Petrovich, Baizer, and Ort (3) favored scheme B as the predominant pathway in the reductive coupling of activated olefins. However, most of their cyclic voltammetric data can be explained by direct dimerization as in scheme A (1).

Recently Bard and Puglisi (4) published results of their studies of the reductive coupling of several activated olefins. They employed a rotating ring-disk electrode and concluded scheme A was much more important than scheme B. The same conclusion was reached by Lamy, Nadjo, and Saveant (5) in their studies of the reduction of various olefinic nitriles, esters, and ketones using linear sweep voltammetry. These workers based their conclusions on the observed dependence of the peak potentials upon the scan rate and substrate concentration.

The present study examines the electrohydrodimerization of **1** using a still different technique, current-reversal chronopotentiometry.

Experimental

Reagents.—Dimethylsulfoxide (Matheson Coleman and Bell, Spectroquality) was usually used as received. When lower water content was desired, it was dried over molecular sieves (Matheson Coleman and Bell, Type 4A, 4-8 mesh) for several days before use. Tetra-*n*-butylammonium perchlorate, TBAP (Matheson Coleman and Bell) was used as received. Occasional inferior batches were reprecipitated from ethanol-water. Prepurified nitrogen (Airco, Inc.) was used for solution deaeration.

The compound **1** was prepared by condensation of benzaldehyde with 3,3-dimethyl-2-butanone followed by recrystallization from ethanol-water.

Apparatus.—The electrochemical cell was similar in design to the Type 1 Polarographic Cell available from Princeton Applied Research Corporation (PAR). A hanging mercury drop electrode utilizing a mercury-coated platinum wire support (6) was used as the working electrode. The electrode area was 0.047 cm^2. For this electrode the spherical correction to the transition time (7) will be less than 5% for times less than 4 sec. The diffusion coefficient of **1** used in this calculation was 3.6×10^{-6} cm^2/sec (1). In the work reported herein, the total electrolysis times did not exceed 2 sec.

A PAR Model 170 Electrochemistry System was the constant current source. Timing circuits within the instrument were used to control the time of current reversal. Since the procedure for initializing the PAR 170 programmer to accomplish this is not given in the manufacturer's instructions, it will be described here. With the programmer set for pulse excitation, the length of the forward electrolysis is given by the pulse duration. The final full scale current control gives the current for the forward electrolysis period and the initial full scale current control gives the current after the reversal. The experiment is initiated by switching the control keyboard from initial to final. This means that anodic current is flowing before the experiment is initiated. This anodic current was exactly compensated by a variable d-c power supply attached directly to the cell in parallel to the output of the PAR 170. The external power supply was varied until the initial potential was about 200 mV positive of the chronopotentiometric wave. This power supply was manually switched out of the circuit just prior to initiating the chronopotentiometric experiment.

The potential-time transients were recorded on a Tektronix Type 564 storage oscilloscope using a Model C-12 camera. Electrochemical measurements were made at 23° ± 2°C. In separate experiments where the temperature was varied over the range of 25°-40°C, the apparent rate constant increased by almost a factor of two for the 15°C increase in temperature. This corresponds to a temperature coefficient of only about 5% per degree centigrade and justifies the lack of precise temperature control for the major part of the work.

Gas chromatography was employed to determine the water concentration in the DMSO. A Perkin Elmer Model F11 Gas Chromatograph with thermal conductivity detector and a 6 ft Porapak Q column at 125°C was used. Methanol was employed as an internal standard in the water determination.

Results and Discussion

The reversal of current direction during a controlled current experiment is a useful technique for probing the rate of chemical reactions following electron transfer. A common way to conduct this current-reversal chronopotentiometric experiment is to allow the forward electrolysis to proceed to the transition time before the current direction is changed. If the product of the electron transfer can be reconverted to reactant at the electrode surface, a reverse transition time, τ_r, will be observed. Furthermore, if the product is stable, the ratio of the reverse transition time to the forward electrolysis time, t_1, is always 1/3 when forward and reverse currents are of equal magnitude (8). The τ_r/t_1 ratio is independent of t_1, where t_1 is less than or equal to τ_f, the forward transition time.

The rigorous solution for the case of a first-order following reaction producing electro-inactive product (9, 10) demonstrates a dependence of τ_r/t_1 on k_1t_1 where k_1 is the first-order rate constant. However, at constant k_1t_1, the ratio is independent of t_1/τ_f. Although no rigorous solution is available for second-order following reactions such as reactions [2] and [3], qualitative considerations lead one to suspect a dependence of τ_r/t_1 on t_1/τ_f (at constant $k_2C^*_Ot_1$, where k_2 is the second-order rate constant and C^*_O is the bulk concentration of the starting material). Furthermore, a distinctly different dependence is anticipated for schemes A and B.

Control of the time of reversal affects the concentration profiles of the various species. During experiments with reversals made at low t_1/τ_f values, concentrations of the parent species, **1**, in the vicinity of the electrode remain relatively high whereas the con-

centrations of the radical anion, 2, are still quite small. If scheme B is followed, the shortening of the reverse transition time should be greater than if scheme A occurs. Mechanism B requires parent, 1, to react with the electrochemically produced radical anion, 2. Early in the electrolysis, abundant 1 is present with which 2 can react. As t_1/τ_f approaches one, the opposite is true. Scheme A will have a greater effect on τ_r/t_1 than scheme B since the concentration of 2 is greater than the concentration of 1.

To test these assumptions, digital simulations were undertaken for each mechanism. The technique of Feldberg (11) was used to obtain theoretical curves of τ_r/t_1 *vs.* t_1/τ_f at different values of $k_AC^*_Ot_1$ and $k_BC^*_Ot_1$. In these simulations, diffusion coefficients were assumed equal, electrode geometry was planar, and the ratio of reverse to forward current densities was taken as 1/2. This value was chosen as a compromise between two competing effects. While a lower value of the reverse current enhances the relative difference in τ_r/t_1 between schemes A and B, it also leads to distorted potential-time curves during the reverse electrolysis due to the fact that a relatively large fraction of the current is being used to charge the electrical double layer. The former effect is useful but the latter aggravates the already difficult task of accurately measuring τ_r.

The rate law for reaction [2] was defined as $d[\mathbf{2}]/dt = -2k_A[\mathbf{2}]^2$ while that of reaction [3] was $d[\mathbf{2}]/dt = d[\mathbf{1}]/dt = -k_B[\mathbf{2}][\mathbf{1}]$. Some of the theoretical curves are shown in Fig. 1 and 2.

The most dramatic difference between the two sets of curves is the opposite sign of the slopes. For scheme A, τ_r/t_1 tends to decrease as t_1/τ_f increases whereas for scheme B the opposite tendency is predicted. This very distinct difference simplifies the experimental determination of which scheme is operative.

The simulations of scheme B did not include solution reaction [4], the "ECE nuance" (12). When reaction [4] was included as a rapid reaction always in equilibrium, only minor differences were observed, τ_r/t_1 changing a few per cent. Small variations were also obtained when the diffusion coefficients of dimeric species in scheme B were set equal to half the diffusion coefficients of monomeric species.

A second difference between the two sets of curves is the steepness at low t_1/τ_f. Those for scheme A drop rapidly, while those for scheme B maintain almost

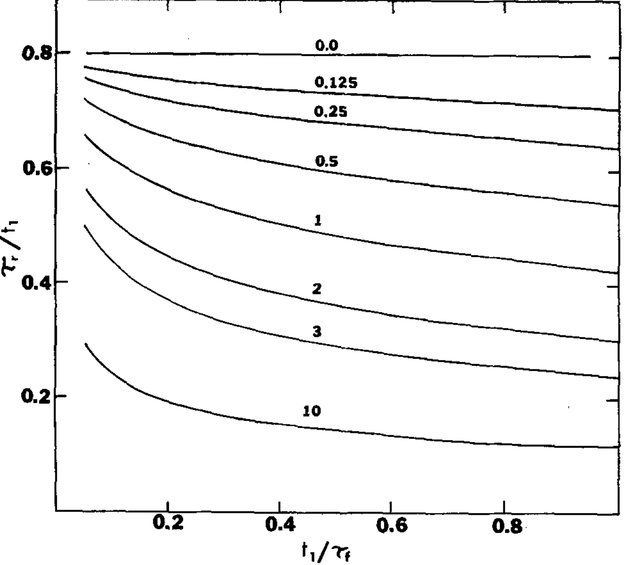

Fig. 1. Digital simulation for scheme A. Ratio of reverse transition time to forward electrolysis time as a function of the ratio of forward electrolysis time to forward transition time for various values of $k_AC^*_Ot_1$ (numbers on curves). Ratio of reverse to forward current densities was 1/2.

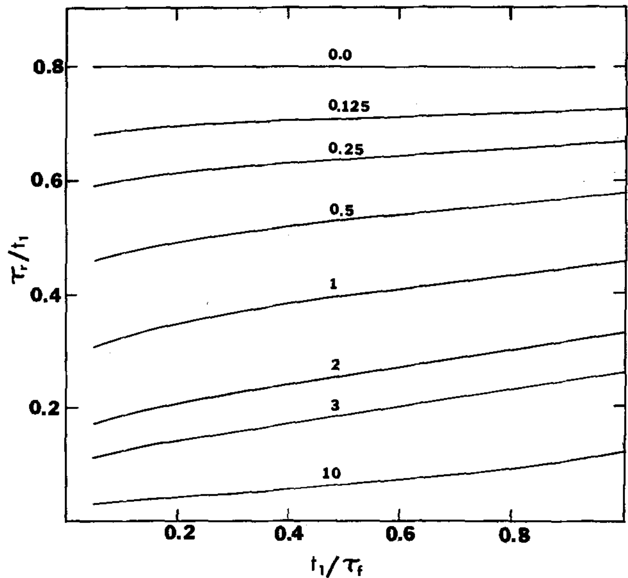

Fig. 2. Digital simulation for scheme B. See Fig. 1 for definition of terms. Numbers on curves are $k_BC^*_Ot_1$.

the same slope throughout. In both sets, the calculated τ_r/t_1 ratio becomes smaller at kCt_1 increases. As the reaction becomes faster, the concentration higher, or the forward electrolysis time longer, the extent of the following reaction increases and τ_r/t_1 decreases.

The upper curve in Fig. 3 shows how the determinations of t_1 and τ_r were made from an experimental potential-time curve. Lines A and B were drawn along the steep portions of the curve. These regions correspond to almost all of the applied current being used to charge the double layer. Lines C and D were drawn along the two electrolysis regions of the curve. Line E was constructed perpendicular to the time axis and through the point of current reversal. Finally, line F was drawn to pass through the point of reversal and have a slope equal to $-\frac{1}{2}$ of the slope of line A. The horizontal distance between the intersection of lines A and C and line E was taken to be t_1. The horizontal distance between the intersection of lines B and D and line F was taken as τ_r.

Separate experiments were performed to determine τ_f. The data analysis illustrated in the lower curve of Fig. 3 is that of Reinmuth (13) where τ_f is taken as the horizontal distance between line G and the intersection of lines H and I. Several determinations of τ_f were made at differing current densities. From these

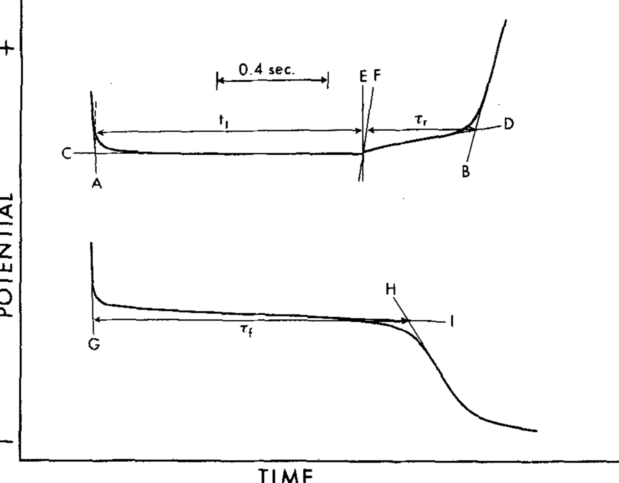

Fig. 3. Top, determination of t_1 and τ_r. Current: 6.32 μA in forward direction, 3.16 μA in reverse direction. Bottom, determination of τ_f. Current: 11.90 μA. Concentration of 1: 1.63 mM (both curves).

an average value of $i\tau_f^{1/2}$ was computed. The standard deviation of this number was always less than 5%. This average was then used to calculate the τ_f for the current densities used in the current-reversal experiments. Using the t_1 and τ_r values obtained as in Fig. 3, a point on the τ_r/t_1 *vs.* t_1/τ_f curve could be plotted. The experimental points shown in this paper are averages of at least two and usually three or more determinations of τ_r/t_1.

The experimental data shown in Fig. 4 were obtained using a 1.63 m*M* solution of **1** and a nominal t_1 of 1 sec. The curve is theoretical for scheme A with $k_AC^*_Ot_1$ equal to 2.24. For the conditions of the experiment, this corresponds to a second-order rate constant of 1.4×10^3 liter · mole^{-1} · sec^{-1}. The general trend of the data in Fig. 4 can leave little doubt that scheme A rather than scheme B is the principal pathway. The value of the rate constant agrees with that found by cyclic voltammetry, 1.3×10^3 liter · mole^{-1} · sec^{-1} (1). [Due to a different form of the rate law used in the theoretical paper (14), the value given in Ref. (1) must be divided by two to be equivalent to the rate constants reported in this paper.]

Strictly speaking, it can only be reported that the data fit a model in which **2** reacts by an irreversible reaction which is second order in **2**. This reaction could be dimerization [2] or any other reaction scheme whose over-all rate law was second order in **2**. For example, reaction **2** could enter into a rapid equilibrium with a small amount of **3** which in turn underwent irreversible protonation. This scheme also has a rate law which is second order in reaction **2**.

It was found earlier (1) that addition of water caused moderate increases in the apparent value of k_A. Similar results were obtained in the present work. Current-reversal chronopotentiometric studies of 2.88 m*M* **1** under the conditions of Fig. 4 again gave $k_A = 1.4 \pm 0.1 \times 10^3$ liter · mole^{-1} · sec^{-1}. Addition of 0.05*M* water caused the apparent k_A to increase to 2.2×10^3 and addition of another 0.05*M* water gave $k_A = 2.7 \times 10^3$ liter · mole^{-1} · sec^{-1}.

Some interesting information concerning the manner in which water affects the reaction is provided by the data presented in Fig. 5. These experiments were performed with a water concentration of 0.10*M* using three different concentrations of **1** and two different values of t_1. If the effect of water is one of increasing the apparent rate constant without modifying the order of the rate equation, a single value of k_A should provide an adequate fit for all the data. This was not found to be the case. This may be seen most clearly

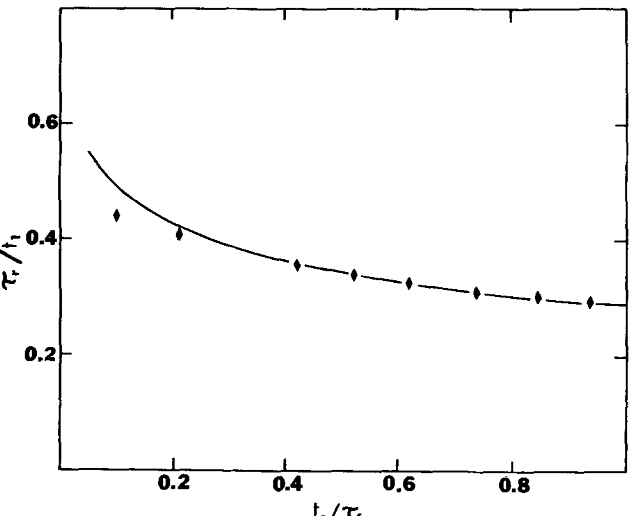

Fig. 4. Current-reversal chronopotentiometric data for reduction of 1.63 m*M* **1**. t_1 = 1 sec. Ratio of reverse to forward current densities was 1/2. Water concentration: 0.05*M*. Curve is theoretical for $k_AC^*_Ot_1 = 2.24$.

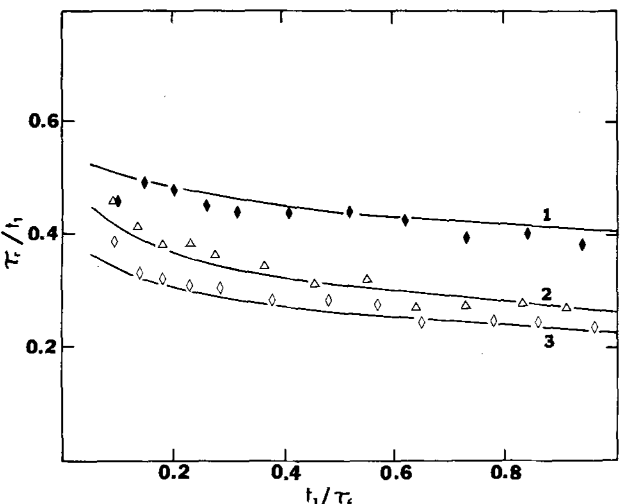

Fig. 5. Current-reversal chronopotentiometric data for reduction of **1** with 0.10*M* water. Curves are theoretical for $k_A = 1.35 \times 10^3$ liter · mole^{-1} · sec^{-1} and a rate constant for parallel first-order reaction of 0.6 sec^{-1}. Curve 1: 1.01 m*M* **1**, t_1 = 0.50 sec; curve 2: 3.03 m*M* **1**, t_1 = 0.50 sec; curve 3: 1.61 m*M* **1**, t_1 = 1.00 sec.

for curves 2 and 3 of Fig. 5 which have almost the same value of $C^*_Ot_1$ and which should be almost coincident if the reaction is still simply second order.

To fit the data of Fig. 5, inclusion of an irreversible, first-order chemical reaction of **2** occurring simultaneously with dimerization was required. The curves in Fig. 5 are simulated curves corresponding to a dimerization rate constant of 1.35×10^3 liter · mole^{-1} · sec^{-1} and a first-order rate constant of 0.6 sec^{-1}.

Thus, at moderate water concentrations (about 0.05*M* as in Fig. 4) the data for various C^*_O, t_1, and t_1/τ_f indicate that **2** reacts by a second-order process. However, at water concentrations greater than or equal to about 0.10*M*, some pseudo first-order reaction of **2** must be included. (Inclusion of some scheme B in parallel with scheme A was not successful in fitting the data.)

The nature of the parallel first-order reaction is not known. Water at higher concentrations may affect the reaction by protonating the radical **2** to form a neutral radical which may dimerize quickly. Further reduction of the neutral radical to form a two-electron reduction product does not seem to be prevalent because the value of $i\tau_f^{1/2}/AC^*_O$ does not increase under conditions where the first-order process is dominant. It was also found earlier (1) that reduction of **1** in DMSO containing 6% water was one of the best conditions for obtaining high yields of dimer.

The principal goal of the project was to assess the relative importance of schemes A and B in the reduction of **1**. In agreement with studies of the reductive coupling of other activated olefins (4, 5), scheme A was found to be dominant.

Chronopotentiometric Investigation of the Oxidation of Aluminum in Chloroaluminate Melts

B. Gilbert,[1] D. L. Brotherton, and G. Mamantov*

Department of Chemistry, University of Tennessee, Knoxville, Tennessee 37916

ABSTRACT

Oxidation of an aluminum electrode in molten $AlCl_3$-MCl (63-37 mole per cent, M = Na or Li) has been investigated by chronopotentiometry. Well-defined and reproducible transition times, caused by the formation of a poorly conducting Al_2Cl_6 layer at the electrode surface and the depletion of current-carrying alkali metal ions, were observed. The observations are in very good agreement with the theoretical predictions similar to those of Braunstein and co-workers. In the range of current densities employed (up to 300 mA/cm^2 at 140°C), the aluminum electrode behaves reversibly.

It has been very recently shown by Braunstein and co-workers (1) that in molten alkali metal fluoride-beryllium fluoride mixtures, the chronopotentiometric oxidation of a beryllium anode results in a layer of nearly pure, almost nonconductive BeF_2 as the mobile alkali metal ions are swept away, and, as the result, the potential of the beryllium anode rises sharply.

The important feature of this phenomena is that the boundary conditions of the diffusion law are not determined by depletion of an electroactive constituent but by migration of the mobile nonelectroactive alkali metal ion. A theoretical treatment based on the concentration cell principle was developed to explain the observed chronopotentiograms.

An aluminum electrode in molten $AlCl_3$-MCl (M-alkali metal ion) melts should exhibit similar behavior. Holleck and Giner (2) have observed passivation phenomena in the anodic oxidation of an Al electrode in $AlCl_3$-KCl-NaCl melts between 100° and 160°C. The phenomena were attributed to the formation of a solid salt layer at the electrode surface, resulting from concentration changes upon current flow.

We were interested in exploring quantitatively the anodization of an Al electrode by applying the theory developed by Braunstein (1). Besides being of fundamental interest, the results of such a study are clearly of importance to the use of Al anodes in chloroaluminate melts, for example, in battery applications (3).

Experimental

The electrochemical cell, instrumentation, and procedure have been described previously (4, 5). An aluminum wire (m5N from Alfa Inorganics) immersed in molten $AlCl_3$-MCl [63-37 mole per cent (m/o)] was used as the working electrode (surface area $\simeq$0.1 cm^2). The reference electrode was an aluminum wire (m5N) immersed in the same melt composition and separated from the main compartment by a thin Pyrex membrane. A platinum wire electrode was used to check the purity of the melt by cyclic voltammetry.

* Electrochemical Society Active Member.
[1] Permanent address: University of Liege, Belgium.
Key words: molten halides, molten chloroaluminates, chronopotentiometry, aluminum oxidation in melts.

Each melt was clear and waterlike at the beginning of each experiment. After several days, the melt became slightly brown and frequently the Al electrode was covered with a black deposit, possibly a layer of aluminum metal-rich alumina caused by oxyanions coming from the Pyrex glass (6). At this point, the measurements were no longer reproducible and were not included.

Basic Relationships

The controlled current oxidation of an Al electrode increases the concentration of $AlCl_3$ (more correctly Al_2Cl_6) in the vicinity of the electrode and the reversible emf should correspond to the resulting concentration cell

$$\text{Al} \left| \begin{matrix} AlCl_3\text{-MCl} \\ y_o \end{matrix} \right\vdots \begin{matrix} AlCl_3\text{-MCl} \\ y = y_o + \Delta y \end{matrix} \right| \text{Al}$$

Such a cell should exhibit an emf corresponding to (1, 7)

$$E = \frac{1}{3F} \int_{y_o}^{y} (1 - t_{Al^{3+}}) \left(\frac{1+2y}{1-y} \right) \frac{d\mu_{AlCl_3}}{dy} dy \quad [1]$$

where y and μ are the stoichiometric mole fraction and chemical potential of $AlCl_3$, respectively, y_o is the initial stoichiometric mole fraction of $AlCl_3$, and $t_{Al^{3+}}$ is the transference number of Al^{3+}.

If we assume that the transference number of Al^{3+} is essentially zero, the only current carrying species (relative to chloride) is the alkali metal cation and the emf becomes

$$E = \frac{RT}{3F} \left[\ln \frac{y}{(1-y)^3} - \ln \frac{y_o}{(1-y_o)^3} + \int_{y_o}^{y} \left(\frac{1+2y}{1-y} \right) \frac{d \ln \gamma_{AlCl_3}}{dy} dy \right] \quad [2]$$

where γ is the activity coefficient of $AlCl_3$ corresponding to above concentration units. The standard state in this case is similar to that employed by Hitch and Baes (8) and corresponds to pure molten $AlCl_3$.

The first two terms in Eq. [2] give the ideal emf; the third term corresponds to the "excess" emf which may be calculated if the variation of the activity coefficient with stoichiometric mole fraction is known.

Similar equations can be developed for other systems, and, in general, for a system $M + nX^- \underset{}{\overset{-ne^-}{\rightleftharpoons}} MX_n$, the emf is given by

$$E = \frac{1}{nF} \int_{y_0}^{y} (1 - t_{Mn+}) \left[\frac{1 + (n-1)y}{1-y} \right] \frac{d\mu_{MX_n}}{dy} dy \quad [3]$$

which gives, if $t_{Mn+} = 0$

$$E = \frac{RT}{nF} \left\{ \ln \frac{y}{(1-y)^n} - \ln \frac{y_0}{(1-y_0)^n} + \int_{y_0}^{y} \left[\frac{1 + (n-1)y}{1-y} \right] \frac{d \ln \gamma_{MX_n}}{dy} dy \right\} \quad [4]$$

Thus, the emf of the cell does not follow the usual Nernst type behavior. However, as shown previously (1), it is possible to obtain the variation of concentrations of MCl and $AlCl_3$ at the electrode surface with time from the solution of the diffusion equation for ordinary chronopotentiometry. These quantities can be substituted into Eq. [2], as shown below, to obtain the variation of cell emf with time, and, thus, the chronopotentiogram. Sand's equation (9) should be applicable (1).

Results

To obtain well-defined and reproducible chronopotentiograms it was necessary to set the potential of the aluminum electrode to the initial equilibrium potential after each chronopotentiogram. In order to get reasonable transition times, high (~200°C) and low (~120°C) temperatures must be avoided. At these temperature extremes the transition times are either much too long (several minutes) or too short (the passivating layer forms very quickly), respectively. If the above conditions are followed, the reproducibility of transition times is better than 5%.

Typical chronopotentiograms are shown in Fig. 1. The potential of the aluminum electrode was corrected for the initial *IR* drop. The applicability of Sand's equation is shown in Fig. 2. Each point is an average of 5-8 measurements. The constancy of the product $i\tau^{1/2}$ shows clearly that in the range investigated, the oxidation process is controlled by diffusion. This conclusion supports the results of Holleck, obtained from measurements of the anodic limiting current of a rotating aluminum electrode (2).

The "ideal" emf in Eq. [2] expressed in terms of equivalent concentrations, becomes

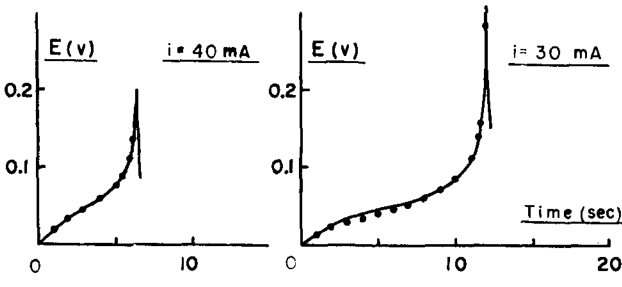

Fig. 1. Typical chronopotentiograms obtained in molten $AlCl_3$-NaCl (63-37 m/o) at 140°C. The points correspond to the calculated curve based on an ideal behavior (Eq. [5]). The experimental curves were corrected for the *IR* drop. The applied currents are 40 and 30 mA, respectively; $A = 0.2$ cm²; $t = 140$°C.

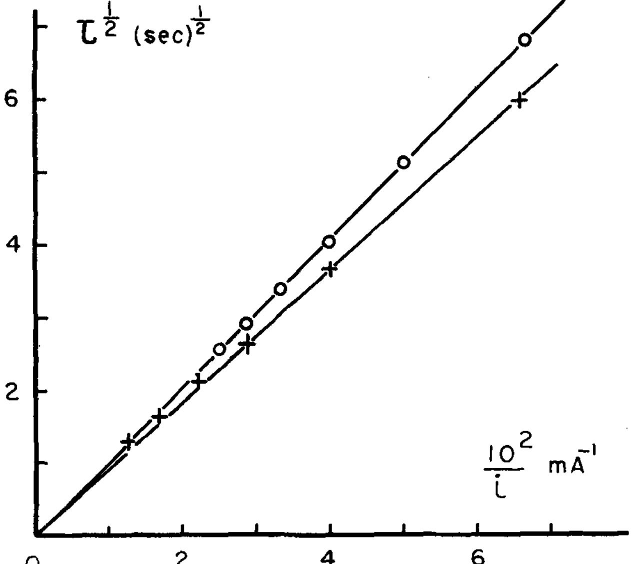

Fig. 2. Plot of $\tau^{1/2}$ vs. $1/i$ for the system $AlCl_3$-NaCl (63-37 m/o). ○, $t = 140$°C; ×, $t = 130$°C.

$$\frac{3FE^{ideal}}{RT} = \ln \left\{ \frac{[1 - C_{NaCl}\overline{V}_{NaCl}][1 + (\overline{V}_{AlCl_3} - \overline{V}_{NaCl})C_{NaCl}]^2}{[\overline{V}_{AlCl_3}C_{NaCl}]^3} \right\} - \ln \left\{ \frac{[1 - C^o_{NaCl}\overline{V}_{NaCl}][1 + (\overline{V}_{AlCl_3} - \overline{V}_{NaCl})C^o_{NaCl}]^2}{[\overline{V}_{AlCl_3}C^o_{NaCl}]^3} \right\} \quad [5]$$

where C^o and C are the initial and instantaneous concentrations (expressed in equivalents/cm³) (1) and $\overline{V}$ is the partial molal volume.

The above equation can be solved knowing that at any time we must have

$$C_{Na^+} = C^o_{Na^+} - \alpha t^{1/2} \quad [6]$$

where

$$\alpha = \frac{2i}{\pi^{1/2}D^{1/2}AnF} \quad [7]$$

and

$$C_{Na^+} = C_{NaCl}$$

For $t = \tau$, we have a pure layer of $AlCl_3$ (Al_2Cl_6) at the electrode surface and $C_{NaCl} = 0$, so $\alpha\tau^{1/2} = C^o_{NaCl}$. C^o_{NaCl} is estimated from the densities of the melt at the investigated temperatures and the stoichiometric mole fractions of NaCl and $AlCl_3$. The densities of the melt were extrapolated from the work of Boston (10).

For $AlCl_3$-NaCl (63-37 m/o), C^o_{NaCl} is 0.00585 equiv/cm³ at 140°C. From this value and Fig. 2, we can determine α and the average interdiffusion coefficient D. D was found to be 1×10^{-6} cm²/sec at 140°C. A value of D of this order of magnitude is not unreasonable considering that the transport process involves the diffusion of Na^+ ions in $AlCl_3$-rich melts; the composition of the melt at the electrode changes continuously during the chronopotentiogram from the initial composition (63 m/o $AlCl_3$) to essentially pure Al_2Cl_6. We have previously reported (11) the diffusion coefficient for Ti(II) in $AlCl_3$-NaCl (65-35 m/o) to be in the range $2.5\text{-}6 \times 10^{-6}$ cm²/sec at temperatures 185°-260°. The diffusion coefficient for Ti(III) in LiF-BeF_2-ZrF_4 (65.6-29.4-5.0 m/o) at 500°C was found to be 1.0×10^{-6} cm²/sec (12). Lower values of D would be expected in viscous BeF_2-rich mixtures. From the above comparison, a higher value of D for Na^+ in acidic chloroaluminates used in this work would be expected compared to the value of D of 3×10^{-7}

cm^2/sec obtained by Braunstein *et al* (1) for the diffusion of Na^+ in BeF_2-NaF (75-25 m/o) at 520°C.

If we make the assumption that the diffusion coefficient is constant as the concentration changes, we can calculate C_{NaCl} as a function of time from Eq. [6] and from that the ideal emf. It was assumed in this calculation that the partial molal volumes are additive; this assumption is only approximately correct for this system (10).

Calculated points are also given in Fig. 1. The "ideal" curve is in reasonable agreement with the experimental curve; however, the calculated points lie slightly below the experimental values except in the final part of the curve. It can also be seen that the calculated curve fits the experimental curve better if the transition time is short.

In our calculation, D was assumed to remain constant as the composition changes (not a correct assumption). Furthermore, for the system $AlCl_3$-NaCl it has been observed (13-15) that above 80 m/o of $AlCl_3$ and above 193°C, two liquid phases occur, of which one is probably almost pure Al_2Cl_6. Hence the point where a pure layer of Al_2Cl_6 is formed at the electrode should occur sooner than in the absence of two liquid phases. The time for which $y = 0.80$ can be easily calculated from Eq. [6] and one obtains in general that $t_{y=0.80} = 0.26\tau$. Thus, if the observed transition time corresponds to the immiscibility, the true transition time is about four times longer. For this condition, the calculated curve exhibits a very flat region with a sudden potential increase when the immiscibility occurs. At this point the concentration of Na^+ ions at the electrode surface is zero. The shape of the calculated chronopotentiogram would be different from what we observed. Nevertheless, in the range of our working temperatures, the pure Al_2Cl_6 produced at the end of the chronopotentiogram, or in the region of immiscibility, should be a solid. Such a solid layer can be easily observed on the electrode for temperatures lower than 120°C and also at very long transition times. If this is the case, the measurements are no longer reproducible. For temperatures between 130° and 160°C, the solid phase is not observed except if the transition time exceeds several minutes. Under these conditions, the results suggest that the melt is supersaturated with Al_2Cl_6 in the vicinity of the electrode, as also noted by Holleck and Giner (2).

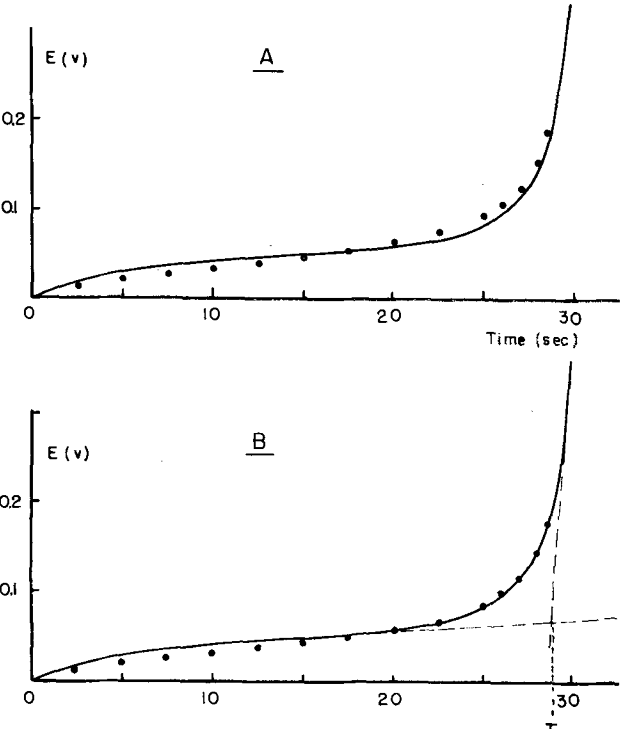

Fig. 3. Chronopotentiogram obtained in molten $AlCl_3$-LiCl (63-37 m/o); $t = 150°C$; $i = 25$ mA; $A = 0.13$ cm^2. The points are calculated from Eq. [5] for curve A and from Eq. [5] + [11] for curve B.

In the case of $AlCl_3$-LiCl, no immiscibility has been reported in the literature, although the only paper reporting the phase diagram of this system is rather old (13). The experimental and calculated chronopotentiograms for $AlCl_3$-LiCl (63-37 m/o) are given in Fig. 3.

A negative deviation in the first part of the theoretical curve and a slight positive deviation for the second half of the curve are observed. The latter observation depends mostly on the chosen value of the transition time τ. τ was determined by the method of Reinmuth (16). The corresponding average interdiffusion coefficient is 4.5×10^{-6} cm^2 sec^{-1}, higher than for the NaCl system as might be expected from the smaller size of the lithium cation.

Over-all, the shape of the experimental curve is only slightly different than for the $AlCl_3$-NaCl system and also fits the theoretically calculated curve. This indicates that the immiscibility did not have time to develop in the case of $AlCl_3$-NaCl.

The preceding calculations deal only with ideal emf. In order to calculate the effect of the "excess" emf, the variation of the activity coefficients with composition must be known. Fannin and co-workers (7) have proposed a least squares empirical polynomial for $d \ln \gamma/dy$ in which the activity coefficients are calculated from vapor pressure measurements. In this case, the excess function becomes

$$E^{excess} = \frac{RT}{3F} \int_{y_0}^{y} (1 - t_{Al^{3+}}) \left(\frac{1+2y}{1-y} \right) (C_1 + 2C_2y + 3C_3y^2)\, dy \quad [8]$$

However, the values of the coefficients C_1, C_2, and C_3 are not given; in any case, this polynomial was determined only in the range 0.55-0.75 mole fraction of $AlCl_3$. In view of the fact that no experimental data are available for the very acidic melts, we have used a very simple function based on the assumption that the melt behaves as a regular solution (17). This assumption is not correct due to strong interactions between the melt constituents; however, it is interesting to know in what way a correction for the activity coefficients will affect the ideal function even if this correction is very approximate. Thus the activity coefficients were estimated from (17)

$$RT \ln \gamma = w(1 - y)^2 \quad [9]$$

where w is a constant.

The excess emf then becomes

$$E^{excess} = \frac{w}{3F} \int_{y_0}^{y} (1 - t_{Al^{3+}}) \left(\frac{1+2y}{1-y} \right) (2y - 2)\, dy \quad [10]$$

This equation contains only one adjustable parameter, w. Comparison of Eq. [10] with Eq. [8] shows that the third term in Eq. [8] ($3C_3y^2$) has been neglected and the constants are related by $C_2 = -C_1/2 = w/RT$; however, there are no basic differences between the two equations.

After integration of Eq. [10] and expressing y as a function of C_{NaCl}, we obtain

$$E^{excess} = \frac{2w}{3F} \left\{ -\frac{(1 - C_{NaCl}\overline{V}_{NaCl})[2 + (\overline{V}_{AlCl_3} - 2\overline{V}_{NaCl})C_{NaCl}]}{[1 + (\overline{V}_{AlCl_3} - \overline{V}_{NaCl})C_{NaCl}]^2} + \frac{(1 - C^o_{NaCl}\overline{V}_{NaCl})[2 + (\overline{V}_{AlCl_3} - 2\overline{V}_{NaCl})C^o_{NaCl}]}{[1 + (\overline{V}_{AlCl_3} - \overline{V}_{NaCl})C^o_{NaCl}]^2} \right\} \quad [11]$$

Since the absolute value of the first term in the parenthesis is always larger than that of the second, the value of the parenthesis is negative and the sign of the excess function is thus opposite to the sign of the constant w. It is also worth noting that this approximate function giving E^{excess} affects mostly the end of the chronopotentiogram; this result is similar to that obtained by Braunstein *et al.* (1) An average value of $w \simeq 7 \times 10^2$ j-mole^{-1} has been calculated to fit the experimental curve for the system $AlCl_3$-LiCl. The final result is given in curve B of Fig. 3 for which the agreement between the calculated and experimental values is quite good, particularly considering the approximations involved.

Conclusions

Excellent agreement between theory and experiment has been obtained for the anodic oxidation of Al in $AlCl_3$-NaCl (63-37 m/o) and in $AlCl_3$-LiCl (63-37 m/o). It is clear that the mechanism resulting in the chronopotentiogram (formation of a poorly conducting Al_2Cl_6 layer at the electrode surface and the depletion of current carrying alkali metal ions) is analogous to that observed for MF-BeF_2 mixtures (1). Since the calculated curves are obtained from assuming a reversible concentration cell, the observed agreement shows that the Al electrode behaves reversibly in the range of current densities employed. Furthermore, the applicability of Sand's equation requires that the oxidation process is diffusion controlled.

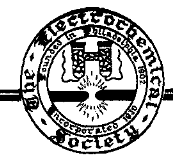
Brief Communication



Electrodeposition of an Amorphous Cobalt Rhenium Alloy

P. J. Cote, G. P. Capsimalis, and V. P. Greco

Watervliet Arsenal, Watervliet, New York 12189

The publication costs of this article have been assisted by the Department of the Army.

We are reporting on the formation of a cobalt-44 atomic per cent (a/o) rhenium amorphous alloy by electrodeposition from a bath developed by Netherton and Holt (1). The bath composition used to obtain the amorphous phase is given in Table I.

Our fabrication of a new amorphous metal is significant in view of the current interest in these materials and the fact that relatively few amorphous alloys have been electrodeposited.

Both x-ray and electron diffraction patterns show the diffuse rings which are characteristic of these materials (see Fig. 1).

Electrodeposition studies were made using the Beckman "Electroscan 30." Current density *vs.* cathode potential scans were obtained in the potentiostatic mode and these revealed a break at around -850 mV as shown in Fig. 2. These data were taken in a quiescent bath. The break is far less pronounced in the stirred baths in which the specimens were prepared. Deposits made above the break generally result in the amor-

NH_4ReO_4	4
pH	7.6

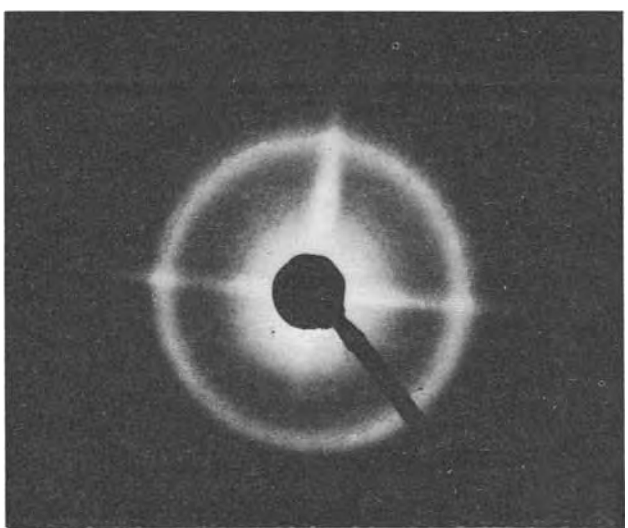

Fig. 1. This is a typical electron diffraction pattern obtained from the amorphous phase. X-ray diffraction gives essentially the same pattern. The first peak position occurs at $\frac{4\pi \sin\theta}{\lambda}$ = 3.0A^{-1}.

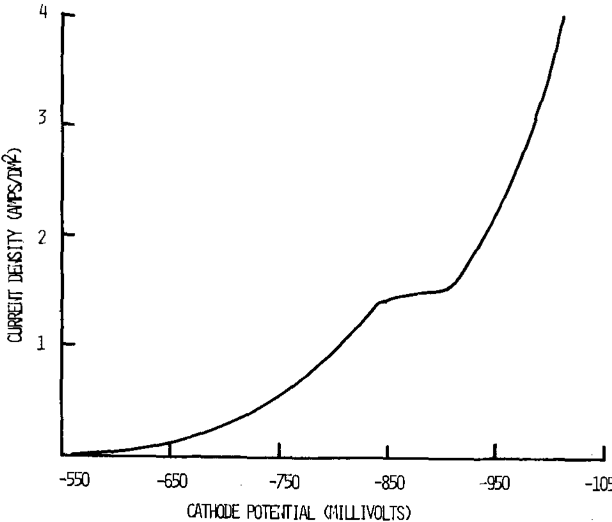

Fig. 2. The current density vs. cathode potential (SCE) shows a break which appears to correspond to the deposition of the amorphous phase under suitable bath conditions.

phous phase, and those made below the break result in a mixture of amorphous and crystalline phases. Similar behavior was reported by Omi *et al.* (2) in the electrodeposition of a Co-25 a/o W alloy. They found two breaks which appear to correspond exactly to the transitions from amorphous to crystalline deposits. Although we see a similar correspondence under the proper bath conditions, we also observe this break with no rhenium in the bath. An explanation for the above is that the break represents the limiting current density for metal deposition. The subsequent sharp increase in slope corresponds to increased hydrogen discharge at the cathode. Making the assumption that the amorphous phase is a result of codeposited hydrogen, we can then understand the relationship between crystalline structure and cathode potential. Approaching the vicinity of the break, there is an increasing percentage of hydrogen codeposited. This corresponds to an increasing percentage of the amorphous phase in the deposit as the cathode potential is made more negative. It is worth noting here that according to (1), the Co-Re alloy composition is relatively insensitive to cathode potential over a wide range.

At the lower current densities, the crystalline phase (hcp) is present in an unusual form appearing as crystalline cones or columns imbedded in an amorphous matrix. All the columns appear to be oriented with the fiber axis parallel to the surface normal, with the <100> crystallographic direction along the fiber axis. This is based in part on the appearance of only the {100} and {200} peaks in the diffraction patterns. Similar observations were reported by Cargill (3) for some of the NiP glasses produced by both electrodeposition and electroless deposition. In his case the fcc crystallites had the <111> direction parallel to the surface normal.

Annealing this alloy for 1 hr at 300°C results in substantial crystallization directly to the stable hcp solid solution determined by x-ray and electron diffraction. Electron microscopy and diffraction from the deposit edges show the presence of some fcc crystallites and whiskers after annealing. The lattice parameter of these crystallites is about 3.9Å. This is consistent with $ReN_{0.45}$ (a_0 = 3.92Å) and with a metastable solid solution of cobalt and rhenium. We note that metastable intermediate phases are commonly seen in annealed glassy metals.

Manuscript submitted Dec. 4, 1973, revised manuscript received Feb. 1, 1974.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1974 JOURNAL. All discussions for the December 1974 Discussion Section should be submitted by Aug. 1, 1974.

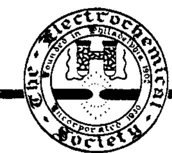
DISCUSSION SECTION



This Discussion Section includes discussion of papers appearing in the *Journal of The Electrochemical Society*, Vol. 120, No. 2, 4, and 6; February, April, and June 1973.

Monolayer Formation in the Reduction of Nickel and Silver Ions from the LiCl-KCl Eutectic

G. J. Hills, D. J. Schiffrin, and J. Thompson
(pp. 157-164, Vol. 120, No. 2)

D. Inman[1] **and D. G. Lovering:**[2] In our opinion, the results given in the paper under discussion could equally well be explained in terms of the discharge of a layer of adsorbed nickel ion containing species prior to the discharge of the ions diffusing from the bulk of the solution.

As the authors of the paper being discussed state themselves, the presence of peaks in the potentiostatic step response would have been expected on the basis of their model. Furthermore, Fig. 4 of the above-mentioned paper is a much scaled-down version of an original figure in a thesis[3] by one of the authors (J. T.). In the latter it is possible to discern finite intercepts in the $\tau^{1/2}$ *vs.* i^{-1} plots. This behavior is typical, and often diagnostic, of an adsorption process. Again, the linear dependence of the peak current on the sweep rate in the "monolayer formation" region (cyclic voltammetry) is also indicative of an adsorption process.

Thus, as a first approximation, an AR, SR type of discharge mechanism[4] would seem appropriate on the basis of these results. The discharge of adsorbed layers of ions in molten salt systems has been indicated on several previous occasions[5] and it is therefore all the more surprising that the authors have not considered this attractive alternative explanation.

The test applied by one of us in a previous study[6] [increasing the sweep rate of repetitive (cyclic) linear-sweep voltammograms until the supposed adsorption-controlled current peak disappeared] could usefully be applied in the present case. Also, since an AR, SR type of discharge mechanism seems appropriate, it would be possible to move the start potential to a value more negative than the supposed AR prepeak, and confirm pure, diffusion-controlled behavior of the remaining (SR) current peak.

Finally, the results for Ag^{I} may also be influenced by adsorption processes. The separation between the two reduction modes could not be discerned in the chronopotentiograms which may depend on both processes. Thus the high values of the diffusion coefficients, calculated on the basis of these chronopotentiograms, may reflect the adsorption contribution to the transition time.

G. J. Hills, D. J. Schiffrin, and J. Thompson: We are grateful to Drs. Inman and Lovering for their discussion of an alternative explanation for the predeposition phenomena and we should have given references to their several papers which are based on the adsorption mechanism.

However, our belief is unaltered that the results presented in our paper are indicative of a monolayer intermediate of adatoms. We certainly do not deny that this process may be preceded by a kinetically important adsorption step but only that we could not separate them except using exceptionally high sweep rates.

The involvement of a monolayer is based primarily on the charge equivalent of the predeposition step which is close to that corresponding to a close packed monolayer of metal atoms covering an area equal to the apparent or formal area of the electrodes. Given that the real surface area is somewhat larger than this, it would still require an unusually high surface charge density of adsorbed nickel ion species to account for the observed cathodic charge (extremes of $zF\Gamma_{\pm}$ are typically ± 20 μcoulombs/cm^2, cf. the present value of 600 μcoulombs/cm^2). Then there is the evidence from other systems in which metal monolayers have been observed[7,8] and from the analogous studies of the adsorption of atomic hydrogen on platinum. More recent still is the direct evidence of predeposited metal monolayers obtained from measurements of the specular reflection of electrode surfaces as a function of overpotential or, as in this case, underpotential.[9,10]

It is, of course, not correct, as Inman and Lovering assert, that the absence of a maximum in the potentiostatic pulse transients is incompatible with a precursor metal monolayer. What we tried to say was that where the number of deposition or nucleation sites is not restricted, then lateral growth from preferred sites (which would give rise to a maximum) is not to be expected.

On the other hand, we accept Inman and Lovering's criticism of Fig. 4 in the paper being discussed. The $\tau^{1/2}$ scale is ten times too great and there was an intercept in the original thesis figure.[3] However, this was small, and, in our opinion, within experimental error. Even so, we do not deny that the intercept may be real and that it may well be evidence for an adsorption process.

We hope to re-examine these systems using an electroreflectance technique and it may be that we shall be able to confirm in these systems also the existence of a metal monolayer. Whether or not it is formed solely from an adsorbed layer of metal ions might also be evident.

On Accelerated Pitting and Crevice Corrosion Tests

J. Degerbeck (pp. 175-182, Vol. 120, No. 2)

M. Grassiani:[11] Referring to the author's conclusions in the paper under discussion concerning the uncertainty of electrochemical tests in evaluation of localized corrosion resistance in calm natural seawater, we should like to quote his own discussion: "the electrochemical specimen having the lowest pitting potential value ought to correspond better to the crevice surfaces attacked in the field test . . ." Since most of field test exposure led to crevice corrosion (either occurring under fouling or artificially achieved), it should be expected that crevice corrosion occurs at lower potentials than the mean pitting potential[12] and

thus, the whole basis for comparison between the two types of tests becomes unreal. Furthermore, it should be emphasized that besides the possible contribution of MnS surface inclusions to the lower pitting potentials observed on some specimens it is more likely that environmental factor variation (like variation of oxygen content even under N_2 bubbling, or variation of stirring by that bubbling) could affect the results. Our experience[13] showed that full deaeration is difficult to achieve or control; on the other hand, one cannot expect to reach the "true" anodic behavior there, where oxygen still cathodically reacts resulting in more noble (and apparent) pitting potentials.

Finally, potentiodynamic polarization techniques should be more cautiously used in order to achieve the best reproducibility with the appropriate potential scan rate.

J. Degerbeck: The purpose of the study in the paper under discussion was to investigate the validity of different tests in predicting the relative corrosion resistance of stainless steels in a specific seawater environment. Among other things we found rather a good correlation between the minimum value of pitting potential and number of crevice attacks in the seawater; correlation coefficient was −0.83 for one of the tests.

Dr. Grassiani's opinion in the above discussion is that it is unrealistic to compare the resistance to initiation of pitting to that of crevice corrosion, since crevice corrosion occurs at lower potentials than pitting. Against this I would raise the following objection:

As there seem to be certain similarities between the mechanism of formation of pitting and crevice corrosion,[14,15] and as practical experience and the main impression from the literature indicate that it is not quite unrealistic to assume that the relative resistance of different steels to initiation of pitting is the same as their relative resistance to initiation of crevice corrosion, I cannot see why it is unrealistic to correlate crevice corrosion from field tests with pitting from laboratory tests. That crevice corrosion occurs at potentials lower than the pitting potential is irrelevant. Further, my opinion is that from a practical point of view, it does not matter what results you compare or correlate as long as the correlation is of value in predicting the corrosion resistance in the actual environment.

In regard to the environmental factors mentioned I agree that they could affect pitting potential results. However, in our investigation we performed every trial in each of the tests exactly under the same conditions.

I am fully aware that the potentiodynamic pitting potential tests used in the present investigation are not the "best" ones. What you gain in accuracy you normally lose in time. We preferred to make use of rather fast tests.

Diffusion Coefficients and Kinetic Parameters in Copper Sulfate Electrolytes and in Copper Fluoroborate Electrolytes Containing Organic Addition Agents

C. J. Milora, J. F. Henrickson, and W. C. Hahn

(pp. 488-492, Vol. 120, No. 4)

L. Grambow and W. Vielstich:[16] We have recently studied the accurate determination of trace diffusion coefficients via the use of rotating electrodes (disk or ring).[17] In determining the Cu^{++} diffusion coefficients in a sulfuric acid electrolyte and in a fluoboric acid electrolyte the investigations of C. J. Milora, J. F. Henrickson, and W. C. Hahn in the paper under discussion suffer from difficulties in the experimental procedure and a misleading assumption of the experimental upper limit of the speed of rotation. Moreover, an inadequate formula was used in the above-mentioned work, which results in an error of calculation of about 4-5%.

The plot of the obtained data for the limiting current i_L *vs.* $\omega^{1/2}$ cannot be extrapolated to zero for either electrolyte (Fig. 3 in the paper under discussion): $i_L = a + b\omega^{1/2}$. Limiting currents for rotation rates >2500 rpm have not been evaluated. In the afore-mentioned paper, authors explain a nonzero value by "anomalous" Adams Riddiford effects, claiming that the Pine Instrument rotating disk does not possess efficient dimensions in the isolating part of the disk. The deviations for $f > 2500$ rpm are assumed to be due to turbulent flow of the electrolyte. However, from the data presented, a maximum Reynolds number of about 2000 can be calculated; the critical value is $Re_{crit} \geqq 1.5 \cdot 10^5$. We assume that this anomalous experimental behavior is caused by the very high current density (up to about 200 mA/cm^2) used. At a scan of 2500 mV/min, more than 2×10^4 copper atom layers are formed during one period. This is a thickness of about $1 \cdot 10^{-3}$ cm. On the other hand, at 2500 rpm the diffusion layer δ_N also falls in the range of $1 \cdot 10^{-3}$ cm. Therefore realistic data cannot be expected.

From the slope of the curve in Fig. 2 in the work being discussed the authors have calculated the $D_{Cu^{++}}$ values using the Levich formula[18] (Eq. [1]). It is well known that this is a first approximation only; one should use the Gregory-Riddiford equation[19]

$$i_L = n \cdot \mathbf{F} \cdot D^{2/3} \cdot c_\infty \cdot \nu^{-1/6} \cdot \omega^{1/2} \cdot \left(1.6126 + 0.5704 \left(\frac{D}{\nu}\right)^{0.36}\right)^{-1} \quad [1]$$

This results in an increase of the evaluated data of about 5%. Thus one obtains from curve A (Fig. 2 of the paper under discussion)

$$D_{Cu^{++}} = 5.41 \cdot 10^{-6}\ \text{cm}^2/\text{sec} \quad [2]$$

instead of $5.23 \cdot 10^{-6}$ cm^2/sec as given in the paper being discussed for the sulfuric acid electrolyte, and from curve B we get

$$D_{Cu^{++}} = 10.34 \cdot 10^{-6}\ \text{cm}^2/\text{sec} \quad [3]$$

instead of $9.88 \cdot 10^{-6}$ cm^2/sec which the authors in the above-mentioned work have given for the fluoboric solution.

As proof we have measured in our laboratory the respective diffusion coefficients by using a much lower concentration of Cu^{++} [$0.011N\ CuSO_4/1.0N\ H_2SO_4$ and $0.0058N\ Cu(BF_4)_2/1.0N\ HBF_4$, respectively] and a faster scan (6000 mV/min), so that the diffusion layer is much larger than the rough copper layer deposited. Figure 1 of this discussion shows the limiting current for the H_2SO_4 electrolyte at a rotating copper disk electrode ($A = 0.5027$ cm^2); the speed of rotation varied from 13.7 to 139.3 sec^{-1} at a temperature of 19°C. The respective plots i_L *vs.* $\omega^{1/2}$ for five different temperatures are given in Fig. 2. The experimental data points lie mostly on a straight line, and the extrapolation at any temperature goes through zero. According to the Gregory-Riddiford equation, the following data are obtained at 25°C

$$D_{Cu^{++}} = 5.41 \cdot 10^{-6}\ \text{cm}^2/\text{sec} \quad [4]$$

for the $CuSO_4$ solution and

for the $Cu(BF_4)_2$ solution.

In the case of the sulfuric acid electrolyte, the authors of the work being discussed arrive at the same result as we do. For the fluoboric acid electrolyte, however, we found a difference of almost 10%.

To explain the varying conductivities in the two solutions we propose the following working hypothesis. The Cu^{++} cation is bound in different complexes in both solutions. The tetrafluoboric anion does not come into consideration for the formation of the complex; we can assume the existence of aquocomplexes in the fluoboric acid solution. More probable is the formation of sulfato complexes in the sulfuric acid electrolyte. This assumption would explain the reduced mobility of the Cu^{++} ions in the sulfuric acid solution, since such complexes have a larger diameter than pure aquocomplexes.

Origin of Activation Effects of Acetonitrile and Mercury in Electrocatalytic Oxidation of Formic Acid

H. Angerstein-Kozlowska, B. MacDougall, and B. E. Conway
(pp. 756-766, Vol. 120, No. 6)

A. Capon and R. Parsons:[20] The paper under discussion brings some interesting new information to bear on the problem of formic acid oxidation. At the same time it neglects some of the information already available in the literature[21] and it seems to us to rule out the possibility of formic anhydride playing the role of the strongly adsorbed intermediate (P) which poisons the faster oxidation process. Although the properties of P are subject to some dispute there does seem to be agreement[21,22] on the facts that two to three electrons are removed to produce each CO_2 molecule from P and that slightly more than one electron per site (eps) is removed in its oxidation to CO_2, the site being measured in terms of hydrogen adsorption. Formic anhydride requires two electrons to be removed for its oxidation to produce two molecules of CO_2, *i.e.*, one electron per CO_2. From the model shown in Fig. 9(a) of the paper under discussion it appears that formic anhydride should occupy six sites so that oxidation would require removal of one-third electron per site. Both these predictions are in disagreement with the experimental observations.

A $\underset{\bullet\bullet\bullet}{C}OH$ species bonded to three Pt atoms in the surface would require removal of one electron per site and three electrons per CO_2; this is in substantially better agreement with the experiment, though the discrepancies are still sufficiently large that it seems likely that another species may be present, but in smaller amount. The formation of $\underset{\bullet\bullet\bullet}{C}OH$ as a predominant component of P appears to account qualitatively for the observed behavior if it is formed by two mechanisms,[22] (*i*) when adsorbed hydrogen is present by reaction of adsorbed carboxyl radicals with adsorbed hydrogen, and (*ii*) in the absence of adsorbed hydrogen, by a slow "disproportionation" mechanism between adsorbed carboxyl radicals and formic acid molecules. The observations reported in Fig. 8 of the paper under discussion also seem to fit this proposal satisfactorily. The observed effects of adsorption of mercury on acetonitrile would seem equally easy to interpret on this model as on the hypothesis of formic anhydride as intermediate P.

It should also be emphasized that the existence of P on the surface cannot account for the observation of the first peak for formic acid oxidation (FA_1). If experiments are performed under conditions where the concentration of P is constant (Fig. 20 of Footnote 22) the peak remains well defined and the current is independent of the direction of the sweep. Thus the rate is determined by a surface reaction, which is in fact the fast route for oxidation of formic acid. A peak of this type cannot be accounted for in terms of a two-step reaction involving a single intermediate COOH. It therefore seems necessary to postulate the existence of at least one subsequent intermediate occupying two sites. We have suggested[22] that this may be $\underset{\bullet\bullet}{C}(OH)_2$ which could be produced in the reaction

$$HCOOH + \underset{\bullet}{C}OOH \rightarrow \underset{\bullet\bullet}{C}(OH)_2 + CO_2 + H^+ + e$$

although this identification is tentative. An explanation of this type also accounts for the single peak in formic acid oxidation[23] on palladium where no inhibiting species P is found.

H. Angerstein-Kozlowska, B. MacDougall, and B. E. Conway: Drs. Capon and Parsons direct attention to the question of the number of electrons per site (eps) required for the oxidation of the poisoning intermediate P that arises spontaneously in formic acid oxidation at Pt. We had ourselves in the paper under discussion also referred to this problem in relation to the previously published[24,25] estimates of this quantity and to possible chemical identities[24] of this species.

The generality of the activating effect of added strongly adsorbed substances on the so-called FA_1 oxidation current for formic acid (as stated in the paper under discussion) requires that a competitive poisoning effect is involved which diminishes the rate and extent of formation of P in the formic acid oxidation reaction, yet does not block the main reaction process. In the paper being discussed we gave evidence that added competitive poisons must act by a "third-body" effect, interfering in the production of P by preventing close approach of whatever intermediates are required for its formation. In the paper under discussion, we proposed the possibility that P was formic anhydride, stabilized by two-site adsorption, that arose from dimerization of adsorbed COOH (I), the principal intermediate in the main reaction sequence of HCOOH oxidation. Formation of such a poison would be retarded by the "third-body" effect. In the light of Capon and Parsons's comments, it is useful first to reexamine the H-blocking and surface-site requirements of formic anhydride species (II). Inspection of molecular models of a Pt (III) surface lattice and of formic anhydride indicates the possibility that the latter species is adsorbed with bonding of the two C atoms on top of two adjacent Pt atoms. This then blocks chemisorption of H only on the two Pt atoms involved so that the eps could be near one or at the least be two-thirds, *i.e.*, close to the figure Capon and Parsons find, and quote from the literature.[22] The only rearrangement required in relation to our previous picture in the paper being discussed is that bonding of C to Pt occurs to the top of Pt atoms, rather than through electrons in trigonal interstitial locations, *e.g.*, in the case of the (111) surface. In fact, it can be argued that this alternative representation of the bonding of II to Pt is more consistent with current ideas[26] about the disposition of d-orbitals at transition metal surfaces, *e.g.*, the orientation of d_{yz} and d_z2 orbitals.

The fact that P can be oxidized, like the species formed in methanol oxidation, in the PtOH region is probably not, however, diagnostic of the nature of P, since many organic substances, and impurities, are also oxidized over the same potential range.

While the "third-body" effect associated with activation of formic acid oxidation receives a simple and direct explanation of terms of blocking of a dimerization type of reaction, a similar effect of a competitive, monofunctionally adsorbed poison could arise in a reaction such as $PtX + Pt \rightarrow Pt_2Y$ where Y is a species requiring two sites for adsorption compared with only one for the reactant species from which it originates.

Further investigations in progress on the activating effect of Hg indicate that the reaction pathway corresponding to the FA_1 current (as in the paper under discussion) must be more complex than the chemically most direct pathway

$$HCOOH + 2Pt \rightarrow PtH + PtCOOH \rightarrow 2H^+ + CO_2 + 2e \quad [1]$$

commonly considered in the literature, and must involve a second intermediate adsorbed on at least two sites (see below), produced from —COOH. Competitive poisoning lifts the inhibition of pathway [1] by preventing [third-body effect (as in the paper being discussed)] formation of the second intermediate and the main poison (which Capon and Parsons suggest is $\underset{\bullet\bullet\bullet}{C}$—OH) and allows an increase of current through pathway [1].

A schematic reaction sequence which could tentatively provide a basis for some of the features of the oxidation of formic acid and the activating effect of competitive poisons is shown below (Fig. 1).

The main pathway of the reaction must proceed through intermediates I and II; intermediate II is

formed from intermediate I by reaction with H and participation of at least one further Pt site. It is then possible that the pathway through II from I could give rise to a current peak without the necessity of invoking[21-23] oxide blocking species, improbable[27] over the potential range of the FA_1 peak. The peak current could arise since θ_H decreases with potential, while the oxidation of II increases with potential. The kinetics of the main pathway are modified by the presence of at least two other side products, P_1 (probably the species $\underset{\bullet\bullet\bullet}{C}$—OH discussed by Capon and Parsons and in their papers[21-23]), which originates in the H adsorption region and P_2 which must be invoked to explain time-dependent diminishing currents in the cathodic sweep after reduction of the surface oxide.

We thus agree with Capon and Parsons that at least two types of poison species, accumulated in the side reactions, are required if the experimental behavior is to be more fully accounted for.

Capon and Parsons[21-23] have suggested that the second poison is $\underset{\bullet\bullet}{C}(OH)_2$ formed by a disproportionation reaction between $\underset{\bullet}{C}OOH$ and HCOOH.

The disproportionation mechanism proposed by Capon and Parsons in the above discussion (cf. Footnote 21) ($HCOOH + \underset{\bullet}{C}OOH \rightarrow \underset{\bullet\bullet}{C}(OH)_2 + CO_2 + H^+ + e$) for $\underset{\bullet\bullet}{C}(OH)_2$ and that[21-23] for formation of $\underset{\bullet\bullet\bullet}{C}$—OH must themselves be complex and may involve other intermediates [$\underset{\bullet\bullet}{C}(OH)_2$ in the case of $\underset{\bullet\bullet\bullet}{C}$—OH], as well as acid catalyzed dehydration in the latter case. As written, the reaction schemes of Capon and Parsons[21-23] are purely formal and would not be easily rationalized in terms of organic reaction mechanisms.

We believe the use of formal reaction schemes, especially for heterogeneous reactions, can be misleading, as the site occupancy and geometry of the adsorbate in relation to that of the lattice must always be carefully considered, as we stressed in the paper which is being discussed.

We feel that it is more likely that $\underset{\bullet\bullet}{C}(OH)_2$ is formed by reduction of $\underset{\bullet}{C}OOH$ by the H dissociated from HCOOH and that

$$\underset{\bullet\bullet}{C}(OH)_2$$

[27] H. Angerstein-Kozlowska, B. E. Conway, and W. B. A. Sharp, *J. Electroanal. Chem.*, **43**, 9 (1973).

is a second intermediate in the main reaction path (see Fig. 1 above).

The possibility of relatively rapid production of intermediate II from COOH + H_{ads} follows from consideration of molecular models insofar as H_{ads} will be located close to the =O function in COOH at completion of the HCOOH dissociative chemisorption step. Reaction of this H with =O will be competitive with ionization of H but the proximity of H to =O and the shielding effect of COOH will enhance the possibility of reaction to form $C(OH)_2$. Formation of COH (P_1) will naturally be a slower reaction, since extra H is required other than that provided directly by the dissociation step, and further geometrical rearrangement is required.

We suggest that outside the H region, the dissociation of the formic acid oxidation current with time is due to formation of P_2 (see Fig. 1 above), *e.g.*, a dimer such as formic anhydride.

The question of accounting for the first anodic current peak (FA_1 in the paper under discussion) which Capon and Parsons mentioned[21] was considered by Gilroy and Conway,[28] who first showed in a general way how auto-inhibition effects could also cause current peaks without involvement of the potential-dependent traces of oxide species which Capon and Parsons invoke. The essential requirement was[28] that a step involving an adsorbed intermediate requires at least one extra site for the production of the next intermediate.

The remarks in the last paragraph of the above discussion seem to be based on a misunderstanding. Nowhere in the paper being discussed have we stated or implied that the formation of the FA_1 peak is associated with accumulation of P_1. On the contrary, FA_1 is a faradaic current peak for formic acid oxidation which we have shown can be modified by additives which change the quantity of P, adsorbed on the surface.

During the course of further work on activating effects in the formic acid oxidation, we have accumulated evidence for the essential features of the reaction scheme shown above, especially with regard to the effects of electrodeposited Hg. This work will be reported in more detail at a future date.

The Anodic Oxidation of Hydrogen on Platinized Tungsten Oxides. II. Mechanism of H_2 Oxidation on Platinized WO_3 Electrodes

B. S. Hobbs and A. C. C. Tseung (pp. 766-769, Vol. 120, No. 6)

G. Vértes and G. Horányi:[29] In the paper under discussion the authors claim that WO_3 is an active support in the catalytic oxidation of hydrogen and a mechanism of H_2 oxidation is proposed. These studies are very similar to our catalytic work concerning the behavior of platinized WC and WO_3 powders in liquid-phase catalytic hydrogenation. We found, however, that WO_3 cannot be regarded as an active support in these processes. It is known from the literature that two fundamental types of mechanisms in liquid-phase hydrogenation may be distinguished. The first one is the atomic or radical mechanism, given by the following scheme

$$H_2 \rightarrow 2H;\ S + \nu H \rightarrow SH_\nu;\ H \rightleftarrows H^+ + e$$

The second one is the ionic mechanism

$$H_2 \rightarrow 2H;\ H \rightarrow H^+ + e;\ S + \nu e \rightarrow S^{\nu-}$$

$$S^{\nu-} + \nu H^+ \rightarrow SH_\nu$$

Accepting the mechanism proposed by Benson *et al.*[30,31] and by Hobbs and Tseung a support effect may be expected in the case of hydrogenation via ionic mechanism.

As mentioned above this effect has not been observed. The rate of hydrogenation of nitrocompounds on platinum without support and with Al_2O_3 or WO_3 supports was the same.

The mechanistic consideration of Hobbs and Tseung is based upon the results of Benson *et al.*[30,31] who found that the reduction of WO_3 was possible only if WO_3 was mixed with platinum black and if water was preadsorbed on the mixture prior to admitting hydrogen to the system. If either one of these conditions was not satisfied, reduction did not take place at all at room temperature. According to Benson *et al.*, WO_3 is reduced by H atoms produced by platinum splitting H_2 molecules. The rapid transport of hydrogen atoms takes place in an adsorbed layer of water. This explanation does not take into consideration the possibility of the existence of electrochemical processes. The existence of the process

$$WO_3 + xH^+ + xe \rightleftarrows H_xWO_3$$

however, cannot be questioned.[32,33]

Thus the treatment of the problem in Benson's papers is inadequate, and the conclusions drawn on the mechanism of the reduction cannot be accepted. In our judgment there is no experimental evidence in the literature which provides the role of H atoms on this reduction. On the contrary, there exist several experimental facts attesting to the possibility of the electrochemical reduction of WO_3 (reduction by Zn + HCl, Sn^{2+}, etc. as has been stated in Glemser's work cited above[32]).

In Part I of the paper under discussion[33] the authors' opinion seemed to be similar to that outlined above. Thus, the conclusions drawn in Part II (*i.e.*, the paper presently under discussion) rather contradict the previous assertions.

In addition, it should be noted that the experimental results reflected in Fig. 2 of the work under discussion do not prove the existence of the chemical pathway of reduction (by H atoms) and the support effect.

This type of curve is well known from catalytical literature. Similar experimental results have been obtained for different reactions on varying the concentration of the catalyst on an inactive support. These problems have been treated extensively, for example, in the theory elaborated by Kobozev which gives a mathematical formulation of the phenomenon.[34,35] From this theory it follows that an increase in the specific catalytic activity at low catalyst concentrations on the support cannot be regarded as a proof of a support effect.

B. S. Hobbs[36] **and A. C. C. Tseung:** In the above discussion G. Vertes and G. Horanyi did not find any difference between the rate of hydrogenation of nitrocompounds on unsupported platinum and on platinum supported on Al_2O_3 or WO_3. They therefore suggested that WO_3 cannot be an active support for hydrogenation reactions and in turn implied that our results are invalid. This is a rather surprising deduction. It is important to note that Vertes and Horanyi did not state the exact experimental conditions of their study, *i.e.*, whether the size of the platinum crystallites on each of the three samples was the same or whether the

[36] Electrical Research Association, Leatherhead, Surrey, England.

hydrogenation results were normalized to unit Pt surface area or unit Pt weight. Unless these points are clarified, it is rather pointless to quote the results as scientific evidence at all. In addition, our tests were done on Teflon bonded electrodes. The pores of our catalysts were basically dry and hence permitted the rapid diffusion of H_2; whereas liquid-phase hydrogenation could well be limited by the rate of H_2 diffusion through the pores of the catalyst since they are filled with liquid. Thus, it is important to know whether the hydrogenation reaction in their case was mainly limited by the mass transfer of the reactants.

We prepared the supported catalysts by mixing a stock preparation of platinized WO_3 with varying percentages of WO_3 and then plotting activity/unit weight of Pt black *vs.* Pt loading (see Fig. 2 in the paper under discussion). The results clearly showed that a synergistic effect was in operation. On the other hand, no such effect was found in the case of platinized B_4C, *i.e.*, regardless of Pt loading (0.01-0.12 mg Pt/cm^2), the activity/unit weight of Pt loading remained unchanged for the platinized B_4C electrodes (Fig. 5 of the paper under discussion).

Furthermore, Vertes and Horanyi suggested that the formation of H_xWO_3 could be via an electrochemical process

$$WO_3 + xH + xe \rightleftarrows H_xWO_3$$

If this mechanism is the main process, then it is impossible to reconcile it with the greatly enhanced activity of platinized WO_3 for the oxidation of hydrogen, since if xH^+ is required to form H_xWO_3, then the support cannot speed up the rate of H_2 oxidation. Benson *et al.*[30] gas-phase studies on the formation of H_xWO_3 only involved the adsorption of one monolayer of H_2O and hence the electrochemical mechanism is rather unlikely. Furthermore, the formation of H_xWO_3 by the Zn + HCl reduction process[32] is likely to involve the formation of a H atom which could then diffuse to the WO_3 surface, resulting in the formation of H_xWO_3. Moreover, Polterak[37] showed that a WO_3 crystal can be reduced to tungsten blue (H_xWO_3) when it is placed near but not touching a cathode undergoing H_2 evolution, thus confirming the validity of our proposed mechanism.

Finally, Kobozev's mathematical formulations[34] tend to agree rather than disagree with our results, since we have shown that the increase in specific activity with decreased Pt loading reached a maximum value when the number of Pt particles to WO_3 particles is about 1:1 and the activity decreases thereafter. In the case of the normal supported catalyst the increase in specific activity is usually associated with decreased Pt crystallite size as the platinum concentration on the supported catalyst is reduced. In our work, we have carefully avoided this pitfall; the catalyst samples were prepared by mixing a stock preparation of platinized WO_3 with varying percentages of WO_3, thus ensuring that the platinum crystallite size remained unchanged.

Contributions of Oxygen, Silicon, and Hydrogen to the Interface States of an Si-SiO₂ Interface

W. Fahrner[1]

ABSTRACT

Oxygen, silicon, and hydrogen ions are implanted with doses of 10^{10}-10^{15}/cm² through the oxide of a MOS structure. The development of induced levels in Si can be observed. Annealing experiments from room temperature to 800°C show the transition from the nonequilibrium incorporation to the initial (nonimplanted) state. Hydrogen implantation hinders the restoration of a Si-SiO_2 interface under H_2 annealing.

In a previous paper (1) we showed that implantation of oxygen at a Si-SiO_2 interface creates two deep-lying levels in Si ($E_c - E = 0.51$ and 0.71 eV). When we measured the oxygen implanted sample three months later, we observed a broad spectrum of surface states, but not a trace of the deep lying levels. Furthermore, it was shown (2) that SiH implantation produces a level $E_c - E$ at 0.58 eV. These results led us to the well-known suggestion that interface states could be explained as the result of nonstoichiometry, *i.e.*, a local abundance of either oxygen or silicon, or a disorder at the interface.

Models corresponding to such an assumption were given for example by Revesz and Zaininger (3) or Kooi (4). According to Kooi's model, hydrogen should interact with the unsaturated dangling bonds and therefore reduce the number of surface states. Thus we included in our studies an investigation involving hydrogen implantation to test this hypothesis.

Experimental

The experimental procedure was as follows: <100> epitaxial n and p samples of about 1 ohm-cm resistivity were cleaned and oxidized in dry oxygen. The lifetime of the minority carriers was better than 80 μsec. The oxide thickness was in the range of 500-1000Å. The samples were then implanted, annealed, and 0.50 mm diameter aluminum dots were evaporated onto the oxide. The accelerator energy was chosen to make the implantation range equal to the oxide thickness. (We used an accelerator energy of 95 keV in order to implant Si through 1000Å SiO_2 f.e.). For this purpose we used the range tables of Johnson and Gibbons (5). We made two experimental series for each implanted ion species. In one series the annealing temperature was kept constant at 500°C, and the ion dose was varied from 10^{10}-10^{15}/cm² in steps of a factor of 10. In the other series the annealing temperature was varied from room temperature to 800°C in steps of 100°C while maintaining the ion dose. In this second series we used the results of the first series to choose a dose where the induced levels could be seen most clearly.

To determine surface state density N_{ss} and, to a rough approximation, the fixed charge density, we used the slow ramp technique (6) in connection with a 71 AR-Boonton 1 MHz bridge. For the higher N_{ss} values we had to measure the sample capacitance at a frequency of 30-50 MHz in order to get a dispersion-free C-V curve. This was done point-by-point with a 33 B Boonton bridge.

For each series a nonimplanted control sample was measured in order to determine the original surface-state density ($\lesssim 10^{10}$/cm² eV⁻¹). Because the C-V curves give more information than just the deduced N_{ss} (ψ_{CB}) plots, we rather present the former ones (ψ_{CB} = energy measured with respect to the conduction band).

Results

An implantation of oxygen caused the appearance of the two deep lying levels (Fig. 1a-e). The lowest dose used of 10^{10}/cm² was low enough to have no measurable effect on the surface states compared to the control sample. [Radiation damage was removed in this series by annealing at 500°C in H_2 for 2 hr (7).] The number of states in the levels grew with increasing ion dose. For an oxygen dose of 10^{13}/cm², only the upper level at 0.51 eV could be seen; the 0.71 eV level disappeared under the low energy tail of the 0.51 eV level. At a dose of 10^{14}/cm², the 0.51 eV level was close to the upper detection limit of N_{ss} by the slow ramp technique. Stability of the samples was excellent, neither leakage currents nor flatband shifts could be observed. Up to the dose of 10^{13}/cm² flatband voltage was above −1V. For the 10^{14}/cm² sample we observed a considerable downward shift to ≈ −7V and a donorlike doping effect.

Key words: surface states, nonequilibrium state of impurities, implantation in a MOS structure.

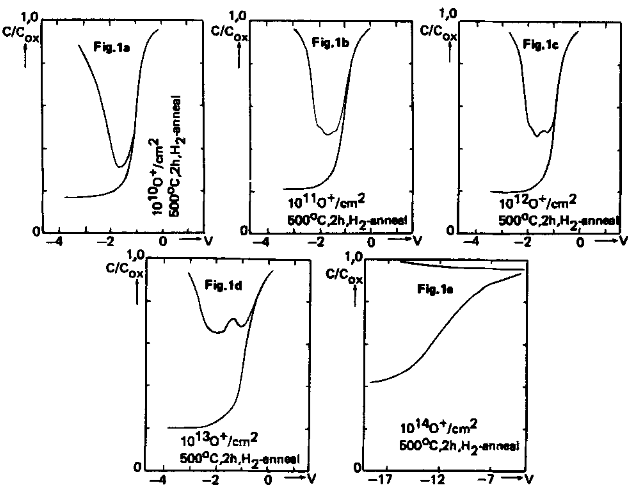

Fig. 1a-e. n-type samples, oxygen implantation through ≈ 500Å SiO_2.

In the second experimental series for oxygen, the results of the annealing experiments are given in Fig. 1f-j. With a fixed ion dose of 10^{13}/cm², which gave a good resolution of the peaks, we started with an annealing temperature of 400°C. The two levels can be seen clearly at the relative values of C/C_{ox} = 0.775 and 0.805, respectively. The 500°C experiment was already done in the first series. On comparison, one sees that the ion doses were not exactly the same because the 0.71 eV level is still slightly visible. The 0.51 eV level did not decrease very much, but the 0.71 eV level is reduced to C/C_{ox} = 0.74. Annealing at 600°C makes both levels disappear; we see only a broad spectrum of surface states. The shape of these curves is identical to that obtained for a 10^{12}O/cm² implanted sample, annealed at 500°C, but measured after an aging period of 3 months. Compared to this aged sample, the stability of the 600°C annealed sample is relatively poor.

For each new measuring cycle, these *C-V* curves were displaced to the right, as indicated by the arrows. The N_{ss} values of the control sample were nearly attained for the 700°C sample even though the same drifting behavior was observed. Finally, at 800°C the N_{ss} values, stability, and flatband voltage of the control sample were reached. A summary of the oxygen results is given in Fig. 2a and b, where the values of N_{ss} *vs.* dose and annealing temperature are plotted.

The same experiments were repeated with ^{30}Si. (This isotope was used instead of ^{28}Si or ^{29}Si in order to

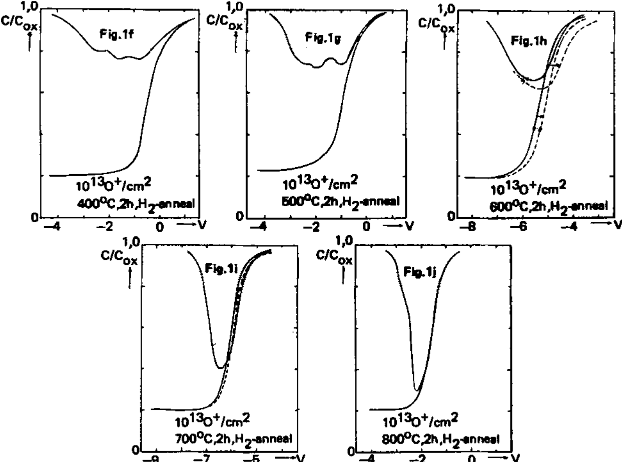

Fig. 1f-j. The same kind of samples as before implanted with 10^{13}O/cm². The annealing temperature was in the range of 400°-800°C.

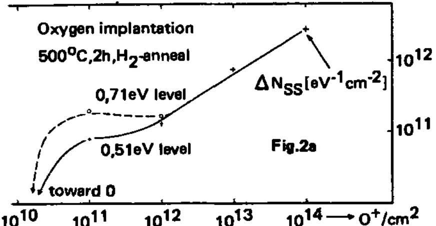

Fig. 2a. Induced N_{SS} values *vs.* oxygen dose, taken either for both oxygen levels or at the 0.51 eV level.

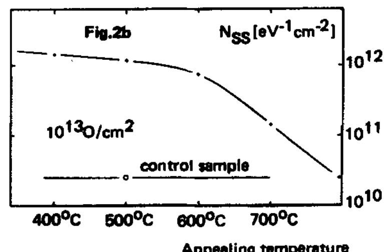

Fig. 2b. Reduction of N_{SS} under annealing. The implantation dose was 10^{13}O/cm². The original surface-state density is reached at 800°C.

block out the CO and N_2 impurities on the ^{28}Si line and the ^{28}SiH impurity on the ^{29}Si line). With varying Si dose (Fig. 3a-d) we see again that a dose of 10^{10}/cm² does not measurably change the number of surface states found in the control sample. At a dose of 10^{11}/cm², the first hint of a level was visible. (The overshoot effect and the capacitance hook of the low-frequency and high-frequency curve, respectively, are caused by the well-understood effects of a elevated surface-state density and the formation of a depletion edge region around the Al dot which acts as a barrier against the n channel.)

Figure 3c shows that the level barely seen in Fig. 3b actually contains three levels of $E_c - E$ = 0.93, 0.63, and 0.34 eV, respectively, (Fig. 4). A significant change in the curves similar to that seen in the transition from 10^{13} to 10^{14}/cm² for oxygen was already observed, when we increased the dose from 10^{12} to 10^{13}/

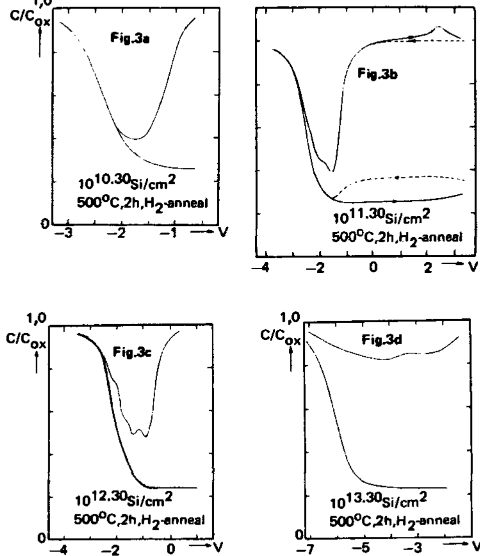

Fig. 3a-d. p-type samples, silicon implantation through ≈ 500Å SiO_2. The dose was in the range of 10^{10}-10^{13}/cm², the annealing temperature was 500°C. *C-V* curves were plotted from accumulation to inversion (full line) and back (dashed line; not shown for every plot). When full and dashed line coincide, only the full line is shown. The dose was in the range of 10^{10}-10^{14}O/cm², the annealing temperature was 500°C.

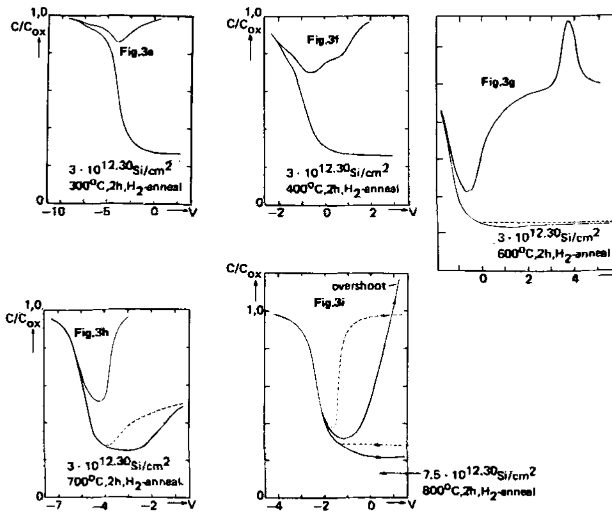

Fig. 3e-i. p-type samples, implanted with 3 · 10^{12} $^{30}Si/cm^2$ through ≈ 800Å SiO_2. The annealing temperature was in the range of 300°-800°C.

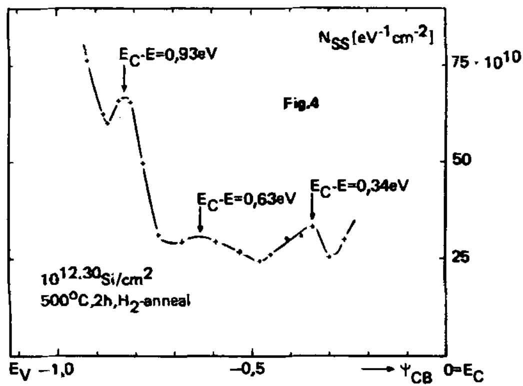

Fig. 4. N_{ss} (Ψ_{CB}) deduced from Fig. 3c

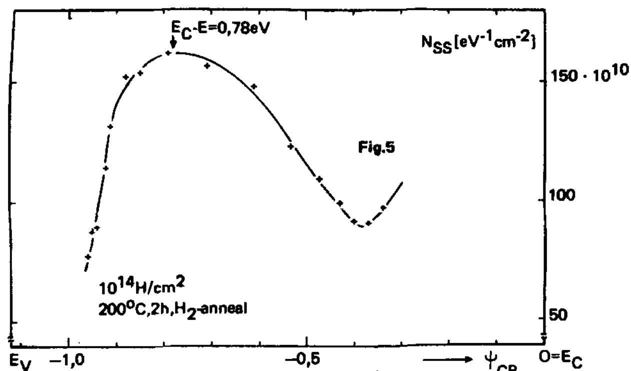

Fig. 5. N_{ss} (Ψ_{CB}) for an H implantation of $10^{14}/cm^2$ and 200°C annealing temperature.

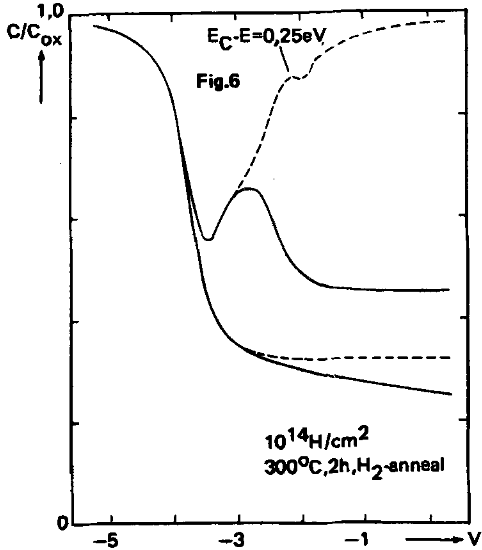

Fig. 6. C-V plot for a 10^{14} H/cm^2 implanted sample annealed at 300°C. A level at $E_c - E = 0.25 \pm 0.05$ eV is seen.

cm^2 for silicon. The minimum surface-state density is now $1.8 \cdot 10^{12}$ eV^{-1} cm^{-2}, the flatband voltage ≈ −7V. For our highest dose of $10^{14}/cm^2$ we obtained a straight line in the low-frequency meaning that N_{ss} was always $\gtrsim 5 \cdot 10^{13}$ eV^{-1} cm^{-2}. From these results it is clear that any information about an induced level must be accompanied by a statement of the implantation and annealing conditions.

We will not discuss the reduction of N_{SS}, V_{FB}, and of the drift by annealing for implanted silicon because the effects were very similar to those already described for oxygen. This can be seen in Fig. 3e-i.

Finally, we want to report on the results of hydrogen implantation. Up to a dose of $10^{15}/cm^2$ we did not see any change in the C-V plots (not shown) compared to the control sample. This indicates that the hydrogen is either distributed over the whole sample volume, or it has diffused out. These assumptions are further supported by two facts. First, hydrogen has a very high diffusion constant of $D = 10^{-5}$ cm^2/sec at 500°C (8) which is comparable to the lithium diffusion constant of $D = 1.8 \cdot 10^{-5}$ cm^2/sec at 1200°C. Second, experimental evidence found by Card and Kao (9) showed that for a proton bombardment at 25 MeV an annealing temperature of 300°C was sufficient to restore the initial high-frequency curves. With a better resolution, however, one finds that this annealing temperature limit must be increased to 500°C. At temperatures equal to or below 200°C, a level $E_c - E = 0.78$ eV for hydrogen is found (Fig. 5). At 300° and 400°C this level disappeared, while another level at $E_c - E = 0.25$ (±0.05) eV appeared (Fig. 6). Only above 500°C was no influence of hydrogen on the surface states and fixed charge density observed.

Discussion

The main results of these experiments are the following. First, surface states cannot be explained as a nonstoichiometry effect of oxygen or silicon. The oxidation temperature is at about 1000°C, but any nonstoichiometry or at least the surface states due to a nonstoichiometry disappear before 800°C are reached. Thus we can only speculate what the actual source of the surface states might be. The cleanliness of the sample preparation obviously influences the number of surface states. It cannot be excluded that surface states are just the product of a small amount of impurities which can never be avoided. The second, and surprising, result is that implanted H does not accelerate the restoration of the interface, but hinders it. (For a sample implanted with "inert" ions, *i.e.*, N, Ar, etc., an annealing temperature of 300°C in H_2 is sufficient to restore the interface). Therefore, it is not possible to reach lower device processing temperatures by H implantation. These two results together show that the suggested models do not correctly describe the influence of oxygen, silicon, and hydrogen on an Si-SiO_2 interface.

ABSTRACT

It has been demonstrated that interface demarcation, achieved by transmitting current pulses across the growth interface, combined with spreading resistance measurements, is uniquely suited for the quantitative investigation of facet growth and associated dopant segregation behavior. Interface demarcation lines (intercepts of the periodically delineated interface with a plane parallel to the growth axis) were used (*i*) as "rate striations" for the determination of microscopic growth rates, (*ii*) as "locators" for the identification of simultaneously grown areas in the core and off-core regions, and (*iii*) as "time reference markers" for the in-time correlation of growth and segregation behavior. Applying this technique to Czochralski-type growth of Ga-doped Ge it was found that facet growth and segregation are more complex phenomena than assumed in the accepted theoretical models.

The dopant segregation associated with facet growth has been extensively investigated in semiconductor crystals since the discovery of the coring effect (1).[1] These studies, based on macroscopic data, have led to the following main conclusions: (*i*) The tendency of growth facet formation during crystal pulling by the Czochralski technique depends on the growth direction; it decreases according to the sequence: <111> > <100> > <110> (2). (*ii*) For a given system the ratio of k_{eff} (facet) to k_{eff} (off-facet) is constant and greater than one (3); the only reported exception is the system Ge-Ga where this ratio is smaller than one (4). (*iii*) The vertical facet growth rate remains virtually constant (under constant pulling rate) irrespective of growth rate variations in the off-facet region (5). (*iv*) The appearance of rotational segregation inhomogeneities in the core region depends on the facet inclination relative to the horizontal and on the thermal asymmetry (5). (*v*) Nonrotational dopant inhomogeneities exhibit no discontinuities from the core to the off-core regions (5).

Investigations comparing the segregation behavior in core and off-core regions have been based primarily on compositional information obtained from transverse resistivity scans across these regions. Because of the curvature of the off-facet growth interface, such results are of limited value since they do not correspond to identical growth interfaces.

Theoretical treatments of the coring effect are based on the concept of intermittent, rapid, lateral layer growth on kinetically supercooled facets (6); the specificity of coring (the variation of the ratio k_{eff} (facet) to k_{eff} (off-facet) with regard to the nature of the dopant and the host crystal is attributed to chemisorption at the growth interface.

The present communication reports on the successful application of a recently developed experimental approach (7) to the quantitative investigation of facet growth and segregation on a microscale and to the comparison of the simultaneous facet and off-facet segregation behavior; this approach combines the interface demarcation with spreading resistance measurements. Emphasis is placed on the demonstration of the usefulness and potential of this approach rather than on the analysis or interpretation of specific facet growth effects.

Experimental Procedure

The segment of the germanium single crystal employed in this study was pulled at a rate of 3.2 cm/hr under seed rotation (3.1 rpm) from a melt doped with gallium (2×10^{20} atoms/cm^3). Interface demarcation during growth (8) was accomplished by transmitting current pulses (20A) of 0.03 sec duration at a repetition rate of 0.5 sec across the growth interface. A 2 mm thick section was obtained by cutting the crystal along the rotational axis. The plane containing the rotational axis was chemically polished (Syton HT-30)

* Electrochemical Society Active Member.

Key words: germanium, facet growth, impurity segregation, interface demarcation, crystal growth.

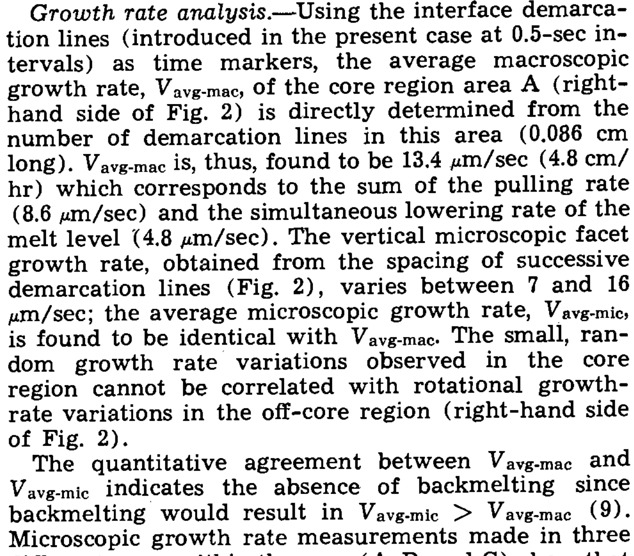
[1] The term core in semiconductor crystals refers to the part of the crystal associated with interface-facet growth and exhibits a higher dopant concentration than the rest of the crystal (with one reported exception pointed out in text); this behavior is referred to as coring effect; a core region is not necessarily located in the central part of the crystal. In this paper the term core is broadly used for the part of the crystal associated with facet growth without consideration of dopant segregation behavior.

and etched in $1HF + 1H_2O_2 + 1CH_3COOH$ for 6 sec to reveal the interface demarcation lines (intercepts of the periodically delineated growth interface with the plane) and the inherent segregation inhomogeneities. The microscopic dopant concentration profile in the crystal section was then determined through spreading resistance scans; a detailed description of this technique has been reported elsewhere (7).

Experimental Results

The present experimental approach is applied to the determination of: (*i*) the microscopic vertical growth rate; (*ii*) the dopant concentration profile; and (*iii*) the dependence of dopant segregation on the vertical growth rate. The growth and segregation behavior in the facet region is then contrasted with that of the corresponding off-facet region.

Figure 1 is a photomacrograh of the germanium segment studied showing the areas analyzed designated as A, B, C, and D. The core and off-core regions as well as the rotational segregation inhomogeneities are clearly visible. Interface demarcation lines are not visible at this magnification. It should be noted that interface demarcation in no way interferes with the basic growth and segregation behavior (8).



Growth rate analysis.—Using the interface demarcation lines (introduced in the present case at 0.5-sec intervals) as time markers, the average macroscopic growth rate, $V_{avg\text{-}mac}$, of the core region area A (right-hand side of Fig. 2) is directly determined from the number of demarcation lines in this area (0.086 cm long). $V_{avg\text{-}mac}$ is, thus, found to be 13.4 μm/sec (4.8 cm/hr) which corresponds to the sum of the pulling rate (8.6 μm/sec) and the simultaneous lowering rate of the melt level (4.8 μm/sec). The vertical microscopic facet growth rate, obtained from the spacing of successive demarcation lines (Fig. 2), varies between 7 and 16 μm/sec; the average microscopic growth rate, $V_{avg\text{-}mic}$, is found to be identical with $V_{avg\text{-}mac}$. The small, random growth rate variations observed in the core region cannot be correlated with rotational growth-rate variations in the off-core region (right-hand side of Fig. 2).

The quantitative agreement between $V_{avg\text{-}mac}$ and $V_{avg\text{-}mic}$ indicates the absence of backmelting since backmelting would result in $V_{avg\text{-}mic} > V_{avg\text{-}mac}$ (9). Microscopic growth rate measurements made in three different areas within the core (A, B, and C) show that the random growth rate variations are identical in magnitude and take place at exactly the same time

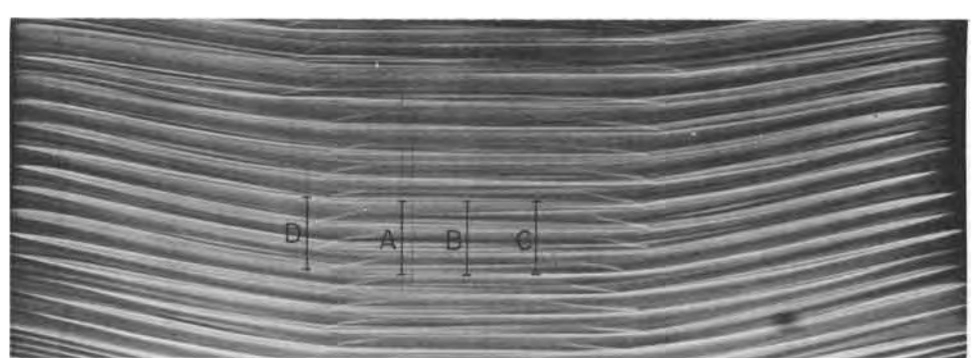


Fig. 1. Differentially etched segment of a Ga-doped Ge single crystal pulled with seed rotation. The areas analyzed, designated as A, B, C, and D, are 0.086 cm long and correspond to a growth period of 64 sec. Traces of the spreading resistance measurements in some instances extend beyond the areas analyzed. Interface demarcation lines are not visible at this magnification. Areas A and D are shown under high magnification in Fig. 2.

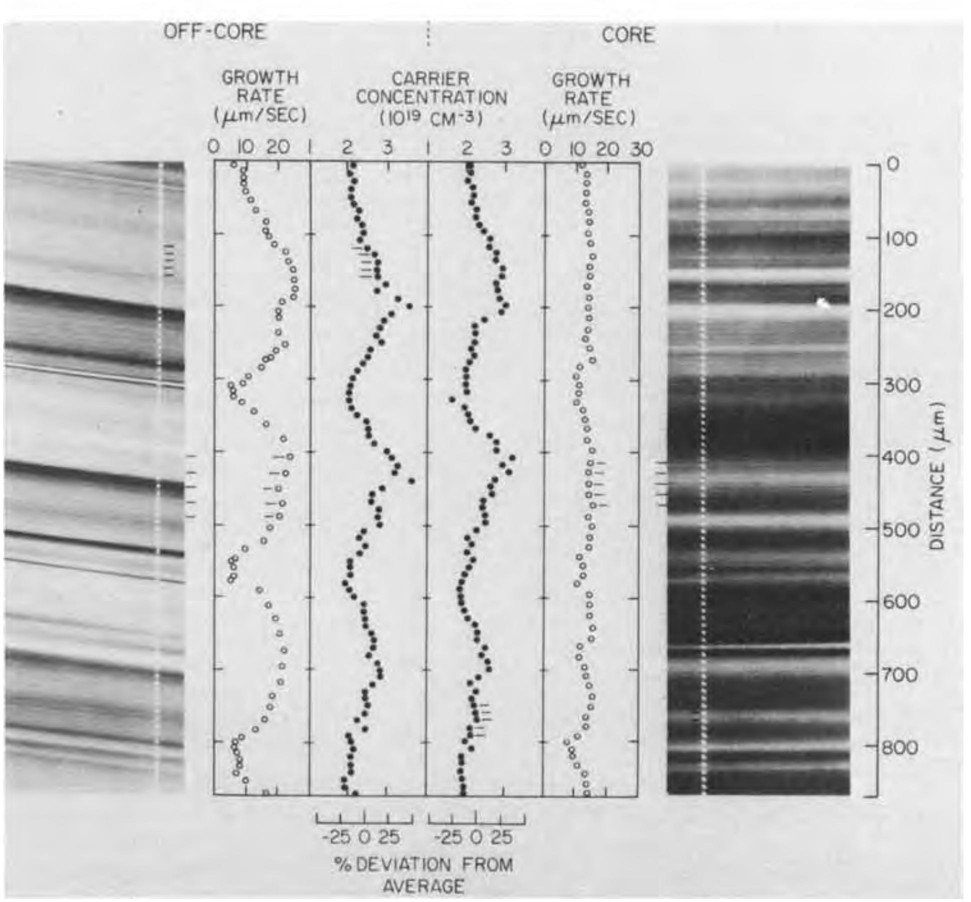

Fig. 2. Differentially etched core area (right-hand side) and a corresponding off-core area (left-hand side) of a Ga-doped Ge single crystal. The core and off-core areas shown here under high magnification are the A and D areas in Fig. 1. The impact traces of the spreading resistance measurements are visible on both crystal areas. The microscopic growth rates and the carrier (dopant) concentrations are plotted as a function of distance. For convenience the correspondence between individual impact traces and the carrier concentration and microscopic rate points is indicated for five points in each plot.

throughout the core region. Thus, it is apparent that the facet advances, at all times, parallel to the established growth interface; off-facet growth rate variations are completely accommodated in the off-facet region adjacent to the facet.

Dopant concentration analysis.—The microscopic dopant distribution in the core region (with a linear resolution of 10 μm) is obtained from spreading resistance scans, the impact traces of which can be seen in the photomicrographs of Fig. 2. The dopant concentration profile of the core area A is given on the right-hand side of Fig. 2. Each point on the graph corresponds to an identifiable impact trace on the crystal; for convenience this correspondence is indicated for five points in the lower segment of the plot by short horizontal lines.

The dopant concentration plot shows segregation inhomogeneities with deviations exceeding $\pm 25\%$ from the average concentration. The inhomogeneities reflect unambiguously the rotational periodicity, consistent with the etching behavior observed on the photomacrograph in Fig. 1. The dopant profile in the core area B, not shown here, exhibited essentially the same periodic inhomogeneities as area A, but with a slight displacement of the dopant concentration maxima and minima in the downward direction. Transverse scans across the core indicated only very small compositional variations in quantitative agreement with the vertical displacements of the concentration maxima and minima.

Analysis of the vertical growth rate dependence of core segregation.—The outstanding feature of the present approach is that it allows an exact analysis of the growth rate dependence of segregation since both the composition and the corresponding growth rate can be determined at any point in the crystal.

An inspection of the dopant concentration and vertical growth rate profiles of the core area A, in Fig. 2, indicates that the Burton, Prim, and Slichter (BPS) analysis (10) is not applicable to core segregation since significant segregation changes are observed under conditions of virtually constant vertical growth rate; in some instances even an increase in dopant concentration is observed under conditions of decreasing vertical growth rate. These results are consistent with the established theoretical models which assume that core segregation depends on the horizontal rather than on the vertical growth rates.

Comparison of the core segregation to the off-core segregation behavior.—The off-core area D (left-hand side of Fig. 2) corresponding to the core area A (right-hand side of Fig. 2) is identified by following the uppermost demarcation line in area A to the off-core area D. Starting with this demarcation line, which represents the growth interface across the core and off-core areas at the same instant in time, the dopant concentration and growth rate for the off-core area are plotted in Fig. 2 as a function of distance.

In contrast to the core segregation, the segregation behavior in the corresponding off-core area D is in quantitative agreement with the BPS theory for steady-state growth conditions; *i.e.*, a plot of $\ln(1/k_{eff} - 1)$ *vs.* growth (from the data of Fig. 2) exhibited a constant slope over the entire area; the value of the corresponding boundary layer thickness (δ) was found to be 320 μm, which is smaller than the value of 580 μm calculated from the Cochran analysis. Irregular small variations in segregation, not associated with growth rate fluctuations are attributed to convection-induced boundary layer perturbations; they do not affect the BPS analysis.

The dopant concentration and its variation in the corresponding core and off-core areas, plotted in Fig. 2 as a function of distance, are virtually identical. This result indicates that the ratio of k_{eff} (facet) to k_{eff} (off-facet) is equal to one under the present growth conditions, rather than less than one as reported previously (3).

Although this result may be valid only for the present experimental conditions, it is, nevertheless, most interesting since the dopant concentration variations in the off-core region are controlled by the vertical microscopic growth rate while in the adjacent core region these variations are presumably controlled by the horizontal growth rate.

The direct comparison of the segregation behavior in the corresponding areas as presented in Fig. 2 is of interest as a spatial dopant distribution analysis. The exact comparison of the segregation behavior in the corresponding core and off-core regions must be based, however, on an analysis of the dopant concentration *vs.* time (as determined from the number of time markers); such analysis takes into account independently fluctuating growth rates in the two regions, causing changes in the curvature of the growth interface. The conversion of the concentration *vs.* distance plots of Fig. 2 to concentration *vs.* time plots is given in Fig. 3. This plot indicates virtually identical segregation behavior in the corresponding regions and, thus, no detectable coring effect.

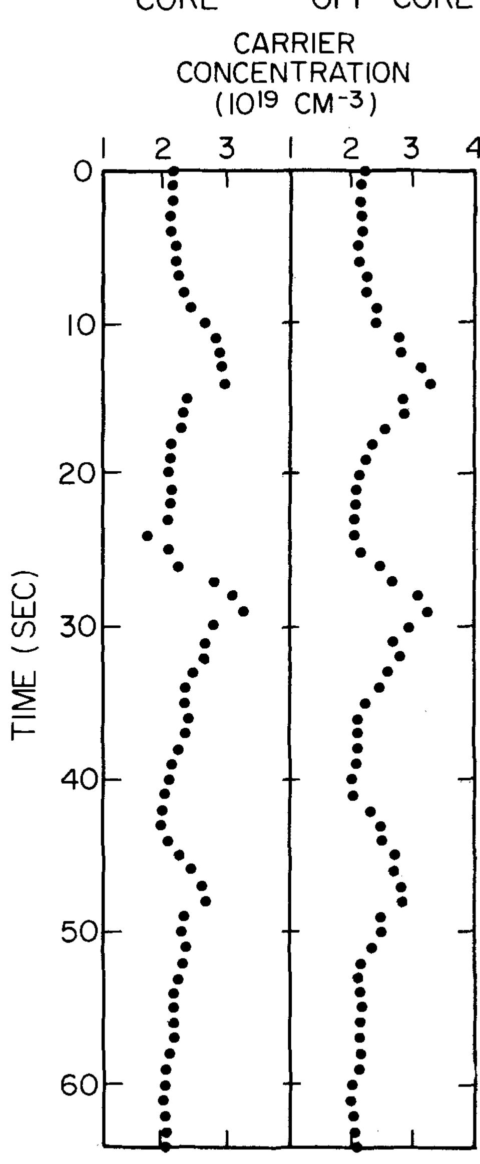

Fig. 3. Carrier (dopant) concentration in the core and off-core areas of Fig. 2 plotted as function of time (as determined from the number of time markers).

Summary

It is shown that the growth interface demarcation technique in combination with spreading resistance measurements constitutes a unique experimental approach for the quantitative investigation of growth and segregation behavior associated with the presence of an interface facet (coring effect).

While the present communication is primarily intended to demonstrate the applicability and scope of the above experimental approach, the limited amount of results presented shows clearly the complexity of these phenomena. Thus, segregation inhomogeneities can appear in the core region with the same periodicity (corresponding to the rate of rotation) and equal in magnitude to those in the adjacent off-core region, although the vertical growth rate of the core remains virtually constant. Furthermore, these inhomogeneities appear in phase in the two regions and exhibit identical dopant concentrations under the experimental conditions reported in this study. The absence of a coring effect [k_{eff} (facet) $=$ k_{eff} (off-facet)] in the present case, is in contrast to earlier results showing [k_{eff} (facet) $>$ k_{eff} (off-facet)]. In the light of experiments now in progress in our laboratory the present data should not be taken as representative of Czochralski-type growth behavior but rather as an indication that, for a given system, segregation at growth facets is a complex function of the growth parameters and particularly sensitive to boundary layer characteristics and the thermohydrodynamic behavior of the melt; furthermore, it was observed that the nature of the dopant affects not only the magnitude of coring but also the extent and stability of faceting.

The Retention of Fluorine by Silicon Surfaces: Interaction with Gold-Refractory Transistor Metallizations

H. Day, A. Christou, and D. J. Bressan

Naval Research Laboratory, Washington, D. C. 20375

The publication costs of this article have been assisted by the Naval Research Laboratory.

ABSTRACT

The interaction of gold-tantalum transistor metallizations with silicon substrates has been studied as a function of fluorine ion contamination. An NH_4F buffered etch solution tagged with 118-min half life ^{18}F was used to quantitatively establish the fluorine contamination as a function of water rinse time and evacuation time before metal deposition. Pinhole formation in the refractory layer due to fluorine ion contamination with a subsequent rapid interdiffusion of gold and silicon during a 300°C anneal was shown to be a probable failure mechanism for transistors.

Efforts to increase the reliability of microwave power transistors have led to the investigation of metallization systems which adhere well and effectively withstand high temperature and high current density without degradation or failure due to (*i*) alloying, (*ii*) interdiffusion of silicon and contact metal (1), (*iii*) interaction of metal and SiO_2 or other passivating layers (2), or to (*iv*) electromigration (3). Metallization systems which have been extensively investigated and are in present use are (*i*) pure aluminum or aluminum with small percentages of other metals added and (*ii*) gold which is usually deposited on a refractory layer in direct contact with silicon or platinum silicide. The purpose of the refractory layer is to provide adherence and to serve as a diffusion barrier between the gold and silicon which form a eutectic melt at 370°C. In the present paper we report some observations on the retention of fluorine by chemically processed silicon surfaces and its interaction at 300°-400°C with subsequently deposited contact metals. These observations lead to the conclusion that absorbed fluorine is directly responsible for the interdiffusion of the gold and silicon through the tantalum layer at elevated temperatures.

Key words: surfaces, metallizations, ion contamination, reliability, transistors.

Experimental

In preparing silicon substrates for ohmic contact formation, SiO_2 is generally removed by etching in hydrofluoric acid buffered with NH_4F to moderate the etch rate. The solution may also contain a chelating

agent to prevent metal ions from plating out on the silicon. As pointed out by several authors (4-6) such a procedure leaves fluorine on the silicon with a concentration which varies with the rinsing agent and the duration and mechanics of the rinse cycle. Due to the strength of the F-Si bond (136 kcal/mole) it was suggested (4) that the fluorine was chemically adsorbed with a surface concentration of the order of one atomic layer. In this experiment it was necessary to measure the concentration without disturbing the distribution and without desorption in order to correlate metallization defects with the fluorine concentration. For this reason, the radiochemical technique was chosen and the etch solution was tagged with the ^{18}F isotope.

Radioactive ^{18}F was prepared according to the reaction $^{16}O(\alpha,pn)^{18}F$ from Li_2O by α-particle irradiation in the Naval Research Laboratory cyclotron. Following procedures worked out by Eisele *et al.* (7) the fluorine was extracted in the form of $H^{18}F$ within 1 hr following irradiation and added directly to the etch solution. The specific activity of the resulting solution was 47,300 cpm/μg of fluorine.

Prior to metallization the silicon wafers were dipped in the etch solution for 10 sec, rinsed, and then counted at various intervals for verification of fluorine contamination, its concentration, and the absence of other radioactive contaminants such as Na. One sample received a tantalum deposition after the first count in order to determine the amount of fluorine desorption in the evacuation and subsequent rf plasma discharge.

Following counting the samples were stored in ambient for approximately 16 hr after which they were all placed in a rf sputter deposition unit along with the fluorine-free control wafer for tantalum-gold deposition. The gold and tantalum were deposited using an argon pressure of 5μ and a rf power of 200W. This resulted in a substrate maximum temperature of about 100°C. The thickness of the tantalum layer was 2000Å while that of the gold layer was 3000Å. After metallization the wafers were annealed in vacuum at 300°C for 8 hr.

In addition to the radiochemical technique, scanning electron microscopy with dispersive x-ray analysis and the electron microprobe analysis were used for correlation of contamination with the physical properties of the layers. Etch pits with associated hillocks were also counted.

Results and Discussion

The raw counting data as a function of time after the first wafer was etched is shown in Fig. 1 with rinse duration as the parameter. The slope of the curves indicate a half life of approximately 118 min which is that of ^{18}F. Therefore, no other radioactive species was involved. The variation of the fluorine ion concentration as a function of rinse duration is shown in Fig. 2. Previous investigations of the effectiveness of the acetone rinse (4, 5) are in general agreement with the results shown here. The value measured for the Ta-metallized sample also indicates that no desorption took place in the sputter deposition procedure. A scanning electron microgram of etch pit and hillock formation with associated energy dispersive x-ray spectra is shown in Fig. 3. This type of fault rather than a general penetration along all grain boundaries is typical of the gold-tantalum system in the presence of fluorine. The x-ray spectra (one taken by scanning the etch pit and the other taken by scanning the surrounding area) show the change in the relative

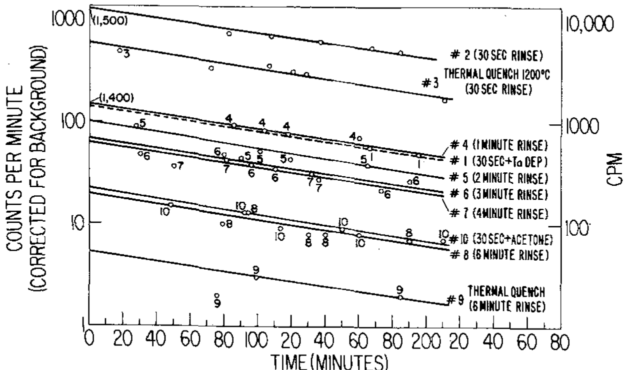

Fig. 1. Radioactivity count *vs.* time after etching wafer No. 1. Rinse duration is the parameter. A thermal quench (No. 3 and 6), an acetone rinse (No. 10), and rf sputter deposition of tantalum (No. 1) are processing variations. No. 1 is referred to the right-hand scale.

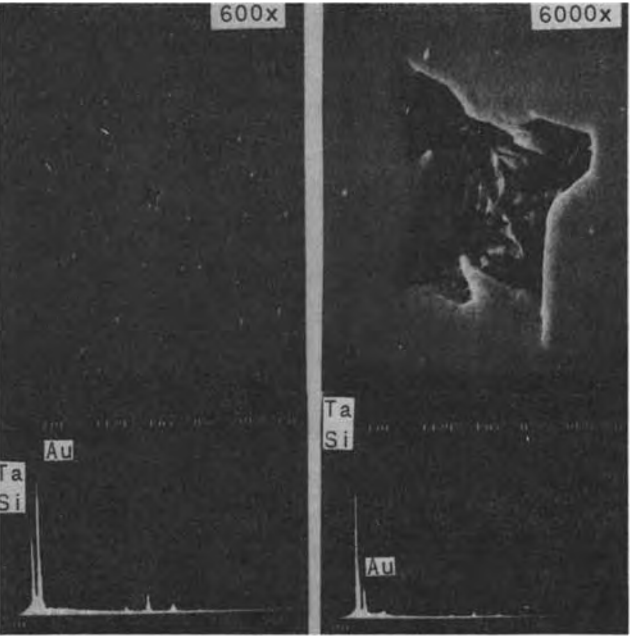

Fig. 3. Energy dispersive x-ray analysis of a typical etch pit (and surrounding area) in a gold-tantalum metallization on a silicon wafer contaminated with fluorine (1 min rinse) and annealed at 300°C for 8 hr.

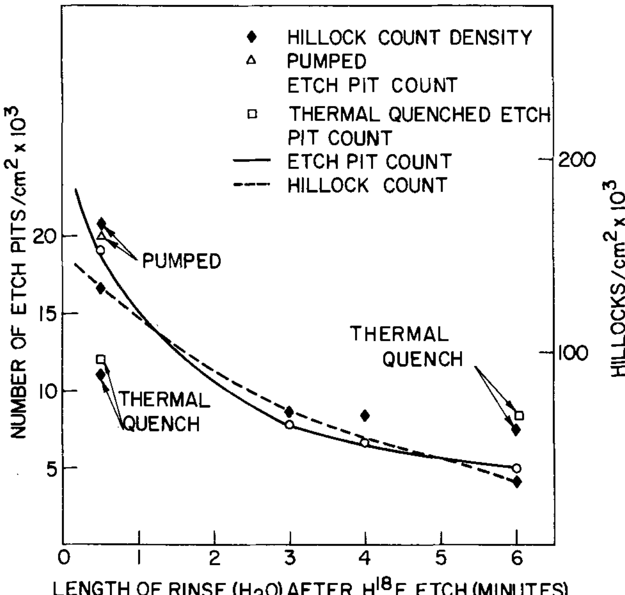

Fig. 4. Etch pit and hillock counts vs. rinse duration with thermal quenching and rf sputter deposition of tantalum as variations in processing.

amounts of Au, Ta, and Si. Fluorine or other contaminant peaks are not evident in the spectra since the concentrations are generally below the sensitivity of this technique. Similarly, x-ray spectra of the hillocks show them to consist solely of Au and Si. Figure 4 shows etch pit and hillock counts in the metallization as a function of rinse time in correlation with the contamination data. The control wafer etch pit count was $10/cm^2$, several orders of magnitude below that of the contaminated wafers. However, the fact that the etch pit count in this case was not zero was surprising since the diffusion was being attributed to the effects of fluorine. This will be discussed later in connection with annealing in ambient and the tantalum reaction with SiO_2.

The reaction of the gold-tantalum film with silicon substrates of 1.0 and 0.008 ohm-cm resistivity was also correlated with fluorine contamination. When annealed at 350°C, metallizations on high resistivity contaminated samples degraded to greater than 1000 etch pits/cm^2 in 72 hr while low resistivity contaminated samples degraded to the same level in only 24 hr. It is known that (9, 10) surface defects can serve as nucleation centers for the formation of precipitates of foreign atoms. From the present investigation it is believed that fluorine will precipitate at silicon surface defects, the density of which is greater in the low resistivity silicon. Therefore, subsequent annealing at 350°C results in enhanced diffusion at silicon defects (10) and the subsequent formation of pinholes in the metallization.

In many cases gold-tantalum metallizations deposited on clean silicon wafers from which the native oxide was not removed have withstood vacuum anneals at 350°C for as much as 800 hr without etch pit formation. Furthermore, samples identical to the fluorine-free control wafer mentioned previously showed no etch pit formation when annealed in ambient at 350°C for 8 hr. This is in agreement with Schaible and Maissel (8) who found that gold would not diffuse through tantalum if oxygen or SiO_2 were present to react with tantalum. This and the foregoing results lead us to the conclusion that the absence of oxygen in the tantalum grain boundaries or the presence of fluorine which is available to react with the oxidized grain boundary leaves the gold free to diffuse through the tantalum and react with the silicon thus causing the etch pit or void and hillock formation. Since fluorine normally etches tantalum the reaction is not necessarily confined to the grain boundary. However, the rate of reaction is expected to be much greater at the grain boundary. The fact that this takes place only at discrete points along the grain boundaries is being investigated further.

Solid-State Coulometric Titration: Critical Analysis and Application to Wüstite

Robert A. Giddings[1] and Ronald S. Gordon

Division of Materials Science and Engineering, University of Utah, Salt Lake City, Utah 84112

ABSTRACT

A critical analysis was performed on galvanic cell techniques which employ calcia-stabilized zirconia electrolytes. The presence of low-level electron or hole conduction in the ionic conducting range of the electrolyte was found to be responsible for oxygen permeation through the electrolyte which can either oxidize or reduce a single-phase oxide and, hence, lead to drift in the open-circuit emf with time. Taking oxygen permeation into account quantitatively, a series of isothermal titration experiments in wüstite was performed in which the cell emf was found to be linear with composition (*i.e.*, oxygen-iron molal ratio). These results are in excellent agreement with a recent composite analysis of all thermodynamic data in the Fe-O system. Previous cell studies in which deviant behavior has been reported are probably due to improper galvanic cell techniques. No evidence was found to support the existence of more than one-phase or second-order transitions within the wüstite phase.

Recently, considerable interest has been generated on the use of solid-state galvanic cells which employ oxide electrolytes (*e.g.* $CaO\text{-}ZrO_2$, $Y_2O_3\text{-}ThO_2$) to study the thermodynamic properties of nonstoichiometric oxide systems. Since voltages may be measured with high precision emf measurements should lead to a direct evaluation of oxygen activities with much greater accuracy than is normally possible with conventional gas equilibration techniques. The precision of measurement in combination with the possibility of coulometric titration, which allows the composition of an oxide to be changed *in situ*, permits not only a continuous determination of oxygen activity as a function of composition, but also the composition limits of the phase itself. In spite of the potential advantages, the use of oxide electrolytes has not always led to increased accuracy in the measurement of oxygen activities. Several workers (1-4) have reported difficulties in operating cells which were stable with time, thereby necessitating the use of empirical correction factors to determine absolute compositions.

Several emf measurements (1, 3, 5-8) of oxygen activities and phase boundary composition limits for wüstite exhibit rather poor agreement with each other and do not agree with a recent composite analysis of the Fe-O system by the authors (9). Included in this composite were seven independent studies, using either CO_2/CO gas equilibration (10-13) or galvanic cell (3, 8) techniques. The composite possessed the following properties: (*i*) the partial molal free energy of oxygen ($\Delta\overline{G}_o$) in wüstite varied linearly with composition (O/Fe)[2] and temperature;[3] (*ii*) the partial molal enthalpy ($\Delta\overline{H}_o$) and entropy ($\Delta\overline{S}_o$) of oxygen varied linearly with composition and were independent of temperature. EMF or gravimetric data which deviated from this linear behavior were rejected for experimental reasons (9).

In the present paper, a critical analysis of galvanic cell techniques, which employ calcia-stabilized-zirconia (CSZ) electrolytes, is given to determine the cause for nonlinear behavior (*e.g.*, $\Delta\overline{G}_o$, $\Delta\overline{H}_o$, $\Delta\overline{S}_o$ *vs.* O/Fe) which has been reported in several emf studies on wüstite (1, 6, 7). Consideration is given to the manner in which the low-level electronic conduction (hole or electron) present in CSZ causes cell instabilities due to oxygen permeation through the electrolyte. Electronic conductivity and oxygen permeation measurements in CSZ are described and assessed as to their bearing on the proper design and operation of a cell for the study of single-phase wüstite. Results from such a properly designed cell are also reported. Finally, a critical analysis of all galvanic cell data (this and previous studies) for wüstite is given which shows that the conflicting results now in the literature can be related to experimental techniques in which cell instabilities were either ignored or improperly taken into account.

Experimental Procedure

Conductivities, oxygen permeation rates, and oxygen activities were determined using galvanic cells which employed calcia-stabilized zirconia electrolytes. The cell geometry employed in the present study is given in Fig. 1. Electrolyte pellets were fabricated from Wah Chang reactor grade ZrO_2 and reagent grade $CaCO_3$ to yield an over-all composition of 0.85 ZrO_2-0.15 CaO. The powders were dry mixed, calcined at 1000°C, hydrated [to form $Ca(OH)_2$], pressed in a ½ in. steel die, and fired in an oxygen atmosphere at 1700°C to yield

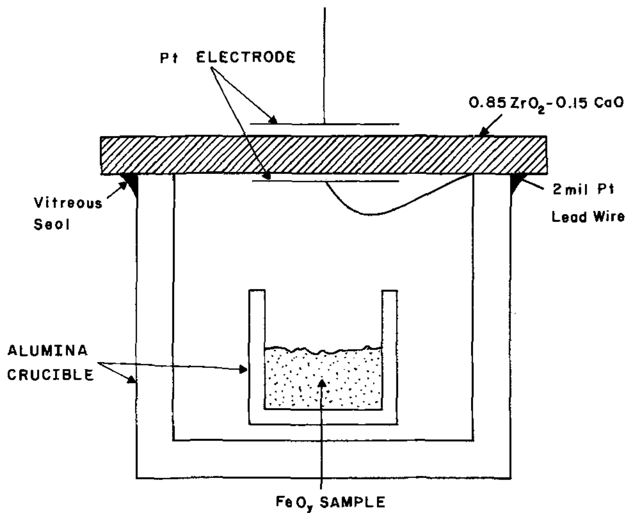

Fig. 1. Schematic of galvanic cell

[1] Present address: Metallurgy and Ceramics Laboratory, General Electric Research and Development Center, Schenectady, New York 12301.

Key words: calcia-stabilized zirconia; oxygen permeation; electron, hole, ionic conduction.

[2] O/Fe, the ratio of the number of moles of oxygen to the number of moles of iron in the wüstite phase, will be the variable to describe composition in this study.

[3] In Ref. (9) it is stated incorrectly that $\Delta\overline{G}_o$ was linear with 1/T for the composite. Actually ΔG_o is linear with *T* and log P_{O_2} is linear with 1/*T*.

pieces approximately 98% of theoretical density. The vitreous seal was prepared from a standard 0080 composition glass ground to −325 mesh. The powdered glass was painted on the crucible-electrolyte joint and, as the cell was raised to temperature, the seal formed *in situ*. Sintered Pt electrodes were used and the inner lead was brought out of the cell between the crucible and the electrolyte, through the glass seal. The electrodes were prepared from unfluxed Pt paste. The foregoing procedure permitted the production of a gas-tight cell chamber with an internal volume of approximately 0.5 cm^3 and an electrolyte area of approximately 0.4 cm^2.

Isothermal, coulometric titration experiments were performed between 965° and 1112°C using samples of loosely packed powdered iron (GAF HP carbonyl 99.6-99.9%). Sample sizes were approximately 0.08g. Cell potentials and titration currents (0.5-0.8 mA) were monitored with a Keithley 610B electrometer and measured with a L&N potentiometer (14).

Results

Due to repeated unsuccessful attempts (14) to produce cells which exhibited (timewise stable) emf's for single-phase wüstite, a thorough characterization of the conduction properties of the electrolyte was deemed necessary prior to undertaking coulometric titration studies. Characterization of the electrolyte was initiated by first determining the reversibility of the electrodes over the range of temperatures and potentials to be used in the study. Then a polarization cell was constructed to determine the magnitude of the low-level hole conductivity. Finally, the rate of oxygen permeation through the electrolyte was measured and correlated with previously determined hole conductivities. After the rate of oxygen permeation (under open-circuit conditions) was found to be of sufficient magnitude to warrant consideration, isothermal, coulometric titrations were performed on a cell containing a sample of wüstite. Corrections were made to the titration data to account for oxygen permeation; then the data were analyzed to give emf *vs.* composition relations.

Conductivity studies.—D-C ionic conductivity.—Recently, Brook, Pelzmann, and Kroger (15) reported nonohmic behavior for the cell

$$PtO_2|CSZ|O_2Pt \quad [I]$$

when operated at 520°C. They observed the current-voltage relationships to be dependent upon the preparation technique for the Pt electrodes. It was expected that electrodes prepared from unfluxed Pt paste would behave in a reversible manner if the cell was operated at temperatures over 900°C. D-C conductivity studies were performed to check the reversibility of the sintered platinum electrodes. At all temperatures between 785° and 1234°C, ohmic (*i.e.* reversible electrode) behavior was observed (14). The activation energy for the conduction process was 31 kcal/mole, a value which is in good agreement with oxygen ion transport as measured by a-c (16, 17) and tracer (18) techniques.

Hole conductivity.—Patterson, Bogren, and Rapp (19) have shown that the steady-state polarization current density in an anionic conductor (*i.e.*, CSZ) is

$$J_{ss} = K\sigma_n[\exp U - 1] + K\sigma_p[1 - \exp - U] \quad [1]$$

in which

$$K = RT/LF \quad [2]$$

and

$$U = EF/RT \quad [3]$$

E is the thermodynamic emf of the cell, L is the thickness of the electrolyte, F is the Faraday constant, σ_n and σ_p are the electron and hole conductivities for the electrolyte equilibrated with the oxygen pressure of the reversible electrode, and RT has its usual meaning.

In order to perform polarization measurements, a blocking electrode must be established. A blocking (or rectifying) electrode is one which allows current of some species to pass in only one direction. The blocking nature can be accomplished in two ways. Generally, electrodes of the polarizing type are constructed from materials which are impervious to the species for which blocking is desired (*i.e.*, O″ in CSZ); if the polarized interface is covered by the electrode, there can be no supply of the species to the interface. Patterson *et al.* (19) employed the impervious electrode technique in their use of a 2.5 mm thick Pt pellet to cover a CSZ electrolyte surface. An alternative method of accomplishing the polarizing effect is to encapsulate a reversible electrode in an environment which contains no supply of the blocked species, thereby preventing that species from entering the electrolyte.

It was decided to construct the polarization cell based on the method of encapsulation. If proper polarization behavior was obtained, it would allow calculation of the electronic conductivity as well as provide strong evidence for the integrity of the encapsulation method. If leaks were present, oxygen from the surrounding air could enter the polarized chamber and result in ohmic behavior for the current-voltage relationships. The cell used for the polarization measurements is given as

$$\text{Pt air}|\text{CSZ}|\text{Pt (encapsulated)} \quad [II]$$

Converted data, according to the method of Patterson *et al.* (19), are presented in Fig. 2 for temperatures between 932° and 1155°C. Linearity was observed between the converted current density and exp U, indicating proper polarization behavior. Values of log σ_p, calculated from the intercepts in Fig. 2 are presented as a function of the reciprocal temperature in Fig. 3 and result in an activation energy of 52.4 kcal/mole for hole conduction. Reasonably good agreement exists between the polarization data of the present study and other reported hole conductivities (19-22). In addition, these measurements indicate the technique for cell encapsulation was sufficient to provide an environment which does not suffer from mechanical leaks to an ambient air atmosphere.

Some comments should be made about potential problems which could be encountered when hot glass sealing techniques are used in cell measurements. Due to high alkali ion mobilities in glasses a possibility exists for the glass to act as a medium for direct oxygen transfer into the sample chamber. At or near the inner platinum electrode (Fig. 1) lead, oxygen ions can be oxidized and released as molecules into the sample chamber. Alkali ions would then diffuse to the high oxygen activity side (outside the cell) and the liberated electrons would pass through the short-circuiting lead wire to the outside of the cell where they would reduce other oxygen gas molecules to oxygen

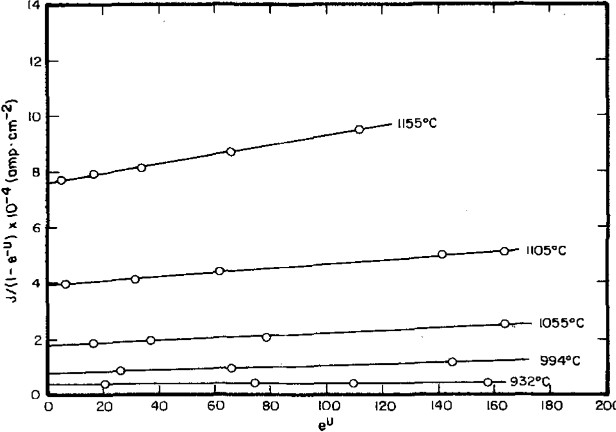

Fig. 2. Converted data for the polarization studies

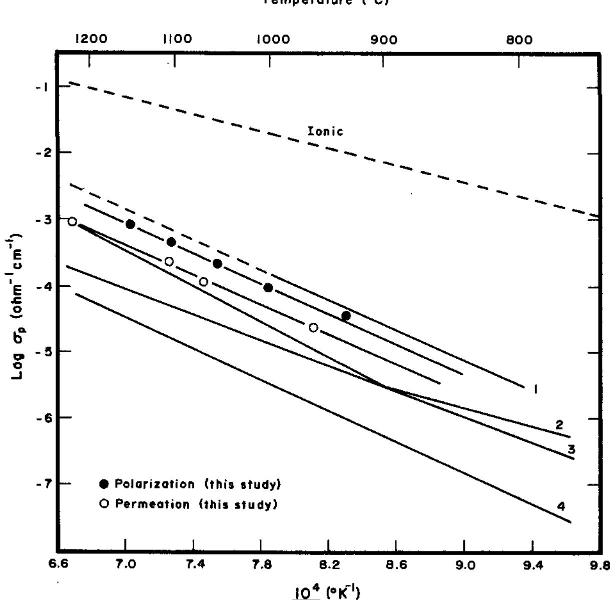

Fig. 3. Hole conductivities in calcia-stabilized zirconia: 1, Patterson, Bogren, and Rapp (19); 2, Kitazawa (22); 3, Heyne and Beekmans (21); 4, Smith, Mesaros, and Amoto (20).

ions. This process would then allow for a continuous passage of oxygen into the sample chamber at a rate controlled by alkali diffusion in the glass. In addition, if the platinum lead wire contacts the CSZ electrolyte, then a similar process would occur with the transfer of oxygen ions from the glass into the CSZ tablet and eventually oxygen molecules would be liberated at the inner electrode. The rate of this process could be governed by either alkali diffusion in the glass or oxygen ion transport in the electrolyte. Finally the type of glass which is used for the seal is also important. A glass containing only aliovalent ions should be used. Variable valent impurities (*e.g.*, Fe) should be avoided since they are easily reduced and may lead to some bulk electronic conductivity in the glass and, hence, to an internal short-circuit.

It is difficult to estimate the exact magnitude of oxygen transfer into the cell by means of the glass seal. However, some comments can be made as to the nature of the results which would be observed if oxygen permeation through the glass or through the CSZ pellet because of a lead wire short-circuit were significantly greater than direct oxygen permeation through the electrolyte. Both of these short-circuiting mechanisms should result in permeation rates with fairly low activation energies (*i.e.*, those corresponding to alkali conduction in glasses (15-18 kcal/mole) or ionic conduction in CSZ (31 kcal/mole). Since the observed permeation rate (Fig. 3) possessed a much higher activation energy (~52 kcal/mole), these short-circuiting, oxygen transport mechanisms can be discounted in the present study. Furthermore if oxygen were permeating into the cell by these processes one would expect to see ohmic behavior in the polarization measurements and not the blocking electrode behavior observed in the present study (Fig. 2).

Thus in galvanic cell studies, in which an encapsulated electrode is used, a polarization measurement is an important quality control check which will not only test for mechanical leaks and lead wire short-circuits, but it will also test the stability of the sealing medium (glass in this study).

Oxygen permeability studies.—The presence of a finite electronic conductivity in CSZ will allow oxygen to permeate through the electrolyte under open-circuit conditions. The rate of oxygen permeation will be controlled by the migration of electronic defects, either holes accompanying oxygen ion migration or electrons flowing in the opposite direction. The permeation rate (P) may be expressed in terms of the steady-state polarization current density (refer to Eq. [1])

$$P\left(\frac{\text{gO}_2}{\text{cm}^2\text{ sec}}\right) = \frac{8}{\mathbf{F}}(J_{ss}) \quad [4]$$

When the electrolyte is being operated at oxygen activities which make holes the predominant electronic species, and when cell emf's are large ($\gtrapprox$0.5V) the rate of oxygen permeation becomes a function of temperature only

$$P = \frac{8K\sigma_p}{\mathbf{F}} \quad [5]$$

Experiments (960°-1222°C) were designed to measure oxygen permeation through a zirconia electrolyte. A known amount of iron was encapsulated in a cell and an open-circuit emf was measured as a function of time. Air was used as the reference potential in order to make $\sigma_p >> \sigma_n$. For all compositions of FeO_y within the wüstite phase field, the emf was large so that Eq. 5 was applicable. The permeation rate was determined from a decay of emf with time as the sample oxidized from an over-all composition of $Fe\text{-}Fe_xO$ to $Fe_zO\text{-}Fe_3O_4$. By knowing the width of the phase field in terms of oxygen content and having measured the time necessary for the sample to oxidize across the field, a permeation rate and, hence, a hole conductivity were calculated. A typical permeation experiment at 1222°C is given in Fig. 4. Hole conductivities, which were calculated from these permeation studies, are presented in Fig. 3 and are in good agreement with those calculated from other permeation measurements (20) and with the measured hole conductivities (19, 21, 22). The high activation energy (approximately 52 kcal) for the permeation rate supports the hypothesis that the source of cell instability is an inherent electrolyte property related to electronic (hole) conductivity.

When $\sigma_n >> \sigma_p$ the rate of oxygen permeation may be taken from Eq. [4] to be

$$P = \frac{8K}{\mathbf{F}}\sigma_n[\exp U - 1] \quad [6]$$

As such, it is expected that an instability in the reverse direction (*e.g.*, the reduction of a wüstite sample by oxygen permeation controlled by electron conduction) would be present in a cell with an $Fe\text{-}Fe_xO$ reference electrode. Rizzo *et al.* (1, 5, 23) have reported instabilities in the reducing direction in studies of wüstite using cells with $Fe\text{-}Fe_xO$ reference electrodes. Electron conductivities calculated from their reported instabilities in both titration (1, 23) and open-circuit permeation (5, 23) experiments are plotted in Fig. 5. Electron conductivities reported by Patterson *et al.* (19) and by Heyne and Beekmans (21) are included

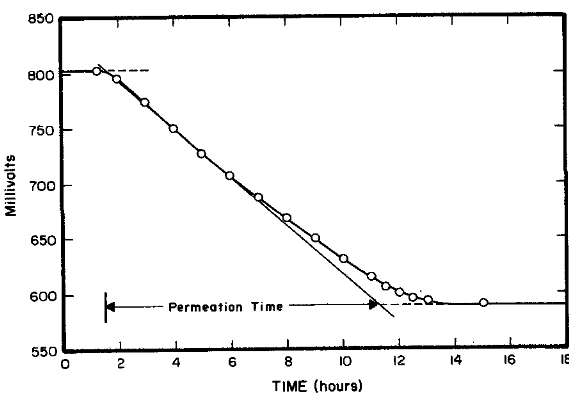

Fig. 4. EMF decay due to oxygen permeation (1222°C)

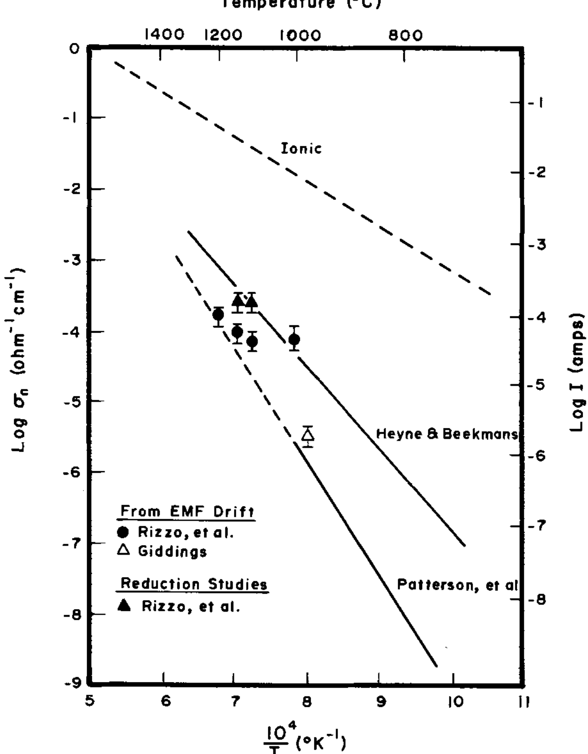

Fig. 5. Electron conductivities in calcia-stabilized zirconia for Fe-Fe_xO potentials.

in Fig. 5. Also included in Fig. 5 is one conductivity calculated from instabilities observed in preliminary work (14) for the present study using a cell similar to that employed by either Rizzo and Smith (8) or Fender and Riley (7). The good agreement between the measured electron conductivities and those calculated from cell instabilities strongly suggests that oxygen permeation in a CSZ cell with a Fe-Fe_xO reference potential is controlled by low-level electron conduction in the electrolyte.

Factors important in cell design.—In view of the foregoing results, it is now possible to make some definitive conclusions concerning the proper design and operation of galvanic cells which employ CSZ electrolytes. A standard criterion for the validity of galvanic cell operation is that the emf be stable with time. However, since electronic conductivities in CSZ are significant in magnitude, at temperatures over 900°C, continuous oxygen transfer is expected and, as such, the emf generated by a single-phase specimen would be expected to decay continuously with time. Therefore, the proper criterion for the operation of a cell should be that the magnitude and the temperature dependence of the cell instability be consistent with electronic conduction in the electrolyte.

The design of a galvanic cell for studies in single-phase, nonstoichiometric oxide systems should minimize the area of the electrolyte which is used to separate environments of differing oxygen partial pressures. Control of the maximum temperature of experimentation is another method of controlling the maximum observed oxygen permeation rate. However, temperature limitations are not always satisfactory since phenomena of interest may not occur at temperatures where permeation is insignificant.

The oxygen potential gradient (and thereby the cell potential) can be minimized by choosing a suitable reference; however, a limited number of metal-metal oxide systems exist that behave in such a manner as to allow their use as reference for galvanic cell measurements. It should be noted that a relatively small oxygen potential gradient does not always ensure small permeation rates. The rate of cell drift expected when the electronic conductivity is due primarily to electron conduction (*e.g.*, Fe-Fe_xO reference potentials) was given by Eq. [6]. The exponential dependence of the drift rate with oxygen potential gradient (*i.e.*, E) can give significant rates of transfer even at relatively low cell voltages. An alternative scale is presented in Fig. 5 to illustrate the expected electron drift currents for a cell potential of 100 mV. (The assumed geometry was 1 cm^2 of electrolyte area and an electrolyte thickness of 0.3 cm.) Drift currents in the milliamp range can be expected at temperatures over 1200°C for a 100 mV cell potential.

The final method by which errors due to oxygen permeation through the electrolyte can be minimized is by increasing sample sizes. If the size of the sample is doubled, the compositional error per unit time is halved. Increasing sample sizes has its limitations; as the sample size increases, generally so does the time necessary for the attainment of equilibrium after a coulometric titration step. Thus, the total compositional error encountered is not halved, but hopefully reduced.

Some comment should be made as to the type of experiments that can be conducted with a CSZ electrolyte in the determination of oxygen activities in single-phase systems. Isothermal titration most readily allows for the characterization of experimental error due to compositional changes encountered through oxygen permeation. If the reference potential is chosen to make hole conductivity the predominant electronic process, and if the potential gradient is sufficiently large, then only the time necessary for completion of the experiment is needed in order to define the compositional error. As the cell potential drops, the oxygen transfer rate becomes dependent upon the potential, and, as such, the time spent at any incremental cell voltage needs to be measured. EMF *vs.* temperature measurements for supposedly isocomposition conditions are, in a strict sense, impossible to perform. At low temperatures and with sufficiently large sample sizes, the condition of isocomposition can be nicely approximated. As the temperature is raised, the potential across the cell will change as will the magnitude of the electronic conductivity. In order to calculate the necessary compositional corrections, the time spent at any temperature and potential will have to be defined. Corrections of this sort are, at best, difficult to make, and as such, emf *vs.* temperature experiments becomes very poorly defined at high temperatures.

In order to calculate valid thermodynamic properties from galvanic cell measurements, the system of interest should be at equilibrium. Rigorously, a single-phase system contained in a galvanic cell which employs a calcia-stabilized zirconia electrolyte can never be at equilibrium in that oxygen is continually transferred through the electrolyte either into or out of the system. The condition of equilibrium can be approximated by having mass transport in the sample be much faster than the rate of oxygen transport into or out of the sample chamber. The requirements that transport processes in the sample be much faster than permeation processes in the electrolyte places stringent restrictions on the choice of single-phase materials which can be satisfactorily studied by galvanic cell techniques.

One advantage of coulometric titration experiments is the ability to change *in situ* the composition of a single phase by very small increments; thereby allowing isothermal emf measurements to be made across phases with narrow ranges of composition. However, in a phase with a narrow range of composition, even a small amount of oxygen permeation through the electrolyte can result in compositional changes that are a large percentage of the total range of nonstoichiometry.

Besides problems which can occur due to oxygen permeation, one must also consider the stoichiometric

stability of the materials which are used for the cell chamber. If a significant amount of oxygen can be taken up or released by the chamber wall, and the electrolyte, then compositional errors can be introduced during coulometric titration experiments. Problems of stoichiometric stability would most probably occur when studying phases of very narrow compositional ranges (*i.e.*, those in which the emf changes rapidly with small changes in composition) or when very small samples (*i.e.*, either sputtered or vapor-deposited, thin films which might be employed to help promote equilibration) are used. The double layer capacitance of the CSZ electrolyte has been found to be approximately 4 μf/cm^2 at 400°C (24). If not taken into account, such a capacitance would introduce an error of $\sim 4 \times 10^{-6}$ coulombs for a total emf change of 1V in a cell of 1 cm^2 electrolyte area. This error is insignificant for the conditions of the present study.

Isothermal coulometric titration.—Based on the criteria for satisfactory cell design developed in the previous section, a cell was designed with the intention of performing isothermal coulometric titration studies on single-phase wüstite

$$\text{Pt, FeO}_y|\text{CSZ}|\text{Air, Pt} \quad (y \text{ variable}) \qquad \text{[III]}$$

Air was used as the reference potential to insure that the electronic conductivity in the electrolyte was due primarily to hole conduction. The use of air as a reference also made the expected cell voltages sufficiently large ($\geqq$ 0.5V) so as to readily allow calculation of corrections due to oxygen permeation through the electrolyte.

Isothermal coulometric titrations were performed at six temperatures: 980°, 1015°, 1023°, 1055°, 1075°, and 1112°C. Titrations were conducted by oxidizing the sample from the $Fe\text{-}Fe_xO$ phase boundary to the $Fe_zO\text{-}Fe_3O_4$ phase boundary (*i.e.*, titration of oxygen into the sample). One isothermal experiment was conducted under both titration "in" and titration "out" conditions to check reversibility.

The oxygen permeation rate through the electrolyte was determined by measuring the rate of emf decay with time at 1118°C, and at an over-all sample composition near the iron-rich boundary. The decay was measured for 12 hr resulting in a 38 mV potential drop. The measured permeation rate corresponded to a hole conductivity in the calcia-stabilized zirconia electrolyte of 6.48×10^{-4} (ohm cm)$^{-1}$ at 1118°C in good agreement with the previous hole conductivity and permeation experiments (Fig. 3). All corrections to titration data were based on conductivities calculated from this singular drift rate measurement. Conductivities at other temperatures were calculated using an activation energy of 52.4 kcal/mole.

Data for the 1112°C titration are presented in Fig. 6. (An adjustable coulomb scale has been used in order to organize the curves on a single figure.) Included in the figure are the data for emf *vs.* coulombs taken from the measurements before and after corrections were made to compensate for the oxygen permeation through the electrolyte. Corrections made on the oxidizing titration data were based on the total time of the experiment. During a reducing titration, a potential is applied to the cell which reverses the oxygen potential gradient across the electrolyte; and as such, corrections made on the reducing titration data were based only on the time the cell was either at or coming to equilibration after a titration step. Good agreement existed between the slopes of the two corrected emf *vs.* coulomb curves, indicating the measurements were reversible and reproducible. The width of the single-phase field determined from the oxidizing titration is 29.02 coulombs which gives the reported boundary composition of 1.1575. The reducing titration indicates the width of the phase field to be 29.05 coulombs, which

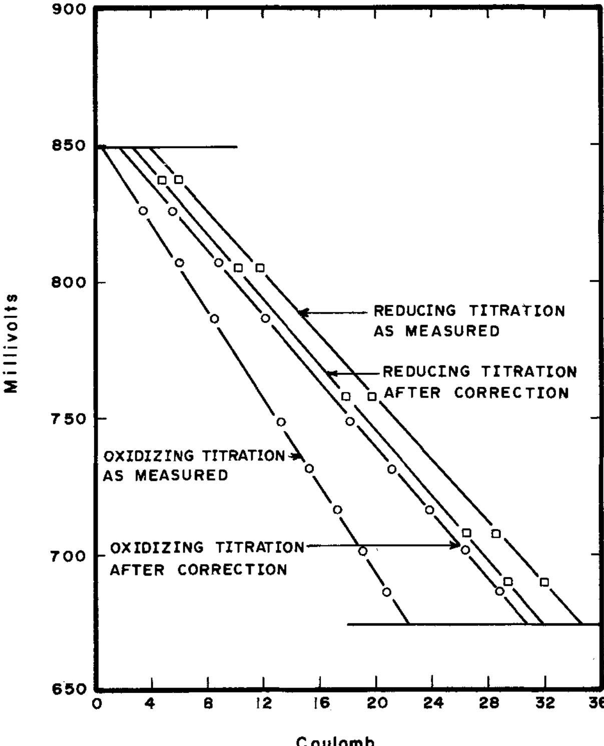

Fig. 6. Isothermal titration at 1112°C showing composition corrections.

corresponds to a composition of 1.1576 for the oxygen-rich phase boundary.

During titrations performed for this study, difficulty was encountered in precisely establishing the single-phase boundaries.[4] In order to determine compositions from the coulometric titrations, it was decided to extrapolate the observed, reproducible linear behavior for single-phase wüstite to the potentials corresponding to the $Fe\text{-}Fe_xO$ and $Fe_zO\text{-}Fe_3O_4$ two-phase equilibria. From the intersection of the lines, the coulombs needed to cross the phase field could be determined, and assuming a composition for the iron-rich boundary, compositions could be calculated for the single-phase regions as well as for the oxygen-rich boundary.

Boundary potentials were taken from the composite analysis (9) described earlier. They may be expressed as follows[5]

$$\text{Fe-Fe}_x\text{O} \qquad E(\text{mV}) = 1354 - 0.3649\, T\ (^\circ\text{K}) \qquad [7]$$

$$\text{Fe}_z\text{O-Fe}_3\text{O}_4 \qquad E(\text{mV}) = 1462 + T(0.4838 - 0.3349 \log T) \qquad [8]$$

The emf *vs.* composition data generated in this study for single-phase wüstite were analyzed in terms of a linear expression, $E = M(\text{O/Fe}) + B$ (T constant).[6] A listing of the coefficients for the emf *vs.* composition relations is presented in Table I. The lines described in Table I are shown graphically in Fig. 7. Data from other galvanic cell measurements are included in the figure and will be discussed in the next section. Included in Table I is a summary of the compositions corresponding to the wüstite oxygen-rich phase boundary as determined by extrapolating the linear single-phase behavior to the oxygen-rich potential. These compositions are in excellent agreement with the com-

[4] This problem is not uncommon in this system and has been reported in several studies (1, 10, 12). Similar problems were encountered in the permeation studies. Reference is made to the nonlinear emf time behavior at the boundaries as shown in Fig. 4.

[5] These emf's are for P_{O_2} = 0.18 atm. (Partial pressure of oxygen in air at Salt Lake City.)

[6] This behavior is consistent with a linear relation between $\Delta\overline{G}_0$ and O|Fe, which is characteristic of the composite data analysis for this system (9).

Table I. Equations describing emf vs. composition behavior

Discussion of Reported Cell Measurements

Several workers (1, 3, 5-8) have studied single-phase wüstite by using galvanic cells with CSZ electrolytes to

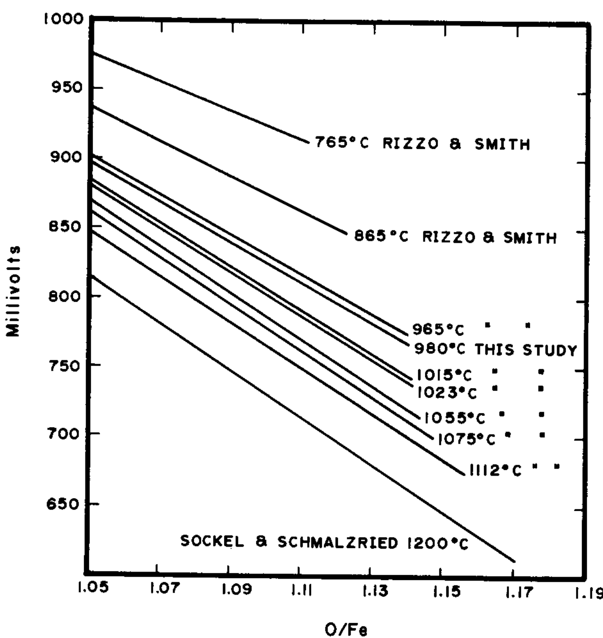

Fig. 7. Linear behavior—cell potential vs. composition

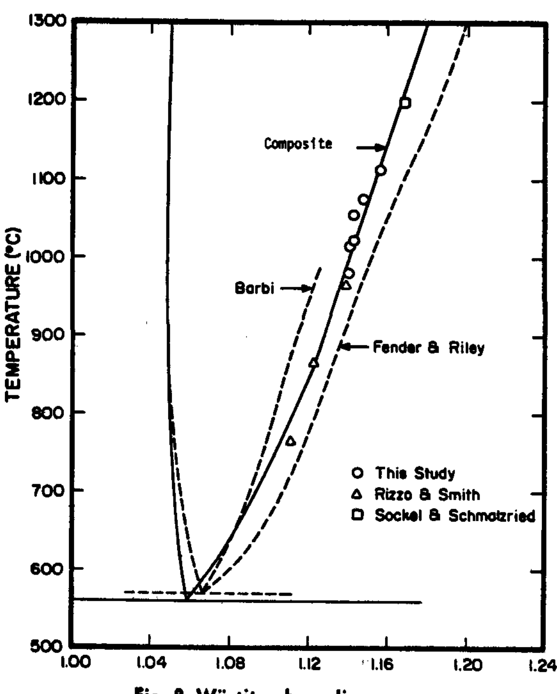

Fig. 8. Wüstite phase diagram

measure oxygen activities as a function of temperature and composition. Considerable disagreement exists between the general functional dependencies observed by some of the workers (1, 6, 7) and those reported in the composite analysis (9) and in the present study. In the present study some general criteria have been identified which must be considered when a galvanic cell with a CSZ electrolyte is used to measure oxygen activities in a single-phase, binary oxide. All of the existing oxygen activity data obtained by emf techniques will be examined critically to determine if the experimental methods employed by the various workers can account for the apparent discrepancies in the data.

Barbi (6) conducted measurements with the cell

$$\text{Pt, Fe-Fe}_x\text{O}|\text{CSZ}|\text{FeO}_y\text{, Pt} \qquad \text{[IV]}$$

He employed an experimental technique similar to that of Kiukkola and Wagner (25) in that three pellets were contained in a common sample chamber through which argon was passed in order to control the oxygen environment. EMF *vs.* temperature studies were performed, and Barbi extrapolated the single-phase, isothermal behavior to the potential corresponding to the oxygen-rich phase boundary to determine the boundary composition. A marked discrepancy exists between Barbi's oxygen potentials and oxygen-rich phase boundary compositions and those reported in the composite (9). The oxygen potentials are higher and the phase boundary (which is given in Fig. 8) is oxygen deficient.

The temperatures employed in Barbi's study ($T \leq 1000°C$) are too low for oxygen permeation to be important and as such, an explanation for the anomalous activities and boundary compositions most probably lies in the use of the flowing gas around the wüstite sample. Due to the low equilibrium oxygen pressures encountered in the iron-oxygen system (for the Fe_zO-Fe_3O_4 equilibrium, $P_{O_2} = 10^{-24}$ atm at 600°C and $P_{O_2} = 10^{-13}$ atm at 1000°C) it is doubtful whether the purity of the argon was sufficient to establish a true equilibrium between the sample and the gas phase. It is expected that the measured single-phase potentials are high due to a local oxidation of the sample by the flowing gas phase. If the measured single-phase potentials are high, then an isothermal extrapolation to a correct boundary potential will result in the boundary composition appearing oxygen-deficient relative to the correct composition.

Rizzo (23) and Rizzo *et al.* (1, 5) determined oxygen activities in single-phase wüstite as a function of temperature (1057°-1200°C) by employing Cell [III] and [IV]. Titration data taken by Rizzo using an air reference cell required no compositional corrections in that the observed emf's were stable with time, an unexpected occurrence in view of the results of the present study. An explanation for the stability can be found by examining the experimental cell geometry employed by Rizzo. Placed within the sample chamber was a zirconium metal shield which was used as an electrical ground as well as an oxygen getter to control the partial pressure of the oxygen in the argon gas flowing through the sample chamber. Stable emf's were generated by adjusting the flow rate of the argon. It is postulated that the result of the above experimental technique was a dynamic equilibrium for the wüstite sample which was not representative of a true static equilibrium condition. By adjusting the argon flow rate to give a stable emf, the sample was made to lose oxygen to the environment at a rate equal to the rate at which oxygen permeated through the electrolyte, thereby generating a steady-state situation, not a true equilibrium condition. In all of these measurements, oxygen activities higher than those in the composite were generated for compositions within single-phase wüstite.

All of the studies by Rizzo *et al.* which employed a cell of Type [IV] (where no zirconium getter was present) exhibited an instability in a reducing direction. The preceding discussion has shown the instability to be consistent with oxygen permeation (refer to Fig. 5). However, the use of a flowing gas through the sample chamber probably led to the generation of metastable results in that all of the reported activities appear to be abnormally high.

Rizzo and Smith (8) employed a cell of Type [IV] to determine the oxygen activity of wüstite as a function of composition at 765°, 865°, and 965°C. They used a cell design which encapsulated the wüstite sample in a zirconia electrolyte tube with a static vacuum environment. Due to the low temperatures employed, the massive sample sizes (approximately 10 times larger than the samples used in the present study), and the low magnitude of the electron conductivity in the electrolyte when Fe-Fe_xO is used as a reference at these temperatures cell emf's would be expected to be stable with time. The linearity in the emf *vs.* composition reported by Rizzo and Smith is consistent with the behavior observed in the present study and the composite analysis. The oxygen-rich phase boundary compositions for wüstite, which are shown in Fig. 8, are in good agreement with those calculated from the composite.

Using a cell similar to that of Rizzo and Smith, Fender and Riley (7) measured oxygen activities in single-phase wüstite. They reported nonlinearity in their isocomposition, emf *vs.* temperature data. The nonlinearity was interpreted in terms of linearity over limited temperature ranges, each separated by a definite break in the slope of the emf-temperature curve. The breaks in slope were attributed to second or higher order phase changes occurring within wüstite and similar to those reported by Kleman (26). Boundary compositions for the oxygen-rich boundary of wüstite were determined by extrapolating the single-phase, isothermal behavior to the boundary potentials. These compositions, which are plotted in Fig. 8, are in marked disagreement with the compositions reported in the composite and in other cell studies (3, 8), and are a direct result of the breaks in the emf *vs.* temperature data. These breaks to lower cell emf's as the temperature increases are consistent with data that would be generated by a cell instability in the reducing direction.

Fender and Riley reported that their cell was cycled over a temperature range between 700° and 1300°C for several days with a reproducibility of better than ± 1 mV. The extreme precision claimed by these workers is difficult to comprehend. At the higher temperatures (> 900°-1000°C), one would expect substantial drift currents due to electron conduction in the electrolyte. (The reader is referred to Fig. 5 for an indication of the expected magnitude of such currents.) It should be noted that the curvature in the emf *vs.* temperature data of Fender and Riley was more pronounced both as the temperature and the cell potential were increased. Both of these effects are consistent with an increased oxygen permeation rate through the CSZ electrolyte which is controlled by low-level electron conduction, and, hence, a reduction of the sample. Fender and Riley report that no drift in cell emf was observed at temperatures up to 1350°C, a remarkable result when compared with the results of the present study and those of Sockel and Schmalzried (3).

Sockel and Schmalzried (3) measured the oxygen activity of wüstite as a function of composition by performing an isothermal titration at 1200°C using a cell of Type [III]. Their experiment was conducted by equilibrating the sample via the gas phase in a static N_2 environment (a procedure similar to the method employed in the present study). Compositional corrections were made on the raw data to account for cell instability (*i.e.*, drift), although no explanation was offered as to the source of the drift. After compositional corrections were made, the emf was found to be linear with composition. The data of Sockel and Schmalzried are presented in Fig. 7, and the composition of the oxygen-rich phase boundary, determined from their measurement, is shown in Fig. 8. Excellent agreement exists between these data and the composite, both with respect to single-phase activities and the composition of the oxygen-rich boundary.

Conclusions

The problem of cell instability is one which has arisen frequently in the application of galvanic cells to the study of oxygen activities in single-phase oxide systems. Even where careful consideration was given to experimental procedures to ensure an equilibrium environment, galvanic cells have generated emf's which were unstable with time. A cause of cell instability has been identified to be oxygen permeation through the electrolyte (*i.e.*, 0.85 ZrO_2-0.15 CaO). The rate of permeation is controlled by low-level hole or electron conduction which is present in the ionic conducting range of the electrolyte.

The identification of oxygen permeation as a source of cell instability provides an important insight into the application of galvanic cells for the study of single-phase compounds. In order to perform reliable measurements of oxygen activities, the effect of oxygen permeation through the electrolyte must be minimized (*i.e.*, low temperatures and large sample sizes) or else the rate of oxygen permeation must be characterized quantitatively so that the composition of the single-phase compound can be determined accurately.

Galvanic cell measurements of oxygen activities in single-phase wüstite (for which the oxygen permeation rate through the CSZ electrolyte was characterized) indicate that the cell emf was a linear function of composition between 980° and 1112°C. A critical analysis of all the reported galvanic cell work in wüstite also revealed the cell emf was a linear function of composition between 765° and 1200°C. The oxygen-rich phase boundary compositions of wüstite which were determined by galvanic cell measurements are essentially those reported in a recent composite analysis and reported originally by Darken and Gurry (10). Those galvanic cell studies in which nonlinear behavior was observed or phase boundary compositions differed markedly from those of the composite are those in which either a static environment was not provided in the sample chamber or else the effect of oxygen permeation through the electrolyte was not properly taken into account. No evidence was found in the present study to support the existence of more than one-phase or second-order transitions within the wüstite phase. as reported by Kleman and Fender and Riley.

Effects of Diffusion on Aluminum Depletion and Degradation of NiAl Coatings

ABSTRACT

Experiments were performed to critically demonstrate the effects of diffusion on the aluminum depletion and degradation of NiAl coatings on superalloys. Pack aluminized IN 100 and Mar-M200 were diffusion annealed in 5×10^{-3} Torr vacuum at 1100°C for 300 hr. Aluminum losses due to oxidation and vaporization were minimal. Metallographic and electron microprobe analyses showed considerable interdiffusion of the coating with the substrate, which caused a large decrease in the original aluminum level of the coating. Subsequent cyclic furnace oxidation tests were performed at 1100°C using 1 hr cycles on prediffused and as-coated specimens. The prediffusion treatment decreased the oxidation protection for both alloys, but more dramatically for IN 100. Identical oxidation tests of bulk NiAl, where such diffusion effects are precluded, showed no signs of degradation at twice the time needed to degrade the coated superalloys. These results, plus limited tests showing the reduced oxidation resistance of aluminum-poor NiAl, suggest a degradation model whereby the coating is first depleted of aluminum by diffusion, as opposed to Al_2O_3 spalling, then rapidly degraded by the formation of spall-prone oxides.

As aircraft gas turbine inlet temperatures have increased, blade materials have been coated to reduce the adverse effects of oxidation. Recent advances in directionally solidified eutectics will allow even higher blade temperatures (~1100°C) and require greater protection from coatings. It has been shown, however, that current NiAl coatings fail during cyclic oxidation at 1100°C in times less than ~1000 hr (1, 2).

The failure of the coating is generally assumed to result from the alternate formation and spalling of an Al_2O_3 film during cyclic oxidation (3-7). Repetition of these processes leads to aluminum depletion and a resultant acceleration of oxidation. That aluminum is removed from the coating is an often demonstrated fact. But that this is a result of the initial oxidation and Al_2O_3 spalling has not been conclusively proven. An alternative process is possible: the aluminum concentration of the coating may first be diluted by interdiffusion with the substrate. This possibility is raised because bulk NiAl does not appear to suffer from cyclic oxidation as severely as NiAl coatings on superalloys (8).

Key words: coatings, superalloys, oxidation, spalling.

It is important to determine which mechanism controls coating breakdown if improvements are to be sought. If spalling of Al_2O_3 controls, then coatings research should endeavor to reduce the growth rate of Al_2O_3 and improve scale adherence. If, on the other hand, diffusion is the predominant mechanism, then coatings research should be directed toward minimizing diffusion.

The purpose of this investigation was to determine the relative importance of diffusion and Al_2O_3 scale spallation to coating breakdown. To achieve this goal, pack aluminized IN 100[1] and Mar-M200[2] were vacuum annealed at 1100°C to allow diffusion to proceed inde-

[1] 0.18 C, 10 Cr, 15 Co, 3 Mo, 5 Ti, 5.5 Al, 1 V, balance Ni.
[2] 0.15 C, 9 Cr, 10 Co, 12.5 W, 1 Nb, 2 Ti, 5 Al, balance Ni.

pendently of oxidation. As-coated and as-diffused coatings were compared before and after cyclic furnace oxidation at 1100°C. The as-coated specimens were also compared to thin samples of bulk NiAl in 1100°C oxidation. The extent of degradation was judged by specific weight change, metallography, and electron microprobe analyses.

Materials and Procedure

Cast coupons of IN 100 were cut into 1.3 × 2.5 × 0.25 cm test specimens. A directionally solidified bar of Mar-M200 was cut into 0.6 × 2.5 × 0.25 cm test specimens. Holes 0.3 cm diam were spark cut in one end of the specimens for subsequent hanging in furnace oxidation tests. The specimens were prepared for coating by vapor-blasting with alumina grit and rinsing in trichloroethylene, then in ethyl alcohol.

Bulk NiAl alloys ranging from 35 to 50 atom per cent (a/o) aluminum were arc-melted into 50g buttons from high purity (99.99%) nickel and aluminum. Thin ($\sim 200\mu$) oxidation specimens of stoichiometric NiAl were produced by mounting and hand grinding slices of the button. Specimens of various hypostoichiometric compositions were sectioned into 0.25 cm thick slices.

Coating of the superalloys was accomplished by a pack aluminizing process described elsewhere (9). Briefly, the pack process consists of heating the specimens to 1100°C for 16 hr in a pack of 98 weight per cent (w/o) Al_2O_3 filler, 1 w/o Al, and 1 w/o NaCl activator. Flushing the pack with argon at 0.5 liter/min prevented oxidation during aluminizing. Variations in the coating weight occurred from specimen to specimen. The limits for IN 100 specimens were 15.9-19.5 mg/cm^2 of aluminum; and the limits for Mar-M200 specimens were 19.8-23.3 mg/cm^2.

Diffusion annealing of the coated specimens was performed in a vacuum tube furnace at 1100°C for 300 hr. The coated specimens were first preoxidized in 1100°C air for 2 hr in order to form an Al_2O_3 film. This was needed to prevent vaporization of the coating during vacuum annealing. A moderate vacuum of 5×10^{-3} Torr also prevented gross aluminum depletion of the coating by curtailing both vaporization and oxidation. A weight gain often occurred for both the preoxidation and vacuum annealing treatments (0.8 mg/cm^2 total max). Since primarily Al_2O_3 was formed, a mass balance calculation could be performed to determine the actual amount of aluminum lost. This loss was found to be 0.9 mg/cm^2 or only 4% of the aluminum deposited during aluminizing.

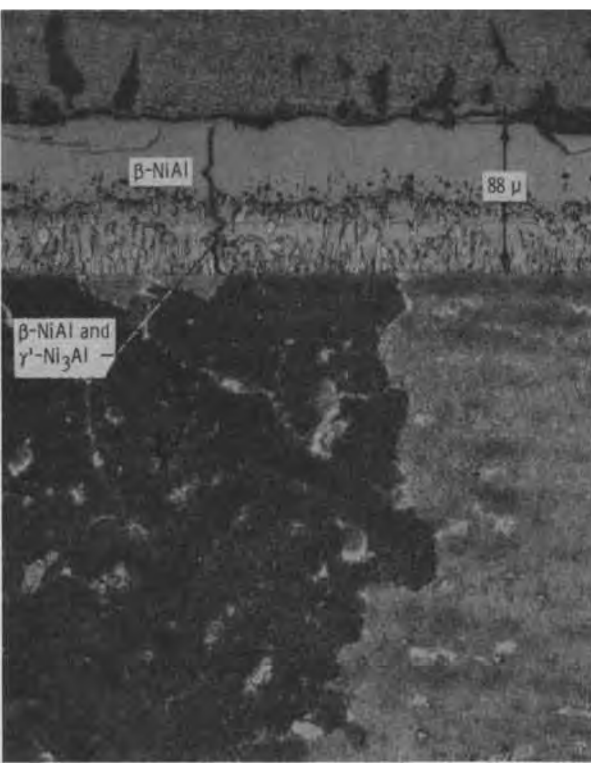
The possibility of vaporization losses through the Al_2O_3 film during annealing was also considered. The major gaseous species over alumina at these conditions would be AlO_2, with a vapor pressure less than 10^{-18} atm and an aluminum loss rate less than 10^{-14} mg/(cm^2·sec), (10^{-8} mg/cm^2 for a 300-hr anneal).

Cyclic oxidation testing was performed at 1100° and 1200°C in vertical-tube resistance furnaces with a hot zone of 30 cm. Specimens were suspended by platinum wire hangers attached to a pneumatic cylinder. They were automatically lowered into and raised out of the furnaces by means of an electronic timer/solenoid switch/pneumatic pump arrangement as described in Ref. (8). For 1100°C tests one cycle consisted of 1 hr in the hot zone followed by 1/3 hr in room air. For 1200°C tests one cycle consisted of 1/10 hr in the hot zone followed by 1/6 hr in room air. Nominal heating and cooling rates were 20°C/sec and 10°C/sec, respectively. Specimens were weighed every 15 hr on an analytical balance accurate to 0.2 mg.

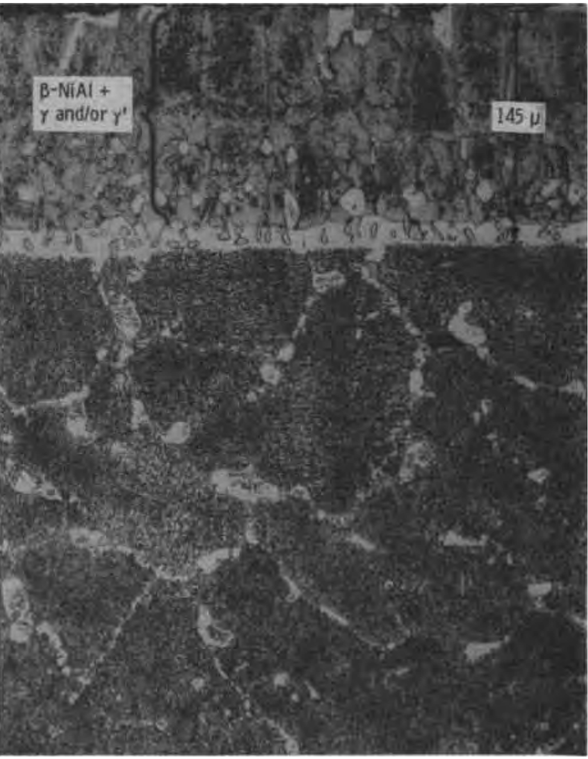
Post-test analyses consisted of surface x-ray diffraction, metallography, and electron microprobe. *In situ* surface scales were identified by diffractometer scans using Cu K_α radiation with a LiF monochromator. Metallographic specimens were copper-plated before standard mounting and polishing. Etching was accomplished by immersion in a 33% H_2O-33% CH_3OOH-33% HNO_3-1% HF solution. Microprobe analyses of the polished cross sections were performed with a 15 kV, 30 nA electron beam integrated over a 40μ wide path.

Results and Discussion

Pack aluminized IN 100.—Diffusion annealing of pack-coated IN 100 at 1100°C for 300 hr produced some very definite effects. Figure 1 shows a striking change



a. As-coated IN 100



b. Diffusion annealed for 300 hr at 1100°C

Fig. 1. Effect of diffusion on coating structure of aluminized IN 100. X250.

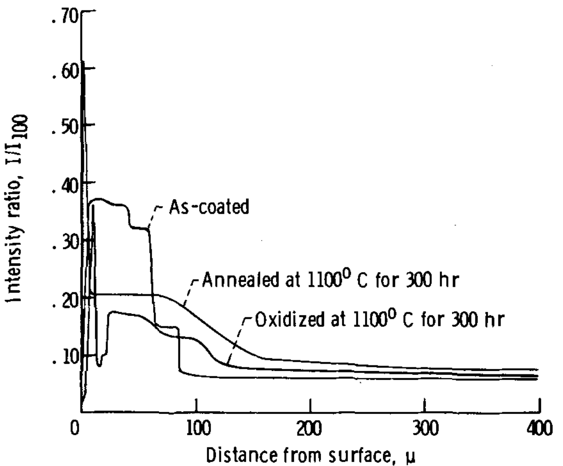


Fig. 2. Aluminum microprobe profiles for pack aluminized IN 100.

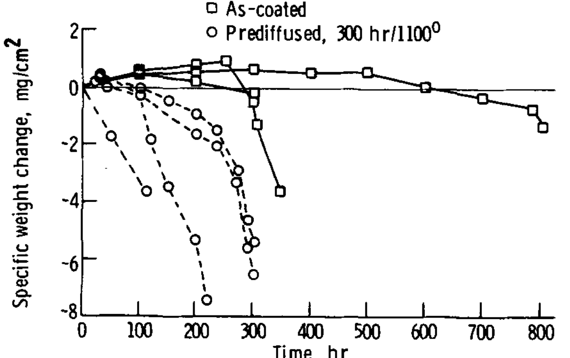

Fig. 3. Effect of diffusion on the oxidation of pack aluminized IN 100. (1100°C, 1 hr cycle furnace tests.)

in coating structure and an increase in over-all coating thickness of 65%. X-ray diffractometer scans identified β-NiAl as the major coating phase for both as-coated and as-annealed coatings. Other phases in the annealed coating were identified as γ-Ni and/or γ'-Ni_3Al. These phases probably corresponded to the light-etching phases and fine precipitates in the coating, as shown in Fig. 1b. Annealing also formed α-Al_2O_3 plus some TiO_2 (rutile) surface scales.

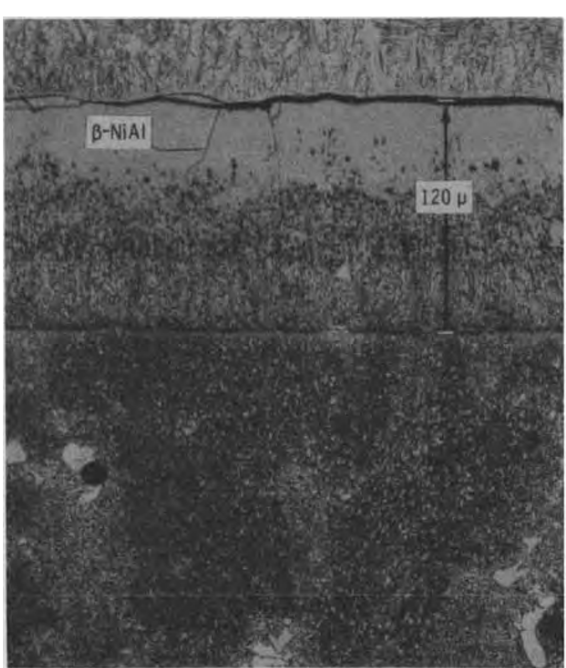
Microprobe profiles for aluminum (Fig. 2) showed that the diffusion annealing treatment decreased the maximum aluminum intensity level in the coating by 40% of the as-coated value and increased the coating thickness by ~60%. (An Al_2O_3 film is indicated by the sharp peaks at the surface.) Similar effects occurred for the specimen cyclicly oxidized (1 hr cycles) at the same temperature for the same amount of time. Here the maximum aluminum intensity level was decreased by 54% of the as-coated value, and a 10μ surface depletion zone occurred due to oxidation. This implies that depletion of aluminum, the accepted cause of failure for NiAl coatings, occurs to a large extent by interdiffusion with the substrate, in addition to the repeated spalling and formation of an oxide film.

The cyclic oxidation behavior of the diffusion annealed specimens was markedly poorer than that of the as-coated specimens (Fig. 3). On the average, diffusion annealed specimens showed a negative weight change (an indication of spalling) at 50 hr, compared to 380 hr for specimens with no preannealing treatment. While considerable scatter in the data exists, the two scatter bands are separable to a significant extent.

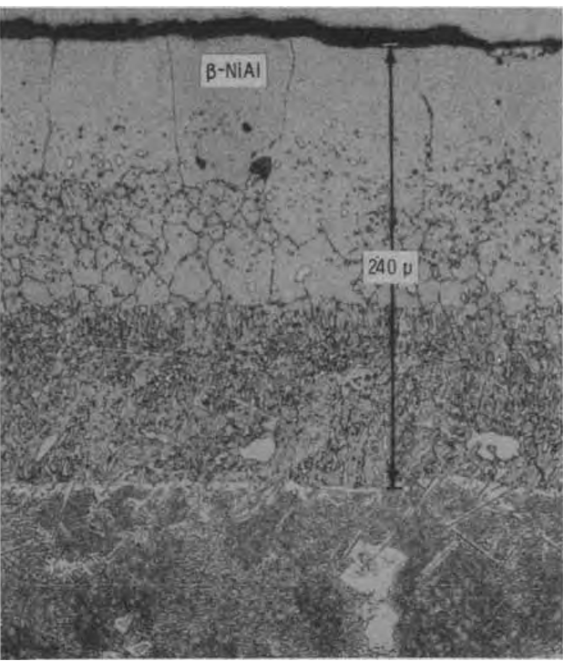
Pack aluminized Mar-M200.—Diffusion also affected NiAl coatings on Mar-M200, though not so adversely in oxidation testing. The microstructures in Fig. 4 show that the 1100°C/300 hr diffusion annealing actually doubled the coating thickness. X-ray diffractometer scans showed that β-NiAl was still the only coating surface phase after annealing.

The microprobe profiles in Fig. 5 show that 1100°C/300 hr diffusion annealing reduced the maximum aluminum intensity level by 48% of the as-coated value and indeed doubled the coating thickness. Cyclic oxidation (1 hr cycles) at the same temperature for 700 hr had the same effect on the aluminum profile. No additional effects of oxidation, such as a surface depletion zone, were apparent.

The gravimetric data in Fig. 6 shows that diffusion annealing was not so degrading for coated Mar-M200 oxidation behavior as it was for IN 100. The average oxidation time needed to produce a negative weight change was 270 hr for diffusion annealed specimens compared to 520 hr for as-coated specimens. Thus,



a. As-coated Mar-M200



b. Diffusion annealed for 300 hr at 1100°C

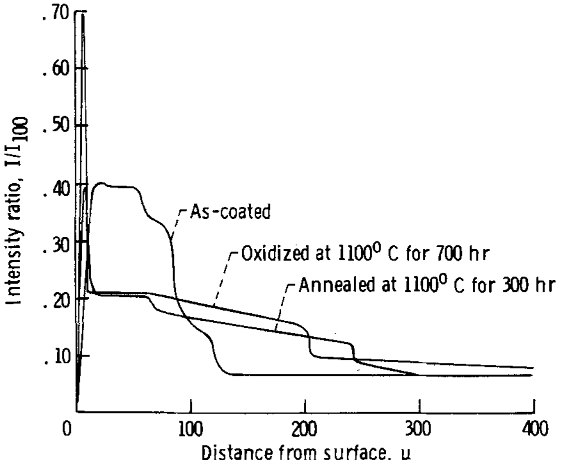

Fig. 5. Aluminum microprobe profiles for pack aluminized Mar-M200.

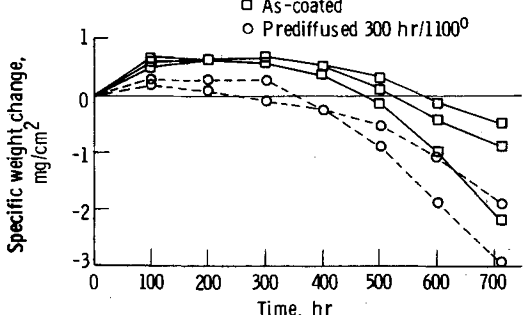

Fig. 6. Effect of diffusion on the oxidation of pack aluminized Mar-M200. (1100°C, 1 hr cycle furnace tests.)

while acknowledging the scatter, the effect of preannealing was apparent. The improved behavior of annealed Mar-M200 coatings compared to the annealed IN 100 coatings may be due to the 36% heavier coatings originally deposited (or 66% thicker coatings after annealing). The result was that the coated Mar-M200 was more protective, on the average, than coated IN 100. Thus the 300 hr preannealing treatment represented a smaller fraction of the coating "lifetime," and was therefore less harmful, for Mar-M200 than for IN 100.

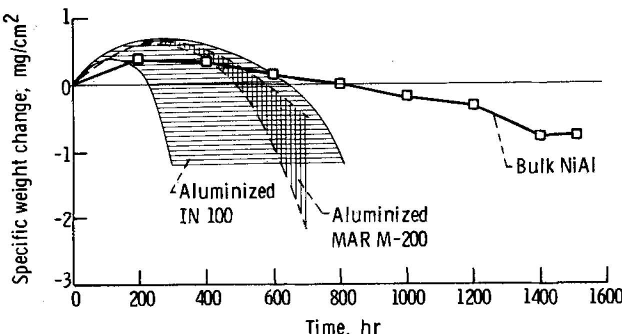

Fig. 7. Comparison of NiAl-coated superalloys with bulk NiAl. (1100°C, 1 hr cycle furnace tests.)

Comparison of bulk NiAl with coated superalloys.—Two thin specimens of bulk stoichiometric NiAl were oxidized under the same conditions as IN 100 and Mar-M200. The thickness used (200μ) was intended to contain no more aluminum per exposed area than the NiAl coatings on the superalloys; *i.e.*, it approximated two coatings back-to-back. Yet the cyclic oxidation resistance was markedly better than either coated IN 100 or Mar-M200, as shown in Fig. 7. The average time for a negative weight change was 800 hr for NiAl compared to 380 and 520 hr for the coated superalloys. Even after 1500 hr of oxidation the bulk NiAl had not yet lost 1 mg/cm². More importantly, the rate of spalling, as indicated by these curves, was only half that for the coated superalloys even at twice the oxidation time.

X-ray diffractometer scans of the bulk NiAl surface identified only β-NiAl and Al_2O_3. However, on coated IN 100 the identified surface phases were Al_2O_3, spinel (a_o = 8.10Å), TiO_2, and γ and/or γ'; and coated Mar-M200 surface phases were Al_2O_3, γ and/or γ', and some NiAl (800 and 700 hr data for the least spalling specimens of IN 100 and Mar-M200, respectively).

No surface depletion or secondary phases were observed metallographically for bulk NiAl, despite considerable efforts at etching (Fig. 8). However the most

b. Pack coated IN 100 after 800 hr

c. Pack coated Mar-M200 after 700 hr

Fig. 8. Comparative degradation of bulk NiAl and aluminized superalloys, oxidized in 1100°C furnace tests, 1 hr cycles. Etched. X250

spall-resistant coated IN 100 and Mar-M200 specimens exhibited martensitic NiAl and γ or γ', indicating a decrease in the aluminum content of the coating from about 50 a/o to at least 37 a/o (6, 10).

Microprobe data on these specimens also bears this out (Fig. 9): virtually no depletion zone was apparent for the pure NiAl specimen, and the over-all aluminum intensity level was reduced by only ~16% of its original value. In comparison the aluminum intensity level for the coated superalloys was reduced by ~49% of the original value.

Since the thin NiAl specimens can be considered simply as a coating without the interdiffusional effects of a substrate, it is apparent that significant gains in coating oxidation life could be obtained by limiting interdiffusion with the superalloy substrates. This harmful interdiffusion may involve both the inward diffusion of aluminum and outward diffusion of nickel as well as the "contamination" of the coating by the substrate alloying elements.

Degradation model.—At this point it was clear that diffusion processes were effective mechanisms in initiating coating breakdown. The data also suggest that complete conversion to Ni_3Al is not necessary for rapid oxidation and spalling to occur, *i.e.*, accelerated oxidation was noted for aluminum-depleted β-NiAl. In order to confirm this behavior, supplementary oxidation tests were performed on aluminum-poor compositions of bulk NiAl. An accelerated 1200°C test with a high cycle frequency (0.10 hr) was used to provide easy differentiation between alloys. The gravimetric data in Fig. 10 show that, indeed, spalling was more pronounced for compositions having less than ~40 a/o aluminum. No gradual trend with composition was observed, rather the gravimetric curves fell into two bands. Metallographic and x-ray diffraction analyses showed that only Al_2O_3 was formed and no depletion zone occurred for the low-spalling alloys, while Al_2O_3 and spinel oxides formed and a 50μ γ/γ' depletion zone occurred for the high-spalling alloys. Similar compositional effects can probably be expected for 1100°C/1 hr cycle testing, but the test times needed would be much longer. [These data are consistent with isothermal work in the Ni-Al system (11). The experiments in this work indicated that the critical amount of aluminum needed for exclusive Al_2O_3 formation lies between 30 and 40 a/o at this temperature.]

Taking the above data into account along with the previously discussed effects of diffusion, it appears that aluminide coating degradation at 1100°C follows this sequence. First the aluminum level is significantly decreased due to diffusion and to a lesser extent by repeated Al_2O_3 spalling. Only after the aluminum content of β-NiAl decreases to where spinel oxides form does oxide spalling becomes the predominant cause of aluminum loss. Surface depletion zones of γ/γ' soon follow, with the final stages of degradation being the same as for previously reported models. Thus, while diffusion may not account for most of the aluminum lost in a severely degraded coating, it is responsible for the initiation of the coating degradation process.

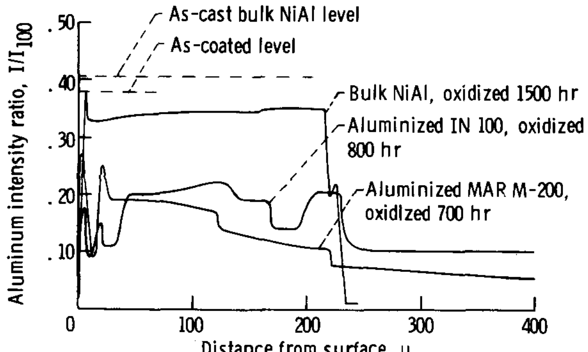

Fig. 9. Comparison of aluminum depletion for bulk NiAl and coated superalloys after cyclic oxidation at 1100°C.

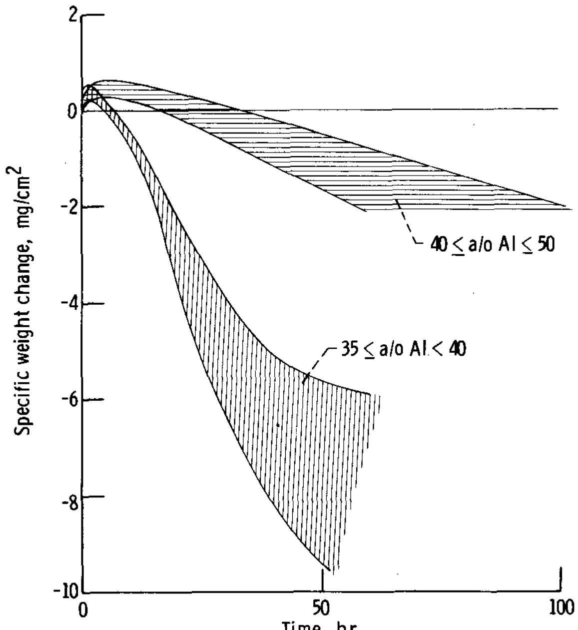

Fig. 10. Effect of composition on cyclic oxidation behavior of bulk NiAl. (1200°C, 1/10 hr cycle furnace tests.)

Admittedly diffusion may play a less important role at temperatures below 1100°C. The activation energy for Al_2O_3 growth was calculated to be about 30 kcal/mole from Arrhenius plots of the parabolic rate constant for Ni-42 a/o Al (11). This is less than the 55 kcal/mole for self-diffusion in Ni-38 a/o Al (12). This implies that diffusion will become less significant relative to Al_2O_3 growth at lower temperatures. However it is difficult to predict the actual temperature at which diffusion is no longer the controlling mechanism for aluminum loss.

Concluding Remarks

Based on a comparison of bulk NiAl and diffusion annealed coatings with as-coated superalloys in 1100°C cyclic oxidation, the following conclusions appear justified: (*i*) loss of aluminum in the coating by diffusion with the substrate triggers coating degradation rather than spallation of Al_2O_3 alone; and (*ii*) this loss of aluminum allows oxides other than Al_2O_3 to form with an increased rate of spalling, which leads to rapid coating failure. Thus the long-time use of NiAl coatings at 1100°C will require a reduction of coating/substrate interdiffusion, possibly by the use of diffusion barriers.

ABSTRACT

Ellipsometric results presented in this paper show that it is possible to grow a uniform Nb oxide film by plasma oxidation, and the index of refraction of this Nb oxide is 2.30. Similarly, in a previous paper we showed that plasma oxidation of Ta produced a uniform Ta oxide film with a refractive index of 2.21. These results are in contrast to the earlier work of Lee *et al.*, who fitted their ellipsometric measurements on the plasma oxidation of Nb and Ta with two-layer models. It is shown that the Nb and Ta oxides in the work of Lee *et al.* were not grown to a sufficient thickness to prove definitively that the oxides were composed of two layers, and that their data can be fitted equally well with one-layer models.

In this paper we would like to report on an ellipsometric study of the plasma oxidation of niobium. In a previous paper (1) we reported on a similar study on tantalum. In these studies we have found that it is possible to grow uniform oxides on niobium and tantalum by plasma oxidation. In contrast, Lee *et al.* (2), in the only previous ellipsometric study of the plasma oxidation of tantalum and niobium, reported that their data were consistent with two-layer oxides. In order to investigate this difference in interpretation, we have performed two-layer calculations on ellipsometric data. It is shown that the Nb and Ta oxides in the work of Lee *et al.* were not grown to a sufficient thickness to prove definitively that the oxides were composed of two layers, and it is also shown that their data can be fitted equally well with one-layer models.

Experimental Procedures

Since the experimental arrangement and procedures have been described in detail in the earlier article on the plasma oxidation of Ta (1), only a brief description will be given here.

The plasma oxidation is carried out in a metal high vacuum chamber which can be evacuated to 10^{-7} Torr during sample cleaning or held at a pressure of 0.05 Torr of oxygen under flow conditions while the sample is being oxidized. The vacuum chamber has two optical windows located so that *in situ* ellipsometric measurements can be carried out during the plasma oxidation. The ellipsometer (3) used is automated and is capable of taking a reading per second. It utilizes a He-Ne laser ($\lambda = 6328Å$) as a light source, the angle of incidence is 59.5°, and the angular resolution of the polarizer null, P, or analyzer null, A, is 0.01°.

With the ellipsometer it was possible to test various treatments of the surface of the sample to find the one that gave the cleanest surface possible prior to growth of the plasma oxide. The criterion used was that the best surface treatment should produce the highest P value possible and a stable A value, since a dirty surface layer would act primarily to reduce the P reading from its true clean surface value and by a much smaller amount lower or raise the A reading depending on whether the surface layer was absorbing or nonabsorbing, respectively. As in the case of Ta (1), the best treatment was found to consist of heating the sample to a white heat in vacuum. This was accomplished by having the sample in the form of a foil, 0.1 mm thick, and passing a large current through it while it was in the high vacuum chamber at a pressure of 10^{-7} Torr. Typically this heat-treatment gave P,A readings of 30.0° and 34.7°, respectively.

The cleaned sample had a wire spotwelded to it for supplying the drive current for the plasma oxidation and then the sample was mounted in place for the optical measurements with mica sheets. The top mica sheet had a hole, 9 × 18 mm, which defined the active area of the sample on which the oxide was formed. The glow discharge cathode, which is a 10 × 4 × 0.5 cm piece of Al covered with 0.1 mm Ta foil, is located 8 cm away from the sample with its 40 cm² front surface facing the sample. A Au probe located close to the sample was used to measure the voltage of the plasma adjacent to the sample.

With the sample mounted, the system was pumped down and then argon gas was admitted to a pressure of 0.05 Torr and a short glow cleaning was employed, by putting −400V on the glow discharge cathode. This ensured that no water or dust particles were in the sample, and changed the P,A readings by only 0.1°. The argon gas was then pumped out of the chamber, and the system was flushed several times with oxygen to ensure that all the argon was removed. A pressure of 0.05 Torr of oxygen under flow conditions was established, −1000V were applied to the glow discharge cathode, and a constant drive current of 10 mA was injected into the sample to initiate the plasma oxidation.

Key words: ellipsometry, refractive index.

During the plasma oxidation the P,A readings were displayed digitally by the automatic ellipsometer and were recorded. In addition, the digital P,A readings were converted to analog signals so that the curve in the P,A plane could be plotted directly on an X-Y recorder during the experimental run. The voltage of the sample and the voltage of the nearby Au probe in the plasma were measured and recorded during a run. The output of a digital clock, together with the constant value of the drive current being supplied to the sample, allowed the total charge q passed through the sample to be measured. Normally P,A readings were taken for a period of 20,000 sec to grow 1500Å of oxide, and with a time of approximately 5 sec to take a P and A reading we ended with 4000 P,A points to characterize a run.

Nb Results and Discussion

The quarter-wave plate used in the phase delay section of the ellipsometer was measured and found to have a phase delay of 89.6° and a fast-slow axis transmission ratio of 1. These values were used to convert the P,A readings into the standard quantities Δ and ψ. [If the phase delay had been exactly 90°, the conversion would be $\Delta = 2P + 90°$ and $\psi = A$, but the slightly different value of the phase delay modifies this conversion very slightly, but in a well-known way (4). The quantities Δ and ψ are defined by $\Delta = \arg R_p/R_s$ and $\tan \psi = |R_p/R_s|$ (5), where R_p and R_s are the complex reflectivities for the light in and perpendicular to the plane of incidence, respectively.] In Fig. 1, we present our ellipsometric results on the plasma oxidation of Nb in the form of a plot of Δ *vs.* ψ. Our experimental data are presented as a solid line through the approximately 4000 data points defining the curve. The scattter of the data is within the thickness of the solid line. The dashed line near the maximum in ψ denotes the experimental region where the P nulls are so broad that the Δ values are not well defined, but the A nulls remain quite sharp so that the ψ values are accurately known.

To get the best fit to our ellipsometric data on the plasma oxidation of Nb shown in Fig. 1, we had to shift our bare surface P value from the experimentally measured value of 30.0° to 30.8° while leaving our bare surface A value at the experimentally measured value of 34.7°. This shift in the bare surface value of P by 0.8° corresponds to assuming that our surface treatment of the Nb sample left a 12Å layer of Nb oxide, which is certainly reasonable since a thin layer of thermal oxide would form spontaneously as soon as the heated-out foil was first exposed to oxygen. Using initial P,A values of 30.8° and 34.7°, respectively, the index of refraction of Nb at 6328Å is found to be 3.0 − i3.6.

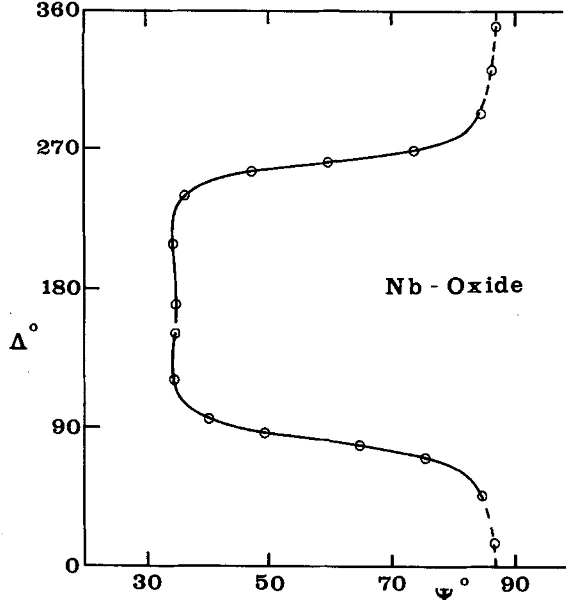

Fig. 1. Ellipsometric results for the plasma oxidation of Nb. The solid curve is the experimental results and the open circles denote the theoretical fit obtained using a refractive index of 2.30 for the Nb oxide. Experimental conditions: sample area 162 mm^2, constant drive current 10 mA, oxygen pressure 0.05 Torr, cathode voltage −1000V, wavelength 6328Å, and angle of incidence 59.5°. Bare-surface values: $\Delta_0 = 151.60°$ and $\psi_0 = 34.64°$.

The data of Fig. 1 could be fitted with an oxide of constant, real index of refraction of 2.30 growing on the bare Nb surface with initial Δ,ψ values of 151.60° and 34.64°, respectively. The theoretical fit obtained with this index is shown in Fig. 1 as a series of open circles. This fit was obtained two ways. First, theoretical P,A curves were generated by varying the index of refraction of the oxide in a standard ellipsometer program (4) while keeping all other parameters fixed, and a visual fit was determined by superimposing these theoretical P,A curves plotted on one sheet of paper on the experimental P,A curve plotted on another sheet of paper. The visual fitting procedure was checked later by an automatic nonlinear least squares fitting ellipsometer program which obtained the best fit between the experimental and theoretical curves by adjusting the real and imaginary parts of the index of refraction of the oxide film to minimize the least squares deviation between the experimental and theoretical values of P and A for a selected set of points on the experimental curve. Using this program, we found almost the same index of refraction for the Nb oxide film, *i.e.*, $\hat{n} = n - ik$, with $n = 2.29 \pm 0.01$ and $k = 0.003 \pm 0.003$. The rms deviation in A was found to be 0.25°. Since the error in k is as large as its value, we suggest that it is valid to take k to be zero within experimental error and use the value of 2.30 for the Nb oxide refractive index which gives an almost perfect visual fit between the experimental and theoretical curves.

The only previous ellipsometric study of the plasma oxidation of Nb is that of Lee *et al.* (2). Our Fig. 1 should be compared with their Fig. 4. Their experimental data consist of 15 points that were taken with a manual ellipsometer, operating at 5461Å and an angle of incidence of 65°, and their experimental points were probably taken by stopping the oxidation process at particular points to make ellipsometric measurements, although this is not stated. Our experimental data were obtained with an automated ellipsometer, operating at 6328Å and an angle of 59.5°, that took data points at least every 5 sec while the oxidation process was proceeding at constant sample driving current. Our experimental data are presented in Fig. 1 as a solid line through the approximately 4000 data points defining our curve.

Lee *et al.* fitted their ellipsometric data on the plasma oxidation of Nb with a two-layer model for the oxide, *i.e.*, an outer layer with an index of 2.15 and an inner layer with an index of 2.37, with the outer layer comprising 40% of the total thickness of the two layers at any stage of the growth. Their fit is presented as a solid curve with the experimental data as superimposed points. As discussed earlier, we have been able to fit our ellipsometric data on the plasma oxidation of Nb by a single uniform Nb oxide layer with an index of refraction of 2.30. This difference in interpretation of the ellipsometry data by Lee *et al.* and ourselves is discussed fully in the next section of this paper.

In Fig. 2 we present our electrical measurements during the growth of the Nb oxide in the form of plots of time, total charge passed q, and sample voltage V *vs.* oxide thickness. As can be seen in Fig. 2, the time or total charge passed q *vs.* oxide thickness plot is well represented by a straight line passing almost through the starting point. The voltage V of the sample with respect to a Au probe nearby in the plasma increases

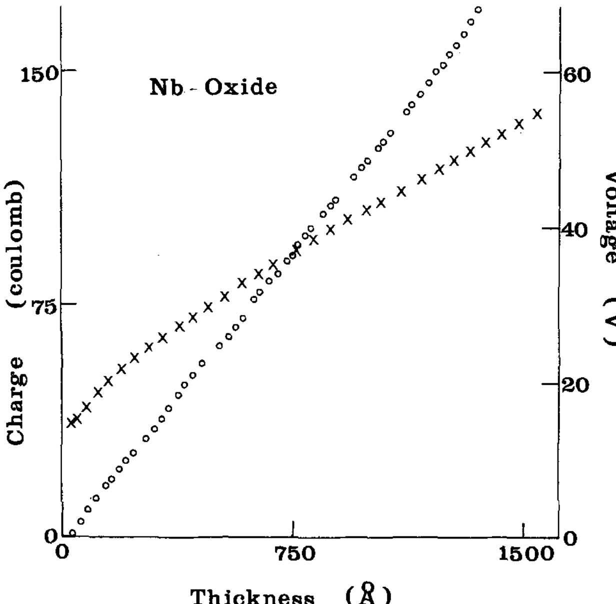

Fig. 2. Electrical measurements for the plasma oxidation of Nb. The open circles denote the total charge passed through the sample vs. the oxide thickness. The crosses denote the voltage of the sample with respect to a Au probe nearby in the plasma vs. the oxide thickness.

fairly quickly to a certain value at low thickness and then increases linearly with thickness thereafter. The electrical behavior reported here for the plasma oxide on Nb is similar to what was found for the plasma oxide on Ta (1). From Fig. 2, it can be seen that the plasma oxide on Nb is growing at an approximately constant rate of 7.5Å per 100 sec. The current efficiency, η, was calculated from $\eta = (GAv\mathbf{F}\rho)M^{-1}$, where G is the oxide growth rate, A is the sample area, v is the valency of the metal ion, **F** is the Faraday constant, ρ is the oxide density, and M is the molecular weight of the oxide, assuming that the oxide being formed is Nb_2O_5 with a molecular weight of 266 and a density of 4.4 g/cm^3 (6). A value of $\eta = 0.2\%$ was found and this is in the same range as the value of 0.4% found for the plasma oxide on Ta (1).

Interpretation of Ellipsometric Measurements of the Plasma Oxidation of Nb and Ta

In this paper for Nb, and in a previous paper (1) for Ta, we have found that our ellipsometric measurements are consistent with a single uniform layer of oxide, with a purely real index of refraction, being formed by the plasma oxidation process. In contrast, Lee *et al.* (2) state that their ellipsometric measurements on the plasma oxidation of Ta and Nb indicate that the oxide being formed consists of two layers, with different indices, that grow simultaneously so that each layer remains a certain fraction of the total thickness. In a situation such as this, some questions naturally arise. Are the two groups seeing different physical behavior? Is the apparent difference in physical behavior just due to differences in interpretation? How valid is a given interpretation? In this section we would like to address ourselves to answering these questions about our experiments and those of Lee *et al.* on the plasma oxidation of Nb and Ta.

It must be clearly understood that ellipsometric experiments do not measure directly the number of layers in an oxide, the indices of refraction of the layers, etc. In an ellipsometric experiment of the type used to follow the growth of films, the state of polarization of light reflected from the investigated surface is determined and expressed by Δ and ψ. Starting from a point Δ_o, ψ_o in the Δ,ψ plane, characterizing the bare, oxide-free surface, Δ and ψ change while the oxide film is formed generating an ellipsometric curve. To deduce information from the ellipsometric curve, a model of the structure of the film has to be assumed and then the free parameters of the model can be determined by curve fitting.

The simplest possible model is that the film is a single uniform layer, characterized by an index of refraction $\hat{n} = n - ik$. This is a two parameter model if the fitting procedure involves varying both n and k, otherwise if k is taken to be zero it reduces to a one parameter model. All the other parameters involved in the calculations, *i.e.*, the angle of incidence θ, the wavelength of the light λ, the refractive index of the surrounding medium $\hat{n}_m$, and the refractive index of the substrate material $\hat{n}_s$ should be known. The starting point Δ_o,ψ_o, if it is truly characteristic of the bare, oxide-free surface, determines the value of $\hat{n}_s$ directly.

The next more complicated model is that the film is composed of two layers. This can be a five parameter model, since each film is characterized by an n and a k, and there has to be an additional parameter to characterize the division of the total thickness between the two films. If it is assumed that the two films have purely real indices, *i.e.*, both k's are zero, then the two-layer model has only three free parameters.

Now, while a limited portion of an ellipsometric curve cannot determine directly parameter values for models, if the ellipsometric data have been taken over a sufficient thickness range certain general features of the ellipsometric curve can distinguish clearly between various possibilities. For example, in the open type of ellipsometric curve, as shown in Fig. 1 for the plasma oxidation of Nb, a periodicity of 360° in Δ of the ellipsometric curve indicates that the oxide film is a single uniform layer with a purely real index. A two-layer model cannot produce such a periodicity of 360° in Δ, although for certain values of indices (purely equal) and ratios of thicknesses of the two films, the resulting ellipsometric curves can be periodic in Δ, where the period is a particular integral multiple of 360°. General features, such as the periodicity in Δ, are more powerful in discriminating between various models than comparing the accuracy of fitting, since a model with more free parameters can usually be made to give a better fit over a limited portion of a curve.

Now with the preceding discussion on ellipsometric curve fitting as background, let us examine the ellipsometric data. There are distinct differences in the general features of the data between our experiments and those of Lee *et al.* As shown in Fig. 1 for Nb and in Fig. 3 of a previous paper (1) for Ta, our ellipsometric data on the plasma oxidation of Nb and Ta shows an almost perfect 360° periodicity in Δ, since ψ is coming back almost exactly to its original value after Δ has changed by 360°. As we have stated earlier, this general behavior is consistent only with a model involving a single uniform layer with a purely real index, and consequently we have used such a model in fitting our data. In contrast, the ellipsometric data of Lee *et al.* (2) on the plasma oxidation of Nb and Ta have the general feature that ψ is significantly lower than its original value as the change in Δ from its original value approaches 360°. Lee *et al.* used a two-layer model to fit their data, but we would like to show in the following that this is not the only model that will reproduce their experimental results since a one-layer absorbing film (nonzero k value) has the same general behavior over the thickness range studied.

We concentrate first on their results on Ta. Lee *et al.* have taken 10 ellipsometer readings during the growth of the oxide. Since a reconstruction of the experimental points from their Fig. 3 would be inexact, we calculated their theoretical two-layer ellipsometric curve and picked out 10 points of this curve which have

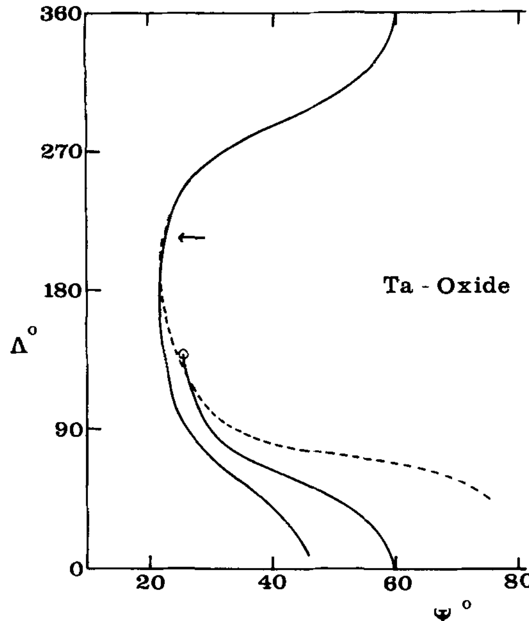

Fig. 3. Comparison of two fitting models for the ellipsometric data of Lee *et al.* on the plasma oxidation of Ta. The solid curve represents a single-layer model with index 2.02 — *i*0.049. The dashed curve represents the two-layer model used by Lee *et al.* Where the dashed curve is not shown it is superimposed on the solid curve within the resolution of the figure. The open circle denotes the bare Ta surface value of the optical parameters, and the growth of the oxide corresponds to moving down the solid or dashed curves. The arrow indicates the final thickness to which the oxide was grown by Lee *et al.* In the model of Lee et *al.*, this final oxide thickness is 1100Å, composed of an outer layer of 473Å with an index of 1.89 and an inner layer of 627Å with an index of 2.22. In the single-layer model with index 2.02 — *i*0.049 this final oxide thickness is 1150Å.

about the same positions as the experimental ones. Since the starting point Δ_0, ψ_0 of the ellipsometric curve is not given, we had to read it from their Fig. 3. Now we fitted a one-layer model to the selected points using a nonlinear least squares fit computer program. This yields a refractive index of the oxide of $\hat{n} = (2.02 \pm 0.01) - i(0.049 \pm 0.003)$. All the other parameters were held constant, in particular we used the same Δ_0, ψ_0 as for the two-layer model.

The results of this comparison are shown in Fig. 3. The solid line shows the one-layer fit and the dashed lines shows the two-layer model. The feature to note is that the two curves superimpose from the starting point (denoted by an open circle) to within 20° in Δ of the last experimental point (located by the arrow). Obviously, the one-layer fit and the two-layer model deviate drastically from one another as the oxide thickness is increased beyond the experimental range published by Lee *et al.* Indeed, the dashed line on the second cycle crossing its counterpart on the first cycle and rising toward a higher maximum is characteristic of such a two-layer model, and the observation of such behavior would have been very strong evidence that their oxide film was composed of two distinct layers. (Certainly, no combination of n and k in a one-layer model would be able to produce such an effect.) However, their published data stop at the point indicated by the arrow.

Over the experimentally measured thickness range, the rms deviation between the one-layer and two-layer curves in Fig. 3 is 0.35° in ψ, *i.e.*, assuming that the error occurs completely in ψ. This deviation is probably no larger than that between the experimental points and the two-layer curve. (Lee *et al.* do not give a numerical value for the deviation for the case of Ta, but from the value given for the case of Nb, and from comparing the two diagrams for Nb and Ta, we conclude that a deviation larger than 0.3° in ψ is very likely in the Lee *et al.* experiment on Ta.)

A similar comparison between a one-layer fit and the two-layer model of Lee *et al.* was carried out for the case of Nb. The least squares fit computer program gives a single layer with the index $\hat{n} = (2.27 \pm 0.01) - i(0.016 \pm 0.004)$. Over the experimentally measured thickness range, the rms deviation between the single-layer ellipsometry curve and the two-layer model of Lee *et al.* is 0.25° in ψ. This deviation is possibly a little higher than that between the experimental points and the two-layer curve, but which fit is actually better depends on the exact positions of the experimental values. Once again, the experimental values do not extend into the thickness range where the one-layer fit and the two-layer model deviate widely, and where experimental points falling on the two-layer curve would have ruled out our alternative interpretation.

In conclusion, the almost perfect 360° periodicity in Δ exhibited by our ellipsometric data on the plasma oxidation of Nb and Ta confirms our interpretation that the oxide being formed consists of a uniform single layer with a zero (or almost vanishing) absorption. The indices of refraction found for these plasma produced oxides are 2.30 in the case of Nb and 2.21 in the case of Ta. In contrast, we have shown that the data of Lee *et al.* on the plasma oxidation of Nb and Ta do not have a unique interpretation. In addition to their interpretation in terms of a two-layer model, a one-layer model involving a uniform but absorbing oxide fits their experimental data equally well over the experimentally measured thickness range. In order for Lee *et al.* to have tested whether their oxide films really consisted of two layers, their ellipsometric measurements should have been carried out to greater oxide thickness where the difference between a two-layer model and an absorbing single layer is readily apparent.

Dielectric Breakdown Properties of SiO_2 Films Grown in Halogen and Hydrogen-Containing Environments

C. M. Osburn*

IBM Thomas J. Watson Research Center, Yorktown Heights, New York 10598

The publication costs of this article have been assisted by the IBM Corporation.

ABSTRACT

Thermal oxidation of silicon, in the presence of chlorine or bromine compounds, effectively improved the dielectric breakdown characteristics (as measured with a voltage ramp) of the resulting SiO_2 films. At high halogen concentrations the oxidation rate was erratic; the optimal initial breakdown properties were attained by oxidizing with about one-half of the halogen-containing additive that would cause etching of the Si. Oxidation in the presence of halides increased the resistance of SiO_2 films to dielectric breakdown under accelerated bias-temperature stressing. The maximum time to failure varied semilogarithmically with HCl concentration and increased by 0.3 to 0.65 decade per per cent of HCl (0-3% HCl range) for applied fields from 2 to 7 MV/cm, respectively. Higher oxidation temperatures further improved the resistance of HCl oxides to dielectric wear-out. The longer wear-out times were attributed to hydrogen rather than the halogen and could be achieved by oxidation in small concentrations of H_2O, annealing in H_2, or implantation of H_2 or H_2O.

Thermal oxidation of silicon in environments containing small concentrations of halogens and halides improves properties of the resultant SiO_2 films (1-8) and underlying silicon (9-12). This procedure effectively reduces fixed oxide charge (1, 3, 5, 7), interface state (1, 8), and mobile charge (1-5, 7) densities. At higher temperatures ($\approx$1150°C), SiO_2 films prepared with HCl additions seem to neutralize Na^+ ion contamination effects, often introduced during later processing (2-4).

Superior SiO_2 dielectric breakdown distributions have also been achieved by oxidation in HCl-O_2 atmospheres at high temperatures or even by HCl cleaning the quartz oxidation tube (13). These oxide films were also considerably more resistant to failure as a result of electrochemical degradation under accelerated bias-temperature aging (6). Substantial reductions in the Si minority carrier generation rates have been noted after HCl oxidation (9, 12) or Cl_2 gettering (12, 14) of metallic impurities from the Si.

Gettering is generally believed to be partially responsible, at least, for these beneficial effects, wherein metal contaminants are removed (as volatile halides) from the oxide or underlying silicon. Presumably, Na removal gives a lower mobile oxide charge, while the elimination of recombination centers like Cu, Fe, or Ag from the silicon results in a lower minority carrier generation rate. This gettering model for the transport of impurities, however, does not explain all properties of halogen-grown oxides, particularly the Na neutralization (2-5) effect and flatband voltage instabilities (15) in which incorporated chlorine (5, 15-17) probably plays a role.

This study was undertaken to more completely establish the influence of hydrogen and halogens on the dielectric breakdown properties of SiO_2 films. Both initial breakdown voltage characteristics and time to failure under accelerated stressing were measured.

Experimental

Metal-oxide-semiconductor capacitor structures were fabricated from moderately doped n- or p-type, (100) silicon wafers. Silicon dioxide layers were grown at 850°-1150°C in atmospheres containing small concentrations of HCl, Cl_2, HBr, CCl_4, C_2HCl_3, or H_2O. Oxidation times were adjusted because of the enhanced oxidation rate in the presence of halogens (15, 19); final oxide thicknesses were measured ellipsometrically. Halogen gas concentrations were limited ($\lesssim$ 10% HCl, 10% HBr, or 2% Cl_2) to prevent silicon corrosion; even so, considerable care had to be taken to ensure uniform oxide growth without localized Si pitting. The problem was more severe with other gases; for example visibly nonuniform oxide films often resulted from oxidation in 1% CCl_4 or 3% C_2HCl_3 at 1000°C. The test structures were completed by depositing through a mask, an array of 100 aluminum dots from an E-gun source and annealing to remove radiation damage incurred during metallization.

Statistical distributions of the breakdown voltages of identically prepared capacitors were determined with an applied ramp voltage by detecting the first breakdown event [see Ref. (20)]; these results constitute an initial or "time-zero" measure of oxide quality. In addition, the times to failure were also determined using accelerated bias-temperature conditions (6). Past work has shown that the initial breakdown distributions provided a quantitative measure of the oxide defect density (13), while the accelerated testing data gave information about the rate at which the dielectric strength decreased (6).

Results and Discussion

Statistical breakdown voltages.—Silicon dioxide films that are thermally oxidized in the presence of halogens show improved time-zero distributions. The results in Fig. 1 show the improvements obtained with 3% HCl or 2% Cl_2 at an oxidation temperature of 1000°C compared with the standard SiO_2 for 450Å films. The maximum dielectric strength remains constant under all oxidation conditions, but the average breakdown voltage is increased and the statistical spread is reduced for the halogen-oxidized films. The defect density was calculated as described in Ref. (20) by associating low-field breakdowns (*i.e.*, those capacitors exhibiting less than 80% of the maximum dielectric strength) with oxide film defects; the standard films had 100 defects/cm² compared to 40 for HCl- and 12 for Cl_2-grown films, respectively. It should be emphasized that the defect density varied with wafer lot and source, cleaning, and cleanliness of the oxidation fur-

nace, and this variation could be very large. Over a three-year period with hundreds of oxidation runs, the standard defect density has varied from 16 to over 300. Therefore the absolute values of the defect density were not as meaningful as the relative fluctuations during a single oxidation since the uniformity within any given run was usually better than 20%.

The influence of HCl, Cl_2, CCl_4, C_2HCl_3, and HBr concentrations during oxidation on the defect density is portrayed in Fig. 2. For HCl oxides, the defect density was lowest when about 3% HCl was added during oxidation. The most substantial improvement appeared between 0 and 1% HCl. The 0% defect density plotted here was typical of what could be consistently achieved with careful preparation. Oxides grown in 6% and 9% HCl did not show visible corrosion even though breakdown measurements revealed that they were inferior to films grown with lower HCl concentrations. Apparently, breakdown distributions reflect corrosion effects more sensitively than visual observations do. Moreover, wafer corrosion could be observed occasionally under these conditions if careful procedures were not followed: the oxidation tube needed to be equilibrated with the temperature and gas concentration of interest for a considerable period of time (~1 day) to minimize corrosive effects (18). The use of longer oxidation times (to produce much thicker SiO_2 layers) revealed substrate attack and nonuniform oxidation effects (18) that were not apparent with the thin films used in this study. With all the halogen additives tested, lowest defect densities were attained at concentrations of about half those necessary to produce nonuniform films. Films grown in 4% H_2O-96% O_2 did not show any improvement in time zero breakdown characteristics; apparently the improvement is a result of the presence of the halogen and not hydrogen or water vapor.

As with conventional oxidation, the defect density increases with oxidation temperature in HCl-grown oxides (Fig. 3). Higher oxidation temperatures for HCl oxides do, however, cause a relatively greater degradation so that the beneficial effects of HCl are no longer significant for an oxidation temperature of 1150°C.

Previous studies have considered various origins of the breakdown voltage improvement seen here. For this purpose, low field breakdowns can be roughly attributed to two types of defects (13), electrical and physical. The former depend both on the presence of electrically charged impurities which enhance the internal electric field and on the presence of interface states which increase oxide conduction levels and result in low field breakdowns. Physical defects reduce oxide uniformity and planarity and consist of substrate bumps or spikes, and oxide pinholes, crystalline regions, and particulate inclusions. The influence of halogen (especially Cl) oxidation, on removing, reducing, or neutralizing electrical disorder is well established (1-5 7, 8, 10-12, 19). Recent work (21) has shown that the majority of defects are probably physical since proper wafer cleaning procedures before oxidation can almost completely eliminate these defects. It can also be postulated that the halogen might reduce the level of physical defects. Impurities or particulates forming protrusions of the silicon surface may be gettered or dislodged by the action of Cl. Likewise airborne particulate matter may react and be diminished in size, if not removed entirely from the system.

Accelerated breakdown.—Effect of halogens.—Dielectric degradation was generally measured under higher temperatures and fields than those normally encountered by the gate insulator in typical FET use, in order to reduce the wear-out time to manageable values of no more than a few hundred hours. Figure 4 displays the distributions of failure times observed on testing 700Å films at 5 MV/cm and 300°C. This figure reveals an increase in failure times of up to two orders of magnitude for films grown in 2% HCl over those grown in pure O_2 at 1000°C. Two reliability features of HCl-grown oxide films should be noted: the longer time for 100% failure, and the smaller spread in failure times. The time required for 100% failure (see Fig. 4) was defined as t_{max} and was previously shown (6) to be a measure of the wear-out of a film that is free of significant defects. Thus, the addition of HCl during oxidation apparently retards the electrochemical-type degradation (6) that normally occurs under accelerated bias-temperature stressing. The narrowing of the distribution of failure times is believed to reflect a

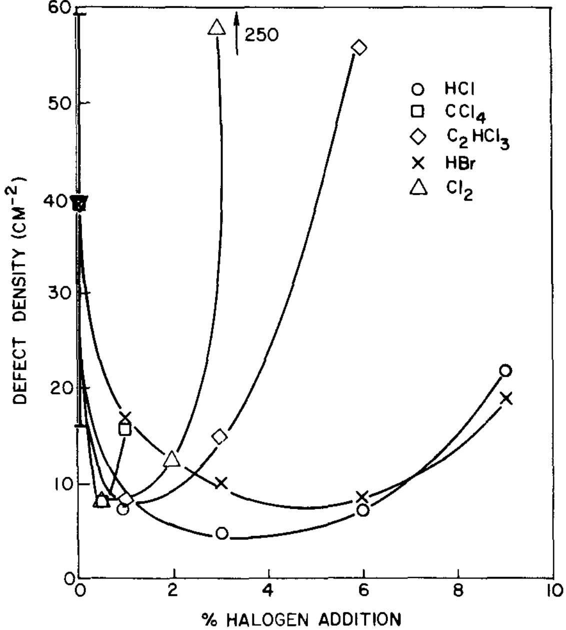

Fig. 2. Effect of halogen added during oxidation on the breakdown defect density.

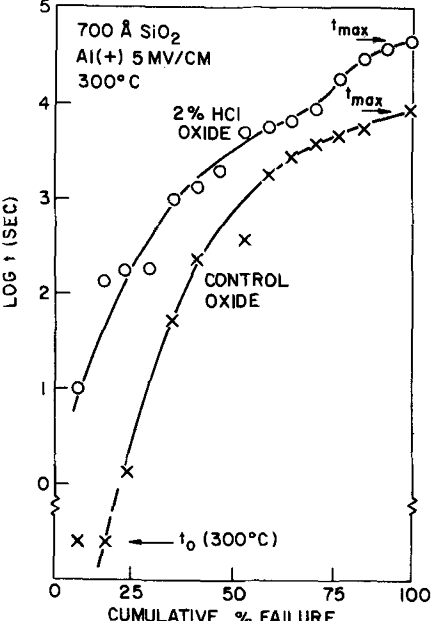

Fig. 4. Statistical failure times for HCl and standard oxides. Both oxides were grown at 1000°C.

tightening of the initial breakdown voltage distribution since HCl-oxides are more uniform and defect-free to begin with; thus, their wear-out times should be less scattered.

A detailed study was made of the effects of HCl concentration and oxidation temperature on the accelerated wear-out process. Using t_{max} as the measure of oxide quality, this parameter is shown in Fig. 5 as a function of applied field and HCl concentration for SiO_2 films grown at 1000°C. Note that for a given field, the wear-out time increases with HCl concentration up to at least 6% HCl. Between 0 and 3% HCl, log t_{max} varied almost linearly with the HCl concentration with slopes ranging from 0.3 decades/% HCl at 2 MV/cm to 0.65 decade/% HCl at 7 MV/cm. The improvement in wear-out time seems to saturate above 6% HCl. On the other hand, the initial defect density increases when more than 6% HCl is used (Fig. 2), and other experiments have shown that the average failure time for 9% HCl was indeed even shorter than that with 3% HCl. These experiments clearly show that over-all component reliability depends on both the initial defect density and the rate of wear-out; the enhanced wear-out time for 9% as compared to 3% HCl oxides is overshadowed by the higher defect density.

The influence of oxidation temperature on wear-out in HCl oxides is shown in Fig. 6 where it is seen that higher temperatures give longer failure times. The oxidation temperature does not affect wear-out times in standard oxides. At 850°C, HCl oxidation gives no improvement in wear-out characteristics compared to the standard SiO_2, even though Fig. 3 shows that this oxidation procedure yields excellent initial breakdown characteristics. With an 1150°C oxidation, however, the initial breakdown characteristics are poor while accelerated breakdown times are the longest observed here. This result further demonstrates that time-zero and accelerated breakdown mechanisms are influenced differently by the presence of HCl in the oxidation atmosphere. Nevertheless, both measures of oxide integrity are involved in the over-all reliability of the dielectric film.

Identical failure times were measured on oxide films grown on both n-type and p-type silicon substrates. Since HCl oxidation markedly reduces minority carrier generation in the underlying silicon (9-12), measurements made with the silicon surface inverted could be suspect. The results shown in Fig. 7 verify the fact that the effects are real and not due to a loss of field in the depleted silicon surface. Note the improved failure times for both electrode polarities. A negative bias on the aluminum electrodes gives the longer wear-out times for standard oxides; with HCl oxidation, the relative advantage of Al(−) over Al(+) is even greater. For Al(+), t_{max} was determined to be thermally activated with $\Delta H = 1.4$ eV for temperatures

between 250° and 400°C. This activation energy agrees well with that obtained earlier for the wear-out of pure SiO_2 films under similar conditions (6).

In contrast to the above HCl oxide results, SiO_2 films grown at 1000°C in the presence of Cl_2 exhibit shorter failure times than the standard oxides (Fig. 8).

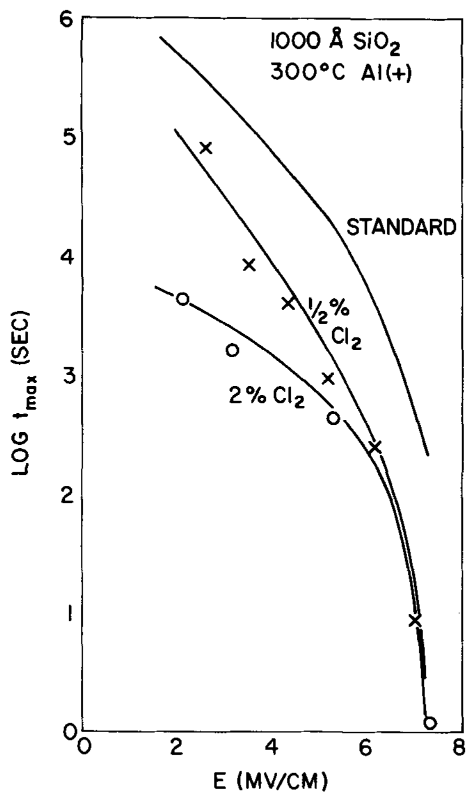

Fig. 8. t_{max} vs. applied field for different Cl_2 concentrations for oxidation at 1000°C.

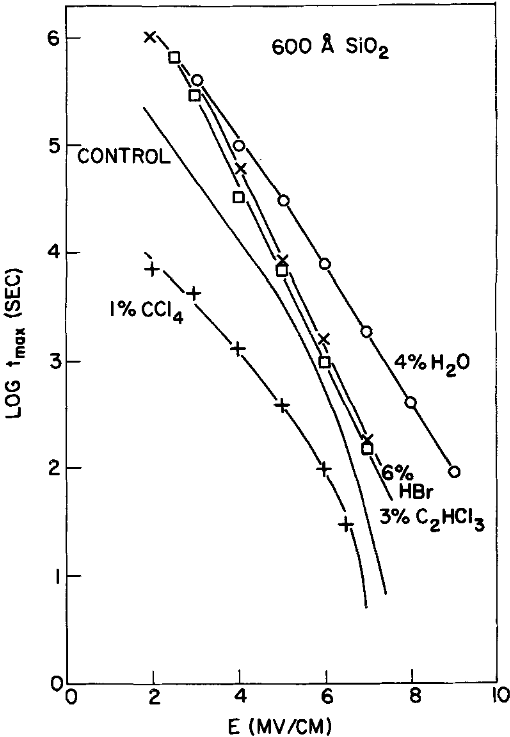

Fig. 9. Maximum time to failure for CCl_4, C_2HCl_3, HBr, and H_2O oxides.

This finding is surprising considering that Cl_2 additions are superior to HCl for improving t_0 breakdown characteristics (recall Fig. 1). Thus, this study shows that HCl and Cl_2 oxidation additives lead to markedly divergent accelerated breakdown characteristics in addition to giving different incorporated Cl profiles in SiO_2 (15, 17), oxide polarizability behavior (15), and oxidation kinetics (18, 19). However, both additives effectively enhance ramp breakdown voltage distributions and minority carrier generation (12).

The effects of the other additives on wear-out is portrayed in Fig. 9. Improvements can be noted for C_2HCl_3, HBr, and H_2O grown films, but CCl_4 gave poorer than normal characteristics. Table I summarizes several properties of MOS structures fabricated using various oxidation ambients. It is seen that Cl can be associated with minority carrier lifetime improvements while both Cl and Br enhance t_0 or ramp breakdown characteristics. Nevertheless, only the hydrogen-containing compounds promote SiO_2 integrity under the accelerated bias-temperature stressing used here. Chlorine, either as Cl_2 or in CCl_4, is indeed detrimental to long term SiO_2 reliability.

Effects of hydrogen.—Annealing studies of standard and H_2O grown oxides give additional information on the hydrogen effects. Films grown in 4% H_2O at 1000°C remain highly resistant to wear-out even after a ½-hr anneal in N_2, although annealing at higher temperatures (1100°-1200°C) eliminates the hydrogen improvement effect (see Fig. 10). Since one might ascribe this enhancement of wear-out resistance to the incor-

poration of hydroxyl groups into the oxide, it should be pointed out that infrared spectroscopy studies (22) have demonstrated that a brief anneal (< ½ hr) at 1000°C in O_2 is sufficient to remove almost all these species. Composite films made of SiO_2 films grown in pure O_2 and 96% O_2-4% H_2O ambients are more reliable than standard films, regardless of the order of the oxidation steps, although they are not as reliable as films completely grown in 4% H_2O (see Fig. 11). Silicon dioxide films annealed in forming gas (20% H_2-80% N_2) also exhibit somewhat better wear-out characteristics provided the annealing temperature was high enough (see Fig. 12). With 900°C annealing, breakdown times are perceptively lengthened at low applied fields while 1050°C annealing results in a 2- to 5-fold change. Ion implantation of either H_2^+ or H_2O^+ appears to lead to higher dielectric wear-out integrity (Fig. 12) but time-zero characteristics of implanted oxides were below standard.

Model.—An earlier study (6) proposed a model to account for dielectric degradation and failure in SiO_2 films: energy states in the SiO_2 bandgap are created at the injecting electrode during accelerated bias-temperature stressing. When charged, these trap states cause a dipole lowering of the injecting barrier and allow excessive current to promote failure by a localized thermal runaway.

The mechanism responsible for interface state generation is still unresolved. Transport of a chemical species (either foreign or intrinsic to SiO_2) through the film or an electrochemical reaction of the electrode metal could contribute to this generation of trap states, albeit in different ways.

Oxides grown in the presence of hydrogen or halogens show the same general electrical deterioration prior to breakdown as do films grown in 100% O_2. About the only difference between the two types of oxides is the time lapse before the observation of degradation. Large flatband voltage shifts appear in Cl_2 oxides (15) stressed at room temperature so that it is not surprising that such films exhibit early failure

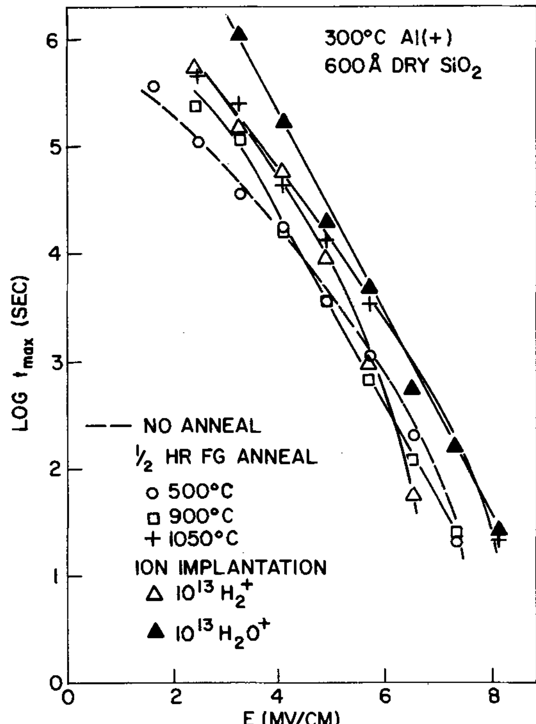

Fig. 12. Improvement in t_{max} as a result of annealing dry oxides in forming gas (20% H_2) at high temperature (○, 500°C; □, 900°C; +, 1050°C) and as a result of ion implantation (△, $10^{13} H_2^+$; ▲, $10^{13} H_2O^+$).

times. On the basis of our earlier model, it appears that dielectric lifetime improvements can be attributed to a slower generation rate of the localized trap states responsible for barrier lowering, and a hydrogen species is associated with a net reduction in the generation rate. There is some other evidence to support this model. For example, the importance of hydrogen

for annealing out (at ~ 500°C) surface states in MOS structures is well established (23). In addition, the introduction of atomic hydrogen at room temperature has been shown to greatly reduce the enhanced conduction that resulted from accelerated stressing of MOS capacitors (6). Annealing studies repeated here have shown that the hydrogen can be introduced either during or after oxidation although it is most effective when added during oxidation, and it also can be implanted.

Field enhancement breakdown.—Electric field enhancement (24-25) due to the presence of mobile ions (particularly sodium) has been shown to be one time-dependent dielectric breakdown mechanism in SiO_2 films. Experiments were conducted as part of this study to verify that this sodium neutralization (2-5) could lead to a reliability improvement in intentionally contaminated films. Oxides 1000Å thick were grown at 1150°C in oxygen containing 0, 3, or 9% HCl; sodium levels of 6×10^{12} and 10^{14} Na^+/cm^2 were evaporated onto the film before metal capacitor dots were deposited.

The current through a Na contaminated film was previously (25) shown to reflect the amount of field enhancement (and hence decrease of the effective Fowler-Nordheim tunneling distance) near the injecting silicon. As the electrically uncompensated sodium was drifted through the oxide, the current increased to a maximum and then decayed provided the sample did not break down during the drift (see insert Fig. 13). As can be readily seen, the maximum current through the HCl oxides below 7 MV/cm was at least 2-4 orders of magnitude lower than in the standard oxide. This measurement is taken as direct evidence that the internal electric field due to the Na space charge can be greatly reduced because of Na neutralization.

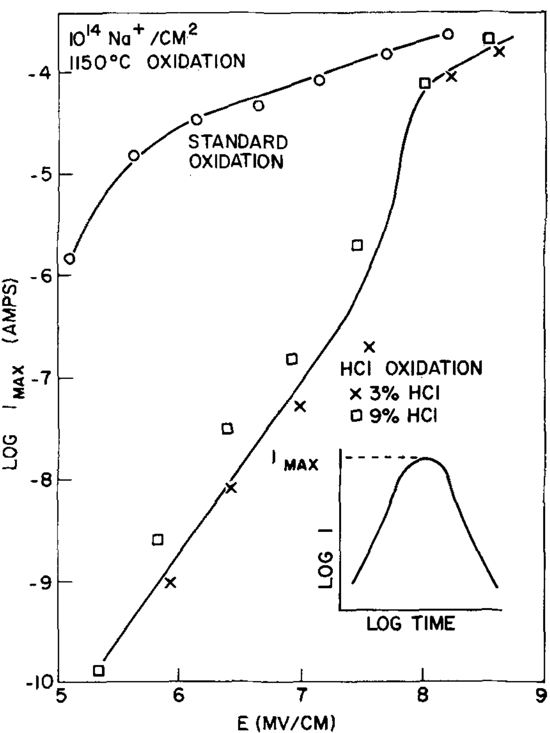

Fig. 13. Current maxima in Na-contaminated HCl oxides. Insert shows time dependence of current through SiO_2.

Summary

Oxidation of silicon in O_2 with HCl, Cl_2, CCl_4, C_2HCl_3, or HBr additions increased the average SiO_2 breakdown voltage and reduced the statistical data spread. The amount of improvement observed varied with the additive species and its concentration during oxidation. The best characteristics were obtained using about half the amount of halogen that would cause visual nonuniformity in the SiO_2 films and Si etching. The breakdown defect density increased more rapidly with oxidation temperature for HCl oxides than for standard oxides. The improvements were tentatively attributed to the removal of heavy metal impurities. The time to breakdown under accelerated bias stressing depended on the species used. Chlorine and CCl_4 oxides had reduced failure times; HCl, HBr, C_2HCl_3, and H_2O oxides had vastly improved dielectric integrity. In the range 0-3% HCl during oxidation, the failure times increased by 0.3-0.65 decades/% HCl for applied fields of 2-7 MV/cm, respectively. The improvement due to HCl seemed to saturate near 6-9% HCl when oxidation occurred at 1000°C, but increasing oxidation temperature gave longer failure times. The measurements indicate that the basic degradation in all the tested oxides was the same as in standard films. The improved wear-out reliability was attributed to the presence of hydrogen rather than halogens, since an improvement was observed in oxides grown in 4% H_2O/O_2 or annealed at high temperature in hydrogen. It was observed that Na neutralization (2-5) could lower the internal electric field due to the Na-ion space charge and hence provide another basis for obtaining highly reliable silicon dioxide films.

Acknowledgments

Helpful conversations with Y. van der Meulen, N. Chou, J. Eldridge, and J. Ziegler are gratefully acknowledged. Ion implantation of hydrogen was suggested by A. Fowler and performed by B. Crowder and N. Penebre. The author would also like to express gratitude to D. Ormond for assistance in sample preparation and measurement. Other samples and encouragement were also provided by T. Fennell, G. Schmidt, E. Terner, and R. Troutman.

ABSTRACT

An efficient and reliable technique for synthesizing sodalite is described. This new synthesis is termed "structure conversion method." It converts a complex sodium-aluminosilicate structure into a sodalite structure while at the same time incorporating the alkali halide and activator compounds to form cathodochromic (CC) or photochromic (PC) sodalite in one step without requiring additional sensitizing procedure. Both PC and CC sodalites of high quality have been synthesized by this method. The results of structural analysis, optical measurements, and electron beam excitation of these materials are presented.

Materials which exhibit a photochromic (PC) effect (1) are of considerable technical interest. They have applications in many areas, such as, filter optics (2), holography (3), information storage (4, 5), and display (6-13). In the field of high density information displays, a storage cathode-ray tube (CRT) requiring no refreshing is particularly advantageous. The storage CRT screen calls for sensitive cathodochromic (CC) materials. The alkali halide family with color centers (14), which is a well-known system exhibiting both PC and CC properties, has been used in some of the applications mentioned above (4-7).

Recently, a series of studies (15-28) has been focused on another material group, *i.e.*, the sodalites. Sodalite, $Na_6Al_6Si_6O_{24}\cdot Na_2X$, is a general name for a group of materials or minerals in which X is Cl_2, Br_2, I_2, $(OH)_2$, S, etc. Rigorously, one distinguishes them as chlorosodalite, bromosodalite, etc. When X takes the form of SO_4, CO_3, WO_4, MoO_4, CrO_4, etc. they are generally referred to as noselites. There have been natural sodalites [known as hackmanites (29, 30) which exhibit the PC property] found on many parts of the earth (16, 18, 30-33). However, synthetic sodalites generally show more sensitivity with respect to the PC and CC properties (27, 26). In fact, they possess certain characteristics which are superior to the alkali halides, such as material stability (nonhydroscopic, higher melting temperature), more effective coloration and bleaching behavior (higher efficiency), and less fatigue (*i.e.*, the probability of forming a complex center is smaller). Therefore, methods of synthesizing both PC sodalite and CC sodalite have become technically important.

