where x_i is the mean depth corresponding to E_i, Δx the mean depth interval corresponding to ΔE, n_{Zr} is the number of Zr atoms per cm^3, $E_d(x_i)$ the mean energy of the incident deuterons at depth x_i, [$E_d(O)$ is the bombarding energy], $\sigma(\theta,E_d)$ the differential cross section at detection angle θ and energy E_d, and K a constant depending on the counting conditions. The spectrum presents a plateau near its peak, which corresponds, according to Eq. [2a] to $800 < E_d < 900$ keV, where $\sigma(\theta,E_d)$ is practically constant (16); the fall of the spectrum is due to the decrease of $\sigma(\theta,E_d)$ at lower energies. In the plateau region

$$N_i = C\Delta x n_{Zr}K' \quad [2b]$$

K' being constant. In fact n_{Zr} depends on C due to the expansion of the Zr-O solution with increasing oxygen content. Δx is related to the energy loss of deuterons and protons produced by the zirconium and oxygen atoms on their path: it depends hence on C. We may write Eq. [2b] in the form

$$N_i = C\Delta x(o)n_{Zr}(o)K'f(C) \quad [2c]$$

with

$$f(C) = \frac{\Delta x(C)n_{Zr}(C)}{\Delta x(o)n_{Zr}(o)}$$

For low values of C, $f(C) = 1$ and C may be deduced directly from the "plateau height" H (*i.e.*, the mean value of the N_i in the plateau region). For high C

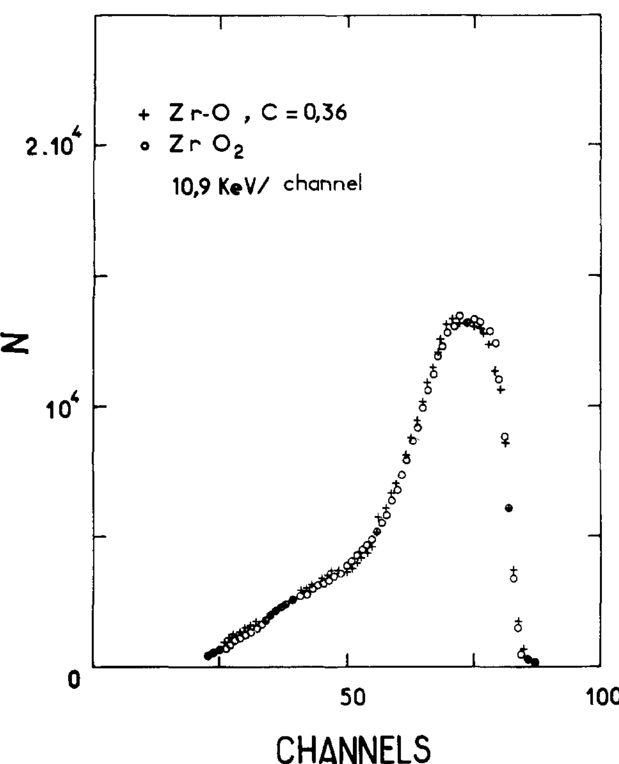

Fig. 1. Normalized experimental spectra obtained for thick thermally grown zirconia (10 μm) and for a Zr-O solid solution, respectively. Conditions: 10.9 keV/channel, the maximum energy of the protons at detection is 1195 keV, corresponding to channel 82.

values Eq. [2c] yields an uncorrected value $C_u = Cf(C)$, which corresponds to neglecting the effect of oxygen on the slowing down of the particles. C is then found by solving this equation, according to $C = g(C_u)$. The corresponding calculations are shown in Appendix A. Figure 2 shows this correction curve; the correction is appreciable for $C > 0.15$, *i.e.*, $\beta > 0.14$.

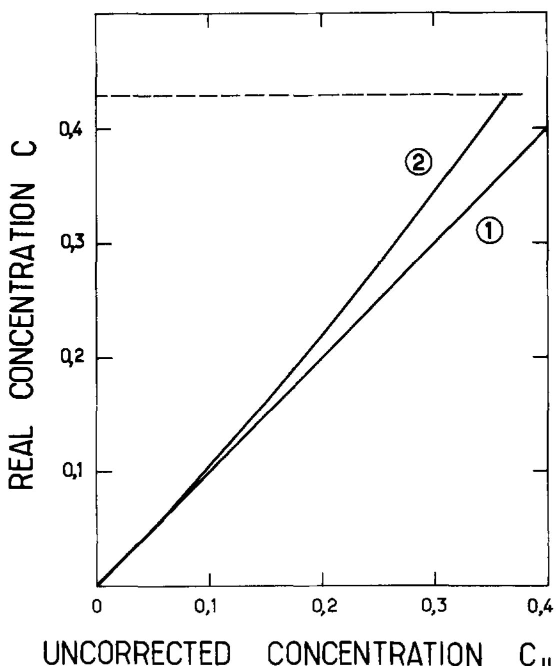

Fig. 2. Curve $C = g(C_u)$ relating the real concentration (oxygen to zirconium atomic ratio), corrected for the stopping power of oxygen, to the uncorrected concentration (curve 2). Curve 1 is the bisectrix of the quadrant, traced for the sake of comparison.

Absolute calibration was achieved by using a reference standard prepared by anodic oxidation of tantalum in well-defined conditions (17, 23). The oxygen content n_S of such an oxide layer is known to within about 2% (24). The standard used here, about 1100Å thick, contained $6 \cdot 10^{17}$ oxygen atoms per cm². The total counting corresponding to the standard is, the energy loss in the film being small

$$N_S = n_S K \sigma[\theta, E_d(o)] = n_S K' \quad [3]$$

Hence dividing [2c] by [3] and inserting the plateau height H for N_1

$$\frac{H}{N_S} = \frac{C_u}{n_S} \Delta x(o) n_{Zr}(o) \quad [4]$$

This equation allows one to calculate C_u with a precision depending on statistics (for H and N_S) and on the knowledge of $\Delta x(o) n_{Zr}(o)$. The latter is calculated in Appendix B. Appendix C contains an improved calibration method. It was estimated that the relative error on the absolute concentrations C is about 3%. Relative values of C may be compared to within about 1%, not including statistics.

It should be emphasized that this oxygen analysis technique is background free [except for possible contaminations by light nuclei like F^{19}, N^{14}; see Ref. (16 and 17)]. The sensitivity limitation is physical: it is due to the presence of a 60Å thick spontaneous oxide on the samples, whatever their oxygen content. This fixes the lower limit of sensitivity for oxygen concentration measurements in zirconium to the order of 50 ppm; 1000 ppm concentrations may already be measured to within 3%, as stated above. Counting rate is hardly a problem: most of the measurements require some minutes only.

Finally it should be noted that the low energy part of spectra like that of Fig. 1 may depend on C, if the energy loss parameters for O and Zr do not vary with energy in constant proportion. This was investigated experimentally by recording a spectrum from a thick zirconia target: the result, represented in Fig. 1, shows that the spectrum is nearly identical to that from a Zr-O solution, although the O/Zr ratio varied from 0.36 to 2. This shows that the shape of the spectra does not depend on C. Hence the area as well as the plateau height of the spectra may be used as a relative measure of C; this improves statistics and simplifies the measurements.

Depth scales.—The depths will be measured from the metal-oxide interface. Let ΔM_S be the total mass per cm² of the Zr-O solution ground off from a sample, $X(t,T)$ the thickness of the oxide after a treatment time t at temperature T°K, M_X the weight of this oxide per cm². We have $\Delta M = M_X + \Delta M_S$. We shall first take as a measure of depth the mass m of zirconium per cm² of the Zr-O solution ground off. m is independent of the Zr-O density, which varies with C. Let $C(m)$ be the corresponding profile; we have

$$\Delta M_S = \int_o^m [1 + aC(m)] dm \quad [5a]$$

with $a = 16/91.22 = 0.175$ (mass ratio). Let $\hat{C}(\Delta M)$ be the experimental profile in the ΔM coordinate, $\hat{C}(\Delta M) = C(m)$. By differentiation

$$\frac{d\Delta M_S}{dm} = 1 + aC(m) = 1 + a\hat{C}(\Delta M) = \frac{d\Delta M}{dm}$$

Integrating

$$m = \int_{M_X}^{\Delta M} \frac{d\Delta M}{1 + a\hat{C}(\Delta M)} \quad [5b]$$

Equation [5b] was integrated numerically by summation using the measured values C_j, ΔM_j for $\hat{C}(\Delta M)$.

$X(t,T)$ was measured for each t,T value with a microscope and M_X calculated using the density 5.6 for zirconia.

Let us suppose that a curve $C_1(m_1)$ may be deduced from a curve $C_o(m)$ by simply muliplying m by α, i.e., $m_1 = \alpha m$. Then $C_1(m_1) = C_o\left(\frac{m_1}{\alpha}\right)$. The corresponding $\Delta M_S{}^1$ is, from [5a]

$$\Delta M_S{}^1 = \int_o^{m_1} [1 + aC_1(m_1)]dm_1$$

$$= \alpha \int_o^{m_o} [1 + aC_o(m)]dm$$

Thus

$$\Delta M_S{}^1 = \alpha \Delta M_S{}^o \quad [6]$$

Hence for profiles having the same shape a single integration of Eq. [5b] yields a universal new depth scale. This simplifies the calculations as will be seen.

The relation between the geometrical depth x and m is

$$m = \mu_{Zr} \int_o^x n_{Zr}[C(x)]dx$$

μ_{Zr} being the mean mass of the zirconium atom. In what follows the dependence of n_{Zr} on C will be neglected. In fact it was shown (12, 19) that the volume associated to each Zr atom in the Zr-O solution varies only by 1.9% for $O \leqq C \leqq C_S$. Hence we shall deduce

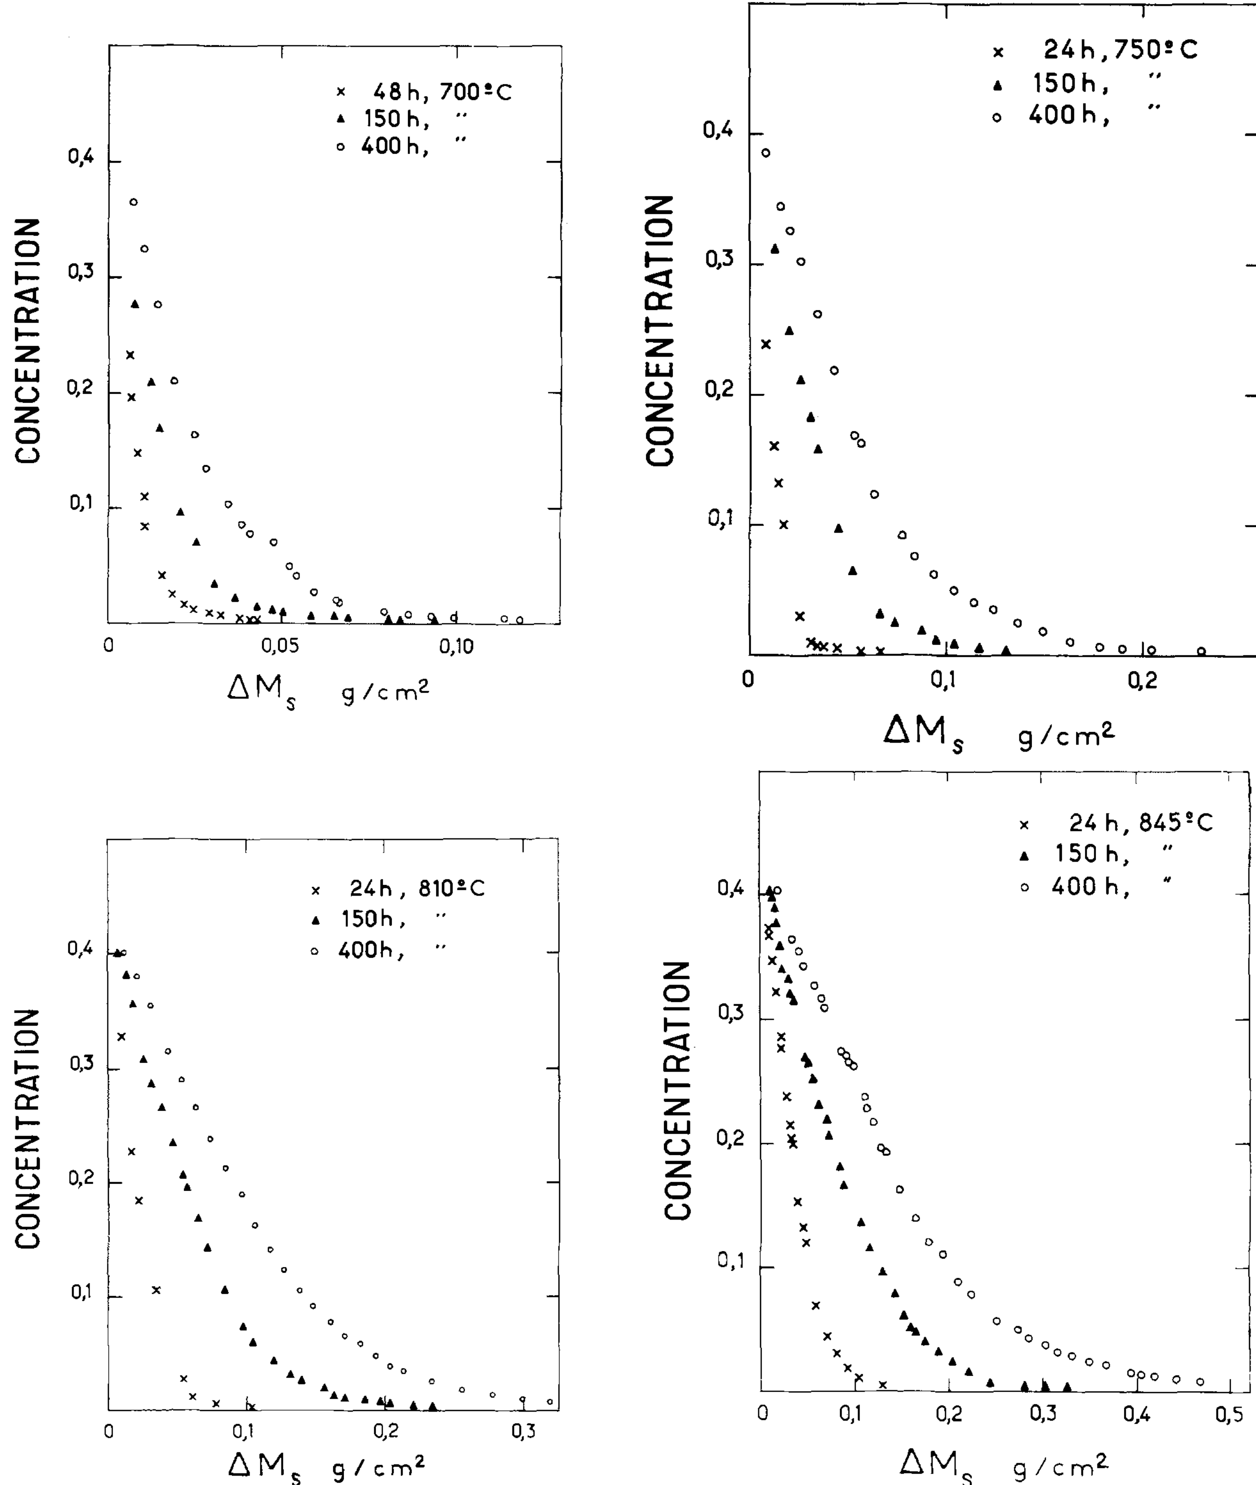

Fig. 3. Concentration profiles for various conditions expressed as a function of ΔM_S, the mass per cm^2 of the ground off Zr-O solution. For low C values 0.1 g/cm^2 is equivalent to 154μ.

x from m simply by using the density 6.5 for zirconium. In fact the only reason to introduce the x scale explicitly is for giving diffusion coefficients in the usual units of cm^2/sec.

$C(x)$, expressed in atom per cm^3, may be calculated similarly. It should be noted that an advantage of expressing C in O/Zr units is that the latter are independent of the depth scale chosen.

It may be noted at this stage that the quantity $\Delta x(C) n_{Zr}(C)$ in Eq. [2c] is just equal to $\Delta m/\mu_{Zr}$ and is hence independent of $n_{Zr}(C)$. The calibration does not depend on densities: from the nuclear point of view the physical state of the target has no influence; the density fixes only the geometrical depth scale. This again shows that m is the natural depth scale for profiles obtained by nuclear methods.

Results and Discussion

Figure 3 shows the experimental results as a function of the ground off mass ΔM_S. Except at 700°C, the penetrations are large with respect to the grain size (0.1 g/cm^2 of zirconium content being equivalent to 154 μm). All curves decrease toward the initial concentration C_o of 600 ppm, *i.e.*, 3×10^{-3} atom oxygen per zirconium. A scaling of the mass scale by $\sqrt{t}$ leads to well superimposed profiles at all temperatures as illustrated in Fig. 4 for one set of curves. One single depth correction for oxygen content was hence made at each temperature, according to the remark above. The resulting profiles $(C - C_o)$ as a function of $m/\sqrt{t}$ are shown in Fig. 5. These curves illustrate clearly a first important result: the diffusion process under study has a parabolic character.

It was next investigated whether these reduced profiles may be fitted with a single calculated curve according to the classical expression of the concentration profile

$$\frac{C - C_o}{C_S - C_o} = \frac{\operatorname{erfc} \dfrac{x + x_o}{2\sqrt{Dt}}}{\operatorname{erfc} \dfrac{x_o}{2\sqrt{Dt}}} \quad [7]$$

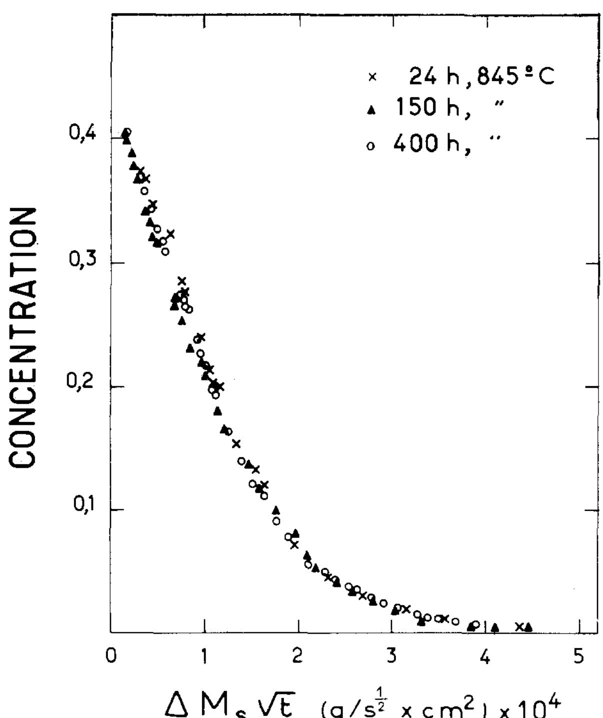

Fig. 4. A typical set of concentration profiles expressed as a function of the reduced coordinates $\Delta M_S/\sqrt{t}$. The $\sqrt{t}$ law is clearly well followed.

This equation is derived assuming a constant diffusion coefficient in the metal and that the thickness of metal x_o incorporated into the oxide developing from the surface varies like $\sqrt{t}$ at each temperature [see Jost (25) and Ref. (18)]. The latter assumption is known not to hold in the case of zirconium as the early stage of the oxidation process is not parabolic (6). From the measurements of the oxide thicknesses $X(t, T)$ performed as mentioned above it was established that the variations with time of the corresponding oxide mass per cm^2 $M_X(t, T)$ may be fitted by an expression of the form

$$M_X(t, T) = M_o(T) + \Gamma(T)\sqrt{t} \quad [8]$$

for large enough t. We shall postulate in what follows that Eq. [7] may be applied to our results with

$$x_o = \gamma(T)\sqrt{t} \quad [9]$$

where $\gamma(T)$ is relative to the mass per cm^2 of zirconium corresponding to $\Gamma(T)$ (which relates to the mass per cm^2 of oxide). $\gamma(T)$ is expressed in $g/sec^{1/2} \times cm^2$ of zirconium. This postulate implies that, at that start of the oxidation, a thin oxide layer is quickly formed, with thickness around $M_o(T)$, while little oxygen diffuses into the metal beneath. Typical values of $M_o(T)$ are around 4 μm. While we cannot state that this assumption is precisely valid, it appeared to be consistent with our results.

Using Eq. [9], Eq. [7] may be written, at a given temperature T

$$\frac{C - C_o}{C_S - C_o} = \frac{\operatorname{erfc}\left(\dfrac{x}{2\sqrt{Dt}} + \dfrac{\gamma}{2\sqrt{D}}\right)}{\operatorname{erfc} \dfrac{\gamma}{2\sqrt{D}}} \quad [10]$$

This equation was used to fit the profiles of Fig. 5, using the experimental values of γ listed in Table I. The values of C_S and D corresponding to the best fit are also listed in this table. It appears that Eq. [10] is well obeyed. The following comments may be made:

(*i*) A constant diffusion coefficient, for concentrations up to saturation, is compatible with the results. It seems, according to these detailed measurements, that the departures from the erfc behavior reported in the previous publications of Ref. (9, 18, and 19) are not confirmed. This is due mainly to the detailed corrections applied here for the oxygen stopping power in the Zr-O solution.

(*ii*) The concentration at the metal-oxide interface is nearly independent of time and temperature, C_S ranging from 0.421 to 0.429. It is most probable that C_S is a constant, the spread being within experimental errors. The corresponding mean value is $C_S = 0.424$, *i.e.*, 29.8 a/o. This is in good agreement with the zirconium-oxygen equilibrium diagram (26, 27); this shows in turn, that during oxidation near-equilibrium prevails at the metal-oxide interface.

(*iii*) The quantity $\psi = \gamma/2\sqrt{D}$ decreases with T from 1.9 to 0.8: hence there is no universal curve describing the profiles at various temperatures. The total

D is given in the usual cm^2/sec units for easy comparison; x was deduced from m using the density 6.5 for zirconium.

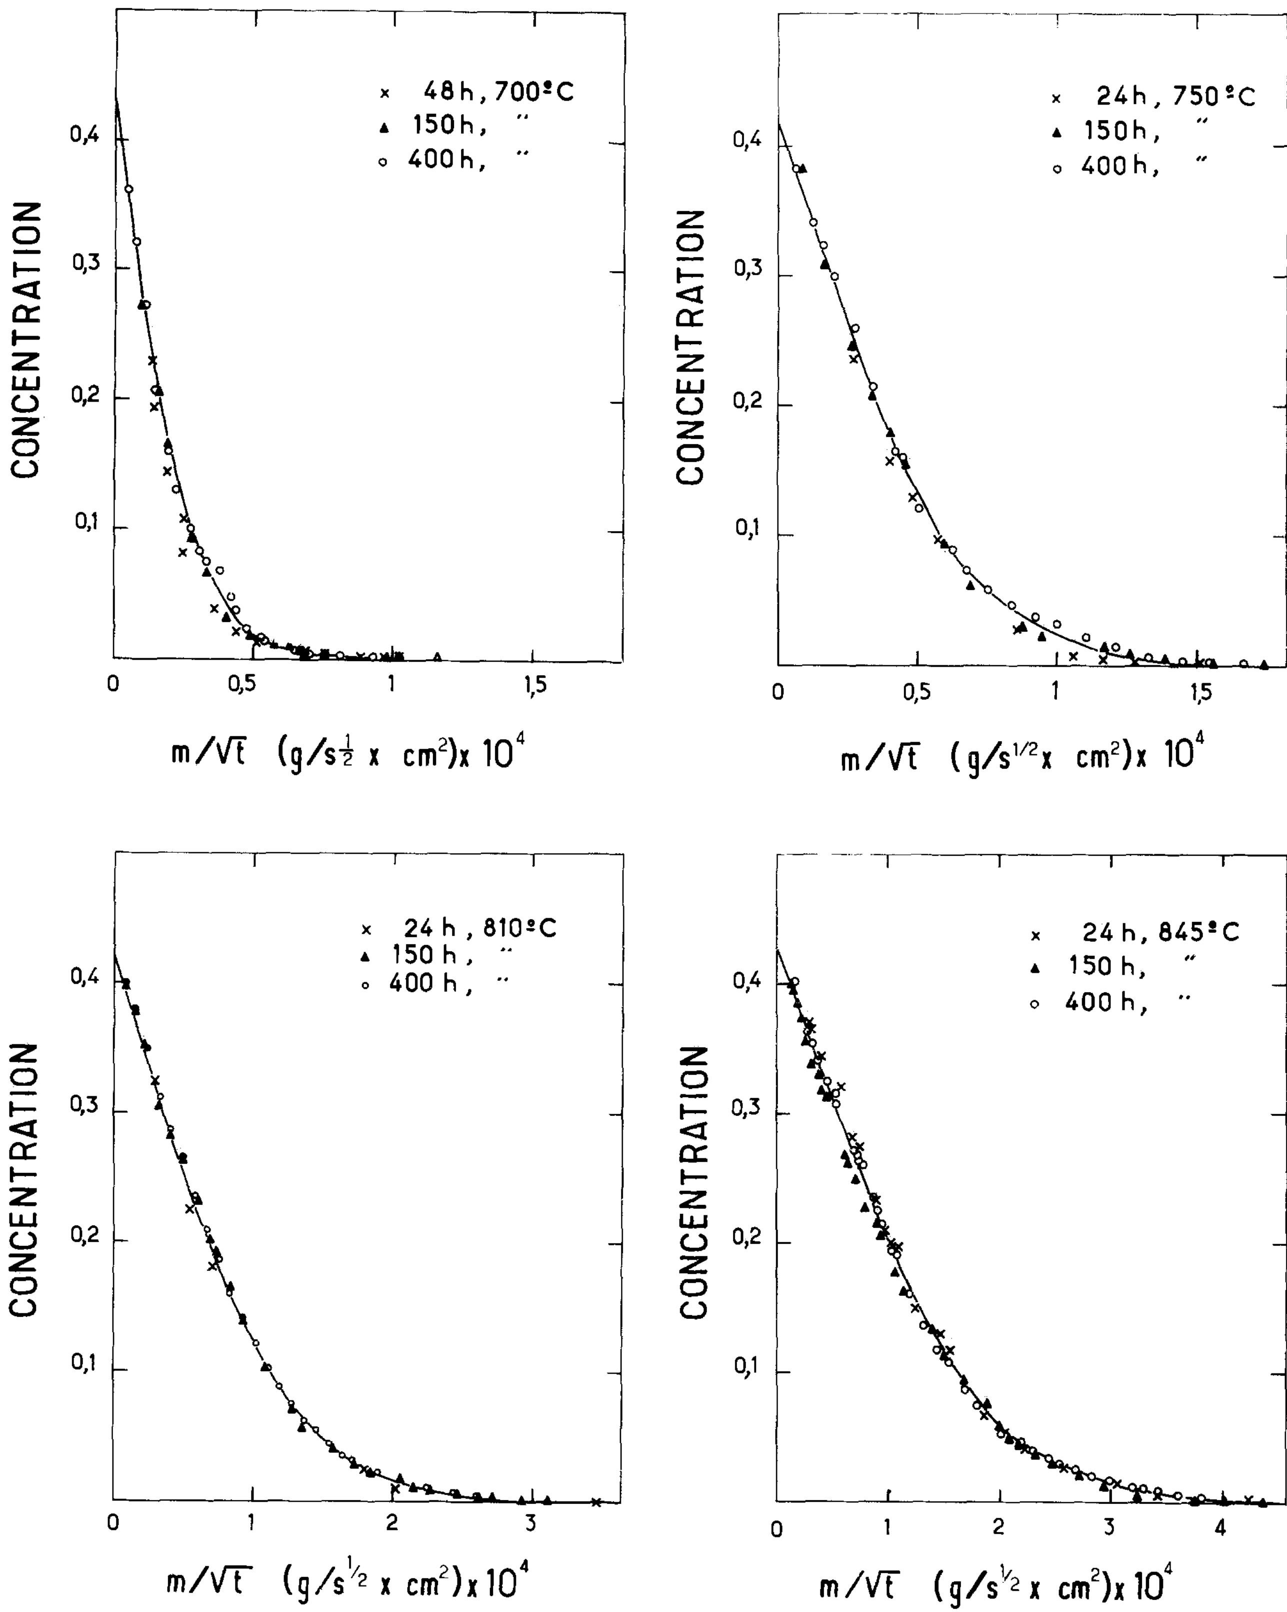

Fig. 5. Concentration profiles expressed as a function of the reduced coordinates $m/\sqrt{t}$. The initial oxygen concentration C_o was subtracted. The solid lines represent the best fit in the reduced coordinate scale, calculated according to Eq. [10], from which the D values were deduced.

mass $M(t)$ of oxygen which is present in the metallic phase is readily calculated to be

$$M(t) = 2\sqrt{Dt}\,(C_S - C_o)\,\frac{\text{ierfc}\,\Psi}{\text{erfc}\,\Psi} \qquad [11]$$

The last factor is due to the growth of the oxide and varies here from about 0.4 $\sqrt{\pi}$ to 0.6 $\sqrt{\pi}$; the value $\sqrt{\pi}$ corresponds to $\psi = 0$, *i.e.*, no oxide growth (simple diffusion with constant surface concentration).

(*iv*) Taking into account the various sources of errors, the values of D given in Table I are known with a relative precision of $\pm$ 10%. The values of D are plotted as a function of $1/T$ in Fig. 6. The resulting straight line indicates that a single mechanism of diffusion predominates in the temperature range considered; this is with high probability bulk diffusion, as grain boundary diffusion was shown to predominate mainly below 650°C (2, 6).

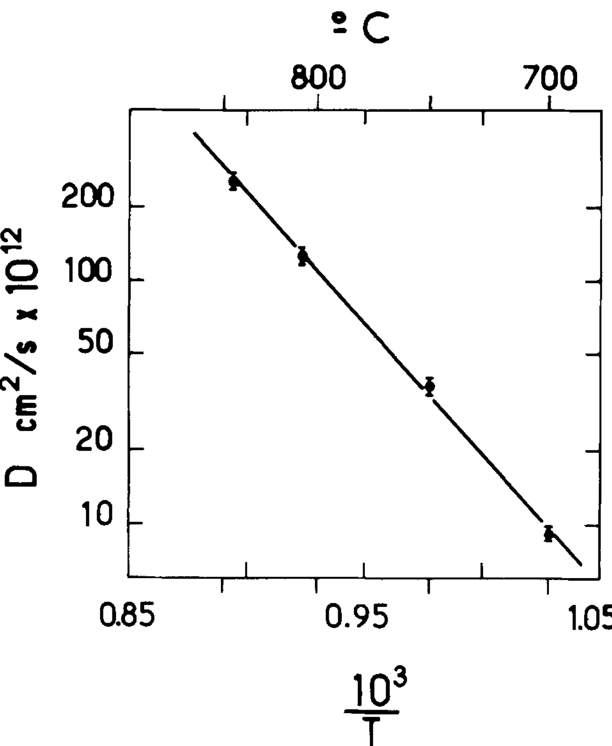

Fig. 6. Variation of the logarithm of the diffusion coefficient D with the reciprocal of the absolute temperature. The error bars correspond to an estimated 10% relative precision.

The temperature dependence of D was fitted with the expression

$$D(T) = D_0 e^{-Q/RT} \quad [12]$$

The best fit yields

$$Q = 49 \text{ kcal/mole}, \; D_0 = 1 \text{ cm}^2\text{/sec}$$

The errors on Q and D_0 may be conveniently discussed as follows. Let ΔQ be the error on Q and $\overline{Q}$ be its true value, $Q = \overline{Q} \pm \Delta Q$ and $\overline{D}$ be the true value of D, $D = (1 \pm \epsilon)\overline{D}$, ϵ being the relative precision on D. From Eq. [12]

$$\overline{D}(1 \pm \epsilon) = D_0 e^{\pm \Delta Q/RT} e^{-\overline{Q}/RT}$$

If the range of T around its central value T_0 is narrow enough, which is the case here, we may write

$$D_0 = \overline{D} e^{+\overline{Q}/RT} (1 \pm \epsilon) e^{\pm \Delta Q/RT_0} \quad [13]$$

We see that the error on D_0 is very large and dominated by the factor $e^{\Delta Q/RT_0}$, which may easily be of the order of 3 (in our case $RT_0 \simeq 2.1$ kcal/mole). Hence the extreme values of D_0 may often differ by one order of magnitude, although D is known with reasonable accuracy. This is due to the fact that D_0 is obtained by a long range extrapolation on the logarithmic scale.

In the present work it has been estimated, considering the 10% precision on $D(T)$, that $\Delta Q = 1$ kcal/mole. Hence the final result is

$$Q = (49 \pm 1) \text{ kcal/mole}$$

$$D_0 = 1 \times (1.8)^{\pm 1} \text{ cm}^2\text{/sec}$$

i.e.

$$0.55 < D_0 < 1.8 \text{ cm}^2\text{/sec}$$

It should be emphasized that the errors on Q and D_0 are by no means independent but related by Eq. [13].

Equation [13] explains why the spread of the published data on D_0 is so huge, from 0.2 to 200, as reported by Quataert and Coen-Porisini (13). When examining the published data, large values of D_0 appear to be associated with large values of Q. As an example let us analyze the data from Ref. (13)

$$D_0 = 15 \text{ cm}^2\text{/sec}, \; Q = 54.7 \text{ kcal/mole}$$

If we assume that the true value of Q is 49 kcal/mole, so as to compare to our result, D_0 must be divided by $e^{2.7} = 14.9$. This yields $D_0 = 1$, exactly our value. It appears hence that the measured values of D should be compared, rather than D_0 and Q, the latter containing often large errors, depending much on the analysis of the data performed by the authors. A similar remark has been made by Kidson (28) in his excellent review of diffusion process in zirconium, who observed that published D_0 and Q values may differ considerably, while "individual D values are in close agreement." The D values of Ref (13) are listed in Table I, for sake of comparison. The agreement is good, except for a somewhat smaller value at 700°C and somewhat larger at 845°C: this explains the higher value of Q reported in this reference. Taking into account that the result of Ref (13) was obtained by a direct method, but with some problems for precise calibration (as discussed above), we may conclude that our results are in satisfactory agreement with recent literature, while the precision is likely to be higher. The comparison with the values reviewed by Kidson (28) is also satisfactory, the various D_0 values reported being within a factor of 2 equal to ours, when the correction for Q is made as above.

It should be recalled at this point that many authors found a plateau in the microhardness-depth curve measured on such oxygen diffused zirconium samples (3, 4, 8, 14). In Ref. (9 and 19) the authors have shown that these plateaus do not correspond to any accident in the concentration-depth curve. This was confirmed again in the present measurements in great detail, the effect being due to a nonlinear relationship between the O/Zr ratio and microhardness (9).

It should be noted, that according to Pemsler (29) D depends markedly on the crystallographic orientation of the zirconium sample. In our case the samples were polycrystalline, but with a recrystallization texture after rolling which is characterized by a preferential orientation of the {1,0, $\overline{1}$,0} planes at 32° with respect to the plane of rolling, the <1,1, $\overline{2}$,0> direction being parallel to the rolling direction (30). The results reported here are hence associated with this texture.

From practical point of view, when studying thermal oxidation of zirconium as a corrosion process, it is most important to know what happens when the heat-treatment is performed in air instead of pure oxygen. Figure 7 displays a typical result for samples treated for 24 hr at 810°C in air and in pure oxygen at atmospheric pressure. The concentration profiles of oxygen appear to be identical within experimental error. It appears hence that nitrogen plays no role in the oxidation of zirconium in the above-mentioned conditions. This was further confirmed by analyzing both the oxides formed and the metal beneath for nitrogen contamination, using the highly sensitive $N^{14}(d,\alpha)C^{12}$ nuclear reaction (31). No detectable N^{14} was observed in the bulk of the samples, a surface contamination of about 0.05 μg/cm² being measured on all samples whether heat-treated or not. It should be noticed that this result was by no means trivial, as according to Croset and Velasco (32), large amounts of nitrogen may be dissolved in tantalum thin films heated in nitrogen containing traces of oxygen. After an initial strong dissolution of nitrogen the latter is rejected and is replaced by oxygen from the traces in the gas, even if the latter represent only 1 ppm nitrogen may hence play an important role when zirconium undergoes corrosion in nitrogen gas containing low concentrations of oxygen. This point merits further investigation.

In conclusion it appears that nuclear microanalysis proves to be a highly powerful method for measuring oxygen depth profiles in metals like zirconium. The technique may be readily extended to depth profiles of other light elements like nitrogen or fluorine. Work

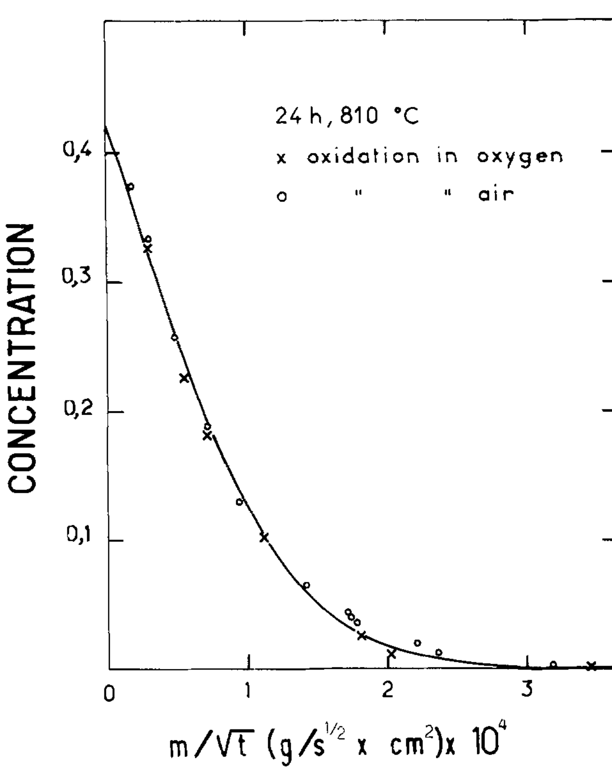

Fig. 7. Comparison of oxygen diffusion profiles represented as in Fig. 5 in zirconium oxidized in identical conditions in pure oxygen and in air.

is in progress for studying oxygen diffusion phenomena in titanium.

Acknowledgments

The authors wish to thank Professor P. Lacombe for fruitful discussions during the early stage of this work. This work was supported by the Centre National de la Recherche Scientifique (RCP No. 157), the DRME, and the DGRST.

Manuscript submitted July 15, 1974; revised manuscript received Sept. 27, 1974.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1975 JOURNAL. All discussions for the December 1975 Discussion Section should be submitted by Aug. 1, 1975.

Publication costs of this article were partially assisted by Centre National de la Recherche Scientifique.

APPENDIX

A. Calculation of $C = g(C_u)$

From Eq. [2c] it is seen that $f(C)$ is independent of the absolute value of the channel width ΔE, as it is a ratio of quantities proportional to ΔE. Hence the energy calibration (amplifier gain, influence of Mylar absorber, etc.) has no influence. Let $\epsilon_o{}^d$ and $\epsilon_o{}^p$ be the atomic stopping powers of oxygen for deuterons and protons in the vicinity of the energies involved (bombarding energy for d, energy at emission for p), $\epsilon_Z{}^d$ and $\epsilon_Z{}^p$ similar quantities for zirconium. The ϵ will be considered as energy independent for the plateau region. The energy loss for the incident deuterons up to depth x is (applying Bragg's rule for compounds)

$$\Delta E_d = x\, n_{Zr}(\epsilon_Z{}^d + C\epsilon_o{}^d) \qquad \text{[A-A-1]}$$

A deuteron reacting at energy E_d gives rise, toward the angle θ, to a proton with energy E_p, $E_p = k(E_d)$, according to the kinematics of the reaction. k is nearly linear, so $E_p = AE_d + B$ and the incoming deuteron energy loss gives rise to a loss $\Delta E_p{}^{in} = A\Delta E_d$. The outgoing proton undergoes a further loss

$$\Delta E_p{}^{out} = \frac{x}{|\cos\theta|}\, n_{Zr}(\epsilon_Z{}^p + C\epsilon_o{}^p) \qquad \text{[A-A-2]}$$

where $x/|\cos\theta|$ is the outgoing proton path length, assuming the sample to be perpendicular to the beam (17). The over-all loss is

$$\Delta E_p = \Delta E_p{}^{in} + \Delta E_p{}^{out} = x n_{Zr}\left[A(\epsilon_Z{}^d + C\epsilon_o{}^d) + \frac{1}{|\cos\theta|}(\epsilon_Z{}^p + C\epsilon_o{}^p)\right] = x n_{Zr} S(C) \qquad \text{[A-A-3]}$$

As this relation is linear in x, we may substitute Δx to x

$$\Delta x(C)\, n_{Zr}(C) = \frac{\Delta E_p}{S(C)} \qquad \text{[A-A-4]}$$

As ΔE_p is proportional to the channel width ΔE

$$f(C) = \frac{S(O)}{S(C)} = \frac{1}{1+\lambda C} \qquad \text{[A-A-5]}$$

where λ depends on a ratio of the stopping powers for O and Zr. λ may be calculated using published stopping powers. We used the values of Williamson *et al.* (33). We get $\lambda = 0.42$.

Thus, from [A-A-5]

$$C_u = Cf(C) = \frac{C}{1+\lambda C}$$

and

$$C = g(C_u) = \frac{C_u}{1-\lambda C_u} \qquad \text{[A-A-6]}$$

An error $d\lambda$ on λ leads to an error dC on C according to

$$\frac{dC}{C} = \frac{1}{C}\frac{\partial C}{\partial \lambda} d\lambda = \frac{\lambda C}{(1+\lambda C)^2}\frac{d\lambda}{\lambda} \qquad \text{[A-A-7]}$$

For $C = 0.4$ this gives $dC/C = 0.12\, d\lambda/\lambda$, *i.e.*, less than 1% even for $d\lambda/\lambda = 8\%$. Hence the error due to the correction itself is negligible.

B. Calculation of $\Delta x(o) n_{Zr}(o)$

From Eq. [A-A-4] this quantity is $\Delta E_p/S(o)$. The ΔE_p corresponding to the channel width ΔE may be measured directly by varying the accelerator energy (*i.e.*, changing physically E_p) and observing the corresponding change in channels for the proton peak from a thin anodic oxide target. $S(o)$ is calculated from the data of Ref. (33). The latter cannot be taken *a priori* to be known to within less than 8%. This uncertainty dominates all others and the absolute calibration for C is precise to within at least 8%.

C. Improving Absolute Calibration

As shown in Fig. 1 the spectra for a Zr-O solution near saturation and for ZrO_2 have the same shape; this indicates that λ is practically constant in a wide energy domain, although the individual values of ϵ vary with energy. In addition it is found from Fig. 1 that the ratio of the plateau heights of the two spectra is in a good agreement with the values calculated using the above λ and concentrations determined as described. This suggests that Eq. [A-A-6] is valid up to $C = 2$, *i.e.*, for zirconia. If this assumption is made, zirconia may be taken as a standard reference, known to within a negligible error. The error on C is then only due to an error on λ. For calculating the corresponding formula let us call H_o the plateau height for ZrO_2, H that for an unknown sample. From Eq. [4]

$$\frac{C_u}{C_u{}^o} = \frac{H}{H_o} = h$$

We have, as $C = 2$

$$C_u{}^o = \frac{2}{1+2\lambda}$$

and as $C_u = C_u{}^o h$, we get

$$C = \frac{2h}{1 + 2\lambda(1 - h)} \qquad \text{[A-C-1]}$$

Let us examine the effect of an error on λ. One calculates readily

$$\frac{dC}{C} = \lambda \frac{2 - C}{1 + 2\lambda} \frac{d\lambda}{\lambda} \qquad \text{[A-C-2]}$$

For C around 0.4 this yields dC/C:0.44 $d\lambda/\lambda$. An 8% error on λ yields 3.5% on C. In fact λ, being a ratio, is better known than that. We may conclude that a 3% precision on C is surely achieved. This is the precision we shall assume in this paper. It should be emphasized that this calibration technique is universal, and allows one to achieve absolute measurements without the need for thin film oxygen standards. The results obtained here with the latter confirm our confidence in this technique. The method may be readily extended to other metals like hafnium, tantalum, titanium, etc.

Preparation and Stabilization of Anodic Oxides on GaAs

S. M. Spitzer,* B. Schwartz,* and G. D. Weigle

Bell Laboratories, Murray Hill, New Jersey 07974

ABSTRACT

Anodic oxidation of GaAs is examined and a technique for growing full surface oxides ≈ 8600Å thick is reported. Anodization in a hot, concentrated (30%) H_2O_2 electrolyte of $pH = 2$ using self-anodizing metal contacts is found to yield uniform oxides with a refractive index of 1.8 and a growth rate ranging from 22 to 50 Å/V. The as-grown oxide will etch in HCl and H_2O. Chemical stability of this oxide is enhanced with baking in dry nitrogen and after 2 hr at 250°C, H_2O will no longer etch the oxide; after 1 hr at 600°C, HCl, HF, HNO_3, NH_4OH will not etch the oxide but hot H_3PO_4 will etch the oxide. The oxide is an amorphous, vitreous film which crystallizes to β-Ga_2O_3 after several hours at 800°C. A thin (<100Å) graded, oxide-GaAs interface was found to grow at anodization potentials >100V and for heat-treatment at temperatures greater than 400°C for 1 hr. The oxide exhibits excellent adherence to the substrate, has good match with the thermal coefficient of expansion of GaAs, and forms a relatively strain-free interface. Since GaAs is consumed during anodization, this provides a technique for surface cleaning using an oxide growth-strip step. Enhanced device reliability is expected to result by utilization of the oxide growth-strip-regrowth cycle during device fabrication, since this will remove contamination from the surface. The findings here enumerated, coupled with ease of oxide growth, suggest ready implementation to a GaAs planar technology.

The growth of amorphous native oxides on compound semiconductors has recently been demonstrated (1, 2), and has been shown to have beneficial passivation effects (3, 4). It has therefore become necessary to expand both our understanding and our technological capabilities to determine the extent to which we can apply these oxide growth concepts to device fabrication techniques. In a recent paper (5), the anodization of GaAs in aqueous H_2O_2 solutions was discussed and application to mesa formation for waveguides and double heterostructure lasers were described. In this paper, we show the results of additional studies on a similar anodization system. We describe how the range of oxide thickness has been extended from the 3000Å previously reported, to greater than 8000Å. We also describe how both the physical and chemical characteristics change with heat-treatment. In addition, a technology is presented which permits full surface anodization, and utility of this oxide as both a surface evaluation tool and a surface cleaning and protection method. Potential device applications of this emerging anodic oxide technology are also discussed.

Experimental Procedure

The anodization process used here is similar to the technique described earlier (2), but has been extended to allow: (*i*) anodization with either a constant voltage source (maximum current limit) or a constant current source (maximum voltage limit); (*ii*) variation of the temperature of the anodization bath from room temperature to the boiling point of 30% H_2O_2 (≈ 106°C); and (*iii*) use of self-anodizing Al-Ni wire or Al tweezers rather than Pt to contact the anode (semiconductor) sample.

The anodization bath consisted of an aqueous solution of 30% H_2O_2, which was buffered to a pH of 2.0 ± 0.5 with H_3PO_4 for standard oxide growth conditions.

Anodization studies were performed on (100)- and (111)-oriented GaAs wafers, which were p-type with a net Zn acceptor concentration in the 1-5 × $10^{18}/cm^3$ range or n-type with a net Si donor concentration in the 0.5-5 × $10^{17}/cm^3$ range. The samples were lapped with 0.3 μm alumina in H_2O and 75 μm was then etched [the arsenic face for (111)-oriented samples] with a bromine methanol solution for a final wafer thickness of 0.3 mm.

The wafers were thoroughly degreased using trichlorethylene and acetone soxhlet cycles, followed by a water and methanol rinse prior to anodization. At this point oxides were grown in a hot peroxide solution under constant voltage or constant current conditions. Room temperature oxides were also grown to provide reference samples. A drying procedure, that of heating in dry nitrogen for 2 hr at 250°C, was established to stabilize the oxide films.

Oxide thickness and index of refraction were measured with an ellipsometer at 6328Å using procedures described for similar studies of the oxidation of GaP (2). Oxide thickness was also measured with a Talystep[1] by comparing the step height of photoresist protected oxide stripes (6) with respect to the GaAs surface, thus producing an independent thickness measurement.

Sample anodization.—During the early anodization studies only partial oxidation of the surface area was possible because the GaAs sample was clamped in Pt tweezers and the sample was immersed in the bath to a depth such that the Pt did not contact the solution. When considering the effects of surface tension and vibration of the solution, a significant portion of the semiconductor sample did not anodize. This problem became particularly severe when small samples were used, such as 6 mm square double-heterostructure laser slices. Furthermore, the effects of high electric field and uncontrollable pH at the air-liquid interface generate a nonuniform oxide band parallel to this interface. Thus the unanodized and nonuniform portions of the wafer were wasted. One of the first problems solved was the development of a means of achieving "full surface" sample anodization, using a metal to contact the semiconductor which itself can be immersed in the electrolytic bath and will self-anodize. In (3% Al), Ni, Al-Ni, and Al were found to anodize quickly, forming a high resistivity oxide which eliminates any shunt path to the solution, thus permitting semiconductor anodization. Silver was found to be unsuitable because the Ag_2O_3 so formed is soluble in the anodization bath and the silver contact dissolves before the semiconductor is anodized to any appreciable thickness. The results on aluminum were particularly interesting because this self-passivating effect stops oxide growth leaving a thin brittle oxide on the Al. This oxide then cracks easily under slight mechanical pressure, thus

allowing good electrical contact to be made to the underlying metal. Such a self-anodizing metal can be affixed to the back of a sample with wax, as shown in Fig. 1. In the case of higher resistivity samples, where current spreading can be a problem or where a full surface back contact is desired (as in MOS samples), a full back surface aluminum or aluminum overlay metallization can be evaporated to act as a sealant for the anodization. For rapid processing, however, the technique used predominantly throughout this series of experiments was to hold the sample with Al-tipped tweezers and then immerse the sample and tweezer tip in the bath as shown schematically in Fig. 2. In this manner, all but about 2 mm^2 of the surface was anodized, and problems associated with the air-liquid interface were eliminated.

Oxidation

The mechanism of anodization of GaAs is thought to involve an ionic drift process, wherein the ionic oxidant drifts through the oxide to reach the oxide-semiconductor interface where the oxidation actually takes place. The partially oxidized gallium (*e.g.*, Ga^{+1}) is now influenced by the electric field in the oxide and starts to drift toward the oxide-electrolyte interface. During its migration, or at least soon after it reaches the oxide-electrolyte interface, the gallium is oxidized further to the Ga^{+3} state, where it finally stabilizes.[2] Therefore, under steady-state conditions, there is charged oxidant moving inward from the electrolyte and charged reductant moving outward from the semiconductor. The assumption is also made that the arsenic oxidizes to its fully stable state (probably As^{+3}) and becomes stationary, being bonded to its neighboring oxygen atoms.

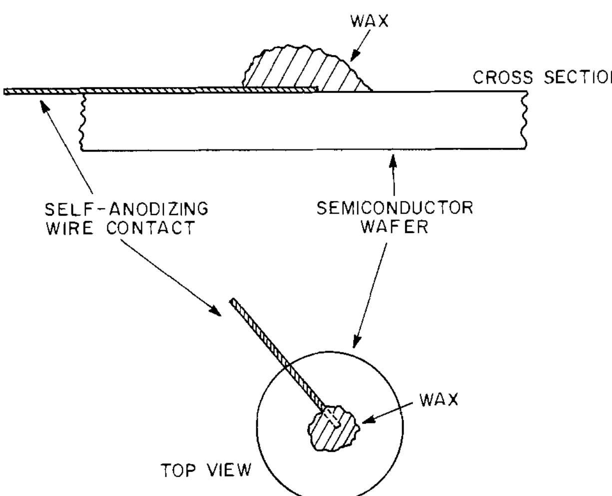

Fig. 1. Technique for full surface oxide growth using a self-anodizing metal contact.

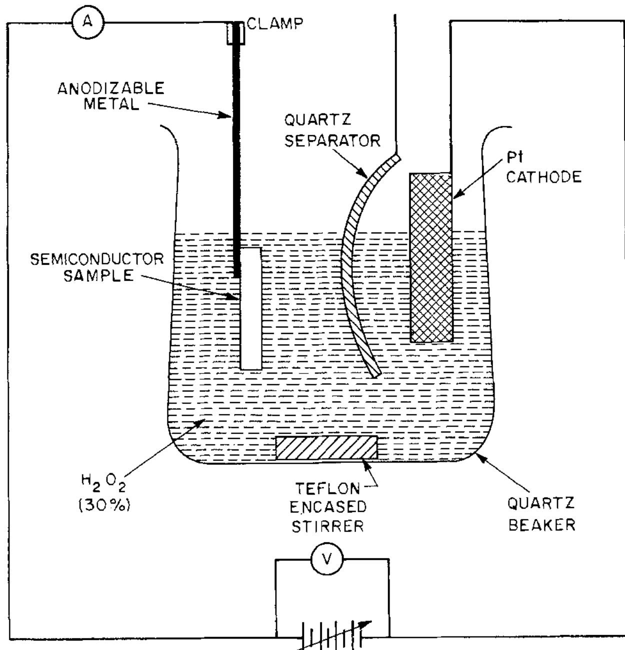

Fig. 2. Schematic of anodization system using self-anodizing contact for full surface oxide growth at room temperature and at 100°C.

Since ionic conductivity is known to be strongly temperature dependent, the logical step in an attempt to increase the ultimate oxide thickness was to raise the temperature of the anodization bath (9). The effect of temperature on the "ultimate" oxide thickness is interpreted as being related primarily to two factors: increased ionization in solution and enhanced drift mobility. The influence of temperature on ionization in solution is well known and for most inorganic acids, the ionization constant increases with increasing temperature; hydrogen peroxide as an inorganic acid shows this property (10), and therefore the concentration of ionic oxidant is increased in solution.

Drift mobility of the ionic oxidant is strongly temperature dependent; the ionic drift rate follows an $\exp(-E/kT)/T$ dependence (11), a rapidly increasing function between room temperature and 100°C. One might also expect enhanced diffusion of species in solution at elevated temperature, but this effect is not believed to be an important contributor to the increased oxide thicknesses. Sample conductivity also has a role in the ionic processes required for anodization. Intrinsic (undoped) samples exhibit a strong temperature-conductivity dependence and oxide growth is enhanced at elevated temperature due to this effect. The conductivity of extrinsic samples ($> 10^{16}/cm^3$) however, is temperature insensitive from room temperature to 100°C, and thus would not contribute to increased oxide growth.

An increase in oxide growth was indeed observed for this hot-peroxide system, and the dependence of oxide thickness on anodization voltage for boiling-peroxide growth is shown in Fig. 3; also included are data for room temperature growth (5). Note that for biases less than 100V the hot-peroxide thickness dependence is linear at approximately 22 Å/V, 20% greater than the room temperature growth. However, at higher voltages, the growth becomes superlinear with voltage approaching 50 Å/V at 180V, more than 2½ times the room temperature growth. The thickest as-grown oxide prepared to date has been 8600Å at ~180V.

Oxide thickness was measured with both the Talystep and ellipsometer because of the interpretational problems reported with the ellipsometry data for room temperature anodizations at biases greater than 150V (5). For the high temperature anodizations at biases less than 100V, agreement was found between the two measurement techniques. The index of refraction of the oxide was measured as $n = 1.8$, identical with the value obtained for room temperature anodization. However, analysis of ellipsometric data for the high temperature oxides, grown at biases greater than 100V, yielded an apparent index of refraction which increased with anodization voltage, up to $n \approx 3.2$ at 190V. Thus, the calculated oxide thickness appeared to decrease with increasing voltage. Because these were clearly anomalous results, Talystep measurements were made which showed that the oxide thickness monotonically increased with applied bias. These results clearly show that the model of a uniform oxide and abrupt in-

[2] Studies on the composition of the grown oxide (7) show nonuniformities of composition similar to those found in anodized GaP (8).

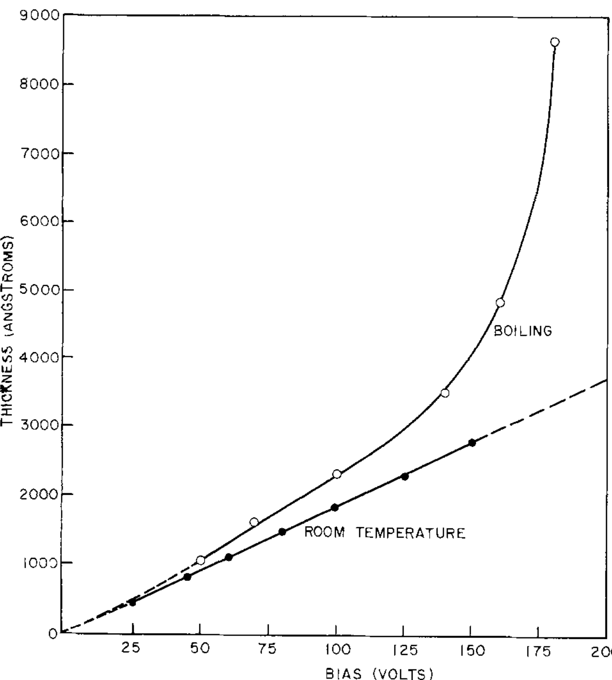

Fig. 3. Oxide thickness produced *vs.* anodization potential for room temperature and boiled anodization.

terface used in the ellipsometric analysis is no longer valid.

It is postulated that a grading of composition at the semiconductor-oxide interface occurs at high bias conditions. Some additional corroborating evidence for the existence of such an interface region is presented below.

Oxidized samples were examined using a phase-contrast microscope at 160×, and the two interfaces (*i.e.*, semiconductor-oxide and oxide-air) could be brought into focus separately. Oxides produced by hot-anodization at 140V were smooth and shiny and of apparent uniform color throughout (Fig. 4a); oxides formed at higher voltages exhibited a dull and/or grainy texture as seen in Fig. 4b. Careful microscopic examination of the dull and of the grainy oxides showed a grainy region forming deep within the oxide; although the oxide-air surface still appears to be smooth in both cases. This grainy region deep in the oxide film, shown clearly in Fig. 4b, grows and becomes more clearly defined with increasing bias, until the entire film becomes very hazy and nonuniform in color with the

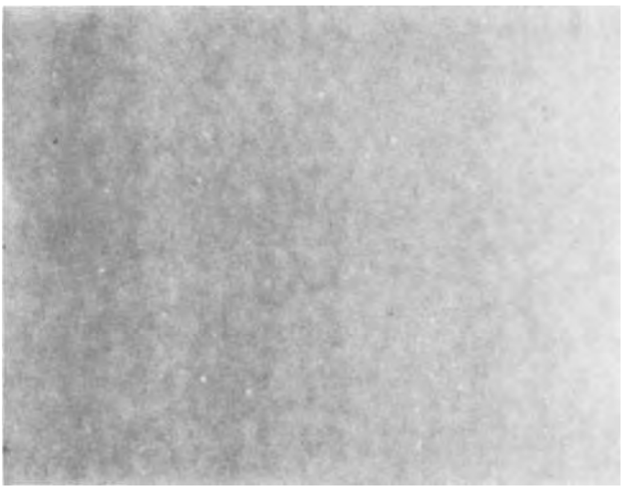

Fig. 4a. Microphotograph of semiconductor-oxide interface of 2200Å thick oxide produced by hot anodization at 140V. Note uniform texture. (Original magnification 160×.)

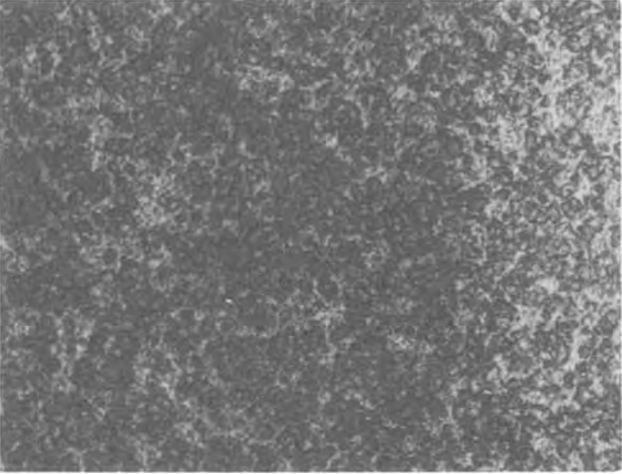

Fig. 4b. Microphotograph of semiconductor-oxide interface of oxide > 8600Å thick produced by hot anodization at 190V. Grainy detail is readily apparent. (Original magnification 160×.)

appearance of patches of color randomly distributed.

Since this structure is voltage dependent and the surface looks as though it may have been decorated by electrical breakdown, an attempt to increase anodization voltage while maintaining shiny, high quality oxides was made by increasing the voltage in step increments during anodization. The reasoning behind this approach was to prestress the oxide with bias less than 140V, then to slowly increase the bias as the oxide thickness increases. A typical step cycle was to anodize for 5 min each at 120, 140, and 160V, and this approach was indeed successful: oxides produced at biases up to 160V were shiny and uniform in color, at biases up to 180V were shiny but gray, and at bias greater than 190V the oxides were again dull and grainy. It should be noted that this voltage step-increment technique is actually a linear piece-wise approximation to a constant current anodization process. Samples have been anodized using both a constant current and constant voltage source, and the following similarities have been observed. In both cases final oxide thickness seems to depend only on the applied bias. In the constant voltage mode, oxide thickness is predetermined by the applied voltage and if the series resistance between the anode and cathode is not exceedingly high, the oxide grows quickly (5-10 min) (5) and is reasonably unchanged if left in the anodic cell for longer times. In the constant current density mode, power must be cut off at some predetermined voltage, otherwise oxide growth will continue as long as the bias continues to be applied to maintain the current level in the system.

Oxide Properties

It was reported that for anodization of GaP a bake-dry cycle was necessary to remove waters of hydration incorporated during oxide growth (2). Oxide layers on GaAs show no change in thickness after oxide growth and after bake cycles up to 400°C. It was thus determined that the procedure used for GaP does not necessarily apply for GaAs. It was observed, however, that when wafers were rinsed in water subsequent to anodization, the water would lightly etch the oxides. However, a dry-bake cycle was found to completely stabilize the oxide with respect to water etching. Thus, for all data presented here unless otherwise indicated, the oxides have been baked for 2 hr in a dry nitrogen ambient immediately following anodization.

The anodic oxide on GaAs is readily etched in HCl solutions; the oxide etch rate *vs.* HCl concentration in H_2O is shown in Fig. 5 for room-temperature anodized oxides; oxides anodically grown in boiling-peroxide exhibited similar etch rates. These data were obtained by first determining the oxide step height with the Talystep, and then measuring the time required to etch

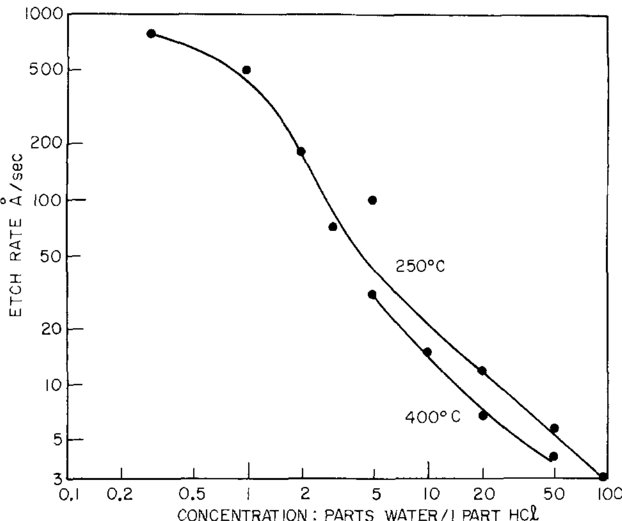

Fig. 5. Oxide etch rate determined by complete removal of a 2000Å room temperature oxide as a function of HCl concentration. Samples were heat-treated at 250°C for 2 hr and at 250°C for 2 hr and 400°C for 1 hr to evaluate chemical stability.

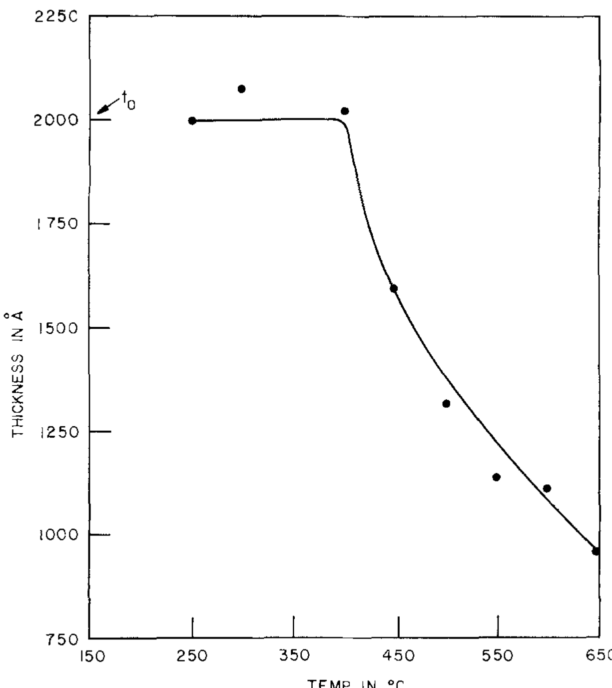

Fig. 6. Oxide thickness as a function of heat-treatment after 1 hr at each given temperature. Oxide originally grown at room temperature and 100V.

to the GaAs surface. The etch rate for oxides baked at 250°C range from approximately 1000 Å/sec in concentrated HCl to 3 Å/sec in 1:100 concentrated HCl to water.

In anticipation of possible high temperature use of these native oxides on GaAs, several physical properties have been examined at elevated temperatures. The etch rate following a 400°C-1 hr bake is also plotted on Fig. 5; note the enhanced chemical stability of the oxide as evidenced by the decreased etch rates. Furthermore, after baking at 600°C, the observed etch rate is less than 1 Å/sec, *i.e.*, below measurable limits even in concentrated HCl. Oxides baked at high temperature do not seem to etch in HCl, HNO_3, HF, NH_4OH, or NaOH; only hot, concentrated H_3PO_4 seems to remove the oxide. The oxide thickness of a room temperature grown, 2000Å thick film was measured after growth, and after sequential bake cycles each at 1 hr at temperatures up to 650°C. These data, plotted in Fig. 6, show virtually no thickness change up to 400°C, but above 450°C, the oxide thickness decreased until only approximately 50% of original thickness remained at 650°C. At 550°C and above, some graininess was observed in the oxide, analogous to the grainy appearance at the interface observed under high bias conditions. Etching studies have also shown that after baking at 400°C, the last 100Å of oxide (*i.e.*, at the semiconductor-oxide interface) has a granular appearance and does not etch easily. Thus, the interface region develops both at high anodization bias and after a baking cycle at 400°C and above. The thickness of this interface region appears to be less than 100Å, and is extremely difficult to remove via etching.

The data showing change in oxide thickness with heat-treatment might suggest structural changes in the native oxide. X-ray diffraction studies on the as-grown oxide as well as after sequentially heating it in dry N_2 for 2 hr at 250°C, 2 hr at 600°C, 2 hr at 700°C, and 10 min at 800°C showed no detectable crystallization, *i.e.*, the film remained amorphous. However, after 1 hr at 800°C a pattern started to develop indicating the presence of β-Ga_2O_3 in small quantities in the glass film. Following 2 hr at 800°C, transmission electron microscopy identified the presence of small grains (200-500Å) of β-Ga_2O_3 distributed in between large grains (2000Å) of an unidentifiable crystalline phase, all encased in an amorphous medium. Whiskers growing from the semiconductor-oxide interface up through the oxide were also observed. After 4 hr at 800°C the entire film crystallized and flaked off the surface of the GaAs. Clearly this crystallization is a dynamic process dependent on time and temperature.

Another important physical property is oxide adherence to the substrate. As-grown oxides and oxides heat-treated up to 700°C for 1 hr all passed the "Scotch tape test." Only when crystallization occurred, after exposure to 800°C for several hours, did the film become brittle and lift from the semiconductor. A preliminary study was made to determine if oxide growth would induce strain in the GaAs substrate, or if potential mismatch in the thermal coefficients of expansion would induce strain after temperature cycling. A piece of GaAs was cleaved and viewed through crossed polarizers under an infrared microscope before and after oxide growth, and again after heat-treatment to 600°C for 1 hr; no strain induced birefringence was observed, indicating at least no gross strain to be present. However, a more sensitive measurement using the technique of automatic Bragg angle control must be made before these strain results are conclusive.

Device Application

The native anodic oxide can be used as a mask for chemical etching, previously described for the formation of passive optical waveguides and mesas suitable for double-heterostructure (DH) lasers (5). There are, of course, many other potential uses and in this section we describe some applications of the oxide in terms of general processing schemes as well as several particular device applications.

Since oxide growth rates are dependent on the anodic current density, oxide uniformity is dependent on sample conductivity or carrier concentration. Thus, an oxide grown on a semiconductor with nonuniform lateral doping (Fig. 7a) will exhibit color bands or fringes (as shown in Fig. 7b) with the thicker oxides growing on more highly doped areas. Oxide growth is also a sensitive function of crystalline perfection, so that some epitaxial growth defects are clearly delineated during oxide growth (seen in Fig. 7b) (9). This is proving to be a simple, yet valuable, surface evaluation technique in the DH laser fabrication technology.

During anodization, approximately 2/3 of the oxide thickness represents GaAs material consumed (5). This provides a controllable technique for sectioning thin

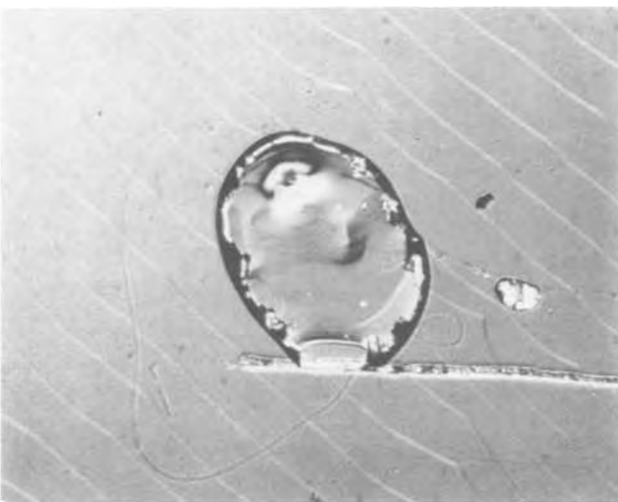

Fig. 7a. Photomicrograph of as-grown p-type LPE layer on GaAs substrate. (Original magnification 160×.)

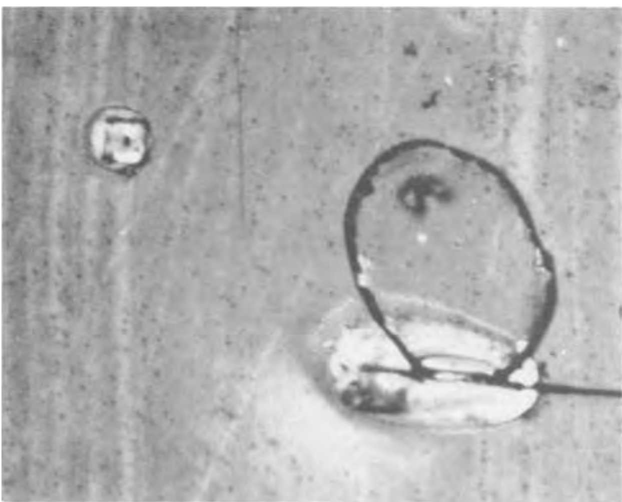

Fig. 7b. Photomicrograph of same area of p-LPE layer after anodic oxidation at 100V. Striated regions indicate nonuniformities in carrier concentration, while ring-like, splotchy areas decorate epi-layer defects. (Original magnification 160×.)

parallel layers for material analysis and semiconductor profiling. This technique also provides an excellent scheme for semiconductor surface cleaning: a predetermined semiconductor surface layer up to approximately 5000Å thick can be removed by oxidation followed by an HCl strip. Aside from being a superior cleaning technique to that of organic solvent cleaning, this technique will remove surface damage which may have been caused during prior processing steps if this damage penetrates less than the thickness of GaAs consumed during anodization. Such cleaning is useful in device fabrication to keep contamination from active regions, to minimize surface leakage, and to provide more reliable low resistance contacts. This technique can be extended to provide surface protection as well as cleaning. If an anodization step is performed after certain processing steps, including the initial materials preparation step of epitaxial layer growth or diffused layer formation, the oxide will keep the semiconductor surface clean from contamination until the next processing step. Measurements of oxides on GaP (12) indicate this oxide does act as an effective mask against mobile ionic species (including Na^+) and on GaAs (13) against the diffusion of atomic Zn. Thus, a further advantage may be obtained in that the native oxide should passivate the semiconductor surface and offer improved device reliability.

One class of devices that may become feasible utilizing this anodization process is the MOS family. In particular, the p- and n-channel insulated gate field effect transistor (IGFET) could be fabricated using the anodic oxide as the gate insulator. An experiment is now in progress to explore these possibilities. Another class, diffused junction devices, can be optimized using well-controlled selective area diffusion (13) along with a diffusion damage buffer (13) as a result of the anodically grown oxides. The sectioning technique provides a fabrication technology for yet another class, mesa or quasi-planar. This mesa geometry can be particularly useful for lasers and LED diode arrays especially where junction isolation and current confinement are required.

The technology of anodic oxidation of GaAs may be very useful in the GaAs-GaAlAs double heterostructure laser technology. The oxidation process seems well suited to the design of new laser structures and the improvement of laser reliability and lifetime. However, discussions of these details will be covered in future efforts.

Summary

1. A technique has been developed permitting the growth of a native oxide on GaAs to an as-grown thickness of up to 8600Å. The oxides formed by anodization with biases to 180V in a boiling H_2O_2-aqueous solution have an index of refraction, $n = 1.8$, and exhibit excellent adherence to the substrate. The growth-bias dependence of such oxides has been measured and found to range from 22 to 50 Å/V.

2. A method for obtaining full surface anodization has been described which allows for more economical use of the semiconductor material, more uniform and repeatable anodizations, as well as eliminating problems at the surface of the solution and of premature oxide breakdown at the air-liquid interface.

3. The anodic oxide was found to exhibit enhanced chemical stability with heat-treatment. The as-grown oxide etches in HCl, and also etches slowly in H_2O. After being baked in dry N_2, the HCl etch rate was unchanged, but H_2O would no longer etch the oxide. Following a bake at 400°C, the observed HCl etch rate decreased, and after a high temperature bake, HCl would no longer etch the oxide at any appreciable rate. A "standard" bake cycle of 250°C for 2 hr was incorporated to prevent water etching; no oxide thickness change was observed following this bake.

4. Gallium arsenide is consumed during anodization at a rate of 2/3 of the oxide thickness growth rate. This technique can be utilized for lateral sectioning and to profile the material, as well as to clean the semiconductor surface via a growth-strip step.

5. A region at the semiconductor-oxide interface with optical and chemical properties differing from both the semiconductor and oxide has been identified using the ellipsometer and chemical etching. This interface is produced when anodizing at biases greater than 150V and can also be produced by heat-treatment at 400°C for 1 hr.

Clearly the most important outcome of this study is the recognition of the potential of this oxide to develop a planar GaAs technology, and the multitude of new device structures such a technology implies.

It has been found that this native oxide acts as a diffusion mask against Zn (13). It is also a barrier against moisture and may act as a barrier to many different atomic species. This oxide is compatible with standard photolithographic processing, will serve as an etching mask, has good adherence, and forms a relatively strain free, high integrity interface with the semiconductor. The ease of oxide formation, coupled with the technology developed here, suggest an interesting and active future for the GaAs-native oxide system.

Vapor Deposition of GaP for High-Efficiency Yellow Solid-State Lamps

Bruce W. Wessels*

General Electric Corporate Research and Development, Schenectady, New York 12301

ABSTRACT

Nitrogen-doped gallium phosphide has been epitaxially deposited on GaP substrates by chemical vapor deposition using phosphine, hydrogen chloride, and gallium as reactants. The morphology of the epitaxial layers and the electroluminescence of the Zn-diffused diodes were investigated as a function of substrate temperature, Ga source temperature, and reactant concentration. It was found that by decreasing the $PH_3/GaCl$ ratio at which the material was grown, the electroluminescence of the diodes prepared from the material shifted to longer wavelengths as a result of increased nitrogen incorporation. Minority carrier lifetime for the n-type epitaxial material was measured by the diode reverse-recovery technique. For diffused diodes, the reciprocal of the minority carrier lifetime is directly proportional to the $PH_3/GaCl$ ratio at which the material was prepared. Possible recombination centers consistent with lifetime-ambient composition behavior are the Si-O complex or Ga vacancy complex. Quantum efficiencies for the encapsulated yellow light emitting diodes with a mesa structure were as high as 0.15% at 20 A/cm^2 and 0.24% under pulsed operation at 100 A/cm^2.

One of the most important materials for the fabrication of efficient solid-state lamps is GaP. By suitably doping GaP grown by liquid phase epitxay (LPE), lamps which emit red (Zn-O doped) and green (N-doped) light have been made. Recently, it has been observed that by increasing the nitrogen doping level in GaP to greater than 1×10^{19} atoms/cm^3, yellow electroluminescence can be obtained (1). Efficient yellow lamps, however, are not easily prepared from GaP LPE material because of formation of GaN in the melt at high N concentrations (2). A growth technique that allows the preparation of GaP with efficient yellow and yellow-orange emission is vapor phase epitaxy (VPE).

Although quantum efficiencies of 0.1% have been observed for yellow Zn-diffused GaP VPE devices, further improvements are required. One area where advances can be made is in the epitaxial growth. In the present work, growth conditions, including reactant partial pressure, growth and source temperatures, have been studied for the Ga-HCl-PH_3-H_2 vapor-growth system and related to the morphology of the epitaxial material as well as to its electroluminescent properties. In addition, the dependence of the space charge current for diffused diodes, the minority carrier lifetime, and quantum efficiency were investigated as a function of the $PH_3/GaCl$ ratio at which the epitaxial material was grown. As a result of this study, yellow light emitting diodes with the highest quantum efficiency yet reported for GaP VPE devices have been prepared.

Experimental

Apparatus.—The system used for vapor phase GaP epitaxial growth was similar to that described by Tietjen and Amick (3) for the deposition of III-V compounds from Group V hydrides, Group III metals, and HCl. A schematic diagram of the reactor is given in Fig. 1. The reactor chamber consists of a high-purity synthetic quartz tube, with stainless-steel piping leading to it. The quartz reactor was placed in a three-zone resistance heated furnace.

Reactant gases included electronic grade HCl, a 5% mixture of electronic grade phosphine in UHP hydrogen, and palladium-diffused hydrogen as the carrier

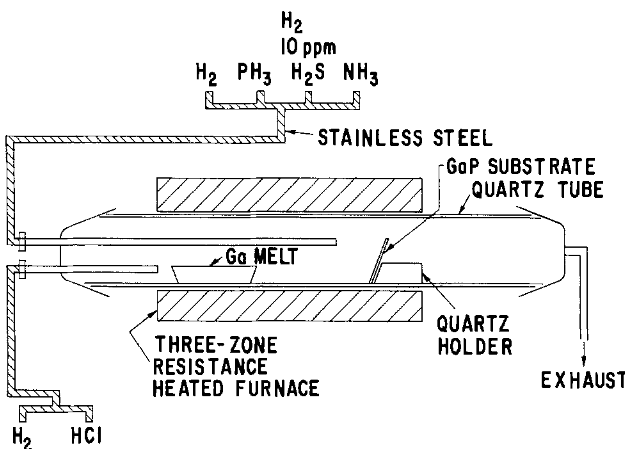

Fig. 1. Schematic diagram of vapor deposition apparatus

gas. A mixture of 10 ppm hydrogen sulfide in hydrogen was used to dope the epitaxial layers n-type to a level of $3 \times 10^{16}/cm^3$. Nitrogen doping of the layers was achieved by incorporating electronic grade ammonia into the gas stream. Elemental Ga of 6 nines' purity was the metallic source. Epitaxial layers were grown on LEC grown gallium phosphide wafers, oriented 10° off the (100) plane. Before deposition the wafers were lapped, chemically polished, and then etched in 3:1:1, H_2SO_4:H_2O:H_2O_2. Subsequently, the wafers were rinsed in deionized water and inserted into the reaction chamber after drying in N_2.

Typical growth conditions consisted of a gallium source temperature of 880°-930°C and a substrate temperature of 780°-840°C. The phosphine and hydrogen chloride flow rates were 1.5 and 3.0-7.5 cm^3/min, respectively, with a total hydrogen flow rate of 650 cm^3/min. The furnace was profiled so that there were two regions of differing temperature gradients: a flat zone at which the Ga source was placed, and a region with an 8°C/cm temperature gradient where the substrate was placed. Growth rates for a HCl input concentration of 4.0 cm^3/min, a source temperature of 890°C, and substrate temperature of 800°C were of the order of 0.3 μ/min.

The following reactions have been found to occur for a similar vapor-hydride system (4). Gaseous HCl reacts completely (>98%) with the gallium source in the metal zone to form gallium monochloride. Phosphine partially decomposes near the deposition zone to form the species P_2 and P_4. Subsequently, at the deposition zone gallium monochloride reacts with phosphorus and hydrogen to form GaP and the byproduct HCl. An important feature of the present system as compared to the Ga-PCl_3-H_2 system (5) is that the relative amount of Ga to P in the ambient can be readily varied making it possible to study the effects of stoichiometry on the properties of epitaxial GaP.

Diodes were prepared from the VPE material by diffusing zinc from a saturated source of ZnP_2 in a closed tube. Diffusions were done at 775°C for 3 hr, which yielded junction depths of about 5μ. The diffused material was scribed into chips 1.45×10^{-3} cm^2 in area, which were then bonded to gold headers with tin. Direct contact was made to the diffused p-side with a 1-mil gold wire. Mesa diodes were constructed by the method described by Logan *et al.* (2).

Measurements.—Electroluminescent spectra for the diodes were obtained using a Spex monochrometer with an RCA C31034 photomultiplier tube. The nitrogen concentration, N, of the epitaxial layers was determined by measuring the room temperature absorption coefficient at 5540Å (A line) and relating it to the nitrogen concentration with the expression $\alpha = \sigma N$ where σ, the absorption cross section, equals 5×10^{-17} cm^2 (2). The absorption cross section has been corrected in keeping with the work of Lightowlers *et al.* (6). The external quantum efficiencies of the solid-state lamps were determined using an integrating sphere. Minority carrier lifetime was measured using the diode reverse-recovery technique of Kingston (7). For the Zn-diffused p^+-n structure the lifetime measured by this method is essentially the minority carrier hole lifetime.

Results

It was found that the morphology, electroluminescent spectral characteristics, and minority carrier lifetime were affected by a number of growth parameters. These parameters included the partial pressures of the reactants, dopant concentrations, source and substrate temperatures, and substrate orientation.

Temperature effects.—The morphology of the epitaxial layers was extremely sensitive to the gallium source temperature. Figure 2 shows the morphology of the epitaxial layers grown at a gallium source temperature of 930°C. A stacking fault density of the order of $10^6/cm^2$ was observed at the surface of the as-grown layers. Upon lowering the source temperature 30°C the density of the stacking faults decreased to less than $10^3/cm^2$.

The electroluminescent spectra of diodes prepared from material grown at various source temperatures also differed as shown in Fig. 3. Spectrum 1 was observed for diodes fabricated from material grown at

Fig. 2. Morphology of GaP epitaxial layer grown at a gallium source temperature of 930°C.

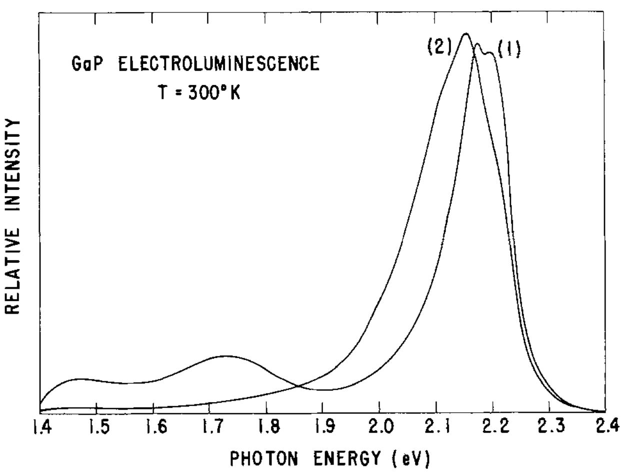

Fig. 3. Electroluminescent emission spectra at 300°K of GaP diodes prepared from material grown with a Ga source temperature of 930°C (spectrum 1) and a Ga source temperature of 900°C (spectrum 2).

a gallium source temperature of 930°C and a high stacking fault density. A relatively large red emission quantum efficiency of 4.4×10^{-5} resulting from zinc-oxygen pair recombination was noted for these diodes. However, for diodes fabricated from material prepared with a Ga source temperature of 900°C and low stacking fault densities (spectrum 2 in Fig. 3) a substantially reduced red emission efficiency of 1.6×10^{-5} was observed. This result suggests that oxygen may play a role in the formation of stacking faults in GaP vapor epitaxial material. The oxygen contamination probably results from the decomposition of the SiO_2 reaction chamber whose decomposition rate increases with increasing source temperature (8).

In addition to the source temperature, the GaP substrate temperature also affected epitaxial morphology. At a substrate temperature of 840°C and a $PH_3/GaCl$ ratio of 0.3 an essentially featureless morphology was observed for the epitaxial layers. But, as the substrate temperature decreased, hillocks began to form as shown in Fig. 4, with hillock concentrations as high as $50/cm^2$ having been observed. The hillocks in themselves are not deleterious to the luminescent efficiency of the material; but it was noted that the leakage current of diodes fabricated from material with a high hillock density is large.

Orientation and layer thickness effects.—Substrate orientation was found to be a critical parameter for achieving high nitrogen incorporation without degradation of epitaxial layer morphology. High nitrogen concentration could not be obtained for growth on the (111) orientation without severe hillock formation. However, when growth was performed upon crystals which were 10° off the (100) plane, high concentrations of nitrogen could be incorporated into the GaP without excessive morphological changes. In fact, nitrogen concentration as high as 4×10^{19} atoms/cm^3 could be obtained with this orientation.

In contrast to previous work (9), it was observed that the quantum efficiency of the grown material was relatively insensitive to the thickness of the layers. Layers as thin as 17μ have been prepared in this study with the resulting diodes having quantum efficiencies similar to those prepared from layers with a thickness of ten times that amount.

Reactant concentration.—It was observed that by changing the molar ratio of $PH_3/GaCl$ in the reactor ambient for a constant phosphine input, both the morphology and luminescent characteristics of the epitaxial layers could be altered. For $PH_3/GaCl$ ratios of 0.5 or less it was noted that when the $PH_3/GaCl$ ratio was decreased, the concentration of hillocks increased. This finding agrees with observations in other hydride growth systems, since similar increases in hillock density with increased III/V gaseous species ratio have been observed in the epitaxial growth of GaAs (10) and $GaAs_xP_{1-x}$ (11).

Table I. Effect of $PH_3/GaCl$ ambient ratio on nitrogen concentration epitaxial layer

Sample No.	PH_3:GaCl	N conc in layer	Emission peak, eV
1	1:1.3	8×10^{17} cm^{-3}	2.21
2	1:3.5	4.4×10^{18} cm^{-3}	2.16
3	1:7.1	1.1×10^{19} cm^{-3}	2.10

More significantly, it was found that by varying the $PH_3/GaCl$ for a constant ammonia input, the amount of nitrogen incorporated into the epitaxial layers could be varied. A low $PH_3/GaCl$ ratio gave layers with large nitrogen concentration, as reported in Table I. Consequently, the spectral characteristics of diodes prepared from grown material could be modified by changing the PH_3/HCl ratio. Figure 5 shows that the electroluminescent spectra of diodes shifted to longer wavelengths due to increased nitrogen content as the $PH_3/GaCl$ ratio was decreased.

