a constant rate (21). One of the polynuclear complexes could be such an intermediary.

Bayerite has a much lower solubility than pseudoboehmite (23) so after an appreciable amount of bayerite had crystallized the concentration of soluble aluminum species at the outer surface would drop below that required for pseudoboehmite deposition. Figure 7 was drawn to indicate complete cessation of pseudoboehmite growth after 16 hr, but it is possible that the film density continued to increase even though the thickness remained unchanged. This could arise from the fact that a concentration gradient of hydrolyzed species would exist within the interstices of the pseudoboehmite layer so that in the inner regions of the film deposition could still be expected.

The pseudoboehmite layer grown at 40°C was much thicker than films grown at high temperatures, say 100°C (4), and also had a considerable porosity, estimated from weight and thickness to be about 50%. This structure, when considered along with the observation that bayerite continued to deposit even after pseudoboehmite growth had ceased, strongly suggests that the low temperature pseudoboehmite layer does not have an impermeable region but rather is open for outward diffusion of hydrolyzed aluminum, as in the Vedder and Vermilyea model. This may be associated with the poorer crystallinity of these films.

Because of the difference in solubilities, the pseudoboehmite should all dissolve eventually and recrystallize as bayerite, as observed for colloidal suspensions (24). There was no indication that this was occurring, which could mean either that the hydrolyzed species precipitated directly as bayerite. or that there was a steady state between pseudoboehmite deposition and dissolution (13). The eventual decrease in bayerite growth was probably due to blockage of the surface with bayerite crystals, which prevented outward diffusion of soluble species and inward diffusion of water.

The absence of any mutual penetration of the two oxide phases cannot be explained. One would infer from this observation that pseudoboehmite layer growth occurs primarily by internal deposition. This might produce stresses that cause a shearing action between platelets, resulting in an expansion of the layer. However, this scheme is difficult to reconcile with the high porosity of the layer.

Conclusions

At temperatures between 50° and 100°C the pseudoboehmite film produced by the reaction of aluminum with water grows initially at a rate determined by the nucleation and growth of hydrolysis sites on the amorphous oxide. The rate-limiting step is probably diffusion of water into the oxide surface. As the oxide thickens, rate control shifts to solid-state diffusion, probably of water, through the pseudoboehmite structure.

At 40°C, a thick porous hydrous oxide layer, probably pseudoboehmite, grows to a limiting thickness. Bayerite crystallization occurs simultaneously with this film growth, and becomes the dominant process at longer times.

Interface Stability in the Electrolytic Decomposition of Silicon Dioxide Films at Elevated Temperatures

J. W. Hinze,*,[1] J. A. Baker,[2] and J. W. Patterson*

Department of Metallurgy and Engineering Research Institute, Iowa State University, Ames, Iowa 50010

ABSTRACT

The stability of planar Si,SiO_2 interfaces was investigated in the electrolytic decomposition of SiO_2 films at 850°C. It was found that voltages greater than the reversible emf of the cell Si|SiO_2|O_2|(P_{O_2} = 1 atm) applied cathodic to silicon rendered the planar geometry unstable so that localized, electrolysis-induced breakdown occurred. This finding is in disharmony with previous observations by Jorgensen. A mechanism for electrolysis-induced dielectric breakdown was proposed to explain the observed breakdown morphologies and voltages. The magnitudes of the observed voltages indicate that ionic as opposed to neutral oxygen transport predominates in SiO_2 films at elevated temperatures.

The intrinsic nature of mass and charge transport in SiO_2 films at elevated temperatures has received increased attention in recent years owing to the technological importance of Si,SiO_2 devices in the electronics industry. Karube *et al.* (1) and Jorgensen (2) have demonstrated that silicon is immobile in SiO_2 compared to oxygen; however, there is controversy concerning the nature and effective charge of the mobile oxygen species (3-6). In an effort to resolve this issue, Jorgensen (2) studied the effect of applied electric fields on silicon oxidation and concluded that oxygen in the form of monatomic divalent ions is mobile in SiO_2. However that study sparked another controversy concerning the reliability of information to be gained from such studies (5, 7, 8).

In a more recent work, Jorgensen (9) studied the decomposition of SiO_2 films at elevated temperatures to further substantiate the migration of divalent oxygen ions. A cell arrangement similar to that shown in Fig. 1 was used for the decomposition experiments. Constant applied currents, with silicon as the cathode, were reported to cause planar thinning of the Si,SiO_2 interface. The cell voltage, monitored with time, was reported to decrease in a fashion qualitatively consistent with a uniform thinning of the resistive SiO_2 film. After a time, the voltage reached a steady-state value indicating that a balance had been achieved between the rate of decomposition and the rate of formation of SiO_2. The observed steady-state voltage was approximately 1.75V at 850°C which corresponds closely to the reversible cell emf one would calculate

from free energy data for the formation of amorphous SiO_2 (10), assuming four equivalents are transferred in the cell reaction.

In a more general vane, however, planar thinning of the SiO_2 films under such conditions would seem rather unlikely; especially in view of past observations of instability of planar electrode interfaces in other electrochemical systems. For example, Rapp (11) and Wagner (12) have observed nonplanar interface growth in the double decomposition of oxides and halides. Conditions were outlined for which the transition from planar to nonplanar morphologies would take place. Tubandt (13) observed the formation of dendritic filaments of silver in his attempts to measure the ionic transference number of AgBr in symmetric cells with silver as the cathode and anode materials. Dendrites originating at the silver cathode grew to the anode thus causing a short circuit to occur. Similarly, metallic sodium dendrites have been observed to form in β-alumina during the charging of sodium sulfur cells (14-15). Finally, unless special precautions are taken, metallic dendrite formation at the cathode is commonly observed during the electrolytic deposition of metals from fused salt and aqueous electrolytes and during the charging of fused salt electrolytic cells.

Dendritic growth in the above instances is not without theoretical justification. In fact, it is to be expected on the basis of simple laws of diffusion. For example, if a small protuberance should form at the cathode, its growth will be favored. This is because the diffusion path length from the anode is shorter to the tip of the protuberance than it is to the trailing planar interface whereas the voltage difference is the same in both cases. Thus the average voltage gradient (the driving force for ion migration) will be greater between the tip and the anode than anywhere else. Therefore, the highest ionic current densities occur immediately between the tip and the anode so that the growth of the protuberance is not only preferential but also self-accelerating.

In view of the foregoing arguments, it seemed surprising to us that some form of localized decomposition was not observed by Jorgensen (9) in his experiments and this prompted the present investigation.

Experimental Procedures and Apparatus

Ultra high purity, high resistivity (1000 ohm-cm) silicon single-crystal specimens were used in this study. The specimens were obtained from Dow Corning Corporation as ¼ in. thick disks with a ½ in. diameter. Thin planar faces, which were parallel to the (111) crystallographic plane, had been electrochemically polished to a mirror finish.

The following procedure was used in the construction of the decomposition cells. The silicon specimens were cleaned by ultrasonic agitation in the following reagents sequentially: trichloroethylene, methanol, distilled water, buffered hydrofluoric acid, distilled water, nitric acid, and distilled water followed by a 5 min rinse in a jet of distilled water. Excess water was stripped off of the specimens with paper tissues, and the specimens were finally dried in an air stream.

After a brief exposure to vacuum at 850°C, purified oxygen at 1 atm pressure was introduced to oxidize the specimens to a thickness the order of 5000Å. Platinum anodes were then applied to each planar interface by electron beam evaporation to a thickness of 1000Å. Into the cylindrical side surface of each of the silicon specimens was drilled a small hole into which a platinum wire with a beaded tip was press fitted. This cell was then placed between two platinum foils on a cell support and electrical leads were attached. During all of the above operations, extreme care was taken to avoid sodium contamination. The specimens were not contacted with the fingers or contaminated laboratory surfaces and tools.

Results and Discussion

Preliminary experiments were conducted to determine the open-circuit emf (E_W) across the cells shown

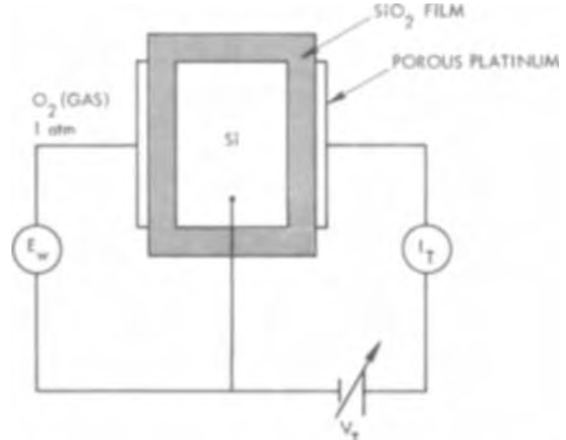

Fig. 1. Schematic diagram of the cell arrangement and external electrical circuitry used to study the kinetics of SiO_2 electrolyte decomposition at elevated temperatures.

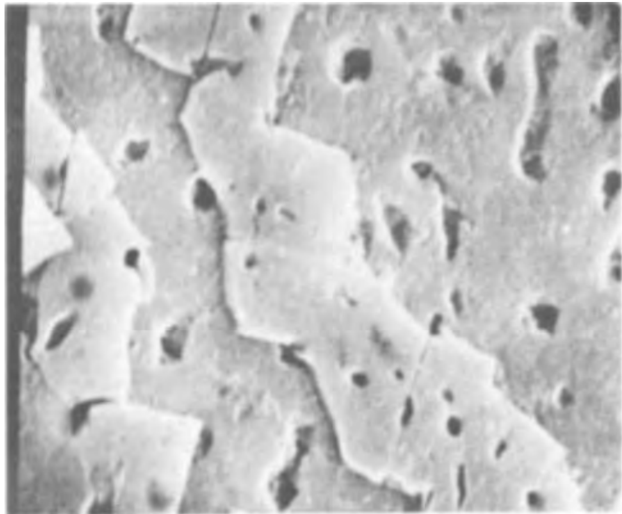
in Fig. 1. These emf's were found to be approximately 420 mV which are around 200 mV lower than those reported by Jorgensen (2). Further preliminary measurements of the silicon oxidation rate under open-circuit conditions were conducted without the platinum electrodes intact. Linear plots of the square of the thickness *vs.* time were observed which yielded a scaling rate constant of 1.25×10^{-11} cm²/hr at 850°C in good agreement with Jorgensen's results (2). The partial surface control observed by Deal and Grove (16) in determinations of the oxidation rate of doped silicon was not observed here.

Decomposition experiments were conducted at 850°C on the cells shown in Fig. 1. Due to the symmetric nature of the cells only half of the cell was used for the study while the open-circuit emf and conductance were measured across the other half as shown in Fig. 1. Formation of a platinum-silicon eutectic at 830°C (17) generally limited cell life because of local deterioration at the center electrode. However with proper care in cell construction useful cell life was on the order of 2-3 weeks. Both constant voltage and constant current decomposition experiments were carried out as part of the present study.

Constant voltages in the range $1.80 < V_T < 5.00$V (silicon as cathode) were applied with the use of an appropriate operational amplifier circuit. A uniform planar decomposition of the Si,SiO_2 interface should result in a timewise current increase as the resistive SiO_2 layer becomes thinner. Instead, localized breakdown of the SiO_2 films occurred as evidenced by intermittent and highly sporadic bursts of current. Moreover, this phenomenon was observed in all the potentiostatic experiments where voltages greater than 1.8V were applied. Thus these constant voltage observations in themselves seem to be inconsistent with the observations of Jorgensen because even though he used constant currents, his constant current voltage always exceeded the thermodynamic emf (1.75V). Indeed his voltages decayed through precisely the same range of values ($1.8 < V < 5.0$V) and yet his films reportedly did not fail locally. Further confirmation of this inconsistency was provided later with constant current experiments as pointed out below.

Figure 2 shows the planar surface of a typical specimen after exposure to a potentiostatic decomposition experiment at 850°C. In Fig. 2a the specimen had been prepared by first etching the platinum electrode away in aqua regia and then removing most of the SiO_2 with HF. This leaves the silicon substrate surface only partially exposed while the remainder is still covered with adherent flakes of SiO_2 scale. It is evident from Fig. 2a that localized pits have been excavated in the silicon substrate, some have penetrated through the SiO_2 flakes, and finally some appear to be forming beneath undamaged regions of these flakes. Figure 2b



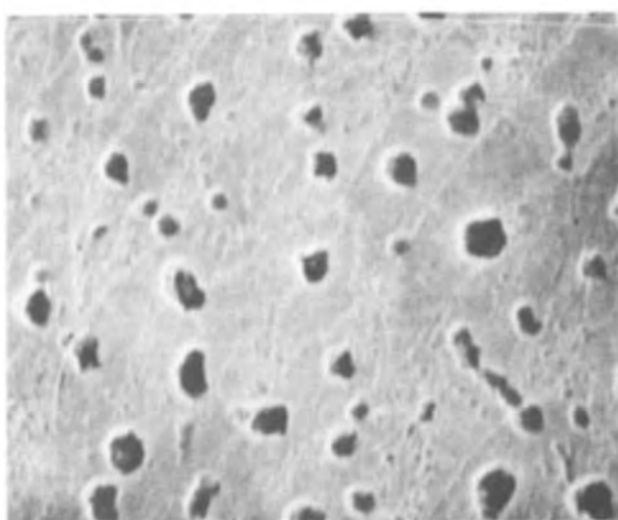


Fig. 2. SEM micrographs of damage to the Si,SiO_2 interface in a decomposition experiment. (a, top) Partially etched specimens showing breakdown damage pits in the silicon substrate surface and in the retained flakes of SiO_2 (magnification ×3000). (b, bottom) Pits in the silicon substrate of a fully etched specimen (magnification ×3000).

merely shows the same specimen (different region) after complete removal of the SiO_2 with the HF etchant. Features of these types were observed for all decomposition voltages greater than 1.8V and the following explanation in terms of localized electrolytic decomposition followed by catastrophic dielectric breakdown is offered.

According to Klein (18) catastrophic dielectric breakdown as opposed to electrolytic breakdown occurs in three stages. In the initial stage a localized avalanche of carriers is initiated when the local voltage gradient exceeds some critical value typically in the range of 10^5-10^7 V/cm for insulators. Snow and Deal (19) found this critical value to be 8×10^6 V/cm for SiO_2 films at room temperature. Localized I^2R-type heating results which causes the current to run away during the second phase of breakdown because the conductivity of insulator materials increases exponentially with temperature. In the final stage, current arcing vaporizes the electrode materials as well as the interposed dielectric insulator in the immediate vicinity of the arc. The damaged region then becomes a nonconductive void, and the breakdown is said to be self-healing (18).

In addition to dielectric breakdown, electrolytic breakdown can also occur if mobile ions prevail in the compound. A most important difference between these two modes of breakdown is that electrolytic breakdown is induced by a critical voltage difference (namely, the thermodynamic emf if no neutral transport exists) but is otherwise independent of the voltage gradient in the specimen. Dielectric breakdown, on the other hand, commences only after a critical voltage gradient is surpassed but is otherwise independent of total applied voltage. In view of these concepts the observed breakdown effects can be rationalized with the aid of the sequence shown in Fig. 3.

In the initial stage, shown in Fig. 3a, electrolysis of SiO_2 commences at the Si,SiO_2 interface. Suppose that small protuberances form as highly conductive, partially reduced pockets of SiO_2 (Fig. 3b). Then once formed, the tip of the most protruding SiO_2 pocket propagates ahead of the others and ahead of the planar interface. That is, the oxygen removal rate from the tip of this protuberance is greater than that from all the other points. This is because the average field gradient from that tip to the anode is greater than that between all the other cathode locations and the anode. Thus the pocket of partially reduced SiO_2 evolves into a dendritic spike in a runaway mode of propagation. Of course, the same analysis holds if the dendrite is silicon which has been produced by the total reduction of SiO_2.

As the tip of the reduced SiO_2 dendrite gets closer to the anode, the local voltage gradient in front of it continues to increase even though the applied voltage remains constant. Eventually the critical gradient (about 8×10^6 V/cm) required for the catastrophic dielectric breakdown of SiO_2 is exceeded. At this point arcing vaporizes the remaining path length as shown schematically in Fig. 3c. Vaporization due to arcing causes the circuit to be broken (*i.e.*, the breakdown is said to be "self-healing"), and the whole process starts over again at the next largest conductive protuberance on the cathode.

The electrolytic breakdown phenomenon observed here provides strong evidence for the domination of charged over uncharged oxygen migration in SiO_2. Significant migration of neutral oxygen would act to annihilate the protuberances as they approached the anode. Furthermore, the electrolytic breakdown phenomenon occurred whenever a voltage greater than the thermodynamic emf was applied cathodic to silicon. Were the flux of neutral oxygen nonzero, an applied voltage perceptibly greater than E_{TH} would have been necessary to cause electrolytic breakdown. These findings lead us to agree with Jorgensen that doubly charged oxygen ions have high mobility in SiO_2 films, at least when electric fields are applied.

In our view, the same basic arguments should apply to galvanostatic decomposition experiments. This view holds that the SiO_2 scale is unstable with respect to

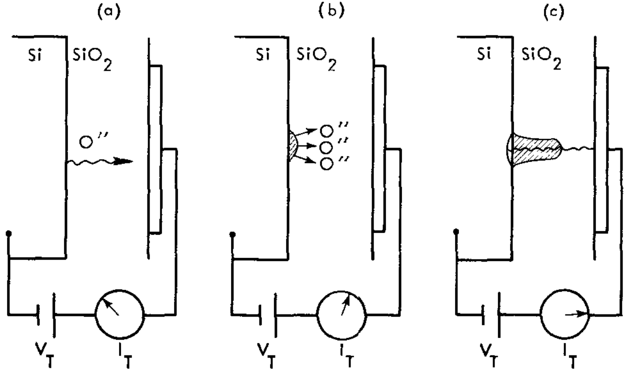

Fig. 3. Proposed sequence for electrolysis-induced dielectric breakdown for SiO_2 layers at elevated temperatures. (a) Initial decomposition of Si,SiO_2 interface. (b) Formation of region of highly reduced SiO_2. (c) Growth of reduced region with subsequent arcing due to dielectric breakdown.

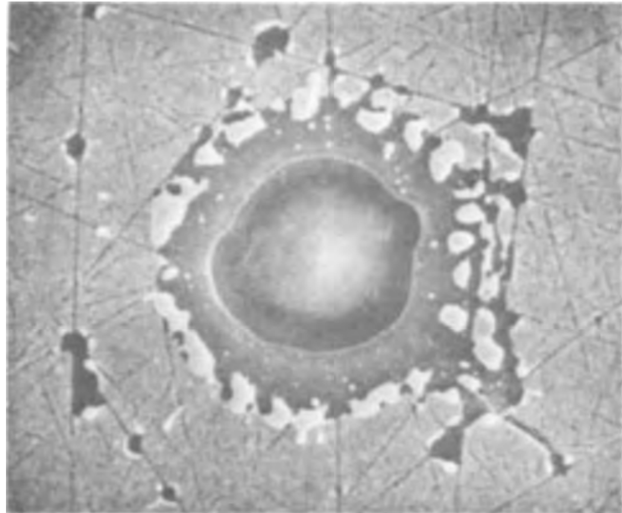
electrolytically induced localized breakdown as long as the applied voltage is of the proper polarity and magnitude to reverse the flow of mobile ions. In other words, the voltage need only be cathodic to silicon and greater than the thermodynamic emf for localized, electrolytically induced breakdown to proceed. Thus when these conditions hold, electrolytic decomposition proceeds preferentially from localized instabilities (protuberances) irrespective of how the applied current (or voltage) may vary with time. Finally, because both the foregoing requirements must necessarily be fulfilled during galvanostatic decomposition, it would seem that localized breakdown, as opposed to the uniform thinning reported by Jorgensen should result in the case of constant current decomposition.

For these reasons two galvanostatic decomposition experiments were carried out at 850°C. In both cases the applied current was fixed at 4 μA and in both cases the voltage over the SiO_2 layer continuously increased and within minutes surpassed the thermodynamic emf. Shortly thereafter the measured voltage suffered intermittent instantaneous decreases (sometimes to zero) with the behavior eventually becoming so erratic as to preclude accurate recording. This behavior is interpreted as catastrophic breakdown preceded by electrolytic decomposition issuing as before from localized sites on the silicon cathode. While this was born out by subsequent visual inspection, no detailed scanning electron microscope examinations were carried out.

To further substantiate the proposed mechanism of electrolysis-induced breakdown, potentiometric studies were conducted with applied voltages of opposite polarity, (*i.e.*, silicon as the anode). Such voltages would not be expected to give rise to pockets of electrolytically reduced SiO_2 because the pockets would now have to form by virtue of oxygen depletion at the platinum electrode. However the abundance of oxygen gas at this electrode would be expected to immediately reoxidize the pockets. Such oxidation would thus reconvert the pockets to insulators thus arresting the electrolysis current required for the breakaway propagation mode and planar geometries would remain stable. If all this is true, catastrophic breakdown with reverse bias should require much larger applied voltages because now the critical gradient on the order of 8×10^6 V/cm (19) must be set up over the entire thickness of the SiO_2 film. For an initial thickness of 5000Å the required voltage would be about 400V at room temperature. The experiments revealed no breakdown up to about 120V with catastrophic breakdown taking place above this value. The observed voltage is sufficiently close to the predicted value of 400V (and sufficiently far from 1.8V) to serve as a confirmation.

Actually the critical breakdown voltage gradient at elevated temperatures has not been previously measured; however, it does not seem unreasonable that the observed voltage should be somewhat less than that predicted from the critical gradient of (8×10^6 V/cm) given by Snow and Deal (19) for room temperature. In other words, the present study merely suggests that the high temperature value of the critical gradient is about one fourth the room temperature value.

The cell used for this study was observed under the scanning electron microscope with the platinum electrode still intact. SEM micrographs of the breakdown pits are shown in Fig. 4. In the lower SEM micrograph, breakdown seems to have caused a crack in the silicon substrate. The pits which formed with reverse polarity are much larger than those shown in Fig. 2. This reflects the fact that much more energy is released in pure catastrophic breakdown than in electrolysis-induced breakdown.



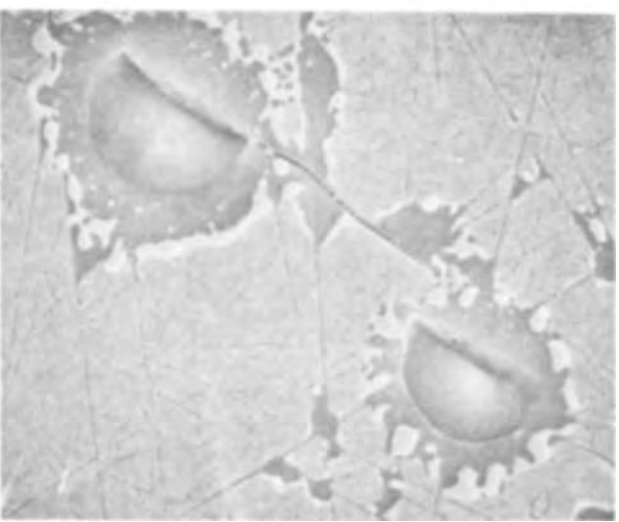


Fig. 4. SEM micrographs of self-healing electrical breakdown of a SiO_2 film induced by a large accelerating field. (a, top) Breakdown in a defect-free region of the SiO_2 film (magnification $\times 1500$). (b, bottom) Breakdown along an imperfection (magnification $\times 1500$).

Conclusion

Two important conclusions result from the above experimental observations. It has been shown that applying voltages greater than the thermodynamic emf across SiO_2 films (the silicon substrate being the cathode) rendered the initially planar scale geometry unstable. In all the decomposition experiments, highly localized damage resulted due to electrolysis-induced dielectric breakdown. In view of the arguments presented above, this phenomenon would be expected to occur in the electrolytic decomposition of all scaling layers as long as cathodic protuberances are more conductive than the surrounding phase, that is, whenever the electric field gradient ahead of the protuberance is greater than it is from the anode to the planar interface of the cathode.

Secondly, on the basis of the breakdown voltages and morphologies for the SiO_2 films, it is concluded that divalent oxygen ions are capable of carrying significant currents in SiO_2 and that neutral oxygen fluxes are negligible by comparison.

The Effect of Heat-Treatment on Photoluminescence Efficiency and Minority Carrier Lifetime in LEC-GaP(Zn,O)

R. Caruso and A. R. Von Neida

Bell Laboratories, Incorporated, Murray Hill, New Jersey 07974

ABSTRACT

High temperature heat-treatment in the interval between 1300° and 1200°C followed by slow cooling (2°-50°C/hr) to 500°C has been found to increase the photoluminescence efficiency (η_{red}) of LEC-GaP(Zn,O) (typically 0.00015% in the seed end to 0.06% in the tail end) to within a factor of 4 of solution grown crystals ($\eta_{red} \approx 0.7$-4%) with comparable hole concentrations. The effect of high temperature annealing is to increase substantially the minority carrier lifetime by reducing the density of nonradiative electron trapping (killer) centers. Subsequent cooling from 1200°-500°C produces an increase in Zn-O pairs over that obtained in as-grown LEC material. The activation energy for the high temperature process involving the removal of killer centers is 6.2 ± 0.5 eV with a relaxation time of 2.1 hr at 1300°C. Arguments are presented to identify further the killer center with a Ga vacancy and the activation energy with that for Ga vacancy diffusion in GaP. Thus, there appears to be an inherent thermodynamic limitation, rather than any impurity-related limitation, to the radiative efficiency of as-grown LEC-GaP(Zn,O). Since annealing appears to be capable of yielding p-type GaP(Zn,O) with η_{red} ranging from at least 0.5 to 1.0% over an entire crystal, this material may be useful in a single epitaxial growth process for device application.

In this paper we characterize the change in photoluminescence properties of LEC-GaP(Zn O) with heat-treatment at elevated temperature. We present data which show that a significant increase in internal red photoluminescence quantum efficiency (η_{red}) can be realized by suitable annealing.

As-grown LEC-GaP(Zn,O) crystals show markedly reduced η_{red} (<0.06%) from that obtained in liquid phase epitaxial (LPE) layers or in solution grown (SG) platelets (>1%) (1). Efficient diodes have been prepared with single LPE growth on SG-GaP(Zn,O) substrates (2), but faced with the low η_{red} of the LEC material, single LPE on LEC-GaP(Zn,O) substrates has not been successful. Obviously, an increase in η_{red} of the pulled crystals to the 1% region would make the LEC p-type material an attractive substrate for device fabrication using single LPE techniques.

The high-temperature annealing experiments are suggested by the results of measurements on LEC-GaP(Zn,O) grown from nonstoichiometric, Ga-rich, melts (3, 4) in which it was found that lower growth temperatures (down to 1200°C) produced material having substantially longer minority carrier lifetimes and higher red photoluminescence efficiency than stoichiometrically grown material.

The minority carrier lifetime of LEC-GaP(Zn,O) crystals is typically two orders of magnitude shorter than equivalently doped SG platelets (1). The major nonradiative shunt path, or killer center, responsible for this short minority carrier lifetime does not appear to be related to impurity effects, notably Si, B, C, N, As, or to changes in the LEC growth parameters. Rather, the killer center appears to be a native defect related to Ga vacancies or Ga vacancy complexes (4). The role of Ga vacancies in determining luminescence efficiency has also been reported in GaAs (5).

Insofar as there are competing centers for electron recombination the photoluminescence efficiency of GaP(Zn,O) is also determined by the number of Zn-O pairs. The seed-to-tail variation in the Zn-O pair concentration in LEC crystals is typically of the order of 1:30 (1). This gradient cannot be completely accounted for by Zn partitioning since the Zn seed-

Key words: GaP(Zn,O), photoluminescence, minority carrier lifetime, light-emitting diode.

to-tail concentration varies typically by 1:6 (1). However, at the same time, there does not appear to be a lower oxygen concentration at the seed end (with either $Zn(PO_3)_2$ or Ga_2O_4 dopants), since measurements of the total oxygen concentration using He (3) activation analysis show an approximately uniform oxygen content (within a factor of 2) in the LEC crystals (6). Apparently then, much of the oxygen in the seed end is not available for pairing with Zn, being interstitial, precipitated, or paired with other species. As will be shown, the results of the high temperature heat-treatment indicate that the seed-end oxygen is most probably complexed with Ga vacancies.

Experimental

The samples for heat-treatment were obtained from 10 p-type LEC-GaP crystals (50-100g). For each annealing experiment a number of pie-shaped samples were cut from a 1/4 in. thick slice and a control sample was saved for representation of the as-grown condition at that point in the crystal. The slices were cut from near the seed and tail ends of these crystals, which had been doped with Zn in the 10^{17}-10^{18} cm^{-3}, range and with 100-300 mg Ga_2O_3 added to the melt. All heat-treatments were made in a tube furnace at temperatures of 1152°, 1200°, and 1300°C.

In a number of preliminary experiments pie-shaped sections ($\approx$1g) were sealed under vacuum in 1.5 in. long silica tubes containing Ga and sufficient powdered GaP to form a saturated solution at the annealing temperature. These samples showed only a 10% increase in minority carrier lifetime (τ_m) after annealing 30 days at 1200°C. However, when similar samples were treated as above but without the addition of any Ga or powdered GaP, τ_m improved by a factor of 10 after 8 days at temperature. Although the tube furnace gradient was uniform to within 1°C over a 3 in. length we were often not able to keep these samples from transporting within the vials, particularly at the highest temperature (1300°C). Accordingly, a system was devised by which the samples could be heat-treated under encapsulation by B_2O_3 (termed liquid encapsulation annealing, LEA). In this way the transport of the samples caused by the temperature gradients was eliminated. Hot-pressed high-purity BN boats, each with a series of 3/4 in. diameter isolated holes, to allow simultaneous heat-treatment of a number of samples, were used to contain the specimens. BN is quite inert to both GaP and B_2O_3 (to 1300°C) but must be kept from reacting with air, so a N_2 ambient was used in the tube furnace. Each sample was covered with about a 5 mm thick layer of B_2O_3. Gaseous phosphorus could be observed emanating from the samples shortly after they were introduced into the furnace. After heating, the samples were removed from the furnace and dropped into boiling water to remove the B_2O_3. Usually the surface of the samples was spalled to a depth of around 20 mils by adhering B_2O_3.

Samples were subsequently thinned and polished to 15 mils thickness for above gap (4880Å) and below gap (5682Å) photoluminescence measurements (at room temperature), from which the minority carrier lifetimes and internal red photoluminescence quantum efficiencies were obtained. This measurement technique has been described explicitly elsewhere (7).

Results

Figure 1a shows the time dependence of heat-treatment at 1200°C on the reciprocal minority carrier lifetime for a seed-end slice and a tail-end slice of LEC grown GaP(Zn,O). In Fig. 1b and c we show the same effect for temperatures of 1300° and 1152°C, respectively, on tail-end slices. It is seen that heat-treatment significantly increases minority carrier lifetime.

In order to determine whether this lifetime change occurs uniformly throughout the crystal two cubes, 1/4 and 1/8 in. on a side, were cut from an LEC slice with the cube centers equidistant from the center of the slice. These cubes were heat-treated together at 1200°C for 2 days. This time period was chosen since it is short compared to the time required for a 1/4 in. thick sample to approach a limiting minority carrier lifetime ($\approx$16 days, Fig. 1a). The minority carrier lifetime at the center of both cubes increased by a factor of 2.4. If we assume that this lifetime change occurs by diffusion of trapping centers to the crystal surface, then the three-dimensional solution (8) for diffusion out of a 1/8 in. cube with the surface boundary conditions set by the limiting minority carrier lifetime gives a value of 3×10^{-8} cm^2-sec^{-1} for the diffusion coefficient. Using this value to calculate the lifetime change to be expected at the center of the larger cube we find that there should be a negligible change for the same period of time. Since, in fact, the change is the same we assume that the minority carrier lifetime increase with annealing occurs mainly by diffusion of electron trapping centers to internal sinks rather than by diffusion to the surface.

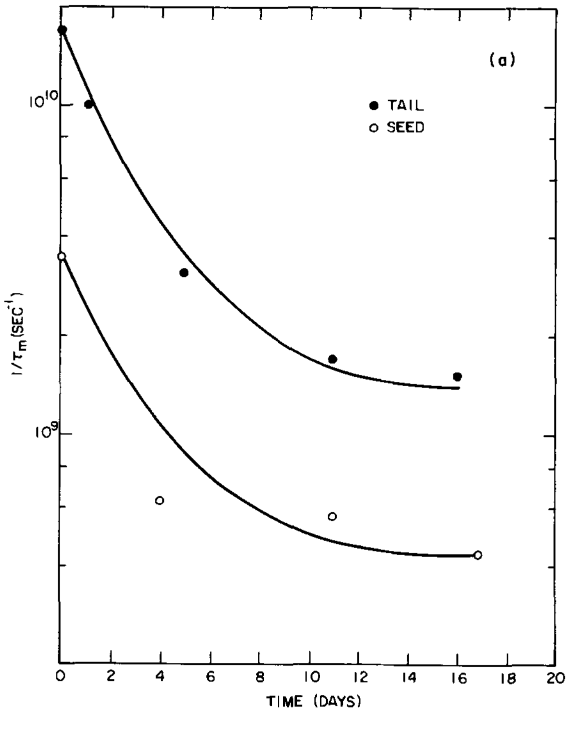
A simple model for diffusion of centers to internal sinks would provide the following equation for the time dependence of minority carrier lifetime (τ_m) on heat-treatment (9)

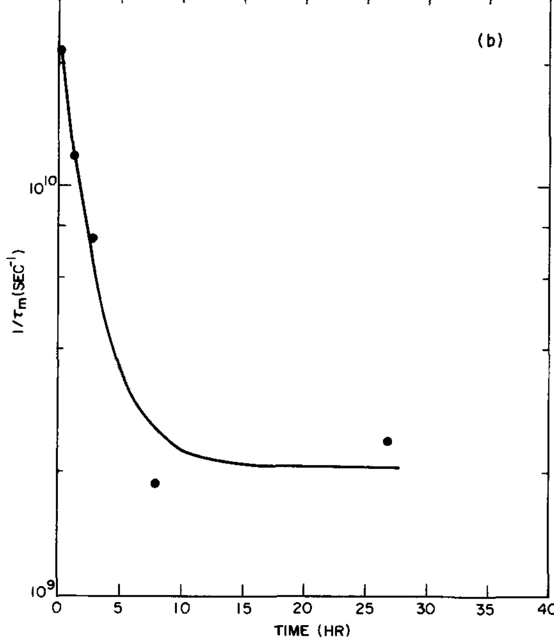
$$(1/\tau_m - 1/\tau_{m,\infty})/(1/\tau_{m,i} - 1/\tau_{m,\infty}) \approx e^{-t/\tau_a} \quad [1]$$

where $\tau_{m,i}$ and $\tau_{m,\infty}$ are the initial and temperature-limiting values of the minority carrier lifetime, τ_a is the relaxation time which depends on the diffusion coefficient of the center and the geometry and density of sinks. The electron capture rate ($1/\tau_m$) is actually a summation of rates for electron capture by zinc-oxygen (Zn,O), isolated oxygen on phosphorous sites (O_P), and nonradiative trapping centers. However, the low photoluminescence quantum efficiencies of these samples, even after heat-treatment (<0.10%), indicates that the capture rate by the radiative centers (O_P and Zn-O) is small compared to that by nonradiative centers. Thus we can take the measured electron capture rate as a quantity proportional to the concentration of nonradiative trapping centers.

In Fig. 2a, we show the results for heat-treatment at 1152° and 1200°C, and in Fig. 2b for heat-treatments at 1300°C when plotted in accordance with Eq. [1]. The agreement seems sufficient to assume a mechanism of the kind described above. The scatter probably reflects differences in initial trapping center concentration and sink density for each of the sections cut from an as-grown slice used in a heat-treatment run. The values for $1/\tau_{m,i}$, $1/\tau_{m,\infty}$, and $1/\tau_a$ for isothermal heat-treatment at the three temperatures are summarized in Table I. With this data, in Fig. 3, a plot of $1/\tau_a$ *vs.* $1/T$ is used to obtain an activation energy of 6.2 ± 0.5 eV for the annealing process.

Below gap (5682Å excited) photoluminescence spectra taken before and after heat-treatment can be used for determining relative changes in concentration of zinc-paired and unpaired oxygen (7). In this study the spectra can be directly compared, since it was found that heat-treatment does not significantly: (*i*) change the absorption characteristics of the samples within the wavelength region of excitation and emission (5,682-10,000Å), (*ii*) change the hole (p) concentration (as evidenced by no significant change in absorption at 10,000Å), and (*iii*) decrease the nonradiative center concentration to a level where radiative centers can compete in the retrapping of thermalized electrons. In Fig. 4a below gap (5682Å excited) photoluminescence spectra are shown for seed-end samples before and after annealing at 1200°C for 15 days. Similar spectra for the tail-end samples are shown in Fig. 4b. Taking the ratio of peak heights before and after heat-treatment for both the Zn-O exciton band (at 7000Å) and the O_P free-to-bound band (at 9200Å) as measures of the change in Zn-O and O_P concentrations we find that the result of heat-treatment is to produce





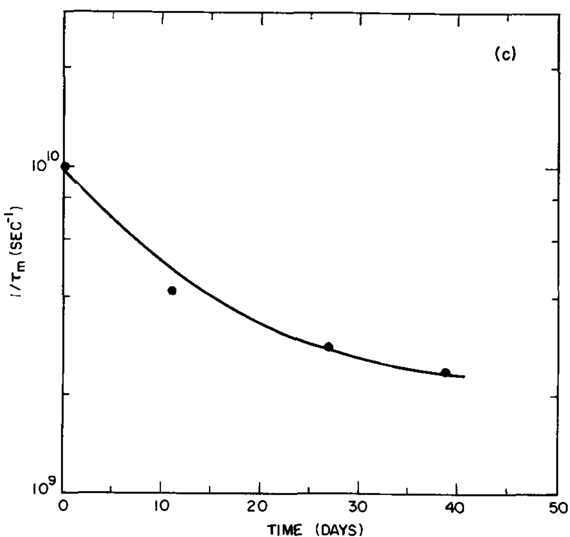


Fig. 1. Time dependence of heat-treatment on reciprocal minority carrier lifetime. (a) at 1200°C for seed-and-tail end samples, (b) at 1300°C for tail-end samples, (c) at 1152°C for tail-end samples. Each data point on a curve represents an individual pie-shaped sample cut from the same slice.

a significant increase in concentration of isolated substitutional oxygen (O_P) in the seed-end samples (Fig. 4a), and no change in the tail-end samples (Fig. 4b). The slight decrease in Fig. 4b is within the ±20% variation we normally found in samples cut from a single slice of GaP. Further, by taking into account the hole (p) dependence of the radiative efficiencies of the Zn-O exciton band and the O_P free-to-bound band, one may also compare the concentrations of O_P and Zn-O pairs in the seed-end and tail-end samples (7, 10). These results are shown in Table II. We can conclude that the 1200°C heat-treatment brings the seed-end O_P concentration up to the same level as in the tail-end samples. The lower Zn-O pair concentration in the seed-end slice, when compared to the tail-end slice after heat-treatment, reflects the lower Zn (hole) concentration in the seed end.

In addition to high temperature annealing experiments which were concerned with the reduction of nonradiative centers in LEC(GaP), a lower temperature heat-treatment range was studied with respect to reformation of Zn-O pairs dissociated at the high temperatures, and possible association of nonradiative trapping centers with another specie. Accordingly, two seed-end samples were treated using a schedule of one day at 1300°C followed by five days at 1200°C (from the kinetic data this anneal has been calculated to be equivalent to 16 days at 1200°C, see Fig. 1a). One sample was then removed and plunged into boiling water. The remaining sample was furnace cooled to

Table I. Effect of heat-treatment on reciprocal minority carrier lifetime

Sample	Heat-treat. temp (°C)	$1/\tau_{m,i}$ (sec^{-1})	$1/\tau_{m,\infty}$ (sec^{-1})	τ_a (hr)
Tail-end slice	1152	1.0×10^{10}	2.2×10^{9}	238

500°C at a rate of 15°C/hr, then removed, and immersed in boiling water. The effect of these differing heat-treatments on minority carrier lifetime and internal above gap red photoluminescence quantum efficiency, η_{red}, is presented in Table III, which shows that slow cooling from the equilibrated 1200°C condition produces a factor of 2 increase in $1/\tau_m$ and a factor of 15 increase in η_{red} (Table III-C) over the quenched sample (Table III-B). Moreover, the effect of heat-treatment B on the increase in minority carrier life-

D_2	8.0×10^{17}	50	0.13	3.6×10^8
E_1	8.0×10^{17}	2.5	0.60	2.1×10^8
E_2	8.0×10^{17}	50	0.65	4.0×10^8

time is comparable to annealing 16 days at 1200°C (See Fig. 1a).

We can further elaborate on these changes with the use of below gap photoluminescence spectra which are shown in Fig. 5. Note that the spectra a (as grown) and b (heat-treatment B), which are similar to those in Fig. 4a, show an increase in the O_P band (9200Å) with high temperature annealing. However, as the sample is now cooled to 500°C (spectra c) the O_P band decreases and the Zn-O band (7000Å) increases due to the pairing up of oxygen with available zinc to produce additional Zn-O pairs. With the data from Table III and the spectra from Fig. 5, we can explain the ~20× increase in η_{red} with heat-treatment B as being due to ~10× decrease in $1/\tau_m$ and a ~2× increase in Zn-O pairs. Then, cooling from 1200° to 500°C (condition C) yields an additional ~15× increase in η_{red} of which ~7× can be ascribed to the increased Zn-O pairing and 2× to a decrease in $1/\tau_m$, which may be due to a pairing of the trapping center with another specie.

Table IV shows the effect of varying the cooling rate upon both η_{red} and $1/\tau_m$. Slices taken from the different crystals were equilibrated at 1200°C and then cooled to 500°C at rates of 2.5°, 15°, 50°C/hr. The slower

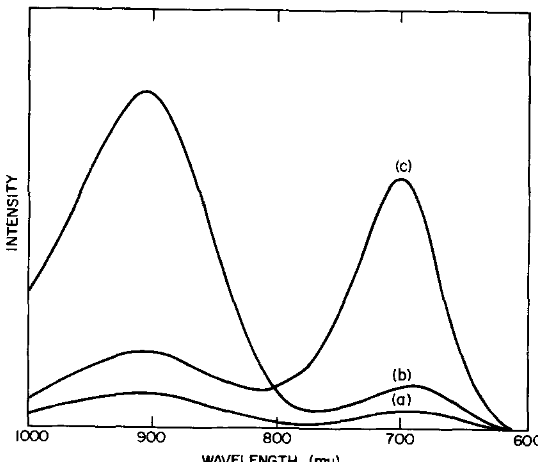

Fig. 5. Below gap (5682Å excited) photoluminescence spectra for a seed-end sample of LEC GaP(Zn,O) (curve a) as-grown, (curve b) after heat-treatment B, (curve c) after heat-treatment C. (Uncorrected for detector response.)

cooling rate is only slightly more effective (at most a factor of 2) in decreasing $1/\tau_m$, which suggests that this additional mechanism for increasing the minority carrier lifetime is a relatively fast process having a low activation energy. Similarly, there is no significant trend in η_{red} with variation of the 1200°-500°C cooling rate. The scatter in the η_{red} data may reflect the different initial oxygen concentrations among the various crystals from which these samples were taken. The Ga_2O_3 additions to the melt varied by as much as a factor of three among these crystals.

Discussion of Results

It has been suggested that the major nonradiative electron trapping center in GaP(Zn, O) is a gallium vacancy or a gallium vacancy associated complex (4). This conclusion resulted from the observation that in crystals grown from 1465° to 1200°C the computed Ga vacancy concentration (which changes by two orders of magnitude) is linear with the measured nonradiative center concentration. The computed P vacancy concentration change over this temperature interval is no more than a factor of two. More recently the solidus boundary of GaP has been constructed by a coulometric titration technique for determining the gallium content of crystals grown at various temperatures (11). The gallium content of an LEC crystal heat-treated at 1200°C until the minority carrier lifetime approached its limiting value increased from 50.0104 to 50.0163%. These values are in close agreement with the solidus composition at 1465° and 1200°C indicating (*i*) that the depletion of trapping centers is coincident with the depletion of Ga-vacancies and (*ii*) that when the Ga-vacancy concentration has decreased to its equilibrium value, the trapping center concentration no longer decreases. This result provides additional evidence for our identification of the nonradiative trapping centers with Ga vacancies.

The fact that the decrease in Ga vacancy concentration occurs more rapidly by LEA heat-treatment than by heat-treatment in saturated Ga-GaP solutions, and further that the decrease is uniform, suggests that vacancy equilibration occurs by different mechanisms. In the LEA case, the crystal rapidly loses phosphorus which could leave in the bulk a network of internal gallium sources or equivalently gallium vacancy sinks. Equilibration could then occur mainly by the diffusion of Ga vacancies to these sinks. In the case of crystals annealed in contact with a GaP-Ga saturated solution a phosphorus pressure is quickly established in the gas phase through dissolution of the powdered GaP in Ga. The bulk composition of the crystal is left relatively unaltered and equilibration would occur mainly by diffusion of Ga vacancies to the surface.

The activation energy obtained from the heat-treatment results, 6.2 ± 0.5 eV, can be equated with the activation energy for Ga vacancy diffusion in GaP. This quantity has not been reported in the literature. With the addition of 1.4 eV (11) for the enthalpy of Ga vacancy formation in GaP we obtain a Ga self-diffusion activation energy of 7.6 eV, which can be compared with values of 5.6 (12) and 3.15 (13) eV for GaAs and GaSb, respectively. This trend, which follows the decrease in melting points (1740°, 1511°, and 979°K) and bandgaps (2.2, 1.4, and 0.72 eV), appears reasonable since the Ga self-diffusion activation energy must be related to bonding strengths of the constituent atoms.

Evidence has been reported for the existence in GaP of a complex center consisting of a Ga vacancy associated with an oxygen atom on a phosphorus site (14, 15). Furthermore, this complex, V_{Ga}-O_P, is almost completely dissociated above ~1100°C. This information can be used to explain the additional decrease in $1/\tau_m$ obtained by slow cooling from 1200° to 500°C (Table III). The low temperature heat-treatment permits some of the Ga vacancies, already decreased by the high temperature treatment, to pair

up with substitutional oxygen, thus decreasing the killer center density.

The existence of V_{Ga}-O_P pairing can also be used to explain the seed-to-tail variation in isolated substitutional oxygen concentration in as-grown LEC-GaP(Zn, O), and its subsequent elimination on high temperature heat-treatment. The already pulled portion of an LEC crystal undergoes some annealing during the pulling operation and can see temperatures below ~1100°C, whereas the tail end is essentially quenched at a temperature much closer to the growth temperature. Therefore we could expect a seed-to-tail decrease in V_{Ga}-O_P pairs and as a result a seed-to-tail increase in isolated substitutional oxygen. High temperature heat-treatment would then eliminate this gradient by breaking up the V_{Ga}-O_P pairs preferentially formed in the seed end.

One can compare the rate of electron capture by nonradiative centers ($1/\tau_n$) in SG GaP(Zn, O) with that in the heat-treated LEC crystals ($1/\tau_m \approx 1/\tau_n$) GaP(Zn, O). It has been found that in SG material $1/\tau_n$ is linearly dependent on hole concentration. For crystals grown over a temperature interval of 1140°-900°C with hole concentrations ranging from 1.6 to 8 $\times$ 10^{17} cm^{-3}, $1/\tau_n$ ranges from ~0.7 to 4 $\times$ 10^8 (sec^{-1}) (16). We find that the measured values for the heat-treated crystals (see Table IV) also fall in this range. The agreement cannot be expected to be exact insofar as the thermal histories of the SG material and the LEC heat-treated crystals are not the same.

A comparison of the above gap red photoluminescence efficiencies of the LEA-LEC crystals with the same SG crystals shows that the efficiencies of the SG crystals are higher by approximately a factor of four over the same zinc-doping range. Since the rates of electron capture by nonradiative centers in the two sets of crystals are approximately the same, the lower efficiency in the LEC heat-treated crystals results from a lower zinc-oxygen pair concentration. In general, the total oxygen concentration in LEC crystals ($\approx 2 \times 10^{18}$ cm^{-3}) (6) as well as the O_P concentration ($\approx 5 \times 10^{16}$ cm^{-3}) (2) is found to be lower than the respective values ($\approx 2 \times 10^{19}$ cm^{-3}) (6) and ($\approx 1 \times 10^{17}$ cm^{-3}) (16) in SG material. This could in part account for the lower Zn-O pair concentration in the LEC heat-treated samples.

Conclusion

The high activation energy, 6.2 eV for Ga vacancy diffusion in GaP implies that the vacancies are essentially frozen in at the growth temperature equilibrium concentration. Therefore the smaller η_{red} of LEC GaP(Zn, O) when compared to material grown at a lower temperature is due to a higher concentration of Ga vacancies which act as very effective nonradiative electron trapping centers. The marked tail-to-seed decrease in Zn-O concentration results from additional pairing of oxygen with Ga vacancies in the seed end which undergoes partial annealing during growth. High temperature (1300°-1200°C) LEA heat-treatment (for removal of Ga vacancies) and low temperature heat-treatment (for pairing of Zn with O) can be used to increase the η_{red} of an entire LEC grown crystal to about 1%. At this level this material may be suitable for a single n on p epitaxial growth technique for LED fabrication.

Energy Transfer Between Pb^{2+} and Eu^{3+} in Germanate Glass

R. Reisfeld and N. Lieblich

Department of Inorganic and Analytical Chemistry, The Hebrew University of Jerusalem, Jerusalem, Israel

ABSTRACT

Energy transfer from Pb^{2+} to Eu^{3+} in germanate glass was detected from the increase of Eu^{3+} fluorescence on excitation via Pb^{2+}. It was found that the transfer is mostly nonradiative, with a small radiative contribution. Probabilities of transfer were calculated from experimental fluorescence data.

Sensitization of fluorescence by energy transfer is potentially of great importance in increasing laser efficiency. In several recent papers (1-3) the advantage of germanate glass as a laser host material was emphasized.

It is the purpose of this work to investigate energy transfer in a germanate glass system in which Pb^{2+} serves as a donor and Eu^{3+} as an acceptor.

Transfer of energy can occur by nonradiative or radiative means. The first theories for nonradiative transfer were given by Förster (4). Dexter (5) extended the theory of Förster for multipolar interactions. The transfer probabilities of electric dipole or quadrapole are proportional to R^{-6} and R^{-8}, respectively, when R is the separation of the two ions. Another nonradiative mechanism is that of spin exchange, which is supposed to be effective only between the nearest neighbors. The radiative transfer occurs when light emitted by the donor is absorbed by the acceptor and reemitted as its fluorescence. A review on energy transfer between rare-earth ions in glasses can be found in Ref. (6). The conditions necessary for an efficient energy transfer to occur are high cross section of light absorption of the donor, and a good overlap between donor emission and the acceptor absorption. A narrow emission band is required for laser materials. These demands are fulfilled in the Pb^{2+}-Eu^{3+} system.

Experimental

The materials from which germanate glasses of final composition $17K_2O \cdot 17BaO \cdot 66GeO_2$ mole per cent (m/o) (7) were prepared, were: GeO_2 Fluka Buchs 99.999%; K_2O_3 Mallinckrodt; $BaCO_3$ Baker Analyzed. The Eu^{3+} added to the glass was Eu_2O_3 Molycorp 99.9% and the Pb^{2+} was PbO of B.D.H.

Five series of glasses of the following compositions were prepared:

1. Eu^{3+} 1,2,3,5,7 weight per cent (w/o)
2. Pb^{2+} 0.5,1,1.5 w/o
3. Pb^{2+} 0.5% and Eu^{3+} 1,2,3,5,7 w/o
4. Pb^{2+} 1% and Eu^{3+} 1,2,3,5,7 w/o
5. Pb^{2+} 1.5% and Eu^{3+} 1,2,3,5,7 w/o

The glasses were prepared by mixing the materials in an electric vibrator for 10 min and then melting them at 1250°C for 12 hr in Pt crucibles. Glass disks 1 mm thick and 12 mm in diameter were prepared by molding the melt on a tile.

Emission and excitation spectra were obtained by using a xenon light source and a spectrofluorimeter built in our laboratory (8).

Decay time of Pb^{2+} fluorescence was measured[1] by a pulse of 10 nsec duration from a N_2 laser of λ 3371Å. All measurements were taken at room temperature.

Results

The absorption and emission spectra of Eu^{3+} in germanate glass were described in Ref. (2) and those of Pb^{2+} in Ref. (9).

Key words: fluorescence europium, fluorescence lead, lead germanate glasses, europium germanate glasses.

[1] We acknowledge the help of Mr. Giyora Doytsch for these measurements.

The evidence for the energy transfer between Pb^{2+} and Eu^{3+} can be seen; (*a*) in the excitation and emission spectra of Eu^{3+}, (*b*) in the emission spectrum of Pb^{2+}, and (*c*) in the fluorescent lifetime of Pb^{2+}.

Figure 1 compares an excitation spectrum of Eu^{3+} only and Eu^{3+} in the presence of Pb^{2+}. The excitation is monitored at $^5D_0 \rightarrow {}^7F_2$ transition of Eu^{3+} at 612 nm. In the glasses doped both by Pb^{2+} and Eu^{3+}, an additional band peaking at 317 nm appears. This band is characteristic of the excitation of Pb^{2+} in germanate glass (9).

Figure 2 represents the emission spectrum of $^5D_0 \rightarrow {}^7F_2$ of Eu^{3+} excited at 317 nm in two glasses; one containing Eu^{3+} only and the other Eu^{3+} and Pb^{2+}. A fivefold increase in the emission intensity of Eu^{3+} is observed as a result of coexistence with Pb^{2+}. The results of the increase of Eu^{3+} fluorescence in singly

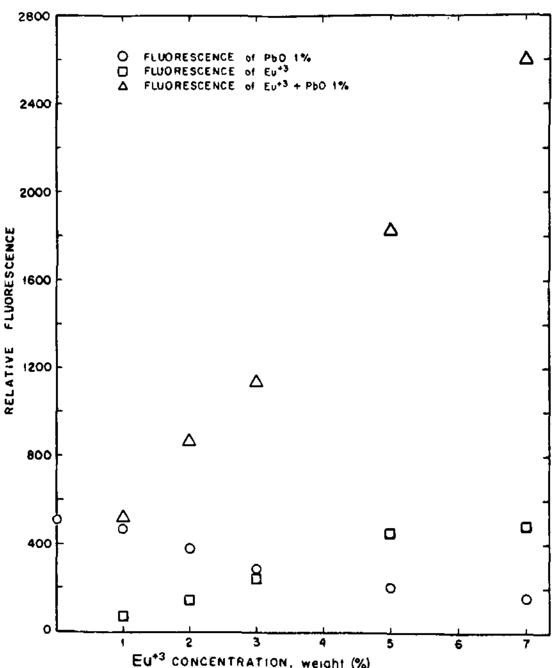

Fig. 3. Concentration dependence of fluorescence. □ 612 nm fluorescence of Eu^{3+} in glasses doped by Eu^{3+} only. △ 612 nm fluorescence of Eu^{3+} in glasses doped by Eu^{3+} and 1% w.p. Pb^{2+}. ○ 430 nm fluorescence of 1 w/o Pb^{2+}, as a function of Eu^{3+} concentration.

and doubly doped glasses as a function of Eu^{3+} concentration, are presented in Fig. 3. A decrease in Pb^{2+} fluorescence in the presence of Eu^{3+} is also demonstrated in this figure. As the Eu^{3+} concentration increases, the Pb^{2+} fluorescence decreases. Intensity data for three series each containing a constant concentration of Pb^{2+}, and a varied concentration of Eu^{3+}, are summarized in Table I.

In the fluorescence decay curves of Pb^{2+} two components are observed: a short lifetime of 10^{-8} sec and a long lifetime of 10^{-7} sec. The explanation for the existence of two components in the lifetime of mercury-like ions can be found in Ref. (10). In the presence of Eu^{3+} both components are shortened; their values are given in Table II.

Calculations were made for energy transfer probabilities and efficiency by using the following formulas (11).

The efficiency of energy transfer can be expressed by

Table I. Increase of Eu^{3+} fluorescence in presence of Pb^{2+} and decrease of Pb^{2+} fluorescence in presence of Eu^{3+}. R.F. is the relative fluorescence

1% Pb^{2+} + 7% Eu^{3+}	20	104

$$\eta_t = 1 - (\eta/\eta_0) \quad [1]$$

where η_0 and η are the fluorescence yields of the donor alone, and the donor in the presence of an acceptor, respectively.

The probability for energy transfer can be expressed as

$$P = \frac{1}{\tau d}\left(\frac{\eta_0}{\eta} - 1\right) \quad [2]$$

where τd is the radiative lifetime of the pure donor level from which energy transfer takes place. In this work the long lifetime of Pb^{2+} was taken.

The mean distance between the ions was calculated by

$$R = \sqrt[3]{1/C_t} \quad [3]$$

where C_t is the sum of Pb^{2+} and Eu^{3+} ions in 1 cm^3 glass.

These results are given in Table III.

Discussion

As seen from the experimental results, the fluorescence intensity of germanate glass doped by Eu^{3+} can be increased by energy transfer from Pb^{2+}. Possibility of excitation of Eu^{3+} by energy transfer at 317 nm is especially important in germanate glasses, since the charge transfer band of Eu^{3+} lies in a region where the host glass absorbs, and therefore it cannot be used for excitation of Eu^{3+}.

The mechanism of the transfer in the system studied occurs both by radiative and nonradiative modes. The nonradiative transfer can be seen from the decrease of the donor's lifetime and the total decrease of Pb^{2+} emission. The radiative transfer can be seen from the dips in the envelope of the emission curve of Pb^{2+} in the presence of Eu^{3+}, in wavelengths at which Eu^{3+} has the highest absorption: 394 nm and 464 nm, Fig. 4. The relative amount of the two modes can roughly be obtained by comparing the difference between the emission spectrum of Pb^{2+} alone and Pb^{2+} with Eu^{3+}, to the area of the "dips" in the emission curve caused by the direct absorption of Eu^{3+}.

The mechanism of multipolar nonradiative transfer between two rare-earth ions was obtained by us (11-14) from the dependence of the transfer probability P on the power of the dopants' concentration. A straight line was obtained when P was plotted against $C_t^{6/3}$ in cases of transfer between Gd^{3+}-Tb^{3+}, Gd^{3+}-Sm^{3+}, and Tm^{3+}-Er^{3+}, indicating a dipole-dipole mechanism, and against $C_t^{8/3}$ in Sm^{3+}-Eu^{3+} in dipole-quadrapole mechanism. In this work a straight line is obtained when values of P are plotted against the first power of C_t. Such dependence does not fit the classical theory of multipolar interactions. Recently, Fong and Diestler (15) proposed a mechanism for a nonradiative energy transferred between ions in crystals by a many body process in which a prediction is made for a linear dependence of energy transfer rate on concentration. Our experimental results are in accordance with this theory. The difference between the concentration dependence found in this work and in our previous work may be attributed to: (*i*) the higher concentration of the dopants which could be due to the higher dissolving property of the germanate glass (the upper limit

of the activator concentration was 3.5 w/o in borate and phosphate glasses (11-14), while in germanate glasses a concentration of 7 w/o could be easily obtained), and (*ii*) the fact that the emission of the donor Pb^{2+} results from allowed transition and has a broad band which overlaps with several absorption bands of Eu^{3+}.

In conclusion, we have shown the existence of energy transfer between Pb^{2+} and Eu^{3+} in germanate glass and this can be utilized for sensitization of Eu^{3+} fluorescence. The exact mechanism via which the energy transfer takes place is still an open question.

Enhanced Conversion of X-Rays into Visible Light in Thin Composite Layers (Composite Anthracene-$PbCl_2$ Screens)

W. Albers and L. A. H. van Hoof

Philips Research Laboratories, Eindhoven, Netherlands

ABSTRACT

The absorption of x-rays by a solid organic phosphor can be enhanced to a great extent by the inclusion of a disperse second solid phase that consists of heavy atoms. In consequence the x-ray to visible light conversion can be enhanced by one or two orders of magnitude when using composite screens. Experiments on composite anthracene-$PbCl_2$ screens reveal an amplification factor of about 30. The experimental results are discussed and are compared with existing theories.

Since 1947 luminescent organic substances, such as anthracene, have been used as scintillators to detect high-energy particles and quanta, such as x-rays, and to measure their energy (1). An anthracene crystal converts x-rays into visible light near u.v. The luminescent radiation output depends on (*i*) the absorption of the x-rays, during which secondary electrons are released, that lose their energy by means of many processes, one of them being a transition of anthracene molecules from the ground state to excited states that can return to the ground state while emitting visible light of wavelengths between 400 and 470 nm, a process which consumes only a few per cent of the total energy of the secondary electrons (2), (*ii*) the absorption and scattering of the luminescent light, the scattering occurring both at the outer surfaces of the crystal and at internal interfaces, due to inhomogeneities such as grain boundaries, inclusions, and cracks.

The absorption coefficient of organic phosphors for x-rays is undesirably low due to the low density and to the low atomic number of the constituent atoms. By separating the functions of x-ray to secondary electron conversion and the secondary electron to visible light conversion [*i.e.*, using the concept of composite product properties (3)] the absorbed fraction of the incident x-rays can be enhanced to a great extent by the inclusion of a disperse second solid phase that (partially) consists of heavy atoms and consequently exhibits a high absorption coefficient for x-rays. The included phase does not need to be a phosphor, but it has to be transparent to the luminescent light of the matrix phase. At a given thickness of the composite layer and at a definite ratio of the volume fractions of the two phases, the x-rays (*e.g.*, of 100 keV energy) will be absorbed predominantly in the second phase releasing secondary electrons. These secondary electrons have a mean free path of the order of 10 μm in the second phase and spend most of their range in the phosphor matrix if the heavy phase particles are substantially smaller than 10 μm. They excite the phosphor matrix resulting in luminescent emission. In this way the x-ray to visible light conversion can be enhanced by more than an order of magnitude in an anthracene screen by the addition of finely dispersed $PbCl_2$ particles.

Experimental

Preparation.—The expectations expressed above have been experimentally verified on the anthracene-$PbCl_2$ composite. $PbCl_2$ exhibits only a poor luminescence, has an energy bandgap of 3.85 eV (4), and is transparent among others to light of 400-470 nm wavelengths.

At 250°C solid $PbCl_2$ grains (diameter 1-10 μm) and liquid anthracene (mp anthracene, 216°C; mp $PbCl_2$, 501°C) were stirred together in a sealed evacuated quartz tube with a pointed base. After homogenization the $PbCl_2$ particles were allowed to precipitate partially and then the mixture was cooled down and solidified. Thus the upper part of the tube consisted of crystalline anthracene, saturated with traces of dissolved $PbCl_2$ [the matrix material, denoted as anthracene(m); the $PbCl_2$ concentration being < 500 ppm according to chemical analyses]. The lower part consisted of anthracene-$PbCl_2$ composite material. Matrix samples of varying thicknesses were cut from the upper part, and from the lower part composite samples containing 30 volume per cent (v/o) $PbCl_2$ grains. The samples were coarsely ground in order to reduce specular reflection at the surface. The surface of the samples was normalized. The thicknesses of the samples varied between 0.01 and 0.4 cm.

Optical measurements.—These samples, situated on a dim black substrate, were subjected to both x-ray and u.v. irradiations perpendicular to the surfaces of the samples in order to determine the conversion efficiency and to characterize the luminescent center in the anthracene-$PbCl_2$ composites.

X-ray to visible light conversion.—The x-rays were delivered by an x-ray tube of the Müller MG 150 Type. The electrode voltage was varied between 50 and 150 kV_p. No filters were used, *i.e.*, the x-ray beams were not monochromatic. The intensity of the backwards emitted luminescent light, (*i.e.*, the direction opposed to that of the incident x-rays) was measured as a function of the sample thickness by means of a photomultiplier (Philips 150 UVP), directed under 45 angular degrees with respect to both the sample surface and the x-ray beam (Fig. 1). The sensitivity of the photomultiplier was the same to within 10% for wavelengths between 400 and 470 nm. Typical results (for 150 kV_p, *i.e.*, a mean value of the x-ray energy of about 100 keV) are shown in Fig. 2. The circles, triangles, and squares correspond to the composite, the anthracene matrix, and the $PbCl_2$ samples, respectively.

Emission spectra.—The emission spectra of composite samples and of anthracene(m) samples of a thickness of 0.055 cm have been measured both under x-ray irradiation of 60 keV (Fig. 3a and 3b) and under u.v. irradiation of 254 nm wavelength (Fig. 4a and 4b).

Discussion

From Fig. 2 it is evident that the conversion factor of composite material is considerably enhanced and

The squares correspond to single-phase $PbCl_2$.

exceeds that of single-phase anthracene(m) by a factor of about 30 for thin films. The luminescence contribution of single phase $PbCl_2$ (squares) is negligible.

The emission spectra shown in Fig. 3 and 4 are essentially the same and are in accordance with published data on the emission spectrum of pure crystalline anthracene (5, 6, 12) exhibiting peaks at about 400, 420, 450, and 470 nm. The x-ray emission spectrum (Fig. 3b) of the anthracene(m) shows the peaks at 470 and 450 nm, but the two peaks at 420 and 400 nm are absent. The x-ray emission spectrum of the anthracene-$PbCl_2$ composite has the peaks at 470, 450, and 420 nm, while the peak at 400 nm is missing (Fig. 3a). In Fig. 4 (u.v. excitation) all peaks are present. The differences can be explained in terms of self-absorption of the luminescent light, due to the fact that the emission and absorption spectra of anthracene mutually overlap (7). The penetration depth of u.v. in both the anthracene(m) and the composite is very small (a few micrometers), such that the self-absorption of the backwards emitted luminescent light is small. For x-rays, however, the penetration depth in the anthracene(m) is considerably larger than in the composite (as argued above), but both are much larger than for u.v. As a consequence the absence of one peak in Fig. 3a and two peaks in Fig. 3b can be attributed to an increase of the self-absorption of the luminescent light.[1] Therefore the diagrams of Fig. 3 and 4 are basically the same and it can be concluded that the presence of dissolved $PbCl_2$ and solid $PbCl_2$ grains does not affect the molecular luminescence mechanism typical for pure anthracene. Consequently the intensities given in Fig. 2 for anthracene(m) and for the anthracene-$PbCl_2$ composite can be compared directly.

The experimental points of Fig. 2 for the composite (circles) can be described by a simple curve (solid line 1) of the form

$$J_{(\mathrm{comp})} = 180C\ (1 - e^{-60D}) \quad [1]$$

where $J_{(\mathrm{comp})}$ is the response of the photomultiplier to the luminescent light emitted backwards by the composite sample, D is the thickness of the sample, and C a constant. Similarly the experimental results of the anthracene(m) (triangles) correspond to

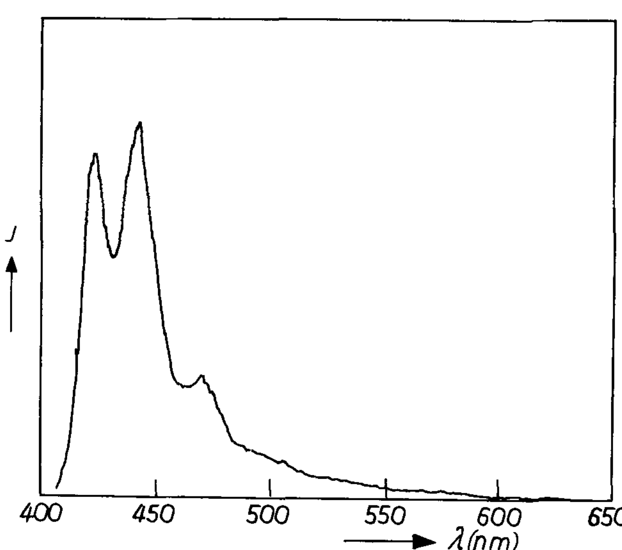
$$J_{(\mathrm{anth.m})} = 66.2C\ (1 - e^{-5.9D}) \quad [2]$$

(see solid curve 2), the slopes, R, at $D = 0$ (dashed lines) being

$$R_{(\mathrm{comp})} = 10800C \text{ and } R_{(\mathrm{anth.m})} = 390C \quad [3]$$

These experimental results of Fig. 2 can be related to physical parameters by considering the luminescence

[1] This is true in spite of the fact that the absorptivity for the luminescent light is larger in the composite than in the anthracene(m), because the absorption coefficient for x-rays has increased much more (see below).



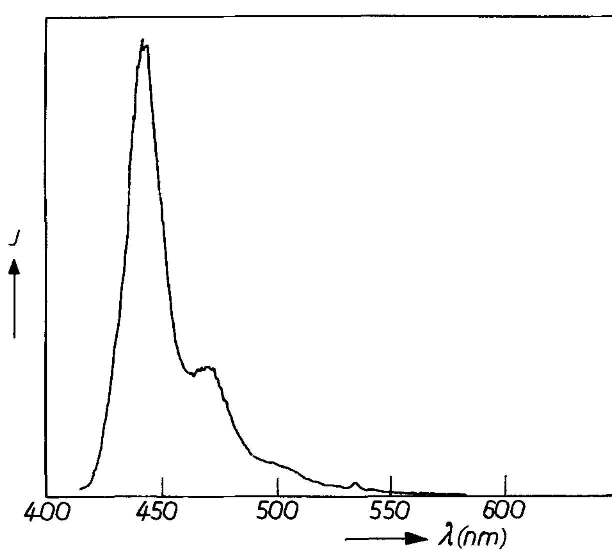


Fig. 3. X-ray emission spectrum. J denotes the spectral power in arbitrary units. a (left), For the anthracene-$PbCl_2$ composite; b (right,) for the anthracene matrix.

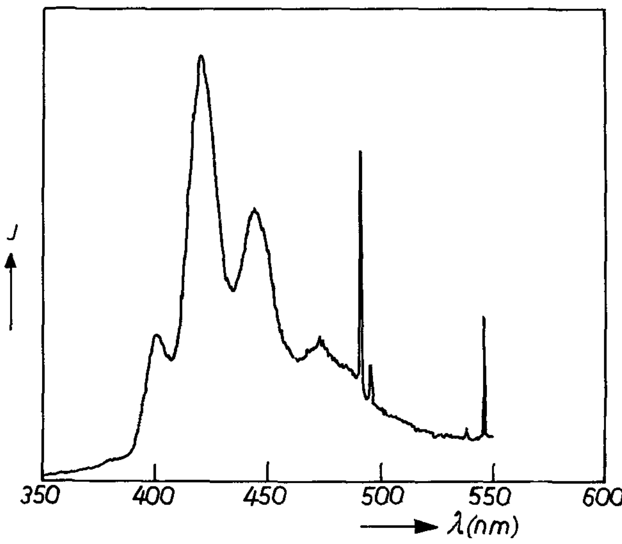

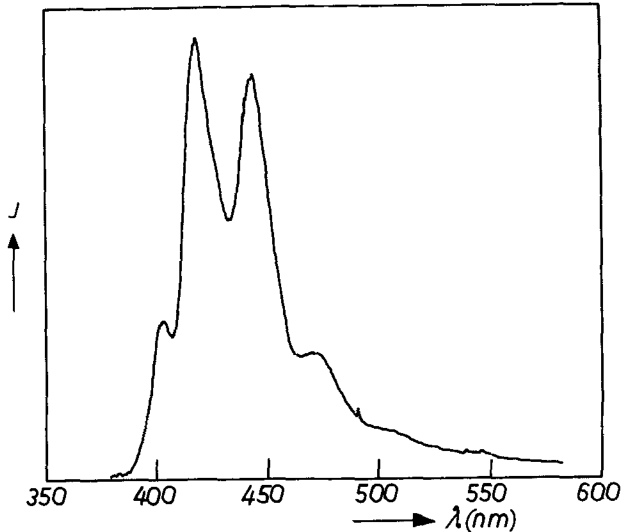

Fig. 4. U.V. emission spectrum. J has the same meaning as in Fig. 3. a (left), For the anthracene-$PbCl_2$ composite (the sharp peaks at 492 and 546 nm originate from the u.v. mercury excitation source); b (right), for the anthracene matrix.

and the absorption processes in more detail (8-10). The luminescent light generated by the incident x-rays travels through the sample and is subject to absorption and to scattering before it leaves the sample through the surface and can be detected by the photomultiplier. The one-dimensional case is considered in Fig. 5. The total luminescent radiant flux passing an infinitesimal thin layer dx is split up into two parts, *viz.*, J_F in the x-axis (*i.e.*, the direction of the incident x-ray beam) and J_B in the opposite direction.[2] A fraction $\tau J_F dx$ of J_F will be absorbed and a fraction $sJ_F dx$ will be lost by scattering in a backward direction, but a fraction $sJ_B dx$ will be added by scattering from flux J_B, as well as a quantity $\frac{1}{2} f\mu I_0 e^{-\mu x} dx$, being the half of the radiation excited by the x-rays in dx (the other half contributes to J_B), such that

$$\frac{dJ_F}{dx} = -(\tau + s)J_F + s\,J_B + \tfrac{1}{2} f\mu I_0 e^{-\mu x} \quad [4a]$$

and similarly

$$\frac{dJ_B}{dx} = (\tau + s)J_B - sJ_F - \tfrac{1}{2} f\mu I_0{}^{-\mu x} \quad [4b]$$

where τ and s are the absorption coefficient and the coefficient of internal scattering of the luminescent radiation, I_0 and μ the intensity and the absorption coefficient of the incident x-rays, and f the luminescence efficiency factor. By common principles the general solution of Eq. [4] has been found to be (8)

$$J_F = A(1-\beta)e^{\sigma x} + B(1+\beta)e^{-\sigma x} - \tfrac{1}{2} f\mu I_0 \frac{\mu + \sigma/\beta}{\mu^2 - \sigma^2} e^{-\mu x} \quad [5a]$$

and

$$J_B = A(1+\beta)e^{\sigma x} + B(1-\beta)e^{-\sigma x} + \tfrac{1}{2} f\mu I_0 \frac{\mu - \sigma/\beta}{\mu^2 - \sigma^2} e^{-\mu x} \quad [5b]^3$$

where σ is the absorptivity, comprising both absorption and internal scattering of the luminescent light according to $\sigma = \sqrt{\tau(\tau + 2s)}$ and $\beta = \tau/\sigma$. The constants A and B can be determined by the boundary conditions $J_F = r_1 J_B$ at $x = 0$ and $J_B = r_2 J_F$ at $x = D$, respectively, in which r_1 and r_2 are the reflection coefficients of the front surface (facing the incident x-rays) and the opposing surface, respectively.

Neglecting specular reflection of the luminescent light at the front surface of the sample (*i.e.*, putting $r_1 = 0$) and for the case where the dim black substrate (see above) has the same reflectivity as a luminescent layer of infinite thickness [which will be true for the composite samples due to the high absorptivity σ, and also for the anthracene(m) samples if it is assumed that in anthracene(m) internal scattering is absent and that the black substrate has a zero reflectivity] then from Eq. [4] and [5] it follows (8, 9)

$$J_B = \frac{f\mu I_0}{(1+\beta)(\mu+\sigma)}\{1 - e^{-(\mu+\sigma)D}\} \quad [6]$$

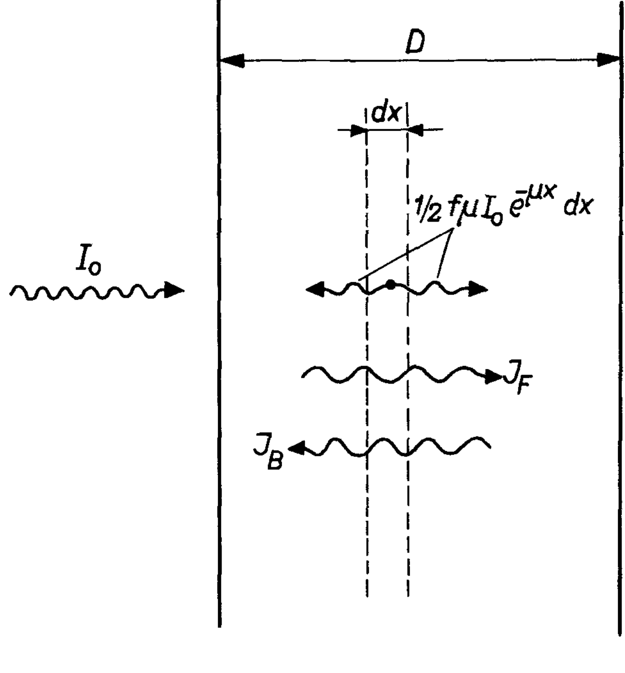

Fig. 5. X-ray luminescence. I_0 = incident x-ray beam; J_F = forward flux of the luminescent light; J_B = backward flux; D = thickness of the sample; $\frac{1}{2} f\mu I_0 e^{-\mu x} dx$ see text.

[2] Sideways directions are not considered because in layers with a large surface compared with the thickness the loss in sideways directions is compensated by an equal contribution from the neighboring parts of the layer.

[3] In Eq. [29] of Ref. (8) printing errors occur in the terms $\frac{1}{2} f\mu I_0 \frac{\mu + \sigma/\beta}{\mu^2 - \sigma^2} e^{-\mu x}$ and $\frac{1}{2} f\mu I_0 \frac{\mu - \sigma/\beta}{\mu^2 - \sigma^2} e^{-\mu x}$ a factor β has been lost. For the same reason Eq. [154] of Ref. (10) should be rewritten.

Equation [6] and Eq. [1] and [2], which also apply to backwards radiation, are of the same form. Therefore from these equations it follows

$$\mu_c + \sigma_c = 60 \text{ cm}^{-1} \quad [7]$$

and

$$\mu_m + \sigma_m = 5.9 \text{ cm}^{-1} \quad [8]$$

where the suffixes c and m refer to the anthracene-$PbCl_2$ composite and to the anthracene(m), respectively. With $\mu_m = 0.20 \text{ cm}^{-1}$ at 100 keV) (11) and assuming $s_m = 0$ (see above), or $\sigma_m = \tau_m$, it follows from Eq. [8]

$$\tau_m = 5.7 \text{ cm}^{-1} \quad [9]$$

Because the major part of the composite consists of anthracene(m), and because, according to preliminary absorption measurements σ_{PbCl_2} equals about 1 cm^{-1} to a good approximation the following holds

$$\tau_c = \tau_m \quad [10]$$

The parameter μ_c can be obtained from

$$\mu_c = V\mu_{PbCl_2} + (1 - V)\mu_m \quad [11]$$

where V is the volume fraction of $PbCl_2$. Equation [11] has been derived by substituting a model for the disperse composite consisting of two layers with equal surfaces, and of thicknesses proportional to V and $(1 - V)$, the first layer being $PbCl_2$ and the other anthracene(m). With μ_{PbCl_2} (100 keV) = 20 cm^{-1}, calculated according to Ref. (11) and $V = 0.3$, from Eq. [11] it follows that

$$\mu_c = 6 \text{ cm}^{-1} \quad [12]$$

and from Eq. [7] that

$$\sigma_c = 54 \text{ cm}^{-1} \quad [13]$$

The fact that $\sigma_c >> \tau_m$ can be attributed both to the pronounced internal reflection of the composite (due to the difference in the refractive indices of the $PbCl_2$ grains and the anthracene matrix) and to the fact that the degree of reabsorption is higher in the anthracene samples (larger penetration depth of the incident x-rays) than in the composite samples. The reabsorption tends to decrease the intensity of the short-wave luminescence and to increase the intensity of the long-wave luminescence via the photon cascade process (7, 12-14). In consequence the mean absorption coefficient of the anthracene samples will approach to the absorption coefficient of the luminescent light of 450 nm wavelength ($\tau_{450} \approx 5 \text{ cm}^{-1}$) (14, 15) while that of the composite samples will tend more to the absorption coefficient of the luminescent light of 420 nm wavelength, being of the order of 100 cm^{-1} (14). From Eq. [6] it follows for the slopes R at $D \rightarrow 0$

$$R_c = \frac{f_c\mu_c I_o}{1 + \beta_c} \text{ and } R_m = \frac{f_m\mu_m I_o}{1 + \beta_m} \quad [14]$$

With the above-derived values for the μ's, while putting $\beta_m = 1$ (no contribution by the internal scattering) and $\beta_c = 0.3$ (internal scattering), for the amplification factor $U_{th} = R_c/R_m$ it follows from Eq. [14] that

$$U_{th} = 46 \frac{f_c}{f_m} \quad [15]$$

The luminescence efficiency factor, f_c, contains a factor Q that is a function of the volume fraction V. Q varies between 1 (for $V = 0$) and 0 (for $V = 1$). In the latter extreme case the composite does not contain any luminescent material and consequently f_c falls to zero (if the $PbCl_2$ luminescence is neglected). The factors f_c and f_m are independent of the degree of self-absorption and photon cascade because the efficiency of (cascade) photoluminescence of crystalline anthracene at room temperature is almost unity (7).

The experimental amplification factor, U_{exp}, at $D \rightarrow 0$ according to Eq. [3] is

$$U_{exp} = 28 \quad [16]$$

From Eq. [15] and [16] it follows that the agreement between theory and experiment is good, if $f_c = 0.6 f_m$.

The above-calculated values have to be considered as mean values, due to the nonmonochromatic character of the incident x-rays and the luminescent light, the range of the secondary electrons in the anthracene can amount up to 10-100 μm, the photon cascade process, the inhomogeneities in the samples, etc.

Finally it has to be remarked that in principle the x-ray to visible light conversion can also be enhanced by covering the anthracene sample with a $PbCl_2$ layer. However the result will be poor compared to the composite. Only a small fraction of the x-rays will be absorbed if the $PbCl_2$ layer is 1-10 μm thick, and if the $PbCl_2$ layer is thicker than 10 μm most secondary electrons, released in the $PbCl_2$ layer, will be trapped in the $PbCl_2$ layer before reaching the underlying anthracene. In the composite structure, however, the incident x-rays successively hit many $PbCl_2$ particles of small dimensions, and as a consequence the conversion is maximum.

Conclusion

For phosphors of a low density and consisting of atoms of a low atomic number the x-ray to visible light conversion can be enhanced by one or two orders of magnitude by the addition of finely dispersed particles (globules, rods, lamellae, etc.) of a heavy phase.

Acknowledgment

Thanks are due to Messrs. J. A. de Poorter, G. de Vries, and R. E. Breemer for the measurements of the emission spectra and to Dr. A. Bril for the stimulating discussions.

Manuscript received Nov. 12, 1973.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1975 JOURNAL. All discussions for the June 1975 Discussion Section should be submitted by Feb. 1, 1975.

The publication costs of this article have been assisted by Philips Research Laboratories.

LIST OF SYMBOLS

- β — τ/σ
- C — a constant including the photomultiplier properties
- D — thickness of the sample, cm
- f — luminescence efficiency factor
- I_o — intensity of the incident x-rays
- J — luminescent radiation output
- μ — absorption coefficient of the incident x-rays, cm^{-1}
- R — slope of J vs. D at $D = 0$
- τ — absorption coefficient of the luminescent radiation, cm^{-1}
- s — coefficient of internal scattering of the luminescent radiation, cm^{-1}
- σ — absorptivity of the luminescent radiation, cm^{-1}
- U — luminescence amplification factor
- V — volume fraction of the $PbCl_2$ particles
- X — distance from the surface, cm

A Comparison of the Semiconducting Properties of Thin Films of Silicon on Sapphire and Spinel

G. W. Cullen* and J. F. Corboy

RCA Corporation, David Sarnoff Research Center, Princeton, New Jersey 08540

ABSTRACT

The Hall mobilities in 0.5 and 1.0 μm thick heteroepitaxial silicon on $(1\bar{1}02)$ sapphire and (100) and (111) spinel substrates are compared. The substrates employed were Czochralski sapphire, alumina rich flame fusion spinel, stoichiometric Czochralski spinel, and a "modified" alumina-rich Czochralski spinel. The semiconducting properties of the silicon on the spinels are similar if the Czochralski grown substrate surfaces are air annealed prior to deposition. The reproducibility achieved in electrical properties in silicon on spinel is related to the method of preparation of the substrate. In comparing the semiconducting properties in silicon on sapphire with silicon on spinel, one finds that the MOS transistor mobilities are more similar than the Hall mobilities.

It is of interest to identify the factors which limit the semiconducting properties of thin (1 μm and less) heteroepitaxial silicon on insulating substrate materials. To this end, it is informative to compare the properties of films deposited on substrates with distinctly different crystallographic and chemical properties. In order to optimize the characteristics of complementary pair MOS transistor (CMOST) circuitry fabricated in silicon on insulators, the effort is directed toward achieving carrier mobilities as similar as possible to bulk values in heteroepitaxial films as thin as 0.5 μm. Therefore, the nature of the substrate material is under continual reexamination.

During the development of the silicon-on-insulator technology, sapphire has been the most commonly employed substrate material (1-3). Excellent progress has been made, and semiconducting properties useful for application in commercial devices have been realized (4-6). Spinel has been considered as a possible alternate substrate because of the relatively good crystallographic match to, and relatively low chemical reactivity with, silicon (7-10). Higher mobilities have been achieved for some, but not all carrier types, orientations, and thicknesses of silicon on spinel (11, 12). As the demand for larger substrate diameters (2 in. and greater) arose to meet the needs of advancing IC technologies, there was a general shift from flame fusion to Czochralski grown material, although at least one organization has adopted the approach of developing methods for the growth of large diameter flame fusion spinel (13). In the case of sapphire, the flame fusion and Czochralski material are chemically identical; therefore, the same conditions can be used for the deposition of silicon on both types of substrates. In the case of spinel, however, the properties of concern for use as a substrate material are a strong function of the method used for the growth of the crystal, and therefore the substrate surface preparation and/or the conditions employed for silicon deposition must be adjusted accordingly (11, 12).

The semiconducting properties in thin silicon films on sapphire have improved as the growth temperature has been decreased and the growth rate increased. These deposition conditions have been used to suppress the chemical interactions between the deposition constituents and the substrate (3). The mismatch between the crystal lattice of the rhombohedral sapphire and the cubic silicon appears not to have been as limiting a factor (12) as was originally anticipated (2). The chemical reactivity of the spinel has proven to be a strong function of the chemical composition, which in turn is influenced by the method of growth (11). Very different semiconducting properties have been observed in silicon deposited on spinels with such subtle differences in the chemical composition that the lattice constants are very nearly the same (11). Here again, it is clear that the chemical reactivity between silicon (and H_2, the carrier gas) and the substrate predominates over lattice matching considerations. On the other hand, on the relatively unreactive flame fusion spinel, mobilities equivalent to bulk silicon mobilities have been measured in p-type 1.5 μm thick (111) silicon (10). This suggests that, under very specific conditions, the influence of lattice matching is seen. It is difficult to explain why the near bulk mobilities have not been achieved in other crystalline orientations or in n-type films; it may be a stress effect (8).

We have previously reported the properties of silicon deposited in a hydrogen atmosphere on Czochralski sapphire (3) and flame fusion spinel (3, 10), and of silicon deposited in a helium atmosphere on stoichiometric Czochralski spinel (12). In this paper the properties are summarized of silicon deposited in hydrogen on alumina-rich flame fusion spinel, stoichiometric Czochralski spinel, and a modified alumina-rich Czochralski spinel. These properties are compared with the characteristics of silicon deposited on sapphire, also in a hydrogen atmosphere.

Substrate Materials

The substrates employed in this study are:

(*i*) Czochralski sapphire (Union Carbide Corporation, Crystal Products Division, San Diego, California).

(*ii*) Czochralski spinel, nominally stoichiometric (*i.e.*, $MgO \cdot Al_2O_3$). The crystals are grown in an inert atmosphere with small additions of oxygen to suppress the formation of iridium (the crucible material) inclu-

Key words: heteroepitaxial growth, silicon on insulators, single-crystal sapphire and spinel, thin film semiconductor.

sions. In this report this spinel is referred to as stoic.-Czo. spinel. The crystals used in this study were both prepared in-house and at Union Carbide.

(*iii*) Czochralski spinel, alumina rich ($MgO \cdot xAl_2O_3$; $1 < x < 1.7$). These crystals are grown in-house in a high humidity ambient in an effort to simulate the chemical composition of flame fusion spinel (14). This material is referred to as the "modified" Czochralski spinel.

(*iv*) Flame fusion (f.f.) spinel, alumina rich ($x \sim 1.7$) grown in-house using procedures previously described (15).

Substrate Surface Preparation and Silicon Growth

Prior to deposition of the silicon, the polished sapphire (polished by Union Carbide or Insaco, Quakertown, Pennsylvania) is exposed to a hydrogen ambient for 30 min at 1300°C. During this treatment ~1 μm of material is removed from the surface (16, 17). The temperature is sufficiently high that annealing of the subsurface work damage also takes place (18). The polished flame fusion spinel (polished by RCA or Insaco) is exposed to hydrogen for 30 min at 1150°C. Both the modified and unmodified polished Czochralski spinel substrate wafers are air-annealed for 5 hr at 1500°-1600°C. This procedure is similar to that reported by Reisman *et al.* (19) for the stoic.-Czo. spinel.

The silicon is deposited in a pure hydrogen ambient using silane as the source gas. A growth temperature of 1000°C is used for the deposition of silicon on sapphire, and 1100°C for the deposition of silicon on spinel. The latter deposition temperature, which was considered to be optimum for the deposition of silicon on (111) spinel (10), was not changed for the deposition on the (100) spinel. In both cases, a deposition rate of 2 μm/min is employed. The substrates are placed on inductively heated pyrolytic carbon coated carbon susceptors in a quartz water-cooled growth ampul. Diborane is used as the p-type dopant source, and arsine is used as the n-type dopant source. Other details of the deposition method have been previously reported (3, 10).

It proved to be possible to reproducibly obtain highly reflective, clear silicon deposits. The high-temperature air anneal appeared to have alleviated the problems that had previously been experienced in obtaining clear samples on the stoichiometric Czochralski spinel. A hazy silicon surface always indicates a degradation in semiconducting properties, and is usually associated with either a leak in the deposition system or the incomplete removal of substrate subsurface work damage. No problems were experienced in surface crazing or substrate cracking with the alumina rich spinels or the sapphire substrates.

Hall Mobilities

The carrier mobilities are measured by the Hall method. The patterns are chemically etched in the silicon. Although this is a destructive method, considerably less scatter has been observed using the Hall method than the van der Pauw method (20). Just prior to making the Hall measurements, the silicon dioxide is stripped from the sample in an aqueous HF solution. This is done in order to provide a reproducible surface-state density. The Hall values reported here were gathered over a period of more than a year, and thus the scatter observed provides a measure of the long-term reproducibility. Except in the case of the stoichiometric Czochralski spinel, less scatter is observed if the films are deposited within a brief time period on a group of substrates prepared at the same time.

Under the conditions described, the mobilities observed on the three types of spinel are similar, and therefore the values have been grouped on one set of curves.

Typical hole mobilities, as a function of the hole concentration, are shown for 0.5 and 1.0 μm thick (100) silicon on (1̄102) sapphire (Fig. 1), (100) silicon on (100) spinel (Fig. 2), and (111) silicon on (111) spinel (Fig. 3). In order to facilitate comparison of these data, the curves presented in Fig. 1 are reproduced (without data points) in Fig. 2, and the curves of Fig. 2 are reproduced on Fig. 3. Due to the scatter observed in the Hall values the curves were not drawn by mathematical methods and are included only to facilitate a general comparison of mobilities of the two film thicknesses on the two substrate substances.

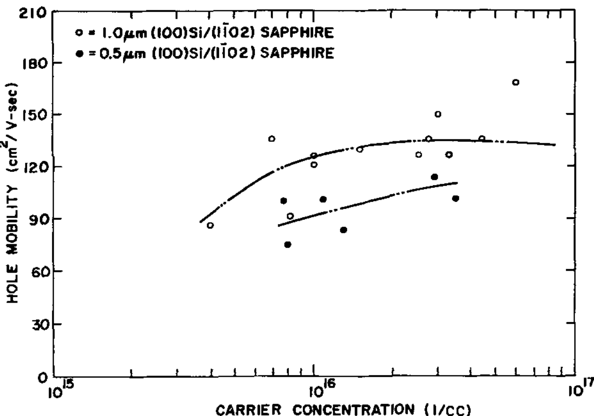

Fig. 1. Hall mobility as a function of hole concentration in 0.5 and 1.0 μm thick (100)Si/(1̄102)sapphire.

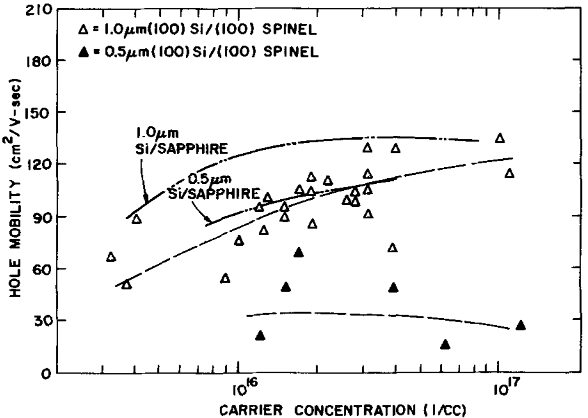

Fig. 2. Hall mobility as a function of hole concentration in 0.5 and 1.0 μm thick (100)Si/(100)spinel. Curves for (100)Si/(1̄102) sapphire are included (without data points) for reference.

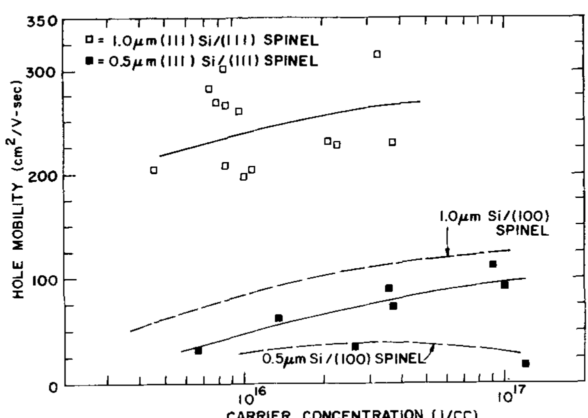

Fig. 3. Hall mobility as a function of hole concentration in 0.5 and 1.0 μm thick (111)Si/(111)spinel. Curves for (100)Si/(100) spinel are included (without data points) for reference.

Typical electron mobilities, as a function of the electron concentration, are shown for 0.5 and 1.0 μm thick (100) silicon on (1̄102) sapphire (Fig. 4), (100) silicon on (100) spinel (Fig. 5), and (111) silicon on (111) spinel (Fig. 6). As with the p-type data, the curves of Fig. 4 are superimposed on Fig. 5, and the curves of Fig. 5 are included in Fig. 6.

A summary of typical carrier mobilities at a carrier concentration of $\sim 1 \times 10^{16}/cm^3$ is presented in Table I.

It is informative to compare the electron mobilities in silicon deposited on the three types of spinel if they are all hydrogen annealed prior to silicon deposition. The electron mobilities in Si/f.f. spinel fall on the

Table I. Typical as-deposited carrier mobility values for 1.0 and 0.5 μm silicon on sapphire and silicon on spinel for a carrier concentration of $1 \times 10^{16}/cm^3$

Film thickness (μm)	Substrate composition and orientation	Mobility (cm^2/V-sec)	% of bulk
	p-type		
	Bulk silicon	350	
1.0	(100)Si/(1̄102)sapphire	120	34
0.5	(100)Si/(1̄102)sapphire	90	26
1.0	(111)Si/(111)spinel	240	69
0.5	(111)Si/(111)spinel	50	14
1.0	(100)Si/(100)spinel	80	23
0.5	(100)Si/(100)spinel	30	9
	n-type		
	Bulk silicon	1100	
1.0	(100)Si/(1̄102)sapphire	500	45
0.5	(100)Si/(1̄102)sapphire	430	39
1.0	(111)Si/(111)spinel	480	44
0.5	(111)Si/(111)spinel	200	18
1.0	(100)Si/(100)spinel	300	27
0.5	(100)Si/(100)spinel	140	13

curves shown above. Some electron mobilities in Si/modified Czo. spinel fall on the curves, but the values are scattered. It is difficult to obtain n-type Si/stoic.-Czo. spinel if the substrate is hydrogen fired. Air annealing of the Czo. spinel substrates has provided reproducibility in electron mobilities in the Si/modified spinel and has made it possible to achieve as-deposited n-type Si/stoic.-Czo. spinel.

Mobility values for (111)Si/(0001)sapphire are not shown here because the values are too low to be of interest in 1 μm thick films. Other investigators have achieved usable mobilities in (111)Si/(112̄0)sapphire (21). The electron mobilities in the 1 μm thick (annealed) (111)Si/(112̄0)sapphire appear to be similar to the values reported here for as-deposited 1 μm (111)Si/(111)spinel. Since (111)Si/(112̄0)sapphire hole mobilities are reported for thicker films (>2 μm), it is not possible to make meaningful comparisons with the hole mobility values reported here.

Recently considerable effort has been directed toward minimizing the changes in the semiconducting properties in the heteroepitaxial silicon during thermal oxidation (3, 22, 23). Exposure to dry O_2 for 1 hr at 1100°C has been taken as approximately equivalent to the thermal treatment employed during processing of the MOS transistor structures. In 1.0 μm silicon on both sapphire and spinel, for carrier concentrations greater than $\sim 2 \times 10^{16}/cm^3$, the carrier mobility typically changes by less than 10%, and the carrier concentration typically changes by less than a factor of 1.5 on thermal oxidation. In films less than 1 μm in thickness, and for carrier concentrations less than $2 \times 10^{16}/cm^3$, the magnitude of the changes on thermal oxidation are scattered and difficult to use as a "material quality" factor. Clear conclusions in this respect must be derived from device data.

Effective (MOST) Mobilities

Typical mobilities measured in MOS transistors fabricated in 1.0 and 0.5 μm thick (100) silicon on sapphire and spinel are shown in Table II. Leakage

Table II. MOS transistor characteristics in (100) silicon on sapphire and spinel

Substrate orientation and type	Silicon thickness (μm)	n-channel μ_{eff} (cm^2/V-sec)	n-channel I_L (A/mil $\times 10^{12}$)	p-channel μ_{eff} (cm^2/V-sec)	p-channel I_L (A/mil $\times 10^{12}$)
(1̄102) sapphire	1.0	420	150	210	170
	0.75	410			
	0.50	340	135		
(100) spinel)	1.0	350	150	210	95
	0.5	250	100		

μ_{eff} measured at $V_{gate} - V_{threshold} = 5V$ (+ or −, depending on the conductivity type).

currents (at 5V source drain) are also included in this table. The Hall characteristics of the (111) silicon on the (0001) sapphire have been too low to warrant fabrication of devices in these films, and insufficient data have been developed in devices fabricated in (111) silicon on (111) spinel to include here.

Discussion

Reproducibility—substrate type and surface treatment.—The sensitivity of the semiconducting properties to preparative variables is a strong function of the reactivity of the substrate to the deposition constituents (H_2, SiH_4, Si, and dopants) and the annealing ambient. It has been previously demonstrated that the stoic.-Czo. spinel reacts with hydrogen, and therefore, higher carrier mobilities are achieved on this substrate using helium as the carrier gas (12). A somewhat surprising result of the previous study was that good mobility values are obtainable in silicon deposited on unannealed stoic.-Czo. spinel. It was proposed that work damage was removed by reaction with the silicon (12). Good mobilities have been occasionally observed in silicon deposited in hydrogen on the unannealed stoic.-Czo. spinel. But when the substrate is not heat-treated prior to silicon deposition, the semiconducting properties, and the reproducibility of the properties, are critically dependent on the quality of the final surface finishing (11). An alternative procedure for the use of the stoic.-Czo. spinel is to anneal the surface in air and deposit the silicon in hydrogen. To date, however, using this procedure, the reproducibility in the semiconducting properties of deposited silicon has not been good, particularly for n-type films.

In respect to chemical reactivity, the modified Czo. spinel is more similar to flame fusion spinel than to the stoic.-Czo. spinel (14). Here the problem is more to achieve reproducibility in the chemical composition of the substrate material. While good semiconducting properties are achievable in silicon deposited in hydrogen on hydrogen annealed modified spinel, better reproducibility is realized on air annealed substrates. The flame fusion spinel has proven to be the least reactive of the spinels in a hydrogen ambient.

Hall mobilities, $n < 1 \times 10^{16}/cm^3$.—The decrease in the Hall mobilities with decreasing carrier concentration below $1 \times 10^{16}/cm^3$ in both p- and n-type silicon on sapphire and spinel has previously been attributed to scattering by space charge regions around crystalline heterogeneities (8, 24). It was proposed that as the carrier concentration decreases, the effective space charge region increases, resulting in degradation of the carrier mobility. More recently, Ham (25) has suggested that the effect is associated with depletion of the carriers in the thin lightly doped films by surface charges. If the films are partially depleted by surface charge, one cannot make the assumption that the current is evenly distributed throughout the thickness of the sample. For any fixed value of surface charge, as the carrier concentration decreases, the thickness of the layer depleted from the silicon/silicon dioxide interface increases and effectively the thickness of the layer in which the Hall measurement is made decreases. While the average mobility measurement is independent of thickness, in the silicon on the insulating substrates the mobility is degraded near the silicon/substrate interface (26) by the relatively high impurity content and poor crystallinity, and thus the net result is that the Hall mobility decreases with decreasing carrier concentration. The analysis of the measured carrier concentration in the lightly doped films is complicated not only by the possibility that the carrier concentration is a function of the film thickness (27), but also by the limitation of the current (by the space charge) to only a portion of the film while the entire film thickness is used in the calculation of the carrier concentration. Ham (25) has demonstrated the influence of the surface charge by measuring the Hall voltage in a gated structure in which the film can be biased to flatband. This provides "bulk" values (*i.e.*, values unaffected by surface charges) wherein it is assumed that the current flow is evenly distributed throughout the thickness of the sample. The mobility value of most interest is the effective MOS transistor mobility, in which carriers only within ~500Å of the silicon/silicon dioxide interface are active. Thus, significantly different values for the transport properties in the thin films may be derived using different measurement techniques. In the conventional (ungated) Hall measurement, the properties near the silicon/substrate interface are weighed in thin (<1 μm) lightly doped ($<1 \times 10^{16}/cm^3$) films. In the gated-Hall-bar measurement (when the film is biased to flatband) the characteristics derived represent an integrated value of properties throughout the thickness of the film. In the effective MOS transistor measurement, the properties near the silicon/silicon oxide interface are weighted. Gated-Hall-bar and MOS transistor measurements require the deposition of a clean oxide and considerable processing. Using these techniques, it is difficult to acquire feedback within the time frame practical in the development of deposition conditions. The unbiased Hall measurements can be made within minutes of a deposition run.

For the reasons outlined above, the Hall mobility *vs.* carrier concentration (unbiased) relationships cannot be used on an absolute scale to compare thin lightly doped film and bulk properties. On the other hand, if the surface charge is fixed immediately prior to the measurement by stripping the oxide in an aqueous HF solution (25), the Hall values are reproducible and characteristic of the specific deposition conditions, film thickness, and type of substrate. Thus, on a relative scale, the unbiased Hall values are useful in the development of deposition conditions and the choice of various film thicknesses and substrate orientations and types.

The optimization of the low carrier concentration thin heteroepitaxial silicon properties is of interest for application in deep-depletion MOS transistor geometries (3). It has been demonstrated that, particularly when spinel is used as the substrate material, the semiconducting properties of the low carrier concentration films are considerably more dependent on the deposition conditions than are the properties of the high carrier concentration films (10).

Hall and MOST mobilities, $n \sim 1 \times 10^{16}/cm^3$.—In order to avoid the ambiguities discussed above, in this section a comparison of Hall and MOST mobilities is made for films with a carrier concentration of $\sim 1 \times 10^{16}/cm^3$. Heteroepitaxial silicon with $n \geq 1 \times 10^{16}/cm^3$ is of interest for application in enhancement type CMOS transistor structures fabricated in silicon on sapphire by the "two-stage" method; *i.e.*, discrete n- and p-type silicon areas are deposited on the same substrate (3, 28).

Hall mobilities of 120 cm^2/V-sec are typically observed in 1 μm thick p-type (100)Si/($1\bar{1}02$)sapphire. On the other hand, the effective mobilities of MOS transistors fabricated in films of the same thickness are typically 210 cm^2/V-sec. While significantly lower Hall mobilities of 80 cm^2/V-sec are observed in 1 μm thick (100)Si/(100)spinel, the effective mobilities of MOS transistors fabricated in 1 μm thick silicon on the two substrates are similar. The mobilities in (100) silicon on spinel degrade more rapidly with decreasing film thickness than the (100) silicon on sapphire. In 0.5 μm thick films, hole mobilities are typically 90 cm^2/V-sec in (100)Si/($1\bar{1}02$)sapphire and 30 cm^2/V-sec in (100)Si/(100)spinel. Insufficient data have been collected in p-channel MOS transistors fabricated in the 0.5 μm thick (n-type) films to make meaningful comparisons between the effective device and Hall mobilities in these films.

Relatively high (Hall) hole mobilities of 240 cm^2/V-sec are typically observed in (111)Si/(111)spinel, but as in the case of the (100)Si/(100)spinel, the electrical properties are a strong function of the film thickness, and the mobilities drop to 50 cm^2/V-sec in 0.5 μm thick (111)Si/(111)spinel. The mobilities observed in (111)Si/(0001)sapphire are too low to be of interest, and other more favorable sapphire orientations for the growth of (111) silicon have not been pursued in this study.

As in the case of the hole mobilities, the effective electron mobilities in the 1 μm thick films of 420 cm^2/V-sec in (100)Si/($1\bar{1}02$)sapphire and 350 cm^2/V-sec in (100)Si/(100)spinel are more similar than the Hall electron mobilities of 500 cm^2/V-sec and 300 cm^2/V-sec, respectively. The effective n-channel mobilities are lower than the Hall electron mobilities in (100)Si/($1\bar{1}02$)sapphire, but slightly higher in (100)Si/(100)spinel. This same trend in electron mobilities is observed in the 0.5 μm thick silicon, except that with the degradation of the Hall electron mobilities in the thinner (0.5 μm) (100)Si/(100)spinel, the effective p-channel value of 250 cm^2/V-sec is 1.8× the Hall electron mobility of 140 cm^2/V-sec. The corresponding values in the 0.5 μm thick (100)Si/($1\bar{1}02$)sapphire are: p-channel mobility, 340 cm^2/V-sec; and Hall electron mobility, 430 cm^2/V-sec.

While the Hall hole mobilities in 1.0 μm thick (111)Si/(111)spinel were double the values observed in (100)Si/($1\bar{1}02$)sapphire, this relationship does not hold up in the n-type films. The Hall electron mobility in 1.0 μm thick (111)Si/(111)spinel of 480 cm^2/V-sec is very similar to the values typically observed in (100)Si/($1\bar{1}02$)sapphire of 500 cm^2/V-sec. As was previously observed, the Hall mobilities in the silicon on spinel are a strong function of the thickness, and the Hall electron mobility of 200 cm^2/V-sec in 0.5 μm (111)Si/(111)spinel is less than half of that observed in the 1.0 μm thick film.

Since the unbiased Hall mobility measurement is weighted by the properties of the material near the silicon/substrate interface, and the (enhancement mode) device measurement is characteristic of the carrier mobilities only within ~500Å of the silicon surface most remote from the silicon-substrate interface, it is not unexpected that the device mobilities are significantly higher than the Hall mobilities for holes in silicon on both sapphire and spinel, and for electrons in silicon on spinel. It is difficult to explain, however, why the n-channel device mobilities in the silicon on sapphire are lower than the Hall electron mobilities measured in equivalent films. It cannot be attributed to the effect of oxidation during device processing, since in general the Hall electron mobilities increase as the compensating aluminum autodoping is deactivated during thermal oxidation (17, 23). In general, however, processing results in the degradation in the carrier mobility even in bulk silicon devices. If the effective (electron) mobility is expressed in terms of the per cent of the mobility commonly observed in MOS transistors fabricated in bulk silicon (~500 cm^2/V-sec) (4), it is found that the per cent of bulk device mobilities in the transistors fabricated in 1.0 μm silicon on sapphire is in excess of 80%, and in 1 μm thick silicon on spinel ~70%. The effective hole mobilities in the 1 μm thick films are similar to the mobility commonly observed in fabricated devices (~200 cm^2/V-sec) (4). Thus, on this basis, the per cent of bulk device mobility values are considerably in excess of the per cent of bulk Hall mobilities.

It is interesting to note that the Hall mobilities in 0.5 and 1.0 μm thick films are more similar in silicon on sapphire than in silicon on spinel. This can be explained on the basis of the differences in the nature of film growth prior to complete coverage of the substrate surface. We have demonstrated previously that the primary reaction which leads to the contamination of the silicon is the chemical reduction of the substrate by silicon (12). Since the reaction products are gaseous, the contamination of the growing film takes place primarily during the period prior to complete coverage of the substrate, and is stopped as the substrate is completely covered and the evolution of gaseous reaction products is blocked off (3). Therefore, the thickness of the heavily contaminated silicon layer adjacent to the substrate can be related to the thickness at which complete coverage of the surface is realized. Under the deposition conditions employed in this study, the surface of the sapphire is completely covered at film thicknesses of ~300Å, while the surface of the spinel is typically covered at a silicon thickness of ~1000Å. It is reasonable to assume that the semiconducting properties improve as the level of contamination by substrate reaction products decreases, and thus the semiconducting properties of the 0.5 μm thick silicon are more similar to the properties of the 1.0 μm thick films on sapphire than on spinel. The reason for the striking differences in the nature of the early growth on the two substrate materials is the subject of current investigation.

Application

Within this organization sapphire is the favored substrate material because of the advantages realized in processing devices in the very thin (<1 μm) (100) heteroepitaxial films. The commercial availability of single-crystal sapphire from a number of sources is also a factor in the choice of sapphire as a substrate material. Interest continues in the silicon-spinel system for special applications of heteroepitaxial semiconductor structures, particularly where other cubic materials (such as the III-V compounds) are included in the device structure and latitude in the choice of cubic orientations is desirable (29). In these applications carrier mobility within the silicon is not specifically the desired property, but good crystallinity is essential, and mobility has been used as a sensitive measure of the crystalline perfection.

Summary

The Hall and effective device mobilities of 0.5 and 1.0 μm thick heteroepitaxial silicon on sapphire and spinel are compared. Larger differences are observed in the Hall mobilities than in the device mobilities. The surface reactivity of the Czochralski spinel can be suppressed by growth of the crystal in a high humidity atmosphere. The differences in the chemical nature of the spinel prepared by the various growth techniques to a large extent can be "leveled" by predeposition surface treatments. The Hall mobilities in 1 μm thick p-type (111)Si/(111)spinel are ~2× the mobilities observed in (100)Si/($1\bar{1}02$)sapphire, but in n-type films the corresponding mobilities are similar. The Hall mobilities in the (100)Si/($1\bar{1}02$)sapphire are higher than in (100)Si/(100)spinel for 0.5 and 1.0 μm, n- and p-type films. The Hall mobilities in 0.5 and 1.0 μm thick films are more similar in silicon on sapphire than in silicon on spinel. This can be related to the observation that, under the deposition conditions employed, the surface of the sapphire is completely covered at a thickness of ~300Å, while the surface of the spinel is covered at a thickness of ~1000Å.

Acknowledgments

The MOS transistors were fabricated and characterized by W. W. Clauhs. Spinel substrate crystals were prepared by Messrs. S. Bolin, J. Creamer, H. Temple, and A. Wasielewski.

ABSTRACT

The solubility of gold has been measured in phosphorus-doped silicon by the method of oxide encapsulation. At high phosphorus concentrations an enhanced solubility was observed. This enhanced solubility is extremely temperature dependent, increasing from a factor of 1.4 at 1200°C to $\simeq$15 at 800°C in silicon doped with 4×10^{19} phosphorus/cm^3. A reasonable agreement has been obtained between the measured enhancement and that calculated using the Shockley-Moll theory.

The effect of gold on the electrical properties of silicon is of technological importance in the semiconductor device field. Gold introduces two known energy levels in silicon; a donor at $E_v + 0.35$ eV and an acceptor at $E_c - 0.54$ eV (1). These levels act as effective recombination centers (2) with the charge state determining the recombination process. Hence, when gold can be controllably introduced into silicon it is possible to effectively control the minority carrier lifetime. This has application in high speed switching transistors. However, when gold is present as an unwanted and uncontrolled contaminant, device parameters can be seriously degraded. Surface contamination of silicon with gold has been observed on wafers that have been subjected to normal processing procedures (3, 4). In a previous paper (5), the authors have shown that gold plates out of a standard HF solution to the extent that one monolayer of gold will form in minutes over the surface of a silicon wafer immersed in 10 ml of HF solution contaminated with gold to 1 ppm by weight.