It is generally believed that the color absorption in sodalites is due to an F-center type impurity, *i.e.*, an electron trapped at a negative ion vacancy, for example, a chlorine vacancy in chlorosodalite. In synthesizing PC sodalites, in addition to negative ion vacancies, an impurity activator is necessary since it acts as an electron donor which, upon u.v. excitation, gives an electron to the F-center trap via the conduction band. Activators such as Fe (21) and OH (34) have been reported to play a role in the PC process in sodalite; however, the sulfur-doped sodalite seems to be most efficient (27) in exhibiting tenebrescence (photochromism). In synthesizing efficient CC sodalites, no activators are necessary, since the high energy electron bombardment can directly fill the F-center trap.

Single-crystal sodalite has been synthesized (35-37), but most work on PC sodalite has been on powder material. This is because the PC sodalite powder is easier to make and is particularly useful for storage display applications. Several processes for synthesizing sodalites have been developed in the past (15-19, 38-48). These can be classified into four major categories: (*i*) hydrothermal growth (38-40, 15, 16, 19, 22, 23, 41, 42); (*ii*) solid-state reaction or sintering (43, 17, 18, 44, 42); (*iii*) diffusion in zeolite (19, 45); and (*iv*) alumino-silicate gel reaction (42, 46-48). However, most of these methods have disadvantages, such as incomplete reaction, low efficiency, high cost, and long processing time. They are, therefore, not very suitable for large quantity industrial processing (see Discussions and Summary section below).

In the present work, a simple, efficient, and economical method of synthesizing PC and CC sodalites is described. This new synthesis is termed "structure conversion method." It converts a commercially available molecular sieve material (complex sodium aluminosilicate), an alkali halide, and a sulfur compound (used as activator for PC but not necessary for CC material) into sodalite in one step without requiring further sensitizing procedures. Both PC and CC sodalites of high quality have been synthesized by this method. Also discussed in this paper are the results of structural analyses, optical measurements, and electron beam excitation of these materials.

Synthesis Procedure

The structure conversion method (SCM) is different from hydrothermal growth, solid-state sintering, and aluminosilicate gel reaction in that it is not a synthesis from the oxide and salt components. It is also different from the diffusion method (19) which diffuses a gaseous sulfur compound and an alkali halide into a zeolite structure $[3(Na_2O\cdot Al_2O_3\cdot 2SiO_2)]$. The procedure of the diffusion method is that the mixture of zeolite and sodium chloride is dried at low temperature and low

*Electrochemical Society Active Member.

Key words: photochromics, cathodochromics, synthesis, sodalite, display.

pressure of 0.05-0.01 mm for 24 hr. The evacuated sample is then slowly opened to H_2S or SO_2 and allowed to come to atmospheric pressure. The diffusion is preferably carried out at 250°C to prevent aggregation and pore blocking. At this temperature, there is no structure change or conversion occurring. However, the basic mechanism of SCM is the conversion of complex sodium-aluminosilicate structure into a sodalite structure while at the same time incorporating the alkali halide (and activator compound) to form CC(PC) sodalite. The complex Na-Al-silicate chosen to be the starting material is the type that contains a basic building block in the form of a tetrahedron with four oxygen ions surrounding a smaller silicon or aluminum ion. These tetrahedra are identical to those in the sodalite structure, thus the starting material, in essence, has a "distorted sodalite structure" or has the same basic structural units as sodalite. Due to this structural distortion, the material can have very large "apertures" and "pores" so that the incorporation of dopants (alkali halide) and activators (sulfur compound) becomes very efficient. There are several different groups of material that have this property. The readily available one is the commercial molecular sieve material.[1] Our experiments indicate that these molecular sieves can easily be converted to sodalite.

Figure 1 describes the synthesis procedure of the structure conversion method. The process of synthesizing PC sodalites is shown in Fig. 1a. The commercial Linde molecular sieve[1] is used as the starting Na-Al-silicate. The alkali halide and the sulfur compound used are reagent grade. These starting materials (all in powder form) are mixed in a quartz boat which is then placed in a furnace under reducing atmosphere. The sulfur compound used can be sodium sulfide, sulfite, or sulfate. Excess sodium halide is always used since the excess salt can be leached out after the heating process. We have experimented with several different kinds of sieve material, namely, sieves with different sizes of pores (Linde 3A, 4A, 5A, 10X, and 13X type which have channel sizes, 3, 4, 5, 8, and 10Å, respectively). Our results indicate that the Linde 13X molecular sieve, $(Na_{86}[(AlO_2)_{86}(SiO_2)_{106}])\cdot XH_2O$, gives the best PC sodalite and Type 4A, $(Na_{12}(AlO_2)(SiO_2)_{12})\cdot XH_2O$, the next best. The Linde 3A, 5A, and 10X sieves which contain potassium and calcium ions do not result in very sensitive PC material by the SCM synthesis. Therefore, in describing the physical properties of the synthesized sodalites below, we shall restrict our discussions to sodalites prepared from the Linde 13X and 4A sieves only.

In the synthesis of sodalites by the structure conversion method, there are three basic processing parameters, namely the furnace temperature, the reducing gas flow rate, and the reaction time. Although sensitive PC sodalites have been made by the SCM over a broad range of temperature (650°-1100°C), with either forming gas or hydrogen as reducing agent and with a variable length of heating cycle (6-16 hr), we find that there is an optimal set of conditions which gives the most consistent results. It is: temperature = 850°C; flow rate = 3 liter/min forming gas (for a 2½ in. furnace tube); and reaction time = 8 hr. The resulting materials are very sensitive PC sodalites; that is, no separate sensitizing step is required. After washing and leaching, the material is checked by x-ray diffraction which confirms that it has a sodalite structure. The x-ray and optical measurements of the PC sodalite will be discussed below.

The synthesis of CC sodalite is essentially identical to that for the PC sodalite. Figure 1b illustrates the procedure. Again we use molecular sieve material as the starting Na-Al-silicate. However, in the synthesis of CC sodalites, the sulfur compound is found to be unnecessary, as has also been pointed out by others (25, 26). Comparing various nonsulfur-doped CC sodalites prepared by the SCM, we find that the Linde 4A type of molecular sieve is best suited for CC sodalite synthesis.

[1] Molecular sieve materials are synthetic sodium-aluminosilicate (often referred to as zeolites). There are several companies which produce them (e.g., Zeolite Chemical Company, Hungerford and Terry Inc., Metalene Chemical Company, etc). Materials used in this work are from Linde Division, Union Carbide Corporation.

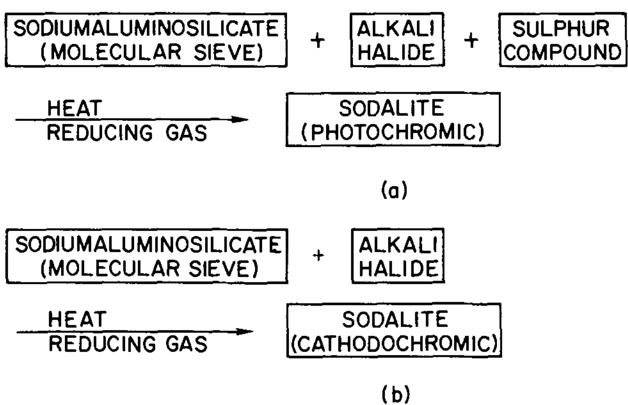

Fig. 1. The synthesis procedure of the structure conversion method (a) for photochromic sodalites and (b) for cathodochromic sodalites.

Physical Properties

X-ray diffraction.—The x-ray diffraction of both the molecular sieves (the starting material) and the resulting material were measured with a Debye-Scherrer powder diffraction camera. The source was CuK_α radiation. The results indeed confirm that the structure conversion is complete. Table I shows the x-ray data for the Linde 13X sieve and the PC chlorosodalite prepared from it by the SCM. The left side of the table also lists the National Bureau of Standards (NBS) diffraction data (33) for a single-crystal chlorosodalite which was taken from Ice River, British Columbia (33). Comparing the result of the synthesized sodalite powder in the center column of Table I with the single-crystal data, one notes that the agreement is indeed very good. It shows not only a matching set of

lines but also a set of comparable relative intensities. Furthermore, the indices of the observed lines (*hkl*) obey the "even" rule ($h + k + l = 2N$) pointed out by Tomisaka *et al.* (40). However, one may point out that there is one extra line exhibited by the synthetic PC sodalite at 3.992Å with relatively weak intensity which is not observed in the single-crystal sample. But this line has been reported by Tomisaka *et al.* on a natural sodalite powder sample from the Princers Mine, Canada. A similar line has also been observed by Williams *et al.* (19) in their synthetic sodalites which were prepared by solid-state sintering, or hydrothermal growth, using Na_2SO_4 as activator or by diffusing SO_2 into a zeolite structure. Thus, one may suggest that this extra line is related to the sulfur activator incorporated in the powder sodalite. The Linde 13X molecular sieve material has a set of diffraction lines entirely different from those of the sodalite. This is shown in the last column of Table I which agrees with the data of Broussard and Shoemaker (49).

The x-ray diffraction results for PC Cl-sodalite prepared from Linde 4A molecular sieve are shown in Table II. Again the synthetic sodalite powder shows a set of interplanar spacings which matches very well with the single-crystal data. One also notes an extra diffraction line. This line corresponds to slightly larger interplanar spacing (4.234Å) and intensity than the extra line which appeared in the sodalite prepared from Linde 13X. Although there is no obvious explanation for this difference, one may point out that Williams *et al.* (19) have also observed similar lines corresponding to 4.23, 4.24, and 4.29Å spacings in their sintered, hydrothermally grown, and H_2S activated sodalites, respectively.

Photochromic behavior.—The best way to calibrate the sensitivity of a PC sodalite is to measure its photoinduced absorption. We have made optical absorption measurements for various sodalites using a Cary 14 spectrometer. The sodalite powder is immersed in a liquid with matching index of refraction. Only sulfur-doped samples show u.v. induced coloration. Figure 2 shows an example of u.v. induced color absorption in a Cl-sodalite. The solid line is the absorption before u.v. excitation and the dotted line is the u.v. induced absorption. The absorption of the background liquid with matching index of refraction (1.486) is also shown in Fig. 2. The absorption coefficient derived from the change in the optical density exceeds 200 cm^{-1} which is by far the highest ever reported for Cl-sodalite. Using this value in the Smakula formula (50, 14), one can obtain an estimate of the switchable color center density which is shown in Table III along with results for Br- and I-sodalites. One notes that the absorption peaks of Cl-, Br-, and I-sodalite (Table III) shift progressively towards longer wavelengths, which correspond to the progressive increase of their lattice constants. This correlation (a linear curve for the relation of peak wavelength *vs.* lattice constant when plotted in log-log coordinates) which is an analog of Ivey's relation (14) for color center absorption in alkali halides, has also been noted by others (22, 23, 25). The typical density of switchable centers of PC

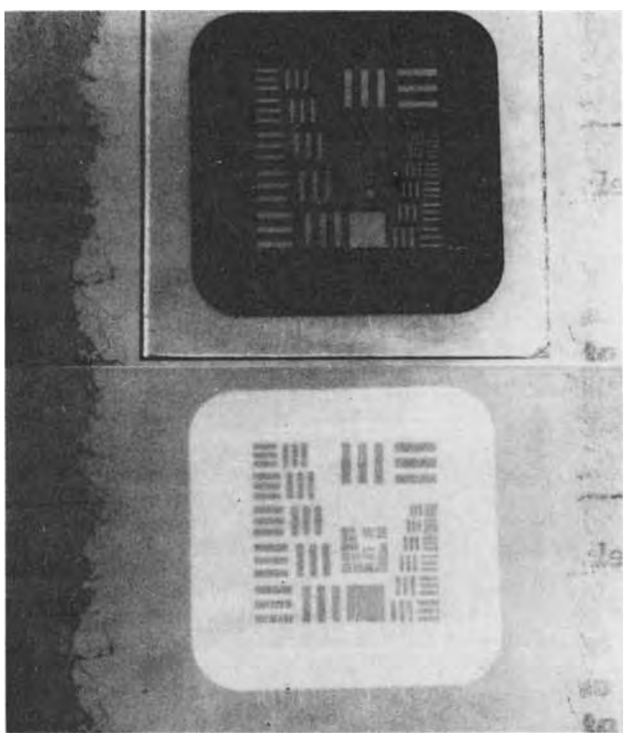

Fig. 3. An image produced on the sulfur-doped photochromic chlorosodalite: the contrast equals 4:1.

sodalite synthesized by the SCM is of the order of $10^{18}/cm^3$. For that density, the material shows a reflective contrast ratio of somewhat better than 4:1. An example of the contrast and resolution capabilities of SCM sodalite is shown in Fig. 3 for a Cl-sodalite. The powder sample was sandwiched between two sheets of plastic (3 mils thick) and was exposed to a u.v. light source [Black Light,[2] broad-band peaked at 3650A and ~15W input power] placed 5 cm above for 5 sec through a glass mask (2.5 mm thick). The two Polaroid pictures (Fig. 3) were taken with the mask covering the sodalites (top) and with the mask removed (bottom). The image has a contrast of about 4:1, and is purple on a white background.

Cathodochromic behavior.—The electron beam coloration experiments were performed in a demountable cathode-ray system. Sodalite powders were sprayed onto NESA[3] glass plates and were tested with electrons of 10-20 kV. Both sulfur-doped and nonsulfur-doped sodalites can be colored by an electron beam but to different degrees. In general the sulfur-doped samples show lower sensitivity in terms of maximum contrast (<10:1) but higher sensitivity to photobleaching. Therefore, they are more suitable for photo-erasable cathodochromic screen applications. The nonsulfur-doped samples are more sensitive in terms of both maximum contrast (20:1 to 40:1) and cathodochromic efficiency but are less sensitive to photobleaching. Thus, they are suitable for high contrast thermal erasable cathodochromic screen applications. Comparing various CC sodalites (nonsulfur-doped) prepared by the SCM, we find that Br-sodalites give the best sensitivity in terms of coloration for a given e-beam charge density. We also find that the 4A type molecular sieve material is better suited for CC sodalite synthesis, *i.e.*, better sodalites can be obtained. Figure 4 shows the cathodochromic characteristic measured for some typical nonsulfur-doped CC sodalites. The powder layer was 1.5 mils thick. The electron beam energy used was 20 kV. The contrast (in transmission) was measured with a brightness spotmeter (Photoresearch Corporation) without optical filter. One notes that the Br-

[2] Black Light, trade name of Spectronics Corporation.
[3] Conductive coating, trade name of PPG Industries.

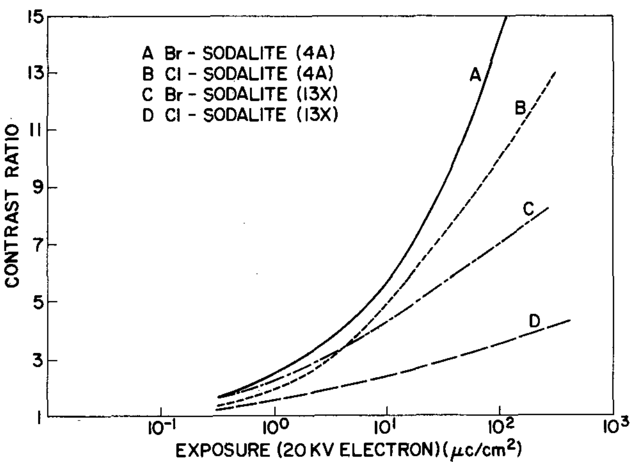

Fig. 4. Cathodochromic characteristics of several nonsulfur-doped sodalites.

sodalite is more sensitive particularly at lower charge density than the Cl-sodalite. One notes also that the sensitivity of the sodalite prepared from Linde 4A molecular sieve is superior to that made from Linde 13X molecular sieve. The Br-sodalite (4A) is most sensitive and can be colored to saturation with a transmission contrast greater than 40:1. This sensitivity is better than most synthetic sodalites reported in the literature.

Discussions and Summary

The earliest work on sodalite sythesis was reported by Friedel and Friedel (38) who had synthesized sodalite by the hydrothermal growth method (HTG). Subsequently, the HTG method has been used by many people (15, 16, 19, 22, 23, 39-42) with various minor modifications or variations. Basically, one starts with a mixture of Al_2O_3, SiO_2, NaCl, NaOH (or Na_2SO_4), and water. The mixture is first heated at low temperature to adjust for a proper amount of water and is then sealed in a gold or platinum tube which is placed in an autoclave under high pressure (~1000 bars) and at a temperature of 350°-460°C for several days. Noble metal tubes have to be used because of the corrosion problem. The result obtained at this stage is not PC (sulfur-doped) or CC (nonsulfur-doped). A sensitization step, heating the material at 900°C in an inert atmosphere or in a reducing atmosphere for some hours, is required to activate the material. Although sensitive sodalites (25, 26) have been produced by the HTG method, it is obviously an expensive and inefficient technique.

The other commonly used method is solid-state sintering (SSS), which is a dry method. It starts with a stoichiometric mixture of aluminum oxide, silicon dioxide alkali halide, and alkali hydroxide or sulfate according to the sodalite formula. This mixture is dry milled and then fired at 750°C in silica dishes. Firing and grinding are repeated many times to insure more complete reaction. A final firing at 900°C under reducing atmosphere is required to activate the sodalite. The inherent disadvantages of this technique are the lengthy procedures required and the problem of incomplete reaction. Sodalites synthesized via aluminosilicate gel (42) also have a similar drawback.

In comparison with the techniques discussed above, the structure conversion method (SCM) is much simpler. It converts a molecular sieve material (complex sodium aluminosilicate) with dopants and activators into a CC or PC sodalite in a single step. This conversion may be described more explicitly as follows. The molecular sieve materials have the basic building blocks of silicon-oxygen and aluminum-oxygen tetrahedra for the sodalite framework. The silicon ion and the aluminum ion both have a coordination number of four; specifically, they are surrounded by four oxygen

ions forming tetrahedra. These tetrahedra are connected together to form a strong framework. The framework, while strong, is not rigid. Within the framework, there are cavities and pores which can be occupied by other ions and molecules. When the proper amounts of sodium and ionic halogen have been incorporated into the cavities, the framework collapses to the sodalite structure. The process of collapse involves the tetrahedra rotating about the twofold axes until the oxygen ions come into contact with the sodium ions which themselves are in contact with the halogen ions. This partial collapse of the framework reduces the edge of the cubic unit from its maximum value of about 9.4 to 8.87Å for chlorosodalite. The chlorine ion in chlorosodalite can easily be exchanged by iodine, bromine, sulfur, etc. However, if the substituted group is larger than Cl^-, then the collapse of the framework is less pronounced. This effect is illustrated (28) by the changes of lattice constant (cubic edge) among various sodalites shown in Table III.

In synthesizing PC sodalite, sulfur ions acting as electron donors in the material are necessary. The sulfur activator is incorporated in the form of Na_2SO_4, Na_2SO_3, or Na_2S. These sulfur oxide molecules or ions have to diffuse into the aluminosilicate framework and become reduced (except in the sulfide case) to sulfur ions, $S^=$, during the structure conversion. Since the structure conversion is carried out in a reducing atmosphere which prevents the sulfur ions from being oxidized to disulfur ions (27, 42) (and perhaps also prevents the oxygen ion from replacing the sulfur ion), very sensitive PC sodalites can be obtained in this single processing step without requiring any additional sensitizing procedure. These sulfur oxide ions are relatively large in size (in comparison with Cl^-); therefore, it is not surprising that the larger pore size (cavities and channels) molecular sieves, like the 10Å pore 13X sieve, are better suited for PC sodalite synthesis where sulfur is required.

In the case of CC sodalite synthesis, the sulfur activator is not required. Therefore, the channel size of the sieve material is not as important an issue as in the case of PC sodalite. In fact, our experimental results show that the Linde 4A sieve (4Å pore size) is best suited to CC sodalite synthesis. For sensitive CC behavior it is essential to have a halogen deficiency (halogen vacancies) in the sodalite structure. Therefore, it is conceivable that when using a 4Å sieve rather than a 10Å sieve as a starting material, a proper amount of halogen deficiency may result, in that the halogen atom, having a radius about twice that of the sodium atom, is more restricted by the 4Å channel relative to the 10Å channel. Furthermore, the CC characteristics of sodalite are somewhat sensitive to the perfection of its structure. This has also been experienced by Schipper *et al.* (42) in their sodalites synthesized by the aluminum silicate gel reaction. The structural perfection of the synthetic sodalite can be characterized by the Al/Si ratio which should be 1 for a perfect sodalite. The Linde 4A sieve has an Al/Si ratio equal to 1 whereas the 13X sieve has an Al/Si ratio less than 1. This may be the reason that the 4A sieve can be consistently converted to better CC sodalites than the 13X sieve, even though quite sensitive CC sodalites have been synthesized from the latter.

In summary, an efficient and reliable technique for synthesizing sodalites has been developed, which we have termed the structure conversion method. For both PC and CC sodalite synthesis, it is a single-step process requiring no additional sensitization procedure. The structure conversion method would be particularly advantageous for industrial processing. It uses commercially available molecular sieves as starting material. The mechanism is one in which the incorporation (through diffusion) of alkali halides and sulfur compounds (required for PC sodalite) is accomplished at the same high temperature at which the structure change or conversion (distorted sodalite to sodalite) takes place. No additional sensitizing procedure is required. Molecular sieve material with larger pore size (Linde 13X) is better suited for the synthesis of PC sodalite since it allows more efficient diffusion of relatively large sulfur oxide ions, whereas molecular sieve material with Al/Si ratio the same as that in sodalite (Linde 4A) is best suited for the synthesis of CC sodalite. Using this technique, PC sodalites having switchable color center densities $>10^{18}/cm^3$ and very sensitive nonsulfur-doped CC sodalites can be obtained routinely.

Acknowledgment

The author expresses his sincere appreciation for many useful discussions with R. Dreyfus, H. Taub, K. Pennington, and A. V. Brown. The assistance of J. Karasinski and D. Paul on the x-ray diffraction measurements, of P. Wraight on some of the cathodochromic characteristic data, and of C. X. Duncombe on sodalite synthesis is gratefully acknowledged. He also thanks Y. J. Doerr and R. Shendo of Union Carbide who have provided him with some technical information and data on Linde molecular sieves.

Manuscript received Sept. 21, 1973. This was Paper 33 presented at the Chicago, Illinois, Meeting of the Society, May 13-18, 1973.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1974 JOURNAL. All discussions for the December 1974 Discussion Section should be submitted by Aug. 1, 1974.

The publication costs of this article have been assisted by Bell Laboratories.

ABSTRACT

This paper reports the first use of an amorphous native oxide on gallium arsenide to mask against zinc diffusion. Anodic oxides were grown at low temperature (≤100°C), and stripes were defined in this oxide using standard photolithographic processing. These samples were diffused, after an appropriate annealing cycle, in a closed system using a zinc source (Zn_3As_2 + GaAs) at 612°C for times up to 2 hr. Diffusion depths were measured using a lap and stain procedure, and the results showed the oxide to be effective as a zinc barrier. Furthermore, no anomalous lateral underdiffusion was observed indicative of a high integrity interface between the oxide and semiconductor.

The planar process, used to advantage in silicon device technology, has not been so fully exploited in the gallium arsenide technology because no similar native oxide had been available. Requirements of an oxide in a typical planar process are that the oxide: (*i*) must be compatible with photolithography, (*ii*) act as a pinhole-free, high breakdown, field strength insulator exhibiting good adherence, and (*iii*) serve as a mask for the controlled diffusion of dopants.

Previous attempts (1, 2) at growing a native oxide on GaAs have produced only brittle, crystalline forms of β-Ga_2O_3 or $GaAsO_4$, which are extremely porous to Zn. Deposited insulators (3-5) such as SiO_2 or Si_3N_4 are not optimum Zn masks because of a large thermal coefficient of expansion mismatch resulting in cracking and lifting of such films at relatively high diffusion temperatures. The use of PSG films as a Zn diffusion mask has been reported (6, 7); however, considerable lateral diffusion is observed indicating a poor quality insulator-semiconductor interface. Deposited aluminum oxide (8) has been used successfully, although the lateral diffusion is a factor of up to 2 times the vertical diffusion depth which is unsatisfactory for precise line definition.

The use of a native oxide film to mask against Zn diffusion is reported for the first time in this paper. Sample preparation including oxidation, annealing and diffusion procedures critical to proper utilization of the oxide as a diffusion mask, and results and conclusions thereof are discussed below.

*Electrochemical Society Active Member.

Key words: anodic oxidation, electro-optical device technology, compound semiconductors.

Sample Preparation

N-type gallium arsenide wafers of {111} orientation and Se-doped in the 10^{17}-$10^{18}/cm^3$ range were polished by lapping with 0.3 μm alumina and etching 75 μm from the arsenic face with a bromine methanol solution for a final wafer thickness of 0.3 mm.

The wafers were thoroughly degreased in a trichloroethylene, acetone, water, methanol rinse cycle prior to anodization. The slices were then placed in a 30% H_2O_2 aqueous solution with pH adjusted to 2 using H_3PO_4 (9), and anodized at voltages ranging from 100-180V d-c at room temperature and at 100°C (10). Following anodization, the samples were baked in a nitrogen ambient for 2 hr at 250°C. A 0.34 mm stripe pattern on 0.63 mm centers was defined using a Shipley AZ-111 photoresist (11).

Annealing and Diffusion

A closed system, routinely used for GaAs laser processing, was utilized for Zn diffusion in this experiment. The Zn dopant is derived from a source of powdered Zn_3As_2 and GaAs, which is also designed to maintain a partial pressure of As over the GaAs wafer during diffusion. A typical diffusion cycle is 25 min at 612°C to obtain a sheet resistivity of 45 ohms/□ on a 1-4 × $10^{18}/cm^3$ p-layer equivalent to a surface concentration of $10^{20}/cm^3$ to a depth of 0.33 μm.

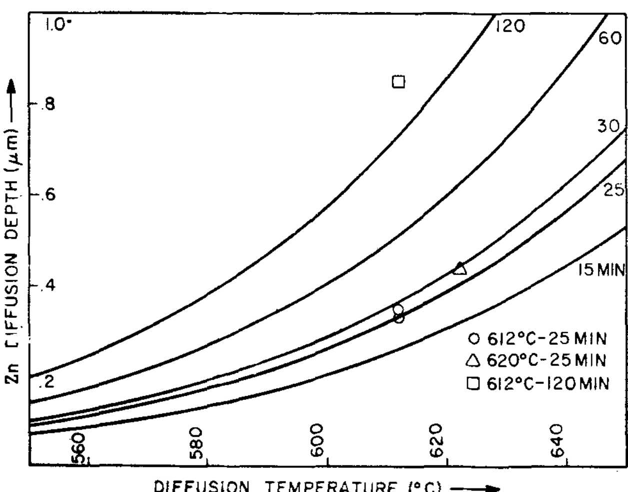

Fig. 1. Calculation of junction depth for Zn diffusion from a 5/50/45 (Ga,As,Zn) source as a function of time and temperature for an ideal closed system. Data points show experimental values determined on a less than ideal closed diffusion system.

When anodized samples were Zn diffused subsequent to the 250°C drying cycle, the oxide took on a mottled, discolored appearance. At this relatively high temperature, the oxide film was not completely stable and it reacted with the Zn. It was found that by annealing the oxide at 600°C for 30 min in dry nitrogen this problem could be eliminated. This annealing step serves to densify the oxide as evidenced by a decrease in thickness ranging from 25-50% indicated in Table I and increases its chemical stability (10). Following the annealing step, the oxide remained visibly unchanged after Zn diffusion at 650°C for times up to 2 hr.

Diffusion depth was measured by lapping the sample with a 0.25 μm diamond suspended in methyl ethyl ketone on a cylindrical drum (12) and then staining with a 30% HNO_3 aqueous solution to delineate the p-n junction. Cylinder lapped sections showed the "standard" Zn diffusion (612°C for 25 min) to penetrate 0.33 ± 0.5 μm, and showed that oxides 1300Å or greater effectively masked the "standard" diffusion, while thinner oxides only attenuated the diffusion depth.

Discussion

The variation of junction depth with time and temperature for a closed system Zn diffusion in several III-V compounds may be written as (13)

$$x_j = X\sqrt{t}\exp(-E/kT) \quad [1]$$

where t is the diffusion time in hours. Casey and Panish (14) have determined $X = 1930$ cm/hr$^{1/2}$ and $E = 1.33$ eV for Zn diffusion in GaAs at temperatures below 744°C. The theoretical junction depth *vs.* diffusion temperature relation is plotted with time as a parameter in Fig. 1. Experimental points are plotted on the same figure showing good agreement between theory and experiment.

Table I summarizes the oxide thickness, diffusion cycle, and junction depth data for the various samples used in this experiment. Note that while thicker oxides were grown and used, only a 1300Å thick oxide after an appropriate annealing cycle was required to mask against a 3300Å Zn diffusion. Figure 2 shows a cylinder lapped section of an 800Å thick oxide. Note that after diffusing a 0.85 μm layer of Zn into the unprotected GaAs surface, a 0.55 μm layer of Zn penetrates under the oxide. With thicker oxides (≥1300Å), however, no Zn penetration through the oxide is observed. In Fig. 3 a cylinder lapped section shows 3600Å of oxide acting as a Zn barrier. In both cases sharp boundaries are observed between diffusion under the protected (oxidized) and unprotected stripes on the semiconductor, *i.e.*, no observable anomalous lateral diffusion within resolvable limits occurs indicative of a high bond strength, low defect density interface between the oxide and semiconductor.

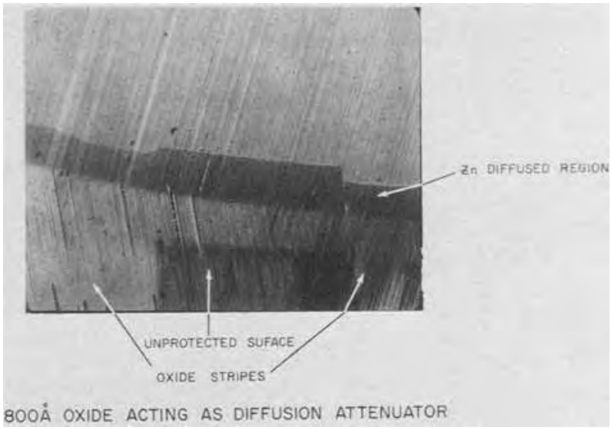

Fig. 2. Cylinder lapped section of 800Å thick oxide stripe geometry on GaAs substrate. Zn junction depth as indicated by chemical staining is 0.85 μm under the unprotected surface and 0.55 μm under the oxide stripe.

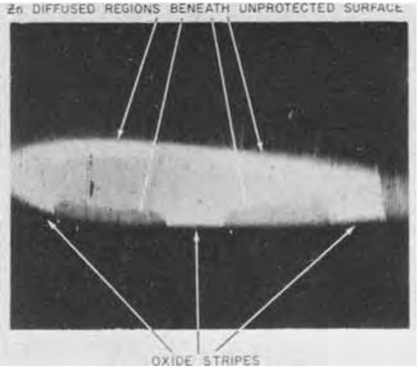

Fig. 3. Cylinder lapped section of 3600Å thick oxide stripe geometry on GaAs substrate. Zn junction depth under the unprotected surface is 0.44 μm and diffusion is masked under the oxide stripe.

An estimate of the diffusion coefficient of Zn in the native oxide can be made using the model described by Baliga and Ghandi (7). If for a given diffusion cycle two different oxide thicknesses are used, the relative diffusion coefficient of Zn in the oxide as compared with GaAs can be written as

$$D_{\mathrm{oxide}}/D_{\mathrm{GaAs}} = \left(\frac{d' - d}{x'_j - x_j}\right)^2 \quad [2]$$

Table I.

Sample	t_{ox} as-grown (A)	Annealing cycle	t_{ox} after anneal (A)	Diffusion cycle	Zn depth GaAs (μm)	Zn depth Oxide (μm)
Gas-011-1	—	600°C for 30 min	800	612°C for 25 min	0.33	0.20
Gas-020-4	1700	650°C for 15 min	800	612°C for 120 min	0.85	0.55
Gas-035-3	2880	600°C for 30 min	1600	612°C for 25 min	0.35	—
Gas-040-3	2375	600°C for 30 min	1300	612°C for 25 min	0.33	—
Gas-040-4	4875	600°C for 30 min	3600	620°C for 25 min	0.44	—

where d' and d are the oxide thicknesses, and x'_j and x_j are the Zn diffusion depths under the respective oxides. For samples where the oxide acted as a Zn barrier, $x_j = 0$. The calculation yields an upper bound on D_{oxide}/D_{GaAs}

$$D_{oxide}/D_{GaAs}|_{upper\ bound} = \left(\frac{d' - d}{x'_j}\right)^2 \qquad [3]$$

and for $d' = 1300Å$, $d = 800Å$, and $x'_j = 2000Å$

$$D_{oxide}/D_{GaAs}|_{upper\ bound} = 0.06 \qquad [4]$$

Thus the diffusion coefficient of Zn in the native oxide is less than one-sixteenth of the diffusion coefficient of Zn in GaAs. In comparison, the diffusion coefficient of phosphorous in SiO_2 is one-tenth that of phosphorous in silicon and the diffusion coefficient of boron in SiO_2 is one-thirtieth that of boron in silicon (15) (for a closed system at 1150°C). These values indicate that the diffusion coefficient of Zn in the native oxide on GaAs falls into the realm of usable values for diffused device fabrication. It should be pointed out that this calculation is of a qualitative nature, used here to illustrate the Zn mask potential of the native oxide.

Conclusions

It has been shown that the anodic native oxide, after an appropriate annealing cycle, can be used as a mask for Zn diffusion in GaAs. Such oxides are grown either at room temperature or at 100°C; they are readily compatible with standard photolithographic processing, and are easily etched in dilute HCl (before annealing at 650°C for 30 min) which does not attack the GaAs surface.

Since Zn can be diffused through the thinner oxides, such thin oxides can be used as diffusion buffers to prevent semiconductor surface damage from reaction with the diffusant. Thus a combination of thick and thin oxides will permit well-controlled selective area diffusion and protect the GaAs surface from damage as well as contamination from the ambient.

No gross strain was found to be present after oxide growth, following a 250°C dry cycle and after annealing at 600°C for 1 hr, as evidenced by viewing the sample through crossed polarizers (10) in an infrared microscope. This, along with the absence of any observable anomalous lateral diffusion, indicates a high integrity oxide-semiconductor interface.

These results suggest a potential GaAs planar technology based on a native oxide. Work is continuing at present to extend the high temperature/time operating limits of the native oxides for use as a diffusion mask to other dopants, and potentially as a restricted area epitaxy mask.

Acknowledgments

We wish to thank R. E. Albano for his assistance with sample diffusion, and Mrs. D. R. Ketchow for her expertise with the cylinder lap technique. We give particular thanks to L. R. Dawson for his help with the lapping and staining procedure and many useful discussions on this experiment.

X-Ray Imaging Technique for Observing Liquid Encapsulation Czochralski Crystal Growth

H. D. Pruett[1] and S. Y. Lien

Western Electric, Engineering Research Center, Princeton, New Jersey 08540

The publication costs of this article have been assisted by the Western Electric Company.

ABSTRACT

An imaging technique has been developed to facilitate growth of uniform diameter crystals by the liquid encapsulation Czochralski method. A point source of x-rays is used to produce a shadow image of the growing crystal on a scintillation screen. A high-sensitivity TV camera converts the shadow image into a real-time display on a TV monitor. System components are described, and results obtained from growing GaP crystals are presented.

In processing semiconductor wafers into electronic devices such as light-emitting diodes, it is desirable to have uniformly sized wafers. This allows the use of standard size masks and fixtures. Uniformly sized wafers can be produced by growing crystals of uniform diameter, or by centerless grinding of oversized crys-

[1] Temporary address: Western Electric, Montgomery Plant, Aurora, Illinois 60507.

Key words: crystal growth, x-ray imaging, gallium phosphide.

tals having nonuniform diameters. For silicon, equipment is commercially available to automatically control the crystal diameter during growth. Furthermore, the raw material costs are low enough that centerless grinding is an economically viable process. For gallium phosphide (GaP), none of the above is true; commercial equipment is not available and material costs are substantial. In addition, pulled GaP crystals tend to be strained and break easily when subjected to centerless grinding. Because of the above considerations, a program to develop a better method of producing GaP crystals of uniform diameter was undertaken. This paper describes the system which was developed to meet this objective.

At present, large GaP ingots are grown by using the liquid encapsulation Czochralski (LEC) method.[2] The growth procedure starts by placing polycrystalline GaP in a quartz crucible, placing a precast slug of B_2O_3 on top of the powdered GaP, and heating the crucible in a graphite susceptor in a chamber pressurized to about 800 psi with an inert gas. At 400°-500°C the B_2O_3 melts, covers the GaP, and thereafter inhibits the evolution of phosphorus whose vapor pressure is about 35 atm at the melting point of GaP. The remaining steps in the growth procedure are similar to those used in normal Czochralski growth, namely, seeding, shouldering, and growth of a uniform diameter body.

As an ingot is being grown, a process which requires several hours, some phosphorus escapes from the melt and condenses on cold surfaces in the chamber, such as, the optical windows used for viewing the growth process. After a few hours at the GaP melting temperature, the normally transparent encapsulant gradually becomes clouded with fine particles of P and/or GaP. Furthermore, thermal gradients in the ambient gas introduce optical distortions. Together, these factors compound the difficulty of accurately determining the size and shape of the growing crystal by visual observation, which is normally done using a closed-circuit TV system. This requirement for more reliable, more quantitative information on which to base control decisions was the primary incentive for developing a better method of sensing the diameter of the growing crystal.

Several techniques were examined (2-4) but none appeared to offer an adequate solution to the diameter sensing problem. It appeared that an x-ray shadow-imaging technique would, however, eliminate the visibility limitations caused by the buildup of phosphorus deposits on the optical windows, clouding of the encapsulant, and thermal gradients in the ambient. This paper describes such an x-ray imaging technique based on a closed-circuit TV system. Although developed for GaP, it can be also applied to the growth of other materials.

Basically, the technique utilizes a small x-ray source to cast a shadow image of the growing crystal onto a fluorescent screen. An intensified TV camera is used to convert the x-ray shadow image into a corresponding visible image which is displayed on a TV monitor. This approach not only eliminates the above visibility problems, but the image produced also provides an excellent indication of the melt temperature. This is because the viewpoint is perpendicular to the axis of rotation of the growing crystal, and, consequently, the shape of the meniscus at the liquid-solid interface is clearly visible. The meniscus shape has proved to give a better indication of the melt temperature in the growth area than can be obtained from any other temperature-sensing apparatus known to us.[3] As is common knowledge, melt temperature is a critical parameter for both the initial seeding operation and the growth of the uniform diameter portion of the crystal. Within a few seconds after the seed is first dipped into the melt, an experienced observer can tell from the meniscus shape whether or not the melt temperature is proper for seeding. The shape continues to be an invaluable indicator of melt temperature during subsequent phases of crystal growth.

[2] Recently, a Bridgman technique for growing large GaP crystals has been disclosed by Blum and Chicotka (1). Material produced by this technique has not yet been evaluated for manufacturing light-emitting diodes.

[3] A qualitative discussion of meniscus shape is given in a related paper (5).

X-Ray Imaging System

A schematic of the over-all x-ray imaging system is shown in Fig. 1. Beryllium entrance and exit windows are used to maximize the x-ray transmission of the system. These windows are supported by stainless steel flanges which have elliptically shaped openings. In Fig. 2, which is a cross-sectional view of the crucible assembly, the area enclosed by the dotted line indicates the approximate field of view provided by the elliptical opening at the exit port.

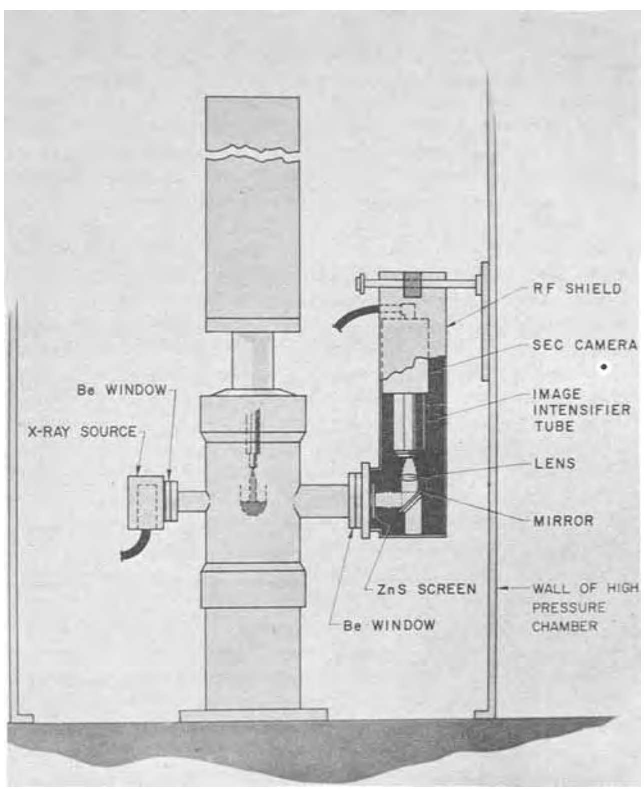

Fig. 1. Drawing of the x-ray imaging system showing location of various components.

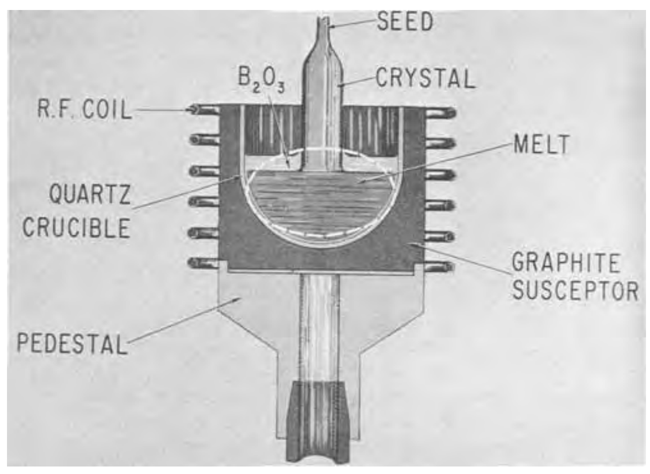

Fig. 2. Cross-sectional view of the crucible assembly. Objects within the area enclosed by the elliptically shaped dotted line are visible in the TV monitor picture.

The x-ray source used in the present system has a tungsten target tube with a focal spot size of 0.5 mm. Output capability of the system is 8 mA at 100 kV. Focal spot size is important in fluoroscopic imaging because it affects edge resolution; this is illustrated in Fig. 3. Assuming that the tube emits radiation uniformly over the focal spot area, the extent of the x-ray penumbra is proportional to both the focal spot size and the object-to-screen distance, but is inversely proportional to the source-to-object distance. In our system, the growing crystal is approximately midway between the source and the screen, resulting in a penumbra of about 0.5 mm at the plane of the fluorescent screen.

A tungsten target x-ray tube was chosen for the present application after studying two interrelated factors. For fluoroscopic imaging, the image contrast should be as high as possible and the total transmitted flux should be the largest value which is consistent with acceptable image contrast. An indication of image contrast can be obtained from a plot of mass absorption coefficient *vs.* x-ray energy. In Fig. 4 such a plot is shown for the materials used in the present crystal puller. At a given energy, the vertical distance between the curves for two materials is a measure of the contrast that can be obtained in a fluoroscopic image involving those two materials. This contrast is relatively independent of x-ray energy in the low energy region, but rapidly decreases for energies at and beyond the onset of Compton scattering. At very high energies, image contrast is mostly dependent on relative absorber thickness rather than on the types of material involved. For the K_α emission of tungsten, image contrast is nearly optimum between GaP and the various

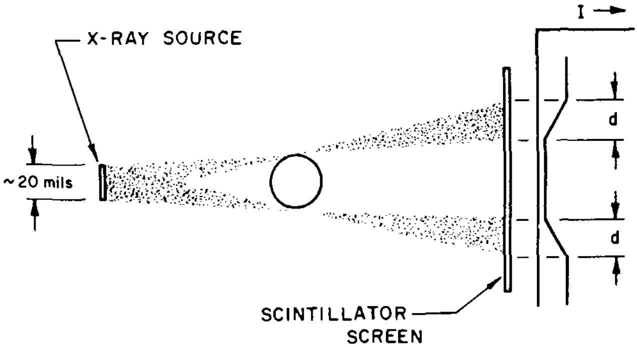

Fig. 3. Drawing which illustrates degradation of edge definition of a shadow image when using a finite sized source of radiation.

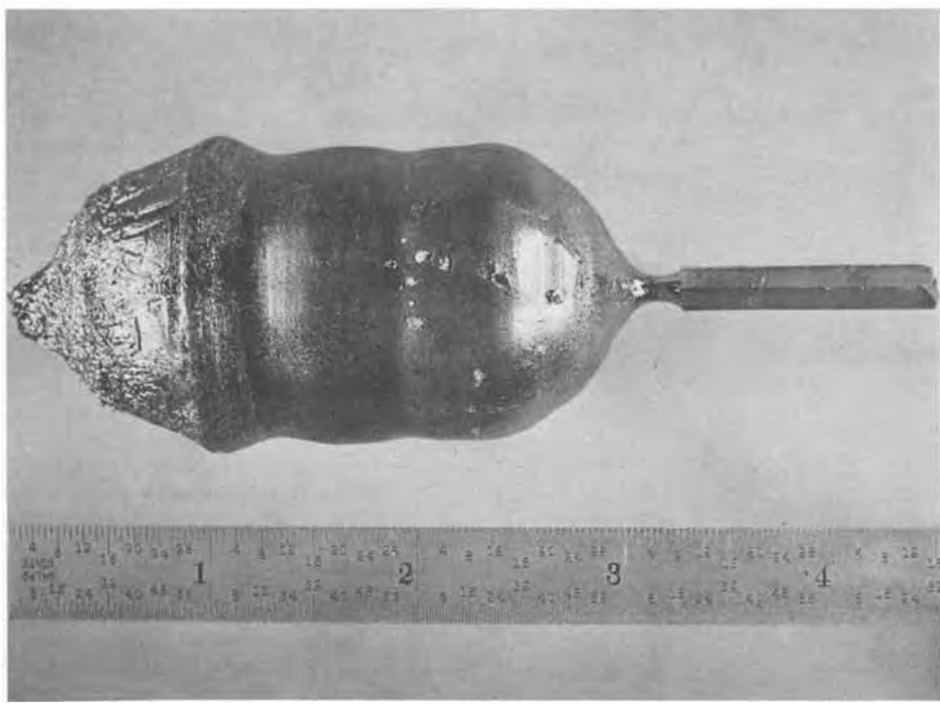

Fig. 7. Photograph of a crystal typical of those which can be grown by means of the x-ray imaging system.

other materials in the crystal puller. At the same time, the over-all x-ray transmission for tungsten radiation is higher than that of any other anode material commonly available in commercial x-ray tubes.

In Table I, the calculated x-ray transmission of the components in the crystal puller is given. Because of its high absorption, the original rf heating coil was replaced with one made of Al. Because of lower conductivity, the calculated joule heating losses are approximately 25% higher than in the original coil, but this was considered a small penalty for the substantial improvement in image quality which was obtained.

An important link in the imaging system is the fluorescent screen used for converting the x-ray shadow image to a visible image. The over-all conversion efficiency of the screen is dependent on its thickness and quantum conversion efficiency. Because of the compromise that must be made between spatial resolution and over-all conversion efficiency, relatively thin screens must be used. Such screens absorb only a few

per cent of the incident x-ray beam. For the present application, a brief study indicated that the best compromise is produced by a ZnCdS screen, Type PFG-4.[4]

An intensified TV camera is used to view the shadow image on the fluorescent screen. The image intensifier tube is a Type WE-30677 and the camera tube is a Type WX-31792, both manufactured by Westinghouse Electric. This combination of components has provided adequate sensitivity for viewing the low level image of the growing crystal.

To maximize the signal-to-noise ratio of the image, the video bandwidth was tailored to meet the spatial resolution inherent in the image. As shown in Fig. 3, the edge definition of a shadow image depends on the source dimensions. A diffuse edge requires less video bandwidth for faithful reproduction than does a perfectly sharp edge. This means that, for a diffuse image, the video bandwidth can be reduced accordingly, thereby reducing the Johnson noise of the circuit. This noise is proportional to the square root of the bandwidth.

Results

Some typical images seen on the TV monitor during the seeding operation are shown in Fig. 5a and 5b. In the lower figure, the shape of the meniscus is clearly visible. As mentioned earlier, this shape is the best indicator of melt temperature available. The TV monitor image and associated video waveform of a selected horizontal scan line are shown in Fig. 6a and 6b. In the upper photograph, the melt level is above the major axis of the elliptical viewing area. At a later date, a crucible lift assembly was added to the crystal puller to allow the melt level to be maintained coincident with this axis. The dark vertical lines in Fig. 6a are due to a calibrated grid attached to the face of the TV monitor and used for visually determining the crystal diameter. By electronically measuring and appropriately converting the time interval Δt shown in Fig. 6, the crystal diameter can be read directly on a digital display. Also, the binary-coded decimal (BCD) input to the digital display can be used to implement a closed-loop system for automatically controlling the diameter of the growing crystal. At the present time, we have implemented the visual display but not the closed-loop control system.

In Fig. 7 and 8 some recently grown crystals are shown. Necking of the seed to reduce dislocation density is an operation which can be readily observed and controlled with the x-ray imaging system. This is illustrated in Fig. 7 where the seed is still attached to the crystal. Through the excellent diameter information presented in the TV monitor picture and associated digital readout, the crystal puller operator has all the information necessary to make control decisions. A reasonably experienced operator can control crystal diameter to 1/16 in. or better, as illustrated in Fig. 7. With closed-loop control, it should be possible to produce crystals similar to the one shown in Fig. 8 whose diameter of 1.56 in. was controlled to $\pm$ 20 mils by manual operation of the crystal puller.

Summary and Conclusions

In this paper an alternative method of observing LEC crystal growth has been presented. The configuration of the system used to implement this x-ray imaging system has been given and some of the performance requirements of the system components have been discussed. Photographs of typical TV monitor images were shown in which the meniscus shape used for deriving temperature information is clearly visible. Photographs of crystals grown solely by observation of the fluoroscopic image were shown to illustrate the diameter control that can be achieved manually. On the basis of our experience and the evidence presented in this paper, we conclude that x-ray imaging permits a substantial improvement in viewing and controlling LEC crystal growth.

ABSTRACT

Instrumental parameters for the determination of the oxygen/silicon ratio in SiO_2 films using Auger electron spectroscopy have been studied and optimized. In the case of a binary system such as this, the ratio of the Auger peak heights from the two components is a measure of their relative abundance and can yield meaningful results when compared with a standard. This method has been utilized to determine the oxygen/silicon ratio in spin-on glass films densified at various temperatures. The oxygen/silicon ratios of nondoped spin-on glass films show a general trend to increase and approach 2 as densification temperatures increase. The structural re-arrangement of the silica network at ~400°C is also reflected by the oxygen/silicon ratios. The oxygen/silicon ratio for other commonly used oxide films produced from steam, oxygen, and CVD was also determined. The techniques and results of this study are discussed.

Auger electron spectroscopy (AES) is a technique increasingly being used for the unambiguous identification of the elemental constitution of a solid surface (1-3). In this relatively new technique, a beam of electrons (typically 1-5 keV) is used to bombard the surface of the solid specimen, giving rise to ionization of the atomic levels. The atom subsequently relaxes either by the emission of x-ray photons or more probably (in the energy range 0-2000 eV) by the emission of Auger electrons. In AES, these Auger electrons which are characteristic of the surface species are detected, thus enabling the positive identification of the surface elements present. Since the mean free paths of these relatively low energy Auger electrons are rather short, they can escape without any significant energy loss only from a region very close to the surface. Typically their escape depth is ~5-10Å and this is why AES is a truly surface technique.

Besides unambiguously identifying the surface elemental constitution, AES yields a wealth of information regarding the chemical nature of the surface species. The differences in the chemical environment are manifest in the Auger spectra in a variety of forms, such as, a shift in the energy of the Auger electrons, changes in the shape and intensity of the Auger peaks, changes in the fine structure, etc. These chemical effects in AES have been discussed in detail by Haas, Grant, and Dooley (4). The chemical effects observed in the Auger spectra thus offer valuable information regarding the chemical nature of the constituents which supplement the knowledge of the elemental constitution. In the case of SiO_2, these effects are very pronounced and are discussed below.

The present Auger spectroscopy investigation of nondoped spin-on glass has been primarily directed at a quantitative evaluation of the oxygen/silicon atomic ratio as a function of the heat-treatment. SiO_2 films produced from the oxidation of silicon by oxygen and steam, as well as chemical vapor deposition (CVD), were also studied for comparison. Although AES is widely used and the characteristic features in the Auger spectra from all the elements are well established, the technique is still mostly qualitative or at best semiquantitative. At the present time, there are no quantitative data available which enable one to translate the number of Auger electrons detected, or more commonly, the Auger peak-to-peak height, to an absolute value of the surface concentration. However, it should be possible to make meaningful measurements of the surface concentration by comparing the Auger peak height with that from a standard. Quartz was used as a standard in this work. In the case of a binary system the ratio of the Auger peak heights from the two components is a measure of their relative abundance. It is this method which has been adopted in the present studies on the oxygen/silicon ratio in spin-on glass.

Experimental

The experimental techniques employed in AES are well established (2, 3) and are not discussed here. The Auger analysis was made in a standard ultrahigh vacuum with a cylindrical mirror analyzer (CMA) incorporating an integral electron gun (Physical Electronics Industries). The ambient pressure during the experiment was typically 1-2 $\times$ 10^{-10} Torr, readily achieved without baking the system. Twelve samples were mounted on the carrousel and each sample could be rotated in turn to face the integral electron gun for Auger analysis. The beam energy, $Ep = 3$ keV, beam current $Ip = 5$ μA, and the modulating signal of 3 eV peak-to-peak, were kept constant throughout the experiment. The necessity for the use of the moderately low beam current is discussed in the following paragraph. As is generally the practice, the derivative of the energy distribution, $dN(E)/dE$ is plotted as a function of the electron energy, E. The Auger spectra were plotted after removing ~20Å from the surface by Xe-ion sputtering. The sputter removal is essential in order to remove the impurities absorbed on the surface. It is assumed that the elemental constitution of the glass at 20Å below the surface is typically characteristic of the "bulk."

Before presenting the results, some of the problems encountered in the Auger analysis of SiO_2 and the assumptions made in the measurement of oxygen/silicon peak height ratios are mentioned. The first major problem encountered in the AES study of SiO_2 is the effect the primary electron beam has on the surface. It is generally recognized that the AES is a nondestructive technique. However, the beam parameters usually employed (typically $Ep = 1$-5 keV, $Ip = 10$-100 μA) do have a profound adverse effect on the SiO_2 surface. Extreme care has to be taken to minimize this effect. The primary effect of the high primary current density is to dissociate the SiO_2 into elemental

Key words: densification of SiO_2, surface analysis, stoichiometry of SiO_2 films.

silicon and oxygen. Under prolonged electron bombardment of the sample, the oxygen is desorbed leaving the surface enriched in "elemental silicon" as evidenced by the growth of the Auger peak characteristic of elemental silicon and the reduction in the oxygen Auger peak. The assumption is made, although presumptuous, that two separate species, namely, elemental silicon and SiO_2, coexist at the surface. Of course, it is quite likely that the surface is composed of SiO_x where $x < 2$. In a separate investigation, we established the optimum beam parameters required to minimize the dissociation effect. A beam current of 5 μA (or lower) is found to be adequate for the analysis without causing any noticeable dissociation effect in the time required for plotting the spectrum (~30 sec).

The method of measuring the ratio of the oxygen/silicon Auger peak heights requires that there is no marked change in the shape of the silicon or oxygen Auger peaks (in SiO_2) due to the chemical effects. For SiO_x samples where $x \simeq 2$, no difference in the silicon or oxygen Auger peak shapes was observed. This was established after studying SiO_2 samples prepared by a variety of techniques, *e.g.*, oxidation in oxygen at 1100°C, oxidation in steam at 1100°C, chemical vapor deposition, and spin-on. Hence, it is valid to measure the oxygen/silicon Auger peak heights ratio in order to make a comparison of the oxygen/silicon content.

All nondoped spin-on glass films on silicon wafers were prepared by flooding the wafer with solution and spinning for 10 sec at 4000 rpm on a Headway Photoresist spinner. The film was then densified for 30 min at temperatures varying from 200° to 1100°C in 100°C increments. These densification cycles were carried out in oxygen and nitrogen ambients, with a 1 liter/min flow rate. The film thickness of spin-on glasses is known to be a function of densification temperature (5). A typical value of film thickness after densification at 1100°C in nitrogen was ~4000Å. SiO_2 films were also prepared by other methods commonly used, *e.g.*, steam grown films at 1100°C, oxygen grown films at 1100°C, and from the chemical vapor reaction of silane and oxygen at 450°C.

Results and Discussion

Figure 1 is a typical Auger spectrum from a SiO_2 sample. For purposes of comparison, the low energy Auger spectrum from a clean elemental silicon surface is also shown. It is worthwhile discussing briefly the main features in the Auger spectra from Si and SiO_2 for a better understanding of the similarities and differences between the two. The principal Auger peak from elemental silicon appears at 92 eV (measured at the maximum negative deflection in the $dN(E)/dE$ curve and has its origin from the $L_{2,3}VV$ transition. In the case of SiO_2, the peak "shifts" to 75 eV. Both these peaks originate in silicon following the $L_{2,3}VV$ transition, the only difference being the chemical nature of silicon in the two cases, one in the form of elemental silicon and the other as SiO_2. The above "chemical shift" is not primarily due to a shift in the binding energies in silicon, but rather has its origin in the change in the density of states in the valence band (strictly, changes in the transition density). There is a group of high energy Auger peaks originating from the KLL type transitions, the strongest peak appearing at about 1620 eV in elemental silicon (Fig. 1). In SiO_2 the strongest peak occurs at about 1617 eV following a general shift of all the KLL Auger peaks by ~3 eV. It is not implied that this measured shift in energy is the true chemical shift due to the changes in the binding energies. The measurement of the absolute chemical shift in the case of insulating surfaces is complicated by the possible changes in the surface potential. In the case of elemental silicon, each KLL Auger peak has two very prominent plasmon loss peaks associated with it. These plasmon loss features are very weak in the KLL Auger spectrum from a SiO_2 surface. The large chemical shift in the low energy Auger spectrum and the plasmon loss features in the KLL spectrum are exploited in distinguishing the presence of the two species, elemental silicon and SiO_2. In the present study, the ratio of the main oxygen, 508 eV Auger peak height (Fig. 1) to the silicon, 75 eV (in SiO_2) peak height is measured as characteristic of the oxygen/silicon ratio of the surface. The ratio of the peak heights was determined at twenty different areas on each sample and the mean value taken. Although one could measure the oxygen, 508 eV/silicon, 1617 eV peak heights, the relatively low intensity of the latter introduces a much larger error.

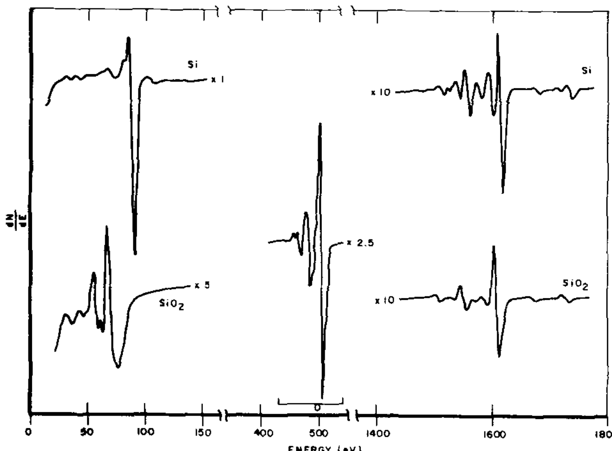

Fig. 1. Typical Auger spectrum of elemental silicon and SiO_2

The oxygen/silicon ratios measured from the Auger spectra are tabulated in Table I for the films studied. The numbers in parentheses represent the oxygen/silicon ratio of the respective films normalized to a value of 2.0 for quartz. It is of interest to note that the oxygen/silicon ratio for the CVD, steam, and O_2 films are close to 2.0. The higher value for the steam-grown oxide (2.05) is in line with the general view that surplus H_2O and/or OH species are incorporated in steam-grown oxide films.

From Fig 2 it is evident that the oxygen/silicon ratio for the nondoped spin-on glass shows a general trend to increase and approach 2 as the densification temperature approaches 1100°C. This behavior is most likely due to the loss of organic solvents at lower temperatures with oxidation and subsequent loss of organic species at higher temperatures. This is supported, in part, by the lower oxygen/silicon ratio for the same films densified under N_2. While the solvent loss at lower temperatures would be similar, the lack of sufficient oxygen for complete oxidation of the organic species produces a lower oxygen/silicon ratio at higher temperatures. The abrupt rise in the oxygen/silicon ratio at ~400°C is due to a structural re-arrangement

Table I. Oxygen/silicon Auger peak height ratios

of the silica network. This is supported by changes that occur in the infrared spectra, etch rate, differential scanning calorimetry, and thermal gravimetric analysis data reported in an earlier study which are characteristic of structural re-arrangement (5) in the silica network. The slight decrease observed in the oxygen/silicon ratio between 900° and 1000°C may also be due to structural re-arrangements, but no additional supporting evidence is available at this time.

ABSTRACT

Colorless $CuAlS_2$ was prepared by using either a small excess of Al or a deficiency of S or Cu. A stoichiometric ratio of the reactants or deficiency of Al yielded a green color product. These crystals showed ESR and optical absorption similar to iron-doped crystals indicating that trace amounts of Fe^{+3} are responsible for the color. Crystals heated in the presence of elements such as Si or Cd lose their color and ESR spectrum, indicative of a reduction of Fe^{+3} to Fe^{+2}. All as-grown and most doped crystals were p-type, while most crystals doped with a combination of Cd/Al were n-type. Colorless $CuAlS_2$ fluoresces with a broad peak at about 600 nm. The fluorescence may be stimulated by infrared after exposure to u.v. Mn-doped crystals exhibit red-orange fluorescence.

$CuAlS_2$ (1) is of interest since it has a related structure and comparable bandgap to ZnS. Thus it might have useful fluorescent or semiconducting properties.

Honeyman (2) reports an optical bandgap of 3.35 eV for $CuAlS_2$ measured on black or deep-green crystals prepared by chemical transport. Optical absorption studies show major peaks at ~900 and 625 nm. Optical studies by Bhar and Smith (3) suggest an indirect gap at 1.84 eV.

Reports of the electrical properties are also in conflict. Honeyman reports n-type conduction with $\rho_{298K} \sim 10^6$-10^7 ohm-cm while Tell *et al.* (4) report p-type conduction ($\rho_{298K} = 10^2$-10^3 ohm-cm) on melt-grown crystals.

To gain a better understanding of $CuAlS_2$, we have studied the optical and electrical properties as functions of stoichiometry and dopants.

[1] Deceased.

Key words: doping, $CuAlS_2$, electrical optical properties.

Experimental

Syntheses were carried out in a manner similar to that described by Honeyman (2). Elemental reagents were weighed in desired proportions and sealed in dried evacuated silica tubing (15 mm OD, 13 mm ID, 15 cm long) with enough iodine to produce a pressure of ~1 atm during reaction. Instead of using powdered metals as Honeyman did, Al and Cu wire of 5*N* purity were used. The use of wires instead of powders reduces the contamination by surface oxide. We found commercially obtained 5*N* Al powder to be highly impure, containing primarily Fe and Si impurities. Also, the commercially obtained 5*N* Cu and Al wires were not as pure as specified. Our emission spectroscopy showed Cu: 2-25 ppm Mg, 0.5-2 ppm Si, and 1-5 ppm Fe; Al: 100-500 ppm Mg, 20-150 ppm Cr, 10-50 ppm Si, and 10-50 ppm Fe.

Reactions were carried out in natural gradient tube furnaces. The ends of the silica tubes containing the reactants were furthest in the furnaces while the other

ends were at the outer extremities. The temperature of the center regions was raised to about 800°C. After about 48 hr, the tubes were cooled, removed, and shaken to remove sulfide crusts which had formed on the Al wire and to break up copper sulfide. The tubes were refired at about 800°-1000°C in the reactant ends and at 400°-600°C in the cooler ends until all the S was taken up. The tubes were then heated at about 1000°C with no gradient for several days. Crystals generally grew as blades out of the crystalline mass.

Some doped crystals were prepared by heating previously prepared crystals in the presence of the dopant elements, Zn, Cd, Si, Ge, Sn, and Al, in evacuated silica tubes at 400°-800°C for from 1 to 24 hr followed by a quench in cold water. Crystals doped with Fe, Cr, and Mn were prepared by starting with the dopant in the reactants and proceeding with syntheses as described.

Crystals were characterized by chemical analyses, emission spectroscopy, and x-ray powder diffraction. Lattice constants were refined by least squares technique from Guinier camera data. Electrical resistivities and Seebeck coefficients were obtained using a two-probe, hot-probe method with silver paste contacts.

Optical transmission data were obtained on polished crystals using a Cary 14 spectrophotometer. Absorption coefficients were calculated employing dielectric constant data of Honeyman (2).

Fluorescent emission spectra of $CuAlS_2$ and Mn-doped $CuAlS_2$ excited by 253.7 nm Hg light were measured on powders between 300 and 750 nm using a ½m Bausch and Lomb monochromator fitted with an EMI extended S-20 response photomultiplier tube. The monochromator detector system was calibrated against an Eppy quartz-iodine standard lamp.

ESR was measured on powdered samples at X band using a Varian spectrometer.

Results and Discussion

Color as a function of stoichiometry.—The color of $CuAlS_2$ is primarily the result of impurities. The valence state of the impurities and the resulting sample color can be controlled by adjusting the stoichiometry. It can be made colorless or pale-green depending on the reactant ratio. Colorless material results from using a small stoichiometric excess of Al or deficiency of Cu or S. Pale-green crystals form when either a stoichiometric proportion of reactants is used or one with a small excess of oxidizing power is used, *i.e.*, deficiency of Al or excess S.

Black crystals formed when stoichiometric ratios of Al and Cu powders (found to contain Fe and Cr impurities) were used. This may account for the black crystals obtained by Honeyman. Use of excess Al powder, even with these impurities, produced colorless material.

It was not possible to distinguish among colorless, green, or black crystals by chemical analyses or x-ray diffraction. The cell dimensions and ranges refined from Guinier camera data from four colorless and four green samples are: colorless, $a = 5.333 \pm 0.002$Å, $c = 10.428 \pm 0.005$Å; green, $a = 5.333 \pm 0.0001$Å, $c = 10.433 \pm 0.002$Å. Reported cell dimensions are smaller (1,2). We observed smaller cells on samples prepared above 1100°C perhaps indicating loss of S.

Emission spectroscopy of green and colorless crystals showed little difference. The major contaminants were Si (~500 ppm) and Fe (~30 ppm); all other elements totaled ~20 ppm.

The nature of the color-producing species was determined by comparing optical absorption data and ESR of colorless and pale-green crystals with data from iron- and chromium-doped crystals.

Crystals were doped with Fe and Cr by incorporating the dopant in the starting ratio. Compositions were prepared of starting formulas $CuAl_{0.99}M_{0.01}S_2$ and $Cu_{0.99}M_{0.01}AlS_2$ when M = Fe and Cr. The colors of the products differed greatly. Substitution for Al produced black crystals when M = Fe and dark-green crystals when M = Cr. Substitution for Cu yielded orange crystals when M = Fe and pink crystals when M = Cr.

The ESR spectrum of the black, iron-doped crystals was identical to but stronger than the spectrum obtained from the pale-green $CuAlS_2$. The ESR of the orange, Fe-doped crystals was much weaker and different from the black Fe-doped crystals. No ESR was observed in the colorless, undoped crystals.

We believe that the iron on the Al site is trivalent. Thus the pale-green color of the undoped $CuAlS_2$ is due to Fe^{+3}. The color can be bleached by reduction of Fe^{+3} to Fe^{+2} when excess Al is used in the preparation.

The evidence for Fe^{+3} as the cause of the color is further substantiated by the optical absorption data in Fig. 1.

The spectrum for the Fe^{+3} doped crystals is qualitatively similar to but much stronger than the spectrum of the pale-green crystals. It is also similar to the spectrum reported by Honeyman (2) indicating that his material probably contained Fe. The absorption peaks near 11,000 and 16,000 cm^{-1} correspond to the Fe^{3+} transitions $^6A_1(^6S)$ to $^4T_1(^4G)$ and $^4T_2(^4G)$, respectively, observed in ZnS and other compounds doped with Fe^{+3} (5).

The colorless $CuAlS_2$ showed no absorption due to Fe^{+3} and a sharper cutoff at the band edge. The absence of color can be attributed to the reduction of the valence state of iron due to the reactant ratio containing greater reducing strength in the form of excess Al.

The optical transmission data for the Cr-doped $CuAlS_2$ are shown in Fig. 2. The dark-green and pink crystals show very different spectra. The green crystals have absorption bands near those of Fe^{+3} and could account for the pale-green color in the undoped crystals. The ESR observed for the dark-green, Cr^{+3}-doped crystals, however, was different from the spectra of the pale-green undoped crystals, again suggesting that Fe^{+3} is the major cause of the color in the undoped crystals. This result is substantiated by Brandt *et al.* (6).

Electrical properties and doping.—Two-probe resistivity measurements[2] at room temperature and Seebeck coefficients are: colorless crystals $\rho = 10^2$-10^4 ohm-cm, 20-50 $\mu V/°C$; green crystals 10^4-10^6 ohm-cm, 20-200 $\mu V/°C$; black crystals 10^6-10^8 ohm-cm, 200 $\mu V/°C$. The resistivity of the black crystals is in the range found by Honeyman (2). The resistivity and p-type character of the colorless crystals agree with Tell *et al.* (4). The

[2] Four-probe resistivities are generally an order of magnitude lower, *e.g.*, a green crystal showed $\rho_{298K} = 2 \times 10^2$ ohm-cm; $Ea = 0.004$ eV, 18 $\mu V/°C$.

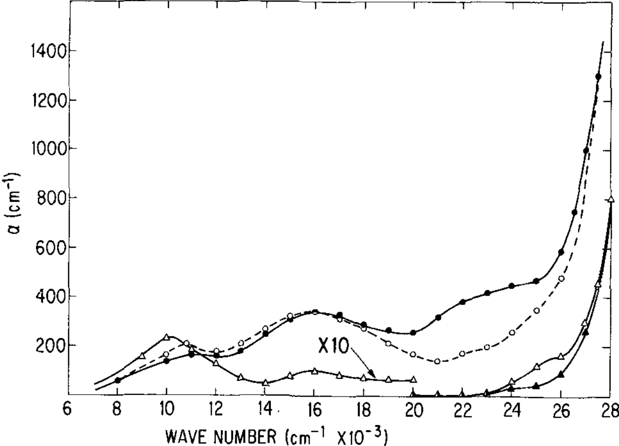

Fig. 1. Absorption coefficients vs. wave number for $CuAlS_2$. ● = Honeyman (2); ○ = Fe doped; △ = green undoped; ▲ = colorless undoped.

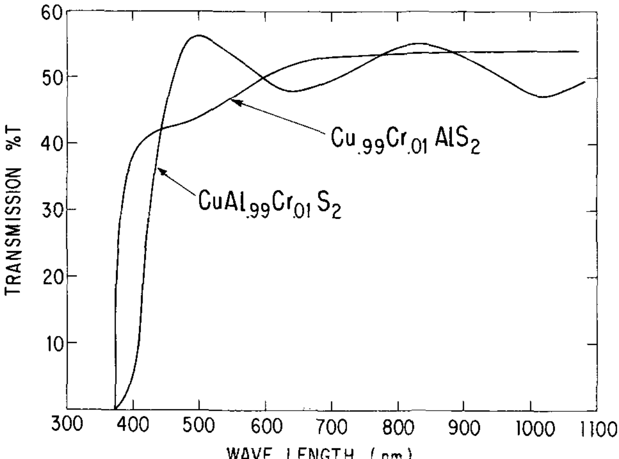

Fig. 2. Optical transmission of Cr-doped $CuAlS_2$ vs. wavelength. The crystal thickness is 85μ.

high resistivity of the black crystals suggests that the Fe levels act as hole traps.

Many attempts were made to dope the crystals in order to produce n-type conductivity. Most crystals doped with Cd or combinations of Cd/Al showed n-type conductivity, with two-probe resistivities at room temperature in the range $\rho = 10^1$-10^4 ohm-cm and Seebeck coefficients in the range -100 to -200 μV/°C. Crystals doped with Cu, Al, and Si were p-type with generally lowered room-temperature resistivities in the range 10^1-10^3 ohm-cm and Seebeck coefficients in the range 5-50 μV/°C.

Crystals either black, green, or colorless, when heated in the presence of any one of the dopant elements Al, Cu, Zn, Cd, Ga, In, Si, Ge, Sn, etc., became pale-yellow. The loss of green color was accompanied by a disappearance of ESR, indicative of a reduction of Fe^{+3} to its divalent state. Green crystals from the same batch were doped with Al, Si, and a combination of Cd/Al, respectively. Absorption coefficients (Fig. 3) show a greater degree of transmission at 25,000 cm^{-1} than the green material and a complete absence of the peak at 16,100 cm^{-1}. The Si- and Al-doped crystals show a peak at 25,640 cm^{-1}. This peak is absent in the crystal doped with the combination of Cd/Al.

The optical and electrical data suggest that the level at 25,640 cm^{-1} may be associated with an acceptor level since it is present in the best p-type conductors and absent when Cd, the n-type dopant, is present.

It is suspected that Cd may substitute for Cu since the ionic radii of Cu^{+1} and Cd^{+2} are comparable. The use of Al in combination with Cd should help to keep Cd from the Al sites where it may act as an acceptor.

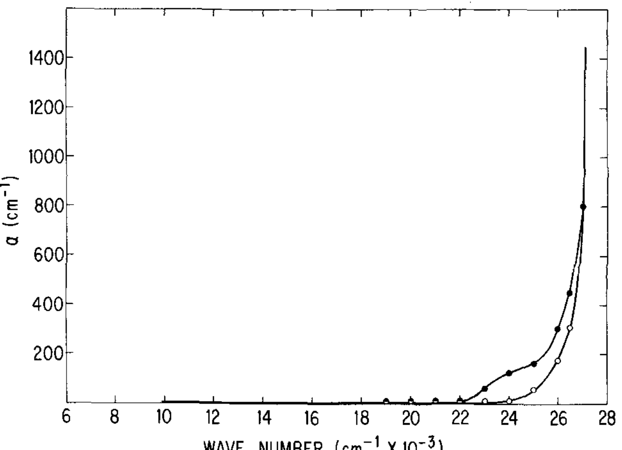

Fig. 3. Absorption coefficients vs. wave number for $CuAlS_2$ ○ = Cd/Al doped; ● = Si and Al doped.

Green or colorless crystals when heated in air between 400° and 600°C become nearly black and the ESR characteristic of Fe^{+3} is enhanced.

Resistivity measurements on crystals heated in air show lowered p-type resistivity in the range 10^0-10^1 ohm-cm. This is in contrast to black, as-prepared crystals and may be the result of Cu^{+2} formation on the surface.

Fluorescent properties and Mn doping.—Colorless crystals of $CuAlS_2$ exhibit weak orange fluorescence as shown in Fig. 4. This fluorescence may be stimulated by infrared radiation after prior exposure to ultraviolet radiation. The stimulated and excitation spectra are shown in Fig. 5. We believe that the infrared-stimulated luminescence is due to the energy exchange between the Fe^{+2} and Fe^{+3} states. This is supported by the observation that the green crystals have a higher stimulated luminescence output than the colorless crystals.

Crystals doped with Mn by addition of Mn into the starting ratio were nearly colorless and exhibited bright orange-red fluorescence (Fig. 6). The infrared-stimulated fluorescence was not seen in these compositions.

Bonding and conduction.—$CuAlS_2$ has a wide bandgap, can be doped p- and n-type, and allows incorporation of many dopants. It may be compared to ZnS which has a wide bandgap (3.7 eV) and is iso-electronic with a related "tetrahedral" structure. In contrast to ZnS which is a poor n-type conductor, it is a good p-type conductor. It has been speculated that the cause of the p-type conduction is the ease of formation of Cu vacancies due to the lesser contribution of Cu to the covalent bonding (4). We wish to offer an alterna-

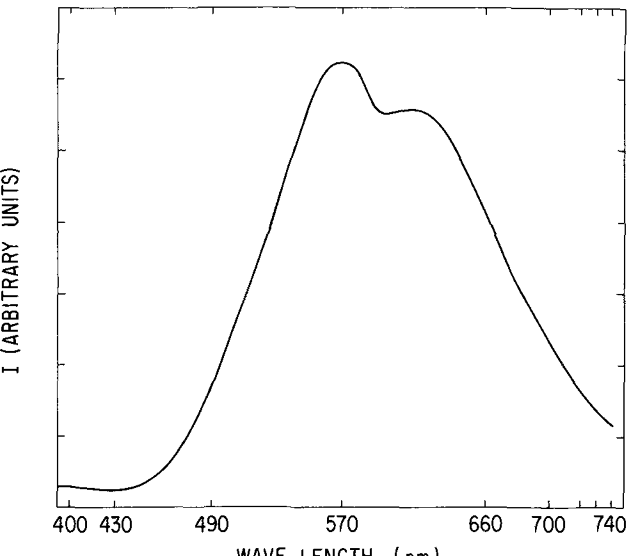

Fig. 4. Fluorescence emission of $CuAlS_2$

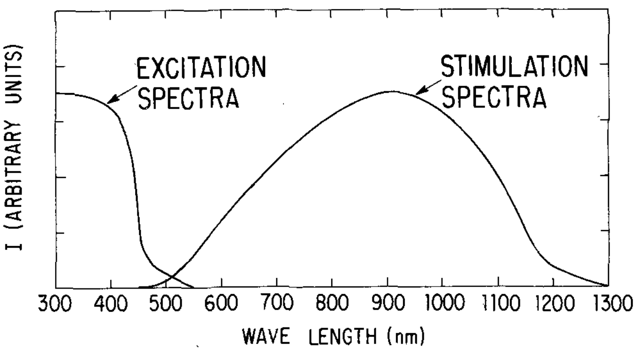

Fig. 5. Stimulation and excitation spectra of $CuAlS_2$

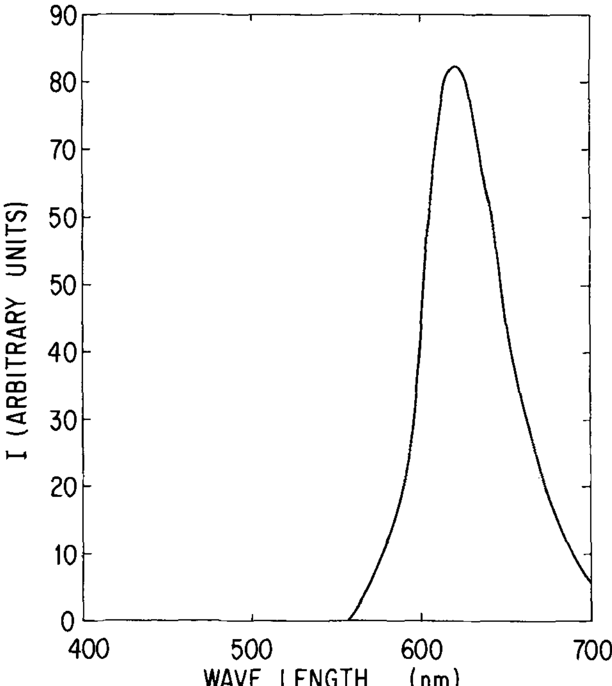

Fig. 6. Fluorescence emission of Mn-doped $CuAlS_2$

tive mechanism. Since Cu d-orbitals have been shown to be close to the valence band in this compound (7) it would seem that if a trace of Cu^{+2} were present, the d^9 level could act as an acceptor state. In contrast, the d^{10} level of Zn in ZnS is very stable.

When attempts are made to dope ZnS p-type, such as, by incorporation of Zn vacancies, the lattice compensates by loss of S. In contrast, $CuAlS_2$ with cation vacancies can compensate by formation of Cu^{+2}.

It would seem from electronegativity differences, a rough measure of covalent character, that the Cu-S bonds having the smaller electronegativity difference should be more covalent than the Al-S bonds. Thus the valence and conduction band edges would be primarily composed of Cu-S states since the splitting of the more ionic Al-S bonds would be greater. The major conduction would occur in the Cu-S bonds where a small amount of Cu^{+2} could act as an acceptor. For similar reasons, Cu_2S is a good p-type conductor while Al_2S_3 is a wide bandgap, practically insulating, semiconductor.

It follows from this limited study that since $CuAlS_2$ is greatly affected by impurities and stoichiometry, further study will require preparation of extremely pure material with more carefully controlled impurity concentrations.

ABSTRACT

Vapor pressure measurements have been made on pure iron pentacarbonyl between +31° and −19°C. The experimental results may be expressed in the form

$$\log_{10} p(\text{mm Hg}) = -(2096.7°\text{K}/T) + 8.4959$$

which corresponds to a heat of vaporization for the liquid carbonyl of $\Delta H = (9.588 \pm 0.12)$ kcal/mole. This result confirms and extends the earlier measurements made by Trautz and Badstübner (2) between 0° and 140°C. The need for careful purification of commercially available iron pentacarbonyl is emphasized, particularly for establishing the correct vapor pressure below 45°C.

Vapor pressure measurements for the liquid-gas equilibrium of $Fe(CO)_5$ were reported originally by Dewar and Jones (1) for temperatures down to −17°C, and by Trautz and Badstübner (2) for temperatures down to 0°C. These data agree only at temperatures above about 45°C. At decreasingly lower temperatures, the measurements in Ref. (1) are increasingly larger than those reported in Ref. (2), and at −7°C they deviate by more than a factor of three from the extrapolated data in Ref. (2). Unfortunately, these differing results have been quoted independently, without explanation for the discrepancy, by incorporating the data of Ref. (2) in data collections (3) and those of

Key words: iron pentacarbonyl, vapor pressure.

Ref. (1) in specification sheets for the carbonyl (4). Since, in the course of absolute line-intensity measurements on Fe-atoms produced by shock-heating trace amounts of $Fe(CO)_5$ in argon, we required accurate vapor-pressure data below 0°C, we have made additional measurements on the purified carbonyl at temperatures between +31° and −19°C, which allowed us to resolve the discrepancy in favor of the data reported in Ref. (2).

Experimental Procedure

The equilibrium vapor pressure of $Fe(CO)_5$ was measured by using a precision bourdon-tube gauge with a fused quartz spiral (Texas Instruments, Model 140A), which has a minimum resolution of 3×10^{-3} Torr and a measurement repeatability of 6×10^{-3} Torr [see Ref. (5)]. The gauge was connected to a removable glass sample-reservoir and to a high-vacuum pumping station by an all-glass system. Backstreaming of diffusion-pump oil was prevented by a liquid nitrogen trap, which was separated from the system during vapor-pressure measurements in order to avoid condensation of the iron pentacarbonyl vapor. The entire apparatus was evacuated routinely to pressures below about 5×10^{-6} Torr and exhibited a leak rate of less than 1×10^{-9} scc/sec helium.

The iron pentacarbonyl used for vapor pressure measurements was obtained by purifying technical grade samples of an assayed purity of better than 99.5% (Matheson, Coleman, and Bell); the major contaminants were iron nonacarbonyl and iron oxide (4). The test sample was transferred into the sample reservoir in a dry nitrogen environment in order to prevent oxidation by atmospheric oxygen and by water vapor (1). The measurement apparatus was evacuated, filled and flushed with dry nitrogen before connecting the sample-reservoir, which contained about 40 cm³ of carbonyl under nitrogen atmosphere. Decomposition of the carbonyl by photon absorption (1) was avoided by shielding the entire apparatus against room-light with cloth-bound tape.

After attaching the sample-reservoir to the system, the iron pentacarbonyl was solidified at liquid nitrogen temperature, and the whole system was evacuated to a pressure of less than 5×10^{-6} Torr. Then the measurement system was isolated from the pump station and its liquid nitrogen cold-trap; without further purification, the sample temperature was raised by suspending the reservoir in different temperature baths which consisted of alcohol-ice mixtures and/or water. Uniform composition of the bath was assured by continued stirring. The bath temperature was measured by an iron-constantan thermocouple gauge with an accuracy of 0.1°C. Vapor pressure measurements for the impure carbonyl were obtained at constant temperatures between about −10° and +50°C and are shown in Fig. 1, together with the data reported in Ref. (1). From these data, it is apparent that the impure liquid iron pentacarbonyl is contaminated by a substance with a gas-phase pressure which becomes increasingly important for temperatures below about 45°C. It is interesting to note that our data for the impure carbonyl agree with those reported in Ref. (1).

A possible contaminant with a gas-phase pressure larger than that of the pentacarbonyl below about +20°C could be carbon monoxide, which is adsorbed in the liquid and which is formed (6) whenever the pentacarbonyl is decomposed under the influence of light or heat to form the solid nonacarbonyl, $Fe_2(CO)_9$. Formation of solid iron oxide will also free CO. Both processes can occur during packing and storage of the pentacarbonyl. The presence of adsorbed carbon monoxide appears reasonable since (*i*) all of the other known and stable decomposition products are solids at the temperatures of interest and (*ii*) the impurity could be removed by distilling some of the carbonyl to waste (see below). In order to remove the impurity

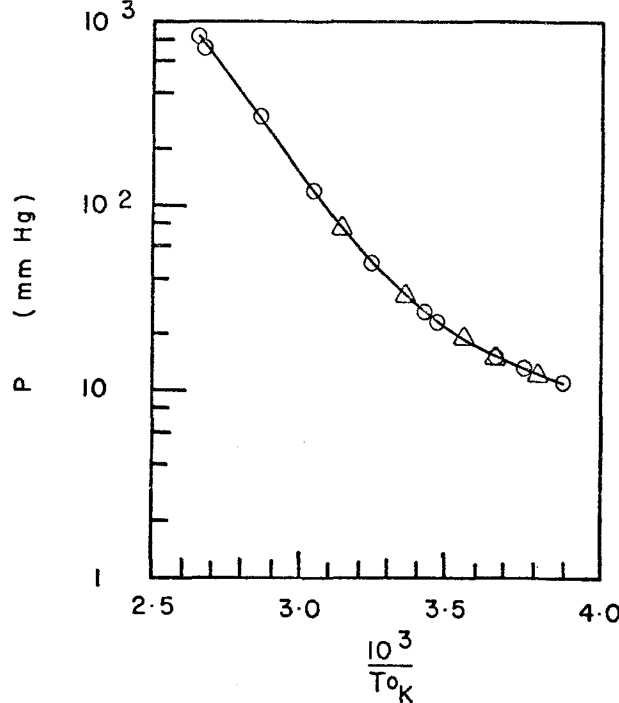

Fig. 1. Measured vapor pressure of $Fe(CO)_5$ before purification (△) and Jones (1906) data (○).

before measuring the actual vapor pressure of iron pentacarbonyl for temperatures below about +31°C, a part of the sample (~3 cm³) was distilled to waste before each measurement. The distillation was accomplished by keeping the sample at a temperature of about −12°C and by pumping the noncondensables into a separate cold trap at liquid-nitrogen temperature. The trap was excluded from the system before each measurement.

Results

The experimental data obtained for the purified iron pentacarbonyl are presented in Table I and are plotted in Fig. 2. The results may be represented by an Arrhenius plot of the form

$$4.573 \log_{10} p = -\Delta H/T + B \quad [1]$$

which corresponds to the integrated Causius-Clapeyron equation for equilibrium between the liquid and the vapor phase. A least squares fit to the data shown in Table I results in the expression

$$\log_{10} p(\text{mm Hg}) = -(2096.7/T) + 8.4959 \quad [2]$$

where T is in °K. Thus, we obtain for the heat of vaporization, ΔH, of the liquid pentacarbonyl the value (9588 ± 120) cal/mole. These results may be compared with those given in Ref. (2). It turns out that our expression [2] agrees within + 1.3% and −0.1% with a least squares fit to the data of Trautz and Badstübner

(2) over the temperature range 0°C ≤ t ≤ 59.9°C and which results in a heat of vaporization of 9487 cal/mole. Because of the excellent agreement between our low-temperature data and those of Ref. (2) over a larger temperature range for pure iron pentacarbonyl, we have to reject the data shown in Ref. (1) and quoted in Ref. (4). By comparing the data obtained for the pure and the impure carbonyl, we estimate a heat for desorption of carbon monoxide from the liquid pentacarbonyl of less than 900 cal/mole, if adsorbed CO is the cause of the increased vapor pressure at low temperatures for the impure carbonyl.

ABSTRACT

The vapor pressure as a function of temperature of several commercial grades of red phosphorus and a specially prepared crystalline sample has been measured. For crystalline red P we obtain a heat of sublimation, $\Delta H_s = 31.9 \pm 1$ kcal/mole. The commercial grades yield vapor pressures, which above 450°C are described by the equation $\ln p = -(10.8 \pm 0.4) \times 10^3/T + (16.5 \pm 0.6)$. The sublimation equilibrium of red P can be utilized for controlling phosphorus pressures, $p > 10$ atm, with a reproducibility of 10% if commercial P of at least 5*N* purity is used. Measurements of the *pVT* relation of phosphorus vapor in the regimes $800°K \leq T \leq 1400°K$ and $3 \text{ atm} \leq p \leq 35$ atm reveal deviations up to 10% from ideal gas behavior. Excellent accuracy in describing the behavior of phosphorus vapor is obtained when van der Waals equation is used in conjunction with the critical data of Marckwald and Helmholz and a critical coefficient of 0.375 for calculation of both the covolume and the interaction parameter. Consideration of the pressure dependence of the equilibrium constant K_p for the reaction $P_4 = 2P_2$ yielded approximate values for the fugacity constant at 1000° and 1100°C. The *pTx* relation at the liquidus in the vicinity of stoichiometric InP for indium-rich and phosphorus-rich compositions were established by simultaneous vapor pressure and DTA measurements. The melting point of stoichiometric InP is 1335° ± 1°K and the corresponding equilibrium phosphorus pressure is 27.5 ± 1 atm. *T-x* liquidus data calculated with the assumption of ideal behavior of the liquid are in good agreement with our experimental data. Interpretation of the liquidus pressure data yields values of the standard enthalpies and entropies at 298°K

$$\Delta H°_{298} = 22.1 \text{ kcal/mole}, \quad \Delta S°_{298} = 15.78 \text{ e.u.}$$

for the reaction

$$InP(s) = In(s) + \tfrac{1}{4}P_4(g)$$

and

$$\Delta H°_{298} = 36.0 \text{ kcal/mole}, \quad \Delta S°_{298} = 25.28 \text{ e.u.}$$

for the reaction

$$InP(s) = In(s) + \tfrac{1}{2}P_2(g)$$

These results are in excellent accord with the standard enthalpies reported by Panish and Arthur and agree within 3% with literature data on the standard entropies of the reactants. The growth of n- and p-type InP crystals via the gradient freeze technique is discussed and the degree of control of the liquidus concentration is evaluated for various conditions of crystal growth.

Recently we have reported on the performance of several $CdSnP_2$/InP heterodiodes and of heavily compensated InP homodiodes prepared by LPE from Sn-solution, and the results of this early work suggest that future developmental work might lead to new practical light sources and detectors in the near infrared (1). As a result of this work it was necessary to obtain accurate data on phase equilibria and vapor pressures of the indium/phosphorus system, which are essential for properly controlling the growth of large homogeneously doped p-type InP crystals required as substrate material.

For a summary of the earlier literature on the properties of InP we refer the reader to the review articles of Folberth (2) and Renner (3). Various techniques for growing InP single crystals have been evaluated by Weisberg *et al.* and by Richman (4), who considered the gradient-freeze method as the most suitable technique, since it provides optimum control of the thermal decomposition equilibrium of InP during the process of crystal growth. Though the gradient-freeze technique, as designed by Weisberg *et al.*, offers an excellent choice for growing n-type InP crystals, modifications become necessary for preparing Zn- or Cd-doped p-type InP crystals, because of vapor transport of the dopants in a temperature gradient. A modified gradient-freeze technique was utilized by us for preparing Zn-doped InP crystals and will be briefly described below.

From the work of van den Boomgaard and Schol (5) on the In/P phase diagram, it is known that the liquidus composition is a strong function of vapor pressure, and preliminary experiments (6) on the stoichiometry of InP prepared at different phosphorus pressures suggest that, similar to the Ga/As (7) and Ga/P systems (8), a small homogeneity range exists in the solid state around the stoichiometric InP composition. Maintaining a constant phosphorus vapor pressure is, therefore, a necessary condition for preparing crystals of uniform stoichiometry.

Two methods have been employed in the past for controlling the phosphorus vapor pressure in a closed reaction volume: (*i*) Utilizing the sublimation equilibrium of red phosphorus, *i.e.*, controlling pressure via the temperature at which excess solid red phosphorus

* Electrochemical Society Active Member.

Key words: In/P phase diagram, phosphorus vapor, sublimation equilibrium of P, III-V compounds.

is held. (*ii*) Keeping all the phosphorus in the vapor phase and controlling pressure via the temperature and the density of the phosphorus vapor. The first method suffers from the fact that it is possible for part of the vapor to condense, forming metastable yellow phosphorus, which has a much higher vapor pressure at the same temperature. Also, the variation in the vapor pressure curves of commercially available phosphorus, which presumably deviate more or less from an equilibrium state, is unknown. In order to establish some confidence in the reproducibility and accuracy of control via method (*i*), we report in the next section our vapor pressure measurements of several commercial red phosphorus samples in the range 650°-850°K and, for comparison, our measurements of yellow P and a specially prepared sample of monoclinic red P.

Method (*ii*) is utilized where the entire closed off reaction volume has to be kept above the critical temperature of phosphorus. Then all of the phosphorus is inevitably in the vapor state and its pressure can only be controlled by the quantity of phosphorus initially loaded into the capsule and the temperature at which it is maintained.

Preuner and Brockmöller (9) determined the pVT relation for phosphorus vapor. They utilized a quartz spiral manometer. Stock, Gibson, and Stamm (10) used a quartz membrane manometer of similar sensitivity for their study. Both investigations were restricted to very low gas densities [Ref. (9): $0.05 \leq d \leq 1.3$ mg/cm^3; Ref. (10): $0.16 \leq d \leq 1.0$ mg/cm^3], where the assumption of ideal behavior appears to be reasonable. The results of the vapor pressure measurements of Ref. (9) and (10) differ by as much as 10-20%, especially for the higher vapor densities. The controversy as to whether the vapor pressure data must be interpreted in the light of the two-step reaction

$$P_4 \overset{K_p}{\rightleftharpoons} 2P_2 \qquad [1]$$

$$P_2 \overset{K_p'}{\rightleftharpoons} 2P \qquad [2]$$

as assumed in Ref. (9), or reaction [1] only (Ref. 10), was resolved by Stevenson and Yost (11), who calculated the equilibrium constant K_p' of reaction [2] from spectroscopic data and showed that reaction [2] does indeed not contribute in a measurable way to the vapor pressure at $T < 1500$°K. Utilizing the data of Ref. (10), a fairly constant value of $\Delta H^o{}_0$ for reaction [1] was obtained from K_p at various temperatures, while the same test of consistency fails for the data of Ref. (9). Thus, the results of Stock *et al.* have been henceforth accepted as a basis for numerous thermochemical calculations and have been incorporated without further experimental check into the most recent literature on the thermodynamic properties of phosphorus [see, for example, the well-known book of Stull and Sinke (12), the JANAF thermochemical tables (13), and the report of Farr (14)]. However, considering the many possible sources of error in the work of Ref. (10), the constancy of $\Delta H^o{}_0$ is perhaps less significant than assumed by Stevenson and Yost (11). Though we do not doubt the validity of their thermodynamic calculations, an independent check of at least some of the data of Stock *et al.* seemed to be in order. In addition, knowledge of the deviation of phosphorus vapor from ideal behavior at elevated pressures would be desirable. This is of interest in crystal growth work and for thermochemical calculations concerning the III-V and II-IV-V_2 phosphides, which exhibit decomposition pressures typically several tens of atmospheres at their melting points. Thus, a new determination was made of the pVT relation for phosphorus vapor in the regimes $800°K \leq T \leq 1400°K$ and $3 \text{ atm} \leq p \leq 35$ atm. This work is presented below in a later section.

The liquidus line of the indium/phosphorus T-x phase diagram has been determined in the indium-rich regime by several authors (15-19, 26), but considerable discrepancies exist between their results. Various values of the melting point of InP have been reported in the literature and they are listed in Table I.

Table I. Literature values of the melting point of InP and of the corresponding equilibrium phosphorus pressure

T_m(InP) [°C]	p_m(InP) [atm]	Reference
1070	—	Köster and Ulrich (16)
1068 ± 2	—	Panish and Arthur (26)
1045	5	Schafer and Weiser (15), Weiser (25)
1062 ± 7	60	Van den Boomgaard and Schol (5)
1070	9-45	Nashelski, Ostrovskaya, Yakobson (19)
1070	15.5	Folberth (3, 20)
1058 ± 3	21 ± 5	Richman (21)
1055 ± 1.5	25 ± 2	Ugai, Bityutskaya, and Popova (40)
1062 ± 1	25.7 ± 1	This work

Doubt regarding the equilibrium dissociation pressure of stoichiometric InP also exists. For example, by use of In-rich pTx data, van den Boomgaard and Schol (5) estimated that the equilibrium phosphorus pressure p_m(InP) was 60 atm at the melting point of stoichiometric indium phosphide (T_m(InP) = 1062° ± 7°C). Richman (4) and Folberth (20) state that stoichiometric InP is obtained in crystal growth experiments when the phosphorus pressure is between 15-25 atm. However, no reliable conclusions regarding p_m(InP) can be drawn from this observation, since the vapor pressure varies drastically with composition and the homogeneity range of InP is very small, so that crystals grown from slightly indium-rich melts may still appear to be single-phase material of stoichiometric composition. The formation of voids, observed by Richman (14), in InP ingots grown at $p \geq 30$ atm, is a kinetic phenomenon and as such not suitable for pinpointing p_m(InP). From a measurement of the thermal decomposition pressure of InP in a confined volume, Richman (21) concluded that the equilbrium phosphorus pressure is 21 atm at the melting point of InP. However, his arguments are based on a single experiment and the extrapolation to 21 atm at 1058°C is strictly a matter of choice. [Compare Fig. 4, Ref. (21) and the discussion in the section on the pTx Diagram of the Indium/Phosphorus System below in this paper.]

Thermodynamic data for the thermal decomposition reactions

$$InP(s) = In(s) + \tfrac{1}{4}P_4(g) \qquad [3]$$

and

$$InP(s) = In(s) + \tfrac{1}{2}P_2(g) \qquad [4]$$

have been computed by various authors (22-26) in the In-rich region from data obtained at low total pressures. For a review of this work we refer to the paper by Panish and Arthur (26), who determined the heats of formation, $\Delta H^o{}_{298} = 22.1$ kcal mol^{-1} and $\Delta H^o{}_{298} = 36.0$ kcal mol^{-1}, for reactions [3] and [4], respectively. An attempt was made by Panish and Arthur at testing the compatibility of the total vapor pressure data of Ref. (5) and (21) by calculating the corresponding partial pressures of P_4 and P_2 and relating their temperature dependence to reactions [3] and [4]. Utilizing K_p values for reaction [1] taken from Ref. (13), the data of Ref. (21) were found to be compatible with the low pressure data, while the results of Ref. (5) were not.

Decomposition pressure curves in the vicinity of the melting point of InP and above will be presented later in this paper, and the relation of these measurements to the results of Ref. (5), (21), and (26) will be discussed. Also, new data on the pTx relation in the vicinity of T_m(InP) are presented, which include liquidus compositions on the phosphorus-rich side of the phase diagram, resulting in reliable values of both T_m(InP) and p_m(InP).

Vapor Pressure of Solid Red Phosphorus

The vapor pressure of red phosphorus was determined in the arrangement schematically shown in Fig.

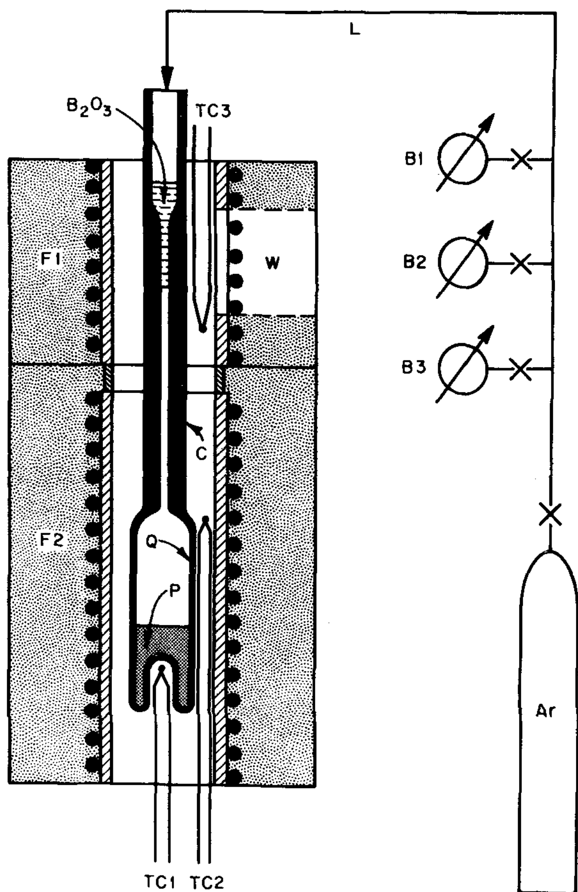

Fig. 1. Arrangement for measuring the vapor pressure of solid red phosphorus. F1, F2 furnaces; W, window in F1; Q, quartz capsule containing the phosphorus; C, capillary tube containing a column of liquid B_2O_3; L, argon feed line attached to C by a double O-ring seal; B1 to B3, Bourdon gauges (−15 to 15 psi, 0 to 200 psi, 0 to 600 psi); TC, thermocouple.

1. The furnace F1 was used to establish a column of molten B_2O_3 in capillary C which closes off the quartz capsule Q containing ~1g of solid red phosphorus. The latter is slowly heated by means of furnace F2. The vapor pressure inside the closed-off volume ($v \approx 4$ cm^3) was balanced by a corresponding argon pressure, thus keeping the meniscus of liquid B_2O_3 in C at a stationary position. The pressure was read on a set of Bourdon gauges, B1 to B3, connected to the argon feed line L and the corresponding temperatures were measured with thermocouple TC located in the recessed portion of capsule Q.

Compared to a quartz Bourdon gauge used as a null indicator in similar work (9, 10, 21, 27), our arrangement has the advantage that at better sensitivity to a pressure differential the B_2O_3 layer can be maintained at a temperature $\gtrsim$ 900°C. This is not possible for a quartz Bourdon gauge indicator because of the inability to control drift at $t > 800$°C due to changes in the elasticity of quartz at such elevated temperatures (9, 10). The capability of keeping the indicator section at high temperature, and of minimizing its volume fraction compared to the total closed off volume, is of importance for two reasons:

1. It permits simulating in the vapor pressure measurements of red phosphorus the conditions encountered during growth of InP crystals via the gradient-freeze technique in a two-temperature zone arrangement as described in Ref. (3) and in a later section of this paper.
2. Isothermal conditions can be established in the measurements of phosphorus vapor densities at high temperatures and pressures (described below). Otherwise, interpretation of the experimental data becomes hopelessly confused because of complications due to nonideal behavior and dissociation.

The results of experiments to determine the vapor pressure of several grades of red phosphorus, each of at least 5N purity, as a function of temperature, and the relation of these data to the results of other (27), are shown in Fig. 2. At temperatures above 700°K the vapor pressures of the commercial grade starting materials are almost identical and the data deviate very little from a straight line, corresponding to an average heat of sublimation $\overline{\Delta H_s} = 21.4 \pm 0.8$ kcal/mole; valid between 700° and 950°K. For clarity only 2 sets of our data for commercial red P are plotted in Fig. 2 and a complete list of the vapor pressure equations observed in the various individual experiments is provided in Table II.

The data represented by full circles in Fig. 2 were obtained when pure white P was the starting material

(material A, Table II), which converts above 350°C into amorphous red P at a rate such that the pressure drops temporarily with increasing T and then merges with the vapor pressure curve of red P. The heating rate in this experiment varied from 3°/min below 500°C to 1.5°/min at higher T. The vapor pressure curve obtained in this manner corresponds to the vapor pressure curve of amorphous red P, material I, reported by Farr (14).

Four experiments with commercial red P were also performed: (*i*) material B = 5*N*, spongy red P supplied by a commercial vendor; (*ii*) material C = 6*N*, dense purple P, and (*iii*) material D labeled by the supplier as "black" 5*N* P, both supplied by a second vendor; (*iv*) material E, which is another batch of material C. The individual vapor pressure curves of these materials correspond to those of material II of Farr (14) and material 3 of Smits and Bokhorst (27). The state of the investigated commercial red P is in between the amorphous and the monoclinic crystalline state.

At $T > 450$°C the reproducibility of vapor pressures of red P from different commercial sources is ~10%. In our opinion, utilizing the sublimation equilibrium of red phosphorus for controlling vapor pressure is advantageous, compared to other techniques, when the temperature distribution over the closed-off reaction volume is nonuniform, the numerical value of v is difficult to assess and when pressures $\geq$10 atm are desired. For $T < 450$°C considerable deviations from the average straight line in the ln p *vs.* $1/T$ plot occur and large differences exist between the vapor pressures of different batches of commercial red P. Because of this uncertainty in vapor pressure, utilization of the sublimation equilibrium appears to us not suitable for controlling phosphorus pressures below 5 atm, unless specially prepared crystalline material is used.

For evaluating the vapor pressure curve of monoclinic red P, 18g of material B were distilled into an evacuated quartz ampul. The resulting white P condensate was sealed-off and then heated for 31 days at 520°C. After this time interval the phosphorus had been converted into a crystalline red material comparable to materials 1 and 4 of Smits and Bokhorst[1] and V of Farr. The vapor pressure curve for this material (material F, Table II) is described by the relation

$$\ln p = -(16.1 \pm 0.5) \times 10^3/T + 22.7 \pm 0.7$$

corresponding to a heat of sublimation $\Delta H_s = 31.9 \pm 1$ kcal/mole, which is somewhat larger than the values of Ref. (14) and (27). However, considering the extremely slow evaporation kinetics of monoclinic red P[2] and taking into account that there is presently no reliable technique available for determining small residues of amorphous red P in the crystalline matrix, the observed difference in ΔH_s is only significant insofar as it indicates that the materials presently looked at, including our material F, may not truly represent an equilibrium state.

[1] Nesmejanov (28) considers the results of Ref. (27) as the best data for the vapor pressure of red P. Note that the data listed in Table 233, of Ref. (28) are not the measured experimental data of Ref. (27) but were calculated with an average value of ΔH_s deduced from their experiments with materials 1 and 4.

[2] In our experiments with material F the temperature was changed in steps yielding initial heating rates of 20°C/hr. During the first hour after each temperature change, considerable deviations toward lower pressure readings occurred and these data were rejected. The data plotted in Fig. 2 correspond to heating rates $\leq$5°C/hr typically encountered 1½ hr after initiating each temperature change.

Density of Phosphorus Vapor in the Regions 800°K $\leq T \leq$ 1400°K and 3 atm $\leq p \leq$ 35 atm

The pressure/temperature relationship for phosphorus vapor of various densities was measured in the apparatus shown in Fig. 3. Pressure measurements were made, as in the afore-described vapor pressure determination of red P, by balancing the phosphorus pressure inside quartz ampul Q by an equivalent argon pressure using a column of liquid B_2O_3 inside C as indicator.

The density of the phosphorus vapor was varied between 5.6 and 39 mg/cm³ by evaporating known weights of P inside Q. The volume of Q varied slightly from experiment-to-experiment ($v_Q \approx 44$ cm³) while the volume of C could be kept constant (capillary length to the meniscus 22 cm, $v_C = 0.57$ cm³). The error in determining the total closed-off volume is

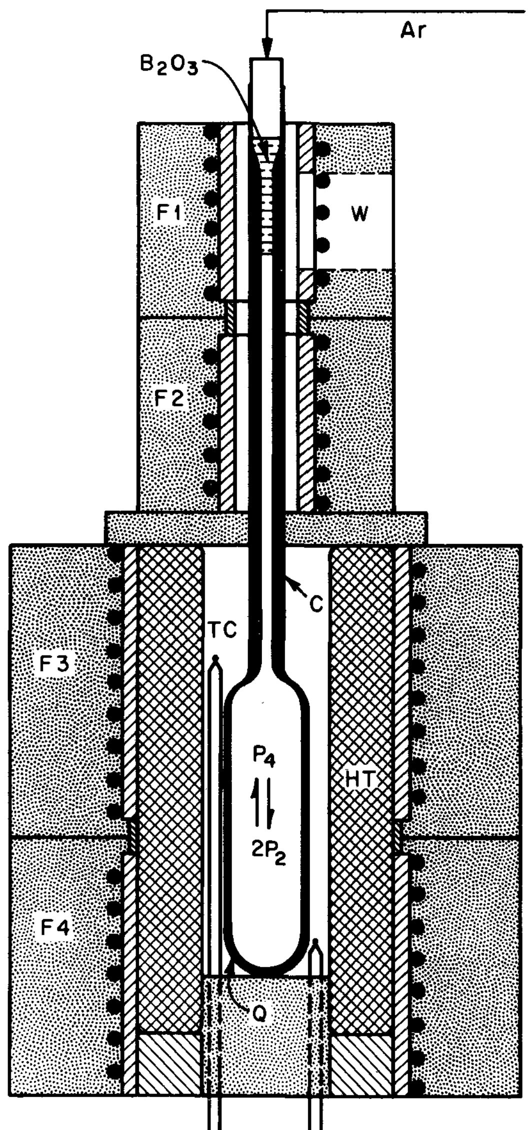

Fig. 3. Apparatus for measuring the pVT relation for phosphorus vapor in the range 800°K $\leq T \leq$ 1400°K and 3 atm $\leq p \leq$ atm. Q, quartz ampul; C, capillary containing a column of liquid B_2O_3; F1 to F4, furnaces; HT, 18 in. long sodium-filled heat tube (Dynatherm Corporation); W, window in F1.

estimated to be < 0.5%. Measurements of v_Q prior to and after performing the experiment were reproducible within 0.2%, so that volume changes due to plastic flow of the quartz tubes at the higher T can be neglected.

For establishing isothermal conditions a vertical arrangement of four independently heated furnaces F1 to F4 were used (Fig. 3). Q and part of C are located in an 18 in. long sodium-filled isothermal furnace liner HT (Dynatherm Corporation) heated by F3 and F4. The temperature distribution in this section is uniform within 2°C for all temperatures $T > 750$°K. F2 is used to extend the isothermal zone as far as possible towards the B_2O_3 section heated by F1. Since the B_2O_3 was kept at $T \geq 1150$°K to provide sufficiently low viscosity, a temperature gradient is necessarily introduced between F1 and F2 when Q is at $T < 1150$°K. However, the volume fraction of phosphorus vapor near the B_2O_3 layer, which is then at a different temperature, can always be kept below 0.5% of the total volume. This corresponds to a maximum error in average temperature of $\lesssim 2°$ when Q is at 800°K.

Temperature measurements were made using Pt/Pt-10% Rh thermocouples, calibrated in the same arrangement against the melting points of Ag, Au, and Cu, and are correct within ± 1°.

The accuracy of the Bourdon gauges used in this work is ± 1% which is the limiting factor in the accuracy of our experiments. Before closing-off by the liquid B_2O_3, some Ar was always trapped in v which expands linearly with T and a small correction in the phosphorus pressure readings for this Ar background was made. The error introduced by the background correction is neglectable for the high vapor density experiments (≤ 0.1%), but becomes substantial (1%) in the lowest vapor density experiments.

Figure 4 shows a family of experimentally determined curves

$$p = p(\rho, T) \qquad [5]$$

for various phosphorus vapor densities $\rho = n/v$ as parameter, where n is the number of moles P_4 in the absence of dissociation. For comparison, also, dashed lines, given by the relation

$$p = (1 + \alpha)\rho RT \qquad [6]$$

are plotted in Fig. 4 and represent the corresponding vapor pressures for ideal behavior of phosphorus vapor of different density. The degree of dissociation $\alpha = \alpha(\rho, T)$ of P_4 molecules, which are predominant at low temperatures, into P_2 molecules, was deduced from values of the equilibrium constant for the dissociation of P_4

$$K_p = \frac{p^2{}_{P_2}}{p_{P_4}} = \frac{4\alpha^2}{1 - \alpha} \cdot p_o \qquad [7]$$

The values of K_p are tabulated in Ref. (13).[3] The deviation of the experimental points from the dashed line corresponds to the error of conventional vapor pressure calculations based on the assumption of ideal behavior.

Comparison of the experimentally determined vapor pressure curves with the corresponding ideal gas curves yields the following general observations:

1. In the temperature and vapor density regimes considered here, sizable errors can be made in calculating phosphorus vapor pressures assuming ideal behavior in the vapor phase (see Table III).

2. All experimental curves rise at a faster rate with temperature than the corresponding ideal gas curves and they are shifted at the lower temperatures to lower pressures as expected from van der Waals equation

$$p = \frac{nR}{v - nb} \cdot T - \frac{n^2 a}{v^2} \qquad [8]$$

[3] Note that actually the reciprocals of K_p, as defined by Eq. [7], are listed in Ref. (13), because P_2 is taken as standard state of phosphorus vapor.

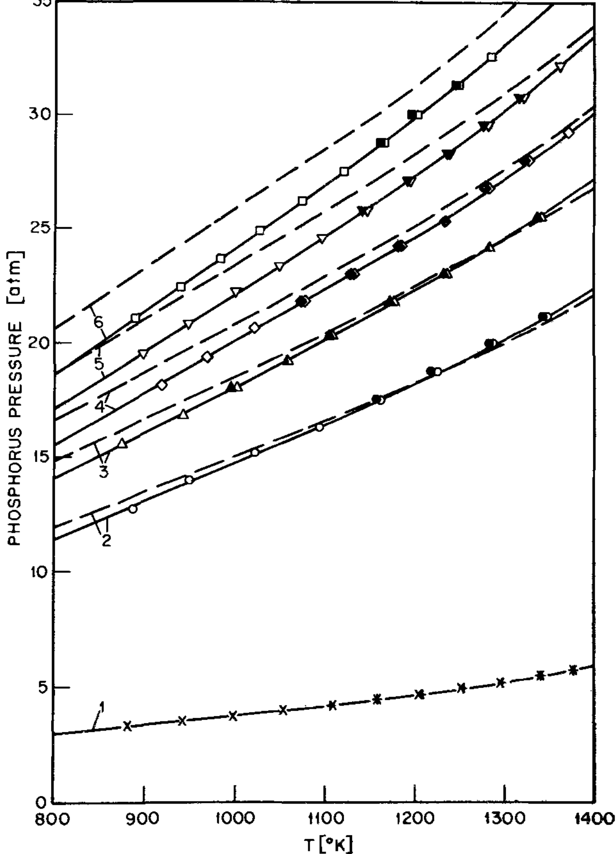

Fig. 4. Phosphorus vapor pressure as a function of temperature *T* for various vapor densities as parameter.

Curve No.	1	2	3	4	5	6
ρ[mole/liter]	0.045	0.181	0.225	0.254	0.284	0.314

Open symbols and x represent data obtained on heating, full symbols and + represent data obtained on cooling. The dashed lines are the corresponding vapor pressure curves for ideal gas behavior, calculated with K_p taken from Ref. (13). For the lowest vapor density, curve 1, the calculated ideal gas values agree within the limits of accuracy with the experimental data.

b is the co-volume of the phosphorus molecules and a is an interaction parameter.

Calculations of a and b from experimentally determined values of the critical temperature T_k and of the critical pressure p_k, assuming a critical coefficient $s = 0.375$,[4] yields $a = 32.4$ atm liter²/mole², $b = 0.121$ liters/mole for $T_k = 968$°K, $p_k = 82.2$ atm (27) and $a = 30.1$ atm liter²/mole², $b = 0.109$ liters/mole for $T_k = 993.8$°K, $p_k = 93.3$ atm (29), respectively. At the higher vapor densities and at moderate

[4] $s \equiv \frac{p_k V_k}{RT_k}$, where V_k is the critical volume.

Table III. RMS deviation of vapor pressure curves calculated by ideal gas law, van de Waals equation, Eq. [9] and [10], and Redlich-Kwong equation, respectively, from experimentally determined vapor pressure curves in the regimes 800°K $\leq T \leq$ 1400°K and 3 atm $\leq p \leq$ 35 atm

$$\Delta = \left\{\frac{1}{n} \cdot \sum^{n} ([p_{exp} - p_{calc}]/p_{exp})^2\right\}^{1/2} [\%]$$

(Curve No. Fig. 4)	Ideal gas	van der Waals	Eq. [9] & [10]	Redlich's Eq.

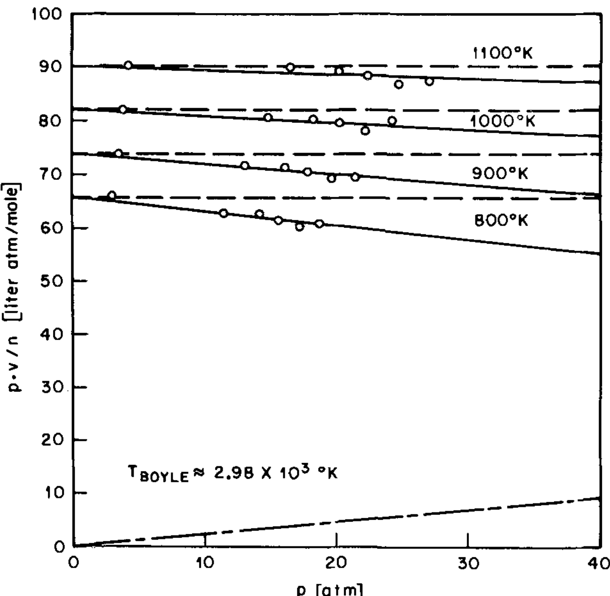

Fig. 5. *p·V/p diagram constructed from the data Fig. 4.* - - - Isotherms $p \cdot V = RT$, ——— smooth average $p \cdot V = RT + Bp$, — · — Boyle curve calculated with critical data of Ref. (29).

T, considerable better fit of the experimental data is obtained with Eq. [8] than with Eq. [6] and the critical data of Ref. (29) yield better results than those of Ref. (27).

Figure 5 shows a $p \cdot V/p$ diagram constructed from the data shown in Fig. 4. The dashed lines parallel to the abscissa represent ideal behavior, *i.e.*, $p \cdot V = RT$, for various isotherms taken in intervals of 100°K between 800° and 1100°K, where dissociation is negligible. The dash-dot line, lower part of Fig. 5, represents the Boyle curve calculated from the critical data given in Ref. (20), *i.e.*, all experimental values of $p \cdot V$ should be below the corresponding ideal gas values. The solid lines through the experimental points correspond to the equation

$$p \cdot V = RT + Bp \quad [9]$$

Taking the slopes B and using the parameters a and b calculated from the critical data of Ref. (29), one obtains the empirical relation

$$B = b - \frac{a}{RT^{\chi}} \quad [10]$$

where $1.03 \leq \chi \leq 1.06$ for $800° \leq T \leq 1100°K$.

A comparison of the root-mean-square deviation of the experimentally determined vapor pressures from vapor pressure curves calculated by Eq. [6], [8], [9], and [10], respectively, is given in Table III. Our data were also compared with vapor pressure calculations according to the equations of Redlich and Kwong (30) and Berthelot. Taking the critical data of Ref. (29) for calculating the second virial coefficients $B = b - a/RT^{3/2}$ with $s = 0.3335$ (Redlich) and $B = b - a/RT^2$ with $s = 0.281$ (Berthelot), it was found that these equations are not suitable for describing the behavior of phosphorus vapor in the considered regimes of p and T, as expected from the experimental result $\chi \approx 1$. Considering the usually large deviations of experimentally determined critical coefficients from 0.375, the data of Ref. (29) provide a surprisingly accurate basis for the calculation of phosphorus vapor pressures according to Eq. [9] and [10].

In discussing the behavior of phosphorus vapor at $T > 1200°K$, where sizable deviations from linearity become apparent in the p vs. T plot (Fig. 4), the following interrelated phenomena have to be taken into account:

1. The increase in pressure at $T \geq 1200°K$ due to dissociation of P_4 molecules according to Eq. [1] becomes larger than the error limits in the vapor pressure determination.
2. The creation of P_2 species in the vapor phase causes changes in the virial coefficients.
3. K_p becomes a function of pressure due to nonideal behavior of phosphorus vapor.

Figure 6 shows a plot of log K_p *vs.* p for two isotherms at 1273° and 1373°K, respectively. For comparison, the data of K_p obtained at the highest pressure considered in Ref. (9) and (10), respectively, are also plotted.[5] The straight lines through the data points correspond to the equation

$$\log K_p = k_1 + k_2 p \quad [11]$$

where k_1 and k_2 are constants. Let

$$K_f = \frac{f^2_{P_2}}{f_{P_4}} = \frac{\gamma^2_{P_2}}{\gamma_{P_4}} \cdot K_p \quad [12]$$

where f_{P_4} and f_{P_2} are the fugacities of P_4 and P_2, respectively, and $\gamma_i = f_i/p_i$ are the corresonding fugacity coefficients. Since, by definition, $\lim_{p \to 0} \gamma_i = 1$, the fugacity constant K_f becomes identical with K_p at the limit $p \to 0$. Neglecting the interaction between different molecular species, γ_i may be related to the second virial coefficients, B_i, of the corresponding component gases by

$$\gamma_i = \exp(B_i p/RT)$$

and

$$\ln K_p = \ln K_f + \frac{B_{P_4} - 2B_{P_2}}{RT} \cdot p \quad [14]$$

which corresponds to Eq. [11]. However, since several simplifying assumptions are made in deriving Eq. [14] and the accuracy of K_p is poor (~20%),[6] it is presently not clear as to whether or not Eq. [14] provides a valid description of the pressure dependence of K_p.

The values of log K_f obtained by extrapolating the straight lines (Fig. 6) to $p = 0$ are tabulated in Table

[5] The values of K_p obtained for the very low p in Ref. (9) and (10) are generally somewhat smaller, but no conclusions regarding the pressure dependence of K_p may be drawn from this observation, since the interpretation of their experimental data depends entirely on the assumption of ideal behavior, which is most likely satisfied, so that the variation of K_p with p must be related to some systematic error in their work.

[6] In our work the limitation in the accuracy of K_p results from a large relative error in α due to the suppression of dissociation at high p. Though at a given T larger values of α are obtained at the lower densities considered in Ref. (9) and (10), the accuracy of their vapor density calculations is severely limited due to several sources of error related to the considerably nonuniform temperature distribution in their apparatus, which is not a factor in our work. A consideration of the propagation of error in calculating K_p from the experimental pVT relation reported in Ref. (9) and (10) reveals, therefore, a similar error level of K_p as encountered in our work at comparatively high pressure.

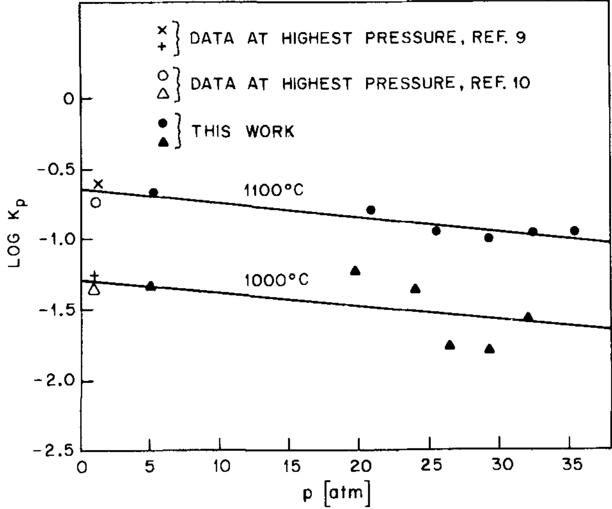

Fig. 6. Pressure dependence of the equilibrium constant K_p for the reaction $P_4 = 2P_2$.

Table IV. Values of the equilibrium constant of the reaction $P_4 = 2P_2$ at 1000° and 1100°C

1373	−0.65	−0.82	−0.79	−0.78

$\overline{K}_p$ = average value of K_p.
* Ref. (9).
** Ref. (10).

IV and compared to the average values of K_p deduced from the data in Ref. (9) and (10). They are 10-20% smaller than the corresponding data of Ref. (9) and (10), while averaging our data, *i.e.*, neglecting any pressure dependence of K_p, leads to values $|\log \overline{K}_p|$ which are ~5% larger than the data of Ref. (9) and (10). For a definitive evaluation of the fugacity constant of phosphorus vapor, new accurate measurements at low total pressure are required. An experiment of this nature is presently being set up and the results of this work will be reported in a future publication.

p-T-x Diagram of the Indium/Phosphorus System in the Vicinity of the Melting Point of InP

The p-T-x relation of the indium/phosphorus system at liquidus compositions near stoichiometric InP was evaluated in a slightly modified version of the previously described apparatus shown in Fig. 3. For performing DTA measurements simultaneously with the vapor pressure determination, an indentation was provided in the bottom of Q, into which two thermocouples were inserted; one for monitoring the sample temperature T and the other for determining the temperature differential ΔT between the sample and an outside thermocouple which measures the environmental temperature inside the heat tube HT. Both T and ΔT were recorded on a Leeds and Northrup Ser. 600 two-pen recorder, which was calibrated by means of a Leeds and Northrup Cat. No. 8686 potentiometer. Most of the voltage, generated by the T-measuring thermocouple, was compensated by means of Leeds and Northrup Model C set point unit to permit sensitive recording in the vicinity of the melting point of InP.

Vapor pressure curves obtained during thermal decomposition of pure InP are shown in Fig. 7. Undoped n-type InP, prepared by gradient-freeze technique from 6N indium at 25 atm phosphorus pressure, was used. Preliminary analytical results indicated an excess of $\sim 10^{19}$ indium atoms/cm^3. In the course of the thermal decomposition reaction the surface of the InP is further depleted of phosphorus, so that an equilibrium between the solid and a liquid solution of InP in In is established, the composition of which varies with T according to the liquidus line of the In/P system. The ratio of the amount of liquid and solid depends on the amount of indium phosphide m_{InP} put into Q, on the free volume v filled with phosphorus vapor, and on temperature. For a given v/m_{InP} there exists a temperature T_m, at which all InP is dissolved, characterized by a discontinuity in the decomposition pressure *vs.* T curve. The composition of the liquid at T_m can be calculated from v and m_{InP} utilizing the vapor density data of the previous paragraph.

Since the same pressure values are obtained in liquid state on heating as well as on cooling we are sure that the melt is always in equilibrium with the vapor phase and a calculation of the composition x_{In} of the liquid at the melting point T_m from m_{InP}, v, and p_m appears to be reasonable. Although the heating and cooling rates in the vicinity of the melting point were reduced from 1°/min to 0.2°/min, the realization of equilibrium in solid state is less clear. Considerable supercooling of the melt was observed and no data for solid material were taken on cooling in the preliminary experiments with pure InP. The consistency of our data and the absence of a steep pressure rise at the

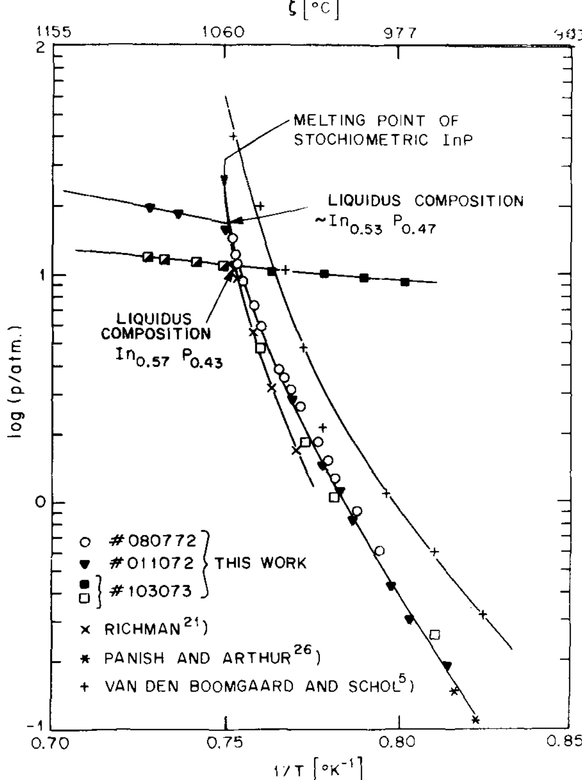

Fig. 7. Thermal decomposition pressure of indium phosphide. +, data of Ref. (5); x, data of Ref. (21); *, data of Ref. (26). □, This work, large free volume of phosphorus vapor, increasing T; ■, same experiment, decreasing T; ▽,○, this work, small free volume of phosphorus vapor, increasing T.

melting point indicate, however, that the solid material was near to equilibrium during the heating cycle.

For comparison we have plotted the vapor pressure curves of Ref. (5) and Ref. (21) in Fig. 7. The data of Ref. (5) are not compatible with our results. The vapor pressure curve of Richman deviates somewhat from our curve towards lower pressures, but the two curves join near the melting point and extrapolate to $p \approx 24$ atm at 1062°C[7] which may be regarded as a lower limit of p_m(InP). Clearly, the values of p_m(InP) given in Ref. (15) and (20) are much too low. Our vapor pressure curve joins smoothly to the low pressure data of Ref. (22) to (26). The two highest total pressure points, taken from the work of Panish and Arthur (26), which overlap in pressure range with our measurements, are in excellent agreement with our data.

In order to extend our measurements to more phosphorus-rich compositions, a set of experiments were performed with additions of phosphorus to the InP. The vapor pressure curves obtained in these experiments are shown in Fig. 8. After evaporation of the added red P the vapor pressure increases linearly with temperature up to the melting point with a slope corresponding to the expansion of the generated phosphorus vapor. Note that no deviation from linearity due to dissociation is observed at $T \geqq 1200$°K, *i.e.*, some of the phosphorus vapor diffuses at these higher T into the solid InP particles, which have much lower equilibrium vapor pressure up to T near to T_m (compare Fig. 7). At $T_m = 1335$°K discontinuities occur in all vapor pressure curves, which are identified as being approximately T_m(InP).[8] In case the phosphorus pres-

[7] At 1058°C, taken as T_m(InP) in Ref. (21), both curves would extrapolate to a pressure <20 atm.

[8] The fact that, regardless of the amount of P added, the same melting point is observed on heating, indicates, that either no equilibrium between the solid and the vapor is reached via solid-state diffusion, *i.e.*, that the major parts of the InP grains remain at nearly stoichiometric composition, or the liquidus is extremely flat.

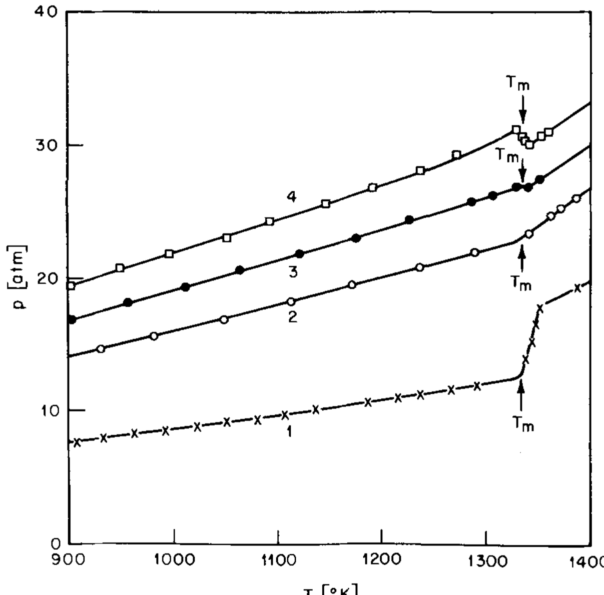

Fig. 8. Vapor pressure of mixtures of InP and red P. x, 10g InP + 0.5g P; ○, 10g InP + 1.0g P; ●, 10g InP + 1.2g P; □, 10g InP + 1.5g P.

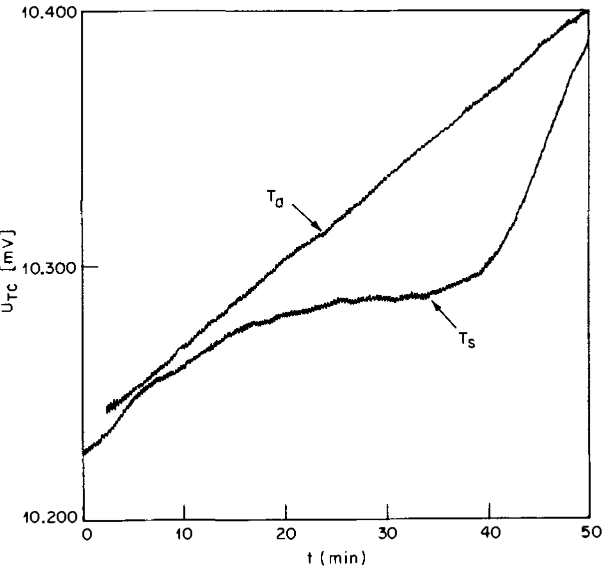

Fig. 9. Pt/Pt 10% Rh-thermocouple voltage vs. time curves monitored during melting in Expt. 3, performed in a modified version of the apparatus Fig. 3. Linear trace corresponds to ambient temperature T_a provided by HT, the other curve represents the changes in the InP-sample temperature T_s.

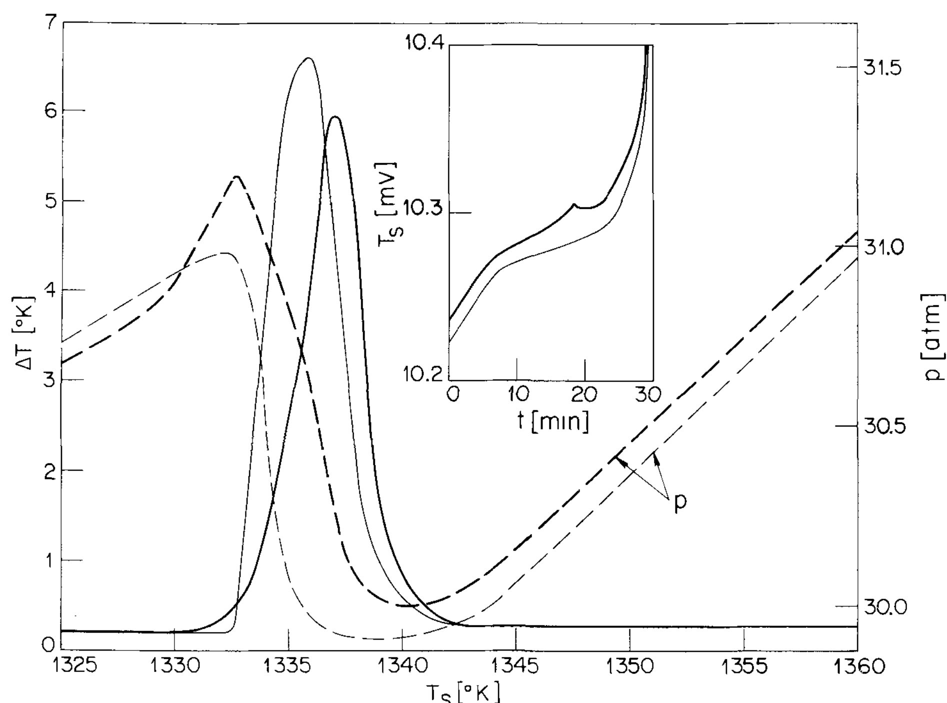
sure at T_m is much smaller than p_m(InP), phosphorus is released from the melt, resulting in a sudden rise in pressure, until its composition corresponds to equilibrium with the vapor phase. On the other hand, a pressure drop is observed due to condensation of P into the melt, when the phosphorus pressure at T_m exceeds p_m(InP). The former is clearly the case for curve 1 (Fig. 8) while the latter applies for curve 4. Thus, within the range of our experiments, the liquidus compositions are established on both the indium-rich and phosphorus-rich sides of InP.

In the two experiments with highest phosphorus additions, (curves 3 and 4) DTA measurements were performed simultaneously with the vapor pressure determinations. Figure 9 shows thermocouple voltage *vs.* time traces, monitored during melting in Expt. 3, which correspond to the sample temperature T_s and to the ambient temperature T_a, respectively. While the temperature T_a of the heat tube HT (Fig. 3) increases linearly with a rate of 0.2°/min, a distinct plateau is observed in the sample temperature at 1334.8°K. Since the pressure during the entire melting period remains constant at 26.9 atm we conclude that these values of T_m and p_m must be very close to the liquidus temperature and pressure of a stoichiometric InP melt. The liquidus composition calculated for Expt. 3 from m_{InP}, m_p, and v, utilizing the vapor pressure information of a previous section of this paper, amounts to $x_{In} = 0.51 \pm 0.01$.

A plot $\Delta T = T_a - T_s$ *vs.* T_s obtained during melting for Expt. 4 is shown in Fig. 10. Also, the variation of vapor pressure in this interval of T_s is shown as dashed curves. The thermocouple voltage *vs.* time recording, corresponding to T_s, is shown in the inset to provide some information on the kinetics of melting. After heating the melt at a rate of 0.2°/min up to ~1100°C, it was cooled at the same rate through the melting temperature without any sign of solidification.



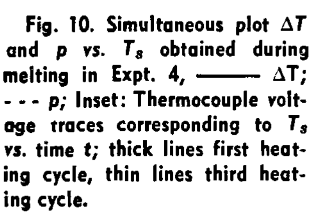


Fig. 10. Simultaneous plot ΔT and p vs. T_s obtained during melting in Expt. 4, ——— ΔT; - - - p; Inset: Thermocouple voltage traces corresponding to T_s vs. time t; thick lines first heating cycle, thin lines third heating cycle.

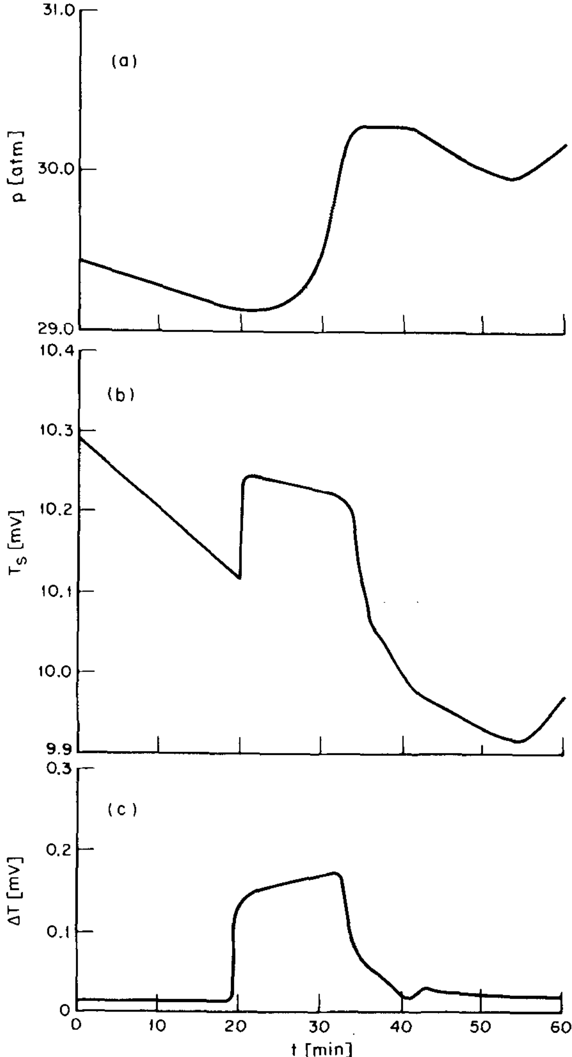

Fig. 11. Plots of (a) p, (b) T_s, and (c) ΔT vs. time obtained during solidification from the supercooled melt in Expt. 4 during the first cooling cycle.

However, a sudden rise in temperature was observed upon supercooling by ~10°, accompanied with an increase in phosphorus pressure.[9]

Figure 11 shows recordings of T_s and ΔT *vs.* time obtained in Expt. 4 (Fig. 8) during solidification from the supercooled melt. Also, in Fig. 11, the behavior of vapor pressure is shown, which, after complete solidification of the melt, exhibited a value similar to that obtained prior to melting. A closed hysteresis loop in vapor pressure is thus obtained on cycling between 1310° and 1350°K. The supercooling temperature 1325°K and the value of the highest plateau temperature $T_p = 1331°$ are reproducible within 1° but a time lag exists between the temperature and pressure *vs.* time curves[10] so that the pressure at T_p differs from the equilibrium vapor pressure at the liquidus temperature $T_m \approx T_p$. The release of phosphorus during solidification is most revealing since it indicates that the solid formed by crystallization is more indium rich than the melt, which supports our conclusion that in Expt. 4 a liquid at the phosphorus-rich side of the In/P phase diagram has been attained. The liquidus composition calculated from m_{InP}, m_p, and v for Expt. 4 amounts to $x_{In} = 0.50 \pm 0.01$, while from the pressure drop at the melting point one obtains a liquidus composition of $x_{In} = 0.494$.

[9] Richman (4) reported supercooling by as much as 50°C in crystal growth experiments at ~25 atm. This was confirmed in Expt. No. 3 where a much larger supercooling of 55°C was observed.
[10] Note that the maximum ΔT occurs at a later time than the first steep increase in T.

Both the ΔT *vs.* T and T_s *vs.* t curves shown in Fig. 10 indicate a wider temperature range of melting in the first melting process (thick lines) than after several successive melting/freezing cycles (thin lines). An explanation for this observation can be given by assuming that a phosphorus-rich layer is formed during the first heating cycle via solid-state diffusion of P into the initially stoichiometric InP. This material starts melting at 1332°K, which is accompanied by a release of phosphorus, so that the vapor pressure curve bends upward. After melting of the outermost P-rich layer of the InP the still stoichiometric part melts and phosphorus is simultaneously condensed into the melt leading to a rapid decrease in pressure. In the subsequent solidification cycle a more homogeneous solid is formed, which is slightly less indium rich than the original material if a finite homogeneity range is assumed for the solid. The temperature range of melting thus decreases and the melting point of 1334.7°K, indicated by the ΔT *vs.* T and T *vs.* t curves for the third melting cycle shown as thin lines in Fig. 10, is lower than the melting point of stoichiometric InP.

From the above-described vapor pressure behavior and temperature characteristics, observed in Expt. 3 and 4, we conclude, that the melting point of stoichiometric InP is $T_m(\text{InP}) = 1335° \pm 1°\text{K}$ and that the corresponding liquidus equilibrium pressure is $p_m(\text{InP}) = 27.5 \pm 1$ atm. Knowing the melting point of InP and taking the estimated entropy of fusion ΔS^F from the work of Panish and Ilegems (31) the liquidus of the In/P system may be calculated by the equation

$$T(x_p) = T_m(\text{InP})/\Phi(x_p) \quad [15]$$

$$\Phi(x_p) = 1 + \frac{1}{2}\frac{R}{\Delta S^F} \ln 4x_p(1 - x_p)$$

which was derived by Wagner (32) and has been successfully applied for calculating the liquidus line of the Ga/Sb system by Schottky and Bever (33). The application of Eq. [15] relies on the assumption of ideal behavior of the liquid, which seems to be satisfied for the In/P system as indicated by the results of Ref. (26) and (31). Table V shows a comparison of our experimental pTx results with calculated liquidus data, which supports the conclusions of Ref. (26) and (31).

In Table VI the liquidus total pressure data are separated into partial pressures of P_2 and P_4. Assuming the activity coefficients of In in the liquid being ≈ 1, these data may be combined with the results of Eq. [15] for calculating free energy changes for the reactions

$$\text{InP(s)} = \text{In(l)} + \tfrac{1}{4}\text{P}_4\text{(g)} \quad [16]$$

and

$$\text{InP(s)} = \text{In(l)} + \tfrac{1}{2}\text{P}_2\text{(g)} \quad [17]$$

according to

$$\Delta G^\circ(16) = -RT \ln (x_{In}[p_{P_4}/\text{atm}]^{1/4}) \quad [18]$$

and

$$\Delta G^\circ(17) = -RT \ln (x_{In}[p_{P_2}/\text{atm}]^{1/2}) \quad [19]$$

The free energy changes Eq. [18] and [19] can be related to the free energy changes of reactions [3] and [4] at 298°K by calculating the "Sigma" functions (34)

Table V. Calculated liquidus temperatures* and experimental liquidus temperatures and pressures** of the In/P system in the vicinity of stoichiometric InP

$\Delta S_{298}(3) = 15.78$ e.u., $\overline{\Delta H_{298}(3)} = (22{,}100 \pm 83)$ cal/mole.
$\Delta S_{298}(4) = 25.28$ e.u., $\overline{\Delta H_{298}(4)} = (35{,}979 \pm 87)$ cal/mole.

$$\sum^{(3)}(T) = -\frac{\Delta G^\circ(16)}{T} + \frac{1}{T}\int_{298}^{429} \Delta C_p(3)\, dT - \int_{298}^{429} \Delta C_p(3)\, d\ln T + \frac{1}{T}\int_{429}^{T} \Delta C_p(16)\, dT - \int_{429}^{T} \Delta C_p(16)\, d\ln T + \frac{\Delta H^F{}_{In}}{T} - \Delta S^F{}_{In} = -\frac{\Delta H^\circ{}_{298}(3)}{T} + \Delta S^\circ{}_{298}(3) \quad [20]$$

and

$$\sum^{(4)}(T) = -\frac{\Delta G^\circ(17)}{T} + \frac{1}{T}\int_{298}^{429} \Delta C_p(4)\, dT - \int_{298}^{429} \Delta C_p(4)\, d\ln T + \frac{1}{T}\int_{429}^{T} \Delta C_p(17)\, dT - \int_{429}^{T} \Delta C_p(17)\, d\ln T + \frac{\Delta H^F{}_{In}}{T} - \Delta S^F{}_{In} = -\frac{\Delta H^\circ{}_{298}(4)}{T} + \Delta S^\circ{}_{298}(4) \quad [21]$$

where $\Delta H^F{}_{In} = 780$ cal/g-atom and $\Delta S^F{}_{In} = 1.817$ e.u. are the heat and entropy of fusion, respectively, for In at its melting point 429.32°K (12) and $\Delta C_p(i)$ is the change of heat capacity for reaction i (i = 3, 4, 16, 17), for example $\Delta C_p(16) = C_p[\text{In(l)}] + \frac{1}{4}C_p[P_4(g)] - C_p[\text{InP(s)}]$. The values of $\Sigma^{(3)}(T)$ and $\Sigma^{(4)}(T)$ listed in Table VI were calculated using heat capacity data given in Ref. (13) for P_4(g) and P_2(g), data given by Hultgren *et al.* (35) for In, and the data of Pankratz (36) for InP. Columns 7 and 8 of Table VI show $\Delta H^\circ{}_{298}$ values for reactions [3] and [4], respectively, calculated from the $\Sigma(T)$ values with $\Delta S^\circ{}_{298}(3) = 15.78$ e.u. and $\Delta S^\circ{}_{298}(4) = 25.28$ e.u., respectively, which provide the best fit of the experimental data. Assuming that the standard entropies of In(s) and P_2(g) and P_4(g) are known correctly [Ref. (12) and (13)], we obtain from the above given $\Delta S^\circ{}_{298}$ values for reactions [3] and [4] a standard entropy of InP $S^\circ{}_{298}(\text{InP}) = 14.76$ e.u. and $S^\circ{}_{298}(\text{InP}) = 14.60$ e.u., respectively. The average of these two numbers $\Delta S^\circ{}_{298}(\text{InP}) = 14.68$ e.u. is about 3% higher than the value of Piesbergen (37), $S^\circ{}_{298}(\text{InP}) = 14.28$ e.u., but within the error limits of our evaluation. The average values of $\Delta H^\circ{}_{298}(3)$ and $\Delta H^\circ{}_{298}(4)$ are virtually identical with the values of Panish and Arthur (26).[11]

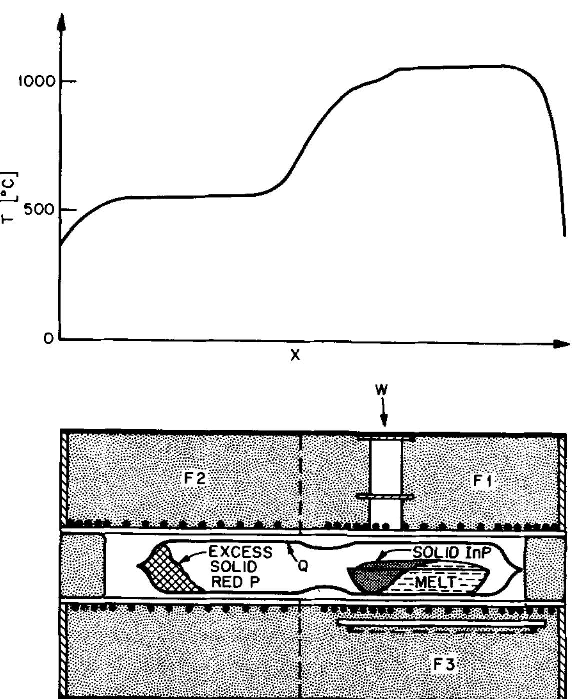

Fig. 12. Arrangement for preparing n-type InP crystals F1 to F3, furnaces; Q, evacuated quartz ampul containing a boat with the melt and excess red P; W, window in F1.

Growth of InP Crystal from the Melt

With the information acquired on vapor pressures and the pTx relation in the indium/phosphorus system near to the melting point of stoichiometric indium phosphide, the degree of control of the liquidus composition under the conditions of crystal growth may be evaluated. Figure 12 shows an arrangement utilized by us for gradient-freeze crystal growth of n-type InP. Furnace F1 was used to bring a boron nitride boat containing indium to a temperature of 1065°C and the excess red phosphorus in the other section of the evacuated quartz tube Q was then heated slowly by means of F2 to maintain finally a phosphorus pressure of 27.5 atm. After synthesis of the InP, the temperature of F1 was lowered at a linear rate 15°C/day until the melt was solidified. A window W was provided in F1 to facilitate proper remelting for seeding purposes as described by Richman (4). In order to minimize heterogeneous nucleation at the bottom of the boat, a third furnace F3 was used to set up a vertical temperature gradient of ~ 4°C/cm.

Considering the slope of the vapor pressure curve of solid red P at 27.5 atm and assuming that the temperature of the excess phosphorus is controlled to within ± 1°, the pressure during this crystal growth procedure is constant to ± 0.65 atm and reproducible

[11] Note added in proof: We would like to note that the above agreement of our data with those derived by others may be fortuitous and does not prove the In/P solutions are, in fact, ideal solutions. The experimental data of this paper meanwhile have been used by M. B. Panish (41) in a simple solution calculation assuming that the excess free energy of mixing $G^E{}_M$ of the binary solution is of the form $G^E{}_M = \alpha X(1 - X)$ where X is the mole fraction of one component and $\alpha = \alpha(T,p)$ is an interaction parameter. A disagreement results between values of α calculated from vapor pressure data and from liquidus data, respectively, when existing thermodynamic data for the standard reference state pressure of liquid P are used. The work of Panish shows that this disagreement can be removed by appropriate modifications in the reference state pressure and that our data and the data of others are also consistent with the simple solution model. However, there exists no measured value for ΔS^F for InP, α is close to zero over a wide range of T and both models yield a calculated liquidus line within the error limits of the experimental data. Therefore, at the present time, the distinction between the ideal solution model and the simple solution model for the In/P system is, in our opinion, a matter of choice.

to within ~ 3 atm if commercial P is used. The change of the liquidus composition with pressure implied by our xp-data is $\partial x/\partial p = 4.5 \times 10^{-3}$ atm^{-1}. With the above-described technique for pressure control, the liquidus composition is constant within $\pm 3 \times 10^{-3}$ and may vary from one experiment to another within 1.35×10^{-2}. Because of the variability in commercial sources of red P, Richman (4) held the entire quartz ampul above the critical temperature of P, thus controlling pressure via the temperature of F2. In this mode of operation, the reproduciblity of phosphorus pressure depends on the reproducibility of the free volume of Q, which requires standardization of the glass blowing procedures, and on a careful determination of the amounts of P used up for synthesis and for establishing 27.5 atm pressure. The nonuniform temperature distribution of the assembly, which changes during crystal growth, makes reliable vapor pressure calculations difficult and we feel, therefore, that utilization of the sublimation equilibrium is the more reliable technique for vapor pressure control, especially if a material exhibiting a well-characterized vapor pressure, as for example our material F, is used.

However, utilization of the sublimation equilibrium of red P for pressure control and optical observation of the seeding process is inadequate for preparing Zn- or Cd-doped p-type InP crystals under conditions of relatively large temperature gradients. Continuous loss of ZnP_2 from the melt via vapor transport to the colder parts of Q leads to a nonuniform dopant distribution in the InP ingot and increases the danger of explosions, since ZnP_2 crystals sticking to the inner walls of Q create strains and often cause cracking of Q during the cooling down procedure.

Zn-doped p-type InP crystals were, therefore, grown under almost isothermal conditions for the entire quartz ampul containing prereacted InP plus the required amounts of P and ZnP_2 to establish at the melting point a phosphorus pressure of 27.5 atm and the desired dopant concentration in the melt. In order to accomplish crystal growth with a reasonable rate, a compromise has to be made between the applied cooling rate of the furnace and the temperature gradient, which were in our experiments 6°C/day and 0.2°C/cm, respectively. Since boats of 12.5 cm length were used, the average temperature of the quartz ampul at the time the solidification process is complete is about 2.5°C lower than at the time of seeding. This corresponds to a change of the liquidus composition of 2×10^{-4}. Crystals were grown by this technique which exhibited resistivities typically 0.07 ohm-cm, corresponding to 10^{18} holes/cm^3 and Hall mobilities of 92 cm^2/Vsec. A similar degree of control of the liquidus composition may be attained during zone melting of InP in an arrangement as described by Folberth and Weiss (38). Further details of the preparation of InP crystals, characterization of their purity and defect structure, and a discussion of kinetic effects during InP crystal growth, will be presented elsewhere (39).

Summary

The vapor pressure curves of solid red phosphorus have been measured for various commercially available products and a specially prepared monoclinic material. The heat of sublimation of monoclinic red P was calculated to be $\Delta H_s = 31.9 \pm 1$ kcal/mole. The commercial products yield vapor pressures which, above 450°C, are described by the equation $\ln p = -(10.8 \pm 0.4) \times 10^3/T + (16.5 \pm 0.6)$. The sublimation equilibrium of red P can be utilized for controlling phosphorus pressures $p > 10$ atm with a reproducibility of 10% if commercial P of at least 5N purity is used.

Measurements of the pVT relation of phosphorus vapor in the regimes $800°K \leq T \leq 1400°K$ and $3 \text{ atm} \leq p \leq 35$ atm reveal deviations up to 10% from ideal gas behavior. Excellent accuracy in describing the behavior of phosphorus vapor is attained by use of van der Waals equation, the critical data of Marckwald and Helmholz, and a critical coefficient of 0.375 for calculating both the co-volume and the interaction parameter. Consideration of the pressure dependence of K_p results in approximate values for the fugacity constant at 1000° and 1100°C.

The pTx relation at the liquidus in the vicinity of stoichiometric InP for indium-rich and phosphorus-rich compositions was established by simultaneous vapor pressure and DTA measurements. The melting point of stoichiometric InP is 1335° ± 1°K and the corresponding equilibrium phosphorus pressure is 27. 5 ± 1 atm. The T-x liquidus calculated on the assumption of ideal behavior of the liquid is in good agreement with our experimental data. Interpretation of the liquidus pressure data yields values of the standard enthalpies and entropies at 298°K

$$\Delta H^o_{298} = 22.1 \text{ kcal/mole}, \quad \Delta S^o_{298} = 15.78 \text{ e.u.}$$

for the reaction

$$InP(s) = In(s) + \tfrac{1}{4} P_4(g)$$

and

$$\Delta H^o_{298} = 36.0 \text{ kcal/mole}, \quad \Delta S^o_{298} = 25.28 \text{ e.u.}$$

for the reaction

$$InP(s) = In(s) + \tfrac{1}{2} P_2(g).$$

These results are in excellent accord with the standard enthalpies reported by Panish and Arthur and agree within 3% with literature data on the standard entropies of the reactants.

The growth of n- and p-type InP crystals via the gradient-freeze technique is discussed and the degree of control of the liquidus concentration is evaluated for various conditions of crystal growth.

Acknowledgments

We would like to thank M. Ilegems for discussion and J. H. Wernick and M. B. Panish for reviewing the manuscript. Also, we thank J. L. Shay for evaluating the electrical properties of our InP crystals.

Manuscript received July 19, 1973.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1974 JOURNAL. All discussions for the December 1974 Discussion Section should be submitted by Aug. 1, 1974.

Brief Communication

Crystal Chemical Relations Between the Nonmetal Borides $B_{48}B_2C_2$ and $B_{48}B_2N_2$ and the Hypothetical "I-Tetragonal Boron"

Klaus Ploog

Mineralogisches Institut der Universität Bonn in KFA-Jülich, D-517 Jülich, Germany and Max-Planck-Institut für Festkörperforschung, D-7 Stuttgart, Germany

The publication costs of this article have been assisted by the Max-Planck-Institut für Festkörperforschung.

Since the crystal structure determination of a tetragonal modification of elementary boron by Hoard *et al.* in 1958 (1) several other authors (2-4) have recently reported the preparation of this tetragonal boron "polymorph" by chemical vapor deposition on carbon substrates. In our own systematic investigations of the vapor deposition of elementary boron (5) however, we have shown that it is impossible to prepare this so-called "I-tetragonal boron" $B_{48}B_2$ in a pure form and that it can therefore no longer be considered a true polymorph of elementary boron. We suggest that the formation of this boron "modification" in the reported experiments (2-4) was induced in such a way that the deposited boron picked up some carbon from the substrate and reacted on the surface. This resulted in the nucleation and growth of crystals, which actually were tetragonal boron carbide and not pure tetragonal boron. The purpose of this note is to give a critical review of the crystal structure of the hypothetical "I-tetragonal boron" and its relations to the two nonmetal borides $B_{48}B_2C_2$ and $B_{48}B_2N_2$.

In order to produce the basic icosahedral framework of the lattice of Hoard *et al.* in a reproducible manner we have developed a new preparative method (6). Pyrolysis of BBr_3-CH_4-H_2 mixtures on Ta substrates at 1200°C yields the boron-rich tetragonal boron carbide $B_{48}B_2C_2$ (lattice constants: $a = 8.722$ and $c = 5.080$Å; density: 2.43 g/ml), while pyrolysis of BBr_3-N_2-H_2 mixtures on BN substrates at 1400°C yields a boron-rich boron nitride $B_{48}B_2N_2$ (lattice constants: $a = 8.646$ and $c = 5.127$Å; density: 2.46 g/ml).

Key words: boron modifications, structure of elemental boron, chemical vapor deposition, nonmetal borides.

By single-crystal structure analysis of both the B-C and B-N phases (space group: $P4_2/nnm$) including very precise intensity measurements (6) we determined the absolute electron densities in the holes of the icosahedral framework by Fourier sections and by least squares techniques. This gave an R factor of 5.8% for $B_{48}B_2C_2$ and 5.5% for $B_{48}B_2N_2$. In this way it was possible to localize the carbon and nitrogen atoms and the single boron atoms and to attach them to definite interstitial icosahedral holes. As a result we found that in $B_{48}B_2C_2$ and $B_{48}B_2N_2$ the unstable $B_{48}B_2$ lattice is stabilized by carbon or nitrogen atoms forming bridges between the B_{12} icosahedra.

The unit cells of the tetragonal nonmetal borides (Fig. 1) contain a total of fifty boron and two carbon or nitrogen atoms. Forty-eight boron atoms form four B_{12} icosahedra, centered in the position 4e $\left(\frac{111}{444}, \frac{133}{444}, \frac{313}{444}, \frac{331}{444}\right)$, which is in agreement with the $B_{48}B_2$ structure of Hoard *et al.* The remaining boron and the respective carbon and nitrogen atoms occupy the positions 2a, 2b, 8i, and 8h between the icosahedra

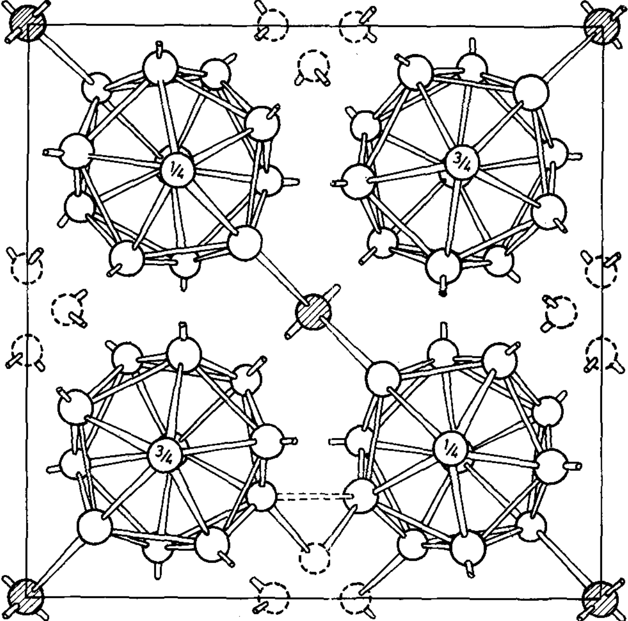

Fig. 1. Unit cell of tetragonal $B_{48}B_2C_2$ and $B_{48}B_2N_2$ projected along the c-axis direction and including the bonding possibilities of the single boron atoms (dashed circles) distributed statistically around 4b. For clarity the borons in 2a and 8h are omitted here. The carbon and nitrogen atoms respectively are represented by hatched circles.

(see Table 1). Within the icosahedra we found boron-boron distances ranging from 1.774 to 1.859Å in $B_{48}B_2C_2$ and from 1.777 to 1.885Å in $B_{48}B_2N_2$, with an average B-B distance of 1.809 and 1.808Å for $B_{48}B_2C_2$ and $B_{48}B_2N_2$, respectively, which are very similar to the values found in elementary boron. Of the twelve icosahedral boron atoms, six have bonds to neighboring icosahedra, among them four with B-B distances of 1.670Å ($B_{48}B_2C_2$) and 1.660Å ($B_{48}B_2N_2$), respectively, and two with B-B distances of 1.686Å ($B_{48}B_2C_2$) and 1.710Å ($B_{48}B_2N_2$), respectively. Of the remaining six icosahedral boron atoms two are bonded to carbon and nitrogen atoms, respectively, in the position 2b $\left(00\frac{1}{2}, \frac{1}{2}\frac{1}{2}0\right)$ with a B-C distance of 1.629Å and a B-N distance of 1.589Å, and four are statistically bonded to two single boron atoms in the statistically occupied positions 8i and 8h. The B-B distances to the atoms in 8i and 8h are respectively 1.622 and 1.728Å for $B_{48}B_2C_2$ and 1.611 and 1.703Å for $B_{48}B_2N_2$.

The boron atoms in the position 2a merely fill interstitial holes and have no bonding functions, whereas the positions 2b deserve special attention. They act as bridges with covalent bondings between four icosahedra. In contrast to the proposal of Hoard *et al.* (1) the positions 2b are, however, occupied by carbon or nitrogen and not by boron atoms. The four icosahedra surrounding the C and N atoms form flattened tetrahedra due to a tetragonal c/a ratio of 0.58 and 0.59, respectively.

Table I. Occupation of the intericosahedral sites in $B_{48}B_2C_2$ and $B_{48}B_2N_2$

Atom		Equivalent position and number of electrons per site		Coordinates x/a	y/b	z/c
B(5)	(in $B_{48}B_2C_2$)	2a	0.64	0	0	0
	(in $B_{48}B_2N_2$)		0.07			
B(6)	(in $B_{48}B_2C_2$)	8i	0.49	0.4330	0	0
	(in $B_{48}B_2N_2$)		1.15	0.4306		
B(7)	(in $B_{48}B_2C_2$)	8h	0.56	0	0.5	0.8557
	(in $B_{48}B_2N_2$)		0.13			0.8655
C	(in $B_{48}B_2C_2$)	2b	5.45	0	0	0.5
N	(in $B_{48}B_2N_2$)		6.55			

A further difference relative to the former structure proposal was found in the two single boron atoms per unit cell, which are statistically distributed over 16 positions, namely 8i and 8h around the positions 4c $\left(0\frac{1}{2}0, \frac{1}{2}00, 0\frac{1}{2}\frac{1}{2}, \frac{1}{2}0\frac{1}{2}\right)$ (see Table I). The holes around 4c, which are surrounded by four icosahedra, measure approximately 3.5Å in diameter. Therefore they are too large to accept just one bonding boron atom in a fixed central position as a link between all four icosahedra. The boron atoms are thus found to be displaced toward every two of the four surrounding icosahedra shown in Fig. 1, which finally yields the statistical distribution. The displacement from the center of the tetrahedral holes is about 0.6Å. It arises from the geometric bonding conditions in the rigid icosahedral framework, in which the B_{12} icosahedra are to be linked by strongly directed covalent bondings.

The instability of the basic B_{48} framework itself and the necessity of incorporating additional foreign atoms into the tetragonal lattice to stabilize it, results from geometric as well as from electronic requirements. The geometric problems arise from the characteristic packing difficulties in three-dimensional network of icosahedral structures. In the tetragonal B_{48} framework, only six of the twelve external intericosahedral bonds, formed by each icosahedron, are radially directed along the quasi-fivefold axis. These six, whilst directed outward, would deviate by more than 25° from the favorable pentagonal axis producing a strain sufficiently large to preclude them from the preferred geometry. To alleviate these packing difficulties, at least two interposed single atoms per cell are required, each of which should possess four valence electrons and should be able to form four bonds directed along the quasi-fivefold axes of four icosahedra located at the vertices of a flattened tetrahedron around the position 2b. Suitable foreign atoms to stabilize the tetragonal framework are carbon and nitrogen, as the covalent radii (B, 0.82 and C, 0.77Å) and electronegativities (B, 2.07 and C, 2.50 Pauling Units) of B and C are similar. Since the electron deficiency of B_{12} icosahedra (cf. below) is counterbalanced by the great electronegativity of N (3.07 Pauling Units), the smaller covalent radius of N (0.74Å) may be compensated in part by contracting the cell in the a-axis direction and by withdrawing the electron density from the boron framework. A further improvement of the packing difficulties in the icosahedral framework is achieved by further interposed single boron atoms located around the position 4c, which, however, can link only two icosahedra, as the spatial separation of the four icosahedra around 4c allows only two at a time to come together close enough for bonding.

To describe the electronic structure of the tetragonal framework we use the concept of closed-shell configuration of B_{12} icosahedra, postulated by Longuett-Higgins and Roberts (7). According to this approximate theory, the hypothetical $B_{48}B_2$ cannot be of a closed-shell type, since there would be a deficit of several electrons per unit cell relative to that of a closed shell. Each boron atom possesses one s- and three p-orbitals. The unhybridized set of 48 atomic orbitals of one B_{12} icosahedron can be combined into twelve equivalent outward-pointing s-p hybrid orbitals and 13 bonding and 17 antibonding molecular orbitals, which lie mainly within the icosahedron and are separated by a substantial energy gap. As the outward-pointing hybrids interact only slightly within the icosahedron, these twelve orbitals provide a single radial s-p hybrid orbital at each vertex of the icosahedron, which can form a strong σ-bond between the

icosahedron and any external group. In order to achieve internally a closed-shell configuration while forming simultaneously twelve externally directed σ-bonds, a regular B_{12} icosahedron requires 38 valence electrons, two more than can be supplied by the twelve boron atoms. Twelve of the electrons are used to form the external bonds whilst the remaining 26 are delocalized in the thirteen bonding orbitals inside the icosahedron. At least part of the deficit of two electrons per B_{12} icosahedron should be transferred from additional intericosahedral atoms.

To perform a count of the electrons per unit cell for $B_{48}B_2C_2$ and $B_{48}B_2N_2$ we used the occupancy numbers in Table I, which were derived for the occupation of the intericosahedral sites by the two boron and the two carbon or nitrogen atoms, respectively. The occupancy numbers were calculated by systematic variation and least squares analysis. Since we were working on a relative scale the figures refer to fully occupied icosahedral position, *i.e.*, five electrons per site. As can be seen from Table I, in $B_{48}B_2C_2$ the total number of electrons for the four intericosahedral atoms per cell is 20.6, giving a calculated electron deficit of 1.4 electrons per unit cell which is possibly transferred to the B_{12} icosahedra. In $B_{48}B_2N_2$ however, this transfer is much lower *i.e.*, only 0.6 electrons per cell. Although conclusions regarding transfer of charge as derived from even the best x-ray data must be regarded with reserve, $B_{48}B_2C_2$ and even more $B_{48}B_2N_2$ do not seem to completely provide conditions necessary for the proposed closed-shell configuration of B_{12} icosahedra.

Nevertheless, the nonmetal borides $B_{48}B_2C_2$ and $B_{48}B_2N_2$ are, in addition to BeB_{12} (8) and $AlBe(B_{12})_2$ (9), two stable phases with the lattice of the hypothetical "I-tetragonal boron," which can be prepared in a reproducible manner and in which the tetragonal icosahedral framework is stabilized by suitable foreign atoms. For the BeB_{12} and the $AlBe(B_{12})_2$, however, unequivocal attachments of the foreign atoms to definite interstitial icosahedral sites are lacking, as yet there exists no accurate determination of the absolute electron densities in the icosahedral holes.

The existence of the so-called "I-tetragonal boron" $B_{48}B_2$ as a true polymorph of elementary boron, postulated by Hoard *et al.* (1), must be definitely excluded. In a paper published in 1967 (10), Hoard and Hughes expressed some doubts on the existence of this phase but were unable to establish the presence of impurities or further improve their structure determination. It seems that the reliable determination of such stabilizing atoms failed because of the ineradicable inaccuracy of the available x-ray data (R-index 11.4%) rather than by the proposed variable degree of internal disorder.

Finally there is the question of the actual analytical composition of the crystals, on which Hoard *et al.* carried out their structure investigations. In the original paper from 1958 the shortness of the bond between the 2b and an icosahedral boron atom was first related to a possible replacement of the 2b boron atom by carbon, nitrogen, or even oxygen impurities. However, in the following sentence they emphasized the absence of carbon and oxygen in the preparation of their crystals and nitrogen was excluded as an "unlikely" impurity, also without direct analysis. Merely on the basis of a total analysis for boron the replacement of "no more than one-fourth, more probably, no significant fraction" of the 2b boron atoms by other impurities was admitted. In order to retain the interpretation for the occupancy of the 2b sites by boron, Hoard *et al.* explained an observed excess electron density in the position 2b by an additional partial occupation of the positions 2a or 4b. The only impurity taken into consideration for this occupation was tantalum arising from the filament. The maximum degree of filling of 2a sites should correspond to an atomic tantalum to boron ratio of about 1/1400 in the crystal. These conclusions were, however, not verified by direct analysis.

Manuscript received Nov. 2, 1973.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1974 JOURNAL. All discussions for the December 1974 Discussion Section should be submitted by Aug. 1, 1974.

DISCUSSION SECTION

This Discussion Section includes discussion of papers appearing in the *Journal of The Electrochemical Society*, Vol. 119, No. 10; October 1972; and Vol. 120, No. 11; November 1973.

Chlorine Adsorption at a Titanium Surface

T. Smith (pp. 1398-1406, Vol. 119, No. 10)

I. H. Khan[1] **and Y. Rajapakse:**[2] We wish to make the following comments on the recent calculations by Smith in the paper under discussion of the diffusion and segregation coefficients and activation energies for chlorine on titanium.

First, examination of the equations in the Appendix of the paper being discussed shows that a factor K/l has been omitted from the expressions for $C(x, t)$ (Eq. [A-14]), $C_s(t)$ (Eq. [A-15]), and $C_s(\infty) - C_s(t)$ (Eq. [A-17]).[3] The correct expressions are

[1] NASA-Ames Research Center, Moffett Field, California 94035.
[2] Stanford University, Stanford, California 94305.

[3] In Eq. [A-14] of the work being discussed the coefficient of exp $(-k_n^2Dt/l^2)$ should be the residue as $s = s_n$. However, the coefficient given in the paper under discussion differs from the residue by a factor of K/l.

$$\frac{C(x,t)}{C_o} = \frac{l}{l+K}\left[1 - 2\frac{K}{l}\sum_{n=1}^{\infty}\frac{\cos(\kappa_n x/l)\exp(-\kappa_n^2 Dt/l^2}{\left[1+\frac{K^2\kappa_n^2}{l(l+K)}\right]\cos\kappa_n}\right] \quad [1]$$

$$C_s(t) = lKC_o/(l+K)$$
$$\left[1 - 2\frac{K}{l}\sum_{n=1}^{\infty} e^{-\kappa_n^2 Dt/l^2}/(1 + K^2\kappa_n^2/l(l+K))\right] \quad [2]$$

$$C_s(\infty) - C_s(t) = 2C_o lK^2\, e^{-t/\tau_1}/[l(l+K) + K^2\kappa_1^2] - \ldots \quad [3]$$

It is to be noted that the first term in the series in Eq. [2] gives the one-term approximation for $C_s(\infty) - C_s(t)$ valid for large values of t.

Second, we will consider the solutions of Eq. [3]-[5] in the paper under discussion for the three unknowns K, C_o, and κ_1

$$2lK^2C_o/[l(l+K) + K^2\kappa_1^2] = a$$

$$lKC_o/(l+K) = b$$

$$\kappa_1 K/l = -\tan\kappa_1$$

where a is the coefficient of $\exp(-t/\tau_1)$ and b is $C(\infty)$ and they are determined experimentally. Eliminating C_o between the first two equations, we obtain

$$(\kappa_1^2 - 2d)y^2 + (1-2d)y + 1 = 0 \quad [4]$$

where $y = K/l$ and $d = b/a$.

For this quadratic equation to have real roots, the discriminant must be positive. Since d is positive and κ_1 lies between $\pi/2$ and π, a necessary condition for real roots is

$$d \geq \kappa_1 - 1/2 \quad [5]$$

For the experiments in the work being discussed the value of d is 0.57. The condition for real roots is obviously violated. Hence, it is not possible to calculate the values of the diffusion and segregation coefficients and activation energies.

Third, we have attempted to calculate the diffusion and segregation coefficients for sulfur on the surface of Ti. Our experimental data yield a value of about 1. Condition [5] is again violated, and our attempts were unsuccessful. The failure to calculate the diffusion and segregation coefficients, using our experimental data as well as those in the paper under discussion, based on corrected Eq. [1]-[3] suggests that the assumptions made in the above-mentioned work for the mathematical model may not be valid.

Last, the solution of Eq. [4] depends on the value of d, which in turn depends on $C(\infty)$. It should be pointed out that $C(\infty)$ may not necessarily be determined by Auger peak height. Initially the Auger peak height increases with time and hence with surface impurity concentration. Subsequently, the peak attains its maximum height and does not increase any further with time. This maximum does not necessarily mean that the surface concentration has reached its equilibrium. This may instead be due to the fact that the Auger peak height is insensitive to surface coverage greater than a few atomic layers.

In view of the considerations mentioned above, it is apparent that it is not possible to calculate the diffusion and segregation coefficients as well as the activation energies for surface diffusion and segregation, using the method described in the paper under discussion. Hence, the mathematical model as well as the method of analysis, calculated results, and conclusions in the above-mentioned paper need reconsideration.

Minority Carrier Generation Studies in MOS Capacitors on N-Type Silicon

D. R. Young and C. M. Osburn (pp. 1578-1581, Vol. 120, No. 11)

W. Zechnall:[4] In the paper under discussion values of the surface generation velocity are reported which were determined from the intercept of the Zerbst plot[5] with $C_{inv}/C - 1 = 0$. However, a theoretical calculation carried out in our laboratories shows that such an intercept can be obtained even without assuming any influence of surface generation. In our calculation we used the exact expression of the volume generation rate which is given by the theory of Shockley, Read, and Hall[6,7]

$$U_{vol} = (p \cdot n - n_i)^2/(\tau_{no}(p + n_i) + \tau_{po}(n + n_i)) \quad [1]$$

n and p are the densities of electrons and holes in the space charge region, and τ_{no} and τ_{po} the low-level lifetimes of electrons and holes. To describe the time behavior of a MOS capacitor during the whole transient this equation must be applied instead of the following simple approximation

$$U_{vol} = n_i/(\tau_{no} + \tau_{po}) \quad [2]$$

which was used both by Zerbst and the author in the above-mentioned work.

This approximation is valid for the transient behavior of a MOS capacitor in the case of large deviations from thermal equilibrium only. Applying the Zerbst analysis resulting from Eq. [2] to our numerical results which were calculated without any influence of surface generation, we obtain the Zerbst plots drawn in Fig. 1.

The Zerbst plots show an intercept with $C_{inv}/C - 1 = 0$, whose magnitude is inversely proportional to the generation lifetime $\tau_{gen} = \tau_{no} + \tau_{po}$. Applying the method of Zerbst to determine the surface generation velocity from the intercepts, we obtain a value of 1.3 cm/sec from curve a (Fig. 1) and a value of 0.13 cm/sec from curve b. These values are virtual ones, because the calculation was carried out for volume generation only. Thus, the very small values of surface generation velocity reported in the paper under discussion are a consequence of the large values of generation lifetime measured. The calculation shows that a reasonable value of surface generation velocity cannot be obtained from the intercept of the Zerbst plot.

[7] R. N. Hall, *ibid.*, **87**, 387 (1952).

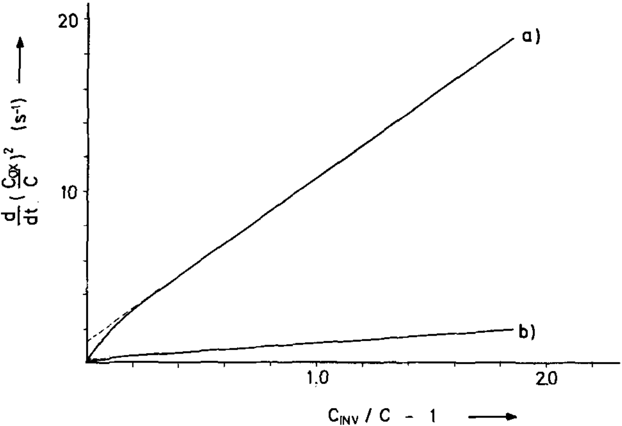

Fig. 1. Zerbst plots obtained from the results of a theoretical calculation. Substrate impurity concentration 10^{15} cm^{-3} (n-type), oxide thickness 1200Å, voltage step from 0 to —10V. Values of generation lifetime: a, τ_{gen} = 11 μsec; b, τ_{gen} = 110 μsec.

D. R. Young and C. M. Osburn: The authors would like to thank W. Zechnall as well as T. W. Collins[8] for their more complete Shockley, Read, Hall analysis of minority carrier generation. Clearly the use of Zerbst plots to obtain a surface generation velocity is in error since other mechanisms give the appearance of surface generation. To correctly interpret lifetime and surface generation from pulsed capacitance relaxation curves, it is necessary to use the exact solution.

A Secondary Battery Based on the Copper(II)-(I) and (I)-(0) Couples in Acetonitrile

B. Kratochvil and K. R. Betty

Department of Chemistry, University of Alberta, Edmonton, Alberta, Canada

The publication costs of this article have been assisted by the University of Alberta.

ABSTRACT

A secondary cell based on the copper(II)-(I) and (I)-(0) couples in acetonitrile has been constructed and studied at room and low temperatures. The over-all cell reaction is $Cu^{++} + Cu(s) \rightleftarrows 2Cu^{+}$. A positive compartment consisting of a graphite sheet in contact with an acetonitrile solution of copper(II) perchlorate was separated by an anionic ion-exchange membrane from a negative electrode of copper metal in acetonitrile. Lithium or sodium perchlorate was added to the negative compartment to decrease internal resistance. The cell develops an open-circuit potential of 1.35V and is reversible at coulombic efficiencies of close to 100%. A test unit was carried through more than 45 charge and discharge cycles at room temperature. Discharge characteristics are poorer at −14°C than at room temperature. The anionic ion-exchange membrane used as a separator was stable to the solvent, chemicals, and potentials used, and effectively blocked transport of copper(II) species. About 90% of full charge was retained after a wet stand of 2 months.

The electrochemical stability, low viscosity, and low freezing point (−45°C) of acetonitrile, CH_3CN, suggest its usefulness as a solvent for batteries designed to operate at low ambient temperatures (1-3). In this solvent the copper(II)-(I) couple has been found to be reversible (4); Biallozor (5) found that, although electrodeposition of copper(I) on platinum from acetonitrile solution is irreversible, the overpotential is relatively low. Owing to appreciable stabilization of copper(I) by acetonitrile (AN), the standard potentials of the copper(II)-(I) and copper(I)-(0) couples differ by 1.283V (6). Cells of the type

$$Cu|CuClO_4,AN||Cu(ClO_4)_2, CuClO_4,AN|C$$

in which the electrode reactions on discharge are $Cu^{++} + e \rightarrow Cu^{+}$ and $Cu(s) \rightarrow Cu^{+} + e$, were assembled and tested at two temperatures.

Experimental

Materials.—Technical-grade acetonitrile (Matheson, Coleman, and Bell) was purified by method D1 described by Coetzee and co-workers (7), with some modifications. The commercial product was refluxed with CaH_2 (Ventron) at a ratio of 10 g/liter. Because no hydrogen evolution was observed, stirring was continued for only 3 hr instead of the recommended 2 days. After addition of 5g of P_4O_{10} (British Drug House) to each liter of decanted material, the mixture was distilled in an all-glass still under high reflux ratio. The first 5% and last 20% of the still output were discarded. The resulting product was refluxed over CaH_2 (5 g/liter) for 1 hr, then distilled slowly under a high reflux ratio. Again the first 5% and last 20% of the still output were discarded. The collected product was placed in a tightly stoppered glass bottle and transferred to a dry box until needed. All flasks were oven dried at least 2 hr at 110°C before use. The water content, determined by Karl Fischer titration, was less than $5 \times 10^{-4}M$.

The preparation of $Cu(ClO_4)_2 \cdot 4CH_3CN$ was as described in Ref. (6); the material had a purity of 99.6% on the basis of analysis for copper by aqueous EDTA titration.

$NaClO_4$ (anhydrous, G. F. Smith Chemical Company) was dried for 20 hr under vacuum, transferred to a dry box, and then used immediately.

$LiClO_4 \cdot 3H_2O$ (G. F. Smith Chemical Company) was recrystallized from water and dried under vacuum, first at 80°C for 24 hr, and then at 100°C for 48 hr. The salt was stored in a dry box in a tightly closed oven-dried reagent bottle.

The negative electrode of the battery was 20 gauge electrolytic copper wire wound on a polyethylene frame. The wire was cleaned by immersion in concentrated HCl for 2 min, then rinsed with distilled water. The wire and frame were dried immediately under vacuum overnight and placed in a dry box for final assembly of the cell. Visual inspection of the wire just before assembly showed no evidence of a surface film.

The positive electrode was an 8 by 8 cm sheet of 0.32 or 0.63 cm pressed graphite. Each sheet was rinsed in distilled water and dried under vacuum 8-10 hr at room temperature before use.

Migration of copper(II) to the negative electrode of the charged cell would result in self-discharge. Therefore an Amfion A-60 anionic ion-exchange membrane, consisting of a polyethylene backbone containing quaternary ammonium anion-exchange sites, was employed as a permselective separator. The membrane was converted from the original chloride form to the

Key words: batteries, acetonitrile, copper.

perchlorate by soaking it in aqueous 1*M* $NaClO_4$ for 1 hr, then was stored in a fresh portion of 1*M* $NaClO_4$ until needed. When a cell was to be constructed, a 12 by 12 cm section of membrane was soaked several hours in technical-grade acetonitrile. Upon soaking, the lateral dimensions increased about 10% over the water-wet form, the thickness decreased, and the flexibility increased markedly. The wet membrane was cut to a final size of 10 by 10 cm, and bolt holes were punched along the edges; it was then dried under vacuum overnight and transferred to a dry box immediately before final assembly of the cell.

Apparatus.—Experiments were performed in a nitrogen atmosphere in a Kewaunee Scientific Equipment glove box, with P_4O_{10} as desiccant.

The test cell is shown in Fig. 1. The geometric cross-sectional area was 64 cm^2. Contact with the graphite electrode was made by a platinum wire press fitted into a hole drilled through the polyethylene case into the graphite.

Voltages were measured with a Heath EU-805 Universal Digital Instrument (UDI) and an Orion Model 701 Digital *p*H meter coupled with Heath EUW-20A and EU-20B chart recorders. The controlled-potential charging source, two Burgess No. 6 1.5V heavy-duty dry cells in parallel, was placed in series with a 20 ohm current limiting resistor. Galvanostatic charging and discharging were accomplished with a Sargent Model IV Constant-Current Coulometer. Control circuitry was breadboarded with a Heath EU-801A Analog-Digital Designer (ADD).

Cells were assembled in the dry box in the fully charged state. By means of a syringe, a solution of $Cu(ClO_4)_2$ in acetonitrile was introduced into the cathodic compartment, and a solution of $LiClO_4$ or $NaClO_4$ in acetonitrile into the anodic compartment. Theoretical capacity was varied by changing the concentration of copper(II) salt introduced. The $LiClO_4$ and $NaClO_4$ solutions were about 0.9*M*, which is near the solubility limits of these salts. In all the cells studied, the quantity of copper metal present in the negative electrode was in excess of that required for complete reduction of the copper(II) added to the positive compartment. The cells were cycled either by discharge through a constant resistance followed by recharge at controlled potential or by galvanostatic discharge and recharge. Discharges through constant resistance were to varying depths, whereas controlled-potential recharge was to full charge as indicated by a final charging current of less than 0.5 mA. Discharges at constant current were to exhaustion as indicated by a cell voltage of 0, whereas constant-current recharges were terminated when 1.60V was reached. After termination of the first recharge process, cells were allowed to stand overnight; then recharge was continued, usually at a lower current level, until acceptance of only a small increment of charge at the lowest current level of 4.65 mA indicated full charge. The overnight stand reduced the effects of concentration polarization caused by the relatively low solubility of copper(I) perchlorate in acetonitrile.

Low-temperature studies were conducted in a dry box by immersing a cell in a bath of dry ice and ethylene glycol at −14°C.

Results and Discussion

Cell tests.—A series of galvanostatic discharges and charges were made at various levels of current, and the voltage was recorded as a function of time. A typical discharge cycle is shown in Fig. 2 for a current level of 9.65 mA. The early part of the discharge occurs at about 1.2V and is followed by a long shoulder before a sharp break downward at about 0.5V. On the same figure is plotted the voltage of the copper(II)-(I) positive electrode against an Ag|0.01*M* $AgNO_3$ reference electrode, connected to the positive compartment by a Luggin capillary and a bridge of $LiClO_4$ in acetonitrile. As expected, polarization occurs principally at the positive electrode. Lithium and sodium perchlorate performed equally well as inert electrolyte; essentially no difference was observed between them.

Voltage-time curves were extrapolated to zero time on the basis of readings obtained 30 and 60 sec after commencement of discharge, and the resulting potential was plotted against current level (Fig. 3). A least squares treatment yielded an intercept of 1.352 ± 0.007V, which is taken to be the open-circuit voltage.

Deliverable capacity to 0.65V cutoff under load is plotted against current drain in Fig. 4. Data were obtained under conditions of continuous discharge after full charge.

Coulombic efficiencies (charge/discharge) were in the range of 1.11-0.92 for eleven galvanostatic cycles. The mean coulombic efficiency was 1.021 ± 0.054. After lengthy discharge the cell tended to accept less than 100% recharge. This tendency is attributed to polarization during the necessarily long recharge that caused early termination of the recharge process at the 1.60V cutoff.

Cycle tests.—A series of discharges to varying depths through constant resistance, followed by recharge at controlled potential, were made. Current-time curves for discharge and recharge are shown in Fig. 5 and 6 for the twenty-third cycle of one cell, a cycle carried to extreme depth. Most of the cycling was by automatic

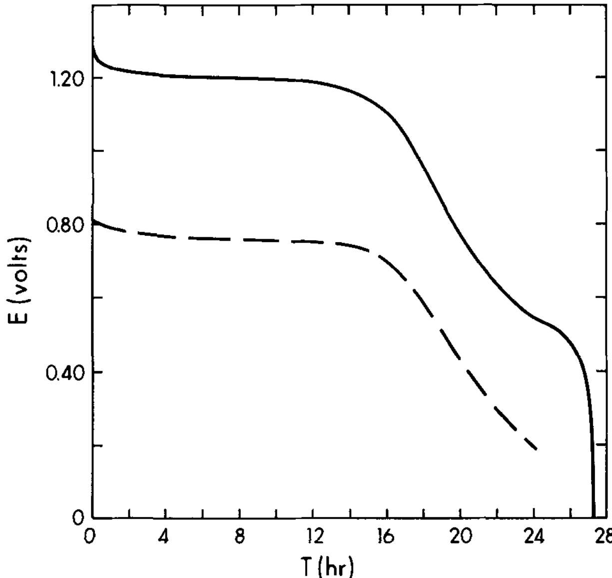

Fig. 2. Constant-current discharge at 9.65 mA for $Cu|CuClO_4||Cu(ClO_4)_2,CuClO_4|C$ in acetonitrile as solvent. Geometric area ≈ 64 cm^2. Solid line represents E_{cell}. Dotted line represents the potential of the positive electrode relative to an Ag|0.01*M* $AgNO_3$ in an reference electrode.

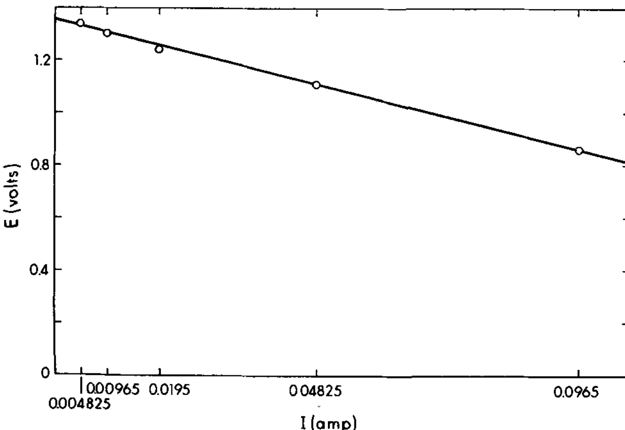

Fig. 3. Voltage at zero time as a function of current drain. Voltages were determined by extrapolation to zero of readings obtained 30 and 60 sec from commencement of discharge. Each point is the mean of two discharge runs.

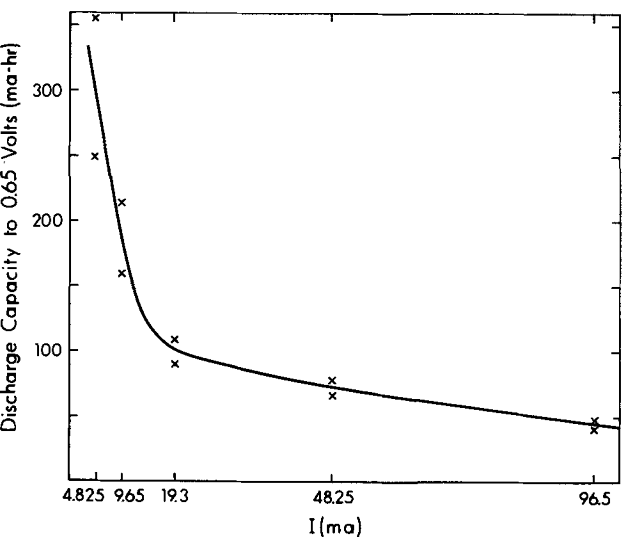

Fig. 4. Discharge capacity to 0.65V under load for Cu|$CuClO_4$||$Cu(ClO_4)_2$,$CuClO_4$|C in acetonitrile as solvent. Constant-current discharge from full charge. Geometric area ≈ 64 cm^2; theoretical capacity = 402 mA-hr.

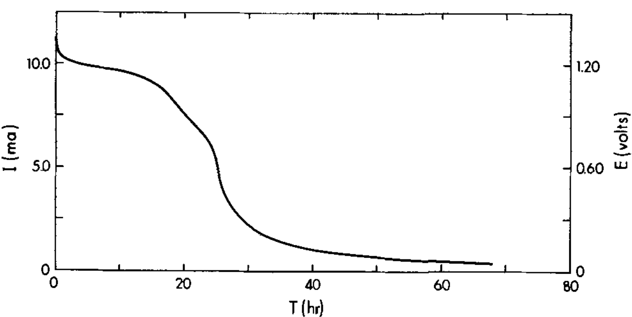

Fig. 5. Discharge through 120 ohm load for Cu|$CuClO_4$||$Cu(ClO_4)_2$,$CuClO_4$|C in acetonitrile as solvent. Twenty-third cycle.

switching from discharge to charge when the cell voltage fell to 0.9V, followed by a switch back to discharge when the charging current fell to 0.5 mA. No deterioration in cell performance was noted after 45 cycles. Current-time curves for the first eleven cycles were integrated with an Ott planimeter to yield coulombic efficiencies; values of 1.00-1.12 were obtained, with a mean of 1.031 ± 0.036. The cell has good shelf-life properties. A fully charged cell lost only 12% of charge after a wet stand of 2 months, and full recharge was accepted.

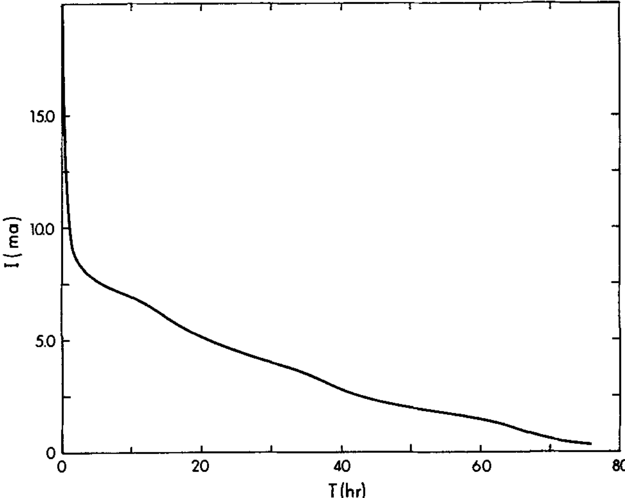

Fig. 6. Controlled-potential recharge for Cu|$CuClO_4$||$Cu(ClO_4)_2$, $CuClO_4$|C in acetonitrile solvent. Twenty-third cycle. Cell heavily polarized by discharge at commencement of recharge. Initial current > 35 mA; charging voltage = 1.55V; series resistance = 20 ohms.

Disassembly of cells that had been extensively cycled revealed that, during recharge, copper(I) tended to replate onto the copper wire as loosely adherent nodules, many of which fell to the bottom of the cell, thereby removing the copper from further reaction. Also, the anion-exchange membrane was considerably distended by osmotic pressure in the positive compartment as a result of exclusion of copper(II) species from the negative compartment. Both the copper electrode and the membrane showed yellow discoloration, probably from copper oxide and hydroxide species formed by reaction with water. The graphite electrodes were clean and showed no sign of deterioration.

Low-temperature studies.—Discharge performance at −14°C was distinctly below that at room temperature. A discharge at 4.65 mA delivered only 94 mA-hr to 0.65V cutoff at −14°C, whereas 356 and 248 mA-hr were obtained at the same current level at room temperature. The discharge curve was similar to that shown in Fig. 2. Cell impedance at 1000 Hz at full charge increased from 5 ohms at room temperature to about 20 ohms at −14°C. The marked drop in cell capacity and the increase in internal resistance are attributed to mass-transport limitations at the lower temperature.

Summary

A secondary cell consisting of the copper(II)-(I) and (I)-(0) couples in acetonitrile is reversible, is capable of repeated cycling, and holds charge well over extended periods. Cell performance is appreciably diminished at lower temperatures. Electrodeposited copper metal is loosely adherent under the conditions studied and is poor in quality. The use of an anionic ion-exchange membrane as a separator provides low resistance to current flow. The membrane studied was stable to the solvent, chemicals, and potentials used, and it effectively blocked transport of copper(II) species. The cell may be discharged to great depth without apparent effect on subsequent performance.

Acknowledgments

The authors gratefully acknowledge preliminary cell design and fabrication by Mr. Gary McCue. They also thank Professor G. S. H. Lock of the University of Alberta, Department of Mechanical Engineering, for several stimulating discussions and for part of the financial support of Mr. McCue.

Work supported in part by the National Research Council of Canada.

Manuscript submitted Nov. 27, 1973; revised manuscript received Feb. 26, 1974.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1975 JOURNAL. All discussions for the June 1975 Discussion Section should be submitted by Feb. 1, 1975.

Formation Processes of the Lead-Acid Battery Negative Plates

D. Pavlov, V. Iliev, G. Papazov, and E. Bashtavelova

Bulgarian Academy of Sciences, Institute of Physical Chemistry, Division of Electrochemical Power Sources, Sofia 13, Bulgaria

ABSTRACT

The advance of the processes within the bulk of the negative plate upon formation in sulfuric acid was studied by electron-microprobe and x-ray diffraction experiments and by microscopic observations. It was found that besides the electrochemical reaction of the *formation* of sponge lead there were also chemical reactions of the formation of lead sulfate which remain included in the lead network of crystals. The electrochemical reduction of lead sulfate takes place after the consumption of lead oxide and tribasic lead sulfate present in the paste. The elementary chemical and electrochemical reactions as well as their mutual relationships are determined as the basis of these measurements.

The change in total porosity and pore size distribution during formation of the lead-acid battery negative plate was studied. Upon formation, both the pore radii and the porosity of the active mass increase. The electrocrystallization processes of lead during formation are also discussed. Upon reduction of $3PbO \cdot PbSO_4 \cdot H_2O$ and PbO a lead crystal network is formed in the first stage. During the second stage, lead, obtained by reduction of lead sulfate, is deposited on the network.

The technology of lead-acid battery plates includes the following stages. By the mixing of a partially oxidized lead powder with a sulfuric acid solution a paste is obtained which consists of lead hydrate, lead monoxide, and basic lead sulfates. Besides these compounds the negative plate paste also contains barium sulfate and an expander. After pasting on a grid and curing, the paste is subjected to formation. During formation, the lead monoxide and the basic sulfates are transformed by electrochemical reactions into active material, *i.e.*, lead at the negative plate and lead dioxide at the positive one.

The influence of barium sulfate, of the expander, and of the conditions of formation on the properties of the negative plate have been studied previously (1-11). The microstructure of the lead crystals obtained upon formation, as well as the way in which these crystals grow, has already been investigated (12-15). The chemical and electrochemical reactions which take place upon formation have been presented by Pavlov (15).

The aim of the present paper is to establish the elementary chemical, electrochemical, and crystallization processes which occur during the formation process and to elucidate their mutual relationships.

Experimental

Traction battery plates with dimensions of 285 × 180 × 4 mm were formed. They were produced with a paste containing 4.5% sulfuric acid, barium sulfate, and expander. The formation was effected in two cells, each constituting two positive and one negative plate. A sulfuric acid solution of density 1.05 was used in a volume of 3000 cm^3. For every gram of paste there was 1.89 cm^3 of sulfuric acid solution. Immediately after pouring the solution in the cells, a current density of 10.00 mA/cm^2 was applied. The following parameters were checked during formation at 2 hr intervals: (*i*) density and temperature of the sulfuric acid solution; (*ii*) distribution of lead over the cross section of the plate; (*iii*) distribution of lead sulfate over the cross section of the plate; (*iv*) phase composition at the surfaces and in the bulk of the plate; (*v*) total porosity and pore size distribution at the surfaces and in the bulk of the plate.

Samples were taken of the negative plates for determinations (*ii*)-(*v*). In order to eliminate differences along the height and width of the plates, material was taken from three different locations of the plates. The samples were collected in the following manner. At 2 hr intervals the formation process was stopped. The negative plates were removed from the cells and washed with water. Three portions were removed from each plate, each containing four grid rectangles. The plates were then returned into the cells, the current was corrected, and the formation process was resumed. The six samples were abundantly washed with water and dried in a nitrogen atmosphere. The samples taken from one of the negative plates were used for observing the distribution of lead along the cross section of the plate and for determining the distribution of lead sulfate across the cross section of the plate. The samples from the second negative plate were used for phase composition and porosity studies.

Key words: lead-acid battery, lead-acid battery technology, lead electrode, formation of the lead electrode, reactions in porous masses.

Determination of the Elementary Chemical and Electrochemical Reactions

Change in the sulfuric acid concentration in the bulk of the electrolyte during formation.—The formation of the battery plates takes place in a sulfuric acid solution. Lead monoxide and the basic sulfates are unstable in sulfuric acid. This is why chemical sulfatization reactions of the lead monoxide and of the basic sulfates take place parallel with the electrochemical reactions. The participation of the sulfuric acid in the chemical reactions leads to a change in its concentration within the bulk of the electrolyte. The density changes of sulfuric acid within the bulk of the electrolyte during formation are represented in Fig. 1. Two stages can be observed on this curve. During the first stage sulfuric acid penetrates into the plates and reacts with the pastes, and hence its concentration in the bulk of the electrolyte decreases. During the second stage the sulfate products obtained during the first stage are formed. Sulfuric acid is evolved as a result of these reactions. It leaves the plates thus increasing the sulfuric acid concentration in the bulk of the electrolyte.

Advance of the reactions of formation of lead across the cross section of the plate.—The samples were enclosed in aluminum molds and soaked under vacuum with polyester resin. After hardening of the resin, the samples were machined until the cross section of the plate appeared clearly. After dry polishing the cross section was observed under a microscope and photographed on color and black-and-white films. Such micrographs are illustrated in Fig. 2. It is easily seen that the formation of lead begins first at those portions of the member grid that are closest to the solution. Lead forms zones which advance at the surface of the plates (Fig. 2b). In those portions of the plate surface not already occupied by the lead zones the paste reacts with sulfuric acid and white lead sulfate zones originate (Fig. 2b). After the lead zones have covered the surface of the plate they advance into the paste (Fig. 2c-e). From the photographs it is seen that a thin layer of white crystals occurs at the boundary between the lead zone and the unformed paste. Between the sixth and the eighth hour of formation the entire cross section of the plate is occupied by the lead zone. The formation process ends at the fourteenth hour, when the lead mass has become dark-gray in color.

Determination of the distribution of lead sulfate across the cross section of the plate.—The samples selected for these studies were placed in cylindrical aluminum molds which were filled with epoxy resin. After hardening of the resin the mold was cut so that the sample was divided into two identical halves. After dry polishing, a conductive 100-150Å thick carbon layer was deposited on the cross section. The determination of the sulfur distribution across the cross section of the plate was carried out with a Hitachi XMA-5 electron microprobe. The electron beam was scanned repeatedly across a 240 × 240μ area and the intensity of the sulfur line was recorded. In this way the average sulfur content over the scanned areas was determined. The electron beam was then scanned on the following point. These measurements made it possible to establish the distribution of lead sulfate along the cross section perpendicular to the plate surface.

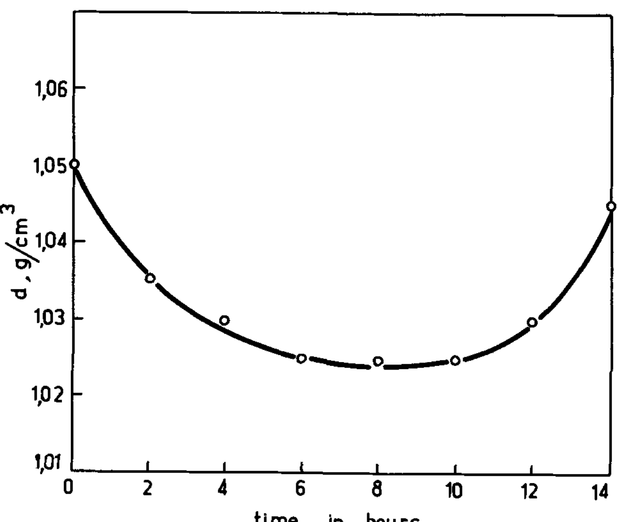

Fig. 1. Change in the electrolyte density within the bulk of the electrolyte during formation.

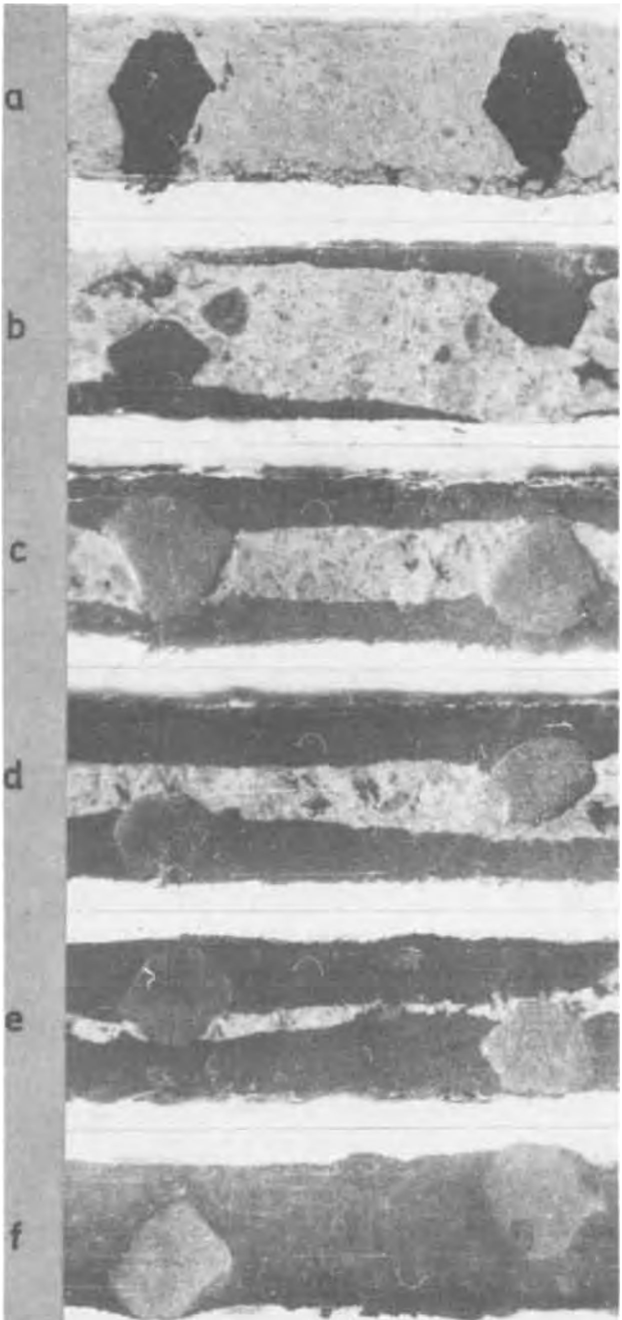

Fig. 2. Micrograph of the cross section of the negative plate during formation. a, Prior to formation; b-e, plates during formation (the dark patches are the lead zone); f, fully formed plate.

Figure 3 represents the results of the measured relative amounts of lead sulfate (free and bonded in the basic sulfate). The thickness of the plate is plotted in relative units on the abscissas axis. From the figure it can be seen that lead sulfate is first formed at the surface of the plate. Then it advances slowly into the inner parts of the paste. At the eighth hour of formation lead

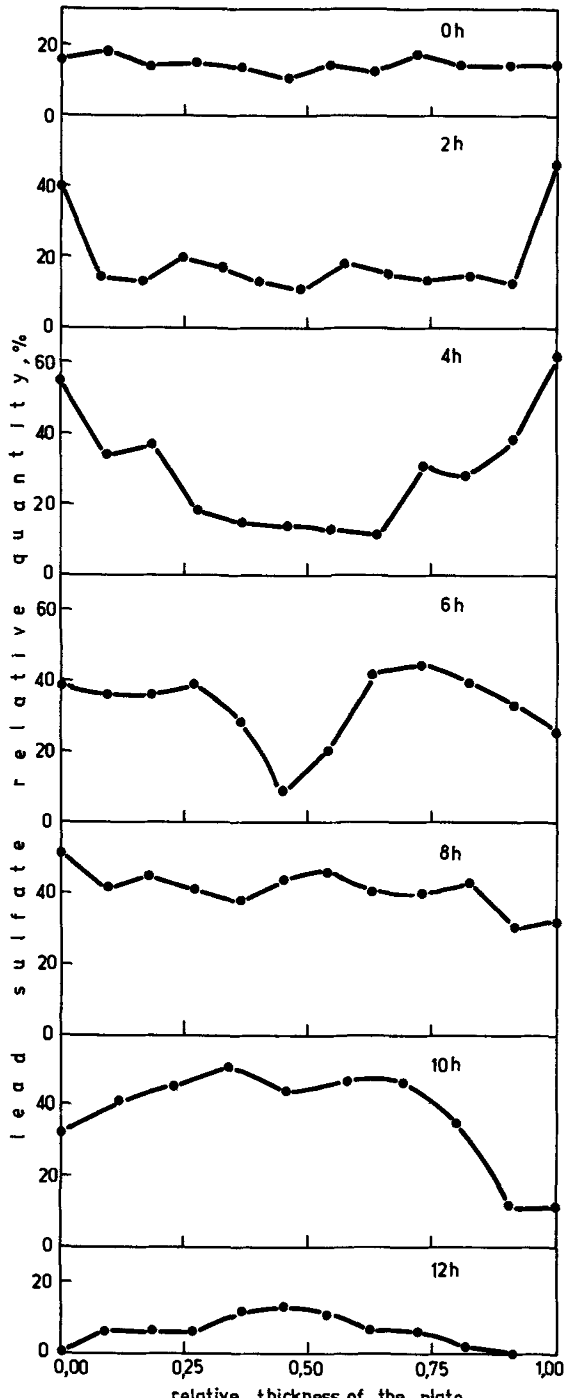

Fig. 3. Change in the distribution of the total amount of lead sulfate along the cross section of the plate during formation.

sulfate is almost uniformly distributed across the entire cross section of the plate. The reduction of lead sulfate takes place after the eighth hour along the entire cross section of the plate. However, this process is most rapid at the surface of the plate (Fig. 3).

The results of these measurements indicate that the processes of sulfatization of lead oxide and of tribasic lead sulfate take place from the surface toward the interior of the plate. From Fig. 2 it is seen that the advance of the lead zone follows a similar path. The end of the sulfatization of the paste occurs at about the same time when the lead zone occupies the entire plate. This indicates that a relationship exists between the processes of formation of lead and lead sulfate. After that, the reduction of lead sulfate occurs in the whole lead zone but most rapidly in the surface portions of the plate.

Phase composition studies of the paste during formation.—The samples were divided across the cross section into three portions: two at the surfaces and one in the bulk. The surface portions were joined together. After grinding, the samples were x-rayed with a TuR M-61 diffractometer with filtered copper radiation.

The quantitative x-ray phase analysis is based on the equation

$$I_i = K \frac{x_i}{\rho_i \Sigma x_j m_j} = K \frac{x_i}{\rho_i m}$$

where I_i is the intensity of the analytical x-ray reflection of the phase we wish to determine, K is an apparatus constant, x_i the weight percentage of the ith phase in the mixture, ρ_i is the density of the ith phase, m_j is the specific absorption coefficient of x-rays by the jth phase, and m is the average absorption coefficient of the sample.

In a three-component system, when the intensity of the analytical reflection of a given phase is referred to the sum of the intensities of the analytical reflections of the three phases, the average absorption coefficient, m, and the apparatus constant, K, are eliminated from the equation. For the first phase the relative intensity is given by the expression

$$\frac{I_1}{I_1 + I_2 + I_3} = \frac{x_1}{\rho_1\left(\frac{x_1}{\rho_1} + \frac{x_2}{\rho_2} + \frac{x_3}{\rho_3}\right)}$$

For a given sample the term included in brackets remains constant in the expressions referring to the three phases.

The aim of the present investigation is to establish the elementary reactions which take place during formation of the plate. It is therefore sufficient to find the changes in the amounts of the individual phases present in the paste during formation, and it is not necessary to determine their absolute contents. In this case the x-ray diffraction method may be used only for determining the changes in the relative intensities of the reflections. The error introduced in this determination depends on the densities of the components.

The analysis of the x-ray diffraction patterns indicates that the cured paste of the negative plate consists of considerable amounts of tet. PbO and tribasic lead sulfate and minor amounts of lead. The following x-ray reflections were used in the study of the change in the amounts of each phase: $d = 3.26$Å for $3PbO \cdot PbSO_4 \cdot H_2O$, $d = 3.00$Å for $PbSO_4$. The reflection with $d = 3.12$Å corresponds to tet. PbO (the strongest reflection in the pattern) and overlaps with the 3.13Å reflection of $3PbO \cdot PbSO_4 \cdot H_2O$ ($I = 35$). The 2.86Å reflection corresponds to lead ($I = 90$ of the pattern) and overlaps with the 2.84Å reflection ($I = 10$) of $3PbO \cdot PbSO_4 \cdot H_2O$.

Figure 4 illustrates the change in the relative intensities of the reflections of the individual phases at the surface and in the bulk of the plate during formation. It should be noted that the numerical values of the relative intensities do not reflect the relative amounts of the phases in the mixture. It is seen that during formation, lead oxide and tribasic sulfate react with sulfuric acid thus leaving lead sulfate in the paste adjacent to the surfaces. The formation of lead in the first 4 hr occurs only at the surface parts of the plate by electrochemical reduction of lead oxide and tribasic sulfate. After the eighth hour, the reduction of the lead sulfate formed during formation begins. This reduction begins first at the surface, and at the fourteenth hour the negative plate is entirely formed.

Elementary chemical and electrochemical reactions and their mutual relationships.—From the results of Fig. 2-4 a model can be suggested for the elementary chemical and electrochemical reactions and for the elucidation of their mutual relationships. This model

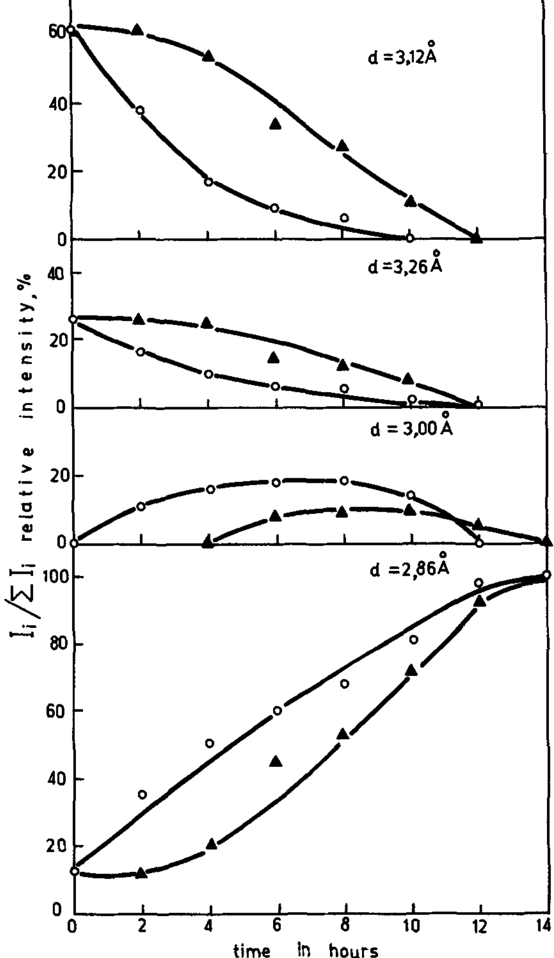

Fig. 4. Change in the phase composition of the negative plate during formation. d = 3.12Å, tet. PbO + 3PbO · $PbSO_4$ · H_2O. d = 3.26Å, 3PbO · $PbSO_4$ · H_2O. d = 3.00Å, $PbSO_4$. d = 2.86Å, Pb + 3PbO · $PbSO_4$ · H_2O. ○, At the surface of the plate; ▲, in the bulk of the plate.

should include the elementary reactions which occur from the two starting compounds of the paste, lead oxide and tribasic lead sulfate.

Figure 5a diagrammatically shows the reactions when lead oxide is the starting compound. Divalent lead ions and OH^- ions are formed upon dissolution of the oxide (reaction [A]). The lead ions may participate in the electrochemical reaction [1′] in which lead is formed, and in the chemical reactions [3] and [4], which are conducive to tribasic lead sulfate and lead sulfate. The hydroxyl ions participate not only in reaction [3] but also in the neutralization reaction [2]. On the one hand reaction [2] influences the dissolution rate of PbO (reaction [A]), and on the other, controls the pH of the pore solution at the considered place in the paste. It should be stressed that the nature of the lead ions which are in equilibrium with lead oxide, tribasic sulfate, and lead sulfate, and which participate in the electrochemical reaction [1′], depends on the pH of the solution. At low pH the lead ions are free Pb^{2+} ions; at pH > 6 they are bonded in complexes such as $Pb(OH)^+$, $Pb(OH)_2$, $Pb(OH)_3^-$, and $HPbO_2^-$. For simplicity let us assume that only Pb^{2+} ions originate in the pores. This means that the rate of the decomposition reactions of the complexes are infinitely large.

If the flow of sulfuric acid arriving from the bulk of the electrolyte toward a given location of the plate which contains lead oxide is smaller than the dissolution rate of lead oxide (reaction [A]), the pH of the pore solution will be close to neutral. As a result reaction [3] occurs in the paste, and tribasic lead sulfate crystals will grow. If the sulfuric acid flow from the bulk of the electrolyte to the given location is larger than the dissolution rate of lead oxide (reaction [A]), the pH of the solution will be low, reaction [4] will take place, and lead sulfate will form. In the presence of an electrode surface (lead mass) close to the location, the electrochemical reaction [1′] takes place. This reaction is the electrochemical reduction of lead oxide to lead. The equilibrium potential of this reaction is given by Eq. [1′a]

$$PbO + 2e + 2H^+ = Pb + H_2O$$

$$E = 0.248 - 0.059\,pH \qquad [1'a]$$

Figure 5b gives the diagram of the elementary chemical and electrochemical reactions which occur when 3PbO · $PbSO_4$ · H_2O is the starting material. As a result of the dissolution of tribasic lead sulfate (reaction [B]) the pore solution contains Pb^{2+}, OH^-, and SO_4^{2-} ions. The Pb^{2+} ions may participate both in the electrochemical reaction 1″ and in the chemical reaction [4]. Whether reaction [4] will occur or not depends on the accession of sulfuric acid from the bulk of the electrolyte. If this flow is larger than the dissolution rate of 3PbO · $PbSO_4$ · H_2O the pH of the pore solution will be low. Reaction [4] will then take place, yielding lead sulfate. The lead ions which are generated upon dissolution of 3PbO · $PbSO_4$ · H_2O participate in the electrochemical reaction [1″]. The equilibrium potential of the Pb/3PbO · $PbSO_4$ · H_2O electrode is given by the equation

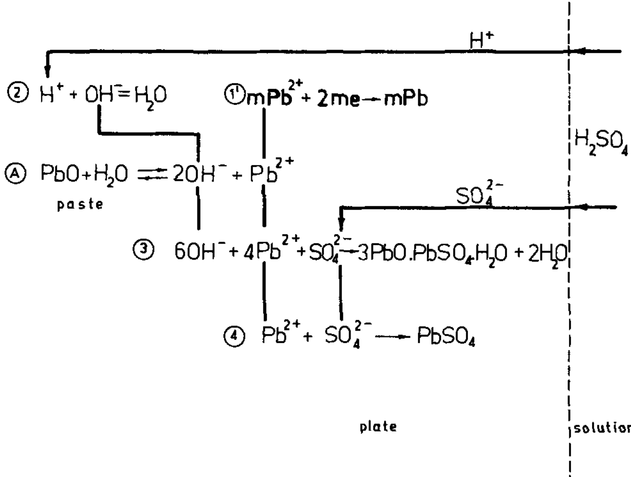

Fig. 5a. Diagram of the elementary chemical and electrochemical reactions with PbO as starting material.

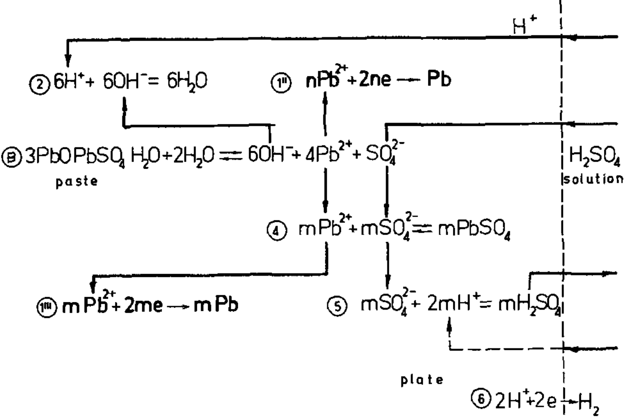

Fig. 5b. Diagram of the elementary chemical and electrochemical reactions with 3PbO · $PbSO_4$ · H_2O as starting material.

$$3PbO \cdot PbSO_4 \cdot H_2O + 8e + 6H^+ = 4Pb + SO_4^{2-} + 4H_2O$$

$$E = 0.030 - 0.044\,pH - 0.007 \log a_{SO_4^{2-}} \quad [1''a]$$

When lead oxide and tribasic sulfate are consumed in the paste or are located at a distance which does not ensure a flow of Pb^{2+} ions toward the electrode surface and which could participate in the electrochemical reactions [1′] and [1″], reduction of the lead sulfate begins. This process may take place provided the electrode potential is more negative than the equilibrium potential of the $Pb/PbSO_4$ electrode

$$PbSO_4 + 2e = Pb + SO_4^{2-}$$

$$E = -0.356 - 0.029 \log a_{SO_4^{2-}} \quad [1'''a]$$

Sulfuric acid originates as a result of the reduction of lead sulfate and diffuses back into the bulk of the electrolyte.

The electrochemical reaction takes place at those locations of the lead zone which are in contact with lead compounds forming with lead electrodes with the most positive equilibrium potentials. These are the electrochemical reactions [1′a] and [1″a] which take place until the eighth hour of formation. When PbO and $3PbO \cdot PbSO_4 \cdot H_2O$ are consumed, reaction [1‴a] will take place and lead sulfate will be reduced.

Lead ions are consumed when the electrochemical reaction takes place in the solution layer at the boundary with the lead crystals. In order to maintain the electroneutrality of the solution in the pores of the plate, in this layer the consumption of the positive charges of the Pb^{2+} ions must be compensated. This may be achieved by migration of H^+ ions from the bulk of the solution toward this layer and of sulfate ions in the opposite direction. These flows control the advance of the lead zone along the thickness of the plate. If the migration flows are hindered at a given place in the plate, the pore solution there is charged negatively by SO_4^{2-} and OH^- ions. This decreases the rate of the electrochemical reaction $Pb^{2+} + 2e = Pb$ since the number of negative ions at this place increases. This decreases the rate at which the lead zone advances along the cross section of the plate. The migration flows are largest at the surface of the plate. Hence, the lead zone advances first along the two surfaces of the plate, and only after having covered them continues toward the bulk of the plate.

Evolution of the Pore Structure of the Plate during Formation

By following the changes in phase composition during formation one can determine the way in which the volume fraction of the plate occupied by matter is built up. The plate shows good working parameters when there is a maximum access of sulfuric acid to lead. This is achieved when the active mass is very porous. Such a structure originates during plate formation. It is therefore desirable to determine the influence of the formation processes on the building up of the porous structure of the active mass. Table I gives the densities and the molar volumes of lead and of the lead compounds present in the plate (16). From Table I it can be seen that there is a considerable difference in the molar volumes of lead and lead compounds.

Table II gives the changes in the molar volume during certain chemical and electrochemical reactions. The

Table I.

Compound	Density, g/cm³	Molar volume, cm³/mole
Pb	11.34	12.28
$PbSO_4$	6.23	47.96
PbO ort.	9.64	29.15
PbO tet.	9.36	23.88
$3PbO \cdot PbSO_4 \cdot H_2O$	6.50	152.00

Table II.

Reactions: Starting product	Reactions: End product	Relative volume change with respect to the initial product, %
PbO	Pb	−23
	$3PbO \cdot PbSO_4 \cdot H_2O$	+60
	$PbSO_4$	+100
$3PbO \cdot PbSO_4 \cdot H_2O$	Pb	−52
	$PbSO_4$	+23
$PbSO_4$	Pb	−60

molar volume increases during all reactions of sulfatization of lead oxide and tribasic sulfate. In all electrochemical reduction reactions the same volume decreases.

The porosity of the active mass is expressed by two parameters: total porosity and pore size distribution. The changes in these parameters in the surface and bulk portions of the plates were followed during formation. The samples for these measurements were taken and dried together with the samples for the phase composition studies.

The measurements of total porosity and pore size distribution were carried out with a Carlo Erba 65 AG mercury porosimeter. The formation of lead amalgam was avoided by creating a thin stearic acid film (17). The samples from the surface and bulk portions were soaked in a 1% stearic acid solution in chloroform for 6 hr. They were then transferred to watch glasses and dried at 105°C. A determined amount of material was weighed and introduced in the glass cell of the porosimeter. The results obtained are given in Fig. 6. The curves of the surface and internal portions of the plates are plotted and compared with that of the unformed plate.

These measurements show that upon formation of the negative plate the pore radii and the total porosity increase. Prior to formation the pore radii range between 0.1 and 0.3μ. After formation, the pore radii vary between 0.6 and 8μ, with a predomination of 1-4μ pores. The active mass has a porosity about 15% larger than that of the unformed plate. However, if we take into account the data of Table II, it becomes clear that this value is too low. This discrepancy is caused by the fragmentation of the samples during preparation. The fragments break down at the locations of the largest pores where the active mass is most brittle. These pores are thus lost in the measurement.

Two stages may be recognized in the evolution of total porosity. During the first one (until the sixth hour) the total porosity of the surface decreases. This indicates that the chemical reaction products predominate over the electrochemical reaction products. During this stage the porosity in the interior of the plate remains constant. This shows that the effect of the sulfatization reactions is compensated for by the effect of lead formation. During the second stage the total porosity both of the surfaces and of the inner parts increases. This is connected with the reduction of lead sulfate.

From Fig. 6 it can be seen that at the beginning of formation, part of the pores decreases in radius. These pores are located at those points of the paste where only chemical sulfatization reactions have taken place. From Table I it is seen that the molecular volume of the products (lead sulfate and tribasic lead sulfate) is larger than that of the starting compounds (lead oxide). On the other hand, at the exterior of the plate, where a lead zone has formed, the pore radius has increased (Fig. 2h). With the advance of formation the lead zone increases, as does the pore radius. Until the sixth hour, this effect is larger at the surface parts than

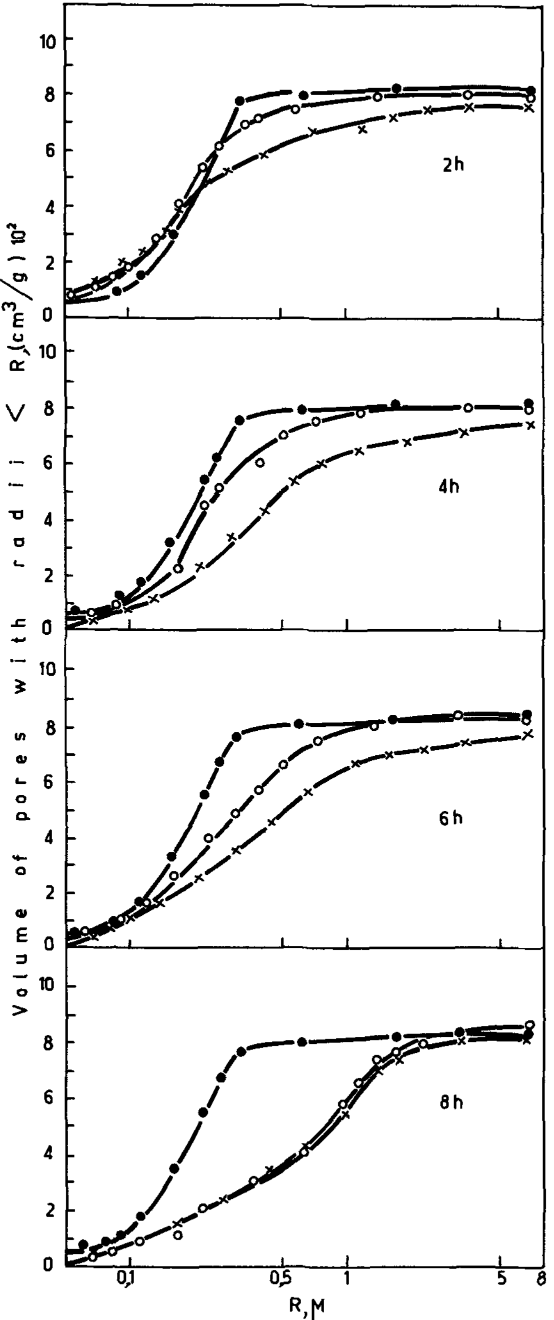

Fig. 6a. Change in pore size distribution and volume porosity until the eighth hour of formation.

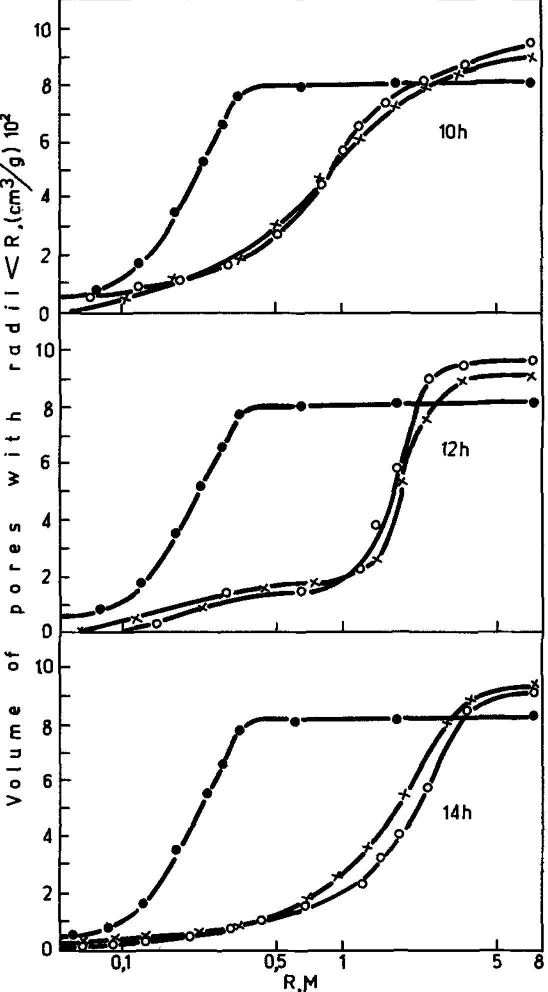

Fig. 6b. Continuation of Fig. 6a. Subsequent change in the pore size distribution and volume porosity after the eighth hour of formation. ●, Unformed plate; ○, at the surface of the plate; ×, in the bulk of the plate.

in the bulk. This is in good accord with the results of the phase composition studies.

From Fig. 6 it is seen that at the eighth hour of formation the pore size distribution in the interior of the plate becomes identical with that of the surface parts. It can be assumed that after this moment the reaction of formation of lead at the surface and in the bulk takes place at the same rate. Hence, the pore size distribution curves after the eighth hour have the same shape.

Electrocrystallization Processes during Formation of the Negative Plate

From the consideration of the elementary chemical and electrochemical reaction mechanism it becomes apparent that the evolution of the lead active mass takes place in two stages. During the first stage the lead crystals are formed at the expense of dissolution of lead oxide and tribasic sulfate. The crystallization process occurs at a pH of the pore solution higher than that of the bulk solution but lower than 6 (the upper limit of stability of lead sulfate). During this stage a network of lead crystals is built up. This network begins from the grid members, grows first at the surface, and then in the interior of the plate. This lead network includes lead sulfate crystals. The growth of the lead crystals is controlled by the flow of lead ions which arrive from the lead oxide and tribasic sulfate which are being dissolved. At a defined thickness of the plate, paste density, and manufacturing technology conditions can be created which could ensure a directed growth of the lead crystals from the surface towards the center of the plate. Such a microstructure of the active mass has been observed (14).

During the second stage the lead sulfate crystals are reduced. They are dissolved and Pb^{2+} ions lose their charge on the primary network of lead crystals. This process occurs at a pH of the pore solution smaller than that of the bulk solution. This gives rise to the secondary structure of the active mass. It may be concluded that the buildup of the active mass of the negative plate depends on current and paste density, sulfuric acid concentration in the electrolyte, and temperature. The determination of the effect of each of these individual parameters is of particular interest since it will widen and increase our knowledge of the elementary processes which take place upon formation of the negative plate.

Manuscript received Jan. 22, 1974.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1975 JOURNAL. All discussions for the June 1975 Discussion Section should be submitted by Feb. 1, 1975.

Impurity Effects in the Dissolution of Anodic Tantalum Oxide

J. P. S. Pringle*

Chalk River Nuclear Laboratories, Atomic Energy of Canada Limited, Chalk River, Ontario, Canada

The publication costs of this article have been assisted by Atomic Energy of Canada Limited.

ABSTRACT

Anodic tantalum oxide dissolves slowly and uniformly in hydrogen fluoride almost saturated with ammonium fluoride. When the oxide is implanted with heavy ions at fluences of around $10^{16}/cm^2$, the dissolution accelerates; implanted with the same fluence of hydrogen, it decelerates. Similar effects have been reported in the literature for impurities incorporated from the electrolyte during anodization, and so the changes in the dissolution rate can be ascribed to the physical presence of the impurities themselves. Accelerated dissolution can be correlated with the concentration profiles of implanted atoms. This provides a new method for measuring the latter, and one that is particularly useful for elements, such as neon, which have no long-lived radioisotopes. The nature of the accelerating process could not be determined owing to limitations in data and analysis.

Anodic tantalum oxide dissolves slowly and very uniformly in concentrated mixtures of hydrofluoric acid and ammonium fluoride. Thin uniform layers can therefore be removed in succession, and this forms the basis of a sectioning technique (1) for measuring the range profiles of implanted radioactive ions (2). Implantation, however, is accompanied by radiation damage, and the latter is known to change the properties of materials. To ensure the precision of the measurements, therefore, it was necessary to find out whether implantation affected the oxide dissolution. Experiments with stable isotopes, performed at fluences of 10^{16}-$10^{17}/cm^2$, showed that indeed it did (3). The implantation of hydrogen slowed the dissolution, but the implantation of other elements accelerated it.

This difference between hydrogen and other implants indicated that radiation damage was not responsible for the changes in dissolution rate. Further confirmation was supplied by reanodizing implanted samples to greater thickness. The anodizing current is thought to flow through the oxide by the simultaneous rearrangement of a number of atoms, both tantalum and oxygen, to new positions (4, 5), so that any structural changes due to radiation damage should anneal out. If the change in dissolution rate remains, therefore, it must be attributed to the continued presence of the implanted species. Experiments with implanted radioactive krypton and copper show that this is precisely what happens; on reanodization, the krypton stays in the oxide and the accelerated dissolution effect stays with it, while the copper migrates out of the oxide entirely, and no accelerated dissolution is observed (3). Impurities incorporated from the solution during anodization, should therefore behave similarly, and this is indeed observed.

Effect of Impurities Incorporated during Anodization

Radioactive ^{32}P and ^{35}S are found in the outer layers of films formed in phosphate and sulfate electrolytes containing $^{32}PO_4^{---}$ and $^{35}SO_4^{--}$ (6, 7), and nuclear microanalysis has shown that nitrogen is incorporated from nitric acid electrolytes (8). Though there is no definite proof that these impurities are present as the oxyanions, this seems probable in view of the oxygen analyses by Amsel *et al.* (8). Naturally, the amount of impurity incorporated varies with the experimental conditions and is very small in the dilute aqueous electrolytes normally used (6, 1). In concentrated electrolytes, however, it can be large. Anodic films formed in these electrolytes are scarcely oxides, and their properties are indeed significantly different. The difference is, however, restricted to the outer layers of the film containing the impurity, since the inner layers appear to be similar in all respects with films formed in dilute electrolytes (6, 9, 10).

Accelerated dissolution of these outer layers in HF reagents has been observed for films formed in con-

centrated H_2SO_4 (8, 9), HCOOH (11), and $Na_2B_4O_7$ in ethylene glycol (9). The acceleration increases with electrolyte concentration (8, 9), and hence presumably with the impurity concentration in the film. Nuclear microanalysis indicates that the SO_4^{--}:Ta ratio in the outer layer of films formed in 95% H_2SO_4 is about 0.75:1, and it is found that such layers dissolve at about eight times the normal rate (8). For comparison, the 10^{16} $^{84}Kr^+/cm^2$ illustrated in Fig. 2 of Ref. (3) are mostly present in the first 300Å of oxide, to give an average Kr:Ta ratio of 0.15:1; and the accelerated stripping that results is, on average, about twice the normal rate. The effects observed with incorporated sulfate and implanted krypton are therefore approximately in proportion.

Not all incorporated impurities accelerate the dissolution, however, as examination of the films formed in 85% H_3PO_4 will show. A report (6) that the outer layers of these films show accelerated stripping is in error, because the film thicknesses were determined by reciprocal capacity measurements. Similar measurements on films formed in concentrated formic acid did not tally with thicknesses obtained by optical and weight gain methods (11). If the corrections indicated in Ref. (11) are applied to the measurements reported in Ref. (6), the latter will agree with (9) and (11) that the outer layer of films formed in 85% H_3PO_4 dissolve at about two thirds the normal rate. Phosphate impurity therefore decelerates the dissolution. Decelerated dissolution has also been observed with implanted hydrogen atoms (3), where it was attributed to the formation of hydrogen bonds. A similar chemical reason may well be responsible for the effect with phosphate.

Studies with phosphate-^{32}P electrolytes have shown that the ^{32}P is incorporated uniformly throughout the outer layer of the oxide (6, 7), and further experiments (6, 9) show that this layer dissolves at a constant rate. The deceleration thus appears to be related to the concentration profile of the presumed phosphate-^{32}P, and a similar comment is probably true for sulfate-^{35}S (6, 9). It should be noted, however, that recent measurements with an ion microprobe mass spectrometer (12) suggest that the phosphorus is not incorporated uniformly, but is concentrated toward the outer edge of the outer layer. Obviously, further work is needed to resolve this discrepancy.

The dissolution of anodic tantalum oxide is thus affected by impurities, however these are incorporated. It is then reasonable to suppose that any change in the dissolution rate will be proportional to the local concentration of the impurity atoms, and hence that the variation in the dissolution rate will be related to their concentration profile. The present paper shows that this variation can indeed be used to measure the concentration profiles of implanted atoms.