The minority carrier lifetime, a quantity that is directly proportional to the quantum efficiency, was measured by the reverse-recovery technique on diodes prepared from n-type material grown at different $PH_3/GaCl$ ratios. As shown in Fig. 6, it was found that the reciprocal of the minority carrier lifetime τ was proportional to the $PH_3/GaCl$ ratio. Moreover, the diode current at a forward bias of 1.5V was investigated as a function of $PH_3/GaCl$ ratio at which the n-type material was grown, and was also found to be proportional to the $PH_3/GaCl$ ratio as shown in Fig. 6. To insure that the changes in the diode current resulted from bulk generation-recombination of carriers and not surface leakage, diodes of different areas were fabricated. It was observed that the current density was essentially independent of area, thus indicating a bulk recombination effect.

For forward biases up to 1.7V, the current-voltage characteristics of the diodes could be fitted with the expression for pure space-charge current, I_{sc}, given by (12)

$$I \simeq I_{sc} = \frac{\pi}{2} \frac{n_i kTW}{\tau_s(V_d - V)} \exp \frac{eV}{2kT} \qquad [1]$$

where n_i is the intrinsic carrier concentration, V_d the built-in potential, W the space charge width, and τ_s the effective carrier lifetime in the space charge region. For a constant dopant concentration, the only

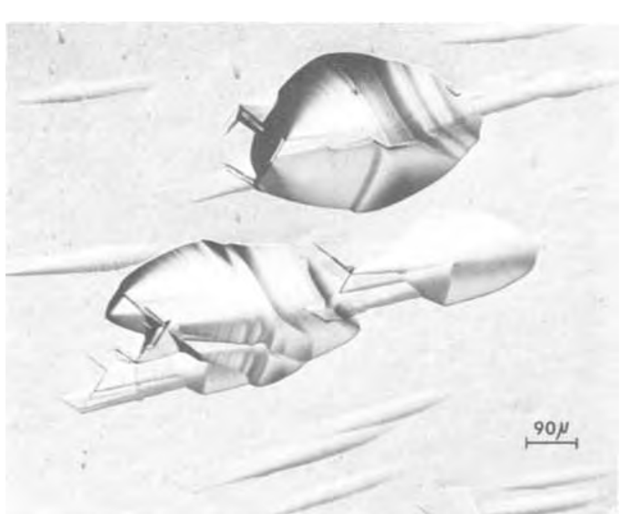

Fig. 4. Morphology of GaP epitaxial layer grown at a substrate temperature of 800°C.

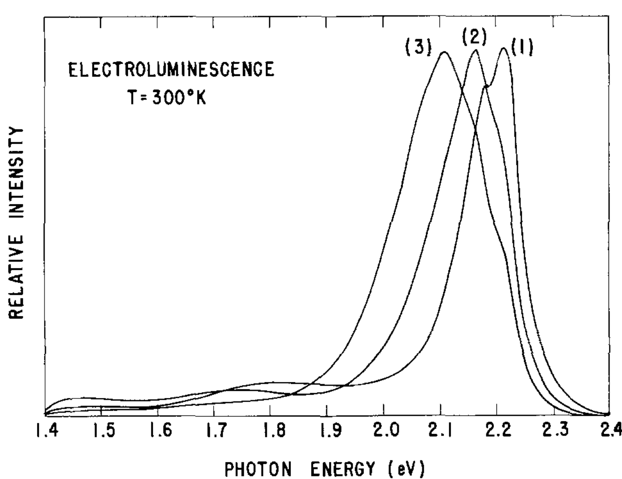

Fig. 5. Electroluminescent emission spectra at 300°K of GaP diodes prepared from material grown with different $PH_3/GaCl$ ratios in the ambient, but at a constant ammonia partial pressure. $PH_3/GaCl$ ratios are given in Table I.

parameter in Eq. [1] which is dependent on material preparation conditions is the lifetime. Thus the observed changes in the diode current with $PH_3/GaCl$ ambient ratio are also due to the dependence of lifetime on the growth ambient.

In support of the increase of the nonradiative lifetime with decreasing $PH_3/GaCl$ ratio, the reciprocal of the electroluminescent quantum efficiency was found to increase with increasing $PH_3/GaCl$ ratio as shown in Fig. 7. However, instead of a simple monotonic relationship between η^{-1} and the $PH_3/GaCl$ ratio, a superlinear dependence was observed. This superlinearity indicates that in addition to the decrease in minority carrier lifetime with increased $PH_3/GaCl$ there is also an increase in the radiative lifetime. The observed increase in radiative lifetime is consistent with the dependence of nitrogen recombination center concentration on $PH_3/GaCl$ ratio reported in Table I.

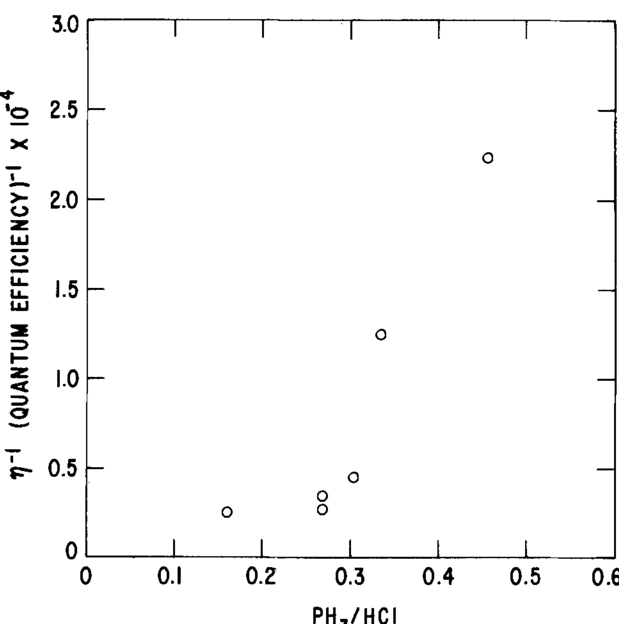

Fig. 7. The reciprocal of electroluminescent quantum efficiency as a function of $PH_3/GaCl$ ratio at which the n-type epitaxial material was grown. The quantum efficiency was measured at 13 A/cm^2.

Electronic properties.—With the VPE technique, net donor concentrations, N_D-N_A, of $2 \times 10^{15}/cm^3$ have been obtained for unintentionally doped epitaxial material. Minority carrier hole lifetimes of 70 nsec have been observed in heavily nitrogen-doped material with a net donor concentration of $3 \times 10^{16}/cm^3$. Quantum efficiencies for encapsulated mesa yellow light emitting diodes with a characteristic spectrum of Fig. 8 are 0.15% at 20 A/cm^2. With pulsed operation, efficiencies of 0.24% have been obtained at 100 A/cm^2 in the better diodes, as shown in Fig. 9.

Discussion

For a single dominant recombination center, the reciprocal of the low-level recombination lifetime is given by (13)

$$\tau^{-1} = CN_{nr} \quad [2]$$

where N_{nr} is the number of recombination centers and C the capture constant. Thus the increase in the reciprocal of the minority carrier lifetime and the space charge current with $PH_3/GaCl$ ratio or P/Ga ratio results from an increase in the generation-recombination center density. The identity of these predominantly nonradiative centers N_{nr} is not known; however, there are several possible candidates.

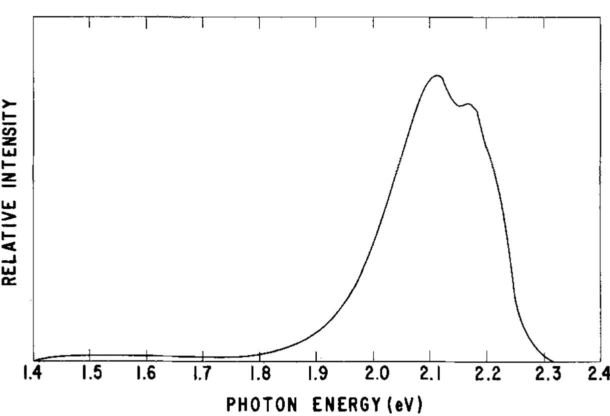

Fig. 8. Electroluminescent spectra at 300°K of a yellow solid-state lamp prepared from VPE material. Current density was 6.9 A/cm^2.

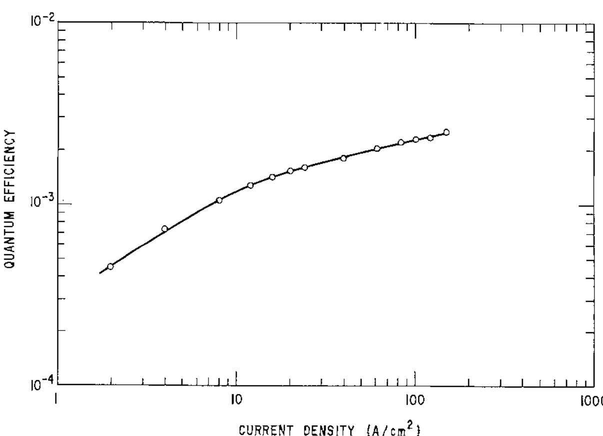

Fig. 9. EL quantum efficiency as a function of current density for a yellow encapsulated solid-state lamp, with a mesa structure.

One type of recombination center previously found to be important in liquid-encapsulated Czochralski GaP (14) and LPE GaP (15) is the gallium vacancy. The concentration of gallium monovacancies is directly proportional to the P/Ga growth ambient ratio, which is the same concentration dependence noted for the unknown recombination center observed in this study. This concentration dependence, however, does not uniquely define the center involved, inasmuch as other centers associated with the gallium vacancy, such as gallium vacancy complexes or substitutional impurities on Ga sites, are also consistent with the observed lifetime-ambient behavior.

Two other possible recombination centers in VPE GaP are Si and Si-O complexes, since both of these species are inadvertently present in the ambient as a result of decomposition of the quartz reactor. Furthermore, both have been cited as effective recombination centers in LPE GaP (16, 17). Evidence in support of Si being important in VPE material is given by the findings of Okamoto *et al.* (18) on the Ga-As-HCl-H_2 system for the growth of GaAs, where they observed that by increasing the As/Ga ratio, the unintentional silicon donor concentration increases in the epitaxial layer.

To further support silicon or silicon complexes acting as the primary (nonradiative) recombination center in GaP, the work of Smith and Abbott (16) on minority carrier lifetimes in LPE GaP can be cited. In their studies, Smith and Abbott noted that the lifetimes decreased for increasing Si dopant concentration (16). They attributed this decrease in lifetime to the acceptor Si (silicon on the phosphorus site) acting as a recombination center. Their conclusion, however, is inconsistent with that of Bachrach *et al.* (17) who found, on studies of deliberately silicon-doped GaP LPE layers, that even at relatively high concentration ($10^{18}/cm^3$) of silicon in the layers, minority carrier lifetimes of 200 nsec could be obtained. Bachrach *et al.* observed that only when GaP layers were simultaneously doped with silicon and oxygen were marked decreases in the lifetimes noted. Consequently, they attributed the decreased lifetime to Si-O complexes.

The present study also suggests that silicon as an acceptor is not the major generation-recombination center insofar as it was observed that the number of centers increased with increasing P/Ga ratio in the ambient. On the other hand, the concentration of silicon acceptors should decrease with increasing P/Ga ratio, as a result of the incorporation of silicon acceptors being dependent on the concentration of phosphorus vacancies. Therefore, a center involving Si on a gallium site such as the Si donor-O complex rather than a silicon acceptor is more likely to be a major recombination center in VPE material.

In view of the experimental evidence, it is not yet possible to resolve which specific impurity is the primary generation-recombination center responsible for decreased lifetime and increased space charge current in diodes fabricated from VPE material grown at high P/Ga ratios. However, it can be concluded from this study that the recombination center involves the Ga site.

Summary

1. A high gallium source temperature resulted in epitaxial GaP with a high stacking fault density and an increased red emission in the electroluminescent spectra.

2. Decreasing the P/Ga ratio in the ambient or decreasing the substrate temperature resulted in epitaxial layers with large hillock densities.

3. By varying the P/Ga ratio in the ambient the amount of nitrogen incorporated in the epitaxial layers could be controlled. It was found that the lower the P/Ga ratio the greater the nitrogen concentration.

4. Relatively long minority carrier lifetimes of 70 nsec and decreased space charge current could be obtained by fabricating diodes from epitaxial material grown at low P/Ga ratios in the ambient. The decrease in the space charge current and the increase in the lifetimes are probably associated with a decrease in the number of Si-O complexes or gallium vacancy complexes incorporated into the layers.

Very High Efficiency GaP Green Light Emitting Diodes

O. G. Lorimor, P. D. Dapkus, and W. H. Hackett, Jr.

Bell Laboratories, Murray Hill, New Jersey 07974

ABSTRACT

GaP green light emitting p-n junction material with an average quantum efficiency for uncontacted diced diodes in air at 7 A/cm^2 of 0.101% has been reproducibly grown in a vertical dipping system using a modified overcompensation process. This value corresponds to an average efficiency of 0.16% for epoxy encapsulated mesa diodes, which is 60% higher than previously obtained. Mesa diode efficiencies as high as 0.230% at 5 A/cm^2 and 0.67% at $\sim$300 A/cm^2 were obtained. The low current value is the highest reported to date while the high current value is equal to the highest previously reported. These efficiencies were obtained through the introduction of several modifications in the previous overcompensation growth procedure. It was determined that a large cooling interval, from 900° to 700°C, with a corresponding decrease in the temperature at which the p-n junction is formed (850°C) was the most important modification that resulted in the efficiency improvement. Minority carrier lifetime measurements revealed spatial variations of the lifetimes in both n- and p-layers. The lifetimes increased with decreasing growth temperature, indicating that LPE growth temperatures as low as possible should be used. Typical values were $\tau_h = 200$ nsec and $\tau_e = 100$ nsec at the junction. An analysis of the exit gas from the LPE growth system lets one estimate that as much as $\sim$5 ppm O_2 could typically be present in the LPE growth system. Deliberate additions of small oxygen concentrations >10 ppm to the inlet gas produced a pronounced reduction in the quantum efficiency and minority carrier lifetimes while oxygen additions $\lesssim$ 10 ppm had no effect on the efficiency or lifetimes.

A considerable effort has been devoted over the past three years to improving the quantum efficiency of GaP green light emitting diodes (LED's) and to understand the operation of the device (1, 2). As a result of this work p-n junction material has been reproducibly grown with electroluminescent (EL) quantum efficiencies of encapsulated mesa diodes averaging 0.1% at 5 A/cm^2 (1). This material has been extensively characterized with respect to doping levels, N concentrations, minority carrier lifetimes (τ_e, τ_h), diffusion lengths (L_e, L_h), and bulk luminescent efficiency. For example, in 0.1% p-n junction material typical values of τ_e and τ_h are 40 and 100 nsec, respectively, with corresponding bulk efficiencies of 0.3 and 0.06% (2). These lifetimes and efficiencies are limited by nonradiative recombination which competes in parallel with bound exciton recombination on the N site.

In order to achieve these efficiencies and lifetimes in our vertical "dipping" liquid phase epitaxial (LPE) growth system (3), it was essential to eliminate oxygen from the system (4). The inlet gas lines were carefully constructed to be as leak free as possible. Because of this leak-free gas system, the efficiencies were independent of whether or not a sodium trap (4) (oxygen getter) was used. The growth system itself was designed to contain no "dead" air spaces which could act as virtual leaks. To minimize oxygen contamination resulting from loading, the growth system was flushed overnight with H_2 after loading and prior to growth.

The overcompensation procedure used to obtain these efficiencies (1) was one where both the n- and p-layers were grown in a single run. A Te,N doped n-layer was first grown by cooling the melt from 900° to 880° or 870°C. After n-growth, without removing the seed from the melt, Zn was added to the melt to overcompensate the Te. The Zn,N layer was then grown by further cooling to 830° or 820°C.

Recently with the dipping system some very long minority carrier lifetimes have been obtained; values of τ_h ranged from 300-800 nsec for net donor concentrations from 1-3 $\times$ 10^{17} cm^{-3}. By varying the growth procedure (5), lifetimes up to 1000 nsec were obtained in undoped, but n-type layers. The cause for these longer lifetimes was unknown but it was speculated that they were due, at least partly, to a general improvement in the growth technique which presumably resulted in a lowering of the O_2 contamination. The relative contribution of each of the variations in the growth procedure (5) was also unknown. The work described herein was initiated with two objectives; to determine, if possible, the origin of the longer lifetimes and to grow p-n junction material incorporating these lifetimes which should be reflected in higher EL efficiencies.

Key words: GaP, LED, GaP-oxygen.

Experimental

The LPE layers were grown in an open flow dipping system which has been in continual use in the GaP green LED optimization program (1-3). The new growth cycle (5), hereafter termed "modified," adopted for this work incorporates a number of procedural changes from the "overcompensation" procedure (1) used previously. Table I enumerates the differences in these two growth procedures. In the present work, the Ga+P melt is placed in a Si_3N_4 coated quartz crucible which in turn is located at the bottom of a freshly cleaned furnace tube. Both the seed and source holders were graphite with the seed holder tube being hollow as previously described. The Si_3N_4 coating of the quartz crucible was used to eliminate oxygen contamination resulting from the reduction of the quartz by the Ga. The graphite holders were to accelerate the loss of oxygen from the melt through the formation of CO. The first grown layer, which is a low doped n-layer, is grown by cooling a melt intentionally doped only with N from 900° to 850°C at a rate of 30°C/hr. Upon reaching 850°C, 0.14 atom per cent (a/o) Zn is dropped into the melt through the hollow seed holder tube while the furnace is held at constant temperature for ½ hr to uniformly distribute the Zn in the melt. The p-layer is then grown by cooling from 850° to

Table I. Comparison of the "overcompensation" growth procedure with the "modified" procedure adopted for this work. Growth parameters other than these remained unchanged

Growth parameter	Overcompensation	Modified
Crucible material	Quartz	Si_3N_4 coated quartz
Seed and source holders	Quartz	Graphite
Cooling interval: n-layer	900° → 880° or 870°C	900° → 850°C
p-layer	880° or 870° → 830° or 820°C	850° → 700°C
Overnight anneal	None	700°C
n-Layer: dopants	Te,N	—,N
N_d-N_a	1-2 × 10^{17} cm^{-3}	$\lesssim$ 1 × 10^{17} cm^{-3}
p-Layer: dopants	Zn,N	Zn,N
N_a-N_d	5-10 × 10^{17} cm^{-3}	5-10 × 10^{17} cm^{-3}

700°C at 30°C/hr. During the p-growth (at ~775°C) Zn is again dropped into the melt, this time with no interruption in the cooling. This second Zn addition is to insure that the net acceptor concentration at the surface is high enough for good elecrical contacts.[1] Upon reaching 700°C the LPE layers were annealed in the Ga+P melt for ~14 hr (overnight). During the entire growth cycle, with the exception of the anneal, the seed was continually being stirred while in the melt to promote more uniform growth. The ambient gas consists of H_2 plus 1.5 × 10^{-3} atm of NH_3 which is unchanged from that used previously. This ammonia addition to the gas stream results in a N concentration in the GaP of 2 × 10^{18} cm^{-3} as measured by optical absorption (1, 4, 8). Since the n-layer is not deliberately doped, the resulting net donor concentration varied considerably, viz., $\simeq 5 \times 10^{15} \lesssim (N_d\text{-}N_a) \lesssim 1 \times 10^{17}$ cm^{-3}. In the p-layer, N_a-N_d varied from 5 × 10^{17} to 1 × 10^{18} cm^{-3} at the p-n junction.

In order to evaluate the relative importance of these changes in the growth cycle from the previous "overcompensation" procedure (1), the changes were sequentially eliminated. These include either a quartz or graphite crucible instead of the Si_3N_4 coated quartz crucible, quartz seed and source holders instead of graphite, variations in the cooling intervals, and the elimination of the anneal. Interspersed with these runs were runs using the complete "modified" procedure to insure the constancy of the system. The effect of each of these changes on the electroluminescent efficiency and minority carrier lifetime was assessed. From these experiments the relative importance of each change was determined.

Most of the quantum efficiency measurements were made on uncontacted diced diodes (9) in air at ~7 A/cm^2. Experience has shown that efficiencies measured in this manner are ~60% of epoxy encapsulated mesa diodes operated at the same current density (9). Equivalent mesa diode efficiencies can be calculated by multiplying the uncontacted diced diode efficiencies by ~1.6. Epoxy encapsulated mesa diodes (10) were fabricated only in the cases of a particularly high uncontacted die efficiency or when measurements at current densities larger than 7 A/cm^2 were desired.

All efficiencies were measured on a pulsed basis in a close coupled cavity. At current densities $\lesssim$ 30 A/cm^2, 15 μsec pulses were used; at current densities $\gtrsim$ 30 A/cm^2, 1 μsec pulses. The narrower pulses were used at the higher current densities to avoid heating during the pulse. Pulses narrower than 1 μsec were not used so as to keep the pulse width much larger than the characteristic response time of the diode (~ largest minority carrier lifetime), thus insuring that a quasi-steady-state distribution of carriers would be obtained during the pulse.

The net donor or acceptor concentrations, $|N_d\text{-}N_a|$, were determined from capacitance measurements of Schottky barrier diodes on an angle-lapped surface (11). The minority carrier lifetimes were determined from a measurement of the green photoluminescent decay time using the 4880Å line from an argon ion laser for excitation (12). The laser power was adjusted so that the generated minority carrier density was comparable to that produced by a diffusion current of ~1-10 A/cm^2 through a p-n junction. The minority carrier lifetime measurements as a function of depth were made on the same angle-lapped sample that was used for the $|N_d\text{-}N_a|$ measurements.

The diffusion length measurements were performed in a Cambridge "Stereoscan" scanning electron microscope. The measurements are made by scanning a focused electron beam across a polished surface perpendicular to the junction on a 15 × 15 mil die. The diffusion lengths are determined from the functional dependence of the induced junction current with scan distance across the junction (13). The electron beam excitation levels were also adjusted to provide carrier densities equivalent to diffusion current densities of ~1-10 A/cm^2 through a p-n junction.

A Varian Model 1532b gas chromatograph was used to analyze the entrance and exit gases of the LPE growth systems during the course of this study. Two molecular sieve 5A columns, one 20 ft × ⅛ in. operating at 50°C and the other 3 ft × ⅛ in. at ~90°C were used. With these two columns the concentrations of the commonly observed unintentionally present gases O_2, N_2, CH_4, and CO could be simultaneously and quantitatively measured at sub-ppm levels in 1 atm of H_2. The chromatograph was quantitatively calibrated for CO, O_2, CH_4 and N_2 by the use of an exponential dilution flask (14). A known volume of sample gas is injected into the flask, also of known volume V, resulting in an initial concentration, C_o. After injection, the concentration of sample gas in the flask decays as $C_o \exp(Ft/V)$ where F is the flow rate through the flask of a carrier gas. Periodically sampling the effluent gas with the chromatograph gives the quantitative calibration. For the four previously mentioned gases, concentrations less than 1 ppm could easily be measured under the experimental conditions used in this study. Additional work on the application of chromatography to the analysis of LPE systems is given elsewhere (15).

Results

The quantum efficiencies of the devices which were fabricated from this material are presented first followed by a more detailed characterization yielding the minority carrier lifetimes and diffusion lengths. These parameters were studied as a function of the growth procedure to determine the critical growth parameters. Finally, in an effort to determine the effects on the efficiency of small amounts of O_2 in the gas stream the results of a gas analysis study of oxygen contamination are presented.

Quantum efficiency.—Twenty-one p-n junctions were grown over a 5 month period using the modified overcompensation procedure described earlier. Figure 1 compares the efficiencies of these junctions to those grown by the former overcompensation process (1). Each data point in Fig. 1 is the average efficiency of

[1] Zn loss in the open flow dipping system and the relative behavior of n- and p-type distribution coefficients (6, 7) has always resulted in a decrease in the net acceptor concentration from the p-n junction toward the surface. This decrease in N_a-N_d is a large effect in the layers grown over the wide temperature interval used in this work.

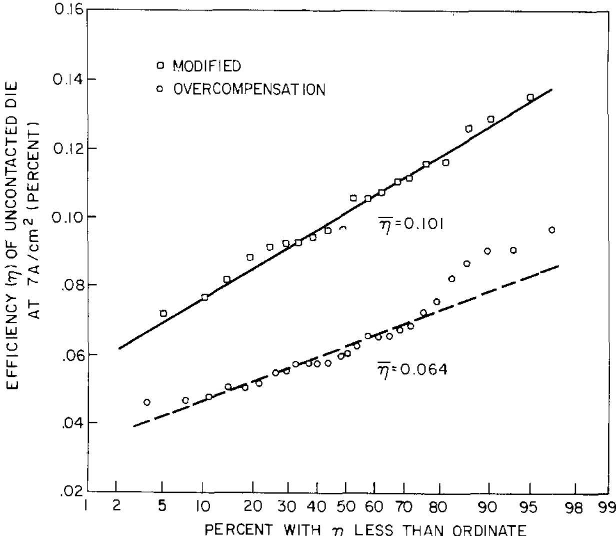

Fig. 1. Comparison of electroluminescent quantum efficiencies of uncontacted die in air at 7 A/cm^2 for the former overcompensation procedure and the present modified overcompensation procedure. Each data point is the average of ~6 diodes. The equivalent epoxy encapsulated mesa diode efficiency is higher by ~60%.

~6 uncontacted diced diodes fabricated from a single p-n junction sample. Prior to this work, the overcompensation process most reproducibly yielded the highest efficiencies we were able to obtain. The average efficiency of the overcompensated junctions is 0.064% while that of the modified process is 0.101%. This is a ~60% increase in average efficiency. Consequently, the modified procedure has resulted in a significant efficiency improvement.

Mesa diodes were fabricated from a number of the more efficient crystals and their efficiencies measured at higher currents. Figure 2 shows the efficiency for three of these epoxy encapsulated mesa diodes as a function of current. A value of 0.67% at ~300 A/cm was observed for 1-623 which is the highest value we achieved. This efficiency is essentially equal to the highest value (0.7%) reported to date by Ladany and Kressel (16). The doping density in the n-layer of diode 1-623 is ~6 $\times$ 10^{15} cm^{-3} while that in 2-576 is 9 $\times$ 10^{16} cm^{-3}. For comparable diffusion lengths, conductivity modulation of the lower doped n-layer in diode 1-623 is expected to result in an enhanced current dependence of the efficiency (17).

For most device applications the low current efficiency is a much more relevant parameter than the high current values. Figure 2 also shows the current dependence of the diode 1-628 with the highest efficiency measured at ~5 A/cm^2 which was 0.230%. This is the highest efficiency at this low current density reported to date. The average extrapolated mesa diode efficiency of the junctions grown by the modified overcompensation process is ~0.16% at 5 A/cm^2.

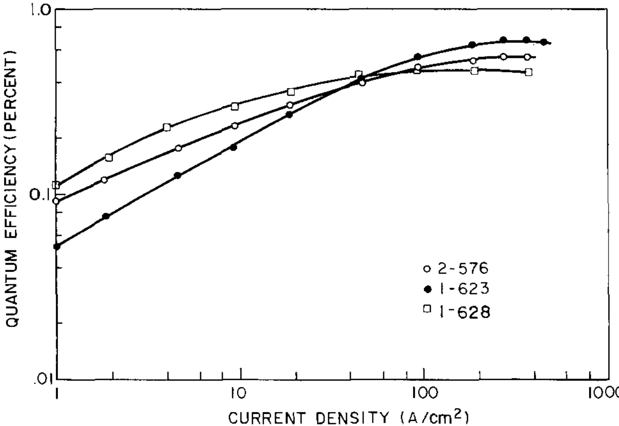

Fig. 2. Quantum efficiency as a function of current density for three high efficiency epoxy encapsulated mesa diodes.

The modified overcompensation process used to achieve these results utilizes several changes in the growth procedure from the former overcompensation process. However, since these changes were simultaneously incorporated into the growth procedure, the relative importance of each was unknown. Consequently, a series of crystal growth runs were made where these changes were systematically eliminated in order to study their relative importance.

Table II presents a summary of the efficiencies of uncontacted diodes for the combinations of quartz, graphite, and Si_3N_4 coated quartz which were used. None of the other growth parameters, *e.g.*, doping levels, the cooling interval, and the annealing cycle were changed. The efficiencies of the material grown with these combinations of materials are judged to be essentially the same. Thus, the high efficiencies do not appear to be unique to only Si_3N_4 coated quartz plus graphite in contact with the melt, but can be achieved in an all quartz or graphite LPE system.

Several growth runs were made using narrow cooling intervals as previously reported (1) or eliminating the annealing cycle, but using the Si_3N_4 coated quartz crucibles and graphite seed holder. Table III compares the quantum efficiencies of these p-n junctions with those grown by the modified process. From this data we conclude that the anneal did not appear to cause the increase in efficiency but increasing the cooling interval did. Consequently, we conclude that the primary new factor in the present growth cycle resulting in the higher efficiencies is the longer cooling intervals and the associated lower growth temperature of the p-n junction.

In the early part of this work the LEC substrate doping levels varied from 1.6-7 $\times$ 10^{17} cm^{-3}. An interesting correlation was noted between the quantum efficiency and doping density of the substrate for the modified overcompensation growths. This correlation is depicted in Fig. 3. The quantum efficiency shows a general decrease from ~0.1 to ~0.04% as the LEC doping level increases from 2 to 7 $\times$ 10^{17} cm^{-3}. When this correlation was observed, the use of LEC wafers with N_d-N_a > 3 $\times$ 10^{17} cm^{-3} was discontinued. Thus there are less data at these higher LEC doping levels. One should note that this effect was observed only for p-n junctions grown in one particular manner in our dipping system and on slices from a single ingot,

Table II. Quantum efficiencies of uncontacted diced diodes for p-n junctions grown with differing materials in contact with the melt while holding the growth cycle optimum

Crucible material	Seed holder material	Number of growth/ runs	Avg η	Max η
Si_3N_4 coated quartz (modified procedure)	Graphite	21	0.101 ± 0.018	0.136
Si_3N_4 coated quartz	Quartz	6	0.082 ± 0.034	0.147
Quartz	Quartz	2	0.100 ± 0.023	0.124
Graphite	Graphite	7	0.088 ± 0.033	0.129

Table III. Quantum efficiencies of uncontacted diced diodes for material grown by various growth cycles using Si_3N_4 coated crucibles and a graphite seed holder

	Cooling interval (°C) n-layer	Cooling interval (°C) p-layer	Number of growth/ runs	Avg η	Max η
Modified	50°	150°	21	0.101 ± 0.018	0.136
Narrow cooling intervals	30°	50°	3	0.078 ± 0.007	0.087
Modified without anneal	50°	150°	2	0.109 ± 0.007	0.116

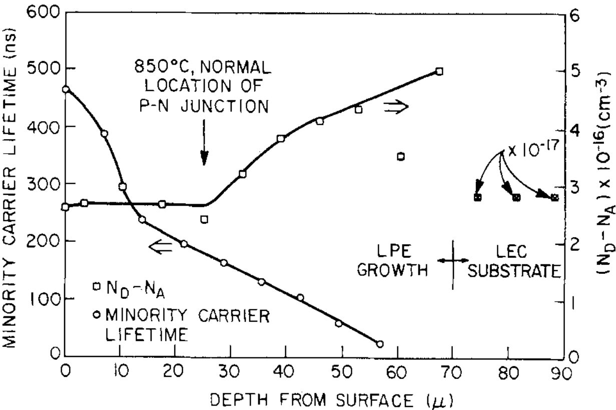

Fig. 4. Minority carrier lifetime and net donor concentration as a function of depth in a layer intentionally doped only with N.

6Rd98. The generality of this effect in other growth systems and for other ingots is not known. However, a survey of p-n junctions previously grown in the Murray Hill crystal growth models laboratory uncovered a similar but less pronounced effect (18).

In an effort to determine the cause for the low efficiencies at higher LEC doping densities, optical absorption measurements were made on the LEC slices. An enhanced absorption of $\alpha \sim 10$ cm^{-1}, was found at the energy of the green emission in the higher doped slices. However, the work of Joyce *et al.* (19, 20) indicates that this additional absorption alone can account for only part of the observed efficiency decrease. The minority carrier lifetimes in the LPE layers were generally found to be independent of substrate doping density.[2]

Minority carrier lifetimes and diffusion lengths.—A number of these high efficiency p-n junctions were characterized by a measurement of the minority carrier lifetimes and diffusion length. Table IV shows a summary of these parameters for four of these samples which ranged in efficiency from 0.136 to 0.077%. Typically the minority carrier lifetimes (τ_h) and diffusion lengths (L_h) in the n-layer near the junction range from 200-250 nsec and 6.5-8μ, respectively. These values are significantly larger than $\tau_h \approx 100$ nsec and L_h which was typically found previously at the lowest doping levels used in the overcompensated junctions (1). Likewise in the p-layer $\tau_e = 120$-180 nsec at the p-n junction with $L_e = 5$-6μ. Previously these parameters were ~ 40 nsec and 3.5-4μ, respectively, at comparable doping densities (1, 2). Thus the present material has significantly longer lifetimes and diffusion lengths than the former material which are reflected by higher bulk efficiencies. The present increase in electroluminescent efficiency is a direct result of these longer lifetimes.

The lifetime measurements also revealed significant variations of τ with depth in the LPE layers. Figure 4 shows the spatial dependence of the minority carrier lifetime and the net donor concentration for an n-layer grown over the temperature interval 900°-700°C. This layer was grown with exactly the same growth procedure as that used for the modified p-n junctions except that no Zn was added to the melt. However, the interruption of the cooling at 850°C provided a doping discontinuity that was revealed by photoetching. Consequently, the location where the p-n junction would have been if Zn had been added was identifiable. In the first grown part of the layer near the n-LPE: n-LEC interface, the lifetime is quite short, $\lesssim 100$ nsec. (Measurements of the minority carrier lifetime cannot be made closer than 3 diffusion lengths from a junction due to "surface" recombination losses at a p-n junction or a LPE-LEC interface.) At the normal location of the p-n junctions the lifetime has increased to ($\sim$150-200 nsec) which is close to that typically measured on the n-side of a junction. However the lifetime increases rapidly from the 850°C location toward the surface (700°C) reaching a value of $\sim$450 nsec at the surface. A similar spatial dependence of the lifetime was observed in all of the n-layers which were examined. Corresponding measurements in p-type material were more difficult as the layers were generally thinner ($\sim$30-40μ). However several thick layers were examined and they also showed an increase in lifetime from the initial growth region (850°C) toward the surface of the layer (700°C). The lifetimes were typically $\sim$100 nsec near the junction and 200-250 nsec at the surface. The increase in lifetime with decreasing temperature most likely results from a general reduction in impurity incorporation or a decrease in the native defect, *e.g.*, gallium vacancy (23), concentration.

In the former overcompensation process the p-n junction was formed at temperatures varying from 880° to 870° instead of the present 850°C. From Fig. 4,

[2] In an LEC ingot, the dislocation density often exceeds 1×10^5 cm^{-2} and increases from seed-to-tail which is the same direction as N_d-N_a increases (21). Recently it has been shown that the efficiency becomes markedly reduced as the dislocation density becomes $> 2 \times 10^5$ cm^{-2} (22). Consequently we may speculate that this efficiency decrease is due to the effects of increasing dislocation density.

Table IV. Representative minority carrier lifetimes and diffusion lengths

Sample	η(%)	N_d-N_a (cm^{-3})	N_a-N_d (cm^{-3})	L_e(μ)	L_h(μ)	τ_e(nsec)	τ_h(nsec)
1-594	0.136	6.0×10^{16}	4.2×10^{17}	5.9	6.8	125	250
1-603	0.097	1.7×10^{16}	6.0×10^{17}	5.3	7.9	—	210
1-617	0.129	7.6×10^{16}	1.1×10^{18}	4.8	6.8	185	200
1-600	0.077	3.3×10^{16}	5.3×10^{17}	5.5	6.6	85	110

it can be deduced that this 20°-30°C temperature difference can result in lifetimes larger by as much as a factor of 2 for the 850°C junction. Consequently, it appears that the lower p-n junction formation temperature presently used is an important factor in the longer, near junction lifetimes measured in the n-layers. Likewise we feel that the longer lifetime in the p-layer is also largely due to the lower growth temperature used for p-growth.

Gas analysis.—A gas chromatograph has been used to monitor the impurity gases found in both the entrance and exit gases of the LPE growth system. The entrance gas, $H_2 + NH_3$, was found to contain less than 1 ppm O_2. However, our gas chromatograph is unable to measure small concentrations of H_2O vapor. A direct measurement for H_2O using other instruments was not attempted due to many experimental difficulties at low concentrations (24). Thus any oxygen present as H_2O in either the entrance or exit gases is not detected.

Oxygen present in the LPE system during growth would be converted to H_2O by reacting with the ~1 atm of H_2 in the hot growth system

$$2H_2 + O_2 \rightarrow 2H_2O \quad [1]$$

making a measurement of O_2 in the exit gas meaningless. However, the possibility of internally liberated oxygen from high temperature reactions such as

$$Ga_2O_3 \rightarrow Ga_2O + O_2 \quad [2]$$

$$4Ga + SiO_2 \rightarrow 2Ga_2O + Si \quad [3]$$

$$4NH_3 + 3SiO_2 \rightarrow Si_3N_4 + 6H_2O \quad [4]$$

$$SiO_2 + H_2 \rightarrow SiO + H_2O \quad [5]$$

makes it desirable to obtain a measure of the oxygen in the exit gas during growth and not before or after growth with the system cold. Consequently, it was decided to make use of the reaction

$$H_2O + C \rightarrow H_2 + CO \quad [6]$$

and deduce the oxygen concentration from a measurement of the CO concentration. Thus a measure of the oxygen both from internally generated sources and $O_2 + H_2O$ in the entrance gases would be obtained. The graphite seed holder, which is dipped into the melt, was used as the source of C in reaction [6].

Using the free energies from the JANAF thermochemical tables (25), the ratio of equilibrium CO to H_2O partial pressures in 1 atm of H_2 is 37 at 925°C and 11 at 825°C. Thus, for temperatures $\gtrsim$ 800°C most of the H_2O which is present would be converted to CO at equilibrium. However, because of the relative small amount of graphite (only the seed or source holder) which is present in the hot zone of the LPE growth system, it may be expected that much less than the equilibrium concentration of $O_2(H_2O)$ would be converted to CO, which in fact, is the case. When a much larger amount of graphite and lower flow rates were used, more, but still only a small fraction, of the $O_2(H_2O)$ was converted to CO. It appears that a much larger surface area of the graphite and perhaps improved gas flow patterns in the system would be required to approach equilibrium. Consequently, a measurement of the CO concentration in the exit gas provides a relative measure of the oxygen contamination only as long as the other experimental conditions are unchanged.

Figure 5 shows the concentration of CO in the exit gas as a function of time for growth run 2-579 which was a "modified" growth. Also indicated on the figure is the approximate melt temperature during the run. Data taken on several other modified LPE runs showed CO concentrations at corresponding times that were the same within a factor of 2. Thus, it is felt that these CO concentration data are representative for a typical LPE growth run in this system.

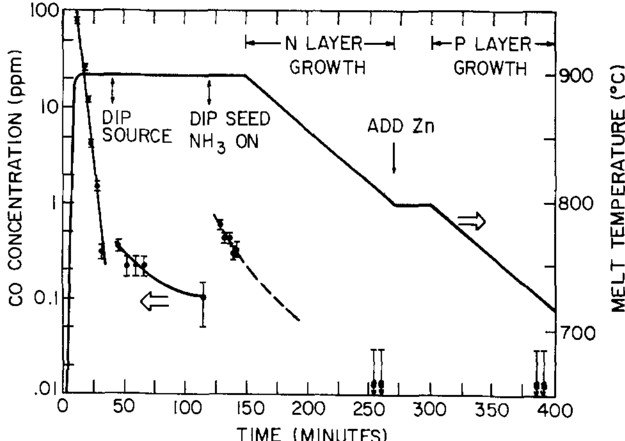

Fig. 5. Carbon monoxide concentration in the exit gas from the LPE growth system and the melt temperature as a function of time for a typical LPE growth run.

Immediately after heating the melt to the initial growth temperature, the CO concentration is quite high, over 100 ppm, and falls to less than 1 ppm in approximately a half hour. This large initial concentration of CO is attributed to outgassing of the melt and adsorbed O_2 or H_2O on the LPE system baking out and being partially converted to CO. A smaller increase in CO appears when the seed is lowered into the hot zone of the growth system and dipped into the melt. However, by the time LPE growth is initiated the CO concentration has dropped to ~0.2 to 0.3 ppm. As is discussed later, this CO concentration could represent up to several ppm of oxygen present in the LPE growth system during growth. The CO concentration decreases still further to a level below the limit of detectability (0.03 ppm) during growth. This continual decrease during growth is observed even when a constant oxygen concentration is added to the inlet gas. Thus this continual CO decrease during growth is attributed to a decreasing percentage of the oxygen being converted to CO as the temperature is lowered and not to a decreasing oxygen concentration in the LPE system.

Several standard LPE runs were made with small deliberate oxygen additions to the inlet gas stream while keeping all other experimental conditions the same. Figure 6 shows the resultant electroluminescent efficiencies and CO concentrations in the exit gas as a function of the oxygen addition to the inlet $H_2 + NH_3$ gas. The two data points at zero oxygen addition are the first and fifth (last) crystal growth runs in this series. The minority carrier lifetimes of the junctions grown with no and ~10 ppm O_2 additions were typical

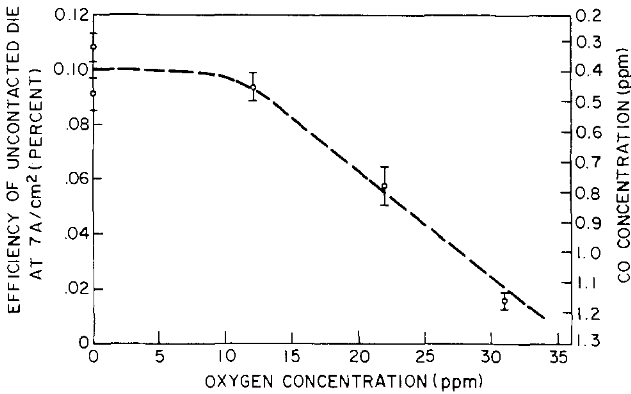

Fig. 6. Average efficiency of uncontacted die in air at 7 A/cm² and carbon monoxide concentration in the exit gas from the LPE system as a function of the oxygen concentration added to the inlet gas.

of those found in high efficiency diodes. The lifetimes in the junctions grown with > 10 ppm O_2 additions are significantly lower. The efficiency is essentially unaffected for oxygen additions $\lesssim$ 10 ppm. This behavior implies that an effective oxygen level up to ~10 ppm exists at all times in the growth system or that another nonradiative center is present in the GaP at levels such that a reduction in the oxygen below ~10 ppm is ineffective in increasing the efficiency. The CO concentrations shown in Fig. 6 are those measured during the early part of n-layer growth where the CO concentration should be most representative of the oxygen addition. The low CO concentrations compared to that expected from the oxygen additions are attributed to a large departure from thermodynamic equilibrium. For none and 12 ppm oxygen additions, 0.4 ppm of CO was observed in the exit gas which is within a factor of two of the data shown in Fig. 5. This implies that several ppm of O_2 may be present during a modified growth run. At higher concentrations of oxygen the CO concentration increases as expected.

These estimated levels are significantly larger than the O_2 concentration (< 1 ppm) measured in the $H_2 + NH_3$ entrance gas. Thus it appears that efforts to further improve the efficiency through reductions in the oxygen contamination will involve the elimination of small (a few ppm at the most) oxygen concentrations.

Conclusions

GaP green light emitting p-n junction material with quantum efficiencies for uncontacted diced diodes in air at 7 A/cm^2 of 0.101% has been reproducibly grown in a vertical dipping system using a modified overcompensation procedure. This represents a 60% efficiency increase from that previously obtained by overcompensation. Although the present results were obtained through the introduction of several modifications in the growth procedure, it was determined that a large cooling interval, 900°-700°C, with a corresponding decrease in the temperature at which the p-n junction was formed, was the single, most important modification. Epoxy encapsulated mesa diodes fabricated from some of the better p-n junction material had quantum efficiencies as high as 0.230% at ~5 A/cm^2 and 0.67% at ~300 A/cm^2. This low current efficiency is the highest observed to date while the high current value essentially equals the highest that has been previously measured by Ladany and Kressel (16).

A correlation between the EL quantum efficiency and the LEC doping density for p-n junctions grown on LEC ingot 6Rd98 was observed. The efficiency of uncontacted die decreased from ~0.1 to ~0.04% as the substrate doping level increased from 2 to 7 $\times$ 10^{17} cm^{-3}. This decrease is likely due to the increased dislocation density in the LEC crystals which has been observed to accompany the increase in N_d-N_a within an ingot.

Minority carrier lifetime measurements as a function of depth revealed significant variations throughout the layers. The lifetime of the n-layers was typically ~200 nsec at the p-n junction and decreased toward the n-LPE-n-LEC junction. N-layers grown down in temperature to 700°C typically had lifetimes on the surface of 400-500 nsec. P-layers showed a similar lifetime variation of from ~200 nsec on the surface which decreased to ~100 nsec near the p-n junction. This general behavior of increasing lifetime with lower temperature of LPE growth suggests that one should form the p-n junction at a temperature even lower than the 850°C used in this study. Still longer near junction lifetimes which should be found would be reflected in a higher electroluminescent efficiency. However, the low solubilty of P below 850°C makes LPE growth much below this temperature difficult.

An analysis of the exit gas from the LPE growth system showed that as much as ~5 ppm O_2 levels could be present in the LPE growth system during growth. Deliberate additions of small oxygen concentrations to the inlet gas showed no change in efficiency or lifetimes for O_2 concentrations $\lesssim$ 10 ppm. For concentrations > 10 ppm pronounced reductions in both the efficiency and lifetimes resulted. This is the first data that have shown quantitatively the effects of small O_2 additions on the quantum efficiency.

Acknowledgments

The authors are indebted to R. H. Saul and R. W. Dixon for valuable discussions and encouragement during the course of this work. We wish to thank S. E. Haszko and G. W. Kammlott for assistance with the SEM measurements. Thanks are also due to T. E. McGahan and L. B. Hooker for experimental assistance and to V. Wohlheiter for coating the quartz crucibles with Si_3N_4. Discussions with M. E. Weiner on thermodynamic considerations were also much appreciated.

Manuscript submitted July 8, 1974; revised manuscript received Oct. 2, 1974.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1975 JOURNAL. All discussions for the December 1975 Discussion Section should be submitted by Aug. 1, 1975.

Publication costs of this article were partially assisted by Bell Laboratories.

Oxide Growth on Etched Silicon in Air at Room Temperature

S. I. Raider,* R. Flitsch, and M. J. Palmer

IBM System Products Division, East Fishkill Facility, Hopewell Junction, New York 12533

ABSTRACT

Oxide growth on etched silicon wafers at room temperature was studied as a function of etching procedure, wafer orientation, dopant concentration, and exposure to ultraviolet light. An impurity film was rapidly deposited on the silicon surface after etching with hydrofluoric acid. Impurity adsorption was distinguished from oxide growth by x-ray photoelectron spectroscopy (ESCA). The impurity film greatly reduced the initial oxide growth rate when compared with oxide growth on a cleaved silicon surface. The thickness of oxide films formed on etched surfaces was determined and compared using ESCA and ellipsometry.

The interaction of silicon with oxygen on atomically clean silicon surfaces has been described (1). The silicon surface for these studies is generally prepared in ultra-high vacuum at elevated temperatures. A related problem of practical importance in semiconductor processing is the growth of oxide films at room temperature on etched silicon single-crystal substrates (2-4). Ellipsometric measurements of film growth have been used to describe oxide growth kinetics on silicon after an initial film is rapidly formed (2, 4). Changes in ultra-thin film thickness were determined from ellipsometric data by employing the index of refraction of silicon dioxide and treating the films as oxides. These films were not characterized although Archer (2) noted that an impurity layer, which could be removed with organic solvents, was present in addition to an oxide film after exposure to air for 24 hr. Recent Auger studies of etched silicon surfaces also indicated the presence of both carbon and oxygen (5-8). The present work describes the growth rate of an oxide at room temperature for a silicon surface prepared by etching in HF and covered with adsorbates.

X-ray photoelectron spectroscopy, or ESCA (electron spectroscopy for chemical analysis), is used here to complement ellipsometric measurements of ultrathin film formation on etched silicon surfaces. ESCA is particularly well suited as a technique for examination of oxide films $\leq$ 100Å thick and can provide analytical and bonding data in terms of photoemitted electron line intensities and binding energies. The basis of the ESCA technique is the excitation of the electronic structure of an atom by x-rays and the analysis of the kinetic energies of the photoemitted electrons. The mean free paths of the monoenergetic, inelastically scattered photoelectrons are $<$ 30Å in the 1 keV energy range. Contributions to a photoelectron line intensity decrease exponentially with distance from the film surface. Photoelectrons excited from core levels are mainly atomic in character but are subject to shifts in binding energy caused by the chemical environment of the atoms. By comparing ESCA and ellipsometric data, the films formed on etched silicon at room temperature are characterized and those factors which affect oxide growth are determined.

Experimental

Sample preparation.—Silicon dioxide films, 2000Å thick, were grown in dry oxygen at 1050°C on chemmech polished silicon wafers. The substrates used were <100>, p-type, 2 ohm-cm, although <111> orientations, n-type silicon and different resistivity wafers were also examined. The 2000Å films were generally etched at 25°C for 30 sec in freshly prepared HF diluted with an equal volume of deionized water. A variety of etching procedures were used in attempts to reduce transfer of contaminants to the silicon surface and for comparisons with reported results. Pendant HF was removed either by rinsing in deionized water for about 10 min until the water resistivity reached 16 megohm-cm or by drying with nitrogen gas without solvent rinsing or by other procedures described below.

Film growth on etched silicon was allowed to occur in air in clean hoods in our oxidation laboratory. The temperature and relative humidity in this area remained at 25° ± 2°C and 30-50%, respectively.

Impurities were adsorbed on sample surfaces either during processing or during exposure to the laboratory environment. Attempts were made to remove the adsorbed contaminants by rinsing in solvents or by heating at different temperatures in nitrogen gas. Oxidants in the nitrogen gas caused some modification of the oxides. Heating with quartz-iodine lamps in vacuum (10^{-7} Torr) reduced the level of surface contamination without modifying the oxides.

Oxide growth rates were determined using groups of wafers exposed to similar environments from which samples were randomly selected for examination by ellipsometry and ESCA. Etched wafers were stored either in metal containers, in plastic containers, or in deionized water. They were either exposed to room fluorescent lighting, 2537Å ultraviolet light (Mineralight, UltraViolet Products, Inc.), or were kept in the dark. Unless explicitly stated, wafers were exposed to air in the dark or in red filtered light. Etched wafers were split into halves and comparisons were made on the same wafer in studies of the effect of light on film growth rates. Cleaved samples were formed by fracturing 2 ohm-cm, p-silicon slugs, essentially along the <111> plane, either in air, deionized water, or deionized water containing 1% isopropanol.

Ellipsometry.—The thicknesses of films formed on silicon substrates were determined using a Rudolf ellipsometer. All data points were measured in two zones with the quarter-wave plate at 45.00°, at a wavelength of 5461Å and with an angle of incidence of 70.00°. For ultra-thin films on silicon substrates, the thicknesses were evaluated using the measured value of Δ and by assuming an index of refraction (n) of 1.47. A change in the imaginary part of the silicon refractive index [0.028 (9, 10)] affects the Δ value and, therefore, the ellipsometric film thickness value for a very thin oxide film; the real part of the index (4.076) will almost exclusively shift the Ψ value and not alter film thickness (11). An alternate value of 0.042 (12) has been assigned to the imaginary part of the silicon refractive index. Use of this value would decrease measured film thicknesses about 1.5Å.

Changes in ellipsometric measurements upon exposure of freshly prepared surfaces to air at 25°C in a darkened room indicated that film formation was occurring. The rate of impurity film growth on a 24Å

* Electrochemical Society Active Member.

Key words: native oxide, x-ray photoelectron spectroscopy (ESCA), ellipsometry, oxidation.

silicon dioxide film was about 0.05Å/min (assuming $n = 1.47$) during the first hour, followed by a much slower subsequent growth. Impurity film growth on freshly etched silicon, which rapidly formed about 7Å of film prior to the first ellipsometric measurement, was about 0.03Å/min during the first hour of exposure to air. Ellipsometer measurements were therefore made within 3 min after the surfaces were prepared.

ESCA.—ESCA has previously been described by Siegbahn *et al.* (13). An AEI photoelectron spectrometer with a magnesium anode in the x-ray source ($K\alpha_{12}$ radiation = 1253.6 eV) was employed in this work. About 10 to 20 min were required for preparing and mounting a sample of appropriate size and for evacuating the spectrometer sample chamber. Spectral data were obtained at a pressure of $<10^{-6}$ Torr from samples 0.2 × 0.5 in. A broad kinetic energy scan (1300 eV) of the sample was first obtained at 2 eV/sec. The kinetic energies of the photoelectron lines of interest were then scanned at a rate of 0.02 eV/sec. All data were referenced to the Au $4f^{7/2}$ line at 83.8 eV (14). The electron binding energies were determined to ±0.1 eV by subtracting the kinetic energies of the emitted photoelectrons and a spectrometer correction from the energy of the incident x-rays; *i.e.*

$$E_b = E_{\text{x-ray}} - E_{\text{kinetic}} - E_{\text{spectrometer correction}}$$

The silicon dioxide binding energy data were corrected for a shift of +0.3 eV which was presumably due to charging (15). The magnitude of this shift was found to be independent of oxide thickness in the thickness range under consideration.

Estimates of the thickness of oxide films formed in air at room temperature were made from comparisons of photoelectron line intensities with intensity data extrapolations of O 1s and Si 2p photoelectron lines in silicon dioxide films oxidized at 850°C (16). The detection limit for an element decreases with film but is about 0.1 monolayer at the film surface. Therefore, trace impurities which might be observed in Auger and backscattering spectra after etching silicon are not detected by ESCA.

The carbon line, C 1s, was monitored on all samples examined. Wagner (17) has reported that the specific intensities of the O 1s and C 1s photoelectron lines are in the ratio of about 2:1. The number of carbon atoms in a given volume of amorphous carbon film is about twice the number of oxygen atoms in a similar volume of silicon dioxide film. A 10Å thick carbon impurity film, assumed to be amorphous carbon, contains 9.0-10.5 × 10^{15} carbon atoms/cm^3 whereas a 10Å thick silicon dioxide film contains about 4.5 × 10^{15} oxygen atoms/cm^3. A carbon impurity film was therefore considered to be equal in thickness to an oxygen film with the same photoelectron line intensity.

Comparison of ellipsometric and ESCA measurements.—Reference oxide thicknesses were obtained from ellipsometric measurements of silicon dioxide films formed at 850°C by oxidation with 1% oxygen in nitrogen. The precision of these ellipsometric measurements is <±1Å.

Changes in ellipsometric data of oxides or etched silicon exposed to atmospheric pressure occur rapidly relative to changes in the ESCA spectra obtained in vacuum. Therefore, ellipsometric measurements of film thickness were made immediately after sample preparation and were followed with ESCA measurements on the same wafer. Discrepancies can exist with respect to the thickness of films and oxides formed on etched silicon at room temperature. These may be related to desorption of volatile surface contaminants in the ESCA vacuum chamber which contribute to the film thickness measured by ellipsometry and/or adsorption of organic impurities in the ESCA spectrometer.

Both techniques provide average measurements of macroscopic sample areas. Discontinuities in ultrathin oxide films formed a room temperature in the presence of surface contaminants generally cannot be discerned using these techniques. The consistency and reproducibility of the ESCA and ellipsometric data obtained, however, permit conclusions to be reached concerning oxide growth at room temperature, despite the small differences in measured film thicknesses.

Results and Discussion

Freshly etched silicon wafers.—Typical ESCA spectra of the elements observed on a thermally grown silicon dioxide film are shown in Fig. 1a and are compared in Fig. 1b with elements observed in the spectrum of a freshly etched 2 ohm-cm <100> silicon wafer. The spectra indicate the presence of oxygen (O 1s), carbon (C 1s), and silicon (Si 2p) photoelectron lines with binding energies of 532.5, 284.3, and 99.3 eV, respectively. An additional Si 2p line found at 103.7 eV, which corresponds to silicon in the silicon dioxide film (Fig. 1a), is not detected in the etched silicon spectrum (Fig. 1b).

The contaminants always found in ESCA spectra of etched silicon surfaces are carbon and oxygen. Fluorine is present in the ESCA spectrum only if a sample is etched and dried without a deionized water rinse. No detectable difference in the ellipsometric film thickness 7-8Å is observed when the etched sample is immediately dried or first rinsed in deionized water for 10-15 min.

The O 1s and Si 2p oxide line intensities on etched silicon (Fig. 1b) indicate that the film thickness of 7.4Å measured by ellipsometry does not correspond to an oxide film thickness. By extrapolation from thermally grown silicon dioxide data to be described elsewhere (16), the O 1s line intensity in Fig. 1b corresponds to an oxide film <2Å thick or $<10^{15}$ oxygen atoms/cm^2. This oxygen line may either be due to oxygen bound to silicon or is associated with oxygen in species adsorbed or incorporated in impurities on the etched surface. Little can be deduced from the oxygen binding energy since no significant O 1s shift is observed for the weak, broad line shown in Fig. 1b from the O 1s line in Fig. 1a.

Significant differences in the concentration of oxygen present on freshly etched silicon surfaces have been observed. Chang (8) has estimated, from Auger spectral line intensities, that 2-5 × 10^{15} oxygen atoms/

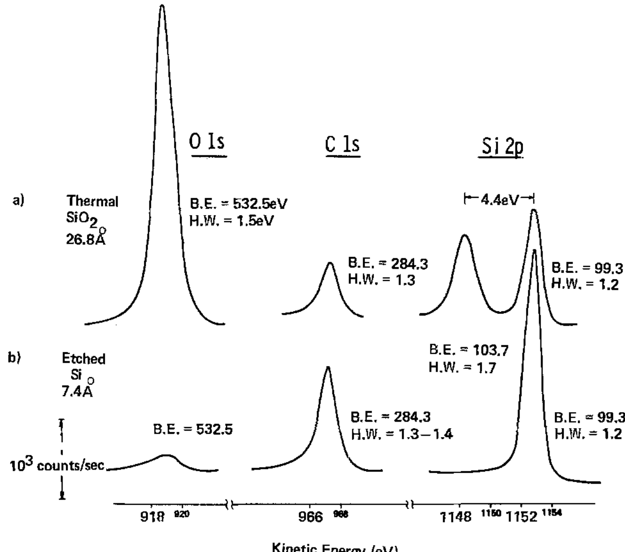

Fig. 1. Binding energies and relative line intensities for O 1s, C 1s, and Si 2p ESCA photoelectron lines (a) from silicon dioxide film grown at 850°C and (b) from a freshly etched silicon surface. Film thicknesses are determined by ellipsometry.

cm^2 are present on his etched, unheated silicon samples which is more oxygen than we observe with ESCA. Charig and Skinner (5) have published an Auger spectrum of unheated, cleaned silicon which appears nearly free of oxygen. We have repeated the etching procedure used by Charig and Skinner but no change was found in the result shown in Fig. 1b for the ESCA oxygen line intensity.

Carbon contamination on the etched silicon surface.—Carbon was always identified on all ESCA spectra. Particular attention was therefore given in an attempt to determine its source and its influence on the room temperature oxidation of etched silicon wafers.

Carbonaceous contaminants may be chemisorbed on our etched silicon samples, together with more volatile impurities, prior to insertion into the ESCA spectrometer. These contaminants contribute to the ellipsometric film thickness. Henderson (7) has observed that etching silicon with HF enhances carbon contamination and has suggested that the carbon impurity is co-deposited within the oxide phase during the etching step. Alternately, organic impurities may be exchanged with adsorbed HF at the etched silicon surface during the deionized water rinse. Other workers (8) have observed carbon contamination on etched silicon, even in oil-free vacuum systems, which suggests that a part of the carbon film may be transferred to the etched silicon samples prior to insertion into the ESCA spectrometer. In addition, carbon contamination may be attributed partly to oil backstreaming from the spectrometer vacuum pumps.

In order to reduce carbon contamination prior to insertion into the ESCA vacuum system, the silicon was etched in distilled HF solution, in distilled diluted (1:10) HF solution, in HF solution pretreated with crushed silicon to getter carbon (18), and in gaseous HF. The etched samples were either rinsed for 10 to 15 min in deionized water and then dried, immediately spun dry in a nitrogen ambient, immersed into distilled acetone to remove HF (2), or immediately rinsed in a carbon tetrachloride solution saturated with iodine. Very little change from samples etched in nondistilled HF, rinsed in deionized water, and dried in nitrogen gas was detected in most of the ESCA spectra. A small decrease in the carbon line intensity was observed when using the distilled acetone rinse. A decrease in ellipsometric thickness was also noted after rinsing in acetone (7.7-6.8Å) which is consistent with Archer's observations (2). Iodine was detected on the sample rinsed in carbon tetrachloride saturated with iodine in addition to the normally observed oxygen and carbon line intensities. The silicon bonding energy was unaffected by this rinse, but the oxygen line was shifted to a lower binding energy (532.0 eV) and the carbon was shifted to a higher binding energy (285.5 eV). The ellipsometric thicknesses of these films ranged from 30 to 40Å.

The ellipsometric film thicknesses of etched silicon were generally not changed by the different etching procedures used. It is not known whether these treatments had any effect on the carbon contamination present at the surface. Part of the nonvolatile carbon contamination on an oxide surface appears to originate from inside the spectrometer after the ellipsometric measurement is made. Transferring the sample in and out of the roughing pump insertion lock section of the spectrometer increases the ellipsometric film thickness. In addition, the sample is contaminated with carbon while in the ESCA vacuum chamber. On an etched silicon sample, an estimated carbon film thickness of 4.5-5.5Å (about $4\text{-}6 \times 10^{15}$ carbon atoms/cm^2) is initially present, which increases to about 7Å after several hours in the ESCA vacuum chamber. Chang (8) has observed less carbon ($2\text{-}20 \times 10^{14}$ carbon atoms/cm^2) in Auger spectra of etched, unheated silicon samples. Less carbon remains adsorbed under vacuum once an oxide surface is formed than on freshly etched silicon surface. After insertion into the ESCA spectrometer, a carbon film on an oxide surface is estimated at be 2-3Å thick initially and increases to about 5Å after 15 hr. The initial carbon film thickness can be reduced to about 1Å by minimizing the sample time in the roughing pump section of the insertion lock and by direct insertion into the ESCA vacuum chamber. A decrease of only about 1Å in carbon impurity level is detected by direct insertion of an etched silicon sample into the ESCA vacuum chamber. The additional carbon adsorbed during insertion into the spectrometer completely masked any improvements which may have been achieved by purification of the etchant or modifications of the etching procedure.

Oxidation and film growth on etched silicon surfaces.—Film growth on etched silicon wafers in air at 25°C exposed to room light was monitored both by ESCA and ellipsometry. Changes in the spectrum of the Si 2p line in the oxide with time are shown in Fig. 2 together with the corresponding ellipsometric changes in film thickness. The baseline of the silicon spectra is the spectrum of a freshly etched silicon surface. For comparison, the Si 2p line from a thermal oxide spectrum is shown in Fig. 2. The magnitudes of the shifts in the oxide binding energies from that of the silicon substrate binding energy, designated by δ, are given in Fig. 2. These shifts in binding energy will be discussed in a subsequent paper (19). The data for the increases in film thickness (ellipsometry) as a function of time on an etched silicon surface are summarized in Fig. 3 together with the estimated oxide thicknesses (ESCA). The initial oxide growth process as determined from ESCA spectra extrapolates back to the origin and has an oxide thickness dependency proportional to the logarithm of the oxidation time. Upon increasing the exposure time of the etched silicon surface to air, the intensity of the Si 2p oxide line is

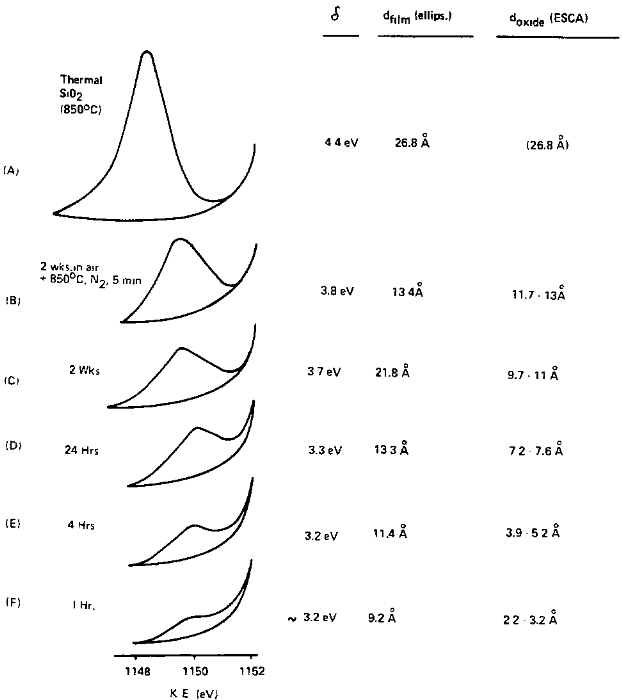

Fig. 2. Changes in the Si 2p oxide ESCA line as a function of exposure time to air at room temperature (samples C through E). The baselines correspond to the spectrum from a freshly etched silicon surface. Spectrum B is sample C exposed for 2 weeks to air followed by an anneal in nitrogen at 850°C for 5 min. Spectrum A is a silicon dioxide film 27Å thick grown in oxygen at 850°C. The difference in binding energies between the maxima of the Si 2p substrate and oxide lines are represented by δ values. The range in oxide thickness is based on estimates using both the Si 2p and O 1s line intensities.

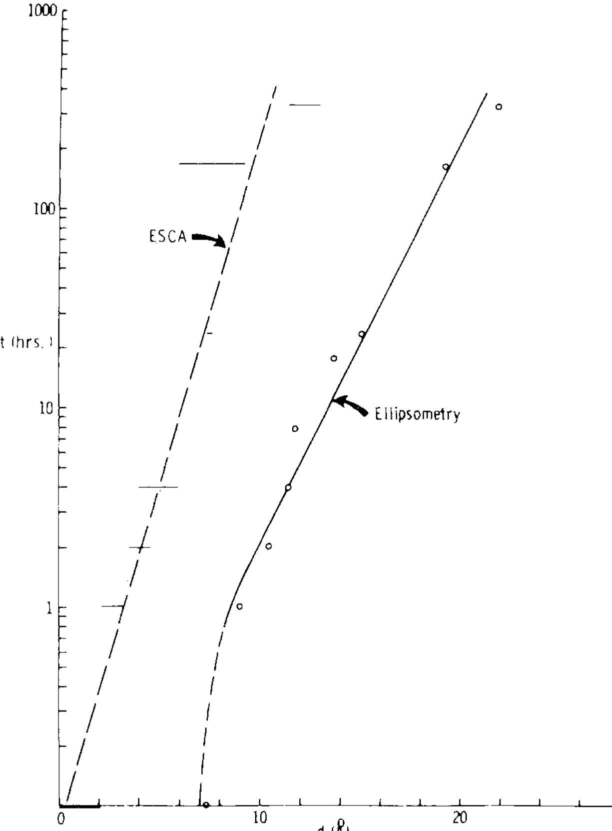

Fig. 3. Ellipsometric and ESCA thickness data plotted as a function of the logarithm of the time of exposure of etched samples to air at room temperature.

increased and its binding energy is shifted toward that of thermally grown oxide films. After exposure to air for 2 weeks, both the binding energy and the line intensity were still significantly different from that of the thermal oxide. After a 1 year exposure to air at room temperature, negligible additional change in the oxide binding energy or line intensity was observed. From this data and the cleavage experiments described below, an equilibrium oxide film thickness for oxide growth at room temperature in air is estimated to be <14Å. This value is considerably lower than previous indications which were based on ellipsometric measurements (2,4).

Oxide growth and impurity adsorption occur simultaneously on etched silicon wafers during exposure to air at room temperature. The difference between an ellipsometric film thickness and estimated film thickness (ESCA) is often too large to be accounted for by nonstoichiometry or densification of the oxide film. Volatile contaminants are presumably adsorbed from air and desorbed in vacuum and contribute to increase the ellipsometric film thickness relative to the estimated ESCA film thickness.

Heating an oxide to 850°C for 5 min in nitrogen at 1 atm pressure was found to remove the adsorbed species from the oxide surface. Milder conditions were sought to remove the adsorbed contaminants from oxide surfaces formed in air at 25°C. Samples were rinsed in various solvents or heated to 200°C in nitrogen for 5 min. Although some scatter is observed, the results given in Table I are characteristic of the changes in ellipsometric film thickness found on different quarters of the same wafer as a function of sample treatment. Solvent rinses (aqueous, organic) reduce the film thickness. An additional decrease is observed by heating at 200°C. However, a significant additional decrease in adsorbed contaminants is obtained by heating the sample at 850°C. It has been reported (8) that a temperature of >800°C is required to remove the carbon adsorbed on silicon.

Table I. Effect of solvent rinses and heating on ellipsometric film thickness of films formed on etched silicon

	Etched Si, A	SiO_2 (thermal), A
t_0	7.2	27
Air; R.T.	18 (5 weeks)	33 (4 months)
Solvent rinse	17	30
200°C, N_2, 5 min	16	—
850°C, N_2, 5 min	12 (ESCA: d_{oxide} = 12)	27 (ESCA: d_{SiO_2} = 27)

Closer agreement is obtained between ESCA and ellipsometry with regard to oxide thickness after heating the exposed etched samples at 850°C in nitrogen. For example, when the etched sample left in air for 5 weeks is heated at 850°C in nitrogen at 1 atm pressure for 5 min, a decrease in ellipsometric thickness from 18 to 12Å is observed. A second example, shown in Fig. 2, indicates that the oxide film thickness (ESCA) increased due to oxygen impurities in the nitrogen gas stream (1-5 ppm) from 10 to 12Å and a small increase in the silicon binding energy of 0.1 eV was detected. Negligible changes in the ESCA spectra were observed for exposed samples after heating at 850°C in vacuum for 15-20 min. The observed difference in binding energies between silicon dioxide and oxides formed in air at 25°C is not related to densification of the oxide film, since similar binding energies are not obtained even after heating at 850°C.

Oxidation of cleaved silicon surfaces.—Silicon single crystals cleaved in air form oxide films more rapidly than do etched silicon wafers. For example, the thinnest oxide film observed on a cleaved silicon surface was 5-7Å thick after 5-10 min exposure to air. This thickness was estimated from ESCA spectra taken 15-20 min after cleaving the sample. If exposure to air is increased about 10 min, the estimated oxide film thickness is 10-12Å. For comparison, etched silicon wafers with either <100> or <111> orientations possess oxide films only 2-3Å after 1 hr exposure to air. After 3 and 24 hr of exposure of the cleaved sample to air, the estimated oxide thickness is 11-13Å. Each of the cleaved samples exposed to air and then examined by ESCA contained carbon contamination on the silicon surface similar in thickness to carbon on etched oxide surfaces.

Cleavage of the silicon crystal either in deionized water or in deionized water containing an intentionally added organic impurity both significantly reduce the rate of oxidation on the clean surface even in the absence of HF. For example, a sample cleaved in deionized water containing 1% isopropanol, dried, and then examined by ESCA about 5-10 min after cleavage possessed an oxide film 1-2Å thick. The cleaved silicon oxidation results are summarized in Table II.

As is shown by the cleavage experiments, an oxide can readily grow on a clean silicon surface in air at room temperature. Etching in HF results either in HF or other impurities to be adsorbed on the silicon surface and reduce the rate of oxide growth. The adsorbed impurities provide a barrier to the initial oxidation of the etched silicon surfaces. Deionized water,

Table II. Oxide growth on cleaved silicon samples

Cleavage ambient	Exposure time (to ambient)	d_{ox} (estimated), A
Air	5-10 min	5-7
Air	20 min	10-12
Air	3 hr	11-12
Air	24 hr	11-13
DI H_2O	5-10 min*	3-4
1% isopropanol in DI H_2O	5-10 min*	1-2

Temperature: 24°C.

which contains organic impurities in the ppm range, reduces the rate of oxide growth on cleaved samples with respect to air. Roikh *et al.* (20) have shown that water vapor in air increases the rate of oxidation of silicon at room temperature when compared with dry air. It is the presence of impurities on the sample surface or in the deionized water which limits the oxide growth rate on silicon rather than the reactivity of water with silicon at room temperature. Isopropanol (1%) in the deionized water further reduces, but does not eliminate, oxide growth.

Factors affecting oxide growth rates on etched silicon.—Oxide growth rates on etched silicon wafers at room temperature were examined by ellipsometry and ESCA as a function of wafer orientation, dopant type and concentration, exposure to ultraviolet light, and storage in deionized water. Typical ellipsometric data are shown in Fig. 4 for growth rates in air on p-type silicon surfaces. Ellipsometric results indicate that a freshly etched <111> oriented wafer surface possesses $\leq$ 5Å of film. The ESCA spectra of these surfaces are identical and indicate the presence of <2Å of oxide. The C 1s line intensities on <111> and <100> etched silicon surfaces are equal. After exposure to air in the dark (in a metal container), both ellipsometry and ESCA indicate that an oxide is forming somewhat more rapidly on the <111> surface than on the <100> surface. This initial difference in oxidation rate may be related to the difference in thickness of the impurity film adsorbed on the silicon surfaces in air.

The dopant concentration in the silicon substrate affects the oxidation of an etched silicon surface (21). Similar ellipsometric and ESCA results were obtained for growth on p-type (boron) and n-type (phosphorus) silicon wafers as a function of dopant concentration. Lightly doped ($\sim$5 $\times$ 10^{14}/cm^3) silicon wafers appear to exhibit the same film growth rate as do the 2 ohm-cm ($\sim$5 $\times$ 10^{15}/cm^3) wafers. However, heavily doped 10^{-3} ohm-cm silicon wafers with about 10^{20} dopant atoms/cm^3 oxidize more readily than the 2 ohm-cm wafers. For example, freshly etched 10^{-3} ohm-cm wafers possess an ellipsometrically measured film 8.5-10Å thick and an estimated (ESCA) initial oxide thickness of 2-4Å. In contrast to the results of Ritter *et al.* (22) which indicated that an anomalously thick oxide layer formed in air on etched, p-type 10^{-2} ohm-cm silicon, p-type 10^{-2} ohm-cm (10^{19}/cm^3) silicon wafers exhibit an intermediate growth rate between that of 2 and 10^{-3} ohm-cm silicon. The rate of subsequent oxide growth in air is more rapid on the heavily doped silicon and is indicated by both ellipsometry and ESCA. It is suspected that differences in impurity adsorption on highly doped silicon surfaces and changes in the reactivity of the heavily doped silicon both contribute as causes for the enhanced oxidation.

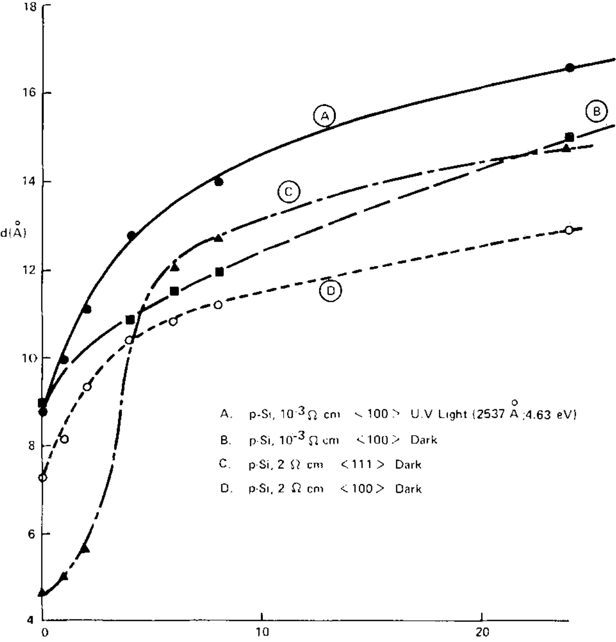

Fig. 4. Film growth rates on etched silicon wafers at room temperature measured by ellipsometry.

Immersion of freshly etched silicon wafers into non-agitated, deionized water at room temperature generally reduced the rate of oxide growth when compared with growth in air. As previously indicated, oxidation of cleaved surfaces also occurs less readily in deionized water than in air. In a static system, the growth of an oxide film on an etched silicon wafer often proceeded at a normal rate only after an induction period. This induction period was occasionally observed for etched wafers immersed in deionized water or for rinsed wafers contained in a closed plastic container. For example, no changes in ellipsometric film thickness from the t_0 measurement were observed for a period of 6-10 hr for samples contained in a closed container. Once oxide growth was initiated, subsequent oxidation within the container occurred at a normal rate. When an etched wafer is rinsed in stirred deionized water, the rate of oxidation is increased. Bubbling nitrogen or oxygen gas through the deionized water also increased the rate of oxidation.

The etched silicon surface is hydrophobic due to the presence of Si-F bonds (23) or adsorbed HF. Covalent organic impurities, present in the deionized water in trace quantities, are preferentially adsorbed on the silicon as the HF goes into solution. These impurities apparently form a barrier film which inhibits aqueous oxidation of the silicon. Water or oxygen permeation into this barrier is enhanced by agitation of the system. Modification of the adsorbed barrier film by coadsorption of water or ionic species from solution can make the surface of the sample appear hydrophilic.

The frequency distribution of laboratory fluorescent lighting extends into the near ultraviolet. Exposure to this light accelerated the oxide growth rate on etched silicon when compared with oxide growth in the dark. The effect of ultraviolet light on oxide growth is shown in Fig. 4 using light with a wavelength of 2537Å. Irradiated films were compared with films grown in the dark after 3 weeks by ellipsometry and ESCA when an oxide has nearly reached its equilibrium thickness in air in the dark. Results in Table III indicate that both the total film and estimated oxide thicknesses are greater after exposure to ultraviolet light than after growth in the dark. The extent to which oxidation is modified by ultraviolet irradiation is much less than is indicated by ellipsometric measurements. The ESCA spectrum indicated that the exposed wafers possessed a significant increase in the thickness of the carbon impurity film on the oxide surface. Multiple carbon lines rather than the single carbon line normally observed suggested that the adsorbed carbon film was modified due to photolysis at the silicon surface. This result suggests that an organic film is present on the silicon surface prior to insertion into the ESCA spectrometer. The presence of ozone or heating of the wafer during exposure were experimen-

Table III. Effect of ultraviolet light on oxide growth in air

Temperature, 25°C.
Exposure time: 3 weeks.

tally eliminated as possible causes for the increase in oxide thickness.

Cabrera (24) has reported that ultraviolet irradiation enhances the oxidation of aluminum and Oren and Ghandhi (25) have made similar observations for oxidation of silicon at elevated temperatures. However, Fehlner (26) has recently noted that ultraviolet irradiation of silicon under clean, dry conditions does not affect silicon oxidation. It remains to be determined whether our observations of the enhanced oxidation of silicon are related only to irradiation of silicon with ultraviolet light or to irradiation in the presence of impurities.

Summary

Impurities are rapidly adsorbed on moderately doped substrates after etching in HF. The film present on a freshly etched silicon surface and measured by ellipsometry is primarily an impurity film rather than an oxide film. A Si 2p oxide photoelectron line is not detected on a freshly etched silicon surface. The intensity of an oxygen photoelectron line for a substrate etched and then rinsed in deionized water indicates that <2Å of oxide is present. A difference in surface behavior is observed between a freshly etched silicon wafer and an oxidized wafer. More carbon is initially adsorbed on an etched surface than on a surface with oxide present. It is likely that <0.1 monolayer of silicon dioxide (detection limit of ESCA) forms on a freshly etched silicon surface rinsed in deionized water and exposed to air and that the oxygen detected in the ESCA spectra is largely from absorbed oxidized impurities. Oxide film thicknesses on etched silicon surfaces, as well as oxide growth rates, are therefore overestimated by ellipsometry.

The initial oxide growth rates on etched silicon surfaces in air or water at room temperature are lower than on cleaved silicon surfaces. HF etching enhances the rate of impurity adsorption on a silicon surface relative to the rate of surface oxidation. An induction period is sometimes observed during which oxide growth does not occur on etched silicon but it is not observed once oxidation is initiated. The thickness of the impurity layer on etched silicon is decreased after oxidation is initiated and its effect on the rate of subsequent oxidation of silicon is also decreased.

A number of factors affect the rate of oxide growth on etched silicon at room temperature. An increased oxide growth rate is observed if the substrate dopant (n- or p-type) concentration is $\geqq 10^{19}/cm^3$. The oxide growth rate in air is greater on <111> oriented substrates than on <100> surfaces. Ultraviolet light (2537Å) also increases the oxide growth rate in air. However, the major effect of ultraviolet irradiation is to increase the nature and film thickness of the carbon impurities at the silicon surface presumably by a mechanism different from that of adsorption in the dark. The equilibrium oxide thickness in air at room temperature is less than 14Å unless the substrate dopant concentration is greater than $10^{19}/cm^3$ or the substrate is exposed to u.v. light during oxidation.

Simple Theoretical Estimates of the Schottky Constants and Virtual-Enthalpies of Single Vacancy Formation in Zinc-Blende and Wurtzite Type Semiconductors

J. A. Van Vechten*,[1]

Bell Laboratories, Murray Hill, New Jersey 07974

ABSTRACT

Phillips and Van Vechten have shown that, because of the high valence electron density in diamond type semiconductors, their vacancies may properly be treated as macroscopic cavities. With this model one may estimate the enthalpy of neutral vacancy formation, $\Delta H(V^x)$, as simply the surface energy of the cavity. Values of $\Delta H(V^x)$ are known for Si and Ge and are 10% less than the theoretical estimates. Here this model is extended to zinc-blende and wurtzite type crystals. The virtual-enthalpies of formation $\Delta H(V_A{}^x)$ and $\Delta H(V_B{}^x)$ are calculated for 17 common semiconductors. Difficulties in analyzing empirical data which arise from the ionization of the vacancies and their interaction with other defects are noted. However, for CdS, where the data are adequate, the empirical values are about 12% less than those calculated.

Phillips and Van Vechten have noted (1,[2] 2) that the Wigner-Seitz atomic radius, r_w, is much greater than the inverse of the Thomas-Fermi screening wave number, k_s, in the diamond type semiconductors

$$k_s(\mathrm{Si})r_w(\mathrm{Si}) = 3.5, \quad k_s(\mathrm{Ge})r_w(\mathrm{Ge}) = 3.6 \qquad [1]$$

Moreover, the surface energy of a metal, E_S, results from the spilling of electronic charge density into the vacuum, where it is not compensated by the positive charge of the ion cores, because the electronic wave functions cannot be abruptly terminated by a finite potential (3, 4). This spilled charge distribution decays as $\rho_0 \exp(-rk_s)$. One expects the range of effects which produce the surface energy of a semiconductor to be similar to or slightly shorter than in the case of a metal (1). Furthermore, because all the lattice sites of a diamond type crystal may be treated as equivalent sites, the macroscopic volume to be associated with a single atomic vacancy is exactly one atomic volume, Ω

$$\Omega = a^3/8 = 4\pi r_w{}^3/3 \qquad [2]$$

where a is the lattice constant. Therefore, if the single vacancy is regarded as a macroscopic cavity of volume Ω, the range over which the surfaces of this cavity would seem poorly defined in a microscopic sense is small compared with the total dimensions of the vacancy. Thus, it was concluded that a single atomic vacancy in a diamond type semiconductor may properly be treated as a macroscopic cavity and the enthalpy of neutral vacancy formation, $\Delta H(V^x)$, may be estimated as its surface area times its surface energy

$$\Delta H(V^x) = \mathcal{A}E_S \qquad [3]$$

To evaluate $\Delta H(V^x)$, one should note that the equilibrium shape of a cavity in a diamond type crystal is not a sphere, but an octahedron with only (111) surfaces, and that E_S is not isotropic (2, 5, 6). The enthalpy or internal energy per unit area of the (111) surfaces, $E_S(111)$, is less than that of any other surface. Thus, if the vacancy has the same equilibrium shape as a macroscopic cavity in the same material, we have

$$\Delta H(V^x) = \mathcal{A}_8 E_S(111) \qquad [4]$$

where $\mathcal{A}_8$ is the surface area of an octahedron of volume Ω

$$\mathcal{A}_8 = 1.1826\,\mathcal{A}_\infty \qquad [5]$$

and $\mathcal{A}_\infty = 4\pi r_w{}^2$ is the area of the Wigner-Seitz sphere. It has been noted (2) that the observed Jahn-Teller distortion of $V_{Si}{}^x$ and $V_{Si}{}^+$ corroborates the assumption that its macroscopic shape is octahedral.

Gilman obtained an empirical estimate for $E_S(111)$ of Si from an irreversible crack-propagation experiment (7). However, similar experiments have not been reported for other semiconductors so it is necessary to make theoretical estimates. It was proposed (1, 2) that

$$E_S(\mathrm{ijk}) = E_S{}^m(\mathrm{ijk}) + E_S{}^b(\mathrm{ijk}) \qquad [6]$$

where $E_S{}^m(\mathrm{ijk})$ is the contribution from long-ranged, metallic forces (3, 4) and $E_S{}^b(\mathrm{ijk})$ is the contribution from short-ranged, directional covalent forces (8). [Note that the energy of the covalent bond is here reckoned as the extra cohesive energy of the covalent phase relative to the metallic phase of the same composition rather than as the total cohesive energy relative to free atoms (8). This covalent energy is calculated in the manner of Hume-Rothery by comparing the electronic band structures of the semiconducting and metallic phases.]

Because both theoretical and experimental values are available for the surface tension of liquid metals (3, 4), it seems wise to relate $E_S{}^m$ to the surface tension and to test the proposed relation with the case of Si. It is assumed that $E_S{}^m(111)$ is just the surface enthalpy per unit area, $H_S{}^l$, of the metallic liquid phase of Si corrected for difference in density between the solid and liquid phases. The value of $H_S{}^l$ is obtained from measurements of the surface tension, $F_S{}^l$, of the liquid, which is indeed the surface free energy per unit area

$$F_S{}^l = H_S{}^l - TS_S{}^l \qquad [7]$$

where T denotes temperature and $S_S{}^l$ is the surface entropy per unit area, $S_S{}^l = -dF_S{}^l/dT$. The generally accepted values for Si at $T^F = 1685°K$ are $F_S{}^l(\mathrm{Si},T^F) = 734$ erg/cm^2 and $S_S{}^l(\mathrm{Si},T^F) = 0.09$ erg/cm^2 (9-11) so that $H_S{}^l(\mathrm{Si},1685°K) = 887$ erg/cm^2. Taking the density of the liquid phase to be 15.3% greater than the solid (8) and the theoretical result that $H_S{}^l$ vary as the $-5/6$ power with density, one estimates

$$E_S{}^m(111,\mathrm{Si}) = H_S{}^l/(1.153)^{5/6} = 788\ \mathrm{erg/cm^2} \qquad [8]$$

The contribution from short-ranged, directional covalent forces, $E_S{}^b(\mathrm{ijk})$, to each of the two surfaces

[2] Note that the values quoted in Ref. (1) differ slightly from those in Eq. [13] because proper account was not made for the surface entropy.