Most metals exhibit a retrograde solubility in silicon. This has also been observed for gold in silicon by Collins *et al.* (1). Therefore in device processing, where each diffusion step is at a lower temperature than the preceding one, gold present to the limit of solid solubility during an earlier step would be expected to form precipitates in the bulk or to be rejected to the surface due to the high diffusion coefficient. Hence, accurate knowledge of the solubility of gold in doped silicon would be very desirable. Much work has already been carried out in this area (1, 6-8) but there is substantial disagreement between published data. The fact that gold can reside both interstitially and substitutionally in the silicon lattice is partially responsible for such disagreement. The work

Key words: silicon, gold, solubility, enhancement, encapsulation.

of Struthers (7) and Collins *et al.* (1) give values of the solubility which Wilcox and LaChappelle (9) determined to be the substitutional solubility. The earlier work of Struthers (6) and data given by Boltaks *et al.* (8) appear to be incorrect due to incomplete equilibration.

Additional complications arise since gold solubility is dependent on the initial impurity type and concentration in silicon. An enhanced gold solubility has been observed by Wilcox *et al.* (10) in silicon containing a high phosphorus concentration. Joshi and Dash (11) and Cagnina (12) found a similar effect. In two cases (10, 11) good agreement was found between this enhancement and the Reiss (13) and Shockley-Moll (14) theories in which the solubility is dependent on the position of the Fermi level. The even greater enhanced solubility found by Cagnina (12) was interpreted as due to the formation of an Au-P compound in addition to the electronic effect resulting from the position of the Fermi level.

Dorward and Kirkaldy (15) argued that if enhanced solubility occurred in heavily doped n-type silicon, then a reduced solubility should be observed in silicon doped heavily p-type. Their experimental observations showed a 40% reduction in the solubility of gold in silicon doped with 10^{19} boron atoms/cm^3 over that doped with $\sim 10^{13}$ boron atoms/cm^3. In contrast, Gubenko and Shmelev (16) observed enhanced solubility of gold in silicon doped with Ga at concentrations of $10^{17} - 4 \times 10^{19}$/cm^3. This enhancement is probably due to high mechanical stress within the samples.

It was felt that there was considerable scope for further work in this area especially if some of the problems from which previous work suffered could be eliminated. The data presented in this paper was obtained using an oxide encapsulation technique in which the equilibrated sample is encapsulated in a thermally grown oxide. The oxide prevents gold loss on cooling and reduces errors resulting from high concentrations of residual surface gold.

Oxide Encapsulation

Shown below are the diffusion coefficients for gold in silicon (assuming a vacancy-controlled mechanism) and for silicon dioxide

Silicon (9)

$$D = 4 \cdot 10^{-9}\ \text{cm}^2/\text{sec at } 1000°\text{C}$$
$$D = 2.5 \cdot 10^{-7}\ \text{cm}^2/\text{sec at } 1200°\text{C}$$

Silicon dioxide (17)

$$D = 3 \cdot 10^{-18}\ \text{cm}^2/\text{sec at } 1000°\text{C}$$
$$D = 10^{-15}\ \text{cm}^2/\text{sec at } 1200°\text{C}$$

Also, the solid solubilities at 1100°C of gold in silicon and silicon dioxide are 3×10^{16}/cm^3 (1) and 3×10^{14}/cm^3 (18), respectively. Hence, if following the equilibration step, an oxide is grown on the silicon surface, problems related to gold migration toward the surface during cooling should be minimized without having to resort to quenching procedures.

In the present experiments, prior to removal from the furnace, the equilibrated sample was oxidized in dry oxygen to form about 1000Å of SiO_2. During the formation of the oxide, most of the excess gold remaining on the silicon surface is rejected to the oxide surface from which it can easily be removed in aqua regia. Measurements of the gold distribution throughout the Si-SiO_2 (5) system show an accumulation of gold in the interface region. This accumulated gold lies in the oxide layer and is distributed over a region $\sim$200Å from the silicon surface.

Measurements of the gold in the silicon indicate no depletion of gold near the interface when excess gold is present before oxidation. The interfacial gold is therefore part of the excess gold and is removed with the oxide before measurements are made. Because no gold is removed from the silicon following equilibration, the measurements remain accurate regardless of the final distribution of the gold within the silicon itself.

Experimental

In order to avoid some of the errors made in earlier measurements, the time required to saturate the silicon with gold was experimentally determined. Slices of silicon had their surfaces coated with gold containing some radioactive Au^{198}. The gold was then diffused for times ranging from 1 hr to 1 week depending on the diffusion temperature. In Fig. 1, the equilibration data is given for a 0.008 in. thick silicon wafer diffused with gold at 1050°C. The experimentally determined, time-dependent gold concentration in the silicon was accurately described by the vacancy controlled diffusion coefficients of Wilcox and LaChappelle (9). It was found that 95% of the solid solubility at 1050°C was reached after 24 hr. The times required to reach 95% saturation were determined for all temperatures of interest. In the case of diffusion at 800°C, the silicon sample was thinned to 0.002 in. prior to diffusion. Also, samples containing a high concentration of phosphorus were thinned down to 0.004 in. and the diffusion times increased to compensate for the expected increase in the gold solubility limit. The diffusions were carried out in a nitrogen atmosphere. Following the diffusion step each sample was oxidized as indicated in the oxide encapsulation technique.

Surface damage can effect the solubility of gold in silicon. Figure 2 shows the profiles of gold in the sur-

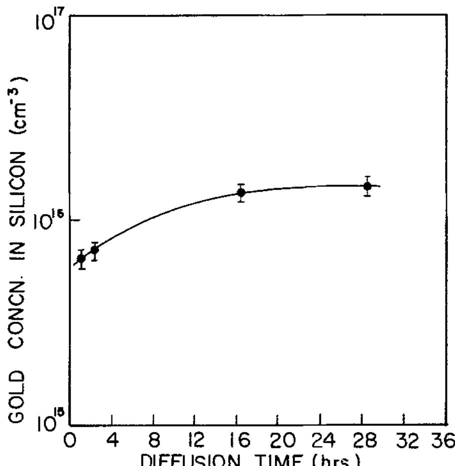

Fig. 1. Equilibration of gold in silicon at 1050°C

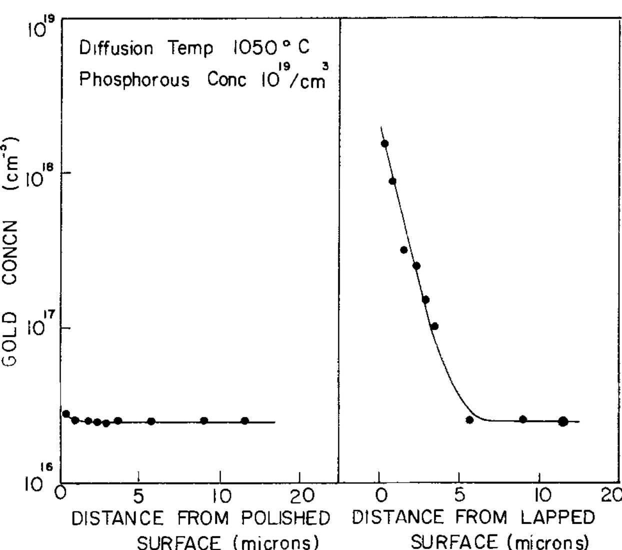

Fig. 2. Distribution of gold at a polished and a lapped silicon surface.

face region for a lapped and a polished surface. In order to avoid errors arising from damage enhanced solubility in the surface layer all samples were prepared with polished surfaces only. Each wafer was counted front and back and again after removal of 12μ of silicon to check that indeed no damage enhancement of the solubility was present.

The gold concentration in the sample was determined by β-particle counting. With β-particle counting it is necessary to correct for attenuation of the radiation due to the distributed nature of the source. The sample was counted with the front and back surfaces alternately facing the detector. If the counts measured were C_F and C_B, then the total count, N, corresponding to all the gold atoms in the sample is given by

$$N = F(C_F + C_B)/2$$

where F is the correction factor for the distributed source. For a uniformly distributed source

$$F = t\lambda/[1 - \exp(-\lambda t)]$$

where t is the sample thickness (cm) and λ is the β-particle absorption coefficient which was measured to be = 50.41 cm^{-1}. The F factor was evaluated for the extremes of nonuniformity in source distribution and was found to vary by less than 4% from the uniform case.

Results and Discussion

The solid solubility of gold in silicon, in the temperature range 1000°-1200°C is shown in Fig. 3 for silicon initially doped with phosphorus to the levels 5.5 $\times 10^{14}$ and $4 \times 10^{19}/cm^3$. The enhanced gold solubility in the heavily doped sample is clearly evident. In the temperature range considered, the solubility was investigated for initial phosphorus doping levels of 5.5×10^{14}, 4.5×10^{15}, 1.2×10^{17}, 10^{19}, and $4 \times 10^{19}/cm^3$. For temperatures above 1000°C, solubility enhancement was observed only in the $4 \times 10^{19}/cm^3$ phosphorus doped sample.

A solubility enhancement factor R_S is defined as

$$R_S = \frac{\text{gold solubility in heavily doped sample}}{\text{gold solubility in a reference sample}}$$

For the current experiments, the solubility in $5 \times 10^{14}/cm^3$ doped silicon was used as the reference level.

In Fig. 4, the solubility enhancement factor is given over the temperature range 1000°-1200°C in silicon doped with 4×10^{19} phosphorus atoms/cm^3.

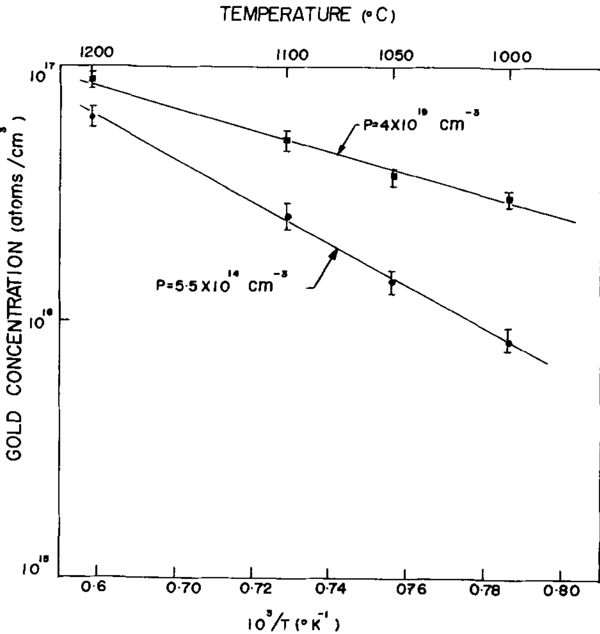

Fig. 3. Measured solubility of gold in phosphorus-doped silicon

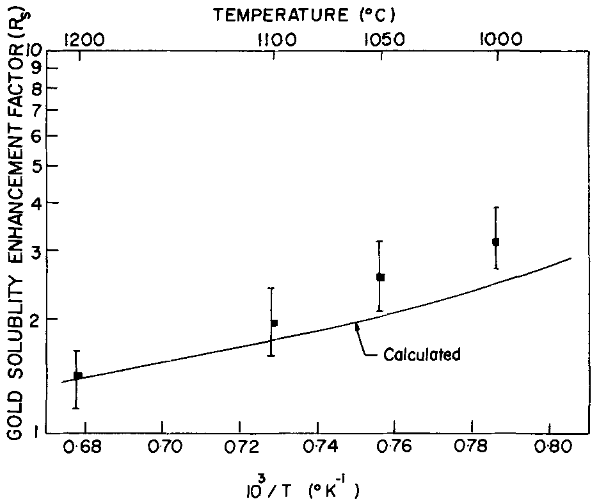

Fig. 4. Temperature dependence of the solubility enhancement of gold in silicon doped with 4×10^{19} phosphorus atoms/cm^3.

Reiss *et al.* (13) have shown that the solubility of impurities in semiconductors may depend on the charge state of the impurity. This idea was further developed by Shockley and Moll (14) such that the total concentration of gold can be written as

$$N_{Au} = \sum_{j=0}^{2} N_{Au}(j) \quad [1]$$

where

$$\frac{N_{Au}(j)}{N_{Au}} = \frac{g(j)\exp\{(jE_F - E(j))/kT\}}{\sum_{j=0}^{2} g(j)\exp\{(jE_F - E(j))/kT\}} \quad [2]$$

where $N_{Au}(j)$ is the concentration of gold centers occupied by j-electrons and $g(j)$ and $E(j)$ are the degeneracies and total energies of such centers, respectively (20).

Since the theory postulates that $N_{Au}(1)$, the neutral center concentration is independent of the Fermi level position, Eq. [2] may be used to express the $N_{Au}(j)$ in terms of $N_{Au}(1)$

$$N_{Au}(j)/N_{Au}(1) = \{g(j)/g(1)\}\exp\{((j-1)E_F) - (E(j) - E(1))/kT\} \quad [3]$$

If $N_{Au}{}^R$ and $N_{Au}{}^F$ are the solubilities in the reference and test samples respectively, Eq. [1] and [3] yield the solubility ratio R_S

$$R_S = N_{Au}{}^F/N_{Au}{}^R$$

R_S was calculated using the parameters

$$g(0) = 1, g(1) = 4, g(2) = 6$$

The energy levels were assumed referenced to a linearly extrapolated energy gap of 1.205 eV at 0°K

$$E(0) = (0.35 + E_V) \text{ eV at } 0°K$$

$$E(2) = (0.97 + E_V) \text{ eV at } 0°K$$

and were assumed to maintain the same relative location in the gap at other temperatures (21, 22).

The degeneracy factors are those corresponding to a simple valence bond model of the gold center, forming 0, 1, and 2 bonds in the donor, neutral, and acceptor states. These values correspond to $g = 3/2$, $g = 1/4$, $E_A = 0.54$ eV, and $E_D = 0.35$ eV in the Shockley and Last notation (23).

The Fermi level was computed using the modified band model described by Barber (24) and extended by Heasell (25). Shallow level excited states were in-

cluded and an empirical adjustment made for the doping dependence of activation energies (26).

The results of one such calculation are shown in Fig. 4. It can be seen that the experimental results show a slightly greater rate of solubility enhancement than predicted on the Shockley-Moll theory.

Samples were also diffused at 800°C. A comparison of calculated and measured enhancement factor as a function of phosphorus doping is shown in Fig. 5. It can be seen that enhancement now occurs at the 10^{18} phosphorus atoms/cm^3 level.

In some samples a phosphorus diffusion was also carried out at 1050°C at the same time as the gold diffusion. The surface concentration of phosphorus in the diffused layer was $10^{21}/cm^3$. According to the present model an enhanced solubility factor of $\simeq 70$ might be expected taking a mean phosphorus concentration throughout the diffused layer of $5 \times 10^{20}/cm^3$. Etching of the first 2μ of surface (*i.e.*, the phosphorus diffused layer), a gold concentration of 1.25×10^{18} atoms/cm^3 was observed in the diffused layer. This represents an enhancement factor of 80.

In almost all the measurements the enhanced solubility was slightly greater than that predicted by the model used.

The effects of the gold concentration on the electrical resistivity were also measured. For the samples with initial phosphorus concentrations of $1.2 \times 10^{17}/cm^3$ and greater, gold concentrations of $8 \times 10^{16}/cm^3$ had no measurable effect. At lower values of phosphorus concentration, the resistivity varied drastically. The results are shown in Fig. 6 compared with the recent theoretical results of Bullis (19). With an initial phosphorus concentration of $5 \times 10^{14}/cm^3$ the silicon converts to p-type when the gold concentration reaches $\sim 6 \times 10^{15}/cm^3$. At 4.5×10^{15} phosphorus atoms/cm^3, conversion to p-type occurs with a gold concentration of $\sim 1.5 \times 10^{16}/cm^3$.

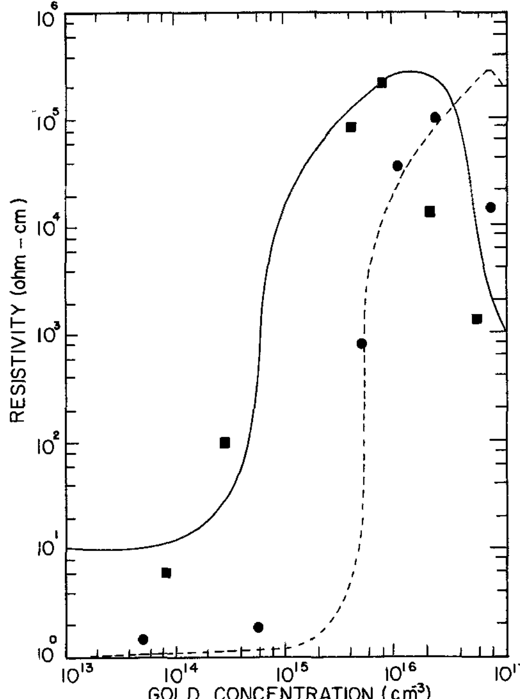

Fig. 6. Effect of gold concentration on the electrical resistivity for silicon with phosphorus concentrations of $5.5 \times 10^{14} cm^{-3}$ (■) and $4.5 \times 10^{15} cm^{-3}$ (●). The lines give the extrapolated theoretical dependence given by Bullis (19).

Summary and Conclusions

Solid solubility measurements were carried out by encapsulating gold in silicon by growing a 1000Å thick layer of SiO_2 over the sample following the diffusion step. This method allowed the total gold taken up by the silicon at the diffusion temperature to be determined and eliminated the need to quench the samples.

The time required to equilibrate the silicon wafers indicated that the vacancy controlled process was the diffusion mechanism.

Phosphorus doping of the silicon resulted in enhanced solid solubility for the gold. A reasonable agreement between the experimental results and the Shockley-Moll theory was obtained. It is not certain whether this mechanism alone accounts for the total enhancement. Uncertainties arise in the calculated values of enhancement since the degeneracy factors and temperature dependence of the energy levels of the gold states are not accurately known. It is possible that ion-pairing or compound formation may be occurring (*e.g.*, Au^{-}-P^{+}). However, if this were a substantial effect, the gold acceptor level would be neutralized and agreement between the gold radiotracer measurements and the electrical compensation would not have been obtained.

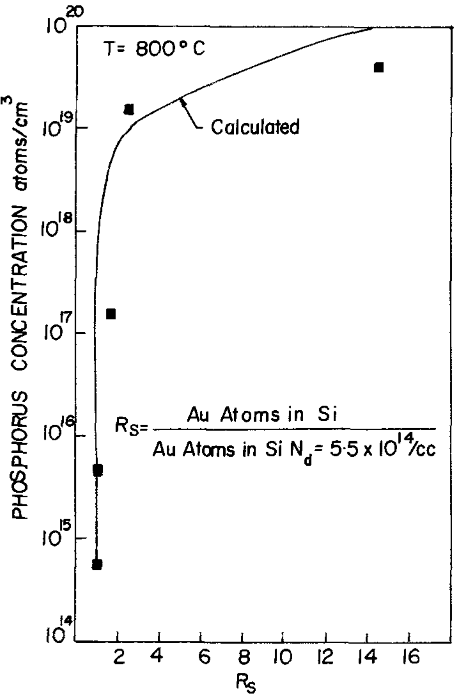

Fig. 5. Solubility enhancement factor at 800°C for gold as a function of phosphorus concentration. The calculated dependence is shown for comparison.

The Incorporation of Phosphorus in Silicon Epitaxial Layer Growth

J. Bloem,* L. J. Giling, and M. W. M. Graef

University of Nijmegen, Laboratory of Physics, Department of Solid State Chemistry, Toernooiveld, Nijmegen, Holland

ABSTRACT

A study has been made of the mechanism governing the incorporation of phosphorus during epitaxial growth of silicon. Several possibilities are mentioned and it is shown that the position of the Fermi level in the solid and the equilibria in the gas phase determine the outcome of the experiment. When PH_3 in H_2 is used as a dopant at the temperatures of interest, P, P_2, P_4, PH, and PH_2 are present also. It is shown that there is a close correlation between the partial pressure of monoatomic P in the gas and the phosphorus concentration in the solid as long as intrinsic conditions apply. Only at high dopant concentration ($P > 3 \cdot 10^{19}$ cm^{-3}) and low temperature ($T < 1500$°K) does the influence of the position of the Fermi level become important.

The incorporation of phosphorus in epitaxial silicon layers grown from the vapor phase has been studied in considerable detail by many workers (1-5). For low partial pressures of the dopant (mostly in the form of phosphine, PH_3), the concentration of phosphorus atoms in silicon is proportional to the partial pressure of the phosphine gas present in the gas mixture, and the slope of a log-log plot of the P^+ concentration in the solid ($[P^+]$) *vs.* the initial (input) phosphine partial pressure ($p^{o}_{PH_3}$) is 1.0. At higher PH_3 pressures a deviation is found and the slope changes from 1.0 to 0.5. A number of explanations have been given for this behavior, of which the most important are: (*i*) variation of growth rate which may influence the dope concentration; (*ii*) clustering of phosphorus in the silicon matrix during cooling, which causes a decrease of the concentration of charge carriers and thus flattening of the curve; (*iii*) transition from intrinsic to extrinsic conditions at high donor concentrations; and (*iv*) the degree of aggregation of phosphorus in the gas mixture.

As yet no clear picture exists as to which effect is dominating. In order to elucidate which mechanism is responsible for the incorporation, a series of precise measurements was started.

Experimental

Silicon doped with phosphorus was epitaxially grown in a horizontal water-cooled reactor having an effective cross section of 12 cm². Substrates were one-side polished p-type Czochralski-grown silicon wafers with a resistivity between 2 and 5 ohm-cm. The orientation of the surface was 3° from the (111)-plane in the nearest <110>-direction. The slices were placed on a SiC-coated graphite susceptor and heated by means of a rf coil. Epitaxial growth was performed by silane, SiH_4, using H_2 as a carrier gas at a velocity of 42 cm/sec. The SiH_4 partial pressure was kept at a constant value of 2.2×10^{-3} atm giving a growth rate of 0.45 μ/min. PH_3 was used as a dopant gas at pressures varying between 10^{-10} and 10^{-3} atm. The purity of the hydrogen gas was continuously controlled ($O_2 < 1$ ppm and $H_2O < 2$-3 ppm).

Before any growth experiment the Si surface was etched *in situ* for 1 min by 1% HCl at 1400°K. The composition of the gas mixture was monitored and controlled by calibrated flow meters. Temperature measurements were made during the reaction, using a calibrated Leeds and Northrup optical pyrometer, and corrected for the emissivity of silicon and for the reflection and absorption of the epitaxial system.

The epitaxial layer thickness was measured using a bevel and stain technique; the layer thicknesses were kept between 4.5 and 8.5 μm. The resistivity of the layers was determined at room temperature by the four-point probe technique; carrier concentrations were calculated using Irving's (6) mobility data. The phosphorus concentration in the crystal is then assumed to be equal to the number of free electrons measured at room temperature (5).

Results and Discussion

The experimental data from experiments at 1400°, 1500°, and 1600°K are collected in Fig. 1, where the

logarithm of the concentration of incorporated phosphorus is plotted against the logarithm of the initial phosphine partial pressure. The experimental points were obtained over a period of several months and the reproducibility of the data is considered to be within ± 10%. Essentially one can consider the curves to be constructed from straight lines with one or two breaks. The principal interest concerns the slope of the lines and the origin of the change of this slope at the breaks. At low PH_3 pressures the slope is unity, at higher pressures the slope changes to 0.5 This change in slope occurs at lower values of $[P^+]$ for higher temperatures. Further it can be noticed that at 1400°K for partial pressures of PH_3 exceeding 10^{-5} atm a second change in slope from 0.5 to 0.25 occurs.

Concerning the mechanism of incorporation of phosphorus in silicon the following possibilities are present.

Effects in the solid.—(*i*) Regarding the correlation between the incorporation of phosphorus and the growth rate of silicon, Rai-Choudhury and Salkovitz (2) found that the Si deposition rate does not influence the doping level. Bloem (7), however, showed that growth rates higher than 1 μ/min caused an appreciable increase in phosphorus concentration in the solid, using a constant PH_3 pressure in the gas phase. In order to prevent this type of kinetic effects and to be able to study the equilibrium segregation of P in Si, a growth rate of 0.45 μ/min was chosen by using a constant SiH_4 partial pressure of 2.2×10^{-3} atm. (At the highest PH_3 concentrations the growth rate appeared to be 10% less.)

(*ii*) A second reason for the flattening of the curve at high PH_3 pressures is the clustering of phosphorus in the silicon upon cooling, which would cause a decrease in the number of electrically active P atoms. Nakanuma (5) showed by radiotracer analysis a one to one correlation between the total concentration of P and the conductivity of the layers, thus making clear that clustering of P can be neglected for concentrations as high as 3×10^{19} atoms/cm³ at least. The experimental data of Nakanuma are in good agreement with the present results.

(*iii*) The change from intrinsic to extrinsic conditions in the solid will cause a change in the slope of log $[P^+]$ *vs.* log p_{PH_3} with a factor two which follows from the ionization equilibrium of phosphorus in the silicon matrix together with the appropriate equilibrium constant

$$PH_3(g) \rightleftarrows P(s) + 3/2H_2(g) \quad K_a = [P] \cdot p_{H_2}^{3/2}/p_{PH_3}$$
$$P(s) \rightleftarrows P^+(s) + e \quad K_b = [P^+] \cdot n/[P]$$

giving

$$[P^+] = K_b[P]/n = K_aK_b\, p_{PH_3}/(n \cdot p_{H_2}^{3/2})$$

for $p_{H_2} \approx 1$ atm this becomes

$$[P^+] = K_aK_b p_{PH_3}/n$$

For intrinsic conditions $n = k_i^{1/2}$, k_i being the intrinsic constant and $[P^+] \sim p_{PH_3}$, whereas for extrinsic conditions with $[P^+] = n$, $[P^+] \sim p_{PH_3}^{1/2}$ (8). In the results presented in Fig. 1 it is seen that the change in slope from 1.0 to 0.5 is found at a lower value of $[P^+]$ for higher temperatures which is in disagreement with a behavior, based on an intrinsic-extrinsic conversion. Moreover, according to Morin and Maita (9) the intrinsic concentrations at the temperatures used are: 3×10^{19} cm^{-3} at 1400°K, 6×10^{19} cm^{-3} at 1500°K, and 1.2×10^{20} at 1600°K, much higher than the value of 10^{18} encountered here. Later in this section it will be shown that the break in the curve from 0.5 to 0.25 for 1400°K at high concentrations could be due to this intrinsic-extrinsic transition.

Effects in the gas phase: thermodynamic discussion.—In the foregoing it has been shown that reactions in the solid cannot explain the main features of the experimental data, therefore the gas phase has to be given closer attention. Rai-Choudhury (2, 3) and Hurle *et al.* (4) performed calculations of the gas phase composition of various phosphorus compounds in hydrogen; however, they did not take into account the presence of PH_3 and monoatomic P, P_4, PH, and PH_2, respectively.

These compounds are stable at the temperatures of interest and are present in concentrations high enough to be of considerable importance. The possible occurrence of other phosphorus-containing compounds, such as PSi, PSi_2, PH_2SiH_3, $PSiH_3$, P^+, P_2^+, etc., is likely to be of minor importance. At least this seems to follow from the present state of knowledge about the relevant thermodynamic data.

Using the most recent JANAF data (10) the equilibrium concentration in hydrogen of P, P_2, P_4, PH, PH_2, and PH_3 were computed as a function of the input concentration of PH_3 at the temperatures of interest. It is assumed, because of the low growth rate which is being used, that equilibrium in the gas phase is attained near the silicon surface, and that transport effects are of minor importance. In that case a thermodynamical approach is allowed.

The equilibria in which the above-mentioned phosphorus components are present may be described by the following reactions and equilibrium constants

$$PH_3 \rightleftarrows 1/2P_2 + 3/2H_2 \quad K_1 = p_{P_2}^{1/2}\, p_{H_2}^{3/2}/p_{PH_3} \quad [1]$$
$$1/2P_2 \rightleftarrows P \quad K_2 = p_P/p_{P_2}^{1/2} \quad [2]$$
$$2P_2 \rightleftarrows P_4 \quad K_3 = p_{P_4}/p_{P_2}^2 \quad [3]$$
$$1/2P_2 + 1/2H_2 \rightleftarrows PH \quad K_4 = p_{PH}/(p_{P_2}^{1/2} \cdot p_{H_2}^{1/2}) \quad [4]$$
$$1/2P_2 + H_2 \rightleftarrows PH_2 \quad K_5 = p_{PH_2}/(p_{P_2}^{1/2} \cdot p_{H_2}) \quad [5]$$
$$1/2H_2 \rightleftarrows H \quad K_6 = p_H/p_{H_2}^{1/2} \quad [6]$$
$$Si(s) \rightleftarrows Si(g) \quad K_7 = p_{Si} \quad [7]$$
$$Si(s) + 1/2H_2 \rightleftarrows SiH \quad K_8 = p_{SiH}/p_{H_2}^{1/2} \quad [8]$$
$$Si(s) + 2H_2 \rightleftarrows SiH_4 \quad K_9 = p_{SiH_4}/p_{H_2}^2 \quad [9]$$

The composition of the system is now solved by means of an iterative computer procedure subject to the conditions that (*a*) the sum of all the partial pressures remains 1 atm, (*b*) the silicon partial pressure is determined by its solid-vapor equilibrium, and (*c*) the phosphorus-hydrogen ratio is determined by the input quantities of PH_3, SiH_4, and H_2. The various equilibrium constants which are used are collected in Table I.

Calculations were made for the partial pressures of P, P_2, P_4, PH, PH_2, PH_3, H_2, H, SiH_4, SiH, and Si. The results are presented in Fig. 2. Over the range of initial

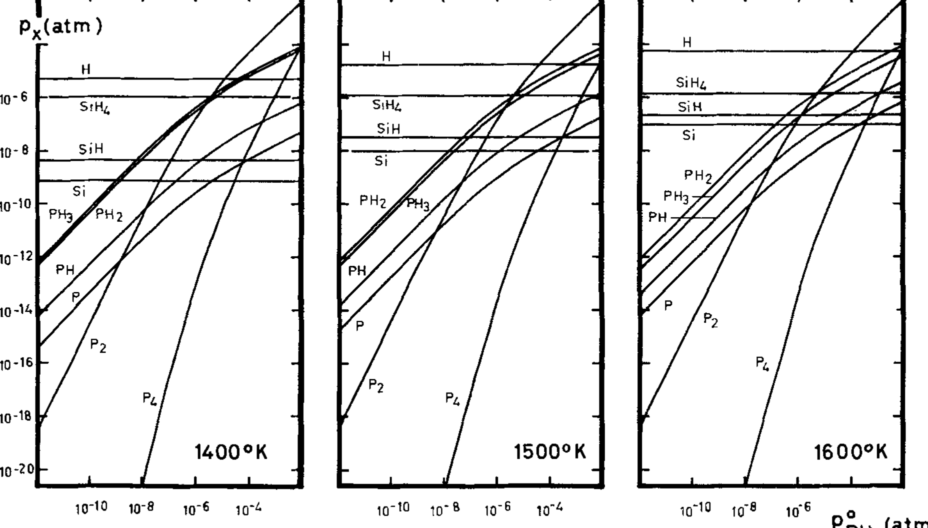

Fig. 2. Computed curves giving the equilibrium partial pressures of the components of the gas mixture vs. the initial partial pressure of PH_3 (p^oPH_3) for three temperatures.

phosphine partial pressures that were considered in these experiments, the main gas components at low pressures appear to be PH_3 and PH_2; at higher initial pressures P_2 has the highest partial pressure. The most significant feature however is that the calculated profiles of P, PH, PH_2, and PH_3 are completely analogous to what empirically has been found for the incorporation of P in the silicon matrix. Since the concentrations of all phosphorus-containing compounds are related by equilibrium equations one is permitted to consider the segregation as originating from one of these compounds. In addition as there is no evidence for the presence of P_2, P_4, PH, PH_2, and PH_3 in the solid state, the segregation of phosphorus in the silicon matrix is best correlated with the vapor pressure of monoatomic P in the gas phase according to

$$P(g) \rightleftarrows P(Si)$$

The calculated results for monoatomic phosphorus are collected in Fig. 3. These curves are in good agreement with the shape of the experimental curves found at the three temperatures (Fig. 1). Attention must be given to the fact that the relative order of the curves is different: the monoatomic phosphorus pressure increases with increasing temperature (Fig. 3), whereas the amount of phosphorus incorporated in silicon decreases with increasing temperature (Fig. 1), demonstrating the temperature dependence of the incorporation process.

Discussing the data in Fig. 1, it can be stated that the slope 1.0 is due to the linear relation between monoatomic P and PH_3 at 1400°K or between P and PH_2 at 1500° and 1600°K, respectively, PH_3 and PH_2 being the main gas components at these temperatures. The slope 0.5 expresses the quadratic relation of P to P_2 in the gas phase.

Table I. The logarithms (to base 10) of the equilibrium constants of the heterogeneous system Si-P-H at 1400°, 1500°, and 1600°K (from Ref. 10). The equilibrium constants correspond to Eq. [1]-[9] given in the text

	$\log_{10}K$	1400°K	1500°K	1600°K
P_2	(Ref. state)	0.000	0.000	0.000
H_2	(Ref. state)	0.000	0.000	0.000
Si(s)	(Ref. state)	0.000	0.000	0.000
PH_3	$\log K_1$	+2.975	+3.154	+3.308
P	$\log K_2$	−6.164	−5.548	−5.008
P_4	$\log K_3$	0.620	0.073	−0.404
PH	$\log K_4$	−5.051	−4.645	−4.289
PH_2	$\log K_5$	−3.060	−2.979	−2.907
H	$\log K_6$	−5.315	−4.756	−4.266
Si	$\log K_7$	−9.107	−7.998	−7.029
SiH	$\log K_8$	−8.378	−7.463	−6.664
SiH_4	$\log K_9$	−5.979	−5.924	−5.875

At 1400°K a second transition of the slope from 0.5 to 0.25 is found. This can be recognized by the intrinsic-extrinsic transition mentioned in the first section, and which occurs at 3×10^{19} atoms/cm^3 at 1400°K (9). In this case one has the following equilibria

$$1/2P_2(g) \rightleftarrows P(s) \qquad K_a = [P]/(p_{P_2})^{1/2}$$
$$P(s) \rightleftarrows P^+(s) + e \qquad K_b = [P^+]\cdot n/[P]$$

giving

$$[P^+] = \frac{K_b \cdot [P]}{n} = K_a K_b (p_{P_2})^{1/2}/n$$

For intrinsic conditions $n = k_i^{1/2}$ and

$$[P^+] \sim p_{P_2}{}^{1/2}$$

For extrinsic conditions $[P^+] = n$, thus

$$[P^+] \sim p_{P_2}{}^{1/4}$$

At higher temperatures the intrinsic carrier concentration of silicon shifts to a higher level and is outside the present range of measurements. For this reason no clear second break is found in the curves at 1500° and 1600°K, although an indication is given at 1500°K in the figure.

The exact position of the change in slope from 1 to 0.5 in the experimental curves deviates slightly from the same position in the calculated curves. This may

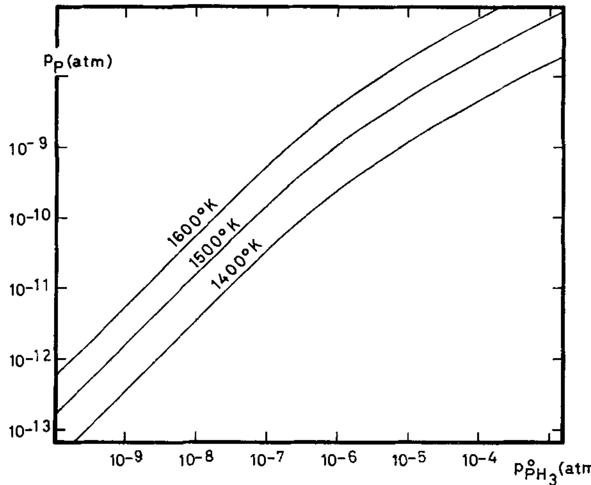

Fig. 3. Computed partial pressures of monoatomic phosphorus (p_P) vs. p^oPH_3 as collected from Fig. 2 for the three temperatures quoted.

be due to the influence on the equilibria of additional compounds mentioned before which were not taken into account in the calculations. However the correspondence is such as to have confidence in the given interpretation. The agreement between the experimental data and the calculated curves also indicates that Henry's law defined as $k = p_P/[P]_{Si}$ is obeyed over the whole range of phosphorus concentrations, which were far below the maximum solubility of P in Si ($\sim 1.5 \times 10^{21}/cm^3$) (11).

Conclusion

The mechanism for the incorporation of phosphorus in epitaxial silicon is governed by the position of the Fermi level in the solid and the chemical equilibria in the gas phase. With increasing phosphine partial pressures a slope bending from 1.0 to 0.5 is found due to transitions in the gas phase, at low temperatures a second break to 0.25 occurs when the donor concentration becomes equal to the intrinsic electron concentration of the silicon matrix.

These results also indicate that the gas phase reactions at or near the silicon surface proceed sufficiently rapidly that equilibrium concentrations of the components may be assumed to be present.

Acknowledgment

The authors gratefully acknowledge the stimulating discussions about the calculation of the above given gaseous equilibria by means of iterative procedures with Ir. A. W. C. van Kemenade of Philips Research Laboratories in Eindhoven, Holland, and Dr. P. Z. A. M. van der Putte of this laboratory. In this respect we also want to mention the assistance of Dr. H. Lydtin from Philips Forschungslaboratorium Aachen, Germany. In addition we are grateful to Mr. P. A. M. de Groot who performed the first experiments on this subject and whose practical advice was of considerable value.

Manuscript submitted Feb. 27, 1974; revised manuscript received May 6, 1974.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1975 JOURNAL. All discussions for the June 1975 Discussion Section should be submitted by Feb. 1, 1975.

The publication costs of this article have been assisted by the University of Nijmegen.

Vapor Phase Epitaxy and Thermodynamic Calculations of $GaAs_{1-x}P_x$ $(0.3 < x < 0.5)$

T. Y. Wu*,[1]

Research Laboratories, General Motors Corporation, Warren, Michigan 48090

ABSTRACT

Various relationships between gas concentrations and solid composition have been established for the vapor phase epitaxy of $GaAs_{1-x}P_x$ $(0.3 < x < 0.5)$. A $GaCl$-AsH_3-PH_3-H_2 process was used to grow such materials at a satisfactory temperature of 790°C. The crystal composition was measured as a function of the input flow rates. Based on these reproducible data, thermochemical calculations were performed with thermodynamic constants evaluated from the literature or determined by fitting the measured data to the calculated equations. The results agree nicely with all the experimental data when the input flow rate ratio $f^o_{HCl}/f^o_{H_2}$ is higher than 0.01. For $f^o_{HCl}/f^o_{H_2} < 0.01$, disagreements occur and the gas-solid relationships are hence established by experimental extrapolations. The crystal composition is strongly affected by $f^o_{HCl}/f^o_{H_2}$ and $f^o_{AsH_3}/f^o_{H_2}$, in addition to $f^o_{PH_3}/f^o_{AsH_3}$. Such phenomena are briefly discussed.

The $GaAs_{1-x}P_x$ materials have been of practical importance for electronic applications. At the present time, commercial light-emitting diodes (LED's) are mainly fabricated with these materials. Red-emitting $GaAs_{1-x}P_x$ $(x \approx 0.4)$ diode indicators and displays were successfully developed a few years ago. More recently, following the observations (1-3) of efficient nitrogen trap processes in indirect $GaAs_{1-x}P_x$, yellow and orange LED's with reasonable efficiency have also been made in such materials with $0.9 > x > 0.6$. Besides electroluminescent applications, high speed current limiting (4) and microwave switching (5) have been achieved in $GaAs_{0.7}P_{0.3}$ due to its velocity-field saturation characteristics. Furthermore, Blakeslee (6) has made superlattice structures in $GaAs_{1-x}P_x$ with a period as small as 110Å by vapor growth. Such structures may very well exhibit novel transport and optical properties like a negative conductance (7).

Although $GaAs_{1-x}P_x$ materials are highly desirable and the AsH_3-PH_3-$GaCl$-H_2 vapor phase epitaxy (VPE) technique has been used extensively, detailed and practical relationships between the input gas concentrations and the resulting crystal composition for such a process have not been available in the literature.

* Electrochemical Society Active Member.
[1] Present address: IBM Laboratories, San Jose, California 95193.
Key words: $GaAs_{1-x}P_x$, vapor phase growth, epitaxial deposition, thermodynamics, computer calculations.

These relationships are necessary to guide experiments in order to achieve a particular composition as desired. It is the objective of the present study to establish such relationships for a crystal composition range of $0.3 < x < 0.5$ at a growth temperature of 790°C. Such a composition range is of particular interest for red LED's.

Ideally, if the growth atmosphere is close to thermodynamic equilibrium with the grown crystal, one can describe the gas-solid interface entirely by theoretical calculations. However, in practice, the growth interface can be far off thermochemical equilibria. Thus theoretical treatments alone cannot produce accurate results. On the other hand it is too time-consuming to establish the entire relationships by experiments. A semi-empirical approach was therefore necessary in order to obtain accurate gas-solid relationships. Such an approach was used in the present study.

Experimental

Procedures.—The reactor system employed in this study is shown in Fig. 1. It is similar to the one used by Tietjen and Amick (8). But, in the present system, the HCl flow can bypass the Ga source for vapor etching of the substrate and is guided to the Ga boat during the growth period to ensure nearly complete conversion of HCl into GaCl. The reactor tube is 5 cm in diameter and 91 cm in heated length. The introduced AsH_3 and HCl are 10% mixtures in H_2, and PH_3 is a 5% mixture in H_2. All the gases are of electronic grade. Ga of 99.99999 purity, loaded in a pyrolytic graphite boat, was used throughout this study. The surface area of the Ga source was around 18 cm^2. Preliminary experiments established that such a source can convert HCl into GaCl almost completely under the present experimental conditions. Chemically polished GaAs of {100} orientation was employed.

As is shown in Fig. 1, the temperatures selected for growth were 900°, 940°, and 790°C for the source, the center zone, and the substrate. Such a profile was found to yield good preliminary growth. At the beginning of a run, this profile was reached with H_2 flowing inside the reactor and the substrate in the cold zone. AsH_3 flow was then established to prevent thermal etching of the GaAs surface and the substrate moved into the deposition zone. Afterward, vapor etch was carried out with a small HCl stream introduced through the upper tubing (see Fig. 1). Three minutes later, HCl was switched into the lower tubing and set at the desired flow rate to initiate the deposition of GaAs. After GaAs was epitaxially grown for 1 hr, the PH_3 flow was started and gradually increased so as to deposit a taper region with x changing from 0 to a certain desired value x_o. And finally a layer of $GaAs_{1-x_o}P_{x_o}$ was grown with the required thickness.

The following ranges of flow rates were used for growth: H_2 (750-1000 ml/min), AsH_3 (5-20 ml/min), HCl (5-25 ml/min), and PH_3 (0.3-4.0 ml/min). Precautions were taken to eliminate deposition on the reactor upstream of the substrate so as to ascertain that all the introduced gases contribute to the growth atmosphere in the substrate region. Such precautions, together with the fact that the input HCl is almost completely converted into GaCl in the present design, allows correlation of the growth atmosphere with the input gas concentration.

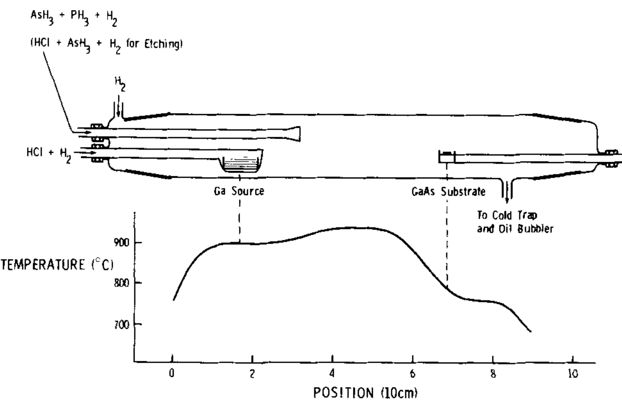

Fig. 1. Schematic diagram of the epitaxial reactor with the temperature profile used in this study.

Results.—Growth morphologies were examined and compared at different flow rate conditions. When the growth atmosphere is nonstoichiometric, pyramids or pits are developed on the as-grown surfaces depending on whether the deposition region is rich in group III element or group V elements. On the other hand, in the stoichiometric case, as-grown surfaces are generally smooth and specularly reflective. Details of such observations were reported previously (9).

Typical layers consisted of 30-50 μm of GaAs, 40-100 μm of graded $GaAs_{1-x}P_x$ and 50-200 μm of $GaAs_{1-x_o}P_{x_o}$. Electron microprobe analysis was carried out across the cross section of every layer to determine the crystal compositions. Very uniform x_o through the final layer has been observed in all cases. The values of x_o and their corresponding sets of flow rates at a growth temperature of 790°C are listed in Table I. Such data were checked and found to be reproducible. It was estimated that all the values of x_o should be accurate within ±0.01 and the various flow rate ratios to be within ±5%. Extreme care was taken to check the reproducibilities and to keep the results within the above accuracies. It should also be pointed out that such correspondence can be used to describe the gas-solid relationships at the growth interface, since, as mentioned above, the input flow rate conditions in the present setup can be related accurately to the growth atmosphere. Part of the data in Table I was therefore adopted in the following calculation to adjust theoretical parameters.

Thermodynamic Calculations

Theoretical model.—The theoretical approach used in this study is formulated with the following assumptions: (*i*) Dynamic thermochemical equilibria are established in a deposition region of uniform temperature and pressure. Such equilibria at the gas-solid interface control the growth of $GaAs_{1-x}P_x$. (*ii*) All the gas species obey the ideal gas law and the GaAs-GaP solid can be described by regular solution behavior. (*iii*)

HCl is completely converted into GaCl by reaction with Ga in the source region. (*iv*) No deposition occurs upstream of the substrate. (*v*) M_2, M_4, and MH_3 (M = As or P) contribute equally to the deposition of $GaAs_{1-x}P_x$, while various mixed species of the type As_yP_z can be neglected.

Assumptions (*iii*) and (*iv*) were found to be reasonably true in the present case. A mass-spectrometric study by Ban (10) has determined the relative abundances and deposition reactivities of various M-containing species at 680°, 780°, and 880°C. Such results indicate that assumption (*v*) should also be a good approximation. However, on the other hand, assumptions (*i*) and (*ii*) deviate to a good degree from the actual cases. These deviations make it impossible to obtain accurate relationships between the gas concentrations and the solid composition based on a theoretical approach alone. Incorporation of experimental data is therefore necessary. Indeed, it was found here that the equations derived with the above theoretical assumptions could be used to describe the vapor growth of $GaAs_{1-x}P_x$, only if the thermodynamic constants were properly adjusted to fit experimental data. A similar technique has been applied successfully by Wu and Pearson (11) to the liquid phase epitaxy of $In_xGa_{1-x}As$.

Based on the assumptions (*i-v*), one can write the following reactions to illustrate the equilibria existing around the gas-solid interface

$$GaCl + \frac{1}{3} AsH_3 + \frac{1}{6} As_2 + \frac{1}{12} As_4 \rightleftarrows GaAs + HCl \quad [1]$$

$$GaCl + \frac{1}{3} PH_3 + \frac{1}{6} P_2 + \frac{1}{12} P_4 \rightleftarrows GaP + HCl \quad [2]$$

$$As_4 \rightleftarrows 2\, As_2 \quad [3]$$

$$P_4 \rightleftarrows 2\, P_2 \quad [4]$$

$$2\, AsH_3 \rightleftarrows As_2 + 3\, H_2 \quad [5]$$

$$2\, PH_3 \rightleftarrows P_2 + 3\, H_2 \quad [6]$$

The equilibrium constant K_j of reaction (j) can be expressed as follows

$$K_1 = \frac{(1-x)\, \gamma_{GaAs}\, p_{HCl}}{p_{GaCl}\, (p_{AsH_3})^{1/3}\, (p_{As_2})^{1/6}\, (p_{As_4})^{1/12}} \quad [7]$$

$$K_2 = \frac{x\, \gamma_{GaP}\, p_{HCl}}{p_{GaCl}\, (p_{PH_3})^{1/3}\, (p_{P_2})^{1/6}\, (p_{P_4})^{1/12}} \quad [8]$$

$$K_3 = \frac{(p_{As_2})^2}{p_{As_4}} \quad [9]$$

$$K_4 = \frac{(p_{P_2})^2}{p_{P_4}} \quad [10]$$

$$K_5 = \frac{p_{As_2}\, (p_{H_2})^3}{(p_{AsH_3})^2} \quad [11]$$

$$K_6 = \frac{p_{P_2}\, (p_{H_2})^3}{(p_{PH_3})^2} \quad [12]$$

where p and γ designate the partial pressure and the activity coefficient, respectively. Since we are dealing with an open-flow system with H_2 as the major gas specie and the GaAs-GaP solid is assumed to be regular, we have

$$p_{H_2} \approx 1 \text{ atm} \quad [13]$$

and

$$\gamma_{GaAs} = \exp\left[\frac{\alpha x^2}{RT}\right] \quad [14]$$

$$\gamma_{GaP} = \exp\left[\frac{\alpha (1-x)^2}{RT}\right] \quad [15]$$

where α is the interaction parameter between GaAs and GaP.

Thus we have established relationships between the solid composition and the partial pressures of various gas species in the deposition region. These partial pressures can be further related to the input flow rates through consideration of mass conservation due to the validity of assumptions (*iii*) and (*iv*). The conservation of chlorine, arsenic, and phosphorus can be described, respectively, as

$$p_{HCl} + p_{GaCl} = p^o_{HCl} \approx \frac{p^o_{HCl}}{p^o_{H_2}} = \frac{f^o_{HCl}}{f^o_{H_2}} \quad [16]$$

$$p_{AsH_3} + 2p_{As_2} + 4p_{As_4} + (1-x)\, p_{HCl} = p^o_{AsH_3} \approx \frac{f^o_{AsH_3}}{f^o_{H_2}} \quad [17]$$

and

$$p_{PH_3} + 2p_{P_2} + 4p_{P_4} + x\, p_{HCl} = p^o_{PH_3} \approx \frac{f^o_{PH_3}}{f^o_{H_2}} \quad [18]$$

where f^o is the flow rate of the incoming gas and p^o represents the partial pressure of this input gas in the growth region prior to deposition.

With Eq. [7]-[18], one can solve for the crystal composition and the partial pressures at any given incoming gas concentrations, once all the equilibrium constants and the interaction parameter are determined.

Determination of constants.—The above approach can be used for any growth temperature. But the present calculation was performed with 790°C, which was found to be satisfactory for $0.3 < x < 0.5$.

The equilibrium constants, *i.e.*, K_1, K_2, K_3, K_4, K_5, and K_6 were evaluated from Kirwan's results (12) to be 10^4, 80, 10^{-5}, 9×10^{-5}, 3×10^{17}, and 3×10^2 atm units, respectively, at 790°C. Panish and Ilegems (13) have reported a value of 0.4 kcal/mole for α. Based on these parameters, preliminary calculations resulted in significant deviations from the experimental data obtained in this study. This can be expected due to the fact that complete thermochemical equilibria do not exist and kinetic effects such as adsorption, surface reaction, and desorption cannot be neglected in actual cases, as were reported by Shaw (14, 15). In order to obtain accurate results with the above-described equations, one thus has to adjust appropriate parameters to fit experimental data. Such adjustments will invalidate some of the above assumptions and thus result in inconsistency in the theoretical model. However, the main purpose of this paper is to establish correct gas-solid relationships for practical use. The adoption of simple, unrealistic assumptions was merely to set up calculation equations to start with.

Since we are mainly interested in calculation of the crystal composition at given gas concentrations, such adjustments should be made with parameters which have major influences on the depositions of GaAs and GaP. Adjustable parameters should therefore be selected among K_1, K_2, and α, which can affect the deposition reactions directly.

By following the same techniques used in Ref. (11), it was found that, with $K_2 = 3 \times 10^2$ atm units, $\alpha = (4.2\text{-}3.8\, x)$ kcal/mole, and other equilibrium constants given above, the calculation resulted in good agreement with the experimental data.

Calculation results.—Such a calculation was carried out to determine the crystal composition x at any given $f^o_{HCl}/f^o_{H_2}$, $f^o_{AsH_3}/f^o_{H_2}$, and $f^o_{PH_3}/f^o_{AsH_3}$. The results are shown in Fig. 2 and 3 together with the experimental data obtained in the study. The solid lines are calculated results and the dashed lines are experimental extrapolations. Good agreement was obtained for $f^o_{HCl}/f^o_{H_2} > 0.01$. However, when $f^o_{HCl}/f^o_{H_2}$ is smaller than 0.01, the calculation fails and the relationships were established entirely by experiments. The failure of the calculation in this region indicates that such a semi-empirical approach can only be applied in limited regions since the actual deposition process can be far more complicated.

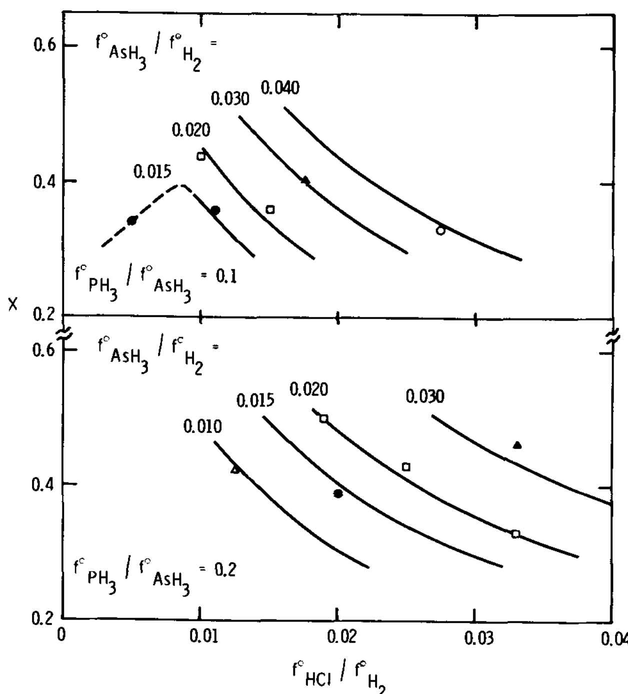

Fig. 2. Crystal composition x as a function of input flow rate ratios $f^o_{HCl}/f^o_{H_2}$, $f^o_{AsH_3}/f^o_{H_2}$, and $f^o_{PH_3}/f^o_{AsH_3}$ (= 0.1 and 0.2) at a growth temperature of 790°C. Solid lines are calculated results. The dashed line is experimental extrapolation. The values of $f^o_{AsH_3}/f^o_{H_2}$ for various measured data are: 0.010 (△), 0.015 (●), 0.020 (□), 0.030 (▲), and 0.040 (○).

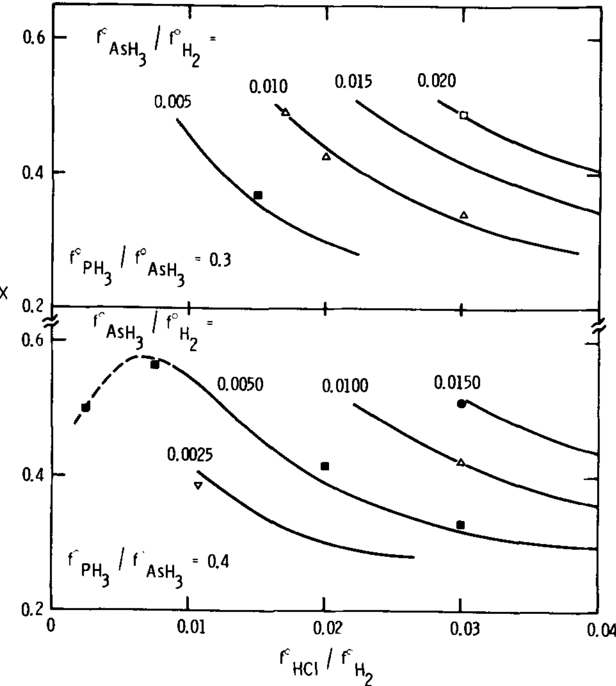

Fig. 3. Crystal composition x as a function of input flow rate ratios $f^o_{HCl}/f^o_{H_2}$, $f^o_{AsH_3}/f^o_{H_2}$, and $f^o_{PH_3}/f^o_{AsH_3}$ (= 0.3 and 0.4) at a growth temperature of 790°C. Solid lines are calculated results. Dashed line is experimental extrapolation. The values of $f^o_{AsH_3}/f^o_{H_2}$ for various measured data are: 0.0025 (▽), 0.0050 (■), 0.0100 (△), 0.0150 (●), and 0.020 (□).

Figure 4 gives the relationships among the incoming flow rates required to grow $GaAs_{0.6}P_{0.4}$ under the present experimental conditions. All the lines are drawn from Fig. 2 and 3, together with the corresponding experimental data in Table I. Similar plots can be obtained for other x and serve as guides to achieve specific compositions.

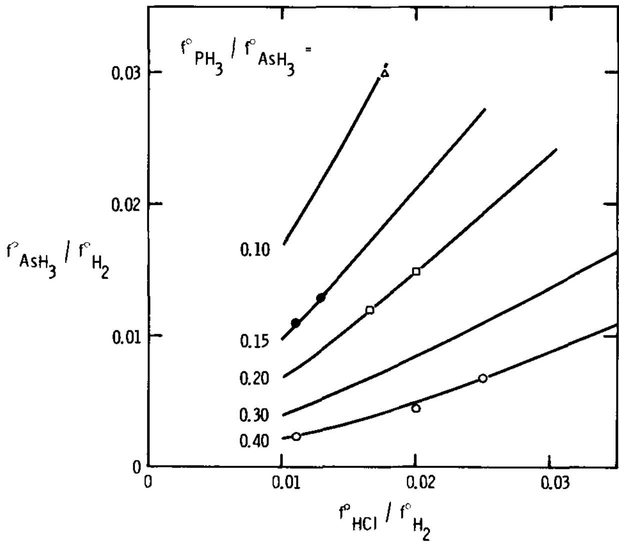

Fig. 4. Input flow rate ratio $f^o_{AsH_3}/f^o_{H_2}$ required to achieve $x = 0.4 \pm 0.02$ with various fixed $f^o_{HCl}/f^o_{H_2}$ and $f^o_{PH_3}/f^o_{AsH_3}$ at 790°C. All the lines are calculated results. The values of $f^o_{PH_3}/f^o_{AsH_3}$ for various measured data are: 0.10 (△), 0.15 (●), 0.20 (□), and 0.40 (○).

Discussion

From the above results, the crystal composition is not only determined by $f^o_{PH_3}/f^o_{AsH_3}$, but is also affected to a great extent by $f^o_{HCl}/f^o_{H_2}$ and $f^o_{AsH_3}/f^o_{H_2}$. In particular, at constant $f^o_{AsH_3}/f^o_{H_2}$ and $f^o_{PH_3}/f^o_{H_2}$, x increases along with $f^o_{HCl}/f^o_{H_2}$ when $f^o_{HCl}/f^o_{H_2} < 0.01$ but decreases as $f^o_{HCl}/f^o_{H_2}$ is increased further. It is difficult to explain such behavior in much detail since precise thermochemistry at a real growth interface is not known. Nevertheless the following interpretations can be made here.

The crystal composition is influenced by two factors: (*i*) the reactant partial pressures and (*ii*) the reactivities of various M-containing species with GaCl. When f^o_{HCl} is much greater than $f^o_{AsH_3} + f^o_{PH_3}$, there is more than sufficient GaCl in the deposition region. In that case, the reactivity influence is overruled by the pressure influence and the crystal composition x is mainly determined by $f^o_{PH_3}/(f^o_{PH_3} + f^o_{AsH_3})$. As $f^o_{HCl}/f^o_{H_2}$ is reduced while keeping $f^o_{PH_3}/f^o_{AsH_3}$ and $f^o_{AsH_3}/f^o_{H_2}$ constant, the relative reactivities of M-containing species will then become increasingly important. The fact that x increases with decreasing $f^o_{HCl}/f^o_{H_2}$ (>0.01) can hence be explained by the over-all higher reactivity of P-containing reactants in this range. The same explanation also holds for the increasing x when $f^o_{AsH_3}/f^o_{H_2}$ is increased with constant $f^o_{PH_3}/f^o_{AsH_3}$ and $f^o_{HCl}/f^o_{H_2}$.

Sedgwick (16) proposed a "quasi-equilibrium" model to describe the H_2 reduction of $SiCl_4$. In this model, only a fraction β of the incoming gases equilibrates with the condensed phase. Shaw (14) has found such a model can be successfully applied to calculate GaAs deposition rates for certain limited growth conditions if a constant, empirical β is assumed. The present results agree with such previous observations. The adjustment of K_2, in the present case, is equivalent to the quasi-equilibrium treatment. It was also found here that such a treatment can be successfully used to calculate x for certain growth conditions, namely, $f^o_{HCl}/f^o_{H_2} > 0.01$ in the present case.

Although the use of a composition-dependent α is inconsistent with the assumption of regular solution behavior between GaAs and GaP, it yields some accurate and practical results in the present calculations. After all, the GaAs-GaP solid solution is by no means strictly regular. Rao and Tiller (17) have found composition-dependent α's can be used to describe similar systems.

It should also be pointed out here that the empirical adjustments of K_2 and α were performed based on part of the reproducible data in Table I only. But the remaining data were also found to agree with the calculated results nicely. This suggests such a semiempirical approach is a good technique for interpolation and reasonable extrapolation with a limited amount of data.

In a previous paper (9), an optimum growth condition was reported for the process used in this study, namely, $f^o_{HCl}/f^o_{H_2} = (f^o_{AsH_3} + f^o_{PH_3})/f^o_{H_2} = 0.02$. Such a condition together with the relationships given in Fig. 4 indicate that $GaAs_{0.6}P_{0.4}$ can be best grown with $f^o_{HCl}/f^o_{H_2} = 0.02$, $f^o_{AsH_3}/f^o_{H_2} = 0.0165$, and $f^o_{PH_3}/f^o_{AsH_3} = 0.19$ at a temperature of 790°C.

Although the present relationships are established for the AsH_3 and PH_3 process, they can be applied equally well to the $AsCl_3$ and PCl_3 process since the thermochemistry at the gas-solid interface is the same for both processes. As a matter of fact, the trichloride process can be considered as a special case of the hydride process, which satisfies $p^o_{HCl} = 3(p^o_{AsH_3} + p^o_{PH_3})$ with $p^o_{AsH_3}$ and $p^o_{PH_3}$ equal to $p^o_{AsCl_3}$ and $p^o_{PCl_3}$, respectively. Thus, the present relationships can be reduced for use in the trichloride case by introducing a restriction that $f^o_{HCl}/f^o_{H_2}$ is equal to $3(f^o_{AsH_3} + f^o_{PH_3})/f^o_{H_2}$. It was indeed found that the results so obtained agree well with the calculated relationships by Bleicher (18) for the trichloride process.

Conclusions

A thermochemical investigation on the VPE of $GaAs_{1-x}P_x$ ($0.3 < x < 0.5$) has been carried out and the following conclusions can be made:

1. The crystal composition x ($0.3 < x < 0.5$) as a function of the input flow rate ratios $f^o_{PH_3}/f^o_{AsH_3}$, $f^o_{AsH_3}/f^o_{H_2}$, and $f^o_{HCl}/f^o_{H_2}$ at 790°C has been obtained for the hydride process. A semiempirical approach was used to establish such relationships. Such an approach demolishes the theoretical consistency, but is certainly a simple way to establish accurate, practical relationships. Similar techniques can be used for other ranges of x or other materials.

2. The flow rate dependences of x for $f^o_{HCl}/f^o_{H_2} > 0.01$ can be explained by the relative abundances and reactivities of various vapor sources.

3. It is concluded that $GaAs_{0.6}P_{0.4}$ vapor epitaxial layers can be best grown with $f^o_{HCl}/f^o_{H_2} = 0.02$, $f^o_{AsH_3}/f^o_{H_2} = 0.0165$, and $f^o_{PH_3}/f^o_{AsH_3} = 0.19$ at 790°C. Such information is particularly important for red-emitting diode application.

4. The above relationships can be reduced and used for the trichloride process which is actually a special case of the hydride process.

5. The results established here are applicable to any such reactors where the input flow rates can be correlated with the incoming gas concentrations in the substrate region.

ABSTRACT

High structural quality epitaxial Si layers have been grown over implanted As patterns. For As doses $\geq 5 \times 10^{14}/cm^2$, it has been necessary either to implant into a heated substrate or to remove the damaged region prior to epitaxial growth. This can be conveniently done by diffusing in an oxygen ambient; consuming part of the damage by oxidation while diffusing the donor impurities away from the damaged silicon. Sheet resistivities of less than 10 ohms/□ have been attained as have minority carrier lifetimes over 20 μsec in the epitaxial layer, with no lifetime difference observed on control areas or regions grown over the buried layers. SiO_2, photoresist and silicon contact masks have been successfully employed. For implantation doses of $3 \times 10^{15}/cm^2$, driven to a junction depth of 3 μm, sheet resistivities of 20 ohms/□ were obtained. The existence of HF staining of the damaged region prior to annealing has been observed.

The need for techniques to reproducibly grow high quality epitaxial silicon layers over low sheet resistivity buried collector diffusions of n-type impurity atoms has been a continuing problem in the fabrication of bipolar integrated circuits. The ability to grow high lifetime, low strained epitaxial films over arsenic buried layers requires a reproducible diffusion source free of variables such as attack of the SiO_2 masked areas, variable etching characteristics, arsenic rich precipitates, etc. Chemical diffusion sources generally suffer from some of the above problems, resulting in the subsequent formation of epitaxial defects especially over impurity rich diffusion "rosettes." As part of an over-all examination of arsenic buried layer sources, ion implanted arsenic techniques were investigated. This paper describes the experimental details which form the basis of the results reported earlier (1).

It was recognized that crystallographic disorder introduced in the silicon lattice by implantation of buried layers could be a potential problem in the epitaxial growth process which is sensitive to minor lattice disorder. The investigation studied the use of room temperature and high temperature implantations followed by epitaxial deposition, and also the use of room temperature implantations followed by a high temperature diffusion drive-in prior to epitaxial deposition. It was found in all cases that although the epitaxial process was extremely sensitive to residual crystallographic damage in the implanted substrates it was equally sensitive to the cleaning sequence used to process the substrates after implantation.

This work has shown that good results are obtained using ion predeposition followed by a diffusion drive-in at 1200°C. Epitaxial silicon layers have been grown consistently free of structural defects and comparable to layers grown on nondiffused, melt doped substrates. In particular "rosettes" have not been observed since the oxide mask used never contains sufficient arsenic to form the necessary arsenic rich oxide phase. High quality base-collector junctions have been fabricated over buried layers formed in the above fashion.

Experimental Procedures

Implantation.—The early work was done with beam energies of 300 keV giving a profile peaked at approximately 0.2 μm (2). This was later reduced to 150 keV. The majority of the substrates were implanted at room temperature, but some experiments were performed with the substrates held on a heated support at temperatures between 500°-600°C to reduce the radiation damage in the Si(3) caused by the implantation.

Diffusion drive-in.—These were performed at 1200°C in pure oxygen for most of this work. Some runs used 10% O_2-90% N_2, 50% O_2-50% N_2, or a short O_2 drive-in followed by a N_2 drive-in. These variations had minor effects on the sheet resistivity of the buried diffusions but no effect on the subsequent epitaxial growth process.

Epitaxial growth.—Epitaxial films in the 2.0-4.0 μm thickness range were grown in a single slice vertical reactor system described previously (4). Growth rates of 0.5 μm/min were used at 1000°C utilizing the silane pyrolysis process. Ten ohm-cm p-type, "Syton" polished substrates misoriented by 3° to the <111> axis were used. The early experiments used substrates which were HCl vapor etched in the epitaxial reactor prior to ion implantation to eliminate minor variations in substrate surface perfection but later work showed that "Syton" polished surfaces were adequate for our purposes. Where no drive-in had been performed the standard preepitaxial, *in situ* HCl vapor etch at 1000°C was eliminated to prevent etching away the implanted As zone.

Epitaxy and substrate characterization.—The structural perfection of the ion implanted substrates with and without epitaxial layers was examined by x-ray topography, interference contrast microscopy, and ellipsometry. Berg-Barrett reflection topography was used with a lateral resolution of two microns, utilizing the $Cr_{K\alpha}$ (220) reflection with an approximate penetra-

tion of 1.5 μm, or the $Fe_{k\alpha}$ (311) with an approximate penetration of 6.5 μm. The use of geometric patterns such as device patterns or simple grids enabled a comparison to be made between the implanted areas and the surrounding silicon matrix. In addition interference microscopy at ×698 was used to compare the surface relief of the epitaxy over implanted areas with the matrix structure and to examine stacking faults, etc. The ellipsometric measurements served to monitor the cleanness of the substrates prior to and subsequent to ion implantation. It also was useful in monitoring the annealing of implanted silicon surfaces as the disordered surface had an apparently low refractive index which reverted to the characteristic silicon value after annealing. The sheet resistivities were measured using a four-point probe and the minority carrier lifetime using a pulsed MOS (C-V) technique (5).

Results

Ion-Implanted Substrates

The first experiments studied doses which yielded sheet resistivities between 10 and 4000 ohms/□ after an anneal but without a diffusion drive-in. Four strips were implanted into a slice held at room temperature with doses of 5×10^{14}, 10^{14}, 2×10^{13}, and 4×10^{12} 300 keV arsenic ions/cm^2, the substrates having been HCl vapor etched immediately prior to implantation. Of these implantations only the heaviest dose rendered the lattice amorphous as seen by x-ray topography and also reflection microscopy. A twenty minute anneal at 1000°C in the epitaxial reactor in hydrogen returned the refractive index of the $5 \times 10^{14}/cm^2$ implanted area to its bulk value, but x-ray topographs indicated that the crystallographic structure was not that of the surrounding matrix. The growth of 2.5 μm epitaxial layers over these stripes showed that excellent quality silicon was obtained over all areas except the heaviest dose region. In Fig. 1a, the x-ray topograph shows the epitaxy in the heaviest dose region to be highly dislocated, perhaps oriented polycrystalline material, and observation under phase contrast microscopy (Fig. 1b) confirms that the layer is highly disordered Si.

To ascertain whether the defective epitaxial layer was caused by residual damage due to a dose above that required to render Si amorphous, implantations were done into samples held at temperatures high enough that the amorphous transition is not expected (6). Doses of 5×10^{14}, 5×10^{15}, and 10^{16} 300 keV As/cm^2, all above the amorphous transition damage range for As in Si at room temperature, were implanted with the substrate held between 500°-600°C. By x-ray and reflectance examination this material was indistinguishable from the nonimplanted zone immediately after implantation. At an implantation dose of $10^{16}/cm^2$ the epitaxial texture was only slightly different from the nonimplanted material. Lang transmission x-ray topographs (7) indicated single-crystal material with dislocation densities of several thousand/square centimeter but this value was also obtained for the nonimplanted area. It would appear that the dislocations were not due to the implantation per se but perhaps related to the method of holding the sample on the heater block during implantation.

Table I. Etching conditions for epitaxial growth over ion implanted buried layers

Drive-in conditions	Amount HCl etched	HCl etch temperature	Epitaxial visual quality
O_2, 15 min; N_2, 4 hr	None	—	Very poor
O_2, 4 hr	None	—	Poor
(0.35 μm SiO_2)	0.1 μm	1000°C	Good
(0.35 μm SiO_2)	0.2 μm	1000°C	Excellent
(0.35 μm SiO_2)	0.3 μm	1000°C	Excellent
(0.35 μm SiO_2)	0.5 μm	1000°C	Excellent
(0.35 μm SiO_2)	1.5 μm	1200°C	Excellent

Although implanting into a hot substrate gave sheet resistivities ~10 ohms/□, the technique was found to be too sensitive to residual surface impurities without HCl vapor etch prior to epitaxial growth. Also, heating the sample during the implantation is generally cumbersome.

Ion Predeposition and Drive-In

HCl vapor etching.—It was decided to use a standard $10^{16}/cm^2$ implantation dose at 150 keV for the diffusion experiments, with a drive-in of 4 hr at 1200°C in O_2. During the implantation the substrates were held near room temperature. These conditions gave a junction depth of 3.0 μm and a sheet resistivity of 7-8 ohms/□. To determine the minimum amount of Si necessary to be removed so that any residual damage in the implanted zone would not affect the epitaxial process, a series of drive-ins and *in situ* (prior to epi growth) vapor etchings were performed as listed in Table I. Since during the 4 hr period at 1200°C approximately 0.35 μm of SiO_2 are formed and subsequently removed by an HF etch prior to epitaxial deposition, 0.15 μm of the original surface will be consumed without any HCl etch. Thus, in two runs, no HCl etching was performed to test whether this in itself was sufficient to give high quality epitaxy. It appears that although cosmetically acceptable epitaxy can be grown this way, x-ray topography indicated clearly that a 0.2 μm HCl etch was necessary to obtain reproducible results.

KMER masks.—The above results were obtained with large area implantations. During processing, some form of mask definition will be required. The simplest approach in terms of number of processing steps would be to use a photoresist mask thick enough to stop the As ions. KMER-II was used and proved to be adequate for the purpose. Substrates were coated with 1μ of KMER-II and buried layer patterns developed. After the ion predeposition was performed, the KMER-II was stripped and then the substrate cleaned and put in the drive-in furnace.

Fig. 1. (a) X-ray topograph and (b) photomicrograph of epitaxial layer grown over 5×10^{14} As/cm^2 implanted region (25°C).

It was found that excellent epitaxy could usually be grown as characterized under interference contrast. However, variation occurred in the quality of the epitaxy, and faceted pads, which by x-ray showed considerable surface damage, were sometimes observed. This was correlated with the ability to remove the polymerized KMER resist after ion implantation and before drive-in. Due to the additional cross linking induced in resist by ion implantation, J-100[1] chemical stripper is insufficient for the total removal of the organic contaminants.

The lack of a readily observable pattern in a mask alignment microscope makes the use of a resist mask somewhat impractical.

Oxide masks.—SiO_2 masks were examined. It was found that the oxide stopped the As implanted into the SiO_2 from diffusing through the oxide during drive-in. During the drive-in in O_2, a 0.1-0.3 μm step was formed in the substrate. This simplifies alignment to these buried features.

Contact (shadow) masks.—At this point the variables noted in the cleaning stimulated an examination of the possible use of "shadow" masking. The potential for minimizing chemical contamination of the Si surface during implantation appeared attractive. Initial results with a Mo mask indicated that sputtering of contaminant Mo onto the Si surface with subsequent drive into the surface at 1200°C could occur (Fig. 2a). Replacement of Mo by a Si mask on the presumption that sputtered Si would not be a contaminant proved correct. Figure 2b and the related topograph Fig. 2c show that high quality epitaxy, with barely a trace of the slightly strained implanted area, can indeed be obtained by this method. The heavily doped, buried layers oxidized faster than the surrounding silicon, and thus steps of $\approx$ 300Å were formed around the edge of the buried layers during the drive-in in O_2.

Effect of HF staining.—Many of the initial results showed staining effects which subsequently gave rough epitaxial surfaces. This has been traced to the original use of an oxide mask which was removed by HF etching prior to the 1200°C drive-in in an attempt to minimize the subsequent step in the substrate. Heavily implanted As surfaces appear to react preferentially with HF forming a stained compound which forms considerable defects during the epitaxial growth stage. Even when the original oxide mask is left on, if the holes are cleaned using 100:1 H_2O:HF prior to drive-in, the problem occurs (in a less dramatic form).

Figure 3 illustrates the texture of epitaxial layers grown over buried layers cleaned in various concentrations of HF before drive-in. Figure 3a (no HF) shows excellent epitaxial Si with no sign of the implanted regions in an x-ray topograph. Figure 3b is from a region with a 50:1 HF etch and Fig. 3c from a region with a 48% HF etch treatment. Both HF cleaned regions show faceted, striated epitaxy. X-ray topographs also show harmful effects of the HF cleans.

Electrical measurements.—Four-point probe measurements have shown that sheet resistivities of 7-8 ohms/□ are obtained for a dose of 10^{16}/cm^2 after drive-in and are only slightly increased by a 0.2 μm vapor etch. For 5 $\times$ 10^{15}/cm^2, ρ_s was 15 ohms/□ and for 10^{15}/cm^2, ρ_s was 80 ohms/□. Minority carrier lifetimes measured on undoped epitaxy over both the buried layers and the surrounding matrix gave values greater than 20 μsec, the upper reliable limit of the method.

Discussion

The growth of epitaxial silicon over implanted buried layers has shown interesting effects related to the decoration of residual implantation damage by the epitaxial growth process. The region shown in Fig. 2 is amorphous after implantation and although after the 1000°C anneal, by resistivity measurements the impurity atoms are incorporated into a Si lattice and the reflectance is identical with bulk Si, the area still shows that residual damage exists by both x-ray topography and by the disordered epitaxial film that forms. The observations of Bicknell and Allen (8) of residual damage existing in P implanted Si after annealing at 1027°C could account for this. The epitaxial growth of Si on such a lattice would be greatly hindered and the meaning of an x-ray topograph of such highly dislocated material would be problematical (9). An alternative concept would be the existence of a high density of point defects in such a disordered lattice resulting in epitaxial disorder. One might expect such a grouping of vacancies to segregate at high temperatures, however, and to precipitate out as stacking faults. No such aggregation of stacking faults has been seen.

The hot implantation (600°C) proved that no residual implantation damage which would affect epitaxial growth existed after a 1000°C anneal even at doses 20-100 times greater than room temperature implantation which yielded poor epitaxial layers. It

would appear that high quality epitaxy could be grown under such implantation conditions.

In terms of the vapor etch experiments it would appear that a 0.2 μm HCl *in situ* etch prior to epitaxial deposition is essential. The incorporation of between 0.15 and 0.2 μm of the implanted substrate surface by oxide formation during the 1200°C O_2 drive-in may not remove all the residual damage, or, in fact, some of the damage may propagate into the substrate during oxidation as dislocations or vacancy migration. The x-ray topography indicates that the additional 0.2 μm vapor etch removes the vestigial damage and also any surface contamination likely to produce traditional structural defects. It is interesting to note that no significant damage propagates more than 0.2 μm from this highly disordered region.

The effect of HF etching on the implanted As areas prior to drive-in seems to relate to a complex chemical reaction at the surface resulting in an inert stain. This reaction appeared strongest for the highest implantation dosage, and the strongest HF etchant solution. The additional reactive energy available in the large number of disordered lattice bonds might create a highly activated surface.

The use of shadow masking and photoresist masking is interesting because of the high structural quality of the resulting epitaxy grown over such buried layers and the processing simplicity. The oxide mask method is compatible with current device processing technology and has been shown to yield excellent epitaxy which is readily processed.

The results shown in Fig. 2a underscore the importance of using masking materials which do not serve as a source of contaminants. Significant quantities of materials get backsputtered off the mask and redeposit on the silicon. The sputtering yield is generally >1 for heavy projectiles and thus tens of monolayers of the mask are removed, some of which will redeposit in the windows. Also, if there is a thin surface layer over the windows of the Si, significant quantities of this material can recoil into the Si. Recent measurements have shown (10) that heavy projectiles passing through a thin oxide layer can recoil several (>2) oxygen atoms/projectile into the substrate.

The ability to tailor buried layer concentrations accurately, reproducibly, and without structural defects is a positive step toward controlled processing. The low As concentration in the oxide mask prevents the formation of As rich precipitates which can cause oxide breakdown. Ellipsometric measurements of the As implanted SiO_2 mask have shown it is easily removed by HF to a residual SiO_2 film equivalence of 5Å.

The 20 μsec lifetimes measured in the epitaxy are encouraging.

Conclusions

1. Structurally perfect epitaxy can be grown over room temperature As implanted Si substrates up to a dose of $1 \times 10^{14}/cm^2$ after annealing.
2. Similarly, epitaxial layers have been grown over As implanted at 600°C up to a dose of $10^{16}/cm^2$.
3. A process has been developed utilizing a room temperature ion predeposition, up to a dose of $10^{16}/cm^2$ followed by a diffusion drive-in at 1200°C in pure O_2, or in O_2-N_2 mixtures.
4. Sheet resistivities as low as 7 ohms/□ have been attained by this method with a 3 μm junction depth; lower sheet resistivities can be obtained by driving the junction in deeper (11).
5. Either SiO_2, photoresist or contact masks may be used with the process.
6. The existence of HF staining of implanted As areas (before anneal) has been noted as a processing variable.

An Analysis of the Temperature Distribution During Crystal Growth by THM

R. O. Bell

Tyco Laboratories, Inc., Waltham, Massachusetts 02154

ABSTRACT

The temperature distribution during crystal growth by the traveling heater method (THM) has been calculated by numerical integration of the Laplace equation for a cylindrical geometry. The boundary between the liquid and solid, which have different physical properties, was assumed to be an isotherm. The radial and longitudinal temperatures, the isotherms, and the interface shape have been calculated for different heater temperatures, interface temperatures and geometries. Also briefly described are a one-dimensional model that neglects radial gradients and an analytical solution for an idealized geometry and boundary conditions. When numerical values are determined, parameters appropriate to the growth of CdTe by Te are used. Some of the practical implications with regard to crystal growth behavior are discussed.

Recently, the traveling heater method of crystal growth (THM) has been applied to a number of compounds including CdTe (1, 2), GaAs (3), GaP (4, 5), CuCl (6), and ZnO (7), and also to several solid solutions such as (Ga, Al) As (3), (Ga, In)P (3), (Hg, Zn)Te (5), and (Pb, Sr)TiO_3 (8). This is a relatively new technique, and the basic process has been analyzed using idealized geometries and temperature distributions, primarily in papers by Wolff and co-workers (3, 9-11).

The usual cylindrical geometry (Fig. 1) has a heater, typically a hot metal ring, which heats the solvent by radiation. The solvent zone is made to migrate along the ampul containing the material of interest by the relative motion of the heater. Heat is transported by thermal conduction along the feed material and growing crystal and then is lost by convection and reradiation. The general heat flow is thus balanced between the heat input from the central heater and loss from the ends of the ampul. As discussed by Chalmers (12, 13), it is important that the growing interface, which will be an isotherm, have minimal curvature. A concave[1] surface is undesirable if nucleation of new crystals from the walls is to be avoided and a highly convex[1] surface should also be avoided to prevent the solvent near the perimeter of the ampul from becoming starved of the material in solution. Thus, one very important parameter is the temperature distribution during THM, which will to a large degree determine the liquid-solid interface shape.

Some experimental measurements of temperature profiles have been made (13), but precise results are difficult to obtain; therefore, we have found it very useful to calculate the temperature distribution. Both the temperature of the solid-liquid interface and the concentration in solution, will be determined by the thermal conditions and by the phase diagram. Changes in physical parameters, such as the amount of solvent or the heater temperature, will change the length of the solvent zone and thus the interface temperature, so the entire process is fairly complicated. This paper is not meant to be an analysis of the entire situation but to provide some guidance with regard to the practical understanding of THM.

THM crystal growth is quite slow (not more than 1 to 2 cm/day and usually something more like 5 mm/day); thus it is not necessary to consider the latent heat associated with the phase transformation or other dynamical properties. To a high degree of approximation, the temperature will be given by the equilibrium situation. In some work on GaP and CdTe, direct rf coupling to the solvent to produce heat throughout the

volume has been used (4, 13), but we will only consider the more usual case where thermal radiation from an external source is used.

Theory

A number of different approaches to the calculation of thermal distribution are possible, of which we have investigated three. The first is a one-dimensional model which neglects radial gradients and gives only the average temperature along the ampul (see the Appendix). This particular model is easily formulated to obtain numerical results with the major drawback, of course, that no isotherms are obtained. The second approach is to analytically solve the Laplace equation in three dimensions (see the Appendix), but in order to obtain a simple series solution of the appropriate equations, it is necessary to assume that the regrowth, solvent, and feed all have homogeneous thermal properties. Even more importantly, thermal radiation which involves a T^4 term cannot be handled directly, but, rather, an effective linear heat transfer coefficient must be used. The third, and most realistic, case and the one on which we will concentrate is the direct numerical integration of the Laplace equation and the boundary conditions to obtain the liquid-solid interface shapes. The principal approximations made in this case relate to the practical impossibility of producing an abrupt temperature step because of longitudinal spreading of the incident radiation between the heater and rod and neglect of the effect of things such as the conductivity of the walls of the ampul, although, in principle, they could be included.

In this paper we will discuss this last case and show some of the results and insights we have obtained. A brief outline of the first two models is given in the Appendix. The numerical methods are also outlined and, although we have not included the FORTRAN computer programs, enough information is given so that the programming should be straightforward.

The approach used here is to integrate the Laplace equation and the boundary conditions numerically using the geometry shown in Fig. 2. The rod is assumed to be symmetrically located in the heater. The set of equations governing the temperature, T, in a cylindrical coordinate system are

$$\frac{1}{r}\frac{\partial}{\partial r}\left(r\frac{\partial T}{\partial r}\right)+\frac{\partial^2 T}{\partial z^2}=0 \quad [1]$$

$$-k_i\left(\frac{\partial T}{\partial r}\right)_{r=a}=q_{i,j} \quad [2]$$

$$-k_i\left(\frac{\partial T}{\partial z}\right)_{z=d}=q_{i,j} \quad [3]$$

$$-k_i\left(\frac{\partial T}{\partial r}\right)_{r=0}=0 \quad [4]$$

$$-k_i\left(\frac{\partial T}{\partial z}\right)_{z=0}=0 \quad [5]$$

$$-k_l\frac{\partial T}{\partial n}=-k_s\frac{\partial T}{\partial n} \text{ at the interface where } T=T_m \quad [6]$$

and

$$q_{i,j}=\sigma\epsilon_i(T^4-T_j^4)+h_s(T-T_a)^{1.25} \quad [7]$$

where k_i is the thermal conductivity of the liquid, k_l, or solid, k_s, depending on whether the temperature is above or below that of the interface; similarly, this applies to the emissivities ϵ_l and ϵ_s. T_j is either the temperature of the heater, T_2, or of the outside environment, T_1. T_m is the temperature of the interface, and T_a the temperature of the air. σ is the Stefan-Boltzmann constant and h_s is the effective heat transfer coefficient for convection.

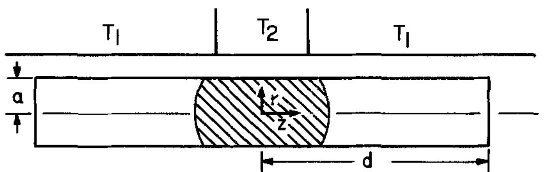

Fig. 2. Geometry assumed for numerical solution of temperature distribution. The interface is assumed to be at a fixed temperature, T_m.

In Eq. [7] which gives the heat flux across the surface, the first term on the right-hand side is the contribution by thermal radiation and the second represents the convective heat transfer. It should be pointed out, though, that the form of this last term is only for free laminar convection across an isothermal surface (14, 15) and thus is only an approximation.

An area where convection has been neglected is in the liquid zone where the heat transport is assumed to be solely by conduction. In principle it should be possible to include convection by using the Navier-Stokes equation coupled to the Laplace equation which has been modified to include the effects of fluid flow (16) but the additional complications were not deemed worth the effort for this initial analysis.

It has also been assumed that the system is opaque making radiative transfer unimportant. For partially transmitting media coupled radiation and convection must be considered (17, 18).

Another approximation that has been made is to assume perfectly abrupt transitions from the hot to the cool zone. In practice, there will be a more or less continuous change which will smooth out the transition. The principal effect will be to decrease the gradient, primarily in the transition region. For the case where the interface is within the heater, this will not be as important as when near or outside in the cool zone.

The equations are converted to difference equations and used to solve for the temperature as a function of the r and z coordinates.

For the numerical solution write Eq. [1] as a difference equation with a spacing of h

$$(2m-2)(T_{n-1,m}+T_{n+1,m})+(2m-1)T_{n,m+1}+(2m-3)T_{n,m-1}-8(m-1)T_{n,m}=0 \quad [8]$$

Here, the m index is for the r coordinate and runs from 1 at $r=0$ to M at $r=a$. Similarly, the n index is for the z coordinate and runs from 1 at $z=0$ to N at $z=d$. Equation [2] becomes

$$-k_i(T_{n,M}-T_{n,M-1})+hq_{i,j}(T_{n,M})=0 \quad [9]$$

Equation [4] gives

$$T_{n,1}-T_{n,2}=0 \quad [10]$$

Similar expressions for Eq. [3] and [5] are

$$-k_i(T_{1,m}-T_{2,m})+hq_{i,j}(T_{1,m})=0 \quad [11]$$

$$T_{N,m}-T_{N-1,m}=0 \quad [12]$$

This gives enough equations so one could, in principle, solve for each $T_{n,m}$, but because Eq. [9] and [11] are nonlinear in T, a closed form solution is probably impossible. We have thus chosen to first assume values for $T_{n,m}$ and use these in an iterative process (Gauss-Seidel method) to calculate new values. Because of the rather slow convergence, it is necessary to use overrelaxation to speed the process (19).

Figure 3 shows a plot of the temperature as a function of length for the center and outer surface of the ampul where we assumed that the 6 cm long and 1 cm diameter ampul is symmetrically located within a 2 cm hot zone at 1000°C. Physical parameters appropriate to the growth of CdTe with a Te solvent were used (Table I). Figures 4 and 5 are plots of isotherms for two different values of the liquid-solid interface (600° and 750°C). Note that only near the junction of the high and the low temperature regions does a nearly flat zone

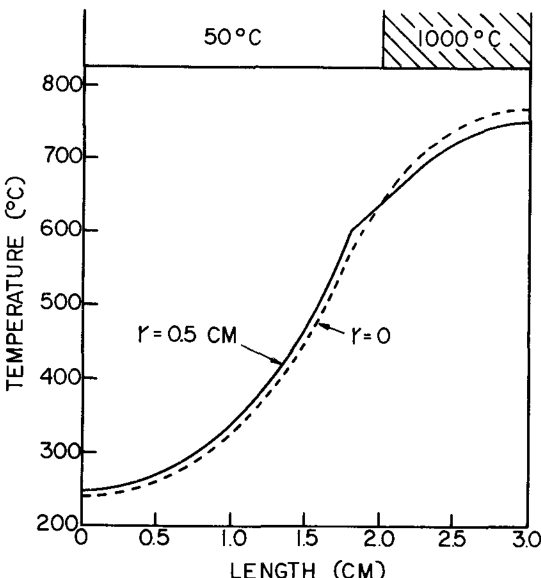

Fig. 3. Temperature distribution along the ampul at the center, $r = 0$, and on the outer surface, $r = 0.5$ cm. An interface temperature of 600°C was assumed. The rod is 6 cm long and is symmetrically located in the 2 cm heater. A heater temperature of 1000°C and air temperature of 50°C was assumed. Parameters given in Table I were used for the calculation.

occur and even here the isotherm is never perfectly flat. The curvature changes from concave (the shape of the growing crystal) when the interface is out of the heater (Fig. 4) to convex when the interface is within the hot zone (Fig. 5). The latter condition is more desirable for preventing new crystallites that nucleate on the walls from growing into the crystal. Naturally a perfectly flat growth interface is ideal, but if that is not possible, then a slightly convex shape is probably better than concave.

Rather than making a complete temperature map for each set of conditions, it is more effective just to look at the shape and position of the interface while holding all parameters fixed except for one which is allowed to vary. Figure 6 shows the changes as the interface temperature changes. The further the interface is from the heater junction, the greater the curvature. Figure 7 shows the result of changing the heater temperature with the interface temperature held constant at 650°C. The highest heater temperatures expand the zone and produce a strongly concave shape. In actual physical situations the effect will not be as drastic because as the temperature is increased the solution will become more concentrated and the liquid-solid transition temperature generally will increase, by an amount given by the phase diagram.

Conclusions

During THM, many different parameters can interact to affect the geometry and temperature of the interface. The amount of material in solution will be determined by the interface temperature which, in turn, is determined by the relative position of the heater and interface. To complicate matters still further, the length of the solvent zone will depend, to some extent, on the amount of feed material in solution.

Naturally, the final adjustment of the growth parameters must be done experimentally, but calculations such as these for a particular solvent-solute will make the problem much easier.

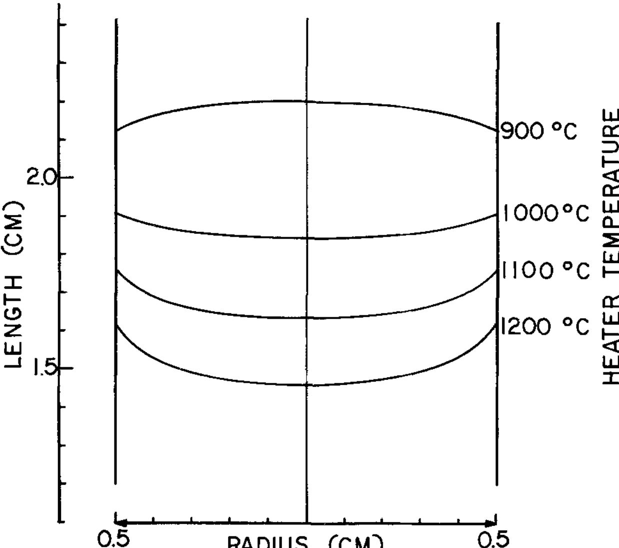

Fig. 7. Shape and position of the liquid-solid interface for various heater temperatures. An interface temperature of 650°C was used, otherwise all other parameters were the same as for Fig. 6.

Some practical implications that have become apparent from these calculations and those in the Appendix are:

1. Only near the junction of the high and low temperature regions does a reasonably flat isotherm occur, and here it is apparently never absolutely flat. For shorter solvent zones, the interface becomes convex and for longer zones, concave. From the point of view of the best crystallinity, a short solvent zone with a long heater is desirable, but in order to obtain fast growth rates and to prevent constitutional supercooling, a large gradient, which implies a short heater, is necessary. Thus, the optimum configuration must be determined for each different crystal-solvent system.

2. If the thermal history of the crystal is important, for example, to control the defect structure, it is necessary to be aware of the thermal distribution and how it changes as the position of the crystal relative to the heater changes. Longer ingots will be annealed at lower temperatures.

3. Keeping other parameters constant, increasing the radius will decrease the thermal gradients along the rod. This is because the heat gain or loss is through the surface whose area is proportional to the radius, but heat transport is along the rod whose cross-sectional area is proportional to the square of the radius.

4. At the beginning and end of THM growth, where only one end of the ampul sticks out of the furnace, a substantial increase in the temperature of the solvent zone can occur. This is because the heat loss can only occur in one direction rather than in two, as at an intermediate position. One way to overcome this is by the use of dummy ends. Naturally, use of an extra long ingot and discarding the ends would work, but the slow growth speeds do not make this very attractive.

5. The temperature is a very strong function of the length of the heater and of the thermal conductivity of the material. Because of this, attempts to determine the absolute thermal profile with a bare thermocouple without the ampul present may be misleading, although relative values make some sense. Since the length of the ampul will have a pronounced effect on the temperature, reproducible experiments can only be made with careful control of the geometry. The principal effect of going to a longer ingot is to decrease the temperature because more radiating surface is available and the heat input can only increase slightly.

Acknowledgments

I would like to acknowledge the support of the United States Atomic Energy Commission (Contract No. AT(11-1)-3545), and the Advanced Research Project Agency (Order No. 1846) for this work. I would especially like to thank Mr. Fritz Wald of Tyco Laboratories, Inc. for many interesting discussions which greatly stimulated this contribution.

Manuscript submitted July 13, 1973; revised manuscript received March 11, 1974.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1975 JOURNAL. All discussions for the June 1975 Discussion Section should be submitted by Feb. 1, 1975.

APPENDIX

In addition to the direct numerical integration of the Laplace equation, two other models have been used and proved useful for determining the effect of various parameters on the temperature distribution during THM. They are briefly discussed in this Appendix.

One-dimensional temperature distribution.—This model is a one-dimensional approximation that neglects radial gradients. Assume that the rod of radius, a, and length, d, can conduct heat along its length and is in thermal equilibrium with its surroundings when radiation and convection are considered. The solvent is located between b and c (Fig. 8a).

The hot zone is at a temperature T_2, the outside at T_1, and the air temperature is T_a. By looking at the heat flow along a small section of the rod and neglecting radial gradients, the equation governing the temperature, T, as a function of position, x, can easily be shown to be

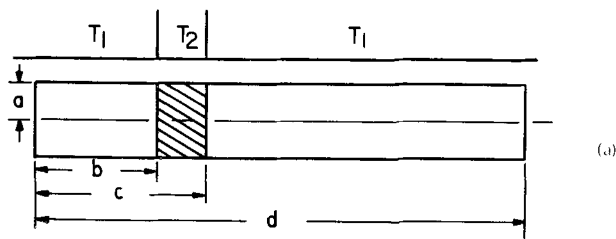
$$\pi a^2 k_i \frac{d^2T}{dx^2} = 2\pi a \epsilon_i \sigma (T^4 - T_i^4) + 2\pi a h_s (T - T_a)^{1.25} \qquad \text{[A-1]}$$

where k_i is the thermal conductivity of material in region i, σ is the Stefan-Boltzmann constant, ϵ_i is the emissivity of material in region i, and h_s is the heat transfer coefficient for convection.

The boundary conditions for insulated ends are

$$\left.\frac{dT}{dx}\right|_{x=0,d} = 0 \qquad \text{[A-2]}$$

i.e., heat flux from the ends is neglected. For freely conducting ends the heat flux should naturally be equated to the loss via radiation and convection. Also, at the interface between two materials of different con-



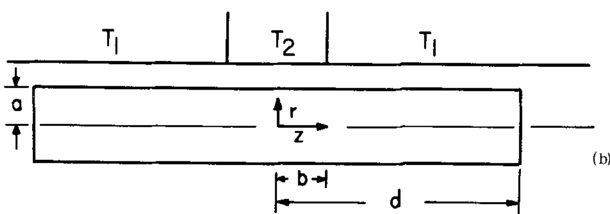


Fig. 8. (a) Geometry used to analyze one-dimensional temperature distribution. The air temperature is T_a. The thermal conductivity and emissivities are different in different regions. (b) Geometry assumed to calculate temperature distribution in a homogeneous rod. The distribution will be symmetrical about $z = 0$.

ductivities, the flux and temperature must be continuous.

To obtain numerical values after dividing through by $\pi a^2 k_i$, Eq. [A-1] and [A-2] are written as difference equations with a spacing of h: and solved for T_{n+1} and T_1

$$T_{n+1} = 2T_n - T_{n-1} + h^2 f(T_n) \quad \text{[A-3]}$$

$$T_1 = T_0 + h^2 f(T_0)/2 \quad \text{[A-4]}$$

where

$$f(T) = \frac{2\epsilon_i \sigma}{k_i a}(T^4 - T_1^4) + \frac{2h_s}{k_i a}(T - T_a)^{1.25} \quad \text{[A-5]}$$

A value of the temperature on the left-hand side, *i.e.*, T_0, was assumed and by successive application of the difference equation and requiring the continuity of the flux at the interface of the two different materials, the temperature, and, therefore, the thermal gradient on the right-hand side was determined. A different value of the initial temperature was assumed and a new gradient at $x = d$ was calculated. An extrapolation was made to provide a starting temperature that satisfies the boundary conditions at $x = d$, Eq. [A-2]. This new starting temperature was used to iterate the whole procedure until the appropriate distribution was determined (20).

Some results are shown in Fig. 9, where the effect of making the total ampul longer and longer is examined. Note that the gradient in the Te zone is smaller than in the CdTe because of the larger thermal conductivity of the Te. The hot zone is assumed to be as long as the Te solvent, although this is not necessary but is only done for convenience. The principal effect of going to a longer ingot is to decrease the temperature, obviously, because more radiating surface is available and the heat input can only increase slightly.

Another interesting result is to compare the temperature distribution when the ampul is symmetrically located and when it is displaced (Fig. 10). A substantial increase in the solvent temperature occurs in the asymmetric case with an increase of temperature at zone center.

Analytical solution for temperature distribution.—If we want a reasonably simple analytical solution, we must restrict our generality. Boundary conditions where thermal radiation is involved require T^4 terms and do not often produce neat or closed form results. We will thus use an effective heat transfer coefficient so that the flux across the surface will be proportional to the temperature difference. We also assume that the thermal properties of the rod are homogeneous and isotropic. For a steady temperature, the equation governing the heat distribution is the Laplace equation.

Using the geometry shown in Fig. (8b), the radius of the rod is a, the total length is $2d$, and the length of the heater, which is centered, is $2b$. The heater temperature is T_2 and the temperature around the rest of the ampul is T_1. It is easy to show that the temperature as a function of radius r, and length, z, is given by the series

$$T = T_2 + \sum_{n=1}^{\infty} C_n \cosh(\alpha_n z) J_0(\alpha_n r) \quad 0 < z < b \quad \text{[A-6]}$$

$$T = T_1 + \sum_{n=1}^{\infty} [A_n \sinh(\alpha_n z) + B_n \cosh(\alpha_n z)] J_0(\alpha_n r) \quad b < z < d \quad \text{[A-7]}$$

The solution will be symmetrical about $z = 0$; thus for $z < 0$, it is necessary to replace A_n by $-A_n$. α_n is the nth root of the characteristic equation

$$\alpha_n J_0'(\alpha_n a) + h J_0(\alpha_n a) = 0 \quad \text{[A-8]}$$

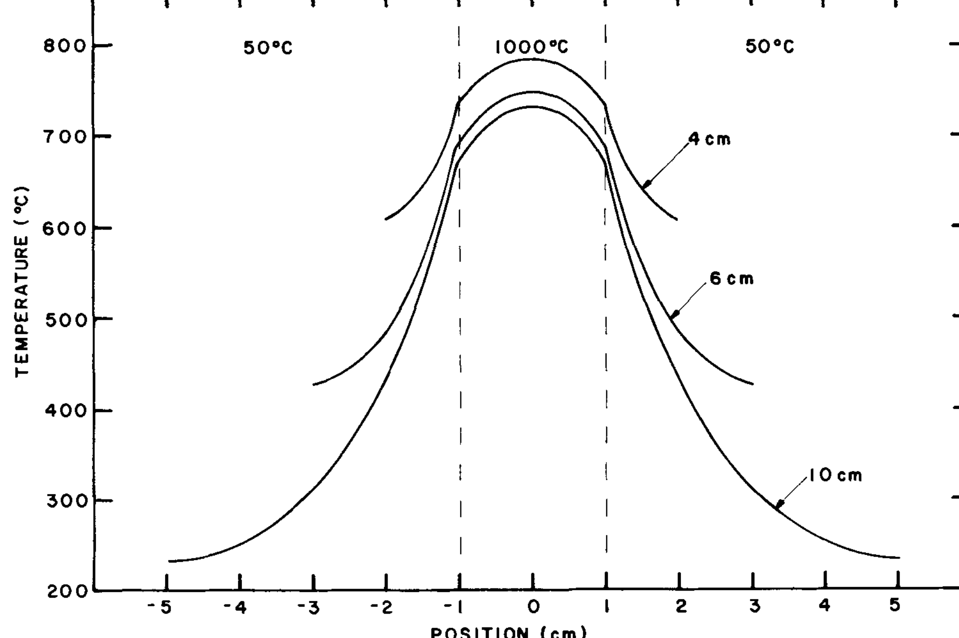

Fig. 9. Temperature along a 1.2 cm diameter ampul for lengths of 4, 6, and 10 cm. For a one-dimensional model, parameters given in Table I were used for the calculation.

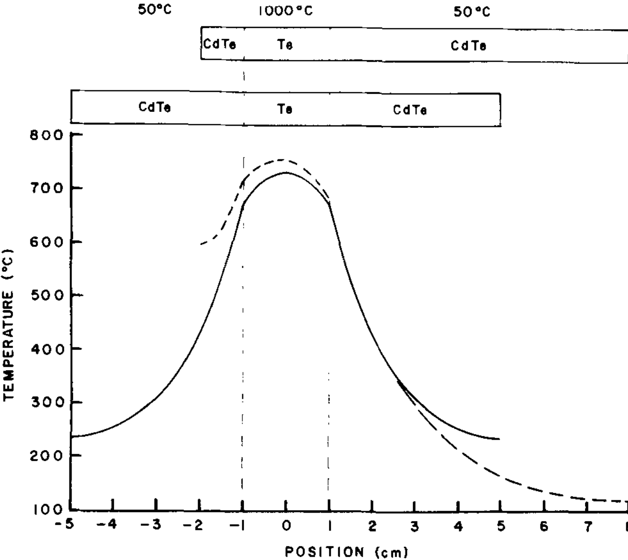

Fig. 10. Temperature distribution for the case of a symmetrically located ampul (solid line) and an ampul displaced 3 cm to the right (dashed line) for a one-dimensional model. Parameters given in Table I were used for the calculation.

$J_0(x)$ is the zeroth order Bessel function. The prime indicates differentiation with respect to the argument. $h = H/K$ where K is the thermal conductivity and H is the linear heat transfer coefficient related to the heat flux through the surface, F, by the boundary condition

$$F = -K\nabla T = H(T - T_1) \qquad \text{[A-9]}$$

The boundary conditions for uninsulated ends are

$$\frac{\partial T}{\partial z} + h(T - T_1) = 0 \quad \text{for} \quad z = d \qquad \text{[A-10]}$$

$$\frac{\partial T}{\partial r} + h(T - T_2) = 0 \quad \text{for} \quad r = a \text{ in Eq. [A-6]} \qquad \text{[A-11]}$$

$$\frac{\partial T}{\partial r} + h(T - T_1) = 0 \quad \text{for} \quad r = a \text{ in Eq. [A-7]} \qquad \text{[A-12]}$$

$$T^+ = T^- \quad \text{for} \quad z = b \qquad \text{[A-13]}$$

$$\frac{\partial T}{\partial z} = \frac{\partial T}{\partial z} \quad \text{for} \quad z = b \qquad \text{[A-14]}$$

Equations [A-11] and [A-12] are already satisfied by the form of the solutions chosen and the characteristic equation. The general procedure to follow is to use Eq. [A-7] to substitute for T in Eq. [A-10].

Multiply by $rJ_0(\alpha_m r)$, integrate from $r = 0$ to $r = a$ and using the properties of integrals involving Bessel functions such as given by Carslaw and Jaeger (21) find

$$B_n = -A_n \frac{\alpha_n + h \tanh(\alpha_n d)}{\alpha_n \tanh(\alpha_n d) + h} \qquad \text{[A-15]}$$

Similar procedures can be used on boundary conditions Eq. [A-13] and [A-14] to obtain

$$A_n = -\Delta T \sinh(\alpha_n b) \frac{2h_a}{[(\alpha_n a)^2 + (ha)^2]} \frac{1}{J_0(\alpha_n a)} \qquad \text{[A-16]}$$

and

$$C_n = B_n + A_n \operatorname{ctnh}(\alpha_n b) \qquad \text{[A-17]}$$

where $\Delta T = T_2 - T_1$. This along with the solution to the characteristic equation, Eq. [A-8], are enough to allow us to calculate T as a function of r and z. This result is similar to that obtained by Cook *et al.* (22) who used modified Bessel functions. It is only slightly more difficult to treat the case where three different lengths of the rod are exposed to three different temperatures, but because the expressions for the coefficients are more cumbersome than Eq. [A-15], [A-16], and [A-17], it would add little to the discussion to write them down.

Solutions have been calculated but are not reported here since the numerical integration presented in the foregoing is a better approximation to physical reality.

Diffusion as the Rate Controlling Step in the Reaction of Tungsten Hexafluoride with Tungsten and the Role of Tungsten Pentafluoride

Lewis V. McCarty,* William E. Reith,[1] and Mariellen T. Simon[2]

Lighting Research and Technical Services Operation, General Electric Company, Nela Park, Cleveland, Ohio 44112

ABSTRACT

Estimated thermodynamic properties of the molecule tungsten pentafluoride indicate that it may be the reactive intermediate formed at high temperatures when tungsten hexafluoride etches tungsten. The calculated concentration of tungsten pentafluoride that can form at equilibrium is adequate to explain the etching reaction between 1500°-2680°K, and it becomes sufficiently unstable above 2300°K to explain the transition from etching to deposition at higher temperatures. The differences in reaction rates in the three carrier gases argon, nitrogen, and helium, point to a diffusion controlled reaction. The reaction rates from diffusion calculations of tungsten hexafluoride into, and tungsten pentafluoride out of the Langmuir sheath are in good agreement with experiment for helium, and are reasonable for argon and nitrogen. Convective distortion of the Langmuir sheath is suspected as the cause of the higher than expected etching rates in the latter two gases as well as the higher than expected rates as the temperature increases.

Tungsten hexafluoride reacts with tungsten in a series of complex reactions. From about 900° to 2300°K the important reaction etches the metal and transports tungsten to cooler parts of the system. Tungsten powder deposits on cold surfaces as the result of a disproportionation reaction that reforms tungsten hexafluoride.

At higher temperatures whatever intermediate compound forms decomposes to tungsten metal and fluorine atoms. Presumably the decomposition reaction has a large enthalpy of reaction, at least larger than that of the etching reaction, and above 2500°K, depending upon the partial pressure of fluorine compounds, it overwhelms the etching reaction and tungsten deposits from the gas. This qualitative reaction scheme is implicit in work reported by Schroeder (1).

More recently Schroeder and Grewe (2) have reported on the preparation of tungsten pentafluoride, and Schroeder and Sieben (3) on its enthalpy of formation. When their data is extrapolated to high temperatures, it suggests that the reactive intermediate may be tungsten pentafluoride. The important reactions would then be

$$5WF_{6(g)} + W_{(s)} \underset{\text{low temp.}}{\overset{\text{high temp.}}{\rightleftharpoons}} 6WF_{5(g)} \qquad [1]$$

$$WF_{5(g)} \underset{\text{low temp.}}{\overset{\text{high temp.}}{\rightleftharpoons}} W_{(s)} + 5F_{(g)} \qquad [2]$$

One purpose of this report is to discuss how well this reaction scheme fits the experimental data.

The experimental part of this work used 25W-1100 hr tungsten coils. Early work indicated that the relatively long cool zone at each end of an electrically heated straight filament caused serious errors during the determination of rates of reaction. This error can be minimized, but not eliminated, by using small wire sizes in coil form.

The use of coils introduces another complication in these measurements. The light from between the turns of the incandescent coil is brighter than the light from the outside of the coils because of internal reflections (4, 5). An empirical correction curve was established for the 25W coils, and all of the optical pyrometer measurements of temperature have been so corrected.

When a filament or coil is heated to incandescence in an inert gas, a Langmuir sheath surrounds the coil (16) with properties that vary depending upon the kinetic parameters of the gas. Variations in reaction rate for tungsten hexafluoride with tungsten in the gases nitrogen, argon, and helium have been observed and are compared with calculated rates of diffusion.

Experimental

Gas flows were measured into a ⅛ in. copper manifold to mix and conduct the gases to the reaction chamber. Nitrogen, argon, or helium were controlled with one Pyrex flowmeter, and a small Pyrex flowmeter with a sapphire ball and Nichrome wire ball retainers measured the tungsten hexafluoride flow. When not in use, both flowmeters, the manifold, and the reaction chamber were flushed with dry, lamp-grade nitrogen. Teflon and Kel-F plastic parts were avoided because they degenerated during repeated use and seemed to absorb tungsten hexafluoride which was released slowly when not wanted.

The reaction chamber was made from 2 in. OD Pyrex tubing with an inlet near the bottom, a 65/40 Pyrex ball joint with an O-ring seal, ¼ in. nickel electrodes, and an exit to a long surge chamber to prevent air sucking into the reaction chamber when the coils were turned off.

Electrically heated, 25W-1100 hr tungsten coils, 49.1-50.7 mm in length, weighing 8.03 ± 0.10 mg were used for the solid reactant. The wire diameter was 1.21 mils, and they were wound on 4.2 mil mandrels with a 118% pitch. A razor blade flattened 3-5 turns on each end of the coils to form an attachment to small bronze clips spaced 17 mm apart on the ends of the nickel leads. When heated the coils sagged under their own weight to a pitch near 140%.

Voltage to the Variacs for a.c., and to the Variacs and rectifier system for d.c., for heating the coils was regulated by a Sola transformer to ± 0.1V. Electrical power to the filament was turned on and off by a mercury relay inserted just ahead of the coil to eliminate any time lag required to energize the electrical equip-

ment. The mercury relay was controlled by a 40 sec timer with an adjustable "on" time cycle. The timer also controlled an electric stopwatch and recorded "on" times to a tenth of a second but was estimated to the nearest hundredth second. In early work 60 cycle a.c. was used to heat the coils for the tests in nitrogen between 2546° and 2716°K. The ripple in light emission from a-c heated coils amounts to several per cent which corresponds to several tens of degrees variation in temperature. To eliminate any possible effect in the reaction zone, d.c. was used for the nitrogen work between 1451° and 1894°K, all of the argon work, and for most of the helium work; a.c. was used for the two helium rate determinations at 2552° and 2636°K. So far as could be determined there was no observable effect caused by changing from a.c. to d.c.