Experimental Procedure

Chemically polished tantalum foils, 3.5 × 1.0 × 0.037 cm (0.015 in.), were anodized to the required thickness at 1 mA/cm² and 25°C in 0.1M H_2SO_4. A small area, 0.5 × 0.8 cm, in the middle of one face was then implanted with the appropriate fluence, usually 10^{16}/cm², of noble gas ions in a mass separator. The fluence was monitored by determining the amount of charge deposited on the foil. Oxide thicknesses on the implanted and nonimplanted areas were then measured by means of a spectrophotometric method (1). Though calibrated for nonimplanted oxide, the method can be applied, with reasonable confidence, to oxides implanted with up to 10^{16} ions/cm² (3). The anodic film was then sectioned by dissolution in HF almost saturated with NH_4F (1), and the thicknesses on both areas measured after the removal of each oxide layer. More complete details can be found in Ref. (3), where the identical procedure was used.

The implanted atoms came to rest only in the surface layer of the anodic film. When sectioning began, therefore, this surface layer dissolved more rapidly than usual, and so the oxide thickness, X, on the implanted area decreased faster than that, X_n, on the nonimplanted area. Once the surface layer had been removed, the remaining oxide on the implanted area was oxide that had not been implanted at all. It therefore dissolved at the same rate as the oxide on the nonimplanted area, so that the film thickness on both areas now decreased at the same rate. The heavy lines in the top part of Fig. 1 illustrate this process schematically. An alternative and more convenient method (3) of presenting the results is given in the bottom part of the figure, where the implantation differential, which is defined as the oxide thickness remaining on the implanted area less that remaining on the nonimplanted area, is plotted against the oxide thickness dissolved from the latter; *i.e.*, $(X - X_n)$ *vs.* $(X_n(1) - X_n)$, where $X_n(1)$ is the initial thickness on the nonimplanted area.

The experimental measurements were in the form of a series $I = 1,2,\ldots, N$ of oxide thicknesses, $X(I)$, remaining on the implanted area as a function of the corresponding thicknesses, $X_n(I)$, remaining on the

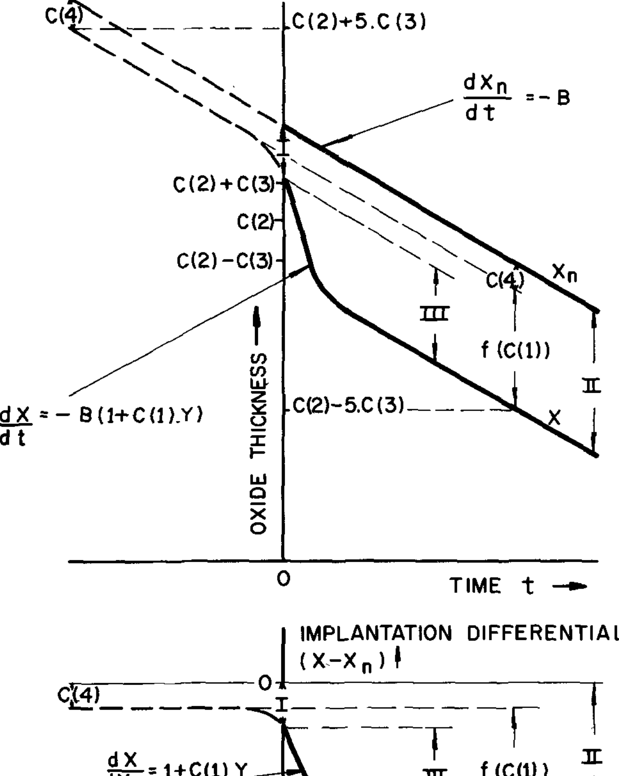

Fig. 1. Schematic diagrams to illustrate the relation between the various parameters discussed in the text. The experimentally measurable quantities defined in Ref. (3) are the initial implantation differential *(I)*, the final implantation differential *(II)*, and the magnitude of the accelerated stripping *(III)*. The upper diagram shows how the thicknesses on the implanted area, X, and the nonimplanted area, X_n, vary with time, while the lower illustrates the corresponding variation in the implantation differential, $X - X_n$, as a function the oxide thickness dissolved from the nonimplanted area, $X_n(1) - X_n$. All experimental results, both here and in (3), are presented in the format of the lower illustration. The constant of integration, C(4), has been drawn as a negative quantity in these diagrams; experimentally it was found to be positive.

nonimplanted area. The standard errors in each measurement, $EX(I)$ and $EX_n(I)$, were calculated as described in (1). The problem was, therefore, to correlate the variation in X with the concentration profile of the implanted atoms.

Mathematical Analysis

Range profiles for ions implanted in anodic tantalum oxide are normally distributed within experimental error (2). Using the nomenclature of previous papers, these profiles can be described by

$$Y = \frac{F}{\sqrt{(2\pi)} \cdot C(3)} \cdot \exp\left[-\left(\frac{X - C(2)}{\sqrt{2} \cdot C(3)} \right)^2 \right] \quad [1]$$

where Y is the local concentration of implanted ions in units of number/cubic angstrom; X is the distance in angstroms from the metal/oxide interface; F is the fluence of implanted ions in units of number/angstrom, equivalent to 10^{-16} times the number/square centimeter; $C(2)$ is the distance in angstroms between the profile mode and the metal/oxide interface; and $C(3)$ is the standard deviation, also in angstroms, of the range profile.

Since the concentration profile remains close to a normal distribution on further anodization (4), Eq. [1] can be applied with little error to reanodized samples as well.

As a first attempt, the accelerated dissolution of the oxide may be attributed to the instantaneous dissolution of a certain volume, $C(1)$ Å^3, in the immediate vicinity of each implanted ion. When one cubic angstrom of implanted oxide is dissolved at the normal rate, therefore, it will be accompanied by an additional $C(1) \cdot Y$Å^3 dissolved instantaneously. If the dissolution rate for the nonimplanted oxide is given by

$$dX_n/dt = -B \quad [2]$$

that for the implanted oxide will be

$$dX/dt = -B(1 + C(1) \cdot Y) \quad [3]$$

where the negative signs occur because the sectioning decreases both X and X_n. The simultaneous integration of Eq. [2] and [3] then describes the relationship between X and X_n, as illustrated in the upper part of Fig. 1.

It is, however, much more convenient to eliminate the time variable. Dividing Eq. [2] and [3] by $dt/dX_n = -1/B$ gives

$$dX_n/dX_n = 1 \quad [4]$$

and

$$dX/dX_n = 1 + C(1) \cdot Y \quad [5]$$

as indicated in the lower part of Fig. 1. The simultaneous integration of Eq. [4] and [5] is now taken with respect to X_n, and can be performed numerically by means of a Runge-Kutta procedure (13) on a computer. The integration is, of course, taken in the direction of decreasing X and X_n.

Figure 1 shows the connection between the parameters $C(1)$, $C(2)$, and $C(3)$, and the quantities previously defined (3). Range profiles in anodic tantalum oxide are not complete normal distributions, because they are truncated by the oxide surface (2). The Runge-Kutta procedure must therefore be started well beyond the oxide surface. In the present analyses it was started at an oxide thickness equivalent to $C(2) + 5C(3)$; that is, five standard deviations before the mode. A constant of integration, $C(4)$, is necessary; as illustrated in Fig. 1, this is simply the difference between X and X_n at the start of the procedure, not at the start of the experimental measurements themselves. Though actually drawn as a negative quantity, $C(4)$ may be positive; its physical significance is discussed later.

Best estimates for the four parameters were obtained by applying the least squares fitting procedure described in (2). The independent variable was X_n, and the dependent variable X. To make the fit, X was computed for the N values of X_n and the values of the four parameters adjusted until the sum of the squares of the differences between observed and calculated values for both X and X_n was minimized. Besides giving best estimates for the parameters, the procedure also provided standard errors in these estimates, and a chi-square probability measurement or fitting probability, $p(\chi^2)_{N-4}$, for the goodness-of-fit.

The least squares fitting procedure has, however, certain limitations, and these became effective in the course of this work. Since they have not been studied to any extent, either here or elsewhere, a detailed discussion is impossible; a few qualitative comments are all that can be presented.

The fewer the experimental points, and the more inaccurate they are, the less the information that can be extracted from them in a least squares fit; that is, the fewer the parameters that can be characterized, the more inaccurate they are, and the greater the difficulty of distinguishing between alternative expressions of fit. It has been recommended that the number of experimental points should be at least three times the number of parameters to be fitted (14), so that at least twelve points were required here. With twelve to sixteen points per sample, the modal values, $C(2)$, were generally reasonable but the standard deviations, $C(3)$, were frequently not. This recommendation is, however, only a rule of thumb, and so it is not very surprising that there should be occasions on which it does not apply. When the number of points was raised to more than six times the number of parameters to be fitted, that is, to twenty-four or more points, reasonable results were always obtained with both parameters, as is demonstrated later.

One criterion for the satisfactory fit of a number of samples is that the fitting probabilities should be scattered about 0.5; that is, some should be better than average and some should be worse. The fits made here with twenty-four or more points all gave fitting probabilities of better than 0.908, which is rather too good to be true. Too good a fit will be obtained if the error in each experimental point has been overestimated; this does not seem likely here, since the magnitude of these errors is well established (1, 2). Alternatively, too many parameters could have been used in the fitting; again this does not seem likely, because the system can hardly be described with less. The obverse of this argument is that the experimental data are insufficient to characterize the number of parameters used, and this explanation is believed correct.

The least squares fitting procedure is thus being pushed rather close to its limit in the present work, and so there is some additional uncertainty in the figures quoted. The mathematical significance of any comparisons is therefore less reliable than usual.

Testing the Proposed Correlation

For test purposes, samples with known concentration profiles were required. These were prepared by implanting $^{84}Kr^+$ and $^{85}Kr^+$ jointly at 40 keV to a total fluence of 10^{16} ions/cm^2; the stable $^{84}Kr^+$ provided the fluence required for the dissolution measurements, while the radioactive $^{85}Kr^+$ acted as the tracer needed for the measurement of the concentration profile. Two such samples were used, one as implanted, while the other was reanodized by 2308Å; the results have been illustrated in Fig. 2 of Ref. (3). The test of the correlation, then, was whether the parameters $C(2)$ and $C(3)$ determined from the dissolution analysis would agree with those obtained from the radioactive measurements within their combined experimental errors.

The range profile in the implanted sample gave

$$C(2) = 1708 \pm 2\text{Å}; \quad C(3) = 84 \pm 2\text{Å}$$

by ^{85}Kr analysis, and

$$C(2) = 1712 \pm 9\text{Å}; \quad C(3) = 100 \pm 15\text{Å}$$

by dissolution analysis. Similarly, the specimen implanted and then reanodized gave

$$C(2) = 2432 \pm 13\text{Å};\quad C(3) = 102 \pm 9\text{Å}$$

by ^{85}Kr analysis, and

$$C(2) = 2433 \pm 2\text{Å};\quad C(3) = 88 \pm 4\text{Å}$$

by dissolution analysis. Since the difference between any pair of measurements is less than twice the root mean square of the component standard errors, the results apparently agree.

In reaching this conclusion, however, several other factors must be taken into account, besides the uncertainty in the least squares fitting procedure described previously.

(i) It has been assumed that the range profile for $^{84}Kr^+$ ($^{85}Kr^+$) implanted to 10^{16} ions/cm² at 40 keV is normally distributed.—This assumption is certainly justified for krypton ions implanted at fluences up to 10^{15} ions/cm², as demonstrated previously (2). The present sample shows that it is justified for 10^{16} ions/cm² as well, since the fitting probability, $p(\chi^2)_{23}$, obtained with the ^{85}Kr analysis was 0.863, well above the acceptance limit of 0.025 (2).

(ii) It has been assumed that the ^{84}Kr concentration profile remains normally distributed on further anodization.—As discussed elsewhere (4), reanodization has the effect of folding a normal distribution into the original profile. If the latter is a complete normal distribution, the final profile will also be normally distributed, and its standard deviation will be equal to the square root of the sum of the squares of the component standard deviations. When the initial profile is a truncated normal distribution, however, the final profile cannot be normally distributed. The departure from normality will depend on the degree of truncation and on the relative magnitudes of the component standard deviations. If the truncation is small and the standard deviation of the folding distribution large, the departure from normality will be negligible, as demonstrated by the 5 keV ^{125}Xe samples reanodized in previous work (4).

In the present work, however, the krypton ions were implanted at 40 keV. Though the degree of truncation is much the same for both 5 and 40 keV (2), the relative magnitude of the standard deviation folded in will be much less for a broad 40 keV profile than for a narrow 5 keV one. It is not surprising, therefore, that the normal distribution should give a poor fit ($p(\chi^2)_{10} < 0.001$) to the reanodized sample by ^{85}Kr analysis. By contrast, the fit obtained with the dissolution analysis ($p(\chi^2)_{10} = 0.958$) was excellent.

(iii) Equation [5] contains the assumption that C(1) is a constant independent of the stripping rate [1].—Three oxide specimens were implanted with 10^{16} 39 keV $^{40}Ar^+$/cm² in the same series of implantations to ensure reproducibility (3), and then analyzed in three different samples of the HF-NH_4F stripping agent. The proportions of HF and NH_4F were adjusted (1) to obtain stripping rates in a ratio of approximately 1:2:4, and the samples were maintained at 26°C by means of a water bath. Average stripping rates were calculated by dividing the total stripping time into the total thickness removed from the nonimplanted area. The results are given in Table I, from which it will be seen that the three $C(1)$ values are indeed similar.

(iv) Equation [5] also requires that C(1) be independent of the implantation fluence F.—In this same series of implantations, an anodic oxide was implanted with 2×10^{16} 39 keV $^{40}Ar^+$/cm². Table I shows that the value of $C(1)$ was again similar to those obtained at 10^{16} ions/cm².

(v) The proposed correlation must give acceptable ($p(\chi^2)_{N-4} > 0.025$) fits to the experimental data.—The initial implantation differential, I, is always negative with these heavy ions, and may be taken as a first estimate for $C(4)$. As indicated in Fig. 1, it must be corrected for that portion of the normal distribution extending beyond the oxide surface, and since this correction is positive, the effects tend to cancel. The initial implantation differentials for the three 10^{16} $^{40}Ar^+$/cm² samples in Table I averaged −16Å, while $C(4)$ averaged +10Å; the truncation correction was therefore +26Å. This positive result with $C(4)$ may perhaps be interpreted as a swelling of the oxide structure due to the implantation of the argon ions. Such an effect would normally be masked by the sputtering responsible for the observed negative implantation differential. When 2×10^{16} $^{40}Ar^+$/cm² were implanted, $C(4)$ was twice as large, exactly as expected from this interpretation.

(vi) The proposed correlation must give reasonable estimates for C(1).—The crude hypothesis, that each implanted ion is embedded in a volume $C(1)$ Å³ which dissolves instantaneously, thus accounts rather well for the observations considered so far. It but remains to examine $C(1)$, which for the sample implanted with 2×10^{16} $^{40}Ar^+$/cm² was found to be 337Å³ (Table I). An estimate for $C(1)$ may readily be obtained from the magnitude of the accelerated stripping (labeled III in Fig. 1) corrected for the truncation effect; the result is 322Å. That is, the implantation of 2 $^{40}Ar^+$/Å² of surface gives rise, on average, to the removal of 322Å³ by accelerated stripping, so that each implanted $^{40}Ar^+$ gives rise to the removal of 161Å³. This figure is just less than half the computed one, and so the latter must be in error.

(vii) Correction for C(1).—The fault is, however, readily corrected. For every cubic angstrom removed from the implanted area by ordinary dissolution, an additional $C(1) \cdot Y$Å³ will be removed by accelerated

Table I. Parameters for 39 keV $^{40}Ar^+$ range profiles determined from dissolution analyses

Standard errors have been quoted. Interpolation of the range data in (2) suggests that the modal range should be about 230Å and the standard deviation 150Å

$dX/dX_n = \exp(C(1) \cdot Y) = 1 + C(1) \cdot Y + \frac{(C(1) \cdot Y)^2}{2!} + \ldots + \frac{(C(1) \cdot Y)^m}{m!} + \ldots$ [8]							
50.1	2	224 ± 5	223.5 ± 4	168.5 ± 6	24 ± 7	31	0.928
$dX/dX_n = 1/(1 - C(1) \cdot Y) = 1 + C(1) \cdot Y + (C(1) \cdot Y)^2 + \ldots + (C(1) \cdot Y)^m + \ldots$ [7]							
50.1	2	161 ± 4	223 ± 4	191.5 ± 6	25.5 ± 6	31	0.858

stripping due to the implanted ions it contains. This additional volume will itself contain implanted ions, and these will give rise to the removal of a further $(C(1) \cdot Y)^2 \text{Å}^3$ by accelerated stripping. The argument repeats in such a way that Eq. [5] becomes

$$\frac{dX}{dX_n} = 1 + C(1) \cdot Y + (C(1) \cdot Y)^2 + \ldots + (C(1) \cdot Y)^m + \ldots \quad [6]$$

Since this argument assumes that there is no overlap between adjacent $C(1)$ cells, $C(1) \cdot Y < 1$; hence [6] may be written

$$\frac{dX}{dX_n} = \frac{1}{(1 - C(1) \cdot Y)} \quad [7]$$

A least squares fit of Eq. [7] gave $C(1)$ as 161Å^3, exactly as required; that is, the quantity labeled $f(C(1))$ in Fig. 1 is now just $2 \cdot C(1)$. Table I shows, however, that though C(2) and C(4) remained the same as before, C(3) ballooned from the expected 150Å to 192Å; Eq. [7] is not, therefore, satisfactory either.

(viii) A second correction.—But it is not realistic to suppose there will be no overlap between adjacent $C(1)$ cells. The ions are implanted at random, and so some will come sufficiently close to cause overlap. The proportion that do so will obviously increase with increasing fluence. Some relatively straightforward mathematics, based on the fraction of the over-all volume present in the C(1) cells, showed that Eq. [7] would convert to

$$\frac{dX}{dX_n} = \exp\,(C(1) \cdot Y) \quad [8]$$

when overlap was taken into account. The least squares fit of Eq. [8] gave results intermediate to those from Eq. [5] and [7], for reasons that are obvious from the series expansions in Table I.

(ix) Further corrections.—Even with these corrections applied, therefore, the correlation is still not realistic. The second correction permits adjacent $C(1)$ cells to overlap completely, which would mean that two $^{40}Ar^+$ ions come to rest in exactly the same place to form $^{80}Kr^{++}$! Furthermore, it is unreasonable that the individual $C(1)$ cells should dissolve instantaneously at an infinite rate; they would dissolve at some multiple of the normal rate. Again, the boundary between the $C(1)$ cells and the rest of the oxide is unlikely to be sharp. The rate of dissolution will decrease with distance from the implanted ion and may also vary with direction. Almost certainly, the rate would change once the implanted atom itself had been dissolved.

These several factors can only be described with the aid of additional parameters. Previous discussion has shown that the available measurements are barely adequate to characterize the four parameters that must be used; they would therefore be quite incapable of resolving more. The conclusion must be, then, that it is impossible to determine the mechanism of the accelerating process from the available data, and hence that it is impossible to determine the true correlation between the concentration profile and the accelerated dissolution.

Nevertheless, the fit of Eq. [5] has given good values for the mode and standard deviation of the krypton and argon profiles studied. Provided sufficient experimental points are taken, therefore, this accelerated dissolution may be used to measure range profiles at fluences of $10^{16}/\text{cm}^2$.

Concentration Profiles Measured by Accelerated Dissolution

When Eq. [5] was fitted to the samples reported in the previous paper (3), reasonable results were obtained for the modes and poor results for the standard deviations. These samples had not, however, been intended for least squares fit analysis, and so relatively few points had been taken. The use of accelerated dissolution for range profile measurements may be illustrated by reference to the 25 keV $^{20}Ne^+$ sample of Fig. 2; the modal range was found to be 257 ± 11Å, and the standard deviation 183 ± 25Å. For comparison, range parameters obtained with various radioisotopes (2) may be extrapolated to 25 keV $^{20}Ne^+$, and give a modal range of about 280Å and a standard deviation of about 180Å; the two estimates are thus in reasonable agreement.

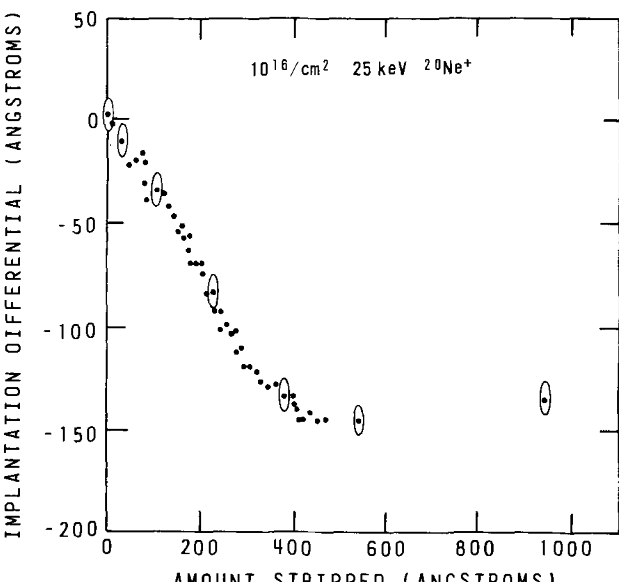

Fig. 2. Accelerated stripping observed with 10^{16} $^{20}Ne^+/cm^2$, implanted at 25 keV. Error ellipses have been drawn around some of the points at radii equal to twice the standard errors to indicate the magnitude of the 95% confidence limits around each point.

This accelerated dissolution method for measuring range profiles is particularly useful with elements, such as the neon discussed above, for which no long-lived isotopes exist.

Conclusions

1. Implantation of impurities changes the dissolution rate of anodic tantalum oxide in buffered HF, and these changes are very similar to those reported with impurities incorporated from the electrolyte during anodization.
2. This observation provides additional evidence that the radiation damage accompanying ion implantation is not responsible for the observed effects.
3. The implantation of heavy ions accelerates the dissolution, and this acceleration can be correlated empirically with the range profile.
4. The mechanism of the acceleration is, however, so complex that it cannot be elucidated from the available experimental evidence.
5. If the ions are implanted at a fluence of about $10^{16}/\text{cm}^2$, an empirical correlation can be used to measure their concentration profiles.

Acknowledgments

It is a pleasure, once again, to acknowledge the assistance of D. Phillips, who performed the experimental measurements. J. A. Davies and D. C. Santry kindly reviewed the manuscript and made valuable suggestions for improvement.

Manuscript submitted Nov. 7, 1973; revised manuscript received Feb. 11, 1974.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1975 JOURNAL.

All discussions for the June 1975 Discussion Section should be submitted by Feb. 1, 1975.

Further Observations on the Marker Behavior of Noble Gases during the Anodic Oxidation of Tantalum

ABSTRACT

Argon, krypton, xenon, and radon have been used as markers for measuring the transport numbers of metal and oxygen during the anodic oxidation of tantalum. Within experimental error, the results are independent of marker concentration over five orders of magnitude, and so the markers do not influence the transport mechanism by their presence, or by any radiation damage accompanying their implantation. Neon behaves in the same way as the heavier gases and is thus also suitable as a marker.

An oxide film on a metal surface will thicken only if metal atoms, or oxygen atoms, or both migrate across it. The actual mechanism can be identified by labeling a thin layer in the oxide with a suitable marker. On further oxidation, the metal atoms migrating outward through the marked layer give rise to new oxide between it and the oxide/environment interface. Similarly, oxygen atoms migrating inward form new oxide between it and the metal/oxide interface. The final position of the marker is thus determined by its position in the initial oxide, as modified by the subsequent metal and/or oxygen migrations to either side. By measuring the position of the marker before and after the oxidation event, therefore, the relative migration of metal and oxygen may be determined.

Though this concept is simple enough in theory, it presents one very formidable difficulty in practice. This is the difficulty of establishing that the chosen marker really is behaving as a marker. Two requirements must be met: the marker must not itself migrate during the oxidation event, and it must not interfere with the oxidation process; that is, it must be both immobile and inert.

These questions have been discussed at length in a recent report on the anodic oxidation of tantalum (1). Because the metal and oxygen migrations in this system are associated with the passage of an electric current, their relative magnitude can be specified in terms of transport numbers. Atoms of the heavier noble gases were used as markers, and their immobility tested against the following argument. If one of the noble gases is immobile, they all will be, and hence the transport numbers measured with the different gases should be exactly the same. Very precise measurements, using a sectioning technique (2) to measure the concentration profiles of radioactive noble gas isotopes (3), showed, however, that they were not exactly the same. The transport numbers measured with ^{41}Ar, ^{79}Kr, and ^{125}Xe were all slightly different from one another, and the differences were significant at the 2.5% probability level. Furthermore, the measurements were in the correct order for a real effect, since ^{79}Kr gave the intermediate result. The small mobility revealed was interpreted as a nonrandom Brownian motion, and an appropriate correction was made to obtain best estimates for the transport numbers. Noble gas markers must therefore be regarded as almost, but not quite, immobile.

No changes in the anodizing behavior had been detected with the markers present, and so they were presumed to be inert. These experiments had, however, been conducted with radioisotopes of the noble gases, and so the implanted concentrations were very low; not more than about 260 atoms per million matrix tantalum and oxygen atoms in fact. [Due to an unfortunate miscalculation, the concentrations quoted in the previous paper (1) are ten times too large.]

Experimental Procedure

A further test for the marker behavior of the noble gases was to implant them at much higher fluence, so that their effect on the transport mechanism, if any, would be enhanced. The maximum fluence obtained in the previous experiments with radioisotopes had been about $10^{13}/cm^2$; by implanting stable isotopes as well, the total fluence could easily be raised to $10^{16}/cm^2$ or more. Radioactive ($\sim 10^{13}$ $^{85}Kr/cm^2$) and stable isotopes (10^{16} $^{84}Kr/cm^2$) were therefore implanted at the same time into a small area, 0.5×0.8 cm, on the face of a 3.5×1.0 cm anodized tantalum foil, according to the procedure described elsewhere (4). Under these circumstances, the radioisotope acted as a tracer for the much larger quantity of stable isotope, and so the concentration profile of both isotopes together could be determined by the usual sectioning technique (2). Within experimental error, these profiles were found to

* Electrochemical Society Active Member.
Key words: tantalum, anodic oxidation, ion implantation, markers.

be normally distributed (5), both before and after further anodization, and so their modes could be used as measures of marker position. Transport numbers were then calculated from the formula derived in Ref. (1), viz.

$$t_m = (h_f - C(2) - r)/(h_f - h_i)$$
$$t_o = (C(2) + r - h_i)/(h_f - h_i) \quad [1]$$

where t_m and t_o are the transport numbers of the metal and oxygen, respectively, h_i is the initial oxide thickness, h_f the oxide thickness after further anodization, C(2) the modal position of the gas in the final oxide, and r the modal range of the gas as implanted.

Implantation fluences of $10^{16}/cm^2$ give rise to noble gas concentrations of several atom per cent in the surface layers of the oxide. Not surprisingly, such massive concentrations of impurity alter the properties of the anodic film. Thus oxide loaded with noble gas dissolves more rapidly in the HF-NH_4F reagent used for sectioning (2), and so the film thickness on the 0.5 × 0.8 cm implanted area thins faster. The difference (film thickness on the implanted area less that on the surrounding nonimplanted area) has been defined as the implantation differential (4), and it varies as sectioning proceeds. A typical (not best) result is illustrated in Fig. 1. The rate of change in the implantation differential is determined by the accelerated stripping rate on the implanted area, and this in turn can be related to the local concentration of noble gas impurity. It is therefore possible to use this variation in the implantation differential to measure the noble gas concentration profile (5). Accelerated stripping thus provides an alternative method for measuring transport numbers at high gas concentrations, and the 10^{16} ^{84}Kr + $^{85}Kr/cm^2$ sample in Table I shows that the results agree, within experimental error, with those obtained from the radioisotope measurements.

Pilot measurements with an ellipsometer indicate that a high concentration of noble gas impurity alters

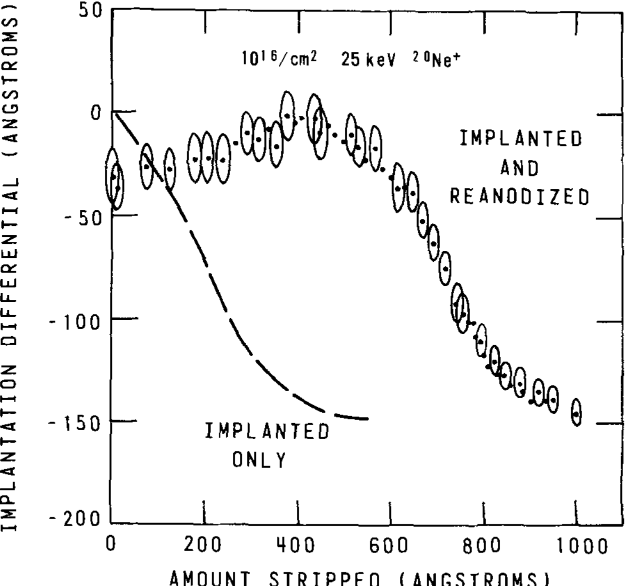

Fig. 1. Variation of the implantation differential for anodic tantalum oxide implanted with 10^{16} 25 keV $^{20}Ne^+/cm^2$, and reanodized from an initial thickness of 913Å to a final thickness of 3048Å. The amount stripped is the total oxide thickness removed from the nonimplanted area during the sectioning process (2); the implantation differential is the film thickness remaining on the implanted area less that remaining on the nonimplanted area. Error ellipses have been drawn at radii of twice the standard errors around some points to indicate the magnitude of the 95% confidence limits around each point. The dashed line indicates the result for a sample, in the same series of implantations (4), that had not been reanodized. The original results are given in Fig. 2 of Ref. (5).

Table I. Comparison of transport numbers for oxygen in the anodic oxidation of tantalum, as determined by radioisotope and accelerated stripping methods and Eq. [1]

Errors quoted are least squares errors of fit, calculated according to Eq. [11] in Ref. (1); the measurements at 10^{16} ions/cm² may well be subject to additional error owing to changes in the optical characteristics of the oxide (4). Anodizing conditions: 1 mA/cm², 0.1M H_2SO_4, 25°C, with approximately 2000A of oxide added.

the optical properties of the anodic film, particularly after further anodization (4). A change in the optical properties will introduce systematic errors into oxide thicknesses measured by the spectrophotometric method (2), and hence into all the quantities appearing on the right-hand side of Eq. [1]. Transport numbers measured with high concentrations of noble gas are therefore inherently less accurate than those measured at low concentrations.

Discussion

Table I shows that the transport numbers are independent of fluence over the five orders of magnitude studied. The radon atoms implanted at a fluence of $10^{11}/cm^2$ will come to rest approximately 100 matrix atoms apart, and so there will, in effect, be large stretches of unimplanted oxide between them. Any interference with the transport mechanism in the natural oxide should therefore be very slight. By contrast, the implantation of 10^{16} $^{84}Kr^+$ and $^{85}Kr^+/cm^2$ puts the krypton atoms in almost nearest neighbor positions to one another. The similarity of the transport numbers under these extreme conditions then strongly suggests that noble gas markers do not affect the transport process by their presence, or by any radiation damage accompanying their insertion. The implication, therefore, is that the noble gas atoms present in high concentrations must be as mobile, or more correctly, as immobile, as those implanted at low concentration.

High concentrations of noble gas impurity could also affect the over-all kinetics of the anodization process. Since anodization normally gives rise to oxide film of uniform thickness (2), any change in the kinetics on the implanted area during further anodization may be expected to give a final oxide thickness different from usual. This would be manifest as a nonzero implantation differential. Reference to Fig. 1, and the corresponding Fig. 2 of Ref. (4) for krypton, will show that the implantation differential was negative immediately after reanodization, so that the final thickness on the implanted area was less. This observation was generally true of reanodized samples containing 10^{16} noble gas atoms/cm² and suggested that the anodization was slightly inhibited by this quantity of noble gas. Such interpretation must be viewed with caution, however, in view of the uncertainty attaching to film thickness measurements at high concentrations of impurity. Nevertheless, from the magnitude of the effect observed at $10^{16}/cm^2$, it is quite clear that the effect at $10^{13}/cm^2$ would be negligible, and hence that the noble gas markers would indeed be effectively inert at the lower fluence.

Because accelerated stripping does not depend on the nuclear properties of the implanted atoms, it could be

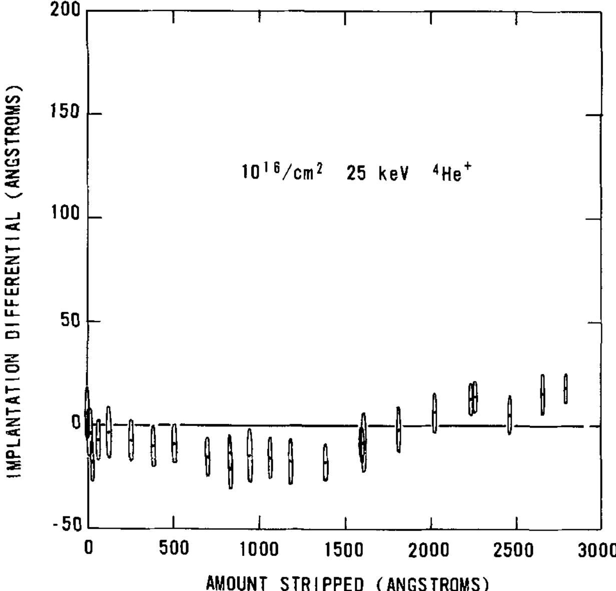

Fig. 2. Accelerated stripping, or lack of it, observed with implanted helium. Similar results were obtained with implantations at 40 and 55 keV.

used to extend the transport number measurements to neon, for which no long-lived radioisotopes exist. The result, as indicated in Fig. 1 and Table I, was the same within experimental error as those obtained with the heavier noble gases, and so neon is also suitable as a marker species. A further extension to helium proved impossible, since no accelerated dissolution was observed with this element (Fig. 2). Either helium does not accelerate the stripping, or it was not present, having diffused out again immediately after implantation. The latter seems quite possible, since it diffuses rapidly in vitreous SiO_2 and GeO_2 (6).

Conclusions

1. Up to $10^{16}/cm^2$, the implantation fluence of a noble gas marker has no effect on the measurement of transport numbers.
2. Noble gas markers do not, therefore, influence the transport mechanism during anodization, either by their presence or by any radiation damage accompanying their implantation.
3. Implanted in trace amounts, $10^{13}/cm^2$ or less, noble gas markers have no effect on the kinetics of the anodization process and are therefore effectively inert.
4. Neon behaves in the same way as the heavier noble gases and is thus also suitable as a marker.

ABSTRACT

A recently developed, simple technique for determining cathode mass transfer coefficients in full scale electrowinning cells is discussed. The approach involves the determination of the limiting current for mass transfer controlled codeposition of silver in the cathode deposit. A rotating disk electrode was used to establish the validity of the method. Examples demonstrate the usefulness of the method for mapping local values of the mass transfer coefficient on the cathode under typical natural and forced convection flow regimes in electrowinning cells.

Recent attempts to develop pollution-free metallurgical technology have led to renewed effort in electrochemical research [see for example (1-3)]. A major effort has been directed towards operation of electrowinning cells at increased current densities either by optimizing cell design or by employing forced convection. For example, by employing a current redistributing anode (4, 5), smooth, compact, and uniform copper was electrowon at current densities 15% higher than those obtainable in conventional cells using the identical electrolyte. Other approaches utilize forced agitation in the electrolytic cell by sparging with gas (6, 8) or by electrolyte recirculation (7). In order to assess the potential of alternative cell designs resulting from such developments, it is desirable to have a rapid, convenient method of determining local values of the cathode mass transfer coefficient (k) *in situ* in full scale electrowinning cells.

[1] Present address: Hooker Chemical Corporation, Niagara Falls, New York 14300.

Key words: natural convection, forced convection, model cells.

The mass transfer coefficient (k), defined as D/δ (see Eq. [1]), has previously been determined by measurement of limiting current (9-11, 20), interferometric methods (12, 13) and by Brenner's freezing method (14)

$$i_{Cu+2} = 2F\, k_{Cu+2}(C_{Cu+2,\,bulk} - C_{Cu+2,\,surf}) = 2F \frac{D_{Cu+2}}{\delta_{Cu+2}} (C_{Cu+2,\,bulk} - C_{Cu+2,\,surf}) \quad [1]$$

In the first method, the local limiting current density (i_L) values are obtained by measuring i_L at various points on the surface of a vertical plate, which contains small cathodes that are insulated from one another and provided with potential probes. Dilute electrolytes are usually used in these measurements to minimize the limiting current. For measuring k in concentrated electrolytes used in practice, a modified approach has been used. Limiting current measurements are recorded using a movable probe electrode (5) placed in close proximity to the working electrode. This technique has been used to gather information on the degree of electrolyte agitation at the cathode in conventional electrowinning cells. However, the hydrodynamics at the probe are not the same as at the cathode surface and hence these measurements are of only limited value. Furthermore, evaluation of the extent of mass transfer from i_L is made uncertain by the area changes at the electrode since the deposits are powdery at the limiting current density.

It should also be pointed out that the value of the mass transfer coefficient measured under limiting current density conditions is not necessarily the same value as that prevalent under normal operating conditions (cf. Eq. [1]) since k depends on the current density itself.

Interferometric methods are based on differing refractive indices of the electrolyte in the diffusion layer and the bulk solution, arising from the concentration changes near the cathode during electrolysis. In Brenner's freezing method, the electrolyte near the cathode is suddenly frozen, and a thin section of the solid is shaved off for analysis of the composition of the layer.

While these techniques are very useful, particularly for bench top systems, they require complicated experimental arrangements. As such they cannot be readily used to determine mass transfer coefficients in large scale cells using concentrated electrolytes.

Principles of the Present Method

The tediousness of the earlier methods for measuring mass transfer coefficients is largely overcome in the present method. This involves determination of limiting current density for the deposition of an ion which is codeposited at its maximum or mass transfer controlled rate. This can be achieved by selecting an ion which is reduced at more positive potentials than that of the major reducible species. Thus, in the case of either copper or nickel electrowinning using sulfate electrolytes, silver can be used. Since the standard potential of silver is ~460 mV more noble than that of copper, Ag^+ (at low concentrations) should plate at its mass transfer controlled (limiting) current density (i_{L,Ag^+}) at the normal operating cathode potential (~ −100 mV *vs.* $Cu/CuSO_4$ sat'd). From an analysis of the Ag content in the cathode deposit, i_{L,Ag^+} can be calculated. From this value and the bulk concentration of Ag^+ in the electrolyte, the mass transfer coefficient for Ag^+ deposition can be calculated from Eq. [2]

$$k_{Ag^+} = \frac{i_{L,Ag^+}}{F C_{Ag^+}} \quad [2]$$

This value reflects the actual operating conditions at the cathode and does not suffer the usual limitations of a measurement made at the limiting current for copper. The assumption that the codeposition of Ag was mass transfer controlled was verified using a rotating disk electrode.

Experimental

Cu and Ni electrowinning electrolytes for the rotating disk electrode studies were prepared from Analar grade chemicals using distilled water. The copper electrolyte was used without purification. However, the nickel electrolyte was initially purified by activated charcoal and H_2O_2 treatment to reduce pitting of nickel deposits. Copper was deposited at a temperature of 25° and 55°C from the electrolyte containing a few ppm Ag^+ (added as Ag_2SO_4) under galvanostatic conditions at a current density of 3.5 A/dm^2, using a stainless steel rotating disk electrode (rde) at various angular velocities. The rotating disk assembly was made by Pine Instrument Company. The electrode surface was polished to a mirror finish with 0.05μ alumina on Buehler microcloth prior to each experiment. After each run the deposited copper was stripped for analysis. The Ag concentration in the metal and electrolyte was determined by atomic absorption spectrophotometry. A similar approach was used for the nickel rde studies except that a titanium cathode was used. Kinematic viscosity measurements of the electrolytes were made using an Ostwald viscosimeter.

A model electrowinning cell constructed of Plexiglas was used to obtain information on the mass transfer profiles in a full height cell. The rectangular cell was 110 cm high with a cross section of 6.5 × 50 cm and was in fact a 50 cm wide section of a full-size industrial cell. The cell contained two Pb-6% Sb anodes and a stainless steel cathode, (electrode gap 2.6 cm). Electrolyte recirculating through the cell at 4.6 liters/min was initially generated and continuously replenished by leaching electrolytic grade copper drillings in the presence of air. The electrolyte contained 25 g/liter Cu and 100 g/liter H_2SO_4 and the cell was operated at 25°C. Under steady-state conditions the copper concentration in the electrolyte could be maintained within ±2 g/liter by controlling the air flow rate to the leaching tank. When operating with electrolyte jetting to provide agitation, the cell contained only a single anode and cathode (spacing 5 cm gap).

The chloride level in the original electrolyte was reduced to a negligible value (1 ppm) by precipitation with Ag_2SO_4, and the silver concentration in the electrolyte was adjusted to about 10 ppm prior to starting the plating run. During the run the silver level in the cell was slightly depleted (~10%) so that an average of initial and final values was used for the calculations.

An additional series of tests using air sparging at 55°C with electrolyte containing 60 g/liter Cu, 140 g/liter H_2SO_4, 5 g/liter Fe and small concentrations of Ni, Co, and As were completed in a modified model cell measuring 110 × 6 × 15 cm.

Results of Rotating Disk Experiments

According to Levich's theory for mass transport by convective diffusion to a rotating disk electrode the limiting current density is given by (18)

$$i_{L,Ag^+} = 0.62\, nF D_{Ag^+}^{2/3} \nu^{-1/6} \omega^{1/2} C_{Ag^+} \quad [3]$$

where D is the diffusion coefficient of the ion, ν is the kinematic viscosity of the electrolyte, ω is the angular velocity of the rotating disk electrode, and C_{Ag^+} is the bulk concentration of Ag^+ ion. It follows from this equation that: (*i*) i_L/C_{Ag^+} is proportional to $\omega^{1/2}$ and (*ii*) at constant ω, i_L is proportional to the bulk concentration of Ag^+ ion.

The experimental curves plotted in Fig. 1 and 2 show that i_L/C_{Ag^+} was proportional to $\omega^{1/2}$ in both copper and nickel electrowinning electrolyte. At constant angular velocity of the rotating disk electrode, i_L was directly proportional to C_{Ag^+} (see Fig. 3). These results are in accordance with theory and showed that Ag codeposition was diffusion controlled.

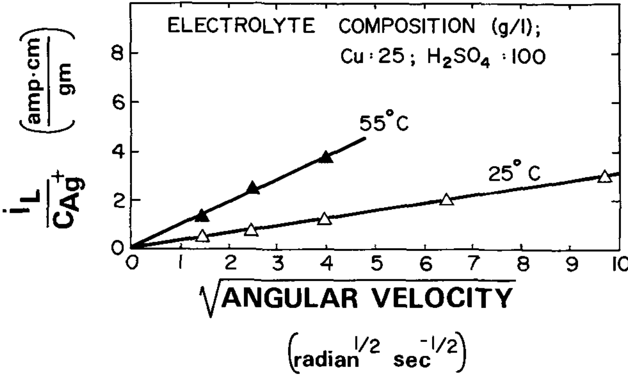

Fig. 1. i_L/C_{Ag^+} curves obtained for Ag^+ in copper electrolyte

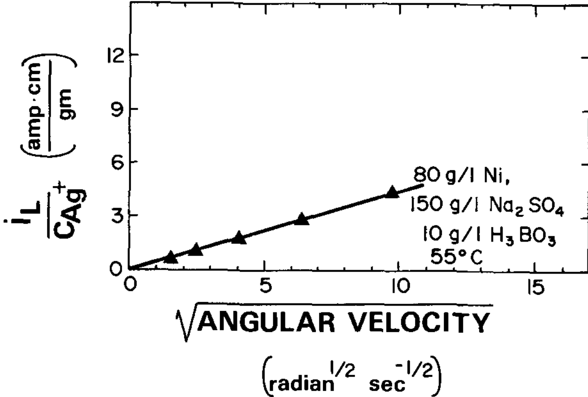

Fig. 2. i_L/C_{Ag^+} curve obtained for Ag^+ in nickel electrolyte

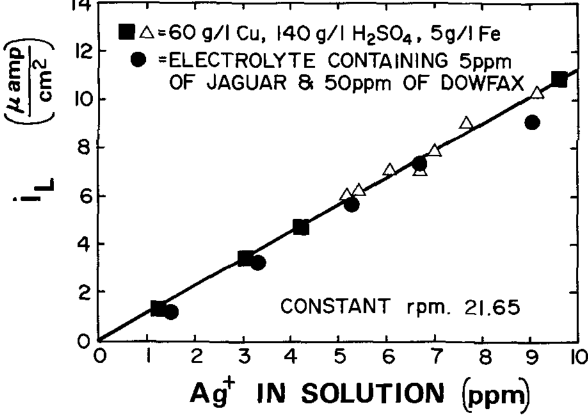

Fig. 3. Dependence of limiting current density for Ag^+ on concentration of Ag^+ in solution.

Electrowinning electrolytes usually contain frothing agents to prevent acid misting and addition agents to improve the quality of the deposit. In the present studies, Dowfax 2AO was added as a frothing agent and Jaguar + as an addition agent. The influence of these additives on Levich plots was examined, and it was found that the linearity and slope of i_L/C_{Ag^+} plot with $\omega^{1/2}$ was unaffected by the additives. With no additives the slope in Fig. 3 was 1.171 (standard error 0.344) and with the additives the slope was 1.106 (standard error 0.339). Varying the applied current density also had no effect on the results (see Fig. 4), which were also independent of the duration of electrolysis (Fig. 5). The presence of iron (5 g/liter) in the electrolyte did not affect the measurements (see Fig. 4).

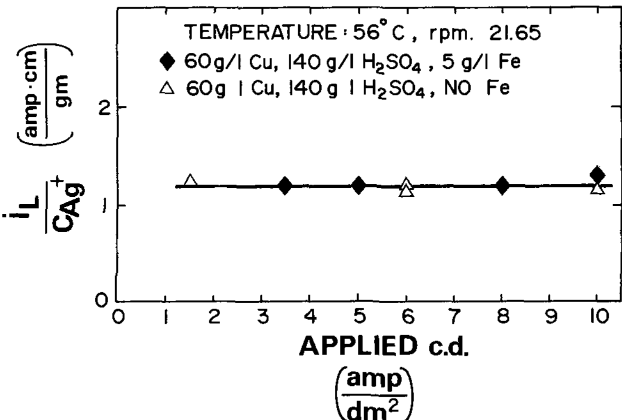

Fig. 4. Dependence of i_L/C_{Ag^+} on applied current density

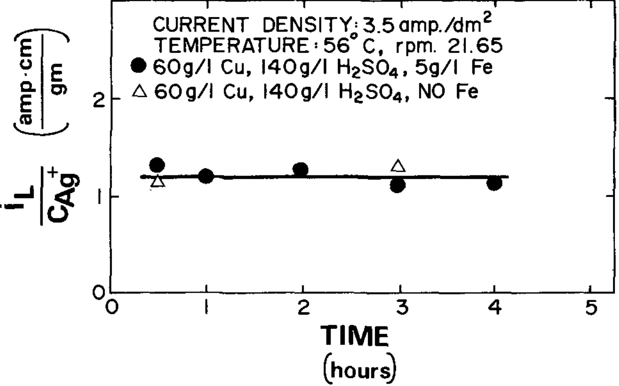

Fig. 5. Dependence of i_L/C_{Ag^+} on duration of electrolysis

Uniform distribution of silver in copper was confirmed by electron probe and chemical analysis of 0.185 mm thick copper deposits.

The diffusion coefficient of Ag^+ ion in various Cu electrowinning electrolytes at 25° and 55°C calculated from these and other Levich plots is presented in Table I along with D_{Ag^+} values reported in the literature. It is seen that the present values are in close agreement with D_{Ag^+} values obtained by transient techniques. The diffusion coefficient of Ag^+ ion in Cu

electrowinning electrolytes containing 60 g/liter Cu and 140 g/liter H_2SO_4 is $1.55 \pm 0.06 \times 10^{-5}$ cm²/sec, at 55°C. In less concentrated electrolytes (Cu:25 g/liter), the diffusion coefficient of Ag^+ ion was 1.96×10^{-5} cm²/sec at 55°C and 4.29×10^{-6} cm²/sec at 25°C.

Results and Discussion of Model Cell Experiments

In order to optimize the design of electrowinning cells it is important to know the local values of the cathode mass transfer coefficient since the maximum current density used during electrowinning is determined largely by the area of the cathode characterized by the lowest mass transfer coefficient (*i.e.*, having the poorest agitation). For example, if the current density in a given copper electrowinning system were gradually increased, the cathode deposit would first become rough and impure in this region of poor agitation. The most desirable conditions for improved electrowinning operations therefore require large mass transfer coefficients that are uniform over the entire cathode. The usefulness of the present method in design and optimization of electrodeposition systems can be illustrated by typical examples from our model cell investigations of copper electrowinning cell performance.

Since the present experimental work was performed with the primary objective of developing a method to assess the performance of various electrolytic cells, no attempt has been made to discuss in detail the hydrodynamic patterns in conventional and forced convection cells which has been reported elsewhere (19). All the results are reported in terms of k_{Ag^+} rather than $k_{Cu^{2+}}$ for reasons discussed later.

In a conventional copper electrowinning cell there are two different hydrodynamic regimes acting on the cathode surface. The electrolyte flow pattern induced by bubbles of anodic oxygen is shown schematically in Fig. 6. The upward flow of electrolyte along the anode is driven by the pump action of anodic gas. The electrolyte near the cathode is characterized by random turbulent flow in the top 5-10 cm. Below that a downward flow is developed over the face of the cathode, with the downward velocity decreasing toward the bottom of the cell. In the lower part of the cell the flow regime is essentially natural convection resulting from density differences caused by electrodeposition.

The vertical mapping of the cathode mass transfer coefficient (k_{Ag^+}) for such copper electrowinning conditions in the model cell is also shown in Fig. 6. These results refer to a vertical mapping along the center line of the cathode.

At the top of the cathode the agitation caused by the anode gas results in a fairly high mass transfer coefficient $k_{Ag^+} = 51 \times 10^{-5}$ cm/sec, compared to the value of $k_{Ag^+} = 28 \times 10^{-5}$ cm/sec at the cathode bottom where natural hydrodynamic conditions predominate.

The electrolyte agitation in an electrowinning cell can be enhanced by employing forced convection, which results in significantly improved mass transport (*i.e.*, increased k) at the cathode surface. A series of tests were carried out to measure the vertical distribution of the mass transfer coefficient for both electrolyte jetted and air sparged systems.

In the electrolyte recirculation system the electrolyte was jetted upwards over the cathode surface from a position near the cell bottom (see Fig. 7). Air sparging was provided by means of a perforated PVC tube sparger with 40 mil vertical holes set at 5 cm spacing.

In the electrolyte jetted system k_{Ag^+} at the bottom of the cathode was 150×10^{-5} cm/sec and only 72×10^{-5} cm/sec at the top (see Fig. 8) indicating significant mass transport enhancement occurred only at the bottom of the cell. Although k_{Ag^+} at the top of the jetted cell was about 40% higher than the value at the top of the natural convected cell, this can be attributed to the higher current density used in the jetted run (*i.e.*, increased agitation from anode gas). The air sparged results on the other hand (see Fig. 8) indicate that the mass transfer coefficient (k_{Ag^+}) was essentially uniform at 300×10^{-5} cm/sec over the entire cathode.

The results presented in Fig. 9 show the effect of the air sparging rate on the cathode mass transfer coefficient. For example, at a low air sparging rate (specific air flow 3.7 cm/min) k_{Ag^+} was 100×10^{-5} cm/sec while at the higher flow (specific air flow 46 cm/min) the mass transfer coefficient k_{Ag^+} was 300×10^{-5} cm/sec. The specific air flow rate is defined as the air flow rate per horizontal cross section between electrodes. The effect of anodic oxygen evolution was not noticeable during these tests simply because the amount of O_2 evolved was small relative to the quantity of air sparged. Similar results were obtained at a more normal electrowinning operating temperature of 55°C as shown in Fig. 10.

Conversion of Mass Transfer Coefficients

In real electrowinning systems, the flow regime consists either of mixed laminar/turbulent flow as in the

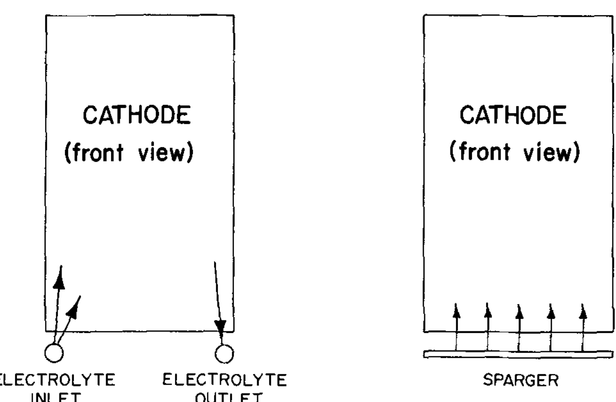

Fig. 7. Diagram of electrolyte jetted and air sparged operation

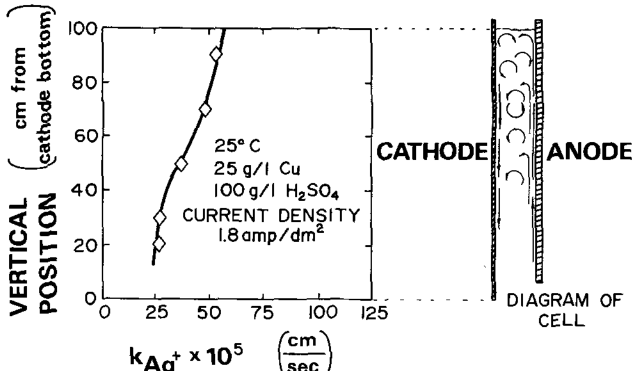

Fig. 6. Vertical distribution of k_{Ag^+} in conventional copper electrowinning cell.

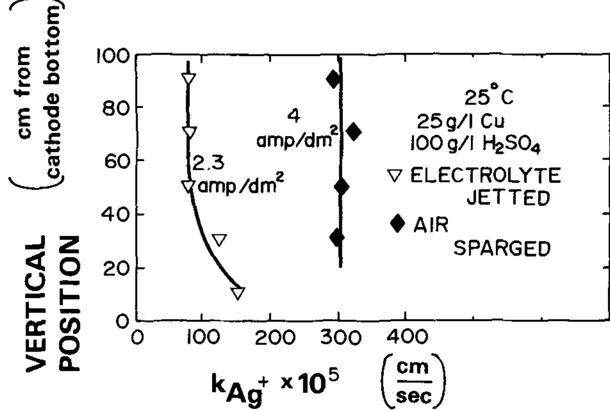

Fig. 8. Vertical distribution of k_{Ag^+} in electrolyte jetted and air sparged copper electrowinning cell.

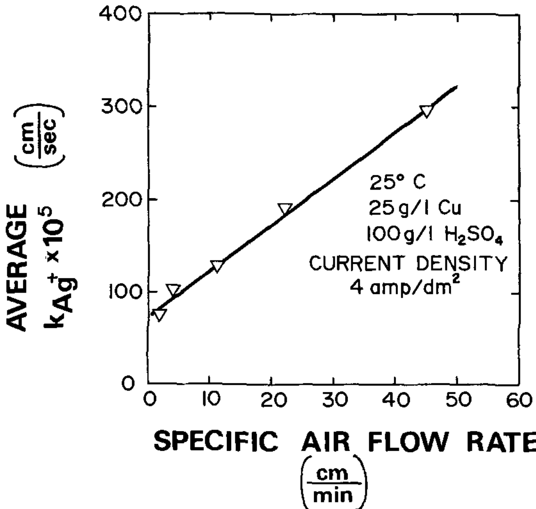

Fig. 9. Dependence of k_{Ag^+} on specific air flow rate

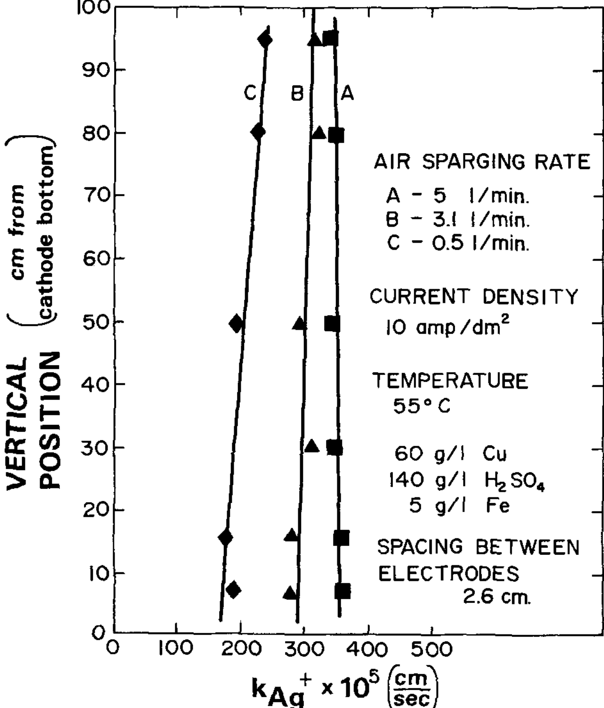

Fig. 10. Effect of air sparging rate on k_{Ag^+} in copper electrowinning.

case of conventional copper or zinc cells, or essentially turbulent flow as in the case of forced convection systems.

The calculation of $k_{Cu^{+2}}$ from k_{Ag^+} tracer data depends on the particular flow regime acting on the cathode. Thus, for electrodeposition in all flow regimes except laminar natural convection the copper mass transfer coefficient can be calculated using Eq. [4] (18, 22)

$$k_{Cu^{+2}} = k_{Ag^+} \left(\frac{D_{Cu^{+2}}}{D_{Ag^+}} \right)^{2/3} \quad [4]$$

For natural convection in laminar regime $k_{Cu^{+2}}$ can be calculated using Eq. [5] (23)

$$k_{Cu^{+2}} = k_{Ag^+} \left(\frac{D_{Cu^{+2}}}{D_{Ag^+}} \right)^{3/4} \quad [5]$$

If experimental values of $D_{Cu^{+2}}$ are not available for the particular electrolyte systems under study, the desired values can be estimated from the correlation published by Hannaert (21)

$$D_{Cu^{+2}}{}^{18°C} = \frac{47 \times 10^{-6}}{5.0 + \Gamma} \text{ cm}^2/\text{sec} \quad [6]$$

$$D_{Cu^{+2}}{}^{60°C} = \frac{118 \times 10^{-6}}{5.0 + \Gamma} \quad [7]$$

where Γ = ionic strength = $\Sigma z_i^2 C_i$ (moles/liter).

While the calculations of the $k_{Cu^{+2}}$ from either equation are straightforward, the correct form of the equation required for the transitional flow regime encountered in most currently operating cells (*i.e.*, nonagitated) is not evident. While this may cause some theoretical discrepancy, the $k_{Cu^{+2}}$ values calculated for real copper electrolytes using Eq. [3] and [4] are in agreement within a few per cent as shown by the following example.

For the 60 g/liter Cu, 140 g/liter H_2SO_4, 5 g/liter Fe electrolyte, at 55°C, $D_{Ag^+} = 1.55 \times 10^{-5}$ cm/sec. Using the generalized correlation (21) $D_{Cu^{+2}}$ for this electrolyte was estimated at 1.0×10^{-5} cm/sec. Therefore using Eq. [2] and [3] to calculate k_{Ag^+} gives the following results: $k_{Cu^{+2}} = 0.75\ k_{Ag^+}$ and $k_{Cu^{+2}} = 0.73\ k_{Ag^+}$. This small difference is within the experimental error involved in applying the silver method to full size cells ($\sim \pm 5\%$) since the results achieved in the full height model cell cannot be as reproducible as those obtained with the rde. This is not due to any failing of the method but rather for example, difficulty in maintaining uniform spacing between electrodes, analysis for small quantities of silver, etc.

The calculated $k_{Cu^{+2}}$ values are slightly lower than the corresponding k_{Ag^+} values, and limiting current densities calculated using $k_{Cu^{+2}}$ are also slightly lower than values based on k_{Ag^+}.

Since the proposed method can be readily used to provide routine measurement of cathode mass transfer coefficients in electrowinning operations, it provides a means of removing guess work from cell optimization and development studies.

Conclusion

The mass transfer controlled codeposition method has been shown to provide a convenient means of obtaining quantitative information useful in optimizing electrowinning cell design. The experimental error involved in applying the silver method to full size cells is about 5%. Such studies are of considerable importance since the maximum current density used during copper electrowinning is determined by the area of the cathode having the poorest agitation (or characterized by the lowest mass transfer coefficient).

The Effect of Oxygen Dissolved in Pt on the Potential of a Pt/O_2 Electrode at Rest

James P. Hoare*

Electrochemistry Department, Research Laboratories, General Motors Corporation, Warren, Michigan 48090

The publication costs of this article have been assisted by the General Motors Corporation.

ABSTRACT

The rest potential of the front side of a Pt foil diaphragm in O_2-saturated acid solution was recorded while the back side of the foil was anodized at a constant current. The rest potential of the front side rose to a value of 0.05V less noble than the reversible value of 1.229V. This behavior is caused by the increase of dissolved oxygen in Pt produced by anodization which affects the rate of the local cell on the front side. From the effects of foil thickness on the rest potential, a value for the diffusion of oxygen along the grain boundaries in Pt was estimated at 1.56×10^{-12} cm^2/sec.

The rest potential of a prereduced, bright Pt electrode in O_2-saturated acid solution is never observed to be much more noble than about 1.06V. If, however, a Pt electrode is strongly preoxidized, the reversible O_2 potential, 1.23V, is observed (1-7) on such a Pt electrode in O_2-saturated solutions. At one time, considerable controversy existed (8) over the reasons why the rest potential on prereduced bright Pt does not reach the theoretical reversible value of 1.23V. In more recent times, there is significant agreement on the point (1, 9-16) that the 1.06V potential is a mixed potential (17) and the Pt/O_2 system is a polyelectrode (18). However, disagreement arises concerning the nature of the oxidation reaction of the local cell. It is generally agreed that the reduction reaction is the 4-electron O_2/H_2O reaction

$$O_2 + 4H^+ + 4e \rightleftarrows 2H_2O \quad [1]$$

Those mechanisms which involve a peroxide couple are discounted because either the potential relationships do not correspond to experimental observation or a source of H_2O_2 is required since H_2O_2 is consumed rather than generated.

It was proposed (12) that the oxidation reaction of the local cell mechanism is the Pt/Pt-O reaction

$$Pt + H_2O \rightleftarrows Pt\text{-}O + 2H^+ + 2e \quad [2]$$

because Pt is not inert and Eq. [2] can take place under the driving force of the local cell. Because the way in which the local cell is set up, a layer of adsorbed oxygen, Pt-O, is formed on the Pt surface. Wroblawa and co-workers (14) rejected Eq. [2] for the reason that a complete layer of Pt-O would be formed in a few hours with the appearance of a 1.23V rest potential, a situation which, of course is contrary to observation. On the prereduced Pt, Wroblawa and co-workers (14) suggested instead that the oxidation reaction is the oxidation of impurities. Such a mechanism appears to be highly unlikely because it is improbable that not only the same amount but also the same kind of impurities would be present in the great variety of systems in which a value of about 1.05V has been reported (11-14, 16, 19, 20).

If a steady-state removal of Pt-O could take place so that the Pt-O coverage would remain at $\theta \sim 0.3$ at a rest potential of 1.06V as observed experimentally (21), the local cell mechanism involving Eq. [2] could be considered favorably once more. There is ample evidence in the literature (21-31) that oxygen can be dissolved in Pt although some workers (32-35) reject this concept in preference to surface or so-called phase oxide layers. It is suggested here that when a prereduced Pt electrode is placed in O_2-saturated acid solution oxygen is adsorbed on the Pt surface until a potential in the vicinity of 1V is reached after which oxygen may be dermasorbed into the surface of the metal. When the rate of formation of Pt-O by local cell action equals the rate at which oxygen is dissolved in the Pt metal, a steady-state coverage is reached at $\theta \sim 0.3$ and the rest potential is about 1.05V (21).

Suppose one were able to charge the Pt metal with dissolved oxygen to the point of saturation. At this point, no more oxygen could be dissolved, and the sur-

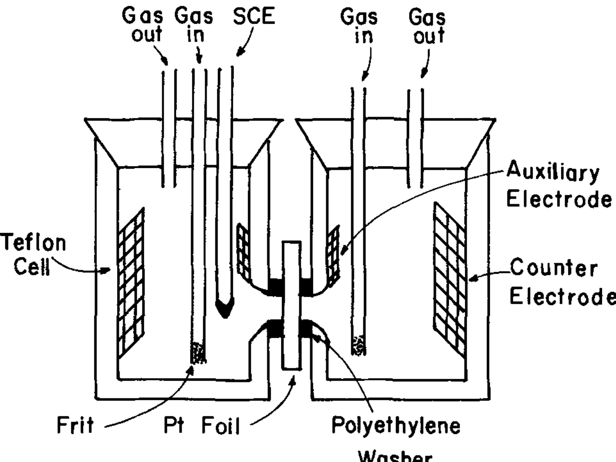

Fig. 1. Diagram of two-compartment cell

face would become covered with a layer of electronically conducting Pt-O. Since the local cell could no longer exist, the potential-determining reaction would become Eq. [1] and the observed potential would be the reversible oxygen potential.

In this report, evidence, obtained from monitoring the potential on the front side of a Pt diaphragm while the back side is anodized,[1] is presented as strong support for the O_2/H_2O, H^+, Pt-O/Pt mechanism of the Pt/O_2 rest potential.

Experimental

All measurements were made on Pt (99.9+ % pure) foil (0.00127, 0.00254, and 0.00508 cm thick) in $2N$ H_2SO_4 made with triply distilled H_2O from an all quartz still. The Pt foils to which Pt lead wires were spot welded were cleaned by successively soaking in concentrated HNO_3 followed by flaming in a burning H_2 jet. This procedure was repeated until all coloration of the H_2 flame disappeared. A two-compartment cell made of Teflon (see Fig. 1) was cleaned by soaking in aqua regia, then concentrated HNO_3, and finally by leaching in triply distilled H_2O for at least a week with frequent changes of water. The cleaned Pt foil was clamped between two halves of the leached cell using polyethylene washers as shown in Fig. 1. If no leaks were found around the washers, the cell was filled with $2N$ H_2SO_4 solution, and the cell tops sealed with molten polyethylene. By observing the foils with a bright light behind them, it was possible to reject them if any pinholes were present. The cell electrodes were then preelectrolyzed anodically for at least 16 hr against removable Pt wire cathodes.

After the preelectrolysis procedure, H_2 was bubbled through both sides of the cell until the potential of the foil became zero with respect to the Pt gauze counter and auxiliary electrodes in each compartment. These steps were taken to ensure that all adsorbed and dissolved oxygen in the Pt as well as any peroxides generated by the preelectrolysis were removed from the system. All gases used were prepurified by passing them through a multicomponent purification train before entering the cell. A probe-type saturated calomel reference electrode (SCE) was inserted through the cell top into the left hand compartment, and the potential of a Pt/H_2 electrode *vs.* SCE was determined. Finally, purified oxygen was bubbled through the left hand compartment, purified nitrogen through the right, and the rest potential (*vs.* SCE) of the front side of the foil was followed with a General Radio Electrometer Model 1230A. All potentials in this report are recorded with respect to the normal hydrogen electrode unless stated otherwise.

[1] One of the reviewers noted that this metal foil diaphragm technique was used by Frumkin and Aladzhalova (40) and by Kobosev and Monblanova (41). It might also be noted that Schuldiner and Hoare (42) used this same technique to study the Pd-H_2 system.

Anodization at constant current of the back side of the foil against a large Pt gauze counterelectrode was begun when the rest potential of the front side of the foil reached about 1V. In a couple of cases as shown in Fig. 2, the potential was permitted to come to a steady state, $1.04V < E < 1.06V$ (requiring 19 to 24 hr) before anodization was begun. If there were no pinholes in the foil or no leaks between the cell compartments, the potential on the front side of the cell was not affected when anodization of the back side was begun; otherwise, the potential of the front side shifted immediately towards more noble values. The potential of the back side during anodization had values between 2.040 and 2.090V ($i = 6.1$ mA/cm^2). At the end of the run, H_2 was bubbled again in the left hand compartment, and the value of the SCE *vs.* Pt/H_2 was rechecked. Values of SCE before and after agreed within 2 or 3 mV. The temperature of all experiments was ambient (24° ± 1°C).

Results

The rest potential of a Pt foil 0.00127 cm thick is plotted as a function of time in Fig. 2 (circles) and the point when anodization of the back side of the Pt diaphragm was begun is indicated by the arrows. Also included in Fig. 2 is the rest potential (triangles) of a Pt gauze auxiliary electrode in the left hand compartment. The data shown in Fig. 2 were repeated at least three times on different samples of Pt foil with similar results being obtained in each case. Before anodization was begun, the potential of both the foil and auxiliary gauze rose with time to a virtual steady value (1.045V, foil; 1.040V gauze). When the anodization of the back side of the foil was begun, no changes were observed in the potential for about 2 hr, after which the potential of the foil began to shift towards more noble values. Eventually, a steady value of 1.180V was reached after about 2 days whereas the Pt gauze auxiliary oxygen electrode reached the steady value of 1.055V.

To be certain that a good seal was formed between the two cell compartments, the foil area (2.81 cm^2) was made much larger than the area exposed to the electrolyte (0.786 cm^2). Since the rest potential reached a steady value of about 50 mV less noble than the reversible value, it was suspected that an area effect may be operative. To check this, three sizes of Pt foil were used. In Fig. 3, the data obtained on 0.00127 cm thick Pt foils of two different total (one side) areas (2.81 and 5.28 cm^2) are presented. The origin of these plots is the time when anodization of the back side was begun. The rest potential of the larger area foil came to a steady value of 1.121V. When a foil with an area of 1.15 cm^2 was used, leaks developed in every case (4 attempts), and the desired data could not be obtained.

Plots of the rest potential obtained on Pt foils of three different thicknesses, 0.00127 cm (area = 2.81

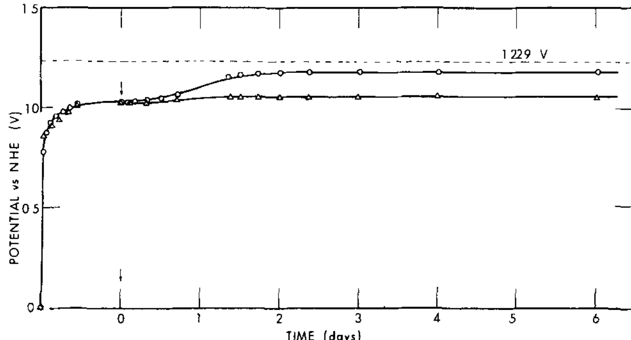

Fig. 2. A plot of the rest potential of the front side of a Pt diaphragm (0.00127 cm thick, 2.81 cm^2 in area) as a function of the time for which the back side was anodized (6.1 mA/cm^2) (circles). Arrows indicate when anodization was begun. Triangles represent data for auxiliary Pt gauze electrode.

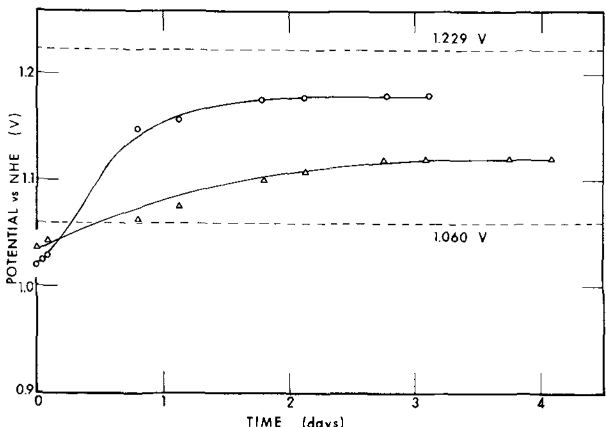

Fig. 3. A plot of rest potential of 0.00127 cm thick Pt foil with areas of 2.81 cm² (circles) and 5.88 cm² (triangles) as a function of time for which the back side was anodized.

cm²), 0.00254 (area = 2.88 cm²), and 0.00508 cm (area = 3.01 cm²) are given in Fig. 4 where the origin is the time when anodization of the back side was begun. In these instances, the front side had not come to a steady value before anodization was begun because it was found that the final result was not affected by the time when anodization was begun. Of course, the initial delay or induction period observed in Fig. 2 is masked by the drifting potential in Fig. 3 and 4. After about 3 days, the potential on the thicker foils reached a steady rate of increase equal to about 4 mV/day. If it can be assumed that this rate is maintained until a value of 1.180V (the potential reached by foils with an area of about 2.9 cm²) is obtained, it can be determined that the required time for 0.00254 cm foil would be 9.5 days and for 0.00508 cm foil, 25.0 days.

Discussion

When the prereduced Pt electrode is placed in O_2-saturated acid solution, the rest potential, E, drifts to more noble values and the coverage, θ, of the metal surface with Pt-O, increases. It has been shown by a number of workers [*e.g.*, (3, 21, 36, 37)] that E rises linearly with θ. At steady state, $dE/dt = 0$ and E has a constant value lying in the potential range between 1.04 and 1.06V. Also, $d\theta/dt = 0$, and θ has a constant value in the range lying between 0.25 and 0.30. Under these conditions, Pt-O is formed by the local cell current density, i_{loc}, as fast as it is dissolved in the Pt metal. Therefore, the rate of disappearance of Pt-O, $-dx/dt$, must be equal to i_{loc}. The Pt metal acts as a vast reservoir for dissolved O. If, for example, one assumes that in the saturated state one O atom is associated with each unit cell of the face centered cubic lattice, there would be, on the average, one O atom for every 4 Pt atoms. From the density of Pt (21.45 g/cm³), the charge in forming an O atom (3.2×10^{-19}C) and the value of i_{loc} (3.2×10^{-7} A/cm²) (38), it would require about 190,000 days to saturate a cubic centimeter of Pt with dissolved oxygen for one side exposed to the local cell current. For this reason this steady-state rest potential seems to remain indefinitely.

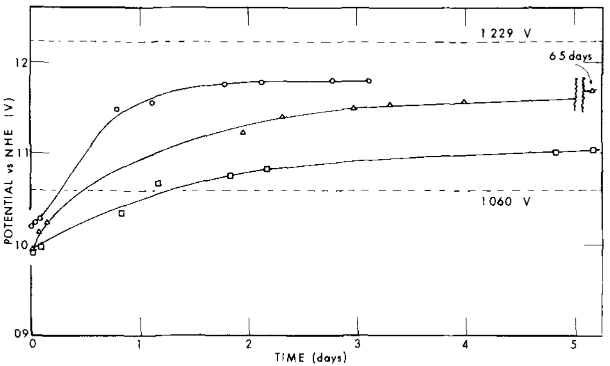

Fig. 4. A plot of the rest potential of Pt foils (area ~2.9 cm²) of three thicknesses (0.00127 cm, circles; 0.00254 cm, triangles; 0.00508, squares) as a function of the time for which the back side of the Pt diaphragm was anodized.

It has been found (21) that anodization at high potentials, ~2V, causes large amounts of O to be dissolved in Pt metal. As the back side of the Pt foil diaphragm is anodized, the concentration of dissolved O, C_a, increases to a point where it becomes more difficult to dissolve the Pt-O on the front side. Consequently, $-dx/dt$ or i_{loc} will fall. Then $-di_{loc}/dt = K(dC_a/dt)$ where K is a proportionality constant. To increase the driving force for Pt-O dissolution, the chemical potential of the Pt-O layer must increase by an increase in θ; as a result, E increases (3) in agreement with the data in Fig. 2-4.

If C_a reaches the saturation value, C_o, $dC_a/dt = 0$ and $i_{loc} = 0$ because no more Pt-O can dissolve. In this case, θ reaches a value of unity and E assumes the value of the reversible oxygen potential 1.229V (3) since the only potential determining process available is the O_2/H_2O reaction, Eq. [1].[2] However, dissolved oxygen can escape from the Pt foil which is outside of the polyethylene washers and which is not in contact with the solution. Here O atoms can diffuse to the surface where they combine and escape to the environment as O_2 molecules. Although the rate of oxygen penetration at escape from the metal lattice may be smaller than the rate of migration within the lattice, there is a leakage of oxygen to the atmosphere, and hence, an area effect because oxygen can exit at all sites to the Pt surface. At those sites exposed to air, the Pt-O film is less stable than at those sites exposed to the O_2-saturated electrolyte. This rate of loss of C_a increases with increasing values of C_a (chemical potential of dissolved oxygen) until the rate of increase due to anodization of the back side equals the rate of loss due to escape from the solution-free Pt surface. At this point, $dC_a/dt = 0$ and C_a equals the steady-state value, C_{ss}. In this situation, i_{loc}, θ, and E reach steady-state values. The area data, in Fig. 3, show that the rest potential in the steady state, E_{ss}, depends on the area of the Pt foil exposed to the external atmosphere.

The discussion so far suggests that as C_a increases and both θ and E increase, i_{loc} should decrease. To check on this, polarization measurements on the front side were made at very low currents after the anodizing current on the back side of the foil was discontinued. The measuring technique using a high resistor made from a pencil line drawn on a strip of Mylar film and placed in the constant current circuit has been described before (38). These data were difficult to obtain because only a few points could be made before the polarization of the electrode caused changes in the system which shifted the rest potential. A sample of the data from which i_{loc} was estimated is shown in Fig. 5 for two different runs made on foils exhibiting an E of 1.155V. The summary of data in Table I shows one other value of i_{loc} obtained at $E = 1.180$V. Indeed, i_{loc} decreases as C_a, θ, and E increase.

The data in Fig. 2 show an induction period after anodization was begun. Such behavior is to be expected because at $E = 1.06$V, C_a is very small, and time is required to increase C_a to the point where it affects i_{loc}. Also, this behavior predicts that an effect of foil thickness on the rest potential should be found in agreement with the data of Fig. 4. Foils of the same area but of

[2] It was pointed out by one of the reviewers that a value of $\theta = 0.65$ was found by Laitinen and Enke (43) on Pt at 1.23V in N_2 and a value of $\theta = 0.71$ by Schuldiner *et al.* (44) on Pt at 1.23V in H_2. Both of these groups of researchers obtained θ at Pt electrodes which were polarized to 1.23V whereas Hoare *et al.* (3) obtained θ at Pt electrodes which exhibited 1.23V at rest. This difference in experimental conditions may account for the differences in reported values of θ at 1.23V.

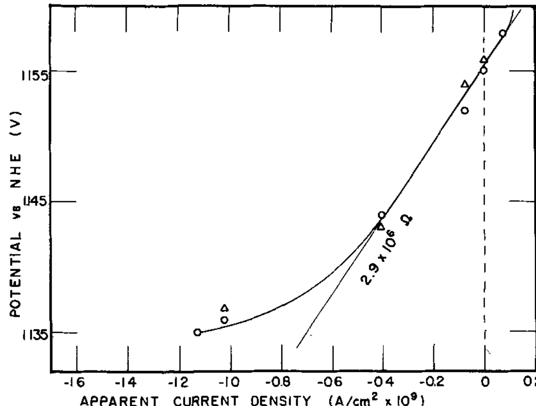

Fig. 5. Constant current polarization curve at low current density obtained on the front side of a Pt diaphragm exhibiting a rest potential of 1.155V after the back side had been anodized for two different runs, circles and triangles.

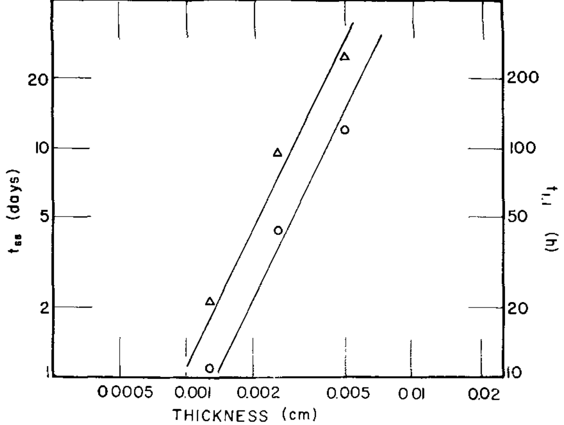

Fig. 6. Plots of $t_{1.1}$ (circles) and t_{ss} (triangles) as a function of the thickness of the Pt diaphragm.

increasing thickness require a longer time at constant current to reach a value of C_a which affects i_{loc} because of the increased volume of metal. If we may assume the relationship

$$t = kd^n \quad [3]$$

where t is the time to reach a given value of E; k, a constant; d, the foil thickness; and n, an exponent, the slope of a plot of log t vs. log d yields a value for n. Such a plot for the times to reach 1.1V, $t_{1.1}$, and steady state, t_{ss}, is given in Fig. 6. Lines with a slope of 2 are drawn through the points and thus a likely value for n is 2. Equation [3] is similar to the time lag relationship.

$$D = d^2/6t_{lag} \quad [4]$$

where D is the diffusion constant and t_{lag} is time required to reach steady state. In this case, $k = 1/6D$, $n = 2$, and $t_{lag} = t_{ss}$. If the data from Fig. 4 are substituted into Eq. [4], a value of D can be obtained as tabulated in Table II. This average value of D (1.56×10^{-12} cm²/sec) is in fair agreement with that (4.4×10^{-11} cm²/sec) obtained before (26). This value of D seems to be large for the diffuson of the relatively large

Table I. Values of the local cell current density at various rest potentials

E (V)	θ	Slope = dE/di (ohm × 10^7)	$i_{loc} = \frac{di}{\theta E}\left(\frac{RT}{F}\right)$ (38) (A/cm² × 10^9)
1.060	0.28	8000	320
1.155	0.80	29	8.84
1.180	0.95	1.4	1.80
1.229	1	—	0

Table II. Determination of diffusion constant of O through Pt metal

t_{ss} (days)	d (cm × 10^3)	d^2 (cm² × 10^6)	D (cm²/sec × 10^{12})
2.3	1.27	1.61	1.36
9.5	2.54	6.45	1.32
25.0	5.08	25.9	2.0
		Average	1.56

O atom through the Pt lattice (39) and indicates that the oxygen diffuses through the Pt along grain boundaries.

Unfortunately, it is not possible to estimate a value for C_{ss} since it is not known what fraction of the anodic current is consumed in the process producing dissolved oxygen, C_a. Consequently, dC_a/dt cannot be determined

In summary, these data support the conclusions that oxygen can be dissolved in Pt, that the rest potential is made up of the O_2/H_2O and the Pt/Pt-O reactions, that a steady rest potential is reached when the rate of Pt-O formation equals the rate of its disappearance by dissolution in the metal, and that the reversible oxygen potential can be observed if a conducting complete layer ($\theta = 1$) of adsorbed oxygen can be maintained on the Pt surface.

Manuscript submitted Nov. 7, 1973; revised manuscript received Feb. 14, 1974.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1975 JOURNAL. All discussions for the June 1975 Discussion Section should be submitted by Feb. 1, 1975.

Technical Notes

Film Formation on Anodically Polarized Lead

H. Vaidyanathan,* Ram A. Narasagoudar, T. J. O'Keefe, W. J. James,* and J. W. Johnson*

Graduate Center for Materials Research, University of Missouri-Rolla, Rolla, Missouri 65401

The publication costs of this article have been assisted by the University of Missouri.

A complexity of processes occurs when lead is anodically polarized in aqueous electrolytes. Anodic disintegration (1), formation of oxides PbO, β-PbO_2, α-PbO_2 (2-6), and the formation of oxysalts (7) have been postulated in addition to the simple generation of Pb^{++} ions. Most of the work to date concerns the formation of these oxides and oxysalts when Pb is polarized in H_2SO_4. However, there are other electrolyte systems where the polarization behavior is more definable, and an understanding of these processes would contribute considerably to solving some unanswered questions of behavior of the common lead-acid cell. In the present study, Pb dissolution was investigated in aqueous HNO_3 solution with a view of relating the polarization characteristics to surface oxidation steps in a typical nonprecipitating medium.

Oxidation steps and subsequent film formation have been characterized by a systematic study of the current (i)-potential (E) relation followed by analysis of the polarized electrodes by x-ray diffraction and scanning electron microscopy (SEM). The i-E relationship was obtained by potential sweep voltammetry (PSV) which has been widely used in studies on the dissolution and deposition of metals (8-11).

Lead wires with a diameter of 1.5-5 mm and 99.9999% purity,[1] supplied by Electronic Space Products, Incorporated, Los Angeles, California, were used for this study. Several potential sweep experiments were carried out, and the i-E curves obtained were reproducible at sweep rates of 1-100 mV/sec. Figure 1 shows one of the typical i-E curves obtained. Two distinct waves with broad maxima, one at $\simeq$0.65V and the other at $\simeq$1.35V, were obtained during the forward (anodic) sweep. The black film began to form on the electrode surface at $\simeq$0.6V and remained visible until the potential reached $\simeq$0.25V during the reverse (cathodic) sweep. Some spalling of the electrode occurred during the potential sweep. The effect of changes in sweep rates on the nature of the i-E behavior is given in Fig. 2. Curve a, which was obtained at 1.0 mV/sec, shows a prominent wave with a broad maximum at $\simeq$1.2V. Curve b, which was obtained at 91 mV/sec, showed no waves during the anodic sweep; however, two waves were obtained with maxima at $\simeq$0.6V and $\simeq$1.3V during the reverse sweep. Curve c shows the i-E behavior at a sweep rate of 200 mV/sec

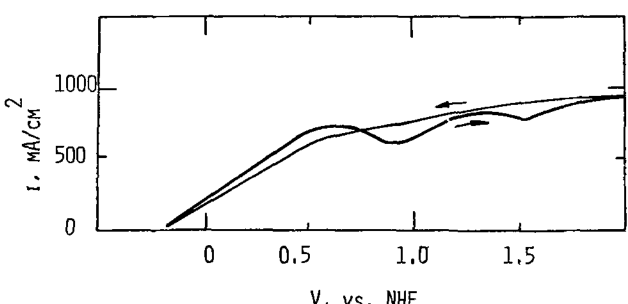

Fig. 1. *i-E* relation obtained for Pb in 1.0M HNO_3 at a sweep rate of 9 mV/sec.

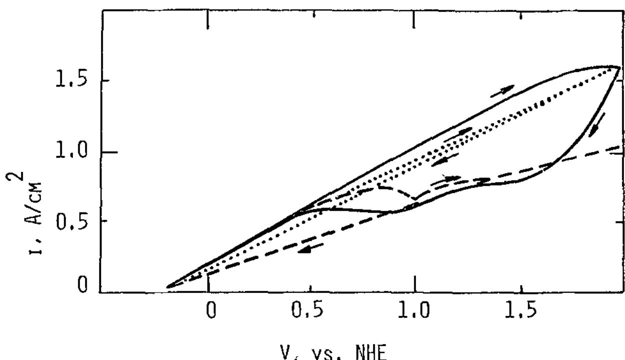

Fig. 2. *i-E* relation obtained for Pb in 1.0M HNO_3 at various sweep rates. Curve a (dashed line), 1 mV/sec; curve b (solid line), 91 mV/sec; curve c (dotted line), 200 mV/sec.

Key words: electron microscopy, potential sweep voltammetry.

[1] Typical impurities in ppm are Fe < 0.1, Ce 0.1, and Mg 0.1.

in which oxidation waves are totally absent. Current density values showed only a slight increase when the sweep rate is increased from 1 to 9 mV/sec, but the increase was appreciable at 90 mV/sec. However, when C.D. values are considered for the reverse sweep alone, they show little response to changes in sweep rate, particularly at high sweep rates.

The i-E behavior of Pb in NaOH has been reported earlier, and two oxidation waves were also found (12). In HNO_3, the oxidation waves appear only at low sweep rates, which suggests that convective conditions in the electrolyte play a positive role in the configuration of the i-E curves. Mass transfer by diffusion also influences the i-E behavior, as reflected by the high C.D. values at 90 mV/sec (curve b). The appearance of oxidation waves at low sweep rates for Pb in HNO_3 is similar to that reported for Zn in alkaline solutions by Powers and Breiter (13). The oxidation waves indicate that more than two oxidation steps are involved when Pb is polarized. The two waves can be associated with the formation of different oxides with different structures and solubilities. The first wave obtained at $\simeq$0.7V may correspond to the formation of PbO and the second wave at $\simeq$1.35V to that of PbO_2. The oxidation steps involved are

$$Pb \rightarrow Pb^{++} + 2e \quad [1]$$

$$Pb + H_2O \rightarrow PbO + 2H^+ + 2e \quad [2]$$

$$PbO + H_2O \rightarrow PbO_2 + 2H^+ + 2e \quad [3]$$

The indications obtained for the formation of PbO and PbO_2 are preliminary. Hence, a detailed analysis of the electrode surface after potentiostating, at various potentials from 0.5 to 1.66V was carried out by x-ray diffraction and SEM in order to substantiate our proposition. Very rapid dissolution occurs when an anodic potential is impressed on the electrode. In addition, the electrode surface gradually turns black due to the accumulation of minute dark particles. The particles do not appear to originate as a result of chemical or electrochemical reaction in solution, but rather as a result of electrochemical reaction at the electrode surface producing distintegrated Pb and/or oxides. The polarized anodes were rinsed with distilled water and acetone and dried carefully in a desiccator in a manner which would not disturb any film present on the surface. X-ray diffraction and SEM studies were done immediately after each potentiostatic experiment. For the SEM studies, the entire electrode was scanned. The lead wires were of proper diameter and length to allow them to be mounted directly in a Debye-Scherrer camera. Table I lists the results of the x-ray analyses. PbO(orthorhombic) is obtained on the surface from 0.5 to 1.78V while indications of β-PbO_2 are obtained only at potentials approximately 1.5V or greater. X-ray identification was largely based on direct comparison with diffraction patterns for pure PbO (yellow) and β-PbO_2. Since only very small amounts of the oxide formed on the electrode, only the major lines of the x-ray pattern were visible, thus making the identification rather difficult. It may be noted that x-ray analyses of cycled electrodes also give evidence for the formation of PbO and β-PbO_2.

Figure 3 shows an SEM micrograph of a Pb anode which was polarized at 0.6V for 20 min. There is no

Table I. X-ray diffraction data

Potential (V)	Electrolyte	d(experimental)	d(ASTM)	Substance

evidence of pitting, and, in fact, there is pronounced faceting, the nature of which is dependent on the individual grain orientation. The pyramids are probably formed by (111) planes, but due to their elongated nature, the surface orientation is more probably (211) rather than (100). It may also be assumed from this that the (111) faces are less active for anodic dissolution in HNO_3 solutions. Faceted surface textures are quite common and have been reported during the anodic dissolution of Cu (16), electrodeposition of Fe (17) and Ni (18), and chlorination of Mo and W (19).

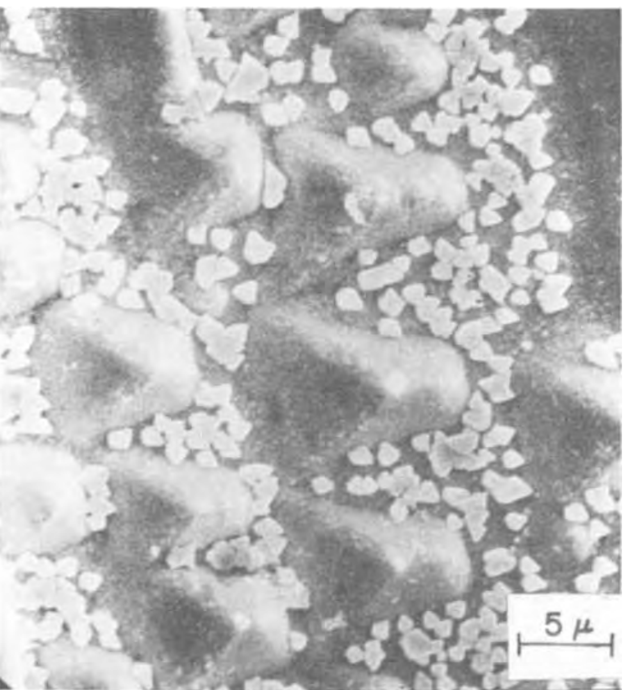

Fig. 4. Scanning electron micrograph of an anodically polarized Pb electrode showing faceted surface structure and oxide particles. Magnification 3000×.

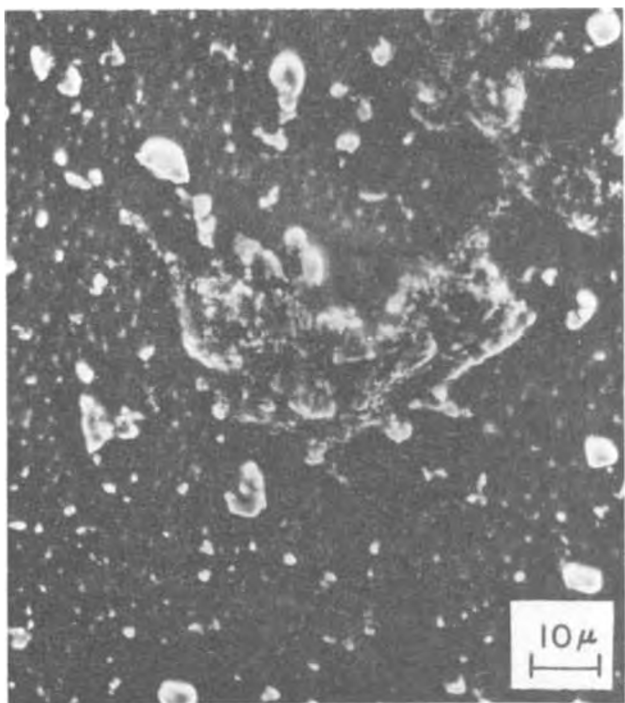

Fig. 5. Scanning electron micrograph of an anodically polarized Pb electrode showing very minute particles of disintegrated Pb and a lump of β-PbO_2. Magnification 1000×.

Figure 4 shows an SEM micrograph of a Pb anode which has been polarized at 0.3V for 40 min. Besides the protruding parts of lead crystals, some other crystalline material is seen on the surface. It occurs mainly in the spaces dividing the individual crystals of Pb, and from x-ray analysis it appears that the material is PbO(orthorhombic). This potential may correspond to the onset of nucleation of the PbO.

Figure 5 shows the SEM micrograph of Pb which has been anodically polarized at 1.3V. The SEM was taken after rinsing the electrode in distilled water and dilute ammonium acetate solution, which dissolves all other oxidation products except PbO_2. The surface contained numerous minute particles. It was felt that this morphology may represent the various stages of uneven dissolution which eventually resulted in disintegration. The single large particle shown appears to have a different morphology and is thought to be β-PbO_2, as shown by x-ray analysis. The visible evidence of spalling of the electrode in Fig. 4 shows that disintegration of the anode is probably occurring. Therefore, the black film obtained during polarization may be due to the finely divided particles of Pb produced as a result of disintegration as well as of oxides.

Anodic film formation of Pb has been discussed at length by several authors (20). We have shown the formation of disintegrated Pb, PbO (yellow), and β-PbO_2, and faceting when Pb is polarized in HNO_3. The voltammetric curves and their strange dependence on sweep rate indicate that oxide film formation is a function of the hydrodynamic conditions in the electrolysis cell, and for the formation of PbO and PbO_2 that current must be supplied for a certain minimum amount of time. In a fast sweep rate study, most of the current is utilized in the discharge of Pb^{++} ions. Mass-transfer effects of Pb^{++} ions thus produced impede the transport of H_2O molecules to the electrode surface. As is evident from Eq. [2] and [3], H_2O is crucial in the formation of PbO and PbO_2.

Hafnium Electrowinning Studies

D. R. Spink*

The publication costs of this article have been assisted by the University of Waterloo.

Hafnium, an electropositive metal, is not deposited from aqueous electrolytes because of the decomposition of water at lower potentials. Therefore, other solvents must be considered for electrowinning of hafnium.

Fused salt media are known as excellent solvents for $HfCl_4$. One of the problems associated with electrowinning of hafnium from fused salts relates to the apparent absence of a significant amount of a reduced state of hafnium in the bulk of the fused salt. Therefore, when $HfCl_4$ is used as the source of hafnium added to the electrolyte, it becomes necessary to provide a suitable complexing agent to stabilize the melt; *i.e.*, to retain the $HfCl_4$ in the melt at the operating temperature. The presence of reduced states of hafnium in the immediate vicinity of the cathode does not ameliorate this situation.

Most electrowinning research has been confined to low $HfCl_4$ concentrations (<10% $HfCl_4$) in fused salt melts and operating temperatures of about 800°C (1-4). The vapor pressure of $HfCl_4$ over most such melts at this temperature is significant so that a gradual loss of $HfCl_4$ from the melt occurs. In cells used for electrowinning hafnium, it is quite difficult to operate with a "hot-top" design to prevent condensation of $HfCl_4$ emanating from the melt; thus the concentration of $HfCl_4$ in the melt is gradually depleted as $HfCl_4$ condenses and deposits in exit ports, seals, etc. Such condensation of $HfCl_4$ in the upper portions of the cell, for example, in the cathode removal chamber, inevitably leads to the further problem of cell contamination resulting from subsequent and unavoidable exposure to moisture (air). $HfCl_4$ may also escape from the cell through the anode (chlorine) off-gas vent and in fact may be of sufficient quantity to plug this vent when a significant vapor pressure of $HfCl_4$ over the salt melt develops at the operating temperaure of the cell.

Thus, one of the objectives of the present work was to determine whether more suitable fused salt electrolytes could be found for the electrowinning process.

The problem of solubility of the vapor, $HfCl_4$, in molten alkali and alkaline earth chlorides is directly related to the phase diagrams of the binary systems $MCl = XCl_4$ (Fig. 1). Any desired composition may be obtained by exposing the melt to the reactive $HfCl_4$ vapor, providing that the pressure is maintained at the value required by the composition and temperature. However, to be considered as potential electrolytes for electrowinning hafnium, the solutions must have decomposition pressures which are negligibly small so that the bath will retain its metal tetrachloride content under normal operating conditions in an inert gas atmosphere but otherwise in an open electrolytic cell. According to Flengas *et al.* this condition restricts the useful composition of the chloride solutions to ranges representing the MCl-M_2XCl_6 subsystem, and to salt components that produce complex M_2XCl_6 compounds of maximum thermodynamic stability (8).

Flengas *et al.* have stressed the fact that solutions containing XCl_4 in excess of the amount required to form the M_2XCl_6 species are thermally unstable and cannot be considered as potential electrolytes.

Howell *et al.* (5) conducted studies on the properties of the low temperature eutectic region, as well as of the high temperature eutectic region of the binary systems MCl-XCl_4. According to the phase diagram and vapor pressure results obtained by these investigators, the range of liquid composition for melts with vapor pressures below 100 mm Hg is reasonably wide for practical use as an electrolyte in the regions of both eutectics.

The objective of the present work, then, was to conduct comparative studies of the electrolysis of melts in the system MCl-$HfCl_4$ corresponding to the lower melting eutectic and the higher melting eutectic to qualitatively determine which was the better system for further study. As far as we could determine, no experimental electrolytic work has been performed over the range of $HfCl_4$ contemplated herein.

Investigation

It should be made clear at the outset that the immediate goal of this work was not to produce pure metal, but only to define the most promising areas with respect to $HfCl_4$ concentration in molten salt baths where stability of the bath coupled with the ability to produce metallic hafnium were of paramount importance.

Materials.—Sodium chloride and potassium chloride were of Analar purity. Pure hafnium tetrachloride was supplied by Teledyne Wah Chang, Albany, Oregon, and by Amax Speciality Metals, Incorporated, Akron, New York. Both companies purified the $HfCl_4$ by special treatments. The only element of interest in the $HfCl_4$

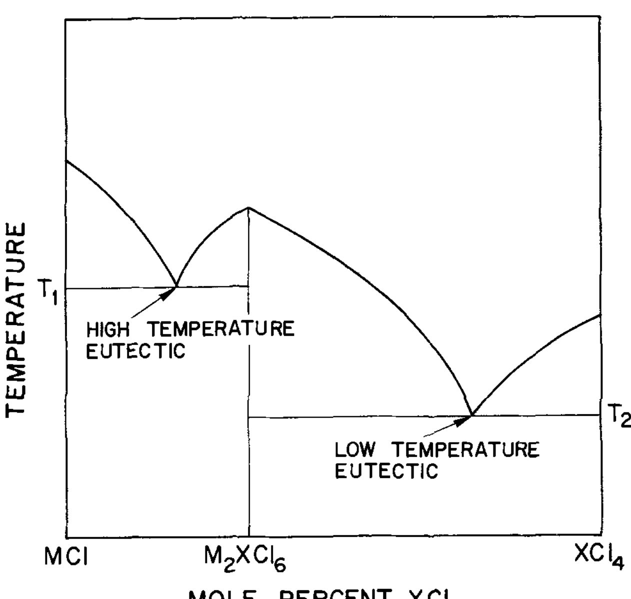

Fig. 1. Generalized phase diagram of the system MCl-XCl_4. M stands for Li, Na, or K; X stands for Zr or Hf.

Key words: fused salts, eutectics, reactive metals.

was the oxygen content which cannot easily be determined directly. Carefully conducted sublimation tests indicated that the material supplied was completely volatile thus indicating the absence of HfO_2 per se; however, there exist strong suspicions that $HfOCl_2$ (anhydrous) is volatile so we have assumed that, regardless of any precautions taken, a small quantity of oxygen would probably be present in all baths made. The presence of large amounts of oxygen in the bath was known to preclude the development of massive crystalline deposits of metallic hafnium; nevertheless, the black, powderlike deposits expected would show characteristic metallic crystalline structure under proper magnification, and further, would indicate the presence of metallic hafnium by the brilliance of the sparks produced by the burning of a small sample in an open flame. While it is accepted that these analytical methods were crude, it was shown that they were satisfactory for the specific evaluation required. Emission spectroscopy and oxygen analysis were employed primarily to verify the acceptability of the above-described techniques.

Equipment.—Two different types of cells were used. For the low melting eutectic, glass cells were used which afforded visual observations of the anode and cathode during the electrolysis experiments. (The heating furnaces were designed with windows such that visual observation of the melt could be made.) All of the low melting runs formed water-clear melts of low viscosity at temperatures below 300°C so that visual observation was an exceedingly simple matter.

For the higher melting eutectic, a glass-lined steel cell was found to be the most practical. Initially, graphite rod (1/4 in. ϕ) was used as the anode in both types of cell. Later, as explained below, 1/4 in. ϕ-nickel rod was used in the glass cells with the low temperature eutectic melts. Various metallic rods were used for cathodes; *e.g.*, 1/16 in. Type 304 stainless steel, 1/4 in. mild steel, and, for the higher temperature melts, 1/8 in. nickel rods. All appeared to perform well.

In most cases, the eutectic was first made in a special melter. The $HfCl_4$ and salts were weighed and added to the melter vessel in a dry box. After appropriate evacuation and argon backfill steps, the melter vessel was placed in a furnace and slowly heated to about 100°C above the melting point of the mix and held there, usually overnight. The melter vessel was constructed to withstand considerable pressure. After cooling, the solidified melt was removed from the melter in a dry box and broken to ~1/8 in. size pieces which were stored in sealed containers. "Black" salt found at the bottom of the melting vessel was removed since it was known to contain most of the oxygen-containing species of hafnium (11).

Procedure.—For the low temperature melts, a new glass cell was made for each experiment. The anode and cathode were first cemented into the openings provided with a Saureisen cement[1] and allowed to set in a drying oven. The premelted salt was added to the cell and the feed port was sealed. The cell was now evacuated several times, backfilling as required with argon. The cell was placed in its special furnace and slowly heated until complete melting was observed. The temperature was fixed at 310°C for most of the low temperature runs; composition of hafnium tetrachloride in the NaCl-KCl (1:1M)-$HfCl_4$ was 63 mole per cent (m/o). The experiments were conducted at cell voltages ranging from 5 to 20V which gave anode and cathode current densities ranging from 19 to 77 A/dm^2. Electrolysis was maintained as long as reasonable voltages could maintain the current flow but rarely longer than a few hours. During these relatively short runs, any attack of the glass container by a reduced state of the hafnium was felt to be negligible.

[1] Saureisen Sealing Cement (No. 33, Powder), Saureisen Cement Company, Pittsburgh, Pennsylvania.

For the high temperature eutectic experiments, a glass-lined steel cell was used. The anode and cathode were cemented into the cell top and ceramic sleeves were employed to obtain suitable electrical insulation. Since the melt could not be observed, somewhat longer periods of heating were provided to assure that a homogeneous melt had been obtained (electrical conductivity of the melt was no measure of the homogeneity of the melt). A temperature of 565°C was used for most of the high temperature experiments. The system used consisted of 27 m/o $HfCl_4$ and 73 m/o salts (NaCl/KCl). The cell voltage ranged from 2.5 to 7.0V, and anode and cathode current densities varied from 9 to 59 A/dm^2 and from 19 to 115 A/dm^2, respectively.

Discussion

The crude experiments strongly indicated that the low temperature eutectic was unsuitable for electrolysis of hafnium. Of concern was the observed instability of the melt resulting in profuse loss of tetrachloride vapor. Without special precautions, the gaseous tetrachloride condensed in, and would consequently plug, the chlorine off-gas line. Perhaps of even greater concern was an observed inability to produce metallic hafnium deposits from the low melting eutectic bath. This was unexpected since the electrolysis could be visually observed. In most cases observed, the cathodic deposit built up readily in a typically dendritic form of growth. The ready evolution of chlorine from the anode was also easily observed and verified by the wet KI test. However, after water leaching, much of the deposit appeared to have been dissolved and that which remained was decidedly not hafnium metal. During leaching, no unusual reactions were observed nor was there any evidence of hydrogen formation or evolution.

One final interesting observation that has been unexplained so far was the disintegration of graphite anodes within the melt during electrolysis of only the low melting hafnium eutectic. (No such degradation occurred in the very similar $ZrCl_4$ eutectic.) The graphite rods swelled and disintegrated below the melt. It is of interest to note that graphite held up satisfactorily in the high temperature eutectic melts containing either $HfCl_4$ or $ZrCl_4$. Nickel anodes were subsequently used for all of the low temperature eutectic experiments and these held up well.

The high temperature eutectics appeared to be much more stable as evidenced by the lack of copious quantities of tetrachloride vapor fumes emanating from the chlorine purge port. Some fuming was observed which would indicate that further testing might evaluate RbCl or CsCl along with KCl as recommended by Flengas (8).

Adherence of the deposit to the cathode gave no problem in any of the baths tested. All cathodes were cleaned well before each run which, according to Lebadeva (10), is a basic requirement for an adherent deposit.

Small metallic crystallites of hafnium were readily produced from the high temperature melts. Current efficiency was estimated to be about 70% in the high temperature experiments. Since no attempt was made in these tests to produce material of high purity, only one sample was analyzed for oxygen; it indicated approximately 1% oxygen. Several of the metallic samples were converted to the oxide for analysis by emission spectroscopy. The resulting hafnium oxide spectra were very clean, indicating only trace quantities[2] of any impurity. These analyses confirmed our belief that for the short reduction periods employed, attack of the glass containers by reduced states of hafnium was not important.

[2] Less than the lower limit for which a specific analytical concentration can normally be determined.

Conclusions

In the series of preliminary screening tests, it was not possible to produce metallic hafnium from the low melting eutectic; furthermore, the instability of this melt makes it unattractive for use as a commercial electrolyte.

The high temperature eutectic not only appeared to be much more stable, but it consistently gave crystalline metallic depsits of hafnium.

Effect of Sodium Ions on the Electrochemical Reduction of Diethyl Fumarate in Dimethylsulfoxide and Acetonitrile

Michael D. Ryan and Dennis H. Evans

Department of Chemistry, University of Wisconsin-Madison, Madison, Wisconsin 53706

The publication costs of this article have been assisted by the National Science Foundation.

Childs *et al.* (1) studied the electrochemical reductive coupling of diethyl fumarate (*trans*-$C_2H_5O_2CCH = CHCO_2C_2H_5$), **1**, in N,N-dimethylformamide (DMF). Their attention was focused on the dimerization mechanism with tetra-*n*-butylammonium iodide as supporting electrolyte. Using double potential step chronoamperometry, these workers showed that the initially formed radical anions reacted by a second-order, irreversible, dimerization reaction in contrast to more complex schemes which had been proposed earlier. This conclusion was confirmed for **1** and other activated olefins by later studies using rotating ring-disk electrode voltammetry (2), linear sweep voltammetry (3), and current-reversal chronopotentiometry (4).

Childs *et al.* (1) noted that the addition of sodium or lithium ions to the supporting electrolyte caused a substantial increase in the rate of dimerization of the radical anions of diethyl fumarate. Lithium also had the effect of decreasing the importance of polymerization side reactions as evidenced by an increase of the coulometric n-value to unity. An analogous effect of sodium and lithium has been reported for the reduction of some α,β-unsaturated ketones in dimethylsulfoxide (5). The increased rate of dimerization was ascribed to ion pair formation between the radical anions and the metal cations with the neutral ion pairs reacting more rapidly than the anion radicals. A quantitative study of the effect of sodium on the reduction of phthalaldehyde in N,N-dimethylformamide has been reported by Lasia (6) who treated his data in terms of the following reactions (A = phthalaldehyde)

$$A + e \overset{E_{1/2}}{\rightleftharpoons} A^{\cdot-} \qquad [1]$$

$$A^{\cdot-} + Na^+ \overset{K}{\rightleftharpoons} NaA^{\cdot} \qquad [2]$$

$$2\,A^{\cdot-} \xrightarrow{k_1} {}^-AA^- \qquad [3]$$

$$A^{\cdot-} + NaA^{\cdot} \xrightarrow{k_2} {}^-AANa \qquad [4]$$

$$2\,NaA^{\cdot} \xrightarrow{k_3} NaAANa \qquad [5]$$

If the rate of the ion pairing reaction [2] is rapid enough so that the reaction can be assumed to be at equilibrium, and if sodium is present in excess, the observed dimerization rate constant, k_{obs}, may be related to K, k_1, k_2, k_3, and C_{Na} by the equation

$$k_{obs} = (k_1 + k_2KC_{Na} + k_3K^2C_{Na}{}^2)/(1 + KC_{Na})^2 \qquad [6]$$

where K is the formation constant for the ion pair (M^{-1}) and C_{Na} is the molar concentration of sodium.

This paper presents results for the reduction of **1** in the presence of sodium in dimethylsulfoxide (DMSO) and acetonitrile (AN). Though these solvents have similar dielectric constants, the tendency for ion pair formation is much greater in AN than in DMSO. Fujinaga *et al.* (7) noted that formation constants for the ion pairs of the radical anions of naphthoquinones and metal ions are greater in AN than in DMSO. As pointed out by Krygowski (8), this is consistent with the concept of donicity (*DN*) defined by Gutmann (9). A high donicity solvent such as DMSO (*DN* = 29.8) stabilizes the unpaired metal ions by solvation in contrast to a lower donicity solvent such as AN (*DN* = 14.1) in which solvation of metal ions is weak and ion pair formation is favored.

Experimental

Materials.—Dimethylsulfoxide (DMSO) and acetonitrile (AN) were Matheson Coleman and Bell Spectroquality solvents. Water content as determined by gas chromatography was about 30 m*M* for each solvent. Tetra-*n*-butylammonium perchlorate (Matheson

Key words: electrohydrodimerization, cyclic voltammetry, ion pairs.

Coleman and Bell) was recrystallized from acetone-water and vacuum dried at room temperature. Anhydrous sodium perchlorate (Matheson Coleman and Bell) was found to contain less than 1 mole per cent (m/o) water by determining loss of weight after vacuum drying at 200°C (10). Diethyl fumarate (Aldrich) was used as received.

Apparatus.—The voltammetric cell has been described elsewhere (11) as has the digital data acquisition system and procedures for analysis of cyclic voltammetric data (12). A silver reference electrode (SRE) comprising a silver wire in contact with 0.10*M* tetra-*n*-butylammonium perchlorate and 0.010*M* silver nitrate in DMSO was used for the DMSO studies and an aqueous saturated calomel electrode (SCE) was used in AN. The hanging mercury drop electrode area was 0.029 cm^2.

Experimental procedures.—Experiments were performed at a temperature of 24° ± 1°C. For sodium perchlorate concentrations less than 0.10*M*, sufficient tetra-*n*-butylammonium perchlorate was added to assure an ionic strength of 0.1*M*.

Rate constants were determined using the method described by Olmstead, Hamilton, and Nicholson (13) where the anodic peak current, i'_a, is measured from zero current rather than from an extension of the cathodic peak. The theoretical results were extended to switching potentials necessary for this research but not encompassed in the work of Olmstead *et al.* by applying digital simulation techniques (14). The rate law for dimerization of the radicals, *R*, was written as $-dC_R/dt = 2kC_R^2$ where k is the second-order dimerization rate constant. Olmstead *et al.* omitted the 2 in their formulation of the rate law.

Results and Discussion

Peak potentials and observed rate constants, k_{obs}, as a function of sodium concentration for DMSO as solvent are presented in Table I. The rate constants are averages of individual values obtained from at least three different scan rates in the range of 0.5-50 V/sec. The shapes of the voltammetric peaks, the peak current ratios, and the dependence of the cathodic peak potential on scan rate were all consistent with an irreversible dimerization following reversible electron transfer (13).

There are several constants which must be evaluated in Eq. [6]. The dimerization rate constant for the radical anions, k_1, was taken as k_{obs} in the absence of sodium ions. The value found was 1.4×10^3 liter·mole^{-1}sec^{-1}. The evaluation of K is based on the dependence of the peak potential on sodium concentration. Two factors cause the peak potential to move in the positive direction as the sodium concentration increases. First, the ion pair formation (reaction [2]) causes a positive shift in the potential. This would

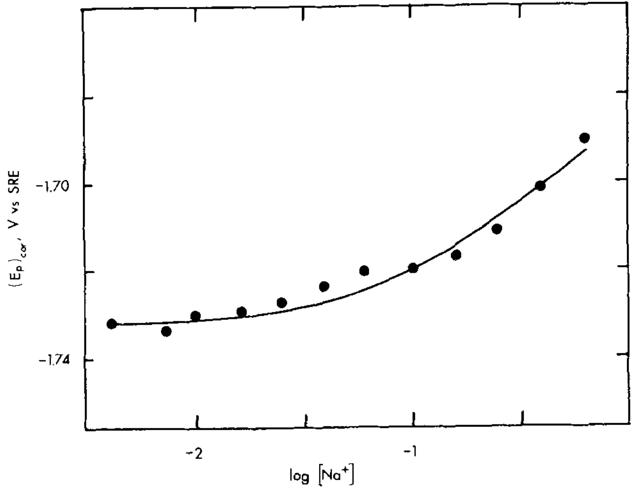

Fig. 1. Corrected peak potentials for reduction of diethyl fumarate in DMSO as a function of sodium concentration. Concentration of diethyl fumarate, 0.96 mM; scan rate, 0.050 V/sec. Peak potentials corrected for effect of chemical reactions following the initial electron transfer (see text).

be observed even if the radicals did not dimerize. Second, the chemical reactions of the anion radicals, reactions [3]-[5], also cause a positive shift in the peak potential. Since the two effects are additive, we may correct the observed peak potentials for the effects of the second factor by applying the theory for an irreversible dimerization reaction following a reversible electron transfer reaction (13) to the observed peak potentials and rate constants in Table I.[1]

Peak potentials corrected in this manner are presented in Fig. 1. The residual dependence of peak potential on sodium concentration should be due only to the first factor (ion pair formation) and the data should be interpretable in terms of the equation (15)

$$(E_p)_{cor.} = E_{1/2} - 0.0285 + 0.0592 \log(1 + KC_{Na}) \quad [7]$$

where $E_{1/2}$ is the half-wave potential for reaction [1]. The curve in Fig. 1 is that predicted by Eq. [7] with $E_{1/2} = -1.704$V *vs.* SRE and $K = 5.8\ M^{-1}$.

The final two rate constants, k_2 and k_3, can be obtained by finding the values which best fit Eq. [6] using the experimental values of k_{obs} and the k_1 and K which were evaluated above. Figure 2 shows the curve predicted by Eq. [6] for $K = 5.8\ M^{-1}$, $k_1 = 1.4 \times 10^3$, $k_2 = 5.0 \times 10^4$, and $k_3 = 3.1 \times 10^5$ liter·mole^{-1}sec^{-1}. The ionic strength was substantially greater for the four highest sodium concentrations than it was for those of 0.1*M* and below. This could have affected the rate constants though the important reactions in this region of concentration (reactions [4] and [5]) are not ion-ion reactions and should not be highly dependent on ionic strength. An alternative fit for sodium concentrations of 0.10*M* and below gives $k_2 = 6.8 \times 10^4$ and $k_3 = 2.0 \times 10^5$ liter·mole^{-1}sec^{-1}. The model assumes that the rate of ion pairing is much greater than the dimerization reactions. Ion pairing rate constants are known to be large. For example, the over-all rate constant for sodium exchange in the 2,5-di-*tert.*-butyl-1,4-benzoquinone radical anion-sodium ion pair is about 10^8 liter·mole^{-1}sec^{-1} (16). In summary, for DMSO as solvent, ion pairing is weak but the rate

[1] This procedure is based on the fact that the boundary value problem comprising reactions [1]-[5] is of the same form as that solved by Olmstead *et al.* (13) when it is assumed that reaction [2] is fast and that the diffusion coefficients of the radical anion and ion pair are identical. The formulation treats the sum of the radical anion and ion pair concentrations as a new variable. The rate constant in the formulation is k_{obs} from Eq. [6] and the standard potential includes the effect of reaction [2], *i.e.*, it is given by $E° + 0.0592 \log(1 + KC_{Na})$. Hence, the theoretical data of Ref. (13) may be used to evaluate k_{obs}. Furthermore, the shifts in peak potential as the sodium concentration is changed are due to both the kinetic effect and the shift in the formal potential. The two effects are additive.

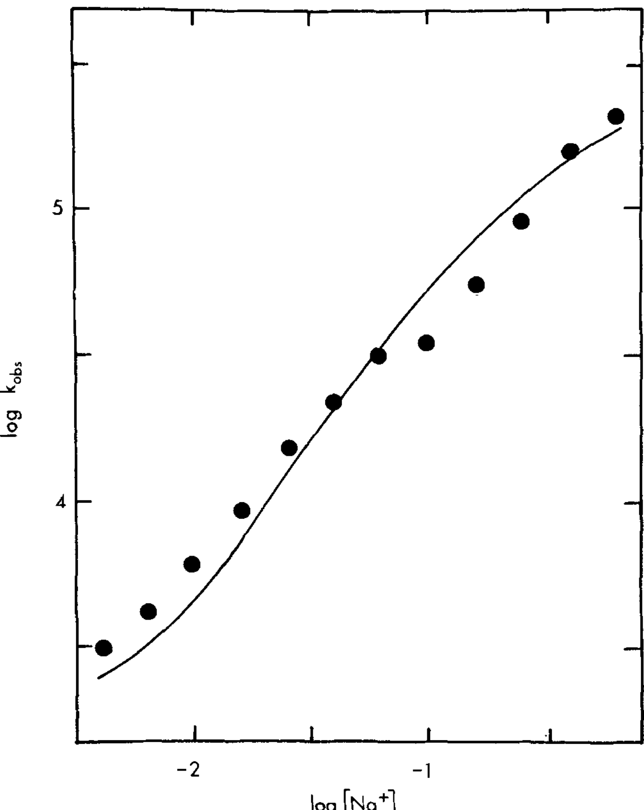

Fig. 2. Observed rate constants for dimerization of radical anions of diethyl fumarate in DMSO as a function of sodium concentration. Concentration of diethyl fumarate, 0.96 mM. Curve is Eq. [6] with $K = 5.8\ M^{-1}$, $k_1 = 1.4 \times 10^3$, $k_2 = 5.0 \times 10^4$, and $k_3 = 3.1 \times 10^5$ liter·mole^{-1}sec^{-1}.

of dimerization of the ion pairs is about two orders of magnitude greater than that of the free radical anions. At low sodium concentrations, the dimerization proceeds by reactions [3] and [4], and as the sodium concentration is increased, reaction [5] becomes important while reaction [3] wanes.

When AN was used as solvent, the dimerization reactions were extremely rapid in the presence of sodium ions. With as little as 2 m*M* sodium, no oxidation peak was obtained for a cyclic voltammogram of 0.29 m*M* **1** at 50 V/sec. This means that k_{obs} is greater than about 10^6 liter·mole^{-1}sec^{-1}. This greatly enhanced rate is due to the greater tendency for ion pair formation in AN as compared to DMSO. Even at low sodium concentrations, the ion pair is the predominant form of the anion radical, *i.e.*, $KC_{Na} >> 1$. Under this condition (and $k_3 > k_2 > k_1$ as was observed in DMSO) Eq. [6] reduces to $k_{obs} = k_3$ and the observed rate constant is no longer a function of sodium concentration. As a result, the kinetic effect on the peak potential for the reduction of **1** in AN will be a constant and any shift in peak potential as the sodium concentration is varied must be attributed to the ion pairing (reaction [2]). The effect is described by Eq. [7] which predicts that the peak potential should shift 59 mV for a tenfold change in sodium concentration when the ion pair is the predominant species ($KC_{Na} >> 1$).

Peak potentials for the reduction of **1** in AN are presented in Fig. 3 along with a line of the theoretical 59 mV slope. These data are consistent with a reaction scheme in which most of the radical anions exist as ion pairs, and the dimerization proceeds by reaction between these ion pairs (reaction [5]).

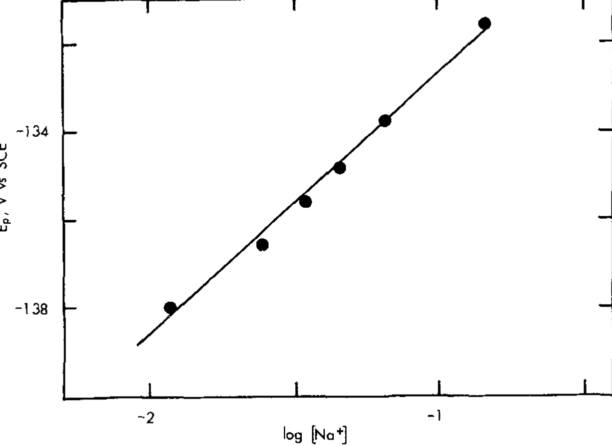

Fig. 3. Peak potentials for reduction of diethyl fumarate in AN as a function of sodium concentration. Concentration of diethyl fumarate, 0.29 mM; scan rate, 0.100 V/sec.

In conclusion, it has been possible to correlate the data for the reduction of **1** in DMSO containing sodium to the mechanism given by reactions [1]-[5]. The ion pair formation constant and the three rate constants were evaluated. In AN, the same mechanism is probably active but the formation constant of the ion pair is large enough that only the pathway involving dimerization of ion pairs is observed.

Electrochemical Measurements of Dilute Thallium Amalgams

Mark Salomon*

Power Sources Technical Area, U. S. Army Electronics Technology and Devices Laboratory, Fort Monmouth, New Jersey 07703

The publication costs of this article have been assisted by the U. S. Army.

In 1919 Richards and Daniels published their detailed work on concentrated thallium amalgams (1). These results were used by Lewis and Randall in their classical thermodynamic treatment of concentrated solutions (2). Richards and Daniels made very precise emf measurements ($\pm 2\ \mu V$) on the concentration cell

$$\mathrm{Tl(Hg)},\ a_{\mathrm{Tl},1}/\mathrm{Tl}^+,\ \mathrm{X}^-,\ \mathrm{solvent}/\mathrm{Tl(Hg)},\ a_{\mathrm{Tl},2} \quad [1]$$

In cell [1], $a_{\mathrm{Tl},1}$ and $a_{\mathrm{Tl},2}$ are the activities of Tl in the amalgams and X^- is the anion. Richards and Daniels also made some measurements on the cell

$$\mathrm{Tl(Hg)}/\mathrm{Tl}^+,\ \mathrm{X}^-,\ \mathrm{solvent}/\mathrm{Tl} \quad [2]$$

but refer to these measurements as being "only approximate." It is noted that the emf's of cells [1] and [2] are independent of the nature of X^- and of the solvent. Cowperthwaite *et al.* (3) made very precise emf measurements (± 0.02 mV) on cell [2] using a 5% Tl amalgam. The Nernst relation for cell [2] is

$$E_2 = E^\circ_2 - (2{\cdot}3RT/\mathbf{F}) \log(N_2 f_2) \quad [3]$$

where N_2 and f_2 are, respectively, the mole fraction and rational activity coefficient of Tl in the amalgam. E°_2 is defined by

$$E^\circ_2 = E^\circ_{\mathrm{Tl(Hg)}} - E^\circ_{\mathrm{Tl}} \quad [4]$$

where $E^\circ_{\mathrm{Tl(Hg)}}$ is the standard potential of the Tl amalgam [the reference state is infinite dilution (2)] and E°_{Tl} is the standard potential of solid thallium. E°_2 is evaluated by plotting the function E' against N_2 and extrapolating to $N_2 = 0$. E' is defined by

$$E' = E_2 + (2{\cdot}3RT/\mathbf{F}) \log N_2 \quad [5]$$

A problem arises in the evaluation of E°_2 because the E_2 values of Richards and Daniels are, supposedly, based on approximate values for the solid Tl electrode. Cowperthwaite's values for cell [2] using a 5% Tl amalgam can be combined with Richards's and Daniels's data for cell [1] to obtain E_2 values as a function of N_2, but Cowperthwaite *et al.* do not state the accuracy of the concentration of the 5% amalgam. This latter method was used by the present author (4, 5) but it was pointed out by Singh *et al.* (6) that these E_2 values differ by as much as 23 mV (positive) from those values based on Richards's and Daniels's approximate measurements. Since the E_2 data of Richards and Daniels are widely quoted, particularly in recent works in nonaqueous solvents (4-8), it is important to have accurate values, and this then is the purpose of this communication.

Experimental

$TlNO_3$ and 1/8 in. Tl wire (Apache Chemicals, 99.999% pure) were treated as follows. The Tl wire was rinsed in dilute H_2SO_4 and distilled water and dried for 12 hr at 60°C in a vacuum oven. The as-received $TlNO_3$ was dried under identical conditions. Reagent grade (Fisher Chemicals) dimethylsulfoxide (DMSO) was used as the solvent and was treated for 2-4 weeks with Type 4A molecular sieves. These chemicals were transferred to an argon-filled VAC dry box in which the oxygen content was less than 1 ppm. An oxide film did form on the Tl wire during the transfer but was scraped off and the Tl would remain clean and bright for several weeks in the dry box. A stock Tl amalgam of ~10% Tl by weight was prepared with triply distilled Hg. More dilute amalgams were prepared by adding Hg to this stock amalgam. A Mettler H15 balance was used for all weighings inside the dry box. The electrolyte used was ~0.1M $TlNO_3$ in DMSO.

The electrochemical cell consisted of five compartments, three of which contained Tl amalgam and the remaining contained Tl wire. The cell was filled in the dry box, sealed by wetting the ground joints with electrolyte, removed to the laboratory, and placed in a water bath. Four temperatures of 15°, 20°, 25°, and 35°C were employed; regulation was ± 0.02°C.

A Keithley 610C electrometer was used for the emf measurements of cell [2]. The output of the electrometer was measured with a Systron Donner 1103 counter with a Model 1936 integrating DVM plug in. Using a calibrated Weston cell as a standard, the accuracy of the emf readings was ± 0.03 mV.

Results and Discussion

All emf readings were stable to within the accuracy limits of the instrumentation (± 0.03 mV). The bias potential between the two Tl electrodes was, within the stated accuracy, zero for all measurements. Some problems did arise with several measurements at 15°C. DMSO freezes at 18.5°C but can be supercooled in the presence of an electrolyte if the cooling is carried out slowly. During the measurements on 0.038, 0.081, and 6.005% Tl in Hg, the temperature was cooled rapidly from 35° to 15°C and the solution froze. Warming and recooling resulted in erratic readings and bias potentials of ~0.5 mV. The emf data for these amalgams were not recorded at 15°C but were obtained by extrapolation as explained below.

The results of the measurements are given in Table I. Over the temperature range studied, it was found that the temperature coefficient, dE/dT, for any given amalgam is constant within the limits of the experimental error. This result is in agreement with those of Richards and Daniels. Because dE/dT is constant, the emf values for the three discarded points at 15°C could be evaluated by simple extrapolation to within

* The data for this amalgam is taken from Ref. (1).
** Values in parentheses are extrapolated (see text); error is ±0.05 mV.

±0.05 mV. These extrapolated E_2 values are given in parentheses in Table I. The plot of E' (Eq. [5]) against N_2 at 20.0°C is shown in Fig. 1. In this figure, the diamond points refer to the present results and the circles refer to the data of Richards and Daniels. It is seen that Richards's and Daniels's values lie within 0.03 mV of the line drawn through the diamond shaped points (this is within the accuracy of the present emf measurements). The extrapolation of E' to $N_2 = 0$ for the present data is simpler than with Richards's and Daniels's original data because E' *vs.* N_2 becomes linear below the point for $N_2 = 0.003254$ (the 0.332% Tl amalgam). Above this point, the plot is nonlinear which results in a slightly less accurate value for $E°_2$ (see below). Table II gives the present values of $E°_2$ as a function of temperature. Also included in Table II is the standard free energy change, $\Delta G°_2$, for the reaction of cell [2], *i.e.*, for

$$\text{Tl(Hg)} = \text{Tl} + \text{Hg} \quad [2']$$

A least squares analysis was performed on the data in Table II and the resulting values for the standard enthalpy and entropy (both are assumed to be independent of temperature) are, respectively, $\Delta H°_2 = 646.1 \pm 4.9$ cal mole^{-1} and $\Delta S°_2 = -0.398 \pm 0.016$ eu. These errors are the statistical standard deviations of the least squares slope and intercept, respectively. A more realistic estimate of these standard deviations can be obtained by combining the variances of the statistical analysis and the experimental error. This then gives

Table II. Standard potentials and free energies for reaction [2]

°C	$E°_2$ (mV)	$\Delta G°_2$ (cal mole^{-1})
15.0	32.99	760.8
20.0	33.06	762.4
25.0	33.16	764.7
35.0	33.33	768.6

$$\Delta H°_2 = 646.1 \pm 5.0 \text{ cal mole}^{-1}$$

$$\Delta S°_2 = -0.40 \pm 0.22 \text{ eu}$$

The rational activity coefficients were calculated from Eq. [3] and are given in Table I. The values of f_2 at 20.0°C are ~2% higher than those calculated by Lewis and Randall[1] who evaluated f_2 from Richards's and Daniels's data and are therefore based on the nonlinear extrapolation. If Lewis's and Randall's data for f_2 are used in Eq. [3] to calculate $E°_2$ at 20.0°C, an average value of 32.78 mV is obtained. The difference between this and the present value for $E°_2$ is much greater than the experimental error and is therefore significant. Values for the activities of Hg in the amalgams were calculated from the Gibbs-Duhem equation and the results are, essentially, identical to those of Lewis and Randall. It is evident therefore that if Richards's and Daniels's statement on the approximate nature of their E_2 values is taken literally, errors can result. This by no means vitiates previous results (4, 5) but rather requires slight adjustments as suggested by Singh *et al.* (6).

Manuscript received Jan. 25, 1974.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1975 JOURNAL. All discussions for the June 1975 Discussion Section should be submitted by Feb. 1, 1975.

[1] Lewis and Randall (2) calculated the f_2 data only for 20.0°C.

The Stability of Carbonate Ion in Fused Nitrate

A. G. Keenan, Carlos G. Fernandez,* and Thomas R. Williamson*

Department of Chemistry, University of Miami, Coral Gables, Florida 33124

The publication costs of this article have been assisted by the University of Miami.

Numerous methods for adding oxide ion to nitrate melts for use in electrochemical studies have appeared in the literature (1). No really convenient source appears yet to be available. In recent publications (2, 3) Fredericks and Temple, in studying the platinum-oxygen electrode in fused nitrates, have used carbonate ion as a source of oxide ion. Between 250° and 350°C

* Electrochemical Society Student Member.
Key words: fused nitrates, carbonate ion, oxide ion, electromotive force, oxygen electrode.

they give the reaction

$$CO_3^{2-} \rightarrow CO_2 + O^{2-} \quad [1]$$

This is based on earlier work of Kust (4-6) who first proposed the reaction. In the presence of a platinum-oxygen electrode, the oxygen flow was considered to drive the reaction to completion by sweeping out the carbon dioxide. The reaction was also assumed to proceed in the absence of the oxygen although in some cases an unspecified amount of dichromate was added "to enhance the evolution of CO_2" (4).

In contrast to the above, Zambonin (7) has reported that carbonate ion is stable in nitrate melts from 230° to 330°C.

In none of the above references was the system investigated sufficienctly thoroughly to allow an unequivocal conclusion regarding the reaction. While pursuing our previous electrochemical studies in nitrate melts (8-10), we have found it necessary to study the matter further. As a result, it has been established that carbonate ion is stable in fused KNO_3 at 350°C up to 100 hr. Purging with oxygen or nitrogen has no effect. If dichromate is added, it reacts stoichiometrically according to the equation

$$Cr_2O_7^{2-} + CO_3^{2-} \rightarrow 2CrO_4^{2-} + CO_2 \quad [2]$$

This reaction has also been proposed by others (11).

Experimental

Reagent grade chemicals were utilized throughout this work. The KNO_3 was dried in a vacuum desiccator at 130°C for 24 hr and then stored at 110°C. $K_2Cr_2O_7$ and K_2CO_3 were dried at 110°C for at least 24 hr. The melt consisted of 10g KNO_3 at 350°C maintained in a fused salt bath. K_2CO_3 was added as pellets formed in a laboratory press. The melt was allowed to stand at 350°C for various times up to 100 hr undisturbed or while being purged with either oxygen or nitrogen gas. It was then frozen, dissolved in boiled distilled water, and titrated with standardized HCl.

The colorimetric indicators methyl red and phenolphthalein were used with boiling in some titrations. In others, a Corning Series 500 Combination Electrode was used to monitor the *p*H curve. This was used in conjunction with a Sargent Constant Rate Buret (Model C) and a Model SR Recorder with a *p*H recording adapter. In all cases a very pronounced classical weak-base titration curve with two end points, one in the region of *p*H 9 and the other at 5.5, was obtained. Blank runs showed that any salt error due to the KNO_3 was negligible. The volume of titrant to the first end point was equal to that from the first to the second. The titration errors were less than 1%. Thus, within this accuracy carbonate is stable and the only base present for the given conditions.

To study the effect of dichromate, known amounts were added to a KNO_3 melt at 350°C containing a known amount of carbonate in various mole ratios up to 1:1. Upon addition of the dichromate, a vigorous evolution of gas was observed and the orange color of the dichromate changed to the easily distinguishable yellow of chromate. Titrations as described above showed, that after the reaction, carbonate was present in the melt in an amount equal to the initial less the number of moles which would have been used up by reaction [2]. When dichromate was added in an amount stoichiometrically equivalent to the carbonate, no carbonate end points were found on titration. Instead, an inflection point was observed at *p*H 3.5 accompanied by a visually observable change from the yellow of chromate to the orange of dichromate. The volume of HCl consumed corresponded to the amount of dichromate originally added according to the known stoichiometry

$$2CrO_4^{2-} + 2H^+ \rightarrow Cr_2O_7^{2-} + H_2O \quad [3]$$

Brief Communication

Computation of Standard Specific Rate Constants of Partial Processes in Mixed Potential Systems

Francis M. Donahue*

Department of Chemical Engineering, The University of Michigan, Ann Arbor, Michigan 48104

In a recent paper the author proposed a method of determining the respective rate laws for partial processes in mixed potential systems (1). This method has recently been applied to electroless copper plating systems (2). The emphasis in that work (2) and subsequent publications (3, 4) was toward a determination of the reaction orders in order to elucidate the reaction mechanism. However, the resulting reaction orders made an exact elucidation impossible: it was possible only to make general remarks concerning possible mechanisms (3, 4). One may question the validity of an indirect analysis particularly when nonintegral reaction orders are obtained and an atomistic mechanism cannot be proposed (2-4). This note will provide a means of testing the analysis further and will indicate how additional information associated with the rate law can be obtained.

Since only selective pieces of data are used in the determination of the reaction orders for the partial processes (1, 2), it is possible that an incorrect analysis and/or poor data could lead to incorrect rate laws. A typical test of the validity of a rate law in chemical kinetics is the determination of the specific rate constant using all of the rate data. At a fixed temperature the computed rate constant should be reasonably constant. Therefore, the computation of the rate constants for the partial processes provides a means of testing both the theoretical analysis and the quality of the data. Furthermore, computation of the standard specific rate constants for the partial processes leads directly to a complete numerical representation of the rate laws.

Casting Eq. [15] and [16] of Ref. (2) in the form of Eq. [4a] and [4b] of Ref. (1), respectively, and rearranging yields

$$k^o{}_a = \frac{(-r_a)\exp\left(\dfrac{\phi^o{}_a - \psi_o}{\beta_a}\right)}{[\mathrm{HCHO}]^{0.18}\,[\mathrm{OH}^-]^{0.18}} \qquad [1]$$

and

$$k^o{}_c = \frac{(-r_c)\,[\mathrm{HCHO}]^{0.23}\exp\left(\dfrac{\psi_o - \phi^o{}_c}{\beta_c}\right)}{[\mathrm{Cu}^{2+}]^{1.7}\,[\mathrm{OH}^-]^{0.18}} \qquad [2]$$

where $k^o{}_c$ includes the ligand concentration and reaction order (2). The data used in the analysis are given in Table I. The plating solutions and plating rates are from recent work (5) while the mixed potentials were given elsewhere (2). The Tafel slopes were those of Paunovic (6) with an appropriate correction for temperature. The standard electrode potential of the formaldehyde reaction was computed in the manner described previously (3, 4) using data from Pourbaix (7). The standard electrode potential of the copper-cupric ion reaction was found in Pourbaix (7). The standard potentials were not corrected for the change in temperature since the values of the temperature coefficients were not known for both partial processes.

The values of the standard specific rate constants computed from Eq. [1] and [2] are given in Table I. The mean value of the anodic constant at 40°C was 9.40×10^{-3} μm/hr $M^{0.36}$ with a standard deviation of 1.9×10^{-3} μm/hr $M^{0.36}$; the mean cathodic constant at 40°C was 1.38×10^{-4} μm/hr $M^{1.65}$ with a standard deviation of 0.53×10^{-4} μm/hr $M^{1.65}$. The precision of the computed values of the rate constants is a significant corroboration of both the theoretical analysis (1) and the experimental data (2, 5).

A question which often arises in analyses of this type is, What is the effect of the temperature coefficient of the standard potential on such computations? Since the temperature coefficient of the copper-cupric ion system is known (8), this effect will be ascertained for the cathodic partial process. Since the mixed potential, ψ_o, is measured with respect to a saturated calomel electrode (SCE) in the same solution, the standard potential of the copper-cupric ion system, *i.e.*, $\phi^o{}_c$ of Eq. [2], must also be measured with respect to SCE. The hypothetical cell for that combination is

$$\mathrm{SCE}//\mathrm{Cu}^{2+}/\mathrm{Cu}\ \text{(standard conditions)} \qquad [3]$$

with a potential

$$\phi^{o}_{Cu/Cu2+} \ (vs.\ \mathrm{SCE}) = \phi^{o}_{Cu/Cu2+,H} - \phi_{SCE,H} \quad [4]$$

The temperature coefficient of the cell is

$$\frac{d\phi^{o}_{Cu/Cu2+}}{dt}(vs.\ \mathrm{SCE}) = \frac{d\phi^{o}_{Cu/Cu2+,H}}{dt} - \frac{d\phi_{SCE,H}}{dt} \quad [5]$$

where the "isothermal" temperature coefficients on the right-hand side of Eq. [5] can be computed according to de Bethune *et al.* (8). The exponent in Eq. [2] becomes

$$\frac{1}{\beta_c}\left[\psi_{oT} - \phi^{o}_{Cu/Cu2+,H,25} + \phi_{SCE,H,25} - \frac{d\phi^{o}_{Cu/Cu2+}}{dt}(vs.\ \mathrm{SCE})\ (t-25)\right] \quad [6]$$

If Eq. [6] replaces the exponent in Eq. [2], a new set of standard specific rate constants may be computed. This substitution was performed and the results are shown in Table II. In all cases the resulting rate constant was from 10 to 40% lower than that computed "ignoring" the temperature coefficient. The mean rate constant at 40°C was 1.11×10^{-4} μm/hr $M^{1.65}$ with a standard deviation of 0.43×10^{-4} μm/hr $M^{1.65}$. While the rate constants computed using the temperature coefficient correction are more correct than those computed ignoring it, the improvement probably does not justify the additional computations, particularly when the temperature coefficient is unknown and must be computed from the standard reaction entropy [see Ref. (8)]. However, in some mixed potential systems the effect could be more dramatic. In the present work, the differences between the mixed and standard potentials were on the order of 800 mV. Therefore, the temperature correction represented only a small fraction of the exponential term. In corrosion systems, for example, where this difference might only be a few hundred millivolts, even a small temperature correction could lead to big differences in the computed rate constants.

The present work indicates that the theoretical analysis (1) is self-consistent and offers a means for the determination of the complete rate laws for partial processes in mixed potential systems. Further, the procedure for effecting these determinations is outlined here and elsewhere (1, 2).

Acknowledgments

The Sulfidation Properties of Cobalt-Iron Alloys in Hydrogen Sulfide-Hydrogen Atmospheres at 700°C

D. J. Young,* P. Mayer,[1] and W. W. Smeltzer*

Department of Metallurgy and Materials Science, McMaster University, Hamilton, Ontario, Canada

The publication costs of this article have been assisted by McMaster University.

ABSTRACT

Cobalt and Co-Fe alloys containing from 1 to 90 weight per cent (w/o) Fe sulfidize according to a parabolic rate relation at 700°C in H_2/H_2S atmospheres corresponding to $p_{S2} = 6 \times 10^{-6}$ and 8×10^{-8} atm. Austenitic alloys (0-13 w/o Fe) sulfidize less rapidly than ferritic alloys (25-100 w/o Fe), minimum values of the parabolic rate constant being found at ~4 w/o Fe for both values of p_{S2}. The scale on austenitic alloys is $(CoFe)_9S_8$ at $p_{S2} = 8 \times 10^{-8}$ atm and at $p_{S2} = 6 \times 10^{-6}$ atm this sulfide is partially overlayed by $(CoFe)_{1-x}S$. This latter sulfide decomposes on cooling to form a two-phase mixture of $(CoFe)_9S_8$ and $(CoFe)_3S_4$. Ferritic alloys form a mixed $(CoFe)_{1-x}S$ monosulfide at both sulfur pressures. The high sulfidation rates of the ferritic alloys are ascribed to the high concentration of defects in the cation lattice of the monosulfide whereas the lower sulfidation rates of the austenitic alloys are controlled by the relatively low diffusivity of metal in almost stoichiometric $(CoFe)_9S_8$.

Commercially available cobalt-base alloys frequently contain minority amounts of iron (1). The well-known susceptibility of iron to sulfur corrosion (2) suggests that its presence in these alloys may be detrimental to their performance at high temperatures. This paper reports the effects of alloy iron content on the sulfidation rates of Co-Fe alloys in H_2/H_2S atmospheres.

The sulfidation of pure cobalt has been investigated under a number of conditions. Parabolic kinetics have been found for the scaling reaction in the temperature range 400°-750°C at sulfur pressures of 100-400 mm Hg by Davin (3) and at a pressure of 1 atm by Mrowec *et al.* (4). The former demonstrated that the parabolic rate constant, k_p, was proportional to $p_{S2}^{1/2}$ at 700°C. In both cases a duplex sulfide scale was produced. This scale has been identified (5) as consisting of $Co_{1-x}S$ in the outer layer and Co_9S_8 in the inner layer.

Studies (6) of the sulfidation of pure cobalt in H_2/H_2S atmospheres have produced similar results although the p_{S2} dependence of the rate has not been determined. For corrosion by sulfur vapor and by H_2S, marker experiments indicated that cobalt was the mobile species within the scale.

The sulfidation properties of iron have been reviewed by Haycock (2). Quite different phenomena are observed according to whether the environment consists of sulfur or of H_2S. In the former case, parabolic kinetics are found and quantitative agreement with Wagner's theory is obtained (7). In the latter case, linear kinetics are found, the resultant scale being highly porous in nature. The reasons for this difference in behavior are not understood.

Key words: parabolic kinetics, $(CoFe)_9S_8$, $(CoFe)S$.

Experimental

Alloys were prepared by vacuum melting the required proportions of cobalt (>99.997 w/o pure) and iron (>99.975 w/o pure). The actual iron contents of the alloys were 0.93, 4.1, 9.6, 49.9, and 90.0 w/o. Alloy rods were annealed in an argon atmosphere at 1200°C for ten days, machined to a uniform diameter (~ 10 mm), and cut into disks with a wire saw. The disks were metallographically polished to 1μ diamond abrasive and stored under acetone prior to use.

Sulfidation kinetics were determined gravimetrically using a McBain balance assembly. The apparatus has been described elsewhere (8). The reaction was investigated at $T = 700° \pm 5°C$ and p_{S2} equal to 8×10^{-8} atm and 6×10^{-6} atm. The sulfur partial pressures were controlled by mixing H_2 and H_2S in known proportions, the required H_2/H_2S ratio being obtained from the known standard free energy change of the reaction (9)

$$H_2S_{(g)} = H_{2(g)} + \tfrac{1}{2} S_{2(g)}$$

Cross sections of the sulfidized samples were examined metallographically. Phases present in the scale were determined by electron microprobe analyses. Point counts obtained from the probe were analyzed with respect to Co and Fe standards. Systematic corrections were applied to the data for atomic number and mass absorption (10).

Results

Kinetics.—The reaction kinetics were invariably parabolic, as shown in Fig. 1 and 2, although induction periods were occasionally found. As can be seen from the plots, the initial reaction stages were not observed. The time taken for the balance to reach mechanical equilibrium was the reason for this delay. It was al-

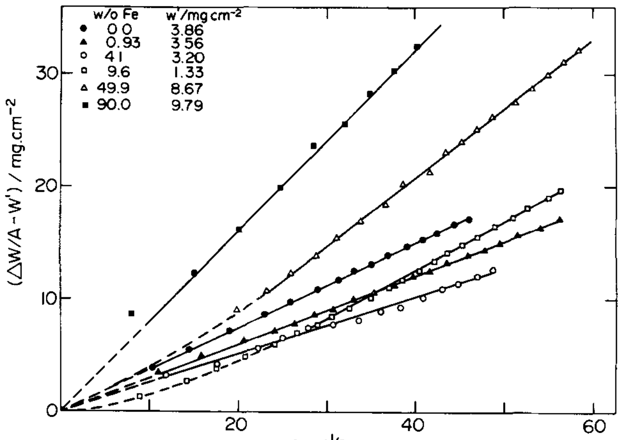

Fig. 2. Parabolic plots for sulfidation of Co-Fe alloys at T = 700°C and $p_{S_2} = 6 \times 10^{-6}$ atm.

lowed for by fitting the data by linear regression to the equation

$$\Delta W/A + W' = (k_p t)^{1/2}$$

where $\Delta W/A$ is the weight change per unit area found after time, t. It is this equation which has been employed in plotting Fig. 1 and 2. Values for W' are shown on the figures.

Variation of the parabolic rate constant with iron alloy content is shown in Fig. 3. A minimum in the rate at about 4 w/o Fe is apparent for both p_{S_2} values. This figure shows that at all alloy compositions a higher reaction rate is associated with the higher p_{S_2} value.

Scale morphologies and constitutions.—In all cases the sulfide scales were tightly adherent to the metal and remarkably compact and pore free. Representative examples are shown in Fig. 4, 5, and 6. Apart from the case of pure cobalt, all alloys developed scales of large grain size. Additional, smaller grains were found at the scale-metal interface on the ferritic alloys.

At $p_{S_2} = 8 \times 10^{-8}$ atm a single layer scale is always formed; at $p_{S_2} = 6 \times 10^{-6}$ atm regions of an additional, two-phase scale are found at the sulfide-gas interface. The extent to which this additional layer covers the inner layer is variable within the utilized exposure periods, but in general increases with increasing alloy iron content up to 49.9 w/o Fe when total coverage is achieved. A single-phase scale was found, however, on the 90.0 w/o Fe alloy.

The constitutions of the sulfide layers within the scales, as determined by microprobe analyses, are summarized in Table I. Only in the case of the 49.9 w/o Fe alloy was it possible to analyze separately the

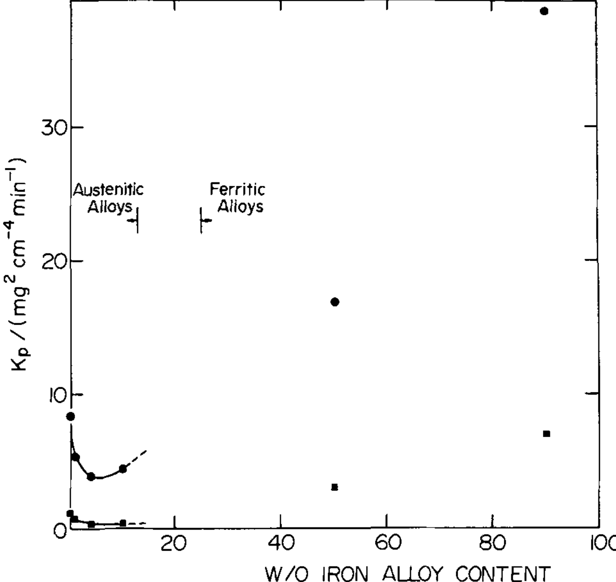

Fig. 3. Variation of parabolic rate constant, k_p, with iron alloy content: ●—$p_{S_2} = 6 \times 10^{-6}$ atm; ■—$p_{S_2} = 8 \times 10^{-8}$ atm.

two phases in an outer sulfide layer. They proved to be $(CoFe)_9S_8$ and $(CoFe)_3S_4$. For the other alloys, the regions of the two phases were of a size comparable to the probe beam and consequently only an average composition could be measured.

Concentration profiles in the scale constituents were also measured. Results for the scales formed on 4.1, 9.6, and 49.9 w/o Fe alloys at $p_{S_2} = 6 \times 10^{-6}$ atm are shown in Fig. 7, 8, and 9.

Discussion

The fact that all the alloys sulfidized according to parabolic kinetics, together with the observation that the resultant scales were compact, implies that the reactions are diffusion controlled. It is then reasonable to assume that the alloy-scale system can be described with the aid of a thermodynamic framework since local equilibrium conditions would prevail.

As a first step, we employ the concentration profiles illustrated in Fig. 7-9 and those from the other sulfidized alloys to construct the 700°C section of the Fe-Co-S phase diagram shown in Fig. 10. It is apparent from this diagram that the sulfidation properties of the austenitic alloys (0-13 w/o Fe) and of the ferritic alloys (25-100 w/o Fe) may conveniently be distinguished.

The similarity in appearance of the two-phase sulfide scales (Fig. 4-6) suggests that the identification of

these phases achieved for the 49.9 w/o Fe alloy applies as well to the other alloys. Assuming that this is the case, the sulfidation products of the various alloys can

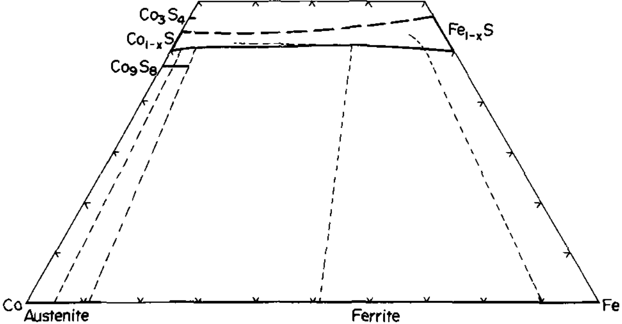

Fig. 10. Partial 700°C isotherm of the Co-Fe-S system as deduced from the composition paths found in the sulfidized alloy samples. Composition paths are shown as dotted lines.

be summarized as in Table II. A common pattern, accordingly, is apparent in the morphological development of sulfides on austenitic alloys. This pattern may be explained in terms of the thermodynamics of the binary Co-S system.

From the data of Rosenqvist (11), the following equilibrium p_{S_2} values at $T = 700°C$ are estimated

$$9/4\,Co + S_{2(g)} = 1/4\,Co_9S_8, \qquad p_{S_2} = 8.0 \times 10^{-10}\ \text{atm}$$

$$2Co_9S_8 + S_{2(g)} = 18CoS, \qquad p_{S_2} = 2.8 \times 10^{-7}\ \text{atm}$$

Thus at the experimental p_{S_2} values of 8×10^{-8} and 6×10^{-6} atm, pure cobalt is expected to form a Co_9S_8 scale at the low sulfur pressure and a duplex scale of Co_9S_8 overlaid by CoS at the high pressure. Since CoS undergoes a eutectoid decomposition at 460°C to Co_9S_8 and Co_3S_4 which is not suppressed by quenching (11), it is to be expected that $Co_{1-x}S$ will appear at room temperature as a two-phase layer if it is a stable product layer at the reaction temperature.

The pattern of sulfide products predicted for pure cobalt is precisely that found for the austenitic alloys. The formation of $(CoFe)_9S_8$ and $(CoFe)_{1-x}S$ is not surprising in view of the similarities in size, polarizability, and ionization potential of Co^{2+} and Fe^{2+}. For the same reasons, the thermodynamics of the mixed sulfides are closely similar to those of the cobalt sulfides. Since $Co_{1-x}S$ and $Fe_{1-x}S$ are isotypic, the two sulfides are mutually soluble in all proportions (Fig. 10). The highly ordered Co_9S_8 structure (12), however, has a limited solubility capacity for substitutional cations. Consequently, the $(CoFe)_9S_8$ phase field extends into the ternary Co-Fe-S isotherm over a finite compositional range.

Turning now to the ferritic alloys, we note from Rosenqvist (11) that at 700°C

$$2Fe + S_{2(g)} = 2FeS, \quad p_{S_2} = 2.9 \times 10^{-11}\ \text{atm}$$

and that no lower sulfides exist. The formation of $(CoFe)_{1-x}S$ on these alloys is therefore readily explicable on the same grounds as enumerated above for the austenitic alloys. $Fe_{1-x}S$ is stable at room temperature and, therefore, a two-phase layer structure is not to be expected in the quenched scales formed on the iron-rich alloys. The appearance of such a product near the gas interface of the scale on the 49.9 w/o Fe alloy indicates that $(CoFe)_{1-x}S$ in this region of the scale

Table II. Phase identification of sulfide scales

	$p_{S_2} = 8 \times 10^{-8}$ atm		$p_{S_2} = 6 \times 10^{-6}$ atm	
	Inner layer	Outer layer	Inner layer	Outer layer
Austenite	$(CoFe)_9S_8$	—	$(CoFe)_9S_8$	$(CoFe)_9S_8 + (CoFe)_3S_4$

90.0 w/o Fe	$(CoFe)_{1-x}S$	—	$(CoFe)_{1-x}S$	—

was essentially $Co_{1-x}S$ while the sulfide nearer the metal was essentially $Fe_{1-x}S$. Reference to the concentration profile of Fig. 9 shows that indeed the fraction of $Co_{1-x}S$ in the mixed sulfide increases with increasing sulfur activity. If the behavior of this solid solution is nearly ideal, this observation is consistent with the fact that $Co_{1-x}S$ coexists with sulfur at a higher pressure than does $Fe_{1-x}S$. A similar effect is found, although to a lesser degree, for the $(CoFe)_{1-x}S$ scale formed on the 90.0 w/o Fe alloy.

The influence of alloy iron content and sulfur pressure on the sulfidation kinetics can be explained qualitatively in terms of the defect structures of the sulfides. While Co_9S_8 is practically stoichiometric, and hence exhibits relatively low cation diffusivity, the monosulfides exhibit large degrees of nonstoichiometry (11). $Fe_{1-x}S$ exhibits at $T = 700°C$ a wider existence range (50-57 a/o S) than $Co_{1-x}S$ (50-54 a/o S). Nonstoichiometry in the monosulfides is known to arise through cation vacancy formation, the vacancy concentration increasing with sulfur pressure. Thus $(CoFe)_{1-x}S$ is expected to possess a high cation diffusivity, the diffusivity increasing both with iron content and sulfur pressure.

The sulfidation properties of the alloys are now explicable. In the case of the ferritic alloys, faster reaction rates are found at the higher sulfur pressure employed and the 90.0 w/o Fe alloy sulfidizes more rapidly than the 49.9 w/o Fe alloy at both sulfur pressures because $(CoFe)_{1-x}S$ of increasing iron content is the sole reaction product. Sulfidation of the austenitic alloys is presumably controlled largely by diffusion through the $(CoFe)_9S_8$ scale and is consequently slower than in the case of the ferrite alloys. The localized appearance of $(CoFe)_{1-x}S$ to ultimately form an outer scale layer is presumably due to the difficulty of nucleating this phase. The nucleation and rate of growth of $(CoFe)_{1-x}S$ on the $(CoFe)_9S_8$ layer of sulfidized austenite is apparently related to iron content. The more widespread nucleation and rapid growth of the former sulfide with increasing alloy iron content is consistent with the fact that $Fe_{1-x}S$ is more stable than $Co_{1-x}S$.

A detailed description cannot presently be given for the minima found in the parabolic sulfidation rates at ~4 w/o Fe (Fig. 3) since the defect structure and diffusion mechanism for Co_9S_8 are unknown. However, we may surmise that the $(CoFe)_9S_8$ phase field narrows as the iron content increases. Such an effect will lead to a diminution of the growth rate. Simultaneously, at the higher sulfur pressure, the amount of $(CoFe)_{1-x}S$ formed increases with iron content. The superposition of these two effects leads to a minimum in the rate constant as the alloy iron content increases. At the lower experimental value of p_{S_2} the monosulfide is not stable for alloys of small iron content, and hence none is formed on the austenitic alloys. Consequently, only a decrease in the parabolic rate constant was observed with increasing iron content in the austenitic alloys. The rate increases, however, for the ferritic alloys where the iron content is so high that the stable reaction product is the monosulfide, $(CoFe)_{1-x}S$.

Summary

The sulfidation of cobalt-iron alloys at 700°C in hydrogen sulfide-hydrogen atmospheres is controlled by cation diffusion through the sulfide scale and parabolic kinetics result. Ferritic alloys sulfidize faster than do austenitic alloys because the scale on the former is composed entirely of high diffusivity $(CoFe)_{1-x}S$ whereas on the latter it is composed largely of the low diffusivity $(CoFe)_9S_8$. A minimum in the sulfidation rate is found in the austenitic alloy range at ~4 w/o Fe alloy content. This effect is thought to result from the simultaneous decrease in diffusivity of $(CoFe)_9S_8$, and increase in ease of $(CoFe)_{1-x}S$ formation with increasing iron content.

The morphology of the sulfide scales on austenitic alloys is the same as that of the scales on pure cobalt. Similarly, the ferrite alloys sulfidize so as to produce the same morphology as that found for pure iron. This close similarity between, respectively, cobalt-rich mixed sulfides and pure cobalt sulfides and between iron-rich mixed sulfide and pure iron sulfide is a consequence of the very similar chemistry of cobalt and iron.

ABSTRACT

The geometry and optical properties of the phosphor screen in a cathode-ray picture tube have been studied in connection with the phoshor particle size distribution. The specific surface area, S_W (cm^2/g phosphor), which determines the amount of light scattering in the screen, is equal to $(k/\rho)(\bar{\phi}_2)^{-1}$, where ρ is specific gravity of phosphor, $\bar{\phi}_2$ is the mean surface particle size, and k is constant. Geometry shows that the total surface area of phosphor particles densely arranged in a single layer on the faceplate is independent of the particle size and is constant. The total surface area of the phosphor particles in the screen, therefore, depends on the number, $\bar{L}$, of particle layers, rather than on the gross thickness. L is equal to $1.65w(\rho\bar{\phi}_2)^{-1}$, where w is the screening weight (g/cm^2). The usefulness of L as a determinant of the brightness of a phosphor screen has been demonstrated. It was found experimentally that the optimum number of the particle layers producing maximum luminescence with minimum scattering is about 1.4.

In cathode-ray picture tubes, phosphors are used as electron-to-visible light transducers. The phosphor is a powder containing a wide distribution of sizes, usually between 1 and 30 μm. Layers of these phosphor particles make up the screen of the cathode-ray picture tube.

The calcium tungstate screen used in x-ray image intensifiers has been studied by Coltman, Ebbighausen, and Altar (1) with the view to determining the energy conversion efficiency from x-rays to light (5%) and the optical properties of the screen to optimize screen thickness. The optical properties of the screen of calcium halophosphate phosphor used in fluorescent lamps have been studied by Butler and Homer (2) and by Bo and Takeyama (3) in order to determine the optimum screen thickness for the absorption and scattering of the exciting ultraviolet light and of the emitted light.

The cathode-ray picture tube screen differs somewhat from the screens for x-ray image intensifiers and fluorescent lamps in the excitation mechanism, the kind of phosphors used, and the method of making the screen. In the case of the picture tube screen, the amount of the emitted light depends on the electron beam accelerating voltage and beam density; the penetration range of the electron beam into the phosphor crystal is determined by the accelerating voltage, and the amount of the emitted light at a given voltage depends on the beam density (4). When the phosphor particle size is larger than the electron penetration range, the light is produced in the particles arranged on the first, gun-side layer of the phosphor screen and must travel through the phosphor screen to reach the observer. Minimization of the absorption and scattering of the emitted light by the phosphor particles must be considered in determining the optimum thickness of a phosphor screen in a cathode-ray picture tube.

This report describes an optical and geometrical analysis of the phosphor screen in a cathode-ray picture tube. In the first part of the paper the optical properties of the turbid screen are discussed in order to determine the contribution of scattering and absorption by the phosphor particles. Then the number of particle layers in a screen is discussed. The optimum number is determined experimentally in the final section, where it is demonstrated to be a useful parameter in the construction of phosphor screens.

Key words: phosphor screen, particle size distribution, television, cathodoluminescence.

Optical Properties of the Turbid Screen

Although the individual phosphor particles are more or less transparent, the resulting screen is translucent or turbid. The absorption and scattering of this assembly of phosphor particles must be considered in determining the total optical properties of the viewing screen. It is difficult to estimate exactly the contribution of each individual phosphor particle; therefore, the macroscopic contribution of all the phosphor particles taken together are considered in this paper.

The optical properties of the turbid phosphor screen can be evaluated by Kubelka's model (5) which is illustrated in Fig. 1. The light is considered to be generated at $x = 0$. The light intensity at x can be expreseed by the following differential equations

$$\frac{di}{dx} = -(\alpha + \beta)i + \beta j \quad [1]$$

$$-\frac{dj}{dx} = -(\alpha + \beta)j + \beta i \quad [2]$$

where i and j are light intensities for the directions indicated in Fig. 1, and α and β are respectively absorption and scattering coefficients of the screen. The α and β differ essentially from the absorption coefficient

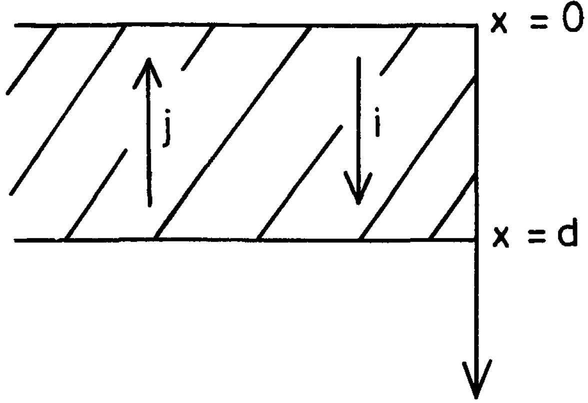

Fig. 1. Optical model of a turbid screen

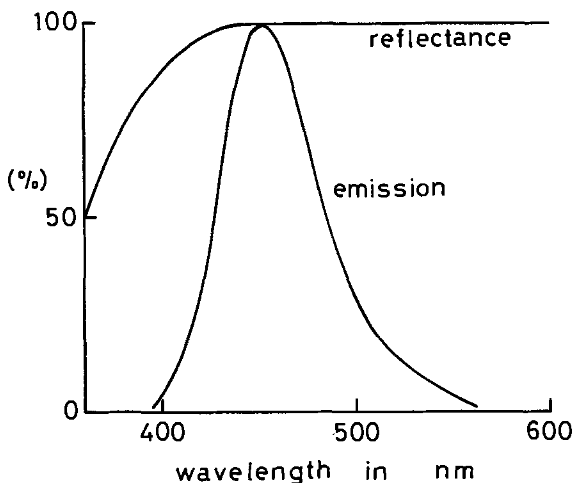

Fig. 2. Emission and reflectance spectra of ZnS:Ag:Cl blue phosphor. Reflectance spectrum was obtained with phosphor screen of 2 mm thickness that gives R_∞.

defined in the Lambert-Beer law and are determined with the phosphor screen. With the boundary conditions, $i = i_0$ at $x = 0$ and $j = 0$ at $x = d$, the solutions of Eq. [1] and [2] are hyperbolic functions, and the reflectance $R(x)$ and transmittance $T(x)$ of the screen of thickness x are expressed by the equations

$$R(x) = \frac{\sinh \gamma x}{a \sinh \gamma x + b \cosh \gamma x} \quad [3]$$

$$T(x) = \frac{b}{a \sinh \gamma x + b \cosh \gamma x} \quad [4]$$

where $a = 1 + \alpha/\beta$, $b = (a^2 - 1)^{1/2}$, $\gamma = \beta b = (\alpha + 2\alpha\beta)^{1/2}$. Then, R_∞ and T_∞ as $x \rightarrow \infty$ are given by

$$R_\infty = 1/(a + b), T_\infty = 0$$

Therefore

$$a = \frac{1}{2}\left(\frac{1}{R_\infty} + R_\infty\right), \quad b = \frac{1}{2}\left(\frac{1}{R_\infty} - R_\infty\right) \quad [5]$$

The ratio of the absorption to the scattering of the screen ($c = \alpha/\beta$) is given by

$$c = \frac{1 + R_\infty^2}{2R_\infty} - 1 \quad [6]$$

Thus, a, b, and c are calculated from Eq. [5] and [6] using R_∞ which is obtained by measurement of a thick phosphor screen.

Figure 2 shows the emission and reflectance spectra of a commercial ZnS:Ag:Cl blue phosphor used for color TV picture tube screen. The spectra were obtained using a thick screen (2 mm) which gives R_∞. As listed in Table I, the c-values calculated in the spectral region of the emission are small enough to neglect the $(\alpha/\beta)^2$ term for the optical properties of the phosphor screen. Similar results are obtained for green and red TV phosphors. Since, in the region of interest, $c \approx 0.00005 = \alpha/\beta$, $\beta >> \alpha$, and the solution of Eq. [1] and [2], integrated from 0 to d is

$$T(d) = (1 + \beta d)^{-1} \quad [7]$$

Equation [7] indicates that the optical properties of the cathode-ray picture tube screen in the spectral region of cathodoluminescence depend on the scattering coefficient of the screen.

Figure 3 shows a photograph of the particles of the commercial blue ZnS:Ag:Cl phosphor. The photograph was obtained with a scanning electron microscope at magnification of 10,000. Light scattering at the boundary surface of the particles can be assumed to be the source of the light scattering of the phosphor screen. In general, light scattering is a complex function of particle shape, roughness, and refractive index, and for our simple shapes it may be a simple function of the total surface area of the particles involved. The calculation of the total surface area of the phosphor powder is complicated by the fact that the particles are not of equal size, but, rather, are distributed in size. Estimation of the total surface area of the phosphor particles involved, therefore, must be made statistically in accordance with the particle size distribution.

Experimentally, several methods of determining particle size are available. It was found in all cases that the particle size distribution was not a normal (Gaussian) distribution but followed a log-normal distribution (6). Figure 4 shows the particle size distributions of the blue ZnS:Ag:Cl and the red Y_2O_2S:Eu phosphors on log-normal probability graph paper. The frequency (probability) of the distribution for each phosphor was calculated from sedimentation and microscopic data falling in a specified size interval. In the microscopic method it was required to count 200 particles, at least, to get a good reproducibility, ±5% error.

Geometric Arrangement of Particles in the Screen

Specific surface area of particles.—The total surface area, S, and the total weight, W, of the phosphor powder in a screen are calculated from the following equations (7, 8)

$$S = \int_0^\infty k_s n\phi^2 \, d\phi; \quad W = \int_0^\infty k_v \rho n\phi^3 \, d\phi \quad [8]$$

The specific surface area S_W ($= S/W$), therefore is given by

$$S_W = S/W = \frac{k_s}{k_v \rho} \int_0^\infty n\phi^2 \, d\phi \bigg/ \int_0^\infty n\phi^3 \, d\phi \ (\text{cm}^2/\text{g}) \quad [9]$$

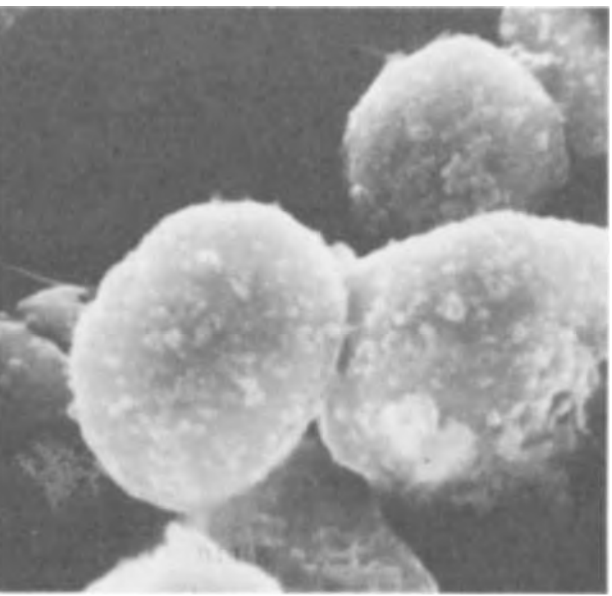

Fig. 3. Scanning electron micrograph of particles of ZnS:Ag:Cl blue phosphor under × 10,000 magnification.

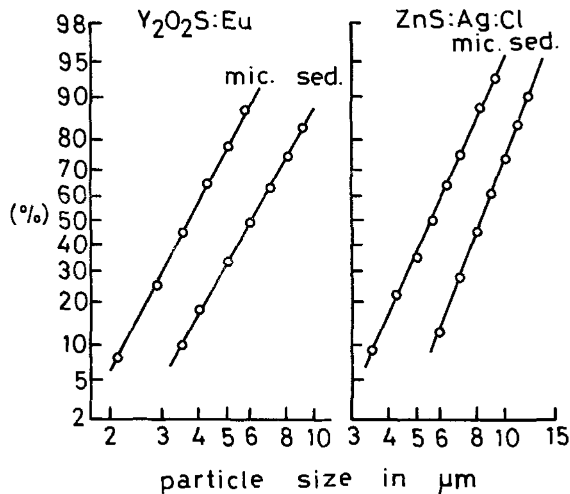

Fig. 4. Particle size distribution of Y_2O_2S:Eu and ZnS:Ag:Cl phosphors plotted on log-normal probability paper. Distribution for each phosphor was obtained by calculation from weight sedimentation (sed.) and microscopic (mic.) data.

$$S_W = \frac{k}{\rho} (\bar{\phi}_2)^{-1} \text{ (cm}^2\text{/g)} \quad [10]$$

where

$$\bar{\phi}_2 = \int_0^\infty n\phi^3 \, d\phi \Bigg/ \int_0^\infty n\phi^2 \, d\phi \text{ (cm)} \quad [11]$$

ρ is density, ϕ is particle size, and $k = k_s/k_v$. Thus, the specific surface area of the phosphor powder, S_W, is calculated by the mean surface particle size $\bar{\phi}_2$. The light scattering in the phosphor screen is connected directly to the mean particle size $\bar{\phi}_2$ by the relation $\beta \sim S_W \sim (\bar{\phi}_2)^{-1}$. Consequently, it is reasonable to use the mean surface particle size $\bar{\phi}_2$ in discussing the geometry and optical properties of the phosphor screen, as will be verified by Fig. 9.

The number of phosphor layers.—The total number of phosphor particles (N) in a screen of screening weight (w) on a unit screening area is given by

$$N = 6w \Bigg/ \left(\pi\rho \int_0^\infty n\phi^3 \, d\phi \right) \text{ (cm)} \quad [12]$$

The number of the particles which are densely arranged in a single layer on unit screening plate is given by

$$\frac{N}{L} = 2/\sqrt{3} \int_0^\infty n\phi^2 \, d\phi \text{ (cm}^{-2}\text{)} \quad [13]$$

Therefore, the number of phosphor layers (L) in a screen of the screening weight w (g phosphor/cm^2) is calculated to be

$$L = 1.65 \, w/(\rho\bar{\phi}_2) \quad [14]$$

If the shape factor varies, the factor 1.65 would be different from 1.65. It is important to note that L is a statistical number defined in terms of $\bar{\phi}_2$ and is not easily related to a physical description of the actual physical arrangement in a real screen. It is nonetheless a useful concept in describing the optical properties of the phosphor screen.

Now we consider the total surface area of the phosphor particles densely arranged in a single layer on the faceplate of the cathode-ray tube. The area of the faceplate is fixed. When the phosphor particles of number n having particle size ($\bar{\phi}_2$) are densely arranged in a single layer on the faceplate, the total surface area (S_1) of the n particles is expressed by

$$S_1 = \pi n (\bar{\phi}_2)^2 \quad [15]$$

The total surface area for other sizes, $\bar{\phi}_2'$, which are g times $\bar{\phi}_2$ (bigger or smaller), *i.e.*, $\bar{\phi}_2' = g\bar{\phi}_2$, can be calculated. The number of particles of size $g\bar{\phi}_2$ required to arrange a single-layer screen on the faceplate is $g^{-2}n$. Then, the total surface area, S_1', for particle size $g\bar{\phi}_2$ is seen to be

$$S_1' = g^2 n\pi\bar{\phi}_2^2 g^{-2} = \pi n (\bar{\phi}_2)^2 = S_1 \quad [16]$$

Thus, the surface area per phosphor layer is not only a constant, but is independent of particle size.

Light out from a multilayered screen.—When the light scattering in the phosphor screen is proportional to the total surface area of the phosphor particles, Eq. [7] can be rewritten as

$$T(L) = \frac{1}{1 + \beta L} \quad [17]$$

When the cathodoluminescence B_o is produced in the particles arranged on the first, gun-side layer of the phosphor screen, the observed screen brightness is defined relatively as $\frac{B}{B_o}(L)$ in order to be consistent with the relation $T(L) = i/i_o$ where i is defined as in Eq. [1]. Then, the screen brightness $\frac{B}{B_o}(L)$ can be expressed as

$$\frac{B}{B_o}(L) = \frac{1}{1 + \beta L} \quad [18]$$

Equation [18] shows the dependence of the screen brightness on the number of phosphor layers. A screen brightness function, $(1 - B_o/B)$, can be defined as

$$1 - \frac{B_o}{B} = -\beta L \quad [19]$$

Note that B_o used in this report is a different arbitrary constant for each screen series because of different particle size distributions and excitation conditions and B and B_o are never measured in absolute units but in terms of photomultiplier readings.

Experimental

Phosphors and screening preparation.—In the study of phosphor screens of different particle size, the phosphors should be similar in the dispersion of their size distribution and in crystal form in order to avoid variances due to the packing of the phosphor particles in the screen. A yellow emitting (Zn,Cd)S:Ag:Cl phosphor was selected in this study because it was relatively easy to control both the dispersion and crystal form of the powder. Phosphors having four different mean particle sizes ($\bar{\phi}_2$ = 6, 10, 15, and 25 μm) were prepared by firing the mixture of ZnS and CdS (1:1 ratio) at various temperatures. X-ray diffraction analysis shows that all of the phosphors were of the hexagonal crystal form (zinc wurtzite). The particle size distribution of the phosphors was determined by the weight sedimentation method. The mean particle size, $\bar{\phi}_2$, was calculated from these sedimentation data. Table II gives the statistical parameters of the phosphor particles. All of the dispersions, σ^2, of the particle size distribution were about the same.

Table II. Statistical parameters of particle size distribution of (Zn,Cd)S:Ag:Cl phosphors used to screen study

$\bar{\phi}_3$ is the mean weight particle size determined from weight sedimentation data. σ is standard deviation of log-normal distribution.

Sample No.	1	2	3	4
$\bar{\phi}_2$ (μm)	6	10	15	25
$\bar{\phi}_3$ (μm)	7	11	19	29
σ	0.37	0.35	0.37	0.35

The phosphor screen was prepared as follows. The phosphor powder was suspended in 1% potassium silicate solution (Kasil No. 1). Then the phosphor suspension was poured into 0.5% barium nitrate solution having glass plates on the bottom of the container. The heights of barium nitrate solution were 10 cm for 6 and 10 μm powders and were 20 cm for 15 and 25 μm powders. The screening weight of the phosphor was determined by weighing the glass plate before and after screening.

Measurements.—The phosphor screens of different screening weights were mounted in a demountable cathode-ray apparatus in which eight screens could be mounted at one time. The screen brightness, B, in relative units, under excitations of 10, 17.5, and 25 kV electron beams, were measured at the glass side (transmitted light) with a Spectraspot Brightness-Photometer. The purpose of the measurements was to determine the dependence on w and L. Since the raster size and electron beam current were not under control, the relationship between the brightness, B, and accelerating voltage cannot be seen in the following results.

Results and Discussion

Particle size and electron penetration range.—Figures 5 and 6 show the results of the screen brightness tests under 10, 17.5, and 25 kV electron beam excitation for phosphor particle sizes $\bar{\phi}_2 = 6$ and 10 μm. When the screen was made with 6 μm phosphor powder, the optimum screen thickness (mg/cm²) shifted to high screening weight with increase in the accelerating voltage (Fig. 5). With phosphor powders above 10 μm, however, the optimum thickness did not change with accelerating beam voltage (Fig. 6).

These results indicate decidedly that the electrons of energy less than 25 kV do not penetrate through the first particle layer of the phosphor screen (gun side) when the screens are composed of particles larger than 10 μm (Fig. 7a). If the phosphor particle size is smaller than the electron penetration depth, the electron beams penetrate the second particle layer through the first particle layer, resulting in a shift of the optimum screening weight with the beam accelerating voltage (Fig. 7b). It can be said that the penetration depth of 25 kV electron beams into (Zn,Cd)S:Ag:Cl phosphor is about 10 μm, which coincides with the penetration range estimated by extrapolation of Feldman's results (9).

Optimum number of phosphor particle layers.—Figure 8 shows the normalized relative screen brightness

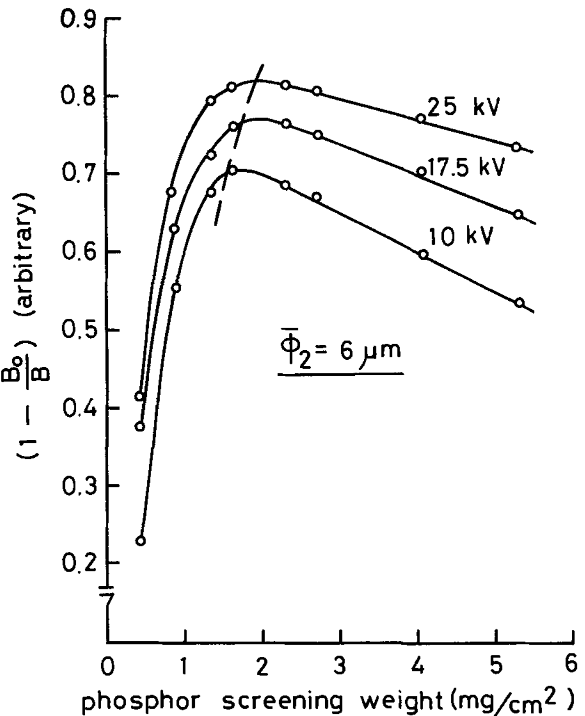

Fig. 5. Screen brightness function ($1 - B_0/B$), in arbitrary units, of phosphor screens of 6 μm powder as a function of screening weight. B_0 is an arbitrary constant which is different for each beam accelerating voltage. Variable is accelerating voltage.

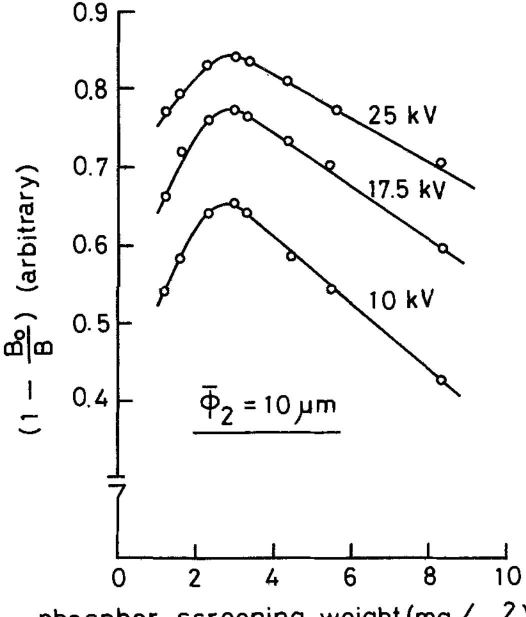

Fig. 6. Screen brightness function, ($1 - B_0/B$), of phosphor screens of 10 μm powder as a function of screening weight. B_0 is arbitrary constant which is different for each beam accelerating voltage. The screens were excited by electron beams of 10, 17.5, and 25 kV.

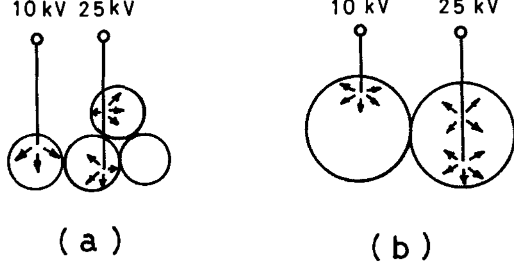

Fig. 7. Penetration model of 10 and 25 kV electron beams into small phosphor particles (a) and into large phosphor particles (b).

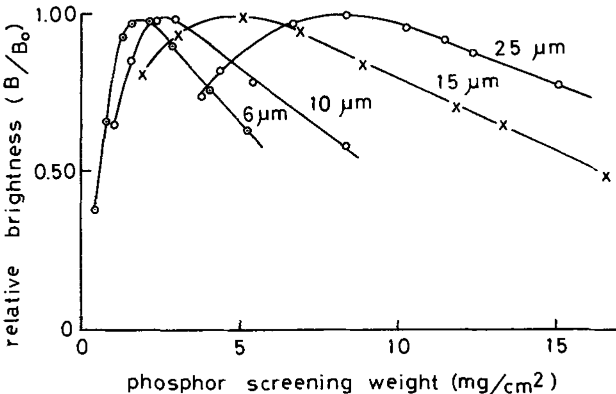

Fig. 8. Normalized relative brightness, (B/B_0), of phosphor screens for various particle size powders as a function of the screening weight. (Each curve is normalized at its maximum brightness B_0.)

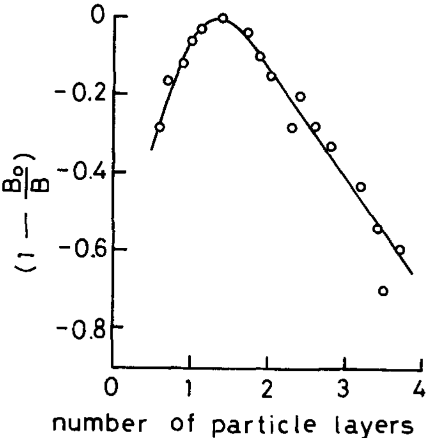

Fig. 9. Brightness function, $(1 - B_0/B)$, of phosphor screens for various particle size powders as a function of L, the calculated number of particle layers. B_0 is a different constant for each particle size powder screen and is assumed to be unity for $L = 1.4$.

for different phosphor particle sizes. It can be seen that the optimum screening weight varies with phosphor particle size as follows: 2.0 mg/cm^2 for 6 μm, 2.8 mg/cm^2 for 10 μm, 4.3 mg/cm^2 for 15 μm, and 8 mg/cm^2 for 25 μm. If an optimum phosphor screen requires a certain number of phosphor particle layers, higher screening weight is required for large particle size. Figure 9 shows the same data of Fig. 8 but the abscissa is expressed in terms of L, the number of particle layers, instead of the screening weight. All of the data fit one curve from which the optimum value of L is calculated to be 1.4. For screens having more than 1.4 layers, the brightness decreases with the increase in L in accordance with Eq. [19]. The scattering coefficient per phosphor layer (β) is determined from the slope to be 0.28.

Demonstration of the significance of L.—In order to see the meaning of the optimum number of phosphor particle layers, a screen containing a P4 phosphor (used in B&W television) was studied. A P4 phosphor is a white-emitting mixture of a blue ZnS:Ag:Cl (455 nm peak) and a yellow (Zn,Cd):Ag:Cl (550 nm peak) phosphor. Since the absorption band of the yellow phosphor extends to the spectral region of the blue phosphor luminescence (Fig. 10), yellow phosphor particles laid down under the blue emitting particles in the screen should absorb the blue luminescence, resulting in a color shift to yellow; Fig. 11 shows the screen brightness function, $(1 - B_0/B)$, at 455 and 550 nm of P4 phosphor screens of various L-values. B_0 is normalized at maximum intensity for each curve. The mean surface particle size of the phosphor powder was 9 μm. This result can be interpreted as follows. When the screening weight is increased to a value

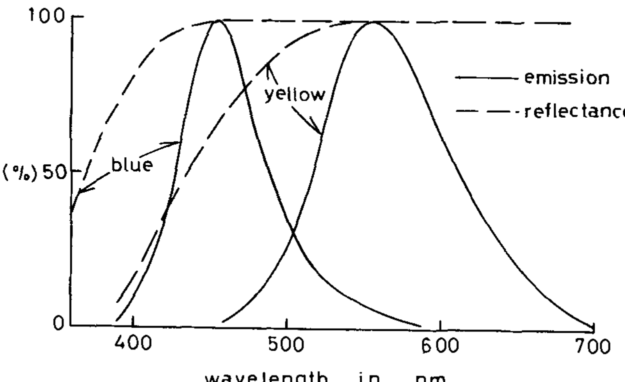

Fig. 10. Emission and reflectance spectra of the P4 blue and yellow sulfide phosphors used in black and white television screen.

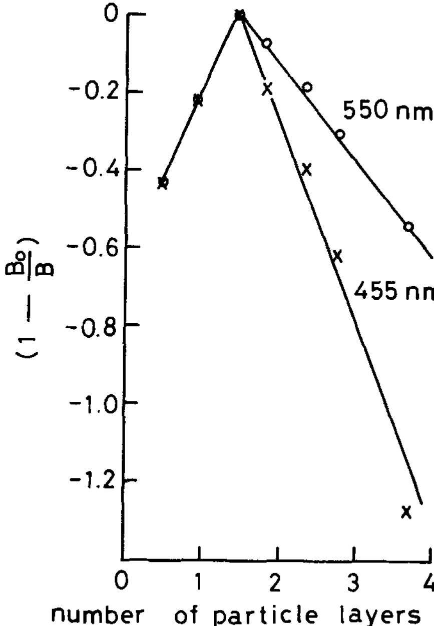

Fig. 11. Screen brightness function, $(1 - B_0/B)$, at 455 and 550 nm of P4-phosphor screens as a function of the number of particle layers, L. B_0 is a different constant for each color brightness and is assumed to be unity for $L = 1.4$.

corresponding to $L = 1.4$ layers, the luminescent color of the screen does not change, indicating that both the blue and yellow phosphor particles just fill in the uncovered spaces on the screen plate; consequently the points for $L < 1.4$ fall on one line in Fig. 11. Above the optimum 1.4 layers, excess yellow-emitting particles on the viewing side of the screen absorb the blue luminescence, giving rise to two lines in Fig. 11 for 550 and 455 nm emission. Since neither phosphor absorbs yellow luminescence, the 550 nm intensity decreases with the slope determined from the curve in Fig. 9. The steeper slope of the 455 nm curve in Fig. 11 is due to absorption of the blue light, plus scattering.

These results (Fig. 9 and 11) definitely indicate that the extra particles in the screens with more than 1.4 layers are not involved in the cathodoluminescence and merely contribute to the scattering and absorption of the emitted light. The optimum number of particle layers, therefore, is the maximum number of particle layers to cover the faceplate with minimum scattering.

The fact that continuum model appears to apply to the slopes of the curves having more than 1.4 particle layers in Fig. 9 and 11 indicates that there is multiple scattering of the generated light even though there are only a few particle layers.

The optimum number of particle layers may vary slightly with the change in the shape factor of the phosphor particles (crystal form), differences in the dispersion of the particle size distribution, and in the screening method especially when one includes an aluminum reflecting layer. In a practical phosphor screen, therefore, a more accurate value of L (optimum) should be determined experimentally in each case.

Summary

It has been shown that the optical properties of the screen of a cathode-ray picture tube are mainly governed by scattering by the phosphor particles. It has been shown that the total surface area of particles arranged in a multilayered screen depends only on the number of layers of the phosphor particles and not on the particle size. The light output is shown theoretically and experimentally to depend on a statistically defined number of layers, L. Approximately 1.4 particle layers represent the optimum screen construc-

tion; the optimum particle size is equal to the electron penetration depth, 10 μm at 25 kV.

The Kinetics of Silicon Deposition on Silicon by Pyrolysis of Silane

A Mass Spectrometric Investigation by Molecular Beam Sampling

R. F. C. Farrow

Ministry of Defence, Royal Radar Establishment, Malvern, Worcestershire, England

ABSTRACT

The kinetics of silane pyrolysis on a silicon (111) surface has been investigated mass spectrometrically by molecular beam sampling over the silane pressure range 1×10^{-5} to 4×10^{-1} Torr and specimen temperature range 20°-1200°C. Silane decomposition was found to occur by the mechanism

$$SiH_4\ (gas) \rightarrow SiH_4\ (adsorbed) \rightarrow Si + 2H_2$$

where both the amount of adsorbed silane and decomposition rate depend linearly on silane pressure. The activation energy for decomposition was 17 ± 2 kcal mole^{-1} and the surface reaction efficiency (α) was found to obey the equation

$$\alpha = 5.45 \exp(-17 \times 10^3/RT)$$

At silane pressures $P_S{}^o > 5 \times 10^{-3}$ Torr, small quantities of disilane formed by the bimolecular surface reaction

$$SiH_4(ads) + SiH_4(ads) \rightarrow Si_2H_6 + H_2$$

were detected with an activation energy for production of 56 ± 6 kcal mole^{-1}. Measurements of silicon growth rate as a function of silane pressure supported the first-order mechanism for decomposition. The condensation coefficient (σ) of silicon adatoms, determined from measurements of the silicon growth rate as a function of temperature and the surface reaction efficiency, was found to be less than 0.3 over the entire temperature range 700°-1200°C, indicating that the majority of silicon adatoms were desorbed. This behavior was accounted for on the basis of a step flow model for silicon growth and an activation energy for surface diffusion of 36 ± 6 kcal mole^{-1} derived. Addition of arsine to the silane was found to inhibit silane pyrolysis. The measurements suggest an activation energy of 18 ± 3 kcal mole^{-1} for desorption of arsenic adsorbed on the silicon (111) surface. Additions of more than 1% diborane to the silane, on the other hand, resulted in a significant increase in silane reaction efficiency.

The pyrolysis of silane (SiH_4) on silicon is a reaction widely used in the electronics industry in the production of homoepitaxial silicon layers. Several investigations have been reported (1-4) on the vacuum deposition of silicon on silicon by silane pyrolysis but the conclusions of the various investigators concerning the kinetics of the decomposition reaction and the pressure dependence of silicon growth rate differ widely. Thus, activation energies for silane decomposition ranging from 10 kcal mole^{-1} (3) to 37 kcal mole^{-1} (1) have been reported. Moreover, there is considerable disagreement as to the mechanism and order of the decomposition reaction. Joyce and Bradley (1) found the growth rate to vary as silane pressure $P_S{}^{1.3}$ whilst more recent investigations (3, 4) have revealed a linear dependence of growth rate on pressure suggesting a first-order decomposition reaction.

Key words: silicon, silane, reaction kinetics.

No investigations have been reported in which the gas phase products of silane pyrolysis, as a function of specimen temperature and silane pressure, have been detected, identified, and recorded. The aim of the present work was to carry out such an investigation, including a study of the influence of arsine and diborane on silane pyrolysis, and to correlate reaction kinetic data with silicon growth rate measurements in an attempt to resolve the existing disagreements mentioned above.

Experimental Procedure

The pyrolysis of silane was studied using the molecular beam sampling system shown schematically in Fig. 1. The system incorporated three apertures, a 0.12 × 10 mm sampling slit (A_1) and two 1 × 10 mm beam collimating slits (A_2 and A_3). High speed differential pumping of the two collimating chambers and the detection chamber was provided by three 1500 liter sec^{-1} oil diffusion pumps (P_1, P_2, P_3), each fitted with molecular sieve traps, and a thermoelectrically cooled chevron baffle to prevent back diffusion of the silicone (Type 705) oil. Base pressures in the low 10^{-10} Torr pressure range, with negligible contribution from hydrocarbon species, were achieved in all four chambers after system bakeout at 300°C. Valve V was closed after bakeout.

The molecular beam of products was detected by an Electronic Associates, Inc. Model 250A quadrupole mass spectrometer (ion source M). Two methods of discriminating the molecular beam of products from the isotropic background were used. In the first, used for all product species except those of disilane which were at a very low concentration, the molecular beam was modulated at 10 Hz by a 12-blade chopper wheel (C) rotated by a magnetic rotary drive. The modulated ion currents of molecular beam species were then monitored by phase-sensitive detection (psd). Pressures of products in the reaction chamber down to 10^{-5} Torr could be conveniently detected by this method. For the detection of the very weak disilane species (pressures in the reaction chamber ranging from 10^{-5} to 10^{-7} Torr), the molecular beam ion currents could be measured with greater statistical accuracy, than by continuous psd, by recording the ion currents of the species with the chopper in the open and closed positions and taking the difference as the molecular beam contribution.

Initial silane pressures in the reaction chamber in the range 10^{-3} to 1 Torr were measured using a capacitance manometer. Silane and dopant gas pressures below 10^{-3} Torr were derived from an ion gauge reading of pressure in the first collimating chamber, the relation between the reaction chamber pressure and that in the collimating chamber having been established from a previous calibration experiment. This method eliminated the need for ion gauge filaments in the reaction chamber which would have been undesirable from the point of view of pyrolysis on the filament and other possible side reactions. The gases used in these experiments were supplied by the Mattheson Company, Inc. The silane was of semiconductor grade (>50 ohm-cm deposited material) used undiluted; the arsine and diborane were also of semiconductor grade, diluted to 5% in helium.

The silicon specimens used in this work were bars, 20 × 3 × 0.4 mm, of 10 ohm-cm, P-type material with the 20 × 3 mm faces parallel to the (111) plane to within ±3°. They were supplied by Chisso, Inc. Both major faces of the bar were polished using the Monsanto method. The chemical precleaning treatment before loading consisted of ultrasonic cleaning in a solvent followed by several cycles of a nitric acid/ethanol/HF cleaning procedure (6). The specimens were held in thick, high-purity tantalum clips and heated resistively. Specimen temperatures were measured using a partial radiation optical pyrometer and were corrected for emissivity using the data of Allen (7).

The specimen was heated to 1250°C in a background pressure of less than 10^{-9} Torr for a few minutes before each run to remove initial oxide and carbon contamination of the silicon surface (5).

The thickness of deposited epitaxial silicon layers was determined using three independent methods: (*i*) measurement of the thickness of the specimen before and after deposition, (*ii*) measurement of the dimensions of stacking fault defects which originated at the substrate-layer interface, and (*iii*) the bevel-stain technique. Agreement between the three methods was well within experimental errors.

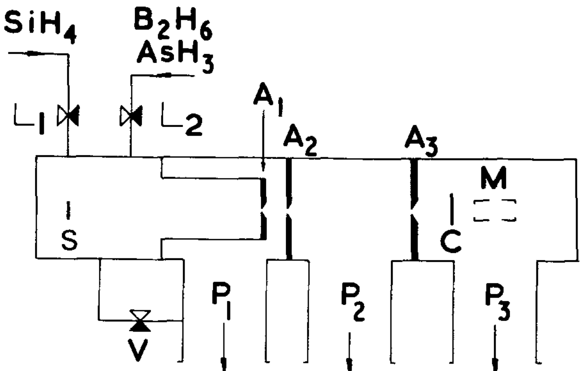

Fig. 1. Schematic diagram of molecular beam sampling system

Results and Analysis of Data

Molecular beam sampling of silane pyrolysis.—The pyrolysis of silane was monitored over the specimen temperature (T_S) range 20°-1200°C and at silane (reactant) pressures in the range 10^{-5} to 4×10^{-1} Torr. The temperature dependence of product species for an initial silane pressure at 20°C of $P_S{}^o = 10^{-4}$ Torr is shown in Fig. 2. The onset of pyrolysis is marked by a rise in the molecular hydrogen signal and a simultaneous fall in each of the Si, $SiH_n (n = 1 \text{ to } 4)$, and H signals. The relative ratios between the Si, SiH_n, and H signals did not change significantly with temperature, indicating that unreacted silane and molecular hydrogen were the only detectable products in the reaction chamber for this value of $P_S{}^o$ and that the Si, SiH_n, and H signals could be attributed to the fragmentation of silane in the mass spectrometer ion source. The observation of molecular hydrogen as a pyrolysis product was consistent with the over-all decomposition reaction

$$SiH_4 \rightarrow Si + 2H_2$$

Surface reaction efficiencies were derived both from the H_2 product signal and the decrease in the unreacted silane signal on the basis of the following arguments.

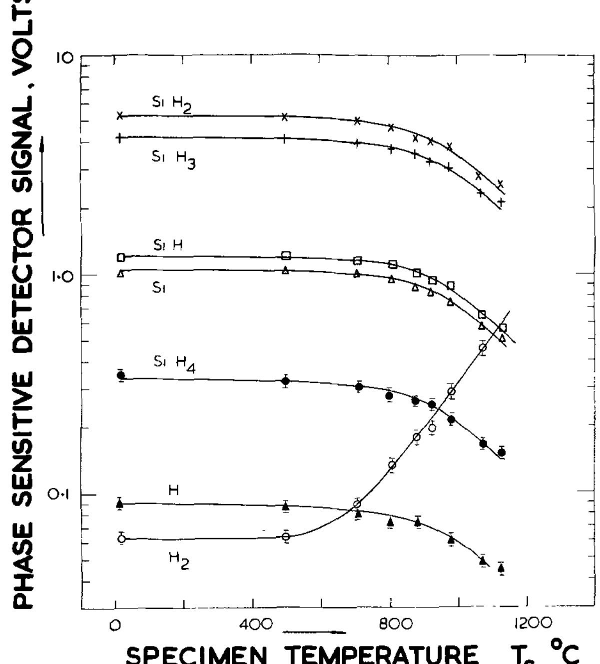

Fig. 2. Temperature dependence of molecular beam products at $P_S{}^o = 10^{-4}$ Torr.

We define the surface reaction efficiency α as the probability that a silane molecule decomposes on striking the silicon surface. Furthermore, let

P_S^T, P_H^T be the partial pressure of silane and hydrogen, respectively, in the reaction chamber at a specimen temperature T_S.

R_i the inlet rate of silane into the reaction chamber in molecules per unit time.

n_S, n_H the rate of collisions of silane and hydrogen molecules, respectively, with the specimen in molecules per unit area per unit time per unit pressure.

A_S the total effective reaction surface area (0.8 cm^2 in the present case).

A_o the effective area (including conductance factor) of the sampling slit (1.2×10^{-2} cm^2 in the present case).

S_S, S_H the speed of the sampling slit in molecules per unit time per unit pressure for silane and hydrogen, respectively.

Then, after steady-state conditions are attained in the reaction chamber, for silane

$$R_i - \alpha n_S P_S^T A_S - S_S P_S^T = 0 \quad [1]$$

and for hydrogen

$$2\alpha n_S P_S^T A_S - S_H P_H^T = 0 \quad [2]$$

Now with pressures P_S^T, P_H^T sufficiently low (*i.e.*, $<10^{-3}$ Torr) that the mean free path λ in the reaction chamber is much greater than the chamber dimensions ($\sim$5 cm), interaction between molecules can be neglected and molecules striking a surface in the reaction chamber are directionally randomized. Under these conditions, $n_S P_S^T$, $n_H P_H^T$, $S_S P_S^T$, and $S_H P_H^T$ can be replaced by

$$\frac{P_S^T}{\sqrt{2\pi m_S kT}}, \frac{P_H^T}{\sqrt{2\pi m_H kT}}, \frac{P_S^T A_o}{\sqrt{2\pi m_S kT}}, \frac{P_H^T A_o}{\sqrt{2\pi m_H kT}}$$

respectively, where m_S and m_H are the molecular masses of silane and hydrogen, respectively. Furthermore, since R_i remained at a steady value determined by the initial setting of the leak value for a particular initial silane pressure P_S^o

$$R_i = \frac{P_S^o A_o}{\sqrt{2\pi m_S kT}} \quad [3]$$

Hence from Eq. [1] and [3]

$$\alpha = \frac{A_o}{A_S}\left(\frac{P_S^o}{P_S^T} - 1\right) \quad [4]$$

and from Eq. [2]

$$\alpha = \frac{2A_o}{A_S}\left(\frac{P_H^T}{P_S^T}\right) \quad [5]$$

Equations [4] and [5] were used to derive α as a function of temperature and pressure from the sampled H_2 and SiH_4 species. The relationship between the (sampled) molecular beam intensities of these species and the partial pressures of H_2 and SiH_4 in the reaction chamber was established from a previous calibration experiment. Significant departure from linearity in the relationship occurred only at P_S^T, $P_H^T > 2 \times 10^{-2}$ Torr. Derivation of α from Eq. [5] involved a determination of the relative sensitivity of the mass spectrometer for H_2 and SiH_4. A known 3% SiH_4-97% H_2 gas mixture was used in this determination.

Values of α, calculated using Eq. [4], are plotted as a function of silane pressure at three different temperatures in Fig. 3. It is seen that for $P_S^T < 10^{-3}$ Torr, α is independent of pressure but apparently decreases with P_S^T for $P_S^T > 10^{-3}$ Torr. Values of α calculated using Eq. [5] agreed well at all pressures with those calculated using Eq. [4] and showed an identical pressure dependence to that shown in Fig. 3. We believe that this pressure dependence is due to a breakdown in

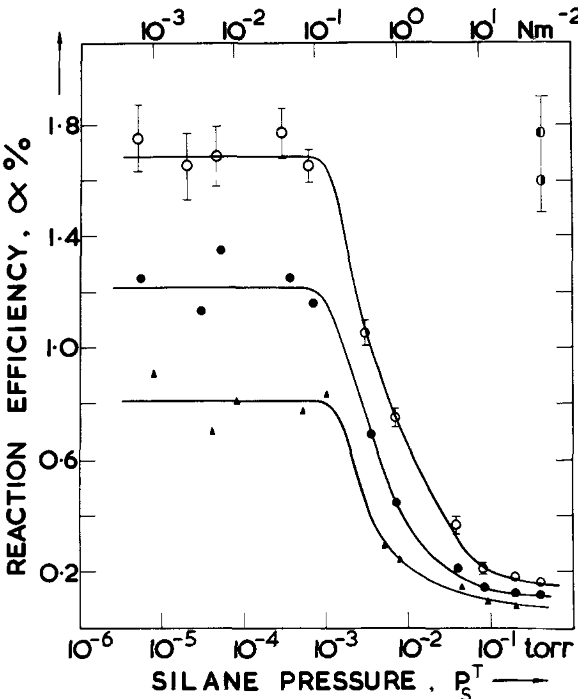

Fig. 3. Surface reaction efficiency, α, for silane pyrolysis as a function of pressure. ○, Calculated from Eq. [4], T_S = 1156°C; ◑, calculated from Eq. [6], T_S = 1156°C; ◐, calculated from Eq. [8], T_S = 1156°C; ●, calculated from Eq. [4], T_S = 1076°C; ▲, calculated from Eq. [4], T_S = 987°C.

validity of Eq. [4] and [5] rather than to a genuine departure from the first-order reaction mechanism indicated by the pressure independent reaction efficiency below $P_S^T = 10^{-3}$ Torr. Equations [4] and [5] were derived on the basis of molecular flow conditions in the reaction chamber. However, at pressures $P_S^T > 10^{-3}$ Torr in the reaction chamber, the mean free path for silane will become less than the diameter ($\sim$ 5 cm) of the pipework forming the walls of the reaction chamber. Thus, over the pressure range 10^{-3} Torr (Knudsen number $\lambda/d = 1$) to 10^{-1} Torr ($\lambda/d = 10^{-2}$), there will be a transition from molecular to streamline flow of molecules between the silane entry port and sampling slit (18). The existence of streamline flow in the reaction chamber is supported by the observation that, at pressures $P_S^T > 10^{-3}$ Torr, silicon deposition occurred not only on the specimen but on one of the specimen clips, the one further down line in the direction of streamline flow between the silane entry port and the sampling slit. As suggested in the discussion, this observation can be explained by transport of silicon from the specimen down the streamlines to the clip.

Under streamline flow conditions, it is expected that only silane molecules within the boundary layer of flow over the specimen will be able to diffuse to the specimen surface and that a considerable fraction of silane molecules entering the reaction chamber will bypass the specimen on streamlines outside the boundary layer. The fractional decrease in silane signal observed when the specimen is heated to a given temperature will thus be less than in the molecular flow regime since the flow of silane molecules outside the boundary layer will remain unaffected by the specimen temperature but will contribute to the sampled silane signal. For the same reason, the ratio of the H_2 to silane signals at a given temperature will be less than in the molecular flow regime. Thus the transition from molecular to streamline flow would account for the apparent systematic decrease in α with pressure shown in Fig. 3.

A quantitative estimate of the effect of streamline flow in the reaction chamber on the reaction efficiency

derived from the sampled species was made in the following way: let

A_T be the cross-sectional area of streamline flow over the specimen ($A_T = \pi D^2/4 = 19.6$ cm^2 in the present case, since silane was carried to and from the specimen in 5-cm diameter pipework).

A_B the cross-sectional area of flow within the specimen boundary layer.

$I_H{}^T$ the mass spectrometer signal for the H_2 pyrolysis product at a specimen temperature T_S.

$I_S{}^T$ the mass spectrometer silane signal at a specimen temperature T_S.

$I_S{}^o$ the mass spectrometer silane signal at ambient temperature.

Q_H/Q_S the mass spectrometer sensitivity ratio for H_2 and silane molecules.

Then

$$\frac{I_S{}^o}{I_S{}^T} = \frac{R_i}{R_i - \dfrac{A_B}{A_T}\alpha' R_i} = \frac{1}{1 - \dfrac{A_B}{A_T}\alpha'} \quad [6]$$

where α' is the proportion of silane flow in the boundary layer region which is decomposed and is given by

$$\alpha' = \frac{\alpha n_S P_S{}^T}{S_S P_S{}^T + \alpha n_S P_S{}^T} = \frac{\alpha A_S}{A_o + \alpha A_S} \quad [7]$$

where $P_S{}^T$ is the silane pressure in the boundary layer and can safely be assumed equal to that outside the layer for the low volumetric flow rates and reaction efficiencies in the present experiments. In deriving Eq. [7], silane molecules in the boundary layer were assumed to diffuse randomly to the specimen surface. In addition, the conductance of the source slit at silane pressures of $P_S{}^T \sim 1$ Torr was assumed to be the same (0.14 liter sec^{-1}) as in the molecular flow regime. The validity of this latter assumption was confirmed by molecular beam intensity measurements which showed that the source slit conductance was constant up to $P_S{}^T \sim 2$ Torr. Equation [6] becomes equivalent to Eq. [4] in the limit when all molecules entering the reaction chamber may take part in random diffusion to the specimen surface, *i.e.*, for $A_B/A_T = 1$.

In the case of the H_2 pyrolysis product we have

$$\frac{I_H{}^T}{I_S{}^T} = \left\{ \frac{2\alpha' R_i A_B/A_T}{R_i - \dfrac{A_B}{A_T}\alpha' R_i} \right\} \frac{Q_H}{Q_S} = \frac{2}{\dfrac{A_T}{A_B \alpha'} - 1} \cdot \frac{Q_H}{Q_S} \quad [8]$$

which becomes equivalent to Eq. [5] in the case of $A_B/A_T = 1$. An estimate of A_B/A_T in the streamline flow regime at $P_S{}^T \sim 1$ Torr was made on the basis of the expected boundary layer width, given by (14)

$$\delta \sim \sqrt{\frac{l\nu}{U}} \simeq 2.2 \text{ cm} \quad [9]$$

where l was taken as the distance (0.9 cm) from the leading edge of the specimen clip to the center of the specimen; ν the kinematic viscosity for silane at 1 Torr, 20°C, was 59 cm^2 sec^{-1}; and U the flow velocity was 10.7 cm sec^{-1} at the specimen position for the 0.14 liter sec^{-1} silane flow.

Assuming the boundary layer cross section to be circular with a diameter of 2δ, a value of $A_B/A_T = 0.77$ would be expected. However, this value can be considered only as an order of magnitude estimate since Eq. [9] is strictly applicable only to flow over an infinitely wide flat plate and takes no account of edge or end effects which are likely in the case of a finite specimen. It is possible, for example, that $A_B/A_T = 0.77$ is an overestimate as a result of "pinch-in" of the boundary layer over the specimen which was both thinner and less wide than the leading specimen clip. Moreover, since both the specimen and clips were rectangular in cross section, the assumption of a circular cross-section boundary layer might also be expected to lead to an overestimate of A_B/A_T. We have found, in fact, that reaction efficiencies derived from sampling data in the streamline flow regime using Eq. [6] and [8] with $A_B/A_T = 0.25$ (see the two half-shaded points in Fig. 3) agree well with values calculated using Eq. [4] and [5].

It may be concluded from the molecular beam sampling data that the invariance of reaction efficiency over the silane pressure range 10^{-5} to 10^{-3} Torr is consistent both with a linear variation of adsorbed silane with pressure and with the first-order, unimolecular surface reaction

$$SiH_4 \text{ (adsorbed)} \rightarrow Si + 2H_2$$

Furthermore, the preceding calculations of reaction efficiency in the streamline flow regime show that the sampling data at pressures above $P_S{}^T = 10^{-3}$ Torr are not necessarily inconsistent with the view that this mechanism is valid up to $P_S{}^T \sim 1$ Torr.

The broad line in Fig. 4 shows the temperature dependence of silane reaction efficiency measured at various initial silane pressures $P_S{}^o$ and plotted on an Arrhenius scale. The line shown was the best fit (within 5%) to the α values derived using Eq. [4] and [5] and represents the equation

$$\alpha = 5.45 \exp\left[\frac{-17 \times 10^3}{RT_S}\right] \quad [10]$$

where R is the molar gas constant, 1.98 cal mole^{-1} deg^{-1}. Moreover, values of α (calculated using Eq. [6] and [8] with $A_B/A_T = 0.25$) derived from sampling data in the streamline flow region at $P_S{}^o = 4.10^{-1}$ Torr were also well represented by Eq. [10]. The temperature dependence of the apparent reaction efficiencies at $P_S{}^o = 2.10^{-1}$ Torr calculated using Eq. [4] are also shown in Fig. 4 for the purpose of comparison with the corrected reaction efficiencies represented by the broad line. It is seen that whilst the effects of streamline flow lead to an apparent reduction in reaction efficiency, they have no effect on the slope of the Arrhenius plot.

Disilane $(SiH_3)_2$ was detected as a pyrolysis product at silane pressures $P_S{}^o > 5 \times 10^{-3}$ Torr. The molecular beam ion currents of disilane species detected at $P_S{}^o = 1.05 \times 10^{-1}$ Torr as a function of specimen temperature are summarized in Table Ia and the total molecular beam ion currents for silane and disilane recorded at $T_S = 1123$°C at four initial silane pressures are given in Table Ib. The tabulated ion currents have been cor-

rected for background ion currents recorded at T_S = 20°C.

The relative intensities of disilane species observed at T_S = 1123°C are compared with Potzinger and Lampe's (8) disilane mass spectrum in the last two lines of Table Ia. The agreement is generally good, considering that errors in the very small disilane ion currents recorded in this work are expected to be about 5%. The disilane species at 63 and 64 amu, not recorded by Potzinger and Lampe, can be assigned to combinations of disilane species containing Si^{29} and Si^{30}.

In order to extract reaction kinetic information from the pressure dependence of the detected disilane species, two main correction factors had to be taken into account. Firstly, at the values of $P_S°$ ($>5 \times 10^{-3}$ Torr) at which disilane was detected, significant attenuation of the sampled molecular beam species occurred as a result of collisions between the beam molecules and background gas (predominantly silane) in the first collimating chamber. Moreover, since the molecular diameter for disilane is greater than for silane, this attenuation will result in a preferential elimination of disilane from the sampled beam. The detected silane and disilane total ion currents have therefore been corrected (to a first approximation) for this attenuation effect assuming the mutual cross section for collision between disilane beam molecules and silane background molecules to be $\pi(1.5\ \sigma_S)^2$ compared with $\pi\sigma_S^2$ for silane-silane collisions, where σ_S is the silane molecular diameter. The disilane total ion currents (TIC) at T_S = 1123°C corrected for this effect are given in the last column of Table Ib. Secondly, in the case of the silane TIC a further correction was necessary since the pressure range of the observations coincided with the transition from molecular to streamline flow in the reaction chamber. Over the pressure range of this transition, the proportion (A_B/A_T) of the silane TIC due to silane which had interacted with the specimen decreased from unity in the molecular flow regime to 0.25 in the streamline flow regime. The effective values of A_B/A_T over the transition range were calculated, using Eq. [6], from the values of $I_S°/I_S^T$ measured over this range. The values of silane TIC corrected for this effect and for attenuation due to scattering are listed in column 4 of Table Ib. A log-log plot of corrected disilane TIC against corrected silane TIC gave a straight line of slope 2.1 ± 0.1. This result is consistent with the expected bimolecular surface reaction for production of disilane

$$SiH_4\ (ads) + SiH_4\ (ads) \rightarrow Si_2H_6 + H_2$$

where the silane molecules are adsorbed on adjacent surface sites.

The activation energy for disilane production at $P_S° = 1.05 \times 10^{-1}$ Torr was derived from an Arrhenius plot of the ratio of disilane TIC to silane TIC (see Table Ia). This plot gave a straight line with a slope corresponding to an activation energy of 56 ± 6 kcal $mole^{-1}$. The two correction factors discussed in the preceding paragraph had no effect on the temperature dependence of silane or disilane TIC.

Silicon growth rate measurements.—Silicon growth rates were measured over the silane pressure range $P_S^T = 10^{-3}$ to 1 Torr and at temperatures from 700° to 1200°C. Silicon layers grown above 800°C were epitaxial with low stacking fault densities (see Discussion). The silicon growth rate was taken as the thickness of deposited silicon divided by the deposition time. Continuous monitoring of the pyrolysis products during deposition confirmed that the rate of silane decomposition was constant over the period of deposition.

The pressure dependence of the growth rate at T_S = 987°C is shown in Fig. 5. It is seen that the observed growth rates all lie within experimental error on a straight line of slope unity. This result, taken together with the pressure independent reaction efficiency indicated by the molecular beam sampling data, provides strong evidence for first-order, unimolecular decomposition of silane over the entire pressure range covered.

The temperature dependence of the silicon growth rate, R, measured at $P_S^T = 10^{-1}$ Torr is shown by the closed circles in Fig. 6. Up to T_S = 1070°C, the growth rate follows an exponential rate dependence with an activation energy of 10 ± 1 kcal $mole^{-1}$. The fall in growth rate at T_S > 1100°C can be attributed to the onset of appreciable silicon evaporation.

From the measured values of silicon growth rate and surface reaction efficiency (see crosses in Fig. 6), the silicon condensation coefficient, σ, defined as the fraction of silicon atoms produced by the pyrolysis of silane which are incorporated into the silicon layer, was calculated in the following way:

On the silicon (111) surface, a growth rate of R micrometers per minute (μm/min) corresponds to a condensation rate of $8.34 \times 10^{16} R$ atoms $cm^{-2}\ sec^{-1}$. Furthermore, the rate of production of free silicon atoms per unit area of specimen surface at $P_S^T = 10^{-1}$ Torr is

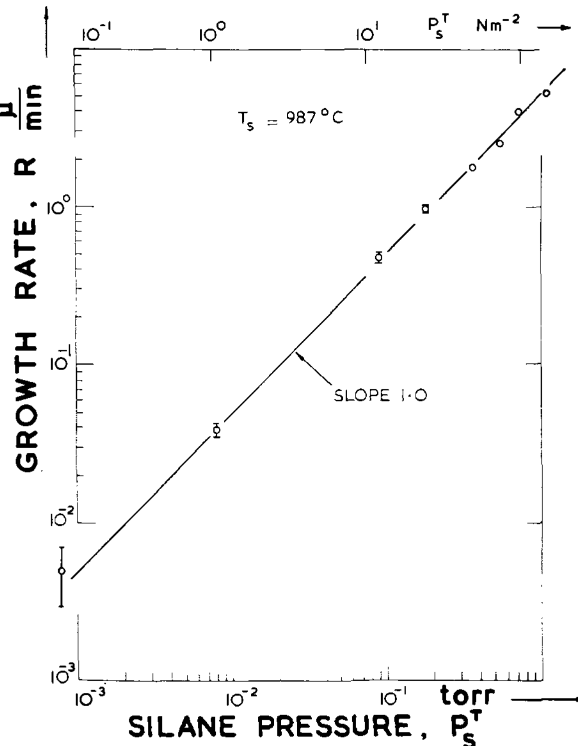

Fig. 5. Pressure dependence of silicon growth rate, R, at T_S = 987°C.

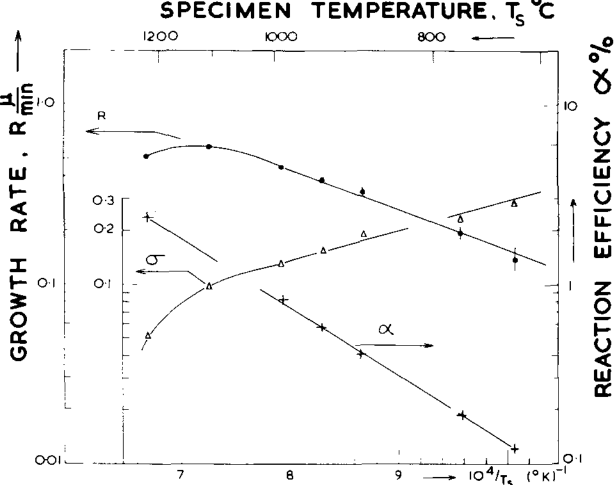

Fig. 6. Temperature dependence of silicon growth rate, R, at $P_S^T = 10^{-1}$ Torr, surface reaction efficiency, α, given by Eq. [10], and silicon condensation coefficient, σ.

$$\alpha P_S^T n_S = 3.6 \times 10^{19}\, \alpha \text{ atoms cm}^{-2}\text{ sec}^{-1}$$

hence

$$\sigma = 0.232 \times 10^{-2}\, R/\alpha \qquad [11]$$

The values of σ calculated using Eq. [11] are indicated by triangles in Fig. 6. It can be seen that σ is less than 0.3 over the entire temperature range covered. This result is in agreement with the conclusion of Henderson and Helm (4) that the majority of silicon adatoms are desorbed from the growth surface and is considered further in the Discussion section.

Effect of arsine on silane pyrolysis.—The effect of arsine on silane pyrolysis was investigated by adding controlled concentrations of arsine to the silane entering the reaction chamber whilst continuously monitoring the pyrolysis products. It was found that the addition of arsine led to a progressive decrease in the efficiency of silane pyrolysis with time. At T_S = 932°C and $P_S^o = 2 \times 10^{-1}$ Torr, for example, the silane reaction efficiencey fell to 50% of the initial value about 9 sec after a concentration of $P^o(AsH_3)/P_S^o$ = 1% arsine was added to the silane. The silane reaction efficiency under these conditions asymptotically approached a lower limit of 20% of the initial value. Similar experiments at higher arsine concentrations showed that the time constant for the fall in silane reaction efficiency decreased with increasing arsine concentration but that the lower limit to the silane reaction efficiency remained unchanged. The temperature dependence of this limiting reaction efficiency measured at $P_S^o = 2 \times 10^{-1}$ Torr is shown in Fig. 4. The values shown were calculated using Eq. [4] and may be compared with the α values also shown in Fig. 4 for $P_S^o = 2 \times 10^{-1}$ Torr measured in the absence of arsine. It can be seen that the activation energy for silane pyrolysis has been increased by 18 kcal mole^{-1}.

Effect of diborane on silane pyrolysis.—The effect of diborane on the silane pyrolysis was investigated both in the same way as for arsine and by monitoring the pyrolysis of silane on an initially boron-covered surface.

The addition of less than 1% diborane to the silane had no detectable effect on the efficiency of silane pyrolysis. At concentrations above 1%, however, the efficiency of silane pyrolysis was measurably increased. For example, at T_S = 850°C and $P_S^o = 4 \times 10^{-5}$ Torr, the silane reaction efficiency increased from α = 0.3 to 0.9% over a period of several minutes after the addition of 10% diborane to the silane. Simultaneous measurements of the diborane pressure in the reaction chamber showed that the diborane reaction efficiency (calculated from the fall in diborane pressure using an equation analogous to Eq. [4]) increased from 0.3 to 0.8% over the same period. The temperature dependence of the enhanced silane reaction efficiency under steady-state conditions is shown in Fig. 4. This shows that the activation energy for silane pyrolysis in the presence of 10% diborane has been reduced to 11 ± 1 kcal mole^{-1}. The corresponding reduction in the activation energy for diborane pyrolysis was from 16 ± 2 kcal mole^{-1} to 12 ± 1 kcal mole^{-1}. Further increase of the diborane concentration led to an even greater enhancement of both silane and diborane reaction efficiencies. In Fig. 4 it can be seen that the activation energy of silane pyrolysis has been further reduced to 7 ± 1 kcal mole^{-1} for $P^o(B_2H_6)/P_S^o$ = 5. The activation energy of diborane pyrolysis under these conditions was 11 ± 1 kcal mole^{-1}.

The catalytic effect of diborane on silane pyrolysis was investigated further by monitoring silane pyrolysis on an initially boron-covered surface. A clean silicon (111) surface was exposed to diborane at a pressure $P^o(B_2H_6) = 0.76 \times 10^{-3}$ Torr at T_S = 1035°C for 300 sec whilst the diborane pyrolysis was continuously monitored. Apart from unreacted diborane, only molecular hydrogen was detected as a pyrolysis product suggesting the over-all decomposition

$$B_2H_6 \rightarrow 2B + 3H_2$$

The diborane reaction efficiency (calculated using an equation analogous to Eq. [4]) increased from an initial value of 0.8 to 45% after about 30 sec, remaining at this value for the remaining 270 sec. This suggests that complete boron coverage of the silicon surface was attained after 30 sec. After 300 sec, the specimen temperature was reduced to 20°C, the diborane leak valve closed and the diborane pumped away. Silane was then admitted to a pressure $P_S^o = 1.2 \times 10^{-5}$ Torr and the specimen temperature rapidly increased to 1035°C whilst the silane pyrolysis was continuously monitored. The time dependence of silane reaction efficiency is shown in Table II where the time zero corresponds to the time at which the specimen temperature reached a stable value of T_S = 1035°C. The initial silane reaction efficiency was 100% and the time dependence of α

Table II. Time dependence of silane reaction efficiency, α, measured on an initially boron-covered surface for $P_S° = 1.2 \times 10^{-5}$ Torr, $T_S = 1035°C$

Time (sec)	0	130	250	370	480	630	760	1000	1330
α (%)	100	27	8	5.5	4.3	3.3	2.7	2.1	1.8

over the first 250 sec is well represented by

$$\alpha = \exp(-10^2 \alpha t) \qquad [12]$$

Assuming that the initial rate of fall of α is the same as the initial rate of coverage of the surface with silicon, a value of $\sigma = 0.25$ for the initial condensation coefficient of silicon on the boron-covered surface at $T_S = 1035°C$ was estimated on the basis of the known impingement rate ($n_S P_S^T$) of silane on the surface at $\alpha = 100\%$. Even after 1330 sec (after which time the boron layer should have been buried by many silicon layers), the silane reaction efficiency (1.8%) was still considerably higher than the value (0.85%) measured on a clean silicon (111) surface. This difference cannot be attributed to the polycrystallinity of the deposited silicon (see Discussion) and may have been due to boron diffusing to the reaction surface from the buried boron layer.

Discussion

Although *in situ* analysis by Auger spectroscopy or reflection high energy electron diffraction (RHEED) to establish the level of contamination of the silicon (111) surface in the present work has not been possible, we believe the surfaces on which our study of silane pyrolysis and silicon deposition (in the absence of arsine and diborane) is based to be at least as impurity free as the "clean" ($<10^{13}$ impurity atoms cm^{-2}) silicon surfaces attained recently by Henderson and Helm (4) by argon ion cleaning. This belief is supported by several experimental results. Firstly, the absence of both three-dimensional nucleation and an induction period, when silicon layers ranging in thickness from a monolayer to several microns were deposited on the initially "flashed" specimen, implies (5) the lack both of surface carbon contamination and of carbon-containing species in the reaction chamber. Secondly, whilst it is conceivable that "flashing" may bring Ni to the specimen surface and change the surface concentration of silicon dopant, this initial surface was rapidly covered with a freshly deposited epitaxial silicon layer during the silane reaction kinetic measurements. In fact, no difference in reaction rates measured on the initially "flashed" and freshly deposited surface could be detected. Finally, electron microscopic and optical examination of layers several micrometers thick, deposited at $T_S > 800°C$ in the reaction chamber, revealed that the surfaces of the layers were essentially featureless except for a low density (10^2-10^3 cm^{-2}) of stacking faults. No pits or growth pyramids were detected. This suggests that our layers were of similar quality to those deposited by Henderson and Helm under "clean" conditions. Below 800°C, the quality of the silicon layers progressively decreased and below 750°C the layers became polycrystalline, probably as a result both of the decreasing surface mobility of silicon adatoms and the correspondingly increasing effect of trace impuritites in the silane and from the specimen environment.

The molecular beam sampling data and growth rate measurements provide strong evidence that, on a clean silicon (111) surface, silane decomposition occurs by the reaction

$$SiH_4(gas) \rightarrow SiH_4(adsorbed) \rightarrow Si + 2H_2$$

where both the amount of adsorbed silane and the decomposition rate depend linearly on silane pressure. The first-order dependence of adsorbed silane on pressure is typical (9) of Langmuir adsorption behavior where the surface is only sparsely covered by a weakly adsorbed reactant, in this case silane. Further evidence for weak adsorption of silane on silicon is provided by the fact that only a small fraction of the molecules impinging on the specimen surface decomposed and that adsorption of silane molecules on adjacent sites, leading to disilane production, was a rare event for all specimen temperatures and silane pressures covered in the present work.

As recently pointed out (4), both the low value and temperature dependence of the silicon condensation coefficient can be adequately accounted for on the basis of a step-flow model for silicon growth. In this model, it is assumed that silicon adatoms are incorporated into an atomic step if they diffuse to the step edge before desorbing. The mean distance, d, which an adatom may diffuse before desorbing is $\sqrt{D\tau}$, where τ is the mean stay time for adatoms given by

$$\tau \approx 1/\nu \exp(\Delta G_{des}/RT_S) \qquad [13]$$

where ν is an atomic frequency and ΔG_{des} is the free energy of activation for adatom desorption. D is the surface diffusion coefficient given by

$$D \approx a^2\nu \exp(-\Delta G_{sd}/RT_S) \qquad [14]$$

where a is the distance of an adatom jump and ΔG_{sd} the free energy of activation for surface diffusion. Then

$$d = \sqrt{D\tau} \approx a \exp[(\Delta G_{des} - \Delta G_{sd})/2RT_S] \qquad [15]$$

Now, in the presence of step sources such as dislocations, the mean step separation is not expected to be an exponential function of temperature and the temperature dependence of the condensation coefficient will be primarily controlled by d. Under these conditions, the slope of the ln σ *vs.* $1/T_S$ plot will correspond to $(\Delta G_{des} - \Delta G_{sd})/2R$. From the data in Fig. 6, we obtain $\Delta G_{des} - \Delta G_{sd} = 14 \pm 5$ kcal $mole^{-1}$ and, assuming that ΔG_{des} equals the Si-Si bond energy (50 kcal $mole^{-1}$) (10), then $\Delta G_{sd} = 36$ kcal mole with a standard deviation of at least 6 kcal $mole^{-1}$; a value intermediate between previous estimates which range from 4.2 kcal $mole^{-1}$ (11) to 58 kcal $mole^{-1}$ (2) and compares reasonably well with Henderson and Helm's (4) recent value of 26 kcal $mole^{-1}$.

Hirth and Pound (12) have shown that with decreasing temperature the separation between monatomic steps on a close-packed crystal surface approaches a steady-state value of $d' \approx 6\sqrt{D\tau}$, which corresponds to a low temperature limit of $\sigma = 1/3$ for the condensation coefficient. From Fig. 6 it is seen that the measured values of σ show no departure from exponential rate behavior with decreasing temperature at $\sigma \sim 1/3$ and would approach a low temperature limit of unity if this behavior continued at temperatures below 700°C. This is not inconsistent with the predictions of Hirth and Pound, since as they have pointed out, if the spacing between monatomic ledges, macroscopic steps, or crystal edges becomes smaller than $\sqrt{D\tau}$, then the condensation coeffiecient will tend to unity. This is to be expected in the present case in view of the increasing polycrystallinity of silicon layers grown at $T_S < 700°C$.

Silicon layers deposited under arsenic inhibited growth conditions and those deposited in the presence of more than 0.2% diborane were polycrystalline at all growth temperatures. The possibility that the considerable changes in silane decomposition rate, observed on the addition of arsine or diborane, may not have been due to arsine or diborane directly but to polycrystallinity of the reaction surface can be discounted, however, since no significant (*i.e.*, > 5%) reproducible difference between silane decomposition rate on an epitaxial silicon (111) surface and that on a polycrystalline surface, measured at the same temperature in the absence of arsine or diborane, could be detected.

The inhibition of silane decomposition in the presence of arsine was also observed (3) in an earlier series of investigations by the present author. Moreover, Gupta (15) and Eversteyn and Put (13) have recently observed this effect in conventional atmospheric pressure reactors. The small number [As(solid)/Si(solid) $< 10^{-3}$] of arsenic atoms incorporated into silicon layers grown under growth-inhibited conditions in both of these investigations suggests that only a small fraction of the silicon surface is covered with adsorbed arsenic adatoms. Since the silicon surface is sparsely covered with silane, one is led to the conclusion that, for a low coverage of arsenic to produce such a drastic effect on the rate of silane decomposition, either the arsenic atoms block off certain sites on the silicon surface which are active in inducing silane pyrolysis or that adsorbed silane molecules are strongly attracted to adsorbed arsenic atoms and that decomposition is then strongly hindered by strong bonding between the arsenic atom and the activated silane complex. Further studies of the arsenic-influenced silicon surface using RHEED/Auger techniques would be necessary to throw further light on the mechanism involved. Whichever mechanism is appropriate, one may assume that, under inhibited growth conditions, desorption of an arsenic adatom from the surface is the rate-limiting step for silane decomposition. Thus the 18 kcal mole^{-1} increase in activation energy for silane decomposition on the addition of arsine may be identified with the activation energy for desorption of arsenic adsorbed on the silicon (111) surface.

The catalytic effect of boron on silane pyrolysis suggests that silane molecules are attracted to boron adatoms on the silicon surface and that decomposition of the silane is not hindered by a strong bond between the activated silane complex and the boron adatom. One possible reason for a weaker bond between boron and the activated silane complex than between arsenic and the complex is that boron (Group 3) is electron deficient compared with arsenic (Group 5). This suggestion is consistent with the fact that phosphine as well as arsine has been found (13) to inhibit silane pyrolysis, whilst diborane has the opposite effect.

Our conclusions on the mechanism, reaction order, and activation energy for silane pyrolysis on a clean silicon (111) surface are in agreement with those of Henderson and Helm (4). The values of surface reaction efficiency given by Eq. [10], however, are some 40 to 50% higher than those derived from Henderson and Helm's published values [see Table I of Ref. (4)] of the rate constant for silane decomposition. This discrepancy is, however, not surprising in view of the large standard deviations in the values ($\pm 10\%$ for our own values and at least $\pm 30\%$ for Henderson and Helm's). Care was taken in the present work to minimize errors in this quantity from possible pyrolysis on the Ta specimen clips and uncertainties in effective reaction surface area. Thus, very thick (2 mm) Ta clips were used which remained cold ($<150°C$) even during specimen heating at 1150°C. The silicon specimen was thin (0.4 mm) so that the ends of the specimen near the clips remained cold and a very sharp temperature gradient existed over only a short length of specimen between the clips and the 80% of specimen surface area over which the temperature was uniform to $\pm$ 10°C. The effective reaction surface area was determined from the dimensions of the uniformly deposited silicon layer examined after unloading. It is interesting that noticeable deposition of silicon occurred on only one of the specimen clips, the one furthest down line in the direction of streamline flow between the silane inlet port and sampling slit. This suggests that the deposition resulted not from pyrolysis on the clip but from condensation of silicon desorbed from the specimen and carried down line to the cold Ta clip. This observation supports the conclusion that the majority of silicon adatoms are desorbed from the growth surface. Direct mass spectrometric detection of the collision-free beam of silicon desorbed from the specimen was not possible in the present work because of the very small solid angle subtended by the specimen at the detector and the large $m/e = 28$ peak due to fragmentation of silane in the ion source.

In view of the excellent agreement between the present work and that of Henderson and Helm (4), where in both investigations care was taken to establish and maintain clean specimen surface conditions using ultra high vacuum techniques, it seems likely that previously reported (1, 2) departures from first-order kinetics of silane decomposition resulted at least in part from specimen surface contamination. Joyce *et al.* (5) have, for example, shown that even small fractions of a monolayer of carbon contamination can result in considerable changes in silicon growth morphology and have demonstrated that the silicon surfaces on which Joyce *et al.* (2) carried out silane reaction kinetic studies were contaminated by carbon and possibly SiO_2. Furthermore, we have found that deliberate carbon contamination of the silicon (111) surface by pyrolysis of ethylene can lead to a reduction in silane pyrolysis rate compared with that on a clean silicon (111) surface. Moreover, in the early work of Joyce and Bradley (1), the silicon growth experiments were carried out in a poor background ($P_B > 10^{-6}$ Torr) vacuum environment with likely specimen contamination from pump oils and residual gases. In the more recent preliminary molecular beam study (3) of silane pyrolysis involving the present author, first-order reaction kinetics were found but an activation energy for silane decomposition of only 10 ± 1 kcal mole^{-1} was reported. We now believe that this value was systematically low by several kcal mole^{-1} as a result of contamination of the silicon (111) surface with boron (resulting from an immediately preceding experiment involving heavy boron doping) released from the system walls during specimen heating.

Conclusions

The pyrolysis of silane on a silicon (111) surface has been investigated mass spectrometrically by molecular beam sampling over a wide silane pressure $P_S{}^T = 10^{-5}$ to 4×10^{-1} Torr) and specimen temperature ($T_S =$ 20° to 1200°C) range. The results are consistent with the mechanism

$$SiH_4(\text{gas}) \rightarrow SiH_4(\text{adsorbed}) \rightarrow Si + 2H_2$$

where both the amount of adsorbed silane and decomposition rate depend linearly on silane pressure, indicating sparse coverage of the silicon surface with silane over the pressure and temperature ranges covered.

Values of the surface reaction efficiency, α, for silane decomposition have been calculated both from the fall in silane pressure in the reaction chamber and from the production of molecular hydrogen. Good agreement between values derived by the two methods was obtained and the reaction efficiency was found to obey the equation

$$\alpha = 5.45 \exp(-17 \times 10^3/RT)$$

An apparent dependence of α on silane pressure above $P_S{}^T = 10^{-3}$ Torr was attributed to the effects of streamline flow in the reaction chamber.

Small quantities of disilane were detected at silane pressures above 5×10^{-3} Torr and were attributed to the bimolecular reaction

$$SiH_4(\text{ads}) + SiH_4(\text{ads}) \rightarrow Si_2H_6 + H_2$$

where the silane molecules are adsorbed on adjacent surface sites.

Measurements of silicon growth rate as a function of silane pressure up to $P_S{}^T = 1$ Torr supported the first-order mechanism for silane decomposition. The condensation coefficient, σ, of silicon adatoms, determined

from measurements of the silicon growth rate as a function of temperature and the surface reaction efficiency, was found to be less than 0.3 over the entire temperature range 700°-1200°C, indicating that the majority of silicon adatoms were desorbed. This behavior was accounted for on the basis of a step-flow model for silicon growth and an activation energy for surface diffusion of 36 ± 6 kcal mole^{-1} derived therefrom.

Addition of arsine to the silane was found to inhibit silane pyrolysis whilst, in contrast, addition of more than 1% diborane to the silane considerably enhanced the silane pyrolysis rate.

The results of the present investigation are in excellent agreement with those of Henderson and Helm (4) whose measurements were made on silicon (111) surfaces with $<10^{13}$ impurity atoms cm^{-2}. Previously reported departures, both from first-order silane pyrolysis and from the present activation energy of 17 ± 2 kcal mole^{-1}, are attributed, at least in part, to specimen surface contamination.

Acknowledgments

The author wishes to acknowledge with thanks the assistance of Dr. W. Bardsley and Dr. J. D. Filby in initiating the present work and is grateful for helpful discussions with Dr. R. M. Logan. The assistance of W. C. Hopper and C. N. Horsfall in the design and construction of the molecular beam chopping mechanism is also acknowledged with thanks. ABSTRACT

SNOS capacitors, which have a polycrystalline silicon gate and a nitride-oxide gate insulator, are fabricated using a wide range of insulator thicknesses and high temperature anneals. The insulator charge depends on the oxide and nitride thickness, and the charge level is most sensitive to the final annealing step before metallization. A premetal anneal in H_2 is required to produce a low fast state density. V_{FB} shifts under bias-temperature stress result from charge accumulation at the nitride-oxide interface.

The metal-insulator-silicon capacitor is a convenient tool for studying the oxidized silicon surface (1-4). This paper describes the characterization of SNOS capacitors which have a polycrystalline silicon gate electrode and a silicon nitride-silicon dioxide gate dielectric. The gate insulator charge, Q_{eff}, and fast surface-state density, N_{fs}, depend on the particular process used to fabricate the capacitor. The flatband voltage shift, ΔV_{FB}, under bias-temperature stress depends on the fabrication process, stress voltage, stress temperature, and stress time. This shift is caused by the difference in nitride and oxide conductivity (5).

Key words: silicon gate, nitride-oxide dielectric, V_{FB} stability, fast surface states.

Sample Preparation

SNOS capacitors were prepared on 1¼ and 2¼ in. silicon substrates. Capacitors with a boron-doped Si gate were made on n-type substrates while p-type substrates were used to make samples with a phosphorous-doped Si gate. A variety of annealing cycles, film thicknesses, and diffusion processes were studied. Table I outlines the process sequence for capacitors with a B-doped Si gate. The process steps appropriate for a P-doped Si gate are shown in parentheses.