Key words: defects, stoichiometry, nonradiative recombination, GaP, CdS.

formed as a crystal is cleaved is just

$$E_S^b(ijk) = N_S^b(ijk)E_b/2 \quad [9]$$

where $N_S^b(ijk)$ is the number of broken bonds per unit area of (ijk) surface and $E_b = E_b(T)$ is the energy of each covalent bond relative to the metallic phase. [A rather complete discussion of $E_b(T)$ is given in Ref. (8) where calculated values are successfully compared with experiments.] For Si at 77°K, one finds

$$E_S^b(111,\mathrm{Si}, 77°\mathrm{K}) = 116 \mathrm{\ erg/cm^2} \quad [10]$$

so that the calculated value of the total (111) surface energy is

$$E_S(111) = 904 \mathrm{\ erg/cm^2} \quad [11]$$

This value may be compared with Gilman's value, 1240 erg/cm², which should be an overestimate of the true value because it was obtained from an irreversible process (7). Because the source of this overestimate is the failure to allow for relaxation processes on the newly cleaved surfaces, a crude estimate of its magnitude would be that it is the same fraction of $E_S(111)$ as the Jahn-Teller relaxation is of $\Delta H(V_{Si}^x)$. The Jahn-Teller relaxation energy for V_{Si}^x is roughly 1 eV (2), and the net value of $\Delta H(V_{Si}^x) \cong 2.4$ eV so, by this criterion, the true empirical value is $E_S(111) = 2.4 \times 1240/3.4 = 875$ erg/cm². Therefore, the agreement with theory is considered to be acceptable.

From the above considerations, one may estimate $\Delta H(V)$ for diamond type crystals as[3]

$$\Delta H(V^x,T) = \mathfrak{A}_8 E_S^m(111) + 4E_b(T) \quad [12]$$

if empirical values for E_S^l are known as they are for Si and Ge (9-11). [Note that the factor 4 follows from the fact that there are four broken bonds about the vacancy and the full energy of the bonds must be ascribed to $\Delta H(V^x)$. One should also note that S_S^l does not vary greatly from one liquid metal to another (10, 11).] For Si and Ge at their respective melting points one calculates

$$\Delta H(V_{Si}^x,T^F) = 2.66 \mathrm{\ eV}, \ \Delta H(V_{Ga}^x,T^F) = 2.21 \mathrm{\ eV} \quad [13]$$

Empirical values may be obtained from quenching experiments (12-14). However, one should take proper account of the ionization state of the vacancies at high temperatures and of the finite quenching rate when these experiments are analyzed (15-17). The empirical values are

$$\Delta H(V_{Si}^x) = 2.4 \pm 0.2 \mathrm{\ eV}, \ \Delta H(V_{Ga}^x) = 2.0 \pm 0.2 \mathrm{\ eV} \quad [14]$$

so that this macroscopic model seems to overestimate the true values of $\Delta H(V^x)$ by about 10%.[4] One should expect such an overestimate to occur because the charge density spilling into the vacancy cavity will overlap along the edges and at the apexes. Thus, these portions of the surface should have a lower energy than the corresponding free surfaces at infinite separation.

[3] Note that $\Delta H(V^x)$ refers to the process in which one lattice site is added to the crystal so that an atom from the bulk moves to the surface leaving a neutral vacancy in the bulk and causing the sample to expand by one atomic volume. No atom is removed to the vapor in this process, which is commonly denoted $O = V^x$. [See Kröger (15), p. 313.]

[4] As the creation of a vacancy produces four broken bonds about the vacant site and as there are twice as many bonds as atoms in the Si structure, it is often noted that Pauling's notion of the additivity of bond energies would lead one to estimate $\Delta H(V^x)$ as twice the heat of atomization or for Si, 9.3 eV. This is far more than the observed values which generally run between 0.5 and 1.0 times the heat of atomization for most materials. In the present discussion the bond energy E_b is far less than half the heat of atomization because it denotes only the energy resulting from the short-ranged, directional covalent forces. [See Ref. (8).] Of course, there is no direct relation between $\Delta H(V^x)$ and the heat of atomization because the vacancy creation process does not involve removing an atom from the sample, but it is worth noting that the relaxation of atomic positions concomitant with the establishment of the equilibrium shape of the vacancy cavity corresponds to a substantial reduction in the long-range contributions to $\Delta H(V^x)$ from the value that would obtain in an unrelaxed lattice. See the discussion of the Jahn-Teller distortion in Ref. (2).

Extension of Theory to Zinc-Blende and Wurtzite Crystals

The lattice constants of GaAs, ZnSe, and CuBr are nearly the same as that of Ge because all these elements occur in the same row of the periodic table (18). For this reason they have nearly the same valence electron density, bulk, and surface plasmon frequencies. Therefore, the use of the macroscopic model to treat vacancies in zinc-blende or wurtzite type crystals is as well justified as its use with diamond type crystals.

Because zinc-blende and wurtzite crystals will contain both anion and cation vacancies, V_B and V_A, one must establish some criterion for the relative size of these two species. It is here assumed that the dimensions of a vacancy cavity are proportional to the tetrahedral covalent radius, r_c, of the relevant element according to the table of Van Vechten and Phillips (18). Then by simple geometry, one finds the effective Wigner-Seitz radius of A is

$$r_w(A) = (16/\pi\sqrt{3})^{1/3} r_c(A) = 1.433 \, r_c(A) \quad [15]$$

Then the area of, for example, an octahedral cavity of appropriate size may be calculated using Eq. [5].

At this point we may make a qualitative observation about the agreement of theory with experiment. Consider the relative energy of neutral cation and anion vacancies which may be discussed in terms of their virtual-enthalpies of formation, $\Delta H(V_A^x)$ and $\Delta H(V_B^x)$. [We recognize that only the Schottky constant enthalpy

$$H_S(AB) = \Delta H(V_A^x) + \Delta H(V_B^x) \quad [16]$$

is a true enthalpy defined in terms of a true chemical potential, but that it is both permissible and convenient to calculate the virtual-enthalpies of vacancies in these compound crystals in a manner analogous to that used with elemental crystals. These virtual-enthalpies are then used in the proper structure element analysis of the thermodynamics of compounds developed by Kröger, Stieltjes, and Vink (19).][5] Because there is only one type of bond in these AB crystals, the short-range or broken bond contribution is the same to $\Delta H(V_A^x)$ as to $\Delta H(V_B^x)$. Therefore, the difference between the two is only in the long-range contribution, $\mathfrak{A}_8 E_S^m(111)$ of Eq. [12], which is proportional to r_w^2. Thus, the present theory predicts that $\Delta H(V^x)$ will be larger for the component with the larger r_c.

If differences in the enthalpies of ionization, $\Delta H_I(V_A^-)$ and $\Delta H_I(V_B^+)$, and of the activities in the liquid or vapor phase are neglected, then the ionized vacancies of the smaller element should be more numerous at the maximum of the solidus. Thus, by considering only vacancy contributions to the defect induced extrinsic carrier concentration of undoped material, one predicts the material to be n-type if $r_c(A) > r_c(B)$ and to be p-type if $r_c(A) < r_c(B)$. In Table I are listed the carrier types and radius ratios of the II-VI compounds. It is commonly believed that the carrier type that may be obtained in these compounds is limited by a vacancy self-compensation mechanism, although antistructure defects, A_B^- or B_A^+, may also be important. [See the accompanying paper (23).] In any event, the comparison in Table I shows perfect agreement between prediction and observation.[6] The same correlation occurs in III-V crystals although most of these can be doped to either type with impurities; undoped GaSb is p-type, while GaP and GaN are n-type. The author knows of no exception to this rule.

[5] Note that real values have been measured for the virtual-enthalpies in several virtual reactions in some alkali-halide and silver-halide crystals. See Ref. (20-22).

[6] A similar correlation was observed by Mandel (24) who used Pauling's table of covalent radii and ascribed the cause to differences in ΔH_I for V_A and V_B. However, that hypothesis was discredited by Kröger (25), and the correlation was not exact. The latter point is further evidence for the superiority of the table of covalent radii in Ref. (18) over the earlier table of Pauling when these are applied to semiconductors.

Table I.

Compound AB	$r_c(A)/r_c(B)$	Conductivity type
ZnO	1.81	n only
CdS	1.25	n only
CdSe	1.15	n only

ZnSe	1.00	n + p
CdTe	1.00	n + p
MgTe	0.93	p only
ZnTe	0.87	p only
BeTe	0.69	p only

In order to make quantitative estimates of $\Delta H(V^x)$, one must determine the shape of the vacancy cavity and the value of the appropriate surface energy. In contrast to diamond, Si and Ge, the equilibrium shape of zinc-blende type crystals is in general the rhombohedral-dodecahedron, which has only (110) surfaces. It is commonly assumed that this distinction results from the fact that the unreconstructed (110) surface has an equal number of anion and cation surface atoms whereas unreconstructed (111) [and (100)] surfaces have only one type of surface atom. Therefore, it seems likely that the distinction between diamond and zinc-blende equilibrium shapes results from Coulomb interactions across several unit cells of surface atoms that would not be operative on the surfaces of a neutral vacancy. Furthermore, the author is unaware of any determination of the Jahn-Teller distortion about V_A^x or V_B^x in a zinc-blende crystal which could serve to settle the question of the shape of the cavity, but the geometry of the lattice seems to favor the octahedral shape of vacancies in Si and Ge (2). Finally, there seems to be no measurements of $E_S(110)$ for zinc-blende crystals like those of Gilman for Si $E_S(111)$ (7), so that it is not possible to test any proposed relation between F_S^l and $E_S(110)$ as was done for $E_S(111)$ in Eq. [11]. Due to the above considerations, it is here assumed that V_A^x and V_B^x have the same octahedral shape as V_{Si}^x and V_{Ge}^x and that the same relation holds between the surface tension of the stoichiometric liquid, $F_S^l(A_{0.5}B_{0.5})$, and the effective $E_S(111,AB)$ on the surface of the V_A^x or V_B^x cavity.

Thus, we have

$$\Delta H(V_A^x) = \mathfrak{R}_8(A)\, E_S^m(111) + 4E_b(AB)$$
$$\Delta H(V_B^x) = \mathfrak{R}_8(B)\, E_S^m(111) + 4E_b(AB) \qquad [17]$$

where $\mathfrak{R}_8(A)$ and $\mathfrak{R}_8(B)$ are defined in terms of $r_c(A)$ and $r_c(B)$ by Eq. [5] and [15]. Values of E_S^m are here calculated using the theory of Schmit and Lucas to calculate H_S^l with the same parameters for the surface plasmon cutoff (3, 4) and of the change in density upon melting and S_S^l as are observed for Si. (Schmit and Lucas calculated H_S^l for 53 metals within 15% of experiment.) The resulting values are shown in Table II.

In Table II, calculated values are also shown for the surface tension of the stoichiometric liquid at T^F, $F_S^l(A_{0.5}B_{0.5}, T^F)$. Although it would seem to be easily possible to measure F_S^l using the method of Sugden (26, 27), only a few measurements have been reported (28, 29) and these generally refer to a nonstoichiometric liquid which is in equilibrium with the solid under some convenient growth condition. Thus, for example, the calculated value for $F_S^l(Al_{0.5}Sb_{0.5}, 1353°K) = 531$ erg/cm² cannot be compared with the reported value, 480 erg/cm² (28), until more information about the experiment is supplied.

Although the values in Table II are appropriate for the crystal at T^F, the variation of the calculated values with temperature is not large. This is because the coefficients of thermal expansion of these crystals are so small that the electron density varies less than 2%. Thus, the dominant term, $\mathfrak{R}\, E_S^m$, varies less than 2%. The temperature variation of the covalent term, $4E_b(T)$, is given in Ref. (8).

Comparison with Experiment

The analysis required to determine $\Delta H(V_A^x)$ and $\Delta H(V_B^x)$ from experimental data is rather more involved than that required to determine $\Delta H(V^x)$ for elemental semiconductors (15-17). As with Si and Ge, one must take account of the ionization state of both types of vacancies at the high temperature, T_h, at which an equilibrium is established and of the escape and agglomeration of these vacancies during the finite time required to cool the sample from T_h to the temperature where measurements are made. As with V_{Si} and V_{Ge}, both V_A and V_B may be expected to form complexes with impurities, C_A and C_B, during the quench so that any ionization energies observed at low temperature must be ascribed to C_A and C_B rather than to V_A and V_B. [The ionization energies $\Delta H_I(V_A^-)$ and $\Delta H(V_B^+)$, etc., can only be determined if simple, single vacancies can be produced near $T = 0°K$ as by electron irradiation.]

The problem of analyzing the data for AB crystals is worse than that with elemental semiconductors because one should expect the vacancies to interact with antisite defects, A_B and B_A (23). If the crystal is grown off-stoichiometry, say with an excess of A, then the excess may be accommodated in the lattice as V_B or A_B or interstitial A,A_i. It seems that the concentration of interstitials $[A_i]$ is significant only for elements of valence $Z_A = 1$, *i.e.*, the alkali and noble metal impurities. Elements with $Z_A = 2$ may occur as interstitials in a concentration sufficient to affect atomic diffusion but they are more commonly found on substitutional sites(30). Except for cases like O in Si where a compound is formed, $[A_i]$ is negligible when $Z_A > 2$. However, the virtual enthalpies of formation of antisite defects, $\Delta H(A_B^x)$ or $\Delta H(B_A^x)$, are comparable with $\Delta H(V_B^x)$ and $\Delta H(V_A^x)$ (23). Moreover,

* Calculated in Ref. (8).

while V_B acts as a donor, A_B will be an acceptor so that the two native defects resulting from an excess of A will compensate each other.

The charge compensation of V_B^+ with A_B^- or A_B^{-2} will occur not only at T_h but also as the sample cools. At T_h the equilibrium concentrations of neutral vacancies $[V_B^x]$ and neutral antisite defects $[A_B^x]$ will be different functions of the partial vapor pressures, P_A and P_B, over the sample (31). However, as the sample is cooled the equilibrium with the vapor is broken and vacancies and antisite defects may be interchanged by reactions of the type

$$A_A^x + V_B^+ = A_B^{-2} + V_A^- + 4e^+ \quad [18]$$

which will occur every time a vacancy migrates to a nearest neighbor site.

$[V_B^+]$ and $[A_B^-]$, $[A_B^{-2}]$, etc., will always be affected by the position of the Fermi level, E_F. They may interact through the charge compensation mechanism to keep the E_F in the gap even though the deviation from stoichiometry may be significant. The author proposes that this effect is the resolution of the paradox that deviations from stoichiometry in GaP produce electrically active "shunt-path killer centers" although they have little effect on the carrier concentration either at T_h or at room temperature (32).

To the author's knowledge, the only case for which adequate information has been obtained to determine $\Delta H(V_A^x)$ and $\Delta H(V_B^x)$ properly is that of CdS (33). Kumar and Kröger have concluded that $\Delta H_S(\text{CdS}) \simeq 5.6$ eV while an analysis of their data similar to that illustrated for GaP in the following paper (23) implies $\Delta H(V_{Cd}^x) \simeq 3.15$ eV and $\Delta H(V_S^x) \simeq 2.45$ eV. These values may be compared with the present theory, Table II, $\Delta H_S(\text{CdS}) = 6.25$ eV, $\Delta H(V_{Cd}^x) = 3.56$ eV and $\Delta H(V_S^x) = 2.69$ eV. We see that the theoretical values are about 12% greater than the empirical values in each case. This compares very favorably with the 10% theoretical overestimate found for $\Delta H(V_{Si}^x)$ and $\Delta H(V_{Ge}^x)$ in Eq. [13] and [14].

We should expect all the theoretical estimates in Table II to be comparably reliable, *i.e.*, 5-20% overestimates, and far more reliable than estimates made by fitting data with a naive van't Hoff plot that neglects ionization states, escape, and interactions.

Added Note

After completion of this work the author was made aware of detailed studies of the surface tension of liquid GaSb (34) and liquid InSb (35) as a function of composition and temperature. For the 50% Ga-50% Sb liquid 10°K above T^F, the apparent values are: $F_S^l = 454$ erg/cm²; $S_S^l = 0.112$ erg/cm² deg.; $H_S^l = 566$ erg/cm². These values differ somewhat from those assumed in the present calculation and would imply $\Delta H(V_{Ga}^x) = 1.79$ eV and $\Delta H(V_{Sb}^x) = 2.25$ eV, which are 10% less than the values in Table II.

Within the Schmit-Lucas theory (3, 4), one may expect H_S^l to be less for a partially ionized liquid than for an elemental liquid of the same valence electron density because interband transitions would be more effective in cutting off the plasmons. However, the magnitude of this effect may not be as large (10%) as the apparent experimental values suggest. It was found that F_S^l varies a factor of 2 across the Ga-Sb composition range so that one should expect the composition of the surface to deviate from that of the bulk in such a way as to minimize the free energy of the system. Furthermore, an unexplained peak in $F_S^l(x)$ is found at the 50% composition.

The situation in liquid InSb is similar to that in GaSb and the discrepancy between apparent values of F_S^l and Table II are somewhat less. However, the data on the temperature variation, which is required to obtain S_S^l and H_S^l, is not sufficiently accurate to discuss a correction.

The author is indebted to Dr. A. S. Jordan for bringing this data to his attention.

Manuscript submitted May 14, 1974; revised manuscript received Sept. 9, 1974.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1975 JOURNAL. All discussions for the December 1975 Discussion Section should be submitted by Aug. 1, 1975.

Publication costs of this article were partially assisted by Bell Laboratories.

Simple Theoretical Estimates of the Enthalpy of Antistructure Pair Formation and Virtual-Enthalpies of Isolated Antisite Defects in Zinc-Blende and Wurtzite Type Semiconductors

J. A. Van Vechten*,[1]

Bell Laboratories, Murray Hill, New Jersey 07974

ABSTRACT

The few theoretical treatments which have been successful in predicting the thermodynamic parameters of substitutional impurities are examined for their implications regarding antisite defects, B_A or A_B, and antistructure pairs, B_AA_B in AB semiconductors. All such theories predict a large concentration of $B_AA_B^x$, especially in III-V's. All predict that B_A^+ or B_A^{+2} and A_B^- or A_B^{-2} should be important to the properties of III-V's. Results of the Phillips-Van Vechten dielectric two-band model are presented for 23 common semiconductors. These are combined with results for vacancies in the accompanying paper to give a detailed account of native defects in GaP both during crystal growth and as the sample cools. The existence curve is calculated and compared with experiment. The interaction between vacancies and antisite defects is invoked to explain why deviations from stoichiometry have slight effects on carrier concentration but large effects on luminescent efficiency.

An antisite defect in a compound crystal, AB, may be an atom of element A which occupies an anion (B-type) lattice site, A_B, or a B-atom which occupies a cation (A-type) lattice site, B_A. (It seems that the terms "antisite" and "antistructure" are used interchangeably in the literature.) An antistructure pair, B_AA_B, would result from interchanging two nearest neighboring atoms in the perfect zinc-blende or wurtzite structure.

Although these defects have always been enumerated among the varieties of native defects in the standard text books (1, 2), the author has been unable to find any previous estimates of the enthalpy changes in the crystal concomitant with their formation.

However, A_B and B_A may be viewed as special cases of substitutional impurities in the AB crystal. A few theoretical treatments of the thermodynamics of substitutional impurities and of their distribution coefficients have been presented which achieve reasonable success in semiconductors (3-6). Therefore, the author here applies preexisting theory for impurities, particularly that of the dielectric two-band model developed by Phillips and Van Vechten (7-9), to the antistructure defect problem.

Despite the fact that appreciable concentrations of antisite defects (10, 11) and, in particular, antistructure pairs (12, 13) have been reported in several materials, it seems that they are often ignored when experimentalists seek to analyze their data. It is shown that there is no basis in theory for the assumption that antistructure defects may be neglected in III-V and SiC crystals. Moreover, the insensitivity of carrier concentration to significant deviations from stoichiometry (14, 15) may be explained in terms of compensation between vacancies and antisite defects which may occur both at the growth temperature, T_h, and during the cooling of the sample. It is noted that vacancies may be converted to antisite defect-vacancy complexes by reactions of the type

$$A_A^x + V_B^+ = A_B^{-2} + V_A^- + 4e^+ \quad [1]$$

which will occur every time a vacancy migrates to a nearest neighbor site. (The superscript x denotes the neutral state of the species.) Such an explanation resolves some paradoxes that arise if one assumes that deviations from stoichiometry may result only from differences in the concentrations of anion and cation vacancies, $[V_B]$ and $[V_A]$. An example of this would be the case of the "shunt-path killer centers" in GaP (14, 15).

Neutral Antistructure Pairs

The enthalpy and entropy of formation of a neutral antistructure pair, $\Delta H(B_AA_B^x)$ and $\Delta S(B_AA_B^x)$, are defined by the reaction

$$A_AB_B^x = B_AA_B^x;\ \Delta H(B_AA_B^x),\ \Delta S(B_AA_B^x) \quad [2]$$

corresponding to the interchange of the two atoms in a unit cell of the crystal. Obviously, $\Delta H(B_AA_B^x)$ and $\Delta S(B_AA_B^x)$ are both zero for elemental crystals like Si and Ge. One would expect their values to be roughly proportional to the ionicity of the compound or the electronegativity difference between A and B (4, 7-9, 16). Thus one should expect, for example

$$\Delta H(Br_{Cu}Cu_{Br}^x) > \Delta H(Se_{Zn}Zn_{Se}^x) > \Delta H(As_{Ga}Ga_{As}^x) > 0 \quad [3]$$

It is easy to estimate $\Delta H(B_AA_B^x)$ using Pauling's table of elemental electronegativities, X_A and X_B, and his rules for the heat of formation of covalent bonds (16). The formula for either the zinc-blende or the wurtzite structure is

$$\Delta H(B_AA_B^x) = 6(X_A - X_B)^2 Z(A)/4 \text{ eV} \quad [4]$$

where $Z(A)$ is the valence of the cation. The factor $Z(A)/4$ appears because, according to Pauling, there are $Z(A)$ bonds "resonating" among 4 ligands to the nearest neighboring atoms. The factor 6 appears because 6 of the 7 A-B ligands attached to these two atoms are replaced by 3 A-A ligands and 3 B-B ligands.

The values obtained from Eq. [4] are presented in Table I, where they are compared with values calculated using the dielectric two-band model (4, 7-9) and treating $B_AA_B^x$ as a pair of impurities, B_A and A_B. In this model one considers two contributions to the excess heat of mixing, $\Delta H(I_xA_{1-x}B)$, of a substitu-

tional impurity, I, on the A sublattice of the AB host crystal at a mole-fraction concentration x (4)

$$\Delta H(I_xA_{1-x}B) = \Delta H_0(I_xA_{1-x}B) + \Delta H_e(I_xA_{1-x}B) \quad [5]$$

The contribution ΔH_0 is that produced by the reduction of the various optical bandgaps, which results from the disorder of the crystal potential concomitant with alloying. These bandgaps are a measure of the separation of valence electron wave functions into bonding (valence band) states and antibonding (conduction band) states so that their reduction reduces the covalent bonding contribution to the cohesive energy of the material. A predictive theory for this effect has been published and compared with optical data for a wide range of pseudobinary alloys (17, 18). The comparison of this theory with empirical liquidus and solidus curves is given in Ref. (4-6).

The second term in Eq. [5], $\Delta H_e(I_xA_{1-x}B)$, is the contribution produced by the effect of the excess or deficit of electrons contributed to the crystal due to the difference in valence between I and the atom it replaces, A in this case. Thus

$$\Delta H_e(I_xA_{1-x}B) = [I](E_F - H_V)(Z(I) - Z(A)) \quad [6]$$

for donor impurities, $Z(I) > Z(A)$, or

$$\Delta H_e(I_xA_{1-x}B) = [I](H_C - E_F)(Z(A) - Z(I)) \quad [7]$$

for acceptor impurities, $Z(I) < Z(A)$ and with corresponding formulas for $\Delta H_e(AB_{1-x}I_x)$. In Eq. [6] and [7], $E_F - H_V$ and $H_C - E_F$ denote the enthalpy differences between the Fermi level and the valence and conduction bands, respectively. In obtaining Eq. [6] and [7], it was assumed (4) that, under the conditions for which equilibrium is obtained while growing the crystal, the dominate ionization state of the impurity had charge $-e(Z(I) - Z(A))$. Thus, the distribution coefficients calculated in this way were those of the fully ionized species; if the neutral state is the dominate species during growth, then $\Delta H(I_xA_{1-x}B)$ will not contain this contribution and the distribution coefficient for the neutral species would be calculated (4).

Because the nearest neighbor antistructure pair $B_AA_B^x$ is neutral within the unit cell, it clearly should be treated as a neutral complex with the corresponding $\Delta H_e = 0$. Thus, for the dielectric two-band model

$$\Delta H(B_AA_B^x) = \lim_{x\to 0}((\Delta H_0(B_xA_{1-x}B) + \Delta H_0(AB_{1-x}A_x))/x) \quad [8]$$

Comparing the value calculated with Eq. [8] with those of Pauling's theory, Eq. [4], in Table I, we see that there are significant differences in the estimates for several compounds, but general agreement as to the over-all magnitude of $\Delta H(B_AA_B^x)$. For SiC, all the III-V's except GaN, and several II-VI's, both estimates of $\Delta H(B_AA_B^x)$ are substantially less than the Schottky constant enthalpy for vacancy pairs or even the virtual-enthalpy of single vacancy formation (19, 20). Therefore, both theories predict that the antistructure pair will be the most common native defect in stoichiometric material.

One may ask if there is any viable theory which predicts substantially larger values for $\Delta H(B_AA_B^x)$ in these materials. The answer seems to be no. The theory of Stringfellow (5, 6) makes the same separation as that at Eq. [5] for the separation of the excess heat of mixing into one contribution, ΔH_e, due to the excess or deficit of electrons provided by I and one other contribution, ΔH_0, due to other effects. Stringfellow treats ΔH_e, in effectively the same manner as Ref. (4) so his $\Delta H_e = 0$ for $B_AA_B^x$ also. Rather than calculating the optical spectrum of the alloy and deducing ΔH_0 therefrom, Stringfellow estimates this contribution from the lattice strain resulting from the difference in covalent radius between I and the atom it replaces. (He uses Pauling's table of tetrahedral covalent radii.) Under those assumptions the estimates of $\Delta H(B_AA_B^x)$ are much less than either of those in Table I. For example, one obtains $\Delta H(As_{Ga}Ga_{As}^x) = 0.008$ eV and $\Delta H(C_{Si}Si_C) = 0.16$. As such values are implausibly small, one concludes that Stringfellow's treatment should be restricted to pseudobinary alloys and single donor or acceptors, as he has done (6, 7).

Weiser also separated the excess heat of mixing into two contributions (3), ΔH_s and ΔH_b. The term ΔH_s is a lattice strain term of the same general magnitude as Stringfellow's ΔH_0, although it is calculated differently. The term ΔH_b resulted from the difference between the unstrained bond energies of A-B bonds and either I-B or B-I bonds. Thus, when applied to the antistructure pairs, this term should be the heat of formation of the A-B bonds, just as with Pauling's theory, Eq. [4]. Therefore, Weiser's theory yields values only slightly larger than those listed for Pauling in Table I.

Having concluded that all reasonable estimates of $\Delta H(B_AA_B^x)$ are small, let us take the case of GaAs, for which both the dielectric theory and Pauling's theory agree that $\Delta H(As_{Ga}Ga_{As}^x) \simeq 0.70$ eV, and consider the experimental evidence. If we assume that

$$\Delta S(B_AA_B^x) = 0 \quad [9]$$

then the equilibrium concentration of these antistructure defects would be $2 \times 10^{19}/cm^3$ at 1100°K and 2×10^{15} at 500°K. However, because they are neutral within the unit cell, they should not be prominent in the luminescence or absorption spectra and will not effect the carrier concentration. It seems that the first report and tentative identification of a concentration, $[As_{Ga}Ga_{As}] \approx 5 \times 10^{19}/cm^3$, was made by Goldstein and Almeleh in 1963 on the basis of electron paramagnetic resonance (EPR) studies (12). Blanc, Bube, and Weisberg made a very good case for this identification and magnitude of concentration with a series of thermally stimulated current, photo- and dark-Hall effect, thermal conductivity, absolute density, and lattice constant experiments in 1964 (13). Furthermore, it is observed that the mobility of high resistivity GaAs is about an order of magnitude less than can be accounted from analysis (21, 22) of the known impurity concentrations and the band structure, which is firmly established. The $As_{Ga}Ga_{As}^x$ defect should be expected to have a small cross section for electron scattering so that $[As_{Ga}Ga_{As}^x] \approx 2 \times 10^{19}/cm^3$ would easily account for this discrepancy. Indeed, the theory of van Roosbroeck and Casey for transport in the relaxation regime (23) requires a large concentration of neutral defects to successfully account for observations on high resistivity GaAs (23, 24).

Because the masses of Ga and As are so similar, one should not expect $As_{Ga}Ga_{As}^x$ to produce a local phonon mode, which would be observed in the infrared spectrum. However, for GaP one would expect $P_{Ga}Ga_P^x$ to produce three local modes, one about 24 cm^{-1} above the optic modes and two in the gap between optic and acoustic modes (25). The infrared spectrum of GaP contains several such features which have never been firmly identified.

Isolated Antisite Defects

One would expect the isolated antisite defects B_A and A_B to act as donors and acceptors, respectively. While they might be fairly deep in SiC, in III-V and II-VI compounds they will probably be multiply ionizable with the first level comparable with the effective mass value. Therefore, in intrinsic GaAs the dominant charge states of the isolated antisite defects are most likely As^{+2} and Ga^{-2}.

The neutral antistructure pair $As_{Ga}Ga_{As}^{x}$, which was discussed in the previous section, may be thought of as the nearest neighbor bound pair of As_{Ga}^{+2} and Ga_{As}^{-2}. The binding energy of such a pair, ΔH_{BA} as defined by the reaction $B_A^{+\Delta Z} + A_B^{-\Delta Z} = B_AA_B^{x}$, ΔH_{BA}, where $\Delta Z = Z(B) - Z(A)$, might be approximated as the electrostatic energy of the ions on the unperturbed lattice

$$\Delta H_{BA} = -\Delta Z^2 e^2/r_0 \tilde{\epsilon}(r_0) \quad [10]$$

where e is the charge of the electron, r_0 is the normal bond length (nearest neighbor distance), and $\tilde{\epsilon}(r_0)$ is value of the spacial dielectric function at r_0. Calculations of $\tilde{\epsilon}(r)$ find that it is approaching the optical dielectric constant (the square of the index of refraction), $\epsilon(\infty)$, as r approaches the normal bond length, r_0, but its value is changing rapidly with r at this point (26, 27). Therefore, although $4e^2/r\epsilon(\infty) = 2.2$ eV for GaAs would be a firm lower limit for the magnitude of $-\Delta H_{BA}$, substantially larger values are also quite plausible.

Because of the uncertainty involved in the evaluation of Eq. [10], as well as the question of the adequacy of the approximation that there is no lattice distortion or central cell correction, it seems wise to continue to rely on the theory for substitutional impurities which was found successful in predicting alloy phase diagrams and distribution coefficients (4-6). According to the theories of Stringfellow and of Van Vechten

$$-\Delta H_{BA} = \Delta H_e(B_A^{+\Delta Z}) + \Delta H_e(A_B^{-\Delta Z}) \quad [11]$$

where $\Delta H_e(B_A^{+\Delta Z})$ and $\Delta H_e(A_B^{-\Delta Z})$ are just the electronic contributions to the excess heat of mixing, Eq. [6] and [7], per defect

$$\Delta H_e(B_A^{+\Delta Z}) = \Delta Z(E_F - H_v) \quad [12]$$

$$\Delta H_e(A_B^{-\Delta Z}) = \Delta Z(H_c - E_F) \quad [13]$$

(It appears that the quantities ΔH_e in Eq. [12] and [13] are contributions to the virtual-enthalpies of the corresponding structural units rather than to true enthalpies defined by true chemical potentials. However, as shown by Kröger, Stieltjes, and Vink, this procedure is both permissible and convenient as long as they are always used in combinations corresponding to real processes (28)[2].) With. Eq. [12] and [13], Eq. [11] reduces to

$$-\Delta H_{BA} = \Delta Z H_{cv} \quad [14]$$

where H_{cv} is the enthalpy of the forbidden bandgap at the appropriate temperature. For GaAs at high temperatures, one estimates $-\Delta H_{AsGa}(As_{Ga}Ga_{As}) = 3.0$ eV in this way as compared with 2.2 eV obtained by using $\epsilon(\infty)$ for $\tilde{\epsilon}(r)$ in Eq. [10].

Now the total virtual-enthalpy of an isolated antisite defect will be

$$\Delta H(B_A^{+\Delta Z}) = \Delta H_0(B_A) + \Delta H_e(B_A^{+\Delta Z})$$

$$\Delta H(A_B^{-\Delta Z}) = \Delta H_0(A_B) + \Delta H_e(A_B^{-\Delta Z}) \quad [15]$$

Because ΔH_e is generally much larger than ΔH_0, one predicts that antistructure pairs, B_AA_B, will be much more numerous than either isolated defect B_A or A_B in stoichiometric material.

[2] Note that real values have been measured for the virtual-enthalpies in several virtual reactions in some alkali-halide and silver-halide crystals. See Ref. (29-31).

The values of $\Delta H_0(B_A)$ and $\Delta H_0(A_B)$ calculated with the dielectric two-band model are given in Table II. In order to obtain ΔH_e, one must know ΔH_{cv} and E_F. The value of ΔH_{cv} at T_h, the temperature of the equilibration, may be deduced from the values (9) of the forbidden bandgap at $T = 0$, $\Delta E_{cv}(0)$, and the variation with temperature of this free energy (32, 33). The value of E_F must be deduced from the condition of neutrality and by considering the ionization of all species present.

Comparison with Experiment

One will note in Table II that the virtual-enthalpy to place an atom on the site of a larger atom is found to be less than the virtual-enthalpy to place the larger atom on the site of the smaller atom. Thus, $\Delta H_0(S_{Zn}) < \Delta H_0(Zn_S)$ and $\Delta H_0(Te_{Zn}) > \Delta H_0(Zn_{Te})$, for example. Because S_{Zn} and Te_{Zn} are donors while Zn_S and Zn_{Te} are acceptors, this effect will produce a tendency toward n-type conductivity in cases for which $r_c(A) > r_c(B)$ and toward p-type conductivity in case for which $r_c(A) < r_c(B)$. (Here, r_c is the tetrahedral covalent radius.) It is shown in the accompanying paper (20) that the virtual-enthalpies of single vacancy formation produce the same tendency to correlate anion to cation radius ratio with normal (undoped) conductivity type and that, if the Van Vechten-Phillips table of tetrahedral covalent radii (34) is used, the agreement with experiment is exact.

However, one may distinguish the effect of differences between $\Delta H(V_A^-)$ and $\Delta H(V_B^+)$ from those resulting from a difference between $\Delta H(B_A^+)$ and $\Delta H(A_B^-)$ if one can determine the deviation from stoichiometry at the maximum of the solidus. For example, in normal, n-type GaP and ZnO, the material is found to be deficient in P and O respectively (15, 35) so that V_P^+ and V_O^+ must be more numerous than P_{Ga}^{+2} and O_{Zn}^{+4}. On the other hand, for normal, p-type GaSb, the material is found to be deficient in Sb so that Ga_{Sb}^{-2} must be more numerous than V_{Ga}^- (10, 11). By comparing Eq. [15] and Table II with the values of $\Delta H(V_A)$ and $\Delta H(V_B)$ given in Table II of the accompanying paper (20), we see that these three empirical conclusions are in agreement with the predictions of the present theory because under intrinsic growth conditions: for ZnO, $\Delta H(V_O^x) = 3.0$ eV $< \Delta H(O_{Zn}^{+4}) \simeq 13.8$ eV; for GaP, $\Delta H(V_P^x) = 2.6$ eV $< \Delta H(P_{Ga}^{-2}) = 2.9$ eV; for GaSb, $\Delta H(V_{Ga}^x) = 2.0$ eV $> \Delta H(Ge_{Sb}^{-2}) = 0.9$ eV.[3] In general, the theory predicts that vacancies will be more important in wide bandgap semiconductors and isolated antisite defects will be more important in small bandgap semiconductors.

In order to compare theory and experiment quantitatively, let us consider the particular case of GaP. The virtual-enthalpies of neutral vacancy formation are given in Table II of Ref. (20) as

$$O = V_{Ga}^x;\ \Delta H(V_{Ga}^x) = 2.98\ \text{eV}$$

$$O = V_P^x;\ \Delta H(V_P^x) = 2.64\ \text{eV} \quad [16]$$

[3] In general, $\Delta H(V^x)$ is greater than the relevant enthalpy, that of the ionized vacancy, but, as values for the enthalpy of ionization are lacking, the point can be made with $\Delta H(V^x)$.

These may be combined with the virtual-enthalpies in the present Table II

$$\Delta H(\text{Ga}_\text{P}^{-2}) = 0.38 \text{ eV} + 2(H_c - E_F) \cong 2.9 \text{ eV} \quad [17]$$

for $E_F - H_v = H_c - E_F \cong 1.25$ eV under intrinsic growth conditions, and similarly

$$\Delta H(\text{P}_\text{Ga}^{+2}) = 0.68 \text{ eV} + 2(E_F - H_V) \cong 3.2 \quad [18]$$

With these one can estimate the real enthalpies of the real reactions

$$\text{P}_\text{P}^x + \text{V}_\text{Ga}^x = \text{P}_\text{Ga}^{+2} + \text{V}_\text{P}^x + 2e^-; \quad \Delta H = 0.44 \text{ eV} + 2\,\Delta H_{cv} \quad [19]$$

where the e^-'s are taken to be in the conduction band, and

$$\text{Ga}_\text{Ga}^x + \text{V}_\text{P}^x = \text{Ga}_\text{P}^{-2} + \text{V}_\text{Ga}^x + 2e^+; \quad \Delta H = 0.72 \text{ eV} + 2\,\Delta H_{cv} \quad [20]$$

However, in order to estimate the solidus curve of GaP (14, 15), it is necessary to determine the virtual-enthalpies of the virtual processes

$$\text{Ga(l)} = \text{Ga}_\text{Ga}; \; \Delta H_f^0(\text{Ga,GaP}) \quad [21]$$

$$\text{P(l)} = \text{P}_\text{P}; \; \Delta H_f^0(\text{P,GaP}) \quad [22]$$

where Ga(l) and P(l) denote the pure, elemental (liquid) Ga and P at the same temperature, T_h, as the sample. Of course, the enthalpy of formation of GaP at T_h, $\Delta H_f^0(\text{GaP})$ is a real enthalpy related to Eq. [21] and [22] by

$$\Delta H_f^0(\text{GaP}) = \Delta H_f^0(\text{Ga,GaP}) + H_f^0(\text{P,GaP}) \quad [23]$$

By combining Eq. [21] and [22] with Eq. [16], we may complete defect incorporation equations

$$\text{Ga(l)} = \text{Ga}_\text{Ga} + \text{V}_\text{P}^x; \; \Delta H(\text{V}_\text{P}^x) + \Delta H_f^0(\text{Ga,GaP}) \quad [24]$$

$$\text{P(l)} = \text{V}_\text{Ga}^x + \text{P}_\text{P}; \; \Delta H(\text{V}_\text{Ga}^x) + \Delta H_f^0(\text{P,GaP}) \quad [25]$$

$$\text{Ga(l)} = \text{V}_\text{Ga}^x + \text{Ga}_\text{P}^{-2} + 2e^+; \; \Delta H(\text{V}_\text{Ga}^x) + \Delta H_f^0(\text{Ga,GaP}) + \Delta H(\text{Ga}_\text{P}^{-2}) + 2H(e^+) \quad [26]$$

$$\text{P(l)} = \text{P}_\text{Ga}^{+2} + \text{V}_\text{P}^x + 2e^-; \; \Delta H(\text{V}_\text{P}^x) + \Delta H_f^0(\text{P,GaP}) + \Delta H(\text{P}_\text{Ga}^{+2}) + 2H(e^-) \quad [27]$$

In [26] and [27] the enthalpy per carrier would be $H(e^+) = E_F - H_v$ and $H(e^-) = H_c - E_F$ if the carriers are taken to be in the bands.

In order to determine the values of $\Delta H_f^0(\text{Ga,GaP})$ and $\Delta H_f^0(\text{P,GaP})$ for a given set of equilibrium conditions, *i.e.*, to apportion $\Delta H_f^0(\text{GaP})$ between the anion and cation lattice sites, let us consider the process by which one atom of Ga and one atom of P are removed from the pure elements to infinity and then placed on the proper lattice sites of the crystal. As is well known, the partial pressures of the elemental vapors over their pure liquids, $p(\text{Ga}^0)$ and $p(\text{P}^0)$, are related to the enthalpy and entropy of vaporization, ΔH_v and ΔS_v, as

$$\ln(p_\text{Ga}^0/p_r) = -\Delta H_v(\text{Ga}^0)/kT_h + \Delta S_v(\text{Ga}^0)/k \quad [28]$$

$$\ln(p_\text{P}^0/p_r) = -\Delta H_v(\text{P}^0)/kT_h + \Delta S_v(\text{P}^0)/k \quad [29]$$

where p_r is a reference pressure and the superscript zero denotes the pure element. Let us simply extend these formulas to the partial pressures and single adsorption reactions over the stoichiometric liquid

$$\ln(p_\text{Ga}^{\text{GaP}^l}/p_r) = -\Delta H_v(\text{Ga}^{\text{GaP}^l})/kT_h + \Delta S_v(\text{Ga}^\text{GaP})/k \quad [30]$$

$$\ln(p_\text{P}^{\text{GaP}^l}/p_r) = -\Delta H_v(\text{P}^{\text{GaP}^l})/kT_h + \Delta S_v(\text{P}^\text{GaP})/k \quad [31]$$

Thus subtracting [28] from [30] and [29] from [31]

$$kT_h \ln(p_\text{Ga}^{\text{GaP}^l}/p_\text{Ga}^0) = \Delta H_v(\text{Ga}^0) - \Delta H_v(\text{Ga}^{\text{GaP}^l}) - T_h(\Delta S_v(\text{Ga}^0) - \Delta S_v(\text{Ga}^{\text{GaP}^l})) \quad [32]$$

$$kT_h \ln(p_\text{P}^{\text{GaP}^l}/p_\text{P}^0) = \Delta H_v(\text{P}^0) - \Delta H_v(\text{P}^{\text{GaP}^l}) - T_h(\Delta S_v(\text{P}^0) - \Delta S_v(\text{P}^{\text{GaP}^l})) \quad [33]$$

Obviously the sum of [32] and [33] must be the free energy of formation of liquid GaP, $\Delta H_f^0(\text{GaP}^l) - T_h\Delta S_f^0(\text{GaP}^l)$, because this combination of these virtual processes is the formation process. Now, in the practical experiment (14, 15) one has the GaP crystal in contact with a Ga-P liquid of variable composition and the vapors are in contact with this liquid. Thus, the prevailing partial pressures vary with the liquid composition primarily because of the entropy factor in the liquid chemical potentials. Therefore, in order to make a meaningful separation of $\Delta H_f^0(\text{GaP})$ and $\Delta S_f^0(\text{GaP})$ for the crystal, we postulate that the apportionment of ΔH_f^0 for the crystal is the same as that of the stoichiometric liquid. Then, we may reduce Eq. [32] and [33] to

$$\Delta H_f^0(\text{Ga,GaP})/\Delta H_f^0(\text{P,GaP}) = \ln(p_\text{Ga}^0/p_\text{Ga}^\text{GaP})/\ln(p_\text{P}^0/p_\text{P}^\text{GaP}) = \ln(a^l(\text{Ga},x_\text{P} = 0.5))/\ln(a^l(\text{P},x_\text{P} = 0.5)) \quad [34]$$

where $a^l(\text{Ga},x_\text{P} = 0.5)$ and $a^l(\text{P},x_\text{P} = 0.5)$ are the activities of Ga and P in this liquid. The formula to separate ΔS_f^0 is entirely analogous. [As usual, for Ga

$$a^l(\text{Ga}) = x^l(\text{Ga})\gamma^l(\text{Ga}) \quad [35]$$

where $x^l(\text{Ga})$ is the atom fraction of Ga in the liquid and $\gamma^l(\text{Ga})$ is its activity coefficient, and the corresponding equation holds for P.]

Let us accept Thurmond's evaluation of the activity coefficients throughout the Ga-P liquid system (36) and Jordan *et al.*'s (14) values $\Delta H_f^0(\text{GaP}) = -1.34$ eV and $\Delta S_f^0 = -7.19$k at $T_h \approx 1400°$C. At the 50-50 liquid composition Thurmond found $\gamma^l(\text{Ga}) = 0.68$ and $\gamma^l(\text{P}) = 1.00$ so that $a(\text{Ga}) = 0.34$ and $a(\text{P}) = 0.50$. Thus, from Eq. [34] we conclude

$$\Delta H_f^0(\text{Ga,GaP}) = -0.82 \text{ eV}, \; \Delta S_f^0(\text{Ga,GaP}) = -4.38\text{k} \quad [36]$$

$$\Delta H_f^0(\text{P,GaP}) = -0.52 \text{ eV}, \; \Delta S_f^0(\text{P,GaP}) = -2.81\text{k} \quad [37]$$

In order to estimate the entropy of the real reactions [24]-[27], it is assumed that the virtual entropies of both V_Ga^x and V_P^x, Eq. [16], are the same as the best estimates (37, 38) of $\Delta S(\text{V}_\text{Si}^x)$ and $\Delta S(\text{V}_\text{Ge}^x)$

$$\Delta S(\text{V}_\text{Ga}^x) = \Delta S(\text{V}_\text{P}^x) = k \ln 3 = 1.10\text{k} \quad [38]$$

This value corresponds to an assumption that the Jahn-Teller distortion about V_Ga^x and V_P^x is 3-fold degenerate, as it is for V_Si^x, and that any contribution to $\Delta S(\text{V}^x)$ due to a shift in lattice mode frequencies (37-39) is negligible. The latter point is supported by recent infrared and Raman studies of lattice modes in defect zinc-blende structure crystals like In_2Te_3 (40). The entropy of the fully ionized antisite defect will be taken to be

$$\Delta S(\text{B}_\text{A}^{+\Delta Z}) = \Delta S(\text{A}_\text{B}^{-\Delta Z}) = \Delta Z \Delta S_{cv}(\text{AB}) \quad [39]$$

where ΔS_{cv} is the entropy of the forbidden gap corresponding to the enthalpy ΔH_{cv} (33). Thus, the entropy of the antisite defect is treated in exact analogy to the treatment of its enthalpy at Eq. [15] and as previously assumed by Stringfellow and by Van Vechten (4-6). For GaP one finds (32-33)

$$\Delta S(\text{P}_\text{Ga}^{+2}) = \Delta S(\text{Ga}_\text{P}^{-2}) = 2\Delta S_{cv}(\text{GaP}) = 12.9\text{k} \quad [40]$$

Therefore, we calculate the enthalpies and entropies of the real reactions [24]-[27] to be

$$\text{Ga(l)} = \text{Ga}_\text{Ga} + \text{V}_\text{P}^x; \; \Delta H = 1.8 \text{ eV} \; \; \Delta S = -3.3\text{k} \quad [41]$$

$$\text{P(l)} = \text{V}_\text{Ga}^x + \text{P}_\text{P}; \; \Delta H = 2.5 \text{ eV} \; \; \Delta S = -1.7\text{k} \quad [42]$$

$$\text{Ga(l)} = \text{V}_\text{Ga}^x + \text{Ga}_\text{P}^{-2} + 2e^+; \; \Delta H = 2.5 \text{ eV} + 2\Delta H_{cv}, \; \Delta S = 9.6\text{k} \quad [43]$$

$$P(l) = P_{Ga}^{+2} + V_P^x + 2e^-;$$

$$\Delta H = 2.8\text{ eV} + 2\Delta H_{cv},\quad \Delta S = 11.2k \quad [44]$$

The above reactions are not adequate to describe the data obtained by measuring the deviations from stoichiometry (14, 15). Indeed, one should not expect them to be adequate because it seems unlikely that the vacancies are predominately in their neutral state during the growth process. Consideration of both the enthalpy and the entropy of ionization argue for this point. It is known that vacancies in Si and Ge have both acceptor and donor states within the gap (38, 41). Near $T = 0°K$ these levels are deeper than half the gap and, for Si, the values are established within about 0.2 eV; expressing the ionization enthalpy, $\Delta H_I(V_{Si})$, in terms of ΔH_{cv} (38-41)

$$\Delta H_I(V_{Si}^-) = 0.52\,\Delta H_{cv};\quad \Delta H_I(V_{Si}^{-2}) = 0.9\,\Delta H_{cv};$$

$$\Delta H_I(V_{Si}^+) = 0.7\,\Delta H_{cv} \quad [45]$$

Therefore, if E_F is at midgap near $T = 0°K$, the predominate charge state is V_{Si}^x. However, at high temperatures at least one charged state is more numerous than V_{Si}^x for any value of E_F (38). This is evidenced by numerous charge state effects in impurity diffusion and defect annealing experiments (42-44). This results from the entropy of ionization, $\Delta S_I(V_{Si})$, which causes the free energy of the levels to vary with temperature so that they become progressively shallower and actually cross at about 800°K; to a good approximation

$$\Delta S_I(V^-) = \Delta S_I(V^{-2}) = \Delta S_I(V^+) = \Delta S_{cv} \quad [46]$$

for Si and Ge (38) and should also hold for $V_A^x = V_A^- + e^+$ and $V_B^x = V_B^+ + e^-$ in the AB semiconductors.

Although, for reasons to be discussed, it is difficult to identify and measure the vacancy ionization levels in most III-V crystals, including GaP, various levels have been measured in several II-VI's especially CdS (45-47). In CdS the two V_S donor levels are rather shallower than the two V_{Cd} acceptor levels

$$\Delta H_I(V_S^+) = 0.07\,\Delta H_{cv};\quad \Delta H_I(V_S^{+2}) = 0.10\,\Delta H_{cv}$$

$$\Delta H_I(V_{Cd}^-) \approx 0.2\,\Delta H_{cv};\quad \Delta H_I(V_{Cd}^{-2}) \approx 0.7\,\Delta H_{cv} \quad [47]$$

Comparing Eq. [47] with [45] it is evident that the values of ΔH_I, relative to ΔH_{cv}, decrease with increasing ionicity of the materials considered and seem to show an asymmetry between V_A and V_B, which may be related to the sizes of the atoms (48). Because P, like S, is smaller than the cation, one may expect the decrease in the ΔH_I's for V_P^+ to be greater than for V_{Ga}^-. However, in the absence of such size effects, one would expect the acceptor states to be shallower than the donor states, as in Si, because vacancies increase the number of lattice sites and thus the number of band states without increasing the number of electrons. In view of the above, the author's present best guess is[4]

$$\Delta H_I(V_{Ga}^-) = 0.2\,\Delta H_{cv},\quad \Delta H_I(V_P^+) = 0.2\,\Delta H_{cv} \quad [48]$$

with $\Delta H_I(V_{Ga}^{-2})$ and $\Delta H_I(V_P^{+2})$ equal to or greater than ΔH_{cv}.

In Fig. 1 we see the existence curve for GaP calculated with the thermodynamic parameters for both vacancies and antisite defects[5] compared with experiment (14). It is noted that this nonadjusted curve is substantially narrower than the experimental data indicate. However if the assumed values for $\Delta H(V_{Ga}^x)$ and $\Delta H(V_P^x)$ are each reduced by 10%, so that Eq. [41] and [42] become

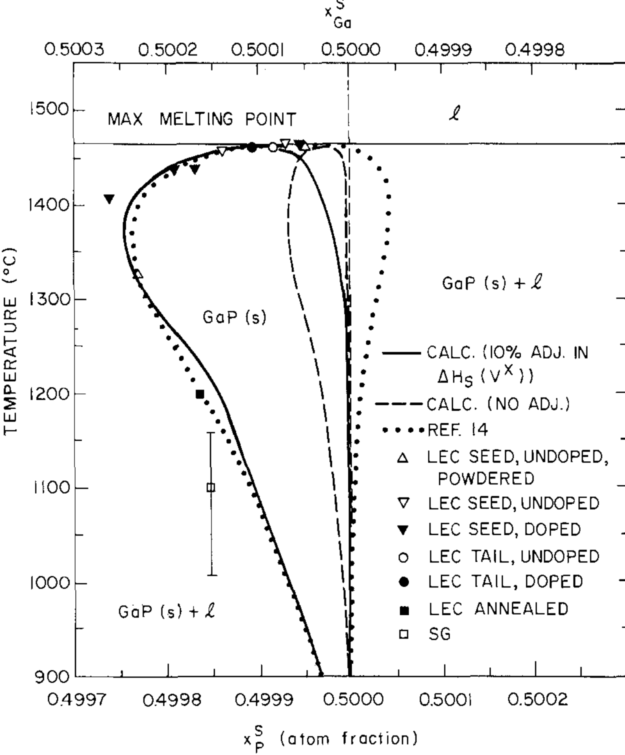

Fig. 1. The existence curve of GaP as calculated and according to the data of Jordan *et al.* (14). LEC and SG denote the data points of samples grown by liquid-encapsulation Czochralski and solution methods. The dotted curve was obtained in Ref. (14) by assuming that only simple, neutral vacancies are present and fitting the resulting four parameters to the data. It is noted that the Schottky entropy thus inferred is implausibly large. The dashed curve is calculated from theory considering vacancies and antisite defects in several ionization states without any adjustment except a reasonable estimate of the defect ionization levels. The full curve results from adjusting only the calculated virtual enthalpies of neutral vacancy form by 10% in accord with empirical results for Si, Ge, and CdS and with the expected theoretical overestimate noted in Ref. (20).

$$Ga(l) = Ga_{Ga} + V_P^x;\ \Delta H = 1.5\text{ eV},\ \Delta S = -3.3k \quad [41a]$$

$$P(l) = V_{Ga}^x + P_P;\ \Delta H = 2.2\text{ eV},\ \Delta S = -1.7k \quad [42a]$$

while the parameters of the antisite defects remain unchanged, then an excellent fit to the data is obtained. (The parameters and results of this existence curve are listed in Table III). We recall that it was necessary to reduce the values of $\Delta H(V_{Si}^x)$ and $\Delta H(V_{Ge}^x)$ by 10% and those of V_{Cd} and V_S in CdS by 12% in order to attain agreement with experiment and that this order of an overestimate should be expected of the macroscopic cavity model (20, 38).

The fit to experiment obtained with this choice of parameters is certainly not unique. One could invoke V_{Ga}^{-2} and V_P^{+2} and vary the antistructure and neutral vacancy parameters in a number of ways to obtain curves that fit the data within experimental accuracy. Indeed, Jordan *et al.* obtained (14) the dotted curve in Fig. 1 by assuming that the only defects present were neutral vacancies and fitting the parameters to the data. The Schottky enthalpy and entropy that they inferred in this way were $\Delta H_S(GaP) = 3.84$ eV and $\Delta S_S(GaP) = 10.1k$ as contrasted with the present (adjusted) estimates, $\Delta H_S(GaP) = 5.06$ eV, $\Delta S_S(GaP) = 2.2k$. While it may be argued that Jordan *et al.*'s estimate of $\Delta H_S(GaP)$ is plausible, their estimate of ΔS

[4] The only way to obtain a detectable concentration of simple, single vacancies at low temperature from which the ΔH_I's could be determined is by electron irradiation at liquid nitrogen temperatures or below. Such experiments, Esposito and Loferski (49), show that the vacancies produced act as nonradiative recombination centers and do not produce luminescence. One might conclude that they are shallower than the ~1 eV deep luminescence centers which they quench. It seems that photocapacitance measurements immediately after low temperature irradiation will yield the best estimates of $\Delta H_I(V_{Ga^-})$ and $\Delta H_I(V_{P^+})$.

[5] This problem may be treated with an approximate, graphical treatment [Kröger and Vink (50)]. However, because both types of ionized defects may be present in comparable concentrations in the region of interest, a computer program which obtains consistency between the assumed Fermi level and the condition of neutrality by iteration was employed.

* $\Delta^s \equiv (x_{Ga}^s - 0.5)$.

seems to be much too great to be assigned neutral vacancies (37-39) and may be taken as evidence that the defects present are mostly ionized under growth conditions.[6] It would seem that one must assume this in order to understand why the defects are electrically active "shunt-path killer centers" at room temperature.

Defect Reactions as the Crystal Cools

The calculation just described estimates the concentrations of simple defects in equilibrium with the liquid under growth conditions. (See Table III.) These concentrations of defects will not be in equilibrium amongst each other, let alone with the exterior of the crystal, at room temperature. Because the defects will migrate about the sample as the crystal cools, one must expect their concentrations to tend toward a new equilibrium at a lower temperature.

To appreciate the prevalence of defect redistribution processes, let us make the conservative estimate that the enthalpy of single vacancy migration in GaP is about 2.0 eV, as compared with 1.3 and 1.0 eV for Si and Ge (38, 39, 52) and about 1.6 eV for GaAs (53), and let us take the entropy of vacancy migration to be 4.1k, as in Si and Ge (38, 39). Then, taking the jump attempt frequency (approximately the Debye frequency) to be 10^{13}/sec, one estimates the jump rate to be 4×10^7/sec at 1400°K and 5×10^4/sec at 1000°K. As a typical crystal cools from 1050° to 950°K in 600 sec (54), a simple vacancy would pass through more than 10^8 lattice sites in that period. Because, according to the present analysis, most of the vacancies are ionized and the concentration of charged impurities is at least $10^{14}/cm^3$ while the concentrations $[Ga_P^{-2}]$ and $[P_{Ga}^{+2}]$ were typically 10^{18} and $10^{14}/cm^3$ during growth and $[Ga_P^{-2}\,P_{Ga}^{+2}]$ dipolar pairs were $10^{19}/cm^3$, simple vacancies will constantly be encountering other defects with which they may form bound complexes. It seems certain that the internal equilibrium between the various point defects and their complexes is closely maintained down to temperatures well below 1000°K. Therefore, relative concentrations of simple point defects and defect complexes will be governed by the appropriate law of mass action relations down to quite moderate temperatures. At room temperature, almost all the vacancies present should be tied up in complexes.

To determine the ultimate fate of the simple point defects introduced during growth, several types of complexes amongst them should be considered. It seems likely that the most common complexes will be those which have no net charge because these would have the greatest binding energy. In addition to the formation of the nearest neighbor complex

$$V_{Ga}^- + V_P^+ = V_{Ga}^- V_P^+ \quad [49]$$

second neighbor complexes such as

$$2V_P^+ + Ga_P^{-2} = V_P^+\,Ga_P^{-2}\,V_P^+ \quad [50]$$

and

$$2V_{Ga}^- + P_{Ga}^{+2} = V_{Ga}^-\,P_{Ga}^{+2}\,V_{Ga}^- \quad [51]$$

may be important. Indeed, a simple point charge model predicts that the binding energy of reactions [50] and [51] would be 2.02 times that of [49], $e^2/r\epsilon$. Because Ga_P^{-2} is likely to be the most common double acceptor present, Eq. [50] is probably the most important processes trapping V_P^+. The interaction of V_P^+ with a single acceptor impurity, A^-

$$A^- + V_P^+ = A^- V_P^+ \quad [52]$$

should have about the same binding energy as [49] and thus would not be competitive with [50].

Now, the concentrations of positively charged and negatively charged simple point defects introduced during growth are in general, not equal. Therefore, the concentrations of some type of simple point defect would be exhausted as reactions [49]-[52] proceed during the cooling unless other reactions occur which interchange one type of point defect for another. Consider the reactions

$$V_{Ga}^- + P_P = P_{Ga}^{+2} + V_P^+ + 4e^- \quad [53]$$

and

$$Ga_{Ga} + V_P^+ = V_{Ga}^- + Ga_P^{-2} + 4e^+ \quad [54]$$

which will occur every time a vacancy migrates to a nearest neighbor site. Obviously, such reactions act to compensate the sample and prevent the Fermi level from approaching either band edge during the cooling.

It seems most unlikely that the activation energy for [53] and [54] could be so large that they would not occur during cooling at a rate sufficient to prevent $[P_{Ga}^{+2}]$ and $[Ga_P^{-2}]$ from being depleted while $[V_{Ga}^-]$ and $[V_P^+]$ are still large. One may estimate the rate of this process by considering one channel for single vacancy migration

$$Ga_{Ga}V_P^+Ga_{Ga}P_P \rightarrow Ga_{Ga}Ga_P^xV_{Ga}^xP_P$$
$$\rightarrow Ga_{Ga}Ga_P^xP_{Ga}^xV_P^x \rightarrow Ga_{Ga}P_P + Ga_{Ga}V_P^+ \quad [55]$$

(The requisite electronic reactions are assumed to occur instantaneously on the scale of atomic motion and are neglected here.) The activation enthalpy for this process would be

$$\Delta H_m^*(V_P,GaP) = \Delta H_m(V,IV) + \Delta H_O(Ga_P) \approx 2.0 \text{ eV} \quad [56]$$

where the asterisk denotes the specific channel [55] and $\Delta H_m(V,IV)$ denotes the enthalpy of single vacancy migration in a hypothetical group IV elemental crystal equivalent to GaP with respect to the homopolar (covalent) portions of the crystal potential. [Presumably, $\Delta H_m(V,IV) \approx \Delta H_m(V^x,Si) \simeq 1.3$ eV for GaP (52).] This crude estimate corresponds with the value assumed above and also corresponds with Lang and Kimerling's empirical estimate for vacancy migration in GaAs (53). Although the entropy of this channel

[6] In the experiments discussed in Ref. (14) there was no way to determine whether the defects introduced were neutral or ionized but compensated (51).

may be too low for it to dominate the atomic diffusion, it is obviously rapid enough to maintain the equilibrium among $[V_{Ga}^-]$, $[P_{Ga}^{+2}]$, $[V_P^+]$, and $[Ga_P^{-2}]$.

Consequently, one would expect reactions such as [50], [51], [53], and [54] to proceed as the crystal cools until almost all the vacancies that were introduced during growth are tied up in neutral complexes such as V_{Ga}^- P_{Ga}^{+2} V_{Ga}^- and V_P^+ Ga_P^{-2} V_P^+, and perhaps V_{Ga}^- P_{Ga}^{+2} Ga_P^{-2} V_P^+ and more complex species. The tendency of the vacancies and antisite defects to produce such complexes amongst themselves rather than to compensate impurities, *e.g.*, Eq. [52], would explain the relative insensitivity of room temperature carrier concentration to deviations from stoichiometry (14) as well as the propensity of such deviations to produce electrically active "shunt path killer centers."

Summary

It has been shown that all viable theories (3-6, 16) which may be applied to predict the concentrations of antistructure pairs, $B_AA_B^x$, and of antisite defects, B_A^+ and A_B^-, imply that these should be significant in zincblende and wurtzite semiconductors. It is concluded that a proper account of the antisite defects is crucial to an understanding of the properties of III-V semiconductors. The theoretical estimates of the dielectric two-band model (7-9) for antisite defects have been combined with those of the macroscopic cavity model for vacancies (20) to show that the available data on the existence curve and electrical properties of GaP can be successfully accounted for with physically and chemically reasonable parameters by taking account of the interaction between these defects.

Acknowledgment

The author is pleased to acknowledge the advice and encouragement of Dr. C. D. Thurmond.

Note added in proof: The vacancy-antisite defect complex $V_{Ga}^-P_{Ga}^{+2}V_{Ga}^-$ proposed above as the "shunt path killer center" in GaP would constitute a cylindrical defect oriented in a <110> direction one atom in diameter and having a length corresponding to 3 second nearest neighbor sites, i.e., $3a/\sqrt{2}$, where a is the usual lattice constant. It appears that such defects have been observed directly in LEC GaAs by a direct lattice imaging electron microscopy technique (55).

Epitaxial Growth by Solid-State Diffusion

T. Gabor and G. H. Dierssen*

3M Company, St. Paul, Minnesota 55133

ABSTRACT

It was demonstrated that CdS can be grown epitaxially by exposing opposite faces of a CdS wafer to cadmium and sulfur vapors, respectively, and thus causing countercurrent diffusion of the cadmium and sulfur to the opposite faces where they form CdS by reaction with the vapor. The effects of substituting zinc for the cadmium vapor, and in another experiment selenium for the sulfur vapor, were also investigated. In the two-component system, good quality single crystal was obtained while in the three-component system void formation was prevalent.

In conventional crystal growth the reactants are brought to the substrate either in a gas or in a liquid phase. Some disadvantages inherent in this approach may be overcome by bringing the reactants to the surface by solid-state diffusion through the substrate itself. One can visualize the driving force being a temperature gradient and/or concentration gradients. Due to the widespread interest in CdS and to its ready availability in single crystalline form, this compound was selected as a model crystal for the experiments; cadmium and sulfur were diffused countercurrently through CdS. The above-described growth by countercurrent diffusion was also combined with exchange reactions. In one experiment zinc was substituted for the cadmium, and in another selenium for the sulfur, thus leading to the CdS → ZnS and CdS → CdSe reactions.

Experimental

The substrates were obtained by wafering a 19 mm diameter cylinder of CdS. To allow optimum utilization with the given shape of the boule, the axis of the cylinder was selected to coincide with the <$10\bar{1}3$> direction. After etching in concentrated HCl for 4 min, the final thickness was 1.4-1.6 mm. On some of the wafers, circular-shaped tantalum markers were deposited by sputtering. The wafers were placed, as shown in Fig. 1, sandwiched between two reservoirs; one containing the Group II, the other the Group VI element.

To decrease the rate of vapor transport of the substrate CdS components to the cool ends, the cross-sections of the reservoirs were decreased by sealing capillary tubes with an about 0.5 mm diameter bore into the neck of each reservoir.

Evacuation was performed at room temperature and the ampules were sealed at 10-45 μm.

A typical temperature profile is shown in Fig. 1. The experimental conditions and thermodynamic data are listed in Table I. The temperature range as recorded over the reservoirs (columns 3 and 6), and the corresponding vapor pressures of the elements (columns 4 and 7) calculated by the formulas of Shiozawa and Jost (1) are listed. Table I also lists the substrate temperature (column 8), the corresponding equilibrium constants (column 9), and the duration of the experiments (column 11). Columns 10, 12, and 13 are discussed below.

Inspection of the system after cooling to room temperature revealed that in all cases a tight seal formed between the substrate and the metal reservoir. However, the chalcogen reservoir was never altogether tight and some sulfur or selenium was found after the experiments between the reservoirs and the outer tube at the cold ends. However, sufficient chalcogen remained in the reservoir throughout the experiments to insure the desired chalcogen vapor pressure.

Results

Some characteristics of the specimens are collected in Table II, while further details are given in the following.

In experiment I, the section of the wafer between the two reservoirs became curved, the cadmium-exposed face being convex and the sulfur-exposed face concave. The data given in columns 2 and 3 of Table II were obtained by measuring the curvature with a traveling microscope along four parallel lines on the polished cross section. The measurements showed that the thickness within the reservoir varied from 1.7 to 1.9 mm, while the original wafer was 1.61 mm thick. The wafer outside the reservoirs retained its original thickness. Reflection x-ray diffraction indicated plastic deformation with a maximum angle of 7°.

In experiment II both the substrate temperature and the sulfur pressure were lowered. Under these conditions, the plane-parallelity of the wafer was retained. One segment of the cadmium exposed surface after experiment II is shown in Fig. 2. The rough surface on

the left is where a tantalum marker was deposited. Both the smooth surface on the right and the rectangular crystallites within the tantalum-marked area are 8 μm higher. The sulfur-exposed face was 0.1 mm lower than the ring which was in contact with the reservoir wall.

In experiment III one side of the wafer was exposed to zinc instead of cadmium vapor. This led to a considerable change in the shape of the specimen. The faces within the reservoirs were relatively flat, but they advanced 0.04 mm into the zinc reservoir and 0.19 mm into the sulfur reservoir. This latter growth is visible at the top right of the polished cross section shown in Fig. 3a and at a higher magnification in Fig. 4. To reveal different characteristics, the two micrographs of Fig. 3 were taken with varying angles of reflected light. The two traces of the planar surfaces on each side of the wafer indicate areas where the original geometry of the wafer was retained due to contact with the reservoir walls. The volume of the wafer outside the reservoirs (below the vertical traces in the micrographs) increased considerably, growing from the original 1.53 mm thickness to a maximum of 1.93 mm. The position of the reservoirs was not centered, hence the different levels at which the straight traces on the opposite faces are found.

As indicated by the white color, most of the specimen was transformed into ZnS. There remained a weak yellow tinge on the face exposed to the sulfur reservoir. This layer was too thin to be revealed in the cross section. However, significant amounts of single-crystalline CdS were present in a narrow layer along the faces of the wafer outside the reservoirs, and the

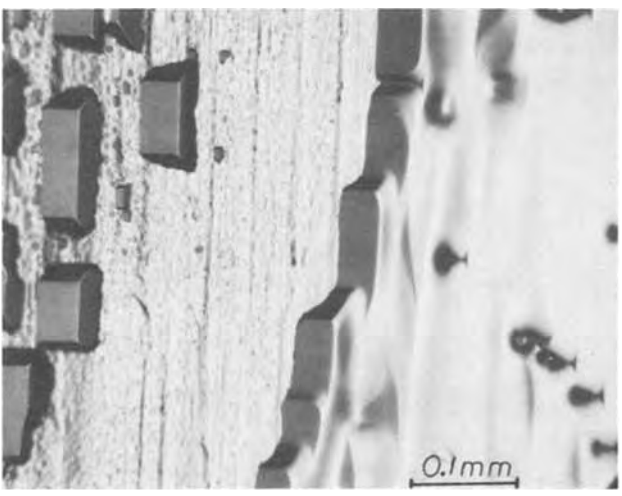

Fig. 2. Smooth surface (right) and tantalum-marked area (left) on cadmium-exposed face after experiment II.

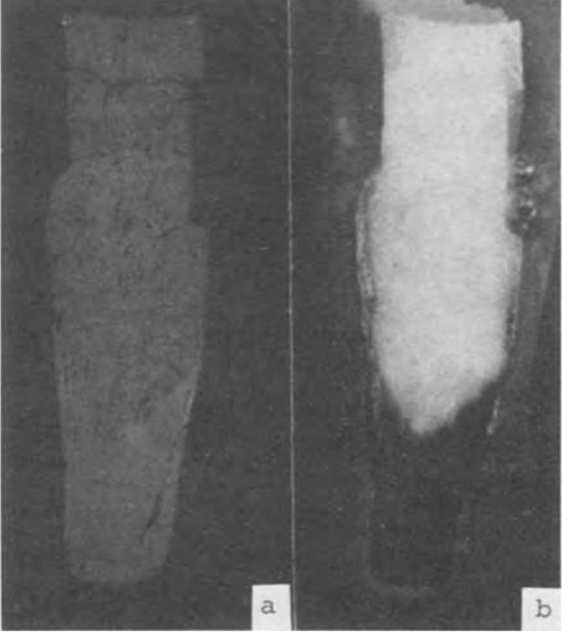

Fig. 3. Polished cross section of part of wafer after experiment III. Photographed at two different illuminations. At the top right of (a), the growth into the sulfur reservoir can be seen. The dark color in (b) indicates CdS, while the ZnS is white.

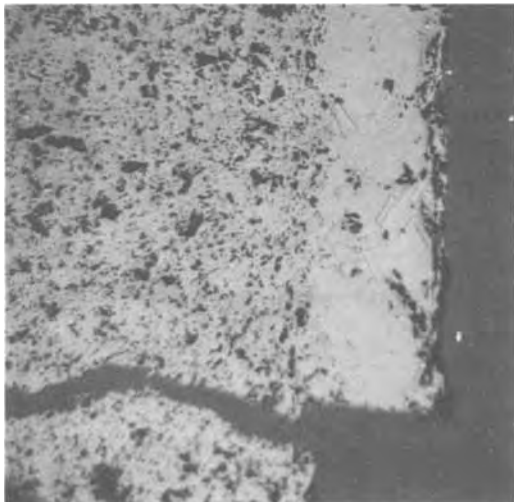

Fig. 4. The top right of Fig. 3 at a higher magnification. The growth on the sulfur-exposed face is single crystalline. The black areas are due to voids.

original CdS was retained at the rim, as is shown by the dark contrast in Fig. 3b. The Cd:Zn atomic ratio was determined by an electron probe and was found to be 1.5 on the face exposed to the sulfur reservoir, 0.003 in the area which was in contact with the reservoir wall and 58.3 on the surface of the wafer outside the reservoirs.

Crystallinity of the ZnS was studied in the cross section by optical microscopy (oriented facets on chemical polishing) and by Laue back reflection measurements. Pronounced single crystallinity was revealed in the material which grew into the sulfur reservoir (Fig. 4) and in narrow layers paralleling the CdS on the surface of the wafer outside the reservoirs. Single crystallinity improved as the measurements were taken closer to the rim (further away from the reservoirs). Even where not single crystalline, the material was found to be textured.

In experiment IV, the sulfur in the reservoir was replaced by selenium. By observing the polished cross section (Fig. 5) of the wafer, one is led to believe that a contour similar to the one shown in Fig. 3 would have formed had sublimation not taken place preferentially on the side facing the hotter of the two reservoirs (selenium). The uniform dark color of the specimen shows that transformation into CdSe has taken place.

A large void runs across the whole wafer roughly parallel to the exposed faces within the reservoirs and bends toward the cadmium reservoir outside the reservoirs. Numerous smaller voids and channels, most of which are perpendicular to the traces of the exposed faces, are also present as is illustrated in the composite micrograph of Fig. 6. In a layer starting somewhat below the original selenium-exposed surface and continuing up to the final surface on that side, the material is spongy and contains pores of irregular shape and size.

Fig. 5. Polished cross section of wafer after experiment IV. The convex-appearing side (top) was exposed to the selenium vapors.

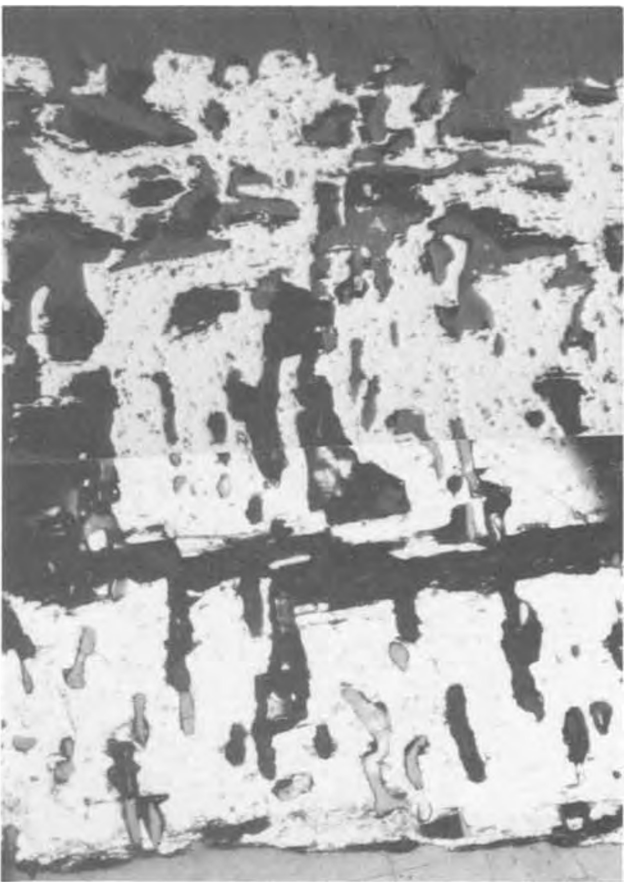

Fig. 6. Selected area of Fig. 5 at higher magnification. The pores in the layer grown on the selenium-exposed face are irregularly shaped while in the original wafer they are perpendicular to the faces.

Etching of the cross section revealed that the wafer consisted of one large crystal and a few grains.

Discussion

As diffusion rates increase with increasing wafer temperatures, it is advantageous to work at high temperatures. However, the sublimation rate also increases with temperature, as the equilibrium constant, K_p, in the equation $K_p = p_{II} \times p_{VI}^{1/2}$ is temperature dependent. The values of p_{II} calculated for the theoretical case of congruent vaporization when $p_{II} = 2\,p_{VI}$ are listed in column 10 of Table I. However, the group II and group VI reservoirs established high p_{II} and p_{VI} values, and thereby decreased sublimation due to a decrease in the equilibrium pressures of p_{VI} and p_{II}, respectively. Due to the square root relationship, an increase in p_{VI} led to a smaller decrease in p_{II} (Table I, column 12) than did the reverse, (column 13), hence the net growth on the cadmium-exposed faces in experiments I and II. The high temperature and sulfur pressure in experiment I led to plastic deformation. This deformation and possible sublimation from the wafer precluded the accurate determination of the solid-state flux. However, one can calculate that the minimum 0.2 mm growth corresponded to a flux of 2×10^{14} sulfur atoms/cm^2 sec.

In experiment II, growth is indicated not only by the 8 μm height difference between the tantalum-marked area and the rest of the surface, but also by the smoothness of the surface. The original etched wafer, and also the sulfur-exposed face (where sublimation exceeded growth by solid-state diffusion) were both strongly faceted. Assuming that no material was lost by sublimation on the cadmium-exposed face and that, except for the rectangular crystallites, no growth occurred over the tantalum-marked area, one may calcu-

late that the solid-state flux of sulfur was 10^{13} atoms/cm^2 sec. The rectangular crystallites probably grew through local discontinuities (*e.g.*, cracks) in the tantalum film.

Numerous studies have been performed on the diffusion in CdS of one of the constituent elements at a time. Still, the mechanism is not yet completely understood (2, 3). When the crystal is in equilibrium with high sulfur pressures, cadmium is thought to be transported as V_{Cd}'' and sulfur as S_i^x (2). However, in case of high cadmium pressures, there is disagreement on whether the mobile species is $Cd_i^{\cdot}$ or Cd_i^x and whether the dominant defect is $V_S^{\cdot\cdot}$ or $Cd_i^{\cdot\cdot}$ (2-4). Also, sufficient information is not available on the interaction between various defects and their effect on concentrations and mobilities. The present case is even more complex, as diffusion mechanisms must continuously change across the specimen, reaching the limiting cases at the two surfaces where the wafer is in equilibrium with high cadmium and high sulfur pressures, respectively. Thus, in case of cadmium transport, there must be a region within the wafer where the mobile species change from V_{Cd} to Cd_i. In this region one would expect to find material with relatively low cadmium defect concentration and thus this region may limit the magnitude of the flux (*i.e.*, the rate of crystal growth on the sulfur exposed face). Similar argument may be applied to the sulfur flux.

Exchange reactions in II-VI compounds have been studied by several authors (5-7). Just as in the case of binary compounds, the situation in the present work was again made more complex by the exposure of opposite faces to p_{II} and p_{VI} vapors. Also, in addition to having to consider the numerous defect species and mobile species as in the case of the binary system, one also has to consider the fact that while the exchange reaction is taking place, one of the elements has to diffuse to the surface and either form a compound there with the vapor or sublime off. For example, at the beginning of experiment III, the cadmium is expected to have sublimed into the zinc reservoir when it was replaced by zinc. However, as the ZnS-CdS interface advanced into the wafer, an ever larger fraction of the cadmium diffused toward the sulfur exposed surfaces, "uphill" along a cadmium concentration gradient in the direction of a decreasing chemical potential (8), as the chemical potential of cadmium had its lowest value where the CdS was in contact with the sulfur vapors. Part of the cadmium reacted with the sulfur forming an epitaxial CdS deposit. One may speculate that cadmium, zinc, and sulfur all moved both as interstitials and as vacancies depending on the existing local activities of zinc and sulfur.

In experiment III, zinc diffused not only toward the sulfur reservoir but also toward the rim of the wafer. As both faces of the wafer outside the reservoirs were exposed to sulfur vapors, zinc displaced cadmium internally and deposited the Cd ions as CdS on both faces. Hence the increase in thickness outside the reservoirs (0.4 mm) was twice that of the increase within the reservoirs (0.2 mm). As ZnS and CdS are mutually soluble in all proportions (9), it is expected that the interface during the exchange reaction was diffuse. Once a critical ZnS concentration was reached, the volume decrease (20% on complete transformation) must have led to the nucleation of voids and the formation of a microcrystalline phase. The varying degrees of crystallinity found makes one believe that the orientation and size of the ZnS crystallites depended on their rate of growth, rapid growth leading to finer grain size. Hence the best crystallinity appeared furthest away from the zinc reservoir. The higher crystallographic quality of the material grown outside the volume of the original wafer makes one believe that the diffusion of zinc through ZnS was a slower process than the diffusion accompanying the CdS → ZnS transformation.

In experiment IV, the CdS → CdSe transformation should lead to a 10% increase in volume. The formation of voids shows that the out-diffusion of sulfur and cadmium took place faster than the in-diffusion of cadmium and selenium from their respective reservoirs. As the presence of a larger ion on a lattice site is known to favor association with a vacancy (10), one may postulate that Se_S^x was associated with V_{Cd}. Thus, movement of the interface toward the cadmium reservoir facilitated the out-diffusion of cadmium toward the selenium reservoir via a vacancy flux. If the sulfur vacancy flux moving toward the cadmium reservoir was larger than the flux due to the "uphill" diffusion of sulfur (see argument advanced for experiment III) which was displaced by selenium, then the agglomeration of vacancies can account for the formation of voids. A significant fraction of the voids must have agglomerated along a plane parallel to the faces of the wafer; however, numerous other voids, most of them elongated in the direction perpendicular to the faces (thus favoring vapor transport) also formed. As contact with the walls of the reservoirs locally prevented the in-diffusion of vacancies (*i.e.*, the out-diffusion of material), void formation was less pronounced between the opposite walls of the reservoirs.

The present work proved the feasibility of epitaxial growth in case of compound semiconductors by solid-state diffusion. The slow rate of growth in case of a binary system and void formation in case of exchange reactions may limit the practicality of the approach.

Technical Notes

Gallium Migration Through Contact Metallizations on GaP

W. A. Brantley,[1] B. Schwartz,* V. G. Keramidas, G. W. Kammlott, and A. K. Sinha

Bell Laboratories, Murray Hill, New Jersey 07974

The thickness of the native oxide film which can be grown on GaP is increased considerably if the semiconductor has a chemically nonreactive, ohmic contact to provide a site for the cathodic component of the oxidation-reduction reaction (1). However, the contacts to GaP cannot be characterized as nonreactive with respect to the oxidation process. Formation of gallium and phosphorus oxides on the gold-based ohmic contacts (2, 3) to GaP during galvanic oxidation (1) has been established from electron microprobe analysis (4). It is believed that the presence of oxides on the surfaces of the contacts could be the cause of subsequent bonding difficulties.

There are several possible mechanisms by which gallium and phosphorus might arrive at the surfaces of the ohmic contacts: (*i*) migration through the metallizations during the contact alloying or during the galvanic oxidation process, (*ii*) surface diffusion, (*iii*) transport through the oxidizing solution, and (*iv*) as a consequence of the dicing process or subsequent etching. Of these possibilities, it is suspected that (*ii*) is not a major transport mechanism, and (*iii*) was demonstrated not to be significant by a controlled experiment in which there was no gallium transport to a gold wire immersed adjacent to the semiconductor in the oxidizing solution. Support for mechanism (*i*) is available from several experiments. An SiO_2 layer was found on gold films evaporated on silicon substrates, after heating at relatively low temperatures ($< 300°C$) in an oxidizing ambient; during the heating, silicon atoms were assumed to migrate through the gold film (5). Rapid dissolution of gallium into thin platinum films on GaP at 250°C has recently been detected by x-ray diffraction (6), and evidence for gallium migration through thin gold and platinum films on GaAs at temperatures above 250°C has been obtained by 2 MeV $^4He^+$ ion backscattering experiments (7). Nakatsuka *et al.* (8) observed that evaporated gold films on GaAs and GaP melted at temperatures considerably below the known (9) Au-GaAs eutectic temperature and proposed that this melting occurs at a gallium-rich composition; the unknown Au-GaP eutectic temperature is expected to be greater than the Au-GaAs eutectic temperature since the melting point of GaP exceeds that of GaAs by 200°C.

These collective results suggest that the metallization-semiconductor interface can be metallurgically reactive at temperatures considerably below binary eutectic values. Nevertheless, even if GaP melts to yield a gallium-rich liquid at the gold film interface, it is not evident how much of the contact film participates in the alloying process. Furthermore, because the GaP contacts are relatively thick ($\sim$ 1.5 μm), it was considered unlikely that gallium and phosphorus would migrate through the entire contacts.

In this work, the origin of the gallium and phosphorus on the surfaces of the contacts to GaP has been investigated by means of secondary ion mass spectrometry[2] (SIMS). This technique can provide (*i*) in-depth mass spectrometric analyses and (*ii*) ion image displays of sputtered secondary ions generated by a high energy primary ion beam impinging on the specimen (10-12). With these options, a relative chemical composition profile with depth can be obtained (provided no artifacts are introduced due to relative sputtering yields of the various components of the metallizations) or the area uniformity for a particular species at a given depth can be observed. For the present experiments, the primary sputtering beam consisted of $\sim$5.5 keV O_2^+ ions, and the secondary ion beam was apertured so that only the signal from the central $\sim$70 μm region of the $\gtrsim$ 200 μm diameter "burn" was detected. A rapid sputtering rate of $\sim$90 Å/sec through the gold films was employed; this burn rate was subsequently established from determination of crater depths by both interference fringe and Talysurf measurements.

Contact metallizations (2, 3) were deposited by electron gun evaporation on <111>-oriented GaP wafers. The p-contact consisted of a Be-Au alloy, and these films were deposited on p-type GaP having $N_A - N_D \gtrsim 5 \times 10^{17}$ cm^{-3}. The n-contact consisted of a Si-Au alloy, and these films were deposited on n-type GaP having $N_D - N_A \gtrsim 3 \times 10^{17}$ cm^{-3}. The films were nominally $\sim$1.5 μm thick, and some specimens were subsequently alloyed for 5 min at 600°C in a forming gas atmosphere to obtain ohmic contacts. In addition, a reference specimen consisting of a pure gold film $\sim$1 μm in thickness on a quartz substrate was prepared.

Examination of $^{69}Ga^+$ profiles through numerous alloyed metallizations indicates that extensive gallium migration does occur through the ohmic contacts. Although $^{31}P^+$ profiles indicate that some phosphorus migration through the contacts also occurs, the SIMS apparatus has much lower sensitivity for phosphorus than gallium (as positive secondary ions), and only the gallium migration has been investigated in detail. Absolute gallium concentrations within the metallizations cannot be established by secondary ion mass spectrometry due to lack of appropriate chemical standards for comparison and possible different sputtering rates for the various gold matrices. Only the presence of gold was detected in the alloyed contacts by x-ray diffraction (13). However, the β-phase (14) between gold and gallium [$\sim$21 atomic per cent (a/o) Ga] has been detected near the metallization-GaP interface by transmission electron microscopy (15). For thinner ($\sim$0.5 μm thick) Be-Au films alloyed with GaP at 600°C, preliminary x-ray diffraction analyses suggest that compounds between beryllium and gold (possibly Au_3Be and Au_2Be) also form (13).

Although absolute gallium concentrations cannot be established, relative comparisons of the extent of gallium migration can be obtained. The gallium signals from the various specimens are compared at some arbitrary depth such as 1000Å, where the metallization

matrix is still gold but the near-surface signal enhancement (12, 16) arising from the presence of a surface gallium oxide is no longer significant. The $^{69}Ga^+$ signals at an estimated 1000Å depth, normalized to a value of unity for the reference specimen, are summarized in Table I. Although the data are not sufficiently precise to warrant comparisons among the several members of each GaP specimen group, the great differences between the groups do permit order of magnitude comparisons. Accordingly, Table I is presented in a decade format where each entry is the logarithm of the upper limit for the decade; for example, an entry of 2 corresponds to a normalized gallium signal lying between values of 11 and 100.