The reaction chamber was flushed for at least 4 min with inert gas for the usual case of a flow of 1517 ml/min measured at 741.7 Torr and 24.0°C, and correspondingly longer times for lower flow rates. The coils were heated to the intended reaction temperature for at least 1 min to remove dirt and oxides from the surface before measuring the current and voltage needed to give a predetermined temperature. They were weighed after cooling and remounted in the reaction chamber. Each was again flushed for at least 4 min with the inert gas, 4-5 min with a mixture of inert gas and tungsten hexafluoride (20.0 ml/min measured at 741.7 Torr and 24.0°C in the usual case), flashed at the predetermined voltage for measured times, flushed once again with pure inert gas, flashed to remove traces of fluoride from the surface, and reweighed.

Temperature measurements of the coils with an optical pyrometer is less than satisfactory because it is difficult to match colors with the calibrated filament. A better technique (6) places a wide ribbon filament back of the coil to be measured, and it is easier to match the coil to this broad area than to the relatively smaller pyrometer filament. In our case an 18A, 75-80 mil ribbon filament, spectrographic lamp was matched to the desired temperature with the optical pyrometer which was focused on the test coil, and not on the ribbon filament. Although the ribbon is out of focus and the edges are apparently "low" in temperature, the central portion is wide enough to appear uniform. After establishing the current to maintain the ribbon at the desired temperature, the coil is matched to the ribbon using the pyrometer telescope and filter. Too much magnification is not an advantage because it becomes difficult to match colors if the individual turns are clearly resolved. Refraction effects in the Langmuir sheath also interfere with the images making complete disappearance into the background impossible.

In spite of the obvious difficulties with the optical determination of coil temperature, a calibration of the technique was accomplished by measuring apparent temperatures of coils and comparing with the true temperature obtained by focusing a micropyrometer on the outside of an individual turn at 125X magnification for the same current. The correction factors, Δ, are fitted by the equation

$$\Delta = [(°K^{3.237})/(7.218 \times 10^8)] \pm 7°$$

The emissivity data for tungsten published by DeVos (7) was used to calculate temperature.

Results

The data in Fig. 1 are typical of the individual weight changes found in this work. The slopes of straight lines such as these have been plotted in Fig. 2, 3, 4, and 5. Figure 2 shows that the etching reaction is more rapid in helium than in nitrogen, and comparable data for argon in Fig. 3 are somewhat slower.

The rate of reaction is proportional to the tungsten hexafluoride concentration in the etching region below 2200°K according to the data of Fig. 3 and 4. There is also a marked lowering of the transition temperature between the etching and deposition regions as the concentration decreases.

Figure 5 shows that the reaction rate is independent of flow rate below one liter per minute, 59 cm/min in this equipment, and increases modestly at higher flow rates.

Discussion

The results in Fig. 2 and 3 illustrate that the inert gas has an influence on the rate of the reaction and the transition from an etching reaction to a deposition reaction. The etching reaction is most rapid in helium and the transition temperature is lowest. Both effects are likely related to diffusion controlled processes, and part of this discussion will be concerned with the role of diffusion through the Langmuir sheath surrounding the hot filament.

Another feature of interest is the shape of the curves. This can be related to the kind of intermediate or lower valence tungsten fluorides that are formed. An attempt has been made to estimate thermodynamic functions for tungsten pentafluoride gas, and its role will be discussed first.

Estimated thermodynamic functions for the molecule $WF_{5(g)}$.—Tungsten forms hexahalides with the three halogens bromine, chlorine, and fluorine. The hexabromide is the least stable and will decompose upon gentle warming to the pentabromide. The hexachloride is more stable and can be heated to its boiling point 346.7°C. The vapor density above the boiling hexachloride shows evidence of dissociation (8), however, and thermodynamic data (9) can be used to show that one of the products is probably tungsten pentachloride. Schroeder and Grewe (2) have shown that 10 Torr of tungsten hexafluoride in contact with tungsten at 500°-700°C will generate tungsten pentafluoride which condenses on a surface cooled to −50° to −60°C. Experimentally, the pentahalides can be formed from the hexahalides, and the temperature at which this occurs is related to the stability of the latter.

The only reliable thermodynamic data for tungsten pentafluoride is as the solid. Schroeder and Sieben (3) used fluorine bomb calorimetry to measure the enthalpy of the fluorination of $WF_{5(s)}$ to $WF_{6(g)}$. This value was combined with the enthalpy of formation of $WF_{6(g)}$ to give the enthalpy of formation of $WF_{5(s)}$ quoted in Table I. Unfortunately, no other experimental data for tungsten pentafluoride solid or gas is available. All of the information needed for the thermodynamic cycles to give the enthalpy of $WF_{5(g)}$ in Table I has been estimated. Fortunately, the absolute value of the estimated enthalpy for the sublimation of the pentafluoride at 298°K is only +17.5 kcal/mole. Because it is so much less than the enthalpy of either species, errors in the estimates are somewhat less important than they might ordinarily be.

Table I. Thermodynamic properties of $WF_{5(c)}$, $WF_{5(l)}$, and $WF_{5(g)}$

Known values:

$\Delta H^\circ_f = -346.1 \begin{matrix} +2.6 \\ -1.0 \end{matrix}$ kcal/mole (3) at 298°K for $WF_{5(c)}$

Estimated values:

Melting point of $WF_{5(c)}$	~ 399°K
Heat of fusion of $WF_{5(c)}$	~ 4 kcal/mole
Boiling point of $WF_{5(l)}$	~ 521°K
Heat of vaporization of $WF_{5(l)}$	~ 12 kcal/mole
Heat capacity of $WF_{5(c)}$	~ 31.7 gibbs/mole
Heat capacity of $WF_{5(l)}$	~ 34.7 gibbs/mole
Heat capacity of $WF_{5(g)}$	~ 26.4 gibbs/mole (298°-521°)

$\Delta H^\circ_f = -328.6$ kcal/mole at 298°K for $WF_{5(g)}$
$S^\circ = 79$ gibbs/mole at 298°K for $WF_{5(g)}$

Heat capacity data are needed to calculate free energy and equilibrium values at high temperatures. The heat capacity for $WF_{5(g)}$ should be somewhat less than that given for $WCl_{5(g)}$ in the JANAF tables (9). What seemed like a reasonable correction for the difference between five tungsten-fluorine and five tungsten-chlorine bonds was obtained by taking 5/6 of the difference between the heat capacities for $WCl_{6(g)}$ and $WF_{6(g)}$. Values were calculated for each 100° interval; some are listed in Table II.

The function $H_T - H_{298}$ in Table II was calculated by averaging the heat capacity values for a 100° interval, multiplying by 100°, and adding to the accumulated function. The entropy as a function of temperature was determined by a similar technique; the entropy increment for each 100° was approximated by dividing the average heat capacity by the average temperature, and successively adding to the original estimate at 298°K, 79 gibbs/mole. The free energy function $\frac{-(G^\circ_T - H^\circ_{298})}{T}$ was calculated from the function $S^\circ_T - \frac{(H^\circ_T - H^\circ_{298})}{T}$. Free energy function values for $F_{2(g)}$ and $W_{(s)}$ from the JANAF (9) tables were combined with the estimated values for $WF_{5(g)}$ to give the estimated free energy values, ΔG°, in Table II.

Neumann and Knatz (17) have independently estimated free energies for $WF_{5(g)}$ which are within 2 kcals/mole of the values in Table II up to 3000°K.

Estimated partial pressures of $WF_{6(g)}$, $WF_{5(g)}$, and $F_{(g)}$ at the surface of hot tungsten.—The estimated free energy values for $WF_{5(g)}$ have been combined with the values available for $WF_{6(g)}$ and $F_{(g)}$ from the JANAF tables (9) to provide free energies of reaction for reactions [1] and [2] between 1400° and 2800°K. The equilibrium constants derived from the free energies of reaction were combined with a mass balance constraint to calculate equilibrium partial pressures of the three gaseous species for the two initial partial pressures of interest in Fig. 6.

A comparison of Fig. 6 with Fig. 3 shows that several of the main features of the reaction can be re-

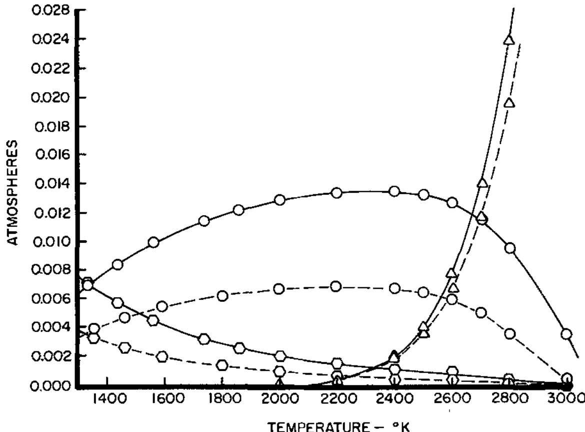

Fig. 6. Estimated WF_6 (○), WF_5 (○), and F atom (△) concentrations; ——— 0.0127 atm of WF_6 initially, - - - - - - 0.0065 atm of WF_6 initially.

lated to the amount of tungsten pentafluoride formed. According to reaction [1] it is the agent responsible for transporting tungsten from the hot coil surface to the cooler gas where disproportionation reforms $WF_{6(g)}$ and solid tungsten as a powder. According to Fig. 6 there should be substantial reaction at 1400°K which increases in amount up to some maximum in the 2200°-2400°K range which agrees with the experimental data of Fig. 3 fairly well. But this simple mechanism would still transport tungsten from the coil to the cooler gas even above 2800°K which is not true.

Reaction [2] becomes important above 2200°K, and when the fluorine atom concentration equals the $WF_{5(g)}$ concentration, etching effectively stops because of the reaction

$$WF_{5(g)} + F_{(g)} \rightarrow WF_{6(g)} \qquad [3]$$

in the cooler gas. At higher temperatures greater amounts of fluorine atoms are evaporating from the coil surface, and deposition of tungsten metal occurs. Because of the rapid increase in fluorine atom concentration at higher temperatures, deposition occurs even though $WF_{5(g)}$ is still an important species in this system.

A good test of whether reactions [1] and [2] account for this system is how well the calculated transition temperature for the etching to deposition ranges agrees with experiment. For 0.0127 atm of $WF_{6(g)}$ initially in Fig. 6, the partial pressures of $F_{(g)}$ and $WF_{5(g)}$ are equal at 2670°K and the experimental value is 2680°K in Fig. 3. For 0.0065 atm of $WF_{6(g)}$ initially the calculated value in Fig. 6 at 2580°K compares with 2510°K determined experimentally.

In spite of the good qualitative agreement of the calculated data based on simple equilibria with experiment, there are quantitative discrepancies in the rates of reaction at lower temperatures. Between 1500° and 2300°K the rate of tungsten removal in Fig. 3 increases by a factor of at least three while the calculated increase in $WF_{5(g)}$ concentration is less than one and one-half. The rate of reaction is not directly proportional to the amount of $WF_{5(g)}$ expected to form.

The role of $WF_{2(g)}$.—Neumann and Knatz have estimated a free energy of formation for $WF_{2(g)}$ (17). Calculations by Neumann and Gottschalk (18) indicate that this molecule is so stable that only etching reactions should have been observed in the temperature range of the present experimental work. This is clearly not the case which suggests that $WF_{2(g)}$ may not be as stable as originally thought. For similar reasons Dittmer *et al.* (19) also estimate a lower stability for $WF_{2(g)}$.

The diffusion of $WF_{6(g)}$ through the Langmuir sheath.—In the etching region, the reaction rates are slowest in argon and greatest in helium, but the rates do not differ as much as expected for a reaction controlled entirely by diffusion. Nevertheless, it was felt worth while to try to estimate the rates on the basis of a diffusion model.

A calculated diffusion value in terms of moles of WF_6 transported to the coil per centimeter per second requires a diffusion coefficient and a thickness of the Langmuir sheath. The diffusion coefficient is a function of temperature, but the temperature profile as a function of distance from the filament is not known accurately. It was assumed that the temperature dependence was a simple linear function of the radius.

The diffusion coefficient, D_{12}, for gas 1 diffusing into gas 2 is given by Kennard (10) as

$$D_{12} = \frac{3}{8\sqrt{2\pi}\,N_o}\,\frac{(RT)^{3/2}}{P}\,\frac{\sqrt{\dfrac{1}{M_1}+\dfrac{1}{M_2}}}{d_{12}^2}$$

where $N_o = 6.023 \times 10^{23}$ molecules/mole, the Avogadro number; $R = 8.3144 \times 10^7$ g cm^2 sec^{-2} deg^{-1} mole^{-1}; P = dynes cm^{-2}; and d_{12} = intermolecular distance in cm. The quantity d_{12} is half the sum of the molecular diameters of tungsten hexafluoride and the inert gas. Molecular diameters in Table III for the inert gases were obtained (11) from gas viscosity measurements. The WF_6 molecular diameter is assumed to be equal to twice the tungsten fluorine bond distance (12), plus twice the fluoride ion radius (13). Substitution of the appropriate intermolecular distances in the diffusion coefficient equation gives the calculated diffusion coefficients of Table IV.

Langmuir sheath thicknesses have been calculated for an 0.0099 cm filament by Covington for a variety of gases (14) from the equation

$$b \ln (b/a) = K_3 \left(\frac{\eta}{\rho}\right)^{2/3} (\theta\beta)^{-1/3}$$

where b = Langmuir sheath diameter, cm; a = filament diameter, cm; K_3 = constant, 2.41 for horizontal filaments and 2.82 for vertical filaments; η = gas viscosity at average temperature, g sec^{-1} cm^{-1}; ρ = gas density at average temperature, g cm^{-3}; θ = difference between filament and bulb temperature, °K; and β = coefficient of thermal expansion, °K^{-1}. The Langmuir sheath sizes in Table V were recalculated for the 25W-1100 hr coils as if they were simple cylinders with an outside diameter of 0.0168 cm. The coils were used

Table III.

Gas	Molecular weight	Molecular diameter
Argon	39.948	2.86×10^{-8} cm
N_2	28.0134	3.16×10^{-8} cm
He	4.0026	2.00×10^{-8} cm
WF_6	297.84	6.44×10^{-8} cm

Table IV. Diffusion coefficients for WF_6 in various gases

N_2	0.46 cm		0.55 cm
A	0.44 cm		0.54 cm

in a "V" shape with the legs somewhat more than 16° from the vertical. Covington (14) has shown that a filament tilted 20° from the vertical behaves like a horizontal filament, and sheath sizes for horizontal filaments were used in the present work.

Diffusion in this system is taking place through a distorted cylinder around a relatively straight length of coil. An equation for cylindrical diffusion through a stagnant film of inert gas was developed that is similar to the spherical case discussed by Bird, Stewart, and Lightfoot (20). For the case of a linear temperature profile represented by the equation

$$T = a - br$$

where r is the radius, the equation becomes

$$Q = \frac{2\pi P D_{12,T_2} \sqrt{a} \ln [X_{B_2}/X_{B_1}]}{R T_2^{3/2} \ln \left[\frac{T_1^{1/2} - \sqrt{a}}{T_1^{1/2} + \sqrt{a}} \cdot \frac{T_2^{1/2} + \sqrt{a}}{T_2^{1/2} - \sqrt{a}} \right]}$$

In this equation Q = moles of WF_6 transported, $cm^{-1}\ sec^{-1}$; D_{12,T_2} = diffusion coefficient, $cm^2\ sec^{-1}$, at T_2; R = 82.0567 cm^3 atm deg^{-1} $mole^{-1}$; T_2 = temperature of coil surface; T_1 = room temperature, 300°K; X_{B_2} = mole fraction of inert gas at coil surface; and X_{B_1} = mole fraction of inert gas outside of Langmuir sheath surface. Rates of WF_6 transport were calculated for the etching region by using the estimated equilibrium concentration at the coil surface to determine the mole fraction of inert gas at the inside boundary of the Langmuir sheath, and the mole fraction of inert gas for 0.0127 atm of WF_6 at the outer boundary. For this purpose, species like WF_5 and fluorine atoms were treated as inert. Since five molecules of WF_6 are required to remove one atom of tungsten according to Eq. [1], the transport rates for WF_6 were divided by five to obtain the calculated rates of tungsten metal removal in Table VI.

The experimental rates in argon at 1475°K, and helium at 1663°K, were determined from the experimental data by dividing by 4.98 cm, the coil length, and 183.84, the atomic weight of tungsten. Data for the other experimental rates in Table VI were read from their respective plots in Fig. 2 and 3.

In Table VI, the calculated rates in helium are 22% too high at 1663°K and 12% too low at 2300°K. In the heavier gases, nitrogen and argon, the calculated values are 34 and 26% too low at 1475°K, and both calculated values are 62% low at 2300°K. All calculated values are within a factor of three of the experimental rates.

Thus, over-all agreement, and the really very good agreement for the helium case, indicates that diffusion is the rate controlling process. It is clear, however, that some process related to higher molecular weight of the inert gas causes a relative increase in reaction rates in argon and nitrogen, and all experimental rates increase more rapidly than predicted by the diffusion model as the temperature increases.

In its originally suggested form, the Langmuir sheath was a relatively viscous, immobile layer of gas around a hot filament in which diffusion controlled the important rate determining properties, and convection was assumed to be unimportant. Brödy and Körösy (15) suggested that this is an oversimplification, and that convection accounted for as much as 10% of the heat transfer observed. Convective flow in nitrogen and argon should be more rapid than in helium because of the greater density difference for a given temperature gradient, and its effects should be more pronounced at higher temperatures as observed in all three gases. Convective flow compresses the lower side of the Langmuir sheath of a nonvertical filament and distorts it so that it is no longer circular. While some allowance for this distortion was made for these diffusion calculations, the results indicate that convective distortion for chemical transport may be more serious than indicated by heat transfer calculations. Convective distortion of the Langmuir sheath provides one reasonably satisfying way of accounting for the discrepancies from a simple diffusion limited rate model.

Table VI. Comparison of experimental rate of tungsten removal with rates calculated from kinetic theory for 0.0127 atm of WF_6

Temp (°K)	Gas mixture	Exp. rate of W removal (moles cm^{-1} sec^{-1})	Calcd. rate of W removal (moles cm^{-1} sec^{-1})
1475	WF_6-A	2.3×10^{-8}	1.7×10^{-8}
1475	WF_6-N_2	2.9×10^{-8}	1.9×10^{-8}
1663	WF_6-He	4.9×10^{-8}	6.0×10^{-8}
2300	WF_6-A	7.8×10^{-8}	3.0×10^{-8}
2300	WF_6-N_2	8.6×10^{-8}	3.3×10^{-8}
2300	WF_6-He	9.7×10^{-8}	8.5×10^{-8}

Figure 5 shows a modest increase in etching rate as the flow rate increases which is believed to be a distortion of the sheath by bulk transport akin to that caused by convection.

The diffusion of $WF_{5(g)}$ through the Langmuir sheath.—If one assumes that the WF_5 molecule is an hexagonal bipyramid in structure, then its radius of interaction with other molecules as a hard sphere should be the same as a WF_6 molecule. On this basis, the somewhat smaller molecular weight of WF_5 increases its calculated diffusion coefficient 0.4% over the corresponding value for WF_6 in argon where the change is greatest. When these coefficients are used in the diffusion equation with the calculated amounts of WF_5 at the coil surface, and assuming zero concentration at the outer edge of the Langmuir sheath, the calculated transport of WF_5 from the coil surface to the outer boundary of the sheath is almost exactly the same as the rate at which it forms from the transport of WF_6 into the tungsten. The values are 0.3% low for WF_5 at 1475°C and about 2% at 2300°K, but at the latter temperature, the equilibrium calculations show the formation of fluorine atoms as well as WF_5.

The effect of WF_6 partial pressure on the rate of tungsten weight loss.—Figure 4 shows that the rate of weight loss is proportional to the partial pressure of tungsten. The diffusion model developed here requires a dependence on $P_{WF_6}{}^{0.98}$ which would be difficult to distinguish from the linear equation.

Boron Diffusion Coefficient Increased by Phosphorus Diffusion

H. Nakamura, S. Ohyama, and C. Tadachi

Musashino Electrical Communication Laboratory, Nippon Telegraph and Telephone Public Corporation, Midori-cho, Musashino-shi, Tokyo, Japan

ABSTRACT

The emitter dip effect has been studied quantitatively at 900°C in boron-base phosphorus-emitter doubly diffused structure. An approximate expression for the emitter dip effect is derived. Experimental results are consistent with this expression. Using this expression and the experimental results, the effective boron diffusion coefficient, which is increased by phosphorus diffusion, is calculated and shown to be increased linearly with phosphorus surface concentration. It is suggested that the emitter dip effect occurs during emitter diffusion, not during cooling, and is not necessarily accompanied with diffusion induced dislocation.

Phosphorus diffusion into silicon has been very important in the semiconductor device industry. However, many anomalous effects have been reported on phosphorus diffusion, *e.g.*, emitter dip effect (1-9), anomalous phosphorus concentration profile (10-13), and diffusion coefficient dependent on concentration (14, 15). The emitter dip effect has been attributed to enhanced base impurity diffusion due to increase of vacancy concentration during emitter diffusion. To explain the mechanism in which the vacancy concentration is increased by emitter diffusion, several models have been reported, *e.g.*, the Fermi level effect (1, 16), dislocation climb (5, 8), or precipitation (4). Although those models seem plausible for the emitter dip effect caused by phosphorus-emitter diffusion, at least two experimental clarifications are required to determine the probable mechanism. One is to clarify the time when the emitter dip effect occurs. The other is whether this effect occurs necessarily accompanied with the diffusion-induced dislocation or not.

The present work was undertaken to clarify the problems described above, and to obtain the diffusivity of boron increased by phosphorus diffusion. First, an approximate analytic expression of the relationships between the amount of dip and various diffusion process parameters, which is analogous to that by Hu and Yeh (8), is derived. Then the experiments are performed carefully to verify the expression and its assumptions. Using this expression and the experimental results, the enhanced diffusion coefficient of boron during phosphorus diffusion is calculated. The significance of the phosphorus surface concentration in the increase of boron diffusion coefficient is determined.

Key words: emitter dip effect, enhanced diffusion, approximate expression.

Derivation of Approximate Expression

An approximate expression of the amount of dip is derived analytically under the condition that the base diffusion is performed by single heat-treatment with constant surface concentration followed by the emitter diffusion.

Assumptions used in the course of derivation of the expression are discussed with relation to the applicable experimental conditions. The base profile after the base diffusion cannot be expressed by complementary error function, because of concentration dependence of boron diffusion coefficient (17). During the emitter diffusion, the surface concentration of the base layer cannot be constant, because the base impurity source is removed. Furthermore, the diffusivity of the base impurity may be positionally affected by a built-in electric field produced by emitter diffusion (6, 7, 18), or some other interaction between impurities and carriers (22). At present, however, it is assumed that the base impurity profile is approximated by complementary error function, both during base and emitter diffusion. This assumption is assumed to be valid in determining the effective diffusion coefficient, if the change of base surface concentration and the interaction between base and emitter impurities are negligible. The former corresponds to the penetration of the base during emitter diffusion being small compared to the initial base depth. The latter corresponds to the base width being large.

Next, it is assumed that the enhancement of base diffusion occurs during emitter diffusion, but not during the cooling process. This assumption is confirmed in a later section of this paper.

It is now possible to analytically derive an expression of the amount of dip. The diffusion process and

the notations used are shown in Fig. 1. The base layer depth after base diffusion x_{j1}, is given by

$$x_{j1} = 2\sqrt{D_{B1}\,t_1}\ \mathrm{erfc}^{-1}\,(C_b/C_{sB}) \qquad [1]$$

where D_{B1} and t_1 are the diffusion coefficient and the time of the base diffusion, C_b is the bulk concentration, and C_{sB} is the surface concentration of the base. After the emitter diffusion, the junction depth at the singly diffused region is given by

$$x_{j2} = 2\sqrt{D_{B1}\,t_1 + D_{B2}\,t_2}\ \mathrm{erfc}^{-1}\,(C_b/C_{sB}) \qquad [2]$$

At the doubly diffused region, it is given by

$$x^*_{j2} = 2\sqrt{D_{B1}\,t_1 + D^*_{B2}\,t_2}\ \mathrm{erfc}^{-1}\,(C_b/C_{sB}) \qquad [3]$$

where D_{B2} and D^*_{B2} are the base impurity diffusion coefficient of the singly diffused and the doubly diffused region, respectively, and t_2 is the emitter diffusion time. Then the amount of dip Δx_j is defined by the difference between Eq. [3] and [2]

$$\Delta x_j = 2\left(\sqrt{D_{B1}\,t_1 + D^*_{B2}\,t_2} - \sqrt{D_{B1}\,t_1 + D_{B2}\,t_2}\right)\ \mathrm{erfc}^{-1}\,(C_b/C_{sB}) \qquad [4]$$

As described previously, the present derivation prefers a condition where the penetration of base-collector junction during the emitter diffusion is small, compared to x_{j1}. This means that $D^*_{B2}\,t_2$ and $D_{B2}\,t_2$ are much smaller than $D_{B1}\,t_1$. Then Eq. [4] is expanded to

$$\Delta x_j = 2\sqrt{D_{B1}\,t_1}\left\{\frac{1}{2}\,(D^*_{B2} - D_{B2})\,t_2/D_{B1}\,t_1 - \frac{1}{4}\,(D^{*2}_{B2} - D^2_{B2})\,t^2_2/(D_{B1}\,t_1)2 + \ldots\right\}\mathrm{erfc}^{-1}\,(C_b/C_{sB}) \qquad [5]$$

When D_{B2} is much smaller than D^*_{B2}, Eq. [5] is reduced. Then, combining with Eq. [1], we obtain

$$\Delta x_j = 2\,\{\mathrm{erfc}^{-1}\,(C_b/C_{sB})\}^2\,x_{j1}^{-1}\,D^*_{B2}\,t_2 \quad \text{for}\ \ D_{B1}\,t_1 >> D^*_{B2}\,t_2 >> D_{B2}\,t_2 \qquad [6]$$

From Eq. [6], it is seen that Δx_j increases linearly with t_2 and D^*_{B2}, and is inversely proportional to x_{j1}. The effect of the base surface concentration is involved in complementary error function term.

Experimental Procedure

The silicon wafers used in this work were mirror polished, 1 ohm-cm, phosphorus-doped Czochralski crystal cut to the (111) surface. The etch pit density was less than 3000 cm^{-2}.

The boron-doped oxide films, which were used as a diffusion source, were deposited on the wafers in an atmosphere of silane, diborane, oxygen, and nitrogen at 400°C. The boron surface concentration was varied by changing the boron content in the oxide layer. The boron base was diffused at 1050° or 1150°C in a nitrogen atmosphere. The boron surface concentration was calculated from the sheet resistance and the junction depth, using data published by Irvin (21).

After the base diffusion, the oxide layer was partly removed by etching in aqueous HF solution, then phosphorus emitter was diffused at 900°C. Here, the diffusion sources used were the phosphorus-doped oxide in an ambient of nitrogen and 1000 ppm $POCl_3$ in an ambient of nitrogen with 1.4% oxygen. The phosphorus-doped oxide films were deposited in an atmosphere of silane, phosphine, oxygen, and nitrogen at 400°C. The phosphorus surface concentration was obtained by the differential conductance method, repeating the anodic oxidation in N-methylacetamide-KNO_3 solution. In Fig. 2, the phosphorus surface concentration is plotted against the molar ratio of phosphine to silane, where the surface concentration corresponding to the $POCl_3$ source is indicated by the crossing point. Junction depth was measured by beveling the specimens and etching in HF-HNO_3 solution. The diffusion induced dislocation was examined by Sirtl etching technique.

Results and Discussion

Experimental verification of Eq. [6].—In this section, the validity of Eq. [6] and assumptions used to derive it are experimentally verified.

Figure 3 shows the dependence of the amount of dip on the emitter diffusion time. Here, after boron bases with various surface concentrations and junction depths were diffused, phosphorus was diffused for 5-100 min at 900°C, using the phosphorus-doped oxide as a source. It was observed that no increment of base-collector junction depth at the singly diffused region was caused during emitter diffusion. This suggests that the condition $D_{B1}\, t_1 >> D_{B2}\, t_2$ in Eq. [6] is satisfied in the present work. In Fig. 3 it is clearly seen that the amount of dip increases linearly with the emitter diffusion time t_2, regardless of various base and emitter diffusion conditions, which is expected from Eq. [6]. The linear relationship between Δx_j and t_2 strongly supports the concept of emitter dip effect occurring during emitter diffusion, which is one of the present assumptions. Additional experiments were carried out to investigate the effect of cooling rate on the amount of dip. The boron-base with 0.35 and 0.49 μm x_{j1} were diffused, followed by phosphorus diffusion for 20 min using 1000 ppm $POCl_3$. The time to remove the wafers was varied from 1 sec to 3 min. Furthermore, the 900°C heat treatment for 5 sec was repeated 3 times after the emitter diffusion for two of the wafers. The results are shown in Table I, where it is found that the amount of dip ranges from 0.05 to 0.07 μm for 0.49 μm x_{j1} and from 0.06 to 0.08 μm for 0.35 μm x_{j1}, independently of cooling rate and heat-treatment. Therefore, it is concluded that the emitter dip effect occurs during emitter diffusion, not during cooling.

Table I. Effect of cooling processes on amount of dip

x_{j1} (μm)	Cooling process	Δx_j (μm)
	Time to remove slices (sec)	
0.49	1	0.05
	10	0.06
	60	0.07
	180	0.06
	900°C, 5 sec heat-treatment for 3 times	0.06
	Time to remove slices (sec)	
0.35	1	0.08
	10	0.07
	60	0.08
	180	0.06
	900°C, 5 sec heat-treatment for 3 times	0.08

Phosphorus emitter was diffused at 900°C for 20 min, using 1000 ppm $POCl_3$ as a source.

This conclusion is inconsistent with that of Gereth *et al.* (3), who suggested that the amount of dip was not dependent on the emitter diffusion time and was increased by slow cooling, and concluded that this effect occurs during cooling. In their cooling effect experiment, the cooling rate was very low (3°C/min) compared to that of the present experiment. It is expected that the very slow cooling would result in the increase of the effective emitter diffusion time and then in increase of the amount of dip. Further, in Fig. 5 of their work, the amount of dip seems to increase with emitter diffusion time. The diffusion temperature of phosphorus in their work was 1000°C, where the penetration of base layer during emitter diffusion in the singly diffused region cannot be neglected. In such a case, it is expected from Eq. [4], that the amount of dip is weakly dependent on the emitter diffusion time.

Next, the effect of the base-collector junction depth upon the amount of dip is studied. The boron-base was diffused, varying the junction depth from 0.25 to 1 μm with constant surface concentrations of 1 and 4 × 10^{19} cm^{-1}. Phosphorus was diffused using a 1000 ppm $POCl_3$ source for 10 and 20 min at 900°C. The result is shown in Fig. 4, where it is found that the amount of dip increases linearly with the inverse of the base-collector junction depth. This result is also consistent with Eq. [6]. From the linear relationships of the amount of dip with t_2 and with $1/x_{j1}$, it is suggested that the penetration of base-collector junction is not retarded by built-in electric field (6, 7, 18) or by interaction between impurity atoms (22). If the penetration of base layer was affected by those two effects, the slopes in Fig. 3 and 4 would not be constant, but show a tapering off of the increase in a longer emitter diffusion time in Fig. 3, and in a smaller base-collector junction depth in Fig. 4. Therefore, it is concluded that the base width is large enough in the present experimental conditions to allow neglecting these effects.

The experimental results described above support the concept that Eq. [6] and its assumption are valid. Now, it is possible to calculate the effective diffusion

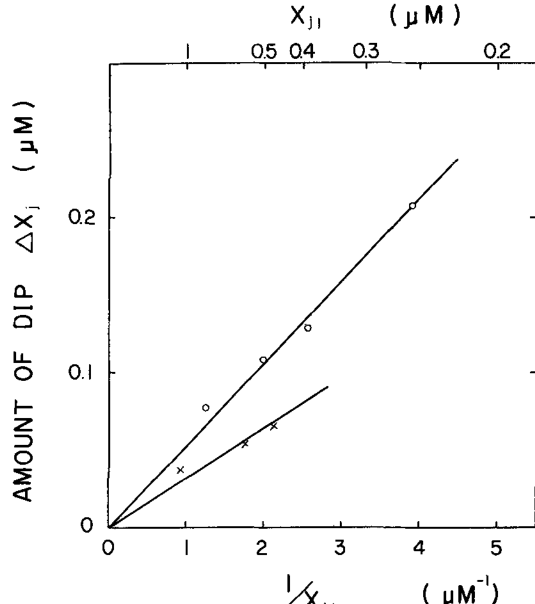

Fig. 4. Amount of dip as function of the reciprocal of the initial base collector junction depth. Phosphorus was diffused using 1000 ppm $POCl_3$ as a source, ○, $C_{sB} = 4 \times 10^{19}$ cm^{-3}, $t_2 = 20$ min; ×, $C_{sB} = 1 \times 10^{19}$ cm^{-3}, $t_2 = 10$ min.

coefficient of boron increased by phosphorus diffusion using Eq. [6].

Effect of boron concentration.—The effect of boron surface concentration upon the amount of dip appears explicitly in the term, $\text{erfc}^{-1}(C_b/C_{sB})$, in Eq. [6]. Simultaneously, it is expected that D_{B2} and D^*_{B2} also include the dependence of boron concentration. In Fig. 5, D_{B2} and D^*_{B2} are plotted against boron surface concentration C_{sB}. Here, to obtain D^*_{B2}, boron was diffused while varying the surface concentration from 8×10^{18} to 2×10^{20} cm^{-3} with a junction depth of about 0.4-0.5 μm followed by phosphorus diffusion at 900°C, using the 1000 ppm $POCl_3$ as a source. To obtain D_{B2}, boron was diffused with various surface concentrations at 900°C. Using the junction depth and the surface concentration, D_{B2} was calculated assuming complementary error function. In Fig. 5, it is seen that both D_{B2} and D^*_{B2} increase with the boron surface concentration.

The net effect of phosphorus diffusion upon the enhancement of boron diffusion is defined by D^*_{B2}/D_{B2}, and is plotted in Fig. 5. The ratio D^*_{B2}/D_{B2} is almost constant in the lower boron surface concentration region below about 4×10^{19} cm^{-3}. The slight decrease of the ratio above it in Fig. 5 cannot be explained at present.

Effect of phosphorus surface concentration.—In Fig. 6, D^*_{B2}/D_{B2} is plotted as a function of the phosphorus surface concentration. Here, after boron was diffused with surface concentration of 4×10^{19} cm^{-3} and to junction depth of 0.47 μm, phosphorus was diffused using the phosphorus-doped oxide as a source, with the surface concentration ranging from 1 to 4×10^{20} cm^{-3}. From this figure, it is seen that the ratio D^*_{B2}/D_{B2} increases approximately linearly with the surface concentration of phosphorus and is about 40 at 4×10^{20} cm^{-3}.

This result is interesting when it is compared with the observation by Yoshida, Arai, Nakamura, and Terunuma (15), who extensively studied the concentration dependence of phosphorus diffusion coefficient at 900°C. They obtained the phosphorus diffusion coefficient experimentally using Boltzmann-Matano's method and found that the phosphorus diffusion coefficient depends not only on the concentration at each point of the diffusion profile, which has been previously reported by Tannenbaum (14), but also on the surface concentration of phosphorus. Their result is reproduced in Fig. 6, indicating the linear relationship between the surface concentration and diffusion coefficient of phosphorus at concentration of 1×10^{18} cm^{-3}. It is seen that the phosphorus diffusion coefficient at 4×10^{20} cm^{-3} of surface concentration is about 300 times larger than the value at the surface concentration below 5×10^{18} cm^{-3}. Assuming boron and phosphorus diffusion by a vacancy mechanism, an increase in diffusivity corresponds to an increase of vacancy concentration. There is a difference of an order of magnitude between the effect of phosphorus surface concentration on the boron diffusion coefficient (40 ×) and on the phosphorus diffusion coefficient (300 ×). Although this cannot be explained at present, it is assumed that the vacancy concentration in silicon is increased linearly by phosphorus diffusion with the surface concentration of phosphorus.

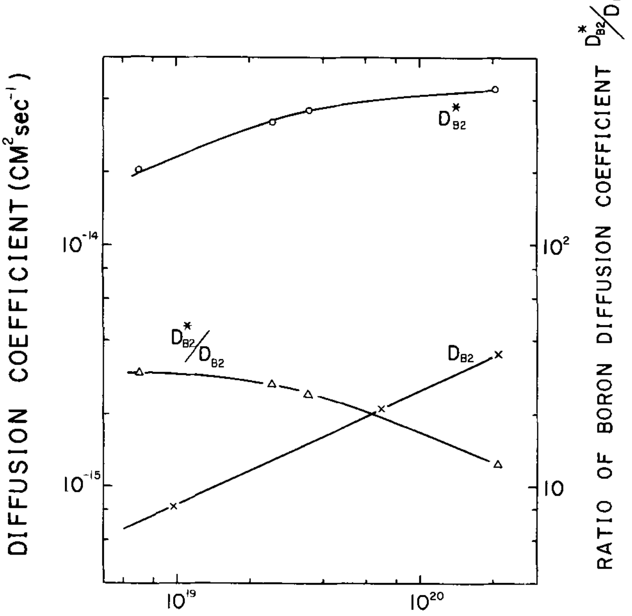

Fig. 5. Boron diffusion coefficients in the doubly diffused and singly diffused region and the ratio of those two as a function of boron surface concentration. Phosphorus was diffused using a 1000 ppm $POCl_3$ source.

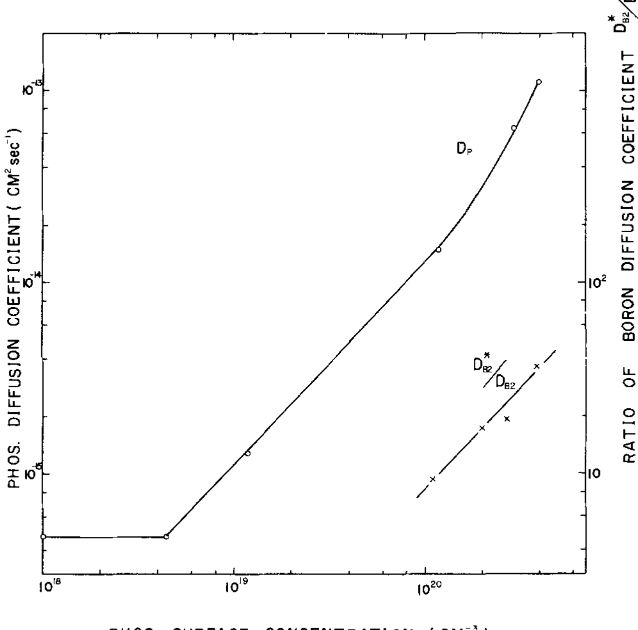

Fig. 6. D^*_{B2}/D_{B2} and phosphorus diffusion coefficient as a function of phosphorus surface concentration.

Diffusion-induced dislocation.—From the fact that the emitter dip effect occurs during emitter diffusion, it is suggested that the Fermi level effect (1, 16) and the precipitation (4) cannot be the cause of this phenomenon, because those two models require that the emitter dip effect occurs in a nonequilibrium state, such as during cooling. On the other hand, the present experimental observations are qualitatively in good agreement with the analytically derived approximate expression by Hu and Yeh (8). Using Prussin's model (19), they calculated the increase of base diffusion coefficient, assuming that the excess vacancy is generated by dislocation climb during emitter diffusion.

To examine the diffusion-induced dislocation, phosphorus was diffused into Si wafers at 900°C, for 30 min to 10 days, using phosphorus-doped oxide films of 0.36 and 0.25 PH_3/SiH_4 ratios. The results are shown in Table II, where it is seen that the diffusion-induced dislocation was not observed within 23 hr of phosphorus diffusion time. In the present work, the longest time t_2 is 100 min which is short enough not to produce the diffusion-induced dislocation. Also in the doubly diffused wafers, the dislocation-induced dislocation was not observed. Therefore, it is concluded that the dislocation climb is not the cause of the emitter dip effect observed in the present experimental conditions.

Table II. Dislocation induced by phosphorus diffusion at 900°C

	3 days	Few
	10 days	Great many

Examined by Sirtl etching technique.

In Ref. (15), cited before, Yoshida *et al.* proposed a new model to explain the effect of surface concentration upon phosphorus diffusion coefficient. The new model consists of vacancies in a state of supersaturation generated in the range of at least 20 μm from a surface when phosphorus atoms enter from the surface into the bulk. Some of the present observations, *e.g.*, the linear relationship of D^*_{B2}/D_{B2} with phosphorus surface concentration and the fact that the emitter dip effect occurs without diffusion-induced dislocation, can be qualitatively explained in terms of this model, although the time dependence of the enhancement due to this model, etc. are not clear at present. The surface effect is suggested to decrease with increasing diffusion temperature (20). Based on this model, it is expected that the emitter dip effect decreases in a higher diffusion temperature.

Conclusion

Quantitative relationships between the emitter dip effect caused by phosphorus diffusion at 900°C and the various diffusion process parameters were obtained experimentally through Eq. [6]. The main results of the present work are summarized as follows:

1. The emitter dip effect occurs during emitter diffusion.
2. The diffusion coefficient of boron at the doubly diffused region is increased linearly with surface concentration of phosphorus.
3. Net effect of the phosphorus diffusion upon the enhancement of boron diffusion, *i.e.*, D^*_{B2}/D_{B2} is approximately independent of the boron surface concentration in the boron surface concentration region below 4×10^{19} cm^{-3}.
4. The emitter dip effect is not necessarily accompanied by the diffusion-induced dislocation.

In order to explain the results described above, it is probably attributable to the excess vacancy generation due to the surface effect of phosphorus diffusion (15).

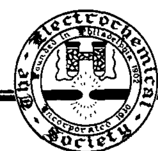
Brief Communications



A Nonaqueous Electrolyte for Anodizing GaAs and $GaAs_{0.6}P_{0.4}$

Edward B. Stoneham

Stanford Electronics Laboratories, Stanford University, Stanford, California 94305

A solution of potassium permanganate in acetone has proved to be effective as an electrolyte for anodizing GaAs and $GaAs_{0.6}P_{0.4}$. This electrolyte may possess advantages over previously reported aqueous electrolytes (1-7) in which difficulties are encountered with pH control, inclusion of H_2O in anodic oxide films, or partial dissolution of the oxide during growth.

Samples of low resistivity n-type GaAs and samples of 3×10^{17} cm^{-3} n-type $GaAs_{0.6}P_{0.4}$ epi grown on low resistivity n-type <100>-oriented GaAs substrates were anodized at various voltages between 0 and 250V. In each case the sample was suspended face down from the end of a 1/16 in. OD aluminum tube attached to a suction pump, the tube making electrical contact to the back of the sample. Only the face of the sample was immersed in the electrolyte which filled an aluminum container of 3 cm^3 volume that acted as the cathode. Fresh electrolyte and a clean container were used for each anodization. The electrolyte was prepared by mixing one volume of a saturated acetone solution of reagent grade $KMnO_4$ at room temperature with 25 volumes of electronic grade acetone. Since the electrolyte was observed to decompose slowly, with visible changes becoming noticeable after about 24 hr of standing at room temperature, the electrolyte was always used within 6 hr of mixing.

Power was furnished by a voltage-regulated supply with a variable current limiter. The current limiter was required for anodizations at 100V or more to prevent bubbling at the sample surface. It was found, for example, that with a current limit of 20 mA, bubbling commenced at the surface of an 8.9 × 6.9 mm sample of $GaAs_{0.6}P_{0.4}$ when the anodizing cell voltage reached 200V. Boiling of the acetone due to the high power dissipation at the sample surface may be responsible.

Each anodization was performed by first bringing the sample into contact with the electrolyte and then connecting the power supply with its voltage V_0 and current limit I_0 preset. Once the anodizing cell voltage reached a plateau the current I would begin to drop monotonically, continuing this way until it reached a value I_{min} at which it would begin to jump upward occasionally. Allowing I to drop below I_{min} resulted in nonuniformity of the anodic oxide and pitting of the sample surface. Therefore, anodization was generally terminated by disconnection of the power supply at a predetermined current I_f somewhere between I_{min} and $4I_{min}$. In this way, anodic oxide layers with no visible nonuniformities were obtained at voltages V_0 up to 150V on a 10.0 × 6.8 mm sample of GaAs and up to 200V on an 8.9 × 6.9 mm sample of $GaAs_{0.6}P_{0.4}$. At higher voltages the coatings became nonuniform.

The value of I_{min} depended on the composition and size of the sample and was roughly proportional to V_0. With V_0 at 100V and I_0 at 20 mA, the current I dropped to the value I_{min} = 2.5 mA in 43 sec when a 10.0 × 6.8 mm sample of GaAs was anodized. Under the same conditions, an 8.9 × 6.9 mm sample of $GaAs_{0.6}P_{0.4}$ gave I_{min} = 2.0 mA in 27 sec.

The anodic oxide thickness on a GaAs sample of 0.5 cm^2 surface area anodized at V_0 = 100V and I_0 = 20 mA with final current I_f = 10 mA was approximately 1800Å, and approximately 1100Å of GaAs was consumed. The corresponding amounts for a $GaAs_{0.6}P_{0.4}$ sample with the same surface area anodized at V_0 = 200V and I_0 = 20 mA with I_f = 10 mA were approximately 1800 and 1200Å, respectively. Examination of these anodized samples with a scanning electron microscope revealed smooth, featureless oxides. Areas in which oxides had been stripped off in concentrated hydrochloric acid appeared clean and smooth.

One sample of $GaAs_{0.6}P_{0.4}$ was anodized and stripped 50 times in succession with V_0 = 50V and still maintained a smooth optically polished appearance. More than 1μ of material had been removed.

Another sample of $GaAs_{0.6}P_{0.4}$ was anodized at 100V and then submerged in the electrolyte and allowed to stand for 35 hr. No change in the oxide's light blue interference color was noticeable, indicating at least a fair degree of stability of the oxide in the electrolyte.

The permanganate-in-acetone electrolyte has been used successfully to rapidly profile 6 × 6 mm zinc-diffused samples of $GaAs_{0.6}P_{0.4}$ by anodizing and stripping between measurements, each anodization taking less than 10 sec.

It should be noted also that the electrolyte was effective in anodizing samples of InSb at up to 100V.

Few Characteristics of Epitaxial GaN—Etching and Thermal Decomposition

Yasuo Morimoto

Research Laboratory, OKI Electric Industry Company, Limited, 550-5, Higashiasakawa, Hachioji, Tokyo 193, Japan

GaN is a III-V compound semiconductor noticed as a material for blue or violet LED's, but its etching behavior has not been extensively studied with only two reports by Chu (1) and Pankove (2). The former was effective for GaN grown by vapor phase epitaxy using $GaBr_3$ and NH_3 (1) but not effective (2) for GaN grown by vapor phase epitaxy using Ga, HCl, and NH_3 (3). The latter etched GaN electrolytically in 0.1*N* NaOH by anodizing the crystal. We have tried to etch GaN crystals by hot phosphoric acid (85%) referring the fact that the nitrides are generally etched with hot phosphoric acid and obtained positive results. The behavior of thermal decomposition of GaN was also investigated in several different ambients at elevated temperature. The GaN crystals used here were grown epitaxially from Ga, HCl, NH_3, and Ar (3) at 1050°C on sapphire substrates. Typical values of the flow rate were 4, 300, and 1000 cm^3/min for HCl, NH_3, and Ar, respectively. Ga metal was placed at 1000°C.

Etching by Hot Phosphoric Acid

The etching depth of GaN is plotted against etching time in Fig. 1(a). The parameter is the temperature of phosphoric acid. ○, ×, and △ indicate the data on good GaN crystals with smooth surface, while ● the data on wrong samples with rough surface (somewhat porous). As is clear from Fig. 1(a) such crystals with a rough

Key words: semiconductor, etching, annealing.

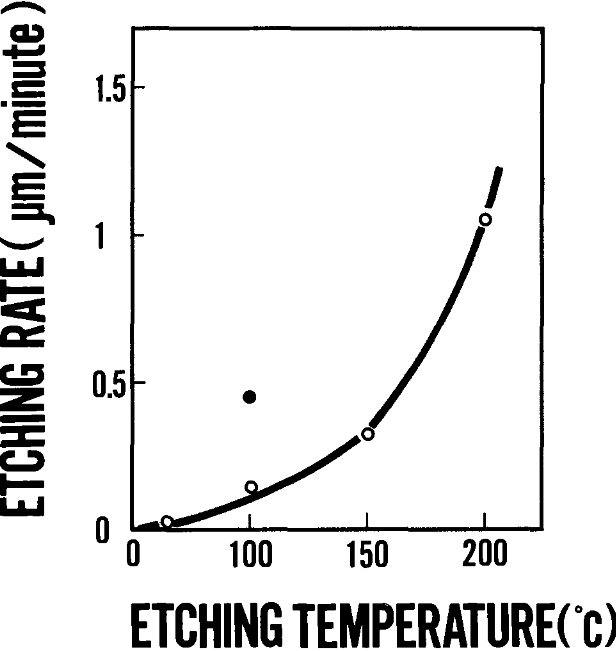

Fig. 1 (b). Temperature dependence of the etching rate. The etchant is phosphoric acid.

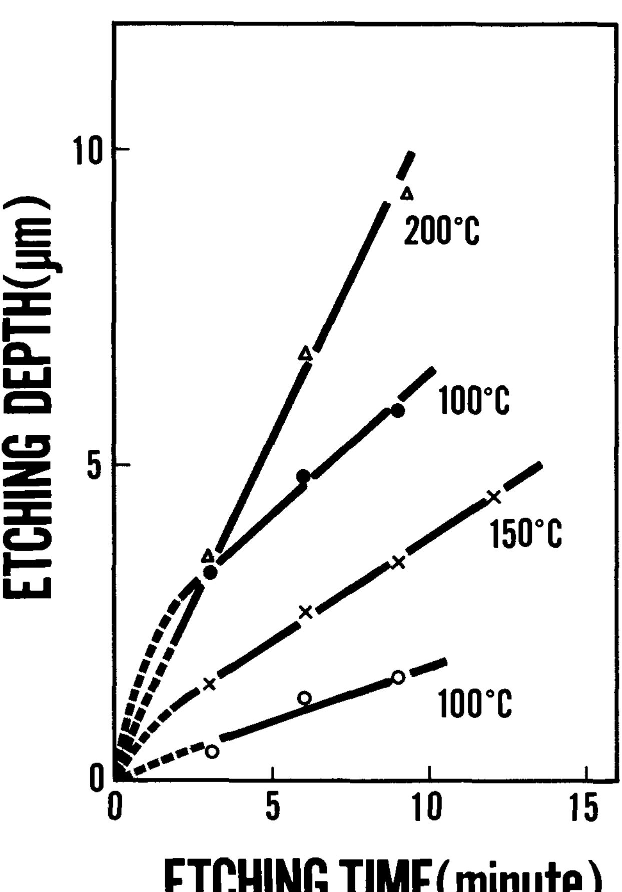

Fig. 1 (a). Etching depth plotted against etching time. The reason why the line joining each point does not cross the origin is mentioned in the text.

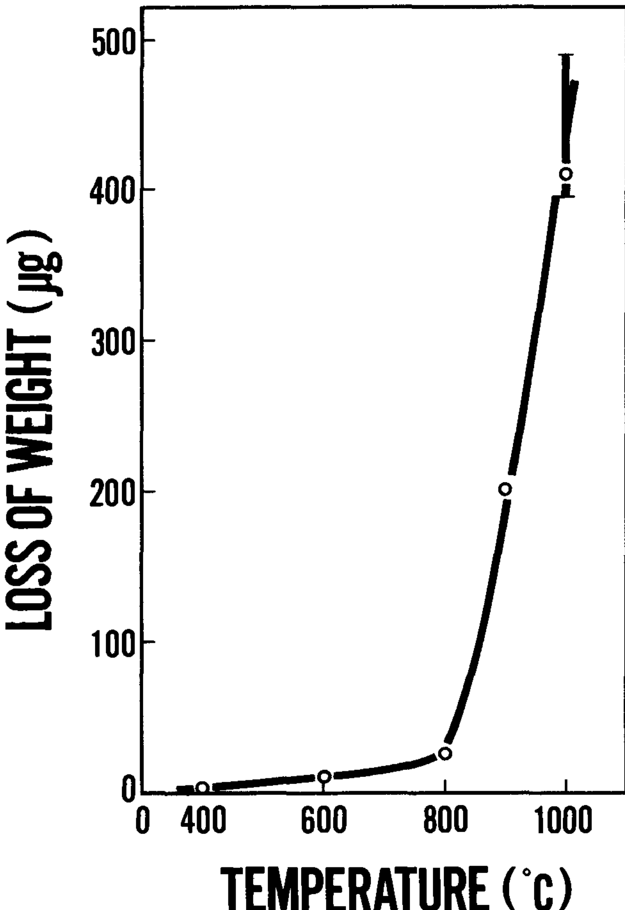

Fig. 2. Weight loss of GaN in H_2 atmosphere at elevated temperature. The annealing time is 20 min.

surface were etched more quickly than those with a smooth surface. Crystals with a smooth surface were colorless and transparent, on the other hand crystals with a rough surface were brownish and not transparent. The crystal growth was not perfectly uniform over all the surface. The rough surface was formed in part of the substrate where the etching rate was faster than on the other smooth part. This effect is observed in Fig. 1(a), that is, the line joining each point does not cross the origin. The etching rate is plotted against the temperature of phosphoric acid in Fig. 1(b). Below 100°C it was negligible. Above 180°C the etching rate was fast, but the smooth surface became rough. The mirror-like surface was not lost by the etching below 170°C for about 1 hr. Thus it was found that the hot phosphoric acid (100° ~ 170°C) was a useful etchant for GaN crystals.

Thermal Decomposition

The weight loss of GaN crystals was measured in N_2, air, and H_2 atmosphere by annealing at elevated temperature to investigate the behavior of thermal decomposition. The annealing time was 20 min. In N_2 and air, no weight loss could be detected, and no change of the crystal surface was observed up to 1000°C. In H_2 atmosphere weight loss could be observed above 400°C as shown in Fig. 2. The surface did not change up to 600°C, but it became a little rough by the annealing at 800°C. Simultaneously the weight loss also became noticeable as shown in Fig. 2. Annealing above 900°C produced small liquid Ga balls (20 ~ 30 μm in diameter) on the surface which became completely gray. Considering the fact that Ga is left on the surface it is evident that the decomposition of GaN proceeds as follows

$$GaN + \frac{3}{2} H_2 \rightarrow Ga + NH_3$$

Corrosion of Pure and Amalgamated Zinc in Concentrated Alkali Hydroxide Solutions

L. Ž. Vorkapić, D. M. Dražić, and A. R. Despić

Electrochemistry Department, Institute of Chemistry, Technology and Metallurgy, Beograd, Yugoslavia

ABSTRACT

Corrosion of pure and amalgamated zinc in pure concentrated KOH solutions was investigated using two methods: (*a*) galvanostatic measurements of the kinetics of hydrogen evolution with electrodic assessment of corrosion properties of the system, and (*b*) volumetric measurement of the hydrogen evolution reflecting directly the rate of corrosion. The latter was followed as a function of time during 150 hr. It was found that the corrosion rate varies considerably with time and was suggested that different factors control the initial and the steady-state corrosion. The initial corrosion rate increases with increasing KOH concentration which is indicative of the chemical mechanism of hydrogen evolution. The change of the corrosion rate with time and the steady-state corrosion rate can be explained in terms of formation of an impermeable ZnO film at the surface. In such a case the concentration dependence of the corrosion rate is inverse with time, which explains some results reported in literature. The amalgamated zinc surface gives complex galvanostatic transients which indicate a new phase formation in the process of initiation of hydrogen evolution, which could pertain to some solid potassium-zinc-mercury alloy.

The problem of corrosion of zinc in alkaline solutions has become a topic of considerable interest with the increasing use of zinc as the anode in a variety of alkaline batteries (primary alkaline zinc battery, secondary silver-zinc, and both primary and secondary zinc-air batteries), some of which contain great promise for propulsion of electric vehicles. This corrosion process is the basic cause for self-discharge and a relatively short shelf life of all the zinc-containing batteries, and one of its products, the gaseous hydrogen, creates problems when sealed batteries are to be produced. However, relatively little work has been done which could help toward a more fundamental understanding of the mechanism and kinetics of reactions constituting the corrosion process and this with some controversial results.

Thus, Snyder and Lander (1) studied corrosion of a system similar to that used in primary batteries by measuring the rate of hydrogen evolution and found that the amount of hydrogen evolved in a given time decreased with increasing KOH concentration. This finding is confirmed by comparable measurements of Dirkse and Timmer (2) both on pure (99.999%) and amalgamated zinc in pure KOH solutions, while in those saturated by zinc oxide much lower corrosion rates were found and no unambiguous concentration dependence.

Contrary to that, Ruetschi (3) found hydrogen evolution on amalgamated zinc to increase with increasing KOH concentration, which is in line with the kinetic work on hydrogen overpotential on zinc in alkaline solutions done earlier by Jofa, Komlev, and Bagotskii (4) and also by Lee (5).

The effect of saturation of the electrolyte by zincate also remained obscure. Ruetschi (3) assumed the large effect to be due to a more rapid formation of a protective film of zinc oxide on the electrode surface in the saturated electrolyte than in pure KOH. The existence of such a film seems indeed to be proved by the microscopic investigations of Powers (6). It is interesting that Powers claims even a catalytic activity of such a film for hydrogen evolution. However, Mansfeld and Gilman (7) deny the necessity of that film formation for the explanation of the corrosion behavior and maintain that addition of zinc oxide acts by reducing the activity of water as the reactant for hydrogen evolution.

It is in this situation that the present work has been undertaken with the ambition to clarify the reasons for the discrepancy between results of different authors and to throw some more light onto the problem.

Experimental

Two kinds of experiments have been carried out.

Galvanostatic transient measurements.—Those were carried out on a pure (99.99% made by Zorka-Šabac) zinc in pure KOH solution of different concentrations (1, 3, 6, and 10M) and on amalgamated zinc in 10M KOH. Zinc electrodes were made from zinc wire imbedded in Teflon and were placed in a closed, thermostated cell as normally used in electrodic investigations. The transients were obtained by perturbing the system with a conventional homemade galvanostat and were recorded on the CRO Tektronix 543B.

Key words: hydrogen evolution on zinc, galvanostatic investigation of the corrosion of zinc, zinc oxide film on corroding zinc, amalgamated zinc surface.

Amalgamation of the zinc surface was done by immersing the electrode into $HgCl_2$ solution of a known mercury content and leaving it in until all the mercury had precipitated on the sample (checked by the KJ and by the copper test). Amounts of mercury were taken so as to render zinc with 0.5, 1, and 2% mercury calculated on the bulk amount of zinc. Since diffusion of mercury into the metal is slow the concentration of mercury in the surface layer must have been higher than the figures cited, but in some proportion with them.

Volumetric measurements of the rate of hydrogen evolution.—This has been done by enclosing pure (99.99%) and amalgamated zinc 5 cm long and 0.5 cm in diameter, machined out of zinc blocks, into a glass tube with a graded side-arm pipette, similar to that used by Dirkse and Timmer (2), where the amount of hydrogen evolved is found from the volume of solution expanded into the pipette. The glass tubes were thermostated to 25° ± 0.05°C. No stirring of the electrolyte was employed. Amalgamation of the zinc surface has been done in the same way as for zinc electrodes.

Results

Electrodic investigations.—For pure zinc good and reproducible galvanostatic cathodic transients were obtained with well-defined plateaus of the activation polarization for hydrogen evolution.

When the electrodes were left for a certain period in the electrolyte to stay at the established mixed potential, as well as when they were submitted to short anodic pulses, a lower potential plateau would appear with well-defined transition time. This could be ascribed to the reduction of zinc dissolved by corrosion or during the anodic pulse.

Figure 1 represents the Tafel lines obtained from the upper potential plateaus, pertaining to hydrogen evolution.[1]

Characteristic are: (*a*) well-defined straight lines over more than two powers of current density with slopes of 120 mV dec^{-1}, and (*b*) decrease of the polarization at a given current density with increasing concentration of KOH. This produced the dependence of the current density on concentration at a constant potential shown in Fig. 2 with the slope of the log-log plot (the reaction order) equal to one.

The corrosion current was also obtained by extrapolating the Tafel lines to the spontaneously established corrosion potentials and the dependence of the obtained result on KOH concentration is also shown in Fig. 2.

The dependence of the corrosion potential on KOH concentration is given in Fig. 3.

[1] All potentials in this and subsequent diagrams are referred to the hydrogen electrode in the same solution.

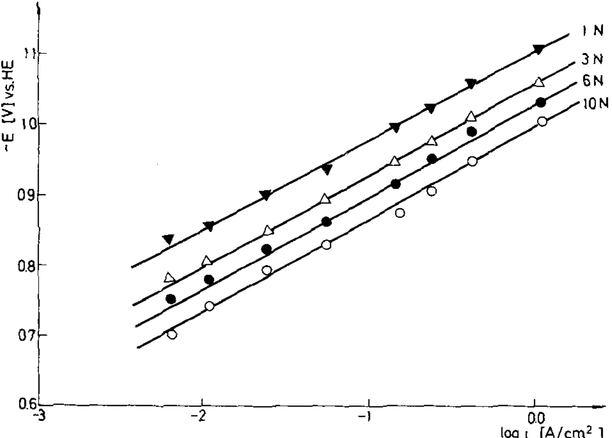

Fig. 1. Cathodic Tafel plots for zinc in KOH solutions of different concentrations.

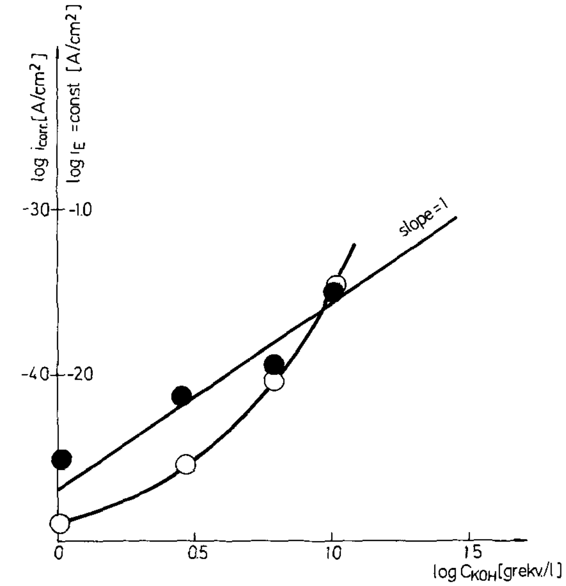

Fig. 2. Concentration dependence of the initial corrosion current density (○) and of the current density at a constant potential of 0.79V vs. HE (●) in same solution for zinc in KOH solutions.

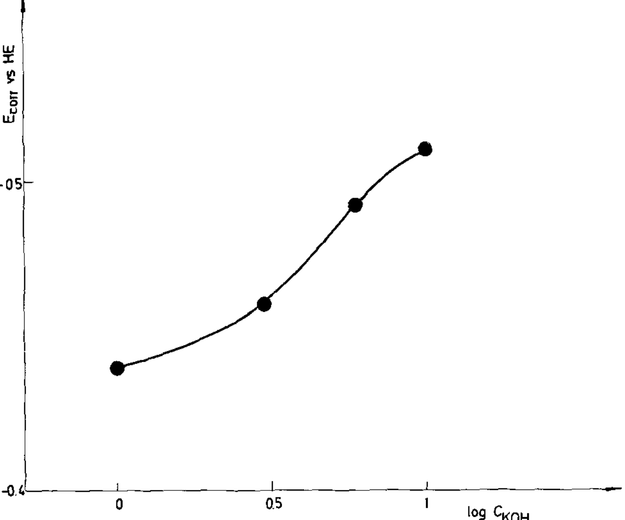

Fig. 3. Open-circuit potential of zinc as a function of the activity of the KOH solutions.

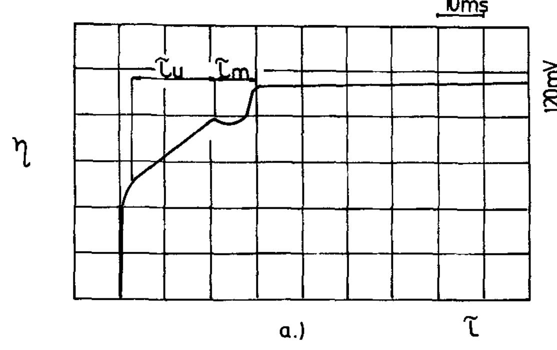
Galvanostatic transients of the freshly amalgamated zinc were of more complex structure than those on pure zinc as shown in Fig. 4a for charging and Fig. 4b for decay.

Characteristic of the rise is (*a*) a sharp increase (after a short transition time which disappears at higher current densities) to a first potential level which is then changing more slowly in an almost linear fashion within a time interval τ_u and (*b*) a potential dip lasting over a period τ_m, upon which (c) the potential is getting onto the plateau which could be ascribed to a steady-state hydrogen evolution.

The duration of the potential dip, τ_m, decreases with increasing current density, while the extent to which the potential falls seems to be independent of it. The potential dip does not appear if the amalgamated zinc is left to stay in the cell for 24 hr before measurements.

Figure 5 shows the dependence of the duration of the linear potential rise τ_u on current density for the freshly amalgamated zinc and for that after 24 hr. Obviously in both cases the product $i \cdot \tau_u$ appears to be constant and in the first case it is 1 mC/cm² while in the second it is 3 mC/cm².



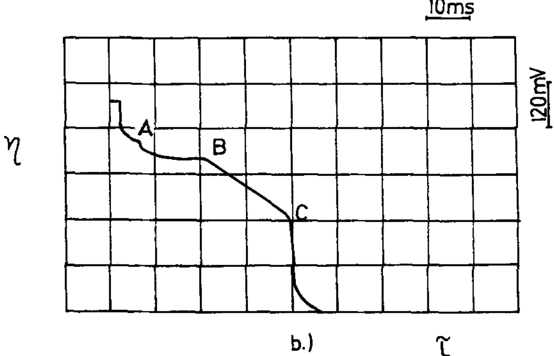


Fig. 4. (a) Galvanostatic cathodic charging curve for amalgamated zinc in 10N KOH solution for 25 mA/cm². τ_u is time interval till the appearance of the potential dip. τ_m is duration of the potential dip. (b) Potential decay after the galvanostatic pulses.

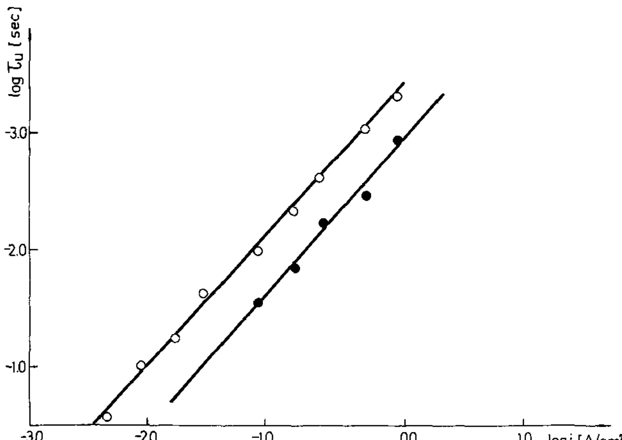

Fig. 5. The dependence of τ_u on current density. ○, Freshly amalgamated surface; ●, amalgamated surface after 24 hr of rest.

The decay curve (Fig. 4b) exhibits two potential arrests A and B, a linear decay to C, and a fast decay portion back to the original mixed potential.

The Tafel lines for hydrogen evolution indicate significant inhibition compared to pure zinc as shown in Fig. 6. The corrosion current obtained by extrapolation is about 50 times smaller at the former than on the latter.

It seems to be practically independent of the amount of mercury absorbed (above 0.5%) indicating that the surface layer is saturated with mercury.

Tafel lines are also different for the freshly amalgamated surface and the one after 24 hr as shown in Fig. 7. Both the hydrogen overvoltage at a given current density and the Tafel slope change, the first being considerably larger and the second somewhat lower

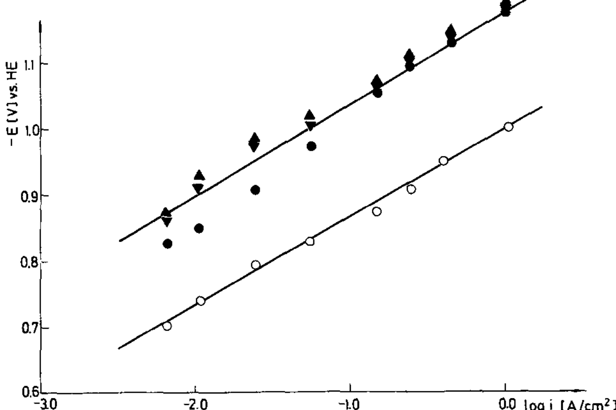

Fig. 6. Cathodic Tafel plots for pure zinc (○) and zinc containing 0.5% (●), 1% (▼), and 2.5% (▲), Hg, in 10N KOH.

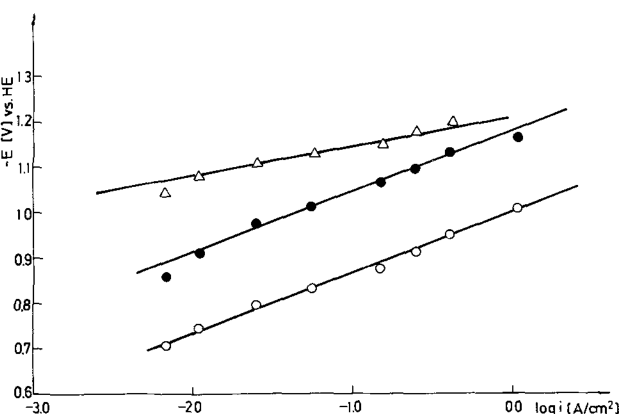

Fig. 7. Cathodic Tafel plots for pure zinc (○), freshly amalgamated zinc (▲), and amalgamated zinc after 24 hr (●) in 10N KOH.

(60 *vs.* 120 mV dec^{-1}) in the case of the freshly amalgamated zinc than in the case of the aged surface.

Rate of hydrogen evolution at the corrosion potential.—Typical results of the volumetric measurements are shown in Fig. 8 as the volume of hydrogen evolved as a function of time from a pure zinc sample in different concentrations of KOH. This was followed for more than 150 hr. The rates of hydrogen evolution at any moment are obtained as corresponding slopes of the curves. These are presented in Fig. 9. Three characteristic features should be noted: (*i*) in all the investigated cases the rate of hydrogen evolution (*i.e.*, the corrosion rate) is strongly time dependent and within the time of observation it is reduced by more than one order of magnitude; (*ii*) the rates are dependent on KOH concentration; (*iii*) the concentration dependence may be different for the initial corrosion rates than for those after more than 100 hr. Thus, a straightforward increase in the initial corrosion rate with KOH concentration is observed, while after more than 100 hr the rate of corrosion in 10M KOH becomes smaller than in 6M solution. This crossover has been confirmed several times and hence can be considered to be beyond doubt, *i.e.*, outside the possible experimental error.

Discussion

The most important result of the present investigation is that corrosion of zinc in pure concentrated alkaline solution is strongly time-dependent and that a period of the order of 100 hr is needed before a steady state (or a negligibly slow change of the rate) is reached. Hence, the initial and the steady-state corrosion rates represent separate problems. In as much as

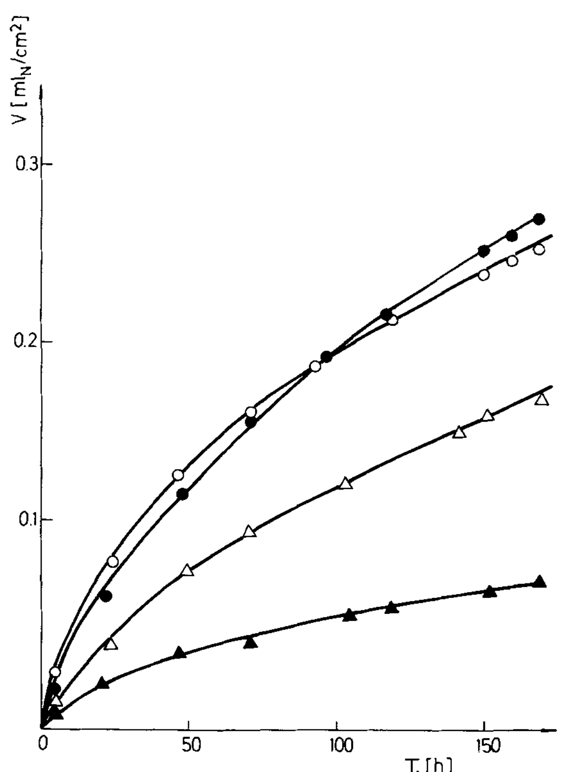

Fig. 8. Volume of evolved hydrogen on zinc in 1*N* (▲), 3*N* (△), 6*N* (●), and 10*N* (○) KOH solution as a function of time.

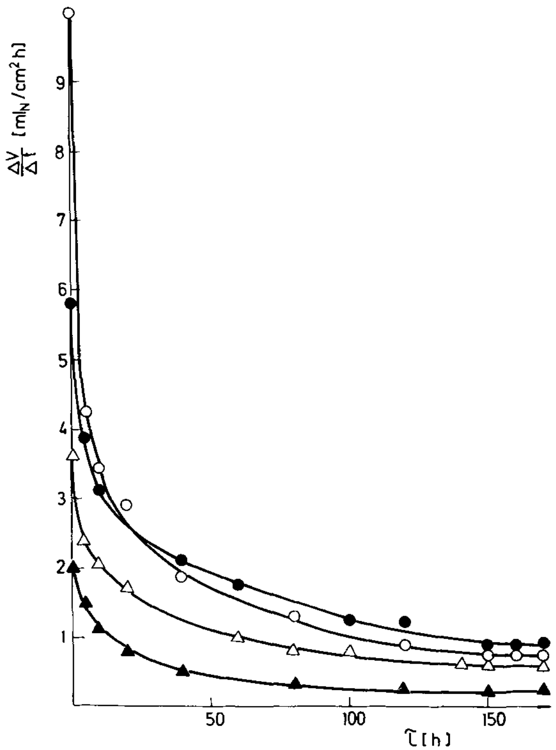

Fig. 9. Rate of hydrogen evolution on zinc in 1*N* (▲), 3*N* (△), 6*N* (●) and 10*N* (○) KOH solution as a function of time.

the mechanism of corrosion may stay the same it is quite likely that the rate-controlling factors are changing from one to the other.

Initial Corrosion Phenomenon

Hydrogen evolution kinetics on pure zinc.—Galvanostatic investigation of the cathodic reaction on pure zinc rendered Tafel lines pertaining to hydrogen evolution well in line with the results of Jofa *et al.* (4) and Lee (5). No doubt is left that at a given potential the rate of hydrogen evolution increases with the increase in KOH concentration and a somewhat surprising result is that this was found to be a straightforward, first-order dependence. The increase in KOH concentration is known to produce also an increase in the activity of KOH, while the activity of water decreases along that change (16).

Jofa *et al.* (4) went into a complex analysis of the possible changes in the double layer structure to show that it is feasible that water discharge is a rate-determining step and still to have the increase in rate at the same time when the activity of that species is decreasing. This however, is hardly necessary when one takes into account the possible effectiveness of some other mechanisms. The first one was popular in the last century and was revived recently by a number of authors [Frumkin, Korshunov, and Bagozkaya (8) on mercury and partly on indium amalgam, Matsuda and Notoya (9) on platinum, and Matsuda and Ohmori (10) on nickel] namely the mechanism according to which the alkali metal cation is discharged electrochemically and the alkali metal formed reacts chemically with water.

This mechanism is made more likely by the findings of Kabanov (11) of the incorporation of alkali metals into lattices of solid electrodes including zinc [Aleksandrova, Kiseleva, and Kabanov (12)] during hydrogen evolution.

The mechanism should consist of the following steps

$$\mathrm{Zn} + \mathrm{K^+} + e \rightarrow \mathrm{K(Zn)} \qquad [1]$$

$$\mathrm{K(Zn)} + \mathrm{H_2O} \rightarrow \mathrm{H_{ads}} + \mathrm{K^+} + \mathrm{OH^-} + \mathrm{Zn} \qquad [2]$$

$$2\mathrm{H_{ads}} \rightarrow \mathrm{H_2} \qquad [3]$$

The transfer coefficients and reaction orders with respect to the alkali metal ions, water, and OH^- ions can be obtained from the following rate equations:

In the case of the rate-determining discharge

$$i = \overleftarrow{k}_1 \frac{\gamma_{\mathrm{K^+}}}{\gamma^{\neq}} C_{\mathrm{K^+}} \exp\left[-\frac{\beta \mathbf{F}}{RT} E\right] \qquad [4]$$

where $\gamma_{\mathrm{K^+}}/\gamma^{\neq}$ is the ratio of activity coefficients of K^+ ion and the activated complex, and E is the electrode potential measured with respect to a reference electrode (*e.g.*, *vs.* NHE) while $\overleftarrow{k}_1$ is the electrochemical rate constant at the reference electrode potential.

In the case of rate-determining chemical reaction [2] with the first step in electrochemical equilibrium

$$i = \frac{\overleftarrow{k}_2}{\gamma^{\neq}} a_{\mathrm{K}} a_{\mathrm{H_2O}} \qquad [5]$$

and

$$a_{\mathrm{K}} = a_{\mathrm{K^+}} \exp\left[-\frac{\mathbf{F}(E - E_{\mathrm{o,K}})}{RT}\right] \qquad [6]$$

$E_{\mathrm{o,K}}$ being the standard electrode potential for K^+ discharge. Hence

$$i = \frac{\overleftarrow{k}_2'}{\gamma^{\neq}} a_{\mathrm{K^+}} a_{\mathrm{H_2O}} \exp\left[-\frac{\mathbf{F}E}{RT}\right] \qquad [7]$$

In the case of rate-determining recombination

$$i = \frac{\overleftarrow{k}_3}{\gamma^{\neq}} a^2_{\mathrm{H_{ads}}}$$

$$a_{\mathrm{H_{ads}}} = k_2 \frac{a_{\mathrm{K}} a_{\mathrm{H_2O}}}{a_{\mathrm{K^+}} a_{\mathrm{OH^-}}}$$

$$= k_2 \frac{a_{\mathrm{H_2O}}}{a_{\mathrm{OH^-}}} \exp\left[-\frac{\mathbf{F}(E - E_{\mathrm{o,K}})}{RT}\right] \qquad [8]$$

and, hence

$$i = \bar{k}_3(k_2')^2 \frac{a^2_{H_2O}}{a^2_{OH^-}} \exp\left[-\frac{2\mathbf{F}E}{RT}\right] \quad [9]$$

The diagnostic criteria arising from the above equations for the cases of the three possible rate-determining steps are summarized in Table I.

It is seen that the obtained value of the Tafel slope is compatible only with the case of the first step being rate determining. However, such a slope would be obtained also in the case of a straight-forward discharge of water. Still, it is the reaction order of one with respect to the potassium ions (as shown in Fig. 2) which is indicative of the mechanism suggested here.

Indeed, it is surprising that a value so much in accordance with theory is obtained, when in such concentrated solutions the activity of water was not kept constant with changing KOH concentration and thus changed the solvation of the species. The result actually means that the ratio of the two activity coefficients (that of potassium ion to that of the activated state) is equal to one, indicating structural similarity between the two states.

Another possibility exists for a mechanistic interpretation of the positive reaction order with respect to the alkali metal which so far was not considered in the literature and was suggested by one of the present authors (D.D.) on the basis of the results of Šepa, Vojnović, and Bugarin [cf. (20)]. It is quite likely that hydrogen of the water molecules in the first hydration sheet of alkali metal ions is more loosely bound than this in free water molecules because of the additional polarization of the molecule which occurs in the strong electrostatic field of the ion. In such a case there could be a preference for hydrogen discharge from these water molecules, and this could also be expected to be first order with respect to alkali metal ions. This is supported by the findings of Šepa, Vojnović, and Bugarin that the decrease in hydrogen overvoltage at one and the same concentration of alkali hydroxide follows the order K, Na, Li; whereas in the case of alkali metal ion discharge (*e.g.*, on mercury) Li is deposited at the most negative potentials, followed by Na and K.

One could easily show that if this new mechanism was operative and if discharge was rate determining, the same rate equation [4] would be applicable as for the alkali metal ion discharge; hence, also the same diagnostic criteria as given in Table I.

Zinc dissolution kinetics.—This has been fairly thoroughly studied in a number of recently published papers [cf., Bockris, Nagy, and Damjanović (13)]. It appears that dissolution follows a complex reaction path with two one-electron transfer unit steps and chemical reaction of the species formed, with OH^- ions to render a very short lived dihydroxy monovalent zinc complex intermediate, as well as tetrahydroxy divalent zinc complex as the reaction product. Since, the second electron exchange is rate determining and this is preceded by the reaction of the zinc species with 3 OH^- ions, the kinetics should be third order with respect to OH^- ions. Since equilibria are established in all steps prior to the formation of the activated state, it is the activity of OH^- ions which should affect the kinetics.

Table I. Diagnostic criteria arising from the chemical mechanism of hydrogen evolution from alkaline solutions

	Rate-determining step			
	$Zn + K^+ + e \rightarrow K(Zn)$	$K(Zn) + H_2O \rightarrow H_{ads} + K^+ + OH^- + Zn$	$2H_{ads} \rightarrow H_2$	Found
Cathodic transfer coefficient	0.5	1	2	0.5
$\left(\frac{\log i}{\log C_{K^+}}\right)_{a_{H_2O}, a_{OH^-}, E}$	1	1	0	1
$\left(\frac{\log i}{\log C_{H_2O}}\right)_{a_{K^+}, a_{OH^-}, E}$	0	1	2	—
$\left(\frac{\log i}{\log C_{OH^-}}\right)_{a_{K^+}, a_{H_2O}, E}$	0	0	−1	0*

* The value of Jofa *et al.* (4).

To assess the latter in the case when zinc is dissolving into solutions free of zincate ions one should use the approach of Kimball (17), *i.e.*, the concept of the "floating" electrode extended to cover the case of divalent metal dissolution (18).

If it is accepted that the univalent intermediate is so unstable that it practically reacts all at the electrode (diffusion away neglected) one could write for the current density

$$i = \vec{k}^o_{Zn} a_{Zn} a^3_{OH^-} \exp\left[\frac{\alpha_a \mathbf{F}}{RT} E\right] - \overleftarrow{k}^o_{Zn(II)} a_{Zn(II)} a_{OH^-} \exp\left[-\frac{\alpha_c \mathbf{F}}{RT} E\right] \quad [10]$$

where $\vec{k}^o_{Zn}$ and $\overleftarrow{k}^o_{Zn(II)}$ are the specific rates at unit activities and at the potential equal to the reference electrode potential, while α_a and α_c have values of 1.5 and 0.5, respectively, as found by Bockris, Nagy, and Damjanović.

The material balance equation taking into account diffusion of the reaction product away from the electrode can be written as

$$\frac{da_{Zn(II)}}{dt} = \frac{i}{2\mathbf{F}} - \frac{D_{Zn(II)} a_{Zn(II)}}{\delta} = 0 \quad [11]$$

where $D_{Zn(II)}$ and δ are the diffusion coefficient of the Zn(II) species and the diffusion layer thickness, respectively.

Hence, replacing [10] into [11] and rearranging, one obtains

$$a_{Zn(II)} = \frac{\vec{k}^o_{Zn} a_{Zn} a^3_{OH^-} \exp\left[\frac{\alpha_a \mathbf{F}}{RT} E\right]}{\overleftarrow{k}^o_{Zn(II)} a_{OH^-} \exp\left[-\frac{\alpha_c \mathbf{F}}{RT} E\right] + 2\mathbf{F} D_{Zn(II)}/\delta} \quad [12]$$

and the current density comes to be

$$i = \vec{k}^o_{Zn} a_{Zn} a^3_{OH^-} \exp\left[\frac{\alpha_a \mathbf{F}}{RT} E\right] \frac{2\mathbf{F} D_{Zn(II)}/\delta}{\overleftarrow{k}^o_{Zn(II)} a_{OH^-} \exp\left[-\frac{\alpha_c \mathbf{F}}{RT} E\right] + 2\mathbf{F} D_{Zn(II)}/\delta} \quad [13][2]$$

In the case when the cathodic reaction is much faster than diffusion away from the Zn(II) species formed by anodic dissolution, as could well be the case considering the relatively high i_o values found in the literature [up to 0.37 A/cm² (13)], Eq. [13] reduces to

$$i = 2\mathbf{F} \frac{\vec{k}^o_{Zn} a_{Zn}}{\overleftarrow{k}^o_{Zn(II)}} \frac{D_{Zn(II)}}{\delta} a^2_{OH^-} \exp\left[\frac{2\mathbf{F}}{RT} E\right] \quad [14]$$

i.e., the reaction becomes second order with respect to OH^- and the Tafel slope obtains a value of 30 mV dec^{-1}. Hence, the Tafel line shifts by 60 mV to the negative side for each power of ten of increase in activity of KOH.

[2] Kaesche (19) has obtained a similar equation, which was subsequently used by Mansfeld and Gilman (7) for calculating Tafel lines for dissolving zinc. That equation, however, suffers from the application of a relatively poorly defined quantity $i_{L \cdot Zn}$ relying on the assumption of the concentration of the reaction product in solution.

In the adverse case

$$i = (\vec{k}^{\circ}_{Zn}a_{Zn})a^{3}_{OH^-} \exp\left[\frac{\alpha_a F}{RT}E\right] \quad [15]$$

i.e., third-order dependence is expected with respect to OH^- and a Tafel slope of 40 mV dec^{-1}. Hence, the Tafel line should shift by 120 mV to the negative side for a tenfold increase in activity of KOH.

The corrosion process on pure zinc.—Since the cathodic and the anodic processes are known, schematic Wagner-Traud type diagrams can be established as shown in Fig. 10, for the two extreme cases of anodic dissolution kinetics [case (a) and case (b)] exemplified by Eq. [14] and [15], respectively.

Considering that the equation for the hydrogen evolution kinetics is also known (Eq. [4]), one can derive quantitative expressions for the rate of corrosion and the corrosion potential.

Thus, from Eq. [4] and [14] and taking $C_{K^+} = C_{KOH}$ and $a_{OH^-} = a_{KOH}$, one obtains

$$i_{corr} = K C_{KOH}^{\left(\frac{1}{1+\beta/2}\right)} a_{KOH}^{\left(\frac{\beta}{1+\beta/2}\right)} = K C^{0.8}_{KOH} a^{0.4}_{KOH} \quad [16]$$

where

$$K = \left\{\left[2F \frac{\vec{k}^{\circ}_{Zn}a_{Zn}}{\overleftarrow{k}^{\circ}_{Zn(II)}} \frac{D_{Zn(II)}}{\delta}\right]^{\beta/2} \bar{k}_1 \frac{\gamma_{K^+}}{\gamma^{\neq}}\right\}^{\left(\frac{1}{1+\beta/2}\right)} \quad [17]$$

Also

$$E_{corr} = E^{\circ}_{corr} + \frac{RT}{(2+\beta)F} \ln C_{KOH}\, a_{KOH}^{-2} \quad [18]$$

where E°_{corr} is the corrosion potential at $C_{KOH}a_{KOH}^{-2} = 1$.

Using Eq. [4] and [15] one obtains

$$i_{corr} = K' C_{KOH}^{\left(\frac{1}{1+\beta/\alpha_a}\right)} a_{KOH}^{\left(\frac{3\beta/\alpha_a}{1+\beta/\alpha_a}\right)} = K' C^{0.75}_{KOH} a^{0.75}_{KOH} \quad [19]$$

where

$$K' = \left[\bar{k}_1 \frac{\gamma_{K^+}}{\gamma^{\neq}} (\vec{k}^{\circ}_{Zn}a_{Zn})^{\beta/\alpha_a}\right]^{\left(\frac{1}{1+\beta/\alpha_a}\right)} \quad [20]$$

Also

$$E_{corr} = E^{\circ\prime}_{corr} + \frac{RT}{(\alpha_a+\beta)F} \ln C_{KOH}\, a_{KOH}^{-3} \quad [21]$$

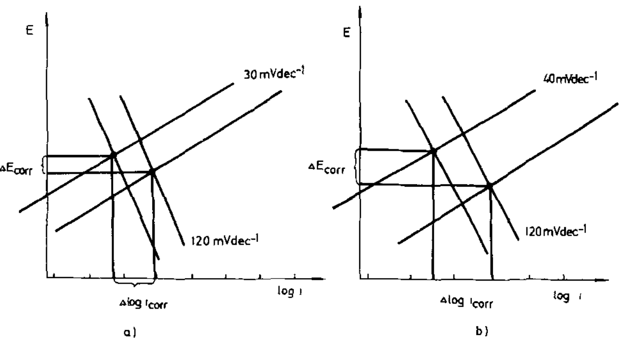

Fig. 10. Change of corrosion potential (ΔE_{corr}) and corrosion current (Δ log i_{corr}) for a tenfold increase in KOH concentration represented by the schematic Wagner-Traud diagram for the corrosion of zinc in alkaline solutions. (a) In the case of dominant hydrogen evolution control and (b) in the case of mixed hydrogen evolution and zinc dissolution control.

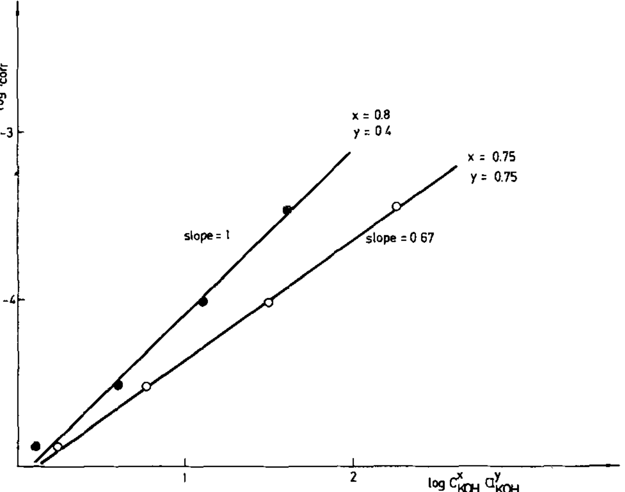

Fig. 11. The dependence of the log corrosion current density of zinc in KOH solutions on the complex variable log $c^{x}_{OH^-} \cdot a^{y}_{OH^-}$ (see Eq. [14] and [15]).

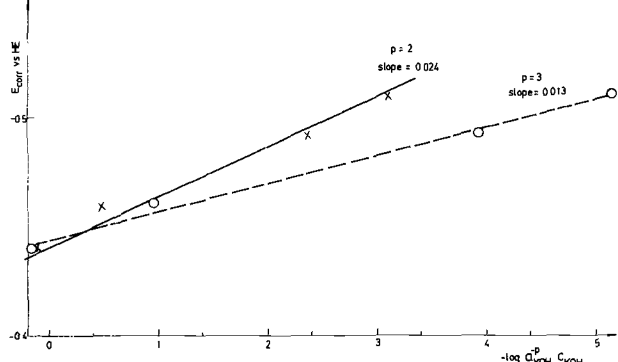

Fig. 12. Plot of E_{corr} as a function of the complex variable log $C_{KOH}\, a^{-p}_{KOH}$ corresponding to Eq. [18] and [21] with $p = 2$ and 3, respectively.

It is seen that the two cases (a) and (b) (Fig. 10) should differ by the dependence of both corrosion current and corrosion potential on the activity of KOH. The numerical values of the exponents in Eq. [16] and [19] were obtained taking $\beta = 0.5$ and $\alpha_a = 1.5$ [as shown in Ref. (13)].

To test the model, plots of i_{corr} and E_{corr} *vs.* log $C^{x}_{KOH}a^{y}_{KOH}$, and log $a^{-p}_{KOH}C_{KOH}$, respectively, with x, y, and p arising from Eq. [16], [18], [19], and [21] are shown in Fig. 11 and 12.[3] The slope of 24 mV dec^{-1} in Fig. 12 corresponding to Eq. [18], both figures clearly show that the first model is the adequate one.

Kinetic behavior of amalgamated zinc.—Galvanostatic transients reveal complex relationships in the polarization of freshly amalgamated zinc electrodes. The shape of the curve can be interpreted in one of two ways: (*i*) The first kink in the charging curve can be due to the activation overpotential of hydrogen evolution on pure zinc amalgam. As the current flows, there occurs a codeposition of potassium metal into the amalgam and this inhibits hydrogen evolution, *i.e.*, raises the polarization to a new steady-state level. (*ii*) The first kink corresponds to the deposition of potassium. As the concentration of potassium increases, so does the polarization, until after about 1 mC/cm^2 of deposited alkali metal a new phase is formed, mercury is depleted temporarily of potassium and thus accepts potassium more readily (lower polarization). This undergoes, however, further concentration polarization, until a steady state is established in which hy-

[3] The activity of KOH was calculated at each concentration using the activity coefficient data of Bender and Ackerloff (16).

drogen is evolved by chemical reaction of potassium with water at the same rate at which potassium is deposited.

The second explanation seems more likely, for in the first case it is difficult to explain the appearance of the potential dip. A creation of a new phase, however, would instantaneously decrease the concentration of potassium in the amalgam and hence, would reduce polarization, until a new accumulation takes place which leads to a new rise up to the steady state.

The assumption of the accumulation of potassium in the amalgam can be justified only if on a freshly amalgamated surface the chemical reaction between potassium and water (second step) is the rds rather than K^+ discharge.

In support of this stands not only the fact that the hydrogen evolution is known to be much more inhibited on Hg than on Zn, but also the experimental finding (Fig. 7) that the Tafel line on a freshly amalgamated surface has a slope of 60 mV dec^{-1}, *i.e.*, suggests a transfer coefficient of one.

The potential decay curve supports the above consideration. The two arrests, however, indicate a transient existence of two different phases. Insufficient information is available for speculation about the structures of those phases. They seem to need a certain amount of mercury, for they do not appear when mercury dissolves deeper into zinc with time (after 24 hr), *i.e.*, reduces in the surface concentration.

Even then and if the rds becomes the K^+-discharge as in the case of pure zinc, a build up of potassium concentration may be needed before the steady-state decomposition rate with the evolution of hydrogen is achieved. This is in accordance with the fact that according to quantitative results more charge is spent for potassium pileup (3 mC/cm^2) when less mercury is present at the surface (after 24 hr).

Steady-State Corrosion of Zinc

The change in the corrosion rate with time can be interpreted as due to increasing coverage of the surface by an impermeable film of zinc oxide. In such a case a $(1 - \theta_{ZnO})$ factor should be introduced into Eq. [15]. In order to assess how θ_{ZnO} changes with time one has to consider a complex kinetics at the surface. The $Zn(OH)_2$ was seen to be formed by the corrosion of the electrode and reaction between Zn^{2+} ions and OH^- ions. It partly diffuses away, and partly undergoes dehydration forming the insoluble and compact ZnO. If one assumes the first-order kinetics for the latter one could write the rate equation as

$$\frac{dn_{ZnO}}{dt} = \frac{k_{ZnO}}{\gamma^{\neq}_{ZnO}} a_{Zn(OH)_2} \quad [22]$$

and a steady-state material balance equation for $Zn(OH)_2$

$$\frac{k_{Zn(OH)_2}}{\gamma^{\neq}_{Zn(OH)_2}} a_{Zn^{2+}} a^2_{OH^-} - \frac{k_{ZnO}}{\gamma^{\neq}_{ZnO}} a_{Zn(OH)_2} - \frac{DC_{Zn(OH)_2}}{\delta} = 0 \quad [23]$$

Taking into account that

$$\frac{d\theta_{ZnO}}{dt} = \frac{1}{(n_{ZnO})_{max}} \frac{dn_{ZnO}}{dt} \quad [24]$$

and

$$\frac{dn_{Zn^{2+}}}{dt} = \frac{i_{corr,o}(1 - \theta_{ZnO})}{2F} - \rho \frac{k_{Zn(OH)_2}}{\gamma^{\neq}_{Zn(OH)_2}} a_{Zn^{2+}} a^2_{OH^-} = 0 \quad [25]$$

where ρ is the thickness of the reaction layer, combining then [22] with [23] and [25] and replacing into [24] one obtains for the rate of increase of surface coverage by ZnO

$$\frac{d\theta_{ZnO}}{dt} = \frac{1/\rho}{(n_{ZnO})_{max}} \frac{k_{ZnO}/\gamma^{\neq}_{ZnO}}{[k_{ZnO}/\gamma^{\neq}_{ZnO} + D/\delta]} \cdot i_{corr,o}(1 - \theta_{ZnO}) \quad [26]$$

which suggests the first-order kinetics for the film formation. One can solve this for the surface coverage as

$$\theta_{ZnO} = (1 - e^{-Ai_{corr,o}t}) \quad [27]$$

where

$$A = \frac{1/\rho}{(n_{ZnO})_{max}} \frac{k_{ZnO}/\gamma^{\neq}_{ZnO}}{k_{ZnO}/\gamma^{\neq}_{ZnO} + D/\delta} \quad [28]$$

Now, for the effective corrosion rate at any time, t, one can write

$$i_{corr,t} = i_{corr,o}(1 - \theta_{ZnO}) \quad [29]$$

and introducing [27] into [29] one obtains

$$i_{corr,t} = i_{corr,o} e^{-Ai_{corr,o}t} \quad [30]$$

The correctness of the above derivation can be checked by the experimental time dependence of the rate of hydrogen evolution for this is directly related to the rate of corrosion. Hence

$$\log r_{H_2} = (\log r_{H_2})_o - Ai_{corr,o}t \quad [31]$$

and the appropriate plot is shown in Fig. 13.

It is seen that, except for 1*N* KOH solution, the plots exhibit fair linearity after a certain induction period. The slopes increase with increasing KOH concentration as should be expected, for they contain the $i_{corr,o}$. The values of the corrosion rate extrapolated to zero time follow the same pattern. The induction period is to be expected since the theoretical relationship has been derived under the assumption that all of the ZnO formed precipitates immediately into an impermeable film. This could be true of a solution saturated with ZnO.

Indeed, in the earlier work cited (2), the corrosion rate was shown to be much lower in ZnO-saturated

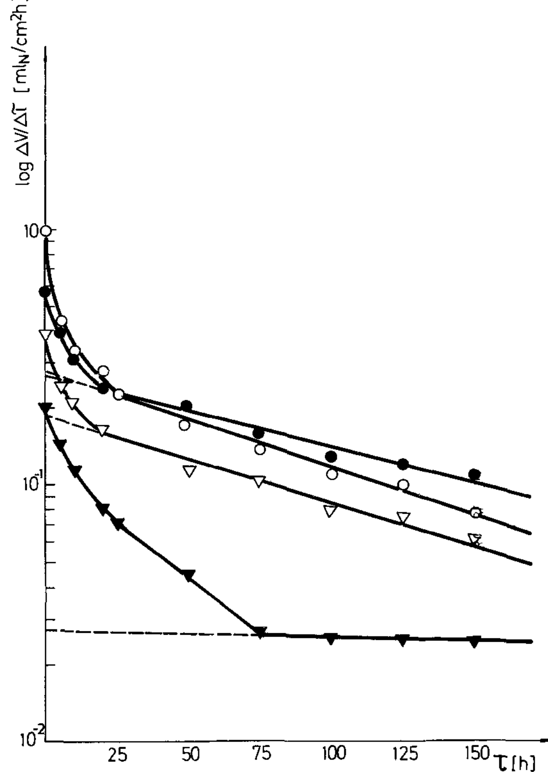

Fig. 13. Plot of log of the rate of hydrogen evolution vs. time for zinc in 1*N* (▼), 3*N* (▽), 6*N* (●), and 10*N* (○) KOH solution.

solution than in fresh KOH. The solutions used in the present work contained no ZnO to start with and some period of accumulation of ZnO to reach saturation is normally expected.

On the whole one can say that the model contains quite a number of simplifying assumptions so that the agreement with the experiment cannot be but crude. However, it reveals one important feature which helps understand some of the experimental puzzles and in particular the reasons for controversial results on the effect of KOH concentration.

It is seen that the initial corrosion rate, $i_{corr,o}$, acts not only as a proportionality constant, but is contained also in the exponent of Eq. [30]. Hence, as this quantity has been shown to be larger at higher KOH concentrations this also means that the decay of the corrosion rate is getting faster as the latter is increased. This explains the crossover of the curves of Fig. 8 and 13 for the 6 and 10M KOH after a certain period of time. But one can foresee also that under some other conditions of experiment under which the $i_{corr,o}$ has a faster increase with the increase in KOH concentration, this crossover can take place much earlier and the concentration dependence of the rate of corrosion is inverse if measured after that has happened. The fact is that, *e.g.*, the data on the rate of corrosion reported by Dirkse and Timmer (2) were taken 1 hr after the immersion of zinc into the electrolyte and, hence, are not the initial corrosion rate values but rather those given by Eq. [24].

Also, Snyder and Lander (1) observed the corrosion in terms of the gassing rate over a long period of time and reported the first values after 2 days.

Addition of zinc oxide to the electrolyte to saturation complicates the interpretation of the results for Eq. [14] is no longer valid and the concept of supersaturation must be introduced if the phenomena are to be explained in the same semiquantitative terms as the ones above. However, one can speculate qualitatively that, if anything, the rate of diffusion of the corrosion products away from the electrode must be slower and, hence, for the same period of time the surface coverage by ZnO in a saturated electrolyte must be much larger than in the pure one. Hence, the corrosion must be correspondingly depressed.

Ellipsometric Study of the Formation of Films on Iron in Orthophosphate Solutions

Z. Szklarska-Smialowska[1] and R. W. Staehle*

Department of Metallurgical Engineering, The Ohio State University, Columbus, Ohio 43210

ABSTRACT

Ellipsometry was used to study optical properties and kinetics of film growth on iron in 0.1*N* sodium orthophosphate solutions differing in *p*H. Properties and thicknesses of films grown at room temperature (22°C) were found to vary within wide limits depending upon *p*H, potential, and presence or absence of oxygen. In aerated Na_3PO_4 solution, γ-Fe_2O_3 or Fe_3O_4 film is formed with a refractive index $n = 2.6$ and absorption coefficient $k = 0.20$. At anodic polarization potentials and at *p*H 7 or higher, iron oxide films are also formed. On the other hand, at open-circuit potentials in aerated solutions of *p*H 7.0 and *p*H 9.1, a multiple phosphate film is produced. It is composed of several layers with n values oscillating between 1.4 and 1.5, and k values from 0 to 0.14. Such a film decreases the corrosion rate of iron shifting its open-circuit potential to more noble values. As a potential is reached at which iron oxide forms, a film composed of both iron oxide and iron phosphate is produced. The growth rate of iron oxide films, and that of phosphate films at higher *p*H values than 7.2, follow a logarithmic law. Below *p*H 7.2, both in aerated and deaerated solutions, an unprotective phosphate film is formed. It is composed of several layers with n values oscillating between 1.34 and 1.36, and k values from 0.013 to 0.45. Its thickness is a linear function of time.

The aim of the present work was to elucidate the kinetics of the film growth on iron in phosphate solutions at various values of *p*H in the presence and absence of air and to determine the optical parameters of these surface layers. Such data are pertinent to understanding the nature of the inhibition provided by phosphate additions.

Phosphates belong to the most popular corrosion inhibitors used for steel in aqueous nearly neutral solutions. It is commonly assumed that they are active in the presence of oxygen only.

Mayne and Menter (1) used electron diffraction to determine the composition of protective films on iron in aerated dibasic and tribasic phosphate solutions. In both solutions the protective film was composed mainly of a cubic oxide having the structure of Fe_3O_4, γ-Fe_2O_3, or an intermediate compound. However, in disodium hydrogen phosphate, particles of $FePO_4 \cdot 2H_2O$ were found imbedded in a matrix of the cubic oxide. On the basis of corrosion measurements and film composition studies, the authors concluded that in 0.1*N* trisodium phosphate in the presence of air, the weak areas in the air-formed film are repaired by the formation of γ-Fe_2O_3, Fe_3O_4, or an intermediate compound with traces of ferric phosphate. In 0.1*N* disodium hydrogen phosphate, $FePO_4 \cdot 2H_2O$ was found in the protective film what, as the authors assume, is essential for the inhibition when the air-formed film is weak.

Kolotyrkin *et al.* (2) assume that in neutral phosphate solutions a passivating monolayer of $FeHPO_4$ and a porous film of $Fe_3(PO_4)_2$ is formed.

According to Pryor and Cohen (3), the inhibition of the corrosion of iron by sodium phosphate solutions in the presence of air is caused by oxygen. They assume that oxygen dissolved in the phosphate solution is mainly responsible for the capacity of phosphate solutions to inhibit the corrosion of iron. Namely, oxygen adsorbed on the metal surface takes part in the reaction with surface iron atoms to form γ-Fe_2O_3. They also suggest that the formation of a protective film of γ-Fe_2O_3 is not instantaneous, and the initial stages of film formation are accompanied by a very slow electrochemical attack, which leads to the formation of hydrated ferric phosphates. Neither the thickness of the protective films nor the kinetics of their formation in phosphate solutions were studied in their work.

Key words: corrosion inhibitors, ellipsometry, passivity, phosphates, thin films, refractive index.

Experimental

All experiments were performed on specimens of 99.99% purity iron in the form of cylindrical disks with exposed area of 0.32 cm^2. The specimen was mounted in a Teflon holder.

The specimen was first rough ground to a 600 grit finish through a series of metallographic papers and then mechanically polished with diamond abrasives to a final finish of 1μ. After mechanical polishing, the specimen was cleaned, degreased, and electropolished. The electropolishing solution was composed of 20 parts of glacial acetic acid with 1 part of 70% perchloric acid. The specimens were exposed for 2 sec at room temperature and a current density of 4 A/cm^2; the specimen was then washed with methanol, dried and placed in the ellipsometric cell.

The ellipsometric measurements were performed in different solutions, either deaerated or maintained in free contact with air. As the *p*H changes, the composition of the anion changes; regions for the existence of the phosphate ions are (4)

$H_2PO_4^-/HPO_4^{-2}$	*p*H 7.19
HPO_4^{-2}/PO_4^{-3}	*p*H 12.09

Since we wished to investigate domains of existence of each anion, the following solutions were used: 0.1*N* Na_3PO_4 (*p*H 12.3), 0.1*N* Na_2HPO_4 (*p*H 9.1), 0.1*N* NaH_2PO_4 (*p*H 4.5), and 0.1*N* Na_2HPO_4 with NaH_2PO_4 (*p*H 7). The solutions were deaerated by bubbling for 24 hr prepurified helium through the solution. All experiments were conducted at 22°C. The electrode potential was measured with reference to a saturated calomel electrode and all data are reported in the calomel scale. Experiments were conducted at open-circuit potential, at different anodic potentials, and sometimes at slightly cathodic potentials.

The ellipsometer was Model 436 from Rudolf and Sons with mercury arc light source. The vacuum wave length of light was 5461Å, and the angle of incidence was 70.96°.

Before measuring the optical parameters of the pure substrate, the specimen was treated with a constant

cathodic current of 40 $\mu A/cm^2$ in the solution to be studied to remove any air-formed film and to maintain a clean surface. The measurements of the optical constants of iron were made as rapidly as possible.

The optical constants of iron and of the films formed on its surface, and the film thicknesses were calculated using the McCrackin computer program (5) and an 360 computer. In the case of multiple films, their refractive indices were calculated under the assumption that there was a stack of several homogeneous layers with different optical parameters.

Results

Polarization curves.—Anodic polarization curves were determined to characterize the general electrochemical response of the iron to the various phosphate solutions. The measurements of the polarization curves were performed in deaerated solutions at a scanning rate of 20 mV/min; the potential sweep started from potentials more negative than the corrosion potential.

Figure 1 gives the polarization curves for all the solutions studied. The critical potential of passivation manifests itself distinctly only in the solution of pH 7. In the 0.1*N* NaH_2PO_4 solution iron does not passivate.

Index of refraction of film-free substrate.—The index of refraction of the film-free substrate for each experiment was determined; the value of the refractive index was 3.14-3.26 and the absorption coefficient was 3.6-4.0. This applied for aerated and deaerated solutions at all values of pH studied.

Iron oxide films at pH 12.3 and 9.1.—Figure 2 shows changes in analyzer angles (ΔA) *vs.* changes in polarizer angles (ΔP) for iron in the three environmental conditions: The first two cases involve 0.1*N* Na_3PO_4 (pH 12.3) and 0.1*N* Na_2HPO_4 (pH 9.1), each taken at a series of applied potentials. The former was taken from -700 to $+600$ mV_{SCE}. Every value of potential was maintained constant for 60 min and during this time the changes in *A* and *P* were noted. Approximately one-third of the measurements taken during 1 hr are plotted. Thus, at -700 mV_{SCE} the (x) symbol refers to values of ΔA and ΔP taken at the same potential over a period of 1 hr. The surface was freshly prepared for each experiment. The third case in Fig. 2 shows the changes with time of ΔA and ΔP for specimens immersed in 0.1*N* Na_3PO_4 at the open circuit potential. These points lie along the same line which was found for the films formed at constant anodic potentials.

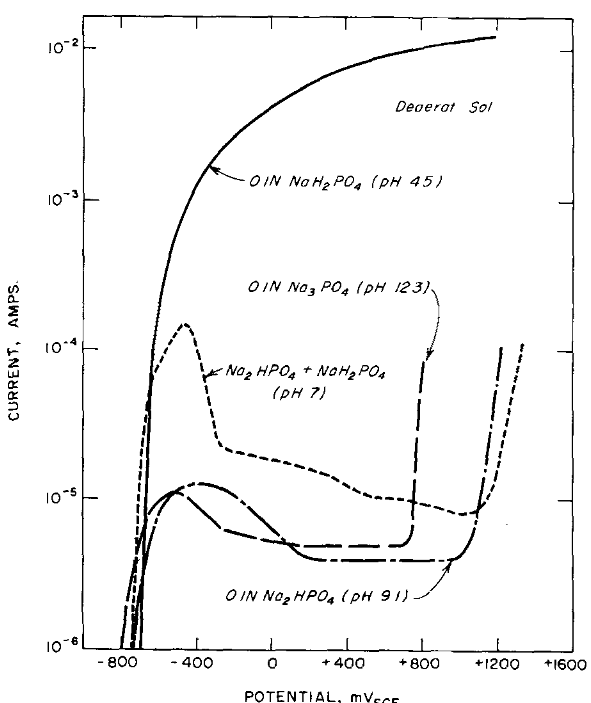

Fig. 1. Current-potential diagrams for iron in phosphate solutions of various pH.

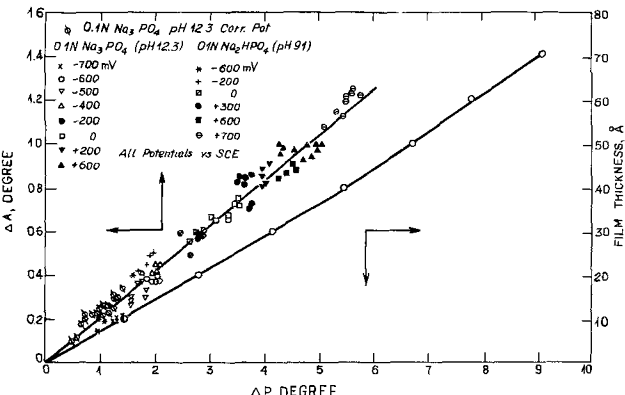

Fig. 2. Relationship of ΔA vs. ΔP for a film grown in 0.1*N* Na_3PO_4 and 0.1*N* Na_2HPO_4 solutions at different applied potentials, and relationship between ΔP and thickness of the film whose complex index was equal to 2.6 (1-0.08*i*).

From Fig. 2 it is possible to calculate an average complex refractive index which applies to all three cases including the whole set of applied potentials at two pH's and the open-circuit potentials at pH 12.3. The data in Fig. 2 give an average refractive index of 2.6 (1-0.08*i*)[2] with $n = 2.6 \pm 0.1$ and $k = 0.21 \pm 0.05$. These values correspond either to γ-Fe_2O_3 or Fe_3O_4. However, the imaginary part of the refractive index is smaller than the range of 0.12-0.20 usually given in the literature for the same type of film (6-8).

Figure 2 also shows the relationship between the thickness of the film and ΔP.

Figure 3 shows that the time dependence of the film thickness under open circuit conditions at pH 12.3 is logarithmic. The growth rate of approximately 5Å per decade is higher than that for the iron base alloys studied by Goswami and Staehle (9) in borate buffer solutions of pH 8.4 where values of 0.9 to 1.5 Å/decade were obtained at constant applied potentials. The growth of the film was accompanied by a substantial increase in potential, shown in Fig. 4. This change corresponds to 35 mV/Å.

Films at pH 9.1 at open-circuit potentials.—Figure 2 showed a series of measurements for the pH 9.1 solution at constant anodic potentials. Here the optical properties of the protective film were identical to those for open-circuit and applied anodic potentials at pH 12.3. However, at open-circuit potential at pH 9.1 quite

[2] The complex index, *N*, of a substance is defined by the equation: $N = n - i \cdot k$, or $N = n(1 - i \cdot K)$ where $nK = k$, n = refractive index, k = absorption coefficient, K = extinction coefficient.