Experimental Techniques

The high frequency (1 MHz) MOS C-V technique was used to measure t_{eq} the equivalent gate dielectric

thickness, and Q_{eff}. The equivalent thickness was calculated using Eq. [1]

$$t_{eq} = t_{ox} + t_n \frac{K_{ox}}{K_n} = \frac{K_{ox}\epsilon_0 A_g}{C_{max}} \quad [1]$$

Q_{eff} was obtained from Eq. [2]

$$Q_{eff} = -\frac{C_{max}}{A_g}[V_{FB} - \phi_{ms}] \quad [2]$$

The following values were used for the gate to substrate work function: $\phi_{ms} = +0.83$ (n substrate, B-doped Si gate) and $\phi_{ms} = -0.80$ (p substrate, P-doped Si gate).

The fast surface-state density was measured by the quasi-static technique (6). Data was obtained by sweeping from inversion to accumulation at a sweep rate of 0.05 V/sec. The value quoted for the fast state density is the number of states per cm^2 between $\psi_s = 0$ and $\psi_s = 2\phi_F$.

All wafers used for V_{FB} stability studies were first checked for mobile ion contamination by the high temperature quasistatic C-V technique (7). In this technique, the capacitor is heated to 200°C and a ramp voltage ($f = 0.02$ Hz) is applied. As the ramp voltage decreases from +5 to −5V, the current through the capacitor, $I = A_g C_{mos} dv/dt$, and the gate voltage are recorded on an x-y plotter. Curve 1 of Fig. 1 shows a typical trace. When the ramp voltage reaches −5V a +10V (for $t_{eq} = 500$Å) fixed bias is applied to the gate as the ramp voltage is removed. After the sample is stressed for 75-175 sec the fixed bias is removed and the ramp voltage, which is then +5V, is reapplied. The current-voltage curve is again recorded as the ramp sweeps from +5 to −5V. The presence of mobile ions is revealed by the bump on the post-stress curve (curve 2). The mobile ion density per cm^2, N_i, is

$$N_i = \frac{AK_I K_t}{qA_g}\left[1 + \frac{t_n K_{ox}}{t_{ox} K_n}\right] \quad [3]$$

In Eq. [3] K_I is the vertical scale of Fig. 1 in amperes/inch, K_t is the number of seconds/inch for the horizontal scale, and A is the cross-hatched area in square inches. The factor $[1 + t_n K_{ox}/t_{ox} K_n]$ appears in Eq. [3] because the mobile ions move only in the SiO_2 layer.

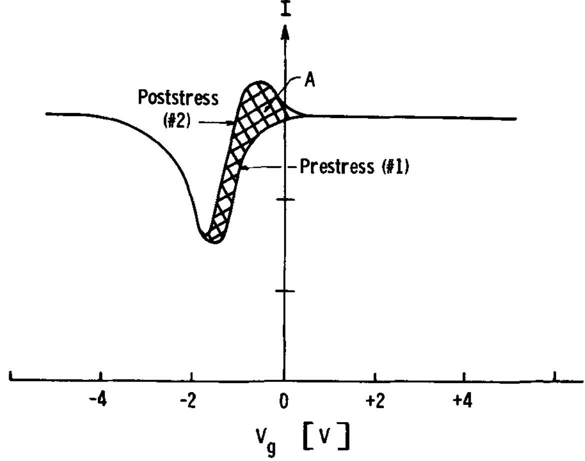

Fig. 1. Mobile ionic charge measurement at 200°C

After the mobile ion density was checked to be less than 5×10^{10} cm^{-2}, V_{FB} shifts were measured by the following procedure. A high frequency C-V was measured before the sample was stressed in the dark at elevated temperature. After the stress was completed the sample was rapidly cooled to room temperature under bias and a second C-V trace was made.

Experimental Results

Q_{eff} and N_{fs} were measured for a variety of annealing cycles as well as for several oxide and nitride thicknesses. All nitride and premetal anneals were done for 0.5 hr.

The following nitride anneals were used: no anneal, H_2 at 900°C, N_2 at 1050°C, and N_2 at 1100°C. These anneals had no significant effect on either Q_{eff} or N_{fs}. This step was therefore eliminated from the process sequence and the remainder of the data in this paper was obtained from devices processed with no nitride anneal.

The premetal anneal greatly influences Q_{eff} and N_{fs}. Table II shows Q_{eff} and N_{fs} for various premetal anneals. Several conclusions are evident from this table: (*i*) A N_2 anneal produces a low or negative Q_{eff} and a high N_{fs}. The H_2 anneal results in a low N_{fs}. (*ii*) The capacitor with a P-doped Si gate has a lower Q_{eff} than the corresponding sample with a B-doped Si gate. (*iii*) For samples with a B-doped Si gate, the 900/300 dielectric has a lower Q_{eff} than the 300/300 insulator.

Table III contains additional data on the t_{ox} and t_n dependence of Q_{eff}. This table shows the same trend as Table II, that is, Q_{eff} decreases as t_{ox} increased, and t_n is held constant. (The devices represented in this table had a 800°C premetal anneal in H_2.) All data in the remainder of the paper, with the exception of Table V, were obtained from capacitors processed with the 800°C premetal anneal in H_2.

Figures 2 and 3 show that Q_{eff} is a function of the silicon gate thickness and diffusion junction depth for devices with a B-doped Si gate. Q_{eff} increases as X_j increases or t_{polySi} decreases. The value of X_j is the junction depth in a single-crystal silicon monitor wafer. Except for these two figures, all data in the paper were obtained from capacitors with a silicon gate thickness of 0.7 μm and $X_j = 1.25$ μm.

Table II. Q_{eff} and N_{fs} for various premetal anneals

Gate dopant	Oxide thickness (A)	Nitride thickness (A)	Q_{eff}/q (cm^{-2})	N_{fs} (cm^{-2})	Premetal anneal* (°C)

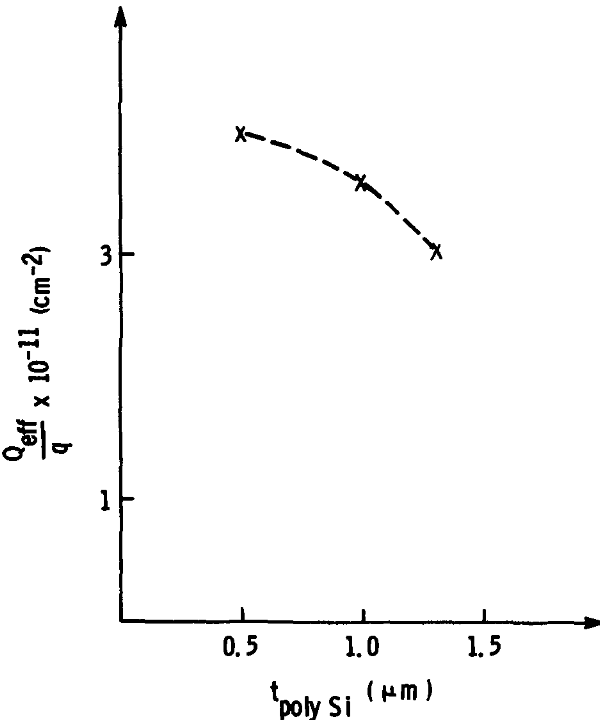

Fig. 2. Insulator charge vs. polycrystalline silicon thickness

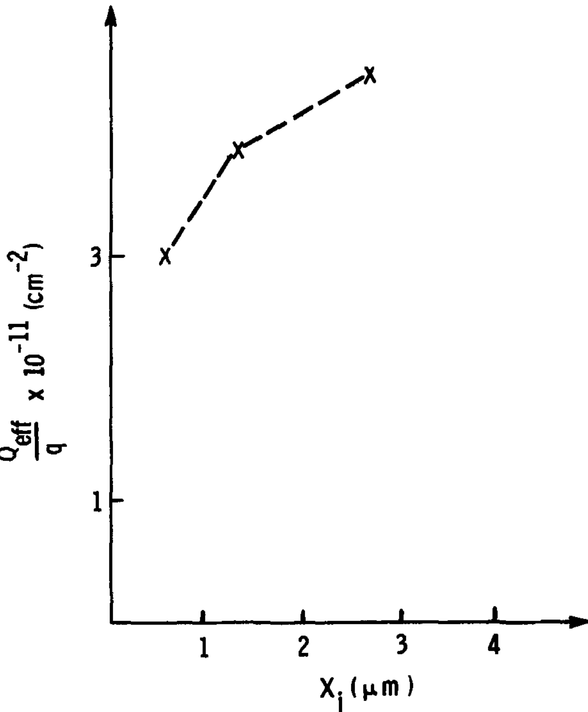

Fig. 3. Insulator charge vs. junction depth

The V_{FB} stability of SNOS capacitors with a boron-doped Si gate was measured for a wide range of bias temperature stress conditions. Figures 4, 5, and 6 show the time, temperature, and voltage dependence of ΔV_{FB} for capacitors with a 300/300 gate insulator. These devices had a 800°C premetal anneal in H_2 and no nitride anneal. Figure 7 shows ΔV_{FB} *vs.* *t* for a similar device which had a P-doped Si gate. Note that ΔV_{FB} (+ stress) > ΔV_{FB} (− stress) for capacitors with a B-doped Si gate whereas the reverse is true for a P-doped gate electrode.

The data in Fig. 4-7 can be described by the following equation

$$\Delta V_{FB} = C \exp(-\beta \Delta H)(V_G)^m(t)^n \quad [4]$$

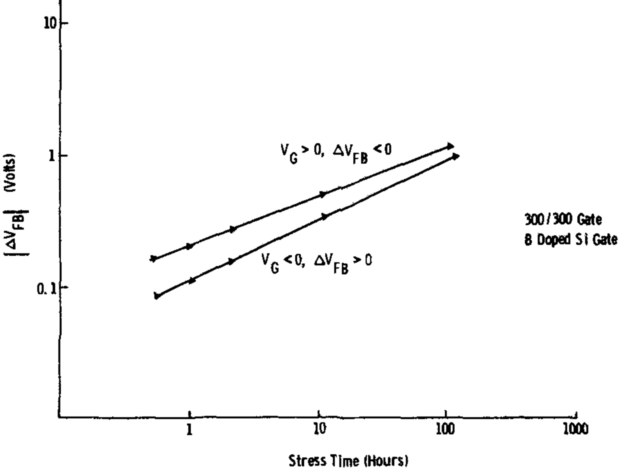

Fig. 4. V_{FB} shift for stress at 200°C, ± 10V

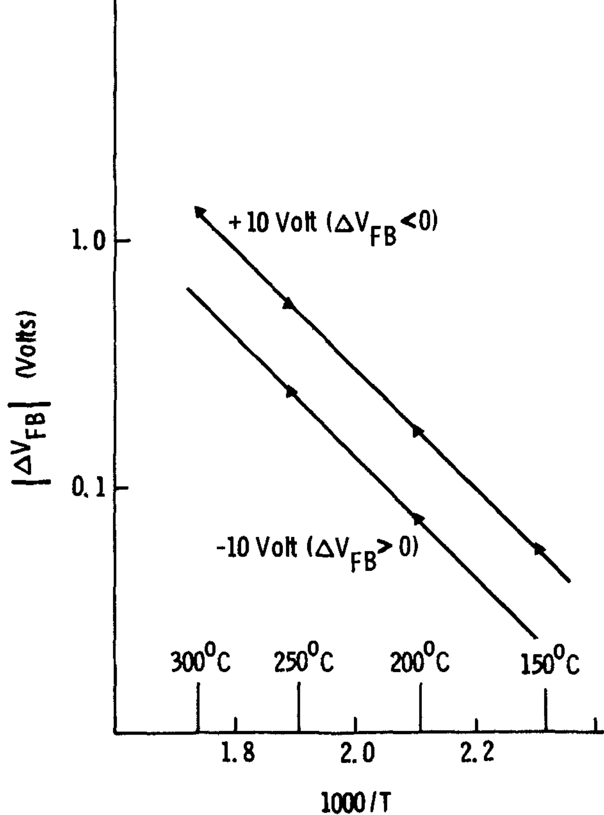

Fig. 5. ΔV_{FB} temperature dependence for a 30 min stress

This equation gives a good fit to the experimental data over the following range of stress conditions: V_G, 8-20V (for the 300/300 gate); *t*, 0.5-500 hr; *T*, 85°-250°C. The parameters calculated from capacitors with a 300/300 gate dielectric are: ΔH, 0.35-0.45 eV; *m*, 3.5-4.0 eV; *n*, 0.35-0.5 eV.

Table IV shows the dependence of ΔV_{FB} on the NH_3:SiH_4 ratio used to deposit the silicon nitride. The data indicates that improved stability is achieved by using a higher NH_3:SiH_4 ratio. With the exception of the devices represented in Table IV, all capacitors were fabricated with NH_3:SiH_4 = 133:1.

Table V shows the effect of various nitride and premetal anneals on the V_{FB} stability. The nitride anneals have little impact on ΔV_{FB}, whereas the premetal anneal in N_2 greatly increases the V_{FB} shift for positive stress. Table VI contains the results of V_{FB} stability measured on capacitors with various oxide and nitride thicknesses. An improvement in V_{FB} stability is achieved by reducing t_n. V_{FB} stability is discussed in

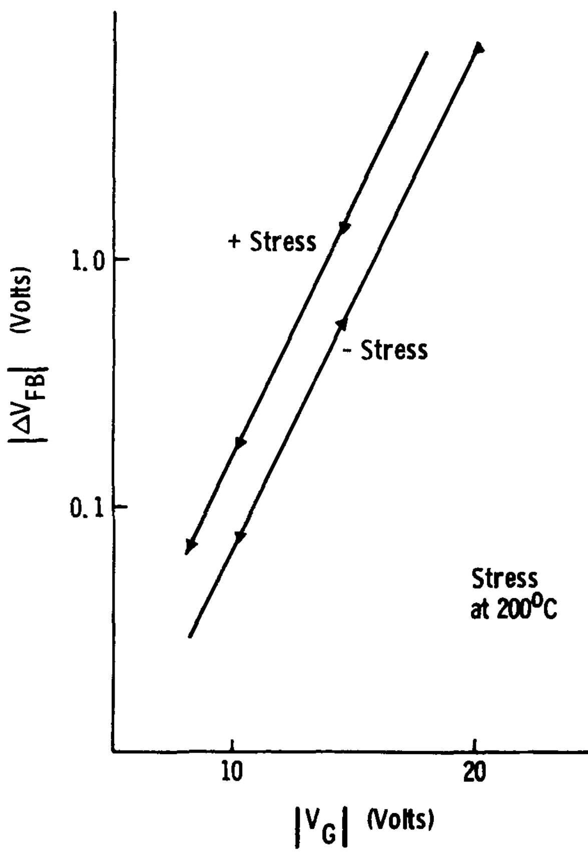

Fig. 6. ΔV_{FB} voltage dependence for a 30 min stress

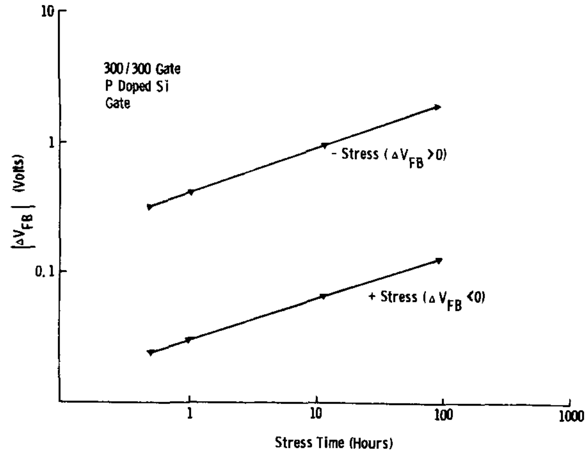

Fig. 7. V_{FB} shift for a stress at 200°C, ± 10V

the next section, and V_{FB} shifts will be shown to result from the dual dielectric instability.

Discussion

Several process parameters affect Q_{eff} of the SNOS capacitors which have a B-doped Si gate. A nitride anneal in H_2 or N_2 has little impact on Q_{eff}. It is felt that this anneal does not influence Q_{eff} because the devices are exposed to subsequent high temperature processing during the diffusion and these process steps wash out any effects of the nitride anneal.

The premetal anneal, which is the last high temperature process step, has a significant effect on Q_{eff} and N_{fs} (see Table II). A premetal anneal in N_2 produces a low or negative Q_{eff} but a high N_{fs}. The low or negative Q_{eff} is produced by negative charges trapped in the acceptor-like surface states which are located near the Si conduction band edge. A low N_{fs} results if a premetal anneal in H_2 is used. Creation and reduction of fast states by N_2 and H_2 annealing has been reported by Deal *et al.* for MNOS capacitors (8).

800°C, hydrogen	−0.6	+0.45
900°C, nitrogen	−4.2	+0.50

Table VI. ΔV_{FB} for a stress at $E_{ox} = 2 \times 10^6$ V/cm, 200°C, 30 min

Oxide thickness (Å)	Nitride thickness (Å)	ΔV_{FB} (+ stress) (V)	ΔV_{FB} (− stress) (V)
300	300	−0.17	+0.08
400	200	−0.13	+0.03
400	100	−0.065	+0.025

$$E_{ox} = \frac{V_G}{t_{eq}} \qquad t_{eq} = t_{ox} + t_N \frac{K_{ox}}{K_N}$$

$$\Delta V_{FB} = \frac{\Delta Q_{no}}{K_n \epsilon_o} t_N$$

An increase in the polysilicon gate thickness or a reduction in X_j reduces Q_{eff} of SNOS capacitors with a B-doped Si gate (see Fig. 2 and 3). A similar effect was reported by Fujimoto *et al.* for SNOS capacitors with a P-doped Si gate (9). The reduction in Q_{eff} is achieved by minimizing the boron penetration into the Si_3N_4.

The dependence of Q_{eff} on t_{ox} and t_n indicates that the charge at the nitride-oxide interface, Q_{no}, makes a major contribution to Q_{eff}. Equation [5] relates Q_{no} to Q_{eff} assuming that Q_{no} is the only charge in the gate dielectric

$$Q_{eff} = \frac{t_n}{t_{eq}} \frac{K_{ox}}{K_n} Q_{no} \qquad [5]$$

The trend of data from Table III (except for $t_{ox} =$ 400Å, $t_n =$ 100Å) agrees with Eq. [5], *i.e.*, an increase in t_{ox} or a reduction in t_n reduces Q_{eff}.

The V_{FB} stability data cannot be explained by mobile ion motion or by slow surface state trapping. The mobile ion density is less than 5×10^{10} cm^{-2}. This density can produce a maximum V_{FB} of 75 mV for the capacitors with a 300/300 gate dielectric. V_{FB} shifts are observed in the 300/300 gate which are much larger than 75 mV. The absence of hysteresis in the room temperature *C-V* curves is indicative of a small slow surface-state density. Slow surface-state trapping produces a positive V_{FB} shift under positive stress and a negative V_{FB} shift for negative stress. However, the

experimental data is of the opposite polarity, *i.e.*, $\Delta V_{FB} > 0$ for negative stress, and therefore slow-state trapping cannot produce the observed V_{FB} shifts.

The dual dielectric instability model predicts that charge accumulates at the nitride-oxide interface when the capacitor is biased because $J_n \neq J_{ox}$. For our samples $J_n >> J_{ox}$ when the bias is first applied. In this case a positive stress produces a negative ΔV_{FB} and conversely. As charge accumulates at the interface, E_{ox} is increased and E_n is reduced until $J_{ox} = J_n$. If the initial current densities are substantially different, a large amount of charge will accumulate at the nitride-oxide interface before the V_{FB} shift saturates.

The dual dielectric instability model predicts a V_{FB} shift which is a function of the stress temperature, time, and voltage (5, 10, 11). This behavior is observed in the SNOS capacitors. The model predicts a reduction in ΔV_{FB} if the nitride resistivity is increased. This increase has been accomplished in three ways: by using a high NH_3:SiH_4 ratio during the nitride deposition (12), by using a thick polysilicon gate, and by using a shallow B diffusion to dope the gate electrode. The last two methods minimize the reduction in nitride resistivity due to boron penetration into the Si_3N_4. Improved V_{FB} stability was also achieved by reducing the nitride thickness. This improvement is expected according to Eq. [6] which relates ΔV_{FB} to ΔQ_{no}

$$\Delta V_{FB} = -\frac{t_n}{K_n \epsilon_o} \Delta Q_{no} \qquad [6]$$

A detailed knowledge of the oxide and nitride conductivity *vs.* field curves, the various barrier heights and the trap distributions throughout the nitride-oxide insulator is necessary to predict the time, temperature, and voltage dependence of the V_{FB} shift. No such attempt was made in this study. However, the qualitative agreement between the experimental data and the model gives good evidence that the dual dielectric instability is the cause of the V_{FB} shifts in our SNOS capacitors.

Acknowledgments

The authors wish to acknowledge the support of the East Fishkill facility, especially P. Stern and R. Holmwood, for processing the wafers and the technical assistance of N. Anantha, D. Fouts, P. Lin, and E. Zachos. Many of the measurements were made by J. Nodich and R. Smith.

Preparation and Performance of Dendritic Heat Sinks

S. Oktay and A. F. Schmeckenbecher

ABSTRACT

A new heat-transfer surface, *i.e.*, a "dendritic" heat sink, is presented. The preparation of the dendrites by forming a "brush" of nickel powder on a surface with a magnet and plating them in place with electroless nickel to form a dendritic finned surface is described. It is shown that, in addition to increased heat-transfer rates due to the compact heat-transfer area, the unique characteristics of the cavities on a dendritic surface improve the boiling mode of heat-transfer. Despite their small size, dendritic heat sinks in a FC88 cooling liquid can dissipate about 6W from the surface (about 0.1 × 0.1 in. or 2.54 × 2.54 mm) of a silicon chip at 45°C. The thermal performance of the dendritic structure and the reliability of the dendritic heat sinks are discussed.

A new heat-transfer surface, called a "dendritic" heat sink, is presented and analyzed. The dendritic structure is prepared by forming a "brush" of nickel powder on a surface with a magnet and plating the needles of the brush with electroless nickel to form a dendritic finned surface. Dendritic structures are found to be especially useful for providing heat sinks on small components such as integrated circuit chips (Fig. 1).

In addition to the increased heat-transfer rates due to the extended heat-transfer area that the dendritic heat sinks provide, it is found that the unique characteristics of the cavities on a dendritic surface improve the boiling mode of heat-transfer. The nature of these cavities and the associated surface roughness are analyzed. The dendritic structure forms "reentrant" type cavities (Fig. 2), which heretofore have not been possible to manufacture on a large scale, and which remain active even in the absence of noncondensable gases. Consequently, the dendritic cavities provide numerous nucleation sites continuously, thereby allowing boiling at lower wall superheat than that possible with conventional engineering surfaces. The performance of these cavities is analyzed from theoretical considerations and related to experimental observations.

Thermal tests show that the cooling efficiency of the dendritic structure in "FC-88" (trademark of Minnesota Mining and Manufacturing Company) cooling liquid is as good or better than that of a solid molybdenum[1] stud which has up to 20 times the weight of the dendritic structure.

It is also noted in Fig. 3 that the bubble nucleation on the dendrites is initiated close to the heated surface while in a stud or in a thick chip the heat must be conducted through a relatively large metal mass before it can be dissipated by boiling.

The reliability aspects of the dendritic heat sinks are also discussed. For example, it is shown that due to the light weight of the dendrites, the projected reliability of flip-chip solder joints to the chip package ("C-4" joint) (1) is improved by 17% over the conventional copper heat sink. The reliability of dendrites is discussed with respect to the results of various environmental tests. Mechanical tests indicated that as much as 1300g are required to shear dendrites from the back of a 2.125 mm (85 mil) chip.

Key words: boiling heat-transfer, electrolessly plated heat sink, electronic components cooling, nucleation sites.

[1] Moly heat sinks were used because of their better thermal expansion characteristics to match that of silicon. While a better match is expected to yield better mechanical (hence, thermal) integrity at the metal-metal interface, it should also be noted that even a better heat conductor such as a copper heat sink with the same surface characteristics as moly is expected to give comparable boiling heat-transfer coefficients at the metal-liquid interface, which is the primary regime with which we are concerned. Also no attempt was made to compare conduction across the plated interface to other type bonded interfaces.

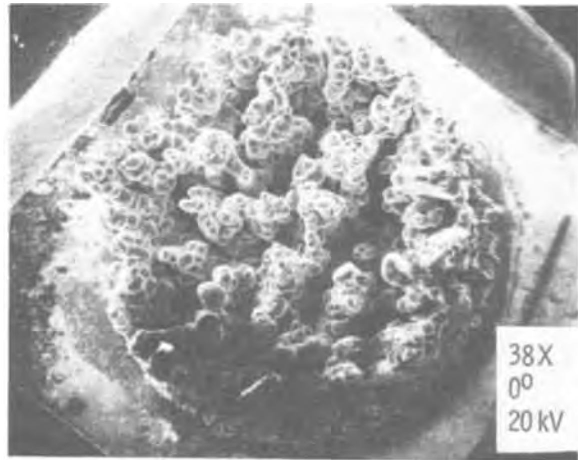
Preparation of Dendritic Heat Sinks

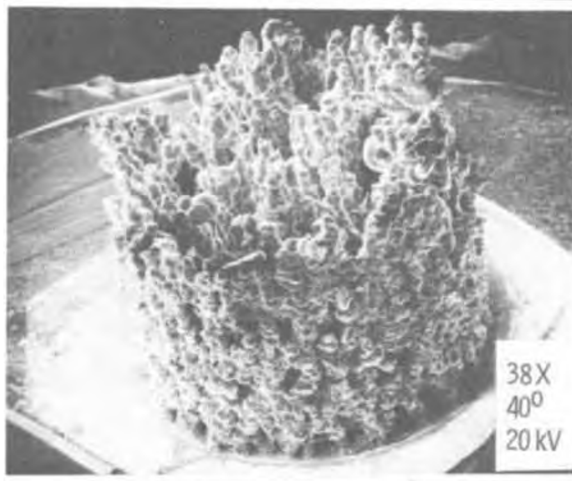
A "skeleton" structure is formed by aligning magnetic powder such as low expansion NiFe alloys in a magnetic field, followed by a plating step which fixes the powder in position and joins the structure to the chip.

To assure good adhesion of the electroless nickel plate to the silicon of the chip, the back of the chip is roughened by sandblasting, plated with a flash of palladium by a dip in 0.1% palladium chloride solution, and annealed at 125°-350°C. Initially the device side of the chip is covered by a layer of a resist material for protection against sensitizing and the subsequent plating steps.

A diverging magnetic field is then generated in the area above the chip by placing the pointed pole of a bar magnet underneath the chip. A small amount of a ferromagnetic powder is placed on the chip. In the diverging field the powder particles are attracted toward the chip. An attracted particle becomes a magnet by itself, attracting more particles. Strings of particles result, which stand up away from the surface of the chip. Adjacent strings repel each other since they are magnetized with their north and south poles in the same direction (Fig. 4). Near the pole of the bar magnet, the strings of particles are forced closer to each other by the stronger field at the pole. A brushlike structure results. The height and width of the structure can be controlled by the amount and the size of the powder particles, by mechanically holding the particles in a mold (Fig. 5), and by the shape and spacing of the magnet.

After the "skeleton" brush has been formed, the assembly is immersed into an electroless plating bath and plated with a 10-25 μm (½-1 mil) thick coat of metal, *e.g.*, nickel. The chemical reducing agent in the electroless bath supplies the electrons for the reduction of the metal salt at the catalytic surface. No electrodes are required and the bath has a "throwing power," *i.e.*, the ability to plate in recesses, cavities, etc. which is limited only by the necessity to resupply the ions of the metal and the reducing agent. Convection and diffusion in the plating bath usually are sufficient to supply the surfaces of the ferromagnetic particles and of the semiconductor chips with the metal ions and reducing agent, resulting in a metal deposit of uniform thickness, even in recesses between the powder particles. Consequently, mechanically strong and well-bodied needles ("dendrites") are formed by a relatively thin metal layer. The plating metal layer closely duplicates the roughness of the ferromagnetic particles as well as cavities formed by the particles. The powder particles, before being put on the chip, are activated for electroless plating by the usual procedures, such as a dip in a palladium chloride solution.





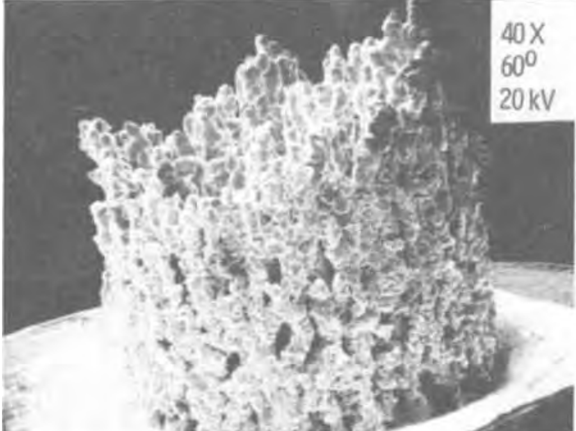


Fig. 1. SEM micrograph of dendritic heat sink

The plating fixes the strings of powder particles in position and joins them to the surface of the chip.

Heat sinks have been formed on integrated circuits by using nickel powder of different particle sizes [carbonyl nickel powder of 2-4 μm diameter, reduced nickel powder of irregular particle size and shape from Fisher Scientific Company, or from Baker and Adamson Chemical Company, "Kovar" (low expansion Fe, Ni, Co alloy) powder from B.S.A. Metals Powders Limited, Birmingham, England, and others].

Figures 6-8 give a scanning electron microscope picture and a microsection of a typical heat sink on a chip formed by the above method.[2]

Many dendritic heat sinks can be formed simultaneously on a wafer before dicing if an electromagnet is used with a pole piece which is somewhat larger than the wafer and which has a small individual pole at each chip site on the wafer (Fig. 9). With the magnet turned off, a layer of nickel powder of uniform thickness is deposited on the wafer by forming a suspension

[2] Scanning electron microscope pictures were taken by E. K. Brandis, IBM Corporation, Hopewell Junction, New York 12533.

of the powder in a liquid and allowing the powder to settle on the wafer. When the magnet is turned on, the powder particles are attracted to the individual poles and can be plated as described to form a heat sink on each chip site. Figure 10 shows a wafer with dendritic heat sinks formed by this procedure.

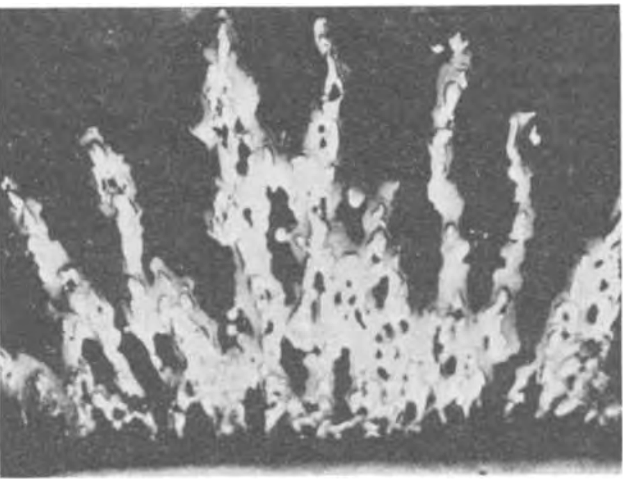

Fig. 8. Microspection of a dendritic heat sink 100X SEM photograph.

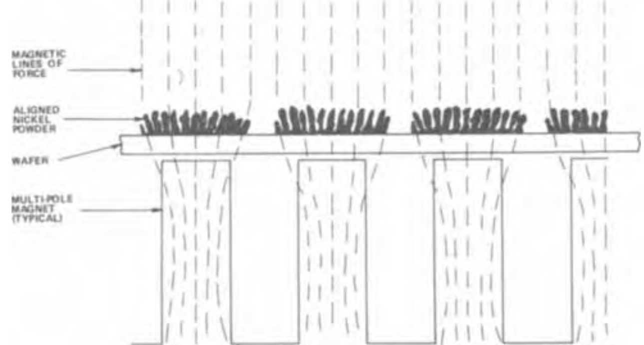

Fig. 9. Multiple plating of dendritic heat sinks

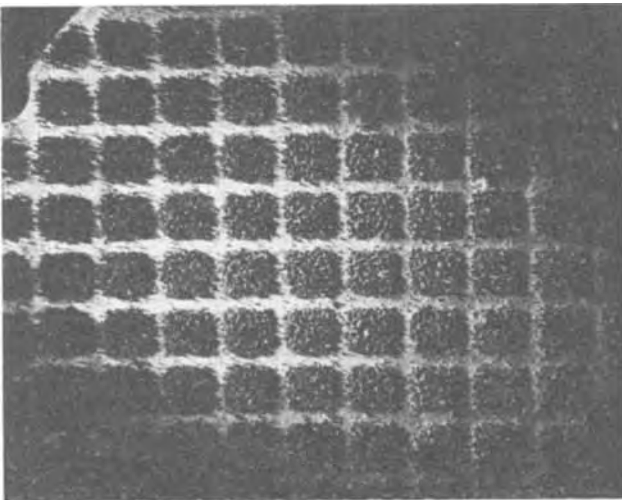

Fig. 10. Dendritic heat sink formed on a wafer

Wafers with dendritic heat sinks have been diced by the standard procedure of slurry dicing. The cuts were clean with no damage to the dendrites (Fig. 11).

Thermal Evaluation of Dendritic Heat Sinks and Analysis of Dendritic Structures

Thermal evaluation of dendritic heat sinks was performed on chips of various sizes which are noted below. The dendrites were approximately 0.75 mm (30 mils) high and made out of nickel powder. The chips were C-4 (1) joined and powered, and the chip temperatures were obtained from measurements made of the V_{BE} of the diodes in the chips. The diodes were first calibrated.

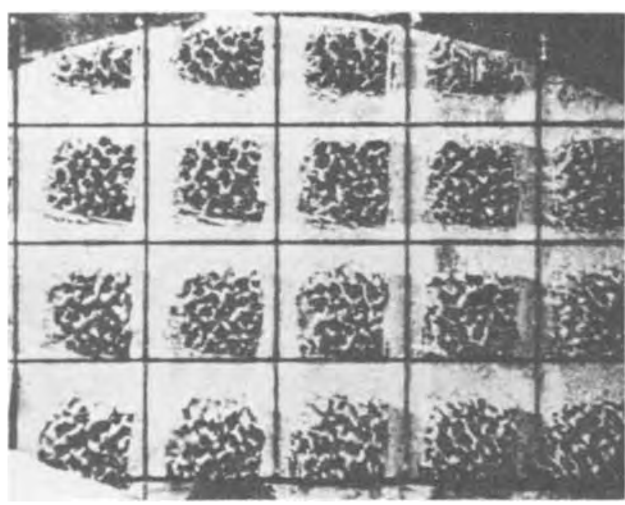

Fig. 11. Wafers with dendritic heat sink after dicing

A series of thermal tests on dendritic heat sinks, as well as on slotted solid moly studs for comparison, was made under identical conditions. The reference temperature of the underside of the substrate directly below the chip was monitored with a thermocouple.

Figure 12a shows that the chip temperature on the dendrite was about 2°C lower than the moly stud. Substrate temperatures were the same for both modules. Initial boiling of the dendrite and stud were 0.25 and 0.50W, respectively. Both modules were boiling throughout at 1W. The "sawtooth" effect (described later) was only 1°-2°C in each case.

Although the dendrites are 1/10 and 1/20 the weight of the stud, there is approximately 3X the surface area.[3] The large surface area, cavities, and crevices contribute to the thermal efficiency of this heat sink. The geometry of the cavities is also important for heat dissipation when FC-88 becomes contaminated.

Thermal studies made in a multiliquid (2) system ("Coolanol 45" trademark of Monsanto Chemical Company over "FC-88" trademark of Minnesota Mining and Manufacturing Company) have led to some interesting cooling characteristics. Figure 12b shows a thermal comparison of a moly stud with a dendritic heat sink. A large "sawtooth effect" (large drop in temperature when boiling starts) is observed only with the moly stud. It was found that the secondary coolant (Coolanol 45) was $\simeq$0.1% soluble in FC-88. This contaminant preferentially wets the heat sink to form a film.

[3] Surface profile measurements made by Micromeritics Instruments Corporation, Norcross, Georgia, yielded the following results on the dendritic heat sinks: specific surface area/weight, 219 cm^2/g; specific surface area/unit, 2.19 cm^2/dendrite. These numbers should be compared with those for the stud: 2.55 cm^2/g and 0.57 cm^2/stud, respectively. Also the porosity measurements using mercury under pressure indicate that reentrant cavities exist in the surface of the dendrites. These surface studies were conducted by S. P. Carbone, IBM Corporation, Hopewell Junction, New York 12533.

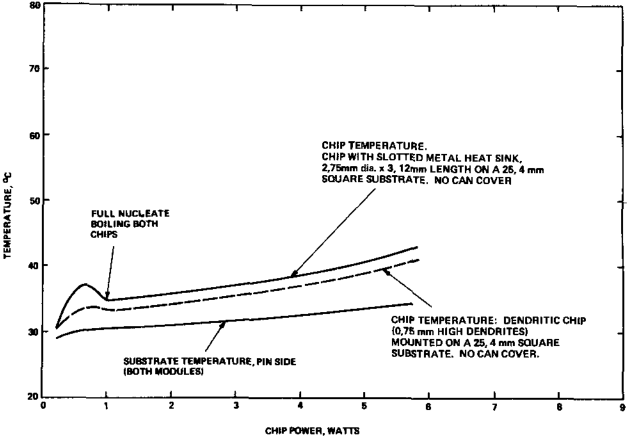

Fig. 12a. Chip temperature vs. chip power (dendritic, stud) in FC88.

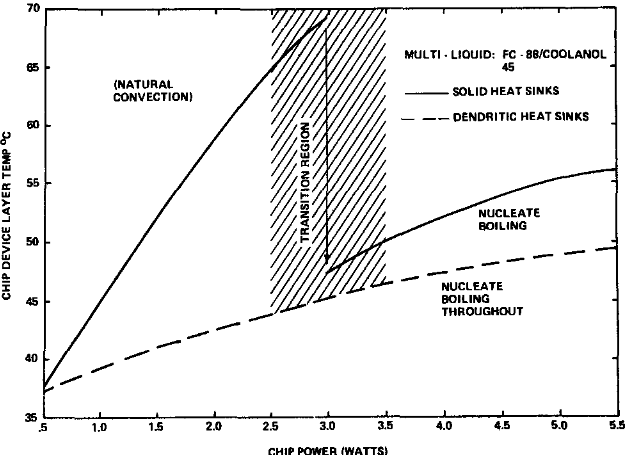

Fig. 12b. Chip temperature vs. chip power (dendritic, stud) in FC88 with a layer of Coolanol 45 on top.

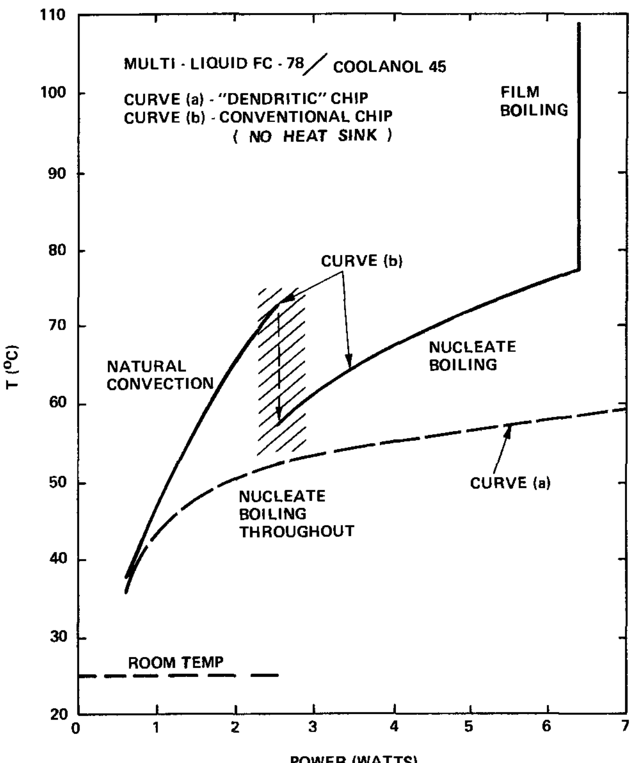

Fig. 12c. Chip temperature vs. chip power (dendritic, plain) in FC88 with a layer of Coolanol 45 on top.

The Coolanol 45 film acts as a thermal insulator on the stud and bubbles do not nucleate on this smooth surface ("hot area boiling"). Boiling starts when the temperature becomes high (>70°C). Once boiling starts, it is vigorous and strips the film. Then heat is conducted away rapidly and the stud approaches its normal cooling curve. If the power is left below 3W (natural convection), the chip temperature can remain above 70°C. This is much higher than the 62°C chip temperature at 5.5W. The dendritic curve exhibits nucleate boiling from 0.5W power with a small "sawtooth" (1°-2°C).

The "fouling" problem can be critical in computers not only if contamination is allowed to accumulate over some period, but also if the parts are not thoroughly cleaned initially.

Figure 13a, shows the chip temperatures obtained with solid heat sink mounted chips. The "sawtooth" effect seen in the figure represents a 30°C jump which

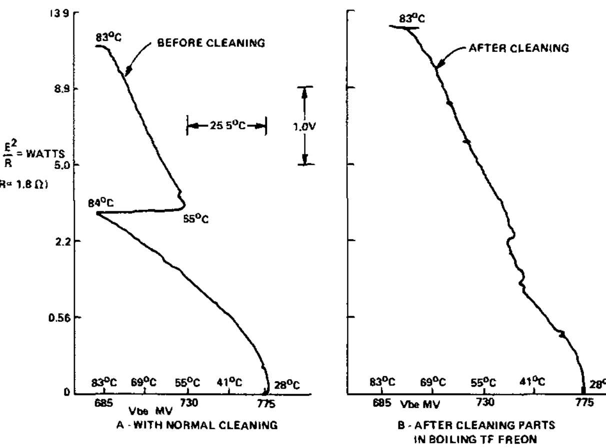

Fig. 13. Chip temperatures vs. chip power with solid heat sink mounted chip (heat sink dimensions given in Fig. 12a).

results in 83°C at approximately 3W. However, soon after the initiation of boiling, the temperature drops down to a normal level and at approximately 6W reaches an average chip temperature of 72°C.[4] After cleaning the part in boiling TF Freon, the "sawtooth" was reduced to a few degrees as seen in Fig. 13b. Note, however, that the cleaning did not change the temperature in the boiling regime. The effect of cleanliness is to initiate boiling at lower power levels.

In the case of dendritic heat sinks, the contamination caused a rise in chip temperature of only 3°C, and thereafter the temperature remained constant for 5700 hr. These dendritic chips have been operating in a cooling loop for 6400 hr. The slight effect of contamination on boiling from the dendrites and the better thermal performance of dendritic heat sinks can be attributed to the surface characteristics of the dendritic structures.

It is known that surface condition is an important variable in boiling heat-transfer. Many types of commercially available surfaces (machined, rolled, or drawn) have been investigated and studies in this area have been published (3). It has been found that a substantial decrease in the nucleate-boiling wall superheat can be obtained by artificially changing the size and distribution of cavities on the surface.

What is perhaps more important is the nature of the cavities which influence the bubble nucleation process. Bubbles form at a heated surface from cavities which already have some gas or vapor present, *i.e.*, so-called active cavities (see Fig. 14a). As the wall surrounding the active cavity is heated, heat is transmitted to the liquid-vapor interface where evaporation takes place, thereby causing the bubble to grow. The bubble continues to grow until an equilibrium condition is reached which is governed by the relationship

$$\Delta p = p_b - p_l = \frac{2\delta}{r} \qquad [1]$$

where p_b is the pressure inside the bubble; p_l is the pressure inside the liquid; δ is the surface tension of the liquid; and r is the radius of the spherical bubble.

[4] To obtain the junction temperature, usually 6°C is added which yields 78°C at approximately 6W.

Then, as the bubble detaches from the surface, a portion of the vapor is trapped inside the cavity as shown in Fig. 14b. This trapped vapor becomes the nuclei for the next bubble. Depending upon the bubble size and the proximity of other cavities, this vapor-trapping process can induce neighboring inactive cavities filled with pure liquid into activity.

The amount of wall superheat needed to grow and detach a bubble of a given size compatible with the liquid properties may be computed from Eq. [1] after relating the temperature (T) to the pressure (p) with the perfect gas approximation in the Clausius-Clapeyron equation (4). Thus

$$T_v - T_{sat} \simeq \frac{R_v T_{sat}^2}{L p_l}\left(\frac{2\delta}{r} - p_g\right) \qquad [2]$$

where T_v is the temperature of the pure vapor and hence that of the wall, approximately; T_{sat} is the saturation temperature of the liquid; R_v is the gas constant of the vapor; L is the latent heat of vaporization; p_g is the partial pressure of any inert gases present in the cavity; and $(T_v - T_{sat}) \equiv \Delta T$ is the wall superheat. Note that Eq. [2] is obtained from Eq. [1] by letting $p_b = p_v + p_g$ where p_v and p_g, are, respectively, the partial pressures of pure vapor of the liquid and any other gases that may be present in the bubble.

It is seen from Eq. [2] that less superheat is required when noncondensable gases are present in the bubble which can be verified easily by experiments. It is also suggested by Eq. [2] that at relatively high gas pressures (p_g), it is possible to form bubbles at wall temperature below the saturation temperature of the liquid, *i.e.*, in subcooled liquid. (An extreme example is the forced flow of air through a tube submerged in a body of liquid.) It is sometimes possible to form bubbles in subcooled liquids even in the absence of inert gases in the cavities in the wall surface. Some cavities can contain pure vapor even at highly subcooled temperatures. To explain this, Rohsenow (5) considers two cases of different contact angle β and opposite curvature of the interface: $p_v > p_l$ in Fig. 14c and $p_v < p_l$ in Fig. 14d. As the surface is allowed to cool below the saturation temperature of the liquid, if the cavity in Fig. 14c contains pure vapor only, the liquid-vapor interface collapses and the cavity becomes filled with liquid, *i.e.*, becomes inactive. "As cavity (d) cools down, however, the interface recedes into the cavity, decreasing the radius of curvature and reducing p_v. Since p_v decreases, T_{sat} of the vapor decreases; the interface does not collapse and the cavity with vapor already in it is ready as an active bubble nucleation site when the wall surface is subsequently heated" (5).

It is clear from the discussion above that if cavities which behave as shown in Fig. 14d can be found, boiling can be initiated at these cavities at all times at a given constant temperature. It can be shown that one such cavity, called a "reentrant" cavity, is that which has a small opening at the surface with a larger diameter cavity below it (see Fig. 15).

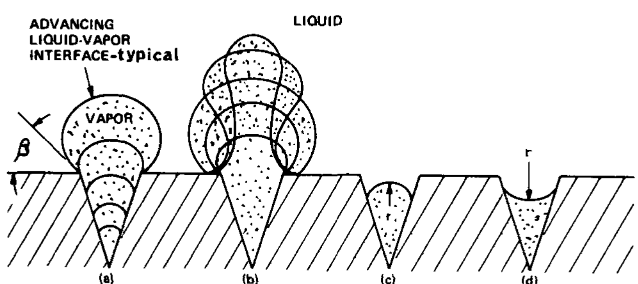

Fig. 14. Nucleation from cavities [from Ref. (5)]

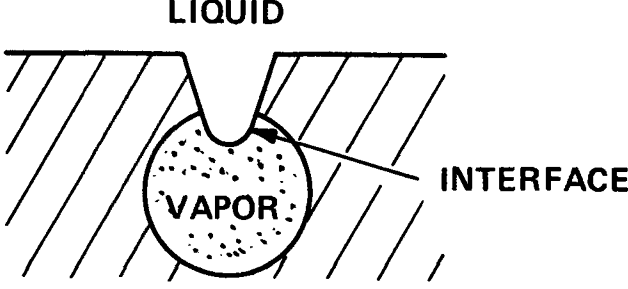

Fig. 15. Idealized "reentrant" cavity

Experiments indicate that with the surface cavities such as shown in Fig. 2, boiling does indeed commence repeatedly at the same wall temperature. On conventional surfaces, on the other hand, the commencement of boiling is not always consistent with a given wall temperature.

In boiling experiments with dendritic heat sinks, the liquid was boiled for long periods of time to drive off the noncondensable gases such as air. Furthermore, the experiments were conducted in a multifluid boiling setup. In this scheme two immiscible liquids are used, where the heavier primary liquid (*e.g.*, FC-78) is in contact with the heat sink. Once the gases are forced out from the primary coolant the secondary coolant (Coolanol 45) on top of the primary coolant forms a barrier between the boiling liquid and the ambient, thus forming a "sealant" against air. In this manner, it was assured to the extent of the solubility of air in the liquids, that the bubbles were not activated by the presence of noncondensable gases, but rather by pure vapor in active cavities.

It was also found, as mentioned before, that boiling on a dendritic surface commences at a lower temperature than that measured on an ordinary surface. For example, it is clear in Fig. 12c that nucleation is prevalent at much lower power levels on "dendritic chips" than on plain chips. This leads to the important result that, since at low power dissipation the corresponding surface temperatures are small, any finite temperature "jump" in transition from natural convective mode to boiling is negligible. In comparison, on surfaces where boiling does not start until high power levels are reached, the unpredictable "jump" in the transition region may be high as seen in Fig. 13a.

The early boiling, *i.e.*, at low wall superheat, on dendritic surfaces may be explained by the fact that the expected distribution of active cavities is much larger with dendrites than with ordinary roughness. In addition, it is known that, aside from the shape of the cavities, roughness alone has an effect on the stability of a bubble. For example, a surface roughness parameter can be related to the contact angle that a bubble forms with the surface which in turn is associated with wettability (6). The stability of the contact angle can then be determined as a function of the surface roughness parameter. Since the roughness of dendritic surfaces is very irregular, it is expected that the probability of finding unstable bubbles, *i.e.*, early detaching bubbles, is high. The boiling process need not wait until a particular nucleation condition for some particular surface is reached. Boiling commences at the lowest wall temperature governing the thermal behavior of any one of the many dendritic cavities.

The irregularity or randomness of these cavities goes down to a very small scale, as evidenced by Fig. 16, which shows a variety of surface structures even at 5000X.

The configuration of the dendritic cavities promote boiling as well as convective cooling since the irregularities provide large surface area. Due to the large area per unit volume, a dendritic finned surface is expected to be advantageous in air cooling also.

Reliability Tests on Dendritic Heat Sinks

The reliability aspects related to dendritic heat sinks can be addressed from two perspectives. One is the reliability of the dendrites themselves, and the second is the influence of the dendrites on the reliability of the total system.

On the latter perspective we placed four chips with dendritic heat sinks in two board cooling loop systems in order to determine if the dendrites do come loose after long periods of operation in a boiling medium and contaminate the system. The results showed that after 6400 hr of operation, no contamination attributable to the dendrites was detected. In order to assess the reliability risk in an accelerated manner, we have also done shear tests on dendrites. A dendritic structure can withstand up to 1300g in shear. This should be compared with a shear failure of the C-4 solder connection (1) of the chip with the package at about 1000g. In relation to the solder joint itself, the light weight of the dendritic heat sinks contributes to the improved reliability of the C-4 joints in fatigue. For example, assuming an ellipsoidal model for the C-4 configuration, and a solder volume of 0.001 mm^3 (70 mils^3) it was shown (7) that the C-4 pad height reaches 0.081 mm (3.23 mils) for the 12 mg dendritic heat sink.

As a comparison, calculations project a delta reliability of +17% relative to the 180 mg molybdenum heat sink due to the increased height of the solder

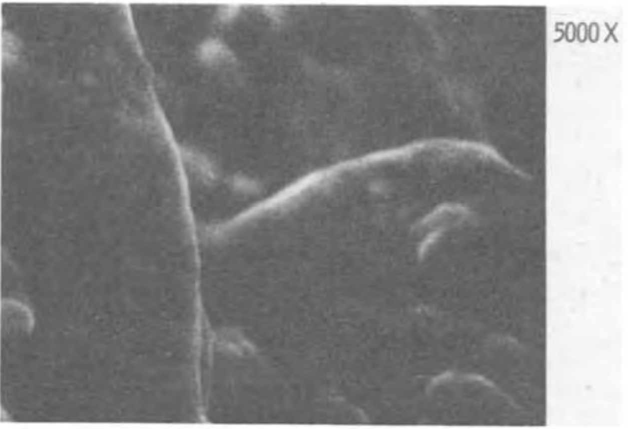

Fig. 16. Dendritic cavities and surface irregularities to 1600X and 5000X.

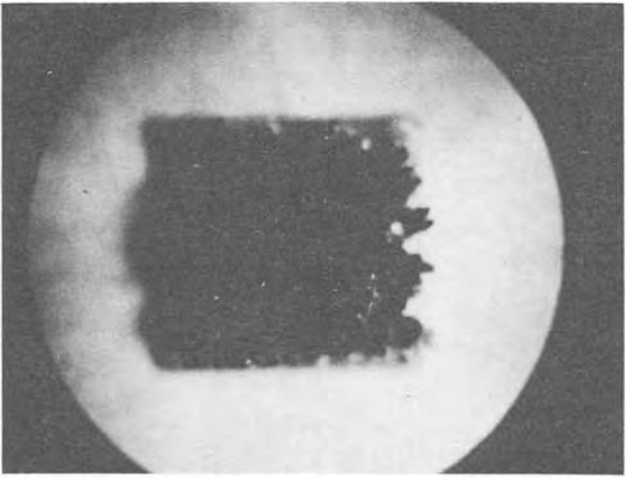

Fig. 17. Honeycomb-like dendritic heat sink made from 2-4μ nickel powder.

pad. Inertial effects due to a higher mass of the stud heat sink have not been considered in this calculation.

Another concern was the possibility of the plating solution being trapped in the porous surface of the dendrites. Such inclusions, if present, might affect the mechanical strength, corrosion resistance, etc. of the heat sinks.

Ultraviolet spectrographic analysis shows that the plating bath contains more than 10% each of nickel, phosphorus, and sodium. Dendrites made from various nickel powders and annealed in nitrogen to 350°C also contain more than 10% nickel, and between 1 and 10% phosphorus, but the sodium content is below the sensitivity of the analysis, *i.e.*, $<0.1\%$. These results seem to indicate that very little of the plating bath is trapped permanently in the heat sinks during plating.

Still another concern was that since the heat sinks consist of a ferromagnetic material, high frequency a-c currents in the circuits on the other side of the chips might be affected. Three chips were a-c tested prior to growing dendrites on them. The a-c test results indicated no change of the a-c characteristics of the chips.

Several dendritic heat sinks on chips of different types have been subjected to various environmental tests. No measurable degradation has been detected.

Two chips of 2.85×2.70 mm (0.112×0.106 in.) with nickel dendrites were heated to 330°C in nitrogen for 2 min and cooled to room temperature. The heat cycle was repeated 10 times. No cracks were observed under the microscope (50X) on the dendrites or between the dendrites and the silicon chips after this treatment. A shock test involved ten impact blows, each in two directions, with a peak acceleration of $4500g \pm 10\%$ and a pulse duration of 200 ± 5 μsec. The shock direction was both parallel and perpendicular to the plane of the chip. None of the four samples tested was visibly affected or damaged by the shock test.

The two chips with dendrites which had been heat-treated as described were vibration tested. The chips were vibrated in three planes, vibration in each plane as follows: (*i*) sweep from 20 to 2000 Hz and return for 20 min; (*ii*) between 20 and 28 Hz, constant amplitude of 0.35 in. peak; and (*iii*) between 28 and 2000 Hz, constant acceleration of 15g peak. None of the samples were visibly affected or damaged by the vibration test.

Other chips with dendritic heat sinks were subjected to 85°C/ 85% RH test for 504 hr. The two chips without the dendrites were used as controls. Fifty standard electrical tests on all modules showed no failure. There was no visible corrosion.

Three chips were also subjected to 50 cycles of wet thermal shock from 0° to 100°C in FC 40 fluorochemical liquid. Two chips had dendritic heat sinks on them while the third, without dendrites, was used as control. Fifty standard electrical tests on all modules showed no failures.

Conclusions

The dendritic structure brings together on a single surface many different types of roughness, such as might be generated artificially by subsequently drawing, filing, sandblasting, etc. the single surface. As discussed above, on such surfaces, the boiling process need not wait until a particular nucleation condition for some particular surface roughness is reached, but a whole "spectrum" of suitable roughnesses is available, yielding always some nuclei for boiling at the lowest wall temperature. Experiments discussed above have shown that on such surfaces superheating (boiling delay) becomes negligible. Consequently, a maximum cooling effect for liquid cooling is achieved. Air cooling with dendritic heat sinks is also possible. This together with the large surface area, low weight, and high mechanical strength makes the dendrites suitable for use as an excellent heat sink in the cooling of integrated circuit chips. The reliability of the dendritic heat sink and of the plated chip itself also seem to be excellent, though these results are based on a relatively small number of samples. The preparation of dendritic heat sinks is simple and inexpensive.

Acknowledgment

The authors wish to thank Messrs. S. Carbone and V. B. Jagirdar for their help in formulating and conducting some of the experiments. The authors also thank Messrs. R. E. Mascitelli, E. D. Renner, and G. Slayton for their competent work in the preparation and testing of the dendritic heat sinks and Mr. H. D. Kaiser for his constant encouragement of our work.

Manuscript submitted Aug. 14, 1973; revised manuscript received Jan. 21, 1974. This was Paper 81 presented at the San Francisco, California, Meeting of the Society, May 12-17, 1974.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1975 JOURNAL. All discussions for the June 1975 Discussion Section should be submitted by Feb. 1, 1975.

ABSTRACT

The partial pressures of the gaseous species in equilibrium with solid silicon in the Si-H-Cl system are presented as a function of temperature for different Cl/H ratios and total pressures. Computations were performed using our recently determined value of $\Delta Hf°_{298}$ ($SiHCl_3$,g) $= -116.9$ kcal/mol. Experimental data concerning the deposition and dissolution of silicon over a temperature range of 1200°-1700°K are compared to the equilibrium data and general conclusions drawn about the probable reaction mechanisms involved, especially for decomposition of the compounds $SiCl_4$ and $SiHCl_3$. Particular emphasis is put on attempting to integrate the diverse body of experimental data that exists for silicon deposition from $SiCl_4$-H_2 and $SiHCl_3$-H_2 mixtures at high temperatures.

A previous article (1) presented a thorough thermodynamic evaluation of the Si-H-Cl system in terms of the increase or decrease of the amount of silicon in the gaseous phase as a function of temperature and Cl/H ratio. One of the purposes of this work is to present the partial pressure of the various species in equilibrium with solid-phase silicon as computed using the same thermodynamic data published in that paper. It is also intended to present a general discussion to assist in understanding the complexity of reaction mechanisms that can be involved during high temperature processing of semiconductor silicon. Comparisons are made, where possible, between well characterized experimental data and that of the computed equilibrium situation.

Equilibrium Concentration of Individual Species

Calculations based on earlier reported thermodynamic data (1) considered fourteen gaseous species to be in equilibrium with solid silicon. The gas phase composition based on these data is shown as a function of temperature for different Cl/H ratios in Fig. 1a-c. The gaseous species Si, Cl_2, and Si_2Cl_6 do not appear on the graphs due to their low equilibrium partial pressures, while SiH_4, SiCl, $SiCl_3$, and Cl appear in only some of the plots. All the aforementioned species can be ignored when describing the equilibrium state of the system under the conditions indicated while maintaining $\gtrsim$99% accuracy. At temperatures higher than 1700°K or Cl/H ratios lower than 0.01 it becomes necessary to consider some of these species. An example of the calculated partial pressures of the minor constituents at conditions of 1600°K and 1 atm is shown in Table I for various Cl/H ratios. The partial pressure of hexachlorodisilane exhibits a maximum in the temperature range of 1200°-1400°K for a given Cl/H ratio.

The three Cl/H ratios chosen have a particular significance with respect to experimental conditions. The lowest value, 0.01, is typical of conditions used for epitaxial deposition and vapor etching of silicon, while 0.1 represents typical conditions for high temperature polycrystalline silicon deposition. The highest value, 1.0, is common to conditions for silicon dissolution (chlorosilane synthesis) or for chlorosilane disproportionation reactions.

Key words: decomposition, deposition, kinetics, reduction, silicon, thermochemical equilibrium.

The effect of pressure on the equilibrium composition of the gas phase is seen by comparing Fig. 1b and 2. At reduced total pressure, $SiCl_4$ and $SiCl_2$ become somewhat more predominant at the expense of the hydrogen containing species. From a thermochemical standpoint, inert gas dilution has a similar effect on the Si-H-Cl system as does reduction of total pressure; *i.e.*, an initial system containing a chlorosilane in hydrogen will reach the same equilibrium point, with respect to all species except H_2 and the inert gas, under comparable conditions such as $P_T = 0.1$ atm and 0% inert gas as opposed to $P_T = 1.0$ atm and 90% inert gas as long as the sum of partial pressures of the silicon containing species is considerably lower than the total pressure. These systems are expected to differ substantially in practice, however, due to changes in gas kinetics.

General Trends in Experimental Data

All experimental data available in the literature can be categorized into two different graphical systems using the following terms: η = fractional silicon yield from a chlorosilane, R = silicon deposition rate, and x = mole fraction of chlorosilane in hydrogen.

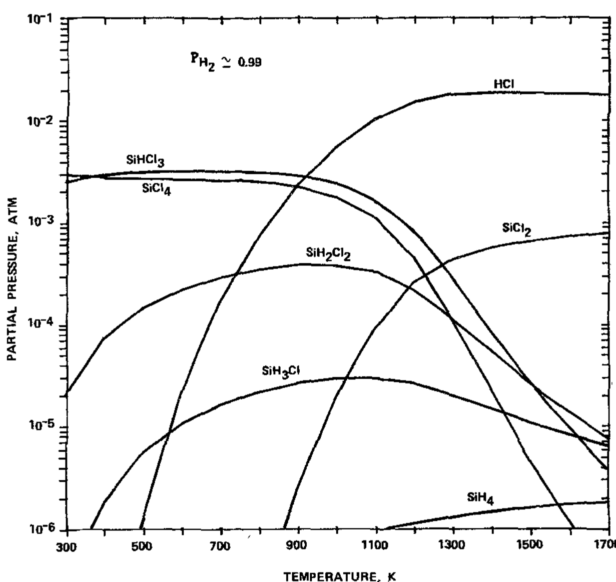

Fig. 1a. Temperature variation of the equilibrium gas phase composition at 1 atm total pressure and Cl/H = 0.01.

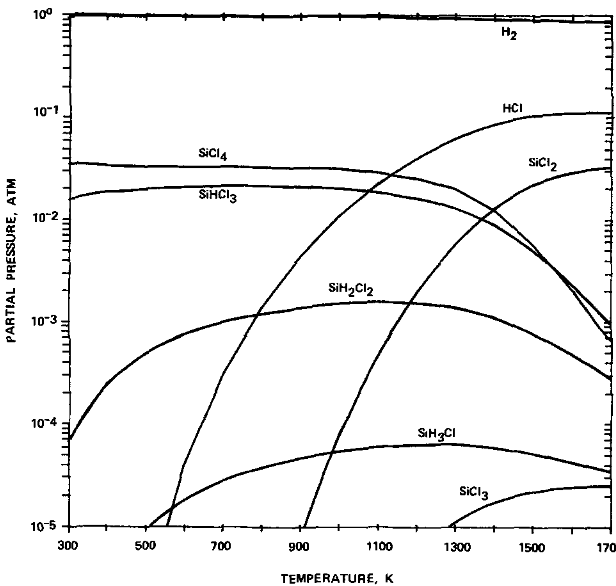

Fig. 1b. Temperature variation of the equilibrium gas phase composition at 1 atm total pressure and Cl/H = 0.10.

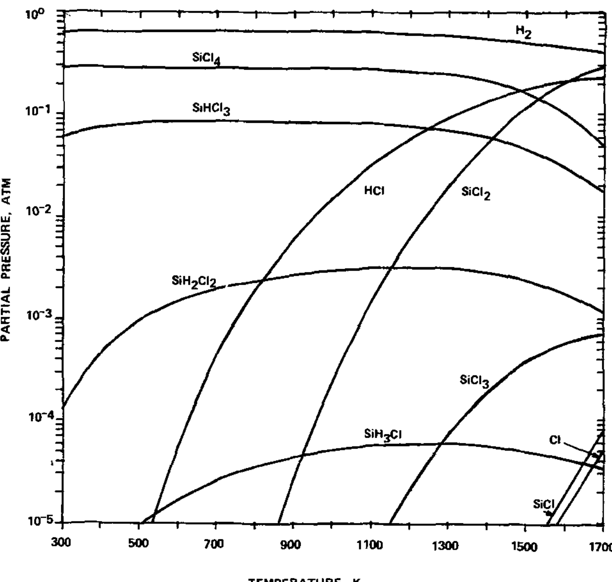

Fig. 1c. Temperature variation of the equilibrium gas phase composition at 1 atm total pressure and Cl/H = 1.0.

The first system indicates the temperature function of η (Fig. 3a) or of R at a constant value of x. The second one portrays the correlation of η or the product $x \cdot \eta$ (Fig. 3b) to the mole fraction x at a fixed temperature. The entity $x \cdot \eta$ is a measure of the potential silicon yield per volume of gas mixture and can be related to the deposition rate R in grams/hour or microns/minute via the absolute or linear flow rate, depending on the geometry of the reactor system. For the first system, the nature of the temperature function is similar, irrespective of whether η or R is used as the parameter. In the case of variable composition, however, the shapes of the curves are different for η as

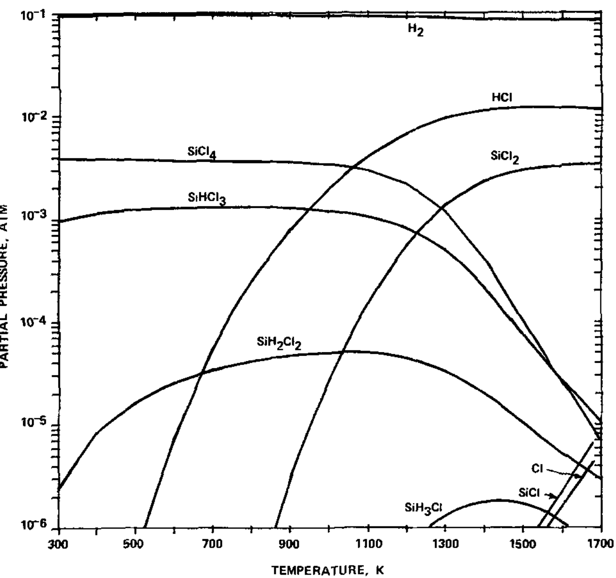

Fig. 2. Temperature variation of the equilibrium gas phase composition at 0.1 atm total pressure and Cl/H = 0.10.

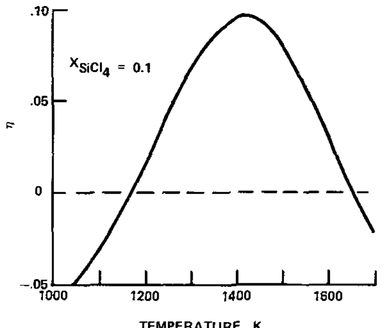

Fig. 3a. Variation of silicon yield with temperature

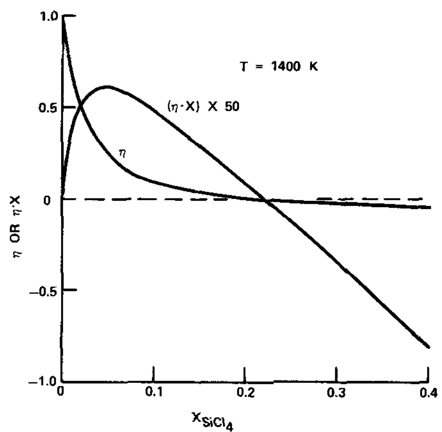

Fig. 3b. Variation of η and $\eta \cdot x$ with mole fraction of $SiCl_4$

compared to $x \cdot \eta$ (or R). This is shown by schematic drawings in Fig. 3a and b.

If the yield or growth rate of silicon is plotted *vs.* temperature, a maximum generally occurs both experi-

0.01	8×10^{-8}	1×10^{-6}	1×10^{-7}	9×10^{-14}	8×10^{-7}	5×10^{-11}
0.10	8×10^{-8}	7×10^{-6}	3×10^{-5}	6×10^{-9}	5×10^{-6}	2×10^{-9}
1.00	8×10^{-8}	2×10^{-5}	6×10^{-4}	2×10^{-6}	1×10^{-5}	2×10^{-8}

mentally and theoretically somewhere between 1000° and 1700°K showing a shift toward lower temperature with increasing mole fraction of the chlorosilane. The fit of the experimental data with theory varies widely depending on reactor geometry and flow rate. Within a given system, the experimental yield curve shows a peak that is more narrow than that of the corresponding theoretical curve, but which coincides fairly well in terms of its maximum. This is demonstrated in Fig. 4, where conversion rates experimentally determined during the growth of polycrystalline silicon are compared with calculated data. In the case of the curves given by Wolf and Teichmann (2), there exists appreciable difference between the η values at low and high flow rates. In contrast to the yield gradients on both sides of the peak, the maxima are nearly unchanged in magnitude.

Plots of yield or growth rate *vs.* mole fraction can be particularly informative in the $SiCl_4$-H_2 system where the dissolution of elemental silicon is observed at relatively low chlorosilane concentrations. The diagram in Fig. 5 indicates that the experimental output of silicon per unit volume is less than the calculated value at low mole fractions as expected. However, at higher mole fractions, the experimental curve generally intersects the corresponding theoretical curve before it reaches the $\eta = 0$ line (threshold line). Similar results are obtained (see Fig. 6) when the linear growth rate of silicon is plotted *vs.* the mole fraction of trichlorosilane.

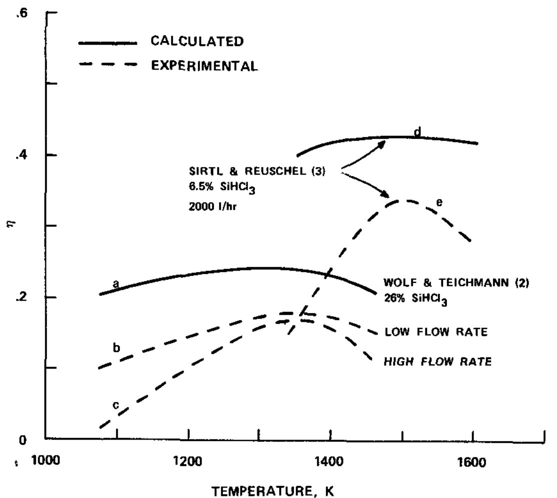

Fig. 4. Temperature comparison of polycrystalline silicon deposition yields from $SiHCl_3$-H_2 mixtures.

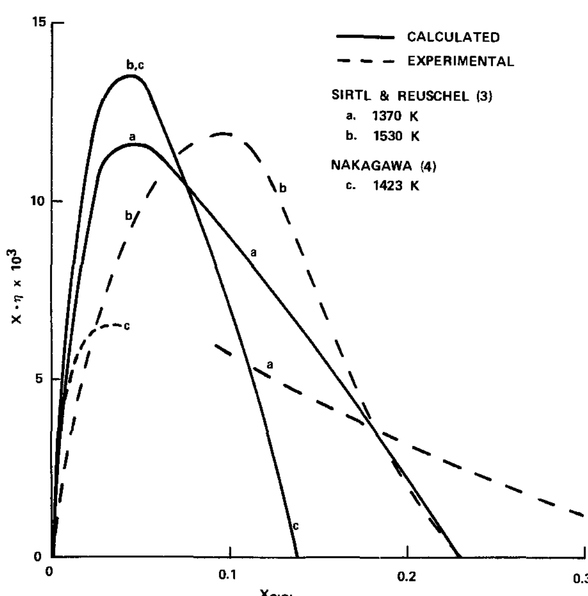

Fig. 5. Comparison of calculated and experimental relative weights of deposited silicon as a function of the mole fraction of $SiCl_4$.

When sufficient information about the linear flow rate in a vertical reactor is available, quantitative comparisons can be made between theory and experiment based on the simplified model of a gas stream impinging perpendicularly on a target. In this case the maximum theoretical deposition rate, assuming that all impinging molecules react at the surface, is

$$R = (\eta f_1 \rho_g / \rho_s) \cdot 10^4 \ (\mu/\text{min}) \quad [1]$$

where ρ_g and ρ_s are the corresponding silicon densities of the input gas and the substrate, and f_1 is the linear flow rate in centimeters/minute. The latter term is obtained from the relation

$$f_1 = f_v / A \quad [2]$$

where f_v is the volumetric flow rate (cubic centimeters/minute) and A is the cross-sectional area (square centimeters) of the reactor at the position of the substrate. The theoretically calculated growth rates expressed in microns/minute are mathematically independent of the gas flowing past the substrate in contrast to rates expressed in grams/minute which require a correction term (6).

Figure 6 demonstrates an effect similar to that in Fig. 5 with the basic difference being the ratio of gas flow to silicon surface area due to use of an epitaxy reactor. This diagram also shows the shift of the theoretical threshold[2] value by reducing the total pressure. The deviation of experimental threshold points from calculated ones is due to kinetic effects as shown by plots of our experimental data (see Appendix) in Fig. 7a and b. The measurement of an equilibrium system by extrapolation of data to zero growth rate and zero flow rate indicates that the approach to equilibrium is highly sensitive to the flow rate, especially at its low values.

A compilation of threshold data in the chlorosilane-hydrogen system is given in Table IIa. Even though some of the theoretical values seem to be closely approached, and in one case even exceeded, lack of sufficient experimental details makes it difficult to examine these data thoroughly. It is clear, however, that measured threshold values occur at higher mole fraction than calculated values. If the threshold point is approached from the region of silicon dissolution (by intentionally adding and changing the hydrogen chloride partial pressure), the situation described in Table IIb is found. It can be seen that just the inverse effect

[2] Threshold is defined here as the conditions of experimental parameters that allow neither a net deposition nor net etching of solid silicon, *i.e.*, conditions that allow no net transfer of silicon to or from the gas phase.

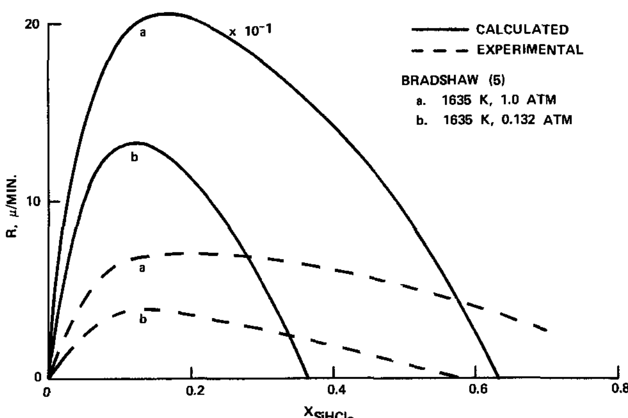

Fig. 6. Theoretical and experimental deposition rate data as a function of $SiHCl_3$ mole fraction at different total pressures.

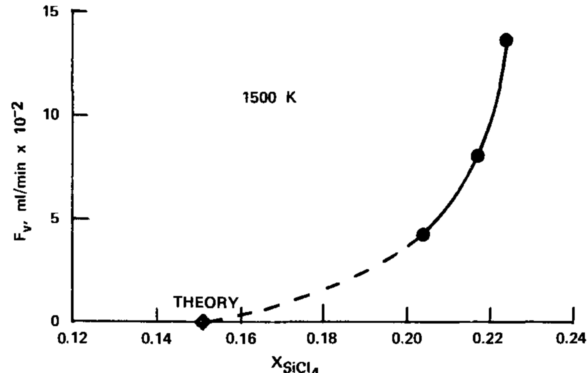

Fig. 7b. Threshold values at different flow rates as a function of $SiCl_4$ mole fraction.

of the above-mentioned phenomenon appears; the experimental threshold values show a shift toward lower Cl/H ratios.

Discussion of Experimental Data

This section does not aim at a thorough mathematical treatment of complex diffusion effects as has been done by others (5, 11, 12, 15-19). It attempts to correlate our theoretical equilibrium curves, which we feel are very accurate, with experimental facts and to explain deviations on the basis of different kinetic models.

If a gaseous compound is decomposed on a heated substrate, surface reactions will be the limiting factor in cases of high flow rates, supported by high concentrations and lower temperatures. Each one of these parameters alone can be of sufficient influence to establish a surface controlled mechanism. The number of active sites at the phase boundary is another critical factor that may be used to determine the character of a heterogeneous reaction.

Kinetically controlled deposition.—As long as the situation in a reactor is completely controlled by surface kinetics, a direct correlation of experimental deposition rates with the corresponding equilibrium situation calculated for given substrate temperatures is impossible. For silicon, this was demonstrated by the work of Theuerer (9) and Bracken (14) where a linear function could be found in a log R *vs.* $1/T$ plot for both $SiCl_4/H_2$ and $SiHCl_3/H_2$ mixtures on single-crystal substrates at temperatures up to 1350°C. Of course, the experimental data have to be lower than the equilibrium values, but the slope of such a curve is indicative only of the activation energy of the rate-limiting step in surface kinetics. Different substrate orientations and their influence on silicon deposition rates have been studied (14, 20, 21) elsewhere. Similar investigations on germanium (22) supported the opinion that significant differences in growth rates occur only in surface reaction-limited systems, with (111) being the least reactive crystal face. The contrary situations, reported by Sheftal' and Givargizov (23) for the $GeCl_4$-H_2 system, can be interpreted in terms of reactants being considerably contaminated with oxygen. In this case, the impurity is able to block active sites but may favor the formation of two-dimensional growth on a (111) plane. When the surface reaction rate becomes comparable with or greater than the diffusion rate of the different gaseous compounds in the diffusion layer, a discussion of the real equilibrium situation is much more meaningful.

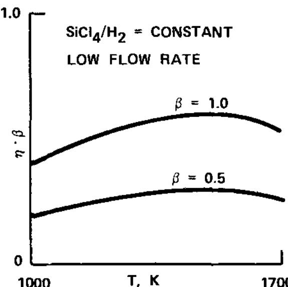
Diffusion-controlled deposition.—The nearly proportional displacement of experimental and theoretical low flow rate data, as shown by curve b in Fig. 4, can be described as resulting from mass transport limitation based on Sedgwick's (6) approach for calculating deposition rate data according to Eq. [3]

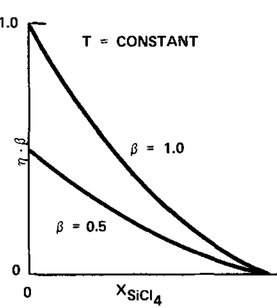
$$R = J \cdot \eta \cdot \beta \quad [3]$$

Here, the silicon deposition rate in grams/minute is simply formulated as the product of the flux (J, grams/minute) of silicon into the reactor, the fractional thermodynamic efficiency (η) under isothermal conditions, and the fractional part (β) of the gas stream that actually reaches equilibrium conditions at the phase boundary. Since equilibrium can be assumed to be established in the vicinity of the phase boundary at low flow rates and high temperatures (1200°-1700°K), the result of inefficient contact ($\beta < 1.0$) of the gas stream with the substrate is schematically shown in Fig. 8 where β is assumed to have a constant value. A similar mass transport limited reaction has been reported by Silvestri (22) in the Ge-H-Cl system and could also be found in Shepherd's paper (12) after comparison with our theoretical data.

The introduction of the factor β certainly is a way to describe and understand a number of experimental curves on a generalized basis and seems to work well in many cases where the process is more or less controlled by diffusion. This is favored by low flow rates,[3] high temperatures, and a large number of active surface sites. In particular, it applies to the growth of

[3] The experimental approach of zero flow conditions in Fig. 7b, for instance, may never reach the theoretical value for the same reason.





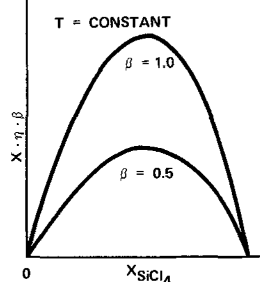


Fig. 8a-c. Effect of contact efficiency, β, of the gas stream on the deposition parameters of silicon from $SiCl_4$-H_2 mixtures.

polycrystalline material as such or to epitaxial deposition processes where polycrystalline material is simultaneously formed as a by-product on the susceptor. The temperature function of η during growth of polycrystalline silicon is shown in Fig. 4. Whereas curve b seems to fit Sedgwick's approach, curves c and e show considerable deviations from such a model in both high and low temperature regions. Before we try to explain this phenomenon, the basic reversible reactions in the $SiHCl_3/H_2$ and $SiCl_4/H_2$ systems shall be pointed out[4]

$$SiHCl_3 = SiCl_2 + HCl \quad [4]$$

$$SiCl_4 + H_2 = SiCl_2 + 2HCl \quad [5]$$

$$SiCl_2 = [SiCl_2] \quad [6]$$

$$[SiCl_2] + H_2 = [Si] + 2HCl \quad [7]$$

$$[SiCl_2] + [SiCl_2] = [Si] + SiCl_4 \quad [8]$$

High flow rates at low temperatures favor a surface reaction like [7] as the rate-controlling step. Support is given to this assumption by kinetic investigations in the system B-H-Cl (24, 25) where the reduction of adsorbed boron-chlorine compounds to elemental boron is claimed to be reaction controlling. Occasionally, concurrent blocking of active centers by traces of oxygen may also contribute to the slope of curves c and e. A similar reason has been suggested by Silvestri (22) in his investigation of germanium deposition from $GeCl_4$-H_2 mixtures.

At high temperatures, however, low surface mobility of the reactants cannot be the reason for increased deviation from the calculated values. The high equilibrium partial pressures of silicon dichloride and hydrogen chloride in this temperature region (see Fig. 1b and c) certainly play a major role in the reaction mechanism responsible for the strongly negative yield gradient. As the reactive diffusion layer markedly increases in thickness at higher temperature, homogeneous reactions of type [4] and [5] can take place there to a larger extent. Since addition of hydrogen chloride to the reaction mixture has been reported to suppress silicon growth more than expected as compared to equilibrium conditions (see Table IIb), it can be assumed that HCl being preformed in the diffusion layer will exert the same influence on silicon deposition in such a case.

Transitionally controlled deposition.—The analysis of epitaxial silicon deposition rates as a function of the mole fraction of chlorosilanes (Fig. 5 and 6) calls for an explanation as to why the theoretical curves reach the threshold point at a lower chlorosilane concentration. A different kinetic model must be used since control by an uninhibited heterogeneous reaction over the entire range of the mole fraction of the chlorosilane would result in the experimental curves being forced to remain within the envelope of the calculated ones, as shown by the idealized situation in Fig. 8b and c. Data by Runyan *et al.* (7), in the case of $SiCl_4$-H_2 and $GeCl_4$-H_2 mixtures, indicate a transition between two different deposition mechanisms since both depressions and protrusions on a (111) surface were enhanced at lower chloride concentrations while they disappeared at higher concentrations. This means that at higher excess of hydrogen the chlorosilane molecules impinging upon the surface are immediately reduced to silicon at or near the point where they hit the surface. At higher chlorosilane concentrations the original molecules or their first reaction product, $SiCl_2$, are forced to travel along the surface until they reach an active site (growth step) where elemental silicon can be formed. Normally, the concentration of hydrogen chloride generated by reactions of type [4] or [5] would be high enough here to suppress silicon deposition according to reaction [7] (see Fig. 1c). As the $SiCl_2$ molecules, however, are strongly concentrated along the edge of a growth lamella (reaction [6]), conditions are ideal for a reaction of type [8] where no HCl is generated to counteract silicon deposition. Presently, however, we are unable to exclude another model according to which an incomplete reaction to form $SiCl_2$ is followed by a more efficient reaction of type [7] near the threshold region. Similar thoughts already were developed in an earlier paper (3).

At a first glance it is surprising to see the threshold value in Fig. 6 shifted to lower mole fractions by applying reduced pressure. As the summary reactions

$$SiHCl_3 + H_2 = [Si] + 3HCl \quad [9]$$

and

$$SiCl_4 + 2H_2 = [Si] + 4HCl \quad [10]$$

show an increase in gaseous compounds by one mole each, the contrary case might be expected. A more thorough examination, however, reveals that the partial reactions [4] and [5] are of the same character. When a temperature region is discussed where the partial pressure of $SiCl_2$ is no longer negligible, reactions producing this molecular species are thermodynamically favored because the reaction entropies of reactions [4] and [5] simply are higher by 4-5 eu as compared to reactions [9] and [10].

Irrespective of most different types of equipment and experimental conditions general outlines can be given as to what extent either surface-controlled or diffusion-controlled reactions are expected to play the predominant role. In Table III the contribution of the

most influential parameters is demonstrated in form of a chart. A fairly reliable prediction can be made about the most probable kinetic regime of a particular reaction system from the six different choices depending on whether the balance of checked conditions lies to the left or right of center.

The Arrhenius equation.—Basically, the shape of the log R *vs.* $1/T$ curve (Fig. 9) arises due to the existence of three different kinetic regimes. At lower temperatures, curve a characterizes the activation energy of the rate-limiting reaction at the silicon surface. At medium temperatures curve b describes a slightly increasing efficiency due to the conditions of diffusion-limited mass transport. The subsequent decrease in growth rate at the highest temperatures (curve c), besides the thermodynamic aspects, can be explained by reactions in the diffusion layer leading to enhanced etching effects on the silicon surface, as stated above. In the case of monosilane, the same phenomenon (26) is attributed to homogeneous nucleation.

Depending on the temperature range being investigated, as well as the concentration and nature of the silicon compound, one or two out of these three principal stages have not been revealed in most of the published experimental curves. Evidently, one has to be cautious in calculating activation energies within a temperature range where an overlapping of surface-controlled and diffusion-controlled reactions on the background of the theoretical maximum yield curve does not allow a simple application of the convenient Arrhenius equation (33).

Thus, different activation energies of the silicon deposition reaction have been reported for different compounds under various experimental conditions (Table IV). However, a family of curves recently obtained for different chlorosilanes at concentrations of 0.1% each (34) seems to indicate the same activation energy at lower temperatures. This is interpreted, at least in the concentration range mentioned, as the migration of silicon ad-atoms being the rate-limiting step. Additional experiments would be welcome to test the validity of this model in different concentration ranges and to further characterize its atomic nature.

Summary

A thorough thermodynamic analysis of the Si-H-Cl system was made to assist in understanding what gas phase species can be involved in the high temperature reactions occurring during silicon deposition under various conditions. Experimental data from the literature were then processed to point out existing trends. Attempts to clarify these trends were made by considering the probable reactions occurring under both diffusion-controlled and kinetically controlled regimes. Mixed regimes were considered and a method was offered to tabularly determine the probable controlling regime. The limitations of applying the Arrhenius equation to deposition rate data were discussed.

APPENDIX

Threshold Experiments

The epitaxial deposition unit consisted of a metered supply of pure hydrogen (accurate to better than ± 10% volume flow), a thermostatically controlled $SiCl_4$ saturator capable of maintaining a $H_2/SiCl_4$ gas phase ratio within an accuracy of $< \pm 0.1\%$ independent of the H_2 flow, and a pedestal reactor. The reactor was such that the feed entered from the bottom and exited at the top. The surface of the silicon wafer substrate to be deposited upon was pointed downward (see Fig. 10). This configuration was used to reduce errors due to thermal convection. Substrate temperatures were measured with a 0.65μ disappearing fila-

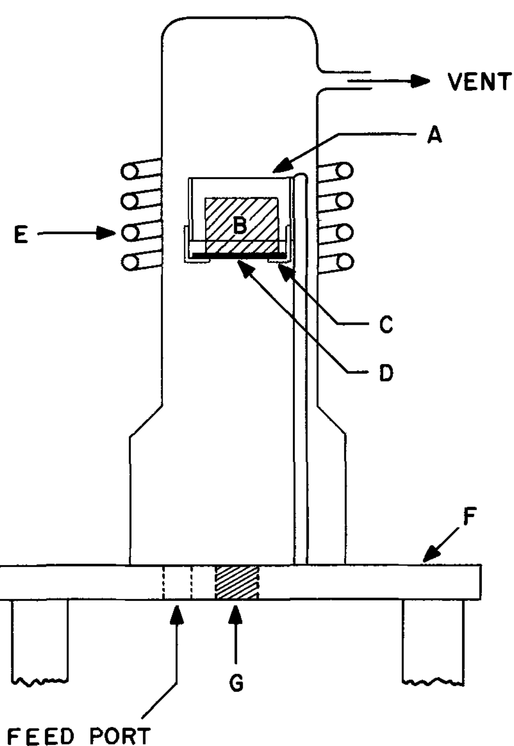

Fig. 10. Bottom feed epitaxial reactor. A, Quartz substrate-susceptor cylinder; B, SiC coated graphite susceptor; C, quartz support hooks; D, silicon wafer substrate; E, induction coil; F, stainless steel baseplate; G, quartz window.

ment pyrometer and corrected for emissivity using a standard curve obtained by prior calibration. Substrate temperature measurement accuracy was better than ±10°C. The thickness of the deposited silicon layer was determined by conventional measurements on stacking faults and is considered precise to within 5-10%.

The substrates were 8 mils thick by 28 mm diameter polished, float-zoned silicon wafers of [111] orientation. Prior to mounting in the reactor, substrates were sequentially cleaned ultrasonically in trichloroethylene, acetone, and methanol followed by drying under a heat lamp.

Conventional silicon epitaxial procedure was used except the pre-cleaning in H_2 at $> 1200°C$ was carried out for 2-5 min instead of the usual 15-30 min. This procedure left a sufficient amount of oxide on the surface such that surface originated stacking faults could easily be generated. Deposition was performed at a corrected temperature of 1225° ± 6°C.

ABSTRACT

The etching rate in dilute acids of iron oxide thin films prepared either by sputtering in CO/CO_2 mixtures or by low temperature chemical vapor deposition techniques, may be modified by irradiation with an argon-ion cw laser. Depending on the exposure time and power levels used, laser irradiation may (*i*) leave the film unaffected, (*ii*) greatly reduce its solubility, or (*iii*) completely remove the film. For exposures ranging from several seconds to a few minutes, the power level necessary to produce low solubility is several hundred milliwatts per square millimeter. Film evaporation begins at a few watts per square millimeter. By rapidly translating the film through the focal point of a laser beam, regions of reduced solubility in the form of a line as narrow as 1 μm have been obtained at writing velocities of 2000 cm/sec. It is proposed that with these techniques, iron oxide "see through" masks for use in integrated circuit technology may be written directly.

It has recently been shown that iron oxide films are suitable as "see through" masks for use in integrated circuit technology. These films may be made by chemical vapor deposition (CVD) using $Fe(CO)_5$ (1) or by rf sputtering of Fe or Fe_2O_3 electrodes in a CO-CO_2 atmosphere (2). Chemical analysis (3, 4) indicates the films are a mixture of Fe_2O_3 and $Fe_2(CO_3)_3$. An essential attribute of these films is their rapid rate of solution in 6M HCl. In this report we investigate the possibility of changing the etching rate of these films using a cw laser beam as a heating agent.

Clearly the etching rate of iron oxide films and ways of modifying it are of great importance in the use of iron oxide as a mask material. In particular,

* Electrochemical Society Active Member.

Key words: photomasks, laser irradiation, thin films.

MacChesney *et al.* have shown that the etching rate in 6M HCl of CVD iron oxide films is quite dependent on the substrate temperature during deposition. Films prepared at about 200°C dissolve very slowly ($t \sim$ 1 hr) in 6M HCl, whereas films prepared at 160°C or lower dissolve in less than 1 min. Sullivan (3) has also shown that heat-treatments can convert a "soluble" film to an "insoluble" film. These results suggested that localized heating might be used to produce insoluble patterns of iron oxide in a soluble iron oxide film. Electron beam heating of iron oxide films has been studied and is discussed in the accompanying article (5). There have been a few reports in the literature of inorganic materials in which the rate of solubility has been modified by electron beam irradiation (6, 7) and a report by Fitzgibbons and Hartwig (8) in which the solubility of an amorphous film of TiO_2 was modified both by electron beam irradiation and by exposure to ultraviolet radiation. In the present work we have found that by controlling the intensity of an incident laser beam the films may be made to behave either as positive or as negative resists. Linewidths as small as 1 μm have been obtained at laser beam scanning velocities of 2000 cm/sec.

Experimental

Two sources of ~2500Å thick iron oxide films were used in this investigation. Some were prepared by sputtering from an Fe electrode in an 80% CO-20% CO_2 plasma and the others, which were prepared commercially by the CVD method, were purchased from Towne Laboratories in Somerville, New Jersey. The samples were irradiated with a Coherent Radiation Model 53 Argon-Ion Laser. In general the 5145Å output was used. A few irradiations were carried out at 4880Å but these showed no observable differences in the resulting changes to the iron oxide film. The output power of the 1.5 mm diameter beam at 5145Å was held constant at either 1.5 or 2.5W.

Two series of experiments were performed. In the first, for various exposure times, the average power threshold required to reduce the solubility of the iron oxide film was determined. The measurements were made by operating the laser at constant power and then controlling the power density at the film by focusing the beam and varying the position of the sample in the divergent cone of light, as shown in Fig. 1a. The samples were irradiated for a constant time ranging from 10 sec to 5 min. Lenses with focal lengths ranging from 5 to 9 cm were used. The resulting thresholds were determined by calculating the average power density over the appropriate cross-sectional area. In these experiments the most consistent results were obtained from the CVD films possibly because they had a very homogeneous thickness range, and the results quoted are those obtained from these films.

In a second series of experiments, iron oxide samples were attached to a 6 in. diameter turntable as shown in Fig. 1b. By using synchronous motors, rotation speeds ranging from about 0.1 to 2000 rpm were obtained giving sample velocities of about 0.1-2000 cm/

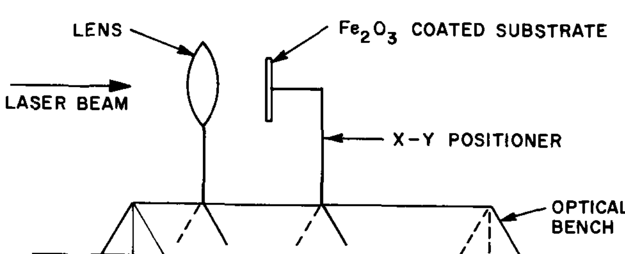

Fig. 1a. Schematic drawing of experimental arrangement for static sample irradiations.

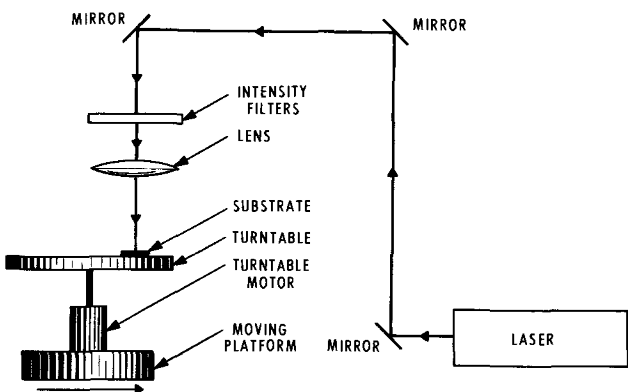

Fig. 1b. Schematic drawing of experimental arrangement for moving sample irradiation.

sec. The turntable motor was attached to a platform which was laterally translated so that the laser beam interacted with the substrate in a series of quasi-parallel arcs. Samples were placed at the focal point of a lens with a 6 mm focal distance and the beam intensity was attenuated by insertion of neutral density filters. With this system, measurements of the minimum linewidths and the feasibility of high speed writing were determined. In these experiments only sputtered films (1000 and 2500Å thick) were studied. In the following discussion only results for the 2500Å thick films are presented. The thinner films behaved in a similar fashion except that smaller linewidths were obtained in general.

Although most measurements were made on samples deposited on glass or fused silica substrates, films deposited on sapphire substrates were also studied to explore the importance of thermal conductivity, and to verify that the observed solubility changes were not strongly substrate sensitive. After irradiation and microscopic inspection, the films were treated with 6M HCl for about 2 min to see if any insoluble material had been produced. Any resulting insoluble material could be left in a 6M HCl bath for 1 hr without apparent change, establishing a ratio of greater than 25 for the etch rate difference before and after irradiation. Exposure of this material for a few minutes to a reducing solution containing powdered iron in 6M HCl would dissolve the irradiated samples (9).

Results and Discussion

The effect of laser irradiation on soluble iron oxide films is a critical function of the laser power density and of exposure time. At insufficient exposure the irradiated section will dissolve in 6M HCl in about the same time as the unexposed films and there is no visual evidence of change. At more powerful exposures the film is made insoluble and there is a noticeable darkening of the film where exposed. The optical absorption spectrum of an exposed film is compared with that of a typical unexposed CVD film in Fig. 2. The results are similar to those obtained on heating iron oxide films in an oven to about 475°C (10). Because of the strong absorption at 589 nm by this insolubilized film one would probably prefer to use a light source of longer wavelength than the often used sodium d-line if one wishes to make use of the irradiated film as a see through mask. It should be pointed out that spectra intermediate between the extremes presented in Fig. 2 should be obtainable at slightly lower laser powers. In these experiments in which the laser beam was incident on the sample for times between 10 sec and 5 min, the threshold flux sufficient to yield an insoluble residue after etching in 6M HCl was determined. The limits for several exposure times are indicated in Table I. It is seen that there is a wide range of power densities in which the solubility is reduced, but there are problems in determining precise limits for the range

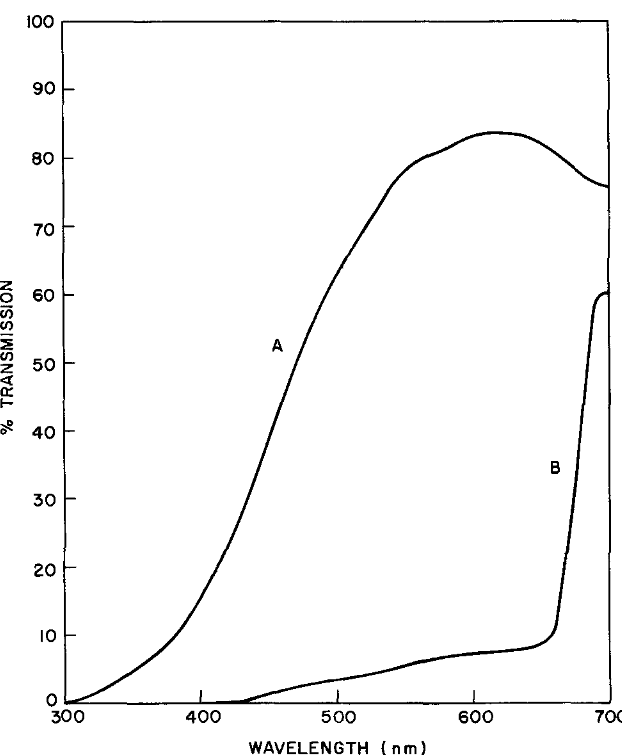

Fig. 2. Optical absorption spectra for iron oxide films. a, Not laser irradiated; b, laser irradiated.

of conditions. At low power densities fogging occurs as the lateral heat conduction becomes increasingly important. Furthermore, at this end, the degree of etch rate varies fairly continuously, approaching the unirradiated value at lower power densities. At the high power density end, the film cracks and bubbles, with occasional breakage of the glass substrate. As the power is increased, the iron oxide is completely removed from the substrate so that the process effectively leads to a positive resist. Qualitatively similar results were obtained with iron oxide deposited on a sapphire substrate but the thresholds were about 50% higher.

To study in greater detail the exposure needed to modify the solubility of iron oxide films upon laser irradiation, and to determine the minimum linewidths readily obtainable, samples were placed on the rotating table and passed through the focal point of the laser beam. As with the static experiments, several different stages of change in the film could be identified, depending on the incident laser intensity. At the highest intensities, the laser beam left a completely transparent path with insoluble iron oxide boundaries (Fig. 3a). At lesser intensities some globules of insoluble material remained in an otherwise transparent path (Fig. 3b). At still lower intensities the laser beam left a darkened path which was found to be insoluble in 6M HCl (Fig. 3c). Finally at the lowest intensities there was no effect on the appearance or solubility of the film. The velocities in these experiments ranged from 0.5 to 2000 cm/sec. At low scan speeds, low laser powers and long focal length lenses were used. The long focal length lenses gave rather large (~100 μm) diffraction limited spots, so that the resulting lines were correspondingly wide. At high scanning speeds, higher laser powers

Table I. Power density requirements for negative resist formation in iron oxide in static experiments

Exposure time (sec)	Minimum power density (mW/mm²)	Maximum power density (mW/mm²)
10	1000	3000
30	800	2000
300	500	1500

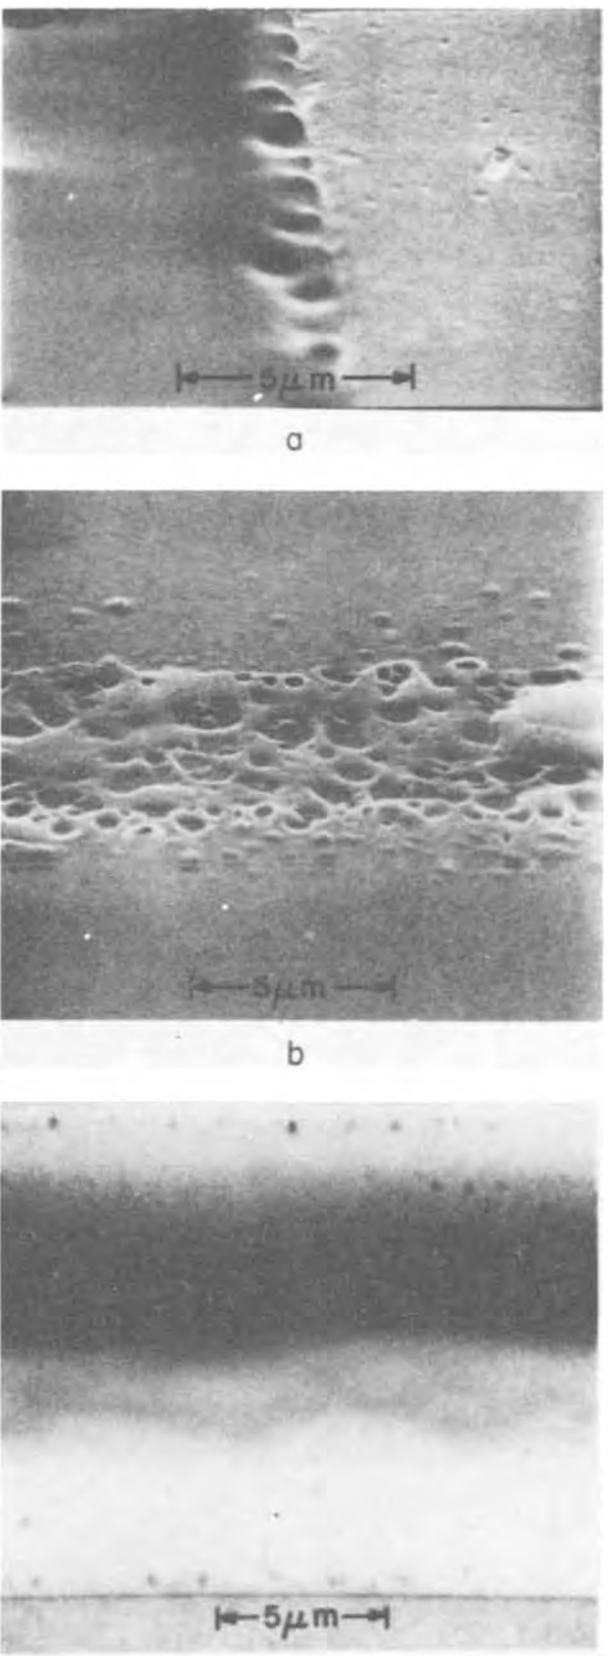

Fig. 3. Scanning electron microscope view of laser irradiated iron oxide films from *kinetic experiments*. a, Edge between completely evaporated iron oxide line on right and unreacted iron oxide film on left. Total width of line was 36 μm. b, Line of insoluble iron oxide globules and voids. Iron oxide in areas above and below this line has been removed by dissolving in acid. c, Line of insoluble iron oxide. Iron oxide in areas above and below this line has not *been removed by dissolving in acid as yet. After dissolving in acid* a small amount of granularity will be noted at the edges of the line.

Table II. Linewidths of iron oxide films (ca. 2500Å thick) on fused silica made insoluble by laser action as a function of scan speed and power density

Scan speed (cm/sec)	Power density (W/mm^2)	Linewidth (μm)
3	3×10^2	70
30	3×10^4	7
2000	10^5	1

were used along with short focal length lenses to obtain a high flux density. Therefore, the widths of the lines we obtained were, in some cases, as small as 1 μm. In Table II some typical scan speeds, linewidths, and power densities are listed for conditions under which the iron oxide films were reduced in solubility (*i.e.*, the formation of a negative resist). Since near the focal point the cross section varies rapidly, accurate power density measurements were not made. The values reported in the table correspond to the approximate center of the power range for negative resist formation. It should be pointed out that at the limit of the range studied, lines as narrow as 1 μm were obtained at writing speeds as high as 2000 cm/sec.

The ultimate limit to the resolution obtainable and maximum writing speed with which solubility changes may be effected no doubt may be extended beyond the limits obtained in this investigation. The purpose of this study was only to demonstrate the general feasibility of laser induced solubility changes. Narrower lines should be obtainable by reducing the focal length of the lens. Similarly, faster writing speeds should be possible by increasing the power density at the sample surface.

The details of the structure of both the sputtered and the CVD films are not yet well understood, nor are the changes which occur upon selective heating. Initially it was felt that the presence of carbon in the films had little effect on the etch rate and it was crystal size that dominated solubility properties (1). However, chemical analyses (3, 4) have now shown that the films typically contain ~25% $Fe_2(CO_3)_3$ in Fe_2O_3, and infrared spectra have confirmed the presence of carbonate in the films. Furthermore, in CVD films deposited on substrates held at 200°C, and found to be insoluble, chemical analysis indicated there was no carbon present. Although it is not known which effect is dominant it is now felt that both crystalline size and also the presence of iron carbonate may influence the solubility. In this study, in addition to the beforementioned visible absorption measurements, a few preliminary reflection electron diffraction measurements have been made in an effort to determine the differences between the laser exposed insoluble films and unexposed films. Diffraction patterns of the laser treated films were sharper than the patterns obtained from untreated films, corresponding to a substantial increase in crystallite size. From the d-spacings the irradiated films were identified as α-Fe_2O_3. This is consistent with other studies in which air annealed films give Fe_2O_3 and vacuum annealed films give Fe_3O_4 and Fe_2O_3 (5).

From the results presented here it is clear that laser induced changes in the solubility of iron oxide films may have application in the production of integrated circuits. The usefulness of iron oxide films as photoresist material with high temperature stability is worth exploring. At relatively low laser intensities the film becomes insoluble and thus acts as a negative resist, whereas at high laser intensities the film may be completely vaporized giving a positive resist. It was observed that the edge definition surrounding this vaporized area was substantially sharper than that obtainable from metallic films and other oxide films that lack such crystallinity changes. This is possibly due to a higher power threshold for removal of the crystallized border material than for removal of the amorphous material (11). Exposure could be carried out by placing a conventional mask over the sample. However, in view of the short exposure times shown to be needed in the present study, the mask step may be completely eliminated, and, with a programmed laser beam, a pattern might be written directly on the photoresist material. (At a scanning speed of 2000 cm/sec a 1 μm wide path will cover a 1 by 1 cm area in about 5 sec assuming no overlap and no time loss at the beginning and end of a pass.) Such a technique would also be particularly appropriate for making iron oxide masks for thin-film circuits on ceramic where minimum linewidths are ~50μ.

Acknowledgment

We thank M. V. Sullivan and P. A. Turner for several helpful discussions. The reflection electron diffraction determinations were done by G. W. Kammlott and the visible absorption spectrum was measured by Mrs. G. A. Pasteur. Assistance in microscopy by Mrs. I. M. Payne was also very helpful.

Manuscript submitted Oct. 11, 1973; revised manuscript received Jan. 28, 1974.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1975 JOURNAL. All discussions for the June 1975 Discussion Section should be submitted by Feb. 1, 1975.

Fe_2O_3—An Inorganic Electron Resist Material

G. W. Kammlott and W. Robert Sinclair*

Bell Laboratories, Murray Hill, New Jersey 07974

The publication costs of this article have been assisted by Bell Laboratories.

ABSTRACT

Fe_2O_3 films of the type used for see-through masks dissolve much more slowly in 6M HCl after irradiation with the electron beam of a scanning electron microscope. The ratio of the time to dissolve irradiated material to the time to dissolve unirradiated material is 25 or greater. The films behave, therefore, as negative resists. Irradiation studies were conducted over a voltage range of 5-30 kV, a current range of 5×10^{-8}-7×10^{-7}A, and scanning rates in the range 1-500 mm/sec. On glass substrates at room temperature a minimum current of 1×10^{-7}A is required at a beam diameter of approximately 1 μm. At 7×10^{-7}A, Fe_2O_3 flakes from the substrate thus establishing a practical maximum current for the process. In general, the line width of the Fe_2O_3 made insoluble increases with increasing voltage and decreases with increasing scanning rate. For a scanning rate of 500 mm/sec and a beam current of 4×10^{-7}A at 10 kV, a line width of 0.8 μm is obtained. Edge definition is excellent. Transmission electron microscopy shows the irradiated, insoluble part of the film to be a mixture of Fe_3O_4 and α-Fe_2O_3. Similar results are obtained for Fe_2O_3 films deposited onto oxidized silicon and silicon, although the latter requires a somewhat higher threshold current. Use of this process is suggested for direct construction of see-through masks without intermediate steps involving organic resists. Because of their dimensional and thermal stability, Fe_2O_3 resist films should also be useful as masks for processes involving high temperatures. These include ion implantation, sputtering, and possibly dopant diffusion.

Fe_2O_3 films prepared by reacting $Fe(CO)_5$ and O_2 at temperatures below 165°C dissolve within a few minutes in 6M HCl (1) at room temperature. Due to this ease of etching, coupled with desirable optical and mechanical properties, the so-called soluble Fe_2O_3 films have been used recently for see-through masks (2) in integrated circuit manufacture. In contrast, Fe_2O_3 films prepared at temperatures of 200°C and higher by the same reaction are relatively insoluble. A film of the high temperature form of the same thickness (*ca.* 2500Å) requires 50 min or more to dissolve in the same solvent. MacChesney *et al.* (1) have attributed this difference in rate of dissolution to differences in grain size in the deposited films. This led to speculation that techniques could be developed for changing the crystallite size in selected areas and, using the consequent large change in rate of dissolution, the Fe_2O_3 film would then behave as a resist material. As we shall show later, the chemistry involved in these reactions is not as simple as initially thought. Nevertheless, electron beam irradiation and laser irradiation (3) have been used successfully to change the rate of dissolution of Fe_2O_3 films. The use of localized electron beam irradiation to decrease the dissolution rate of soluble Fe_2O_3 films in selected areas is the topic of this paper.

Inorganic materials are not usually thought of as resist materials. We are aware of three other studies of inorganic systems, however, where substantial changes in the rate of dissolution as a result of electron beam irradiation have been reported. O'Keeffe and Handy (4) found that electron beam irradiation of SiO_2 could increase the etch rate by a factor of 3. Hill (5) studied the electron irradiation of Al_2O_3 and Ta_2O_5 films and noted a decrease in the rate of dissolution. Fitzgibbons and Hartwig (6) irradiated a gel-like film of TiO_2 and obtained an insoluble film.

Experimental

Material.—Amorphous Fe_2O_3 films which dissolve quickly in 6M HCl can be prepared either by chemical vapor deposition (CVD) (1) or by sputtering (8). Although patterns have been written on films prepared either way, only the results on CVD films will be presented since results on the sputtered films showed greater spread in results possibly because they were less homogeneous in thickness. The CVD films used (2500Å thick) were from a commercial source (Towne Laboratories, Somerville, New Jersey). For transmission electron microscopy (TEM), films of Fe_2O_3 deposited on carbon coated glass substrates were obtained from the same source.

Instrumentation.—All electron beam exposures were carried out with a Cambridge Stereoscan Mk IIa scanning electron microscope (SEM) equipped with a beam blanking unit, a specimen current amplifier, and a 400μ final aperture. Accelerating voltages of 5-30 kV were used and specimen currents ranged from 5×10^{-8} to 1×10^{-6}A. The electron beam was approximately 1 μm in diameter or less with a current density of up to 50 A/cm^2. The focused beam scanned the Fe_2O_3 film in two perpendicular directions to yield grid patterns of various sizes. Most patterns measured 1 mm × 1 mm and were written at beam speeds up to 500 mm/sec. The SEM was also used for subsequent evaluation of the patterns, and transmission electron microscopy (TEM) was carried out with a Siemens Elmiskop 1A.

Experimental Procedures

Since Fe_2O_3 films are sufficiently conductive all current measurements were obtained by grounding them via a current amplifier. Condenser lens currents were varied to yield various sample currents, and the beam was then focused. The size of scanned area and the line speed determined the beam speed and the frame speed was set to yield between 100 and 250 lines per frame.

All exposures were evaluated visually (most of the patterns were readily seen with the unaided eye) as well as with a low power light microscope. Subsequent immersion in 6M HCl for approximately 2 min dissolved the unexposed areas. Some of the remaining grid patterns were then evaluated with the SEM.

For TEM, an Fe_2O_3 film (~1000Å) deposited on carbon coated glass was floated onto a water surface and

* Electrochemical Society Active Member.

Key words: photomasks, electron irradiation, thin films.

mounted on a copper grid. Patterns were then written with the SEM in a similar fashion but no etching treatment was given in this case.

Results

At 5 kV some patterns written at 3×10^{-7}A and at beam speeds of 0.1 and 0.25 mm/sec were observable during the first period of the etching process. These patterns were removed from the substrate by 6M HCl along with the unexposed film. This is not surprising since calculation indicates that most of the energy loss in the Fe_2O_3 film occurs above the film-substrate interface for these conditions (8). Thus a layer of acid-soluble film remains between the irradiated film and the substrate.

At 10 kV all patterns remained after etching. However, a minimum current of 1×10^{-7}A is required to form an insoluble film. The maximum effective beam speed changed drastically with current increase. At 1×10^{-7}A the maximum effective beam speed was 1 mm/sec, at 2×10^{-7}A 50 mm/sec, and at 3×10^{-7}A up to 500 mm/sec. At the latter two currents the resulting line width was 0.8μ (cf. Fig. 1) leading to a calculated current density of 40 A/cm². When the beam speed at 3×10^{-7}A was slowed down the line width broadened to 1.2μ at 250 mm/sec and 1.5μ at 100-25 mm/sec. One of the remarkable features of these lines is the excellent edge definition as indicated in Fig. 1. Similarly, at 4×10^{-7}A and 250 mm/sec the line width was 1.5μ and at 25 mm/sec 2μ. Further slowing down of the beam resulted in flaking of the written path leaving a bare central area with a wall of unetched material on either side of the path (cf. Fig. 2).

Similar results were obtained at 20 and 30 kV with increases in line width by approximately a factor of 2 at comparable beam speed and current levels.

The electron irradiated films that remain on the glass substrate after etching are quite difficult to dissolve in 6M HCl. They are not noticeably attacked in less than an hour. This leads to a ratio of dissolution times for the irradiated material to the unirradiated material of at least 25.

Measurements of a less thorough nature have been made with Fe_2O_3 on an oxidized (2000Å) silicon slice and also on an unoxidized silicon slice. With the oxidized silicon the electron beam and writing parameters are essentially the same as for the glass substrate. With the unoxidized silicon much slower scanning rates are required indicating perhaps that the greater thermal conductivity of silicon as compared with glasses affects the process.

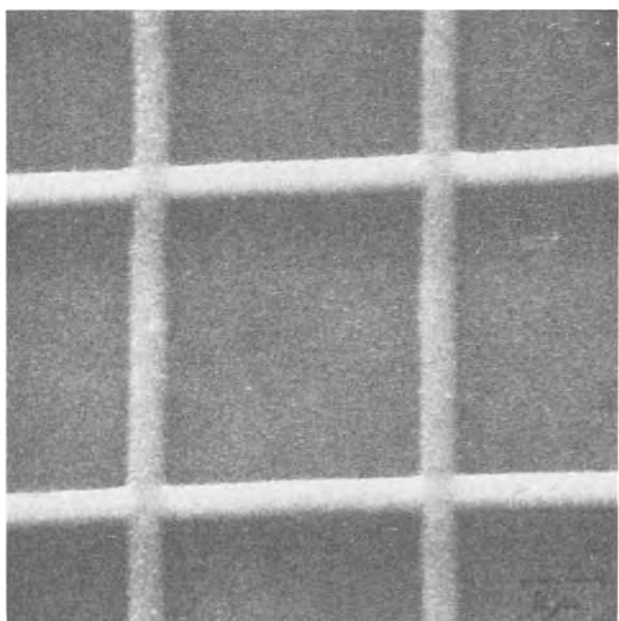

Fig. 1. Pattern written at 10 kV 3×10^{-7} and 500 mm/sec beam speed.

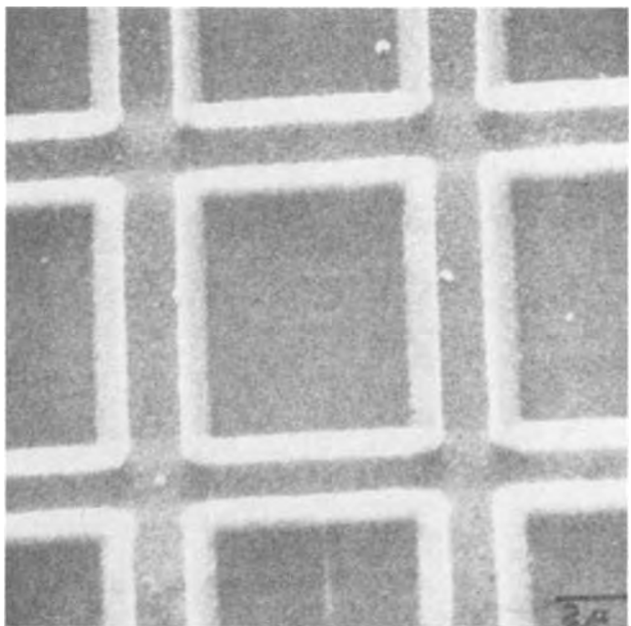

Fig. 2. Pattern written at 10 kV 4×10^{-7} and 10 mm/sec beam speed.

Transmission electron micrographs clearly show the pattern written by the electron beam as a matrix of crystallized material with crystallite sizes up to 0.5 μm. Selected area diffraction of the unexposed squares and exposed line support this observation. While the unexposed areas yield rather broad ring patterns because of crystallite sizes well below 100Å, the exposed areas show a number of superimposed single-crystal patterns (cf. Fig. 3). For more detailed identification of the materials involved in the reaction process, samples were prepared by annealing films in air and in vacuum as well as by beam exposure with the lines closely spaced to yield large areas of totally exposed material. Several large area electron diffraction patterns were obtained. The unexposed film, as well as films annealed in vacuum at 300°C for 2 hr and in air at 450°C for 1-5 hr yield similar broad diffuse ring patterns, although changes in color and rate of solution in 6M HCl are clearly obtained. Sharp ring patterns were obtained for these films when exposed in the TEM at high current levels for less than 1 min. A square exposed in the SEM at 10 kV and 3×10^{-7}A, and also films annealed at 450°C for 15 hr in air and in vacuum gave rise to sharp ring patterns. The d-spacings were determined using densitometer tracings and an Au standard diffraction pattern and compared to data in the ASTM powder diffraction file. The film annealed in air was identified as α-Fe_2O_3. The vacuum-annealed film was Fe_3O_4, and the material exposed to the electron beam a mixture of the two iron oxides.

Discussion

The original hypothesis on which this work was based was that we could heat an Fe_2O_3 film with an electron beam to obtain larger crystallites and that these larger crystallites, following MacChesney's surmise, would have a much slower rate of solution in 6M HCl. The results tend to confirm these ideas but the sinter-mechanism of grain growth involved is not yet resolved. At the outset, one might expect some correlation between the product of the maximum scanning speed and the current. However, as indicated earlier, this does not hold as the scanning rate increases. In this discussion no reference has been made to the heat of crystallization which should become increasingly significant as the scanning rate increases.

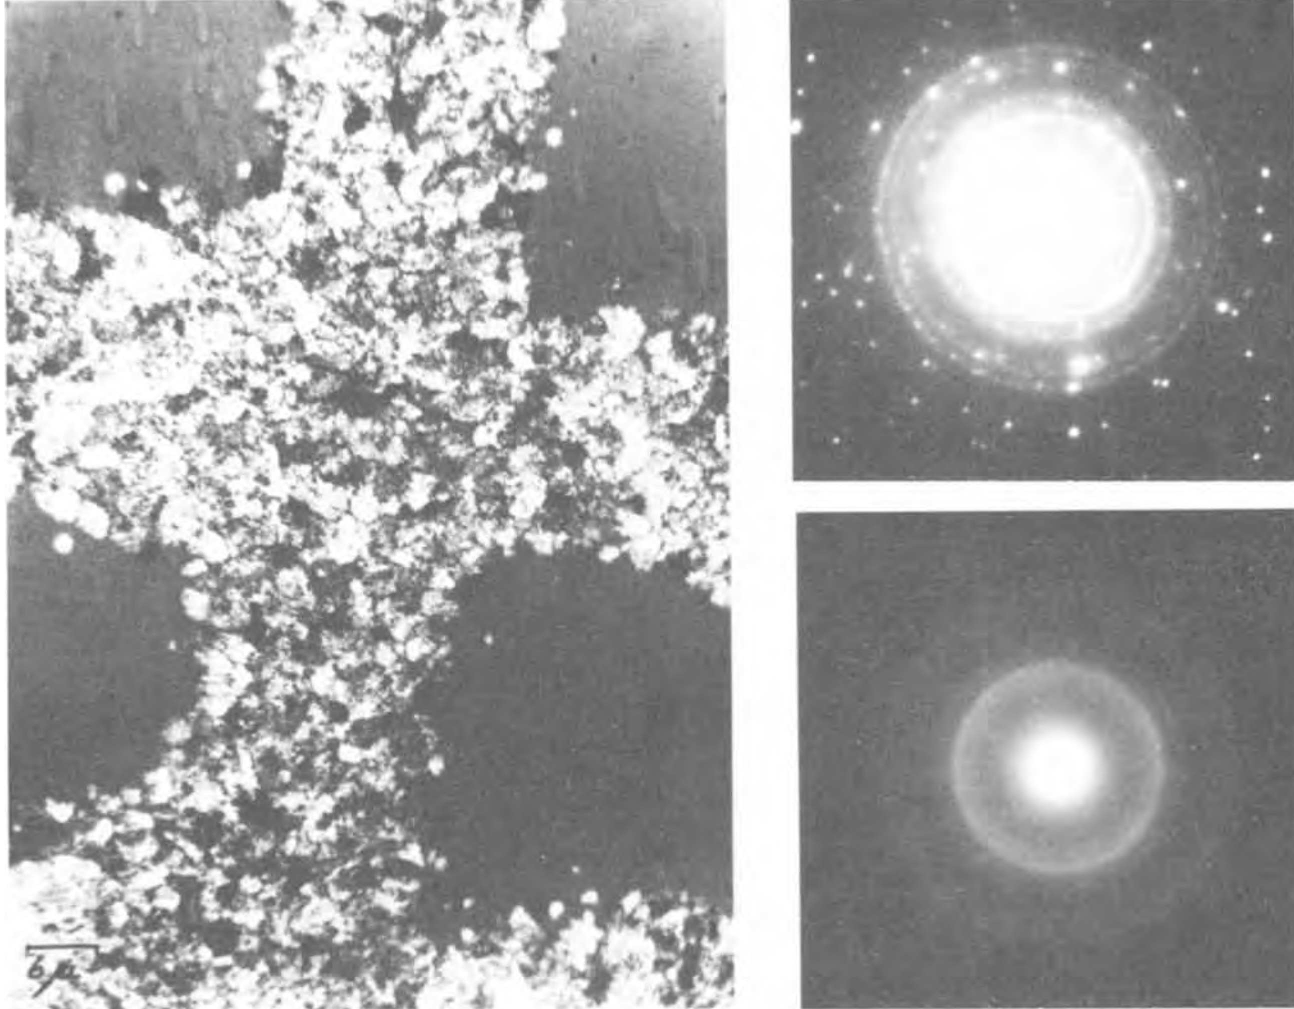

Fig. 3. Transmission electron micrograph of pattern written into Fe_2O_3 film at 3×10^{-7} 10 kV and 100 mm/sec beam speed. Selected area diffraction patterns from unexposed and exposed area show crystallization due to beam exposure.

Before any meaningful discussion of the kinetics of this crystallization process can be made, the heat of reaction and activation energy of the process must be determined. In addition, it is now known that there is a significant amount of carbonate in the film (9, 10) and the slowing down of the dissolution process in acid might be explained, with our present meager knowledge of the system, simply in terms of the loss of an acid soluble carbonate on heating. These are probably not the only approaches available to an understanding of this interesting process. However, more experimental information is needed to characterize the reaction(s) involved. Since inorganic resist materials could have advantages over organic resists in some processes, better understanding of the chemistry and physics of this system may enable a more efficient search to be made for other inorganic resists. It would be surprising if Fe_2O_3 were unique in its properties.

From the results obtained it is evident that one should be able to "write" contact or projection Fe_2O_3 masks using a programmed electron beam. Writing machines have already been built and used in various laboratories using organic resists. Here, the Fe_2O_3 will be both the mask material and the resist material. The fact that the ratio of dissolution time of the exposed Fe_2O_3 to dissolution time of the unexposed Fe_2O_3 is so large means that the solution process need not be closely controlled. The danger of undercutting, present when organic resists are used, is eliminated. We anticipate that the consequent cut in processing steps will result in masks with fewer defects and concomitant savings.

Summary

The rate of solution in 6M HCl of Fe_2O_3 films of the soluble type used in making see-through masks has been made drastically slower by a factor of 25 or greater by irradiation with electrons in a SEM. For 2500Å films on a glass substrate a minimum current of 1×10^{-7}A at 10 kV is required. At higher than 7×10^{-7}A at 10 kV the films distort and may detach from their substrates. The total voltage range studied was 5-30 kV. Scanning rates from 1 to 500 mm/sec were used. In general, the line width of insolubilized Fe_2O_3 increased with increasing voltage and with decreasing scanning rate. Similar results were obtained on silicon substrates with 2000Å of thermal SiO_2. One can also write on unoxidized silicon substrates using different experimental parameters.

The films before electron irradiation are amorphous. After writing in the SEM, the films are a crystalline mixture of α-Fe_2O_3 and Fe_3O_4.

ABSTRACT

Previous analyses of the liquidus and solidus lines in III-V pseudobinary systems are combined and extended. (*i*) The ideal, strictly regular, athermal, and quasiregular models are investigated for each phase. (*ii*) A quantitative measure, σ(°C) of a fit is defined and determined. (*iii*) All sets of values for the parameters of a model giving a value of σ less than a critical value (7°-16°C) characterizing the experimental accuracy are determined and treated on an equal footing. It is found that the strictly regular liquid-quasiregular solid model is the simplest model giving satisfactory fits for all of the seven systems chosen as the best defined experimentally. Moreover these fits are obtained over a range of values of the three model parameters. As a consequence, thermodynamic properties of the liquid are not closely specified by the analysis. In contrast, for the solid at one temperature, $T = m$, we find $\Delta G_M^{xs} = (b \pm 200) y_1 y_2$, where the y's are mole fractions and m and b are determined from the fits: m and b are correlated to the properties of the III-V components, and m is 0.98 ± 0.03 of the average of their melting points while, within ± 250 cal, b is proportional to the sixth power of the fractional difference in their lattice parameters. Three of four other systems with data satisfy these correlations. Seven others with no data are discussed. The stability of a quasiregular phase is discussed and the conditions for the formation of normal and "inverted" miscibility gaps established.

The nine III-V binary systems containing either Al, Ga, or In on the one hand and P, As, or Sb on the other, all show a single, zinc-blende structure compound at 50 atom per cent (a/o). The eighteen ternary systems formed by taking at least one element from each of the above two groups all have a single pseudobinary section between two III-V compounds. Considerable, though by no means complete, data is available for the pseudobinary sections. Foster and Scardefield (1, 2) and Foster, Scardefield, and Woods (3, 4) have recently determined solidus points for four of these in which a complete range of solid solutions is formed. A thermodynamic analysis by Foster and Woods (5, 6, 3, 4) indicates that six pseudobinary sections can be satisfactorily fit on the assumption that the liquid phase is essentially ideal while the solid phase is athermal (zero enthalpy of mixing, nonzero excess entropy of mixing). Panish and Ilegems (7) obtain what they consider somewhat poorer fits on the assumption that both liquid and solid phases are strictly regular (nonzero enthalpy of mixing, zero excess entropy of mixing). The latter authors were in general not primarily concerned with an optimum fit in the pseudobinary section, but rather with acceptable over-all fits in both the ternary proper and in the pseudobinary section.

For eleven pseudobinary sections Stringfellow (8) has obtained qualitative agreement using a strictly regular model in which the adjustable parameters are fixed by considerations independent of the experimental liquidus and solidus lines. Subsequently he has recalculated (9) the interaction parameters for the solid solutions. A proportionality constant occurring in his calculation is chosen so that the interaction parameters agree as closely as possible with those obtained by Panish and Ilegems (7). Steininger (10) has shown for a number of binary and pseudobinary systems that, given either the liquidus line or the solidus line, the other can be calculated accurately assuming ideal solutions. Moreover, this is the case even when an ideal solution model does not fit the individual liquidus and solidus lines well.

In this paper we present the results of computer fits to those seven, III-V, pseudobinary sections for which the data seem most reliable. Our working premise, which proved correct, was that the quasiregular liquid-quasiregular solid model, containing a maximum of

* Electrochemical Society Active Member.

Key words: inverted miscibility gap, Gibbs free energy of mixing, lattice parameter, miscibility gap.

four adjustable parameters, two for each phase, is sufficiently flexible to lead to satisfactory fits. The objectives are to combine and extend the previous analyses by:

1. Obtaining, hitherto unavailable, quantitative measures of all fits obtained. This measure, denoted by σ, is defined in the next section.
2. Establishing the simplest variants of the general model (those with the maximum number of zero values for the four adjustable parameters) that give satisfactory fits for all the systems.
3. Determining the sensitivity of σ to the exact values of the adjustable parameters. Thus an essential part of our investigation is not only to determine the minimum σ attainable, but also to fix the range over which the adjustable parameters can be changed without significantly increasing σ above this minimum value.

After defining a quantitative measure of fit, σ, a critical value is adopted for each system below which σ must fall if a fit is to be considered satisfactory. Then all sets of values for the adjustable parameters giving a value of σ less than the critical value are to be considered on equal terms with that parameter set that gives the minimum value. Admittedly, an element of arbitrariness in the specification of a critical value for σ cannot be avoided in practice. Nevertheless, this is preferable to a procedure in which no specification is made and the best fit obtained is taken as unique. Among the specific interesting results obtained within the general objectives, are answers to the following questions: (a) Does the ideal liquid-athermal solid model, proposed by Foster and Woods, describe the III-V pseudobinaries better than an ideal liquid-strictly regular solid model? (b) Is the two parameter, ideal liquid-quasiregular solid model better than the two parameter, strictly regular liquid-strictly regular solid model? (c) Which, if any, thermodynamic properties are most closely and reliably fixed as a result of the fits to the liquidus and solidus lines?

We find that ideal liquid-athermal solid and ideal liquid-strictly regular solid models give essentially the same fits except for GaAs-GaSb. However, the computer fits show there is no basis for choosing either of these models over the more general ideal liquid-quasiregular solid model, since satisfactory fits are obtained for a significant range in the adjustable parameters of the solid phase. The ideal liquid-quasiregular solid model gives satisfactory fits for five of the seven systems and appears slightly inferior to the strictly regular liquid and solid model, which gives satisfactory fits for six systems. The simplest variant of the full quasiregular model that fits all seven systems with the presently available data is the three parameter, strictly regular liquid-quasiregular solid model. For each system, satisfactory fits are obtained along a line segment in the plane of the two adjustable parameters for the solid phase. Thus although the thermodynamic properties of the pseudobinary liquid phase are not closely defined, the excess Gibbs free energy of mixing of the solid phase is defined at one temperature, $T = m$, to within ± 200 cal in terms of a parameter, b. Correlations are found between these parameters and the properties of the III-V compounds defining a pseudobinary section. The parameter, m, is 0.98 ± 0.03 of the average of the melting points. The paramter, b, is proportional to the sixth power of the fractional difference in the room temperature lattice parameters. Analysis of four additional III-V pseudobinary sections shows these correlations hold well for two systems, fair for the third, and not at all for the fourth. The discrepancy in the last case is most likely due to significant errors in the experimental solidus points and a calculated solidus line, believed to be more accurate, is given. The seven remaining pseudobinaries for which there are no data are also discussed in view of the empirical correlations found.

The plots of only a few phase diagrams are given in this paper. The disposition of the experimental points can be seen in plots already given in Ref. (1-6) or, for all the III-V pseudobinaries, in Ref. (7). Moreover, on page size graphs the agreement between experimental points and the calculated phase diagrams would look near perfect when the fits are within 16°C or, as in most cases here, within 10°C.

Before presenting the results, the necessary thermodynamic background is outlined in the next section along with a discussion of some relevant, general properties of a quasiregular phase that have not been given previously.

Thermodynamic Background

A binary phase is called a simple solution (11) if the excess Gibbs free energy of mixing can be represented in terms of a composition-independent parameter, Ω, as

$$\Delta G_M^{xs} = \Omega x_1 x_2 \quad [1]$$

where x_1 and x_2 are the mole fractions of components 1 and 2, respectively. We assume throughout that Ω depends linearly on the temperature, T, *i.e.*

$$\Omega = W - VT \quad [2]$$

Solutions described by Eq. [1] and [2] have been called quasiregular in the past and, although objections (7) have been made against this terminology, we use it in favor of the lengthy phrase "linear temperature dependence, simple solution." It follows immediately that the enthalpy and excess entropy of mixing are given by

$$\Delta H_M = W x_1 x_2 \quad [3]$$

and

$$\Delta S_M^{xs} = V x_1 x_2 \quad [4]$$

so that Eq. [2] is tantamount to the assuming that ΔH_M and ΔS_M^{xs} are independent of T. Special cases of the quasiregular model of a phase include the ideal model ($W = V = 0$), the strictly regular model ($W \neq 0$, $V = 0$), and the athermal model ($W = 0$, $V \neq 0$).

A quasiregular solution described by Eq. [1] and [2] can become unstable relative to internal decomposition, *i.e.*, a miscibility gap can form. The behavior of this phenomenon can be elucidated by determining the zeros of the first and second composition-derivatives of the Gibbs free energy of mixing. Since the argument follows that widely given (11, 12) for strictly regular solutions, it is not repeated here. However, the main results and how they differ from those for the strictly regular solution have not been previously discussed and so are summarized. A miscibility gap, whose extremes at any T are symmetric about $x = 1/2$, is present whenever $\Omega \geqq 2RT$, where R is the gas constant. In view of Eq. [2] this condition can be written as

$$W \geqq (V + 2R)T \quad [5]$$

The critical temperature at which the miscibility gap disappears, T_c, is determined by taking the equality sign in Eq. [5], *i.e.*

$$T_c = W/(2R + V) \quad [6]$$

Thus for the special case of an athermal solution, $W = 0$, the critical temperature is zero. In contrast to the situation for strictly regular solutions, there are two kinds of miscibility gaps possible: the normal type that disappears for $T > T_c$ and an inverted miscibility gap that appears for $T \geqq T_c$ and becomes wider as the temperature is increased. The former type is possible for strictly regular solutions, but not the latter. The situation can be summarized by reference to Fig. 1 in which the W-V plane is divided into four quadrants by the lines $W = 0$ and $V = -2R$. No miscibility gap occurs for values of W and V in quadrant I, Ω is negative at all temperatures, and T_c from Eq. [6] is negative. In quadrant II a normal miscibility gap oc-

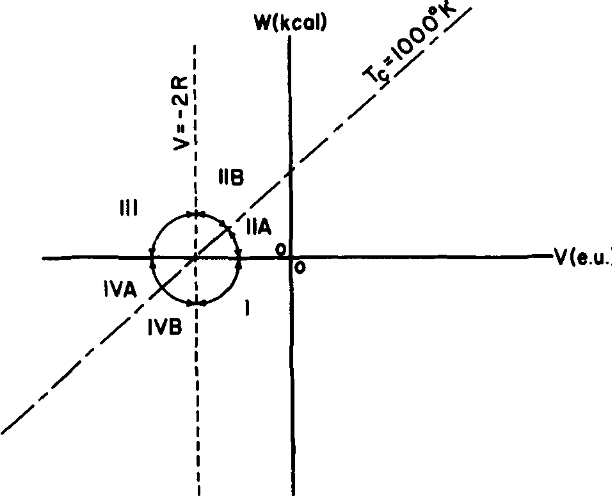

Fig. 1. Structure of the W-V parameter plane for a quasiregular solution.

curs for temperatures between 0° and ∞°K. From Eq. [6] the critical temperature, T_c, is the same for all values of W and V lying on a straight line through the point, $W = 0$, $V = -2R$, and ranges in value from 0°K along the line $W = 0$ to infinity along the line $V = -2R$. The line labeled $T_c = 1000$°K is obtained by substituting 1000°K for T_c in Eq. [6]. Thus below this line and above the line, $W = 0$, (in region IIA) T_c lies between 0 and 1000°K. In region III an inverted miscibility gap occurs at all temperatures, Ω is positive at all temperatures, and T_c is negative. In region IV inverted miscibility gaps occur above a critical temperature that ranges from zero along the line, $W = 0$, to infinity along the line, $V = -2R$. Thus, in region IVB an inverted miscibility gap occurs only for temperatures above a critical temperature which lies above 1000°K. It can be appreciated that these general properties of a quasiregular solution are a useful guide in fitting phase diagrams. Thus, if a continuous range of solid solutions are formed at 1000°K, only those values of W and V in the contiguous regions IIA, I, and IVB need be considered.

Although we are unaware of the existence of inverted miscibility gaps in any inorganic system, they have been observed in the triethylamine-water (13) and ethyl ether-ethyl acetate (14) systems. Closed miscibility gaps, terminating at an upper and lower consolute temperature, have been observed for a number of systems (14) including nicotine-water, β-picoline-water, etc., but this more complex behavior is not describable in terms of the quasiregular model with temperature and composition-independent parameters, W and V.

For a quasiregular solution the chemical potentials of the two components are determined by Eq. [1] and the definition of the Gibbs free energy of mixing

$$\Delta G_m = \Delta G_M{}^{xs} + RT(x_1 \ln x_1 + x_2 \ln x_2) \quad [7]$$

$$= x_1\mu_1 + x_2\mu_2 \quad [8]$$

and are given by

$$\mu_1 = RT \ln x_1 + \Omega x_2{}^2 + \mu_1{}^\circ \quad [9]$$

$$\mu_2 = RT \ln x_2 + \Omega x_1{}^2 + \mu_2{}^\circ \quad [10]$$

where $\mu_1{}^\circ$ and $\mu_2{}^\circ$ are the chemical potentials of pure 1 and pure 2, respectively, and are for the pure solids when Eq. [1] is applied to a solid solution. When Eq. [1] is applied to a liquid solution then $\mu_1{}^\circ$ and $\mu_2{}^\circ$ are taken as the chemical potentials of, respectively, pure liquid 1 and pure liquid 2. The assumption that any one of Eq. [1], [9], or [10] holds over the entire composition range leads to the other two, provided Ω does not depend on composition. (If the chemical potential is known for one component, that for the other can be obtained by an integration of the Gibbs-Duhem relation.) On the other hand, the assumption that μ_1 is given by Eq. [9] with a parameter Ω that depends on composition, leads to equations for $\Delta G_M{}^{xs}$ and μ_2 that are different than Eq. [1] and [10].

The phase lines describing the coexistence of two phases in a binary system are determined from the condition that the chemical potential of each component be the same in both phases. For a coexisting liquid and solid these are

$$\mu_1(L) = \mu_1(S) \quad [11]$$

$$\mu_2(L) = \mu_2(S) \quad [12]$$

where L and S identify, respectively, the liquid and solid phases. Utilizing Eq. [9] and [10] and (with the conventional definitions for $\mu_1{}^\circ(L)$, $\mu_1{}^\circ(S)$, etc., cited after Eq. [10]) assuming $\Delta C_p = 0$ between the liquid and solid phases of both pure 1 and pure 2 leads to the two equations

$$RT \ln x_1 + \Omega_L x_2{}^2 = RT \ln y_1 + \Omega_S y_2{}^2 + \Delta H_1(T/T_1 - 1) \quad [13]$$

$$RT \ln x_2 + \Omega_L x_1{}^2 = RT \ln y_2 + \Omega_S y_1{}^2 + \Delta H_2(T/T_2 - 1) \quad [14]$$

where y_1 and y_2 are the mole fractions in the solid solution, R is the gas constant, ΔH_1 and T_1 are the heat of fusion per mole and melting temperature of pure 1, and ΔH_2 and T_2 are the analogous quantities for pure component 2.

Since we are attempting quantitative fits of phase diagrams it seems appropriate to comment on the "approximation" that led to the last terms in Eq. [13] and [14]. For simplicity these comments are made with reference to Eq. [13], and hence component 1, alone. Completely analogous comments hold for Eq. [14] and component 2. The last term in Eq. [13], $\Delta H_1(T/T_1 - 1)$, is commonly identified as an approximation for the difference between the chemical potential of pure solid 1 and that of pure liquid 1. The approximation is admittedly correct in the near vicinity of the melting point, T_1, but is somewhat in doubt for the wide temperature ranges over which it must often be used, *e.g.*, for III-V pseudobinaries involving GaSb the extreme temperature ranges are 712°-525°C for the pseudobinary with InSb and 712°-1485°C for that with GaP. An accurate expression for the desired chemical potential difference depends on obtaining the heat capacity difference between solid and liquid over temperature ranges where one of these phases is unstable or, at best, metastable. Experiments at elevated pressures would generally extend the temperature range of one phase so that its heat capacity at normal pressure could be obtained by extrapolation. Obtaining the heat capacity of the other phase outside its normal temperature range would depend on the ability of preparing a supercooled liquid, possible in some instances, or on the unlikely possibility of preparing a superheated solid over a wide temperature range. Alternatively, the measured heat capacities for each phase in the neighborhood of the melting point can be extrapolated outside the normal temperature range for each phase and the correction term calculated and added to $\Delta H_1(T/T_1 - 1)$. Following this course with the measurements of Lichter and Sommelet (15) we arrive at a ΔC_p for GaSb given by

$$\Delta C_p(\text{cal/°K-mole}) = C_p(L) - C_p(S) = 1.4 - 3(10^{-3})(T - 985) \quad [15]$$

This leads to correction terms that are 1.4% or less of the main term for all temperatures between 525° and 1500°C and therefore negligible. However, the validity of the extrapolation for ΔC_p can be questioned for temperatures increasingly removed from the melting point. Thus from a fundamental point of view,

Table I. Properties of III-V compounds

** Ref. (17).

the entire discussion above seems operationally meaningless. Therefore we redefine the chemical potentials of the pure components. At and above the melting point, T_1, $\mu_1°(L)$ is the chemical potential of the stable phase, pure liquid 1. At and below the melting point, $\mu_1°(S)$ is the chemical potential of the stable phase, pure solid 1. Below T_1, $\mu_1°(L)$ is the chemical potential of a hypothetical liquid phase, which coincides with real liquid phase at T_1, but otherwise is defined by the equation

$$\mu_1°(L) = \mu_1°(S) - \Delta H_1(T/T_1 - 1); T < T_1 \quad [16]$$

Above T_1, $\mu_1°(S)$ is the chemical potential of a hypothetical solid phase defined in terms of that of the real liquid phase by

$$\mu_1°(S) = \mu_1°(L) + \Delta H_1(T/T_1 - 1); T > T_1 \quad [17]$$

Similar definitions are adopted for component 2. With these definitions the last terms in Eq. [13] and [14] are exact by definition and the assumption that $\Delta C_p = 0$ for each pure component is unnecessary.

Computational Procedure

The experimental liquidus points, $(T_{j,\text{expt}}, x_j)$, and the experimental solidus points, $(T_{k,\text{expt}}, y_k)$ were taken from tabulations, or more often, scaled from graphs. The basic equations are [13] and [14] with Ω_S and Ω_L depending linearly on temperature as shown in Eq. [2]. The computer calculation starts with initial guesses for the solid parameters, W_S and V_S, and the liquid parameters, W_L and V_L. (In a given calculation some or all of these may be fixed throughout the calculation at any desired value including zero. The latter situation corresponds to one of simple variants of the general quasiregular liquid-quasiregular solid model. Thus, if all four parameters are fixed at zero, one has the ideal liquid-ideal solid model.) The first experimental liquidus composition is then inserted into Eq. [13] and [14] along with the initial values for W_S, V_S, W_L, and V_L, and these two simultaneous equations are solved for the liquidus temperature for x_1, $T_{1,\text{calc}}$, and the composition of the coexisting solid. This procedure is repeated for each of the N liquidus points. The M experimental solidus compositions, y_k, are then inserted one at a time into Eq. [13] and [14] and these solved simultaneously for the solidus temperature for y_k, $T_{k,\text{calc}}$, and the composition of the coexisting liquid. A residual function, or standard deviation, σ, is calculated using the equations

$$\sigma^2 = \sigma^2_{\text{LIQ}} + \sigma^2_{\text{SOL}} \quad [18]$$

and

$$\sigma^2_{\text{LIQ}} = \sum_{j=1}^{N} (T_{j,\text{calc}} - T_{j,\text{expt}})^2/N \quad [19]$$

$$\sigma^2_{\text{SOL}} = \sum_{k=1}^{M} (T_{k,\text{calc}} - T_{k,\text{expt}})^2/M \quad [20]$$

The values of the adjustable parameters are then changed in a systematic "trial-and-error" manner based on the simplex minimization technique of Nelder and Mead (16). For each set of values of W_S, V_S, W_L, and V_L a value of σ is calculated. The cyclic calculation continues until a minimum value is found. It should be noted that the over-all residual function σ is constructed from those for the solid and liquid with equal weight given to each, regardless of the relative numbers of liquidus and solidus points. Thus the calculated liquidus and solidus lines must individually fit the data well if a low σ is to be attained, and a very good fit to a large number of solidus points cannot offset a poor fit to a few liquidus points.

Experimental Data

The III-V compounds along with their melting points, heats of fusion, and lattice parameters (17) are given in Table I. Estimated values are indicated by an asterisk. The values for melting points and heats of fusion, both estimated and weighted experimental values, are the same as those used by Foster and Woods (1-6). Their papers should be consulted for the literature references. Panish and Ilegems (7) used estimated values for the heats of fusion of GaP, InP, and AlAs that are 1-3 kcal different. The pseudobinaries analyzed and the number of liquidus points and solidus points used are listed in Table II. Critical values of σ were assigned on the assumption that ordinarily an accuracy of 7°C can be expected for the liquidus and solidus points. Using Eq. [18], [19], and [20] this gives a value of 10° when both liquidus and solidus points are available. For GaP-InP the four liquidus points were obtained by extrapolation of a fit to the ternary liquidus using a strictly regular model (18). We still assume an accuracy of 7° for these points but recognize this may bias the situation in favor of models assuming a strictly regular liquid. For GaAs-GaSb the four solidus points are confined to a narrow composition range near pure GaAs and the solidus line drops very sharply with temperature. Consequently, the critical value of σ_{SOL} was doubled to 14°C, giving a critical value of 16°C for σ. For InAs-InSb there is significant scatter among independent data sets in certain composition intervals along both the liquidus and solidus. Consequently, we have increased the critical value to 11°C for both phase lines to give a critical value of 16°C for σ.

Results

Ideal liquid-quasiregular solid model.—The general type of result obtained is shown in Fig. 2 for GaAs-GaP where labeled contours of constant σ are shown in the W_S-V_S plane. Contours for the lower values of interest are of the same elongated shape but too closely spaced to be presented clearly. Therefore they are omitted in favor of a "best-fit line segment" with a table giving the variation of σ for a few values of V_S along the best-

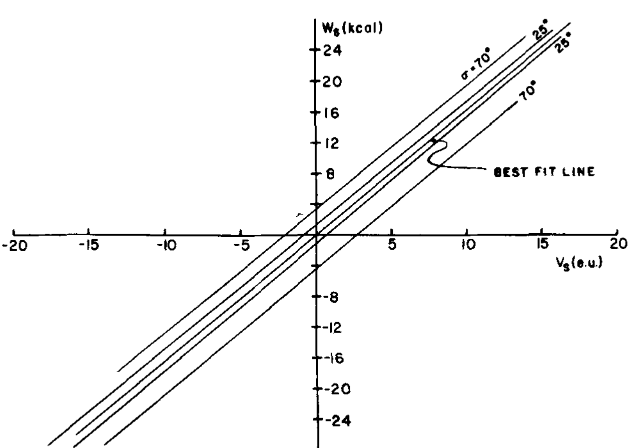

Fig. 2. Contours of constant σ and the best-fit line in the W_S-V_S plane obtained with the ideal liquid-quasiregular solid model for the GaAs-GaP pseudobinary. Variation of σ along the best-fit line:

V_S	−15.6	−6	0	+8.0	+14.7
σ	10.0	5.0	1.8	5.0	10.0

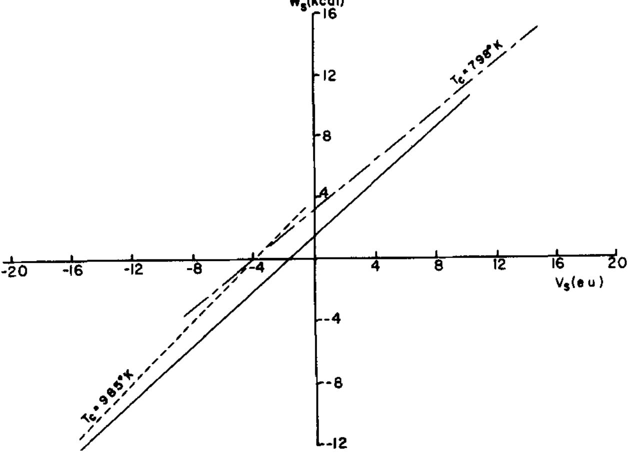

Fig. 3. Best-fit line and lines of constant critical temperature, T_c = 798° and 985°K obtained with the ideal liquid-quasiregular solid model for the GaSb-InSb pseudobinary. See Fig. 4 for the variation of σ along the best-fit line.

fit line. The best-fit line segment was obtained by fixing V_S, finding the lowest possible value of σ and the value of W_S associated with it, then connecting all such points in the W_S-V_S plane. It is seen that σ varies slowly along the best-fit line but rapidly at right angles to it. Thus although the smallest value attained for σ is 1.2°C at W_S = 1.8 kcal and V_S = 2.0 eu, the value of σ does not reach 10°C until one moves along the best-fit line to V_S = 14.7 eu or to V_S = −15.6 eu. Even if the critical value of σ is revised downward to 5°C, all of the W_s-V_s values for $-6 \leq V_S \leq +8$ are to be considered equally good on the basis of the currently available experimental data for the pseudobinary. A similar result is shown in Fig. 3 for GaSb-InSb. However, for clarity, no contours are shown, only the best-fit line segment. Instead, the upper half of the line corresponding to a critical temperature of 798°K, as calculated using Eq. [6], and the lower half of the line corresponding to a critical temperature of 985°K for an inverted miscibility gap are shown. It can be anticipated that if the best-fit line segment were extended to intersect these lines of constant critical temperature that the value of σ would increase rapidly since the experimental data show no miscibility gap in the 798°-985°K interval.

All of the systems analyzed show the same behavior as seen in Fig. 2 and 3, differing only in the position of the best-fit line, the lowest value of σ attained on it, and the rate of change of σ along it. The data can be summarized by giving the slope and intercept of the best-fit line along with Fig. 4, showing the variation of σ along the best-fit line in a plot of σ against V_S. However, to avoid the incorrect assumption that σ increases infinitely rapidly in a direction perpendicular to the best-fit line, the best-fit line is written as

$$W_S = mV_S + b \pm \delta \qquad [21]$$

Here m and b are the slope and intercept, respectively,

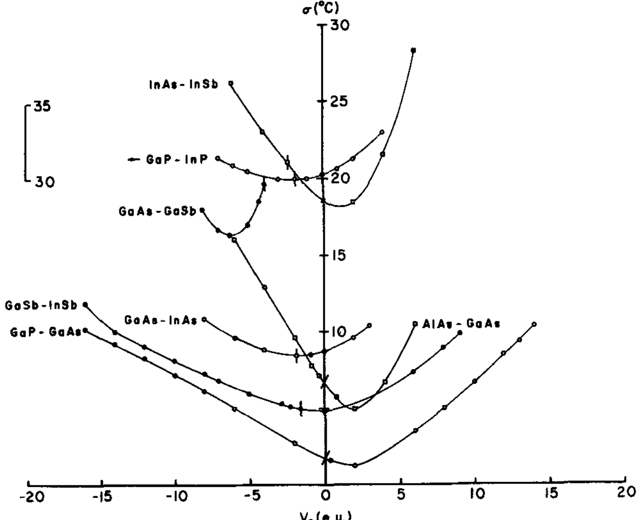

Fig. 4. Ideal liquid-quasiregular solid model. Variation of σ with V_S along the best-fit line in the W_S-V_S plane. For InP-GaP the values of σ are given at the left-hand side of the figure.

of the best-fit line, while δ is the amount W_S can be moved from its best-fit position in a direction perpendicular to the best-fit line before σ increases by 5°C. Then Eq. [21] along with Fig. 4 can be used to delineate a long rectangular area in the W_S-V_S plane that includes and somewhat exceeds the elongated oval-like area for which σ is less or equal to $\sigma_{MIN} + 5$. These parameters are listed in Table III for the various systems. Also given are the minimum value of σ and the values of W_S and V_S for which σ reaches the listed cutoff value. The cutoff value of σ is identical to the critical value assigned in Table II if a good fit is obtained. Finally the value of σ is given for the ideal

Table III. Summary of results for the ideal liquid-quasiregular solid model

InAs-InSb	930	2300		18.4	Bad	21	68	−2.4	5741	3.7	95	93	17

liquid-ideal solid model, which is seen to be satisfactory for only two systems.

It is seen that five of the seven pseudobinaries are fit satisfactorily and three of these are fit very well. The fit for InAs-InSb is unsatisfactory but close enough to be considered doubtful. The fit for GaP-InP is bad. In both of these cases the lowest value attained for σ corresponds to a high value for σ_{LIQ} and a satisfactory value for σ_{SOL}, *i.e.*, the model does not fit the liquidus points well. At the cutoff values listed in Table III for these two systems the value of σ_{SOL} has increased by 5° over the minimum value attained. If the estimated liquidus points for GaP-InP are excluded, a satisfactory best fit of 7°C is obtained while the best-fit line is essentially unchanged.

The InSb-InAs pseudobinary seems the best defined experimentally of all those considered. Therefore, we conclude the liquid in this pseudobinary is not adequately described as ideal. This is perhaps not surprising in view of the complicated nature of the Sb-As binary system in which the liquidus shows a minimum. However, one would also expect some difficulty in fitting the liquidus for the GaSb-GaAs system. That this does not occur may be due to the fact that the Sb-As interactions are reduced in significance at the higher temperatures encountered in the GaSb-GaAs pseudobinary.

The values of V_S giving the lowest σ when $W_S = 0$ (indicated by the short vertical bar on each curve of Fig. 4) are what would be calculated from the values of V_S/RT given by Foster and Woods (3-6). Therefore, our results include theirs and yield a quantitative measure of the fits possible with the ideal liquid-athermal solid model. More importantly, by comparison with the value of σ for $V_S = 0$, strictly regular solid, it is seen that the ideal liquid-athermal solid model is not significantly better than the ideal liquid-strictly regular solid model except for GaAs-GaSb. Furthermore, there is no basis for categorizing the solid solutions more specifically than as quasiregular.

In view of the generally wide ranges of values for W_S and V_S that lead to satisfactory fits, especially for those systems for which the smallest values of σ are attained, the values calculated for the enthalpy and excess entropy of mixing of the solid solutions are subject to such a wide uncertainty as to be meaningless. In contrast, the values calculated for the excess Gibbs free energy of mixing, as well as those for the chemical potentials are more closely defined at one temperature between the melting points of the pure compounds. This can be seen by inserting the value of W_S from Eq. [21] for the best-fit line segment into Eq. [1], [9], and [10]. One obtains

$$\Delta G_M^{xs}(S) = \{(m - T)V_S + b \pm \delta\}y_1y_2 \quad [22]$$

$$\mu_1^{xs}(S) = \{(m - T)V_S + b \pm \delta\}y_2^2 \quad [23]$$

$$\mu_2^{xs}(S) = \{(m - T)V_S + b \pm \delta\}y_1^2 \quad [24]$$

As a concrete illustration, fits with $\sigma \leqq 7°C$ are obtained for GaP-GaAs along a best-fit line segment for all values of V_S between -9.8 and $+10.3$ eu. Equally acceptable values for the excess entropy of mixing of the 50 mole per cent (m/o) solid therefore range from -2.5 to $+2.5$ eu while those for the enthalpy of mixing range from -1.0 to $+1.0$ kcal/mole. In contrast, the value calculated for $\Delta G_M^{xs}(S)$ for 50 m/o is $b = -200 \pm 200$ cal/mole at $T = m = 1637°K$ (about halfway between the melting points of GaAs and GaP). Therefore for each system analyzed, the most significant thermochemical quantities following from a fit of the phase lines are the excess Gibbs free energy of mixing and the chemical potentials of the solid phase at a temperature $T = m$. In other words, the interaction parameter for the solid, Ω_S, is closely defined as a result of a fit of the phase diagram only near one temperature, $T = m$, where it is equal to b.

Finally, the GaAs-GaSb system is unique among those analyzed in that the experimental solidus points are not distributed well across the composition range, but are concentrated in the 85-100 m/o GaAs interval due to difficulty in obtained equilibrated samples. This provides an opportunity to illustrate an element of flexibility possessed by the quasiregular model of the solid which is not shared by a strictly regular model. In Fig. 5 three different calculations of the phase lines using the ideal liquid-quasiregular solid model are shown. The temperature scale is magnified to show the desired detail and as a consequence only the low-temperature portion containing no experimental points is seen. For all three calculations the liquidus line is essentially the same and fits the experimental points well with $\sigma_{LIQ} = 6°C$. The values used for W_S and V_S are listed in the figure caption and all fall along the best-fit line segment given in Table III for GaAs-GaSb. The best fit of the solidus points is obtained with curve 1 and is somewhat better than those obtained with curves 2 and 3. Note that curves 1 and 3 are within 15°C of one another and curves 2 and 3 are within 3°C of one another. However, curves 1 and 2 correspond to a complete range of solid solutions from 0°K to the respective solidus lines. In contrast, curve 3 shows a narrow miscibility gap in the solid solution that extends from 45 to 55 m/o GaAs at a peritectic temperature of 734.5°C. An optimum fit using a strictly regular model for the solid is significantly poorer as can be inferred from Fig. 4. Moreover, the values required for W_S are near 4300 cal so that the sole option is a miscibility gap in the solid solution from 0°K to over 712°C.

Strictly regular liquid and solid.—Contours of constant σ plotted on the plane of the two adjustable parameters, W_S and W_L show the same elongated form as for the previous model. The results can again be presented by listing the parameters of the best-fit line segment

$$W_S = sW_L + i \pm \delta \quad [25]$$

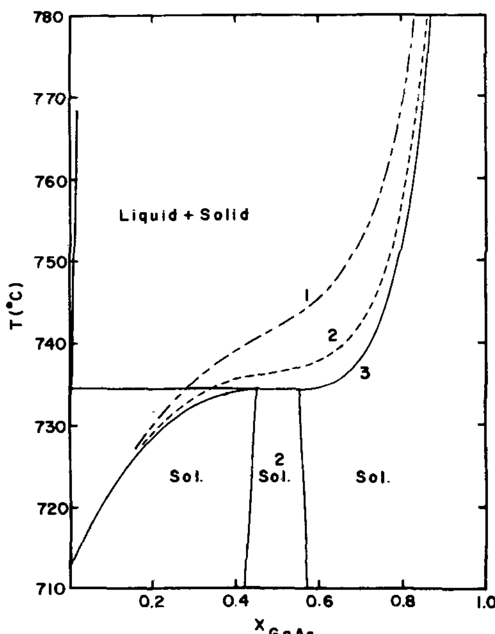

Fig. 5. Detail in low-temperature range of GaAs-GaSb phase diagram calculated using ideal liquid-quasiregular solid model. Liquidus lines coincide for all three calculations. The peritectic shown is for curve 3 only.

Solidus	W_S(cal)	V_S(eu)	σ_{SOL}(°C)
1	−2514.	−6.0	15.6
2	0.0	−3.385	18.6
3	+608.2	−3.854	20.4

and by showing the variation of σ along this line segment in a plot of σ against W_L. The slope, s, and intercept, i, of the best-fit line are listed in Table IV along with the parameter δ which has the same definition as previously. For two systems the best-fit line consists of two segments. Also shown are the lowest value of σ and the values of W_L and W_S for specified cutoff values of σ.

For comparison the values (8) of W_L and the revised values (9) of W_S given by Stringfellow and the associated values of σ and σ_{LIQ} calculated by us are given in the last four columns. (The associated values of σ_{SOL} can be calculated using Eq. [18].) With the exceptions of the AlAs-GaAs, GaP-GaAs, and InAs-InSb systems, the values of σ are more than 20°C over the 10°-16°C critical values chosen by us as characterizing a good fit. With the exception of the GaAs-GaSb system, σ_{LIQ} is one to two times as large as σ_{SOL} for the five systems with liquidus points, while σ_{SOL} is 23°C or less.

The variation of σ along the best-fit line is shown in Fig. 6 for the various systems. Using the same critical values of σ as before, the fits for six of the systems are satisfactory. Comparison of the fits in Fig. 6 for the strictly regular model with those in Fig. 4 shows that four pseudobinaries are fit to better than 10°C with both models. The strictly regular model fits the GaP-InP system much better with $\sigma_{MIN} = 8.5°$ as opposed to 30°; the InAs-InSb system slightly better with $\sigma_{MIN} = 13°$ as opposed to 18.4°; and the GaAs-GaSb system significantly worse with $\sigma_{MIN} = 31°$ as opposed to 13.9°. On the basis of fits to the phase lines we would judge the strictly regular model to be slightly superior at present and, when it is remembered that there is a general paucity of liquidus points, to be potentially superior when more liquidus points are obtained.

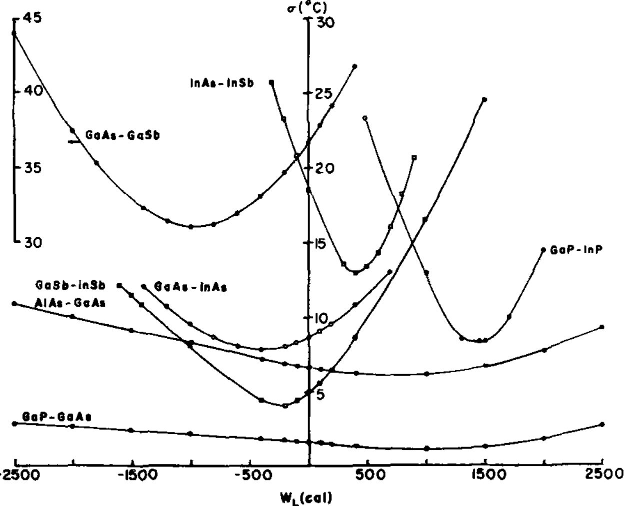

Fig. 6. Strictly regular liquid and solid model. Variation of σ with W_L along the best-fit line in the W_S-W_L plane. For GaSb-GaAs the values of σ are given along the left-hand side of the figure.

Table IV shows that, except for GaP-InP, there is a wide percentage spread in the values of W_L associated with σ-values less than the cutoff value. Therefore, the enthalpy of mixing of the liquid phase does not emerge from an analysis of the phase lines as a sharply defined quantity. In contrast the variation in W_S is considerably less for three systems, so that the enthalpy of mixing of the solid phase is defined to within ±100 cal out of a total of 2000-4000 cal for GaP-InP, GaAs-GaSb, and InAs-InSb. For all systems except GaP-InP the range obtained for the enthalpy of mixing of the solid includes the value obtained from the ideal liquid-quasiregular solid model for the excess Gibbs free energy of mixing of the solid at the intermediate temperature $T = m$ (b in Table III).

Quasiregular liquid-ideal solid.—The minimum value of σ_{SOL}, obtainable with the quasiregular liquid-ideal solid model will be close to that obtained with the ideal liquid-ideal solid model shown in the next to last column of Table III. The minimum value obtainable for σ must be no smaller than this, and therefore the quasiregular liquid-ideal solid model will give unsatisfactory fits for at least five of the seven systems considered. This model is not pursued further.

Strictly regular liquid-quasiregular solid.—The liquidus and solidus lines for all seven systems are satisfactorily fit by one, if not both, of the two parameter models discussed in the sections on Ideal liquid-quasiregular solid model and Strictly regular liquid and solid. Therefore it has already been established in principle that the strictly regular liquid-quasiregular solid model, which contains these simpler models as special cases, will give a satisfactory fit for all seven systems. It therefore is the simplest variant of the full quasiregular model that will satisfactorily fit all seven systems. It has been applied here only to those four systems for which there are more than two liquidus points. For each of these systems it was found that for a fixed value of the liquid parameter, W_L, that satisfactory fits were obtained along a best-fit line in the W_S-V_S plane, similar to the situation with the ideal liquid-quasiregular solid model for which $W_L = 0$. Enough different values of W_L were used to establish the absolute minimum in σ. The results are summarized in Table V which lists several values of W_L for each system, including $W_L = 0$ for comparison, the slope, m, and intercept on the W_S axis, b, of the best-fit line (Eq. [21]), the minimum value of σ obtained for the fixed value of W_L, and the value of V_S at which the minimum occurred. Similar to the situation for $W_L = 0$, which is discussed in the section on Ideal liquid-quasiregular solid model and summarized in Table III, the value of σ varies slowly along the best-fit line and generally there is a wide range of W_S or V_S values along this line for all of which σ is less than the critical value characterizing a satisfactory fit.

Table V. Summary of results for the strictly regular liquid-quasiregular solid model

Asterisk entry indicates best fit

	W_L, cal	$W_S = mV_S + b$		Best fit	
		m(°C)	b(cal)	σ_{MIN}(°C)	V_S(eu)
GaP-InP	2000	1482	3808	14	−1.5

	−500*	1194	4550	15.2	−5.5
	−1000	1194	4500	17.0	−5.0
	−1500	1210	4200	25.6	−4.0
InAs-InSb	0	930	2300	18.4	+1.0
	450*	987	2180	12.6	+1.0
	900	987	2250	20.5	+1.0

The general features of Table V are: (*i*) a satisfactory fit is obtained with some value of W_L for each system; (*ii*) the lowest value of σ is not much lower than that obtained with one of the simpler models when the simpler model gives a satisfactory fit; (*iii*) the parameter m, defining the slope of the best-fit line does not vary much over the range of W_L shown; and (*iv*) the parameter b defining the intercept of the best-fit line on the W_S axis does not vary much with W_L except for the GaP-InP system, where large values of W_L are required to obtain a satisfactory fit.

For the GaP-InP system σ values less than the adopted critical value of 10°C are obtained only for values of W_L between 1000 and 2000 cal. By interpolation of the data in Table V this range can be narrowed to about 1300-1700 cal. For the GaSb-InSb system a range of W_L values even wider than the +300 to −800 cal range shown allows values of σ less than the 10°C critical value, the very slow variation of σ along a best-fit W_S-V_S line (see Fig. 4) being accompanied by a similar slow variation with W_L. Values of σ less than 6°C are obtained for values of W_L between −700 and +150 cal. For the GaSb-GaAs system the value of W_L must lie between 0 and about −600 cal in order to attain a value of σ below 16°C. For the InAs-InSb system the value of W_L must lie by interpolation between about +200 and +650 cal in order to attain a σ below 16°C.

It appears that when a system is fit well by the ideal liquid-quasiregular solid model, that analysis using the strictly regular liquid-quasiregular solid model will improve the fit but will not greatly change the parameters m and b of the best-fit line along which the values of W_S and V_S giving satisfactory fits lie. Therefore, we infer that the values of m and b given in Table III for the three systems not analyzed with the strictly regular liquid-quasiregular solid model (because of a paucity of liquidus points) can be grouped with the values of m and b in Table V for those systems that were analyzed.

Discussion

From Table IV and V it can be seen that the liquid parameter, W_L, is not closely fixed as a result of fitting the liquidus and solidus lines and no clear regularities are apparent. For this reason and because there are only three systems for which more than four liquidus points have been measured (the four points of the GaP-InP system are estimated), the quasiregular liquid-quasiregular solid has not been used. At present it appears that this model will be capable of providing a satisfactory fit when more liquidus points are available, indeed the strictly regular liquid-quasiregular solid model may also. More important, we infer from the calculations discussed thus far that the full quasiregular model will still yield a best-fit line in the W_S-V_S plane that is close to those given in Table V and III. In other words, a fit of the liquidus and solidus lines by the models discussed has afforded a characterization of the thermodynamic properties of the solid phase that most likely will not be basically changed by application of the quasiregular model to both phases. This characterization is shaped by the choice of the quasiregular model of a phase as a general framework. But it is also influenced by the procedure of adopting a critical value of σ and accepting on equal terms all fits with σ values less than this, rather than simply taking the one fit with the minimum value of σ. The latter would lead to a unique value of W_S and V_S and a definite enthalpy and excess entropy of mixing of the solid. The former leads to the result that for the solid phase at one temperature, $T = m$, the excess Gibbs free energy of mixing is equal to b with an uncertainty of about ±200 cal. We wish now to discuss these parameters.

Table VI. Solid solution parameters *m* and *b* from computer fits of pseudobinary sections

	$2m/(T_1 + T_2)$	b, cal	b(calc), cal
AlAs-GaAs	1.01	0.0 ± 300	0.0
GaP-InP	0.96	3616 ± 200	3948
GaAs-InAs	0.98	2550 ± 200	2589
GaSb-InSb	0.97	1338 ± 400	1233
GaP-GaAs	1.01	31 ± 200	55
GaAs-GaSb	0.96	4550 ± 200	4299
InAs-InSb	0.98	2180 ± 150	2180

Table VI shows the ratio of m to the average melting point (in °K) of the two III-V compounds defining a pseudobinary section, the value of b obtained from the computer fits, and a calculated value, b(calc), obtained from the equation

$$b(\text{calc}) = 237.5(10^8)\left\{\frac{2(a_1 - a_2)}{(a_1 + a_2)}\right\}^6 \qquad [26]$$

where a_1 and a_2 are the room temperature lattice parameters of the III-V compounds. It can be seen that m is 0.98 ± 0.03 of the average melting points of the III-V components in all cases and that b(calc) is within 250 cal of the center of the range in b determined from the computer fits. The case of GaP-InP is interesting in that the value of b for $W_L = 0$ does not fit the empirical correlation given by Eq. [26]. However, as W_L is changed toward 1500 cal in order to obtain a fit better than the critical value of 10°C, the value of b increases sufficiently to agree with b(calc) to within 232 cal. The correlation of b with fractional lattice parameter difference is also shown in Fig. 7 where b is plotted against the sixth power of this variable. Based on the premise that the III-V solid solutions can be described as strictly regular, Stringfellow (9) has presented arguments that the interaction energy ought to vary as the square of the lattice parameter difference and the negative 4.5th power of the average lattice parameter of the two pure III-V compounds. If the values of b given in Table VI are plotted against this variable and a best straight line drawn, the fit is decidedly inferior to that afforded by Eq. [26].

The values of b given in Table VI are within 500 cal of the values for the solid parameter, W_S obtained by Panish and Ilegems (7) using a strictly regular model for both the liquid and solid phases. However, the thermodynamic interpretation of the two quantities is different as discussed previously. Moreover it is not clear how closely the value of W_S in the strictly regular model is defined using the available pseudobinary and ternary data. As indicated in the section on Strictly regular liquid and solid, the pseudobinary data alone does not always suffice to yield a closely defined value for W_S.

Encouraged by the remarkable correlation established for m and b in Table VI, we postulate that for all eighteen III-V pseudobinary sections that: (*i*) the strictly regular liquid-quasiregular solid model will

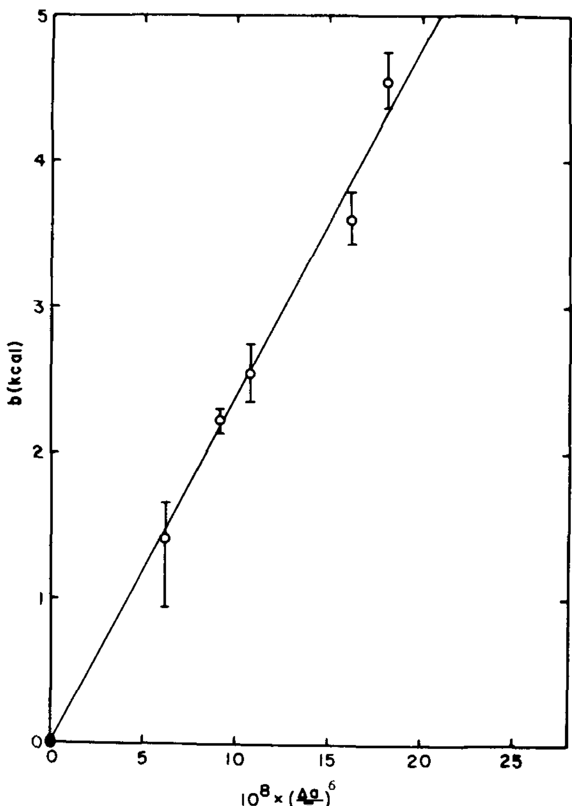

Fig. 7. Intercept b of the best-fit line in the W_S-V_S plane for various pseudobinary systems (from Tables III and V), plotted against the sixth power of fractional difference in room temperature lattice parameters of III-V components. $\Delta a = |a_1 - a_2|$, $\bar{a} = (1/2)(a_1 + a_2)$

give a satisfactory fit of the liquidus and solidus lines as more liquidus and solidus points are obtained, and (*ii*) the excess Gibbs free energy of mixing will be given by

$$\Delta G_M^{xs}(S) = by_1y_2$$

$$= 237.5(10^8)\left[\frac{2(a_1 - a_2)}{(a_1 + a_2)}\right]^6 y_1y_2 \text{ cal/mole} \quad [27a]$$

at

$$T = m = 0.495\,(T_1 + T_2) \quad [27b]$$

We are aware of no experimental thermochemical data to check this correlation. Unfortunately, its application to pseudobinary phase diagram calculations is somewhat restricted because in effect it only predicts the best-fit line in the W_S-V_S plane along which the values of W_S and V_S giving a minimum σ must lie. The range of, say V_S-values giving satisfactory fits, or the value of V_S giving the best fit, are unknown. The value that ought to be used for the liquid parameter, W_L, is also left unspecified. However, it would appear from the systems analyzed that the V_S-values ought to be generally small, between about +2 and −5 eu. Moreover for the systems analyzed there is a measure of independence between the liquidus and solidus lines so that the assumption of an ideal liquid does not greatly affect the position of the calculated solidus line although it may well lead to a poor fit of the liquidus. With these facts in mind some comments can be made about those pseudobinary sections for which there is no data, while for four pseudobinaries, for which there is data, the applicability of the empirical correlation can be checked.

If the lattice parameters differ by no more than 4% from their average value for a particular pair of III-V compounds forming a ternary system, then G_M^{xs} for the solid solution in the pseudobinary section will be 200 cal/mole or less. In this case the solid solution can be fairly well described as ideal in the temperature interval between the melting points of the pure compounds. (Of the remaining seven ternary systems with no data, AlP-GaP, AlP-AlAs, and AlAs-GaAs fall in this category.)

On the other hand when this difference is 9.9% or greater, as is the case of AlP-AlSb, GaP-GaSb, and InP-InSb, then b is 22,000 cal/mole or greater. The possibility of a miscibility gap in the solid solution can be examined by constructing a best-fit line according to Eq. [21] on a plot such as Fig. 1 with m and b given by Eq. [27b] and [26], respectively. The following common conclusion is reached. Unless the values of V_S giving satisfactory fits are either larger than 36 eu or smaller than −80 eu, all three systems will show a miscibility gap in a temperature range between the higher melting point and at least as low as the lower melting point. Specifically, either a normal miscibility gap with T_c greater than the higher melting point ($-3.97 < V_S < 36$), or an inverted miscibility gap with T_c less than the lower melting point will form ($-80 < V_S < -3.97$). The large magnitudes required of V_S to avoid a miscibility gap seem unlikely to be encountered.

For the AlAs-AlSb system, for which the lattice parameters differ by an amount that is 8.08% of the average parameter, the calculated value of b is 6340 cal/mole and the situation is intermediate. Except for a short segment, the predicted best-fit line in the W_S-V_S plane lies between the line of constant critical temperature equal to 2043°K, the melting point of AlSb, and that of constant critical temperature equal to 1330°K, the melting point of AlSb. Values of V_S greater than −3.7 are associated with a normal miscibility gap with $1330°K \leq T_c \leq 2043$. Values of V_S less than −4.2 are associated with an inverted miscibility gap with T_c in the same range. Only for $-4.2 < V_S < -3.7$ is there complete solid solution in the 1330°-2043°K interval.

There are four remaining pseudobinary sections for which there is experimental data but which were not discussed in the main section of this paper. They were analyzed using the ideal liquid-quasiregular solid model and again a best-fit line was found in the W_S-V_S plane. The results are summarized in Table VII. In the case of the first two systems there is excellent agreement between the parameters of the best-fit line, m and b, as obtained from the computer fits and the values calculated for these parameters from the corre-

Table VII. Results from ideal liquid-quasiregular solid model for four additional systems

lations represented by Eq. [27b] and [26]. The fact that σ_{MIN} for the AlSb-GaSb system is no lower than 26°C can be attributed in large part to the scatter of the experimental data and in part to the fact that the two liquidus points between 55 and 100 m/o GaSb are about 40° below the calculated liquidus.

The poor fit obtained for the AlSb-InSb system is essentially all due to the scatter in the data. The liquidus points of Goryunova (23) are some 35°C higher than those of Koster and Thoma (19) in the 20-45 m/o AlSb interval. The solidus points of Goryunova (23) show a scatter of about ± 12°C between 0 and 60 m/o AlSb and are about 20°C higher than the point of Wooley and Smith (22) at 15 m/o AlSb. In spite of this, the agreement of the value of m obtained from the computer analysis with that calculated from Eq. [27b] is within 5%. The value of b is about 450 cal below the value of 625 cal calculated from Eq. [26], somewhat more than the ± 250 cal deviation expected. If the liquidus points of Goryunova are eliminated, the results shown in the asterisk entry of Table VII are obtained. The value of σ_{MIN} is lowered to about the limit set by the scatter of the solidus data, but the values of m and b obtained are in poorer agreement with the predicted values. When the liquidus points of Goryunova *et al.* are used, and those of Koster and Thoma eliminated, a value of 28.6°C is obtained for σ_{MIN} (σ_{LIQ} being 22.6°C) even with the strictly regular liquid-quasiregular solid model. Therefore we conclude the liquidus points of Goryunova *et al.* are seriously in error, especially in the 25-45 m/o AlSb interval. The phase lines have been calculated using the ideal liquid-quasiregular solid model and are shown along with experimental points in Fig. 8. The lower solidus line was obtained using W_S = 625 cal, V_S = 0 eu, a point on the predicted best-fit line. Decreasing W_S by 200 cal to 425 cal, the uncertainty in the intercept, b, of the best-fit line, yields the upper solidus line. Both calculated solidus lines are within 5°-10°C of one another and are 15°-20°C below the experimental points between 25 and 50 m/o of AlSb. We would conjecture the actual solidus line lies closer to those calculated than to the experimental points.

For the InP-InAs system the value of m agrees with that calculated from Eq. [27b] but the value of b is significantly larger than the calculated value of 25 cal. The poor fit is almost entirely due to the three solidus points being significantly below the calculated line. In view of the poor agreement with our correlation and because the solidus points (24) appear to have been determined from cooling curves, we conclude the solidus points are significantly in error. Therefore possible solidus lines were calculated in the following manner. The liquidus points were fit alone using the strictly regular liquid-quasiregular solid model with fixed values of W_S and V_S satisfying the theoretical best-fit line equation (m = 1228, b = 25). For W_S = 1253 cal, V_S = 1.0 eu, a best value of 3°C is obtained for σ_{LIQ} with W_L = 30 cal. For W_S = 25 cal, V_S = 0.0 eu, we find σ_{LIQ} = 3°C at W_L = 70 cal. The solidus lines generated with either set of parameters are within 2°C of each other, as are the liquidus lines. The calculated lines are shown in Fig. 9 along with the experimental

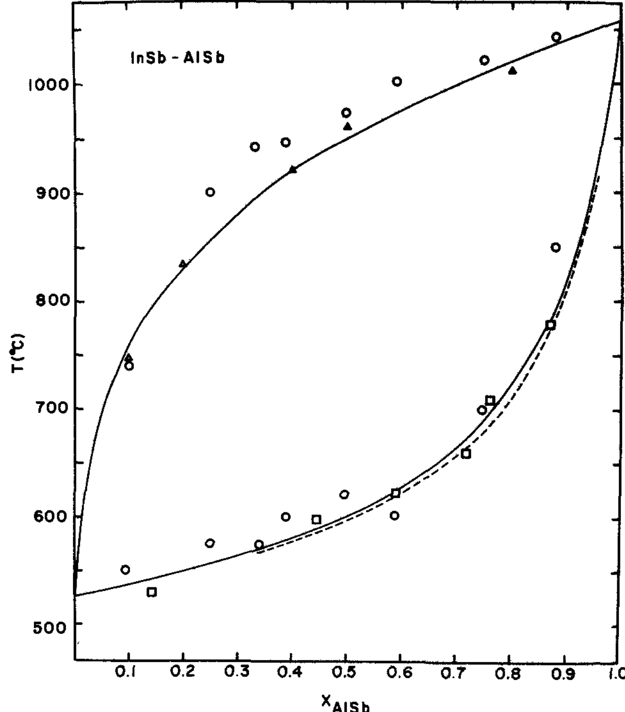

Fig. 8. Pseudobinary section for AlSb-InSb. The lines are calculated using ideal liquid-quasiregular solid model with points on predicted best-fit line, W_S = 625 cal, V_S = 0 eu (lower, dashed solidus), and with W_S = 425 cal, V_S = 0 (upper solidus). Experimental data are shown as points. Circles, Goryunova *et al.* (23); triangles, Koster and Thoma (19); squares, Wooley and Smith (22).

system, discussed in connection with Fig. 5, is omitted. The ideal liquid-quasiregular solid model was used for the AlAs-GaAs and GaP-GaAs systems having no experimental liquidus points. The strictly regular liquid-quasiregular solid model was used for the others. In every case the values of the model parameters giving the best fit were used as given in Table V or Table III and Fig. 4. We believe the calculated points in Table VIII are the best present estimates and are especially helpful for those systems like GaSb-InSb and InSb-InAs where there is noticeable scatter in the experimental solidus points.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1975 JOURNAL.

All discussions for the June 1975 Discussion Section should be submitted by Feb. 1, 1975.

ADDENDUM

After submission of this paper for publication a redetermination of the solidus line in the GaAs-GaSb system appeared in print (26). Five solidus points are given, which extend as low as 30 m/o GaAs. Moreover a peritectic temperature of 745°C with a miscibility gap from 38 to 61 m/o GaAs is estimated. A fit of 13°C can be obtained to the liquid and solidus points with $W_L = -500$ cal, $W_S = 5566$ cal, and $V_S = 1.5$ eu. However although the calculated miscibility gap extends from near 40 to near 60 m/o, the calculated peritectic temperature is only 733°C. Using the quasiregular model for both liquid and solid one can obtain a peritectic temperature of 740°C and a 45-55 m/o miscibility gap only if it is assumed that: (*i*) the value of 712°C for the melting point of GaSb is low by at least 4°C, or (*ii*) the value of 15.8 kcal/mole for the heat of fusion of GaSb is high by 2.2 kcal. The required errors are greater to account for the reported peritectic temperature of 745°C and miscibility gap extending from 40 to 60 m/o. We feel these assumptions are unlikely. Therefore either the experimental peritectic temperature and miscibility gap are considerably in error or the quasiregular model is inadequate for GaAs-GaSb and most likely for all III-V pseudobinaries in which the lattice parameters of the components differ by more than 7% of their average value. It is apparent that more data on the miscibility gap in GaAs-GaSb solid solutions are highly desirable.

Thermal Nitridation of Magnesium at Lower Temperatures and Pressures of the Nitrogen Atmosphere

J. Kodymová-Turková, L. Láska, and V. Krejčí

Institute of Physics, Czechoslovak Academy of Sciences, Na Slovance 2, Praha 8, Czechoslovakia

ABSTRACT

The dependence of the thermal nitridation of polycrystalline magnesium specimens, located in pure nitrogen, on time, temperature, and pressure has been investigated. Parameters of the experiments were chosen with regard to the conditions of nitridation in a d-c and rf discharge plasma. The temperature dependence was measured up to 500°C and was not detectable below 300°C. The long term kinetic plot at intermediate temperature 450°C, following the initial period, can be approximated by a logarithmic dependence, and the best explanation of the nitridation mechanism seems to be Fehlner and Mott's conception based on boundary diffusion. The value of the activation energy of the process calculated from the linear parts of the nitridation curves at different temperatures was 19.2 kcal/mole. The pressure dependence of the nitridation was measured in the range of 0.2-400 Torr and could best be described by a $p^{1/4}$ dependence.

Although definite analogies exist between oxidation and nitridation, much less attention has been given to nitride systems and the theoretical approach to gas-solid reactions is concerned with oxidation only.

The present paper describes the thermal growth of magnesium nitride on polycrystalline magnesium in N_2 under the same conditions (pressure and temperature) as we used for experiments in d-c and rf glow discharges (1). The results allow us to distinguish between thermal effects and those effects due to the plasma, in the nitridation process. The authors of existing publications on this subject generally aimed at finding the most effective methods of producing the nitride and therefore investigated the thermal process at higher temperatures and higher gas pressures than occur in a discharge plasma [summarized in Ref. (2, 3)]. A few studies on kinetics under widely varying conditions have been reported: these include linear, parabolic, and logarithmic laws of nitridation and 5-50 kcal/mole activation energy for this process (4-11).

Experimental Arrangement and Procedure

The metallic samples were used in the form of round specimens (diameter 10 mm, thickness 0.45-0.7 mm) cut from a magnesium sheet which contained the following amounts of impurities: Mn, 1.41%; Zn, $<$ 0.003%; Fe, $<$ 0.001%; Cu, 0.0005%; Pb, Ni, Si, Al, $<$ 0.0005%; and Ag, $<$ 0.0002%. Although there was a relatively high content of Mn compared with the samples used in Ref. (5), the agreement of our results indicates that it has no significant effect on the magnesium nitridation.

The surface of the specimens was cleaned by a chemical treatment: they were immersed in dilute nitride acid, washed in distilled water and ethyl alcohol, and dried. The specimens prepared in this way were placed into molybdenum glass ampoules whose volumes (30 ml-2 liters) were large enough to ensure that the N_2 pressure decrease due to the chemical reaction would not exceed 5%. Outgassing of the ampoules and specimens was achieved by heating them to 200°C while pumping continuously with an oil diffusion pump to a pressure of 10^{-6} Torr. Finally, the ampoules were filled with spectroscopically pure nitrogen to the appropriate pressure (measured by an oil manometer) and sealed. The thermal treatment was accomplished in an oven of 0.75 m^3 volume whose temperature was measured by a thermocouple and maintained automatically at a constant value.

Key words: magnesium thermal nitridation, kinetics.

The concentration of the magnesium nitride produced during the nitridation period was determined immediately after opening the ampoule by the following chemical method: the nitride was dissolved in 1*N* hydrochloric acid so that the nitrogen bound in the nitride changed into ammonium ions according to

$$Mg_3N_2 + 8HCl \rightarrow 3MgCl_2 + 2NH_4Cl$$

The quantitative determination of NH_4^+ after the reaction with the Nessler agent (alkaline solution of mercury(II)-potassium iodide) was carried out by a colorimetric method. The sensitivity of the chemical analysis was 5×10^{-3} mg NH_4^+/liter. The average error of the whole analytical determination, including the colorimetric measurements, was about 6%. The film thickness was calculated using the factor 1 μg N_2/cm^2 = 130Å. Each point plotted on the graphs is an average value taken from at least four measurements.

Results and Discussion

The process of magnesium nitridation was investigated in a temperature range from 200° to 500°C and pressure range from about 0.2 to 400 Torr. The results are summarized in Fig. 1-4.

We have found the first signs of measurable nitridation at a temperature of about 300°C, in agreement with Ref. (5, 9). Higher values given, *e.g.*, in Ref. (4, 6) may probably be ascribed to a lower sensitivity of the methods used for the nitride determination. At temperatures higher than 500°C the investigation became difficult due to the relatively high vapor pressure of magnesium (12) and the film formation was then influenced by magnesium sublimation (1, 5, 6, 8, 9). The dependence of the extent of nitridation on temperature has an exponential character, as expected.

In most of our measurements, the specimens were exposed to nitrogen for a time comparable with the analogous plasma experiments. In addition, we have also investigated the kinetics of the magnesium nitridation at the intermediate temperature 450°C for 10 hr (Fig. 1). During this long period a film thickness of about 1300Å was achieved. To interpret the course of the nitridation curve in Fig. 1, some of the theories and models which have been proposed to explain intermediate temperature oxidation (13-15) might be applied. After an initial period, which lasted about 20 min, the average film thickness was about 75Å. The sensitivity of the chemical method of analysis was sufficient to yield a measure of the nitridation after 10 min from the beginning of the experiment. After this

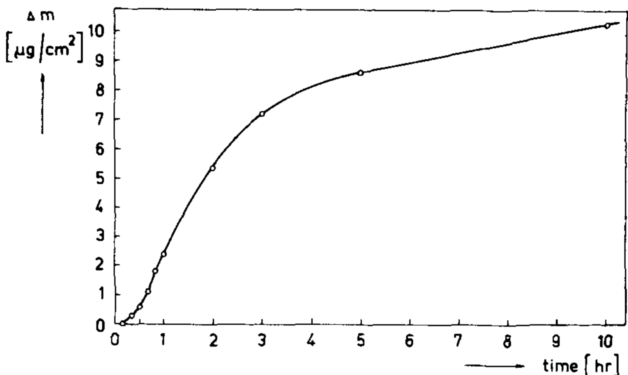

Fig. 1. Time dependence of nitridation of magnesium at 450°C and p = 1.2 Torr (Δm is weight of nitrogen uptake per unit surface area).

time we have always observed an increase of the nitridation rate. It seems that the process of successive heating of the ampoules, gas, and specimens, and the associated transient thermal phenomena, was the rate-determining process in the initial stages of reaction.

The long term kinetic plot is approximately logarithmic in form. Such a kinetic form is predicted by the Cabrera-Mott model (16) of high field ionic transport and also by the Fehlner-Mott model (17) of grain boundary diffusion coupled with a bimolecular process for grain growth. Perrow *et al.* (18) employed transmission electron microscopy to study the structure of thin nickel oxide films (thicknesses comparable with those of our magnesium films) formed on polycrystalline metal substrate and found that the main defects inside the films were the boundaries between the small oxide crystallites which acted as low resistance diffusion paths especially at intermediate temperatures. The character of the boundaries among various oriented grains of the metal substrate is often transmitted to the growing film and anomalous structures can arise as Finch and Quarell (19) found for magnesium oxide films formed on magnesium. It is quite likely that nitridation of magnesium involves a complex heterogeneous multistage process since existing oxidation theories cannot unequivocally describe the details of the present results.

In Fig. 2 parts of the nitridation curves (without the initial periods) are plotted for specimens exposed to nitridation at different temperatures for 1 hr only, the time important for our plasma experiments. A pressure of about 1 Torr was chosen for the same reason. For the small film thickness of about 300Å a phase boundary reaction determines the growth rate resulting in a

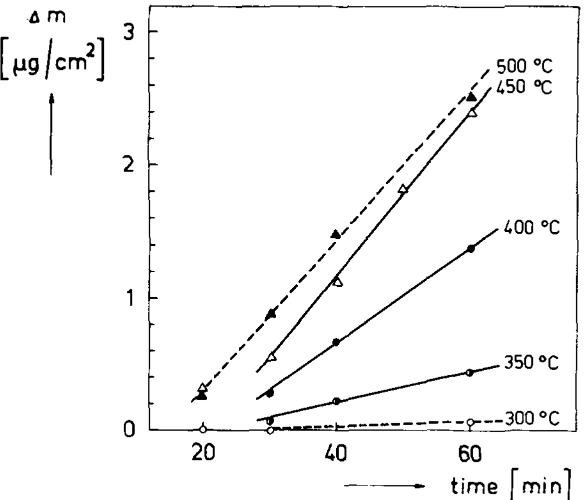

Fig. 2. Linear parts of nitridation curves at different temperatures (p = 1.2 Torr).

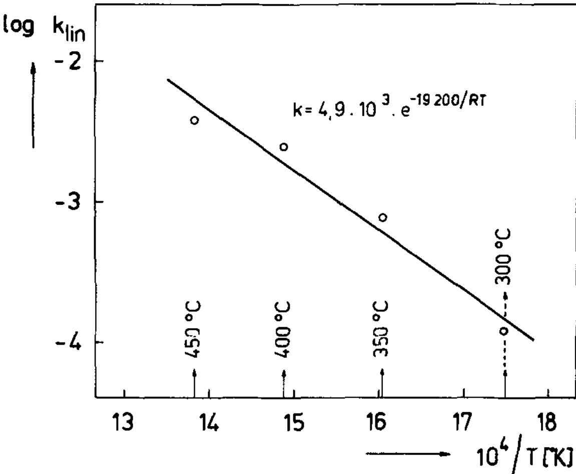

Fig. 3. Plot of logarithm of linear rate constant *vs.* 1/*T*

linear relation between weight gains and time. The linear dependence in this period is understandable and can be explained by the fast growth of nitride crystallites at the beginning of the gas-solid reaction.

The value of the rate constant at 450°C calculated from the curve in Fig. 2 is equal to 3.8 × 10^{-3} mg/cm² hr and is in good agreement with the value 4.0 × 10^{-3} mg/cm² hr, given by Sthapitanonda and Margrave (5). Their published results and those in Ref. (11) are only suitable for a comparison with our data from the point of view of the similar experimental conditions. A plot of log k_{lin} *vs.* $1/T$ is shown in Fig. 3. The value of the activation energy of the process calculated from this dependence is 19.2 kcal/mole [22.3 kcal/mole in Ref. (5)]. In Ref. (6, 7) values of 49.9 and 31.7 kcal/mole were found for very thick films where lattice diffusion is the rate-controlling process and the magnesium nitridation has a parabolic time dependence. The relatively low value of Q obtained in our case supports the suggested mechanism of nitridation. The value 5.8 kcal/mole reported by Belin (8) for the domain of exponential dependence of nitridation, when the nitride film grew on well outgassed Mg, shows that the purity of the surface of the specimens plays an important role in the whole process.

The dependence of the nitridation rate on the gas pressure at 450°C and after 30 min reaction is shown in Fig. 4. We can state that the influence of gas pressure for the very short exposure periods is relatively small and that it can be best approximated by a fourth root dependence. It appears to be consistent with the assumption of a boundary diffusion mechanism rather than with the porous model adopted in Ref. (5) on the

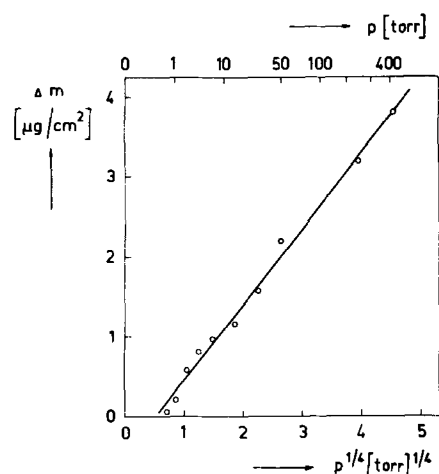

Fig. 4. Extent of reaction after 30 min at 450°C at different pressures.

basis of the fact that the ratio of molar volumes of magnesium to magnesium nitride is smaller than unity.

ABSTRACT

Rates of oxidative vaporization of Cr_2O_3 on preoxidized resistively heated chromium were determined in flowing oxygen at a pressure of 0.115 Torr for temperatures from 1000° to 1300°C. Reaction controlled rates were obtained from experimental rates by a gold calibration technique, and these rates were shown to agree with those predicted by thermochemical analysis. The activation energy obtained for the oxidative vaporization reaction corresponded numerically with the thermochemical enthalpy of the reaction. A theoretical equation is given for calculating the rate from thermodynamic data using boundary-layer theory.

Numerous investigators have studied the kinetics of chromium(III) oxide (Cr_2O_3) scale formation on chromium and chromium-containing alloys heated in oxidizing environments (1-8). Gravimetric measurements above 1000°C yield a net weight loss which has been shown to be due to the loss of the gaseous species chromium(VI) oxide (CrO_3) formed from the reaction of the Cr_2O_3 protective scale with oxygen (3). The volatilization of CrO_3 has been incorporated into the analyses of the kinetics of oxidation of materials with Cr_2O_3 scales (7, 9). However, Caplan and Cohen (5), Hagel (3), and Graham and Davis (10) appear to be the only investigators to have measured explicitly the oxidative vaporization of Cr_2O_3.

Caplan and Cohen (5) established that CrO_3 was the species which accounted for the evaporation of chromium oxide when Cr_2O_3 was heated in oxygen, although they did not identify CrO_3 in the vapor phase. Grimley *et al.* (11) subsequently identified this molecule in the vapor phase by mass spectrometry. Hagel (3) measured the rate of weight loss of Cr_2O_3 heated in oxygen and obtained a vaporization-temperature relationship which he used to correct his scale formation data. Hagel's vaporization corrections may be valid for his data obtained in a single experimental arrangement. However, his vaporization data cannot be considered as valid for other experimental arrangements (6, 9) because the volatilization reaction was undoubtedly gas diffusion controlled under the conditions of his experiments (furnace tests with static oxygen pressure of 76 Torr). The danger in using furnaces to study reactions that yield volatile products has been explained by Fryburg (12). Experimental techniques required to obtain meaningful data for such reactions have been described by Fryburg and Petrus (13, 14) for the oxidation of platinum. They showed that above a certain gas pressure (dependent on sample size and geometry) oxidative vaporization reactions become limited by mass transport through a boundary layer. Bartlett (15) has developed mass transport equations

Key words: oxidation, vaporization, kinetics, chromium, thermodynamics, activation energy.

which adequately explain experimental results over a wide range of temperature, pressure, and flow rate for the oxidation of both platinum and tungsten. Considerations such as these must be applied when studying the oxidative vaporization of Cr_2O_3.

Recently Graham and Davis (10) investigated the oxidative vaporization of hot-pressed and sintered samples of Cr_2O_3 in free and forced convection in the pressure range from 10^{-3} to 1 atm. They properly treated the mass transport problem and showed that the total pressure and flow dependencies were consistent with the assumption that the rate controlling step was the diffusion of $CrO_3(g)$ through a stagnant boundary layer. However, this study was made only at 1200°C and rates were not measured in the reaction controlled regime.

The work reported here was undertaken to determine the rate of oxidative vaporization of $Cr_2O_3(s)$ in molecular oxygen and its dependence on temperature. The work was part of a study of the enhanced oxidation of Cr_2O_3 and chromium produced by exposure to oxygen atoms [see following paper (16)]. The experimental arrangement used in the program was dictated by requirements of the oxygen atom study. While this arrangement did not lend itself to a simple theoretical mass transport analysis, meaningful rate data were obtained by the use of a gold calibration technique.

Experimental

Samples.—Test samples (12 cm long by 0.3 cm wide and 0.04 cm thick) were prepared from a chromium-0.1 weight per cent (w/o) yttrium alloy made from iodide chromium by arc melting and drop casting into a water-cooled copper mold. The small yttrium addition improves oxide adherence. Samples were diamond sawed from hot rolled sheet of the alloy. Sample surfaces were cleaned with a dental abrasive unit (using 50 μm alumina powder and nitrogen gas) and anodically electropolished in a 2% sodium hydroxide solution for from 1 to 3 min with a current density of 0.3 A-cm^{-2}. Prior to testing, samples were washed with hot water and rinsed in ethanol.

Emission spectrographic and chemical analysis of samples yielded the following typical impurity analysis in parts per million: 230 iron, 10 aluminum, 8 copper, 5 calcium, 2 magnesium, 60 carbon, 50 oxygen, 5 nitrogen, and 5 hydrogen.

Apparatus.—A schematic diagram of the experimental arrangement is shown in Fig. 1. The sample was supported vertically by a fixed clamp at the top and a movable clamp at the bottom to allow for thermal expansion when the sample was heated. The bottom clamp was mounted in a linear ball bushing in such a fashion that it was free to move vertically but constrained from rotating.

The test chamber was evacuated with two 425 liters-min^{-1} mechanical pumps. A 400 liters-sec^{-1} oil diffusion pump was also available for high vacuum pumping. Gases were admitted into the system through a Pyrex tube (1.4 cm OD) connected to a flow control and a mixing manifold. The glass tube was arranged so that incoming gas impinged directly onto the flat side of the sample. Research Grade gases were used in all experiments.

Gas pressures in the test chamber were measured with a vacuum thermocouple gauge; the filament was heated by a 30.00 mA current from a regulated d-c power supply. Thermocouple voltages were read to the third decimal place with a digital voltmeter. The thermocouple gauge was calibrated for oxygen against a McLeod gauge. For other gases and gas mixtures, calibration was against a fused quartz precision pressure gauge.

Temperature control for the resistively heated sample was facilitated by a Pt-Pt13%Rh thermocouple (0.127 mm diameter wire) spot welded to the back face of the sample at its midpoint. This thermocouple was

the primary element for a precision set-point, proportional controller-indicator. The output of the controller was used to drive a voltage controlled 100A d-c power supply. The power supply output was fed to the sample through insulated, water-cooled feedthroughs and flexible copper braid.

For all experimental conditions the sample temperature was held constant with time to at least ±0.5°C. Temperatures were also measured with a micro-optical brightness pyrometer ($\lambda = 650$ nm) to supplement the thermocouple. The pyrometer was sighted through a shutterable window onto the back surface of the sample and the pyrometer-read temperatures were corrected for window absorption and sample emissivity. Corrected pyrometer temperatures measured next to the thermocouple junction were found to be in agreement with the thermocouple-indicated temperatures if a value of 0.7 was used for the sample emissivity. This value is consistent with literature values (17) for the emissivity of oxidized chromium.

The pyrometer was used mainly to survey the length of a sample for temperature gradients. Samples were discarded if the central portion opposite the opening to the collection target was not uniform in temperature to within ±5°C.

Products vaporizing from the sample passed through an opening (2.6 cm on a side) in a water-cooled copper shield and were condensed on a cooled platinum target. Eight targets (5.1 cm on a side and 0.125 mm thick) were clamped against an eight-sided copper mounting block by copper frames screwed to the block. The block in turn was attached to a cylindrical copper reservoir through which coolant was circulated. The whole assembly could be externally rotated relative to the sample so that a designated target could be brought into position opposite the sample. Targets not directly in front of the sample were masked from the sample by the copper shield. In addition, the opening in the shield could be closed with an externally controllable water-cooled shutter. Target to sample distance was approximately 1.8 cm.

Ethanol was used as the coolant for the target assembly. It was cooled in a dry ice-alcohol bath. Tests were made prior to actual experiments to determine target temperature as a function of sample temperature and time. For these tests a thermocouple was at-

tached to the face of a target facing the sample. These tests demonstrated that the target temperaure could be held below 70°C for indefinite periods of time when the sample temperature was 1300°C. Lower sample temperatures yielded proportionately lower target temperatures.

Procedure for $Cr_2O_3(s)$ oxidations.—Cleaned chromium samples were preoxidized *in situ* before an oxidation experiment by heating to the desired oxidation temperature for one-half hour in 0.115 Torr of flowing oxygen. For the temperatures of the experiments (1000°-1300°C) approximately 0.01 mm (0.4 mil) oxide scales were formed as shown in Fig. 2.

Oxidation runs at each pressure and temperature were started by opening the shutter and collecting effusate on a target for a measured length of time. At 1000°C runs extended for 8-10 hr per target, but at 1250°C runs were only of the order of 10 min in length. Generally between 5-25 μg of chromium were collected on a given target. After a series of runs (one for each of the eight targets) was completed, the sample was cooled and the block and targets were warmed to room temperature. Clean dry air was admitted to the system and the targets were removed for condensate analysis. The condensate was dissolved from each target with a stream of distilled water and the resulting solution was diluted to a measured volume. Each solution was quantitatively analyzed for chromium content by atomic absorption spectroscopy. The spectrometer was calibrated with solutions prepared from a purchased standard potassium dichromate solution. The analysis method had a sensitivity of 0.02 ppm chromium; sample solutions were usually held in the range from 0.2 to 2 ppm.

Procedure for gold calibrations.—In order to obtain "reaction controlled" rates from our experimental rates, it is obvious that we must determine the fraction of the CrO_3 formed that is actually condensed on the target. This is the "collection fraction" of the apparatus. In addition, the oxidative vaporization may be diffusion limited (12, 13,18). If so, we must determine the fraction of CrO_3 volatilizing from the specimen surface that diffuses through the boundary layer to the target. This is called the "escape fraction."

These two fractions were determined by measuring the rate of evaporation of gold ribbons in the apparatus. The gold was 99.99% pure with silver and silicon being the major metallic impurities. The gold samples were made the same length and width as the chromium samples but the thickness was only 0.025 cm. Gold samples were cleaned in aqua regia and rinsed with water and ethanol.

The gold samples were mounted and heated in an identical manner to the chromium samples. Because of the high thermal conductivity of gold, temperature gradients were unavoidable: usually a temperature drop of about 20°C existed over the length from the midpoint to the top or bottom edge of the collection opening. Temperatures were measured with the optical pyrometer at 0.5 cm intervals over the 2.6 cm collection opening. Rates of evaporation were calculated and summed for 0.5 cm increments along the sample using the average temperature of each increment.

Experimental runs were performed at temperatures around 1000°C both under good vacuum conditions ($<5 \times 10^{-6}$ Torr) and under the conditions of the oxidation experiments: with flowing oxygen at 5 liters-hr^{-1} (STP) and 0.115 Torr pressure. Between 25 and 50 μg of gold were collected on each platinum target. The quantity of gold on each target was determined by dissolving the gold in a stream of concentrated nitric acid, diluting with water to a measured volume, and analyzing the solution by atomic absorption spectroscopy. The sensitivity of the gold analysis was 0.1 ppm.

Thermochemical Predictions

Fryburg and Petrus (13) showed that kinetic data, obtained from a study of the oxidative vaporization of platinum, could be correlated with equilibrium thermodynamic data. It is useful to reverse this process and to predict kinetic behavior from thermodynamic data. Kellogg type (19) equilibrium thermochemical diagrams aid in such predictions, as demonstrated by Gulbransen and Jansson (20-23) for the chromium-oxygen system. Gulbransen and Jansson employed the free energy of formation ($\Delta G°_f$) and equilibrium constant ($\log K_p$) data for the gaseous chromium-oxygen molecules CrO, CrO_2, and CrO_3 as compiled by Schick (24) from the original mass spectrometric studies of Grimley *et al.* (11). The diagrams show that the important molecular species in equilibrium with $Cr_2O_3(s)$ and $O_2(g)$ should be $CrO_3(g)$ and $CrO_2(g)$ in the temperature range 1000°-2000°K and at oxygen pressures greater than 10^{-6} atm. The results of a recent transpiration study of the Cr_2O_3-O_2 system by Kim and Belton (25) which apparently yielded more reliable data for $CrO_3(g)$ were employed by Kohl and Stearns (26) to construct revised diagrams which showed that the CrO_3 molecules should be greater than an order of magnitude more abundant than indicated by Gulbransen and Jansson. Recent mass spectrometric studies on the vaporization of $CrO_3(c)$ by Schafer and Rinke (27), McDonald and Margrave (28), and Washburn (29) have established the existence of several "new" chromium oxide vapor species: $(CrO_3)_3$, $(CrO_3)_4$, $(CrO_3)_5$, Cr_3O_7, Cr_4O_{10}, and Cr_5O_{13}. In addition, $Cr_2(g)$ has been identified by Kant and Strauss (30). Therefore we have recalculated diagrams for the chromium-oxygen system and included the new vapor species.[1]

A thermochemical diagram at 1500°K is shown in Fig. 3. The diagram was constructed by the methods outlined by Gulbransen and Jansson (20). For O_2 pressures greater than 10^{-8} atm, $CrO_3(g)$ is still the predominant vapor species above $Cr_2O_3(s)$ but the new species $Cr_3O_7(g)$ becomes more important than $CrO_2(g)$ for O_2 pressures greater than 10^{-1} atm. The slope of the $CrO_3(g)$ line in the $Cr_2O_3(s)$ phase region is ¾ and can be expected to describe the dependence of $CrO_3(g)$ pressure on oxygen pressure [as shown by Graham and Davis (10)].

From the respective diagrams at different temperatures one can obtain the vapor pressures of each species as a function of temperature for any given oxygen pressure. Thus, in Fig. 4 we have plotted the vapor pressure of the major species over the $Cr_2O_3(s)$ phase, for an oxygen pressure of 1.51×10^{-4} atm (0.115

[1] Thermodynamic data for Cr(g), CrO(g), and $CrO_2(g)$ were taken from Schick (24). Data for $Cr_2O_3(s)$ were calculated from $\Delta G°_f$ values given by Wicks and Block (31). Thermodynamic data for $CrO_3(g)$ and the "new" chromium-oxygen molecules are given in the following paper (16).

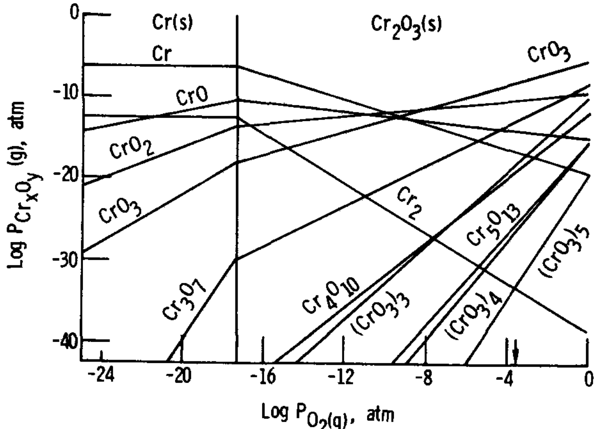

Fig. 3. Equilibrium thermochemical diagram for the chromium-oxygen system at 1500°K. Arrow indicates experimental oxygen pressure (1.51 × 10^{-4} atm).

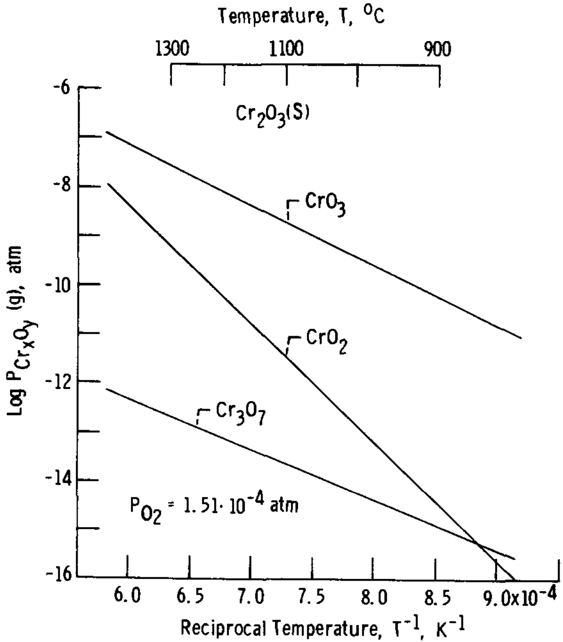

Fig. 4. Equilibrium vapor pressures of various oxide species of the chromium-oxygen system over Cr_2O_3(s) vs. (1/*T*) under an oxygen pressure of 1.51 × 10^{-4} atm.

Torr), against reciprocal temperature. From this figure it is obvious that CrO_3(g) will be the major vapor product in the oxidative vaporization of Cr_2O_3(s) under our experimental conditions over the entire temperature range of this study. The slope of the CrO_3(g) line in Fig. 4 is related to the enthalpy change for the reaction

$$\frac{1}{2}Cr_2O_3(s) + \frac{3}{4}O_2(g) = CrO_3(g) \quad [1]$$

In the case of the oxidative vaporization of platinum, the enthalpy change was shown to be equivalent to the energy of activation for the reaction (13) and thus it is not unreasonable to expect the same kind of correlation in the present studies.

The vapor pressure of CrO_3(g) can be expressed analytically as

$$\log P_{CrO_3(g)}\ (\text{atm}) = \frac{-1.247 \times 10^4}{T} + 3.20 + \frac{3}{4}\log P_{O_2(g)}\ (\text{atm}) \quad [2]$$

over the temperature range 1270°-1570°K where the thermodynamic data[2] have been taken from the work of Kim and Belton (25). Using the Hertz-Langmuir equation and the vapor pressure of CrO_3(g) from Eq. [2] one can calculate the rate of vaporization of CrO_3(g) and/or the rate of loss of chromium due to vaporization of the oxide. The rate of loss of chromium is given by

$$\dot{m}_{Cr}(\text{g-cm}^{-2}\text{-sec}^{-1}) = P_{CrO_3(g)}(2\pi RTM_{CrO_3})^{-1/2}M_{Cr}$$

$$= 44.35\, P_{CrO_3(g)}\ (\text{atm})\ \frac{M_{Cr}}{M_{CrO_3}{}^{1/2}T^{1/2}} \quad [3]$$

where *M* is the appropriate molecular weight. We have used this equation[3] to calculate the predicted maximum rate of oxidative vaporizations of Cr_2O_3(s). This rate corresponds to "reaction controlled" conditions uninhibited by mass transport through a boundary layer.

Results and Discussion

Preliminary calibrations.—Oxidative vaporization reactions obey linear kinetics, that is, the rates are time independent. Preliminary experiments validated the time independence of the rates for the oxidative vaporization of Cr_2O_3. In addition, oxidative vaporization reactions may be diffusion limited (12, 13, 18). Experiments at different oxygen pressures and experiments with inert gas additives (14) indicated that the oxidation was slightly diffusion limited for our experimental arrangement. The experimental conditions were dictated by the fast-flow, intermediate-pressure requirements of our oxygen-atom oxidation studies described in the following paper (16). The oxygen-atom output optimized at an oxygen pressure of 0.115 Torr with a flow rate of 5 liters-hr^{-1}(STP). Consequently, all the results reported in this paper were obtained at one pressure and one flow rate; namely, 0.115 Torr and 5 liters-hr^{-1}(STP).

To obtain reaction controlled rates it was necessary to correct the measured rates. This was done by determining the "escape fraction" of the CrO_3(g) formed in the oxidation reaction. In addition, the geometrical collection fraction for the apparatus was required. This fraction allowed correction for the fact that even in the absence of a boundary layer not all of the vapor product reaches the collection target (due to finite size of target, shield, etc.). Both the escape fraction and the geometrical collection fraction were determined experimentally using gold samples of the same width as the Cr-0.1Y samples.

The geometrical collection fraction was obtained by comparing the measured rate of evaporation of gold in a vacuum of $<10^{-5}$ Torr with the rate calculated from the vapor pressure data of Hultgren *et al.* (33). Two gold samples were used and measurements were made at temperatures between 1000° and 1012°C. An average value of 0.455 ± 0.05 was obtained for the geometrical collection fraction.

The escape fraction was obtained by comparing the measured rate of evaporation of gold in a vacuum of $<10^{-5}$ Torr with the rate measured under the conditions of the oxidation experiments; namely, 0.115 Torr of oxygen flowing at 5 liters-hr^{-1}(STP). Numerous experiments yielded an average value of 0.335 ± 0.04 for the escape fraction.

Reaction controlled rates were calculated from our experimentally measured rate by dividing the measured rate by the product of the escape fraction and geometrical collection fraction, namely 0.153 ± 0.03. The error we have associated with this product arises from the precision of our experiments and does not include errors arising from inaccuracies in the vapor

[2] The results of Kim and Belton (25) were obtained in a temperature range of 1600°-1860°K. We have adjusted their vapor pressure expression to our temperature range by use of the heat contents of CrO_3(g), O_2(g), and Cr_2O_3(s).

[3] Note that this equation is slightly different from that given previously by Kohl and Stearns (26) and Rapp (32). The previous equation was not dimensionally correct and yielded results about 40% too high.

pressure of gold. We estimate this inaccuracy to be as much as ±50%. Because of the magnitude of this possible error we have not corrected our escape fraction for the fact that the atomic weight and other atomic parameters of gold are different from those of $CrO_3(g)$. Calculations indicate that the diffusivity of $CrO_3(g)$ is about 10% greater than the diffusivity of gold. In addition, we have assumed that the escape fraction is independent of the temperature of the sample. This assumption is based on the fact that for the oxidative vaporization of platinum the escape fraction was shown to be independent of sample temperature (14).

Analysis of oxide scale and identification of oxide condensate.—Numerous samples of our oxide scales were subjected to x-ray diffraction. The analyses always confirmed that the scale was Cr_2O_3.

Two samples were subjected to ion microprobe mass analysis:[4] one was unoxidized starting material and the other was a sample which had undergone several oxidative vaporization experiments. Yttrium was detected in the oxide layer of the reacted sample at a concentration approximately four times that detected in the bulk unoxidized sample. Samplings in different regions of the oxidized sample showed the yttrium content to vary by a factor of five, while comparable data taken from the unoxidized sample showed yttrium to be constant. The spectrum obtained from the oxidized layer also revealed increases in the levels of all metallic contaminants, especially Fe, Al, Ca, and Mg. In addition, the elements Si, Mn, Na, and Co were identified as low-level metallic impurities. From these results it is concluded that the nonvolatile oxide forming metallic impurities tend to concentrate in the surface oxide layer on the oxidized chromium where chromium has been lost by vaporization. However, because our oxide scales were generally removed between experiments, this effect should not have been cumulative and should not have affected our results.

The oxide condensate obtained in these experiments formed a reddish brown deposit on the platinum targets. When collected on polished platinum targets the condensates were always readily soluble in water, forming yellow-colored solutions. If the platinum became etched (from cleaning in aqua regia) the deposits were often only partly soluble in water and required 1:1 HCl or fusion with $K_2S_2O_8$. For all the experiments reported here only polished platinum targets were used, and the targets were cleaned with $K_2S_2O_8$. In addition, the oxide deposits were always dissolved as soon as feasible after a series of experiments.

Attempts to identify the deposits by electron diffraction were unsuccessful and only Cr_2O_3 was identified. Apparently, the hydrocarbon background in the electron diffraction unit reduced the CrO_3 to Cr_2O_3. We have assumed that the deposits were $CrO_3(s)$ based on their reddish-brown color, their water solubility (Cr_2O_3 is insoluble in H_2O), the yellow color of the water solutions, the thermochemical predictions, and the findings of Caplan and Cohen (5) and of Grimley *et al.* (11).

Pressure dependence.—Experiments were performed to determine the order of the reaction with respect to the pressure of oxygen. Thermodynamic analysis indicates that the rate should depend on the ¾ power of the oxygen pressure. Runs were made at a given temperature in which the total pressure and gas flow rate were maintained constant, and the oxygen partial pressure was varied by dilution with nitrogen gas. The oxygen pressures were varied from 0.115 to 0.070 Torr. Greater dilution with nitrogen seemed to produce a permanent decrease in the rate of oxidation and resulted in an hysteresis effect with changing pressure. Nitrogen was used as the dilution gas because its molecular weight, collision cross section, and collision integral are nearly the same as those of oxygen. Thus, by keeping the total pressure of O_2-N_2 mixture constant, the escape fraction should also remain constant. A log-log plot of our rates of oxidation *vs.* the partial pressure of oxygen for a temperature of 1200°C is presented in Fig. 5. A line of slope = ¾ has been drawn through the points. It is evident that the rate obeys a ¾ dependency on oxygen pressure within experimental precision.

Temperature dependence.—The effect of temperature on the rate of oxidative vaporization was measured over the range from 1000° to 1300°C at a constant oxygen pressure of 0.115 Torr. Measurements at lower temperatures were impractical because of the unreasonably long times involved in collecting a measurable condensate. A typical set of results is shown in Fig. 6 in the form of an Arrhenius plot. The experimental rates, corrected for geometrical and diffusion-limitation factors, are represented by the circled points. The solid line through these points was derived from a least squares fit of the data, and yields an activation energy of 61.5 ± 5 kcal-mole^{-1} for the oxidation process.

We have extensively investigated the effect of varying several experimental parameters on the value obtained for the activation energy. Parameters varied included sample, oxygen pressure (0.050, 0.075, and 0.115

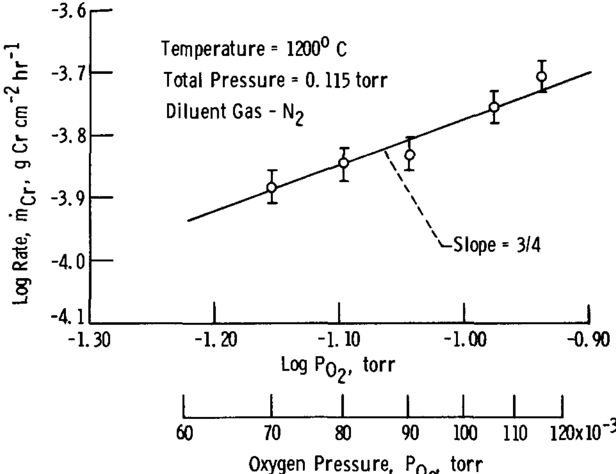

Fig. 5. Pressure dependence of oxidative vaporization of Cr_2O_3

[4] We wish to thank Applied Research Laboratories, Sunland, California, for providing the ion microprobe analyses.

Torr), flow rate (2 and 5 liters-hr^{-1}), sample-target separation (1.8 to 3.0 cm), and sample composition (Cr-0.1Y and Ni-40Cr). Although the actual rates varied with some of these parameters, the temperature dependence did not and the energy of activation was found to be the same within experimental precision of ±5 kcal-mole^{-1}.

Included in Fig. 6, as the dashed line, are the predicted rates calculated from Eq. [3] for a pressure of 0.115 Torr. As noted earlier, the experimental energy of activation and the enthalpy of reaction may be expected to be numerically equal for oxidative vaporization reactions of the type being considered. Actually the two quantities are different by a small amount due to a temperature term that arises from the Hertz-Langmuir equation. The energy of activation can be calculated from the enthalpy of the reaction by the relationship (34)

$$E_{act}/R = \Delta H^{\circ}{}_T/R - T/2 \qquad [4]$$

The enthalpy in this temperature range is $\Delta H^{\circ}{}_{1400} =$ 57.1 kcal-mole^{-1}. Thus the calculated energy of activation is 55.7 kcal-mole^{-1} as given in Fig. 6.

The experimental rates are not exactly comparable to the rates calculated from thermodynamic data because the temperature of the oxygen in our experiments is not at the temperature of the specimen, in fact, it is probably closer to room temperature.[5] To facilitate comparison we have adjusted our experimental rates by multiplying by the factor[6] $(300/T)^{1/2}$, where room temperature has been taken as 300°K. These adjusted results are given as the squared points in Fig. 6. The line through these points was derived from a least squares fit and yields an "adjusted" energy of activation of 59.9 ± 5 kcal-mole^{-1}. This value may be compared with our calculated value of 55.7 ± 2 kcal-mole^{-1} and is found to be in agreement within experimental error. The rates represented by the squared points may be compared with the calculated rates and are seen to be roughly one-half of the calculated rates. This is probably within the experimental error of our measurements which depend directly on the accuracy with which we could measure the vaporization rate of gold in our apparatus. In addition, we have probably underestimated the temperature of the gas in the boundary layer.[5] If so, the "adjusted" rates may have been reduced too much and a value closer to the experimental rates may be more accurate. In any case, the agreement is quite good for this type of measurement.

Theoretical rate equation.—We have shown that the kinetics of the oxidative vaporization of $Cr_2O_3(s)$ in the reaction controlled region can be adequately described by the equilibrium thermodynamic data. It is, therefore, possible to derive an equation for the rate of oxidative vaporization in any pressure region under various flow conditions, requiring only the equilibrium constant of the reaction and the Nusselt number obtained from dimensionless fluid correlations. The development parallels that of Bartlett (15).

The oxidation process is represented by the reaction

$$1/2\, Cr_2O_3(s) + 3/4\, O_2(g) \underset{k_b}{\overset{k_f}{\rightleftarrows}} CrO_3(g) \qquad [4]$$

[5] The quantity of importance in experiments involving gas-solid reactions is the collision flux of the gas with the solid. This depends on the pressure and the temperature of the gas. When a small diameter filament is heated in a bulb containing gas at a pressure low enough that the mean-free path is comparable to the diameter of the bulb (Knudsen region), all the gas molecules striking the wire have a temperature equal to that of the bulb. As the pressure is increased and/or the diameter of the wire is increased, the gas molecules striking the wire will have temperatures approaching the wire temperature. In the viscoelastic pressure region one usually takes the gas temperature in the boundary layer as the average of the wire and bulb temperature. In our experiments the ratio of the mean-free path to the ribbon width was about 0.2. While this is not in the Knudsen region, it is fairly close and for the sake of simplicity we have assumed that the gas striking the chromium ribbon is at room temperature.

[6] The collision flux, Z, varies as $T^{-1/2}$ as indicated by the well-known kinetic theory equation $Z = p(2\pi MRT)^{-1/2}$.

At pressures where the mean free path (λ) of the $CrO_3(g)$ is large compared with the width (L) of the chromium ribbon, all the $CrO_3(g)$ formed escapes from the ribbon and the rate is reaction controlled. At higher pressures where $\lambda/L < 1$, some of the volatilizing $CrO_3(g)$ will be back reflected to the chromium ribbon where it will decompose and the rate will be diffusion limited. In this case the rate will be determined by the rate of mass transport of $CrO_3(g)$ through a stagnant boundary layer of oxygen (because $P_{CrO_3} << P_{O_2}$). The mass flux of $CrO_3(g)$ across the boundary layer is given by

$$\dot{m}_D = \frac{k_m M_{CrO_3}(P_{CrO_3,s} - P_{CrO_3,\delta})}{P_t} \qquad [5]$$

where $\dot{m}_D$ is in g-cm^{-2}-sec^{-1}; k_m is the mass transfer coefficient which can be calculated from boundary layer theory (mole-cm^{-2}-sec^{-1}); $P_{CrO_3,s}$ and $P_{CrO_3,\delta}$ are the steady-state values of the partial pressures of $CrO_3(g)$ at the surface of the chromium ribbon and at the outer edge of the boundary layer, respectively; and P_t is the total pressure or the stagnation pressure in a flowing system.

Generally, $P_{CrO_3,\delta} = 0$ and Eq. [5] reduces to

$$\dot{m}_D = k_m M_{CrO_3} P_{CrO_3,s}/P_t \qquad [6]$$

The rate of formation of $CrO_3(g)$ by chemical reaction is given by

$$\dot{m}_R = M_{CrO_3}(k_f P_{O_2,s}{}^{3/4} - k_b P_{CrO_3,s}) \qquad [7]$$

where k_f and k_b are the forward and backward rate constants of the reaction, respectively. $P_{O_2,s}$ is the partial pressure of oxygen at the surface of the chromium ribbon.

However, because $P_{CrO_3(g)} << P_{O_2}$, $P_{O_2,s}$ can be taken equal to the pressure in the system: P_{O_2}. We have tacitly assumed in Eq. [7] that the condensation coefficient of $CrO_3(g)$ on the chromium is one.

The exact value of $P_{CrO_3,s}$ is unknown. However, it can be eliminated from Eq. [6] and [7]. In addition, from consideration of the mass balance, $\dot{m}_D = \dot{m}_R$; and by definition, $K_e = k_f/k_b$. Performing these operations and substitutions, we obtain

$$\dot{m}_D = \frac{M_{CrO_3} k_b K_e P_{O_2}{}^{3/4}}{1 + k_b P_t/k_m} \qquad [8]$$

The backward rate constant k_b is simply the surface collision frequency of $CrO_3(g)$ molecules in mole-cm^{-2}-sec^{-1} per unit pressure, and is given by the kinetic theory expression

$$k_b = (2\pi M_{CrO_3} RT)^{-1/2} \qquad [9]$$

Inserting this expression into Eq. [8], we obtain

$$\dot{m}_D = \frac{(2\pi M_{CrO_3} RT)^{-1/2} M_{CrO_3} K_e P_{O_2}{}^{3/4}}{1 + (2\pi M_{CrO_3} RT)^{-1/2} P_t/k_m} \qquad [10]$$

where R is in erg-mole^{-1}-K^{-1} and P is in dyne-cm^{-2}.

Equation [10] is valid at all pressures and at temperatures for which reaction [4] occurs. At low pressures where $1 >> (2\pi M_{CrO_3} RT)^{-1/2} P_t/k_m$, Eq. [10] reduces to

$$\dot{m}_D = (2\pi M_{CrO_3} RT)^{-1/2} M_{CrO_3} K_e P_{O_2}{}^{3/4} \qquad [11]$$

which is analogous to Eq. [3] except it is in units of grams $CrO_3(g)$ rather than grams Cr. The rate of oxidation is proportional to $P_{O_2}{}^{3/4}$ and is reaction controlled. At high pressures where $1 << (2\pi M_{CrO_3} RT)^{-1/2} P_t/k_m$, Eq. [10] reduces to

$$\dot{m}_D = M_{CrO_3} k_m K_e P_{O_2}{}^{3/4}/P_t \qquad [12]$$

The mass transfer coefficient, k_m, is related to the Nusselt number (Nu_m) for mass transfer by the relation

$$k_m = \frac{Nu_m P_t D_{CrO_3}}{LRT_g} \quad [13]$$

where D_{CrO_3} is the diffusion coefficient of CrO_3 in cm^2-sec^{-1} and L is a characteristic dimension of the sample, *i.e.*, the ribbon width.

All of the quantities in these two equations ([12] and [13]) are known except the diffusion coefficient and the Nusselt number. The former can be calculated from the Chapman-Enskog equation and the Nusselt number is obtained from semiempirical correlations used extensively in engineering analyses (35).

Summary of Results

Experimental rates for the oxidative vaporization of Cr_2O_3 in low pressure, flowing oxygen, when corrected for geometrical and diffusion-limiting factors, agree within experimental error with rates calculated from equilibrium thermodynamic data.

The experimentally determined pressure and temperature dependencies also agree within experimental error with the dependencies predicted from equilibrium thermodynamic data. Both experiment and thermodynamic data show that the reaction varies as the 3/4 power of the oxygen pressure. The experimental energy of activation, adjusted for the fact that the oxygen is not at the temperature of the specimen, was 59.9 ± 5 kcal-$mole^{-1}$ and the enthalpy calculated for the reaction was 55.7 ± 2 kcal-$mole^{-1}$.

Predicted on these findings one can conclude that the rate of oxidative vaporization of Cr_2O_3 in oxygen can be calculated realistically from equilibrium thermodynamic data. An equation is derived for calculating the rate under any conditions of temperature, pressure, and flow condition using thermodynamic data and the Nusselt number obtained from dimensionless fluid correlations

ABSTRACT

Rates of oxidative vaporization of Cr_2O_3 have been found to be markedly enhanced in the presence of oxygen atoms. Investigations were conducted over the temperature range 200°-1250°C. For Cr_2O_3 the enhancement was about 10^9 at 550°C in oxygen containing 2.5% atoms. Rapid oxidative vaporization of bare chromium was observed below 800°C, the rate being about one-half that of Cr_2O_3. Results are interpreted in terms of thermochemical analysis.

Some years ago one of us demonstrated that oxygen atoms caused a marked enhancement in the rate of oxidation of platinum (1, 2). Subsequently, Rosner and Allendorf (3) extended these studies to molybdenum and tungsten obtaining similar enhancements in the rates of oxidation. Madix (4), using atomic beam techniques, found an enhanced oxidation of germanium and silicon with oxygen atoms. All of these metals form volatile oxides in the temperature range in which the enhanced oxidation was discovered.

This paper reports on the enhancement, by oxygen atoms, of the oxidative vaporization of an oxide; namely, Cr_2O_3. The normal oxidation reaction is represented by the equation

$$1/2Cr_2O_3(s) + 3/4\,O_2(g) \rightarrow CrO_3(g) \qquad [1]$$

In oxygen, at reduced pressures, this oxidative vaporization is detectable above roughly 900°C [see preceding paper (5)]. In partially atomic oxygen, the rate is enhanced so markedly that oxidation is readily measured down to 200°C. We have determined the rate of oxidative vaporization of Cr_2O_3 in partially atomic flowing oxygen at a total pressure of 0.115 Torr[1] from 200° to 1250°C. The experimental rates were corrected by the method given in the preceding paper (5) to give "reaction controlled" rates. Oxidative vaporization rates were also calculated from the equilibrium thermodynamic data for comparison.

During the course of this investigation we observed, below 800°C, a direct oxidative vaporization of chromium metal by the oxygen atoms. This has also been noted by Sutcliffe (6). As a result, measurements were also made of the rate of oxidative vaporization of electropolished chromium in partially atomic oxygen.

Experimental Procedure

The main features of the experimental arrangement and the procedures used in this investigation were described in the preceding paper (5). As before, samples were prepared from a chromium-0.1 weight per cent (w/o) yttrium alloy. In the present experiments the oxygen was dissociated by a 100W, 2450 MHz microwave power supply with a slotted wave guide [item 9, Fig. 1 of Ref. (5)]. The amount of dissociation in the region of the oxidation sample was determined with a platinum resistance thermometer [item 1, Fig. 1 of Ref. (5)], similar to one used previously (1), that could be moved directly in front of the specimen in the flow stream of oxygen. The sensing element of this thermometer was made from platinum ribbon 0.025 mm thick, 0.25 mm wide, and 3 cm long. The central 2 cm was tapped off with 0.025 mm diameter wires for potentiometric readings. The platinum ribbon was operated at 900°C, a temperature at which the recombination coefficient for oxygen atoms is close to one (7, 8). The percentage of oxygen atoms in the oxygen can be obtained from the measured joule heating resulting from the recombination of the atoms, knowing the heat of recombination and the pressure of the oxygen [see Ref. (1) for details]. Corrections[2] were made for the heating resulting from O_2 ($^1\Delta_g$) molecules that are also formed in the discharge (9, 11).

Research Grade oxygen was used. This gas contained less than 1 ppm of water vapor so it was necessary to add 5% of nitrogen (also Research Grade) to the oxygen in order to produce a more useful concentration of oxygen atoms.[3] With the nitrogen added we obtained about 2.5% oxygen atoms at the sample, and with the pure oxygen we obtained about 1.2%.

The procedure for conducting experiments was similar to that described in the preceding paper (5). For Cr_2O_3 oxidations the chromium ribbons were all preoxidized at a high temperature: 1100°-1300°C. This was done, as before, *in situ* for one-half hour in the flowing oxygen at 0.115 Torr, and the thickness of Cr_2O_3 scale formed was 0.01 mm (0.4 mil) or greater. The temperature of the specimens was obtained from the reading of the thermocouple spot welded onto the back. This was checked with the micro-optical pyrometer at the higher temperatures.

In addition, it was necessary to stabilize the discharge before the oxidations could be performed. The first stabilization of the day required 30 min run-in time to obtain constant oxygen atom output. If the arc was shut off during the day, 5 to 10 min run-in was sufficient. During these arc stabilizations the shutter was kept closed so that the specimen was not exposed to any atoms. The oxygen atom output was very stable after the initial run-in and was reproducible from day to day as long as the oxygen inlet tube remained clean. Over long periods of time the output dropped slowly. Periodically, the inlet tube was removed and cleaned in 5% HF followed by copious rinsing with distilled water.

The oxide condensate formed in these experiments was always readily soluble in water, and we have as-

Key words: oxidation, vaporization, kinetics, chromium, thermodynamics, oxygen atoms, activation energy.

[1] This pressure was the optimum for oxygen atom production.

[2] Auxiliary experiments were run in which a long silver ribbon was placed in the gas inlet tube, just downstream from the discharge. This effectively removed all the oxygen atoms as indicated by blackening of only the upstream end of the silver (9). The blackening results from formation of AgO (10) by the oxygen atoms. The residual heating caused by the O_2 ($^1\Delta g$) in the gas was found to be 10% of heating obtained without the silver ribbon. This percentage remained the same with or without the nitrogen addition to the oxygen.

[3] The water vapor in the oxygen was maintained as low as possible to prevent complications from the reaction (12)

$$½Cr_2O_3(s) + ½\,O_2 + ½H_2O(g) \rightarrow CrO_2OH(g)$$

The added N_2 is dissociated in the discharge and the nitrogen atoms react very rapidly with O_2 and/or NO to form oxygen atoms. No nitrogen atoms reach the sample.

sumed it was CrO_3 based on the reasoning used in the preceding paper (5). As before, the water solutions were analyzed for chromium by atomic absorption spectroscopy.

Thermochemical Predictions

Equilibrium thermochemical diagrams have proven useful in describing the chemistry of oxidation and vaporization for many metal-metal oxide-oxygen systems (13-18). The preceding paper (5) demonstrated that the thermodynamic description could also be correlated with the kinetic behavior for the oxidative vaporization of a condensed phase metal oxide, Cr_2O_3, reacting with molecular oxygen. Here we extend the use of thermochemical diagrams to provide a description of the oxidative vaporization of condensed phase chromium and Cr_2O_3 reacting with atomic oxygen. The effect of adding atomic oxygen is equivalent to increasing the chemical potential of oxygen.

Thermochemical diagrams for the chromium-atomic oxygen system at 800° and 1500°K are given in Fig. 1 and 2, respectively. (Details of the method of construction and sources of thermodynamic data are given in the Appendix.) For comparison we give a diagram for the chromium-molecular oxygen system at 800°K in Fig. 3. A similar diagram at 1500°K was given in Fig. 3 of the preceding paper (5).