Considerably lower gallium signals from the reference gold film on quartz and from the unalloyed films, compared to the alloyed films, prove that the source of the gallium near the surface of the ohmic contacts is the underlying GaP and that the overwhelming portion of the migration takes place during the alloying process for the contacts. Some gallium migration evidently also occurs during the contact deposition. (The reference specimen was investigated subsequent to several metallizations on GaP to allow ample opportunity for gallium contamination of the SIMS specimen chamber.) Variation over half an order of magnitude in deposition rate, while inducing considerable changes in microstructure of the films, did not significantly alter the extent of the gallium migration. Excessive gallium signals throughout the alloyed films precluded determination of area uniformity of the gallium migration. However, examination of Ga^+ ion images from a specimen where an additional unalloyed gold film was deposited over an underlying alloyed film indicates that the migration probably is not uniform. In addition, preliminary experiments suggest that the near-surface gallium level in contact metallizations may be increased an order of magnitude by the dicing process. Extensive gallium migration through gold-based ohmic contacts to GaAs also has been found during the present SIMS investigation.

It is possible that gallium migration during the alloying heat-treatment is beneficial to the formation of ohmic contacts to GaP. The beryllium or silicon contact dopants used to provide degenerate doping of GaP are both Ga-site substitutional impurities whose incorporation should be favored by an excess of gallium vacancies in GaP at the metal-semiconductor interface. The role of phosphorus vacancies in the GaP arising from the phosphorus migration is not known although competition between phosphorus and gallium vacancies might be expected for the amphoteric silicon dopant. (Analogous considerations would be applicable for contacts to GaAs.) On the other hand, it is recognized that the presence of gallium and phosphorus oxides at the surface of the contacts can cause problems with device bonding.

Table I. Gallium migration through metallizations on GaP

Metallization*	Relative $^{69}Ga^+$ signal at 1000Å depth†
Gold on quartz substrate (reference specimen)	0
As-deposited n- or p-contact	2
Alloyed n- or p-contact	5-6

* Each GaP metallization group consists of several specimens.
† These values are logarithms of the upper limit of the decade(s) within which the relative Ga^+ signal values lie. For example, a value of 2 corresponds to a relative signal between 11 and 100. All the relative Ga^+ signals are normalized to the reference specimen whose near-surface Ga^+ signal has been assigned a value of unity (and thus a logarithm of 0).

Acknowledgment

The authors acknowledge the assistance of several individuals during this investigation. R. K. Lewis and B. Autier of Cameca Instruments, Incorporated performed the SIMS experiments. C. R. Paola established deposition procedures and prepared the reference specimen. Some of the specimens were kindly provided by P. E. Fraley and J. J. Bastek. The authors are particularly grateful to Mrs. M. H. Read for the x-ray diffraction analyses and to T. T. Sheng and P. M. Petroff for the transmission electron microscopy.

Manuscript submitted June 27, 1974; revised manuscript received Sept. 23, 1974.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1975 JOURNAL. All discussions for the December 1975 Discussion Section should be submitted by Aug. 1, 1975.

Publication costs of this article were partially assisted by Bell Laboratories.

Some Effects of "Trichloroethylene Oxidation" on the Characteristics of MOS Devices

Gilbert J. Declerck,[1] Takeshi Hattori,[2] Gerald A. May, Jacques Beaudouin, and James D. Meindl*

Stanford Integrated Circuits Laboratory, Stanford, California 94305

The use of phosphosilicate glass (PSG) as a stabilizing film on top of thermally grown SiO_2 has become almost a universal step in integrated circuit processing (1). It is well known that PSG getters sodium ions and acts as a barrier against sodium ion drift through silicon dioxide, thereby stabilizing the threshold voltage of MOS transistors. It is also well known that PSG has several undesirable effects, among which are polarizability and phosphorus penetration through the oxide to the silicon-SiO_2 interface. The PSG stabilization is also thought to bring about an increase in surface-state density, rendering it objectionable for CCD and related processes.

In an effort to circumvent the need for PSG, it has been found that the use of a chlorine-bearing species (Cl_2, HCl, or C_2HCl_3) in an oxidizing ambient can have both the gettering and passivating effects of PSG, without its more insidious side effects. The gettering effect is due to the chlorine in the oxidizing atmosphere preventing positive alkaline ions from being introduced into the growing oxide through the formation of volatile chloride compounds (2). Chlorine incorporated into the oxide also has a passivating effect against sodium drift. One possible explanation is that sodium ions are immobilized by the chlorine ions (3). Another explanation is that the sodium ions are still penetrating through the oxide but have no effect on the silicon surface potential because they become neutralized in an interaction with a chlorine-associated species near the interface (4). In any event, proper introduction of chlorine into the oxidizing atmosphere eliminates the necessity of postoxidation PSG stabilization.

Until recently, most procedures have introduced chlorine into the oxidizing atmosphere in the form of HCl. This method has several drawbacks associated with it. HCl is a very dangerous acid and cannot be handled easily. In addition, it can be very corrosive in the presence of small amounts of water vapor, causing etching of the quartz and stainless steel chambers associated with the usual oxidation furnace and exhaust systems. Because of these deleterious effects, a more manageable chlorine source has been sought. Lately, the use of trichloroethylene (TCE) has been reported to be an effective agent for reducing positive ion instabilities (5). It has some distinct advantages over HCl in that it is much easier to handle and is far less corrosive.

The purpose of this work is to further investigate the use of TCE for improving MOS structures. HCl grown oxides have not only shown improved electrical stability, but also high minority carrier lifetime (6, 7) and very low surface-state densities (8). Because these effects are also assumed to be related to the gettering action of the chlorine, measurements of these quantities were performed on TCE oxide samples as well, and the results are presented in this work. Beside an increase of minority carrier lifetime, as already reported before (6), we also found long storage times, low surface-state densities, and low noise characteristics. It may be expected that TCE oxides have great potential for high transfer efficiency CCD's requiring low surface-state densities and high storage times. In addition, it can also be very useful for MOS circuits, and particularly for low noise transistors.

Experimental Procedure

MOS capacitors with and without TCE were fabricated on n-type (100)-substrates. As a comparative standard, oxides were grown at 1200°C for 14 min in a dry oxygen flow of 1500 cm^3/min in a 50 mm quartz tube. TCE oxides were grown under the same conditions, but with varying flows of dry nitrogen through a bubbler filled with TCE. To insure good reproducibility, this flow was established 30 min prior to actual oxidation. The temperature of the bubbler was constant at 34°C within a few degrees. All wafers were given a 2 min nitrogen anneal before pulling them from the oxidation furnace. To avoid interface and lattice stresses, the pull rate was approximately 1 min. The wafers were then metallized on both sides by means of a tantalum filament evaporation system and capacitors were made using standard photolithography. Portions of each sample were annealed at 450°C in forming gas for 30 min or at 500°C in wet nitrogen for 10 min. Our results showed no difference between the two low temperature annealing steps.

Several samples of MOS capacitors using the procedure described above were prepared. Measurements of flatband voltage yielded the fixed oxide charge which was in the low 10^{10} cm^{-2} range for all TCE samples. Bias temperature stress was performed at 200°C for 10 min with a field of 2×10^6 V/cm and the resulting flatband voltage shift was measured. Storage times were found by pulsing the capacitors from accumulation into deep depletion (9-12). Fast surface-state densities were measured by the quasistatic C-V method (13, 14). All of the measurements were performed on both the standard oxide samples and the TCE oxide samples.

Next, MOS transistors were fabricated using a standard p-channel process. The run was divided into three groups according to the type of gate oxidation. The first group had a TCE oxide. The second had a standard thermal oxide with no phosphorus stabilization. The third group had a standard oxide with the usual phosphorus stabilization. All of these samples were metallized by electron-gun evaporation. The noise performance of each of the three groups was then compared.

Results

Oxidation rate.—It has been reported that in the presence of HCl or Cl_2 the oxidation rate of silicon is increased (15). The principal reasons are an enhanced diffusion of O_2 and H_2O in these oxides and an enhanced reaction at the silicon-SiO_2 interface (16). We have found that in the presence of TCE the oxidation rate is also increased, as shown in Fig. 1. Oxide thickness is plotted *vs.* the amount of N_2 flow through the TCE bubbler. The data show the same parabolic dependence on TCE flow that has been previously seen for HCl (15). The same graph has been reproduced through several runs, so that it may be concluded that the TCE oxide thickness is predictable when the oxidation parameters are known. It should be mentioned that a TCE-N_2 flow over 150 cm^3 is

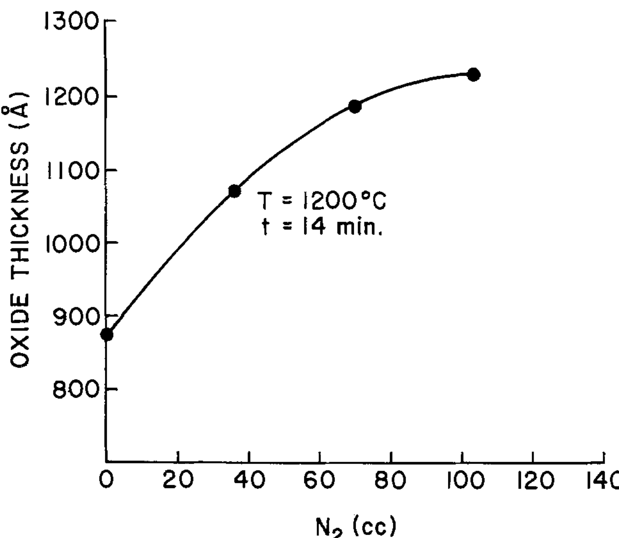

Fig. 1. Oxide thickness vs. TCE flow

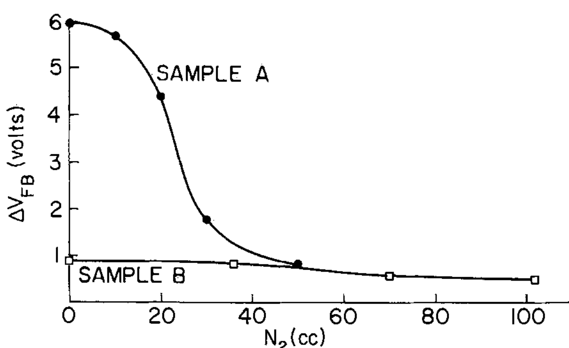
probably too high because these oxides were very leaky and no oxide thickness or other parameters could be measured.

Stability.—The effect of TCE on the change in flat-band voltage after bias temperature stress is shown in Fig. 2. As the oxide thickness of each sample is different, the measured shift provides the actual mobile oxide charge from the relation $Q_{mobile} = C_{ox}\Delta V_{FB}$. The results are also plotted in Fig. 2. This figure shows that the magnitude of the mobile charge is strongly dependent on the amount of TCE in the oxidizing atmosphere.



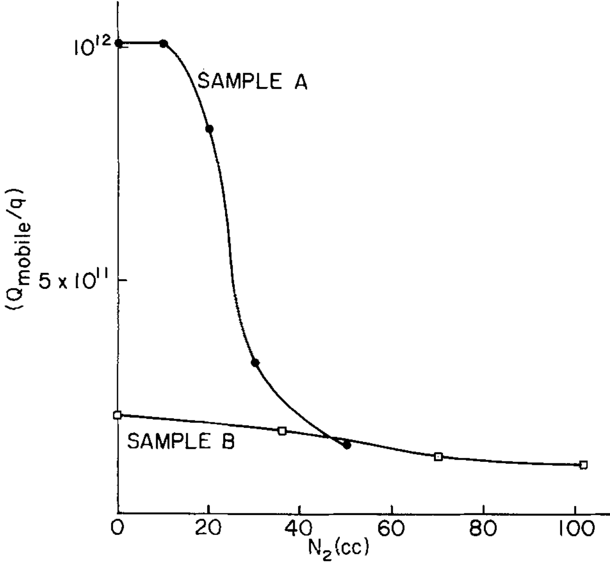


Fig. 2. Flatband shift (ΔV_{FB}) and mobile oxide charge (Q_{mobile}/q) vs. TCE flow.

Sample A is typical for a wafer contaminated with about 1×10^{12} mobile ions per cm^2. The contamination probably occurred during metallization (evaporation from tantalum filament). The ΔV_{FB} exhibits a strong thresholdlike behavior *vs.* TCE flow (15). About 60 cm^3 N_2-TCE is necessary to reduce ΔV_{FB} to a minimum of 0.5V.

Sample B was measured on wafers metallized after the metallization system had been cleaned. The total amount of mobile ions is reduced to about 1×10^{11} per cm^2 in the standard sample. However, at the 60 cm^3 N_2-TCE flow there remains a ΔV_{FB} of 0.5V. It is unlikely that this shift is due to mobile sodium ions, because the same shift is also seen on very clean electron-gun metallized samples. Furthermore, if the temperature of the B-T experiment is lowered to 150°C, the shift is negligible (less than 0.1V).

Storage time.—Another noteworthy effect of TCE is the increase in capacitor storage time over that of the standard thermal oxide. This effect is shown in Fig. 3. It should be noted that the substrate doping was 1-2 $\times$ $10^{15}/cm^3$, the oxide thickness was about 1000Å, and the capacitors were pulsed from accumulation (+2V) to deep depletion (−7V). These parameters influence the storage time, so that it is important to keep them in mind when comparing different experiments. Storage times for our standard oxides are less than a few seconds, while for moderate flows of TCE the storage time was consistently above 1 min. For large TCE flows the storage time decreases. No attempt is made here to derive bulk lifetime in a quantitative fashion, since recent reports (12) have shown that lifetime is not so easily predictable from storage time, as previously thought (9-11). However, it is still true that longer storage times give a qualitative indication that the combined effect of bulk generation rate (inversely proportional to bulk lifetime) and of surface generation rate (proportional to surface-state density and to surface-state capture cross section) is slower.

Surface states.—Fast surface-state densities were measured by the quasistatic C-V method (13, 14). A plot of the fast surface-state density *vs.* TCE flow is shown in Fig. 4. It should be brought to mind that these samples were metallized by evaporation from a tantalum filament. The figure shows that the surface-state density for the standard oxide, without any form of stabilization, is about 2-3 $\times$ 10^{10} eV^{-1} cm^{-2}. This low value can be attributed to the high temperature nitrogen step after oxidation and to the wet nitrogen or forming gas anneal after metallization. However, by the use of moderate flows of TCE, surface-state densities can be reduced below 10^{10} eV^{-1} cm^{-2}. Exact measurements below this value are limited by the sensitivity of the quasistatic C-V method (14). Further experiments using, *e.g.*, the Nicollian-Goetzberger con-

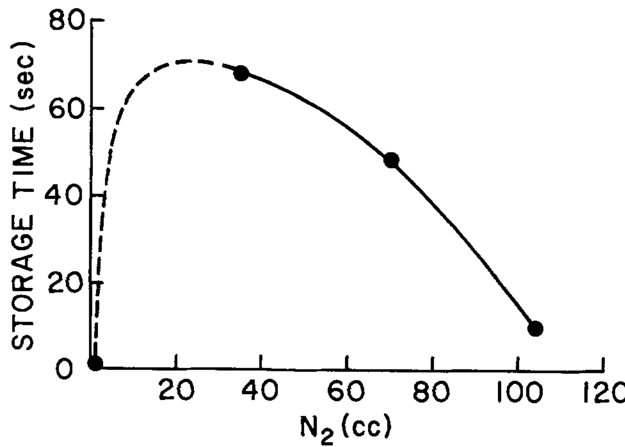

Fig. 3. Storage time vs. TCE flow

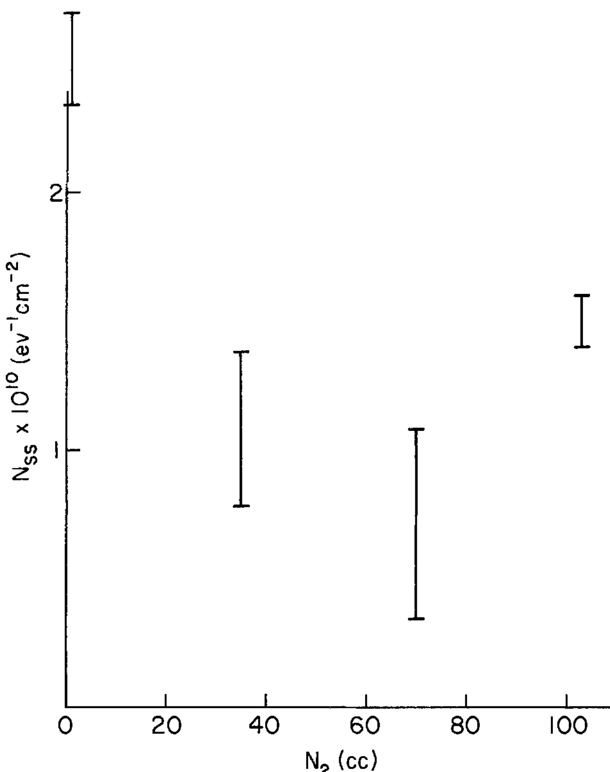

Fig. 4. Surface-state density vs. TCE flow

ductance technique are needed to accurately determine these values.

Samples made without TCE but metallized with electron-gun evaporation had measured surface-state densities in the same range as the best TCE samples. At the same time these "electron-gun" samples show very little sodium contamination in our bias temperature stress measurements. It is known that very clean samples having little sodium contamination will have a correspondingly small surface-state density when using appropriate annealing techniques. This could explain the fact that the surface-state densities in samples with electron beam evaporated metal were as low as in TCE samples with filament evaporated metal.

MOS transistor fabrication.—As mentioned in the experimental procedure, p-channel transistors using TCE oxides were fabricated. The gate oxides of these transistors were grown using an N_2-TCE flow of 50 cm^3. This flow was chosen because previous measurements on the MOS capacitors had shown that it was nearly the optimum value for small flatband shift, long storage times, and low surface-state densities. The gate oxide thickness of both the standard and the TCE transistors was kept equal by adjusting the oxidation time for the standard transistors. The metallization was performed by an electron-gun evaporation.

Measurements of the low-frequency (1/f) noise in the saturation region of the MOS transistor were compared between the TCE samples and the standard samples. Some of the standard devices were carried through the standard phosphorus stabilization (1050°C for 10 min in the phosphorus deposition furnace, but with the $POCl_3$ source off). Noise measurements were interpreted in terms of the input-referred noise voltage e_n which has been shown by many authors (17) to have a frequency dependence in the saturation region given by

$$e_n^2 \alpha \frac{N_{ss} t_{ox}^a}{Af} \mathbf{F}(V_{GS} - V_T) \quad [1]$$

where N_{ss} = surface-state density; eV^{-1} cm^{-2}; t_{ox} = gate oxide thickness; $A = WL$ of the device, where W is the channel width and L is the channel length; and $1 < a < 2$. $\mathbf{F}(V_{GS} - V_T)$ is a function describing a weak (linear or logarithmical) dependence of e_n on the effective gate voltage $V_{GS} - V_T$ (17). e_n has the dimensions of $V/\sqrt{Hz}$.

Figure 5 gives a plot of the input-referred noise voltage *vs.* frequency for the TCE sample, the P_2O_5-stabilized sample, and the standard sample without P_2O_5. The drain current was 1 mA at V_{DS} = 10V. All the samples show the characteristic 1/f dependence up to about 10^5 Hz. Beyond this point, the channel current noise predominates. The noise voltage for the TCE and standard samples without P_2O_5 was the same, while the P_2O_5-stabilized sample has a noise voltage between 4 and 10 times greater. It must be mentioned that this comparison is only true for the standard P_2O_5 stabilization employed here. Using lower temperatures and shorter times for the stabilization yields lower surface-state densities (18). However, these stabilization techniques are much more difficult to apply than the TCE method described here.

Referring to the noise voltage equation, we may conclude that the difference in surface-state densities between the devices is at least one and maybe two orders of magnitude. By a quasistatic C-V measurement N_{ss} was proven to vary on the P_2O_5-stabilized samples between 5×10^{10} eV^{-1} cm^{-2} and a few 10^{11} eV^{-1} cm^{-2}. Consequently, the noise measurements given here also indicate that on the other samples (TCE and standard without P_2O_5), the density is significantly less than 10^{10} eV^{-1} cm^{-2}.

Figure 6 shows the dependence of noise voltage on drain current for the TCE sample. Figure 7 gives the variation of noise voltage with current at 1 kHz measuring frequency. The rise of the 1/f noise at higher current levels can be explained by the function $\mathbf{F}(V_{GS}$

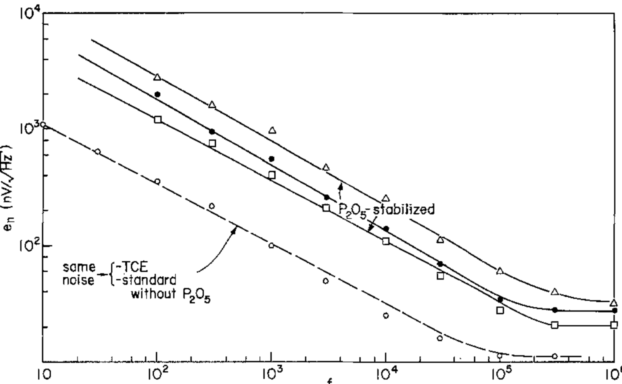

Fig. 5. Input-noise voltage (e_n) vs. frequency at I_D = 1 mA and V_{DS} = 10V.

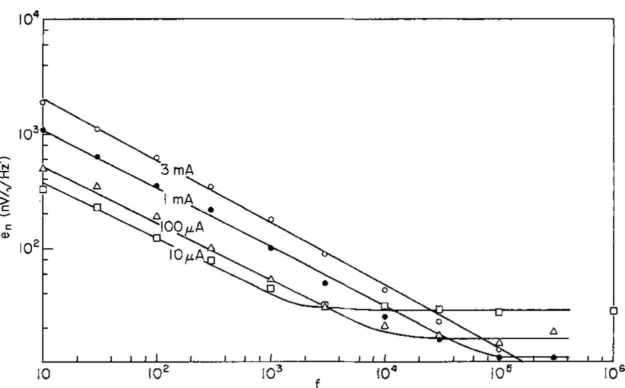

Fig. 6. Input-noise voltage (e_n) vs. frequency for TCE sample at different bias currents.

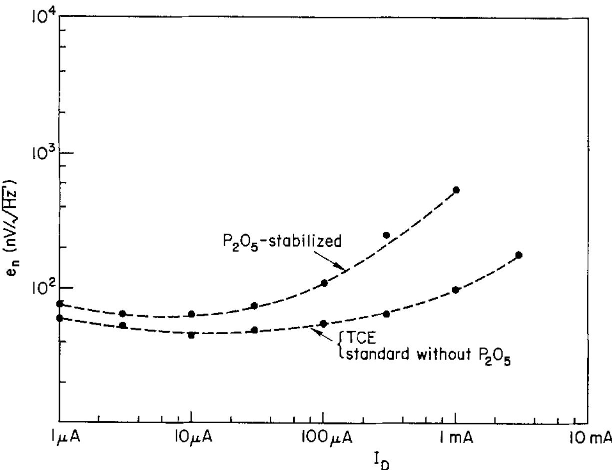

Fig. 7. Input-noise voltage (e_n) vs. current at $f = 1$ kHz

$- V_T$) in Eq. [1] or can be due to an increase in surface-state density near the bandedges. It is seen that the increase in 1/f noise is less pronounced on the TCE and standard samples without P_2O_5. The small rise at lower currents is due to an increase in channel resistance thermal noise.

As a last point, we would like to compare our noise results with published low noise data. Looking at Fig. 6 and 7 we see that the 1 mA bias current used in Fig. 5 was not lying in the optimum low noise region. A noise voltage of 15-20 $nV/\sqrt{Hz}$, found by Ronen (17) at 1 kHz and at 1 mA on specially designed transistors with $W = 1600$ μm is regarded to be an extremely low noise result. This value must be compared with the 60 $nV/\sqrt{Hz}$ that we found at 150 μA on our transistors with $W = 250$ μm (because of the change in current levels with smaller W/L and assuming about the same channel length). When the area factor is considered in Eq. [1], it is clear that the 60 $nV/\sqrt{Hz}$ must be divided by a factor of two or three, which brings us to a value comparable to Ronen's figure. Using the TCE technology, and optimizing the geometry, very good low noise transistors can be made.

Conclusion

The TCE capacitors we fabricated showed good stability, long storage times (>1 min), and low surface-state densities (a few 10^9 eV^{-1} cm^{-2}). A strong indication that these characteristics are maintained through a complete processing schedule has been given by the successful fabrication of low noise MOS transistors. Further work should be done in evaluating storage times, transfer efficiency and dark currents on charge coupled devices, and MOS image sensors processed using the TCE technology.

In addition, the increased oxidation rate is helpful in keeping the $\sqrt{Dt}$ products small, by allowing oxides to be grown at lower temperatures. A careful study of TCE oxides grown by a wet/dry oxidation schedule at lower temperatures (~900°C) would be interesting for DMOS and related devices, in which high temperature oxidations may not be desirable.

On the Technique and Evaluation of Angle-Beveling Silicon Epitaxial Layers

P. J. Severin, H. Bulle, G. Poodt, and J. D. Wasscher

Philips Research Laboratories, Eindhoven, Netherlands

For advanced applications of epitaxially grown structures the dope concentration profile and the extent of the concentration gradient between substrate and epitaxial layer are of paramount importance. In order to study these properties with surface probing techniques the interior should be exposed by beveling the slice. The method this paper is focused on, is the spreading resistance technique (1), which is accepted now as a very powerful tool for investigating epitaxially grown structures. Recently also the electroreflectance method was reported (2) to yield promising results when applied to an angle-polished junction. Also the capacitance-voltage (3) and the voltage breakdown methods (4) can be used on beveled structures to profile the junction.

Any technique integrates over a certain length and for obtaining a large resolving power in-depth the bevel angle should be as small as possible. This implies, however, that for precise correlation between horizontal position and depth below the original surface the departure from ideal flatness of the slice is taken into account. This note deals with the preparation and evaluation of small bevel angles down to 1/2000. It is concerned with basically known tools and techniques: lapping jigs, polishing procedures, the interference microscope and interferometers. However, in order to fully and correctly exploit the possibilities of the spreading resistance and other methods, on a bevel these techniques should be very critically and carefully applied.

The preparation and evaluation procedures are intimately connected. The use of the polishing jig is described in the next section. In semiconductor device technology patterns are optically imaged on a slice which therefore should be sufficiently flat. A laser-operated interferometer developed originally to study this surface topography of a silicon slice, is briefly sketched in the third section. Its use in conjunction with the polishing jig for evaluating the local bevel angle, taking into account any departures from perfect flatness of the slice, is explained in the fourth section. It is also shown that by tilting the slice differences in height as low as 60Å can be measured.

Preparation of the Bevel

Conventional angle-lapping jigs have been used for bevel and stain measurements at relatively large angles by Bond and Smits (5, 12), Fuller and Ditzenberger (6), Gutsche (7), Kane and Larrabee (8), and Herff and Roeder (9). The reliability of these instruments is limited by mechanical tolerances: the play increases with use because it cannot be avoided that powder penetrates between inner and outer cylinders during the lapping process. Moreover, the angle can be measured on the interferometer only before lapping. Here we first describe a more stable and versatile tool, shown schematically in Fig. 1, which matches well the interferometer to be described later.

The piston A to which the slice S is attached can slide without play in the holder B and can be fixed at any height and position by screw C. This assembly rests on three balls on the support ring D and can be moved with respect to the support by two screws E. With one screw the assembly can be tilted about the axis between the other screw and the third ball. In this way the angle between the axes of B and D can be varied in a simple and precise way. The holder B and the support D are held in position by three resilient clamps F. A basically similar device used for polishing parallel optical flats is described by Bennett and Wilson (10). The jig rests on a number of pieces of silicon G glued to the support D. Hence during lapping and polishing no foreign particles are produced and because their total surface area of about 10 cm^2 is much larger than the area to be beveled, the pressure and rates are constant during the process. The slice is mounted on the piston A in a thick layer of beeswax by heating. When it is allowed to cool slowly, the slice assumes its equilibrium position.

Key words: angle-beveling, silicon, thin layer, interferometer.

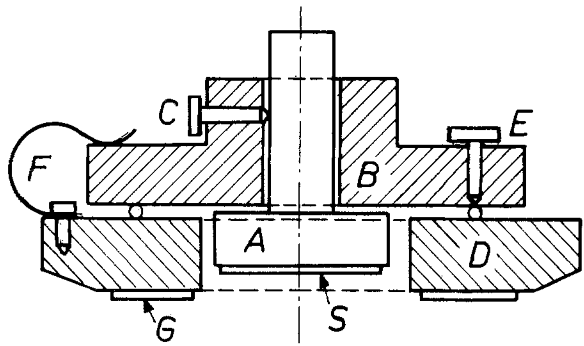

Fig. 1. Schematic view of the angle-polishing jig. The slice S is waxed to the piston A, which fits tightly into holder B and can be clamped with screw C. With the screws E the slice can be tilted with respect to the support D, which rests on pieces of silicon G.

The lapping and polishing is done on a machine[1] on which the slice is subjected to three different motions. The slice is lapped on a glass plate through a slurry of water and Al_2O_3 [2] for a few minutes under a load of 1500g and then thoroughly rinsed with water. The subsequent polishing is done on a disk[3] into which diamond paste[4] can be embedded under supply of water. After polishing, which takes about 2 min, at a few times higher speed the roughness is reduced sufficiently to make the surface mirror-like. At this stage the surface shows some pits and scratches due to deep lapping damage, but usually the polishing process is not continued. It has been found that there is about a 20% difference in spreading resistance between touched and nontouched parts. Because profiles are measured generally on a logarithmic scale, this difference in calibration is unimportant.

The Interferometer

A bevel of relatively steep slope and mirror surface quality can easily be evaluated with an interference microscope which typically covers under 100× magnification a field of view of 1500 μm diameter. In order to obtain a reliable value for the slope at least a dozen contour lines should be visible, which implies that the slope should be steeper than 1/250 if the reference plane covers half the field of view. It has been found that for very steep angles reliable results can be obtained. However, for smaller angles the slice turns out not to be flat enough to unambiguously define its slope with respect to the reference flat. Moreover, the method

[1] Kent Mk2, Engis Limited, Mailstone, England.

[3] Hyprocel Pa-W*, Slough Products, Bruxelles.
[4] Type C, size 0-3 μm, H. Struers Chemiska Lab., Copenhagen, Denmark.

is time consuming and it is impossible to obtain an over-all impression. In this section an instrument of greater field of view is described with which the untouched part of the surface of a beveled slice can be seen and used as a horizontal reference in determining the slope of the bevel.

The optical layout of this interferometric instrument which is not at all critical, is shown in Fig. 2. A HeNe laser (1) operating at 6328Å at about 2 mW power level provides an extremely monochromatic, coherent, relatively intense, and narrow light beam. The light is incident on a diffuser (3), which serves as an intense and monochromatic light source. Via a semireflecting mirror (5) the enlarged-diameter parallel beam is incident on the polished side of the silicon slice (7) which is positioned face to face with a semireflecting optical flat (8), about 1 cm thick. The fringe system arising from multiple interference at the positions of appropriate slice-flat distance is imaged by a lens (9) onto a screen, a television camera, or a photographic camera (10). As the light turns out to be still so coherent that speckles can be seen, the diffuser (3) is mounted on a motor axis which revolves sufficiently fast that they disappear. In Fig. 2 the slice is shown resting on the back side with an optical flat at a few millimeters distance, adjusted with three screws to be more or less parallel to the polished side of the slice. The instrument can also be used with the polished side down and the support G resting on the optical flat. The angle with the optical flat is adjusted with the screws E.

The distance between two contour lines corresponds to a height difference equal to $\lambda/2 = 0.316$ μm and the resolving power is about one fifth of this difference. In the next section it will be shown how this can be improved by an order of magnitude to be about 60Å.

Evaluation of Bevel Angle

In general a slice is not flat and, although the bevel as produced may be flat, local thickness of a beveled epitaxial layer plotted *vs.* horizontal position may not be a straight line. Typical surface topographs of silicon slices can be seen in Fig. 3. Usually the contour lines show a maximum or a minimum, manifested by closed lines, and sometimes saddle points.[5] The radius of curvature of an extremum is roughly between 2 and 20m for 250 μm thick Si slices. Hence the slope may change over 5 mm by an angle 1/500. However, with the procedure described such variations in slope do

[5] This implies that concavity measured as a standard routine (11) and commonly called bowing or dishing, does not adequately describe the topography of silicon slice. This has been neglected in the ASTM test for thickness of epitaxial layers in silicon by angle bevel and stain technique (12).

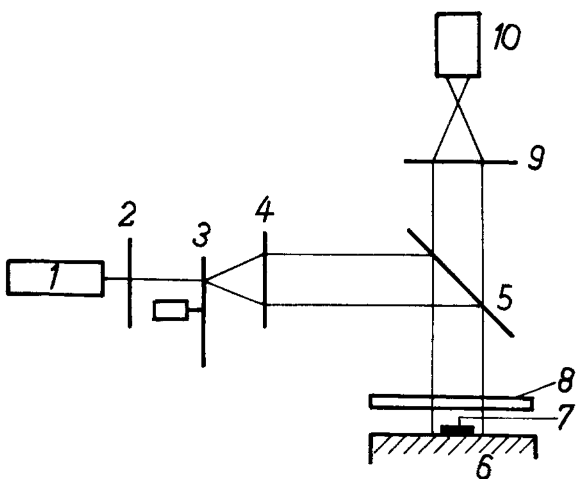

Fig. 2. The layout of the interferometer with the slice placed polished side up: laser (1), mirror (5), diffuser (3), lenses (2, 4, 9), optical flat (8), slice (7), (television) camera (10). With the slice fixed to the jig, the jig rests on the optical flat and the light is incident from below.

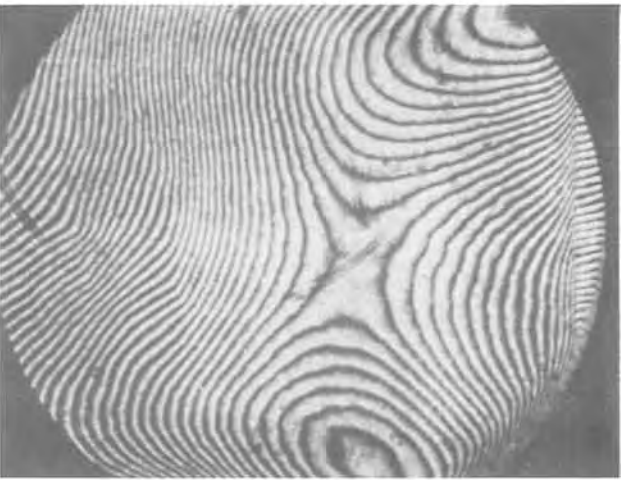

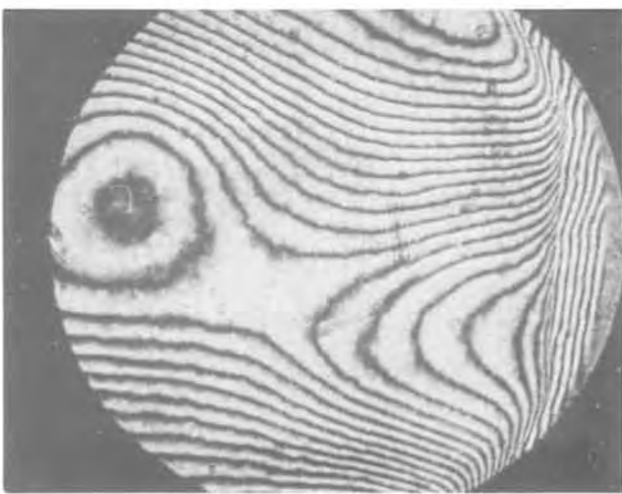

Fig. 3. Typical topographs of silicon slices. On the right-hand side of the reference flat the aluminum support is visible, which also reflects.

not present a real problem because the profiles of both the original surface and the polished beveled surface can be measured accurately.[6] To produce a bevel the slice is mounted on the jig of Fig. 1 and the mirror (8) of Fig. 2 is placed on top of the silicon pieces G of the jig. Using the screws E the piston A is adjusted such that on the television monitor a pattern arises with easily recognizable features. This pattern is photographed. Then the desired angle is adjusted with

[6] Sometimes the curvature is so strong that the camera does not resolve the contour lines at a few millimeters from the center. Such slices cannot successfully be beveled and should be rejected for IC processing as well.

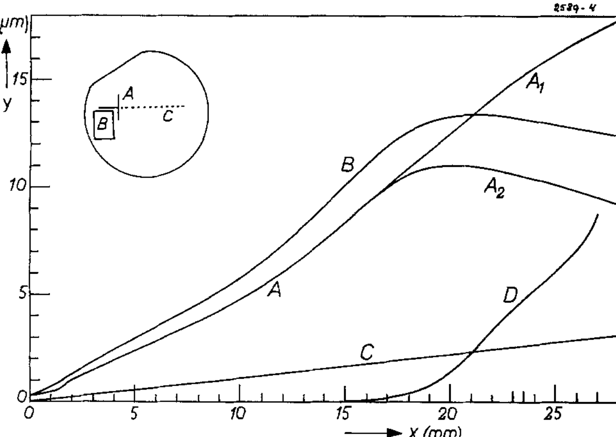

Fig. 4. Profiles of the original surface (A), of the beveled surface (B) and the depth below the surface (D). The auxiliary line C is the difference between the left-hand sides of A and B. When the right-hand side of B is corrected by the difference C, the line A_2 is found. The difference between A_1 and A_2 yields curve D which represents the true depth below the original surface. In the inset the scratch mark A, the patch of paper B and the spreading resistance track C are shown.

screws E and the piston is lowered until the slice touches the optical flat and is fixed again with screw C. After lapping and polishing, the slice is positioned again such that the pattern on the nontouched part of the slice compares well to the photograph made earlier and photographed again. Then the bevel angle is determined from the two photographs under the microscope as described in detail below. Of course, the pattern on the slice before beveling is arbitrary, because it only serves the purpose of providing a reference to the position of the beveled surface by means of the nontouched part adjusted to show identical patterns in both situations.

In practice the procedure runs as follows. A mark, labeled A in the inset of Fig. 4, is scratched on the slice. In order to see this mark on the photograph a small rectangular patch of paper, noted B in Fig. 4, is glued to the slice. The slice is adjusted to such an angle with the optical flat that a number of closely spaced interference fringes perpendicular to the track C is visible, and photographed (Fig. 5a). This slope may correspond to the desired angle, otherwise the desired angle is adjusted, the patch of paper is removed, and the slice is beveled. As before, a patch of paper is glued on the slice and the slice is adjusted as well as possible in the same position as before beveling and photographed (Fig. 5b). Then, from the photographs the profiles along the track to be made, are measured and plotted. Of course it will not be possible to reproduce precisely the pattern on the nontouched part. This is shown clearly in Fig. 4, where curve A represents the profile as measured on the original photograph. After beveling, the profile labeled B is measured, which is different from the original one, though the left-hand side nontouched parts should be identical. This arises from the fact that the angles with respect to the optical flat in the two cases were slightly different. This can be corrected by pivoting curve B around the origin so that A and B are coincident. The difference between curve A and the first part of curve B turns out to be, as expected, a straight line, labeled C. Extrapolating this correction, due to a slightly different tilt of the slice, over the range where the slice has been beveled, the true surface profile curve A_2 is obtained from the measured curve B. The difference between curve A_1 and A_2, plotted as a curve labeled D, is the true depth below the original surface. Due to the surface topography and the nature of the polishing process, there is no linear relation between depth and horizontal position. Therefore some method to obtain a curve like curve D of Fig. 4 is definitely indispensable for precise and accurate work, in which the local thickness should be precisely and accurately known.

A particularly interesting application of this technique in which tilt is used to increase the resolving power of details in height, runs as follows. The slice is positioned almost parallel to the optical flat (Fig. 6a) and the positions of the fringes are plotted as curve A in Fig. 7. Thereupon the slice is tilted (Fig. 6b) and the positions of the fringes are plotted again. From this plot a vertical distance increasing linearly with horizontal position corresponding to the tilt angle should be subtracted, yielding curve B in Fig. 7. The number of observation points has been increased with the slope. In this way details in height structure are revealed which cannot be obtained with the conventional interference contrast microscope. In the example shown the slice has been tilted by about 1/1000 and vertical details as small as 60Å can be resolved. This can be decreased further. Of course, there is no reduction of the horizontal scale so that this technique could be considered to be a nontouching version of the moving stylus method.

Manuscript submitted March 15, 1974; revised manuscript received Nov. 26, 1974.

Fig. 5. Topograph of a slice adjusted before beveling (a, left) and after beveling (b, right). A small rectangular patch of paper glued on the slice, serves as a starting point for the photographic analysis and spreading resistance measurements.

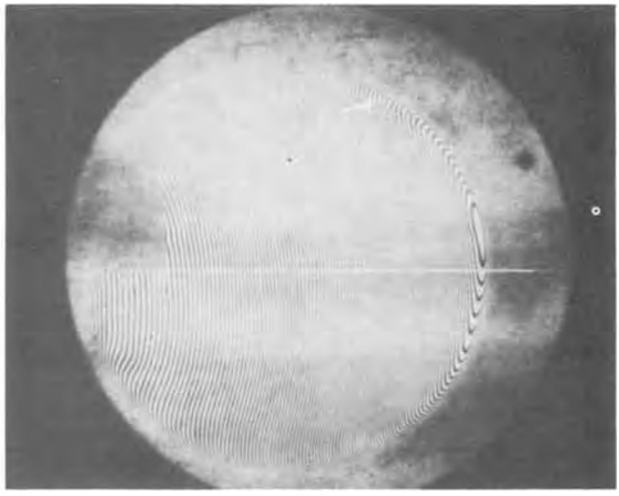

Fig. 6. Topograph of a silicon slice adjusted to be almost parallel (a, left), and under an angle of about 1/1000 (b, right) to the optical flat.

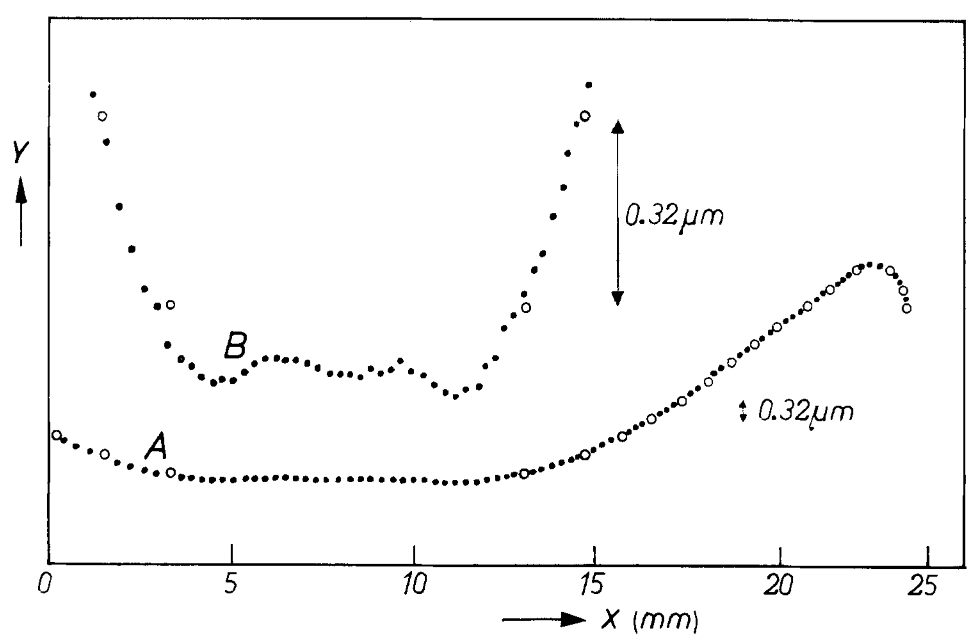

Fig. 7. The position of the fringes measured on the topograph shown in Fig. 6a yields curve A (○). The position of the fringes measured on the topograph shown in Fig. 6b yields curve B (●) after a vertical distance linearly related to the horizontal position has been subtracted. The closed circles have been drawn in curve A after curve B had been obtained. Note that the vertical scales for curves A and B differ by a factor 10.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1975 JOURNAL. All discussions for the December 1975 Discussion Section should be submitted by Aug. 1, 1975.

Publication costs of this article were partially assisted by Philips Research Laboratories.

The Use of Metalorganics in the Preparation of Semiconductor Materials

VI. Formation of IV-VI Lead and Tin Salts

H. M. Manasevit* and W. I. Simpson

Rockwell International Corporation, Electronics Research Division, Anaheim, California 92803

The ever-increasing interest in the use of IV-VI compounds, particularly PbTe and $Pb_{1-x}Sn_xTe$, for *IR* detectors and the success demonstrated in the use of metalorganics in preparing III-V and II-VI compounds and alloys (1) prompted a study to extend the metalorganic chemical vapor deposition (CVD) technique to the preparation of IV-VI compounds also. Growth studies were performed on PbTe and on single-crystal insulating substrates transparent in the visible part of the spectrum. The transparent substrates were used in order to help in determining the onset of crystal growth as evidenced by a darkening of the substrate and to facilitate optical studies and microprobe analyses of the crystals formed. These substrates included mechanically polished Al_2O_3, $MgAl_2O_4$, and BaF_2, and freshly cleaved (in air) MgO, NaCl, CaF_2, and BaF_2. BaF_2 was the primary insulator used in these investigations since in thin wafer form it is transparent to 11-12 μm radiation, is more stable than NaCl at temperatures $\sim$625°C, and matches the thermal expansion of the IV-VI's relatively closely (2).

The metalorganic compounds used in this study, some of their pertinent properties, and the suppliers are listed in Table I.

The Pb, Sn, and Te compounds were used as received in stainless steel bubblers except for purging with H_2 carrier gas prior to use in film growth experiments. The bubblers were maintained at room temperature during film growth. Pd-purified H_2 at a total flow of about 10 liters/min was used as the carrier gas in the deposition experiments. H_2S and H_2Se were at a minimum purity of 99.5 and 98.0%, respectively (Matheson Gas Products, East Rutherford, New Jersey).

BaF_2 and CaF_2 were purchased from the Harshaw Chemical Company (Solon, Ohio). Rockwell polished single-crystal BaF_2 windows and BaF_2 and CaF_2 wafers cleaved from 1 in. diameter rods were used as substrates. Cleaving into (111)-oriented substrate blanks was performed just prior to use in a film growth experiment. The α-Al_2O_3 was Czochralski material from Union Carbide Corporation (San Diego, California) and polished by Insaco (Quakertown, Pennsylvania). The $MgAl_2O_4$ was produced and polished by Union Carbide Corporation. The NaCl and MgO were single crystals that were cleaved just before use.

The PbTe substrates were all wafers sawed from crystals obtained from Electronic Materials Corporation (Pasadena, California) and polished in our laboratory (3). A slice of $Pb_{0.80}Sn_{0.20}Te$ was also obtained from this vendor for use as a standard for electron microprobe (EM) analysis of film composition. The probable accuracy of the composition was quoted by the supplier as ±1 mole per cent (m/o) as measured by the x-ray lattice parameter method.

Elemental scans by the EM were used to determine that the films formed were free of major impurities and consisted of the desired elemental constituents. Electrical measurements ranged from conductivity-type determinations with a thermoelectric probe to measurements of the carrier mobility and concentration in the films by the van der Pauw technique (4) at both room temperature and 77°K. Ohmic contact was made to the film usually by pressing small beads of In metal onto the film surface. Optical data to provide bandgap (and thus composition) information were obtained from transmittance scans made with a Beckman Model IR-5A infrared double-beam spectrophotometer.

The reactor used for this work was similar to the vertical quartz tube used in previous studies at Rockwell of III-V and II-VI film growth by the metalorganic CVD process (5-7). Measurements of the temperature of film deposition were accomplished by means of an infrared radiation thermometer (Infrared Industries Model TD-6B) used to sense the temperature of the SiC-coated pedestal through the wall of the quartz reactor tube.

Because it was noticed early in the studies that DMTe reacted with a hot BaF_2 surface, presumably forming BaTe, most of the subsequent compound growth studies involved premixing the reactants prior to their introduction into the reactor (except as noted). After film growth, the Group IV metalorganic reactant flows were stopped, and the film was maintained at the growth temperature in flowing H_2 and the Group VI containing gas for 1 min. The DMTe or hydride flow was then stopped, and the rf field was switched off.

PbTe Growth using Tetraethyllead (TEPb) or Tetramethyllead (TMPb) and Dimethyltellurium (DMTe)

Both TEPb and TMPb when mixed with DMTe and pyrolyzed in H_2 at temperatures as low as 475°C led to the formation of PbTe. The initial experiments were performed with TEPb, which was more readily available than the reportedly "unstable" TMPb (8), and

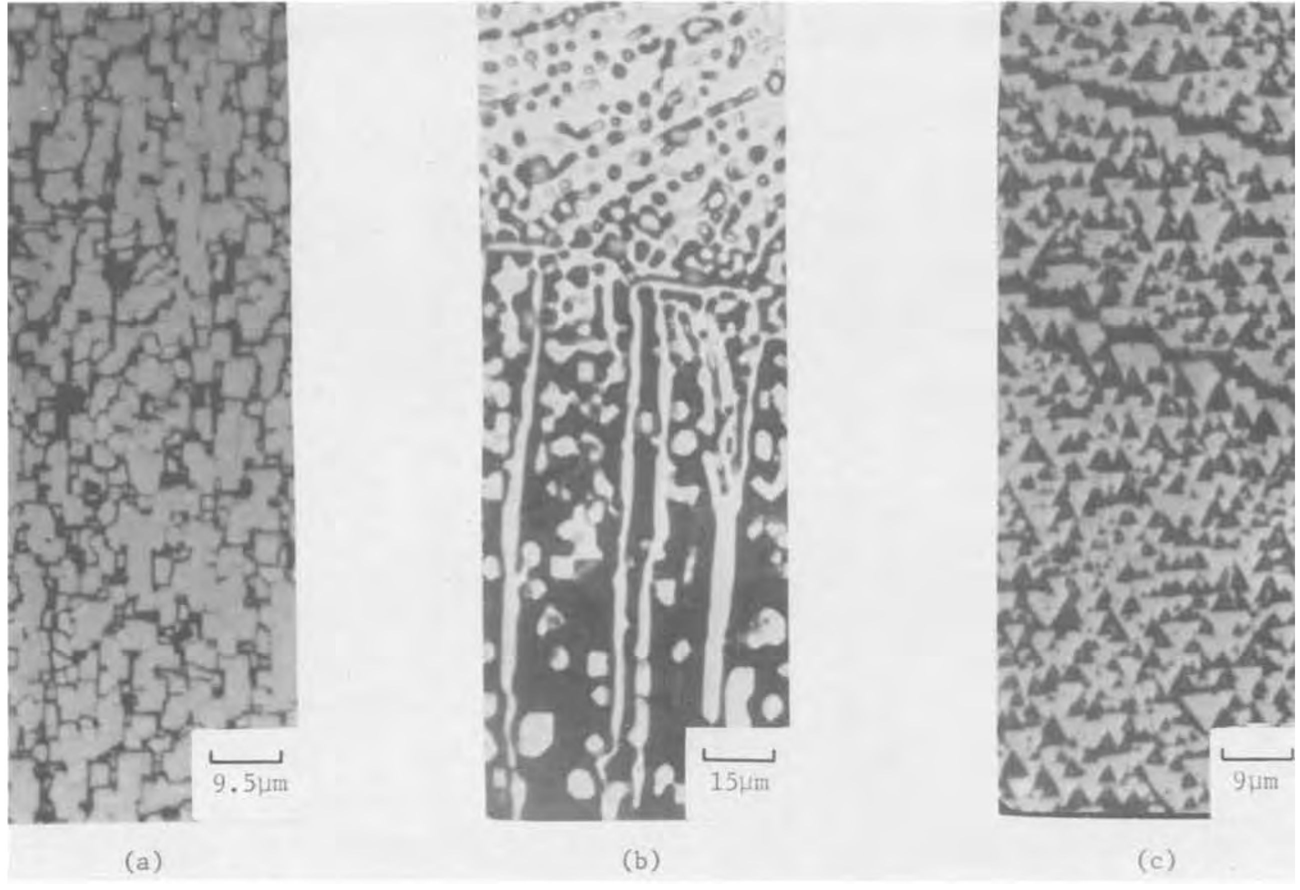

Fig. 1. Ordered growth of PbTe on cleaved (a) (100)MgO, (b) (100)NaCl, and (c) (111)BaF_2

conditions were established for growth of PbTe on BaF_2, MgO, NaCl, (0001)Al_2O_3, and (111)$MgAl_2O_4$.

The crystallographic ordering of the overgrowths shown in Fig. 1 suggested that epitaxy of PbTe had been obtained on cleaved (100)-oriented MgO, (100)-oriented NaCl, and (111)-oriented BaF_2 at film growth temperatures of 500°-525°C. Cleavage steps on the NaCl surface tended to act as scavengers for the film nuclei. The PbTe film on NaCl also displayed a "worm-like" structure, perhaps caused by an erosion of the NaCl surface in H_2 prior to being completely covered with PbTe. A 7.5 μm thick overgrowth on BaF_2 (Fig. 1c) displayed the trigonal structure usually associated with (111) growth.

Growth phenomena on Al_2O_3 and $MgAl_2O_4$ were different from those obtained on the other substrates. Crystallite growth was obtained on (0001)Al_2O_3 and (111)$MgAl_2O_4$ under film growth conditions which led to continuous film growth on BaF_2. Most of the crystallites were highly ordered on (0001)Al_2O_3 surfaces (see Fig. 2). They displayed a threefold specular reflection during rotation while the film was growing. By changing the deposition procedure slightly, that is, introducing TEPb into the reactor first, DMTe next, and then the TEPb-DMTe mixture, a continuous film on both (0001)Al_2O_3 and (111)$MgAl_2O_4$ was formed, as shown in Fig. 3. It was assumed that a first deposit, presumably of Pb, was converted to PbTe by the DMTe, and that subsequent growth of PbTe took place preferentially at nucelation sites produced in the previous steps. The true nature of this growth process has not yet been determined. Films at least 5 μm thick did not peel or pop off the substrates, in spite of the considerable tension generated by the large differences in thermal expansion coefficients

[$\alpha_{PbTe} = \sim 27 \times 10^{-6}/°C$; $\alpha_{Al_2O_3} = \sim 8 \times 10^{-6}/°C$; $\alpha_{MgAl_2O_4} = 7.5 \times 10^{-6}/°C$] [Ref. (2)]

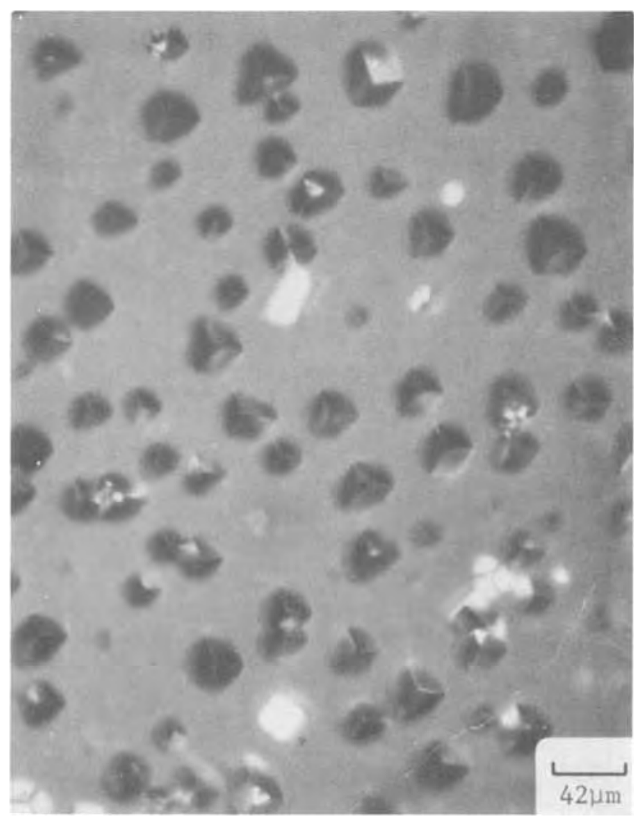

Fig. 2. Highly ordered PbTe crystallite growth on (0001)Al_2O_3

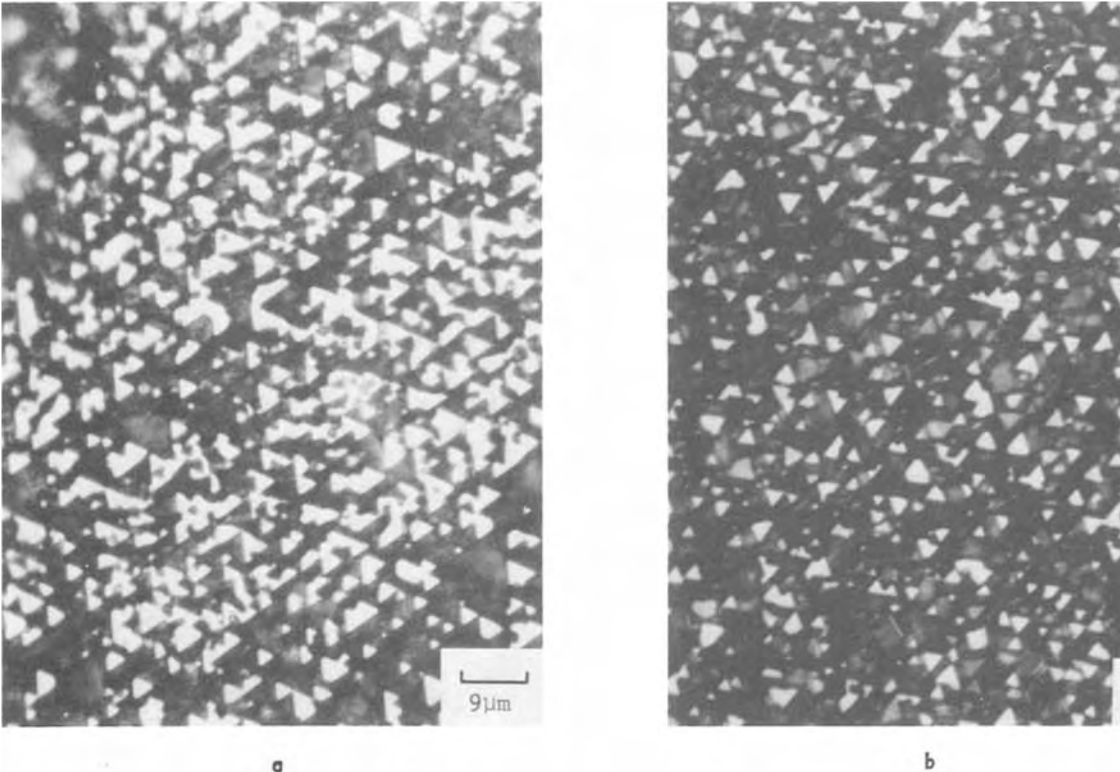

Fig 3. PbTe growth on (a) (0001)Al_2O_3 and (b) (111)$MgAl_2O_4$, after nucleating the film growth with Pb deposit. (Film thickness ~3 µm)

X-ray measurements established the relationships shown in Table II. Although the (111)PbTe and BaF_2 planes are parallel, 60° azimuthal rotation in the (111) plane is observed for these cubic materials. A 30° azimuthal rotation is noted for ~(111)PbTe on (111)$MgAl_2O_4$.

Optical transmittance scans made on the PbTe films indicated a bandgap energy of ~0.33 eV at room temperature, which is in agreement with other published values (9, 10).

Studies using the lower boiling tetramethyllead (TMPb) in place of TEPb as the source of Pb were found to be quite beneficial; PbTe growth rates at ~575°C increased from ~4-5 µm/hr (when the flow through the TEPb was 1 liter/min) to values up to about 60 µm/hr (when the flow through the TMPb was 400 cm^3/min). When the H_2 flow rates through TMPb and DMTe were adjusted to provide a flow ratio of about 1.3:1, a high quality p-type film of PbTe was grown at 625°C on a cleaved (111)BaF_2 substrate. The 13.8 µm thick film displayed the following electrical properties at room temperature: mobility (μ) = 632 cm^2/V-sec; hole concentration (p) = 1.7×10^{18} cm^{-3}. For a flow ratio of about 3:1 and a growth rate of ~32 µm/hr, an n-type film was grown. At room temperature, a mobility of 900 cm^2/V-sec was measured for the 16 µm thick film with a carrier concentration (n) of 5.3×10^{16} cm^{-3}; at 77°K, μ = 22,500 cm^2/V-sec and n = 4.3×10^{16} cm^{-3}. At higher TMPb-DMTe flow ratios (6:1) deposits on BaF_2 were formed with meshlike structures which appeared to be composed of needles and molten metal intermixed.

Growth of $Pb_{1-x}Sn_xTe$ Films using TEPb or TMPb, DMTe, and Tetraethyltin (TESn)

By pyrolyzing three-component mixtures of TEPb or TMPb, DMTe, and TESn in H_2, epitaxial films of

Fig. 4. Thick $Pb_{0.8}Sn_{0.2}Te$ film on substrate of cleaved (111)-oriented BaF_2 (substrate is resting on SiC-covered C pedestal).

$Pb_{1-x}Sn_xTe$ were readily formed at ~550°-625°C on (100)PbTe and cleaved (111)BaF_2 substrates. In these experiments, films with values of x up to 0.4 were produced. Growth rates of 6-8 μm/hr were realized at 550°C for $Pb_{0.8}Sn_{0.2}Te$ when flows of 1 liter/min were used to transport the TEPb or flows of 50 cm^3/min were used for the TMPb, with the concentration of TESn essentially constant at a H_2 flow of 3 liters/min. At 625°C, the growth rate of the alloy was ~20 μm/hr with the TESn flow at 2 liters/min.

Polished (111)BaF_2 surfaces, which were found to be generally not amenable to the growth of good quality PbTe nor $Pb_{1-x}Sn_xTe$, also seemed to suffer from the same type of atmospheric contamination that prevented good film growth on cleaved (111)BaF_2 surfaces that were exposed to the laboratory atmosphere for a few minutes. However, polished (100)BaF_2 was sufficient in many cases for the growth of almost featureless (100)-oriented PbTe and $Pb_{1-x}Sn_xTe$ films.

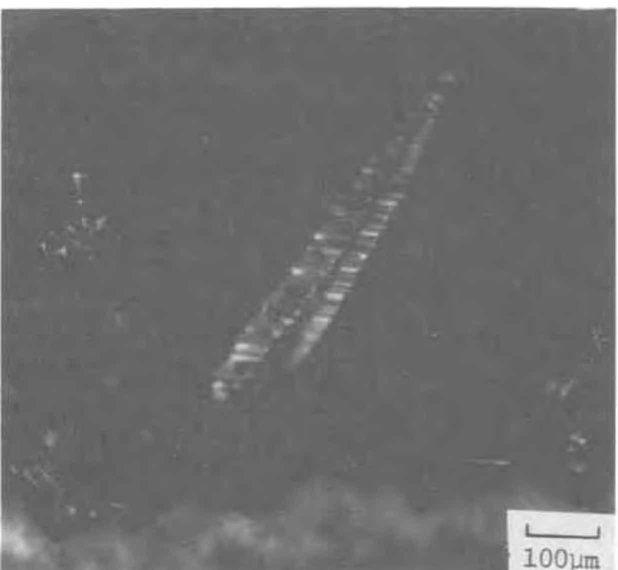
Films with $x \sim 0.2$ on cleaved (111)BaF_2 were p-type as grown, with room temperature resistivities (ρ) $\approx 2 \times 10^{-3}$ ohm-cm, hole concentrations (p) $\approx 5 \times 10^{18}$ cm^{-3}, and mobilities (μ) $\approx$ 570 cm^2/V-sec; at 77°K, $\rho \approx 2.5 \times 10^{-4}$ ohm-cm, p $\approx 7 \times 10^{18}$ cm^{-3}, and $\mu \approx$ 3500 cm^2/V-sec, properties consistent with those measured in some films of this composition grown by a two-source vacuum deposition method (11). Additional electrical and device properties of these films will appear elsewhere (12).

The growth of very thick (~100 μm) epitaxial $Pb_{0.8}Sn_{0.2}Te$ films on cleaved (111)BaF_2 substrates resulted in spike formation at the periphery of the substrate, and cleavage steps on the surface were clearly revealed (Fig. 4). Figure 5 illustrates the nature of some of the crystal spikes that emanated from the edges. The "shingled" effect was common on these growth spikes. Many of the crystals seemed to grow in a helix form and to possess a hollow interior. The growth habit of these crystals could be the basis of an interesting study.

A film of $Pb_{0.8}Sn_{0.2}Te$ grown to a thickness of ~100 μm on polished (100)PbTe possessed a heavily textured surface. It was characterized by a number of prominent crystallographic "out-croppings" similar to those occurring in thick films grown on BaF_2. A photomicrograph of the surface of such a thick (100)-oriented film is shown in Fig. 6.

Studies using Tetramethyltin (TMSn) as a Source of Sn

Tetramethyltin (TMSn) was evaluated as a possible source of Sn in place of TESn, in order to determine if films of composition $Pb_{0.8}Sn_{0.2}Te$ could be grown at high growth rates using the lower boiling (more volatile) TMSn. Several experiments using the TMSn, however, demonstrated that at 550°-600°C the efficiency of Sn formation from TMSn is inferior to that from TESn; even at relatively high flow rates of car-



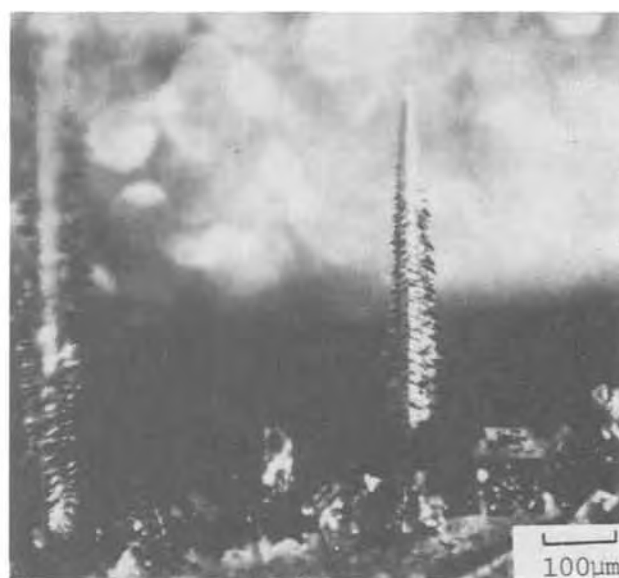


Fig 5. Various crystallite growth forms found around periphery of $Pb_{0.8}Sn_{0.2}Te$ deposit on BaF_2 shown in Fig. 4.

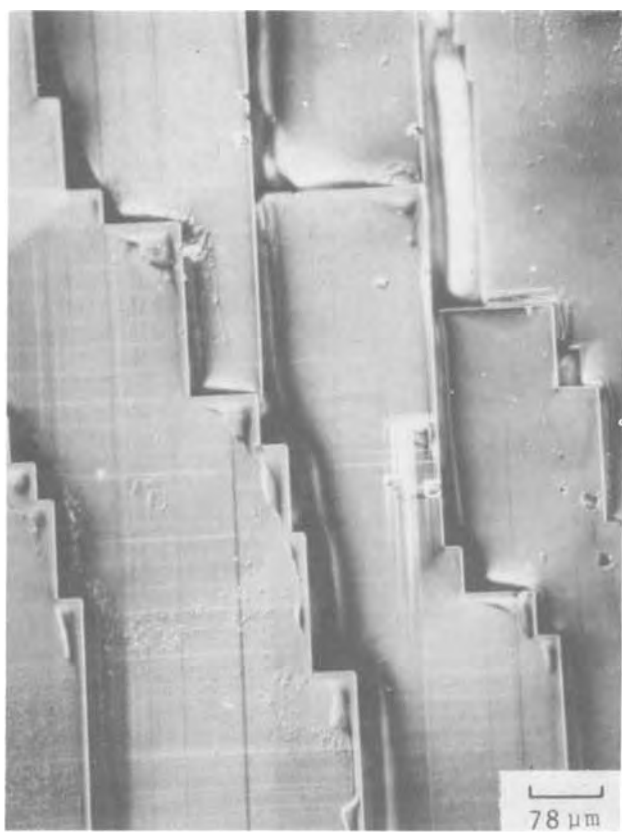

Fig. 6. Surface of (100)-oriented p-type $Pb_{0.8}Sn_{0.2}Te$ film (~100 μm thick) grown on polished (100)PbTe substrate.

rier gas through the TMSn (200 cm^3/min) alloys with $x > 0.1$ did not readily form.

Growth of PbS and PbSe

Single-crystal continuous films of PbS and PbSe were grown on cleaved (111)BaF_2, cleaved (111)CaF_2, and (0001)Al_2O_3 by pyrolyzing TMPb-H_2S and TMPb-H_2Se mixtures, respectively, at ~550°C. Film growth and coverage on Al_2O_3 was much more uniform and extensive than that obtained for PbTe growth on Al_2O_3. For growth rates of 0.1-0.3 μm/min films as thick as 25 μm possessed a purple cast. Scanning electron microscope (SEM) photographs taken normal to the surface revealed the nature of the surface of a few films that were grown during these preliminary studies. Pyramidal growth is displayed (Fig. 7) by these PbS and PbSe films on (0001)Al_2O_3 and (111)BaF_2. Needle growth was observed on the edges of BaF_2 substrates when thick films were grown, as occurred for PbTe and $Pb_{1-x}Sn_xTe$.

PbS and PbSe showed the same epitaxial relationships toward (0001)Al_2O_3 and (111)BaF_2 as did PbTe, and growth on (111)CaF_2 paralleled that obtained for PbTe on (111)BaF_2, including the 60° azimuthal rotation in the (111) plane.

Growth of Sn-VI Films

Some preliminary experiments were also made to determine if reaction of TESn with DMTe, H_2S, and H_2Se would lead to Sn-VI compound formation. In all experiments, the H_2 flow through the TESn was kept constant at 2 liters/min. The flow through DMTe and the H_2S and H_2Se flows were arbitrarily set at 75, 25, and 50 cm^3/min, respectively.

At 625°C, some ordered growth of SnTe was obtained on the substrates examined, cleaved (111)BaF_2, and polished (100)PbTe. Considerable trigonal structure usually associated with (111) growth was obtained on the BaF_2, particularly near the edges of the substrate (see Fig. 8a). Growth on (100)PbTe produced the array of islands shown in Fig. 8b. Large crystallites with parallel faces and, in some cases, prominent hollow centers grew at the edges of the PbTe substrates under these less-than-optimum growth conditions (Fig. 8c).

The nature of the growth of the S and Se chalcogenides of Sn, which possess an orthorhombic structure, was not like that of cubic SnTe. Tin sulfide films, ~3 μm thick, grown at 550°C simultaneously on cleaved (111)BaF_2 and (111)CaF_2 tended to peel from the BaF_2 but adhered to the CaF_2. At 500°C, tin selenide grew as crystallites on BaF_2. An orienting influence of the substrate is suggested by the parallelism and 60° symmetry displayed by many of the crystallites (Fig. 9). In the early growth stages the films possessed a yellow-orange color; thicker films were gray (13). Both compounds nucleated poorly on (0001)Al_2O_3. It was not determined if the Sn was in the divalent or quadrivalent state. It was presumably in the former because of the reducing atmosphere used. Further studies in the growth of the Sn chalcogenides are contemplated.

Conclusion

The metalorganic CVD process has been extended to include the formation of films of a number of Pb and Sn-Group VI compounds and alloys. Epitaxial films of PbTe, $Pb_{1-x}Sn_xTe$, PbS, and PbSe have been grown to date on substrates such as PbTe, BaF_2, Al_2O_3, and $MgAl_2O_4$. Tin chalcogenides were also formed. Tetraethyllead or tetramethyllead was used as the source of Pb, tetraethyltin for Sn, dimethyltellurium for Te, and H_2S and H_2Se as the sources of S and Se, respectively.

The as-grown $Pb_{1-x}Sn_xTe$ films were p-type; PbTe films could be grown either p- or n-type by controlling the ratio of the reactants in the gas phase and the growth temperature. For the same carrier concentration range, the Hall mobilities of the films are comparable to those grown by vacuum deposition processes.

Acknowledgments

The authors are grateful to their associates in the Rockwell Electronics Group for assistance with these investigations: J. P. Wendt for measurement of the electrical properties of the films; R. F. Cunningham for the electron microprobe analyses; J. E. Coker and G. W. Johnson for sawing and polishing the PbTe substrates; and L. A. Moudy, Dr. J. L. Kenty, and R. E. Johnson for x-ray and scanning electron microscope examination of some of the films. We also acknowledge the support of Dr. J. L. W. Pohlmann of the Night Vision Laboratory who monitored the cited contract and Dr. R. P. Ruth for reviewing the manuscript.

Brief Communications

Ohmic Contacts to Al-Implanted ZnSe

B. K. Shin,[1] D. C. Look,[2] and Y. S. Park

Aerospace Research Laboratories, Wright-Patterson Air Force Base, Ohio 45433

The production and characterization of ohmic contacts is an important part of semiconductor technology. In this paper we report the formation of ohmic contacts on ZnSe, by evaporating or sputtering Au or Pt onto the Al-implanted, n-type substrate. Although these metals normally form rectifying Schottky barriers on n-type ZnSe, such barriers are precluded if the implanted layer is degenerate. An advantage of Au or Pt contacts is that much higher operating temperatures are possible than with the commonly used In or Ga.

The Al implantation was carried out at 90 keV to a dose of 10^{15} ions/cm^2 at room temperature.[3] The substrate was a high-resistivity ($\sim 10^9$ ohm-cm) crystal cut to expose the (110) face. Before implantation, the surface was mechanically polished and chemically etched at 90°C for 1 min in a mixture of 2 parts H_2SO_4 and 3 parts saturated aqueous solution of $K_2Cr_2O_7$, followed by a 20 sec rinse in a boiling 25% solution of NaOH. In a previous paper (1) it was reported that crystals implanted in such a manner and annealed in evacuated fused-silica ampuls for 4 hr at 900°C showed nearly degenerate electrical characteristics, with an effective electron mobility of about 4 cm^2/V-sec and an effective sheet carrier concentration of about 10^{15} cm^{-2}. When unimplanted samples and samples implanted with Ar ions were annealed under the same conditions, they remained highly resistive. This showed that the Al implantation was essential for the production of the conductive layer, *i.e.*, neither the annealing alone nor the radiation damage produced by Ar ions were sufficient to appreciably change the conductivity of the original substrate. The thickness of the implanted and annealed conductive layer was roughly checked by the use of the etch described above. This etch removes about 50 A/sec from unimplanted ZnSe at room temperature and the rate for implanted ZnSe

Key words: metal-semiconductor contacts, contact resistance, ion implantation.
[3] The ion implantation was done at NASA Langley Research Center.

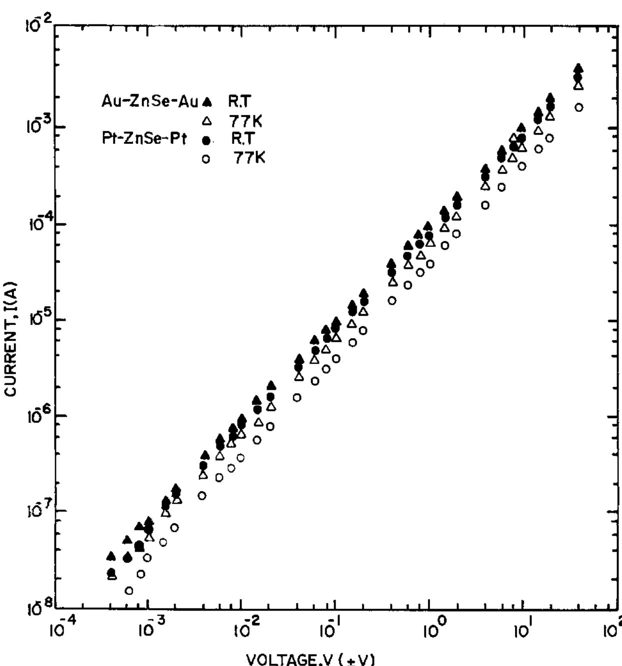

Fig. 1. I-V characteristics of Au and Pt contacts on Al-implanted, annealed ZnSe at 77° and 300°K.

is probably about the same. It was found that etching for about 1000 sec was necessary to reduce the conductivity to that of the original substrate. This suggests that the implanted layer, after annealing, was about 5 μm thick, giving an average doping concentration of about 10^{18}-10^{19} cm^{-3}. Such a concentration is consistent with the observed nearly degenerate electrical characteristics.

Two Au (or Pt) contacts, of 0.1 cm diameter, were evaporated (or sputtered) 0.35 cm apart on the implanted, annealed surface. Current *vs.* voltage measurements were carried out at 77° and 300°K, over a voltage range of 4 × 10^{-4}-40V. The magnitude of the current was the same for both voltage polarities. The results are plotted in Fig. 1. Both Au and Pt contacts were found to be ohmic over five decades of voltage; however, the Pt did show some departure from ohmic behavior below 1 mV. The contact resistance, R_c, was determined from the relationship

$$R_c = \frac{1}{2} (R - R_{\square} L/W) \quad [1]$$

where $R \equiv V/I$, $R_{\square}$ is the sheet resistivity [denoted by ρ' in Ref. (1)], L is the contact spacing, and W is the sample width. The results of this calculation are presented in Table I, but it must be emphasized that Eq. [1] is only approximate with our contact geometry. For comparative purposes we also list the contact resistivity (2), $\rho_c \equiv R_c A_c$, where A_c is the effective contact area, taken in this case to be just the actual contact area. It is seen that $\rho_c \simeq$ 10-20 ohm-cm^2 for contacts produced in the manner described above.

Table I. Contact properties of Al-implanted annealed ZnSe

Contact metal	Temperature (°K)	$R_{\square}$ (kohm/□)	R (kohm)	R_c (kohm)	ρ_c (ohm-cm^2)
Au	300	8.76	10.40	2.13	16.72
	77	14.10	16.10	3.10	24.33
Pt	300	13.70	12.60	0.95	7.45
	77	28.50	25.40	1.60	12.56

The small temperature dependence of ρ_c suggests that a tunneling mechanism dominates the thermionic emission. For tunneling in a Schottky barrier at low temperatures and low bias voltages ($V << E_b/q$), ρ_c is dominated by (3, 4) exp (E_b/E_{oo}) where E_b is the effective barrier height, and $E_{oo} \equiv (\hbar q/2)\ (N/\epsilon m^*)^{1/2}$. Here N is the doping density (assumed equal to the carrier concentration), ϵ is the specific permittivity, and m^* is the effective mass. If $N \simeq 10^{18}$-10^{20} cm^{-3}, then E_b must be about 0.1-1 eV, a reasonable range, to give the right order of magnitude for ρ_c. However, this model would predict linear I-V characteristics only for $V \lesssim E_{oo}/q$, and since E_{oo} = 20-200 meV for $N = 10^{18}$-10^{20} cm^{-3} we would not expect linear behavior above about 100 mV. The fact that such behavior is observed even at 10V suggests that the barrier becomes completely transparent in both forward and reverse bias conditions when a highly doped shallow layer having a surface carrier concentration of $\sim 10^{15}$ cm^{-2} is formed.

The Semiconductive Property of Gamma-Ferric Oxyhydroxide

Katsumi Kaneko and Katsuya Inouye

Department of Chemistry, Faculty of Science, Chiba University, Chiba, Japan

The recent investigations by Cohen *et al.* on the passive films deposited upon iron or platinum from neutral ferrous sulfate solution (1) or ferrous perchlorate solution (2) strongly suggest that the composition of these films corresponds to crystalline γ-FeOOH. It appears that the electrical properties of FeOOH-type oxides have not been studied extensively, although the ultimate characteristics of such substances should have pregnant implications for the function of surface films.

Key words: passive film on iron, γ-FeOOH, electrical conductivity.

In the preceding study on the electrical properties of ferric oxyhydroxides (3), the present authors found that α-, β-, and γ-FeOOH are semiconductors which show d-c conductivity in the order of 10^{-9} ohm^{-1} cm^{-1} and high-frequency (7 MHz) conductivity of 10^{-6}-10^{-7} ohm^{-1} cm^{-1} and which probably have negative carriers. The appropriate value of conductivity ob-

tained for each ferric oxyhydroxide was in the order: γ-FeOOH > β-FeOOH > α-FeOOH. These facts were further utilized to discuss the conduction mechanism based on the crystallographic structure of each compound.

In the course of further study, particular changes in the conductivity were observed with respect to the temperature and the oxygen pressure, more markedly for γ-FeOOH than for α-FeOOH and β-FeOOH. Pure α- and β-FeOOH crystals were prepared as described in the preceding report (3) by the hydrolysis of ferric sulfate and ferric chloride solutions respectively at suitable *p*H ranges. γ-FeOOH was obtained by warming at 60°C for 50 min a solution of 500 ml 0.2M ferrous chloride, 100 ml 2M hexamethylenetetramine, 13.5 ml concentrated HCl, and 100 ml 1M sodium nitrite. The resulting precipitate was washed thoroughly and dried at 100°C for 3 hr for α- and β-FeOOH, and at 60°C for 10 hr for γ-FeOOH. Specimens formed as disks of crystals under a pressure of 150 kg/cm^2 were set between electrodes in a glass cell, evacuated at 10^{-5} Torr, and thus held for 14 hr at the different temperatures of 100°, 110°, 125°, and 140°C. After this pretreatment, the conductivity was determined over the temperature range from −170° to 140°C and various frequencies. For the samples pretreated at 125° and 140°C, the effect of oxygen on the conductivity was examined at 30°C and various total pressures over the range 10^{-2}-10^{+2} Torr.

It was found that the logarithm of conductivity is proportional to the reciprocal of experimental temperature for each oxyhydroxide. The dependence of log σ on $1/T$ was almost identical for α- and β-FeOOH irrespective of the pretreating temperature, whereas that for γ-FeOOH varied with the pretreating temperature. Moreover, γ-FeOOH pretreated at 125° and 140°C revealed two different slopes of the temperature dependence of d-c conductivity, as shown in Fig. 1, which gave the activation energies of *ca.* 0.1 eV at the lower temperature region and 0.3-0.4 eV at the higher temperature region. It may thus well be that γ-FeOOH has two conduction mechanisms depending on the temperature. The dividing temperature between the two mechanisms is higher for the 140°C pretreatment than for the 125°C one. The activation energy for the low pretreatment temperature appears to decrease with increasing pretreatment temperature; it could not be determined whether a change in mechanism occurs at these temperatures (100° ~ 110°C), because the conductivity was too low to measure.

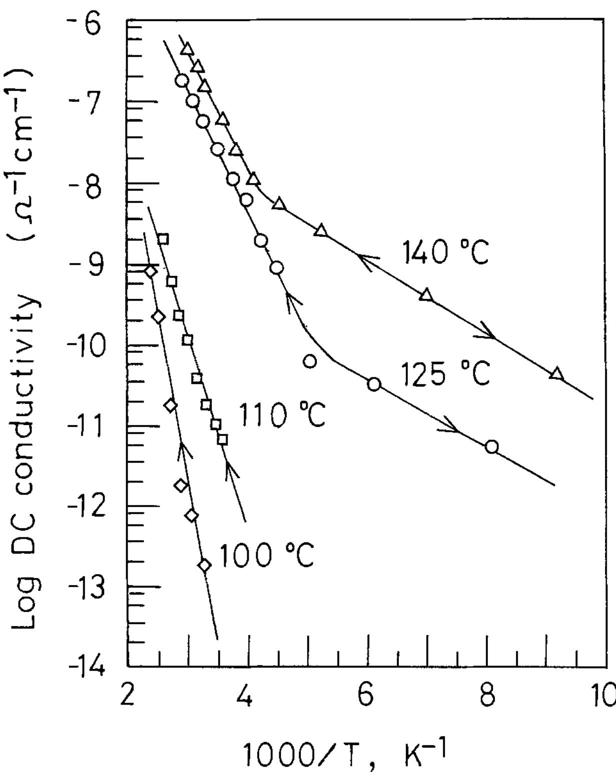

Fig. 1. Temperature dependence of d-c conductivity for γ-FeOOH preheated at different temperatures.

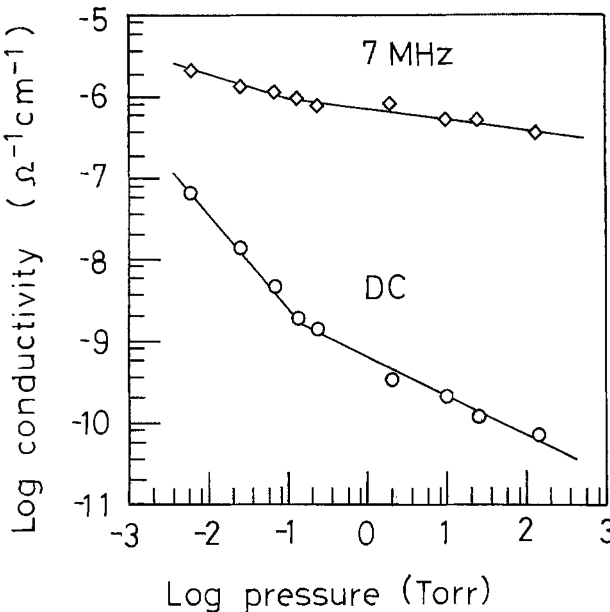

Fig. 2. Decrease of conductivity with oxygen pressure for γ-FeOOH at 30°C preheated at 125°C for 14 hr under 10^{-5} Torr.

The conductivity decreased generally with the oxygen pressure for each oxyhydroxide, but the relationship was most noticeable for γ-FeOOH as shown in Fig. 2, which shows the relationship between the logarithms of conductivity and oxygen pressure for γ-FeOOH pretreated at 125°C. In this figure, two different slopes are observed in both the d-c conductivity and the high-frequency conductivity with a borderline at approximately 0.1 Torr.

These observations may testify that the baking and evacuation of γ-FeOOH in particular result in the formation of oxygen defects in crystals, making the movement of electrons more facile presumably by the increase in mobility. It is interesting that the changes in Fig. 1 were almost reversible with increasing and decreasing temperatures. By irradiating γ-FeOOH with electron beam at 50 kV for not less than 10 min in the vacuum of 10^{-5} Torr, the electron diffraction pattern corresponding to (200) became diffuse and faint, indicating possibly the destruction of intra-lamellar lattices of γ-FeOOH crystals. The sharpness of diffraction pattern was recovered by cooling the sample.

It is very likely therefore that γ-FeOOH has a particularly sensitive and mobile structure and the characteristics recognized may be pertinent to the stationary stability of the passive state of iron surfaces.

The detailed results of this experiment will be published elsewhere.

A Polarization Cell for Organic Electrolytes

G. A. Capuano*

Department of Chemistry, University of Quebec in Montreal, Montreal, Quebec, Canada

and W. G. Davenport

Department of Mining and Metallurgical Engineering, McGill University, Montreal, Quebec, Canada

ABSTRACT

An all-glass cell for studying the polarization behavior of organic electrolytes has been developed. The cell is completely enclosed so that the tests can be carried out in isolation from atmospheric moisture. Cathode overvoltages are measured by means of a metal *vs.* ion reference electrode situated behind the cathode and a 0.8 mm diameter Luggin capillary drilled through the cathode to its working face. Two side reference electrodes are also affixed into the cell. The cell has been tested using a $CuSO_4$, H_2SO_4 aqueous electrolyte and an ethyl benzene-toluene 1:1 (50 weight per cent $AlBr_3$) organic electrolyte. The aqueous tests indicated that the cathode overvoltage can be determined and reproduced by three independent measurement techniques. Tests with the organic electrolyte have led to consistent Tafel plots which indicate that the cell can be successfully used for corrosive, high viscosity organic electrolytes.