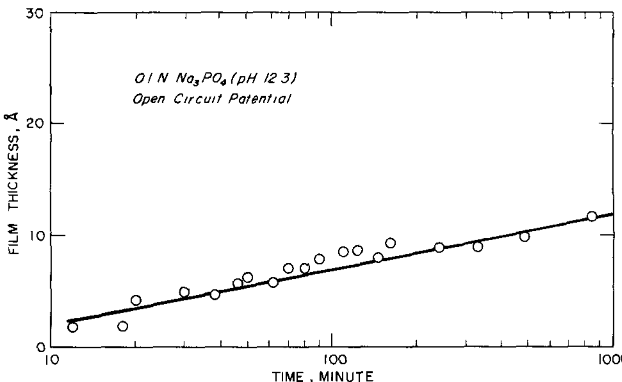

Fig. 3. Film thickness vs. time for iron at open-circuit potential in 0.1*N* Na_3PO_4 solution.

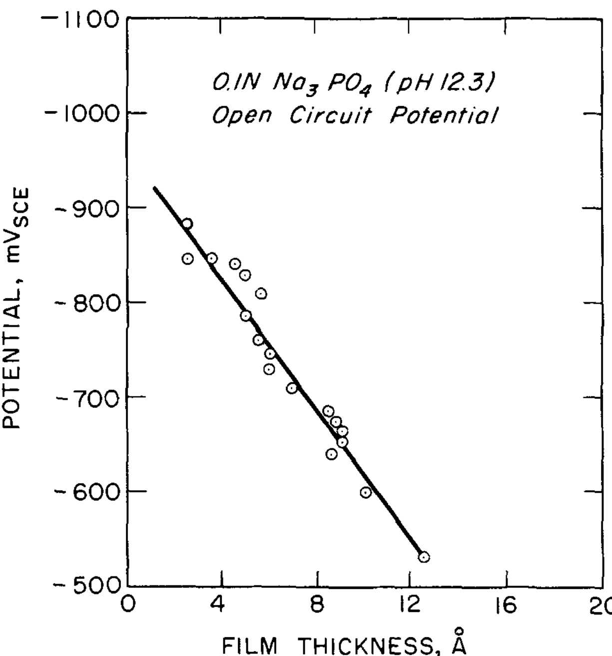

Fig. 4. Dependence of the open circuit potential on thickness of the oxide film formed in 0.1N Na_3PO_4 solution.

different results from those at applied anodic potentials were obtained. Figures 5-8 show as an example the results of an experiment where optical and electrochemical parameters were determined for films grown under open circuit conditions at pH 9.1. In this experiment the initial solution was deaerated and the specimen had been cleaned by cathodic reduction. After the experiment started, the solution was brought into contact with air.

Figure 5 shows analyzer *vs.* polarizer readings. These are correlated with regions of film thicknesses and different refractive indices. These measurements were continued until the readings of A and P could be made with sufficient accuracy, because reliable interpretation of ellipsometric data depends upon a reasonable amount of light transmission in the film. When the experiment was terminated, five different refractive indices had been found. Their values and the extent of the applicable thickness ranges is not consistent in detail, although the over-all behavior is generally similar.

If these experiments had been continued, additional layers of similar refractive indices would probably been formed.

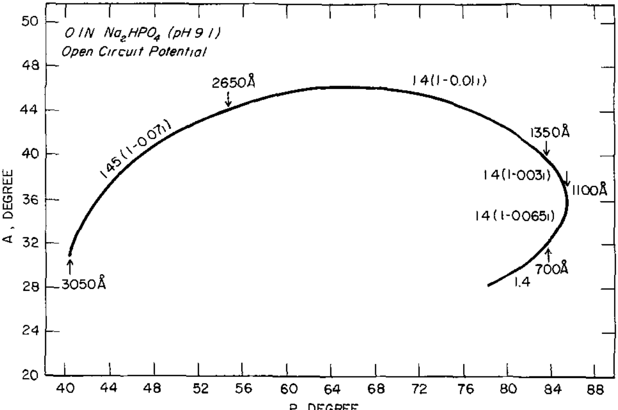

Fig. 5. Values of P and A for a film formed at corrosion potential in 0.1N Na_2HPO_4 solution. Thickness corresponds to limits where specific optical constants were observed.

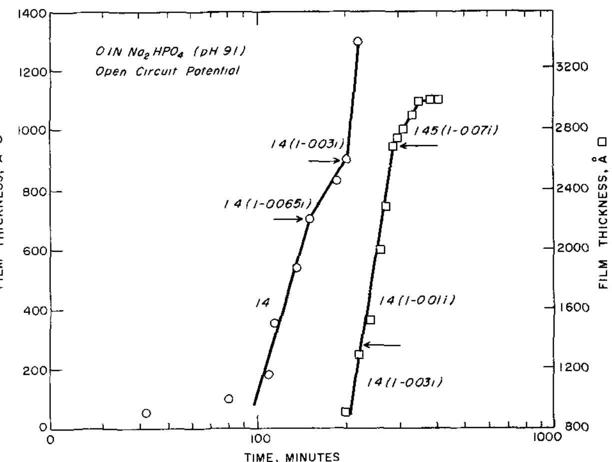

Fig. 6. Film thickness *vs.* time for the film whose optical parameters are given in Fig. 5.

Figure 6 shows film thickness *vs.* time. As can be seen, the maximum film thicknesses are very large compared to those in Fig. 2 for films found at pH 12.3. The changes in the slopes of film thickness *vs.* log time correspond generally to changes in the refractive index, and there is no progressive trend in the rates, *i.e.,* they do not progressively increase or decrease in any clear order. The reasons for this behavior are not clear. However, some lack of reproducibility for the first film formed would be expected in view of the uncertainties in surface preparation and because the surface was maintained initially at cathodic potentials. Also hydrogen effusion for the cathodic potential could disturb the initially formed film. The early stage of film growth is slow, since the surface is at a relatively low potential and the rate of production of iron ions is low. When the potential begins to rise, the rate of formation of iron ions increases, and it is then possible to produce sufficient material to form the rapidly growing film. It is difficult to assign a specific growth law to this early stage of film growth.

Growth rates for the films of Fig. 6 are tabulated in Table I along with other data from the other experiments. These rates are three orders of magnitude greater than the rates in pH 12.3 or at anodic polarization at pH 9.1.

The open-circuit potential increases in the noble direction with time at pH 9.1 as shown in Fig. 7. The figure exhibits an intermediate range where the potential changes very little; this corresponds to the highest imaginary value of K. The highest values of absorption coefficients are connected with high semiconductive properties of the films (10); thus, a relatively negligible change in potential in this region seems to correlate well with a relatively higher electronic conductivity.

The relationship between film thickness and potential is shown in Fig. 8. The initial rate of change of potential is 0.031 mV/Å. This increases at -670 mV to a rate of 0.23 mV/Å. This potential of -670 mV_{SCE} (-430 mV_H) is substantially noble to the potentials for the formation of Fe_2O_3.[3] Despite the fact that the iron oxide forms, no change was observed in the refractive index. Since the film of Fig. 8 was so thick before the iron oxide formed it was difficult to see any influence of the new iron oxide on the refractive index. Therefore it was decided to grow a thinner initial film prior to forming the iron oxide. This was accomplished by growing films at controlled potentials. A potential -720 mV_{SCE} was selected as the initial polarizing potential. This was in a range where the optical constant was clearly not that of an iron oxide, and was clearly low enough so that the iron oxide

[3] Equilibrium potentials for Fe/Fe_2O_3 are -785, -590, and -472 mV_H for pH's of 12.3, 9.1, and 7, respectively (4).

* The layers within the given film are numbered starting from the metal surface.

† We have omitted from this table growth rate of the earliest films since the kinetics law was uncertain.

would not form. Figures 9 and 11 show that this low optical constant of $N = 1.4$ was maintained so long as the potential of −720 mV was maintained. The growth rate of these early stages is very high similar to that in Fig. 6. These experiments showed that the expected result occurred, *i.e.*, the refractive index changed when the iron oxide was formed. The earliest growth pattern did not follow a distinct law; this is the same as the earlier results from Fig. 6. The first very steep growth curves of Fig. 10 and 12 showed rates of 2950 and 1650 Å/decade, respectively. While these are lower than that of Fig. 6, they are obtained potentiostatically. They are, nonetheless, very high. After applying the high anodic potentials, these rates were reduced to 100 and 45 Å/decade, respectively. Also, for these thinner films it was possible to see the change in the refractive index when iron oxide formed which had not been possible for the thicker films.

Films at pH 7.0.—In deaerated solution of pH 7 at corrosion potential, no conclusive results as to the

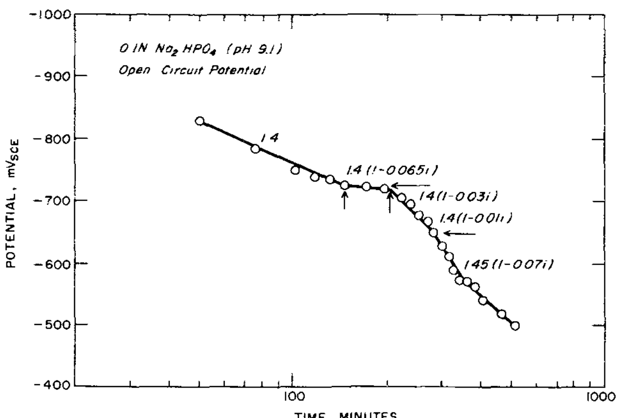

Fig. 7. Potential *vs.* time during growth of the same film as in Fig. 5 and 6.

optical parameters of the produced film have been observed. On the contrary, at potentials more positive and more negative than the corrosion potential, the re-

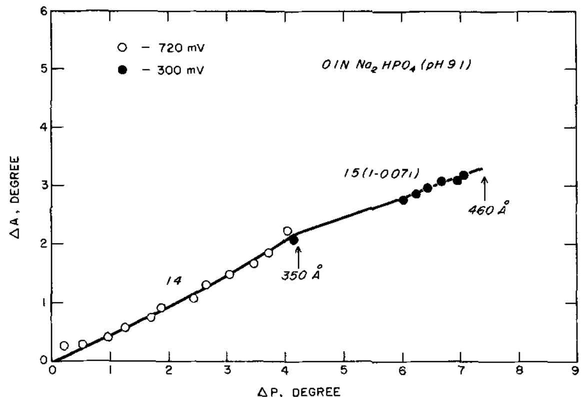

Fig. 11. Effect of anodic polarization on ΔA vs. ΔP relationship for a film produced in 0.1N Na_2HPO_4 solution.

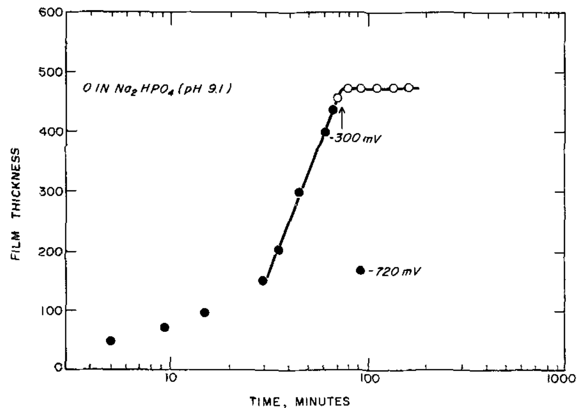

Fig. 12. Effect of time on thickness of the film whose optical parameters are given in Fig. 11.

sults are more reproducible and have shown that quite different films are produced in both cases. At pH 7 the properties of the films below (−750 mV) and above (−680 mV) the corrosion potential were studied. Optical parameters, film growth, kinetics, and current-time behavior were determined. Below the corrosion potential a film was formed, and it grew to a thickness of 600Å in 300 min, as shown in Fig. 13 and 14. Figure 13 shows ΔA *vs.* ΔP for the 0.1N (NaH_2PO_4 + Na_2HPO_4) solution at −750 mV; Fig. 14 shows film thickness and current *vs.* time for the same conditions. Two clearly different but linear growth laws were obtained. Below 250Å, the film growth rate was 12.5 Å/min and above, it was 1.15 Å/min. The initial film

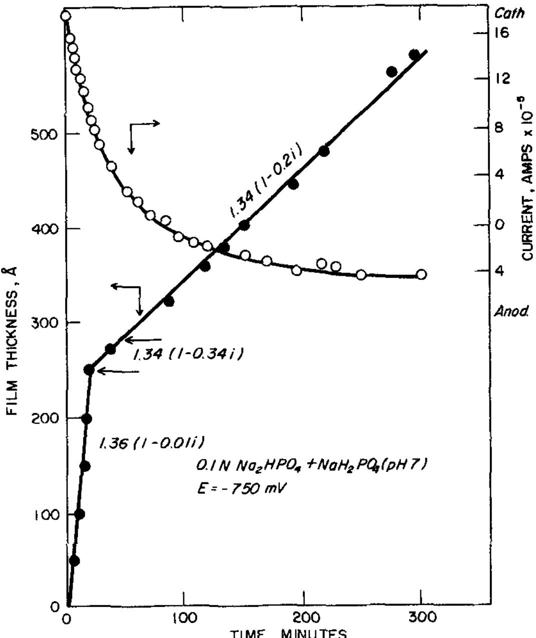

Fig. 14. Thickness and current vs. time during the growth of the film whose optical parameters are given in Fig. 13.

corresponded to a refractive index of 1.36(1-0.01i); a transition film seems to exist from 250 to 280Å with a substantial increase in K and is 1.34(1-0.34i). The remainder of the film grew to 580Å with a similar refractive index.

Figures 15-18 show data taken above the corrosion potential at −680 mV. These films are very complex and exhibit ten layers after 230 min. Further, the film grows to slightly more than ten times the thickness in the same exposure time, as does the film at −750 mV. Figures 15 and 16 show patterns exceedingly more complex than their counterparts obtained under open-circuit conditions at pH 9.1 (Fig. 5). The changes in slopes of film growth rates in Fig. 16 are generally similar to those of Fig. 6. These growth rates are compared with those of previous experiment in Table I. A particular linear dependence between film thickness and time from 2000 to 2800Å was present, and it is shown in detail in Fig. 17.

The relationship between film thickness and current at −680 mV is shown in Fig. 18. The behavior is complex but after reaching 800Å the current decreases and the film becomes protective. The current becomes slightly cathodic and stays very close to zero.

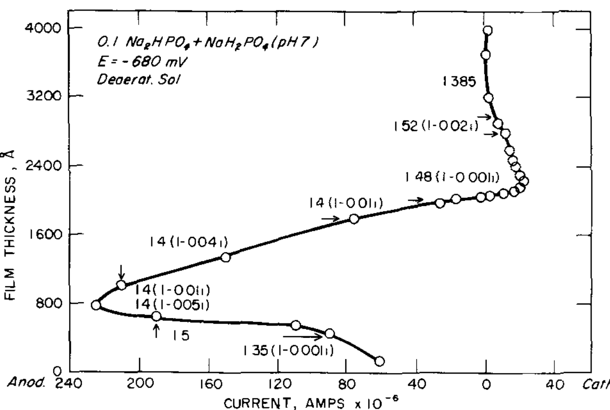

Fig. 18. Changes in current with film thickness for experiment given in Fig. 15.

Films at pH 4.5.—Since Fig. 1 shows that there is no passive state, the film growth was investigated only at the corrosion potential at *p*H 4.5 in the 0.1*N* NaH_2PO_4 solution. The plots of ΔA *vs.* ΔP and film thickness *vs.* time in Fig. 19 and 20 at *p*H 4.5 are similar to Fig. 13 and 14 for the region below the corrosion potential (−750 mV) at *p*H 7. There is a transition in the growth rates at the same value of 250Å. The early film grows at a rate of 25 Å/min while the slow rate at greater thickness is 1.5 Å/min. These rates are comparable to ones in Fig. 14.

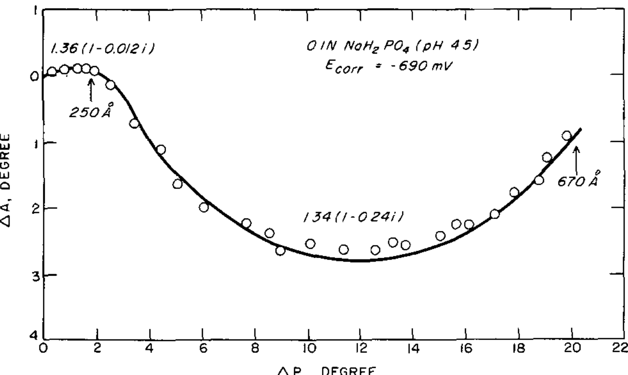

Fig. 19. Relationship of ΔA *vs.* ΔP of a film produced in deaerated 0.1*N* NaH_2PO_4 solution at open-circuit potential.

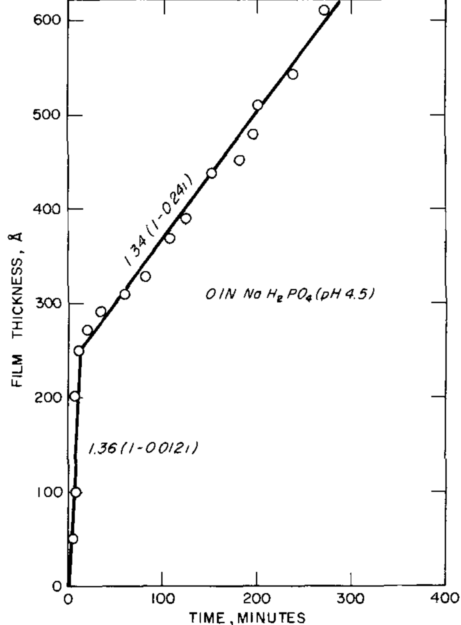

Fig. 20. Film thickness vs. time of the film whose optical parameters are given in Fig. 19.

Effect of initial oxide.—To study the effect of the surface being initially covered by an oxide film on the formation of successive deposits in aerated solutions of phosphates, measurements similar to the above were performed without initially reducing the air-formed oxide film on the iron surface. It was found that at *p*H 9.1 at open-circuit potential the oxide film continued to grow. At *p*H 7, a film was produced with refraction index equal to 1.4-1.5. At *p*H 4.5, a layer with n = 1.34-1.36 was formed.

Discussion

Polarization curves.—The anodic polarization curves of Fig. 1 exhibit three important patterns. First, the polarization curve for *p*H 4.5 exhibits no tendency towards passivation. Secondly, the peak potentials of Fig. 1 are substantially noble to the values for the equilibrium formation of the iron oxides. This result has been observed by many authors (11). A third important feature of the polarization curves involves the comparison with film thickness as determined ellipsometrically at potentials active to the peak potential. In all cases a film of optical significance was found in a region active to the peak potential. For the experiments at *p*H 9.1 and 12.3 there were iron oxide films

and for pH 7 these probably were phosphate films. At potentials noble to the peak potential the protective capacity of these films increases. This pattern has also been observed by Sato and Kudo (8) for iron oxide films formed in borate buffer solutions.

In general there are four classes of films formed on iron in phosphate solutions. The existence of these regions depends upon pH and oxygen present (or potential).

While a considerably greater amount of information is required relative to effects of concentration of the phosphate ions, a broader range of pH and potential, we have identified the following important general classes of films.

Class I films.—Class I is the compact iron oxide film produced at pH 12.3 in both open circuit in aerated solutions and in applied anodic potential conditions at pH 9.1. These films have the same optical properties over a wide range of potentials and are so similar to iron oxide as to leave only the conclusion that the films are in fact the γ-Fe_2O_3 or Fe_3O_4. These films are characterized by a relatively low logarithmic growth rate (5 Å/decade) and a high value of the field strength equal to 35 mV/Å.

Class II films.—Class II are the relatively complex multilayered films produced at pH 9.1 under open-circuit conditions in deaerated solutions below the potential of iron oxide formation and at pH 7 at −680 mV. These films grow very much thicker than those of Class I with 3000-4000Å being obtained in less than 1000 min. The existence of the multiple layers in the Class II films are easily recognized by changes in optical properties, corresponding generally to changes in slope of the thickness-time and potential-time data. The optical constants correspond directly to the separable kinetic regions. These films have a very low field strength of 0.031 mV/Å compared to the very high value of Class I films. As shown in Table I, the refractive index varies between 1.4 and 1.52, and the absorption coefficients range from 0 to 0.14. The changes in the complex indices are not quite systematic, but a certain general tendency can be noted. Namely, the refractive indices of the first layer numbered starting from the iron surface are comparatively low; they increase with thickness, and finally, they decrease again. The absorption coefficients show a similar tendency; that for the first layer is 0 or close to it, the next layer has a considerable k value, and the coefficients of further layers are low again. The Class II films appear to produce an ultimately protective condition despite the much greater thickness than the Class I films.

Class III films.—These films are similar to those of Class II but differ in one important respect: the protective properties are improved due to the simultaneous formation of an iron oxide.[4] However, no changes in the refractive index are observed under these conditions, as shown in Fig. 5. Evidently, a small content of Fe_2O_3 in the thick film does not affect its optical properties. On the other hand, when the film with the refractive index equal to 1.4-1.5 is not too thick, as shown in Fig. 9 and 11, the formation of a mixture of oxides and of the compound with the refractive index 1.4-1.5 involves an increase of both the n and k values.

Class IV films.—The Class IV films are epitomized by those found below the corrosion potential at pH 7 and at the open-circuit potential at pH 4.5. These films at these conditions are nonprotective; they have similar optical and kinetic properties. These Class IV films are characterized also by the following: (*i*) the growth laws are linear for the first two layers; (*ii*) the real parts of the refractive indices are relatively lower than for Class II films; (*iii*) the transitions between growth laws for the two pH's occur at approximately the same thickness; (*iv*) the imaginary parts of the films are substantially lower for the first layer than the second; (*v*) the imaginary part of the second layer of the Class IV films is much larger than any of those in Class II and Class III. The Class IV film is sufficiently porous and nonprotective that the corrosion potential remains relatively constant.

[4] When such a layer is formed, the shift of potential is higher than in the case of Class II films, namely 0.1-0.23 mV/Å.

Optical constants.—The consideration of optical constants is inextricably involved with the previous discussion of multiple layers and the relative protective behavior of the films. However, several specific points should be made here.

The question arises as to how far from reality are the complex indices and the number of layers calculated on the basis of ellipsometric measurements. All the A *vs.* P relationships were obtained experimentally, but the refractive indices were computed for different segments of the curves in such a way to fit them best to the results of measurements. In some cases, for the same segment of the curve, different optical parameters could be obtained, but the differences were small and did not essentially influence the calculated film thicknesses.

Figure 21 gives, as an example, the theoretical shape of A *vs.* P relationships for iron whose complex index is $3.2(1\text{-}1.24i)$, and on whose surface homogeneous films with different refraction indices are present. The dashed curve represents our experimental curve also shown in Fig. 5. As it may be seen, the latter does not correspond to any of the theoretical curves describing the optical parameters of films composed of only one homogeneous layer. This suggests that the real film must be composed of several layers differing in optical parameters.

The correctness of the calculated optical constants seems verified by the good agreement of any particular optical constant with specific region on the thickness-time or potential-time plots. Further, when the optical constants change, the thickness-time and potential-time slopes change also. In some cases a change in optical constants does not produce a change in thickness or potential *vs.* time slopes when there is a relatively small difference in successive optical constants in the same experiment. An example of no change in the thickness-time behavior with a small change in optical constants is shown in Fig. 6. A similar result for potential-time is shown in Fig. 7. Here the slope changes very little for slight changes in the optical constants.

The changes in refractive indices may be due to variations in the density and in the molecular weight of the compounds being formed (12), *e.g.*, the water content can vary within considerable limits. The changes in absorption coefficients are presumably related to the unstoichiometric composition of the film.

It is necessary to remark here that in the case of the actively dissolving iron, the roughness of the surface should be taken into consideration since it affects the P and A values. Unfortunately, any accurate theoretical treatment of this influence is lacking. In our case

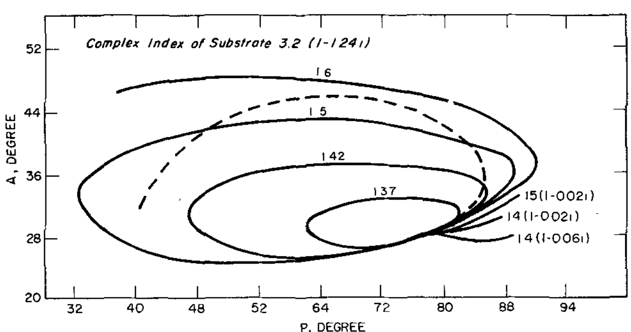

Fig. 21. Theoretical A vs. P relationships (full lines) for homogeneous films with different complex indices, and experimental curve (dashed) as in Fig. 5.

an intensive corrosion occurred in NaH_2PO_4 solution at *p*H 4.5, but no visible roughening or pitting was observed during these experiments. Nevertheless, we fully realize that some of the calculated values of the refractive indices can be inaccurate.

Composition of films formed on iron in phosphate solutions.—Depending upon the domain of existence of different phosphate anions and upon the presence or absence of oxygen, the films being formed on iron show various optical parameters and protective capacities. The composition and the structure of these films *in situ* is not known. All previous investigations were made after putting the specimens out from the solution, and this could change the composition of the film.

In deaerated monosodium phosphate at *p*H 4.5 Pryor and Cohen (3) have found by chemical analysis a product of the formula $Fe_3(PO_4)_2 \cdot 9H_2O$. By x-ray analysis they have identified this compound as vivianite $Fe_3(PO_4)_2 \cdot 8H_2O$. In the presence of air, $FePO_4 \cdot xH_2O$ has been found, with x equal to about 30. The refractive index of vivianite is 1.58 to 1.65 (13), which is different from our value found for the film formed at corrosion potential at *p*H 4.5.

In aerated disodium hydrogen phosphate Mayne and Menter (1) have observed the presence of $FePO_4 \cdot 2H_2O$ in addition to iron oxides.

In tribasic phosphate solution mainly Fe_3O_4 or γ-Fe_2O_3 is formed (1). The formation of iron oxides in this solution is confirmed by our ellipsometric studies, because the refractive index of the film formed in this solution is in the range of values found by different authors for anodic films and for Fe_3O_4 or γ-Fe_2O_3 obtained by gaseous oxidation of iron.

Under our experimental conditions, when the measurements are performed *in situ*, other compounds are probably formed in mono- and disodium phosphates. The occurrence of a sharp difference between the optical and the protective properties of films produced within the domain of relative predominance of $H_2PO_4^-/HPO_4^{2-}$ (*p*H 7.2) suggests that the films produced under these conditions have different structures and chemical compositions. It is possible that below *p*H 7.2 the compound $Fe(H_2PO_4)_2 \cdot xH_2O$ is formed, while above 7.2 until *p*H 12 $FeHPO_4 \cdot xH_2O$ is produced. Such compounds have been found to occur in the Fe_2O_3-P_2O_5-H_2O system (14). In the presence of oxygen these ferrous salts can be oxidized to ferric phosphates.

Inhibition of iron by phosphates.—In agreement with Pryor and Cohen's viewpoint (3), the passivation of iron in NaH_2PO_4 solution (*p*H 4.5) does not occur. The film with refractive index from 1.34 to 1.36, composed probably of $Fe(H_2PO_4)_2$, is unprotective. The corrosion potential does not change during corrosion, and with time a linear growth of the film is observed. The low refractive index of this film seems to indicate that it is not composed of a solid deposit, but rather of a supersaturated solution of iron phosphate.

The films produced in Na_2HPO_4 and Na_3PO_4 are protective. In deaerated Na_2HPO_4 solutions at first iron undergoes corrosion connected with the formation of some kind of phosphate film with refractive index from 1.4 to 1.52. This film is probably composed of $FeHPO_4$. By blocking the metal surface, it shifts the potential to more positive values. The phosphate films are thick and grow according to logarithmic laws. At higher anodic potentials the iron oxide is formed together with iron phosphates improving the protective capacity of the film. Similarly, in Na_3PO_4, on a clean surface, at first a protective phosphate film (refractive index 1.4-1.5) is produced, and hereafter the iron oxide is also formed. In the last case, *i.e.*, in the presence of iron oxide, the film grows much more slowly.

The protective capacity of phosphates is less than that of iron oxide. A direct evidence of this fact is the magnitude of the potential drop on 1Å film thickness: it is higher in the case of oxide (35 mV/Å) than in the case of phosphate (0.031 mV/Å). When a mixture of phosphate and oxide is formed, this value is equal to 0.23 mV/Å.

When an air-formed film is left on the metal surface before starting the experiment, different trends are observed, but the patterns are understandable in terms of different classes described before. Thus, when the air-formed film is present on the iron surface at *p*H 9.1, an iron oxide film grows at open-circuit potential, instead of the phosphate film produced on a clean surface. This is due to the fact that the potential of the primarily oxidized specimen quickly attains a value at which the iron oxide forms. However, at *p*H 7, iron phosphates are formed with refractive indices from 1.4 to 1.52. This means that the air-formed film is not protective at that *p*H value, and the relatively high corrosion rate produces a thicker film which eventually reaches a protective capacity.

Table II surveys the types of films grown in phosphate solutions at open-circuit potentials. The importance of the initial surface condition: clean or preoxidized, and the correlations with the refractive indices are quite obvious. Not knowing surely the chemical composition of phosphate films formed in solutions at different *p*H's, we can distinguish them only after their refractive indices.

Table I shows that among the classes of films the real part of the refractive index correlates well with the protective capacity of the films. A value of 2.4 corresponds to Class I, which is the most protective; values from 1.4 to 1.5 correspond to Classes II and III, which are less protective; and values from 1.34 to 1.36 correspond to Class IV, which is unprotective.

Table II. Types of films grown in phosphate solutions at open-circuit potential

Phosphate conc. 0.1*N*	*p*H	Iron surface	Solution	Suggested film composition	Protective ability	Optical parameters *n*	*k*
Na_3PO_4	12.3	clean	deaerated	iron phosphates*	weak	1.4 ÷ 1.52	0 ÷ 0.14
Na_3PO_4	12.3	clean	free access of air	iron oxide	yes	2.6	0.20
Na_3PO_4	12.3	with air-formed oxide film	free access of air	iron oxide	yes	2.6	0.20

* After reaching the potential of iron oxide formation, a protective mixture of iron oxide and iron phosphate is formed on the phosphate layer.

Summary

1. The type of films produced on iron in 0.1N sodium orthophosphate solutions at open-circuit potentials depends upon the pH, potential, and presence of oxygen and may be considered as four separate classes.

Class I: At pH 12, *i.e.*, in the presence of PO_4^{3-} ions, the iron oxide film is formed with a refractive index $n = 2.6$, and an absorption coefficient $k = 0.20$.

Class II: At pH values higher than 7.2, and at potentials below the potential of iron oxide formation in the presence of HPO_4^{2-} ions, phosphate films manifesting higher refractive indices, from 1.4 to 1.52, and absorption coefficients from 0 to 0.14, are produced. They exhibit some protective capacity; in the presence of these films the open-circuit potential shifts to more positive values which are greater with increasing thickness. Below the potential of iron oxide formation the shift of potential is small, namely 0.031 mV per 1Å.

Class III: These are similar to Class II films but contain iron oxide which forms simultaneously with the iron phosphates. The shift of potential at potentials higher than that of the iron oxide formation is 0.1-0.23 mV per 1Å. This indicates that the protective properties of the film composed of iron oxide and iron phosphate are much better than those of the film formed at lower potentials.

Class IV: At pH values lower than 7, *i.e.*, in the presence of $H_2PO_4^-$ ions in the solution, a phosphate film with a low refractive index of 1.34-1.36 and an absorption coefficient of 0.013-0.45 is formed. This film does not protect the iron against corrosion. The open-circuit potential of iron does not change during the film growth. The properties of films grown in deaerated and aerated solutions are alike.

2. The kinetics of the film growth on iron in 0.1N sodium orthophosphate solutions depend upon the type of the film being formed. In $H_2PO_4^-$ solutions, the thickness of the film is a linear function of time, while in HPO_4^{2-} solutions it follows a logarithmic law. The thickness of iron oxide films growing in PO_4^{3-} solution also follows a logarithmic law but at a very much lower rate than in the HPO_4^{2-} solution.

3. There appears to be a correlation between the real part of the refractive index and the protective capacity of the film. Lower values correspond to a less protective film.

The Anodization of Several Rare Earth Metals in Sodium Silicate Solutions

Leonard Gruss* and Thomas Mackus

Pitman-Dunn Laboratory, Frankford Arsenal, Philadelphia, Pennsylvania 19137

ABSTRACT

The rare earth metals, *e.g.*, Sm, Gd, Dy, Ho, Er, and Yb including Y, were anodized in a 0.1*N* solution of reagent grade sodium metasilicate. A current density of 0.16 A/cm^2 was employed in all reactions. The reaction cell was thermostated at 14.5° ± 0.5°C. Dielectric breakdown (sparking) was observed with all of the metal-electrolyte combinations investigated. The anodic spark reaction process produced coatings the components of which were derived from the anion constituent of the electrolyte. Orthosilicate coatings were produced on samarium and gadolinium metals and mixtures of orthosilicate and a distorted sesquioxide coating were produced on yttrium, dysprosium, holmium, erbium, and ytterbium metals. Powder x-ray diffraction techniques were utilized to identify the anodic spark reaction products. Diffuse reflectance spectra between 200 and 700 mμ were also obtained for the anodic spark products. The reflectance spectra confirmed the results of the x-ray diffraction study that single compounds exist in the anodic products for samarium and gadolinium metals and mixtures exist in the anodic products of yttrium, dysprosium, holmium, erbium, and ytterbium metals when these metals were anodized in sodium silicate solutions.

Numerous authors (1-10), beginning with Giuscá in 1934, synthesized various rare earth silicate compounds. The orthosilicate (1:1) and the pyrosilicate (1:2) compounds are the most common variety for rare earth silicates. The usual procedure for the preparation of polycrystalline rare earth silicates involves firing a rare earth sesquioxide with silica at temperatures in excess of 1000°C.

This investigation was undertaken to study the preparation, structure, and composition of a variety of rare earth silicates by the anodic spark reaction of rare earth metals in sodium silicate solution. It was shown previously (11, 12) that the rare earth metals are typical of those metals which form oxide barrier films at their interfaces. Greene and Lee (11) studied the electrochemical characteristics of the rare earth metals in dilute phosphoric acid solution using potentials up to 4V in the noble direction. Gruss and Mackus (12) prepared rare earth aluminates by anodic oxidation of rare earth metals in sodium aluminate solution. The anodic spark reaction process produced aluminates with perovskite structures when the base metal was samarium, europium, or gadolinium. Mixtures of perovskite and garnet structured coatings were produced with dysprosium, holmium, erbium, ytterbium, and even yttrium.

Experimental

The rare earth metals in rod form were mounted in tight-fitting Teflon sleeves. These sleeves served to mask the anode at the air-electrolyte interface and to fix the area for anodization. Prior to anodization the metals were polished with a series of silicon carbide abrasive papers down to a 3/0 emery and finally with microcut polishing paper (GRIT=600 soft) and washed with absolute ethanol. Samarium, gadolinium, yttrium, dysprosium, holmium, erbium, and ytterbium metal rods (99.9% pure) were anodized in a 0.1*N* solution of reagent grade sodium metasilicate. A current density of 0.16 A/cm^2 was employed in all reactions. The reaction cell was thermostated at 14.5° ± 0.5°C. The cell was equipped with a magnetic stirrer and a platinum cathode whose area was at least equal to the anode surface area in all experiments.

The voltages were monitored by an Electronic Measurements constant current power supply and a Hewlett-Packard 410c voltmeter and recorded on a Speedomax strip chart recorder.

The analyses of the anodic spark reaction products were performed on the insoluble material which was ejected from the anode surface during the spark reaction. X-ray diffraction patterns were obtained on all samples using a Debye-Scherrer 114.59 mm camera (Norelco) and a Norelco basic x-ray diffraction unit employing nickel filtered copper K_α radiation. The results of powder x-ray diffraction analysis on the anodic products are shown in Table I.

Diffuse reflectance spectra between 220 and 700 mμ were obtained for the anodic spark products using a Cary Model 14 Spectrophotometer equipped with a Model 1411 diffuse reflectance (ring collector) accessory.

Results

The composite voltage-time curves for the anodic reactions of six rare earth metals and yttrium in sodium silicate solution are shown in Fig. 1. The curves of Sm, Gd, Y, Dy, Ho, and Er are typical of metals which form oxide-barrier films at their interfaces, *i.e.*, Ta and Zr. Extremely large slopes occurring within the first 15-20 sec of anodization are evident and correspond to the growth of thin transparent insulating films.

Yb, which tends to be anomalous compared to the other rare earths (*e.g.*, anomalous atomic volume, melting point, and density), also exhibited significantly different voltage-time curves. The curve for Yb is somewhat typical of valve metals except that a much longer period of time was required to achieve dielec-

Table I. The anodic spark reaction products of the rare earth metals when anodized in sodium silicate solutions

tric breakdown. Electroluminescence was observed with all of the metal-electrolyte combinations investigated. The electroluminescence appeared over the entire anodic film at voltages below the spark potential and was present with spark discharges at 400V. The color of the electroluminescence varied from one rare earth metal to another but no color variations were noted with increases in voltage.

The appearance of sparking was noted with all of the rare earth metals including yttrium. The sparks were as described by Guntherschulze (13), *i.e.*, increasing in size and becoming less mobile as the voltage increased toward the maximum. The potentials at both initial and highly energetic sparking conditions and the final potentials are given in Table II. The final potentials were obtained from the constant current density experiments after 30 min of anodization. The voltage-time curve was found, in all cases, to be strongly correlated with both the initial and highly energetic sparking condition. Initial sparking and the first significant change in the slope occurred simultaneously. Highly energetic sparking was concurrent with the onset of the second major change in slope.

The very strong adherent anode coatings display striking colors characteristic of the individual rare earth cations. The colors are described in Table III. These coatings were very hard and had the appearance of fired ceramics.

The anodic spark reaction process produced coatings (Table I) the components of which are derived from the anion constituent of the electrolyte. Orthosilicate coatings were produced on samarium and gadolinium metals, and mixtures of orthosilicate and a distorted sesquioxide coating were produced on yttrium, dysprosium, holmium, erbium, and ytterbium metals. It is possible that noncrystalline or silicate glass compounds may also be present, but if so they are undetected in the x-ray diffraction analysis.

Diffuse reflectance spectra in the near u.v. to visible range were obtained for the spark reaction products. The reflectance spectra for samarium, holmium, and ytterbium products are shown in Fig. 2. In these re-

Table II. Spark initiation, high energetic, and maximum anodization potentials for anodic films on rare earth metals when anodized in $Na_2SiO_3 \cdot 9H_2O$

Metal	Initial spark potential, V	Highly energetic spark potential, V	Maximum potential, V

Metal	Color
Samarium	Light brown
Gadolinium	Light tan (off-white)
Yttrium	Pale blue-green
Dysprosium	Pale yellow
Holmium	Peach
Erbium	Dark pink (magenta)
Ytterbium	Tan

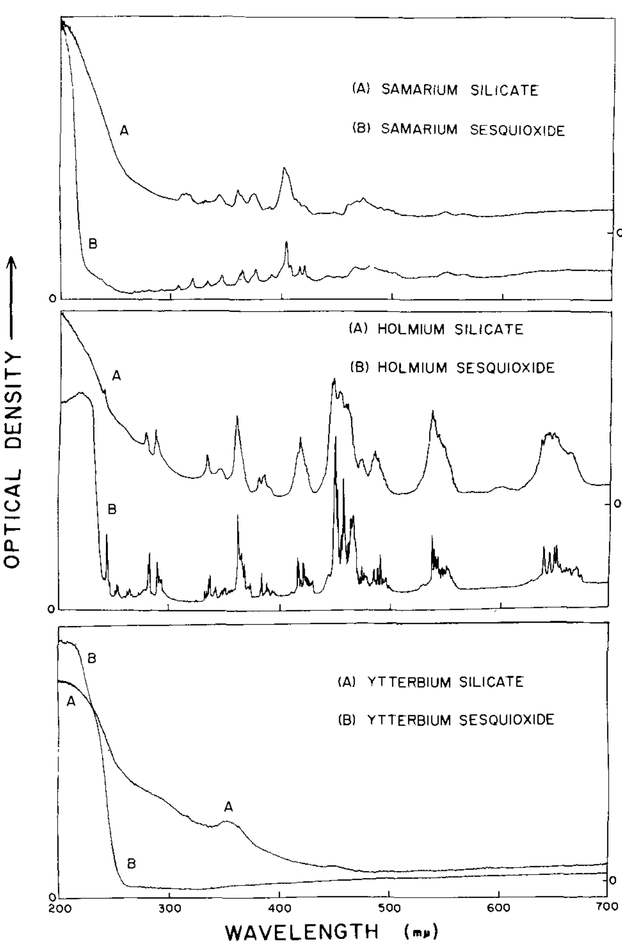

Fig. 2. Comparison of the diffuse reflectance spectra of the spark reaction products of samarium, holmium, and ytterbium metals with the reflectance spectra of the sesquioxides of these metals, respectively.

gions of the spectrum the sharp absorption peaks characteristic of the rare earth ion were observed. These peaks are intra f-f transitions of predominantly electric dipole character (14) resulting from spin-orbit interactions, and to a lesser extent, due to the extent of the crystalline field. For the samarium and gadolinium products the spectra contained slightly displaced peaks from the corresponding peaks of similar sesquioxides. In addition, in the region of strong optical absorption only a single absorption edge was observed for the orthosilicate product, indicative of a single compound. The spectra for dysprosium, holmium, and erbium products also contained slightly shifted peaks when compared to the corresponding sesquioxides. The observed spectra in the region of strong optical absorption for the orthosilicate-distorted sesquioxide products are suggestive of the existence of two absorption peaks as is found in a mechanical mixture. This datum apparently confirms the results of the x-ray diffraction study that single compounds exist in the anodic products for samarium, and that gadolinium metals and mixtures exist in the anodic products of yttrium, dysprosium, holmium, erbium, and ytterbium metals when these metals are anodized in sodium silicate solutions. In addition, many of the peak intensities of the orthosilicate and orthosilicate-distorted sesquioxide products increase and/or decrease from similar peaks found in the sesquioxides.

Discussion

It is noted in Table II that both the initial spark potential and highly energetic spark potentials decrease with a decrease in size of the rare earth metal atom. This decrease in the spark potentials from Sm to Yb is similar to the decreasing values for the standard oxidation potentials of the rare earths described by the equation (15)

$$RE(s) \rightleftarrows RE^{+3}(aq) + 3e^-$$

The high values of the standard oxidation potentials which are in accord with their electropositive character places yttrium metal between gadolinium and dysprosium metals. The values of both the initial and highly energetic spark potentials also place yttrium metal between gadolinium and dysprosium. This was also found when the rare earth metals were anodized in a sodium aluminate solution (12). The chemistries of the rare earths (16) in the +3 oxidation state are nearly identical although slight quantitative differences exist varying systematically from lanthanum through lutetium with yttrium being placed approximately between dysprosium and holmium.

X-ray diffraction analyses showed that the anode metal was chemically combined in the crystalline spark reaction products forming stable orthosilicate or orthosilicate-distorted sesquioxide rare earth compounds (Table I). This was true with all rare earth metals studied. The diffraction lines of the metal sesquioxide are shifted toward small d spacings or small lattice parameters. This is in agreement with Si (0.42Å, atom radius) incorporated into the rare earth oxide lattice. Emission spectroscopy studies confirmed the fact that a large amount of Si is present in the anodic products.

The crystalline orthosilicate spark products obtained from the anodic reactions of Sm, Gd, Y, Dy, Ho, Er, and Yb metals in 0.1*N* sodium silicate solutions are similarly produced when Sm_2O_3, Gd_2O_3, Y_2O_3, Dy_2O_3, Er_2O_3, and Yb_2O_3, respectively, and silica are carefully mixed, pressed into pellets or cylinders, and fired in an atmosphere using a program controlled furnace in excess of 1000°C (2-4, 7).

The growth mechanism which apparently accounts for the compositions of the anodic coating formed in sodium silicate solutions is similar to that reported by McNeill and Gruss (17) and by Gruss and Mackus (12) who studied anodic film growth by anion deposition in sodium aluminate solution. Gruss and Mackus showed that the rare earth metals and yttrium form a film of oxide of the anode metal prior to the deposition of the anion constituent. The metal oxide film is apparently the anodic barrier film common to anodes such as Ta and Zr which exhibit strong tendencies to form these barrier films in most electrolytes. With silicate solutions this is followed by precipitation of the anion constituent on the anode surface possibly as H_2SiO_3 (or SiO_2) which apparently dehydrates to SiO_2 at elevated temperatures. It seems likely that sparking induces the reaction between the metal oxide and the anion constituent. In addition to the reactions described, there are undoubtedly other anodic phenomena occurring simultaneously at the anode, *i.e.*, at high *p*H (*p*H of sodium silicate is 12.3) SiO_4^{-4} anions exist which can combine with the rare earth cations formed at the anode surface.

If a rare earth ion such as Yb^{+3} is added to a rare earth sesquioxide lattice, *i.e.*, Er_2O_3, no interactions take place between the erbium and ytterbium cations in the solid solutions (18). The electrostatic field generated by the Yb^{+3} ion in the erbium oxide lattice has no effect on the erbium ion. In other words, the erbium ion when in the ground state is completely independent of the ytterbium ion. However, when Si^{+4} is added to a rare earth sesquioxide lattice the tightly bound f electron levels are no longer shielded from the changes in the electrostatic field produced by the addition of Si^{+4} to the rare earth oxide lattice. This was observed in the diffuse reflectance spectra of the rare earth silicates where the f-f transition absorption peaks were shifted. In addition, there are variations in the transition probability as indicated by the increases and/or decreases in some of the peak intensities. Where mixtures occurred as with orthosilicate-distorted sesquioxide products, the extra peaks, already mentioned, are merely the absorption peaks of the two compounds some of which are superimposed upon each other, and others are shifted when compared to the rare earth oxide absorption peaks.

The Rate of Electroless Copper Deposition by Formaldehyde Reduction

James Dumesic, James A. Koutsky, and Thomas W. Chapman*

Department of Chemical Engineering, University of Wisconsin, Madison, Wisconsin 53706

ABSTRACT

In situ measurement of electroless plating rates of copper onto glass substrates has been achieved. The technique employs optical absorption measurements of the depositing copper film on rotating cylindrical glass substrates which are immersed in the plating solution. The substrates have been sensitized and activated by tin and silver solutions, respectively. Effects of stirring and composition of the plating solutions on the copper deposition rates are reported. It appears that the copper deposits at an anomalous initial rate which usually decreases with time to a steady final rate. The initial and final rates behave differently with respect to composition of the plating solution. Dissolved oxygen has a significant effect in retarding the initial rate of deposition. Structural characteristics of the film produced from such solutions are also reported.

The qualitative aspects of electroless deposition are well known (1). The patent literature is filled with reports on bath stabilization, control, and regeneration, plate improvement, prevention of stardusting, and metal ductility improvement (2-23). Fundamental studies, however, are relatively few, and mechanistic conclusions often seem to contradict one another. Of primary concern is understanding the deposition processes of the sensitizer (usually a $SnCl_2$ solution), the activator species (usually a noble metal), and the growth of the electroless metal film. Sard's work on carbon substrates indicated a time-dependent deposition of small sensitizer particles (24). Fillar concluded for glass substrates that sensitization was highly dependent on the rate of particle formation which was directly related to pH and hydrodynamic conditions of the rinsing step after removal from the sensitizing bath (25). Cohen *et al.* (26) have investigated the sensitization mechanism using Mössbauer spectroscopy. Their results indicate that stannic hydroxide is found in a colloidal state. The surface of the colloid appears to contain bound stannous ions. Feldstein and co-workers found that aged solutions of stannic chloride led to a polymeric form of β-stannic acid and that this material improves sensitizer performance (27-30). The efficiency of the sensitization step is improved giving a greater density of sites for electroless deposition.

Activation is believed to be the reduction by the tin of a heavy metal which aids the subsequent electroless deposition. The reduction appears to be at the $SnCl_2$ precipitate surface (24). Growth of the electrolessly deposited metal film appears also to be initiated at the particle surfaces.

The adhesion strength and uniformity of the electrolessly deposited film appears to be a complex function of surface roughness and the condition of both sensitization and activation steps. It has been reported that the bond between the substrate and the metal plate is mainly mechanical (31). This view is reflected in the rationale for such pretreatment as tumbling and blasting of the substrate or various chemical roughening techniques (3, 5, 7, 9, 23, 32-34).

* Electrochemical Society Active Member.
Key words: copper, formaldehyde, electroless plating.

This paper reports the results of a study of the rates of copper deposition on activated glass substrates. The system chosen for study was the formaldehyde reduction of copper with $SnCl_2$ sensitization and $AgNO_3$ activation.

The Rate of Copper Deposition During Electroless Plating

In order to understand more clearly the nature of the deposition process, as well as to establish optimum plating conditions, one would like to have quantitative information regarding the rate of metal reduction. Specifically, it would be desirable to elucidate the mechanisms of the chemical reactions in electroless plating so that the relation of plating conditions to metal film properties might be correlated on a sound theoretical basis.

There have been several studies of the rate of electroless plating, but most of these have yielded an integral or average reaction rate (1). That is, rates are reported as the total amount of metal deposited in a finite reaction time. Furthermore, in most of these experiments no special care was taken to control the mass transfer conditions so that the surface concentrations of reactants were not known. Under these circumstances it is difficult to analyze the data in terms of molecular mechanisms or even to relate a rate to the proper solution composition.

Donahue has measured differential deposition rates by monitoring the changing resistance of a metal foil or wire as the cross section was increased by electroless deposition (35). A possible problem with this approach is that it gives the rates of deposition only on solid metal surfaces but not on a developing electroless deposit. The latter situation is of more basic interest than the former because the initial reaction on the activated substrate must be critical in determining adhesion and other film properties.

We have sought to develop an experimental method for measuring the kinetics of electroless deposition that avoids the difficulties mentioned above. In particular, we wanted a method for measuring differential electroless deposition rates on activated substrates under known mass transfer conditions.

Morphological studies of the deposited films were also made in order to understand more fully the basic mechanisms with regard to copper deposition. Specifically, it was desired to see if the morphology of the film was related to the rate data. Also, it was desired to compare the morphology obtained qualitatively with results of other authors (2, 27-30, 36, 37).

Experimental Method and Procedure

A simple geometry for which mass transfer rates are uniform and have been quantitatively characterized is the rotating cylinder. This system is a suitable one for studying heterogeneous processes. The rotation of the inner cylinder of a concentric pair provides efficient stirring for species transport to the cylindrical surfaces. Even for processes that are partially mass-transfer limited, the correlations developed by Eisenberg *et al.* (38) make it possible to compute the surface concentrations from the bulk concentrations if fluxes are known.

A rotating cylinder apparatus, consisting of a glass Beckman colorimeter tube (OD= 24.23 mm) inserted into an 80 mliter beaker, was assembled. The colorimeter tube was mounted on the shaft of a variable speed stirring motor (0-1600 rpm) and aligned coaxially with the beaker. A sketch of the apparatus appears in Fig. 1.

The outer surface of the colorimeter tube was sensitized and activated in the usual way. The active surface was prepared by washing the tube in concentrated nitric acid, rinsing in distilled water, rotating at 200 rpm for 10 sec in the sensitizer, rotating at 200 rpm for 60 sec in tap water, rotating at 200 rpm for 30 sec in activator, and rotating at 200 rpm for 10 sec in distilled water. The rate of withdrawal from the sensitizer was 1 in./sec. Tap water was used in the second rinse because it appears to give more uniform sensitization over the surface than is the case with distilled water or an alkaline rinse (25).

The tube was placed in the beaker containing the copper-formaldehyde plating solution so that copper deposition occurred on the activated surface. In subsequent tests it was established that an immersion in a formaldehyde solution prior to the plating solution gave some interesting results. It was found that the amount of copper deposited from the plating solution could be monitored continuously *in situ* by visible spectroscopy. Light of wavelength 630 mμ from a helium-neon gas laser was passed through the active surfaces of the inner tube to a 2 mm diameter phototransistor. The transmittance of the copper film, measured as the voltage output of the photocell, was correlated with copper deposition, in micrograms Cu/square centimeter, by dissolving the copper from various samples with nitric acid and determining the mass of copper by atomic absorption spectroscopy. The precision of the calibration was about 5% over the thickness range of interest.

Filling the inner tube with distilled water rather than air reduced the refraction of the light beam and decreased the noise to signal ratio. The illumination of the photocell could be adjusted to a suitable (linear response) range by the use of polarizing filters in the beam.

According to the established correlation between optical transmittance and copper coverage, it was possible to convert the measured photocell signals directly to plots of copper coverage *vs.* time. In this way it was possible to monitor the progress of the reaction from zero time up to a coverage of 150 μg Cu/cm^2 or about 1600Å in thickness, at which point the film becomes too opaque to permit further measurements.

A number of experiments were done at various values of rotation speed (0-1100 rpm), copper concentration (0.003-0.03M), formaldehyde concentration (0.06-0.38M), and *p*H (0.0055-0.0175M OH^-). The EDTA/Cu^{+2} ratio was held constant at 1.05, and the temperature was 21°C. Oxygen was excluded from the plating bath by continuously sweeping nitrogen across the plating bath surface.

Ordinary sodium silicate glass was used in this investigation. Qualitative microscopic studies were made on glass slides whereas the rate studies used cylindrical glass tubes. Substrate surfaces were first washed in "Alconox" solution and subsequently immersed in concentrated nitric acid for 10 sec. They were then thoroughly rinsed with distilled water.

Table I indicates the solution recipes used for most of the investigation. Solutions were made with distilled water. The solutions were always freshly prepared and kept in brown glass containers. The long term instability of the $AgNO_3$ solution is well known and care must be taken in its use.

For the microscopic studies cleaned glass slide substrates were dipped into the sensitizing solution and kept immersed for various times. They were then removed manually at an approximate rate of 1 in./sec. The surfaces were rinsed by immersion in tap water and withdrawn again at nearly 1 in./sec and placed into the activation bath for various times. They were removed at the same rate, rinsed in distilled water, and immersed into the electroless copper bath for various times.

Bright field reflectance and transmission optical microscopy were used to characterize the deposits and the glass substrate surfaces. The deposits were also characterized by electron diffraction and bright field electron microscopy. In order to do this, we removed the deposits from the substrate by first evaporating a thin supporting carbon film onto the specimens at 10^{-4} Torr. Polyacrylic acid solution was placed on the carbon film and after drying, the hardened polyacrylic acid was mechanically removed from the substrate. The copper deposits were removed by this procedure because they more readily adhered to the carbon than to the glass substrate. In the case of thicker deposits the supporting carbon film was not necessary. The

polyacrylic acid was readily dissolved by water, and by flotation the specimen film was picked up on electron microscope grids.

Experimental Results

Some typical experimental results of the rate studies are presented in Fig. 2, 3, and 4. Precision of data is well within 10% in measurement of copper coverage. Figure 2 shows the growth of the copper film with time in a standard plating bath at various stirring speeds. Figure 3 gives the growth curves with good stirring at two different copper levels. Figure 4 shows the effect of formaldehyde concentration on film growth. Note that 10 μg Cu/cm² corresponds to an average copper film thickness of 112Å, based on a solid film with the bulk density of metallic copper.

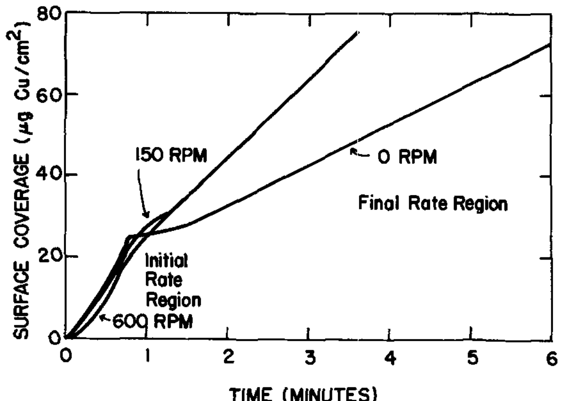

Fig. 2. Surface coverage as a function of time at three different stirring speeds. Bath composition was 0.186M HCHO, 0.02M $CuSO_4$, (NaOH) = 0.005M.

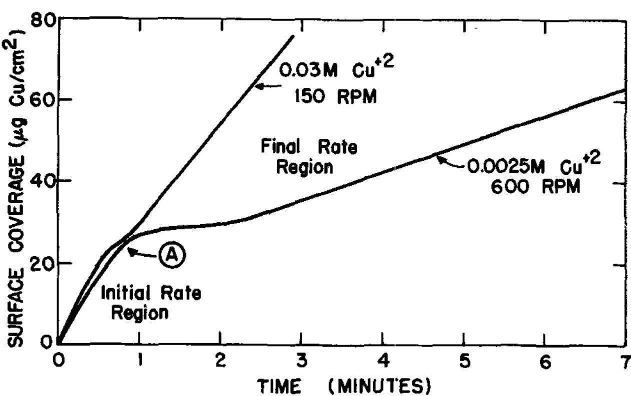

Fig. 3. Surface coverage as a function of time at two different copper levels. (HCHO) = 0.186M; (NaOH) = 0.005M.

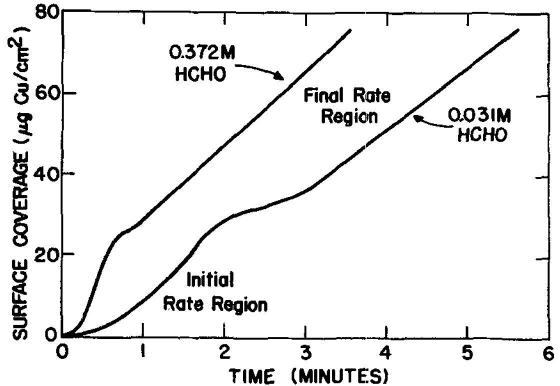

Fig. 4. Surface coverage as a function of time at two different formaldehyde levels at 600 rpm. ($CuSO_4$) = 0.02M; (NaOH) = 0.005M.

Perhaps the most striking feature of the film growth curves is the apparent existence of two distinct growth regions. At surface coverages above 30 μg Cu/cm² one finds a constant rate of film growth, which we refer to as the final rate. At short times, or at coverages less than 25 μg Cu/cm², the rate of copper deposition is generally different from the steady final rate. In most cases it appears that the deposition rate is approximately constant at coverages from zero to about 25 μg Cu/cm² and that this initial rate is usually larger than the subsequent final rate. At coverages around 25 μg Cu/cm² there is a distinct break in the film growth curves where the deposition rate changes abruptly from the initial rate to the final rate. In cases where the initial rate is considerably higher than the final rate, there is actually an arrest in the growth curve at the transition point (point A in Fig. 3).

In order to represent the results in a relatively concise form, we have calculated the slopes of the two portions of the growth curves to report initial and final rates in micrograms Cu/square centimeter-minute for each experimental condition. The initial rates are presented in Fig. 5, 6, and 7 as functions of copper, formaldehyde, and hydroxide concentrations, respectively. Final rates are given as functions of the same variables in Fig. 8, 9, and 10.

Effect of stirring.—The primary reason for choosing the rotating cylinder geometry for these experiments was to make possible the estimation of mass transfer rates and surface concentrations. This arrangement not

only provides uniform stirring but also lends itself to quantitative investigation according to the correlation of Eisenberg *et al.* (38). The mass transfer correlation may be expressed as

$$Nu = 0.0791\, Re^{0.7} Sc^{0.356} \qquad [1]$$

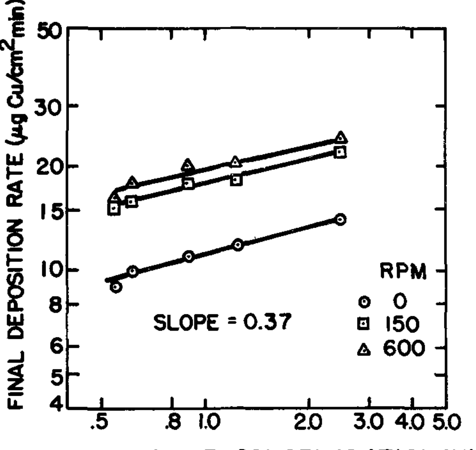

Fig. 10. Final deposition rate as a function of hydroxide concentration at various stirring speeds. ($CuSO_4$) = 0.02M; (HCHO) = 0.186M.

where

$$Nu \equiv \frac{k_c d}{D}$$

$$Re \equiv \frac{d^2 \Omega}{\nu}$$

$$Sc \equiv \nu/D$$

An estimate of the mass transfer coefficient k_c from Eq. [1] allows computation of the surface concentrations of reactants according to

$$\Delta c_i = N_i/k_c \qquad [2]$$

where Δc_i is the difference between the bulk and surface concentrations and N_i is the flux of species i at the surface. Assuming $(Sc)_{Cu^{+2}} = 3000$, $D_{Cu^{+2}} = 3 \times 10^{-6}$ cm²/sec, and $\nu = 10^{-2}$ cm²/sec, we can estimate the copper concentration difference as a function of deposition rate and stirring speed.[1] The results are given in Table II where Δc_i for copper, $\Delta c_{Cu^{+2}}$, is given for various deposition rates and stirring speeds. These calculations indicate that mass transfer limitations should be significant only at high deposition rates, low stirring speeds, and low copper concentrations. According to Fig. 5 and 8, this effect was important at copper concentrations below 0.03M Cu^{+2} if the stirring rate was less than 1100 rpm for the high initial rates and below 0.02M Cu^{+2} at less than 600 rpm for the final rate.

For example, for the experimental point A in Fig. 5 where the observed deposition rate was 28 μg Cu/cm²-min, Table II indicates that the surface concentration of Cu^{+2} was about 3×10^{-3} moles/liter rather than the bulk value of 5×10^{-3} moles/liter. On the other hand, at point B, where the observed rate was 42 μg Cu/cm²-min, Table II indicates that the surface concen-

[1] The Reynolds numbers attained in this study (10^6 at 150 rpm) were somewhat higher than those covered in Eisenberg's experiments. Equation [1] probably gives a conservative estimate of k_c at these higher Reynolds numbers.

Table II. Effect of stirring speed on copper concentration differences between bulk and surface values

$\Delta c_{Cu^{+2}}$ (moles/liter)

Deposition rate (μg Cu/cm²-min)	Ω = 150 rpm ($k_c = 4 \times 10^{-3}$ cm/sec)	Ω = 600 rpm ($k_c = 1 \times 10^{-2}$ cm/sec)	Ω = 1100 rpm ($k_c = 1.6 \cdot 10^{-2}$ cm/sec)
5	0.3×10^{-3}	0.1×10^{-3}	0.08×10^{-3}
10	0.6×10^{-3}	0.3×10^{-3}	0.2×10^{-3}
20	1.3×10^{-3}	0.5×10^{-3}	0.3×10^{-3}
30	2.0×10^{-3}	0.8×10^{-3}	0.5×10^{-3}
40	2.6×10^{-3}	1.0×10^{-3}	0.7×10^{-3}
100	6.6×10^{-3}	2.6×10^{-3}	1.6×10^{-3}

tration of Cu^{+2} was about 9×10^{-3} moles/liter, which was relatively much closer to the bulk value of 10^{-2} moles/liter. Therefore, under conditions of point A, the observed rate was probably controlled at least partly by mass transfer rather than entirely by reaction kinetics; at point B the transport effects are less important.

Similar calculations could be made for formaldehyde and hydroxide. These species, however, should not be mass-transfer limited in the range of concentrations studied because of the large excess of formaldehyde and the high mobility of hydroxide.

Effect of copper concentration.—Aside from the mass transfer limitations observed at low copper concentrations and slow stirring, the initial rate of deposition (Fig. 5) appears to be independent of copper concentration. On the other hand, the final rate (Fig. 8) is dependent on copper level. There is no clear asymptotic behavior with respect to stirring in Fig. 8, but at 1100 rpm the order with respect to copper appears to be 0.37.

Effect of formaldehyde concentration.—In all experiments a large excess of formaldehyde was present. It is interesting to observe from Fig. 6 that the initial rate is first order in formaldehyde with very high rates being attainable. On the other hand the final rates shown in Fig. 9 are nearly independent of formaldehyde level.

Effect of hydroxide concentration.—As with the formaldehyde the hydroxide has a strong effect on the initial rate, the order of the reaction appearing to be unity (see Fig. 7). According to Fig. 10, the pH has less of an effect on the final rate since the order with respect to (OH^-) is 0.37.

Qualitative Observations Related to Deposition Rates

In addition to the quantitative rate measurements described above there were a number of interesting qualitative observations made in the course of this study that may be of some help in elucidating the mechanism of this complex process.

Effect of dissolved oxygen.—In early experiments no effort was made to exclude oxygen from the plating bath. It was found under these conditions that an initial induction period of negligible deposition rate was encountered after which plating proceeded at a constant rate. The length of the induction period was a function of stirring speed, ranging from 2 min with no stirring to 16 min at 600 rpm. The plating bath appeared to become more effective with repeated use, the induction period getting shorter, but bubbling of oxygen between platings led to constant induction times which depended only on stirring speed.

Subsequent tests indicated that the effect of dissolved oxygen was to form an oxide layer on the catalytic surface. Only after formaldehyde reduces the oxide layer can plating occur. For example, if plating is interrupted during the final rate period and the specimen is exposed temporarily to a water bath containing dissolved oxygen, plating can be resumed only after a finite induction period of several minutes in the plating bath. A similar treatment in the absence of oxygen yields no delay in the resumption of plating.

Further evidence for surface oxidation is obtained from optical measurements. When a freshly formed copper surface is exposed to oxygen, the optical absorbance (at 630 $m\mu$) decreases slowly. Quantitative measurements by dissolution and atomic absorption analysis show that no copper is being lost from the surface. Instead, a changing surface causes decreased reflectivity. Exposure to the formaldehyde in the plating bath increases the absorbance to its original value very rapidly.

Effect of formaldehyde pretreatment of the activated surface.—To avoid complications from oxygen in the kinetic measurements, we excluded oxygen from the plating bath, and the activated (Ag) substrate was exposed to a formaldehyde solution for 1-2 min. This latter procedure prevented a delay in the copper plating reaction, possibly reducing any silver.[2] This procedure led to the deposition kinetics described above. If an activated substrate which has been left in the formaldehyde solution for 5 min or more is placed in the plating solution, neither an initial rate period nor an induction time is observed. That is, the final steady deposition rate is attained over the entire range of measurement.

This phenomenon can be related to the physical appearance of the substrate. The freshly activated substrate has a brown color and when it is placed in the formaldehyde bath, it turns yellow immediately. After about 5 min in the pretreatment solution, the substrate slowly turns to a brown color again. It is only when the substrate is in the yellow state that a high initial plating rate without an induction time upon placement in the electroless copper solution is observed. When the substrate is brown in color a constant final rate is observed with or without an induction time.

Effect of activation conditions on plating rates.—In the rate measurements described above, standardized conditions (solution concentrations indicated in Table I) were used in the sensitization and activation steps. Variation of the tin concentration in the sensitizing bath or of the rinsing conditions can alter the amount of tin and hence silver on the activated surface. Tests were made with a plating bath that yielded an initial rate of 30 and a final rate of 13 μg Cu/cm^2-min under standard conditions. When less tin and silver were placed on the substrate, an initial rate of 17 μg Cu/cm^2-min was observed. With heavier activation an initial rate of 54 μg Cu/cm^2-min occurred. In all cases the final rate was approximately the same.

Observations at the point of rate change—Near the point at which the deposition rate undergoes a discontinuous change it was observed that gas evolution begins. At about the same time the copper film first becomes shiny in appearance.

The question of whether the onset of gas evolution is a determining factor in the rate change was investigated by measuring the copper film growth with the plating bath under a positive pressure of 13 psig. Pressurization prevented bubble formation, but the deposition rates were unchanged, and the rate transition was not affected. It should be mentioned, however, that fine cracks developed in the copper deposit when the bath was depressurized. This could be due to gas, probably hydrogen, being nucleated rapidly within the film as the pressure is released (39). The large stresses produced by the formation of the expanding gas could rupture the film.

Microscopic observations.—Electron microscopy gave interesting qualitative results reminiscent of previous investigators (24,27-30,36). The sensitization and activation steps left small particulate deposits which were distributed over the surface in varying degrees of surface density as shown in Fig. 11.

It appears that the colloidal tin particles which were initially on the substrates became enveloped with silver deposits. It appeared that prolonged immersion in the sensitizing solution had little effect on the resulting density of particles after activation. Also varying times of immersion in the activation solution from 10 sec to 5 min did not affect the density and size of particles. It is interesting to note that a large fraction of even the smallest particles are bridged in some manner (see arrows in Fig. 11), which is similar behavior to that observed in vacuum deposited metals during the initial nucleation and growth steps (40,41).

Subsequent electroless deposition of copper to a coverage of about 80 μg/cm^2 produced a rather open network structure (Fig. 12). A diffraction study (Fig. 13) of the copper deposit reveals random orientation which was also reported by Sard (24). Note the bridged

[2] There was not sufficient HCHO carried over to cause any significant copper reduction.

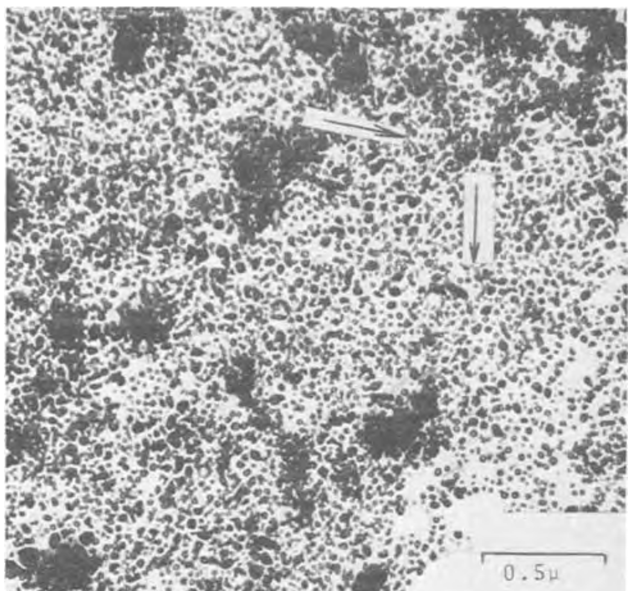

Fig. 11. Electron micrograph of a detachment replica of a silver-tin activated surface. Silver-tin particles are characteristically bridged (see arrows). Particle density corresponds to about 10^{11}/cm². Magnification bar is 0.5μ.

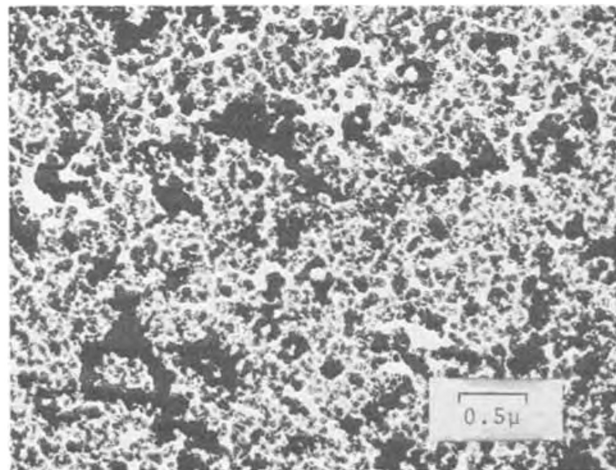

Fig. 12. A copper film coverage corresponding to 80 μg Cu/cm². Note film is highly porous at this stage. The copper forms an interconnecting network of crystals. Magnification bar is 0.5μ.

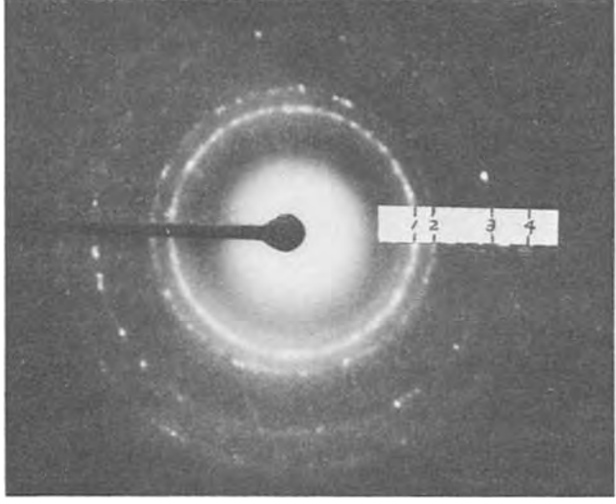

Fig. 13. A diffraction pattern of the copper film shown in Fig. 12. Pattern is of polycrystalline copper with the strong (111) and (200) reflections (lines 1 and 2, respectively) and the moderately strong (220) and (311) reflections (lines 3 and 4, respectively). Note that there is no preferential orientation.

structures which exist in the thicker copper film with no indication of specific crystallographic branching. The growth of the film appears to be a three-dimensional type with impingement of crystals forming bridges.

The copper film appears to grow in a random fashion with no epitaxial or texture orientation indicating that the growth is not as specific as for metal deposition from the vapor onto solid substrates or for certain metals, notably nickel and cobalt, which are deposited electrolessly from solution in a textured fashion (36, 37, 42). It appears that the initial and final growth rates of copper cannot be explained in terms of a textured growth which predominates in the final rate step. Note the high degree of porosity which indicates that calculation of thickness from mass based on a solid film would give values considerably lower than actual values.

Discussion

From this work it appears that a constant deposition rate occurs only after a contiguous film of copper has been formed. Initially a different mechanism may operate which manifests itself as differences in both rate and rate dependence on solution composition. Specifically, the final rate appears to be independent of formaldehyde concentration whereas the initial rate is independent of copper concentration but depends strongly on formaldehyde concentration.

One might question whether the shape of the film growth curves is just an artifact of the optical measurements. Our direct measurements of the absorbance *vs.* coverage calibration which included points from 3 to 70 μg/cm² establish a clear, unambiguous observation. It is possible that minor errors in coverage measurements could arise from structural differences related to bath compositions. Therefore an experimental calibration should be determined for any particular plating system.

Microscopic investigation led us to suspect that the observed change from the initial to the final rate could be related to coverage of the catalytic silver-tin particles by the growing copper film. From Fig. 11 it is possible to estimate the silver-tin particle surface area within an order of magnitude. There are about 10^{11} particles/cm² and the average size of a particle is about 200Å. Therefore, a total particle area of about 1 cm²/cm² of nominal area of substrate is estimated from the micrographs. On the basis of monolayer coverage of copper atoms on the silver-tin particles this area corresponds to about 10^{15} Cu atoms/cm² of substrate at total coverage. The value of surface coverage of 25 μg/cm² corresponds to about 10^{17} Cu atoms/cm² of substrate. This calculation indicates that the change in the deposition mechanism which was observed in the rate studies occurs when a copper film of about 10^2 atoms in thickness has been established. This is probably the point at which the silver particles are in fact completely covered with copper and at which the surface film becomes a true copper surface. The specific chemical mechanisms which occur in the two regions are not yet clear and require further study. Paunovic's work (43) shows that the electroless reduction of copper by formaldehyde on a copper surface is a mixed potential process, which should occur at a constant rate as long as the solution composition is constant. In his study he used a plating bath containing 0.1M $CuSO_4$, 0.05M HCHO, 0.175M EDTA, and NaOH to make the pH 12.5. The rate he measured, both electrochemically and directly, was 1.8×10^{-3} A/cm² or 33 μg Cu/min-cm². This rate agrees well with the final rates we have observed (cf. Fig. 8). Unfortunately, Paunovic did not vary his solution composition so that more extensive comparison is not possible. It is interesting to observe from his individual electrode polarization studies that

the reduction of copper is more reversible than the oxidation of formaldehyde. The shapes of the polarization curves [Fig. 8 in Ref. (43)] may explain why the final rate is apparently independent of formaldehyde concentration. It would be interesting to see how these polarization curves do in fact depend on reagent concentrations.

Whether the initial rate of deposition results from a mixed-potential process is not clear at this time. If it does, our observations indicate that the electrocatalysis of the two half-reactions must be quite different on the silver-tin particles than on a fresh copper surface. On the other hand, a completely different chemical mechanism may be operating in this region.

The most crucial step of the electroless deposition process with respect to adhesion and probably with respect to film structure and strength as well, must be the initial growth of the metallic film when metal-substrate bonds are being formed. The unusual rate phenomena observed in this work should be studied more thoroughly to understand the basic mechanisms of reduction, deposition, and film growth. In particular, it would be desirable to make rate measurements of the type described here for other activating systems such as palladium chloride and for various substrates and reducing agents of practical interest.

For plating baths of the type we have studied, the kinetics of deposition are relatively fast. In any commercial plating process which uses these solutions and does not make special provisions for efficient stirring, however, the average deposition rate and metal coverage will probably be controlled by diffusion and mass transfer.

Conclusions

An experimental technique has been developed for the direct measurement of electroless plating rates. The advantages of this method are that it can reveal the initial growth of the metallic film on an activated substrate and it provides uniform and well-characterized stirring.

The deposition of copper from a formaldehyde-EDTA plating solution onto a tin-silver-activated glass substrate exhibits a dramatic change in mechanism when the copper film reaches an average coverage of about 25 $\mu g/cm^2$.

The initial rate period is independent of copper concentration but varies with formaldehyde concentration. The converse is true during the final rate. All rates depend on *p*H. Oxygen in the system can have a severe inhibiting effect on the deposition rate. The chemistry of this process is very complex and not yet understood very well. It seems likely, however, that the observed phenomena are caused by changes in the nature of the catalytic surface.

Microscopic observations have shown that the metallic films start from very small (200A), highly dispersed, and partially bridged silver-tin particles and grow into a fairly rough and porous, polycrystalline copper film. No texturization or oriented overgrowth of the electroless copper film was observed.

ABSTRACT

The electrode reduction mechanism of (E)-phenyl-2-nitro-1-propene (PNP) in N,N-dimethylformamide (DMF) has been studied by polarographic, cyclic voltammetric, and rotating disk techniques. The compound is reduced in two polarographic steps in DMF and DMF-water solutions. Data taken at potentials of the first polarographic plateau suggest that the compound is reduced to a product via a mechanism involving coupling of the ion radicals of the precursor. The rate of the coupling reaction has been studied as a function of concentration of the PNP and water content of the solvent. Oscilloscopic recording of rapid cyclic voltammetry experiments demonstrate that the second polarographic step represents a two-electron reduction of the parent compound, PNP.

A wealth of electrochemical and electron spin resonance data demonstrate the great stability of the anion π-radicals of a large variety of aromatic nitro compounds in aprotic solvents such as acetonitrile, dimethylsulfoxide, and N,N-dimethylformamide (DMF) (1, 2). Nitro group elimination (3) and aromatic ring-halide elimination (4, 5) represent some decay pathways of certain species of this general type. Hoffman *et al.* (6) found that the anion radicals of various electrochemically generated tert-alkyl nitro compounds are intrinsically unstable, cleaving to nitrite ion and corresponding alkyl free radicals in glyme solvent. The small amount of data presented relative to nitroalkene π-radicals, intermediate to the above examples in extent of resonance stabilization, is inconclusive as to the general behavior of such species in aprotic media (7-9). As part of a systematic study into this matter, the compound 1-phenyl-2-nitro-1-propene (PNP) [I] was synthesized and its electrochemical behavior in DMF and DMF-water solutions observed. Techniques employed in the study include conventional d-c polarography, rotating disk, and cyclic voltammetry.

$$C_6H_5(H)C=C(NO_2)CH_3 \quad [I]$$

Results

Polarography.—The compound PNP features two polarographic waves in DMF containing 0.1M tetra-N-propylammonium perchlorate (TPAP) (Fig. 1). The waves exhibit half-wave potentials ($E_{1/2}$) of -0.99 and -1.68V *vs.* saturated calomel electrode (SCE) and are diffusion controlled. Complete polarographic data are presented in Table I. The diffusion current constant (I_d) of the more negative potential plateau in dry DMF[1] is much less than that for a one-electron

transfer process involving materials of comparable diffusion coefficients. Addition of the proton donors water and hydroquinone (HQ) to the test solution had no effect on the diffusion current or shape of the first plateau (Fig. 1). The $E_{1/2}$ of the wave is, however, shifted towards less negative potentials by large ratios of proton donor to electroactive compound. The characteristics of the second polarographic wave proved to be sensitive to added proton donors (Table I, Fig. 1). The diffusion current is increased to a limiting value, a factor of ten greater than that of the wave in pure solvent, upon addition of large quantities of water or HQ. This change is accompanied by a significant positive shift in the $E_{1/2}$ of the wave (Table I). Consistent with previously published data, HQ proved to be much more effective than water as a donor in DMF (10). Similar polarographic behavior is reported by Baizer and co-workers for several 1,2-diactivated olefins (11, 12).

Cyclic voltammetry.—Typical cyclic voltammograms of PNP recorded at a planar platinum disk electrode (ppde) at varying concentrations in DMF are shown in Fig. 2. Data for voltammetric studies at concentrations of 0.1 and 1 mM PNP are presented in Table II.

Voltage excursion and reversal 120 mV cathodic of the first plateau revealed cyclic voltammetric waves with very little anodic current in solutions containing 1 and 10 mM PNP in dry DMF (Fig. 2). The potential sweep rate (v) ranged to a maximum of 12.48 V/min in experiments conducted on 1 mM solutions (Fig. 2). In a series of experiments conducted at 1 mM PNP the cathodic peak potential $[(Ep)c]$ shows negative shifts of 30 mV per tenfold increase in v. This cathodic shift is accompanied by a 9% decrease in the current function, $(ip)c/v^{1/2}$ (Table II).

Similar voltammetric experiments in solutions containing 0.1 mM PNP in dry DMF produced cyclic waves possessing significant anodic currents (Fig. 2). The $(Ep)c$ and current function of the recorded voltammograms were essentially constant with respect to a varying potential sweep rate (Table II). The cathodic to anodic peak separation $[(Ep)c-(Ep)a]$ is 60 mV at all values of v.

Chronoamperometric experiments were conducted in conjunction with the cyclic voltammetric experiments at the same ppde and under identical conditions of concentration of PNP and supporting electrolyte at potentials corresponding to the first polarographic plateau. Diffusion current plots, $it^{1/2}/C$ *vs.* t, of data taken from current-time decay curves (0.3-1.4 sec) of the reduction of PNP at 0.1 and 1.0 mM in dry DMF correspond closely to similar plots for the known one-

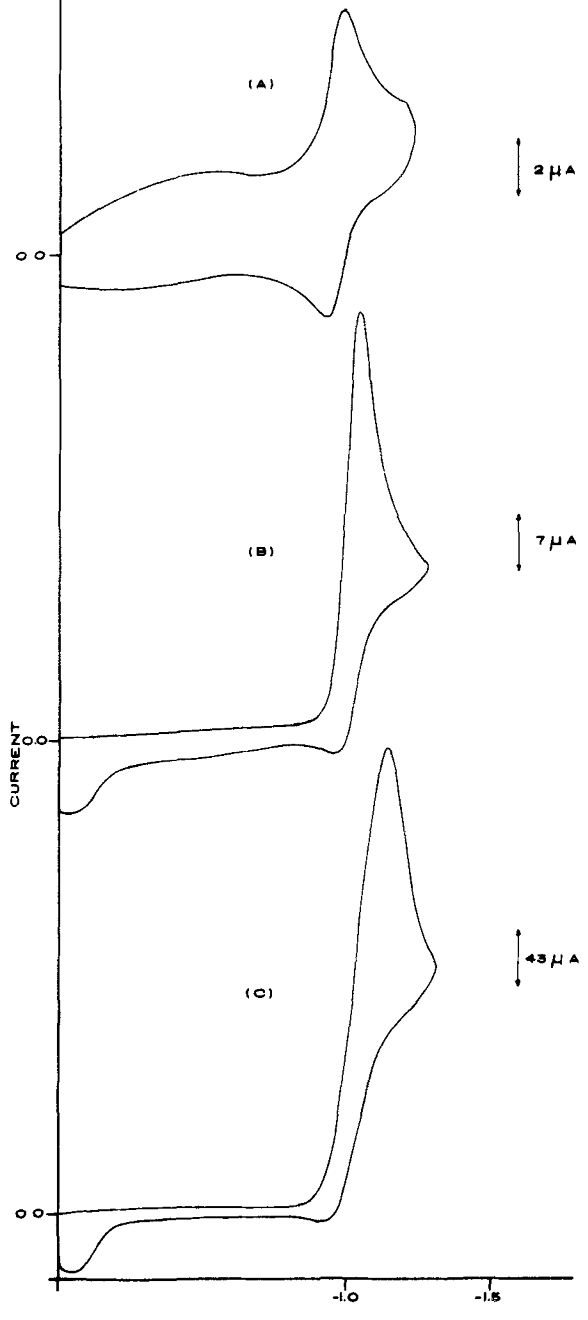

Fig. 2. Single sweep cyclic voltammograms taken at a ppde at potentials of first polarographic wave in DMF containing 0.1M TPAP and (a) 0.1 mM PNP recorded at 12.48 V/min. (b) 1 mM PNP recorded at 12.48 V/min. (c) 10 mM PNP recorded at 9.65 V/min. E_λ is 120 mV.

electron reduction of nitrobenzene under the same experimental conditions.

The influence of water on the process occurring at potentials of the first polarographic wave was studied with cyclic voltammetry at a ppde (Table II). Controlled quantities of water were added to solutions 0.1 and 1.0 mM in PNP and cyclic voltammograms were recorded. Addition of water to solutions 0.1 mM in PNP had a slight but discernible influence on the $(Ep)c$, current function, and anodic to cathodic current ratio $[(ip)a/(ip)c]$ of the cyclic curves (Table II). At a proton donor to PNP ratio of 2.4×10^4 moles to one, a 10% decrease in the current function and a 20 mV negative shift in the cathodic wave is noted to accompany a tenfold increase in v. Only an immeasurably small anodic current is observed on the reverse sweep

segment of cyclic experiments conducted at a v of less than 6.24 V/min (Table II, Fig. 3). Only a positive shift in $(Ep)c$ relative to the same values in dry solvent is noted in water addition experiments conducted at 1 mM PNP (Table II).

The dependence of cyclic peak characteristics on the concentration of PNP in dry DMF is significant to the interpretation of the electrochemical process responsible for the first diffusion plateau. In general, the cyclic voltammetric data taken at 0.1 mM PNP suggests the reversible, one-electron formation of an intermediate followed by a chemical reaction slow relative to the voltage excursion rate (13, 14). At higher concentrations of PNP (1.0 and 10.0 mM) the behavior suggests a rapid chemical reaction coupled to an initial electron-transfer process. The influence of the precursor concentration on the rate of the coupled homogeneous chemical reaction and the chronoamperometric data is consistent with second order kinetics involving dimerization of intermediate radicals of the precursor (hydrodimerization). Nicholson *et al.* (15) and Saveant *et al.* (16) have presented the theory of cyclic voltammetry for an electrochemically initiated homogeneous dimerization reaction with diagnostic criteria analogous to those developed for other electrochemical reaction mechanisms (13, 14). The cyclic voltammetric data in Table II for PNP are in general good agreement with the dimerization criteria.

Oscilloscopic recording of current response to rapid voltage excursion and reversal past the diffusion plateau of the diminished second wave, revealed data definitive of the electrochemical process responsible for the wave. Cyclic voltammograms recorded at a ppde in 1 mM PNP at 24 and 240 V/min (Fig. 4) show that the cathodic current of the second wave grows in intensity with increased sweep rate to a limiting value equal to that of the first wave, a one-electron process.

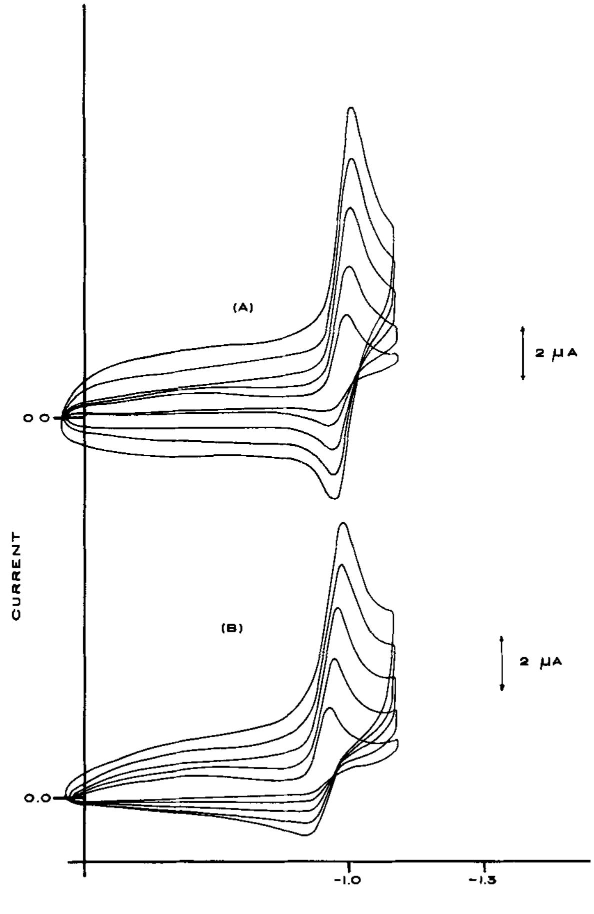

Fig. 3. Single sweep cyclic voltammograms of PNP at 0.1 mM in DMF recorded at a ppde at potentials of first polarographic wave. (a) Solution contained no added water and voltammograms recorded at 12.48, 9.38, 6.24, 3.12, and 1.25 V/min. (b) Solution contained 2.4M H_2O and voltammograms recorded at 12.48, 9.38, 6.24, 3.12, and 1.25 V/min. E_λ is 120 mV.

These data and the enhanced anodic current of the first wave recorded under the same conditions are consistent with an electrochemical reduction process involving an initial one-electron transfer to the parent

compound at the first wave and a subsequent one-electron addition to the ion radical at the second wave. Chemical reactions following the first transfer are not apparent at very rapid potential excursion rates. The sensitivity of the second wave to small quantities of proton donors (Fig. 1) is consistent with a rapid protonation of an initially produced dianion of PNP. In summary the cyclic voltammetric data are consistent with a general reduction scheme of the type

Rotating ring-disk electrode studies.—Confirmation of hydrodimerization as the major reduction pathway of PNP in DMF at its first polarographic step and a determination of the rate constant for the coupling reaction was sought with rotating ring-disk electrode (RRDE) techniques. Rotating disk electrode voltammograms taken at scan rates of 20-25 mV/sec of 1 mM solutions of PNP in DMF show a reduction wave with $E_{1/2} = -0.49$V *vs.* Ag reference electrode. Values of the Levich constant, $i_{d,l}/C_R\omega^{1/2}$ (where $i_{d,l}$ is the disk current on the mass transfer limiting plateau) given in Table III, show no dependence on rotation rate (ω). The diffusion coefficient for PNP, D, evaluated from the Levich equation

$$i_{d,l} = 0.62nFAD^{2/3}\nu^{-1/6}C_R\omega^{1/2}$$

(where $n = 1$, and ν, the kinematic viscosity, is 0.00849 cm^2/sec for DMF) was found to be 2.4×10^{-5} cm^2/sec. Coulometry carried out at -1.10V *vs.* Ag-R.E. shows n_{app} values of 0.97 and 0.98 for 2.78 and 4.79 mM solutions, respectively. The independence of the Levich constant with rotation rate and the above coulometry data suggest the absence of polymerization which often accompanies hydrodimerization reactions in aprotic solvents (*e.g.*, for diethyl fumarate and fumaronitrile) (14, 20).

Rotating ring-disk electrode experiments were performed to gather additional data relative to the mechanistic characteristics of the reduction process. A typical RRDE voltammogram of this system is shown in Fig. 5. Collection efficiency (N_K) (where $N_K = i_r/i_d$) measurements as a function of disk current (*CONI*) (where $CONI = i_d/i_{d,l}$) were made at various rotation rates (ω) and concentrations. Representative data of these experiments are presented in Table IV. The trend of increasing N_K with decreasing *CONI* has been shown to be indicative of a hydrodimerization reaction proceeding by a coupling of radical anions rather than attack of the parent compound by radical anions (17, 20). The experimental points were fit by simulating such a mechanism for different values of the simulation rate constant parameter

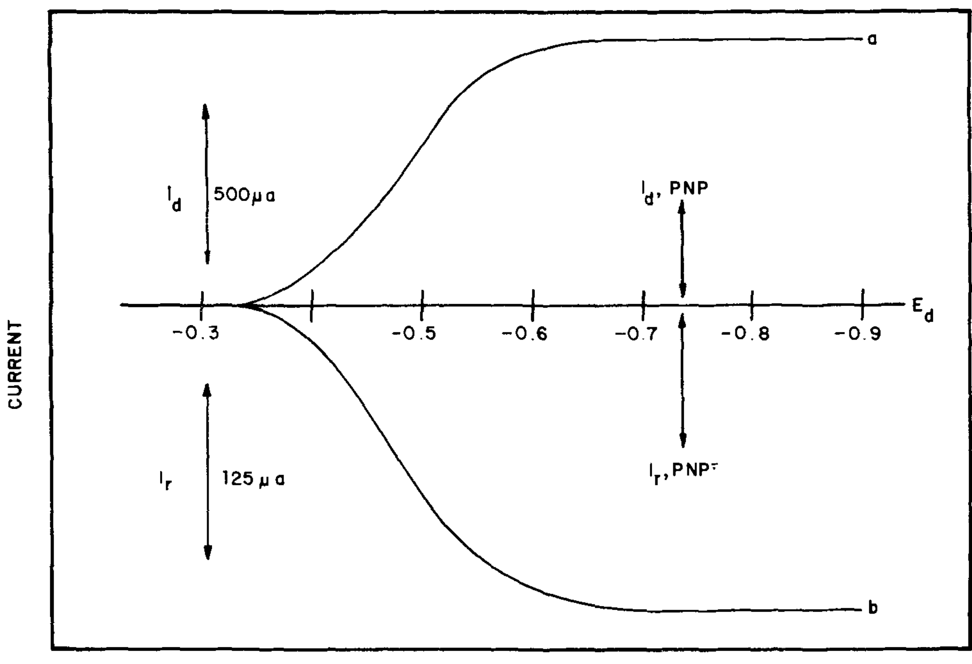

Fig. 5. RRDE voltammograms of PNP at 2.89 mM in DMF determined at a scan rate of 30 mV/sec and a rotation rate of 201 rad/sec. (a) i_d vs. E_d (b) i_r vs. E_d, $E_r = -0.10$V vs. Ag R.E.

$XKTC = (0.51)^{-2/3}\nu^{1/3}D^{-1/3}D\omega^{-1}k_2$. The lines in Fig. 6 correspond to XKTC values of 2.2 for line b and 0.9 for line a. These lines correspond to the following experimental conditions: line a, concentration of PNP equal to 2.78*M* at a rotation rate of 305 radians/sec; line b, concentration of PNP equal to 4.79 mM at a rotation rate of 201 radians/sec. Values of k_2, determined

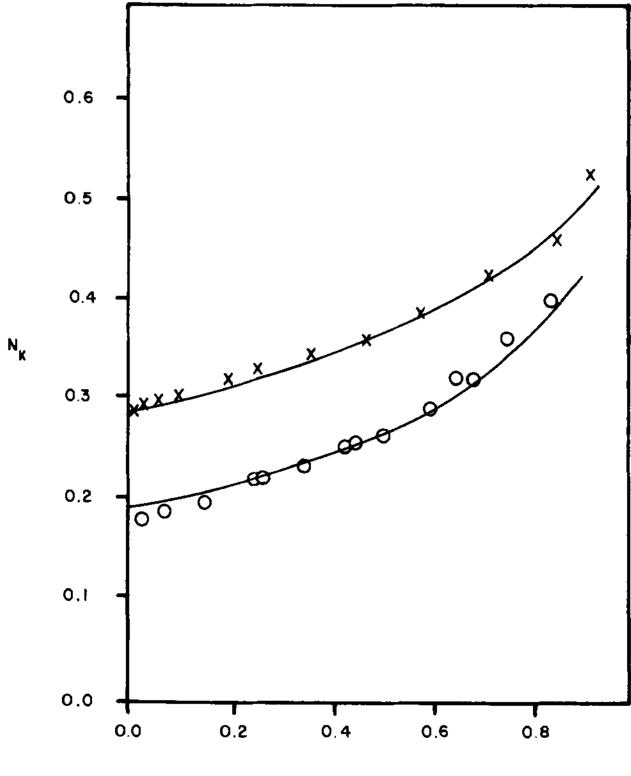

Fig. 6. Collection efficiency (N_K) vs. 1-*CONI* for a 2.78 mM PNP solution (X), and a 4.79 mM PNP solution (0). The rotation rates were 305 rad/sec and 201 rad/sec respectively. Solid lines are theoretical curves corresponding to dimerization mechanism and for (X) *XKTC* = 2.2 and (○) *SCTC* = 0.9.

Table V. Calculated rate constants for reactions of radical anion of PNP obtained from RRDE results[a]

ω (sec^{-1})	Concentration (mM)	XKTC[b]	k_2 (l/mole-sec)
99	2.78	2.1	1.5 × 10^4
	4.79	3.1	1.3
201	2.78	1.0	1.5
	3.20	1.3	1.6
	4.79	2.2	1.8
305	2.78	0.9	1.3
			Avg = 1.7 × 10^4

[a] The solutions were all 0.1M TBAI in DMF.
[b] $XKTC = (0.51)^{-2/3}\nu^{1/3}D^{-1/3}C\omega^{-1}k_2$, $\nu = 0.00849$ cm²/sec.

from these XKTC values and the diffusion coefficient are given in Table V; an average of $1.7 \times 10^4 M^{-1} sec^{-1}$ is obtained.

Discussion of Results

Cyclic voltammetric, chronoamperometric, and rotating-ring disk data suggest that a dimeric coupling reaction (hydrodimerization) represents a major mode of decay of the anion radical of the compound PNP, produced by an initial one-electron transfer in DMF solvent. The compound is reduced also at more negative potentials via an *ec* process involving protonation of the dianion of the parent.

The radical anion coupling rate found here for PNP, $1.7 \times 10^{-4} M^{-1} sec^{-1}$, is intermediate to those found for other substituted olefins (17-20); the dialkyl fumarate radical anions couple with a $k_2 \simeq 10^2 M^{-1} sec^{-1}$, while that for fumaronitrile radical anions is $6 \times 10^5 M^{-1} sec^{-1}$. The 1-phenyl, 2-cyano substituted olefin, cinnamonitrile, yielded a k_2 value of $9 \times 10^2 M^{-1} sec^{-1}$.

Baizer and co-workers (11) found that the radical anion of benzalacetophenone in DMF decayed most rapidly of the five, 2-substituted 1-phenyl olefins he studied (—COφ > —CN > —$COOC_2H_5$ > —$CON(CH_3)_2$ > —C_6H_5) with a lifetime approximately 1/40th of that of diethyl fumarate. Comparison of the k_2 computed for PNP with these data illustrated the relatively great reactivity of radical ions of nitrosubstituted olefins.

The cyclic voltammetric data from the study of the influence of water on the electrochemical reaction occurring at potentials of the first polarographic plateau suggests that proton donors influence the rate of chemical reactions coupled to the electron transfer but do not alter the mechanism of the processes controlling the shape and behavior of the cyclic curves (15). Similar conclusions were reached by Baizer and co-workers (11) and Bard and co-workers (18) from a variety of data. The magnitude of the influence of water is slight but data taken at precursor concentrations of 0.1, 1.0, and 10.0 mM are consistent with an increase in the rate of reactions coupled to the initial electron transfer (Table II, Fig. 3).

Studies of *cis-trans*-pairs of some activated olefins (19) have demonstrated that the anion of the *cis*-isomer may undergo a rapid isomerization to form the *trans*-radical anion as well as react more rapidly in self or cross-coupling reactions. No evidence of such behavior by the E-isomer of PNP is found in the short-term electrochemical data presented herein. The fact that only the E-isomer is produced in the synthesis of PNP, by the condensation of benzaldehyde, with nitroethane is probably pertinent to this point.

Experimental

Apparatus.—The ppde employed in the cyclic voltammetric experiments was a Beckman platinum button electrode with an area of 80 mm². The reference electrode employed in the polarographic and cyclic voltammetry experiments, an aqueous saturated calomel electrode, made contact with the solution through an agar plug behind a Pyrex frit. Water leakage

through this tip was found to be negligible. The cyclic voltammetric data were recorded on a Bolt-Barnak-Newman X-Y Plotter using a Wenking potentiostat and exact wave form source for potential variation and control. The polarograms were recorded with a Beckman Electroscan 30 electroanalytical system.

A Tascussel Electronique Bipotentiostat, Model Bipad 2, was used for all RRDE experiments. A Digitec digital voltmeter, Model 204, and a Fairchild digital multimeter, Model 7050, were used to measure the steady-state ring and disk currents simultaneously. A Wavetek function generator provided a d-c potential ramp for voltammetric experiments recorded on a Mosley Model 2D-2 X-Y recorder. The platinum-Teflon rotating ring-disk electrode, having a disk radius (r_1) of 0.187 cm and inner (r_2) and outer (r_3) ring radii of 0.200 and 0.332 cm, respectively, was constructed by Pine Instrument Company, Grove City Pennsylvania. The maximum collection efficiency, N, for the RRDE used in these experiments was 0.555 (20). The reference electrode was a silver wire spiral.

Chemicals.—Spectroquality DMF containing approximately 0.03% water was obtained from Eastman Organic Chemicals. The solvent was vacuum distilled from anhydrous $CuSO_4$ before use. Hydroquinone was obtained from J. T. Baker Chemical Company and was recrystallized from a 50% water-ethylether solution. All nitroalkenes were synthesized by the method of Hass, Susie, and Heider (21). The compound PNP exhibited a melting point of 64°C after several recrystallizations from absolute ethanol.

The Electrocapillary Phenomena at the Lead Electrode

Ikram Morcos*

Hydro-Quebec Institute of Research, Varennes, Quebec, Canada

ABSTRACT

The electrocapillary phenomena was studied on the lead electrode by the method of meniscus rise in Na_2SO_4 solutions. The potential and concentration dependence of meniscus rise at potentials approximately cathodic to the pzc suggest that the electrode is polarizable. A sharp increase in the interfacial tension at $-1.1V$ is attributed to anion adsorption. Charge density and differential capacity values are calculated from the meniscus rise data for 0.01M Na_2SO_4 solution, and are compared to the results of electrocapillary and capacity measurements on both mercury and lead electrodes, respectively. A reduction in the increase of meniscus rise with potential starting at about $-1.55V$ with 1M Na_2SO_4 suggests the occurrence of cation specific adsorption.

An adequate understanding of the electrochemical activity of solid electrodes requires a better knowledge than is presently available of the electrode/electrolyte interface. The meniscus rise technique has been shown (1-10) to be valuable in previous studies of the interfacial tension at solid electrodes. An extensive application of this technique to various systems is therefore desirable.

The development of the meniscus rise technique, and hence that of the interfacial phenomena at solid electrodes, requires, besides the examination of different systems, some comprehensive measurements on a given

* Electrochemical Society Active Member.
Key words: electrocapillary phenomena, lead electrode, meniscus rise, interfacial tension, double layer.

system. During the past few years both approaches were examined and on the basis of the experimental data (both published and unpublished), it was concluded that a proper interpretation of the results of one comprehensive study, involving such variables as the electrolyte's nature and concentration, cannot be realized before the outline of the general features of interfacial phenomena at solid electrodes is well understood. Unfortunately the nature of the problem is such that progress can be only very slowly made and that there is not one single system that can be applied to reveal all the complexities of the problem. The following explain more precisely the nature of such complexities.

1. The chemical and electrochemical nature of the solid surface strongly influences the potential dependence of the interfacial tension. In the absence of a theory to explain the role played by the electrode surface it is necessary to obtain experimental data on various surfaces of different nature. A consideration of the data obtained on mercury-plated gold (1-6), platinum (3-5), gold (3-5), silver (7), cleavage graphite (3, 8, 9), and silicon (10) electrodes illustrate this point.

2. In addition to electrode's polarizability, variables such as surface roughness and heterogeneity influence the experimental values of meniscus height. While it is possible to obtain an electrode surface which satisfies just a certain degree of the theoretical requirements, it is almost impossible to find a solid surface which is polarizable and free of both surface roughness and heterogeneity. Even variation in surface roughness and heterogeneity can be sometimes more easily realized by using different types of metals than by treating the surface of one metal.

3. Some of the electrochemically inert electrodes, which would have been ideal for a comprehensive study of the effect of ionic nature and concentration, have certain properties which severely limit their use for such studies. Examples are the cleavage surface of single-crystal graphite and silicon electrode in acid medium. The former surface has a lower surface tension (8) than that of water which almost prevents the adsorption of solvated ions. The result is that the potential dependence of meniscus rise is very slightly influenced by either the nature (9) or the concentration of ionic species. In the case of silicon (10) where a polarizable oxide layer forms in acid medium, the interpretation of concentration dependence of meniscus rise is complicated by the presence of potential drops across the space charge and oxide layers and the limiting effect of surface states on surface charge density.

4. The effect of nature and concentration of ions on the potential dependence of meniscus rise on solid metals indicates a completely different type of adsorption between the anion and the metal surface as compared to that observed on mercury. The understanding of the nature of this adsorption requires among other things a comparison between the data observed on different metals.

The aim of the present paper has been to examine the interfacial phenomena at the lead electrode. Recent work on the voltammetry (11) of that electrode suggests the presence of a relatively wide polarizable region. Although the softness of lead and its rapid oxidation on air make it difficult to prepare an ideal surface for the meniscus rise measurement, the indicated polarizable behavior is a sufficient justification for the study.

Experimental Procedure

Most experimental aspects concerning the apparatus and procedure of measuring the meniscus rise were discussed in previous papers. The test electrodes used in the study were polycrystalline lead plates 2 cm wide, 4 cm long, and about 0.05 cm thick. The preparation of a smooth, bright lead plate constituted a particularly difficult problem. Several methods of preparing the surface were tried and the best surface finishing was obtained by chemically polishing the lead plates after mechanical polishing with sandpapers No. 240, 320, 400, and 600 followed by 0.3 alumina on a felt wheel. Chemical polishing was done in a mixture prepared by adding 80 mliters of glacial acetic acid to 20 mliters of 30% H_2O_2. The electrodes were then thoroughly washed in triply distilled water. Several plates were usually treated in the described manner before one could be found eligible for use. Only those plates that continued to exhibit their brightness were used. In meniscus rise experiments, the final test for the eligibility of a certain surface is based on observing a horizontally straight solid/liquid contact line (meniscus edge).

Test solutions were prepared from A.R. quality sodium sulfate, ultra pure sulfuric acid, and triply distilled water twice from a permanganate solution. Solutions of 1.0, 0.1, and 0.01M Na_2SO_4 and 0.01M H_2SO_4 were used. The *p*H of the test solution was measured from samples taken from the cell after each experiment and was found to be 5.2, 4.95, 5.88, and 2.1, respectively. A mercury-mercurous sulfate electrode, which has been prepared several weeks prior to the measurements, was used as a reference electrode. The stability of this reference electrode was tested as a function of both time and *p*H. This was carried out in 1M Na_2SO_4 solution against a two-phase lead amalgam lead sulfate electrode. The emf between the two electrodes was found to be remarkably stable during a period of 1 hr and between *p*H 2.75 and 12.59. The emf read at both *p*H extremes was -0.981 and -0.980, respectively.

A large Teflon cell of 12.3 cm diameter was applied. The counterelectrode consisted of a spectroscopic grade rod of graphite.

The advancing equilibrium meniscus rise was measured at prefixed potentiostatically controlled potential values and the measurement was carried out from the most cathodic to the most anodic potential value. The measurement was carried out under helium atmosphere and in helium-saturated solutions. The current density was calculated for the immersed area of the electrode and was found not to exceed 10 $\mu A/cm^2$.

Results and Discussion

Figure 1 shows plots of potential dependence of the advancing meniscus rise on partially immersed polycrystalline lead plates in 0.01, 0.1, and 1.0M Na_2SO_4 solutions. The three plots show well-defined minima located in the potential region between -1.35 and $-1.25V$ (*vs.* Hg/Hg_2SO_4). The plots also show that at $-1.1V$ the meniscus rise drops sharply and, therefore, results in the occurrence of well-defined maxima. Differential capacity measurements carried out by several investigators (12-16) in sulfate solutions show that the pzc of lead is located at potentials between -0.62 and $-0.67V$ (*vs.* NHE). These values agree with the minima of Fig. 1 and, therefore, the latter minima should correspond to the pzc of lead in the same solutions.

A detailed discussion of the electrocapillary curves of Fig. 1 can be more conveniently carried out if one considers the corresponding variation in interfacial tension with potential. Irrespective of the polarizability of the electrode and subject only to the thermodynamic validity of the contact angle at the three phase region, the interfacial tension γ_{SL}, at the solid/liquid interface is related to the advancing meniscus rise by an equation previously (6) derived

$$\gamma_{SL} = \gamma_{SV} - \gamma_L(2kh^2 - k^2h^4)^{1/2} \quad [1]$$

where

$$k = \frac{\rho g}{2\gamma_L} \text{ and } \gamma_{SV} = \gamma_S - \pi$$

and the different terms are as follows: γ_S and γ_L the

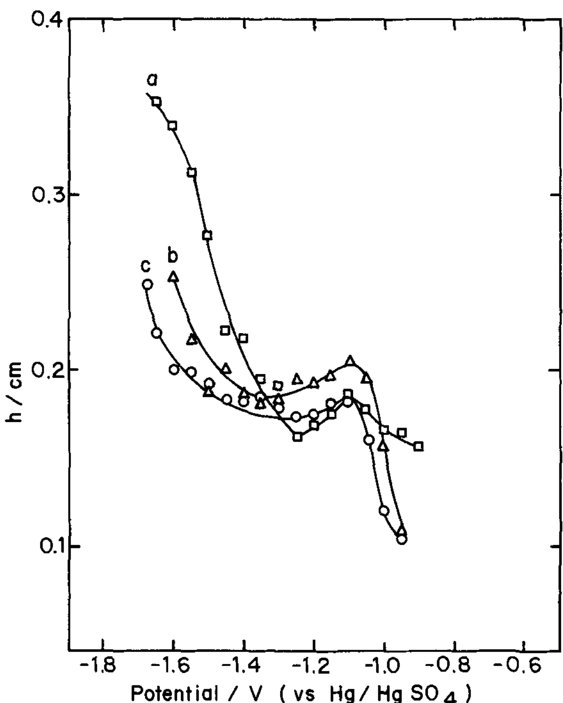

Fig. 1. Meniscus rise vs. potential relationships on chemically polished polycrystalline lead electrode in helium atmosphere. Curve a, 1.0M Na_2SO_4; curve b, 0.1M N_2SO_4; curve c, 0.01M Na_2SO_4.

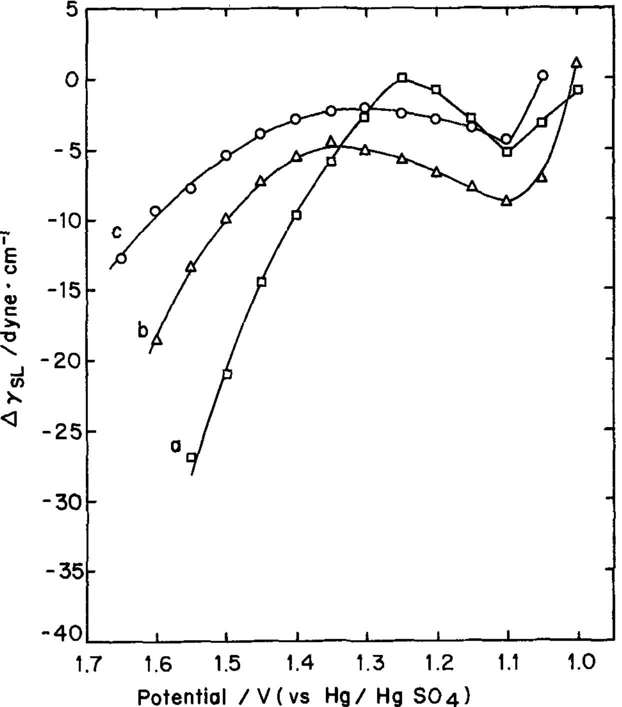

Fig. 2. Interfacial tension vs. potential relationships on chemically polished polycrystalline lead electrode in helium atmosphere. Data calculated by Eq. [1] using plots of Fig. 1. Curve a, 1.0M Na_2SO_4; curve b, 0.1M Na_2SO_4; curve c, 0.01M Na_2SO_4.

solid's and liquid's surface tensions, respectively, π the spreading pressure of water, ρ the liquid's density, and g the gravitational constant. In the absence of gas evolution, which is the case with the lead electrode as shown by voltammetry (11), the thermodynamic validity of the contact angle (and hence that of the meniscus rise) is justifiable (10). A knowledge of the absolute value of γ_{SL} requires a knowledge of γ_S. But since the latter quantity cannot be obtained, only variations in γ_{SL} as a function of the potential can be evaluated assuming that the values of both γ_{SV} and γ_L are independent of the potential.