The atomic oxygen thermochemical diagrams differ markedly from the molecular oxygen ones in several respects. In addition to Cr and Cr_2O_3 condensed phases, a CrO_3 condensed phase is present at high oxygen atom pressures. Whereas the complex chromium-oxygen molecules are relatively unimportant in the molecular oxygen case, the polymeric $(CrO_3)_n$ and Cr_nO_{3n-2}, molecules ($n = 3$, 4, and 5) are the predominant species in the vapor phase at high oxygen atom pressures, particularly over the CrO_3 phase. In addition, the actual vapor pressures of the oxides are markedly higher in the atomic oxygen case. At 800°K comparison of the vapor pressure of $(CrO_3)_3$ under our oxygen atom partial pressure of 3.8×10^{-6} atm (denoted by arrow in Fig. 1) with the vapor pressure of CrO_3 under our molecular oxygen partial pressure of 1.5×10^{-4} atm (denoted by arrow in Fig. 3) indicates an enhancement in oxide vapor pressure of about 10^{13}. The oxidative vaporization rate should be enhanced by a similar factor. At 1500°K the situation is a little different. Under our oxygen atom concentration (denoted by arrow in Fig. 2), the polymers of CrO_3 are not stabilized at this higher temperature and the main oxide product is again the monomer, CrO_3. Comparison of the vapor pressure of CrO_3 from Fig. 2 at $P_O = 3.8 \times 10^{-6}$ atm with the vapor pressure from Fig. 3 of the preceding paper (5) at $P_{O_2} = 1.51 \times 10^{-4}$ atm, indicates an enhancement of about 10^2.

It is instructive to plot the vapor pressures of the various oxide species against T^{-1} for our oxygen atom partial pressure, $P_O = 3.8 \times 10^{-6}$ atm, as presented in Fig. 4. The polymers of CrO_3 are stabilized over

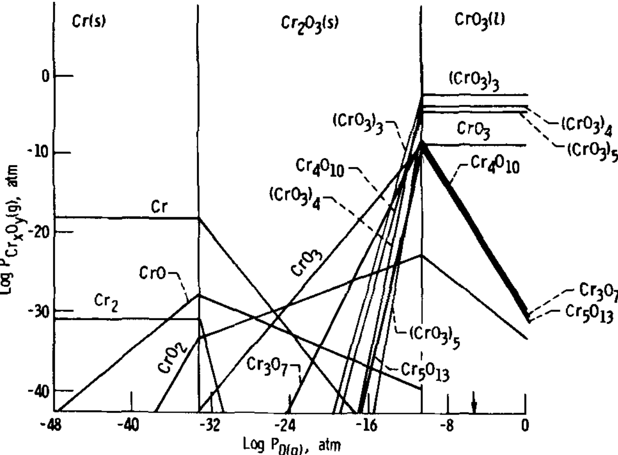

Fig. 1. Equilibrium thermochemical diagram for the chromium-atomic oxygen system at 800°K. Arrow indicates experimental oxygen atom partial pressure (3.8×10^{-6} atm).

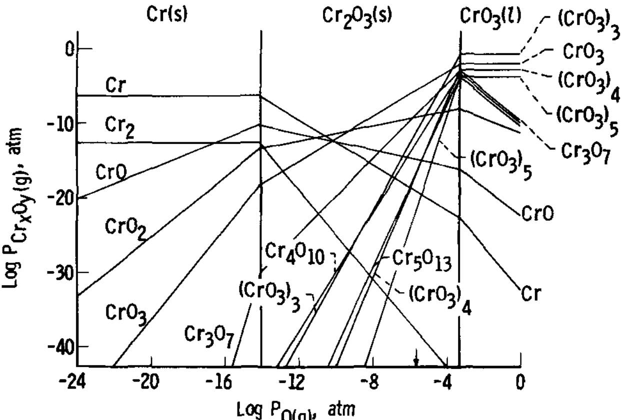

Fig. 2. Equilibrium thermochemical diagram for the chromium-atomic oxygen system at 1500°K. Arrow indicates experimental oxygen atom partial pressure (3.8×10^{-6} atm).

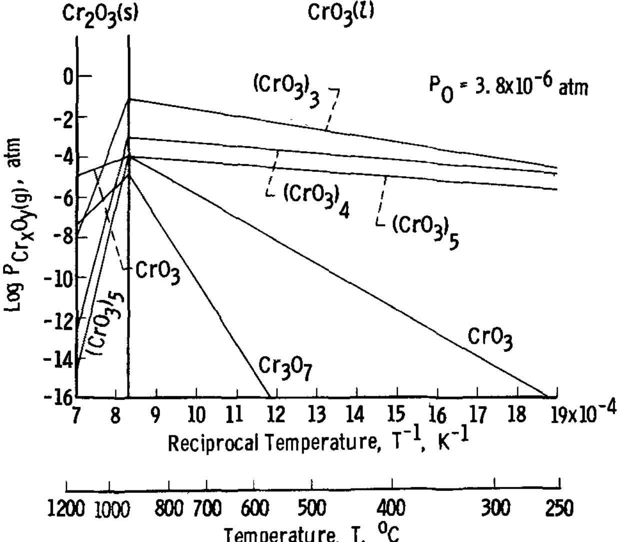

Fig. 4. Equilibrium vapor pressures of various oxide species of the chromium-atomic oxygen system vs. reciprocal temperature under an oxygen atom partial pressure of 3.8×10^{-6} atm.

$CrO_3(l)$ and are the principal vapor species up to the Cr_2O_3-CrO_3 phase boundary at a temperature around 950°C. At temperatures above this, the pressure of the polymers decreases dramatically and the monomer of CrO_3 becomes the most abundant oxide species as in molecular oxygen. Because the rate of oxidative vaporization should vary with the vapor pressures, we conclude that the rate in oxygen atoms should increase with temperature to 950°C and then fall abruptly with increasing temperature.

For comparison with our corrected experimental rates of oxidative vaporization of Cr_2O_3, rates have been calculated from the oxide vapor pressures obtained from the thermochemical diagrams using the Hertz-Langmuir equation, as in the preceding paper (5). However, in this case more than one oxide species were significant. Therefore rates were calculated for each species and the individual rates summed to give the total rate of oxidation.

Results and Discussion

General

The rates of oxidation presented in this paper have been corrected for a "geometrical factor" and a "diffusion-limitation factor" (escape fraction) as described in the preceding paper (5). No corrections have been made for the fact that the diffusing CrO_3 moiety may change with temperature, exhibiting slightly different diffusivities. This would be a secondary effect. All rates reported here were obtained with an oxygen flow rate of 5 liters-hr^{-1} (STP) and a pressure of 0.115 Torr in the main chamber. Turning on the microwave discharge to produce atoms had negligible effect on the pressure.

The rates of oxidation of Cr_2O_3 measured at different temperatures in oxygen containing 2.5% O atoms are shown in Fig. 5 (upper solid curve). Also shown for comparison are rates of oxidation of Cr_2O_3 in molecular oxygen (dashed curve), which vary from 0.5 mg-cm^{-2}-hr^{-1} at 1300°C to 0.005 mg-cm^{-2}-hr^{-1} at 1000°C. Obviously, the rate of oxidation of Cr_2O_3 has been greatly enhanced by the small concentration of oxygen atoms. Rapid oxidation rates, nearly 10 mg-cm^{-2}-hr^{-1}, were observed in the region around 550°C.

Unexpectedly, a rapid, direct oxidative vaporization of chromium metal was observed below about 800°C. This occurs partly because of the rapid removal of the Cr_2O_3 by the oxygen atoms at temperatures at which Cr_2O_3 can reform only slowly. Consequently, rates of oxidation of electropolished chromium were also determined and these results are shown in the lower solid curve of Fig. 5.

It is informative to express the oxidation results in terms of the "oxidation probability"[4] of the oxygen atoms, ϵ_o. These have been calculated from the rates and the measured flux of oxygen atoms, and are presented in Fig. 5 along the right-hand ordinate. The maximum values, which occur at 550°C, are $\epsilon_o = 3 \times 10^{-2}$ for Cr_2O_3 oxidation and $\epsilon_o = 1.4 \times 10^{-2}$ for the Cr oxidation. In the high temperature region (950°-1250°C), $\epsilon_o = 2 \times 10^{-3}$ for the Cr_2O_3 oxidation.

The peculiar temperature dependence of the Cr_2O_3 rates displayed in Fig. 5 is similar to that predicted from thermochemical diagrams. We believe it arises from the fact that the oxygen atoms stabilize the polymers of CrO_3 at the lower temperatures and the oxidative vaporization reaction proceeds via the reaction

$$Cr_2O_3(s) + O(g) \rightarrow (CrO_3)_n(g) \quad [2]$$

where $n = 3$, 4, and 5. That is, the CrO_3 evaporates as fast as it is formed by the oxidation reaction, and in polymeric form. However, at 550°C the polymers apparently become unstable on the surface of the speci-

[4] The "oxidation probability" as used by Rosner (3) is a dimensionless reaction probability defined as the ratio of the flux of metal atoms (regardless of their chemical state of aggregation) away from the reacting surface to the collision flux of O(g) with the surface.

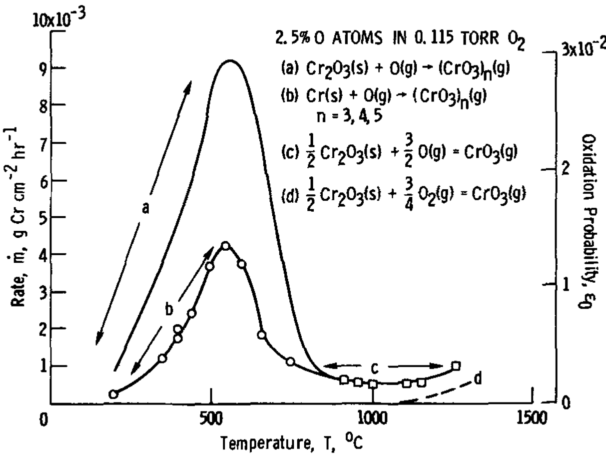

Fig. 5. Oxidative vaporization of Cr_2O_3 and chromium in partially atomic oxygen.

men and have difficulty forming. As the temperature increases, the probability of formation decreases. The rate drops because the monomer cannot evaporate at this low temperature. Evaporation of the monomer becomes significant only above 800°C, and above this temperature the oxidative vaporization proceeds via reaction

$$1/2Cr_2O_3(s) + 3/2\,O(g) \rightarrow CrO_3(g) \quad [3]$$

The rates for chromium (lower solid curve) display the same type of temperature dependence (from 200° to 800°C), and the same explanation would apply to these data. The oxidation, in this region, is represented by the reaction

$$Cr(s) + O(g) \rightarrow (CrO_3)_n(g) \quad [4]$$

where $n = 3$, 4, and 5.

Oxidation of Cr_2O_3

Results in temperature range 200°-800°C.—The rapid removal of the Cr_2O_3 from the preoxidized chromium observed in this temperature region resulted in rates that were time dependent even though one would expect time-independent rates for this type of reaction that should follow linear kinetics. This was especially noticeable around 550°C. A series of 1-min runs at this temperature yielded a rapidly decreasing rate that leveled off at a value equal to that of the electropolished chromium (lower solid curve). Therefore, individual experimental values have not been given for the rates of oxidation of Cr_2O_3 in the range 200°-800°C. The curve represents the maximum values observed and should correspond to the rate for a thick layer of Cr_2O_3 on the chromium substrate. The oxidation process occurring in this temperature region is represented by reaction [2]; namely, $Cr_2O_3(s) + O(g) \rightarrow (CrO_3)_n(g)$, where $n = 3$, 4, and 5.

Because of the semiquantitative nature of the Cr_2O_3 results in this lower temperature region, it was not possible to determine the order of this reaction with respect to oxygen atoms. However, an Arrhenius plot of the results in the region 200°-550°C, presented in Fig. 6, indicates that the reaction is occurring with a small activation energy. The points have been taken from the smoothed curve presented in Fig. 5 (upper solid curve), and obviously do not give a linear curve on the Arrhenius plot. We have drawn two straight lines through the data merely for the purpose of calculating the activation energies. The lower temperature value, 8.4 kcal-$mole^{-1}$, was probably less affected by the rapid removal of Cr_2O_3 and is probably the more reliable value. In any event both values are small and in the range observed for metal-oxygen atom reactions (2, 3).

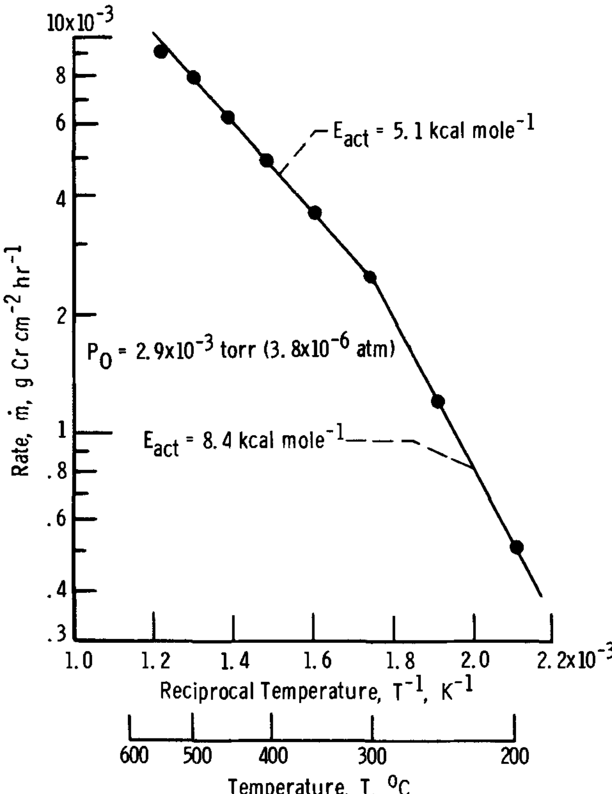

Fig. 6. Arrhenius plot of the oxidative vaporization of Cr_2O_3 in partially atomic oxygen from 200° to 550°C.

Results in temperature range 900°-1250°C.—Above 900°C the reported rates of oxidation of Cr_2O_3 in oxygen atoms were time independent and not complicated by removal of Cr_2O_3; the rate of removal of Cr_2O_3 was less in this region and the rate of formation by oxidation of the underlying chromium by normal oxygen was greater. We did, however, observe a temperature hysteresis effect in this temperature regime; runs repeated at a given temperature were higher than previously if the specimen had been oxidized at a higher temperature in the time intervening. The effect appeared to be caused by a greatly increased roughening of the oxide surface which occurred around 1200°C, and/or by a greater thickness of oxide scale that formed at the higher temperatures. In any event, the rates in this temperature regime were obtained from specimens that were all preoxidized at 1300°C. This procedure eliminated the temperature-hysteresis effect.

The oxidation process in this temperature region is represented by reaction [3]; namely, $1/2Cr_2O_3(s) + 3/2\,O(g) \rightarrow CrO_3(g)$. The rates of this reaction appear to be independent of temperature from 950° to 1250°C (see Fig. 5); they are nearly constant up to 1100°C above which they increase due to the addition of oxide from the oxidation by oxygen molecules. The two simultaneous reactions seem to be additive and independent of each other.

Results of detailed studies of the rates in this region are shown in Fig. 7, where we have plotted the rate arising from only the oxygen atoms against the temperature. The rate arising from the oxygen molecules has been subtracted from the total rate; below 1100°C this correction is insignificant and at 1250°C it is roughly 33% of the total rate. It is evident from Fig. 7 that indeed there is little activation energy required for the reaction of oxygen atoms with Cr_2O_3 in this temperature regime. A linear least squares analysis of an Arrhenius plot of this data yielded an $E_{act} = 0.57$ kcal-mole^{-1}. This low activation energy for the oxygen atom reaction is similar to the results obtained with the metals platinum (2) and molybdenum and tungsten (3).

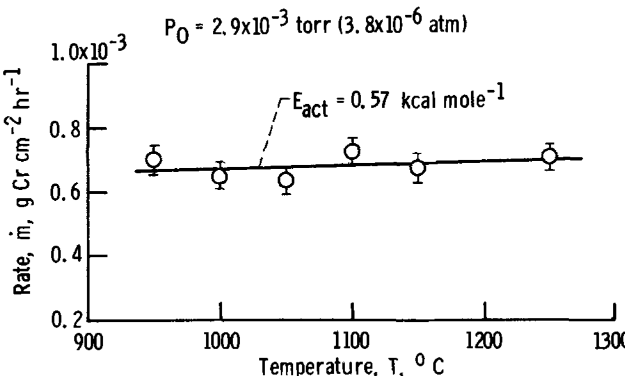

Fig. 7. Oxidative vaporization of Cr_2O_3 by oxygen atoms from 950° to 1250°C.

We have investigated the effect of varying the oxygen atom concentration on the rate in this temperature regime. The concentration of oxygen atoms was lowered by removing the 5% N_2 from the oxygen stream. While only two concentrations were available by this technique, the runs could be cycled readily between the two oxygen atom concentrations and the points presented represent the average of several runs.[5] In addition, the origin represents a bona fide point.

The results at a temperature of 1050°C are presented in Fig. 8, where the rate is plotted against the three-halves power of the partial pressure and of the collision flux of the oxygen atoms. The results indicate that the reaction is 3/2 order with respect to oxygen atoms. The 3/2 order is unusual because the reaction of oxygen atoms with metals always exhibits first-order kinetics (2, 3). In addition, oxygen atom recombination on solid surfaces usually follows first-order kinetics (6). However, in this case the 3/2 order is predicted by the stoichiometry of the oxidative reaction

$$1/2Cr_2O_3(s) + 3/2\,O(g) = CrO_3(g) \quad [5]$$

It appears, therefore, that the rate-determining step must be quite complicated, involving the formation of an activated complex on the surface consisting of three oxygen atoms and a Cr_2O_3 moiety

$$Cr_2O_3(s) + 3\,O(g) \rightarrow 2CrO_3(g) \quad [6]$$

It is surprising that the activation energy for such a complex reaction should be as low as 0.5 kcal-mole^{-1}.

Comparison with thermodynamic predictions.—As in the reaction of Cr_2O_3 with molecular oxygen [see preceding paper (5)] the rate data can be compared with rates predicted from thermodynamic data. This comparison is presented in Fig. 9 where we have plotted

[5] The standard deviation of the mean of the individual runs was ±4%.

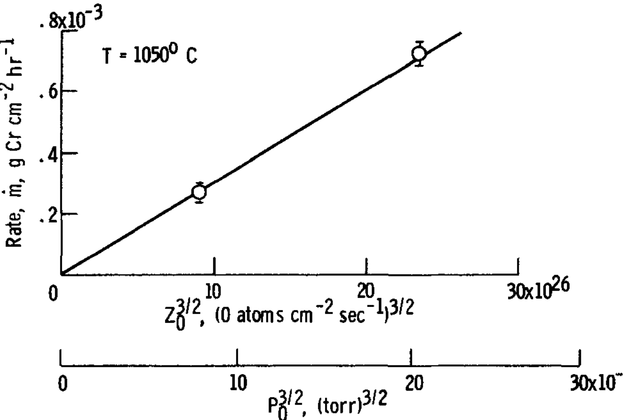

Fig. 8. Oxidative vaporization of Cr_2O_3 vs. the 3/2 power of the oxygen atom collision flux at 1050°C.

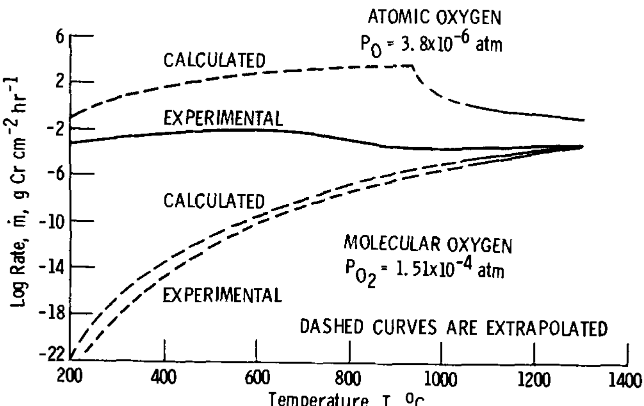

Fig. 9. Experimental and calculated rates of oxidative vaporization of Cr_2O_3 in partially atomic and molecular oxygen.

the logarithm of the rate against the temperature. We have also included the comparison in molecular oxygen from our preceding paper and have extrapolated these to 200°C using a linear extrapolation of log rate *vs.* T^{-1}. The calculated and experimental rates in partially atomic oxygen are in qualitative agreement; both indicate a marked enhancement in the oxidation rate and exhibit a maximum in the rate at intermediate temperatures. Nevertheless, there is a large difference in the values of the rates[6] and in the temperature at which the maximum occurs. Both of these factors are dependent on the concentration of oxygen atoms on the surface of the Cr_2O_3. We believe the disparity arises from the fact that the concentration of oxygen atoms on the surface is much less than the equilibrium value corresponding to the gaseous partial pressure. This results from rapid recombination of the adsorbed oxygen atoms on the hot surface. While it has been shown that Cr_2O_3 at room temperature has a very low recombination coefficient for oxygen atoms (6, 19), the recombination coefficient increases rapidly with increasing temperature (6).[7] This might offer an explanation for the drop in rate at 550°C. However, we feel that destabilization of the CrO_3 polymers is a more plausible explanation because of the thermodynamic data presented in the section on Thermodynamic Predictions.

Enhancement in the oxidation rate.—It is interesting to consider the enhancement in the rate of oxidation of Cr_2O_3 effected by this small concentration of oxygen atoms in the gas phase. The enhancements have been calculated at different temperatures from the results given in Fig. 9, and are presented in Fig. 10. We have given here the enhancement calculated from both the experimental and the calculated rates. The enhancements are truly enormous at the lower temperatures, the experimental values being 10^{20} at 200°C and 10^9 at 550°C. At 1000°C the enhancement is 100. Of course, with larger concentrations of oxygen atoms, the enhancements would be even greater. In this respect, more valid values for the enhancements can be obtained by comparing the "oxidation probabilities" of the oxygen atoms and of the O_2 molecules in the oxida-

[6] It should be noted that these experimental rate data in oxygen atoms have not been corrected [as was done in preceding paper (5)] for the fact that the temperature of the oxygen was not the same as the sample. The correction is insignificant in comparison to the discrepancy between the experimental and calculated rates.

[7] It should be noted that an oxygen atom recombination coefficient changing with temperature would affect the value of the energy of activation obtained from the data that we have presented in Fig. 6 and 7. In fact, this may account for lack of linearity throughout the entire temperature range displayed by the data for reaction [2] presented in Fig. 6. Certainly the recombination coefficient on Cr_2O_3 is increasing in this temperature range (6). This would have the effect of depressing the higher temperature data and may also indicate that the value of 8 kcal-mole^{-1} should be the preferred value for the energy of activation for reaction [2].
The data for reaction [3] presented in Fig. 7 fall nicely on a straight line and yield a very reasonable value for the energy of activation. It appears that the oxygen-atom recombination coefficient on Cr_2O_3 in this temperature range is either constant or changes little.

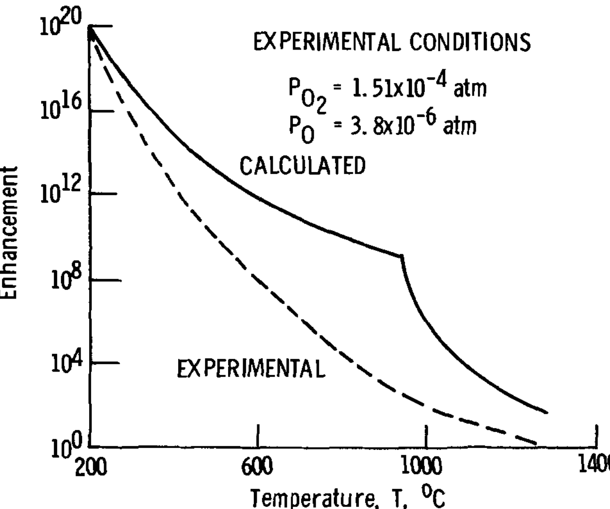

Fig. 10. Enhancement of oxidative vaporization of Cr_2O_3 in partially atomic oxygen.

tive vaporization of Cr_2O_3. Table I illustrates such a comparison for the temperature range 1000°-1300°C where the analogous reactions [1] and [3] are occurring; that is, oxidation to the $CrO_3(g)$ monomer is taking place. The ϵ_o for the oxygen atoms is constant and is given in column 2. The ϵ_{o_2} have been calculated from the smoothed data of the preceding paper (5) and are given in column 3. The enhancement is given in column 4 and varies from 10^4 at 1000°C to 40 at 1300°C.

Oxidation of Chromium

A very interesting discovery of this work was the occurrence of the rapid, direct oxidative vaporization of chromium metal by oxygen atoms in the region below 800°C. The rates of oxidation of electropolished chromium in oxygen atoms (lower solid curve of Fig. 5) were time independent, as one would expect for such a reaction. Below about 800°C the chromium ribbons remained bright and shiny after a series of oxidations wherever they had been exposed to the oxygen atoms, though some bright green Cr_2O_3 was formed toward the ends of the ribbons near 800°C. The rates were fairly reproducible and were generally about one-half the rates observed for Cr_2O_3, based on the amount of product. The rates displayed the same peculiar dependence on temperature that the Cr_2O_3 rates did, and we explain this behavior on the same basis. The reaction occurring is represented by reaction [4]; namely, $Cr(s) + O(g) \rightarrow (CrO_3)_n(g)$, where $n = 3$, 4, and 5.

We have investigated the order of this reaction at a temperature of 450°C. The results are given in Fig. 11 where the rate of oxidative vaporization of chromium is plotted against the partial pressure and the collision flux of oxygen atoms. The results follow first-order kinetics quite nicely. The oxygen atom concentration was varied as described above. The points represent the average of several runs and the origin again represents a bona fide point. The first-order kinetics for the reaction of chromium with oxygen atoms is in agreement with the results found for the other metals. The rate-determining step is probably similar to that postulated by one of us for platinum, molybdenum, and tungsten (2); namely

Table I. Comparison of oxidation probabilities of O atoms and O_2 molecules in the oxidative vaporization of Cr_2O_3

Temp, °C	ϵ_O	ϵ_{O_2}	$\epsilon_O/\epsilon_{O_2}$
1000	2×10^{-3}	2.4×10^{-7}	8.5×10^3
1100	2×10^{-3}	2.9×10^{-6}	6.9×10^2
1200	2×10^{-3}	1.3×10^{-5}	1.5×10^2
1300	2×10^{-3}	5.3×10^{-5}	3.8×10^1

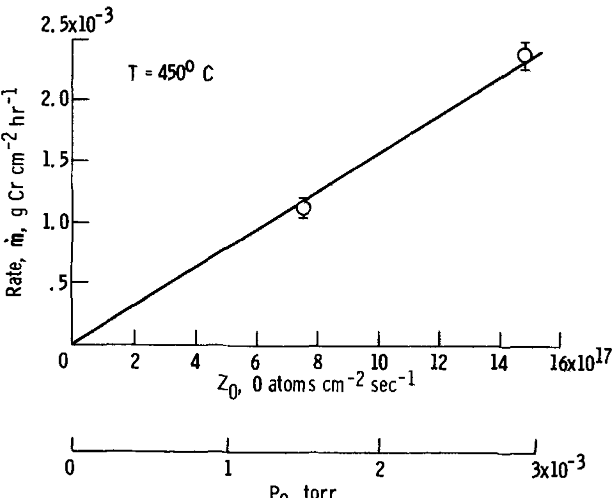

Fig. 11. Oxidative vaporization of chromium vs. oxygen atom collision flux at 450°C.

$$CrO_2(ads) + O(g) \xrightarrow{slow} CrO_3(ads) \xrightarrow{fast} (CrO_3)_n(g) \quad [7]$$

The "oxidation probabilities" of the oxygen atoms in this reaction have been calculated and are presented in Fig. 5. Because the reaction is first-order, the "oxidation probability" is equivalent to the "collision efficiency" which is defined as the fraction of oxygen atoms striking the surface that react. The maximum value of the "collision efficiency" occurs at 550°C and is $\epsilon_0 \approx 0.014$, *i.e.*, one oxygen atom reacts in every 70 atoms that strike the chromium metal. This may be compared with the "collision efficiency" of oxygen atoms in the platinum metal oxidation (2), $\epsilon_0 = 5 \times 10^{-6}$, and with the "oxidation probability" reported for molybdenum and tungsten (3) which vary from about 0.1 to 0.5 depending on the temperature. It should be noted, however, that the chromium-oxygen atom reaction occurs at noticeably lower temperatures than the reaction of the other metals. This results partly from the high volatility of CrO_3 down to 200°C, but it also indicates that the activation energy for the reaction must be low, as observed with the other metals. An Arrhenius plot of our rate data for electropolished chromium in the temperature range 200°-550°C is presented in Fig. 12. A least squares analysis of this data yields an activation energy of 7.2 kcal-mole^{-1}. This is in good agreement with the values found by Rosner (3) for similar reactions of molybdenum and tungsten with oxygen atoms; namely 6 kcal-mole^{-1} and 4 kcal-mole^{-1}, respectively. These results emphasize the fact that these metal-oxygen atom reactions can occur at any temperature above which the oxide product is volatile. We have also shown in this paper that the same is probably true for oxide-oxygen atom reactions, in which a lower valent oxide can be oxidized to a higher valent, volatile oxide.

Summary and Implications

We have shown that the oxidative vaporization of Cr_2O_3 is markedly enhanced by oxygen atoms over the entire temperature range of this study: 200°-1250°C. A rapid direct oxidative vaporization of chromium metal also occurs in the presence of oxygen atoms from 200° to 800°C. The kinetic parameters for the reactions studied are summarized in Table II.

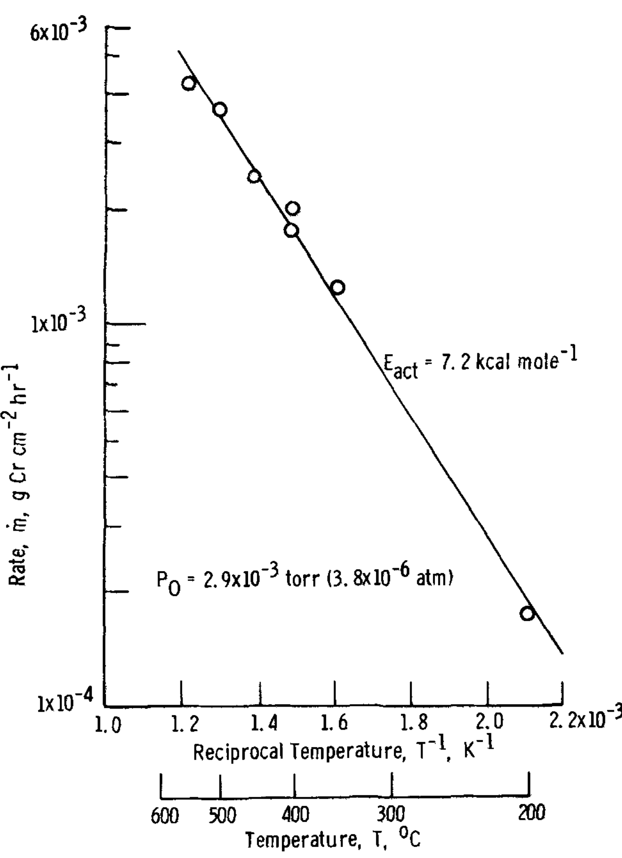

Fig. 12. Arrhenius plot of oxidative vaporization of chromium in partially atomic oxygen from 200° to 550°C.

Based on the high reactivity of oxygen atoms and the low activation energy found for the oxidative vaporization of Cr_2O_3, we predict that an enhanced oxidation in oxygen atoms should be exhibited by any oxide for which there exists a stable, gaseous oxide of high volatility with the metal in a higher valence state. Of course the enhancement would occur only in the temperature and pressure range where the higher valent oxide was volatile and abundant. The following systems fulfill these criteria

$$B_2O_3(s) \rightarrow BO_2(g)$$
$$Al_2O_3(s) \rightarrow AlO_2(g)$$
$$U_3O_8(s) \rightarrow UO_3(g)$$
$$UO_2(s) \rightarrow UO_3(g)$$
$$ReO_2(s) \rightarrow Re_2O_7(g)$$
$$ReO_3(s) \rightarrow Re_2O_7(g)$$
$$Mn_2O_3(s) \rightarrow Mn_2O_7(g)$$
$$MnO_3(s) \rightarrow Mn_2O_7(g)$$
$$V_2O_3(s) \rightarrow V_4O_{10}(g)$$

It is evident from this study that the high rate of removal of the so-called protective oxide Cr_2O_3 and the subsequent high rate of removal of underlying chromium metal by oxygen atoms poses a serious problem in the selection of materials for reentry vehicles which experience high heating rates under conditions such that high oxygen atom concentrations are present.

Our measurements on the chromium-atomic oxygen system have revealed some interesting phenomena and raised some interesting questions. More sophisticated methods, such as high pressure mass spectrometry and

Acknowledgments

It is a pleasure to thank J. R. Stephens for supplying us with the chromium used in this study. We also wish to thank J. W. Graab and W. F. Davis for carrying out the chemical analyses.

Manuscript submitted Nov. 30, 1973; revised manuscript received Feb. 11, 1974. This paper was presented in part as Paper 105 at the Boston, Massachusetts, Meeting of the Society, Oct. 7-11, 1973.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1975 JOURNAL. All discussions for the June 1975 Discussion Section should be submitted by Feb. 1, 1975.

APPENDIX

Thermochemical diagrams were constructed following the method outlined by Gulbransen and Jansson (14-18). Thermodynamic data for O(g), Cr(g), CrO(g), and CrO_2(g) were taken directly from Schick (20); the log K_p [8] values for Cr_2O_3(s) were calculated from $\Delta G°_f$ values given by Wicks and Block (21). Thermodynamic data for Cr_2(g) were taken from Kant and Strauss (22). The data for the condensed phase of CrO_3 (mp = 470°K) are given by Schick to 800°K. The values of log K_p to 1600°K were obtained by linearly extrapolating the low temperature values given in Schick *vs.* reciprocal temperature up to 1600°K. For CrO_3(g), the values of log K_p were obtained by use of the relationship: $\log K_{p,CrO_3(g)} = \log P_{CrO_3(g)} + \frac{1}{2} \log K_{p,Cr_2O_3(s)} - \frac{3}{4} \log P_{O_2(g)}$. The values of $\log P_{CrO_3(g)}$ as a function of temperature and oxygen pressure were taken from the work of Kim and Belton (12) for the temperature range 1500°-1800°K. The values of $\log K_{p,CrO_3(g)}$ at lower temperatures were obtained by linear extrapolation of the high temperature values *vs.* reciprocal temperature down to 500°K.

The mass spectrometrically determined vapor pressure data of Washburn (23) for the $(CrO_3)_3$, $(CrO_3)_4$, $(CrO_3)_5$, Cr_3O_7, Cr_4O_{10}, and Cr_5O_{13} molecules over CrO_3(s) were used to obtain the necessary thermodynamic data for these molecules. The reliability of thermodynamic data derived from Washburn's measurements are based on the assumption that the complex chromium-oxygen molecules observed in the mass spectrometer were in equilibrium with the condensed phase CrO_3 and with each other in the Knudsen cell source. Washburn's vapor pressure measurements covered the temperature range of 415°-568°K. By combining his vapor pressures and heats of sublimation with our selected value[9] of 4.0 kcal-mole^{-1} for the heat of melting of CrO_3(s), values were obtained for the heats of vaporization and for the vapor pressures of the chromium-oxygen molecules over CrO_3(l) at temperatures above 470°K. These vapor pressures were extrapolated linearly *vs.* reciprocal temperature to 1600°K. The log K_p values for the molecules were obtained by use of expressions of the type

$$\log K_{p,(CrO_3)_3(g)} = \log P_{(CrO_3)_3(g)} + 3 \log K_{p,CrO_3(l)}$$

and

$$\log K_{p,Cr_3O_7(g)} = \log P_{Cr_3O_7(g)} + \log P_{O_2(g)} - \log P_{(CrO_3)_3(g)} + \log K_{p,(CrO_3)_3(g)}$$

from 500° to 1600°K. Washburn found that the oxygen partial pressures in his Knudsen cell were a factor of 10^{-10} less than that expected from thermodynamic calculations. Therefore in order to calculate the equilibrium O_2 partial pressures at the various temperatures it is assumed that CrO_3 vaporizes congruently and that the sum of the number of moles of Cr_3O_7, Cr_4O_{10}, and Cr_5O_{13} equals the number of moles of O_2(g). The values of log K_p for all of the species under consideration are given from 500° to 1600°K in Table A-I. The not-well characterized CrO_2(c) phase was not considered in the present treatment because calculations showed that even higher oxygen pressures were needed to stabilize this phase than were needed to stabilize CrO_3.

The partial vapor pressures of the molecular species were calculated by consideration of the expression for the equilibrium constant in terms of the activities of reactants and products for the appropriate chemical reactions, and use of the relationship

$$\log K_{\text{reaction}} = \Sigma \log K_{p,\text{products}} - \Sigma \log K_{p,\text{reactants}}$$

[8] Log K_p stands for the logarithm (to the base 10) of the equilibrium constant for the reaction of forming the given compound from its elements in their standard states.

[9] The selected value of $\Delta H_m(CrO_3)$ of 4.0 kcal-mole^{-1} is obtained by consideration of the values listed by Coughlin (24) of 3.77 kcal-mole^{-1}, Schick's (20) estimate of 5.36 kcal-mole^{-1}, and the experimental value of 3.9 kcal-mole^{-1} recalculated from the data given by McDonald and Margrave (25).

Thermodynamic Properties, Transference Numbers, and Ionic Mobilities in Molten Lithium Chloride-Cadmium Chloride Mixtures from EMF Measurements

Wishvender K. Behl[*,1]

Brookhaven National Laboratory, Upton, New York 11973

The publication costs of this article have been assisted by Brookhaven National Laboratory.

ABSTRACT

Thermodynamic and transference properties of the system $LiCl\text{-}CdCl_2$ were investigated at 650°C by emf measurements. For a study of thermodynamic properties, a cell using a porcelain conductive only to lithium ions was employed to separate the two salt compartments, whereas for the study of transference properties a liquid junction between the two salt compartments was established through a coiled quartz tube filled with alumina powder. Results are presented for the relative Gibbs partial molar free energies of both components and transference numbers and mobilities of cations relative to chloride ion over the entire composition range of the system.

Porcelains or glasses conductive only to alkali ions have been recently used (1-5) as membranes in concentration cells to determine the thermodynamic properties of molten alkali halide-metal halide mixtures from emf measurements. A potassium ion conducting glass has also been used (6) as a membrane in solid-state cells to determine the free energy of formation of double salts of KCl with $MgCl_2$, $CaCl_2$, $SrCl_2$, and $BaCl_2$. In the present studies, a porcelain conductive only to lithium ions (1) was used as a membrane to study the thermodynamic properties of lithium chloride-cadmium chloride mixtures at 650°C from emf measurements on concentration cells of the type

$$\underset{(-)}{Cl_2(g)\text{-}C} \mid \underset{A}{LiCl(l)} \mid \begin{matrix}Li^+\text{ conducting}\\ \text{porcelain}\end{matrix} \mid \underset{B}{\begin{matrix}LiCl\\ CdCl_2\end{matrix}}(l) \mid \underset{(+)}{C\text{-}Cl_2(g)} \quad [I]$$

The transference numbers of the cations relative to the chloride ion in mixtures of lithium chloride-cadmium chloride were also determined in the present studies from emf measurements on concentration cells with transference of the type

$$\underset{(-)}{Cl_2(g)\text{-}C} \mid \underset{A}{LiCl(l)} \mid \begin{matrix}Al_2O_3\\ \text{powder}\end{matrix} \mid \underset{B}{\begin{matrix}LiCl\\ CdCl_2\end{matrix}}(l) \mid \underset{(+)}{C\text{-}Cl_2(g)} \quad [II]$$

The liquid junction between the two salt compartments was established (7, 8) through a coiled quartz tube filled with alumina powder. The transference numbers determined in the present studies were combined with the equivalent conductance data of Bloom *et al.* (9) to calculate the cation mobilities relative to the chloride ion in lithium chloride-cadmium chloride mixtures. The emf method has been previously used by several workers to determine the transference numbers of cations relative to the common anion in mixtures of molten chlorides (7, 8), fluorides (10), and nitrates (11).

Experimental Procedure

Reagent grade lithium chloride and cadmium chloride (Fisher Scientific Company) were purified by the standard treatment (1, 7, 8) with hydrogen chloride gas. The cell designs for cells [I] (1, 6) and [II] (7) have been described in detail elsewhere. For emf measurements on cell [I], lithium chloride was contained in a porcelain tube (McDaniel Refractory) made of mullite, SiO_2, and containing approximately 1% Li_2O. The porcelain tube was placed in a Vycor container (57 mm diameter) containing the lithium chloride-cadmium chloride mixture. The mole fraction of lithium chloride in the mixture was varied from 0.1 to 0.9 by addition of weighed amounts of purified lithium chloride. For emf measurements on cell [II], the porcelain tube was replaced by a Vycor tube connected to the outer Vycor container by a coiled quartz tubing filled with predried alumina powder (Grade T-61, 120 mesh, Aluminum Company of America). The liquid junction between lithium chloride and the lithium chloride-cadmium chloride mixture was established through the alumina powder in the coiled quartz tube. The powdered alumina was found ideal for these experiments since it not only prevented any gravitational flow from one side to the other but was also inert to any cation exchange that usually occurs (7) between the lithium chloride and quartz frit membranes.

Spectrochemical grade graphite rods (Ultra Carbon Company) were used as electrodes. Chlorine and hy-

drogen chloride gases (Matheson Company) were used directly from the cylinders. A wire-wound furnace was used to heat the cell assembly and the temperature was controlled at 650°C within ±2°C with a Honeywell Brown Pyrovane temperature controller.

Results and Discussion

The emf measurements on cells [I] and [II] were carried out at 650°C over the entire composition range of the LiCl-$CdCl_2$ mixtures. The emf values were extremely stable and reproducible within ±0.5 mV. The emf data, mean values of two separate experiments for both cells [I] and [II], are summarized in Table I.

The electrode reactions at the negative and positive electrodes in cell [I] are, respectively, given by

$$LiCl \rightarrow Li^+ + \tfrac{1}{2} Cl_2 + e^- \quad [1]$$

$$\tfrac{1}{2} Cl_2 + Li^+ + e^- \rightarrow LiCl(CdCl_2) \quad [2]$$

with the porcelain conducting only Li^+ ions from the left- to right-hand compartment. The over-all cell reaction for cell [I] is thus given by

$$LiCl(l) \rightarrow LiCl(CdCl_2)(l) \quad [3]$$

Thus, on passage of 1 faraday of electricity, 1 mole of lithium chloride is transported from the left-hand compartment of cell [I] to the right-hand compartment. The relative partial free energy of lithium chloride (G^M_{LiCl}) is, therefore, given by

$$G^M_{LiCl} = -\mathbf{F}E_{Cell} \quad [4]$$

where **F** is the Faraday constant. The relative partial free energy of lithium chloride (G^M_{LiCl}) was calculated by use of Eq. [4] and the data over the whole composition range of the mixtures are presented in Table II. The activities (a_{LiCl}) and partial excess free energies of lithium chloride (G^E_{LiCl}) in the mixtures were then determined by use of equations

$$G^M_{LiCl} = 2.303\, RT \log a_{LiCl} \quad [5]$$

$$G^E_{LiCl} = G^M_{LiCl} - 2.303\, RT \log x_{LiCl} \quad [6]$$

The activities (a_{LiCl}) and partial excess free energies of lithium chloride (G^E_{LiCl}), so obtained, are also summarized in Table II. A plot of G^E_{LiCl} *vs.* lithium chloride mole fraction is shown in Fig. 1.

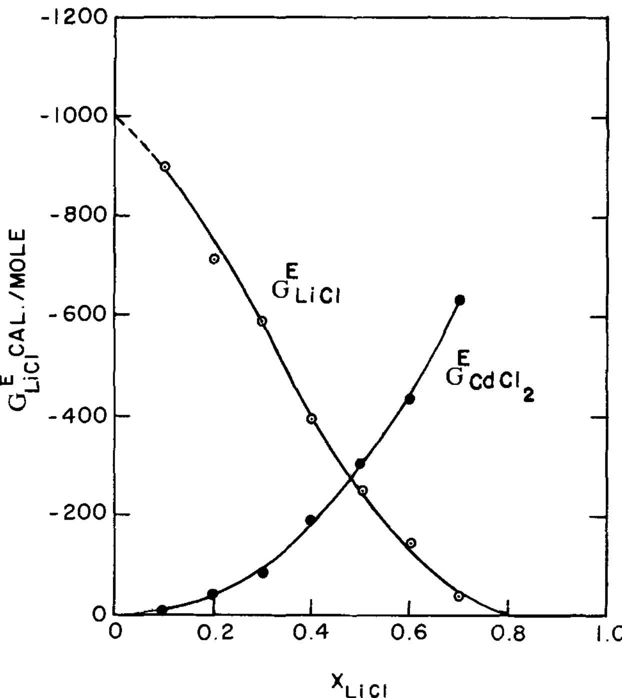

Fig. 1. Excess partial molar free energies of lithium chloride and cadmium chloride as a function of lithium chloride mole fraction in LiCl-$CdCl_2$ mixtures at 650°C.

The excess partial molar free energy of cadmium chloride in the mixtures was obtained by graphical integration of the Gibbs-Duhem equation

$$G^E_{CdCl_2} = \int_0^{x_{LiCl}} \frac{G^E_{LiCl}}{(1 - x_{LiCl})^2}\, dx_{LiCl} - \frac{x_{LiCl} G^E_{LiCl}}{1 - x_{LiCl}} \quad [7]$$

For the purpose of integration of Eq. [7], the limiting value of G^E_{LiCl} was obtained by extrapolating the G^E_{LiCl} *vs.* x_{LiCl} plot presented in Fig. 1 to zero mole fraction of lithium chloride.

The relative partial molar free energies ($G^M_{CdCl_2}$) and activities (a_{CdCl_2}) of cadmium chloride in the mixtures were then obtained by use of the relations

$$G^M_{CdCl_2} = 2.303\, RT \log a_{CdCl_2} \quad [8]$$

$$= 2.303\, RT \log x_{CdCl_2} + G^E_{CdCl_2}$$

These data are also summarized in Table II.

The excess integral molar free energy of mixing, g^E, in mixtures of lithium chloride-cadmium chloride was calculated from the excess thermodynamic quantities presented in Table II by use of the equation

$$g^E = x_{LiCl} G^E_{LiCl} + x_{CdCl_2} G^E_{CdCl_2} \quad [9]$$

The excess integral molar free energies (g^E) as a function of lithium chloride mole fraction are summarized in Table II.

From the data presented in Table II, it is seen that the mixtures of lithium chloride and cadmium chloride show a slight negative deviation from Raoult's law over most of the composition range.

In contrast to cell [I], the current in cell [II] is conducted by the cadmium and chloride ions as well as by the lithium ions. The emf of cell [II] is, therefore, given by (12)

$$E_{Cell} = -\frac{1}{F}\int_A^B t_{13} d\mu_{LiCl} - \frac{1}{2F}\int_A^B t_{23} d\mu_{CdCl_2} \quad [10]$$

where F is the Faraday constant and t_{13} and t_{23} are, respectively, the transference numbers of the lithium ion (cation 1) and cadmium ion (cation 2) relative to the chloride ion (anion 3); μ_{LiCl} and μ_{CdCl_2} are the chemical potentials of lithium chloride and cadmium chloride in the mixture, respectively. The derivation of Eq. [10] has been discussed in detail by Wagner (12). Now, making use of the Gibbs-Duhem equation

$$d\mu_{CdCl_2} = -\frac{x_{LiCl}}{1 - x_{LiCl}} d\mu_{LiCl} \quad [11]$$

and the following other relations

$$d\mu_{LiCl} = 2.303RT \log a_{LiCl} \quad [12]$$

$$t_{13} + t_{23} = 1 \quad [13]$$

$$x_{LiCl} = \frac{2x'_{LiCl}}{1 + x'_{LiCl}} \quad [14]$$

Equation [10] can be rewritten as

$$E_{Cell} = -\frac{2.303\,RT}{F}\int_A^B \frac{t_{13} - x'_{LiCl}}{1 - x'_{LiCl}} d \log a_{LiCl} \quad [15]$$

where x_{LiCl}, x'_{LiCl}, and a_{LiCl} are, respectively, the mole fraction, equivalent fraction, and activity of lithium chloride in the $LiCl$-$CdCl_2$ mixture. Partially differentiating Eq. [15] with respect to log a_{LiCl}, we have

$$\left(\frac{\partial E_{Cell}}{\partial \log a_{LiCl}}\right)_B = -\frac{2.303\,RT}{F}\left(\frac{t_{13} - x'_{LiCl}}{1 - x'_{LiCl}}\right)_B \quad [16]$$

Using the activity values of lithium chloride in the lithium chloride-cadmium chloride mixtures determined from emf measurements on cell [I], the term on the left side of Eq. [16] can be obtained by graphical differentiation of the E_{Cell} *vs.* log a_{LiCl} plot presented in Fig. 2.

The transference numbers of the lithium ion (t_{13}) and the cadmium ion (t_{23}) relative to the chloride ion are then determined by use of Eq. [16] and [13], respectively. The transference number data, so obtained, are summarized in Table III.

The mobilities of the lithium ion (b_{13}) and cadmium ion (b_{23}) relative to the chloride ion are related (7,13)

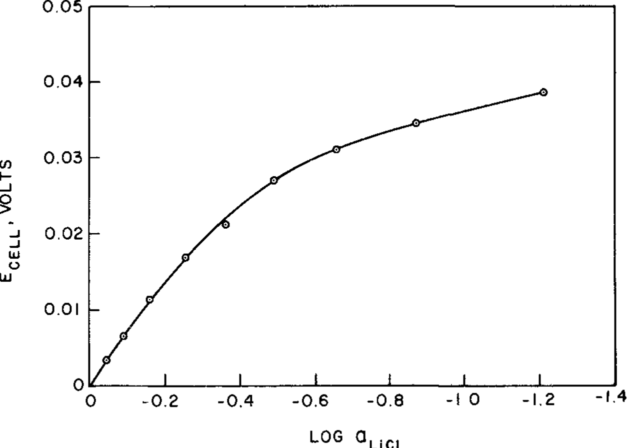

Fig. 2. E_{Cell} *vs.* log a_{LiCl} plot for the cell: $Cl_2(g)$-C | LiCl(l) || $\frac{LiCl}{CdCl_2}$ (l) | C-$Cl_2(g)$.

to the cation transference number (t_{13} and t_{23}) and equivalent conductance (λ) of the lithium chloride-cadmium chloride mixture by the equations

$$b_{13} = \frac{t_{13}\lambda}{x'_{LiCl}F} \quad [17]$$

and

$$b_{23} = \frac{t_{23}\lambda}{x'_{CdCl_2}F} \quad [18]$$

The equivalent conductance (λ) of lithium chloride-cadmium chloride mixtures at 650°C was obtained from the specific conductance and density data of Bloom *et al.* (9) and combined with the experimentally determined cation transference numbers (t_{13} and t_{23}) to obtain the cation mobilities relative to the chloride ion by use of Eq. [17] and [18]. These data are also summarized in Table III. The cation mobilities are also plotted in Fig. 3 as a function of the lithium chloride mole fraction. The alkali ion was found to have relatively larger mobility as compared to the cadmium ion over the whole composition range of the mixtures. This behavior is similar to the behavior in systems $LiCl$-$PbCl_2$ (7, 14), $LiCl$-$CeCl_3$ (8), $NaCl$-$CeCl_3$ (8), KCl-$PbCl_2$ (15), KCl-$CaCl_2$ (7), KCl-$MgCl_2$ (7), and KCl-$CeCl_3$ (8) where the alkali ion has been found to have a relatively larger mobility than the mobilities of the second cation in the mixture over most of the composition range.

Summary and Conclusions

Thermodynamic properties, cation transference numbers, and cationic mobilities in lithium chloride-cadmium chloride mixtures at 650°C were determined

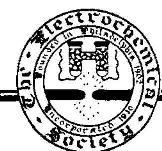
Technical Notes



Nitrogen Doping Behavior in GaP Using NH_3 as the Dopant Source

D. D. Roccasecca, R. H. Saul,* and O. G. Lorimor

Bell Laboratories, Murray Hill, New Jersey 07974

The publication costs of this article have been assisted by Bell Laboratories.

Efficient green luminescence in GaP arises from the decay of excitons bound to nitrogen atoms which occupy phosphorus sites (1). The most efficient green LED's have utilized liquid phase epitaxy (LPE) layers where ammonia was the source of nitrogen (2-5). Using this approach, efficiencies as high as 0.33% have been achieved for encapsulated 15 × 15 mil die operated at 10 mA (6). Nitrogen incorporation as a function of ammonia partial pressure p_{NH_3} (in a ~1 atm H_2 carrier) has been reported by several workers (2, 7) for doping levels in the 10^{18} atoms/cm³ range[1] where the highest efficiencies are obtained. Basically, it has been found that the N concentration increases linearly with p_{NH_3} until $p_{NH_3} \simeq 10^{-3}$ atm, at which time the N concentration reaches a constant value. The morphology of the LPE becomes disturbed at this and higher values of p_{NH_3}. The initial linear behavior is consistent with the isoelectronic behavior of N in GaP while the limiting value corresponds to the p_{NH_3} over liquid Ga in

* Electrochemical Society Active Member.
Key words: light emitting diodes, liquid phase epitaxy, impurity incorporation.

[1] The nitrogen concentrations have been corrected in accordance with the recent work of Lightowlers *et al.* (8).

equilibrium with solid GaN, $p^*_{NH_3}$ (9). Using a model due to Phillips and Van Vechten (10), Stringfellow (11) has computed the temperature dependence of N and the corresponding limiting values of $p^*_{NH_3}$. These calculations and those of Thurmond and Logan (9) assume that NH_3 does not dissociate under the high temperature conditions of LPE. In the experimental phase of the latter work, this condition could be met provided a new quartz furnace tube and a low oxygen (and water vapor) ambient was used.

Although NH_3 is thermodynamically unstable at elevated temperatures, catalysts [*e.g.*, Pt and W (12)] are generally required to promote NH_3 decomposition, which can be described by the following equation

$$NH_3 \rightarrow (1-x)NH_3 + \frac{1}{2}X\,N_2 + \frac{3}{2}X\,H_2 \quad [1]$$

where x is the mole fraction of consumed NH_3. This reaction has been studied by Ban (13) using a time-of-flight mass spectrometer. His results, using an H_2 carrier gas, indicate that over the temperature range 700°-950°C, $x \leq 0.03$ for quartz and graphite catalysts. The relatively high NH_3 stability under these conditions suggests that both quartz and graphite are suitable structural materials for growth reactors which utilize NH_3. However, during the course of developing a multislice LPE system for GaP green LED's (5), we observed, as shown in Fig. 1, that the incorporated N level was substantially lower than previously reported (2, 7). Moreover, for this system which utilized a quartz reactor and graphite boat, the incorporated N level was found to be sublinear with the inlet NH_3 pressure for low flow rates (50 cm^3/min). (All flow rates are the room temperature flow rates.) Further, for a given p_{NH_3}, the incorporated N level increased with the total gas flow rate. These results suggested that N incorporation was kinetically controlled, perhaps as a result of NH_3 decomposition. The work described here was undertaken to determine the extent of NH_3 decomposition for typical LPE conditions which are appropriate for green LED's and to study the (catalytic) effect of graphite and quartz on NH_3 stability. While the quantitative results are specific to the operation of our LPE system (5), the results are thought to be generally applicable to other systems (including vapor epitaxy systems) which utilize NH_3 and the same construction materials, *viz.*, quartz and graphite.

Returning to Fig. 1, we note that if NH_3 decomposition were significant, the value of p_{NH_3} over the growth solution could be substantially lower than the values deduced from the relative inlet NH_3 and H_2 flow rates. The actual values of p_{NH_3} were therefore determined by titrating the exit gas with a solution of known pH (9). Since these values were time invariant, the outlet pressure should nearly equal the NH_3 pressure over the melt. At room temperature, where NH_3 is stable, the inlet and outlet pressures were determined to be equal by the titration method and agreed within 10% of the value calculated from the inlet flow rates. At typical LPE temperatures (~1000°C) however, the outlet pressure was generally found to be lower than the inlet pressure. This behavior is illustrated in Fig. 2, where it is shown that for a total flow rate of 50 cm^3/min (the volume of the reactor tube is ~5 liters with a diameter of 7 cm at the location of the graphite boat), the ratio of outlet to inlet values of p_{NH_3} decreases monotonically with increasing inlet p_{NH_3}; that is, the higher the inlet p_{NH_3} for a given flow rate, the greater the amount of NH_3 consumed within the reactor. Note also that when He is substituted for H_2 as the carrier gas, the NH_3 consumption is substantially increased. This result is qualitatively consistent with the decomposition reaction given by Eq. [1]. Using the curve in Fig. 2, one can approximate the outlet p_{NH_3} values corresponding to the data in Fig. 1. The corrected values given by the crosses in Fig. 1, lie reasonably well on a linear extrapolation of published data for higher doping levels. This agreement clearly demonstrates that the actual p_{NH_3} in the system controlling the incorporation is more accurately measured at the outlet rather than at the inlet due to NH_3 decomposition. As one might infer from Fig. 1, for higher flow rates (shorter residence time) NH_3 stability is enhanced, which is borne out by the increased outlet p_{NH_3} values for a given inlet p_{NH_3}.

The results of Ban (13) and of Thurmond and Logan (9) indicate that for graphite-quartz systems, negligible NH_3 decomposition occurs, although the latter suggest that under certain conditions quartz can behave as a catalyst. To identify the structural material catalyzing or reacting with NH_3, measurements were made at room temperature and at 1026°C, with and without the graphite boat, using a high p_{NH_3} value (3×10^{-3} atm) to provide a worst case situation. The

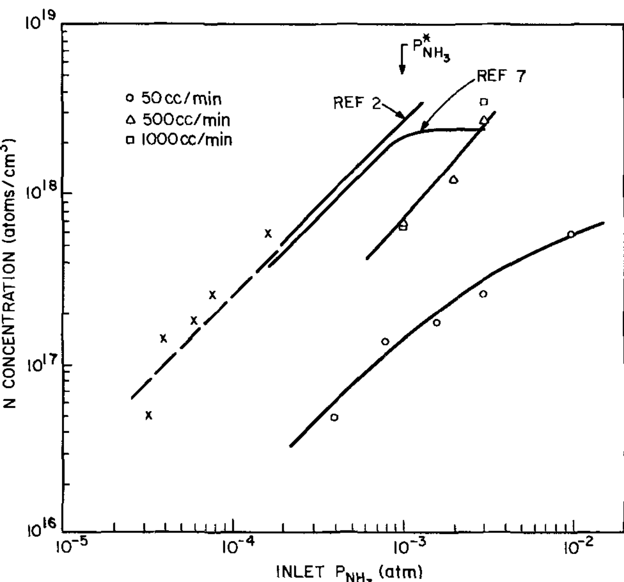


Fig. 1. Incorporated nitrogen concentration for crystals grown from an initial temperature of 1015°C as a function of inlet NH_3 partial pressure. The crosses are corrected values as discussed in the text.

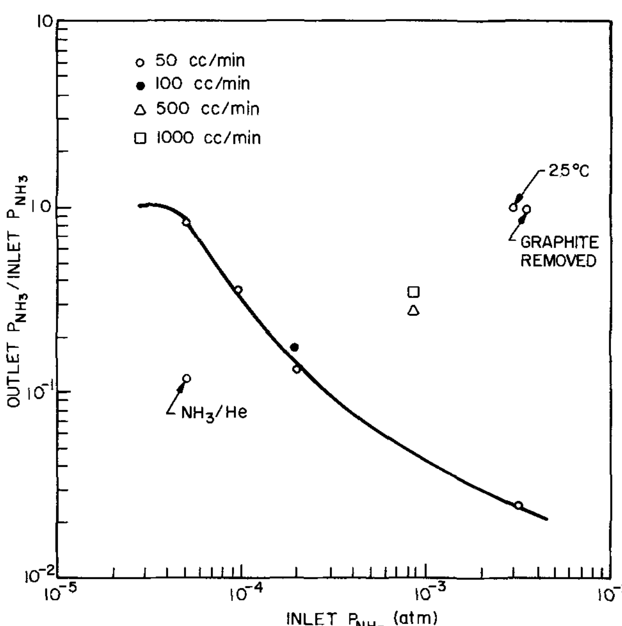

Fig. 2. The variation of the ratio of effluent to inlet values of NH_3 partial pressure at ~1000°C for various conditions. The values refer to typical LPE conditions except where indicated (see text).

results shown in Fig. 2 clearly show that the graphite boat and not the quartz reactor is causing the NH_3 consumption. Additionally, we find that the type and surface area of the graphite effects NH_3 stability, although this was not extensively studied. From a practical standpoint, *viz.*, the growth of N-doped LPE material, we believe that the influence of graphite on the stability of NH_3 is a general effect whose magnitude will depend upon the specific system geometry. However, as shown in Fig. 1, the use of high flow rates (500-1000 cm^3/min) makes it possible to controllably achieve high N levels, appropriate for green LED's under conditions approaching those where NH_3 is stable.

During the latter stages of this work, gas chromatography was used to identify and monitor some of the major gas species present in the reactor at various temperatures and under actual LPE conditions. A GOW-MAC gas chromatograph, Model 69-570, was used. This unit permits continuous flow of the reactor effluent gas through a sampling coil, with a bypass to flush the sample gas into the appropriate column. The purest available grade of He was used as the carrier gas. Three columns were employed in this work. A 5A Molecular Sieve (¼ in. OD × 4 ft) column was used to detect O_2 and N_2 with detection limits of 10 and 0.5 ppm, respectively. The high detection limit for O_2 results from H_2 interference (the major constituent of the effluent gas). However, this could be lowered to ~0.1 ppm by using a He ambient within the reactor. A Porapak "Q" (¼ in. OD × 4 ft) column was used for detecting CH_4 with a detection limit of 0.5 ppm and a Chromasorb 103 (¼ in. OD × 3 ft) column was used for NH_3 detection to ~3 ppm. All columns were maintained at room temperature except the latter which was maintained at 70°C. Since the sensitivity improves with decreasing detector (thermistor bridge) temperatures, the chromatograph was modified so that the Chromasorb column was thermally isolated from the detector, thus permitting the column to be operated at elevated temperatures while maintaining the detector at room temperature.

Gas calibration was accomplished with an exponential dilution flask (EDF) (14), using He as the carrier. Each gas at 100% concentration was injected into the EDF with a syringe, and the detector cell output was measured at known time intervals. The peak and integrated output signals, c_o, corresponding to the initially injected and thus known gas concentration was determined from the following equation

$$c = c_o \exp - ft/v \qquad [2]$$

where c is the detector output (proportional to the gas concentration) at time t, f is the flow rate through the EDF, and v is the EDF volume. Generally, the value of c_o was chosen to be in the range where measurements were to be made. Finally, the delay time (after injection into the appropriate column) for detecting the output signal serves as a signature for the specific gas involved.

Since oxygen is deleterious to the efficiency of GaP green LED's and, as suggested previously (9), may contribute to NH_3 dissociation, the reactor effluent at room temperature was analyzed for O_2 and N_2 using a He ambient for increased sensitivity. As indicated elsewhere (5), the loading end of the reactor is enclosed in an N_2 filled enclosure to minimize entrance of air into the reactor. This was just one of many precautions to minimize O_2 contamination. The present results indicate that such enclosures are quite effective. For example, 50 min after loading and using a reactor flow rate of ~500 cm^3/min, the O_2 level in the exit gas was reduced to 6 ppm compared to 55 ppm for N_2; after 150 min, these values dropped to <2 and 34 ppm, respectively. After overnight flushing these values fell to ~1 and ~5 ppm and correspond to a background level of air resulting from leaks in the extensive gas panel used for vapor doping the LPE layers (5).

Table I. Concentration of N_2 and CH_4 in reactor exit gas for various reactor temperatures using a flow rate of 500 cm^3/min

	Concentration (ppm)				
	25°C	700°C	850°C	925°C	1015°C
N_2	5-10	14	16	32	50 (230)*
CH_4	<0.5	<0.5	2	22	200 (2000)*

* Parentheses denote 50 cm^3/min flow rate.

For a 500 cm^3/min flow rate, p_{NH_3} (inlet) $\simeq 10^{-3}$ atm, and a H_2 carrier gas, the determined CH_4 and N_2 concentrations for various temperatures are given in Table I. The conditions at 1015°C are those which correspond to actual LPE conditions for green LED's. First, these results indicate that substantial levels of CH_4 are generated within the reactor at elevated temperatures; additional experiments deleting NH_3 from the gas stream show that most of this results from the direct reaction of graphite with the H_2 carrier. Decreasing the flow rate to 50 cm^3/min, increases the CH_4 level to ~2000 ppm at 1015°C. The presence of such high levels of CH_4 may affect the gaseous reactions in vapor epitaxy systems but does not appear to be of consequence for LPE. These results also show that the N_2 level increases monotonically with reactor temperature, reaching ~50 ppm at 1015°C. This increasing decomposition of NH_3 with increasing temperature has the effect of displacing the curve in Fig. 2 downward with increasing temperature. Decreasing the flow rate to 50 cm^3/min, increases the N_2 level to ~230 ppm, with a corresponding decrease in the effluent p_{NH_3} value. As expected, when one deletes the NH_3 or the graphite boat, the initial (25°C) N_2 value for all reactor temperatures is measured. Using the measured N_2 levels, the corresponding concentrations of consumed NH_3 according to Eq. [1] are twice the N_2 values. The values deduced from the titration and chromatographic measurements of p_{NH_3} indicate that at least half of the consumed NH_3 is decomposed into its elemental constituents.

The NH_3 dissociation behavior described above essentially relates to the doping of the growth solution. We find that under identical growth and doping conditions, the incorporated N concentration also depends on substrate orientation. The results shown in Fig. 1 are for {111}P (or B-face) oriented substrates. The N concentration for {100} and {111}Ga (or A-face) oriented crystals are respectively 50 and 75% lower than for {111}P crystals grown simultaneously in the same melt. Orientation dependence of the distribution coefficient has been explained in terms of surface band bending (15); however, it is not clear how this model is applicable to isoelectronic impurities such as N. We note that the present results are consistent with the "available site" model (16), wherein impurities which substitute on a Group V site (P site for N) are incorporated more readily on the corresponding Group V face. Further work is needed to fully understand these effects; however, it is clear that the higher N concentration for the {111}P orientation is desirable for efficient green LED's.

In conclusion, we find that contrary to previous work (9, 13), NH_3 can rapidly dissociate at elevated temperatures in the presence of graphite. The decomposition is undesirable not only for N incorporation in GaP but also, for example, halogen transport methods for growing GaN, InN, etc. In experimental systems where the mass of graphite is small, this problem will not be serious. However, for large capacity, commercial-type systems, such as the one studied in this work, as much as 95% of the available NH_3 can be decomposed. (We note that in Ban's reactor, the surface area of the graphite liner was 25 cm^2, while the LPE boat we use has an area of ~400 cm^2.) Consequently, for

systems where graphite is the only practical structural material, values of flow rate, inlet p_{NH_3}, etc., must be found to give the desired p_{NH_3} values appropriate to the reaction zone. In our case, monitoring the NH_3 concentration in the effluent gas, determined by either titration or chromatography, was extremely useful for establishing optimum doping conditions. We note that reduction of the effective surface area of graphite components, *e.g.*, by applying pyrolytic coatings, is a means of minimizing catalytic NH_3 decomposition; this was not found necessary, however, for reproducibly achieving high efficiency LED's. Finally, preliminary data on the orientation dependence of N incorporation suggests that the {111}P orientation is preferable for efficient LED's.

Vapor-Phase Epitaxial Growth of CdSe on Sapphire and CdS

W. M. Yim* and E. J. Stofko

RCA Laboratories, Princeton, New Jersey 08540

The publication costs of this article have been assisted by the RCA Corporation.

Epitaxial growth of CdSe on sapphire has been reported previously by using an organometallic CVD process (1) and also, very recently, by using a vacuum evaporation technique (2). In general, CVD methods are often preferable since they provide a greater degree of flexibility and control as one could adjust the input vapor concentrations to achieve precise stoichiometry. In a previous work (3) we demonstrated the single-crystal epitaxy of ZnSe and CdS on sapphire by reaction of the Group II metal vapors with the Group VI hydride gases in an open-flow system. We have now extended this technique to the preparation of CdSe.

We report in this paper the epitaxial growth of high purity, single-crystal CdSe on sapphire, as well as on CdS, by using the hydride CVD technique. Also included are some electrical data obtained on the epitaxial layers.

The CVD apparatus is similar to that previously used for epitaxial growth of other II-VI compounds (3), but with one important modification to be described shortly. The cadmium was transported as vapor by passing 100 cm^3/min H_2 over molten Cd at ~500°C; the selenium was introduced from a separate inlet as gaseous hydride, 20 cm^3/min H_2Se; and an additional 500 cm^3/min H_2 was used as carrier gas. The cadmium and H_2Se vapors were carried downstream and reacted to form CdSe on a substrate at ~700°C.

Two substrate materials were used almost exclusively; these were single-crystal wafers of sapphire with (0001) orientation and CdS single-crystal wafers of both (0001) and $(000\bar{1})$ orientations. The sapphire substrates, ~10 mil thick and ~1 cm^2 in surface area, were supplied with a mirror-smooth finish by Insaco (Quakertown, Pennsylvania), and were used with no further surface polishing prior to the epitaxial growth. The CdS substrates (~20 mil thick and ~1 cm^2) were cut from melt-grown boules obtained from Eagle-Picher (Miami, Oklahoma), and were chemically polished with a 30% HCl solution in water

In order to achieve epitaxy consistently and reproducibly, we found it important to preheat all substrates in ~100 cm^3/min H_2 for several minutes until the temperature reached to about 600°C before inserting them in the deposition zone.[1] Perhaps more important, we found it necessary to separate the cadmium and H_2Se vapors until they meet and react very near the substrate. This was accomplished by extending the Cd vapor inlet tube to a location as close as 1 cm from the substrate, while keeping the H_2Se inlet tube at about 10 cm upstream from the Cd inlet. Without separating the reactant gases and placing one of the gas inlets in close proximity of the substrate, many whiskers and platelets were found to form inside the CVD apparatus ahead of the deposition zone. When this occurred, the deposited layers on various substrates, particularly on sapphire, were nearly always polycrystalline.

With the above growth conditions, we have obtained relatively high deposition rates: the average value is 3 μ/min on sapphire, 2 μ/min on $(000\bar{1})$ CdS, and 1 μ/min on (0001) CdS. Emission spectrographic analysis showed the deposited layers to be high purity with the major metallic impurities of <1 ppm Cu, 3 ppm Si, and 3 ppm Mg.

Typical microstructure of as-grown epitaxial layers on sapphire is shown in Fig. 1(a). The hexagonal growth features shown here, as well as in Fig. 2(a) and Fig. 2(b) for CdSe on (0001) and $(000\bar{1})$ CdS substrates, respectively, are characteristic of epitaxy of a wurt-

* Electrochemical Society Active Member.

Key words: chemical vapor deposition, heteroepitaxy, CdSe, resistivity, photosensitivity.

[1] While detailed examinations are lacking, there appeared no deleterious thermal etching of the substrates after the preheating.

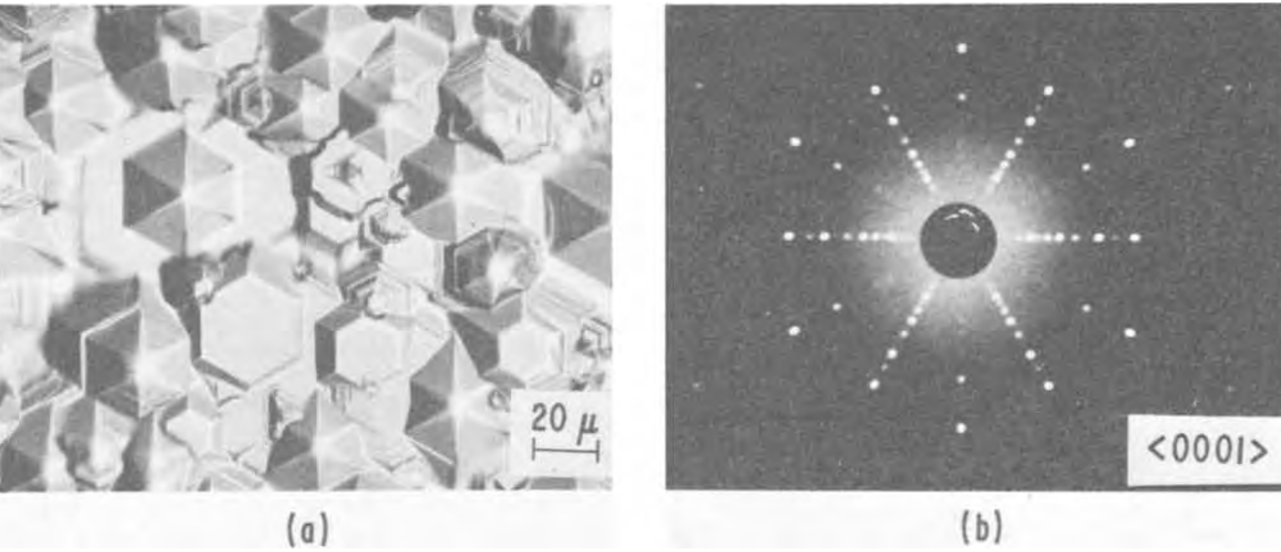

Fig. 1. As-deposited CdSe epitaxial layer on (0001) sapphire: (a) microstructure, (b) x-ray Laue pattern. The <0001> axis of CdSe is perpendicular to the plane of the paper.

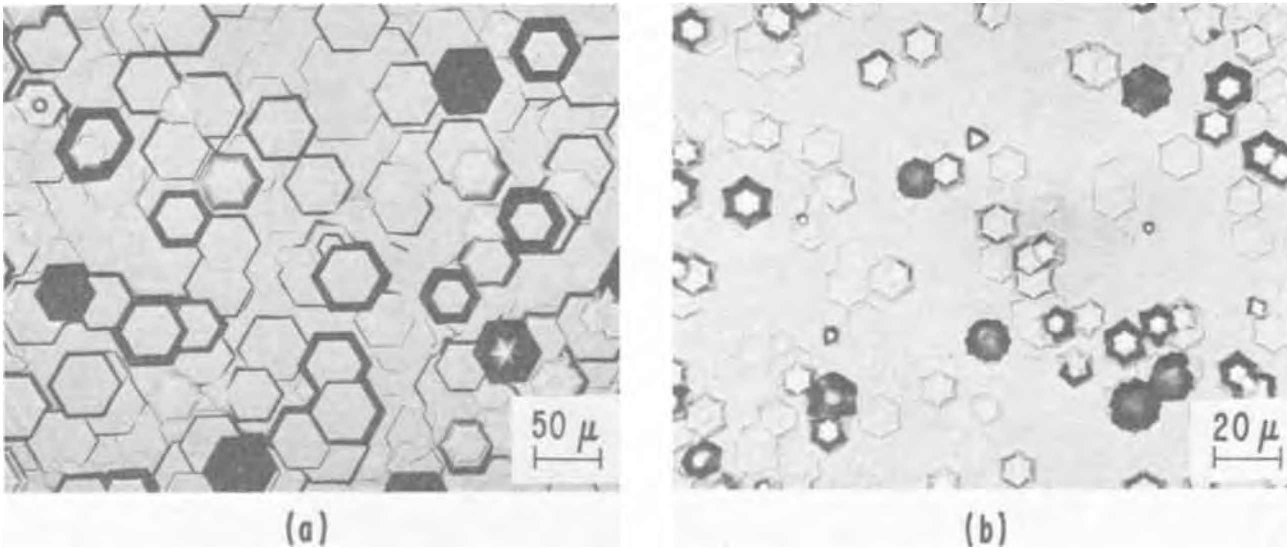

Fig. 2. Microstructure of as-deposited CdSe epitaxial layer on (a) (0001) CdS and (b) (000$\bar{1}$) CdS. The x-ray Laue patterns for these CdSe layers are very similar to that shown in Fig. 1(b).

zite structure material grown with the c-axis perpendicular to the surface. The x-ray Laue pattern of Fig. 1(b) proves this, and that the well-resolved sharp diffraction spots indicate a high degree of single crystallinity. In the present work only the hexagonal structure was observed for CdSe deposited in the substrate temperature range investigated of 550°-750°C, although the cubic form is known and is frequently obtained, mixed with the hexagonal form, in vacuum-evaporated CdSe on various substrates heated up to about 400°C (4).

All the epitaxial CdSe layers grown without intentional doping showed high resistivity[2] and photosensitivity. Dark resistivity values measured at room temperature for the undoped CdSe were between 5×10^6 and 1×10^7 ohm · cm and, with As doping by introducing a small flow of AsH_3 during epitaxial growth, a resistivity value as high as 1.2×10^9 ohm · cm was obtained. Because of the high resistivity we were unable to determine the free carrier concentration by conventional Hall-effect measurements. However, assuming a Hall mobility of 65-650 cm²/V-sec, the latter being a value reported for melt-grown CdSe crystals (5), we arrive at a free carrier concentration of 10^9-10^{10}/cm³ for the 10^7 ohm · cm material at room temperature. The CdSe can easily be made more conductive, if desired, either by increasing the Cd vapor flow or by decreasing the H_2Se flow; for instance, by using 2.5 cm³/min H_2Se which is only a tenth of the flow rate described above, we obtained CdSe of $\sim 10^2$ ohm · cm.

[2] All were n-type, doped or undoped, consistent with the well-known difficulty of obtaining p-type CdSe.

The ratio of two resistance values (one measured in the dark and the other obtained by illuminating the same specimen with a microscope lamp), which was taken arbitrarily as a measure of the photosensitivity, was 3000 for the 10^7 ohm · cm material. This single-crystal layer had a low electron trap density at room temperature of $\leq 10^{14}$/cm³, as measured with the "dark current doubling" method of Rose (6). By contrast, a vacuum-deposited polycrystalline CdSe film (4) with a dark resistivity and a resistance ratio similar to that of the 10^7 ohm · cm layer mentioned above, had one order of magnitude larger trap density of 1.4×10^{15}/cm³. It might well be that the lower trap density is related to improved crystallinity of the epitaxial layer.

Acknowledgments

We are grateful to Dr. H. Kiess of RCA, Zurich for making the trap density measurements, and to Dr. A. Rose for valuable discussions.

Trimethylstibine as a Source of Sb for Doping Epitaxial Si Layers

H. M. Manasevit,* W. I. Simpson, and F. M. Erdmann

Rockwell International, Electronics Research Division, Anaheim, California 92803

The publication costs of this article have been assisted by Rockwell International.

A suitable source of Sb has not been developed for doping epitaxial Si layers even though Sb would be preferable to As or P because of its lower diffusivity. Stibine (SbH_3) might be a possible source of Sb, but its instability at ambient temperatures could offer problems in dopant control.

Previously trimethylstibine (TMSb) had been successfully used in our laboratories as a source of Sb in forming alloys of $GaAs_{1-x}Sb_x$ (1), and Gittler and Porter (2) have prepared Sb-doped SiO_2 from a mixture of TMSb, SiH_4, and O_2. It was of interest to determine if TMSb could also be used to introduce Sb into a growing layer of Si at the relatively high growth temperature.

The apparatus used in these studies is shown schematically in Fig. 1. The TMSb (bp = 80.6°C) was kept in a stainless steel reservoir with the tip of the inlet tube above the surface of the liquid. The Si source was SiH_4 in a carrier gas of Pd-purified H_2 (total flow = 6 liters/min). Chemically polished (111) p-type Si and mechanically polished $(10\bar{1}4)$- and $(01\bar{1}2)$-oriented Al_2O_3 were used as substrates. The latter Al_2O_3 orientation leads to (100)Si overgrowth; the former to (111)Si overgrowth (3). A 15-min H_2 etch of the substrates at ~1250°C preceded Si deposition. The films on Si substrates were nominally 10 and 25 μm thick and grown at 1050°C at a rate of ~0.6 μm/min; those on Al_2O_3, 1.5-1.85 μm thick, and grown at ~1075°C at about the same rate.

Only resistivity (4-point probe) measurements were made on the as-grown Sb-doped films on Si substrates, while Hall-effect measurements were made on the Si-on-sapphire (SOS) films after their properties were stabilized by annealing in dry O_2 at 1100°C for 1 hr.

The initial depositions were performed with the TMSb maintained at −45°C by means of a chlorobenzene slush; but it was found that the TMSb vapor would require excessive dilution in order to produce films with doping levels in the 10^{16}-10^{18} cm^{-3} range. The TMSb vapor pressure was, therefore, reduced by

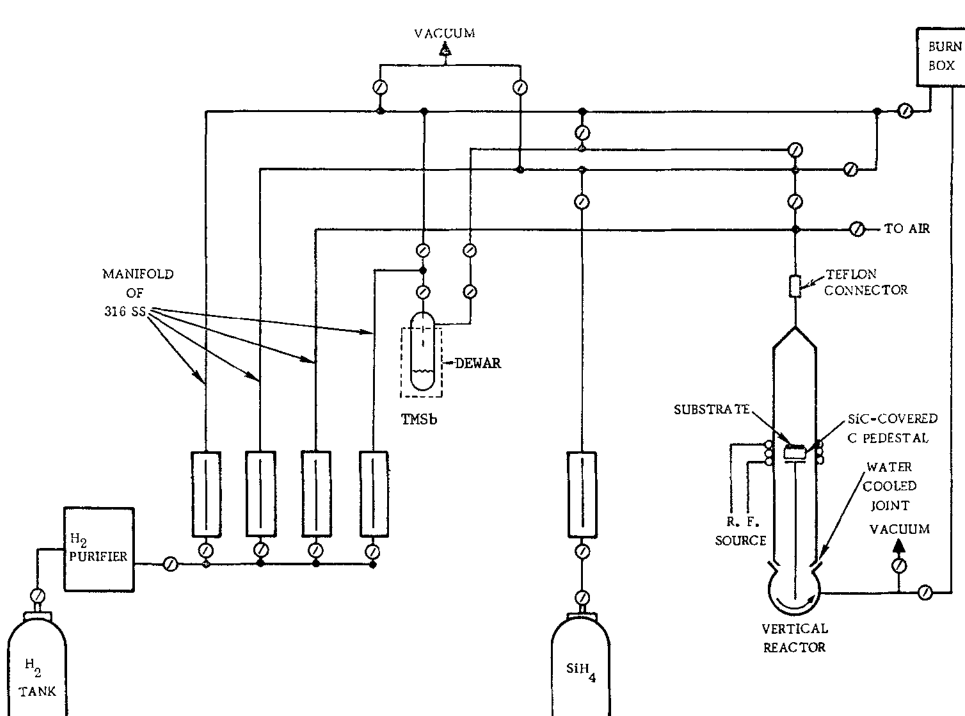

Fig. 1. Schematic diagram of chemical vapor deposition apparatus.

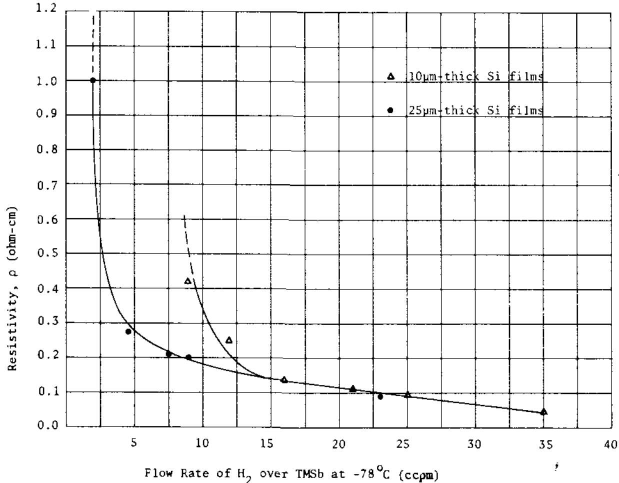

Fig. 2. Resistivity of Si homoepitaxial films vs. flow rate of H_2 over TMSb at $-78°C$.

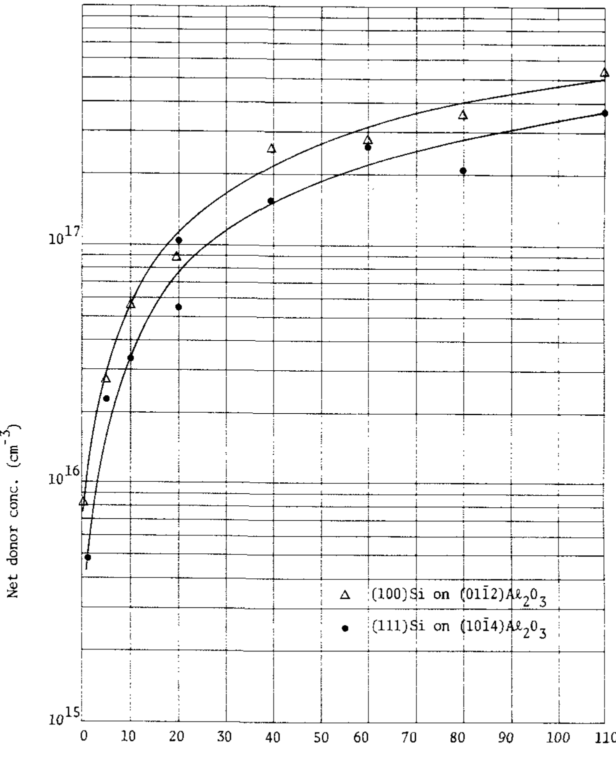

Fig. 3. Net donor concentration in Si-on-Al_2O_3 films vs. flow rate of H_2 over TMSb at $-78°C$.

using a dry ice-acetone slush to lower the TMSb bath temperature to $-78°C$. The results of these preliminary studies are recorded in Fig. 2 and 3, in which the electrical properties of the films are plotted *vs.* the flow rate of H_2 over TMSb at $-78°C$.

Figure 2 depicts the resistivity data obtained for the homoepitaxial growth of relatively thick Sb-doped Si films on (111)Si. At resistivities less than about 0.15 ohm-cm, *i.e.*, for carrier concentrations greater than 5×10^{16} cm^{-3} (4), the resistivity *vs.* flow rate curves for the 10 and the 25 μm thick films are in good agreement, but at higher resistivities the curves do not coincide. This deviation, which occurs at flow rates less than about 15 ccpm, is not believed to indicate that there is a systematic dependence of resistivity on thickness or a limitation on the use of TMSb as a source for low concentrations of Sb. It was probably the result of the very limited number of experiments made during this preliminary study and inefficient equilibration of the relatively low H_2-TMSb flows with the SiH_4 and much higher H_2 flows before these components were introduced into the reactor.

Figure 3 shows that TMSb is an effective source of Sb dopant for both (111)Si and (100)Si thin films grown on Al_2O_3. It is also of interest that the donor concentrations in (100)Si films grown on $(01\bar{1}2)Al_2O_3$ tend to be consistently higher than in (111)Si films grown simultaneously on $(10\bar{1}4)Al_2O_3$.

The plots in Fig. 2 and 3 do indicate that the higher H_2 flow rates and, therefore, increased concentrations of TMSb produce decreases in resistivity and increases in donor concentration in Si epitaxial films, as expected.

In summary, these preliminary studies have demonstrated the feasibility of using TMSb as a source of Sb for doping epitaxial Si layers. Further studies are required in order to (*i*) learn how to control the doping better, (*ii*) establish the doping limits possible using TMSb, and (*iii*) determine if carbon is a contaminant. A preferable process for producing homogeneously doped layers would involve the use of prepared cylinders of carrier gases containing controlled amounts of TMSb.

Acknowledgments

The authors wish to acknowledge the assistance of J. P. Wendt in carrying out many of the electrical measurements, and Drs. R. P. Ruth and A. C. Thorsen in reviewing the manuscript.

Relationship Between Process-Induced Defects and Soft P-N Junctions in Silicon Devices

L. E. Katz

Bell Laboratories, Allentown, Pennsylvania 18103

The publication costs of this article have been assisted by Bell Laboratories.

Soft reverse-breakdown characteristics in Si devices have been a recurring problem for the semiconductor industry. Extensive literature (1-8) has been published concerning causes and mechanisms for soft junctions. The undesired electrical characteristics have been attributed to both defects and impurities. Precipitates, dislocations, stacking faults, and other unspecified defects have been proposed as culprits.

The aim of this study was to make a large number of diodes and transistors by using a simple processing scheme and then to investigate the correlation between degraded electrical characteristics and any defects revealed by etching.

Experimental Procedure

Polished (100)-oriented, Czochralski low-dislocation wafers, P-doped with 0.7-1.2 ohm-cm resistivity, were obtained from various suppliers. A ring-dot type structure was used for the devices. The base and emitter windows were respectively 125 and 75 μm in diameter. Approximately 3000 devices were made on each wafer. The processing steps are listed in Table I.

Electrical evaluation was accomplished by measuring the collector-base and collector-emitter reverse breakdown voltages, BV_{CB} and BV_{CEO}, on a curve tracer, generally at 10 μA, although on occasion 1 or 5 μA were used. Defects were revealed by Sirtl etching (9) for short times (20 to 120 sec).

Defects Produced by Oxidation and Reoxidation

Several groups of wafers were processed through the procedure outlined in Table I. Following base reoxidation, the diodes were evaluated by measuring BV_{CB}. Depending on several variables, the most important being the ambient during the high temperature operations, yields for various wafers ranged from about 50 to more than 90%. A BV_{CB} value of ~60V was expected based on the resistivity and procedure employed, and any value substantially below this was

Key words: defects, silicon, soft junctions.

considered to represent a loss in yield, as was a "rounded knee" in the *I-V* curve. Upon processing through the emitter cycle, a further reduction in yield was usually observed.

Since in some cases reduced yields were measured after base reoxidation, a number of wafers processed to this point were etched to determine if defects were present that could be responsible for the leakage. Two types of defects were revealed by etching, as shown in Fig. 1. One type (Fig. 1a), which is bow-shaped, has been identified by transmission electron microscopy (TEM) as an extrinsic stacking fault bounded by Frank partial dislocations. Other authors have made similar determinations (10). The depth of the stacking fault is thought to be ~1/5 to 1/10 of its length (11), indicating a depth of ~1 to 2 μm for the stacking fault present following reoxidation. Such defects are fairly common in (100) steam-oxidized Si wafers containing nonhomogeneities. The other defect (Fig. 1b), which is kite-shaped upon etching, is observed only within diode regions. Preliminary TEM analysis (12) shows the defect to be a rod-shaped precipitate extending into the Si.[1] The densities of both defects vary widely, but observations of many samples give a general density of stacking faults in the mid-10^4 to mid-10^5/cm^2 range averaged over the regions between diodes. The stacking faults are generally observed outside the diode regions, but apparent traces of stacking faults are

[1] The defect will be referred to as a rod in this paper.

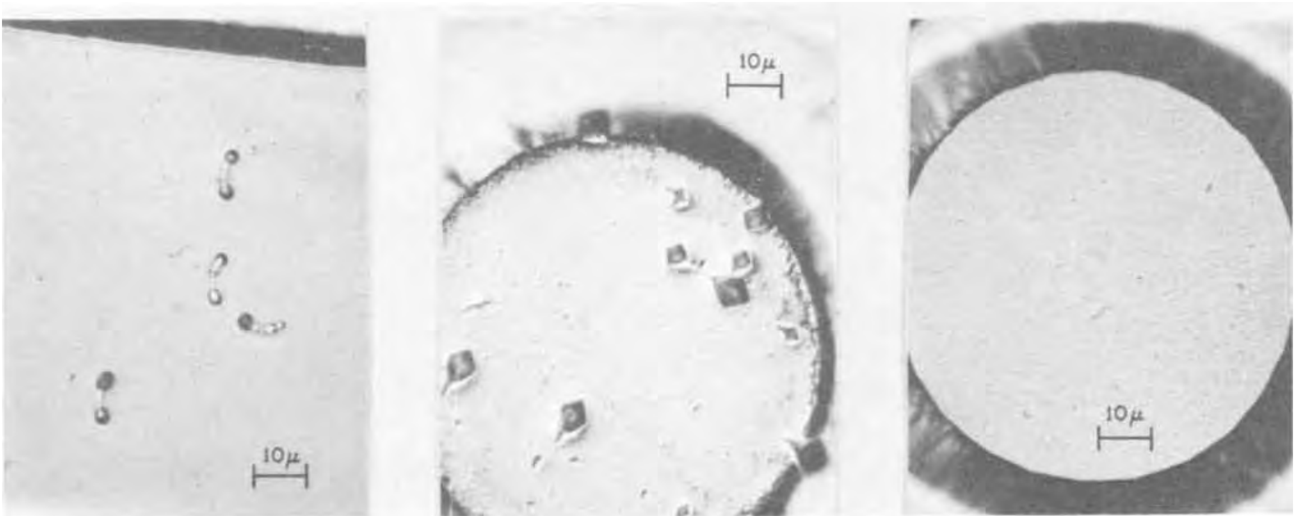

Fig. 1. Etching defects following base reoxidation: (a, left) region between diodes; (b, center) degraded reverse characteristic, and (c, right) good reverse characteristics.

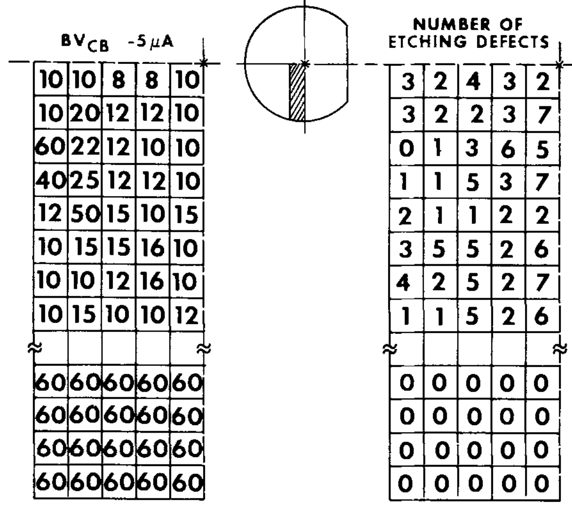

Fig. 2. Correlation between electrical characteristics (BV_{CB} at 5 μA) and rod defects after base reoxidation.

sometimes present within the diode regions. The rod defect has a density of $\sim 2 \times 10^5/cm^2$ averaged over the diode regions, a value comparable to the stacking fault density. It is noted that many diodes are free of these defects (Fig. 1c). They appear to form most frequently in areas of the wafers that have stacking faults between the diodes.

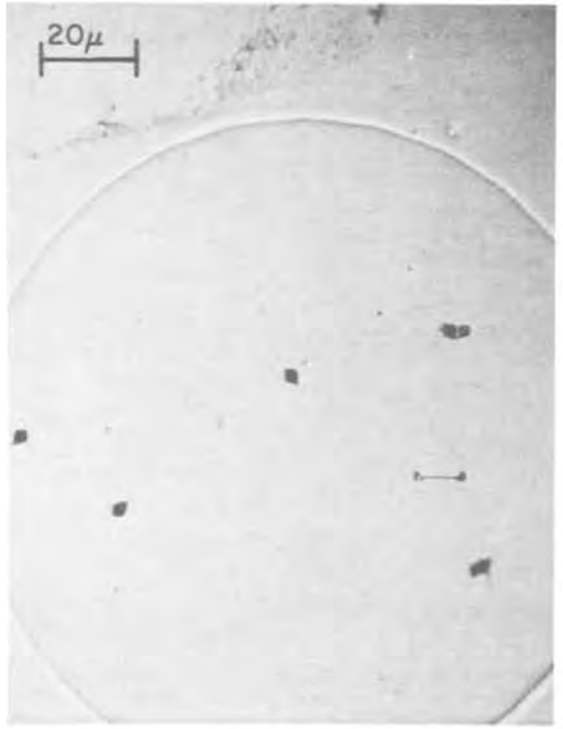
The stacking faults revealed by etching are oriented in the <110> directions. This is characteristic of stacking faults in Si, since they form on (111) planes which intersect with a (100) surface in the <110> directions.

Since defects were detected after the base reoxidation step, wafers were etched sequentially following each of the previous high temperature operations to determine the step at which defects are introduced. Stacking faults were observed in wafers which had been subjected to the initial oxidation and remained the only defects revealed by etching after boron predeposition and drive-in. It was only after the base reoxidation step that rods were observed. It was found that the formation of these defects during reoxidation could generally be avoided by using a highly oxidizing ambient at the drive-in stage.

The etching experiments suggested that the rods might be responsible for the observed degradation of the base-collector characteristics. Two studies were carried out to determine whether this was the case. The first of these studies was based on the correlation that previous authors have established between light emission from microplasmas and electrical breakdown (13, 14). Diodes (on several wafers) that exhibited poor breakdown characteristics following the base reoxidation step were biased to a voltage where light emission could be observed. The light levels were generally low. Photographs were taken of light emission patterns, the diodes were then Sirtl etched, and the etch patterns were photographed. Comparison of many light emission photographs with the corresponding etching photographs showed that every light emission spot corresponded to a rod defect, indicating that the defects are responsible for breakdown. Every etch defect could not be correlated with a light spot, but this is probably a consequence of the difficulty in observing and photographing the light spots.

Direct evidence that the rod defects are responsible for degrading the collector-base reverse characteristics is provided by the second study, in which a large number of diodes on one wafer were first probed electrically and then etched to reveal the defects present. The results are shown in Fig. 2. For each of the diodes, the left side of the figure gives the value of BV_{CB} measured at 5 μA, and the right side gives the number of defects observed after etching. The figure also includes a sketch of the wafer, on which the area where data were taken is indicated by cross-hatching. It is seen that the maximum voltage, 60V, was obtained for every diode that was free of defects—even one located in an area where all the other diodes were degraded. On the other hand, a significantly lower voltage was obtained for every diode that contained even one defect. This correlation strongly supports the conclusion that the reduction in device yield observed after the base reoxidation step is due to the formation of rod defects.

In view of the adverse effect of the rods on device yield, it is of considerable interest to know the nuclea-



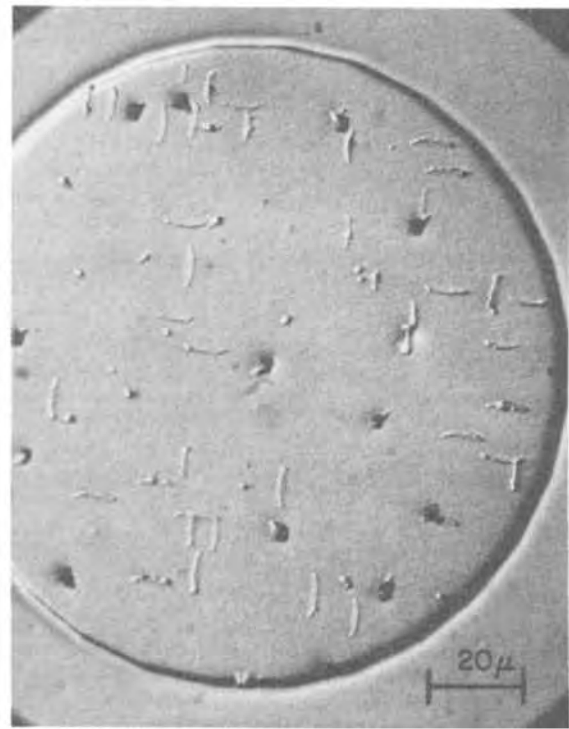


Fig. 3. Relationship of rods to stacking faults: (a, left) formation of rods on stacking faults and (b, right) rods and stacking faults

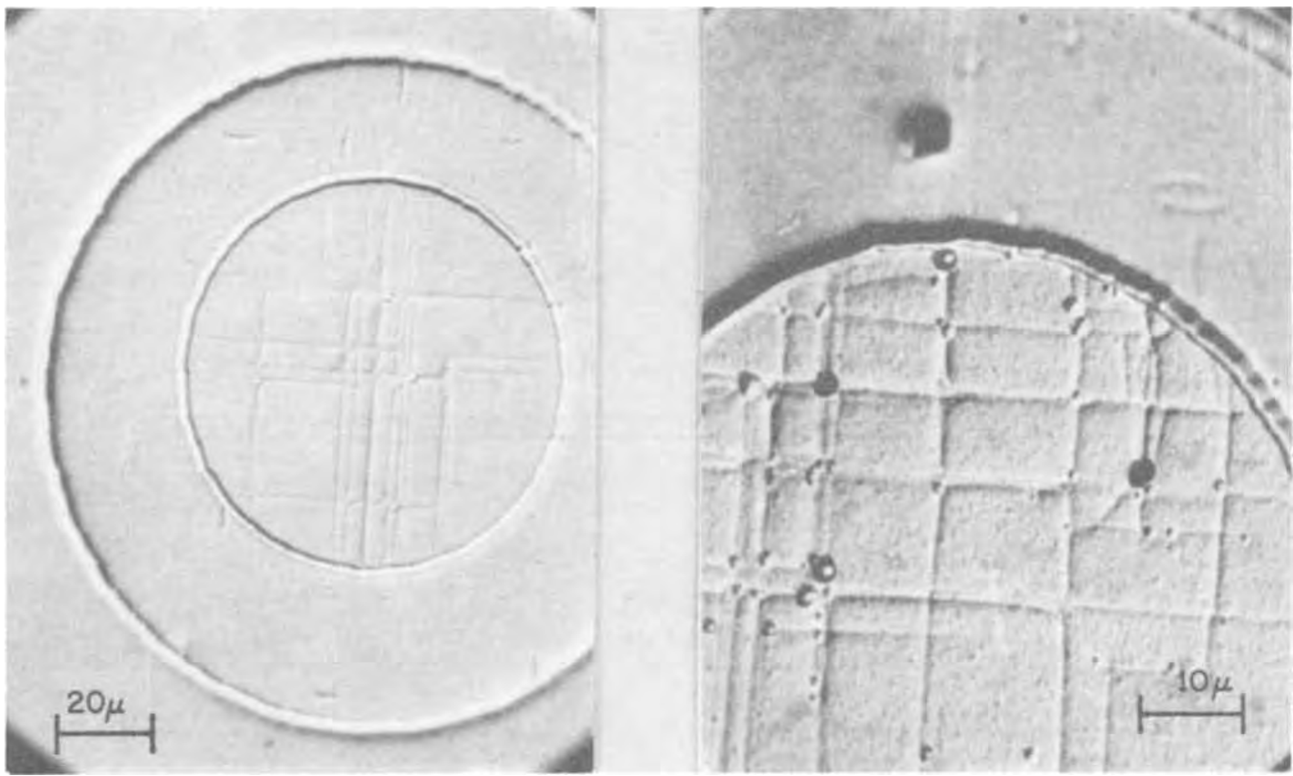

Fig. 4. Etching defects following emitter diffusion: (a, left) small defects and linear defects in emitter, good reverse characteristic and (b, right) small and large defects in emitter, degraded reverse characteristic.

tion mechanism, whether they are precipitates and if so, their chemical composition, and especially how to formulate the processing sequence to either prevent their formation or render them harmless.

With regard to the nucleation of the rods, an obvious question is whether the stacking faults are the nucleation sites. Some information concerning this question is provided by Fig. 3. The photograph on the left shows several rod defects. In one case the defect formation on the Frank partial dislocations at the end of the stacking fault is observed. A similar development, more fully matured, appears on the same photograph. Another diode with a poor reverse characteristic is shown in the photograph on the right. Based on these etching studies, it appears that in some instances the rods are nucleated by Frank partial dislocations associated with stacking faults, but that in general this is not the case.

Defects Produced by Emitter Diffusion

Let us go one step further and examine etching behavior following emitter diffusion. Linear etch defects associated with the high concentration phosphorus diffusion are evident with the emitter region (inner circle in Fig. 4a and b). Two other types of etching defects are also observed within emitter regions: (*i*) small defects without an apparent preferred orientation; (Fig. 4a and b) (*ii*) larger defects, oval in shape, with apparent <100> orientations, which are probably traces of the rod defect previously observed (Fig. 4b). In order to determine whether either type of defect causes degradation of the emitter-collector reverse characteristics, a large number of diodes on one wafer were first probed electrically and then etched to reveal defects, the same procedure used to investigate the defects formed in base reoxidation. The results are summarized in Fig. 5. The electrical data, which are given on the left side of the figure, show that for each diode either BV_{CEO} was greater than 40V, or the emitter and collector were shorted or showed poor electrical characteristics. The measurements were made on two areas of the wafer, one with high device yield and the other with low yield. It was found that the small, unoriented defects do not degrade the junctions, since many diodes containing several of these defects exhibited hard breakdown. On the other hand, the large (100)-oriented defects are clearly associated with collector-emitter shorting. The number of these defects observed in each diode is given on the right side of Fig. 5. It is seen that every diode containing one or more defects exhibits shorting or poor electrical characteristics, while every diode without defects exhibits hard breakdown. Thus, the only shorted diode in the high yield region is also the only one containing a defect, and the three

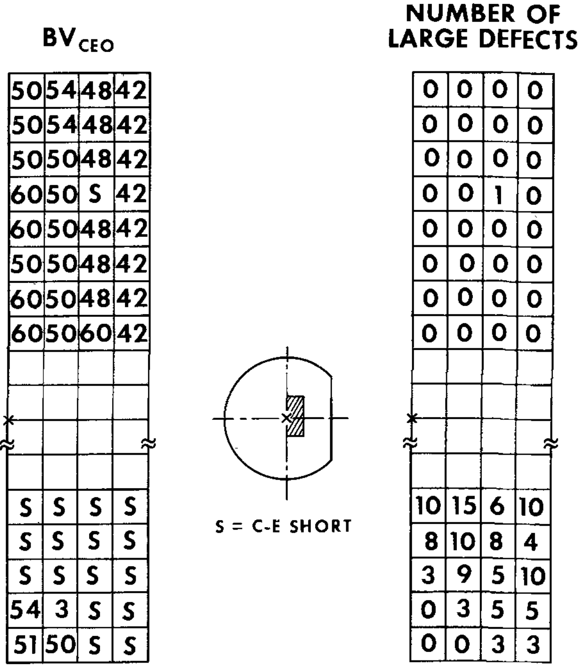

Fig. 5. Correlation between electrical characteristics (BV_{CEO}) and large etching defects after emitter diffusion.

hard breakdown diodes in the low yield region are the only ones without defects. Use of an oxidizing ambient during the base drive-in cycle reduced the number of defects produced during emitter diffusion.

Conclusions

A simple processing scheme has been examined to determine the nature of defects which form, the steps during which they form, and their effect on yield. Oxidation induced stacking faults were observed following the first high temperature operation A rod defect formed during the base reoxidation step and correlated with light emission spots as well as soft and low breakdown on a one-to-one basis. Upon processing through the emitter cycle, another defect—presumably resulting from the rod defect—formed and correlated on a one-to-one basis with collector-emitter shorts.

In some cases the partial dislocations associated with the extrinsic stacking faults were the nucleation sites for the rods. In other cases, rods were observed to be separate from stacking faults. Use of a strongly oxidizing ambient during base drive-in tended to suppress the formation of defects during subsequent processing.

Analytical Determination of Boron in Chemically Deposited Polycrystalline Silicon

M. Briska and A. Kiofsky

IBM Laboratories, D-703 Boeblingen, West Germany

The publication costs of this article have been assisted by IBM Corporation.

Polycrystalline silicon has become increasingly interesting in semiconductor technology, *i.e.*, for self-aligned MOS devices. It can be formed by chemical vapor deposition (CVD) in the way described by Eversteyn and Put (1).

Doping of the films is achieved by conventional impurity diffusion into the deposited layer or by codeposition of the dopant out of the gas phase.

A first correlation between resistivity and doping concentration for phosphorous and boron-doped polycrystalline films was established recently by Fripp and Slack (2) for a doping range from 5×10^{15} to 7×10^{17} B atoms/cm^3.

For the doping concentrations of the polycrystalline layers these authors took the values which they found for simultaneously deposited poly and single crystalline epitaxial layers via resistivity measurement and Irvin's curves (4).

For many purposes higher p-doping levels (10^{17}-10^{20} atoms/cm^3) are used which correspond to boron amounts in the microgram range, which is, as shown in the following, accessible to quantitative chemical analysis. The analytically determined values are compared with the sheet resistivity of the polycrystalline silicon layers.

Experimental Procedure

Preparation of the polycrystalline Si film.—The B-doped polycrystalline Si films (0.6μ thick) were prepared by the pyrolytic decomposition of SiH_4-H_2 and B_2H_6-Ar gas mixtures in a conventional induction heated reactor. The decomposition temperature was 920°C. By variation of the B_2H_6-Ar partial pressure one is able to produce p-doping levels of the polycrystalline Si films in the range of 10^{17}-10^{20} B atoms/cm^3. All these films were grown over a thin Si_3N_4 film on silicon wafers.

Key words: boron determination, silicon films, sheet resistivity.

Performance of the chemical analysis and the sheet resistivity measurements.—For the chemical analysis the back side of a wafer was covered (by evaporation) with a Cr-Cu-Au film of 2000Å. This is to protect the back side of the Si wafer from the NaOH attack when dissolving the polycrystalline Si film on the front side. The Si film is dissolved in 25-50 ml 0.4% NaOH at 100°C. The complete dissolution is achieved when the brown-blue color of the Si_3N_4 underlay appears. The amount of silicon dissolved is determined by weight difference.

The NaOH solution is concentrated and transferred into a 20 ml volumetric quartz flask. Corresponding to the expected B concentration, 2-4 ml of the solution, containing 20 mg NaOH, are pipetted into a Pt crucible and evaporated to dryness at 110°C. The residue is moistened with 0.1 ml H_2O and 1 ml 0.1% curcumine solution in CH_3COOH is added. The solution remains for 7-8 min at room temperature. Then 1 ml H_2SO_4/CH_3COOH 1:1 is added and the whole mixture is kept for another 25 min at room temperature. After that the mixture together with 25 ml water is transferred into a quartz separation funnel. The B-curcumine complex is extracted with 6 ml cyclohexanone containing 1% phenol, adjusted with acetone to a total of 10 ml. The absorbance of the solution is measured against water at 555 mn and compared with those of a boron standard

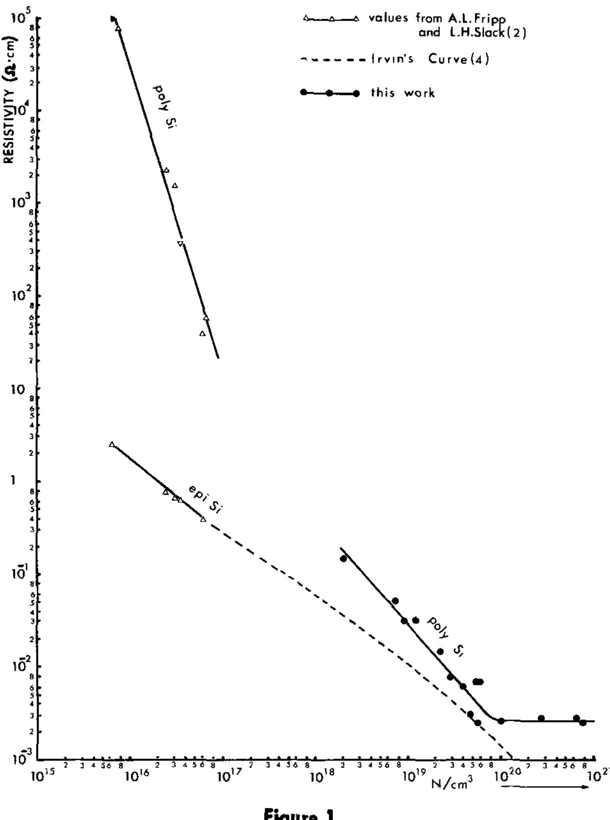

Figure 1

solution. The optical pathlength is 5 cm. The detection limit of the method is 10 ng.

The sheet resistivity measurements were performed by four-point probe measurement and thickness measurements by infrared spectrometry.

Results

In Fig. 1 the results are graphically exhibited. The number of boron atoms/cm^3 found by chemical analysis are plotted on the abscissa and the corresponding sheet resistivity on the ordinate. We included into this graph values found by Fripp and Slack (2). For their values, the abscissa does not represent boron concentration but electrically determined carrier concentration.

The experimental error both in sheet resistivity measurements and chemical boron concentration cannot account for the fairly high spread of the single measurements. Also variation in thickness, which affects the resistivity of polycrystalline films (3) is believed not to be responsible for the effect as all films had constant thickness of 0.6μ with a variation of less than $\pm 3\%$. Traps at grain boundaries leading to inconsistent resistivity measurements are used as explanation. It is shown that at higher boron concentrations the resistivity of the polycrystalline film approaches that of single crystalline films of the same carrier concentration.

The fairly constant level in resistivity of 3×10^{-3} ohm-cm for dopant concentrations $> 5 \times 10^{19}$ atoms/cm^3 is explained by the solid solubility of boron in silicon at the film preparation temperature of 920°C, which results in a calculated resistivity limit of 2.5-3 $\times$ 10^{-3} ohm-cm (1).

Surface Photovoltage Method Extended to Silicon Solar Cell Junction

E. Y. Wang

Electrical Engineering Department, Wayne State University, Detroit, Michigan 48202

and C. R. Baraona and H. W. Brandhorst, Jr.

NASA Lewis Research Center, Cleveland, Ohio 44135

The publication costs of this article have been assisted by Wayne State University.

Previous investigators (1-4) have shown that the surface photovoltage (SPV) method can be used to measure the minority carrier diffusion length in semiconductor materials. The conventional SPV method uses the surface junction formed in bulk materials due to the existence of surface states. The SPV method associated with lifetime gradient or resistivity gradient in semiconductor by electron irradiation has been reported previously (5). More recently, the SPV method has been applied to epitaxial semiconductor layers (6). In the present work we extend the conventional SPV method to a diffused junction such as that found in the silicon solar cell. The purpose of this paper is to show that the minority carrier diffusion lengths measured with the diffused junction and with a surface junction are identical. This extended SPV method provides a means to nondestructively measure minority carrier diffusion lengths before and after diffusion processing, using the same measurement technique. In addition, the SPV method uses capacitive contacts to eliminate contamination to the devices. This contact contamination would interfere with subsequent device fabrication processes and with the diffusion length measurement itself.

Key words: surface photovoltage method, silicon solar cell, minority carrier diffusion length.

Theory

The theory of the SPV method has been studied previously (3-9); however, the theory is briefly outlined here for completeness. The induced surface photovoltage (V_{sp}) in p-type material is a function of excess minority carriers (Δn) at the surface. The minority carriers are injected by illumination through the front surface of the specimen. Δn depends on the incident photon flux density (ϕ), the optical absorption coefficient (α), and the minority carrier diffusion length (L). For the one dimensional case, Moss (7) has shown that

$$\Delta n = \frac{\gamma\phi(1 - R)\alpha L}{(D/L + S)(1 + \alpha L)}$$

where γ is the quantum efficiency, R is the reflection coefficient, D is the minority diffusion coefficient, and S is the surface recombination velocity. In the extended SPV method, it is more appropriate to consider S as the junction recombination velocity. The assumptions in obtaining the above relationship are

I. $\alpha d_1 << 1$
II. $d >> L$
III. $p >> \Delta n$
IV. $d_1 << L$
V. $\alpha d > 1$

where d is the specimen thickness, d_1 is the depth of the surface junction, and p is the majority carrier concentration.

V_{sp} is some function of Δn at the depth of the junction, but its exact dependence need not be known. The incident monochromatic photon flux is adjusted as the wavelength is varied to make V_{sp} constant. In the 0.8 and 1.03 μm wavelength range used in the measurement, γ, R, and S are essentially constant. Hence ϕ will be a linear function of $1/\alpha$. The diffusion length is determined from the intercept of this straight line at $\phi = 0$ on the ϕ *vs.* $1/\alpha$ plot.

It is important to examine whether each of the basic assumptions of the SPV method is still valid when extended to silicon solar cell diffused junctions.

I. $\alpha d_1 << 1$. The depth of a solar cell diffused junction (d_1), obtained from theoretical error function calculations or from experimental results (10), is about 0.25 μm. The internal electric field in the n region is estimated to be 10^4 V/cm, using impurity gradient data derived from Hall and resistivity measurements. The field-free region is estimated to begin at a depth of 0.7 μm beneath the illuminated surface for 10 ohm-cm cells and even less for a 0.7 ohm-cm cell. The wavelength region used in the SPV measurement is from 0.8 to 1.03 μm. The corresponding α values are 890 and 33.0 cm^{-1}, respectively (11). The maximum product of αd_1 in the study is therefore about 6.23×10^{-2}, and the condition $\alpha d_1 << 1$ is amply satisfied.

II. $d >> L$. The thickness of the solar cell diodes (d) was about 300-400 μm. The measured minority carrier diffusion lengths shown in Fig. 1-4 are 170 and 70 μm for the 10 and 0.7 ohm-cm material, respectively. d is only about a factor of two larger than measured L for 10 ohm-cm cells. Philips (6) has shown, however, that the $d >> L$ condition can be relaxed and ϕ *vs.* α^{-1} will maintain a linear relationship. In fact, Bullis and Baroddy (12) have concluded from their experimental results that as long as $d > 1.2L$, the L values obtained in the SPV method are relatively independent of d.

III. $p >> \Delta n$. Solar cells were made using the same material and processes as for the junction devices used for SPV measurements. The short circuit current of the solar cells was measured over a range of illumination intensity which included the light level used in the SPV measurements. The short circuit current was linear with intensity, indicating the excess minority carrier density, Δn, was much less than the majority carrier concentration p in the base region of the diode. Hence, the condition $p >> \Delta n$ is also fulfilled.

IV. $d_1 < L$. Since $d_1 = 0.25$ μm and $L = 70$ μm for 0.7 ohm-cm cells, and 170 μm for 10 ohm-cm cells, the condition $d_1 < L$ is always met.

V. $\alpha d > 1$. The cell thickness is about $3\text{-}4 \times 10^{-2}$ cm and values of α range from 890 cm^{-1} at wavelength of 0.80 μm to 33 cm^{-1} at 1.03 μm. $\alpha d > 1$ is generally satisfied except at longer wavelengths (> 1.03 μm).

Experimental Arrangement

The experimental arrangement is similar to that reported elsewhere (1-3). A small area of the specimen is illuminated by a mechanically chopped light beam from a monochrometer. The illuminated area is held constant. The intensity is controlled by varying the voltage of the light source, so that the relative photon flux density is only proportional to the product of the thermopile reading and the wavelength. The photovoltage is coupled through a dielectric to a conducting glass contact on the front surface and through a metallic pressure type back contact to a phase sensitive detector. The detector is tuned to the chopper frequency. The relative photon flux density is measured by a thermopile. The samples measured were of typical solar cell configuration, although they had no evaporated metal contacts. The phosphorous diffused n-type junctions were about 0.25 μm deep. p-type base materials of two different resistivities were used: 10 and 0.7 ohm-cm.

Typical results are shown in Fig. 1 and 2. Measurements were made on each diode for differing values of V_{sp}. All the results show a linear dependence of $K\phi$ on $1/\alpha$ with a constant intercept at $K\phi = 0$, where K is arbitrary normalized constant. The minority carrier diffusion length obtained by the SPV method is 170 μm for the 10 ohm-cm cells, and 70 μm for the 0.7 ohm-cm cell. Cells were then etched in a solution of 2 parts acetic, 3 parts nitric, and 1 part hydrofluoric acid for a time sufficient to remove the n layers, while still maintaining $d > L$. The etched specimens were then measured by the conventional SPV technique. The results are shown in Fig. 3 and 4. The minority carrier diffusion lengths are in good agreement with the values obtained from the measurements of the diffused junction diodes. The minority carrier diffusion lengths measured by the x-ray method (13) on the solar cells also agree with the values obtained by the SPV method.

Discussion and Conclusion

Experimental errors mainly originate from two sources, energy flux density calibration of the thermo-

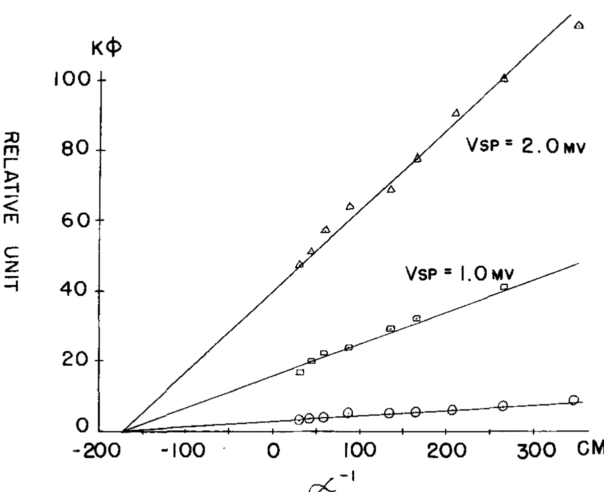

Fig. 1. Relative photon flux density ($K\phi$) vs. the inverse of the optical absorption coefficient (α) for typical 10 ohm-cm silicon solar cell.

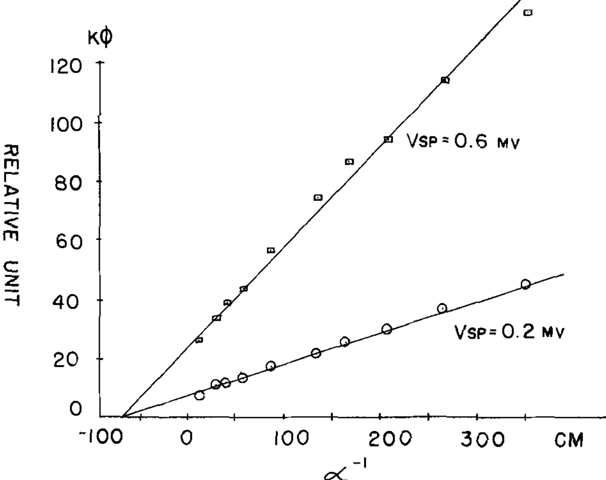

Fig. 2. Relative photon flux density ($K\phi$) vs. the inverse of the optical absorption coefficient (α) for a typical 0.7 ohm-cm silicon solar cell.

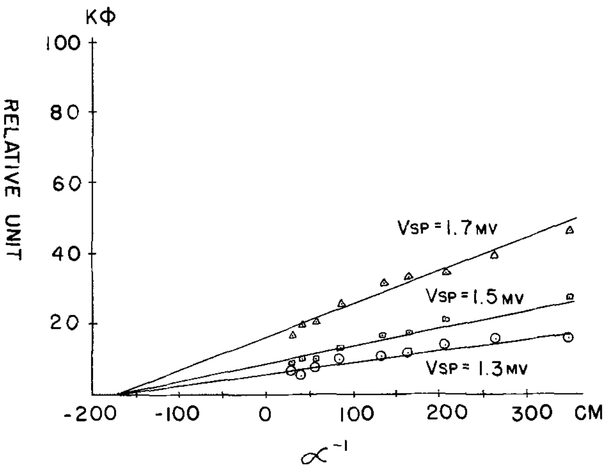

Fig. 3. Relative photon flux density ($K\phi$) vs. the inverse of the optical absorption coefficient (α) for the 10 ohm-cm silicon base material.

pile readings and uncertainty in α^{-1} value because of the wavelength resolution of the spectrometer. From the estimate of the sensitivity of the microvoltmeter (± 1.0 μV), the thermopile reading error could be $\pm 10\%$ at low $K\phi$ values and $\pm 2\%$ at high $K\phi$ values. Because of the nature of the variation of α^{-1} with wavelength, the uncertainty in α^{-1} is $\pm 2\%$ at short wavelength and $\pm 4\%$ at longer wavelengths.

In conclusion, our results show that the minority carrier diffusion lengths obtained from solar cell diffused junctions, and from the same bulk material with the n-regions removed by etching, are identical within experimental error by using the SPV method. The minority carrier diffusion values obtained here also agree with those obtained by the x-ray method. These

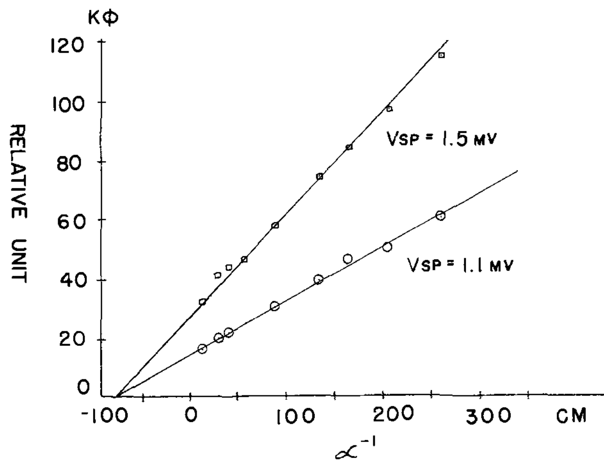

Fig. 4. Relative photon flux density ($K\phi$) vs. the inverse of the optical absorption coefficient (α) for the 0.7 ohm-cm silicon base material.

results indicate that the basic assumptions of the SPV method are indeed still valid for diffused junctions, as well as for surface junctions. The results further suggest that the influence of energy band bending on the n-region of solar cells is negligible. This is to be expected since the solar cell n-region is heavily doped (almost degenerate), and since the surface of n- or p-type bulk silicon material usually exhibits n-type behavior (14). If this were not the case, the minority carrier diffusion lengths obtained would not have been identical.

Conductance-Viscosity Studies on Some Moderately Concentrated Nonaqueous Electrolyte Solutions from –50° to 125°C

I. Solutions of Bu_4NI, KSCN, and NH_4Br in N,N-Dimethylformamide

T. V. Rebagay,[1] J. F. Casteel, and P. G. Sears*

Department of Chemistry, University of Kentucky, Lexington, Kentucky 40506

The publication costs of this article have been assisted by the University of Kentucky.

ABSTRACT

Conductances, viscosities, and densities have been determined at 25° intervals between −50° and 125°C for moderately concentrated solutions of Bu_4NI, KSCN, and NH_4Br in N,N-dimethylformamide. Results are summarized for the fitting of the experimental data as functions of temperature and molality to appropriate equations by computer least squares procedures. Activation energies of viscous flow and conductance, molar conductance-viscosity products, and specific conductance maxima also are discussed.

N,N-dimethylformamide, hereafter designated DMF, has several advantageous physical properties such as a convenient and broad liquid range (−61° to 153°C), a medium dielectric constant (36.7 at 25°C), and low viscosity (0.796 cP at 25°C). Previous typical studies (1-4) dealing mostly with dilute solutions at one or more temperatures between 15° and 50°C have shown DMF to be an excellent electrolytic solvent. The principal objective of the research reported herein has been to extend the existing knowledge about DMF as an electrolytic solvent by obtaining and discussing matching conductance and viscosity data for moderately concentrated solutions of three salts in DMF at eight temperatures over an unusually broad 175° range. Concentrations of salts ranged up to 6, 8, and 30% by weight (approximate upper limits of solubility at −50°C) for NH_4Br, KSCN, and Bu_4NI, respectively.

Experimental

DMF (Fisher Certified) was rendered anhydrous by refluxing over freshly ignited calcium oxide and then fractionated at 10 mm using a 1m distillation column packed with 6-mm porcelain saddles. A 60% middle fraction was retained for use in preparation of solutions. The values for the conductance, viscosity, and density of the solvent at 25° were in good agreement with those previously reported (1).

Eastman Grade Bu_4NI, Mallinckrodt Analytical Reagent NH_4Br, and Baker Analyzed Reagent KSCN were dried for several days in a desiccator over anhydrous barium perchlorate and used without further purification. Subsequent Karl Fischer analyses on similarly dried compounds gave a maximum water content of 0.01%.

Solutions in glass-stoppered flasks were prepared on a weight basis using calibrated weights and applying appropriate buoyancy corrections. Sufficient amounts of the solutions were prepared to permit separate portions of a solution to be used for the determinations of conductance, viscosity, and density. All measurements on each solution were completed within 18 hr after its preparation.

Each conductance cell was U-shaped with the two arms connected with smaller tubing which primarily controlled the magnitude of the cell constant. Standard tapered glass connections with marked positions made possible the reproducible placement of electrode inlet tubes in the cells. Platinum electrodes, 15 mm in diameter and welded to nickel lead wires, protruded from firm mountings in the ends of the inlet tubes into the solution. The electrodes were platinized (6 coulombs-cm^{-2}) following the recommendation of Jones and Bollinger (5). Cell constants at 25°, ranging from 6.301 to 41.47 cm^{-1}, were based on resistances of several aqueous potassium chloride solutions of known molarities and on the corresponding conductance data of Lind, Zwolenik, and Fuoss (6). The values for the constant of a cell at temperatures other than 25° were calculated from the value at 25° and the cell dimensions by the method of Washburn (7).

Resistances of the solutions contained in the conductance cells were measured with a Dike-Jones bridge assembly manufactured by the Leeds and Northrup Company. For resistances exceeding 30,000 ohms, the cell was shunted in parallel with 30,000 ohms and the series cell resistance was computed from the measured parallel resistance. Resistances of solutions measured at 50, 1000, and 2000 Hz were found to have negligible frequency dependence. No solvent corrections were applied to the conductances of the nonaqueous solutions since the conductance of the solvent in each case was <0.01% that of the solution.

The equipment and procedures which were used in the determination of viscosities and densities have been discussed thoroughly in previous articles (8, 9). Densities were necessary for calculating absolute vis-

[a] Solubility exceeded.

cosities and converting concentrations from a weight to a volume basis.

The temperature was controlled within 0.05° at 25° and higher temperatures with a Model H-1 high temperature bath (Cannon Instrument Company) and within 0.2° at 0°C and lower temperatures with a manually controlled low-temperature bath which also has been described elsewhere (10).

All determinations were made in duplicate with very good precision except in about five cases at the lowest temperatures where differences as great as 0.5% were observed. Mean values for the experimental data were fitted to various equations by least squares analyses performed with an IBM 360/65 computer using double precision Fortran IV programming.

Results and Discussion

The experimental data are presented in tabular form in Table I. Also any part or all of the data can be calculated within specified limits through the use of equations and constants provided in this article.

The molar conductance for each of the three electrolytes in DMF increases with increasing temperature and decreasing concentration in a typical manner. For corresponding concentrations and temperatures, the molar conductance of NH_4Br is significantly less than those of KSCN and Bu_4NI indicating that NH_4Br is less dissociated than the other two electrolytes in DMF.

The viscosities of solutions of each salt in DMF increase with increasing concentration and decreasing temperature as expected. Two other trends observed from the viscosity data for each system were that the temperature coefficient of solution viscosity increases with increasing electrolyte concentration and that the relative viscosity (η/η_0) decreases with increasing temperature.

The nonlinear nature of plots of $\ln \eta$ *vs.* $1/T$ and $\ln \Lambda$ *vs* $1/T$ clearly indicates that simple Arrhenius expressions for describing the temperature dependence of viscosities and conductances, in which E_{vis} or E_{con} is a constant, are not applicable. Moreover, Girifalco equations such as $\log \eta = A + B/T + D/T^2$ and $\log \Lambda = A' + B'/T + D'/T^2$, which previously had been found to describe very well the behavior of other nonaqueous salt solutions of comparable concentrations over a 75° range (11), were not satisfactorily applicable to the data for the DMF-salt solutions over the broader 175° range in this study.

Taking into account theoretical considerations, computational advantages, and agreement between observed and calculated values, viscosity and molar conductance data as functions of temperature were fitted finally to the following equations, respectively

$$\eta = \exp\,(\alpha + \beta/T + \gamma/T^2 + \delta/T^3 + \epsilon/T^4) \qquad [1]$$

$$\Lambda = \exp - (\alpha' + \beta'/T + \gamma'/T^2 + \delta'/T^3 + \epsilon'/T^4) \qquad [2]$$

Equivalent forms of Eq. [1] and [2] are expanded Arrhenius expressions such as $\eta = A \exp\,(E_{vis}/RT)$ and $\Lambda = A' \exp\,(-E_{con}/RT)$ in which E_{vis} and E_{con} are not constants but functions of temperature. Also, the common logarithm forms of Eq. [1] and [2] are related to expanded Girifalco equations (11, 12). The above equations may be changed to common logarithmic form by dividing each constant listed in Table II and Table III by 2.30258.

The parameters obtained through fitting mean experimental values of η and Λ to Eq. [1] and [2], using a nonlinear least squares program of the type described by Wentworth (13), are compiled in Tables II and III, respectively. The deviation data in these tables confirm that the equations apply excellently to the experimental data over the entire 175° range. Specifically, the mean and maximum deviations respectively between calculated and observed values are $\leq 0.27\%$ and $\leq 0.62\%$ for viscosities and $\leq 0.35\%$ and $\leq 0.56\%$ for molar conductances.

Viewing viscous flow and conductance as rate processes, activation energies of viscous flow and conductance for the DMF-salt solutions were calculated using Eq. [3] and [4] which were obtained by taking the natural logarithm expressions for Eq [1] and [2] and, in each case, differentiating with respect to $1/T$ and multiplying the result by R

$$E_{vis} = R\, d(\ln \eta)/d(1/T) = R(\beta + 2\gamma/T + 3\delta/T^2 + 4\epsilon/T^3) \qquad [3]$$

$$E_{con} = -R\, d(\ln \Lambda)/d(1/T) = -R(\beta' + 2\gamma'/T + 3\delta'/T^2 + 4\epsilon'/T^3) \qquad [4]$$

Values of E_{vis} and E_{con} at −25°, 25°, and 75° calculated using Eq. [3] and [4] are presented in Table IV for a few typical solutions of the three salts in DMF. Generally, the values of E_{vis} and E_{con} increase with increasing salt concentration and decreasing temperature. Except for the most dilute Bu_4NI-DMF solutions at the lowest temperatures, $E_{vis} > E_{con}$. Values of E_{vis}/E_{con} (also included in Table IV) in some cases are close to unity and for all solutions increase with increasing temperature.

Values of the molar conductance-viscosity product, $\Lambda\eta$, have ranges of 23.0-40.6, 32.2-53.9, and 10.7-33.8 ohm^{-1}-cm^2-$mole^{-1}$ cP for DMF solutions of Bu_4NI, KSCN, and NH_4Br, respectively. For the four most dilute Bu_4NI-DMF solutions, the $\Lambda\eta$ product exhibits a maximum near −25° or 0°; for all other solutions of the three salts, the $\Lambda\eta$ product decreases with increasing temperature and increasing salt concentration. The relatively low products for the NH_4Br-DMF solutions are attributed primarily to the low values of Λ for NH_4Br.

The results for both activation energies and $\Lambda\eta$ products generally reflect closer correlation between conductance and viscosity behavior for the Bu_4NI-DMF system than for the KSCN-DMF and NH_4Br-DMF systems.

[a] Does not include datum for 1.157 molal solution.

The densities for the DMF-salt solutions as a function of temperature are described excellently by the following quadratic equation

$$\rho = a + bT + cT^2 \quad [5]$$

Parameters for fitting the density data to Eq. [5] along with deviation data are compiled in Table V.

The viscosity, molar conductance, and density data as similar functions of molality can be described excellently by the following general polynomial equation in which $Y = \eta$ or Λ or ρ

$$Y = c_1 + c_2 m^{1/2} + c_3 m + c_4 m^{3/2} + \ldots \quad [6]$$

Results for fitting the experimental data by normal least squares analyses to Eq. [6], together with corresponding deviation data, are summarized in Tables VI-VIII, respectively.

Equations are not provided for calculating the specific conductances (κ) of the salts in DMF as functions of temperature and molality; however, κ can be calculated from molar conductance and other data as follows

$$\kappa = \Lambda C/1000 = \Lambda \rho m/(1000 + mM_2) \quad [7]$$

in which C is the molarity (moles of solute per liter of solution) and m is the molality (moles of solute per 1000g of solvent). For the NH_4Br-DMF system, κ exhibits a maximum for the 0.732 molal solution at −50° and otherwise increases continuously with increasing concentration at all other temperatures. For the Bu_4NI-DMF system, κ exhibits maximum values for 0.376, 0.563, 0.692, 0.908, and 1.015 molal solutions at −50°, −25°, 0°, 25°, and 50°, respectively, whereas κ increases with increasing concentration at 75° and higher temperatures. This type of behavior for the Bu_4NI-

DMF system has been observed previously for other nonaqueous systems (14) but differs from that reported for solutions of electrolytes in water and ethanol for which a maximum in κ tends to occur at approximately the same concentration at each temperature (15, 16). For any electrolyte solution in which κ exhibits a maximum as a function of concentration at some temperature, it is noteworthy that κ decreases with increasing concentration for concentrations above the maximum. In such a case, the effect of introducing additional conducting particles or ions is more than counterbalanced by the effect of an increase in viscosity and a concomitant decrease in ionic mobilities, or by the effect of increased ionic association, or both, resulting in a net decrease in the specific conductance of the system.

Related conductance-viscosity studies on moderately concentrated solutions of electrolytes in other pure and mixed nonaqueous solvents over the same 175° range will be presented in subsequent articles in this series.

Investigation of Subvalent Ion Effects During Aluminum Anodization in Molten $NaCl-AlCl_3$ Solvents

R. J. Gale and R. A. Osteryoung*

Department of Chemistry, Colorado State University, Fort Collins, Colorado 80521

The publication costs of this article have been partially assisted by the Colorado State University.

ABSTRACT

Anode current yield variations with current density have been measured in the nominal 1:1 and 1:2 molar $NaCl-AlCl_3$ molten electrolytes by an anodic stripping procedure. In the range of apparent current densities 0.03-6.30 mA cm^{-2}, the *brutto* electrode reaction was found to be a faradaic three-electron oxidation. Subvalent ion effects could not be positively established. Experimental difficulties in removing final traces of impurities limit the precision of coulometric determinations in these systems; however, the anodic stripping procedure does provide a sensitive means of detecting corrosion losses of aluminum.

It has recently been reported (1, 2) that the anode current yields for aluminum dissolution in molten $NaCl-AlCl_3$ solvents are appreciably higher at low current densities than required for the three-electron oxidation reaction

$$Al(0) - 3e^- \rightarrow Al(III) \quad [I]$$

As early as 1857 (3), high current yields for the anodic dissolution of aluminum were recorded, and they have since been observed for a variety of electrolytes; aqueous (4, 5), organic (6-8), and nonaqueous (1, 2, 9). In general, the alternative explanations to account for these deviations from a faradaic three-electron oxidation are (*i*) the formation of subvalent aluminum ions, (*ii*) spallation or electrophoretic removal of colloidal aluminum particles, and (*iii*) chemical corrosion, *i.e.*, direct electrolyte or impurity attack on the anode surface.

Delimarskii *et al.* (1) found that the anode current yields in the $NaCl-AlCl_3$ (1:2M) electrolyte at 160°C were dependent on the anodic current densities for the range 10-150 mA cm^{-2} and, for all experiments, the anode current efficiencies were usually >100% and exceeded the cathode current efficiencies (weight losses corresponding to faradaic three-electron oxidation of aluminum are 100%). From studies in the equimolar $NaCl-AlCl_3$ melt at 300°C, Storozhenko (2) determined current yields >100% for the anodic dissolution of annealed aluminum anodes and, similarly, the current yields increased with decreasing anodic current densities, to reach a value 230% at the minimum investigated current density of 0.11 mA cm^{-2}. Delimarskii and co-workers considered that chemical corrosion or losses from spallation were unable to explain the magnitude of their anode current yields, whereas the results of Storozhenko are stated to have been corrected for losses due to chemical corrosion. Accordingly, both sets of data were interpreted by the assumption that considerable quantities of univalent aluminum ion are formed under the conditions of anodization, especially at current densities of 10 mA cm^{-2} and lower.

It was of interest to examine this phenomenon in more detail as the presence of free or complex univalent aluminum ion in larger than trace quantities might have significant consequences in many of the chemical or electrochemical studies, in particular chloroaluminate solvents, *e.g.*, materials corrosion in aluminum deposition or battery electrolyte applications. The introduction of univalent aluminum would arise from commonly used melt purification procedures, which involve either equilibration with metallic aluminum (10) or preelectrolyses between aluminum electrodes (2, 11). In addition, on the basis of the above experimental findings (1, 2), potentiometric techniques which involve anodization to determine melt pCl^- and alkali metal chloride-$AlCl_3$ equilibrium compositions, such as the one adopted in this laboratory (12), would be susceptible to the anode current yield variations with current density. In order to reexamine the dependence of the anode current yields on current densities, a coulometric procedure was chosen in which a constant quantity of aluminum was electrodeposited on an inert electrode substrate and then stripped from the electrode. This method enabled precise *in situ* measurements, whereas the precision of gravimetric methods is limited by the presence on the electrodes of solidified salt which has to be removed before weighing or accounted for quantitatively.

Experimental

Melt purification.—Preelectrolyses were carried out in a cell, similar in all essential details to one previously described (11), and under a purified nitrogen atmosphere (Vacuum/Atmospheres Company dry box with HE-493 Dri-Train). To the cell, containing an aluminum anode rod (6.35 mm diameter, Johnson Matthey Specpure grade) and an Al wire spiral cathode (23 mil, Alfa Inorganics, m5N purity), were added 2 g-mole quantities of aluminum chloride (Fluka A.G., iron-free) and sodium chloride (Fisher Scientific Company) and the temperature was raised to between 175° and 200°C. Before electrolysis was commenced, dark coatings formed on both electrodes in the molten electrolyte; Uhlig (13) noted that similar coatings were formed for the 40-60 mole per cent (m/o) $NaCl-AlCl_3$ system. The impure, straw colored melt was then electrolyzed for 10 days with an anodic current density of ~0.25 mA cm^{-2}, to produce a clear, colorless melt. At the end of the electrolysis, the anode surface was dark and pulverulent. No dark coating appeared on a clean Al anode rod introduced into the purified melt, nor did one occur with subsequent anodization of this rod. Attempts to analyze these dark coatings are described in a later section of this paper.

* Electrochemical Society Active Member.

Key words: fused salts, $NaCl-AlCl_3$ melt, aluminum electrode, subvalent aluminum, Al(I) ion.

Gravimetric coulometry.—The current efficiency for Al deposition was determined with a Sargent coulometric current source. Aluminum foil samples (10 mil, Alfa Inorganics, m5N purity) were weighed and used as cathodes at a current density of 1.4 mA cm^{-2} (geometrical area) for 20,000 sec (i = 48.25 mA). The aluminum electrocrystallized from this purified melt in a fine, dendritic form, cf. (14). Samples were carefully removed from the melt and placed in a fritted-glass sintered crucible, initially washed in dried dimethyl sulfoxide, thoroughly washed with distilled water, and finally dried *in vacuo* and reweighed. The cathodic deposition efficiency calculated on the basis of three electrons was 100.0 ± 0.4% (standard deviation σ, five experiments).

Anodic stripping.—Preliminary deposition and stripping experiments were made in the purification cell, at 175° ± 2°C, with a PAR Model 170 electrochemistry system (Princeton Applied Research Corporation) in the constant current mode. A multipurpose instrument (15) coupled to a Houston Instruments X-Y recorder, Model 2000, was used to record cyclic voltammograms. The reference electrode comprised a spiral of Al wire (Alfa Inorganics, m5N purity) contained in a fine fritted-glass sintered compartment; the auxiliary electrode was an Al wire spiral immersed in the bulk solution. Two types of solid working electrodes have been used: (*i*) a ⅛ in. diameter tungsten rod electrode (Alfa Inorganics, m3N8 purity), and (*ii*) a 3 mm diameter vitreous carbon rod electrode (Atomergic Chemetals Company, Type V 25-52). The tungsten rod was sealed into a Pyrex glass tube using a bead of uranium glass, ground flat on an emery wheel, and polished with 600 grit silicon carbide powder. Final treatment consisted of lapping on a polishing wheel to a mirror-bright finish with Type B Alumina powder (Fisher Scientific Company), thoroughly rinsing with distilled water, and drying at 110°C *in vacuo*. The vitreous carbon electrode was sealed into a Pyrex glass tube with the procedure described by Gupta (16), and its surface was prepared in an identical manner to that of the tungsten electrode. These electrodes were immersed into the molten electrolyte at least 2 hr before commencement of experiments, and, immediately prior to each experiment, they were treated by cyclic potential sweeps from +0.40 to +1.80V *vs.* Al reference in similar melt composition, for a few minutes, to minimize effects from electroactive impurities. Cyclic voltammograms shown in Fig. 1 indicate the extent to which the background currents vary when these

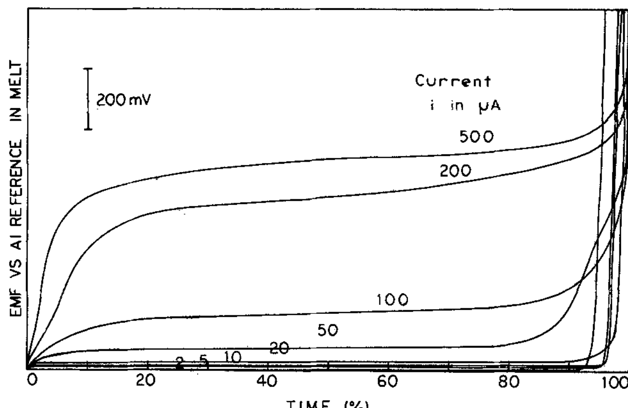

Fig. 2. Anodic stripping curves at various current densities in melt A, W electrode.

electrodes were immersed for 24 hr. The results of the preliminary experiments are illustrated in Fig. 2 and summarized in Table I. Cathodic depositions were made at 100 μA currents for 100 sec and the aluminum was immediately stripped at 2, 5, 10, 20, 50, 100, 200, and 500 μA anodic currents with appropriate recorder time base settings. The transition time, τ, was determined from the emf/time curves by extrapolation of the maximum gradient values at the completion of stripping. The precision of the technique is estimated to be of the order ±1% for all current densities used; however reproducibility was slightly better for the tungsten electrode than for the carbon electrode, which may have a higher content of electroactive impurities. The composition of the melt used for preliminary experiments, melt A, was calculated to have a pCl^- of 1.31 by the potentiometric-anodization procedure of Boxall *et al.* (12), using an assembly program for a PDP-12 digital computer.

Corrosion experiments.—It was of importance to investigate whether or not the deviations from 100% relative efficiencies in Table I at the lower current densities represented a dependence of the current yield on the anodic current density because of a greater contribution from subvalent ion formation to the net dissolution mechanism, or indeed, if the relative efficiency loss could be ascribed to side reactions or corrosion processes. Aluminum was deposited on the tungsten electrode at 100 μA for 100 sec and the electrode was left on open circuit for 1000 and 5000 sec before stripping at an anodic current of 100 μA. The measured relative efficiencies were 97.6 ± 0.5% (σ, five experiments) and 91.1 ± 0.8% (σ, five experiments) for 1000 and 5000 sec, respectively, which indicated

* Calculated for the geometrical area of the W electrode, ⅛ in. diameter.

that under these conditions corrosion losses of the freshly deposited aluminum were occurring. The sources of oxidizing agents in a "purified" melt are either (*i*) the cell and its component parts, (*ii*) the electrode substrates or their insulation sheaths, (*iii*) the dry box atmosphere, or (*iv*) residual impurities in the chemicals. Certain of these variables could be excluded by redesign and Fig. 3 is a schematic of a revised cell. Experiments with melt compositions B, C, D, and E were made in this cell. The melt compositions were varied by the addition of solid $AlCl_3$, followed by preelectrolyses.

Analyses of dark coatings.—There have been reports that a dark deposit forms on the surfaces of aluminum anodes (1, 2) in alkali metal chloride-$AlCl_3$ electrolytes. Delimarskii *et al.* have suggested that this is in good agreement with the hypothesis of disproportionation of monovalent aluminum during anodization, according to reaction [V], to produce finely dispersed aluminum metal. Correspondingly, Storozhenko suggested that, at current densities <60-80 mA cm^{-2}, the fraction of univalent aluminum ions became greater than the equilibrium value and that aluminum powder appeared in the anolyte region and on the anode. As no dark coatings were observed to form on aluminum surfaces after melts had been purified by sufficient periods of preelectrolyses, it is possible that the coatings are associated with an impurity in the system which diffuses or is electrophoretically attracted toward the anode. To obtain samples for analyses, the dark coating was scraped from an anode and extracted from the solidified salt with liquid SO_2 (17). A qualitative emission spectrographic determination showed the major metallic constituents in the residue to be Si, B, Sn, Mn, and Al, in agreement with the results of Fung, Mamantov, and Young (10) for analyses of dark-brown deposits found in NaCl-$AlCl_3$ melts with elemental aluminum.

Results and Discussion

The data in Tables I and II indicate that there is no dependence of the anode current yield on the current density, within the experimental accuracy of these results, if the variations from 100% relative anode dissolution efficiencies are ascribed as due entirely to corrosion losses. As the cathodic current yield was determined to be 100.0 ± 0.4% at 175°C on the basis of three electrons, the anode dissolution for the current density range 0.03-6.30 mA cm^{-2} may be described by the reverse of this reaction. The magnitude of the mean corrosion rate found in melt A at 175°C (~10% in 5000 sec) represents an aluminum loss of 9×10^{-12} mole cm^{-2} sec^{-1} and compares to a minimum corrosion value quoted by Delimarskii *et al.* (1) of 1×10^{-9} mole cm^{-2} sec^{-1}. Skala (18) has reported a corrosion rate for iron in a ternary KCl-NaCl-$AlCl_3$ melt (14-22-64 m/o) of 2×10^{-10} mole cm^{-2} sec^{-1} and has suggested that the most active impurities to cause the oxidative losses are hydrogen compounds. Del Duca (19) found anode current efficiencies of 100 ± 1% and 98 ± 2% at current densities 0.3 and 0.5 mA cm^{-2}, respectively, for aluminum dissolution in an equimolar NaCl-$AlCl_3$ melt. Figure 2 illustrates that the anodic polarization increases to higher potential values *vs.* Al reference with increase in the anodic stripping current density. In melt A, the dissolution of aluminum from a charge of ~1 mcoulomb polarized the Al electrode about +600 mV at 6.30 mA cm^{-2}, which very approximately represents the emf difference between an Al electrode in NaCl saturated NaCl-$AlCl_3$ and one in the 1:2M melt composition. The corresponding polarization increase found in the nominal 1:2M melt E was of the order +50 mV at 500 μA. Holleck and Giner (20) have reported similar passivation phenomena of the Al electrode in a ternary KCl-NaCl-$AlCl_3$ melt.

Relative yield after corrosion	Not determined	93 ± 5 (5000 sec)	98 ± 1 (1000 sec)	96 ± 1 (1000 sec)

Several factors may contribute to the discrepancy between the current yields determined by this study and the results obtained earlier (1, 2); in previous studies higher contents of impurities may have been present and the corrosion rates at open circuit may have been smaller than those experienced under conditions of anodic polarization. In addition, it is feasible that the systems may not have achieved an equilibrium state with respect to subvalent aluminum formation. Wagner (21) has derived illustrative equations to determine current yields from electrolyses of solutions containing an electroactive metal present in several cationic valency states. Following this example, and disregarding all reactions of the divalent aluminum state to simplify discussion, the reactions at the anode can be written

$$Al(0) - e^- \xrightarrow{k_1} Al(I) \quad [II]$$

$$Al(I) - 2e^- \xrightarrow{k_2} Al(III) \quad [III]$$

$$Al(0) - 3e^- \xrightarrow{k_3} Al(III) \quad [IV]$$

where k_1, k_2, and k_3 are the net rates of the reactions in mole unit $area^{-1}$ sec^{-1}. Then, within the restrictions imposed by Nernstian behavior, diffusion, transference, and ionic charge balance of the Wagner steady-state model, the number of moles, ϵ, of aluminum dissolved at the anode per faraday of electricity passed is given by the expression

$$\epsilon = \frac{k_1 + k_3}{k_1 + 2k_2 + 3k_3}$$

The limitations implicit from a consideration of the electrode kinetics in this manner should be recognized. (*i*) If $k_2 = k_3 = 0$, Al(I) ions will be formed in accordance with reaction II, and $\epsilon = 1$. (*ii*) If $k_1 = k_2 = 0$, then Al(III) ions will be formed by reaction [IV] only, and $\epsilon = 1/3$. (*iii*) If $k_1 \sim 0$ and $k_3 > 0$, the diffusion of Al(I) ions from the bulk electrolyte to react at the anode according to reaction [III] would give $\epsilon < 1/3$. (*iv*) A value of $\epsilon = 1/3$ is not unique to (*ii*). If $k_1 = k_2$ and $k_3 \geqq 0$, $\epsilon = 1/3$, and without a knowledge of all the rate constants for each discrete reaction step involved, the steady-state concentration of Al(I) ions at the electrode surface cannot be calculated. The occurrence of the homogeneous disproportionation reaction, if sufficiently high concentrations of Al(I) ions are able to accumulate in the vicinity of the anode

$$3Al(I) \rightleftharpoons 2Al(0) + Al(III) \quad [V]$$

could further complicate analyses of the causes underlying the anode current yield values.

For the reverse of reaction [V] as written, Storozhenko (2) has determined from the solubilities of aluminum in tetrachloroaluminate melt equilibrium constants of 24.7×10^{-6} (200°C), 33.8×10^{-6} (300°C), and 59.1×10^{-6} (400°C). These values may be compared to the thermodynamic functions calculated by Foster *et al.* (22) for the gaseous phase equilibria; for the reverse of reaction [V], the equilibrium constants are $10^{-26.2}$ (227°C) and $10^{-14.0}$ (427°C). Univalent aluminum compounds have been studied fairly extensively in the vapor phase at high temperatures, *q.v.* the compilation of thermochemical data for AlCl (23) (references therein) and Ref. (24, 25). However, scant information is available with regard to the stability of subvalent species of aluminum in either liquid or solid phases.[1] *A priori* no correlation between the relative stabilities in the vapor and the solution phases is possible, as the changes of the free energy and entropy accompanying dissolution of a molecule, such as aluminum monochloride in a molten salt, depend on properties specific to the solute and the solvent phase. Lower oxidation states of certain metals are known to be stabilized in chloroaluminate melts with high aluminum chloride contents, *e.g.*, Cd_2^{2+}, Pb^+ Sn_2^+ (30), and Hg_3^{2+} (31). Possible reasons for this stabilization have been discussed by Anders (32), Skala (18), and Mamantov (33). These include, firstly, steric factors and charge densities of anions which affect the stability of low valent cations and, secondly, increased stabilization is expected to occur as the solvent media are made increasingly acidic in the Lewis sense. This is because low valence state cations are generally less acidic than those in higher valence states. Nevertheless, the equilibrium constants for the reverse of reaction [V] in an equimolar melt composition as derived by Storozhenko would necessitate a considerable increase in stabilization of univalent aluminum species in comparison with the respective gaseous phase equilibria. Until the impurities that cause aluminum loss can be eliminated, or at least their effects quantitatively monitored, the aluminum solubility studies are liable to the same indeterminate errors as would be nonequilibrium anodic current yield measurements.

[1] Despite varied experimental approaches (26-29) no compound of subvalent aluminum, stable at room temperatures, has yet been characterized unequivocally; Kinsella (29) was unsuccessful both with solid-state preparative methods, which seemed to be most promising from a thermodynamical standpoint, and electrolytic techniques involving anodization.

ABSTRACT

The purpose of this work was to find an electrolyte which increased the rate of propane electro-oxidation over that observed in phosphoric acid. The monohydrate of trifluoromethanesulfonic acid has been demonstrated to have a positive effect. The limiting current at 135°C was more than 1000% greater than that observed in phosphoric acid under comparable conditions. Hydrogen oxidation was shown to be more facile in $CF_3SO_3H \cdot H_2O$. Experiments are described which provide some insight into the nature of the electrochemical oxidation process.

Direct oxidation hydrocarbon air fuel cells have been the goal of many investigators since Grubb and Niedrach (1) reported the electro-oxidation of saturated hydrocarbons. The rates for the oxidation of hydrocarbons were very low and could not be considered for a practical fuel cell system. Since that time, numerous attempts have been made to develop electrocatalysts which exhibit superior activity for hydrocarbon oxidation. This approach did not develop a material which demonstrated a performance and economy which warranted the advanced development of hydrocarbon air fuel cell systems. Another approach toward the improvement of the electro-oxidation of hydrocarbons is to investigate other electrolytes, the subject of the present paper.

It was demonstrated by Cairns (2, 3) in the mid 1960's that the electrolyte had a considerable effect on the rate of oxidation of alkanes. The highest current densities were supported in hydrofluoric acid. Hydrofluoric acid could not be considered suitable due to the great chemical activity of the system. Though other acid electrolytes have been examined, phosphoric acid is the electrolyte most commonly used in hydrocarbon air fuel cells (4, 5).

An analysis of the problem indicates that certain specifications are necessary for the ideal (hypothetical) electrolyte. These specific properties include:

(*i*) The electrolyte should be a good medium for the efficient reactions of hydrocarbons and air.

(*ii*) The electrolyte must be a good medium for ionic charge transport.

(*iii*) The electrolyte should be a good solvent for the reactants, the hydrocarbon and air.

(*iv*) The electrolyte must act as a suitable medium for mass transport for the diffusion of materials to catalytic surfaces and removal of products of the reaction.

(*v*) The electrolyte must be physically, chemically, and electrochemically stable over the operating temperature and potential range.

(*vi*) The electrolyte should not interfere with the catalytic reactions.

(*viii*) The electrolyte should not be strongly reactive with the cell construction materials or matrix.

Based on these specifications, the literature was examined for possible acid electrolytes (6). A promising system of compounds is the perfluoroalkane sulfonic acids. These acids have high acid strengths and are excellent ionic conductors (7). The simplest acid, trifluoromethanesulfonic acid, forms a stable monohydrate which melts at 34°C and boils at 96°C/1 mm Hg. The objective of this research was to investigate the electrochemical oxidation of propane in trifluoromethanesulfonic acid monohydrate and compare the results with those for the reaction of propane in 85% phosphoric acid.

Experimental

Apparatus.—Electrochemical measurements were conducted in a three-compartment glass cell of approximately 30 ml capacity in which the working and countercompartments were separated by a medium glass frit. A Luggin capillary provided contact between the working electrode and the dynamic hydrogen electrode system (8). All potentials given will be with reference to the DHE. The working electrode assembly was removable so different electrode materials could be investigated. In the development of the current potential curves a platinum mesh (99.99%) of approximately 4 cm^2 "real" surface area was utilized. A

* Electrochemical Society Active Member.

Key words: electrolyte, performance enhancement, anion adsorption, reaction mechanism, limiting current, propane oxidation, $CF_3SO_3H \cdot H_2O$.

smooth platinum wire (99.99%) of approximately 0.5 cm^2 "real" surface area was used in the experiments determining the adsorption of propane on the electrode. The counterelectrode was a platinized platinum mesh connected to a Pt wire lead. Potentials were controlled by a Wenking Potentiostat (Model 66TS3). Pretreatment steps were effected by switching potentiometers into the input circuit of the potentiostat using mercury-wetted relays fired at times from 1 msec to 10 sec regulated by a bank of wave form generators (all wave form generators were Tektronix Model 162). A digital panel meter (Electronic Research Company, Model 4000) was used to read all voltage and cell current values in the development of the current density-potential curves. The cell current values were obtained using the digital panel meter in parallel with a known resistance. Charging curves were displayed on a dual beam oscilloscope (Tektronix Type 555 with a Type 1A7 vertical plug in) and photographed with a Polaroid camera (Tektronix 75 mm/lens, Series 125). All experiments were repetitive runs to establish the reproducibility of results. An air oven maintained cell temperature to ±0.5°C of the desired value.

Materials.—Trifluoromethanesulfonic acid was obtained from 3M Company, Minneapolis, Minnesota. The acid monohydrate was prepared by the method of Gramsted and Hazeldine (7) and redistilled 3 times at atmospheric pressure, collecting the fraction between 184°-186°C. The resultant product is a white, needlelike, crystalline product (mp 33.8°C). Fisher reagent grade phosphoric acid was purified by refluxing 1 volume 30% H_2O_2 with 2 volumes of 85% H_3PO_4 and reconcentrated to 85% H_3PO_4 (9). High purity helium 99.995% and instrument grade propane 99.5% minimum purity were obtained from the Matheson Company. The helium used for purging was deoxygenated by passing over a bed of copper turnings at 400°C. The helium was appropriately humidified to maintain the H_3PO_4 concentration at 85% regardless of cell temperature.

Experimental techniques.—The surface area of the electrode was determined by using a cathodic galvanostatic pulse after a series of potential pretreatment steps. This "real" electrode area was calculated assuming a value of 210 μcoulombs/cm^2 as the maximum cathodic galvanostatic charge associated with the deposition of a monolayer of hydrogen on the electrode surface (10). The potential pretreatment step provided a reproducible electrode surface for charge measurements as previously described by Brummer *et al.* (11) and Gilman (12).

Current density ("real" area)-potential diagrams were constructed at several temperatures from 55° to 135°C for the background (using helium), for hydrogen, and for propane. In performing the current *vs.* potential runs, a potential value was set and the system allowed to equilibrate for 5 min before the current value was recorded. The potential was scanned in the anodic direction and back toward the open-circuit potential to establish the hysteresis in the system and electrolyte stability.

Work was begun on the adsorption characteristics of propane in $CF_3SO_3H \cdot H_2O$ using the galvanostatic method of Brummer *et al.* (11). A series of potential steps are imposed on the electrode followed by a galvanostatic pulse. The potential was raised from open circuit to 2.00V for 10 sec in $CF_3SO_3H \cdot H_2O$. It was found that the 2.00V step *vs.* 1.35V step used for phosphoric acid was necessary to obtain a reproducible surface area determination. All other steps used were the same for $CF_3SO_3H \cdot H_2O$ and for 85% H_3PO_4. The 2.00V step was followed by a 0.1 msec step at 0.05V. This was followed by an adsorption step at a selected potential and time. The difference between the potential time curves of helium run in the electrolyte (background) *vs.* propane in the electrolyte gives a measure of the charge due to adsorption of propane on the electrode.

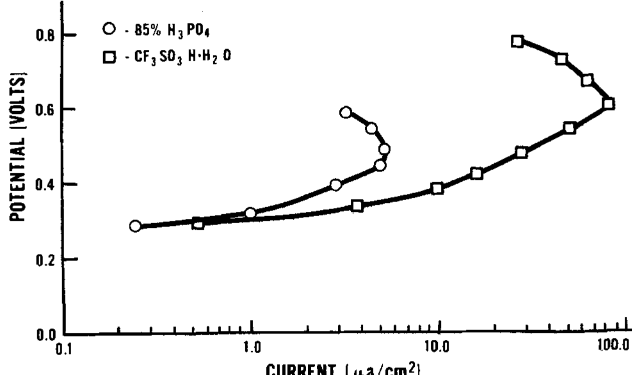

Fig. 1. Current density-potential diagram comparing the electrochemical oxidation of propane on smooth platinum at 135°C in $CF_3SO_3H \cdot H_2O$ and in 85% H_3PO_4.

Several experiments were performed using the multipulse potentiodynamic method (13). After the pretreatment potential steps and an adsorption potential step a voltage ramp was imposed on the electrode. The current changes and the potential ramp on the electrode were followed using an oscilloscope.

Results and Discussion

The principal objective of this effort was to determine if the subject electrolyte enhanced the electrooxidation of propane compared to that observed in 85% H_3PO_4. In order to have a direct basis for comparison with our cell, a number of the experiments performed by Brummer *et al.* (11) in H_3PO_4 were repeated. Our results were generally in good agreement with those reported earlier where the limiting currents at 135°C occurred between 0.5 and 0.6V. The accumulation of charge on the electrode surface was found to be very potential dependent with the greatest adsorption occurring at about 0.3V. A significant portion of the reaction intermediates on the electrode desorbed when the working electrode was cathodically pulsed. The remaining intermediates could only be removed when the potential was raised to a highly oxidizing level.

The first experiments were to examine the electrochemical oxidation of propane in $CF_3SO_3H \cdot H_2O$ and compare these results with those in 85% H_3PO_4 at 135°C. This comparison is presented in Fig. 1. At all potentials, the current density values are higher for the reaction in $CF_3SO_3H \cdot H_2O$ than in 85% H_3PO_4. The limiting current density value in $CF_3SO_3H \cdot H_2O$ is approximately 82 μA/cm^2 and in 85% H_3PO_4 the limiting current density is approximately 5.5 μA/cm^2. Thus, on a strictly comparative basis, the oxidation of propane was enhanced by a factor of 15 in the acid monohydrate.

Table I shows the temperature dependence of the propane reaction in the acid monohydrate. The data for the reaction of propane in 85% H_3PO_4 at 135°C are also shown for comparison purposes.

The effect of temperature can be observed on the reaction of propane in $CF_3SO_3H \cdot H_2O$ compared to the reaction of propane in 85% H_3PO_4 in Table I. The current density values, at a set potential, increase with temperature in $CF_3SO_3H \cdot H_2O$, which is as expected.

Table I. Summary of propane current density data for 85% H_3PO_4 and $CF_3SO_3H \cdot H_2O$ at several potentials

Potential vs. DHE, V	85% H_3PO_4 at 135°C, μA/cm^2	$CF_3SO_3H \cdot H_2O$ at 95°C, μA/cm^2	$CF_3SO_3H \cdot H_2O$ at 115°C, μA/cm^2	$CF_3SO_3H \cdot H_2O$ at 135°C, μA/cm^2
0.4	1.4	0.68	1.3	25.0
0.5	5.3	2.8	4.5	53.0
0.6	4.7	7.2	9.4	66.0
Limiting current	5.5	24.0	16.0	82.0

At all temperatures, the limiting current values for $CF_3SO_3H \cdot H_2O$ are higher than the limiting current value for 85% H_3PO_4 at 135°C. At 115°C, the limiting current density value for the reaction of propane in the acid monohydrate appears to go through a minimum value. It is felt that there is insufficient data to state at this time that this is a true minimum. The limiting current density value at 115°C is, however, a reproducible value. The implication that a minimum exists in the limiting current density at 115°C awaits further testing at 110° and 120°C. Some experiments were run at 55°C where the system exhibited anomalous behavior on a day to day basis indicating a lower temperature limit for cell operation.

The temperature dependence of current density at 0.50V is shown in the Arrhenius-type plot of Fig. 2. This potential was chosen so as to compare the activation energy calculated for $CF_3SO_3H \cdot H_2O$ with those calculated by Cairns (2) for several inorganic acids. The value calculated for the oxidation of propane in $CF_3SO_3H \cdot H_2O$ is 13 kcal/mole as opposed to a value of approximately 16 kcal/mole for the oxidation of propane in such electrolytes as H_2SO_4, HF, H_3PO_4, and $CsCO_2$. The reasons for the decrease in activation energy are not apparent from this data; however, one of the implications of this lower activation energy is that to achieve a reaction rate of propane equivalent to that observed in $CF_3SO_3H \cdot H_2O$ at 135°C, it would be necessary to operate at a much higher temperature in 85% H_3PO_4.

Previous results in $HClO_4$, H_2SO_4, and H_3PO_4 indicate that two general classes of intermediates are formed on the electrode, one which desorbs on cathodic pulse and another which does not (2, 10). The former consists of hydrocarbon radicals or fragments. The nondesorbable class consists of a highly oxidized species, considered to be a carbon bonded to at least 1 oxygen atom, and a polymeric carbon material. Using the galvanostatic method in $CF_3SO_3H \cdot H_2O$, the anodic charging curve with propane was observed to have a single wave instead of the characteristic double wave observed in H_3PO_4. Furthermore, the total charge due to adsorbed intermediates was very low, often barely distinguishable from a charging curve under helium.

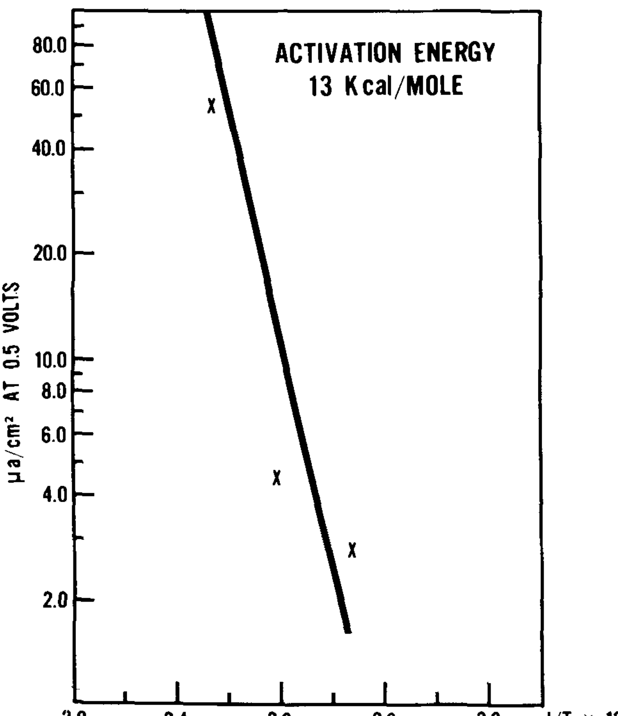

Fig. 2. Log of the current density (at an anode potential of 0.5V) as a function of reciprocal absolute temperature for the oxidation of propane on smooth platinum in $CF_3SO_3H \cdot H_2O$.

In order to determine whether the highly oxidized species could be formed on the electrode, experiments were performed using carbon dioxide as the reactant. Following potential pretreatment steps as described above, CO_2 is adsorbed on the electrode at 0.15V. The intermediate thus formed is considered to be the same as the highly oxidized species formed in the anodic oxidation of hydrocarbons in inorganic acids (14). The anodic charging curve for "reduced" CO_2 in $CF_3SO_3H \cdot H_2O$ was similar to those obtained using propane and helium. All anodic charging curves obtained in $CF_3SO_3H \cdot H_2O$ were analogous to the "reduced" CO_2 anodic charging curve in H_3PO_4 (15). These results indicate that the adsorbed polymeric carbon material formed during the oxidation of propane in H_3PO_4 is not present in the acid monohydrate. The formation of the polymeric material is considered to be an undesirable side reaction. The oxidation of propane in the acid monohydrate would appear to proceed by a more straightforward reaction path.

A single oxidation peak for propane in the acid monohydrate is indicated from results obtained from the multipulse potentiodynamic method. Whereas these results are preliminary they are reproducible. It is obvious that additional work must be performed on the adsorption of propane on smooth platinum to elucidate the mechanism of the oxidation process in the electrolyte. However, all of the results to this point suggest that the mechanism is different from that observed for propane in H_3PO_4.

An investigation of the current-potential behavior of hydrogen in $CF_3SO_3H \cdot H_2O$ could offer an additional insight into the behavior of the electrolyte. It has been previously demonstrated that higher oxidation rates are supported in acid electrolytes with lower tendencies of acid anion adsorption on platinum (4). Assuming more active sites are available for reaction, enhanced oxidation of hydrogen would be observed in the acid monohydrate. The current density-potential curves for hydrogen at a platinum electrode in phosphoric acid and at two temperatures of $CF_3SO_3H \cdot H_2O$ are shown in Fig. 3. The limiting current value in 85% H_3PO_4 at 135°C is approximately 20 $\mu A/cm^2$. The limiting current values for $CF_3SO_3H \cdot H_2O$ at 95° and 115°C are approximately 75 and 118 $\mu A/cm^2$. At a 20°C lower temperature, the oxidation of hydrogen in $CF_3SO_3H \cdot H_2O$ is almost 6 times more rapid than the reaction of hydrogen in 85% H_3PO_4 at 135°C. As is clear from the graph, at all potentials the current densities are higher at a given potential in $CF_3SO_3H \cdot H_2O$ at 115°C than in 85% H_3PO_4 at 135°C. It is significant that enhancement of the oxidation of both hydrogen and propane oxidation in $CF_3SO_3H \cdot H_2O$ as compared to 85% H_3PO_4 was observed. A possible factor in the enhancement is the reduced amount of acid anion adsorption resulting in additional active sites on the electrode as a result of a reduced amount of electrolyte adsorbed on the electrode.

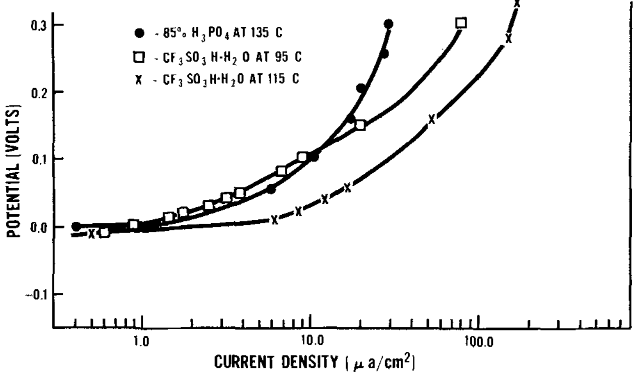

Fig. 3. Current density-potential diagram for the oxidation of hydrogen on smooth platinum in 85% H_3PO_4 at 135°C and in $CF_3SO_3H \cdot H_2O$ at 95° and 115°C.

One important consideration is the stability of the acid monohydrate, at elevated temperatures, over several weeks or months. Experiments were conducted over a 6 week period in which the limiting current density values were compared with values in freshly prepared acid monohydrate. Over the 5 week period, at 135°C, the limiting current density declined to 78 $\mu A/cm^2$, which is close to the value of 82 $\mu A/cm^2$ in freshly prepared acid monohydrate. Although over time the electrolyte developed a slightly darker appearance, it must be emphasized that there was no significant decrease in the electrochemical performance of the reaction of propane in $CF_3SO_3H \cdot H_2O$ over 6 weeks.

Vapor pressure data available indicates the electrolyte would be unsuitable for use at 150°C or above (7). By altering the chain length of the alkane group this problem may be alleviated. Increase in chain length decreases the vapor pressure. If no loss in the activity of the reaction of propane occurs, the lowering of the vapor pressure would be desirable. Fuel cell construction materials specifically designed for phosphoric acid fuel cells may not be useful in the $CF_3SO_3H \cdot H_2O$. In that case new cell materials would have to be developed.

Conclusion

Trifluoromethanesulfonic acid monohydrate increases the performance of a platinum wire electrode in the electro-oxidation of propane and hydrogen. Results with propane in $CF_3SO_3H \cdot H_2O$ indicate a different over-all process as compared to that observed in 85% H_3PO_4. Much needs to be learned about the physical characteristics, such as vapor pressure and gas solubilities, in $CF_3SO_3H \cdot H_2O$ before it can be used as an electrolyte in a practical fuel cell. However, the enhancement observed with trifluoromethanesulfonic acid monohydrate indicates that the perfluoroalkanesulfonic acids as a class of compounds are worthy of further experimentation for hydrocarbon air fuel cell use.

ABSTRACT

Transference numbers of the cations relative to the chloride ion in molten mixtures of alkali chloride-cerium chloride were determined from emf measurements on concentration cells with transference of the type

$$\begin{array}{c|c|c|c|c} (g)\ H_2, HCl - C & MCl & Al_2O_3 & MCl & C - HCl, H_2\ (g) \\ (-) & & \text{powder} & CeCl_3 & (+) \end{array}$$

where M is Li, Na, or K. The cells were operated with a mixture of hydrogen and hydrogen chloride gases instead of chlorine gas to minimize the possibility, if any, of the oxidation of cerous chloride to ceric chloride. The emf measurements were carried out at 850°C, and results are presented over the entire composition range of the systems studied. It was also shown that, in these mixtures, the alkali ions possess a relatively larger mobility than the cerous ion.

Transference properties of molten salt mixtures have been extensively studied (1, 2) in the past. However, even though a large number of these studies have been devoted to molten halide mixtures, data on the transference properties of molten alkali chloride-cerium chloride mixtures are nonexistent. In the present studies, transference numbers of cations relative to the chloride ion in molten mixtures of $LiCl$-$CeCl_3$, $NaCl$-$CeCl_3$, and KCl-$CeCl_3$ were determined from emf measurements on concentration cells with transference of the type

$$\begin{array}{c|c|c|c|c} (g)\ H_2, HCl - C & MCl & Al_2O_3 & MCl & \\ (-) & & \text{powder} & CeCl_3 & \\ & A & & B & \end{array}$$

$$C - HCl, H_2\ (g) \quad [I]$$
$$(+)$$

where M is Li, Na, or K. These cells were operated with a mixture of hydrogen and hydrogen chloride gases instead of chlorine gas to minimize the possibility, if any, of the oxidation of cerous chloride to ceric chloride. The emf method has been employed by several workers to determine the transference numbers of cations relative to common anion in mixtures of molten chlorides (3, 4), fluorides (5), and nitrates (6).

Experimental Procedure

Reagent grade chemicals (Fisher Scientific Company) were used in these experiments. Sodium and potassium chlorides were melted under vacuum, resolidified, and stored in an argon atmosphere. Lithium chloride and cerous chloride heptahydrate ($CeCl_3 \cdot 7H_2O$) were dehydrated by heating at 110°-120°C for 24 hr under a flowing atmosphere of hydrogen chloride (HCl) gas. The temperature was then raised to about 50° above the melting points of lithium chloride (610°C) and cerous chloride (822°C) and the hydrogen chloride gas bubbled for another 3-4 hr. In case of lithium chloride, the treatment with hydrogen chloride gas was followed by bubbling chlorine gas for 2-3 hr to remove the black organic impurities. The temperature was then lowered and anhydrous lithium and cerous chlorides, so obtained, were stored in an atmosphere of argon gas.

The cell design used for the emf measurements and other experimental details have been described earlier (3). Briefly stated, a 5-in. long quartz tube (25 mm diam) closed at the bottom and containing the pure alkali chloride was placed in an outer Vycor container (57 mm diam) containing the alkali chloride-cerous chloride mixture. The liquid junction between the alkali chloride and alkali chloride-cerous chloride mixture was established through a coiled quartz tubing (6 mm diam) filled with predried powdered alumina (Grade T-61, 120 mesh, Aluminum Company of America). The mole fraction of the alkali chloride in the mixture was varied from 0 to 0.9 by the addition of weighed amounts of purified alkali chloride. The powdered alumina was found ideal for these experiments since it not only prevented any gravitational flow from one side to the other but also was inert to any cation exchange that usually occurs (3) between the alkali chlorides and the commonly employed quartz frit membranes.

Spectrochemical grade carbon rods (Ultra Carbon Company) were used as the electrodes. The hydrogen and hydrogen chloride gases were used directly from the cylinders. A wire-wound cylindrical furnace was used to heat the cell assembly and the temperature of the cell controlled within ±2°C with a Guardsman-West temperature controller. The emf measurements were made with a Leeds and Northrup K-5 potentiometer.

Results and Discussion

Designating the alkali ion (M^+), cerous ion (Ce^{+++}), and chloride ion (Cl^-) as ions 1, 2, 3, respectively, the emf of cell I is given by (3, 7)

$$E_{\text{cell}} = -\frac{1}{\mathbf{F}}\int_A^B t_{13} d\mu_{\text{MCl}} - \frac{1}{3\mathbf{F}}\int_A^B t_{23} d\mu_{\text{CeCl}_3} \quad [1]$$

where **F** is the Faraday constant and μ_{MCl} and μ_{CeCl_3} are, respectively, the chemical potentials of alkali chloride and cerous chloride. The transference numbers (t_{13} and t_{23}) of the alkali ion (cation 1) and cerous ion (cation 2) are defined relative to the chloride ion (anion 3) and are related to each other by the equation

* Electrochemical Society Active Member.

Key words: alkali chloride-cerium chloride mixtures, concentration cells with transference, emf measurements, molten salt mixtures, transference numbers.

$$t_{13} + t_{23} = 1 \quad [2]$$

Equation [1] can be simplified (4) and rewritten as

$$E_{cell} = -\frac{2.303\,RT}{\mathbf{F}} \int_{A}^{B} \frac{t_{13} - x'_{13}}{1 - x'_{13}}\, d \log a_{MCl} \quad [3]$$

where x'_{13} and a_{MCl} are, respectively, the equivalent fraction and activity of the alkali chloride in the mixture; R and T have their usual thermodynamic significance. The equivalent fraction (x'_{13}) is related to the mole fraction (x_{13}) by the equation

$$x'_{13} = \frac{x_{13}}{3 - 2x_{13}} \quad [4]$$

Partially differentiating Eq. [3] with respect to $\log a_{MCl}$, we have

$$\left(\frac{\partial E_{cell}}{\partial \log a_{MCl}}\right)_{B} = -\frac{2.303\,RT}{\mathbf{F}} \left(\frac{t_{13} - x'_{13}}{1 - x'_{13}}\right)_{B} \quad [5]$$

Since the activities of alkali chlorides in molten mixtures of alkali chloride-cerium chloride are known (8), the term on the left side of Eq. [5] can be obtained by graphical differentiation of E_{cell} *vs.* $\log a_{MCl}$ plots. The transference number of the alkali ion (t_{13}) relative to the chloride ion can then be obtained by use of Eq. [5]. The transference number of the cerous ion (t_{23}) relative to the chloride ion, by definition, is given by Eq. [2].

At a given composition of the molten salt mixture, the transference numbers of the cations (t_{13} and t_{23}) relative to the chloride ion are related (2) to their respective mobilities by the equations

$$b_{13} = \frac{t_{13}\lambda}{x'_{13}\mathbf{F}} \quad [6]$$

and

$$b_{23} = \frac{t_{23}\lambda}{x'_{23}\mathbf{F}} \quad [7]$$

where b_{13} and b_{23} are, respectively, the mobilities of the alkali ion (M^+) and cerous ion (Ce^{+++}) relative to the chloride ion; x'_{13} and x'_{23} are the corresponding equivalent fractions of the alkali chloride and cerium chloride in the mixture; and λ is the equivalent conductance of the molten salt mixture. Since no conductivity measurements have been reported in the literature for the alkali chloride-cerium chloride mixtures, the cation mobilities (b_{13} and b_{23}) cannot be calculated from the transference number data alone. It is, however, possible to calculate cation mobility ratios from the transference numbers. Thus, combining Eq. [6] and [7], we have

$$\frac{b_{13}}{b_{23}} = \frac{t_{13}\, x'_{23}}{t_{23}\, x'_{13}} \quad [8]$$

The mobility of the alkali ion relative to the cerous ion (b_{12}) is similarly obtained by combining Eq. [6] and [7]. Thus

$$b_{12} = b_{13} - b_{23} = \left(\frac{t_{13}}{x'_{13}} - \frac{t_{23}}{x'_{23}}\right)\frac{\lambda}{\mathbf{F}} \quad [9]$$

Since by definition, $t_{23} = 1 - t_{13}$ and $x'_{23} = 1 - x'_{13}$, Eq. [9] can be simplified as

$$b_{12} = b_{13} - b_{23} = \left(\frac{t_{13} - x'_{13}}{x'_{13}\, x'_{23}}\right)\frac{\lambda}{\mathbf{F}} \quad [10]$$

The emf measurements on the molten salt mixtures $LiCl$-$CeCl_3$, $NaCl$-$CeCl_3$, and KCl-$CeCl_3$ were carried out at 850°C over the entire composition range of the mixtures. These data are summarized in Table I. The activities of the alkali chlorides in these mixtures are known (8) at 825°C. Assuming that the excess free energies of mixing remain constant as the temperature is increased from 825° to 850°C, the activities were recalculated at 850°C and are also summarized in Table I.

* From Ref. (8).

In an effort to determine the magnitude of "liquid junction potential" between pure molten potassium chloride and cerium chloride, Bronstein (9) measured the emf of the cell

C, Cl_2 (–) | KCl | Vycor glass | KCl | quartz frit | $CeCl_3$ | Cl_2, C (+) [II]

At 850°C, the emf of cell [II] was found to be 0.600V. This value is considerably higher than the value of 0.236V obtained in the present studies employing cell [I] where MCl now refers to KCl and mole fraction of KCl in the right-hand half-cell is zero. The higher emf in cell [II] may be due to exchange of K^+ from the melt with the quartz frit so that over a period of time, the quartz frit would behave as a K^+ conductive membrane. This explanation seems plausible in view of the value of 0.572V obtained by Egan (8) for cell [III] at 825°C.

(g) H_2, HCl – C (–) | KCl | K^+ glass | 10 mole % KCl, 90 mole % $CeCl_3$ | C-HCl, H_2 (g) (+) [III]

Behl and Egan (3) noticed a similar exchange of Li^+ from the melt with a quartz frit in their experiments with the system $LiCl$-$PbCl_2$. The alumina powder used to establish the liquid junction in cell [I] was found to be inert (3) toward any exchange with alkali ions from the melt.

The plots of E_{cell} *vs.* $\log a_{MCl}$ based on data presented in Table I for the molten salt mixtures $LiCl$-$CeCl_3$, $NaCl$-$CeCl_3$, and KCl-$CeCl_3$ are, respectively, shown in Fig. 1-3. From these plots, the term $(\partial E_{cell}/\partial \log a_{MCl})$ was determined at various mole fractions by graphical differentiation and substituted in Eq. [5] to obtain the transference numbers of the alkali ions (t_{13}) relative to the chloride ion. The transference numbers of the cerous ions (t_{23}) were then determined by use of Eq. [2]. These data are summarized in Table II.

The transference numbers (t_{13}) of alkali ions relative to the chloride ion in mixtures of molten alkali

* x_{13} = mole fraction; x'_{13} = equivalent fraction.

chloride-cerium chloride were found to be greater than the equivalent fraction (x'_{13}) of the alkali chloride in the mixture over the entire composition range. If $t_{13} = x'_{13}$ over the whole composition range of the mixture, it can be seen from Eq. [3] that the emf of cell [I] would be zero over the whole composition range of mixtures. Examples of such behavior have been reported in literature for the systems $AgNO_3$-$NaNO_3$ (10) and NaCl-KCl (3). Further, in such cases, Eq. [10] predicts that the cation mobilities b_{13} and b_{23} would be identical over the whole composition range.

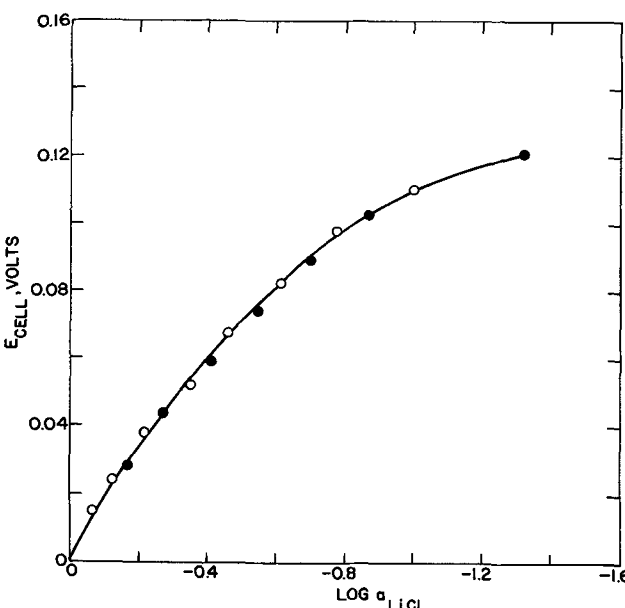

Fig. 1. E_{cell} vs. log a_{LiCl} plot for the system $LiCl-CeCl_3$. Open and closed circles represent data of two separate experiments.

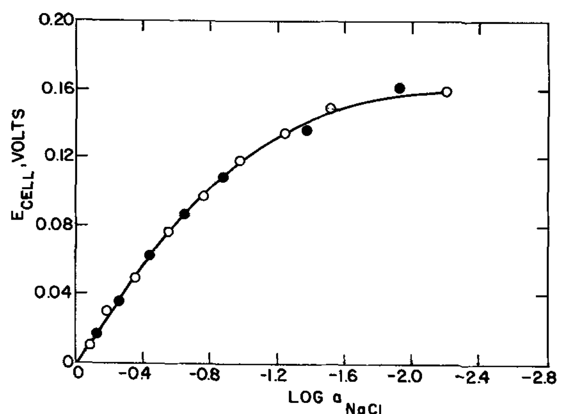

Fig. 2. E_{cell} vs. log a_{NaCl} plot for the system $NaCl-CeCl_3$. Open and closed circles represent data of two separate experiments.

This has been experimentally demonstrated in the case of the system $AgNO_3$-$NaNO_3$ (11). Since $t_{13} > x_{13}$ over the whole composition range of the alkali chloride-cerium chloride mixtures, it can be seen from Eq. [10] that the alkali ions possess relatively higher mobilities than the cerous ion over the entire range of composition of these mixtures. Plots of the term ($t_{13} - x'_{13}$) *vs.* x'_{13} for the systems $LiCl-CeCl_3$, $NaCl-CeCl_3$, and $KCl-CeCl_3$ are presented in Fig. 4. There is close similarity in behavior of the three systems. The cation mobility ratio (b_{13}/b_{23}) in alkali chloride-cerium chloride mixtures was also determined by use of Eq. [8] over the whole composition range, and the data are summarized in Table II. The mobility (b_{13}) of the alkali ion relative to the chloride ion was found to be much greater than the mobility (b_{23}) of the cerous ion relative to the chloride ion. These results are not surprising in view of the smaller equivalent conductance (12) of pure cerium chloride as compared to the equivalent conductances (12) of pure alkali chlorides. The mobilities of the alkali ions in the systems $KCl-PbCl_2$ (13), $LiCl-PbCl_2$ (14), $KCl-CaCl_2$ (3), $KCl-MgCl_2$ (3), and $LiCl-CdCl_2$ (4) have also been found to be greater than the mobilities of the second cation in the mixture by a similar order of magnitude over most of the composition range of the mixtures.

Summary and Conclusions

The emf method was employed to determine the transference numbers of the cations relative to the chloride ion in molten mixtures of $LiCl-CeCl_3$, $NaCl-CeCl_3$, and $KCl-CeCl_3$ at 850°C. Even though the individual cation mobilities relative to the chloride ion in these mixtures could not be calculated due to the absence of any conductance data, it was possible to

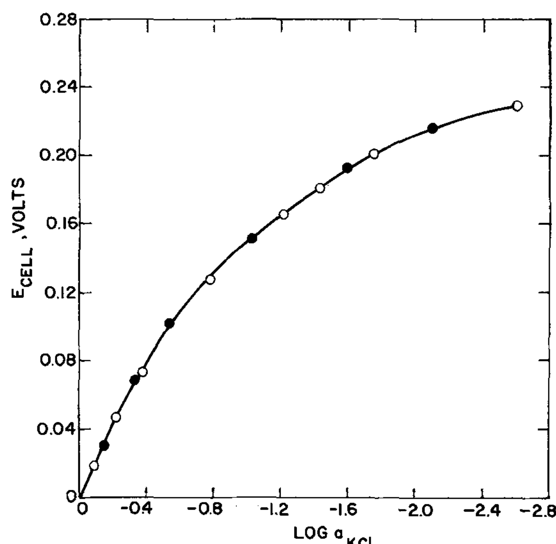

Fig. 3. E_{cell} vs. log a_{KCl} plot for the system $KCl-CeCl_3$. Open and closed circles represent data of two separate experiments.

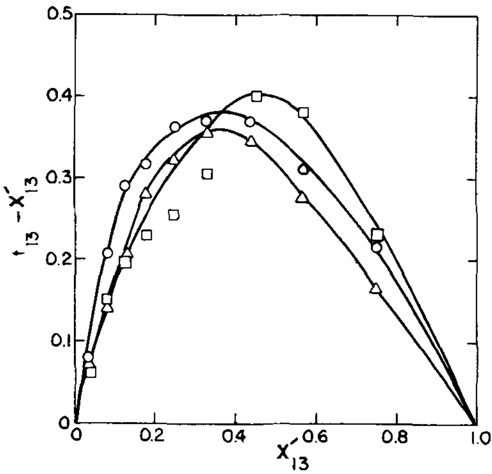

Fig. 4. (t_{13} — x'_{13}) vs. x'_{13} plots for the systems LiCl-$CeCl_3$ (○), NaCl-$CeCl_3$ (△), and KCl-$CeCl_3$ (□).

show that the alkali ions possessed relatively larger mobility than the cerous ion over the whole composition range of the mixtures.

Acknowledgment

The author would like to thank Dr. J. J. Egan, Brookhaven National Laboratory, Upton, New York, for making available the thermodynamic data on alkali chloride-cerium chloride mixtures and for many helpful suggestions.

Manuscript submitted Oct. 25, 1973; revised manuscript received March 6, 1974. This was Paper 269 presented at the Chicago, Illinois, Meeting of the Society, May 13-18, 1973.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1975 JOURNAL. All discussions for the June 1975 Discussion Section should be submitted by Feb. 1, 1975.

ABSTRACT

Kinetic parameters of the deposition-dissolution process for solid alkali metals in alkali metal chloride-$AlCl_3$-propylene carbonate solution were evaluated using micropolarization measurements at 25°C. The exchange current densities were evaluated at different molalities of the alkali metal chlorides, and the cathodic transfer coefficients were calculated from the concentration dependence.

Interest in nonaqueous high energy batteries is reflected in an increasing number of investigations concerning the electrochemical behavior of active metals in nonaqueous solvents. So far very few investigations have reached the stage of evaluating kinetic parameters of the charge transfer process. The feasibility of electrodeposition of all the alkali metals from the corresponding solutions of the alkali metal chlorides in $AlCl_3$-propylene carbonate has been demonstrated (1). Lithium, sodium, potassium, rubidium, and cesium were deposited at ambient temperature, showing stable and reversible behavior. The alkali metal chlorides are practically insoluble in PC, however in the presence of $AlCl_3$, a complex is formed between the chloride and $AlCl_3$ according to the reaction

$$MCl + AlCl_3 = M^+ + AlCl_4^- \quad [1]$$

where M represents the alkali metal. This reaction is responsible for high solubility and conductivity of all the alkali metal halides in PC; it allows the study of the electrochemical behavior of alkali metals with a common anion species.

In the present work, kinetic parameters of the deposition-dissolution process for solid alkali metals in alkali metal chloride-$AlCl_3$-PC solutions have been evaluated using micropolarization measurements at 25°C. The micropolarization experiments were conducted over a range of alkali metal chloride molalities (0.01-1.0*M*) in constant unit molality solutions of $AlCl_3$ in PC.

Key words: electrode kinetics, alkali metals, propylene carbonate, exchange current density, transfer coefficient.

Previous Work

Despite the increasing interest in dissolution-deposition processes in nonaqueous solutions, few investigations dealt directly with the kinetics of the electrode process. Moreover, most of the literature dealt exclusively with lithium systems. Although the work of Harris and Tobias (2) included deposition tests of active metals from cyclic esters, these were mostly qualitative in nature and did not reach the stage of systematic kinetic measurements.

The electron transfer kinetics of Li/Li^+ reaction in PC was studied by several laboratories. Burrows and Jasinski (3) measured the exchange current density of Li(s) in 1M $LiClO_4$-PC at 28°C, using micropolarization measurements. However, the reported exchange current density appears too low (0.0275 mA/cm^2), probably due to the inclusion of an ohmic drop in the potential measurements. Meibuhr (4) measured the exchange currents of lithium in different $LiClO_4$ concentrations in PC, at temperatures up to 70°C. At 28°C, for 1M $LiClO_4$-PC solution, the exchange current, i_o = 0.95 mA/cm^2, and the transfer coefficient, $\alpha = 0.67$, were calculated from the linear polarization curves and from the concentration dependence of the exchange current. The solution was stirred by bubbling argon, and the ohmic drop was excluded using a pulse technique. The Nernstian behavior of the lithium electrode was confirmed by concentration cells. The enthalpy of solvation at zero polarization was estimated as 8.5 kcal/mole, and the reaction order was one, which reaffirmed the assumption that the charge transfer was the rate-determining step. In a second article, Meibuhr (5) studied the anion effect on the electrode kinetics of Li/Li^+ in PC. The exchange currents for unit molarity solutions of $LiAlCl_4$, $LiPF_6$, and $LiBF_4$ are 0.40, 0.29, and 0.5 mA/cm^2, respectively. The transfer coefficient for $LiAlCl_4$ was $\alpha = 0.8$. The water content of the solutions had a major influence on the electrode performance. Scarr (6) measured the kinetics of lithium electrode in different concentrations of $LiClO_4$ in PC. Film formation and two levels of activity were observed, depending on the pretreatment of the electrode. The film was broken at high currents. The exchange current density of a film-free electrode in 1M $LiClO_4$ PC solution is 1.78 ± 0.33 mA/cm^2. Generally, good agreement was found between Meibuhr's and Scarr's results, which are complementary, since Scarr worked at moderately high currents, while Meibuhr's work is restricted to the zone of linear current-potential dependence. Butler, Cogley, and Synnot (7) studied the aging effect on the kinetics of lithium in $LiClO_4$ solution in PC. Even when the solvent was quite "dry" (<0.001*M* H_2O), the exchange current dropped from 10.2 mA/cm^2 at 1 sec after the exposure of the freshly cut lithium surface, to 1.6 mA/cm^2 after 1 hr. The effect of water was also dramatic; the presence of 0.02*M* H_2O reduced the exchange current to 0.026 mA/cm^2 after 1 hr. It seems that most measurements were taken on aged surfaces; the exchange currents of fresh surfaces may have no practical meaning. The effect of water content on the behavior of lithium electrodes in $LiClO_4$ (8, 9) showed that LiOH was formed on the electrode during the deposition of lithium from $LiClO_4$ solution in PC.

The anodic polarization of lithium in 1.0*M* $AlCl_3$ PC solution was investigated by Jackson and Blomgren (10), using an interrupter and a constant load pulse technique. Severe polarization of the concentration type was observed, which could be caused by the formation of LiCl layer during the anodic discharge. Sufficient stirring removed the product which dissolved in $AlCl_3$ solution and eliminated the concentration polarization.

In a study of the anodic behavior of sodium in $NaClO_4$ PC solution, Meibuhr (11) reports that the exchange current depends strongly on the Na^+ concentration. At 1M $NaClO_4$ and at 19°C, the exchange current was 0.21 mA/cm^2.

The behavior of lithium in related solvents is reported in several papers. The electrochemical behavior of Li in solutions of $LiClO_4$, KPF_6, and of KCNS in ethylene carbonate was reported by Pistoia *et al.* (12, 13). Ethylene carbonate was proposed as a superior solvent for high energy batteries due to its higher conductance and lower viscosity, and due to the better anodic polarization characteristics found for Li in $LiClO_4$-EC solution.

The kinetics of Li(Hg) in LiCl solution in DMSO was reported by Cogley and Butler (14, 15). The Tafel equation with cathodic transfer coefficient α = 0.75 was obeyed over the current density range of 10^{-5} to 3×10^{-3} A/cm^2. The exchange currents were in the order of 0.1-1.0 mA/cm^2.

Tiedemann and Bennion (22) compared their kinetic measurements of Li in dimethyl sulfite to similar measurements in PC, however it should be kept in mind that their measurements were performed in different solvent, and medium effects must be considered as partly responsible for the higher exchange currents in dimethyl sulfite; the effect of the medium on the electrode kinetics is discussed in detail by Jorné (1).

Experimental

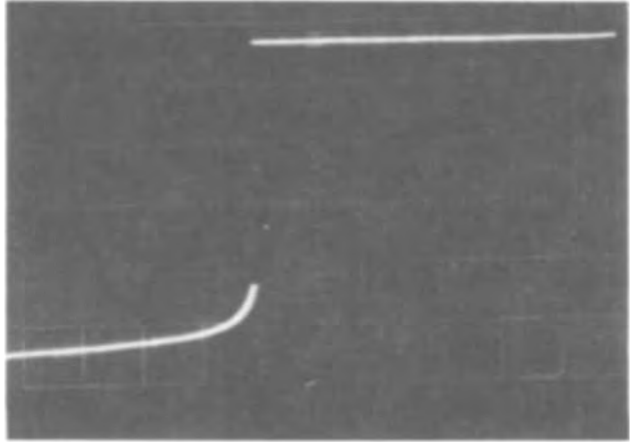
The micropolarization measurements of the alkali metals were performed in the same six-compartment cell where the cell potentials were measured (1, 16). The galvanostatic experiments were conducted between two alkali metal electrodes where the central one served as the working electrode. The central working electrode was prepared in the glove box by sealing an approximately 5 cm long portion of a bright alkali metal wire in epoxy resin. The end of the wire, not sealed in epoxy resin, was used for an electrical contact by attaching it to an alligator clip. The other end of the coated wire was cut at a right angle to the wire to expose the bright alkali metal surface with an area equal to the cross-sectional area of the wire. The other alkali metal electrodes were simply the original bright wires. Alkali metals react slowly with epoxy resin. The polarization experiments were performed within a few hours after the exposure and no signs of reaction between the metals and the resin were observed throughout the measurements. In addition, the small bias potentials between the coated and uncoated electrodes (1) indicate this effect to be negligible. In the case of rubidium and cesium, the working electrodes, as well as the counterelectrodes, were prepared by pouring the molten metals into the cup electrodes (1, 16). The solutions were stirred during the micropolarization experiments by a small magnetic stirrer at the bottom of the central cell, just under the electrode's surface. The stirring was somewhat less efficient in the cases of Rb and Cs because the stirrer was underneath the cup, while the active surface of the electrode was facing upward. The small currents employed insured that concentration overpotentials were negligible, even in the cases of Rb and Cs.

Preanodization was found necessary to obtain reproducible results. The standard procedure was to anodize the working electrode for 10 min at a current density of 0.1 mA/cm^2 prior to each micropolarization cycle. The potential was measured between the central working electrode and one of the two Tl(Hg)/TlCl reference electrodes. The current was increased first in the anodic direction, then back toward the cathodic direction, then back to the equilibrium state. The current was applied by a constant current power supply, Model C 612 Electronic Measurements, and was measured by a Keithley 601 Electrometer. The potential was measured by an AC/DC Differential Voltmeter (John Fluke Model 887-A). The cells were suspended in constant temperature baths at 25° and 35°C ± 0.01°C. The preparation of the electrodes and the assembly of the cells have been described previously (1, 16). Propylene carbonate (Jefferson Chemical Company, Hous-

ton, Texas) was distilled in a low pressure distillation column packed with stainless steel helices; the reflux ratio was 60 to 100; and the head temperature was 65°C. The solutions were treated with molecular sieves 4A. This treatment increased the stability of the alkali metals in the solutions. Gas chromatographic analysis showed the water content to be always below 50 ppm. All operations were conducted inside the argon glove box (1, 16). Addition of $AlCl_3$ to PC results in violent reaction, accompanied by high heat of solution and darkening of the solution. This was avoided by adding the alkali metal chloride first, then adding the $AlCl_3$ very slowly while cooling the solution with a cooling mixture of chloroform-carbon tetrachloride-dry CO_2 (1). Solutions prepared in this way were almost colorless. The stability of the solutions increased as the ratio of the alkali metal chloride to $AlCl_3$ molalities approached unity.

Because of the relatively low conductivity of the solutions (10^{-3}-10^{-2} ohm^{-1}-cm^{-1}), it was necessary to correct the overpotentials for ohmic drop between the working electrode and the tip of the reference electrode's connection. The ohmic drop was determined by a rapid current interrupter technique, in which the constant current was interrupted, and the potential was traced on a fast oscilloscope. The immediate drop in the potential was the *IR* drop, and the ohmic resistance was calculated by dividing it by the total current. The ohmic drop was then subtracted from the total overpotential. Rectangular wave form pulses were derived from an E. M. Test Pulser, Lawrence Berkeley Laboratory. The potentials were observed on a Tektronix Oscilloscope, and the potential trace was analyzed from the polaroid prints. The oscilloscope was operating at 0.01-1.0 msec/cm and 50-200 mV/cm. The ohmic drop was determined at four different currents for each cell, both in anodic and cathodic directions. The currents employed during the pulse measurements were higher than the currents employed during the micropolarization experiments, and it has been assumed that the current distribution remained unchanged. Typical oscilloscope traces of the potential during current interruptions both in the cathodic and the anodic directions, are presented in Fig. 1. Currents were in the order of 0.1-1.0 mA, and the calculated ohmic resistances were in the order of 100-300 ohms. The calculated resistance from the four measurements agreed within 10%.

The polarization experiments were conducted at different alkali metal chloride molalities in $AlCl_3$ (1*M*)-PC solution and 25°C.



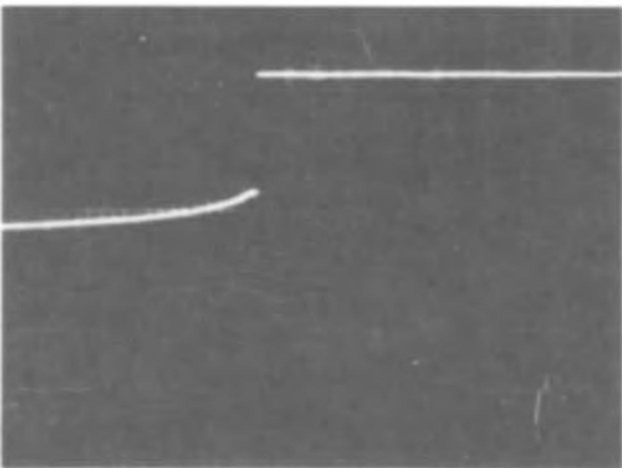


Fig. 1. *IR* drop determination in the six-compartment cell using a current interrupter technique. Rb/RbCl(0.10*M*) in $AlCl_3$(1.0*M*)-PC at 25°C. Top, cathodic current, $I = 1.0$ mA; bottom, anodic current, $I = 0.5$ mA. Vertical scale, 50 mV/cm; horizontal scale, 1 msec/cm.

Results

Micropolarization of the alkali metals in their chloride solutions in $AlCl_3$ (1M)-PC.—Micropolarizations of the alkali metals in different molalities of alkali metal chlorides in $AlCl_3$ (1*M*)-PC solution are presented in Fig. 2-6. The temperature was held constant at 25° ± 0.01°C. The overpotentials are *IR* free, and the ohmic drop was estimated from the current interrupter technique. At low overpotentials, linear behavior was observed for all the metals; deviation from linearity was observed at potentials above approximately 50 mV, where the nonlinear Tafel behavior became appreciable.

The exchange current densities were calculated from the slopes of the linear polarizations, assuming single electron charge transfer controlled mechanism according to the equation

$$i_a^o = \frac{1}{A}\frac{RT}{\mathbf{F}}\frac{\partial i}{\partial \eta_{i=0}} \quad [2]$$

and the results are presented in each figure (Fig. 2-6).

Enthalpy of activation at zero polarization.—Micropolarizations of the lithium electrode in different LiCl concentrations in $AlCl_3$ (1*M*)-PC were performed at three different temperatures: 25°, 30°, and 35°C. Fig-

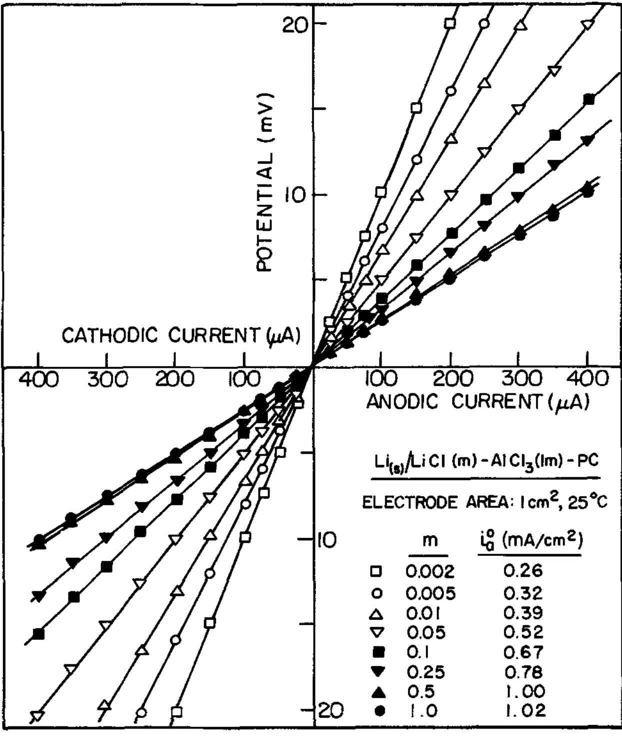

Fig. 2. Micropolarization of Li(s)/LiCl(*M*) in $AlCl_3$(1*M*)-PC solution.

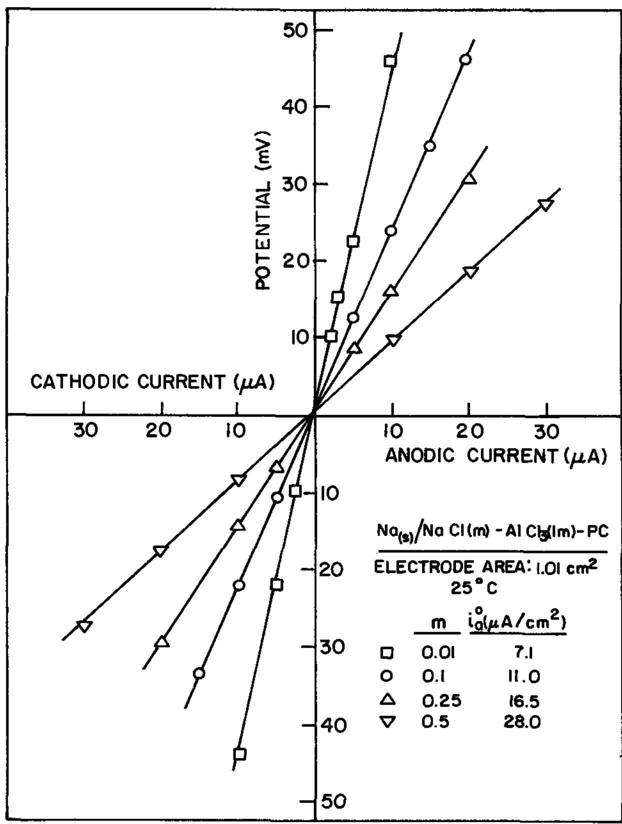

Fig. 3. Micropolarization of Na(s)/NaCl(M) in $AlCl_3$(1M)-PC solution.

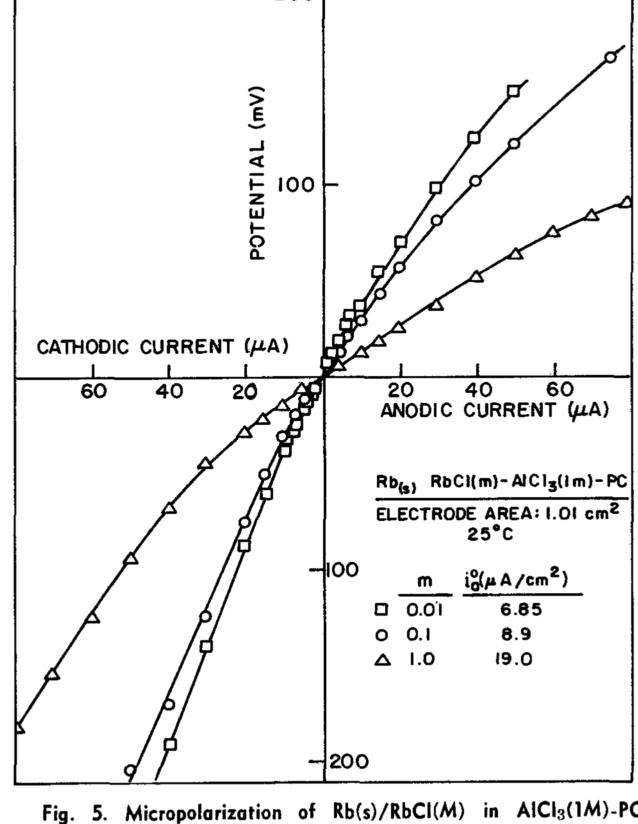

Fig. 5. Micropolarization of Rb(s)/RbCl(M) in $AlCl_3$(1M)-PC solution.

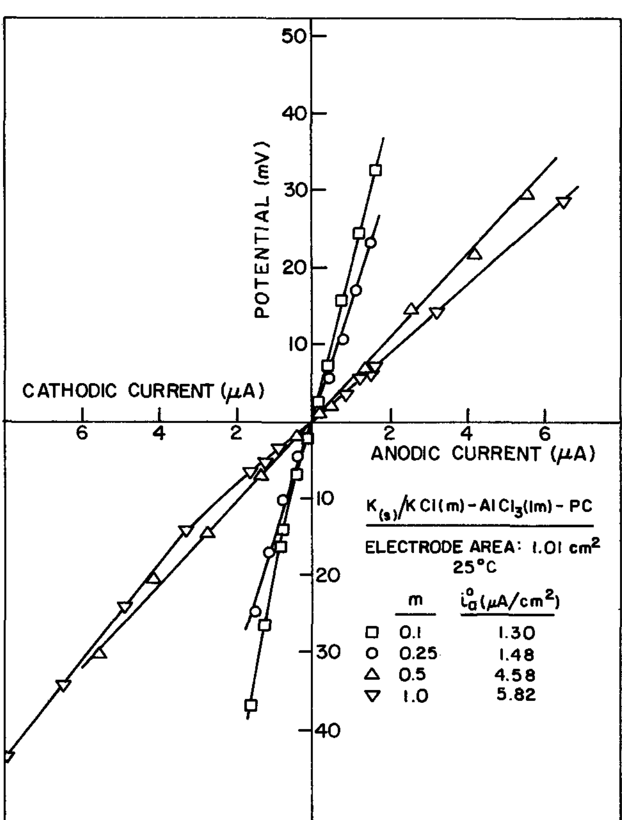

Fig. 4. Micropolarization of K(s)/KCl(M) in $AlCl_3$(1M)-PC solution.

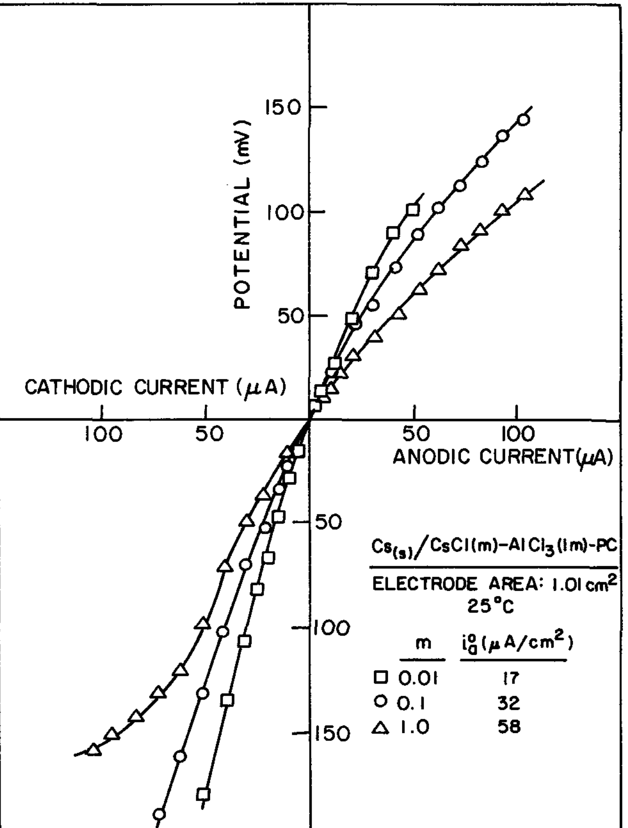

Fig. 6. Micropolarization of Cs(s)/CsCl(M) in $AlCl_3$(1M)-PC solution.

ure 7 presents the plot of the apparent exchange current densities, i_a^o, *vs.* $1/T$ for the various LiCl molalities. The slopes of the lines are about equal, and the average enthalpy of activation at zero polarization was calculated as

$$\Delta H_o^* = -R \frac{\partial \ln i_a^o}{\partial (1/T)} = 8.6 \text{ kcal/mole} \quad [3]$$

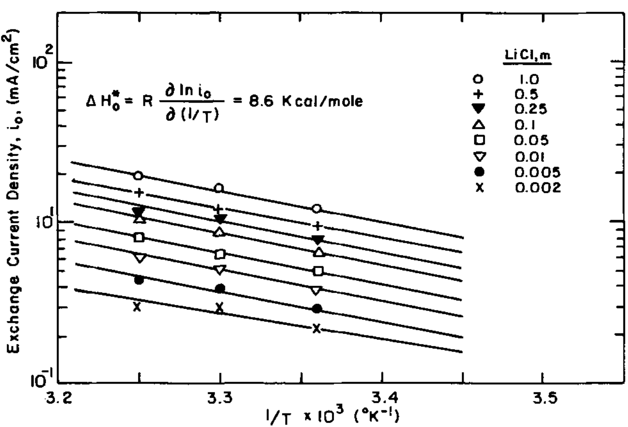

Fig. 7. Determination of the enthalpy of activation at zero polarization for Li/LiCl(M) in $AlCl_3$(1M)-PC solution.

The value of $\Delta H_o{}^*$ is within the order of magnitude expected for soft metals. A similar value of 7.1 kcal/mole was obtained for the sodium electrode in $NaClO_4$ solution in PC (1).

The micropolarization behavior of a cesium electrode in $CsAlCl_4$ (0.25M) solution in PC is presented in Fig. 8. The plot of $i_a{}^o$ *vs.* $1/T$ is presented in Fig. 9, from which the enthalpy of activation at zero polarization is 10.4 kcal/mole. A somewhat lower exchange current density was obtained for the Cs electrode at 23.5°C. At this temperature cesium is solid, while the other temperatures employed are above the melting point of cesium, *i.e.*, 28.5°C.

Discussion

Micropolarizations of the alkali metals in alkali metal chloride solutions in $AlCl_3$ (1*M*)-PC were presented in Fig. 2-6. The apparent exchange current densities were calculated from the slopes at the point of zero current. A linear behavior can be observed for all

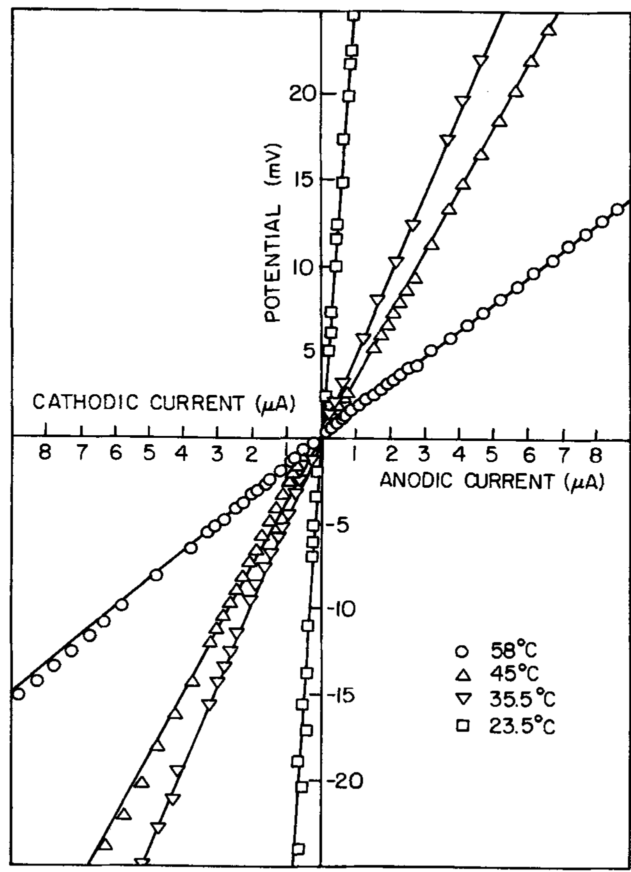

Fig. 8. Micropolarization of Cs(s)/$CsAlCl_4$(0.25M) in PC

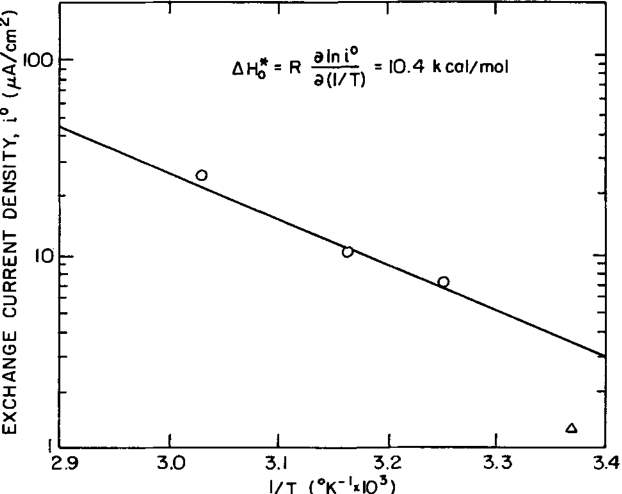

Fig. 9. Determination of the enthalpy of activation at zero polarization of Cs(s)/$CsAlCl_4$(0.25M), PC. ○, Liquid Cs; Δ, solid Cs.

the alkali metals over a wide range of alkali metal chloride concentrations. Using a low current and moderate stirring ensured the elimination of concentration overpotential. The apparent exchange current densities were not corrected for the nonuniform current densities across the surface of the electrodes. The influence of the nonuniformity of the current across the electrode is discussed in the Appendix, where it is shown that, despite relatively low conductivities, this correction is negligible for the present case, because of low exchange current densities.

The comparison of the magnitude of the exchange currents to corresponding values in the literature is restricted to the lithium system, because no information is available for the rest of the alkali metals. The exchange current density of Li in $LiAlCl_4$ (1*M*), according to the present results, is 1.02, 1.5, and 2.0 mA/cm² at 25°, 30°, and 35°C, respectively. These values are in general agreement with the exchange currents of 0.40, 1.05, 1.49, and 2.35 mA/cm² reported by Meibuhr (5) for $LiAlCl_4$ (1M) at 19°, 35°, 46°, and 55°C, respectively. A plot of the exchange current densities *vs.* $1/T$ is presented in Fig. 7, and the calculated enthalpy of activation at zero polarization, $\Delta H_o{}^* = 8.6$ kcal/mole, is in agreement with an enthalpy of 6.4 kcal/mole, reported by Meibuhr (5). Kinetic measurements of Li in $LiClO_4$ solutions in PC were performed by Meibuhr (4) and Scarr (6). The exchange current densities in $LiClO_4$ (1M) solution were 0.95, 1.8, 3.4, and 5.25 mA/cm² at 28°, 43°, 58°, and 67.5°C, respectively (4), and 1.78 mA/cm² at 23°C (6). The i^o values for $LiClO_4$ solution in PC are of the same order of magnitude as those obtained here for $LiAlCl_4$. Butler *et al.* (7) found that the current density changes significantly during the first few minutes after the preparation of a clean fresh Li surface. However, all earlier experiments, as well as the present ones, were performed on aged surfaces, which is a more practical condition. Preanodization of the surface was necessary to obtain reproducible results. It is not clear whether this procedure removes adsorbed impurities or breaks an insulating film on the electrode. Scarr (6) reports two levels of activities of Li electrode in $LiClO_4$ solution in PC, depending on the pretreatment of the surface, and the lower level of activity was associated with film formation.

The exchange current densities for the rest of the alkali metals are lower than those for Li. The wide differences in the exchange currents in the alkali metal series are discussed in detail elsewhere (1), where the medium effect and the influence of the individual ionic energetics on the electrode kinetics is discussed with regard to the behavior of the alkali metal amalgams.

The free energies of transfer of the alkali metal ions from water to $AlCl_3$-PC solution are: −0.6, −4.2, −4.7, −3.1, and −5.0 kcal/mole for Li^+, Na^+, K^+, Rb^+, and Cs^+, respectively (1). A large negative free energy of transfer means that the ion is on a low energy level, strongly solvated, and as a result, the exchange current density is low. The low exchange current densities of some of the alkali metals might also be the result of their reactivity toward impurities, water traces, and possibly the solvent itself. This is especially true for potassium, which showed reactivity toward PC solutions which had not been treated with molecular sieves.

The exchange current density of a Na electrode in NaCl(0.5*M*) solution in $AlCl_3$ (1*M*)-PC is 28 $\mu A/cm^2$ at 25°C, which can be compared qualitatively to a value of 12 $\mu A/cm^2$ for a Na electrode in $NaClO_4$(0.5M) solution in PC at 19°C (11).

The reported exchange current densities are subjected to the influence of the films formed due to the inherent reactivity of the alkali metals with PC. Film formation was observed on Li electrodes in PC (6, 23).

The transfer coefficients of the electrochemical reaction at the alkali metal electrode interface can be calculated from the dependence of the exchange current density on the concentration of the reduced ion (19, 20)

$$1 - \alpha_c = \frac{\partial \log i_a^o}{\partial \log m_{M^+}} \quad [4]$$

where α_c is the cathodic transfer coefficient. Figure 10 presents the plot of log i_a^o *vs.* log m_{MCl} for all the alkali metals, as well as the calculated α_c. The cathodic transfer coefficient for Li is $\alpha_c = 0.75$, in agreement with $\alpha_c = 0.8$ reported for $LiAlCl_4$ in PC, and α_c = 0.62-0.72 for $LiClO_4$ in PC (4-6). The lithium system was further investigated at three different temperatures, 25°, 30°, and 35°C. The plots of log i_a^o *vs.* log m_{LiCl} at the three temperatures are presented in Fig. 11, and the parallel lines show that the transfer coefficient does not change over this temperature range. An average $\alpha_c = 0.75 \pm 0.05$ was calculated for the three temperatures.

The behavior of the alkali metals in the Tafel region should be investigated in the future. Cyclic polarizations were obtained for K. Rb, and Cs and are covering the Tafel region (1). Although the polarizations include the ohmic drop between the working and the reference electrode, Tafel behavior can nevertheless be observed qualitatively in some of these figures. It is believed that the exchange currents in this region are higher than the values obtained in the micropolarization experiments because of continuous renewal of the active surface and the breakage of possible film formation at high deposition or dissolution rates.

APPENDIX

Nonuniform Current Distribution and Ohmic Drop Effects in Micropolarization Measurements

Under nonuniform current density conditions, the exchange current, i^o, determined from the linear polarization, depends on the location of the reference electrode, because the measured overpotential is related to the local current density which differs from the average current density. The correction can be obtained by solving the secondary current distribution subjected to a boundary condition of linear polarization. The present analysis follows the treatment of Tiedemann, Newman, and Bennion (21) concerning the error in measurements of electrode kinetics caused by nonuniform ohmic potential drop to a disk electrode.

The correction for the apparent exchange current $i^o/i^o_{apparent}$ was solved for the general arbitrary location of the reference electrode (21), and is plotted against J

$$J = (\alpha_a + \alpha_c) \frac{F r_0 i^o}{RT\kappa_\infty}$$

J represents, in a way, the throwing power of the system.

The exchange current densities reported in the present work are the apparent ones; however, the corrections are negligible. Considering the extreme conditions, $r = 0.5$ cm, $\kappa_\infty = 5 \times 10^{-3}$ ohm^{-1}-cm^{-1}, $i^o = 1.0$ mA/cm^2, and assuming $(\alpha_c + \alpha_a) = 1$, we can estimate the largest possible J for the present systems to be

$$J = 4$$

Since the reference electrodes were located far away from the disk electrode, the correction, according to curve B in Fig. 1 (21) is about $i^o/i^o_{apparent} = 1.1$, which

is negligible, especially since the errors in the exchange current values are probably more than 10%. It should be mentioned here that the extreme conditions given above were realistic only for the lithium system. For the rest of the alkali metals the exchange current densities are ten times lower, and the conductivities are somewhat higher, both resulting in lower J, and the correction is probably in the order of 1%.

ABSTRACT

The mass transfer of a dilute species in a liquid in a propagating crack is treated. The analysis includes the effect of convective flow of the liquid. The results of the calculations show that the crack tip is devoid of the minor species, and that the mass flux of this component is also negligible in this region. Therefore, minor components could not behave as "critical" species in such systems. Calculation of the flux distribution allowed the determination of the potential distribution in the crack.

The failure of structural materials such as metals and their alloys by stress corrosion cracking is a complex phenomenon which involves the interplay of metallurgical, mechanical, and enviromental influences. For an alloy of a particular metallurgical condition in a constant environment, the crack propagation may be investigated as a function of stress intensity,[1] a mechanical variable. It is generally found for titanium and aluminum alloys (1-3) that the rate of crack extension is dependent on the stress intensity at low stress levels but becomes independent of the stress intensity at higher levels. Several workers (4-6) have suggested that the process limiting the crack growth rate at high stress intensities is related to mass transfer of components in the environment. "Cavitation" caused by limitations on the fluid flow in a propagating crack could also limit the cracking rate, as discussed recently (7).

The alloy titanium-8% aluminum-1% molybdenum-1% vanadium has been found to be susceptible to stress corrosion cracking in molten LiCl-KCl eutectic (8). A plateau velocity of 1 cm/sec was observed at high stress intensities, and the crack extension rates were a function of stress intensity at lower stress intensities. The presence of the plateau velocity could not be explained by cavitation (7), so the possible role of mass transfer has been investigated. Possible species which could limit the rate of crack extension in the molten salt environment are Li^+, K^+, or some impurity such as H_2O (or OH^-). The first two are ruled out by the dependence of the cracking rate on electrical potential (8, 9). Water was present in the commercial eutectic material at about 1 ppm (reported as OH^-), and the SCC tests were carried out under potential conditions

* Electrochemical Society Active Member.

Key words: stress corrosion cracking, molten salt, corrosion, convective diffusion.

[1] The stress intensity is related to the stress, flaw size, and specimen geometry for materials which obey the laws of linear elastic fracture mechanics (1, 2).

where water was reacting at mass transfer limited rates. However, when additional water was deliberately added to the melt, the crack velocity was unchanged. The water concentration could not be varied over wide limits because of limited solubility, so the tests were not as conclusive as one would like. Therefore, the mathematical treatment of the mass transfer of dissolved water to a crack tip was studied, and the present contribution presents the results of that study.

The rate of electrode reactions in electrolytic systems is influenced by activation, ohmic, and concentration effects. The activation and ohmic influences are dominant at low currents and high concentrations of reacting species, and the interplay between the two determine the distribution of current in the system. In situations where the concentration of the reacting species becomes depleted at the electrode, the rate of reaction and current distribution on the electrode are determined by the relative accessibility of various parts of the surface to mass transfer of the reacting component. Even if the surface is uniformly accessible to mass transfer, the potential distribution near the electrode may be nonuniform. Variations in the electrical potential along the surface may lead to discharge of other species besides the one under mass transfer control. Nonuniform potential distributions would be important in systems where the electrode is large and where there are two or more electroactive species in solution. Of particular interest in the present study is the potential distribution associated with the mass transfer behavior in the crack and its possible role in determining the distribution of other (anodic dissolution) reactions within the crack.

Model

The physical model to be treated here is sketched in Fig. 1. The crack is wedge shaped, with a geometrically sharp tip, and extends through the thickness of the material. The coordinate system moves with the crack tip, so that the sides of the crack appear to move with the velocity V (1 cm/sec for LiCl-KCl) away from the tip. The flow pattern of the liquid has been determined from a treatment of the fluid mechanics of the system (7) and is shown also in this figure. The assumption is adopted here that these velocity profiles are not changed by the mass transfer processes which we are considering. This is justified by the small concentration of the species of interest and may be checked by using the results which are obtained below. This inclusion of convective effects on mass transfer has not been considered previously for stress corrosion calculations.

The steady-state velocity profiles in the liquid were found to be (7), for a small crack angle, $2\theta_w$

$$v_r = -\frac{V}{2}\left\{1 - 3\frac{\theta^2}{\theta_w^2}\right\} \quad \text{(radial component)} \quad [1]$$

$$v_\theta = \frac{V\theta}{2}\left\{1 - \frac{\theta^2}{\theta_w^2}\right\} \quad \text{(angular component)} \quad [2]$$

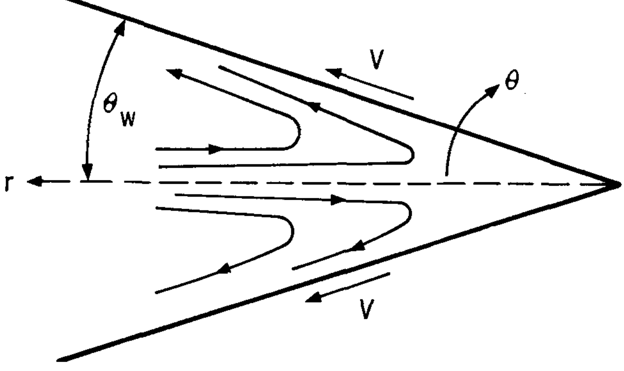

Fig. 1. Fluid flow in a propagating crack

These relationships are valid near the crack tip and out to distances from the crack tip of

$$r = O\left(47\frac{\nu}{\theta_w^2 V}\right)$$

where the notation O ( ) denotes "order of magnitude of." With the physical properties of molten LiCl-KCl[2] and a crack angle, $2\theta_w$, of 10^{-2} radians, this amounts to

$$r = O(10^{+3}\text{ cm})$$

At greater distances from the crack tip, inertial and pressure forces determine the fluid flow characteristics, except near the crack walls where viscous forces are also important. We shall not be interested in such large distances from the crack tip except for completeness. Also, seepage of liquid in from the sides of the crack for plates of finite thickness becomes important at distances from the crack tip where the thickness is of the same order as $\theta_w r$.

The equation of convective diffusion for this system is, at steady state

$$v_r\frac{\partial c}{\partial r} + \frac{v_\theta}{r}\frac{\partial c}{\partial \theta} = D\left(\frac{\partial^2 c}{\partial r^2} + \frac{1}{r}\frac{\partial c}{\partial r} + \frac{1}{r^2}\frac{\partial^2 c}{\partial \theta^2}\right) \quad [3]$$

where c = concentration, D = diffusion coefficient, and v_r, v_θ are given in Ref. (1) and (2).

The boundary conditions are

$$c = 0 \text{ at crack wall} \quad [4]$$

$$c \rightarrow c_\infty \text{ at } \theta = 0,\ r \rightarrow \infty \quad [5]$$

An auxiliary condition is

$$\frac{\partial c}{\partial \theta} = 0 \text{ at } \theta = 0 \quad [6]$$

since by symmetry there is no transfer of material across the crack center line. Equation [3] is valid for uncharged species, or for charged species where migration effects are not important. Migration makes no substantial contribution to Eq. [3] for our case because the concentration of any minor species is small as compared to that of K^+, Li^+, and Cl^-. The boundary conditions are appropriate when the species, H_2O, is being consumed (reduced) at limiting current. Since most of the stress corrosion tests have been carried out under potentiostatic conditions, almost to the lithium deposition potential, this is justified. We are also assuming that the discharge of water does not introduce a passive film on the surface which would change the discharge characteristics. Titanium displays no passivation characteristics in the molten salt, so this assumption may be reasonable.

Mathematical Treatment

For cracks of small angle, the θ-dimension can be scaled accordingly, and the distance from the crack tip can be made dimensionless in such a way that different regions of mass transfer are revealed.

Introduction of the new variables

$$\theta^* = (\theta/\theta_w)$$

$$r^* = \frac{rV}{D}(\theta_w)^2$$

into Eq. [3] yields

$$-\frac{1}{2}(1 - 3\theta^{*2})\frac{\partial c}{\partial r^*} + \frac{1}{2}\theta^*\frac{(1-\theta^{*2})}{r^*}\frac{\partial c}{\partial \theta^*} = \frac{1}{r^{*2}}\frac{\partial^2 c}{\partial \theta^{*2}} + \theta_w^2\left(\frac{\partial^2 c}{\partial r^{*2}} + \frac{1}{r^*}\frac{\partial c}{\partial r^*}\right) \quad [7]$$

The last two terms, which contain the contribution of radial diffusion, may be discarded except for very small

[2] The viscosity, ν, of molten LiCl-KCl at 375°C is 1.33 × 10^9 cm^2/sec. The velocity, v, of cracking in the plateau is 1 cm/sec.

values of r^*. All the other terms are of order unity, but these two terms are of order θ_w^2 or 10^{-4} for r^* of order unity. Since appreciable mass transfer occurs only at larger values of r^*, we neglect these radial diffusion terms in the remainder of this work.

The radial convection term (first term on the left) and the angular diffusion term (first term on the right) are the most important terms for r^* of order unity. The second term on the left (angular convection) will become important at larger values of r^*. Attempting a separation of variables on the two dominant terms leads one to expect a solution of the form

$$c \sim \frac{e^{-K/r^*}}{r^{*s}} f(\theta^*)$$

where K is the separation constant and f is a function to be determined. The expectation that the angular convection term would become important at larger values of r^* suggests that additional terms could be added to this solution in the form

$$c \sim \frac{e^{-K/r^*}}{r^{*s}} f_0(\theta^*) + r^* \frac{e^{-K/r^*}}{r^{*s}} f_1(\theta^*) + r^{*2} \frac{e^{-K/r^*}}{r^{*s}} f_2(\theta^*) + \ldots .$$

The equation for the concentration can be recognized as an ordinary perturbation expansion for the solution of Eq. [7]. We are finally led to adopt the form

$$c = \frac{e^{-K/r^*}}{r^{*1/2}} \sum_{n=0} (r^*)^n f_n(\theta^*) \qquad [8]$$

where K is a constant and the f_n's are functions to be determined. Substitution into the equation of convective diffusion gives

$$f_0'' + \frac{1}{2}(1 - 3\theta^{*2}) K f_0 = 0$$

$$f_0 = 0 \text{ at } \theta^* = 1,\ f_0' = 0 \text{ at } \theta^* = 0 \qquad [9]$$

K is an eigenvalue and f_0 is arbitrarily set equal to 1 at $\theta^* = 0$. For $n = 1, 2, 3, \cdots$

$$f_n'' + \frac{1}{2}(1 - 3\theta^{*2}) K f_n = \frac{1}{2}\theta^*(1 - \theta^{*2}) f'_{n-1} - \frac{1}{2}(1 - 3\theta^{*2})(n - 3/2) f_{n-1} = g_n \qquad [10]$$

With this form for c, the neglected radial diffusion terms become of the same order as the retained terms when r^* is of order θ_w. The solution to Eq. [9] is

$$f_0 = a_0 \left\{ \left(\frac{3K}{2}\right)^{1/8} e^{-\frac{1}{2}\sqrt{\frac{3K}{2}}\theta^{*2}} {}_1F_1 \left[\frac{\sqrt{\frac{3K}{2}} - \frac{K}{2}}{4\sqrt{\frac{3K}{2}}}, \frac{1}{2}, \sqrt{\frac{3K}{2}}\theta^{*2} \right] \right\} \qquad [11]$$

where ${}_1F_1(b, d, x)$ is the confluent hypergeometric function. The function has a series form (10)

$${}_1F_1(b, d, x) = 1 + \frac{b}{d}x + \frac{b(b+1)}{2!d(d+1)}x^2 + \ldots \qquad [12]$$

K is chosen such that

$$f_0 = 0 \text{ at } \theta^* = 1$$

$$(i.e.,\ {}_1F_1 = 0 \text{ at } \theta^* = 1) \qquad [13]$$

Also, a_0 is chosen arbitrarily so that

$$f_0 = 1 \text{ at } \theta^* = 0$$

The solution will be renormalized by "matching" with the outer diffusion layer solution (see below).

For the solution to the nonhomogeneous equation

$$f_n'' + \frac{1}{2}(1 - 3\theta^{*2}) K f_n = g_n$$

we try[3]

$$f_n = h_0(\theta^*) \int_0^{\theta^*} g_n f_0(\theta^*) d\theta - f_0(\theta^*) \int_0^{\theta^*} g_n h_0(\theta^*) d\theta + B_n f_0(\theta^*) \qquad [14]$$

Since f_0 is an eigensolution of the homogeneous equation, a solution is possible only if

$$\int_0^1 g_n f_0 d\theta = 0$$

This is true for $n = 1$, and it is this requirement that dictates the power s of r^* in the leading term of the solution in Eq. [8]. The value of B_n in the above solution must be selected to meet the requirement

$$\int_0^1 g_{n+1} f_0 d\theta = 0$$

Although Eq. [12] provides an analytic solution to Eq. [9] for each eigenvalue K, it is not in a convenient form for the calculation of the higher f_n's. From Eq. [13] it is also difficult to determine the eigenvalues accurately, but it does allow one to estimate the eigenvalues. Therefore, a numerical technique discussed by Newman (11) was used for the calculation of eigenvalues and eigenfunctions. This then allowed the numerical integration of the ordinary, inhomogeneous, linear, second order differential Eq. [10] for the f_n's. The eigenvalues so obtained were checked by using condition of Eq. [13].