A number of alkyl benzene-$AlBr_3$ electrolytes have been developed for the plating of aluminum onto metal substrates (1-4). The mechanisms of plating from these electrolytes are not well known, and as a first step in understanding the plating process, an investigation into cathode overvoltages was undertaken. A polarization cell with which overvoltages can be measured while the electrolyte is isolated from the atmosphere was developed specifically for this purpose.

* Electrochemical Society Active Member.
Key words: alkyl benzene electrolytes, aluminum plating, organic electrolytes, overvoltages, polarization cell.

The cell was constructed from glass rather than an organic polymer (plastic) so that it can be used for a wide range of organic electrolytes without fear of contaminating the solution with the container material. It is the object of this paper to describe the design of the polarization cell and its testing and use.

The Cell

The polarization cell is described in Fig. 1, 2, 3, and 4. It consists of a cylindrical glass body with the working electrodes occupying the cross section of the cell, at each end. A reference electrode is situated behind the

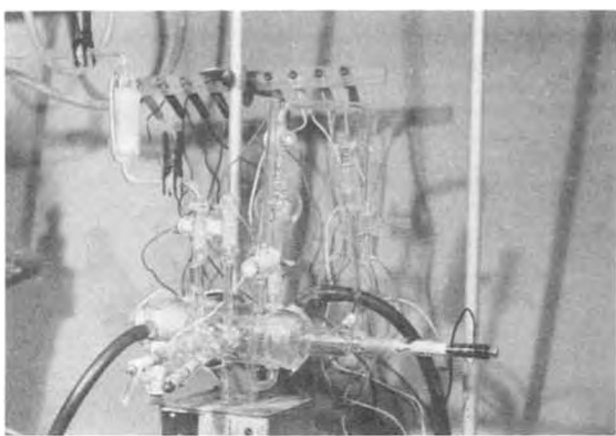

Fig. 4. Photograph of polarization cell with electrical and cooling connections made.

cathode, and it penetrates to the front through a 0.8 mm glass-lined hole (Luggin capillary). The reference electrode is the metal *vs.* ion type, in which the metal is that being plated and the ions are those in the electrolyte. Since the back reference electrode and the working electrode (cathode) are the same material, the dynamic potential difference between them (assuming no *IR* drop or concentration polarization) represents the cathode polarization for any given plating condition.

Comparison with previous cells.—The back electrode design of the present cell is similar to that used by Piontelli (5, 6) for aqueous electrolytes. Piontelli suggests that of all the capillary systems, this configuration provides a minimum of electrical field distortion at the cathode surface. One problem with the Luggin capillary technique is, however, that it introduces a resistance error between the tip of the capillary and the working face of the cathode. In the case of the reference electrode used in the present cell this manifests itself in an electrolyte resistance which is roughly equivalent to the thickness of the glass lining of the hole through the cathode (0.01 mm).

This resistance problem has been attacked in several ways by other workers, principally Eisenberg (7), and Cahan (8), who also reviews the criteria of good polarization cell design. Eisenberg (7) studied cathode polarization for LiCl-$AlCl_3$-propylene electrolytes using side reference electrodes in a polypropylene cell. However, this method is subject to concentration polarization errors if the electrolyte is not evenly stirred throughout the cell. It must, therefore, be regarded only as an indirect measurement technique.

Cahan (8) employed a Teflon cell with a thin conical or horizontal slot around the circumference of the cathode surface in place of a Luggin capillary. This design eliminates current distortion at the cathode surface due to the reference electrode and it permits estimation of the resistance error between the cathode and the reference electrode. Cahan's measurements show that the error in this cell is equivalent to about a 0.02 mm column of liquid which is of the same order as that in the present cell ($\approx$0.01 mm). The thickness of the horizontal slot can be varied in the Cahan cell, a facility which can be important when stable potentiostatic control is required. Thus the Cahan cell has a number of desirable features. Unfortunately it requires machining during its fabrication which means that its container material is restricted to Teflon or other polymer materials.

Many organic electrolytes will attack polymers so that prior to the development of the present cell it was decided that glass is the only completely satisfactory material. As it turned out this was a propitious choice because Teflon is slowly attacked by the alkyl benzene electrolytes. With an all-glass construction, a back reference electrode connected to the cathode surface via a glass-walled capillary through the cathode, appeared to be the best system of measurement from the points of view of minimizing current distortion and the resistance error.

Experimental

The components of the experimental cell are presented in detail in Fig. 1. The cell consists of a cylindrical glass body, 2 cm in diameter and 7.5 cm long, built within a thermostatically controlled ($\pm$0.1°C) water chamber. The anode is a rod of the metal under study, machined to fit the 24/40 T glass joint of the cell. The electrolyte is stirred by means of a micromagnetic Teflon-covered bar. Grease is avoided in all joints and connections of the cell, and Teflon leaves are employed where necessary.

The cathode is a platinum disk, 0.5 mm thick (Fig. 1) and 1.8 cm diameter, affixed by melted glass onto a 24/40 T glass joint. The electrical connection to the power supply is through a platinum wire welded to the back of the cathode.

A 0.8 mm hole was drilled through the platinum disk and its supporting glass joint half way between the center and the border of the disk. This hole (2-3 mm long) provides the connection between the reference electrode and the front of the cathode. It is the actual Luggin capillary of the reference electrode. The side of the hole was insulated by melting a drop of glass into the hole followed by forcing a 0.8 mm diameter needle through it. Microscopic examination showed that the walls were 0.01-0.015 mm thick after this operation. The final step in completing the cathode and back reference electrode system was to weld a receptacle for the reference electrode into the hollow 24/40 T joint (Fig. 1).

The metallic part of the back reference electrode is either a 1 mm diameter platinum wire freshly plated with the metal under study or a 1 mm wire of the

metal under study. It is placed 0.75 cm from the main body of the electrolyte (Fig. 1). Moving the electrode tip ±0.25 cm from this point was found to have no effect on the polarization measurements. Two auxiliary side reference electrodes are equispaced between anode and the cathode.

The auxiliary apparatus for the cell consists of a potentiostat Type 20 PRT-10X which is used to supply constant current, and a high impedance digital millivoltmeter Type ARIES 1000 with an accuracy of 0.1% of the full scale reading which is used to measure the potential across the electrodes. An ammeter Type MAR 298 with an accuracy of 0.1% of the full scale reading is used for the measurement of current density. These instruments are all "Tacussel" design (TechnEurope, Montreal).

Testing the cell.—The usefulness and accuracy of the cell were tested with (*i*) an aqueous solution 1*N* in $CuSO_4$, 1*N* in H_2SO_4 using a copper anode and copper-plated platinum reference electrodes; and (*ii*) an organic electrolyte, ethyl benzene-toluene 1:1 by volume with 50 weight per cent (w/o) $AlBr_3$, using an aluminum anode and aluminum reference electrodes.

The copper sulfate electrolyte was used to evaluate the consistency of the back and side reference electrodes in determining cathode overvoltages. This electrolyte is much more easily prepared and handled than the organic electrolyte and it was, therefore, the first electrolyte studied in the cell. The subsequent organic electrolyte tests used only the back reference electrode and the performance of the cell was evaluated for this system on the basis of the consistency and reproducibility of the measured overvoltages. The results were also compared on the basis of a standard Tafel plot.

Procedures.—The basic experiments for both the aqueous and organic tests were started by filling the cell with prepared electrolyte (an outline of the preparation is appended at the end of the paper), followed by a brief period of plating the particular metal onto the cathode and the back and side electrodes. This was accomplished by connecting the cathode and reference electrodes in turn as the cathode. Once this procedure was complete, the electrodes were connected in their proper working and measuring circuits and normal plating was begun under controlled current density conditions. The potential measurements were made after 1 min of plating at each preset current density.

Measurements and interpretation.—The measurements taken for the copper sulfate electrolyte were (Fig. 3): $E_{(C\text{-}Rf3)}$, $E_{(C\text{-}Rf1)}$, $E_{(Rf3\text{-}Rf1)}$, $E_{(Rf1\text{-}Rf2)}$, where the E values represent the difference in potential between the respective electrodes as indicated in Fig. 3.

The results were interpreted on the basis of the following considerations.

(*i*) Since for each system all the electrodes are of the same metal and since the electrolyte composition is uniform throughout the cell due to its stirring system; then the static potential of each electrode is the same, *i.e.*

$$e_A = e_C = e_{Rf1} = e_{Rf2} = e_{Rf3} \qquad [1]$$

(*ii*) E_C, the dynamic potential of the cathode during current flow is $e_C + \eta_C$ where η_C is the cathode overvoltage. In the absence of concentration gradients in the cell, as is assumed here, η_C is due entirely to the electrode reactions themselves.

(*iii*) Thus the potential difference between C and Rf3 (the back reference electrode) during current flow is given by

$$E_{(C\text{-}Rf3)} = (e_C + \eta_C) - e_C = \eta_C \qquad [2]$$

which means that the overvoltage is measured directly, assuming there is no *IR* drop between the cathode surface and the Luggin capillary.

(*iv*) Similarly

$$E_{(C\text{-}Rf1)} - E_{(Rf3\text{-}Rf1)} = e_C + \eta_C - e_{Rf1} + IRel_{(C\text{-}Rf1)} - [e_{Rf3} - e_{Rf1} + IRel_{(Rf3\text{-}Rf1)}] \qquad [3]$$

where $IRel_{(C\text{-}Rf1)}$ and $IRel_{(Rf3\text{-}Rf1)}$ are the *IR* voltage drops in the electrolyte between C and Rf1 and between Rf3 and Rf1, respectively. In this case the cathode C, and Rf3 are essentially at the same position so that the two *IR* drops cancel and

$$E_{(C\text{-}Rf1)} - E_{(Rf3\text{-}Rf1)} = \eta_C \qquad [4]$$

It can be seen that measurements (*iii*) and (*iv*) provide two independent methods of determining η_C. In addition, η_C can be obtained from measurements of $E_{(C\text{-}Rf1)}$, $E_{(Rf1\text{-}Rf2)}$, and f, the ratio of the electrolyte resistances between C and Rf1 and between Rf1 and Rf2. From these measurements

$$E_{(C\text{-}Rf1)} - E_{(Rf1\text{-}Rf2)} \cdot f = e_C + \eta_C - e_{Rf1} + IRel_{(C\text{-}Rf1)} - [e_{Rf1} - e_{Rf2} + IRel_{(Rf1\text{-}Rf2)}]f \qquad [5]$$

from which

$$E_{(C\text{-}Rf1)} - E_{(Rf1\text{-}Rf2)} \cdot f = \eta_C \qquad [6]$$

f was determined in preliminary experiments during which a few milliamperes of current were passed through the cell between the anode and Rf3. The resistances were determined from the current flow and the measured voltages between the pertinent electrodes. For our specific cell, f has the value of 1.10.

In summary then, measurements of four potential differences and a preliminary determination of the relative resistances between electrodes provides three independent methods of determining the cathode overvoltage. In testing the cell, these three determinations were employed to check the reproducibility and internal consistency of the polarization measurements.

Test Results

Cathode overvoltage, copper sulfate system.—The cathode overvoltages for the aqueous electrolyte as determined[1] by Eq. [2], [4], and [6] are presented in Table I. It can be seen that the values are in good agreement (within ±3%) for the three independent determinations. It can be noticed that the overvoltages obtained by Eq. [6] become slightly larger than those of Eq. [2] at the high current densities. This may be the result of a slight concentration gradient in the cell due to imperfect stirring. If such a concentration gradient exists, then Eq. [1] becomes

$$e_C = e_{Rf3} = e_{Rf1} + \eta_G = e_{Rf2} + \eta_G \qquad [7]$$

where η_G is the concentration polarization due to the difference in cation concentration between the electrodes C, Rf3 and Rf1, Rf2 (assuming the latter are at the same concentration as a result of the stirring system). Equation [6] then becomes

$$E_{(C\text{-}Rf1)} - E_{(Rf1\text{-}Rf2)} \cdot f = \eta_C + \eta_G \qquad [8]$$

and since

$$\eta_C = E_{(C\text{-}Rf3)} \qquad [2]$$

then

$$\eta_G = E_{(C\text{-}Rf1)} - E_{(Rf1\text{-}Rf2)} \cdot f - E_{(C\text{-}Rf3)} \qquad [9]$$

[1] Small residual static potentials were observed before and after each test. For purposes of calculation these were subtracted from their equivalent dynamic potential. They were not significant at current densities above 2 mA cm^{-2}.

Table I. Calculated cathode overvoltages, aqueous electrolytes 300°K

Current, mA	Current density, mA/cm²	η_C (mV) Eq. [2]	η_C (mV) Eq. [4]	η_C (mV) Eq. [6]	η_G (mV) Eq. [9]
1.0	0.4	−9.4	−8.7	−8.8	+0.6
2.0	0.8	−30.7	−30.2	−31.3	−0.6
4.0	1.6	−77.8	−77.8	−78.0	−0.2
8.0	3.2	−90.4	−90.2	−89.4	+1.0
16.0	6.4	−116.1	−117.0	−114.9	+1.2
20.0	8.0	−117.4	−117.4	−120.3	−2.9
24.0	9.6	−117.8	−117.9	−123.0	−5.2
30.0	12.0	−119.1	−119.6	−125.1	−6.1

Table I shows this effect and it indicates that η_G never became more than 5% of η_C during the testing. The factor η_G does not come into Eq. [2] and [4].

Table I indicates, therefore, that the overvoltage determinations in the cell are reproducible by three independent measurement techniques, and that the cell can be used with confidence. Calculations using Eq. [6] are not, however, as satisfactory as those using Eq. [2] and [4] because a concentration polarization error may be introduced.

Cathode overvoltage, organic system.—The applicability of the cell for use with organic electrolytes was tested by determining cathode overvoltages for the ethyl benzene-toluene-$AlBr_3$ system at several temperatures and current densities. The measured variable was $E_{(C\text{-}Rf3)}$ which directly gives η_C (Eq. [2]). The polarization behavior of the ethyl benzene-toluene-$AlBr_3$ system had not been studied prior to this work so that the only method of testing the consistency of the experimental data was by means of a Tafel plot of η_C *vs.* $\log i_C$ (cathode current density).

This plot (Fig. 5) gave a series of parallel lines in which η_C consistently decreases with increasing temperature. The lines also appear to straighten above η_C values of 20 mV. This would be expected if the Tafel equation

$$\eta_C = A - B \log i_C \qquad [10]$$

is obeyed, *i.e.*, if the controlling electrode mechanism is charge transfer.

The organic electrolyte data are, therefore, internally consistent leading to the conclusion that the cell is suitable for organic polarization studies. It has subsequently been used to examine a number of alkyl benzene-$AlBr_3$ electrolytes.

Discussion

The cell was found to be specifically suitable for electrolytes which must be protected from the atmosphere and which tend to be contaminated by polymer container materials. High viscosity electrolytes such as ethyl benzene-toluene-$AlBr_3$ solutions can also be handled quite readily.

As was pointed out at the beginning of this paper, the main defect of the cell design is the *IR* voltage drop between the tip of the Luggin capillary of the back reference electrode and the working face of the cathode. This has not been taken into consideration in Table I or Fig. 5.

The distance between the capillary tip and the cathode surface is the thickness of the glass wall. The magnitude of the *IR* voltage error can be estimated by the equation

$$E_{IR} = \frac{i_C \delta}{K} \qquad [11]$$

where i_C is the current density, δ is the glass wall thickness, and K is the specific conductance of the electrolytes. This calculation is equivalent to considering that the Luggin tip is at a distance δ in front of the cathode (9).

Thus with an ethyl benzene-toluene-$AlBr_3$ electrolyte ($K = 4 \times 10^{-3}$ ohm^{-1} cm^{-1}) and a glass thickness of 0.001 cm, the values of E_{IR} from Eq. [11] are 1.25, 2.5. and 4 mV at current densities of 5, 10, and 15 mA/cm^{-2}, respectively. The actual values of E_{IR} are likely to be considerably less than these calculated values because the capillary tip is displaced horizontally rather than in front of the cathode, and because of the edge effect which tends to slightly increase the potential around the cathode hole due to field distortion (10, 11). In any case the error does not significantly alter the results shown in Fig. 5.

The cell can also be used for anode polarization but this aspect of its operation has not been tested.

Conclusions

1. A cell has been developed for studying the polarization characteristics of organic electrolytes. The cell is specifically useful for electrolytes which must be protected from the atmosphere and which should not be exposed to organic materials of construction.
2. The cell employs a back reference metal *vs.* metal ion electrode, and two side electrodes. By this arrangement cathode overvoltages can be measured by three independent techniques to check the consistency of the cell operation.
3. The cell has been tested successfully with an aqueous copper sulfate solution and with an organic ethyl benzene-toluene-$AlBr_3$ electrolyte.

Acknowledgments

The authors wish to thank the National Research Council of Canada and the Defence Research Board of Canada for financial support of this work. The authors also wish to thank Dr. R. Minto for his valuable suggestions and Mr. R. Striegler for his technical assistance.

Manuscript submitted July 30, 1973; revised manuscript received Sept. 18, 1974.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1975 JOURNAL. All discussions for the December 1975 Discussion Section should be submitted by Aug. 1, 1975.

APPENDIX

Electrolyte Preparation

1. Aqueous electrolyte, copper sulfate, sulfuric acid: reagent grade. Copper anode: electrolytic copper 99.994% Cu, Canadian Copper Refiners Company, Limited, Montreal. The electrolyte was prepared from triple distilled water and it was deoxygenated by bubbling with dry nitrogen for 15 min, *in situ*.

2. Organic electrolyte. $AlBr_3$: prepared from high purity aluminum and bromine (2). Ethyl benzene: practical grade, Eastman Organic Chemicals, Rochester, New York. Toluene: commercial grade, Esso Imperial Oil Company, Montreal. Aluminum anode: ALCAN 1S 99.9% Al. The conductivity of the electrolyte was adjusted up to 4×10^{-3} ohm^{-1} cm^{-1} by bubbling HBr through the solution (2).

Primary Sodium Batteries with Beta-Alumina Solid Electrolyte

F. G. Will* and S. P. Mitoff

General Electric Corporate Research and Development, Schenectady, New York 12301

ABSTRACT

The principal characteristics of a new class of high-energy density primary batteries are described. These batteries employ sodium beta-alumina as a solid electrolyte membrane that separates the reactants, sodium-mercury amalgam as the anode, and halogens, water, or air as the oxidants. The batteries operate at or near ambient temperatures and produce very high cell voltages and energy densities. They have an essentially nondetectable rate of self-discharge, and shelf and operating times of ten years appear feasible. A present limitation is their low power drain capability. The operating features of the sodium-mercury amalgam anode, the cell polarization characteristics, and the discharge behavior of cells employing various liquid cathodes are described.

In certain applications of primary batteries, such as in heart pacemakers, electronic watches, automatic exposure cameras, etc., very long life as well as small size and weight are the overriding considerations while the attainable power levels are only of secondary importance.

The useful life of conventional primary batteries, for example, silver-zinc, mercury-zinc, and dry cells, is limited by systematic self-discharge mechanisms, passivation phenomena, or spontaneous events, such as internal electrode shorting. Self-discharge mechanisms include mainly the diffusion of soluble active material from one electrode to the other and electrode dissolution accompanied by gas evolution. Typical values for the specific energy and energy density of aqueous-type primary batteries are 90-130 W-hr/kg (40-60 W-hr/lb) and 350-600 W-hr/dm^3 (6-10 W-hr/$in.^3$).

Batteries employing organic electrolytes attain considerably higher energy densities than these. However, they share with batteries using aqueous electrodes a noticeable rate of self-discharge which is usually caused by a finite solubility of the cathode.

Primary batteries with beta-alumina solid electrolyte offer a combination of unique features not readily attainable with liquid electrolyte batteries. Most significant among these are very low self-discharge rate, high cell voltage, and very small size and weight. The essentially nondetectable rate of self-discharge results from using a solid ionic conductor, sodium beta-alumina (1, 2). This solid electrolyte acts as an ideal membrane, permitting only the migration of sodium ions and certain other monovalent cations (3) while completely preventing the permeation of anions and neutral reactants. Furthermore, there is no electrode dissolution or electrode shorting similar to that often encountered in aqueous electrolytes. Since the electronic conductivity of sodium beta-alumina is also very low (4), the usual self-discharge mechanisms are virtually absent and primary batteries with beta-alumina as the electrolyte inherently have the potential of achieving very long life. A disadvantage of such batteries is the comparatively low ionic conductivity of the solid electrolyte at or near ambient temperature. Typically, the room temperature conductivity of sodium beta-alumina is two to three orders of magnitude lower than that of the best aqueous electrolytes. As a result, the power densities attainable at room temperature with primary batteries employing beta-alumina are significantly lower than those common for aqueous-type batteries.

In this paper, consideration will be given to the general characteristics of primary sodium cells with beta-alumina as the solid electrolyte and halogens, oxygen, or water as the oxidants. After describing some general aspects of cell operation, the sodium-mercury amalgam anode, common to all of the primary bat-

* Electrochemical Society Active Member.

Key words: primary batteries, solid electrolyte batteries, sodium-halogen batteries, sodium amalgam, beta-alumina.

teries considered here, is discussed in some detail. The polarization curves of cells employing cathodes of bromine, iodine, oxygen, and water are presented and, lastly, the discharge behavior of cells with bromine and iodine cathodes is discussed.

Experimental

The experiments were carried out in simple glass cells. Figure 1 shows a schematic of the cell design. The anode consists of a disk of sodium beta-alumina ceramic sealed into a closed-end glass tube containing a sodium-mercury amalgam for room temperature operation. A Kovar alloy wire is sealed into the glass tube and contacts the reductant. The cathode half-cell design depends upon the oxidant used. Shown in Fig. 1 is the design for use with halogens or water as the oxidant. In these cases, the reactants are liquid and a metal screen or graphite felt serves as a current collector. Suitable metals include tantalum, niobium, and platinum for use with the halogens and nickel, iron, or platinum for use with water. The halogens are dissolved in suitable solvents, such as water or organic solvents. When water is used as the oxidant, small amounts of solutes are added, such as NaOH or Na_2CO_3, to establish initial conductivity. The catholyte is contained in a vented glass vessel. For experiments with sodium/air cells, a polypropylene felt was used to contain the electrolyte between the beta-alumina disk and a Teflon-polymer bonded platinum electrode. Aqueous solutions of NaOH or Na_2CO_3 served as the electrolyte.

The sodium beta-alumina disks have the chemical composition $Na_2O \cdot 9Al_2O_3$ with 1% MgO and 0.5% Y_2O_3 as additives. They are prepared by pressing the blended beta-alumina and oxide powders at room temperature and sintering in air at 1830°C. Further details on the preparation can be found in Ref. (2). The sintered disks have a diameter of 1 cm and thickness of 0.1 cm. Their density is 3.18 g/cm^3 or 98% of theoretical, they are nonpermeable to helium and have a conductivity of 10^{-3} ohm^{-1} cm^{-1} at 25°C.

The anodes were prepared by vacuum-distillation of sodium into the anode half-cell and sealing under vacuum. In those cases where sodium-mercury amalgams were prepared, the sodium was distilled into the appropriate amount of mercury in the half-cell. All reactants used were reagent-grade.

Results and Discussion

General aspects of cell operation.—During cell discharge, the following reactions take place at the electrodes

$$\text{anode:} \quad Na \rightarrow Na^+ + e^- \quad [1]$$

$$\text{cathode:} \quad \tfrac{1}{2} Br_2 + e^- \rightarrow Br^- \quad [2a]$$

$$\tfrac{1}{2} I_2 + e^- \rightarrow I^- \quad [2b]$$

$$\tfrac{1}{2} O_2 + H_2O + 2e^- \rightarrow 2\,OH^- \quad [2c]$$

$$H_2O + e^- \rightarrow OH^- + \tfrac{1}{2} H_2 \quad [2d]$$

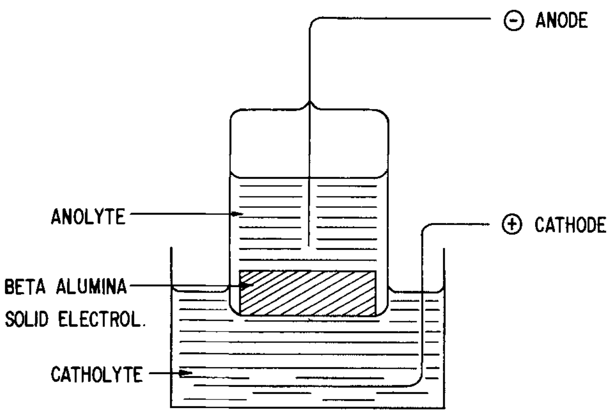

Fig. 1. Cell schematic

Sodium ions, generated at the sodium amalgam/beta-alumina interface, migrate through the solid electrolyte into the catholyte. As anions cannot permeate through the solid electrolyte, the solute concentration in the catholyte increases in accordance with the cell reactions

$$\tfrac{1}{2} Br_2 + Na \rightarrow NaBr \quad [3a]$$

$$\tfrac{1}{2} I_2 + Na \rightarrow NaI \quad [3b]$$

$$\tfrac{1}{2} O_2 + H_2O + 2Na \rightarrow 2NaOH \quad [3c]$$

$$H_2O + Na \rightarrow NaOH + \tfrac{1}{2} H_2 \quad [3d]$$

During cell discharge, there is a major volume decrease in the anode compartment due to sodium leaving the anode, but only relatively minor volume changes occur in the cathode compartment due to salt formation. Typically, the volume of the catholyte increases for reactions [3a]-[3c] by 5-15% and decreases for reaction [3d] by 3-5%, owing to hydrogen evolution. The precise numbers depend upon the desired concentration range of the solute or whether precipitation of solid reaction products, such as NaBr, is allowed to occur.

Sodium-mercury amalgam anode.—For cell operation at or near room temperature, pure sodium is unsuitable for all but very small power densities. Sodium is solid below 97.5°C, and the diffusion of sodium in the solid state is very slow. The self-diffusion coefficient at 25°C is only $5 \cdot 10^{-9}$ cm^2/sec (5). The problem of slow diffusion is circumvented by using sodium-rich mercury amalgams as the anode. These amalgams are at least partly liquid at the cell operating temperature. The diffusion coefficient of sodium in liquid mercury is more than three orders of magnitude larger than in solid sodium, that is $8 \cdot 10^{-6}$ cm^2/sec at 22°C (6).

The phase diagram of the sodium-mercury system is shown in Fig. 2. The initial amalgam composition in the fully charged condition of the cell preferably lies in the range of 70-90% sodium by weight. At these high sodium concentrations, the fraction of liquid phase becomes very small; at lower concentrations, the weight and volume penalty due to the mercury becomes very noticeable. Cell operation is not feasible at temperatures below 21.5°C, which corresponds to the

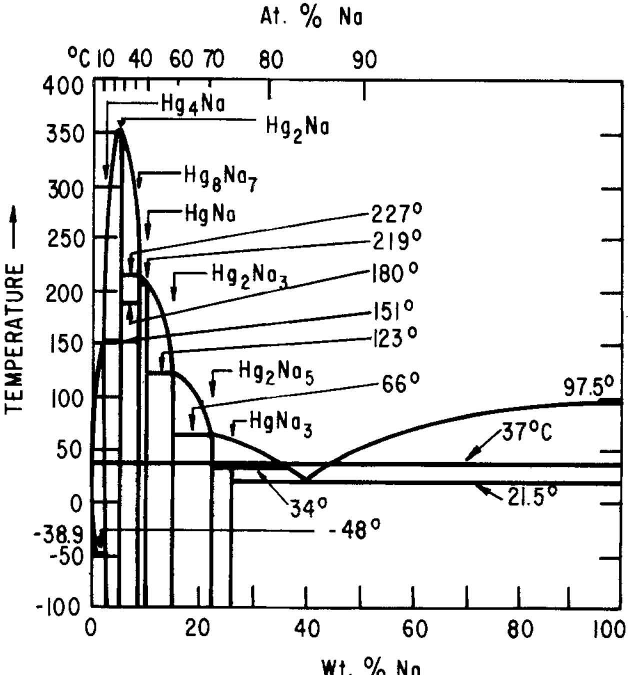

Fig. 2. Phase diagram of sodium-mercury system [from C. J. Smithells, "Metal Reference Book," Vol. I, p. 399, Interscience Publishers, New York (1955)].

freezing point of the eutectic composition at 39.8% sodium. During cell discharge at constant temperatures above 21.5°C, one proceeds in the phase diagram on a horizontal line from right to left as sodium is ionized and leaves the anode compartment. The proportion of liquid to solid-phase increases until the all-liquid part of the diagram is reached. The end of useful cell discharge is determined by that sodium content which corresponds to the formation of solid intermetallic compounds as evident from the phase diagram. For example, at an operating temperature of 37°C, the end of discharge corresponds to a final sodium content of 38%.

The effect of initial sodium content (fully charged condition) on the electrode capacity per unit weight and volume is shown in Fig. 3 for operation at 37°C. The capacity values decrease from the theoretical limits 1.16 A-hr/g and 1.13 A-hr/cm^3, calculated for pure sodium assuming 100% utilization, to zero in the trivial case where the initial sodium content in the amalgam is equal to the final content of 38%. For a starting composition of 90% sodium, the capacity values are 0.97 A-hr/g and 1.04 A-hr/cm^3, while for a 70% Na/30% Hg amalgam, the values are 0.60 A-hr/g and 0.81 A-hr/cm^3. Thus, for equal electrode capacity, the weight penalty due to the use of amalgams instead of pure sodium amounts to between 20 and 94% and the volume penalty to between 9 and 40%.

The sodium content and the fraction of liquid phase in the sodium-mercury amalgam as a function of the depth of discharge are plotted in Fig. 4. The curves refer to 37°C operation and initial amalgam compositions of 90, 80, and 70% Na by weight, respectively. Complete discharge corresponds to an amalgam composition of 38% Na. The fraction of liquid phase at the beginning of discharge amounts to 18, 36, and 54% for initial composition of 90, 80, and 70% Na. The fraction of liquid phase increases steeply during cell discharge, and the amalgams become completely liquid at 96, 92, and 85% depth of discharge.

Cathode operation.—The kinetics of halogen reduction (Eq. [2a] and [2b]) and, in particular, oxygen reduction (Eq. [2c]) and hydrogen evolution in aqueous solutions have been the subject of numerous studies. Comparatively little information is published on halogen reduction in nonaqueous solutions. This applies especially to the study of very concentrated halogen solutions. Highly concentrated halogen solutions are desirable from a standpoint of optimizing the energy density of the cell. However, the use of high halogen concentrations leads to precipitation of solid reaction products (NaBr, NaI) as the salt solubility is exceeded during discharge.

Salt precipitation has been observed on both the graphite current collector and the beta-alumina surface. Different crystal morphologies have been identified, depending upon the nature and amount of solvent, the nature of the substrate, and the current density. Conditions have been identified under which the effect of crystal formation on cathode polarization is small compared to other sources of polarization. More details about crystal formation will be published in a subsequent paper (7).

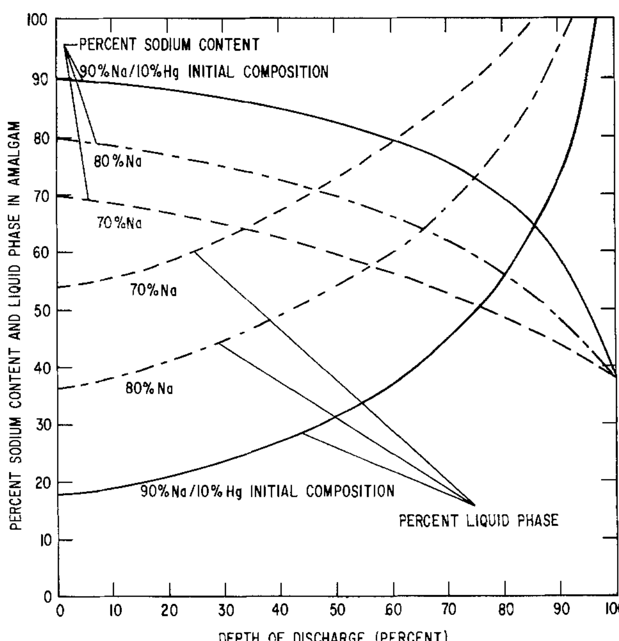

Fig. 4. Fraction of sodium content and of liquid phase in the amalgam as a function of the depth of discharge; 37°C operation; initial amalgam compositions 90, 80, and 70% Na by weight.

By far the largest contribution to cathode polarization derives from the polarization of the interface beta-alumina/catholyte. A study of this interfacial polarization has been undertaken (7, 8) and will be published separately.

Cell polarization.—Current-voltage curves for four different sodium-mercury amalgam primary cells at 25°C are shown in Fig. 5. The anode in all of these cases consists of a 70% Na/30% Hg amalgam by weight. The catholytes consist of 1 g-atom Br_2 dissolved in an aqueous solution of 1*N* NaBr (curve a), 1 g-atom I_2 dissolved in a solution of 1 mole NaI per liter of propylene carbonate (curve b), an air-saturated 1*N* $NaHCO_3$ solution (curve c), and a 1*N* NaOH solution (curve d). Current collectors consist of Pt screens or TFE-bonded porous Pt (curve c).

The observed open-circuit voltages for the Na/Br_2 and Na/NaOH cells correspond within 30 mV to the thermodynamically expected values of 3.78 and 1.89V.

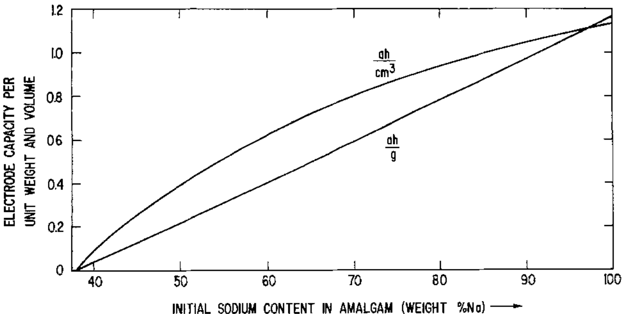

Fig. 3. Effect of initial sodium content in amalgam on electrode capacity per unit weight (A-hr/g) and unit volume (A-hr/cm^3) for 37°C operation.

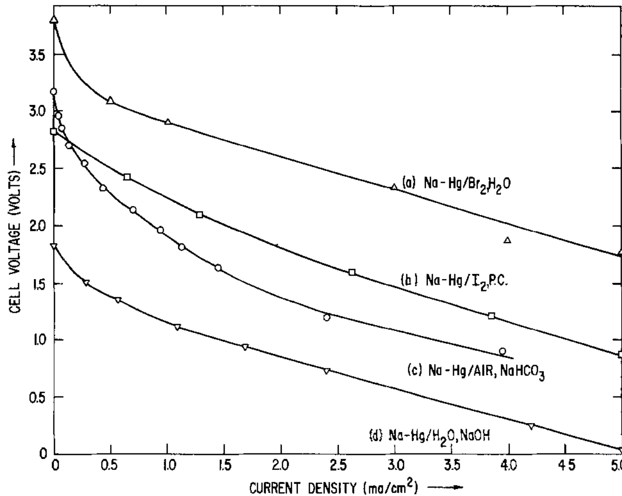

Fig. 5. Current-voltage curves for sodium-mercury amalgam primary cells with various cathodes at 25°C.

The open-circuit voltage for the Na/I_2, P.C. (propylene carbonate) cell is 2.83V or 0.52V lower than calculated for an aqueous solution. This reflects the different energy of solvation in the organic as compared to the aqueous solvent (9). The open-circuit voltage of the Na/air cell is 3.18V which is approximately 0.3V lower than the calculated value for the pH of 1N $NaHCO_3$ solution. This discrepancy is caused by the oxygen electrode and is usually interpreted in terms of mixed potentials involving couples such as O_2/H_2O, O_2/H_2O_2, and Pt-O/H_2O (10).

At low current densities, all four cells show the effects of an activation-controlled process. Independent investigations (7, 8), using a reference electrode in the beta-alumina, have shown that the interface beta-alumina/catholyte is the source of this polarization. Its magnitude depends upon the pretreatment of the beta-alumina and the nature of the solvent.

At higher current densities, the curves in Fig. 5 become straight lines with slopes which are nearly identical for all four cells. The discharge behavior in this range of currents is determined by the ohmic resistance of the beta-alumina solid electrolyte. The slopes correspond to a unit area resistance of 300 ohm-cm^2 which translates into a resistivity of 3000 ohm-cm for the beta-alumina thickness of 0.1 cm. This value for the resistivity is three times larger than resistivities calculated from four-probe alternating current measurements made at a frequency of 10 kHz. Part of this discrepancy is due to intergranular resistances in the polycrystalline solid electrolyte which are shunted by capacitances (11).

Another part has been found to derive from the diffusion of small amounts of water into the surface layers of the beta-alumina. This effect exists even when propylene carbonate is used as a solvent in an open cathode half-cell such as shown in Fig. 1 since propylene carbonate absorbs water from the environment.

In all cases reported in this paper, water was present only in the cathode compartment of primary cells. Under these conditions, the beta-alumina used in this study (2) undergoes only slow changes in electrical resistivity, but the mechanical integrity remains unaffected. Some cells have now been operating for 3 years and continue to discharge. If, on the other hand, water is present in the anode compartment, the ceramic electrolyte fails mechanically within a few hours or weeks, depending upon the magnitude of the current density. Increasing current density enhances the rate of failure. While it is known that hydronium ions enter beta alumina (12), the detailed effects of this process are as yet unknown.

Cell discharge as a function of time.—The curves in Fig. 5 are initial polarization curves, obtained at low depths of discharge. At larger depths of discharge, the effect of crystal formation often becomes evident in increased cell polarization, especially in the case of very concentrated halogen solutions. Figure 6 shows the cell voltage as a function of discharge time at a constant current density of 0.1 mA/cm^2 and 25°C for various halogen cells. The discharge voltages are smaller than those shown in Fig. 5 for the same current density. This is due to the use of beta-alumina of slightly different composition and pretreatment, resulting in higher ohmic and interfacial losses. The discharge times are expressed as depth of discharge on the abscissa of Fig. 6 to accommodate all curves with quite different discharge times on a single graph. Cell discharge was limited by the exceedingly small volume of catholyte, only $6 \cdot 10^{-3}$ cm^3, used in these cells. By choosing such small amounts of catholyte, a full cell discharge could be accomplished in times varying from 2 to 24 hr.

Curves 1 and 2 in Fig. 6 refer to 1 g-atom Br_2 per liter of a saturated solution of NaBr in water (curve 1) and in propylene carbonate (curve 2). For the aqueous solution, about 65% of the Br_2 originally present is

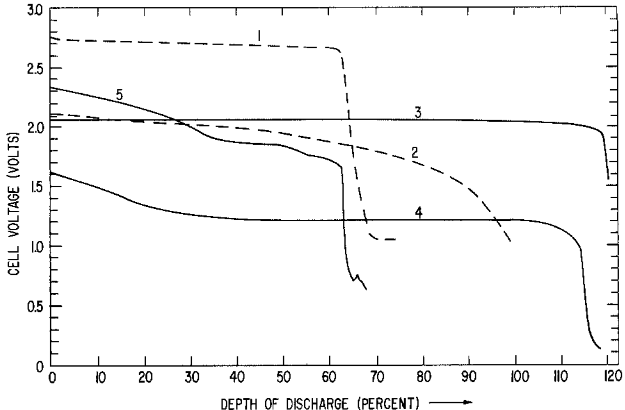

Fig. 6. Cell voltage as a function of depth of discharge for sodium-mercury amalgam cells at 0.1 mA/cm^2 and 25°C. Curve 1, 1N Br_2 in NaBr-saturated H_2O; curve 2, 1N Br_2 in NaBr-saturated propylene carbonate; curve 3, 2N I_2 in NaI-saturated H_2O; curve 4, 2N I_2 in NaI-saturated PC; curve 5, 80%I_2/20%H_2O by weight.

reduced, whereas nearly 100% is reduced in propylene carbonate solution. The balance of the Br_2 in the aqueous solution has been lost by evaporation. Losses by evaporation are less significant in the propylene carbonate solution due to the lower vapor pressure of Br_2 above such solutions. The actual discharge times were 121 and 144 min for the aqueous and propylene carbonate solutions, respectively. The discharge voltage is consistently smaller in the propylene carbonate solution due to the different solvation energy as compared to aqueous solutions and decreases visibly during cell discharge, whereas the voltage for the aqueous solution remains relatively constant. Microscopic examination reveals that this different behavior is caused by different morphologies of the crystal layers growing on the beta-alumina surface.

Curves 3 and 4 in Fig. 6 refer to catholytes prepared from 2 g-atoms I_2 per liter of a saturated solution of NaI in water (curve 3) and propylene carbonate. These cathodes discharged for nearly 3 hr to yield essentially theoretical capacity. The finding that, in fact, more than 100% depth of discharge appears to be obtained is explained by the difficulty in determining the minute amount of catholyte, only $6 \cdot 10^{-3}$ cm^3, to a better accuracy than 20-25%. The discharge curve in aqueous solution is remarkably flat while a continuously decreasing discharge voltage is observed in propylene carbonate solution. This behavior is similar to that found in the Br_2-containing solutions, and different crystal morphologies are again the reason for the observed behavior.

Curve 5 in Fig. 6 is obtained with a catholyte consisting of a mixture of 80% I_2 and 20% H_2O by weight. The mixture contains solid I_2 and I_2 dissolved in H_2O. This catholyte discharged for nearly 24 hr, yielding about 65% depth of discharge. Titration for undischarged I_2 yielded less than 2% of the originally present I_2. The balance was lost by evaporation.

The foregoing cell discharge tests establish the feasibility of discharging halogen cathodes containing very concentrated halogen solutions to large depths of discharge. However, only very small solution volumes were used in these experiments to achieve reasonably short discharge times. These studies lead to the formation of only very thin crystal layers and cannot be expected to represent the discharge behavior of cells with many years life. The long-term discharge performance and other detailed characteristics of sodium-amalgam/bromine cells, with 10 yr design life, are described in Ref. (7).

Cell performance characteristics.—A summary of the more significant performance characteristics of primary cells employing cathodes of bromine, iodine, air, and water is presented in Table I.

Table I. Summary of cell performance characteristics at 25°C

Cell couple	Open-circuit voltage (V)	Voltage at 0.1 mA/cm^2 (V)	Specific energy W-hr/kg theor.	Specific energy W-hr/kg practical	Energy density $W-hr/dm^3$ theor.	Energy density $W-hr/dm^3$ practical

The theoretical values for specific energy and energy density were calculated on the basis of an initial amalgam composition 90% Na/10% Hg and 90% by weight halogen in the catholyte. The "practical" values are computed optimum values for current densities not exceeding 0.1 mA/cm^2. These values take into account all cell components such as the beta-alumina electrolyte, cell casing, and current collectors. Sodium amalgam/bromine cells with a stored energy corresponding to 350 W-hr/kg and 295 $W-hr/dm^3$ have actually been operated to depths of discharge up to 45%, simulating 4½ yr operating life.

Conclusions

Primary batteries employing sodium beta-alumina as a solid electrolyte membrane, sodium-mercury amalgam as the anode, and halogens, air, or water as the cathodes are feasible for operation at or near room temperature with a combination of unique features: Essentially nondetectable rate of self-discharge, long shelf and operating life, and very high cell voltages and energy density. Limitations of these cells are their inability to perform at large power levels and at temperatures below 21°C. For sodium amalgam/bromine cells, open-circuit voltages of 3.8V and operating voltages of 3.5V at 0.1 mA/cm^2 have been obtained. Cells have been built with a stored energy corresponding to 350 W-hr/kg and 295 $W-hr/dm^3$ and operated to depths of discharge up to 45%, simulating 4½ yr operating life.

Structural Transformations of the PbO_2 Active Material during Cycling

A. C. Simon,* S. M. Caulder,*[,1] and J. T. Stemmle[1]

Electrochemistry Branch, Naval Research Laboratory, Washington, D. C. 20375

ABSTRACT

A combined optical and scanning electron microscope study of the $PbSO_4$/PbO_2 electrode has revealed changes in the $PbSO_4$ crystallography and the tendency of PbO_2 to form a network during life cycle tests. It was found that during cycling a definite coralloid structure developed. The mode of deposition and crystal form of the $PbSO_4$ crystals changed with increasing cycle life.

In a previous paper (1) certain observations were made concerning the structural changes that occurred in the PbO_2 electrode during cycling. These changes were observed with the optical microscope. Samples of the positive, or PbO_2/$PbSO_4$ electrode, of the lead-acid battery were examined, in both the charged and discharged state, at various points in the cycle life. Properly prepared samples (2) were sectioned and polished so that the microstructure could be examined in the section. It was found that plates having radically different microstructures after curing and forming were

Key words: lead dioxide, lead-acid battery, coralloid microstructure, porous electrode structure, lead sulfate, anodic film microstructure.

all transformed into almost identical structures in less than 50 cycles. This led to the conclusion that the structure developed during cycling was independent of either the method used to cure the plates, or to accomplish their formation.

While the microstructure of the formed electrode was usually rather dense and contained only very small voids, after a few cycles the voids became much larger and the material surrounding the voids at first became more dense and compact, but later disintegrated into very loosely joined particles. From this it was concluded that gas bubbles, formed during the last stages of the charge process, forced apart the active material to form channels during their escape to the surface. In the early cycles it was assumed that this pressure pushed the active material that formed the walls of these channels into the more dense than original state that was found with microscopy. At a later stage, when the walls became thinner due to the considerable loss of active material that was washed away as sediment, the gas escaped by breaking through the existing walls into adjacent channels.

More recently, examinations made with the scanning electron microscope, SEM, together with reevaluation of some of the earlier optical microscope observations, and consideration of other recently discovered properties of the PbO_2 active material, has led to a considerably different concept of the active material structure and the manner of its formation.

Compilation of Various Observations and Their Significance

Observations with the SEM.—Samples for the SEM examination were obtained by subjecting positive electrodes to capacity charge-discharge operation for a total of 56 cycles, at which point failure was complete. Discharges were made at 35.9 mA/cm^2, charges at 14 mA/cm^2 in an excess of 1.28 sp gr acid. The system was positive limited so that both charge and discharge of the positive electrode was complete. The positive plate voltages were checked by means of a $PbO_2/PbSO_4$ reference electrode. Samples were obtained for examination at the end of formation and after 10, 20, 30, 40, and 50 cycles. To avoid the artifacts occurring at the plate surface, examination was made upon the rough cross sections obtained by breaking the plate into small portions. The accuracy of the observations made on the above samples was checked by additional examination of commercial plates which had received various numbers of SAE type cycles.

The SEM observation revealed the same uniform closely packed active material structure after formation that had been seen in the optical microscope studies. The exposed surfaces were smooth and exhibited very little detail, other than an occasional basic sulfate crystal that had not been completely converted to PbO_2 (Fig. 1).

With an increasing number of cycles it was apparent that larger voids were being formed but the structure that was being developed was not clearly revealed in the charged electrode until after 30 deep cycles (Fig. 2).

In the case of examination of the discharged, or reduced, plate, the structure was even more evident, mainly because of the manner in which the lead sulfate crystals clustered along the branches of the interdependent parts (Fig. 3). It was clear that this coralloid structure was the three-dimensional counterpart of the void-filled structures observed, after cycling, with the optical microscope (Fig. 4). The connected but involuted nature of the structure was not evident in cross sections taken for optical microscopy, nor was the extensive surface porosity that was revealed by SEM examination. The three-dimensional structure seen in Fig. 2 is definitely not the result of gas action. Study of many such areas has made it clear that the structure is an interconnected and continuous entity of a very extensive nature. The voids are incidental to its formation and are not the cause. The porous and detailed fine structure that is shown along the branches indicates that no extensive and violent turbulence of

the electrolyte has occurred in the vicinity, as would be the case if gas bubbles had been generated that were sufficiently violent to cause channeling.

Although operating conditions had been different, there was a parallelism in the structural changes that occurred in the above capacity discharge experiments. and those that took place in plates that had received SAE type cycling. It was evident that the same structural changes had taken place in both cases but that these changes had occurred much more rapidly under the conditions where the cell was completely discharged at each cycle.

Evidence for the presence of electrochemically active and inactive forms of PbO_2.—It has been found that electrochemically active and inactive forms of PbO_2 coexist in the positive active material of the lead acid battery (3, 4). Studies with nuclear magnetic resonance (NMR) have shown that electrochemically prepared samples of PbO_2 have hydrogen present in at least two configurations, while chemically prepared samples showed only one hydrogen-containing species. The chemical nature of the hydrogen species common to both the chemical and electrochemical preparations is not yet clear. The hydrogen-containing species found in the electrochemically prepared samples was determined not to be present as water. Its exact chemical makeup is also not clear. The relaxation curves resulting from perturbations of this hydrogen bonding are different for the chemically and electrochemically prepared PbO_2. It has been found that the relaxation curves of the electrochemically prepared material more and more resemble that of the chemically prepared form as the electrochemical type is cycled (4). Since it is well known that chemically prepared PbO_2 is unsuited for the manufacture of active material because it does not develop capacity and cycle properly, it can be assumed to be relatively inert to electrochemical action. It is significant that the electrochemically prepared PbO_2, after considerable cycling, apparently develops the NMR curves of the chemically prepared form, with an accompanying loss of capacity.

Relevant observations from optical microscopy.—In studies with the optical microscope (5) residual particles of PbO_2 were always found within the crystals of lead sulfate formed during discharge (Fig. 5). The reason for this residue was puzzling. Before the knowledge was available that an active and inactive form of PbO_2 were both present in the active material, it could only be assumed that PbO_2 was somehow encapsulated within the growing $PbSO_4$ crystals before dissolution of the PbO_2 structure could be completed. Most logically this could occur as some parts of the PbO_2 structure became electrically isolated by prior dissolution of its connecting network with other portions. However, it was realized that this explanation was not entirely satisfactory because the PbO_2 particles within the $PbSO_4$ crystals appeared to have fairly uniform distribution, both throughout the active material and within the $PbSO_4$ crystals as well (Fig. 5). Moreover, the particles were relatively isolated from one another and did not occur as agglomerates, as one would expect if portions of the PbO_2 structure became isolated. It is now evident that these embedded particles are the inactive form of PbO_2.

Another observation resulting from optical microscopy was that the recharge process, the oxidation of PbO_2, began with the growth of the residual encapsulated PbO_2 particles. Many observations were made of electrode sections in various stages of recharge and it was found that a significantly large number of the embedded PbO_2 particles were surrounded by void areas within the $PbSO_4$ crystal, indicating dissolution of the surrounding $PbSO_4$ during the growth of the PbO_2 particle. In periods of discharge similar voids surrounding the PbO_2 particles were never found within the $PbSO_4$ crystals. Moreover it was very frequently observed that dissolution of $PbSO_4$ crystals during charge resulted in a splitting into smaller crystals. Such splitting was the result of preferential dissolution around PbO_2 particles of such alignment

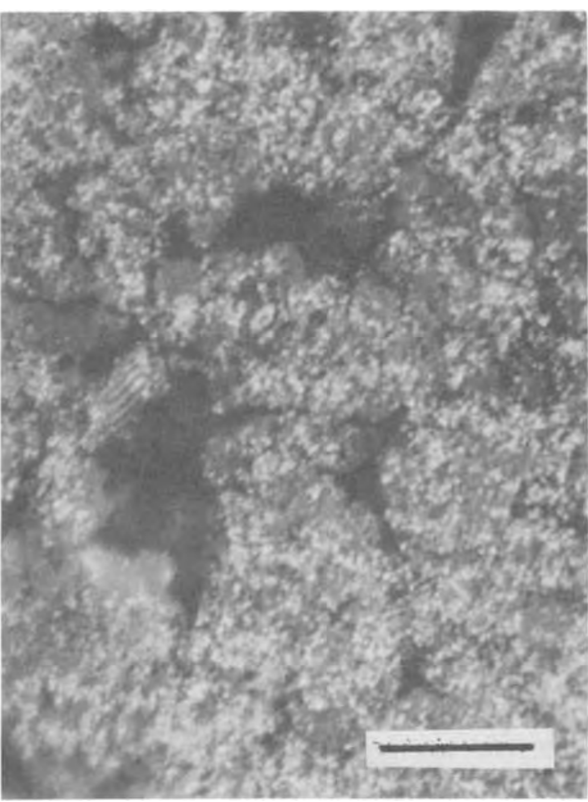

Fig. 5. Discharged plate, cross-sectioned $PbSO_4$ crystals containing large amounts of unreacted PbO_2 particles. Light gray $PbSO_4$ crystals, of regular outline, contain bright particles of PbO_2 encapsulated within their structure. Darkest areas are voids in the active material. As seen with the optical microscope. Scale length = 10 μm.

as to cause separation of a large $PbSO_4$ crystal into several smaller ones, each surrounded by a chain of PbO_2 particles that were growing and merging into one another.

It could not be determined if this was the only mechanism of growth, since it was also possible that the dissolution of $PbSO_4$ crystals in a given area might also contribute to growth of PbO_2 at a more distant point. However, it was indicated that the embedded residual particles of PbO_2 initiated the growth of the PbO_2 resulting from the next charge cycle, by providing nuclei for the crystallization process of the PbO_2.

One further point of observation was that these nucleating PbO_2 particles were not always at what appeared to be the surface of the $PbSO_4$ crystal. Often the embedded particle, with its significant surrounding void space, appeared to occur deep within the crystal, as judged from the cross section. The possibility exists that the $PbSO_4$ crystal allowed migration of the reacting ions to the deeply embedded site, but it seems more likely that what appeared in section to be one crystal might in actuality have been two or more, joined along faces not visible in the section, or that the apparently deeply buried PbO_2 particle might have acually been at the surface in a plane either above or below that which was sectioned.

Conclusions

It can therefore be reasonably concluded that these embedded PbO_2 particles that remain at the end of discharge are the inactive form of PbO_2 that is resistive to reduction to $PbSO_4$, although still fully capable of acting as nuclei for the crystallization of the active form.

Examination of discharged plates show that, even at the first discharge, there is a large amount of residual PbO_2 embedded in the lead sulfate crystals, even though this is the first reduction of the PbO_2 that was created in the forming process. It seems safe to assume that the electrolytic formation has not resulted in PbO_2 that is 100% in the active form.

The clearly defined coralloid structure that develops after a period of cycling can therefore be explained upon the basis of a "memory" pattern that remains from cycle to cycle and that originates in the presence of inactive particles of PbO_2.

Assuming the initial presence of inactive PbO_2 particles, uniformly distributed throughout the active material matrix, it is possible to imagine the release of these inactive particles as the surrounding active form of PbO_2 is dissolved during the discharge process. These particles will then settle upon all available surfaces and, while a small portion may be lost from the plate, a larger portion will settle upon the surfaces of growing $PbSO_4$ crystals, to be subsequently encapsulated. Other of the inactive particles so released will settle upon remaining PbO_2, to be again released as this substrate is further dissolved. The continuation of this process will tend to concentrate the majority of the inactive particles in or on the lead sulfate crystals and there will, of course, be none left in the voids created by the dissolution of the active PbO_2.

On the initiation of the next charge cycle the inactive particles in the surface of the lead sulfate act as nuclei for the growth of the active PbO_2 and, as these PbO_2 particles enlarge and $PbSO_4$ dissolves, further particles are uncovered which will also enlarge and grow together in the sites where $PbSO_4$ crystals had been formed. There is no tendency for the PbO_2 to extend for any great distance into the spaces left void in the previous discharge, so that these remain defined. With the next cycle of discharge the $PbSO_4$ crystals will tend to congregate more closely on the existing PbO_2 structure and as the active portion of the PbO_2 dissolves, the inactive portion will tend to be concentrated even more in the areas where the PbO_2 structure of the previous charge was located. The void areas surrounding this network will therefore slightly enlarge.

By a continuation of this charge-discharge cycling a well-defined PbO_2 coralloid structure eventually emerges, which can be repetitively reproduced on each charge cycle, by reason of the residual inactive PbO_2 particles which it contains.

The observed coralloid PbO_2 structure appears to be of an ideal construction for a porous electrode. From optical microscopy of sections it was learned that its convolutions have a very dense PbO_2 core, which should provide the maximum of strength and electrical conductivity in such an interwoven structure. At the same time the surfaces of the convolutions are found to consist of many small joined particles that present an enormous surface area, of great porosity. The much larger voids that occur between the convolutions of the PbO_2 structure would seem able to provide free flow of electrolyte and to insure that an adequate amount is present at the reacting surfaces.

However, the loss of capacity is already in an advanced stage when the coralloid structure reaches its most perfect form. There are two possible explanations for this that are immediately evident. It is noted that when a positive plate is cycled, particularly at higher discharge rates and to a low terminal voltage, there is a continual change in the method of $PbSO_4$ crystal deposition as the cycling continues. On initial discharge cycles, the $PbSO_4$ crystals deposit in considerable disorder, with crystals of a considerable size range piled haphazardly upon one another. The result is a porous $PbSO_4$ layer and one that probably reaches a considerable thickness before it is able to passivate the remaining PbO_2 (Fig. 6). As cycling continues, however, the crystals become more uniform in size and are arranged so that they appear to be tightly interlocked, with little or no porosity visible between the crystals (Fig. 7). It is evident that such a struc-

ture can passivate the underlying PbO_2 much sooner than was the case in earlier cycles. Correlation between capacity loss and the occurrence of this over-

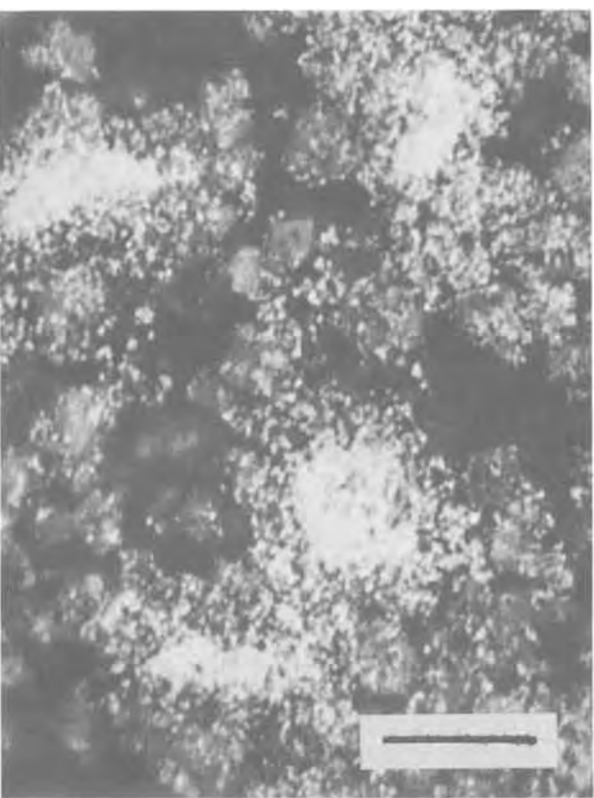

Fig. 8. Cross sections of convolutions of the coralloid structure of a discharged plate, as seen with optical microscope. Very bright areas are at the centers of the convolutions and show dense packing of the remaining PbO_2 within the $PbSO_4$ crystal envelope. Cross section is made perpendicular to the long axis of convolution growth. Scale length = 10 μm.

Fig. 9. Same area as Fig. 8, but with polarized illumination. Dark areas corresponding to bright areas of Fig. 8 are in reality slate gray or black, and, as can be seen, are surrounded by a layer of $PbSO_4$ crystals. Scale length = 10 μm.

lapped, tightly packed $PbSO_4$ film is good, which lends credibility to this explanation.

Another possibility is that the occurrence of the coralloid structure is itself the cause of the loss of capacity. It has been found that the individual convolutions of the coralloid structure, while porous on the outside, have a very dense core structure. This is illustrated in Fig. 8. This photomicrograph, of a discharged plate, shows a cross section of several coralloid convolutions, at right angles to their long axis. The bright, nearly featureless areas are the remaining densely packed PbO_2 at the center of the convolutions. These are surrounded by light gray material that consists of cross sections of $PbSO_4$ crystals. These can be seen more clearly in Fig. 9, the same area but seen by polarized light. The bright material in Fig. 8, which looks black in Fig. 9, could be either electrochemically active or inactive PbO_2. The point to be made, however, is that a relatively large amount of PbO_2 remains at the end of discharge, either because of the passivation by the $PbSO_4$ crystals that surround it, or because the material may be the inactive form of PbO_2, or because the PbO_2, although electrochemically reactive, is so densely compacted that extensive reaction becomes difficult. This compacted condition seems to be directly related to the development of the coralloid structure. Unfortunately the centers of the coralloid convolutions appear to be dense at some portions of cycle life and porous at others, under conditions not yet defined. For this reason correlation between the dense structure and loss of capacity has not been found.

It is also possible that the increasing amount of the inactive form of PbO_2 may be the sole cause of capacity loss. This might also explain the gradual break up of the coralloid structure that is observed toward the end of cycle life. It may be that the increasing amount of this inactive form provides so many nucleation centers that very small PbO_2 crystals of the active species are formed, that are incapable of joining to form the aggregates responsible for the coralloid structure.

In any case, the observations recorded here are considered of sufficient importance to warrant further investigation of the coralloid structure and of the inactive form of PbO_2, as these observations may lead to methods for increasing battery life, energy density, and capacity.

Conduction Characteristics of Polycrystalline Lead Fluoride

C. C. Liang* and A. V. Joshi*

P. R. Mallory and Company, Incorporated, Laboratory for Physical Science, Burlington, Massachusetts 01803

ABSTRACT

The effect of the aliovalent cation dopants on the ionic conduction characteristics of the polycrystalline lead fluoride was studied in the temperature range between 25° and 350°C in order to determine the predominate mobile species in both α-PbF_2 and β-PbF_2. It was found that the activation energy of motion was 11.6 ± 0.6 kcal/mole for α-PbF_2 and 14.3 ± 0.6 kcal/mole for β-PbF_2. Doping with YF_3 did not result in a change in the value of the activation energy for either α-PbF_2 or β-PbF_2. However, the activation energy of motion for the KF-doped α-PbF_2 was 8.9 ± 0.3 kcal/mole and that for the KF-doped β-PbF_2 was 4.1 ± 0.3 kcal/mole. It was concluded from these results that Frenkel disorder is predominate in the lead fluoride lattice. The interstitial fluoride ions are the principal mobile species in the nominally pure as well as the YF_3-doped α- and β-PbF_2 and the fluoride ion vacancies are the principal mobile species in the KF-doped α- and β-PbF_2.

The solid electrolyte properties of lead fluoride in both orthorhombic form (α-PbF_2) and cubic form (β-PbF_2) was investigated by Kennedy, Miles, and Hunter (1). It was found as in the early work by Tubandt (2) that the conductivity of lead fluoride is predominately due to the fluoride ions. Furthermore, Kennedy *et al.* (1) reported that the activation energy of movement for the mobile species was about 0.5 eV in both forms.

Although Kennedy *et al.* (1) suggested a fluoride ion vacancy transport mechanism in both α-PbF_2 and β-PbF_2, the conduction mechanism has not been investigated in detail.

In the present investigation the effect of aliovalent cation dopants on the conduction characteristics of lead fluoride were studied in order to elucidate a mechanism for the transport process of the fluoride ions.

Experimental

Material preparation.—Alpha Inorganics lead fluoride (99.9+%) was used in this study without further purification. Potassium fluoride and yttrium fluoride (ROC-RIC) were used as the dopants. They were dried before use by heating in an evacuated flask at about 130°C for several hours then transferred to a

* Electrochemical Society Active Member.

Key words: lead fluoride, ionic conductivity, ionic conduction mechanism, solid electrolyte.

Vacuum Atmospheres dry box under a helium atmosphere. The oxygen and moisture content in the dry box was always maintained below 15 parts per million (ppm). All the sample preparation and measurements were conducted in the dry box.

In order to prepare the potassium- or yttrium-doped lead fluoride a stock solid solution was prepared by melting a well-blended powder mixture of PbF_2 and KF or YF_3 in a mole ratio of 98 to 2 at about 850°C. The resulting clear melt was quenched to ambient temperature and pulverized by means of a Fisher mechanical grinder. The dilution of the doped lead fluoride was accomplished by similar procedures.

It was noted that the doped lead fluoride obtained by quenching the melt to ambient temperature was in the cubic form. However, the orthorhombic form could be obtained by grinding the cubic form of the doped lead fluoride in the mechanical grinder for about two hours or by pressing the powder in a steel die at 100,000 psi at room temperature then pulverizing the pressed pellet using the mechanical grinder.

Conductivity measurement.—The total conductivity of the nominally pure and doped PbF_2 in both orthorhombic and cubic form was measured at various temperatures. Lead electrode [containing 10 weight per cent (w/o) of electrolyte] or graphite electrodes were used in the conductivity cells. The $Pb/PbF_2/Pb$ or graphite/PbF_2/graphite conductivity cells were fabricated according to the following procedures:

A weighed amount of lead fluoride powder was prepressed at 4000 psi in a 0.6 in. diameter steel die. While the prepressed pellet remained in the steel die the electrode powder was placed on both sides of the pellet, the total assembly was pressed at 100,000 psi to form the conductivity cell.

Inasmuch as the cubic form lead fluoride could be converted to the orthorhombic form at pressures above 30,000 psi (1) a conductivity cell for the cubic form lead fluoride could not be fabricated by the pressing of the cubic lead fluoride powder. In order to obtain a conductivity cell of lead fluoride in the cubic form the orthorhombic lead fluoride conductivity cell was heated to about 350°C. Since the cubic lead fluoride has a lower density than the orthorhombic lead fluoride, the conversion of α-PbF_2 to β-PbF_2 would result in a volume expansion of the pellet. This volume expansion often caused cracking of the pellet as noted by Kennedy *et al.* (1). Nonetheless, it was reported (1) that the rate of interconversion is highly temperature dependent and the temperature where the phase transition is observed depends on the heating rate. It was found during our investigation that in order to avoid cell cracking due to the volume expansion upon conversion of α-PbF_2 to β-PbF_2 the temperature of the sample must be increased gradually. A rate of 1°C/min was found to be sufficient to convert the lead fluoride from the orthorhombic form to the cubic form without fracturing the pellet.

The geometric area of the lead fluoride pellet was calculated from the diameter and the thickness was determined by measuring a lead fluoride pellet of the same weight formed under similar conditions but without the electrodes.

The conductivity of the pellet was determined from the resistance of the conductivity cell which was held in a lava cell holder and measured by means of a General Radio conductance bridge at 1000 Hz. Resistance measurements were also made with square wave excitation from 1,000 to 10,000 Hz of a bridge constructed from Helipot precision potentiometers. A Tektronix Type E differential preamplifier made possible the application of only 3 mV peak to peak to the sample. Same results were obtained using both techniques.

A Blue M Model M10A resistance furnace was used to maintain the temperature of the conductivity cell above ambient.

X-ray diffraction analysis.—The x-ray diffraction patterns of the nominally pure and doped lead fluoride were obtained at room temperature using a Philips diffractometer with CuKα radiation through a Ni filter.

Transference number measurement.—The transference numbers of F^- in the YF_3-doped α-PbF_2 were determined at 110°C using the Tubandt method. A Pb/α-$PbF_2//\alpha$-$PbF_2//\alpha$-PbF_2/graphite cell was used for the measurement. The weight change in both the Pb/α-PbF_2 and the α-PbF_2/C pellets after the passage of a current was used to determine the transference number. An Electronics Measurements M-621 constant current supply was used to provide the current for electrolysis. The electrolysis was carried out at a constant curent of 1 mA for exactly 80 hr. A silver coulometer was used to measure the total number of coulombs used for the electrolysis. The weights of the pellets in the cell were weighed using a Mettler H15 balance before and after the electrolysis.

Results

The x-ray diffraction patterns showed that the lead fluoride pellet formed from the commercial powder material was in the orthorhombic form (α-PbF_2). No impurity was found by the x-ray diffraction analysis. Nonetheless, some impurities were found by spectrophotographic analyses. The impurity contents are shown in Table I. The conversion to the cubic β-PbF_2 was accomplished by heating the pellet gradually to about 350°C. Once the β-PbF_2 was formed it remained stable at room temperature and pressure. Kennedy *et al.* (1) found that the room temperature equilibrium potential of the Pb/β-$PbF_2//KF_{aq.}//\alpha$-PbF_2/Pb cell was +1.7 mV and suggested that β-PbF_2 was in fact more stable than α-PbF_2 at room temperature and pressure.

Figure 1 shows the temperature dependence of the total conductivity for the nominally pure lead fluoride in both α and β forms. Inasmuch as the electronic conductivity is negligible compared with the ionic conductivity in lead fluoride (1, 3) the data shown in Fig. 1 may be regarded as characteristic for ionic conduction. It was noted that the conductivity of lead fluoride was generally independent of the electrode material. Similar results were obtained when either graphite or lead was used as the electrodes in the conductivity cells. The conductivity of β-PbF_2 was higher than that of α-PbF_2 at the same temperature. However, similar activation energies for conduction were found for both α-PbF_2 in the temperature range between 25° and 300°C and β-PbF_2 in the temperature range between 25° and 350°C. It is noted that Kennedy *et al.* (1) concluded from their conductivity measurements that both forms of lead fluoride exhibited the same activation energy of movement. Nonetheless, the values of the activation energy calculated from the data shown in Fig. 1 were 11.6 ± 0.6 kcal/mole for α-PbF_2 and 14.3 ± 0.6 kcal/mole for β-PbF_2. It is most likely that these activation energies were for the mobility of the conducting species inasmuch as the conductivity was measured at relatively low temperatures (1). No attempt was made to study the conduction characteristics in the intrinsic region.

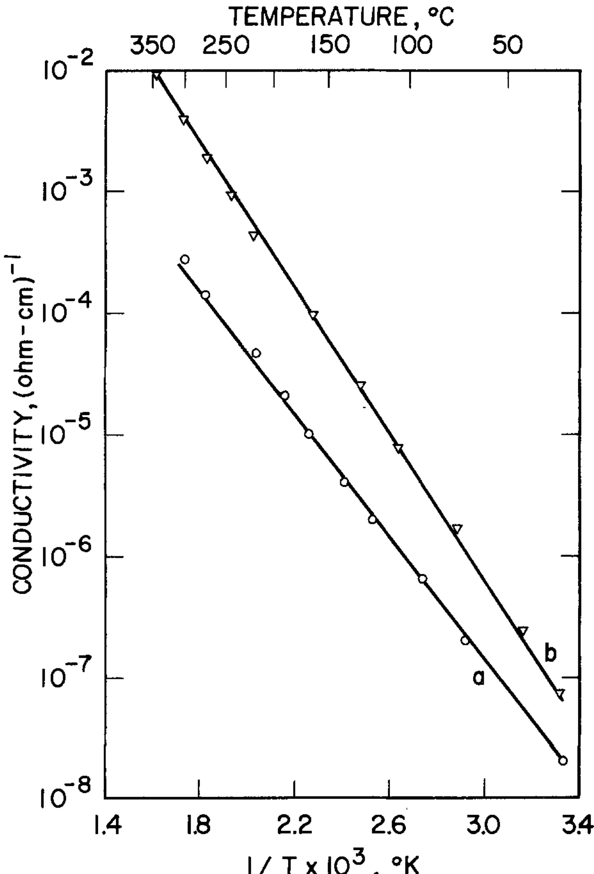

Fig. 1. The temperature dependence of the total conductivity of polycrystalline lead fluoride. a, α-PbF_2; b, β-PbF_2.

The conduction characteristics of both forms of lead fluoride were altered by doping with potassium fluoride. The conductivity was increased substantially by the incorporation of potassium fluoride in the lead fluoride lattice. Furthermore, a substantial decrease in activation energy was observed for both α-PbF_2 and β-PbF_2 upon doping with KF.

Figures 2 and 3 show that the conductivity of the doped lead fluoride at room temperature increased linearly with the potassium fluoride concentration up to 1 mole per cent (m/o). Figures 4 and 5 show the temperature dependence of the conductivity for the KF-doped lead fluoride in comparison with that for the nominally pure lead fluoride in both forms. These results showed that the inclusion of potassium fluoride

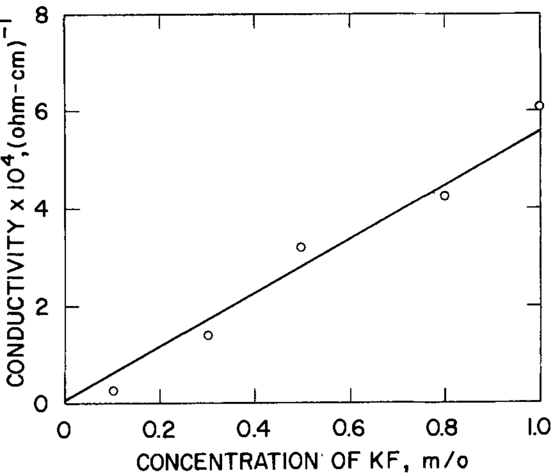

Fig. 3. The effect of KF dopant on the conductivity of β-PbF_2 at 25° ± 2°C.

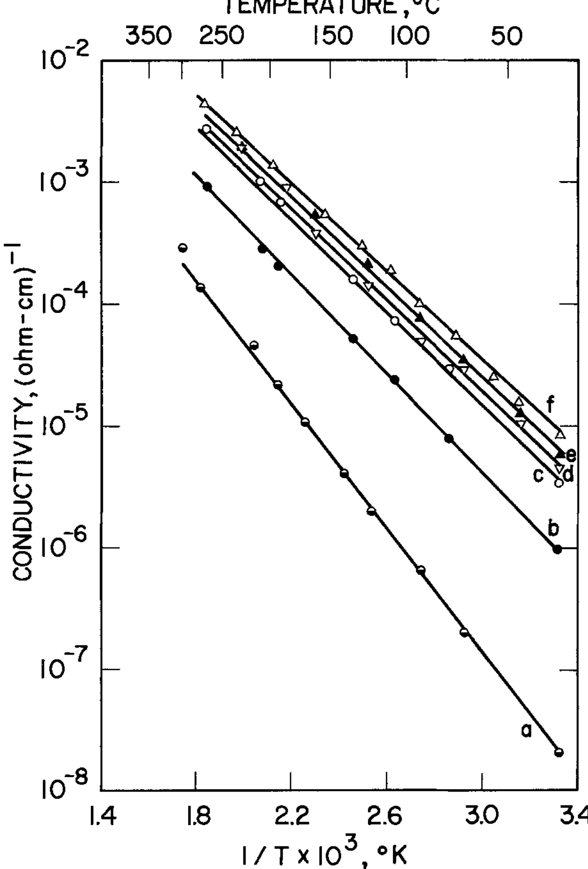

Fig. 4. The temperature dependence of the total conductivity of polycrystalline α-PbF_2. a, Nominally pure; b, 0.1 m/o KF; c, 0.3 m/o KF; d, 0.5 m/o KF; e, 0.8 m/o KF; f, 1 m/o KF.

changed the activation energy of mobility from 11.6 ± 0.6 kcal/mole to 8.9 ± 0.3 kcal/mole for α-PbF_2 and from 14.3 ± 0.6 kcal/mole to 4.1 ± 0.3 kcal/mole for β-PbF_2. The change in the activation energy indicated a change in the conduction mechanism. It was known from the transference number meausrements (1, 2) that the ionic conductivity of lead fluoride was predominately due to the fluoride ions. The transport of fluoride ions are either via interstitials or via vacancies. The effect of doping on the transport mechanism was shown by the change in activation energy. In order to determine whether the interstitial or the vacancy was the prevailing mechanism, the effect of trivalent cations on the conduction characteristics of lead fluoride was also investigated. It was found that

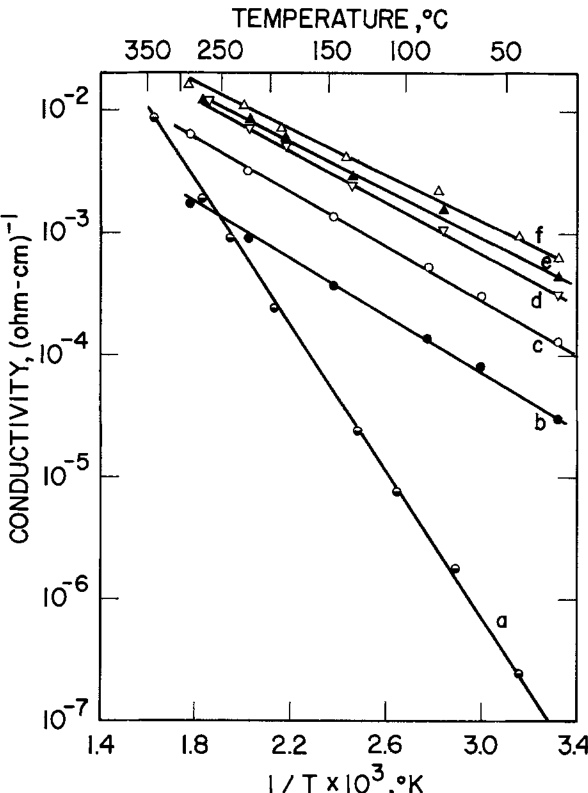

Fig. 5. The temperature dependence of the total conductivity of polycrystalline β-PbF_2. a, Nominally pure; b, 0.1 m/o KF; c, 0.3 m/o KF; d, 0.5 m/o KF; e, 0.8 m/o KF; f, 1 m/o KF.

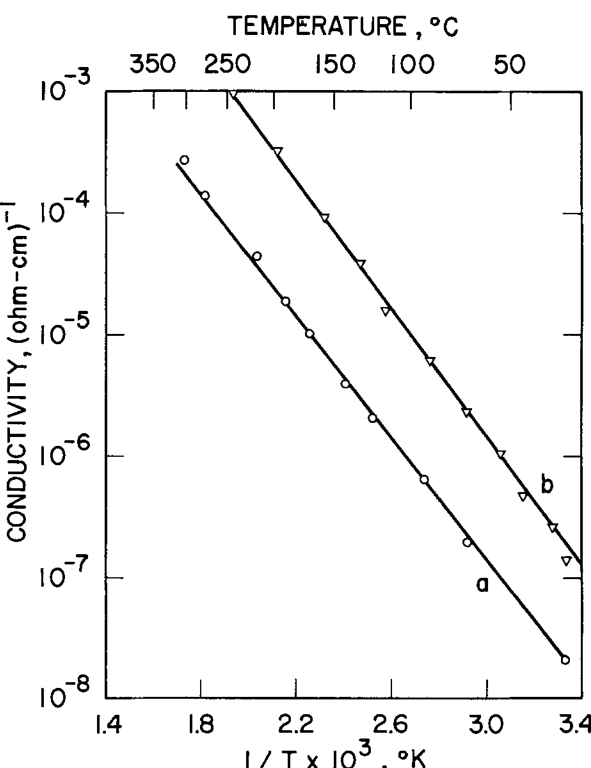

Fig. 6. The temperature dependence of the total conductivity of polycrystalline α-PbF_2. a, Nominally pure; b, 0.3 m/o YF_3.

the conductivity of PbF_2 was increased by doping with YF_3. However, the activation energy for the conduction process remained the same as shown by Fig. 6 and 7. These results indicated that the conduction mechanism was not affected by the incorporation of the trivalent yttrium ions.

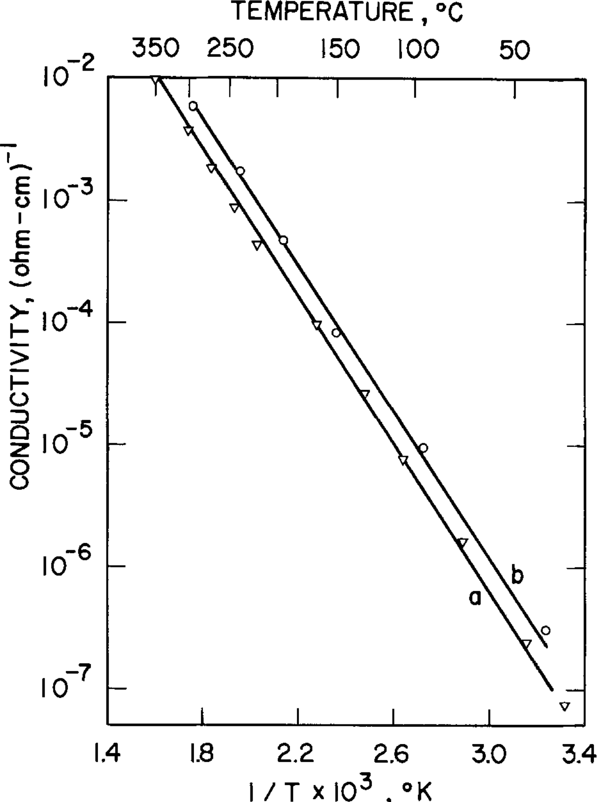

Fig. 7. The temperature dependence of the total conductivity of polycrystalline β-PbF_2. a, Nominally pure; b, 0.3 m/o YF_3.

The transference number of the fluoride ion in the yttrium-doped α-PbF_2 was determined using the Tubandt method at 110°C. A value of 0.94 ± 0.02 was obtained as shown in Table II.

Discussion

Inasmuch as lead fluoride is an anionic conductor (1, 2), either the fluoride ion vacancy and interstitial fluoride ion pairs (Frenkel disorder) or the lead ion and fluoride ion vacancies (Schottky disorder) are the predominate defects. In the case of Frenkel disorder, the fluoride ion vacancies and/or the interstitial fluoride ions may be the mobile species; in the case of Schottky disorder the fluoride ion vacancies are the mobile species.

It is known (4) that the cubic lead fluoride has Frenkel defects. Accordingly, the interstitial fluoride ions and the fluoride ion vacancies are the intrinsic point defects. Upon doping with KF and YF_3, the fluoride ion vacancies and the interstitial fluoride ions are generated respectively as shown by the following equations

$$KF \rightarrow K_{Pb} + F_F + V_F \quad [1]$$

$$YF_3 \rightarrow Y_{Pb} + 2F_F + F_i \quad [2]$$

Where K_{Pb} denotes the potassium ion at a lead ion site in the lattice with an effective charge of -1, $Y^{\cdot}_{Pb}$

Pb/α-PbF_2 pellet	83.7969	83.8339	+0.0370

Current = 1 mA.
Total change = 288.0 coulombs.
Transference number of the fluoride ion, $t_{F^-} = 0.94 \pm 0.02$.

the yttrium ion at a lead ion site with an effective charge of +1, F_F, $V_F^{\cdot}$, and F_i represent respectively the fluoride ion at a fluoride ion site, the fluoride ion vacancy with an effective charge of +1 and the interstitial fluoride ion with an effective charge of −1.

Our experimental results showed that upon doping with KF the conductivity of β-PbF_2 was increased substantially. Furthermore, Fig. 5 shows that the activation energy of motion is decreased from 14.3 ± 0.6 kcal/mole for the nominally pure β-PbF_2 to 4.1 ± 0.3 kcal/mole for the KF doped β-PbF_2. These results indicate a difference in conduction mechanisms. In view of Eq. [1] we conclude that the predominate mobile species in the KF-doped β-PbF_2 are fluoride ion vacancies while that in the nominally pure β-PbF_2 are interstitial fluoride ions.

These conclusions are also supported by the conduction characteristics of the YF_3-doped β-PbF_2. Upon doping with YF_3 the concentration of the interstitial fluoride ions was increased resulting in a conductivity increase for β-PbF_2. Nonetheless, the activation energy of motion remained unchanged indicating common mobile species which are interstitial fluoride ions (Eq. [2]). Accordingly, in the cubic form for lead fluoride the activation energy for the mobility of interstitial fluoride ion is 14.3 ± 0.6 kcal/mole and that of the fluoride ion vacancy is 4.1 ± 0.3 kcal/mole.

For the orthorhombic α-PbF_2 we have considered both the Frenkel and the Schottky disorders. In the situation where Frenkel disorder prevails it has been shown in Eq. [1] and [2] that fluoride ion vacancies and interstitial fluoride ions are generated by doping with KF and YF_3 respectively. In the situation where Schottky disorder is the predominate defect structure, doping with KF also results in an increase in the fluoride ion vacancy concentration as shown in Eq. [1]. The inclusion of YF_3 in α-PbF_2 with Schottky disorder will generate the lead ion vacancies as shown in the following equation

$$2YF_3 \rightarrow 2Y_{Pb}^{\cdot} + 6F_F + V_{Pb}'' \quad (3)$$

where $Y_{Pb}^{\cdot}$ and V_{Pb}'' represent respectively the yttrium ion at a lead ion site with an effective charge of +1 and the lead ion vacancy with an effective charge of −2. However, results from the transference number measurements (Table II) showed that the YF_3-doped α-PbF_2, same as the pure lead fluoride (1, 2) is an anion conductor. Furthermore, from the activation energy shown in Fig. 6 it is noted that the same transport mechanism prevails in the YF_3-doped and the nominally pure α-PbF_2. Therefore, we concluded that lead ion vacancies cannot be the principal conducting species. Furthermore, if Schottky disorder were the predominate defect structure then the mobile species would be the fluoride ion vacancies in both the nominally pure and the KF-doped α-PbF_2. However, Fig. 4 shows that the activation energy of motion for the nominally pure α-PbF_2 is different from that for the KF-doped α-PbF_2 indicating different mobile species in the two α-PbF_2 under discussion. Therefore, it is unlikely that Schottky disorder is predominate in α-PbF_2.

Our experimental data would indicate that (*i*) two mobile species are present in α-PbF_2 (Fig. 1, 4, and 6) and (*ii*) both of the mobile species transport fluoride ions (Table II). Therefore, we concluded that Frenkel disorder is also predominate in α-PbF_2 as in β-PbF_2. Accordingly, in α-PbF_2 the activation energy for the mobility of the interstitial fluoride ion is 11.6 ± 0.6 kcal/mole and that for the mobility of the fluoride ion vacancy is 8.9 ± 0.3 kcal/mole.

Growth of Oxide Films at Pt Anodes at Constant Current Density in H_2SO_4

A. Damjanovic, A. T. Ward, B. Ulrick, and M. O'Jea

Xerox Corporation, Webster Research Center, Webster, New York 14580

ABSTRACT

Constant current charging curves from 10^{-6} to 10^{-1} A-cm^{-2} are used to study the mechanism of growth of anodic oxide films at platinum in H_2SO_4 solutions. At any constant current density the potential initially changes linearly with time. In this linear region no O_2 is evolved. The linear region is followed by a region in which potential changes logarithmically with time while oxygen evolution becomes the predominant reaction. The thickness of the oxide films at which the transition occurs depends on the applied current density but for all current densities it is less than 10Å. Both in the linear and the logarithmic region the ellipsometric thickness-time relationships essentially parallel the V-t relationships. The rate of growth is described by $i = i_0 \exp [\alpha(V - V_0)/d]$ where d is the thickness and V_0 the potential at which oxide film starts to grow. From the transfer coefficient α, that is equal to 158 Å-V^{-1}, it was deduced that the oxide phase is composed of divalent platinum ions, *i.e.*, the oxide phase is PtO. It is suggested that the rate-determining step is a process at the metal/oxide interface rather than a process at the oxide/solution interface or a process within the bulk of oxide. The distribution of the potential between the oxide film and the double layer is discussed. It is shown that the potential difference across the solution double layer is constant for the growth at current densities examined here. This is possible if the electrochemical reaction in the double layer is fast.

The nature of the "oxygen containing films" at platinum electrodes at potentials anodic to about 0.7V *vs.* hydrogen electrode has been the subject of numerous recent studies (1-20). Views of various workers range from "...the film is all absorbed oxygen..." (13)—even at potentials as high as 2.2V and for coverages over 2.5 oxygen atoms per platinum atom in the surface,—to "...it is a phase oxide...,"—particularly above 1.0V. The latter potential was taken to represent, somewhat arbitrarily, a border between potential regions of chemisorbed oxygen (from about 0.7-0.95), and oxide phase (9, 21) (above about 1.0V). Electrochemical or chemical evidence alone was not sufficient to resolve the problem. It is only in recent studies, particularly those based on reflectance and ellipsometric measurements (3-6), low energy electron diffraction (22), and field ion spectroscopy (23) that conclusive evidence was provided favoring the view that above 1.0V "...the film is made of an oxide of platinum forming a definite phase..." (6) while below about 1.0V "...the film is composed of [reversibly (21)] chemisorbed oxygen species" (4, 6). The latest evidence, both from the ellipsometric studies and Auger spectroscopy (24) indicated that divalent platinum constituted the oxide phase. This is in agreement with an early finding of Anson and Lingane (1) that the chemically stripped anodic oxide films correspond mostly to PtO.