Figure 2 shows those plots of $\Delta\gamma_{SL}$ as a function of the applied potential which have been obtained by means of Eq. [1] from the data of Fig. 1. In calculating $\Delta\gamma_{SL}$ the value of $\gamma_S - \gamma_{SL}$ which corresponds to the minimum meniscus height in 1M $(Na)_2SO_4$ solution has been taken as a reference point. At any given potential and concentration $\Delta\gamma_{SL}$ is given by

$$\Delta\gamma_{SL} = (\gamma_S - \gamma_{SL}) - (\gamma_S - \gamma_{SL})_{\text{at minimum } h \text{ in } 1.0\text{M } Na_2SO_4}$$

With regard to the polarizability of the lead electrode, Fig. 2 indicates that as the potential is increased in the anodic direction, the metal surface exhibits three relatively well-defined states.

At potentials more negative than about -1.3 (which corresponds to the pzc) both the potential and concentration dependence of γ_{SL} strongly suggest a polarizable surface. In this region, with both 0.01 and 0.1M solutions $\Delta\gamma_{SL}/\Delta E$ shows a satisfactory agreement with $\Delta\gamma/\Delta E$ observed on mercury. With 1M solution the variation in $\Delta\gamma_{SL}$ is higher than the corresponding variation in mercury but is still within the same order of magnitude. The higher value probably results from the effect of solid surface roughness which becomes more influential with the increase in concentration.

At potentials more positive than -1.1V, γ_{SL} shows a sudden increase with all concentrations. This potential coincides almost exactly with the cathodic side of the bottom of the current peak which is observed in fast, anodic, linear potential sweeps on the lead electrode in sulfate mediums (11). The peak occurs at -0.342 (*vs.* NHE) and is attributed to the formation of $PbSO_4$. That leaves little doubt that the increase in interfacial tension observed at -1.1 (*vs.* $Hg/HgSO_4$) is connected with the chemisorption of $SO_4^=$ on the lead electrode. In that respect it seems that the variation in the interfacial tension is more sensitive than linear sweep voltammetry with regard to anion chemisorption. The mere adsorption of anions causes a sharp increase in the interfacial tension while the peak in voltammetry sweep does not appear before the potential of $PbSO_4$ formation is reached. It could be argued that the increase in interfacial tension (drop in meniscus rise) at -1.1 is due to the adsorption of OH^- rather than $SO_4^=$ ion. Figure 3, however, shows that the same drop in meniscus rise takes place with 0.01 H_2SO_4 at exactly the same potential, which confirms that the observed effect is due to $SO_4^=$ ion.

The increase in γ_{SL} due to anion adsorption is contrary to what usually takes place on mercury where anion adsorption reduces γ. The most probable interpretation for the increase in γ_{SL} is that anion adsorption must have resulted in reducing the charge density at the surface by interacting with the available free charge. It is interesting to note that from measurement of surface conductance on a gold electrode, Anderson and Hansen (17) have concluded that adsorption of $SO_4^=$ ion reduces the amount of free charge at the gold surface.

In the potential region between -1.1 and -1.3V (*vs.* $Hg/HgSO_4$) the potential dependence of meniscus rise suggests the occurrence of slight $SO_4^=$ adsorption. This suggestion is based on the fact that $\Delta\gamma_{SL}/\Delta E$ is less than that observed on mercury. Carr *et al.* (12) reached the same conclusion from measurement of differential capacity. According to the latter authors (12), differential capacity *vs.* potential plots in dilute sulfuric acid solutions give rise to curves with well-defined minima only when the electrode was exposed before each fixed potential to a fixed negative potential of about -1.77 (*vs.* $Hg/HgSO_4$). In meniscus rise measurement, caution must, however, be taken in interpreting the concentration dependence of γ_{SL} near the potential of zero charge because surface roughness and

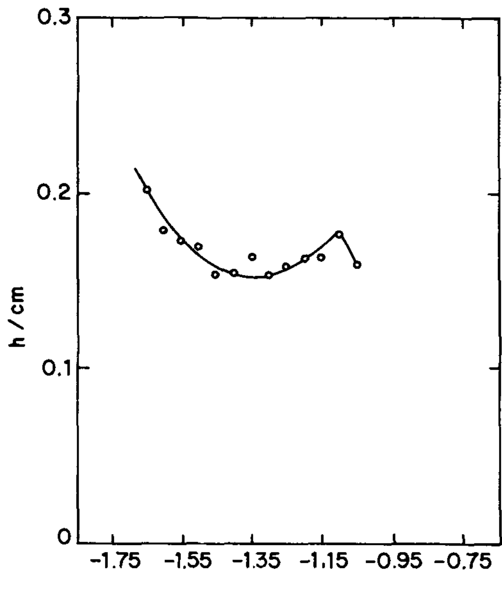

Fig. 3. Meniscus rise *vs.* potential relationship on chemically polished polycrystalline lead electrode with 0.01M H_2SO_4 and helium atmosphere.

heterogeneity exerts their maximum effects in this potential region.

A quantitative comparison between the data of meniscus rise and differential capacity, C_d, on both the lead and mercury electrodes is desirable. This can only be realized by differentiating twice the meniscus rise *vs.* potential plots, and calculating C_d according to (9)

$$q = (2k)^{1/2}\gamma_L \frac{1 - kh^2}{(1 - \frac{1}{2}kh^2)^{1/2}} \left(\frac{\partial h}{\partial E}\right)_\mu \quad [3]$$

$$C_d = \frac{\partial q}{\partial E} \quad [4]$$

Figure 4 shows the charge density *vs.* rational potential plot calculated by means of Eq. [3] using the data of Fig. 3 for 0.01M Na_2SO_4. Figure 5 shows the differential capacity *vs.* potential calculated by means of

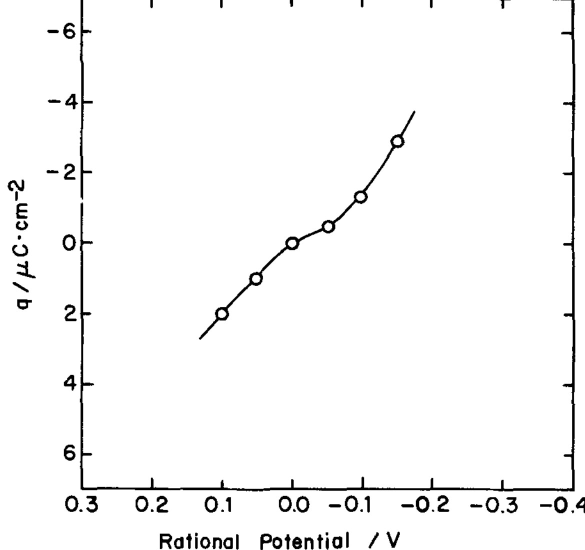

Fig. 4. Charge density *vs.* rational potential relationship on a polycrystalline chemically polished lead electrode with 0.01M Na_2SO_4 and helium atmosphere. Data are calculated by Eq. [3] from curve c of Fig. 1.

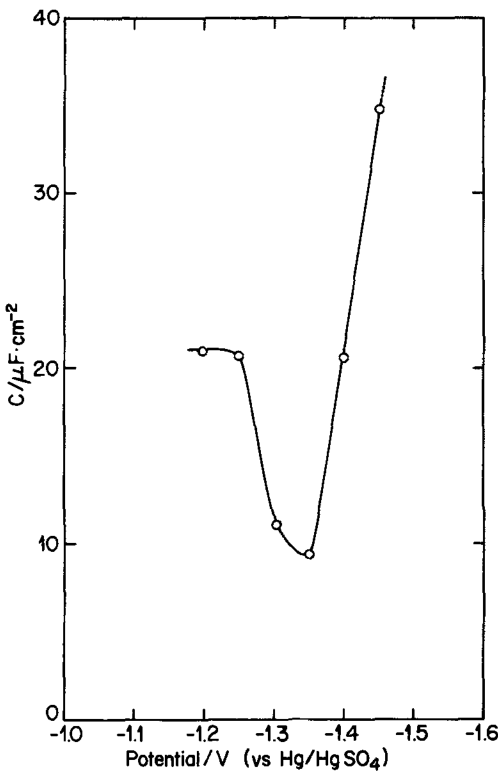

Fig. 5. Differential capacity *vs.* potential relationship on a polycrystalline polished lead electrode with 0.01M Na_2SO_4 and helium atmosphere. Data calculated by Eq. [4] from Fig. 4.

Eq. [4] using the data of Fig. 4. At potentials more negative than -1.35 (*vs.* $Hg/HgSO_4$) the plot shows a satisfactory agreement with the same data directly measured on either lead or mercury. At potentials more positive than the above-mentioned value the effect of anion adsorption limits the increase in capacity.

Much of the deviation from polarizability discussed above results from anion adsorption. It is noticed however that with 1.0M Na_2SO_4 solution, the rate of meniscus rise increase with potential decreases at potentials more cathodic than about $-1.55V$ (*vs.* $Hg/HgSO_4$). Since hydrogen is known to adsorb only poorly on the lead electrode and since this cathodic decrease in $\Delta h/\Delta E$ is not observed with dilute solutions of 0.01 and 0.1*M*, its occurrence with 1.0M solutions probably results from some specific adsorption of the sodium ion on the lead surface.

Acknowledgment

The author wishes to thank Mr. A. Gendron for his assistance in the physical realization of the work.

Cyclic Voltammetry and Chronocoulometry with *trans*-$Rh(en)_2Cl_2^+$ at Mercury Electrodes

Janis Gulens,[1] Dusan Konrad,[2] and Fred C. Anson

Arthur Amos Noyes Laboratory of Chemical Physics, California Institute of Technology, Pasadena, California 91109

ABSTRACT

Cyclic voltammetric, coulometric, and chronocoulometric data associated with the reduction of $Rh(en)_2Cl_2^+$ at mercury electrodes are reported that confirm previous results indicating the occurrence of a two-electron reduction to produce the hydrido complex, $Rh(en)_2H(OH_2)^{2+}$, which engages in a pH dependent equilibrium involving $Rh(en)_2^+$: $Rh(en)_2H(OH_2)^{2+} + OH^- \rightleftharpoons Rh(en)_2^+ + 2H_2O$. The resulting presence of $Rh(en)_2^+$ at the electrode surface has a number of interesting consequences which are described. Among these are the electrochemical production of metal-metal bonded rhodium-mercury adducts, apparent strong adsorption of $Rh(en)_2^+$ on the electrode surface, and anomalous cyclic voltammograms with inverted peaks.

As part of a study of the possible role of adsorbed transition metal complexes in the catalysis of electrode processes, we have been investigating the electrochemistry of some complexes of rhodium(III) because of their prominence as catalysts in homogeneous reactions (1, 2). Previous polarographic and controlled potential electrolytic studies of various hexacoordinate chloroaminorhodium(III) complexes (3-6) have established a common pattern of a single, two-electron reduction in which halide is liberated and tetracoordinate rhodium(I) complexes are produced. In the case of the *trans*-$Rh(py)_4Cl_2^+$ complexes the polarographic behavior observed was taken to indicate that the rhodium(I) product was adsorbed on the mercury electrode (4).

We chose to investigate the electrochemical behavior of *trans*-$Rh(en)_2Cl_2^+$ in the hope of generating $Rh(en)_2^+$ as an intermediate which might be reacted with added, electrochemically inactive substrates. We were further intrigued by the reports (7) that controlled potential, electrolytic reduction of this complex under certain conditions yielded a rhodium(II) product which is a rare oxidation state for rhodium (1). In a recent paper (8) it was shown that the electrolysis product thought to contain rhodium(II) (7) was actually a rhodium(I) adduct of mercury(II) formed by a combination of electrochemical and chemical reactions at the surface of the mercury pool electrode. During the course of that study there came to light a number of features of the electrochemistry of *trans*-$Rh(en)_2Cl_2^+$ at mercury electrodes which have not been previously described. They form the basis for this report.

Experimental

The preparations of the complexes *trans*-$Rh(en)_2Cl_2^+$, $(en)_2RhHgRh(en)_2^{4+}$, and $(en)_2RhHg(OH^2)^+$ were described previously (8). The experiments reported here were performed in supporting electrolytes consisting of sodium methane sulfonate plus added buffering agents, but the behavior in nitrate or perchlorate supporting electrolytes is essentially identical [*trans*-$Rh(en)_2Cl_2^+$ and $[(en)_2Rh]_2Hg^{4+}$ complexes are only sparingly soluble in $NaClO_4$]. All solutions were prepared from triply distilled water and were deaerated with prepurified nitrogen.

Cyclic voltammograms were obtained with a conventional, operational amplifier based electrochemical apparatus and were recorded by photographing the traces stored on a Tektronix Model 564 oscilloscope. The cells and hanging mercury drop electrode (area = 0.029 cm^2) were conventional. Potentials were measured and are quoted with respect to a sodium chloride saturated calomel reference electrode which had a potential 5 mV more negative than a SCE.

Chronocoulometry (9) was performed using the previously described digital data acquisition and analysis system (10). Usually 100 data points were taken at 200 μsec intervals. The chronocoulometric values for surface concentrations of adsorbed electroactive species were obtained by subtracting the charge changes measured in rhodium-free solutions from the intercepts of charge-$(time)^{1/2}$ plots or, in some cases, from the charge value of the first data point (acquired 200 μsec after the potential step was applied). The accuracy of the resulting values of the quantity of adsorbed species is discussed in the text.

Controlled potential electrolyses at stirred mercury pool electrodes were carried out by means of a Wenking potentiostat (Model TR). The electrolyses currents and their time integrals were displayed on a pen and

ink recorder. Changes in solution pH resulting from electrolysis were determined with a conventional pH meter and a Fisher Scientific Company "Blue Glass" pH electrode which was calibrated so that its readings could be converted directly to the analytical concentrations of H^+ and OH^- in the range from 10^{-3} to 10^{-1}M.

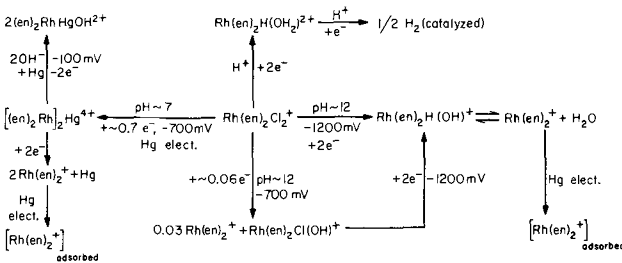
Steady-state background currents continued to flow at the end of the controlled potential electrolysis of solutions of *trans*-$Rh(en)_2Cl_2^+$ or *trans*-$Rh(en)_2Cl(OH)^+$ at -1100 or -1200 mV. The magnitude of these currents increased as the applied potential became more negative but they were typically of the order of 20-30 $\mu A/cm^2$ after a 40-50 min electrolysis. Under these conditions the background correction ($Q_{background} = i_{steady\ state} \times t_{electrolysis}$) amounted to *ca.* 10-15% of the total charge consumed.

Spectra of the electrolysis solutions were obtained at various stages during an electrolysis by transferring aliquots under nitrogen to previously purged spectrophotometer cells and recording the spectra with a Cary Model 11 or Beckman spectrophotometer.

Results and Discussion

The electrochemical behavior of *trans*-$Rh(en)_2Cl_2^+$ is complicated by a tendency toward severe "maxima" related stirring of the solution at both hanging and dropping mercury electrodes. Further complications are introduced by the pH dependent chemical reactions engaged in by the initial product of the electrode reaction to yield electroinactive final products. A combination of pulse techniques and controlled potential electrolyses with continual spectral monitoring of the solution was employed to try to deal with the many experimental obstacles inherent in the electrochemistry of this complex and its reduction products. Because the behavior observed is quite dependent on pH it seems profitable to divide the description of the results on the basis of the solution pH.

The most prominent of the electrochemical and coupled chemical processes exhibited by the $Rh(en)_2Cl_2^+$ system are summarized in Scheme I which may be useful as a reference guide during the discussion to follow.



Scheme I - Electrode Reactions of $Rh(en)_2Cl_2^+$ on Mercury

Reduction of trans-$Rh(en)_2Cl_2^+$ in the presence of protons.—In acidic solutions the *trans*-$Rh(en)_2Cl_2^+$ complex displays its least complicated behavior. Cyclic voltammetry in solutions in which the hydrogen ion concentration is greater than the concentration of the complex gives two well-separated waves during potential scans in the direction of more negative potentials and no corresponding oxidation waves when the scan direction is reversed. The peak potential of the first reduction wave varies with the scan rate ($-E_p =$ 580, 630, and 700 mV for scan rates of 0.46, 4.6, and 46 V/sec, respectively) while the peak current varies linearly with the concentration of the complex and with the square root of the scan rate. The potential of the second reduction wave also shifts with scan rate ($-E_p =$ 1140, 1190, and 1280 mV for the same three scan rates) and the peak current is proportional to the square root of the scan rate and to the sum of the concentrations of the rhodium(III) complex and hydrogen ion.

The number of electrons consumed in the charge-transfer process associated with the first reduction peak under pulsed conditions was determined chronocoulometrically (9) from the slope of charge-(time)$^{1/2}$ plots for a potential step from -200 to -700 mV. Such plots were linear with slopes (*ca.* 600 μcoulombs cm^{-2} $sec^{-1/2}$ mM^{-1}) consistent with diffusion controlled reduction of the complex with the consumption of two electrons. The intercept of these plots on the charge axis matched that obtained in rhodium-free solutions indicating that the complex is not adsorbed on the electrode in detectable quantities.

Controlled potential reduction of *trans*-$Rh(en)_2Cl_2^+$ at a Hg pool cathode at -700 mV proceeds normally in acidic solutions without any spectral evidence for the formation of an intermediate product. The starting complex is converted quantitatively to *trans*-$Rh(en)_2H(OH_2)^{2+}$ which was identified from its known ultraviolet spectrum (7). The electrolyses consumed 2 Faradays of electricity and 1 mole of protons per mole of *trans*-$Rh(en)_2Cl_2^+$. The electrode process under both pulsed and controlled potential electrolytic conditions thus appears to proceed as follows

$$Rh(en)_2Cl_2^+ + 2e \rightarrow Rh(en)_2^+ + 2Cl^- \quad [1]$$

$$Rh(en)_2^+ + H_3O^+ \rightarrow Rh(en)_2H(OH_2)^{2+} \quad [2]$$

Cyclic voltammetry conducted in acidic solutions containing only *trans*-$Rh(en)_2H(OH_2)^{2+}$ gives rise to a single reduction wave with a peak potential near -1200 mV which matches the second wave obtained with solutions of $Rh(en)_2Cl_2^+$. There is no oxidation wave during the positive going potential scan. The peak current is proportional to the concentration of hydrogen ion and controlled potential electrolyses (at -1300 mV) of acidic solutions of *trans*-$Rh(en)_2H(OH_2)^{2+}$ result only in the consumption of hydrogen ion with 100% faradaic efficiency. The large initial electrolyses currents decay smoothly to large steady-state currents and result in an increase in solution pH. Coulometric measurements showed that 1 Faraday of charge is consumed per mole of hydrogen ion reduced. Further reduction at -1300 mV at the steady-state current level results in a continuous increase in pH with the production of 1 mole of hydroxide ion for each Faraday of charge consumed. The cathodic peak present in acidic solutions at -1200 mV was absent from the electrolysis solutions at this point. The u.v. spectrum of the *trans*-$Rh(en)_2H(OH_2)^{2+}$ complex remained unchanged throughout the electrolyses as the pH increased from 3 to 11. The *trans*-$Rh(en)_2H(OH_2)^{2+}$ complex thus appears to be effective in decreasing the hydrogen overvoltage at mercury, but the mechanism for this catalytic action is uncertain.

Reduction of trans-$Rh(en)_2Cl_2^+$ at intermediate and high pH values.—The cyclic voltammetric behavior of *trans*-$Rh(en)_2Cl_2^+$ in neutral and alkaline solutions becomes increasingly more complicated as the concentration of the complex is increased and/or the potential scan rate is decreased. However, relatively straightforward behavior can be obtained by working with dilute solutions (0.1 mM) at sweep rates from 0.5 to 50 V/sec and the results of experiments conducted under these conditions will be analyzed first. Figure 1 shows a typical set of voltammograms obtained at pH 12 in which two reduction waves, at *ca.* -650 and -1100 mV, and an oxidation wave near -200 mV are present. The ratio of the peak current to the square root of the scan rate becomes larger as the scan rate is increased for both the first reduction wave and the oxidation wave. At a fixed scan rate the peak current for the oxidation wave does not increase linearly with the concentration of the complex but at a somewhat lower rate.

Controlled potential electrolyses of alkaline solutions of *trans*-$Rh(en)_2Cl_2^+$ at -700 mV consume only

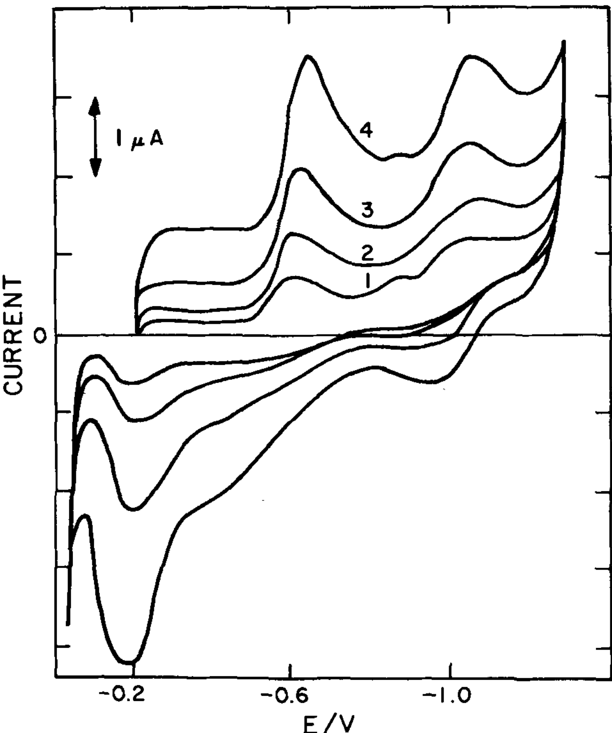


Fig. 1. Cyclic voltammograms for *trans*-$Rh(en)_2Cl_2^+$ at pH 12. Conc. of complex: 0.1 mM. Supporting electrolyte: 1M CH_3SO_3Na (sodium methane sulfonate), 0.01M NaOH. Scan rates (V/sec): curve 1, 0.46; curve 2, 0.92; curve 3, 1.84; curve 4, 3.68.

ca. 0.05 Faradays of electricity per mole of the complex before the electrolysis current decreases to a very small value. Spectral analysis of the resulting solutions shows that the initial complex has been converted quantitatively into *trans*-$Rh(en)_2Cl(OH)^+$, the spectrum of which has been reported (11). A cyclic voltammogram of this solution, Fig. 2, contains a single reduction wave with a scan rate dependent peak potential near −1000 mV. This conversion of the dichloro

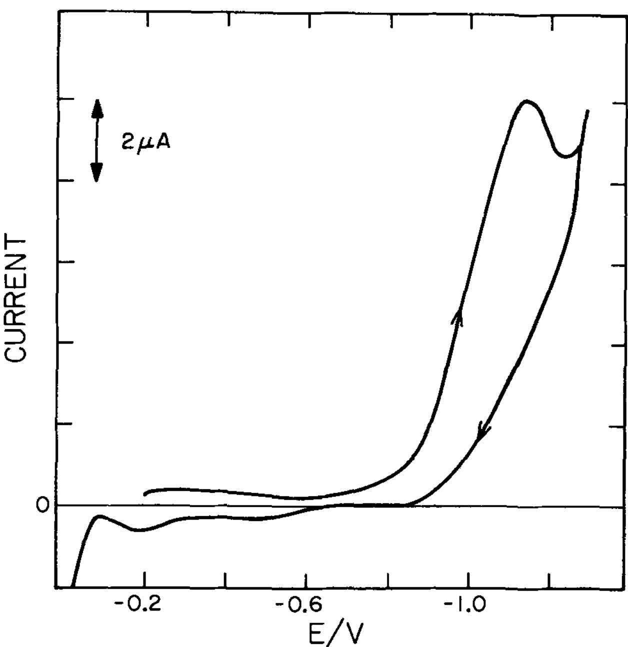

Fig. 2. Cyclic voltammogram for *trans*-$Rh(en)_2ClOH^+$ at pH 12. Conc. of complex: 0.9 mM. Supporting electrolyte as in Fig. 1. Scan rate: 0.46 V/sec.

to the monochloro complex most likely proceeds by means of a Rh(I)-catalyzed inner sphere redox reaction in which the $Rh(en)_2^+$ generated electrochemically, reaction [1], catalyzes the loss of one and only one chloride from the dichloro complex by reducing it via a chloride bridged transition state, reaction [3] (12-14)

$$Rh(en)_2^+ + Rh(en)_2Cl_2^+ \rightarrow [(en)_2Rh - Cl - Rh(en)_2Cl^{2+}] \rightleftharpoons$$
$$\xrightarrow{OH^-} (en)_2RhClOH^+ + Rh(en)_2^+ + Cl^- \quad [3]$$

Since the *trans*-$Rh(en)_2Cl(OH)^+$ product is reduced at considerably more negative potentials than the initial *trans*-$Rh(en)_2Cl_2^+$ complex, only a small amount of electricity is consumed during the controlled potential electrolysis at −700 mV before the solution is converted to an electroinactive form. This same catalytic decomposition of $Rh(en)_2Cl_2^+$ by a product of its reduction is responsible for the peak current for reduction of *trans*-$Rh(en)_2Cl_2^+$ near −650 mV (Fig. 1) being disproportionately large at high sweep rates when less time is available for the decomposition to occur. However, even at the highest sweep rates employed in Fig. 1, the appearance of the second reduction wave near −1100 mV gives evidence of some *trans*-$Rh(en)_2Cl(OH)^+$ having been formed within the diffusion layer via reaction [3].

Controlled potential electrolysis of neutral and alkaline solutions of either *trans*-$Rh(en)_2Cl_2^+$ or *trans*-$Rh(en)_2Cl(OH)^+$ at −1200 mV proceeds smoothly without any evidence for the formation of an intermediate, and 2 Faradays/mole of rhodium are consumed (after correcting for the background currents; see the Experimental section). The spectrum of the resulting solution is consistent with that reported for *trans*-$Rh(en)_2H(OH_2)^{2+}$ (7), which is in equilibrium with $Rh(en)_2^+$ according to reaction [4] (7)

$$Rh(en)_2^+ + 2H_2O \rightleftharpoons Rh(en)_2H(OH_2)^{2+} + OH^- \quad [4]$$

Chronocoulometry was employed to demonstrate that the number of electrons involved during pulsed electrolysis of *trans*-$Rh(en)_2Cl_2^+$ is the same as that consumed during controlled potential electrolysis, namely two electrons per molecule of complex. Charge *vs.* $(time)^{1/2}$ plots were analyzed as a function of the concentration of *trans*-$Rh(en)_2Cl_2^+$ and the electrode potential (Fig. 3 and 4). Linear plots result when the potential is stepped from −200 to −800 mV with the most dilute solutions but the slopes of the plots are about 25% smaller than would correspond to a diffusion controlled two-electron reduction. At higher concentrations of the complex the deviations from linearity of the plots in Fig. 3 doubtless reflect the increased importance of reaction [3] in the presence of the larger concentrations of the $Rh(en)_2^+$ catalyst being generated in the diffusion layer. When the potential is stepped to more negative potentials such as −1100 mV (Fig. 4), both *trans*-$Rh(en)_2Cl_2^+$ and *trans*-$Rh(en)_2Cl(OH)^+$ are reduced at diffusion controlled rates and the chronocoulometric plots are linear for all initial concentrations of the complex. The ratio of the slopes of the plots to the concentrations of rhodium(III) present are also correct for a two-electron, diffusion controlled reduction.

The electrolysis product obtained at −1100 or −1200 mV was identified spectrally (7) as $Rh(en)_2H(OH_2)^{2+}$. This complex gives no reduction wave in alkaline solutions before the evolution of hydrogen which is, however, catalyzed by the presence of the complex.

Cyclic voltammograms for *trans*-$Rh(en)_2Cl_2^+$ recorded in neutral, unbuffered supporting electrolyte (1M sodium methane sulfonate) are shown in Fig. 5. These voltammograms resemble those obtained at pH 12 (Fig. 2). The only significant differences are the shifts in the peak potentials to more positive values for

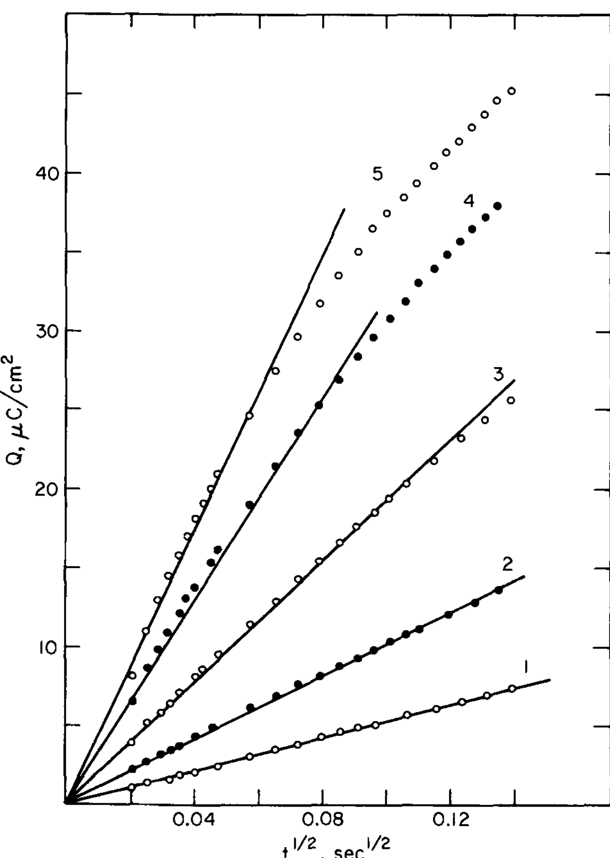

Fig. 3. Chronocoulometric plots for the reduction of *trans*-$Rh(en)_2Cl_2^+$ at −800 mV. Supporting electrolyte as in Fig. 1. Initial potential: −200 mV. The double-layer charging blank, $Q_{d.l.}$, was subtracted from each point. Conc. of the complex (mM): curve 1, 0.1; curve 2, 0.2; curve 3, 0.4; curve 4, 0.65; curve 5, 0.9.

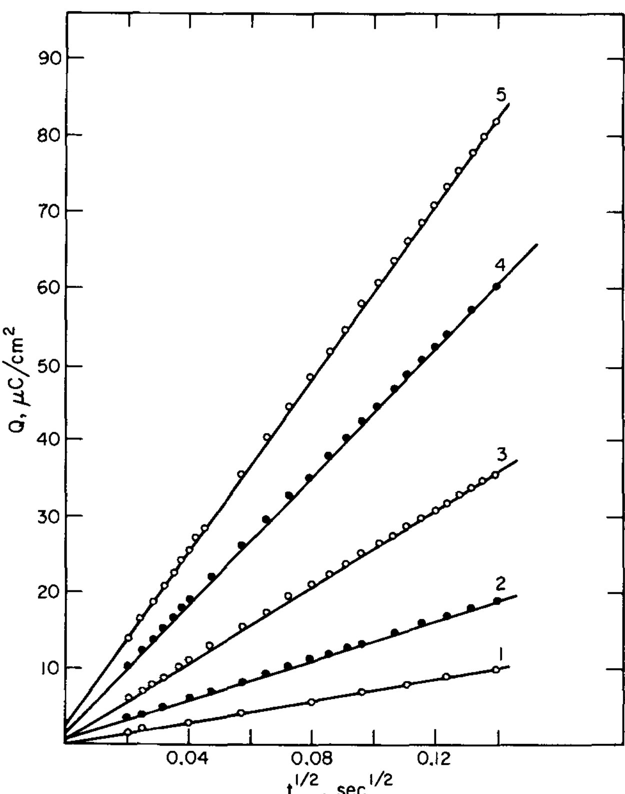

Fig. 4. Chronocoulometric plots for the reduction of *trans*-$Rh(en)_2Cl_2^+$ at −1100 mV. All other conditions as in Fig. 3.

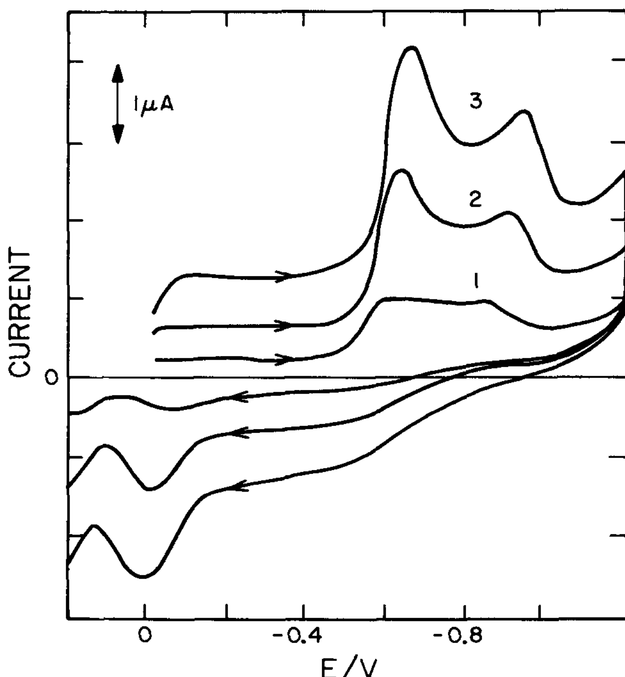

Fig. 5. Cyclic voltammograms for *trans*-$Rh(en)_2Cl_2^+$ at *p*H 7. Conc. of complex: 0.1 mM. Supporting electrolyte: 1M CH_3SO_3Na. Scan rates (V/sec): curve 1, 0.46; curve 2. 1.84; curve 3, 3.7.

the second reduction wave (−900 *vs.* −1100 mV at *p*H 12) and the single oxidation wave (0 *vs.* −200 mV at *p*H 12) as well as a decrease in the magnitude of the peak current for the oxidation wave.

The chronocoulometric charge-(time)$^{1/2}$ plots measured at −700 mV in neutral supporting electrolytes show deviations from linearity that become quite pronounced as the initial concentration of $Rh(en)_2Cl_2^+$ is increased (Fig. 6A). At the higher concentrations the rate of accumulation of charge, *i.e.*, the current, is considerably below the rate that would correspond to a diffusion controlled, two-electron reduction. However, when the potential to which the electrode is stepped in the chronocoulometric experiment is made more negative, *e.g.*, −1100 mV, linear, two-electron, diffusion controlled, charge-(time)$^{1/2}$ plots are obtained (Fig. 6B).

Controlled potential electrolysis of initially neutral, unbuffered solutions of *trans*-$Rh(en)_2Cl_2^+$ at −1200 mV consumes 2 Faradays/mole of complex and yields solutions of higher *p*H (*p*H 10-11 depending on the initial concentration of complex) with a spectrum matching that of $Rh(en)_2H(OH_2)^+$. However, when the electrolysis is conducted at potentials between −700 and −1000 mV, where deviant chronocoulometric plots are obtained, a new, highly colored electrolysis product appears and attains a maximum concentration after 0.7 to 1.2 Faradays of charge per mole of complex have been passed. The spectra of this new species is quite similar to that reported by Gillard and co-workers (7) who have previously described controlled potential electrolyses of neutral solutions of *trans*-$Rh(en)_2Cl_2^+$. They believed they had generated a dimeric complex of Rh(II) to which they ascribed the spectrum of the colored product, but recent experiments (8) have identified the species as a mercurated adduct of Rh(I), $(en)_2RhHgRh(en)_2^{4+}$ which is formed by the simultaneous occurrence of a reduction and an oxidation reaction at the mercury electrode at potentials between −700 and −1000 mV. The reactions by which this intermediate is thought to be generated are as follows (8)

$$Rh(en)_2Cl_2^+ + 2e^- \rightarrow Rh(en)_2^+ + 2Cl^- \quad [1]$$

$$2Rh(en)_2^+ + Hg \rightarrow (en)_2RhHgRh(en)_2^{4+} + 2e^- \quad [5]$$

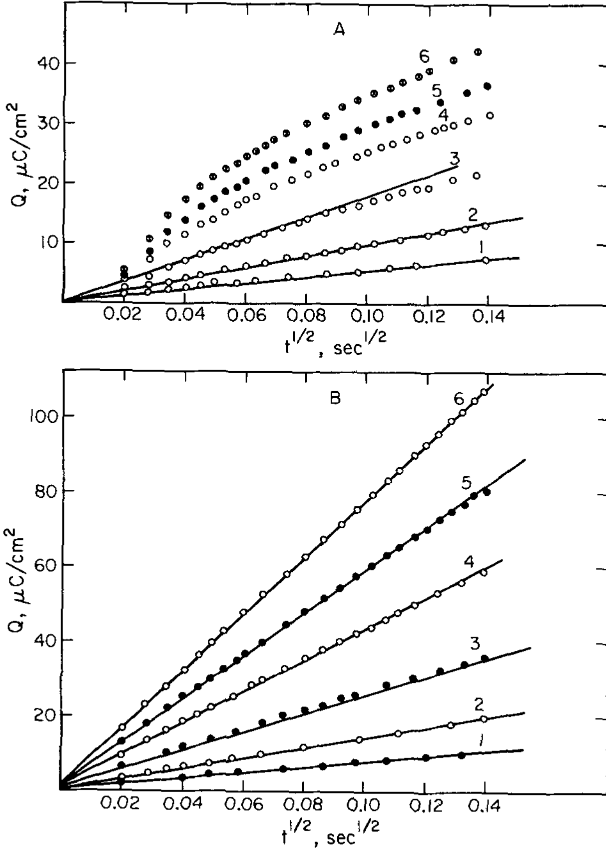

Fig. 6. Chronocoulometric plots for the reduction of *trans*-$Rh(en)_2Cl_2^+$ at pH 7. Supporting electrolyte: 1M CH_3SO_3Na. Conc. of complex (mM): curve 1, 0.1; curve 2, 0.2; curve 3, 0.4; curve 4, 0.7; curve 5, 0.95; curve 6, 1.3. Initial potential: —200 mV. Final potential: A, —700 mV; B, —1100 mV. The double-layer charging blank, $Q_{d.l.}$ was subtracted from each point.

The fact that electrons are liberated in reaction [5] is the main reason that chronocoulometric plots having slopes well below the level corresponding to a two-electron reduction of *trans*-$Rh(en)_2Cl_2^+$ are obtained at -700 mV (Fig. 6A) despite the fact that all of the Rh(III) is reduced to Rh(I). And the increasing deviations of these slopes from the two-electron value at larger initial concentrations of *trans*-$Rh(en)_2Cl_2^+$ reflects the increasing importance of reaction [5] as the concentration of $Rh(en)_2^+$ generated at the electrode surface in reaction [1] increases. The reason that the mercurated product is not observed at low pH is that the concentration of $Rh(en)_2^+$ generated in acid solutions is much lower because the equilibrium involved in reaction [2] lies far to the right. At high pH, the *trans*-$Rh(en)_2Cl_2^+$ initially present is converted to *trans*-$Rh(en)_2Cl(OH)^+$ very early in the electrolysis (*vida supra*) and the latter complex can be reduced only at more negative potentials where reaction [5] proceeds at an insignificant rate (8).

Oxidation of trans-$Rh(en)_2H(OH_2)^{2+}$.—No oxidation waves for *trans*-$Rh(en)_2H(OH_2)^{2+}$ appear in acidic solutions, but in neutral and especially in alkaline solutions this complex does exhibit oxidation waves. Figure 7 shows a cyclic voltammogram for this complex in 1M NaOH in which the potential was first scanned to more positive values and then reversed. The two reduction waves observed during the last half of the cycle only appear when the positive scan is allowed to traverse the potential region around -300 mV where the single oxidation wave appears. The oxidation wave moves steadily to more positive potentials as the scan rate is increased until it merges with the background current corresponding to oxida-

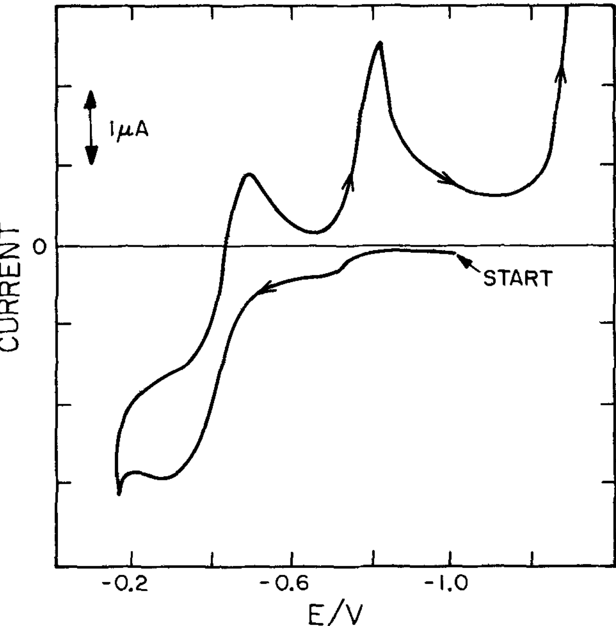

Fig. 7. Cyclic voltammogram for *trans*-$Rh(en)_2H(OH_2)^{2+}$ in 1M NaOH. Conc. of complex: 1 mM. Scan rate: 0.18 V/sec.

tion of the mercury electrode in the highly alkaline electrolyte.

Controlled potential electrolysis of the same solution at -100 mV leads to the stepwise formation of two mercurated complexes according to reactions [5] and [6] which each liberate 1 Faraday/mole of rhodium (8)

$$(en)_2RhHgRh(en)_2^{4+} + 2\,OH^- + Hg \rightarrow 2(en)_2RhHgOH^{2+} + 2e^- \quad [6]$$

Thus these two rhodium-mercury complexes are the logical candidates for assignment to the two reduction waves observed during the last half of the cyclic voltammogram in Fig. 7. This assignment was confirmed by recording the voltammogram for alkaline solutions of $(en)_2RhHgOH^{2+}$ and $[(en)_2Rh]_2Hg^{4+}$ (prepared electrolytically). These voltammograms, Fig. 8 and 9, show that $(en)_2RhHgOH^{2+}$ gives rise to a reduction wave having a peak potential between -500 and -600 mV while $[(en)_2Rh]_2Hg^{4+}$ is reduced between -800 and -900 mV. Thus the reduction wave

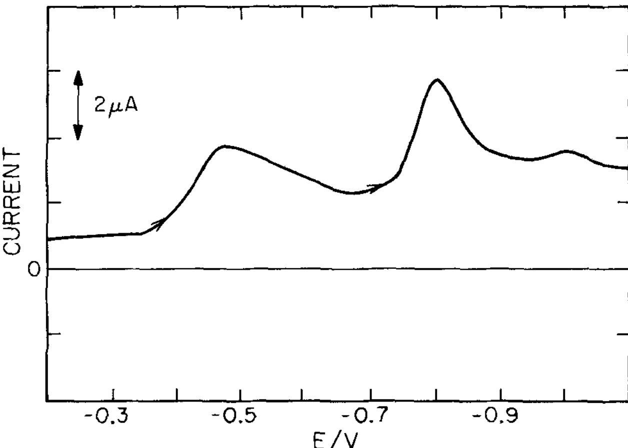

Fig. 8. Voltammogram for $(en)_2RhHgOH^{2+}$. Conc. of complex, 1 mM. Supporting electrolyte: 0.1M CH_3SO_3Na, 0.1M NaOH. Scan rate: 0.46 V/sec.

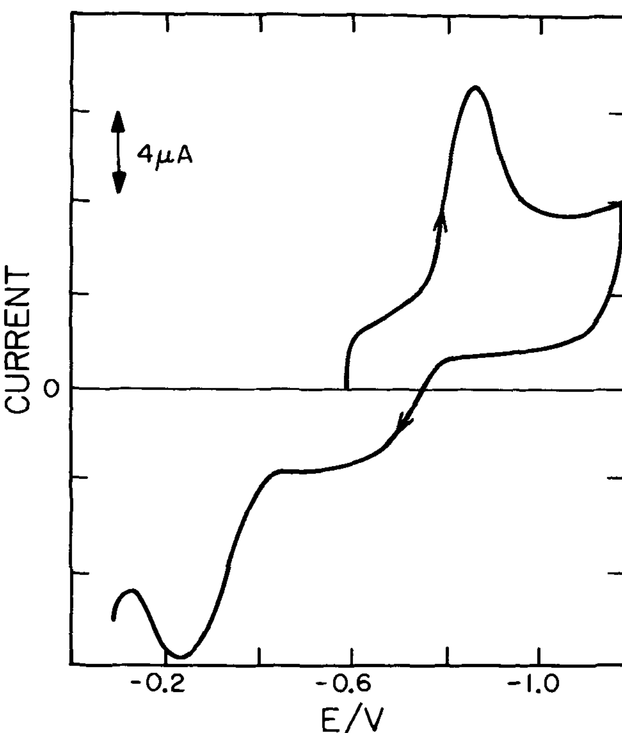

Fig. 9. Cyclic voltammogram for $(en)_2RhHgRh(en)_2^{4+}$. Conc. of complex: 0.5 mM. Supporting electrolyte: 0.1M CH_3SO_3Na, 0.1M NaOH. Scan rate: 4.6 V/sec.

near −500 mV in Fig. 7 can be attributed to reaction [7]

$$(en)_2RhHgOH^{2+} + 2e^- \rightarrow Rh(en)_2^+ + Hg + 2\ OH^- \quad [7]$$

and the wave near −800 mV to reaction [8]

$$[(en)_2Rh]_2Hg^{4+} + 2e^- \rightarrow 2Rh(en)_2^+ + Hg \quad [8]$$

Although $[(en)_2Rh]_2Hg^{4+}$ is not present in the solution used to record Fig. 8, a reduction wave for this complex appears because it is formed in the diffusion layer next to the electrode by reaction between $(en)_2RhHgOH^{2+}$ and the $Rh(en)_2^+$ that is generated at the electrode during the first reduction wave

$$(en)_2RhHgOH^{2+} + Rh(en)_2^+ \rightarrow [(en)_2Rh]_2Hg^{4+} + OH^- \quad [9]$$

Controlled potential electrolysis of alkaline solutions of $(en)_2RhHg(OH)^{2+}$ at −1000 mV produced results that are consistent with this interpretation. The concentration of $(en)_2RhHg(OH)^{2+}$, determined spectrophotometrically (8) during the course of the electrolysis, decreases linearly with the quantity of electricity consumed while the concentration of $[(en)_2Rh]_2Hg^{4+}$ increases. The maximum concentration of the latter is reached after approximately 1 Faraday of charge/mole of complex has been consumed, at which point the concentration of $(en)_2RhHgOH^{2+}$ has become essentially zero. Continued electrolysis at −1000 mV requires an additional Faraday per mole of rhodium and converts all of the $[(en)_2Rh]_2Hg^{4+}$ into $Rh(en)_2H(OH_2)^{2+}$.

The foregoing results allow the oxidation wave appearing near −300 mV in Fig. 7 during an initially positive potential scan with alkaline solutions of $Rh(en)_2H(OH_2)^{2+}$ to be ascribed to reactions [5] and [6] occurring at potentials too close together to yield separate waves. The same reactions are also presumed to account for the oxidation waves observed during the second, oxidative portion of the cyclic voltammograms of *trans*-$Rh(en)_2Cl_2^+$ (Fig. 1) and *trans*-$Rh(en)_2ClOH^+$ (Fig. 2) because $Rh(en)_2H(OH_2)^{2+}$ and (therefore) $Rh(en)_2^+$ are generated at the electrode during the initial reductive potential scan. The oxidation wave exhibits a peak potential that is more negative (*ca.* −300 mV) at *p*H 14 (Fig. 7) than in less alkaline solutions (*ca.* −50 mV in Fig. 1). This *p*H dependence could result from the *p*H dependence of equilibrium (2) that produces the $Rh(en)_2^+$ intermediate as well as from the direct involvement of hydroxide in the second stage of the oxidative electrode reaction (Reaction [6]).

Possible adsorption of $Rh(en)_2^+$.—The strong tendency for $Rh(en)_2^+$ to behave as a Lewis base to form rhodium-mercury bonds (8) made it seem likely that this complex would be adsorbed on the surface of mercury electrodes. To examine this possibility, chronocoulometric experiments were conducted with solutions of $Rh(en)_2H(OH_2)^{2+}$ at *p*H values from 5.3 to 14 in the expectation that equilibrium (2) would provide a source of $Rh(en)_2^+$ in these solutions. Single potential steps were applied to the electrode from various initial values (between −1200 and −400 mV) to the most positive value possible at each *p*H without producing direct oxidation of the electrode to give $Hg(OH)_2$. The charge-time data resulting from each potential step were recorded every 200 μsec. (Table I shows a typical set of data points obtained, in this case, at *p*H 14.) Examination of the data on a point-by-point basis reveals that the initial rate of charge consumption is quite large, exceeding in some cases the rate at which the bulk complex could be directly oxidized under diffusion limited conditions (Table I). However, the high initial rates diminish within a few hundred microseconds to values far below the diffusion limited values. This pattern of charge-time behavior is consistent with the presence of an adsorbed complex, *e.g.*, $Rh(en)_2^+$, whose rate of oxidation is limited by charge-transfer kinetics at the most positive accessible potentials. The rapid decline in the rate of accumulation of charge indicates that when the adsorbed complex is oxidatively removed its rate of replenishment from the reservoir of unreacted $Rh(en)_2H(OH_2)^{2+}$ complex is quite low.

Inasmuch as we were unable to find conditions where diffusion controlled oxidation rates could be sustained, the chronocoulometric data could not be analyzed in the usual way by plotting the charge *vs.* $(time)^{1/2}$ and extrapolating to zero time to determine the quantity of adsorbed reactant (9). Instead, the first data point, recorded 200 μsec following the positive potential step, was taken as an approximate measure of the quantity of adsorbed complex. The double-layer charging blank, measured by stepping the potential between the same two values in rhodium-free electrolyte, was subtracted from the first data point to obtain approximate values for the adsorption. This procedure will underestimate the amount of adsorption if the rate of oxidation of the adsorbed complex is too low for the reaction to be complete in 200 μsec, but the fact that the rate of charge accumulation is considerably smaller by the time 400 μsec has elapsed (Table I)

Table I. Charge-time data during the oxidation of a 1.06 mM solution of $Rh(en)_2H(OH_2)^{2+}$ at −200 mV in 1M NaOH

Time, msec after potential step	Charge,[a] μcoulombs/cm² for initial potentials (mV) of −1200	−1000	−800	−600	−400	Calculated charge for a two-electron diffusion controlled case
0.2	8.1	16.2	19.3	13.9	8.6	9.0
0.4	10.3	19.6	22.7	17.1	10.9	12.7

20.0	15.8	24.8	27.7	24.0	16.4	90.0

[a] The double-layer charging blanks, $Q_{d.l.}$, were subtracted from the charge values at each potential.

makes this an unlikely source for serious error. An overestimate of the adsorption will result if the true double-layer charging blank is diminished by the adsorption or if significant unadsorbed reactant diffuses to the electrode during the first 200 μsec. Neither of these sources of possible error appeared to be significant enough to affect the qualitative features observed.

The fact that the oxidative current falls rapidly to very low values could reflect a sluggishness in the rate of reaction [2]. Mild evidence against this interpretation was obtained by extending the measurements to much longer times and observing no significant increase in the slopes of the charge-(time)$^{1/2}$ plots. An alternative possible origin of the brevity of the oxidation currents is that the product of the oxidation of the adsorbed complex is itself adsorbed. This could result in a sizable diminution in the rate of an oxidation reaction which required the formation of mercury-rhodium bonds by depriving the rhodium complex of access to the mercury surface.

Figure 10 summarizes the estimated adsorption as a function of initial potential and solution *p*H. In converting the measured charges into moles of adsorbed complex it was assumed that the electrode reaction releases two electrons per molecule of $Rh(en)_2^+$, *i.e.*, that the net reaction product is $(en)_2RhHgOH^{2+}$. The uniform increase in adsorption with *p*H is the strongest evidence for the suggestion that the adsorbing species is $Rh(en)_2^+$ formed via the equilibrium expressed in reaction [4].

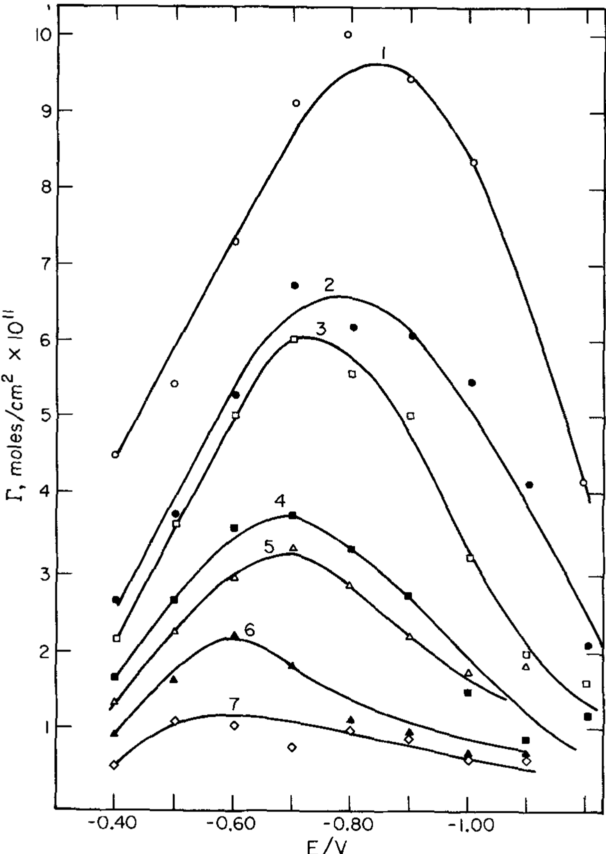

Fig. 10. Approximate adsorption of what is thought to be $Rh(en)_2^+$ (see text) as a function of *p*H and electrode potential. The solution contained 1.06 mM $Rh(en)_2H(OH_2)^{2+}$, 1M CH_3SO_3Na, and NaOH to adjust the *p*H. The plotted values of Γ are based on the total charge passed 200 μsec after an anodic potential step was applied less the double-layer charging blank. The initial potentials are plotted as abscissa. The final potentials and *p*H values were: curve 1, −200 mV, *p*H 14; curve 2, −150 mV, *p*H 13; curve 3, −150 mV, *p*H 11.9; curve 4, −50 mV, *p*H 10.8; curve 5, −50 mV, *p*H 10.1; curve 6, +100 mV, *p*H 9; curve 7, +100 mV, *p*H 5.3.

The dependence of the adsorption on the initial electrode potential lacks a ready rationalization. The decrease in the adsorption at the most positive potentials no doubt results from the partial oxidation of the adsorbed complex at the initial potential because small anodic currents were obtained at initial potentials of −500 or −400 mV in these solutions. The decrease in adsorption at the most negative potentials may be a reflection of the Lewis acid base nature of the adsorption reaction. The Lewis acidity of the mercury surface will be a function of its charge density, increasing at positive charges and declining at negative charges (15). At the most negative charge densities the formation of the rhodium-mercury adsorption bond may be hindered because the mercury based orbitals into which the rhodium(I) complex donates electrons becomes increasingly occupied.

Whatever the origin of the potential dependence of the adsorption, it is worth noting that it may afford a simple and direct means for generating high local concentrations of (unadsorbed) $Rh(en)_2^+$. Exposing a mercury electrode to a solution of $Rh(en)_2H(OH_2)^{2+}$ at potentials between −600 and −800 mV appears to result in the adsorption of $Rh(en)_2^+$. If the potential is now stepped in the negative direction to, say, −1200 mV, a portion of the adsorbed complex should be desorbed but no faradaic reduction current will flow. If suitable substrates are added to the solution, it may be possible to observe an enhancement in their rates of (*e.g.*, oxidative addition) reaction with the $Rh(en)_2^+$ because of its transiently increased concentration. Experiments to test this possibility are planned.

Chronocoulometry of $[(en)_2Rh]_2Hg^{4+}$.—In alkaline solutions $[(en)_2Rh]_2Hg^{4+}$ can be oxidized (reaction [6]) as well as reduced (reaction [8]). Figure 11 shows charge-(time)$^{1/2}$ plots for the reduction reaction at several potentials. The slopes correspond to a two-electron, diffusion controlled reduction and the small intercepts indicate little or no adsorption of the complex. By contrast, when the potential is stepped to values where the complex is oxidized, the chronocoulometric plot (Fig. 12) displays a large intercept indicative of substantial adsorption of an oxidizable species. The slope of the plot corresponds to a two-electron, diffusion controlled oxidation reaction. A possible explanation for this superficially discrepant behavior takes advantage of the fact that adsorbed $Rh(en)_2^+$ will contribute to the intercepts of anodic but not to cathodic chronocoulometric plots because it is not reduced. Adsorbed $Rh(en)_2^+$ may be produced at intermediate potentials in alkaline solutions of $[(en)_2Rh]_2Hg^{4+}$ as follows

$$[(en)_2Rh]_2Hg^{4+} + OH^- \rightarrow (en)_2RhHgOH^{2+} + Rh(en)_2^+ \quad [10]$$

Reaction [10] resembles reaction [2] and the resulting $Rh(en)_2^+$ would adsorb on the electrode and contribute to anodic but not cathodic chronocoulometric intercepts. The fact that the apparent adsorption of $Rh(en)_2^+$ is larger in solutions of $[(en)_2Rh]_2Hg^{4+}$ than in solutions of $Rh(en)_2H(OH_2)^{2+}$ may reflect the difference in the equilibrium quotients for reactions [2] and [10].

Note that reduction of solutions of $[(en)_2Rh]_2Hg^{4+}$ at −1200 mV will produce high local concentrations of $Rh(en)_2^+$ from the combination of the desorption of the initially adsorbed $Rh(en)_2^+$ and the faradaic reduction of $[(en)_2Rh]_2Hg^{4+}$ according to reaction [8]. Thus, solutions of this cation offer another route to $Rh(en)_2^+$ which has the advantage [over the previously described desorptive route via $Rh(en)_2H(OH_2)^{2+}$] that the $Rh(en)_2^+$ can be generated

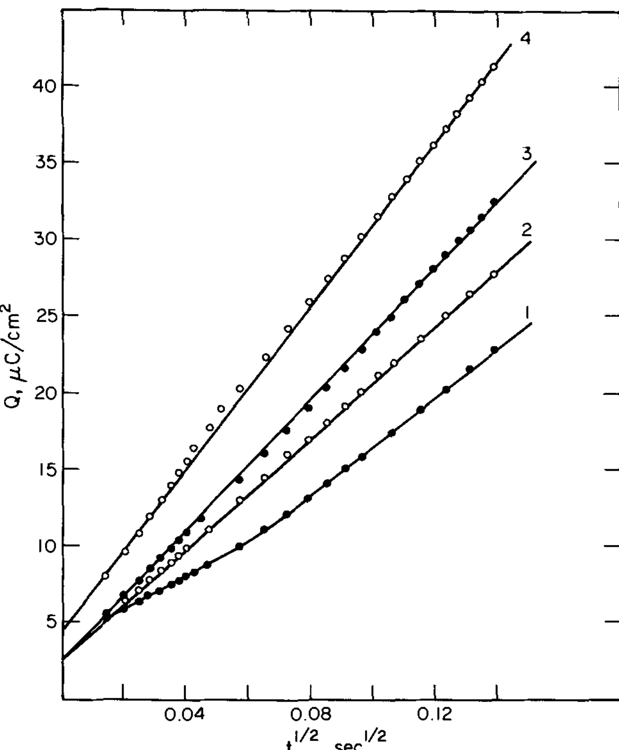

Fig. 11. Chronocoulometric plots for the reduction of $(en)_2RhHgRh(en)_2^{4+}$. Conc. of complex: 0.57 mM. Supporting electrolyte: 1M CH_3SO_3Na, 0.1M NaOH. The double-layer charging blank, $Q_{d.l.}$ was subtracted from each point. Initial potential: —600 mV. Final potential (mV): curve 1, —900; curve 2, —1000; curve 3, —1100; curve 4, —1200.

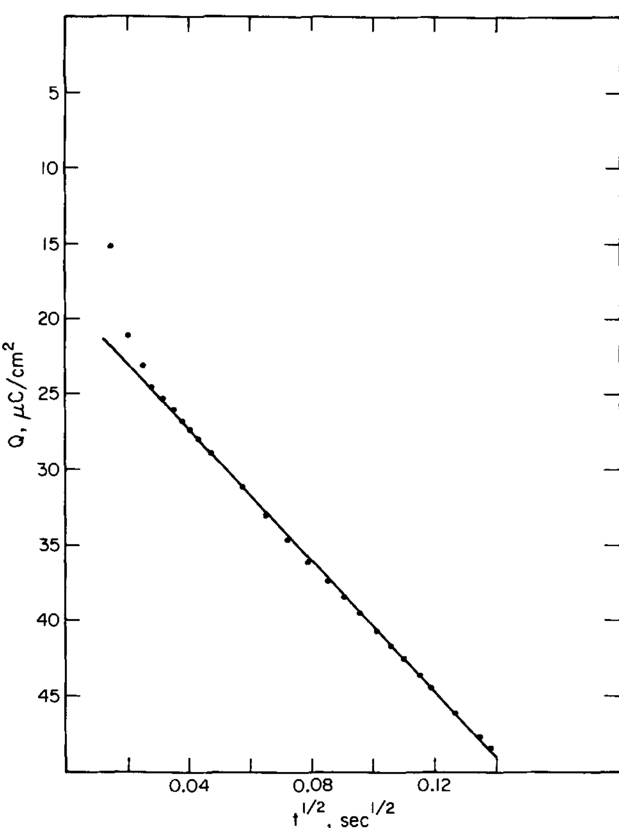

Fig. 12. Chronocoulometric plot for the oxidation of $(en)_2RhHgRh(en)_2^{4+}$ at —150 mV. All other conditions as in Fig. 11.

steadily at a rate limited only by the diffusion of the mercurated complex to the electrode surface.

When $[(en)_2Rh]_2Hg^{4+}$ is reduced at intermediate potentials (−700 or −800 mV) the currents are smaller than the diffusion limited current and their time dependence gives evidence of an apparent inhibition of the electrode process by a product of the reaction. The adsorption of $Rh(en)_2^+$ which is maximal at these potentials (Fig. 10) would produce an electrode surface bearing a net positive charge (the quantity of adsorbed cations exceeds the negative electronic charge) that could easily result in a sharp decrease in the rate of reduction of a tetrapositive reactant, $[(en)_2Rh]_2Hg^{4+}$, because of its repulsion from the diffuse double layer. Such an effect would also help to account for the previous observation (8) that $[(en)_2Rh]_2Hg^{4+}$ is slowly reduced at −700 mV although this is also the potential where the same complex can be generated during the reduction of *trans*-$Rh(en)_2Cl_2^+$ via reactions [1] and [5]. During the initial stages of such an electrolysis when the concentration of $Rh(en)_2^+$ is largest, its adsorption on the electrode could be responsible for the temporary inhibition of reaction [5] while reaction [1] proceeds. Later, when the *trans*-$Rh(en)_2Cl_2^+$ has been largely consumed, the concentration of $Rh(en)_2^+$ at the electrode surface will be smaller and its adsorption will decrease which could lead to an increase in the rate of reduction of $[(en)_2Rh]_2Hg^{4+}$ as its repulsion from the diffuse layer diminishes. Additional measurements are needed to verify this line of speculative reasoning but the evidence clearly indicates the presence of some kind of inhibitive coupling between the electrode reaction and its product.

Anomalous cyclic voltammograms.—As mentioned earlier, most of the complexes studied exhibited unusual cyclic voltammetric behavior at higher concentrations and with scan rates that require several seconds for the recording of the voltammogram. Figure 13 is an example of the kind of voltammetric behavior typically observed under these conditions. The major anomalous feature in the voltammogram is the appearance of a reductive current peak during the oxidative half of the potential cycle. Often this feature is

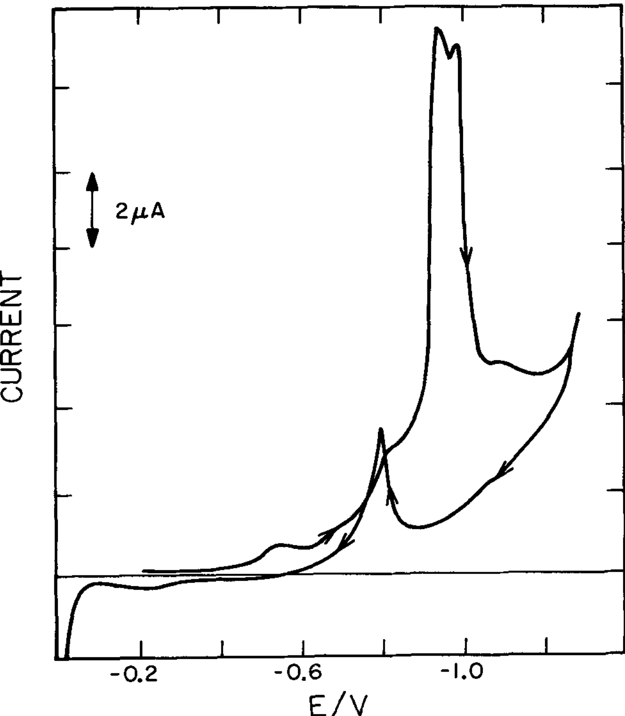

Fig. 13. Cyclic voltammogram for 0.9 mM *trans*-$Rh(en)_2Cl_2^+$ at a low scan rate: 0.18 V/sec. All other conditions as in Fig. 1.

preceded by the appearance of several, less prominent current peaks during the reductive half of the potential cycle. Such "wrong-way" current peaks in cyclic voltammograms have been previously reported in a variety of systems (16-19), especially those involving the generation of free radicals capable of spontaneous reactions with mercury electrode surfaces to yield organomercurial products (16-18). Although we were usually able to find conditions (high scan rates, low concentrations) where these anomalies were absent, it seems worthwhile to report their prominence under other conditions and to express our concurrence with the suggestion (16) that their origin is related to that of polarographic maxima, namely convective stirring of the electrode-electrolyte interface (20). The sudden changes in interfacial tension usually associated with such stirring of the interfacial region are accentuated by rapid changes in the concentrations of adsorbing species, $Rh(en)_2^+$ in the present case. The fact that the "wrong-way" current peaks appear at just the potentials where the chronocoulometric data show the greatest adsorption of $Rh(en)_2^+$ adds support to this interpretation, as does the similarity between the chemistry of organic radicals and $Rh(en)_2^+$, both of which attack mercury electrodes to produce mercurated products (8, 16, 18).

Acknowledgments

Electromigrational Depletion (ED) Chronopotentiometry Temperature Dependence of Diffusion in Molten BeF_2-LiF

C. E. Vallet,[1] H. R. Bronstein, and J. Braunstein

Chemistry Division, Oak Ridge National Laboratory, Oak Ridge, Tennessee 37830

ABSTRACT

New chronopotentiometric measurements with a Be anode in highly viscous molten 95 mole per cent BeF_2-5 mole per cent LiF mixture are described in the range of temperature 564°-704°C. The transition is a result of electromigrational depletion (ED) of mobile nonelectroactive lithium ions. The equation of the chronopotentiogram is derived with the linear phenomenological equations of the thermodynamics of irreversible processes. Interdiffusion coefficients are derived from analysis of emf-time data along the chronopotentiograms rather than from a transition time alone. The low values, 3×10^{-9}-3×10^{-7} cm^2/sec and high Arrhenius energy, 50.5 kcal/mol, are compared with the results of molecular dynamics computer experiments and the values of other transport coefficients in this and related systems.

Transport and thermodynamic properties of beryllium fluoride-alkali fluoride mixtures are of interest in connection with theories of ionic liquids and structural relationships to silicates and other glass-forming systems. Although studies of thermodynamic properties (1), transference numbers (2), and electrical conductance (3) have been reported for BeF_2-rich fluoride systems, little diffusional behavior has been reported, except for recent molecular dynamics (MD) computer experiments (4).

Recently we have shown that on the basis of unicationic conduction (2) in MF-BeF_2 mixtures (by M^+ relative to F^-) a chronopotentiometric transition is expected, and was demonstrated, at a Be anode in molten BeF_2-rich mixtures containing NaF (5). The transition is a result of electromigrational depletion of mobile nonelectroactive alkali ions rather than, as in ordinary chronopotentiometry (6), faradaic depletion of electrically immobile electroactive constituents (5).

[1] On leave from the Laboratoire de Thermodynamique, Associe au C.N.R.S., Universite de Provence, France.

Key words: beryllium electrode, BeF_2 distillation apparatus, glasses, irreversible thermodynamics, transference number.

This phenomenon, which we shall term ED, has been observed also with an aluminum anode in alkali chloride-aluminum chloride melts (7). Mutual diffusion coefficients were estimated from measured transition times with the Sand equation (6), which had been derived approximately for ED chronopotentiometry (5). The calculations also required estimation of the activity coefficients and the electrode areas (5, 7).

In this paper we derive the equation of the chronopotentiogram more rigorously with the linear phenomenological equations of the thermodynamics of irreversible processes (8), considering the possible coupling between migrational and diffusional flows and focusing attention on the assumptions in the derivation. We also present new chronopotentiometric data at five temperatures in the system 95 mole per cent (m/o) BeF_2-5 m/o LiF for which activity coefficient data are available (1). Beryllium anodes of known area and geometry were employed. We present the computation of the diffusion coefficient from emf-time data along the chronopotentiogram, rather than from the transition time alone. Finally, we discuss the resulting diffusion coefficients and their temperature dependence in the light of the MD computer experiments and the values of other transport coefficients in this system.

ED Anodic Chronopotentiometry of Be in BeF_2-Rich Mixtures with Alkali Fluorides

Conditions for ED chronopotentiometry.—The distinction between ED and ordinary chronopotentiometry may be indicated with reference to Fig. 1, which illustrates schematically the various flows in a voltammetric experiment with a binary electrolyte mixture, here LiF-BeF_2. In chronopotentiometry a constant current is caused to flow between a working electrode or indicator electrode and a counterelectrode. The potential is measured between the indicator electrode, which becomes concentration polarized, and a reference electrode (or reference half cell) through which no current flows. The indicator electrode current may be made anodic or cathodic, depending on the properties of the system and the aim of the investigation.

In ordinary chronopotentiometry (6) the electroactive constituent is present at very low concentration in a supporting electrolyte. The function of this supporting electrolyte is to suppress migration of the dilute electroactive solute whose electrical mobility may be as high as or higher than that of one of the supporting electrolyte's ionic constituents. Under these circumstances the transference number of the constituent

$$t_i = \frac{e_i Z_i c_i' u_i}{\sum_j e_j Z_j c_j' u_j} \quad [1]$$

where the e are the signs of the ionic charges (± 1), the Z are ionic charge magnitudes, u the mobilities, and c' the molar concentrations, is constrained to be essentially zero. If the faradaic process at the electrode consumes the dilute electroactive constituent and convection is absent, only diffusion can resupply it to the electrode, since its electrical migration has been suppressed. As the diffusion layer extends further from the electrode surface, the region near the electrode becomes depleted of electroactive constituent and a sharp change of emf, or chronopotentiometric transition, occurs as a new faradaic process must take place to sustain the constant current. The current is carried by the supporting electrolyte which is present at high concentration. If the solute is sufficiently dilute, the supporting electrolyte also provides a uniform environment so that the activity coefficients do not change during the electrolysis.

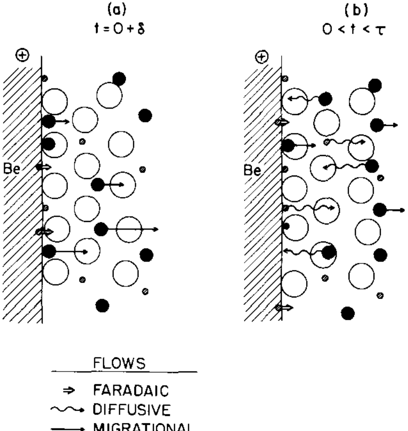

Fig. 1. Schematic representation of faradaic, diffusive, and migrational flows in anodic chronopotentiometry of Be in BeF_2-LiF mixtures. Ion constituents: ▨, Be^{2+}; ●, Li^+; ○, F^-.

ED chronopotentiometry is possible in a system where the electroactive constituent has very low electrical mobility relative to the reference constituent. For example, in molten LiF-BeF_2 mixtures, the transference number of Be^{2+} is zero and that of Li^+ is one, relative to fluoride, over a wide range of compositions (2). [In silicates (9) and in cryolite mixtures (10), the current is carried by alkali ions, and the situation is probably similar in alkali halide-aluminum halide mixtures (7).] When a constant anodic current is initiated at a Be electrode, the faradaic process is the formation of BeF_2 at the electrode surface. If the current relative to fluoride ion constituent is carried only by Li^+ ion constituent, the fluoride ions in the vicinity of the electrode would be depleted of Li^+ virtually instantaneously. However, back diffusion of Li^+ (actually interdiffusion of Be^{2+} and Li^+), driven by the concentration gradient, supplies Li^+ to the electrode to sustain the current, as illustrated in Fig. 1. The emf of the Be electrode relative to a reference electrode changes as electrolysis continues to form BeF_2. The emf undergoes an abrupt change when nearly all the Li^+ in the region near the electrode has been replaced by Be^{2+}. Electromigrational depletion of the nonelectroactive solute Li^+ is thus the characteristic feature of ED chronopotentiometry that is the analog of the faradaic depletion of electroactive constituent in ordinary chronopotentiometry. ED analogs of polarography, linear sweep voltammetry, and other electrochemical scanning methods should also be observable.

Phenomenological equations for binary systems.—Since the melt has only two components, a single diffusional flow is possible, mutual diffusion of LiF and BeF_2. In addition there is an electrical flow. Thus one might write the linear phenomenological equations in terms of these flows (5), the forces consisting of a gradient of chemical potential ($\nabla\mu$) and a gradient of electrical potential ($\nabla\psi$); but this formulation is nonsymmetric and does not in general satisfy the Onsager reciprocal relations.

The proper flows for symmetric formulation of the phenomenological equations may be derived from the dissipation function, Φ, written initially in terms of the flows of the ionic constituents lithium, beryllium, and fluoride. The forces are the gradients of electrochemical potential [$\nabla\tilde{\mu}_i = \nabla(\mu_i + \mathbf{F}e_iZ_i\psi)$] of these constituents. Thus

$$\Phi = J_L \nabla\tilde{\mu}_L + J_B \nabla\tilde{\mu}_B + J_F \nabla\tilde{\mu}_F \quad [2]$$

In order to simplify the equations, the flows (J_i), concentrations (c_i), chemical potentials (μ_{ij}), and electrochemical potentials ($\tilde{\mu}_i$) will be taken to refer to equivalents rather than moles.[2]

[2] The equations are thus applicable to charge unsymmetric binary mixtures as well as to mixtures of univalent salts without the need for carrying the ionic charge magnitudes through the derivation. Note, however, that the chemical potential per equivalent will be simply the molar chemical potential divided by the number of eqivalents, e.g., $\mu_{BF} = \frac{1}{2}\,\mu_{BeF_2}{}^{(m)}$ so that the activity coefficients need not be redefined to correspond to an equivalent fraction concentration scale.

The flows of Li^+, Be^{2+}, and F^- are related to the current density

$$J_L + J_B - J_F = I/\mathbf{F} \quad [3]$$

and the ionic electrochemical potentials may be combined to give the chemical potentials of the components

$$\mu_{LF} = \tilde{\mu}_L + \tilde{\mu}_F; \quad \mu_{BF} = \tilde{\mu}_B + \tilde{\mu}_F \quad [4]$$

The two chemical potential gradients are related through the Gibbs-Duhem equation

$$c_L \nabla\mu_{LF} + c_B \nabla\mu_{BF} = 0 \quad [5]$$

The dissipation function, with flows all written relative to any common reference frame, becomes

$$\Phi = [J_B - (c_B/c_L)J_L - I/\mathbf{F}]\nabla\mu_{BF} + I/\mathbf{F}\,\nabla\tilde{\mu}_B \quad [6]$$

The appropriate phenomenological equations, incorporating the Onsager reciprocal relation, may be written[3]

$$-[J_B{}^F - (c_B/c_L)J_L{}^F - I/\mathbf{F}] = \mathfrak{D}\nabla\mu_{BF} + L\nabla\tilde{\mu}_B \quad [7]$$

$$-I/\mathbf{F} = L\nabla\mu_{BF} + K\nabla\tilde{\mu}_B \quad [8]$$

where the flows are taken relative to fluoride ion constituent. The left-hand side of Eq. [7] may be simplified using Eq. [3], and the gradient of electrochemical potential can be eliminated by combining Eq. [7] and [8] to give

$$(1 + c_B/c_L)J_L{}^F = (\mathfrak{D} - L^2/K)\,\nabla\mu_{BF} - (L/K)I/\mathbf{F} \quad [9]$$

Identification of the phenomenological coefficients.—The conventional transport coefficients may be related to the phenomenological coefficients in the usual way. Thus Eq. [8] reduces, with $\nabla\mu_{BF} = 0$, to Ohm's law, whence

$$K = \kappa/\mathbf{F} \quad [10]$$

where κ is the specific conductance. Division of Eq. [7] or [9] by $I/\mathbf{F}$ and allowing the chemical potential gradient to vanish shows that

$$L/K = -(1 + c_B/c_L)t_L{}^F \quad [11]$$

where $t_L{}^F = [J_L{}^F/(I/\mathbf{F})]|_{\nabla\mu_{LF}=0}$ is the Hittorf transference number of lithium relative to fluoride. Similarly, the term $\mathfrak{D} - L^2/K$ may be related to the Fick's law mutual diffusion coefficient, D, in the volume fixed frame of reference if the partial equivalent volumes are constant.

$$D = -\frac{J_B{}^V}{\nabla c_B} = -\frac{J_L{}^V}{\nabla c_L} \quad [12]$$

From Eq. [7] and [8], noting that the left-hand side of Eq. [7] is independent of reference frame and $\mu_{BF} = \mu_{BF}{}^\circ + RT \ln c_B f_{BF}$

$$(\mathfrak{D} - L^2/K) = -\frac{J_B{}^V - (c_B/c_L)J_L{}^V - \left(\frac{L}{K} + 1\right)\frac{I}{\mathbf{F}}}{(RT\Gamma/c_B)\nabla c_B} \quad [13]$$

where

$$\Gamma = \left(1 + \frac{d \ln f_{BF}}{d \ln c_B}\right) \quad [14]$$

The equivalent concentrations and partial equivalent volumes are related as

$$c_B\overline{V}_B + c_L\overline{V}_L = 1; \; \overline{V}_B\nabla c_B + \overline{V}_L\nabla c_L = 0;$$

$$\overline{V}_F = \frac{c_L\overline{V}_L + c_B\overline{V}_B}{c_L + c_B} \quad [15]$$

[3] Although the friction coefficient formalism is now frequently employed, we found the derivation in terms of the flow coefficients simpler in this case and more closely related to the measured transport parameters. In any case, these are insufficient data to calculate the entire set of ionic friction or flow coefficients for the LiF-BeF_2 system. The development, however, somewhat parallels Laity's general treatment in the friction coefficient formalism (8b, c).

Combining Eq. [13], [12], and [15], and allowing I to vanish

$$(\mathfrak{D} - L^2/K) = D(1 + c_B\overline{V}_B/c_L\overline{V}_L)c_B/RT\Gamma \quad [16]$$

Mutual diffusion coefficient.—Substitution of Eq. [11] and [16] into Eq. [9] leads finally to the relations between the current density, concentration gradient, and mutual diffusion coefficient[4]

$$J_L{}^F = -D\frac{\overline{V}_F}{\overline{V}_B}\frac{\partial c_L}{\partial x} + t_L{}^F I/\mathbf{F} = -D\frac{\partial c_L}{\partial \xi} + t_L{}^F I/\mathbf{F} \quad [17a]$$

$$I\Big|_{J_L{}^F = 0\,(x=0)} = \mathbf{F}J_B{}^F\Big|_{(x=0)} = \mathbf{F}(D/t_L{}^F)\left[\frac{\overline{V}_F}{\overline{V}_B}\right]\frac{\partial c_L}{\partial x} = \mathbf{F}(D/t_L{}^F)\frac{\partial c_L}{\partial \xi} \quad [17b]$$

In the above equations, ξ is a distance variable such that equal increments $d\xi$ contain equal numbers of fluoride, $d\xi = (\overline{V}_B/\overline{V}_F)dx$. Equation [17b] provides one of the boundary conditions for the system, since $J_L{}^F$ must vanish at the electrode surface ($x = 0$), as no lithium ion constituent crosses the electrode surface. $\overline{V}_F$ is the equivalent volume of the mixture. Differentiation of Eq. [17a] with respect to the distance variable leads to the analog of Fick's second law (11). In the first approximation, constancy of D, $t_L{}^F$, and $\overline{V}_F$ are assumed.

$$\frac{\partial c_L}{\partial t} = \frac{\partial}{\partial \xi}D\frac{\partial c_L}{\partial \xi} - I/\mathbf{F}\frac{\partial t_L{}^F}{\partial \xi} \cong D\left[\frac{\overline{V}_F}{\overline{V}_B}\right]\frac{\partial^2 c_L}{\partial x^2} \quad [18]$$

The other boundary condition is that of semi-infinite linear plane diffusion

$$c_i(x \to \infty) = c_i{}^0,\; 0 < t < \infty \quad [19]$$

where the superscript zero refers to the initially uniform concentration. The initial condition is also the usual one of initially uniform composition

$$c_i(t = 0) = c_i{}^0,\; 0 < x < \infty \quad [20]$$

In the system LiF-BeF_2, as in many binary molten salt mixtures, the partial equivalent volumes (12) are constant so that the single volume fixed Fick's law diffusion coefficient applies. In the LiF-BeF_2 system, furthermore, the partial equivalent volumes are very nearly equal, so that the bracketed term in the boundary condition Eq. [17b] is very close to unity. If also $t_L{}^F = 1$, the diffusion equation together with the initial and boundary conditions reduce to those for ordinary chronopotentiometry (6); however, D cannot be considered constant since the medium composition and viscosity change drastically during the chronopotentiogram. As a first approximation, nevertheless, we calculate, with the Sand equation an average value of D or (more correctly) of

$$\overline{D/t_L{}^{F^2}} \qquad \overline{D/t_L{}^{F^2}}\left[\frac{\overline{V}_F}{\overline{V}_B}\right]$$

which we shall designate $\overline{D}$.

In a subsequent paper we shall analyze the concentration dependence of the diffusion coefficients as determined from the mean values obtained with differing initial melt compositions. Here we shall be concerned principally with the above mean value calculated from the chronopotentiogram.

Computation of the Mean Diffusion Coefficient

Equation of the chronopotentiogram.—Although $\overline{D}$ may be calculated from a measured transition time

[4] The same result (Eq. [17b]) would be obtained with flows written in the volume fixed frame of reference as in Eq. [13] since, at the electrode surface ($x = 0$), $J_B{}^V = I/\mathbf{F}$ and $J_L{}^V = 0$.

with the Sand equation, there are several reasons why it seems worthwhile to analyze the experimental chronopotentiograms avoiding the graphical concept of transition time (13) and, rather, to focus on the early portion of the chronopotentiogram rather than only the later portion. As Bos and Van Dalen (14) have pointed out for ordinary chronopotentiometry, the final part of a chronopotentiogram is very sensitive to various errors involving, *e.g.*, the geometry of the cell, convection in the melt, and capacity current. In ED chronopotentiometry, especially in systems such as LiF-BeF_2, there is the additional complication that large changes of D and of t_L may occur in the composition region near that corresponding to the transition time, here pure BeF_2.

The emf along the chronopotentiogram (corrected for the IR drop) may be obtained by integration of Eq. [8] and has been shown to be given (2, 5, 15) by

$$\frac{2\mathbf{F}E}{RT} = \left[\ln\frac{y}{(1-y)^2} - \ln\frac{y_o}{(1-y_o)^2}\right]\overline{t_L{}^F} + \frac{2\mathbf{F}E^E}{RT} \quad [21]$$

where y is the mole fraction of BeF_2 (the zero subscript referring to the initial composition) and the second term of the right-hand side is the "excess term" calculated from activity coefficient data. If the transference number varies with composition, $\overline{t_L{}^F}$ represents its mean value. Here we proceed with the assumption $t_L{}^F = 1 - t_B{}^F = 1$. Equation [21] may be solved numerically by successive approximations to give the concentration as a function of time

$$y(t) = \mathbf{F}(E,t,E^E(y(t)))$$

The diffusion coefficient can then be calculated at each time (or each concentration) from the chronopotentiometric expression for the concentration at the electrode surface for a constant diffusion coefficient (5, 6).

$$c_{LiF} = c^0{}_{LiF} - \alpha t^{1/2} \quad [22]$$

where $\alpha = (2/\pi^{1/2})I/(\mathbf{F}\bar{D}^{1/2})$ and the equivalent concentrations are related to the mole fraction as indicated previously (5).[5]

Excess term.—In the absence of the excess term in Eq. [21] it is possible to solve Eq. [21] explicitly for the concentration as a function of time from the emf values as a function of time along the chronopotentiogram. Although the contribution from nonideality is small for high BeF_2 content melts, the computation presented here takes it into account, so that this procedure can be applied without change at lower BeF_2 contents. From the data given by Hitch and Baes (1) between 500° and 700°C, the activity coefficient of LiF, γ_{LiF} on the mole fraction scale, for solutions dilute in LiF, *i.e.*, between 85 and 100% BeF_2, is well described by

$$\ln \gamma_{LiF} = \text{constant} + 5.34y \quad [23]$$

The Gibbs-Duhem relation leads to the relation for the activity coefficient of BeF_2 in this composition range

$$d \ln \gamma_{BeF_2} = -5.34\left(\frac{1-y}{y}\right)dy \quad [24]$$

and the "excess term" becomes (5)

$$\frac{2\mathbf{F}E^E}{RT} = -5.34(\ln(y/y_o) + (y - y_o)) \quad [25]$$

Diffusion coefficient.—In practice, some 10-25 (E, time)$_i$ pairs were read from a recorded chronopotentiogram. The combination of Eq. [21] and [25] was solved by computer successive approximations to give a set of (time, y)$_i$ pairs. The final value of y_i is approached to better than 5×10^{-11}, and this precision was found necessary for the description of the chronopotentiograms at long times.

The corresponding (time, c_{LiF})$_i$ pairs also were calculated and, by applying Eq. [22], a diffusion coefficient $\bar{D}_i$ corresponding to each (E, time)$_i$ pair was obtained. The results of these computations will be presented later as plots of $\bar{D}$ *vs.* c_{LiF} and $\bar{D}$ *vs.* time.

[5] It should be noted that $\bar{V}_B$ refers to the partial equivalent volume of BeF_2 in this paper and V_{BeF_2} referred to the partial molar volume of BeF_2 ($\bar{V}_{BeF_2} = 2\bar{V}_B$) in Ref. (5).

Experimental

Apparatus.—Instrumentation.—Measurements were made with a modified Q2943-cyclic voltammeter (16), designed and built at the Oak Ridge National Laboratory and operated in the chronopotentiometric mode with a three-electrode system, the counterelectrode being grounded. Readout of the voltage-time curve was on a Minneapolis-Honeywell X-Y recorder with 11 × 18 in. chart paper.

Cell.—The cell, shown in Fig. 2, was of all-metal construction except for Teflon insulators in the cool region, boron nitride spacers which were not in contact with melt, and beryllium oxide insulators for the beryllium working electrodes. The cell containing the molten fluoride mixture was a crucible of nickel into which dipped the electrodes and thermocouple well. The cell envelope, of stainless steel, was in two sections, fitted with a Teflon O-ring and bolted together to provide a vacuum-tight seal. The upper part of the container was water cooled and the cover was provided with risers for entry of the electrodes, thermocouple well, manual stirrer, gas entry and exit, and a port for sample additions. The latter port was provided with a ball-valve to which a sample container could

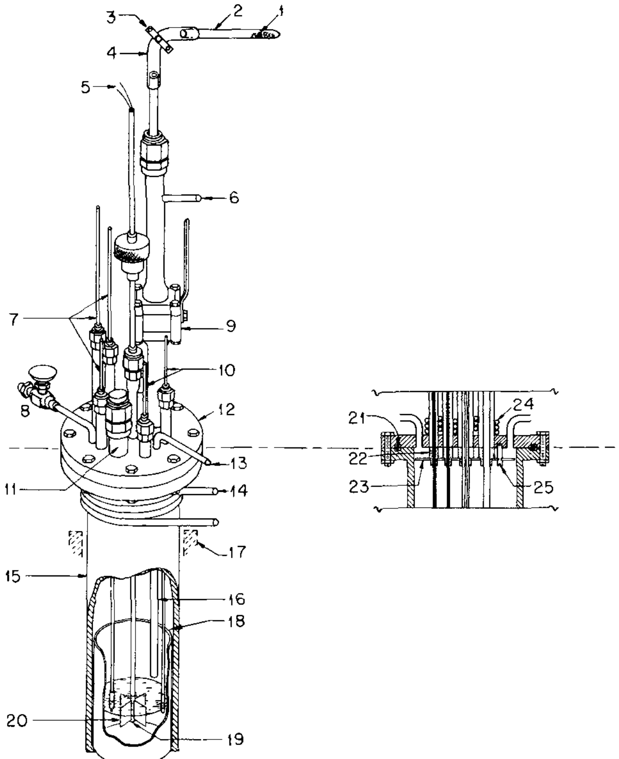

Fig. 2. All metal cell and container assembly for chronopotentiometry in LiF-BeF_2. 1, LiF crystals; 2, glass tubing; 3, pinch clamp; 4, Teflon tubing; 5, thermocouple leads; 6, helium or vacuum inlet; 7, working electrodes; 8, valve; 9, ball valve; 10, reference electrodes; 11, reserve port; 12, stainless steel flange, 13, helium or vacuum inlet; 14, cooling water; 15, stainless steel container; 16, sample tube; 17, Marshall furnace (3½ in. core); 18, nickel crucible; 19, thermocouple junction; 20, manual stirrer; 21, Teflon O-ring; 22, boron nitride spacer; 23, stainless steel support for boron nitride spacers; 24, cooling coils (not shown on perspective drawing); 25, support (typical of three).

be connected, evacuated, and sparged with cover gas before opening the valve and adding the sample. The electrode leads could be moved vertically through Teflon sleeves in the Swage-Lok[6] fittings. The sample-addition port also permitted insertion of a new electrode if necessary. The cell was heated in a Marshall furnace, with automatic temperature control provided by a Leeds and Northrup DAT controller and Chromel-Alumel thermocouple. Temperature measurements of the melt were made with a Chromel-Alumel thermocouple using a precision Rubicon potentiometer and a Brown Electronik recorder having a full scale chart span of 1 mV.

Electrodes.—The counterelectrode was the crucible itself, in electrical contact with the grounded cell container. The reference electrode was a beryllium rod (about 2 mm in diameter and 2 cm in length, threaded to a nickel rod). Working electrodes, as illustrated in Fig. 3, were employed after several previous attempts to provide a well-defined area. The machined solid cylindrical beryllium slug, the top of which was machined to a conical taper, was attached to a threaded tantalum rod through a cylindrical copper spacer so that thermal expansion would not loosen the tight fit of the beryllium slug against the beryllium oxide insulator. An uninsulated beryllium rod was apparently wetted by the salt, resulting in a gradually changing area. Although an inert metal lead such as tantalum should in principle not interfere with the anodic chronopotentiograms, erratic results and spurious emf readings resulted from electrodes without the BeO insulators. With only Be and BeO exposed to the melt, reproducible chronopotentiograms were obtained over long periods of time. The geometric area of exposed beryllium was calculated from micrometric measurements and measurements with an optical microscope of the dimensions. A typical area was about 0.28 cm^2.

Materials.—Chemicals employed were single-crystal chips of optical grade LiF from Harshaw and twice-distilled BeF_2. The distillation apparatus of all nickel construction employed to purify the beryllium fluoride is illustrated in Fig. 4. The BeF_2 was loaded into the upper cup which had a center tube for insertion of the thermocouple well of the outer jacket when the apparatus was assembled. The unit as shown was raised into a rigidly mounted Marshall furnace by means of laboratory jacks. A Chromel-Alumel thermocouple in the upper well permitted control of the distillation temperature. The still was evacuated to a pressure of several microns of mercury and the distillation of the BeF_2 was accomplished by maintaining the temperature of the upper cup at 850° while the lower funnel and receiving cup were maintained at about 300°. The condensate of BeF_2 on these cooler surfaces was in the form of a fine powder. At the end of the distillation period, usually 2-3 days, the powder was treated with an HF-H_2 mixture and then sparged with He. The apparatus was then raised farther into the furnace and the temperature in the region of the funnel and receiving cup was adjusted so that the BeF_2 would melt and collect in the receiving cup. The unloading of the apparatus was done in a large dry box. A typical analysis of the optically clear material showed the following elements detected (concentration in ppm): K, 7; Li, 15; Na, 70; Ca, 20; Mg, 3; Mn, 16; Cr, 10; Ti, 5.

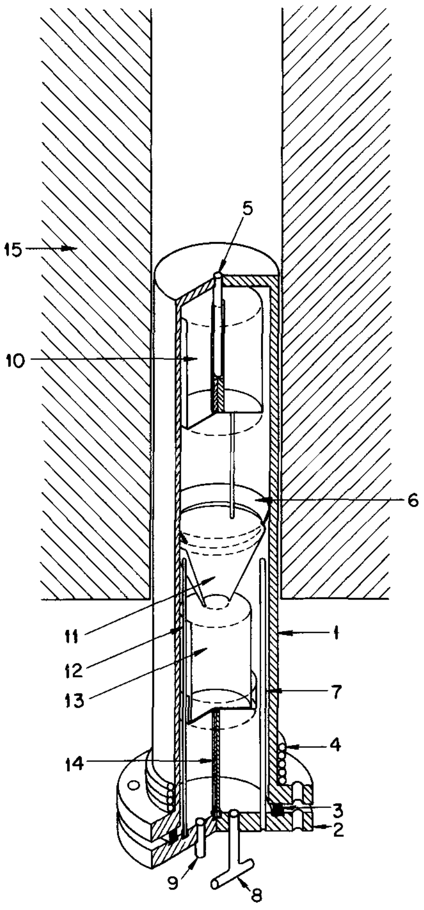

Fig. 4. Nickel apparatus for purification of BeF_2 by hydrofluorination, sublimation, and melting under vacuum. 1, Nickel container vessel (ca. 3¼ in. × 14 in.); 2, bottom flange; 3, Teflon O-ring; 4, cooling coils for water circulation; 5, thermocouple well which fits into the upper cup, 10, sleeve; 6, permanent guide welded to container wall to prevent material from dropping elsewhere than into the funnel, 11, and thence into the lower cup, 13; 7, thermocouple well for measuring temperature near funnel; 8, gas or vacuum entry; 9, exit for gases; 10, upper (loading) cup; 11, funnel; 12, support members for funnel and upper cup; 13, lower (receiving) cup; 14, support and holder for lower cup, 13; 15, furnace (3½ in. core).

Procedure.—The chronopotentiograms were run anodically in a conventional manner, but since the instrument operates from a fixed initial potential of the working electrode, this potential was first adjusted precisely to the open-circuit voltage of the cell consisting of the working and reference electrode. This was generally within a few millivolts of zero since both electrodes are of beryllium, but it was found essential to avoid current flow through the electrode prior to the chronopotentiogram for reproducible results. Cathodic half-cycles showed no migrational depletion transition (5), nor would one be expected from the theory of ED with $t_L^F = 1$. The initial *IR* drop in cathodic half-cycles was very close to that in the anodic half-cycles. Following a chronopotentiogram, the emf was monitored, with occasional manual stirring, during the decay of the cell emf to a steady near-zero value before the next chronopotentiogram.

Results

Chronopotentiograms.—The above experimental and computational procedure were used for the temperature dependence study of interdiffusion coefficients in molten LiF-BeF_2 mixtures of high BeF_2 content. The composition was 95 m/o BeF_2, and the temperature range was 564° to 704°C. As reported by Cantor *et al.* (12), viscosity of the melts increases drastically with increasing BeF_2 content. According to their data, the melt studied here has a viscosity at 600°C of about 5.7×10^3 P; this high viscosity probably accounts for the reproducibility of fairly long time chronopotentiograms without interference by convection.

Typical chronopotentiograms are shown in Fig. 5. First of all, they demonstrate the reproducibility of recordings obtained under identical conditions at different times. During the week separating the recording of the two chronopotentiograms, measurements were performed at higher and lower temperatures with the same melt and electrodes.

The chronopotentiograms are characterized by an initial *IR* drop corresponding to the low specific conductance expected for BeF_2-rich LiF-BeF_2 melt from data (3) for 34 to 70 m/o BeF_2 and for pure BeF_2 (17). The initial rise is correspondingly smaller for chronopotentiograms at lower BeF_2 contents. Although the initial *IR* drop is appreciable, we believe that the variation during the course of the chronopotentiogram is not. Successive chronopotentiograms at short time intervals show virtually the same *IR* drop even when the successive transition times decrease markedly because the higher BeF_2 concentration at the electrode surface has not had time to decay to the bulk concentration. When the concentration has become uniform, as indicated by a constant low emf value between working and reference electrode, both *IR* drop and over-all chronopotentiogram show reproducibility comparable to Fig. 5.

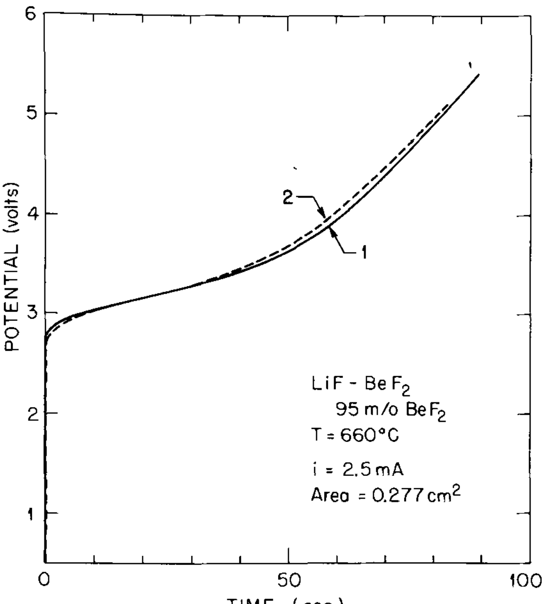

Fig. 5. Typical recorded chronopotentiograms taken eight days apart: temperature, 660°C; current, 2.5 mA; current density, 0.009 A/cm².

The initial rise is very rapid and showed no evidence of significant charging current for time scales down to 2-3 sec even with an oscilloscope. However, at long times the chronopotentiograms do not rise sharply. This lack of sharpness may have a contribution from a charging current and from convection, but must also be due to the fact as the melt composition in the vicinity of the electrode approaches pure BeF_2 the transference number of Be(II) must approach unity unless other constituents (*e.g.*, trace impurities or electrons) become significant for current transport relative to fluoride. In any case the assumption $t_B^F = 0$ probably becomes invalid for pure BeF_2. Because of the voltage output characteristics of the cyclic voltammeter, the high resistance of the melt prevented the use of higher current densities which would provide shorter transition times, and even with low current densities, as shown in Fig. 5, the recording of the potential at higher times was limited. In melts of lower BeF_2 content this problem is reduced, and transition times of the order of 10 sec or less are feasible. Clearly, graphical determination of a transition time would be uncertain and might lead to erroneous values of the diffusion coefficient.

Diffusion coefficients.—The chronopotentiograms for 95 m/o BeF_2 were analyzed by first calculating $\overline{D}$ and c_{LiF} (the concentration at the electrode surface) from the recorded emf-time data with Eq. [21], [22], and [25], and plotting $\overline{D}$ *vs.* t or $\overline{D}$ *vs.* c_{LiF}. The sensitivity of the calculated values to experimental errors varied. Thus, an error in temperature of as much as 5°, or in the zero of time of as much as 1 sec, would have virtually no effect. Variations in reading the initial *IR* drop had appreciable effects at very short times, decreasing rapidly with time. An error in the electrode area or initial composition had relatively little effect at short times, and an increasing effect at longer times. A plot of $\overline{D}$ *vs.* c_{LiF} calculated from the chronopotentiograms in Fig. 5 is shown in Fig. 6 along with points calculated with variations of 10% in the electrode area, 0.5 m/o in the initial composition, 50 mV in the initial *IR* drop, 5° in temperature and 1 sec in the time. Although the effect of an error in area or initial composition is large at low c_{LiF} (long times), extrapolation to the bulk concentration nevertheless leads to values of $\overline{D}$ in agreement with the other calculations. Too large an estimated *IR* drop leads to exceptionally high values of $\overline{D}$ at very short times, and too low an estimate gives low values of $\overline{D}$ at very short times.

This behavior was useful for checking the consistency of the estimated *IR* drop. In addition, plots of *IR* drop *vs.* current, when data for different currents were available, showed the expected proportionality, and the slope increased strongly with decreasing temperature, as seen in Fig. 7.

Figure 8 shows, as functions of time and of calculated LiF concentration, calculated diffusion coefficients obtained at 660°C with four different current densities. At each current density, as seen in Fig. 8a, the calculated $\overline{D}$ is found to increase, the rate of increase with time becoming faster with increasing current density. However, we do not believe that these variations with current density derive from convection or joule heat; for the results may all be superimposed and show no systematic variation with current density if compared in terms of the calculated values of c_{LiF} as seen in Fig. 8b. In the absence of further information

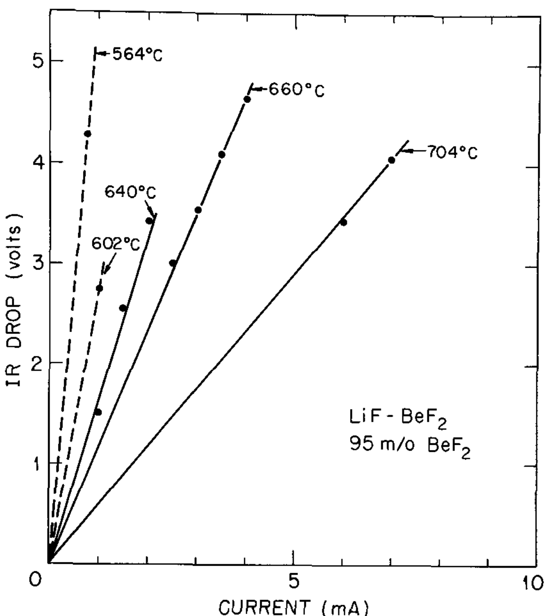

Fig. 7. IR drop vs. current at the five temperatures investigated

on the form of the variation of the diffusion coefficient (and transference number) with concentration, we initially focused on the nearly constant values of $\overline{D}$ obtained from the early part of the chronopotentiograms, but beyond the initial uncertainty of emf, in order to obtain values corresponding to melt composition as near 95 m/o BeF_2 as possible. (The region of near constancy in Fig. 6 and 8b, $\overline{D} = 6 \times 10^{-8}$ cm²/sec, is $10^{-3} > c_{LiF} > 10^{-4}$ and corresponds to BeF_2 concentrations $0.97 < y < 0.997$.) Because of uncertainties in the composition dependence and weighting, this seemed more appropriate than a least squares fit or extrapolation. It may be noted that the values of $\overline{D}$ are determined largely by the region of the chronopotentiogram near, but generally before, the inflection. A further refinement and check of the reasonableness of the values was made by comparison of the early portion of experimental chronopotentiograms with curves calculated for different constant diffusion coefficients.

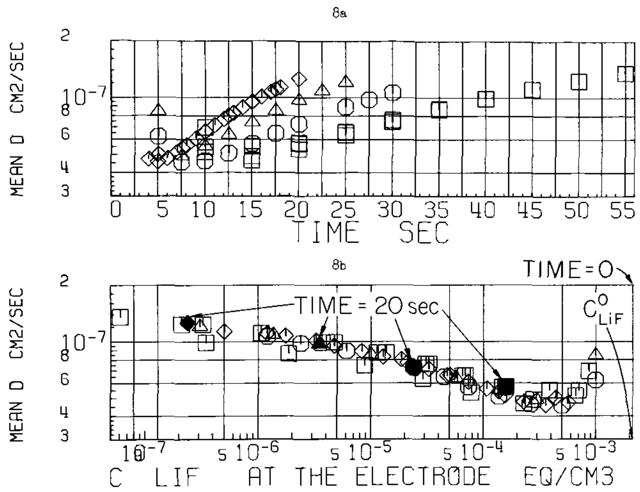

Fig. 8. Computer plots of interdiffusion coefficient $\overline{D}$ calculated from chronopotentiograms at 660°C with area = 0.277 cm² and current densities, A/cm². ◇, 0.0144; △, 0.0126; ⦶, 0.0108; ⊡, 0.0090. The abscissas are: (a, upper) time; (b, lower) LiF concentration at the electrode.

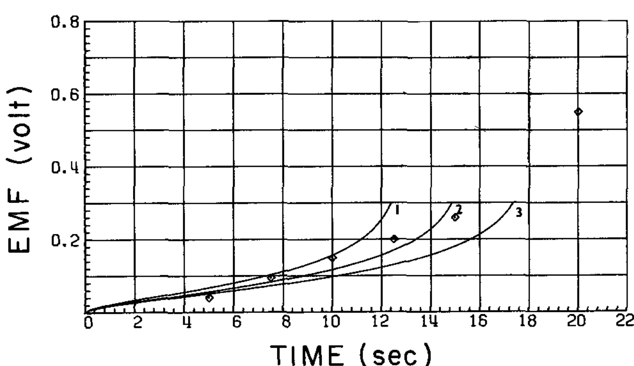

Fig. 9. Comparison of calculated and experimental chronopotentiograms with three values of constant *D*. The experimental points (◇) are for 0.95 BeF_2-0.05 LiF at 704°C. i = 7 mA, area = 0.277 cm²; ———, calculated chronopotentiograms: $\overline{D}$/cm²/sec = curve 1, 2.5 × 10^{-7}; curve 2, 3 × 10^{-7}; curve 3, 3.5 × 10^{-7}.

Figure 9 shows a comparison of points from an experimental curve, recorded at 704°C with a current of 7 mA, and chronopotentiograms calculated with $\overline{D}$ values of 2.5×10^{-7}, 3.0×10^{-7}, and 3.5×10^{-7} cm²/sec, showing that the value of $\overline{D}$ is between 2.5 and 3.0×10^{-7} (but closer to the former value). From similar calculations at this temperature with chronopotentiograms at the same and other current densities, the value of $\overline{D}$ is found to be $2.5 \pm 0.2 \times 10^{-7}$. Constancy of $\overline{D}$ with changing current density, shown by $\overline{D}$ *vs.* c_{LiF} plots for the 660° data in Fig. 8b, is indicated for the 640°C data by means of chronopotentiograms calculated with fixed $\overline{D}$ and compared with the experimental chronopotentiograms at different current densities in Fig. 10. These checks are analogous to the check of $i\tau^{1/2}$ product constancy in ordinary chronopotentiometry. The results at different temperatures are summarized in Fig. 11 and Table I. The value at the lowest temperature was obtained only from $\overline{D}$ *vs.* c_{LiF} plots, since the high resistivity at this temperature led to a very limited emf-time trace in the chronopotentiograms. Absolute errors of $\overline{D}$ may, indeed, be larger than the reproducibilities listed in Table I. As shown in Fig. 6, uncertainties in the initial *IR* drop, electrode area, and initial composition may have a significant effect in calculated $\overline{D}$ values in the region of near con-

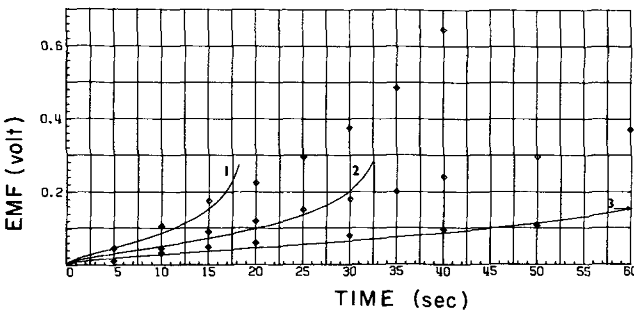

Fig. 10. Constancy of $\bar{D}$ with different current densities in 0.95 BeF_2-0.05 LiF at 640°C. The lines are calculated with a fixed value of $\bar{D}$, 3.0 × 10^{-8} cm^2/sec. Curve 1, i/mA = 2; curve 2, i/mA = 1.5; curve 3, i/mA = 1. The points are the experimental emf-time data.

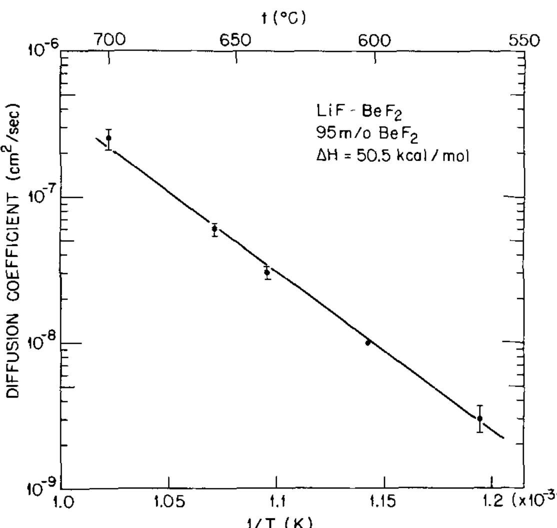

Fig. 12. Temperature dependence of interdiffusion coefficients in 95 m/o BeF_2, LiF-BeF_2, melt.

stancy of $\bar{D}$ in the $\bar{D}$ *vs.* c_{LiF} plots. The probable error in estimating the initial *IR* drop is ±5 mV which would lead to an additional uncertainty of about 2.5% in $\bar{D}$. An estimate of limits of error in the electrode area obtained by repeating the micrometric measurements was found to be of the order of 1%, corresponding to a 2% additional uncertainty in $\bar{D}$. The error in the bulk concentration was estimated from the weighing errors to be 0.03%, leading also to a possible error of about 2.5%.

In conclusion, we estimate the over-all uncertainties in mean diffusion coefficients to be between 5 and 10%. Since most of the above errors probably have small temperature dependence, they will introduce less error into the Arrhenius coefficient than into the absolute value of $\bar{D}$. In Fig. 12, values of interdiffusion coefficients are plotted logarithmically as a function of the reciprocal temperature. The results indicate a mean activation energy for diffusion of 50.5 (± ~0.5) kcal/mole. Within the estimated error limits, it is not possible to determine unambiguously whether the plot is linear or curved, but it may be noted also that logarithmic viscosity-reciprocal temperature or conductivity-reciprocal temperature plots show no or very little curvature (12, 17).

Discussion

The strong composition and temperature dependence of transport properties in BeF_2-LiF mixtures clearly indicate the need for measurements at more closely spaced initial compositions and temperatures in order to obtain reliable values. We believe that the reasonableness of the values reported here demonstrates the potential of ED voltammetry for such studies.

The high mean Arrhenius activation energy for diffusion, in 0.95 BeF_2-0.05 LiF, 50.5 kcal/mole in the temperature range 564°-704°C, reflects the high values of the temperature coefficients of other transport parameters in this system. Thus Cantor *et al.* (12) report activation energies for viscous flow of 40 kcal/mole for 95 m/o BeF_2, 52 kcal/mole for 99 m/o BeF_2, and 59.6 kcal/mole for pure BeF_2. The activation energy for electrical conductance (17) in pure BeF_2 is 44 kcal/mole. The values of $\bar{D}$ reported in this paper, obtained for mixtures of initial composition 95 m/o BeF_2, are calculated from the region of near constancy of $\bar{D}$ in the chronopotentiograms. This region, as noted above, corresponds to BeF_2 mole fraction at the electrode surface $0.97 < y < 0.997$.

The temperature coefficient of $\bar{D}$ is less sensitive than its absolute value to errors in electrode area and shape, but also to uncertainty in the transference number or the form of the concentration dependence of $\bar{D}$. Thus the same value of the activation energy is found if calculated from $\bar{D}$ at any fixed value of the calculated c_{LiF} at the electrode surface.

Regarding the shape of the electrode, the equations employed have been based on linear diffusion to a plane electrode, while the actual electrode was a short cylinder. The correction for cylindrical diffusion has been treated by Evans *et al.* (18) in terms of the index $\theta = D^{1/2} \tau^{1/2}/r_o$ (where r_o is the electrode radius). The value of θ is ~ 0.005 for a diffusion coefficient of 3 × 10^{-8} cm^2/sec in our system, indicating a correction less than 0.5%. Although the equations of Evans *et al.* cannot be expected to apply accurately to ED

chronopotentiometry of $LiF-BeF_2$ systems, the very low diffusion coefficients, although not constant, lead to very thin diffusion layers, even during times up to 20 and 30 sec. Figure 13 is a plot of calculated LiF concentration as a function of distance from the electrode at times between 0.05 and 24 sec (assuming $\overline{D} = 6 \times 10^{-8}$ cm²/sec) at 660°C and a current density of 0.0090 A/cm². The concentration rises from that at the electrode surface to the bulk concentration in shorter distances than in "ordinary" chronopotentiometry of dilute aqueous solutions with transition times below 2 sec (6a, b). These curves, together with the high viscosity, indicate why convection is not a serious problem even with fairly long times.