The equation for f_0, Eq. [9], is an ordinary, homogeneous, second order differential equation. It is nonlinear, however, since K is unknown. A second differential equation is introduced

$$\frac{dK}{d\theta^*} = 0 \qquad [15]$$

and both f_0 and K are unknowns. Equations [9] and [15] are a nonlinear system of two, coupled, ordinary differential equations with boundary conditions

$$f_0 = 0 \text{ at } \theta^* = 1$$
$$f_0 = 1 \text{ at } \theta^* = 0$$
$$f_0' = 0 \text{ at } \theta^* = 0$$

The equations can be linearized about a trial solution, producing a series of coupled, linear differential equations. In finite difference form these give coupled, tridiagonal matrices which can be solved on a high speed, digital computer. The nonlinear problem can then be solved by iteration [see Newman (12)].

The solution for f_n is then determined numerically by evaluating the integrals in Eq. [14]. The linearly independent solution for the homogeneous Eq. [9] was actually determined by finite difference methods but with different boundary conditions from those used for f_0.

The mass flux to the walls is determined from the derivatives of the f's at the wall.

The results of these calculations are shown on Fig. 2 and Table I. In Fig. 2, only the first three f's are plotted although the first nine were used to calculate the concentration profiles. f_0 has a rather simple behavior,

[3] Here $h_0 = f_0(\theta^*) \int_0^{\theta^*} \frac{d\theta^*}{f_0^2(\theta^*)}$ is a second solution of the homogeneous equation.

Table I. Derivates of the f_n's at the wall ($\theta = 1$)

$f_0' = -1.0830$
$f_1' = -0.07550$
$f_2' = -8.866 \times 10^{-4}$
$f_3' = +1.744 \times 10^{-5}$
$f_4' = -3.297 \times 10^{-7}$
$f_5' = +1.335 \times 10^{-8}$
$f_6' = -6.893 \times 10^{-10}$
$f_7' = +4.501 \times 10^{-11}$
$f_8' = -3.455 \times 10^{-12}$

beginning at the value of 1 at the crack centerline and decreasing to 0 at the wall. The higher terms have a more complicated behavior. For small values of r^*, the first term in the series (Eq. [8]) is dominant and involves only f_0. For larger r^*, the higher terms become important and serve to give a concentration profile which shows the greatest change near the wall. This is shown in Fig. 3 for two different values of r^*. At the largest value of r^* ($r^* = 20$), the concentration profile is compared to that calculated from the boundary layer results (next section) to demonstrate how well the two agree. More is said about this later.

In Fig. 4 is shown the concentration profile down the crack centerline. From these results it is seen that at $r^* = 0(1)$ the concentration is already very small, and by the time r^* becomes of the order of θ_w, where the radial diffusion terms become important in Eq. [7], c/c_∞ is of the order of 10^{-347}.

These calculations were made for the first eigenvalue, K_0, where

$$K_0 = 7.65902$$

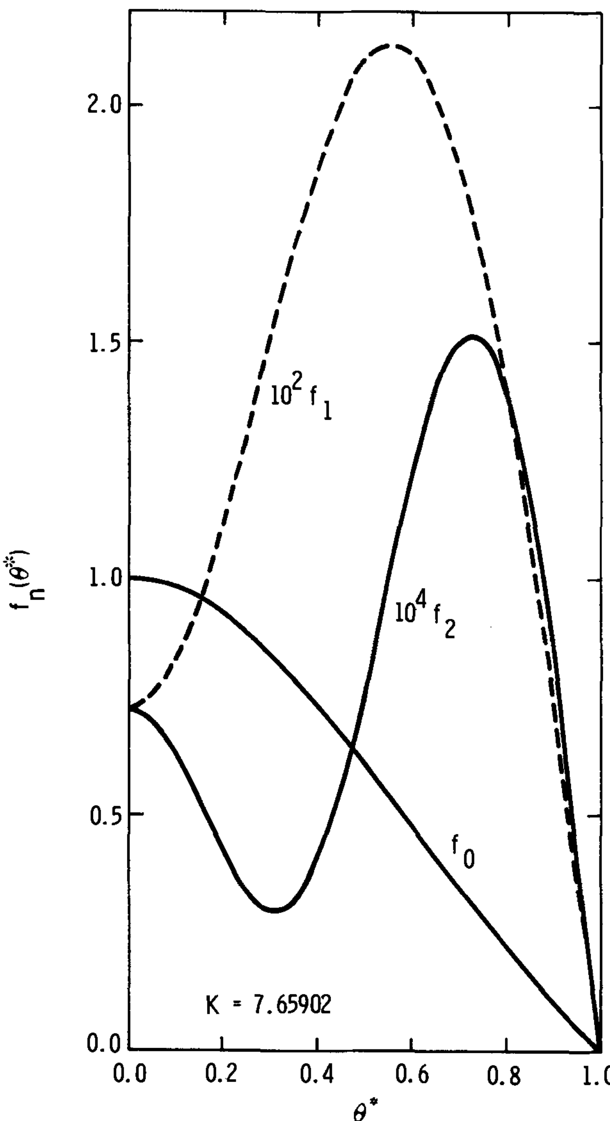

Fig. 2. $f_n(\theta^*)$ for first eigenvalue

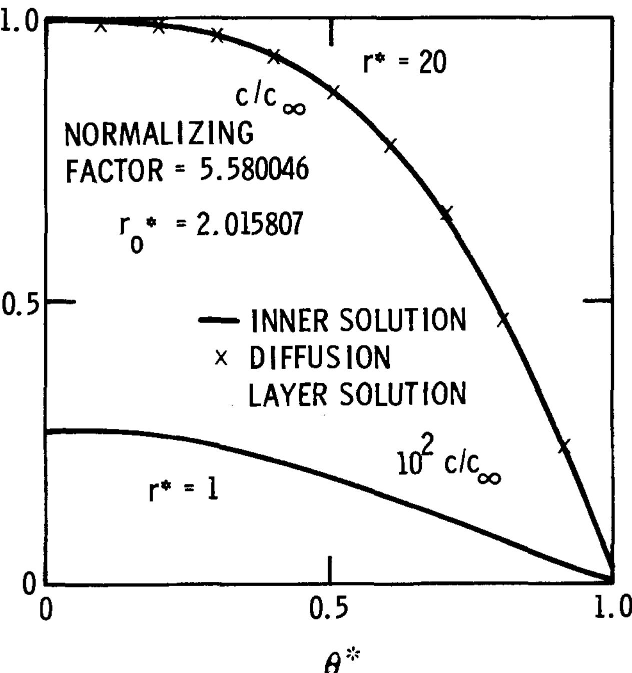

Fig. 3. Concentration profiles across crack

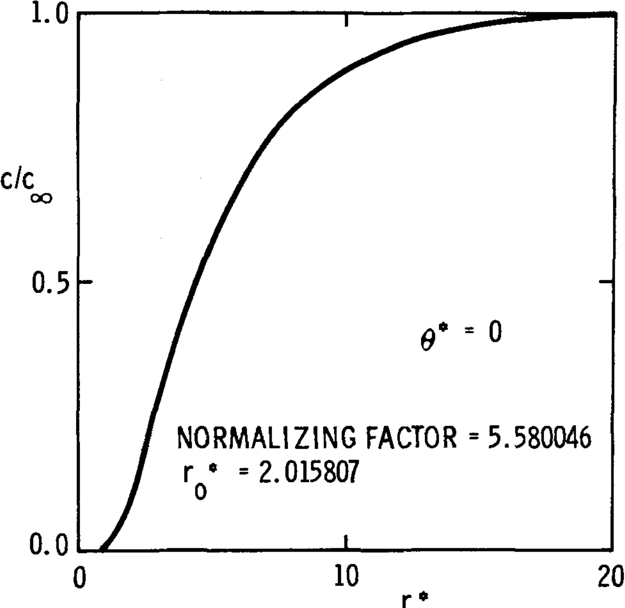

Fig. 4. Concentration profile along crack centerline

The next higher eigenvalue was found to be

$$K_1 = 150.03633$$

The complete solution would be expected to be a linear combination of the eigensolutions with the associated eigenvalues. Since the solution for K_1 could not be matched with the boundary layer region, and the associated concentration profiles across the crack showed an oscillatory behavior, with the concentration even becoming negative, the contribution of this solution to the complete solution must be negligible. Higher eigenvalues and eigensolutions were expected to show similar behavior and therefore were ignored. The lowest solution was judged to be quite adequate for matching all the boundary conditions.

Diffusion layer region.—For large values of r^*, the concentration profile showed the greatest variation near the crack wall, and the concentration approached a constant value near the crack centerline. The boundary layer type behavior leads one to search for such

a region which would describe the asymptotic characteristics of the region just examined for large values of r^*.

Adopt the variables

$$r^* = r^*$$
$$y = r^*(1 - \theta^*)$$

Introducing these variables into Eq. [7] and ignoring the radial diffusion terms, we have

$$-\frac{1}{2}\left\{-2 + \frac{6y}{r^*} - 3\left(\frac{y}{r^*}\right)^2\right\}\frac{\partial c}{\partial r^*} - \frac{1}{2}\left\{3\left(\frac{y}{r^*}\right)^2 - 2\left(\frac{y}{r^*}\right)^3\right\}\frac{\partial c}{\partial y} = \frac{\partial^2 c}{\partial y^2} \quad [16]$$

Now, terms of order y/r^* and higher are neglected to yield

$$\frac{\partial c}{\partial r^*} = \frac{\partial^2 c}{\partial y^2} \quad [17]$$

with boundary conditions

$$c = 0 \text{ at } y = 0$$
$$c = c_\infty \text{ as } y \to \infty$$

Implicit in these assumptions is the expectation that most of the concentration variation will occur near the wall in this region. Also, the second boundary condition above expresses that the concentration approaches a constant far from the crack wall, and that this constant is the bulk concentration.

Since this is a diffusion layer region, we try a similarity transformation of Eq. [17]. The similarity variable is

$$\eta = \frac{y}{g(r^*)}$$

and Eq. [17] is transformed into two ordinary differential equations

$$\frac{d^2c}{d\eta^2} + 2\eta\frac{dc}{d\eta} = 0 \quad [18]$$

$$g\frac{dg}{dr^*} = 2 \quad [19]$$

The solutions to these equations are

$$c = \frac{2c_\infty}{\sqrt{\pi}}\int_0^\eta e^{-x^2}dx = c_\infty \operatorname{erf}(\eta) \quad [20]$$

$$g = (4r^* + 4r_o^*)^{1/2} \quad [21]$$

Equation [20] is the error function solution which is commonly encountered in diffusion layer problems and is tabulated by Abramowitz and Stegun (13). The constant r_o^* in Eq. [21] may be arbitrarily chosen to give the best "match" with the solution from the region where $r^* = 0(1)$ [see, for example, Van Dyke (14)].

The concentration profile given by Eq. [20] has been shown already in Fig. 3. The comparison there indicates that the diffusion layer solution provides a good description of the asymptotic behavior of Eq. [8] for values of r^* of about 20 and above.

In Fig. 5 the flux to the wall is plotted as a function of r^*. The solid line was calculated from the solution obtained in the $r^* = 0(1)$ region. The dotted line was calculated from the diffusion layer results. There is a good match for values of r^* greater than about 10. This could be viewed as the inner limit of validity of the diffusion layer results. One also notes that for $r^* = 0(1)$, the flux has decreased markedly to near zero. For $r^* = 0(\theta_w)$, the flux is so small as to be insignificant.

Matching of results.—Figures 3 and 5 indicate that the results from the two regions agree and may be "matched." The procedure for doing this was as follows. It was noted that the concentration along the crack centerline approached an asymptotic value as r^* approached 20 (see Fig. 4), which was the bulk concentration, c_∞. Both sides of Eq. [8] were divided by c_∞ to produce a dimensionless equation. Using $c/c_\infty \to 1$ as $r^* \to 20\,(\theta^* = 0)$, one may renormalize the equation (essentially renormalize f_o at $\theta^* = 0$). The normalization factor was found to be 5.580046. The renormalized Eq. [8] is then

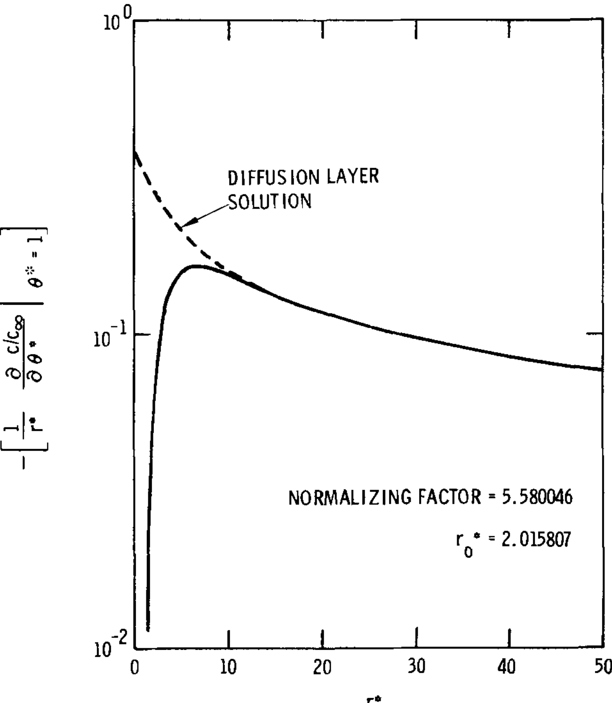

Fig. 5. Flux to the wall

$$c/c_\infty = \frac{e^{-K_o/r^*}}{r^{*1/2}} N \sum_{n=0}^{\infty} (r^*)^n f_n(\theta^*) \quad [22]$$

where $N = 5.580046$. Equation [22] was then used to calculate the concentration profile across the crack. The agreement between the inner region and the diffusion layer region was good at large r^*. It was found that the match could be improved, however, by choosing a value of r_o^* (see Eq. [21]) of

$$r_o^* = 2.015807$$

The results have been given in Fig. 3 and 5. The justification for choosing r_o^* to give the best match has been discussed by Van Dyke (14). Thus, Eq. [8] gives an adequate description of the results for $\theta_w < r^* \leq 20$. The diffusion layer solution should be used for larger values of r^*.

Other regions.—Far from the crack tip, outside the diffusion layer, the concentration is constant and is identical to the bulk concentration. That is, there is no effect of diffusion in this region and no other mechanism to create concentration differences.

For values of r^* of the order of θ_w, all terms in Eq. [7] are important. The concentration and flux to the wall have already decreased to such a low level that one can ignore them for the purposes of this paper. For $r^* = O(\theta_w)$

$$r = O\left(\frac{D}{\theta_w V}\right) = O(10^{-3}\,\text{cm})$$

At still smaller values of r^*, *i.e.*, $r^* = O(\theta_w^2)$ or $r^* \approx 10^{-5}$ cm, only the diffusion terms are important in Eq. [7]. Here again, the exceedingly small values of concentration and flux make this region unimportant for the present treatment.

Potential Distribution in the Crack

The results of the flux distribution calculation can be used to evaluate the potential distribution in the system. We start with the equation for the divergence of the current

$$\frac{\partial}{\partial r}(ri_r) + \frac{\partial}{\partial \theta}(i_\theta) = 0 \qquad [23]$$

since there is no buildup of charge anywhere. Integration of this equation with respect to θ, from 0 to θ_w, yields

$$\int_0^{\theta_w}\left[\frac{\partial}{\partial r}(ri_r)\right]d\theta + i_\theta \Big|_{\theta=\theta_w} = 0$$

If we introduce

$$-\kappa\frac{\partial \phi}{\partial r} = \kappa i_r$$

where κ is the conductivity, and assume that variations of potential are predominantly radial

$$-\frac{\partial}{\partial r}\left(r\frac{\partial \phi}{\partial r}\right)\kappa\theta_w + i_\theta\Big|_{\theta=\theta_w} = 0 \qquad [24]$$

The current and flux to the wall are related by

$$i_\theta\Big|_{\theta=\theta_w} = -\frac{n\mathbf{F}D}{r}\frac{\partial c}{\partial \theta}\Big|_{\theta=\theta_w}$$

This is appropriate for either of the reactions

$$OH^- + e^- \rightarrow \tfrac{1}{2}H_2 + O^{-2}$$

or

$$H_2O + e^- \rightarrow \tfrac{1}{2}H_2 + OH^-$$

Equation [24] becomes

$$-\frac{\partial}{\partial r}\left(r\frac{\partial \phi}{\partial r}\right)\kappa\theta_w - \frac{n\mathbf{F}D}{r}\frac{\partial c}{\partial \theta}\Big|_{\theta=\theta_w} = 0 \qquad [25]$$

The potential may now be calculated from the flux distribution by determining $\frac{\partial c}{\partial \theta}\Big|_{\theta=\theta_w}$ from Eq. [22] or [20]. Since both equations are written in terms of r^* and θ^*, we write Eq. [25] as

$$-\frac{\partial}{\partial r^*}\left(r^*\frac{\partial \phi}{\partial r^*}\right)\kappa\theta_w - \frac{n\mathbf{F}Dc_\infty}{r^*\theta_w}\frac{\partial(c/c_\infty)}{\partial \theta^*}\Big|_{\theta^*=1} = 0$$

Integration twice with respect to r^* yields

$$\phi_{r^*} - \phi_0 = \frac{n\mathbf{F}Dc_\infty}{\kappa\theta_w^2}\int_0^{r^*}\frac{1}{r^*}\int_0^{r^*}\frac{1}{r^*}\frac{\partial(c/c_\infty)}{\partial \theta^*}\Big|_{\theta^*=1}dr^*dr^* \qquad [26]$$

Introduction of Eq. [22] into [26] gives

$$\phi_{r^*} - \phi_0 = -\frac{n\mathbf{F}Dc_\infty N}{\kappa\theta_w^2}\sum_{n=0}^{\infty}\int_0^{r^*}\frac{1}{r^*}\int_0^{r^*}\frac{e^{-K_0/r^*}}{4^{*3/2}}(r^*)^n f_n'(\theta^*=1)dr^*dr^* \qquad [27]$$

A similar equation may be written for the potential variation in the diffusion layer region.

The potential variation in the solution for $1 \leq r^* < 20$ was calculated from Eq. [27] by numerical Simpson integration. For the diffusion layer region, the integration could be carried out directly to obtain an analytic result. The results of these calculations are shown in Fig. 6. In the region between the crack tip and $r^* \simeq 1$, there is negligible current flow and therefore a negligible potential variation. Larger current flow in the outer regions of the crack cause larger potential differences in the solution. The potential difference between two points would be directly proportional to the bulk concentration of the reactant and inversely proportional to the square of the crack angle.

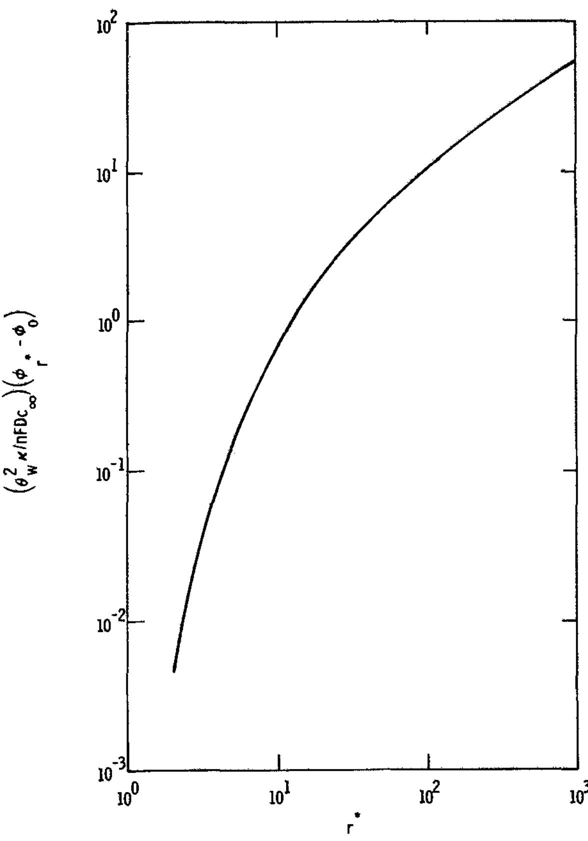

Fig. 6. Potential as a function of distance from the crack tip

The calculation of the potential drop down a crack for a specific system may be helpful. We shall calculate the total potential drop down the crack. The outer limit of the validity of the model is where seepage of liquid in from the sides becomes important. For a specimen 1 cm thick, seepage becomes important where the thickness is of the same order as $\theta_w r$. Therefore

$$r = 1/\theta_w = 2 \times 10^2\,\text{cm}$$

where $2\theta_w$ is 10^{-2} radians. Since

$$r^* = r\left(\frac{V}{D}\theta_w^2\right)$$

then introduction of the velocity of cracking (1 cm/sec) and a diffusion coefficient of 10^{-5} cm²/sec, yields

$$r^* = 500$$

The total potential difference between this point and the crack tip is

$$(\phi_{500} - \phi_0)\frac{\kappa\theta_w^2}{n\mathbf{F}Dc_\infty} = 33.9$$

For $c_\infty = 8.2 \times 10^{-8}$ moles/cm³ (*i.e.*, 1, ppm weight); $\kappa = 1.2$ mho/cm [ref. (15)]; $\mathbf{F} = 9.65 \times 10^4$ coulombs/equiv; $n = 1$; $D = 10^{-5}$ cm²/sec; $\theta_w^2 = 0.25 \times 10^{-4}$; and $\phi_{500} - \phi_0 = 890$ mV. In order to have a potential drop of this magnitude over a crack length of 1 cm, the concentration would have to be larger by about 200, or the crack angle would have to be smaller by an order of magnitude.

Summary

As a summary, Fig. 7 indicates the different regions that have been revealed in this investigation and the different modes of mass transfer in them. Again, for

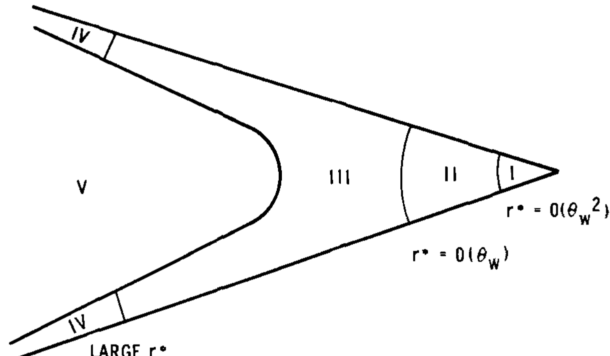

Fig. 7. Regions of mass transfer. Region I, diffusion only; region II, all terms important; region III, radial diffusion negligible; region IV, radial convection, angular diffusion; region V, concentration constant.

distances nearer the crack tip than 10^{-3} cm, the solution is essentially devoid of the reactive species, and their flux is also negligible.

Conclusions

From the results of this study, it may be concluded that minor components being consumed in a crack at rates limited by mass transfer have vanishingly small concentrations near the crack tip. In addition, the flux or minor components is extremely small in the crack tip region. It is unlikely that such species would be important as critical species in crack extension processes. More specifically, small amounts of OH^- H_2O, or O_2 dissolved in molten LiCl-KCl cannot be critical species in the cracking of Ti 8-1-1.

Figure 7 contains information which should be useful for other systems. For example, Ti 8-1-1 is susceptible to cracking in aqueous halide solutions (1) with crack velocities which range from 10^{-3} to 10^{-1} cm/sec. Aluminum alloys crack in aqueous solutions (2) with velocities between 10^{-8} and 10^{-3} cm/sec. Beck and Grens (5) have presented a model for SCC in aqueous solutions which neglects convective effects. The Beck-Grens model would therefore be appropriate for describing events in the crack tip region only (region I in Fig. 7). The size of region I for aqueous solutions would be (*i*) for titanium alloys

$$r^*_{\mathrm{I}} = O(\theta_w^2) = \frac{rV\theta_w^2}{D}$$

and

$$r_{\mathrm{I}} = O\left(\frac{D}{V}\right)$$

or

$$10^{-4}\ \mathrm{cm} < r_{\mathrm{I}} < 10^{-2}\ \mathrm{cm}$$

for the range of velocities given above, and (*ii*) for the velocities given for aluminum alloys

$$10^{-2}\ \mathrm{cm} < r_{\mathrm{I}} < 10^{3}\ \mathrm{cm}$$

These estimates should be regarded as the outer limits of distance from the crack tip for which the Beck-Grens (5) type treatment could be used. Other comparisons with the Beck-Grens model are difficult to make because of the different assumptions involved in their treatment as compared to ours.

The present results are useful in assessing the importance of minor components in controlling the potential drop down cracks. For the molten salt system, it appears that the concentration of H_2O would have to be larger than 1 ppm before a sizable potential drop would be expected. The full treatment of the superposition of anodic processes on the mass transfer limited processes of minor components will be presented in a subsequent paper. It should be noted from Fig. 6, however, that the tip of the crack is less cathodic than the mouth of the crack, with the present assumption of a cathodic process occurring at a mass transfer limited rate. This could permit a different process to occur anodically at the crack tip even though the external surface is cathodically polarized.

It is tempting to extrapolate the results to solutions of higher concentration. One would be led to conclude that none of the reactive species could get to the crack tip, no matter what the bulk concentration. However, this conclusion is probably not justified, because it is doubtful if the same analysis could be used for more concentrated solutions. One could expect in such solutions that the mass transfer processes could change the fluid flow characteristics, with results which might be quite different than those found here.

Manuscript submitted Sept. 6, 1973; revised manuscript received March 15, 1974. This was Paper 244 presented at the Chicago, Illinois, Meeting of the Society, May 13-18, 1974.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1975 JOURNAL. All discussions for the June 1975 Discussion Section should be submitted by Feb. 1, 1975.

Electrochemical Behavior of Iron Within Crevices in Nearly Neutral Chloride Solutions

E. McCafferty*

Naval Research Laboratory, Washington, D. C. 20375

The publication costs of this paper have been assisted by the Naval Research Laboratory.

ABSTRACT

In crevices where the internal iron is not short-circuited to external metal, the corrosion rate is determined by the limiting cathodic current for oxygen reduction. This limiting current, and accordingly the corrosion rate, is independent of *p*H and Cl^- concentration but is suppressed to a constant value when the height of the crevice is less than the thickness of the oxygen diffusion layer. When iron in the crevice is short-circuited to external, open platinum, the initial crevice corrosion rate is independent of crevice height but increases with increasing Cl^- concentration and area of external electrode. At constant Cl^- concentration, the crevice corrosion rate of internal iron short-circuited to open external iron decreases with increasing chromate ion concentration. At a constant chromate ion concentration which does not give protection, the crevice corrosion rate is greater the greater the chloride ion concentration for short times, but at longer times the rates are essentially independent of bulk chloride concentration.

Rosenfeld and Marshakov (1) have shown that crevice corrosion usually proceeds in two main stages: (*i*) initiation by differential aeration and (*ii*) propagation by crevice acidification. Initially, the sheltered metal in contact with a restricted oxygen supply becomes anodic relative to the open metal to which it is connected. At longer times, the presence of the crevice plays a different role, that of causing corrosion products to accumulate within the crevice so as to change the local solution composition and *p*H.

Reports that not only crevices (1, 2) but also stress-corrosion cracks (3, 4) and pits (5, 6) acidify locally has led to the view that all three forms of localized corrosion share the unifying feature of being "occluded corrosion cells" (7) having restricted exchange with bulk electrolyte and thus common solution chemistries. Thus, most recent studies have utilized the thermodynamic, rather than kinetic, approach, with emphasis on factors such as resultant crevice solution chemistry, *p*H, and electrode potential (8-11). Little recent work has been done on the polarization kinetics of metals under crevices. One exception has been the correlation between the shape of cyclic anodic polarization curves for various engineering alloys in 3½% NaCl with their longer range performances in natural seawater (12). Polarization curves have been reported in some well-defined but synthetic, generalized "occluded corrosion cells" *sans* crevices, in which the "internal" metal was activated by anodic polarization (13) or by deaeration (14). Other investigators have reported current-time (15) and potential-time (10, 16), but not current-potential relationships.

The purpose of this study was to take up the systematic approach of Rosenfeld and Marshakov (1) in order to investigate in an organized manner kinetic aspects of a fairly simple crevice system. Iron was chosen, partly because of the attention given this metal in a wide variety of open systems. The effect of variable crevice height, chloride ion concentration, and chromate inhibitor is considered.

Experimental

Electrode.—Ferrovac E high purity iron with the following impurities was used in this study: 0.007 C, 0.01 Mn, 0.002 P, 0.007 S, 0.006 Si, 0.025 Ni, 0.007 Cr. An iron electrode (1¼ in. diameter) was encased in a Teflon holder by pressing the cylindrical iron bar through an undersized opening in the Teflon. The uppermost rim of Teflon was machined away, and the electrode edge masked with alkyd varnish, a material found suitable in preventing the formation of unintentional, microscopic crevices (17). Before use, the exposed iron face (7.9 cm^2 projected area) was dry-polished through 3/0 emery papers and washed with ethanol.

Crevice assembly.—The electrode holder was machined to fit into the cell as shown in Fig. 1. A central feature of the assembly is the provision for an adjustable crevice height. The crevice was formed by positioning the optically polished bottom surface of a glass disk a measured distance from the iron surface by means of a micrometer attached to the disk top. Two small holes (<1 mm diameter) through the glass disk led to Ag/AgCl reference electrodes, prepared by chlorodizing silver wire (18). These Luggin capillaries enabled measurement of the electrode potential at the center and near the edge of the crevice. Thus, electrochemical processes within the crevice could be monitored. The solution in the capillary section was the same as the bulk electrolyte and was kept from draining into the crevice by filter-paper plugs packed into the capillary bottom. Electrode potentials were thus measured *vs.* Ag/AgCl in the test solution but were converted to potentials *vs.* a commercial Ag/AgCl standard electrode.

Solutions.—Sodium chloride solutions were used: (*i*) with sodium chromate inhibitor (*p*H = 8.4), to study the initiation of crevice corrosion on passive iron, and (*ii*) without inhibitor (*p*H = 5.5), to study active

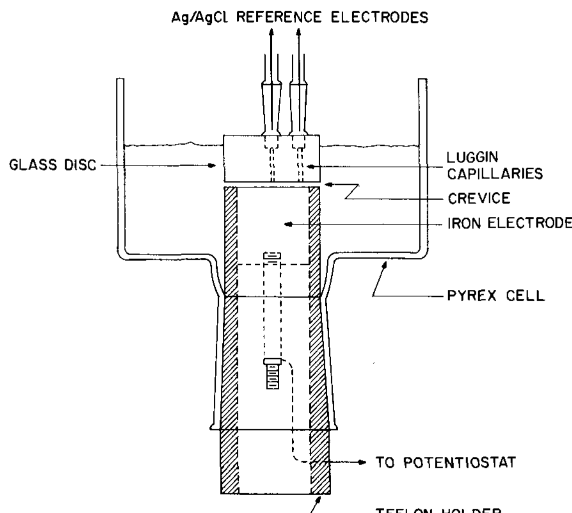

Fig. 1. The crevice corrosion cell. (Micrometer assembly and auxiliary electrode not shown.)

crevices. The 3½% NaCl solution (wt/vol) was of particular interest because the chloride ion concentration (0.6*N*) is the same as in natural seawater. All solutions were prepared from reagent grade chemicals and double-distilled water prepared in a quartz still. During all experiments, the cell electrolyte was open to the air and quiescent.

Procedures.—For the $CrO_4^{=}/Cl^-$ solutions, a ring-shaped piece of iron (area ≅ 50 cm^2) cut from the same bar as the crevice iron was used as the external open electrode. This split-electrode arrangement allowed measurement of current between active internal and passive external electrodes. After 15 min immersion in a given solution, the two parts were short-circuited through a Wenking potentiostat used in a two-electrode configuration (19), which essentially uses the potentiostat as a zero resistance ammeter. Electrode potentials of internal and external iron and crevice corrosion current were recorded for approximately 48 hr of coupling. Chromate ion and chloride ion concentrations were varied, but the crevice height was fixed at 10 mils (0.25 mm) for this set of experiments.

Two types of crevices were investigated for the chromate-free solutions: (*i*) "isolated" crevices, in which internal iron was not connected to external metal, and (*ii*) "coupled" crevices, in which internal iron was short-circuited to external metal.

The former configuration allowed study of local cell activity within a crevice, and the latter simulated the more practical case in an overlapping joint, for example, where metal within the crevice is in electrical contact with metal outside the crevice.

The effect of crevice width, *p*H, and Cl^- ion concentration was studied for the "isolated" crevice. The narrower "isolated" crevices were polarized galvanostatically using a series of variable resistors in series with a 45V battery ($R_{ext} >> R_{cell}$). (Use of the potentiostat in the normal three-electrode configuration yielded oscillations in current for the narrower crevices, but there were no problems with thicker crevices or with the two-electrode configuration for "coupled" crevices.)

For "coupled' crevices in the chromate-free solutions, a platinum gauze electrode was used as the open, external electrode in order to confine corrosion to the internal iron. Crevice iron and external platinum were immersed (uncoupled) for 24 hr to reach steady-state potentials prior to coupling through the potentiostat in the two-electrode configuration. Evans polarization diagrams were determined for different crevice heights, Cl^- concentrations, and external areas.

Results and Discussion

Inhibitor-Free Solutions

Isolated crevices.—Polarization curves were determined after 24 hr immersion in 0.6*N* and 0.06*N* NaCl solutions. Steady-state open-circuit potentials were established in about 10 hr, as shown in Fig. 2. In all cases, open-circuit potentials measured at the crevice center were identical with potentials measured near the crevice edge.

Figure 3 shows typical polarization curves in 0.6*N* NaCl for both the open sample and for "isolated" crevices, *i.e.*, crevice metal not coupled to open external metal. In all cases, the cathodic branch was determined first, open circuit was reestablished, and the anodic branch then determined. For cathodic polarization, electrode potentials measured via the Luggin capillary at the crevice center were the same as those near the edge. For anodic polarization, there were slight differences between the two locations (5-20 mV) in a few cases, but only at high anodic overvoltages.

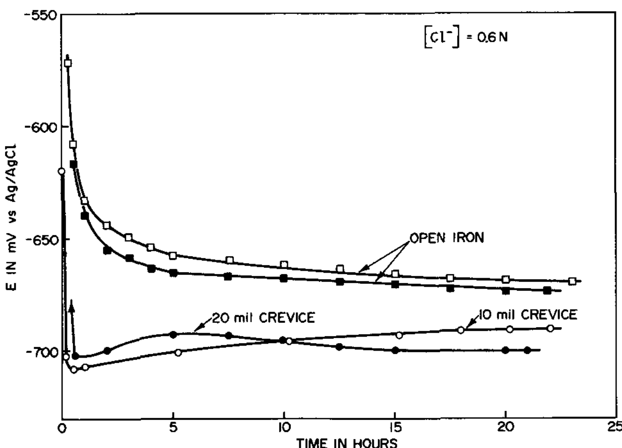

Fig. 2. Establishment of steady-state open-circuit potentials for open and crevice iron in 0.6*N* NaCl.

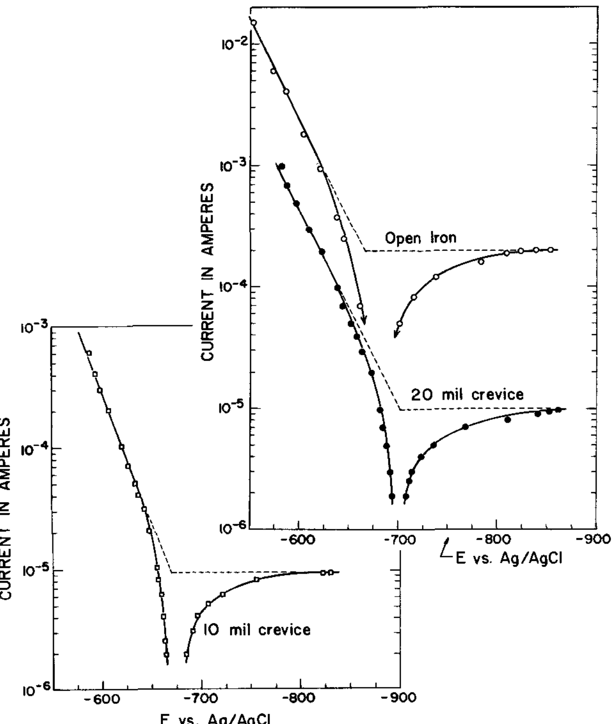

Fig. 3. Polarization curves for open iron and iron in "isolated" crevices in 0.6*N* NaCl after 24 hr immersion.

The shape of the cathodic curves in Fig. 3 is characteristic of a diffusion controlled process. The over-all cathodic reaction in nearly neutral solutions is the reduction of oxygen (20)

$$O_2 + 2H_2O + 4e^- \rightarrow 4\,OH^- \quad [1]$$

The anodic branches are activation controlled, with Tafel slopes of 40-60 mV/decade. All anodic curves were well behaved, and none displayed the peculiar property observed by Rosenfeld and Marshakov (1), in which some anodic curves started out in the direction of more negative potentials before turning back toward more positive potentials.

For both the crevices and open sample, the corrosion rate at open-circuit potential is equal to the limiting cathodic current for oxygen reduction, according to

$$i_{net} = i_{Fe} + i_{O_2} = 0 \quad [2]$$

With these "isolated" crevices, the limiting cathodic current density for oxygen reduction is less than that for the open sample, and correspondingly so is the iron corrosion rate, as shown in Fig. 3. This same effect has been seen by Rosenfeld and Marshakov (1).

At higher negative potentials than in Fig. 3, the predominant cathodic reaction is hydrogen evolution (21)

$$4H_2O + 4e^- \rightarrow 4\,OH^- + 2H_2\,(gas) \quad [3]$$

($E^\circ = -0.83V$ *vs.* NHE $= -1.03V$ *vs.* Ag/AgCl), rather than oxygen reduction. With extensive cathodic polarization, the shape of the polarization curve changed from diffusion control to activation control, and exhibited a Tafel slope of 120 mV/decade, characteristic of hydrogen evolution (22). In the oxygen reduction region, the polarization behavior was independent of pH and Cl^- ion concentration, as required by Eq. [1] and shown in Fig. 4 for a 10 mil crevice.

The effect of the "isolated" crevice is thus to stifle the oxygen reduction reaction, even for a relatively wide opening of 125 mils (3.19 mm), as seen in Fig. 5 for 0.06*N* NaCl. The limiting cathodic rate is further suppressed to a constant value for crevice heights between 5 and 20 mils (0.13-0.51 mm). The crevice height of 20 mils (0.51 mm) is significant in that it is approximately the thickness δ of the oxygen diffusion layer near the electrode surface calculated from (23)

$$i_{l,c} = n\mathbf{F}\frac{D}{\delta}C \quad [4]$$

where $i_{l,c}$ is the mass-transfer limited cathodic current density for the open sample (0.20 mA/7.9 cm^2), $n = 4$ electrons transferred per mole O_2 according to Eq. [1], and C and D are the diffusion coefficients and concentration, respectively, of oxygen. With $D = 1.65 \times 10^{-5}$ cm^2/sec (24) for 0.05*N* NaCl at 25°C, and $C = 8.2$ mg/liter (25), Eq. [4] gives: $\delta = 0.063$ cm, or 25 mils. This value agrees with that of Rosenfeld and Vashkov (26) who calculated the thickness of the diffusion layer to be 0.50 mm (20 mils) for iron in 0.5*N* NaCl. Experiments by Rosenfeld and Marshakov (1b) with variable crevices gave $\delta = 0.25$-0.50 mm.

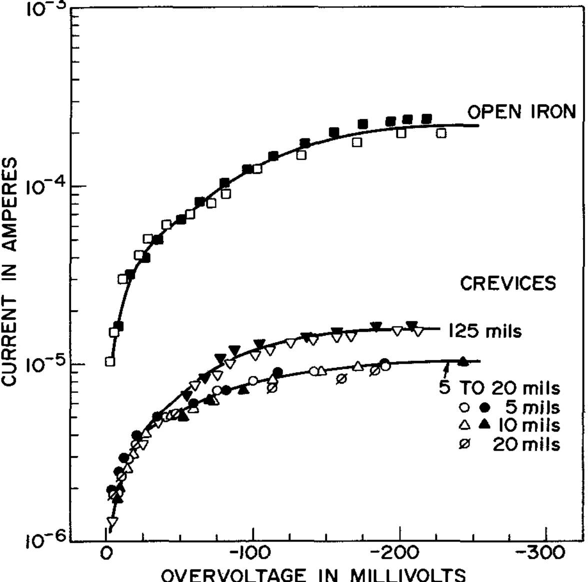

Fig. 5. Effect of crevice height on the cathodic polarization of iron in 0.06*N* NaCl.

Thus in crevices not coupled to outside open metal, when the crevice height is comparable to the thickness of the oxygen diffusion layer, diffusion of oxygen into the crevice is impeded and hence the corrosion rate is reduced, according to Eq. [2].

All polarization curves reported were steady-state curves. Figure 6 shows potential-time dependence for the galvanostatic cathodic polarization of a 20 mil crevice in 0.06*N* NaCl. For the lowest applied currents, only a few minutes were necessary to establish a steady-state potential, but several hours were necessary to reach a steady potential near the limiting cathodic current for oxygen reduction.

Coupled crevices.—The effect of activating the crevice iron was studied by coupling it to external, open platinum. This arrangement simulates practical cases, as in an overlapping joint, for example, where metal within the crevice is in electrical contact with metal outside the crevice. The iron in the crevice was con-

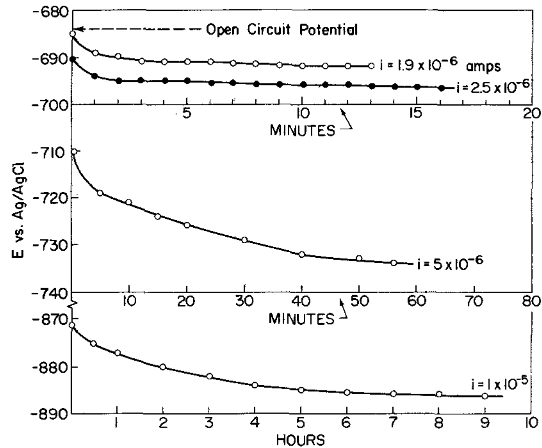

Fig. 6. Establishment of equilibrium potentials during the galvanostatic polarization of iron in a 20 mil (0.50 mm) crevice in 0.06*N* NaCl.

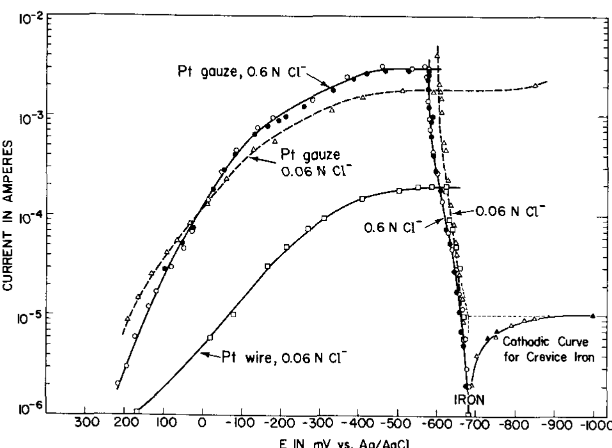

Fig. 7. Effect of Cl^- ion concentration and area of external platinum on the polarization behavior of the couple: iron (10 mil crevice)/platinum (open).

nected to the external platinum gauze using the potentiostat in the two-electrode configuration (19). This arrangement forces the cathodic reaction (oxygen reduction) to continue outside the crevice at the platinum surface after the oxygen within the crevice has been consumed, and the anodic reaction (iron dissolution) is confined to the crevice. Typical Evans polarization diagrams are shown in Fig. 7. Initially, the iron and platinum were uncoupled for 24 hr, so that each electrode reached its own steady-state potential. These open-circuit potentials for uncoupled iron and uncoupled platinum (zero current flow) tend toward the bottom of the diagram. With increased current flow, these two potentials approach each other and nearly coincide except for a moderate *IR* drop (at most 50 mV). The current at the intersection of the iron and platinum polarization curves is the short-circuit corrosion current for that couple.

As with the "isolated" crevices, the electrode potentials of iron at the crevice center and near the crevice edge were either identical or displayed but small differences (5-15 mV).

Figure 7 also compares the crevice corrosion current for the "isolated" (uncoupled) crevices to that for the iron/platinum couples. In the former case, the crevice corrosion current is only 1×15^{-5}A (Fig. 4), and is determined by the rate of oxygen reduction within the crevice. As seen in Fig. 7, the corrosion rate of the coupled crevices is also under cathodic control but is determined by the rate of oxygen reduction at the open electrode outside the crevice.

Table I summarizes the results of various experiments which investigated the effect of crevice height, chloride ion concentration, and area of external platinum on the corrosion rate of the couple: iron (crevice)/platinum (external).

Table I shows that the presence of the crevice increases but slightly the corrosion current compared to the open sample (*e.g.*, 1.8-2.1 mA for crevices coupled to platinum gauze in 0.06*N* NaCl *vs.* 1.5 mA for the open iron coupled to the same platinum gauze). Thus even a crevice as narrow as 3-10 mils does not hinder the corrosion of iron in the crevice once the iron has been activated by coupling to an external cathode. However, the crevice does restrict the attack to the metal near the crevice edge, as was also the case for the $CrO_4^{=}/Cl^-$ solutions.

Figure 7 shows that for a given crevice height and chloride content, a decrease in area of the external cathode causes a decrease in crevice corrosion current. The ratio of open to sheltered metal has been shown to be important in longer range, more practical immersion tests. For example, Ellis and LaQue (27) have reported a linear increase in weight loss with increasing external area for stainless steel in flowing seawater.

Table I shows that increasing the bulk chloride ion increased the corrosion current, for a given external area and crevice height. However, a change in crevice height for a given external area and chloride content (either 0.06*N* or 0.6*N*) had no effect on the crevice corrosion rate. The explanation may be that the concentration of chloride ions entering the crevice is not strongly dependent on the crevice height. Work by Ulanovskii and Korovin (28), has shown that the increase in Cl^- ion concentration during the anodic polarization of graphite is about the same for 0.2 mm (*i.e.*, 10 mil) as for 0.6 mm (24 mil) crevices.

Table I also shows that the measured crevice corrosion current was not affected by nuances in the experimental procedure. With 0.6*N* NaCl, the short-circuit current was the same for galvanostatic polarization as for potentiostatic polarization. Also, it made no difference if the platinum external electrode was positioned horizontally or vertically (same area in each case). In some cases, the short-circuit current measured by the potentiostatic method was checked with a simple zero-resistance ammeter (29). The two values always agreed within 5%.

The average *p*H within the crevice was measured after each run for the 0.06*N* NaCl solutions. The bulk electrolyte was slowly pipetted off below the crevice level; and the crevice was opened. The average crevice *p*H was 4.7 ± 0.3, as measured both by narrow range *p*H papers and the micro-*p*H electrode. This same value was recently measured for iron in 3½% NaCl in another study in this laboratory by Bogar and Fujii (9), who sampled crevice electrolytes with a microcapillary and touched the extracted drops to narrow-range *p*H papers.

An accumulation of ferrous ions within the crevice has been found (2, 12) to accompany the low *p*H. Possible equilibrium reactions leading to an increase locally in H^+ ions involve the hydrolysis of ferrous ions entrapped within the crevice, and have been summarized by Peterson (2). Detailed step-by-step mechanisms for dissolution within crevices have not been determined. However, Fig. 7 does show that in the early stages of the corrosion process, the Cl^- ion does not stimulate the anodic reaction. At constant potential (and constant *p*H = 4.5, in view of the above), the anodic rate is lower for the higher Cl^- ion concentration, in agreement with result for open iron in deaerated systems (30, 31).

Chromate Solutions

Effect of coupling.—Results for a typical experiment in which iron within the crevice (7.9 cm^2 area) was coupled to open, external iron (~50 cm^2 area) are shown in Fig. 8. The time axis is logarithmic for illus-

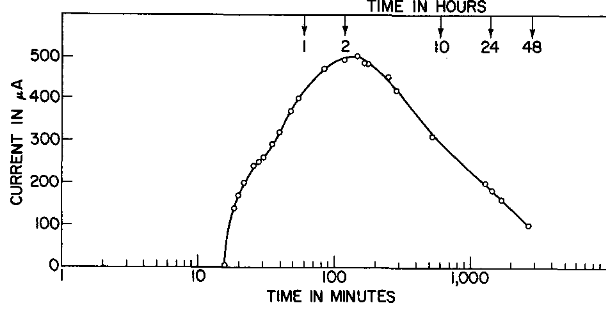

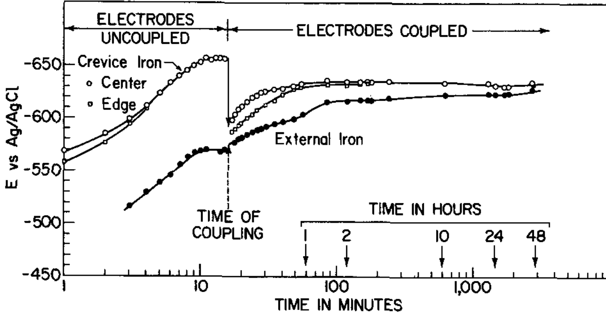

Fig. 8. Effect of coupling iron within a 10 mil (0.25 mm) crevice in 0.006N Na_2CrO_4 + 0.6N NaCl to open external iron. (Area of crevice iron = 7.9 cm^2, area of external iron = 50 cm^2).

tration purposes only. For the first 15 min of the experiment, the crevice iron and external iron were uncoupled, *i.e.,* each at its own open-circuit potential. At 15 min time, the electrodes were short-circuited using the potentiostat in the two-electrode configuration. Upon coupling, the potentials of the crevice iron and external iron shifted toward each other but were not identical due to an *IR* drop between the crevice interior and outer electrode. In all experiments, the initial shift in potential upon coupling was larger for the crevice iron than for external iron. At the end (48 hr) of the experiment shown in Fig. 8, the potential difference between crevice iron (laden with corrosion products) and passive external iron was only 7 mV. The maximum potential difference for this experiment was 34 mV at 0.5 hr time.

Figure 8 shows that there was no difference in electrode potential between the crevice center and crevice edge before coupling. After coupling, the potential of the crevice edge was usually intermediate between that of the crevice center and external iron, as seen in Fig. 8. But at the end of every experiment, there again was no difference in potential between the two locations in the crevice. This suggests that at long times the occluded internal electrolyte develops a uniform composition throughout the crevice.

Figure 8 also shows the current between inner and outer iron surfaces when coupled. The current reached a maximum at about 2 hr, and then gradually decreased with time.

This decrease in current can be attributed to two related effects. First, as the crevice iron becomes active, the accumulation of ferrous ions within the crevice causes a decrease in local *p*H, as discussed earlier. (For all cases except 0.6N Cl^-/0.6N $CrO_4^=$, where there was little crevice corrosion, the measured crevice *p*H after 48 hr was in the range 4.5-6.0, as compared to the bulk *p*H of 8.4) In going from neutral to acidic solutions, the anodic polarization curve for active iron is shifted to lower current density values at constant potential for open iron in deaerated 1N chloride (32, 33). Using open iron in bulk solutions deaerated by intentional degassing as a "scaled-up model" for crevice iron in small volumes deaerated by oxygen consumption, then the anodic partial curve for crevice iron will intersect the cathodic curve for open iron at a decreased current. As shown in Fig. 8, and was typical, the electrode potential of the crevice iron was essentially constant after the maximum in crevice corrosion current had been reached.

If there is an increase in Cl^- content within the crevice, as predicted (5b) or observed with artificial crevices (8, 13, 34, 35), this will also cause a decrease in anodic current according to the "halide-inhibited" mechanism of iron dissolution (30). Only if there is a drastic increase in chloride concentration (approximately 3-6M) coupled with an intense acidity (*p*H < 0) will there be acceleration of the anodic reaction caused by the conjoint action of Cl^- and H^+ ions (31, 36).

Secondly, insoluble corrosion products which accumulate within the crevice form a resistive barrier. For the experiment in Fig. 8, gross bleeding of rust out of the crevice was first noticed at about 10 hr time. All crevices which underwent corrosion were heavily laden with corrosion products after termination of the 48 hr runs.

The effect of the chromate ion is seen in Fig. 9 which shows the crevice corrosion current at a constant chloride ion concentration of 0.6*N*. The crevice corrosion current decreases with increasing amounts of chromate inhibitor. Duplicate runs in Fig. 9 show that the trends are clear although the exact shapes of the curves are not identically reproducible.

The effect of the chloride ion is shown in Fig. 10, which plots the crevice corrosion current for a constant chromate ion concentration of 0.006*N*. In the early stages of the process, the corrosion current is greater the greater the Cl^- ion concentration. However, at longer times, all the crevices exhibit essentially the same rate. This suggests that the long-term

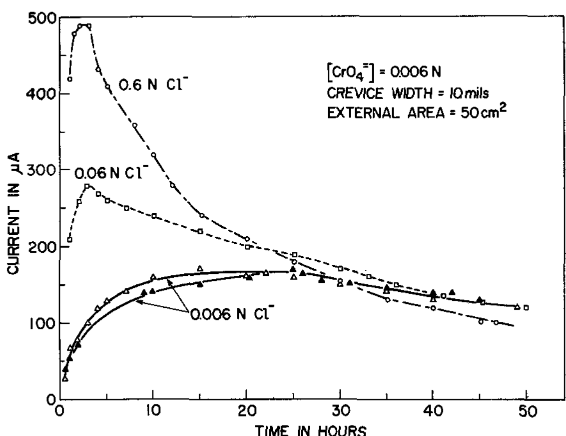

Fig. 10. Effect of chloride ion concentration on the crevice corrosion of iron at constant chromate ion concentration.

Table II. Comparison of electrode potentials for crevice iron and external iron coupled in $CrO_4^{=}/Cl^-$ solutions

$[CrO_4^{=}]$	$[Cl^-]$	$(E_{external} - E_{crevice, center})$ in mV Max. ΔE	24 hr	48 hr
0.006N	0.6N	34 (0.5 hr)	9	7
		21 (1.5 hr)	14	17
0.06	0.6	24 (4.5 hr)	12	15
0.6	0.6	14 (1 hr)	5	—
		5 (2 hr)	—	—
0.006N	0.006N	99 (14 hr)	71	58
		106 (24 hr)	106	87
0.006	0.06	73 (1 hr)	44	57
0.006	0.6	34 (0.5 hr)	9	7
		21 (1.5 hr)	14	17

crevice corrosion rate is controlled by the common local chemistry set up in each of the occluded cavities. In each case, the band of rust around the crevice mouth serves to restrict exchange of the local and bulk electrolytes.

Potential difference between inner and outer surfaces.—Table II compares the electrode potentials between the internal active iron and the external passive iron when coupled in $CrO_4^{=}/Cl^-$ solutions. The potential of the crevice edge was measured with the reference electrode located within the crevice top, as shown in Fig. 1. The potential of the open, external iron was measured with a similar reference electrode located outside the crevice. The electrode potential of the crevice was more negative than that of the open metal due to a restricted oxygen supply to the crevice (1, 5, 37), but the potential difference between the two was fairly small, *i.e.,* 10-100 mV for the active crevices (*i.e.,* excluding the 0.6N Cl^-/0.6N $CrO_4^{=}$ solution, which showed little crevice corrosion). Data for duplicate runs in Table II show the maximum potential difference between the crevice center, and the open iron was reproducible to within 15 mV.

Steady-state potential differences between inner and outer stainless steel surfaces in 3½% NaCl have been recently reported to be 50-150 mV (10, 16). According to Korovin and Ulanovskii (37), when the oxygen concentration in seawater is lowered from 9 to 1 mg/liter, the change in potential of a 13% chromium steel coupled to platinum is shifted but 85 mV in the negative direction. This information as well as the data reported here shows that neither the initiation nor continuation of crevice corrosion requires a large potential difference between inner and outer metal surfaces. As noted by Karlberg and Wranglen (10), the concept that there is a large potential difference between the crevice and external metal is based upon potential measurements of uncoupled, unpolarized components in solutions of differing oxygen content. As shown in Fig. 8, the potential difference between the inner and outer surface is much larger before coupling than after.

Distribution of crevice attack.—Attack in the crevice was not uniform. In all cases, attack was most severe around the edges of the iron surface near the crevice opening. This observation is consistent with that of Karlberg and Wranglen (10) who noted that attack with 13 and 17% chromium steels always started near the mouth of the crevice.

A mathematical analysis of current distribution in a system similar to but not identical with an active crevice has been given by Waber (38). Current flow between a coplanar anode and cathode in contact and both under a thin film of electrolyte was concentrated at the anode/cathode juncture. It was shown that the zone of attack would spread inward with increasing thickness of the electrolyte layer and with increasing conductivity.

Summary

For isolated crevices (internal iron not short-circuited to external iron):

1. The anodic corrosion rate was determined by the limiting current for oxygen reduction.
2. The limiting cathodic current, and hence the corrosion rate, was less than that for the open sample.
3. For crevice heights less than the thickness of the oxygen diffusion layer, the limiting cathodic current, and hence the corrosion rate, was suppressed to a constant value.
4. The limiting cathodic current for oxygen reduction was not dependent on pH nor Cl^- concentration.

For coupled crevices (internal iron short-circuited to external iron or platinum):

1. The initial current depended on the chloride ion concentration and area of external electrode but not on the crevice height.
2. In the $CrO_4^{=}/Cl^-$ solutions, the crevice corrosion currents increased with time to maxima but then decreased.
3. At constant chloride ion concentration, the crevice corrosion current decreased with increasing chromate ion concentration.
4. At constant chromate ion concentration, the crevice corrosion current was greater the greater the Cl^- ion concentration for the early stages of the process, but at longer times the corrosion rates were the same.
5. Attack within the crevice was not uniform and was most severe near the crevice mouth.

ABSTRACT

The passive layer was formed potentiostatically on iron in basic solution containing various chelating agents: o-phenanthroline, malonic acid, 8-hydroxyquinoline. 0.15*N* borate-0.15*N* boric acid solution was also used for comparison. A cathodic potential pulse was applied to the passivated iron in the same solution, and cathodic reduction was then carried out galvanostatically in basic solution without chelating agents. The cathodic pulse reduced adsorbed oxygen on passive iron, and the coverage by adsorbed oxygen decreased depending upon the properties of the chelating agents. o-Phenanthroline did not influence the coverage of adsorbed oxygen since it diffused away in the form of the ferrous-o-phenanthroline from the metal surface. The coverage by adsorbed oxygen in the solution containing malonic acid and 8-hydroxyquinoline was low, and the cause was attributed to the replacement of adsorbed oxygen by oxalic acid or metallic chelate. The thicker passive layer was produced in the borate-boric acid solution, and the adsorbed oxygen was replaced by the ring polymer which exists predominantly in the mixed solution and acts as a corrosion inhibitor.

Experimental conditions necessary to achieve the passivity of iron are well known; however, there are few papers (1-3) which treat the effects of chelating agents or other organic compounds on passivated iron. Passivation should be influenced by chelating agents in solution since the sorbed layer on the passive film plays an important role in passivation as previously reported (1, 2).

In this paper, the effect of chelating agents on the transient behavior of passivated iron was studied under the same conditions as those described previously (4).

Experimental

Iron samples were the same as those used before (4). 0.01M sodium borate was used for pretreatment and for cathodic reduction. The solution was deaerated with purified nitrogen and preelectrolyzed at 80 $\mu A/cm^2$ for 48 hr. The 0.01M sodium borate solutions used for anodization contained 0.002M of the following analytical grade chelating agents: o-phenanthroline, malonic acid, and 8-hydroxyquinoline. A solution of 0.15*N* borate and 0.15*N* boric acid was used for comparison. All were deaerated with purified nitrogen for 48 hr, but not preelectrolyzed.

The experimental techniques were the same as those described previously (4). Passivation was performed potentiostatically for 20 min and the specimen was then subjected to a single cathodic potential pulse. The specimen was then washed twice with 0.01M sodium borate solution and cathodic reduction was carried out in 0.01M sodium borate at 20.9 $\mu A/cm^2$. The change in potential with time was followed by an X-Y recorder equipped with a preamplifier having an input impedance of more than 10^{13} ohms.

Results

Current-time curves.—A cathodic potential pulse was applied to the passivated iron which had been preanodized in solutions containing chelating agents. The response current of the pulse at 1460 mV is shown in Fig. 1 and 2 for 0.01M borate solution containing 0.002M o-phenanthroline and 0.002M malonic acid, respectively. 0.002M 8-hydroxyquinoline and 0.15*N* boric acid-0.15*N* borate solution were also used as chelating agents.

For the preanodizing potential of 1460 mV, the response current depended upon the chelating agent and the pulse amplitude, except with 0.002M 8-hydroxyquinoline (not shown). With less noble preanodizing potentials such as 900 mV, the response currents were appreciable for all chelating agents studied.

Logarithmic current-time curves.—The log of response current of various pulses at 1000 mV is shown in Fig. 3 and 4 for 0.01M borate solution containing 0.005M o-phenanthroline, and 0.002M 8-hydroxyquino-

line. In the initial stage of pulsing, the logarithmic current is linearly related with time. This was also true in all solutions, but the slope of the straight line depended upon the solution used.

Current-preanodizing potential curves.—The response current of the 300 mV pulse at 5.0 msec was plotted against preanodizing potential for various solutions in Fig. 5. In each solution, a minimum current density was observed near the oxygen evolution potential. The current increased with decreasing preanodizing potential and passed through a maximum. Generally, if the solution contained a chelating agent, the response current of a cathodic potential pulse became lower than that in solutions without chelating agents. At potentials more noble than 800 mV the response current in 0.15*N* borate-0.15*N* boric acid solution was the same as in solutions containing chelating agents.

Cathodic reduction.—After the solution had been subjected to a pulse, the solution was replaced by a 0.01M borate solution containing no chelating agent. Typical reduction curves are shown in Fig. 6. The cathodic decay curves were similar in each case, *i.e.*, they decayed through two plateaus. The passive layer which had been formed anodically in each experimental solution was reduced at first plateau, *i.e.*, around −200 mV (RHE). Hydrogen evolved at the second plateau, *i.e.*, around −270 mV (RHE). The latter potential depended upon the solution in which the specimen had been anodized. These potentials corresponded to −920 mV (SCE) for the complete re-

duction of the passive layer and to −1000 mV (SCE) for the hydrogen evolution, respectively (5).

The amount of charge needed for reduction of the passive layer can be estimated from Fig. 6 and is plotted *vs.* preanodizing potentials in Fig. 7. There is

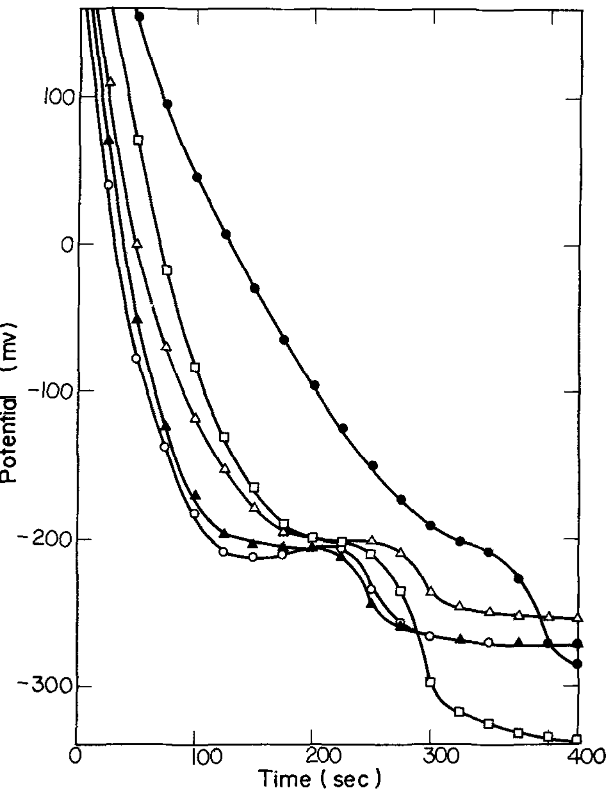

Fig. 6. Cathodic reduction curves. Anodized first in (—●—) 0.01M $Na_2B_4O_7$ containing 0.002M malonic acid; (—△—) 0.15*N* borate-0.15*N* boric acid; (—□—) 0.01M $Na_2B_4O_7$ containing 0.002M 8-hydroxyquinoline; (—▲—) 0.01M $Na_2B_4O_7$ containing 0.002M o-phenanthroline; (—○—) 0.01M $Na_2B_4O_7$ at 1220 mV. approximately a linear relationship between preanodizing potential and the amount of charge in agreement with Nagayama's and Cohen's result (5). As shown in Fig. 7, the iron passivated in 0.002M malonic acid, 0.002M 8-hydroxyquinoline, or 0.15*N* borate-0.15*N* boric acid needs more charge to reduce the passive film than that formed in pure 0.01M borate solution. In the solution with o-phenanthroline, however, the amount of charge needed was smaller and decreased with increasing o-phenanthroline concentrations.

Discussion

From many experimental facts, it was suggested previously (4) that cathodic potential pulsing did not affect the constitution of so-called bulk oxide, but only the sorbed layer on the surface of passivated iron, and that the reaction [I] occurred under pulsing

$$Me_xO_y - O + H_2O + 2e \rightarrow Me_xO_y + 2\,OH^- \quad [I]$$

where Me_xO_y is the passive film and −O is the adsorbed oxygen on passive film. The response current of the pulse was explained by the cathodic reduction of the adsorbed oxygen, since the transient current caused by discharging the electric double layer could be neglected in a potentiostatic experiment using a high response potentiostat.

In Fig. 8, the current at zero time is plotted on a logarithmic scale as a function of electrode potential for various preanodizing potentials. The electrode potential was obtained by subtracting the pulse amplitude from the preanodizing potential as done before (4). The linear relationship between $i_{t=0}$ and the electrode potential holds in 0.01M borate solution containing 0.005M o-phenanthroline. This relationship was not influenced by the presence of the chelating agents added in 0.01M borate, and also held in 0.15*N* borate-0.15*N* boric acid solution, as shown in Fig. 9.

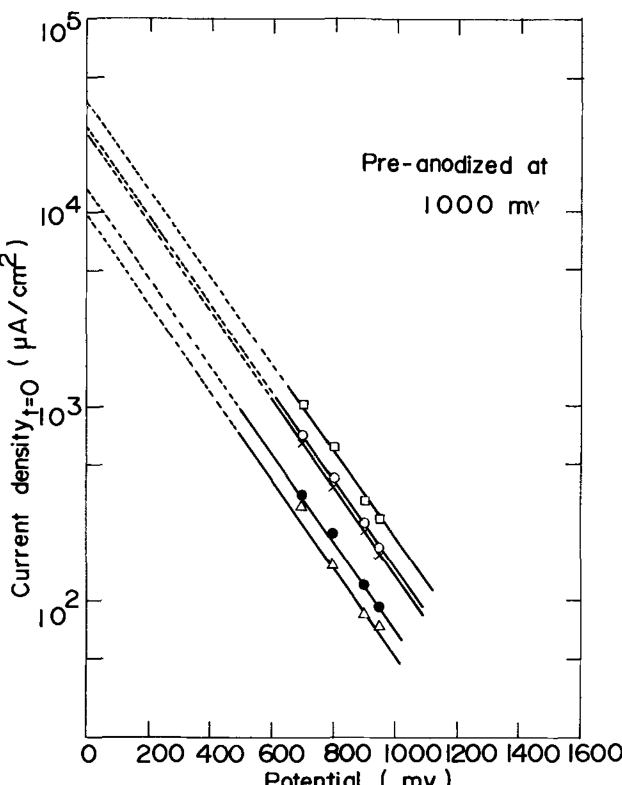

Fig. 9. The response current at the time of zero vs. the electrode potential for the specimens preanodized at various potentials in various solutions. —□—, Borate-boric acid (pH, 8.41; and —○—, 0.01M $Na_2B_4O_7$ with no chelating agent; —×—, with 0.002M malonic acid; —●—, with 0.005M o-phenanthroline; and —△—, with 0.002M 8-hydroxyquinoline.

As discussed previously (4), the slope in Fig. 9 corresponds to the left-hand side of the following equation

$$\left(\frac{\partial \log i}{\partial V}\right)_{t=0} = -\frac{\alpha n F}{2.303 \times RT}$$

From this result, α was estimated to be 0.1. This value was constant, independent of the presence of the chelating agent.

The intercept at the electrode potential of zero in Fig. 9 gives the current density, $i^*_{\substack{t=0 \\ V=0}}$ given by Eq. [7] in Ref. (4). i^* for various preanodizing potentials in various solutions is indicated in Table I. If the value of k_o is known, the concentration of adsorbed oxygen on passivated iron can be calculated.

k_o was estimated by the same method as that discussed before (4). That is, if the logarithm of the left-hand side of Eq. [5] in Ref. (4) is plotted vs. the electrode potential, the intercept at the electrode potential of zero should give $k_o/2.303$. Based upon such consideration, Fig. 10 was constructed. The logarithm of the left-hand side of Eq. [5] is linearly related with the electrode potential in each solution. Also, the slope of the straight line is always constant. k_o was calculated from the value of the intercept which depended upon the solution used, and the result is indicated in Table I.

Finally, the concentration of adsorbed oxygen on passivated iron was calculated by using Eq. [7] in Ref. (4) and k_o obtained above. The result is shown in Table I. In each solution, the concentration of adsorbed oxygen increased with increasing preanodizing potential. This behavior is discussed below by considering the coverage of passive iron by adsorbed oxygen.

The coverage θ was obtained under the assumption that the coverage θ^* at 1360 mV in the solution without the chelating agent is equal to 1.0. The result is plotted

Table I. The concentration of adsorbed oxygen on passivated iron before applying cathodic potential pulse at various preanodizing potentials

	Preanodizing potential (mV)	i^*_o (mA/cm²)	C^*_o (10^{-10} mole/cm²)

against preanodizing potential in Fig. 11. At each preanodizing potential, the concentration of adsorbed oxygen decreased by the addition of the chelating agent in solution. Especially, with malonic acid and 8-hydroxyquinoline, the coverage was low. Each chelating agent used is discussed below.

o-Phenanthroline.—When the iron was anodized in solutions containing o-phenanthroline, the iron surface became intensely red. This color disappeared on further anodization.

Ferrous iron forms a red complex with o-phenanthroline according to the following (6)

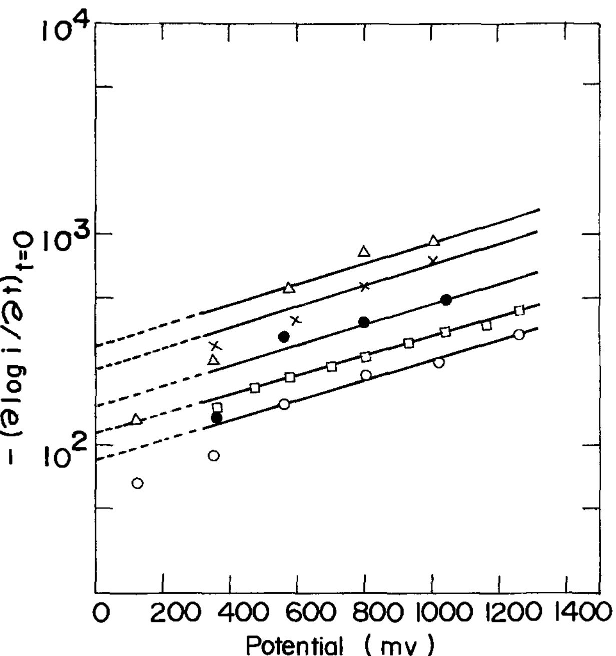

Fig. 10. — $(\partial \log i/\partial t)_{t=0}$ vs. the electrode potential. —△—, Borate-boric acid (pH, 8.41); and —×—, 0.01M $Na_2B_4O_7$ with 8-hydroxyquinoline (0.002M); —●—, with malonic acid (0.002M); —□—, with no chelating agent; and —○—, with o-phenanthroline (0.005M).

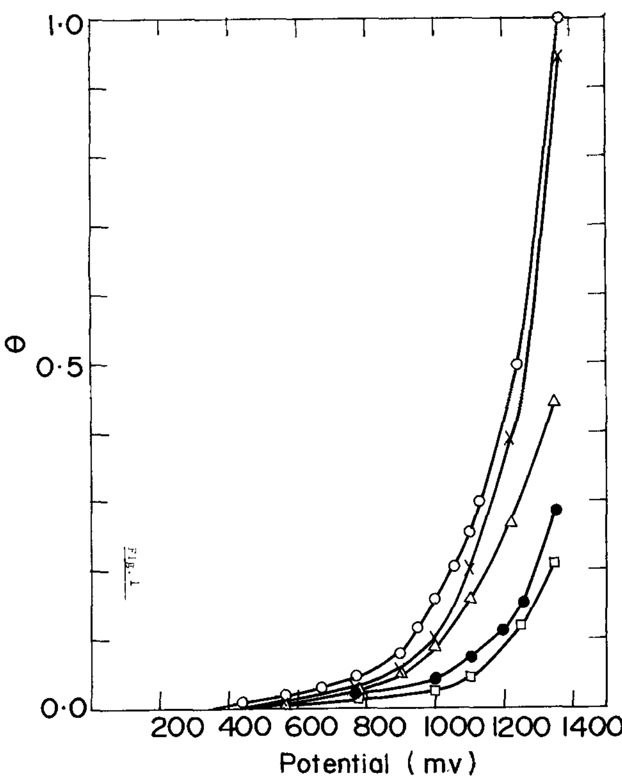

Fig. 11. The coverage θ vs. the anodizing potential. —○—, 0.01M $Na_2B_4O_7$ without chelating agent; and —×—, with 0.005M o-phenanthroline; and —△—, borate-boric acid (8.41, pH); —●—, 0.01M $Na_2B_4O_7$ with 0.002M malonic acid; and —□—, with 0.002M 8-hydroxyquinoline.

$$3\ (\text{o-phenanthroline}) + Fe^{2+} \longrightarrow \left[(\text{o-phenanthroline}) \frac{Fe}{3} \right]_3^{2+} \quad [II]$$

This is also a ferric-o-phenanthroline complex, but its color is light blue.

The appearance of the red color and its subsequent disappearance indicates the formation of the complex on the surface and its consequent diffusion to the bulk of the solution. Obviously, another possibility is the conversion of the "compound" on the surface to a less intensely colored state.

Given the former explanation, adsorbed oxygen exists on the passivated iron without being disturbed by o-phenanthroline. This is supported by the deduced observation that coverage by adsorbed oxygen was comparable in the solution with or without a chelating agent.

Malonic acid.—As shown in Fig. 7, the amount of charge needed for reduction of the passive film formed in solutions containing malonic acid was very large compared with the other solutions. The interpretation of this large amount of required charge is as follows. Malonic acid is known to be oxidized anodically according to the following reaction (7)

$$\begin{matrix} COOH \\ | \\ CH_2 \\ | \\ COOH \end{matrix} + 3\,O^{2-} \rightleftharpoons \begin{matrix} COOH \\ | \\ COOH \end{matrix} + CO_2 + H_2O + 6e \quad [III]$$

The standard potential for reaction [III] has not yet been measured exactly. However, it is known that this reaction can occur without accompanying oxygen evo-

lution on platinum (7). If iron is anodized in the solution containing malonic acid, reaction [III] may occur simultaneously with the oxidation of iron.

The reduction curve may involve reduction of anodically produced oxalic acid as well as the passive film. The following mechanism should be considered (7)

$$\begin{array}{l} COOH \\ | \\ COOH \end{array} + 2H^+ + 2e \rightleftharpoons \begin{array}{l} CHO \\ | \\ COOH \end{array} + H_2O \qquad [IV]$$

The aldehyde produced can be further reduced to alcohol depending upon the reduction conditions. The bulk solution used for reduction did not contain any chelating agent, but oxalic acid may still be adsorbed on passive iron after replacing the solution with one without the chelating agent.

Figure 11 shows that the coverage of adsorbed oxygen in the solution with malonic acid is lower than that without the chelating agent. The lower coverage in this solution can be explained by the adsorption of oxalic acid.

8-Hydroxyquinoline.—In the solution containing 0.002M 8-hydroxyquinoline, a small response current was observed for the whole range of preanodizing potentials, as shown in Fig. 5. In the cathodic reduction, 8-hydroxyquinoline affected the hydrogen overpotential, as indicated in Fig. 6. The amount of charge needed for reduction was approximately the same as that in the solution without chelating agent.

The solution pH in this experiment was always 9.2. At this pH, 8-hydroxyquinoline should be dissociated as shown below

[8-hydroxyquinoline (N, OH) $\rightleftharpoons$ 8-quinolinolate (N, O^-) $+ H^+$] [V]

8-Hydroxyquinoline is known to be a corrosion inhibitor for aluminum, and an aluminum chelate on the metal surface has been postulated (8) because the surface loses its metallic luster.

In the case of iron, a metal chelate is believed to form on the surface since the response current was very small. Iron has six electrons in d-orbitals. In the excited state, these electrons can be arranged in such a way that two electrons with opposite spin direction occupy each of three d-orbitals (9). Therefore, there are two unfilled d-orbitals. These orbitals may be occupied by the lone paired electrons of nitrogen and oxygen in 8-hydroxyquinoline.

The lowest coverage was observed with 8-hydroxyquinoline, as shown in Fig. 11. An iron chelate on passive iron could account for this experimental fact. That is, a part of the adsorbed oxygen would be replaced by the produced metallic chelates, and hence the coverage of adsorbed oxygen should decrease, as indicated in Fig. 11.

0.15N borate-0.15N boric acid.—This solution has been used for the study of the passivity of iron (5, 10-12), and its buffer property is the focus of attention. However, borate is a corrosion inhibitor (13).

An equivolume mixture of 0.15*N* borate-0.15*N* boric acid has a *p*H of 8.41, and there is the evidence that polymers are present in the mixed solution (9). The predominant species appears to be the ring polymer as shown below

[Ring polymer: HO–B(–O–)–O–B–OH, ring B–O–B–O–B–O with HO and OH on lower B] [VI]

The coverage of adsorbed oxygen on iron passivated in this solution was lower than in 0.01M borate. This may be due to the displacement of adsorbed oxygen by this polymer.

It was found that the passive layer produced in this solution was thicker than that in 0.01M borate. This can be seen from the observation shown in Fig. 7 where the amount of charge for the reduction of the passive layer in this solution was larger than that formed in 0.01M borate. The polymer shown above appears to act as a corrosion inhibitor which causes a thicker film and a smaller coverage of adsorbed oxygen in this solution than has been seen previously.

Conclusions

The passive layer was formed on iron in solutions containing various chelating agents, and a cathodic potential pulse was applied to the specimen. Adsorbed oxygen on passive iron was reduced by the cathodic pulse, and the coverage by adsorbed oxygen decreased depending upon the properties of the chelating agents. o-Phenanthroline reacted with iron to form the ferrous-o-phenanthroline complex which diffused away from the metal surface after passivation. This agent did not influence the existence of adsorbed oxygen. The coverage by adsorbed oxygen in the solution with malonic acid and 8-hydroxyquinoline was lower than that without the chelating agent. The lower coverage was attributed to the replacement of adsorbed oxygen by oxalic acid or metallic chelate. The thicker passive layer was produced in the borate-boric acid solution, and the adsorbed oxygen was replaced by the ring polymer which exists predominantly in the mixed solution.

ABSTRACT

Composite oxide films on aluminum were produced by reaction with boiling water followed by anodic oxidation in a phosphate electrolyte tagged with P^{32} tracer. The amount of phosphorus remaining in the film was followed during stepwise dissolution. It was found that the phosphorus concentration in the barrier portion of this film was two orders of magnitude lower than in a conventional anodic oxide. The amounts of hydrous oxide and barrier oxide in the composite film were determined using a combination of film stripping and metal dissolution procedures. The weight of barrier oxide was only 75% of the weight of a conventional anodic oxide, while the dielectric constants of the two films were about the same. Some important properties of the hydrous oxide were inferred from the behavior observed in these experiments.

When aluminum is first reacted with hot water and then anodically oxidized, the resulting film consists of a barrier oxide layer next to the metal and a layer of pseudoboehmite, a hydrous oxide, at the outer surface. The barrier portion consists of both anodic oxide and dehydrated hydrous oxide. The unusual anodization kinetics and special properties of these composite oxides have been discussed in previous papers (1, 2). In those studies it was possible only to estimate the individual amounts of barrier oxide and hydrous oxide in the final film since no technique was available for direct measurement of these quantities. One estimate indicated that about 25% less barrier oxide was needed to support a particular voltage during anodization than was the case for a conventional anodic oxide (2). This higher field strength did not appear to be accompanied by any significant change in dielectric constant. We have now investigated this more rigorously and find that this earlier estimate was essentially correct. These results are presented here.

A mechanism has been proposed by Vedder and Vermilyea (3) for the growth of the pseudoboehmite layer during reaction with water. They have proposed that growth of the film occurs by transport of hydrolyzed Al species through the liquid phase to deposition sites, and that sufficient film porosity is maintained to support this mechanism, even after long reaction times. On the other hand, a mechanism proposed for the growth of the composite oxide barrier layer stipulates the presence of an inner region of the pseudoboehmite layer that is impermeable to the anodizing electrolyte (2). There is circumstantial evidence for such a region, based on dielectric measurements (4). To help resolve this issue, composite oxides were anodized in a phosphate electrolyte tagged with P^{32}, and the activity of the film was measured after successive thinning in a conventional H_3PO_4-CrO_3 stripping solution. Phosphate anions are strongly adsorbed onto aluminum oxides (5), thus assuring a high P^{32} content in the composite film. The results presented here are interpreted as supporting the existence of an inner region that is impermeable to solvated anions.

Key words: anodic oxide, hydrous aluminum oxide, pseudoboehmite film, phosphorus distribution.

Experimental

General.—Specimens with an area of 100 cm^2 were cut from 99.99% Al foil, electropolished in a perchloric acid-acetic anhydride bath, rinsed, and then reacted with boiling distilled water for 5 min. Anodic oxidation was done at a constant current to 175V in an electrolyte of either 0.01M NaH_2PO_4 or 100 g/liter H_3BO_3 at 90°C.

The outer portion of the film, which is the hydrous oxide layer, was dissolved in a stirred solution of 5% H_3PO_4 + 2% CrO_3 at 85° ± 0.1°C. Dissolution was done in a stepwise manner with a measurement of specimen weight after each step, the weight change being assumed as due to loss of hydrous oxide alone. However, it was recognized that some nonuniform attack on the film can occur, causing a slight dissolution of the barrier portion as well. Therefore, an individual specimen was occasionally removed from this sequence and reanodized to 175V in order to replace such barrier oxide, and the weight gain, which is entirely barrier film, was used as a correction on the stripping weight loss. Specimen weights after stripping and after reanodization were measured with an accuracy of ±10 μg. In some instances, the capacitance at 120 Hz was measured in a neutral ammonium borate solution.

After stripping, the remaining oxide was recovered by dissolving the Al metal in warm 10% Br_2-methanol, then rinsing the oxide in warm methanol, and drying.

The oxide was weighed before and after heating for 2 hr at 900°C to remove any structural water.

P^{32} tracer measurements.—Radioactive P^{32} was added to the formation electrolyte as chloride-free phosphoric acid (obtained from New England Nuclear Corporation). The small additional quantity of radioactive material had no appreciable effect on the solution concentration or its *p*H. The amount of tracer used resulted in an initial counting rate of several thousand counts per minute; this necessitated a fairly large coincidence correction during the first periods of film stripping, but had the advantage of permitting an appreciable counting rate as the boundary of the phosphorus-containing film was approached. The counting rate was also corrected for isotopic decay of the tracer (half-life of P^{32} is 14.3 days).

Absolute values of the phosphorus content of the films were determined by comparison with the activity of standard volumes of the anodizing solution. Aliquot portions of the electrolyte in the form of fine droplets were distributed uniformly over the surface of a sheet of nonanodized aluminum with the same counting geometry as the anodized specimens. (The effective area of the anodized specimen, however, is twice that of the geometric area presented to the Geiger-Mueller tube, since both sides of the foil contribute to the counting rate. This is because the foil used is only 0.075 mm thick and thus essentially transparent to the β-particles emitted by P^{32} [E_{max} = 1.7 Mev].) The aluminum foil was then dried at 50°C and counted; no corrections for self-absorption were necessary.

A 0.01*M* NaH_2PO_4 solution was used to anodize three specimens each at constant currents of 1.0 and 0.3 mA/cm^2. These were rinsed in distilled water for 1 hr to remove superficial phosphate ion, then washed with acetone, and air dried before measuring the activity, weight, and capacitance, in that order. The films were stripped in 30 sec steps, rinsed for 10 min after each step, and the sequence of measurements repeated. Single specimens were removed after 1, 2, 2½, and 4 min stripping times and reanodized in nontracer electrolyte to get a correction for barrier film attack. Activity measurements were stopped after a total of 3 min stripping, but weight and capacitance measurements were continued with two specimens for a total stripping time of 9 min. The oxide remaining on the four specimens removed early from the stripping sequence was quantitatively recovered after dissolving the metal substrate in bromine-methanol solution.

Results

The weight losses obtained during stripping of the tracer specimens are shown in Fig. 1. The open circles represent the average for all specimens at that time. There was no significant difference between the averages of the specimens anodized at 1 mA/cm^2 and at 0.3 mA/cm^2. For times of 4 min and longer, only one specimen from each current density was still being stripped. The filled circles represent the weight gain of single specimens during reanodization after the indicated stripping time. Initially, it had been hoped that capacitance measurements could be used as a measure of barrier film dissolution during stripping, but the capacitance increase was always much larger than predicted from the weight gain. This indicates that the small amount of barrier attack was localized, rather than uniform across the film. After correcting for barrier film loss, it was found that the weight of the 0.3 mA/cm^2 sample remained constant between 4 and 9 min stripping times, while the 1.0 mA/cm^2 sample lost only an additional 3.50 μg/cm^2 over this time interval. After 9 min stripping, the average corrected weight loss was 46.4 μg/cm^2. This represents the weight of hydrous oxide in the composite film.

The average weight of a pseudoboehmite film produced during a 5 min reaction with boiling water is 63.5 μg/cm^2 (4). The difference between this figure and 46.5 μg/cm^2 (17.0 μg/cm^2) represents the hydrous oxide converted to barrier film, 26.8% of the initial amount.

The oxide remaining on each of the four samples that had been stripped for times of 4 min or less before reanodization was recovered after dissolving the metal in bromine-methanol solution. Adding the corrected stripping weight loss to this weight gave the total composite oxide weight. The average for the four samples was 102.4 μg/cm^2, with a range of 97.1-110.8 μg/cm^2. The average weight of barrier oxide was found to be 55.9 μg/cm^2, obtained by subtracting the 46.5 μg/cm^2 of hydrous oxide from the total weight.

Because of the similarity of experimental conditions to those used previously (1), it was expected that current efficiency of anodic oxidation would be 100%, as in the earlier case. Rather than make this assumption, the weight of anodic oxide was calculated by subtracting from the weight of barrier oxide the contribution from converted hydrous oxide. That is, remembering that the pseudoboehmite contains about 27% water (1, 6), the weight of Al_2O_3 from converted hydrous oxide is 0.73 × 17.0 μg/cm^2 which, when subtracted from the total barrier weight gives an average weight of anodic oxide of 43.5 μg/cm^2. The average charge for anodic oxidation was equivalent to 44.9 μg/cm^2, for an average current efficiency of 96.6%. Within the accuracy of this experiment, this is not significantly different from 100%.

A summary of these film weights is presented graphically in Fig. 2. It should be pointed out here that there is no intention to claim that the anodic oxide and converted hydrous oxide exist as distinct layers, an inference that might be drawn from the bar graph in

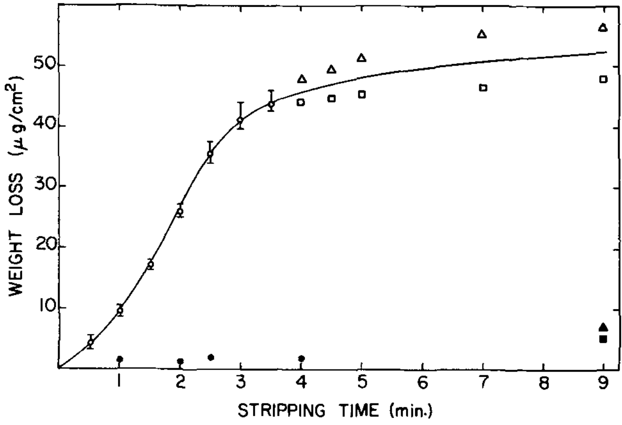

Fig. 1. Weight loss of composite oxides in 5% H_3PO_4 + 2% CrO_3 solution at 85°C. Symbols represent average for all specimens (○) and results with single specimens anodized at 0.3 mA/cm^2 (□) and at 1.0 mA/cm^2 (△). Filled symbols represent weight gain during reanodization of single specimens.

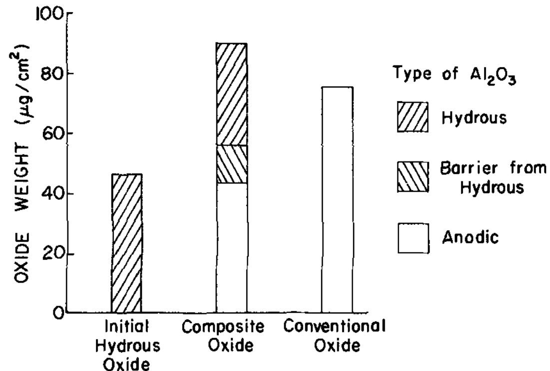

Fig. 2. Weight and distribution of oxide films produced by anodic oxidation to 175V. Note that weights are only for Al_2O_3, the weight of water in each oxide has been subtracted.

Fig. 2. The distribution of the oxide from the two sources is not known at this time. Shown for comparison is the weight of a conventional 175V anodic barrier oxide formed in an identical phosphate electrolyte at 1 mA/cm^2 and a temperature of 98°C (7). The composite oxide is able to support this voltage with 25% less barrier film. This is in agreement with previous results arrived at by less rigorous methods (1, 2).

The reciprocal capacitance of the conventional film was 31.7 $cm^2/\mu f$ compared with 22.2 $cm^2/\mu f$ for the composite oxide anodized at 1 mA/cm^2. The reciprocal capacitances are almost in the same proportion as the barrier film weights, indicating that the dielectric constants of the two films are about the same.

In this experiment, there seemed to be no effect of current density on the amount of hydrous oxide converted to barrier film. To verify this, some measurements were made at essentially the same conditions, but using 100 g/liter H_3BO_3 in place of the phosphate electrolyte and covering a range of current densities from 0.1 to 10 mA/cm^2. The average corrected stripping weight loss was 47.0 $\mu g/cm^2$ and varied by only ± 3% over the full range of current density. Moreover, this figure differed by only 0.5 $\mu g/cm^2$ from the corresponding value obtained in the phosphate electrolyte. Thus, neither current density nor electrolyte had any effect on the conversion of pseudoboehmite to barrier oxide.

In this experiment, it was found that the charge required to reach 175V decreased by 7% for a tenfold increase in current density (0.256 coulomb/cm^2 at 0.1 mA/cm^2 and 0.238 coulomb/cm^2 at 1.0 mA/cm^2). This is the same dependence as found for conventional barrier oxides (8).

Phosphorus distribution.—The activity of each specimen decreased sharply as the hydrous oxide was removed by stripping. From the relationship between P^{32} activity and weight of total phosphorus, the average phosphorus remaining in the film after each strip was found to be as shown in Fig. 3. There was very little variation among samples, and no dependence on the current density used during anodization. For example, for each of the first four strips the range of activity was less than ± 5%, while for the last two strips this increased to about ± 10%. Activity measurements were stopped when the measured activity dropped to the magnitude of the background correction. This occurred before all the hydrous oxide was dissolved. The vertical line in Fig. 3 represents the weight of hydrous oxide in these composite films.

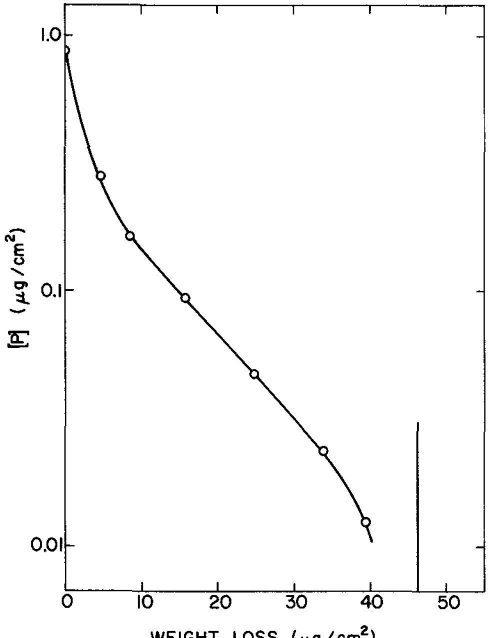

Fig. 3. Phosphorus content of composite oxide during stepwise dissolution. The vertical line represents weight of hydrous oxide determined by extended stripping.

The curve in Fig. 3 should not be considered a profile of the phosphorus distribution through the pseudoboehmite because the highly porous nature of the film makes it likely that dissolution occurred preferentially along pores and channels most accessible to the solution. These same regions would presumably be the places where phosphate anions were initially specifically absorbed, although additional inward diffusion may have occurred under the driving force of the anodization field. The fact that the same phosphorus distribution was obtained at both 0.3 and 1.0 mA/cm^2, with their corresponding immersion times in the anodizing solution of about 830 and 245 sec, indicates that this is a steady-state distribution governed by the porosity gradient in the film.

After stripping 39.5 $\mu g/cm^2$ of hydrous oxide all but 0.0127 $\mu g/cm^2$ phosphorus, about 1% of the initial phosphorus, had been removed. The remaining phosphorus was in the small amount of hydrous oxide still on the surface and in the barrier film. Only 2 $\mu g/cm^2$ of barrier film had been dissolved at this time. These figures can be analyzed in two ways. First, since the initial weight of pseudoboehmite was 63.5 $\mu g/cm^2$, the remaining phosphorus could be considered to have been distributed in 24.0 $\mu g/cm^2$ of hydrous oxide, for an average concentration of 5.3×10^{-4} μg P/μg oxide. In the second calculation, the remaining phosphorus could be treated as being wholly in the barrier film. Since the weight of barrier film was found to be 55.9 $\mu g/cm^2$, this is equivalent to an average concentration of 2.3×10^{-4} μg P/μg oxide. These concentrations can be compared with the phosphorus in a conventional 175V anodic oxide formed in the tagged phosphate electrolyte at 1 mA/cm^2 and 98°C. In that case, the average concentration was found to be 2.3×10^{-2} μg P/μg oxide (7), or about 100 times the level in the composite oxide barrier film.

Discussion

The very low concentration of phosphorus in the portion of the pseudoboehmite film incorporated into the barrier layer indicates that this inner portion of the hydrous oxide was essentially impermeable to phosphate anions. There does not appear to be a sharp boundary defining this region, but rather a porosity gradient through the film, so that other ions might be excluded from a greater or lesser thickness depending on their size and penetrating ability. In the present case, the 17.0 $\mu g/cm^2$ of pseudoboehmite incorporated into the barrier film represents a thickness of 710Å, using a density of 2.44 g/cc (6) for the pseudoboehmite. The over-all thickness of the initial hydrous oxide layer was about 4000Å (4).

According to the model proposed by Vedder and Vermilyea (3) for the growth of hydrous oxide, hydrolyzed aluminum species are produced at the base of the film and are then transported, through solution that has penetrated the film, to deposition sites. This picture is not compatible with our finding that the inner portion of the film is impermeable to solvated species. An alternate model for the growth of hydrous oxide has been proposed (9).

The dissolution rates in 5% H_3PO_4-2% CrO_3 of the hydrous and composite films, as calculated from the slopes of the plot of weight loss *vs.* time in Fig. 1, are about 0.3 and 0.015 $\mu g/cm^2$-sec, respectively. The rate of dissolution of a conventional barrier oxide formed in phosphate electrolyte is reported to be 0.29 $\mu g/cm^2$-sec (7); this is just about the same as the stripping rate of hydrous oxide. This was very surprising, since it was expected that the porosity and large specific surface area of the hydrous film (4) would promote much more rapid dissolution than for a compact barrier oxide. Perhaps the internal surfaces on which N_2

adsorbs during a BET measurement are not accessible to solvated species. It is also possible that the macroscopic porosity observed in electron micrographs (3, 10) is a property of the dry state only, and that water is imbibed into the structure to produce swelling and a reduction in porosity when the film is wet.

The very low stripping rate of the composite oxide barrier film may be due to the presence of γ-alumina, which, when produced by thermal oxidation, has been observed to be only very slowly dissolved, if at all, by the stripping solution (11). Jackson and Waddell (12) have reported that the surface of the barrier film of a composite oxide formed in a boric acid electrolyte is γ-Al_2O_3, with a small amount of amorphous oxide distributed in the crystalline oxide. Our own electron diffraction studies confirmed the presence of a γ-alumina surface, for films formed in both borate and phosphate electrolytes. The phosphate film had a higher degree of crystallinity and showed a (511) preferred orientation.

The usual product of the dehydration of boehmite is γ-alumina (13). The γ-alumina in the composite oxide might be the result of field-assisted dehydration. The (511) orientation found in one sample could result from slippage of the oriented pseudoboehmite layer during dehydration. On the other hand, γ-alumina has been found in conventional anodic oxides (1) so the origin of this phase is not certain.

We have no ready explanation for the higher field sustained by the composite oxide during anodic oxidation. There are examples in the literature of systems where the field strength of the oxide has been increased, for example, by incorporation of anions (14), but this has been accompanied by a decrease in dielectric constant. This coupling is not present in the composite oxides, for which the dielectric constant appears to be about the same as for a conventional film. The γ-alumina phase is not known to be a particularly good insulator or dielectric so the mere presence of this phase cannot explain the effect. It was thought that the unusual electrical properties might arise from a particular orientation of the γ-oxide on the surface, but although a phosphate-formed film showed a preferred orientation that was missing from the borate-formed specimen, they had identical field strengths. It has been suggested that the special properties of this film may be due to the presence of a hydrogen aluminum spinel structure (2). The information obtained in the present experiments was not of a nature to test this hypothesis.

Since current density had no effect on the amount of pseudoboehmite converted to barrier oxide, but the amount of anodic oxide deposited decreased with current density in the expected fashion, the net result is that the weight of composite barrier film showed a lesser dependence on current density than in the case of a conventional anodic oxide.

The same anodization kinetics and film properties were obtained using borate or phosphate electrolyte. Shimura (15) also found only a small effect of electrolyte type on anodization kinetics of composite oxides. These observations are in accord with the idea that film growth by cation transport does not occur at a surface in contact with electrolyte, but rather at the barrier oxide/hydrous oxide interface (2). New barrier film is produced by a reaction between Al cations and pseudoboehmite (*e.g.*, $Al^{+3} + AlOOH + H_2O \rightarrow Al_2O_3 + 3H^+$) and/or by a reaction between cations and water released from the pseudoboehmite by a prior dehydration step.

Conclusions

1. The innermost region of the pseudoboehmite film produced in boiling water is essentially impermeable to phosphate anions and presumably other solvated species of similar size.
2. From the relatively slow stripping rate of the hydrous oxide it is inferred that the large internal area measured by nitrogen adsorption is not accessible to aqueous solution at ordinary temperatures and pressure.
3. Previous estimates of hydrous oxide conversion and reduced barrier film weight in the composite oxide have been confirmed by direct gravimetric analysis.
4. The amount of pseudoboehmite transformed to barrier film is independent of the current density used during anodic oxidation.

Electroless Cobalt Deposition from Acid Baths

F. Pearlstein and R. F. Weightman

ABSTRACT

An acid electroless cobalt plating bath was developed which utilizes dimethylamine borane (DMAB) as the reducing agent and which provides bright deposits at over 13 μm/hr at 70°C. The bath, slightly modified, is also usable at room temperature for deposition on palladium-activated nonconductors. Additions of even small quantities of hypophosphite to the DMAB bath resulted in failure to achieve deposition; the effect of hypophosphite additions on the single electrode potentials was determined and the results discussed. Electroless cobalt-boron deposits were found superior, in some respects, to electroless nickel-phosphorus for providing protection for steel against corrosive attack. A double layer deposit of electroless nickel plus electroless cobalt topcoat provided more effective protection for steel than either deposit, alone, of the same total thickness. Chromating treatments were found effective for retarding the tendency for tarnishing of cobalt during salt exposure. The magnetic properties of some electroless cobalt-boron deposits were determined; the coercivity was considerably lower than that of electroless cobalt-phosphorus deposits.

Electroless cobalt deposition was first described by Brenner and Riddell (1). Since that time, a great deal of interest has been shown in the electroless cobalt deposits because of their ability to be readily plated upon suitably activated plastic (2) and because of the wide variety of magnetic properties attainable. Electroless cobalt deposits have been employed for high quality, high density recordings and for computer storage elements in high speed switching devices (3). The magnetic deposits are produced from hypophosphite-based baths and consist of cobalt-phosphorus (4-10) or ternary alloys of cobalt and phosphorus plus an additional metal element (11-18).

It is well known that from baths containing hypophosphite reducing agent, electroless cobalt deposits can be produced only from alkaline-type baths whereas nickel deposits are produced from both alkaline and acid baths (19). The acid-type electroless nickel baths have enjoyed the greater commercial acceptance because of higher deposition rates and elimination of unpleasant ammonia fumes. In the desire to develop a useful acid-type electroless cobalt plating bath, attention was directed to the use of other reducing agents. Dimethylamine borane (DMAB), for example, is a more powerful reducing agent than hypophosphite and is capable of providing electroless cobalt deposits from both acid and alkaline baths (20, 21).

The studies reported herein were conducted to develop acid electroless cobalt plating baths and to determine some characteristics of the baths and properties of deposits.

Experimental

Preliminary studies involved preparation of acid-type electroless cobalt plating baths containing cobalt sulfate, dimethylamine borane (DMAB), and an organic radical (to function as buffer, exaltant, and/or chelate) such as acetate, lactate, citrate, succinate, or glycolate. Succinate was indicated from these experiments to be the most effective additive of the group for providing sound deposits at high rates.

Experimental electroless cobalt plating baths were prepared with reagent grade chemicals except for DMAB[1] which was 99+% purity. A thermostatically controlled water bath was used to heat and maintain solutions within 1.0°C of the desired temperature.

Key words: electroless plating, cobalt, nickel, amine borane, hypophosphite.

[1] Callery Chemical Company, Callery, Pennsylvania 16024.

Copper panels (2 × 2.5 cm) were alkaline cleaned, chemically polished, and palladium activated [30 sec in a solution of 0.1 g/liter $PdCl_2$ and 0.1 ml/liter HCl (38%) at 25°C], thoroughly rinsed, dried, and reweighed. Deposition tests were conducted for a 1 hr period with an area to volume ratio of 1:20.

The effect of bath constituent concentration, bath pH, and bath temperature on electroless cobalt deposition rate was determined.

The effect of hypophosphite additions to an acid-type electroless cobalt plating bath (utilizing DMAB reducing agent) on deposition rate was determined. The steady-state potential of 13 μm electroless cobalt-boron plated specimen in the baths of mixed DMAB-hypophosphite was also determined. The specimen was successively immersed for 5 min periods into baths (at 70°C) containing 0, 0.25, 0.5, 1.0, 2.0, 4.0, 6.0, and 8.0 g/liter sodium hypophosphite monohydrate. The potential of the specimen was measured at the end of each 5 min immersion period *vs.* a saturated calomel electrode immersed into the bath for 5 sec. A Hewlett Packard 410C Vacuum Tube Voltmeter, with input resistance of 10^8 ohms was used for taking the potential measurements. Similar tests were conducted with an alkaline cobalt bath[2] containing various proportions of DMAB and hypophosphite and with the acid and alkaline bath in which the cobalt salt was replaced with the molar equivalent of nickel sulfate.

The ability for clean, nonactivated copper to spontaneously initiate deposition of cobalt from the acid-type electroless plating bath at 70°C was determined as a function of DMAB concentration. Potential measurements were also made. Deposition tests were conducted on other substrates including steel, electroless nickel, platinum, and palladium-activated plastic.

A heavy (about 200 μm) deposit of electroless cobalt was applied to steel and hardness measurements made perpendicular to the surface using a Vickers indentor with 50g load applied. The deposit hardness was also determined after heat-treatment at 250°C in an air oven.

Electroless cobalt deposits were analyzed for composition, *i.e.*, cobalt (electrodeposition method), boron (atomic absorption method), carbon (Leco Automatic Carbon Determinator), and nitrogen (Kjeldahl distillation-titration method).

[2] 35 g/liter $CoSO_4 \cdot 7H_2O$, 80 g/liter $Na_3C_6H_5O_7 \cdot 2H_2O$, 50 g/liter NH_4Cl, 60 ml/liter NH_4OH (28% NH_3); 80°C.

Electroless cobalt deposits were applied to steel Hull Cell panels[3] (6.7 × 10 cm) from the acid-DMAB bath in nominal thicknesses of 2.5, 5, and 10 μm and tested for corrosion resistance during exposure to 5% neutral salt spray. For comparative purposes, tests were also conducted with conventional electroless nickel-phosphorus[4] plated steel panels. A set of panels was also prepared with a double layer deposit consisting of approximately 7.5 μm electroless nickel followed by a topcoat of 2.5 μm electroless cobalt and subjected to the salt spray test. Triplicate panels were prepared for each type and thickness of deposit was tested. The steel panels were prepared for electroless plating as follows: (*i*) 1 min in 50% (volume) hydrochloric acid (38%) at 25°C (to remove protective zinc coating), cold water rinse (CWR); (*ii*) 5 min in orthosilicate soak alkaline cleaning bath at 85°C and soft bristle brushing, CWR; (*iii*) 1 min in 50% (volume) hydrochloric acid (38%) at 25°C, CWR.

Chromating treatments were applied to electroless cobalt, freshly deposited on steel, by immersion for 10 sec in 200 g/liter $Na_2Cr_2O_7 \cdot 2H_2O$ —6 ml/liter H_2SO_4 (sp. gr. 1.84) or in Alodine 1200S[5] (7.5 g/liter, pH 2.1) at 25°C, rinsed, and dried. The specimens were evaluated for tarnish resistance during salt spray exposure.

Cobalt deposits were applied to chemically polished and palladium-activated copper panels from the following baths:

Bath constituent	Co-B (acid)	Co-B (alk)	Co-P (alk)
Cobalt sulfate, $CoSO_4 \cdot 7H_2O$ (g/liter)	25	30	30
DMAB, $(CH_3)_2HNBH_3$	4	4	—
Sodium hypophosphite, $NaH_2PO_2 \cdot H_2O$ (g/liter)	—	—	20
Sodium succinate, $C_4N_4Na_2O_4 \cdot 6H_2O$ (g/liter)	25	—	—
Sodium citrate, $Na_3C_6H_5O_7 \cdot 2H_2O$ (g/liter)	—	80	80
Ammonium chloride, NH_4Cl (g/liter)	—	50	50
Ammonium hydroxide (28% NH_3), NH_4OH (ml/liter)	—	60	60
Temperature, °C	70	80	80
pH	5.0	9.0	9.0

The coercive force of various thicknesses of the deposits was determined using a vibrating sample magnetometer.[6]

Results and Discussion

The effect of dimethylamine borane (DMAB) concentration on deposition rate was determined from solutions containing 25 g/liter cobalt sulfate heptahydrate and 15 g/liter sodium succinate hexahydrate. Results are shown in Fig. 1. The baths were adjusted to pH 5.0 with sulfuric acid solution and were operated at 80°C. Deposition rates increased essentially linearly with DMAB concentration to a maximum at about 4 g/liter. At above this DMAB concentration, catalytic particles formed in the solution which tended to settle to the beaker bottom and resulted in rapid bath decomposition.

The effect of succinate concentration on deposition rate was determined from solutions containing 25 g/liter cobalt sulfate heptahydrate and 4 g/liter DMAB at pH 5.0 and at 80°C (see Fig. 2). When no succinate was present, spongy cobalt formed within the solution accompanied by rapid bath decomposition, and virtually no deposition was produced on the palladium-activated copper specimen. Satisfactory bath stability was provided by the presence of 10 g/liter or more of the succinate in the bath. Succinate also provided buffering action, *i.e.*, prevented rapid change in bath pH during deposition. Deposition rates were highest and essentially constant at sodium succinate hexahydrate concentration of 15-30 g/liter. A 25 g/liter concentration was adopted for additional studies.

The effect of bath pH (measured at 25°C) on deposition rates was determined. Both initial pH and the pH after completion of deposition test are shown in Fig. 3.

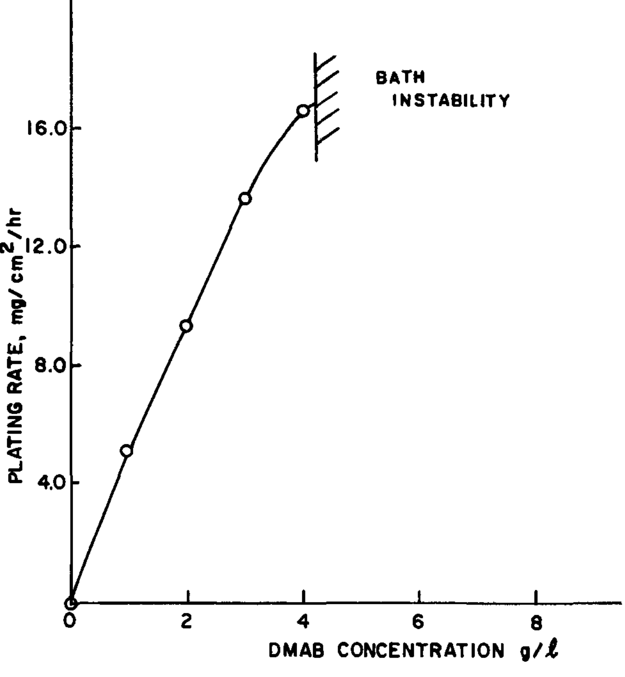

Fig. 1. Effect of DMAB concentration on electroless cobalt plating rate. Bath: 25 g/liter $CoSO_4 \cdot 7H_2O$, 15 g/liter $C_4H_4Na_2O_4 \cdot 6H_2O$; pH 5.0; temp. 80°C.

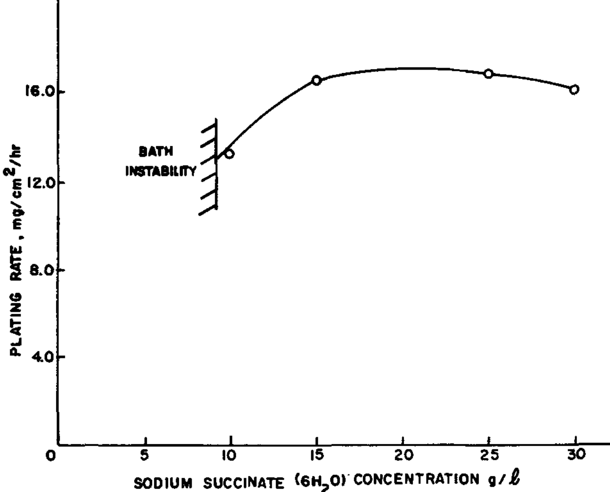

Fig. 2. Effect of succinate concentration on electroless cobalt plating rate. Bath: 25 g/liter $CoSO_4 \cdot 7H_2O$, 4 g/liter DMAB; pH 5.0; temp. 80°C.

The deposition rate increased markedly with bath pH. Baths of pH above about 5.5 tended to be unstable and deposits formed on beaker walls and bottom.

It is interesting to note that baths at pH 4.5 or lower increased in pH during the deposition test, while baths at pH 5.5 or above decreased. Normally, electroless plating baths decrease in pH during use because hydrogen ions are a product of the reaction (19, 22). However, DMAB is subject to acid catalyzed hydrolysis (24) leading to consumption of H^+

$$(CH_3)_2HN \cdot BH_3 + 3H_2O + H^+ \rightarrow (CH_3)_2NH_2^+ + H_3BO_3 + 3H_2$$

Indeed, it was found that even when no electroless plating was occurring, baths (80°C) at pH 4.5 or below increased in pH with time, and that gassing was evident within the solutions. At bath pH of 5.0, little

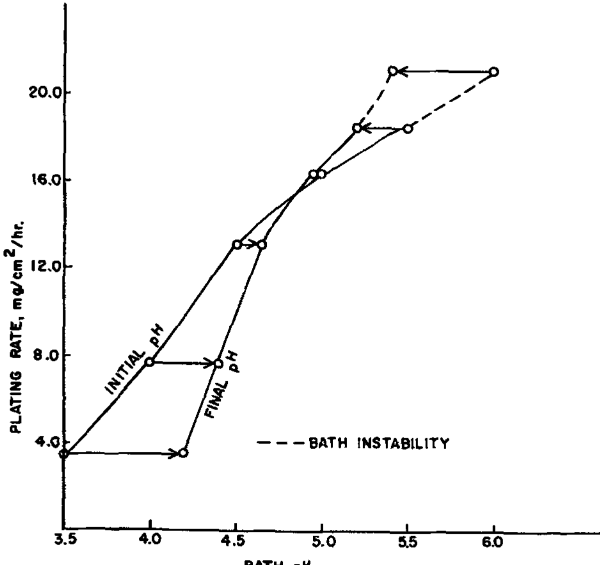

Fig. 3. Effect of bath pH on electroless cobalt plating rate. Bath: 25 g/liter $CoSO_4 \cdot 7H_2O$, 25 g/liter $C_4H_4Na_2O_4 \cdot 6H_2O$, 4 g/liter DMAB; temp. 80°C.

change in pH resulted during (or without) deposition and subsequent tests were conducted with baths at this pH unless otherwise noted.

Electroless cobalt deposition rates were little affected by cobalt salt concentration within the range of 15-45 g/liter and tests were continued with baths containing 25 g/liter cobalt sulfate heptahydrate.

The rate of cobalt deposition increased with increasing bath temperature in a manner typical of most electroless plating baths (24-26) (see Fig. 4). At 90°C, the bath was subject to spontaneous production of cobalt particles and rapid decomposition. At 80°C, the bath was stable during the 1 hr plating tests but there was a tendency for catalytic particles to form in the bath during more extended plating periods thereby causing bath decomposition. The bath can be made much less susceptible to such decomposition by introducing trace amounts of a catalytic poison (*e.g.*, 1-2 mg/liter lead acetate trihydrate or thiourea). However, at bath temperatures of 80°C or above, wasteful consumption of DMAB by hydrolysis is probably significant (23) and it is thus advisable, from a practical standpoint, to operate the bath at lower temperatures except where very high deposition rates are of primary importance. At 70°C, the bath is operable without the necessity of addition of catalytic poison stabilizers, and hydrolysis losses are minimized.

Deposition rates are quite low at a bath temperature of 40°C or lower. However, the baths can be used even at room temperatures (22°-27°C) for applying thin, conductive deposits to palladium-activated nonconductors, provided the bath pH is increased to about 6.3.

There was a tendency for gas pits to form on the electroless cobalt deposits. Workpiece movement was helpful in alleviating this condition, but addition to the bath of about 15 g/liter or more sodium sulfate also reduced the tendency for pitting to occur. The presence of sodium sulfate in the bath had no apparent deleterious effects and did not affect deposition rate.

The electroless plating bath of preferred composition is 25 g/liter cobalt sulfate ($CoSO_4 \cdot 7H_2O$), 25 g/liter sodium succinate ($C_4H_4Na_2O_4 \cdot 6H_2O$), 15 g/liter sodium sulfate (Na_2SO_4), and 4 g/liter dimethylamine borane [$(CH_3)_2HNBH_3$]. The bath at pH 5.0 and at a temperature of 70°C produces bright electroless cobalt deposits at a rate of about 13 μm/hr.

Baths of mixed DMAB-hypophosphite.—The effect of hypophosphite additions to the electroless cobalt plating bath on deposition rate at 70°C is shown in Fig. 5. As little as 1 g/liter sodium hypophosphite monohydrate substantially reduced the deposition rate; 4 g/liter or more prevented deposition entirely. It was thus demonstrated that, not only is hypophosphite reducing agent unable to provide electroless cobalt deposition from acid solutions, but its presence prevents deposition from a DMAB bath. The steady-state mixed potentials of an electroless cobalt specimen in the baths of increasing hypophosphite concentrations are also shown in Fig. 5. The curve of potentials *vs.* hypophosphite concentration closely paralleled that of deposition rate.

The deposition potential for cobalt in the electroless plating bath (70°C, pH 5.0), but from which the reducing agents were excluded, was determined by applying increasing cathodic current in very small increments to a gold electrode. The cathode potential at which the first signs of cobalt deposition appeared was about −0.67V (SCE).[7]

[7] Similar tests were conducted in the same bath but with 23.4 g/liter $NiSO_4 \cdot 6H_2O$ present instead of the cobalt salt. The deposition potential for nickel was determined to be about −0.59V (SCE).

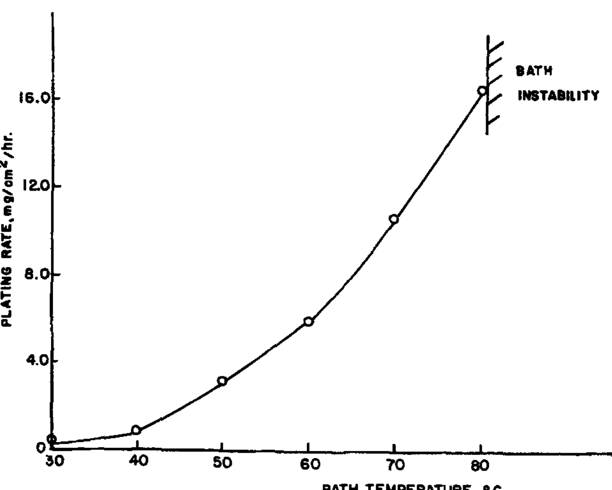

Fig. 4. Effect of bath temperature on electroless cobalt plating rate. Bath: 25 g/liter $CoSO_4 \cdot 7H_2O$, 25 g/liter $C_4H_4Na_2O_4 \cdot 6H_2O$, 4 g/liter DMAB; pH 5.0.

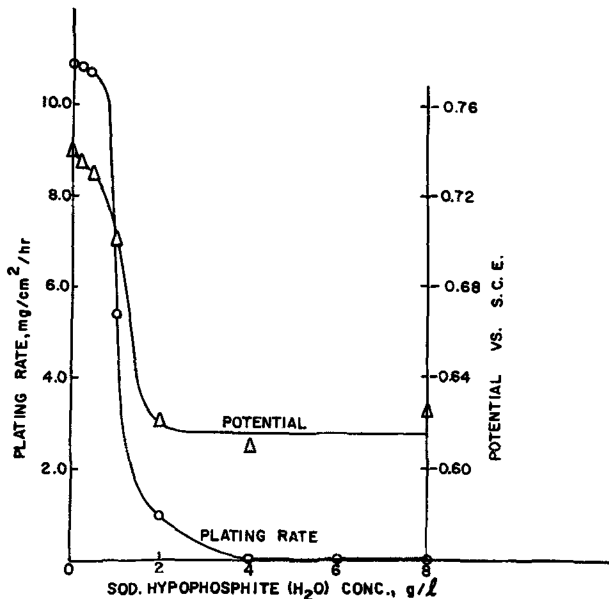

Fig. 5. Effect of hypophosphite additions to bath on electroless cobalt plating rate and potential. Bath: 25 g/liter $CoSO_4 \cdot 7H_2O$, 25 g/liter $C_4H_4Na_2O_4 \cdot 6H_2O$, 15 g/liter Na_2SO_4, 4 g/liter DMAB; pH 5.0; temp. 70°C.

It can be seen from Fig. 5 that when about 2 g/liter or more of the hypophosphite is present in the bath, the steady-state mixed potential of the catalytic surface is not attained at which cobalt can be deposited and is at a level characteristic for baths containing hypophosphite alone. Gassing at the palladium-activated specimens was observed in all solutions, though the rate was considerably decreased in the baths from which deposition was not obtained. The action of hypophosphite may be considered analogous to lowering the hydrogen overvoltage of a surface and thus preventing the metal deposition from occurring.

The effect of hypophosphite-DMAB combinations in alkaline electroless cobalt plating baths, from which deposits are produced when either reducing agent is present alone, on deposition rate and potential are shown in Fig. 6. Marked antagonism is indicated between the hypophosphite and DMAB from the deposition rate measurements, and solutions with relatively little hypophosphite behave more like baths containing only hypophosphite. The hypophosphite might be considered as preferentially adsorbing or dehydrogenating on the surface thereby nullifying the presence of DMAB. The decrease in steady-state mixed potential of electroless cobalt is most pronounced in the solutions containing little hypophosphite and it decreases more gradually with further increases in hypophosphite.

Similar studies of nickel deposition rate in mixed hypophosphite-DMAB baths were conducted from both acid and alkaline solutions. Marked antagonism was not exhibited for the nickel plating baths (see Fig. 7). Nickel deposition rates from the alkaline baths were not greatly affected by the relative proportions of hypophosphite and DMAB (see Fig. 8). It is evident that the metal ions also provide some interaction with one or both of the reducing agents as witnessed by the differences in behavior of the cobalt and nickel baths.

Deposition on various substrates.—Substrates that are sufficiently catalytically active to spontaneously initiate deposition by immersion in the (25-25-15-4) electroless cobalt plating bath (*p*H 5.0, 70°C) are steel, electroless nickel, palladium, or gold. Aluminum is spontaneously plated, presumably by first providing a displacement deposit of cobalt. A thin immersion zinc deposit on aluminum, by treatment in zincate solution, is desirable for rapid, uniform coverage with cobalt.

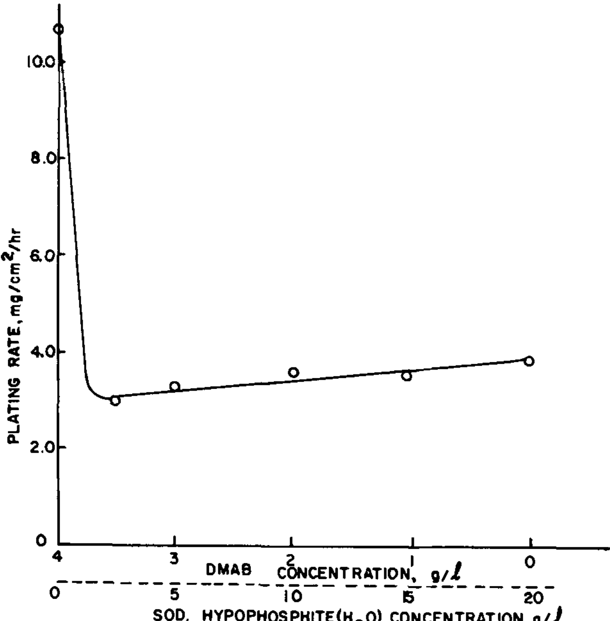

Fig. 6. Effect of DMAB-hypophosphite combinations on electroless cobalt plating rate from alkaline bath. Bath: 35 g/liter $CoSO_4 \cdot 7H_2O$, 80 g/liter $Na_3C_6H_5O_7 \cdot 2H_2O$, 50 g/liter NH_4Cl, 60 ml/liter NH_4OH (28% NH_3); temp. 80°C.

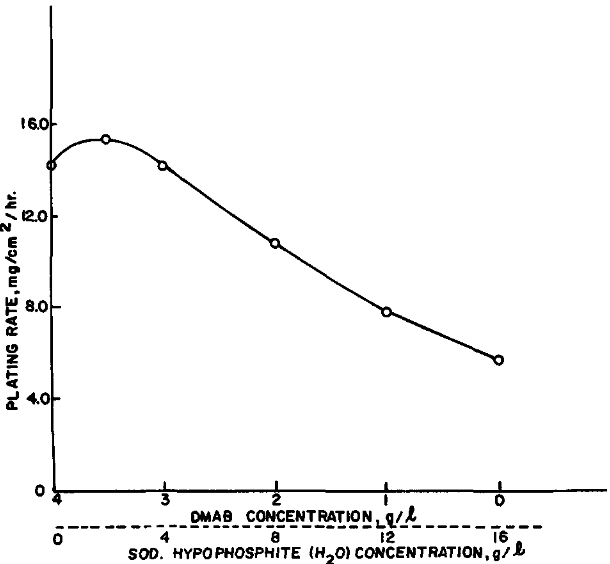

Fig. 7. Effect of DMAB-hypophosphite combinations on electroless nickel plating rate. Bath: 23.4 g/liter $NiSO_4 \cdot 6H_2O$, 25 g/liter $C_4H_4Na_2O_4 \cdot 6H_2O$, 15 g/liter Na_2SO_4; *p*H 5.0; temp. 70°C.

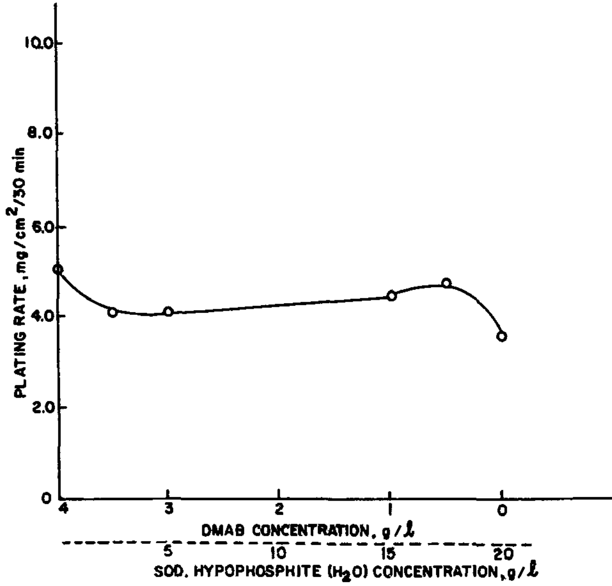

Fig. 8. Effect of DMAB-hypophosphite combinations on electroless nickel plating rate from alkaline bath. Bath: 32 g/liter $NiSO_4 \cdot 6H_2O$, 80 g/liter $Na_3C_6H_5O_7 \cdot 2H_2O$, 50 g/liter NH_4Cl, 60 ml/liter NH_4OH (28% NH_3); temp. 80°C.

Copper, brass, silver, platinum, titanium, or stainless steels usually do not initiate electroless cobalt deposition unless one of the following steps are taken: (*i*) activation of the surface by nucleation with a catalytically active metal such as palladium; (*ii*) contact in the solution with an actively plating metal; (*iii*) momentary application of sufficient cathodic current to apply a thin cobalt film electrolytically. Nonconductors are readily plated after palladium activation (27).

The effect of DMAB concentration on the potential of electrolytic copper (99.9% purity) in the cobalt plating bath is shown in Fig. 9. The potential became more negative with increased DMAB concentration, and though gassing was visible in all baths containing DMAB, deposition was usually not initiated. However, occasionally spontaneous initiation occurred as illustrated by the dotted line in Fig. 9 and has even occurred in the baths containing only 4 g/liter DMAB.

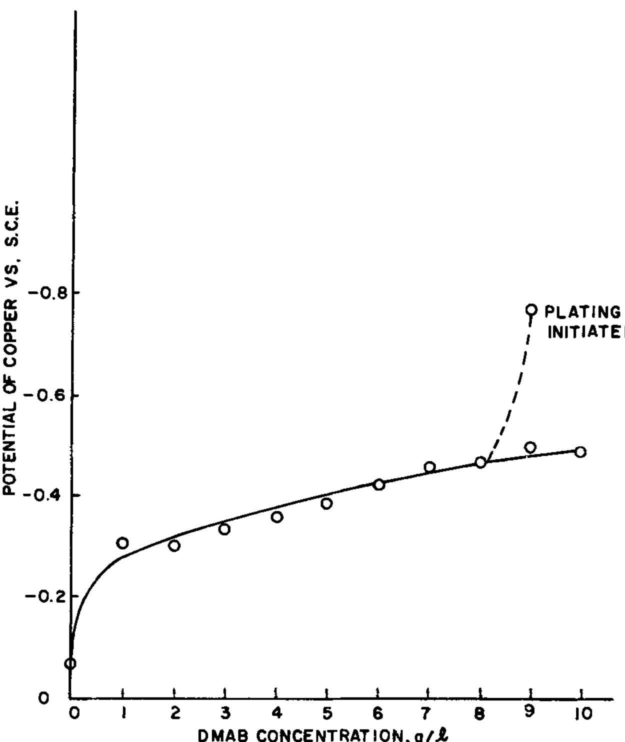

Fig. 9. Effect of DMAB concentration on the steady-state potential of copper in electroless cobalt plating bath. Bath: 25 g/liter $CoSO_4 \cdot 7H_2O$, 25 g/liter $C_4H_4N_2O_4 \cdot 6H_2O$, 15 g/liter Na_2SO_4; pH 5.0; temp. 70°C.

The explanation for this phenomena is not known, but catalytic particles that enter the bath may provide the initiating influence by chance contact. Platinum is more catalytically active than copper, acquiring a potential of −0.54V in the 4 g/liter DMAB baths, but, as mentioned earlier, did not initiate cobalt deposition.

It was found that when the succinate of the electroless cobalt plating bath of preferred composition was substituted by the equivalent molar quantity of sodium malonate, deposition was more likely to be spontaneously initiated on copper, and deposition rates were unaffected by the substitution. It thus appears that the succinate has an inhibiting effect on the catalytic initiation of cobalt deposition on copper and that malonate can be used in place of succinate in the bath if spontaneous deposit initiation on copper is desired.

Deposit properties.—Composition—The composition of electroless cobalt deposits from the preferred (25-25-15-4) bath (pH 5.0, 70°C) was determined to be: cobalt, 96.0% by weight; boron, 1.7% by weight; carbon, 0.97% by weight; and nitrogen, 0.05% by weight. The presence of carbon and nitrogen indicates organic or organometallic compounds in the deposit.

Hardness.—Electroless cobalt-boron deposits were found to have a hardness of 270 kg/mm^2 (Vickers) in the as-plated condition. After heating 24 hr at 250°C,

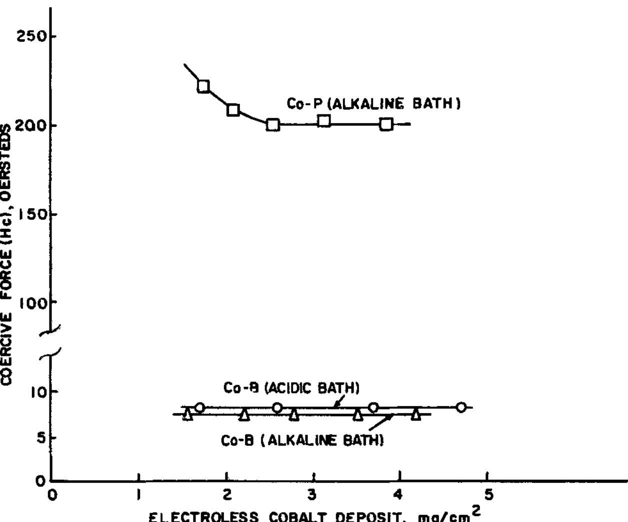

Fig. 10. Coercive force of electroless cobalt deposits produced from various baths.

the hardness increased to 480 kg/mm^2. Additional heating at 250°C further increased the hardness to a maximum of about 640 kg/mm^2 after a total heating time of 4 days.

Magnetic properties.—The coercive force of electroless cobalt deposits produced from three baths are shown in Fig. 10. The coercive force of the cobalt-boron deposits was constant, over the range of thickness tested, at about 8 oersteds. The coercive force of cobalt-phosphorus deposits was considerably higher and increased with decreasing deposit thickness.

Corrosion prevention.—The results of salt spray exposure tests on electroless cobalt and nickel plated steel panels are shown in Table I. All of the electroless cobalt or electroless nickel deposits were quite protective to steel for up to 48 hr salt spray exposure. With longer exposure times, the protective value of the coatings increased with thickness. The electroless nickel deposits were somewhat more protective of steel than cobalt deposits. However, edge corrosion was very pronounced with electroless nickel coated specimens while the electroless cobalt plated steel was resistant to edge corrosion.

The corrosion potential of electroless cobalt-boron deposits, immersed in 50 g/liter sodium chloride solution for 24 hr, was −0.60V (SCE). Steel and electroless nickel in the salt solution have corrosion potentials of −0.63 and −0.35V, respectively. The pronounced edge corrosion encountered with electroless nickel plated steel is undoubtedly the result of the adverse electrochemical relationship of the couple. The potentials would indicate cobalt and steel to be much more galvanically compatible in salt solution than nickel and steel.

From the corrosion potentials it can be predicted that a double layer deposit of electroless nickel-phosphorus followed by a topcoat of electroless cobalt-

Table I. Corrosion resistance of electroless cobalt or nickel plated steel

Deposit	Deposit thickness, μm	Corrosion rating* after exposures to salt spray, avg of 3				
		24 hr	48 hr	72 hr	96 hr	168 hr
Electroless cobalt	3	5	4	3+	3 (sl. E)	2 (E)
Electroless cobalt	5	5	5	4	3+	3 (sl. E)
Electroless cobalt	10	5	5	5	5	3+ (sl. E)
Electroless nickel	3	4 (E)	4 (E)	4 (E)	3+ (E)	2+ (E)
Electroless nickel	6	5 (E)	5 (E)	5 (E)	5 (E)	5 (E)
Electroless nickel	12	5	5 (E)	5 (E)	5 (E)	5 (E)

* Ratings (excluding edges): 5 = no basis metal attack; 4 = traces of basis metal attack; 3 = slight basis metal attack; 2 = moderate basis metal attack; 1 = considerable basis metal attack. E = edge corrosion; sl. E = slight edge corrosion.

boron would probably provide synergistic protection because of the ability of the cobalt to sacrificially protect the nickel layer from corrosive penetration. This relationship with the synergistic protection of electrodeposited nickel double layers has been well established (28-30). Double layer deposits (7.5 μm electroless nickel-2.5 μm electroless cobalt) on steel were found capable of preventing basis metal attack (even at edges) during 168 hr salt spray exposure and were superior to the same total thickness of either layer alone.

Tarnish resistance.—Electroless cobalt-boron deposits tarnish rapidly during salt spray exposure to produce a tenacious, unattractive, mottled, blue-brown film.

Consideration was given to blackening the electroless cobalt deposits in order to avoid the tarnishing during salt spray exposure and also to provide a nonreflective surface often desired for military equipment. Some success was achieved in providing a blackened surface by immersion for 10 min in 10 g/liter potassium persulfate solution at 25°C.

Immersion of electroless cobalt deposits in a dichromate-sulfuric acid solution greatly improved the resistance of the surface to tarnishing; the surface remained bright and untarnished after 72 hr salt spray exposure. The solution was mildly corrosive to the cobalt-boron, removing about 0.1 μm during the 10 sec immersion. No visible film was produced by the treatment.

The proprietary chromating solution was noncorrosive to the electroless cobalt and also substantially improved resistance to tarnishing though not quite as effectively as the other solution. Longer immersion times (*e.g.*, 30 sec or more) in the proprietary solution resulted in the imparting of a visible iridescent film that provided improvement of the deposit in resistance to basis metal corrosion during salt spray exposure.

The chromate treatments described above may be valuable for application to thin, magnetic, electroless cobalt deposits since even slight atmospheric corrosion can significantly alter the magnetic properties (9).

Conclusions

An acid electroless cobalt plating bath at pH 5.0 of the following composition is capable of producing bright deposits (96.0% Co, 1.7% B, 0.97% C, 0.05% N) at a rate of about 13 μm/hr at 70°C: 25 g/liter cobalt sulfate ($CoSO_4 \cdot 7H_2O$), 25 g/liter sodium succinate ($C_4H_4Na_2O_4 \cdot 6H_2O$), 15 g/liter sodium sulfate (Na_2SO_4), and 4 g/liter dimethylamine borane [$(CH_3)_2HNBH_3$].

Steel, electroless nickel, gold, aluminum (zincate treated), or palladium-activated nonconductors spontaneously initiate electroless cobalt deposition from the acid bath; copper, silver, brass, or platinum usually do not initiate deposition.

The hardness of as-plated electroless cobalt deposits is 270 kg/mm^2 (Vickers) and can be increased to 640 kg/mm^2 by heating at 250°C. The coercive force of cobalt-boron deposits are relatively low at about 8 oersteds.

Electroless cobalt deposits can provide effective protection for steel against corrosive attack. Synergistic protection is provided by a double layer deposit consisting of electroless nickel-phosphorus and electroless cobalt topcoat. A chromating treatment improves resistance of the cobalt to tarnishing.

The presence of even small quantities of hypophosphite in electroless cobalt plating baths with DMAB results in marked reduction of deposition rate or cessation of deposition.

The Electroreduction of Oxygen and Hydrogen Peroxide on Sodium-Tungsten Bronzes

Jean-Paul Randin*

Hydro-Quebec Institute of Research, Varennes, Quebec, Canada

The publication costs of this article have been assisted by the Hydro-Quebec Institute of Research.

ABSTRACT

Sodium-tungsten bronzes of the general formula Na_xWO_3 ($0.34 < x \leq 0.89$), with high and low platinum contents, were investigated regarding their electrocatalytic activity towards the reduction of oxygen and hydrogen peroxide in sulfuric acid solutions. Contrary to the findings of some other workers Na_xWO_3 are found to be poor catalysts for the cathodic reduction of oxygen. The presence of platinum in the bronze at concentrations in the 1000 ppm range does not increase significantly the catalytic properties of the bronze electrode. Sodium tungsten bronzes are relatively good catalysts for the cathodic reduction of hydrogen peroxide in acid solutions. The reaction is first-order with respect to the H_2O_2 concentration and zero-order with respect to the H^+ concentration. The steady-state current-potential curve exhibits a slope of 2 RT/F and, at more cathodic potentials, a characteristic inhibition inflection. In contrast to other electrodes the cathodic reduction of H_2O_2 on Na_xWO_3 occurs at potentials less cathodic than those required for the reduction of oxygen.

Sodium-tungsten bronzes containing traces of platinum have been reported to exhibit good electrocatalytic activity for the oxygen reduction reaction (1-6). These findings stimulated considerable interest but other reports (7-10) failed to confirm the exceptionally good catalytic behavior reported by Bockris *et al.* (1-6). In the present study bronzes of the general formula Na_xWO_3 ($0.34 < x \leq 0.89$), with high and low platinum contents, were investigated regarding their electrocatalytic activity towards the oxygen reduction in 1N H_2SO_4. Since hydrogen peroxide is in some cases an intermediate in the reduction of oxygen to water, the irreversibility of the over-all reduction of oxygen in these cases can perhaps be due to the reduction of H_2O_2 to H_2O. Because this problem had not been explicitly considered previously on sodium-tungsten bronzes, it was also investigated in the present work.

Experimental

Sodium-tungsten bronze samples with an x value between 0.34 and 0.89, and platinum content from 1 up to 1200 ppm were investigated. The preparation and analysis of these samples were described recently (11).

A three-compartment cell was used with a rotating disk electrode system. Steady-state current-potential curves were automatically recorded with the system described recently by Bélanger (12). Some runs were performed with a conventional galvanostatic setup and the results were found to be the same both with the potentiostatic and the galvanostatic methods. For the reduction of oxygen long times were necessary to reach the steady-state values, especially in the low current region and during the first scan. Polarization times up to 8 hr were used with the galvanostatic method with potential variations corresponding to about 40 mV. Reproducible results were usually obtained with the potentiostatic method using 10 mV potential step per 5 min. The rotating disk technique was used to eliminate diffusion effects although there was no significant increase of current with increasing rotating speeds in the linear sections of the current-potential curves. Unless otherwise noted, the measurements were carried out at a rotation speed of 900 rpm. The instruments and the cells employed, as well as the details on the electrode mounting and gas purification, were similar to those used in our previous work (13-15).

All solutions were made from sulfuric acid (ULTREX, J. T. Baker Chemical Company), sodium sulfate (J. T. Baker Chemical Company, certified), unstabilized hydrogen peroxide (Fisher Scientific Company, certified), and conductivity water. The peroxide concentration was determined by titration with potassium permanganate after the completion of a set of measurements. Great care was taken to eliminate impurity effects by working under carefully controlled conditions. No preelectrolysis was conducted in the present work, however, since it was previously noted that preelectrolysis tends to produce impurities, especially from the anode (13).

The oxygen gas (99.99%) and the mixtures oxygen-helium (1 and 10% O_2) used in the present study were passed through a gas train which included in order, silica gel, active carbon, silica gel, ascarite and a glass wool filter to remove water, organics, and CO_2.

A hydrogen reference electrode in the same solution or a Hg/Hg_2SO_4 (1N H_2SO_4) electrode was used as reference electrode. All electrode potentials are given with respect to a standard hydrogen electrode.

Experiments were carried out at room temperature unless otherwise specified.

Results

The electrocatalytic reduction of oxygen.—Open circuit potentials were poorly reproducible, and it took a long time to reach a stable value. After 1 hr of stabilization, the rest potential was usually around 0.4V, with extreme values from 0 to 0.6V. The open-circuit potential did not vary significantly whether oxygen, helium, or hydrogen was bubbled into the electrolyte.

A Tafel relationship for the cathodic reduction of oxygen was obtained only over a short range of potentials, *i.e.*, from about 0.1 to −0.2V (Fig. 1). In this potential range the current-potential curve is free of hysteresis between the ascending (potentials acquiring more negative values) and descending curves. When the potential is increased cathodically, interference from the hydrogen evolution reaction seriously affects the results and pronounced hysteresis was observed between the ascending and descending curves. Tafel slopes ranging between 120 and 280 mV/decade were obtained, most of them exhibiting a value around 200 mV/decade.

Key words: electrocatalysis, platinum-traces, inhibition, hydrogen tungsten bronze.

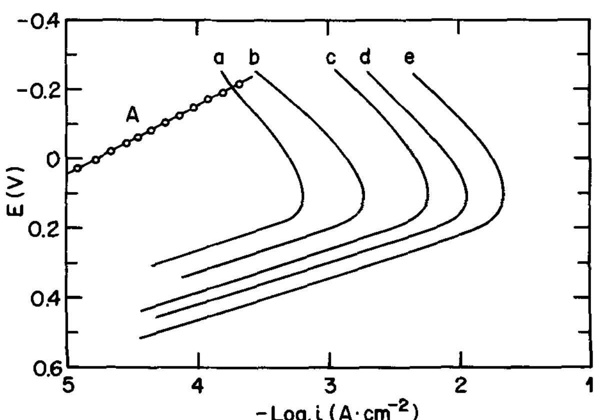

Fig. 1. Potentiostatic, steady-state (point-by-point) current-potential relationships on $Na_{0.65}WO_3$ at 900 rpm. Curve A: for the reduction of oxygen (in O_2-saturated 1N H_2SO_4). Curves a-e: for the reduction of H_2O_2 in He-saturated 1N H_2SO_4 solutions containing (a) 0.0046, (b) 0.0094, (c) 0.046, (d) 0.093, and (e) 0.18M H_2O_2.

The addition of platinum in the bronze sample increases the rate of the oxygen reduction reaction by a very small amount only (Table I). The composition of the bronze samples devoid of platinum has no significant effect on the catalytic behavior of this material for the oxygen reduction reaction (Table II).

The electroreduction of hydrogen peroxide.—Open-circuit potentials.—Open-circuit potentials of sodium-tungsten bronze electrodes in 1N H_2SO_4 solutions in the presence and absence of hydrogen peroxide are shown in Fig. 2 as a function of pH. The various pH values were obtained by adding small amount of solid NaOH to the electrolyte. The measurements were carried out only at pH ≤ 3 since at greater pH values the sodium-tungsten bronze is attacked and catalytic decomposition of H_2O_2 occurs. The open-circuit potential has low reproducibility, and long times (at least 24 hr) were needed to reach a stable value. At a given pH, the mixed potential depends on the H_2O_2 concentration but no clear relationship was found. At a given H_2O_2 concentration the open-circuit potential depends linearly on pH with a slope of about 80 mV/pH (Fig. 2). The results did not depend significantly on whether the solution was saturated with oxygen or helium. An open-circuit potential *vs.* pH curve with a slope of about 30 mV/pH was found in the absence of H_2O_2 and O_2 (Fig. 2).

Table I. Effect of platinum on the rate of the oxygen reduction reaction on $Na_{0.6}WO_3$

Pt content (ppm)	Current density at $E = -0.17V$ (mA · cm^{-2})
2	0.07-0.15
100	0.12-0.19
200	0.19
500	0.20
1200	0.26

Table II. Effect of the x value in Na_xWO_3 on the rate of the oxygen reduction reaction

(Samples with platinum content in the ppm range)

x value	Current density at $E = -0.17V$ (mA · cm^{-2})
0.34	0.07-0.19
0.58	0.07-0.15
0.64	0.08-0.15
0.82	0.12
0.89	0.11

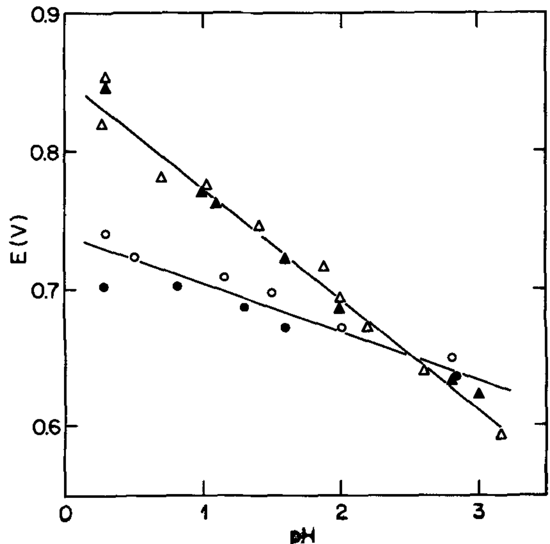

Fig. 2. Rest potential *vs.* pH for a $Na_{0.65}WO_3$ electrode in the presence and absence of H_2O_2 in 1N H_2SO_4 + small amount of solid NaOH. He-saturated 0.1M H_2O_2 (△), O_2-saturated 0.1M H_2O_2 (▲), He-saturated (○), O_2-saturated (●).

Steady-state current-potential relationships.—No detectable spontaneous decomposition of H_2O_2 was observed on Na_xWO_3 in acidic media. The reduction current can, therefore, be attributed only to the reduction of H_2O_2. Steady-state current-potential curves for several concentrations of H_2O_2 are presented in Fig. 1. At potentials anodic enough to avoid interference from the hydrogen evolution reaction, the current-potential relationships present no hysteresis between the ascending and descending curves. A Tafel region is observed between 0.5 and 0.2V with a slope of about 120 mV/decade, *i.e.*, $2 \times 2.3\ RT/F$. At potentials more cathodic than about 0.2V a characteristic inhibition inflection of the type discussed by Gilroy and Conway (16) is observed. The dependence of the current density in the inflection region on the rotation speed (Fig. 3) indicates that the reduction of H_2O_2 is first-order with respect to hydrogen peroxide concentration and that the process is under combined diffusion and kinetic control.

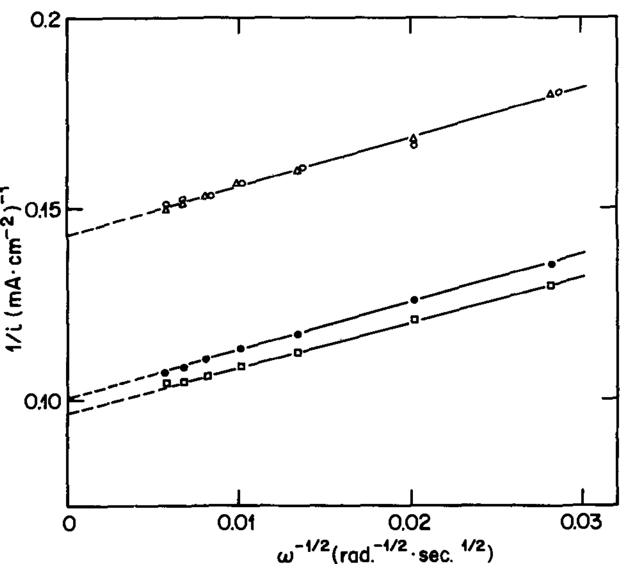

Fig. 3. Plots of $1/i$ in the inhibition inflection region *vs.* $\omega^{-1/2}$ for the reduction of H_2O_2 in He-saturated 1N H_2SO_4 + 0.052M H_2O_2 on $Na_{0.65}WO_3$. E = 0.2V (○), 0.1V (□), 0.0V (●), and −0.1V (△).

The anodic oxidation of H_2O_2 was attempted on sodium-tungsten bronzes, but it was found that these electrodes show no activity for this reaction.

Reaction orders.—The plot of the reaction rate *vs.* the H_2O_2 concentration (Fig. 4) indicates that a reaction mechanism first-order with respect to hydrogen peroxide takes place at constant potential. The reaction order with respect to hydrogen is close to zero between *p*H approximately 0 and 1.8. At *p*H values higher than about 2, the shape of the current-potential curve in the inhibition region is slightly different from that observed at lower *p*H. This behavior suggests that the electrode surface changes in this *p*H range. Impedance measurements carried out in solutions of *p*H around 3 exhibited a peak in addition to those found at lower *p*H (15). This peak was attributed to the dissolution of the bronze electrode. This side reaction may interfere with the hydrogen peroxide reduction reaction and prevent the determination of the true reaction order over a wide *p*H range.

Apparent heat of activation.—Arrhenius plots of the current density at constant potential *vs.* $1/T$ give an apparent heat of activation equal to 8.3 kcal/mole (Fig. 5). A hydrogen electrode in $1N$ H_2SO_4 was used as the reference electrode. The activation energy has not been corrected for the temperature coefficient of the reversible H_2O_2-H_2O potential, nor for changes in H_2O_2, H_2O, or H^+ activity as a function of temperature. Neglecting the changes in activity coefficient and taking -0.658 mV/(°) as the $(dE_o/dT)_{isoth}$ (17) for the H_2O_2/H_2O couple, the heat of activation at constant overpotential would be about 10 kcal/mole.

Effect of the bronze composition.—The rate of the peroxide reduction reaction was found not to depend significantly on either the x value in Na_xWO_3 (for x between 0.34 and 0.89) or the platinum content of the bronze electrode (between a few ppm up to 1200 ppm).

The electroreduction of $O_2 + H_2O_2$.—Investigations in $1N$ H_2SO_4 solutions containing O_2 and H_2O_2 were carried out to detect any possible coupling of the O_2 and H_2O_2 reduction processes. The sum of the current-potential curves for the oxygen reduction alone (in O_2-saturated $1N$ H_2SO_4) and for the hydrogen peroxide reduction alone (in He-saturated $1N$ H_2SO_4 + H_2O_2) is equal to the experimental curve for the reduction of $O_2 + H_2O_2$ carried out at once (in O_2-saturated $1N$ $H_2SO_4 + H_2O_2$). This result indicates the absence of coupling between the two reactions.

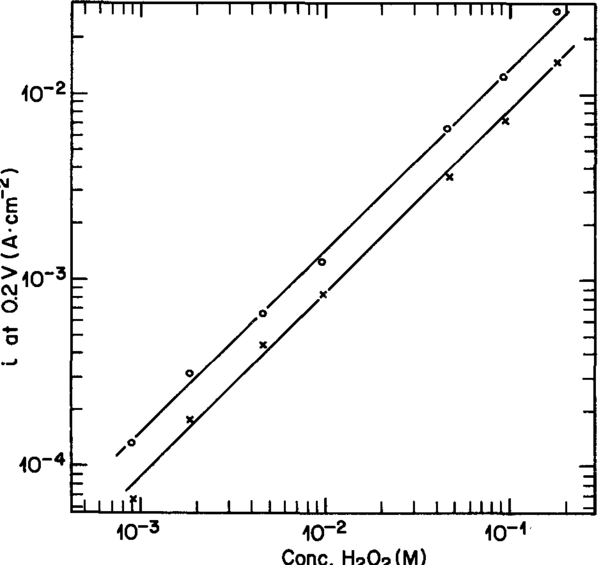

Fig. 4. A plot of the current density at 0.2V (x) and at the current maximum (○) *vs.* the concentration of H_2O_2 in He-saturated $1N$ H_2SO_4 on $Na_{0.65}WO_3$ at 900 rpm.

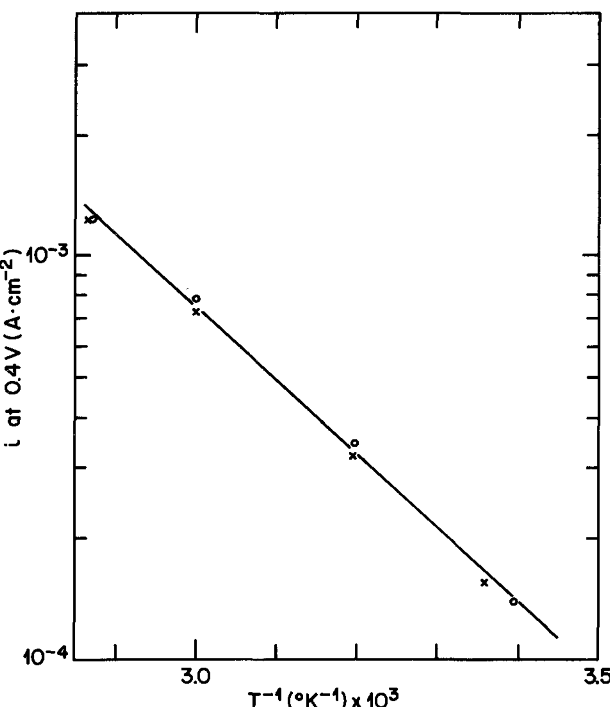

Fig. 5. Current density *vs.* T^{-1} plots for $Na_{0.58}WO_3$ (x) and $Na_{0.65}WO_3$ (○) in He-saturated $1N$ H_2SO_4 + $0.05M$ H_2O_2. The apparent heat of activation calculated from these plots is 8.3 kcal/mole.

Discussion

Reduction of H_2O_2.—The reduction of H_2O_2 on Na_xWO_3 is found to be first-order with respect to the H_2O_2 and zero-order with respect to H^+ ions. The Tafel slope is close to $2 \times 2.3\ RT/\mathbf{F}$. The same reaction orders were found on Hg (18) and Pt (19-20), whereas a first-order reaction with respect to both H_2O_2 and H^+ was found on pyrolytic graphite and active charcoal (21). A Tafel slope of $2 \times 2.3\ RT/\mathbf{F}$ was also found on pyrolytic graphite (21), whereas on platinum a very high slope yielding $(1 - \alpha) = 0.2$ was obtained (19). The same mechanism as that advanced by Bagotskiy *et al.* (18) for the reduction of H_2O_2 on Hg is proposed for Na_xWO_3. The current-potential relation may be represented by

$$i = k\,[H_2O_2]\exp\left(-\frac{(1-\alpha)\eta\mathbf{F}}{RT}\right) \qquad [1]$$

with the following mechanism

$$H_2O_2 + e^- \xrightarrow{\text{rds}} OH_{ads} + OH^-$$

$$\xrightarrow[\text{homogeneous}]{H_3O^+} OH_{ads} + 2H_2O \qquad [2]$$

$$OH_{ads} + e^- \rightarrow OH^- \xrightarrow[\text{homogeneous}]{H_3O^+} 2H_2O \qquad [3]$$

The OH^- produced by the electron transfer reactions [2] and [3], in acidic solutions, is immediately neutralized by H_3O^+. Assuming $\alpha = 1/2$, the observed Tafel slope is consistent with the proposed mechanism.

The current density at the maximum of the current-potential curve is proportional to the concentration of H_2O_2 in the solution (Fig. 4), suggesting that the maximum may be associated with the diffusion limiting current for the reduction of peroxide. However, the plot of $1/i$ *vs.* $\omega^{-1/2}$ (Fig. 3) indicates that diffusion plays only a minor role in the reaction kinetics at, or near, the maximum of the current-potential curve. The inflection in the current-potential curve should

therefore be attributed to some kind of inhibition phenomenon.

Following earlier suggestions by Bagotskiy and Vasilev (22), inhibition and passivation in oxidation reactions were discussed quantitatively by Gilroy and Conway (16), and found to be either the result of an inhibiting species produced in a competing reaction, or of self-inhibition arising from the decomposition of adsorbed radicals. Since inhibition of the reduction of H_2O_2 has not been observed on other electrodes (18-21), it may be assumed that the sodium-tungsten bronze electrode plays an important role in the inhibition process. Furthermore, it is unlikely that a parasitic oxidation reaction of the bronze itself is responsible for the negative Tafel slope, since the shape of the current-potential curves does not depend on the concentration of H_2O_2.

Since the position of the current-potential curves is a function of H_2O_2 concentration, it is suggested that, at a given potential, the same fraction of surface sites are blocked independently of the H_2O_2 concentration. This situation can arise from a parallel reaction such as the hydrogen bronze formation

$$Na_xWO_3 + zH^+ + ze^- \rightarrow Na_xH_zWO_3 \quad [4]$$

This reaction has been shown to occur in the potential range in which the inhibition region begins, *i.e.*, about 0.2V (13). The activity of $Na_xH_zWO_3$ for the reduction of H_2O_2 may be much lower than that of Na_xWO_3. If this is the case, the number of active sites decreases with the progress of reaction [4].

The inhibition of the cathodic reduction of H_2O_2 on Na_xWO_3 may, therefore, be described as the result of a competition for surface sites between peroxide and proton. This phenomenon is similar to that described by Gilroy and Conway (16) for the case of anodic oxidation in competition with oxide formation. In the present study, the reverse situation, *i.e.*, cathodic reduction occurring in competition with hydride formation, has been shown to take place.

To take into account the preceding results, the reaction mechanism can be formulated as follows

$$S + H_2O_2 \rightleftharpoons S(H_2O_2)_{ads} \quad [5]$$

$$S(H_2O_2)_{ads} + e^- \xrightarrow{\text{rds}} S(OH)_{ads} + OH^- \xrightarrow[\text{homogeneous}]{H_3O^+} S(OH)_{ads} + 2H_2O \quad [6]$$

$$S(OH)_{ads} + e^- \rightleftharpoons S + OH^- \xrightarrow[\text{homogeneous}]{H_3O^+} S + 2H_2O \quad [7]$$

where S represents an undefined surface adsorption site at the bronze electrode (see the text following Eq. [3]). As mentioned earlier, the above sequence of reactions [5] to [7] would be proceeding in competition with the parallel reaction [4] suggested here.

The mixed potential established at the bronze electrode is a complex one and does not seem to be defined primarily by the H_2O_2/O_2 couple. The presence of H_2O_2 seems to have more effect than that of oxygen. The behavior of Na_xWO_3 differs substantially from that of the noble metals for which the mixed potentials are defined by the H_2O_2/H_2O and O_2/H_2O_2 couples. It also depends on pH (about 60 mV/pH) but is independent of the hydrogen peroxide concentration (23). The poor reproducibility of the results obtained with Na_xWO_3 prevent one from drawing definite conclusions from these measurements. Since sodium is leached out of the electrode (13-15, 24) it is possible that the mixed potential depends on Na^+.

Effect of the x-value and platinum content of the Na_xWO_3 electrodes on the reduction of oxygen or hydrogen peroxide.—Frumkin *et al.* (25) have suggested that the electrocatalytic properties of an electrode depend mainly on the chemical composition, *i.e.*, electronic properties, of its surface and not on its bulk properties. Several studies (13-15, 24) have shown that sodium depletion occurs at the sodium tungsten bronze surface. Consequently, the surface composition of a polarized Na_xWO_3 electrode changes little as a function of the bulk x value (15). It is therefore not surprising that the bulk x value in Na_xWO_3 has no significant effect on the rate of the oxygen reduction reaction (Table II). Similar results were found for the hydrogen peroxide reduction (see above) and the hydrogen evolution reaction (26).

In Table I the rate of the oxygen reduction reaction on Na_xWO_3 is found to depend only slightly on the platinum content of the electrode. This finding is in sharp contrast with the result of Bockris *et al.* (6) who found that the rate of oxygen reduction is accelerated several thousand times by the presence of 400 ppm of platinum in the bronze electrode. In the present work and other related studies (13-15) the platinum content of the Na_xWO_3 electrode in the range 0-1200 ppm was found not to have a significant influence on the various electrochemical phenomena investigated. In particular, the flatband potential of the semiconducting surface layer did not change with the platinum content (15). Therefore this element does not influence the electronic structure of the catalytic surface.

The results reported by Bockris *et al.* (6) for the reduction of oxygen on platinum-free bronze samples are quite similar to those observed in the present work. The chief discrepancy between the results of Bockris *et al.* (6) and those of the present study [and of other investigations (7-10)] occurs with the samples containing platinum. It may therefore be suggested that the platinum incorporation differs substantially from one investigation to the other. However, a bronze sample containing about 1200 ppm of Pt and prepared in Bockris' laboratory[1] was tested by the present author and found to behave similarly to the samples investigated in the present study. This is not surprising because of the similarity of the methods of preparation (11, 24, 27). Therefore, it is unlikely that the method of preparation is the only factor responsible for the discrepancy. Experimental factors may be the cause of some of the difference, although it is not evident why results obtained with platinum-free samples do not differ substantially from one study to another.

Conclusions

1. Sodium-tungsten bronzes are relatively good catalysts for the cathodic reduction of hydrogen peroxide in acid solutions.
2. Sodium-tungsten bronzes are poor catalysts for the oxygen reduction reaction, in agreement with previous work (7-10).
3. The presence of platinum in the bronze at concentrations in the 1000 ppm range does not increase significantly the catalytic properties of the bronze.
4. The electrocatalytic properties of the bronzes do not depend significantly on the x value in Na_xWO_3.
5. There is no coupling effect between the oxygen and hydrogen peroxide reduction reactions.

Electrochemical Redox Patterns for Pyridinium Species: 1-Methylnicotinamide and Nicotinamide Mononucleotide

Conrad O. Schmakel,[1] K. S. V. Santhanam,[2] and Philip J. Elving*

The University of Michigan, Ann Arbor, Michigan 48104

ABSTRACT

The detailed mechanisms for the electrochemical reduction in aqueous media of pyridinium species have been elucidated on the basis of the electrochemical, spectrophotometric, and chemical properties of two such species and their reduction products: 1-methyl-3-carbamoylpyridinium ion (1-methylnicotinamide; MCP^+) and nicotinamide mononucleotide (NMN^+). An initial reversible pH-independent one-electron (1*e*) addition to the pyridinium ion to produce a free radical is followed by its irreversible dimerization to an apparent 6,6′ species. At more negative potential, the free radical is reduced to an apparent 1,6 dihydropyridine species (2*e* reduction product; NMN^+ may form some 1,4 isomer); the dimer is stable to reduction within the available potential range. At sufficiently positive potential, both 1*e* and 2*e* reduction products can be oxidized back to MCP^+ or NMN^+. Rate constants for the free radical dimerization at 30° is $6 \times 10^7 l$ mol^{-1} sec^{-1} for MCP^+ and $2 \times 10^6 l$ mol^{-1} sec^{-1} for NMN^+; activation energies are 4.1 kcal mol^{-1} for MCP^+ and 3.6 kcal mol^{-1} for NMN^+. While MCP^+ is negligibly adsorbed, its dimeric and dihydropyridine products are strongly and moderately adsorbed, respectively; NMN^+ and its reduction products are negligibly adsorbed. Both reduction products are susceptible to acid-catalyzed hydrolysis; the rate increases with decreasing pH; at any given pH, the dimer is less stable than the dihydropyridine species.

Among the principal components in the electron transport chain in biological oxidation-reduction reactions are pyridinoproteins, which utilize pyridine nucleotides as coenzymes. A basic understanding of the electrochemical redox behavior of pyridine nucleotides should contribute to a better understanding of the electron transport chain, since the site of both biological and electrochemical redox activity in the pyridine nucleotides is the pyridine ring. Of the relevant nucleotides, nicotinamide mononucleotide (NMN^+) (Fig. 1) is the simplest one structurally; its behavior would provide the basis for understanding that of the larger pyridine nucleotides such as NAD^+ (nicotinamide adenine dinucleotide; also called diphosphopyridine nucleotide or DPN^+) and $NADP^+$ (nicotinamide adenine dinucleotide phosphate; triphosphopyridine nucleotide or TPN^+).

The polarographic behavior of many 1-substituted 3-carbamoylpyridinium ions[3] (1-14) has been investigated on the basis of their being model compounds for understanding the polarographic behavior of NAD^+. However, only in the case of the 1-methyl-3-carbamoylpyridinium ion (1-methylnicotinamide; MCP^+) (Fig. 1) have extensive data been collected. Although

[1] Present address: Abbott Laboratories, Scientific Divisions, North Chicago, Illinois, 60064.

[2] Permanent address: Tata Institute of Fundamental Research, Bombay 5, India.

Key words: dihydropyridines, dimerization, free radicals, methyl nicotinamide, nicotinamide mononucleotide.

[3] These have included the following where the N(1) substituent is indicated: CH_3 (1-10), C_2H_5 (2), C_3H_7 (2), C_4H_9 (2), $CH_2C_6H_5$ (2, 8), $CH_2CH_2SO_3^-$ (8), $CH_2C_6H_4SO_3^-$ (8), D-glucopyranosidyl (9, 10), D-glucopyranosidyltetraacetate (6, 9, 10).

Fig. 1. Reaction paths for the electrochemical behavior of 1-methyl-3-carbamoylpyridinium ion (MCP^+; 1-methylnicotinamide), nicotinamide mononucleotide (NMN^+), and their reduction products. In the case of NMN^+, the CH_3 group is replaced by a ribosophosphate group and some of the dihydropyridine species (III) may be present as the 1,4 isomer.

there is general agreement concerning the over-all process for MCP^+, there is considerable disagreement on specifics, *e.g.*, under similar conditions $E_{1/2}$ for the first of the two polarographic waves seen has been reported (1-3, 7) as varying from -0.94 to $-1.11V$. Two recent papers (15, 16) report polarographic patterns for MCP^+, which are more complex than those seen by other investigators or in the present study. Wave I is reported (7, 17, 18) to be due to a reversible 1*e* process, but the over-all electrochemical process is irreversible due to subsequent dimerization (1, 17, 18); however, the dimerization rate constant obtained by cyclic voltammetry (18) differs by many orders of magnitude from that obtained by pulse radiolysis (19). Other inconsistencies in the literature involve potential data, presence or absence of catalytic hydrogen evolution,[4] chemical and electrochemical properties of the reduction products, correlation of ultraviolet spectral properties of the latter with structure, and the role of adsorption phenomena.

NMN^+ is in many respects a more realistic model compound for understanding NAD^+ and $NADP^+$ than MCP^+; the electronic structure of the pyridine ring in NMN^+ is more closely related to that of the coenzymes because of the similar inductive effects of the N-substituents, *e.g.*, the action of dilute base on MCP^+ is different from that on NMN^+ and NAD^+ [the amide group of MCP^+ is readily hydrolyzed, but the nucleotides cleave at the nicotinamide-ribose linkage (20)]. In addition, NMN^+, like the coenzymes, has a bulky N-substituent which presumably is effective in determining the isomeric form of the initial electrochemical reduction product, *e.g.*, a 4,4' as opposed to a 6,6' dimer. NMN^+ enjoys the same freedom from the adenine moiety as does MCP^+, which simplified interpretation of ultraviolet spectra (here characteristic only of the pyridine ring) and eliminates adsorption due to the adenine moiety (21). The two previously reported electrochemical studies (15, 22) of NMN^+ are fragmentary and some of the results seem questionable; interesting results obtained for NMN^+ by Berg and Hanschmann (23, 24) have, unfortunately, not yet been published.

Because of the uncertainties in the reported behavior of MCP^+ and the lack of information on NMN^+, the electrochemical behavior of these two compounds was systematically investigated with emphasis on the use of rapid perturbation techniques to study intermediate species and adsorption, and on the detailed examination of final products prepared by macroscale electrolysis.

[4] A catalytic hydrogen evolution reaction occurs when a compound is present whose protonated adduct under the experimental conditions is more easily reducible, i.e., has a lower activation energy in respect to net addition of an electron to the proton, than the uncomplexed proton itself.

Table I. Buffer and background electrolyte solutions[a]

Buffer No.	pH range	Composition
1	0.0-1.0	HCl + KCl
2	2.0-8.0	$Na_2HPO_4 \cdot 7H_2O$ + citric acid monohydrate + KCl
3	3.9-5.9	HOAc + NaOAc
4	9.0-10.0	K_2CO_3 + $KHCO_3$
5	9.0-10.0	K_2CO_3 + $KHCO_3$ + KCl[b]
6	9.0-10.0	K_2CO_3 + $KHCO_3$ + Et_4NCl[c]
7	9.0-10.0	NH_3 + NH_4Cl
8	11.0-12.0	KOH + KCl

[a] The final ionic strength of buffer solutions used in all experiments was 0.5*M* unless otherwise stated.
[b] KCl concentration: 0.4*M*.
[c] Et_4NCl concentration: 0.4*M*.

Experimental

Chemicals, apparatus, and procedures used have largely been described (25).

Chemicals.—The reported analytical data and spectrophotometric assay indicated sufficient purity for polarographic study of the following: nicotinamide mononucleotide (NMN^+) (Sigma; P-L Biochemicals), reduced nicotinamide mononucleotide (NMNH) (Sigma), and 1-methyl-3-carbamoylpyridinium chloride (MCP^+) (Sigma).

The buffer solutions used, prepared from reagent grade chemicals, are listed in Table I.

Results and Discussion

D.-C. polarography.—1. MCP^+.—Above pH 9, MCP^+ exhibits two well-defined waves (Table II; Fig. 2A). A catalytic hydrogen wave[4] (Fig. 3), whose height in-

[a] Wave slope calculated as $(E_{1/4} - E_{3/4})$.
[b] Diffusion current constant, $I = i_d/Cm^{2/3}t^{1/6}$.
[c] Limiting currents of these waves exhibit partial kinetic character due to merging catalytic hydrogen wave; I values calculated for comparison.
[d] 1-Methyl-3-carbamoylpyridinium ion is unstable in basic solutions.
[e] Phosphate buffer, 0.3M ionic strength.
[f] Borate buffer, 0.5M ionic strength.
[g] Poorly defined wave.

creases with decreasing pH, begins to merge with wave II below pH 8 and with wave I below pH 3.

At pH 9.6, both waves are diffusion controlled (h and temperature variation), of equal height (diffusion current constant, I, magnitudes correspond to 1e faradaic processes), and proportional to concentration (I is 1.94 $\pm$ 0.05 for both waves between 0.05 and 4.7 mM).

$E_{1/2}$ for wave I is pH-independent (average value: -1.03V). Addition of surface-active Et_4N^+ (pH 9.4 buffer 6) shifts it 70 mV more negative. Increase in ionic strength of pH 9.4 KCl/carbonate buffer from 0.1 to 2.0M shifts $E_{1/2}$ from -1.02 to -1.04V. $E_{1/2}$ shifts with concentration at low concentration (-1.06V at 0.05 mM and -1.10V at 0.01 mM). Wave I is due to a reversible electron transfer, *e.g.*, slopes of the wave $(E_{1/4} - E_{3/4})$ and log $[i/(i_d - i)]$ *vs.* E plot are generally of the magnitude expected for a reversible 1e cathodic wave followed by an irreversible chemical reaction (26, 27); the log plot is not always strictly linear over the entire rising portion of the wave. Such deviations are probably due to the dimerization and adsorption phenomena subsequently discussed.

Above pH 9, $E_{1/2}$ for wave II is virtually pH-independent, but depends somewhat on background electrolyte nature. Increase in ionic strength of pH 9.4 KCl/carbonate buffer from 0.1 to 2.0M shifts $E_{1/2}$ from -1.64 to -1.55V. Increase in MCP^+ concentration from 0.01 to 4.7 mM shifts $E_{1/2}$ from -1.52 to -1.63V. Based on its slope, wave II involves an irreversible electron transfer. Below pH 8, the wave II current depends on pH, being due to a faradaic reduction plus catalytic hydrogen evolution[4] due to reduction of the protonated product; the combined wave is peak-shaped (Fig. 3). At pH 7.4, the total wave II current decreases with increasing t (i_l proportional to $h^{-0.23}$), suggesting that an adsorbed species is the catalyst for hydrogen evolution. At pH 6.7, an increase in phosphate buffer capacity from 0.004 to 0.04M increases the wave II height fivefold to a magnitude about 20 times that of wave I.

2. *NMN*$^+$.—NMN^+ displays a single cathodic wave (wave I) below pH 6 (Table III). At pH 1, the wave is ill-defined (i_l has kinetic character) and occurs near background discharge. With increasing pH, wave I decreases in height to a limiting value at pH 4-5 (equivalent to a 1e reduction) and becomes diffusion controlled; the height remains constant to pH 10-11, where it begins to decrease because of hydrolysis. $E_{1/2}$ is independent of pH up to pH 5, becomes about 80 mV more negative between pH 5.0 and 7.5, and then is constant up to pH 12; the shift is due to the secondary

[f] NMN^+ is unstable in basic solutions.
[j] Ionic strength = 0.10M. Wave II ill-defined.
[k] Ionic strength = 2.0M.

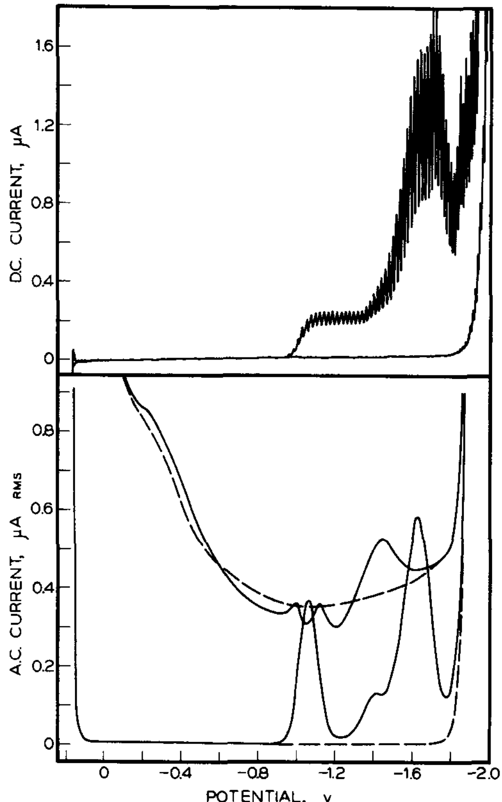

Fig. 3. D-C and a-c polarograms of 0.77 mM 1-methyl-3-carbamoylpyridinium ion in pH 7.4 McIlvaine buffer. (Cf. Fig. 4 caption for curve identification.)

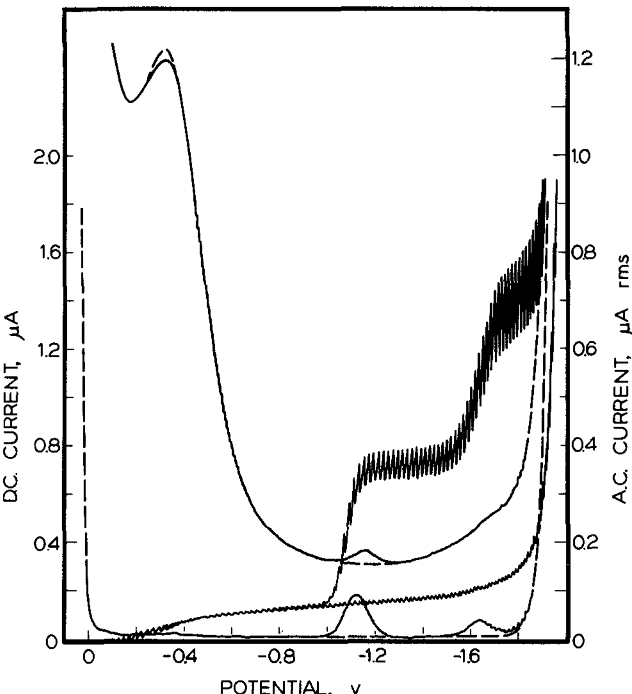

Fig. 4. D-C and a-c polarograms of 0.32 mM NMN^+ in pH 9.6 Et_4NCl/carbonate buffer. D-C polarograms shown with and without electroactive species present. Solid lines represent in-phase (lower curves) and quadrature (upper curves) components of total a-c current; dashed lines represent corresponding background currents.

phosphate dissociation of NMN^+ [the corresponding pK_a for AMP is between 6.0 and 6.7 (28)]. MCP^+, as expected, does not exhibit a similar $E_{1/2}$ shift.

At pH 6, where the background discharge potential is identical to that for background alone, i_l for wave II is kinetically controlled and greater than that of wave I, since it results—similarly to MCP^+—from simultaneous formation of the 2e product by a second 1e addition to the pyridine ring and catalytic hydrogen evolution. Below pH 6, the wave II height increases rapidly with decreasing pH, which accounts for the positive shift in background discharge, *i.e.*, unless polarographic sensitivity is very low, the rising portion of wave II serves as discharge. Above pH 6, wave II decreases in height, reaching at pH 9 a height identical to that of wave I; above pH 10, it is obscured by reduction of nicotinamide formed by NMN^+ hydrolysis.

Consequently, due to hydrogen evolution at lower pH and decomposition at higher pH, the characteristics of waves I and II can be studied thoroughly and simultaneously only between pH 9 and 10. The polarographic patterns obtained in this pH region depend on ionic strength and surfactant presence, *e.g.*, Et_4N^+. The latter is adsorbed at the interface in the potential region where faradaic processes occur. Wave II is also better defined in presence of KCl.

Increase in ionic strength (pH 9.3 KCl/carbonate buffer) from 0.1 to 2.0*M* shifts waves I and II positively by 100 and 170 mV, respectively (Table III). Wave II, which appears as an ill-defined shoulder on background discharge at low ionic strength (0.1*M*), becomes well-defined at higher ionic strength with a height about equal to that of wave I. However, with increasing Et_4NCl concentration (ionic strength held constant), wave I shifts to more negative potential and wave II appears and grows in height; the background discharge potential remains constant.

At sufficiently high Et_4NCl concentration, *e.g.*, buffer 6, NMN^+ exhibits two well-defined, diffusion-controlled (*h* and temperature variations) waves of about equal height, whose *I* values correspond to 1e processes (Fig. 4). Wave I slope varies with temperature (1.4°-36.0°) as expected for a reversible wave. Wave II is irreversible, based on its slope. With increasing concentration, the two waves remain of equal height, but wave I $E_{1/2}$ shifts from -1.12V at 0.01 m*M* to -1.06V at 0.86 m*M*.

Cyclic voltammetry.—The results discussed were obtained at a hanging mercury drop electrode (hmde), *e.g.*, Tables IV and V, except for those in the subsection on the pyrolytic graphite electrode (pge).

1. *MCP^+*.—At slow scan rate ($v = 0.1$ V/sec), sweeps to more negative potential above pH 9 produce a cathodic peak at -1.13V (wave I process). Below pH 9, an additional cathodic peak appears at -1.70V due to the catalytic process; at pH 7.3, the rising portion of this peak serves as background discharge.

Table IV. Effect of scan rate on cyclic voltammetric behavior[a] of MCP^+ and NMN^+

9.60	53.0	16.8		
12.0	56.0	17.2		
14.4	63.0	16.2		

[a] Data for pH 9.25 KCl/carbonate buffer.
[b] The second NMN^+ cathodic peak is not well defined.

Potential sweep reversal immediately after peak Ic produces a pH-independent anodic peak ($E_p = -0.3$ to -0.4V), due to oxidation of the 1e reduction product to MCP^+, which shifts positively with increasing v and merges with anodic background discharge above 5 V/sec (Table IV). The ratio of anodic to cathodic peak heights varies with experimental conditions from 0.5 or less to nearly one, *e.g.*, at $v = 0.1$ V/sec, the ratio decreases with decreasing pH due to acid catalyzed decomposition of the reduction product (cf. discussion of reduction product stability).

At pH 9.3, the peak Ic current function, $i_p/v^{1/2}$, is almost constant with increasing v, indicating diffusion control (Table V). The peak IIc current increases markedly with increasing v, surpassing the peak I current above 9 V/sec; the broadness of peak II and the relative constancy of its i_p/v ratio with increasing v are suggestive of an adsorption-controlled faradaic process.

An anodic peak complementary to cathodic peak Ic appears only at v exceeding 20 V/sec, where potential reversal at 40 mV or more beyond peak Ic ($E_p = -1.26$V) produces an anodic peak ($E_p = -1.20$V) (the peak is barely evident at 16 V/sec) (Fig. 5). The 60 mV peak potential difference suggests a reversible 1e process. Appearance of a reversible anodic peak only at high v demonstrates the presence of a chemical reaction following charge transfer. The prewave or prepeak at *ca.* -0.6V is due to adsorption of the reduction product. No anodic peak complementary to peak IIc appears.

2. *NMN^+*.—The cyclic voltammetric behavior of NMN^+ is generally similar to that of MCP^+. At $v = 0.1$ V/sec, a single ill-defined peak Ic ($E_p = -0.93$V) is produced at low pH, close to background discharge. With increasing pH, Ic becomes better defined and its current decreases to a limiting value above pH 6; E_p becomes more negative between pH 5 and 7 and then is constant (Fig. 6), similar to dme wave I. On varying v from 0.005 to 0.5 V/sec at pH 8.0, the $i_p/v^{1/2}$ ratio remains constant, suggesting diffusion control, but E_p shifts 20 mV more negative.

In slightly alkaline solution, peak IIc ($E_p = -1.69$V at pH 9) appears. The fact that its current is less than 10% that of Ic, supports the ultimate wave I product not being further reduced in the wave II process. (Peak IIc may also be due in part to reduction of nicotinamide present as a minor impurity or formed by NMN^+ hydrolysis; cf. discussion of controlled potential electrolysis.)

Reversing the potential sweep after the appearance of either peak Ic or IIc yields a single anodic peak Ia, corresponding to oxidation of the 1e reduction product. In alkaline solution, repetitive cycling in a potential region, which includes peaks Ic and Ia, causes no

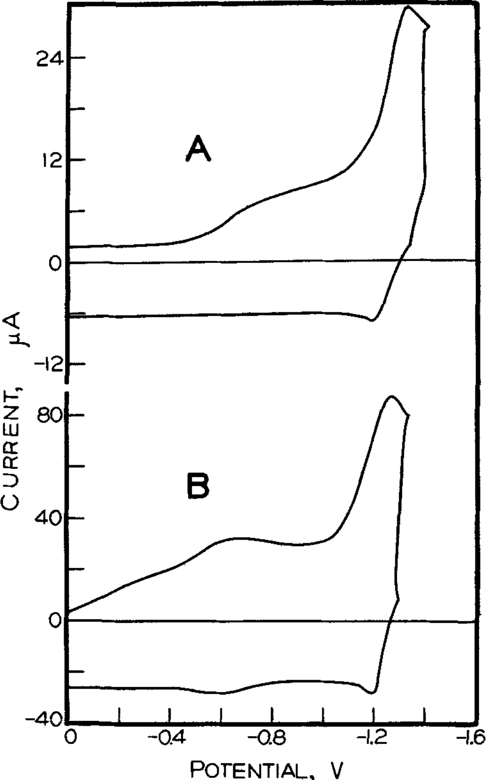

Fig. 5. Cyclic voltammograms in pH 9.0 carbonate buffer of (A) NMN^+ (0.48 mM; scan rate = 20 V/sec) and (B) 1-methyl-3-carbamoylpyridinium ion (1.22 mM; scan rate = 90 V/sec).

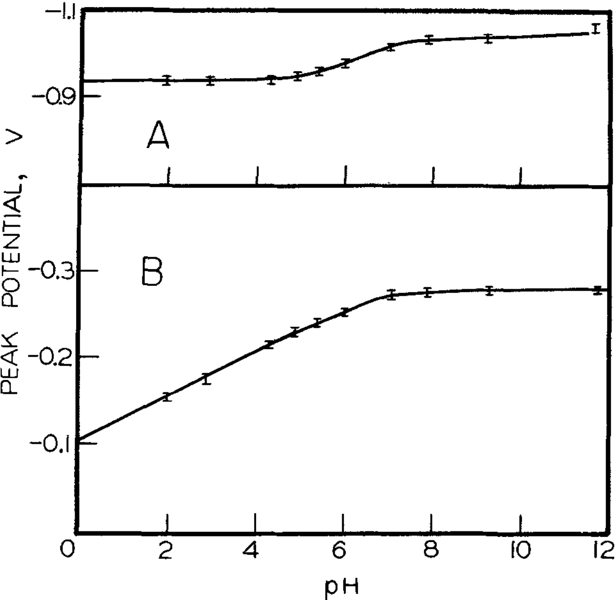

Fig. 6. Variation in potential of (A) cathodic peak Ic and (B) anodic peak Ia (oxidation of ultimate peak Ic reduction product) of NMN^+ with pH on cyclic voltammetry at the hanging mercury drop electrode or hmde. Scan rate = 100 mV/sec.

diminution of the cathodic peak current, indicating that the oxidation regenerates the original electroactive species. If the sweep is reversed before peak Ia is reached, the peak Ic current is about 5-10% less. Other evidence indicates the peak current ratio of 0.5 (Table IV) to be fortuitous, *e.g.*, after controlled potential electrolysis, the anodic peak exceeds 0.5 times the original cathodic peak.

Above pH 7, peak Ia E_p is pH-independent at -0.27V (Fig. 6). Below pH 7, the oxidation becomes more dif-

ficult with decreasing pH. Below pH 6, the peak Ia current decreases rapidly with decreasing pH due to acid instability of the 1e reduction product.

NMN^+ exhibits a detectable anodic peak, reversible or complementary to peak Ic, at and above 6 V/sec (Fig. 5), whereas MCP^+ exhibits such a peak only above 16 V/sec, suggesting that the primary oxidizable product in the Ic process reacts chemically more rapidly in the case of MCP^+.

3. Cyclic Voltammetry at PGE.—The behavior of MCP^+ and NMN^+ at the pge (Fig. 7A and 8) is essentially the same as at the hmde (differences are likely to be due to greater adsorption on the pyrolytic graphite electrode or pge). At pH 10, MCP^+ shows peak Ic ($E_p = -1.16$); on the reverse sweep, the resulting product is oxidized at -0.34V. Similarly, NMN^+ at pH 9.6 shows a cathodic peak at -1.12V and an anodic peak at -0.04V.

Although oxidation of the postulated dihydropyridine product of the wave II process cannot be seen at the dme or hmde due to prior oxidation of mercury, it is readily observed at the pge (cf. section on controlled potential electrolysis). Oxidation of 1,4-NMNH, which is a possible 2e reduction product of NMN^+, is shown in Fig. 8. A negative potential sweep produces no cathodic behavior other than that due to NMN^+, present as an impurity; on the return sweep, an anodic peak appears at 0.35V due to oxidation of 1,4-NMNH. When the sweep is again reversed toward more negative potential, a cathodic peak appears at -1.12V due to reduction of NMN^+ produced on the anodic sweep.

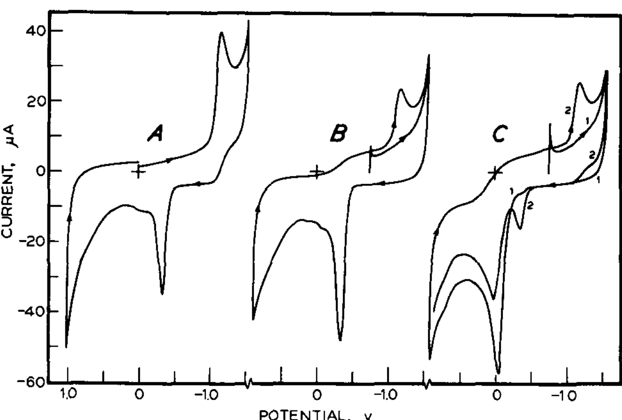

Fig. 7. Electrolysis of 1.20 mM 1-methyl-3-carbamoylpyridinium ion in pH 10 Et_4NCl/carbonate buffer. Cyclic voltammograms at the pge: A, before electrolysis; B, after electrolysis at -1.40V; C, after electrolysis at -1.80V.

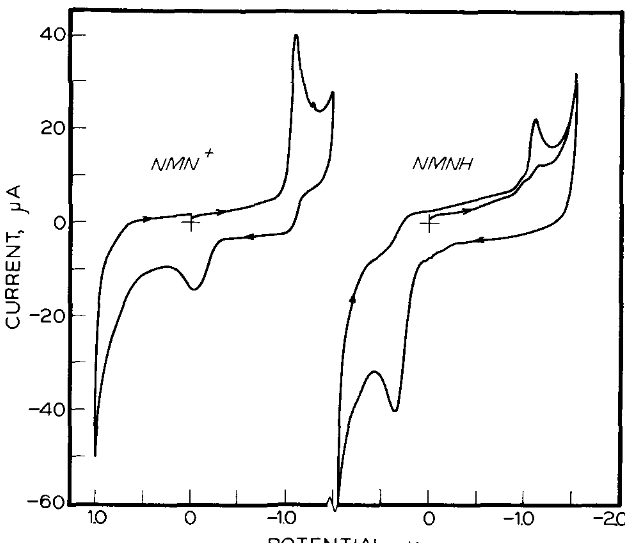

Fig. 8. Cyclic voltammograms of NMN^+ (1.44 mM) and 1,4-NMNH (1.30 mM) at the pge in pH 9.6 Et_4NCl/carbonate buffer. Scan rate = 100 mV/sec.

A.-C. polarography.—In the potential region where there is no faradaic process, the quadrature (out-of-phase) a-c current component is proportional to the differential double layer (DL) capacity at the solution-electrode interface and thus provides a convenient index to adsorption at the interface of the electroactive species and its products.

The initial discussion of the behavior of MCP^+ is based on a-c polarography at 50 Hz with a 3.54 mV rms amplitude and a 3 sec droplife, *e.g.*, Fig. 10A.

In the potential region prior to the first reduction step, the DL capacity is only slightly altered by even a relatively high MCP^+ concentration (1.2 mM). An apparent trend towards greater adsorption with increasing negative potential beyond the electrocapillary maximum (ecm) is not unexpected for a positively charged species; however, little can be said concerning the adsorbability of MCP^+ beyond -0.9V because of its reducibility.

The faradaic peak (in-phase component) at -1.07V corresponds to the wave I process. DL capacity changes in this potential region are due to surface-activity of the dimeric reduction product. The quadrature response is complicated by the simultaneous faradaic current increase due to the reduction and capacity current decrease due to strong adsorption of dimer. A tensammetric peak at -1.43V (due to desorption of dimer) is primarily capacitive in nature but has a resistive in-phase component at -1.41V, probably because the adsorption-desorption process is partially diffusion controlled thus introducing a resistive component to the electrode impedance (absence of a d-c polarographic wave at about -1.4V is proof that the a-c peak arises from adsorption-desorption phenomena). Increases in MCP^+ concentration and ionic strength decrease the DL capacity in the vicinity of -1.0V, increase the tensammetric peak height, and shift the latter to more negative potential, as the result of an increase in the surface activity of the dimer.

The faradaic peak at -1.62V corresponds to the wave II process; no quadrature component is observed. The DL capacity in this potential region is identical to that for background electrolyte alone, showing that the 2e reduction product is not adsorbed in the potential region where it is formed.

Additional evidence concerning the adsorbability of the two reduction products was obtained from the a-c polarographic behavior of solutions of the products prepared by controlled-potential electrolysis (cf. section on latter).

Replacement of KCl/carbonate buffer by Et_4NCl/carbonate buffer considerably alters the pattern; adsorption effects are largely eliminated, *i.e.*, the DL capacity is essentially identical to that for background electrolyte alone. A shoulder on the in-phase and quadrature components of wave I may indicate a shift of the tensammetric peak seen in KCl/carbonate buffer to more positive potential due to preferential adsorption of Et_4N^+.

In pH 7.4 McIlvaine buffer, the behavior of MCP^+ is essentially the same as in KCl/carbonate buffer, except that the catalytic hydrogen wave obscures the in-phase potential region beyond -1.4V (Fig. 3). The quadrature component in this potential region is relatively unaffected.

The following behavior of MCP^+ and NMN^+ was observed, using a signal of 7.1 mV rms amplitude at 50-800 Hz, and a natural droptime (Table VI).

A well-defined in-phase peak, which corresponds to wave I, is observed in pH 5.2 acetate and pH 9.0 carbonate buffers for MCP^+ ($E_s = -1.10$V) and for NMN^+ ($E_s = -1.03$ and -1.15V). Peak currents are only a small fraction of those calculated for a reversible 1e process uncomplicated by accompanying chemi-

[b] Blanks indicate that measurements were not made at the conditions involved.

cal reactions (29); loss of the primary electrochemical product by a chemical reaction would account for this. The variations of E_s and i_s with frequency are as expected for a chemical reaction involving the primary product.

MCP^+ shows additional peaks at −1.39 and −1.69, which correspond to the tensammetric process and wave II.

In both pH 9.3 KCl/carbonate and pH 9.6 Et_4NCl/carbonate buffers at 50 Hz (Fig. 4), NMN^+ gives faradaic peaks at −1.12 and −1.64V, which correspond to the two d-c waves. Addition of NMN^+ causes little alteration in the DL capacity, indicating no appreciable adsorption of either NMN^+ or the two reduced species. Increase in ionic strength at pH 9.3 from 0.1 to 2.0M slightly increases the surface activity of NMN^+ but neither product is adsorbed. Similar behavior is seen in acidic solution; E_s for wave I becomes more positive below pH 6 in accord with the d-c behavior.

In Et_4NCl/carbonate buffer, the a-c currents for the faradaic NMN^+ processes represent less than 3% of that expected for a simple reversible 1e process and are not appreciably altered on increasing the alternating voltage from 50 to 800 Hz. Thus, both a-c polarographic steps are over-all irreversible.

Controlled potential electrolysis and coulometry.—1. MCP^+ wave I process.—MCP^+ (1.20 mM) was electrolyzed in pH 10 buffer 5 at −1.25V, at which potential adsorption of the reduction product would be expected, and in pH 10 buffer 6 at −1.40V, at which potential the DL capacity is identical to that for background alone; except where subsequently indicated, the final electrolyzed solutions had nearly identical faradaic and spectral properties, thus showing little effect due to adsorption on the nature of the electrolysis products. A faradaic n of 0.96 ± 0.01 was obtained. A persistent bright greenish-yellow color developed during electrolysis. Shifting of the applied potential to −1.80V, when electrolysis was complete, gave no additional current flow, confirming that the final wave I product is neither an intermediate in the formation of wave II nor further reduced to a different product.

Solutions before electrolysis had the single characteristic MCP^+ absorption band at 264 nm (ϵ = 4600) [literature (22): λ_{max} = 264 nm; ϵ = 4600] (Fig. 9A). Spectra, taken after electrolysis, had maxima at 277 nm (ϵ = 12,500) and 358 nm (ϵ = 8300) (Fig. 9B) (ϵ values, calculated asusming a dimeric wave I product, are averages for the two backgrounds).

Polarography of the electrolyzed solution showed absence of the two MCP^+ cathodic waves and a diffusion controlled (h study) anodic wave ($E_{1/2}$ = −0.45V in buffer 5) (Fig. 2B), which was 71% of the wave Ic height. On cyclic voltammetry at the pge (Fig. 7B), a sweep initiated at −0.75V showed only background behavior; on the return sweep, a large anodic peak ap-

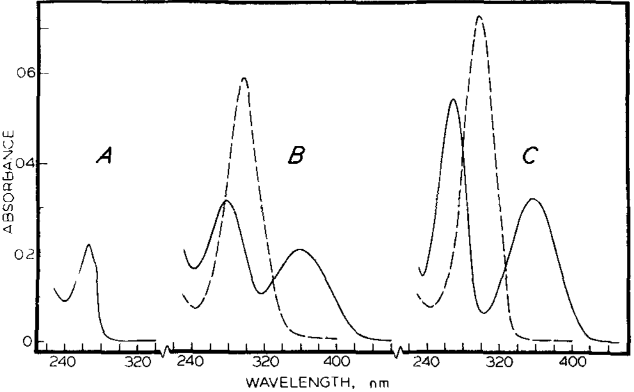

Fig. 9. Electrolysis of 1.20 mM 1-methyl-3-carbamoylpyridinium ion in pH 10 Et_4NCl/carbonate buffer. Absorption spectra obtained by a 1/25 dilution of electrolysis solutions with buffers indicated. peared at −0.34V. On further reversal toward more negative potential, a cathodic peak due to reduction of MCP^+ appeared at −1.17V. Thus, the reduction product formed under lengthy macroscale conditions is the same as that formed under the more temporal conditions of cyclic voltammetry; oxidation of this product produces the starting material.

A-C polarography of the electrolyzed solution showed the absence of faradaic peaks corresponding to MCP^+ reduction (Fig. 10B) and the presence of both in-phase and quadrature components of the tensammetric process involving dimer desorption at −1.4V. This is added support for the previous interpretation of the a-c polarographic pattern of MCP^+ (Fig. 10A). Actually, the dimer is strongly adsorbed over a rather wide potential region on both sides of the ecm. The faradaic peak at −0.30V (in-phase component) corresponds to the d-c anodic wave and exhibits a maximum of the first kind as does the d-c wave.

Electrolytic oxidation of the MCP dimer solution at −0.40V consumed less than one electron per original MCP^+ molecule. The resulting solution showed a well-defined polarographic wave, whose $E_{1/2}$ of −1.05V agrees with that of MCP^+ and whose height agreed with the faradaic n just mentioned.

These results may be rationalized on the basis of the product of the wave I process being a dimer, which slowly decomposes. The magnitude of the anodic wave due to the dimer may be less than that of the predecessor cathodic wave due to (*i*) chemical decomposition of the dimer (cf. discussion of its acid-catalyzed hydrolysis) and (*ii*) an expected difference in diffusion coefficients between the original species and the derived dimer (if decomposition is assumed to be negligible, a ratio of 0.71 for the anodic-cathodic wave heights corresponds to a diffusion coefficient ratio of 0.50).

2. MCP^+ wave II process.—Electrolyses in both backgrounds at −1.80V gave a faradaic n of 1.95 ± 0.02, and colorless solutions of nearly identical spectral and faradaic properties, *e.g.*, maxima at 270 nm (ϵ = 11,400) and 358 nm (ϵ = 6600) (Fig. 9C), and the absence of both original cathodic waves and no new waves corresponding to oxidation of the 2e product (Fig. 2C); a small amount of the 1e product was formed (2.5 ± 0.5% as estimated from the anodic wave height). Oxidation of the 2e product is readily observed at the pge (Fig. 7C). Sweep 1 to negative potential, initiated at −0.75V, shows only background cathodic behavior; on the return sweep, a large anodic peak appears at −0.04V due to oxidation of the 2e product; subsequent reversal toward more negative potential (sweep 2)

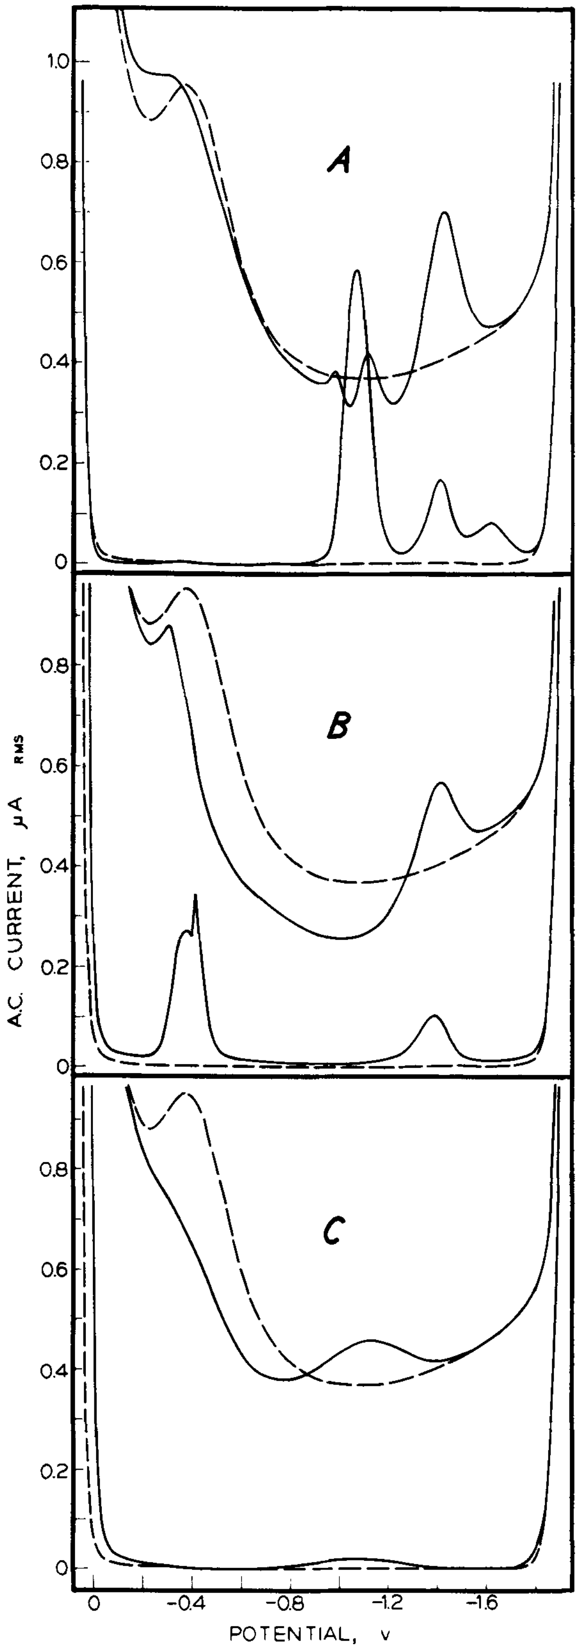

Fig. 10. Electrolysis of 1.20 mM 1-methyl-3-carbamoylpyridinium ion in pH 10 KCl/carbonate buffer. A-C polarograms: A, before electrolysis; B, after electrolysis at −1.25V; C, after electrolysis at 1.80V. produces a cathodic peak at −1.18V due to reduction of MCP^+ formed during the oxidation step. Finally when the sweep is once again reversed toward more positive potential, an anodic peak appears at −0.34V (dimer oxidation) in addition to the one at −0.04V.

A.-C polarography of the electrolyzed solution shows the expected absence of faradaic behavior (Fig. 10C). Absence of the tensammetric process at −1.4V further supports assignment of this peak to dimer desorption. The 2*e* product, which is less strongly adsorbed than the 1*e* product, most strongly affects the DL capacity in the potential region on either side of the ecm; it is involved in a rather broad desorption hump centering at −1.12V. Beginning at about −1.5V, the DL capacity is identical to that for background alone, confirming that the 2*e* reduction product is not adsorbed in the potential region of its formation.

3. Stability of MCP^+ reduction products.—The temporal stability was determined by keeping an aliquot of each *p*H 10 electrolyzed solution at 25°C under nitrogen for 2 hr and periodically running spectra. Based on the 358 nm adsorption, the dimer concentration decreased at a rate of 6%/hr and that of the 2*e* product at 2%/hr. Since the time required for electrolysis was relatively short (40 min for the 1*e* product and 60 min for the 2*e* product), little product was lost and molar absorptivities were calculated assuming no loss.

Aliquots of each solution were also diluted (1/25) with carbonate or McIlvaine buffer (room temperature under air) to obtain solutions of *p*H 9.3, 7.4, and 4.5; the dimer half-life in these was 112, 5.1, and 0.1 min, respectively, emphasizing the rapid increase in decomposition rate with decreasing *p*H. In all cases, as the two dimer absorption bands decreased in intensity, a new band developed at 296 nm (Fig. 9B). At *p*H 7.4, an isosbestic point formed at 331 nm, suggesting that the dimer decomposed directly to its acid catalyzed product without going through an intermediate. At *p*H 4.5, the 296 nm band formed rapidly but then slowly decreased in intensity; this phenomenon was not investigated further. At *p*H 9.3, the final decomposed solution also had a small shoulder at 265 nm, which may be due to oxidation of a small portion of the dimer to MCP^+ in the presence of air (under the experimental conditions, this reaction is slow compared to the acid catalyzed decomposition; cf. subsequent discussion).

The effect of *p*H on stability of the 2*e* product is similar, except that, at any given *p*H, the decomposition is much slower. In *p*H 9.3 carbonate buffer, the half-life of the 2*e* product was 420 min; as the absorption band due to the acid catalyzed product developed, an isosbestic point formed at 316 nm. No evidence of direct oxidation by air was found. In *p*H 4.5 McIlvaine buffer, the final acid catalyzed product had an absorption band at 298 nm (Fig. 9C).

In another experiment, aliquots of solutions of both reduction products were diluted (1/2) with carbonate or McIlvaine buffer to *p*H 9.9 and 7.7 solutions, which were examined after 24 hr (room temperature under air). Polarography of the dimer solutions revealed disappearance of the anodic wave and, at *p*H 9.9, the presence of a broad wave characteristic of H_2O_2, superimposed on which was the MCP^+ pattern; based on the wave II height, 49% of the dimer was oxidized. This solution had peaks at 264 nm due to dimer oxidation and at 292 nm due to acid decomposition of dimer; the intensity of the latter accounted for 32% of the dimer. Thus, about 81% of the dimer could be accounted for. At *p*H 7.7, the spectrum indicated virtually complete decomposition of dimer; a polarogram revealed only solution discharge at *ca.* 0.25V more positive than for background electrolyte alone. Evidently, the decomposition product catalyzes hydrogen ion reduction under the conditions used.

The *p*H 9.9 2*e* product solution also gave a H_2O_2 wave, which was much smaller than that for the 1*e* product, and the MCP^+ pattern, which accounted for 12% of the 2*e* product. Analysis at the pge indicated that 60% of the 2*e* product still remained; absorption at 358 nm showed 57% 2*e* product. The increased absorption in the 280-300 nm region indicated that the 2*e*

product not accounted for (approximately 30%) probably had decomposed to the acid catalyzed product. At pH 7.7, virtually all of the 2*e* reduction product decomposed (based on the spectrum and the absence at the pge of the 2*e* product anodic peak); a polarogram revealed only solution discharge at 0.12V more positive than for background electrolyte alone (the decomposition product of the 2*e* reduction product also catalyzes hydrogen ion reduction).

4. NMN^+ wave I process.—Electrolysis on the limiting portion of NMN^+ wave I at −1.2 or −1.3V (generally in pH 9.6 buffer 6, where the NMN^+ waves are well defined and diffusion controlled) gave *n* values of 1.00 ± 0.01. A transient greenish-yellow color reached maximum intensity when electrolysis was 80-90% complete. When electrolysis was continued for an additional 0.5 hr after the current fell to background level, the current remained unchanged but the color diminished in intensity, yielding a clear, faintly yellow solution. A plot of log current *vs.* time was linear, showing that the electrolysis rate was first order and that no mechanistic complications were involved such as a slow chemical step prior to electron transfer or formation of an intermediate which could undergo a slow chemical transformation followed by further reduction.

The results (cf. also subsequent discussion) suggest that most of the NMN^+ is directly converted to a relatively stable dimer which does not absorb appreciably in the visible region. A small portion may be involved in formation of an unstable by-product, which produces the transient color and slowly decomposes to a compound which is not reduced at the applied potential.

The two characteristic NMN^+ cathodic waves were absent from polarograms of the electrolyzed solutions; two new waves appeared, one anodic ($E_{1/2} = -0.25V$) and a smaller cathodic wave ($E_{1/2} = -1.6$ to $-1.7V$, depending on pH); the latter corresponds to reduction of free nicotinamide. The anodic wave is diffusion controlled and independent of concentration; it corresponds to oxidation of dimer to NMN^+ and correlates with the cyclic voltammetric anodic peak. Electrolysis on its limiting portion (−0.1V) regenerated NMN^+.

Prior to electrolysis, the NMN^+ solution exhibits the 265 nm absorption band ($\epsilon = 4900$) characteristic of the pyridinium ion (Fig. 11A). On dilution with 1*M* KCN, the 265 nm band is replaced by one at 327 nm ($\epsilon = 6300$) (Fig. 11A) due to cyanide addition at the 4-position of the pyridine ring [literature (20, 30): $\lambda_{max} = 327$ nm; $\epsilon = 5900$]. The 265 nm band also disappears during electrolysis, and bands with maxima at 263 nm

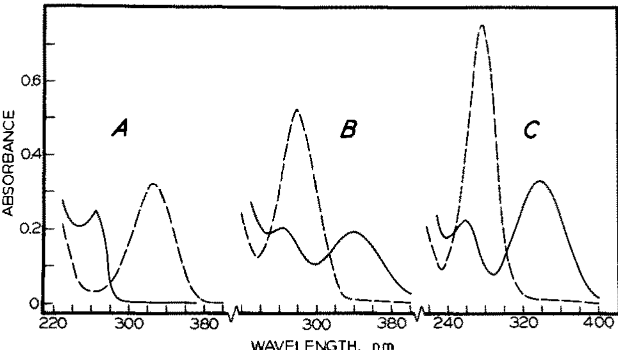

Fig. 11. Electrolysis of 1.37 mM NMN^+ in pH 9.6 Et_4NCl/carbonate buffer. Adsorption spectra obtained by a 1/25 dilution of electrolysis solutions with buffer indicated. Solid line (pH 9.6 carbonate buffer): A, before electrolysis; B, after electrolysis at −1.3V; C, after electrolysis at −1.8V. Dashed line: A, cyanide addition product of NMN^+ (1.0M KCN); B, acid catalyzed decomposition product of dimer (0.2M phosphate buffer; pH 6.7); C, acid catalyzed decomposition product of dihydropyridine species (0.1M phosphate buffer; pH 6.8).

($\epsilon = 7800$) and 339 nm ($\epsilon = 7400$) appear and grow (Fig. 11B). (ϵ values, calculated assuming a dimeric product, represent the average for two electrolyses at pH 9.6.) Reduction of the pyridine ring during electrolysis is also indicated by the fact that dilution of the electrolyzed solution with 1*M* KCN gave the same spectrum as dilution with carbonate buffer.

5. NMN^+ wave II process.—Electrolyses on the limiting portion of wave II at −1.8V gave an average *n* of 1.93. No transient color appeared; the completely electrolyzed solution was only a faint yellow. Aliquots of the latter solution, diluted with pH 9.6 carbonate buffer, had maxima at 259 nm ($\epsilon = 4400$) and 339 nm ($\epsilon = 6500$) (Fig. 11C). Dilution with 1*M* KCN gave an identical spectrum, indicating involvement of the pyridine ring in the reduction.

Polarograms of the electrolyzed solutions showed a small dimer anodic wave; based on its height, approximately 17% NMN^+ was converted to the 1*e* product. The pge voltammetric pattern was similar to that for 1,4-NMNH (Fig. 8).

6. Stability of NMN^+ reduction products.—At pH 9-10, solutions of both NMN^+ reduction products exhibit two ultraviolet absorption bands due to the reduced pyridine structure. Both products decompose in pH 7 phosphate solution (acid catalyzed hydrolysis). The decomposition rate increases with decreasing pH; at any given pH, the dimer is less stable than the 2*e* product. During hydrolysis, the two absorption bands decrease in intensity and a more intense band develops at 278 nm (Fig. 11B and 11C). In pH 2 McIlvaine buffer, the 278 nm band forms rapidly but then slowly decreases in intensity with time.

7. Mercury adduct formation.—Mercury adducts were formed on adding $HgCl_2$ solution (0.04*M* phosphate buffer; pH 6.7) to solutions of each reduction product of MCP^+ and NMN^+; the final solutions had a pH of 9.3. On addition of excess $HgCl_2$, the two characteristic dimer absorption bands disappeared and a new band appeared at 293 nm ($\epsilon = 28{,}200$) for MCP^+ and at 281 ($\epsilon = 26{,}200$) for NMN^+; spectral properties of the adducts were much the same as those of the acid-catalyzed hydrolysis products. The dihydropyridine products behaved similarly; unfortunately, insufficient $HgCl_2$ was added to determine λ_{max} and ϵ.

Addition of excess $HgCl_2$ or concentrated HCl to relatively concentrated MCP dimer solutions instantaneously discharged the bright greenish yellow color due to loss of the 358 nm band; the tail of this band extends well out into the visible region and is undoubtedly responsible for the color. Although the tail of the 358 nm band of the 2*e* product extends almost as far out into the visible region as does that of the dimer, its solutions are colorless.

Redox Pattern

The reaction scheme outlined in Fig. 1 seems best to fit the electrochemical, chemical, and spectral data for the redox behavior of 1-methyl-3-carbamoylpyridinium ion (MCP^+), nicotinamide mononucleotide (NMN^+), and their reduction products.

The electrochemical behavior of the MCP^+ and NMN^+ ions is in some ways similar to that of nicotinamide itself (25). However, as might be expected for a positively charged pyridinium nucleus, the first reduction step is independent of pH and occurs at slightly more positive potential; thus, two well defined 1*e* waves appear in slightly alkaline solution rather than the merging waves seen for nicotinamide (25). The initial reversible uptake of an electron to form a neutral free radical (II) (source of polarographic wave I) is followed by irreversible dimerization to an apparent 6,6′ dimer (IV). At the wave II potential, the ion (I) is reduced to the dihydropyridine (III) (apparently the 1,6 species, although some 1,4 isomer may be produced in the case of NMN^+); the dimer is not reduced at this potential. The dimer (IV) can be oxidized to MCP^+ or

Downloaded 26 Jun 2008 to 212.100.132.146. Redistribution subject to ECS license or copyright; see http://www.ecsdl.org/terms_use.jsp

NMN^+ at a potential considerably more positive than that of wave I; the dihydropyridine species (III) is oxidizable at still more positive potential.

Other details of the individual mechanistic steps and of the supporting evidence and arguments are given in the following sections.

Characterization of reduction products.—Although the three isomeric 1-substituted 3-carbamoyldihydropyridines can be distinguished by their nmr spectra (31-35), much more emphasis has been placed on their characteristic ultraviolet absorption spectra in the 240-400 nm region (36-41). Most 1-substituted 3-carbamoylpyridinium ions show a single absorption band at about 265 nm, which, on reduction, is replaced by a single band at about 410 nm for 1,2-dihydropyridines and at about 350 nm for 1,4-dihydropyridines, and by two bands at about 265 and 360 nm for 1,6-dihydropyridines; these patterns have also been theoretically predicted (41).

Postulation of the 6,6′ dimer and the 1,6-dihydropyridine species for the two electrochemical reduction products of each compound reflects the two absorption bands observed in the 240-400 nm region, *e.g.*, Fig. 11. Although the 1,6 isomers are clearly the major products, small amounts of other isomers might be present, *e.g.*, in the case of the 2*e* product, the 1,4 isomer would be expected to exhibit a single absorption band at about the same wavelength as the long wavelength band of the 1,6 isomer, *e.g.*, the 1,4 isomer of reduced MCP has a single band at 360 nm ($\epsilon = 7000$) (42). In the case of NMN^+, particularly, the presence of some 1,4-isomer cannot be entirely excluded (compare Fig. 11C and 12), especially since the 2*e* electrochemical reduction product of NAD^+ is partially enzymatically active, indicating the presence of 1,4-NADH (43). The 1,2 isomer can be excluded in all cases, because the final electrolysis solutions were essentially colorless.

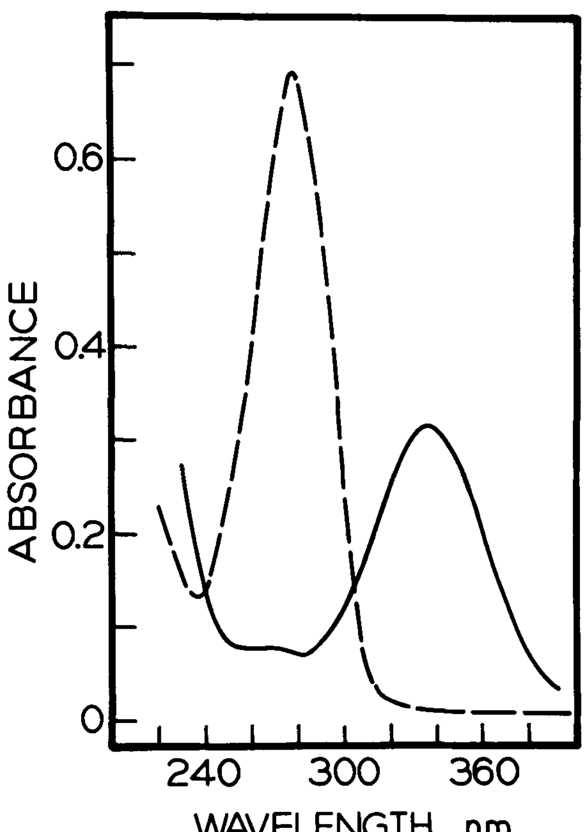

Fig. 12. Absorption spectrum of 1,4-NMNH ($5.2 \times 10^{-5}M$). Solid line: pH 9.4 carbonate buffer. Dashed line: pH 6.8 phosphate buffer (0.2M) (acid catalyzed decomposition product of 1,4-NMNH).

It should be mentioned that the validity of using spectral arguments for the dihydropyridine species for assigning the position of dimerization in partially reduced pyridines has not been thoroughly tested, *e.g.*, using the criteria outlined, structures were readily assigned to dimers of nicotinamide model compounds prepared by zinc reduction (37) but others have suggested caution (44).

The results of reducing MCP^+ by a variety of other than electrochemical methods are generally in good accord with those recorded in the present study, *e.g.*, irradiation with x-rays results in free radical formation and a dimeric product (19, 45), whose physical and chemical properties, including even molar absorptivities, are in remarkably close agreement with those of the electrolytically prepared dimer. The same is true of the dimeric products prepared by Zn reduction (37, 46) and of the 2*e* reduction product prepared with borohydride (47).[5] Dithionite reduction, on the other hand, leads exclusively to a 1,4-dihydropyridine (31, 32, 42).

1. Hydrolysis of reduction products.—The two reduction products of each compound undergo acid-catalyzed decomposition even in neutral or alkaline solution containing such proton donors as $H_2PO_4^-$. The decomposition rate increases with decreasing pH; the dimer is less stable than the dihydropyridine species at any given pH. The decomposition, which involves hydrolysis of the 4,5 C=C bond and is an example of enamine nucleophilicity (48, 49), accounts for the loss of absorption in the 260 and 340 nm regions and the concomitant increase in absorption in the 280 nm region (Fig. 9 and 11).

Since the two MCP^+ reduction products are directly oxidized in alkaline solution by molecular oxygen to MCP^+ and H_2O_2, two decomposition paths are possible on exposure to air. However, both reactions occur so slowly for the 1,6-dihydropyridine species that, after 24 hr, only about 40% of the latter is lost, less than half of which is due to oxidation by O_2; both reactions occur more rapidly for the dimer, all of which disappears after 24 hr with about half being oxidized to MCP^+. The more ready oxidation of the dimer by oxygen is consistent with the electrochemical oxidation potentials.

The proposed structures of the reduction products are also supported by their formation of mercury adducts, probably in a manner analogous to the addition of $HgCl_2$ to NADH (50, 51).

2. Rationalization of previous results.—Previous electrolyses (1) of MCP^+ did not take into account the acid instability of the reduction products. The product, isolated after electrolyses for several hours on the wave I potential in pH 7-8.1 phosphate buffers, had a molecular weight close to that for a dimeric product and a single absorption peak at 298 nm; it was postulated to be a 6,6′ dimer. The final wave I electrolysis solution gave a cathodic polarographic wave at about −1.65V (depending on pH), which was attributed to reduction of the 4,5 double bonds of the dimer; no mention was made of an anodic wave due to dimer oxidation. Electrolysis on the −1.65V wave gave a *n* of 2.11 with no change in ultraviolet absorption spectrum; this was explained on the basis that, since the 4,5 double bond was only cross conjugated with the main 298 nm chromophore, $-\overset{|}{N}-\overset{|}{C}=\overset{|}{C}-\overset{|}{C}=O$, removal of the 4,5 double bond by reduction would leave the basic chromophore intact.

In view of the present results, the compound previously isolated was actually the acid-catalyzed decomposition product of the dimer, which, in the pH range employed, has a rather short half-life relative to the electrolysis periods used. This would account for presence of the 298 nm band and absence of the anodic

[5] Under certain conditions, borohydride reduction can lead to all three products (36-39, 47).

wave. The cause of the cathodic wave at −1.65V is less clear, since its characteristics were not given. In pH 7.7 McIlvaine buffer, the decomposition product of the dimer causes a catalytic hydrogen wave since background discharge is about 0.25V more positive than for background electrolyte alone; at 5 μA, the early discharge had a potential of −1.67V. It may be that, under the conditions previously used (1), the catalytic wave exhibited a limiting portion, which might easily be taken to represent further reduction of the dimer. Electrolysis on this wave would not alter the catalyst (the dimer decomposition product) and no change in the ultraviolet spectrum would be expected. During electrolysis, the limiting current of the wave might be expected to drop due to an increase in solution pH (the capacity of the 0.1M phosphate buffer used would be low around pH 8).

The present investigation has shown that the actual dimer cannot be further reduced after being prepared either at the hmde or under macroscale conditions.[6]

In the previous study (1), after electrolysis at potentials on MCP^+ wave II in pH 7.8-9.2 phosphate buffers, a product was isolated with a single band at 360 nm, which was identified as the 1,4-dihydropyridine compound. Under the pH conditions and time periods employed, a significant portion of the product should have been the acid-catalyzed decomposition product of the dihydropyridine species. The 1,4- and 1,6-dihydropyridine species exhibit extreme acid lability and decompose at pH 8 and below (42).

Characteristics of electron transfer and associated chemical reactions.—In slightly alkaline solution, $E_{1/2}$ values for both MCP^+ waves are in good agreement with those in one report (7), 80 mV more positive than those in a second (1), and 90 mV more negative than those of a third report (3); the last study used the iodide salt, but in the others the experimental conditions were about the same. Since $\Delta E_{1/2}$ between the two waves is the same in all four studies, it is likely that the various reference electrodes differed in potential although all are reported to be *vs.* SCE; liquid junction potential effects should be small. [The potential scale used in the present investigation was frequently checked by examining a 0.5 m*M* $CdCl_2$ solution in 1.0*M* HCl; at all times, the latter exhibited an $E_{1/2}$ of -0.642 ± 0.002V, which is identical to the accepted value of −0.642V (26).]

1. Evidence for wave I electron transfer reversibility and subsequent dimerization.—The generally reversible characteristics of the first MCP^+ electron-transfer process as determined from analysis of the cyclic voltammetric and d-c polarographic waves—and to a lesser extent, those of NMN^+—observed in the present study agree with previous suggestions, for which substantial proof was not offered. The essentially irreversible faradaic a-c response for wave I results from the dimerization subsequent to electron transfer; under the a-c conditions used, the reversibility of the over-all electrochemical process is tested. The basic requirement for chemical irreversibility on a-c polarography is that the period of the applied alternating voltage sufficiently exceeds the half-life associated with the chemical step that reoxidation of the initial reduction product cannot contribute significantly to the alternating current (39). The greatest applied frequency (800 Hz) corresponds to a period of 1.8 msec; based on the dimerization rate constants found for the MCP and NMN free radicals, a free radical half-life of at most a few tenths of a msec would be predicted.

Dimerization reactions involving the primary product of electrochemical reduction can be differentiated from first order follow-up chemical reactions by the cyclic voltammetric potential difference, $E_p - E_{p/2}$, which should theoretically be 39/*n* mV for the second order reaction and 48/*n* mV for the first order, compared to 57/*n* mV in absence of a coupled chemical reaction (29). Measurement of $E_p - E_{p/2}$ for peak Ic of MCP^+ and NMN^+ over a large number of curves ($v <$ 0.2 V/sec) gave an average value of 42 mV for each, suggesting dimerization.

The significance of the positive shifts in wave I $E_{1/2}$ with increasing MCP^+ and NMN^+ concentration and drop-time is somewhat obscured in the case of MCP^+ by the presence of adsorption phenomena involving the reduction product. In the absence of adsorption, such shifts (for a reversible electrode process) are indicative of irreversible dimerization subsequent to charge transfer (53). The shifts in $E_{1/2}$ for MCP^+ wave II with concentration and ionic strength are explicable in terms of the rates of two competing reactions: dimerization of the initially produced radicals and their reduction to produce wave II, *e.g.*, an increase in depolarizer concentration will increase the dimerization rate more rapidly than the rate of the electron-transfer process; thus, in order to obtain wave II, it is necessary to increase the rate of electrochemical reduction of the radicals, *i.e.*, to make the electrode potential more negative (54).

The effects of ionic strength and surfactants on the polarographic pattern of NMN^+ appear to be related to changes in the DL structure and the two charge centers of the electroactive species. The ionic strength effect suggests existence at low ionic strength of an intramolecular complex of the ion-pair type between the negatively charged phosphate group and the positively charged pyridinium ion; such complexation could increase the electron density in the nicotinamide nucleus. With increasing ionic strength, the complex dissociates, causing wave I to become more positive and wave II to appear and grow; in the absence of tetraalkylammonium salts, wave II exhibits partial kinetic control even at 0.5*M* ionic strength. Wave II of MCP^+, which has no phosphate moiety, is well defined, even at low ionic strength. The occurrence of MCP^+ wave I at a more negative potential than wave I of the dissociated form of NMN^+, may be due to the dimerization reaction as well as to structural features (cf. section on formal potentials).

2. Free radical dimerization rates.—Three approaches for calculating the dimerization rate constant, k_d, from cyclic voltammetric data are pertinent to the present situation. Nicholson (55, 56) has described two methods. One is based on the shift of peak potential, E_p, with scan rate, v; its accuracy depends on accurate measurement of E_p, compensated for iR drop; the method can be employed to estimate k_d when no anodic peak corresponding to oxidation of the reduced species is seen provided that E° is known. The other approach involves graphical correlation of the ratio of the anodic and cathodic peak heights (i_{pa}/i_{pc}) for the oxidation and the formation of the free radical with the kinetic parameter product, $k_d \tau C$, where τ is the time interval between E° (generally taken to be close to $E_{1/2}$) and the potential at which direction of the potential sweep is reversed, and C is the bulk solution concentration of the original electroactive species.

Saveant (57) obtained a closed form solution relating k_d to the ratio of the observed peak current, i_{pa}, to the normal diffusion peak current, i_{pd}, at the same v

$$i_{pa}/i_{pd} = (2 \pi k_d \tau C)^{-1/3} \quad [1]$$

A plot of the current ratio *vs.* $\tau^{-1/3}$ should yield a straight line, from which k_d can be calculated; practically, i_{pd} can be replaced by i_{pc}.

The rate constant for dimerization of the MCP free radical produced in the first electron transfer process has been estimated (18) on the basis of E_p shift with v to be 2.24×10^{-2} l mol^{-1} sec^{-1}. This value is in marked contrast to the rate constant of 6.9×10^7 l mol^{-1} sec^{-1} determined by pulse radiolysis (19).

[6] The possible very small wave or peak at −1.6V on a polarogram of the wave I electrolysis product (Fig. 2B) is insignificant due to the fact that, when the same solution was electrolyzed at −1.7V under macroscale conditions, the current fell to the level of that of the background electrolyte alone after the first few minutes.

In the present investigation, analysis of the i_{pa}/i_{pc} ratios for 15 measurements for τ ranging from 2 to 8 msec at 30° gives a k_d for the MCP free radical of (6.1 $\pm$ 1.1) $\times$ 10^7 l mol^{-1} sec^{-1} (mean and standard deviation). Use of Eq. [1] gives a k_d 8% higher: (6.6 $\pm$ 2.2) $\times$ 10^7 l mol^{-1} sec^{-1}. The accuracy of the k_d measurement is estimated to be $\pm$15-20%, based on measurement errors of 3-4% in τ and 5% in the current ratio.

The good agreement of MCP dimerization rate obtained in the present study with that obtained on pulse radiolysis is of special significance since it would tend to indicate that the dimerization rate of the free radical, which is a neutral species, is not appreciably affected by the occurrence of the corresponding chemical reaction at the solution-electrode interface in the electrical double layer region. It is possible that the deviation of the earlier reported (18) electrochemically determined dimerization rate, which is stated to be probably inaccurate due to complications caused by adsorption, resulted from an error in calculation.[7]

The dimerization rate constant at 30° for the free radical produced from NMN^+ is (1.5 $\pm$ 0.1) $\times$ 10^6 l mol^{-1} sec^{-1} (3 measurements; calculated by peak ratio method); Eq. [1] gives a comparable figure.

Activation energies, calculated from Arrhenius plots for the range of 7°-50°, are 4.1 kcal mol^{-1} for MCP^+ and 3.6 kcal mol^{-1} for NMN^+; the corresponding calculated frequency factors at 25° are 6 $\times$ 10^{10} and 8 $\times$ 10^8 l mol^{-1} sec^{-1} compared to that of about 10^{11} l mol^{-1} sec^{-1} expected for a reaction between neutral free radicals (58), where there are no extensive solvation differences between reactants and products. Consequently, the low experimental frequency factor for NMN^+ may indicate a large solvation difference between its free radical and the corresponding dimer, and/or the presence of small residual charges on the free radicals with the accompanying electrostatic repulsion. It is possible that the negative nature of the NMN free radical, as a result of the secondary phosphate dissociation (pK_a 6-7), is the cause (cf. previous discussion of the shift with pH of $E_{1/2}$ for NMN^+ wave I).

3. *Formal potentials.*—When a rapid chemical reaction follows a charge-transfer reaction, the resulting polarographic $E_{1/2}$ is not a simple criterion for the ease of reduction of the molecule. Different compounds can be validly compared only when the potentials are corrected for the effect of the chemical reactions. This can be done, using cyclic voltammetric peak potentials and the relationship (56)

$$E_p = E_c^\circ - \frac{0.058}{3\,n\,\mathbf{F}} \log \frac{4.78 \times 3\,\pi\,D_0}{D_R} \cdot \frac{R\,T\,k_d\,C^\circ}{n\,\mathbf{F}\,v} \quad [2]$$

Using the k_d determined in the present study, E_c° for the initial electron addition process (wave I)

$$MCP^+ + e \rightleftarrows MCP\cdot \quad [3]$$

is calculated to be -1.18V; the corresponding E_c° for NMN^+ is -1.24V. However, in view of the uncertainties in k_d and in equating D_0 and D_R, it would be best to round both values off to -1.2V.

4. *Adsorption and catalytic hydrogen evolution.*—The differences in adsorption at the interface between cationic MCP^+ and NMN^+, and between their neutral reduction products reflect the presence of a hydrophobic substituent on N(1) of MCP^+ and a hydrophilic substituent on N(1) of NMN^+. The difference in adsorption of the MCP dimeric product (strongly adsorbed) and dihydropyridine product (moderately adsorbed) also reflects the difference in hydrophobic nature of the two compounds.

Adsorption of reduction products plays a role in the catalytic evolution of hydrogen. In the case of MCP^+, for example, additional current in wave II region below pH 8 (Fig. 3) has been ascribed to catalytic hydrogen evolution because the limiting current increases rapidly with decreasing pH, increases with increasing buffer capacity at a given pH, and exhibits partial kinetic behavior. At pH 7.4, the catalytic wave peak current occurs at -1.72V, which is near the initial limiting portion of wave II. Little adsorption of either reduction product should occur at this potential since a-c desorption peaks for both products occur at more positive potential. On the other hand, the mercury height-dependence of the catalytic wave suggests that an adsorbed species acts as catalyst, giving rise to a so-called surface catalytic wave (59). This situation is explicable on the basis that weak adsorption corresponding to a very low surface coverage occurs even at potentials more negative than those of the desorption peaks (54). Surface catalytic waves have been shown (54) to occur even with surface coverages as low as 0.5%. With increasing negative potential, the surface coverage, although small, should decrease, which would account for the peaked shape of the wave, *i.e.*, the rate of the electrode reaction increases with increasing negative potential but less catalyst is available due to decreasing surface coverage. The increase in catalytic wave height with decreasing h is due to the greater surface coverage at longer drop-time.

[7] Reference to the dissertation (17), on which the paper (18) was based, revealed that a scan rate of 57.3 V/sec had to be used in order to obtain a minimum detectable anodic peak corresponding to the free radical oxidation. However, calculation, based on Nicholson's graphical method (56), shows that, for k_d = 10^{-2} l mol^{-1} sec^{-1}, an i_{pa}/i_{pc} ratio of close to one would be observed even at the slow scan rate of 0.1 V/sec.

Determination of Water Contamination in Liquid Inorganic Oxyhalide Electrolytes

Kenneth French,* Peter Cukor, Carmine Persiani, and James Auborn*

GTE Laboratories Incorporated, Waltham, Massachusetts 02154

The publication costs of this article have been assisted by GTE Laboratories Incorporated.

Liquid inorganic oxyhalides have found application in at least three areas of advanced technology. Selenium oxychloride and phosphorus oxychloride were found to be desirable materials as solvent media for liquid lasers (1). These oxychlorides readily dissolve rare earth and other metallic salts and do not contain hydrogen atoms which tend to quench laser fluorescence. Solutions of rare earth salts in phosphorus oxychloride have also been used in electroluminescence studies (2). Thionyl chloride, sulfuryl chloride, and phosphorus oxychloride have been proposed for use as solvents in high energy density lithium batteries (3). These solvents can be rendered ionically conducting with the dissolution of lithium salts. They are compatible with strong oxidizing agents, such as chlorine, and do not irreversibly decompose when subject to electrical potentials several times the open circuit voltage of the cells in which they are used. Although lithium metal is stable to attack in these electrolytic solutions, the solvents can be electrochemically reduced at catalytic surfaces and act as cathode depolarizers.

It is important in these applications that the solution be free from water contamination. Water reacts with these oxyhalide solvents readily, making their purification and storage a difficult task. In the course of the reaction of oxyhalides with water, a halogen atom is replaced with an OH group

$$MOCl_n + H_2O \rightarrow MO(OH)Cl_{n-1} + HCl$$

Infrared spectrophotometry provides a convenient method of measuring the extent of this reaction.

[1] Electrochemical Society Active Member.
Key words: lithium, oxyhalides, batteries, infrared trace analysis.

This paper reports on procedures of purification and storage of oxyhalides and on infrared spectrophotometric methods for the determination of the extent of their reaction with water.

Experimental

Phosphorus oxychloride ($POCl_3$) was purchased from Baker and Adamson, and thionyl chloride ($SOCl_2$) and sulfuryl chloride (SO_2Cl_2) were purchased from Research Organic Inorganic Chemical Corporation. These solvents were purified by stirring over lithium metal in a dry argon atmosphere for 24 hr followed by distillation from this mixture.

Lithium chloride was purchased from Foote Mineral Company and dried in vacuum at 200°C. Aluminum chloride (99.999%) was purchased from Rocky Mountain Research, Incorporated and used without purification. All handling of these materials was conducted inside a glove box flushed with dry argon.

Electrolytes were prepared in thionyl chloride ($SOCl_2$) and sulfuryl chloride (SO_2Cl_2) by dissolving equimolar amounts of lithium chloride and aluminum chloride in the purified solvents. The resulting solutions showed evidence of water contamination upon infrared analysis. It was determined that the contamination was introduced into these solutions by the aluminum chloride, as mixtures of lithium chloride with these solvents produced liquids without evidence of water contamination. The solutions were dried further by placing a piece of clean lithium metal in the electrolytic solution and allowing them to stand until the OH absorption band, which is the spectral evidence of water contamination, gradually diminished.

To obtain calibration curves, samples of solvents or the electrolytes were placed in dried 0.5, 1, or 10 cm cells having infrasil windows inside an argon filled glove box. These cells were fitted with ground glass joints and sealed by means of halocarbon grease so that they could be removed from the glove box to the Perkin Elmer Model 621 infrared spectrophotometer. The spectra were recorded using an empty cell as reference. After obtaining infrared absorption spectra of the dry liquids, the cells were returned to the glove box where known amounts of water were added by means of a microliter syringe. Spectra were obtained for each addition and changes in absorption bands were observed.

Results and Discussion

The spectra of freshly prepared oxyhalides are shown in Fig. 1-3. Also shown on these figures are the spectra of these solvents after the addition of a known amount of water. The reaction of water with phosphorus oxychloride and thionyl chloride manifests itself in the spectra by the appearance of a broad hydrogen bonded OH band while the reaction with sulfuryl chloride produces sharp, free OH absorption bands (4-6).

These spectral data allow the construction of calibration curves using essentially the method of additions. The calibration curves, slopes, and intercepts, as well as the conditions under which the curves were obtained, are summarized in Table I.

The phosphorus oxychloride calibration curve departed from linearity at the low concentration range (0-10 ppm) when 1 cm cells were used. A smooth but nonlinear curve was obtained when calibration procedure was repeated with 10 cm cells. (Fig. 4).

It was possible to prepare $POCl_3$ solution virtually free of water reaction products. Thionyl chloride and sulfuryl chloride solutions showed the presence of some residual water reaction products (about 5 ppm) even in the freshly prepared solvents. Thus calibration curves prepared using these materials did not intercept the vertical axis at zero absorption value.

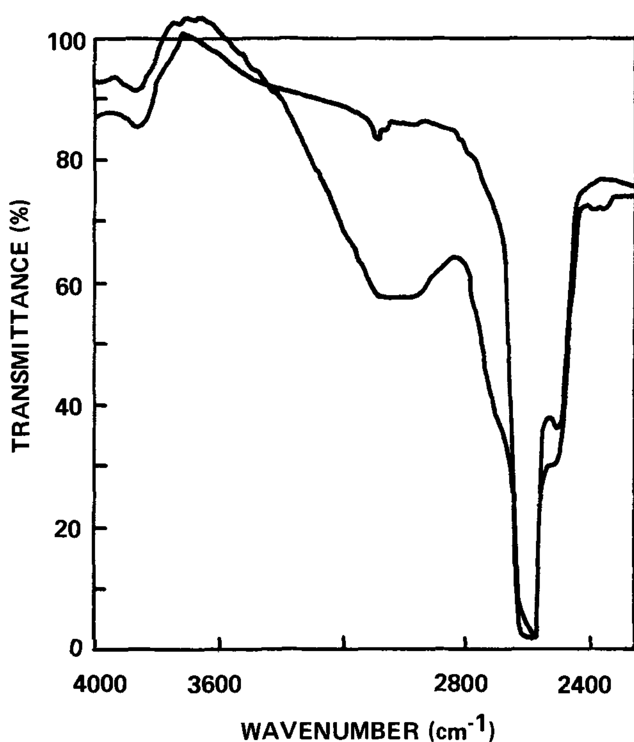

Fig. 1. Spectra of dry and water contaminated $POCl_3$ (1 cm cell, 40 ppm).

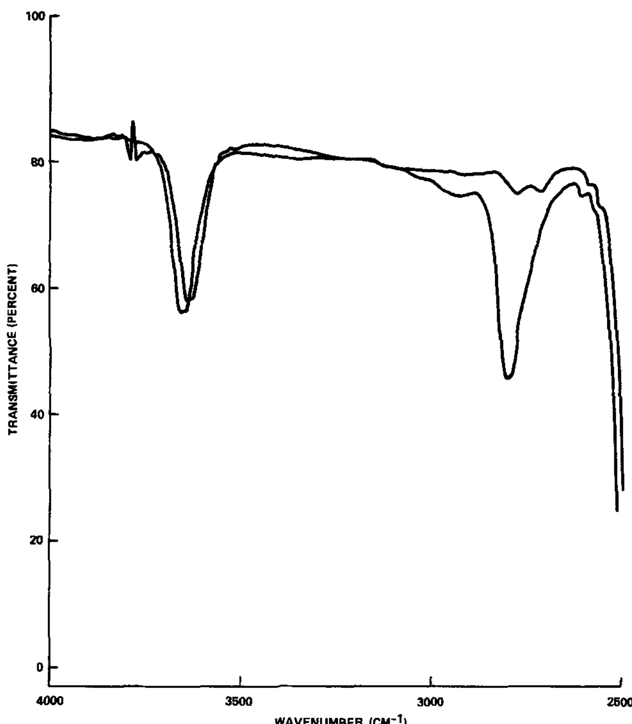

Fig. 2. Spectra of dry and water contaminated $SOCl_2$ (0.5 cm cell, 40 ppm).