Due probably to this divergence of views regarding the "nature" of the oxygen-containing films, little attention has been paid to the analysis of the kinetics and mechanisms of the anodic film growth at platinum. This is sharply contrasted to the extensive work of anodic oxide formation on valve metals, or on metals "known to passivate," such as nickel or iron. Reddy, Genshaw, and Bockris (5) have concluded from their steady-state ellipsometric measurements that the oxide films at platinum grow by "a place exchange mechanism" leading to the direct logarithmic law of growth. Vetter and Schultze (15) examined the rate of growth as a function of time at various constant potentials; from their data it is evident that the same law of growth holds for oxide film grown at constant potentials. For polarization at constant current density, however, Vetter and Schultze (16) have observed a different law of growth; it can be described by the well-known Mott's equation for growth of oxide films in the presence of a high electric field within an oxide film.

In the present study we have examined the kinetics of oxide film growth at platinum anodes at the early stages of polarization with various constant current densities, and analyzed the mechanism of growth in the potential region in which no significant oxygen evolution occurs.

Key words: platinum, chronoellipsometry, anodization.

Experimental

An all-Pyrex, two-compartment cell used in present experiments was similar to a cell previously described (25). A platinum wire test electrode (diameter = 0.5 mm) was "sealed" at one end into a soft glass tube that fitted a Beckman stopcock closing the main compartment. Geometrical area of the electrode was 0.5 cm^2. Stated purity of the metal was better than 99.999%. The solution was made with triple-distilled water (with two distillations in an all quartz system) and Analar grade H_2SO_4. Final cleaning of the cell and electrodes was made *in situ* with triple-distilled water and then acid solutions of the same concentrations as used in subsequent experiments.

Prior to any measurement a test electrode was abraded with polishing papers (ending with 40), and then after extensive washing was subjected to a few high (~2.0V) anodic pulses (10-30 sec) followed by cathodic (0.0V) pulses (20-60 sec). The roughness factor of electrodes was determined by capacitance measurements in the potential region close to 0.5V, and current densities were corrected for the roughness of the electrodes.

A potentiostat (Tacussel PRT 40-1X) connected for a galvanostatic mode of operation was used. Potentials of the test electrode with respect to a hydrogen electrode in the same solution were measured with an electrometer (Keithley 610) and recorded with time on a strip-chart recorder (Mosley 1100). For high current densities and fast rise of potentials, an oscilloscope (Tektronix, Type 564 with 2A63 differential amplifier and 612 oscilloscope camera) was used.

In a few experiments, a rotating disk platinum electrode with a concentric ring electrode was used to de-

tect the early stages of oxygen evolution. After a constant current was applied to the test electrode, first oxygen gas evolved at the disk electrode was quantitatively detected (as a function of time) at the ring electrode kept at 0.5V. Solution in these experiments was saturated with argon.

Finally, in as yet preliminary experiments, the early stages of oxide growth at platinum at a constant current density were followed with time by an automatic ellipsometer (Rudolf Research Inc. Automatic Ellipsometer). The thickness of oxide film was determined *in situ* upon reflection of polarized light from a mirror-polished platinum disk electrode (diameter = 12 mm). The cell used in this work was similar to those described by other workers (26). All experiments were performed at room temperature. Potentials refer to hydrogen electrode in the same solution (HE).

Results

Preliminary experiments.—At prereduced electrodes in solutions saturated with oxygen under 1 atm pressure a potential close to 0.98V was readily established in less than 1 min. In argon-saturated solutions an unstable, slowly drifting potential in the region 0.3-0.7V was observed. When a constant current is applied to an electrode at rest a linear V-t region is observed at potentials above 1.0V. This linear region is followed by a region in which the potential changes only very slowly with time (Fig. 1). This region does not, however, represent a steady state: in this region too the potential increases with time, but now according to a direct logarithmic rather than a linear law. The logarithmic dependence extends to at least $2 \cdot 10^4$ sec (Fig. 2). Irrespective of whether a constant current is applied to an electrode in oxygen- or argon-saturated solution the slopes of the charging curves in the linear region were the same above 1.0V. For this reason, only the data obtained in oxygen-saturated solutions are presented here.

Vigorous stirring of the solution by bubbling, or rotation of a disk electrode, had no effect on the V-t curves. This result shows that the mechanism of anodic film growth at platinum does not follow the dissolution-precipitation path. Finally, a test was made to ascertain whether mechanical damage of the electrode surface, which could result from polishing, affected the polarization behavior of the electrodes. No significant change in the V-t curves was detected at mechanically polished as compared to initially flamed (presumably annealed) electrodes providing the electrodes were treated by alternative anodic-cathodic pulses and the correction for roughness factor was made. Electrodes were always prereduced prior to an experiment by potentiostating in the potential region 0.4-0.5V for a few minutes. When an electrode was not well reduced, the rate of change of potential was high

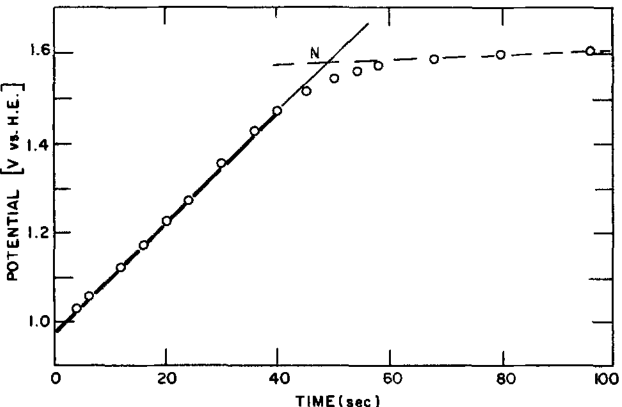

Fig. 1. Change of potential with time of polarization with constant current density $i = 1.82 \cdot 10^{-5}$ A-cm^{-2}. Solution 2N H_2SO_4. The linear region is followed by a quasi steady state.

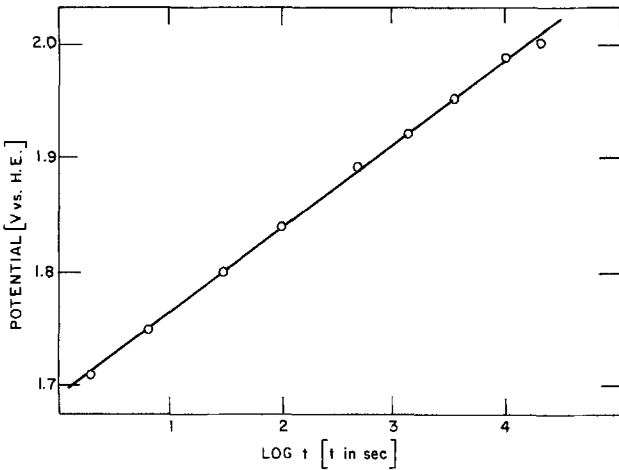

Fig. 2. Change of potential with time during the extended growth of oxide film. $i = 5.5 \cdot 10^{-4}$ A-cm^{-2}. Solution 2N H_2SO_4.

and not reproducible. The electrolyte was frequently replaced with fresh solution to avoid possible contamination with H_2O_2.

Charging curves at constant current densities.—A series of charging curves for different constant current densities ranging from about 10^{-6}-10^{-1} A-cm^{-2} are plotted *vs.* total charge, q, in Fig. 3. These curves are obtained in 2N H_2SO_4 solution. Identical data with respect to HE are obtained in 0.1 and 0.01N solutions. A linear dependence of V on q is evident in all charging curves at or above 10^{-6} A-cm^{-2}. Charging curves below 10^{-6} A-cm^{-2} frequently exhibit a shoulder around 1.2-1.3V, after which the potential increases linearly with time.

The linear V-t relationship has frequently been reported (14, 16-18. 27, 28) and is interpreted to represent the buildup of an oxygen-containing film at electrodes without oxygen evolution. The rotating disk-ring electrode assembly offers here an additional proof for this. When a constant current is applied across the disk electrode no current is detected at the ring electrode for as long as the potential of the disk remained in the linear V-t region (29). Accordingly, all, or at least the major part of the current at the disk goes for formation of oxygen film. Only close to, or after the knee in the V-t curves (cf., N in Fig. 1) oxygen starts to evolve at the disk and is detected at the ring electrode. At this point the ring current increases rapidly and soon reaches the value that corresponds almost completely to the current at the disk electrode. Addi-

tional experiments verified that the response of the ring electrode was fast so that the "delay" in the ring current was due only to the "induction" period for oxygen evolution at the disk electrode.

pH dependence.—The effect of pH is shown in Fig. 4, where the V-q curves at a given current density in solutions of different pH are plotted. In this figure the potentials refer to NHE. There is a strong dependence of the position of the V-q lines on pH, but the slopes of the charging curves at a given current density are not affected by pH. For any constant charge, q, and current density, i, the potential with respect to NHE changes by about -60 mV per unit of pH, *i.e.*

$$\left(\frac{\partial V}{\partial \mathrm{pH}}\right)_{q,i} \approx -2.3\,RT/\mathbf{F} \quad [1]$$

Ellipsometric determination of film thickness.—The changes in azimuth and ellipticity associated with the changes in the electrode surface from the initial, freshly reduced film-free state[1] to the final anodically oxidized state were used to calculate the change $(\Delta_0 - \Delta)$ in the relative phase retardation, Δ, between components of the light polarized perpendicular and parallel to the plane of incidence, respectively. This change was used to calculate the mean film thickness, d, using Drude's approximation,[2] $[(\Delta_0 - \Delta) = kd]$, a relationship valid for films thin compared with the wavelength of light.

The optical constants ($n_1 = 2.80$; $n_2 = 1.94$; $\kappa_2 = 4.36$) used here to calculate thickness were taken from the work of Kim, Paik, and Bockris (6) who determined these parameters entirely from ellipsometric data. Here, n_1 is the refractive index of the film, and n_2 and κ_2 are the refractive index and absorption constant, respectively, of the platinum substrate. With angle of incidence $\phi = 75°$, corrected for refraction through the cell windows and wavelength $\lambda = 5460$Å, the constant k in Drude's equation is calculated as 0.263 Å^{-1}. The film thicknesses are then typically less than 10Å, and the use of Drude's equation is justified.

Ellipsometric data revealed a linear change of Δ with time, t, during the initial stages of polarization at constant current density. The variation of Δ or d *vs.* t at different applied current density is somewhat obscured due to the scatter of data and the narrow region of accessible current densities for ellipsometric work. However, the Δ-t, or d-t relationships essentially

[1] The film-free condition exists under potentiostatic conditions at 0.5V HE. At 0.98V the phase retardation was somewhat lower reflecting the presence of adsorbed species on the electrode.

[2] The assumption implicit in Drude's approximation is that the refractive index of the film is independent of thickness. Since the adsorbed layer and the film ultimately formed may not have similar refractive index the Drude assumption will lead to a small but constant error in calculated thicknesses.

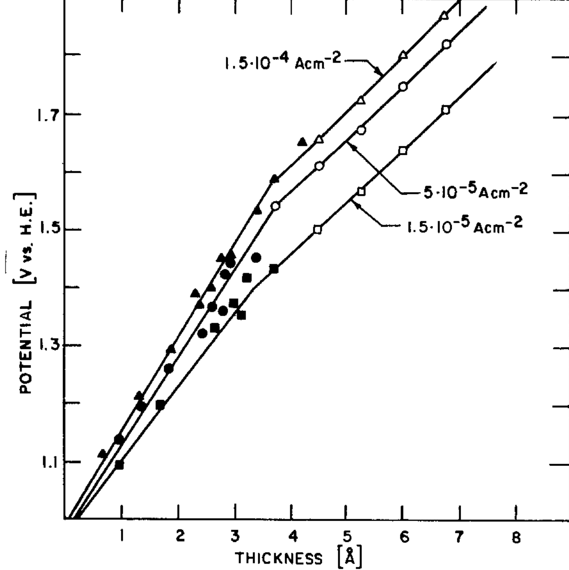

Fig. 5. The dependence of potential on ellipsometric thickness in the initial linear (full symbols) and subsequent logarithmic growth (open symbols) of oxide films. ■ and □, $1.5 \cdot 10^{-5}$; ● and ○, $5 \cdot 10^{-5}$; and ▲ and △, $1.5 \cdot 10^{-4}$ A-cm^{-2}. Solution 2N H_2SO_4.

parallel the V-t relationships both in the linear V-t and the logarithmic growth region. When Δ or d is plotted against V, linear relationships appear for both growth regions as shown in Fig. 5. Here, only the growth in the linear region is discussed; the discussion of the extended growth region is deferred to a subsequent paper.

Discussion

Since in the linear V-q (or V-t) region all the current is used to build up an oxide film (with no significant losses to corrosion or oxygen evolution) the kinetic data in this region appear particularly suitable for the study of the mechanism of initiation and growth of the anodic oxide films at platinum. Only in this region do oxides grow under controlled and ideal conditions of constant current density. Once oxygen starts to evolve, or becomes a major product in the over-all reaction, oxides continue to grow but now at a much reduced and no longer constant rate. As is discussed later, the observed linear change of the potential with time represents the change of the potential across the oxide film only, the potential across the double layer being constant for a constant current density. Once oxygen starts to evolve the total potential difference across the electrode is expected to rearrange and redistribute across the oxide film and the double layer. The new distribution will now be controlled by the major on-going reaction, the oxygen evolution reaction, and no longer directly by the growth of the oxide film. Though in this region most of the current is used for oxygen evolution, the observed potential change still represents the change in the thickness of the oxide film (25). The analysis of the oxide growth, however, becomes more complex since both the current for oxide growth and the potential difference across the oxide film change with time (25, 30). Under potentiostatic conditions too, the mechanistic analysis of oxide growth is rather complex since again both the potential difference across the oxide film and the current density for oxide growth (or O_2 evolution) change simultaneously with time. In this paper the rate of growth is analyzed for the initial, linear region before the onset of oxygen evolution.

The rate equation of oxide growth.—The most significant aspect of the present results, and the one which is characteristic for the mechanism of growth, is that the $(\partial V/\partial q)_i$ slopes increase linearly with logarithm of the applied current density. The linear relationship extends for over several decades of cur-

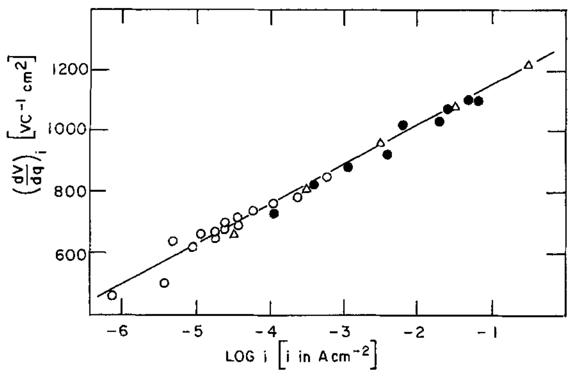

Fig. 6. The dependence of slopes in *V-q* diagrams on current density. ●, Oscilloscope recording; ○, recording with a mechanical recorder. Solution 2*N* H_2SO_4. △, Data of Vetter and Schultze (16) in 1*N* H_2SO_4 solution.

rent density (Fig. 6). In Fig. 6 in addition to many data obtained in the present work, data from the work of Vetter and Schultze (16) are included for comparison. The latter data are, however, scaled to the present data by a factor of 1.3 to compensate for the difference in electrode roughness. The fact that a single scaling factor brings both the position and slopes of $(\partial V/\partial q)_i$ *vs.* log i to overlap, justifies in itself the scaling procedure. From Fig. 6 one obtains

$$\left(\frac{\partial V}{\partial q}\right)_i = c \ln i + b \quad [2]$$

with $c = 57$ V-cm^2-C^{-1}, and $b = 1280$ V-cm^2-C^{-1} when i is in A-cm^{-2}. Writing $b = -c \ln i_o$ with i_o as a constant, [2] transforms to

$$\left(\frac{\partial V}{\partial q}\right)_i = c \ln \frac{i}{i_o} \quad [3]$$

From Fig. 2, the dependence of potential on logarithm of current density at any constant charge, q, is obtained (Fig. 7). From Fig. 7 it follows that

$$\left(\frac{\partial V}{\partial \ln i}\right)_q = aq \quad [4]$$

With a equal to 62 V-cm^2-C^{-1}. It is convenient to convert q into average thickness, d, of the oxide film according to $d = rq$ where r is a conversion factor.

At constant pH and temperature, V is a function of ln i and d, only, *i.e.*

$$V = V(\ln i, d) \quad [5]$$

and from [3] and [4] one obtains

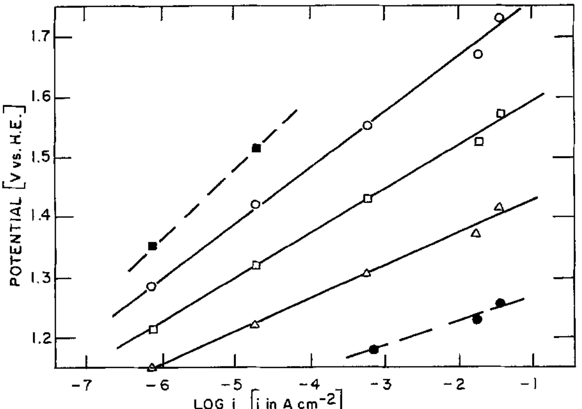

Fig. 7. "Tafel slopes" for oxide growth at constant thickness of oxide film. ■, 800; ○, 655; □, 510; △, 365; and ●, 220 μC-cm^{-2}. Solution 2*N* H_2SO_4.

$$dV = (ad/r)\, \partial \ln i + (c/r) \ln (i/i_o)\, \partial d \quad [6]$$

Integration of [6] yields

$$i = i_o \exp\left[\frac{\alpha(V - V_o)}{d}\right] = i_o \exp\left[\frac{\alpha \Delta V_{of}}{d}\right] \quad [7]$$

Here, V_o is the potential at $d = 0$, and ΔV_{of} the potential difference across the oxide film. Factor $\alpha(= r/a)$ is the transfer or field coefficient as it is sometimes called. It follows that $a = c$, in fair agreement with the experimental data.[3] Constant i_o, the exchange current density for oxide growth, is equal to $1.8 \cdot 10^{-10}$ A-cm^{-2}.[4] Further, an inspection of Fig. 3, as well as of Fig. 1 in the paper of Vetter and Schultze (16), shows that the intercepts increase slightly with current density. The linear V-q lines intercept at a negative value of charge. This charge is associated with oxygen adsorption before the onset of oxide film formation [about 130 μC-cm^{-2} (4)]. Since the coverage with adsorbed oxygen at oxide electrodes (38) is only 0.02-0.03 all the oxygen ions adsorbed on the oxide-free surface are used in the very initial formation of the oxide film before the linear V-q relationship is established.

Tafel slopes.—It has been the practice to call the V-log i lines in Fig. 7 the Tafel lines, and the $(\partial V/\partial \log i)$ slopes, the Tafel slopes. The slopes increase with increasing thickness in accordance with [4]. They approach zero for d = zero. Ord and Ho (18) have determined Tafel slopes for oxide growth over a range of potentials (or thicknesses) by interrupting the growth at a constant polarization current (of 10 μA-cm^{-2}) at various times of polarization and analyzing the open-circuit self-discharge transients. With this technique the Tafel slopes are found to be proportional to the (ellipsometric) thickness of the oxide film and to extrapolate to zero value at about 1.0V (or more precisely at 0.98V), the potential that corresponds to the onset of oxide growth. Vetter and Schultze (16) also have examined the kinetics of oxide growth under galvanostatic conditions. In their work, galvanostatic, anodic, or cathodic pulses of various current densities (all $\geq 10^{-4}$ A-cm^{-2}) were superimposed over a basic anodic charging curve (of 20 μA-cm^{-2}) at different points on the curve, that is, at different thickness of the oxide film. From these superimposed pulses, they determined overvoltages for different superimposed current densities, and calculated both anodic and cathodic Tafel relationships. Again, the anodic slopes increase linearly with the (coulometric) thickness of the oxide film. However, the slopes $b = b^o(1 + a_+\theta)$, assume a constant value ($b^o = 36$ mV) when coverage (θ) approaches zero.

The constant $b^o a_+/(2q_{H_2})$ calculated with their data for $a_+(=1)$ and $q = \theta \cdot 2q_{H_2}$, where q_{H_2} is coverage with hydrogen ($=210$ μC-cm^{-2}), is 86 V-cm^2-C^{-1}. This value should compare with 57 V-cm^2-C^{-1} of the present work. In view of the different experimental procedures, the agreement appears satisfactory.

Mechanism of oxide growth and transfer coefficient.—Following Mott (31) and Cabrera and Mott (32), the rate of growth of oxide films in the presence of a high field is given by

$$i = k \exp\left[-\frac{Q - ne^{-}\lambda E}{kT}\right] \quad [8]$$

where Q is the activation energy in the absence of the electric field, E, given by $\Delta V_{of}/d$, n and λ are valence and distance from initial position of an (interstitial) cation to its position in the activated state (the half-jump distance), respectively, and e^- is the unit charge.

[3] In contrast to c, the a parameter is affected by parallel displacement of V-t curves. Consequently, the c parameter is more accurate. In the following we place $a = c = 57$ V-cm^2-C^{-1}.

[4] Vetter and Schultze (16) give $i_o = 10^{-16}$ A-cm^{-2}. The discrepancy is apparently due to the different experimental procedure (superposition of galvanostatic pulses) used by Vetter and Schultze in obtaining i_o.

Other symbols have their usual significance. We use this Mott formalism to analyze the experimental data. From [7] and [8]

$$\frac{\partial^2 V_{of}}{\partial \ln i \, \partial d} = \frac{kT}{ne^- \lambda} = \frac{1}{\alpha} \left[= \frac{a}{r} \right] \quad [9]$$

This derivate is proportional to the slope of $(\partial V/\partial q)_i$ *vs.* log i in Fig. 6, and is readily obtained if the conversion factor, r, is known. This factor can be calculated for a given stoichiometry or structure of the surface oxide. Early chemical (1), as well as the most recent ellipsometric (6, 7) and Auger spectroscopy (24) evidence indicates that the anodic layer is made of divalent Pt-oxide, *i.e.*, PtO. No data on crystal structure of PtO appears to be available. From the x-ray density of Pt_3O_4, which is probably close in density to PtO, the conversion factor is equal to $9 \cdot 10^3$ Å-cm^2-C^{-1}. With this factor, α is calculated as 158 Å-V^{-1}. From [9] and with $\alpha = 158$ Å-V^{-1}, $n\lambda$ is equal to 3.99Å, and for $n = 2$, *i.e.*, for Pt^{2+} as the carrier of the ionic current, λ is about 2.0Å. This is a reasonable value for the half-jump distance in platinum oxides.[5] If one assumes that $n = 4$ (*i.e.*, PtO_2 structure), and with $\alpha \approx 90$ Å-V^{-1} calculated for PtO_2, λ becomes impossibly small ($\sim$0.6Å). Similarly, if $n = 1$ (*e.g.*, a kind of suboxide structure), λ becomes too large to correspond to reality. The analysis of the transfer coefficient led, therefore, to the same conclusion as ellipsometry or Auger spectroscopy: the anodic oxide films at platinum above about 1.0V *vs.* HE are made of divalent Pt ions, *i.e.*, the oxide phase is PtO.

According to the original Mott's model of oxide growth, interstitial cations are formed in a rate-determining step at the metal/oxide interface and diffuse in the high field to the surface of oxide film. Other models or reaction steps besides the formation of interstitials at the metal/oxide interface may be assumed and are suggested in the literature to be rate determining (16, 33, 34). For instance, a positive vacancy may be created at the oxide/solution interface by pulling out a metal ion in the first layer of the oxide and placing it over the surface where it forms with $O^=$ or OH^- a new element of the oxide phase. The positive vacancy then migrates in the field toward the metal/oxide interface. At the interface it is filled by a metal ion from the surface of the metal whereby a vacancy in the metal surface is formed. If the surface vacancy is filled with an oxygen atom from the oxide phase a negative vacancy is created in the oxide which then diffuses toward the oxide/solution interface. In this simple example both positive and negative vacancies in a cooperative way participate in the transport of charge and matter through the oxide film (though not necessarily in equal proportions).[6] If $i_+ \approx i_-$, the over-all rate is given by Vetter and Schultze in a form that is similar to

$$i = \sqrt{i_+ i_-} = \text{const} \exp \left[\frac{(n_+ e^- \lambda_+ + n_- e^- \lambda_-) \Delta V_{of}}{2kTd} \right] \quad [10]$$

Here, (+) and (−) stand for positive and negative valencies, respectively. Since $\lambda_+ \approx \lambda_-$, the rate equation reduces to [8] when $n_+ \approx n_-$. For $n_+ \neq n_-$, α in Tafel slopes (cf., Eq. [9]) will be a multiple of $e^- \lambda/kT$ only when $n_+ + n_-$ is even. The same equation as [8] is obtained also for diffusion across the oxide film as rate-determining step.

If the growth occurs along two parallel but independent paths, it is expected that the rates for these two paths are sufficiently different so that the overall rate is still controlled by a single path and rate-determining step. If the rates along the two paths are comparable then unless $n_1\lambda_1 = n_2\lambda_2$ no linear change of potential with thickness is expected for a constant current growth of oxide films. The observed linear V-t relationships at platinum, and the simple factor for the field coefficient $\alpha = \left[2 \frac{e^- \lambda}{kT} \right]$ points, therefore, to a simple mechanism of growth with a single reaction path. Moreover, since the observed law of growth holds from the earliest stages of growth when the coverages with oxygen are less than 1 and therefore the diffusion within the oxide film is not as yet operative, the rate-determining step is a process at the metal/solution, initially, and subsequently at the metal/oxide interface. The process at the oxide/solution interface is not expected to be the rate-determining step. It would require a change in the activation energy (and hence in i_o) as the oxide film grows from a monolayer to a multilayer. No such change is observed.

Finally, a comment about the nature of the oxide films and the relation of the nature of the films to the type of the ionic current in the oxide growth. The low angle electron diffraction revealed (22) that the oxide films on platinum have some degree of arrangement or crystallinity, though they still may be classified as "amorphous." Were the oxides crystalline, the ionic current will be due to the transport, via point defects (interstitials or vacancies), of cations only since their ionic radius is so much smaller than that of an oxygen ion. If oxides are, however, amorphous the possibility may arise that anions participate in the ionic current. It is now known that anionic current may even dominate in the anodic growth of oxides at tantalum, niobium, zirconium, and some other metals (35). With respect to structures, these oxides when amorphous are classified as glassy or network formers (33). A network of channels extends through these structures, so that large anions can easily move through these channels, and therefore anionic current is possible. Anodic oxides at platinum are not network formers if for no other reason than because of their stoichiometry, and the transport through the oxides is expected to be by cations only.

Potential distribution across the metal-solution interface.—The kinetics of oxide growth according to the model discussed here depends on ΔV_{of} rather than on the observed difference in potential ΔV. The potential difference ΔV between metal and solution is divided into the potential difference across the oxide film, ΔV_{of}, and across the double layer, ΔV_{dl}, *i.e.*

$$\Delta V = \Delta V_{of} + \Delta V_{dl} \quad [11]$$

Here, ΔV is linearly related to the measured potential, V. These partial potential differences adjust themselves in such a way that for any thickness of the oxide film, the (ionic) current across the oxide film, i_{og}, equals that across the double layer, i_{dl}. The dependence of ΔV_{dl} on current density and thickness of oxide film is now discussed.

It is reasonable to assume that ΔV_{dl} depends on current density in a usual way as

$$\Delta V_{dl} = f(i) = \frac{RT}{\gamma \mathbf{F}} \ln (i_{dl}/i_{o,dl}) \quad [12]$$

Here, γ is the transfer coefficient for a reaction across the double layer, *e.g.*, for

$$H_2O \rightarrow OH + H^+ + e^- \quad [13]$$

and $i_{o,dl}$ is the exchange current density for such a reaction. With [12] into [7] it follows that

$$\frac{d}{\alpha} \ln (i_{og}/i_o) = \Delta V - \frac{RT}{\gamma \mathbf{F}} \ln (i_{dl}/i_{o,dl}) \quad [14]$$

where i_{og} is equal to i_{dl}. Equation [14] requires that at any constant current ΔV changes linearly with d and that slopes $d\Delta V/dd$ increase with applied current den-

[5] For Pt_3O_4 the distance between two Pt or two O atoms is about 3.9Å. These are also distances between interstitial positions. Half-jump distance is then approximately 1.95Å.

[6] Vacancies in the surface of metal may either diffuse into the bulk or upon accumulation cause the interface to collapse.

sity, as observed in present experiments. However, it requires also that the intercepts on the V-axis increase with increasing current density. For [13] as rate-determining step, γ is ½ and the intercept should shift about 120 mV toward higher potentials for any tenfold increase in current density. Such shift is not observed. If a step that follows [13] is rate determining, γ is larger than ½, and smaller shifts would be expected. Even then the shift will easily be detected when current density changes by few orders of magnitude. For instance, for $\gamma = 2$ the shift would be 150 mV when current density changes by five orders of magnitude as in present experiments. Larger values for γ are not reasonable since only two electrons are involved in charge transfer of the over-all reaction ($H_2O \rightarrow O + 2H^+ + 2e^-$). It is concluded, bearing in mind the qualification provided by Eq. [12], that ΔV_{dl} is a constant independent of applied current density, *i.e.*

$$\Delta V_{dl} = \text{constant} \neq f(i) \quad [15]$$

Now, if ΔV_{dl} is a function of d, for instance due to some catalytic effects, Eq. [7] would read

$$\frac{d}{\alpha} \ln (i/i_o) = \Delta V - f(d) \quad [16]$$

and for a constant current density one obtains

$$\left(\frac{\partial \Delta V}{\partial d}\right)_i = \frac{1}{\alpha} \ln (i/i_o) + \frac{df(d)}{dd} \quad [17]$$

Since $(\partial \Delta V/\partial d)_i$ = constant, $df(d)/dd$ is either a constant independent of applied current density or zero, *i.e.*

$$\Delta V_{dl} = f(d) = md + V_o' \quad [18]$$

With [18] the rate equation, [7], reduces to an expression of the same form as [7] but with different values for i_o and ΔV_o, and no conclusion is possible regarding the dependence of ΔV_{dl} on d. However, irrespective of whether ΔV_{dl} is dependent or independent on i_{dl}, since the latter current density was found (30) to be invariant with d, it follows that $\Delta V_{dl} \neq f(d)$. The change of electrode potential, ΔV, with time during the constant rate of growth reflects then the change in ΔV_{of}. This is possible only if the reaction across the double layer is fast, *i.e.*, $i_{o,dl} >> i_{dl}$. It may be noted that the first discharge step such as that given by Eq. [13] was reported to be fast both in anodic oxidation of hydrocarbons (36) and in oxygen evolution at platinum (30, 37).

pH dependence.—The observed pH dependence apparently reflects the change with pH of the potential at which oxides start to grow. Only when the field in the double layer of as yet unoxidized platinum surface reaches certain critical values, platinum atoms are pulled out with a significant rate from their regular position in the lattice of the metal. The potential corresponding to this field is then pH dependent. It simply follows the change with pH of the potential of zero charge. If so, the rate of growth itself is not (directly) dependent on pH. This will be the case if the reaction across the double layer is fast and the rate of oxide growth is controlled by a process at the metal/oxide interface (or initially before oxides are formed at the metal/solution interface), as it is suggested in the present study.

The Codeposition of Copper and Arsenic from H_2SO_4-$CuSO_4$-As_2O_3 Solutions

Electrochemical Formation of Copper Arsenides

Jacques Dewalens, Luc Heerman,[1] Luc Van Simaeys

Laboratory of Inorganic Chemistry, University of Louvain, 37, Schapenstraat, 3000 Louvain, Belgium

ABSTRACT

The induced codeposition of copper and arsenic from H_2SO_4-$CuSO_4$-As_2O_3 solutions (50-500 g/liter H_2SO_4) leads to the formation of copper arsenides. The codeposition potential at 50°C is 0.200 ± 0.010V (NHE), almost independent of electrolyte composition. Potentiostatic E-i curves exhibit two waves for solutions with molar ratios Cu/As > 2.25. This is explained by induced codeposition with maximum induction as a limiting factor by which is understood that deposition of one arsenic atom as copper arsenide requires neutralization of at least two copper ions (corresponding to formation of Cu_2As, the arsenic richest phase observed). The phases $Cu_{5-x}As_2$, β-$Cu_{3-x}As$, Cu_6As, and the α-phase (solid solution) are obtained as pure single phases. The phase α-$Cu_{3-x}As$ which normally can be obtained only by thermal synthesis at high pressures was also obtained pure. Cu_2As, on the contrary, was found only in mixtures with other phases, mainly $Cu_{5-x}As_2$. Some of the products formed could not be identified.

The phase diagram of the copper-arsenic system has been recently reviewed (1) (Fig. 1). Copper arsenides can be synthesized from copper and arsenic compounds by precipitation from aqueous solution (2) and from the elements by solid-state diffusion at high temperatures (3-5). In this paper some results on the codeposition of copper and arsenic as copper arsenides from H_2SO_4-$CuSO_4$-As_2O_3 solutions are reported with special emphasis on the electrochemical factors governing the formation of the different phases present in the deposits. This work originated from a study of the codeposition of copper and arsenic under the conditions prevailing during certain stages of the electrorefining of copper. Although the principal objective of this study was thus not the electrochemical synthesis of copper arsenides, the results presented here may very well possess some preparative potentialities. It is interesting to note that copper arsenides are good electronic conductors as was shown by electrical measurements on thermally prepared products (6).

Experimental

Reagents and solutions.—Solutions were prepared from analytical grade As_2O_3 (Merck), As_2O_5 (Union Chimique Belge), $CuSO_4 \cdot 5H_2O$ (Union Chimique Belge), and H_2SO_4 (Merck). Solutions contained 500 g/liter H_2SO_4 unless indicated otherwise. Deionized water was used throughout. Purified nitrogen was passed through the solutions to remove dissolved oxygen. During the experiments solutions were kept under inert atmosphere by passing nitrogen over the electrolytes to avoid possible air oxidation of the products deposited on the cathode. All experiments were performed at 50°C unless indicated otherwise.

Solubility of As_2O_3 in sulfuric acid solutions.—In a preliminary series of experiments the solubility of As_2O_3 in concentrated sulfuric acid solutions, eventually with addition of copper sulfate or As_2O_5, was investigated. Solutions were prepared at about 90°C, rapidly cooled down to the desired temperature, and analyzed daily over a period of three weeks (see below). From the results in Fig. 2, it is clear that As_2O_3 easily forms sursaturated solutions and part of this work was performed with such solutions.

X-ray diffraction revealed that the precipitates in equilibrium with the solutions consist of claudetite (monoclinic As_2O_3) for solutions containing sulfuric acid either with or without addition of copper sulfate. Addition of As_2O_5, however, increases the solubility of As_2O_3 and leads to the precipitation of arsenolite (cubic As_2O_3).

It must be noted that the solubilities of As_2O_3 found in this work, about 4 g/liter As(III) at 25.0°C and 7.5 g/liter As(III) at 50.0°C, are somewhat lower than those reported previously by Anderson and Story (7) but are in good agreement with recently determined values (8).

Cell and electrodes.—Experiments were performed in a glass cell containing approximately 1000 mliters of electrolyte. The electrode assembly consists of a 2 × 2.5 cm² cathode flanked on either side by two 5 × 5 cm² anodes. Either platinum or copper electrodes were used in this work, the anodes being made of the same material as the cathode. Just prior to the measure-

Key words: codeposition, copper, arsenic, copper arsenides.

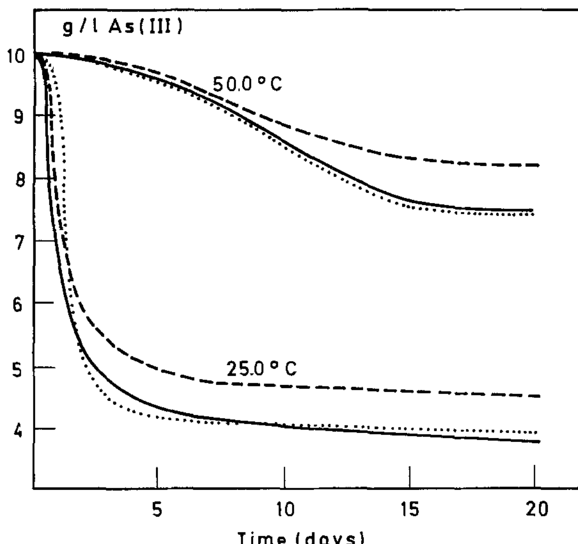

Fig. 2. Solubility of As_2O_3 in concentrated sulfuric acid solutions; initial concentration 10 g/liter As(111) (26.4 g/liter As_2O_3) ...... 500 g/liter H_2SO_4; ——— 500 g/liter H_2SO_4, with addition of 10 g/liter copper ions; ------, 500 g/liter H_2SO_4, with addition of 15 g/liter As(V).

ments, cathodes of electrolytic copper sheet were dipped for 1 min in 1:1 nitric acid, rinsed with distilled water, and transferred immediately to the polarization cell. In some cases, copper electrodes were prepared by depositing a thin layer of copper on electrolytic copper sheet from a solution of the same composition as used for the measurements but without addition of As_2O_3. The results obtained with both types of copper electrodes were essentially the same but electrodeposited electrodes gave a somewhat better reproducibility. Most experiments were performed without stirring of the solution (natural convection), otherwise solutions were gently stirred with a Teflon-coated magnetic stirring bar.

Electric circuit and measurements.—*E-i* curves were recorded using a conventional galvanostatic or potentiostatic circuit. The most reliable results were obtained, however, by the potentiostatic method since very often stable potentials could not be obtained at constant current density. Potentiostatic *E-i* curves were recorded at a sweep rate of 34.4 mV/min starting from the rest potential in the cathodic direction. Potentials were measured *vs.* SCE with a bridge filled with the test solution. Experimental potential values are converted to normal hydrogen scale (NHE). Electrolysis at constant potential was performed with a potentiostat provided with an integrating coulometer. For all experiments a constant charge, about 5×10^3 coulombs, was passed through the polarization cell.

Analytical methods.—The products formed on the cathode were stripped from the electrode and washed with deionized water, alcohol, and ether. Samples were dissolved in a mixture of concentrated HNO_3 and H_2SO_4 and this solution was evaporated until the appearance of white fumes. Attempts to determine arsenic in the presence of copper by atomic absorption analysis were unsuccessful (9). Therefore, arsenic was separated from the solution by adding hydrazine sulfate to a 5 mliter sample, distilling as $AsCl_3$ after addition of 50 mliters conc HCl, and collecting the gases in 250 mliters of a solution containing about 250 g/liter NaOH. This distillation was repeated twice and arsenic was determined in the distillate by iodometric titration. Copper was determined by EDTA titration.

The formation of arsine, AsH_3, was detected by placing a filter paper moistened with a 5% alcoholic solution of $HgCl_2$ in the gas stream (10). No attempt was undertaken for quantitative determination of this (poisonous) compound.

X-ray diffraction analysis.—X-ray diffraction patterns of the products formed on the cathode were taken with a Philips-Norelco unit using nickel filtered CuK_α radiation. Products were identified with respect to the X-ray Diffraction Powder Data File (11), except Cu_2As which was recently described by Naud and Priest (1).

Results

E-i curves recorded for solutions containing different concentrations of As_2O_3 in the absence of copper ions in the electrolyte for platinum or copper electrodes are shown in Fig. 3. The hydrogen evolution proceeds with considerable overvoltage at platinum electrodes in solutions containing As_2O_3, the deposition potentials shifting toward more negative potentials with increasing concentration. The effect of arsenic compounds on the hydrogen evolution reaction has been reported earlier (12). The hydrogen evolution reaction is accompanied by the formation of arsine. The standard free energy of formation of this compound has been reevaluated as $\Delta G°_f = 26.0$ kcal/mole (13), considerably lower than the value $\Delta G°_f = 42.0$ kcal/mole previously reported in the literature (14). Taking this new value the formation of arsenic becomes possible at potentials about 0.23V more positive than the values calculated by Pourbaix (15). On copper electrodes, the hydrogen evolution reaction for the base solution, *i.e.*, no As_2O_3 present in solution, proceeds with higher overvoltage than observed for platinum electrodes, as could be expected. Addition of As_2O_3 to the electrolyte, however, has relatively little effect on hydrogen overvoltage in comparison with the effect found for platinum electrodes. Gas evolution is accompanied by the formation of a thin layer of copper arsenide on the electrode, the composition of which was not identified with certainty.

If electrolysis was continued over extended periods of time at constant current density, at least 20 hr at 10 mA/cm^2, the formation of a colloidal brick-red precipitate in the solution was observed. This precipitate possibly consists of solid hydrogen arsenides such as As_2H_2 or As_2H_4, the existence of which has been reported in the literature (16).

E-i curves were then recorded for solutions containing either a constant concentration of copper ions with various additions of copper ions. Some typical curves are shown in Fig. 4-5. Strong potential oscillations were

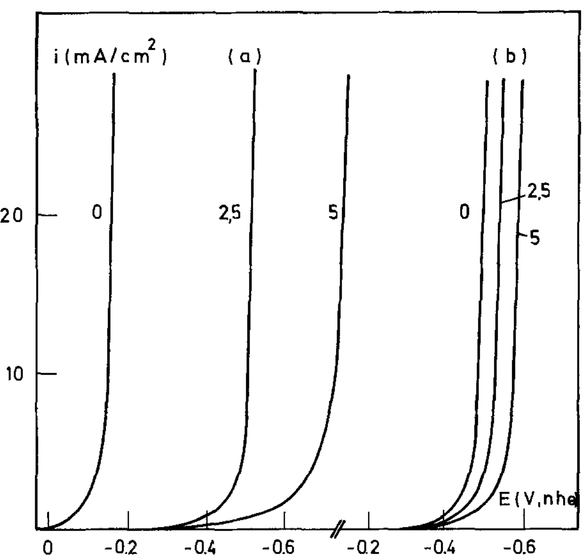

Fig. 3. (a) *E-i* curves for hydrogen evolution reaction on platinum electrode in presence of As(III); 500 g/liter H_2SO_4, 50°C, arsenic concentration indicated for each curve. (b) Same as (a), copper electrode.

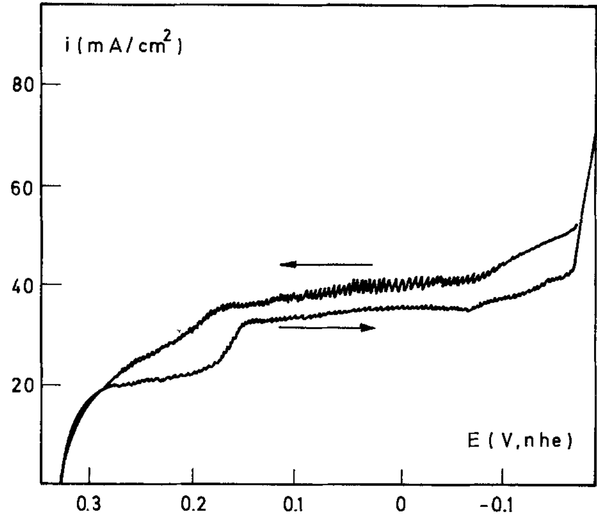

Fig. 4. Potentiostatic *E-i* curve for solution containing 500 g/liter H_2SO_4, 5 g/liter As(III), 20 g/liter copper ions, copper electrode, 50°C, sweep rate 34.4 mV/min.

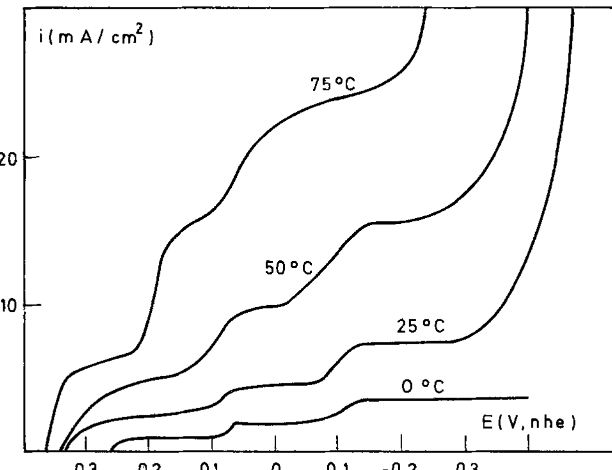

Fig. 5. Potentiostatic *E-i* curves at different temperatures for solution containing 500 g/liter H_2SO_4, 5 g/liter As(III), 5 g/liter copper ions, copper electrode, sweep rate 34.4 mV/min.

observed during galvanostatic measurements in the potential region of the second wave and specially in the potential region of the third wave. Therefore the curves in Fig. 5 have been somewhat idealized. The E-i curves exhibit either two or three waves, depending on the experimental conditions. The first wave corresponds to the deposition of copper metal but at potentials of about +0.200V (NHE) a second wave appears. In the potential region of this second wave, copper and arsenic are codeposited with formation of copper arsenides as was shown by x-ray diffraction studies, the composition of these compounds being discussed later. The exact potential at which the deposition of copper arsenides starts was determined by electrolysis at controlled potential and x-ray analysis of the cathodes. In this way the codeposition potential was found to be 0.200 ± 0.010V (NHE), independent of bath compositions (copper ion concentration was varied between 0.5 and 20 g/liter and arsenic concentration between 2.5 and 10 g/liter).

The appearance of the third wave depends on the bath composition, or, more specifically, on the molar copper/arsenic ratio in the electrolyte. This is shown in Fig. 6 where the heights of the first and second waves are plotted as a function of the copper ion concentration for a constant arsenic content of the solution. For solutions with a molar ratio Cu/As > 2.25 only two waves are observed and the height of the second wave

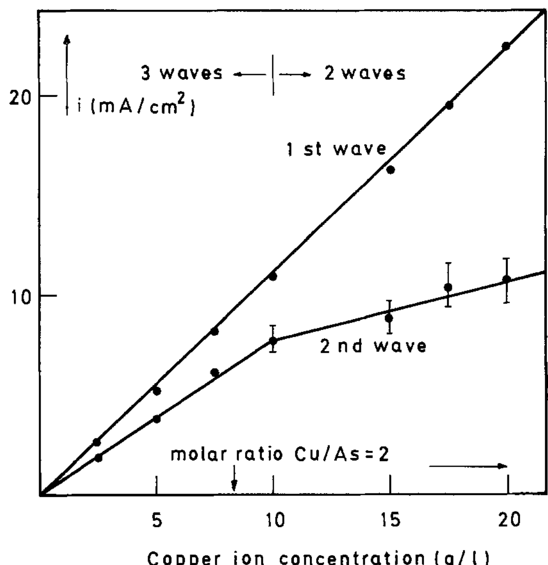

Fig. 6. Height of first and second waves as a function of copper ion concentration for solutions containing 500 g/liter H_2SO_4 and 5 g/liter As(III), copper electrode, 50°C.

becomes almost independent of the copper ion concentration. For solutions with a molar ratio Cu/As < 2.25 three waves are observed and the height of the second wave increases linearly with the copper ion concentration. From the temperature dependence of the height of the different waves shown in Fig. 5, the activation energy was calculated as about 4.5 kcal/mole for all three waves, indicating the diffusional nature of the processes involved.

Similar results were obtained for solutions containing 50 or 200 g/liter H_2SO_4. The products formed on the cathode were subjected to chemical analysis allowing decomposition of the E-i curves as shown in Fig. 7. The results clearly indicate that the second wave is only due to deposition of arsenic, copper being deposited at the limiting current of the first wave. Whereas arsine formation is almost negligible in solutions for which two waves only are observed, this process becomes much more important in solutions with a higher relative arsenic concentration, thus solutions for which three waves are observed. In the latter case the beginning of the third wave coincides with gas evolution at the electrode. Semiquantitative tests have shown that the gas evolved at the electrode at the beginning of

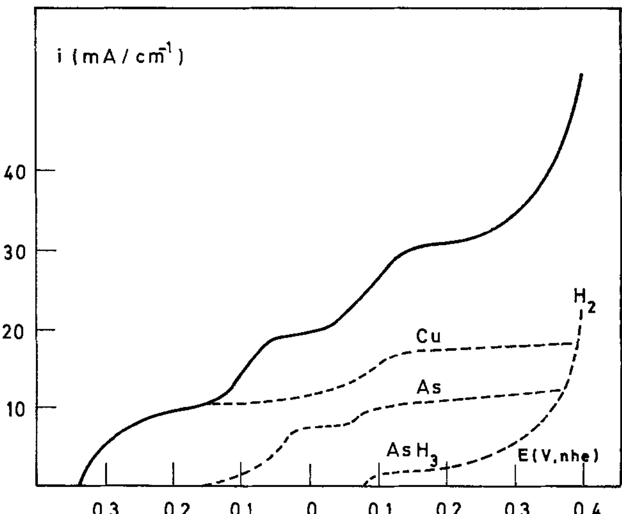

Fig. 7. Decomposition of *E-i* curve into partial curves for solution containing 500 g/liter H_2SO_4, 5 g/liter As(III), 5 g/liter copper ions, 50°C.

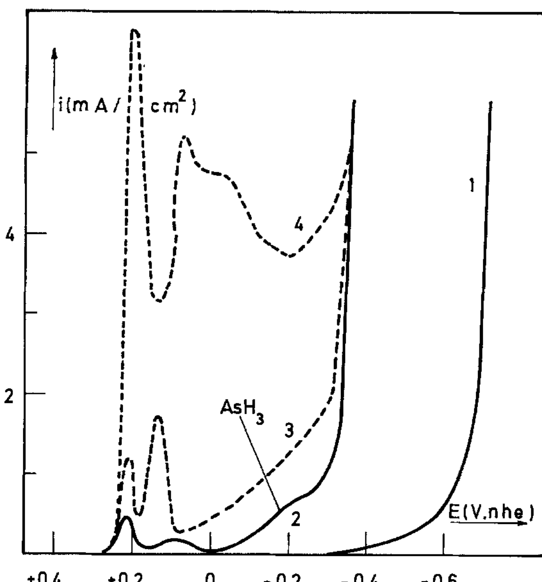

Fig. 8. Potentiostatic *E-i* curve for As(III) reduction on copper arsenide electrodes in absence of copper ions in the electrolyte; 500 g/liter H_2SO_4 5 g/liter As(III), 50°C. Curve 1, platinum; curve 2, $Cu_{5-x}As_2(Cu_{2.4}As)$; curve 3, β-$Cu_{3-x}As$; curve 4, Cu_6As; sweep rate 34.4 mV/min.

the third wave consists mainly of arsine. This was also confirmed by voltametric measurements on arsenic reduction on copper arsenide electrodes prepared by electrolysis shown in Fig. 8. Whereas hydrogen evolution starts at about −0.300V (NHE), the formation of arsine is already observed at much more negative potentials, about −0.100V (NHE). The two reduction peaks at more positive potentials cannot be explained with certainty but are eventually due to the deposition of amorphous elemental arsenic or to the charging of the copper arsenide with arsenic, leading to the formation of a compound with a higher arsenic content.

The results presented thus far naturally lead to the conclusion that the codeposition of copper and arsenic is a case of induced codeposition in the terminology of Brenner (17), *i.e.*, codeposition under such conditions where one of both elements (arsenic) cannot be deposited in the absence of the other (copper). Indeed, in the presence of copper ions, trivalent arsenic is reduced at +0.200V (NHE) with formation of copper arsenides, whereas in the absence of copper ions arsenic can be reduced only to arsine. This must be coupled with the finding that the arsenic richest phase observed in the deposits by x-ray diffraction is Cu_2As. This fact necessitates the concept of a maximum induction, by which is understood, as applied to the present case, that at least two copper ions must be discharged to make deposition of one arsenic atom as copper arsenide possible. In this way it is easily understood that only two waves are observed for solutions containing excess copper ions, *i.e.*, ratios Cu/As > 2. The second wave corresponds to a true diffusion limiting current since all the arsenic arriving at the electrode surface is reduced to copper arsenide and its concentration at the electrode surface is zero, explaining also the formation of trace amounts only of arsine. This is not the case however for solutions containing excess arsenic, *i.e.*, ratios Cu/As < 2, for which three waves are observed. In this case the reduction of arsenic as arsenide is limited by the slow mass transfer of copper ions to the electrode and the concentration of arsenic species at the electrode surface is not zero. The excess therefore can be reduced as arsine. The experimental results clearly indicate that the appearance of the third wave is associated with the presence of excess arsenic in solution. It is well known that gas evolution leads to an increased mass transfer to the electrode (18, 19). Therefore, the evolution of arsine enhances the transport of copper ions and arsenic species to the electrode and this explains the increase of the partial curves for copper and arsenic in the potential range of the third wave. The fact that the transition from two to three waves does not occur exactly at the ratio Cu/As = 2 can be explained by the experimental fact that Cu_2As is never obtained pure but always in mixtures with the phase $Cu_{5-x}As_2$.

The composition of the deposits can be calculated from the partial currents of copper and arsenic. At the limiting current plateau of the second wave, the composition of the deposits can be represented by $Cu_{2.15}As$ as calculated from the left side of Fig. 6 (three waves) while the copper content of the deposits increases to a composition of about Cu_6As at the extreme right side of Fig. 6 (two waves). Of course, if working at current densities below the limiting current of the second wave, the copper content can reach still higher values, as is clear also from the partial curves of Fig. 7, specially if the Cu/As ratio in the bath is high.

With this discussion in mind, the formation of different phases in the deposits as observed by x-ray diffraction can be discussed more easily. In the most general way it can be stated that the formation of different phases is determined mainly by the concentration of copper ions and arsenic species at the electrode surface, *i.e.*, by the bath composition. A survey of the various phases found in the deposits is given in Table I. Although often a mixture of different phases was obtained, all the phases described in Table I could be obtained pure under the proper experimental conditions, with exception of Cu_2As. The phase Cu_2As, recently described by Naud and Priest (1), can be obtained by selective wet oxidation of phases with a higher metal content (1, 2) or by leaching of copper-rich arsenides in concentrated sulfuric acid (20) but could not be obtained either by precipitation methods or by direct synthesis from the elements. It must be noted furthermore that not all the products formed on the electrode could be identified with respect to the ASTM Powder Diffraction Data File (10). At the beginning of the second wave, *i.e.*, at potentials +0.200V (NHE), the deposition of metallic copper is accompanied by the formation of two unidentified phases containing arsenic, one phase (X) being obtained from solutions with relative high copper ion concentrations, the other phase (Y) being obtained from solutions with relative low copper ion concentrations. At slightly more negative potentials, +0.190V (NHE), these products can be obtained without deposition of

Table I. Summary of various phases obtained by codeposition of copper and arsenic from H_2SO_4-$CuSO_4$-As_2O_3 solutions

1. Cu_2As	Arsenic richest phase obtained by codeposition; never obtained pure, always in mixtures with $Cu_{5-x}As_2$; previously obtained by selective wet oxidation (1, 2) or leaching (20) of metal-rich copper arsenides.
2. $Cu_{5-x}As_2$	Composition range $Cu_{2.10}As$-$Cu_{2.45}As$; phase most frequently obtained from solutions with high relative arsenic concentrations (three waves), specially at limiting current of second and third wave; according to Naud and Priest (1), the domain of homogeneity of the orthorhombic (low temperature) form corresponds to $Cu_{2.40 \pm 0.03}As$.
3. β-$Cu_{3-x}As$	Composition range $Cu_{2.59}As$-$Cu_{3.10}As$; domain of homogeneity at 300°C corresponds to $Cu_{2.60}As$-$Cu_{2.85}As$ (1); domain of homogeneity at 25°C estimated as $Cu_{2.60}As$-$Cu_{2.70}As$ but phases with slightly higher copper content than $Cu_{3.0}As$ can be obtained (21); obtained from solutions with excess arsenic (three waves) in potential region before reaching limiting current of second wave and from solutions with excess copper ions (two waves).
4. α-$Cu_{3-x}As$	Frequently obtained in mixtures with $Cu_{5-x}As_2$; occasionally pure in conditions where normally β-$Cu_{3-x}As$ would be expected; normally only prepared by thermal synthesis at high pressures (22).
5. X	Not identified with respect to ASTM Powder Diffraction File; solutions with excess copper ions (two waves); 0.200-0.190V (NHE); see text.
6. Y	Not identified with respect to ASTM Powder Diffraction File; solutions with excess arsenic (three waves); 0.200-0.199V (NHE); see text.
7. Cu_6As	Phase ϵ(Cu_9As-Cu_4As); this phase is not yet very well known, see Naud and Priest (1); composition range $Cu_{6.03}As$-$Cu_{9.10}As$.
8. Phase α	Solid solution containing up to 7 a/o arsenic (23).

metallic copper. Both products are crystalline as is shown by their x-ray spectra but are not really stable, *i.e.*, after removal from the electrode the x-ray pattern is characteristic for a mixture of metallic copper with a little β-$Cu_{3-x}As$. This indicates that both products must be rich in copper as could be expected from the ratio of the partial currents of copper and arsenic at their formation potential although precise determination of the composition of these products has not been possible. Deposition from solutions with high relative arsenic concentrations (three waves) at the limiting current of the second wave and in the entire potential range of the third wave almost always yields formation of the phase $Cu_{5-x}As_2$, eventually in mixtures with some Cu_2As and β-$Cu_{3-x}As$ or α-$Cu_{3-x}As$. This is easily understood since under these conditions the effect of maximum induction is maximal. The domain of homogeneity of the phase $Cu_{5-x}As_2$ (orthorhombic low temperature form) at room temperature was estimated by Naud and Priest (1) as $Cu_{2.40 \pm 0.03}As$. It has not been possible by any means (x-ray diffraction after thermal treatment, washing with organic solvents) to show the presence of elemental arsenic in the deposits. Therefore it seems not unlikely that the domain of homogeneity of the phase $Cu_{5-x}As_2$ can be extended to much higher arsenic contents by electrochemical synthesis, although the presence of amorphous arsenic in the deposits cannot be totally excluded. The phase β-$Cu_{3-x}As$ was obtained by deposition from solutions with high relative arsenic concentrations in the potential range preceding the limiting current of the second wave and also from solutions with high relative copper ion concentrations. The phase α-$Cu_{3-x}As$ which was found frequently in mixtures with other phases, mainly $Cu_{5-x}As_2$, was occasionally obtained pure under such conditions where normally β-$Cu_{3-x}As$ should be expected. It is interesting to note that normally the phase α-$Cu_{3-x}As$ can be obtained only by thermal synthesis at high pressures (22). Deposition from solutions with high relative copper ion concentrations (two waves) always leads to the formation of copper-rich phases such as β-$Cu_{3-x}As$, α-$Cu_{3-x}As$, Cu_6As (phase ϵ; composition range found in this work $Cu_{6.03}As$-$Cu_{9.10}As$) and even the α-phase [solid solution containing up to 7 atom per cent (a/o) arsenic]. With the foregoing discussion in mind, it is obvious that there are no sharp changes in composition at the points corresponding to a compound of specific composition, but rather a gradual transition from one phase to another and, intermediary, the coexistence of several (generally two) phases.

Finally, some comparison can be made between the codeposition of copper and arsenic as described in this paper and some data on the codeposition of copper and antimony reported by Raub (24, 25). The standard electrode potentials of arsenic and antimony

$$HAsO_2\,(aq) + 3H^+ + 3e^- \rightarrow As + 2H_2O \qquad E^\circ = +0.2475V$$

$$As_2O_3 + 6H^+ + 6e^- \rightarrow 2As + 3H_2O \qquad E^\circ = +0.2340V$$

$$SbO^+ + 2H^+ + 3e^- \rightarrow Sb + H_2O \qquad E^\circ = +0.212V$$

$$Sb_2O_3 + 6H^+ + 6e^- \rightarrow 2Sb + 3H_2O \qquad E^\circ = +0.152V$$

are rather close to the standard electrode potential of copper

$$Cu^{++} + 2e^- \rightarrow Cu \qquad E^\circ = +0.337V$$

Raub (24) studied the codeposition of copper and antimony from cyanide baths in which copper is far less noble than antimony, being 0.7 to over 1V more negative. The copper-antimony system is then of the regular type, characteristic for systems where the deposition potentials are far apart, the classic example of the regular type being the copper-bismuth system described in detail by Brenner (26). Raub (24) also studied the codeposition of copper and antimony from ammoniacal baths eventually with addition of Rochelle salt, in which copper is more noble than antimony, the difference of deposition potentials being of the order of 0.5V. Raub (24) found that the copper content of the alloys deposited from such ammoniacal baths showed almost no variation with the metal percentage of copper in the bath although the metal percentage varied by a factor of 2.5. Brenner (25) calls this lack of a trend unique among alloy plating baths. The same lack of a trend is now also observed for the copper-arsenic system. Indeed, taking again the data of the left side of Fig. 6, the composition of the deposit, corresponding to $Cu_{2.15}As$ [68.5 weight per cent (w/o) copper], remains constant if the concentration of copper in the bath is varied fourfold from 2.5 to about 10 g/liter.

Although the data of Fig. 6 are obtained for a constant bath concentration of arsenic, the composition of the deposit remains constant as the ratio copper/arsenic in the bath, $Cu/As < 2$. In this paper, the phenomenon was explained by maximum induction. A comparison of the standard potential of copper and arsenic shows that codeposition should readily occur in acid solutions at the potentials where the formation of copper arsenides was observed. Therefore, the term induction refers to the kinetic impossibility of depositing elemental arsenic rather than to the thermodynamic impossibility. The free energy of formation of the copper arsenides is then not a prime factor governing the composition of the deposits and it is easily understood that the composition of the alloys is determined only by the bath composition for solutions with molar ratios $Cu/As > 2$, *i.e.*, the composition of the alloys is diffusion controlled.

In sharp contrast however with the findings in this paper for the copper-arsenic system, Raub (24) observed that the copper content of the alloys with antimony became independent of the copper percentage in the bath for a composition at the copper-rich side of the phase diagram (about 5 w/o copper; α-phase). The results of Raub (24) can be explained by an induced codeposition of copper and antimony whereby, at least in principle, several reasons can be imagined why only the α-phase is obtained. The most plausible explanation seems to be that only the α-phase has a sufficiently large energy of formation to cause a sufficient shift of the deposition potential of the alloy.

Little information is available on the energy of formation of copper antimonides or arsenides: the heat of formation of Cu_3Sb, 2.5 kcal/mole, is rather low when compared with the heat of formation of Cu_3As, 25.6 kcal/mole (27). No information is available on the energy of formation of the α-phases although the explanation given here seems to be corroborated by the E-i curves given by Raub (25), this point being discussed already by Brenner (25) who supposed the formation of an intermetallic compound. It would certainly be advisable to repeat at least part of Raub's experiments (24) at controlled potential and, as already noted by Brenner (25), the codeposition of copper and antimony probably would be easier from acid solutions.

Acknowledgment

The authors wish to express their sincere thanks to Prof. Dr. R. Breckpot for his advice. One of the authors (J. D.) is indebted to the I.R.S.I.A., Belgium, for the award of a research scholarship.

Fabrication of Beta-Alumina Tubes by Electrophoretic Deposition from Suspensions in Dichloromethane

John H. Kennedy* and Alain Foissy

Department of Chemistry, University of California, Santa Barbara, California 93106

ABSTRACT

Thin-walled tubes of β-alumina (0.03-0.1 cm thick) have been produced by electrophoresis using a suspension of 1μ β-alumina powder in dichloromethane. Trichloroacetic acid was added to facilitate particle charging. The particles were negatively charged and were deposited on graphite rod mandrels. Density of the material after sintering ranged from 2.9 to 3.1 g/cm^3, and conductivities in good agreement with pressed powders were measured. Sodium-sulfur cells were constructed and operated using electrophoretic tubes as the electrolyte.

The phenomenon of electrophoresis has been known since 1809 with the work of F. F. Ruess although it was not until 1879 that H. von Helmoltz (1) introduced the concept of the double layer to explain electrophoretic mobility. Electrophoresis has since become an important tool in biochemistry, physiology, and medicine. Electrophoretic deposition of ceramic powders is of much more recent origin. In 1962, Avgustinik *et al.* (2) and in 1969 Andrews *et al.* (3) reported on the deposition of Al_2O_3 in various media such as ethanol and acetone. In the last few years the use of electrophoresis for obtaining ceramic bodies has increased with the work of Boncoeur and Carpentier (4), and especially noteworthy is the research on β-alumina depositions. Lazennec and Fally (5) patented methods for forming thin-wall tubes of zirconia and β-alumina using nitromethane and acetone/ethanol as solvent media, while Powers (6) reported on β-alumina deposition from various alcohols.

Basically, electrophoretic deposition of a powder suspended in a solvent depends on the powder's ability to become charged either positively or negatively. Three mechanisms for this generation of charge have been proposed: (*i*) an unequal transfer of positive or negative ions from the surface of the solid to the liquid; (*ii*) a preferential adsorption of ions on the solid particles from the liquid medium; and (*iii*) an orientation of dipolar molecules present on the surface of the solid particle. These three mechanisms give rise to an electric double layer at the particle surface and to a potential difference across the phase boundary. Stern (7) proposed a model in which the double layer is divided into two parts; the first part consists of counterions attracted to the charged surface, and these ions are located in the "Stern layer" which has the thickness of about one solvent molecule. The second part is mobile and is called the diffuse layer. The potential difference between the solid surface and the Stern layer is called the "Stern potential" while the potential difference between the Stern layer and the bulk solvent is called the "zeta potential."

When an electric field is applied the solid particles move with their Stern layer, and thus, electrokinetic studies are directly related to the zeta potential. If we assume that the double layer acts as an electric capacitor, the electrophoretic velocity is given by

$$v = \frac{\zeta E \epsilon}{4\pi\eta}$$

where ζ is the zeta potential, E is the potential gradient, ϵ is the dielectric constant of the medium, and η is the viscosity of the medium. The deposition rate is

Key words: beta-alumina, electrophoresis, ionic conductivity, sodium/sulfur cell, solid electrolyte.

basically the product of electrophoretic velocity and concentration of the particles in the suspension.

Although electrophoretic velocity is a primary consideration, other variables play an important role and, for example, Powers reported that depositions of β-alumina could only be obtained from solvents having dielectric constants in the range 12-24 (6).

Experimental

Beta-alumina (Alcoa 325 mesh) was ground for 2 weeks in an aluminum oxide ball mill to achieve particle sizes of about 1μ. Ethylene glycol (10 drops in 400g of β-alumina) was employed as a grinding aid. No α-Al_2O_3 from wear was detected in the final powder by x-ray diffraction. After grinding the powder was kept in an oven at 110°C.

Dichloromethane (MC and B), analytical reagent quality, was used without further purification. All other chemicals were also analytical reagent grade and used without further purification.

Suspensions of pure β-alumina were made by adding 40g (unless otherwise stated) of the ground material to 500 ml of dichloromethane and 1-12g of trichloroacetic acid. The mixture was placed in a ball mill for about 12 hr. Other methods of mixing the materials were tried but no change in deposition rate was noted.

Suspensions of doped β-alumina were prepared by first mixing β-alumina powder with 2 weight per cent (w/o) MgO and 2 w/o Na_2CO_3 in a ball mill for 12 hr. The mixture was heated for 10 hr at 1200°C and then used as above for preparing suspensions.

Figure 1 shows the setup for electrophoretic depositions. A 400 ml beaker served as a container, and a stainless steel screen basket served as the negative electrode. The basket geometry also helped to prevent stream lines. The positive electrode was a graphite (Union Carbide Corporation) rod (0.25 in. diameter) and was rotated at 60 rpm. The suspension itself was stirred continuously with a magnetic stirrer. During the deposition, the voltage was controlled with a variable power supply (100-500V), and the current was monitored. Except for the study of yield with voltage, all depositions were carried out with an applied voltage of 200V. Deposition time varied from 30 to 300 sec. A series of suspensions in which all variables were held fixed gave a deposit weight range of ±2% from the mean.

After electrophoresis the tubes formed on the graphite rods were allowed to air-dry for one day. The green density was not measured because the tubes were still on the graphite mandrel. Qualitatively, the deposits made at high acid concentration appeared more porous than those obtained at low acid concentrations. The rods were then placed in coarse β-alumina powder and heated at 800°C for 3 days to burn out the graphite. The tubes of β-alumina were cleaned with compressed air to remove ashes and were kept at 110°C until sintered. The tubes were 3-4 cm long with an internal diameter of 0.6 cm and a wall thickness of 0.03-0.10 cm.

Sintering of undoped material was carried out at 1700°C for 1.5-2 hr while sintering of doped material was accomplished at 1750°C for 5 hr. It was reported previously (8) that the presence of MgO decreased the rate of sintering. During sintering in an air atmosphere the tubes were completely covered with coarse β-alumina powder to provide a sodium oxide pressure and avoid any loss of sodium content. No α-alumina or sodium aluminate was detected by x-ray diffraction on the sintered materials. The average grain size was about 20μ, and the highest density deposits exhibited some elongated grains about 100-200μ in length.

Sodium analysis was carried out using atomic absorption after ion exchanging the β-alumina with molten silver nitrate as reported previously (8).

Results

Grinding.—Two suspensions were prepared containing 40g β-alumina, 1g trichloroacetic acid, and 500 ml of dichloromethane. One of the suspensions was mixed by grinding in the ball mill for 12 hr and yielded 0.6 g/cm^2-min of β-alumina electrophoretic deposit. The second suspension was mixed merely by stirring and yielded only 0.1 g/cm^2-min. Thus, the grinding/mixing technique gave a suspension which deposited 6 times faster than the same suspension without this procedure. The process aided in generating the necessary charged particles, *i.e.*, established a large zeta potential which increased electrophoretic velocity. It may have also affected the viscosity of the suspension to a small degree.

Voltage.—The role of voltage on the rate of electrophoretic deposition was studied using a suspension containing 40g β-alumina, 4g trichloroacetic acid, and 500 ml of dichloromethane. The yield as a function of applied voltage is shown in Fig. 2. As expected from the equation for electrophoretic velocity, a straight line was obtained. The slope was 1.87×10^{-3} g/cm^2-min-V. These results are consistent with those obtained with MgO (2).

Deposition time.—It was observed that there was a small decrease in current during deposition. However, the rate of deposition was essentially constant (± 3%). Suspensions containing 1g trichloroacetic acid deposited at 0.59 g/cm^2-min while suspensions containing 6g trichloroacetic acid deposited at 0.96 g/cm^2-min

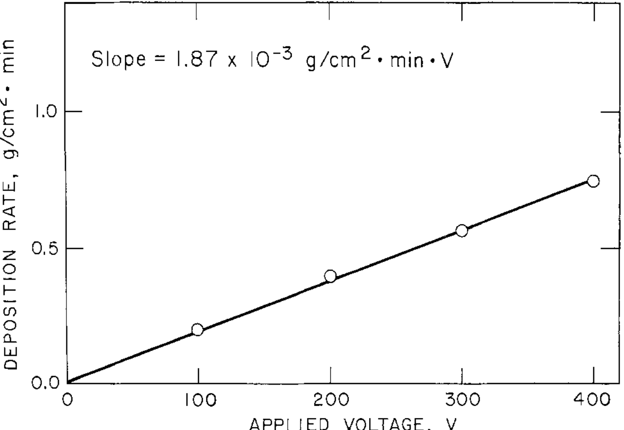

Fig. 2. Electrophoretic yield as a function of voltage. Suspension contained 40g β-alumina, 4g trichloroacetic acid, and 500 ml dichloromethane.

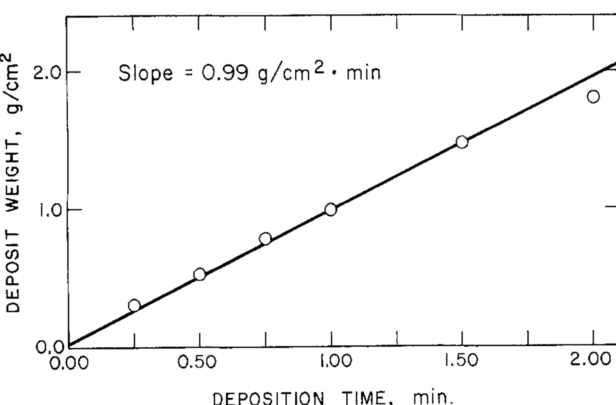

Fig. 3. Electrophoretic yield as a function of time. Suspension contained 40g β-alumina, 6g trichloroacetic acid, and 500 ml dichloromethane, 200V applied voltage.

(Fig. 3). This again is consistent with the results obtained with MgO (2).

Acid concentration.—With suspensions of β-alumina in dichloromethane it was necessary to add an acid, and trichloroacetic acid gave the best results. When no acid was present the suspensions tended to flocculate rapidly and settle. Addition of 1g of acid to this suspension immediately stabilized it. However, with this small amount of acid, deposition was slow (or did not occur at all in some cases). Benzoic acid did not stabilize the suspension nearly as well and deposits could not be made. Large amounts of acid, $>$ 10g trichloroacetic acid, again resulted in little or no deposition. The best deposits were obtained when 2-6g of trichloroacetic acid were added to the suspension (Table I).

Presence of water.—To observe the influence of water on the electrophoretic deposition a suspension containing 40g β-alumina, 6g trichloroacetic acid, 500 ml dichloromethane, and 1 ml water was prepared. The water formed a new phase which disappeared after the grinding/mixing procedure. A deposition using this suspension was flaky and adhered poorly to the graphite. The deposit also had a wet appearance and cracked during drying. Occasionally this type of behavior was observed with supposedly dry suspensions and was attributed to traces of moisture introduced inadvertently.

Density of deposit.—Densities were measured by the hydrostatic method using toluene. Weight/volume measurements, used for pellets, were considered to be inaccurate here because of the uncertainty in measuring the tube thickness. The values ranged from 2.9 to 3.1 g/cm³, but no marked correlation could be found between density variation and deposition or sintering conditions. This density range was the same as that found for sintered pellets which gave high electrical conductivity (8).

Conductivity of deposits.—Silver electrodes were vacuum deposited on the β-alumina tubes which were then placed in the apparatus shown in Fig. 4. Measurements were made in a nitrogen atmosphere to prevent oxidation of the silver electrodes, and measurements were made from 25°-600°C. Arrhenius plots were made as shown in Fig. 5. Tubes sintered for 1.5 hr had activation energies of about 4.9 kcal/mole while those sintered for 2 hr exhibited activation energies of about 4.3 kcal/mole. These values are consistent with those obtained by Kennedy and Sammells for sintered pellets (8). The resistivity of the electrophoretic tubes at 300°C was about 25 ohm-cm which agrees well with other data for polycrystalline material (9). Doped β-alumina did not give appreciably different results which was surprising based on previous studies with pressed pellets and may reflect that additional sodium and magnesium did not deposit with the β-alumina even though they were present in the suspension. Sodium analyses showed no increase over undoped β-alumina suspensions. Additional doping studies will be pursued in the future.

Results are summarized in Table I. It can be seen that high acid concentrations resulted in tubes of low density and very high resistivity. Otherwise no correlation was noted between electrophoresis conditions and the properties of the tubes obtained. The resistivities at 25°C were unusually low for undoped material although the sodium contents were quite high and

could account for the relatively high conductivities found for the electrophoretic tubes.

Sodium-sulfur cells.—Although the primary objective of this project was the fabrication of high density, high conductivity β-alumina tubes, it was only natural to attempt to use the tubes for sodium-sulfur cells. The experimental setup is shown in Fig. 6 and was fabricated from Type 304 stainless steel. After heating to 300°C in a dry box the cathode chamber was filled with a mixture of 2.3g sulfur and 1.5g graphite, and the anode compartment was filled with 1g molten sodium. An open-circuit voltage of 2.12V was observed and was stable for several weeks in the dry box. A load curve is shown in Fig. 7. The apparent internal resistance was 104 ohms which is considerably higher than the 1 ohm resistance of the electrolyte calculated from the a-c conductivity. This added resistance was attributed to the graphite-sulfur mixture and its contact with the β-alumina. This resistance increased with time which supports the hypothesis of contact resistance since tube resistances were stable. In any event the tubes appeared suitable for sodium-sulfur cells, and, in fact, showed no visible damage after 2 weeks use at 300°C.

Discussion

Powers (6) proposed two possible mechanisms for the generation of charged β-alumina particles

$$NaAl_{11}O_{17} + H^+ \rightarrow HNaAl_{11}O_{17}^+ \quad [1]$$

$$NaAl_{11}O_{17} \rightarrow Al_{11}O_{17}^- + Na^+ \quad [2]$$

The first gives rise to positively charged particles which would migrate to the cathode. The presence of acid would be necessary for this mechanism. This effect was observed by Lazennec and Fally (5). The second mechanism requires no acid and yields negatively charged particles which would migrate to the anode. This was the type of behavior reported by Powers.

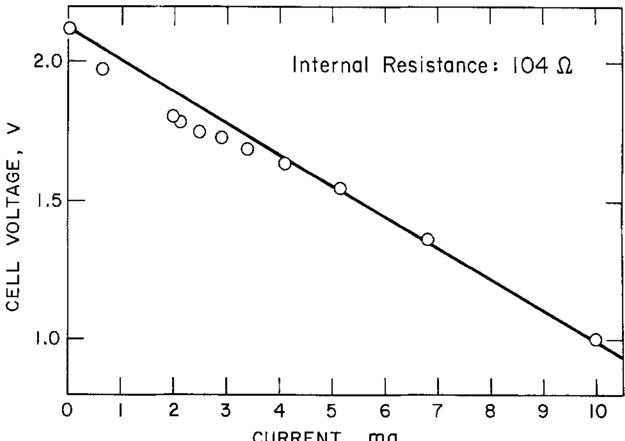

Fig. 7. Load curve for sodium-sulfur cell at 300°C

Our own studies showed that under certain conditions positively or negatively charged particles could be obtained, and indeed in some cases no deposits were obtained. We found that the presence of acid was necessary for electrophoretic depositions, and yet the particles were negatively charged. It should be kept in mind that the solvent used in these studies (dichloromethane) has a dielectric constant of 9 which is at the low end of the range suggested by Powers (6). Our choice was made before Powers' study was available, and was made on the basis of good suspension characteristics, *i.e.*, the suspensions were stable for long periods of time. Thus, charge production in the pure solvent may be marginal and the presence of acid improved charge generation.

It should also be remembered that generation of charged particles is only part of the story. The Stern layer moves with the particle, and thus, it is the zeta potential which is the determining factor. In the usual case, the charge on the particle is partially neutralized, but in special cases complete neutralization or even reversal of charge can occur (10). Thus, it is conceivable that even by mechanism [1] the particle with its Stern layer could be negatively charged if the acid anion is a surfactant in the system. In the case of trichloroacetic acid this probably does not occur, but cannot be overlooked.

Another explanation of our results which appears more plausible is that the charging of β-alumina particles is kinetically slow. This would help explain why long mixing/grinding procedures were necessary. It could also explain the need for acid by proposing a catalytic role for H^+

$$NaAl_{11}O_{17} + H^+ \rightarrow HAl_{11}O_{17} + Na^+ \quad [3a]$$

$$HAl_{11}O_{17} \rightarrow Al_{11}O_{17}^- + H^+ \quad [3b]$$

In this proposed mechanism H^+ ion-exchanges with Na^+, and it is the acid form which dissociates in dichloromethane to give negatively charged particles. The ion-exchange properties of β-alumina are well known (9). A minimum amount of acid would be required to give charged particles, while too high an acid content would allow mechanism [1] to compete and also tend to decrease the zeta potential by adsorption of H^+ in the Stern layer. The presence of proton-form β-alumina on the grain surface could also lead to the high resistivity results reported in Table I for high acid concentrations.

Obviously, one cannot prove or disprove these hypotheses by comparing results obtained by three different research groups all working in different solvent systems. More work needs to be done in this area especially since the product, β-alumina shapes by elec-

trophoretic deposition, has excellent physical and electrochemical properties.

Catalysis in Nickel Electroless Plating

M. Lelental

Research Laboratories, Eastman Kodak Company, Rochester, New York 14650

ABSTRACT

The kinetics of the metal deposition from electroless plating baths has been studied. In addition, transition metal doped nickel electroless plating baths have been formulated which exhibit increased rates of metal deposition. Among all dopants examined, copper proved to be most effective. Addition of 10-20 mole per cent copper to a nickel-dimethylamineborane electroless plating bath leads to a considerable increase in the rate of metal deposition. This increase is due to the deposition of Ni-Cu alloys of a significantly improved catalytic activity in comparison with pure nickel. X-ray photoelectron spectroscopy has been employed to demonstrate the autocatalytic nature of the nickel deposition process. It is proposed that this improvement arises because the presence of copper leads to the promotion of weak chemisorption of hydrogen on the catalytic surface.

Nickel electroless plating baths have found widespread industrial applications. Numerous studies involving the use of additives such as stabilizers, surfactants, and brighteners have been reported (1-3). Feldstein has also studied the effect of complexing agents used in such baths on plating rates (4). In addition, nickel electroless plating solutions incorporating other metal ions which deposit nickel alloys have been formulated (5, 6). Such mixed electroless plating baths have been employed to alter the physical and chemical properties of the metal deposit. The most commonly employed catalyst for the initiation of deposition of metal from electroless plating baths is palladium.

Most of the work dealing with these electroless plating processes has been of an empirical nature dealing with bath formulations and measured electrical and magnetic properties of the metal deposits. The detailed mechanism of the deposition process remains, however, uncertain. It is generally accepted that deposition from these thermodynamically unstable but kinetically stable plating baths is an autocatalytic process. An intriguing question in this respect involves the possible role of the palladium catalyst in advanced stages of the plating process. With the development of modern probes for surface analysis such as Auger and photoelectron spectroscopy it is now possible to determine if palladium diffusion to the surface of the metal deposit occurs in these plating processes.

The present paper describes the use of x-ray photoelectron spectroscopy to elucidate the autocatalytic nature of nickel electroless plating initiated by palladium catalyst. In addition, the kinetics of metal deposition from nickel electroless plating solutions doped with various transition metal ions have been studied. The amount of dopant ranged from the ppm level for the nobel metals up to 50 mole per cent (m/o) for Group VIII on 1B metals. Deposition of nickel alloys characterized by different electronic properties allows the evaluation of electronic effects on the catalytic activity of alloys in such plating processes.

Key words: nickel, electroless, plating, amineboranes.

Experimental

The palladium catalyst used in this work was prepared as thin metal films deposited on microscope slides by the vacuum evaporation technique of Hamilton and Logel (7). The rate of metal deposition was determined using ground-glass microscope slides (18.6 cm^2) with a palladium coverage of 1.4×10^{-6} g/cm^2. Dopants were added to the plating bath as received from the supplier without further purification. Purity of the materials used as dopants ranged from 99.9 to 99.999%. Selection of dopants was based on their known behavior as hydrogenation catalysts, as well as on expected electronic effects due to the formation of nickel-dopant alloys. An appropriate amount of a complexing agent was added with the dopant in order to keep the metal-to-ligand ratio constant. A nickel pyrophosphate electroless plating bath of the following composition has been used for the majority of doping experiments

$NiCl_2 \cdot 6H_2O$	25 g/liter
$Na_4P_2O_7 \cdot 10H_2O$	50 g/liter
Adjust pH to 10.5 with NH_4OH	
Dimethylamineborane	10 g/liter

Compositions of the deposits, as well as amount of deposited metal, were determined using atomic absorption spectroscopy and neutron activation analysis after dissolution of the deposits in aqua regia. The thickness of the Ni deposits were then calculated from these coverage values (milligrams per square centimeter). The distribution of a dopant in the deposits was examined by Auger spectroscopy.

Results and Discussion

Surface examinations of nickel deposits.—In order to be able to interpret the results of the doping experiments, it was necessary to determine the role of the original palladium catalyst in an advanced stage of nickel electroless plating. Particularly, it seemed important to establish the autocatalytic character of the nickel deposition process. Although it is widely accepted that deposited nickel is a catalyst for the continuation of electroless plating, it is possible that palladium diffuses through the nickel layer and thereby participates in a catalytic surface reaction even in an advanced stage of plating. This would require a completely different approach to the doping of the nickel electroless plating baths. Therefore, it was necessary to establish the behavior of the palladium catalyst during the course of nickel electroless plating. For this purpose nickel deposits of different thicknesses (10-250Å) have been prepared using as a catalyst palladium nuclei evaporated on ground-glass substrates. The amount of palladium on the top surfaces of the deposits has been determined using photoelectron spectroscopy (ESCA, Fig. 1).

The disappearance of the Pd-ESCA signal after deposition of a 200Å thick layer of nickel indicates that palladium does not diffuse during the course of nickel electroless plating. It should be emphasized that the sensitivity of the ESCA measurement allows the determination of as little as 3% of the original Pd coverage used in the experiment described. Taking into account that the ESCA half-thickness layer of nickel for Pd-3d electrons is equal to approximately 30Å, one would expect a noticeable Pd signal in the case of a 250Å thick nickel sample if the palladium had diffused through the nickel layer. The distribution of palladium in the thick nickel coatings was also examined using Auger spectroscopy. Results of the Auger examinations fully support previous ESCA observations. Results of surface examinations of nickel deposits clearly indicate that palladium does not diffuse through the nickel layer and prove the autocatalytic character of nickel electroless plating. This implies that the course of the nickel electroless plating depends to a great extent on the catalytic properties of the deposit.

Doping of nickel electroless plating baths.—Dopants used in this work can be divided into two categories.

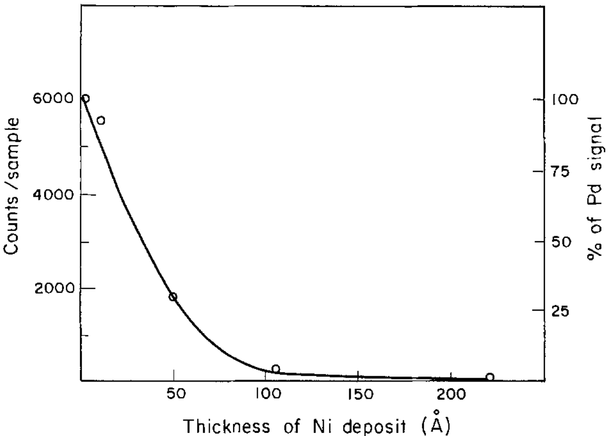

Fig. 1. ESCA examination of Ni deposits prepared by palladium-catalyzed nickel electroless plating.

The first group constitutes the platinum-group metals, as well as the IB-group metals that were added to the nickel electroless plating bath in trace amounts in relation to the concentration of nickel (Table Ia). The second group comprises other metals expected to affect the properties of nickel electroless plating baths that were added in an amount considerably greater than the dopants listed in Table Ia (Table Ib).

Among the dopants listed in Tables Ia and Ib, copper seems to be most interesting. Addition of copper to the nickel electroless plating bath leads to a significant increase in the plating rate. Addition of copper to the nickel also leads to the considerable change of the electronic properties of the deposits and allows one to interpret the behavior of nickel electroless plating baths on the basis of theory of catalysis. Therefore, copper was studied in considerable detail.

Copper-doped nickel electroless plating baths.—The unexpected increase in the activity of nickel electroless plating baths caused by the addition of copper ions is reflected in a considerable increase in the rate of metal deposition. Figure 2 shows the rate effect as a function of composition of the bath, and Fig. 3 gives the rate effect in terms of the alloy composition caused by the baths depicted in Fig. 2.

Figures 2 and 3 indicate that the increase in the activity of nickel electroless plating baths caused by the addition of copper ions is not limited to the one type of bath. Nickel solutions containing different complexing agents, such as organic amines (ethanolamine), carboxylic acids (gluconic acid or citric acid), as well as inorganic complexing agents (sodium pyrophosphate-ammonia), exhibit similar change in activity after the addition of copper ions.