The diffusivity is expected to fall with increasing BeF_2 content in qualitatively the same manner as the electrical conductance and the fluidity. Hence the relatively small variation of $\overline{D}$ along the chronopotentiogram, with an increase indicated in, *e.g.*, Fig. 6, 8, and 11, was not at first expected. It may reflect a value of t_L^F decreasing faster than the decrease of D in the ratio $\overline{D/t_L^{F2}}$, and indicates the need for extension of transference number measurements to higher BeF_2 contents. Such measurements would be of interest also in connection with a distinction between mass transport mechanisms in silicate glasses and in fluoride glasses and crystals. In molten $LiF-BeF_2$ at compositions between 30 and 70 m/o BeF_2, as in molten silicates, the Hittorf transference number of the alkali ions is unity. In the silicate glasses, the alkali ion transference number (relative to the lattice) remains unity up to virtually pure silica, while for fluoride glasses and for fluoride crystals, fluoride ions rather than alkali ions are the current carriers (19).

The interdiffusion coefficients $D_{Li\text{-}Be}$ reported in Table I are smaller than diffusion coefficients measured in ordinary molten salt solutions (7, 20-22), but this is to be expected in view of the high viscosity and low electrical conductivity of these melts. (If the transference number of Be^{2+} becomes nonzero ($t_L^F < 1$), the calculated values of D would be still smaller.) Although to our knowledge, no direct measurements of diffusivities have been reported for binary $LiF-BeF_2$ melts, it is interesting to compare our results with conductance data and with self-diffusion coefficients calculated from molecular dynamics computer experiments for BeF_2-containing melts (4). It should be noted, however, that the authors of these MD computations have pointed out that at this stage the results for transport properties must be considered of a more qualitative nature than the structural data derived from their MD pair correlation functions (4).

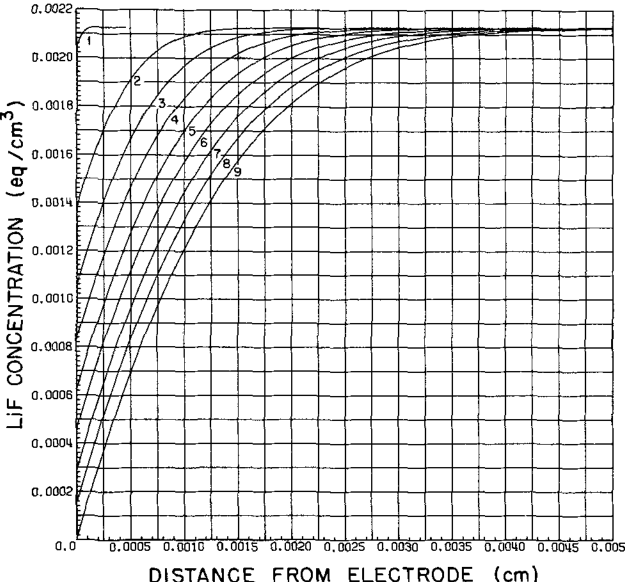

Fig. 13. LiF concentration vs. distance from electrode at different times during a chronopotentiogram at 660°C, D is assumed to be constant, 6×10^{-8} cm²/sec and the current is 2.5 mA. Curve 1, time = 0.05 sec; curve 2, time = 3.05 sec; curve 3, time = 6.05 sec; curve 4, time = 9.05 sec; curve 5, time = 12.05 sec; curve 6, time = 15.05 sec; curve 7, time = 18.05 sec; curve 8, time = 21.05 sec; curve 9, time = 24.05 sec.

As has been shown (8, 23), the interdiffusion coefficient approaches the self-diffusion coefficient of a constituent (here lithium ion) as its concentration approaches zero. Our chronopotentiometric diffusion coefficient, measured in 95 m/o BeF_2, is a mean value over the concentration range 95-100 m/o BeF_2, and should be close to the self-diffusion coefficient of Li^+. Because of the high activation energy it would be preferable to compare results at the same temperature. The MD computations for 74 BeF_2-1 LiF (98.7% BeF_2) (4) were carried out for only a single temperature, 837°K, the lowest for which we have experimental results. Here, our results were least precise because of the high resistivity, but are in accord with our higher temperature results.

Although the Nernst-Einstein relation is not expected to be accurate, it will probably not be off by an order of magnitude, and provides a means to compare the magnitudes of the diffusional mobilities estimated from available conductance data (3). Furthermore, it has been noted (24) for a number of molten salt systems that, as the temperature (and, consequently, the fluidity) decreases toward the glass transition temperature, and the density of mobile particles decreases correspondingly, the validity of the Nernst-Einstein equation approaches that for crystals. At higher temperatures the diffusional mobility becomes higher than the electrical mobility. The specific conductance may be expressed, in terms of external mobilities, u_i, as

$$\kappa = \mathbf{F}\,[(u_B/u_L)c_B - (u_F/u_L)c_F + c_L]u_L \quad [26]$$

where c_i's are in equivalents per cubic centimeter. If the reference frame is taken the same as that for the self-diffusion coefficient of an ion, D_i, the latter may be expressed (25) in terms of the Nernst-Einstein equation as

$$D_i = (RT/\mathbf{F})|u_i| \quad [27]$$

By combining Eq. [26] and [27], the specific conductance may be written in terms of self-diffusion coefficient as

$$\kappa = (\mathbf{F}^2/RT)\,[(D_B/D_L)c_B + (D_F/D_L)c_F + c_L]D_L \quad [28]$$

The specific conductance of pure BeF_2 (17) is 2.3×10^{-7} ohm^{-1}-cm^{-1} at 837°K, and the specific conductance of 95 m/o BeF_2 is assumed to be of the order of 10^{-5} ohm^{-1}-cm^{-1}. The MD calculations suggest a diffusion coefficient ratio of 1/10 for D_B/D_L and nearly equal self-diffusion coefficients for Be^{2+} and F^-, whence $D_F/D_L \approx 0.1$.

For pure beryllium fluoride at 1153°K, Eq. [28] becomes

$$\kappa = (\mathbf{F}^2/RT)\,[c_B + (D_F/D_B)c_F]D_B \quad [29]$$

and the result $D_F/D_B \approx 1$ of the MD calculations (4) was employed. The conductance value at 1153°K was estimated by extrapolation with the equation reported to fit the data in the range 800°-960°K.

For 50 m/o BeF_2, although here the Nernst-Einstein equation indubitably does not apply, conductance data (3) were extrapolated to the temperature of the MD computation, 1035°K.

Table II summarizes estimates of self-diffusion coefficients for several compositions in the BeF_2-LiF system.

In the 50% mixtures the estimated self-diffusion coefficient of Li^+ from the conductance results is of the same order of magnitude as the MD result, and of the magnitude expected in normal molten salts; these val-

Table II. Estimated self-diffusion coefficients in BeF_2-LiF

m/o BeF_2	Temperature/°K	Type of experiment	Self-diffusion coefficient/cm²/sec or N.E. self-diffusion coefficient
50	1035	Conductance[a]	$D_L = 5 \times 10^{-5}$
50	1035	MD[b]	$D_L = 2 \times 10^{-5}$

[a] From Ref. (3) extrapolated with fitting equation in the range 673°-803°K; D_B and D_F are estimated as $0.1 \times D_L$.
[b] From Ref. (4).
[c] From Ref. (3); conductance is estimated from pure BeF_2 data.
[d] From Ref. (3) extrapolated with fitting equation in the range 803°-963°K.
[e] Assuming MD result $D_B \simeq D_F$.

ues are quite close also to the voltammetric diffusion coefficient of U(IV) in a LiF-BeF_2-ZrF_4 solvent mixture containing 34% BeF_2 at 480°-600°C (22) where extrapolation to 1035°K would lead to a value of 1×10^{-5} cm²/sec. At high BeF_2 contents, and in pure BeF_2, the MD computations do not show as much of a decrease in magnitude as both the chronopotentiometric and conductance results. Although the comparison is only qualitative, it indicates the need for further theoretical and experimental work to resolve the discrepancy, particularly since MD is one of the most promising new tools for investigating models of molten salt structure and transport (26).

Finally we would like to point out other areas where the concepts of ED voltammetry may be useful. These may include studies of polarization and transport in membranes (27), in crystals such as sodium beta alumina (28) and in ionic glasses (29); however, in rigid glasses space charge phenomena, that are probably not significant in liquid systems, must be considered (29).

Migrational contribution to the chronopotentiometric transition in ordinary (faradaic depletion) chronopotentiometry has been considered previously (30) in terms of corrections to the Sand equation and enhancement of the transition. Chronopotentiometry in the absence of supporting electrolyte has been proposed as a means to determine transference numbers (31). In these cases, however, the basis of the chronopotentiometric transition has been the faradaic process. In contrast, as we have tried to indicate, the basis of ED chronopotentiometry is migrational depletion of a mobile nonelectroactive constituent.

Equivalent Circuit for the Uncompensated Resistances Occurring at Ring-Disk Electrodes

Mani Shabrang* and Stanley Bruckenstein**

Chemistry Department, State University of New York at Buffalo, Buffalo, New York 14214

ABSTRACT

An equivalent circuit for the ring-disk electrode is proposed and tested. The model assumes that the resistance between the auxiliary electrode and the disk (or ring) electrode is the series combination of two resistances. One resistance is shared by both the disk and the ring electrodes, whereas the other is characteristic of the disk (or the ring) electrode. Changing the position of the Luggin capillary tip produces different uncompensated ohmic potential drops. The *IR* drops can be interpreted by assuming that the tip of the Luggin capillary is being located somewhere on these resistances.

A detailed interpretation of results obtained at the rotating ring-disk electrode requires a thorough understanding of current and potential distributions in the electrochemical cell. This point is well appreciated at a rotating disk electrode and extensive theoretical and experimental work on this problem has been carried out (1-7). However, only Gabrielli *et al.* (8) and Miller and Bellavance (4) have investigated ohmic potential effects at ring-disk electrodes. In their studies they found that current passing through the disk electrode affected the ring electrode potential, and vice versa. Their results were represented by a set of linear equations involving the ring and the disk current and the electrode potentials. However, to our knowledge, no work has been done proposing and verifying a simple equivalent circuit for a ring-disk electrode that could serve as an experimental framework for further studies of ohmic potential effects.

This work is concerned with testing a proposed equivalent circuit for a ring-disk electrode where the ohmic and nonohmic components are represented as shown in Fig. 1. A conventional, four-electrode, ring-disk potentiostat (9-14) is assumed to be used. Point T represents the tip of the Luggin capillary which can be anywhere on resistances in the three branches of the equivalent circuit, and R_{aux} represents the resistance between the capillary and the auxiliary electrode.

An uncompensated resistance exists between the tip of the Luggin capillary and the disk electrode, $R_C + R_D$. Similarly an uncompensated resistance exists between the tip of the Luggin capillary and the ring electrode, $R_C + R_R$. R_C is assumed to be common to both the disk and the ring electrodes. The values of R_C, R_R, and R_D depend on the physical dimensions of

Key words: pseudocollection, resistance measurement, ohmic coupling.

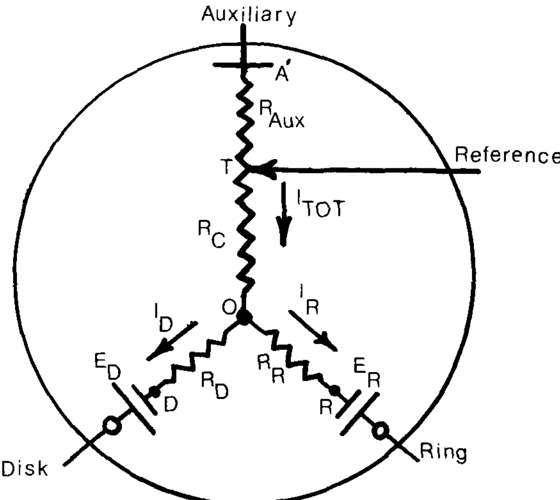

Fig. 1. Equivalent circuit of ring-disk electrode

the electrode and the location of the Luggin capillary. E_D represents the half-cell potential of the disk electrode and I_D is the disk current in question. E_R and I_R are the corresponding values for the ring electrode. E_D and E_R are assumed to contain all the impedances associated with double layer and faradaic processes. Thus, R_C, R_D, and R_R in the equivalent circuit are associated with the current distribution characteristic of the resistance measurement techniques. In our experiments, the current distribution was a primary one.

As is shown below, experiments can be devised to determine R_C and various combinations of R_C and the other resistances in Fig. 1. The number of independent experiments exceeds the number of unknown resistances in our model, hence the system is overdetermined and the validity of the equivalent circuit can be verified.

The utility of this equivalent circuit lies in the fact that it provides a framework for correcting ohmic potential effects of the ring on the disk electrode, and vice versa. This utility is only slightly diminished by the fact that changes in current distribution with potential will have a small effect in the measured value of the resistances.

It is, of course, necessary to keep in mind that the resistances referred to are calculated quantities, and that the fundamental analysis of the ring-disk system will eventually have to be done in terms of current distribution and ohmic potential drop.

Experimental

Reagents.—Solutions of 0.01*M* sulfuric acid were prepared from triply distilled water and a Baker reagent grade sulfuric acid.

Cell.—The glass cell and the auxiliary equipment are described elsewhere (15-16).

Electrodes.—The two electrodes used in the experiments were: (*i*) A platinum-ring, platinum-disk with a disk diameter, d_1, of 7.6 mm and ring-inner diameter, d_2, of 8.0 and ring-outer diameter, d_3, of 8.4 mm. Teflon was the insulating material. (*ii*) A platinum disk electrode with a diameter of 2.20 mm. Teflon was the insulator.

These electrodes were electrochemically pretreated before each experiment as discussed in Ref. (17), and were all polished to a final mirror finish using 0.05μ alumina on Buehler microcloth.

Instrumentation.—A lock-in amplifier, Model RJB made by Electronics and Missiles and Communication Inc., Mount Vernon, New York, was used for a-c studies.

Hewlett-Packard Model 3300A and Heathkit Model IG-18 function generators were used to supply the modulation signal and the reference signal of the lock-in amplifier.

All potentials were measured and reported *vs.* the saturated calomel electrode. Experiments were run at $25° \pm 2°C$.

Resistance measurements.—Small changes in the conventional four-electrode potentiostat, allowing independent control of the ring and the disk electrode potentials (9), convert it to an instrument that provides independent galvanostatic control of both the ring and the disk electrodes, Fig. 2. This circuit was used to determine R_C.

Measurements of the total resistive component of the impedance between the Luggin capillary and the ring or disk electrodes were carried out by means of a modulation technique using the lock-in amplifier at 1000 Hz. The arrangement for this measurement is

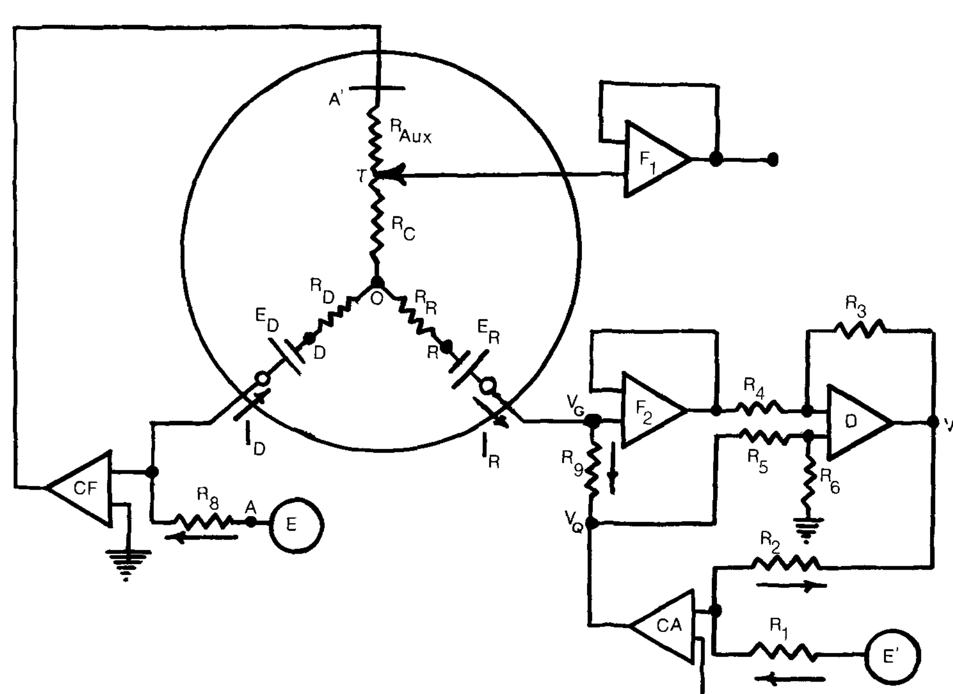

Fig. 2. Circuit for independent galvanostatic control of the ring and the disk electrode. The direction of the current inside and outside of the cell is shown.

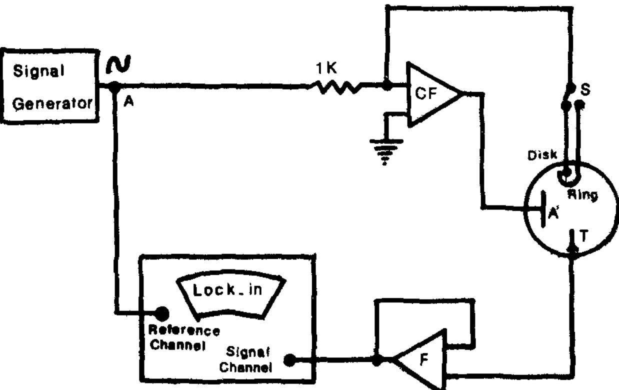

Fig. 3. Schematic of the a-c modulation technique used to measure the uncompensated resistance for the disk and ring electrodes.

shown in Fig. 3. A 0.5-2V a-c signal was applied at the point A resulting in an a-c current of 0.5-2 mA through the auxiliary electrode and the ring or the disk electrode. The uncompensated a-c ohmic potential drop appears at the output of amplifier F.

The resistance between the ring and the disk electrodes was measured using the arrangement shown in Fig. 4. Its value is the ratio of the in-phase component of V_O and i. The operational amplifier follower F is used to measure the potential of point O in the equivalent circuit of Fig. 1.

The Luggin capillary was positioned, by eye, to lie on the axis of rotation, unless otherwise stated.

Theoretical

Determination of R_C.—The potentials at the points O, T, and D in Fig. 1 are represented by V_O, V_T, and V_D. If the ring current, I_R, is zero we can write

$$V_T{}^{\circ\prime} - V_D = I_DR_C + I_DR_D \quad [1]$$

where I_D is the disk current and $V_T{}^{\circ\prime}$ is the potential at the point T when there is no ring current. Now if some current passes through the ring electrode and I_D is held constant, using Kirchhoff's current law at the point O, we can write

$$V_T - V_D = I_DR_C + I_RR_C + I_DR_D \quad [2]$$

Note that V_D, the potential of the disk electrode, does not change since I_D is constant even though the potential at point T has changed from $V_T{}^{\circ\prime}$ to V_T.

Subtracting Eq. [1] from Eq. [2] yields

$$V_T - V_T{}^{\circ\prime} = I_RR_C \quad [3]$$

The change in potential at point T is the same as change in the output of the operational amplifier follower F_1 in Fig. 2. Hence R_C can be determined from Eq. [3].

R_C can also be determined in a similar manner, if we hold I_R constant and control the disk current at two values, zero and I_D. In this case we measure $V_T{}^{\circ}$, where $V_T{}^{\circ}$ is the potential at T when $I_D = 0$, and we obtain

$$V_T{}^{\circ} - V_R = I_RR_C + I_RR_R \quad [4]$$

When current I_D is passed through the disk we write

$$V_T - V_R = I_RR_C + I_DR_C + I_RR_R \quad [5]$$

where V_R is the potential at point R. Note that since I_R does not change, V_R in Eq. [5] and [4] has the same value. Subtracting Eq. [4] from Eq. [5] yields

$$V_T - V_T{}^{\circ} = R_CI_D \quad [6]$$

Hence, we have two independent ways to determine R_C.

Note that if the Luggin capillary tip is positioned at a point in space equivalent to point O in Fig. 1, R_C is zero and $V_T - V_T{}^{\circ\prime}$ ($V_T{}^{\circ}$) in Eq. [3] (and [6]) is zero. If the Luggin capillary tip is positioned at a point in space that effectively lies on R_D (or R_R), $V_T - V_T{}^{\circ\prime}$ (or $V_T{}^{\circ}$) becomes a negative quantity and R_C appears to take on negative values. Such negative values have no physical significance and arise only due to formulation of the problem. In practice, the Luggin capillary tip must be placed very close to the plane of the rotating ring-disk electrode to observe these "negative resistances," and the quantitative aspects of this work will deal only with positive values of R_C.

Determination of R_D and R_R, the equivalent circuit associated with the a-c impedance measurements illustrated in Fig. 3, is shown in Fig. 5 (18). Point T corresponds to point T in Fig. 1 and 2, and point W in Fig. 5 corresponds to point D of Fig. 1 and 2 if the disk electrode is involved, or point R if the ring electrode is involved. R_{ohm} in Fig. 5 corresponds to the appropriate combination of uncompensated primary resistances, either $R_C + R_D$ or $R_C + R_R$. At high frequencies, only R_{ohm} determines the voltage difference between the reference and the working electrode and the total ohmic resistance between W and T is then given by

$$R_{ohm} = \frac{V_T}{I} \quad [7]$$

where V_T is the in phase voltage response measured by the lock-in amplifier and I is the modulation current. Thus R_D and R_R can be calculated by subtracting R_C from the corresponding R_{ohm} value.

If the disk and the ring electrodes are shorted together, according to the equivalent circuit in Fig. 1, the measured value of $R_{ohm,tot.}$ will correspond to R_C in series with the parallel combination of R_D and R_R, *i.e.*

$$R_{ohm,tot.} = R_C + \frac{R_DR_R}{R_D + R_R} \quad [8]$$

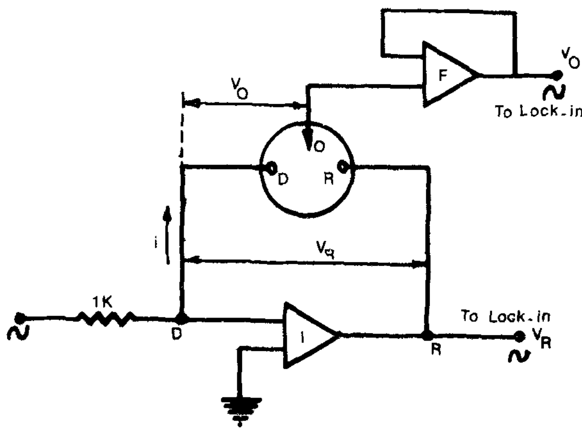

Fig. 4. Schematic of the setup for voltage divider test

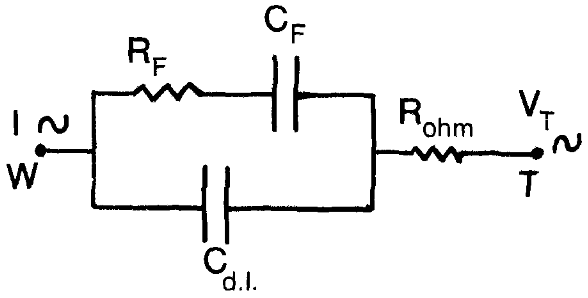

Fig. 5. Equivalent circuit for a-c measurements (18). C_F, R_F = faradaic capacitance and resistance, respectively; $C_{d.l.}$ = double layer capacitance; R_{ohm} = ohmic resistance; W = working electrode; T = reference electrode; I = modulation current; V_T = voltage response.

Another experiment to further confirm the validity of our model, involves passing current only through the disk and ring electrode with no current passing through the auxiliary. R_D and R_R then form a voltage divider between points D and R in Fig. 1 and the reference electrode can be used to determine the potential at point O. Equation [9] gives the relation between the uncompensated resistances R_D, R_R, and the measured potentials

$$\frac{R_D}{R_D + R_R} = \frac{V_O}{V_R} \quad [9]$$

V_O is amplitude of the a-c potential of point O, measured by operational amplifier follower F; V_R is the amplitude of the a-c output of the operational amplifier *I*, in phase with V_O. It is the a-c potential of the ring electrode *vs.* the disk electrode, which is at ground potential.

Results and Discussion

Resistance Common to Ring and Disk Electrodes

R_C was measured by the method described in the preceding section for a particular fixed distance between the ring-disk electrode and the Luggin capillary corresponding to a position in space lying between O and A′ in Fig. 1. The values of R_C were calculated using, as it was appropriate, either Eq. [3] or [6]. Table I gives the results found with electrode No. 1 in 0.01*M* sulfuric acid, and it is seen that the precision of the measurements approaches 2% with increasing current level. The direction of the current does not affect the calculated value of the common resistance, and thus confirms the ohmic behavior of R_C.

In their experiments, Gabrielli *et al.* (8) measured two resistances, $R_R{}^D$ and $R_D{}^R$, which they called the coupling resistance of the ring on the disk and the disk on the ring, respectively. The values of these two resistances were reported to be within 5% of each other, and for a primary current distribution presumably correspond to the value of the common resistance, R_C, in our equivalent circuit. Also, their resistances $R_R{}^R$ and $R_D{}^D$ should correspond to R_R and R_D, respectively.

The values of R_C decreased the closer the tip of the Luggin capillary was placed to the surface of the ring-disk electrode. We found that up to a distance of nearly 5 mm, R_C values calculated using either of the methods based on Eq. [3] or Eq. [6], were equal to each other.

Total Uncompensated Ohmic Resistance

Disk electrode.—The modulation technique for determining the uncompensated ohmic resistance that is represented in Fig. 3 was tested by using disk electrode No. 2 in 0.01*M* sulfuric acid (specific conductivity $\kappa = 0.00616$ ohm^{-1}-cm^{-1}) in the current range of 0.5-2.0 mA. The Luggin capillary was placed at different distances, all far from the disk electrode, and the in-phase uncompensated ohmic potential drop between the tip of the Luggin capillary and the disk electrode was measured using a-c currents of 0.5-2.0 mA about a zero current level. At 1000 Hz, the calculated mean resistance, R_x, was 377 ± 4 ohms in agreement with Newman's formula (1) which predicted 369 ohms. The results of all a-c measurements were reproducible in the range of frequencies between 100 Hz and 10 kHz.

Ring-disk electrode.—The above results validated the a-c technique of Fig. 3 as a reliable method for determining uncompensated ohmic potential drops, *i.e.*, the primary resistance. Next, R_x was determined for the disk of ring-disk electrode No. 1, yielding a value of $R_x = 96 \pm 2$ ohms. If the ring of this electrode is insulated from the solution using varnish, $R_x = 110 \pm 2$ ohms, which compares favorably with the theoretical value for a 7.6 mm diameter disk electrode, 107 ohms (1). The decrease of R_x produced by a ring electrode is in the expected direction, when one qualitatively considers the changes in the potential field produced by a conductor in the insulating plane surrounding the disk electrode. The effect of the ring electrode on the disk electrode primary resistance prevents us from using Newman's formula (1) in the interpretation of results presented below.

Next, the modulation technique was applied using electrode No. 1 to determine $R_C + R_D$, $R_C + R_R$, and $R_C + R_D R_R/(R_D + R_R)$ for six locations of the Luggin capillary by placing switch S in Fig. 3 in the appropriate position, or by shorting the ring to disk electrode with the switch in either position. R_C was determined simultaneously as described in the preceding section. The results are given in Table II, where $R_{ohm,tot.} = R_C + R_D R_R/(R_D + R_R)$.

Values of R_D and R_R were calculated from the initial values of R_C and R_{ohm}. These values of R_C, R_R, and R_D were then used to calculate $R_{ohm,tot.}$, and agree well (1-2%) with the value measured when the ring and disk are shorted.

Table III shows the results of the experiment carried out to verify Eq. [9] for runs 2, 4, and 5 of Table II. In the last entry of Table III the ring and disk were interchanged such that the output of the operational amplifier I, V_D, was the potential of the disk *vs.* the virtually grounded ring electrode. The results are in good agreement with the predicted values.

Effect of R_C, R_D, and R_R on I-E Curves at Ring-Disk Electrode

An uncompensated voltage drop equal to $(I_D + I_R)R_C$ will be shared between the disk and the ring. This common uncompensated *IR* drop will have a significant effect on the *I-E* curves obtained simultaneously for the disk and the ring electrodes. For example, if ΔI_D and ΔI_R represent changes in the disk and the ring current, respectively, the potential of the ring electrode will vary by an amount $R_C(\Delta I_D + \Delta I_R) + R_R \, \Delta I_R$. Thus a changing disk current will produce a change in the ring potential sufficient to change the ring current by ΔI_R. If the ring electrode is potentiostated on the rising portion of an *I-E* curve, ΔI_R will change markedly as opposed to the change when the

ring potential is on a limiting current region. An example of this phenomenon is shown in Fig. 6 where the ring electrode, being potentiostated on the rising portion of the hydrogen evolution curve, behaves as if it is collecting a soluble species being generated at the disk electrode.

Similar effects, presumably due to such an interaction, were studied by Gabrielli *et al.* (8) using ring-disk electrodes of different dimensions in the case of the anodization of iron in 2*N* sulfuric acid. Miller and Bellavance (4) also considered such interactions, using a potentiometric ring-disk experiment.

Rapid changes in current at the disk electrode will produce a rapid change in potential at the ring electrode as a result of the change in potential of the ring electrode double layer capacitance, so that even in the absence of a faradaic ring electrode process a current will flow in the ring electrode circuit. This phenomenon has been observed by Albery (19) in his studies of ring electrode current when an a-c current is passed through the disk electrode.

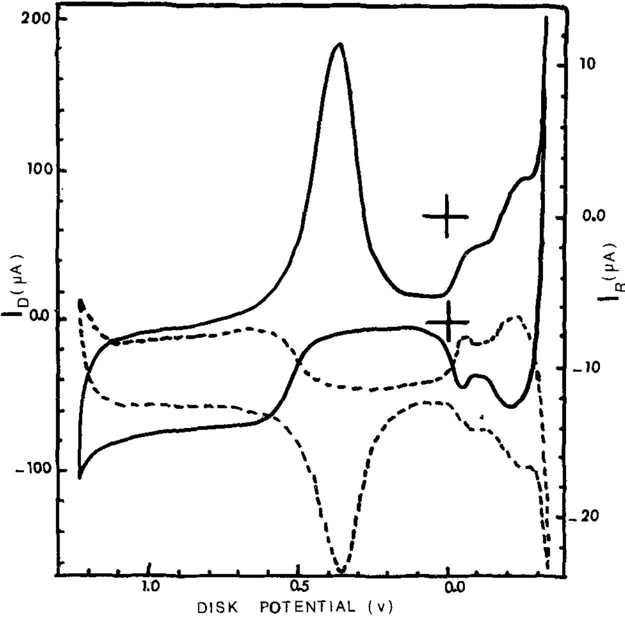

Fig. 6. Cyclic voltammogram in 0.01*M* H_2SO_4 using electrode No. 1. Solid curve and dashed curve represent disk and ring voltammogram, respectively. Ring is potentiostated at −0.450V. Scan rate = 100 mV/sec. Rotation speed = 2500 rpm. These *I-E* curves were recorded on an EAI, X-Y-Y′ 1131 Variplotter.

We propose that the term "pseudocollection" be used to denote changing ring electrode currents arising because of uncompensated ohmic potential effects at ring-disk electrodes. We also propose the term "inverse pseudocollection" to represent the analogous effect of changing disk electrode currents arising because of uncompensated ohmic potential effects at ring-disk electrodes.

We have observed, as has Miller (20), that it is possible to reverse the direction of the pseudocollection effect by positioning the tip of the Luggin capillary very close to the plane of the rotating ring-disk electrode. In the case of electrode No. 1, on the axis of rotation, the reversal appears when the Luggin capillary is closer than 2 mm. This reversal of the sign of the pseudocollection effect corresponds to a negative value of R_C, *i.e.*, position of the Luggin capillary along the resistor R_D, as interpreted in the theoretical section.

The formulation of Gabrielli *et al.* (8) would formally predict this change in signs of the pseudocollection effect if negative resistance values would have been considered by them. However, in the absence of an equivalent circuit such as Fig. 1, there is no justification for introducing the concept of a negative resistance, nor would there be the obvious idea of moving the Luggin capillary tip toward the electrode to find a "negative resistance" region.

We have also been able to find positions in space which produce a change in the sign of the inverse pseudocollection effect. Generally, regions close to the ring electrode produce this change in the sign of the inverse pseudocollection effect.

Finally, there is a locus of points for which both the pseudo- and inverse pseudocollection effects disappear simultaneously. This result, along with the negative resistance effects are decisive tests of the equivalent circuit given in Fig. 1.

Pseudocollection effects will be most significant when large disk currents flow, when the disk current changes rapidly, or when the supporting electrolyte resistance is large, as for example, in dilute aqueous solution or in many nonaqueous solvents. In principle, they may also be observed if the ohmic potential drop changes become large enough to shift the ring electrode potential from the limiting current plateau to the rising portion of a current potential curve.

It is, of course, necessary to recognize that the test of the equivalent circuit we have proposed is based on a primary current distribution. Thus, somewhat different values of R_C, R_D, and R_R will be found for the same position of the Luggin capillary for different current distributions resulting from kinetics and mass transfer effects. However, our model suggests strategems that will be successful in minimizing the pseudocollection effect for any current distribution.

Conclusion

The proposed equivalent circuit, involving a common uncompensated resistance with the uncompensated resistances of the ring and the disk electrodes, agrees well with experiment. Using this model there should be little difficulty in designing circuits to feed back the necessary *IR* correction for the ring and disk potentiostat, and thus eliminate much of the undesirable interactions that can occur because of the coupling these uncompensated resistances produce between ring and disk electrodes.

Triangular Sweep Voltammetry Studies on Porous Silver in KOH: Effect of Temperature and Sweep Rate on Double-Layer Capacitance

E. G. Gagnon*

Electrochemistry Department, Research Laboratories, General Motors Corporation, Warren, Michigan 48090

ABSTRACT

Triangular sweep voltammetry data for commercially available porous silver in 31 weight per cent KOH between 21° and −47°C are presented. Experimental problems with distributed capacitance and impurity effects are discussed. When experimental conditions are optimized, however, the double-layer capacitance of the porous electrode, based upon the BET area of the electrode, compares well with literature values for solid silver.

One method of characterizing flooded porous electrodes is to determine the double-layer capacitance (DLC) of the electrode in the environment in which it is to be used. The wetted surface area obtained from DLC measurements does not, however, always agree with the dry areas obtained from BET data. In part, DLC measurements using classical methods such as a-c bridge or interrupter methods meet with difficulties introduced by ohmic effects within the pore structure of the electrode. Recently, the effect of electrolyte resistivity within the pores of the electrode was treated mathematically (1) for the triangular voltage sweep method. The theory was later verified experimentally for porous electrodes constructed of silver (2) and nickel (3). This paper gives additional information regarding the effect of temperature and sweep rate on the DLC of porous silver.

Experimental

Materials.—Silver electrodes (99.8% pure) were punched from a sheet of sintered, porous silver, battery plaque available commercially. The test electrodes had a diameter of 3.5 cm, a thickness of 0.127 cm, a porosity of 62%, and a BET area of 0.175 m^2/g (or 8660 cm^2 of internal area). Copper was identified to be the major impurity by spectrographic analysis (≈ 0.20%). The electrolyte was a 31 weight per cent (w/o) KOH solution and was prepared by diluting reagent grade 45 w/o KOH with distilled water (specific resistance of 3×10^5 ohm-cm) obtained from a Barnstead still; the major impurity in the electrolyte was 2×10^{-4}% Cu.[1]

Cell.—The electrochemical cell and the Teflon test electrode holder were described before (2). A Hildebrand-type Hg/HgO (31 w/o KOH) reference electrode with a Luggin capillary was used. The complete cell and the reference electrode were assembled in a Tenney constant-temperature cabinet (Model TR-5) and tests were conducted between 21° and −47°C. Prior to all testing, the electrolyte was equilibrated at the test temperature for periods of at least 18 hr (overnight).

Measurements.—Triangular voltage sweeps (TVS) were performed using a Wenking (Model 66TS10) potentiostat in conjunction with an Exact (Model 5000 series) signal generator. A Moseley (Model 7004 AM) X-Y recorder recorded voltammetry data from which capacitances were calculated. Results using sweep rates of 6 and 59 mV/sec are discussed; higher sweep rates could not be used because of severe distributed capacity effects (2). Voltage excursions of 140 mV were used to (*i*) minimize transient faradaic currents (2) and (*ii*) determine capacity solely as a function of potential; sweep results over a wide range of potentials often give smeared-out voltammetry curves in which the behavior of the electrode at one potential reflects changes that occurred at another potential.

Results and Discussion

Figure 1 shows a composite of eleven single-sweep voltammetry curves obtained for a porous silver electrode in 31 w/o KOH at 21°C. The first sweep is emphasized by the darker line and begins at −0.10V *vs.* Hg/HgO. The potential is then varied cathodically to −0.24V at a sweep rate of 59 mV/sec and then anodically back to −0.10V at the same sweep rate. Each successive cathodic sweep begins in intervals of 50 mV

[1] Spectrographic analysis.

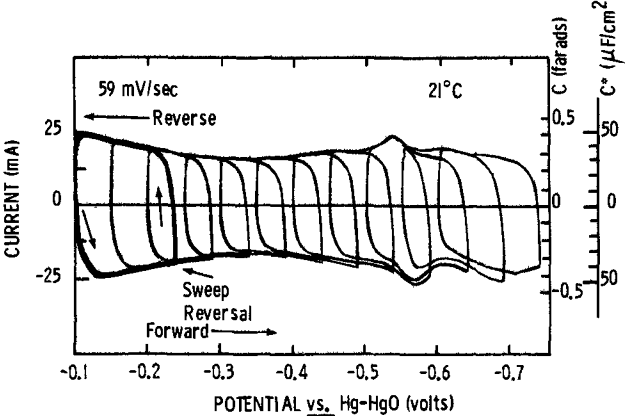

Fig. 1. TVS data at 21°C; k = 59 mV/sec

and at zero current. Over most of the potential region scanned, the results superimpose to form an envelope of potential *vs.* current. The apparent capacity, C, is readily calculated from the voltammetry data simply from

$$C = i/k \quad [1]$$

where i is the measured current (mA); k is sweep rate (mV/sec); and C is capacity (farads). The apparent capacity, C, and the capacity per BET area of the electrode, C^* (μf/cm^2) are plotted at the right ordinate in Fig. 1. Capacitance varies with potential and minimums are seen at -0.350V (forward direction) and -0.325V (reverse direction); pseudocapacity peaks are also observed in the vicinity of -0.55V. Similar results at $-18°$, $-33°$, and $-47°$C are shown in Fig. 2, 3, and 4, respectively; the results were obtained with the same electrode over a period of several days and are typical of data obtained with this particular porous silver sample.

Impurities.—Anodic and cathodic pseudocapacity peaks of about 50 μf/cm^2 occur at about -0.55V (Fig. 1). Also in the vicinity of -0.175V, anodic and cathodic peaks are seen most clearly at $-33°$ and $-47°$C; perhaps the peaks are not as noticeable at the higher temperatures because they are masked by small

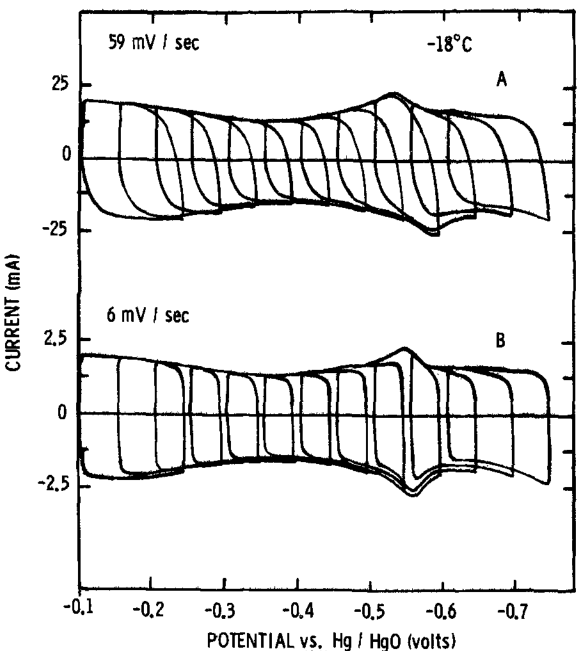

Fig. 2. TVS data at -18°C: A, k = 59 mV/sec; B, k = 6 mV/sec.

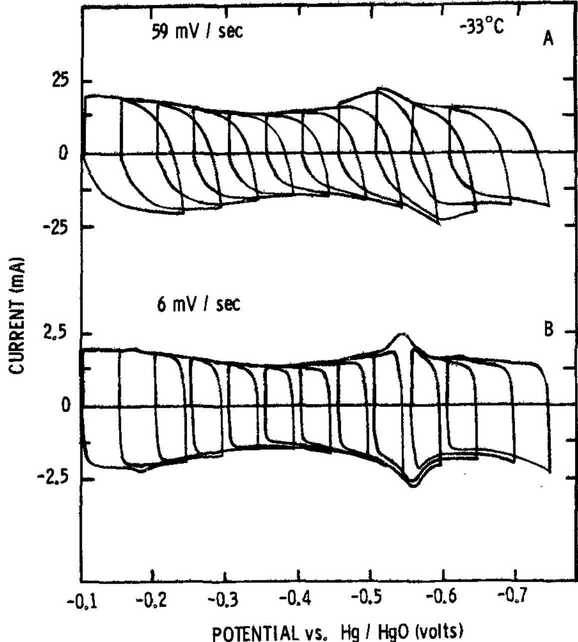

Fig. 3. TVS data at -33°C: A, k = 59 mV/sec; B, k = 6 mV/sec.

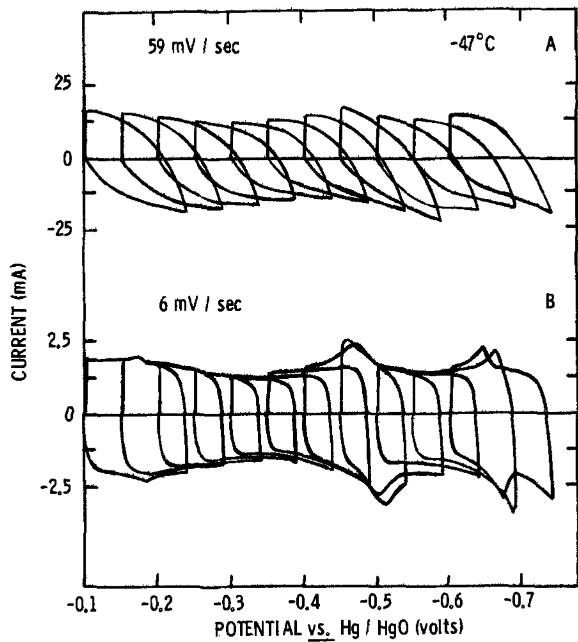

Fig. 4. TVS data at -47°C: A, k = 59 mV/sec; B, k = 6 mV/sec.

amounts of faradaic current. Similar peaks were reported by others (4, 5) using porous silver electrodes. In all probability, the peaks are due to impurities present in the electrode which are desorbing and readsorbing within the pore structure. This is because the peak separation decreases with decreasing sweep rate, which often is a good indication of adsorption-desorption processes (6). The charge associated with the various peaks, however, corresponds to a very small fraction of a monolayer and therefore to a small amount of impurities. For example, the charge associated with the largest cathodic peak at -0.57V (Fig. 1) is about 0.6 μcoulomb/cm^2. This is approximately 0.3% of the 210 μcoulomb/cm^2 value for monolayer coverage (7); it also corresponds very nearly to the level of copper impurity in the metal. Bird *et al.* (4), using a potential step method, concluded that the various peaks observed in

1M KOH were due to copper impurities in their electrodes, according to the following reactions

$$Cu_2O + H_2O = 2CuO + 2H^+ + 2e^- \quad [2]$$

$$2Cu + H_2O = Cu_2O + 2H^+ + 2e^- \quad [3]$$

where the respective $E°$ values are pH-dependent according to

$$E° = 0.747 - 0.059\,pH \quad [2a]$$

$$E° = 0.471 - 0.059\,pH \quad [3a]$$

In this study, additions of copper ions to the electrolyte enhanced the peaks in question. Thus, it is postulated that the peaks are associated with the Cu(II)/Cu(I) couple at −0.18V and the Cu(I)/Cu(0) couple at −0.55V.

Distributed capacity effects.—Figure 5 illustrates the behavior expected with a porous electrode as a function of temperature for the case where capacity is constant and faradaic current is negligible (1). The figure shows the time to reach a steady current after the sweep begins (t') and after the sweep reverses (t'') increases as temperature decreases. The current density during the initial portion of the sweep is predicted (1) from

$$i(L) = \beta_1 kC' \quad [4]$$

where $i(L)$ is the current density; k is the sweep rate (dV/dt), and C' is the apparent capacity per geometric area of the electrode. The parameter β_1 has a numerical value between 0 and 1 and is dependent on two dimensionless parameters $L\lambda/d$ and $t/\rho_e C'L$, where L is the thickness of the electrode, λ is the labyrinth factor, d is the distance between the tip of the Luggin capillary and the surface of the electrode, and ρ_e is the effective specific resistance of the electrolyte in the pores of the electrode. When $\beta = 1$ (dashed line, Fig. 5), distributed capacity effects are negligible. Conditions which increase $L\lambda/d$ (e.g., thicker electrodes) and/or decrease $t/\rho_e C'L$ (e.g., lower temperatures and higher resistivities) enhance distributed capacity effects (solid lines, Fig. 5). Similarly, the current density after sweep reversal is predicted (1) from

$$i(L) = \gamma kC' \quad [5]$$

where γ is a function of basically the same dimensionless parameters as β_1, except its value ranges between +1 and −1 as the value of $t/\rho_e C'L$ increases.

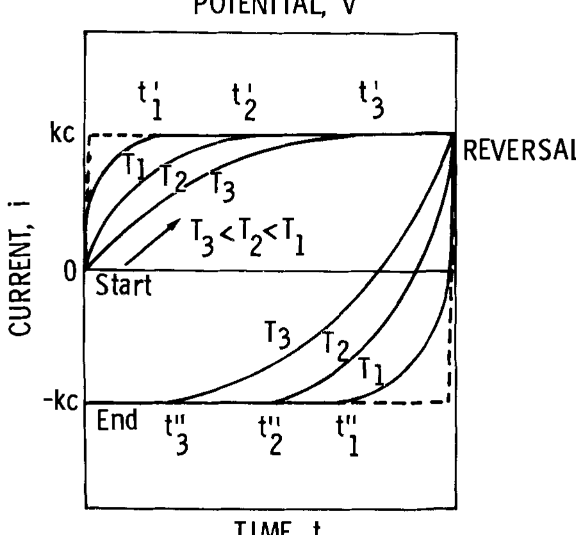

Fig. 5. Current vs. time or potential during a TVS for cases where capacity is constant and faradaic current is negligible. Solid lines illustrate distributed capacity effects as a function of temperature. Dashed line illustrates case where distributed effects are negligible.

The experimental results (Fig. 1-4) given here clearly follow the general pattern expected, even though there are potential regions where capacity is obviously not constant (e.g., in the vicinity of −0.55V). It can be shown (8) that when all other parameters are kept constant (e.g., k, L, C, etc.), t' (Fig. 5) is proportional to ρ_e. Values of t' estimated from sweeps beginning at −0.30V, such as shown in Fig. 1-4, are plotted as a function of temperature in Fig. 6; also included are values of ρ_e (solid line) which are calculated using

$$\rho_e = \rho\lambda \quad [6]$$

and experimentally determined values of the bulk resistivity, ρ, of 31 w/o KOH (9) and the labyrinth factor, λ, of 2 determined previously (2).

Capacitance data.—A capacitance minimum occurs in both the forward (−0.35V) and reverse (−0.325V) directions. At 21°C, C_{min} is about 32 μf/cm² and is independent of sweep rate. As temperature decreases, there occurs an apparent shift in the potential of the cathodic minimum, E^c_{min}. (Fig. 7) and in the capacitance C_{min}. (Fig. 8). Between 21° and −47°C, E^c_{min}. shifts 80 mV cathodically at 59 mV/sec, whereas at 6 mV/sec, the shift is 20 mV. Similarly, over the same temperature range, C_{min}. decreases about 10 μf/cm² at 59 mV/sec and about 2 μf/cm² at 6 mV/sec. The higher sweep rate results show significant shifts in C_{min}. and E^c_{min}. with decreasing temperature, but with the slower sweep rate the shifts over the same temperature range

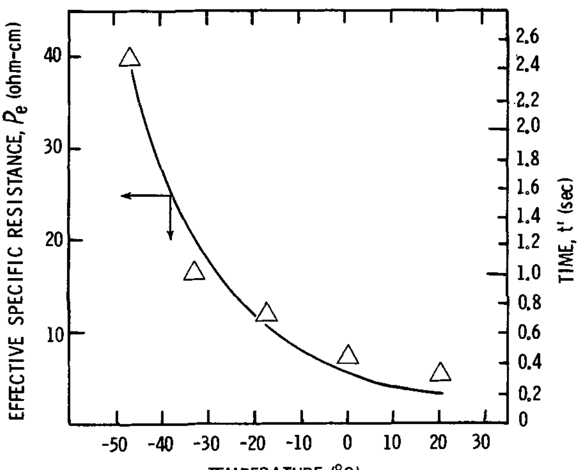

Fig. 6. Effective specific resistance of the electrolyte in the pores of the electrode (solid line) and times to reach a constant current, t' (points), vs. temperature.

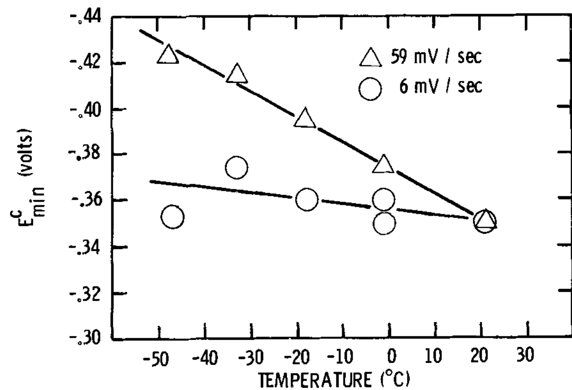

Fig. 7. The potential of the capacitance minimum, E^c_{min}, (forward direction) vs. temperature as a function of sweep rate.

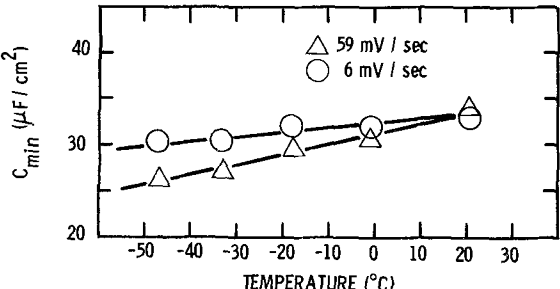

Fig. 8. The capacitance minimum, $C_{min.}$, vs. temperature as a function of sweep rate.

are markedly reduced. Thus it would appear that the high sweep rate results are mostly artifacts of the system and the result of a distributed capacitance effect. The magnitude of the results is specific to this particular electrode/electrolyte system and does not necessarily apply to other porous silver electrodes. This is especially true if the physical properties (*e.g.*, ρ, λ, L, etc.) of the electrodes differ.

The pzc is usually taken as the potential at which a well-defined minimum occurs in the potential-capacity data (10) with dilute solutions (0.01M or less). With concentrated solutions, however, the pzc is not well defined even with mercury surfaces. For solid silver, reported pzc values show a wide variation including 0.046V *vs.* NHE in KNO_3 (11); -0.70V *vs.* NHE in Na_2SO_4 (12), and $NaClO_4$ (13). It is even more difficult to determine the pzc with porous electrodes. For example, consider the case where an adsorption pseudocapacitance due to a faradaic process occurs in the same potential region as the pzc. Normally, with mercury surfaces, measurements at high frequencies often eliminate the contribution of an adsorption pseudocapacitance (10). With porous electrodes, however, high frequency techniques are not always applicable because of distributed capacity effects. Also, the use of dilute solutions to determine the diffuse layer capacitance near the pzc is not possible, again because of massive distributed capacity effects. Although the pzc is an important parameter of the metal, it depends markedly on the properties of the solution in contact with the particular metal. Therefore, it is not clear at this point whether the $C_{min.}$ observed in this work actually corresponds to the pzc, even though both often occur in the same vicinity.

The capacity values obtained over the entire potential range (32 to 50 μf/cm^2) are in good accord with literature values for solid silver in 1M Na_2SO_4 (14), 1M K_2SO_4 (15), 1M KNO_3 (15), and 30 w/o KOH (16). When one wishes to compare the electrochemically active surface area of porous silver electrodes, it is best done at the $E_{min.}$ preferably under similar test conditions. Thus, a proper sweep rate must be selected; it can be estimated using the equations discussed in the paper or determined experimentally. Obviously the same principles apply to other porous electrode systems. Using these concepts, it is possible to understand why Evans (17) was unable to use fast sweep rates in determining the capacitance of carbon powders in NaCl solutions while the use of slow sweep rates gave consistent and meaningful results.

Conclusions

The TVS technique is a fast and effective method of electrochemically studying the surface characteristics of porous silver in alkaline solutions. The technique is very sensitive to trace amounts of electrochemically active species present at the surface (*i.e.*. coverages of less than a monolayer can be detected). DLC, free from pseudocapacity effects can be determined, however, only in certain potential regions where a capacitance minimum occurs in the vicinity of -0.35V *vs.* Hg/HgO. Values of capacitances based on the BET area of the electrode agree with literature values for solid silver. Methods of avoiding some experimental difficulties arising from the porous nature of the electrode are discussed in terms of a distributed capacitance model.

Current Distribution on a Plane below a Rotating Disk

Robert V. Homsy and John Newman*

Inorganic Materials Research Division, Lawrence Berkeley Laboratory, and Deparment of Chemical Engineering, University of California, Berkeley, California 94720

ABSTRACT

The current distribution on a stationary disk electrode below a rotating disk at high Schmidt numbers is calculated at various fractions of the limiting current. Numerical results for the case of Tafel polarization show that the current density on the plane becomes more nonuniform as the limiting current is approached.

The rotating disk system has been used extensively in electrochemical investigations primarily because the disk is a surface of uniform accessibility and it is easy to use. A slightly more complicated system consisting of a fluid driven by a rotating disk above a stationary plane has been studied recently (1-3). The electrode surface is a coaxial disk imbedded in the stationary plane. Figure 1 shows the system. A diffusion-layer solution to the equation of convective diffusion was found for high Schmidt numbers at conditions of limiting current (1). The current distribution was found to be nonuniform, increasing from zero at the center of the electrode to infinity at the leading edge. We shall apply here the same procedure which has been used previously (4-10) for various geometries to study the behavior of this system at current densities below the limiting current.

In the treatment of the problem the following assumptions are made:

1. The working electrode is a coaxial disk imbedded in an infinite, insulating plane.
2. The rotating disk acts as a counterelectrode at infinity. (For the case in which the separation distance between the rotating disk and the plane is finite, Laplace's equation should be solved in a different way for the potential in the solution outside the diffusion layer, in order to account for the fact that the rotating disk is an insulator, or another electrode, as the case might be.)
3. The flow is fully developed and laminar.
4. Dilute solution theory applies with constant diffusion coefficients, mobilities, and activity coefficients.
5. Radial diffusion is negligible (valid at high Péclet numbers).
6. The treatment presented here applies to either metal deposition from a single salt solution or electrode reactions with an excess of supporting electrolyte.

Mathematical Formulation

At high Schmidt numbers the concentration varies from its bulk value only in a thin diffusion layer near the electrode surface, well within the hydrodynamic boundary layer. It is then valid to approximate the radial velocity by the first term in an expansion in distance from the electrode

$$v_r = - y\,\beta(r) \quad [1]$$

where $\beta = - \partial v_r/\partial y$ at $y = 0$. A full discussion of the hydrodynamics of this system may be found elsewhere (1). For this system $\beta = - r\Omega\sqrt{\Omega/\nu}\, F'(\mathrm{O})$, where $F'(\mathrm{O})$ is a constant determined by the dimensionless separation distance, $\mathcal{Z} = L\sqrt{\Omega/\nu}$.

The axisymmetric diffusion-layer solution may be superposed (8) to yield the concentration derivative evaluated at the electrode surface in terms of the derivative of the surface concentration

$$\left.\frac{\partial c}{\partial y}\right|_{y=0} = -\frac{\sqrt{r\beta}}{\Gamma(4/3)} \times \int_0^x \left.\frac{dc_o}{dx}\right|_{x=x_o} \frac{dx_o}{\left[9D\int_{x_o}^x r\sqrt{r\beta}\,dx\right]^{1/3}} \quad [2]$$

where $x = r_o - r$ is the distance from the edge of the electrode. Substitution for x and β yields

$$\left.\frac{\partial c}{\partial y}\right|_{y=0} = -\frac{(1-\zeta)^{1/3}}{r_o\Gamma(4/3)}\left(\frac{2\mathrm{Pe}}{3}\right)^{1/3} \times \int_0^\zeta \left.\frac{dc_o}{d\zeta}\right|_{\zeta=\zeta_o} \frac{d\zeta_o}{(\zeta-\zeta_o)^{1/3}} \quad [3]$$

where $\mathrm{Pe} = \beta r_o^3/2rD = -\frac{1}{2}F'(\mathrm{O})\ \mathrm{Sc}\ \mathrm{Re}^{3/2}$ is a Péclet number, $\mathrm{Re} = r_o^2\ \Omega/\nu$ is the Reynolds number based on the radius of the electrode, $\zeta = 1 - \xi^3$, and $\xi = r/r_o$ is the dimensionless radius.

The current density normal to the surface of the electrode is related to the concentration derivative by the relation

$$i = \frac{nFD}{1-t}\left.\frac{\partial c}{\partial y}\right|_{y=0} \quad [4]$$

where n is the number of electrons produced when one reactant ion or molecule reacts and t is the transference number.

The potential in the solution outside the diffusion layer is the same as that for the rotating disk. At the surface of the electrode the potential is given by (4)

$$\Phi_o = \frac{RT}{ZF}\sum_{m=0}^{\infty} B_m P_{2m}(\eta) \quad [5]$$

where $Z = -\ z_+z_-/(z_+ - z_-)$ for a single salt and

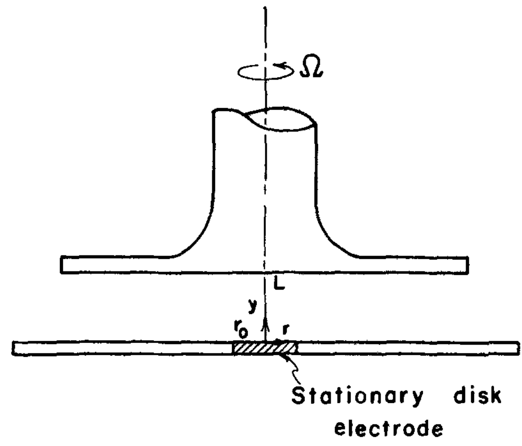

Fig. 1. Disk electrode imbedded in a stationary plane below a rotating disk.

* Electrochemical Society Active Member.

Key words: current distribution, mass transfer, electrode kinetics.

$-n$ with supporting electrolyte, $P_{2m}(\eta)$ is the Legendre polynomial of order $2m$ and $\eta = \sqrt{1 - \xi^2}$ is the rotational elliptic coordinate at $y = 0$. The expansion coefficients B_m are given by

$$B_m = -\frac{ZFr_o}{\kappa RT}\pi\frac{(4m+1)[(2m)!]^2}{2(2^m m!)^4}\int_0^1 i\eta P_{2m}(\eta)\,d\eta \quad [6]$$

where κ is the conductivity of the bulk solution.

The electrode potential is the sum of the potential drop in the solution Φ_o, the concentration overpotential η_c, and the surface overpotential η_s

$$V = \Phi_o + \eta_c + \eta_s \quad [7]$$

The concentration overpotential is taken to be (11)

$$\eta_c = \frac{RT}{ZF}\left[\ln\left(\frac{c_o}{c_\infty}\right) + t\left(1 - \frac{c_o}{c_\infty}\right)\right] \quad [8]$$

while the surface overpotential may be related to the current density by the Butler-Volmer expression

$$i = i_o\left(\frac{c_o}{c_\infty}\right)^\gamma\left[\exp\left(\frac{\alpha ZF}{RT}\eta_s\right) - \exp\left(-\frac{\beta ZF}{RT}\eta_s\right)\right] \quad [9]$$

where i_o is the exchange current density at the bulk concentration, and α, β, and γ are kinetic parameters. It is convenient to refer the current density to the average limiting current density (1)

$$\langle i_{lim}\rangle = -\frac{i_o}{\Gamma(4/3)}\frac{N}{J} \quad [10]$$

where

$$N = -\frac{nZF^2Dc_\infty}{RT\kappa(1-t)}\left(\frac{2Pe}{3}\right)^{1/3} \quad [11]$$

and

$$J = \frac{i_o r_o ZF}{RT\kappa} \quad [12]$$

are dimensionless parameters.

Equations [3]-[9] constitute a set of seven equations containing the seven unknowns, c_o, $\partial c/\partial y$ at $y = 0$, i, Φ_o, B_m, η_c, and η_s. The numerical method of calculation is the same as has been used previously (7). There are six parameters which must be specified in the dimensionless problem: N, J, t, α, β, and γ, along with the fraction of limiting current we wish to study. The latter may be set by specifying the current density at the leading edge of the electrode, $i(1)$. Such a choice eliminates an iteration loop in the numerical procedure.

Results and Discussion

Because mass-transfer effects are important at higher current densities, we have used Tafel polarization throughout in calculating the current distributions. Thus, we have taken the exchange current density i_o to be much less than the average current density, so that the surface overpotential η_s is large and one of the terms on the right in Eq. [9] can be neglected. When operation is at an appreciable fraction of limiting current, this means that $J << N$ according to Eq. [10]. In the figures, $J = 0$ designates the use of the Tafel approximation.

Figures 2 and 3 show, respectively, the dimensionless current density and concentration distributions on the surface of the electrode for $N = 10$ at various fractions of the limiting current. All other parameters were arbitrarily set at 0.5. The limiting current curve was obtained from previous work (1). Figures 4 and 5 show the effect of increasing N on the current density and surface concentration for a fixed current density at the leading edge ($i/\langle i_{lim}\rangle = 1.429$).

Figure 2 shows that the current density rises monotonically from zero at the center of the electrode to a finite value at the leading edge for current densities

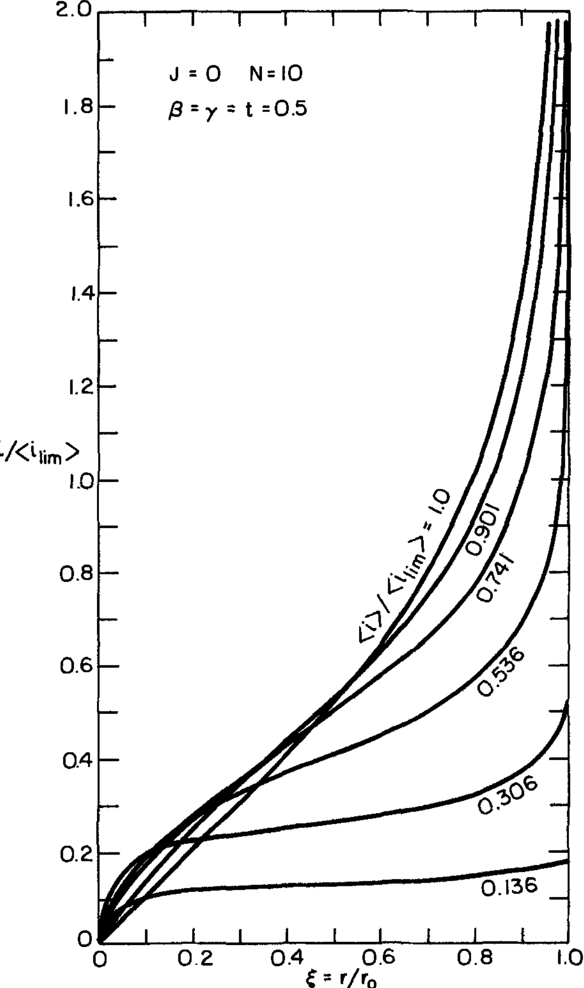

Fig. 2. Current distribution for Tafel polarization

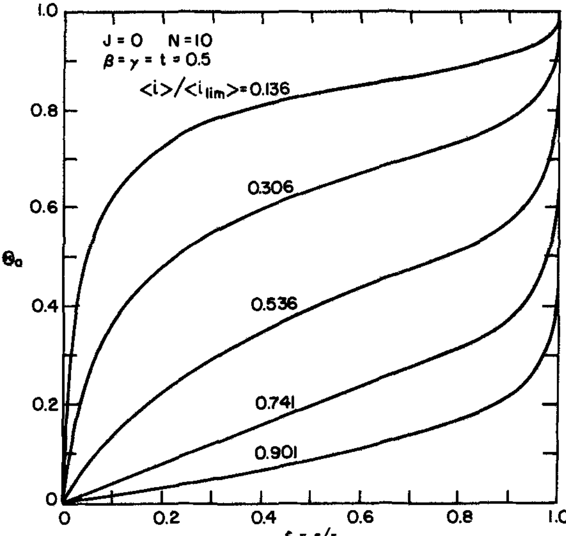

Fig. 3. Surface concentration distribution for Tafel polarization

below limiting. This behavior would be expected since both the limiting (1) and primary (4) current distributions are infinite at the leading edge of the electrode. The current density becomes more nonuniform as the limiting current is approached and is seen to exceed the limiting current locally near the center of the electrode. This latter behavior has been ob-

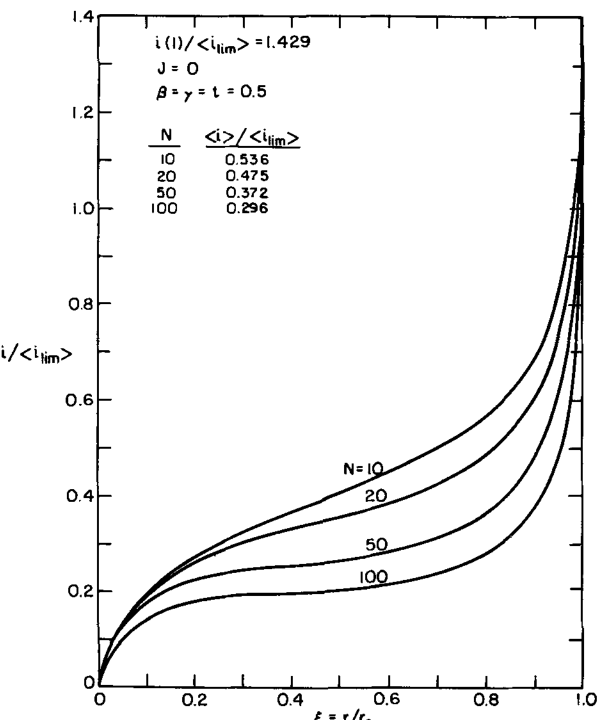

Fig. 4. Effect of variation of N on the current distribution for Tafel polarization.

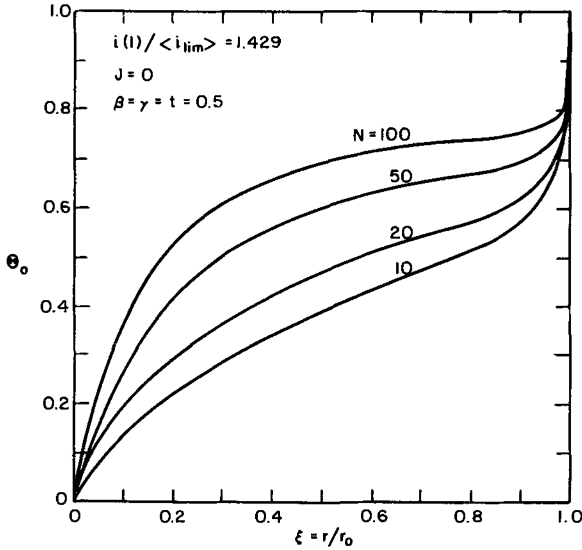

Fig. 5. Effect of variation of N on the surface concentration distribution for Tafel polarization.

served for other geometries (4, 6, 7, 10). The surface concentration increases monotonically from zero at the center of the electrode to its bulk value at the leading edge (see Fig. 3). As the current density approaches its limiting value, the surface concentration tends toward zero. Figures 4 and 5 show that as N is increased, both the current density and concentration distributions tend to be more uniform, as might be expected since the rate of stirring (Péclet number) is increased.

Summary

The current density and concentration distributions on the surface of an electrode imbedded in a stationary plane below a rotating disk have been calculated at various fractions of the limiting current. At high Schmidt numbers the concentration varies from its bulk value only in a thin diffusion layer near the electrode surface. The potential distribution in the diffusion layer is determined from a superposition of the diffusion-layer solution to the equation of convective diffusion and electrode kinetic expressions, while the potential in the bulk of the solution is obtained from Laplace's equation. The calculation method used here is the same as was applied previously to the rotating disk and sphere and plane electrodes. Results for the case of Tafel polarization show that the current density becomes more nonuniform as the limiting current is approached.

LIST OF SYMBOLS

- B_m — expansion coefficients in the series for the potential
- c — concentration of the reactant, mole/cm^3
- c_o — concentration of the reactant at the electrode surface, mole/cm^3
- c_∞ — concentration of the reactant in the bulk, mole/cm^3
- D — diffusion coefficient of the reactant, cm^2/sec
- $\mathbf{F}$ — Faraday's constant, 96,487 coulombs/equiv.
- $F'(O)$ — dimensionless radial velocity derivative evaluated at the plane
- i — normal current density at the electrode surface, A/cm^2
- i_o — exchange current density, A/cm^2
- $\langle i \rangle$ — average current density, A/cm^2
- $\langle i_{lim} \rangle$ — average limiting current density, A/cm^2
- J — dimensionless exchange current density
- L — separation distance between stationary plane and rotating disk, cm
- m — index of summation in the series for the potential
- n — number of electrons produced when one reactant ion or molecule reacts
- N — dimensionless parameter related to the significance of mass transfer (see Eq. [11])
- P_{2m} — Legendre polynomial of order 2m
- Pe — Péclet number, $-F'(O)$ Sc Re$^{3/2}/2$
- r — radial coordinate, cm
- r_o — radius of electrode, cm
- R — universal gas constant, 8.3143 joule/mole-deg
- Re — Reynolds number, $r_o^2\Omega/\nu$
- Sc — Schmidt number, ν/D
- t — transference number of reactant
- T — absolute temperature, °K
- v_r — radial velocity component, cm/sec
- V — potential of the electrode, V
- x — distance from the edge of the electrode, cm
- x_o — integration variable in Eq. [2]
- y — normal distance from the electrode surface, cm
- z_i — charge number of species i
- Z — $-z_+z_-/(z_+ - z_-)$ for a single salt; $-n$ for reactions with excess supporting electrolyte
- $\mathfrak{Z}$ — dimensionless separation distance between stationary plane and rotating disk, $L\sqrt{\Omega/\nu}$
- α, β, γ — parameters in the kinetic expression (see Eq. [9])
- $\beta(r)$ — radial velocity derivative at the plane, $-\partial v_r/\partial y$ at $y = 0$, sec^{-1}
- $\Gamma(4/3)$ — the gamma function of 4/3, 0.89298
- ζ — $1 - \xi^3$
- ζ_o — integration variable in Eq. [3]
- η — rotational elliptic coordinate at $y = 0$, $\sqrt{1 - \xi^2}$
- η_c — concentration overpotential, V
- η_s — surface overpotential, V

Θ_0 dimensionless concentration of the reactant at the electrode surface, c_0/c_∞
κ conductivity of the bulk solution, ohm^{-1}-cm^{-1}
ν kinematic viscosity, cm^2/sec
ξ dimensionless radial coordinate, r/r_0
π 3.14159
Φ_0 potential in the bulk extrapolated to the electrode surface, V
Ω angular velocity of rotating disk, rad/sec

Electrochemical Oxidation of Nitrite Ions at Platinum, Gold, and Glassy Carbon Anodes in Acetonitrile

H. W. Salzberg*

Department of Chemistry, The City College of the City University of New York, New York, New York 10031

ABSTRACT

Electrochemical oxidation of nitrite ions has been studied in nominally anhydrous acetonitrile at platinum, gold, and glassy carbon electrodes. Tafel slopes, a-c polarography, and potential values indicate the electron transfer is reversible. It is believed that the NO_2 radical-molecule leaves the carbon and platinum surfaces by a unimolecular step, most probably desorption, and that the NO_2 leaves the gold surface by dimerization as well as by unimolecular desorption.

Until recently, the electrochemical oxidation of nitrite ion in organic media was terra incognita. The first on the subject was by Cauquis and Serve (1) who worked in nitromethane, nitrobenzene, and acetonitrile, running polarographic and cyclic voltammetric measurements on a smooth platinum rotating electrode. Their conclusion was that the discharge is reversible and bimolecular, forming N_2O_4 in one step, followed by various chemical processes in a complicated over-all pattern. The half-wave potential, relative to $Ag/AgCl_{(s)}$ was about +0.77V.

Wargon and Avia (2) studied the oxidation of $NaNO_2$ at platinum electrodes, with dimethyl sulfoxide as solvent, and concluded that the rate-determining step (rds) was the discharge of the nitrate ion, which was therefore irreversible. Castellano, Wargon, and Arvia (3) reported on the electrochemical oxidation of $AgNO_2$ in acetonitrile on platinum. By analysis of product mixtures they concluded that the initial oxidation is followed by a large number of simultaneous competing processes, between initial products and water or nitrite ion. However, they do not commit themselves as to whether or not the first electrochemical oxidation is reversible.

Unpublished work in this laboratory had indicated that on platinum in acetonitrile, the discharge was reversible but that the subsequent rds was unimolecular. This study was therefore undertaken.

Experimental

The principal measurement techniques were steady-state voltammetry and a-c polarography.

Voltammetric measurements were made using the familiar interrupter method to eliminate ohmic drop. Interruption was by a positive 5-10 μsec pulse every millisecond, from a General Radio 1340 pulse generator, through a pnp transistor in series with the electrolysis cell. During the interruption period, the potential, *vs.* a reference, was observed with a 5103N dual trace Tektronix memory oscilloscope. The second trace on the scope was used to observe the potential drop across a 1000 ohm resistor in series with the cell, to make sure that the current was completely interrupted. Cell current was obtained potentiometrically rather than with a microammeter. The measurement gave only the average current during the on-off cycle but since the interruption period was only about 0.5-1% of the cycle, the error is negligible.

The a-c polarographic measurements were made with a Heathkit EUA19-2 polarography module, the a.c. being supplied from a Wavetek 134 function generator and the output being fed into the oscilloscope.

The cell was a lipless beaker with a Teflon cap through which the electrodes were inserted. The platinum and the gold electrodes were Beckman button type, with the metal recessed in glass, so that no edges were exposed. Two platinum anodes were used, one 0.24 cm^2 and the other 0.18 cm^2 in area. The gold anode was 0.0079 cm^2 and the carbon anode 0.031 cm^2. The carbon was a Chemtrix A-111 glassy carbon electrode, modified by using a carbon rod to make contact with the glassy carbon surface. No roughness factors were measured. The cathode was a 0.24 cm^2 platinum electrode. Two alternative references were used. One was a silver wire, the other a platinum electrode which had been silver plated. The potential difference between them was less than the minimum value to which potentials were measured.

Before use, the electrodes were washed with nitric acid and distilled water. Sometimes they were then air dried, sometimes washed with acetone, and sometimes wiped with filter paper. No differences in performance could be ascribed to different pretreatments, except that failure to clean with nitric acid often resulted in discrepant and irreproducible behavior.

The solvent was acetonitrile, reagent grade, not distilled but dried over Linde Molecular Sieves, 3Å. The

electrolytes were reagent grade $LiNO_3$, vacuum dried at 150°-200°C, anhydrous $LiClO_4$, used as obtained from the supplier, Alpha Inorganics, reagent grade $AgNO_3$, used without pretreatment, and $AgNO_2$, prepared by precipitation from aqueous $AgNO_3$ and $NaNO_2$ followed by filtration, washing, drying, and prolonged vacuum dessication. No differences in performance could be ascribed to different batches of solvent and electrolyte.

During measurements, the cell was isolated from the atmosphere by being kept in a resin assembly vessel surrounded by dessicant. Electrical contact was with copper wires thrust through cork stoppers held in the necks of the lid. During runs, dry nitrogen was passed through the cell to remove any oxygen. The scrubber nitrogen gave no polarographic oxygen peak and so was used without additional treatment. The combination of nitrogen scrubbing and surrounding dessicant kept water and oxygen at a minimum, although not eliminating these two potential trouble makers.

The electrolytes were weighed out in the laboratory atmosphere before being put into the cell. A test sample of $AgNO_2$ showed no weight gain after several hours in the laboratory. However, weighing the $LiNO_3$ and the $LiClO_4$ in the laboratory air must have introduced some traces of water.

After the addition of the silver nitrite, the solvent was added to the cell through a tube leading into the dessicator, without opening the system. During this addition, about 20-30 cm^2 of liquid surface were exposed to the laboratory air for about half a minute or more. Some oxygen and water must have been absorbed.

When $LiClO_4$ or $LiNO_3$ or $AgNO_3$ was to be added, a set of data was first obtained using $AgNO_2$ only, to act as a base line. The reaction chamber was then opened and the additional electrolyte added.

Usually, 50-60 mliters of acetonitrile were added to 1.5g of $AgNO_2$, not all of which dissolved. The solutions may, therefore, be considered saturated with respect to $AgNO_2$ and about 0.15-0.1M. The concentration of Ag^+ must have decreased slightly during the runs, since some silver did plate out on the cathode, but the concentration change was so slight that the reference potentials may be considered to have remained constant during the run.

All runs were made with all the electrodes in the solution at the same time, so that differences between potentials could not be ascribed to measuring at different times with different solutions. Sometimes the complete curves for each electrode were obtained sequentially. At other times, measurements were obtained by switching back and forth between electrodes after each point. The results were the same. Each set of measurements was made on freshly prepared solution.

To measure decay times, the current was run for several minutes at a selected value, usually in the 10^{-5} A/cm^2 range, until the potential had reached a steady state. The circuit was then opened manually, triggering the scope for a single sweep in the memory mode. The procedure was repeated until fairly reproducible decay times were observed, the decay time being defined here as the time for the potential to drop to a point which then did not change for at least 20-30 sec.

To measure equilibrium potentials, NO_2 gas was produced by adding concentrated H_3PO_4 to solid $NaNO_2$. The evolved gas was then passed through the cell and solution. When brown fumes were observed in the gases exiting from the reaction chamber, the gas stream was diverted and the electrode potentials were measured. Measurements were made with the oscilloscope, using a 1 megohm probe, with the reference electrode grounded. The measurements used about 70 nA with current densities in the microampere/square centimeter range.

Discussion

Tafel lines.—Figure 1 shows typical results of potential-current density measurements. The potentials reported are relative to an $Ag/AgNO_2$ reference. Table I summarizes data taken on different days, some with different batches of solvent and electrolyte. The day-to-day variations for each anode are less than the spread between results with different metals. Table II lists the range of potential values (taken from the experimental Tafel curves) for the electrodes at 10^{-5} and 10^{-3} A/cm^2. Except for carbon and gold at 10^{-3}, the curves, although quite close to each other, do not overlap. The large (0.24 cm^2) platinum electrode consistently registered higher potentials, at corresponding current densities, than the smaller (0.018 cm^2) platinum electrode. The difference was usually about 25-30 mV and could possibly be due to differences in roughness.

The addition of sufficient $AgNO_3$ or $LiNO_3$ to make the concentration of added salt about 0.1-0.2M had no discernible effect. On addition of enough $LiClO_4$ to make the solution 0.1-0.2M, the Tafel slopes remained the same but the curves were shifted slightly toward more positive potentials, about 10-15 mV on gold and platinum and even less on carbon. This effect probably was due to adsorption.

Decay times.—Table III shows the time taken for potentials to drop to open-circuit values when the current was interrupted.

Equilibrium potentials.—Table IV shows the potentials at open circuit in saturated $AgNO_2$ with the mixture of NO_2 and N_2O_4 at one atmosphere.

A-C polarography and cyclic voltammetry.—These results were not graphed. The cyclic voltammograms showed no reverse (cathodic) wave at sweeps as high as 10 V/min. The a-c polarograms were produced by superimposing 5 mV of 400 Hz a.c. on d.c., using $LiNO_3$ or $LiClO_4$ as indifferent electrolyte. Small but definite a-c peaks of about 2-3 μA were observed in the region 0.4-1V, positive to the reference. The actual potentials were unimportant since they included an unknown ohmic drop. However, the fact that the a-c peaks were observed only within a potential range indicates that they were not the results of capacitance but indicated a reversible electron transfer.

Discussion

Most of the foregoing results are consistent with the following picture

$$NO_2^- - e \rightleftharpoons NO_{2(ads)} \begin{cases} \rightarrow \text{desorption or reaction with } H_2O, \text{ dissolved } O_2, \text{ etc.} \\ \rightarrow \text{dimerization to } N_2O_{4(ads)} \end{cases}$$

On all three electrodes, the electron transfer is reversible and the rate-determining step is the removal of the adsorbed NO_2.

The reversible currents in a-c polarography are direct evidence for the reversibility of the electron transfer step.

Indirect evidence for Nernstian reversibility consists of the slopes of the Tafel lines in Fig. 1 and the close approximation of working potentials as shown in Table II. The spread between the potentials at the gold, carbon, and the smaller platinum electrode was less than 100 mV and even taking into account the higher potentials on the larger platinum electrode, the greatest spread was only 120 mV. For electron transfer processes known to be irreversible, differences in electrode potentials are much higher. For example, hydrogen overvoltages at different metals show differences of as much as a volt. Large potential differences would indicate Nernstian reversibility and the small differences shown here are a necessary, but not sufficient, condition for reversibility.

The small potential differences observed here could be at least partly due to differences in surface roughness but are more likely due to differences in surface spacings. Entities as large as nitrite ions and NO_2 molecules should be adsorbed on several surface atoms at the same time. Since the surface spacings of these three electrode materials are not the same, even if the total area were the same, the fraction available for nitrite ion adsorption would be different and the true current densities could differ considerably from apparent current densities. Also, since the surfaces are polycrystalline and heterogeneous, the activities of the adsorbed NO_2 molecules should be different for each electrode at a given current density and should increase somewhat with increasing coverage.

The results shown in Table IV are also necessary but not sufficient for reversibility of the rate-determining step. For the electron transfer at the working electrodes to be reversible, it would have to be reversible under open-circuit conditions in the presence of NO_2 gas. Under such conditions the potentials observed should be equilibrium potentials, dependent only on the free energies of the nitrite ions in solution and the dissolved NO_2 molecules and independent of electrode material. As shown in Table IV, these potentials are just about the same at all three electrodes, allowing for the crudity of the measurement.

The slopes of the Tafel lines shown in Fig. 1 and Table I offer further evidence for reversibility of electron transfer. A reversible one-electron transfer would yield a Tafel slope of 0.06 if the following rate-determining step (rds) is first order with respect to the product of the electron transfer. If the rds is bimolecular, the slope would be 0.03. If the slow process following the electron transfer is a combination of simultaneous first- and second-order steps proceeding at comparable velocities, the Tafel slope should be intermediate between 0.03 and 0.06.

If the reversible step involved the transfer of two electrons, the slopes should be 0.03 for a first-order rds and 0.015 for a second-order rds.

The slopes of carbon and gold are both intermediate between 0.03 and 0.06, arguing for a simultaneous dimerization of the adsorbed NO_2 and removal by desorption or reaction with dissolved oxygen, or water, or NO_3^-, or similar substances that might be present. The slope on carbon, being so close to 0.06, would indicate that very little dimerization occurred. Support for this argument comes from the data of Table III, which shows that the decay time for gold is ten times that for carbon and twenty times that for platinum. This means either that there is a very high surface concentration of NO_2 on gold, which in turn would mean a high potential, or that adsorbed N_2O_4 is present and disassociates into NO_2. Since the potentials on gold are lower than on platinum, rather than higher, the latter explanation would hold rather than the former.

Table IV. Equilibrium potentials

Electrode	Potential *vs.* $Ag/AgNO_{2(s)}$
Pt	+0.078
C	+0.060
Au	+0.068

In the case of the platinum electrodes, the slopes are about 0.07, slightly higher than that expected for a normal first-order removal of the product of a reversible one-electron transfer. If the surface were to be covered with a tightly held monolayer of adsorbed NO_2 further nitrite oxidation would then take place on this monolayer producing N_2O_4 in a bimolecular two-electron process, with a Tafel slope of 0.09. A Tafel slope of 0.07 could then be considered to be a combination of such a process with a simultaneous reversible one-electron unimolecular removal. However, the data of Table III show that the removal of $NO_{2(ads)}$ from platinum is faster than from carbon, which suggests that the NO_2 is not strongly adsorbed and that such a monolayer would not form. Also, if there were a monolayer of strongly adsorbed NO_2, one would expect to see a cathodic wave in running cyclic voltammetry. No such wave was observed.

An alternative explanation for the increase in Tafel slope would be based on surface heterogeneity. For a reversible electron transfer process, the Nernst equation holds and the potential is a function of the activity and therefore activity coefficient of the $NO_{2(ads)}$. If over each decade change in current, the surface free energy of the adsorbed NO_2 increased by about 250 cal/mole, the increase in activity coefficient would produce an increase in potential of 12 mV, which is the difference between the observed 0.072 slope and the 0.06 slope expected. This, of course, assumes a tenfold increase in concentration of adsorbed NO_2, which is contradictory, since any increase in surface free energy would increase the rate constant for the desorption process. However, since NO_2 molecules do attract each other and dimerize, intermolecular attractions should at least partly counterbalance increased desorption rates, and increased activity coefficients could account for the Tafel slope being 0.072 rather than 0.060.

I am troubled by the discrepancy between my observed potentials and the value of 0.77V *vs.* $Ag/AgCl_{(s)}$ reported by Cauquis and Serve (1), who are very careful, scrupulous, and competent workers. I can only cite the differences in solvent, concentration, supporting electrolyte, reference electrode, and method of measurement.

Conclusions

To summarize, on gold, glassy carbon, and bright platinum, in acetonitrile, the oxidation of nitrite ion is a reversible one-electron process. The subsequent removal of $NO_{2(ads)}$ on gold and carbon is by simultaneous dimerization and either desorption or reaction with water, oxygen, or NO_3^-, or some combination thereof. On platinum, the rate-determining step is the first-order removal of adsorbed NO_2.

Solution-Precipitation Mechanism in Lead-Acid Cell Electrode Reactions

J. L. Weininger*

General Electric Company, Corporate Research and Development, Schenectady, New York 12301

One of the most interesting aspects of the reaction mechanism at electrodes of galvanic couples is the path by which the reaction proceeds, whether through the solid state or by the way of the electrolyte. Solution transport of the electroactive material (in the solution-precipitation mechanism) is known to occur at lead, cadmium, zinc, and other electrodes.

Archdale and Harrison (1) have used rotating-disk and ring-disk electrodes to demonstrate the solution-precipitation mechanism for Pb dissolving in H_2SO_4 at low anodic potential with the formation of Pb^{2+} and subsequent precipitation of $PbSO_4$. They also found that at more anodic potential the reaction may proceed in the solid state by nucleation and growth.

Hughel and Hammar (2) first applied scanning electron microscopy (SEM) to the electrode materials of the lead-acid battery. They showed the morphology of the various battery materials before cycling. Others have also used SEM to investigate the behavior of lead alloys in acid solutions (3) and the function of lignin in the negative electrode (4). In the present work this method has been extended to cycled negative electrodes. In addition to the expected isotropic structure of the porous electrode, at sufficiently large magnification there were observed extremely intricate, open, symmetrical crystal structures which derived from a solution-precipitation mechanism. This report also attempts to relate the observed dimensions of the microcrystals to a recently developed criterion of Vetter (5) which involves an evaluation of the concentration gradients in the electrolyte relative to the minimum solubility necessary for solution transport of the electroactive material.

Experimental

The structure of the negative electrode was monitored during cycle life. It differed from conventional

* Electrochemical Society Active Member.

Key words: scanning electron microscopy, lead negative electrode, lead and lead sulfate crystal structure.

lead-acid battery electrodes by having a lead-plated copper screen substrate and by the addition of a polymeric binder (neoprene) to the paste. The purpose of the polymer addition was to produce a flexible, more durable negative electrode. Addition of carbon black compensated for the conductivity lost by the presence of polymer.

The same active material,[1] containing a leady oxide (approximately 25% Pb and 75% PbO) and an organic expander was used for the test electrode and for the control electrode.

The polymer-bonded electrode had an area of 5 $\times$ 5 cm, 0.3 cm thickness, and a theoretical capacity of 3.0 A-hr. It was charged and discharged at the C/4 rate (6 mA/cm^2) against two conventional positive electrodes with a combined higher capacity than the negative. Periodically, small samples of the negative were taken from a location near the edge of the electrode, washed in distilled water, and mounted for examination in SEM. Micrographs in this report are of samples taken during cycles 29 and 73. To illustrate the SEM method a few micrographs of conventional electrodes after their formation and at the end of cycle life are also shown.

Scanning Electron Microscopy

The initial appearance of the active electrode materials, after formation but before cycling, is shown for conventional negative (Fig. 1) and positive (Fig. 2) pasted electrodes. The original outline of the litharge particles from which the materials were formed can be noted in both cases. At the negative plate, formation produced acicular lead crystals as long as 15μ and approximately 0.75μ thick; at the positive plate PbO_2 dendrites, 500-1500Å wide, with dendrite separation of about 500Å, were produced.

Figures 3, 4, and 5 are micrographs of the polymer-bonded electrode at the end of discharge in cycle 29. Figure 3 shows a field of star-like $PbSO_4$ crystals, one of these structures is enlarged in Fig. 4. The individual crystals are 1.4μ wide and up to 50μ long. In the central cluster the separation of crystals varies from 0 to about 1.6μ. Small dots or balls are also visible in these micrographs. At the much larger magnification of 40,000$\times$ these clumps have a coral structure (Fig. 5). The individual coral strands are 500-750Å wide and have a similar distance of separation between individual strands.

Figures 6, 7, and 8 are micrographs obtained at the end of charge during cycle 73. Figure 6 shows very

Fig. 6. Negative electrode at end of charge 73,500X

large, 0.65μ thin blades of crystals. In Fig. 7 similar crystals are covered with round structures which on further magnification (Fig. 8) have a remarkable flower-like structure. The central part has petals, about 0.5μ thick, separated from each other at a distance of 0.1-0.2μ.

Finally, returning to conventional pasted electrodes, Fig. 9 depicts a negative electrode at the end of cycle life, after 163 cycles when the cell could no longer accept a reasonably large charge. The bulky crystals are 0.5-5μ large with an average distance of separation of about 2μ. They resemble a sponge lead structure, shown by Hughel and Hammar (2) for a formed negative plate without expander.

Solution-Precipitation Mechanism

The above micrographs indicate that the microcrystals were grown by a solution transport mechanism. For a more quantitative description of this process, Vetter established the criterion

$$\Delta c << c$$

where Δc is the concentration gradient of $PbSO_4$ or that of Pb(II) ions and c is the solubility of $PbSO_4$. The value of c_{PbSO_4} in 1.12 sp. gr. and 1.26 sp. gr. H_2SO_4 at 25°C is, respectively, 21.8×10^{-6} and 6.6×10^{-6} mole/liter (6). Δc can be estimated from the electrode, diffusion, and electrical parameters by the expression

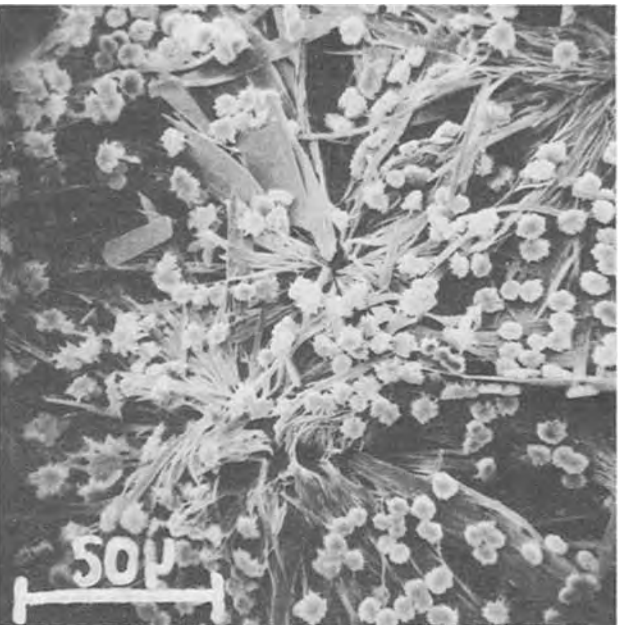

Fig. 7. Negative electrode at end of charge 73,500X

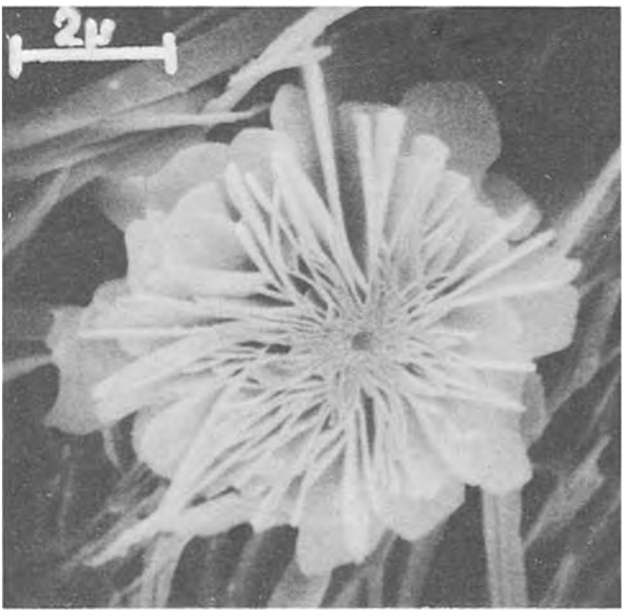

Fig. 8. Portion of Fig. 7 enlarged, 10,000X

$$\Delta c = \frac{I \cdot 2P}{A^2 \cdot \rho^2 \cdot (1 - P)^2 \cdot d \cdot n\mathbf{F} \cdot D}$$

where I (in A/cm^2) is the current density applied to the electrode, having a porosity P (pore volume/total volume), internal surface area A (cm^2/g), density ρ (g/cm^3), electrode thickness d (cm), and a diffusion coefficient D (cm^2/sec) of the soluble species. Burbank, Simon, and Willihnganz (7) quote internal surface area of 7-24.5 m^2/g for positive electrodes. A smaller internal surface area is expected for negative electrodes (compare, for example, Fig. 1 and 2), for which a reasonable assumption of internal surface area would be 0.1 to 1 m^2/g. Taking the lower value of 0.1 m^2/g and evaluating Δc from the experimental conditions used in cycling the electrodes shown in the micrographs, one obtains $\Delta c = 6.6 \times 10^{-7}$ mole/l from these parameters: $I = 0.006$ A/cm^2, $P = 0.5$,

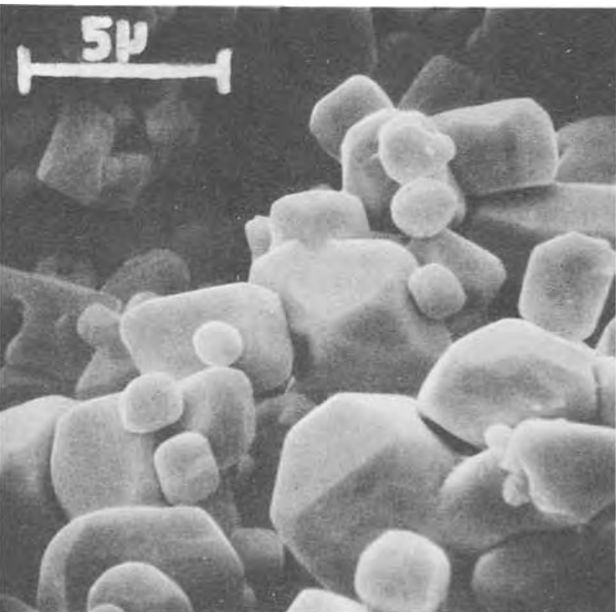

Fig. 9. Negative plate at end of cycle life-cycle, 5000X

$A = 10^3$ cm²/g, $\rho = 11$ g/cm³, $d = 0.3$ cm, $n = 2$, $\mathbf{F} = 10^5$ A · sec/equiv., and $D = 5 \times 10^{-6}$ cm²/sec. Compared to $c = 6.6 \times 10^{-6}$ mole/liter, this fulfills Vetter's criterion for the condition of the solution-precipitation mechanism.

In this order of magnitude calculation Vetter's criterion, $\Delta c << c$, applies equally to the charge and discharge mechanisms of the electrode reaction, for at steady-state dendrite growth is controlled by the diffusion of Pb(II) ions from or to the solution, depending on whether Pb or $PbSO_4$ is formed.

For the charging process, corresponding to Fig. 6-8, the specific gravity of 1.26, the density of Pb, and the solubility of $PbSO_4$ in that solution are used. Even with the small internal surface of 0.1 m²/g the criterion $\Delta c << c$ is fulfilled by a factor of 10; the factor would increase to 1000 for 1 m²/g. For the discharged electrode, corresponding to the conditions in Fig. 3-5, the density of $PbSO_4$ and its solubility in the less concentrated 1.10 sp. gr. acid would be used.

The structures shown in the micrographs vary widely in terms of internal surface area and porosity. However, they can be placed in context with Vetter's criterion. It can be postulated that the structures shown in series of Fig. 3-5 and Fig. 6-8 cease to grow by solution-precipitation in the open areas because of large porosity in those locations which depletes the concentration of active soluble material (Δc is large). On the other hand, in the dense tight central structures with large internal surface areas the mechanism proceeds and allows unique crystal structures to grow.

Some Observations on Rechargeable Lithium Electrodes in a Propylene Carbonate Electrolyte

R. Selim and P. Bro*

P. R. Mallory and Company, Incorporated, Laboratory for Physical Science, Northwest Industrial Park, Burlington, Massachusetts 01803

Organic electrolyte lithium systems have been reported which give promising results when operated as rechargeable batteries (1-8). It is characteristic of most of this work that either the discharges were initiated shortly after the completion of the charges, the stoichiometric lithium capacities were in a considerable excess of the charge per cycle, or the capacities of deposition were far less than those likely to be useful in practical cells (of the order of 5 mA-hr/cm²). These circumstances tend to obscure the intrinsic cycling characteristics of the lithium electrode and may lead to tenuous conclusions about the suitability of a system as a rechargeable organic electrolyte lithium battery.

In our work (1) with such solvents as propylene carbonate, butyrolactone, dimethylformamide, and dimethylsulfoxide, as well as in subsequent unpublished work with other solvents, we have found the behavior of lithium on electrodeposition, as well as anodic discharge of the electrodeposit, to be similar for different solvents. We have recently performed some further experiments designed to give a clearer picture of the cyclability of the lithium electrode in a propylene carbonate solution of lithium perchlorate. The results will be found, we believe, to be similar in nature to those found under equivalent conditions in other solvent systems. We believe the methodology described herein reflects more accurately the intrinsic properties of lithium under practical conditions than do other methods

reported so far. A brief description of the experiments and some results will be given in this report.

Experimental

The cell arrangement was extremely simple and was designed to insure a uniform current distribution across the face of the working electrode. The cell was a 3¼ in. length of a ¾ in. diameter glass tubing supported vertically in a heavy brass base to minimize vibration. The working electrode, in the bottom of the tube, was a brass cylinder with an O-ring which was machined to fit tightly in the glass tube. The top of the cell was closed by a rubber stopper through which projected a stainless steel lead connected within the cell to an expanded stainless steel circle on which was pressed a circle of lithium foil. This served as the counterelectrode and was positioned parallel to and about 1½ in. above the face of the brass working electrode.

Solutions were prepared from distilled propylene carbonate and vacuum oven-dried $LiClO_4$ and contained about 40 ppm of water. Before each run the working electrode surface of the brass cylinder was metallographically polished. Solutions were prepared and the cells assembled, filled, and closed in a dry box in an inert argon atmosphere.

Cathodic deposition and anodic stripping were done at constant current and the cell voltage was monitored. The end of anodic stripping was signalled by an abrupt voltage excursion. The stripping efficiency was calculated by dividing the number of coulombs passed before this rapid polarization by the total number of coulombs passed during the previous deposition. The amount of metallic lithium remaining on the electrode was calculated from the volume of gas evolved when the rubber stopper was removed and the cell placed in a closed system containing water.

Results and Discussion

The efficiency of the charging process was close to 100% as determined by the chemical analysis of the lithium deposit within a few hours of the charging cycle (Fig. 1). When the lithium deposit was permitted to age the amount of metallic lithium present on the electrode decreased, most likely because of its reaction with the solvent. About 15% of the lithium was lost from the electrode in 40 hr at 25°C. The appearance of the deposit suggested a mossy structure and some of the loss may have been physical rather than chemical.

In a parallel series of experiments it was found that the discharge efficiency of the fresh lithium deposit was about 60% (Fig. 2). However, the discharge efficiency decreased much more rapidly with an increasing age of the deposit than did the lithium content of the deposit. After 40 hr at 25°C it approached zero even though the deposit still contained 80% of the original metallic lithium. None of the residual lithium was available for discharge. Our tentative conclusion is that the chemical reaction(s) between the lithium and the electrolyte had gradually changed the physical structure of the lithium deposit to render most of the lithium inaccessible to the current collector.

An illustration that lithium/electrolyte reactions may have such an effect is given in Fig. 3 where it may be seen that the deliberate addition of water to

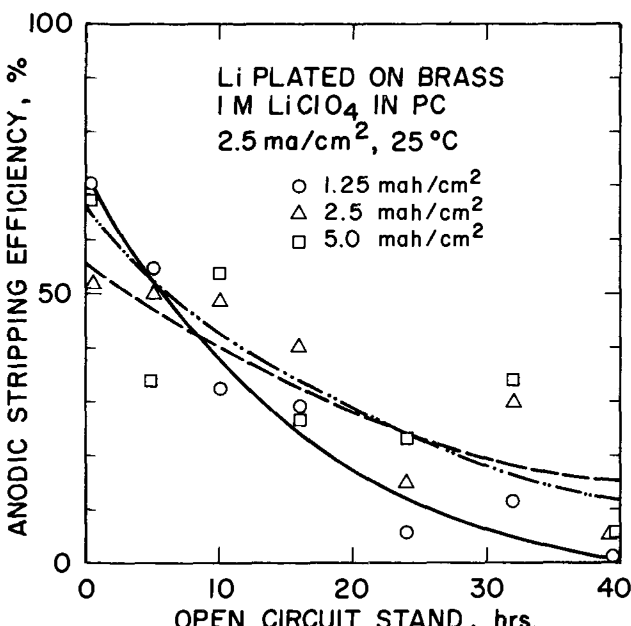

Fig. 2. The discharge efficiency of electrodeposited lithium

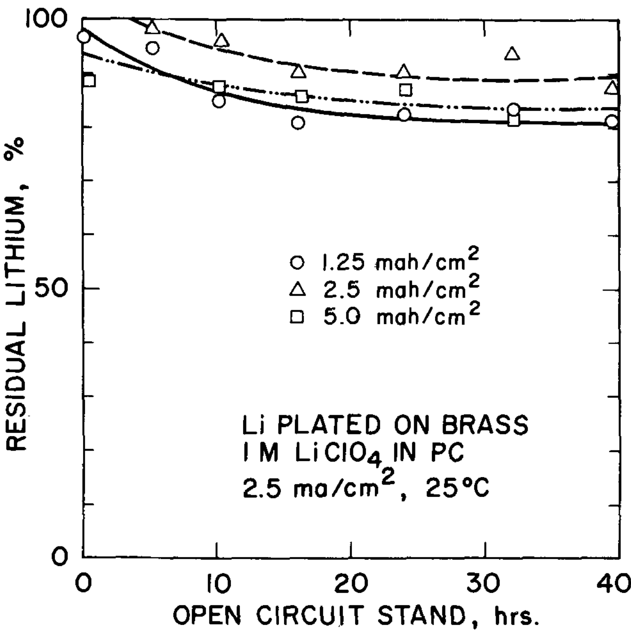

Fig. 1. Chemical analysis of lithium deposition efficiency

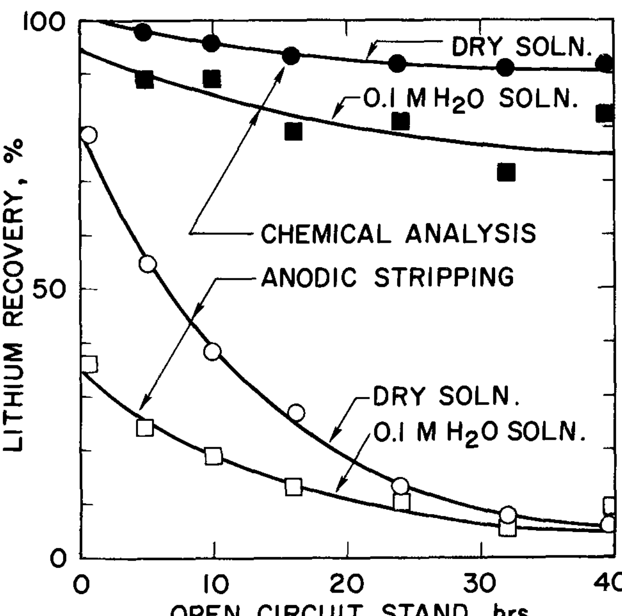

Fig. 3. Chemical and electrochemical availability of electrodeposited lithium in wet and dry electrolytes. 1M $LiClO_4$ in PC at 25°C, 2 mA/cm^2, 2.5 $mA\text{-}hr/cm^2$.

the electrolyte decreased the discharge efficiency markedly relative to that observed in the dry electrolyte. The discharge efficiency of the fresh lithium was 80% in the dry electrolyte and 35% in the 0.1M H_2O electrolyte. After 40 hr, the efficiencies had decreased to almost zero despite the presence of about 90 and 75% of the original metallic lithium in the electrodes for the dry and the wet electrolytes, respectively. It was interesting to note that the lithium deposit was quite compact in the 0.1M water solutions and almost completely nondendritic in nature.

If the lithium/electrolyte reactions were that significant in affecting the discharge efficiency, they should also affect the charging efficiency at some current density. The data in Fig. 4 show that this was so. In the dry electrolytes the charging efficiency decreased noticeably below 0.1 mA/cm²; in the 0.3M H_2O electrolyte it decreased below 2 mA/cm². At a current density of 0.01 mA/cm², the charging efficiencies were comparable for the two solutions.

The contributions of dendritic or loose lithium to the discharge inefficiencies of fresh lithium deposits may be judged from the data in Fig. 5. The electrolyte was swirled about the lithium electrodes by strong handshaking to dislodge dendrites and loose fragments

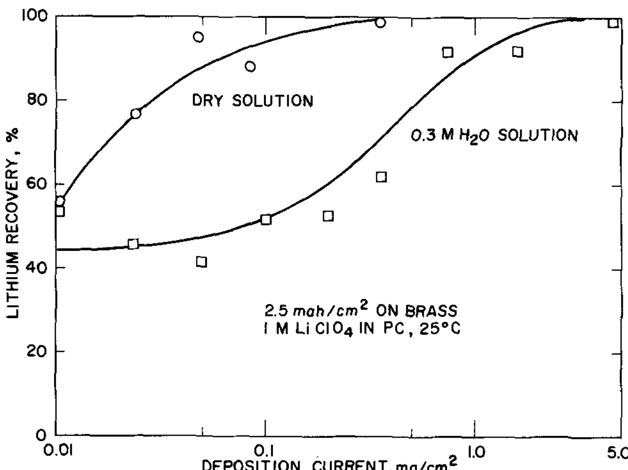

Fig. 4. The effect of parasitic reactions on the charging efficiency.

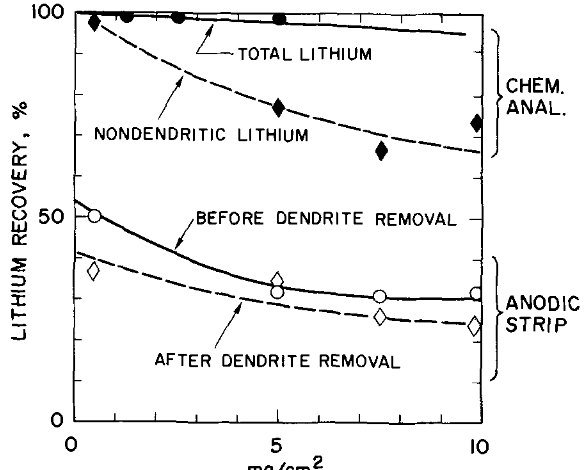

Fig. 5. The effect of the lithium morphology on the charge recovery. 1M $LiClO_4$ in PC at 25°C, 5 mA/cm².

from the lithium deposits, and the electrodes were then either discharged or analyzed for residual metallic lithium. At a current density of 5 mA/cm² for the charging cycle it was found that the fraction of dendrites and loose fragments amounted to 5% at 1 mA-hr/cm² and 30% at 10 mA-hr/cm², as determined by chemical analyses. The discharge efficiencies of the undisturbed deposits decreased from about 50 to 30% over the same specific capacity range, and only slightly lower values were obtained when the dendrites and loose fragments were removed from the lithium electrode prior to the discharge. The difference between the lithium contents as determined by chemical analyses after dendrite removal and the lithium contents as determined by electrochemical discharge showed that the discharge inefficiencies must be attributed to the physical state or morphology of the deposit proper and are not attributable to gross dendrites or loose lithium fragments. An arbitrary distinction is made here between the microscopic dendrites that form a mossy structure and the large dendrites that may be seen protruding well above the surface of the mossy deposit.

The experimental results raise some questions in regard to the suitability of lithium electrodes for rechargeable organic electrolyte batteries. It would seem that a low intrinsic lithium/electrolyte reactivity may be a prerequisite for the satisfactory cycling of such a battery. It is our concern, however, that any polar solvent is intrinsically reactive toward lithium because of the existence of an electron deficient region about a highly electronegative atom, which forms the positive end of the dipole. This intrinsic reactivity may go undetected by static experiments but may be crucial in deposition and reanodization experiments of the type described herein.

We would encourage investigators of rechargeable organic electrolyte lithium batteries to include in their reports data on cells with stoichiometric anode capacities comparable to the coulombic charge per cycle and data on cells that are permitted to remain on open circuit for various extended periods of time after charging and prior to discharge. The satisfactory performance of an organic electrolyte lithium battery in such experiments is a necessary, but not sufficient, condition for satisfactory cyclability.

Discharge Behavior of Li/MoO_3 Cells

Nehemiah Margalit*

ESB Incorporated, Technology Center, Yardley, Pennsylvania 19067

The system Li/MoO_3 was proposed, as early as 1965 by Knapp (1), for use in nonaqueous cells using organic solvents. Since then several investigators have used the system (2-8) but the cathode reaction remained unknown. The assumption was made that the cathode reaction involved a two-electron transfer per molecule of MoO_3 and that reported coulombic efficiencies did not exceed 75% to a 1.8V cutoff. Campanella and Pistoia (2) using Li/0.9M $LiAlCl_4$ γ-butyrolactone/MoO_3 cells recognized that the operating voltages of their cells exceeded the open circuit voltage predicted from thermodynamic data, assuming the products to be Li_2O and MoO_2 or Mo_2O_5. Further investigation by the latter led them to the conclusion that the electrochemical reaction involves a two-electron transfer (6).

Li/MoO_3 cells discharged in our laboratory (4, 8) exhibited two useful discharge plateaus at the end of which a maximum of 1.5 Faradays per mole of MoO_3 was obtained. Therefore, an attempt was made to verify both the two-electron hypothesis and the true nature of the discharge curve using a slow, continuous discharge of a complete cell.