The limit of detection of the method was around 0.5 ppm water reaction product, using a 10 cm cell, and water contamination free material.

The spectra of the electrolytes exhibited a broad OH band in the 3000-3700 cm^{-1} region as a result of addition of water (Fig. 5 and 6). The shape and location of this band is typical of metal hydroxides and of hydrated salts. It was also observed that the OH band orginally present in the solvent disappeared upon addition of the $AlCl_3$ suggesting that the following re-

Table I. Conditions of construction of calibration curves of solvents and electrolytes

Solvent	Calibration wavelength, cm	Base line	Cell path, cm	Absorbance slope, ppm H_2O	Intercept absorbance	Background interference,* ppm H_2O
$POCl_3$	3200	Horizontal at 3600	1	0.0075	0.010	~0
$POCl_3$	3200	Horizontal at 3600	10	(See Fig. 4)		
$SOCl_2$	2800	Through 3200 and 2600	0.5	0.0058	0.019	3
$SOCl_2$	2800	Horizontal at 3100	10	0.052	0.28	4
SO_2Cl_2	3700	Through 3800 and 3620	0.5	0.0018	0.025	10
SO_2Cl_2	3700	Through 3820 and 3620	10	0.060	0.45	6
	3600	Horizontal at 3620		0.038	0.18	5
$SOCl_2$ electrolyte	3380	Through 3040 and 3720	0.5	0.0053	0.14	25
SO_2Cl_2 electrolyte	3400	Through 3600 and 3080	0.5	0.0011	0.02	10

action is taking place

$$\underset{\displaystyle OH}{\underset{|}{SOCl}} + AlCl_3 \qquad SOCl_2 + \underset{\displaystyle OH}{\underset{|}{Al}}\text{-}Cl_2$$

Calibration curves were prepared to determine the amount of water that has reacted with the electrolyte (Table I). These calibration curves, constructed essentially by the method of additions, did not pass through the origin because of the presence of residual water contamination in the freshly purified electrolyte. The SO_2Cl_2 electrolyte consistently showed much less water than the $SOCl_2$ electrolyte.

It was also possible to determine the moisture content of "anhydrous" $AlCl_3$. A known amount of this substance was dissolved in dry $SOCl_2$ and aliquots of this solution were further diluted with dry solvent. A spectrum was obtained of the original solution and of each dilution. These spectra exhibited, due to the moisture content of $AlCl_3$, a broad OH band very much similar in shape and location to the OH band present in the electrolyte. A curve of absorption *vs.* $AlCl_3$ concentration was constructed and was found to be parallel to the corresponding electrolyte calibration curve. Hence the electrolyte calibration curves can be used to determine the moisture content of $AlCl_3$.

Conclusions

Phosphorus oxychloride, thionyl chloride, and sulfuryl chloride may be prepared in dry form by stirring over lithium in dry argon atmosphere followed by distillation. These solvents react with water to form OH containing species. The concentration of these contaminants may be determined by infrared spectrophotometry. $POCl_3$ and $SOCl_2$ yield upon reaction with water broad hydrogen bonded OH bands with minimums at 3200 and 2800 cm^{-1}, respectively. SO_2Cl_2 reacts with water and exhibits a sharp, free OH band at 3700 and at 3600 cm^{-1}. The optimum limit of detection of the contamination products is around 0.5 ppm.

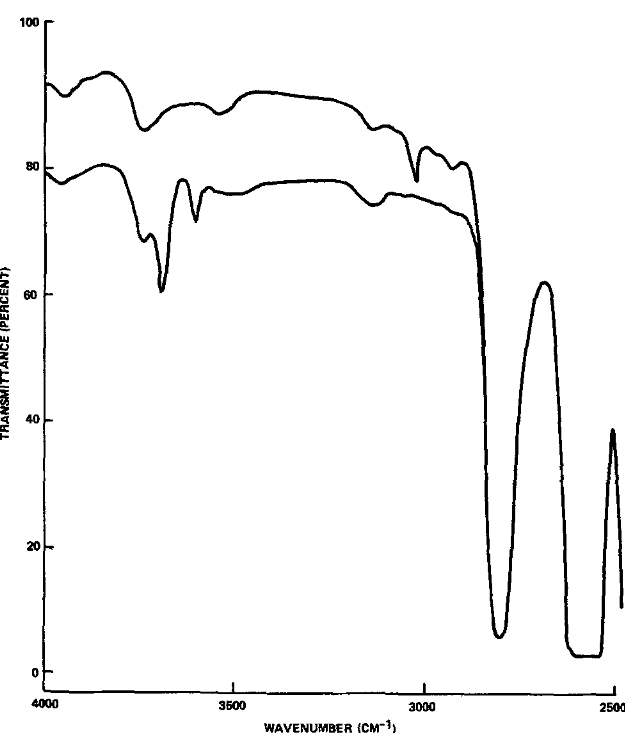

Fig. 3. Spectra of dry and water contaminated SO_2Cl_2 (0.5 cm cell, 90 ppm).

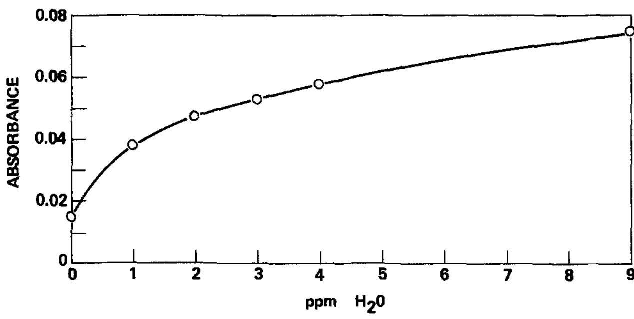

Fig. 4. Calibration curve for the determination of water contamination in $POCl_3$ using a 10 cm cell.

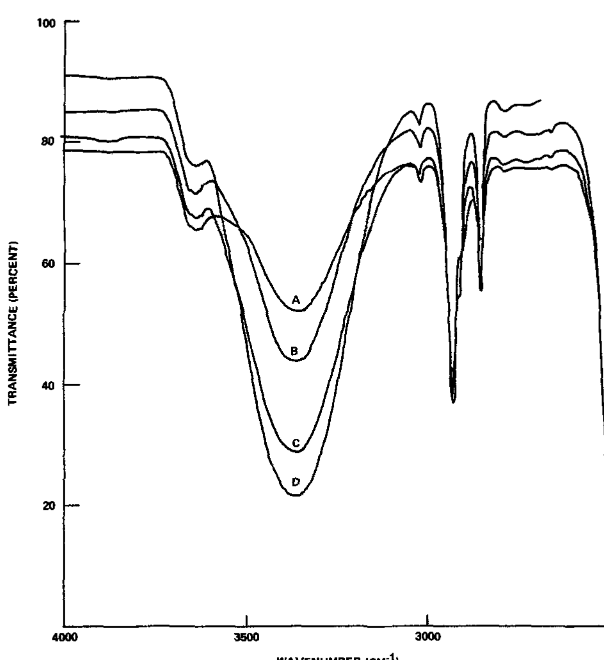

Fig. 5. Spectra of $SOCl_2$ electrolyte containing various amounts of water.

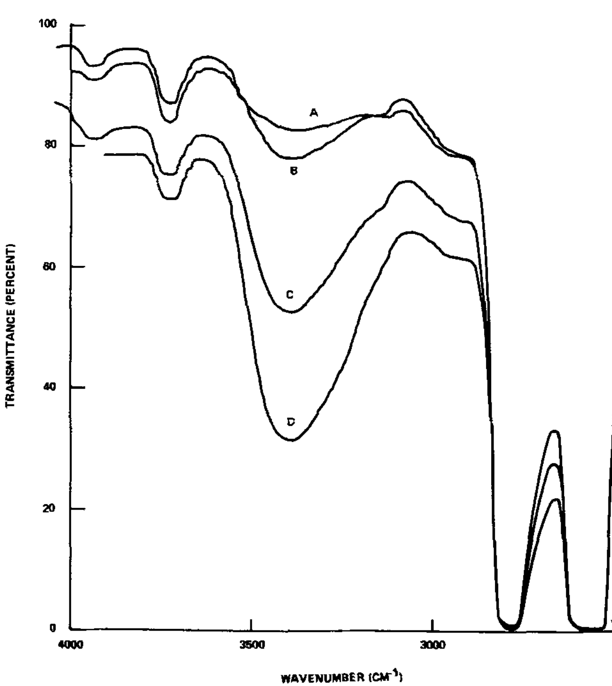

Fig. 6. Spectra of SO_2Cl_2 electrolyte containing various amounts of water.

Electrolytes prepared by dissolving in these solvents a $LiCl/AlCl_3$ mixture exhibit in their spectra a broad OH band around 3400 cm^{-1} due to the presence of moisture in $AlCl_3$. It is possible to measure by infrared spectrophotometry both the extent of water contamination of the electrolytes and the moisture content of the original $AlCl_3$ crystals. Efforts to free the electrolyte from water related contamination were successful when an SO_2Cl_2 solvent was used but were less fruitful for $SOCl_2$ containing electrolytes.

Acknowledgment

The authors gratefully acknowledge the contributions of Mr. Edward W. Lanning to portions of this work related to the analysis of $POCl_3$. This work was supported in part by the U.S. Navy Office of Naval Research.

Electrochemistry in n-Hexanol.
I. The H_2(g,Pt) | HCl(hex) | TlCl(s) | Tl(Hg) Cell

Carlos H. Contreras-Ortega and Peter A. Rock

Department of Chemistry, University of California, Davis, California 95616

The publication costs of this article have been assisted by the University of California.

n-Hexanol is a potentially useful model solvent for the electrochemical study of processes thought to occur in biological membranes. The dielectric constant of n-hexanol (13.3 at 25°C) is comparable to that found for biological membranes (~10) (1), and n-hexanol is amphipathic. n-Hexanol has a wide liquid range (−47°-158°C), a low vapor pressure (1 Torr at 25°C), and it is not difficult to prepare in a high purity, anhydrous state.

This paper reports the results of our electrochemical measurements on cells of the type

$$H_2(g,Pt)\,|HCl(hex)\,|TlCl(s)\,|Tl(Hg,X_{Tl}) \quad [1]$$

The cells were found to behave reversibly, and the stanard cell voltage for cell [1] was computed as $\mathcal{E}° = -973 \pm 10$ mV at 296°K [strong electrolyte standard state for HCl(hex), and a pure Tl(s) standard state for Tl(Hg)].

Because of the need to exclude oxygen and water from the cell, the entire cell was set up and studied as a closed system on the vacuum line (2, 3). The H_2(g) [99.999 atomic per cent (a/o)] used was purchased from the Matheson Chemical Company. The purity of the H_2(g) was checked by mass spectrometry. Before use in the emf cells the H_2(g) was run through a "DEOXO" hydrogen purifier (Englehard Industries), and then through $CaSO_4$ drying towers. Thallium amalgams were prepared from weighed quantities of reagent grade Tl (precleaned with 0.01*M* H_2SO_4) and reagent grade Hg. The amalgam was washed with dilute (0.001*M*) HNO_3, thoroughly dried under high vacuum, and stored in a reservoir on the vacuum line.

The n-hexanol used (98% purity) was obtained from the Aldrich Chemical Company. The n-hexanol was purified by successive distillations over CaH_2(s) (Fisher Scientific Company, purified grade). The first distillation was carried out at 1 atm under helium (bp 157°C). The middle 65% of the distilled n-hexanol was then transferred (without exposure to the atmosphere) to the distillation apparatus on the vacuum line. The n-hexanol was then vacuum distilled over

Key words: n-hexanol, hydrogen electrode, alcohols, thallium electrode.

dry $CaH_2(s)$ at a pressure of 43-49 Torr and a head temperature of 75°-85°C. The distillation column was an 18 mm diameter Pyrex tube 120 cm in length, which was packed with 3 × 5 Raschig rings. Only the middle 75% of the distillate was used to make the cell solutions. The purity of the n-hexanol was checked by NMR, mass spectrometry, and infrared spectrometry. The anhydrous HCl(g), the TlCl(s), and the hydrogen electrodes (Pt black on Au coils) were prepared as described previously (3). The HCl(hex) solutions were prepared on the vacuum line from an hydrous HCl(g) and purified n-hexanol.

The cell construction was of the simple H-type with a central, large-bore stopcock. The cell was set up to operate as an automatically controlled, closed system on the high vacuum line. Samples of Tl(Hg), TlCl(s), and HCl(hex) were run into the cell from their respective storage compartments on the vacuum line after the cell was mounted on the line. The $H_2(g)$ was continuously recycled through the cell by means of automatic pumps (4). Pressures were measured on a differential manometer with a cathetometer; atmospheric pressure was read with a barometer. The emf measurements were made with a Leeds and Northrup Company certified 7555 Type K-5 potentiometer and a Leeds and Northrup Company 9828 electronic null detector. All cells were run at room temperature (296.0° ± 1.0°K), which was periodically recorded while the measurements were in progress.

The molalities of the HCl(hex) cell solutions were determined as follows: samples of the cell solution were obtained from the cells and weighed; the weighed samples [~15g and 15 ml of 0.1M $NaClO_4(aq)$] were added to water and titrated potentiometrically (Beckman E-2 glass electrode *vs.* saturated calomel) with carbonate-free NaOH(aq). The NaOH(aq) was standardized potentiometrically against HCl(aq) obtained by dilution of constant-boiling HCl(aq). The possible interference of n-hexanol with the analysis was ruled out by titration of known quantities of HCl(aq) in the presence and absence of added n-hexanol. The mole fraction of thallium in the amalgams, X_{Tl}, was determined by the acidimetric method of Richards and Daniels (5).

The results of our measurements on cells of the type [1] are presented in Table I. The emf, pressure, and temperature meaurements were taken at 1 hr intervals during the life of the cell and the results were averaged. The period of stability of the cells ranged from 13 to 43 hr with a mean lifetime of 25 hr. The pressures reported have been corrected for the vapor pressure of the cell solutions (~1.0 Torr). Barometer location and temperature corrections have also been applied. Reversibility checks (emf *vs.* meter-scale position) gave no evidence of a hysteresis loop; this is strong evidence that the cells were operating under reversible conditions.

* The last three cells in this table were run with 99.5% D_2, 99.9% DCl, and >95% n-hexanol-OD rather than H_2, HCl, and n-hexanol-OH. The reported emf values for the deuterium cells were converted to hydrogen cells by subtracting 3.1 mV from the measured emf values (6).

† The values of $\mathcal{E}$ given in this column were calculated from Eq. [5] and [6] using $\mathcal{E}° = -940.5$ mV and $2\omega A = 780.5$ mV.

The postulated cell reaction for the cell [1] is

$$H_2(g) + 2TlCl(s) = 2Tl(Hg) + 2H^+(hex) + 2Cl^-(hex) \quad [2]$$

Application of the Nernst equation to this cell reaction yields ($\omega = RT/F$)

$$\mathcal{E} = \mathcal{E}° - \frac{\omega}{2} \ln \left\{ \frac{a^2_{Tl(Hg)} a^2_{H^+} a^2_{Cl^-}}{a_{H_2(g)} a^2_{TlCl(s)}} \right\} \quad [3]$$

If we take $a_{H_2(g)} \simeq (P_{H_2}/760)$, $a_{Tl(Hg)} = X_{Tl}\gamma_{Tl}$, $a_{TlCl(s)} = 1$, and $a_{H^+}a_{Cl^-} = m^2_{HCl}\gamma_\pm^2$ then

$$\mathcal{E} - \frac{\omega}{2} \ln \left(\frac{P_{H_2}}{760} \right) + \omega \ln X_{Tl}\gamma_{Tl} + 2\,\omega \ln m_{HCl} = \mathcal{E}_H \quad [4]$$

where

$$\mathcal{E}_H = \mathcal{E}° - 2\,\omega \ln \gamma_\pm \quad [5]$$

The values of γ_{Tl} (relative to the hypothetical, ideal, unit-mole-fraction solute standard state for Tl in Hg) at various X_{Tl} values were obtained from the data of Richards and Daniels as described in Ref. (3). As m_{HCl} approaches zero, we expect from Debye-Hückel theory that the value of $\ln \gamma_\pm$ for HCl(hex) should approach that given by the equation

$$\ln \gamma_\pm \simeq -15.3 m^{1/2}/(1 + m^{1/2}) \quad [6]$$

Consequently, a plot of the Hitchcock extrapolation function $\mathcal{E}_H$ *vs.* $m^{1/2}/(1 + m^{1/2})$ should have a (theoretical) slope of $2\omega A = 2 \times 25.506 \times 15.3 = 780.5$ mV and an intercept of $\mathcal{E}°$. A least squares analysis of a plot of $\mathcal{E}_H$ *vs.* $m^{1/2}/(1 + m^{1/2})$ using the data in Table I yielded a slope of 517.1 ± 43.0 mV and an intercept of $\mathcal{E}° = -917.6 \pm 3.8$ mV.

The value of the experimental slope is significantly less than the theoretical value, but it should be noted that the Debye-Hückel limiting law slope is more difficult to reach the lower the value of the dielectric constant of the solvent. If we require that the slope of the Hitchcock plot be the Debye-Hückel theoretical value, then a least squares analysis of the data yields an intercept of $\mathcal{E}° = -940.5 \pm 10.2$ mV. If we assume that $\ln\gamma_\pm$ for HCl is given by Eq. [6], then an $\mathcal{E}°$ value can be computed for each cell in Table I. The average of the eight $\mathcal{E}°$ values is $\mathcal{E}° = -940.6 \pm 4.3$ mV. Consequently, we consider our best estimate for the standard potential of cell [1] to be $\mathcal{E}° = -940 \pm 10$ mV.

Because $\mathcal{E}° = -32.8$ mV at 296°K for the reaction Tl(Hg) = Tl(s) (3), we compute a standard potential of $\mathcal{E}° = -973 \pm 10$ mV at 296°K for the cell

$$H_2(g, Pt) | H^+Cl^-(hex) | TlCl(s) | Tl(s) \quad [7]$$

The standard potential for the reaction

$$H_2(g) + 2TlCl(s) = 2Tl(s) + 2H^+(aq) + 2Cl^-(aq) \quad [8]$$

is $\mathcal{E}° = -556.8$ mV at 25°C (6). Combination of this result with our value of $\mathcal{E}° = -973$ mV for the reaction

$$H_2(g) + 2TlCl(s) = 2Tl(s) + 2H^+(hex) + 2Cl^-(hex) \quad [9]$$

yields, for the reaction

$$H^+(aq) + Cl^-(aq) = H^+(hex) + Cl^-(hex) \quad [10]$$

a value of $\Delta G° \simeq 40.1$ kJ·mole^{-1} (molality scale) or $\Delta G° = 31.6$ kJ·mole^{-1} (mole fraction scale) for the standard Gibbs energy of transfer of HCl from water to n-hexanol. The positive value of $\Delta G°$ reflects the stronger solvation of the proton in water than in n-hexanol. The standard potential at 297°K for the re-

action

$$H_2(g) + 2TlCl(s) = 2Tl(Hg) + 2H^+(DMF) + 2Cl^-(DMF) \quad [11]$$

(where DMF is N,N-dimethylformamide) is −887 mV (3). For the reaction

$$H^+(hex) + Cl^-(hex) = H^+(DMF) + Cl^-(DMF)$$

we compute $\Delta G^\circ = +8.3$ kJ·mole^{-1} (molality scale) or + 6.7 kJ·mole^{-1} (mole fraction scale). The positive value of ΔG° reflects the fact that alcohols generally are stronger bases than amides.

Our electrochemical results show that the hydrogen electrode is a well-behaved reference electrode in anhydrous hexanol. In some of our cells the voltage was stable to better than 50 μV for periods ranging up to 20 hr. n-Hexanol thus appears to warrant further investigations both as a low dielectric constant solvent for conventional electrochemical studies, and as a model solvent for bioelectrochemical processes.

Thermodynamics and Kinetics of Pack Aluminide Coating Formation on IN-100

S. R. Levine and R. M. Caves

National Aeronautics and Space Administration, Lewis Research Center, Cleveland, Ohio 44135

The publication costs of this article have been assisted by the National Aeronautics and Space Administration.

ABSTRACT

The effect of variation of pack activators, compositions, temperature, and time on the thickness and structure of aluminide coatings formed on the nickel-base superalloy IN-100 was studied in one-step packs containing aluminum at unit activity. Times were varied from 4 to 24 hr and temperatures were varied from 982° to 1149°C in NaCl-activated packs. The other halides of sodium and the ammonium halides were primarily used to activate 1093°C, 16-hr packs. In addition, an analysis of the thermodynamics and kinetics of aluminizing was carried out. The mechanism of coating formation in each pack was established from agreement between observed coating weights and predictions based on a gaseous diffusion model and solid-state diffusion considerations which used published diffusion data for the Ni-Al system. Pack temperature rather than pack aluminum activity controls the principal coating phase formed. The halides ranked according to aluminum weight gain in 1 w/o (weight per cent) Al packs are F ≅ Cl > Br > I. Solid-state nickel diffusion controlled the rate of coating formation in fluoride-activated packs. Gaseous diffusion controlled the rate of coating formation in bromide-, iodide-, and NH_4Cl-activated packs containing 1 w/o Al. In NaCl-activated packs containing 1 w/o Al the ability of the substrate to supply nickel appeared to be in balance with the ability of the pack to supply aluminum. However, the observed rate constant and activation energy indicated that solid-state diffusion controlled coating growth. Increasing pack aluminum content from 1 to 5 w/o shifted control of coating formation from the gas phase to the solid state in the 16-hr, 1093°C, NaBr-activated pack. Regardless of the rate-controlling step, the kinetics of coating formation were parabolic. The activation energy for coating formation controlled by solid-state diffusion was 88 kcal/mole. Similar coating microstructures and weight gains were obtained for each halogen regardless of whether its source was a sodium or ammonium halide.

Aluminide coatings are commonly used to extend the life of superalloys in the oxidation/corrosion/erosion environment encountered in gas turbines (1). Such protection is provided by aluminum oxide scales which preferentially form on the β-MAl phase which is analogous to NiAl in the Ni-Al binary system. Generally these intermetallic aluminide coatings are diffusion formed by exposing the blade or vane alloy surface to an aluminum-rich environment at elevated temperature. The aluminides may be applied by a number of methods including pack cementation, slurry spraying and sintering, and slurry spraying and fusing in the presence of a fluxing agent (2, 3). The pack cementation method is the most established and commonly used technique for large scale batch processing of engine components currently in commercial flight service.

Although the commercial pack aluminides are performing successfully in the 700°-1000°C metal operating temperature range of current engines, the requirements of higher operating temperatures for improved engine performance with even longer times between overhaul will place ever more stringent demands on coating technology. Even if new coating systems come into use for these high-temperature needs, the relatively low-cost aluminide coatings will continue to be used at peak temperatures to 1100°C. One way to improve such aluminide coatings is by gaining a more thorough understanding of the pack cementation process and then using this insight to optimize pack conditions for each alloy and application.

A fairly extensive background on pack aluminizing exists in the literature, but knowledge of the effect of pack variables on coating structure and performance remains far from complete (2, 4-6). Goward and Boone (5) have summarized the formation mechanisms for aluminide coatings. They formulate two classifications: (*i*) the low-temperature, high-activity pack and (*ii*) the high-temperature, low-activity pack. Each coating class has its peculiarities and advantages. The two-step high-activity process (application followed by diffusion annealing) tends to first form M_2Al_3 which reverts to MAl on annealing. Such coatings incorporate substrate constituents and microstructural features, whereas the low-activity process (which also may re-

Key words: nickel alloys, protective coatings, diffusion.

quire two steps) tends to form MAl and to incorporate only selected substrate constituents (4). In the high-activity process, aluminum is supplied at a rate much greater than it can react to form β-MAl. Thus M_2Al_3 is formed by inward diffusion of Al. In the low-activity process the rate of supply of aluminum is less than the rate at which nickel can be supplied through β, and thus nickel-rich β is formed. The advantages derived from each pack class might be conferred upon a coating by a one-step hybrid pack in which aluminum is present at unity activity and the temperature is high enough to maintain β-formation.

The purpose of this study was to develop a fuller understanding of the important processing variables, transport mechanisms, and thermodynamics of the pack aluminizing process. This was done by studying the effect of several pack activators, pack compositions, temperatures, and times on the thickness and structure of pack aluminide coatings formed on nickel-base superalloy IN-100 in high-activity, high-temperature hybrid packs.

Prior exploratory studies evolved a pack consisting of 1 w/o NaCl, 1 w/o Al with the balance inert Al_2O_3 filler to which the substrates are exposed for 16 hr at 1093°C under an argon atmosphere. In this study the fluorides, chlorides, bromides, and iodides of sodium and ammonium were used as activators. Pack times were varied from 3 to 24 hr, pack temperatures were varied from 982° to 1149°C, and activator and aluminum concentrations were varied over the range of 1-3 and 1-5 w/o, respectively.

The coated specimens were evaluated by weight gain, optical metallography, microhardness measurements, electron microprobe raster micrography (EMP), x-ray fluorescence (XRF), and x-ray diffraction (XRD).

Experimental Procedures

Coating deposition.—Commercially cast IN-100 having a nominal composition of 5.5 w/o Al, 15.3 w/o Co, 9.6 w/o Cr, 3.2 w/o Mo, 4.3 w/o Ti, 0.9 w/o V, 0.17 w/o C, with the balance nickel and minor trace elements, was the substrate used for this study. Specimens were cast in two configurations: 5.1 × 2.5 × 0.25 cm coupons and 10.2 × 2.5 × 0.64 cm erosion bars. Specimen edges were radiused from 0.04 to 0.08 cm by abrasive tumbling or grinding on a water-wetted belt sander. Both types of specimens were then grit blasted with −100 mesh Al_2O_3 to produce a uniform matte finish, rinsed, measured, vapor degreased, rinsed in distilled water, and weighed prior to placement in the pack.

The pack box consisted of an aluminized Inconel retort as shown in cross section in Fig. 1. The specimens were rested in a premixed powder consisting of Alcoa A-1 grade −100 mesh alumina powder, −100 mesh 99% pure Al, and reagent grade activator salt. The packs contained at least 1 w/o Al and 1 w/o activator. The balance was Al_2O_3. In one NaI-activated pack the activator content was raised to 3 w/o and in one NaBr-activated pack the aluminum content was raised to 5 w/o.

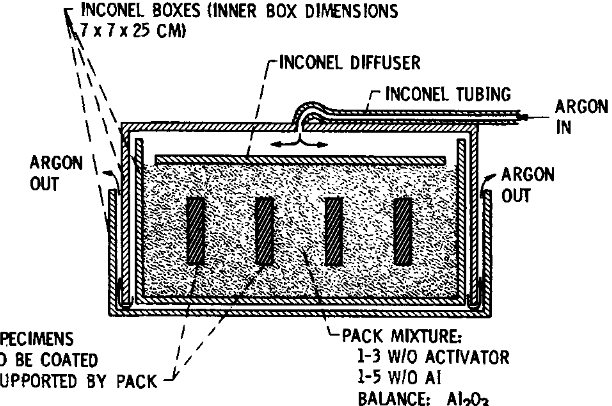

Fig. 1. Schematic cross-section view of an assembled pack box

The assembled pack was purged for 1 hr with high-purity argon prior to insertion into the preheated box furnace which was controlled to ±15°C. The packs required about 1 hr to heat up to the furnace temperature. Pack times are reported as time at temperature rather than as time in the furnace. Argon flow was maintained at 0.057 m^3/hr throughout the time the packs were above room temperature. Upon completion of the scheduled exposure, the pack was removed from the furnace and cooled to room temperature. The specimens were removed from the powder, brushed, rinsed in distilled water, and weighed to determine aluminum pickup.

Additional evaluations.—Metallographic cross sections of some specimens in the as-coated condition were examined to evaluate the effect of the various pack conditions on coating structure and thickness. In addition, microhardness measurements were made with a Knoop indentor driven by a 200g load. The EMP analyses by electron backscatter and element x-ray raster micrography were performed on some metallographic cross sections of the coated specimens to determine qualitative element distributions. Also, XRF analyses *in situ* and XRD analyses of scrapings and *in situ* were performed.

The pack materials from completed 16 and 24 hr, 1093°C, NaCl-activated packs were analyzed for Cl, Na, and Al. Three bulk samples from the 24-hr pack were leached to extract the following elements: one sample was water leached to extract Cl and Al present as soluble halide salt; another was HCl leached to extract Na and Al; and a third was given a redundant NaOH leach to check the extraction of Cl and Al. Sodium was analyzed by flame emission spectroscopy, Al was determined by atomic absorption spectroscopy, and Cl was determined by spectrophotometry using the mercuric thiocyanate procedure. Sequential leaches on single samples were used to analyze a bulk sample and a sample taken from within 0.5 cm of the specimen surface in the 16-hr pack.

Results

The results of aluminide coating deposition on IN-100 in packs activated with the halides of sodium and ammonium are presented in Table I.

Effect of time.—Chloride-activated packs.—Coating deposition times of 4, 6, 8, 16, and 24 hr at 1093°C were used with the baseline NaCl-activated pack. As shown in Table I, the variation in coating weights and thicknesses of specimens within a pack was generally small. There was more variation in these measurements between packs as primarily observed in the 16-hr packs. This variation influenced coating composition and microstructure. A satisfactory explanation for this behavior could not be found. Variations in temperature, variable levels of residual oxygen, nitrogen, and moisture in the assembled packs, or incomplete mixing of the pack ingredients may be responsible.

The XRD analysis indicated that the coatings deposited by 1093°C, NaCl-activated packs were primarily β-MAl. M_2Al_3 was detected *in situ* as a minor coating phase in a coating put down in 8 hr and in the heaviest coating put down in 16 hr.

Photomicrographs of coatings deposited by the NaCl-activated packs are presented in Fig. 2. The zone adjacent to the substrate which etched distinctly lighter in the 4-, 8-, and 16-hr pack coatings is of relatively constant thickness (16-30 μm) as a function of time compared to the growth of the outer or primary coating layer (32-77 μm). In all coatings a discontinuous layer of carbides similar in appearance to the substrate carbides was clearly visible in the as-polished samples. The samples coated for 4 and 8 hr have microstructures characteristic of "low-activity" pack coatings

with carbides concentrated in the light etching zone adjacent to the substrate (5). In the samples aluminided for longer times the carbides also penetrate the primary layer. Some substrate carbide depletion (not shown) was noticeable after 16 hr. After 24 hr the thickness of the substrate carbide depleted zone was comparable to the coating thickness. Since the carbides in the coating are rich in Ti, Mo, and V as were the substrate carbides, they are presumed to be of the MC type (7). Their distribution and the occurrence of carbide depletion of the substrate indicates formation of these carbides in the coating by precipitation as well as by inclusion as a result of coating growth. An additional minor coating phase, revealed as the light etch-

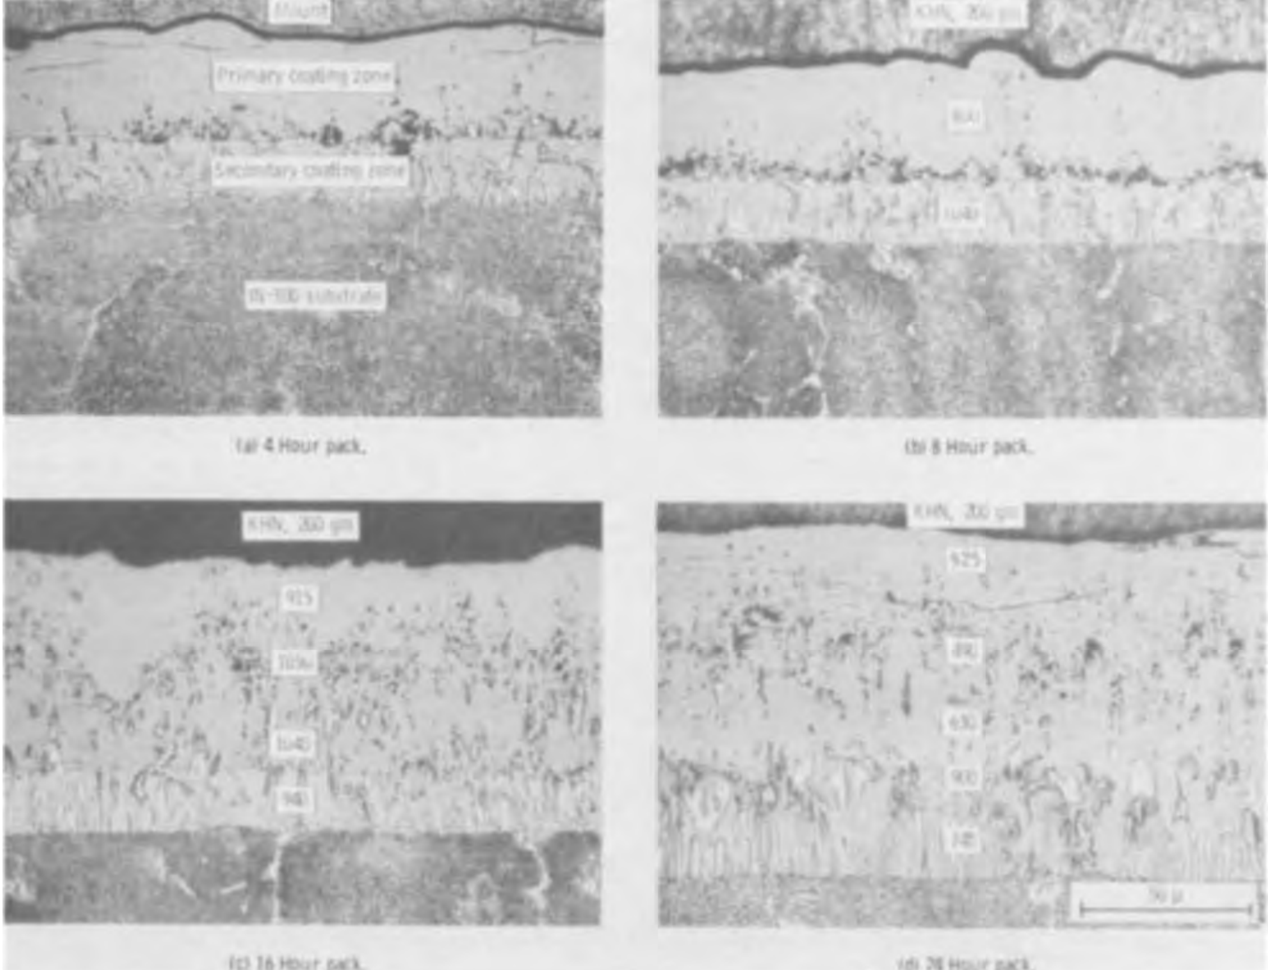

Fig. 2. Cross-sectional microstructures of aluminide coatings deposited on IN-100 in 1093°C NaCl-activated packs

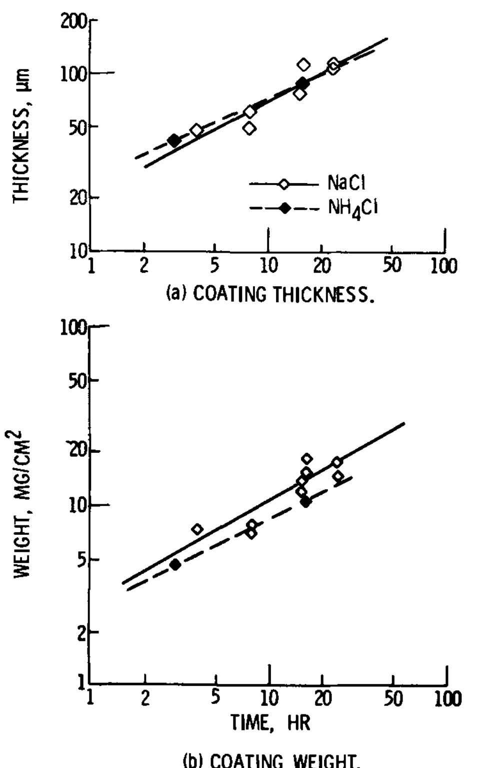

Fig. 3. Growth of aluminide coatings on IN-100 in sodium and ammonium chloride-activated 1093°C packs.

ing particles concentrated primarily in the lighter etching zone, is rich in Cr, Mo, and V and lean in Ni, Co, and Ti. Occasional Al_2O_3 inclusions (large dark particles) and other particles (primarily rich in Cr) are also found in the primary layer.

The coating deposition data for NaCl-activated packs, as plotted in Fig. 3, were fit to power law growth equations

$$x = (kt)^{1/n}; \qquad w = (k't)^{1/n'} \qquad [1]$$

appropriate for diffusion through a growing phase or depleting zone in the pack. Analysis of thickness (x) and weight (w) data gave $1/n$ and standard deviation values of 0.54 ± 0.10 and 0.56 ± 0.12 for thickness and weight data, respectively, indicating parabolic behavior. Fitting the thickness data to a parabolic growth equation ($n = 2$) gives a rate constant (k) of 1.6×10^{-9} cm²/sec with a standard deviation of $\pm 0.4 \times 10^{-9}$ cm²/sec.

The data for NH_4Cl-activated packs, as plotted in Fig. 3, were fit to the power law growth equation. Using the standard deviations found for NaCl, the values of $1/n$ and their standard deviations are 0.46 $\pm$ 0.10 and 0.49 $\pm$ 0.12 for thickness and weight gain data, respectively. These values suggest that parabolic kinetics prevailed in NH_4Cl-activated packs. The parabolic rate constant was $1.3 \pm 0.4 \times 10^{-9}$ cm²/sec (again using the standard deviation obtained for NaCl).

NaBr-activated packs.—Microstructures of coatings deposited in 4-, 8-, 16-, and 24-hr, 1 w/o aluminum NaBr-activated, 1093°C packs are presented in Fig. 4. The outer inclusion-free zone of the coatings deposited in 4-, 8-, and 16-hr packs shows a change in color as a function of depth not seen in coatings deposited in NaCl-activated packs. This is indicative of a transition from Al-rich MAl at the surface to Al-lean MAl in the

50 μ

Fig. 4. Cross-sectional microstructures of aluminide coatings deposited on IN-100 in 1093°C NaBr-activated packs

coating interior (4). The interface between the inclusion-free outer zone and the inner zone is quite irregular in NaBr-activated packs when compared to the interface developed in NaCl-activated packs (Fig. 2). This irregularity is indicative of sensitivity to small local variations in pack composition as previously reported by Brill-Edwards and Epner (6).

The aluminum weight gain data are plotted against pack time in Fig. 5. When fit to the power law rate equation, $1/n$ and standard deviation, values of 0.44 $\pm$ 0.13 and 0.44 $\pm$ 0.04 were obtained for thickness and weight gain data, respectively. Thus coating formation adheres fairly well to a parabolic growth law. The parabolic rate constant was 7.9×10^{-10} cm²/sec with a standard deviation of $\pm 2.3 \times 10^{-10}$ cm²/sec. This is less than the parabolic rate constants calculated for coating formation in chloride-activated packs. The differences in rate constants, coating microstructures, and sensitivities to local variations in pack composition between coatings formed in chloride- and bromide-activated packs may be indicative of a difference in the rate-controlling step in coating formation in these packs.

Effect of temperature.—Coating deposition temperatures of 982°, 1038°, 1093°, and 1149°C were used with NaCl-activated packs run for 16 hr. Inclusion of data from 15-hr, 1093°C packs is felt to introduce a negligible error. The log of coating weight squared at constant time is, to a good approximation, a linear function of reciprocal absolute temperature as can be seen from Fig. 6. A +15°C variation in temperature gives an 18% increase in coating thickness. Regression analyses of weight gain and coating thickness data for assumed parabolic behavior gave activation energies of 88 kcal/mole. The standard deviations of the activation energy (slope) were ± 11 and ± 13 kcal/mole for the lines fit to thickness and weight data, respectively.

The XRD results confirmed that the primary coating phase was β. Photomicrographs of coatings deposited at each of the four pack temperatures are shown in Fig. 7. Coatings deposited at 982° through 1093°C are very similar in general microstructure. They all have the characteristic inclusion-free outer or primary β-layer and a distinctly defined, lighter etching zone having a high concentration of MC carbide inclusions. Second-phase inclusions are concentrated at the inner part of the primary layer in the 982° and 1038°C deposited coatings as they were in the coating applied in the 8-hr, 1093°C pack. Longer times or higher temperatures spread the distribution of these particles throughout the outer layer. The growth of the primary β-layer was much more sensitive to temperature than was the growth of the secondary zone adjacent to the substrate. Carbide depletion of the substrate to a depth comparable to the coating thickness (not shown), recrystallization of the columnar secondary zone, formation of a layer of γ (nickel solid solution) at the coating substrate interface, and growth of a zone of large equiaxed grains essentially free of second-phase inclusions in the outer β-layer have all occurred in the coating deposited at 1149°C. The coating is also considerably softer than coatings deposited at lower temperatures. These features are characteristic of a partially depleted aluminide coating on IN-100 (8). In summary, coating microstructures obtained in 982° or 1038°C, 16-hr packs (Fig. 7a and b) and 1093°C, 4- and 8-hr packs (Fig. 2a and b) have microstructures characteristic of low-activity pack coatings (*i.e.*, a single-phase β outer coating zone) whereas the coating microstructures obtained at higher temperatures or longer times are hybrids incorporating features found in heat-treated high-activity pack coatings and low-activity pack coatings as discussed by Goward and Boone (5).

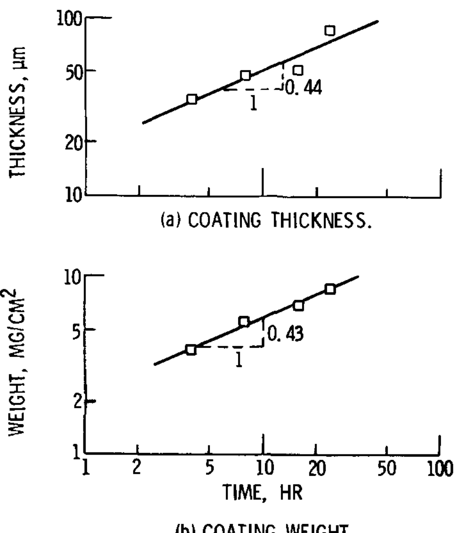

Fig. 5. Growth of aluminide coatings on IN-100 in 1 w/o aluminum sodium bromide-activated 1093°C packs.

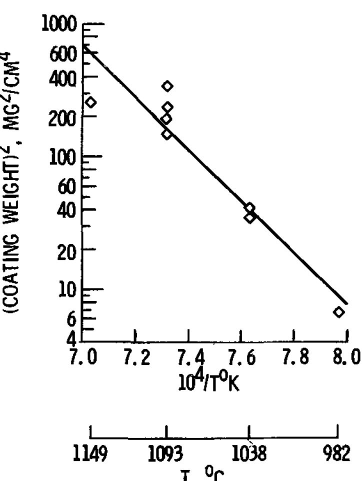

Fig. 6. Effect of temperature on the formation of aluminide coatings on IN-100 in 15- and 16-hr NaCl-activated packs. $w^2 = k_0 t \exp(-1000\,Q/RT)$.

Effect of activators.—The results of activator variation in 16-hr, 1093°C packs are listed in Table I and plotted as bar graphs in Fig. 8a and b. In all cases the XRD analysis of the coatings detected β as the major coating phase. Examination of Fig. 8a and b indicates that aluminum pickup generally increases with decreasing atomic number of the halogen. The XRF analyses of the surface (Fig. 8c and d) indicated that the trend for surface nickel content was approximately the inverse of the trend for aluminum pickup; *i.e.*, surface nickel content generally increased with increasing atomic number of the halogen. These observations indicate that the ability of higher molecular weight halogens to deposit aluminum is less than that of lower molecular weight halogens. Thus gas phase kinetics and thermodynamics must play a significant role in aluminum deposition under some conditions.

The changes in halide and the accompanying changes in the rate of coating formation have an effect on the coating microstructure and phase distribution as can be seen in the photomicrographs in Fig. 9 and 10. The coatings formed in 16-hr, fluoride- and chloride-activated packs have microstructural features derived from both the heat-treated high-activity and the low-activity pack classifications. The bromide- and iodide-activated pack coatings (Fig. 9c and d and 10c and d) have microstructural features peculiar to low-activity pack coatings. Aluminum content in these coatings is generally lower than in lower temperature or shorter time NaCl-activated pack coatings having about the same weight (Fig. 3a and b and 7b). Consequently, the coatings formed in bromide- and iodide-activated

packs are generally softer than coatings formed in corresponding fluoride- and chloride-activated packs.

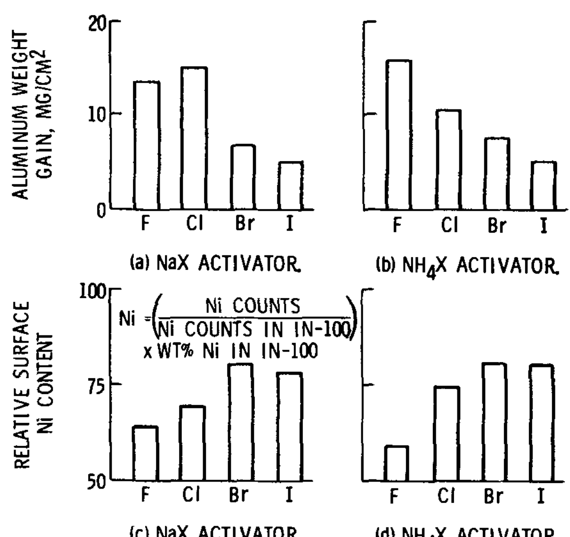

Fig. 8. Aluminum weight gain and surface nickel content in 16 hr, 1093°C packs as a function of halide activator.

However, they have microstructures similar to these NaCl-activated pack coatings.

Effect of pack composition.—An increase in pack aluminum and NaCl content from 1 to 2% had no significant impact on aluminum pickup in a 1093°C, 16-hr pack. Also, an increase in NaI content from 1 to 3% had no significant impact on aluminum deposition in a 1093°C, 16-hr, 1% aluminum pack. However, an increase of aluminum content from 1 to 5% in a 1% NaBr, 1093°C, 16-hr pack increased aluminum pickup from 6.8 to 16.1 mg/cm^2. The microstructure of this coating, shown in Fig. 11, is very similar to microstructures of 16- and 24-hr NaCl-deposited coatings. This sensitivity to pack aluminum content indicates that gas phase kinetics play a significant role in the rate of aluminum deposition in NaBr-activated packs. Similar behavior could be anticipated in NH_4Br- and iodide-activated packs based on the strong similarities between coatings put down by these packs and the 1 w/o Al, NaBr-activated pack.

Discussion

Pack stability.—In this study aluminide coatings were deposited on IN-100 in a semiopen system. The ability of such a system to maintain stable bulk pack aluminum deposition capability throughout an experiment is a natural first subject for discussion. For ex-

ample, a maximum in coating microhardness was observed at 16 hr and M_2Al_3 was detected as a minor phase only in 8- and 16-hr coatings deposited in 1093°C, NaCl-activated packs. These observations may be indicative of a decline in bulk pack aluminum deposition capability with time or may merely be due to the growth of a depleted zone in the pack adjacent to the specimen surface.

To obtain some feeling for the stability of the various packs and eventually permit an analysis of the kinetics of aluminum deposition, thermodynamic analyses for the initial bulk pack compositions were performed. The results of the thermodynamic analyses of the bulk pack compositions, as discussed in detail in Appendix A, are presented in Table II. On the basis of condensed phases present, the packs fall into three groups: sodium halide-activated packs with NaX(l) and Al(l) present; NH_4F-activated packs with AlF_3(s) and AlN(s) present; and NH_4X (X = Cl, Br, or I) activated packs with Al(l) and AlN(s) present. Based on the nature of the condensed phases present at local equilibrium in the bulk pack as listed in Table II, the sodium halide- and ammonium fluoride-activated packs should be stable as a function of time whereas the other ammonium halide-activated packs may not be stable.

The results of Cl, Na, and Al analyses of pack material from a 24-hr NaCl-activated, 1093°C pack as listed in Table III did not confirm that a significant decrease in bulk pack aluminum deposition capability occurred. Calculation of the partial pressures of reactive species in the pack at 24 hr from the results of the chemical analyses gave values equal to or greater than those calculated for the initial conditions. Thus the absence of M_2Al_3 in the 24-hr pack is attributed to formation of a depleted zone in the pack at the specimen surface. More direct evidence of depleted zone formation was obtained from the XRD and chemical analyses of samples taken from the bulk pack and from within 0.5 cm of the sample surface after completion of a 16-hr, 1093°C, NaCl-activated pack as reported in Table III. Aluminum was detected by XRD as a minor phase in the bulk pack but was not detected at the specimen surface. Conversely, NaCl was detected as a possible minor phase at the specimen surface but was not detected in the bulk pack. Chemical analyses of these samples, as listed in Table III, confirm the XRD results. The Al content of the bulk pack was considerably higher than that of the pack close to the specimen surface whereas the Na and Cl constants of the bulk pack were found to be lower than at the specimen surface. Thus a depleted zone is formed in the packs. Formation of a depleted zone in aluminiding packs was previously reported by Brill-Edwards and Epner (6). An idealized sketch of the depleted zone is shown in Fig. 12. The actual depleted zone probably does not show an abrupt transition since gaseous diffusion permits gradual depletion of aluminum over an extended transition zone.

Since no condensed halide source is present in NH_4X (X = Cl, Br, or I) activated packs whereas NaX(l) is present in corresponding sodium halide packs the stability of the NH_4X packs may be considerably lower than that of NaX-activated packs. Also, for example, extremely high initial deposition rates may be obtained with NH_4Cl during the early part of the coating cycle when the partial pressure of AlCl(g) is more than an order of magnitude higher than in the NaCl-activated pack. However, the coating deposition data for NaCl- and NH_4Cl-activated packs, plotted in Fig. 3, suggest

that the NH_4X (X = Cl, Br, or I) activated packs behave similarly to NaX-activated packs in the sense that initial deposition rates are not significantly different and that rapid dilution of the NH_4Cl-activated pack does not occur in spite of the absence of a condensed halide phase. In addition, there is strong correspondence between the microstructures and weights of coatings applied by corresponding halides of sodium and ammonium as can be seen from Fig. 9 and 10 and Table I.

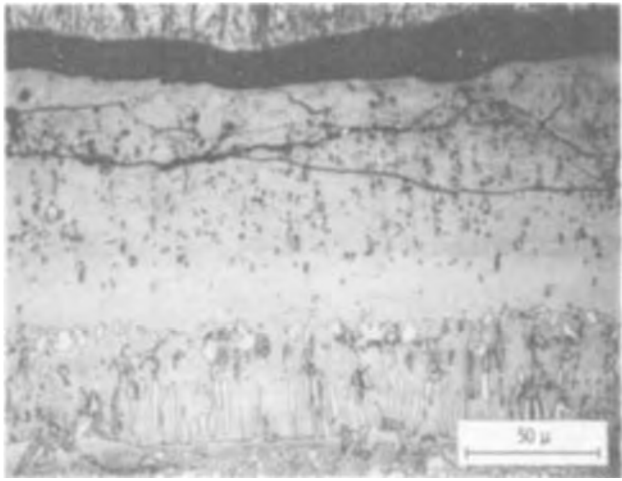

Fig. 11. Cross-sectional microstructure of an aluminide coating deposited on IN-100 in a 1 w/o NaBr, 5 w/o Al, 16-hr, 1093°C pack.

Pack kinetics.—Experimental.—In this study parabolic rate constants of $1.3 \pm 0.4 \times 10^{-9}$ cm²/sec for NH_4Cl-activated coating deposition and $1.6 \pm 0.4 \times 10^{-9}$ cm²/sec for NaCl-activated coating deposition were obtained. These values are less than rate constants reported by Janssen and Rieck (9) for growth of NiAl between Ni_2Al_3 and Ni_3Al and for nonstoichiometric NiAl from NiAl and Ni. Extrapolation of their results to 1093°C gave rate constants of 5×10^{-9} cm²/sec for the former reaction and 6×10^{-9} cm²/sec for the latter. The difference between rate constants for coating formation on IN-100 and diffusion in binary couples could be due to both the effects of solutes such as Cr, Co, and Ti derived from the IN-100 substrate and to the order of magnitude variation in diffusivity between stoichiometric NiAl (in which the diffusivity of nickel is a minimum) and nickel-rich NiAl (10) (which controls layer growth as determined by Janssen and Rieck).

Also, in this study an activation energy of 88 ± 13 kcal/mole was obtained for the deposition process in NaCl-activated packs. This value is in poor agreement with a value of 41 kcal/mole reported by Janssen and Rieck (9) for diffusion of nickel in β as determined by layer growth studies. However, the activation energy falls close to the upper end of the range of values for nickel diffusion in NiAl reported by Hancock and McDonnell (10): 73.4 ± 2.3 kcal/mole for stoichiometric NiAl to 42.5 ± 6.3 kcal/mole for the 48.3 a/o (atom per cent) Ni composition. The activation energy is also in agreement with the activation energy of 81 kcal/mole reported for Co tracer diffusion in NiAl by Berkowitz *et al.* (11). Based on the coating growth rate constants and activation energies observed in this study and their reasonable agreement with data for the NiAl system (9-11), we conclude that nickel diffusion through the coating may be the rate-controlling step in Na_4Cl- and NH_4Cl-activated packs run between 982° and 1149°C. Additional support comes from metallography and XRD results which indicated that the coating was primarily β and from the observed insensitivity of NaCl packs to 1% variations in aluminum and activator content.

In NaBr-activated packs high sensitivity of coating weight to pack aluminum content was observed. The kinetics of aluminum deposition in 1 w/o NaBr packs adhered reasonably well to a parabolic growth law, but the parabolic rate constant ($7.9 \pm 2.3 \times 10^{-10}$ cm²/sec) was smaller than in NaCl-activated packs ($1.6 \pm 0.4 \times 10^{-9}$ cm²/sec). Based on the sensitivity of NaBr packs to aluminum content and the lower aluminum pickup of 1 w/o Al bromide- and iodide-activated packs compared to chloride- and fluoride-activated packs, the authors conclude that gas phase kinetics was the rate-controlling step in aluminum deposition from bromide- and iodide-activated packs containing 1 w/o aluminum.

Analytical.—To further elucidate the role of gas phase kinetics in aluminide coating formation, analyses of aluminum transport from the bulk pack through the pack depleted zone to the surface of the coating were carried out. The starting points for the analyses were the thermodynamic calculations discussed in Appendix A and the pack depletion zone model, Fig. 12. The analyses of gas phase kinetics are discussed in Appendix B where the calculation of instantaneous fluxes of aluminum for a simplified case is outlined. The in-

stantaneous flux is given by

$$\frac{N_{Al}d}{A} = \frac{\sum_{i=1}^{n} D_i(P_i - P'_i)}{RT} \quad [2]$$

where D_i and P_i are the diffusivity and partial pressure of the ith aluminum-bearing species with the prime referring to the sample surface, d is the diffusion distance and N_{Al} is the rate of transport of Al in moles/second. The computations included mass balances on H, X, and Na and allowed for condensation of NaX(l) as appropriate. In NH_4X-activated packs dilution by 9.8 moles of argon (4 hr of argon flow) was used to arrive at bulk pack compositions. In the case of NH_4F pseudoequilibrium bulk pack compositions were used since dilution with 9.8 moles of argon results in disappearance of the AlF_3(s) phase. The computations were made for an assumed surface aluminum activity of 1×10^{-2}. This is a reasonable choice for average aluminum activity in view of the fact that Steiner and Komarek (12) report an activity of 1×10^{-2} for aluminum in stoichiometric NiAl at 1000°C. Results are listed in Table IV for major diffusing species.

From the instantaneous fluxes the diffusion direction of each species in the pack depleted zone was ascertained. These are illustrated in Fig. 13 (a) for the simplified model for NaX-activated packs in which NaX(l) condensation was not considered, (b) for the complete model for NaX-activated packs where NaX(l) condensation was considered, and (c) for NH_4X-activated packs. Instantaneous fluxes of major species are compared to the net instantaneous aluminum flux in Fig. 14. Aluminum is deposited primarily by AlX. NaX(l) condensation (Fig. 14b) augments aluminum deposition by not requiring halogen removal by AlX_2 and AlX_3 diffusion (Fig. 14a). In reality, the actual fluxes for NaX-activated packs are probably bounded by the complete and simplified models. Evidence of NaX condensation in the depleted zone was obtained. However, some depletion of Na as a result of reaction with alumina and by transport out of the semiopen system does occur.

In addition to aluminum being deposited, loss of substrate species from IN-100 can contribute to observed net specimen weight change and thus cause misinterpretation of coating weight. Analyses were performed for Ni and Cr. Very small amounts of nickel are lost from the substrate as nickel and nickel halide. At 1366°K the partial pressure of nickel over the alloy is only about 10^{-10} atm (13). This gives a nickel flux of about 10^{-14} moles/cm²-sec from the coating surface to the bulk pack.

The estimated Cr partial pressure over IN-100 is 0.1 $P_{Cr} = 1.3 \times 10^{-7}$ atm at 1366°K (13). This gives a Cr flux of about 1.3×10^{-11} moles/cm²-sec. Thus, at worst, the chromium weight loss in a 16-hr, 1093°C pack was about 1% of the aluminum weight gain.

The rate of aluminum deposition dw/dt in milligrams per square centimeter-second was computed from the instantaneous fluxes according to the following equation

Table IV. Major instantaneous fluxes and net aluminum deposition rate constants and weights for gaseous diffusion from a bulk 1 w/o Al pack to a surface at aluminum activity 1×10^{-2}

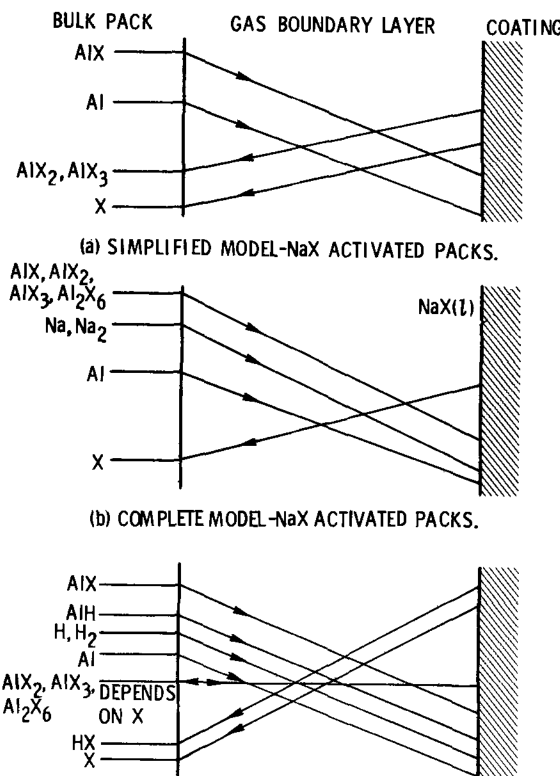

Fig. 13. Schematic showing gas diffusion directions during aluminum deposition.

$$\frac{dw}{dt} = \left(\frac{\rho}{w}\right)\left(\frac{\epsilon}{l}\right)(m_{Al}1000)\left(\frac{N_{Al}d}{A}\right) \quad [3]$$

The term $\rho/w = 1/d$ defines the growth of the pack depleted zone in terms of coating weight w and pack aluminum content $\rho = 8$ mg/cm^3 in 1 w/o Al packs. The term ϵ/l corrects for diffusion through a porous medium. The effective transport area of the pack is to a good approximation, equal to the pack porosity, $\epsilon = 0.79$. In addition, the transport path is nonlinear and a correction factor $l = 4$ was arbitrarily assumed. The third term converts from moles of aluminum to milligrams. Integration gives

$$w^2 = \frac{2\rho\epsilon}{l}\left(\frac{N_{Al}d}{A}\right)2.7 \times 10^4 t \quad [4]$$

The aluminum deposition rate constants

$$k_{Al} = \frac{2\rho\epsilon}{l}\left(\frac{N_{Al}d}{A}\right) 2.7 \times 10^4 \quad [5]$$

are listed in Table IV. Inclusion of sodium halide condensation results in a 1.7 to 11-fold increase in k_{Al} depending on the halide. The moles of NaX(l) condensed are about equal to the moles of Al deposited according to the complete solution.

Computed instantaneous fluxes were relatively insensitive to large changes in assumed surface aluminum activity. For example, a tenfold decrease in surface aluminum activity would increase the computed instantaneous flux by a factor of 2 and the coating weight by only a factor of $\sqrt{2}$.

Predicted aluminum weight gains for 16-hr, 1 w/o Al packs are also listed in Table IV. These predicted values are plotted against observed aluminum weight gains in Fig. 15. For NaX-activated packs an average predicted value was used. The good agreement between observed and predicted coating weights in bromide- and iodide-activated, 1 w/o Al packs confirms that deposition is controlled by gaseous diffusion. The choice of an l value of 5 would have given better

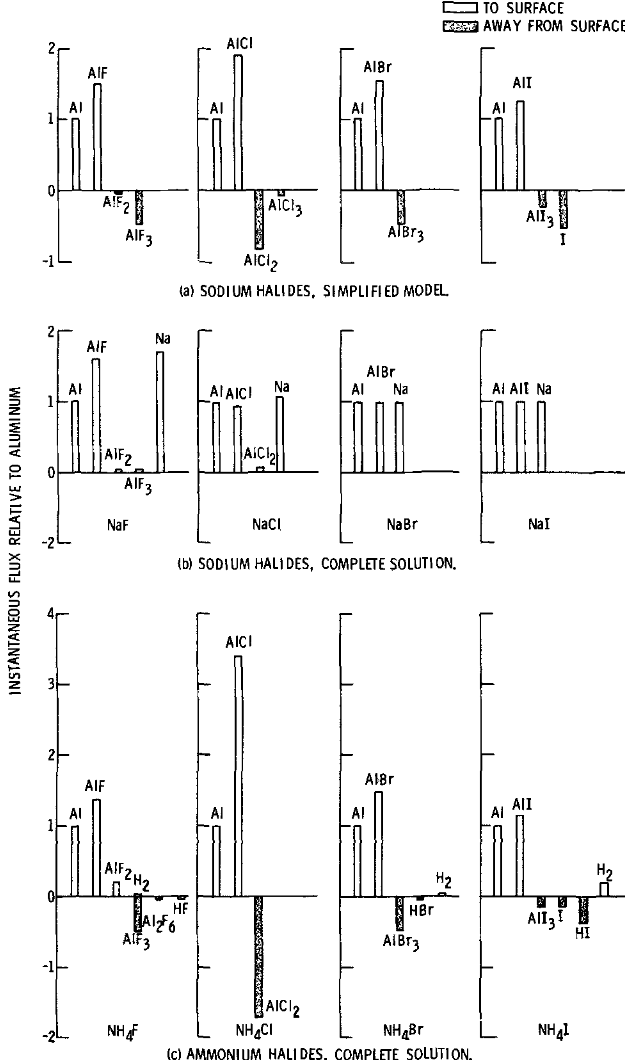

Fig. 14. Instantaneous fluxes of diffusing species relative to net instantaneous aluminum flux. Surface aluminum activity, 0.01; 1 w/o Al; 1093°C packs.

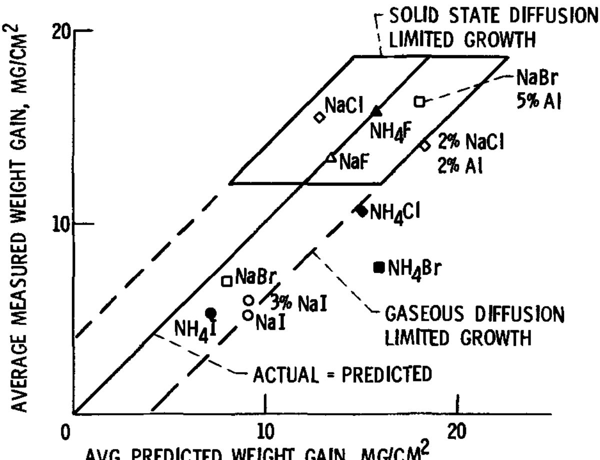

Fig. 15. Comparison of actual and predicted aluminum weight gain for IN-100, 1093°C, 16-hr packs. 1 w/o Al and activator unless indicated otherwise.

agreement. Earlier it was stated that solid-state diffusion of nickel may be the rate-controlling step in NaCl- and NH_4Cl-activated packs. However, good agreement between observed and predicted weights based on the gaseous diffusion model indicates that gaseous diffusion controls coating deposition in NH_4Cl-

activated packs. There appears to be a balance between the predicted ability of the pack to supply aluminum and the observed ability of the substrate to absorb aluminum via nickel diffusion in NaCl-activated packs. However, in 1 w/o Al packs activated with NaCl, based on the observed rate constant and activation energy, the solid-state diffusion step can be considered rate controlling. If gaseous diffusion was rate controlling a pseudoactivation energy of 50 kcal/mole would have been observed rather than 88 kcal/mole. The pseudoactivation energy for gaseous diffusion was determined from the temperature dependence of k_{Al} computed for NaCl-activated packs. Although this activation energy does not take surface aluminum activity variation into account, the influence of this factor is expected to be small since k_{Al} was shown to be relatively insensitive to large changes in surface aluminum activity. Similarly, in the 5 w/o Al pack activated with NaBr the agreement between observed and predicted coating weights based on the gaseous diffusion model is good. However, based on coating weight and microstructure, the solid-state diffusion step can be considered rate controlling.

In fluoride-activated packs predicted coating weights based on gaseous diffusion models were two to five times greater than observed weights. The net aluminum deposition rate constants for assumed parabolic behavior, when put on a thickness basis (using a conversion factor of 7.7×10^{-4} cm/mg/cm²), were 1.0×10^{-8} and 4.8×10^{-8} cm²/sec for the NH_4F and NaF activators, respectively. These rate constants are greater than rate constants for NiAl growth as determined from Janssen and Rieck (9) by more than an order of magnitude. Thus, *a posteriori*, solid-state diffusion controls the rate of coating growth when the net aluminum deposition rate constant is greater than 5×10^{-9} cm²/sec (8.4×10^{-3} mg²/cm⁴-sec) at 1093°C in the Ni-Al system. Since observed coating weights were limited to 15.3 ± 3.3 mg/cm², solid-state diffusion controls deposition on IN-100 when the net aluminum deposition rate constant exceeds $4.3 \pm 1.8 \times 10^{-3}$ mg²/cm⁴-sec or $2.5 \pm 1.1 \times 10^{-9}$ cm²/sec. Predicted coating weights for fluoride-activated packs are plotted on a solid-state diffusion control basis in Fig. 15.

Concluding Remarks

In this experimental and analytical study of high-temperature packs having aluminum present at unit activity, MAl coating formation was controlled by either solid-state or gaseous diffusion. Although the experiments were performed on IN-100, the analysis is quite general and may be applied to any nickel-base superalloy. Based on these results it appears that the classification of aluminide packs into "high-activity" and "low-activity" as proposed by Goward and Boone (5) can be extended. Coating formation can be more accurately described in terms of the ability of the pack to supply aluminum and the ability of the substrate to supply nickel. The primary variable is temperature rather than pack aluminum activity. This is illustrated in Fig. 16 where the classifications proposed by Goward and Boone are shown on the left. Coatings similar to those produced in low-activity packs can be produced in packs having aluminum present at unit activity provided that they are carried out at high temperature as illustrated on the right of Fig. 16. The coating formation process can be controlled either by diffusion in the gas phase or solid phase depending on the activator and pack aluminum content.

Summary of Results

The effect of variation of pack activators, pack compositions, temperature, and time on the thickness and structure of aluminide coatings formed on nickel-base alloy IN-100 was studied in a series of one-step packs in which aluminum was initially present at unit activity. Times were varied from 4 to 24 hr and temperatures were varied from 982° to 1149°C in NaCl-activated packs. The other halides of sodium and the ammonium halides were primarily used to activate 1093°C, 16-hr packs. Through an analysis of the thermodynamics and kinetics of reactions in the pack and comparison with published diffusion data in the Ni-Al binary system the mechanism of coating formation in each pack was established. The following are the results of this study:

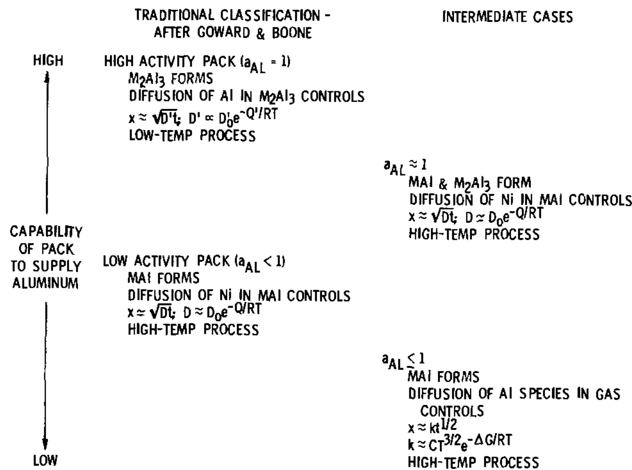

Fig. 16. Proposed expanded classification of aluminide packs

1. Coating weights can be successfully predicted from analyses of pack thermodynamics and diffusion in the pack and coating.
2. Pack temperature rather than pack aluminum activity controls the principal coating phase formed.
3. The halide pack activators ranked in order of decreasing aluminum weight gain in 1 w/o aluminum packs are: $F \cong Cl > Br > I$.
4. Solid-state nickel diffusion was the rate-controlling step in coating formation in fluoride-activated packs. Gaseous diffusion controlled the rate of coating formation in 1 w/o Al bromide- and iodide-activated packs and NH_4Cl-activated packs. In NaCl-activated packs containing 1 w/o Al the predicted ability of the pack to supply aluminum was in balance with the ability of the substrate to supply nickel. However, the observed rate constants and activation energy indicated that the solid-state diffusion step controlled coating growth.
5. An increase in pack aluminum content from 1 to 5 w/o shifted control of coating formation from gas phase diffusion to solid-state diffusion in 16-hr, 1093°C NaBr packs and resulted in a coating similar in weight, thickness, and microstructure to those formed in NaCl-activated packs.
6. Regardless of the rate-controlling step, the kinetics of coating formation were near parabolic.
7. The activation energy for coating formation controlled by solid-state diffusion was 88 ± 13 kcal/mole on IN-100.
8. Similar coating microstructures and weight gains were obtained for each halogen regardless of whether its source was a sodium or ammonium salt. Coating microstructures bore greatest resemblance to "low-activity" pack coatings with some features peculiar to "high-activity" pack coatings apparent in coatings applied for longer times or at higher temperatures.

Manuscript submitted Dec. 10, 1973; revised manuscript received March 15, 1974. This was Paper 84 presented at the Boston, Massachusetts, Meeting of the Society, Oct. 7-11, 1973.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1975 JOURNAL. All discussions for the June 1975 Discussion Section should be submitted by Feb. 1, 1975.

APPENDIX A

Thermodynamics

Calculation of bulk pack composition at equilibrium was accomplished with the aid of CEC 71, a computer program by Gordon and McBride described in NASA SP-273 (14). The thermodynamic data for the program were taken from the JANAF tables (15). Data for NaI(g), which were not available in the JANAF tables, were computed from spectrochemical data by B. J. McBride, Lewis Research Center (private communication). Pack compositions prior to establishment of equilibrium were computed from the pack starting materials.

To illustrate the calculation, the outline of an approximate hand calculation method for sodium halide-activated packs follows:

1. Chemical reactions

$$3NaX(l) + Al(l) = AlX_3(g) + 3Na(g) \quad [A\text{-}A\text{-}1]$$

$$Al(l) + 2AlX_3(g) = 3AlX_2(g) \quad [A\text{-}A\text{-}2]$$

$$Al(l) + AlX_2(g) = 2AlX(g) \quad [A\text{-}A\text{-}3]$$

$$Na(g) + X(g) = NaX(l) \quad [A\text{-}A\text{-}4]$$

2. Equations

a. Sodium balance

$$M_{NaX(g)} + M_{Na(g)} + M_{NaX(l)} = M^{o}_{NaX(s)} \quad [A\text{-}A\text{-}5]$$

b. Halogen balance

$$M_{X(g)} + M_{NaX(g)} + M_{NaX(l)} + 3M_{AlX3(g)} + 2M_{AlX2(g)} + M_{AlX(g)} = M^{o}_{NaX(s)} \quad [A\text{-}A\text{-}6]$$

c. Equilibrium, Eq. [A-A-1]

$$K_3 = P^3_{Na}P_{AlX_3} \quad [A\text{-}A\text{-}7]$$

Note that K_3 corresponds to AlX_3.

d. Equilibrium, Eq. [A-A-2]

$$K_2 = \frac{P_{AlX_2}{}^3}{P_{AlX_3}{}^2} \quad [A\text{-}A\text{-}8]$$

e. Equilibrium, Eq. [A-A-3]

$$K_1 = \frac{P_{AlX}{}^2}{P_{AlX_2}} \quad [A\text{-}A\text{-}9]$$

Note that K_1 corresponds to AlX.

f. Equilibrium, Eq. [A-A-4]

$$K_4 = \frac{1}{P_{Na}P_X} \quad [A\text{-}A\text{-}10]$$

Elimination of $M^o_{NaX(c)}$ between Eq. [A-A-5] and [A-A-6] permits the resulting equation to be rewritten in terms of pressures. This leaves five equations in five unknowns. The solution was performed for NaF and NaCl activators. The results agreed with the computer program to within 20% for the former and 3% for the latter. The difference was primarily due to exclusion of minor species in the hand calculation. Results of the computer solutions are listed in Table II. In one case, the NaF-activated pack, the presence of Al_2O_3 was included in the machine calculations. The species present at equilibrium were Al(l), Al, AlF, AlF_2, AlF_3, AlO, AlOF, Al_2F_6, Al_2O, Al_2O_2, Al_2O_3(s) ,Ar, F, Na, NaF(l), NaF, NaO Na_2, and Na_2F_2. No significance difference in the partial pressures of F, AlF, AlF_2, and AlF_3 were noted when the results were compared with the calculation made with Al_2O_3 omitted. Thus Al_2O_3 was omitted from all other calculations. One shortcoming of the analysis of the NaF-activated pack should be noted: cryolite formation was not considered. Since the cryolite melt is extensively dissociated (18) the impact of cryolite formation on this analysis is considered small.

APPENDIX B

Kinetics

Instantaneous fluxes of gaseous species from the bulk pack to the substrate surface and vice versa were computed for 1 atm total pressure and a surface aluminum activity of 1×10^{-2}. The results are summarized in Table IV. Several checks on diffusion conditions were made prior to performing the calculation. First, it was established that diffusion occurs in the viscous flow regime. For molecular diffusion to occur the pack particle size would have to be reduced from about 100μ to about 0.1μ. Second, it was established that interchange between argon and hydrogen occurs very rapidly in the NH_4F-activated pack and therefore diffusivities were computed based on argon as the major constituent. The computation was performed for equilibrium conditions after dilution by 9.8 moles of argon in NH_4Cl,Br- and I-activated packs and pseudo-equilibrium conditions in NH_4F-activated packs. Diffusivities were estimated from the Gilliland equation (16)

$$D = \frac{0.0043\left[T^3\left(\frac{1}{m_a}+\frac{1}{m_b}\right)\right]^{1/2}}{P(V^{1/3}{}_a + V^{1/3}{}_b)^2} \quad [A\text{-}B\text{-}1]$$

Molar volumes at the normal boiling point were computed from data in the literature (17) and from an estimated value of 18 cm^3/g-atom for aluminum.

In making the instantaneous flux calculations the roles of $Na_i(g)$ and NaX in sodium halide-activated packs and of HX(g) and $H_2(g)$ in NH_4X-activated packs were included. Solution of this problem involving as many as ten simultaneous equations was accomplished on a digital computer. The instantaneous flux calculation in outline form for a simplified case for NaX-activated packs wherein the roles of $Na_i(g)$ and NaX are neglected follows:

1. Chemical reactions

a. Bulk pack

$$Al(l) + X(g) = AlX_1(g) \quad [A\text{-}B\text{-}2]$$

$$Al(l) + 2X(g) = AlX_2(g) \quad [A\text{-}B\text{-}3]$$

$$Al(l) + 3X(g) = AlX_3(g) \quad [A\text{-}B\text{-}4]$$

b. Surface

Substitute Al (Al in NiAl) for Al(l) in Eq. [A-B-2], [A-B-3], and [A-B-4].

2. Equilibrium equations

a. Equation [A-B-2]

$$K_1 = \frac{P_{X(g)}a_{Al}}{P_{AlX_1(g)}} = \frac{P_4 a}{P_1} \quad [A\text{-}B\text{-}5]$$

b. Equation [A-B-3]

$$K_2 = \frac{P^2{}_{X(g)}a_{Al}}{P_{AlX_2(g)}} = \frac{P^2{}_4 a}{P_2} \quad [A\text{-}B\text{-}6]$$

c. Equation [A-B-4]

$$K_3 = \frac{P^3{}_{X(g)}a_{Al}}{P_{AlX_3(g)}} = \frac{P^2{}_4 a}{P_3} \quad [A\text{-}B\text{-}7]$$

For reactions in the bulk pack the aluminum activity is set equal to $P_{Al(g)}/P_{Al(l)} = 1$. For reactions at the surface, aluminum activity was set at 1×10^{-2} and the pressures are distinguished by primes.

3. Instantaneous fluxes

a. Aluminum to the surface

$$\frac{N_{Al}}{A} = \frac{D_1}{RT}\frac{(P_1 - P'_1)}{d} + \frac{D_2}{RT}\frac{(P_2 - P'_2)}{d} + \frac{D_3}{RT}\frac{(P_3 - P'_3)}{d} \quad [A\text{-}B\text{-}8]$$

The contribution of Al(g) diffusion to the net aluminum flux is negligible.

b. Halogen balance at the surface

$$0 = D_1(P_1 - P'_1) + 2D_2(P_2 - P'_2) + 3D_3(P_3 - P'_3) + D_4(P_4 - P'_4) \quad [A\text{-}B\text{-}9]$$

The unknowns are P'_1, P'_2, P'_3, P'_4, N_{Al}/A, and d. Multiplication of both sides of Eq. [A-B-8] by d gives the combined variable $N_{Al}d/A$ and leaves five

equations and five unknowns. Therefore, each pressure and the instantaneous fluxes of all species can be estimated. P'_i and the instantaneous fluxes are listed in Table IV. Instantaneous fluxes were found to be relatively insensitive to changes in surface aluminum activity. A tenfold decrease in aluminum activity increases the net instantaneous aluminum flux by a factor of 2.

SYMBOLS

A	area, cm^2
a	activity of aluminum at the coating surface, dimensionless
D_i	diffusivity of the ith species, cm^2/sec
d	diffusion distance, cm
K_j	equilibrium constant for the jth reaction
k, k'	rate constant
l	path length correction factor
M	moles
m_a, m_b	molecular weight, grams/mole
N_{Al}	aluminum flow, moles/sec at any instant
n, n'	rate equation exponent
P_i	partial pressure of the ith species in the bulk pack, atm
P'_i	partial pressure of the ith species at the coating surface, atm
Q	activation energy, kcal/mole
R	gas constant, cm^3-atm/°K-mole or cal/°K-mole
T	absolute temperature, °K
t	time, sec
V_a, V_b	molar volume at the normal boiling point, cm^3/mole
w	coating weight, mg/cm^2
X	halogen atom, F, Cl, Br, or I
x	coating thickness, cm
ϵ	pack porosity
ρ	pack aluminum concentration, mg/cm^3

Chemomechanical Polishing of CdS

Vincent Y. Pickhardt and Donald L. Smith

Perkin-Elmer Corporation, Norwalk, Connecticut 06856

The publication costs of this article have been assisted by the Perkin-Elmer Corporation.

ABSTRACT

The chemomechanical polishing of the "A" or cadmium-rich face of cadmium sulfide has been accomplished. The etchant contained 90 mliters nitric acid, 300 mliters precipitated silica, and 10g aluminum chloride per 1000 mliters water. Best results were obtained using a poromeric polishing disk with 370 g/cm^2 work pressure at 240 rpm polishing wheel speed. Surfaces were completely featureless when viewed by Nomarski and Michelson interference microscopy at 155 and 400×, and gave good LEED patterns after brief heat-cleaning under vacuum.

CdS is a desirable substrate for the epitaxial growth of semiconductor thin films for electrooptic devices. For such applications, the crystals must be flat, highly polished, and damage-free. Many etchants have been suggested in previous articles (1-3), but none of them produces all of these surface requirements simultaneously. We describe below a procedure utilizing both mechanical and chemical polishing which produces excellent results on the (0001A) face of CdS.

Experimental Procedure

Undoped, single-crystal CdS (Eagle-Picher ultrahigh purity grade) was x-ray oriented to within 2° of the (0001) plane and sawn by a continuous loop wire saw into 8 x 10 x 2 mm wafers. The "A" face was differentiated from the "B" face by a 60 sec etch in 50%[1] HCl (1). The oriented crystals were mounted on a 3 cm diameter titanium polishing block with the "A" face exposed. A schematic of the equipment is shown in Fig. 1. The block and its closely fitting dressing ring are held by rollers about half way out to the edge of the 10 in. diameter motor-driven polishing pad, and the block and ring rotate about their axis due to friction with the pad, providing compound motion.

The wafers were first mechanically polished on a 3μ silicon carbide-impregnated polishing disk with water as lubricant, to remove all surface and subsurface wire saw damage. Both polishing block and dressing ring were then cleaned in a concentrated detergent to remove any particle contamination. Final chemical polishing was completed on the same apparatus. The etchant which produced best results contained 90 mliter HNO_3, 300 mliter precipitated silica, 10g $AlCl_3$ (anhydrous powder), and 1 mliter concentrated detergent as an anticoagulant per 1000 mliters deionized

Key words: chemomechanical polishing, cadmium sulfide, polishing.

[1] All concentrations of HCl and HNO_3 are expressed as a volume per cent of the standard 38% and 70% assay solutions respectively.

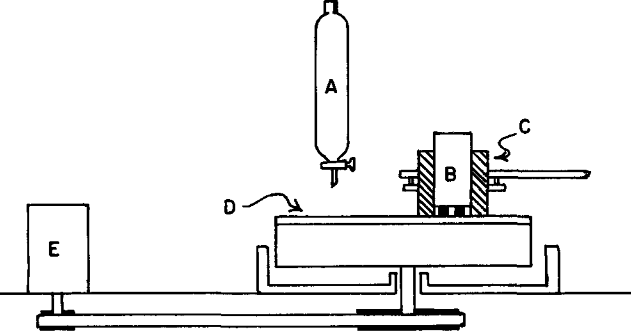

Fig. 1. Schematic of chemomechanical polishing equipment: A, separating funnel; B, polishing block containing crystals; C, dressing ring; D, polishing pad; E, motor drive.

water. This was fed to the polishing pad immediately after mixing at approximately 25 mliters/min. The crystals were weighted to 370 g/cm². Best results were obtained using a Politex-Pix poromeric polishing pad at a speed of 240 rpm.

Results

After approximately 30 min of polishing with the above etchant, the crystal surfaces showed a flat, highly polished, "mirror-like" finish. Surfaces were completely featureless when viewed by Nomarski microscopy at 155 and 400×. When viewed by Michelson interference microscopy at 370× the crystals showed no defects and showed flatness to better than 300Å (resolution limit) over the 0.3 mm field.

Fig. 2. "B" face of polished CdS wres viewed by Nomarski microscopy at 400× magnification. The "A" face is not shown because it is featureless under the same conditions of observation.

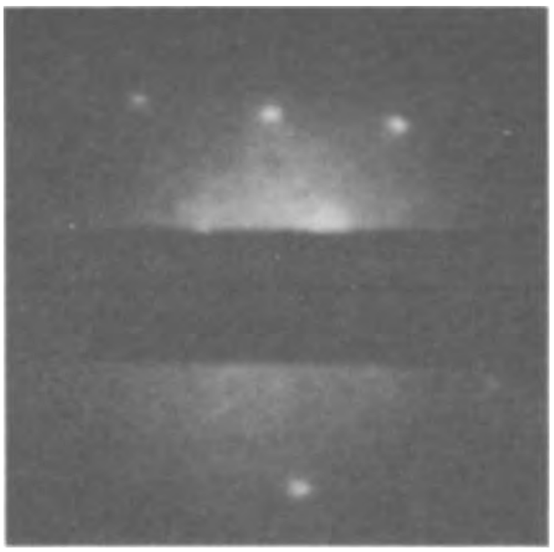

Fig. 3. LEED pattern of polished CdS after 450° flash; 92 eV

Table I. Auger spectra of CdS(0001A)

Element	Nominal eV	Auger peak strengths, μV Before flash	After flash
S	152	78	109
Cl	181	1.0	0.4
C	272 }	3.6	2.4
Cd	277, 283 }		
Cd	321	2.1	2.7
Cd	376, 382	16.6	19.2
O	510	<0.1	<0.1

Of utmost importance is removal of all subsurface damage from sawing and mechanical polishing operations. Although a polishing time of 30 min is suggested, in some instances this must be lengthened to remove preferential etching caused by leftover subsurface damage. Extreme care must be taken while handling crystals so as not to introduce damage between operations. The etchant composition is also important. An increase in acid concentration produces large etch pits, a decrease in concentration produces surface "scratching." Deletion of $AlCl_3$ produces preferential etching and surface "scratching." Increasing the silica content leads to the same pits encountered with higher acid concentrations, and deletion produces an orange-peel effect across the crystal face.

On the "B" face, the same etchant produces an orange-peel texture and "scratches." An etchant consisting of 150 mliters HCl and 5g $AlCl_3$ per 1000 mliters H_2O, on a Pellon Pan-W polishing pad produces somewhat better results. Shallow scratches were apparent when the surface was viewed by Nomarski microscopy at 400× magnification although no preferential etching or orange-peel effect was observable (see Fig. 2).

Polished "A"-surfaces were also examined by low-energy electron diffraction (LEED) and Auger spectroscopy at 10^{-9} Torr using a hemispherical grid apparatus. A 1-min flash to 450°C was sufficient to generate the sharp (1 x 1) LEED pattern shown in Fig. 3, whereas ion bombardment is generally required to generate any LEED pattern on CdS (4) and other semiconductors. The diffraction pattern was observable down to 20 eV, below which surface charging became a problem, and up to 180 eV, above which the diffraction features faded into the diffuse background. Table I compares Auger spectra taken before and after the 450°C flash. The only contaminants detected were C and Cl. Both of these were reduced considerably, though not completely eliminated, by the 450°C flash, with accompanying increases in the Cd and S signals. Based on the quality of the LEED pattern and on relative Auger peak strengths, residual contamination is estimated to be about 1/10 monolayer.

Hall Effect, Schottky Barrier Capacitance, and Photoluminescence Spectra Measurements for GaAs Epitaxial Layer and Their Correlation

T. Katoda and T. Sugano

Department of Electronic Engineering, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo, Japan

The publication costs of this article have been assisted by The University of Tokyo.

ABSTRACT

The main causes of a decrease in the electron mobility of GaAs epitaxial layers grown by the vapor phase deposition system are confirmed to be due to the compensating acceptors and the space charge regions, both of which are associated with copper contamination, from a discussion on the correlation among the results of measurements (listed in the title) on the same samples. Deep traps do not play an important role in determining electron mobility because of their scattering cross section as small as 1.04×10^{-22} cm^2.

GaAs space charge regions have been suggested as one of the "mobility killers" (1-4). On the other hand, deep traps in the GaAs have been detected by measurement of Schottky barrier capacitance (5-8) or by photoluminescence measurement (9-11). However the correlation between them has not been discussed and consequently the species which form space charge regions or deep traps have not been identified.

In this paper the results of independent measurements such as the Hall effect, Schottky barrier capacitance, and photoluminescence measurements on the same samples are shown, and the correlation among them and with the growth conditions are discussed. Figure 1 shows the measurements which were conducted in this work, the quantities which can be obtained from these measurements, and the correlation among them which is subsequently discussed in this paper. Here the relation of the compensation ratio of impurities, and densities of space charge regions and deep traps to contamination by copper is confirmed by independent measurements. The electron mobility in GaAs in the presence of deep traps is consistently explained from the correlation among electron mobility, density of deep traps, and their scattering cross section obtained by measuring the Schottky barrier capacitance.

Experimental

Sample preparation.—N-type GaAs layers were epitaxially grown on semi-insulating Cr-doped GaAs substrates by the Ga-$AsCl_3$-H_2 reaction system as shown in Fig. 2.

The purity of Ga and $AsCl_3$ were both 99.99999%. Hydrogen was purified by a Pd diffuser, all components of which were made of stainless steel to avoid contamination by copper. The reaction tubes used were high-purity, fused quartz tubes (class SSGH, Toshiba Denko) aged in pure hydrogen atmosphere at 1000°C before use. The substrates were mechanically polished and chemically etched by a mixture solution with H_2O_2:1, H_2O:1, and H_2SO_4:3 before deposition. Growth parameters of the samples are listed in Table I.

Hall measurement.—Electron mobility and density, and their temperature dependences, were measured by the van der Pauw method (12). Ohmic contacts were made by alloying the mixture of In and Sn to the epitaxial layer. Their ohmic property was checked from

room temperature to the liquid nitrogen temperature and confirmed to be good.

Measurement of frequency dependence of Schottky barrier capacitance.—To determine the relation of frequency dependence of capacitance of Schottky barrier diodes on electron mobility in the epitaxial layer, Schottky diodes were fabricated on the same epitaxial layers as those used in mobility measurement. The configuration is shown in Fig. 3. Ohmic contacts were made on the side edges and the top surface of the epitaxial layer.

Measurement of photoluminescence.—Photoluminescence spectra were measured for some of the samples whose electron mobility and density as well as Schottky barrier capacitance were measured. Photoluminescence spectra were also measured for GaAs epitaxial layers grown in a fused quartz tube with and without aging in purified hydrogen. Measurements were conducted at room temperature, the liquid nitrogen temperature, and about 10°K. The excitation source was He-Ne laser and the detector was a RCA 7102 photomultiplier.

Results of Hall and Schottky Barrier Capacitance Measurements

Experimental results of temperature dependence of electron mobility.—Some of the experimental results on electron mobility *vs.* temperature characteristics are shown in Fig. 4. Hereinafter those curves are classified into four groups for the convenience of discussion.

In Fig. 4(a), the curves belonging to groups A and B are shown. The former is characterized by small magnitude and small temperature dependence in a range near room temperature. The carrier density of those samples at room temperature is as high as 6.40×10^{15} cm^{-3} and electron mobility is as small as 3170 cm²/V·sec (sample No. 233).

Electron mobility of the samples belonging to group B in Fig. 4(a) is fairly large: for example, 6000 cm²/V·sec at room temperature. But at the liquid nitrogen temperature, electron mobility is not increased as much as expected from the theory of polar optical mode scattering and ionized impurity scattering.

Electron mobility of the samples belonging to group C reveals a large dependence on temperature, although the magnitude is as small as 1800 cm²/V·sec at room temperature (sample No. 206); while that of the samples belonging to group D likewise displays a large dependence on temperature, although the magnitude is as large as 7200 cm²/V·sec at room temperature (sample No. 204).

Theoretical consideration on temperature dependence of electron mobility.—Theoretical curves of temperature dependence of electron mobility are shown in Fig. 4(a) and 4(b) by solid-line curves. Each curve is calculated to be fitted to the curves in each group by assuming the particular magnitude of contributions caused by various scattering mechanisms. The scattering mechanisms, taken into account in this calcula-

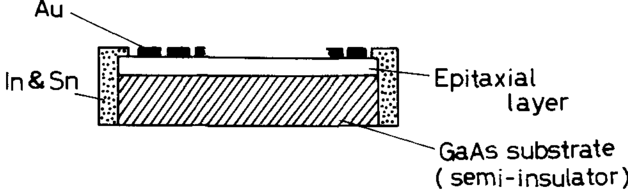

Fig. 3. Cross section of Schottky barrier diodes. The In and Sn alloy forms an ohmic contact and the Au dots form the Schottky barrier with a GaAs epitaxial layer.

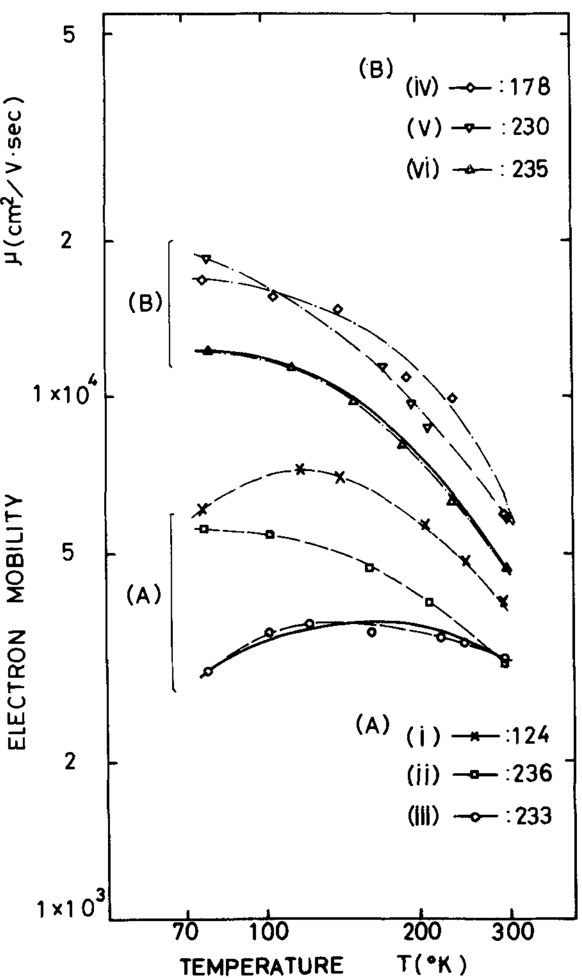

Fig. 4(a). Temperature dependence of electron mobility (I). In groups A and B, scattering by ionized impurities and space charge regions are dominant.

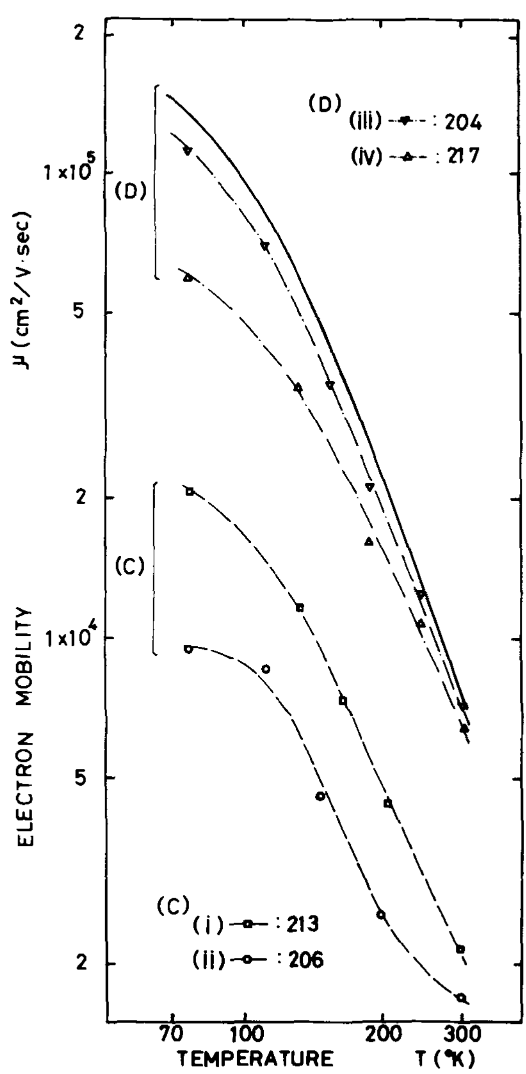

Fig. 4(b). Temperature dependence of electron mobility (II). In group C, scattering by ionized impurities, whose density changes largely with temperature, is dominant; in group D, scattering by polar optical phonon is dominant.

tion, are as follows:

(*i*) *Polar optical mode scattering.*— Electron mobility determined by this mechanism, μ_{PO}, is given by

$$\mu_{PO} = 5.31 \times 10^3 \cdot x(z)(e^z - 1)z^{-1/2} \quad (\text{cm}^2/\text{V}\cdot\text{sec}) \qquad [1]$$

where $z = \theta/T$, θ is the longitudinal optical phonon temperature (416°K for GaAs), and function $x(z)$ calculated by Petritz and Scanlon (13) is used.

(*ii*) *Piezoelectric scattering.*—Electron mobility determined by piezoelectric scattering, μ_{PE}, derived by Van Daal (14) and Hutson (15), is given by

$$\mu_{PE} = 3.16 \times 10^5 (300/T)^{1/2} \quad (\text{cm}^2/\text{V}\cdot\text{sec}) \qquad [2]$$

(*iii*) *Deformation potential scattering.*—The following expression derived by Bardeen and Shockley (16) is used for electron mobility due to this mechanism, μ_{DP}

$$\mu_{DP} = 5.5 \times 10^8 T^{-3/2} \quad (\text{cm}^2/\text{V}\cdot\text{sec}) \qquad [3]$$

(*iv*) *Ionized impurity scattering.*—The result according to the Brooks-Herring theory (17) is used for electron mobility by this scattering, μ_I

$$\mu_I = 1.87 \times 10^8 \cdot T^{-3/2}/N_I \{\ln(1.17 \times 10^4 \cdot T^2/n') - 1\} \quad (\text{cm}^2/\text{V}\cdot\text{sec}) \qquad [4]$$

$$n' = n + (N_D - N_A - n)(n + N_A)/N_D$$

where n is the electron density, N_D is the shallow donor density, N_A is the acceptor density, and N_I is the ionized impurity density.

(*v*) *Space charge scattering.*—The expression of the electron mobility, μ_{SC}, derived by Weisberg (1, 18)

$$\mu_{SC} = 2.4 \times 10^9/NsQ(T \cdot m/m_0)^{1/2} \quad (\text{cm}^2/\text{V}\cdot\text{sec}) \qquad [5]$$

is used. In the expression, m_0 is the mass of a free electron, m is the effective mass of an electron, Ns is the density of space charge regions, and Q is the scattering cross section.

For the sake of simplicity, the relation

$$1/\mu = \sum_i (1/\mu_i) \qquad [6]$$

is assumed, where μ is electron mobility and i denotes the ith kind of scattering mechanisms.

Discussion

Temperature dependence of electron mobility.—Experimental curves of electron mobility *vs.* temperature characteristics can be explained as follows:

Groups A and B.—Two curves calculated by assuming that piezoelectric scattering, deformation scattering, scattering by polar optical phonon, ionized impurity, and space charge regions are predominant as shown in Fig. 4(a).

Equation [6] is a poor approximation when contributions caused by more than two types of scattering are comparable in magnitude, but good agreement between the calculated and the experimental curves still can be obtained if the ionized impurity density at 77°K and the values of the product of the space charge region density and the scattering cross section at 300°K are assumed for each curve in Fig. 4(a), as listed in Table II.

It may be concluded that scattering by ionized impurities and the space charge regions are playing an important role in determining electron mobility in the case of groups A and B.

Groups C and D.—The solid-line curve in Fig. 4(b) is calculated by considering polar optical phonon scattering, piezoelectric scattering, deformation potential scattering, and ionized impurity scattering. Both scattering by space charge regions and by neutral impurities has been neglected.

Table II. Carrier density, donor density, acceptor density, compensation ratio, and space charge region of the samples belonging to groups A and B

Sample No.	Carrier density (77°K) : n (cm^{-3})	Donor density : N_{D^+} (cm^{-3})	Acceptor density : N_{A^-} (cm^{-3})	Compensation ratio : $(N_{D^+} + N_{A^-})/n$	Space charge region : NsQ
233	5.80×10^{15}	4.66×10^{16}	4.08×10^{16}	15.0	8.87×10^4
236	1.38×10^{15}	1.23×10^{16}	1.09×10^{16}	16.8	1.07×10^5
124	6.75×10^{16}	$\sim 6.75 \times 10^{16}$	~ 0	~ 1.0	6.31×10^4
235	4.40×10^{16}	8.20×10^{16}	3.80×10^{15}	2.73	4.61×10^4
230	6.30×10^{15}	8.60×10^{15}	2.30×10^{15}	1.73	2.23×10^4
178	1.57×10^{15}	5.19×10^{15}	3.62×10^{15}	5.17	2.55×10^4

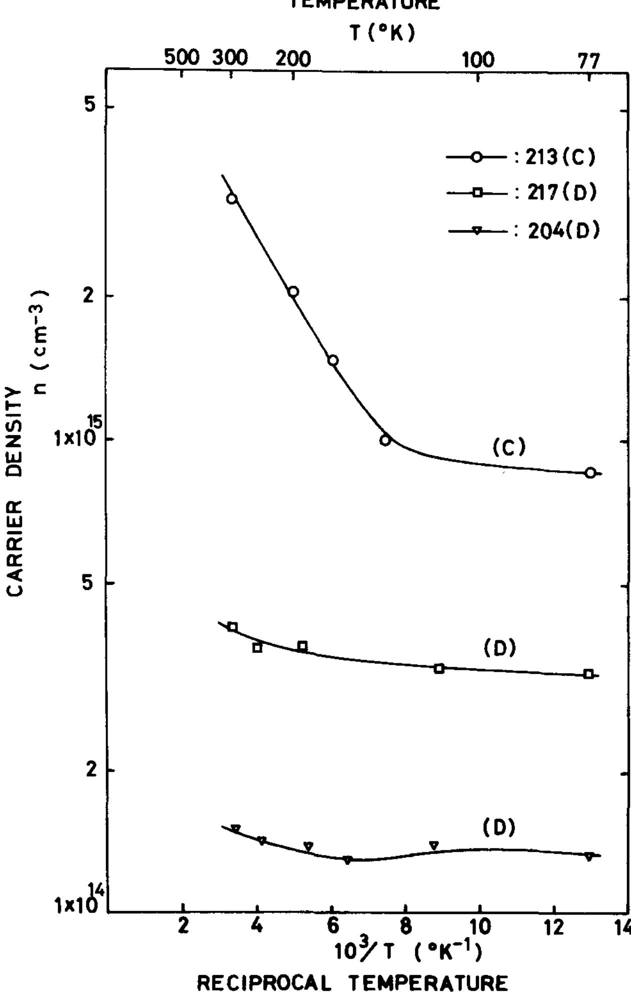

Fig. 5. Temperature dependence of carrier density of the samples classified into groups C and D in Fig. 4(b).

The density of the total impurity is assumed to be $N_I = 4.0 \times 10^{14}$ cm^{-3} at room temperature. Curve (iii) in Fig. 4(b) is for sample No. 204, whose carrier density is 1.5×10^{14} cm^{-3} at room temperature. A small disagreement of the calculated curve with the experimental result is found, however, since sample No. 204 is assumed to be slightly compensated and contains neutral impurities, and since the approximation of $1/\mu = \sum_i (1/\mu_i)$ is not necessarily valid for highly pure samples, such a small difference is reasonable. The temperature dependence of electron mobility in group C can be explained by considering the presence of impurities, as discussed in the next section.

Temperature dependence of electron density.—The temperature dependence of carrier density of the samples belonging to group C in Fig. 4(b), obtained by the Hall measurement, is plotted as shown in Fig. 5. For comparison, characteristics of the samples belonging to group D are shown in the figure. Carrier density of the samples belonging to groups A and B revealed a temperature dependence similar to those of the samples in group D. It is evident from the figure that the samples in group C show much larger temperature dependence of carrier density above 150°K than those in group D.

The values of activation energy obtained from these curves are listed in Table III, and that of the sample in group C is 5.0 ~ 5.5 times larger than those of the samples in group D.

The temperature dependence of the ionized impurity density corresponding to the electron mobility *vs.* temperature characteristic curve (i) in Fig. 4(b) (sample No. 213) is shown in Fig. 6. It is much larger than temperature dependence of the carrier density shown in

Table III. Activation energy of carrier density vs. temperature characteristics shown in Fig. 5. Sample No. 213 is classified into group C and samples No. 204 and 217 are classified into group D

Sample No.	Activation energy (eV)
204	4.88×10^{-3}
217	4.48×10^{-3}
213	2.46×10^{-2}

Fig. 5. This difference can be understood if the donor and acceptor levels in the forbidden gap are assumed to be as shown in Fig. 7. When the Fermi level crosses the donor level with an increase in temperature, and the acceptor level is located above the donor level, some of the donor and acceptor impurities are ionized at high temperatures while they are neutral at low temperatures. The former are positively charged and the latter are negatively charged. Then the change of the total ionized impurity (equal to the sum of ionized donors and ionized acceptors) is much larger than that of the carrier density (equal to the difference between the ionized donors and ionized acceptors).

The species which form such levels have not been clarified, however, the peak corresponding to the activation energy of the carrier density *vs.* the temperature characteristics of sample No. 213 is visible in the photoluminescence spectrum of the same sample, as shown in Fig. 8.

Experimental results of frequency dependence of Schottky barrier capacitance.—Figure 9 shows two examples of frequency *vs.* capacitance characteristics of

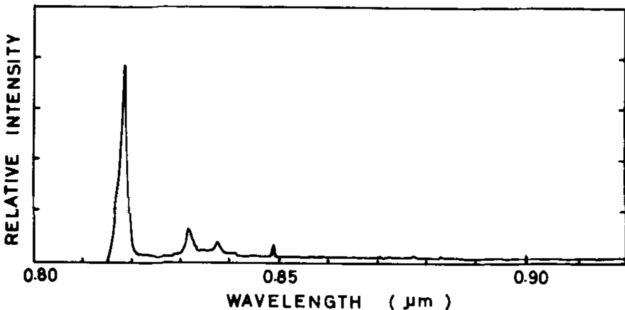

Fig. 8. Photoluminescence spectrum from sample No. 213 whose carrier density vs. temperature characteristics is shown in Fig. 5. The peak from 0.83 to 0.85 μm corresponds to its activation energy.

Schottky barrier diodes fabricated on epitaxial layers on semi-insulating GaAs substrate. The electron mobility *vs.* temperature characteristics of sample No. 233 in Fig. 9(a) is shown as curve (iii), and that of sample No. 230 is shown as curve (v) in Fig. 4(a). Those samples whose frequency *vs.* capacitance characteristics are shown in Fig. 9(b) correspond to the samples in Fig. 4(b). The capacitance of all samples except No. 217 reveals a large dependence on frequency.

Analysis according to the Hesse theory.—From these data, the relation $\Delta V/\Delta(1/C^2) - C$ is plotted, where V is voltage, C is capacitance, and Δ denotes the difference of measured quantities. The relation $dV/d(1/C^2) - C$ in the case of a Schottky barrier diode is given by Hesse (19) as

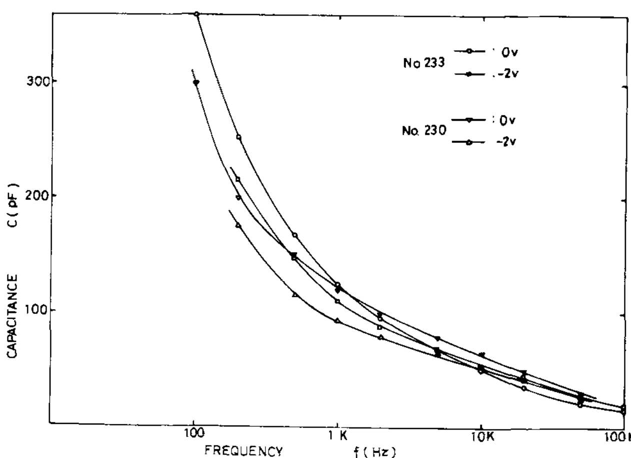

Fig. 9(a). Frequency dependence of a Schottky barrier capacitance (I) for the samples in groups A and B.

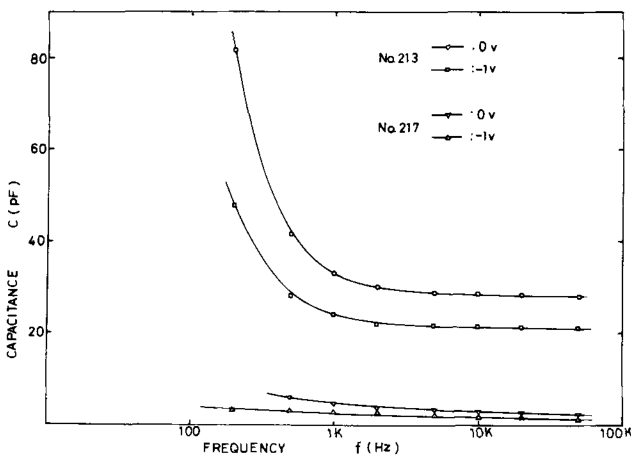

Fig. 9(b). Frequency dependence of a Schottky barrier capacitance (II) for the samples in groups C and D.

$$\frac{dV}{d(1/C^2)} = \frac{q(N_D + N_T)}{2\epsilon}\left[1 - \frac{C}{C_\infty} g(\omega)\right] \quad [7]$$

where N_D is the density of the shallow donor; N_T, the density of the deep donor; ω, the signal angular frequency at measurement; C_∞, the value of capacitance at infinite frequency; $g(\omega)$, the function indicating the frequency dependence of charging and discharging characteristics of deep donors; q, the electron charge; and ϵ, the dielectric constant.

Equation [7] indicates that the relation of $dV/d(1/C^2) - C$ is linear, and extrapolations to zero capacitance should converge at a point regardless of the measuring frequency, from which the value of $N_D + N_T$ is calculated.

Figure 10 shows examples of the plotting of $\Delta V/\Delta(1/C^2) - C$. Although the lines do not necessarily converge at a point for zero capacitance, the value of $N_D + N_T$ is approximately given as listed in Table IV. One of the reasons for this nonconvergence may be that Eq. [7] includes an effect of only a single level.

From the Hesse theory, the value of $E_F - E_T$, also can be obtained, where E_F is the Fermi level and E_T is the trap level. Table IV shows examples of $N_D + N_T$, $E_C - E_T$, and N_T/N_D. The value of $E_C - E_T$ is calculated by adding $E_C - E_F$ to $E_F - E_T$, where E_C is the bottom level of the conduction band. Their levels are 0.18, 0.28, and 0.54 eV from the conduction band edge. 0.18 eV is near the level of 0.20 eV, which has been attributed to an unidentified defect (20), and 0.54 eV is near the level of 0.56 eV due to the same defect (21) or the level of 0.55 eV made by copper. These results are likely to imply that those samples, which contain such deep traps, are contaminated by copper.

The charging and discharging time constant τ also can be approximately calculated from the following equation with Eq. [7]

$$g(\omega \to \infty) = 1 - \frac{1}{\omega\tau} \cdot \frac{N_D + N_T}{N_D} \quad [8]$$

The value of $dV/d(1/C^2)$ at 20 kHz was used as in the calculation for sample No. 230.

Analysis according to Zohta's theory.—Zohta (22) showed that the variation of $\Delta V/\Delta(1/C^2)$ with frequency can be expressed as

Table IV. Various values obtained by plotting the relation $\Delta V/\Delta(1/C^2) - C$

Sample No.	$N_D + N_T$ (cm^{-3})	N_D (cm^{-3})	N_T (cm^{-3})	N_T/N_D	$E_C - E_T$ (eV)
213	5.26×10^{16}	3.2×10^{15}	4.9×10^{16}	15	0.18
217	4.44×10^{14}	4.0×10^{14}	4.4×10^{13}	0.11	
230	3.63×10^{17}	1.1×10^{16}	3.5×10^{17}	32	0.28
233	1.55×10^{18}	4.7×10^{16}	1.5×10^{18}	32	0.54

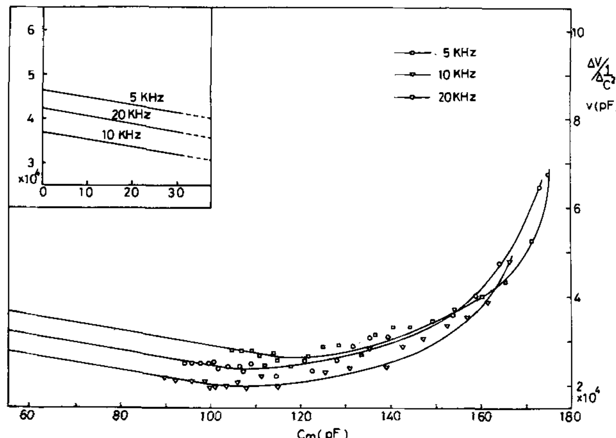

Fig. 10(a). Experimental values of $\Delta V/\Delta(1/C^2)$ as a function of C_m. $C_m = \sqrt{C(C + \Delta C)}$. (Sample No. 233.)

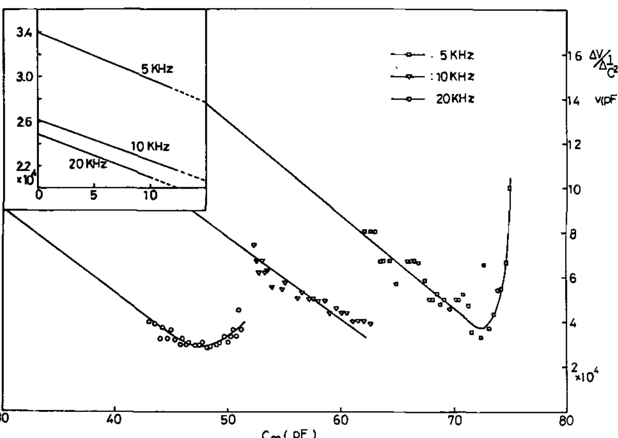

Fig. 10(b). Experimental values of $\Delta V/\Delta(1/C^2)$ as a function of C_m. $C_m = \sqrt{C(C + \Delta C)}$. (Sample No. 230.)

$$[\Delta V/\Delta(1/C^2)]_\omega = \frac{1}{2} q\epsilon A^2 [(N_D - N_A) + N_T(1 - C\lambda_0/\epsilon A)(1 - j\omega\tau)(1 + \omega^2\tau^2)^{-1}] \quad [9]$$

where N_D and N_A are the shallow donor and acceptor densities respectively, N_T is the density of deep traps, C is capacitance at angular frequency ω, A is the area of a Schottky barrier diode, τ is a charging and discharging time constant, and λ_0 is the distance from the plane where the energy band starts bending to the plane, where the bulk Fermi level equals the potential of the trap level. The solid-line curve in Fig. 11 shows an example of plotting the real part of Eq. [9] for sample No. 230. N_D, N_A, and N_T in Tables II and IV were used in the calculation. The broken line in Fig. 11 shows the relation of $\Delta V/\Delta(1/C^2)$ *vs.* the frequency obtained from the experiment. Considerably good agreement is evident between the theoretical (solid) curve and the experimental (broken) curve if $\tau = 5.76 \times 10^{-4}$ sec is assumed.

The value of $\tau = 5.76 \times 10^{-4}$ sec is in rather good agreement with 3.20×10^{-4} sec obtained from the Hesse method. A slight difference exists because the value of $\Delta V/\Delta(1/C^2)$ at 20 kHz was used as that for $\omega \to \infty$ in the analysis according to the Hesse theory; however, 20 kHz is too low to approximate $\omega \to \infty$. τ obtained to fit Eq. [9] to the experimental results is used later in calculating the scattering cross section of deep traps.

Correlation among the experimental results, compensation ratio, and space charge scattering.—Figure 12 shows the relation between the compensation ratio and the value of the product of the space charge region

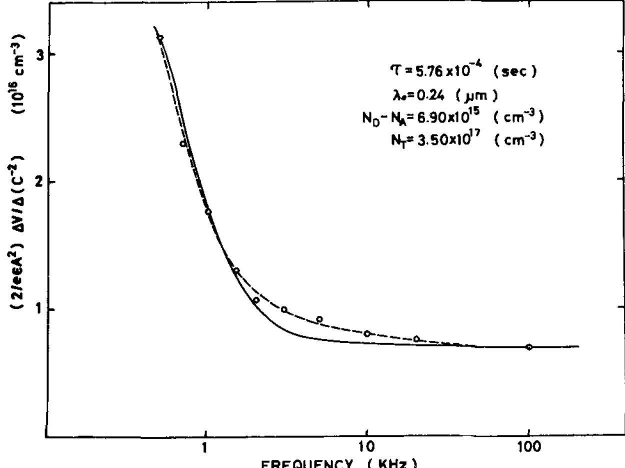

Fig. 11. Frequency dependence of $\Delta V/\Delta(C^{-2})$, where V is voltage and C capacitance; ○ represents an experimental value and the solid line is the theoretical one.

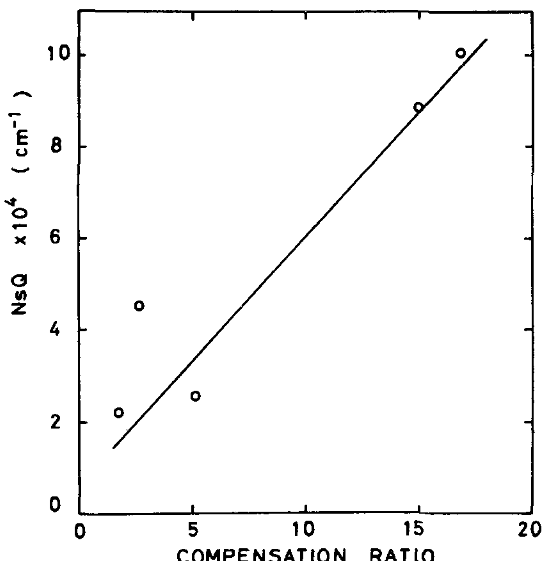

Fig. 12. Relation between the compensation ratio and the value of the product of density of the space charge region Ns and scattering cross section Q.

density and their scattering cross section listed in Table II for samples belonging to groups A and B. It is obvious that the value of NsQ increases with the compensation ratio (23). Correlation between the sources of compensating impurities and the space charge region has been discussed by Ikoma (2, 3) regarding heat-treated GaAs samples. He suggested that the space charge region is related to the inhomogeneity of the epitaxial layer.

The parameter γ which is defined by

$$\gamma = R_{AB.CD}/R_{BC.DA} \quad (R_{AB.CD} \geqq R_{BC.DA})$$

$$\text{or} \quad R_{BC.DA}/R_{AB.CD} \quad (R_{BC.DA} \geqq R_{AB.CD})$$

is a measurement of macroscopic inhomogeneity of the epitaxial layer, as Ikoma proposed. $R_{AB.CD}$ indicates resistance of the epitaxial layer; that is, it equals the voltage across contacts C and D divided by the current flowing between contacts A and B of the sample used in the van der Pauw method (12).

The γ-values for the samples discussed in this paper are listed in Table I; γ is generally small except for a few samples, which implies that the samples are macroscopically homogeneous. Thus, the source of the space charge region is not related to the macroscopic inhomogeneity of the epitaxial layer.

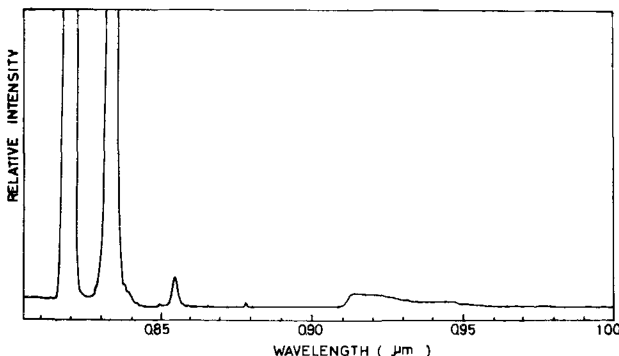

Fig. 13. Photoluminescence spectrum of sample No. 233

Correlation among density of space charge region, compensating acceptors, and photoluminescence spectra.—As already discussed, there is correlation between density of the space charge region and that of the compensating acceptors.

Figure 13 shows an example of the photoluminescence spectrum from GaAs epitaxial layer (sample No. 233) whose electronic properties were discussed in previous sections. As is well known, the peak in a range from 0.91 to 0.95 μm in Fig. 13 corresponds to a level caused by copper. Existence or nonexistence of this peak for each sample is listed in Table I. This peak frequently appears in the photoluminescence spectra of samples belonging to groups A and B, whose compensation ratio is rather large. This suggests that there is correlation among density of the space charge region, the compensation ratio, and contamination by copper.

Recalling that space charge region is a model (1) for a scattering center which has a large scattering cross section, the space charge region is suggested to be formed by clusters of impurities such as copper, or copper and defect complexes in the crystal. When most of the copper atoms in the epitaxial layer form clusters, the level they make may be shifted. This is an explanation of the reason why, in the spectrum of sample No. 219 which belongs to group B of mobility *vs.* temperature characteristics, the peak between 0.91 and 0.95 μm disappears.

Correlation between the level of deep traps measured by Schottky barrier capacitance method and photoluminescence spectra.—The level of deep traps 0.54 eV in sample No. 233 obtained by measuring the Schottky barrier capacitance *vs.* the frequency characteristics in Fig. 9(a) corresponds to existence of the peak between 0.91 and 0.95 μm due to the copper (9, 11) in Fig. 13.

Correlation among electron mobility, aging time of fused quartz tube in purified hydrogen, and photoluminescence spectra.—The mean value of the electron mobility in the GaAs epitaxial layer grown in the vapor phase system rises with the aging time of a quartz tube at high temperature such as 1000°C in purified hydrogen, as shown in Fig. 14.

The photoluminescence peak between 0.91 and 0.95 μm of GaAs epitaxial layers caused by copper atoms disappears after sufficient aging of a fused quartz tube. This implies that the main source of copper atoms, which are suggested to form space charge regions and compensate the donor impurities decreasing the electron mobility in GaAs epitaxial layer, is eliminated by aging of a fused quartz tube (24).

Cross section of deep traps.—The trap density of samples No. 230 and 233 are thirty times larger than that of the shallow donor impurity shown in Table IV, but these deep traps are electrically neutral at least at a low field. On the other hand, the mobility determined by neutral impurity scattering is derived as follows (25)

$$\mu_N = 8.36 \times 10^{19} \, (1/N_N) \quad (\mathrm{cm^2/V \cdot sec}) \qquad [10]$$

where N_N is the density of neutral impurity. Here neutral impurity implies the neutral fraction of shallow donors and shallow acceptors. If mobility is calculated by substituting deep donor density into N_N in Eq. [10], too small a value is obtained as electron mobility. Furthermore, electron mobility at low field can be explained without counting the effect of these deep donors. This implies that those deep traps have very small scattering cross sections, neither assuming a significant role in determining electron mobility nor corresponding to the space charge regions.

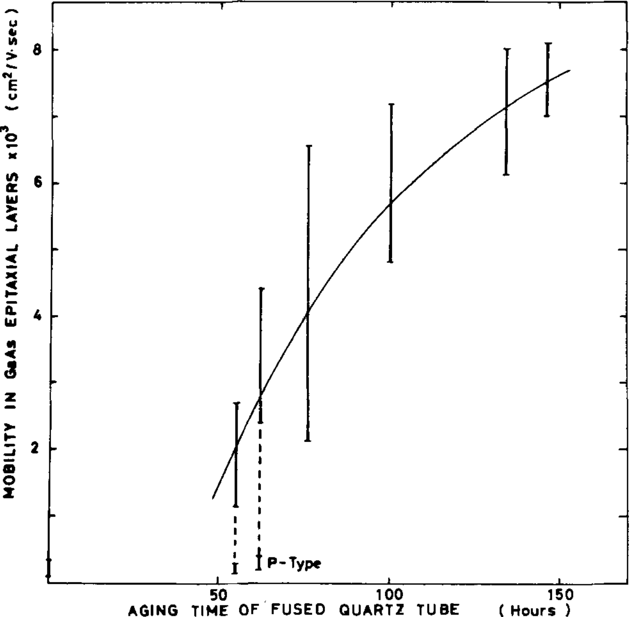

Fig. 14. Aging time of a fused quartz tube in purified hydrogen and electron mobility in GaAs epitaxial layer grown in that quartz tube.

The cross section σ of deep traps, on the other hand, can be calculated by using the charging and discharging time constant $\tau = 5.76 \times 10^{-4}$ sec for sample No. 230 obtained from the analysis according to the Zohta theory, following the relation

$$1/\tau = N_T \cdot v_{th} \cdot \sigma \qquad [11]$$

where N_T is the density of deep traps and v_{th} is the electron thermal velocity. If the value $N_T = 3.50 \times 10^{17}$ cm^{-3} listed in Table IV is substituted into Eq. [11], the small cross section $\sigma = 1.04 \times 10^{-22}$ cm^2 is obtained as expected from the relation between electron mobility and density of the deep traps.

Conclusions

The conclusions obtained from this work are as follows:

1. The Hall measurement of GaAs epitaxial layers grown in a vapor phase system revealed that compensating acceptors and space charge regions are two of the physical origins of decreasing electron mobility, and that both compensation and formation of the space charge region are related to contamination by copper. These results are supported by Schottky barrier capacitance measurement and by photoluminescence spectra of the same samples. In the Schottky barrier capacitance measurement deep traps whose energy level is identical to one made by copper were measured; in the photoluminescence measurement, a peak due to copper was observed.

2. Electron mobility of GaAs epitaxial layers grown in a fused quartz tube before and after aging in a hydrogen atmosphere suggested that compensating acceptors and space charge regions are mainly introduced from an unaged fused quartz tube. The photoluminescence peak attributed to copper appeared in the samples made in an unaged fused quartz tube, and disap-

peared in the samples made in an aged fused quartz tube.

3. The small scattering cross section of the deep traps obtained by Schottky barrier capacitance measurement ($\sigma = 1.04 \times 10^{-22}$ cm^2) implies that those deep traps assume no significant role in determining the electron mobility in GaAs. This result supports the theory that electron mobility in GaAs epitaxial layers can be explained without considering the effect of deep traps.

4. A photoluminescence peak, corresponding to the activation energy, was found, which determines the temperature dependences of electron density and mobility.

Acknowledgments

We express our deep appreciation to S. Akai and T. Suzuki, Research Laboratory, Sumitomo Electric Industries, for their supply of GaAs substrate and to H. Imai, Department of Electronic Engineering, the University of Tokyo, for his photoluminescence measurements in cooperation with our work.

This work has been supported by the Grant-in-Aid, for Scientific Research from the Ministry of Education, Japanese Government and also by the Electrical Communication Laboratory, Nippon Telegraph and Telephone Public Corporation. Their support is greatly appreciated.

Ge-Nitride, Ge-Oxide, and Ge-Oxynitride Formation by Ion Implantation

H. J. Stein

Sandia Laboratories, Albuquerque, New Mexico 87115

The publication costs of this article have been assisted by Sandia Laboratories.

ABSTRACT

The first formation of compounds of Ge by ion implantation into Ge has been achieved. Infrared absorption bands characteristic of four-fold coordinated GeO_2 and of Ge_3N_4 were observed after implantation with 3×10^{17}/cm^2 200 keV O_2^+ or N_2^+ respectively, into high-resistivity Ge substrates. The absorption band for Ge_3N_4 was also produced by 60 keV N^+ implantation into Ge, and the band intensity increased approximately as the square root of the number of implanted nitrogen atoms. Implantation with 2×10^{17} 200 keV NO^+/cm^2 produced an absorption band with a peak position between those for GeO_2 and Ge_3N_4, which is analogous to the band position for $Si_xO_yN_z$ relative to Si_3N_4 when $y \simeq z$. Sample temperatures were $\lesssim$ 200°C during implantation, and the samples were subsequently annealed to 500°C. Absorption band positions for the Ge compounds formed by ion implantation were observed to shift 20-30 cm^{-1} toward higher wave numbers upon annealing. This shift is attributed to densification by an annealing of implantation-produced expansion.

Thin insulating films are an essential part of planar semiconductor-device technology. Oxide films on silicon are readily formed by thermal oxidation of the Si substrate to produce chemically stable insulating films. To obtain stable insulating films on other semiconductors, however, it is usually necessary to form the films by evaporation, by sputtering, or by chemical reactions which do not incorporate substrate atoms.

Key words: ion implantation, compounds, germanium, infrared absorption, annealing.

Ion implantation provides another method to form thin films which incorporate substrate atoms, and a number of authors have demonstrated that silicon oxide and silicon nitride can be formed by the implantation of oxygen (1-4) or nitrogen (3-6), respectively, into silicon. There are no known previous

studies of germanium oxide (GeO_2) or germanium nitride (Ge_3N_4) formation by ion implantation, and relatively few studies of chemically formed GeO_2 or Ge_3N_4 films.

The usual methods for forming GeO_2 yield either an amorphous film or a hexagonal crystalline film (7), both of which are very chemically active. Therefore, thermally produced GeO_2 has not been useful in Ge device fabrication. It is of interest to determine if tetragonal GeO_2, which is more stable chemically than the hexagonal or amorphous GeO_2, will be produced by oxygen implantation into Ge. Previous studies (8) have shown that absorption due to Ge-O-Ge stretching for the fourfold coordination of Ge with oxygen in hexagonal or amorphous GeO_2 occurs at about 880 cm^{-1}, whereas the stretching mode for sixfold coordination of Ge with oxygen in tetragonal GeO_2 occurs at about 700 cm^{-1}. Thus, infrared absorption can be used to distinguish between hexagonal or amorphous and tetragonal GeO_2.

Nagai and Niimi (9) formed amorphous Ge_3N_4 in films by reacting $GeCl_4$ and NH_3 on Ge substrates held between 400° and 600°C, and Bagratishvili *et al.* (10) formed amorphous Ge_3N_4 films by reacting N_2H_4 and Ge. Such films have dielectric characteristics (10, 11) comparable to those for Si_3N_4, and they are characterized by a broad infrared absorption band with a substrate-temperature-dependent peak between 720 and 780 cm^1 (9, 10).

We report here on germanium nitride and germanium oxide formation by nitrogen and oxygen implantation into Ge. A 3×10^{17} 200 keV O_2^+/cm^2 implantation was used to form Ge oxide. The formation of Ge nitride was investigated by performing an implant with each of the following fluences: 10^{16} 60 keV N^+/cm^2, 10^{17} 60 keV N^+/cm^2, and 3×10^{17} 200 keV N_2^+/cm^2. In addition, an implantation with 2×10^{17} 200 keV NO^+/cm^2 was performed to investigate the formation of Ge oxynitride.

Experimental Details

Samples with optical faces of 1.27×0.63 cm and a thickness of $\sim$ 1 mm were cut from high resistivity n-type Ge. The sample faces were finished with successively finer (15, 6, and 1 μm) diamond polishing compounds. To further minimize surface damage on the optical faces they were rubbed lightly for 15 min on a POLITEX pad in a solution of 1 part NH_4OH to 700 parts of 30% H_2O_2. The composition of the solution was adjusted to obtain a pH of 7. Differential transmittance measurements were made at room temperature in a Beckman IR-12 spectrophotometer. Unimplanted Ge samples were matched in thickness and surface preparation to samples selected for implantation, and these unimplanted samples were used in the reference beam of the spectrophotometer for the differential measurements. During implantation the samples were clamped to an Al holder by a Ta coverplate with an aperture slightly smaller than the samples. Magnetically selected and electrostatically scanned ion beams between 5 and 20 $\mu A/cm^2$ were used for the implantation. Secondary electrons were electrostatically suppressed. Isochronal annealing of the implanted samples was performed for 20 min periods in 100°C increments within a nitrogen atmosphere tube furnace. Oxidation of Ge was observed upon annealing at 600°C, therefore the annealing study was terminated at 500°C.

Experimental Results

Differential transmittance spectra for Ge after implantation with O_2^+, NO^+, and N_2^+ are shown in Fig. 1. The results are arbitrarily displaced along the transmittance axis to provide separation among the spectra. Absorption bands at approximately 860, 750, and 685 cm^1 for O_2^+, NO^+, and N_2^+ implanted Ge are attributed to GeO_2, $Ge_xO_yN_z$ (germanium oxynitride), and Ge_3N_4, respectively. From calculated (12) ion ranges and ion profiles (peak range $\sim$ 2500Å, standard

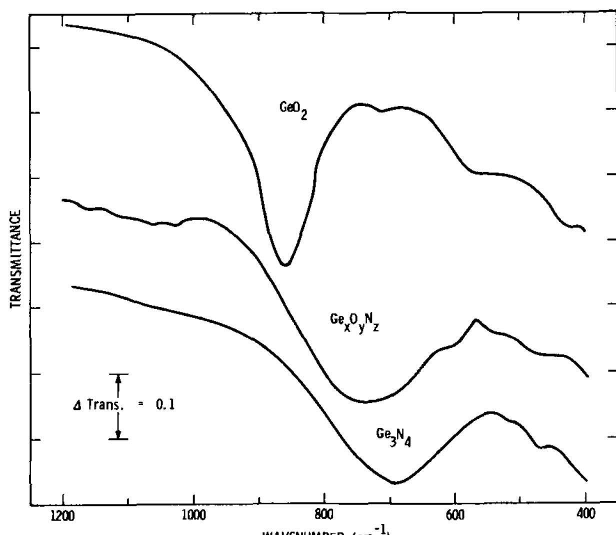

Fig. 1. Transmittance *vs.* wave number for GeO_2, Ge_3N_4, and $Ge_xO_yN_z$ films formed by 200 keV implantation of Ge with 3×10^{17} O_2^+/cm^2, 3×10^{17} N_2^+/cm^2, and 2×10^{17} NO^+/cm^2, respectively. Spectra are arbitrarily displaced along transmittance axis to provide clarity.

deviation $\sim$ 800Å) combined with measured ion fluences, implantations with 3×10^{17} cm^{-2} 200 keV N_2^+ or O_2^+ are expected to give volume concentrations of nitrogen or oxygen approximately equal to the volume concentration of Ge. Sputtering by the incident ions and a change of atomic composition during implantation will, however, tend to broaden the ion profile and reduce the volume concentration of the implanted ions. The number of nitrogen and oxygen atoms per unit area are obviously equal for the NO^+ implantation, and the volume concentration of the two atoms are expected to be approximately equal.

Figure 2 shows the transmittance for the samples of Fig. 1 after annealing at 500°C. The major absorption bands are observed to sharpen slightly and shift toward higher frequencies upon annealing. Small changes in weak absorption bands also occur upon annealing. Some of the annealing-induced changes only make existing bands more apparent. For example, a weak band near 600 cm^{-1} is readily distinguishable in the oxynitride after annealing to 500°C, but it is also present as a shoulder on the major absorption band before annealing. Figure 3 shows the major band posi-

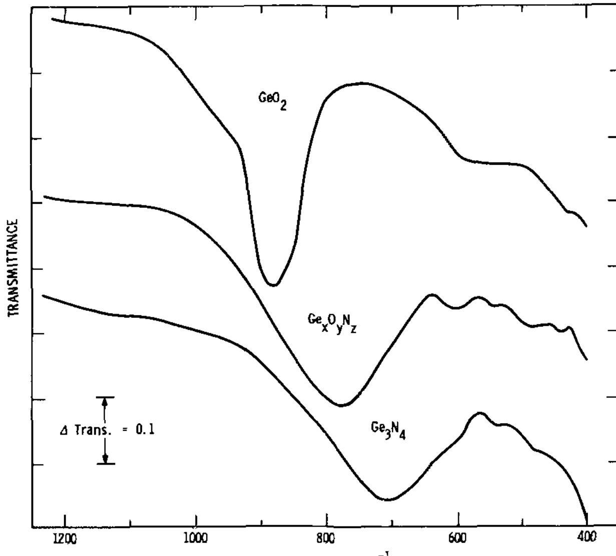

Fig. 2. Transmittance *vs.* wave number for the samples of Fig. 1 after annealing at 500°C.

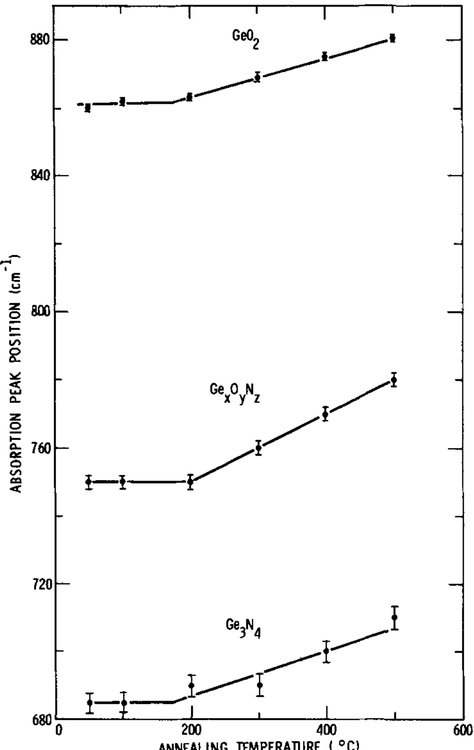

Fig. 3. Wave number positions for absorption peaks as a function of annealing temperature for the GeO_2, $Ge_xO_yN_z$, and Ge_3N_4 films formed by ion implantation.

tions for GeO_2, $Ge_xO_yN_z$, and Ge_3N_4 as a function of annealing temperature. The point of contact of the minimum in transmittance to a smoothed line parallel to the background transmittance was used to determine the peak position. Uncertainty in band position increases with band width. The onset of the 20-30 cm^{-1} upward frequency shift is shown to occur at an annealing temperature near 200°C. This indicates the effective temperature during implantation of the samples was < 200°C.

Figure 4 shows the germanium nitride bands produced by 10^{16} and 10^{17} 60 keV N^+/cm^2 compared to the band produced by 3×10^{17} 200 keV N_2^+/cm^2. Volume concentrations for nitrogen are ~ 2 and 20% of the Ge concentration within a standard deviation of the peak ion range following 10^{16} and 10^{17} 60 keV N^+/cm^2 implantations, respectively. In order to have a common annealing history for the samples, the results shown

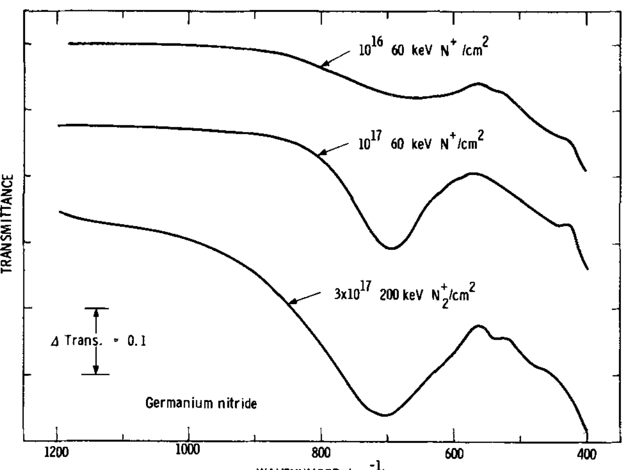

Fig. 4. Absorption bands produced by implantation of 10^{16} and 10^{17} 60 keV N^+/cm^2 into Ge compared to that produced by 3×10^{17} 200 keV N_2^+/cm^2. All samples were annealed at 500°C prior to the measurements.

in Fig. 4 are those measured after annealing at 500°C. The area in the absorption band increases approximately with the square root of the implanted nitrogen atoms, and there is a small shift of the absorption band toward higher frequency with increasing nitrogen fluence.

Discussion

The strong absorption band near 860 cm^{-1} and the weak band near 570 cm^{-1} shown in Fig. 1 for O_2^+ implanted Ge suggest fourfold coordinated GeO_2 formation by oxygen implantation into Ge. A second weak band near 700 cm^{-1} may indicate that a small fraction of the GeO_2 exists in the tetragonal phase. However, the 700 cm^{-1} band anneals out between 300° and 500°C and is missing in the GeO_2 results shown in Fig. 2. Therefore, the structural form for GeO_2 produced by implantation with 3×10^{17} O_2^+/cm^2 is essentially the same as that formed by thermal oxidation (7, 8). Higher fluence implants, which would increase the oxygen concentration relative to Ge, may favor formation of the tetragonal phase. The Ge-O-Ge stretching mode for dispersed-interstitial oxygen (13) in Ge also occurs near 860 cm^{-1} and has been observed in oxygen-implanted Ge (14). But, the solubility (13) of dispersed oxygen is $\approx 10^{18}$ cm^{-3}, and the width at half maximum for the dispersed oxygen band (13) is only 6 cm^{-1} compared with a more typical GeO_2 half-width of ≈ 90 cm^{-1} observed for the oxide band in the present experiment.

An upward frequency shift and sharpening of absorption bands upon annealing was previously shown for compounds formed in Si by ion implantation (4). Studies (15) on pyrolytically grown Si-oxide films have shown that the Si-O stretching bandwidth decreases and the band position shifts to higher frequencies on decrease of porosity in the films. Since implantation causes annealable expansion of Si (16) and presumably of Ge also, the slight sharpening and the upward frequency shift of the band positions for the Ge compounds formed by ion implantation is attributed to densification associated with the annealing of implantation-produced expansion.

The broad absorption band near 700 cm^{-1} following 200 keV N_2^+ implantation is interpreted as evidence for amorphous Ge_3N_4 formation. Absorption results in Fig. 4 indicate that Ge_3N_4 is also formed by 60 keV implantation with 10^{16} and 10^{17} N^+/cm^2. The magnitude of the absorption in the bands produced by nitrogen implantation increases approximately as the square root of the implanted nitrogen atoms, which suggests a bimolecular process for forming Ge_3N_4. This dependence may occur simply because the available uncompounded Ge is being depleted. However, a previous study showed that Ge_3N_2 was formed from the reaction of nitrogen with germane (GeH_4) (17), so that Ge-N precursors may also be involved in Ge_3N_4 formation by ion implantation. The absorption characteristics for Ge_3N_2 are not known. The dependence of the band position on implanted nitrogen atoms suggests that nitrogen deficiency in the implanted layer causes a lowering of the Ge-N vibrational frequencies.

Etch rates in HF solution are slow for both Si_3N_4 (18) and Ge_3N_4 (10). Therefore, Si oxynitrides ($Si_xO_yN_z$) with faster etch rates are sometimes used rather than Si_3N_4 in masking applications where the layer must be removed by an etching process. The infrared absorption band for $Si_xO_yN_z$ is shifted toward higher wave numbers relative to Si_3N_4 dependent on the values of y and z (18). The same effect is apparently occurring for $Ge_xO_yN_z$. The band position for $Ge_xO_yN_z$ relative to that for Ge_3N_4 is in accord with that for $Si_xO_yN_z$ relative to Si_3N_4 (18) when $y \simeq z$.

Conclusions

Ion-induced absorption bands show that Ge oxide, Ge nitride, and Ge oxynitride can be formed by ion implantation into Ge. These compounds are expected to exist in thin layers dependent on the ion ranges in

Ge. A shift in the absorption bands toward higher wave numbers upon annealing is typical of compounds formed in Si by ion implantation and is attributed to densification of the implanted layer by annealing of displacement-produced expansion.

The absorption band formed by oxygen implantation into Ge is characteristic of fourfold coordinated GeO_2, which is the usual form produced by thermal oxidation of Ge and is not a useful dielectric film for device applications. The absorption band formed by nitrogen implantation into Ge is in reasonable accord with that for amorphous Ge_3N_4, and previous studies of amorphous Ge_3N_4 have shown that it is a suitable dielectric material for device applications. Thus, ion implantation offers an alternate method for producing potentially useful dielectric films on Ge.

Implantation of NO^+ into Ge produces an oxynitride with a band position between that for the nitride and the oxide, completely analogous to absorption in $Si_xO_yN_z$ for approximately equal concentrations of oxygen and nitrogen.

Naval Research Laboratory, Washington, D. C. 20375

The publication costs of this article have been assisted by the Naval Research Laboratory.

ABSTRACT

Thin film systems based on platinum-tantalum-gold and tungsten-tantalum-gold have been investigated as metallization contacts for microwave power transistors. Platinum and tungsten deposited between layers of tantalum effectively stabilized the tantalum against grain boundary diffusion. The present investigation shows that Pt-Ta-Au and W-Ta-Au metallizations (*i*) are metallurgically stable, (*ii*) resist electrochemical corrosion, and (*iii*) are readily processed with existing technology.

In a previous investigation on the structure and thermal stability of rf sputtered Ta-Au films (1), the formation of TaAu above 450°C and the low-temperature grain boundary diffusion of gold resulted in an appreciable increase in sheet resistance. The growth of the TaAu layer followed a parabolic rate law and the low-temperature grain boundary diffusion occurred with an activation energy of 0.41 eV. Annealing the films up to 600°C also resulted in (*i*) particle growth with an activation energy of 0.5 eV for gold and 0.4 eV for tantalum, and (*ii*) reduction of thermal stresses and defect density in the films. Finally, the results of Ref. (1) indicate that when modified to prevent grain boundary diffusion, Ta-Au should be suitable for applications in devices which operate at high temperatures.

Key words: metallizations, sputtering, microwave transistors, reliability, thermal stability, thin films.

In the work reported here, platinum and tungsten layers have been sputter deposited between 1000Å tantalum layers in order to stabilize the tantalum against grain boundary diffusion at gold or tantalum grain boundaries. The resulting structures were then overlaid with 2000-5000Å of sputtered gold. We report the effects of annealing on the structure of Ta-Pt-Ta-Au and Ta-W-Ta-Au films deposited on polished (111) oriented quartz and (100) silicon. The films were in-

vestigated using x-ray and electron diffraction methods, electrical resistivity measurements, and optical and scanning electron microscopy. The interdiffusion between gold, tantalum, and platinum has been studied by Auger electron spectroscopy.

This investigation is part of a larger effort to increase the reliability of microwave power transistors. One approach has been the application of metallizations which can withstand the high temperatures encountered in these devices without undergoing degradation or failure due to alloying or to interdiffusion of silicon, silicon dioxide, and metal. Aluminum and gold are the two major types of metal contacts currently in use. The aluminum contact usually incorporates small amounts of silicon and/or copper for the purpose of minimizing interdiffusion, alloying, and electromigration. In some cases, a stable silicide (*i.e.*, platinum silicide) (3) is used with aluminum to isolate the aluminum from the silicon. The gold system generally incorporates a stable silicide as the low resistivity contact to silicon followed by a barrier layer (usually one or more refractory metals) and gold as the conductor. The barrier layer serves the purpose of isolating the gold from the silicon since that combination has a low melting point (eutectic temperature) of 377°C. The gold systems are potentially better from the standpoint of electromigration and high-temperature stability. Some of the metallization systems investigated in the literature include Mo-Au (4), W-Au (5), W:Ti-Au (6), Ti-Pt-Au (7), and more recently, Ta-Au (1) and Ta-Pt-Au (2).

Experimental

Film deposition.—The metal films used in this study were rf sputter deposited using an argon pressure of 5μ and an rf power of 200W. The substrates used were polished (111) oriented quartz plates, 3 cm in diameter. For studies of Au-Si interdiffusion, (100) silicon substrates were used. The substrates were etched in buffered HF followed by a 15 min rinse in hot deionized water. Tantalum (800-1200Å thickness) was deposited first onto the substrate, followed by a 300-500Å layer of platinum or tungsten, and followed by a second layer of 1000Å of tantalum. A 2000-5000Å layer of gold was deposited as the top layer. The diffusion barrier thickness was maintained constant at 2500Å. During deposition, the cathode to substrate distance was maintained at 7.5 cm. Thin film thermocouple substrate temperature measurements indicate that the steady-state temperature during sputtering was 100°C. In all cases of sputter deposition, the substrate holder was water cooled to prevent further temperature increases.

The deposited Ta-Pt-Ta-Au and Ta-W-Ta-Au specimens were annealed in vacuum at pressure less than 10^{-5} Torr. Tantalum tube furnaces with a 7 cm opening were used. The temperature variation was maintained at ± 5°C. The specimens reached temperature at a rate of 20°C/min. Isochronal annealing experiments were carried out by maintaining each specimen at temperature for 2400 sec. Isothermal experiments were carried out by annealing at a fixed temperature for up to 800 hr.

X-ray diffraction and film examination.—All x-ray data were obtained with a GE XRD-3 diffractometer using Ni filtered copper radiation as described previously (1). The calculation of stresses and strains in gold and tantalum was determined according to the method of Greenough (8). Each diffraction peak was scanned at 0.5°/min to determine the position of the peak. Three points which straddle the peak were then selected for intensity counting. The stress, after the necessary corrections was determined by the method described previously (1). Since the radiation penetrates the thin film and barrier layer, diffraction from the single-crystal substrate is always obtained. To eliminate overlapping, a method suggested by Walker (9) was used. The substrate was misoriented by changing 2θ at the Bragg angle. By misorienting the substrate, the substrate peaks fall to zero since the planes parallel to the front surface are off axis. Instrumental broadening corrections were used to correct for inaccuracies in measurement of the peak position. The total change in the lattice parameter can be due to residual strain, solid solution effects, or a combination of both (9). Solid solution effects were eliminated by the independent measure of the lattice parameter using a multiple exposure technique (9).

Optical and scanning electron microscopy were used to analyze specimens in which large changes in resistivity were observed. In addition, the behavior of the Ta-Pt-Ta-Au metallization scheme at temperatures up to 550°C was investigated by Auger electron spectroscopy (AES). Surface composition was measured by AES while simultaneously sputter etching the specimen. In this way, a profile of the in-depth composition variations of the thin film layer was obtained (10).

The electrical resistivity measurements were carried out using a conventional in line four-point probe (2). The sheet resistance and the resistivity were obtained from the measured data using the method of Smits (11). Activation energies were obtained from isochronal and isothermal anneals. The annealing stage limits were determined on the basis of the minimum values of $\Delta\rho/\Delta T$, the isochronal derivative. Changes in electrical resistivity were also studied as a function of the ratio of platinum to tantalum and tungsten to tantalum (Pt/Ta, W/Ta).

In the present investigation a corrosion test similar to the one devised by Cunningham *et al.* (6) was applied. The test specimens were prepared with 15μ Ta/Au metal stripes spaced 10μ apart on glass plates. The gold-tantalum test stripes were examined for corrosion resistance by placing a drop of 0.001*N* phosphoric acid on the test slices and biasing the first and fourth stripes to 6V. The corrosion and electrolysis action was monitored by optical microscopy.

Results and Discussions

As-deposited film structure.—The grain size of the deposited tantalum, tungsten, and gold films was in the range of 100-300Å, 200-400Å, and 300 to 600Å, respectively. Likewise, the grain size of the platinum was 200-400Å. The gold films were strongly (111) textured while the tantalum and platinum did not show any observable texture. The electrical resistivity of the gold films after deposition was measured to be 1.25 times the bulk resistivity. The sputtered tantalum films were prepared with a resistivity of 2.1 times that of bulk tantalum while the tungsten films were prepared with a resistivity of 3.0 times that of bulk tungsten. The tantalum films were deposited as bcc-Ta as verified by electron diffraction examination.

Isochronal and isothermal anneals.—Resistivity.—Isothermal and isochronal annealing of Ta-Pt-Ta-Au specimens with a variable platinum:tantalum layer thickness ratio shows that resistivity changes up to 650°C occur in two discrete stages and that the resistivity changes depend on the Pt:Ta thickness ratio (2). Figure 1 shows isothermal resistivity data at 350° and 450°C for various Pt:Ta ratio specimens with a barrier layer (Pt + Ta) and gold layer thickness of 2500 and 2000Å, respectively. Annealing at 350°C produces a decrease in resistivity which can be attributed to annealing out of vacancies and dislocations. Since electrical resistivity of the gold films after deposition was measured to be 1.25 times the bulk resistivity, isothermal annealing of the films with the absence of solid solution formation, decreases the density of structural defects quenched in during sputtering. The lowest resistivity was obtained with a Pt:Ta ratio of 0.24. Annealing at temperatures between 450° and 540°C resulted in a maximum 10% increase in resistivity for Ta-Pt-Ta-Au specimens with a Pt:Ta ratio of 0.15. Isochronal annealing of the same specimens indicates the existence of two annealing stages (stage I, between 27° and 450°C and stage II between 450°

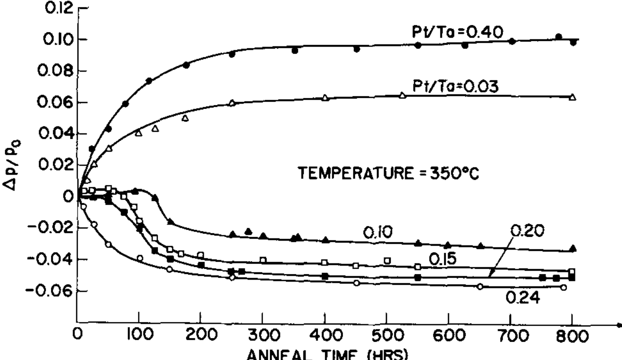

Fig. 1a. Isothermal annealing curves at 350°C for Ta-Pt-Ta-Au with various Pt/Ta ratios.

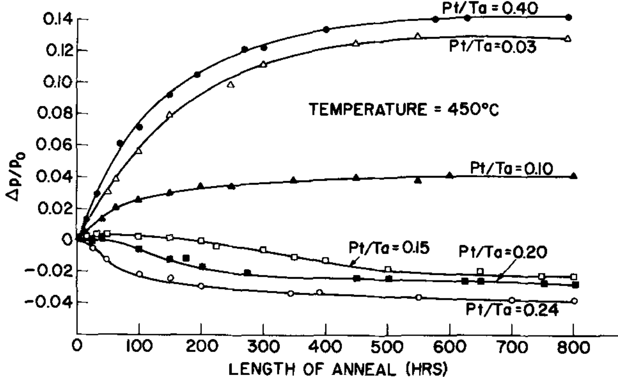

Fig. 1b. Isothermal annealing curves at 450°C for Ta-Pt-Ta-Au Ref. (2).

and 650°C). At temperatures above 450°C, the observed resistivity changes are attributed to interdiffusion between gold and tantalum at the Au-Ta interface and between tantalum and platinum at the Pt-Ta interface. This has been verified by x-ray diffraction and Auger electron spectroscopy and is discussed in the following sections.

The effect of platinum on the stage I resistivity changes is pronounced. Specimens without the platinum layer resulted in a 100% increase in $\Delta\rho/\rho_0$ after annealing at 450°C for 600 hr, as described in Ref. (1). The addition of 300Å of platinum between the tantalum layers eliminated the increase in resistivity. In as much as the increase in resistivity for Ta-Au specimens has been attributed to gold precipitation at tantalum grain boundaries (1) the addition of platinum tends to inhibit gold grain boundary diffusion by precipitating to and passivating the tantalum grain boundaries. The interdiffusion problem is discussed in a later section. Figure 2 shows the effect of varying the thickness platinum to tantalum ratio. The lowest resistivity was obtained with a Pt:Ta ratio of 0.24, while maintaining the total thickness of the barrier layer (Pt + Ta) constant at 2500Å. Increasing the Pt:Ta ratio above 0.24 results in a rapid increase in resistivity. These specimens, qualitatively analyzed by energy dispersive x-ray analysis, show that for Pt:Ta > 0.24, the interdiffusion of gold and platinum dominates and degrades the gold film resistivity. Since the resistivity did not degrade for $0.10 < \text{Pt:Ta} < 0.24$, one can assume that a reliable diffusion barrier was formed with platinum effectively precipitating to the tantalum grain boundaries. In addition, as the anneal temperature is increased from 350° to 525°C, the interdiffusion between Au and Ta (1) increases, resulting in higher levels of resistivity as shown in Fig. 2.

Interdiffusion.—Figures 3a-c show typical depth-composition profiles for as-sputtered and annealed SiO_2/Ta-Pt-Ta-Au metallizations. The as-sputtered composition profile of Fig. 3a shows no interdiffusion between the various constituents. Sharp interfaces are shown between the gold and the tantalum. The diffuse

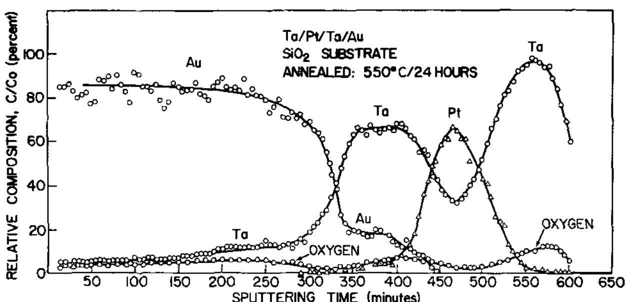

Fig. 3c. AES composition-depth profiles for Ta-Pt-Ta-Au annealed at 550°C for 24 hr.

interfaces between the platinum and tantalum may be attributed to the decreased thickness of the platinum layer (approximately 300Å) and to differential sputtering. Annealing at 450°C for 24 hr (Fig. 3b) resulted in the interdiffusion between Ta and Pt, with Pt spreading into the Ta films. The interface between the Au and Ta became diffused and was characterized by a gold tail into the Ta film. However, the Ta-Pt-Ta has remained an effective barrier to gold-SiO_2 interdiffusion. The Pt film has diffused into both Ta films with an enhanced diffusion toward the free surface. The Au-Ta interface composition is shown to be approximately 43% Au, 43% Ta, 8% Pt, and 4-6% O. The important observation at 450°C is the out-diffusion of Ta to the Au surface which considerably affects the conductivity characteristics of the metallization scheme (1).

The out-diffusion of Ta to the gold surface, likewise, was observed after annealing the SiO_2/Ta-Pt-Ta-Au specimens at 550°C for 24 hr (Fig. 3c). The Au is shown to have diffused through the Ta. The Ta-Pt-Ta barrier, even after prolonged annealing at 550°C, has effectively prevented the interdiffusion of gold and silicon dioxide. Also shown, in the 450° and 550°C SiO_2/Ta-Pt-Ta-Au specimens is the reaction between the tantalum and the oxide. From Fig. 3b and c, oxygen was always found with tantalum, probably in the form of Ta_2O_5 as reported by others (12). It is speculated that the oxygen comes from the SiO_2 surface which reacts with the tantalum and out-diffuses to the gold surface. The reaction between the tantalum and the oxide at the Ta-SiO_2 interface may account for the increased Ta concentration adjacent to the oxide found in the 550° and 450°C specimens. The tantalum at the interface is in the form of both bcc-Ta and Ta_2O_5.

X-ray diffractometer traces from SiO_2/Ta-Pt-Ta-Au samples annealed at 350°, 450° and 550°C are shown in Fig. 4. After a 24 hr anneal at 350°C, the compounds TaPt and Ta_2Pt were formed. Annealing at 450° and 550°C the compounds TaAu, TaPt, and Ta_2Pt were formed. The AES results indicate that TaAu formed at the original gold-tantalum interface at temperatures above 450°C and that the displaced tantalum is distributed through the gold layer. The XRD and AES measurements indicate that the gold-tantalum reaction has a tendency to be self-limiting. The amount of Ta distributed in the Au layer remained constant at temperatures between 350° and 550°C (apparently annealing above 450°C is necessary for TaAu formation). The AES results also indicate that the compounds Ta_2Pt and TaPt form in the platinum zone and at the tantalum-platinum interfaces. The 300-500Å platinum film is distributed throughout the tantalum layers. Likewise, the tantalum at both Pt-Ta interfaces diffuses into the platinum film. The Pt-Ta reactions are self-limiting with a critical temperature of 350°C for their activation.

Experiments with Ta-W-Ta diffusion barriers.—Experiments with Ta-W as the diffusion barrier were conducted. Isothermal annealing produced increases of 0.10 and 0.33 in $\Delta\rho/\rho_0$ at 350° and 420°C, respectively. Figure 5a shows the resistivity isothermal annealing curves for Ta-W-Ta-Au and indicates that Ta-W is not as effective as Ta-Pt in minimizing interdiffusion and compound formation between the gold and silicon. As shown in Fig. 5a, a W/Ta ratio of 0.10 was found to optimize the barrier effectiveness of the refractory layer. The Ta-W-Ta-Au (W/Ta of 0.10) when annealed at 350°C resulted in a 10% increase in resistivity, and a 25% increase in $\Delta\rho/\rho_0$ when annealed at 420°C for 400 hr. Figure 5b shows a comparison of the Ta-Pt and Ta-W diffusion barriers with Ta and tantalum-palladium. The isothermal annealing experiments of Fig. 5b clearly indicate that metallurgical stability can be obtained with Ta-Pt diffusion barriers. In contrast to Ta-Pt, microcracks in Ta-W and Ta-Pd layers and rapid interdiffusion between Pd and Au result in resistivity increases of over 20% for Ta, Ta-W, and Ta-Pd diffusion barriers. Scanning electron microscopy investigation of the Ta-W layer showed microcracks in the tungsten, propagating to the tantalum layers as the primary reason for the increase in resistivity at 450°C. Figure 6 shows cracking of the Ta-W layer at 450°C. At temperatures of up to 525°C interdiffusion between Ta and W was not detected. Similarly, the Au-Ta interdiffusion as expected was detected at temperatures above 450°C. Cracking in the Ta-W layers prevented useful conclusions from Auger (AES) data to be obtained.

Mechanical stability and corrosion resistance.—*Internal stresses.*—Stress, particle size, and film adhesion are the important parameters which affect the mechanical stability of thin films on a substrate. In the present investigation, the variation of internal stresses and particle size with anneal temperature has been determined. The stresses in the gold film of the Ta-Pt-Ta-Au and Ta-W-Ta-Au structures were tensile in nature before annealing. The average stress in the sputtered gold obtained from x-ray peak shift data

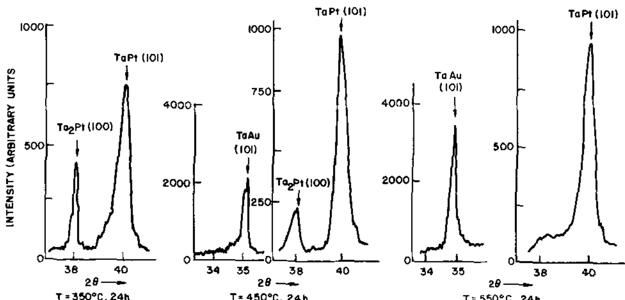

Fig. 4. XRD traces for Ta-Pt-Ta-Au annealed at 350°, 450°, and 550°C.

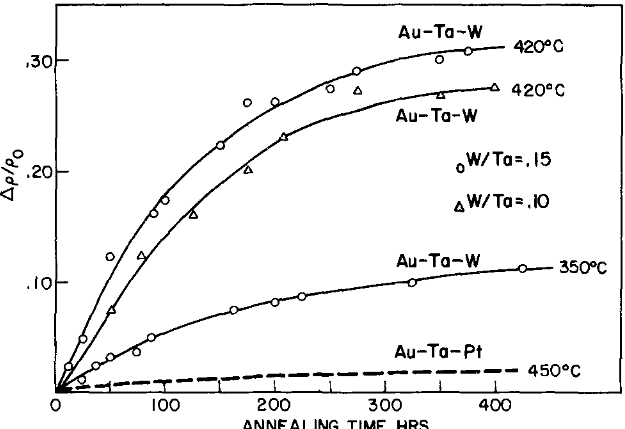

Fig. 5a. Isothermal annealing curves for Ta-W-Ta-Au thin films with W/Ta ratios of 0.10 and 0.15.

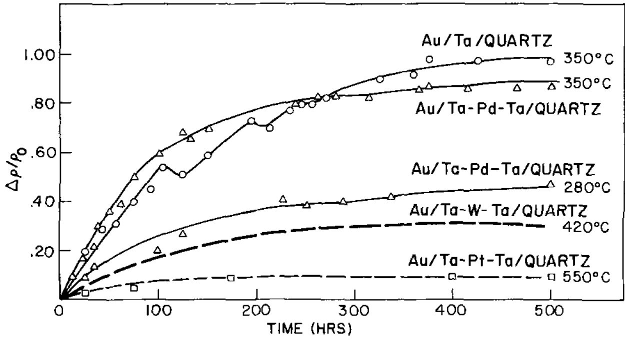

Fig. 5b. A comparison of isothermal annealing behavior of Ta-Pt, Ta-W, Ta-Pd, and Ta diffusion barriers.

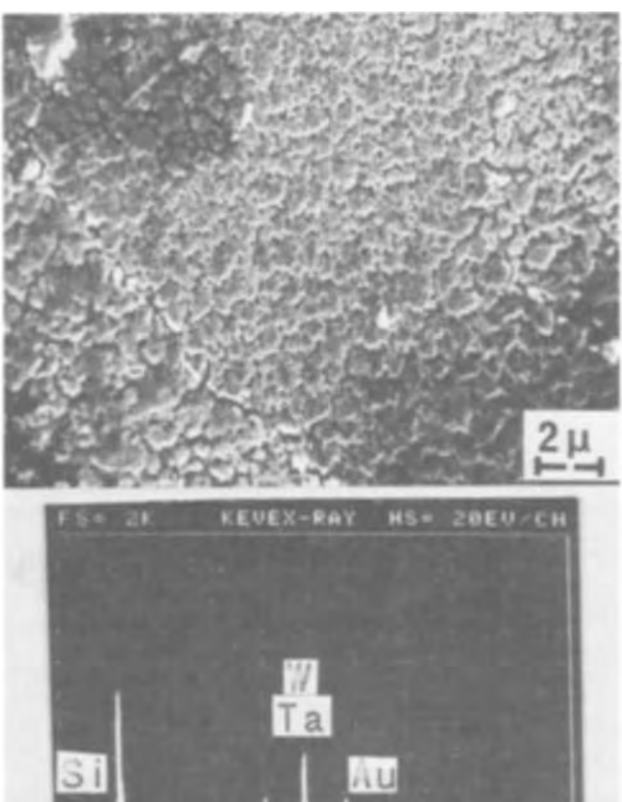

Fig. 6. Microcracks in the Ta-W layer after annealing at 470°C for 2 hr.

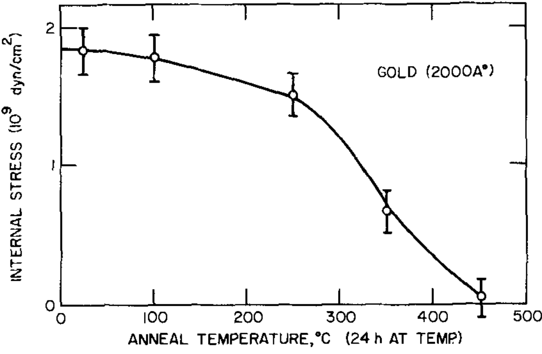
was 1.8×10^9 dynes/cm². Tensile stresses were also observed in the barrier layer. Annealing the Ta-Pt-Ta-Au and Ta-W-Ta-Au structures with 2000Å of gold at 450°C for up to 24 hr resulted in a decrease of internal stress in gold from 1.8×10^9 dynes/cm² to 0.1×10^9 dynes/cm². The results summarized in Fig. 7 indicate that a significant decrease in internal stress of sputtered Ta-Pt-Ta-Au films can be obtained by annealing up to 450°C. The rapid decrease in internal stress observed in the Ta-W layer at 200°-300°C indicates the occurrence of a rapid stress relief taking place probably by film microcracks. The internal stress reduction of the magnitude shown in Fig. 7 is too large to be accounted for by dislocation and vacancy annihilation.

Corrosion resistance and etchability.—The Ta-Pt-Ta-Au and Ta-W-Ta-Au structures subjected to the corrosion test showed vigorous electrolysis upon application of a 6V bias. After approximately 1 min, loose Au appeared at the anode, after 10 min the anode lost its supply of Au and electrolysis continued via the unattacked Ta-Pt strip. No Ta-Pt or Ta-W dissolution was observed on any strip for the 30 min duration of the experiment. This observation is not surprising since the oxides of tantalum, platinum, and tungsten being insoluble in water will not self-bias the Ta-Pt and Ta-W systems and result in rapid corrosion. At an external bias of 6V, the Au ion is transported in the electrolyte to the nearest cathode region where it plates out. The Ta-Pt and Ta-W layers remain relatively unattacked since the amount of oxygen evolution at a 6V bias is insignificant.

An etching process has been worked out for the Ta-Pt-Ta-Au and Ta-W-Ta-Au systems using an iodine-saturated solution of KI at 90°C for the gold and a $KOH:H_2O_2$(9:1) saturated solution at 27°C for tantalum. Typical etching rates of 1000Å/60 sec were obtained with undercutting maintained to less than



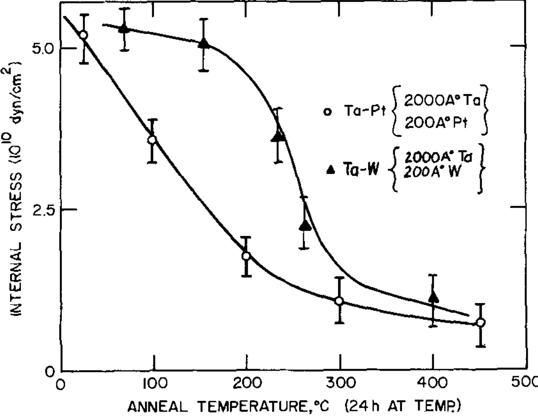


Fig. 7. Variation of internal stress with anneal temperature obtained from peak shift data in the Ta-Pt-Ta-Au and Ta-W-Ta-Au systems.

3000Å. An additional etch for the Ta-based films which also reduces undercutting is the $HNO_3:HC_2H_3O_2:HF$ in the proportions 6:2:1 and diluted 1:1 with deionized water. Typical etching rates, obtained with $HNO_3:HC_2\ H_3O_2:HF$ etch, were 1000Å/20 sec. The $KOH:H_2O_2$ etch, however, was more desirable due to the reproducibility of etching rates and the elimination of damage to the underlying thermal SiO_2 film or the exposed Si substrate. In applying each etch, one uses standard photolithographic techniques to define a pattern on the Au film followed by etching away the excess Au. By allowing the Au pattern to act as a mask, the wafer can then be placed in the chosen etch for a period of up to 45 sec, removed, and rinsed in running DI H_2O. No etching of Si occurs with both etches if 30-45 sec dips are used followed by a DI-H_2O rinse.

Summary and Conclusions

A stabilized tantalum-gold thin film system has been investigated as a metallization contact for microwave power transistors. The stabilized tantalum was used as a barrier metal in order to minimize interdiffusion and compound formation between the gold and the silicon. In the present investigation, the tantalum was stabilized against rapid diffusion of gold at tantalum grain boundaries by alloying a 200-500Å film of platinum between 1000Å layers of tantalum. The entire structure when overlaid with up to 3000Å of sputtered gold resulted in the following characteristics: (*i*) the resistivity decreased by 6% when annealed at 350°C for 800 hr, but increased by only 3% when annealed at 450°C, and (*ii*) evidence of diffusion through tantalum grain boundaries was absent. The present investigation has shown that the Ta-Pt-Ta-Au metallization (*i*) is metallurgically stable with no significant degradation of resistivity below 500°C, (*ii*) resists electrochemical corrosion, and (*iii*) is readily processed with existing technology. The Ta-Pt-Ta-Au system should find applications as a metalliza-

tion for microwave power transistors and in other devices where protection against corrosion and electromigration at a high current density is important. In contrast to Ta-Pt-Ta-Au, the Ta-W-Ta-Au metallization undergoes resistivity degradation of up to 15% at 450°C as a result of microcracking in the tungsten layer. The microcracks in tungsten provide diffusion paths for gold-silicon interdiffusion.

ABSTRACT

The diffusion of phosphorus into thin SiO_2 films on Si was studied to assess the significance of an anomalous, rapid diffusion mode. Diffusions were performed over a wide range of temperature and time using neutron-activated, red phosphorus diffusion sources. It was found that diffusion anneals in P vapors catalyzed a localized amorphous-to-crystalline transformation in the initially amorphous films, creating rapid diffusion paths at the interfaces between the crystalline islands and the surrounding amorphous matrix. The shape of the penetration profiles confirmed that interfaces contributed to the flux of P through the film. Both rapid and normal diffusion coefficients were determined and are discussed. Crystallization with subsequent rapid diffusion may be a contributing factor to the failure of SiO_2 diffusion masks.

Although the diffusion of P in amorphous SiO_2 films has frequently been investigated (1-5) there is considerable discrepancy in the measured values of diffusivity and fundamental uncertainty concerning the diffusion process (3). In view of the widespread use of P in Si device technology, we felt it imperative to clarify the question of P diffusion in amorphous SiO_2 films by undertaking a further study. Our results provide additional data for diffusion in the amorphous matrix and identify a hitherto unrecognized diffusion process in "amorphous" films involving migration along the interface between crystallized islands and the amorphous matrix which surrounds them. The localized crystallization of the film is attributed to a catalytic influence of phosphorus.

Experimental

Our study employed 0.5μ amorphous films of steam grown SiO_2 on (100) Si wafers (B-doped, 2 ohm-cm) and was performed over a wide range of temperature (1100°-500°C) and time (1 hr-4 days) using P^{32} isotope. The source of the radioisotope was neutron-activated, red phosphorus powder which was encapsulated, together with the SiO_2/Si samples in evacuated silica ampoules. At diffusion temperatures, the phosphorus source vaporized and provided constant surface concentration boundary conditions. Serial sectioning in 50-200Å steps was performed by timed etching of the amorphous SiO_2/Si with a diluted "P"-etch (6). The etch rate was established with the aid of ellipsometry measurements of thicknesses successively removed. The activity of each section was determined by liquid scintillation methods.

Results and Discussion

Evidence of crystallization.—The extended depth of P penetration as illustrated by Fig. 1, suggested that structural defects (*i.e.*, crystallites) were contributing to the flux of P through the SiO_2 films in addition to that anticipated from ordinary diffusion in the amorphous matrix. Structural defects were further suggested by the appearance of numerous, small areas of high P concentration on autoradiographs of the diffused films (7). Reflection electron diffraction from the surface of the same films showed the presence of α-crystobalite, a crystalline phase which apparently resulted from a catalytic influence of P, as samples given simulated diffusion anneals without P showed no evidence of crystallization (Fig. 2). Subsequently, some diffused wafers were diced and portions with structural defects, as determined from autoradiographs, were back-etched and examined by electron transmission and diffraction microscopy techniques. It was determined that the defects were crystallized islands, surrounded by amorphous material (7). In fact, many were several microns in diameter and easily seen by optical microscopy (Fig. 3).

* Electrochemical Society Active Member.

Key words: diffusion mask, α-crystobalite, network diffusion, interface diffusion.

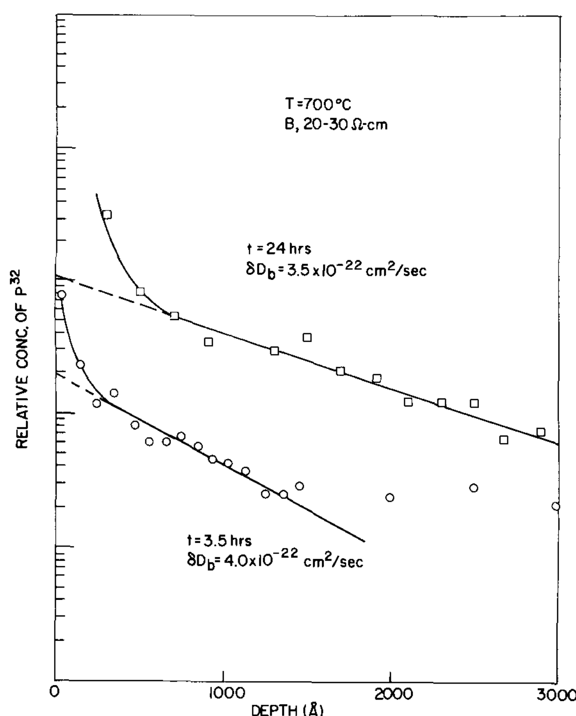

Fig. 1. Phosphorus penetration profiles due to rapid diffusion along the crystalline-amorphous boundary. The relatively close agreement between δD_b values for two different diffusion times substantiates the use of Fisher's boundary diffusion model.

The density of crystallites necessary to account for the level of P activity seen in the tailing regions of our profiles is approximately $10^4/cm^2$ assuming the individual crystals are a few microns in diameter. Confirmation of the above density and size of defects by optical microscopy is possible for samples diffused at 700°C and above. At lower temperatures, the presumed smaller size of the crystallites (*i.e.*, submicron) precluded observation by optical means.

Penetration profiles.—On the basis of this experimental evidence, and with the aid of Fig. 4, we can explain our profiles as follows: In the vicinity of a crystallized island, a rapid diffusion path exists at the interface between crystalline and amorphous regions. The diffusivity in the boundary, D_b, may be a few orders of magnitude greater than the diffusivity in the undisturbed amorphous network, D_n. Therefore, depending where on the film surface the P^{32} vapors impinge, there will occur different modes of diffusion. One mode is directly into the amorphous matrix, which gives the first portion of our profile where the concentration falls smoothly from its high initial value at the surface until it intercepts the linear portion at a depth of a few hundred angstroms. A typical experimental profile is shown in Fig. 5 where D_n has been determined by fitting the profile to a complimentary error function. In Fig. 4, this diffusion is responsible for the isoconcentration contours that are parallel to the specimen surface as occur at some distance from the crystalline region. In Fig. 6, we show the values of D_n plotted against $1/T$ together with data from two other investigations (2, 3). The second diffusion mode, as evidenced by the linear portion of the profile in Fig. 1 is due to a combination of rapid diffusion down the crystalline-amorphous boundary with eventual lateral migration into the amorphous network away from the boundary. Lateral migration into the crystallized region is neglected; it should not appreciably affect our results owing to the anticipated lower diffusivity of P in this denser phase. In analyzing these and similar profiles, we have used the expressions

$$\delta D_b = 2.8\left(\frac{D_n}{\pi t}\right)^{1/2}\left(\frac{\partial \ln c}{\partial x}\right)^{-2} \quad [1]$$

$$\beta = \frac{\mathrm{Cot}^2\psi}{\pi^{-1/2}} = \frac{\delta D_b}{D_n\sqrt{D_n t}} \quad [2]$$

which are based on the well-known Fisher analysis modified to take account of the lack of lateral migration into the crystallized region (8). Here δ is the width of the interface, $\left(\frac{\partial \ln c}{\partial x}\right)$ the slope from the penetration profile, and t the duration of the diffusion anneal. The calculated values of δD_b for a set of measurements on films prepared from 2 ohm-cm, B-doped Si are shown plotted *vs.* $1/T$ in Fig. 7. In Fig. 4, the second diffusion mode is responsible for the bending of the isoconcentration contours down at the boundary,

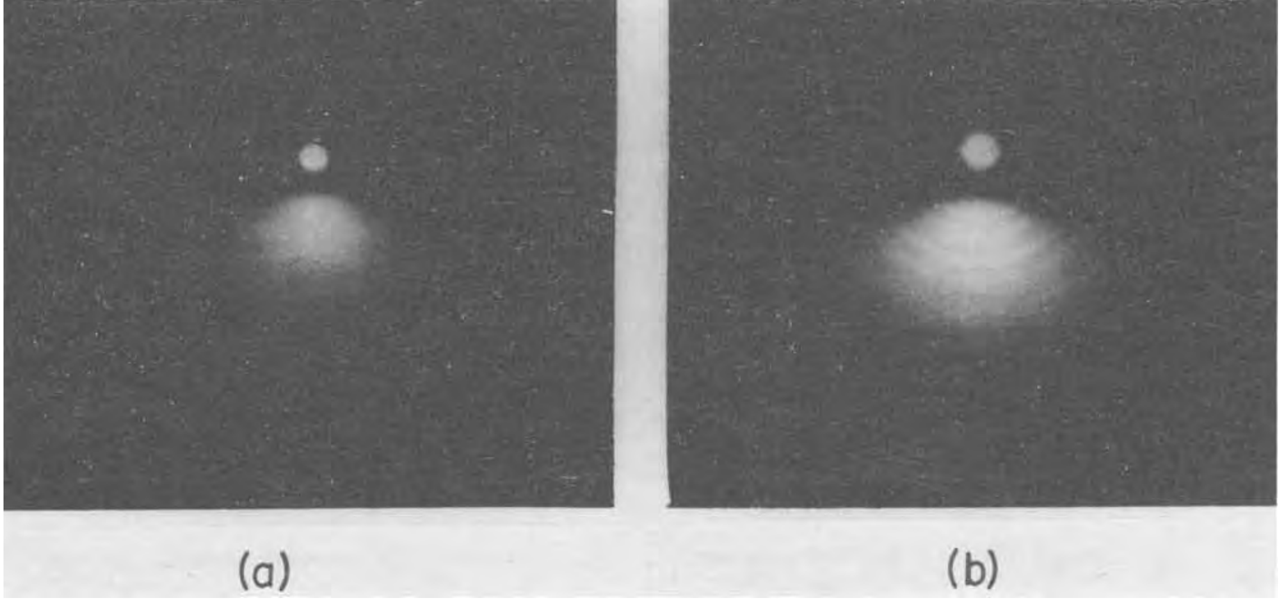

Fig. 2. Reflection electron diffraction patterns from (a) SiO_2 film given a simulated diffusion anneal for 92 hr at 700°C without phosphorus, (b) film diffused with phosphorus for 92 hr at 700°C. In (a), the undiffused film stays amorphous. The presence of α-crystobalite is indicated in the pattern in (b).

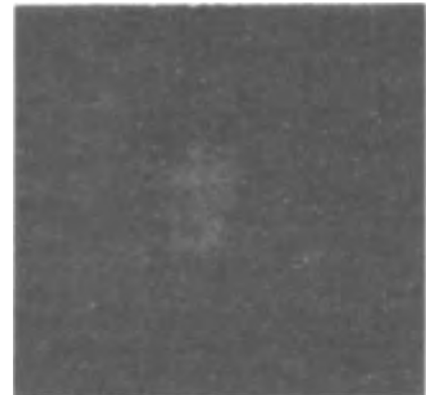

Fig. 3. Crystalline island in a P-diffused SiO_2 film (400×)

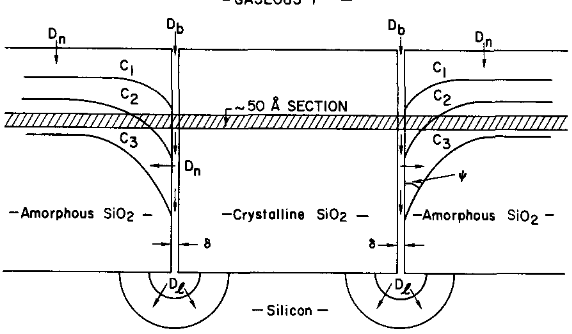

Fig. 4. Isoconcentration contours for P in an SiO_2 film in the vicinity of a crystallized island. The concentrations decrease with depth into the film or $C_1 > C_2 > C_3$. The network diffusivity is denoted by D_n, diffusivity in the crystalline-amorphous boundary by D_b, and diffusion into the underlying Si by D_l. The cross hatched portion indicates the material removed in a typical section.

which they all intercept at the same angle ψ. Some of the P atoms starting out in the boundaries penetrate completely through the film and become incorporated in the underlying Si where they enhance the exposure of autoradiographs in places corresponding to defect locations. This effect was confirmed by autoradiographs taken of wafers from which the oxide was completely removed after diffusion.

Diffusion coefficients.—Two distinctly different types of diffusion behavior are expected for dilute impurities in directionally bonded, amorphous materials. The first, more rapid, mechanism involves migration through the interstices of the structure while the second, slower, mechanism involves migration as part of the network structure. Examples of the former are the diffusion of inert gases (9, 10) and alkali and noble metal impurities (11, 12) in SiO_2 and possibly noble metal impurities (13, 14) in chalcogenide glass films. Examples of the latter are the diffusion of various network forming ions in SiO_2 films (15). Many of these ions are also common dopants for Si (*e.g.*, Al, B, P, As, Sb).

We find the network diffusivity for phosphorus to be

$$D_n = D_n^\circ \, e^{-Q_n/kt} = 2.0 \times 10^{-10} \text{ (cm}^2\text{/sec) } e^{-1.7 \text{ eV}/kt}$$

from measurements over the range 1095°-772°C. No attempt has been made to assess the errors in D_n° and Q_n which may be considerable. A clear indication of slow network diffusion as shown in Fig. 5 was difficult to obtain and analyze because of interferences from concomitant processes such as formation of phosphosilicate glass (PSG) layers on the surface and crystallization of the film. Both of these influenced our profiles significantly. The high temperature extrapolation of our data still comes reasonably close to the data of Allen, Bernstein, and Kurtz (2) shown in Fig. 6, par-

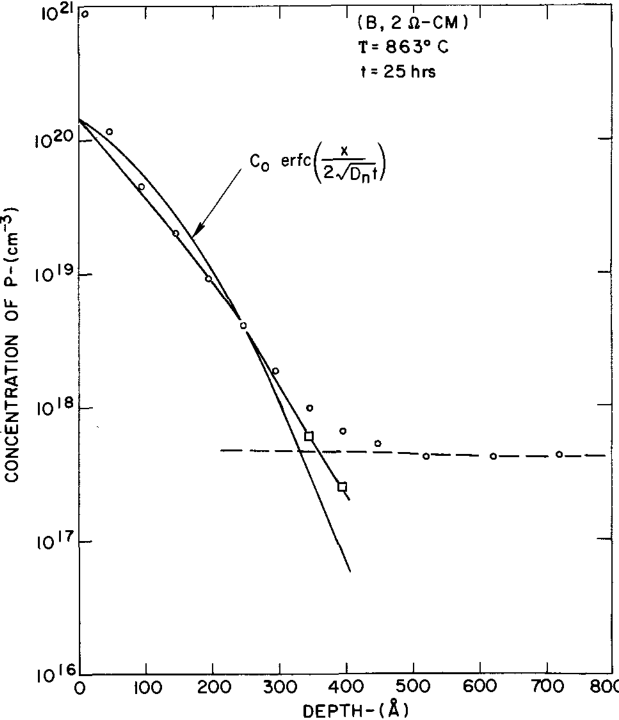

Fig. 5. Phosphorus penetration profile due to slow network diffusion. The open circles represent experimentally determined points; the open squares represent an estimated portion of the profile obtained by subtracting the background activity associated with the crystallites. The background level is represented by the horizontal, broken line. The solid line through the plotted points is the apparent shape of the experimentally determined profile. High surface concentrations are attributed to the formation of a thin PSG layer. The complimentary error function was calculated assuming Co, the solid solubility for P in SiO_2, to be $\sim 1.4 \times 10^{20}$ cm^{-3} and D_n as 7.0×10^{-18} cm^2/sec.

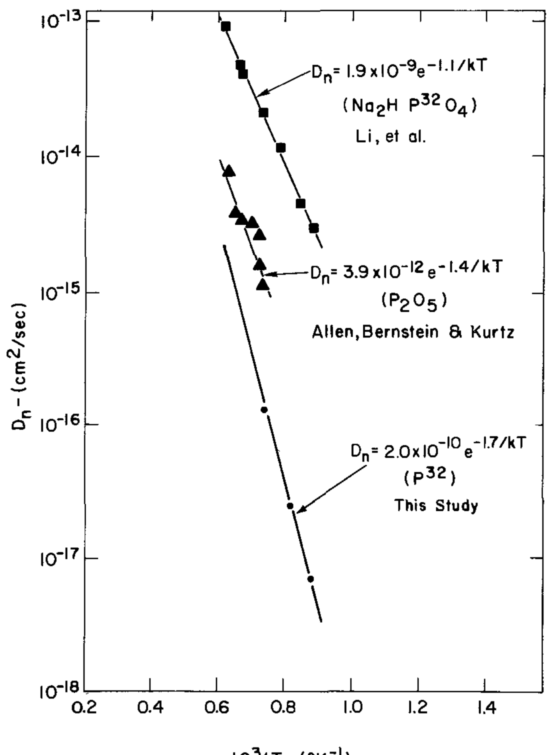

Fig. 6. Log D_n *vs.* $1/T$ for diffusion of P^{32} in SiO_2 film

ticularly in view of the large spread in other reported values. (15). Here the discrepancy may be related to

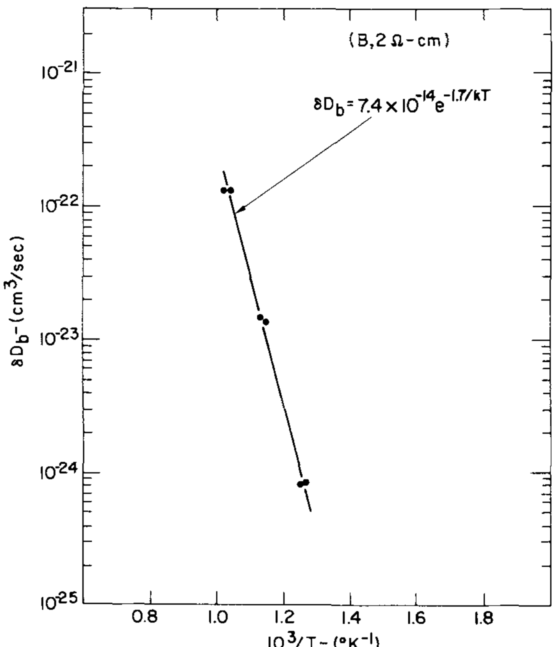

Fig. 7. Log δD_b vs. $1/T$ for diffusion of P^{32} in SiO_2 films. Two measurements were made at each of the temperatures, 700°, 600°, and 516°C. Values of δD_b displaced laterally for clarity in plotting.

a difference in experimental method; our method involved direct profiling of the SiO_2 while Allen *et al.* determined their values of D_n from profiling measurements of the underlying Si, using a two-phase diffusion model. A consequence of their method is that the effective concentration of P in their oxide was probably several mole per cent, considerably higher than the $10^{20} - 5 \times 10^{18}/cm^3$ range of our measurements. Although we do not think a significant concentration effect occurs in our case, at higher P levels D_n may become strongly concentration dependent because the phase diagram (16) indicates that the melting point of PSG falls rapidly with increasing P content. Therefore, in view of their higher concentrations, higher D_n values appear reasonable. Concentration effects may not have much bearing on the very large discrepancy between our data and that of Li *et al.* (3). The introduction of network modifying Na^+ ions from their disodium-phosphate source is more likely the cause. The well-known affinity of Na^+ ions for P in PSG suggests that the high diffusivity they see is due to some influence of Na on the local environment of P, resulting in enhanced mobility.

The low values for $D_n°$ and Q_n we report are not easily reconciled with a specific diffusion mechanism. Diffusion mechanisms for the motion of network-forming ions are undefined in contrast to the situation for interstitial species where detailed models have been suggested (9). Also, the information obtained in this study is insufficient in itself to indicate a mechanism, as will be clear after the following discussion of possible approaches to the problem.

Well above the glass transition temperature, the diffusion of constituent ions or molecules of a fluid is traditionally thought to be directly related to viscous flow of the fluid through the Stokes-Einstein equation. Under these conditions, a free volume model (17-20) successfully accounts for the viscosity of some fluids; organic liquids are one example (21). The situation for oxide glasses is less clear, both from the point of view of viscosity mechanisms (22-25) and the connection between viscosity and the migration of individual ions or network units (26). Well below the glass transition temperature of silica, where our measurements were made, the activation energy for viscous flow (27) is ~ 7 eV or 4 times larger than for P diffusion. This suggests that an interpretation of diffusion analogous to viscosity treatments would not succeed. Another approach is to apply concepts of defect diffusion as in crystalline materials although there is yet no proof that distinct defects contribute to diffusion in silica (12).

Assuming they might, the low values of $D_n°$ and Q_n suggest a similarity to diffusion of metal ions in crystalline oxides under extrinsic conditions. The values of the preexponential terms are typically several orders of magnitude lower than in the intrinsic case because they incorporate the relative concentrations of athermal defects. For example, the concentration of Si vacancies which might exist by virtue of structural discontinuities or impurity association. Activation energies would likewise be low for they involve only migration energy of the diffusing species. Other types of defect mechanisms could also be mentioned but it seems pointless to speculate further on these or any other mechanisms without additional information. In particular, we are uncertain regarding the coordination of P in the network, the exact diffusing specie and the nature and possible influence of defects. Structural information on P coordination would be most useful here, but suitable studies such as infrared spectroscopy or radial distribution function measurements were beyond the scope of this work. Knowledge of the charge state of the diffusing specie might identify it, but our own attempts at ionic drift measurements were unsuccessful because of reactions between the metal electrode and the oxide films at the high temperatures required. A realistic test of the influence of defects on diffusion in SiO_2 films is obviously important but obtaining samples with controlled defect concentrations seems to be a major problem (12).

Diffusion down the crystalline-amorphous interface is given by

$$\delta D_b = \delta D_b° \, e^{-Q_b/kt} = 7.4 \times 10^{-14} \text{ cm}^3/\text{sec} \, e^{-1.7 \text{ eV}/kt}$$

The activation energy is the same as we found for the amorphous matrix. This suggests that the migration process along the interface is similar to that in the network. Estimating the boundary width, δ, at 10^{-7} cm fixes $D_b°$ at ~ 10^{-6} cm²/sec. In the defect picture of diffusion, a larger preexponential factor for interface *vs.* network diffusion could imply that greater defect concentrations occur in the boundaries. This correlates with the customary notion that such regions have fewer or weaker bonds than the bulk.

A considerable error may occur in δD_b due to scatter in the measurement and possibly to the continued nucleation and growth of crystallites during diffusion. Continued nucleation and growth would invalidate Fisher's analysis which presumes stable boundaries. However, the change in the slope of the profiles with time follows Fisher's kinetics (Fig. 7) which implies that the extent of crystallization of our films becomes stabilized in times which are short compared with the durations of the diffusions.

Conclusions

From a practical standpoint, the formation of crystallites such as we have seen in a diffusion mask during P diffusion, or in an SiO_2 layer during PSG deposition, will leave the underlying Si susceptible to P penetration in localized areas (28) where such unintentional doping may be undesirable. It seems unlikely that a network-forming ion like phosphorus should catalyze crystallization, especially in view of the results of Sugano *et al.* who did not find evidence of crystallization in P-doped oxides (29). However, analogous crystallization effects have been attributed to the presence of As which is also a network forming ion in arsinosilicate glasses (30). The reason cited was that As_2O_5 was capable of forming distinct compounds with SiO_2 which may have provided nuclei for the subsequent growth of crystalline SiO_2. Compounds such as $P_2O_5 \cdot SiO_2$ or $P_2O_5 \cdot 2\, SiO_2$,

which are known to occur from phase segregation in PSG films (31), are possible candidates for nuclei (7). Crystalline areas in films may also act as sites for accumulation of undesirable metallic ions such as Na, but attempts to see such an effect using Na^{22} tracer and autoradiography techniques were inconclusive due to sensitivity problems.

Acknowledgment

The authors are particularly indebted to R. MacInnes for diffusing and profiling the specimens and to R. Robinson for autoradiography with tagged Na. The authors wish also to extend their appreciation to Dr. E. Bassous, Mrs. D. Bauer, and Mr. J. A. Kucza for advice and assistance in sample preparation, and to Drs. D. Gupta, A. Mayadas, and R. Rosenberg for many helpful discussions.

Etching Studies of Anomalous Defects in P-Type GaP Crystals

T. Iizuka[1]

Bell Laboratories, Murray Hill, New Jersey 07974

The publication costs of this article have been assisted by Bell Laboratories.

ABSTRACT

Anomalous defects in GaP crystals prepared by Czochralski, solution-growth, and vapor-growth techniques have been investigated by chemical etching, optical microscopy, and scanning electron microscopy. These defects were found in as-grown highly Zn-, Cd-, or $Zn(PO_3)_2$-doped GaP crystals with carrier concentrations ranging from $8 \times 10^{17}/cm^3$ to $2 \times 10^{19}/cm^3$. Thermal oxidation (at 850°C for 5¾ hr in air) of vapor-grown crystals doped with Zn, or Cd, produced the same defect in the surface layers (20μ depth) of the crystals. The anomalous defects were developed distinctly by chemical etching as characteristic deep etch pits both on P$(\bar{1}\bar{1}\bar{1})$ and on {110} cleavage surfaces. These pits were distinguished from ordinary dislocation etch pits both by their morphology and etching behavior. The density of the pits was between 10^2 and $10^6/cm^2$. From detailed observation, it has been proposed that the anomalous defects are special dislocations modified with some impurities. It seems that the relevant impurities are zinc (or cadmium) and/or oxygen.

Zinc and oxygen are used in GaP crystals for the fabrication of red-light emitting diodes; therefore, understanding the behavior of Zn and O in the crystal is of great importance. (Zn,O)-doped, liquid encapsulated Czochralski (LEC) crystals are especially important from the standpoint of device production. At the present time, efforts to prepare efficient diodes by single n-tipping on LEC p-type substrates have been unsuccessful.

[1] Present address: Electrotechnical Laboratory, Tokyo, Japan.
Key words: etching, defect, GaP.

The present work is concerned with anomalous etch pits (hereafter defects responsible for the formation of the anomalous etch pits are called anomalous defects) which are observed in highly Zn-, Cd-, or $Zn(PO_3)_2$-doped GaP crystals. Also considered are thermal oxidation-induced defects in GaP crystals which appear to be the same as the anomalous defects in as-grown crystals. As for the oxidation of GaP crystals, compositions of the thermal oxidation products have been reported by Gershenzon *et al.* (1) and Rubenstein (2). Recently, aqueous oxidation of GaP and GaAs crystals has been done by Schwartz (3). No detailed studies on the oxidation mechanism, however, have been reported. It has not been demonstrated whether the oxidation takes place at the oxide-GaP interface by the inward transport of oxygen through the oxide film or at the outer surface of the film by the outward motion of Ga and P through the film. In this work, the thermal oxidation is performed and described only from the anomalous defect point of view.

Experimental

In this work, liquid encapsulated Czochralski (LEC) crystals, solution-grown (SG) crystals, and halogen transported vapor-grown (VG) crystals were investigated. Most of these crystals were doped with Zn, Cd, or $Zn(PO_3)_2$, and the carrier concentrations ranged from $8 \times 10^{17}/cm^3$ to $2 \times 10^{19}/cm^3$. Undoped, S-, Te-, and Ga_2O_3-doped crystals were also examined for comparison. Slices cut parallel to the {111} planes from these crystals were mechanically polished and inspected by transmitted visible light. The slices were then chemically etched with chlorine-saturated methanol to obtain smooth $P(\bar{1}\bar{1}\bar{1})$ surfaces. The slices were cleaved along {110} surfaces and then etched with a ferricyanide etchant (4) [50 mliters H_2O, 6g KOH, 4g $K_3Fe(CN)_6$ for 5 min at the etchant's boiling temperature]. Most of the work was done on the $P(\bar{1}\bar{1}\bar{1})$ and {110} surfaces. Observation of the etched surfaces was performed with an optical microscope. The detailed structure of the etch pits was investigated with a scanning electron microscope.

Thermal oxidation of GaP crystals in air in an open tube was performed at 850°C for 5-3/4 hr. Annealing of the samples in evacuated ($\leq 10^{-7}$ and 10^{-3} Torr) capsules was also performed at 850°C for 5-3/4 hr to examine the net effect of the annealing on the samples. After these treatments, the $P(\bar{1}\bar{1}\bar{1})$ surfaces were examined with an optical microscope. The compositions of the film were analyzed by x-ray diffraction. The films were dissolved in HCl, and then the samples were etched with the ferricyanide etchant for the optical observation.

Results

General observations.—Very characteristic anomalous etch pits differing from ordinary dislocation etch pits have been observed in GaP crystals doped with Zn, Cd, or $Zn(PO_3)_2$. Characteristics of the crystals examined are summarized in Table I.

Table I. Sample characteristics

Sample	Growth method	Dopant	$N_A - N_D$ (cm^{-3})	As-grown anomalous etch pit density (cm^{-2})
RD 47 (seed end)	LEC	$Zn(PO_3)_2$	1.3×10^{18}	0
RD 47 (tail end)	LEC	$Zn(PO_3)_2$	4×10^{18}	10^4
RD 43	LEC	$Zn(PO_3)_2$	5×10^{18}	10^5
RD 124	LEC	Zn	2.6×10^{18}	0
RD 70	LEC	Zn	3×10^{18}	0
RD 125	LEC	Zn	2×10^{19}	0
MS 90502	SG	Zn	6×10^{18}	10^6
H 227	VG	Zn	3×10^{18}	10^2
H 611	VG	Zn	5×10^{18}	10^6
H 203	VG	Zn	1.5×10^{19}	10^4
H 194	VG	Cd	8×10^{17}	10^3
H 161	VG	Cd	1×10^{18}	10^3

In general, the ferricyanide etchant does not reveal distinct dislocation etch pits on either the $P(\bar{1}\bar{1}\bar{1})$ or the {110} cleavage surfaces of ordinary GaP crystals. However, this etchant can reveal distinctly the anomalous etch pits on these surfaces of highly Zn-, Cd-, or $Zn(PO_3)_2$-doped GaP crystals. It should be emphasized that this is a notable difference in the etching behavior between the anomalous defects and ordinary grown-in dislocations. Etchants for chemical polishing, for example, chlorine-saturated methanol or warm aqua regia, do not develop the anomalous etch pits on either the $P(\bar{1}\bar{1}\bar{1})$ or {110} surfaces of GaP crystals containing the anomalous defects. The shape of the anomalous etch pits revealed with the ferricyanide etchant on the $P(\bar{1}\bar{1}\bar{1})$ surface is typically an elongated triangle with the long axes parallel to the <211> directions as indicated in Fig. 1. The tangent of the short curved side of the pits is parallel to <110> directions. The orientations of the two long sides of the pits are not simple, low index crystallographic orientations. Occasionally equilateral triangle anomalous etch pits were found on the $P(\bar{1}\bar{1}\bar{1})$ surfaces. Figures 2a and b are micrographs of anomalous etch pits taken with a scanning electron microscope, indicating the deep structure of the pits. It is believed that the dark appearance of the anomalous etch pits comes from their depth. On Ga(111) surfaces of these crystals, dark triangle etch pits differing from ordinary dislocation etch pits were also revealed after the ferricyanide etching. Special structures, for example, decorated dislocations with Zn, or Cd, which were expected to correspond to the anomalous defects were not detected by transmitted visible light inspection through the crystals.

Distribution of the anomalous etch pits.—Czochralski-grown crystals.—It was observed that large anomalous etch pits were mainly distributed in annular rings on the $P(\bar{1}\bar{1}\bar{1})$ slices cut perpendicular to the growth axis of a highly $Zn(PO_3)_2$-doped LEC crystal, RD 43, as schematically shown in Fig. 3. In the central region, denoted I in the figure, the density of the anomalous etch pits was about $1 \times 10^5/cm^2$ and the pit size was the largest, approximately 15μ along the long axis (see Fig. 1). In the surrounding region II, the density of the pits decreased to the lowest value, about $7 \times 10^4/cm^2$ and the size was reduced to less than 5μ. In region III, the density was the largest $2 \times 10^5/cm^2$, and the size was about 10μ. In the outermost region, IV, there

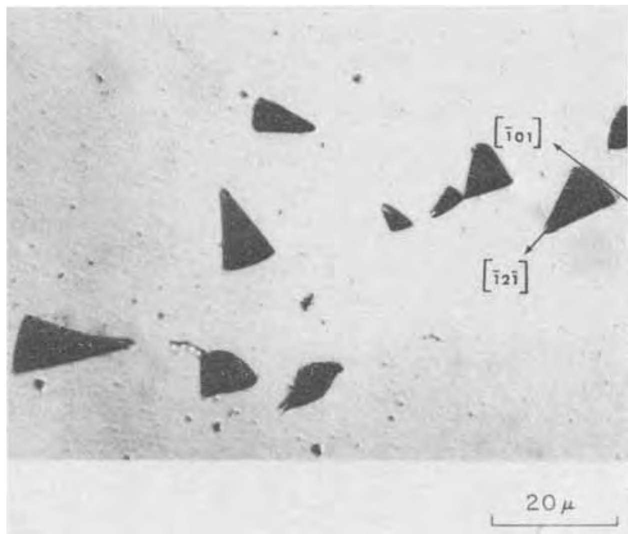

Fig. 1. Typical anomalous etch pits developed with ferricyanide etchant on a $P(\bar{1}\bar{1}\bar{1})$ surface of a highly $Zn(PO_3)_2$-doped LEC crystal ($N_A - N_D = 5 \times 10^{18}/cm^3$).

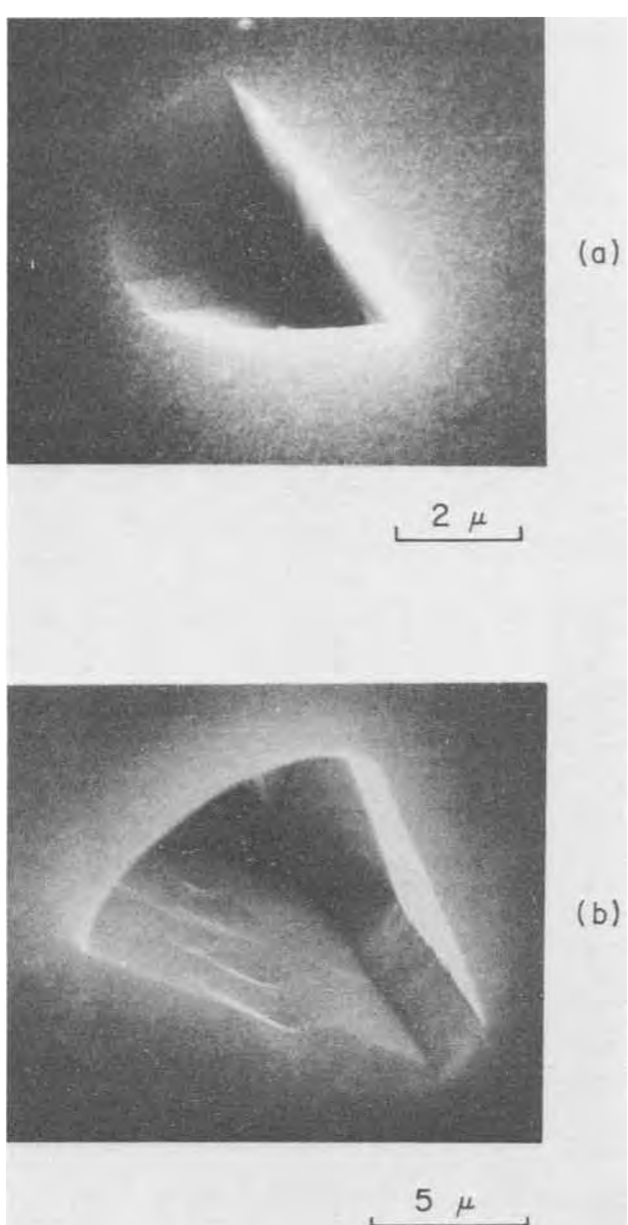

Fig. 2. Scanning electron micrographs of anomalous etch pits developed with ferricyanide etchant on P($\bar{1}\bar{1}\bar{1}$) surfaces of (a) the same sample as Fig. 1, and (b) a highly Zn-doped VG crystal ($N_A - N_D = 1.5 \times 10^{19}/cm^3$).

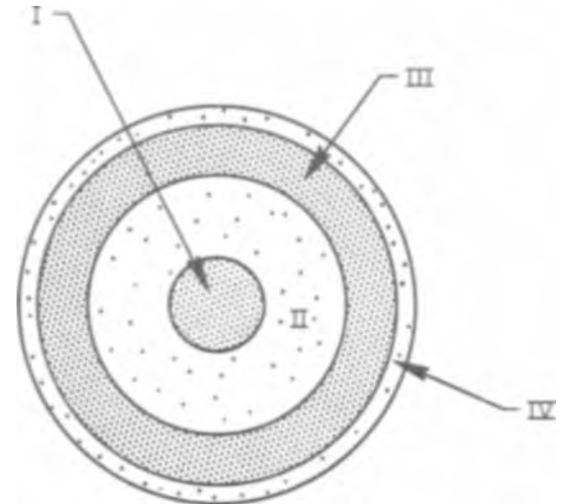

Fig. 3. Schematic annular ring distribution of large anomalous etch pits on a P($\bar{1}\bar{1}\bar{1}$) surface of a LEC crystal.

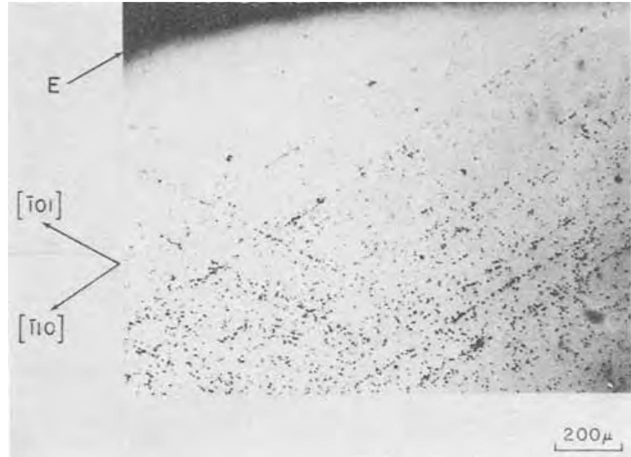

Fig. 4. Arrays of anomalous etch pits along <110> directions at the edge of P($\bar{1}\bar{1}\bar{1}$) surface of a LEC crystal. Arrow E indicates wafer edge.

were a few small (1μ) pits. In a region between III and IV, the anomalous etch pits were distributed as arrays along <110> directions as shown in Fig. 4. It is well known that impurities are sometimes preferentially distributed in annular ring patterns in a {111} slice cut perpendicular to the growth axis of Czochralski crystals by the facet effect. For example, Cronin *et al.* (5) have reported the appearance of annular facets of high tellurium concentrations in Te-doped Czochralski-grown GaAs crystals. Therefore, the similar annular ring distribution of the large anomalous etch pits in a highly $Zn(PO_3)_2$-doped LEC crystal suggests that the anomalous defects are correlated with similarly distributed impurities incorporated during crystal growth. In a slightly less $Zn(PO_3)_2$-doped LEC crystal than above, the anomalous etch pits were found only on stacking faults or twin lamella grooves as shown in Fig. 5, and no anomalous etch pits were observed in other regions of this crystal. The anomalous etch pits have not been formed in the following LEC crystals: (*i*) three heavily Zn-doped different crystals with carrier concentrations of 2.6×10^{18}, $3 \times$

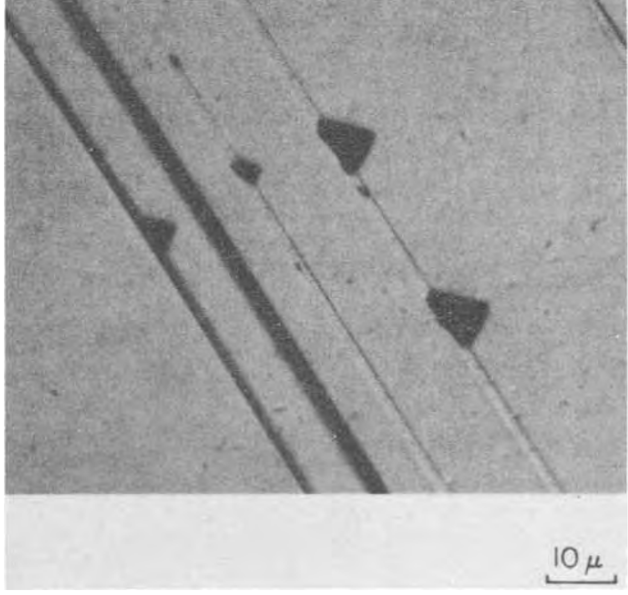

Fig. 5. Anomalous etch pits on stacking fault (or twin lamella) grooves in a tail part of a $Zn(PO_3)_2$-doped LEC crystal RD 47 ($N_A - N_D = 4 \times 10^{18}/cm^3$).

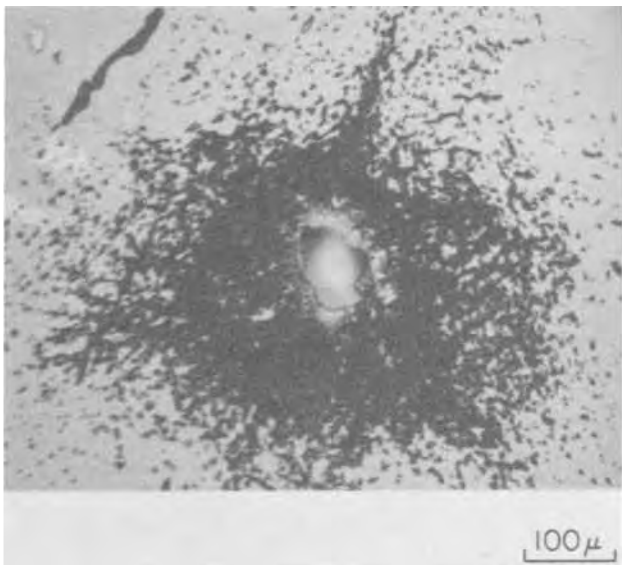

Fig. 6. A cluster of anomalous etch pits around an impurity inclusion on a P($\bar{1}\bar{1}\bar{1}$) surface of a highly Zn-doped SG crystal ($N_A - N_D = 6 \times 10^{18}/cm^3$).

10^{18}, and $2 \times 10^{19}/cm^3$, (*ii*) undoped, Ga_2O_3-, and lightly $Zn(PO_3)_2$-doped crystals, and (*iii*) highly S-doped crystals[2] ($N_D - N_A \sim 9 \times 10^{17}$, $3 \times 10^{18}/cm^3$).

Solution-grown crystals.—Clusters of the anomalous etch pits have been observed in a highly Zn-doped SG crystal with a carrier concentration of $6 \times 10^{18}/cm^3$. They were mostly distributed around impurity inclusions as shown in Fig. 6. Figure 7 shows a pair of {110} cleavage surfaces of the crystal etched with the ferricyanide reagent. There is a one to one correspondence between the pits on the cleaved halves. In S-, or Te-doped SG crystals with carrier concentrations of 2×10^{17} and $8 \times 10^{17}/cm^3$, the anomalous etch pits have not been observed.

Vapor-grown crystals.—Many anomalous etch pits have been observed in a highly Zn-doped VG crystal with a carrier concentration of $5 \times 10^{18}/cm^3$ (Fig. 8). The density of the pits was of the order of $10^6/cm^2$. On the other hand, in other Zn-, or Cd-doped VG crystals with carrier concentrations ranging from $8 \times 10^{17}/cm^3$ to $1.5 \times 10^{19}/cm^3$, the anomalous etch pit densities were between $10^2/cm^2$ and $10^4/cm^2$. In those crystals with a low density of the anomalous etch pits, it was observed that the pits were preferentially located on stacking faults or on microtwin lamella grooves. The anomalous etch pits have not been observed in Te-doped VG crystals with carrier concentrations of 3×10^{16} and $1 \times 10^{17}/cm^3$.

Thermal oxidation-induced anomalous defects.—In addition to the grown-in anomalous defects, it has

[2] These highly S-doped LEC crystals were supplied from Sanyo Electric Company, Ltd., Osaka, Japan.

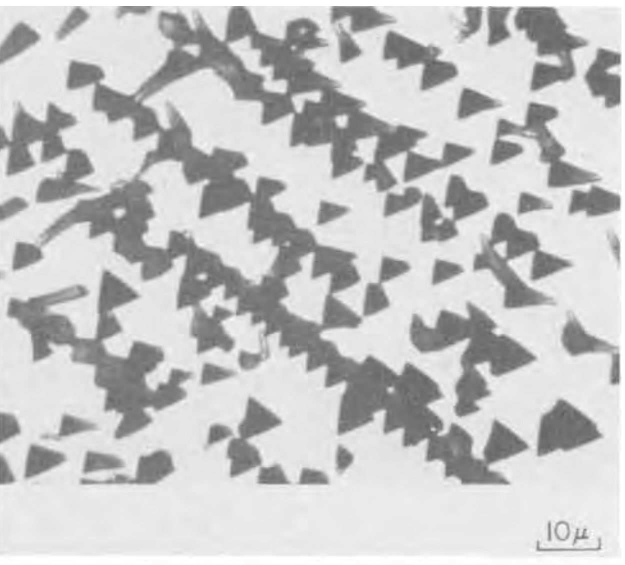

Fig. 8. Anomalous etch pits on a P($\bar{1}\bar{1}\bar{1}$) surface of a highly Zn-doped VG crystal.

been found that the anomalous defects were generated by thermal oxidation of GaP crystals previously doped with Zn or Cd. Interference color films were formed on the oxidized surfaces and the films were identified as being primarily $GaPO_4$ by x-ray diffraction method. The formation of $GaPO_4$ by the thermal oxidation of GaP crystals has previously been reported by Gershenzon *et al.* (1) and Rubenstein (2). Surfaces of samples annealed in vacuum were inspected with an optical microscope, and it was found that there was no visible trace of the oxide films. Relatively few anomalous etch pits (density: 10^2-$10^4/cm^2$) were found in some as-grown Zn-, or Cd-doped VG crystals as was described in the section on Vapor-grown crystals. However, after the thermal oxidation and subsequent etching of these crystals with the ferricyanide etchant, it was found that many more (10^5-$10^6/cm^2$) anomalous etch pits were newly formed on the surface (Fig. 9). It was found that some anomalous etch pits were distributed on intersections of the surface with stacking faults or on microtwin lamellae parallel to the <110> directions on the P($\bar{1}\bar{1}\bar{1}$) surfaces. Successive polishing and etching showed that the newly formed defect is a short line defect (less than 20μ in

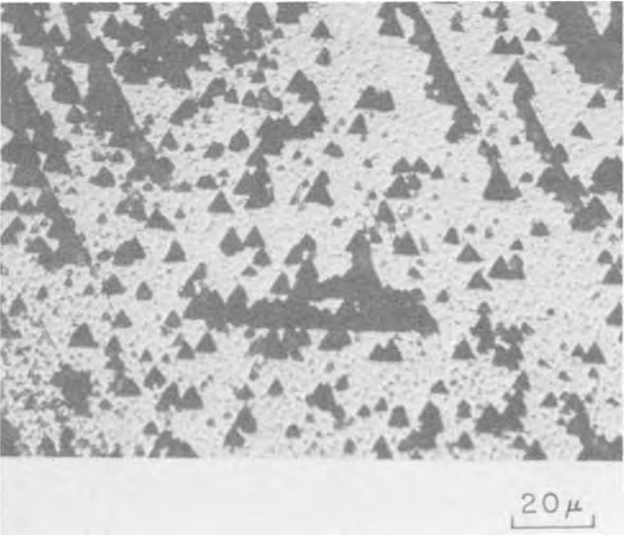

Fig. 9. Anomalous etch pits on a P($\bar{1}\bar{1}\bar{1}$) surface developed with ferricyanide etchant after thermal oxidation of a Cd-doped VG crystal ($N_A - N_D = 8 \times 10^{17}/cm^3$).

length) and that the density is highest, 10^5-10^6/cm^2, on the exposed surface and gradually decreases to the original value at a certain depth (~20μ from the exposed surface). On the other hand, annealing of these crystals in high vacuum (≤10^{-7} Torr) at 850°C for 5¾ hr, and subsequent etching did not reveal any new anomalous etch pits on the surfaces. Annealing in low vacuum (≤10^{-3} Torr) and etching sometimes produced new anomalous etch pits of a low density (10^2-10^4/cm^2) and sometimes did not produce the pits. These results indicate that these anomalous defects are produced by thermal oxidation and that the oxidation occurs readily even in the presence of a minute amount of residual air in the ampoule in the case of low vacuum sealing (≤10^{-3} Torr). When Te-doped VG crystals ($N_D - N_A \sim 3 \times 10^{16}$, 1×10^{17}/cm^3) were oxidized under identical conditions, no anomalous etch pits were produced on the surfaces.

Discussion

Correlation of the anomalous defects with dislocations.—A good correspondence between the distributions of the anomalous etch pits on the cleaved halves (Fig. 7) indicates that the anomalous defect is a dislocation. At the periphery of the {111} cross-sectional slices of Czochralski-grown crystals, arrays of dislocation etch pits running parallel to <110> directions are frequently observed as star patterns (6). These dislocations are attributed to slip caused by thermal stress during crystal growth (6). Therefore, the arrays of the anomalous etch pits in the <110> directions at the periphery of the LEC crystal, RD 43 (Fig. 4), suggest that the anomalous etch pits are attributed to grown-in dislocations. Dislocations are frequently generated around impurity inclusions in various kinds of crystals due to the difference of thermal expansion coefficients between the inclusion and the matrix. The clusters of the anomalous etch pits around the impurity inclusions (Fig. 6) indicate that the pits are due to the dislocations. Therefore, it has been concluded that the anomalous defect is a dislocation, or rather an anomalous dislocation.

Thermal oxidation-induced anomalous defects.—It has been deduced that the thermal oxidation-induced defects are identical with the anomalous defects observed in as-grown crystals from the following results:

(*i*) The characteristic etching behavior of the oxidation-induced defects is the same as those of the grown-in anomalous defects. That is, oxidation-induced defects are revealed distinctly with the ferricyanide etchant as dark etch pits both in the P($\bar{1}\bar{1}\bar{1}$) and {110} surfaces.

(*ii*) The detailed structure of the thermal oxidation-induced pits as obtained with a scanning electron microscope is the same as that of the grown-in defect.

(*iii*) The oxidation-induced defects are formed in highly Zn-, or Cd-doped VG crystals. The grown-in anomalous defects are found in as-grown crystals doped with the same kind of impurities.

(*iv*) The oxidation-induced defects are preferentially located on stacking faults or on microtwin lamellae in the VG crystals. This behavior is the same as that of the anomalous defects in as-grown VG crystals.

At the present time, there is no decisive evidence that the location of the oxidation-induced anomalous defects corresponds to that of grown-in dislocation outcrops. As was described in the section on Thermal oxidation-induced anomalous defects, however, the oxidation-induced anomalous defects are line defects (less than 20μ in length) propagating from the surface into the bulk. Also, the densities of the oxidation-induced anomalous etch pits at the oxidized surfaces are nearly the same as those of grown-in dislocations. Therefore, it is believed that dislocations close to the

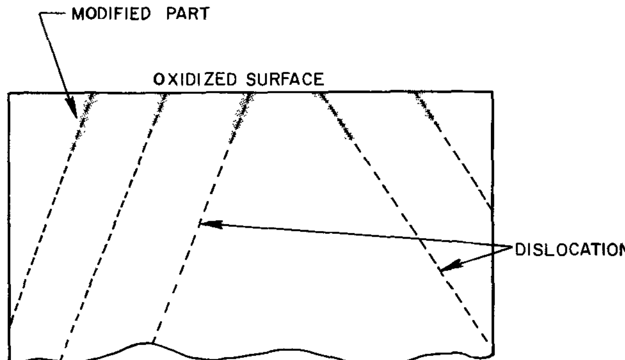

Fig. 10. A proposed structure of thermal oxidation-induced anomalous defects.

oxidized surface are partly modified to form the anomalous defect as schematically shown in Fig. 10, and that oxygen plays a role in the formation of the anomalous defect.

Correlation of the anomalous dislocation with impurities.—As was described in the section on Results, the anomalous dislocations were found in highly $Zn(PO_3)_2$-doped LEC crystals, but they were not detected in highly Zn-doped LEC crystals. In highly Zn (or Cd)-doped VG and SG crystals, however, they were formed. No anomalous dislocations, however, were found in S-, or Te-doped VG and SG crystals. Also, they were not found in undoped, highly S-, or Ga_2O_3-doped LEC crystals. On the other hand, the anomalous dislocations were newly formed by the thermal oxidation of highly Zn-, or Cd-doped VG crystals. From these results, it has been concluded that the anomalous dislocation is correlated with some impurities. It seems probable that the relevant impurities are both zinc (or cadmium) and oxygen, or zinc (or cadmium). At the present stage, however, there is no decisive proof that the impurities are both zinc (or cadmium) and oxygen, or zinc (or cadmium). A definitive identification of the impurities remains to be obtained.

The distinct development of the anomalous etch pits on the P($\bar{1}\bar{1}\bar{1}$) and the {110} surfaces with the ferricyanide etchant is probably due to such a characteristic nature of the defects. Also, for the same reason, the large anomalous etch pits are formed in the region I and III of Fig. 3 which are believed to contain higher concentrations of the impurities than the rest. Further investigation of the anomalous dislocation is in progress.

The Heterogeneous Precipitation of Silicon Oxides in Silicon

ABSTRACT

Long-time, high-temperature oxidation of dislocation-free silicon single crystals is observed to result in the precipitation of silicon oxides. Precipitation is found to occur in banded or striated distribution across the oxidized wafers. The distribution pattern assumed by the precipitates is identical to the pattern assumed by shallow, noncrystallographic etch pits observed upon etching the unoxidized wafers. By employing optical and transmission electron microscopy, the distribution, the morphology, and the structure of the precipitates have been examined. The precipitates are distributed in discrete clusters separated by precipitate-free regions. They have been identified to be a mixture of both α and β crystobalite. The formation of precipitates results in the faceting of the crystal surfaces as a result of the diffusion and oxidation inhibiting effects of the precipitates. The heterogeneous nucleation is postulated to occur at vacancy clusters in the crystals, and models are presented for the nucleation phenomena and to account for the faceting effect of the precipitates.

The behavior of oxygen in single-crystal silicon has been a subject of great interest over the years. As is well known, oxygen can be associated with silicon in the form of a dissolved impurity incorporated into the crystal during growth. It can also be introduced into the crystal by diffusion during thermal oxidation. The solid solubility limit of oxygen in silicon has been reported to be in the range of 10^{18} atoms/cm^3 (1). Excess oxygen above the solubility limit can precipitate. The phenomenon associated with the precipitation of oxygen in silicon has been studied by a variety of techniques. Among the principal techniques and the essential results obtained the following stand out:

(*a*) Perhaps the most extensively used method for detecting the presence of oxygen in silicon is the infrared absorption technique. The infrared absorption band of silicon at 9μ is found to be related to a silicon-oxygen molecular vibration. From the observation of a decrease in this absorption band when silicon containing dissolved oxygen is heat-treated at elevated temperatures (~1000°C), the hypothesis of clustering and precipitation of oxygen in the form of Si-O complexes has been advanced (2-5). Corbett *et al.* (6) have proposed the existence of a number of vacancy-oxygen complexes as evidenced by the appearance and the disappearance of infrared absorption bands of different wavelengths when irradiated silicon is annealed.

(*b*) In recent years, careful observation of the surfaces of Sirtl (7) etched silicon crystals has revealed the presence of large densities of noncrystallographic etch pits. These etch pits, which appear roughly circular when viewed at high magnification, have been variously called anomalous etch pits, empty etch pits, and saucer pits. These pits have been related to vacancy-oxygen complexes in the crystal (8). A large concentration of vacancies are retained in crystals grown from the melt. These vacancies are then postulated to interact with dissolved oxygen during the cooling stage with the resulting complex having a mobility less than that of either individual vacancies or oxygen atoms. With increasing size, these complexes become immobile and eventually can be observed by the etch pitting technique or by x-ray techniques following suitable decoration by a fast diffusing metal such as copper (8).

(*c*) X-ray diffraction methods have been used to detect the presence of small, localized, strain-producing centers by first decorating these centers with copper (*9*). X-ray transmission topographs of copper-decorated crystals have revealed the presence of radial distribution of strain-producing centers which have been suggested as being due to oxygen-vacancy complexes. The anomalous x-ray transmission technique was employed by Patel and Batterman (*9*) to detect the presence of a pre-precipitation stage in silicon. They observed a reduction in the anomalously transmitted x-ray intensity when silicon containing oxygen was heat-treated at 1000°C. This change in the transmitted x-ray intensity was observed to occur before the decrease in the 9μ infrared absorption band manifested itself, indicating that early stages of impurity clustering were affecting the anomalous x-ray intensity.

Other evidence for precipitation of oxygen is found in the observation that new donor states are introduced into silicon following low-temperature annealing (<500°C) (10). These donors can be annealed out at high temperatures (~1000°C) and the donor concentration is found to be related to the measured oxygen concentration in the crystal. Heat-treatment of silicon has also been observed to influence its plastic deformation characteristics and it has been proposed that silicon-oxygen clusters function as dislocation generating sites during deformation (11).

Precipitation of SiO_2 has been observed to occur at dislocations when silicon is annealed at high temperatures for extensive periods of time in oxygen ambients (12). It has been suggested that SiO_2 precipitation occurs when silicon containing oxygen is heat-treated at high temperatures (13).

The heterogeneous precipitation of impurities can also occur at strain-producing centers other than dis-

Key words: oxygen, vacancies, clusters, crystobalite.

locations. The technique for investigating the nature and distribution of vacancy clusters in silicon uses this phenomenon of heterogeneous precipitation. Both copper (8) and lithium (14) have been found to preferentially precipitate at vacancy clusters. Batavin (15) has suggested that SiO_2 precipitates nucleate at vacancy clusters.

The present work is concerned with the precipitation of the oxides of silicon in dislocation-free crystals. The effects of extended oxidation on the nature and distribution of crystalline silicon oxides in silicon are examined.

Experimental Procedure

Single crystals grown by both the floating zone and Czochralski techniques were the vehicles for the experiments. The crystals were dislocation free and wafers cut from the crystals were chemically-mechanically polished to remove surface damage. The wafers were oxidized at 1200°C for periods of time ranging from 1 to 60 hr in a steam ambient. Careful precautions were taken to avoid the generation of dislocations in the wafers due to thermal, stress-induced slip. The distribution, the morphology, and the structure of the precipitates formed were investigated by optical and transmission electron microscopy. For transmission electron microscopy, thin foils were prepared by the conventional jet thinning techniques. The oxygen content of the crystals prior to oxidation varied from a high value of $\sim 10^{18}$ atoms/cm^3 to below the detectability limit for the floating zone crystals.

Experimental Results

Extended oxidation of dislocation-free wafers resulted in distinct effects when the as-grown crystal contained an inhomogeneous distribution of vacancy clusters. Considerable evidence exists in the literature that vacancy clusters frozen into the solid during crystal growth function as heterogeneous nucleation sites for metal precipitates (8, 14) as well as for the formation of extrinsic stacking faults (16, 17). Long oxidation at high temperatures ($>>2$ hr at 1200°C) resulted in the formation of discrete precipitates. These precipitates formed in regions of the wafer which contained a high density of vacancy clusters as evidenced by the observation of a high density or noncrystallographic etch pits upon preferential etching prior to oxidation.

Surface structure.—Following extended oxidation the SiO_2 films formed were removed by dissolution in HF and the surfaces observed using optical microscopy. At low magnifications, the oxidized wafers were found to exhibit a banded or sometimes spiral shaped distribution of bright and dark regions. The changes in the surface brightness were related to the changes in the direction of scattered light from the surface. The patterns of differing brightness were identical to the patterns of shallow etch pits observed prior to oxidation and following preferential etching. The significant difference was that following extended oxidation the banded or "swirl" type patterns become observable without the need for preferential etching such as Sirtl etching or the equivalent. These patterns were frequently observable through the SiO_2 films formed on the surface. Figures 1a and b are typical examples of wafers exhibiting this behavior. In Fig. 1a, bright bands are observable across the wafer whereas in Fig. 1b, the central portion of the wafer contains a circular bright region.

Examination of the surfaces at high magnification using interference contrast techniques revealed that the bright regions of the wafers were composed of varying densities of star shaped or square hillocks with an apparent presence of a second phase at the apices of the hillocks. Figures 2 and 3 show interference contrast optical micrographs of the surfaces of the oxidized wafers. In Fig. 2 are shown micrographs obtained at different regions of a <111> oriented wafer. The star shaped hillocks vary in density from near zero to 10^7/cm^2 (as subsequently determined by transmission electron microscopy). The four micrographs in Fig. 2 show the typical density distribution of the hillocks in a wafer. The apparent presence of a second phase at the apices of the hillocks is also revealed in these micrographs and was subsequently confirmed by electron microscopy as discussed in the next section.

Figure 3 shows similar hillock formation on <100> oriented wafers. In this case, the hillocks are in the

form of squares. The hazy regions of the wafer observed when viewed at low magnification are evidently a result of faceting of the crystal surface.

Precipitate morphology and distribution.—Transmission electron microscopy at regions which generated surface hillocks confirmed the presence of precipitates in the crystal. A notable aspect of the precipitates was the striking nature of the precipitate distribution. Figure 4 is a transmission electron micrograph of precipitates in a <111> oriented wafer. These precipitates were generated as a consequence of a 1200°C oxidation for 10 hr. The following are the significant features of the precipitate morphology and distribution:

(*a*) The precipitation is observed to have occurred in discrete regions with clusters of precipitates concentrated within an area of ~1 μm^2.

(*b*) The precipitate density within the clusters has been found to vary from a single particle to 10^{10} precipitates/cm^2.

(*c*) The particle size within each cluster has been found to range from ~100 to ~4000Å with occasional large individual particles ~1 µm in size.

(*d*) The clusters are separated by distances of 1 µm or more with almost completely precipitate-free regions surrounding each cluster. The density of precipitate clusters has been observed to be as high as $10^7/cm^2$. Although the individual precipitate particles exhibited no characteristic shape, the clusters displayed a tendency to form in triangular patterns [on (111) surfaces] with edges aligned along equivalent <110> directions.

Since the crystal surfaces were found to be nonplanar with discrete hillocks at the site of each precipitate cluster, it should be expected that the nonplanarity affect the observed diffraction contrast in the electron microscope. This expectation was borne out when the specimens were oriented for exact two beam diffracting conditions. Figure 5 shows the precipitate clusters imaged under two beam (Si reflections) bright field conditions. Each precipitate cluster is surrounded by triangular shaped thickness extinction contours appearing as alternate dark and bright bands. This verifies the facts that each cluster is situated at the apex of a triangular shaped hillock in the silicon. The degree of surface tilt associated with each cluster would determine the number of fringes observed around the clusters. From an examination of a large number of specimens, it was found that the number of dark and white fringes surrounding the precipitates varied. Figure 6 shows a case where the precipitate cluster is surrounded by one dark and one bright fringe. Figure 7 is a {220} weak beam image of a number of precipitate clusters with differing numbers of thickness extinction contours around the different clusters. A rough estimate of the tilt in-

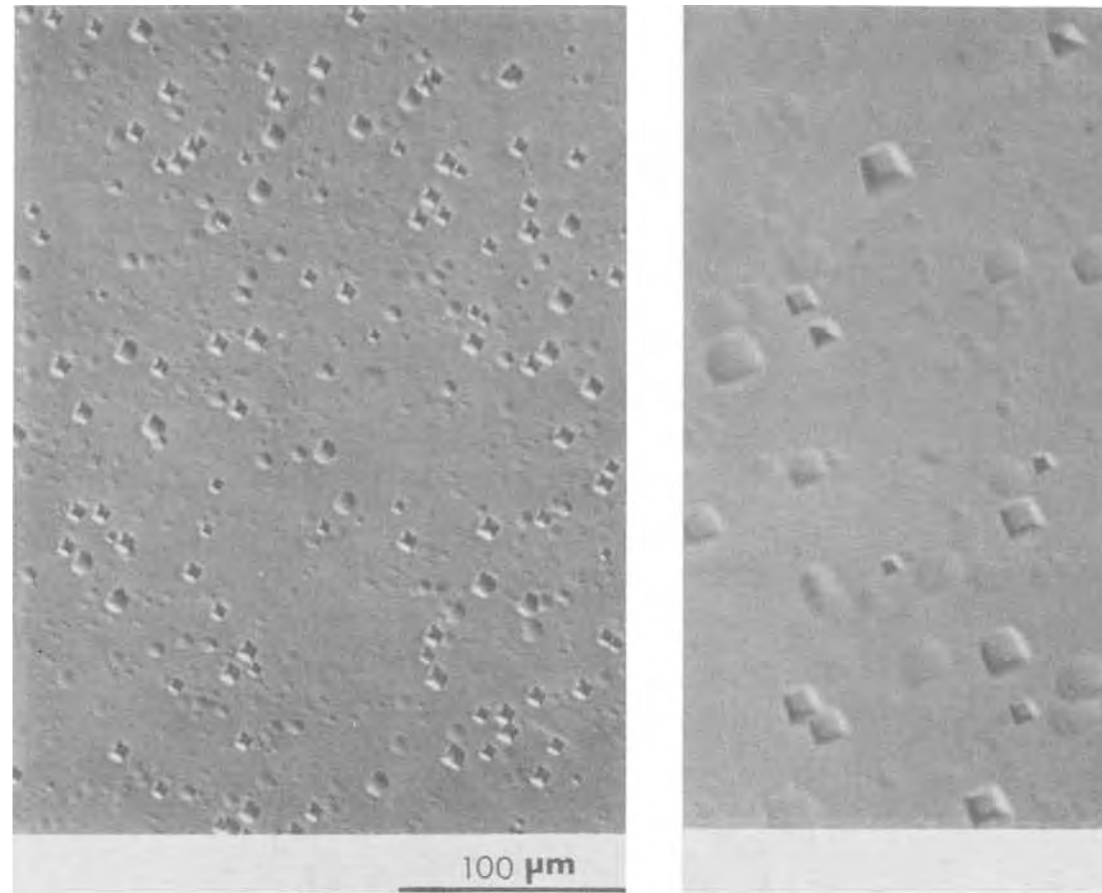

Fig. 3. <100> oriented wafers showing the formation of square shaped hillocks after extended oxidation.

volved at each hillock can be made by using weak beam imaging techniques and the method described by Bicknell (18). The width of the extinction fringes around the precipitate clusters was measured in the $\{220\}_{Si}$ weak beam image and using the formula $1/S'$ $\cot \theta =$ fringe width, the angle θ was computed. Here S' is the deviation parameter (19) and θ is the inclina-

tion of the surface at the facets (or hillocks) to the normal to the electron beam direction $\langle\bar{1}\bar{1}\bar{1}\rangle$ or the silicon surface. Figure 8 is a typical example of a {220} weak beam image of the precipitate clusters and the thickness extinction contours surrounding the clusters. From an analysis of a number of samples, it was found that the angle of tilt of the sides of the hillock with the surface of the sample varied between 0.7° and 2°.

Figure 9 shows precipitation in a $\langle 100\rangle$ oriented wafer. Figure 9a shows a single large precipitate located at the center of a hillock whereas Fig. 9b is a micrograph of a precipitate cluster. The thickness extinction contours again verify that the precipitates are located at the top of a hillock, in this case a square shaped hillock with the sides aligned along orthogonal $\langle 110\rangle$ directions.

mitted their identification by selected area diffraction analysis. Figure 10a and b show typical diffraction rings due to the precipitates seen in association with the silicon spots. Although each precipitate particle was a single crystal, the large particle density in any given cluster and the relatively small precipitate size resulted in discontinuous diffraction rings made up of spots. The two patterns shown in Fig. 10 were obtained from two different orientations, viz., (111) and (110).

Table I shows average interplanar spacings calculated from measured reflection spacings on the diffraction patterns. X-ray data on α and β crystobalite are also shown. The measured interplanar spacings can be correlated with the known interplanar spacings of both α and β crystobalite. A similar result was obtained by Bialas and Hesse (12) for precipitates nucleated at dislocations. They found, however, that some precipitates exhibited moiré patterns furnishing a second means of determining the precipitate structure. From the analysis, they concluded that the precipitates are predominantly β-SiO_2. In the present work, extensive examination did not reveal the presence of moiré fringes in any of the precipitates. This might indicate that no coherency exists between the precipitate and silicon lattices.