The acceleration factor, defined as the ratio of the rate of deposition of Ni-Cu alloy to the rate of deposition of pure nickel, changes with the copper content in the solution. For room-temperature plating it is a maximum at 15-20 (m/o) of copper in the nickel electroless plating bath. This corresponds to 30-50 m/o

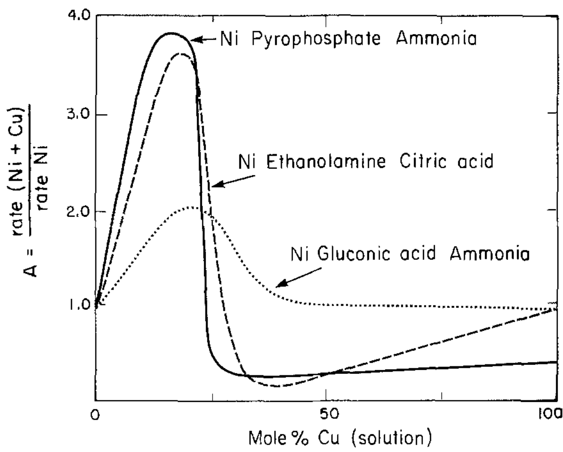

Fig. 2. Activity of Cu-doped Ni electroless plating baths (21°C, 10 min plating).

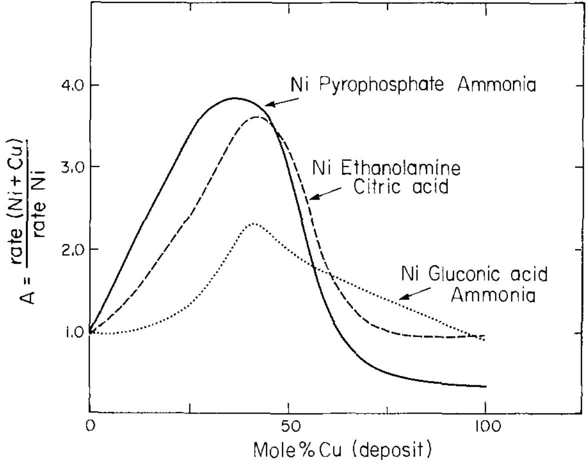

Fig. 3. Activity of Cu-doped Ni electroless plating baths as a function of deposit composition (21°C, 10 min plating).

copper in the deposit. The increase in the rate of plating due to the addition of Cu(II) ions to the nickel bath is more pronounced in the advanced stage of the process (Fig. 4).

These observations seem to indicate strongly that the increased activity of Ni-Cu electroless plating baths is due to the formation of more catalytically active deposits composed of nickel-copper alloys. This can be interpreted on the basis of the Dowden-Reynolds d-band theory for the activity of hydrogenation catalysts (8). This theory takes into account the differences in electronic properties of nickel and nickel-copper alloys. It is widely accepted that molecular or atomic hydrogen, or hydride ion bound to the catalytic surface, is the active intermediate during the course of nickel electroless plating. Feldstein (9) has shown that hydrogen gas formation in alkaline medium is proportional to the rate of metal deposition in such Ni electroless plating solutions. According to Brenner (10) the actual reductant for nickel is hydrogen acting by heterogeneous catalysis at the catalytic surface as follows

$$Ni^{+2} + H_2 \text{ (or 2H)} \xrightarrow[\text{catalyst}]{} Ni^o + 2H^+ \quad [1]$$

Mechanisms suggesting hydride ions as the reducing intermediate have been proposed by Hersch (11) and later modified by Lukes (12) (Eq. [2])

$$Ni^{+2} + 2H^- \text{ (catalyst)} \rightarrow (Ni^o + 2H) \rightarrow Ni^o + H_2 \quad [2]$$

Both these mechanisms imply that the interaction of one or another form of hydrogen with a catalytic surface takes place during the course of nickel electroless plating. This would indicate a certain similarity between catalytic hydrogenation reactions and nickel electroless plating. This analogy allows the interpretation of the catalytic properties of the deposits formed during electroless plating on the basis of the theory of catalysis developed for hydrogenation reactions. The catalytic activity of transition metals has been ascribed to their d-band holes. The technique of alloying transition metals with IB metals to decrease their d-band hole density and hence control their catalytic activity has been utilized by numerous workers (13-20). Thus, the activity of the transition metals for the hydrogenation reaction should diminish with increasing IB metal content, falling to zero with the alloy composition corresponding to the filled d-band. Magnetic susceptibility measurements of Ni-Cu alloys indicate that the number of d-band holes decreases linearly with increasing copper content, falling to zero at approximately 60 atom per cent (a/o) copper (21). However, the correlation between d-band holes and catalytic activity, in some cases, is not satisfactory. Sachtler has partly explained this difficulty by noting that bulk and surface composition, as well as electronic properties, can differ appreciably (14).

The homogeneity of the Ni-Cu deposits formed by electroless plating has been examined using Auger spectroscopy. The sputtering profile of nickel in a ~1.5μ thick (83 m/o Ni; 17 m/o Cu) nickel-copper deposit is shown in Fig. 5. No significant differences in the nickel content as a function of depth have been observed. This would indicate that there is no substantial enrichment of the top surface with copper as has been observed by Sachtler (14) in the case of Ni-Cu films prepared by vacuum deposition.

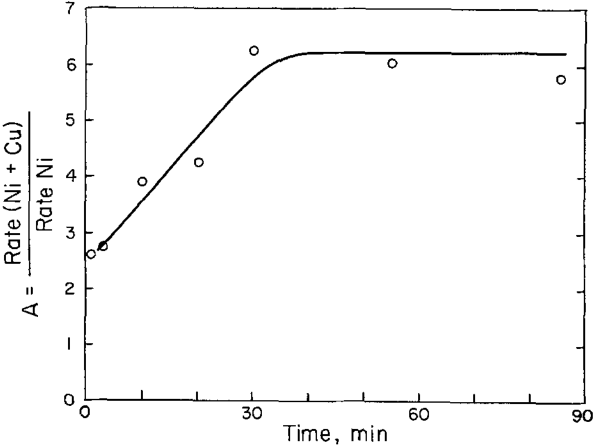

Fig. 4. Effect of Cu dopant on activity of Ni electroless plating bath in different stages of the plating (Ni-Cu-pyrophosphate-ammonia, 21°C, 90 m/o Ni-10 m/o Cu).

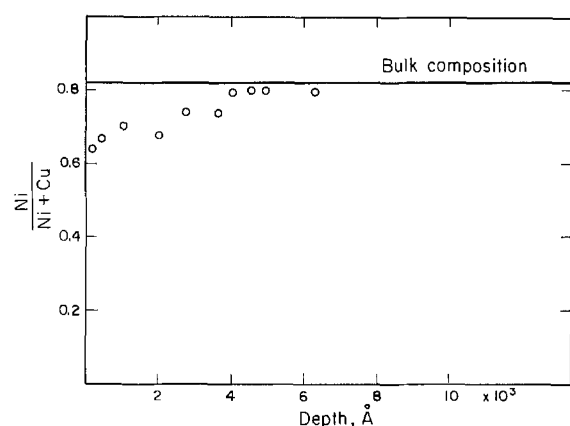

Fig. 5. Sputtering profile of Ni in a Ni-Cu deposit

Boron is often present in electrolessly plated nickel when amine boranes or sodium borohydride is used as the reducing agent (22). Auger examinations of Ni and Ni-Cu coatings revealed no boron. Also, analysis of Ni and Ni-Cu deposits carried out in these Laboratories excluded the possibility of a boron content greater than 1% in these deposits. Therefore, it is not expected that change in the catalytic activity of the deposits is caused by change in boron content. However, Auger spectroscopy demonstrated a carbon content of about 10 m/o throughout the Ni-Cu deposit. This can be interpreted as resulting from occluded dimethylamine. A detailed description of the Auger analyses of such Ni deposits is described elsewhere (23).

Change in the concentration of reducing agent affects the rate of metal deposition to the same degree in Ni, as in Ni-Cu electroless plating baths (Fig. 6).

As is indicated in Fig. 6, the acceleration factor A does not change significantly in the range of DMAB concentrations most commonly used for nickel electroless plating.

Catalytic properties of Ni-Cu alloys.—A number of investigations have been undertaken to elucidate the influence of the electronic structure of alloys, particularly nickel-copper systems, on catalytic activity since the proposal of the d-band theory by Dowden and Reynolds (8). There have been pronounced discrepancies between activity pattern expected on the basis of the d-band theory and experimental results reported for nickel-copper alloy catalysts. The theory states that the catalytic activity of transition metal IB-group metal catalysts should decrease with increased content of IB-group metal. This decrease is expected on the basis of the decrease of d-band holes with the addition of IB-group metal to the transition metal catalyst. However, Russell (24), Emmett (25), and Takeuchi (26) have reported that maximum catalytic activity of nickel and nickel-copper catalysts for hydrogenation reactions is found in some cases in the alloy region and that it is approximately ten times as active as pure nickel. Hall and Emmett (18) reported that for the hydrogenation of ethylene over a series of nickel-copper alloys a large promoting effect of chemisorbed hydrogen on the reaction rate in the copper-rich range was observed. These promoted alloys were more active than pure nickel. Recently Roberti (15) postulated that the increased activity of nickel-copper alloys is caused by weakening of the metal-adsorbate bond. Takeuchi (17) reported that the heat of adsorption of hydrogen on nickel and nickel-copper catalysts changes monotonically with the composition of alloy from 27 kcal/mole for pure nickel to 13 kcal/mole in the case of 75 a/o Cu alloy. This can be interpreted on the basis of the complexity of the hydrogen chemisorption processes. There is definite evidence that more than one type of chemisorption of hydrogen is possible, the difference being mainly in the strength of adsorbant-adsorbent bond. The decrease in the heat of H_2 chemisorption observed by Takeuchi can be explained by taking this fact into account. The chemisorption of hydrogen on the various nickel-copper alloys was investigated in detail by Sinfelt *et al.* (19). The presence of two forms of chemisorbed H_2 (*i.e.*, strongly and weakly chemisorbed hydrogen) was observed by these workers. They reported that with nickel catalyst the amount of weakly adsorbed hydrogen is small compared to the total adsorption. But the fraction of weakly adsorbed hydrogen increases considerably when a small amount of copper is added to the nickel. They concluded that the addition of copper to nickel decreases markedly the average strength of adsorption of hydrogen (*i.e.*, strongly adsorbed hydrogen becomes a much smaller fraction of the total). The composition of the Ni-Cu alloys produces similar effects on the weak chemisorption of hydrogen and the catalytic activity of these alloys in electroless plating processes (Fig. 7). Assuming that hydrogen or hydride ion chemisorbed on the catalytic surface is the active intermediate involved in the reduction of Ni and Cu ions in electroless plating it is likely that the kinetics of metal deposition depends on the strength of the "hydrogen"-catalyst bond. The data presented in Fig. 7 suggest that the increase in the rate of electroless plating observed for Ni-Cu alloys is related to the promotion of weak chemisorption of hydrogen by incorporation of copper in the nickel catalyst. Although the mechanism of the promotion of weak chemisorption by the addition of copper to the nickel catalyst is not fully understood, there is a widespread belief that chemisorption and catalysis are not determined by collective (*i.e.*, bulk) properties of the catalyst, such as the filling of its d-band, but by the chemical properties of its surface atoms. These properties are affected to a great extent by the neighboring atoms. In coordination chemistry, it is well known that metal ligand bond strength is influenced in a very pronounced way by the other ligands in the coordination sphere. This is a second-order effect similar to that which should be expected for chemisorption by metals and metal alloys. Wise's (27) interpretation of the fact that the catalytic properties of transition metals, as well as the weak adsorption of hydrogen, are enhanced by the addition of IB-group metal is based on the hypothesis that catalytic action is related to the promotion of an electron to a localized band. According to Wise, d orbitals of transition metals are split into two groups, *i.e.*, e_g and t_{2g}. For the interpretation of the catalytic properties of Ni-Cu alloys, it is relevant that the narrow Ni e_g band with its high density of states will be more readily filled than the relatively broad t_{2g} band by the introduction of s electrons from

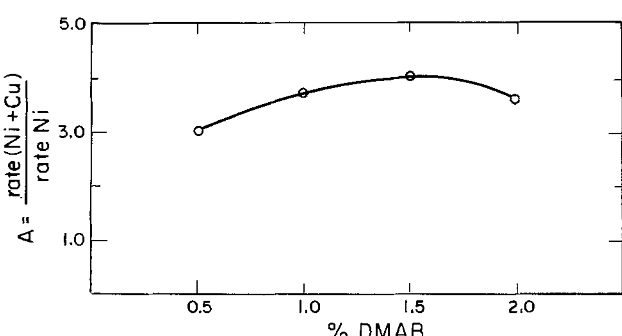

Fig. 6. Activity of Cu-doped Ni electroless plating bath as a function of DMAB concentration (Ni-Cu-pyrophosphate-ammonia, 21°C, 90 m/o Ni-10 m/o Cu).

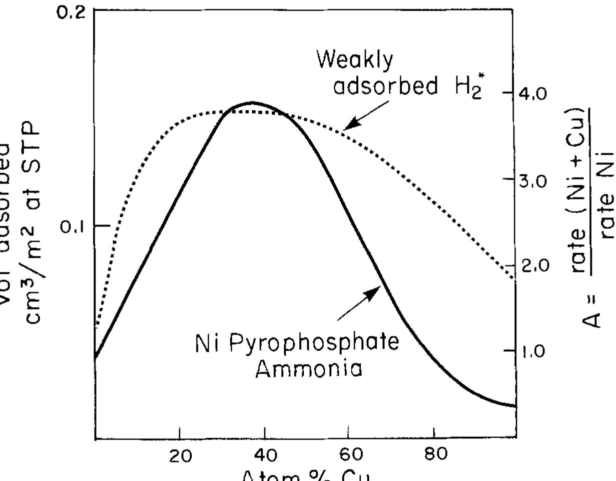

Fig. 7. The effect of composition of Ni-Cu alloys on weak chemisorption of hydrogen and catalytic activity of these alloys in electroless plating. *Sinfelt *et al.* (19).

copper. The selective filling of one of these subbands at a certain alloy composition may be responsible for the observed change in the relative amounts of strongly and weakly chemisorbed intermediates, as well as for the maximum catalytic activity observed at a fixed alloy composition. This would strongly imply the existence of a bond for adsorbed intermediates that energetically is most favorable for catalytic reaction.

Conclusions

The observed increase in the activity of nickel electroless plating baths resulting from the addition of copper ions manifested by an increased rate of metal deposition should be interpreted on the basis of the generally accepted mechanism of nickel electroless plating. The increased activity of Ni-Cu electroless plating baths is due to the increased catalytic activity of the deposited Ni-Cu alloys. It is proposed that this increased catalytic activity is related to the promotion of weak chemisorption of hydrogen due to the addition of copper to the nickel deposit. The role of hydrogen intermediates in the nickel electroless plating process, as well as chemisorption of hydrogen on Ni and Ni-Cu surfaces, has been discussed. There seems to be a correlation between the increased activity of these baths and the promotion of weak chemisorption of hydrogen by the deposited Ni-Cu alloys. This seems to imply that the rate of Ni and Ni-Cu electroless plating is a function of the strength of the binding in the weak state of adsorption state.

Acknowledgments

I wish to thank Dr. R. C. Baetzold and Messrs. J. E. Moore and R. E. Mack for ESCA and Auger spectroscopic examinations of Ni and Ni-Cu deposits.

The Electrophoretic Forming of Beta-Alumina Ceramic

R. W. Powers*

General Electric Company, Research and Development Center, Schenectady, New York 12301

ABSTRACT

The forming or shaping of beta-alumina ceramic is usually difficult with conventional ceramic processing. In this paper, electrophoretic deposition is shown to be an operationally simple, rapid, and reliable technique for forming a wide range of beta-alumina shapes required in electrochemical devices. The following topics are discussed in detail: the basis for selection of a suitable vehicle for holding beta-alumina particles in suspension, the control of electric charge on the particles, the milling of starting powder to provide a small particle size with minimum contamination by wear of the grinding media, the deposition procedure, and the removal of electrophoretic deposits from forming mandrels. Finally, some properties are given for sintered ware formed by electrophoretic deposition.

The high ionic conductivity of beta-alumina and the use of this material as electrolyte in sodium-sulfur cells were made known about 7 years ago (1). The conductivity arises from the rapid migration of monovalent cations, *e.g.*, sodium, in loosely packed planes of oxygen atoms (2). These conducting planes are sandwiched at approximately 11Å intervals between spinel blocks consisting of four closely packed layers of oxygen atoms with aluminum in interstitial positions. In contrast to the large conductivity in the conducting planes, that perpendicular to these planes is very low. The mechanical properties of beta-alumina are likewise very anisotropic. Cleavage occurs readily

Key words: beta-alumina, ceramic processing, electrophoretic deposition, electrophoretic forming.

parallel to the conducting planes but not across such planes. Consequently, to obtain strong isotropic material for use in electrochemical devices, fine-grained polycrystalline ceramic is required. The forming or shaping of polycrystalline beta-alumina ware is difficult with most conventional ceramic processing techniques. This paper is mainly concerned with the use of electrophoretic deposition for this purpose. The background considerations to an operationally simple, reliable, versatile procedure are described in some detail.

Fabrication of ceramic ware usually follows a three-step procedure. The first involves preparation of powder of the composition required in the end product or one which transforms to such a composition during subsequent processing. The second step involves shaping or forming of the powder into a shape similar to that required in the end product. Finally, this "green" ware is heated to high temperatures. In this sintering step, the material shrinks, porosity is greatly reduced, and mechanical strength along with other required properties is developed. Although the main concern of this paper is with the second of these steps, that of forming, certain aspects of powder preparation and of sintering are discussed, particularly as they pertain to electrophoretic forming.

Although the phenomenon of electrophoresis—the motion of electrically charged particles in an electric field—has been known for over 160 years, its use in the forming of ceramic ware is a development of the past few years. Some highlights in the history of this development, which really constitute the basis of our present capability, are indicated in Table I.

An important advantage of electrophoretic deposition for ceramic forming is that of high throwing power. Another is the short deposition times required. Most of the ware discussed in this paper were deposited in about 1 min. A third important advantage of electrophoretic forming is its versatility. A wide variety of shapes are possible. "Tooling" is relatively simple. Only the mandrels on which the deposit is laid down require precision machining.

Two important properties of beta-alumina that relate to processing were described above: the anisotropy of the electrical conductivity and of the mechanical strength. Among its other properties that especially need to be taken into account for electrophoretic forming is its limited stoichiometric range. Sodium beta-alumina always contains sodium oxide in excess of that corresponding to the composition of the ideal structure, $Na_2O \cdot 11Al_2O_3$. It is really not a compound in the strict chemical sense, but rather a phase of rather narrow compositional range. According to Roth and Mitoff, the single-phase field at 1725°C extends from $1.2\ Na_2O \cdot 11Al_2O_3$ to $1.4\ Na_2O \cdot 11Al_2O_3$ (8). Its hard and abrasive nature creates problems in reduction to sufficiently small particle size without undue contamination from abrasion of the grinding media. The thermal shock resistance is high. Beta-alumina powders absorb considerable quantities of water. Concentrations in excess of 3 weight per cent (w/o) have been found by the author in powders as received from the supplier.

Experimental Procedures

The forming operation in the fabrication of beta-alumina ware by electrophoretic deposition can be subdivided into three separate steps: (*i*) reduction of the particle size of the starting powder and charging of the individual particles in suspension in a suitable organic liquid; (*ii*) deposition of the beta-alumina particles onto a mandrel; and (*iii*) removal of the deposit from the mandrel. Problems are associated with each of these steps. They are discussed here after the experimental procedures used in this work have been described.

Starting powders.—Most work has been carried out with two commercially available beta-aluminas: Monofrax H beta-alumina from the Carborundum Company and XB-2 beta-alumina powder from Aluminum Company of America. The nominal compositions of these materials are given in Table II. Monofrax H beta-alumina, a fused product, is generally available in the form of bricks. These were jaw crushed, ball milled dry with alpha-alumina balls, and then screened to provide powder in the range of 44-105μ. Alcoa XB-2 beta-alumina, a calcined product, was obtained in the form of a fine powder. Additives, of the order of 1 w/o, were often added to the as-received material. These included, for example, additional soda by way of anhydrous sodium carbonate as well as magnesia from basic magnesium carbonate. Furthermore powders with soda contents corresponding to those in β''-alumina have also been deposited satisfactorily. Appropriate quantities of the additives in powder form were mixed thoroughly with the beta-alumina powder by tumble mixing for 24-48 hr. The resulting mixture of powders was calcined in an oxygen atmosphere for 24 hr at 1400°C. Such calcined material served as the starting powder for the deposition work.

Suspension preparation.—In this work, reduction in size of the starting powder and electrical charging of the particles were carried out simultaneously by milling under the vehicle, *i.e.*, the organic liquid in which the beta-alumina particles are suspended during deposition. Three different kinds of milling (ball, vibratory, and jet) were examined in the course of this work. While the greatest effort was given to ball milling, some very satisfactory results have also been obtained with vibratory milling. Particle size reduction by jet milling, before dispersion in the vehicle, was not satisfactory.

n.i. means not indicated in manufacturer's literature.

Both ball and vibratory milling have been carried out in 32 oz wide-mouth polyethylene bottles as received from the supplier without use of special cleaning procedures. Their use as mill jars reduces contamination since any abraded material is burned out during sintering. These containers were half-filled with grinding media, either 1100g of alumina media or 1800g of zirconia. When suspensions were ball milled, the volume of the vehicle was 200 ml. However, for some experiments with vibratory milling, the vehicle volume was increased to 300 or 400 ml. The amount of starting powder in the charge ranged from 35 to 300g.

Ball milling was done on a Model 764 AV Norton jar mill, while vibratory milling was carried out with a Sweco Model M18L55 mill.

Deposition.—Deposition in electrophoretic forming is carried out by applying a d-c voltage between the mandrel and a counterelectrode, both immersed in the beta-alumina suspension. Following the initial stages of this work, the containers for the suspension were made to serve also as counterelectrodes. They are usually made of an 18-8 stainless steel.

Photographs of several mandrels with their corresponding suspension containers appear in Fig. 1 and 2. In Fig. 1, a mandrel for forming open-end tubes up to 8 in. long is shown in the foreground. Mandrels for forming cylindrically shaped objects must be tapered slightly to facilitate removal of the deposit after drying. The other mandrel shown is for forming closed-end tubes up to 4.5 in. long. Mandrels for forming 3 cm disks and a pocket-shaped article are shown in Fig. 2. The Teflon polymer ring shown with the disk mandrel is used to shape the electric field. Its use permits a deposit of uniform thickness over the face of the disk. Only relatively scratch-resistant materials have been used for mandrel construction. Nickel, 18-8 stainless steel, and 36-Invar have all proved satisfactory. Mandrels are usually buffed to obtain smooth surfaces.

Considerable attention must be given to the materials allowed to contact the suspension in order that the charge on the beta-alumina particles not be adversely affected. Difficulties were encountered with paper masking tape as well as silicone rubber. Also polymethylmethacrylate containers were found to affect adversely the charge on the particles. Borosilicate glass containers are innocuous, however.

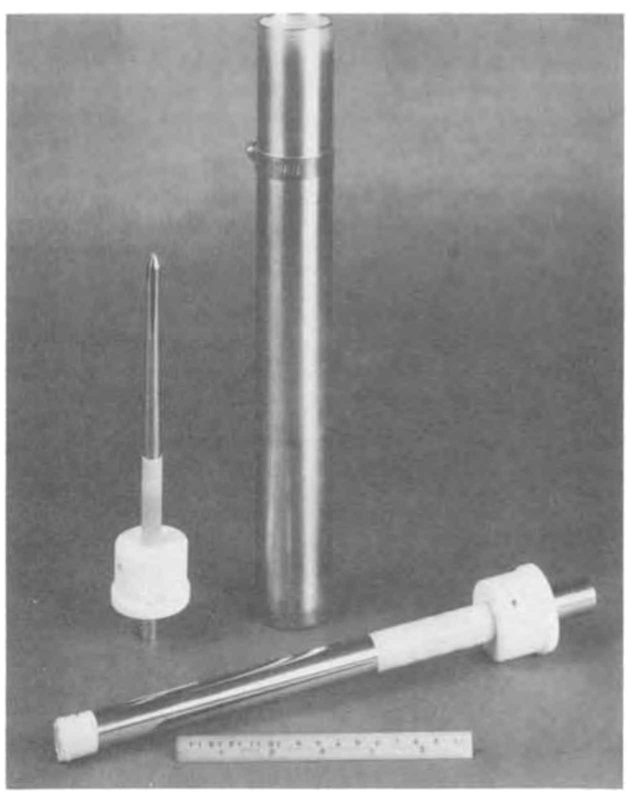

Fig. 1. Mandrels and suspension container for forming tubes

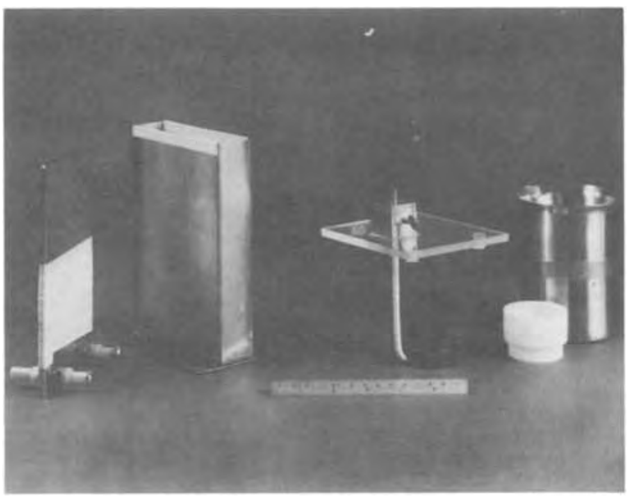

Fig. 2. Apparatus for forming disks and pocket-shaped pieces

A d-c high-voltage supply has been used to apply voltages in the range 200-1000V between the mandrel and counterelectrode. Such voltages correspond to fields at the electrode surface between 280 and 1400 V/cm for the tube mandrels as shown on Fig. 1. At present, it is the practice to use the highest fields permitted by the power supply. This procedure usually reduces deposition times to about 1 min and makes stirring of the suspension unnecessary during deposition. However, were the deposition extended over several minutes, stirring would be needed to avoid excessive settling of the beta-alumina particles in suspension. Suspensions are vigorously stirred with a magnetic stirring bar before a deposition.

The very simple electrical circuit used for electrophoretic forming is shown in Fig. 3. In essence, the series combination of deposition cell, current meter, current recorder, and charge integrator is placed across the d-c power supply. A high impedance voltmeter indicates the cell voltage. As a safety precaution, the suspension container which surrounds the forming

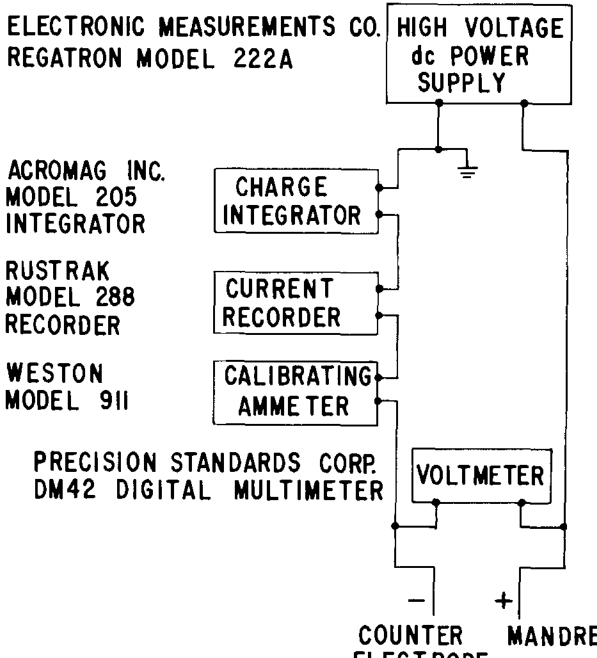

Fig. 3. Circuit diagram for electrophoretic deposition

mandrel is maintained at or very near ground potential.

Sintering.—Sintering of green beta-alumina ware has been carried out on alpha-alumina saggers in molybdenum-wound furnaces. The saggers are heated inside a dense alpha-alumina tube filled with either an oxygen or an air atmosphere. This protects the ware from the hydrogen atmosphere which needs to envelop the furnace muffle to prevent oxidation of the molybdenum winding. Sintering has been done between 1700° and 1825°C.

Problem Areas in Electrophoretic Forming

The first operation in electrophoretic forming, the preparation of a suitable suspension, is critical since it involves three problem areas all of which require considerable attention. They include selection of a suitable organic liquid in which the beta-alumina particles can be suspended during deposition, control of electric charge on the particles, and the techniques by which milling of the particles is carried out. In contrast, the second operation, the deposition process itself, is more straightforward. Likewise, the final operation, the removal of the deposit from the forming mandrel, also involves relatively simple considerations.

Selection of a suitable vehicle for dispersion of beta-alumina particles.—The electrical conductivity of a number of suspensions is shown in Fig. 4 as a function of the dielectric constant of the vehicle with which the suspension was prepared. In each case, the suspension contained 35g of fused beta-alumina powder suspended in 200 ml of the vehicle. The suspensions had been ball milled for 16 hr with alpha-alumina grinding media. The conductivities were measured in a concentric cylinder arrangement and were computed from the dimensions of the deposition cell, the voltage drop, and the initial current before any appreciable quantity of deposit covered the forming electrode.

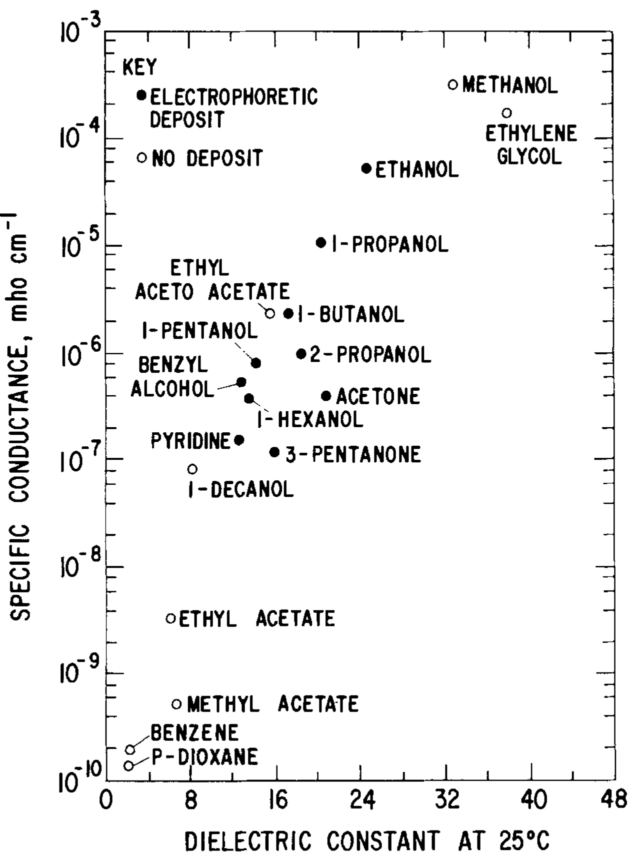

Fig. 4. The electrical conductivity of suspensions vs. the dielectric constant of their vehicles.

Two features on Fig. 4 are noteworthy. The first is that, in general, the conductivity increases rather sharply with the dielectric constant of the vehicle, approximately seven orders of magnitude rise for a change in the dielectric constant from 2 to 40. The second and perhaps more surprising feature is that electrophoretic deposits were obtained only from vehicles with dielectric constants in the range from about 12 to 25 as indicated by the filled circles on the figure.

As discussed in the following section, the predominant charging mode for the beta-alumina particles is assumed to be dissociation of sodium cations. The absence of deposition from vehicles such as benzene or p-dioxane is consistent with this interpretation as their low dissociating power would not likely give rise to effective particle charging. On the other hand. mainly practical considerations limit use of vehicles of high dielectric constant. Their high conductivity is further enhanced by ohmic heating during the passage of current. Deposits formed from vehicles with dielectric constants slightly below 25 (for example, from ethanol) tended to be very fluid and to slide off the mandrels. In some instances, this situation made determination of the existence of a deposit very difficult although usually this behavior was accompanied by a sudden large increase in current for constant applied cell potential. Anodic film formation on mandrels was also noted with vehicles of high dielectric constant.

The importance of the dielectric constant in the selection of a vehicle was confirmed by the observation of beta-alumina deposits from an equal volume mixture of methanol and p-dioxane although deposition did not occur from these liquids separately. In other experiments, deposition was obtained from a technical grade methyl acetate, containing approximately 15% methanol but not from the reagent grade ester.

Following initial experiments with a large number of vehicles and mixtures of vehicles, nearly all subsequent work was carried out with n-amyl alcohol (pentanol-1). Its dielectric constant, ϵ, is 13.9. With it, neither the formation of anodic films on the mandrels nor that of fluid deposits is observed. Since reagent grade material is sold by a number of manufacturers, a reproducible vehicle is readily available. Finally, n-amyl alcohol is relatively nontoxic. It has been used as an industrial solvent for many years (9).

Control of electric charge on beta-alumina particles.—As indicated on Fig. 4, no electrophoretic deposits were obtained with ethyl acetoacetate ($\epsilon = 15.4$). Nor were any found with ethylene diamine ($\epsilon = 14.2$) nor with water/p-dioxane mixtures with compositions corresponding to dielectric constants in the range 12 to 25. With pyridine ($\epsilon = 16.3$), a deposit was obtained with the mandrel negative whereas with all the other vehicles used in the survey experiments, results from which are shown in Fig. 4, deposits appeared on the positive electrode. Clearly, then, there are some complications in controlling the surface charge on beta-alumina particles.

Charging modes for beta-alumina.—The results of many experiments are consistent with the hypothesis that there are two very different charging modes for beta-alumina. One, as mentioned above, is the dissociation of sodium ions to give rise to a negatively charged particle. Thus,

$$(\beta\text{-alumina}) \rightarrow (\beta\text{-alumina})^- + Na^+ \quad \text{dissociation mode}$$

However, another mode is the adsorption of protons or conceivably other cations which lead to positively charged particles. Thus,

$$(\beta\text{-alumina}) + HA \rightarrow (\beta\text{-alumina H})^+ + A^- \quad \text{adsorption mode}$$

Proton donors might be water or organic acids such as benzoic or stearic acid.

The two charging modes are competitive. For nearly all the work discussed in this paper, dissociation was used as the predominant mode. However, the negative charge on the beta-alumina particles prepared from a fused block can be neutralized by the addition of a few tenths of a per cent water to the n-amyl alcohol vehicle, as made evident by the absence of a deposit. And, usually with ½% water in the vehicle, the particles are positively charged. The absence of a deposit with ethyl acetoacetate and ethylene diamine and a deposit on the negative electrode with pyridine likely resulted from the presence of small amounts of water in these vehicles. The addition of about 1% benzoic or stearic acid (based on beta-alumina) will also give rise to positively charged particles. The Marcoussis group of Compagnie Generale d'Electricité have, in fact, used proton adsorption as the predominant charging mode in their electrophoretic deposition work with both zirconia and beta-alumina (7). The activator used was benzoic acid. Likewise, very recently Kennedy and Foissy have used trichloracetic acid in a methylene chloride vehicle to obtain beta-alumina particles with a positive charge (10). The existence of competing charging modes for electrophoretic particles is not unique to beta-alumina. Very similar phenomena are found with certain micas. For example, pyrophyllite particles can be charged negatively by dissociation of potassium ions as well as by adsorption (11).

Effects of water.—In addition to charge neutralization and charge inversion described above, there are actually a number of other effects of water on the behavior of beta-alumina/n-amyl alcohol suspensions. With suspensions which are "excessively dry" as defined more precisely below, very smooth, uniform deposits can be obtained which, however, undergo creep for several minutes after removal from the suspensions. In extreme cases, 50-90% of the deposit may flow off the mandrels. Fortunately, there is a level of water content, not difficult to reproduce experimentally, over which very satisfactory, smooth, uniform deposits can be obtained. Charge neutralization and inversion are obtained with larger additions, at concentrations of about 0.2 and 0.5%, respectively, using fused beta-alumina powder. With still larger amounts of water, *e.g.*, 5%, charge neutralization occurs a second time as deposits are not obtained. Where there is but a small amount of deposition, near the neutralization point, the suspensions appear flocculated. Deposits are weak. The suspensions settle more rapidly and give rise to a sediment about twice as voluminous as from suspensions yielding good deposits. Most of these phenomena can be understood qualitatively in terms of a theory of electrophoretic deposition proposed by Hamaker and Verwey (5). A very clear review of this theory has been given by Troelstra (12).

Suspensions of beta-alumina appear ideally suited for illustrating the stability aspects of suspensions. Since two opposing charging mechanisms are known, wide variations in the repulsive force between particles are possible. For example, negatively charged particles with very strongly repulsive interactions are available through the use of nearly water-free n-amyl alcohol suspensions. Such suspensions give rise to deposits that undergo viscous flow off the mandrels as decribed above. Neutral suspensions or those of particles with weakly repulsive interactions carrying either positive or negative charge can be obtained by addition of appropriate quantities of water. These latter are examples of flocculating suspensions. Vehicles other than n-amyl alcohol can also be used. It would appear that a beta-alumina suspension of intermediate stability, *i.e.*, one stable at larger interparticle separation distances, are most desirable for electrophoretic deposition.

Practical control of water content.—The treatment to be given a beta-alumina powder to control the water concentration depends strongly on its porosity. That of low porosity, such as obtained by crushing and grinding fused beta-alumina bricks, does not require further drying if stored in dry, tightly capped polyethylene containers. In fact, if such powder is dried overnight in a vacuum oven at 220°C, deposits are obtained which undergo viscous flow. On the other hand, calcined beta-alumina powder is a much more porous material. Drying in air at temperatures somewhat in excess of 600°C is required to remove sufficient water so that a satisfactory negative charge is developed on the particles. Normally, drying is accomplished simultaneously with the 1400°C calcination operation described above. Weight losses of 3.0-3.5% in excess of those attributable to additive decomposition are measured with this powder on calcination. These losses arise mostly from water contained in the as-received powder. Such dried calcined powders are stored in tightly capped polyethylene bottles and redried in a vacuum oven at 200°C overnight immediately before use. Also, in order to achieve reproducible deposits, considerable care need be exercised to use clean, dry, grinding media. Most lack of reproducibility in early work was traced subsequently to insufficient attention to this point. The n-amyl alcohol is used as received without further drying.

Milling problem.—The milling or grinding of beta-alumina/n-amyl alcohol suspensions is carried out for two very different purposes: to develop a suitable charge on the particle surfaces, and secondly, to facilitate production of dense ware during sintering. Beta-alumina powders are charged positively when first placed in n-amyl alcohol, presumably as a result of water adsorption from the atmosphere. During milling, this charge is first neutralized, and subsequently, a negative charge develops after 2-8 hr, depending on the powder, grinding media, and the method of milling. A limitation of the dissociative charging mode is that beta-alumina particles must not be removed from the suspension before deposition, after milling to small particle size. Otherwise, a positive charge is acquired which then is most difficult to neutralize by further milling. Consequently, whatever contamination is introduced into the suspension from media wear will likely be incorporated in the electrophoretic deposit.

The gist of the milling problem is the need to develop techniques to produce an adequately small particle size in an exceedingly hard and abrasive substance without incurring appreciable wear of the grinding media. There can be various deleterious effects from such wear. For example, silica, often present in alpha-alumina grinding media to improve the wear resistance, will increase the electrical resistivity of beta-alumina (13). Moreover, the addition of alpha-alumina itself to the beta-alumina by grinding media wear effectively decreases the sodium oxide concentration. If such contamination is sufficient to lead to a second phase on sintering, the ware will often crack during cooling to room temperature.

A more rational approach to the milling problem can be made from an understanding of the factors affecting the rate of grinding and the rate of media wear. Both were found to depend strongly on the nature of the powder undergoing grinding, the type of grinding, and the grinding media. The grinding rate is also markedly dependent on the size of the particles undergoing milling while the wear rate is also a sensitive function of the concentration of beta-alumina particles in suspension.

The fact that the milling rate of beta-alumina powder depends greatly on the method of preparation of that powder is illustrated with scanning electron micrographs shown in Fig. 5. Inspection indicates that calcined beta-alumina powder can be reduced to a smaller size in 4 hr of ballmilling than fused beta-alumina powder in 5 hr.

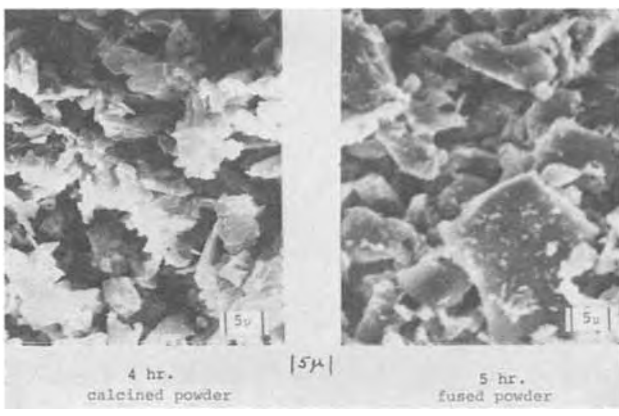

Fig. 5. Scanning electron micrographs of different powders, ballmilled with 91% Al_2O_3.

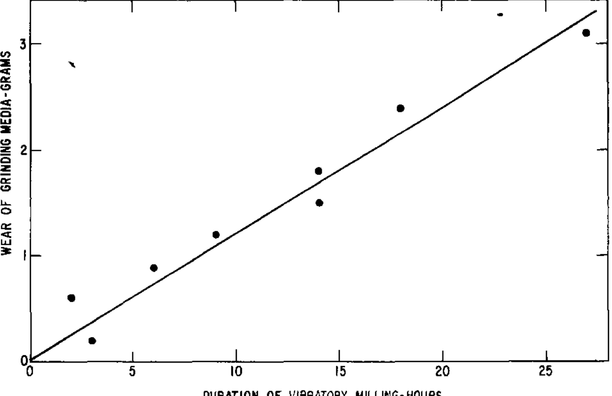

Fig. 6. Wear of 1800g 0.5 in. zirconia cylinders in vibratory milling 150g modified calcined powder suspended in 300 ml n-amyl alcohol.

The micrographs of Fig. 5 also illustrate the fact that ballmilling to about 10μ size can be accomplished in only a few hours. However, more protracted milling times are required to reduce the size to only a few microns. This fact is true for vibratory milling as well as for other media such as zirconia. On the other hand, the wear of the grinding media is nearly proportional to the milling time for both ball and vibratory milling. This is shown for vibratory milling with zirconia media in Fig. 6.

A comparison of micrographs also indicates the more rapid grinding achieved by vibratory milling. This fact is confirmed by data on the degree of sintering attained on ceramic that had been milled under different conditions as indicated in Table III. The density of completely sintered beta-alumina lies between 3.25 and 3.26 g/cm^3. All the specimens, on which data are given in this table, were deposited electrophoretically in the form of closed-end tubes and subsequently sintered at 1800°C. Data are given for several specimens from suspensions similarly prepared in order to indicate the degree of reproducibility in the density and wear measurements. Examples are 5H3-5 and 5K1-2; 5G2-1 and 5H2-2; 5F3-3 and 5L1-1. Wear of the grinding media is expressed in Table III as a fraction of the amount of beta-alumina present in suspension.

An important point with regard to particle size is also brought out by data in this table. Specimens 5F3-3, 5F3-4, and 5F3-5 were the third, fourth, and fifth tubes deposited respectively from suspension 5F3. Neither in this series, nor in others, have systematic trends in sintered density been observed with the order in which tubes were deposited from a suspension. A trend should be observed if there was any substantial preferential deposition by particle size, as reported previously for alpha-alumina (6). Such a preferential deposition might also be indicated by differences in microstructure between the inner and outer walls of electrophoretically deposited, sintered tubes. This has never been observed.

Data in Table III also demonstrate the more rapid milling and lower wear rate of zirconia compared to alpha-alumina media. This fact is also brought out in Table IV in which wear data are collated for a number of different alpha-alumina media as well as for zirconia. Also shown is the need for some silica in alpha-alumina grinding media in order to keep wear at tolerable levels. Alumina balls containing 91% alumina were selected over other alumina media as the best compromise between wear rates and risk of contamination by silica.

Wear rates, unlike milling rates, depend rather strongly on the concentration of the suspensions as indicated on Fig. 7. The reduced rates with more concentrated beta-alumina suspensions should be noted. The advantages to milling more concentrated suspensions are really twofold. Not only is the absolute amount of wear product reduced, but in addition, it is diluted with a larger amount of beta-alumina. The

Table III. Optimum density of sintered beta-alumina for various milling conditions

Table IV. Wear data for various grinding media

Data set A Wear of 1100g of media in ballgrinding 35g of fused powder in 200 ml n-amyl alcohol for 16 hr		
99.5%	alpha-alumina balls ⅜ in. diam., supplier A	43g
99.5%	alpha-alumina balls 1 cm diam., supplier B	18g
91%	alpha-alumina balls (6% SiO_2) ½ in. diam.	10g
85%	alpha-alumina cylinders ½ in. × ½ in. (11% SiO_2)	9g
Data set B Wear in ballgrinding 100g calcined powder in 200 ml n-amyl alcohol for 16 hr		
91%	alpha-alumina balls (1100g)	2.9g
ZrO_2	Cylinders ½ in. × ½ in. (1800g)	0.9g

highest concentration milled was 200g of beta-alumina per 200 ml n-amyl alcohol. A "suspension" of this concentration behaves as a wetted solid prior to milling although it becomes fluid after several minutes of milling. It must be diluted to about 100g/200 ml after milling to avoid problems with viscous flow following electrophoretic deposition.

In the course of studying the effect of additives on wear of grinding media, aluminum tristearate was found to improve the smoothness of electrophoretic deposits. The effect is illustrated in the photograph shown in Fig. 8. The center tube was deposited from a suspension without aluminum stearate. Admittedly, the difference is more pronounced for deposits derived from fused powder than from calcined powder. The finding is of some importance. Wholly apart from appearance, a smooth surface on an electrophoretic deposit facilitates inspection for flaws such as cracks or holes.

Miscellaneous problems associated with deposition.—A mixture of topics falls within this heading including a discussion of the factors affecting the yield in electrophoretic deposition as well as practical methods for controlling the dimensions of ware, factors affecting the green density, and some specialized problems occurring with the forming of flatware.

Factors influencing yield.—Hamaker showed sometime ago that yield or amount of electrophoretic deposition is given by the expression

$$y = a\int \mu FCAdt$$

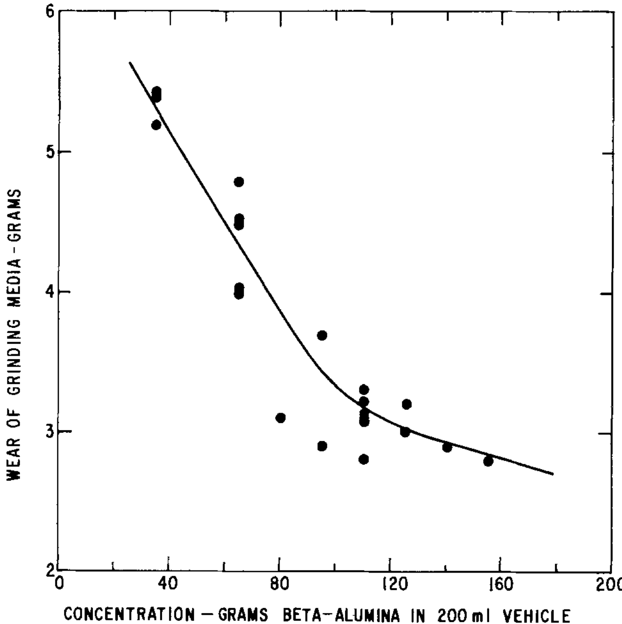

Fig. 7. Wear of 1100g 0.5 in. diameter 91% alumina balls in ballmilling various concentrations of modified fused powder for 16 hr.

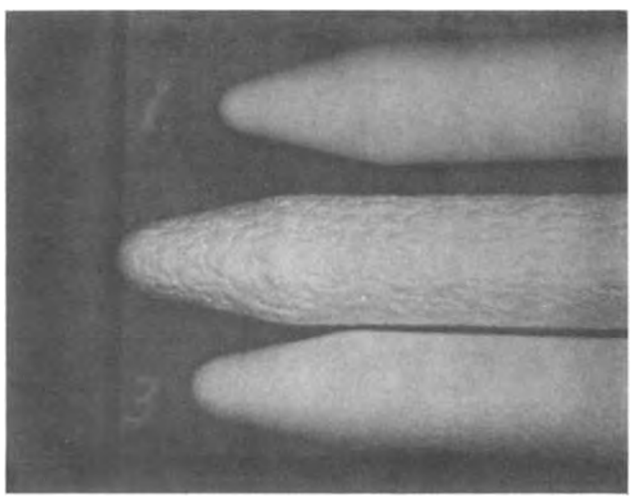

Fig. 8. The effect of aluminum stearate on the smoothness of beta-alumina deposits.

Here μ is the electrophoretic mobility, the velocity of a particle in a unit field of 1 V/cm; F is the electric field; C is the concentration of particles in grams per cubic centimeter; A is the electrode area; and t is the time (14). The coefficient, a, takes account of the possibility that not all particles which migrate to the electrode may deposit. Hamaker's expression has been confirmed by later work (15).

If a number of depositions are carried out successively from a suspension onto nearly identical mandrels for equal times at constant cell voltage, the yield, and correspondingly the wall thickness, decline because of the drop in concentration of beta-alumina. The simple technique used in this work to hold the thickness constant in successive depositions was to increase the time to maintain the product, Ct, invariant. Information on the measured masses of 18 closed-end tubes, six from each of three suspensions prepared in the same manner and deposited according to this scheme, is indicated in Table V below. It should be noted in these examples that over 80% of the beta-alumina had been deposited from the suspensions. However, there is usually noticeable degradation in the quality of deposits for more than about 70% depletion.

For deposition onto identical mandrels using the same fields and deposition times, the mass of the first deposit from a suspension is a good measure of the electrophoretic mobility of the suspended particles. The data presented in Table V are illustrative of beta-alumina powder containing 1% magnesia and 1% zirconia as additives. Vibratory milling of the suspensions had been carried out for 18 hr with zirconia grinding media. The deposit thickness was approximately 1.5 mm after sintering. Since the electrophoretic mobility

Table V. Variations in mass of electrophoretically deposited tubes

Depositions were carried out at 990V from suspension containing 100g calcined beta-alumina powder per 200 cm³ n-amyl alcohol

Suspension		a	b	c
Tube No.	Deposition time, sec	Mass, g	Mass, g	Mass, g
1	44	13.90	13.78	13.63
2	48	13.96	13.05	13.60
3	54	13.61	13.89	13.71
4	64	13.97	14.06	13.96
5	77	14.05	13.90	14.05
6	105	13.70	13.93	14.11
Average mass		13.87	13.77	13.84
Standard deviation		0.17	0.36	0.22
Standard deviation as % of mass		1.2	2.6	1.6

does depend somewhat on the powder composition as well as on the particle size, *i.e.*, on the milling time, cell voltage and deposition times would require adjustment for powders of other compositions and particle sizes as well as for other deposit thicknesses.

Green density.—An important parameter affecting the degree of sintering is the density of ware in the green state. Two factors which exert a noticeable influence on the green density are the concentration of beta-alumina and the concentration of aluminum stearate. This is demonstrated in Fig. 9 where green densities are plotted as a function of the cell voltage. For both fused and calcined beta-alumina powder, there are clear indications of the advantage of using higher concentrations to obtain larger green densities. The densities achieved with calcined powder were slightly greater than with the fused starting material. Depositions are not usually carried out, however, with concentrations of beta-alumina powder much in excess of 100g/200 ml vehicle because of problems with viscous flow after deposition. Aluminum tristearate concentrations of 0.12%, based on the amount of beta-alumina, are normally used since this concentration is nearly as effective as larger ones in improving the smoothness of deposits. Furthermore, green densities obtained with this concentration are not much less than those obtained in the absence of aluminum stearate. Suspensions for which green density data are presented in Fig. 9 were milled with alpha-alumina media. Somewhat higher green densities, typically 1.74 g/cm^3, are obtained with zirconia media, likely as a result of finer grinding.

Various deposit configurations.—The versatility of electrophoretic deposition as a forming technique for beta-alumina ceramic is illustrated in Fig. 10. Here are shown a number of items of green ware: closed-end tubes of different lengths, an open-end tube 6 in. long and 0.75 in. diameter, a 3 cm disk, and a pocket-shaped piece.

Some special problems with the forming of disks and other flat ware.—When electrophoretic deposition occurs on a polished disk mandrel, the thickness of the deposit is generally greater at the edge than at the center. For example, one green disk was only 1.04 mm thick at the center, but 1.40 mm near the edge. The variation in deposit thickness can be nearly eliminated by the use of an insulating Teflon polymer sleeve which fits around the edge of the mandrel, as shown in Fig. 2. The sleeve shapes the electric field and gives rise to a nearly uniform current density over the electrode face. The fact underlying this design is that the current density over a disk will be uniform, regardless of the shape or position of the counterelectrode, if the insulating sleeve extends above the surface of the electrode a distance of at least the disk radius (16). A green disk formed using the Teflon polymer sleeve was 1.70 mm thick at the center and 1.72 mm at the edge. Beta-alumina disks, which are at least 1.5 mm thick, warp little during sintering.

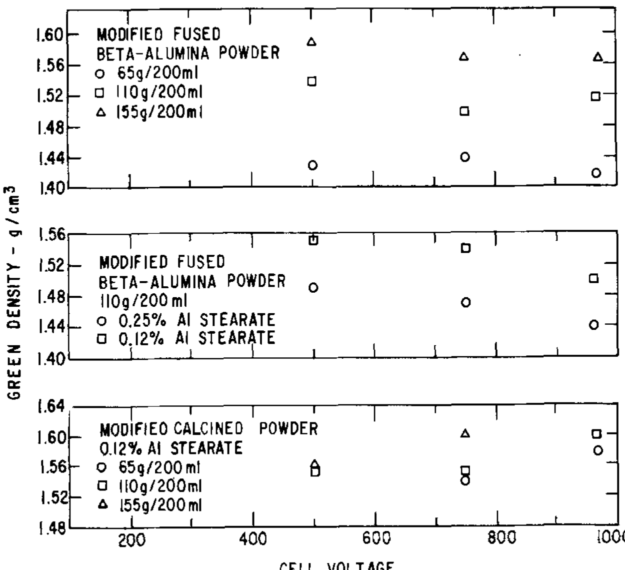

Fig. 9. Dependence of green density on cell voltage

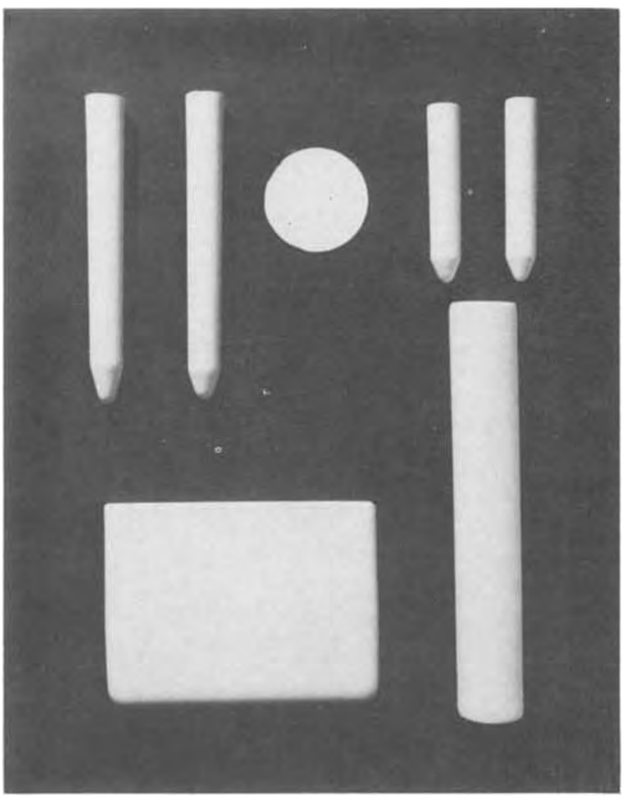

Fig. 10. Green ware formed by electrophoretic deposition

Removal of electrophoretic deposits from mandrels.—The need for removal of deposits from mandrels after forming involves some problems not encountered in the use of electrophoretic deposition for coating purposes. These problems have been treated in very different ways in previous applications of electroforming. Andrews, Collins, Cornish, and Dracass removed alpha-alumina ogives from aluminum formers with a polyvinyl chloride sheath metallized on its outer surface and dusted with talc on its inner surface (6). This sheath covered the former during deposition and subsequently, deposit and sheath together were slid off the aluminum former. On the other hand, Lazennec, Fally, and Leboucq removed zirconia and beta-alumina closed-end tubes from aluminum mandrels after air-drying and isostatic pressing (7). The working hypothesis underlying the work described in this report was that satisfactory removal of deposits depends on the nearly complete elimination of vehicle from the deposit. This hypothesis originated from the commonplace observation that soil, mainly an aqueous suspension of aluminosilicates, adheres to smooth metal surfaces much less tenaciously when dry. Experience has indicated the need for only slight modifications in this hypothesis. Two kinds of problems are encountered in securing the satisfactory release of green beta-alumina deposits from mandrels: those related to sticking and those associated with cracking.

Release of green deposits in the form of closed-end tubes can usually be accomplished after drying overnight in air at room temperature. At most, 24 hr are needed. However, up to 3 days of drying may be required for the 3 mm thick deposits formed on larger

mandrels such as the one for forming pocket-shaped pieces. Despite careful drying, deposits from suspensions containing aluminum stearate in excess of about 0.25%, based on the amount of beta-alumina, often cannot be removed from mandrels in one piece. These findings raise the question whether the deposit adherence noted by previous groups may have been caused by the presence of binders in the deposit. Andrews, Collins, Cornish, and Dracass in their electroforming work with alpha-alumina used 0.5% dewaxed shellac in their preferred formulation while Lazennec, Fally, and Leboucq used up to 2% of a polycarbonate in their work with zirconia.

Comparison of present process with that developed previously.—It seems appropriate to conclude this discussion of the problems in the electrophoretic forming of beta-alumina ware with a brief comparison of the features of the process described in this paper with one described previously (7). This comparison is indicated in Table VI.

The Properties of Sintered Beta-Alumina Deposits

The properties of sintered beta-alumina depend on details associated with each of the three major fabrication steps, the preparation of starting powders, the forming of green ware, and finally, the sintering procedure. A brief description of this final operation used with beta-alumina green ware formed by electrophoretic deposition was given in a previous section of this paper. Only an indication of the range of properties that can be obtained will be given here.

When sintering is carried out at temperatures between 1700° and 1825°C for times ranging from a few minutes to a few hours in either an air or an oxygen atmosphere, densities ranging from 2.98 to 3.26 g/cm^3 are obtained on single-phase material. These values correspond to residual closed porosity from 10 to less than 1%. Microstructures of three different specimens, all based on calcined starting powder, are shown on Fig. 11. A very coarse-grained structure from a specimen with a density of 3.15 g/cm^3, appears in part A. The more or less rounded dark spots on the photomicrograph indicate pores while those with straight sides likely indicate the position of grains which were removed during mechanical polishing prior to etching in phosphoric acid. The micrograph for a specimen of high density (3.24 g/cm^3) and small grain size is shown in part B while one, also of small grain size but with high porosity, is shown in part C. The density of this third specimen was only 2.98 g/cm^3. While this specimen was not leak tight to helium, other specimens of this low density have been tight.

D-c specific resistivities as low as 105 ohm-cm and as high as 26,000 ohm-cm have been measured at room temperature. While a small grain size is desirable for mechanical strength and uniformity of current distribution, the lowest specific resistivities are usually observed with specimens of large grain size. Consequently, a compromise must be sought between these conflicting requirements. A more rational basis for this compromise is considered in another paper (17).

Table VI. Comparative features of present process and that developed previously

Feature	Previous work	This paper
Charging mode for particles	Proton adsorption	Dissociation of Na^+
Activator used	Benzoic acid	None
Charge on particles	Positive	Negative
Vehicle	$CH_3NO_2/CHCl_3$ mixture	N-amyl alcohol
Binder	Diphenol polycarbonate	None
Cell voltage	300-500V	300-1000V
Hydrodynamic conditions during deposition	Mandrel rotated and suspension stirred	No stirring during deposition
Method used to remove deposits from mandrels	Drying followed by isostatic pressing	Drying

Summary

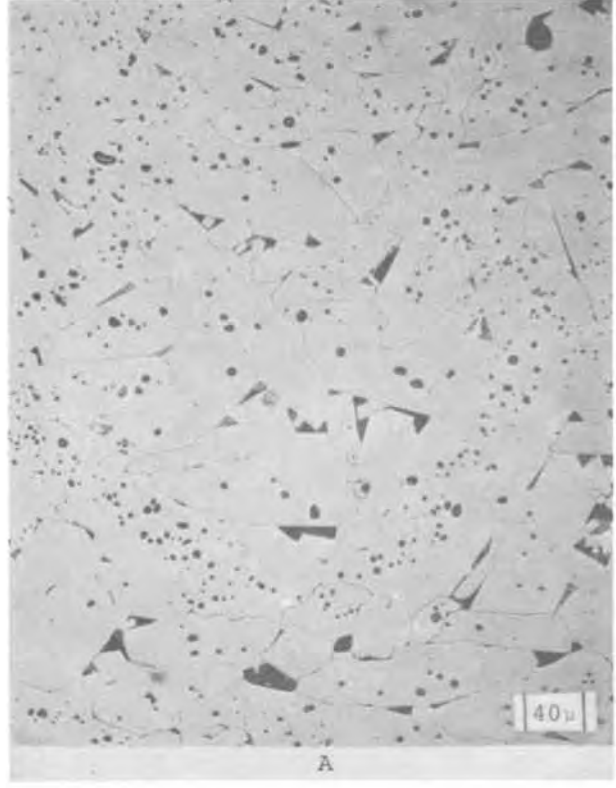
In this study, electrophoretic deposition was examined as a method for forming green beta-alumina ware. Ceramic articles are often fabricated in a three-step procedure: (*i*) the preparation of starting powders, (*ii*) the forming of such powder into a compact shape similar to that required in the final product, and (*iii*) the sintering of this green ware to reduce porosity and to develop other necessary properties. For beta-alumina, the second step of this sequence is difficult with conventional ceramic processing. Electrophoretic deposition offers the advantages of speed and versatility, making available a variety of shapes with a minimum of precision tooling. Deposits are essentially without a preferred orientation.

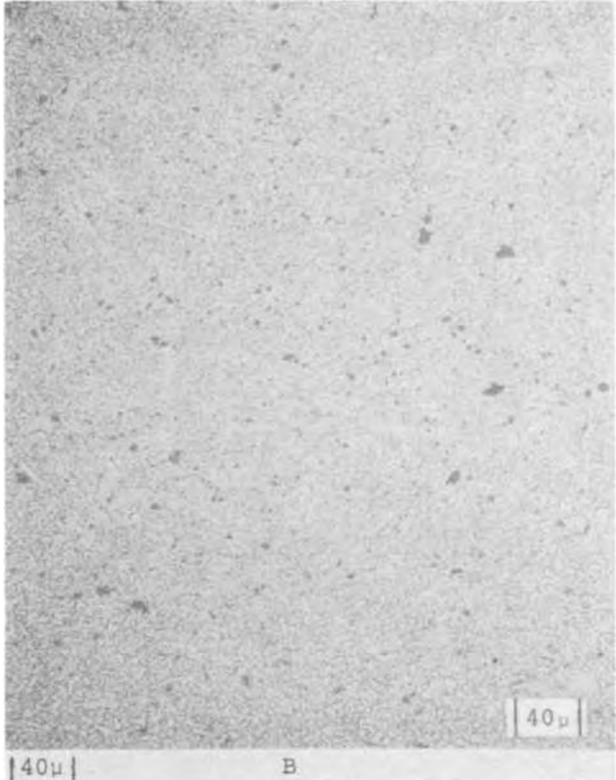
The electrophoretic forming operation in turn is also comprised of three main steps: (*i*) the preparation of a suitable suspension of powder dispersed in a vehicle, *i.e.*, organic liquid; (*ii*) the deposition of the powder from the suspension onto a mandrel using an electric field; and (*iii*) removal of the green deposit from the mandrel. The first of these steps is crucial. Three major problem areas were identified with it: (*i*) the selection of a suitable vehicle in which to suspend the beta-alumina particles, (*ii*) control of the charge on these particles, and (*iii*) milling of the particles to effect a suitable charge and to produce the fine size required for high densification on sintering. Problems associated with the other two steps were of a more straightforward nature.

Selection of vehicle for dispersing beta-alumina particles.—With the predominant charging mode used in this study, satisfactory electrophoretic deposits are obtained only with vehicles with dielectric constants in the range 12-25. Most work has been carried out using n-amyl alcohol as the vehicle because its dielectric constant is 13.9 at 25°C. Furthermore, neither the formation of anodic films nor that of fluid deposits is a problem with it. This alcohol is available as reagent grade material from a number of manufacturers. Finally, this vehicle is relatively nontoxic.

Charge control of beta-alumina suspensions.—Two different competing charging modes are known for beta-alumina. Negative charging, the predominant mode used in this study, arises from dissociation of sodium ions from the particles. On the other hand, positively charged particles can be obtained by adsorption of protons from water or organic acids such as stearic or benzoic. Suitable charging is mainly a matter of controlling the water content of the suspension. A variety of phenomena have been encountered depending on this water concentration. These can be generally understood in terms of the Hamaker-Verwey theory of electrophoretic deposition.

Milling problem.—This problem comes about from the need to mill an exceedingly hard, abrasive substance to about 1μ size particles with very little contamination of the suspension by the wear products of the grinding media. The preferred practice at this time involves: (*i*) the use of a more friable beta-alumina; (*ii*) the use of a very high powder concentration during milling, *e.g.*, 100-200g beta-alumina in 200 ml vehicle; (*iii*) vibratory milling being preferred over ballmilling because of its speed and the somewhat lower wear of the grinding media; (*iv*) zirconia media being used in preference to those of alpha-alumina. If slight contamination of the suspension by zirconia is intolerable, 91% alpha-alumina grinding balls are used. Smoother electrophoretic deposits are obtained





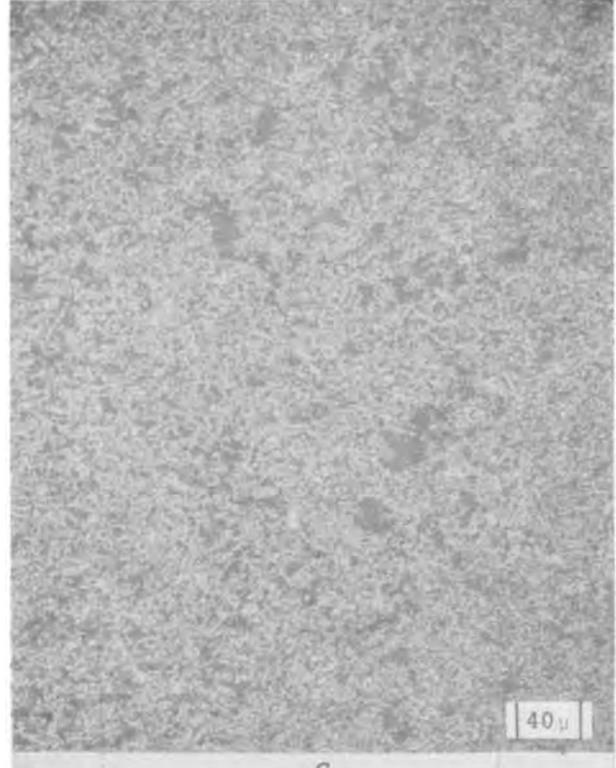


Fig. 11. Various microstructures observed with ware formed electrophoretically.

on milling with *ca.* 0.12% aluminum tristearate in the suspension.

Assorted problems with deposition.—More nearly constant ware thicknesses can be obtained on successive deposition from a suspension if the deposition time is extended to maintain the product of deposition time and beta-alumina concentration a constant. Green densities were found to increase with the beta-alumina concentration of the suspension and to decrease with the aluminum tristearate concentration. Disks of uniform thickness can be deposited electrophoretically through the use of an insulating Teflon polymer ring fitting about the face of the disk-mandrel.

Removal of deposits from mandrels.—Deposits can be taken from slightly tapered mandrels after thorough removal of the vehicle either by air-drying or by accelerated drying in a vacuum oven.

A wide variety of properties can be obtained with electrophoretically deposited ware, depending mainly on the sintering conditions but also to some extent on the nature of the starting powders as well as on details concerned with the forming operation.

A Method for Characterizing the Structure of Hydrophilic Porous Gas Diffusion Electrodes

Christer Morén

Department of Chemical Technology, Royal Institute of Technology, 100 44 Stockholm 70, Sweden

ABSTRACT

An apparatus, the dilactres cell, has been developed for determining structure parameters on operating porous gas diffusion electrodes. The experimental values of these parameters have been compared with the predictions of the thin-film model where all forms of polarization are present. The experimentally obtained polarization curves are within 15% of the computed ones for Ni-electrodes operating on air in 5M KOH at 50°C with Ag as catalyst.

Various models have been proposed for porous gas diffusion electrodes with different types of reactant and product transport as well as different liquid configurations.

The simple pore model was developed by Austin *et al.* (1), who proposed that reactant gas dissolves in the electrolyte and diffuses to the electrode surface near the three-phase boundary of solid-liquid-gas. The simple pore model has also been studied by Srinivasan, Hurwitz, and Bockris (2).

The thin-film model was postulated by Will (3, 4). Will studied the mechanism of ionization of molecular hydrogen on partially immersed Pt electrodes in acidic solutions. He experimentally proved the existence of an electrochemically active electrolyte film. The effects of activation control were neglected and an arbitrary film thickness parameter was utilized for calculating the current. Austin (5) and Lindström (6) postulated that the walls of the gas filled pores in a gas diffusion electrode are covered by a thin electrolyte film.

Grens *et al.* (7) as well as Bennion and Tobias (8, 9) took into account the activation polarization in their calculations. Iczkowski (10) formulated an electrolyte film mechanism for a hydrogen gas diffusion electrode. Rockett and Brown (11) made a theoretical analysis of a single pore coated with a thin film of electrolyte and compared it with data from nickel electrodes operating on oxygen in 80% KOH. Numerical calculations were carried out by Srinivasan and Hurwitz (12) for a thin-film model in the case where all forms of polarization are present, varying the kinetic and physical parameters. Lindström (13) and Lindholm *et al.* (14) correlated the electrochemical activity with the electrolyte film resistance.

A meniscus model was introduced by Bockris and Cahan (15) who observed a meniscus with a finite contact angle on Pt electrodes in H_2SO_4.

Pshenichnikov (16) considered wide film-covered pores, the walls of which were penetrated by electrolyte filled micropores.

Katan and Grens II (17) studied the influence of differential pressure on electrode activity for oxygen cathodes made up of beds of uniform silver spheres. The extent and nature of this dependence they explained through use of the concept of pendular and funicular liquid configuration in the pore space of the electrode.

The statistical concept of porous structure was adapted by Markin *et al.* (18) as well as by Micka (19-21), who considered a macrohomogeneous system on which he applied a statistical model based on the assumption that the electrode reaction proceeds on active centers, distributed statistically in a large number over the entire volume of the operating layer.

Key words: porous gas electrodes, hydrophilic, tortuosity, film resistance, differential pressure.

According to the film model the walls in the gas filled pores are covered by a thin electrolyte film. The reaction gas diffuses to the electrode surface and reacts there so that electrons are transferred from, or to, the electrode. In addition ionic current transport must proceed along these films.

Mass transport is often the primary cause of polarization in air and oxygen cathodes. This polarization can be attributed to one or more of the transport steps: diffusion of oxygen molecules in the gas phase, diffusion of oxygen molecules in the liquid phase, diffusion or migration of hydroxyl ions in the liquid, and diffusion of water in the liquid phase.

Lindström (13) characterized the electrochemical structure with the aid of certain parameters, mainly the pore size distribution, film area, film perimeter, film thickness, interstice tortuosity, and film tortuosity. He determined these parameters on single porosity gas electrodes. The measurements were performed in separate stages with different sets of apparatus. The dilatometry measurements were not performed with the electrodes operating as cathodes. According to the film resistance measurements he had to provide the coarse pore layer with a fine pore layer on both sides, with the gas being supplied to a ring arranged around the periphery. The principal disadvantages of these methods are that the physical measurements are carried out separately while there is no current flow.

Most theoretical treatments assume that the concentration of electrolyte is constant in the liquid films in porous electrodes. In oxygen and air electrodes there is always a concentration of the electrolyte in the films due to water removal and formation of hydroxyl ions on account of the reaction

$$O_2 + 2H_2O + 4e^- \rightarrow 4\,OH^-$$

The concentration of electrolyte is counteracted by diffusion of water in the gas phase as well as in the liquid, but the water vapor transport is counteracted by convective diffusion of oxygen in the gas phase toward the electrolyte side.

Lindholm (23) investigated the dilution of electrolyte with increasing current density for hydrogen electrodes. For oxygen electrodes Micka (24) calculated the concentration of KOH in the pores according to the model of porous electrodes of second order. His calculations were based on approximate solutions yielding rather high concentrations which attained saturation. In another paper (25) he used more exact transport equations resulting in lower concentration gradients.

The purpose of this paper was to determine certain structure parameters and their influence on the behavior of operating air cathodes, *i.e.*, with current flow. For this purpose a special apparatus was developed, the so-called dilactres cell, which stands for: DILatometry, ACTivity, and film RESistance. In the dilatometry measurements, the penetration of gas into the electrode at varying differential pressures was investigated. From these data, the film area and film thickness were calculated. The activity measurements gave the polarization curve. In the film resistance measurements, the voltage drop in the electrolyte film was measured, when an ionic current was forced through the film network. After necessary corrections the effective specific resistance (ohm-cm) in the film was obtained, based on the current per unit cross-sectional area of the electrode. This film resistance is a very important factor since together with the current distribution in the pore, it determines the ohmic potential drop in the electrolyte film. Even the film tortuosity was calculated from the resistance values.

The experimental polarization curves have been compared with the predictions of the thin-film model, as proposed by Srinivasan and Hurwitz (12).

General Experimental Arrangement

The apparatus consisted of the dilactres cell, air pressure and flow regulation equipment, and monitoring instrumentation. The arrangement is shown in Fig. 1-3. Figure 1 is a schematic diagram of the apparatus with electrical connections. The probe is pulled out to make the drawing clearer. Figure 2 shows the electrical circuits. In Fig. 3 the relations between the probe, working electrode, and reference electrodes during film resistance measurements are shown.

Dilactres cell.—The dilactres cell consisted of a turned out block of polymethylmethacrylate, PMMA. The working and counterelectrodes were kept at a fixed distance by means of a distance element, made from PMMA, so that a definite volume of electrolyte was kept between the electrodes. At the top of the cell a riser, consisting of a thin calibrated glass tube equipped with a movable graduated scale, was inserted for dilatometry measurements. A canal was milled around the electrolyte compartment and con-

nected to a thermostat controlled waterbath. The whole cell assembly was inserted into a temperature controlled air bath. A thermocouple was placed inside the cell in the electrolyte to check the settings of the temperature regulators, and data collection was never started until the bulk electrolyte attained 50°C to assure temperature equilibrium.

Working and counterelectrodes.—The working electrodes, called A, B, and C, respectively, were hydrophilic double layer gas diffusion electrodes. From each type of electrode, A, B, and C, three 20.5 × 11.7 cm electrodes were manufactured. From each of these plates two electrodes were punched with external surface areas, exposed to the electrolyte, of 16 cm^2 and 1 cm^2, respectively, so that a total of 18 electrodes were investigated. Three large electrodes were chosen in order to study the structure homogeneity from plate to plate and two smaller sizes were investigated in order to check a possible bulging of the electrode, when the differential pressure was applied. It was also a check on the functioning of the distance element.

The fine pore layers were identical for the three electrode types and consisted of a 0.029 cm thick sintered Ni-layer with a porosity of 0.43 and a mean pore radius, r_{mf}, of 1.15×10^{-4} cm. The fine pore layers contained no catalyst. The coarse pore layer of electrode A was a sintered Ni-layer with a porosity, U, of 0.74 and a thickness, L, of 0.051 cm. The mean coarse pore radius, r_2, was 5.84×10^{-4} cm. Electrode B was a compressed version of electrode A with a porosity of 0.63 and L equaling 0.034 cm. r_2 was 2.11×10^{-4} cm. Electrode C was identical to A except for the coarse pore layer thickness which was 0.068 cm. The silver catalyst content in the coarse pore layers was 9.3% by weight.

L was determined on electrode cross sections in a scanning electron microscope. r_2 and r_{mf} have been defined as the pore radii, when half the fraction of the electrode void volume was displaced by Hg in the Hg-porosimeter. The porosity was determined both by Hg-porosimetry and by weighing electrodes manufactured without fine pore layers.

Counterelectrodes identical to the working electrode were not possible to use during the dilatometry measurements, because anodic gas evolution would arise when the electrodes were loaded. Because of this difficulty a porous Fe-electrode was chosen as counterelectrode. The thickness and external surface area were 0.26 cm and 16 cm^2, respectively. It was discharged according to

$$Fe + 2\,OH^- \rightarrow Fe(OH)_2 + 2e^-$$

Reference electrodes.—The capillary K_1 in Fig. 1 was inserted through the wall of the cell and connected to a Hg/HgO reference electrode kept at 50°C in the thermostated air bath. The tip of the Luggin capillary was placed in the bulk electrolyte about 0.5 mm from the working electrode. The very fine capillary K_2 in Fig. 1 was inserted through the probe, see below, to the outer surface of the probe electrode and connected to another Hg/HgO reference electrode in the air bath. The electrolyte in the latter reference electrode could be forced out into the capillary, when the probe was withdrawn from the working electrode surface, by means of an applied N_2-pressure.

Pressure and flow regulation.—The air was obtained from the laboratory air system. It passed through an oil filter and was dried with $Mg(ClO_4)_2$ before use.

The air pressure was kept constant at the gas side of the working electrode by means of a precision reducing valve from Drägerwerk Lübeck. The pressure was measured with a mercury manometer. The differential pressure read on the manometer was corrected with the electrolyte column pressure in the dilatometry riser.

A nitrogen differential pressure of 40.9 cm of H_2O was applied to the counterelectrode in order to avoid electrolyte leakage out into the gas room. It was necessary to apply this pressure merely because the electrode holder was designed to accept gas diffusion electrodes as counterelectrodes.

Electrolyte.—Five molar KOH at 50°C was used as bulk electrolyte throughout the whole investigation. It was prepared as 5.06M KOH at 20°C from reagent grade KOH-pellets and distilled water.

Experimental Procedure

Dilatometry measurements.—These were performed in order to determine the electrolyte film area and the film thickness. The circuit, as shown in Fig. 1, was used to measure the penetration of gas into the working electrodes at varying differential pressures. The amount of expelled electrolyte was read off to the nearest half-scale division on the riser, which corresponds to 2.7×10^{-3} cm^3 of liquid for the large riser used with the 16 cm^2 electrodes and 5.9×10^{-4} cm^3 of liquid for the small riser used with the 1 cm^2 electrodes.

In order to investigate the influence from the counterelectrode discharge on the dilatometry measurements, the 16 cm^2 counterelectrode was discharged together with both 1 and 16 cm^2 air electrodes during a time equaling the dilatometry test time. The cathodic current density was varied between 0 and 0.2 A/cm^2 and the differential air pressure was kept constant at P_{max}. The volume change by time in the riser was measured as a function of current density on the cathode. For low current densities, any change of the electrolyte height in the riser was not observed. For higher current densities a very slow continuous rise of the electrolyte was noticeable. For a cathodic current density of 0.2 A/cm^2 the rising speed, on an average for the three electrode types, amounted to 1.1×10^{-2} cm^3/5 min (2 scale divisions/5 min) for the 16 cm^2 cathodes and 3.0×10^{-4} cm^3/5 min (0.5 scale divisions/5 min) for the 1 cm^2 cathodes. This very slow rising, which corresponds to density differences between Fe and $Fe(OH)_2$, removal of H_2O from the electrolyte due to cathodic reaction, removal of H_2O by the gas stream, and a possible temperature increase were easily separated from the rapid rise, when the air pressure was changed in the dilatometry measurements.

During the dilatometry measurements the differential air pressure was increased stepwise up to a pressure, P_{max}, where no further penetration of gas was observed.

With the aid of the equations derived below it is possible to calculate the film area and the mean film thickness from the dilatometry measurements. The equations are essentially based on the model for the interstice network as introduced by Lindström (13). An increase of dP for a differential pressure, P, results in a further gas penetration, dW, corresponding to a cross section with an area equal to $dW/L \cdot s$ and the film perimeter dN. If the contact angle is denoted

θ and the surface tension σ, the balance between the capillary force and the differential pressure can be expressed by

$$dN \cdot \sigma \cdot \cos \theta = P \cdot \frac{dW}{L \cdot s} \qquad [1]$$

where L is the thickness of the coarse pore layer and s is the interstice tortuosity, see Eq. [6] below. Lindström used L instead of $L \cdot s$ in Eq. [1], but the use of the latter quantity seems more plausible. Dilatometry experiments give $W = f(P)$ from which

$$dW = f'(P)dP \qquad [2]$$

Combining Eq. [1] and [2] gives

$$dN \cdot \sigma \cdot \cos \theta = P \cdot f'(P) \cdot \frac{dP}{L \cdot s} \qquad [3]$$

Integration gives

$$N \cdot L \cdot s = \frac{1}{\sigma \cdot \cos \theta} \int_0^P P \cdot f'(P)dP \qquad [4]$$

The contact angle was supposed to be zero degrees. The surface tension was calculated from literature data (22) given at 25°C. The temperature coefficient was supposed to equal the temperature coefficient for pure water. Neglecting the pressure influence, σ was found to be 8.48×10^{-2} cm of H_2O·cm (= 83 dyne/cm) at 50°C for 5M KOH.

The film area A^* was calculated as

$$A^* = N \cdot L \cdot s/a \qquad [5]$$

where a is the external electrode area. A^* equals the film area per unit of external electrode area (cm²/cm²). The mean film thickness FT was calculated as the volume of the electrolyte film at P_{max} divided by the total film area. Figure 4 shows $A^* = f(P)$ and in Table II the A^* values at P_{max} are tabulated.

Activity measurements.—The cell permitted measurements of the electrode activity, *i.e.*, recording polarization curves. For this purpose current was supplied from a Wenking Potentiostat, operated galvanostatically, and measured with an Unigor 1P ammeter. The working electrode potential *vs.* the Hg/HgO reference electrode was measured with a digital multimeter MN-124 from Schneider Electronique. The *IR* drop between the tip of the reference capillary and the electrode surface was recorded on an SS-5157 Synchroscope oscilloscope, when the current was interrupted. A rapid electronic switch was built at our laboratory for this purpose. It was triggered by a pulse generator PG 56 from Advance Instruments. All polarization curves were corrected for this *IR* drop, which never exceeded 2% of the total polarization.

Before recording the polarization curves the electrodes were activated during 10 cycles with a constant current density of 0.025 A/cm² at a differential air pressure of 410 cm of H_2O. Each cycle consisted of 2 hr of oxidation plus 1 hr of reduction.

The potential *vs.* Hg/HgO as a function of the differential air pressure was determined stepwise from 40 cm of H_2O to P_{max} for a constant current density of 0.025 A/cm², see Fig. 5. Polarization curves were determined in the current density range 0-0.2 A/cm², see Fig. 6.

The electrode homogeneity was confirmed with the activity measurements, in that, no significant activity differences existed between the large and small electrodes.

Film resistance measurements.—To get an idea of the ion transport along the electrolyte film, the film resistance, Z'. see below, was measured. Together with the current distribution the film resistance determines the ohmic potential drop in the film. The interstice and film tortuosities were also determined. The interstice tortuosity, s, is the effective tortuous length for the current to traverse through the coarse pore layer when this layer is completely soaked with electrolyte divided by the coarse pore layer thickness. In the same way the film tortuosity, f, is the effective tortuous length for the current to traverse through the film network in the coarse pore layer divided by the coarse pore layer thickness. The expression for the interstice tortuosity is derived in the following manner. If an electric current flows through an electrolyte path of uniform cross section, the resistance of the path is given by

$$R' = \frac{e \cdot L'}{a'} \qquad [7]$$

where e = the electrolyte resistivity (ohm-cm); L' = the length of the electrolyte path (cm); and a' = the cross sectional area of the electrolyte path (cm²).

If the electrolyte resistance is measured through a completely drowned porous body with a thickness L' and an outer surface cross-sectional area of a', the resistance will be higher than was R', the resistance of the electrolyte alone since (*i*) the mean length of path traversed by the current is longer and (*ii*) the cross-sectional area which is available to current flow is smaller. Let the effective tortuous length through the porous body traversed by the current by L'', and the apparent cross-sectional area of the electrolyte saturated porous body, available to current flow be a'', then

$$R'' = \frac{e \cdot L''}{a''} \qquad [8]$$

Dividing Eq. [8] by [7]

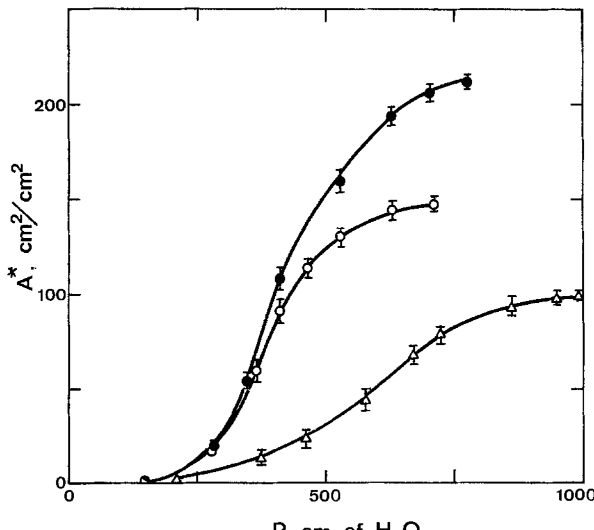

Fig. 4. Electrolyte film area as a function of the differential air pressure at 50°C. ○, electrode A; △, electrode B; ●, electrode C.