Experimental

Standard button cell hardware was used as casing for making cells 0.41 cm high and 1.1 cm in diameter. The anode was punched from a high purity lithium ribbon (Foote Mineral Company, 99% pure) and rinsed twice with hexane (MC/B, Manufacturing Chemists, spectroquality grade). The cathode was made from MoO_3 powder (Mallinckrodt, analytical reagent), porous carbon powder, and Teflon in several ratios with the active material weighing between 85 and 95% of the finished cathode. The solvent, γ-butyrolactone (Eastman), was distilled on a spinning band column (Nester/Faust, NF 276) at 5 mm Hg. The middle fraction, boiling between 68.0 and 68.8°C (uncorrected) was collected. The salt $LiAsF_6$ (U.S. Steel), was used as received. One point five molar solutions prepared in a dry room and sealed in a glass vessel were stored for periods exceeding 5 months without apparent deterioration. Cells were assembled in the dry room, allowed to reach a constant open circuit voltage, and finally discharged at room temperature across 15×10^3 (±1%) ohm resistors. Readings were obtained daily, manually, using a high internal impedance digital voltmeter.

Results and Discussion

Initial open circuit voltages exceeded 3V in agreement with Knapp and Dey (1, 7). However, these voltages were reduced to 2.85V after standing for several days at room temperature. Discharge data indicated utilization of about 50% based on 2 Faraday per mole of MoO_3. The discharge curves consistently exhibited what appeared to be an end of a first plateau at about one-third of the obtained discharge capacity. Of particular interest was the discharge behavior at 35°C as shown in Fig. 1. Such cells delivered better than 70% of their theoretical capacity and the end of what appears as a first plateau was at about one-third of the obtained capacity. Such cells delivered 0.5 Faraday/mole, at the end of the first plateau, and a total of 1.5 Faraday/mole for the total discharge.

A re-examination of other authors' published discharge data (2-4, 7, 8) indicates that similar points of inflection are characteristic of Li/MoO_3 systems. Indeed what seems to be a slowly growing concentration polarization is consistently ending at about 25% utilization on the basis of two electrons/molecule for highly efficient systems (3, 4, 7, 8), *i.e.,* 0.5 Faraday/mole. Indeed such a distinct two plateaus discharge has been shown by Dey (7) for a battery. Such discharge characteristics of MoO_3 have been recently reported for both nonaqueous and aqueous systems. Popov and Laitinen (9) obtained, in a molten salt environment, a product whose empirical formula is $Li_5Mo_2O_8$. In such a product, the formal oxidation state of molybdenum is +5.5. At the same time Gabano *et al.* (10) reported that upon reducing MoO_3 in 7*N* H_2SO_4, one observes a major reduction plateau starting at a calculated product composition of about $MoO_{2.8}$ and ending at a calculated product composition of about $MoO_{2.2}$. A comparison of the latter data with those presented here reveals that in both cases, formal charges of +5.5 and +4.5 can be calculated for the boundary of what seems to be the major plateau. The formation of a new cathode material in our Li/MoO_3 cells after the apparent $n = 0.5$ reduction is further confirmed by a 2.4-2.5V open circuit voltage observed for partially discharged cells.

The above is not in disagreement with the reduction mechanisms proposed by Popov and Laitinen (9), Gabano (10), or Campanella and Pistoia (6) as the initial electrochemical reaction could involve a two-electron step. However, as Popov and Laitinen propose, the primary reaction product probably reacts further with MoO_3 to form polymolybdates, hence the net observed changes of 0.5 electrons per MoO_3 molecule with initial open circuit voltages of 2.85V.

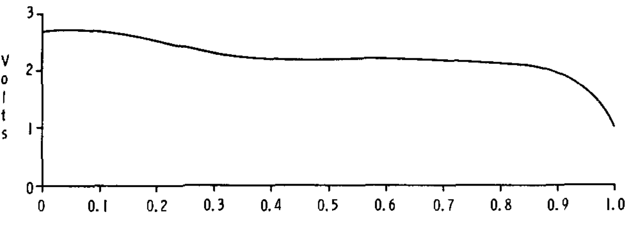

Fig. 1. Discharge behavior of Li/1.5M $LiAsF_6$-γ-butyrolactone/MoO_3 cells. 35°C, 15.0 × 10^3 ohm load, 577 hr of discharge.

On the Ultraviolet Inhibition of Electroless Plating on Plastics

M. Schlesinger and B. K. W. Baylis

Department of Physics, University of Windsor, Windsor, Ontario, Canada

In a recent communication (1) we reported on the inhibition of electroless metal plating on glass using ultraviolet light. We employed in that study the so-called conventional sensitizing activating surface pretreatment path. The observation was made that u.v. inhibition had not proved possible if the catalyzing ($PdCl_2/SnCl_2/HCl$) accelerating (HCl or NaOH and similar) path was followed.

It is the aim of the present note to give some results concerning the successful u.v. inhibition and growth patterning of electroless deposition on plastics using the catalyzing path. Specifically, our results to date show that the effect of u.v. light can be presented as follows

$$C \rightarrow R_1 \rightarrow A \rightarrow R_2 \rightarrow M$$
$$\uparrow$$
positive

where C stands for the combined $PdCl_2/SnCl_2/HCl$ catalytic bath [Shipley 9F (2)], R for a DI water rinse, A for the accelerator, and M for the metallizing bath [a room temperature Ni-P bath, the composition of which is reported in Ref. (3)].

If u.v. light is applied after catalyzing, deposition of the positive occurs essentially only on the areas protected by the mask, resulting in sharply defined metal strips separated by bare plastic. Exposure of the substrate to ultraviolet radiation at other stages in the above sequence results in either "positives" or even "negatives" (1) depending on the specific stage at which the irradiation takes place. The resulting images show markedly less contrast because there is considerable background remaining.

As noted in Ref. (5) the substrate and its condition seem to play an important role in determining the activity of the catalyst. It seems to play an important role also in determining the effectiveness of the u.v. inhibition or promotion of growth (*i.e.*, the creation of a positive or negative image of the photomask).

Key words: electroless, u.v. inhibition, catalytic systems, plating.

Most of the above observations were made on platable grade ABS[1] which had been properly precleaned. Other plastics on which it has been possible to obtain patterns are epoxy, Plexiglas, Formvar, Polyamide, and cellulose acetate. It would appear at this stage that deglazing or some roughening of the surface prior to the sequence of premetallizing baths is of prime importance.

Further study of the above effects is being undertaken in our laboratory.

Direct Electrochemical Determination of Hammett Substituent Constants

Thomas L. Riechel,[1] Janice J. Kim,[2] and Peter A. Rock*

Department of Chemistry, University of California at Davis, Davis, California 95616

Probably the best known, and the most successful, semi-empirical, linear-free-energy relationship is that proposed by Hammett (1, 2). The Hammett rho-sigma equation

$$\log \frac{k}{k'} = \rho\sigma \qquad [1]$$

has been found to correlate the rate and equilibrium constants of a great variety of side-chain reactions of *meta*- and *para*-substituted benzoic acid derivatives. In this equation k is a rate or equilibrium constant of a substituted benzoic acid derivative, k' is the corresponding constant for the unsubstituted derivative, ρ is the reaction series constant, and σ is the substituent constant. The reaction series constant is independent of the nature of the substituent, but depends on the solvent, the temperature, and the particular reaction series. The Hammett substituent constant σ is defined (1) by the equation

$$\sigma \equiv \log \frac{K}{K'} \qquad [2]$$

wherein K is the thermodynamic acid dissociation constant for a *meta*- or *para*-substituted benzoic acid in water, and K' is the acid dissociation constant for benzoic acid in water, both at 25°C.

The calculation of σ values using Eq. [2] together with separately determined experimental values of K and K', yields σ values as small differences between two (relatively) large numbers, that is, $\sigma = \log K - \log K'$. The determination of accurate (± 0.004 or better) σ values requires even more accurate (± 0.002 or better) pK values in aqueous solution for benzoic acid and its *meta*- and *para*-derivatives.

The potentially most accurate method for the determination of pK values for benzoic acids in water is from electrochemical cell data. The most extensive electrochemical study of the ionization constants of benzoic acids in water is that reported by Briegleb and Bieber (3). However, the accuracy of the pK values reported by Briegleb and Bieber has been criticized in two review articles on the ionization constants of acids (4, 5). Furthermore, there are disagreements between the electrochemically determined pK values of Briegleb and Bieber and the spectrophotometrically determined pK values of Wilson *et al.* (6). The possible uncertainties ($\sim\pm 0.02$ pK units) in the measured pK values of benzoic acids may give rise to considerable uncertainties ($>\pm 0.04$ pK units) in the values of the Hammett substituent constants calculated from these pK values.

The inherent difficulties associated with the determination of σ values as small differences between two large numbers can be eliminated by a direct measurement of σ. We have used the electrochemical double cell

$$\begin{aligned}&H_2(g,Pt)|C_6H_5COOH(m_1), C_6H_5COONa(m_2),\\ &NaCl(m_3)|AgCl(s)|Ag(s)|AgCl(s)|XC_6H_4COOH(m_4),\\ &\qquad XC_6H_4COONa(m_5), NaCl(m_6)|H_2(g,Pt)\end{aligned} \qquad [3]$$

(where X represents a *meta*- or *para*-substituent, and the m_i values are molalities) for the direct electrochemical determination of Hammett σ values; this communication outlines the basic method and reports our results for the σ value of *meta*-methylbenzoic acid.

Experimental

The cell electrolytes were prepared in a glove box under a nitrogen atmosphere. The distilled water used to prepare the cell solutions was boiled and stored under a nitrogen atmosphere. The benzoic acid and the m-methylbenzoic acid (Eastman reagent grade) were dissolved in CO_2-free NaOH(aq) and recrystallized by addition of HCl(aq). Primary standard NaCl, constant-boiling HCl(aq), and carbon dioxide-free NaOH(aq) were used to prepare the cell solutions.

The hydrogen electrodes (7) were closed-loop, platinum coils, 5 mm in diameter and 20 mm in length, consisting of seven turns of 0.020 in. diameter Pt wire. The coils were soaked in reagent-grade acetone, and cathodically cleaned at 50 mA in 3M H_2SO_4(aq) overnight. After the acid cleaning, the electrodes were rinsed in distilled water and a light coating of Pt black was electroplated onto the coils [5 mA for 5 min and then 10 mA for 6 min in 10% $H_2PtCl_6 \cdot 6H_2O$ in 2M HCl(aq) plating solution]. Bias potentials between hydrogen electrodes were found to be less than 20 μV. New electrode coils were prepared for each cell. The platinum electrode lead was brought into the cell from above through a Pt-to-soft-glass seal. The silver-silver chloride electrodes were prepared on closed-loop platinum coils using the thermal electrolytic method (7). Bias potentials of aged electrodes were less than 20 μV. Ag/AgCl electrode leads were brought into the cell from above via a Pt-to-soft-glass seal.

The design of each half of the double cell was of the basic H-type with a large-bore, ground-glass stopcock between the chambers. A H_2 gas presaturation chamber was attached to each of the hydrogen electrode compartments. The H_2 gas was run through a DEOXO hydrogen purifier (Englehard Industries), then through the presaturator (filled with cell electrolyte), and then into the cell.

The electrodes were presoaked in cell electrolyte overnight, then the cell was filled with electrolyte and the electrodes were mounted in the cell by means of ground-glass joints. The respective halves of the double cell were connected externally and the entire assembly was immersed in an oil bath (recirculation sump type). The temperature of the oil bath thermostat (± 0.002°K) was maintained by a proportional heater and monitored with a certified Leeds and Northrup Company platinum resistance thermometer and a G-2 Mueller bridge. Hydrogen gas was bubbled through the cell for approximately 1 hr before the emf measurements were begun. The cells were then closed and the double cell emf was measured on a certified Leeds and Northrup Company universal potentiometer. The cells attained a stable ($<\pm 0.1$ mV) voltage within 1-2 hr.

Results

The over-all reaction of cell [3] can be obtained as follows (L = left, R = right hand side cell electrolyte)

$$\tfrac{1}{2}H_2(g,L) = H^+(aq,L) + e^-$$

$$AgCl(s) + e^- = Cl^-(m_3) + Ag(s)$$

* Electrochemical Society Active Member.
[1] Present address: Department of Chemistry, University of California, Riverside, California 92501.
[2] Present address: Department of Chemistry, University of California, Berkeley, California 94700.
Key words: hydrogen, Hammett, substituent, electrode, sigma.

$$\begin{array}{r}
Cl^-(m_6) + Ag(s) = AgCl(s) + e^- \\
H^+(aq,R) + e^- = \tfrac{1}{2}H_2(g,R) \\
\hline
\tfrac{1}{2}H_2(g,L) + H^+(aq,R) + Cl^-(m_6) \\
= \tfrac{1}{2}H_2(g,R) + H^+(aq,L) + Cl^-(m_3)
\end{array} \quad [4]$$

Application of the Nernst equation to this reaction under conditions where $a_{H_2(R)} = a_{H_2(L)}$ (equal hydrogen pressures) yields ($\mathcal{E}^\circ = 0$)

$$\mathcal{E} = -\frac{RT}{\mathbf{F}} \ln \left\{ \frac{a_{H^+(L)} a_{Cl^-(m_3)}}{a_{H^+(R)} a_{Cl^-(m_6)}} \right\} \quad [5]$$

We now define

$$K' = \frac{a_{H^+(L)} a_{C_6H_5COO^-}}{a_{C_6H_5COOH}} \quad [6]$$

and

$$K = \frac{a_{H^+(R)} a_{XC_6H_4COO^-}}{a_{XC_6H_4COOH}} \quad [7]$$

Combination of Eq. [6], [7], and [2] with Eq. [5] yields

$$\mathcal{E} = +2.3026 \left(\frac{RT}{\mathbf{F}} \right) \sigma - \frac{RT}{\mathbf{F}} \ln \left\{ \frac{m_3[m_1 - m_{H^+(L)}][m_5 + m_{H^+(R)}]}{m_6[m_4 - m_{H^+(R)}][m_2 + m_{H^+(L)}]} \right\} - \frac{RT}{\mathbf{F}} \ln \left\{ \frac{\gamma_{C_6H_5COOH}}{\gamma_{XC_6H_4COOH}} \cdot \frac{\gamma_{Cl^-(m_3)}}{\gamma_{Cl^-(m_6)}} \cdot \frac{\gamma_{XC_6H_4COO^-(m_5)}}{\gamma_{C_6H_5COO^-(m_6)}} \right\} \quad [8]$$

Under conditions where the ionic strengths of the L and R solutions are approximately equal, Eq. [8] reduces to

$$\mathcal{E} = + \left(\frac{2.3026\, RT}{\mathbf{F}} \right) \sigma - \frac{RT}{\mathbf{F}} \ln \left\{ \frac{m_3[m_1 - m_{H^+(L)}][m_5 + m_{H^+(R)}]}{m_6[m_4 - m_{H^+(R)}][m_2 + m_{H^+(L)}]} \right\} \quad [9]$$

This equation shows that the use of the double cell [3] yields a direct relationship between the measured cell voltage and the Hammett substituent constant. A determination of $\mathcal{E}$ to $\pm$ 0.1 mV, which is not difficult to achieve in cells of the type of cell [3], yields a σ value to within $\pm$ 0.003 units.

An example of the type of results that can be obtained from emf measurements on cells of the type of cell [3] is provided by the following data for the case where X is *meta*-methyl. For a cell with the concentrations: $m_1 = 1.824 \times 10^{-4}$ mole $\cdot$ kg^{-1}; $m_2 = 1.734 \times 10^{-4}$ mole $\cdot$ kg^{-1}; $m_3 = 0.1013$ mole $\cdot$ kg^{-1}; $m_4 = 1.614 \times 10^{-4}$ mole $\cdot$ kg^{-1}; $m_5 = 1.933 \times 10^{-4}$ mole $\cdot$ kg^{-1}; and $m_6 = 0.1020$ mole $\cdot$ kg^{-1}, the following voltages were obtained: -4.82 mV (25.228°C); -3.94 mV (30.000°C); -3.14 mV (35.326°C); -2.41 mV (40.221°C); -2.13 mV (45.323°C); -1.87 mV (50.314°C). The ionic strengths of the two cell electrolyte solutions were 0.1015 (L) and 0.1022 (R).

The procedure used to calculate a σ value was as follows: K_a values for benzoic acid and *meta*-methylbenzoic acid were calculated from the data summarized by Larson and Hepler (5), (benzoic acid "best values" were used); these K_a values were used to estimate $m_{H^+(L)}$ and $m_{H^+(R)}$ from solution of the quadratic equation; the values of $m_{H^+(L)}$ and $m_{H^+(R)}$ were then used to calculate the second term (call it the molality term) on the right-hand side of Eq. [9]; a value of σ was then calculated from Eq. [9] using the measured emf value and the estimated value of the molality term. A revised value of K_a for meta-methylbenzoic acid was then calculated from the σ value using Eq. [2] and Larson's and Hepler's "best" value for the K_a of benzoic acid. The revised value of K_a for *meta*-methylbenzoic acid was then compared with the original value. If the difference was greater than or equal to 1×10^{-7}, then σ was recalculated using the revised K_a value. Iterations were continued until the difference between K_a estimates was less than 1×10^{-7}. Computer runs starting with both high and low initial estimates for the K_a value of *meta*-methylbenzoic acid were made to insure that the function was converging on the true value of σ. These initial variations of the value of K_a, as well as variations over the range of reported K_a values for benzoic acid itself, did not significantly affect the final value of σ. In each case five or six iterations were necessary to reach the chosen maximum error limit. The log (K/K') values obtained at the various temperatures are: log (K/K') $= -0.016 \pm 0.002$ (25.2°C); $+0.007 \pm 0.002$ (30°C); $+0.027 \pm 0.003$ (35.3°C); $+0.046 \pm 0.002$ (40.2°C); $+0.053 \pm 0.002$ (45.3°C); and $+0.060 \pm 0.001$ (50.3°C).

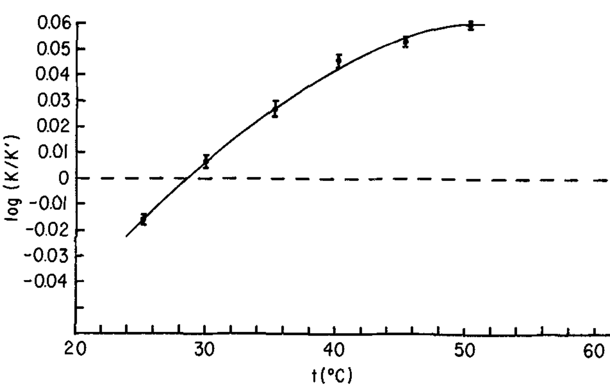

Fig. 1. Plot of log(K/K') vs. temperature (°C) for *meta*-methylbenzoic acid in water.

A plot of log (K/K') *vs.* temperature for *meta*-methylbenzoic acid is given in Fig. 1. It can be seen in this figure that, in terms of the usual interpretation of Hammett σ values, the *meta*-methyl group might be regarded as either electron donating or electron withdrawing relative to hydrogen, depending on whether the temperature chosen to define σ is below or above about 29°C, respectively.

The value of σ obtained at 25°C (-0.016) is in fair agreement with that calculated from the data given in Ref. (3), namely, $\sigma = -0.03$; a value of $\sigma = -0.07$ is calculated from data given in Ref. (6). Extrapolations of the data given in Ref. (3) and (6) also lead to the conclusion that log (K/K') changes sign; however, the sign change occurs at temperatures of 48° and 44°C, respectively.

The Growth of Anodic Aluminum Oxide Layers after a Heat-Treatment

C. Crevecoeur and H. J. de Wit

Philips Research Laboratories, Eindhoven, The Netherlands

ABSTRACT

Aluminum was anodized in a solution of ammonium pentaborate in ethylene glycol with a current density of 0.25 mA/cm^2 to voltages between 9.8 and 183V. After annealing to 400°C in oxygen the specimens were reanodized in the same solution, either with a constant rate of voltage increase or at constant voltage. In both cases the current displays a peak as a function of time. With increasing voltage the peak occurs slightly above the original forming voltage, at constant voltage an induction period occurs before the current starts to increase. After passage of the peak annealed and unannealed specimens behave in the same way. The efficiency of the reanodization after annealing has remained unity: the layer grows. Transmission electron micrographs of layers stripped after interruption of the reanodization show that in the peak growth occurs inhomogeneously: black spots occur which are thickenings of the layer, the surface of which increases as the reanodization is interrupted in a later stage. The effect can formally be described as a two dimensional phase transformation. A model in which the theory of the kinetics of phase transformations is combined with the experimental exponential relation between ionic current and field during anodization leads to an equation which in most cases accurately describes the reanodization curves.

Heating of anodic oxide layers is customary during the production of electrolytic capacitors. In dry capacitors, for instance, in which the counterelectrode consists of a layer of so-called "manganese dioxide," the latter is applied by dipping the anodized metal in a solution of manganese nitrate in water and oxidizing the wet sample at 300°-500°C in air. This procedure does not improve the quality of a capacitor and the question arises whether the heating of the anodic oxide is on its own, at least partly, responsible for this effect.

With this in mind we investigated the influence of annealing on the properties of anodic oxide layers. We have concentrated our attention on aluminum. This is a suitable metal with which to investigate annealing effects, because the anodic oxide remains noncrystalline and protects the metal from oxidation during heating. Heating of anodic tantalum oxide on the other hand causes a reaction between the oxide and the metal (1) as well as sharpening of the x-ray diffraction diagram (2) as reported by Vermilyea. A disadvantage of aluminum is its low melting point.

In general, when during anodization the current or voltage is suddenly changed or interrupted and reapplied, transient effects can be observed. Evidently adaption of the conductivity of the layer to the newly applied field requires some time. The transient becomes very pronounced if the oxide layer is heated (250°-450°C) before being submitted to further anodization. Reanodization curves of annealed films, obtained by regularly increasing the voltage across the cell, exhibit a very characteristic current peak, as reported first by Dignam (3). He showed that the ionic conductivity of the aluminum oxide after annealing was very small but that it could be restored by the application of a high electric field. Earlier Vermilyea (1) had reported that the ionic conductivity of anodic tantalum oxide decreased after annealing. After applying a constant voltage, new oxide would grow preferentially at metal grain boundaries and singularities within the grains, until finally the growth became uniform. Recently Kudo, Watase, and Kato (4) reanodized heated anodic tantalum oxide by the application of a constant voltage. They concluded that the relatively small number of charge carriers present after heating was increased not only by the applied electric field but also by the current.

We have made a detailed investigation of the reanodization of anodic aluminum oxide and found that, after annealing, further growth started inhomogeneously. This is shown in Fig. 10. The process can formally be described as a two dimensional phase transformation in which the annealed oxide with a low ionic conductivity is transformed into oxide with a normal ionic conductivity. A model will be presented in which the theory of the kinetics of phase transformations developed by Johnson and Mehl (5) and Avrami (6) is combined with the experimental exponential relation between ionic current and applied electric field for anodization as found by Güntherschulze and Betz (7) and Bernard and Cook (8). This leads to an equation which in most cases gives an accurate description of the reanodization curves.

Key words: annealing of anodic films, reanodization, heterogeneous growth, phase transformation, surface gain after electroetch.

Experimental

In a reanodization experiment an aluminum sample is successively cleaned, anodized, annealed, and re-

anodized. In this section the details of these different stages are described.

Pretreatment

Samples were punched from aluminum foil 0.3 mm thick, supplied by Merck, purity 99.95%, the main impurity being Si. The samples were spoons with a circular area of 14 mm diameter and a handle 4 mm wide and 2 cm long. The anodized surface used was about 3.7 cm^2.

The samples were roughly cleaned by immersion in an aqueous solution of caustic soda, 4g NaOH per liter, at 50°C for 15 sec, and more thoroughly by electropolishing in a bath consisting of 140 mliters C_2H_5OH, 40 mliters $HClO_4$ (70%), and 20 mliters 2-butoxyethanol (9). To avoid recrystallization of the aluminum during the experiments the samples were heated at 600°C for 15 min. To remove the thermal oxide layer and to polish, the samples were electropolished in the above-mentioned bath again for 2 min at 0.2 A/cm^2.[1] Then the samples were stored. Deionized water was used for rinsing.

Before anodization, the surface layer of the samples was removed by immersion in a bath containing 1.5 mliters HF (50%), 10 mliters H_2SO_4 (96%), and 90 mliters water at room temperature for 15-30 sec, followed by rinsing in methanol.

Anodization

Immediately hereafter the sample was anodized in a solution of 17g ammonium pentaborate in 100 mliters glycol (10). This electrolyte was chosen because it was known that anodic oxide layers were formed with a current efficiency of unity and because layers formed in this electrolyte showed a good thermal stability. The electrolyte was prepared at 90°C in the absence of air.

The anodization process was performed at 24° ± 1°C at constant current density, viz., 0.25 mA/cm^2. The voltage was measured relative to a platinum cathode. The voltage drop across the electrolyte was small (about 0.2V). When the voltage across the cell had reached a previously determined value, V_f, the current was interrupted. This voltage is called the forming voltage in this investigation and is therefore defined only for this particular current density. Rinsing in methanol completed the anodizing process.

Annealing

Finally the samples were heated for 15 min in oxygen at 400°C and immediately afterward used in one of the following experiments.

Reanodization

Reanodization was carried out in two ways, either with a regularly increasing voltage or with a constant voltage applied across the cell. The former method gives a good qualitative indication of the effects, whereas only the latter method is suitable to obtain quantitative results.

Reanodization with a constant rate of voltage increase.—Anodic oxide films were, after annealing, reanodized by applying a voltage increasing at a constant rate. Once the voltage reached the original forming voltage, V_f, the current started to increase and displayed a peak at the voltage V_{max}. After passage of the peak the current eventually reached the anodizing value, which depended on the choice of dV/dt. The characteristic maximum in the current is caused by annealing: a nonheated sample shows below V_f a gradual increase in the reanodization current, until the final anodization value has been reached.

These phenomena were investigated by Dignam (3) with thin films. He remarked that the charge required to reach, at reanodization, a voltage > V_f was the same for heated and nonheated films. He concluded that a heat-treatment hindered the growth of the anodic oxide film. Our results obtained on thick films are in complete agreement with those of Dignam. In Fig. 1 reanodization curves of a heated and a nonheated layer have been plotted. During the passage of the peak the film becomes thicker, as follows from capacitance and ellipsometric measurements. At voltages beyond V_{max} the current-time relations of the two layers coincide.

Some difference remains, however. When anodization of the heated sample is continued, say, beyond 150V, small breakdowns take place, attended by evolution of gas and a current efficiency less than unity. A nonannealed sample can be anodized with hardly any evolution of gas at up to 210V in this particular electrolyte.

When etched foil, as used in capacitors, is anodized, the current density and therefore also the thickness of the anodic oxide layer are unknown. This is also the case if for some reason the oxide layer has been thinned chemically. The occurrence of the peaks can be used to determine the forming voltage, V_f, which in this investigation is used as a measure of the layer thickness. To that purpose peaks have been measured with a constant rate of voltage increase on annealed samples. Figure 2 shows the relation between V_f and

[1] Electropolishing is improved if the thermally grown oxide layer is first removed by etching.

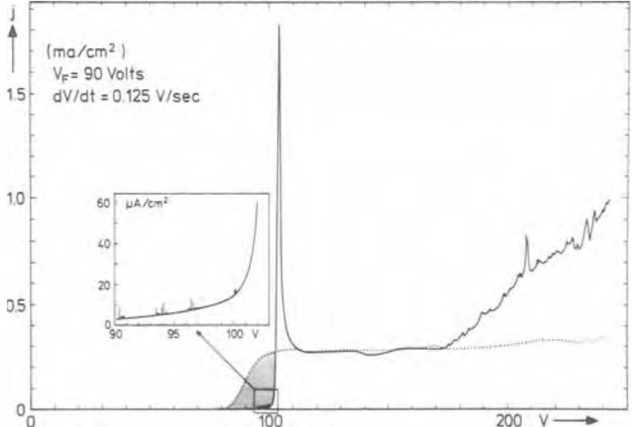

Fig. 1. Current density as function of voltage increasing at a constant rate. The dotted line shows the reanodization of a nonannealed sample, the solid line represents the reanodization of an annealed sample. The shaded areas are equal.

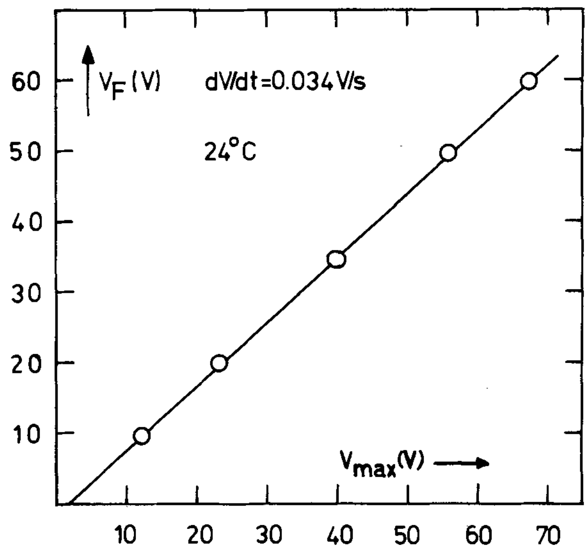

Fig. 2. The forming voltage V_f as function of V_{max}, the voltage of which the current is maximum, when a heated sample is reanodized with dV/dt = 0.034 V/sec. From this plot the layer thickness can be obtained.

V_{max}. Similar relations can be found in Dignam's work (3).

Reanodization at constant voltage.—Nonheated films.—Let us first consider the reanodization of a nonannealed sample. The dotted line in Fig. 3 represents the reanodization of such a sample, measured by the application of a constant voltage across the aluminum and the electrolyte. The current varies in inverse proportion with time, as it should do (10). This $1/t$ law is obtained by means of the fact that the thickness of the anodic layer, L, is proportional to the charge passed per square centimeter, q: $L = \alpha\lambda q$, in combination with the exponential dependence of the ionic current density j on F, the applied field: $j = j_o \exp(BF)$; here α is the current efficiency, λ the ratio of the equivalent weight of aluminum oxide to the product of the Faraday number times the density of the oxide. At a constant voltage across the cell, this leads to the differential equation

$$dt = \frac{1}{\alpha\lambda j_o} \exp\left(-\frac{BV}{L}\right) dL$$

Integration gives

$$j = \frac{q_f}{BF}\left(\frac{1}{t + t_o}\right) \quad [1]$$

where use has been made of the fact $BF >> 1$ (11, 12). q_f is the charge per centimeter square consumed during the anodization up to V_f, during which a layer with a thickness of, say, L_o was built up; t_o may then be considered as the time it would take to anodize a layer to the same thickness L_o at constant voltage starting from the bare metal (if this were possible).

t_o is given by

$$t_o = \frac{q_f}{j_o BF} \exp(-BF)$$

The charge consumed during the reanodization at time t is

$$q \equiv \int_o^t j\, dt = \frac{q_f}{BF} \ln\left(\frac{t + t_o}{t_o}\right) \quad [2]$$

t_o, a quantity which we shall use later on, can be obtained from plots of $1/j$ *vs.* t or from plots of q *vs.* log t. Extrapolation, in the latter plot, of the straight line for large values of t toward $q = 0$ gives t_o directly. The broken lines in Fig. 4a and b represent examples of the growth of nonannealed samples at constant voltages.

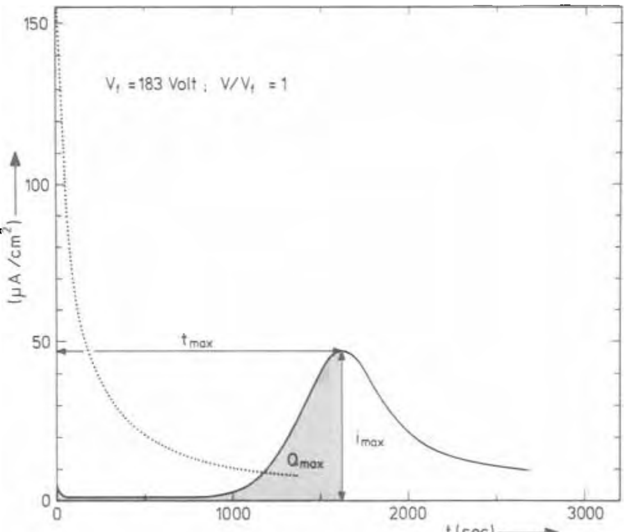

Fig. 3. Reanodization at a constant voltage V of a nonheated sample (dotted line) and a heated sample (solid line). The meaning of the symbols is explained in the text.

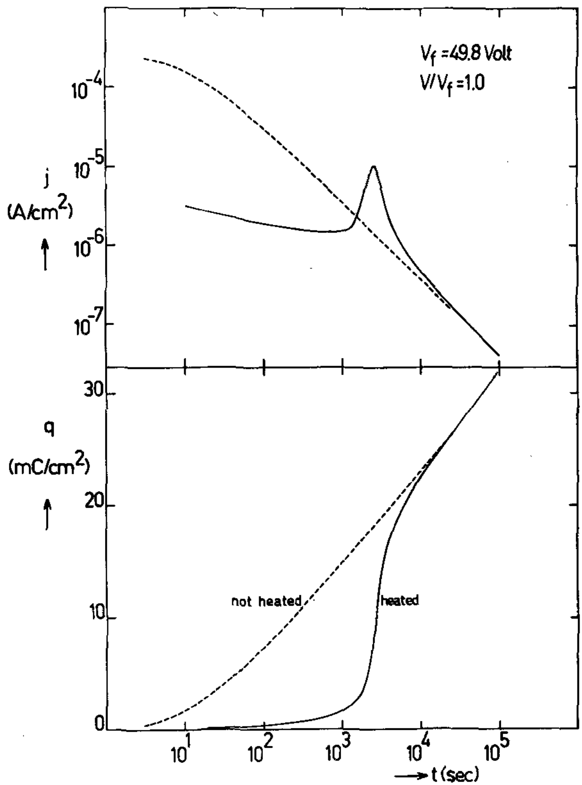

Fig. 4. Reanodization, at a constant voltage of 50V, of heated and nonheated samples. (a, upper) The current as a function of time; (b, bottom) the charge consumed during reanodization as a function of time.

Annealed films.—When a constant voltage is applied to an annealed film, the current will first charge the capacitor and then drop to low values. After some time, however, the current starts to rise and displays a peak. An example of such a peak is represented by the solid line in Fig. 3. During passage of the peak the capacitance of the sample diminishes and again we associate the peak current with film growth. Compared with the nonannealed film the annealed layer starts growing only after an induction period, which is clearly demonstrated in Fig. 4a. At longer times the current decays and the annealed and nonannealed samples become the same.

In Fig. 4b the charges are plotted as a function of log t. In the annealed sample the charge begins to flow at a later stage as compared with the nonannealed sample, but again in the case of long periods of time the curves merge, indicating that the efficiency of the reanodization after annealing has remained unity.

Properties of the peak.—The occurrence of a current peak after a heat-treatment is a general phenomenon. Peaks have been observed when different electrolytes (*e.g.*, ammonium hydrocitrate in water or an oxygen discharge) as well as different heating temperatures (250°-450°C) were used.

The time after which the current peak appears in Fig. 3 as well as its form, are very sensitive to experimental conditions. It is important to remove, before anodization, any layer already present on the bare metal (and to replace it by another one!). Also the manner of rinsing after the first anodization may influence the peak. To obtain reproducible results, the complicated ritual of pretreatments described in the preceding section had to be developed. More experimental results are given in Ref. (13).

The characteristics of the peak have been examined as functions of the applied field, of the thickness of the film, of the temperature at which reanodization takes place, of the chemical treatments of the film, and of

the electrolyte composition. In this paper only the dependence on the first two parameters is discussed.

The time needed to reach the maximum current (t_{max}) has been measured with samples of three different thicknesses as a function of the applied field and is plotted in Fig. 5. V/V_f is proportional to the applied field. According to Bernard and Cook (8) the field is 8.6×10^6 V/cm for $V/V_f = 1$ at the current density of 0.25 mA/cm² used by us. t_{max} depends exponentially on the applied field and does not depend very much on the thickness of the film. About the same field dependence has been found for the current at the maximum (j_{max}). It appears that j_{max} increases as the thickness of the film increases, which results in high maximum currents (of the order of several milliamperes) when thick layers are measured at high fields. In such cases the spacing between cathode and sample was reduced to ≈ 1 mm, resulting in a cell resistance of about 25 ohms. The disadvantage of this is that the temperature may rise and the supply of electrolyte may be inadequate.

Another quantity of interest is the charge per centimeter square necessary to reach the maximum current density, $q_{max} \equiv \int_0^{t_{max}} j dt$. This quantity is plotted in Fig. 6. It does not, as one might think at first, depend on the applied field. In order to compare the form of the peaks, measured on layers with different thicknesses, we plotted the current and time in reduced units: j/j_{max} and t/t_{max}. An example of such a plot is given in Fig. 7. At low fields the peaks are more or less of the same form, although the layer with $V_F = 50$V shows a high current in the beginning. As we shall show afterward this current, which we shall call the induction current, also represents growth of the layer.

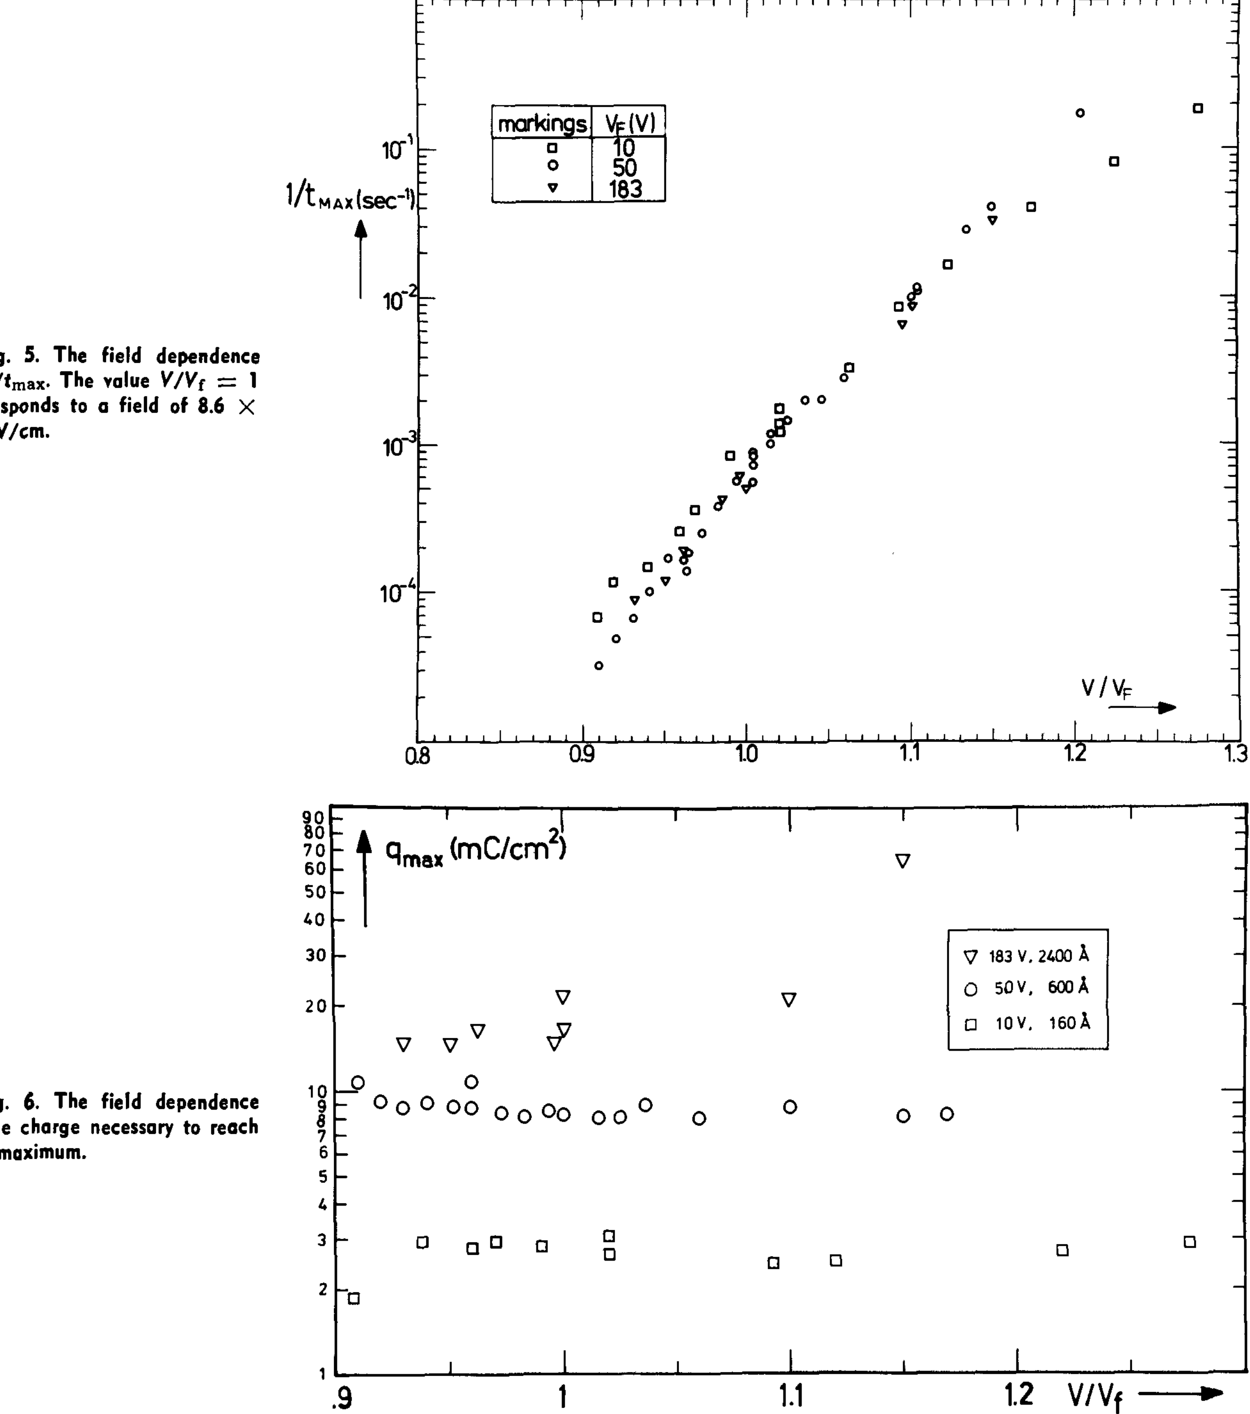

Fig. 5. The field dependence of $1/t_{max}$. The value $V/V_f = 1$ corresponds to a field of 8.6×10^6 V/cm.

Fig. 6. The field dependence of the charge necessary to reach the maximum.

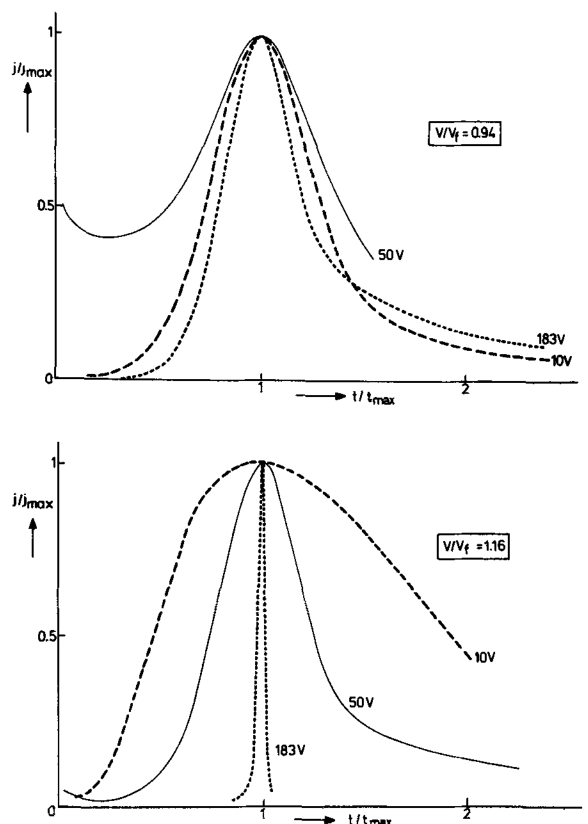

Fig. 7. The field dependence of the shape of peaks, measured at constant voltage and plotted in reduced units j/j_{max} and t/t_{max}.

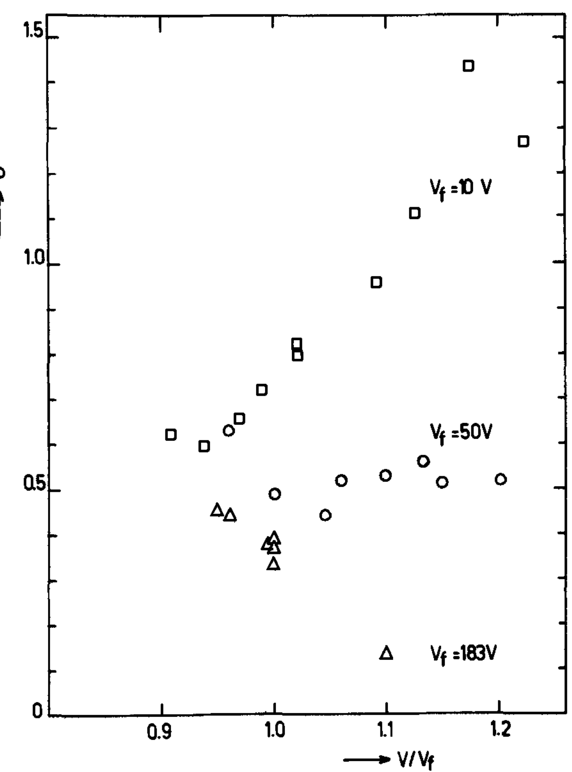

Fig. 8. The width b, taken from plots in reduced units as presented in Fig. 7, as a function of the field. The values of b are taken at $j/j_{max} = 0.5$.

At high fields the form of the current peaks of the three layers is very different. The thin layer shows a very broad peak, the thick layer a very narrow one. In Fig. 8 we have plotted the width b, taken from the reduced plots at $j/j_{max} = 0.5$, as a function of the reduced field. The contrasting behavior of layers having V_f = 10V and V_f = 180V is evident. In particular the 180V peak at a high field shows the presence of an induction time, prior to which hardly any growth of the layer occurs.

Optical and electron microscopic observations.—In Fig. 9 we have once more plotted a reanodization curve measured with a constant dV/dt. The plot is surrounded by dark field photographs of the surface of

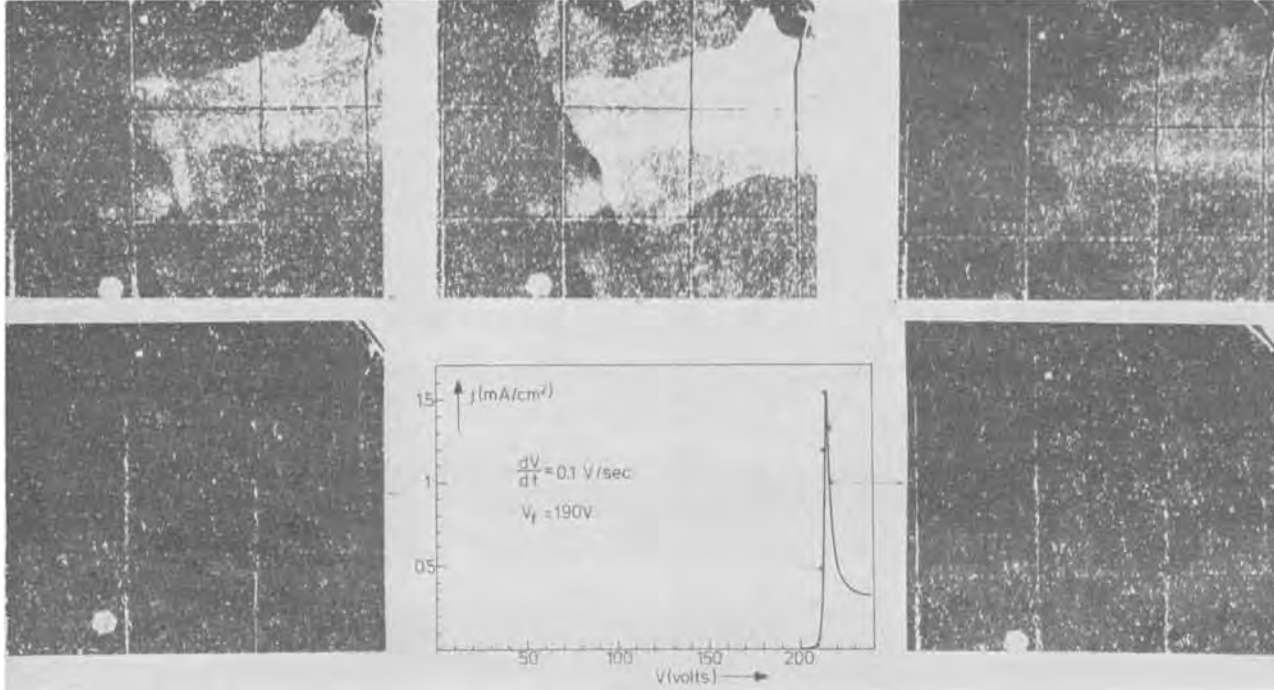

Fig. 9. The change of the reflectivity of a heated sample during reanodization. The arrows indicate the moment the pictures were taken. At a lower value of dV/dt the reflectivity change is more uniform. The peak is rounded off as compared with the one in Fig. 1, because of a higher cell resistance (about 2000 ohms).

the specimen taken during the reanodization. The surface of the specimen changes as the current reaches its peak. Beyond it the sample regains its original appearance. The pattern of white spots visible on the sample consists of small crater like holes, already present on the bare metal. It does not change during the treatments.

The reflectivity changes are visible only with thick layers. We have examined this phenomenon in more detail with an electron microscope. For greater simplicity we shall restrict ourselves to reanodization at constant voltage.

At different stages of the reanodization process the current was interrupted and the sample was immersed in a solution of bromine in methanol. After dissolution of the aluminum, the anodic oxide layers could be isolated and examined in transmission. We were able to investigate, with the microscope working at 80 kV, layers up to 1500Å thick.

Nonannealed and reanodized samples do not show heterogeneities on reanodization. Heated and reanodized layers, however, showed a number of dark spots on the screen of the microscope. Since these spots do not show any crystallinity, we must conclude that the spots are thicker places in the layer. Hardly any contrast is found over a spot and it has about the same thickness everywhere.

An example of such an experiment on 600Å thick layers, reanodized at $V/V_f = 1$ is shown in Fig. 10. The number and size of the spots increase as the reanodization proceeds. At the maximum of the peak about 50% of the surface of the sample is covered and a number of spots are in contact with each other. Finally the whole surface is dark, a situation roughly coinciding with the end of the peak. (The photographs were printed with a maximum of contrast.)

Such observations are characteristic of reanodization experiments of heated films. The heterogeneous growth is also observed if reanodization is performed with a constant dV/dt or with a constant current. The electrolyte has an influence on the form of the dark spots but not on the fact that heterogeneous growth takes place.

Discussion

First of all we want to summarize the main results. The ionic conductivity of an anodic oxide layer becomes very small in heated as compared with nonheated specimens. If a heated layer is reanodized by the applying of a constant voltage, heterogeneous growth will start after an induction period. As seen in the electron microscope, this phenomenon is very reminiscent of a phase transformation: poorly conducting Al_2O_3, white in the micrographs, is transformed into Al_2O_3 with a normal ionic conductivity, which becomes thicker and shows up as black material. In view of this we will describe the process formally with terms borrowed from the theory of phase transformations like phase and nucleus, without implying that these "phases" are defined in the chemical sense. Therefore we say that as the current increases, nuclei arise which grow out in a direction parallel to the surface of the sample, transforming the nonconducting into conducting oxide. Since the Al_2O_3 layer is very thin, the phase transformation is essentially two dimensional. When the whole surface has been covered, the layer behaves again like a nonheated sample.

In the following we shall construct a model to describe the reanodization behavior after annealing. Since we do not know even qualitatively what causes nucleation and why an incubation time (t_{inc}) is necessary, we shall only consider processes occurring after the incubation period. Only the stage in which nuclei are growing, where the peak in the current appears, is treated. Two assumptions, namely, (*a*) why the nuclei grow at all, and (b) how the oxide grows after ionic conductivity has been restored, underlie this model.

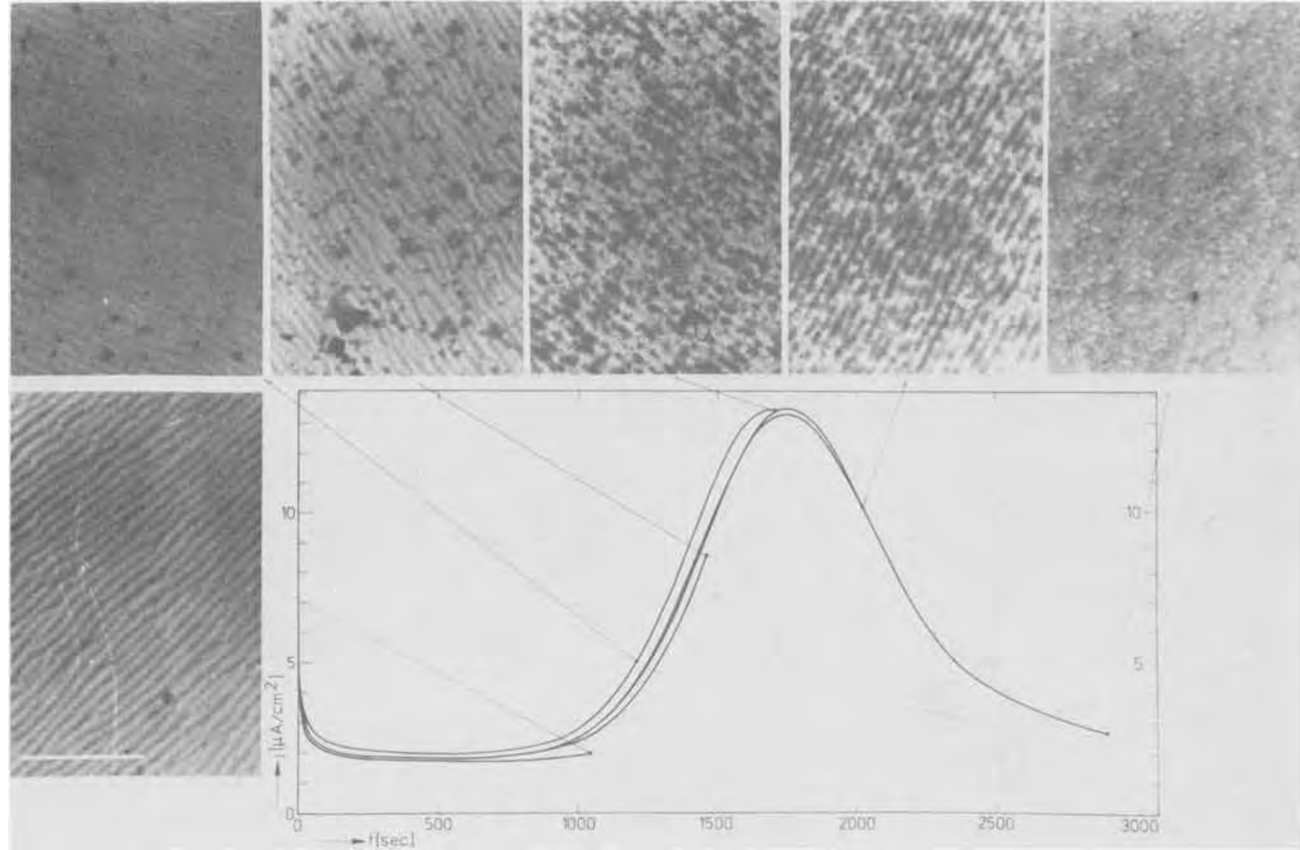

Fig. 10. Transmission electron micrographs showing heterogeneous growth at reanodization of six heated layers. The arrows indicate the moments at which the current through a sample was interrupted. $V_f = 50V$; $V/V_f = 1$. The bar represents 1 μ.

(a) As soon as the ionic conductivity has been restored locally, the layer will become thicker at that particular spot and a step is formed on the oxide film, as is shown very schematically in Fig. 11. Close to such a step the lines of constant potential and the field lines in the anodic oxide layer are shown. It is evident that the highest electric field is to be found in the old nonconducting oxide near the edge of the step. We suppose that this high field causes the annealed oxide to become conducting. The anodic oxide will start to grow rapidly in the vertical direction which means that the step moves along the surface until it collides with another growing spot. Because the field distribution near the step does not change, this model leads to a constant lateral growth velocity.

(b) We have shown that, to a first approximation, the growth beyond the peak is the same as with a nonannealed sample. Such evidence is contained in Fig. 4, where annealed and nonannealed films are compared at long reanodization times. In Fig. 3, remembering that annealing causes postponed growth, we can make the current decay of the nonannealed sample coincide with that of the annealed sample by a mere shift of the former by 1500 sec. Finally the appearance of the sample before and after the peak is the same (Fig. 9). Therefore we suppose that, as soon as the ionic conductivity of the layer has been restored, the thickening of the oxide will follow the relations valid for the growth of an anodic oxide at constant voltage.

Let us suppose that at time t' a surface $O(t')$ has been transformed into a conducting oxide. $O(t')$ is the surface of all the dark spots in the electron micrographs. At time $t' + dt'$ this surface will have increased by an amount dO, because the size of the spots has increased and in addition new spots have been formed. The situation at t' and $t' + dt'$ has been sketched in Fig. 12.

The current at time t due to the region dO transformed between t' and $t' + dt'$ will be given by

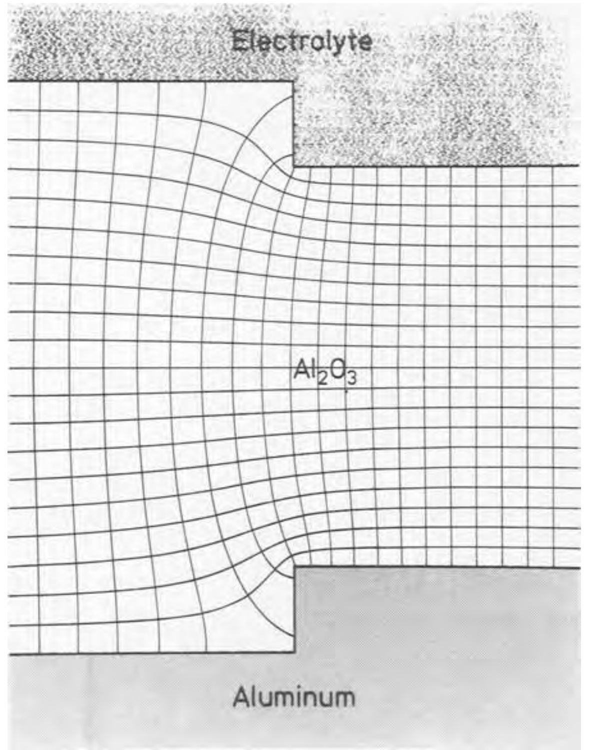

Fig. 11. The field distribution and lines of constant potential near a step in the oxide. The high field inside the old, "nonconducting" oxide near the edge of the step, explains the lateral growth of the step.

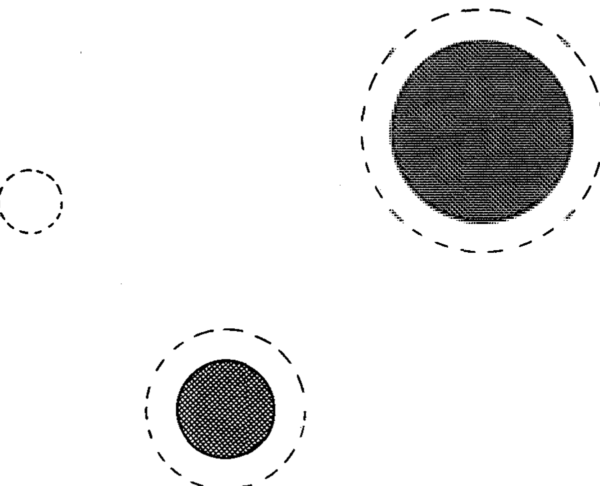

Fig. 12. Schematic presentation of the heterogeneous growth at reanodization. The solid line shows the situation at time t', the "black spots" are growing at a constant speed. The broken line represents the situation at time $t' + \Delta t'$. Lateral growth has taken place and a new spot is present.

$$di(t) = \frac{q_f}{BF} \frac{dO}{t_o + t - t'} \quad [3]$$

To find an expression for the total current we have to integrate over t', and therefore we replace dO by $(dO/dt')\,dt'$.

Since the nuclei start to grow only after an incubation time we have

$$i(t) = \frac{q_f}{BF} \int_{t_{inc}}^{t} \frac{dO/dt'}{t_o + t - t'}\,dt' \quad [4]$$

(dO/dt') can be obtained from the theory of the kinetics of phase transformations developed by Johnson and Mehl (5) and Avrami (6). In our case we have to apply this theory to the case of two dimensions and to assume furthermore that the growth velocity of a nucleus is constant, that the number of nuclei increases linearly with time, and that nucleation is random. Then the theory leads to the following equation for the fraction of the surface α which at time t' has been transformed from phase 1 into phase 2 (translated into our language, this means: from nonconducting oxide into conducting oxide): $\alpha = 1 - \exp(-kt'^3)$ in which k is the rate constant of this transformation. For small values of t', when the nuclei do not yet touch each other, $\alpha \sim (t')^3$, as follows directly from our assumptions that the number of nuclei is proportional with time and that the area of a single nucleus is proportional to the square of the time. At longer times, α will tend to unity because the transformation will then be near completion.

Instead of the rate constant k of the reaction phase 1 → phase 2, we shall use the quantity $w = k^{-1/3}$. Since the transformation of nonconducting oxide into conducting oxide only starts at $t = t_{inc}$ we must use $t' - t_{inc}$ rather than t'. Thus at the time t' the fraction of the surface which is covered with conducting oxide is

$$1 - \exp - \left(\frac{t' - t_{inc}}{w}\right)^3 = \frac{O(t')}{S}$$

where S is the surface area of the sample. w is found to represent with fair accuracy the width of the peak at half the height of the current maximum.[2] Differen-

[2] w has to be distinguished from the quantity b introduced earlier which is the width of the peak at half the height of the current maximum expressed in the reduced time t/t_{max}.

tiating this expression and using Eq. [4], we obtain for the current density

$$j(t) = \frac{3q_f}{wBF}\int_{t_{inc}}^{t} \frac{\left(\frac{t'-t_{inc}}{w}\right)^2 \exp -\left(\frac{t'-t_{inc}}{w}\right)^3}{t_o + t - t'}\,dt' \quad [5]$$

which can be written, with $y \equiv \frac{t'-t_{inc}}{w}$ and $z = \frac{t-t_{inc}}{w}$

$$j = \frac{3q_f}{wBF}\int_{0}^{z} \frac{y^2 \exp(-y^3)}{t_o/w + z - y}\,dy \quad [6]$$

Figure 13 shows that beyond the incubation period this equation accurately describes the reanodization current.

The parameters w and t_{inc} have to be fitted, the other quantities (q_f/BF, and t_o) in Eq. [5] can be obtained from measurements of nonannealed films. We also fitted these, however, and used the values obtained in this way as a check of the correctness of the equation. In Fig. 14, values of t_o of annealed samples, obtained by means of relation [6], and of nonannealed samples, obtained with the help of the relations [1] or [2], are compared. From the reasonable agreement shown in Fig. 14 and also from the fits of calculated and observed peaks, an example of which is given in Fig. 13, we conclude that the growth of an annealed anodic oxide layer follows the laws (Eq. [1] and [2]) holding for the nonannealed films. A further result of this description is that formula [6] immediately leads to a value of q_{max} which is independent of V/V_f. In Fig. 16 we have once more plotted the charge q, consumed during reanodization, but now as a function of time at three different values of the applied field. It is obvious that the values of q_{max}, which are given here by the points of inflection of the curves, remain the same when the field is changed. To calculate the charges we have to integrate Eq. [6]

$$q(t'') = \int_0^{t''} j(t)\,dt = w\int_0^{z''} j(z)\,dz$$

$$= q_f/BF \int_0^{z''} dz \int_0^{z} \frac{3\,y^2 \exp(-y^3)}{t_o/w + z - y}\,dy$$

This shows that the charge is a function of only the quantity (t_o/w). Indeed it can be shown that to a good approximation q_{max} is given by

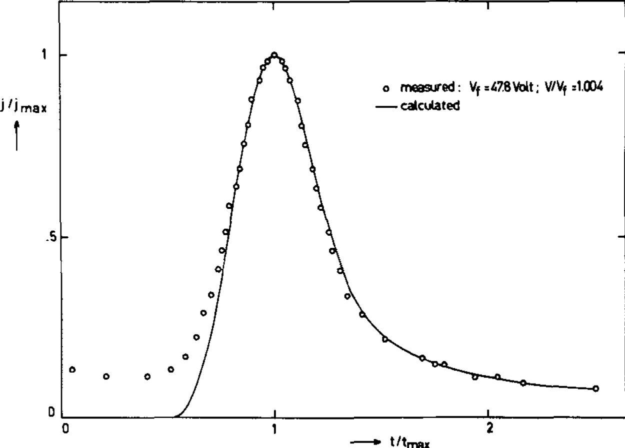

Fig. 13. Comparison between a measured and a calculated peak, plotted in reduced units.

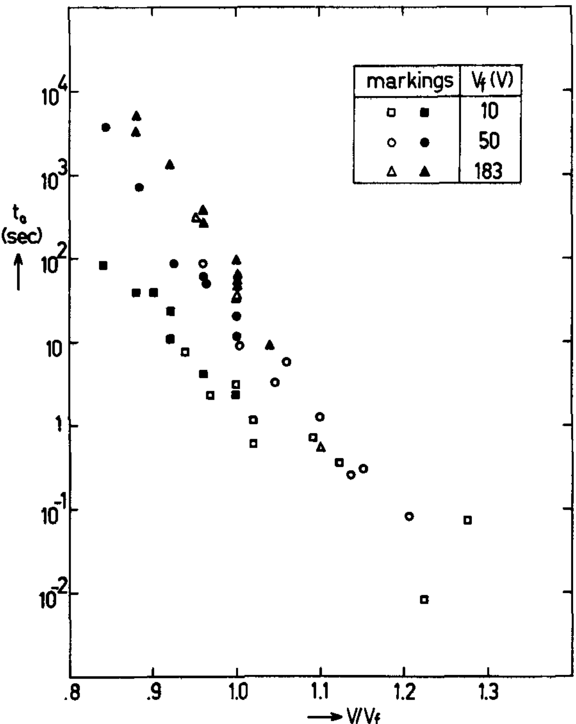

Fig. 14. The field dependence of t_o. The black markings represent values obtained in reanodization measurements of nonheated samples. The open markings were obtained by the fitting of formula [6] to the reanodization curves of heated samples.

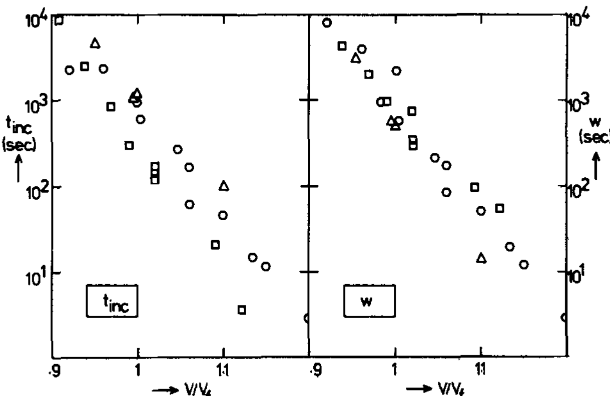

Fig. 15. The field dependence of t_{inc} and the width w of the peaks. The meaning of the markings corresponds to those of Fig. 14.

$$q_{max} = q_f/BF \ln(w/t_o)\{1 - \exp(-z_{max}^3)\} \quad [7]$$

in which the factor between brackets is the fraction of the surface covered with new oxide.

In Fig. 15, w and t_{inc} are plotted as a function of V/V_f. Comparison with Fig. 14 shows that the field dependence of w and t_o is essentially the same, so that the quantity $\ln(w/t_o)$ is hardly dependent on the field. In other words: the shape of the $q - \ln(t)$ curves in Fig. 16 which is determined by the relation between t_o, w, and t_{inc}, is independent of the field; the curve is only shifted as a whole, but this keeps the height of q_{max} unaltered. It is also evident from Fig. 14 and 15 that t_o is very small as compared with w. Since, for anodizing at constant voltage, $q \sim \ln(t/t_o)$, the growth of the oxide that has become conducting occurs mainly within a few times t_o. Consequently the height of the step is the same almost everywhere and the schematic drawing of Fig. 11 represents the actual situation reasonably well. This explains why the optical density of the electron micrographs is so uniform

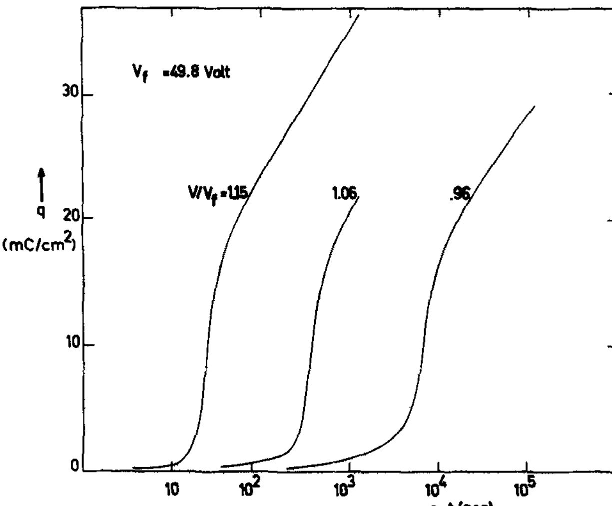

Fig. 16. q as function of time at different field strengths. The main effect of a different field is a translation of the curve along the abscissa.

over the dark spots. The thickness change after passage of the front of the nucleus can be calculated as well as measured. The measurement was performed by dipping an anodized and annealed sample halfway into the solution and then reanodizing this part of the sample until the current maximum occurred. Afterward the reanodized part of the sample was compared with the rest of the sample. With an ellipsometer and on the assumption that, on reanodization, 50% of the oxide had been transformed, an increase in thickness ΔL was found of 65Å for a 50V layer.

A thickness change due to the annealing itself could not be demonstrated either by ellipsometry or by measurement of the capacitance. According to formula [7] the increase in thickness, ΔL, should be $\Delta L = (L/2BF) \ln (w/t_0)$. For a 600Å thick layer (V_f = 50V) ΔL = 75Å, which is of the right order of magnitude.

Finally we used our experiments to determine the surface area of etched aluminum foil. Such foil is used in the production of electrolytic capacitors to obtain a large surface in a small volume. The etching was performed on a specimen similar to those used in the anodization experiments, by passing 50 coulombs/cm^2 through the sample in a solution of 200g NaCl in 1 liter water at 90°C. The sample was rinsed in deionized water, ultrasonically cleaned, dipped into a chromic acid-phosphoric acid-water solution at 95°C, and rinsed in methanol.

Fig. 17. Electron transmission photographs of layers reanodized with a constant voltage after heating. The current was interrupted at the maximum of the peak. The bar in the lower right corner represents 1μ. Layers reanodized with V/V_f = 0.9 and the layer with V_f = 15V and reanodized with V/V_f = 1.1 show a second growth mechanism which seems to be related to the surface area of the dissolved aluminum.

(*a*) The sample was anodized at up to 50V with a constant dV/dt of 0.043 V/sec.[3] As compared with a nonetched sample, the etched sample needed a 9.4 times greater current.

(*b*) From capacitance measurements of this anodized sample at frequencies for which tan δ is minimum on the etched and a nonetched sample it followed that the capacity had increased by a factor of 9.7.

(*c*) The etched sample was heated at 400°C during 15 min and reanodized at constant voltage to measure t_{max}. By means of Fig. 5, V_f could be obtained and, together with the charge used for anodization, the surface covered by anodic oxide was obtained, which increased by a factor of 9.2 again as compared with a nonetched sample.

(*d*) The use of Fig. 6 and q_{max} of the same sample revealed the etch factor to be 9.4 immediately.

Thickness dependence of the growth mechanism.—In this section we shall summarize gaps in our knowledge of the growth mechanism of annealed oxide layers, and illustrate these with a few more experiments.

The quantities w and t_{inc} are at present only numbers that follow from curve-fitting, but their behavior is still largely unknown. A detailed knowledge of the nucleation process and of the factors determining the growth velocity of a nucleus is still lacking. Therefore the remarkable field dependence of the width of the peak as given, in Fig. 7b, in reduced units as a function of specimen thickness, which is governed by the ratio of w/t_{inc}, remains unexplained and is the more puzzling since t_{max}, the time until the maximum of the peak appears, is hardly dependent on thickness.

In Fig. 17 a number of transmission electron micrographs of layers with different thickness have been collected. The layers were reanodized at different values of V/V_f and the reanodization was stopped in the maximum of the peak. Figure 17 clearly shows that the local growth, as described above, is not always evident. Especially with low fields, the growth may be characterized by the appearance of many nuclei not growing out in all directions. The nuclei form a pattern that may be related to the aluminum substrate removed. At any rate it will be evident that in these cases formula [5] cannot represent the whole curve.

Another interesting point is the relatively high "incubation" current of the layer having $V_f = 50V$ in Fig. 7a. This measurement is only a weak reflection of another growth mechanism which we are studying at present and which, at room temperature, shows its maximum effect with layers obtained with $V_f = 35V$. Figure 18 shows plots of peaks measured at the same applied field. The vanishing of the peak, as well as a shift in t_{max}, can be observed. The sharp decay of the current after the small peak, which in our model represents the impinging of growing nuclei on each other, indicates nevertheless that there still exists something like a peak. Since also in this case we measured a current efficiency of unity we conclude that another, still unknown mechanism is operating. It may be that the growth of such layers is governed by a surface layer as is suggested by the following experiment. We also prepared layers having $V_f = 35V$ in another way. We anodized the aluminum samples up to $V_f = 50V$, annealed them, and dissolved part of the layer in the above-mentioned HF solution. Then part of the sample was scanned at constant dV/dt and, with Fig. 2 we obtained a value for V_f. An example of such a peak is shown likewise in Fig. 18.

The greatest challenge, however, is to know what happens during annealing of the anodic oxide film. Diffraction of x-rays or electrons did not reveal the slightest change after annealing. From the experiments in which part of the layer is dissolved after annealing

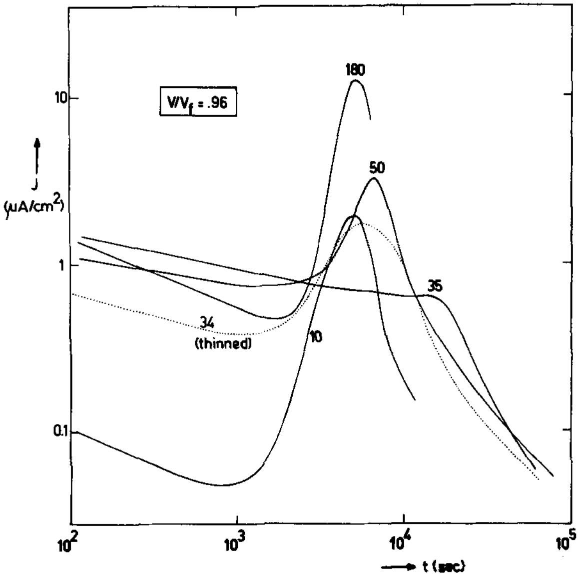

Fig. 18. Peaks obtained on layers having different thicknesses. The forming voltage V_f is indicated in the figure. A layer with $V_f = 35V$ does not show a well resolved peak on being reanodized. The peak is present, however, when a layer with $V_f = 50V$ is partly dissolved, as indicated by the dotted line.

it will be clear that the peaks are not due to some barrier near the interface electrolyte-anodic oxide. We will deal with these problems in a later paper.

Acknowledgment

We would like to thank Miss G. Stienstra and Mr. H. B. Haanstra for the electron microscopic investigation of our samples, Mr. L. P. van Kemenade and Mr. C. Wyenberg for the performance of the many experiments, and Mr. C. J. Loyen and Dr. F. Meyer for the ellipsometric measurements.

Manuscript received Feb. 11, 1974. This was Paper 18 presented at the Chicago, Illinois, Meeting of the Society, May 13-18, 1973.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1975 JOURNAL. All discussions for the June 1975 Discussion Section should be submitted by Feb. 1, 1975.

The publication costs of this article have been assisted by Philips Research Laboratories.

Fine Structure in the Optical Spectra of Divalent Europium in the Alkaline Earth Sulfates

F. M. Ryan,* W. Lehmann,* D. W. Feldman, and J. Murphy

Westinghouse Research Laboratories, Pittsburgh, Pennsylvania 15235

ABSTRACT

Fine structure has been observed in the fluorescence and excitation spectra of Eu^{+2} in $CaSO_4$ and in the fluorescence spectrum of Eu^{+2} in $BaMg(SO_4)_2$. The fine structure in the fluorescence of Eu^{+2} in $CaSO_4$ is identified as a zero phonon line with many sharp phonon replicas. The fine structure in its excitation spectrum is due to the closely spaced energy levels in the excited state produced by a strong exchange interaction splitting of the $4f^65d$ states. The fine structure in the fluorescence of Eu^{+2} in $BaMg(SO_4)_2$ is due to the normal splitting of the $4f^7$ excited state and the dominance of $4f^7 \rightarrow 4f^7$ transitions.

The alkaline earth sulfate compounds activated with Eu^{2+} generally exhibit broad, featureless fluorescence and excitation spectra. Their decay times are relatively short (~0.1 μsec) and the resulting fluorescence is located in the near ultraviolet. These are familiar characteristics that are common to a great many other Eu^{+2} activated phosphors. The fast decay has been attributed to the fluorescence being an "allowed" $f^6d \rightarrow f^7$ transition. The broad featureless fluorescence envelopes are accounted for by a large Stokes' shift due to the different coupling to the lattice modes of the excited f^6d states relative to the f^7 ground state.

In recent years, it has become apparent that in certain hosts Eu^{+2} can exhibit much more interesting optical spectra characterized by sharp fluorescence and/or absorption lines. The presence of such sharp line spectra has caused some detailed experimental measurements and theoretical analyses to be made on these systems. There are four types of such spectra which have been reported to date: (type 1) sharp structure in the $f^6d \rightarrow f^7$ transitions in both absorption and fluorescence due to local vibrational modes, (type 2) sharp structure in the $f^6d \rightarrow f^7$ fluorescence and absorption transitions due to selective coupling to certain lattice modes and/or to structure in the phonon density of states of the lattice modes, (type 3) sharp structure in absorption due to a splitting of the f^6 levels by interaction with the single 5d electron and the crystal field, and (type 4) sharp structure in fluorescence due to $f^7 \rightarrow f^7$ transitions in the special case where the lowest lying excited state is an f^7 state rather than an f^6d.

Type 1 spectra are exhibited by Eu^{+2} in the alkali halides (1) where the Eu^{+2} is substituting for a monovalent ion and an adjacent compensating vacancy forms. The high energy and low damping of the local vibrational modes about the vacancy give sharp structure to both the optical fluorescence and absorption spectra. Types 2 and 3 spectra have been reported for Eu^{+2} in calcium fluoride (2, 3) where a zero phonon line accompanied by sharp vibrational sidebands have been observed in fluorescence while some sharp lines can be seen in absorption. Type 4 spectra have been reported for Eu^{+2} only in the alkaline earth aluminum fluorides (4, 5) and in potassium and sodium magnesium fluoride (6).

We have examined Eu^{2+} in the alkaline earth sulfates. We have observed sharp line spectra in only two compounds, $CaSO_4{:}Eu^{+2}$ and $BaMg(SO_4)_2{:}Eu^{+2}$. Our interpretation of the data is that $CaSO_4{:}Eu^{+2}$ exhibits types 2 and 3 spectra for Eu^{+2} and $BaMg(SO_4)_2{:}Eu^{+2}$ exhibits the type 4 spectrum. The purpose of this paper is to present the optical spectra of Eu^{+2} in these two compounds and to compare the spectra with theory. Possible explanations will be given for the uniqueness of such spectra to $CaSO_4$ and $BaMg(SO_4)_2$ among all of the alkaline earth sulfates.

Sample Preparation and Structure

The simple sulfates of Ca, Sr, and Ba used in our investigations were precipitated from purified nitrate solutions with H_2SO_4. $MgSO_4$ was formed by reacting MgO with H_2SO_4. The phosphors were made by firing these sulfates with a mixture of europium oxide and $(NH_4)_2SO_4$. The firing was done in capped quartz tubes at 900°C in a nitrogen atmosphere. The resulting phosphor cakes were washed in water or methanol to remove unreacted $(NH_4)_2SO_4$, and then air dried. Compounds were also prepared containing two cations, such as BaMg $(SO_4)_2$. They were formed by firing the individual sulfates together at 900°C. In addition to $BaMg(SO_4)_2$, only two other compounds containing two divalent cations were found to exist, $Mg_2Ca\ (SO_4)_3$ and MgSr $(SO_4)_3$. The structures of these compounds are unknown but their existence is established by powder x-ray analysis. No attempt was made to form sulfate compounds containing more than two divalent cations. The structures of the compounds that have been determined are summarized in Table I along with the cation site symmetry and the number of oxygen neighbors of the cation site (7, 8).

$CaSO_4$ has several crystalline modifications. When prepared according to the conditions we employed it has an orthorhombic crystal structure ("anhydrite") with the space group D^{17}_{2h} (Cmcm). In this structure the calcium ions are surrounded by eight nearest neighbor oxygen atoms belonging to the various sulfate groups about it. The calcium sites are all crystallographically equivalent with point group symmetry C_{2v} (mm2) which lacks inversion symmetry. The divalent europium ions would be expected to substitute for calcium ions without compensation of any kind and therefore to have C_{2v} (mm2) site symmetry.

$MgSO_4$ has two crystalline modifications, the α form exists above 800°C and the β form below 800°C. They differ only slightly and both forms have an orthorhombic crystal structure.

Table I. The determined crystal structures, cation site symmetries, and numbers of oxygen nearest neighbors of the alkaline earth sulfate compounds

Compound	Crystal structure	Cation site symmetry	Oxygen neighbors
α-$MgSO_4$	Orthorhombic	(C_i = T)	6
β-$CaSO_4$	Anhydrite (orthorhombic)	(C_{2v} = mm2)	8
$BaSO_4$	Barite (orthorhombic)	(C_{1h} = m)	12
$SrSO_4$	Barite (orthorhombic)	(C_{1h} = m)	12

The crystal structure of $BaMg(SO_4)_2$ has not been determined but powder x-ray diffraction photographs show it to possess a structure that differs from both $BaSO_4$ (orthorhombic "barite") and $MgSO_4$ (α or β orthorhombic). Ionic size considerations suggest that the europium ions would replace only barium ions in this structure. This is confirmed by x-ray diffraction data. Samples prepared by balancing the europium doping level with a corresponding reduction in the barium concentration, typically $Ba_{0.95}Eu_{0.05}Mg(SO_4)_2$, show an identical x-ray pattern to undoped $BaMg(SO_4)_2$. On the other hand, samples prepared by attempting to balance the europium doping with a corresponding reduction in the magnesium concentration show additional lines in their x-ray patterns due to a second phase of $BaSO_4$. The europium atoms must therefore be substituting for barium atoms in $BaMg(SO_4)_2$.

Experimental

Low temperature optical measurements were performed with the samples immersed directly in either liquid nitrogen (77°K) or liquid helium below the λ point (1.8°K). The powder samples were formed into solid disks by saturating them with a potassium silicate cement. This prevented them from being eroded by the liquid refrigerants used.

Fluorescence spectra were taken with either a 0.25m Jarrel-Ash spectrometer (low resolution) or a 0.5m Jarrel-Ash spectrometer operating in 2nd order (high resolution). The detector used was an EMI 9558QA photomultiplier tube with an S-20 photosurface. All fluorescence data were corrected for the variation in response of the detector and the spectrometers at the various wavelengths studied.

For obtaining excitation spectra, the 0.25m spectrometer and the photomultiplier monitored the fluorescence of the samples at the desired wavelength while excitation energy was obtained from a 500W xenon short-arc lamp followed by a double 0.25m Jarrel-Ash spectrometer. The dependence of the output energy of this system on wavelength was determined and used in correcting the excitation spectra.

To measure the fluorescence decay times the samples were mounted on a cold finger inside of a vacuum chamber. Short rectangular pulses of 10 keV electrons were used for exciting their fluorescence. The current densities of excitation were kept well below 10^{-6} A/cm^2 to avoid producing saturation effects such as nonexponential decays. The fluorescence was passed through a 0.25m spectrometer adjusted to the wavelength of interest and the radiation was detected with a 9558QA photomultiplier tube. A multichannel storage analyzer was used to measure the time constants of the weak and very fast signals by using a sampling oscilloscope as a "fast" to "slow" time transducer. The output of the oscilloscope was stored on a "slow" 100 channel analyzer (PAR Model TDH-9). Decay times as short as 10 nsec could be measured with this arrangement so that the decay times measured were always much longer than the limits of the system.

Raman measurements were performed to gather further data on lattice vibrations. The excitation source used in obtaining the Raman spectra was an argon ion laser with a power level of about one watt in the 5145Å line. The monochromator was a Spex 1400 double monochromator in tandem with a 0.25m Jarrel-Ash monochromator used as a band pass filter to further block scattered 5145Å light. The detector was an EMI 95025 photomultiplier with an S-11 photosurface and was used in the d-c current mode. The samples were powders which were pressed into a recess in a metal block with the laser beam focused onto the surface.

Theoretical Discussion of the Excited States of Eu^{+2}

The energy level diagram and some of the features one might expect to see in the spectra of Eu^{+2} in various hosts are shown in Fig. 1.

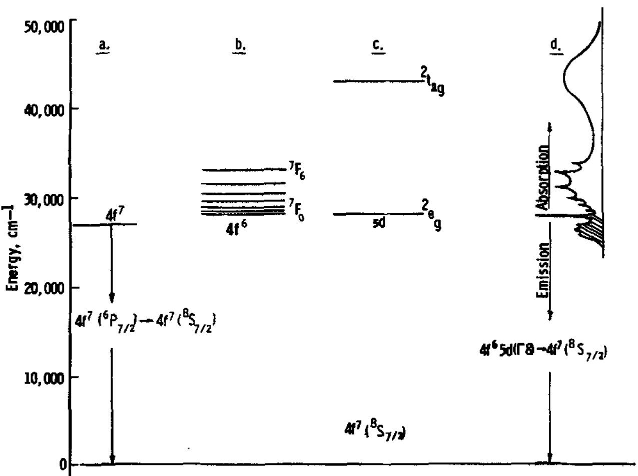

Fig. 1. The energy level diagram for Eu^{+2}

In the ground state of the Eu^{+2} ion there are seven 4f electrons which arrange themselves into a $4f^7$ ($^8S_{7/2}$) configuration. The lowest lying excited states may be formed from states within the $4f^7$ configuration or from states within the $4d^65d$ configuration. Excited states within the $4f^7$ configuration are isoelectronic with Gd^{+3}. The lowest lying of them is $^6P_{7/2}$, then $^6P_{5/2}$, and so on. The decay time of transitions from these states would be in the millisecond range and transitions from the ground state to them would be very weak. Transitions between the ground state and excited states of the type $4f^7 \rightarrow 4f^65d$ are allowed transitions and would completely dominate any $4f^7 \rightarrow 4f^7$ type transitions except in fluorescence if the lowest lying excited states are $4f^7$ states. Fluorescence transitions from these $4f^7$ states would then be observed unless thermal depopulation to the fast-decaying nearby $4f^65d$ states occurs. In almost all Eu^{+2} hosts the $4f^65d$ states are lower in energy than the $4f^7$ levels and $4f^7 \rightarrow 4f^7$ transitions are not observed.

Some general features of the $4f^65d$ states are shown in the center of Fig. 1. In this configuration there are six 4f electrons which, in the absence of any interaction with the 5d electron, would arrange themselves into seven levels, $^7F_0$ through $^7F_6$, shown at Fig. 1b, analogous to the ground states of Eu^{+3}. There are a total of 49 states contained within these seven spin-orbit energy levels which will be further split by the crystal field. There is also a single 5d electron. Under the influence of a cubic crystal field, but ignoring any interaction with the $4f^6$ electrons, the states of the 5d electron would be split into two bands, a $^2t_{2g}$ and an ^2e_g shown at Fig. 1c. The ^2e_g level is expected to be much lower and is 4-fold degenerate. When combined with the 49 states of the $4f^6$ configuration this ^2e_g state yields a total of 196 nearly degenerate states. If the interaction between the $4f^6$ electrons and the 5d electron is sufficiently strong, the states are strongly mixed and much of this degeneracy can be lifted. The $4f^65d$ system therefore can potentially exhibit a large number of distinct optical transitions in its absorption or excitation spectra. In many cases, however, the interaction is weak and the composite $4f^65d$ system retains much of the character of the uncoupled $4f^6$ and 5d levels. On the right side of Fig. 1, the unshaded part of 1d, is shown this type of absorption spectrum. It has been observed for Eu^{+2} in CaF_2, EuO, EuSe, and EuF_2 (9). Two broad bands are seen in absorption corresponding to transitions to the ^2e_g and ^2t_g bands of the 5d electron. Superimposed on the lower ^2e_g bands are seven narrow bands, referred to as a "staircase spectrum," which retain the character of the seven $4f^6$ levels. No structure is seen in the $^2t_{2g}$ band probably because the spin orbit splitting which occurs only in $^2t_{2g}$ washes out any structure.

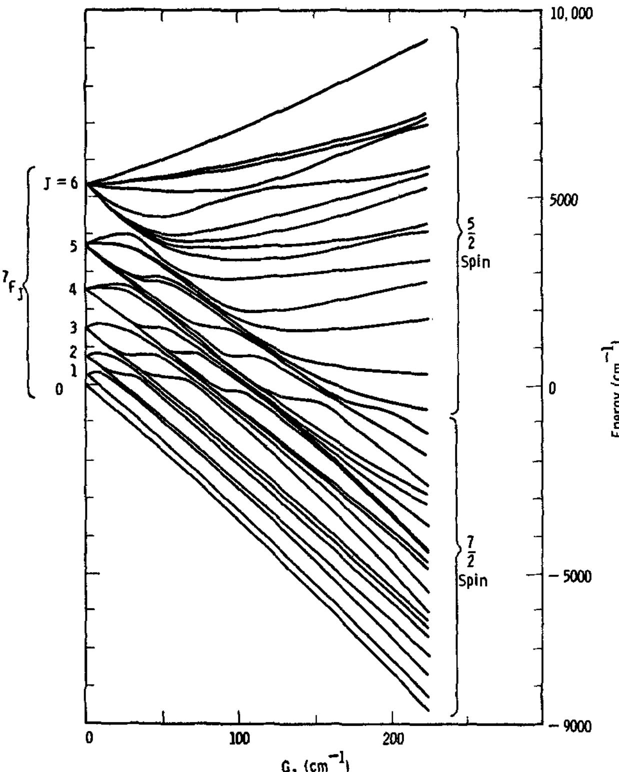

Fig. 2. The quartet energy levels of the $4f^65d$ system as a function of the exchange parameter, G_1.

In the case of strong interaction between the $4f^6$ electrons and the 5d, one would expect that very little of the characteristic $4f^6$ structure would remain and that the absorption spectrum would reflect only the nature of the composite $4f^65d$ system. Weakliem (10) has recently made the first calculation of the energy levels of the $4f^65d$ system taking into account the exchange interaction between the $4f^6$ electrons and the 5d. The results of his calculation are shown in Fig. 2 which shows the set of $4f^6(^7F_J)5d(^2e_g)$ energy levels of the system as a function of the exchange parameter, G_1.[1] In the limit of weak exchange the levels resemble the $4f^6$ levels. As the exchange interaction is increased all resemblance to the $4f^6$ levels ceases and the levels separate into two groups, a group of levels with spin $= 5/2$ and a group with spin $= 7/2$. The six 4f electrons have a total spin of 3 and the d electron a spin of 1/2. The 5/2 spin levels arise from the case where the 5d electron spin is antiparallel to the spin of the $4f^6$ electrons, leading to a small exchange energy, and the 7/2 spin levels when the spins are parallel, leading to a large exchange energy. Therefore, in the region of large exchange parameter G_1, the 7/2 levels have a large slope while the 5/2 levels tend to become independent of G_1. A conclusion which can be drawn from Fig. 2 is that at large values of G_1, the 7/2 spin levels are well defined and distinct from the 5/2 spin levels. Thus spin selection rules should be obeyed. Only the quartet levels are shown on Fig. 2. Interspersed with these are also the doublet levels of the system which behave similarly. They have been omitted from Fig. 2 to keep it from being too cluttered.

We will now calculate the number of discrete levels that one might expect to observe in the absorption spectrum of Eu^{2+} in a host with site symmetry C_{2v} (typical of $CaSO_4$) in the region of strong exchange interaction ($G_1 \sim 200$ cm^{-1}). Consider the two electronic systems composed of the six 4f electrons forming the ^7F_J levels and the single d electron forming the ^2e_g level coupled together by an exchange interaction. The crystal field splitting of the 5d energy levels can be represented by the dominant term, the cubic field component (O_h). The single d electron state, ^2e_g, transforms as $D_{3/2}$ of the O_h double group. The product of the $D_{3/2}$ representation with the representations of the cubic field-split sublevels of the ^7F_J states are shown in Table II. There are 33 $D_{3/2}$ quartet levels of the total system, and 16 $D_{1/2}$ and 16_2S doublet levels. Reducing the symmetry to C_{2v} will split the 33 $D_{3/2}$ quartets into 66 doublets so that the number of levels in C_{2v} symmetry will be $66 + 32 = 98$. Since we are concerned only with the spin 7/2 states, the degeneracy ratio of the 7/2 to the 5/2 states yields $4/7 \times 98 = 56$ levels that might be observable in optical absorption or fluorescence excitation in C_{2v} symmetry and strong exchange. This number will be referred to later in the paper.

A final feature shown on the right in Fig. 1 (the shaded area of Fig. 1d) is the type of fluorescence that might be observable in a transition from the lowest lying $4f^65d$ level to the ground state. Ordinarily this will be a narrow band. If in a particular host the Stokes' shift is small enough (particularly at low temperatures), a zero phonon line and some sharp phonon sidebands might also be observable. This fluorescence should exhibit a decay time in the order of tenths of a microsecond.

Discussion of the Observed Fluorescence Spectrum of Eu^{+2} in $CaSO_4$

The 1.8°K fluorescence spectrum of Eu^{+2} in $CaSO_4$ is shown in Fig. 3 and 4. Fine structure can also be seen at higher temperatures but some thermal broadening occurs and the structure is seen best at low temperatures. The line marked E_0 in fluorescence is located at exactly the same energy in absorption as in fluorescence. We therefore conclude that E_0 is a zero phonon line (a purely electronic transition involving no phonons). In absorption (here actually fluorescence excitation) E_0 is labeled A_0. E_0 has a fluorescence decay time of 0.40 ± 0.04 μsec.

We assign the lines E_1 through E_{16} as phonon replicas of E_0. In order to make this assignment it is first necessary to show that it is very unlikely that any of these lines are due to purely electronic transitions. These lines are separated from one another and from E_0 by some hundreds of cm^{-1}. In order for them to be due to purely electronic transitions these separations must be accounted for by having transitions from different excited states to the same ground state, as any splitting of the $^8S_{7/2}$ ground state should be much smaller than 100 cm^{-1}. If they are due to transitions from different excited states separated by some hundreds of cm^{-1}, one would only observe such a multitude of transitions at low temperature if the transition rate to the ground state from each excited state was much faster than the nonradiative single phonon emission relaxation rates

between the excited states. The experimentally measured fluorescence decay rates of E_1 through E_{16} are all identical and equal to that of E_0 (0.40 ± 0.04 μsec). The nonradiative interexcited state relaxation rate could hardly be slower than this and should be $\sim 10^{-10}$ sec or faster (11). We therefore rule out the possibility of any of the lines E_1 through E_{16} being other than phonon replicas of E_0.

The assignment of E_1 through E_{16} as phonon replicas of E_0 is consistent with some experimental observations of their properties. One expects the fluorescence of phonon replicas to decay at the same rate as the zero phonon line. As previously mentioned, the experimentally determined fluorescence decay times of all of the lines from E_0 to E_{16} are identical at 0.40 ± 0.04 μsec. Another observation is that E_0 is the only fluorescence line that shows self-absorption. If the concentration of luminescence centers is increased one expects only the zero phonon line to show self-absorption, the absorbed energy being redistributed among the phonon lines. One sees in Fig. 3 that as the europium concentration is increased from 0.01-2 molar per cent (m/o), E_0 drops considerably in intensity relative to the other lines. The spectrum of the 2 m/o sample in Fig. 3 has been scaled down to better display this change.

The conclusion we reach from these observations and arguments is that our assignment of E_1 through E_{16} as phonon replicas of E_0, while not absolutely certain, is undoubtedly correct. Figure 4 shows all of the lines observed in detail. The separations of the lines from E_0 are listed in Table III.

Hobdon (3) has observed similar sharp phonon structure for Eu^{+2} in CaF_2. The europium site in CaF_2 has inversion symmetry, so that only even phonons will be observed in a fully allowed electric dipole transition. Hobdon explained the sharpness of the phonon sidebands as being due to a combination of this selective coupling and peaks in the phonon density of states distribution in CaF_2. The (C_{2v}) europium site in $CaSO_4$ lacks inversion symmetry so that all phonons may be involved. The sharpness of the phonon sidebands therefore may reflect structure in the phonon density of states curve in $CaSO_4$. An alternate explanation is that at least some of the lines could be due to resonant modes introduced by the addition of europium to the $CaSO_4$. In hopes of testing these models we took Raman spectra of both pure $CaSO_4$ samples and samples containing various amounts of europium, up to a 10% molar replacement of calcium. The phonon energies observed are listed in Table III. The second column of Table III shows the separations in energy of the phonon peaks from the zero phonon line, obtained from the fluorescence data. The energies of these peaks range from about 100 cm^{-1} to more than 1000 cm^{-1}. If one assumes that these are due to normal lattice vibrational modes the lower energy peaks would be due to vibra-

tions between the cations and the SO_4 groups. The high energy peaks would be due to internal modes of the SO_4 groups. The peaks probably represent peaks in the density of states of the various lattice modes as the selection rules allow all phonons to be coupled to. The third column of Table III shows the phonon energies obtained by Raman spectroscopy for pure $CaSO_4$. The phonons observed by Raman spectroscopy are located at $\vec{k} = 0$ rather than at the point of maximum density. Consequently, good agreement between the energies listed in the center column and the fluorescence phonon energies should not occur. Typically, the energy at the zone boundary is 10-20% greater than the energy at $k = 0$ for optical modes, and therefore the disagreement may be expected to be of this order. The Raman data does show, however, that normal lattice vibrations do occur over the energy range in which the fluorescence phonon sidebands are observed. The assignment of these peaks to structure in the density of states of the normal lattice modes of $CaSO_4$ is therefore a reasonable one.

One cannot rule out the possibility that at least some of the phonon peaks are due to resonant vibrational modes caused by the disruption of the lattice by the addition of europium ions. To investigate this possibility we took Raman spectra on $CaSO_4$ samples containing various Eu^{+2} concentrations ranging up to 10%. In addition to the Raman lines seen in pure $CaSO_4$, new lines appeared in the samples doped with Eu^{+2}. The strengths of these new lines are linearly proportional to the Eu^{+2} concentration. Since x-ray photographs verify that the Eu^{+2} forms a perfect mechanical mixture with the Ca^{+2} ions in $CaSO_4$ (up to at least 10% Eu^{+2}) with no formation of second phases, it must be concluded that the new lines are indeed resonant modes due to substitutional Eu^{+2}. The energies of these lines are listed in the right-hand column of Table III. None of the phonon peaks seen in fluorescence have energies identical with the resonance lines seen by Raman spectroscopy, which one might expect if they were both due to resonant modes. We therefore conclude that lines E_1 through E_{16} are due to density of states peaks in the normal lattice modes of $CaSO_4$ and are not due to resonant modes. Why we have failed to observe the resonant modes in the fluorescence sidebands is not clear. We can speculate that perhaps they are broader in the fluorescence spectrum than they are in the Raman spectrum, and that the resonant sideband peaks are hidden under the broad sideband fluorescence envelope. It is also possible that the relative strength of the resonant modes is greater in a Raman process than in fluorescence, as the coupling mechanisms are different in the two cases.

Excitation.—The excitation spectrum of Eu^{+2} in $CaSO_4$ is shown in Fig. 5. This spectrum was taken on a sample containing only 0.0005 m/o Eu^{+2} and at 1.8°K in order to display all of the fine structure present. The zero phonon line which was labeled as E_0 in fluorescence, is here also labeled A_0. A total of 56 lines have been counted in this spectrum spread over an 8000 cm^{-1} width. The excitation spectrum beyond 33,000 cm^{-1} is not shown on Fig. 5 but it consists of a broad envelope peaking at 41,200 cm^{-1} which has no fine structure contained in it. Several sharp lines in the absorption spectrum of Eu^{+2} in CaF_2 have been seen by Kaplyanskii and Feofilov (2) but nowhere in the literature has such a profusion of lines been reported. One possible reason for the failure of others to see such a spectrum is that they measured absorption spectra and not fluorescence excitation spectra. In order to observe impurity ion absorption in solids by direct absorption it is necessary to keep the doping level fairly high. High ion concentrations however broaden the sharp line spectra reported here so that they cannot be directly observed. The experimental sensitivity in measuring excitation spectra is much higher so the spectra of impurity ions at low doping levels can be measured easily.

We attribute the multitude of sharp lines observed in the excitation spectrum of Eu^{+2} in $CaSO_4$ to purely electronic transitions to the various levels of the $4f^6(^7F_J)5d(e_g)$ system, split by a strong exchange interaction between the 4f electrons and the 5d. The theory presented in a previous section predicts 56 levels and we have counted 56 lines. Such an extremely good agreement is, perhaps, fortuitous. Some of the lines seen in the excitation spectrum may, in fact, be phonon replicas and conversely, some of the exchange split lines may be unresolvable due to proximity to nearby lines. We do however believe that the spectrum is principally due to exchange interaction, and the existence of the large number of levels observed is our main evidence for this identification. No assignment of these lines to particular energy levels is given but their energies and relative excitation strengths are listed in Table IV.

Discussion of the Optical Spectra of Eu^{+2} in $BaMg(SO_4)_2$

Fluorescence.—Fluorescence spectra of Eu^{+2} in $BaMg(SO_4)_2$ at 300° and 77°K are shown on Fig. 6 and the 1.8°K spectrum of some of the higher energy lines in Fig. 7. Their energies are listed in Table V. At 300°K the spectrum consists of a broad band with some sharp lines superimposed. Upon cooling to 77°K the band emission has disappeared and only the sharp lines remain at this and lower temperatures. The sharp lines labeled D and E have disappeared at 77°K and line C is reduced considerably in strength relative to line B_0. The decay time of the broad band as well as the sharp lines at 300°K is equal to 0.05 μsec. The decay times of all of the sharp lines at 77°K and below are equal and have a value of 3.5 msec. This is in contrast to the value of 0.40 μsec found in $CaSO_4$.

* Phonon replicas of B_0.

Similar slowly decaying sharp line spectra have been reported by Hoffman *et al.* (4, 5) for Eu^{+2} in the alkaline earth aluminum fluorides. They concluded that the sharp lines are due to transitions within the 4f configuration which occurs when the lowest lying excited state is a f^7 state rather than a f^6d. Our assignment of the sharp lines in the spectrum is the following: Line B_0 is a zero phonon line due to the transition ${}^6P_{7/2} \rightarrow {}^8S_{7/2}$ and the lines at lower energy than line B_0 are phonon replicas of line B_0. Line C is at 56 cm^{-1} higher energy than B_0 and is due to a transition from another state which is thermally populated following a Boltzmann distribution. It is probably a level of the ${}^6P_{7/2}$ excited state that is split by the noncubic crystal field at the Eu^{+2} site. Lines D and E, which lie about 300 cm^{-1} above line B_0 and also show marked temperature dependence are probably associated with ${}^6P_{5/2} \rightarrow {}^8S_{7/2}$ transitions. At 300°K the f^6d state is strongly populated and the fast decay characteristics of an $f^6d \rightarrow f^7$ transition is observed. Since the ${}^6P_{7/2}$ levels are in thermal equilibrium with the f^6d levels they also exhibit the fast decay time at this temperature. Our assignments of the transitions responsible for the observed lines are also listed in Table V.

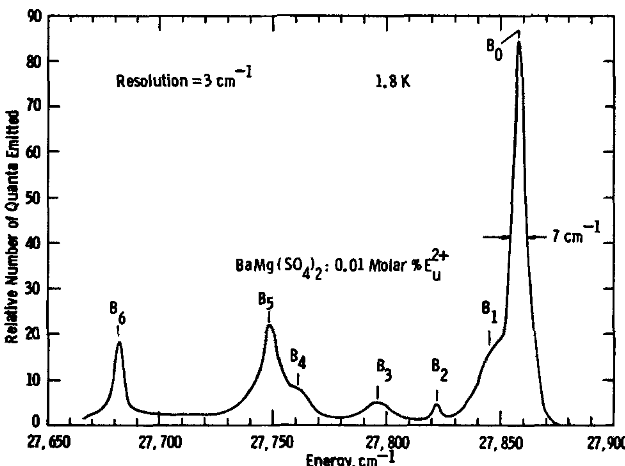

Fig. 7. The 1.8°K fluorescence of Eu^{+2} in $BaMg(SO_4)_2$. Phonon replicas of B_0 with energies less than 27,650 cm^{-1} are not shown.

Excitation.—The excitation spectrum of Eu^{+2} in $BaMg(SO_4)_2$ is shown in Fig. 8. Seven well-defined narrow bands can be seen, located between 30,000 and 35,000 cm^{-1}. Another excitation band exists at higher energy but it has no structure to it and is not included on Fig. 8. The structure in the lower band is due to transitions to the seven ${}^7F_J$ levels of the Eu^{+3} core superimposed on top of the ${}^2e_g$ state of the additional 5d electron (9). Also shown in Fig. 8 is a best fit of the seven bands to the free ion spacing of the $4f^6$ levels assuming a spread of 5040 cm^{-1}. This fit is reasonable even though the spacings between the levels do not coincide perfectly with the free ion spacings. The effect of the crystal field on the free ion levels will be different in the various states contained within each ${}^7F_J$ level. Certain states will be shifted in energy more than others and the transition probabilities may be altered. Exchange coupling, which has so far been ignored, will also have some effect. As a result, some distortion of the envelope shapes or positions is to be expected. Because the distortion is small the excited state $4f^65d$ configuration of Eu^{+2} in $BaMg(SO_4)_2$ rep-

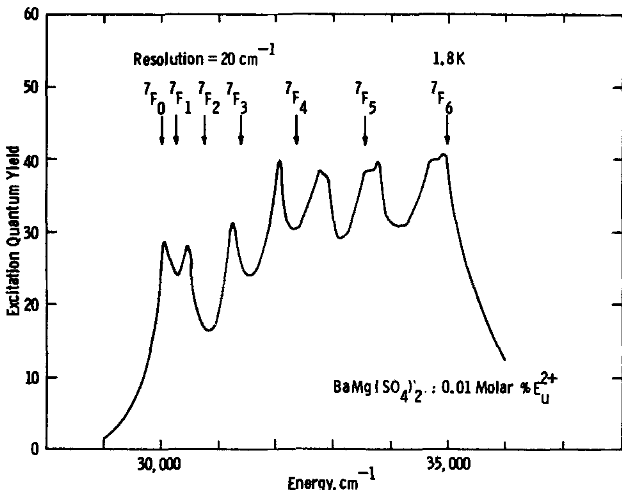

Fig. 8. The 1.8°K excitation spectrum of Eu^{+2} in $BaMg(SO_4)_2$

resents an example of weak exchange interaction of the $4f^6$ and 5d electrons.

The Optical Properties of Eu^{+2} in the Other Alkaline Earth Sulfates

The optical spectra of Eu^{+2} in the remaining alkaline earth sulfates will not be presented in this paper. The fluorescences of these compounds are all fast in decay and are located at various wavelengths in the near-ultraviolet. In all of these compounds the crystal field has depressed the ^2e_g band well below the lowest lying $4f^7$ configuration so that no $4f^7 \rightarrow 4f^7$ transitions may be observed. They all have much broader fluorescence envelopes than in $CaSO_4$ due probably to larger Stokes' shifts. As a result, none of them exhibit a zero phonon line and therefore none of the interesting phonon structure seen in $CaSO_4$. While some structure can be seen in the excitation spectra of these compounds it is not nearly as detailed as that of $CaSO_4$ so that its presentation would be of little value.

Conclusion and Discussion

We have observed types 2 and 3 optical spectra for Eu^{+2} in $CaSO_4$ and type 4 in $BaMg(SO_4)_2$. At low temperatures a strong zero phonon line is observed in fluorescence for Eu^{+2} in $CaSO_4$ accompanied by many sharp phonon sidebands, reflecting the phonon density of states distribution in $CaSO_4$. The fast fluorescence transition is $4f^65d \rightarrow 4f^7$ as the lowest lying excited state is a $4f^65d$ level. The many sharp lines seen in the excitation spectrum can be accounted for by a strong exchange splitting of the $4f^65d$ states.

The lowest lying excited state of Eu^{+2} in $BaMg(SO_4)_2$ is a $4f^7$ state so that slow $4f^7 \rightarrow 4f^7$ fluorescence transitions with vibronic sidebands are observed. The excitation spectrum shows that in $BaMg(SO_4)_2$ there is a weak exchange interaction between the $4f^6$ electrons and the 5d.

It is interesting to question why such spectra are not observed in the other alkaline earth sulfates, or for that matter in many other hosts. The conclusions we reach are listed below for types 2, 3, and 4 spectra. [The conditions necessary for observing type 1 is discussed in Ref. (1).] These conclusions should be applicable to Eu^{+2} in any host, although we specifically address ourselves to the question of why certain types of spectra appear in certain alkaline earth sulfates and not in others.

Type 2.—In order to observe a type 2 spectrum in fluorescence it is necessary that the coupling to the phonons in the excited state of the Eu^{+2} ion differ from the coupling in the ground state by a small enough degree so that a zero phonon line can be observed. That is, a small Stokes' shift must occur. This condition is met in $CaSO_4$ whose fluorescence envelope is much narrower than that for the other hosts studied where $4f^65d \rightarrow 4f^7$ transitions dominated. If the phonon spectrum of the host has sharp structure in it or if resonant modes are present, the phonon replicas of the zero phonon line will exhibit this sharp structure, as in the case of $CaSO_4$.

Type 3.—In order to see many sharp lines in the excitation or absorption spectrum of Eu^{+2} there must be a strong exchange interaction between the 5d electron and the $4f^6$ electrons. In the alkaline earth sulfates only $CaSO_4$ shows this strong exchange term. This suggests that $CaSO_4$ is the least covalent compound of the alkaline earth sulfates.

Type 4.—In order to observe a type 4 spectrum the lowest lying $4f^65d$ level must be located above the lowest lying $4f^7$ level. There are two conditions that must be met in order for this to be the case. The first is that the crystal field strength cannot be too large. A strong crystal field splitting of the d states will depress the ^2e_g state so that it in combination with $4f^6$ lies below the lowest $4f^7$ level. Apparently the strengths of the crystal field at the Eu^{+2} site in $BaMg(SO_4)_2$ is less than in the other hosts studied so that this condition is satisfied. This would occur, for example, if the nearest neighbor spacing of the oxygen atoms to the Eu^{+2} ions were greater in the $BaMg(SO_4)_2$ lattice than in the other hosts. In the absence of structural data this suggestion must remain speculative, as must arguments based on the different oxygen coordinations in the structures. The second condition that must be is that the exchange interaction cannot be too strong. A strong exchange interaction will depress the $4f^65d$ levels as shown on Fig. 2. As we have shown, the exchange interaction of the 5d electron with the $4f^6$ electrons is very weak (50 cm^{-1}) in $BaMg(SO_4)_2$. The exchange interaction would depend on the degree of localization of the 5d electron near the Eu^{+2} core. This localization would be dependent on the degree of covalency present in the interaction of the 5d electron with the surrounding ions. We therefore suggest that in $BaMg(SO_4)_2$ a greater degree of covalency exists and that this is responsible for the weak exchange term.

Acknowledgments

Infrared Reflectivity and Free Carrier Absorption of Si-Doped, N-Type GaAs

J. K. Kung and W. G. Spitzer

Departments of Physics and Materials Science, University of Southern California, Los Angeles, California 90007

ABSTRACT

The infrared plasma reflectivity and free carrier absorption of heavily Si-doped n-type GaAs are examined and the results show that shallow reflectivity minima ($R_m \approx 14\%$) and increased free carrier absorption cross sections are a consequence of high levels of compensation in the samples. The frequency dependence of the extinction coefficient k in compensated as well as uncompensated samples is found to be different from that described by the Drude-Zener theory in the frequency region near or higher than the plasma-edge frequency. Based on the experimentally observed frequency dependence of k, correction factors are evaluated in determining carrier concentration from the frequency of the infrared plasma reflectivity minimum when the reflectivity minimum is shallow. The correction factors are applied to the measured results of a series of samples and the resulting carrier concentrations are compared with those obtained from Hall effect measurements.