Although no strong displacement fringe contrast around individual precipitate particles was observed, frequently, the diffraction spots due to the precipitates were found to be streaked. Streaking or the observation of rel-rods can be attributed to either the existence of coherency strains or the presence of faulted structures. Examination of some of the larger particles exhibiting streaked diffraction spots indicated the possible existence of faulting within the precipitates. Figures 11a and b are bright and dark field images of a precipitate which gave rise to streaks at the precipitate reflections. The corresponding diffraction pattern from the precipitate is shown in Fig. 11c. The precipitate exhibits a high density of fine parallel striations. These striations are observed to lie normal to the direction of streaks in the precipitate diffraction spots. This is shown in Fig. 11c where the streaks (arrowed) are shown to be normal to the striations in the precipitate. The dark field image in Fig. 11b was obtained from the streak spots indicating that the streaking is associated with the striations in the precipitate. Similar striated structures have been shown to be a result of faulting in the structure (20). It can hence be concluded that the precipitates are faulted. The β-phase of crystalline SiO_2 is a high-temperature phase stable above 577°C and has a cubic structure (A_o = 7.18Å) whereas the α-phase is a low-temperature phase with a tetragonal structure (A_o = 4.971Å and C_o = 6.918Å). Consequently, the β-phase which would be unstable below 577°C could transform to the α-phase and if the transformation

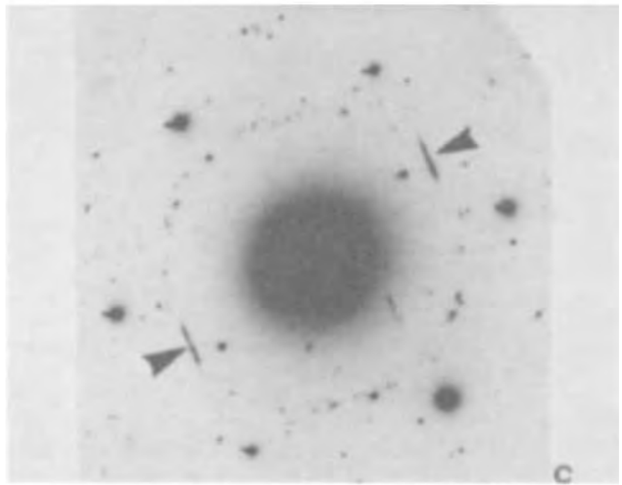

Fig. 11. Bright and dark field images (a and b) of precipitate showing the presence of a faulted structure; c is the corresponding diffraction pattern displaying streaked precipitate reflections. (The diffraction pattern has been rotated to correct for image rotation in the microscope.)

is incomplete due to thermal or strain energy considerations the structures resulting could be faulted. The classic case of faulting resulting from a phase transformation is the case of cubic austenite transforming to tetragonal martensite in ferrous alloys where the martensite phase is often found to be faulted and twinned.

Discussion

The results presented above show that oxides of silicon can heterogeneously nucleate at specific regions of a crystal, the nucleation sites not being dislocations, stacking faults, or other crystallographic defects. From the observation of the common distribution pattern of the precipitate clusters and the so-called shallow or empty etch pits observed on etched surfaces prior to oxidation, the precipitate nuclei are suggested to be vacancy clusters. These vacancy clusters or, more exactly, vacancy-solute atom clusters, are formed in the crystals during growth. The concept of vacancy-solute atom clusters functioning as nuclei for precipitation in solid solutions is not new. Hart (21) has suggested that precipitation processes are initiated by the migration of small groups of solute atoms and vacancies which gradually agglomerate to form large clusters which function as precipitate nuclei. Embury and Nicholson (22) suggest that the precipitate distribution in aluminum alloys is largely controlled by the distribution and concentration of vacancies. The stability of solute-vacancy clusters has been related to one of two causes. In one case, it is proposed that vacancies are integral chemical constituents of the precipitating phases which reduce the volume free energy of the system and facilitate nucleation and growth (21). An alternative proposal maintains that stable vacancy-solute atom clusters result purely from size effect considerations. If the precipitation of an equilibrium phase results in an increase in the atomic volume, the incorporation of vacancies in the precipitate nuclei will assist in the reduction of the misfit strain energy of the precipitate. It has been suggested that vacancy assisted nucleation occurs only in systems where an increase in the atomic volume takes place during precipitation (22). The high-temperature crystalline phase of SiO_2 forms with an increase in the atomic volume, the specific volume of SiO_2 being about 10% higher than of silicon. Consequently, precipitation of SiO_2 at sites of excess vacancy clusters is eminently feasible. The lack of evidence for any elastic or plastic strains around the precipitates indicates that the difference in atomic volume between the two phases (SiO_2 and Si) is accommodated by the vacancy clusters.

The quenched in supersaturation of vacancies, *i.e.*, the vacancy clusters can either be annihilated during oxidation by forming dislocation loops or, if the binding energy between vacancies and oxygen atoms is

sufficiently high, they can form stable complexes with oxygen. The absence of dislocation loops in the structures observed and the presence of precipitates indicates that the latter mechanism prevails. However, it is known that oxidation of silicon can also generate faulted dislocation loops at the sites of vacancy clusters (16, 23). This apparent dichotomy is related to the particular thermal conditions required to generate the two defect types, viz., faulted loops or oxide precipitates.

Precipitation of crystalline oxides occurs only with extended oxidation at high temperatures as demonstrated in this work. Stacking fault nucleation, on the other hand, occurs under more moderate conditions of oxidation or in the early stages of a longtime-high temperature oxidation process. The transformation of a vacancy cluster into secondary defects can be represented as follows:

Finally, since the initial indications of precipitation were evident as a result of faceting of the crystal surface, a model is proposed to account for this effect. As demonstrated, each precipitate cluster is observed to be located at the apex of a hillock or elevated region surrounded by facets in the crystal surface. The schematic sketches in Fig. 12 show the proposed model. The vacancy clusters distributed inhomogeneously through the crystal nucleate particles of crystalline silicon dioxide in the early stages of oxidation. The formation of the precipitates at the surface will inhibit further oxidation of the silicon at the precipitate sites. This can occur as a result of the oxide particles functioning as a mask to the diffusion of oxygen into the silicon as well as by preventing the silicon-oxygen reaction at the precipitate sites. Since the precipitates are closely clustered in discrete regions, oxidation of

$$\frac{a}{3}\{111\} + \frac{a}{6}\{11\bar{2}\} \rightarrow \frac{a}{2}\{110\}$$

—— Oxidation ——→ Further precipitation of crystalline SiO_2 at dislocations formed as a consequence of the unfaulting reaction.

The transformations depicted indicate that a vacancy cluster can nucleate oxide precipitates either directly or indirectly through a series of transformations involving a stacking fault. A brief examination of the feasibility of these two reactions and the probability of their occurrence is worth considering.

The discussion above indicates that the direct nucleation of crystalline SiO_2 at vacancy clusters is possible. This is aided by strain energy considerations as well as perhaps by the reaction kinetics of the system at high temperatures. However, the second reaction involving a stacking fault is also possible. As mentioned before, extrinsic stacking faults can nucleate at vacancy clusters. With longer oxidation, the faults can function as nucleation sites for precipitates of oxides. It has been suggested by Sanders and Dobson (24) that oxide platelets observed at stacking faults by Booker and Stickler (25) after severe oxidation are likely to be a result of preferential growth of the surface oxide into the silicon where the Frank dislocation intersects the oxide-silicon interface. The next stage in the transformation involves the annihilation of the stacking fault by the nucleation of a Shockley partial which reacts with the Frank to form an undissociated dislocation of the type $a/2$ {110}. This unfaulting reaction has been shown to occur in close-packed metals (26). The nucleation of a Shockley partial is stress aided, consequently misfit strains around a precipitate can initiate the unfaulting reaction. Experimental evidence exists to show that stacking fault annihilation in silicon occurs by the unfaulting reaction (27). The product of the unfaulting reaction is a dislocation which can function as a heterogeneous nucleating agent for further SiO_2 precipitation.

Although both mechanisms discussed are possible, the weight of evidence in favor of the direct nucleation mechanism is perhaps greater. The annihilation of stacking faults would result in dislocations which should be evident in the structures observed. As demonstrated, the structures observed were completely devoid of dislocations or stacking faults.

the surrounding precipitate-free silicon can continue unimpeded. This would result in a greater consumption of the silicon surrounding the precipitates leading to the formation of raised hillocks with the precipitates on top of the hillocks. The crystallographic nature of the hillocks, *i.e.*, triangular and square shaped on (111) and (100) surfaces is evidently a result of different oxidation rates on close-packed planes as opposed the rates on nonclose-packed planes. The effect is the analog of the formation of triangular and

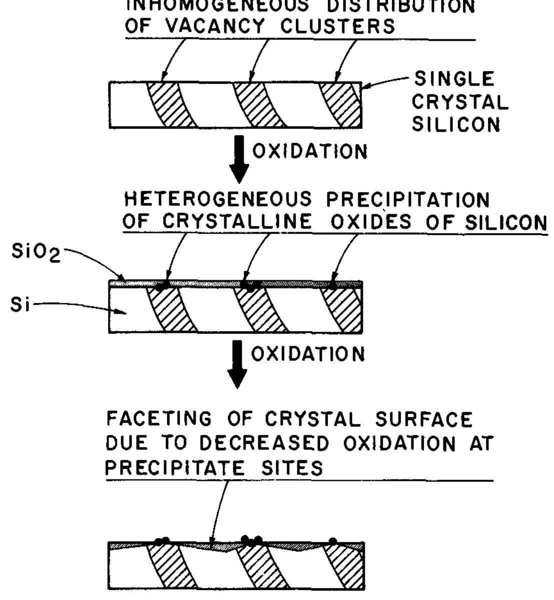

Fig. 12. Schematic sketches showing the proposed model to account for the faceting of the crystal surface as a result of precipitation.

square pits at sites of defects in crystals of the two orientations upon preferential etching.

Summary

In summary, it has been postulated that crystalline oxides of silicon can nucleate heterogeneously at sites of vacancy clusters. Both α and β crystobalite phases appear to coexist in the material. Some evidence for faulting in the precipitates is presented. The formation of clusters of oxide particles in the surface regions of the crystal leads to faceting of the surface due to the oxidation and diffusion regarding effect of the precipitates. The precipitation phenomenon is discussed with respect to models of nucleation at vacancy complexes and both direct and indirect nucleation models have been examined.

ABSTRACT

The application of Vickers microhardness to glass surfaces has been reviewed, and despite differences of opinion as to its theoretical significance, it is judged useful for engineering applications. The technique has been applied to the study of sintered films of borosilicate glass on alumina substrates. The range of glaze thickness and load magnitude for which the hardness remains unchanged is defined. The effect of the degree of sintering (*i.e.*, extent of densification), degree of phase separation, and aging of the HF etched surface on the microhardness have been measured. Hardness can also be used to detect surface stress which occurs in the region of glass-metal interfaces.

A characterization technique is desired to determine the effects of many processes and treatments on the nature of 1-5 mil thick glazed surfaces. The technique should be essentially nondestructive, able to be performed rapidly, and not be affected by inhomogeneities of the glass surface. Two alternatives for glass surface characterization are as follows:

(*i*) Infrared transmission spectroscopy yields considerable information about the composition of glass films (1). Although informative, it is limited to films generally below ½ mil in thickness and is an averaging technique over the area of the incident beam. In addition, transmission techniques generally yield information about bulk rather than surface characteristics.

(*ii*) Etching and corrosion studies also yield considerable information about glass composition (2, 3). Selective etching is also useful for determining strain and density in deposited SiO_2 films (4). Its destructive character is the main disadvantage of etching. Since

there is a wide variety of glass compositions, a corresponding variety of etchants is also needed.

Microhardness—Definition

For our purposes, we defined the hardness of a material as the resistance it offers to indentation by a much harder body. In practice, it is assumed that the indenter is so hard that it does not undergo any deformation. The hardness of the material under study is measured as the ratio of the load to the area of the permanent depression produced by that load. Hardness is therefore presented in units of pressure, most commonly kilograms per square millimeter. A very small square pyramidal diamond with 136° apex angle was used as the indenter in our experiments.

For 25-100g loads on hard glasses, the base diagonal of the indentation is only 8-16μ long and 1-2μ deep so the term "microhardness" is accurate. The small size of this indent makes it likely that it will be placed in a flawless area on most glass samples. For example, Ernsberger (5) has shown that in average plate glass there are about 10,000 flaws/cm^2, or an average of only one per 10^4 μ^2. One should be cautioned that while it is unlikely that an indent will fall on a glass flaw, the stress fields of flaws may be close enough to interact and give some value for the hardness below the ultimate hardness of the glass, due to the high magnitude of the stress fields around the flaws according to Shand (6) and Marsh (7).

History.—One of the earliest applications of hardness measurements to glass was performed by Taylor (8), but the first comprehensive study was by Ainsworth (9-11). Ainsworth established the useful range of the operating parameters in the actual indenting process, contact duration of the diamond with the glass surface, and the independence of hardness and applied load. Ainsworth also demonstrated that the general Meyer equation, $P = aD^n$, where a and n are constants, held for diamond indention on glass and that $a = 1$ and $n = 2$ within a load range of 10-140g.

Ainsworth also succeeded in showing many relationships between changes in hardness and other known properties of glass. For example, Poole (12) reported on the viscosity composition dependence of K_2O-SiO_2 glasses; he noticed an inflection in the 19 and 22% K_2O regions. Ainsworth's hardness *vs.* composition data shows inflections in the same composition region. Several other investigators have clearly demonstrated the correlation of microhardness with other properties of glass [*e.g.*, Douglas (13), Westbrook (14), Frischat (15), and Izumitani (16)].

More recent work by Prod'homme (17) takes issue with Ainsworth's contention that hardness is load independent. Some of the difference is due to the fact that Prod'homme made measurements up to a 300g load, much higher than those of other workers in the field. At this high stress, glass cracking can often be observed, as it was by us; it introduces a large variation in hardness measurements.

Prod'homme extended the hardness measurements to many soft glasses such as the selenides and antimonides, where Vickers hardness is only 10-25% of that of silica. By doing this, he was able to show a relationship between viscosity and hardness over a 25-fold range of microhardness.

The ease and precision of microhardness measurements have led to several attempts to find a basic mechanism for the formation of the indent in glass. However, there is no agreement on the physical meaning of Vickers hardness of glass. Ernsberger (18) maintains that hardness can best be interpreted through densification, while Marsh (7) claims a relationship between hardness and the elastic limit of glass. Regardless of the final resolution of this dispute there is a clearly established correlation between diamond hardness and observed strength of glasses (19).

Sample Preparation

Our studies were restricted to a commercially available borosilicate glass.[1] The samples were prepared in the following manner. (*i*) A slurry consisting of ball-milled glass in terpineol was deposited by spraying on 99% alumina substrates; (*ii*) after an initial drying cycle the samples were sintered at 810°C during a 45 min heating and cooling cycle in a controlled atmosphere, three-stage sintering furnace; (*iii*) in some cases after sintering, the glass surface was lapped flat and fire polished by passing through the furnace again.

Experimental Technique

It is extremely important to note that hardness data is only meaningful in a statistical sense. Thus, our technique was designed to minimize operator-dependent errors. A Miniload[2] hardness tester equipped with a Vickers diamond was used to perform these characterizations. The method consists essentially of bringing the diamond into contact with the test surface under controlled conditions with a known load and measuring the diagonal length of the resultant impression.

The diagonal length of the indent was measured with an eyepiece micrometer. The index line is first set at zero on the micrometer scale, scanned across the indent, and read only after final adjustment. In this equipment, the micrometer scale is not superimposed on the indent but is read at the bottom edge of the field of view. The operator can make successive measurements, uninfluenced by knowledge of previous diagonal lengths. Measurements were never made for periods exceeding 2 hr to avoid operator fatigue.

For the 136° square pyramidal diamond used the hardness can be calculated from $V_H = 1854\ P/d^2$. When P is in grams and d is in microns, the hardness units are in kilograms per square millimeter.

To test our technique a standard steel test block was measured. Table I shows these calibration results. Four groups of ten indentations were made in the test sample. To determine the best load application range, a series of measurements was made on borosilicate glass films on alumina substrates. These results are shown in Table II and are derived from four groups of five measurements at each of the indicated loads. In our case, the glass seemed to crack at load values above 100g.

The difference between the two standard deviations given in Table II for any sample and load is due to

850	—	—	717.5	16.69	742.4	14.05	753.8	10.46

two effects. One is caused by the difficulty of accurately measuring the dimensions of the indent; this is more prominent in the case of the lower loads which produce small indents in this hard glass. The second effect is due to significant differences in hardness between the very edges of a glaze film and the bulk of the surface. These two effects were reduced in subsequent experiments by making all hardness measurements at a 100g load in a relatively central area of the part.

Variations in hardness due to slurry batch-to-batch variations, origins of powder used to make the slurry, and spraying *vs.* doctor-blading application techniques were also studied. No statistically significant hardness variations were detected. Hardness was also found to be independent of glaze thickness in the 15-125μ range. However, thin glazes displayed an increased tendency to crack around the indent.

Sintering process effects on hardness.—In some initial experiments it was observed that fired sample hardness was lower than that of samples which had been fired, lapped, and refired. This variation suggested that the singly fired parts were not fully sintered. Consequently, an experiment was conducted where a series of parts was sintered at various temperatures with the hardness measured after firing and then again after being lapped and refired. Table III lists these results and Fig. 1 displays them graphically. Each entry in Table III represents at least two samples with seven measurements per sample. In a separate experiment the role of controlled lapping on the measured hardness of refired parts was investigated and found to be without effect.

Table III shows distinct time and temperature correlation, since refired parts had higher hardness at the same firing temperature than once-fired parts. This indicates more complete sintering and more densification. The shape of the curves also reveals that even the once-fired parts were essentially sintered at temperatures above 810°C, and no further densification was to be expected. Below 810°C the linear curve shows gradual pore elimination. Note that because of the time and temperature phenomena, the refired parts appear to be completely sintered at a lower temperature. This hardness measurement technique can clearly allow monitoring of processes dependent on sintering or densification. An additional experiment described in the section on aging effects shows that repeated firings at 810°C caused no further densification.

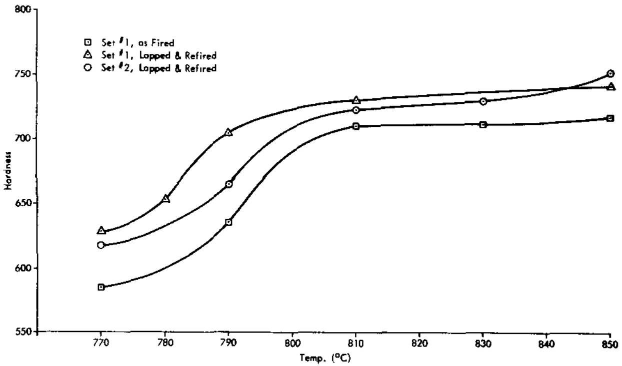

Fig. 1. Effect of firing temperature on hardness of borosilicate glass

Phase separation role.—Under the proper conditions, borosilicate glass tends to phase separate by two different mechanisms (20): spinodal and nucleation and growth into boron oxide and silica-rich phases. These phases may be fairly large in area, sometimes as much as 1-2 mil in diameter (21).

Since these two phases can differ markedly in hardness, measuring this characteristic should be useful for determining the extent of phase separation. Accordingly, five samples were prepared. Two were held for 24 hr at 750°C, two for 48 hr at 650°C, and the last was a control. From earlier work, it was expected that the control would be slightly phase separated and that the heat-treated samples would be extensively separated. Twenty-five hardness measurements were made on each sample and are shown as histograms in Fig. 2-6.

Figure 6, the control sample histogram, displays essentially a normal curve shape, implying a homogeneous surface with only measurement errors. On the other hand, Fig. 2-5 show a wide dispersion of hardness.

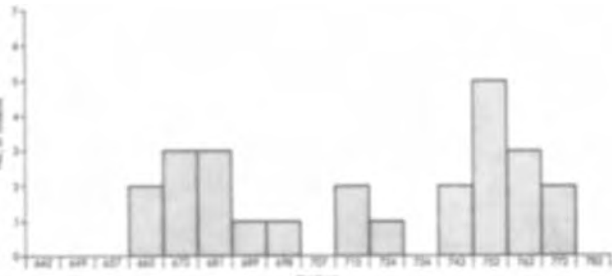

Fig. 2. Hardness distribution: 48 hr at 650°C (sample 1)

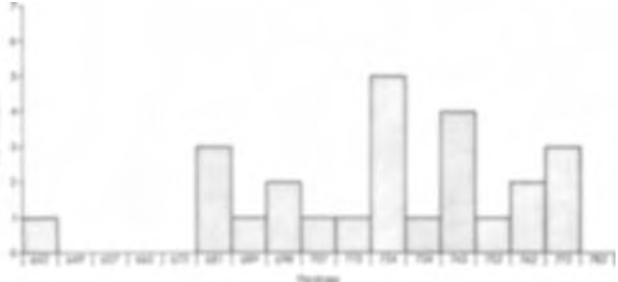

Fig. 5. Hardness distribution: 24 hr at 750°C (sample 2)

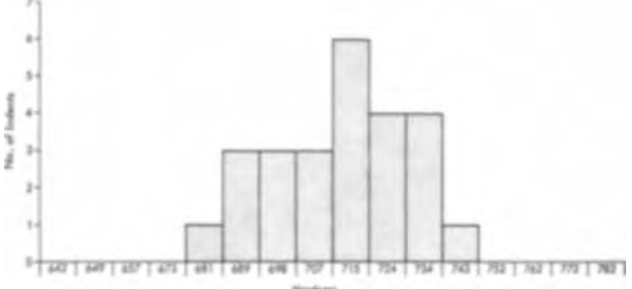

Fig. 6. Hardness distribution (control)

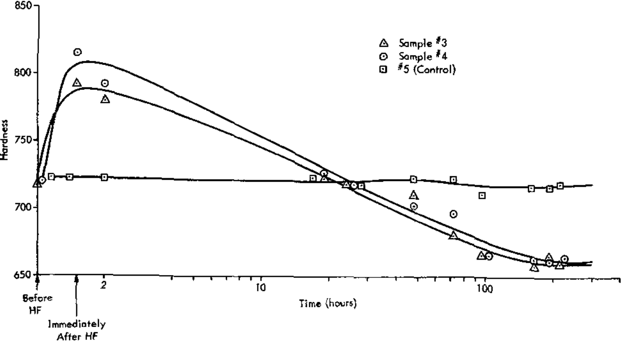

Fig. 7. Decay of hardness after HF etching

The higher values are thought to correspond to the indenter placement, primarily in a silica-rich phase, and the lower values to a boron oxide rich phase. The diamond pyramid hardness can be used to determine the extent of phase separation as long as the dimensions of the heterogeneous regions are of the same magnitude as the diamond impression. Despite this restriction, Vickers hardness measurements can be used to detect many types of surface inhomogeneities.

Glass surface stability.—The following experiments addressed some of the questions one might pose concerning the stability of a processed glass surface. The first experiment, as previously mentioned, examined whether repetitive firing at the critical temperature of 810°C caused the hardness to change. After eleven refirings there was no change in hardness or standard deviation. The second experiment examined surface hardness after HF[3] etching of the surface. Two parts were treated with HF and the third part was used as a control on the experiment. Table IV lists the hardness and standard deviation of these parts before and after treatment and until 9 days after treatment. Figure 7 shows these hardness values as a function of time. One additional part was HF etched, and immediately after etching was placed in an oven for 1 hr at 150°C. The hardness of this sample at all critical times is given in Table V.

A similar decay was observed in strength measurements on etched soda-lime glass by Ray and Stacy (22).

[3] One part 49% HF, seven parts DI water.

After 1 hr at 150°C	665.3/16.82
1 hr after cooling	670.0/16.16
1 day after HF cleaning	666.6/14.21

This decay is hypothesized to occur according to the following mechanism. Borosilicate glasses show a characteristic rise in hardness following HF surface etching, which is most likely due to rounding of flaw tips and the subsequent reduction of interaction of those flaw tips and the indenter's stress field.

The presence of phase separation permits substantially faster etching of the boron oxide rich phase than the silicon oxide rich phase. This selective etching increases the surface area. Contained on this surface area are an increasing number of phase boundaries which are probable sites for the initiation of new flaws. Another consequence of the increased surface area would be the opportunity for a higher flaw density and ultimately a hardness lower than the original hardness. Since the rate of flaw formation is expected to increase at higher temperatures, the rapid attainment of equilibrium hardness by heating is understandable.

Our final experiment examined the possibility of determining the amount of stress existing at a point on the glass surface. For this purpose, 700-800Å chromium films were vacuum evaporated on borosilicate glass surfaces heated to between 100°-250°C. These films were subsequently etched by conventional photolithographic processing into strips ¼ in. wide and a few inches long. The thought was to provide a highly stressed surface near the chrome strips to determine if this stress affected hardness. It was expected that the different substrate temperatures during evaporation would produce different stress values in the chrome. Hardness measurements were taken in five spots on and around the lines. The five spots measured were: 1, in the middle of the chrome lines; 2, at the edge of the line but on it; 3, half on the chrome and half on the glass; 4, on the glass at the edge of the line; and 5, approximately 1.0 mil away from the line in the glass. Figure 8 shows the location of the indentations. Five measurements were made for each site on each sample. Table VI lists the hardness results for each sample at each of the locations. The films had to be very thin to measure the hardness immediately adjacent to them because the very gradual slope on the diamond face would impinge upon a thick film. The hardness is quite low adjacent to the strips (positions 3 and 4); a small distance from the strip the hardness again returns to its normal value. This observation is consistent with the work of Carlson (26) on bonded laminates, from which we can infer that the residual stresses in the glass are largest near the edges of the metal film. As mentioned earlier, the indenter hardness is expected to decrease when mea-

sured in the immediate region of an existing stress field. These results tend to make us agree with Marsh (7) that the hardness measures some yield stress such as the maximum shear stress or the maximum principal stress. Thus, this tool seems to offer substantial promise as a qualitative microstress measuring device. To offer a quantitative tool, further refinements must be made experimentally and mathematically.

Conclusions

Vickers microhardness can be used to characterize many changes in a glass surface. Unfortunately, the hardness data cannot be reduced to indicate specific physical effects. Microhardness is especially valuable for studying surface inhomogeneities, surface stress, and surface density variations, *e.g.*, incompletely sintered glass surfaces.

Vickers microhardness has several technical advantages over standard measurements. These measurements can generally be made on actual parts rather than on special samples only. Hardness measurements can be made rapidly and are nearly nondestructive, since only a very small surface area is affected. Furthermore, microhardness is an especially valuable tool for glass surfaces because the ensuing measurements are usually flaw independent. Vickers microhardness measurements do have some limitations which should be restated: they are extremely operator dependent and are restricted to specularly reflecting surfaces.

A New Method for Chemical Vapor Deposition of Silicon Dioxide

Y. Avigal, I. Beinglass, and M. Schieber[*,1]

School of Applied Science and Technology, Hebrew University of Jerusalem, Jerusalem, Israel

ABSTRACT

A new method for the deposition of SiO_2 films prepared by the oxidation of alkyl-silane vapors is reported. It is found that the oxidation of tripropylsilane $(C_3H_7)_3SiH$ in oxygen at a temperature of about 650°C yields transparent adhesive and uniform films of SiO_2 grown on silicon substrates. The growth rate of the films as a function of various growth parameters is studied. The films have been characterized using *IR* absorption, spark source mass spectrometry, and emission spectroscopy. The structure of the films has been studied by optical microscopy and scanning electron microscopy and the index of refraction by ellipsometry. The applicability of these films to the planar MOS technology in microelectronics is evaluated by the following properties: etch rate, masking efficiency, flatband voltage, and electrical stability. Finally, the characteristics of MOS field effect transistors built with these oxides are given and shown to be almost comparable to those built with thermally grown SiO_2.

Dielectric films of SiO_2 for MOS application are usually prepared by thermal oxidation which is performed at temperatures between 900° and 1200°C. The thermally grown films are used as a selective masking (1) and as a gate (2) oxide. The disadvantage of the thermally grown oxide is a relative high temperature of formation which can cause a shift of the p-n junction boundaries during the oxidation. Films of SiO_2 produced by the decomposition of ethyl-silanes such as tetraethoxysilane, TEOS (3), have a high porosity and high etch rates, a tendency to cracking and a high load of carbon contamination. Therefore, they cannot be used as gate dielectric films. Thin films of SiO_2 produced by the method of oxidation of silane (4) have a low temperature of deposition but cannot be used as gate oxide unless an extra step of annealing at high temperature is added (11). This is due to the high flatband voltage and the low electrical stability of the MOS devices produced with these unannealed films.

We have been interested in studying the possibility of growing SiO_2 films at a relatively low temperature of deposition. The grown films should be used as gate oxides and selective masks against doping. The proposed growth method is that of chemical vapor deposition. CVD of SiO_2 films obtained by the oxidation of alkyl-silicon compounds. We have proved the compatibility of SiO_2 films produced by this method at temperatures as low as 700°C for the various uses of SiO_2 films in microelectronics.

Experimental Procedure

The films were deposited in an apparatus shown in Fig. 1. The source material for silicon was liquid tripropylsilane, TPS (K and K Laboratories, Incorporated) which was kept at a temperature of 30°C. The vapors of TPS were carried by a flow of N_2 and O_2 and deposited on a substrate of (100) n- or p-type Si with a resistivity of 10 ohm-cm. The Si substrate wafer is first brought to the desired temperature at a flow of 1800 cc/min pure N_2 in a resistance furnace. A total flow of 400-1410 cc/min O_2 is then introduced in the reactor and a part of the $N_2 + O_2$ mixture up to 240 cc/min is then passed over the TPS source material for 5-20 min. The coated SiO_2 wafers are then removed and the thickness measured with a Tolansky interferometer.

The reaction of deposition of SiO_2 in the case of complete oxidation of TPS can be written as

$$2(C_3H_7)_3SiH + 31\,O_2 = 2SiO_2 + 18CO_2 + 22H_2O$$

In fact the oxidation is not complete, as can be detected qualitatively by the smell of various organic by-products.

Figure 2 shows the variation of the rate of deposition of SiO_2 as a function of the substrate tempera-

Key words: thin films, SiO_2 films, MOS-FET devices, chemical vapor deposition, organometallic derivatives of silicon.

ture, at a constant flow rate of the gas mixture through the TPS bubbler. The oxygen flow was 400 cc/min and 1410 cc/min.

Figure 3 shows the variation of R with the flow rate through the TPS at a constant substrate temperature of 770°C, a flow rate of 1000 cc/min of N_2, and at a flow rate of 925 and 1410 cc/min of O_2 respectively.

Both in Fig. 2 and Fig. 3 R goes through a maximum which has a different location for different oxygen on over-all flow rates. We believe that both maxima are due to variation in the distribution of the amount of deposit along the reaction tube. This distribution was inspected and found to go through a maximum.

Differences in the O_2 flow rates do not seem to affect the rate of deposition *per se* but rather through its effect on the over-all flow rate, meaning, we believe, that even in the case of 400 cc/min O_2, there was an excess of O_2 to allow for complete oxidation of the TPS. All three deposition parameters, *i.e.*, temperature, over-all flow rate, and TPS concentration in the gas phase, affect the distribution of deposit along the tube. An increase in the temperature causes a higher temperature gradient in the entering gases with the result of a shift in maximum of the deposit distribution toward the inlet of the reaction tube. An increase of the flow rate causes a lower drift of the SiO_2 clusters along the gas stream which also causes a shift in the maximum of deposit distribution towards the outlet of the reaction tube. An increase in the TPS concentration in the gas phase causes a higher rate of nucleation and aggregation of the SiO_2, which shifts the maximum in the deposit distribution towards the inlet of the tube.

One can conclude that for a constant location of the substrates in the reaction tube, the deposition rate across it would go through a maximum when the combination of all three parameters would locate the maximum in the deposit distribution right above the substrate.

Characterization of the Grown Films

The TPS oxidized films have been analyzed by emission spectrography. Table I summarizes the experimental results. The only major impurities (noting the net impurities concentration) are B, Al, and Ca

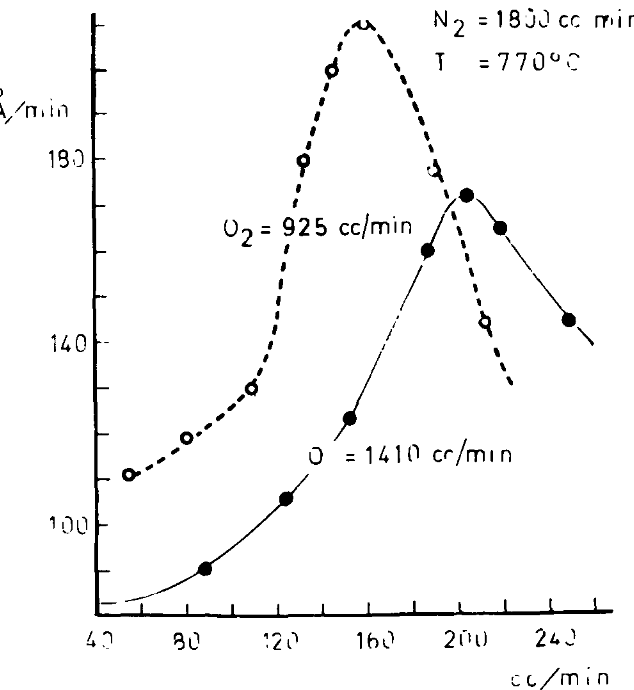

Fig. 3. The variation of the rate of deposition of SiO_2 films on Si by oxidation of TPS as a function of the molar fraction of TPS in the gas phase.

Table I. Emission spectrographic analysis (in ppm) of thin films of SiO_2 on Si substrate produced by the oxidation of TPS

	Blank	TPS	Net impurities in TPS
B	30-300	150-1500	120-1200
Si	6-60	30-300	23-240
Mg	5-50	30-300	25-250
Pb	30-300	20-200	—
Fe	0.6-6	10-100	10-94
Al	2-20	100-1000	100-1000
Ca	30-300	150-1500	120-1200
Ti	—	10-100	10-100
Cu	0.3-3	3-30	3-30
Na	30-300	30-300	—

which originate from the commercially available source material. No attempts have been made to purify the raw material. The procedure of the preparation of the sample on electrodes is solution of the SiO_2 film by hydrofluoric acid (at this step the Si forms gases) damping the electrode in the solution and drying the electrode.

The carbon contamination of the SiO_2 films has been analyzed by spark source mass spectrometry. The total amount of carbon detected in our films is below 5 ppm. The very low carbon contamination in our films relative to the higher concentration in the TEOS grown films can be explained by the much higher oxygen concentration in our system which allows for a more efficient oxidation of the organic carbon.

The microstructure of the grown films has been analyzed by scanning electron microscopy. It has been found to be an island-type growth, the diameter of which first increases with the increasing temperature of deposition, and then decreases, as shown in Fig. 4B. It is interesting to note that with each temperature, there is a variation in the island diameter which corresponds to the temperature variation in the rate of growth, and even the shape of the respective curves is also similar, as can be seen by comparing Fig. 4B and 2. The thickness of these islands must be lower than their radius (which is 700-1000Å at most), otherwise the metallic layer in some of the built capacitors would come in contact with the substrate between those islands with the result of a short circuit. Such a behavior was not found.

The index of refraction of the SiO_2 films has been measured by ellipsometry. It has been found that the TPS oxidized films have a high index of refraction, 1.46-1.48 which is similar to that of the thermal oxide (5), or to the densified silane oxidized films (4) as can be seen in Table II which lists the index of refraction of SiO_2 films, grown by different methods.

The infrared spectrum of the SiO_2 films deposited at 750°C is shown in Fig. 5. It can be seen that there is no shift in the absorption band on annealing the deposit at 850°C.

The etch rate of the TPS oxidized SiO_2 films has been determined in both P etch (15:10:300 HF:HNO_3:

Table II. Refraction index *n*, etch rate (ER) in Å/sec in P etch and buffered HF, and the dielectric constant *E*, for SiO_2 films produced by different methods

Silane oxidation plus densification	1.46-1.49 (4)		18-21.3 (4)	
Pyrolytic decomposition	1.43 (6)	6-20 (6)		
Pyrolytic decomposition plus densification	1.45-1.46 (6)	2-2.9 (6)		
Thermal oxidation (steam)	1.475 (5)	2	18.1	3.83 (1KH)

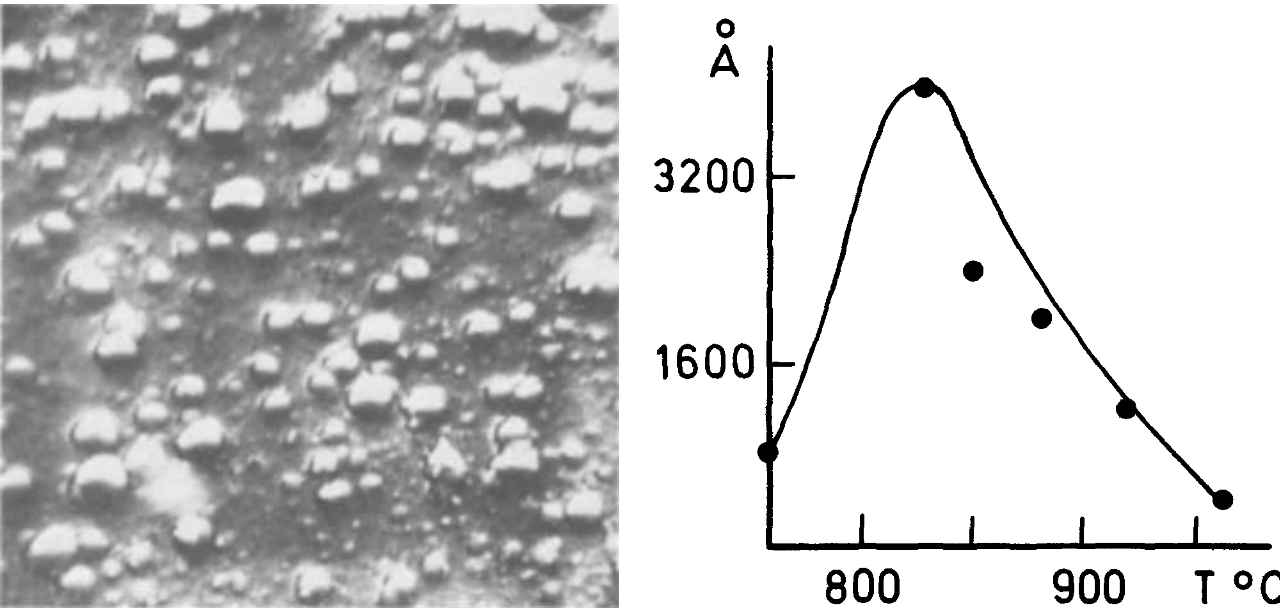

Fig. 4. The variation of the site of the growth islets of SiO_2 films as a function of the deposition temperature. (A, left) Scanning electron micrograph at 45° incidence and × 13,000 as a function of temperature. (B, right) Diameter in angstroms as a function of temperature.

H_2O) and buffered etch (454g NH_4F, 654g H_2O, 163 cc HF) and is listed in Table II. It can be seen that the TPS oxidized films have a low etch rate comparable to that of the thermal (6) or the densified silane oxidized films (4).

The masking efficiency of the SiO_2 films has been determined by measuring the diffusion of boron through TPS oxidized and thermally grown films, deposited on 1 ohm-cm n-type (100) silicon wafers. The source of boron used for diffusion has been BN wafers which are first oxidized at 900°C to form B_2O_3 (7). The oxidized BN wafers have been used to predeposit boron at 1150°C for 15 min in argon, followed by a drive-in process for 210 min at 1150°C. The SiO_2 films were removed after the completion of the diffusion process and the depth of p-n junction, X_j, was measured by the "lapping and staining" method (8), as a function of the thickness of the films, X_o. There is a linear dependence of X_j *vs.* X_o as predicted by the "two boundaries" model of diffusion (9) as shown in Fig. 6, for both thermal films grown in (wet O_2) at 1100°C and the oxidized TPS films deposited at 780°C. The slope of the line, r, is related to the diffusion constants of the boron in the SiO_2 film D_1 and in the silicon, D_2. The constant D_1 is determined by knowing r and D_2. Our shape of the graph of X_j *vs.* X_o is similar to that of Anand *et al.* (10). It can be seen that the D_1 values of the oxidized TPS films are similar to those of the thermally grown films.

The dielectric constants have been measured using a Boonton capacitance bridge. The results are summarized in Table II. The capacitance-voltage, C-V, curves of MOS capacitors produced by the oxidized TPS films, as deposited at 800°C has been measured and proved to have a high flatband voltage, V_{fb} of about 15V.

After annealing at 800°C for 30 min in N_2 the V_{fb} is reduced to −3V as shown in Fig. 7. The bias temperature, *BT*, stability test of the C-V curves measured at a field of $\pm 1.5 \times 10^6$ V/cm, and a temperature of

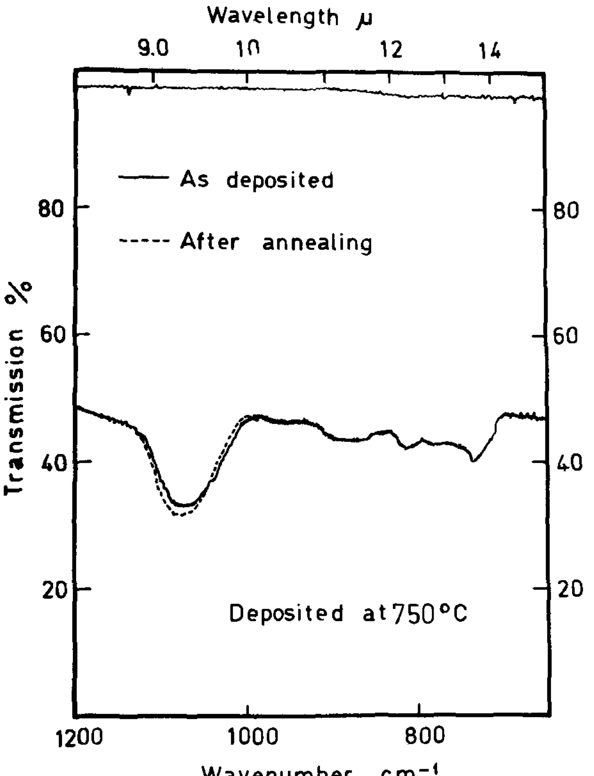

Fig. 5. Infrared spectra of the SiO_2 films as grown at 750°C before and after annealing at 850°C.

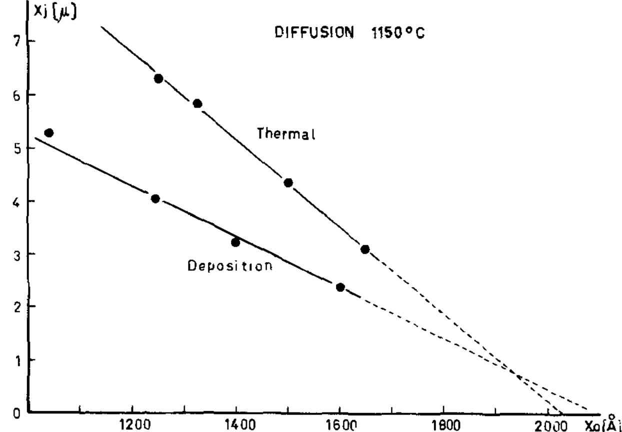

Fig. 6. Masking efficiency of the SiO_2 films against diffusion of boron at 1150°C for 210 min expressed in terms of X_o = thickness of the films (Å) as a function of X_j = depth of the p-n junction.

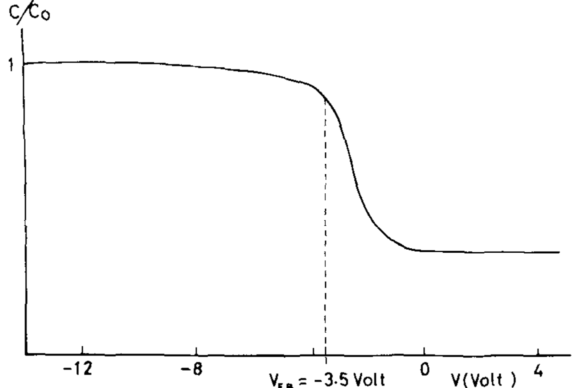

Fig. 7. Capacitance vs. voltage of the SiO_2 films after annealing at 800°C showing a flatband voltage of −3V.

250°C for 30 min have shifted the V_{fb} by less than 0.5V, which shows that MOS capacitors produced with the oxidized TPS films have a high electrical stability, and can be used as a gate oxide for MOS applications.

An MOS field effect transistor has been built using the oxidized TPS films of 1000Å thickness as the gate oxide. Figure 8 shows the current-voltage characteristics of the FET before and after annealing in N_2 for 30 min at 850°C. It can be seen that the amplification increases from 300 to 2000, for unannealed and annealed oxidized TPS films, respectively. Figure 9 shows the threshold voltage of the MOS FET produced with a gate oxide of oxidized TOS SiO_2 film as deposited and after annealing in N_2 for 850°C. It can be seen that the threshold voltage decreases with annealing from 16 to 2.97V respectively.

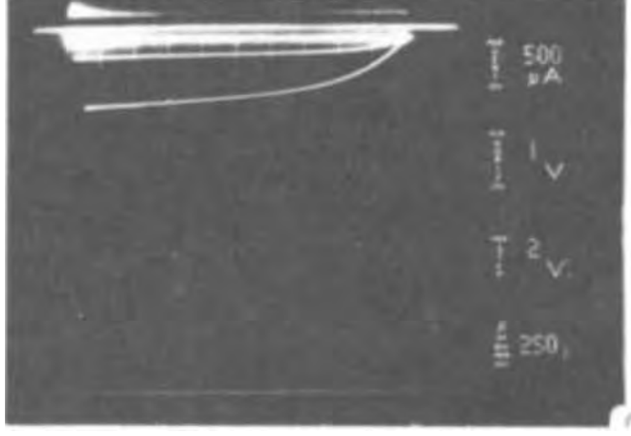
Table III. The diffusion constants is the SiO_2 films D_1 (cm^2/sec) and in the silicon substrate D_2 (cm^2/sec), and the ratio $r = (D_1/D_2)^{1/2}$ for films of SiO_2 grown by thermal oxidation (wet O_2) and oxidation of TPS. The diffusion temperature is 1150°C

Growth method	r	D_2 (cm^2/sec)	D_1 (cm^2/sec)
Oxidized TPS	2.16×10^{-2}	1.2×10^{-12}	5.6×10^{-16}
Thermal oxidation	1.25×10^{-2}	1.2×10^{-12}	1.87×10^{-16}
Thermal oxidation (9)	1.65×10^{-2}	4.2×10^{-13}	1.3×10^{-16}
Pyrolytic TEOS (10)	8.2×10^{-2}	2.5×10^{-13}	17×10^{-16}
Thermal oxidation	2.3×10^{-2}	2.5×10^{-13}	1.3×10^{-16}

Discussion

One of the advantages of the TPS oxidized SiO_2 films over the thermal films is a lower temperature of deposition. The annealing temperature of these oxides for their use as a gate oxide in MOS devices might be lowered below the 850°C currently used.

The values for the etch rate and index of refraction of our TPS oxidized films before annealing are equal to those of the oxidized silane and the decomposed TEOS films after annealing as can be seen in Table II. The stretching modes of the *IR* spectrum of our TPS oxidized films did not change their frequency after annealing while the oxidized silane or decomposed TEOS did change their frequency. All these facts prove that the oxidized TPS films, even unannealed, have a high density and a low porosity and, therefore can compare even to the thermal oxidized films as efficient mask against diffusion of boron. The diffusion constants D_1 of boron in the TPS oxidized films are only slightly higher than the thermally oxidized films and much lower than the decomposed TEOS as is seen in Table III.



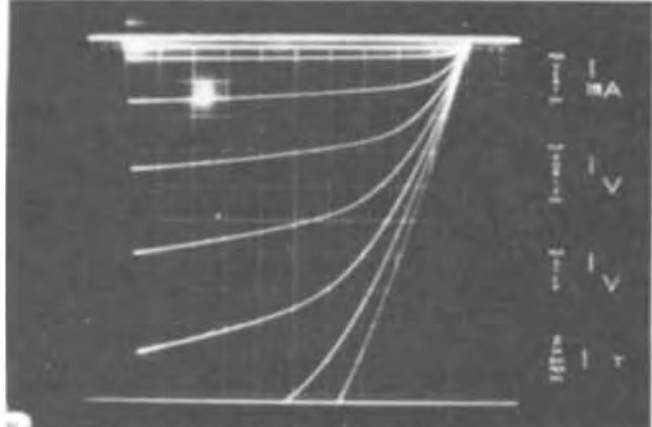


Fig. 8. Drain current T_D vs. drain voltage V_D before and after annealing of a MOS field effect transistor produced with SiO_2 film gate deposited from oxidized TPS before and after annealing.

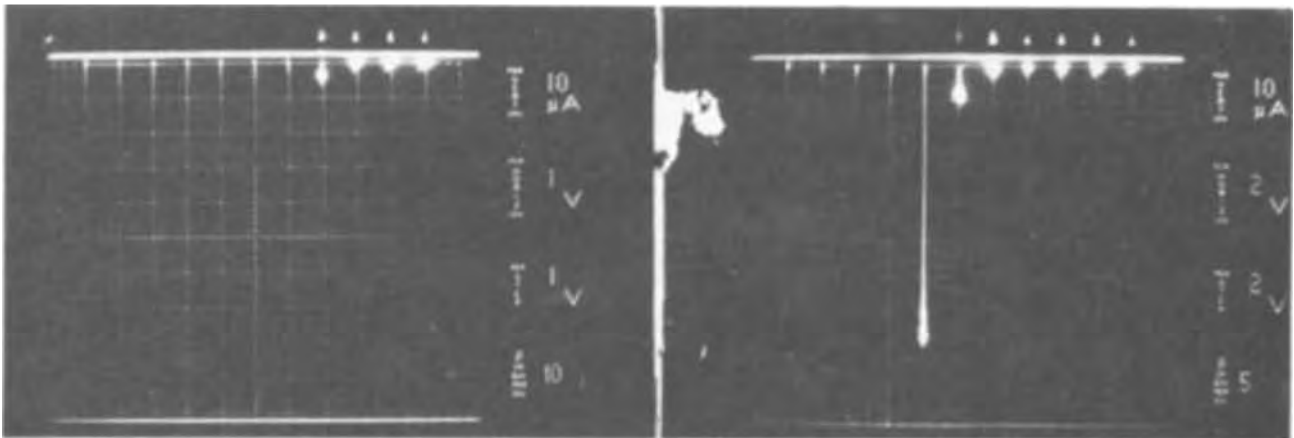

Fig. 9. Threshold voltage of the FET before and after annealing.

Only for the use as a gate oxide was it necessary to anneal the TPS oxidized films. Such an annealing process has reduced the defects and caused a reduction of the flatband voltage. The bias temperature stability of the *C-V* curves of the MOS structures grown by the oxidized TPS are comparable to those of the thermally oxidized films. The lower temperature of deposition of the TPS oxidized films offers a clear advantage over the thermally oxidized films since in the former case the lower temperature of deposition avoids any shift of the p-n junction boundaries, through diffusion.

Conclusion

It has been proved that the TPS oxidized SiO_2 films deposited at about 750°C even in an unannealed state can be used as an efficient mask against boron diffusion and if annealed at about 850°C can be used as a gate oxide in MOS devices. The quality of the TPS oxidized SiO_2 films is superior to that of oxidized silane or decomposed TEOS and almost comparable to that of the thermally oxidized films. The fact that they are grown at a much lower temperature than the thermally oxidized films makes the TPS oxidized films attractive for potential use in MOS devices.

Acknowledgments

The authors wish to thank Dr. K. H. Zaininger, Mr. J. Shaw, and Mr. F. Taft of the RCA Laboratories, Princeton, New Jersey, for their help in manufacturing the MOS FET produced with our gate oxide SiO_2 films prepared by the oxidation of TPS.

ABSTRACT

This paper reports a study of the water vapor pressure and low level sodium impurity dependence of the oxidation rate of silicon at 1000° and 1230°C. The oxidation studies were carried out in an rf heated cold wall oxidizer which is also described. The important aspect of the oxidizer is that the sample is placed between two closely spaced silicon blocks to give a very uniform temperature region and therefore uniform oxide properties. It is shown that the oxidation rate coefficient (in the parabolic range) increases monotonically with water vapor pressure. However, the rate also shows some dependence on the other gas phase constituents. At constant H_2O partial pressure the parabolic rate constant increases, going from H_2O-argon mixture to pure H_2O (vacuum) or H_2O-hydrogen mixture. For sodium concentrations in the range 0.4-10 ppm (atomic) in the water vapor atmosphere no changes in oxidation rate were observed at 1000° or at 1230°C.

The over-all phenomenology of thermal oxidation of silicon has been well established by many workers and is summarized by Deal and Grove (1) and Pliskin (2). More recently Revesz and Evans (3) have investigated the oxidation process with special emphasis on impurity effects. They report changes in the coefficients in the growth rate expressions due to sodium doping of the oxidizing atmosphere for certain restricted conditions. Also these authors (3) have assumed an expression to calculate the oxidant partial pressure (water vapor) in flowing systems which differs from conventional practice (4).

[1] Present address: Bell Laboratories, Reading, Pennsylvania 19604.
Key words: oxidation, silicon, impurities, rf heating.

One other study (5) has investigated the effect of sodium on silicon oxidation under conditions of high sodium content. However the oxide formed was an unidentified crystalline phase. Therefore these results do not appear to be relevant to this investigation.

In the present work, we describe a cold wall oxidation apparatus which has proved useful for producing films of uniform properties, in particular, oxide thickness and electrical characteristics. We have determined the water vapor partial pressure in several chemically different flowing atmospheres, and report the effect of these variables on oxide growth rate. Finally, we will present methods and results for growth of oxide films

in wet atmospheres of known sodium concentration in the range $\leq$ 10 ppm.

Experimental

The cold wall oxidation system is shown schematically in Fig. 1. The entire system is maintained within a closed laminar flow clean bench. The system is cleaned by etching and washing in the usual manner with filtered ($\lesssim$ 0.2 μm) deionized water of greater than 15 megohm-cm resistivity and sodium content $\lesssim$ 1 ppb.[2] All of the glass components are commercial high purity SiO_2 (G.E. 204 or 510). The only other parts exposed to the ambient of the sample are fabricated from Teflon or device grade single crystal silicon (see Fig. 2). The principal difference between this system and previous ones, *e.g.*, see Ref. (3), is in the use of a susceptor structure which completely encloses the sample. This is illustrated in Fig. 3, and contrasts with the usual practice of lying the sample on a heated substrate. In the present case the sample is in a cavity formed by a pair of nested single crystal silicon blocks,[3] as illustrated in Fig. 3. The temperature in the sample space has been measured by sliding the thermocouple (Pt-Pt 10% Rh), without the silica sheath that normally encloses it, along the entire length of the cavity above the surface where the sample is placed. The temperature was constant to within ±2°C. Power was supplied by a 450 kHz-10 kW generator which was simply set at a constant power level and was stable enough to maintain the

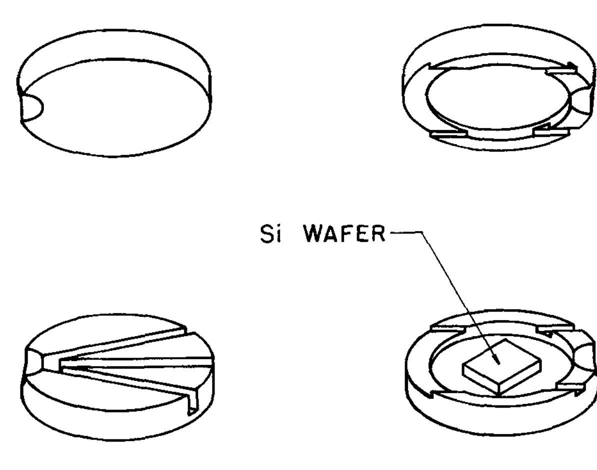

Fig. 3. Expanded diagram of the silicon susceptors for gas preheating and wafer oxidation. Dimensions of each piece are 2 in. diameter × ½ in. thick.

temperature constant to ±5°C for several hours at 1230°C. In addition, the gas atmosphere which flows over the sample is preheated to the same temperature as the sample. As a result, there was no difference in the measured temperature in the sample space with or without the flowing atmosphere (this was tested with 50 liters/hr of argon at STP). Equilibrium thermodynamic calculations of gas phase partial pressures are meaningful under these conditions.

Ambient atmospheres used for the oxidation consisted of pure water vapor and water vapor-argon or water vapor-hydrogen mixtures. The water vapor source and saturator for gas mixtures consisted of a two liter fused silica flask covered with a heating mantle. The water temperature was maintained by a controller (Fisher Scientific Company, Model 15-177-150) with a thermistor probe immersed in a well in the flask. This system maintains the water temperature constant to ±0.2°C. The gas was admitted to the saturator through a fritted silica disk. The degree of saturation of the argon or hydrogen was determined by disconnecting the system at point A in Fig. 1 and collecting the water by passing the gas through a condenser. This determination was made as a function of the saturator temperature for flow rates as measured at point C in Fig. 1. The flow rates used were determined by a standard wet test meter to be: argon, 51 liters/hr; hydrogen, 156 liters/hr. For these flow conditions the pressure in the system, as measured with gauges g_1 and g_2, never deviated from atmospheric by as much as 5%. When the flowing atmospheres were used the system was exhausted at point B in Fig. 1. In one series of experiments, oxidation was carried out in pure water vapor at various reduced pressures. For these experiments the pressure was controlled by setting the temperature of the vapor source at some value between 40° and 100°C. The pressure, as measured on gauge g_3 in Fig. 1, was then maintained at the vapor pressure of water (6) corresponding to the source temperature. This was done by adjusting a needle valve (V_1) in the line connecting the reservoir to a water aspirator.

When films were to be grown from water vapor contaminated with sodium, the following procedure was used. A two liter solution of a chosen concentration would be made up from deionized water and reagent NaOH. One liter of the solution was used as a vapor source for the oxidation. A separate fused silica boiler and oxidizer chamber, like those in Fig. 1, were used so as not to contaminate the apparatus used for normal clean steam growth. During growth, about 200 cc of the NaOH solution would be converted to steam. To determine the sodium content of this vapor, the solution in the boiler was replaced by the remaining

liter of original solution. Again about 200 cc of solution was converted to steam and collected at point A in Fig. 1. The sodium content of this solution was determined by measuring its conductivity at 60 Hz. The measurement was calibrated with standard solutions maintained at the same temperature (21°C). In all cases, the distillate naturally contained less sodium than the solution, *e.g.*, 10 ppm (atomic) Na solution gave a 1.2 ppm distillate. The sodium content of selected samples was determined[4] by standard etching and flame photometry methods (7, 8, 12).

The oxide film thickness was determined by multiple beam interferometry with the standard step etching and evaporated metal coating method. A Zeiss Model WL microscope fitted with a Leitz multiple beam interferometry attachment was used for these measurements (error ±1% in the range covered). Uniformity of oxide thickness over the wafer surface was determined from capacitance measurements. This was determined by a 1 MHz capacitance bridge C-V measurement (error ±1%) of many capacitors formed by evaporating aluminum "dots" (area = 2.1 mm² ±1%) through a mask over the surface of the oxidized wafer.

Results and Discussion

The results of the determination of the water vapor pressure in argon and hydrogen flow streams as a function of the saturator temperature are given in Fig. 4. The water pressure was calculated from the expression

$$P_{H_2O} = \left[\frac{n_{H_2O}}{n_{H_2O} + n_{gas}} \right] P_{total} \quad [1]$$

where P_{total} is essentially 1 atm. The n's are numbers of moles of water or gas (H_2 or Ar) which have passed through the system in some time interval. These were determined by collecting and weighing the water and measuring the gas flow rate at room temperature. The figure also shows by the curve (Revesz-Evans), the vapor pressure of water (6) in an arbitrary gas stream as calculated via the expression given in Table 3 of Revesz and Evans (3)

$$P_{H_2O} = \left[\frac{P_{pure\ H_2O}}{P_{pure\ H_2O} + P_{gas}} \right] P_{total} \quad [2]$$

While Eq. [2] appears to be a correct statement of Dalton's law, as it would be for a closed system, it is not applicable to a flowing system. We can see that this expression should be incorrect by going to the limit of a 100°C saturator temperature, *i.e.*, $P_{pure\ H_2O}$ = 1 atm. In this limit even though the gas pressure at the inlet to the saturator is 1 atm no gas flows in (neglecting diffusion). Therefore the gas flowing from the outlet is pure steam, however Eq. [2] would predict a water vapor pressure of ½ atm instead of 1 atm. From a comparison of the calculated curve with the experimental data, it is also clear that the method of calculation given in Ref. (3) is incorrect.

[4] The authors are indebted to R. Hunsberger of Western Electric Company, Reading, Pennsylvania, for performing these analyses.

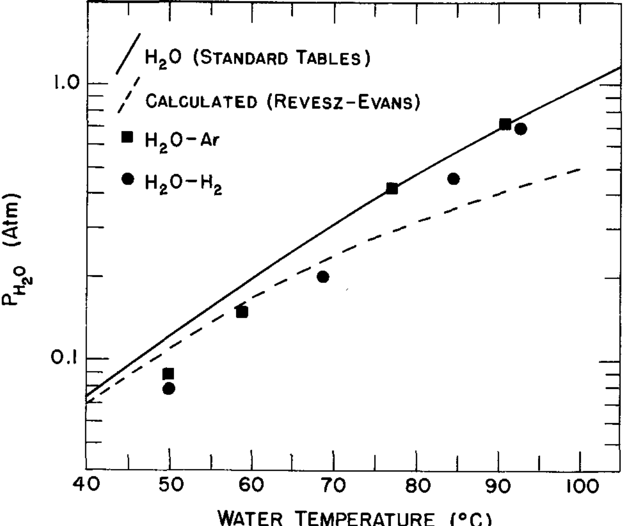

Fig. 4. Water partial pressure in flowing argon and hydrogen atmospheres as function of saturator temperature.

The final curve in Fig. 4 is the vapor pressure of pure water (6). Comparison of this curve with the data clearly indicates that the flowing atmospheres used in the present experiments were not saturated under all conditions. Studies were not carried out as a function of flow rates even though that might have resulted in finding conditions where saturation could be achieved (4). The rationale for this was that high flow rates were required to adequately flush the oxidizer tube and thus maintain an oxidation ambient of known composition. Since the steps taken in this work to reach saturation were not fully successful we suggest that the normal practice of simply bubbling the gas through the water is not likely to produce saturation. In that case, changes in gas flow rate might result in vapor pressure changes and thus in a corresponding fluctuation of the oxidation process. In Ref. (4) independence of oxidation rate on flow rate was used to indicate a saturated flow stream. While such a condition is practical, it is not necessarily saturated, *i.e.*, at equilibrium. It is only necessary to be in a steady state. We conclude that a flowing gas stream will not in general be saturated even if reasonable steps are taken and therefore the water pressure should be experimentally determined. This point has not been specifically established in most of the previous work (1-3).

Having established the growth conditions, the thickness of oxide grown was determined as a function of growth time. In the thickness range studied (0.1-1.5 μm), the thickness across a given sample, from capacitance measurements, was uniform to within ±3%. The oxide "quality" was measured by $\frac{Q_{FB}}{q} \left(\equiv \frac{C_{ox}\Delta V_{FB}}{q}, q = \text{magnitude of the electronic charge} \right)$ (7) as the oxidizer "cleaned up" by exposure to pure steam at the high temperature. Presumably this "cleaning up" is the leaching of impurities such as sodium from the silica walls of the system. This was shown to take place by Yurash and Deal (7) who measured the increased sodium content of steam as it passed through an oxidation system. Burgess and Donega (10) have also directly demonstrated the decrease in sodium content of the oxidizer atmosphere with time.

After about 50 accumulated hours at temperature, samples with Q_{FB}/q values below 1×10^{11} cm^{-2} were obtained. In the time range studied, 20 to 300 min, the oxidation time at temperature is well defined (±2% for the shortest times) as a result of the rapid heating and cooling of the rf heated oxidizer. The thickness-time relation was determined within experimental reproducibility to obey $x \propto t^{1/2}$, where x is oxide thickness and t is oxidation time. For films in the thickness range 0.1-1.5 μm this is to be expected, and thus values of the growth rate coefficient B of Ref. (1) were calculated [note: B is defined in the relation $x^2 + Ax = B(t + \tau)$]. The results are presented in Fig. 5.

The general agreement between our results and those taken from Ref. (1), and the essentially linear dependence on water pressure, are apparent. This result implies that the wet oxygen atmosphere used in Ref. (1) was saturated.

The deviation of the pure water vapor data from linearity, at low pressures, could be the result of a small air leak in the system. This is possible because the requirement of cleanliness prevents completely vacuum sealing (*e.g.*, by the use of grease on the joints). This would mean at low pressures the actual

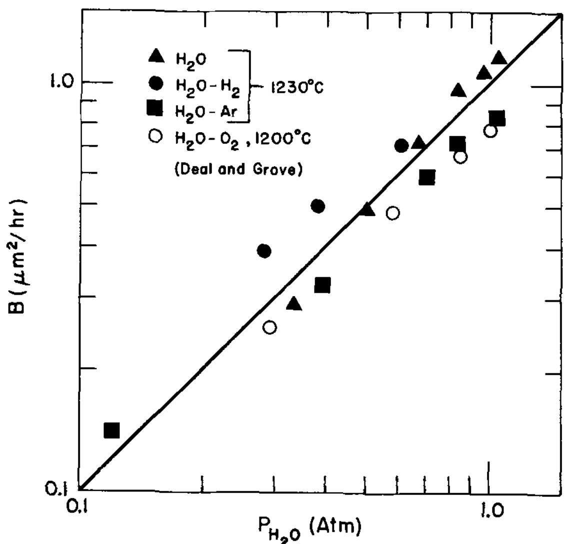

Fig. 5. Parabolic oxidation rate constant as a function of water vapor partial pressure. The 45° line on the figure is included only to indicate the form of a linear relation.

water pressure is less than that indicated so that the data points would move to lower pressure and thus nearer a linear relation. The differences for the several gas mixtures with the same water vapor pressure are outside the estimated error due to thickness and time measurements given above. However fitting the data to linear relations by a least-squares regression analysis gave the following values for the growth rate coefficients

pure water vapor, $B\,(\mu m^2/hr) = (1.13 \pm 0.13) P_{H_2O}\,(atm)$

hydrogen-water vapor, $B = (1.24 \pm 0.17) P_{H_2O}$

argon-water vapor, $B = (0.82 \pm 0.07) P_{H_2O}$

The error limits given specify the three standard deviation confidence band. Therefore we see that it is not statistically meaningful to distinguish between the pure water vapor and water vapor-hydrogen data. However there does seem to be a statistically significant difference between those data and the water vapor-argon data.

The expression for the parabolic growth rate coefficient in the phenomenological theory (1) is

$$B = \frac{2D_{eff}C^*}{N_1}$$

The symbols have the same meanings as given by Deal and Grove (1). C^*, the concentration of oxidant in the oxide at the gas-oxide surface, must be assumed to be proportional to the oxidant partial pressure to be consistent with the observed linear pressure dependence. In fact, the coefficient B should be proportional to the concentration of the diffusing species in oxide sites from which diffusion can proceed.

Deal and Grove (1) calculated this concentration and compared it to the water solubility of Moulson and Roberts (13) with good agreement. However as pointed out by Revesz and Evans (3) since Deal and Grove found $C \propto P_{H_2O}$ and Moulson and Roberts found $C \propto P^{1/2}{}_{H_2O}$ the agreement must be considered fortuitous. Pliskin (2) has also attempted to rationalize the linear pressure dependence on the assumption that ". . . the surface is covered with silanol groups. . .", resulting in the following reaction equation

$$2H_2O + 2Si \rightarrow 2SiOH + H_2$$

and

$$2SiOH \rightarrow 2Si + 2\,OH \text{ (into oxide)}.$$

This would lead to a linear pressure dependence as can be seen by adding the equations and writing the mass action expression for the resulting equation, *i.e.*

$$\frac{P_{H_2}a^2_{OH}}{P_{H_2O}{}^2} = K$$

and therefore

$$(\gamma C_{OH}) = (K/P_{H_2})^{1/2} P_{H_2O}$$

Thus assuming the activity coefficient γ is constant one gets the desired expression of C^* in the notation of Deal and Grove (1)

$$C_{OH} = C^* = \left(\frac{K}{\gamma^2 P_{H_2}}\right)^{1/2} P_{H_2O}$$

However, note the dependence on hydrogen pressure, P_{H_2}. The data in Fig. 5 for H_2O-H_2 mixtures does not show a dependence on hydrogen pressure.

We therefore conclude that to date there is no acceptable model for the processes going on at the gas-oxide interface. The data of Fig. 5 would indicate some role for other gas phase species at present not understood or previously reported. Some interesting complimentary effects have been observed (11) in dry oxygen oxidation, namely, several oxygen species appear to be involved in the Si-SiO_2 interfacial reaction in the linear oxidation region. It should be mentioned that we have carried out a limited number of oxidations in pure 100°C steam at different temperatures between 900° and 1230°C. The slope of the ln B *vs.* $1/T$ plot agrees closely with Ref. (1). The agreement of our results with those of Grove and Deal (1) when such results were obtained under comparable conditions indicates that the carrier gas effects just cited are not spurious.

Finally, Revesz and Evans (3) reported significant increases in the kinetic coefficient B [called k in Ref. (3)] due to sodium "doping" for certain wet and dry oxidation conditions. Specifically, the wet oxidation which is of relevance to our work was carried out in very low water vapor pressure ambients, 0.031 atm (assuming saturation) resulting in very slow oxidation. Since the method of doping used in Ref. (3) involved contaminating a substrate or placing sodium oxide in the tube furnace, no specific control of sodium level was possible. However the authors state the average sodium content of the oxides was 10^{20} cm^{-3}. Therefore the conditions used in Ref. (3) of low oxidation rate and rather high sodium concentration accentuated the effect on growth rate. In addition the nonmonotonic effect of doping with temperature was not explained and leads one to suggest the possibility of large variations in the actual doping levels.

In the present study we have controlled the doping to lower levels. This is demonstrated by the results of sodium analysis for our highest doping level which are presented in Fig. 6.

A graphical integration gives an average concentration of less than 3×10^{19} cm^{-3}. Therefore we expect significantly less sodium in all of our samples and corresponding less effect on growth rates than in Ref. (3). Specifically with ambient doping in the range from 0.4 to 10 ppm no consistent change in B was observed. Some typical data demonstrating this point are presented in Table I. It is apparent that with low sodium levels and high oxidation rates (due to the higher water vapor pressures) typical of oxidation conditions for electronic applications, no significant sodium effect should be expected in the growth rate. This is in contrast to the electrical properties such as interfacial charge which are very sensitive to sodium content. These effects have been observed and will be reported separately.

Conclusions

The principal conclusions from this study are:

1. An rf heated cold wall oxidizer can be constructed which produces uniform oxides over large areas.

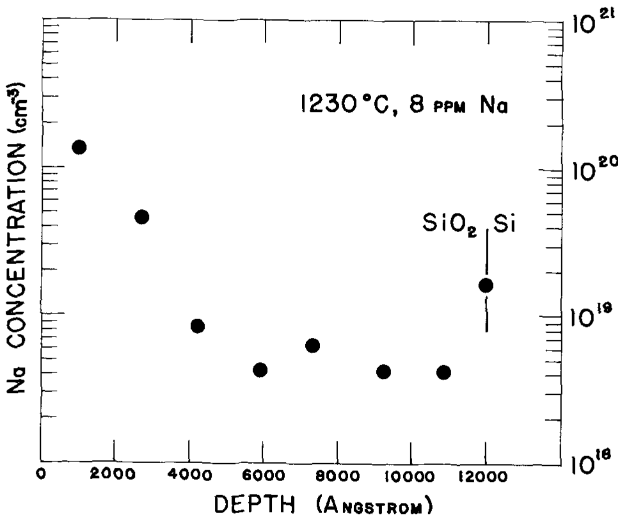

Fig. 6. Sodium distribution in thermally grown SiO_2. Oxidation condition: 1230°C, steam atmosphere containing 8 ppm Na.

2. Flowing gas streams used as carrier gas for wet oxidation may not be saturated. Above 80°C saturator temperature the effect is probably less than 20% for typical flow conditions.
3. The parabolic growth rate during wet oxidation of silicon does show some dependence on details of the gas phase composition other than simply oxidant partial pressure.
4. No effect of gas stream sodium impurities on growth rates was observed during wet oxidation of silicon for Na concentrations below 10 ppm in the oxidation atmosphere.

At present quartz is the most important material for producing tubes and boats for diffusion and oxidation processes in silicon device technology. The advantage of quartz compared to other materials is its combination of purity, resistance to mechanical and temperature changes at high temperature, and good workability. But there are limits for the application of quartz. At temperatures exceeding 1200°C it becomes increasingly soft and devitrifies, especially where it contacts other materials. In this state, quartz tubes slowly sag and flatten, and also become more permeable to gases and trace impurities. High temperatures are, however, necessary to accelerate the different diffusion and oxidation processes.

Quartz can be obtained in a relatively pure quality. However, even these pure grades contain undesirably high levels of some metal impurities such as sodium, which must be excluded from various oxidation processes.

One of the most disturbing effects in silicon device processing is the generation of clusters of dislocations at contact points between the quartz boat and a silicon wafer during high temperature processing, partly caused by mechanical stress at these points of the wafer. This phenomenon is shown in Fig. 1 by a wafer that had been dislocation-free before processing. The mechanical stress that produced these dislocations was due to the difference in thermal expansion coefficients between the silicon wafers and the quartz boat.

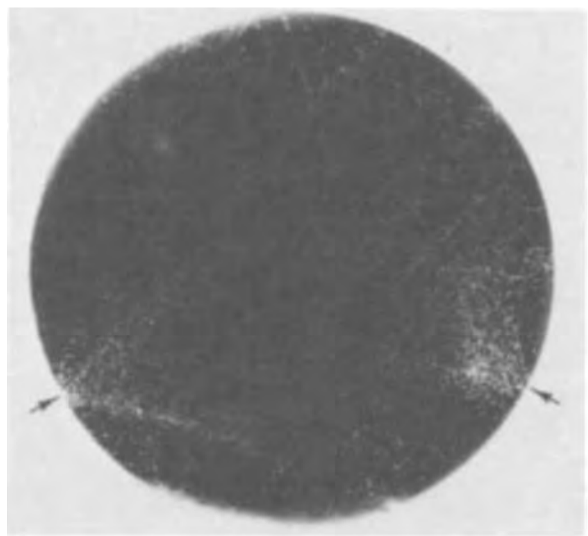

Fig. 1. Clusters of dislocations generated on a silicon wafer at its two contact points with a quartz boat used during processing.

The use of silicon tubes prepared by chemical vapor deposition (CVD) eliminates most of the difficulties encountered with quartz tubes. Polycrystalline silicon does not soften like quartz at temperatures approaching 1400°C; its resistance to cracking caused by thermal shock is excellent; its purity level is very high; and its coefficient of expansion is nearly identical with that of the silicon wafers.

Si-tubes and boats can also be made from monocrystalline or polycrystalline bulk silicon by coring, sawing, and grinding methods. This is, however, an expensive and difficult process due to the somewhat brittle material.

Preparation of Silicon Tubes

Polycrystalline silicon tubes and other shaped hollow bodies are produced by the same basic CVD method used to deposit semiconductor-grade silicon rods: the hydrogen reduction of pure trichlorosilane. In the case of hollow bodies, however, it is necessary to deposit silicon on a substrate such as pure graphite (1, 2), the outside dimensions of which become the inside dimensions of the silicon form being grown. The over-all chemical reaction taking place at temperatures exceeding 1000°C is

$$SiHCl_3 + H_2 = Si + 3HCl$$

It is important during deposition of silicon tubes that there be no intergrowth of the silicon and graphite resulting from, for example, rough or porous surfaces. In addition, the formation of silicon carbide at the interface due to excessive temperatures must be prevented in order that silicon can be easily separated from graphite after deposition. The deposition reactors shown in Fig. 2 are modifications of the Siemens silicon deposition process for producing polycrystalline silicon rods. The tubular graphite substrates are electrically connected through the base plate via graphite chucks to a power supply. In the first case, a single test tube-shaped substrate is used for producing a closed-end silicon tube. A long graphite connecting-rod extends coaxially to the closed end of the substrate where electrical contact is made by a screw-type connection.

The other diagram in Fig. 2 shows an example for simultaneously making two open-ended silicon tubes

* Electrochemical Society Active Member.

Key words: semiconductor tubes and boats, silicon tubes and boats, quartz tubes and boats, vapor deposition, trichlorosilane reduction, silicon deposition.

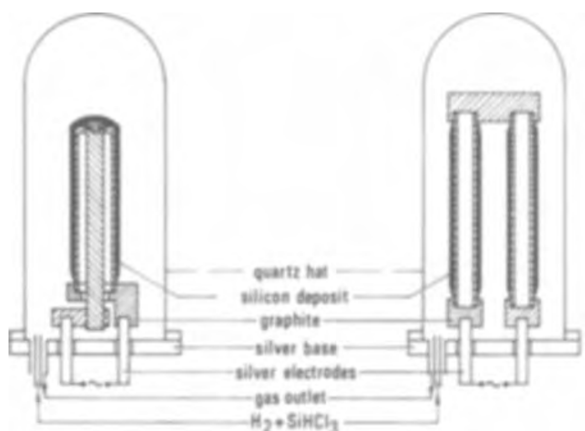

Fig. 2. Different reactor systems for the production of silicon tubes.

by connecting the tubular substrates in series by means of a conductive material such as a graphite bridge. Silicon is deposited at a substrate temperature greater than 1000°C using the appropriate flow rate (50-500 liters/min) and mole ratio (5-50% $SiHCl_3$) of the trichlorosilane-hydrogen gas mixture, the exact conditions being very dependent upon the reactor configuration used, and the surface quality and the degree of crystallite size wanted. Equal deposition conditions are required over the entire surface area in order to obtain a uniform and smooth silicon layer. Silicon deposition is discontinued at a predetermined diameter and the resulting tube is removed from the deposition apparatus, cut to length, and separated from the graphite mandrel. Separation can be accomplished by burning out the graphite or, in the case of a closed-end silicon tube, by simply pulling the graphite tube out of the silicon tube.

Other shaped hollow bodies are produced in a similar manner, the main difference being the configuration of the substrate material used. Figure 3 shows the as-cut end sections of silicon tubes with circular and rectangular cross sections. These tubes are 1.6m in length.

Tube ends can be either left as-cut, or ground to form a male taper for mating with a female quartz joint (Fig. 4). They can also be joined to a Pyrex® tube of the same diameter by standard glass blowing techniques to form a vacuum-tight and mechanically stable connection.

Finally the tubes are etched in an HF-HNO_3 solution to remove surface impurities and to produce a silicon tube with the equivalent purity level of normal polycrystalline silicon in rod form.

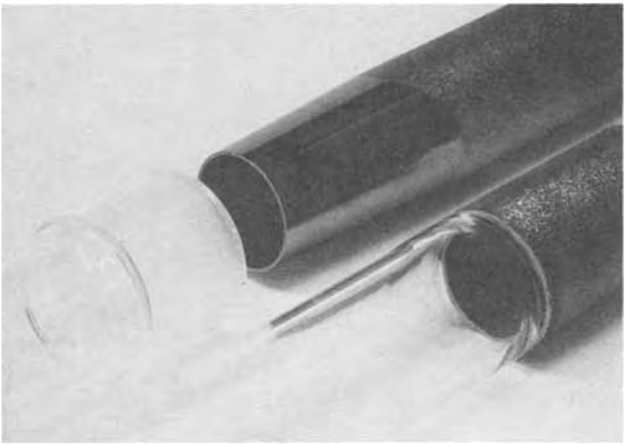

Fig. 4. Silicon tubes with ground taper and silicon-glass connections

Preparation of Silicon Boats

In contrast to quartz, silicon is not workable by glass blowing techniques. Therefore, one must begin with silicon tubes having a suitable cross section, either circular or somewhat rectangular. Since boats are made by diamond sawing, the polycrystalline silicon material must be of a high quality, free of mechanical stresses which can cause cracks during sawing of the somewhat brittle material. It should be largely homogeneous in spite of the fact that there is a high degree of crystallite texture due to crystal growth from the gas phase. The crystal size has to be much smaller than the over-all layer thickness of the deposited silicon hollow body. This is attainable through optimized deposition parameters as indicated by the very smooth and nodular-free silicon surface seen in Fig. 5 which actually shows the outline of the machined graphite substrate surface.

Silicon boats for supporting silicon wafers are used for open tube diffusion or oxidation processes, diffusion in vacuum, and other diffusing and heat-treating techniques. These boats should consist of only one part due to their increased mechanical stability and easier handling when filled with slices. It is possible to develop such silicon boats for supporting single silicon slices (Fig. 6a) in vertical or horizontal positions in a parallel or perpendicular direction to the diffusion transport gas. On the right side of Fig. 6a is a boat which is similar to conventional quartz boats with a parallel arrangement. The third boat (in the center) with cross standing silicon slices was developed for arrangements having little space. Figure 6b presents silicon boats for supporting vertical or horizontal stacks of silicon slices. On the left side is a boat for

stacks of any desired magnitude held at one end with a short silicon rod, and on the right side is a both-end-open silicon tube with a small contraction for holding a stack of silicon slices in the inside.

Properties of Silicon Tubes and Boats

A material properties comparison must be made in order to understand why silicon can replace quartz in certain semiconductor device processes.

Silicon tubes do not lose their rigidity at high temperatures due to their polycrystalline structure. A 50 mm ID tube unsupported over a length of 1.2m visually exhibited no sagging after being exposed to a temperature of 1300°C for over 2000 hr. Even a 100 mm ID tube heated to nearly 1400°C (mp of Si 1420°C) for over 400 hr showed no evidence of changing its structural shape (3).

A closed-end silicon tube (50 mm ID) with a glass tube connection was evacuated and heated to about 1350°C at the closed end in order to test porosity and stability. It proved to be highly vacuum tight and no sagging was observed. The glass connection was stable up to 400°C. In contrast to polycrystalline material, monocrystalline silicon begins to soften at temperatures near its metling point.

Thermal shock resistance of silicon tubes was tested by repeatedly pushing a tube from room temperature into a 1150°C furnace and, then after 15 min, pulling it back into its original position. Although heating rates of up to 500°C/min and cooling rates of as high as 900°C/min were reached, the tube suffered no cracking, distortion, or other adverse effects.

The structural rigidity and stability of silicon tubes at high temperatures and in high temperature gradients results in them having much longer lifetimes than quartz and, therefore, allows development of device processes that are not temperature limited due to the sagging or devitrification of a quartz tube. For example, higher temperature diffusions than normal can result in increased device capacity due to the shorter diffusion times required. Silicon tubes have also been found to be equally stable in oxidizing or reducing atmospheres in contrast to a ceramic tube which exhibits a shorter lifetime in a reducing atmosphere due to its chemical change.

The lower heat capacity of silicon compared to quartz and mullite (70% Al_2O_3 and 30% SiO_2) allows more optimal thermal properties for furnace design and operation. When a silicon tube is used in place of both a quartz tube and ceramic liner, the lower system heat capacity of about 20% allows for more rapid heat-up and cool-down of the furnace. In addition, heat-up rates for silicon have been found to be more linear with time (3) than for quartz. The higher ther-

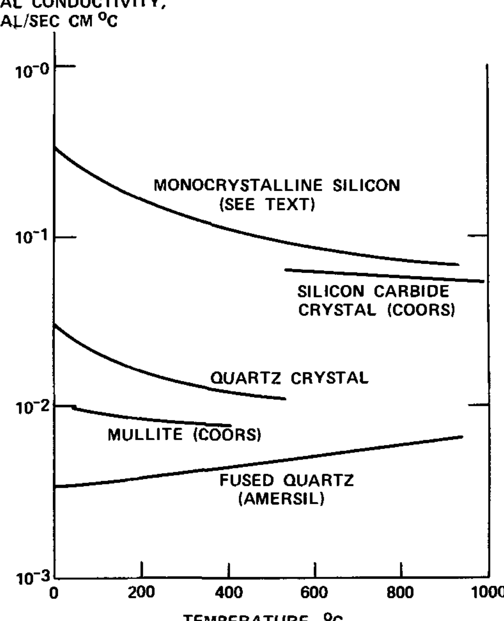

Fig. 7. Comparative thermal conductivities.

mal conductivity of silicon as compared to quartz (Fig. 7) also allows for improved thermal performance of the furnace system. It is possible at sufficiently high temperatures to obtain a longer uniform temperature zone in a silicon tube since the transport of thermal energy along the tube is more efficient. However, this effect does not result in a larger heat loss from the furnace, because normal cooling of the silicon tube extending outside the furnace results in a sharp temperature decrease. This is enhanced by the multitude of grain boundaries which impede heat conduction at low temperatures. Although the thermal conductivity of polycrystalline silicon will be less than that of the monocrystalline form at temperatures less than about 300°K, the thermal conductivities will be very nearly equivalent at typical furnace temperatures (4).

Measurement of the force required to draw a boat through a tube indicates that the coefficient of friction for silicon-on-silicon is more than an order-of-magnitude less than for quartz-on-quartz at a temperature of 1200°C (3) due to the softening of quartz at high temperatures. Softening may also result in sticking problems between the quartz boat and the quartz tube. Friction on quartz at high temperatures produces quartz powder which disturbs diffusion processes. This is avoided by using a silicon system.

In contrast to quartz, polycrystalline silicon tubes, even when evacuated, are not permeable to most trace impurities (copper being an obvious exception) at high temperatures and have been found to be a better gettering agent for these impurities than monocrystalline silicon under specific operation conditions. A redoping effect from polycrystalline silicon tubes to silicon slices has not been observed.

The generation of slippage and clusters of dislocations at the contact points of quartz and silicon during the diffusion and oxidation processes at high temperatures has been avoided by using silicon boats to keep silicon wafers dislocation-free (5).

Purity of Hollow Bodies

Emission and spark-source mass spectroscopy combined with neutron activation analysis have provided a measurement of the level of impurities found in pure quartz, graphite (as a substrate) and polycrystalline silicon tubes. The results of these analyses, which are summarized in Table I, indicate that silicon is much purer than quartz in its purest available form. If a comparison is made using the activation analysis re-

Table I. Quartz, silicon tube, and graphite substrate impurities (ppba)

Ti	—	—	—	6	—
Zn	2.0	2.0	0.3	—	—

sults to be consistent, the average ratios of the impurities in quartz to those in silicon can be classified as

Quartz/Silicon Ratio	Impurities
>1000	Na, Sb
100-1000	Au, Co, Cr, Fe
10-100	Cu, Zn

The low level of Na in silicon tubes is very advantageous since Na from quartz is a detrimental impurity in some oxidation processes. The low impurity level of Au, Fe, and Cu is also significant. These impurities exist at a lower level in the silicon tube due to the CVD technique, the elemental diffusivities and vapor pressures, and the final chemical etching of the silicon surface, which can getter many impurities very easily.

Silicon tube purity was also tested by resistivity measurements made on single crystals produced from polycrystalline tubes by the Czochralski and multiple-pass floating zone methods. Analyses indicated a donor level of 1.4 ppba (75 ohm-cm) with an acceptor level of 0.8 ppba (350 ohm-cm).

The foregoing analyses indicate, therefore, that the polycrystalline boats or tubes used for device processing actually have a purity comparable to that of the slices used.

Conclusions

Silicon tubes with dimensions up to 1.8m long by 100 mm inside diameter can be prepared by chemical vapor deposition on the correspondingly shaped surface of heated graphite which can be separated from the silicon afterwards. Similarly, one can produce silicon hollow bodies with a noncircular cross section making possible the preparation of a variety of different silicon boats for supporting silicon slices during diffusion and oxidation processes. For this purpose CVD-silicon is considered superior to conventional quartz for reasons of purity, permeability to trace impurities, and mechanical stability at high temperatures.

Catalyzed Crystallization in SiO_2 Thin Films

E. I. Alessandrini and D. R. Campbell*

IBM Thomas J. Watson Research Center, Yorktown Heights, New York 10598

The publication costs of this article have been assisted by the IBM Corporation.

Considerable interest has been shown in thermally grown silicon oxide films from the standpoint of device-oriented properties as well as structural properties. Defects in oxide films have been reported (1-4) and are believed to be small crystallites formed at localized nucleation centers, such as impurities, during heat-treatment. However, the type of impurities and the conditions which induce crystallization in the amorphous films are not clearly understood.

This paper describes the structural aspects of phase transformations in SiO_2 films when P^{32} is diffused in the amorphous oxide. The purpose of this investigation was to determine the effect of the impurity as a function of time and temperature and compare the results with similarly treated films without phosphorus. It will be shown that the transformation from the amorphous to a crystalline phase was dependent on the catalytic behavior of the phosphorus.

Experimental Procedure

Thin films of amorphous SiO_2 were prepared by dry thermal oxidation and grown to 1000Å in thickness on silicon wafers (Czochralski, p-type, boron doped, 2 ohm-cm) 1 in. in diameter with a (100) orientation. Two series of experiments were carried out: (*i*) phosphorus was diffused into the amorphous films using P^{32} isotope at two different times and temperatures (525°C for 100 hr under a low P pressure followed by 25 hr at 1200°C anneal in vacuum) and (*ii*) undiffused films given the same heat-treatments. The source of the radioisotope was neutron activated, red phosphorus

powder which was encapsulated together with the SiO_2/Si samples in evacuated silica ampuls. At the temperatures of treatment, the phosphorus source was completely vaporized.

Upon completion of the heating cycles, autoradiographs were made of the P^{32} diffused samples (Fig. 1), and structural defects were suggested by the appearance of numerous small areas of high P^{32} concentration. Some of these wafers were diced and portions which showed high P^{32} concentrations as well as portions showing the least concentrations were prepared for examination in an electron microscope by back jet-etching through the Si substrates using a 9:1 HNO_3:HF etchant. In addition, undiffused wafers were also prepared and examined by the same technique for comparison.

Experimental Results and Discussion

Prior to heat-treating the SiO_2/Si samples transmission and reflection electron diffraction patterns were obtained. The results indicated that the 1000Å SiO_2 film was amorphous, and the electron micrographs confirmed this result. After P^{32} was diffused at 525°C for 100 hr, samples were taken, using the autoradiographs, from heavily concentrated P^{32} areas as well as from areas of the lowest concentration in the amorphous films. Electron micrographs and selected area diffraction patterns from these areas showed the onset of crystallization (Fig. 2), and the areas of heavy concentration of the radioactive isotope were found to be completely crystallized while the least concentrated areas showed scattered crystallites in an amorphous matrix. The particles, shaped as spherulites, can be seen in dark field (Fig. 2) when a reflection of the diffraction pattern is used for image formation.

The electron diffraction patterns showed random orientation of the crystallites. The data were analyzed,

Intensities-Relative

as shown in Table I, and the structure was identified as that of $2SiO_2 \cdot P_2O_5$. According to the phase diagram (Fig. 3) the appearance of this phase at 525°C heat-treatment seemed reasonable.

In the second portion of this investigation, these films were given an additional annealing treatment at 1200°C in evacuated silica ampuls for 25 hr. A transformation was apparent from both the electron diffraction patterns and micrographs (Fig. 4). The analysis of the diffraction data proved that two polymorphic SiO_2 structures were now present. They were the α-quartz form as well as the α-cristobalite form (Fig. 5). The diffraction pattern in Fig. 6 has been indexed. We have found that the major constituent was α-quartz. Since it is known that the polymorphic phase transformation of SiO_2 is very sluggish, it seems likely that continued annealing for long periods of time at 1200°C would result in the complete phase change to α-cristobalite.

The undiffused films were given heat-treatments of similar times and temperatures. Results were obtained using the identical techniques for sample preparation and examination as in the case of the diffused films. They showed that no crystalline phase developed (Fig. 6).

In summary, our primary concern in this study was the correlation between impurity and its effect on the formation of crystallites of SiO_2 in the amorphous film matrix. No attempt was made to analyze the steps that constitute the chemical reaction which led to

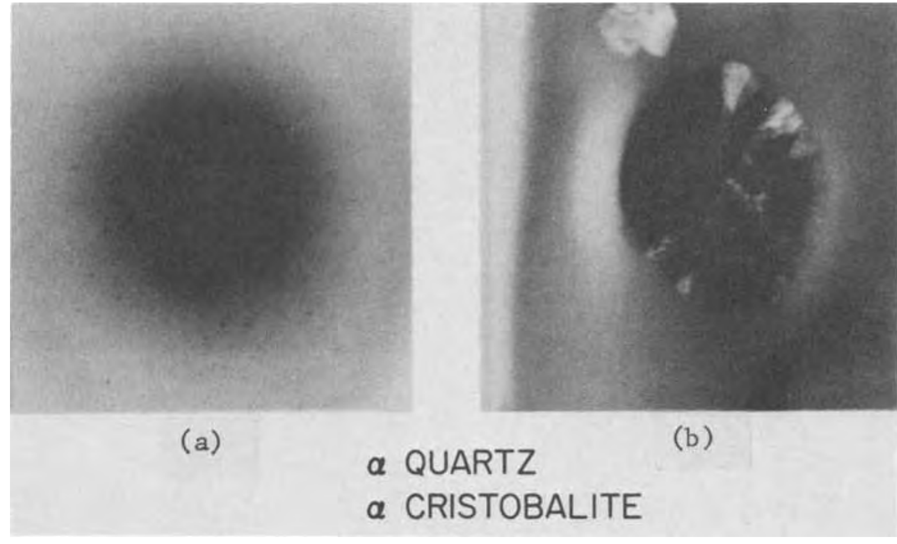

Fig. 4. P^{32} diffused SiO_2 film on (100) Si wafer after 100 hr at 525°C. (a) Selected area electron diffraction pattern of α-quartz and α-cristobalite. (b) Electron micrograph of same area 100,000X.

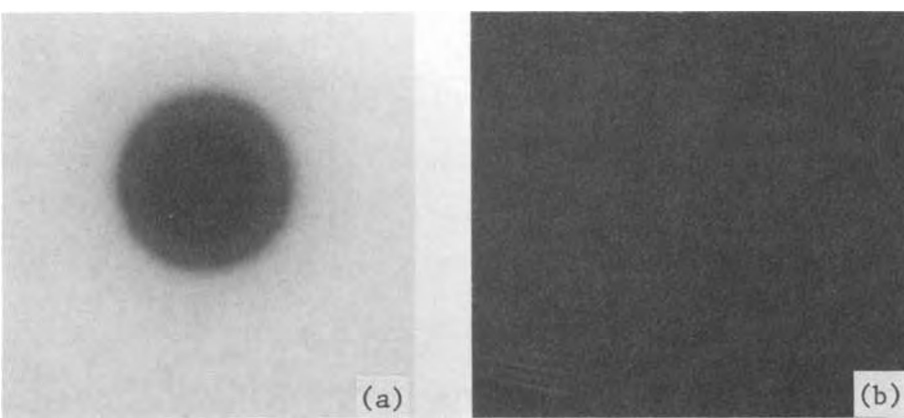

Fig. 6. Amorphous SiO_2. Undiffused SiO_2 film on (100) Si wafer heat-treated 525°C, 100 hr plus; additional 25 hr at 1200°C. (a) Electron diffraction pattern. (b) Electron micrograph 63,000X.

crystalline compound formation. Rather, we simply note that the phase change after the heat-treatment at 525°C for 100 hr as shown by varying P^{32} concentrations in the autoradiographs and determined by electron microscopy suggests evidence of a first stage of crystallization. This stage is characterized by the appearance of phosphosilicate compounds which in turn become the nuclei for the subsequent growth of crystalline phases of SiO_2.

Our work has shown that crystallization does occur when P-rich crystallites form, and their formation is directly dependent on the sufficient transport, by diffusion, of P into localized areas of the amorphous SiO_2 films. In this study, the presence of a gas phase provided for the rapid transport of P^{32} at the film surface. The formation of $2SiO_2 \cdot P_2O_5$ in turn catalyzed the SiO_2 phases. Crystallization did not occur in the uniformly P-doped samples of Sugano *et al.* (3) probably because diffusion in the solid amorphous phase is too slow to allow for the formation of suitable nuclei (5).

Acknowledgments

The authors are grateful to K. N. Tu for helpful discussions, E. Bassous for growing the films, and K. Grebe for technical assistance in cutting samples.

C-MOS and Complementary Isolated Bipolar Transistor Monolithic Integration Process

Mougahed Darwish and R. Taubenest

Centre Electronique Horloger S.A., Neuchâtel, Switzerland

The publication costs of this article have been assisted by the Centre Electronique Horloger S.A.

Circuits using integrated complementary MOS and bipolar devices combine the low power consumption of MOS and the current handling capabilities of bipolar technology with optimum use of device area. In addition, the use of the silicon surface properties directly combined with the volume electrical effects have opened a new area of circuit engineering, as exemplified by the BIGFET (1). Earlier attempts of device integration are found in the literature (2, 3). The major difficulties with these earlier fabrication schemes involve a disproportionately large number of masks, a number of difficult overlapping diffusions, and a lack of electrical isolation between the bipolar structures.

In this work, by using the epi layer with the C-MOS process, the bipolar transistors can be isolated, *vs.* the nonisolated bipolar transistors provided by conventional C-MOS process. This feature has significant advantages in circuit design. Since the present work was not oriented to a particular circuit application, there was sufficient latitude in optimizing geometry and electrical parameters. It was found that the use of a vertical npn and a lateral pnp transistor design lent itself particularly well to our fabrication process.

A listing of the various structural elements and electrical parameters for C-MOS and complementary bipolar devices shows that there are a number of common features (Tables I and II). By judicious combination it is possible to reduce the complexity of an integration scheme to a minimum number of steps. It can be seen that it is possible to fabricate at the same time:

1. The n-type substrate of the MOS transistors and the n epi layer of the bipolar transistors.
2. The p^- diffusion regions which may serve simultaneously as the pockets for the n-channel MOS and as the isolation for the bipolar transistors.
3. The p^+ diffusion regions, forming the (*i*) source and drain of the p-channel MOS, (*ii*) the base of the npn transistors, and (*iii*) the emitter and collector of the pnp transistors.

Key words: monolithic integration, complementary, isolated bipolar, MOS, semiconductor devices.

In this way, three masks and three diffusions (plus one epi layer) suffice to form the primary steps. To complete the devices another three masks are necessary for: (*i*) thin oxide regions (source-drain-gate and contacts), (*ii*) contact windows, (*iii*) metallization.

Depending upon the application it may be necessary to use one or two additional masks due to two inherent characteristics of such fabrication schemes:

1. The lateral pnp bipolar transistor will have a comparatively low current gain, since the major part of the carriers injected by the lower (bottom) portion of the emitter will not reach the collector (4).
2. For the vertical bipolar transistor npn the depth X_{p^+} of the base is larger than the emitter junction depth X_{n^+}. Consequently, the p-MOS using the same p diffusion will be larger than the n-MOS using the n^+ emitter diffusion. This could possibly be a serious limit of the high frequency performance of the p-channel MOS.

This can be eliminated by using two additional masks to form:

1. A buried layer blocking the useless carrier injection from the bottom of the emitter. Consequently, the current gain of the pnp will be improved.
2. A supplementary p^+-diffusion (called p^{+2}) to form source and drain of the p-channel MOS independently of the p^+ base diffusion.

By way of comparison a set of six masks are also used for metal gate C-MOS and for conventional bipolar technology. Si-gate C-MOS needs six or seven masks (6, 8).

The choice of a six, seven, or eight mask process will depend on the circuit application. In each case the technique makes efficient use of chip area and results in electrically isolated devices. A further advantage is that only conventional masking and fabrication procedures are used. The experimental procedure and results presented here are for devices using the maximum number of eight masks.

Table I. Basic elements for complementary MOS-transistors

	Elements: Substrate n-Type	Diffusion p^-	Diffusion p^+	Diffusion n^+
Function	p-channel	n-channel	source-drain p-channel	source-drain n-channel
Properties	$C_S \simeq 10^{15}$ at/cm^3	$C_S \simeq 8\cdot10^{15}$ at/cm^3	$C_S > 10^{15}$ at/cm^3; $X_{p^+} < X_{SUBSTR.}$	$C_S > 8\cdot10^{15}$ at/cm^3; $X_{n^+} < X_{p^-}$

Table II. Basic elements for complementary bipolar transistors

	Elements: Substrate p-type	Epitaxial layer n-type	Diffusion p^-	Diffusion p^+	Diffusion n^+

(d) Delineation of contacts and interconnections.

Experimental

p-type silicon wafers of the (100) orientation and 2-5 ohm-cm resistivity were cleaned using standard cleaning processes and oxidized in wet oxygen at 1200°C. The oxide layer thickness was approximately 1 μm. Then windows were cut into the oxide layer where the buried layers were to be diffused with standard photolithographic and etching techniques (Fig. 1a). The diffusion of the buried layer was carried out using a solid-solid vacuum diffusion process (5) or, alternately, the more convenient doped oxide diffusion process (6). The junction depth and the resistivity of the antimony-doped regions were 4μ and 130 ohms/□, respectively.

After the appropriate etching and cleaning steps the n-type epitaxial layer was grown using the thermal decomposition of silane. The thickness of the layer was approximately 7 μm, and the resistivity was in the range of 1.5-2.5 ohm-cm (Fig. 1b).

After a second thermal oxidation ($SiO_2 \sim 1\mu$) and the appropriate photoresist work, the oxide windows for the isolation diffusion and the p-well were etched, followed by a closed-capsule diffusion at 1200°C for 10 hr. In this case the source-wafers were of p-type with a resistivity of 0.3-0.4 ohm-cm (Fig. 1c).

It should be noted that the condition $X_{p-} > X_{epi}$ will be attained during the following heat-treatments.

The base-diffusion (p^{+1}) of the vertical npn transistors and the emitter and collector diffusions of the pnp's is accomplished by a boron doped oxide diffusion step, giving a penetration of 2.6μ and a sheet resistivity of around 600 ohms/□ (Fig. 1d).

The base-diffusion is followed by a photoetching step which opens the regions where source-drain-gate of n- and p-channel MOS will be formed at the same time as the p^+ and n^+ regions of the bipolar elements. After the formation (7) of the gate oxide (1100Å) a 6000Å layer of polycrystalline silicon is deposited (Fig. 1e), the gate electrodes delineated and the remaining thin oxide on the source-drain regions is etched away. Next a boron-doped oxide layer is deposited on the entire surface (Fig. 2) and openings are etched out where the n^+ regions will be diffused (source and drains and polycrystalline Si layer for gate of the n-channel MOS, emitter of the npn transistor, n-contacts). The etching process is followed by a phosphorus-doped oxide deposition. Finally the p^{+2} and the n^+ regions (MOS) are diffused in a single diffusion cycle (6), giving a penetration of 1μ and a sheet resistivity of 100 ohms/□, both for boron and phosphorus.

An evaporated and photoetched layer of aluminum (1 μm) provides for the necessary contacts and interconnections. A final annealing step in forming gas at 400°C reduces oxide charge (8).

Results

As shown in Tables III and IV the electrical parameters of typical devices constructed in this manner

Table III. Characteristic properties of the MOS transistors

Type of transistor	$V_{Th.extr.}$ (volts)	β
n-channel	0.68	13
p-channel	0.80	3.8
parasitics	>5.45	—

$W = L = 10\ \mu$m.

W, gate width; L, gate length; $\beta = 2\left[\left(\frac{\partial\sqrt{I_D}}{\partial V_G}\right)_{V_D}\right]^2$.

Table IV. Characteristic properties of the bipolar transistors

Type of transistor	h_{fe} at $I_B = 1\ \mu A$ $V_{CE} = 1V$	BV_{EBO} (V)	BV_{ECO} (V)	BV_{BCO} (V)
npn	150	13	10	38.5
pnp	8	38.5	35	38.5

The gain of the pnp transistors is controlled by β^* in the following equations: $h_{fe} = \frac{\alpha}{1 - \alpha}$ where $\alpha = \gamma_i\beta^*$ and $\beta^* = 1/(\cosh W_p/L_p)$. The symbols have the usual meaning.

compare favorably with the conventional discrete technology.

The properties of the npn and the pnp transistors are given in Table IV.

The γ may be optimized by the proper choice of the diffusion parameters of the p^{+1} diffusion and the buried layer diffusion, W_p, by adjusting the physical dimensions and L_p by choosing arsenic instead of antimony as the dopant for the buried layer because of the higher minority carrier lifetime (9).

Conclusion

It should be stressed that the MOS + bipolar approach also allows for a high degree of freedom in the optimization of the respective elements. The diffusions n^+, p^{+1} and the buried layer are available for the optimization of the bipolar part of the circuit. The bipolar transistors are less sensitive to the surface concentration in the p-wells. This allows easy adjustment of the threshold voltage of the MOS transistors for optimization in particular applications. Otherwise, the limitations and tolerances of the separate bipolar and C-MOS processes apply to this technology.

One immediate application of this technology is in the area of light emitting diode displays. The MOS circuits perform the appropriate logic and decoding functions and the bipolar devices provide the switching and current handling.

More generally, such a technology is useful in applications where logic and analogic functions are required simultaneously as for instance in thermocompensation circuits. The bipolar is used as an analog device while the MOS performs the digital part.

Brief Communications

Luminescence of Alkali-Alkaline Earth-Phosphates Activated with Eu^{2+}

M. S. Waite

Division of Materials Science and Physics, Thames Polytechnic, London, S.E. 18, England

The publication costs of this article have been assisted by the Thames Polytechnic.

Orthophosphates of formula $M^IM^{II}PO_4$, where M^I = Li, Na, and K and where M^{II} = Ca, Sr, and Ba, have been examined as hosts for various activators, but principally Ce^{3+}, Sn^{2+} (1, 2), and Cu^+ (3). The Ce^{3+} doped phosphors were found to possess moderate efficiencies, up to 4%, under electron beam excitation (1) and high efficiencies under 254 nm excitation, 88% (quantum efficiency) being quoted for $LiSrPO_4$:Ce (3). High quantum efficiencies under 254 nm excitation can also be observed with Cu as activator (3). As part of a survey of Eu^{2+} doped phosphors we have examined the effect of Eu^{2+} activation on this group of materials and the preliminary results are summarized below.

Phosphors were prepared by firing $M^I_2CO_3$, $M^{II}CO_3$, and $(NH_4)_2HPO_4$ with Eu_2O_3 to a fixed dopant concentration of 2 mole per cent (m/o). The firing was carried out in two stages: an initial firing at 800°-900°C being followed by firing in 2% H_2/N_2 at 1000°-1200°C. All the members of this group showed Eu^{2+} band luminescence but with considerable variation in efficiency to ultraviolet and electron beam excitation. X-ray powder photographs were taken of the powdered phosphors and the *d* (hkl) values compared with those reported by Wanmaker and Spier and with other literature values (4-7). The "heavier" members of this group of compounds, where M^I = K, Na and M^{II} = Ba, Sr, Ca, are polymorphic, the low temperature form being orthorhombic with the β K_2SO_4 structure (8). The phosphors prepared by the techniques outlined above are predominantly of this form, in agreement with the conclusions expressed by Wanmaker and Spier (3). The *d* (hkl) values for the lithium containing phosphors also agree with those reported by these authors.

Emission spectra under 365 nm excitation are given in Fig. 1. Estimates of the efficiencies under both 365 and 250-270 nm excitation have been made using as standards several phosphors from Levy West Laboratories: Zn_2SiO_4:Mn, ZnS:Ag, and ZnS:Cu (Table I). Although a thorough optimization has not yet been completed it seems that the K- and Ba-containing phosphors are the most efficient. This is in contrast to the case of cerium and copper doping where the lithium-based phosphors were found to be the most efficient. Assuming a value of at least 80% for the quantum efficiency of the standard willemite sample under 254 nm excitation,[1] then the efficiency of $KBaPO_4$:Eu, which is comparable, may prove high enough for commercial application.

Key words: luminescence, phosphates, Eu^{2+} activation.

[1] Manufacturer's recommendation.

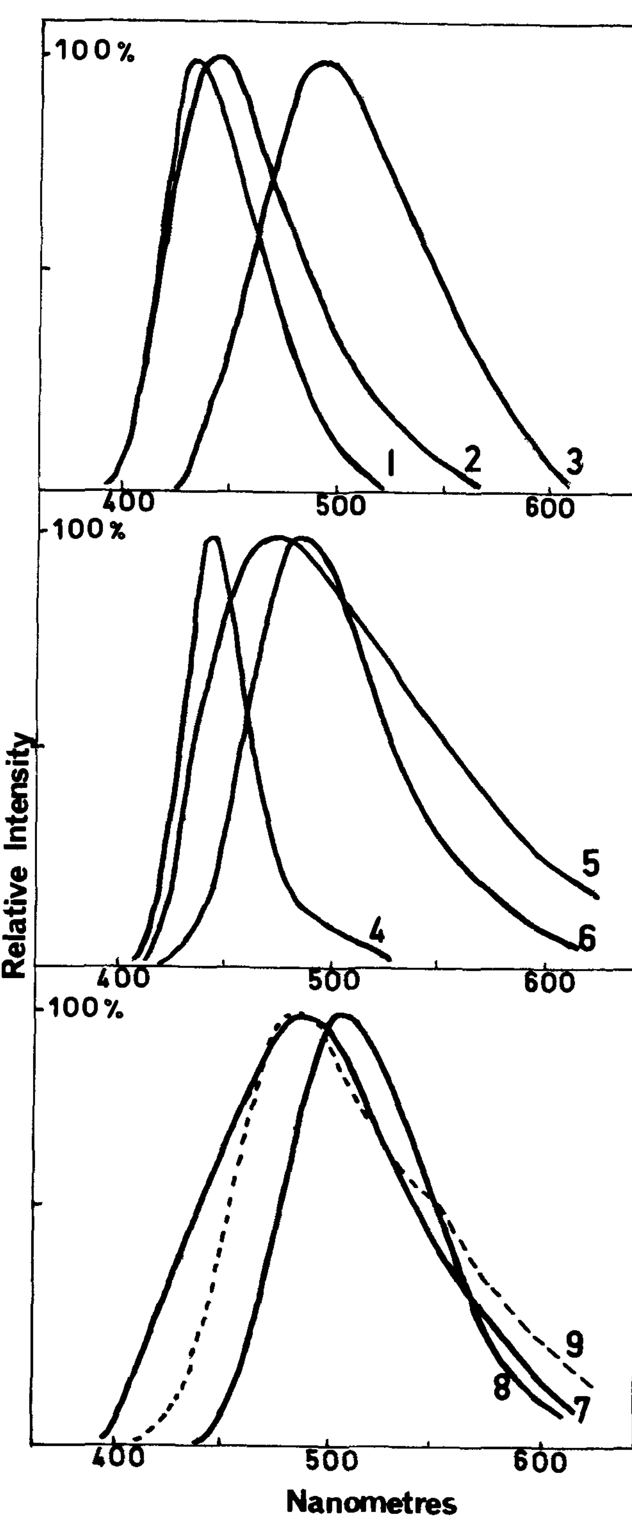

Fig. 1. Emission spectra under 365 nm (Hg) excitation. Curve 1, $KaBaPO_4$; curve 2, $NaBaPO_4$; curve 3, $LiBaPO_4$; curve 4, $KSrPO_4$; curve 5, $NaSrPO_4$; curve 6, $LiSrPO_4$; curve 7, $KCaPO_4$; curve 8, $NaCaPO_4$; curve 9, $LiCaPO_4$.

Measurements of the CR efficiencies were made for several of these phosphors. The results are given in Table II with the response times to pulsed beam excitation as determined by Wight and Bramwell, Services Electronics Research Laboratories, Baldock, England. $KSrPO_4$ shows the best combination of efficiency (~5%) with fast response (<200 nsec) and narrow band width (<40 nm).

Table I. Emission characteristics with ultraviolet excitation

Phosphor	Emission max. (nm)	Band width (nm)	Band area (relative to standard)* (365 nm excitation)	(250-270 nm excitation)
$KBaPO_4$:Eu	430	50	185	105
$NaBaPO_4$:Eu	440	70	135	80
$LiBaPO_4$:Eu	483	85	15	15
$KSrPO_4$:Eu	430	35	65	30
$NaSrPO_4$:Eu	455	120	10	10
$LiSrPO_4$:Eu	470	70	20	15
$KCaPO_4$:Eu	485	110	35	35
$NaCaPO_4$:Eu	505	78	40	20
$LiCaPO_4$:Eu	485	105	60	45
ZnS:Ag (Levy West Type G231, Ni killed, Batch No. 16538C)			100	
ZnS:Cu (Levy West Type FF12, Batch No. 117)			92	
Zn_2SiO_4:Mn (Levy West Type H916, Batch No. 233)				100

* Believed correct to ±5%.

Table II. Efficiencies and response times to electron beam excitation

Phosphor	Energy efficiency, %*	Response times, nsec† Rise	Decay
$KBaPO_4$:Eu	2.4 ± 0.3	315	220
$NaBaPO_4$:Eu	2.0 ± 0.2	630	680
$KSrPO_4$:Eu	5.2 ± 0.5	185	170
$KCaPO_4$:Eu	0.2 ± 0.03		
$NaCaPO_4$:Eu	4.0 ± 0.5	480	560
$LiCaPO_4$:Eu	0.5 ± 0.1	460	640

* Beam voltage, 8 kV; current density, 0.01-1.0 $\mu A/cm^{-2}$.
† 25 kV, 1 μA pulses of width 10 μsec; response time quoted as $1/e$ value.

Thus, the preliminary investigation indicates that several members of this group of phosphors may possess promising characteristics as lamp or CRT phosphors and a more detailed investigation of the connection between structure or composition and efficiency is being carried out.

Acknowledgments

We are grateful to D. R. Wight and Miss S. Bramwell for permission to publish the response time measurements and to A. Vecht of Thames Polytechnic and P. J. Dean and D. Robbins of the Royal Radar Establishment, Malvern, England, for valuable discussion.

We gratefully acknowledge the permission of the Ministry of Defence to publish this work.

Manuscript received Feb. 5, 1974.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1975 JOURNAL. All discussions for the June 1975 Discussion Section should be submitted by Feb. 1, 1975.

Self-Aligned Gaps—An Alternative Technique for Closely Spaced Metallization Patterns

J. D. E. Beynon, R. A. Haken, and I. M. Baker

Department of Electronics, University of Southampton, Southampton, England

Recently much interest has been shown in producing narrow lateral gaps in metallization patterns, particularly for charge-coupled structures. A recent paper by Berglund *et al.* (1) describes a technique in which the lateral gap between electrodes can be made very small, or even eliminated, by separating adjacent electrodes by a vertical gap. The necessary discontinuity in the metallization is achieved by using a "shadowing" effect during vacuum deposition of the metal. The structure described by Berglund *et al.* relies on the formation of a ledge (or hangover) at the insulator step; this is accomplished by selectively undercutting a double-insulator system that exhibits a disjoint etching characteristic. The ledge is subsequently used to form the required "shadow" in the metallization. They did not consider using an oxide step for producing the shadow because such steps do not have vertical edges; they also envisaged difficulty in generating a well-collimated metal vapor beam during deposition.

We have found, however, that closely spaced metallization patterns can be fabricated by using oxide steps to produce a shadow in the beam of metal vapor when this is deposited obliquely to the plane of the slice. In this connection we have investigated the effect of etch temperature upon the profile of the oxide step [Haken *et al.* (2)]; we have found that a near vertical oxide edge can be obtained near the top of the step if the etch temperature is no more than 25°C (at higher temperatures the oxide edge becomes shallower). By evaporating the metal at a relatively low rate (of the order of 10^{-3} cm^{-3} sec^{-1}) and by employing a source-to-target distance of 20 cm, we have obtained sufficiently good resolution in the shadow to produce satisfactory self-aligned gaps.

Using this technique, we have produced CCD's with aluminum [Baker *et al.* (3)] and gold/nichrome metallization; a typical gap in a 32 bit CCD shift register with gold/nichrome metallization is shown in Fig. 1 where the oxide step height is 0.3 μm. The interelectrode gap is 0.5 μm and the total length of gap in one of these registers is 0.64 cm.

This technique compares favorably with others that have been proposed for producing closely spaced metallization patterns. Its main advantage is the extreme simplicity with which small gaps can be fabricated; only one mask is needed to define the oxide steps which are subsequently used to form the shadows in the metal vapor beam. We intend to publish a more detailed account of CCD device fabrication using this technique shortly.

Key words: charge-coupled devices, self-aligned gaps.

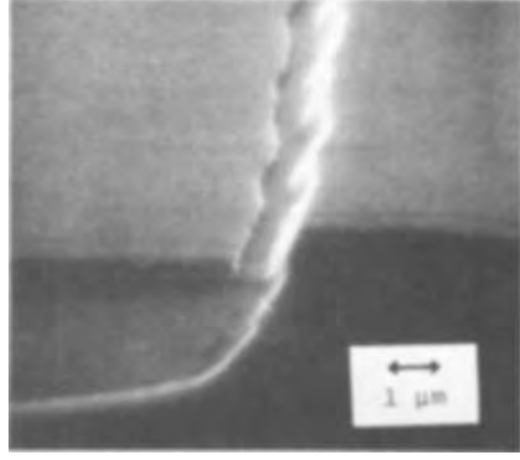

Fig. 1. Part of one of the interelectrode gaps in the CCD structure described in the text. The oxide step height is 0.3 μm and the gap width is 0.5 μm. (The large depth of field of the electron microscope is partly responsible for the ragged appearance of the oxide step; note, however, how the edge of the metal faithfully follows the profile of the top of the oxide step.)

Manuscript received Dec. 17, 1973.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1975 JOURNAL. All discussions for the June 1975 Discussion Section should be submitted by Feb. 1, 1975.

The publication costs of this article have been assisted by the Department of the Army.

RN

In an attempt to decrease atmospheric pollution in major population centers throughout the world and to partially reduce the automotive demand on the world's limited petrochemical supply, numerous foreign and domestic research programs have been initiated to develop power sources to supplement or replace the combustion engine in ground transportation vehicles. All-electric and hybrid-electric vehicles have been proposed, designed, and developed in an attempt to save the environment and to more efficiently use existing petrochemical fuels. Although hybrid-electric vehicles have been successfully demonstrated, the major emphasis of this paper is on all-electric vehicles and their potential electrochemical power sources. To develop competitive vehicles of these types, power sources with increased thermal, electromechanical, and electrochemical energy conversion efficiencies and transfer systems must be developed. Vehicles which are efficient, cost effective, and reliable, and require very little maintenance over extended periods of time, are a primary developmental goal. The over-all advantages of a total-electric or hybrid-electric vehicle are: (*i*) reduction of emission and noise pollution; (*ii*) increase in off-road mobility for military applications through the use of electronic slip control of the vehicle's speed, acceleration, and braking; (*iii*) regenerative braking to regain energy in the form of momentum normally wasted in conventional braking; and (*iv*) relatively low maintenance requirements. Currently, the major disadvantages of an electric vehicle are limited range and speed, and high cost. Electric vehicles are initially far more expensive than conventional automobiles due to limited production (approximately 20,000/yr in the United States). Once electric vehicles become publically accepted for both urban and rural transit, the "hard-tool" production of standard vehicles will be undertaken, and their initial cost will decrease significantly.

Foreign Developmental Programs

Currently, eight countries are conducting the majority of the active research in the area of all-electric and hybrid-electric vehicles: United States, U.S.S.R., United Kingdom (U.K.) Japan, Sweden, France, Italy, and the Federal Republic of Germany (F.R.G.). Most foreign and domestic programs include development of a variety of potential electrochemical power sources plus road testing of advanced prototype vehicles made of new lightweight plastic and composite materials.

If one were to try to rate all of these countries in the area of electric vehicle and battery/fuel cell development, one might obtain some close variation of the following:

Vehicle development	Battery/fuel cell development
1. U.K., U.S., Japan	1. Japan
2. F.R.G.	2. U.S.
3. U.S.S.R.	3. U.K.
4. France	4. France, F.R.G.
5. Italy	5. Sweden, U.S.S.R.
6. Sweden	6. Italy

These rankings are based upon the total amount of R&D funding programmed up to 1975, the number of fundamental and applied research programs, and the actual number of successful prototype electrochemical power sources experimentally demonstrated in laboratory cells and tested vehicles.

Federal Republic of Germany (F.R.G.).—In the F.R.G., no national program per se exists for the development of electric vehicle systems. The government, however, does have some major influence on the direction and funding of programs that are presently being pursued since sponsorship of a majority of the effort is by industrial consortiums that are under close government control. Nine major German industrial firms, with a budget estimated to be greater than $650,000 for battery and fuel cell development alone, are presently involved in the various phases of electric vehicle R&D.

In 1970, Dr. Helmut Meysenber, the Technical Director of the Rheineschwestfaelisches Electrizitaetswerke, AG (RWE), announced the organization and financing of a group of companies to develop electric vehicles by 1972. Included in this group were Rheineschwestfaelisches Electrizitaetswerke, AG, VARTA, AG (traction batteries), Robert Bosch (motors and controls), Messerschmitt Bölkow Blohm (MBB) (assembly), and Farbrenfabriken Bayer, AG (plastic body). Figure 1 shows two versions of this group's electric transport vehicle which has now been produced on an experimental basis and which was demonstrated at the 1972 Munich Olympics.

A second major program has been undertaken by Volkswagen's Wolfsburg Research and Development Center (manufacture), Robert Bosch (motors and controls), and VARTA, AG (traction batteries) for the development of a prototype vehicle, the "Electrovan," shown in Fig. 2, which is equipped with a roll-on/roll-off battery exchange rack. Further, a third group, Mercedes (Daimler-Benz Aktiengesellschaft) (design and manufacture), Robert Bosch (motors and controls), and VARGA, AG (traction batteries), has developed a hybrid-electric bus and a transport van, shown in Fig. 3-5 which in 1972 were road tested in Frankfurt and Hamburg (1-4).

Japan.—In 1966, the Japanese set up a program to tackle positively technical problems and to develop new technologies to keep pace with the growth momentum of their economy. A system of National Research and Development Programs was established and, in conjunction with their requirements, the Agency of Industrial Science and Technology of the Ministry of International Trade and Industry (MITI) launched a program for the development of electric vehicles with a 1971-1975 budget of $14 million. This over-all program is illustrated in Fig. 6.

During the 1971-1975 time period, R&D efforts were initiated for the development of an over-all structure most suitable for an electric vehicle, plus an epochal improvement in component parts was initiated. The plan for the electric vehicles entails the simultaneous pursuit of a wide variety of associated R&D areas, which have been grouped into five projects: (*i*) establishment of test and evaluation criteria; (*ii*) development of experimental vehicles; (*iii*) development of components; (*iv*) development of charging systems; and (*v*) study of utilization systems.

The design objectives set forth thus far outline the development of a small- and medium-scale transport vehicle, a small- and medium-scale passenger vehicle, and a bus specified in Table I. The Japanese have recently tested a municipal transportation system designed around a lead-acid battery, electric-drive, mass-transport vehicle.

The success of past tests has led to the purchase of additional buses which use the roll-on/roll-off modu-

lar battery pack concept. The construction of the Osaka electric bus and its recharging station are shown in Fig. 7 and 8; these are similar to West German all-electric buses developed by MAN, VARTA AG, and RWE. Daihatsu and Nissan Motor Company Limited have also produced commercial electric vehicles for a number of years. Recently, both companies have produced several electric vans demonstrated at EXPO-70. These are shown in Fig. 9 and 10 (5-8).

The United Kingdom.—The first electric vehicle appeared before a startled British public in 1837, the same year Queen Victoria came to the throne. Although a primitive form of vehicle, this electric car

was a prototype for a new viable means of transport in the United Kingdom. Today, the electric vehicle population in the U.K. is estimated to exceed one-half million. The majority of these are industrial trucks, but a surprising number are registered road vehicles.

Although no known national program for the development of electric vehicles exists in the U.K., the government does influence the existing effort through the Electricity Council. The U.K. is one of the world's leaders in electric vehicle design, development, and application, and exports electric vehicles to a number of other nations (more than 30 companies produce electric vehicles in the U.K.). Funding for the development of electrochemical power sources this year alone is estimated to exceed $950,000. Figure 11 points out the depth of the U.K. program, and its primacy in many developmental areas was the announcement in late 1972 of the operation of the world's first sodium-sulfur battery-powered vehicle. Even though this vehicle is in the early prototype stages, it is the

Table I. Projected specifications and performance of Japanese electric vehicles (end of 1973) (8)

Parameters	Cargo vehicle		Passenger vehicle		Bus
	Small scale	Medium scale	Small scale	Medium scale	
No. of passengers	2	2	4 or 2	5 or 3	60-80
Payload (kg)	200	1,000	100	300	—
Total weight (kg)	1,100	3,500	1,000	2,000	15,000

sodium-sulfur traction battery, successfully demonstrated in this test-bed vehicle, that is receiving worldwide R&D interest. This work is detailed more fully in the section on the sodium-sulfur battery (9-14).

U.S.S.R.—In 1899, a Soviet electrical engineer, I. V. Romanov, demonstrated a battery-powered "electric carriage," the first Soviet all-electric vehicle, in St. Petersburg which could travel 36 miles at a speed of 18 mph. The first Soviet electric-powered "car" per se was built in 1935, and from 1948 to 1959 several prototypes were tested in the Moscow and Leningrad areas. A coordinated effort for the development of electric vehicles did not begin until 1968, when a council was set up under the direction of the Ministry of the Electrical Engineering Industry of the U.S.S.R. and the American Academy of Sciences, to tackle the scientific problems involved, which included: the Ministry of Automobile Transportation, the Yerevan Polytechnical Institute imeni Karl Marx, and the All-Union Scientific Research Institute for Electric Transport.

Between 1969 and today, a variety of prototype vehicles have been tested, and a series of experimental vehicles were produced at the Cheboksari Motor Works shown in Fig. 12.

Armenian scientists have developed a computer model for the optimal design of electric vehicles, making it possible to swiftly and objectively assess prototype proposals. The newest Soviet prototype vehicle is shown in Fig. 13 (15-24).

All-Electric Vehicle Requirements

The U.S. Department of Transportation has estimated that the minimal energy and power requirements for an all-electric family car are 135 W-hr/lb and 100 W/lb, respectively. Under normal interstate highway driving conditions, this vehicle would have a range of 200 miles per charge at an average speed of 60 mph, which is adequate for urban transit in and out of most major metropolitan areas in the United States. These requirements are summarized in Table II. Minimal requirements for other types of all-electric vehicles are presented in Table III (25-27).

Electrochemical Power Sources

Three types of electrochemical power sources are available for all-electric vehicles: aqueous electrolyte storage batteries, organic or molten electrolyte high energy batteries, and fuel cells. The major battery systems of significant R&D interest are summarized in Table IV; presently, the lead-acid, nickel-zinc, zinc-air, sodium-sulfur, and lithium-sulfur traction

Ag-Zn	440	120	Low
Ni-Zn	330	40	Low
Ag-Cd	270	50	Low
**Ni-Fe	265	17	Low
**Ni-Cd	210	17-20	Low
**PbO_2	170	17+	Low

* Low temperatures are operational temperatures below 100°C.
** Conventionally used storage batteries in both industrial and commercial all-electric vehicles.

batteries are very promising for application in urban transit and interstate vehicles.

Lead-acid traction battery.—Developed in 1852 and technically explained by Gladstone's "Double Sulfation Theory" in 1888, the lead-acid battery has become the predominant battery system used in more than 90% of the all-electric vehicles produced today because of its long service life, high reliability, and low cost (approximately $0.30-1.00/lb, depending upon the battery's quality). Improvements in both materials and electrode designs have extended the service life of this battery from 300 to 2000+ recharge cycles. Currently, improved lead-acid batteries are being successfully tested in urban transit vehicles and buses in the F.R.G. and in Japan. The Electro Bus and the associated recharge system developed by VARTA, AG, Daimler-Benz, and Bosch, of the F.R.G., has been successfully tested and was found to require minimal maintenance and to have significantly reduced emissions (see Fig. 3-5). The Japanese have also demonstrated an all-electric bus in Osaka, and a fleet of electric delivery vans at EXPO '70 (see Fig. 7 and 8). Additional applications of lead-acid batteries in short range all-electric and hybrid-electric vehicles will increase throughout the 1970's, with improvements in the charge acceptability and capability of the battery. Specific improvements in lightweight alloys for cell connectors and in superthin, long-life separators, plus the use of bipolar or foil electrodes, are anticipated. Even with these innovations, it is rather doubtful that the lead-acid battery will meet the requirements for an all-electric vehicle capable of extended travel on interstate highways due to its limited energy density (see Fig. 14). For an all-electric vehicle to commercially compete with internal combustion engines, batteries having greater energy densities must be developed (29, 30).

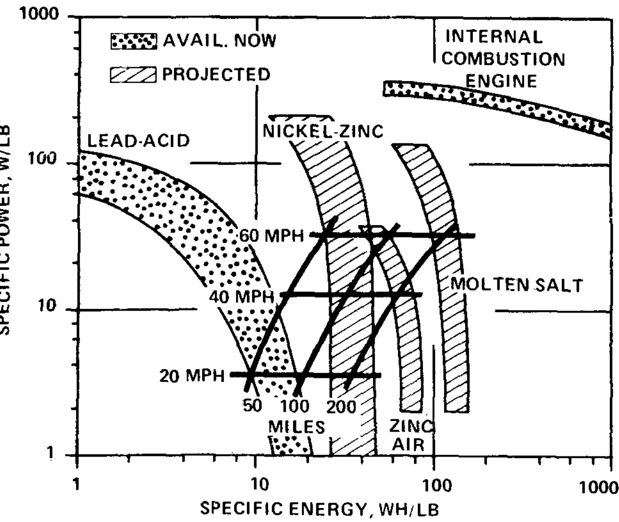

Fig. 14. Power source comparison with vehicle requirements. 200 lb vehicle (500 lb batteries).

Nickel-zinc traction battery.—Initially discovered in the 1800's, the nickel-zinc alkaline battery has been extensively investigated by the Soviets since the mid-1950's, and by the United States since the 1960's. Today, active research continues in the United States, U.S.S.R., F.R.G., and Japan for applications in hybrid-electric engine vehicles. The nickel-zinc battery operates according to the following electrochemical reaction, producing aproximately 1.7V per cell with a theoretical energy density of 146 W-hr/kg. Currently, Furukawa Battery Company Limited of Yokohama, Japan, has developed several prototype 96V, 140 A-hr batteries with nylon and cellophane separators, achieving an energy density of 45-50 W-hr/kg, with a service life of 200 cycles. It was found that the relatively short cycle life was due to separator failure at high electrolyte temperatures generated during charging. Improved heat-resistant separators similar to those used in NASA silver-zinc batteries (sterilized separators) may double the service life of this battery. Similar U.S. research by ESB Incorporated and by Energy Research Corporation has resulted in the successful demonstration of prototypes having energy densities twice that of lead-acid batteries. Potentially, the nickel-zinc battery is the best battery for hybrid-electric vehicles because of its stable discharge voltage, wide operational temperature range, deep discharge capability (50-75% discharge), and relatively low cost. Nickel-zinc batteries having power densities of 100+ W/lb, costing approximately $2.00/lb, will probably be a reality within the next 5 years (27-33).

Zinc-air traction battery.—In recent years, the zinc-air alkaline storage battery has dominated the field of metal-air batteries because of its low cost, high energy density, and favorable electrochemical reactivity. Having a theoretical energy density of 614 W-hr/lb and an open-circuit voltage of 1.65V, the zinc-air battery is promising; however, serious problems regarding zincate ion, carbonate, and zinc dendrite formation have limited cycle life. In developing a secondary zinc-air system, four basic prototype systems have been investigated (33-34): (*i*) the mechanically rechargeable battery (1964); (*ii*) the noncirculating alkaline electrolyte battery (1968); (*iii*) the circulating alkaline electrolyte battery (1968); and (*iv*) the zinc-feeding-fuel battery (1970). A 1 kW mechanically rechargeable zinc-air battery has been

developed and evaluated by General Motors Corporation in an Opel Kadett test-bed vehicle. The battery had an energy density of 42 W-hr/lb and a power density of 31 W/lb and could meet the power requirements for urban transit vehicles. This battery was shelved, however, because of practical recharge problems. Noncirculating alkaline electrolyte zinc-air batteries have also been investigated, but during charging have suffered from zincate ion and dendrite formation on the surface of the zinc anode. After a number of charges, the dendrites penetrate through the separator, short circuiting the cells. The British Electricity Council Research Centre in Capenhurst, England, has developed a hydrodynamic zinc-air cell to reduce zinc dendrite formation by bubbling argon gas over the anode's surface. Tests indicated that at a current density of 800-1500 A/m^2 a smooth homogeneous electrodeposition of zinc on the anode resulted (see Fig. 15 and 16).

A circulating electrolyte zinc-oxygen 27 kW battery created by Gulf General Atomic has achieved a 27 W-hr/lb energy density and a 20 W/lb power density. This system was technically encouraging, but because of its complexity, was not economically feasible for commercial vehicles.

Sony Corporation Limited of Japan has developed a new pulverized zinc fuel battery, which is externally charged by a zinc and electrolyte regeneration unit (see Fig. 17 and 18). This battery achieved an energy density of 41 W-hr/lb and a power density of 10 W/lb for a 50-100 hr operation at a cost of approximately $100/kW. The Sony battery is very complex and must be simplified before serious consideration can be given to standard production of this power source (35).

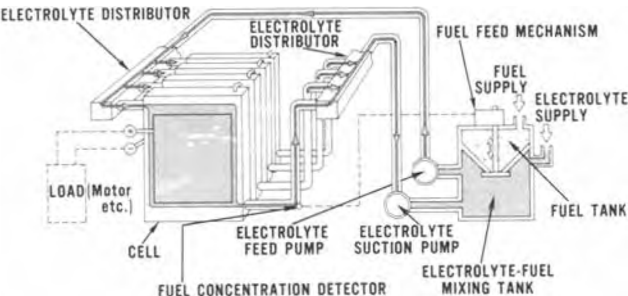

Fig. 17. Flow diagram of Sony metal fuel battery system

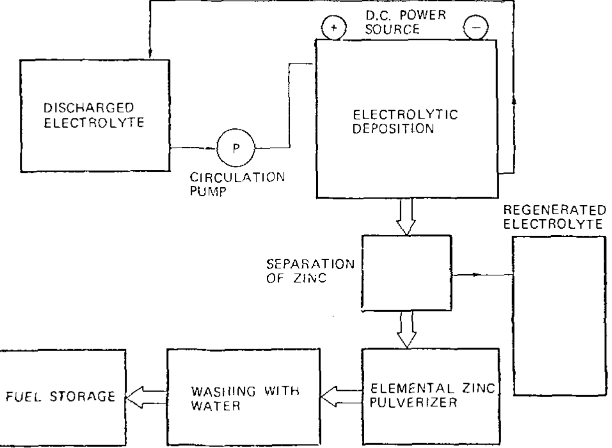

Fig. 18. Flow diagram of fuel and electrolyte regeneration process by Sony.

Sodium-sulfur and lithium-sulfur high energy batteries.—The sodium-sulfur (Na-S) storage battery originally developed by Dr. Nils Weber and Dr. Joseph Kummer of Ford Motor Company Research Laboratories, Dearborn, Michigan, in 1966, appears to be the most promising electrochemical power source for long-range (200$^+$ miles/charge at 60 mph) all-electric vehicles. This battery has a theoretical energy density of 346 W-hr/lb and an open-circuit voltage of from 1.8 to 2.1V. The battery operates at an optimal temperature of 300°C.

The over-all reaction mechanism is shown in Fig. 19, and the construction of a Japanese prototype by Yuasa Battery Company Limited and Toshiba is shown in Fig. 20. Interest in, and research on, this battery has rapidly increased since 1966 because of the battery's following advantages (36):

(*i*) It has high energy and power densities due to lightweight reactant materials.

(*ii*) Due to the economical abundance of reactant materials, the battery's cost/kW-hr may be smaller than that of lead-acid traction batteries.

(*iii*) No self-discharge mechanism is foreseen.

(*iv*) No shape changes on electrodes occur because the reactants are liquids.

(*v*) No gases are generated during charging.

(*vi*) There is no danger of electrolyte spillage.

The service life of this battery depends upon the life of the beta-alumina ($Na_2O \cdot 11\ Al_2O_3$) ceramic separator which is permeable only to the sodium ion along the C-axis. Yuasa, Toshiba, and Toyota Motors Research Laboratory have conducted extensive research to increase the strength and lower the internal resistance of the ceramic. The resistivity has been reduced by the addition of impurities such as Mg^{+2}, Ni^{+2}, Cu^{+2}, and MgO, but the exact doping procedure is proprietary and the subject of patent

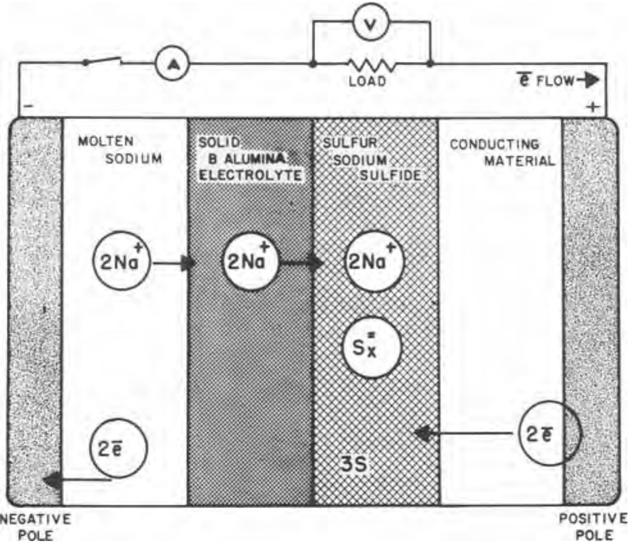

Fig. 19. Reaction mechanism for sodium-sulfur high energy traction battery.

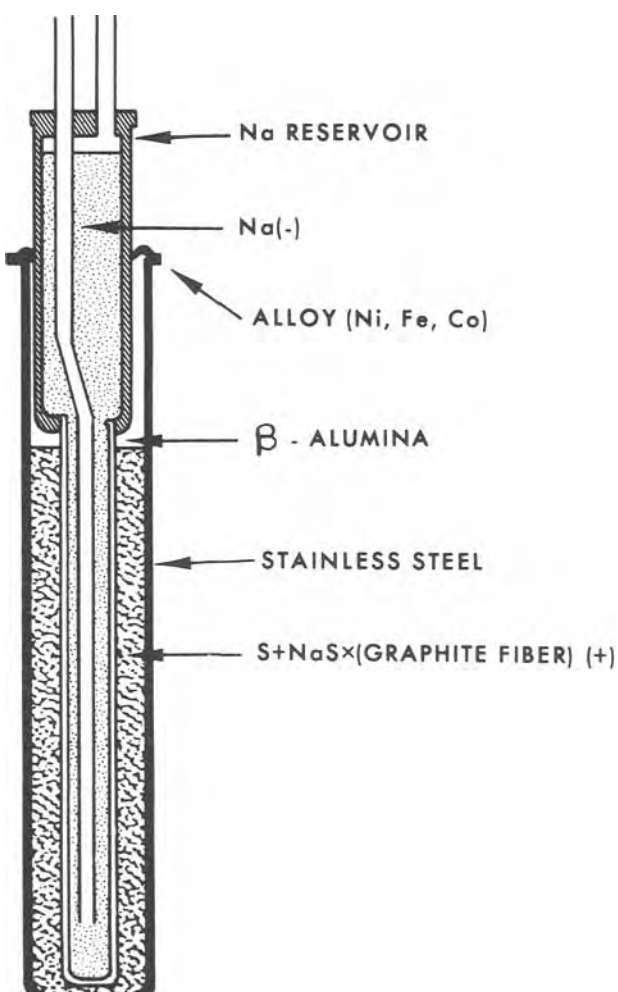

Fig. 20. Sectional view of Yuasa's sodium-sulfur battery

applications. Continued progress in developing improved ceramic materials, sealing techniques, and production methods are anticipated with limited production of sodium-sulfur battery-powered vehicles expected by 1978.

Lithium-sulfur high energy batteries have a theoretical energy density of 700 W-hr/lb and an open-circuit potential of 2.25V at operating temperatures of 300°-370C°. The electrolytes are a molten LiI-KI-LiCl eutectic salt, with molten lithium and sulfur as the anode and cathode. This battery has a high discharge rate capability, and should be particularly useful in large power installations. Currently, the major problems of this system are high temperature corrosion and solubility, sulfur loss, and sulfur electrode inefficiencies. Application of this battery in electric vehicles appears remote (possibly by the mid-1980's) because of these material problems (32).

Other prototype batteries have been developed by Companie General d'Electrique (CGE) of France, the Czechoslovak Academy of Sciences in Bratslavia, and British Railways of the U.K. Recently, British Railways and the Electricity Council Research Center (ECRC) have completed initial road testing of the world's first sodium-sulfur powered vehicle, an 18 cwt Bedford delivery van (see Fig. 11 and 21), employing thirty 1 kW module, sodium-sulfur cells achieving 100 miles per charge at 40 mph (37).

Fuel Cells for Ground Propulsion Systems

Fuel cells, which were discovered by Sir William Grove in 1839 and greatly improved through the 1950's and 1960's, have been successfully employed in electric vehicles produced by ASEA of Sweden, Shell Thornton Limited of the U.K., General Motors Corporation, Union Carbide, and several other companies in the United States. These systems, using ammonia, hydrazine, and hydrogen fuels, are reliable, pollution free, and very efficient, but because of the use of exotic noble metal catalysts, are rather expensive and complex for standard production. Even with reduced catalyst loadings and the use of substitutes, such as tungsten carbide and tungsten bronzes for platinum and palladium electrodes, costs will be greater than that for lead-acid, nickel-zinc, and possibly sodium-sulfur systems. Currently, the "Target" program involving Pratt and Whitney Aircraft Corporation and thirty utility companies, plus the EXXON-Alsthoms corporation programs, are the only two major U.S. fuel cell programs. Major breakthroughs must result from these programs to revive the fuel cell for ground propulsion systems. Only with the initiation of a "Hydrogen Economy," with economic methods of hydrogen generation by electrolysis or thermal cracking of water, hydrogen transmission via conventional gas lines, and noncryogenic or pressurized storage of hydrogen, will the fuel cell emerge as a practical propulsion source for commercial transportation. Philips Research Laboratories of the Netherlands has developed new rare earth intermetallic compounds, which store large quantities of room temperature hydrogen at 5 atm pressure

$$LaNi_5 + H_2 \underset{\text{heat}}{\overset{\text{5 atm}}{\rightleftarrows}} LaNi_5H_6$$

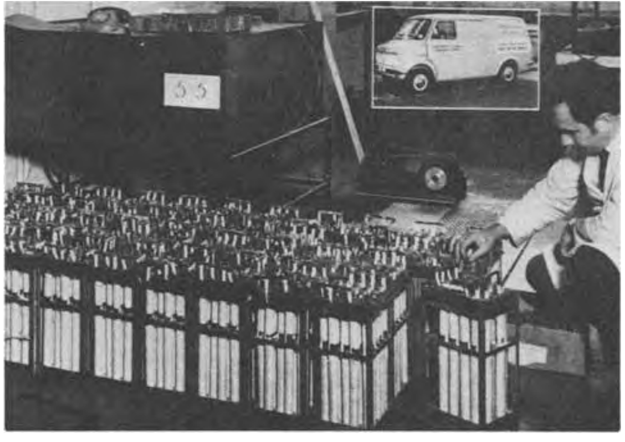

Fig. 21. British Railway's and ECRC's 30 kW sodium-sulfur powered delivery van.

$$SmCo_5 + H_2 \underset{heat}{\overset{5\,atm}{\rightleftarrows}} SmCo_5H_3$$

These reversible hydride complexes have been developed for the Stirling engine, but fuel cell applications are evident; however, large scale production of hydrogen to meet current domestic energy demands has yet to be demonstrated (38, 39).

Raw Material Requirements

The materials required for the large scale production of these electrochemical power sources include elements such as lithium, sodium, sulfur, chlorine, alumina, lead, and graphite, which are economically abundant. Other elements such as nickel, cadmium, zinc, and the noble metal catalysts are not abundant in the United States and will have to be imported from Canada or the U.S.S.R. to satisfy the demands of a growing electric vehicle population. This importing activity will not improve the balance-of-payments situation abroad and, with the high demand anticipated, the price of these metals will increase rapidly. Construction materials for containers, cell connectors, and contacts which are corrosion resistant, thermally and chemically stable, and enhance electrical conductivity, such as niobium, tantalum, and tungsten, are not presently available to meet this demand; thus, substitute materials such as aluminum, stainless steel, high temperature plastics, and graphite must be used. Fuels such as hydrazine for fuel cells are also very expensive because of the high production costs. Breakthroughs in the synthesis of hydrazine, along with improvements in the distribution and availability of these fuels, must be made before the fuel cell can readily compete with the internal combustion engine and appeal to the buying public (40).

Conclusion

Review of the power requirements, cost and availability of materials and reactants, reliability and service, safety, and public appeal indicates a high temperature alkali metal battery system such as the sodium-sulfur and lithium-sulfur battery is most promising and offers the greatest potential for satisfying the foregoing requirements for conventional six-passenger cars. Currently, lead-acid traction batteries are adequate for powering lightweight (1500 lb) all-electric commuter cars in urban areas where the maximum driving range is less than 25 miles per day. Secondly, fuel cells offer an effective energy density, power density, and reliability; however, the cost and availability of fuels and catalysts limit their applications. Possibly, by the mid 1980's, when the availability and public acceptability of hydrogen as a fuel is a reality, fuel cells will begin to emerge as a significant power source for both propulsion and domestic power applications. Greater investment by the United States Government in R&D relating to electrochemical power sources in this crucial area is necessary. The magnitude of the technical problems involved and the significance of the potential technological achievements should be recognized in conjunction with the necessity to limit pollution in the metropolitan areas.

Manuscript submitted Aug. 3, 1973; revised manuscript received Nov. 12, 1973. This was Paper 10 presented at the Boston, Massachusetts, Meeting of the Society, Oct. 7-11, 1973.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1974 JOURNAL. All discussions for the December 1974 Discussion Section should be submitted by Aug. 1, 1974.

Thin Oxide Films on Iron[1]

Morris Cohen*

Division of Chemistry, National Research Council of Canada, Ottawa, Ontario, Canada

The first two papers (1, 2) I presented at a Meeting of the Electrochemical Society were given at Birmingham, Alabama in 1946. They were concerned with a technique for studying corrosion and an inhibitor for stopping corrosion. The next paper (3) was the first paper on inhibition by sodium nitrite. The final conclusion in that paper was as follows: "The mechanism for inhibition is probably the formation of a tight oxide layer which is formed by the combined action of nitrite and oxygen and is repaired by the nitrite." It was also proposed that the same type of mechanism was applicable to chromate inhibition. At the time this was quite contrary to the most commonly accepted dogma on passivity and inhibition. This review will deal with attempts our laboratory has made to determine the mechanisms of formation of and the properties of these thin oxide films on iron.

Chemically Formed Films—Inhibitors

The early work on nitrite showed that the weight loss of iron in solution decreased as both the concentrations of nitrite and oxygen (4, 5) were increased. At intermediate concentrations pitting was observed. There was also some decrease in the nitrite concentration during the exposure of the iron specimen to the nitrite solution. Ammonia was shown to be a by-product of the reaction of nitrite with iron. On this basis it was postulated that the film was formed by adsorption of nitrite on the iron surface followed by a reaction to form oxide and ammonia. This is illustrated in Fig. 1. The O-O distance in the nitrite is not too far removed from the Fe-Fe distance in iron. This same type of adsorption-reaction mechanism was also proposed for other oxidizing inhibitors such as chromate and molybdate (6). In the case of the nitrite the reduction product of the inhibitor is soluble and hence a protective film containing iron and oxygen, and possibly hydrated oxide would be formed. Under sufficiently inhibiting conditions only an anhydrous cubic oxide is observed by electron diffraction (9). With chromate the reduction product is insoluble Cr_2O_3 and this would be expected to be found in the film (7). Figure 2 is the electron diffraction pattern of the "Fe_3O_4-γ-Fe_2O_3" film formed on a single crystal of iron exposed to sodium nitrite solution. This film is epitaxial with the underlying metal and about 20-30A in thickness. In Table I the amount of Cr_2O_3 in film formed in chromate solution as a function of exposure conditions, is presented.

Nonoxidizing inhibitors require the presence of oxygen to prevent corrosion. This is illustrated for sodium phosphate (10) in Fig. 3. This figure also shows the relationship between corrosion rate and potential. It can be seen that inhibition of corrosion in solutions containing the nonoxidizing phosphate ion occurs only in the presence of oxygen. The phosphate is a buffer which prevents acidity from developing and also acts to precipitate ferric phosphate in pores which may develop in the film. The amount of phosphate in the film depends on the surface preparation of the iron and the corrosivity of the solution (11). An electron micrograph of an iron specimen which had been exposed to a phosphate solution containing chloride ion showed large inclusions which gave the diffraction pattern of a hydrated $FePO_4$.

Key words: passivity, inhibition, thin films.

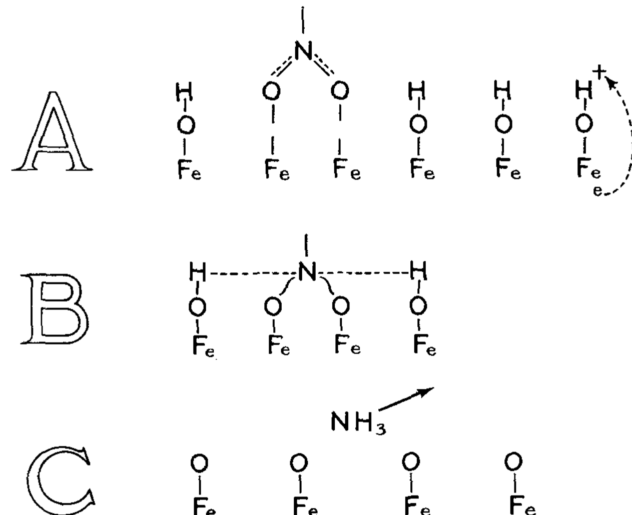

Fig. 1. Adsorption of NO_2^- on iron and reaction to form NH_3, H_2, iron oxide film.

The behavior in both oxidizing and nonoxidizing inhibitors (6) in the presence of oxygen is shown in Fig. 4. A much higher concentration of nonoxidizing anion is required to inhibit the corrosion of iron. In all cases when the corrosion is inhibited the potential of the iron is greater than 0, (hydrogen scale) and < -500 mV when corroding. The films are mainly composed of "Fe_3O_4-γ-Fe_2O_3." Some γ-FeOOH and other ferric compounds may also be present under some conditions. Phosphorus and chromium compounds in the films were determined using radio-tracer techniques (7-11).

Electrochemically Formed Films

Electropolishing.—In the course of this work it was desirable to start with a clean smooth surface having a reproducible type of oxide film on it. To this end a technique was developed for electropolishing in a 5% perchloric-acetic acid mixture (12) which produced a smooth iron surface covered with a thin film of the "Fe_3O_4-γ-Fe_2O_3" type oxide. This film, and variations thereof, were studied using reflection high energy electron diffraction (13). Lattice spacing measurements were made both immediately after electropolishing and after aging in air or vacuum. Some specimens were also first cathodically reduced in a borate buffer solution (14), and then exposed to air. The results are shown in Table II. It can be seen that the lattice parameter of the freshly electropolished specimen (8.26) is lower than that for either γ-Fe_2O_3 (8.32) or Fe_3O_4 (8.38). On annealing or aging over a period of time the lattice parameter gradually changes

Table I. Amount of chromium (as Cr_2O_3) in film formed in chromate solution

to a final 8.38. This would indicate that the electropolishing (plus initial air exposure) produces a film which is cation deficient in relation to γ-Fe_2O_3. On aging in air or vacuum, iron diffused into the film gradually converts through γ-Fe_2O_3 to Fe_3O_4. If the E.P. film is cathodically reduced and the specimen exposed to air the iron oxide has an average lattice parameter closer to that of γ-Fe_2O_3. This oxide also converts to Fe_3O_4 on vacuum annealing. The diffraction patterns are similar to those shown in Fig. 2 for films formed in nitrite solution. This indicates that the film is a highly epitaxed microcrystalline cubic iron oxide with an average crystallite size of 20-30Å. The thickness of the electropolished film on this (112) surface was estimated to be 17Å by the cathodic reduction technique.

Anodic passivity.—Having now developed the techniques for reproducible surface preparation, analytical cathodic reduction and electron optical examination of the thin films, we felt it should be possible to do a more definitive study on films formed by anodic oxidation, that is the so-called anodically formed passive

film. For a number of reasons, such as pH control, the solution used for cathodic reduction, *i.e.*, a borate buffer, modified slightly to remove chloride and give a pH of 8.4 was used in these studies (15, 16). This was a solution in which it was possible to form a passive film from an originally bare surface [something which could not be done with chloride or sulfate (17)].

The typical potentiostatic polarization curve obtained in the borate buffer solution is shown on line 1 of Fig. 5. The specimens were electropolished and cathodically reduced before the anodic polarization. Essentially no dissolution of iron occurs between about −200 mV and +850 mV (SCE). Only small amounts of iron are observed between −500 mV and −250 mV. Typical potentiostatic charging curves in the passive region are shown in Fig. 6. Graphical integration of these curves gave the number of coulombs passed during polarization while analysis of the solution for Fe^{++} gave the number of coulombs used for iron dissolution. The difference was used in forming the film. These results are also shown in Fig. 5. As can be seen the thickness of the passive film varies from about 8Å at −400 mV to 30Å at 850 mV. Above this potential oxygen evolution sets in and renders the coulometric method inaccurate for the estimation of thickness. In these neutral solutions the anodically dissolved iron was always in the ferrous state. Some specimens were passivated at constant current. The number of coulombs used to reach the various passive potentials was about the same as for a short time potentiostatic oxidation. Electron diffraction patterns of the films formed by anodic oxidation of an iron single crystal were similar to those on

specimens formed by oxidation in nitrite solution or by electropolishing. The film was a highly oriented epitaxial microcrystalline cubic oxide.

A typical cathodic reduction curve for these films is shown in the top part of Fig. 7. Two waves are evident, one for the reduction of γ-Fe_2O_3 (to give Fe^{++} in solution) and the other for the reduction of Fe_3O_4 (to give a combination of Fe^{++} in solution and deposited iron). The amount of iron cathodically produced in the solution after various anodic treatments is shown in the bottom part of Fig. 7. These were done with no intermediate exposure to air or oxygen. The initial cathodic reduction current efficiency is low,

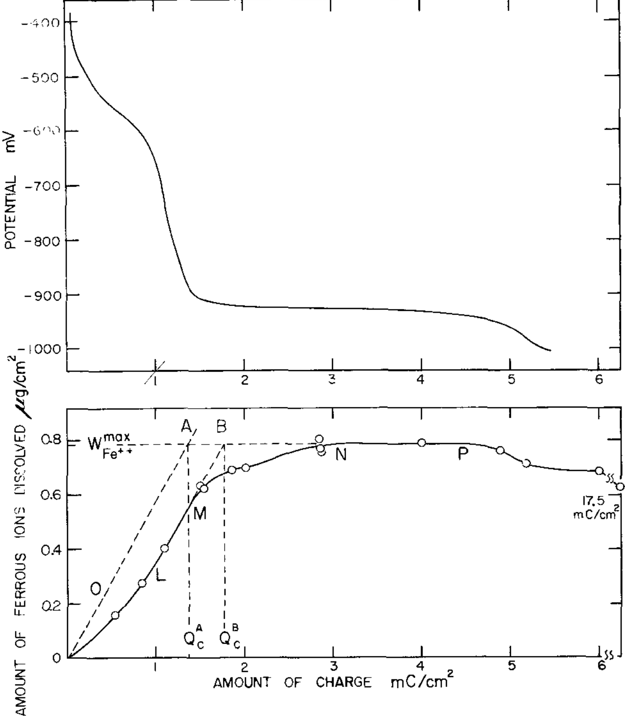

Fig. 7. Top curve: Cathodic reduction at 10μ A/cm² of anodically oxidized specimen. The two waves correspond to the reduction of γ-Fe_2O_3 and Fe_3O_4. Bottom curve: The amount of Fe^{++} in solution after various times of cathodic reduction. The dotted line represents a current efficiency of 100% for the reduction of γ-Fe_2O_3.

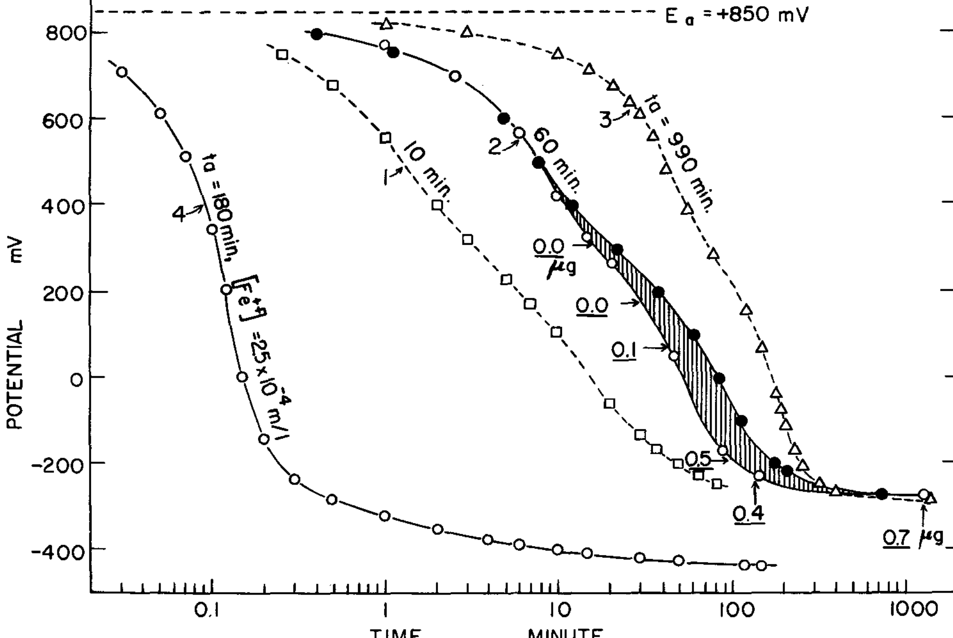

Fig. 8. Decay curves for potential of iron anodically oxidized at +850 mV for various times. Ferrous iron was added to the solution to obtain curve 4. The numbers on curve 2 correspond to the amount of iron in solution.

if based on the reaction

$$3H_2O + Fe_2O_3 + 2e \rightarrow 2Fe^{++} + 6\,OH^- \quad [1]$$

This was taken to indicate that the outer layer of the film was composed of a cation-deficient γ-Fe_2O_3 of the general formula $Fe_{2-x}O_3$, the x being accounted for by the presence of a higher valent iron species in the outer layer of the film such as Fe^{6+}. This behavior was observed with films formed well below the oxygen evolution potential and hence could not be attributed to oxygen adsorption.

A series of experiments were also performed in which, after anodic polarization, the open-circuit potential of the specimen was followed with time. This type of decay curve is shown in Fig. 8. In the absence of Fe^{++} the rate of decay of the potential is very slow and depends on the time of the polarization. If ferrous iron is added the decay is very rapid and the final steady-state potential is lower. In all cases the final steady-state potential is still in the passive region. At much longer times the film finally breaks down and corrosion starts. The final steady-state potential is also dependent on the pH of the solutions.

During the decay the reaction is probably

$$Fe_{2-x}O_3 + xFe \rightarrow Fe_2O_3 \quad [2]$$

This is a solid-state reaction in which diffusing iron from the underlying metal reacts with the outer oxide and corresponds to what was earlier observed during vacuum aging of the electropolished film. The reaction with Fe^{++} in solution would follow a nominal equation such as

$$Fe_{2-x}O_3 + 3xFeOH^+ \rightarrow (1 + x)Fe_2O_3 + 3xH^+ \quad [3]$$

The rate of this reaction should depend on diffusion of $FeOH^+$ in the solution to the oxide surface and would be faster than the solid-state diffusion required in reaction [2].

The effect of pH and Fe^{++} concentration on the steady-state potential of the passive film would indicate that the electrochemical reaction determining the potential of the passive film is

$$Fe_2O_3 + 3H_2O + 2e \rightleftharpoons 2Fe^{++} + 6\,OH^- \quad [4]$$

From the potentials measured and the known values of the other reactants one can calculate the free energy of formation of γ-Fe_2O_3. This comes out to -166.5 kcal/mole and is quite reasonable in relation to Fe_3O_4 and α-Fe_2O_3. γ-Fe_2O_3 is intermediate in stability between these two oxides.

On the basis of the above considerations a general picture of the oxide film is shown in Fig. 9. Although phase boundaries are shown these do not exist as real phase boundaries. Rather the oxide is composed of a cubic array of oxygen into which iron atoms fit. Close to the metal surface the oxide has an oxygen-iron ratio close to that of Fe_3O_4 while close to the surface it is $Fe_{2-x}O_3$. In between the ratio is close to that of γ-Fe_2O_3. On aging in the solution or in an oxygen-free atmosphere the whole oxide gradually converts to Fe_3O_4. On adding Fe^{++} ion the outer layer is quickly converted to γ-Fe_2O_3.

Kinetics of anodic oxidation.—The good reproducibility obtained during anodic oxidation of iron in the neutral borate-buffer solution indicated that this system could be used for a detailed study of the

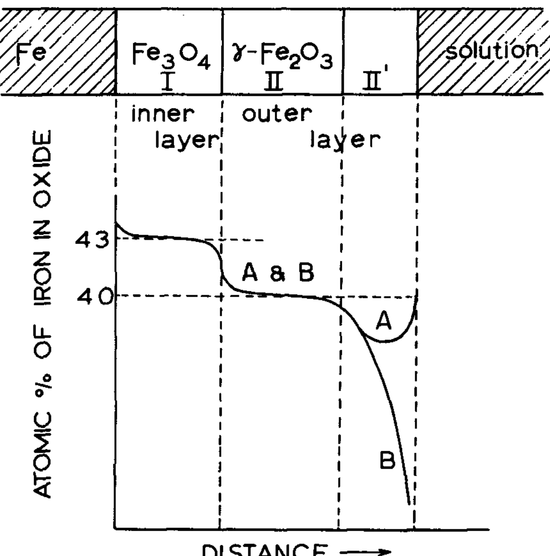

Fig. 9. Schematic composition of anodic oxide film. A, in the presence of iron; B, in the absence of iron.

kinetics of oxide growth during anodic polarization. This study was reported in two papers on initial and steady-state kinetics (18, 19). Specimens were prepared by anodic oxidation at a low potential for a set time to produce a thin oxide of known thickness. They were then further oxidized potentiostatically by raising the anodic potential and following the change of current with time or galvanostatically by applying a constant current and following the potential change with time. Some results are shown in Fig. 10 and 11. As can be seen in Fig. 10 the total charge is dependent on the applied potential but the slope of the log i *vs.* coulombs curve is constant over the whole potential

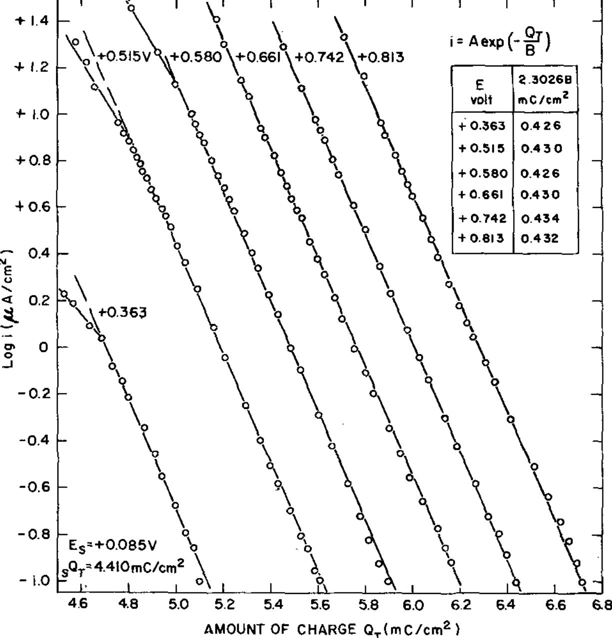

Fig. 10. Potentiostatic oxidation of iron with pre-existing thin oxide film of 4.410 mC/cm² formed at +0.085V.

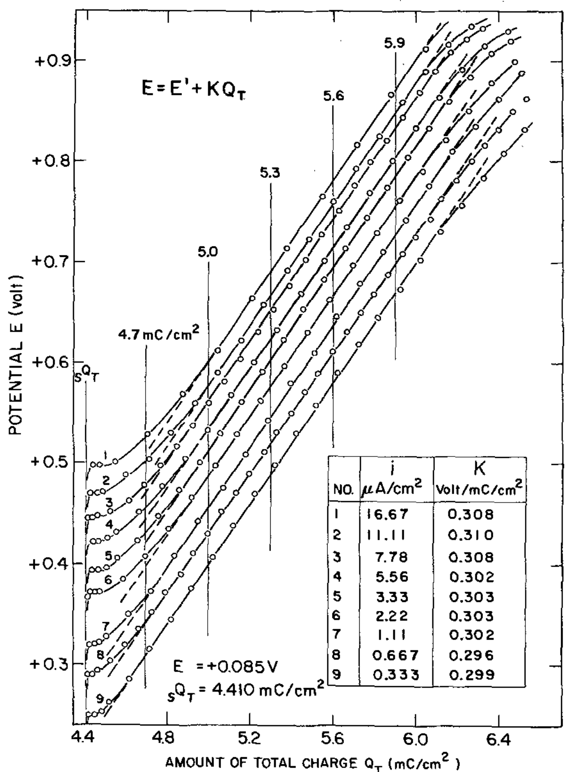

Fig. 11. Galvanostatic oxidation of iron with same pre-existing film as in Fig. 10.

range. All the results could be expressed by the equation

$$i = A \exp\left(\frac{-Q_T}{B}\right) \qquad [5]$$

where the value of A is dependent on the charging potential and B is constant. Q_T is the total charge used in forming the film and hence is a measure of its thickness. One can also obtain an i/Q_T curve from the data of Fig. 11. These agree with the data obtained potentiostatically. Also from Fig. 11 it can be seen that the thickness, (Q_T), is a linear function of the potential with a slope which is independent of the current density. One can also obtain polarization curves (log i *vs.* E) at different thicknesses from this data. In the steady growth region the slope is constant and independent of thickness. The slope is also independent of pH.

Some potentiostatic experiments were also run in the temperature range of 0°-35°C. Again curves obeying the equation $i = A \exp -Q_T/B$ were obtained. However, the value of B changed with temperature.

Although there had been a number of mechanism proposed for explaining the kinetics of anodic growth of thin oxide films, none appeared satisfactory for this set of results. We therefore adapted the place-exchange mechanism which had been proposed for dry oxidation. A more detailed mechanism was worked out (18) which proposed the simultaneous (or cooperative) rotation of rows of atoms. The applied potential supplied part of the driving force. A schematic representation of the process is shown in Fig. 12. The activation energy for growth increases with thickness until it exceeds the activation energy required for diffusion or other growth processes. Because of the applied potential the oxide can become thicker than under conditions of dry oxidation.

Oxidation in low pressure oxygen.—We have made a number of attempts to measure the rate of dry oxidation of iron at room temperature. Microbalance measurements, using either a quartz beam type or a sensitive Cahn type, were not sufficiently sensitive. Two techniques were successful. In one of these (20) the reaction was followed by measuring the change of pressure with time at constant volume. With the other the (21, 22) intensity of an electron beam excited OK_α X-ray line was measured to determine the amount of oxygen in the surface.

The pressure-change apparatus was constructed of stainless steel, except for a fused silica specimen chamber. It could be baked and pumped to a base pressure of about 10^{-8} Torr. The uptake measurements were made at about 10^{-2} Torr. The change of pressure was measured using a calibrated Pirani gauge. The specimens were electropolished and hydrogen reduced before the reaction. Using 10 cm² specimens the measurements were sensitive to about 2×10^{-8} g/cm². With smaller specimens, such as the 2 cm² single crystals the sensitivity was less, about 1×10^{-7} g/cm² or the equivalent of just under 1Å of Fe_3O_4.

Results for three different specimens are shown in Fig. 13. The uptake in all cases is approximately logarithmic and the thickness approaches 13-16Å de-

Fig. 12. Illustration of place-exchange mechanism for anodic oxidation of iron. Note simultaneous rotation of rows.

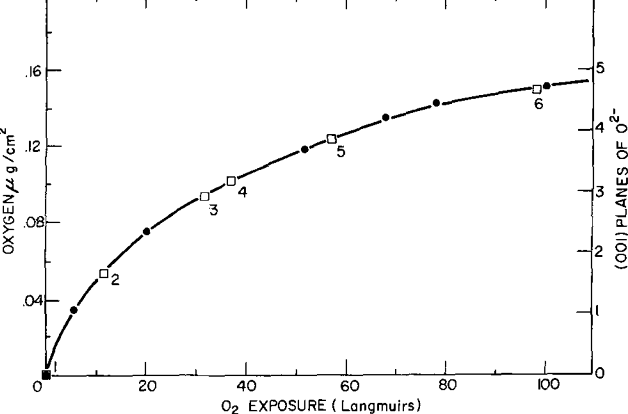

Fig. 14. Oxidation of iron in RHEED-XRE apparatus. The squared numbers were points at which electron diffraction patterns were measured.

pending on the orientation. The polycrystalline oxide has the highest uptake. The oxide on the single crystal specimens was shown by electron diffraction to be a well-oriented epitaxial microcrystalline oxide of the Fe_3O_4-γ-Fe_2O_3 type, similar to that observed previously for oxide formed by anodic oxidation or air exposure of a cathodically reduced specimen. Surface area measurements were made using krypton adsorption and the surface roughness (≈ 1.2) was the same for all the specimens. The small anisotropy of oxidation is probably due to varying grain (or subgrain) size with surface orientation. The observed thickness is about the same as that reported above for iron which was electropolished or etched and exposed to atmospheric air and in the middle range of the thicknesses formed by anodic oxidation of iron in the borate buffer solution.

A RHEED-XRE apparatus (21) was used to examine the growth of oxide on iron at lower pressures. In this apparatus it was possible both to obtain reflection high energy electron diffraction of the surface and to measure the oxygen uptake by the x-ray emission from the surface oxygen of the OK_α line. This x-ray emission could be excited by the high energy electron beam (40-50 kV) or by an auxiliary low energy (500-2000V) beam directed at right angles to the speci-

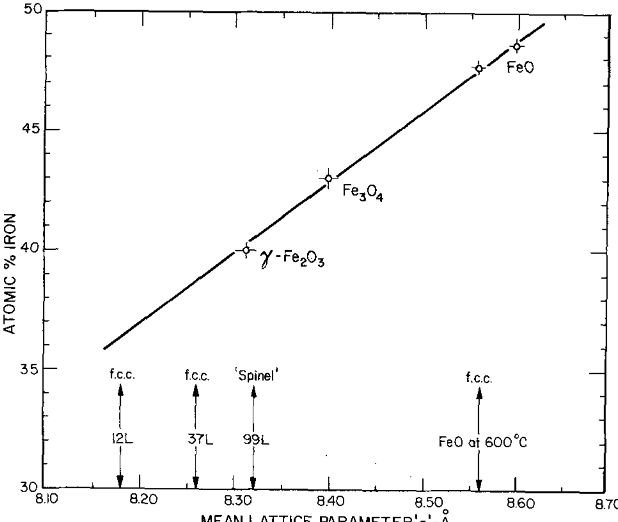

Fig. 16. Variation of oxide lattice parameter with Fe concentration in oxide. The first oxide formed (at 12L) is iron deficient and changes towards the spinel with further exposure.

men. The latter was used in these studies of oxygen take-up (22).

In this study the single crystal high purity iron was further purified in the apparatus to remove carbon, sulfur, and oxygen. It was then exposed to low pressure oxygen, and measurements were made. It was found that over the oxygen pressure range of 5×10^{-8} to 2×10^{-6} Torr and for specimen temperatures from 25° to 150°C, the rate of oxidation at any specific thickness was directly proportional to pressure. In the very early stages of oxidation of a clean surface the sticking coefficient was close to one and dropped to 10^{-3} and lower after some oxide formation. The x-ray emission measurements were calibrated using specimens prepared in the pressure-change apparatus. The sensitivity was, of course, considerably higher than that of the pressure-change equipment.

A typical oxidation curve is shown in Fig. 14. Reflection high energy electron diffraction patterns before and during the oxidation are shown in Fig. 15. Although these measurements were made at 150°C almost identical results are obtained at lower temperatures in this exposure range. The mean lattice parameter parallel to the surface was determined from the diffraction patterns and varied from 8.18 ± 0.04 at low exposures to 8.34 ± 0.06 for long exposure times. The relationship of these observed lattice parameters to those of the oxides of iron is shown in Fig. 16. It can be seen that the oxide starts out with a structure corresponding to an oxide containing even less iron than γ-Fe_2O_3 and as it thickens (and ages) gradually moves through γ-Fe_2O_3 to Fe_3O_4. The thickness at 99L ($L = 10^{-6}$ Torr sec) exposure is about 10Å. With longer times of exposure (10^4L) the oxide thickens to about 20Å.

These results are consistent with those obtained with the other techniques of dry oxidation, anodic oxidation, electropolishing, and electropolishing and etching, or cathodic reduction and air exposure. The low lattice parameter (cation vacancies in an essentially γ-Fe_2O_3 structure) is typical of conditions where oxygen incorporation into the oxide is more rapid than iron diffusion. With time all the oxides tend to "anneal" towards a γ-Fe_2O_3-Fe_3O_4 composition. In all cases the oxide is thin, highly oriented but microcrystalline. The rate of oxidation is essentially logarithmic and hence the oxide is highly protective.

Acknowledgment

This work was not done in the author's basement on weekends and evenings. I would therefore like to thank the National Research Council for both facilities and encouragement in doing this work and the many colleagues who have participated in this rather long and difficult but satisfying research into the varied facets of the thin film oxidation of iron.

Manuscript received Feb. 6, 1974.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1974 issue of the JOURNAL. All discussions for the December 1974 Discussion Section should be submitted by Aug. 1, 1974.

The Current Understanding of Charges in the Thermally Oxidized Silicon Structure

Bruce E. Deal*

Research and Development Laboratory, Fairchild Camera and Instrument Corporation, Palo Alto, California 94304

The publication costs of this article have been assisted by the Fairchild Camera and Instrument Corporation.

ABSTRACT

Generally accepted facts along with unanswered questions, concerning the four charges, Q_{ss}, Q_o, N_{st}, and N_{ot}, associated with the thermally oxidized silicon system are presented and briefly discussed. The discussions and information presented are based on comprehensive investigations carried out in the semiconductor industry over the past ten years. Although reasonably good empirical information concerning charge dependence on device processing is available, much remains to be learned regarding the physical origin of these charges. A simplified model is presented which indicates that most of the charges can be related to silicon bond defects in the thermally oxidized silicon structure.

In May 1962, the first complete technical session to deal with passivating properties of thermal oxides on silicon was held at the Electrochemical Society Meeting in Los Angeles, California. Prior to that, the only significant work on the subject was from Bell Laboratories, where such scientists as Atalla, Law, Ligenza and Spitzer, Frosch and Derrick, and others (1), had provided the background for oxide passivation of silicon devices.

Ten years ago, in 1963, several companies started programs involving silicon surface studies and MOS development. These programs were later to mushroom into the largest concentrated effort of this type that the industry had seen or perhaps will ever see (2). While these efforts were primarily directed towards MOS devices, the results now also apply to bipolar structures which have become equally sensitive to surface properties due to recently developed technology. Charges present in oxidized silicon structures affect threshold voltages, effective mobilities, and device stability in MOS devices, and also low current beta, junction leakage, noise, and breakdown voltage in discrete transistors and linear and digital integrated circuits. Many of the detrimental effects in bipolar devices are due to channeling or inversion of the silicon surface as a result of charges in the oxide.

It has been adequately demonstrated that the basis for all silicon device passivation is thermal silicon dioxide. While other dielectrics such as vapor deposited silicon oxide or nitride, phosphosilicate glass, or aluminum oxide, are useful, they are generally employed as secondary layers either over the thermal oxide or on top of the metallization. A discussion of charge effects in these double dielectric structures will be presented in a later paper.

This paper will review the current understanding of charges in thermally oxidized silicon. Facts about the four types of charges will be listed and discussed along with comments about unanswered questions. The discussion will be based on the author's experience over the past ten years, as well as on information gained from other investigators.

Since it has been demonstrated that most of the charge effects are directly or indirectly related to the thermal oxidation process, a short discussion of thermal oxidation kinetics will first be presented, followed by a brief description of the four types of charges. After the primary tabulation and discussion of the facts and unanswered questions about these charges in the SiO_2-Si system, the paper will conclude with a hypothesis concerning the possible physical origins and interrelationship of the charges.

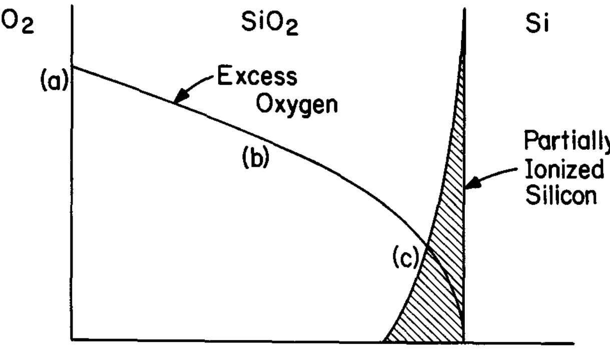
* Electrochemical Society Active Member.
Key words: silicon, silicon dioxide, oxide charges, semiconductor passivation.

Thermal Oxidation of Silicon

The thermal oxidation of silicon is commonly carried out in a water vapor or oxygen atmosphere over the temperature range of 800°-1250°C. The oxidation proceeds by three consecutive reactions: (*i*) the transfer of the oxidizing species into the oxide already formed, (*ii*) the diffusion of the species through the oxide, and (*iii*) the reaction of oxygen with silicon at the oxide-silicon interface region to form SiO_2 (3). These processes are illustrated in Fig. 1. The kinetics of silicon oxidation have been studied in detail (3-7), and a relationship has been established which is based upon all three of the individual reactions mentioned above. This relationship is included in Fig. 1 and agrees with experimental data that have indicated a parabolic, diffusion-controlled oxidation mechanism at high temperatures, a linear, surface-controlled reaction at low temperatures, and a combination of the two at intermediate temperatures. Thus, processing steps, such as boron or phosphorus glass formation, which affect the diffusion process through the oxide, also affect the oxidation rate at high temperatures. On the other hand, anything affecting the nature of the silicon surface, such as crystal orientation, heavy doping, or the like, will affect the oxidation process at low temperatures.

It is interesting to note that the activation energy of 45 kcal/mole determined for the surface reaction controlled, linear rate constant is identical to the Si-Si bond energy reported by Jaccodine (8). Thus, the rate-determining step for the reaction of Si and O_2 to form SiO_2 is probably related to the breaking of a Si-Si bond.

As is shown in Fig. 1, a thin region of oxide which contains partially ionized or excess silicon exists near the SiO_2-Si interface where diffusing oxygen reacts to form new SiO_2. This partially ionized silicon plays an important part in charge formation as will be described in the following sections. The amount or density of the ionized silicon depends upon the final high temperature oxidation or annealing conditions. Unlike the excess silicon, the "excess" oxygen distributed throughout the oxide apparently is not charged in its final form and, thus, does not act as a charge in the thermally oxidized silicon system.



$$x_o^2 + Ax_o = B(t + \tau)$$

where: $A \equiv 2D(1/k + 1/h)$

$B \equiv 2DC^*/N_I$

$\tau \equiv$ Constant

For "large times,"

$$x_o^2 \simeq Bt$$

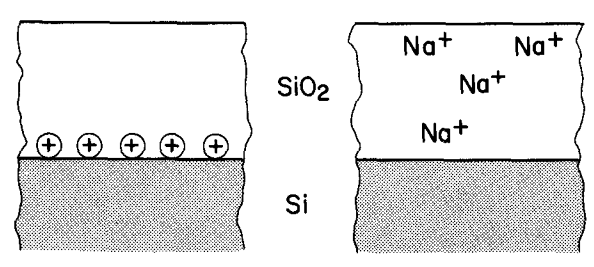
For "small times,"

$$x_o \simeq \frac{B}{A}(t + \tau)$$

Fig. 1. Schematic illustration of proposed mechanism, plus the general relationship, for the thermal oxidation of silicon (3). The three stages of oxidation are indicated by (a), (b), and (c). In the general relationship, *A*, *B*, and τ are constants and x_o is the oxide thickness after time t.

Charges in Thermal Oxides

The four types of charges found to be associated with the thermally oxidized silicon structure are shown in Fig. 2. They are as follows: Q_{ss}, fixed surface state charge; Q_o, mobile impurity ions; N_{st}, fast surface states; N_{ot}, radiation induced charge.



FIXED SURFACE-STATE CHARGE, Q_{SS} MOBILE IMPURITY IONS, Q_O

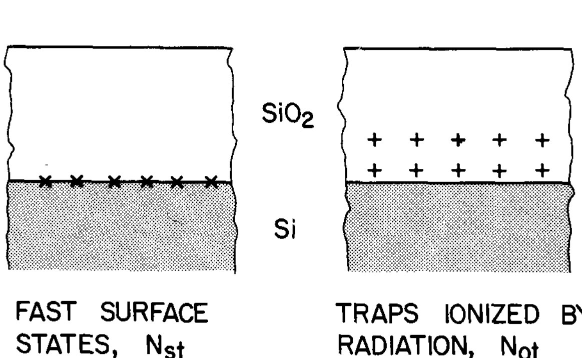


Fig. 2. The four types of charges associated with the thermally oxidized silicon structure.

The understanding of the origin and nature of these charges is very important if they are to be reproducibly controlled or minimized during device processing (9-13). The net result of any charge residing in the oxide is to induce a charge of opposite polarity in the underlying silicon. The amount induced will be inversely proportional to the distance of the charge from the silicon surface. Thus, an ion residing in the oxide very near the SiO_2-Si interface will reflect all of its charge in the silicon, while an ion near the oxide outer surface will cause little or no effect in the semiconductor. The charge is measured in terms of net charge per unit area at the silicon surface.

The author has established that there are at least seventeen basic effects whereby the effective density of one or more of these charges is changed by a particular processing step. These effects have been determined by carefully chosen and controlled experiments, and are locally referred to as the "XVII drifts of silicon oxide technology." It does not have to be emphasized that a proper understanding of these "drifts" is a critical factor in the fabrication of reproducible and reliable devices—either MOS or bipolar. Space does not permit a discussion of all seventeen instabilities, but important examples will be presented in the following sections.

Most oxide charge evaluations can be made using the capacitance voltage (*C-V*) method of analysis. This method is simple and rapid (14-15) and in most cases provides a quantitative or at least a semiquantitative measure of surface charge.

The value of any given charge such as Q_{ss}, residing as a sheet near the SiO_2-Si interface, can be determined using the *C-V* method of analysis by the following relationship

$$\frac{Q_{ss}}{q} = (-V_{FB} + \phi_{MS})\frac{C_o}{q} = (-V_{FB} + \phi_{MS})\frac{k_o \epsilon}{q x_o}$$

where V_{FB} is flatband voltage; ϕ_{MS}, metal-semiconductor barrier energy difference; C_o, oxide capacitance; q, electronic charge; k_o, oxide dielectric constant; ϵ, permittivity of free space; and x_o, oxide thickness.

A typical *C-V* plot is shown in Fig. 3 where Q_{ss} can be determined from the above relationship by measuring the flatband voltage V_{FB}. Additional charges introduced into the oxide will cause a further shift of V_{FB}, thus displacing the *C-V* curve along the voltage axis. Other more precise, but also more com-

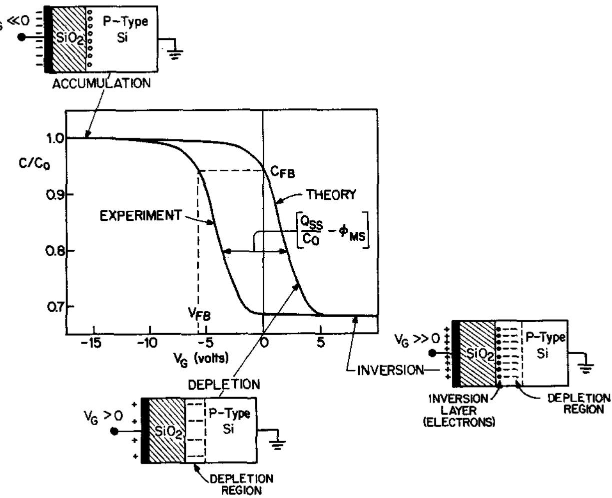

Fig. 3. Determination of fixed surface-state charge Q_{SS} by comparison of experimental and theoretical capacitance-voltage (*C-V*) curves. For theoretical curve, Q_{SS} and $\phi_{MS} \equiv 0$.

plicated, methods for charge measurement are reported in the literature, especially for fast state analysis (9, 16-20).

The author has made extensive use of the C-V analysis method over the past ten years and has noted that C-V curves are so sensitive to process variation that it is possible to determine what oxide has been produced in what furnace at what time and even in what mood the operator was that particular day.

Facts and Unanswered Questions Regarding Oxide Charges

As mentioned in the introductory remarks, a considerable amount of work has been carried out over the past ten years concerning silicon passivation, with emphasis on the four types of charges in thermal oxides. Much is known about each of these charges, and as a result, sophisticated MOS and bipolar devices can be routinely fabricated. On the other hand, many questions remain unanswered. In this section some of the more generally accepted facts will be listed and briefly discussed, along with unanswered questions. It is to be expected, of course, that not everyone will agree on all the facts presented, but it is hoped that this presentation will provide a stimulus for additional thinking and investigation into the subject.

Mobile Impurity Ions (Q_o)

Facts.—

1. Q_o is normally due to positive alkali ions (Na^+, K^+, Li^+) in the oxide. These ions will drift under bias above 100°C or, in some cases, at lower temperatures, causing device instabilities.
2. Hydrogen ions (H^+ or H_3O^+) will drift under bias at room temperature.
3. Under certain conditions negative charges in oxides have been noted. They will not drift, however, in the vicinity of 300°C or lower over time periods of hundreds of hours.
4. All mobile ions can be gettered at elevated temperatures (>900°C) using a complexing agent such as phosphosilicate glass.

The mobile impurity ions in thermal oxides were the first charge to be extensively investigated since further studies in the SiO_2 system could not be carried out until the mobile impurity level was minimized. While various mechanisms and origins for the charge were initially proposed, as indicated by Donovan's famous elephant (Fig. 4), experimental evidence proved the alkali ions to be the major cause of this instability (21-22). These ions can be incorporated into the oxide during any or all device processing steps, and any processing material, solvent or ambient can serve as a source (23). Figure 5 shows the relationship among the drifts of Li^+, Na^+, K^+, and Cs^+ at various temperatures. The rate of drift decreases for the heavier elements, which have larger ionic radii and, consequently, lower mobility.

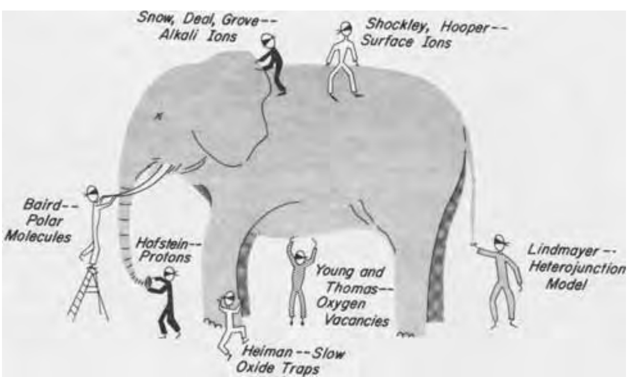

Fig. 4. Indication of early confusion regarding source of MOS instability as represented by Donovan's "blind men and the elephant" drawing. (Courtesy of R. P. Donovan, Research Triangle Institute, RTI Park, North Carolina.)

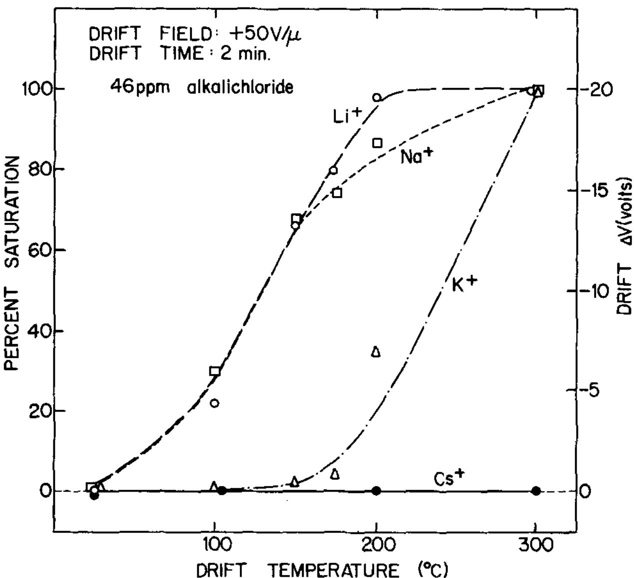

Fig. 5. Comparison of drift rates for various alkali ions through 0.2μ thermal silicon dioxide over the temperature range 25°-300°C.

Other species such as mobile protons (24) and immobile negative ions (25-26) have been shown to contribute to ionic charge. Fortunately essentially all such impurities can be removed or complexed by a high temperature gettering step (27), although precaution during device fabrication is considered a safer method for producing more stable and reliable devices (28).

Questions.—

1. What is the nature of "inactive" alkali ions?
2. What is the source and mechanism of proton drift?
3. What is the role of chlorine in improving oxide properties, gettering impurities, etc.?

Conflicting data have been presented regarding alkali content, particularly sodium, of thermal oxides. The majority of results to date indicates that more sodium is present than is indicated electrically. Thus, the questions arise as to the nature of the "inactive" sodium, under what circumstances can it be made electrically active, how does it affect other oxide properties and how is it related to other charges in the oxide?

Another question involves proton or hydrogen drift in MOS structures. Initial work by Hofstein (24) indicated that more than one hydrogen species might migrate in oxides along with multiple types of sodium. Unfortunately, measurement of such species is difficult at best and detailed facts about the phenomena are minimal.

The most significant development in thermal oxide technology in recent months has been the incorporation of a chlorine species into the structure (29-30). The reports have indicated that all sorts of good things result. It is reasonably certain that a gettering or complexing of impurity ions occurs, but additional studies are required to establish definite mechanisms and also to verify other reported advantages. In addition, possible detrimental effects, such as corrosion of aluminum interconnections, must be evaluated.

Fixed Surface-State Charge (Q_{ss})

Facts.—

1. Q_{ss} is a positive, stable charge in the oxide, very close to the SiO_2-Si interface. It cannot be

charged or discharged by varying the silicon surface potential.
2. Its value depends upon the final oxidation or annealing conditions (oxygen triangle).
3. Its value is a function of silicon orientation.
4. Its value can be increased by a negative field on the gate of a MOS structure in the temperature range 100°-400°C. The amount of this increase is proportional to the initial Q_{ss} value and the applied negative field (drift VI).

The presence of a positive, fixed, surface-state charge Q_{ss} in thermally oxidized silicon is well established (9, 12, 31). It is somehow related to the oxide structure in the interface region between the SiO_2 and the silicon. The value of Q_{ss}/q can range from the low 10^{10} cm^{-2} to 10^{12} cm^{-2}. The dependence of the Q_{ss} density on the annealing ambient, such as O_2, H_2O, nitrogen or argon, and on annealing temperature is also relatively well known (13, 31-32); the oxygen-nitrogen temperature effect is represented by the familiar Q_{ss} triangle in Fig. 6. Not so well understood is the proposed mechanism which explains the Q_{ss} dependence upon oxidation and annealing conditions. The latter is indicated in Fig. 6 by the three cross-sections (a), (b), and (c) of the oxidized silicon structure, which will be further discussed in the next section.

A fact not well known is that for extra long annealing times (>60 min) at high temperatures (1200°C) in an inert ambient such as nitrogen, the effective value of Q_{ss} actually increases. This is contrary to the prediction of Fig. 6, and has caused some investigators difficulties in duplicating the oxygen triangle relationship.

The dependence of Q_{ss} on silicon orientation is apparently related to the oxidation reaction (6). From the oxidation relationship, values of the surface controlled rate constant B/A are found to be a function of orientation in the same ratio as is Q_{ss}. Thus, the origin of Q_{ss} may well be traced to a Si-Si bond reaction which is also the basis for the surface controlled oxidation reaction.

The effect of a negative field at slightly elevated temperatures on Q_{ss} is an extremely interesting phenomenon (31, 33-34) and helps to shed considerable light on the origin of Q_{ss}. The dependence of the amount of Q_{ss} increase on the initial Q_{ss} value is shown in Fig. 7, and the significance of this relationship will be discussed in the next section.

Questions.—
1. What is the exact origin of Q_{ss}?
2. What is the mechanism of drift VI?
3. What causes the effective Q_{ss} density to increase with long anneal times in inert ambients at high temperatures?
4. What are the relationships among the origins of the various charges?

The question involving the nature or origin of Q_{ss} has been the subject of considerable discussion. Most investigators now agree in principle that Q_{ss} results from a nonstoichiometric silicon-oxygen structure in the Si-SiO_2 interface region (see Fig. 1). Whether it is called excess silicon or deficient oxygen is not important; in either case a positive charge results, and the density of this charge is dependent upon the final high temperature annealing or oxidation conditions and the silicon orientation.

Experimental data such as the Q_{ss} triangle, the dependence upon orientation and oxidation, the negative field effect and the long annealing times in an inert ambient, help to establish more definite conclusions about the origin of Q_{ss}. For instance, cross section (a) of Fig. 6 shows the proposed origin of Q_{ss} due to the generation of a thin region of partially ionized silicon in response to the field caused by inward diffusing oxygen as thermal oxidation takes place. At high temperatures, where oxygen diffusion is the rate determining or slower step, most of the excess silicon reacts with oxygen, thus, leaving a minimum amount of Q_{ss}. In sketch (b) of Fig. 6, the slower process during silicon oxidation at low temperature is the silicon-oxygen reaction. Thus, excess silicon ions are piled up and a high Q_{ss} density results

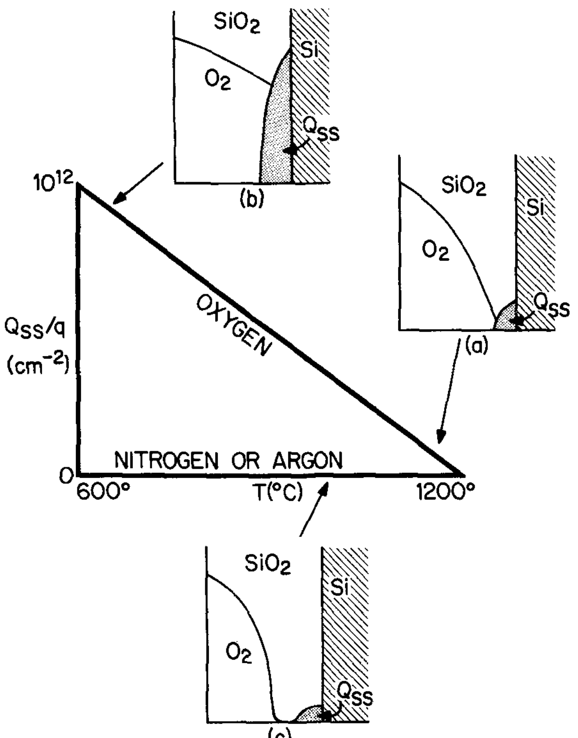

Fig. 6. The dependence of Q_{SS} on final oxidation temperature and ambient as represented by the Q_{SS}-oxygen triangle. Data are for (111) oriented silicon. Also shown are sketches of thermal oxide cross section indicating proposed relationship of Q_{SS} to oxidation conditions.

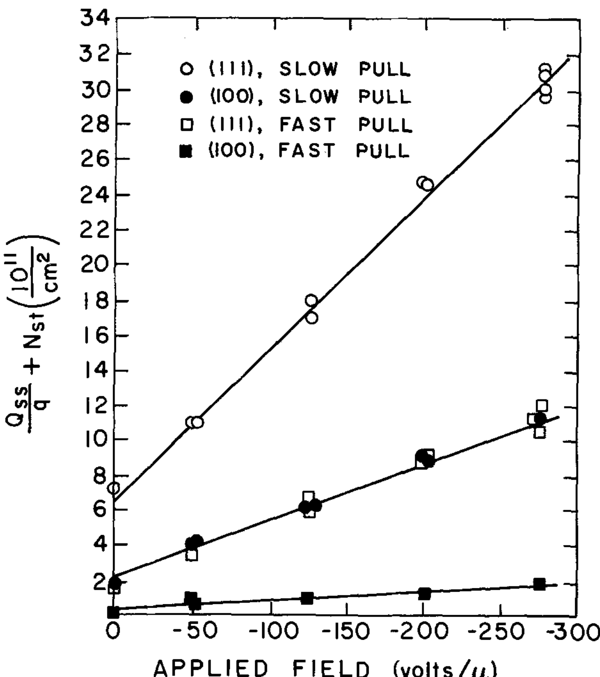

Fig. 7. Steady-state values of $Q_{SS}/q + N_{st}$ as a function of applied negative field for four different MOS structures with various initial Q_{SS} values (31). [1200°C dry O_2 oxidation; $x_o = 0.20\mu$; p-type Si, $N_A = 1.4 \times 10^{16}$ cm^{-3}.]

[Fig. 6(b)]. If, however, the ambient is changed to an inert gas, the situation shown in Fig. 6(c) results, where the excess silicon reacts with oxygen at any temperature, resulting in a low Q_{ss}. It should be noted that the minimum density of Q_{ss} under these latter conditions probably represents some equilibrium value, and that under ideal conditions the Q_{ss} value could go to zero.

Further insight into the origin of Q_{ss} may be obtained from the drift VI data of Fig. 7. If it is assumed that Q_{ss} is actually due to partially ionized silicon atoms, such as Si^{+}, then it can be proposed that the effect of a negative applied electric field is to break a second (already strained) silicon bond, resulting in a Si^{++} species. Thus, a dependence on initial Q_{ss} density is expected.

The increase of effective Q_{ss} with a long time, high temperature anneal in nitrogen is indicated in Fig. 8. Note that whether the structure initially exhibits a high or low Q_{ss}, the Q_{ss} drops to a low value in a short time in N_2. Subsequent annealing results in a higher effective Q_{ss} at the higher temperatures. A possible explanation for this effect may also be related to the breaking of Si-Si or Si-O bonds at the interface region—possibly due to thermal energy rather than electrical effects. It might even be possible for oxygen ions to leave the structure or at least the interface region by out-diffusion. In any case, an additional positive charge results. This effect is very similar to that found by Hess and Fowkes (35) when thermal oxides are subjected to a reducing ambient at lower temperatures, *e.g.*, 900°C.

The question of interrelationships among the origins of all the charges, especially Q_{ss}, N_{st}, and N_{ot}, will be discussed in the final section of this paper. As observations regarding N_{st} and N_{ot} are made in the next sections, the possibility of common origins with Q_{ss} will become more apparent.

Fast Surface States (N_{st})

Facts.—

1. N_{st} is located at the SiO_2-Si interface and can be charged or discharged with changing silicon surface potential.
2. N_{st} includes several types of fast states, appearing both at discrete energy levels and as a continuous distribution throughout the silicon bandgap.
3. The value of fast state density increases with a high temperature annealing treatment in an inert ambient.
4. Fast state density is initially proportional to Q_{ss} and exhibits the same silicon orientation dependence.
5. The N_{st} density can be minimized by a hydrogen anneal above 300°C, including the active metal, "alneal" process.

Fast surface states have been studied over a longer period of time than any of the other charges associated with passivated semiconductors. They were even studied in the early days of germanium; yet they are still the least understood. Fast states derive their name from the fact that the traps responsible are in direct electrical communication with the silicon and, thus, respond rapidly to changes in surface potential. This leads to the familiar charging and discharging as the potential sweeps across the bandgap.

Since the intensive investigations were started approximately ten years ago, considerable empirical data concerning fast states have become available (13, 19, 20, 32, 36). The C-V method of analysis has helped to provide qualitative or even semiquantitative measurements in the 10^{10} or 10^{11} cm^{-2} range. As mentioned in an earlier section, other more sensitive analytical methods are available. Using these techniques, several types of fast states have been identified throughout the silicon bandgap. The general distribution is shown in Fig. 9. Indications of these states can also be noted as distortions in C-V plots [Ⓐ, Ⓑ, Ⓒ, and Ⓓ of Fig. 10(a)].

The C-V method can also be used to obtain a more accurate measure of fast state density by carrying out the measurement at liquid nitrogen temperature. This method was originally reported by Gray and Brown (18), and an example of the resulting plot is shown in Fig. 10(b).

It has been noted that fast state densities are generally initially proportional to Q_{ss} and thus also depend on silicon orientation. It is also known that high temperature anneals in inert ambients, such as nitro-

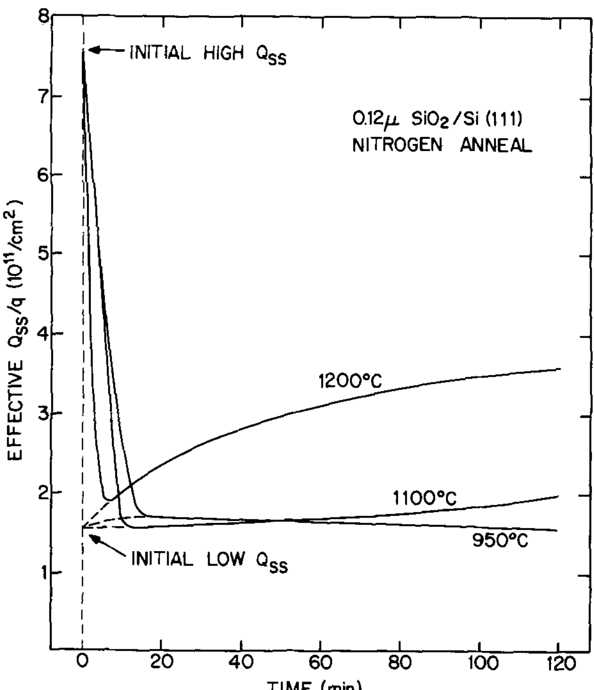

Fig. 8. Dependence of effective Q_{ss}/q on anneal in nitrogen for times of 0-120 min at various temperatures.

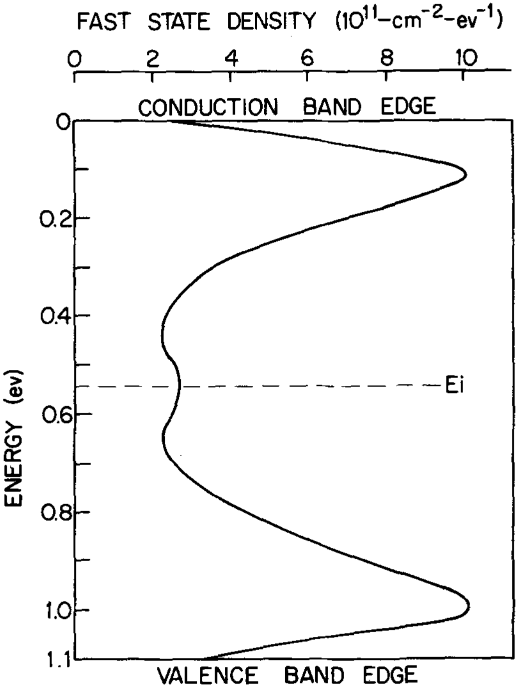

Fig. 9. Approximate distribution of fast states associated with the silicon-silicon dioxide interface produced by thermal oxidation in dry oxygen.

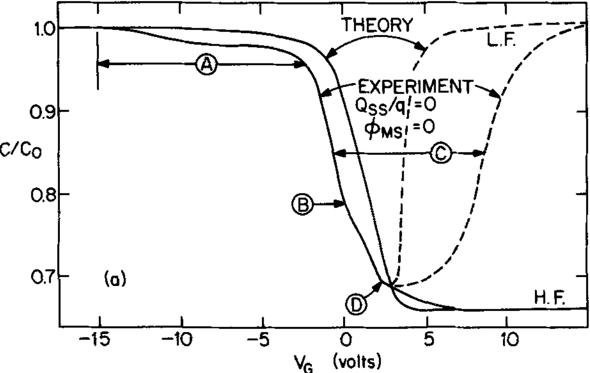

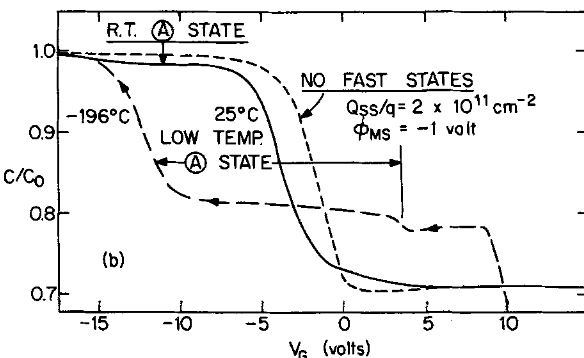

Fig. 10. Examples of fast surface states as indicated in MOS C-V plots; (a) 25°C, (b) 77°K.

gen, will increase fast state density (13, 32). Similarly, treatment in hydrogen or an active hydrogen species produced by the reaction of an active metal with water on the oxide surface (alneal process) will reduce fast state density, supposedly by complexing the defect responsible for N_{st} (13, 37).

Dependence of many device electrical properties on fast states has been established. These include threshold voltage and transconductance in MOS transistors and junction noise and leakage, low current beta and breakdown characteristics in bipolar devices. Bipolar transistors in linear integrated circuits are especially sensitive to fast states—almost to the same extent as MOS structures.

Questions.—
1. What is the physical origin of fast states?
2. What are the differences among the various types of discrete and continuous states?
3. How is N_{st} related to Q_{ss} as well as to impurity ions?

The dependence of device properties on fast states as mentioned above makes it imperative that fast states be controlled and minimized during processing. In order to accomplish this, the physical origin of fast states should be known. It is assumed at present that these states result from either defects in the structure of the interface region between the silicon and the oxide, or to impurities in this region, or both. In either case, the net result is trapping of holes or electrons at particular surface potentials or energy levels. The initial relationship of N_{st} to Q_{ss} would favor the structural defect mechanism. Also, the fact that additional fast states are formed during the negative field treatment, during ionizing radiation treatment, and during high temperature anneals leads to a similar conclusion. It then follows that a hydrogen species could react with the defect structures to complex the action of the fast state. On the other hand, the presence of impurity ions such as gold, copper and even sodium, can cause effects attributable to fast state action.

The answer to these questions probably indicates that both possibilities are true. Such an assumption would also explain the various types of states found throughout the bandgap. In any case, it is reasonable to assume that a close relationship exists between the origin of fast states and other charges—particularly Q_{ss}.

Radiation Induced Charge (N_{ot})

Facts.—
1. N_{ot} is a positive charge located in the oxide, generally near the SiO_2-Si interface. It is caused by ionizing radiation such as x-rays, electrons, neutrons, etc.
2. Fast states are also produced at the SiO_2-Si interface by ionizing radiation.
3. The value of N_{ot} is a function of the dose and energy of the radiation as well as the field across the oxide during radiation.
4. Both charges, N_{ot}, and radiation induced fast states, are eliminated by a low temperature anneal in an inert ambient.
5. The annealing of radiation induced charge is hindered by a dense dielectric layer such as silicon nitride over the thermal oxide.

Early in the development of MOS transistors, it was discovered that ionizing radiation would cause a positive space charge in the oxide, leading to a threshold shift of ten's of volts to over one hundred volts. Simultaneously, additional fast states were formed at the Si-SiO_2 interface during the irradiation. Fortunately, both charges could be annealed out at relatively low temperatures (300°C) without the presence of hydrogen. The only disadvantage was that MOS devices could not be used for applications, such as space flights, where radiation would be a factor. Since the time when N_{ot} was first identified, the phenomenon has been studied continuously (38-41). Most of the efforts have been aimed towards understanding the mechanisms of the radiation induced charge in the oxide and how this charge might be eliminated or minimized.

It has been determined that the number of trapped holes is a function of radiation dose and energy. Also, the amount of resulting charge will depend upon the magnitude and polarity of the electrical field applied across the oxide during radiation (42). The radiation may occur during use of the device in radiation environments or during particular device processing steps, such as electron beam metallization, ion implantation, or sputtering of metals or dielectrics.

Examples of radiation induced space charge formation in various structures are shown in Fig. 11. The effect of gate bias during irradiation as well as the effect of additives or other treatments of the oxide are shown.

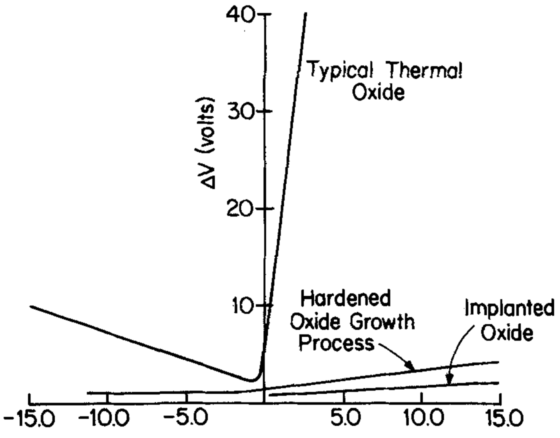

Fig. 11. Dependence of radiation induced charge N_{ot}, as indicated by MOS threshold voltage shift ΔV, on gate voltage during irradiation and on oxide type (41).

It has also been determined, that, while the space charge and fast states produced by radiation can normally be easily annealed out by a 300°C treatment, the presence of a dense dielectric over the thermal oxide retards this annealing. An example of a typical *C-V* plot before and after radiation, and then after annealing with or without a nitride layer is shown in Fig. 12. Note first that the positive space charge N_{ot} causes a parallel shift of the *C-V* curve in the negative direction. Also note that the fast states produced during the irradiation are continuous over the bandgap, unlike the normal oxide fast states which are present at discrete energy levels. Finally, note that without a nitride layer, all fast states are annealed, but that with the nitride layer, the discrete fast states remain as does some of the positive space charge.

Questions.—

1. What is the origin and mechanism of the radiation induced space charge N_{ot}?
2. How can N_{ot} be minimized?
3. What is the annealing mechanism for N_{ot} and associated N_{st}?
4. What is the effect of secondary dense layers such as Si_3N_4 on the annealing of N_{ot}?

Two schools of thought have developed for postulating a mechanism for the formation of N_{ot}, the radiation induced positive space charge. One model is based strictly on considerations involving the SiO_2 structure. Electron-hole pairs are produced by the radiation. The holes are trapped by broken silicon-oxygen bonds while the electrons migrate away (41, 43). The traps themselves may or may not be present before radiation. The second model involves the activation of impurity ions such as sodium, which in turn either act as positive charges, or indirectly result in trapped holes (41, 44).

Different solutions to the radiation problem may thus be required depending upon the true mechanism responsible for the charge, or one solution may coincidentally satisfy more than one possibility. Thus far, three solutions are proposed. These are: (*i*) to modify the SiO_2 structure so that silicon-oxygen bond strain energy is reduced, (*ii*) to add impurity species such as chromium to compensate trapping centers or to complex impurity ions, or (*iii*) to produce absolutely pure SiO_2 to eliminate impurity trapping centers. The answer to the question about the annealing mechanism is obviously tied to the formation of N_{ot} and preventive mechanisms thereof, and an answer to one question will help answer the others.

The effect of dense secondary layers on N_{ot} formation or annealing is complex due to the possible presence in the oxide of several types of fast states as well as the space charge. Again, the correct mechanism of radiation induced space charge formation must be understood in order that effects due to added dielectrics can be understood and controlled.

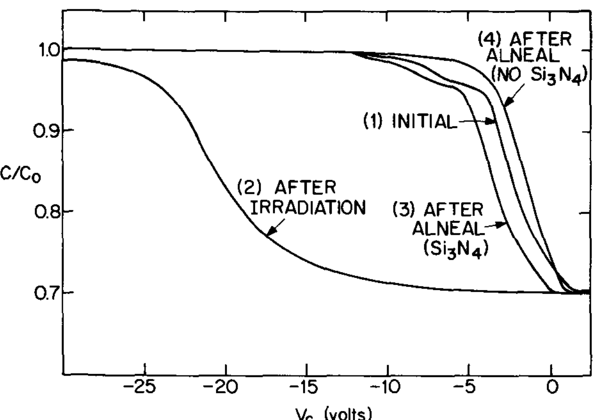

Fig. 12. Effect of irradiation on charges in MOS structures, with and without a silicon nitride layer over thermal oxide, as indicated by C-V plots. Curves (1) and (2) are the plots before and after irradiation, with or without the nitride layer. Curve (3) is the plot after a 450°C hydrogen alneal treatment with the nitride, and curve (4) is the same for no nitride.

Conclusions—Possible Common Origins of Oxide Charges

The current understanding of charges in the thermally oxidized silicon system has been presented. Generally accepted facts about these four types of charges have been listed and briefly discussed along with questions still remaining to be answered. Most of the unanswered questions are related to the origin of the charges or the mechanism of their formation and elimination. On the other hand, a fairly complete set of empirical data is available, providing a reasonable basis for understanding their process dependence. However, for ultimate control of these charges and related device electrical characteristics, a knowledge of their origin and physical nature will be required.

It would seem appropriate at this point to present a possible model of origin for three of the charges—Q_{ss}, N_{st}, and N_{ot}—based on common structural features. The model may well be oversimplified, but on the other hand could provide a basis for more detailed considerations. Figure 13 shows a representation of a thermally oxidized silicon structure. Three regions are indicated: silicon, the transition region between the silicon and the oxide, and the thermal silicon dioxide. Both the silicon and silicon dioxide lattices are represented by a two dimensional network, not necessarily to scale on an absolute or relative basis.

First, the plane separating the bulk silicon from the silicon-oxygen transition region indicates some unsatisfied silicon bonds which are the origin of the traditional fast surface states N_{st}'. Two of these bonds are shown to be satisfied or complexed by a hydrogen species. A second fast state (N_{st}'') results due to a missing oxygen atom. This oxygen deficiency is established during the thermal oxidation process and also resulted in a partially ionized, excess silicon species. The latter, which is located in the oxide-silicon transition region, is believed to be the source of Q_{ss}.

If a negative field is applied across the oxide, a second silicon-oxygen bond at the partially ionized silicon atom responsible for Q_{ss} is broken and additional positive charge occurs in the oxide (drift VI). A corresponding additional fast state may also result at some nearby point on the silicon surface. In addition, if the structure is subjected to a long, high temperature anneal in an inert ambient or in a reducing atmosphere, additional silicon-oxygen bonds are broken and/or oxygen ions are removed, producing more positive charge in the oxide (drift XVII).

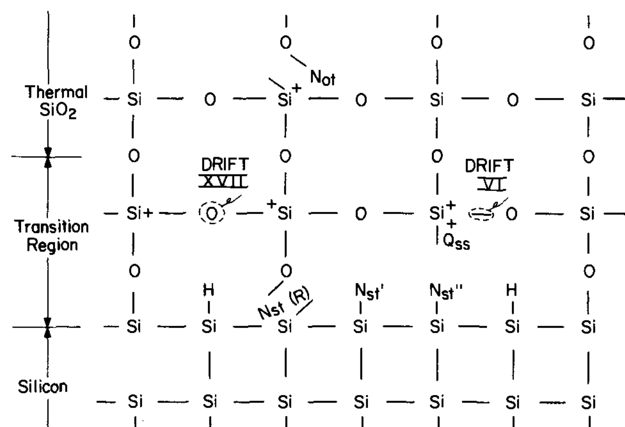

Fig. 13. Two dimension sketch of thermally oxidized silicon structure showing possible origins of charges.

Finally, if the structure is exposed to ionizing radiation, a silicon-oxygen bond in the oxide may be broken (or it already may be broken) and holes formed by electron-hole generation are trapped at the silicon defect. At the same time, a silicon-oxygen bond at the silicon surface is broken, leading to fast state formation.

It is thus obvious that the physical origin of all the charges, except Q_o, may well be based upon factors related to the silicon bond structure or defects thereof. Whether a particular process causes a silicon bond defect depends on the structural configuration, bond energy, and other considerations. Whether this bond defect in turn will result in either Q_{ss}, N_{st}, or N_{ot} will depend primarily upon its location in the oxidized silicon structure. Such a proposal does not even rule out the reported effects due to impurity ions such as sodium or aluminum. The presence of these species could physically distort the silicon-oxygen bond structure or result in chemical reactions which would also lead to charge effects.

Acknowledgments

The author wishes to thank Maija Sklar for her many contributions during the past ten years in many of the programs referenced in this paper. In addition, valuable assistance has been provided by Phil Fleming, Ed MacKenna, Pat Castro, Pat Kodama, and other persons too numerous to list. Finally, the author values his previous association with Drs. Andy Grove and Ed Snow at the Fairchild Research and Development Laboratory, and acknowledges their outstanding contributions in the various areas of semiconductor device physics and surface passivation technology.

Manuscript submitted Sept 25, 1973; revised manuscript received Dec. 5, 1973.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1974 JOURNAL. All discussions for December 1974 Discussion Section should be submitted by Aug. 1, 1974.

Electrochemical Aspects of Thrombogenesis— Bioelectrochemistry Old and New

P. N. Sawyer, S. Srinivasan,* B. Stanczewski, N. Ramasamy,* and W. Ramsey

Electrochemical and Biophysical Laboratories of the Vascular Surgical Services, Department of Surgery and Surgical Research, State University of New York, Downstate Medical Center, Brooklyn, New York 11203

The fact that living cells such as blood cells carry a surface charge in much the same manner as colloidal particles has been known since the work of Abramson (1, 2). That these surface charges allow the cells and tissues with which they come into contact to exhibit electrochemical properties has only recently been considered. It is the purpose of this review to trace the development of ideas and observations which have led to the use of interfacial electrochemistry to examine biological problems and develop solutions to these problems in the area of thrombosis and related diseases.

Before the details of thrombosis or blood clotting are discussed, it appears appropriate to outline briefly the phenomena involved in intravascular blood coagulation as it appears *in vivo*.

Thrombosis is, by definition, the deposition of polymerized fibrinogen, *i.e.*, fibrin and trapped particulate blood cells including platelets on the blood vessel wall.

Thrombosis occurs at the site of a vascular injury as a multistage process. Blood coagulation during bleeding from blood vessels is the mechanism by which we normally prevent fatal hemorrhage. It is also, in its pathological state, the mechanism by which we experience abnormal vascular occlusion. First the platelets in circulating blood recognize the site of injury and adhere to it. The adhered platelets then aggregate releasing in the process a number of proteins and other agents. This first step is called primary hemostasis. This results in a platelet plug formation which serves as a temporary seal (3, 4).

The blood coagulation cascade is activated leading to a fibrin clot. This process resulting in polymerization of fibrinogen to fibrin is secondary hemostasis (3, 4). The fibrin polymer traps in its strands a number of blood cellular elements including erythrocytes and leukocytes and additional platelets. In a normal system following fibrin polymerization the healing process is initiated by fibroblastic invasion of the thrombus (5).

A study of these interfacial reactions and the ways that thrombosis can be modified, initiated, and/or inhibited by artificial prostheses is the subject of this review.

Historical

Very early in studies of blood cells and blood vessel walls, there was established a relation between the surface charge carried by the blood cell and the charge on the blood vessel wall.

Between 1925 and 1950, only three or four investigators (3-6) seriously measured the surface charge characteristics of blood cells and cursorily evaluated blood vessel walls, suggesting both that these charges were related to diapedesis of white cells to points of inflammation and to the interactions of platelets and other cells with blood vessel walls during thrombosis (6). They include Abramson, who did the first meticulous work on electrophoretic characteristics of platelets, red cells, white cells, and proteins (Table I) (1, 2). He found that all of these elements had a consistent cataphoretic mobility in the same range. He also showed that platelets have developmental characteristics which would permit specific adhesion to blood vessel walls through pseudopod formation.

In 1950, members of this group discovered that the vascular wall developed a transmural potential that was negative with respect to an externally applied electrode (Fig. 1) (7, 8). These measurements were made using calomel electrodes; one electrode was connected to the blood stream through a salt bridge while the second electrode was similarly attached to the exterior of the arterial wall. An electrometer was used to make the measurement (Fig. 1). The decrease of surface potential, or its reversal, related to injury, frequently produced surface thrombosis and intraluminal occlusion (6, 7) (Fig. 2).

The concept of injury potential has been expressed possibly by Gerard (9). One may conceive of injury potential as the exposure of the inner content of a cell to the external milieu. An ion flow is supposedly generated yielding an electric (ionic) current. This explanation is obviously simplistic, but the true explanation is unknown. Becker (10) and Pilla (11) have proposed that the phenomena called "injury potentials" are related to interactions between the nervous system,

Table I. The cataphoresis of platelets in plasma. The speed of polymorphonuclear leucocytes is given in the last column. Although red cells and small lymphocytes have different velocities, note that platelets and polymorphonuclear leucocytes have the same velocity (six horses).

Plasma	Age (hr)	Platelets V_o (μ/sec/V/cm)	Platelets V (μ/sec/V/cm)	Polymorphonuclear leucocytes V (μ/sec/V/cm)

body tissues, and tissue regeneration as well as possibly being involved in local cell regeneration.

It was next discovered that the application of an electric field would produce thrombosis on the blood vessel wall beneath a positively charged electrode attached to the external surface of the blood vessel wall, while the area beneath the negative electrode was free of deposits (Fig. 3). This led to the development of a series of experiments in which it was shown that negatively charged electrodes could very effectively delay thrombosis in injured blood vessels (12), the corollary of the positive electrode experiment (7). In the attempt to gain additional information, three sets of experiments were carried out in the subsequent 20 years relating to these original observations.

The interfacial phenomena that can occur at solid liquid boundaries in biological systems are represented in Fig. 4. A simplified schematic of a biological membrane and the charge distribution at the membrane solution interface are shown in Fig. 5. The studies carried out were all related to the phenomena described above (13-20).

The studies on the blood vessel wall included (*i*) measurement of ion fluxes across the arterial and venous blood vessel walls (13, 14); (*ii*) the role of metabolic factors in the maintenance of the blood intimal interface of blood vessels (15, 16); (*iii*) study of the electrokinetic phenomena in the vascular tree and its relationship to thrombogenesis (17, 18); and (*iv*) the importance of maintaining ion fluxes across the vasculature or graft in determining its patency *in vivo* (19, 20).

The ion transport across the vena cava is one order of magnitude greater than that across the aorta under aerobic conditions. The ion diffusion across the vena cava is opposite from that across the aorta under conditions of no pressure (Fig. 6). The results lend support to the view that the ion diffusion across arteries is

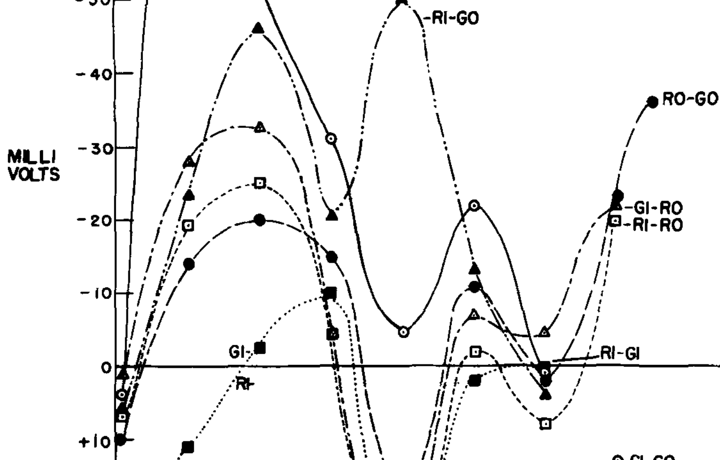

Fig. 2. Transmural potentials across freeze dried grafts and recipient arteries; reversal of sign due to injury or any other local abnormality. (RI, electrode inside recipient artery; RO, electrode outside recipient artery; GI, electrode inside graft; GO, electrode outside graft.)

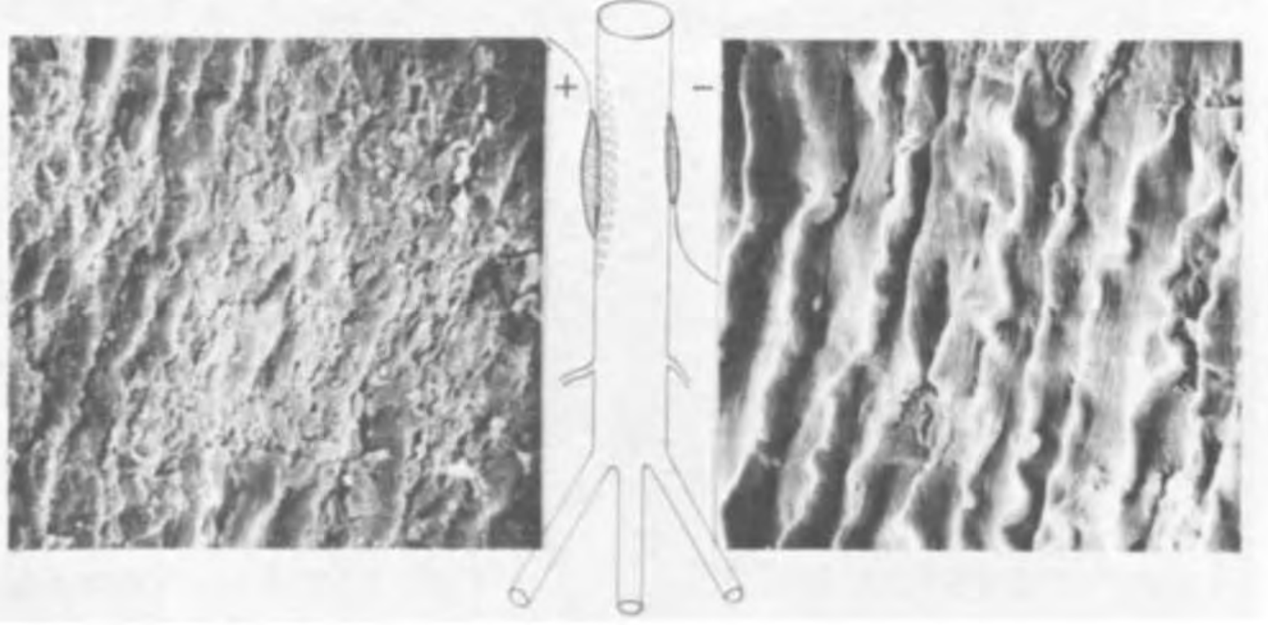

Fig. 3. A positive negative electrode pair applied to aortic wall. SEM photographs of the blood vessel wall (a, left) showing thrombus deposition on the wall beneath the positive electrode and (b, right) showing the area beneath the negative electrode free of deposit.

"controlled diffusion" while venous transport may be "active" in character.

The systematic studies of solid and porous prosthetic surfaces and arterial prostheses during the period of development indicated that porosity was critical to long term function (19, 20) (Fig. 7). Pressure equivalent electro-osmosis or actually "transverse streaming potential" appears important in the maintenance of the charge characteristics of the vascular blood interface.

This is illustrated by the fact that the morphology of a thrombus on arterial and venous surfaces is different (as revealed by histological examination). Thrombosis on arterial surfaces is sculptured by high pressure rapid flow of the arterial stream. On the venous side injury produces a more rapid buildup of transluminal thrombosis due to low pressure flow. This occurs probably because the interacting blood elements, platelets, blood cells, and activated blood coagulation proteins involved in thrombosis have a longer contact period with the injured area.

The electrochemical interactions between an electronic conductor and blood cellular elements were studied (21, 22). It was observed that blood cell precipitation on electrodes does occur at potentials more positive than 300-400 mV *vs.* NHE. The cell precipitation appears to be a potential- and not a current-dependent phenomenon (Fig. 8). This study indicated that intravascular thrombosis on prosthetic metallic materials might also be a potential-dependent process.

Characterized clean metallic surfaces used as arterial and venous blood vessels functioned as thrombus preventing or depositing surfaces depending on their spontaneous corrosion potential in contact with blood (23, 24). With platinum, potentials were set at specific values to either prevent or elicit deposition of thrombi. Copper prostheses were implanted in animals, and the developed junctional thrombi were examined with both light and electron microscopy. These were shown to contain the components of spontaneous intravascular thrombi (25) (Fig. 9 a-c). Most importantly, it was also shown that thrombus formation on electrodes at critical potentials depends on an intact coagulation system

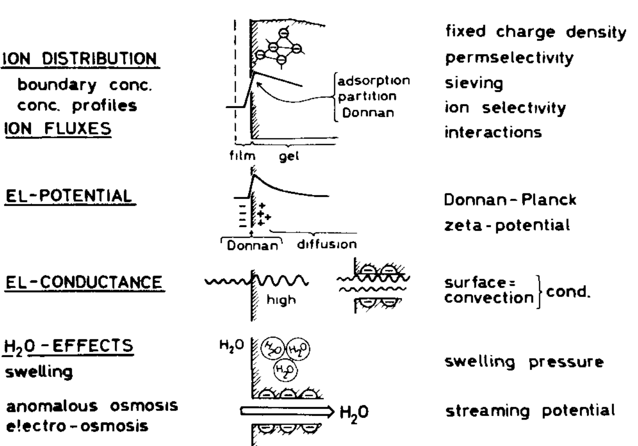

Fig. 4. Scheme of general phenomenology at a fixed charge membrane.

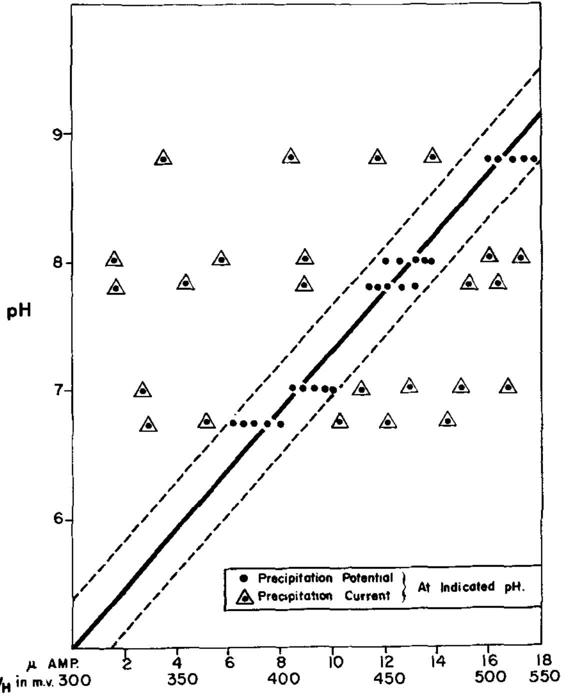
(26). Thus in hemophiliac dogs (dogs that lack one of the blood coagulation enzymes, Factor VIII) electrical thrombus could not be initiated. This was also the case for dogs which have platelet abnormality, or which, following administration of anticoagulant drugs, do not exhibit potential induced thrombus formation (Table II). Histologic and physiologic evidence was provided in these experiments to show that electrical thrombosis is similar to its biological counterpart, spontaneous thrombosis, and that the triggering of



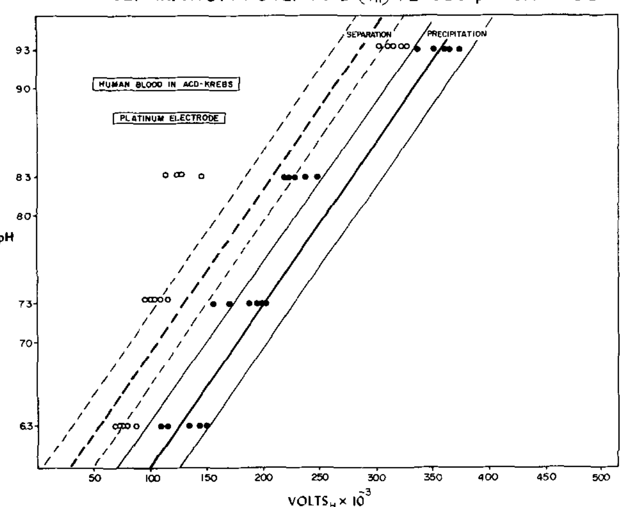


Fig. 8. a(top), Precipitation potentials of human platelets (with respect to normal hydrogen electrode) as a function of pH. The results show that cell deposition is potential not current dependent. b (bottom), Human leukocyte, precipitation potentials on Pt electrodes (with respect to normal hydrogen electrode) as a function of pH.

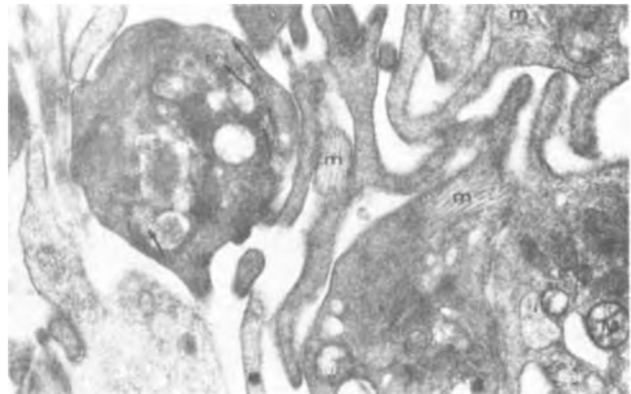
thrombosis is related to the interfacial potentials of appropriately organized homogeneous surfaces.

The Beginning of Modern Information

In vivo streaming potential measurements are a measure of the net surface charge of the blood vessel wall under physiologic conditions. When arteries are removed from the *in vivo* position as high pressure conduits, most of the streaming potential seen *in vivo* can be regained *in vitro* by placing the blood vessel in a streaming potential apparatus in which Ringers or other solutions of known ionic composition are used as the high pressure perfusate (18). Many of the phenomena observed in the vascular tree *in vivo* can be duplicated in a streaming potential apparatus *in vitro*, including the effects of injury, drug effects, changing ion concentration on either side of the blood vessel



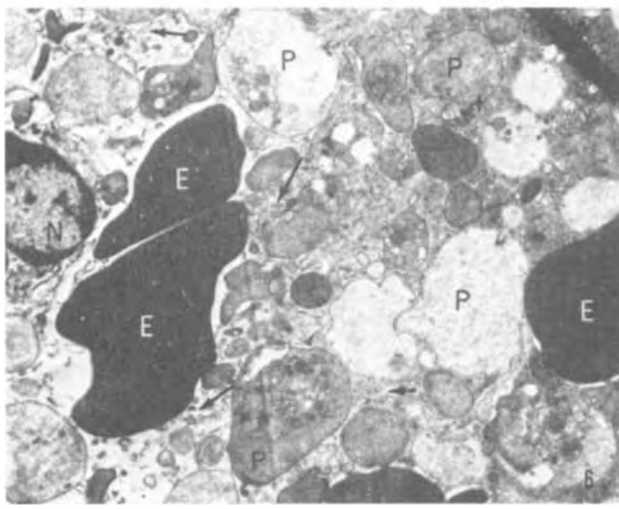


Fig. 9. Electron microscopic photographs of junctional thrombi formed at the junction between a copper tube and its containing vessel. Magnification 7000×. a (top left), Multiple masses of erythrocytes (E) agglutinated by a fibrin matrix (F); b (top right), leucocytes, erythrocytes, and platelet masses (m) agglutinated between fibrin sheaths; c (bottom left), degranulated platelets (P) and massed erythrocytes (E) along with granulocytes (N).

wall, etc. (Fig. 10). Some work has also been done evaluating the blood vessel wall as a rectifier (Fig. 11 a and b), and as a diffusion membrane. The vessel wall, because of its porosity and blood pressure, functions as an electro-osmotic membrane. Ion diffusion across the wall appears modulated by enzymatically supported active transport (27). The several enzymatic processes effecting ion transport can be shown to exist by changes produced by hypoxemic conditions, by other types of metabolic inhibition, and by temperature variations.

Recently, a series of more sophisticated studies has been carried out testing the effect of different types of injury on the streaming potential *in vivo* (28).

Four comparative evaluations were carried out: (*i*) the effect of types of injury on streaming potentials; (*ii*) the effect of position of the injury on the morphology of proximal and distal artery or vein; (*iii*) the type of thrombus deposited following various types of injury; and (*iv*) the effect of various anticoagulants on the deposited thrombus. The resulting disordered wall with deposited thrombi (Fig. 13) and the modifications brought about by different types of anticoagulant agents during blood interactions with altered surfaces have been examined using both light and scanning electron microscopy (Fig. 14) (29).

Evolving Concepts

Thus, it has become apparent that intravascular thrombosis has many classic characteristics of a physical chemical phenomenon. Recent studies of several enzymatic reactions which relate to thrombosis seem to illustrate the physical biochemistry of these reactions. Though the results of these studies are frequently semiquantitative, the information seems real and significant.

Table II. Potential dependence of electrical wire thrombosis in dogs (normal, hemophiliac, and under the influence of some drugs)

Series	Number of experiments	Thrombus formation			
		Electrodes + No. of vessels	0.2-0.4 NHE Thrombus	Electrodes No. of vessels	0.2-0.4 NHE Thrombus
Normal dogs	25	44	33	47	11
Hemophiliac	2	4	0	—	—
Heparinized 2 mg/kg	4	8	0	—	—
Coumadinized	4	6	0	2	0
Thrombocytopenic plates 50,000/mm³	4	6	0	2	0
Control-nitrogen mustard	2	4	4	—	—

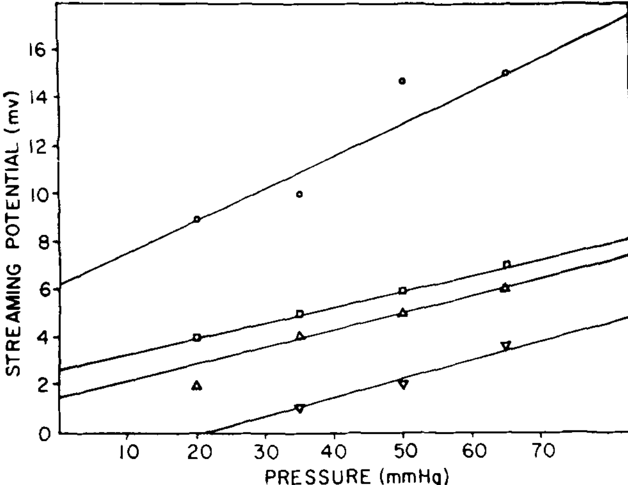

Fig. 10. Effect of change of ionic concentration of the fluid on the streaming potential-pressure behavior of a carotid artery in vitro. ○——○ Krebs/1000; □——□ Krebs/100; △——△ Krebs/10; ▽——▽ Krebs/1).

It is now obvious that the blood vascular interface develops an electric field in the range of 10^6-10^7 V/cm. Blood cells and blood proteins carry a net negative surface as does the blood vessel wall. The charge on the vessel wall appears to be potentiated by the physicochemical phenomena described earlier. Therefore we are in essence statistically unclottable. Special local conditions have to be created to initiate thrombosis.