Infrared plasma reflectivity and free carrier absorption measurements of n-type GaAs have been reported by a number of investigators. The reflectivity of samples with a carrier concentration $n_e > 10^{17}$ cm^{-3} shows the effect of a plasma frequency ω_p which is higher than that for the fundamental lattice reflectivity band (1) (restrahl). A reflectivity minimum is observed (1) at a frequency above the plasma-edge frequency. The minimum is deep with $R_m \leq 2\%$ and the frequency $\omega(R_m) \equiv \omega_m$ has been used as a measurement (2, 3) of n_e. In some cases n_e is determined from another measurement and the reflectivity data have been used with n_e to obtain carrier effective mass values in a number of semiconductor materials (1, 4).

In some recently reported measurements (3) of Si-doped GaAs it was found that the R_m value could vary from <4% to as large as 14%. The Si doping level and the thermal history of the sample both influence the R_m value. The present study relates the presence of the shallow reflectivity minimum (large R_m) to an increase in the free carrier absorption cross section. The validity of using ω_m as a measure of n_e for a sample with a shallow minimum is also examined.

Background

The classical Drude-Zener theory for the free carrier contribution to the complex dielectric constant gives the well-known expression (6)

$$\epsilon = \epsilon_1 + i\epsilon_2 = \epsilon_\infty - \frac{4\pi n_e e^2}{m^*}\left\langle\frac{\tau^2}{1+\omega^2\tau^2}\right\rangle + i\frac{4\pi n_e e^2}{m^*\omega}\left\langle\frac{\tau}{1+\omega^2\tau^2}\right\rangle \quad [1]$$

where m^* is the carrier effective mass, τ is the carrier scattering relaxation time, and ϵ_∞ is the limiting value for the high frequency dielectric constant. If $(\omega\tau)^2 >> 1$ then one has

$$\epsilon_1 = n^2 - k^2 = \epsilon_\infty\left(1 - \frac{\omega_p^2}{\omega^2}\right) \quad [2]$$

and

$$\epsilon_2 = 2nk = \frac{\epsilon_\infty\omega_p^2}{\omega^3}\left\langle\frac{1}{\tau}\right\rangle \quad [3]$$

where $\omega_p^2 = \frac{4\pi n_e e^2}{\epsilon_\infty m^*}$, ω_p is the plasma frequency, and n and k are the optical constants, refractive index and extinction coefficient, respectively.

Key words: carrier concentration, compound semiconductor, reflectivity minimum frequency, free electron absorption cross section.

Reflectivity curves with R_m near zero, like those labeled (a) and (b) in Fig. 1, have been widely interpreted (1, 4, 5) by using the Drude-Zener (D-Z) theory. The normal incidence reflectivity is given by the usual expression

$$R = \frac{(n-1)^2 + k^2}{(n+1)^2 + k^2} \quad [4]$$

As will be discussed k is proportional to an inverse power of the frequency and an R_m value near zero means k is small ($k^2 << 1$) at $\omega \geq \omega_m$. Setting $k = 0$ gives $R_m = 0$ when $n = 1$ and hence Eq. [2] becomes

$$\left(\frac{\omega_p}{\omega_m}\right)^2 = \frac{\epsilon_\infty - 1}{\epsilon_\infty} \quad [5]$$

or

$$\omega_m^2 = \frac{4\pi n_e e^2}{(\epsilon_\infty - 1)m^*} \quad [6]$$

Because of the small k value ϵ_2 has little influence on R for $\omega \geq \omega_m$ and also has little influence on the value of ω_m. If m^* and ϵ_∞ are known then Eq. [6] shows that n_e is determined from a measurement of ω_m^2 and this method of obtaining n_e has been used (3, 7, 8) because it is nondestructive and needs no physical contacts to the samples. The n_e values obtained in this way are in good agreement with those measured by the Hall effect.

Moss *et al.* (9) and Köhl (10) have considered the situation when k_m, the value of k at ω_m, is not small and thus R_m is not near zero. A relationship between n_m, k_m, and ϵ_∞ is obtained from Eq. [2], [3], and [4] and if $(\omega\tau)^2 >> 1$ this relationship is

$$k_m^2 = \frac{(\epsilon_\infty - n_m^2)(n_m^2 - 1)}{5n_m^2 + 3\epsilon_\infty - 2} \quad [7]$$

Also if one assumes τ is energy independent so that the energy averages $\langle\rangle$ can be omitted, then Eq. [1] can be used to obtain a modified form of Eq. [5]

$$\frac{\omega_p^2}{\omega_m^2} = \frac{\epsilon_\infty - n_m^2 + k_m^2}{\epsilon_\infty} + \frac{4n_m^2k_m^2}{\epsilon_\infty(\epsilon_\infty - n_m^2 + k_m^2)} \quad [8]$$

If $(\omega\tau)^2 >> 1$, the second term on the right becomes negligible. The procedure used is to assume n_m values for a given ϵ_∞, calculate the k_m and use these to obtain R_m and $(\omega_p/\omega_m)^2$. Thus the dependence of $(\omega_p/\omega_m)^2$ on R_m is established and the measurement of both ω_m and R_m should give n_e.

There are some difficulties with the above procedure when applied to n-type GaAs. Equation [7] is obtained

from Eq. [2] and [3] and depends upon their validity. Equation [2] has not been established for shallow minimum cases although it is known to be correct for deep minimum samples (1). From free-carrier absorption measurements Eq. [3] is known to be valid for n-type GaAs only under very restrictive conditions (11, 12). For the samples used in the present study Eq. [3] does not apply. Moreover, the second term on the right side of Eq. [8] is dependent upon the validity of Eq. [3].

The inability of the D-Z theory to correctly predict ϵ_2 and hence the free carrier absorption for samples with $n_e \geqq 1 \times 10^{17}$ cm^{-3} and $\omega \geqq \omega_p$ is seen from the following considerations. When $(\omega_p/\omega)^2 << 1$ then $\epsilon_1 \simeq n^2 \simeq \epsilon_\infty$ while the ϵ_2 equation becomes

$$k \simeq \frac{\epsilon_\infty^{1/2}\omega_p^2}{2}\left\langle\frac{1}{\tau}\right\rangle \omega^{-3}$$

Thus the classical theory predicts $k \propto \omega^{-3}$ when $(\omega\tau)^2 >> 1$ and $\omega^2 >> \omega_p^2$. It has been established that under these conditions (1, 13, 14) the measurements of samples with $n_e \geqq 1 \times 10^{17}$ cm^{-3} show an absorption coefficient $\alpha = 2\omega k/c$ which is ω^{-3} and hence $k \propto \omega^{-4}$. For $n_e \geqq 1 \times 10^{17}$ cm^{-3}, the $\omega^2 >> \omega_p^2$ means that the frequency range considered will be $\geqq 300$ cm^{-1} which is the region measured in the studies referred to in Ref. (1, 13, 14). The behavior of k near ω_p is not known from measurements of n-type GaAs. It has been shown (12) in samples with $n_e < 10^{16}$ cm^{-3} and for frequency $\leqq 200$ cm^{-1} the classical $k \propto \omega^{-3}$ dependence is observed. This latter result agrees with the theoretical expectation (15, 16) that for $kT >> \hbar\omega >> \hbar/\tau$ the quantum and classical theories produce the same results.

In the present discussion we will be confined to $\omega > 300$ cm^{-1}, $n_e \geqq 10^{17}$ cm^{-3}, and room temperature where the $k \propto \omega^{-4}$ dependence is observed. In this region the absorption has been explained (16) in quantum mechanical calculations as a linear combination of optical and acoustical mode lattice scattering absorption and impurity scattering absorption. Thus, the total free carrier absorption coefficient, α_{fc}, can be written at any frequency as

$$\alpha_{fc}(\omega) = A_L(\omega)n_e + B_I(\omega)n_eN_I \qquad [9]$$

where A_L and B_I are the frequency dependent terms from the lattice scattering and impurity scattering calculations, and N_I is the total ionized impurity concentration. If $n_e = N_D - N_A$ and $N_I = N_D + N_A$ then $N_I = n_e + 2N_A$ and

$$\alpha_{fc} = A_Ln_e + B_In_e^2 + 2B_In_eN_A \qquad [10]$$

Thus when an n-type sample is heavily compensated the absorption cross section, α_{fc}/n_e is increased by $2B_IN_A$ over that of a singly doped sample. An increase in α_{fc}/n_e of double-doped samples has been observed in both n-type Ge (17) and Si (18).

In a recent study (3) of annealing effects in n-type, heavily Si-doped GaAs it was observed that samples which have Si concentrations [Si] $> 10^{19}$ cm^{-3}, the n_e can be changed substantially by annealing and the changes are reversible. The n_e was varied from 8×10^{18} cm^{-3} to 1.5×10^{18} cm^{-3} for material with [Si] $= 4 \times 10^{19}$ cm^{-3}. All of the samples, but particularly those with smaller n_e, had R_m values which were larger than those previously observed for Te- and Se-doped material. A comparison is given in Fig. 1 which uses some previously published data (1) along with measurements made in this study.

In the present work the following properties will be studied for samples with shallow reflectivity minima:

1. To experimentally establish the magnitude and frequency dependence of k and ϵ_2 for $\omega \geqq \omega_p$ and $(\omega\tau)^2 >> 1$.
2. To use the measurements of reflectivity and absorption to determine if the D-Z expression for ϵ_1 is satisfied.
3. To determine the relationship between ω_m and R_m by using ϵ_1 and ϵ_2 functions which are consistent with experiment. This relationship has not been determined properly for samples with deep as well as shallow minima.

Experimental Results and Discussion

Absorption in samples with large R_m.—Figure 1 shows the reflectivity of five Si-doped samples taken from the same section of an ingot but with the samples in various anneal stages. Samples 3, 4, and 5 all have R_m near 13% and are referred to as shallow minimum samples. Relevant information on these samples is listed in Table I. The measured extinction coefficient for these same five samples is shown in Fig. 2 for $\omega > \omega_m$. Since $\omega_p/\omega_m < 1$ we also have $\omega > \omega_p$. As Fig. 2 indicates, the $k \propto \omega^{-4}$ dependence is also observed in the shallow minimum cases. Figure 3 shows the measured $\alpha = 2k\omega/c$ at a frequency of 1250 cm^{-1} ($\lambda = 8.0$ μm) plotted against n_e for the five samples of Fig. 1 and 2 as well as the values for a series of samples with deep minima taken from a previous study (1) and one Te-doped sample measured here and called 6. All of the deep minimum samples lie on a smooth curve and the fact that the curve is not a straight line of slope 1 is an indication of the presence of the $B_In_e^2$ term in Eq. [10]. Samples 1 and 2 lie close to the extrapolation of the curve, however samples 3, 4, and 5 are all well above the curve indicating a large contribution from the $2B_IN_An_e$ term. This result is consistent with the interpretation that the decrease in n_e between samples 1 and 2 and samples 3, 4, and 5 is at least partially because of increased compensation as a result of annealing rather than solely the loss of ionized impurity through, for example, precipitation. Since the predicted frequency dependence (16) of B_I is $\omega^{-3.3}$ it is also consistent that samples 3, 4, and 5 which have larger contributions from impurity scattering than singly doped samples of the same n_e will also continue to have $\alpha \propto \omega^{-3}$ (or $k \propto \omega^{-4}$) as indicated in Fig. 2. Therefore the samples with shallow minima are indeed samples of larger than usual absorption cross section.

Table I. List of samples studied in this work
Samples a and b are taken from Ref. (1)

Sample No.	Dopant	N_I	Anneal condition	n_e (Hall effect) (±10%)	R_m	ω_m (cm^{-1})
1	Si	4×10^{19} cm^{-3}	1100°C/15 min	8.0×10^{18}	4.7%	935
2	Si	4×10^{19} cm^{-3}	600°C/290.5 hr + 1100°C/15 min	8.0×10^{18}	4.9%	940
3	Si	4×10^{19} cm^{-3}	750°C/320 hr	1.9×10^{18}	12.5%	542
4	Si	4×10^{19} cm^{-3}	600°C/290.5 hr	1.5×10^{18}	13.7%	465
5	Si	4×10^{19} cm^{-3}	400°C/1178 hr	1.5×10^{18}	12.6%	456
6	Te	—	as grown	2.8×10^{18}	3.7%	594
a	Se	*	*	5.4×10^{18}	1.0%	770
b	Te	*	*	1.1×10^{18}	0.6%	440

* Samples a and b are from Ref. (1). The N_I and anneal condition are unknown.

Fig. 1. Reflectivity in per cent as a function of frequency ν (cm^{-1}) of seven samples. Curves a and b are reproduced from Ref. (1), Fig. 5. All seven samples are listed in Table I.

Verification of the Drude-Zener ϵ_1 expression for large R_m cases.—The infrared transmission measurements of samples 5 and 6 of Table I were made over an extended frequency range $\omega \gtrsim \omega_m$. The measurements near ω_m will permit us to obtain experimental n and k values near n_m and k_m and thus test the validity of Eq. [1] near ω_m. Sample 5 is a shallow minimum sample with $R_m = 12.6\%$, while sample 6 is a fairly deep minimum sample having $R_m = 3.7\%$. Since R is changing with ω in the range of the transmission measurements we use the customary practice of determining α from both T and R measurements at each ω by using

$$T = \frac{(1 - R)^2 e^{-\alpha x}}{1 - R^2 e^{-2\alpha x}}$$

where x is the sample thickness. Having α and hence k one obtains n from Eq. [4]. Thus the experimental frequency dependence of k, nk, and $n^2 - k^2$ can be given for each sample. Figure 4 gives k and Fig. 5 gives nk for both samples. Figure 6 gives $\epsilon_\infty - n^2 + k^2$ which should be equal to $\epsilon_\infty \omega_p^2/\omega^2$ if D-Z theory is obeyed and $(\omega\tau)^2 >> 1$ as in Eq. [2]. For both samples the k curves of Fig. 4 are close to ω^{-4} dependencies throughout the $\omega > \omega_m$ region. However, the Te-doped, deep minimum sample No. 6 shows a substantial steepening of the slope as ω approaches ω_m while the shallow minimum sample No. 5 maintains the near $k \propto \omega^{-4}$ dependence through its ω_m position. However, Fig. 5 shows a reversal of this behavior for the nk curves in that sample No. 5 deviates from the ω^{-4} dependence. From these figures it is not clear whether $k \propto \omega^{-4}$ or $nk \propto \omega^{-4}$ is the better approximation near ω_m. In Fig. 6, the value of ϵ_∞ used is 11.0 and the points

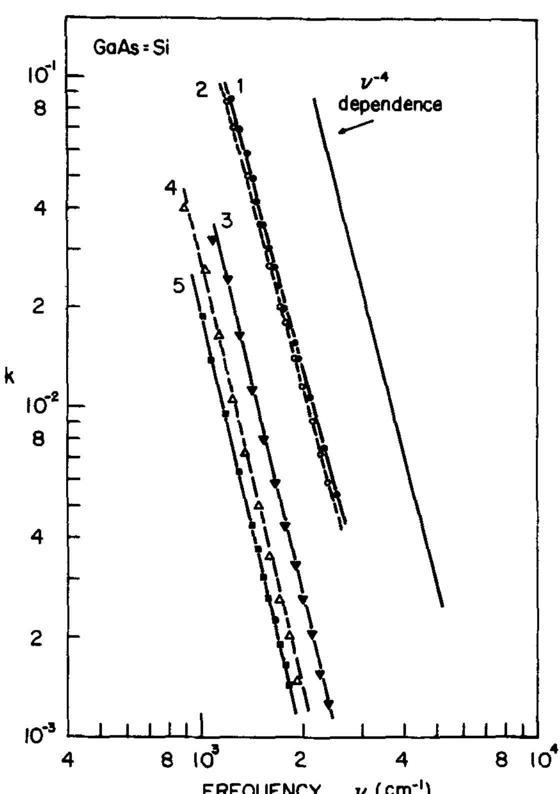

Fig. 2. The measured extinction coefficient k vs. the frequency ν (cm^{-1}) of samples 1-5 of Fig. 1.

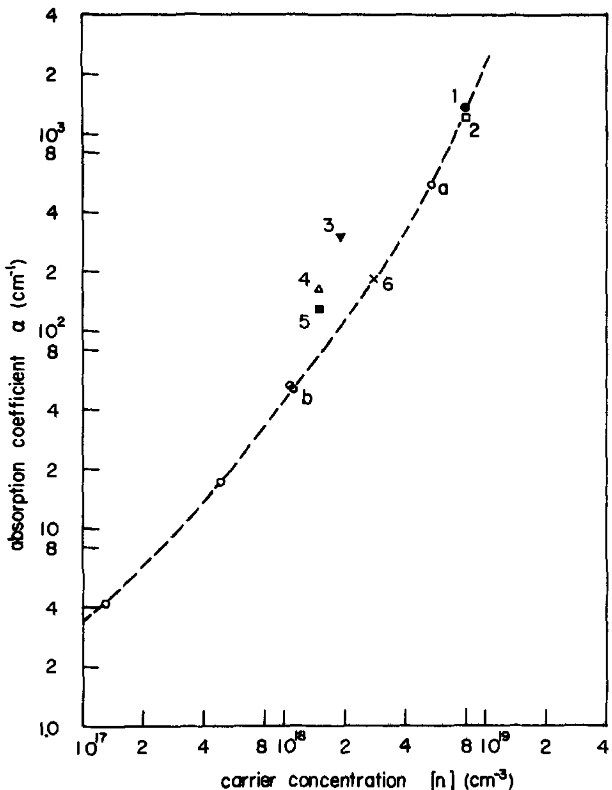

Fig. 3. Absorption coefficient, α, as a function of carrier concentration at frequency $\nu = 1250$ cm^{-1} ($\lambda = 8$ μm). Data points labeled 1-6 and a, b are from samples listed in Table I. The data points drawn as open circles are obtained from Fig. 3 of Ref. (1).

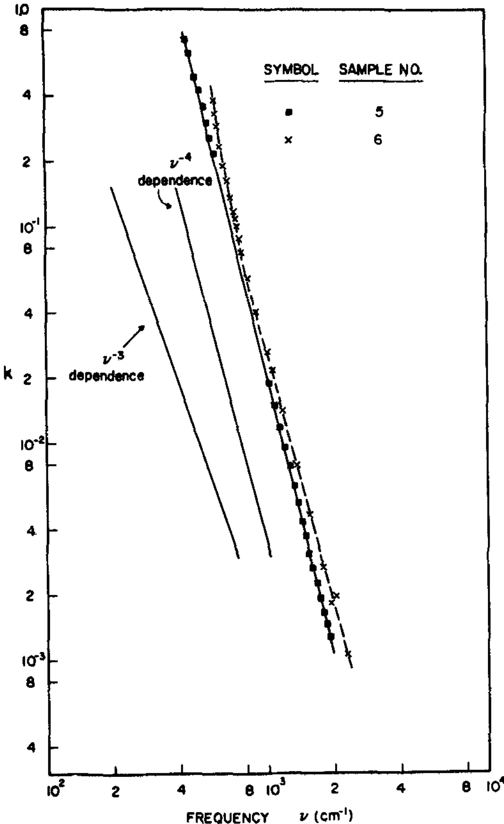

Fig. 4. Measured extinction coefficient, k, of samples 5 and 6 vs. frequency ν (cm^{-1}). The frequency range includes the frequency of the reflectivity minimum for each sample.

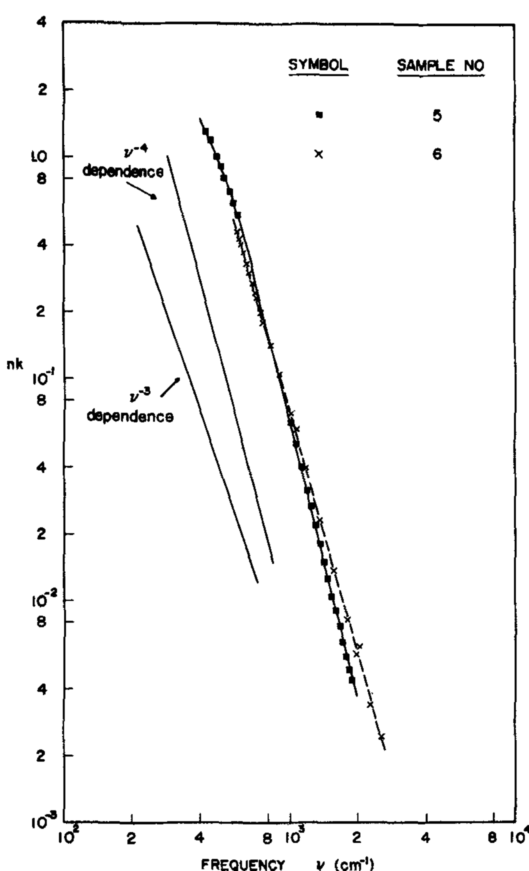

Fig. 5. The nk product of samples 5 and 6 vs. frequency ν (cm^{-1})

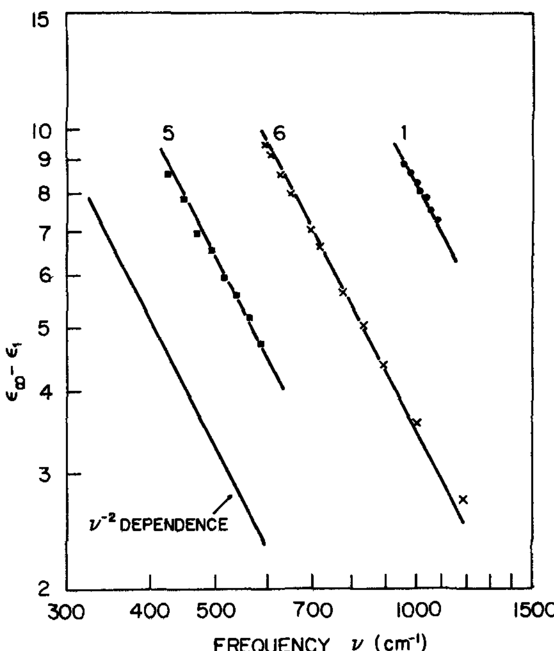

Fig. 6. $\epsilon_\infty - \epsilon_1$ vs. frequency of samples 1, 5, and 6. The lines are drawn with a slope of -2.

for both samples lie close to lines of slope negative 2 indicating that $(\epsilon_\infty - n^2 + k^2) \propto \omega^{-2}$ and the m^* values obtained are 0.085 m_o for sample No. 5 and 0.074 m_o for sample No. 6. For completeness, sample No. 1 of Table I which has an $n_e = 8.0 \times 10^{18}$ cm^{-3} was also measured and $m^* = 0.088\ m_o$ was obtained. These values compare favorably with literature values (19) of 0.076 m_o, 0.078 m_o, and 0.091 m_o for samples No. 5, 6, and 1, respectively, although sample No. 5 value is about 12% high. It appears that $(\omega_m\tau)^2 >> 1$ is a reasonable assumption for the shallow minimum case as well as the deep one and Eq. [2] is correct for $\omega = \omega_m$ as well as $\omega > \omega_m$.

Relationship between R_m and ω_p/ω_m.—It is clear from the sections above that the D-Z equation for ϵ_1 is valid for both deep and shallow minimum samples and that $(\omega_m\tau)^2 >> 1$. It is also clear now that the calculations made by previous authors in which R_m as a function of ω_p/ω_m was determined by using Eq. [3] for ϵ_2,

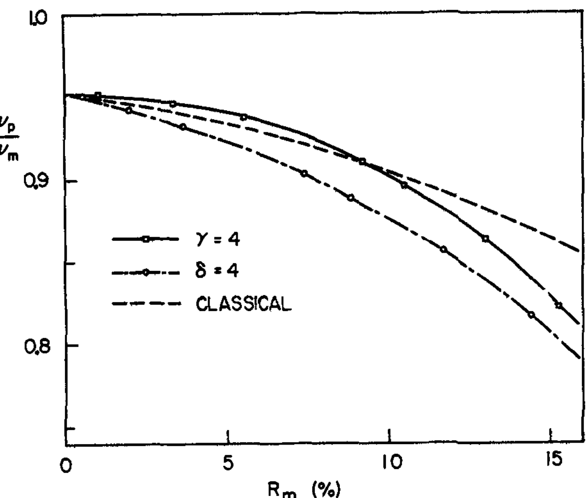

Fig. 7. Plasma frequency divided by the frequency of reflectivity minimum as a function of the value of the minimum reflectivity. The curve labeled "classical" is taken from Ref. (9) for comparison.

11	12.4%	460	1.7	1.4	1.3	1.9	−10.5%	−26.3%
12	11.4%	530	2.2	1.9	1.8	2.3	−4.3%	−17.4%
a	1.0%	770	5.4	5.4	5.4	5.4	0.0%	0.0%
b	0.6%	440	1.2	1.2	1.2	1.1	+9.1%	+9.1%

are not correct for n-type GaAs. We will replace ϵ_2 with two different forms and obtain relationships for each case. In both cases we use $\epsilon_\infty - n^2 + k^2 = C/\omega^2 + \tau^{-2}$, where $C = \omega_p{}^2\epsilon_\infty$.

1. Let $k = D\omega^{-\gamma}$ where D = constant and γ is a power. If $(\omega\tau)^2 >> 1$ and by using the condition that

$$\frac{d}{d\omega}\left(\frac{1+R}{1-R}\right)_{\omega=\omega_m} = 0$$

then one can get

$$k_m{}^2 = \frac{(n_m{}^2 - 1)(\epsilon_\infty - n_m{}^2)}{(3\gamma - 2)n_m{}^2 + (1-\gamma) + \epsilon_\infty} \qquad [11]$$

Since the experiments show that $k_m{}^2 << 1$ a term involving $k_m{}^4$ was dropped in obtaining Eq. [11].

2. Let $nk = G\omega^{-\delta}$ and in similar manner to 1 we obtain

$$k_m{}^2 = \frac{(n_m{}^2 - 1)(\epsilon_\infty - n_m{}^2)}{(3\delta - 4)n_m{}^2 + (1-\delta) + 3\epsilon_\infty} \qquad [12]$$

If $\delta = 3$ we then have the D-Z model and Eq. [12] reduces to Eq. [7].

Since Eq. [2] is still correct, then again with $(\omega_m\tau)^2 >> 1$ we obtain

$$\left(\frac{\omega_p}{\omega_m}\right)^2 = \frac{\epsilon_\infty - n_m{}^2 - k_m{}^2}{\epsilon_\infty} \qquad [13]$$

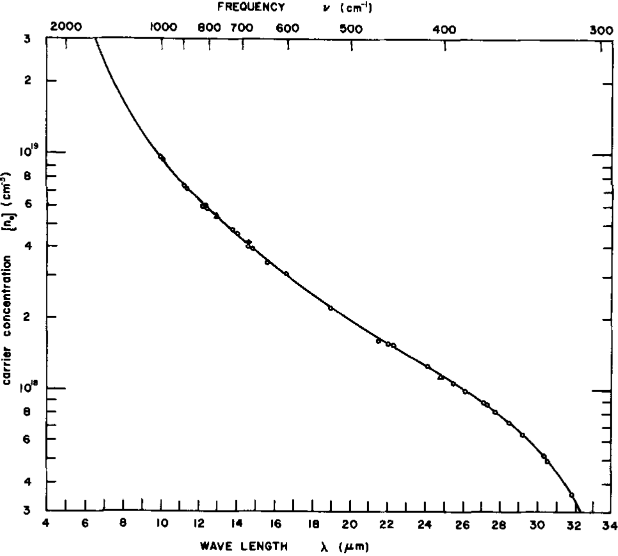

Fig. 8. Carrier concentration as a function of frequency and wavelength for the plasma edge reflectivity minimum. This curve is taken from Ref. (7).

In both cases we can get k_m for $\epsilon_\infty = 11.0$ and $\gamma = \delta = 4$ by letting n_m assume a range of values. For each set of n_m and k_m values we obtain $(\omega_p/\omega_m)^2$ from Eq. [13] and an R_m from Eq. [4]. The results are given in Fig. 7 where the classical curve is calculated (9) with the D-Z model and not assuming $(\omega\tau)^2 >> 1$. All three cases agree within 8% for ω_p/ω_m if $R_m \leq 15\%$. The results of these calculations were tested as follows: a series of samples were measured to determine R_m and ω_m. From the curves in Fig. 7 the ω_m was corrected to its value when $R_m = 0$ and this corrected ω_m was used with the curve of Okada and Oku (7) (see Fig. 8 for this curve) to give n_e. The results are given in Table II in which the n_e obtained as described are compared with Hall data for the same samples. The reproducibility of the Hall data is estimated to be ±10%. Except for sample No. 3 all n_e values from the Hall effect and ω_m without any correction agree within 15% and in most cases within 10%. When ω_m is corrected with the $\gamma = 4$ curve and used to obtain n_e the comparison with the Hall values is not substantially improved. The values for only two of the 14 samples disagree by more than 15% while the majority are again within 10% agreement. It appears that the measured ω_m is a reliable method of determining n_e within the stated errors for both deep and shallow minimum ($R_m < 15\%$) samples and that application of the calculated corrections does not necessarily improve the reliability.

Diffusion of Gallium Through Silicon Dioxide Films into Silicon

Sigurd Wagner

Bell Telephone Laboratories, Incorporated, Holmdel, New Jersey 07733

and Edward I. Povilonis

Bell Telephone Laboratories, Incorporated, Murray Hill, New Jersey 07974

ABSTRACT

Metal-oxide-silicon capacitors with shallow (~0.1 μm) diffusions of gallium through silicon dioxide films into silicon were studied with capacitance-voltage techniques. The first part of the paper is a discussion of the ionization of the gallium acceptor in the silicon space charge region, and of the unusual capacitance-voltage characteristics of very shallow diffused layers. It is concluded that in a space charge region even a comparatively deep level like that of gallium is largely ionized so that nearly all of the dissolved gallium contributes to the *C-V* signal. Furthermore, very shallow diffusions give *C-V* curves identical to those of the bulk substrate material. However, the entire curve is shifted on the voltage axis in linear proportion to the amount of in-diffused impurity. This voltage shift is used to determine the amount of gallium in silicon. In the second part the following experimental results are reported: After comparatively short diffusion times the concentration of gallium in silicon is linearly proportional to (p_{H_2}/p_{H_2O}) in an ambient gas containing hydrogen and water over β-Ga_2O_3 at 850°-1050°C. This implies that initially the gallium concentration is a function of p_{Ga_2O} rather than p_{Ga}. The diffusion coefficient of gallium in the oxide film, derived from the amount of gallium which diffused through the film into the silicon at 800°-900°C is $D_{Ga(SiO_2)} = 0.73 \times \exp(-2.46 \text{ eV}/kT)$. The density of mobile charge in the SiO_2 film was found to be higher than 1×10^{12} cm^{-2} under all diffusion conditions except when Ga_2O vapor is suppressed.

The rate of diffusion of gallium through silicon dioxide films is several orders of magnitude higher than that of the other Group III and Group V elements used as dopants for silicon (1-3). Thus silicon dioxide does not "mask" against gallium. By the same token silicon can be doped with gallium even when covered with oxide.

We have studied the formation of shallow Ga diffusion layers in Si covered by SiO_2. The purpose of this work was to find a reliable technique for the prevention of conductivity-type inversion at p-Si/SiO_2 interfaces. When thick native oxide layers are grown on boron-doped silicon, boron is depleted from Si because of a distribution coefficient which favors dissolution in SiO_2. The concurrent reduction of the acceptor density in Si facilitates the formation of an n-type inversion layer under the influence of an electric field originating at positively charged conductors on top of the SiO_2, or at positive charges within the SiO_2. This inversion can be prevented by diffusing Ga through the SiO_2 film to form a shallow but highly doped p-type layer in the Si.

In the work presented here the diffusion length of gallium in silicon was of the order of 0.1 μm. When such profiles are established in n-type substrates, their resistivity and doping level cannot be conveniently measured by profiling and four-point probing. Under the load needed to make good contact the points punch through the junction. In addition, angle lapping and staining reveal p-n junctions which must be estimated if they are less than 0.1-0.2 μm deep. Therefore we diffused gallium into p-type substrates and determined concentrations, or amounts, of gallium from capacitance-voltage measurements. These measurements are carried out after diffusion with the metal-silicon dioxide-silicon capacitor formed by the deposition of aluminum field plates on the oxide film.

Two aspects of *C-V* measurements on shallow diffusions of gallium deserve some attention. One is the comparatively deep acceptor level of gallium in silicon and the consequent deionization in the silicon space charge region. The other aspect arises from the unusual *C-V* characteristics of very shallow profiles. Their evaluation is different from that used for bulk doped material. The next section of this paper is devoted to this discussion. The reader who is primarily interested in the experimental results is asked to proceed immediately to the section on Diffusion of Gallium.

Key words: diffusion, silicon dioxide films, silicon, gallium.

Capacitance-Voltage Characteristics of Shallow Gallium Diffusions

Deionization of Gallium Acceptors

In equilibrium, not all of the gallium dissolved in the silicon is ionized when its concentration exceeds $\sim 10^{16}$ cm^{-3} (4). This deionization occurs because the Fermi function becomes a significant fraction of unity at the energy level of the gallium impurity. At low gallium concentrations this level is comparatively deep. Its ionization energy is 65 meV.

During the measurement of the resistivity or of the Hall coefficient the holes acquire little kinetic energy. They are virtually in equilibrium with the lattice. Therefore the measured quantity is converted first to the concentration of ionized acceptors by using the appropriate low-field mobility. Second, the total concentration of donors, ionized and un-ionized, is calculated using the equilibrium relation between ionized and total dopant concentration

$$N_{Ga} = N_{Ga^-} \times \left[1 + g \times \exp\left(\frac{E_{Ga} - E_F}{kT}\right)\right] \quad [1]$$

This equation is derived from one given by Wolfstirn (4). The degeneracy, g, is 4 (5).[1] E_F is the Fermi energy and E_{Ga} is the acceptor energy. Wolfstirn has shown that the ionization energy of the gallium acceptor, $\epsilon_{Ga} = \Delta E_{gap} - E_{Ga}$, depends on the concentration of gallium. The simplest model for such a dependence assumes ϵ_{Ga} to be a linear function of the average separation between gallium atoms (6, 7). In Fig. 1 this linear least squares fit of the first set of Wolfstirn's data is shown. ϵ_{Ga} was taken to be constant at its low concentration value of 65 meV up to $N_{Ga} = 4.3 \times 10^{17}$ cm^{-3}. Above this concentration the ionization energy is $\epsilon_{Ga} = 23.2 + 31.5 \times 10^6/(N_{Ga})^{1/3}$ or, after substitution with $r_{Ga} = (3/4\pi N_{Ga})^{1/3}$, $\epsilon_{Ga} = 23.2 + 50.5 \times 10^6$ r_{Ga} (meV). If no band edge tailing or broadening of the impurity level occurs the Fermi level coincides with the valence band edge at $N_{Ga} > 5 \times 10^{19}$ cm^{-3}. The maximum solubility of Ga in Si is 4×10^{19} cm^{-3} (8). Thus, by extrapolating beyond $N_{Ga} = 1.62 \times 10^{18}$ cm^{-3}, we set up the curve drawn in Fig. 2 for conversion of N_{Ga^-} to N_{Ga} using Eq. [1].

With MOS capacitances the evaluation of total dopant concentrations from measured data is conceptually less straightforward. MOS capacitors under bias are in quasi equilibrium. The Fermi level is constant throughout the semiconductor. However, the potential of the band edges and the impurity levels varies between the edge of the space charge region and the oxide-silicon interface. Over a large portion of the depletion layer the Fermi level lies much higher than the acceptor level, $E_F >> E_{Ga}$. Then, regardless of the gallium concentration, $N_{Ga} \cong N_{Ga^-}$.

In a uniformly doped semiconductor in depletion the band bending is parabolic. The electrostatic potential $\psi(x)$ at a distance x from the interface is a quadratic function of $(x - x_2)$ where x_2 denotes the edge of the depletion region

$$\psi(x) = \frac{q}{2\epsilon_S}(N_{Ga^-})(x - x_2)^2$$

where q is the electronic charge and ϵ_S is the permittivity of the semiconductor. At $x > x_2$ the exponent of Eq. [1] is determined by the energy difference between the gallium impurity level and the Fermi level in the bulk of the silicon. At $0 < x < x_2$ the exponent is modified to

$$E_{Ga} - E_F(x < x_2) = E_{Ga} - E_F(x \geq x_2) - \psi(x)$$

Ten per cent or more deionization may be considered significant. This occurs when $E_{Ga} - E_F(x < x_2)$ is more positive than $-5\ kT/q$, *i.e.*, with $N_{Ga} \gtrsim 2 \times 10^{16}$ cm^{-3} (Fig. 2).

As described in the next section, we derive N_{Ga} from the voltage and the capacitance at inversion where the band bending is at a maximum. It is possible to estimate the portion of the depletion region where ionization is incomplete ($E_{Ga} - E_F(x_i) \geq -5\ kT/q$) and to estimate the accuracy of N_{Ga} extracted from these measurements. We assume a highly doped substrate with $E_{Ga} = E_F$. For this case $N_{Ga} = 5\ N_{Ga^-}$ (Eq. [1]). N_{Ga} can be determined by numerically solving the equation $E_{Ga} - E_F = 0$, or by locating the intercept of the line $N_{Ga} = 5N_{Ga^-}$ with the curve of Fig. 2. The resulting values are $N_{Ga^-} = 2.5 \times 10^{18}$ cm^{-3} and $N_{Ga} = 1.25 \times 10^{19}$ cm^{-3}. The corresponding bulk Fermi level is about 20 kT/q below midgap and the surface potential in inversion is $\psi_S = 40\ kT/q$. Then

$$\frac{(x_i - x_2)^2}{x_2^2} = \frac{\psi(x_i)}{\psi(x = 0)} = \frac{5}{40}$$

and

$$\frac{x_i - x_2}{x_2} \cong 0.35$$

It follows that for this worst case assumption of a very high and uniform gallium concentration the acceptors are completely ionized over two-thirds of the space charge layer. Extensive deionization ($E_{Ga} - E_F \geq -$

[1] $g = 4$ is taken from Ref. (4). This value is accurate within about 10% (5).

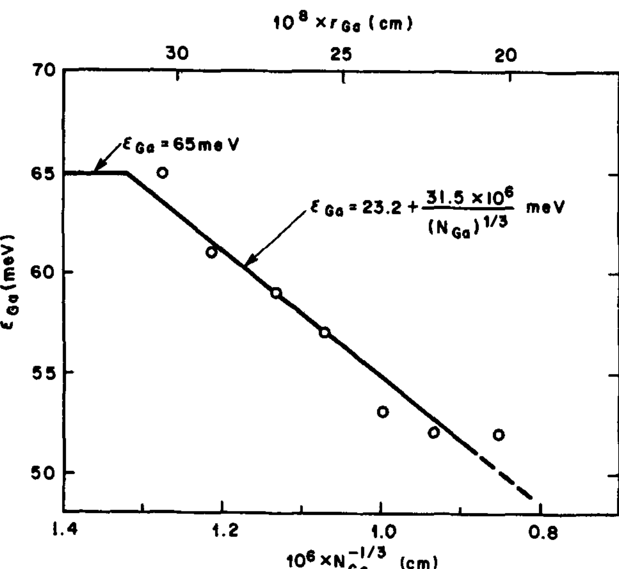

Fig. 1. Dependence of the energy level of the gallium acceptor, ϵ_{Ga}, on the mean distance between gallium atoms. The data are taken from Wolfstirn (4).

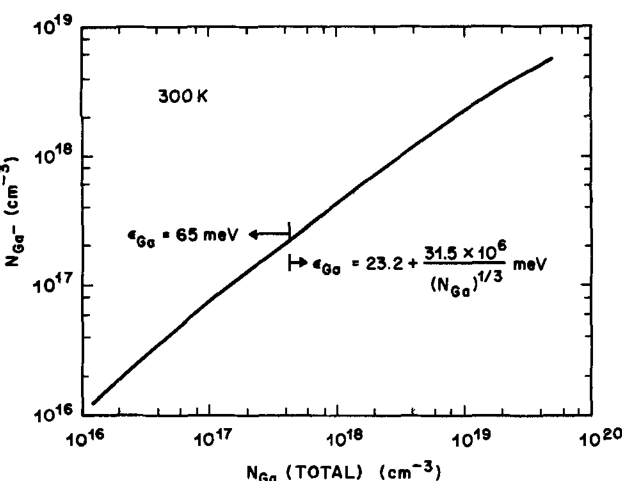

Fig. 2. Density of ionized gallium acceptors, N_{Ga^-}, as a function of the total gallium concentration, N_{Ga}.

$2kT/q$) occurs within $0.8\, x_2 \lesssim x < x_2$. At inversion 80% or more of the gallium dissolved in the depletion layer is ionized and contributes to the capacitance signal. When the doping level is uniformly lower than in this example, or when a diffusion profile with high N_{Ga} at $x = 0$ and low N_{Ga} at x_2 is measured, nearly all of the gallium will be ionized at inversion. A similar argument shows the edge of the depletion layer, x_2, to be slightly but not significantly deeper than x_2 for the completely ionized case.

We conclude that the inversion voltage and the minimum capacitance give closely the total amount of gallium atoms in the depletion layer.

Shallow Diffused Layers

Two basic types of high frequency *C-V* curves are obtained with shallow diffusion profiles of gallium in p-type silicon. Their occurrence depends on the Ga concentration in the profile and on the depth of the diffusion. The depth is defined by the point where the concentration of the indiffused Ga is equal to the net acceptor concentration of the substrate, which was about 2×10^{15} cm^{-3} in this study.

In the first type of *C-V* curve, the depletion width in inversion is smaller than the depth of the Ga profile. A *C-V* curve similar to one for uniformly doped silicon is obtained. The minimum capacitance corresponds to a weighted average density of ionized acceptors in the depletion region. In this case, the average gallium concentration was obtained by a graphical method (9).

The second type of *C-V* curve is obtained when the depletion width in inversion is larger than the diffusion depth. The *C-V* curve is then typical for the substrate material, but the entire curve is shifted to more positive voltages. This voltage shift is proportional to the amount of indiffused Ga. A shift of the inversion voltage, or the threshold voltage, of a metal-oxide-semiconductor transistor has been discussed recently, in the light of diffusion (10, 11) and of ion implantation (12-16) of dopants, or as a general feature of nonuniformly doped surfaces (17, 18).

C-V curves which are intermediates between these two types are obtained when the depletion width at inversion is comparable to the depth of the Ga diffusion.

The properties of MOS capacitors with shallow diffusions are calculated for a capacitor with a "box" diffusion profile. The capacitor is schematically shown in Fig. 3. Numerical results of the calculations are demonstrated on a capacitor with a bulk doping level $N_B = 2 \times 10^{15}$ cm^{-3}, and an oxide thickness $t_{ox} = 0.1$ μm, as a function of N_A, the concentration of indiffused acceptors, and x_1, the depth of this diffusion (Fig. 4).

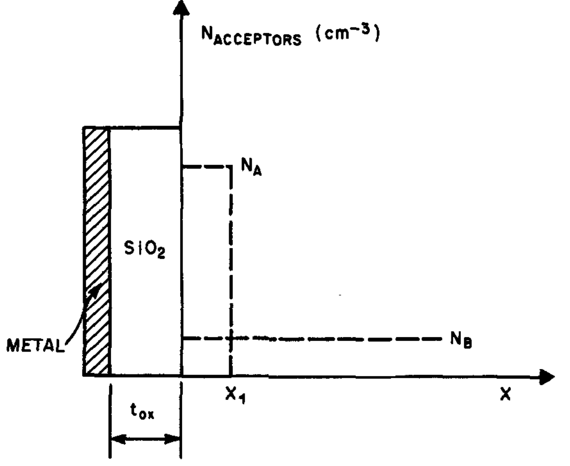

Fig. 3. Metal-oxide-silicon capacitor with a "box" diffusion profile with concentration N_A and depth x_1 in silicon with bulk doping N_B.

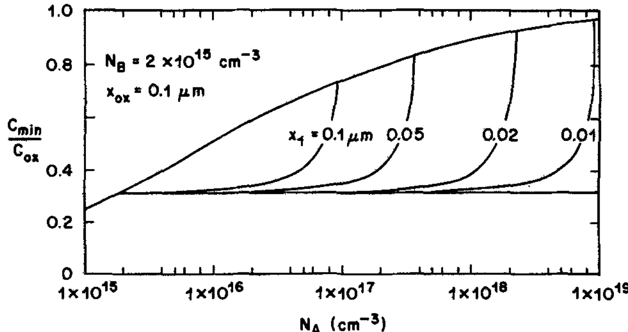

Fig. 4. Normalized minimum capacitance, C_{min}/C_{ox}, of a MOS capacitor with a "box" diffusion profile of concentration N_A and depth x_1.

In the following derivation N_A and N_B are taken to be independent of depth and the density of fixed charge and the density of interface states are assumed to be zero. Also, the depletion approximation is used, *i.e.*, the space charge in the silicon is assumed to be made up only of ionized acceptors.

First, the work function difference between the silicon and the metal, ψ_{MS}, is defined. Then the Poisson equation for the capacitor of Fig. 3 is solved to give a relation between surface potential, ψ_S, and depletion width, x_2. Using this equation, the normalized high frequency capacitance in inversion, C_{min}/C_{ox}, and the inversion voltage, V_i, are calculated.

Work function difference.—For the doping profile given in Fig. 3, the Fermi potential in the bulk is $\phi_{F,2} = (kT/q) \ln (N_B/n_i)$. That for surface region is $\phi_{F,1} = (kT/q) \ln (N_A + N_B)/n_i$, where k is the Boltzmann constant, T the absolute temperature, q has the magnitude of the electronic charge, and n_i is the carrier concentration of intrinsic silicon. The work function difference between the Si and the metal is determined by the work function of the Si in the surface region, $\psi_{Si} = \psi_{Si,i} + (kT/q) \ln (N_A + N_B)/n_i$, with $\psi_{Si,i}$ denoting the work function of intrinsic silicon, which is the reference state for potentials.

The flatband condition in the absence of fixed or mobile charge and of interface states obtains at a voltage

$$V_{FB} = \psi_M - \psi_{Si} = \psi_M - \psi_{Si,i} - \frac{kT}{q} \ln \frac{N_A + N_B}{n_i}$$

The equations derived in this section, however, will be applied to capacitors in inversion, *i.e.*, when the space charge extends beyond x_1 to x_2. It is then more convenient to retain the flatband condition for the original material (doping N_B throughout), and to redefine flatband for the diffused silicon as the condition where there is no electrostatic potential difference between the surface ($x = 0$) and the bulk (x_2). This condition is realized when the actual surface potential is $\psi_S = (kT/q) \ln (N_A + N_B)/N_B$. This surface potential is taken into account by redefining the work function of the Si to be that of the bulk material with N_B acceptors

$$\psi_{Si} = \psi_{Si,i} + \frac{kT}{q} \ln \frac{N_A + N_B}{n_i} - \frac{kT}{q} \ln \frac{N_A + N_B}{N_B}$$
$$= \psi_{Si,i} + \frac{kT}{q} \ln \frac{N_B}{n_i}$$

This definition is made to facilitate a comparison of the equations for diffused with those for undiffused capacitors. In addition, the inversion potential of the capacitor becomes formally independent of the acceptor concentration in the surface region.

Surface potential and depletion width.—The one-dimensional Poisson equation at points between the edge of the depletion region, x_2, and x_1 is

$$\frac{d^2\psi}{dx^2} = \frac{q}{\epsilon_S} N_B \quad (x_1 < x < x_2)$$

where ϵ_S is the permittivity of the silicon. For $0 < x < x_1$ it is

$$\frac{d^2\psi}{dx^2} = \frac{q}{\epsilon_S} (N_A + N_B) \quad (0 < x < x_1)$$

The signs on the right are positive because of the negatively charged acceptors. By integration with the boundary condition $E(x > x_2) = 0$ one obtains the field strength $E(x)$. A second integration with the boundary condition $\psi(x_2) = 0$ leads to the surface potential, $\psi_S = [\psi(x = 0) - \psi(x_1)] + \psi(x_1) = \frac{q}{2\epsilon_S} (N_A x_1^2 + N_B x_2^2)$. The depletion width x_2, as a function of the surface potential ψ_S is

$$x_2 = \left(\frac{2\epsilon_S}{qN_B} \psi_S - \frac{N_A}{N_B} x_1^2\right)^{1/2} \quad [2]$$

High frequency capacitance in inversion.—At the point of inversion a small amount of electrons, δq, removed from the field plate induces 1/2 δq of electrons at the SiO_2/Si interface and 1/2 δq ionized acceptors at the edge of the depletion region. Therefore, the surface potential of inversion is determined by the doping level at the edge of the depletion region. It is equal to twice the bulk Fermi potential. A term of $3(kT/q)$ is added to bring the capacitor into deep inversion for more realistic calculated C_{min}/C_{ox} values

$$\psi_{S,i} = \frac{kT}{q} \left(2 \ln \frac{N_B}{n_i} + 3\right)$$

The depletion width in inversion, from Eq. [2], is

$$x_{2,i} = \left(\frac{2\epsilon_S}{qN_B} \psi_{S,i} - \frac{N_A}{N_B} x_1^2\right)^{1/2}$$

The capacitance per unit area of the space charge layer in the silicon is given by

$$C_{S,i} = \frac{\epsilon_S}{x_{2,i}}$$

Adding the reciprocal capacitances of this depletion layer and of the oxide layer one obtains an expression for the high frequency inversion, or minimum, capacitance normalized to the capacitance of the oxide layer

$$\frac{C_{min}}{C_{ox}} = \frac{1}{1 + \frac{C_{ox}}{C_{S,i}}}$$

$$= \left[1 + \frac{\epsilon_{ox}}{\epsilon_S} \frac{1}{t_{ox}} \left(\frac{2\epsilon_S}{qN_B} \psi_{S,i} - \frac{N_A}{N_B} x_1^2\right)^{1/2}\right]^{-1}$$

In Fig. 4, C_{min}/C_{ox} of a capacitor with a 0.1 μm SiO_2 layer and $N_B = 2 \times 10^{15}$ cm^{-3} is plotted *vs.* N_A for several values of x_1. These curves demonstrate that the doping level in the diffused layer can become quite high before the minimum capacitance rises above the value for the substrate. The bottom horizontal line is for $x_1 = 0$ which represents a concentration profile of gallium in the form of a delta function at the SiO_2/Si interface. It has the same effect as a fixed negative charge. The top curve corresponds to C_{min}/C_{ox} of substrates uniformly doped with N_A. The sharp intercepts with this curve are artifacts resulting from the simplifying assumption of an abrupt transition of the hole concentration from $(N_A + N_B)$ to N_B at x_1.

Inversion voltage.—The inversion voltage, V_i, is the sum of the surface potential in inversion and the voltage drop across the insulator

$$V_i = \psi_{S,i} + \frac{Q_s}{C_{ox}}$$

$$= \psi_{S,i} + \frac{1}{C_{ox}} \left[N_A x_1 + N_B \left(\frac{2\epsilon_S}{qN_B} \psi_{S,i} - \frac{N_A}{N_B} x_1^2\right)^{1/2}\right]$$

V_i is a virtually linear function of $N_A x_1$ for x_1 up to $x_1 = x_2$. An example is shown in Fig. 5. $N_A x_1$ is the amount of indiffused gallium which acts like a negative fixed charge at the SiO_2/Si interface.

Conversely, the amount of gallium in the silicon can be determined from the inversion voltages before and after the diffusion

$$N_A x_1 \cong C_{ox} \Delta V_i = C_{ox} (V_{i,\text{ after Ga}} - V_{i,\text{ before Ga}})$$

If the diffusion profile follows a complementary error function, the concentration of dopant at the interface $(x = 0)$ is

$$N(x = 0) \cong \frac{\sqrt{\pi}}{2\sqrt{D_2 t}} C_{ox} \Delta V_i$$

where D_2 is the diffusion coefficient of the dopant in silicon, and t is the diffusion time.

Diffusion of Gallium

Following a survey of the literature on the diffusion of gallium in silicon and in silicon dioxide, the experimental procedures and the equipment are described. Next, results are presented concerning the dependence of the Ga concentration in Si on the ratio of the partial pressures of H_2 and H_2O over the Ga_2O_3 source. The Ga concentration in Si is found to depend on the Ga_2O pressure in the gas phase. Another paragraph deals with the determination of the effective coefficient of diffusion of Ga in SiO_2. The section concludes with a discussion of the mobile ionic charge introduced to the SiO_2 by the Ga diffusion.

Previous Studies

The first investigation of the coefficient of diffusion of gallium in silicon was carried out by Fuller and Ditzenberger (19). Using bare crystals and a small quantity of Ga_2O_3 as a source in quartz ampuls initially filled with 10^{-3} mm air, these authors determined $D_{Ga}(Si) = 3.6 \times \exp(-3.51 \text{ eV}/kT) \text{cm}^2 \text{ sec}^{-1}$ for temperatures between 1105° and 1360°C. Frosch and Derick

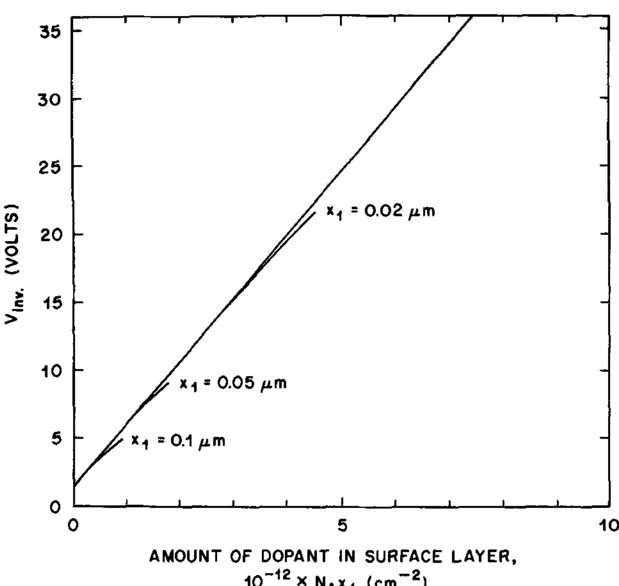

Fig. 5. Inversion voltage V_{inv}, of a MOS capacitor with a "box" diffusion profile, as a function of the indiffused amount of dopant, $N_A x_1$.

(2) developed a two temperature zone open tube technique to diffuse Ga into Si at 1200° and 1300°C using a Ga_2O_3 source and a wet hydrogen carrier gas; in a later study (20), they determined the weight loss of Ga and of Ga_2O_3 in H_2-H_2O mixtures at 950°C, and the surface concentration of Ga in Si wafers as a function of the composition of the carrier gas (H_2-H_2O and CO-H_2O mixtures) flowing over a Ga_2O_3 source. Kurtz and Gravel (21) employed the technique of Frosch and Derick, with a Ga source and a dry argon carrier, to determine the diffusion coefficient in bare Si at 1130°-1358°C, $D_{Ga}(Si) = 164 \times \exp(-4.07/kT)$. Boltaks and Dzhafarov (22) annealed "in gallium vapor" at 1180°-1340°C silicon wafers into which high concentrations of antimony had been diffused and found accelerated diffusion of Ga in comparison to control samples where $D_{Ga} = 2.1 \exp(-3.51/kT)$. In the first radiotracer study Kren, Masters, and Wajda (23) used an elemental radioactive gallium source for diffusion into oxide-covered silicon at 1200°C in evacuated ampuls. The concentration profile of Ga followed a complementary error function with $D_{Ga} = 2.9 \times 10^{-12}$ cm² sec^{-1}, while the density of holes as determined by incremental sheet resistance measurements was found to be lower than N_{total} at $N_{total} \gtrsim 1 \times 10^{18}$ cm^{-3}. (In tracer measurements on bulk Ga-doped Si, Wolfstirn (4) had found considerable deionization.) The results of Kren and co-workers are supported by the data of Okamura (24) who neutron activated Ga diffused at 1250°C ($D_{Ga} = 1.3 \times 10^{-11}$ cm² sec^{-1}) from a Ga droplet on a Si wafer in an ampul filled with dry argon, and also found deionization at $N_{total} \gtrsim 1 \times 10^{18}$ cm^{-3}. Makris and Masters (25) diffused Ga in evacuated ampuls at 900°-1050°C from Ga-doped Si powder into Si wafers. The Ga diffusion profiles were measured after neutron activation, and the resulting diffusion coefficients were combined with data from Ref. (19, 21-23) to give D_{Ga} (intrinsic Si) $= 60 \times \exp(-3.89$ eV$/kT)$. The diffusion coefficient of Ga in highly boron-doped Si was found to increase linearly with the boron concentration at $N_B \gtrsim 1 \times 10^{19}$ cm^{-3}. In a study of the diffusion of Ga into Si from Ga doped (1-4×10^{18} cm^{-3}) epitaxial silicon layers covered with Si_3N_4, Ghoshtagore (26) determined the coefficient "free from surface effects" $D_{Ga} = 0.374 \times \exp(-3.39$ eV$/kT)$ between 1143°-1393°C. In three studies Okamura (24, 27, 28) observed retardation of gallium diffusion both during codiffusion with donors and during diffusion into heavily doped n-type silicon as well as enhanced solubility in the latter. Retardation of the Ga diffusion during codiffusion with arsenic and phosphorous is also described in a communication by Nakajima and Ohkawa (29). An increase of the hole lifetime by the preparation of a Si-Ga alloy from Ga films spread over Si wafers has been reported (30).

Frosch and Derick (2) demonstrated the high diffusivity of Ga through SiO_2 films. Using their two temperature zone technique with Ga_2O_3 as a source in wet nitrogen-hydrogen gas, Grove, Leistiko, and Sah (3) determined the diffusion coefficient of Ga in SiO_2 through 1 to 4 μm SiO_2 films at 1100° and 1250°C. From the measurement of the junction depths, they arrived at a value for $D_{Ga}(SiO_2) = 1.04 \times 10^5 \times \exp(-4.17$ eV$/kT)$, as well as at a value for the distribution coefficient between Si and SiO_2, $m \cong 20$. In a recent communication, Nakajima and Ohkawa (31) reported more rapid diffusion of Ga at 1000°C in Si under SiO_2 than in bare Si. They used evacuated quartz ampuls and enough elemental Ga to establish a saturated vapor atmosphere.

Experimental

Si wafers 9-11 mil thick, 1 1/4 in. diameter, with (111) surfaces from one p-type (boron-doped) ingot with $\rho = 4$-9 ohm-cm (1.5-4×10^{15} cm^{-3}) and 9-11 mil thick, 1 1/4 in. diameter (111) wafers from one phosphorus-doped ingot with $\rho = 6$-7 ohm-cm (7-8×10^{14} cm^{-3}) were used. The silicon oxide films were grown in steam at 1050°C (for $t_{ox} \leq 1$ μm) and at 1200°C (for $t_{ox} = 2$ μm). After the oxidation the wafers were annealed for 1/2 hr at 1050°C in pure nitrogen to reduce the fixed charge density at the SiO_2/Si interface.

The gallium diffusions were carried out in a quartz container with a quartz furnace tube. The atmosphere of the furnace consisted of forming gas (15% H_2, 85% N_2) with varying amounts of water introduced as shown schematically in Fig. 6. The quartz container is shown in Fig. 7; it incorporates a rack for holding the wafers as well as two crucibles filled with the gallium source. Other than in a few preliminary experiments with elemental Ga, β-Ga_2O_3 was used as a source material.

After the gallium diffusions the oxide layers were etched back by 100Å in dilute HF and aluminum was then evaporated through shadow masks for field plates. The metallization was followed by a 1/2 hr anneal at 400°C in hydrogen for reduction of the interface state density. The capacitance measurements were carried out with equipment and procedures similar to those described by Lopez (32).

The mobile ionic charge in the oxide films was derived from the ion drift current measured by the ramp method (33, 34). At a temperature of 300°C the voltage ramp was started at -1×10^6 V-cm^{-1} with a rate of voltage change of 0.048 V-sec^{-1}. Some samples were measured with the bias-temperature stress technique at 300°C and 1×10^6 V-cm^{-1} with a stressing time of 10 min.

Mass Transport Species

Three gallium-containing species are known to exist over Ga_2O_3: Ga, Ga_2O, and GaO (35, 36). GaO is a typical high temperature species with a positive heat of formation at room temperature [$\Delta H_{f,298}GaO(g) = 66.8$ kcal (37)]. Its maximum partial pressure at 1000°C is of the order of 10^{-18} atm. Therefore it is not considered in the following discussion about the mass transport species. The molecule which performs the mass transport to the silicon can be determined from the dependence of the concentration of gallium in the silicon at $x = 0$ on the ratio (p_{H_2}/p_{H_2O}) in the gas phase. Ga was diffused into wafers covered by 0.1 μm SiO_2 at 850°, 950°, and 1050°C with (p_{H_2}/p_{H_2O}) ranging from 1.23 to 2020. To be useful in device processing the diffusion times were the shortest still leading to reproducible high concentrations of Ga in Si at the SiO_2/Si interface, $N_{Ga}(x = 0)$. The resulting gallium concentrations as a function of temperature, T, and of (p_{H_2}/p_{H_2O}) are listed in Table I, and are plotted in Fig. 8. In an intermediate range, $N_{Ga}(x = 0)$ depends linearly on (p_{H_2}/p_{H_2O}). A linear dependence points to Ga_2O as the species dominating the transport of gallium to the silicon. This follows from the equations relating p_{Ga} and p_{Ga_2O} to (p_{H_2}/p_{H_2O}), which are derived below.

The vapor pressures of Ga and Ga_2O over $Ga_2O_3(s)$ are determined by the ratio (p_{H_2}/p_{H_2O}) as follows:

p_{Ga}: $Ga_2O_3(s) + 3H_2(g) = 2Ga(g) + 3H_2O(g)$

$$K_{p,1} = p_{Ga}^2\left(\frac{p_{H_2O}}{p_{H_2}}\right)^3$$

$$p_{Ga} = (K_{p,1})^{1/2}\left(\frac{p_{H_2}}{p_{H_2O}}\right)^{3/2}$$

p_{Ga_2O}: $Ga_2O_3(s) + 2H_2(g) = Ga_2O(g) + 2H_2O(g)$

$$K_{p,2} = p_{Ga_2O}\left(\frac{p_{H_2O}}{p_{H_2}}\right)^2$$

$$p_{Ga_2O} = K_{p,2}\left(\frac{p_{H_2}}{p_{H_2O}}\right)^2$$

The oxide is virtually saturated with respect to the diffusing Ga species. Therefore the activity of the species dissolved in the oxide at the SiO_2/Si interface equals that at the gas/SiO_2 surface and the silicon surface is in equilibrium with the gas phase. The net reactions for the dissolution of the Ga carriers in Si are:

(*a*) Ga(g) = Ga(Si)

$$a_{Ga(Si)} = x_{Ga(Si)} \times \gamma_{Ga(Si)} = p_{Ga}/p^{\circ}_{Ga}$$

For dilute solutions of Ga in Si, $\gamma_{Ga(Si)}$ is assumed to be constant. It is, after reformulation of the atomic fraction $x_{Ga(Si)}$ as the number of Ga atoms in one cubic centimeter of Si, $N_{Ga(Si)}$, inversely proportional to Henry's constant, H_{Ga}

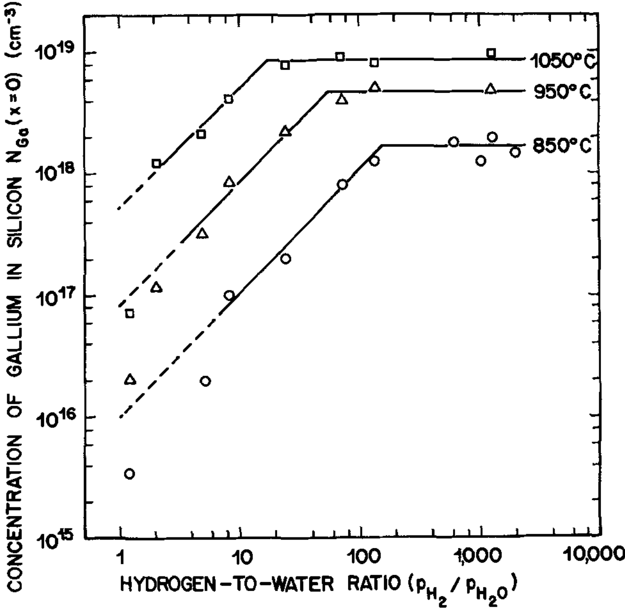

Fig. 8. The concentration of gallium in silicon at the SiO_2/Si interface, N_{Ga} ($x = 0$), as a function of (p_{H_2}/p_{H_2O}), and of temperature.

$$N_{Ga(Si)} = H_{Ga} \times p_{Ga} = H_{Ga} \times K_{p1}^{1/2}\left(\frac{p_{H_2}}{p_{H_2O}}\right)^{3/2}$$

$$= \text{const}(T) \times \left(\frac{p_{H_2}}{p_{H_2O}}\right)^{3/2}$$

(*b*) $2Ga_2O(g) + Si(s) = 4Ga(Si) + SiO_2(s)$

$$K_3 = \frac{a_{Ga}^4(Si)}{p_{Ga_2O}^2}$$

$$a_{Ga(Si)} = K_3^{1/4} \times p_{Ga_2O}^{1/2}$$

Introducing a formal Henry constant

$$N_{Ga(Si)} = H_{Ga} \times K_3^{1/4} \times p_{Ga_2O}^{1/2}$$

$$= H_{Ga} \times K_3^{1/4} \times K_{p,2}^{1/2}\left(\frac{p_{H_2}}{p_{H_2O}}\right)$$

$$= \text{const}(T) \times \left(\frac{p_{H_2}}{p_{H_2O}}\right)$$

Thus, if the species responsible for the doping of the silicon is Ga vapor, the concentration of Ga in Si, $N_{Ga}(x = 0)$, has to be proportional to $(p_{H_2}/p_{H_2O})^{3/2}$. However, it is found experimentally (Fig. 8) that $N_{Ga}(x = 0)$ is linearly proportional to (p_{H_2}/p_{H_2O}) in accordance with the preceding equation. The Ga_2O vapor is therefore the source of the gallium dissolved in the silicon.

2020	1.4×10^{18}	—	—	—	—	—

Above a certain ratio (p_{H_2}/p_{H_2O}), $N_{Ga}(x = 0)$ is found to remain constant. This limit of (p_{H_2}/p_{H_2O}), which depends on the temperature, is reached when the vapor pressure of gallium, p_{Ga}, reaches the equilibrium pressure over the liquid gallium. The ensuing formation of a condensed gallium phase reduces the number of degrees of freedom by one. According to the phase rule, p_{Ga_2O} is then constant for a given temperature. It is determined by the equilibrium

$$\frac{1}{3}Ga_2O_3(s) + \frac{4}{3}Ga(l) = Ga_2O(g)$$

$$K_{p,3} = p_{Ga_2O}$$

The pressures of the gaseous species participating in this equilibrium, p_{Ga} and p_{Ga_2O}, are plotted as a function of $1/T$ in Fig. 9. Also shown in Fig. 9 is the equilibrium constant for the formation of $Ga_2O(g)$ from $Ga_2O_3(s)$ in a H_2-H_2O atmosphere, $K_{p,2}$. When $p_{H_2} = p_{H_2O}$, p_{Ga_2O} is equal to this constant. The curve $(p_{H_2}/p_{H_2O})_{max}$ denotes the hydrogen-to-water ratio needed to raise p_{Ga_2O} to its maximum value, *viz.*, in equilibrium with Ga_2O_3 and Ga.

The sources of the thermodynamic data used in this graph are: (fef_T is the free energy function) $\Delta H°_{f,298}$ of β-Ga_2O_3, Wagman *et al.* (37); $\Delta H°_{f,298}$ of $Ga_2O(g)$, Thurmond and Frosch (38); fef_T of $Ga_2O_3(s)$ and of $Ga_2O(g)$, Cochran and Foster (39); fef_T of Ga(g), Munir and Searcy (40); fef_T of $H_2(g)$, fef_T of $H_2O(g)$, and $\Delta H°_{f,298}$ of $H_2O(g)$, JANAF Tables (41).

The sharp drop of $N_{Ga}(x = 0)$ as (H_2/H_2O) is going to unity is due to the insensitivity of the inversion voltage shift method to very small ($< 2 \times 10^{11}$ cm^{-2}) amounts of indiffused Ga. This tends to give values for $N_{Ga}(x = 0)$ which are too low (Fig. 8).

Our results imply that SiO_2 constitutes a diffusion barrier for Ga, but not for Ga_2O. The four points obtained by Frosch and Derick (20) on pre-oxidized silicon agree with our data. On the other hand $N_{Ga}(x = 0)$ reaches the solubility limit (8), $\sim 4 \times 10^{19}$ cm^{-3}, after long diffusion times (42). $N_{Ga}(x = 0)$ is then determined by the chemical potential of gallium. The unpublished study by Moore who is reported (43) to have found $N_{Ga} \propto (p_{H_2}/p_{H_2O})^{3/2}$ was presumably carried out on bare silicon or with long diffusion times on oxidized wafers.

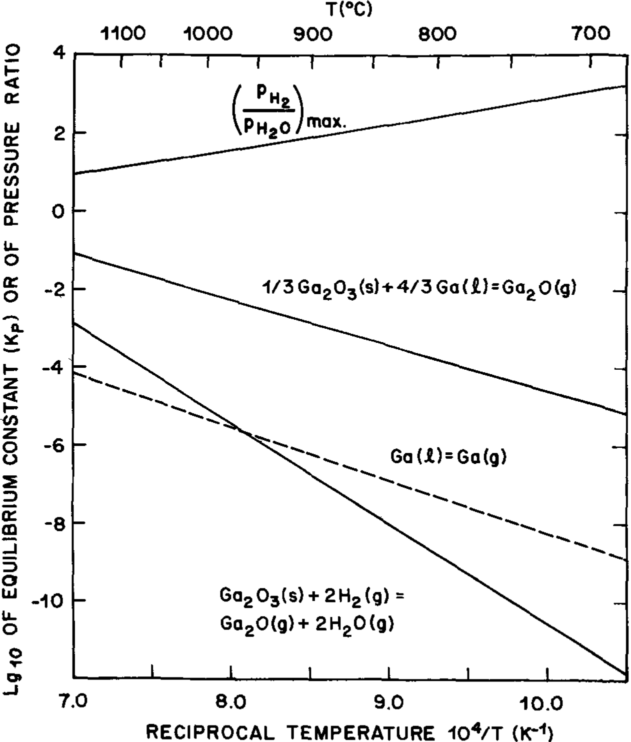

Fig. 9. Equilibrium constants for the formation of Ga_2O vapor and of Ga vapor (see text for references.) $(p_{H_2}/p_{H_2O})_{max}$ is the ratio needed to bring p_{Ga_2O} in the reaction listed at the bottom up to the maximum p_{Ga_2O} given by the equilibrium between $Ga_2O_3(s)$ and Ga(l).

Coefficient of Diffusion of Ga in SiO_2

The diffusion coefficient of Ga in SiO_2 films was determined from the amount of Ga diffused into the Si. At a given temperature and for a given diffusion time, this amount depends on the thickness of the oxide film. Sah and co-workers (44) have solved the equations for this sequential diffusion. The dopant concentration in the semiconductor as a function of position and time is

$$N_2(x,t) = m(1-\alpha)N_o \sum_{n=0}^{\infty} \alpha^n \text{erfc} \frac{(2n+1)t_{ox} + rx}{2\sqrt{D_1 t}}$$

t is the time, N_o is the solubility of the diffusant in the oxide, t_{ox} is the thickness of the oxide layer, x is the depth in the silicon measured from the SiO_2/Si interface, D_1 is the diffusion coefficient in the SiO_2, and D_2 that in the Si. $m = N_2/N_1$ is the distribution coefficient between Si and SiO_2, $\alpha = (m - r)/(m + r)$, with $r = \sqrt{(D_1/D_2)}$.

The total amount of gallium diffused into the silicon up to time t is

$$Q(t) = \sum_{x=0}^{\infty} N_2(x,t)dx$$

$$= 4m\, N_o(1-\alpha)D_1 t \sum_{n=0}^{\infty} \alpha^n \text{ierfc}\, y(0) \quad [3]$$

with

$$y(0) = \frac{(2n+1)t_{ox}}{2\sqrt{D_1 t}}$$

From the work of Grove *et al.* (3) α is known to be smaller than unity. In an argument similar to the one presented by these authors we reason that the value of ierfc $y(0)$ drops rapidly with increasing $y(0)$. As a consequence the series in Eq. [3] converges strongly and is well approximated by its first term to give

$$Q(t) \cong 4m\, N_o \alpha(1-\alpha)D_1 t \text{ ierfc} \frac{t_{ox}}{2\sqrt{D_1 t}}$$

$Q(t)$ was determined at 800°C ($t = 4$ 1/2 hr), 850°C ($t = 1$ hr), and 900°C ($t = 10$ min) for $0.1 \leq t_{ox} \leq 2.0$ μm. The diffusion length of gallium in bare silicon, $2\sqrt{D_2 t}$, was taken from the paper by Makris and Masters (25). It ranges from 0.015 to 0.020 μm under these conditions (Table II). The depletion width in inversion, x_2, is then larger than the depth of the profile regardless of the surface concentration. We have discussed earlier in this paper that $Q(t)$ can be determined from the shift of the inversion voltage ΔV_i which results from the indiffusion of gallium

$$Q(t) \cong C_{ox} \cdot \Delta V_i$$

ΔV_i for the wafers diffused at 800°-900° C is listed in Table III.

The logarithm of the first integral of the complementary error function is very closely a linear function of $t_{ox}/2\sqrt{D_1 t}$ with the slope depending on the

Table II. Diffusion coefficient of gallium in silicon, D_2, taken from Makris and Masters (25), diffusion time t, and diffusion coefficient of gallium in SiO_2, D_1 (this study)

T (°C)	D_2 (cm² sec⁻¹)	t (sec)	D_1 (cm² sec⁻¹)
800	5.9×10^{-17}	16,200	2.0×10^{-12}
850	2.1×10^{-16}	3,600	8.3×10^{-12}
900	1.1×10^{-15}	600	1.9×10^{-11}

Table III. Shift of the inversion voltage, ΔV_i, and amount of gallium diffused through SiO_2 of thickness t_{ox}, as a function of temperature. $(p_{H_2}/p_{H_2O}) = 1200$

	ΔV_i (V)			Q_t (cm^{-2})		
t_{ox} (μm)	800°C	850°C	900°C	800°C	850°C	900°C
0.1	4	7	17	8.6×10^{11}	1.5×10^{12}	3.7×10^{12}
0.2	6.5	11.5	27	7.0×10^{11}	1.2×10^{12}	3.0×10^{12}
0.3	10	13.5	36	7.2×10^{11}	9.7×10^{11}	2.6×10^{12}
0.4	11	20	48	5.9×10^{11}	1.1×10^{12}	2.6×10^{12}
0.5	17	24	50	7.3×10^{11}	1.0×10^{12}	2.2×10^{12}
1.0	21	30	60	4.5×10^{11}	6.5×10^{11}	1.3×10^{12}
2.0	—	28	32	—	3.0×10^{11}	3.5×10^{11}

$$Q(t) = \frac{1}{q} C_{ox}\Delta V_i = 2.16 \times 10^6 \times \frac{\Delta V_i \text{ (V)}}{t_{ox} \text{ (cm)}} \text{ (cm}^{-2}\text{)}$$

range of this approximation. For $0 < t_{ox}/2\sqrt{D_i t} \lesssim 1$, the slope is $B = -1.05$ with base 10 logarithms

$$\log_{10}\text{ierfc}(t_{ox}/2\sqrt{D_i t}) \cong \log_{10}(1/\sqrt{\pi}) + B(t_{ox}/2\sqrt{D_i t})$$

Thus

$$\log_{10}C_{ox}\Delta V_i \cong \log_{10}\left[\frac{4}{\sqrt{\pi}} mN_o\,\alpha(1-\alpha)D_i t\right] + B(t_{ox}/2\sqrt{D_i t})$$

$$= \lim_{t_{ox}\to 0}(\log_{10}C_{ox}\Delta V_i) - 1.05(t_{ox}/2\sqrt{D_i t})$$

In Fig. 10, $Q(t)$ is plotted logarithmically *vs.* t_{ox}. The slopes in Fig. 10 were evaluated for D_i which is listed in Table II. A least squares treatment gives for the temperature range from 800° to 900°C, $D_{Ga(SiO_2)} = 0.73 \times \exp(-2.46 \text{ eV}/kT)$. Combined with the data points of Grove *et al.* (3) for 1100° and 1250°C, $D_{Ga(SiO_2)} = 1.0 \times 10^5 \times \exp(-4.17 \text{ eV}/kT)$, an equation covering the range from 800° to 1250°C is obtained

$$D_{Ga(SiO_2)} = 5.2 \times 10^{-4} \times \exp(-1.77 \text{ eV}/kT)$$

This is the line plotted in Fig. 11. The lack of agreement between the results of Grove and co-workers and of the present study is certainly not satisfactory. It is understandable in view of the numerous approximations which had to be made in both investigations. In view of the results on the mobile charge in SiO_2, presented in the next section, one may speculate that our study gives a coefficient for the diffusion of "Ga_2O" through SiO_2, while Grove *et al.* measured the coefficient for the diffusion of "Ga." Then, of course, it would not be permissible to combine these data to the line shown in Fig. 11. This plot, however, was found to be useful and realistic for device development work.

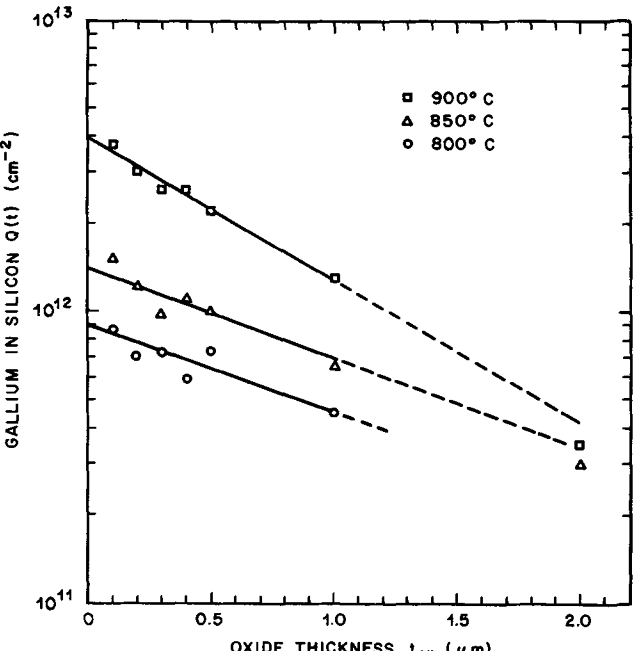

Fig. 10. Semilogarithmic plot of the amount of gallium diffused through SiO_2, $Q(t)$, as a function of oxide thickness, t_{ox}, and of temperature. $(p_{H_2}/p_{H_2O}) = 1200$.

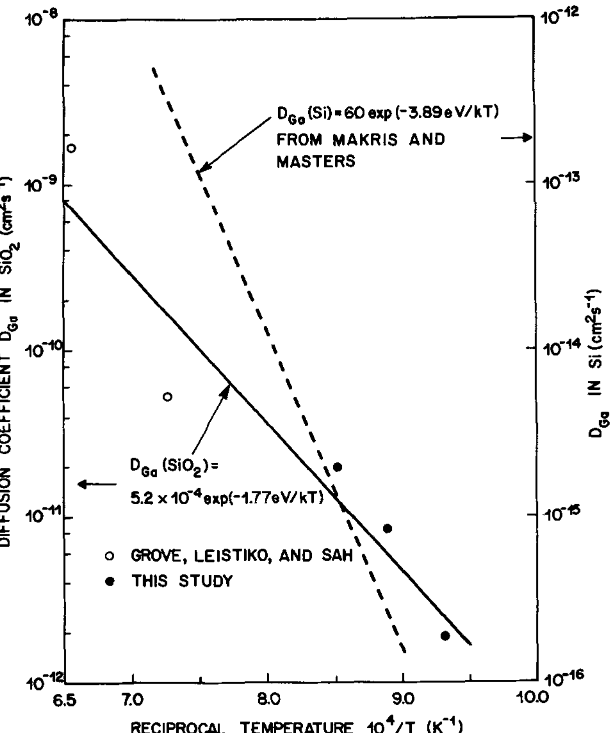

Fig. 11. Left ordinate: Diffusion coefficient of gallium through SiO_2 films. The straight line is from a least squares regression on the data of Grove *et al.* (3) and of this study. Right ordinate: Diffusion coefficient of gallium in silicon, selected by Makris and Masters (25).

With the intention of reproducing the results of Nakajima and Ohkawa (31) who found Ga diffusions which were deeper in SiO_2 covered Si than in bare Si, we diffused Ga into bare and oxidized (0.1, 0.5, and 1.0 μm SiO_2) n-type wafers. At 950°C (5 hr) and $(p_{H_2}/p_{H_2O}) = 66.0$, and at 1050°C (20 min) and $(p_{H_2}/p_{H_2O}) = 7.67$ we found junctions to be deeper in bare Si by about 0.1 μm. It was quite difficult to delineate the junctions in the oxide-covered portions by angle lapping and staining. They were found to be very diffuse and prone to either under or overstaining.

Mobile Charge in SiO_2 after Ga Diffusion

In samples where the gallium dissolved at the surface of the silicon, $N_{Ga}(x = 0)$, has reached its equilibrium value, the equilibrium concentration is also attained by the gallium species in the oxide film. A correlation between these two concentration values may be expected.

During *C-V* measurements on highly gallium-doped substrates we noticed effects typical of mobile positive charge in SiO_2. High frequency *C-V* curves shifted parallel to the voltage axis after bias at room temperature. The inversion capacitance increased with increasing positive voltage, a characteristic of lateral a-c current flow brought about by positive charge in the oxide (45). It was reasonable to expect this positive charge, which had been introduced during the gallium diffusion, to be related to the gallium dissolved in the oxide. Then the positive charge in the equilibrated oxides should be correlated with $N_{Ga}(x = 0)$. In the simplest case of constant chemical activity coefficients, and of all positive charge being mobile at 300°C, a linear

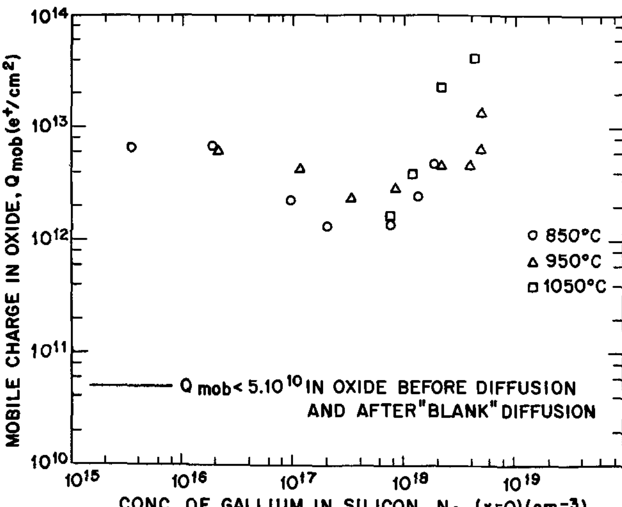

Fig. 12. Mobile charge in SiO_2, Q_{mob}, plotted vs. the concentration of gallium in silicon at the SiO_2/Si interface, N_{Ga} ($x = 0$). The samples are those used for Fig. 8.

dependence of this mobile charge, Q_{mob}, upon $N_{Ga}(x = 0)$ is expected.

The mobile charge measured with the ramp technique is listed in Table I and plotted in Fig. 12 *vs.* $N_{Ga}(x = 0)$. Voltage shifts after bias-temperature stressing gave similar results. The stressing of most oxide films, however, resulted in dielectric breakdown. Some samples could not be measured even with the ramp technique because of breakdown.

The mobile charge in the oxide films before the gallium diffusion was equal to or less than 5×10^{10} e^+/cm^2. The quartz boat and the Ga_2O_3 were also free of mobile charge as demonstrated by the following experiment. An oxide covered wafer was annealed for 3 hr at 850°C in the boat on the wafer rack and in the presence of the Ga_2O_3 source. In the oxidizing gas (2% O_2 in N_2) no gallium was transported from the source to the wafer, and indeed the Q_{mob} was less than 5×10^{10} e^+/cm^2.

It is surprising to see Q_{mob} to be large and approximately constant independent of the value of $N_{Ga}(x = 0)$. (At $N_{Ga}(x = 0) > 2 \times 10^{18}$ cm^{-3} the oxide films were visibly damaged; we ascribe the rise of Q_{mob} in this range to a change in the properties of the oxide.) Two qualitative explanations come to mind: first, the amount of gallium dissolved in the oxide is equal to a constant and uniform concentration of native defects in the oxide; second, that most of the gallium dissolved resides near the interfaces, and that the amount of gallium is determined by the characteristics of these interfaces.

All data in Fig. 12 are for 0.1 μm thick oxide films. Q_{mob} in 0.5 and 1.0 μm oxides was comparable to that shown in Fig. 12. Therefore Q_{mob} is not proportional to the volume of the oxide and the first explanation cannot be correct. The alternate interpretation of a strong accumulation of gallium near the interfaces is more likely. This interpretation is supported by the analogy of Ga_2O to Na_2O. Ga_2O vapor may dissolve in SiO_2 in the same manner as Na_2O leading to the U-shaped concentration profiles which have been measured for sodium (46). It is possible to calculate distribution profiles for these ionic impurities using the image force model put forward by Williams and Woods (47). A maximum concentration of the order of 10^{13} ions per cm^2 of interface can be estimated in qualitative agreement with our data. However, both the theoretical basis and the existing experimental data are insufficient for a rigid treatment and the agreement mentioned above may be fortuitous.

Qualitative experiments on the removal of the mobile charge were carried out. It was found that a variety of controlled annealing procedures as well as the formation of a phosphate glass layer can reduce the density of mobile ions.

Summary

It was shown in this study that:

1. The amount of dopant in shallow diffused layers in Si covered with SiO_2 films can be obtained from the shift of the MOS inversion voltage which arises from the diffusion.
2. For comparatively short diffusion times the concentration of Ga in Si covered with SiO_2 films is linearly proportional to (p_{H_2}/p_{H_2O}) over a β-Ga_2O_3 source. Therefore, the molecule Ga_2O performs the transport of gallium to the silicon.
3. The diffusion coefficient of Ga in SiO_2 films in the temperature range from 800° to 900°C has not been measured previously. It is $D_{Ga(SiO_2)} = 0.73 \times \exp(-2.46\ \text{eV}/kT)$.
4. Mobile charge with a density of at least 1×10^{12} cm^{-2} is introduced to the SiO_2 films under all diffusion conditions except when the molecule Ga_2O is not present.

Optical Investigation of Different Silicon Films

Ch. Kühl, H. Schlötterer,* and F. Schwidefsky

Siemens AG, Forschungslaboratorien, München, Germany

ABSTRACT

In the case of weak absorption, the spectral reflectance of a thin film on a nonabsorbing substrate can be used to determine the spectral dependence of the absorption constant. For this purpose, a relatively simple method is described evaluating the envelopes of the interference extrema. This method as well as a Kramers-Kronig analysis were applied to epitaxial, polycrystalline, and amorphous silicon films in the energy range 0.5-5.5 eV. With decreasing crystal quality, changes in the spectral dependence of the optical constants of these films are observed. This can be understood in terms of a decreasing long range order.

Optical investigations are very promising for evaluating film properties because of the nondestructive measuring technique. In order to examine the quality of semiconducting thin films on insulating substrates, electrical and optical measurements can be performed. Evaluating electrical measurements with very thin films can sometimes be problematical because of the increasing surface contribution with decreasing film thickness. Results of optical investigations in the region of weak absorption can easily be assigned to the volume of the thin film.

The determination of the optical constants of an absorbing material seems to be somewhat difficult. Many optical measurement techniques applied to thin films already exist and are summarized, *e.g.*, by Heavens (1). Schopper (2) measures amplitude and phase of the reflected and the transmitted beams on both sides of the film and calculates the refractive index n, the absorption index k, and the thickness d of the film. Malé's (3) evaluation requires the reflectance at each side of the film and the transmittance of the film. Then a set of curves must be drawn giving reflectance and transmittance *vs.* thickness for a set of values of n and k. Brattain and Briggs (4) measure the transmittance of the films of several thicknesses and fit the values of n and k by a trial-and-error method. Howson (5) determines the optical constants of the film from transmission measurements, evaluating the transmittance halfway on the $h\nu$-axis between two neighboring interference extrema. Also common for determining the optical constants of relatively thin films is the analysis of elliptically polarized light.

* Electrochemical Society Active Member.

Key words: thin film, absorption, refractive index, Kramers-Kronig-analysis, optical interferences.

In the present paper, a method of determining the spectral dependence of the optical constants is described in which only the reflectance of one single film is required. Since in the case of multiple interference both the reflection and the transmission coefficients contribute to the amplitude of the reflected beams, reflection measurements also provide information similar to transmission measurements. One advantage of evaluating reflection measurements rather than transmission measurements for thin films is based on the fact that, contrary to the transmittance, the average oscillatory reflectance does not slope down to zero with increasing film absorption. Therefore, the reflectance extrema can be better located and analyzed. Furthermore, the reflection measurements are independent both of the quality of the rear surface and of the plane parallelism of the substrate; films on higher absorbing substrates can easily be measured, too.

Experimental

Reflection measurements were performed with a Zeiss two beam spectrophotometer Model DMR 21 having a wave number range of $\nu^* = 1/\lambda = \nu/c = 4\text{-}50 \times 10^3\ \text{cm}^{-1}$ (corresponding to $\lambda = 2.5\text{-}0.2\ \mu\text{m}$ or $E = 0.5\text{-}6.2$ eV). For this purpose, a reflection attachment had to be constructed which is not commercially available, since the Zeiss spectrophotometer is designed for transmission measurements only. The angle of incidence is $\theta = 30°$. In order to obtain absolute values for the reflectance of the samples, the absolute reflectance of the aluminum mirror used in the reference beam had to be known. The reflectance of that mirror was obtained using a Beckman two beam spectrophotometer Model DK 2A with a special "VW" re-

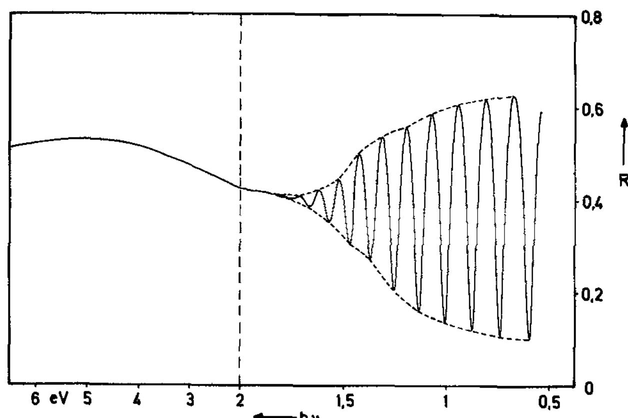

Fig. 1. Spectral reflectance curve of a polycrystalline silicon film. The dashed lines represent the envelopes of the reflectance extrema.

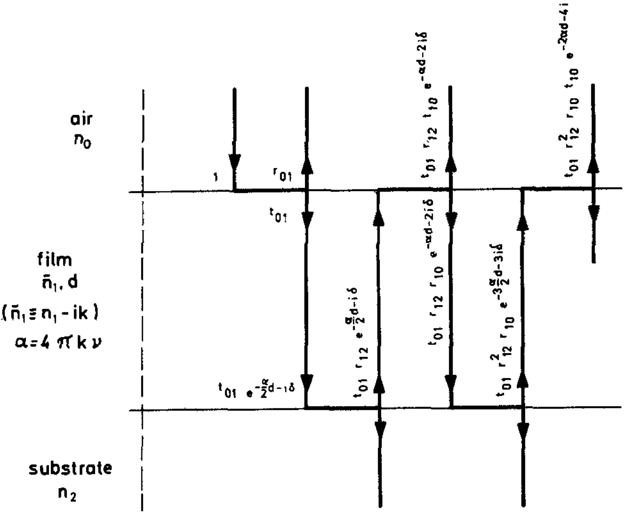

Fig. 2. Amplitudes of light for an absorbing thin film in the case of multiple interference at normal incidence. For simplicity and clearness: no oblique incidence contrary to the experiment, and lateral displacement of the light rays.

flection attachment (6). Thus, a reflectance calibration of our attachment for the Zeiss spectrophotometer was performed. Measurements were made with a series of epitaxial, polycrystalline, and amorphous silicon films on several substrates. Figure 1 shows a typical reflectance interference curve of a polycrystalline silicon film on spinel (sample 2 of Table I). The envelopes connect the extrema of the interference fringes and are used to determine the absorption constant. Silicon films with different substrate temperatures were investigated and for the present paper the results of the silicon films listed in Table I are shown, each one representative for the respective substrate temperature. Samples 1 and 2 were obtained by chemical vapor deposition with thermal decomposition of silane, whereas sample 3 was obtained by vacuum evaporation in a diffusion pumped system using an electron beam gun. The size of the coherently scattering regions near the surface was obtained by means of reflection electron diffraction (7). The geometrical film thickness was measured with a Perthen stylus tracer Model ECW-L.

Method of Analysis

Theory.—Let us consider a homogeneous, isotropic, plane parallel, thin film with the thickness d_1 and the complex refractive index $\bar{n}_1 = n_1 - ik_1$ (n_1 denotes the real refractive index, and k_1 the absorption index) at normal incidence of the light (Fig. 2). The adjoining media air (n_o) and substrate (n_2) are assumed to be nonabsorbing ($k_o = k_2 = 0$) and infinite.

In an absorbing medium, the intensity of light decreases exponentially with $e^{-\alpha x}$, where x denotes the light path in the film and α the absorption constant which is related to k by $\alpha = 4\pi k\nu^*$. Taking into account multiple interference, the complex amplitude reflectivity can be obtained by summing up all interfering beams leaving the film surface. The amplitude reflection $\bar{r}$ and transmission coefficients $\bar{t}$ at an interface are given by the Fresnel coefficients listed in Table II. For simplicity, in the following we shall omit for the film the index and only write n, k, α, d.

Using the complex Fresnel coefficients the complex amplitude reflectance of the film is given (1) by

$$\bar{r} = \bar{r}_{01} + \frac{\bar{t}_{01}\bar{r}_{12}\bar{t}_{10}e^{-\alpha d - 2i\delta}}{1 - \bar{r}_{12}\bar{r}_{10}e^{-\alpha d - 2i\delta}} \quad [1]$$

where $\delta = 2\pi n d\nu^*$ denotes the phase difference caused by traversing the film once from one interface to the other. With the simplifying assumption $k^2 << n^2$, which is fulfilled for silicon films in the infrared and part of the visible region we obtain for the intensity reflectance

$$R = |r|^2 = \frac{r_{01}^2e^{\alpha d} + r_{12}^2e^{-\alpha d} + 2r_{01}r_{12}\cos 2\delta}{e^{\alpha d} + r_{01}^2r_{12}^2e^{-\alpha d} + 2r_{01}r_{12}\cos 2\delta} \quad [2]$$

where r_{ij} denotes the real part of the complex Fresnel coefficient $\bar{r}_{ij}$ (Table II).

The extrema of the reflectance $R(h\nu)$ are determined by the extrema of the cos 2δ terms (cos 2δ = ± 1). With increasing αd, ΔR decreases, where $\Delta R = R_{max} - R_{min}$ and R_{max}, R_{min} denote the values of the corresponding envelopes at a certain energy.

Application.—Figure 1 shows that there are two regions of the reflectance curve that can be evaluated. The region where interference fringes are registrated is treated first. Here the wave number position as well as the absolute height of the extrema of the interference fringes can be analyzed. The refractive index of the film is obtained from the wave number position of the extrema (8) provided the film thickness is known. The condition cos $2\delta = \pm 1$ is fulfilled for both kinds of extrema when $\delta = z\pi$ with $z = 0, 1/2, 1, 3/2, \ldots$ yielding $n = z/2d\nu^*$.

The absorption constant can be obtained by analyzing the height of the reflectance curve. Here either the zero passages or the extrema of the cos 2δ term in Eq. [2] can be regarded. The condition of cos $2\delta = 0$ is satisfied halfway on the $h\nu$-axis between two neighboring extrema. In that way, Howson (5) determines the absorption constant but applied to transmission measurements. His method of analysis seems to be

Table I. Silicon films used in this investigation

Sample	Crystal quality	Substrate	Substrate temperature, °C	Deposition rate, μm/min	Film thickness, μm
1	Single crystalline	Sapphire	1050	1	0.65
2	Polycrystalline	Spinel	680	0.05	0.83
3	Amorphous	Spinel	20	1	0.44

Table II. Fresnel coefficients for the interfaces air-film, film-air, and film-substrate

$\bar{r}_{01} = \dfrac{n_o - \bar{n}_1}{n_o + \bar{n}_1}$	$\bar{r}_{10} = \dfrac{\bar{n}_1 - n_o}{\bar{n}_1 + n_o}$	$\bar{r}_{12} = \dfrac{\bar{n}_1 - n_2}{\bar{n}_1 + n_2}$
$\bar{t}_{01} = \dfrac{2n_o}{n_o + \bar{n}_1}$	$\bar{t}_{10} = \dfrac{2\bar{n}_1}{n_o + \bar{n}_1}$	$\bar{t}_{12} = \dfrac{2\bar{n}_1}{\bar{n}_1 + n_2}$

rather inaccurate because of the relatively steep slope of the interference fringes. From the maximum and minimum reflectance values which satisfy the condition $\cos 2\delta = \pm 1$ the envelopes mentioned before can be constructed. At a definite energy either the difference or the quotient of these envelopes can be regarded. However, the quotient method is advantageous as it is nearly independent of a possible error in the reflectance calibration of the spectrometer, which is not the case with the difference method.

Calculating the quotient $Q = R_{max}/R_{min}$ from Eq. [2] yields the following equation for $e^{\alpha d}$

$$e^{4\alpha d} - (r_{01}^2 - 1)\frac{2r_{12}}{r_{01}}\left(\frac{Q+1}{Q-1}\right)e^{3\alpha d} + \left\{\frac{r_{12}^2}{r_{01}^2}(r_{01}^2-1)^2 - 2r_{12}^2\right\}e^{2\alpha d} + (r_{01}^2-1)\frac{2r_{12}^3}{r_{01}}\left(\frac{Q+1}{Q-1}\right)e^{\alpha d} + r_{12}^4 = 0 \quad [3]$$

Only one of the four solutions of this equation is physically suitable, namely

$$e^{\alpha d} = \frac{r_{01}r_{12} - r_{12}/r_{01}}{Q-1}\left(\frac{Q+1}{2} + \sqrt{Q}\right) + \sqrt{\left(\frac{r_{01}r_{12} - r_{12}/r_{01}}{Q-1}\right)^2 \cdot \left(\frac{Q+1}{2} + \sqrt{Q}\right)^2 + r_{12}^2} \quad [4]$$

Using Eq. [4], it is possible to determine absolutely the spectral dependence of α or k by means of the quotient of the envelopes of the reflectance interference curve of the film. For this purpose, the spectral dependence of the refractive index of the film, the refractive index of the substrate, and the film thickness have to be known. It must be kept in mind, that α represents a mean value of the exponential loss of light intensity throughout the film volume including volume scattering. However, surface scattering, due to interface irregularities of the film is considered where necessary by taking into account the intensity loss at both interfaces. The wavelength dependence of the specular reflectance of a rough surface is treated according to the method of Bennett *et al.* (9). The roughness correction was tested by comparing the absorption constant thus obtained with the absorption constant of the same film, but subsequently polished (no correction necessary). There was a good agreement between both results within $\pm$ 4%.

Equation [4] has been derived for the case of normal incidence of the light. Since we measure at oblique incidence ($\theta = 30°$), we have to correct the refractive index of the film regarding the angle of incidence by substituting n by

$$n' = \sqrt{n^2 - \sin^2\theta} \approx n - \frac{\sin^2\theta}{2n} \quad [5]$$

Other effects due to the oblique incidence of light such as polarization effects are neglected, as we measure with natural light.

The validity of the approximations of Eq. [4] and [5] has been tested by comparison with numerical calculations based on the Fresnel formulas for oblique incidence without any approximations. This comparison shows that the error in α calculated according to Eq. [4] for silicon films with a film thickness $\sim$1 μm is smaller than $\pm$ 2%, thus justifying our approximations globally.

Taking into account all possible sources of errors, namely, the determination of Q, the film thickness with a possible gradient, the refractive index of both film and substrate, the mathematical simplifications, and the roughness correction, the error $\Delta\alpha$ of the determination of the absorption constant with the quotient method is estimated to be $\Delta\alpha \leqq \pm$ (10% + 100 cm^{-1}) for silicon films in the thickness range d = 0.2-2 μm. Using the same substrate for the films, the uncertainty of $\pm$ 100 cm^{-1} caused by the possible error in the refractive index of the substrate can be neglected when different films are to be compared.

The region where no interference fringes are recorded can be evaluated with a Kramers-Kronig analysis with respect to n and k (10). Since the energy range was rather limited with our measurements, a method of Roessler was applied (11) allowing for the unknown reflectance values by taking into account the absorption index measured at a definite energy.

Results with Silicon Films

Both, refractive index n and absorption index k of the samples 1, 2, and 3 listed in Table I have been determined in the whole measured spectral region. The slight dispersion of the refractive index of the spinel (sapphire) substrate (12, 13) from n_2 = 1.74 (n_2 = 1.78) at λ = 0.435 μm to n_2 = 1.695 (n_2 = 1.738) at λ = 2 μm has been taken into account. The rear surface of the spinel is unpolished and therefore its contribution to the finally reflected intensity can be neglected because of the small aperture of the spectrometer.

Figure 3 shows that in the region where interference fringes can be recorded both the polycrystalline and the amorphous silicon film have a higher refractive index than the epitaxial film, whereas the latter does not differ essentially from bulk silicon, regarding the refractive index.

In the adjoining region, where no interference fringes are recorded, and the Kramers-Kronig analysis can be applied, the refractive index of the epitaxial silicon film shows three maxima which are located at nearly the same energies as the corresponding maxima of bulk silicon. The polycrystalline and amorphous silicon films show only one broad maximum. With decreasing crystal quality (size of the coherently scattering regions: for the polycrystalline film 4 nm, for the amorphous film 0.7 nm) that maximum is shifted toward smaller energies.

Figure 4 shows the spectral dependence of the absorption index also evaluated both from the interference fringes and by means of a Kramers-Kronig analysis. It can be seen clearly that, in the region where interference fringes are recorded, the absorption index strongly increases with increasing lattice disorder, thus offering a quick and reliable criterion for the crystal quality of the films. Again, the polycrystalline and amorphous silicon films, unlike the epitaxial film, show only one broad maximum.

Discussion

The spectral dependence of the refractive index shows a discontinuity at the energy where detectable interference fringes end and the pure surface reflectance without interference fringes begins. The occur-

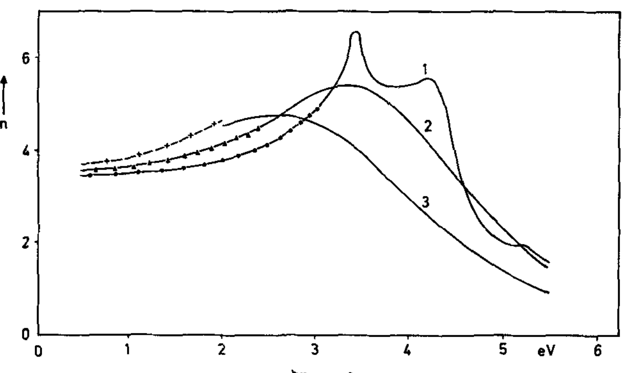

Fig. 3. Spectral dependence of the refractive index for different silicon films. Curve 1, epitaxial; curve 2, polycrystalline, and curve 3, amorphous. ●▲+, Film volume (by interference method); ——, film surface (by Kramers-Kronig analysis).

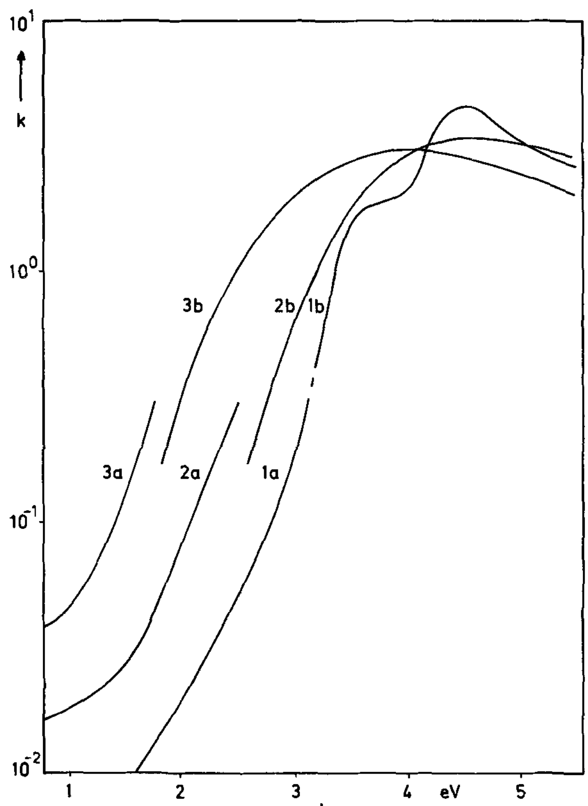

Fig. 4. Spectral dependence of the absorption index for different silicon films. Number 1, epitaxial; 2, polycrystalline; and 3, amorphous. a, Film volume (by interference method); and b, film surface (by Kramers-Kronig analysis).

rence of the discontinuity can be understood if one considers the different light paths the two methods comprise. As the light traverses through the whole film in the case of an interference measurement, one obtains the mean value of the local optical constants. On the other hand, the results of the Kramers-Kronig analysis evaluating the surface reflectance of the film yield the optical constants of a very thin region near the surface, showing a lower value of the refractive index compared to the value obtained by the interference method. It has been reported in an earlier paper that the infrared refractive index of similar films decreases with increasing grain size (14). It has been shown, too, that for polycrystalline silicon films the surface grain size increases with increasing thickness (15). Thus, the discontinuity of the spectral dependence of the refractive index obtained by the two methods of analysis can be understood assuming a gradient of the refractive index, the smaller value being at the surface. Some interference measurements with films of different thicknesses have confirmed these assumptions. The discontinuity of the spectral dependence of the absorption constant can analogously be explained by a gradient of k.

In order to have a continuous reflectance curve for the Kramers-Kronig analysis in the interference region the reflectance values were calculated according to the effective refractive index, and then fitted by a constant of proportionality to the surface reflectance curve.

To be able to analyze the different spectral behavior of sample 1, 2, and 3 a plot of $\epsilon'' = 2nk$ is shown in Fig. 5. Since ϵ'' is mainly determined by energy band structure properties, the optical transitions with the epitaxial silicon film can easily be assigned to the respective maxima of the ϵ''-spectrum. Thus the first peak at 3.6 eV corresponds to transitions $\Gamma'_{25} - \Gamma_{15}$ for $\mathbf{k} = (000)$, the second peak at 4.3 eV, to $X_4 - X_1$ for

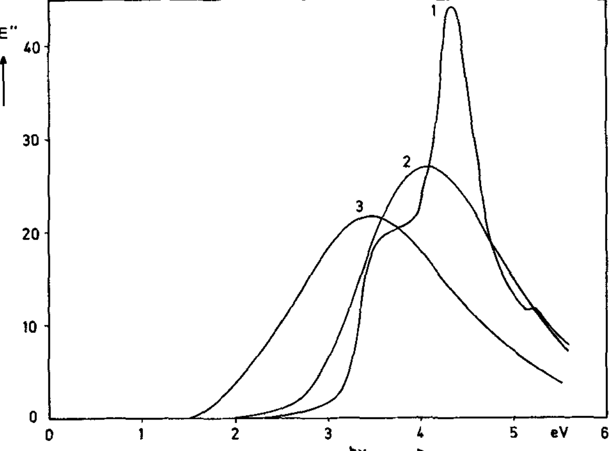

Fig. 5. Spectral dependence of the imaginary part ϵ'' of the dielectric constant for different silicon films. Curve 1, epitaxial; curve 2, polycrystalline; and curve 3, amorphous.

$\mathbf{k} = 2\pi/a$ (100), and the third peak at 5.3 eV, to $L'_3 - L_3$ for $\mathbf{k} = 2\pi/a$ (1/2 1/2 1/2) (16). According to Kramer (17), the band edges near the axis $L - \Gamma$ are less influenced by disorder than at other $\mathbf{k}$-points in the first Brillouin zone. A comparison of the epitaxial silicon film with the amorphous one shows clearly that the second maximum corresponding to $X_4 - X_1$ transitions is affected the most by the disorder of the film and disappears. This is in good agreement with Kramer's statement.

The only maximum of the amorphous film lies at nearly the same energy as the first maximum of the epitaxial silicon film, but it is considerably broader than the latter. The broadening of the maximum can be understood considering the smearing of the band edges with crystals of high disorder contrary to the sharp band edges observed with single crystals. This can also be expressed as a lifetime broadening (17) consisting in the increase of the energy uncertainty with decreasing lifetime of the crystal electrons, *i.e.*, decreasing coherence length of the lattice.

Figure 3 shows a shift of the extrema of the n-spectrum toward lower energies with increasing crystal disorder, which is also observed with the corresponding ϵ'-curves ($\epsilon' = n^2 - k^2$). A similar shift in the ϵ'-curves will be obtained by increasing the damping factor in the classical dispersion relation often used for the description of the spectral dependence of the refractive index.

In the infrared, the refractive index of polycrystalline and amorphous silicon films is increased compared with epitaxial silicon films. This fact can be understood with a model described in a previous paper (18), giving a connection to the internal surface. The increase of the refractive index has been confirmed by applying the optical sum rules (19) as has been done by Philipp (20) for silicon and SiO_y films. The first sum rule is given by

$$\epsilon_{o,\text{eff}} = 1 + \frac{2}{\pi}\int_0^{E_o} E^{-1}\epsilon''(E)\,dE$$

where $\epsilon_{o,eff}$ is the optical dielectric constant for $h\nu = 0$, associated with optical transitions in the energy range $E \leq E_o$. For our silicon films, a plot of ϵ_o *vs.* E_o shows that the saturation value of ϵ_o is close to the increased $n^2(\text{o})$ as has been expected. [$n(\text{o})$: refractive index as extrapolated to $E = 0$ from the Kramers-Kronig calculations.] The $\epsilon_{o,\text{eff}}$ *vs.* E_o curve of our amorphous silicon film differs from that reported by Philipp. As it is known [see *e.g.*, (14)] that the preparation conditions have a distinct influence on the optical properties of films, those differences can be due to different preparation parameters.

Further information is obtained applying the second sum rule (19), which is given by

$$n_{eff} = \frac{8\pi\epsilon_0 m}{h^2 N e^2} \int_0^{E_0} E\epsilon''(E)dE \quad \text{(in SI-units)}$$

where m is the free electron mass, N the atom density, and n_{eff} the effective number of electrons per atom in the energy range $E \leq E_0$. For our silicon films with increasing E_0, n_{eff} approaches asymptotically a value of approximately 4, independent of the crystal disorder. Comparing this result with the results of Philipp (20) for SiO_y films, a noticeable oxygen content can be excluded for our silicon films.

Altogether it has been shown that the difference in the spectral dependence of the optical constants of epitaxial, polycrystalline, and amorphous silicon films both in the region where interference fringes can be recorded and in the adjoining region where Kramers-Kronig analysis can be applied, can be understood by considering the degree of crystal disorder of the films.

Acknowledgments

The authors wish to express their appreciation to Mr. R. Gessner, Mr. U. Klein, and Mrs. S. Rheinboldt for providing the samples used in this investigation and to Dr. E. Preuss for valuable discussions.

Manuscript submitted Oct. 15, 1973; revised manuscript received June 5, 1974.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1975 JOURNAL. All discussions for the June 1975 Discussion Section should be submitted by Feb. 1, 1975.

The publication costs of this article have been assisted by Siemens AG.

Polymeric Resists for X-Ray Lithography

L. F. Thompson, E. D. Feit, M. J. Bowden, P. V. Lenzo, and E. G. Spencer

Bell Laboratories, Murray Hill, New Jersey 07974

ABSTRACT

It has been demonstrated that high resolution patterns can be delineated in poly(methyl methacrylate) using x-ray radiation modulated by an absorbing mask. For this technique to be effective, families of both positive and negative x-ray resists must be available which have properties that allow exploitation of x-ray lithography. This paper describes the evaluation of several polymeric electron resists for x-ray resists and demonstrates a good correlation between x-ray energy absorbed and electron energy absorbed for equivalent degrees of chemical reaction. The incorporation of heavy atoms in the resist to enhance the x-ray energy absorption and hence increase the material sensitivity has been demonstrated. The effects of a resist's contrast on ultimate pattern resolution and fidelity is discussed in relationship to the x-ray mask contrast.