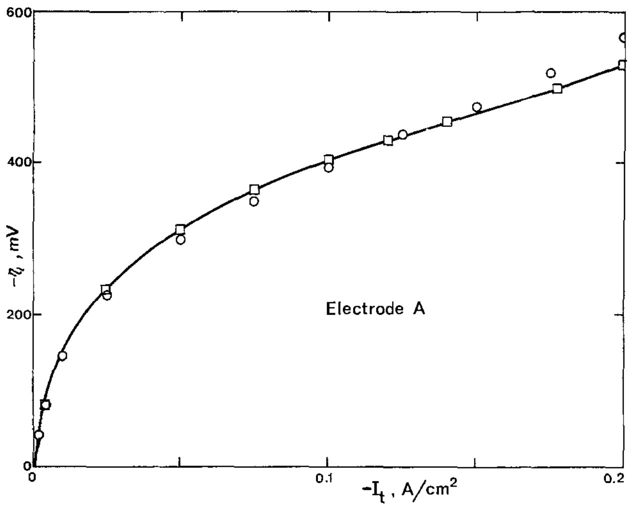

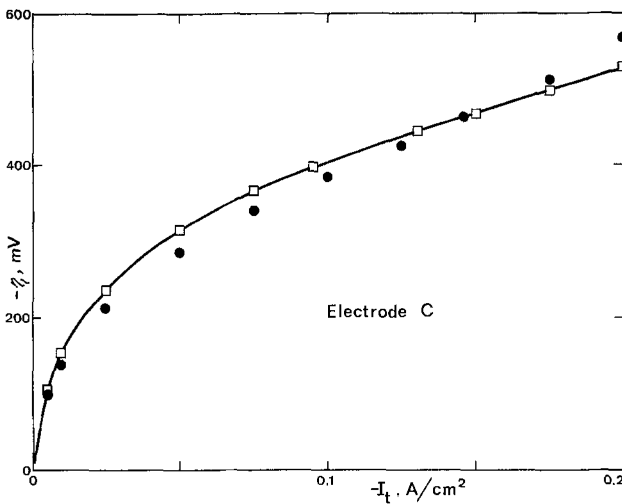

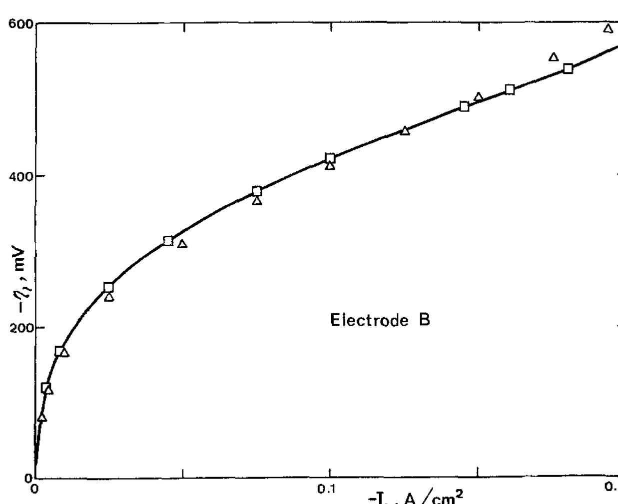

Fig. 6. Experimental and theoretical polarization curves at 50°C. □, Theoretical values; ○, Δ, and ●, experimental values for the electrodes A, B, and C, respectively.

$$\frac{R''}{R'} = \frac{L''/L'}{a''/a'} \quad [9]$$

The ratio L''/L' is defined as the interstice tortuosity s. The ratio a''/a' may be designated as τ. If the resistivity factor R''/R' is called G, substituting in Eq. [9] gives

$$G = s/\tau \quad [10]$$

If $s \cdot \tau = U$, where U is the porosity, then substitution in Eq. [10] gives

$$G = s^2/U \text{ or } s = \left(\frac{Z^o}{e} \cdot U\right)^{1/2} \quad [11]$$

where

$$G = Z^o/e \text{ and } Z^o = \frac{\Delta V_s}{I \cdot L} \text{ (ohm-cm)} \quad [12]$$

ΔV_s = potential drop in the liquid, filling the coarse layer, with corrections made for the potential drop in the separator, fine pore layer (see below), and the IR drop in the bulk electrolyte from the electrode surface to the Luggin capillary tip, (V); I = probe current density (A/cm²); L = thickness of the coarse pore layer (cm).

The film tortuosity factor is calculated in an analogous way as

$$f = \left(\frac{Z'}{e} \cdot \frac{FT \cdot A^*}{L}\right)^{1/2} \quad [13]$$

where the effective specific film resistance is

$$Z' = \frac{\Delta V_f}{I \cdot L} \text{ (ohm·cm)} \quad [14]$$

ΔV_f is measured in the same way as ΔV_s, but P equals the maximum differential pressure P_{max}.

U in Eq. [11] is the fraction of the coarse pore layer volume occupied by electrolyte, when the electrode is completely soaked.

$\frac{FT \cdot A^*}{L}$ in Eq. [13] is the fraction of the coarse pore layer volume occupied by the electrolyte film at P_{max}. The film resistance measurements were carried out by means of a special probe, see Fig. 1-3. The main probe body was made of PMMA. A porous iron electrode with current collector was attached to the front of the probe. The diameter of the hole in the tip of the probe reference capillary (see above) was less than 0.1 mm in order to diminish as far as possible the influence from the capillary on the current distribution in the vicinity of the tip. The probe reference electrode (K_2 in Fig. 1) was connected to the reference electrode (K_1) in the bulk electrolyte via a digital voltmeter from Schneider Electronique. To avoid electronic contact between the probe and the working electrode, a microporous separator, Dynel Acropor WA, covered the probe electrode surface. Before use the probe electrode was soaked with KOH and oxidized for 3 hr with a current corresponding to 70% of the useful capacity. When the film resistance measurements were performed the probe was pressed against the gas side of the working electrode and current was allowed to pass between the probe electrode and the counterelectrode. The probe current density was 0.015 A/cm² and the potential drop between K_1 and K_2 was measured. After the necessary corrections, see below, for the potential drop in the separator, fine pore layer, and bulk electrolyte between K_1 and the working electrode surface,

the film resistance was calculated according to Eq. [14]. Because of the low exchange current density for the oxygen reduction on the working electrode, the resistance of the electrolyte film is much less than the resistance of the charge-transfer reaction so that no electrode reaction occurs in the working electrode due to current flow between the probe and the counterelectrode, *i.e.*, only ionic current flows through the working electrode. During the film resistance measurements the counterelectrode reaction was

$$Fe + 2\,OH^- \rightarrow Fe(OH)_2 + 2e^-$$

and the probe reaction was

$$Fe(OH)_2 + 2e^- \rightarrow Fe + 2\,OH^-$$

For low differential air pressures the probe disturbed the activity of the working electrode, but this disturbance was eliminated with increasing pressure and was below 1% for $P = 410$ cm of H_2O and not detectable at P_{max}. For differential pressures less than P_{max} the gas filled pores were shunted with soaked pores, *i.e.*, the measured apparent film resistance was a pure film resistance only for $P = P_{max}$. The working electrode current density was varied between 0 and 0.05 A/cm^2 during the film resistance measurements with no significant change of the Z' values. Neither was any change observed when the probe size was changed from 0.33 to 1.00 cm^2.

Corrections for the voltage drop in the fine pore layer of the working electrode and in the electrolyte filling the separator were made in the following way. Three electrodes of different thicknesses solely consisting of fine pore layers without any catalyst were prepared and tested with a probe current density of 0.015 A/cm^2, see Table III. The potential drop in the electrolyte filling the fine pore layer was not changed when P was increased up to P_{max}. This potential drop is supposed to be a linear function of the electrode thickness. This leads to finding the least squares solution of an overdetermined system of three linear equations

$$\Delta V_1 + 0.051 \cdot \Delta V_2 = 5.3$$
$$\Delta V_1 + 0.073 \cdot \Delta V_2 = 6.9$$
$$\Delta V_1 + 0.087 \cdot \Delta V_2 = 7.95$$

ΔV_1 = the potential drop in the probe separator (mV) and ΔV_2 = the potential drop/cm of the fine pore electrode thickness (mV/cm).

The equation system above is rewritten as

$$\Delta V_1 + 0.051 \cdot \Delta V_2 - 5.3 = r_1$$
$$\Delta V_1 + 0.073 \cdot \Delta V_2 - 6.9 = r_2$$
$$\Delta V_1 + 0.087 \cdot \Delta V_2 - 7.95 = r_3$$

Minimizing $(r_1^2 + r_2^2 + r_3^2)$ gives the solution

$$\Delta V_1 = 1.54\ \text{mV}$$
$$\Delta V_2 = 73.61\ \text{mV/cm}$$

with a root-mean-square error of 9.16×10^{-3}. This leads to a potential drop of 3.7 mV in the 0.029 cm thick working electrode fine layer plus probe separator. Figure 7 shows the apparent film resistance as a function of the differential air pressure and Table II shows s and f for the three electrodes A, B, and C.

Theoretical Model

The experimental results have been compared with the thin-film model according to Srinivasan and Hurwitz (11) where all forms of polarization are present.

The basic assumption in the thin-film model is that a thin film of liquid is spread over and in contact with the solid phase in the pore (Fig. 8). It is assumed that the thickness of the film is constant along the pore and small compared with the radius of the pore. It is further assumed that all the current is generated on the electrode surface in the film region.

A reaction sequence of the following type is assumed for this model: (*i*) diffusion of the reactant gas from the outer end of the porous electrode to the gas/electrolyte interface; (*ii*) dissolution of reactant gas in the electrolyte at the gas/electrolyte interface; (*iii*) radial diffusion of the dissolved gas through the electrolyte film; (*iv*) electrosorption of dissolved reactant gas at the electrode $(O_2)_{ads}$; (*v*) charge-transfer reaction of $(O_2)_{ads}$ to give $(O_2^-)_{ads}$; (*vi*) charge-transfer reaction of $(O_2^-)_{ads}$ to give products; (*vii*) diffusion of products away from the electrode and migration of ions through the film.

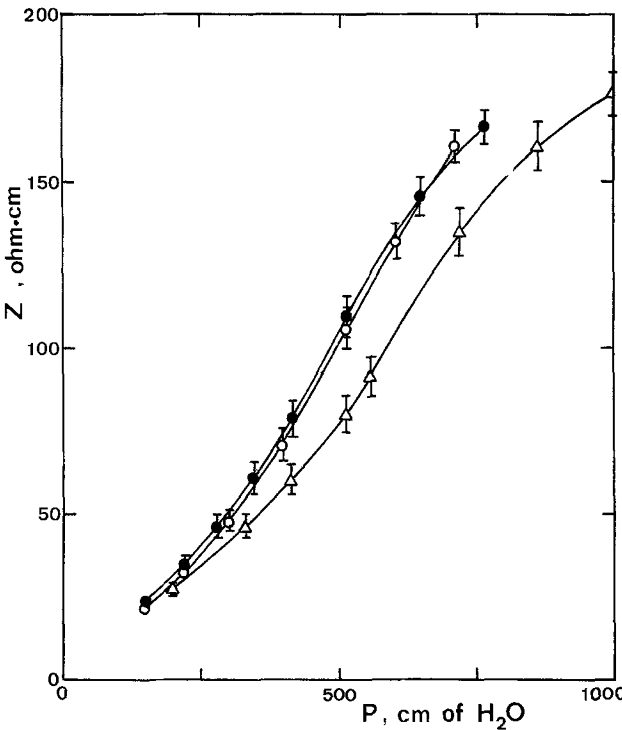

Fig. 7. The apparent film resistance as a function of the differential air pressure at 50°C. ○, Electrode A; △, electrode B; ●, electrode C.

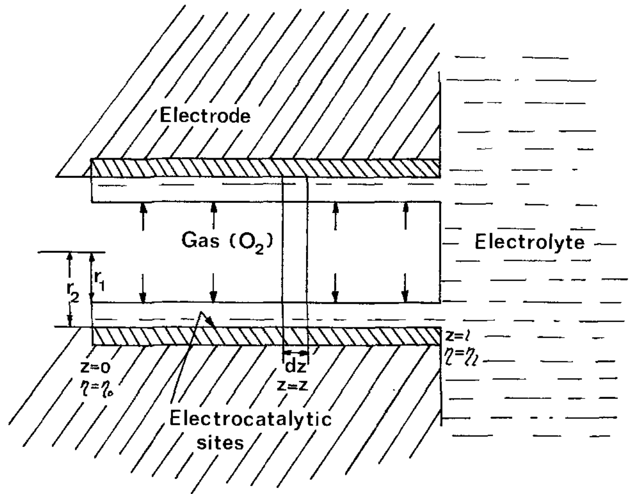

Fig. 8. Schematic representation of a single pore of a porous gas diffusion electrode using the thin-film model. Thickness of film is largely exaggerated.

It is assumed that step (*v*) is the activation controlling intermediate step at the electrode.

The rate of the electrode reaction in an element dz of the electrode is given by

$$di = 2\pi\, r_2\, dz\, i_o \left[\exp\left(\frac{\eta F}{2RT}\right) - \frac{C}{C_o} \exp\left(-\frac{\eta F}{2RT}\right) \right] \quad [15]$$

Table I. Physical parameters determined before the dilactres measurements were performed

Electrode type	$L \times 10^2$, cm	$r_2 \times 10^4$, cm	$r_{mt} \times 10^4$, cm	Porosity U
A	5.1	5.84	1.15	0.74
B	3.4	2.11	1.15	0.63
C	6.8	5.85	1.15	0.74

where i_o is the exchange current density (current/internal surface area) of the electrode reaction when the concentration of the reactant at the electrode is C_o. The current i is cathodic, hence $i < 0$ and $\eta < 0$. η is the sum of activation and concentration overpotentials. The symmetry factor is assumed to be ½. The average potential drop in the element, dz, is expressed by

$$d\eta = i \frac{dz}{\kappa\pi(r_2^2 - r_1^2)} \quad [16]$$

where κ is the specific conductivity of the electrolyte ($\kappa = 1/e$). In order to ascertain the concentration C at the electrode surface in the steady state, Srinivasan and Hurwitz assumed that the reactant gas has a flux only in the r direction and that the reactant is only consumed at the electrode surface

$$di = 2\pi r dz D n\mathbf{F}\left(\frac{\partial c}{\partial r}\right) \quad [17]$$

Integrating Eq. [17] using the boundary condition that at

$$r = r_1 \qquad C = C_o \quad [18]$$

gives

$$C = C_o - \frac{1}{2\pi Dn\mathbf{F}}\left(\frac{di}{dz}\right)\ln\left(\frac{r_1}{r_2}\right) \quad [19]$$

Using Eq. [19] in Eq. [15]

$$\frac{di}{dz} = 2\pi r_2 i_o\left[\exp\left(\frac{\eta\mathbf{F}}{2RT}\right) - \left\{1 - \frac{1}{2\pi Dn\mathbf{F}C_o}\left(\frac{di}{dz}\right)\ln\left(\frac{r_1}{r_2}\right)\right\}\exp\left(-\frac{\eta\mathbf{F}}{2RT}\right)\right] \quad [20]$$

Rearranging Eq. [20]

$$\frac{di}{dz} = \frac{4\pi r_2 i_o \sinh\left(\frac{\eta\mathbf{F}}{2RT}\right)}{1 + \frac{r_2 i_o}{Dn\mathbf{F}C_o}\ln\left(\frac{r_2}{r_1}\right)\exp\left(-\frac{\eta\mathbf{F}}{2RT}\right)} \quad [21]$$

Differentiating Eq. [16] with respect to z

$$\frac{d^2\eta}{dz^2} = \frac{di}{dz}\cdot\frac{1}{\kappa\pi(r_2^2 - r_1^2)} \quad [22]$$

Combining Eq. [22] and [21] gives

$$\frac{d^2\eta}{dz^2} = \frac{[4r_2 i_o/\kappa(r_2^2 - r_1^2)]\sinh\left(\frac{\eta\mathbf{F}}{2RT}\right)}{1 + \frac{r_2 i_o}{Dn\mathbf{F}C_o}\ln\left(\frac{r_2}{r_1}\right)\exp\left(-\frac{\eta\mathbf{F}}{2RT}\right)} \quad [23]$$

Making the substitutions

$$\frac{\eta\mathbf{F}}{2RT} = y \quad [24]$$

and

$$\frac{z}{l} = x \quad [25]$$

Eq. [23] reduces to

$$\frac{d^2y}{dx^2} = \frac{a\cdot\sinh(y)}{1 + b\exp(-y)} \quad [26]$$

where

$$a = \frac{2r_2 i_o l^2\mathbf{F}}{\kappa RT(r_2^2 - r_1^2)} \quad [27]$$

$$b = \frac{r_2\cdot i_o}{Dn\mathbf{F}C_o}\ln\left(\frac{r_2}{r_1}\right) \quad [28]$$

In terms of the dimensionless parameters x and y, the current generated from $z = 0$ to $z = z$ is given by

$$i_z = 2\kappa\pi(r_2^2 - r_1^2)\frac{RT}{l\mathbf{F}}\left(\frac{dy}{dx}\right)_{x=x} \quad [29]$$

and the total current generated from $z = 0$ to $z = l$ by

$$i_t = 2\kappa\pi(r_2^2 - r_1^2)\frac{RT}{l\mathbf{F}}\left(\frac{dy}{dx}\right)_{x=1} \quad [30]$$

Equation [26], which is a second order differential equation, is not possible to solve analytically in the general case. It was replaced by a system of two first order equations and solved numerically employing the Runge Kutta technique. The calculations were conducted on an IBM 360/75 computer with FORTRAN IV programming.

The only unknown parameter was the exchange current density. The value of i_o was curve fitted to 6×10^{-6} A/cm^2 of internal surface area for all the tested electrodes.

The physical parameters determined before the dilactres method was applied are listed in Table I and the parameters determined with the dilactres method are listed in Table II. The effective pore length, l, in the model was calculated at $f \cdot L$.

The D, C_o, and κ-values for 5-9M KOH at 50°C are listed in Table IV.

D, the diffusion coefficient of oxygen in KOH solution and C_o, the solubility of oxygen in KOH, were calculated from data given by Davis, Horvath, and Tobias (26). D was calculated taking into account the deviations in temperature and viscosity from literature data. C_o was calculated taking into consideration the different P_{max} values, the varying atmosphere pressure, and the water vapor pressure variation with film electrolyte concentration. The electrolyte conductivity was measured in our laboratory with 5-9M KOH.

In Fig. 6 the theoretical and experimental polarization curves are compared. The D, C_o, and κ values are calculated for a constant electrolyte concentration of 5M KOH in the film. The theoretical current density, I_t (A/cm^2 of external surface area) was calculated as

$$I_t = i_t\frac{A^*}{2\pi r_2 l} \quad [31]$$

and $\eta = \eta_l$ at $z = l$

Theoretical polarization curves were also calculated for a hypothetical case where the electrolyte concen-

tration varied linearly from 5M at the fine pore layer/coarse pore layer intersection to 9M at the gas side of the coarse pore layer, but the curves were almost identical to the curves with constant electrolyte concentration. Maximally they differed a few millivolts for the largest current density.

In Fig. 9 the theoretical current distribution relations for three different I_t-values are shown for the electrodes A, B, and C. The theoretical ΔV_f-values, ΔV_{ft}, used to calculate the theoretical Z'-values, were calculated according to Eq. [16] as

$$\Delta V_{ft} = \frac{i_t f L}{\kappa \pi (r_2^2 - r_1^2)} \quad [32]$$

Table V shows the experimental Z'-values compared with the theoretical ones.

Discussion

In this study measurements were performed on porous gas diffusion electrodes in order to determine certain structure parameters and their influence on the behavior of these electrodes.

Regarding the absence of hysteresis when the differential air pressure was increased and decreased, respectively, indicates an "open structure" without ink-pot pores. The similarity between the dilatometry curves for the 16 and 1 cm² unloaded electrodes indicates rather homogeneous structures of the working electrodes. The similarity between the dilatometry curves when the electrodes were loaded indicates that the influence from the counterelectrodes could be neglected, after correction of the very slow continuous rise in the riser under current load, since the same counterelectrode size was used during all the experiments and consequently they were differently loaded without influencing the dilatometry curves.

The absence of differences in the dilatometry curves when the working electrodes were loaded from 0 to 0.2 A/cm² also indicates that for $P < P_{max}$ the liquid filled pores still have electrolyte concentrations nearly equaling the bulk electrolyte concentration. If that were not the case the curves in Fig. 4 should be shifted toward higher P-values, because the surface tension increases with increasing electrolyte concentration. The effect is certainly counteracted by increasing the differential pressure, but this effect is much smaller than the former. Regarding the investigated coarse pore layer thicknesses, the current was found not to be proportional to the thickness of the coarse pore layer. An electrode with a thin coarse pore layer (electrode A) generates more current per centimeter thickness than an electrode with a thick coarse pore layer (electrode C), which indicates that electrode C is utilized less effectively than electrode A despite the fact that electrode C has a much larger A^*-value.

The differential pressure required for funicular-pendular transition according to Katan and Grens II (17) was calculated. This pressure is well above the maximum differential pressure used in this investigation. This is confirmed by the fact that the activities in Fig. 5 do not decrease as the differential pressure is increased. However, it is hard to compare the highly regular silver sphere beds used in Ref. (17) with the pressed and sintered electrodes used in this investigation.

The rather low probe current density, 0.015 A/cm², used during the film resistance measurements was chosen in order to make sure that the electrolyte resistivity did not change to any great extent as a consequence of an increase in electrolyte concentration within the pores with increased probe current density. The fact that probe current densities of 0.005 and 0.010 A/cm² resulted in the same film resistance, within the confidence limits, was taken as a proof of a rather constant electrolyte resistivity. However, the confidence interval of Z' allows for a possible resistivity change corresponding to a concentration increase from 5 to about 6M KOH in the pores, because the changes in the resistivity with increased electrolyte concentration in this concentration range are rather small. A comparison between the interstice tortuosity values, s (Table II), shows that s is slightly increased when the thickness of the coarse layer is increased, which indicates that the average angle of the electrolyte filled interstices against the electrode surface increases, when ionic current is allowed to flow through the completely soaked electrode (A *vs.* C). The average angle is also increased when the coarse layer is compressed (A *vs.* B).

The relatively high film tortuosity values, f (Table II), can be attributed to the presence of narrow passages in the film network, the effect of which is more pronounced when the electrode is compressed.

The film resistance was investigated in order to estimate the resistance of the film network to hydroxyl ion transfer. The thin film of electrolyte has a relatively high effective specific resistance mainly due to its narrow cross section. This resistance directly in-

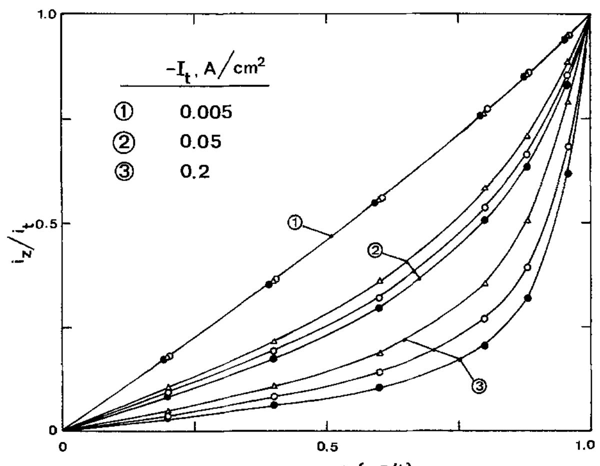

Fig. 9. Theoretical current distribution relations for three current densities. ○, Electrode A; △, electrode B; ●, electrode C.

fluences the effective mass transport of ion by making the latter more difficult.

The experimental Z'-values are of about the same magnitude as the resistance values predicted by the thin-film model (Table V). Noticeably electrode B has the greatest Z'-value despite its thicker film. This depends to a large extent on its relatively large effective pore length, $f \cdot L$.

Due to lack in proportionality between activity and coarse pore layer thickness, one might expect that only a small portion of the pore length is utilized for generation of the main part of the current. This is supported by the theoretical current distribution relations (Fig. 9) where approximately 50% of the current is generated in 10% of the pore length for a current density of 0.2 A/cm^2. This effect is more pronounced the higher is the value of the current density. Due to this mass transport effect, expressed by the Z'-values, higher current densities are supposed to concentrate the reaction toward the pore end, *i.e.*, toward the bulk electrolyte side of the pore. This also explains the small calculated activity differences mentioned above, when a linear concentration gradient was supposed to exist along the pore. So the way a large Z'-value influences the performance is not so much by increasing the ohmic polarization as by reducing the reaction zone.

The differences between the experimental and theoretical polarization curves in Fig. 6 at higher current densities can be partly explained by a possible blocking of the pores by nitrogen and lowering of the oxygen partial pressure inside the pore, which has not been accounted for in the model. This partial pressure lowering has the effect of extending the region of activity by lowering of the generated current at every point along the pore.

A higher KOH concentration than calculated in the reaction zone close to the fine pore layer also results in higher polarization due to lowering of the D and C_o-values.

It is obvious that one way of improving the electrodes in the high current density range, due to bad utilization of the effective pore length, would be to make the electrodes thinner, thereby reducing the internal mass transport. By doing so A^* is also reduced so these effects must be optimally balanced.

Conclusion

The dilactres method as described here has proved to be a valuable tool for the characterization of hydrophilic gas diffusion electrodes. The method allows determination of the structure parameters: interstice tortuosity, film tortuosity, effective specific film resistance, effective pore length, mean film thickness, and film area on operating electrodes.

These structure parameters were put into the equations according to the thin-film model. The experimental and calculated polarization curves as well as the experimental and calculated film resistance values are in relatively good agreement, indicating that the thin-film model rather appropriately describes the operation of the investigated electrodes in a practical current density range.

In conclusion, the structure parameters determined with the dilactres method seem to form a good base for optimization of hydrophilic porous gas diffusion electrodes.

Low Temperature Studies of Electrochemical Kinetics

II. Double Potential Step Chronocoulometry of Ethyl Cinnamate and Diethyl Fumarate

Roman D. Grypa*[,1] **and J. T. Maloy****

Department of Chemistry, West Virginia University, Morgantown, West Virginia 26506

ABSTRACT

Low temperature studies of the double potential step chronocoulometry (DPCC) behavior of ethyl cinnamate (EC) and diethylfumarate (DEF) have been conducted. The results have been compared with working curves obtained using digital simulation. At fixed concentration, both EC and DEF appear to undergo electrohydrodimerization through a radical anion dimerization mechanism at all temperatures employed (203°-316°K). Comparisons at different concentrations (C_B) reveal that the $Q(2t_f)/Q(t_f)$ behavior of DEF is a smooth function of t_fC_B, while that of EC is a smooth function of $t_fC_B^{1/2}$. Since the gross low temperature cyclic voltammetry of EC and DEF is identical, an ecc mechanism is proposed to account for this discrepancy in behavior with changes in C_B. On the basis of a radical ion dimerization mechanism, the rate constants for DEF and EC at 25° are 45 and 225 liters/mole-sec, respectively; activation energies are 4.6 and 6.2 kcal/mole.

In a previous paper (1), low temperature studies of the cyclic voltammetry of diethyl fumarate (DEF) were presented in an attempt to form some generalizations about the temperature dependence of the electrochemical processes associated with the electrohydrodimerization (EHD) reactions of diactivated olefins

$$\begin{matrix} R_1 & & H \\ & C = C & \\ H & & R_2 \end{matrix}$$

In that paper, it was observed that either two or three reduction processes occur, depending on the temperature: at high temperature only the reduction of the parent olefin and a dimeric product are observed, even though the second one-electron reduction of the olefin occurs at a potential intermediate to that of the two processes observed; at low temperature both one-electron reductions of the parent olefin may be observed because the temperature reduction has inhibited the dimerization reaction; at intermediate temperatures all three processes occur.

Extensive mechanistic studies have been conducted with DEF ($R_1 = R_2 = -CO_2Et$) using a variety of techniques. Double potential step chronoamperometry studies (2) have established that the EHD reaction of DEF probably proceeds through the dimerization of two radical ions; this judgment has been rendered on the basis of a comparison of experimental current-time data with working curves generated for a variety of proposed mechanisms using digital simulation techniques. The rate constant for the dimerization reaction at 25°C has been found to be 37 liters/mole-sec and the energy of activation has been estimated to be 4.5 kcal/mole using a two-point fit. Thus, DEF has been extensively characterized by voltammetric and chronoamperometric techniques; it is well suited as a model compound with which others may be compared.

Early room temperature voltammetric studies (3) of ethyl cinnamate (EC; above structure with $R_1 = -C_6H_5$ and $R_2 = -CO_2Et$) revealed the possibility of an additional chemical complication not observed in the DEF system. While DEF exhibits the characteristic 15-18% decrease in $i_p/v^{1/2}$ with increasing scan rate as predicted for a dimerization mechanism (4), EC exhibits a marked increase in $i_p/v^{1/2}$ ratio at slow scan rates. Since this behavior would be characteristic of a first-order ece mechanism, it was suggested that the dimerization of EC was influenced by this second kinetic perturbation; thus, two processes have been assumed to be in direct competition for the electrogenerated radical ion of EC. These differences have been discussed previously (1). Low temperature electrochemistry (5) appeared to offer some hope of resolving this mixed mechanism so that one of the proposed reaction routes could be enhanced at the expense of the other. This study was initiated, then, in the hope that the activation energies of these two purported processes were sufficiently different to permit their resolution. This objective was not attained. However, extensive double potential step chronocoulometry (DPCC) studies performed on the DEF and the EC system at several different temperatures and concentrations reveal that there is a significant difference be-

tween the two systems, while low temperature cyclic voltammetry (CV) studies indicate that some aspects of the two systems are very similar. These experiments and a discussion of their implications constitute the remainder of this work.

Experimental

Reagents, apparatus, and procedure have been discussed previously (1). Reagent grade ethyl cinnamate was supplied by Eastman Organic Chemicals; it was vacuum distilled at 123°C and 4 Torr and the middle 80% was stored in a desiccator prior to use. All electrochemical experiments were performed with a Princeton Applied Research Model 170 Electrochemical System using a positive feedback voltage to compensate for cell resistance at all temperatures. DPCC experiments were run at a variety of temperatures using initial and final potentials selected on the basis of CV experiments so that the electrode reaction proceeded under diffusion limiting conditions at all times. The duration of the interval between the initial and final potential step, t_f, was varied between 0.25 and 50 sec.

Voltammetry of Ethyl Cinnamate

Low temperature CV studies were performed on several dimethylformamide (DMF) solutions containing EC and using tetra-n-butyl ammonium iodide (TBAI) as the supporting electrolyte. Figure 1 shows a series of complete CV scans obtained for the EC system at various temperatures and scan rates. As in the case of DEF, as many as three reduction processes occur depending on the scan rate and the temperature. At 295°K, these three reduction processes occurred at −1.24, −1.86, and −2.05V *vs.* Ag-QRE. (The silver wire quasi-reference electrode was immersed in the DMF-TBAI solution at the temperature of the run.) Decreasing the experimental temperature to 203°K eliminated the third reduction peak and shifted the first two reduction peaks to −1.35 and −2.05V *vs.* Ag-QRE, respectively; the second reduction peak grew to become almost identical to the first reduction peak at low temperatures. If the experimental temperature was increased to 316°K, a decrease in the scan rate increased the size of the third reduction peak so that it approached one-half the height of the first reduction peak. At the same time, a decrease in scan rate decreased the size of the second reduction peak. This behavior is analogous to that of DEF.

Table I shows the dependence of the three reduction processes for the EC system upon the scan rate and temperature. A decrease in temperature increases the anodic to cathodic peak current ratio obtained for the first reduction wave from CV scanning just past the first reduction wave; at low temperatures, this ratio

approaches a maximum value of 1.0, indicating that the kinetic perturbation is inhibited at reduced temperature. However, anodic to cathodic peak current ratios obtained from *CV* scanning the entire potential range do not approach this maximum. At low temperatures, the height of the second reduction peak approaches that of the first reduction peak. If one goes to high temperatures, the ratio of the height of the third reduction peak to that of the first reduction peak increases as the scan rate is decreased. This ratio never exceeds 0.5 at high temperatures and slow scan rates. The arguments applied previously (1) to the DEF system can be applied to the EC system also; therefore, the $(i_{pc3}/i_{pc1})/(1-(i_{pa1}/i_{pc1}))$ ratio should be an approximate measure of the relative concentration of the species involved in the third reduction with respect to its radical anion precursor. This ratio should not exceed 0.5 (even in the absence of the second peak) if the third wave is due to the one-electron reduction of a dimeric product; that this is true is even more obvious in the case of EC than it was with DEF.

A summary of the CV data for the first reduction wave of EC at various temperatures is shown in Table II. Since resistance compensation was employed throughout, most of the increase in peak separation as the temperature is lowered may be attributed to the quasi-reversibility of the EC reduction (5). It may also be due to incomplete iR compensation because a QRE was employed (1). This effect with EC is not as pronounced as it is with DEF. The $(i_{pc}/C)(T/v)^{1/2}$ behavior shown is not unlike what one would expect for a dimerization mechanism; at scan rates lower than those in Table II, however, higher $(i_{pc}/C)(T/v)^{1/2}$ ratios were obtained at 295°K than would be expected in a simple dimerization.

Digital Simulations

Three different types of EHD mechanisms were considered possible in this study. The first was a second-order ece mechanism

$$R + e^- \longrightarrow R^{\overline{\cdot}}$$

$$R^{\overline{\cdot}} + R \xrightarrow{k_2} R_2^{\overline{\cdot}}$$

$$R_2^{\overline{\cdot}} + e^- \longrightarrow R_2^=$$

where the parent olefin is reduced at the electrode surface to form the radical anion, which reacts with incoming olefin in the rate-determining step to form a mononegative dimer which undergoes subsequent reduction at the initially applied potential to form the dimer dianion. The second was a second-order ec mechanism

$$R + 2e^- \longrightarrow R^=$$

$$R^= + R \xrightarrow{k_2} R_2^=$$

where the olefin undergoes an initial two-electron reduction to form the monomer dianion; this is followed by reaction with incoming olefin to produce the dimer dianion. The third was a second-order dimerization mechanism

$$R + e^- \longrightarrow R^{\overline{\cdot}}$$

$$2R^{\overline{\cdot}} \xrightarrow{k_2} R_2^=$$

in which the olefin undergoes an initial one-electron transfer to form the radical anion; this is followed by reaction with another radical anion to produce the dimer dianion. In each of these mechanisms, only the radical anion is regarded as electroactive after the second potential step.

Working curves for the kinetically perturbed DPCC experiment have been obtained through previously published digital simulation techniques (2). The simulation employed predicts the effect of both diffusion and chemical reactions on the measured current and charge parameters; it is generally accurate within ordinary electrochemical uncertainty (~1%). Figure 2 illustrates the working curves obtained for the three, second-order EHD reactions considered. Each of these working curves shows the variation of the ratio of the charge at time $2t_f$ to that at time t_f as a function of the logarithm of the product of the initial electrolysis time and the bulk concentration of olefin in solution, C_B. Variations in the shape of these curves are due to the mechanistic perturbation experienced by the formation of the radical anion of the diactivated olefin. The top curve represents the DPCC results expected in the second-order ece mechanism; the middle curve is that expected for the second-order ec mechanism; the bottom curve shows that expected for the dimerization mechanism. These working curves may be compared with data obtained experimentally to elucidate the reaction mechanism. The shape of best fit determines the preferred mechanism; thus the radical anion dimerization mechanism is indicated by lower experimental charge ratios at longer times. The dotted lines in Fig. 2 show the co-ordinates when $k_2t_fC_B$ is 1.0. Thus, the second-order rate constant may be obtained conveniently from the reciprocal of the t_fC_B product at the particular charge ratio indicated for each mechanism. For the second-order radical anion dimerization mechanism, the rate constant is the reciprocal of that t_fC_B product which gives a charge ratio of 0.69.

mine rate constants for each sample at different temperatures. Rate constants were determined by comparison of experimental charge ratios with theoretical working curves obtained from digital simulations.

Figure 3 illustrates fitting experimental data obtained at different temperatures to the simulated radical anion dimerization working curves for various concentrations of DEF. Attempts to fit the experimental charge ratios to either the second-order ec or ece working curves were unsuccessful because neither of these mechanisms agreed with the experimental data at both large and small charge ratios. At room temperature the rate constants obtained in this study agreed remarkably with previously reported kinetic data for the DEF system obtained using chronoamperometry (2). A reduction in temperature did not result in any observable change of the radical anion dimerization mechanism, as shown by the smooth fit of the experimental data to the simulated working curve. Only a decrease in the rate constant was obtained, as noted by the positive shift of the experimental points as the temperature was lowered.

The addition of a proton source to the DEF system caused no observable change in the apparent radical anion dimerization mechanism. This is shown on the left side of Fig. 3. These points give reasonable agreement with the dimerization working curve at all temperatures. Moreover, the addition of a proton source increases the rate constants for this system.

The decrease in rate constants with decreasing temperature is shown in Table III. A 100-fold decrease is obtained by reducing the experimental temperature from 295° to 203°K. The presence of 53 mM water increases the rate constant for DEF from 45 to 58 liters/mole-sec at 295°K. However, these rate constants also decrease as the experimental temperature is lowered.

Rate constants obtained from the DPCC experiments provide a valid method to determine the activation energy, E_a, of this radical anion dimerization reaction. Figure 4 shows a plot of log k_2 *vs.* $1/T$ used to determine the activation energy of these systems. A linear relationship is obtained by plotting the temperature dependence of experimental rate constants in this manner. Curve C represents the plot obtained for the DEF system. Curve B, that for DEF-H_2O, also exhibits a linear relationship. That these two lines are parallel indicates that these two systems have identical activation energies. The relatively small activation energies determined in this manner are shown in Table III; these agree well with that reported previously (2).

A somewhat different behavior can be observed when one compares the experimental data obtained for

Experimental temperature: (△ ○ □) 295°K; (▲ ◐ ◧) 253°K; (▲ ● ■) 223°K; (▲ ◑ ◨) 203°K. EC concentration: (■ ◨ ◧ □) 1.43 mM; (▲ ▲ ▲ △) 4.15 mM; (● ◑ ◐ ○) 14.89 mM.

the EC system with that obtained for the DEF system. The right-hand side of Fig. 5 illustrates that it is much more difficult to fit a radical anion dimerization working curve to this data. Charge ratios obtained from solutions having different bulk olefin concentrations do not appear to be the same smooth function of the $t_f C_B$ product as the charge ratios obtained for the DEF system appear to be. That is, one can fit a radical anion dimerization working curve through experimental data for a specific concentration, but no one line can be fit through the experimental data for a variety of concentrations. This effect does not appear to be due to the expected scatter of the experimental data. Close scrutiny of the data reveals that there is a regular variation in these plots with increasing bulk EC concentration. (This was not observed in the case of DEF.) This suggests that the charge ratio for EC might be shown as a smooth function of $t_f C_B{}^j$ (where $j \neq 1$); of course, this would have mechanistic implications because the over-all order of the reaction could be expressed (2) as $j + 1$.

Several different values of j were tried in an attempt to show the charge ratio for EC as a smooth function of $t_f C_B{}^j$. The best agreement of different concentrations at all temperatures was obtained by plotting these experimental points as a function of $t_f C_B{}^{1/2}$. (This implies that the rate-determining sequence is of 3/2 order over-all.) The curves to the left in Fig. 5 represent this. The dotted curves represent working curves for the 3/2-order reaction obtained through digital simulation. In these simulations, it was merely assumed that the conversion of $R^{\cdot-}$ to electroinactive product occurred by a 3/2-order step

$$\frac{d[R^{\cdot-}]}{dt} = -k[R^{\cdot-}]^{3/2}$$

The agreement in shape with the 3/2-order reaction is reasonable at all temperatures. The effect seems genuine; its meaning is open to interpretation.

Although low temperature DPCC studies were done with the hope of resolving a reported mixed mechanism, this expectation was not realized. Rate constants obtained by fitting the EC system to a second-order dimerization mechanism, therefore, are not strictly reliable. The rate constants measured at fixed concentration are probably proportional to the actual rate constants so that the activation energies determined in this manner are valid. For EC, curve A in Fig. 4 exhibits a greater slope than that for DEF and consequently, EC has a higher activation energy associated with it.

If one (improperly) assumes that EC reacts according to a second-order dimerization mechanism, it may be shown that the reaction of the anion of EC proceeds more rapidly than that of DEF. This may be seen in Table III; at room temperature, EC has a rate constant of 225 liters/mole-sec compared to one of 45 liters/mole-sec for DEF. As in the studies involving DEF, these rate constants decrease about 100-fold by lowering the experimental temperature to 203°K.

Discussion

Even though it was not possible to resolve any mixed mechanism for the EC system by temperature reduction, sufficient information has been obtained by comparing DEF and EC to raise some fundamental questions about the mechanism of EHD reactions. The DPCC experiments outlined above indicate clearly that the dimerization of EC does not exhibit the same concentration dependence as that of DEF, which is believed to proceed through radical anion coupling. On the other hand, low temperature CV experiments have established that the two compounds exhibit similar gross voltammetric behavior. There is reason to suspect that a cyclic product like that recently reported by Klemm and Olson (7) for EC results when DEF undergoes an EHD reaction also (1). Thus, whatever mechanism is invoked, it must account both for differences and similarities between the two compounds. In addition, it should account for the fact that the bulky EC radical ion reacts faster than the more compact DEF radical ion while experiencing a greater barrier to activation than the DEF ion experiences.

An appealing compromise exists in the invocation of an ecc mechanism not unlike that recently discussed by King (8). This mechanism would suggest that the initial step in the EHD reaction is a rapidly established equilibrium between two radical anions and a dimer dianion

$$2R^{\cdot-} \overset{K_{eq}}{\rightleftharpoons} R_2{}^{=}$$

Protonation of $R_2{}^{=}$ would result in R_2H^- which then could undergo a first-order cyclization reaction in the rate-determining step

$$R_2H^- \xrightarrow{k_1} \text{cyclic product}$$

This mechanism has the distinct advantage of appearing to be first order if Keq is large while appearing to be second order if Keq is small. An intermediate equilibrium constant results in an apparent reaction order somewhere between first and second order as observed

in the case of EC. [The necessary conditions for this are discussed in detail in Ref. (8).] Those mechanisms already reported as proceeding through a second-order dimerization pathway may only appear to do so because Keq is small.

This line of reasoning has some intuitive appeal. The substitution of a C_6H_5 group in EC for a CO_2Et group in DEF would probably increase the delocalization of the unpaired electron in the radical anion. This would tend to minimize the repulsive forces inhibiting dimerization, so that one would expect a larger equilibrium constant for EC than for DEF. Thus, the over-all rate of dimerization for EC may be faster than that of DEF and need not be of second order. If one believes that the rate-determining step is the cyclization reaction, this argument may also be applied to aid in the understanding of the difference in activation energies obtained. If this scheme is operative, the barrier to ring closure would be expected to be less in a CO_2Et-substituted compound like DEF than in a C_6H_5-substituted compound like EC, due to the added steric hindrance offered by the phenyl rings in the latter compound.

Of course, at this point, any discussion of an ecc mechanism of this sort is speculative. Other ecc mechanisms involving some sort of equilibrium step could exhibit the same 3/2-order dependence. Examples of these include: (*i*) the reaction of R and $R^{\cdot-}$ in the equilibrium step, followed by the catalytic regeneration of R through the reaction of $R_2^{\cdot-}$ with more $R^{\cdot-}$ to produce $R^{=}$; and (*ii*) the parallel *trans* dimerization of $R^{\cdot-}$ occurring simultaneously with *cis-trans* isomerization (the equilibrium step) followed by *cis-trans* dimerization. Neither of these mechanisms lead to the formation of the cyclic compound observed by Klemm and Olson in the rate-determining step, however. Regardless of the mechanism, none of the working curves simulated for this paper take the initial equilibrium into account. This step is, nevertheless, eminently amenable to treatment using digital simulation techniques. These simulations are presently underway and it is expected that their results will be the topic of a future communication.

Acknowledgment

Acknowledgment is made to the Donors of the Petroleum Research Fund, administered by the American Chemical Society, for the support of this research. This work was presented as Paper 322 at the 25th Annual Pittsburgh Conference on Analytical Chemistry and Applied Spectroscopy, Cleveland, Ohio, March 1974.

Manuscript submitted June 3, 1974; revised manuscript received Oct. 2, 1974.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1975 JOURNAL. All discussions for the December 1975 Discussion Section should be submitted by Aug. 1, 1975.

Publication costs of this article were partially assisted by the Petroleum Research Fund.

Charge Asymmetrical Ternary Molten Salt Systems: Theory of Dilute Solutions

Donald R. Sadoway* and S. N. Flengas**

Department of Metallurgy and Materials Science, University of Toronto, Toronto, Ontario, Canada M5S 1A4

ABSTRACT

The thermodynamic properties of dilute solutions of $MnCl_2$ in the ternary system $MnCl_2$-NaCl-CsCl have been investigated by the measurement of the reversible emf of the formation cell

$$Mn_{(s)} \mid MnCl_2(X_1) - NaCl(X_2) - CsCl(X_3) \mid Cl_2(g, 1\text{ atm}), C\text{ (graphite)}$$
(liquid)

The partial molar properties of $MnCl_2$ have been found to be in good agreement with values predicted by the complex-ion model reported in previous publications from this laboratory (1-3). In the present paper it is shown that these rather involved expressions reduce to useful, simple equations of the form

$$(\Delta Z)_{123} = (1 - t)\ (\Delta Z)_{12} + t(\Delta Z)_{13}$$

where Z represents either an integral or a partial molar property. The ternary solution is denoted by the subscripts 1,2,3, while the two binaries, each containing the reactive-metal chloride, are denoted by 1,2 and 1,3; t is a concentration variable. It is also shown that the following expression applies to the activity of the reactive-metal chloride (component 1) in solution

$$(a_1)_{123} = (a_1)_{12}{}^{1-t} \cdot (a_1)_{13}{}^{t}$$

For dilute solutions obeying Henry's law, the activity coefficients are given by

$$(\gamma_1)_{123} = (\gamma^0{}_1)_{12}{}^{X_2} \cdot (\gamma^0{}_1)_{13}{}^{X_3}$$

where $(\gamma^0)_{i,k}$ is the Henrian activity coefficient in the binary i,k and X_k is the mole fraction of k present in the ternary solution, providing that X_1 in the ternary 1,2,3 is the same as that in the two binary solutions 1,2 and 1,3.

Previous work in this laboratory has shown that the thermodynamic (1-3) and transport (4) properties of molten salt solutions consisting of a divalent-metal chloride and an alkali-metal chloride may be explained by a thermodynamic model which is based on the existence of tetrahedrally coordinated complex ions.

The complex ions are thought to form by reactions of the type

$$MX_2 + 2X^- \rightarrow MX_4{}^{2-} \quad [1]$$

The present treatment of complexing in fused salts follows postulates previously cited (1-4).

The process of mixing X_{MCl_2} moles of MCl_2 with X_{ACl} moles of ACl in a binary system MCl_2-ACl, where $X_{MCl_2} + X_{ACl} = 1$ and $0.33 > X_{MCl_2} > 0$, may be represented by the following two-step mechanism

$$X_{MCl_2}MCl_{2(l)} + X_{ACl}ACl_{(l)}$$
$$\rightarrow X_{MCl_2}A_2MCl_{4(l)} + (X_{ACl} - 2X_{MCl_2})ACl_{(l)}$$
$$\rightarrow \{(A_2MCl_4)_{X_{MCl_2}}(ACl)_{X_{ACl}-2X_{MCl_2}}\}_{\text{solution}} \quad [2]$$

The first of these reactions represents the formation of the pure complex compound, while the second represents the mixing process.

The detailed derivation of the expressions which describe the concentration dependence of the enthalpy of mixing and of the entropy of mixing in the MCl_2-ACl binary systems has been given elsewhere (2). The expressions have been found to represent to a high degree of accuracy the concentration dependence of the calorimetrically determined enthalpies of mixing reported by Papatheodorou and Kleppa (5-7) and by McCarty and Kleppa (8) in the reactive-metal chlorides $MnCl_2$-ACl, $FeCl_2$-ACl, $CoCl_2$-ACl, $NiCl_2$-ACl, $MgCl_2$-ACl, and $CdCl_2$-ACl, where A represents Li, Na, K, Rb, and Cs.

The corresponding mixing reactions and the relevant expressions for the concentration range $1.0 > X_{MCl_2} > 0.33$ also may be found elsewhere (1-3). These equations are not required for the purposes of the present study.

The partial molar properties of the $MnCl_2$-ACl systems were investigated in this laboratory (2) by an emf method, and their concentration dependence was found to be in excellent agreement with that predicted by the model. The expressions include a number of interaction parameters which have been shown (1, 2) to depend on the ionic radii of the species present in the various systems.

Further development of the model (3) has shown that the expressions for two binary systems such as MCl_2-ACl and MCl_2-BCl, where A and B are two different alkali-metal cations, may be expanded to predict the enthalpy of mixing of the combined ternary system MCl_2-ACl-BCl. In this case the process of mixing X_{MCl_2} moles of MCl_2 with X_{ACl} moles of ACl and X_{BCl} moles of BCl, where $0.33 > X_{MCl_2} > 0$ and $X_{MCl_2} + X_{ACl} + X_{BCl} = 1$, may also be represented by a two-step mechanism

$$X_{MCl_2}MCl_{2(l)} + X_{ACl}ACl_{(l)} + X_{BCl}BCl_{(l)} \rightarrow N_{A_2MCl_4}A_2MCl_{4(l)} + N_{B_2MCl_4}B_2MCl_{4(l)} + N_{ACl}ACl_{(l)} + N_{BCl}BCl_{(l)}$$
$$\rightarrow \{(A_2MCl_4)_{N_{A_2MCl_4}}(B_2MCl_4)_{N_{B_2MCl_4}}(ACl)_{N_{ACl}}(BCl)_{N_{BCl}}\}_{\text{solution}} \quad [3]$$

The important thing to note is that the over-all solution reaction is split into two steps. The first involves the formation of pure complex species, while the second represents the mixing process.

Key words: manganese chloride, complex formation, electromotive potential, thermodynamic properties.

In the Appendix the expressions which describe the concentration dependence of the integral enthalpy and entropy of mixing are given. It should be noted that the interaction parameters which appear in these equations are those representing the constituent binary systems MCl_2-ACl and MCl_2-BCl.

The model for ternary solutions, so far, has been tested with respect to only a few available calorimetric data on integral enthalpies of mixing (3) for concentrated solutions.

In the present investigation the partial molar properties of dilute solutions composed of $MnCl_2$ and various proportions of NaCl and CsCl have been investigated by an emf method involving the use of manganese chloride formation cells.

The mathematical expressions which describe the concentration dependence of the partial molar properties, and, particularly, their behavior in dilute solutions have been derived. The experimental results for partial molar enthalpies of mixing and activities of $MnCl_2$ are in excellent agreement with the theory even in the dilute concentration range where all the partial molar properties acquire limiting values. The ternary system $MnCl_2$-NaCl-CsCl was chosen as a test system because the $MnCl_2$-NaCl binary system shows only moderate deviations from ideality, while the $MnCl_2$-CsCl system is a highly reactive system with pronounced negative deviations from ideality. For example, the minimum integral molar enthalpy of mixing in the former is -1.8 kcal, compared to -5.3 kcal in the latter (5). Accordingly, the prediction of the behavior of such a ternary system should represent a severe test of any significant thermodynamic model.

Experimental

The electromotive force was measured for the cell represented schematically as

$$(-)\ Mn_{(s)} \left| \begin{array}{ll} MnCl_2 & (X_1) \\ NaCl & (X_2) \\ CsCl & (X_3) \end{array} \right| \begin{array}{l} \text{asbestos} \\ \text{diaphragm} \end{array} \left| \begin{array}{ll} MnCl_2 & (X_1) \\ NaCl & (X_2) \\ CsCl & (X_3) \end{array} \right| Cl_2\ (g, atm), C(graphite)\ (+)$$

In order both to establish electrical contact and to prevent the diffusion of chlorine gas to the manganese electrode, the cell consisted of two compartments joined by an asbestos diaphragm. Its fabrication is described elsewhere (15).

The cell reaction may be written as

$$Mn_{(s)} + Cl_2\ (g, 1\ atm) + [(MnCl_2)_{n1}(NaCl)_{n2}(CsCl)_{n3}] \rightarrow [(MnCl_2)_{n1+1}(NaCl)_{n2}(CsCl)_{n3}] \quad [4]$$

where the n's denote mole number.

The cell emf is related to the activity of manganese dichloride by the Nernst equation

$$E = E^\circ - \frac{RT}{2\mathbf{F}} \ln a_{MnCl_2} \quad [5]$$

where R is the ideal gas constant, equal to 1.987 cal/mole-°K, T is the temperature in Kelvins, $\mathbf{F}$ is the Faraday constant, equal to 23,060 cal/volt-equivalent, and E° is the standard formation cell potential of pure liquid $MnCl_2$ in volts at the same temperature T. The values of E° used in this study were previously determined in this laboratory (2).

The preparation of materials and cell design have been described elsewhere (2). The main improvement in the present apparatus was the use of vacuum-cast manganese rods as electrodes. These were 40 mm long and 6 mm in diameter connected to either platinum or tungsten leads. All emf's reported in the present work have been corrected for thermoelectric voltages determined experimentally.

The tube furnace used was wound with Kanthal wire. It had a 2 in. zone over which the temperature varied by 1°K. Melt depths never exceeded 1 in. Actually, temperature profiles were measured in several melts, and variations of the order of only 0.5°K were found. A grounded Inconel sheath was placed between the cell wall and the furnace tube to eliminate induced emf's from the a-c field of the furnace windings. Cell potential did not vary as power to the furnace was switched on and off.

In order to test for reversibility, all cells were subjected to a polarization test using an external dry cell. About 1 mA was passed through the experimental cell for approximately 60 sec. Cell voltages returned to within 0.5 mV of their values before perturbation less than 15 sec after the external dry cell had been disconnected. This observation was the same regardless of the polarity of the applied voltage.

The fact that voltages were reproducible over a period of 24 hr was also a demonstration of the cell's reversibility.

Results

Table I displays measured cell emf's which have been expressed as least squares lines of the form $E = a - bt$, where E is the cell potential in volts and T is temperature in Kelvins. Melt compositions are expressed in terms of both principal mole fractions, X_i, and the corresponding ternary concentration variables, y and t, defined as

$$t = X_{CsCl}/(X_{NaCl} + X_{CsCl}) \quad [6]$$

$$y = X_{NaCl} + X_{CsCl} = 1 - X_{MnCl_2} \quad [7]$$

Plots of cell potential *vs.* temperature are shown in Fig. 1 a-c. The concentrations of the solutions studied are shown on the inset composition triangle. An increase in the value of t from zero to unity at constant y represents a change in the composition of the solvent from NaCl-rich to CsCl-rich. The plots are linear and demonstrate that at a given concentration level of $MnCl_2$, as the CsCl concentration of the melt increases, the cell potential also increases.

Figure 2 shows emf isotherms at 810°C displayed on a plot of cell potential *vs.* $\log_{10} X_{MnCl_2}$ at various values of t. Experimental data are plotted, and the lines drawn through these points represent the best straight lines having a "two-electron" slope of $-RT/2\mathbf{F}$. Also included in the figure are measurements performed previously in this laboratory (2) on concentrated binary solutions of $MnCl_2$-NaCl and $MnCl_2$-CsCl. It may be seen that the results of the present study are consistent with those of Kucharski and Flengas (2) and reveal the anticipated extension to dilute solutions.

Table II displays partial molar enthalpies of mixing, partial molar entropies of mixing, activities, and activity coefficients of $MnCl_2$ calculated from the experimental results. The pertinent formulas are also given in the table.

Discussion

The Appendix traces the method by which the previously derived expressions [1]-[3], which describe the concentration dependence of an integral or a partial molar property in binary and ternary fused salt systems, may be reduced to useful simple equations of the form

$$(\Delta Z)_{123} = (1-t)(\Delta Z)_{12} + t(\Delta Z)_{13} \quad [8]$$

where Z represents any such property. The ternary solution is denoted by the subscripts 1, 2, 3, while the two constituent binary solutions are denoted by the subscripts 1, 2 and 1, 3. Component 1 is always the divalent metal chloride, and t is the concentration variable defined by Eq. [6].

It is worth noting that although the general expression, Eq. [8], was derived on the assumption of tetrahedrally coordinated complexes of the type

** Standard error of estimate.

A_2MCl_4, the corresponding treatment for complexes of the type $AMCl_2$ and A_2MCl_6 yields Eq. [8]. The compounds $KAg(CN)_2$ (9) and K_2ZrCl_6 (10) are examples of nontetrahedrally coordinated complexes. In addition, similar treatment of the previously derived thermodynamic relationships in the concentration range $1.0 > X_{MCl_2} > 0.33$ also yields Eq. [8]. Hence, Eq. [8] appears to be of general applicability in expressing the relationship between the thermodynamic properties of binary and ternary fused salt systems containing a reactive component.

If Z is taken to represent the partial molar enthalpy and entropy of component 1, $\overline{H}_1$ and $\overline{S}_1$, the relationship $RT \ln a_1 = \Delta\overline{H}_1 - T\Delta\overline{S}_1$ and Eq. 8 yield the following expression for the activity of MCl_2 in a ternary system

$$(a_{MCl_2})_{123} = (a_{MCl_2})_{12}^{(1-t)} (a_{MCl_2})_{13}^{t} \quad [9]$$

Equation [9] is valid when X_{MCl_2} has the same value in the ternary solution 1, 2, 3, as in the binary solutions 1, 2 and 1, 3. Equation [9] may be written in terms of activity coefficients as

$$(\gamma_{MCl_2})_{123} = (\gamma_{MCl_2})_{12}^{(1-t)} (\gamma_{MCl_2})_{13}^{t} \quad [10]$$

In very dilute solutions γ_{MCl_2} becomes independent of composition. As X_{MCl_2} approaches zero in a ternary solution, $(1 - t) \rightarrow X_{ACl}$, $t \rightarrow X_{BCl}$ and Eq. [10] may be written as

$$(\gamma_{MCl_2})_{123} = (\gamma°_{MCl_2})_{12}^{X_{ACl}} \cdot (\gamma°_{MCl_2})_{13}^{X_{BCl}} \quad [11]$$

where $(\gamma°_{MCl_2})_{12}$ and $(\gamma°_{MCl_2})_{13}$ represent the limiting values of γ_{MCl_2} at infinite dilution in the MCl_2-ACl and MCl_2-BCl binary systems, respectively, and X_{ACl} and X_{BCl} represent the mole fraction of ACl and BCl, respectively, in the ternary solution. Thus, with values of only the Henrian activity coefficient of MCl_2 in the two appropriate binary systems, Eq. [11] is able to estimate values of the activity coefficient of MCl_2 anywhere in the dilute region of the ternary system.

Table II shows a comparison between values of γ_{MCl_2} determined experimentally in the present study and values of γ_{MCl_2} calculated by Eq. [11]. For these calculations the values of γ_{MCl_2} at $X_{MCl_2} = 0.01$ in the appropriate binary solutions served as values for $(\gamma°_{MCl_2})_{ik}$. Good agreement is obtained between observed and predicted values.

Figures 3a and b show plots of log γ_{MCl_n} vs. t in the systems $NiCl_2$-NaCl-KCl (12) and $CoCl_2$-NaCl-KCl (13), studied by Hamby and Scott, and $MnCl_2$-NaCl-CsCl, studied in the present investigation. The linear-

(~) Values of $\gamma^\circ_{MnCl_2}$ in the two binary systems: $(\gamma^\circ_{MnCl_2})_{12} = 3.99 \times 10^{-2}$; $(\gamma^\circ_{MnCl_2})_{13} = 7.55 \times 10^{-4}$.

ity of these curves demonstrates the validity of Eq. [10] even for concentrated solutions. Figure 3b also includes data from the study by Pelton and Flengas (14) of the AgCl-NaCl-RbCl system. As expected, Eq. [10] is obeyed in this system, although AgCl is not a divalent transition-metal chloride and is not known to form tetrahedrally coordinated complexes.

The integral enthalpies of mixing in the binary systems, $MnCl_2$-NaCl and $MnCl_2$-CsCl, as well as those in the ternary system, $MnCl_2$-NaCl-CsCl, have been measured calorimetrically in this laboratory (12). Figure 4 shows plots of ΔH^{int}_{mix} *vs.* t at various fixed concentrations of $MnCl_2$. The linearity of these curves demonstrates the validity of the "t-fraction average" rule proposed herein.

The least squares analysis of these data revealed linearity to 99.9% confidence limits. It should be noted that Eq. [A-5] is observed in solutions highly concentrated in $MnCl_2$.

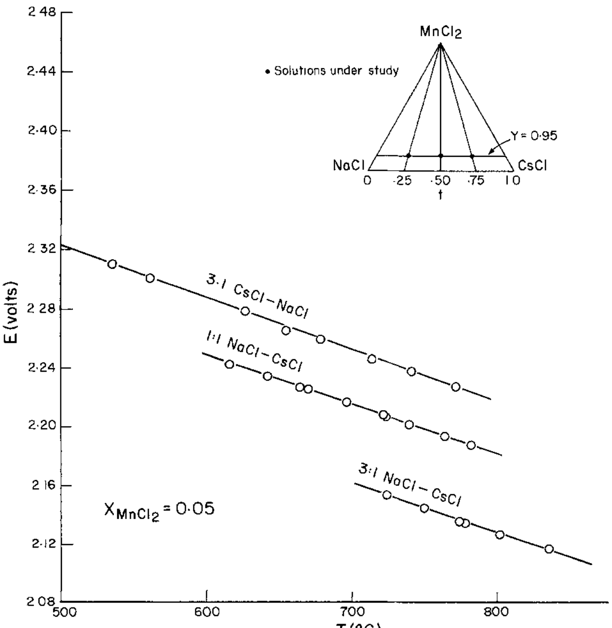

Fig. 1c. Temperature dependence of emf in the system $MnCl_2$-NaCl-CsCl at $X_{MnCl_2} = 0.05$.

The partial molar enthalpies of $MnCl_2$ in the binary systems $MnCl_2$-NaCl and $MnCl_2$-CsCl have been measured in this laboratory by an emf method (2). In the present study $\Delta\bar{H}_{MnCl_2}$ has been determined for dilute solutions in the ternary system, $MnCl_2$-NaCl-CsCl. Figure 5 shows a plot of $\Delta\bar{H}_{MnCl_2}$ *vs.* t for $X_{MnCl_2} = 0.01$. By statistical analysis this curve is found to be linear within 99.9% confidence limits, as expected from the theoretical treatment.

Thus, by the use of Eq. [A-5], [A-6], [10], and [11] the thermodynamic behavior of MCl_2 in the ternary solution, MCl_2-ACl-BCl, is completely characterized by expressions which contain thermodynamic quantities representing only the binary solutions, MCl_2-ACl and MCl_2-BCl. Table II also includes partial molar enthalpies and activities predicted by the theory. The binary data used for these calculations, with the exception of values for ΔS_R, were those determined by Kucharski and Flengas (2) in their emf study of the binary systems, $MnCl_2$-NaCl and $MnCl_2$-CsCl. Values for ΔS_R in the present study were determined from

the slope of a plot of log $\gamma^{\circ}_{MnCl_2}$ *vs.* $1/T$ in the appropriate binary systems.

Conclusions

The treatment of binary and ternary fused salt solutions in terms of a thermodynamic model has led to the derivation of simple expressions which relate the thermodynamic properties of ternary fused salt solutions to the properties of constituent binary solutions. The relationship in generalized form is summarized by Eq. [8] which contains only experimentally determinable quantities and which may be used without detailed knowledge of the thermodynamic model.

Limiting laws for dilute solutions have also been derived. The expressions have been verified by the results of the present investigation of the system $MnCl_2$-NaCl-CsCl, as well as by the results of several other ternary systems in the literature. The applicability of these expressions to a range of systems suggests that the structural model on which the derivations are based is physically meaningful.

APPENDIX

Expressions for the Thermodynamic Properties of Ternary Solutions of the Type MCl_2-ACl-BCl Derived from the Complex Ion Model (3)

For a melt having the primary composition X_{MCl_2}, X_{ACl}, and X_{BCl}, where $0 < X_{MCl_2} < 0.33$, the reactions

$$MCl_2 + 2ACl \rightarrow A_2MCl_4 \quad [A\text{-}1]$$

$$MCl_2 + 2BCl \rightarrow B_2MCl_4 \quad [A\text{-}2]$$

produce new species.

The expression which describes the concentration dependence of the enthalpy of mixing in the ternary system MCl_2-ACl-BCl has been derived elsewhere (3).

For a solution of composition $0 < X_{MCl_2} < 0.33$ the molar integral enthalpy of mixing is given by

$$\Delta H^{int}_{mix} = (1-y)[(1-t)(b_R)_{12} + t(b_R)_{13}] + \frac{(1-y)^2(2-3y)}{(2y-1)^2}[(1-t)(2b_1+b_2)_{12} + t(2b_1+b_2)_{13}] + \frac{2(3y-2)^2(1-y)}{(2y-1)^2}[(1-t)(2b_1+b_2)_{12} + t(2b_1+b_2)_{13}] - \frac{(1-y)(3y-2)^2}{(2y-1)^2}[(1-t)(3b_1+b_2)_{12} + t(3b_1+b_2)_{13}] + \frac{2(1-y)^2(3y-2)}{(2y-1)^2}[(1-t)(b_1+b_2)_{12} + t(b_1+b_2)_{13}] \quad \text{[A-3]}$$

By a rearrangement of terms Eq. [A-3] is further reduced to

$$\Delta H^{int}_{mix} = (1-y)[(1-t)(b_R)_{12} + t(b_R)_{13}] + \frac{(3y-2)(1-y)}{(2y-1)^2}\{(3y-2)[(1-t)(b_1)_{12} + t(b_1)_{13}] + (2y-1)[(1-t)(b_2)_{12} + t(b_2)_{13}]\} \quad \text{[A-4]}$$

where the interaction parameters b_R, b_1, and b_2 are defined by equations 14 and 18 of Ref. (2) and have values determined in the appropriate binary system.

The substitution of y by its equivalent, $1 - X_{MCl_2}$, in Eq. [A-4] followed by factoring and comparison of the resulting expression with the corresponding expressions for the binary systems yields the much simpler relationship

$$\{\Delta H^{int}_{mix}(X_{MCl_2}, t)\}_{123} = (1-t)\{\Delta H^{int}_{mix}(X_{MCl_2})\}_{12} + t\{\Delta H^{int}_{mix}(X_{MCl_2})\}_{13} \quad \text{[A-5]}$$

which is valid when the concentration of MCl_2 in the ternary solution 1, 2, 3 is the same as that of the two constituent binary solutions, 1, 2 and 1, 3. The expressions for ΔH^{int}_{mix12} and ΔH^{int}_{mix13} are given by equation 19 of Ref. (2).

Partial differentiation of Eq. [A-4] followed by rearrangement of terms yields the result

$$\{\Delta \overline{H}_{MCl_2}(X_{MCl_2}, t)\}_{123} = (1-t)\{\Delta \overline{H}_{MCl_2}(X_{MCl_2})\}_{12} + t\{\Delta \overline{H}_{MCl_2}(X_{MCl_2})\}_{13} \quad \text{[A-6]}$$

The integral entropy of mixing may also be treated as the sum of two terms: an internal entropy change associated with reactions [A-1] and [A-2] and a configurational entropy change due to the mixing of the products of these reactions. Since it is assumed that there is no interaction between A_2MCl_4 and B_2MCl_4, the internal entropy change is given by

$$\Delta S^{internal} = (1-y)[(1-t)(\Delta S_R)_{12} + t(\Delta S_R)_{13}] \quad \text{[A-7]}$$

where $(\Delta S_R)_{12}$ and $(\Delta S_R)_{13}$ are the molar entropies of formation of pure A_2MCl_4 and B_2MCl_4, respectively. The configurational term is given by

$$\Delta S^{configurational} = -R[N_i \Sigma \ln N_i] \quad \text{[A-8]}$$

where N_i is the ionic fraction of species i and the summation is extended over all ionic species present in the reacted system.

Accordingly, the molar integral entropy of mixing in the ternary system MCl_2-ACl-BCl for the composition range $0.33 > X_{MCl_2} > 0.0$ is given by

$$\Delta S^{int}_{mix} = (1-y)[(1-t)(\Delta S_R)_{12} + t(\Delta S_R)_{13}] - R\left[(1-t)\ln(1-t) + t\ln t + \frac{(1-y)}{(2y-1)}\ln\frac{(1-y)}{(2y-1)} + \frac{(3y-2)}{(2y-1)}\ln\frac{(3y-2)}{(2y-1)}\right] \quad \text{[A-9]}$$

Rearrangement of terms, substitution of $y = 1 - X_{MCl_2}$, and comparison of the expression for the binary systems yields the much simpler expression

$$\{\Delta S^{int}_{mix}(X_{MCl_2}, t)\}_{123} = (1-t)\{\Delta S^{int}_{mix}(X_{MCl_2})\}_{12} + t\{\Delta S^{int}_{mix}(X_{MCl_2})\}_{13} \quad \text{[A-10]}$$

Partial differentiation of Eq. [A-10] followed by substitution of $y = 1 - X_{MCl_2}$ gives

$$\Delta \overline{S}_{MCl_2} = (1-t)(\Delta S_R)_{12} + t(\Delta S_R)_{13} - R\ln\frac{X_{MCl_2}(1-2X_{MCl_2})}{1-3X_{MCl_2}} \quad \text{[A-11]}$$

The logarithmic term may be factored to give

$$\Delta \overline{S}_{MCl_2} = (1-t)\left[(\Delta S_R)_{12} - R\ln\frac{X_{MCl_2}(1-2X_{MCl_2})}{(1-3X_{MCl_2})^2}\right] t\left[(\Delta S_R)_{13} - R\ln\frac{X_{MCl_2}(1-2X_{MCl_2})}{(1-3X_{MCl_2})^2}\right] \quad \text{[A-12]}$$

Comparison of Eq. [A-12] with equation 47 of Ref. (2) gives

$$\{\Delta \overline{S}_{MCl_2}(X_{MCl_2}, t)\}_{123} = (1-t)\{\Delta \overline{S}_{MCl_2}(X_{MCl_2})\}_{12} + t\{\Delta \overline{S}_{MCl_2}(X_{MCl_2})\}_{13} \quad \text{[A-13]}$$

These equations demonstrate that the values of the integral and partial molar enthalpies and the integral and partial molar entropies of mixing in a ternary solution are the "t-fraction average" of the corresponding properties in the two constituent binary solutions having the same MCl_2 concentration as the ternary solution.

The Triangular Voltage Sweep Method for Determining Double-Layer Capacity of Porous Electrodes

IV. Porous Carbon in Potassium Hydroxide

E. G. Gagnon*

Electrochemistry Department, General Motors Research Laboratories, Warren, Michigan 48090

ABSTRACT

Triangular sweep voltammetry data for a number of commercially available carbons in 31 weight per cent KOH are discussed. A capacity minimum of 10 μf/cm^2 was observed about 0V *vs.* Hg/HgO for five carbon blacks. Results indicated that the carbon blacks with internal structure were completely wetted; results with one activated carbon having fine micropores (<25Å) indicated partial wetting. Experimental methods for minimizing faradaic current and distributed capacity effects are discussed.

Many electrochemical processes involve porous electrodes. To optimize porous electrode design for specific applications, it is necessary to know how much of the internal structure of the porous electrode is actually used during the reaction. Although the BET surface area method is often used for this purpose, it does not always give a reliable estimate of the surface area available for electrochemical reaction. One method of determining the wetted surface area available for electrochemical reactions involves a measurement of the double-layer capacity (DLC) of the electrode-electrolyte interface using the triangular voltage sweep (TVS) technique (1). However, complicating effects may arise with porous electrodes due to distributed capacity (*i.e.*, nonuniform reactions through the electrode) and faradaic current (2). These effects must be eliminated or at least minimized. This paper shows how the TVS technique was used to determine the wetted surface area of several commercially available carbons in KOH.

Theory

Faradaic currents are often caused by processes which are complex and difficult to describe mathematically (*e.g.*, removal of impurities on the electrode surface or the adsorption of species present in the solution). Distributed capacity effects arise when the exterior surface of the porous electrode charges or discharges faster than the interior. An increase in the resistance of the electrolyte in the pores of the electrode enhances this effect. Four cases of interest have been previously discussed (2) for the TVS method and some of the essential features pertinent to this study are summarized in Fig. 1. The triangular sweep voltammetry data for the cases discussed apply to potential regions where the capacity is constant.

It has been demonstrated (2) that faradaic currents can be eliminated, or at least minimized, by testing at lower temperatures. [A precise definition of what is meant by low temperature depends upon the physical properties of the porous electrode and the electrolyte (3).] At lower temperatures, distributed capacity effects can become quite serious. Likewise, the use of high surface area materials can give rise to severe distributed capacity effects, even at room temperature. The principal equations describing this effect are summarized below. In the absence of faradaic current, the current-time curve in region abc (Fig. 1C) can be predicted from

$$i(L) = \beta_1 kC' \qquad [1]$$

$$\beta_1 = f_1(\psi, t/\rho_e C'L) \qquad 0 \leqq \beta \leqq 1$$

$$\psi = L\lambda/d$$

and the current-time curve is region cde (Fig. 1C) can be predicted (3) from

$$i(L) = \gamma kC' \qquad [2]$$

$$\gamma = f_2(\psi, t/\rho_e C'L) \qquad 1 \geqq \gamma \leqq -1$$

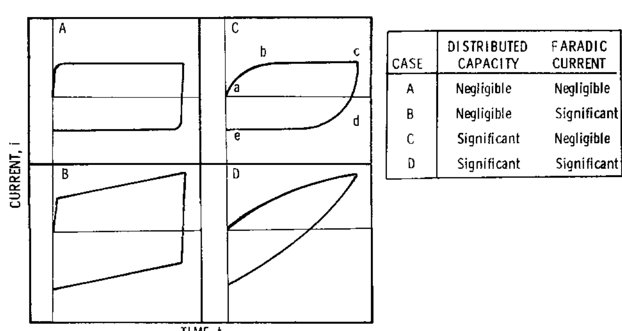
where $i(L)$ is the current density at the face of the porous electrode; k is the sweep rate; C' is capacity based upon the geometric area of the electrode thickness, L; λ is the labyrinth factor; d is the distance between the tip of the Luggin capillary and the surface of the test electrode; t is time; ρ_e is the effective specific resistance of the electrolyte in the pores of the electrode.

Predicted and experimental results (2, 3) have shown that as time decreases, or as the specific resistance of the electrolyte increases, distributed capacity effects become more severe.

The electrical double-layer at the electrode-electrolyte interface has a thickness of only a few angstroms in concentrated electrolytes and therefore follows the microcontours of the surface. Thus the DLC of the electrode is proportional to surface area at least in potential regions where capacity is constant and faradaic current and distributed capacity effects are negligible. With high surface area materials, severe distributed capacity effects can arise (see Eq. [1] and [2]), but the effects can often be minimized experimentally.

Experimental

Materials.—Five commercially available carbon blacks and one activated carbon were used. Table I gives the specific BET surface area of each carbon and the percentage of internal surface estimated using



CASE	DISTRIBUTED CAPACITY	FARADIC CURRENT
A	Negligible	Negligible
B	Negligible	Significant
C	Significant	Negligible
D	Significant	Significant

$$\frac{A_{BET} - A_d}{A_{BET}} \times 100$$

where A_{BET} is the BET surface area and A_d is the surface area calculated from the average particle size dimensions and a volume-to-area ratio of $(4/3\pi r^3)/4\pi r^2 = r/3$ where r is the average particle radius. Table II gives the source of the carbons used and the heat-treatments used to stabilize the carbon properties by removing impurities and increasing the electrical conductivity. Each carbon was supported on unpressed porous nickel MetNet (4) disks having a geometric area of 9.6 cm². The MetNet disks were dipped for several minutes into suspensions of carbon and reagent grade isopropyl alcohol (10g carbon/400 ml IPA). The electrodes were then air-dried at 100°C.

Procedures.—Details of the electrochemical cell, the Teflon test electrode holder, and preparation of the solutions are given elsewhere (5). An Hg/HgO [31 weight per cent (w/o) KOH] reference electrode with a Luggin capillary was used. The complete cell and the reference electrode were assembled in a constant-temperature cabinet. Prior to all testing, the electrolyte was equilibrated at the test temperature for periods of at least 18 hr. After the electrodes were immersed in the KOH, they were potentiostated at −0.50V *vs.* Hg/HgO for several hours to consume the dissolved oxygen in the pores of the electrode; no other precautions were taken to deaerate the KOH.

Triangular voltage sweeps (TVS) were performed using a potentiostat in conjunction with a signal generator; an X-Y recorder plotted current as a function of potential, from which capacities were calculated. In all of the tests, small voltage excursions of 140 mV were used to minimize transient faradaic currents in order to determine capacity solely as a function of potential. Experimental conditions were selected to allow the individual voltammetry sweeps to superimpose, giving an envelope of potential *vs.* current. Capacities were calculated from

$$C = i/k$$

where C is capacity (farads), i is current (mA), and k is sweep rate (mV/sec).

Results and Discussion

Carbon blacks.—Proper experimental conditions had to be determined for each carbon black. For example, Fig. 2 shows a composite of three single TVS curves for 82 mg of sample E (Table III) supported on MetNet in 31 w/o KOH at 21°C. Each sweep begins at a different potential, covers a voltage excursion of 140

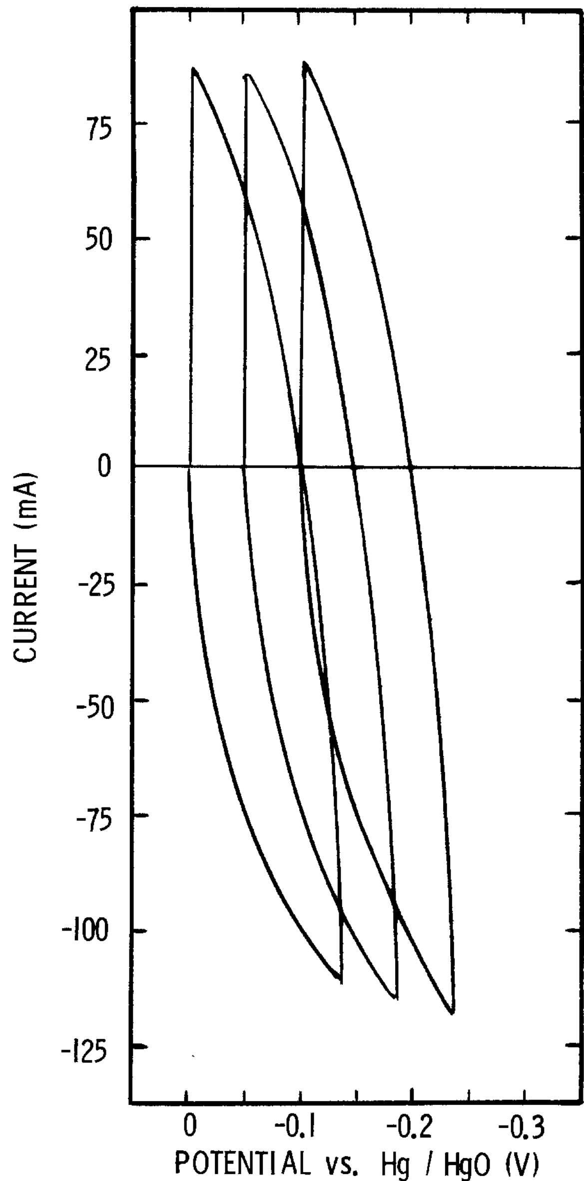

Fig. 2. TVS results for sample E at 21°C; $k = 60$ mV/sec

mV, and has the same sweep rate of 60 mV/sec. The results show severe distributed capacity effects (Fig. 1C) with perhaps some additional contributions of faradaic current (Fig. 1D). Decreasing the sweep rate by an order of magnitude to 6 mV/sec (Fig. 3) markedly reduces the distributed capacity and faradaic current effects. Only a small faradaic current effect is

[1] All capacity values were determined using a sweep rate of 6 mV/sec except for sample F which required a sweep rate of 0.6 mV/sec.
[2] After soaking in KOH for 2 days.

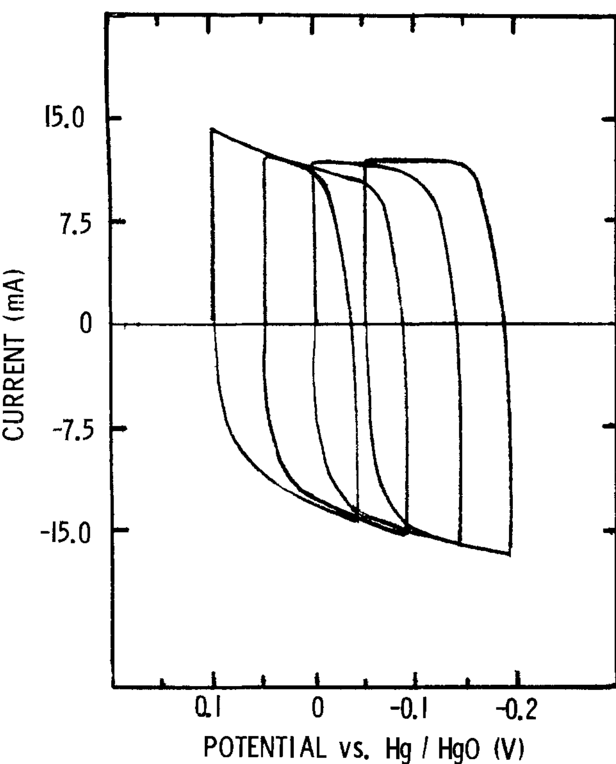

Fig. 3. TVS results for sample E at 21°C; $k = 6$ mV/sec

seen in the cathodic direction. The voltammetry data superimpose to form an envelope of potential *vs.* current where the minimum in the vicinity of 0V *vs.* Hg/HgO (anodic direction) corresponds to a capacity, $C_{min}{}^{a}$ of 1.87f or $C^{*} = 9.9$ μf/cm^2, based upon the BET surface area of the carbon. The effect of lowering the temperature to -46°C, while keeping the sweep rate at 6 mV/sec is seen in Fig. 4. At the lower temperature faradaic current is markedly reduced (compared to the 21°C data, Fig. 3), but distributed capacity effects are slightly enhanced; the capacity minimum, $C_{min}{}^{a}$ is 1.70f or $C^{*} = 9.3$ μf/cm^2 and are slightly lower than the 21°C values.

To determine the reliability of the capacity data, a different loading of sample E was tested. If capacity is constant and both faradaic current and distributed capacity effects are negligible, a plot of capacity *vs.*

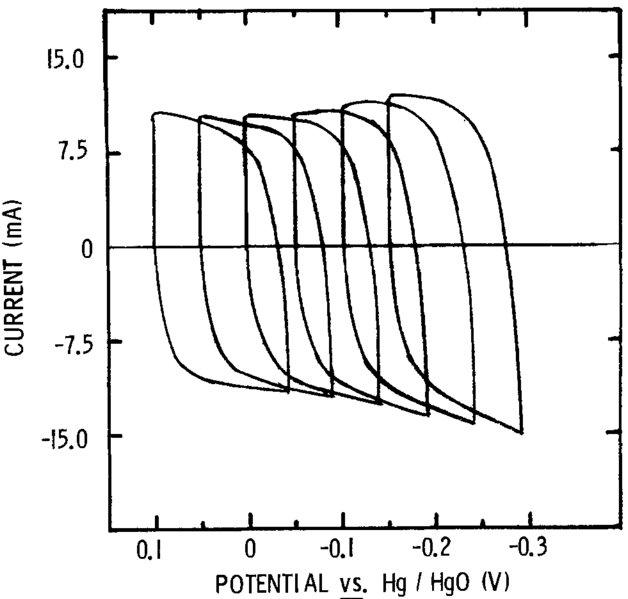

Fig. 4. TVS results for sample E at -46°C; $k = 6$ mV/sec

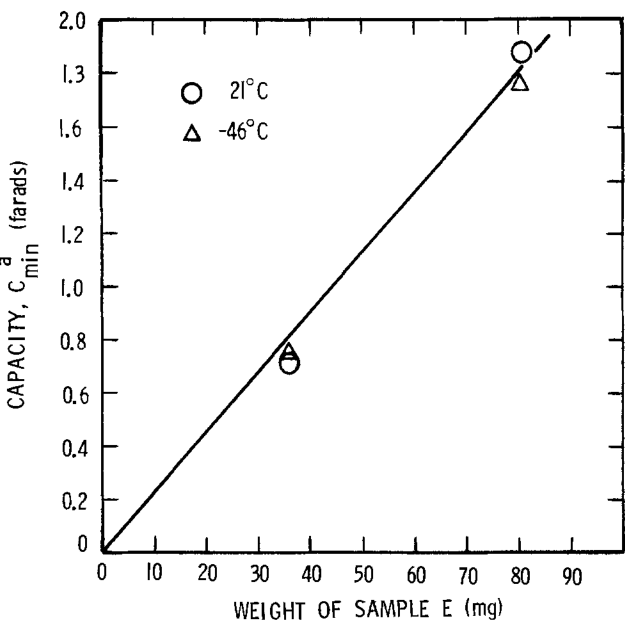

Fig. 5. Capacity *vs.* weight of sample E at 21°C and -46°C; $k = 6$ mV/sec.

sample weight should be linear. Figure 5 shows such a plot to be linear giving an average capacity, C^{*}, of 9.8 μf/cm^2 (based upon the BET surface area of 230 m^2/g).

Figure 6 shows a near parabolic dependency of current (hence capacity) with potential for sample E at -46°C; similar results were also observed for the other carbons tested.

Table III gives a compilation of capacity values obtained for all of the carbons tested; included are values obtained at 21° and -46°C and for different loadings wherever possible. Figure 7 shows that the plot of $C_{min}{}^{a}$ *vs.* BET surface area using all of the carbon black data is linear with a slope of 9.6 μf/cm^2. This average value is in good agreement with results by Soffer and Folman (6) where integral capacities of 10.7 and 9.5 μf/cm^2 were found for blocks of porous carbon.

Two of the carbon blacks had internal structure (samples C and E), whereas the others did not (Table I). Results in Fig. 7 suggest that the internal structures of samples C and E were completely wetted by the KOH, and that the technique gives a reliable estimate of the wetted surface area available for electrochemical reaction.

The capacity-potential curves in the region of the minimum (Fig. 6) take the form of a shallow parabola and are similar in shape to results reported by Randin and Yeager (7) using stress annealed pyrolytic graphite. The capacity at the minimum ($\sim$10 μf/cm^2) is also lower than that of metallic electrodes under similar conditions [*i.e.*, approximately 30 μf/cm^2 (1, 2) for

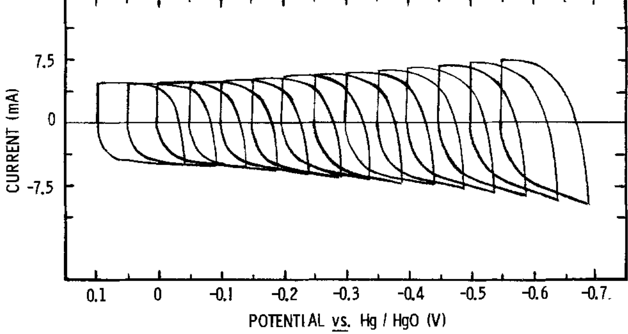

Fig. 6. Effect of potential with sample E at -46°C; $k = 6$ mV/sec.

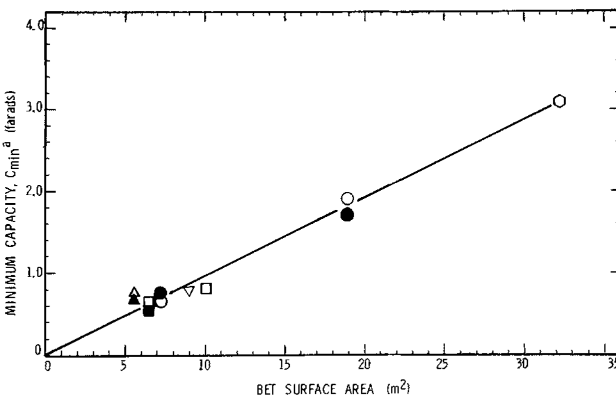

Fig. 7. Minimum capacity vs. BET surface area for commercially available carbon blacks. △ Sample A at 21°C; ▲ sample A at −46°C; ▽ sample B at 21°C; ⬡ sample C at 21°C; □ sample D at 21°C; ■ sample D at −46°C; ○ sample E at 21°C; ● sample E at −46°C.

silver and nickel in 31 w/o KOH]. Since carbon is a semiconductor and has a space charge region, the observed capacity at an electrode-electrolyte interface should reflect this property. Thus, in concentrated electrolytes where diffuse double-layer effects can be considered negligible, one would expect that

$$\frac{1}{C^*} = \frac{1}{C_{DL}} + \frac{1}{C_{sc}} \qquad [3]$$

where C_{DL} is the ionic double-layer capacity and C_{sc} is the space charge layer capacity. A rough estimate of C_{sc} for the carbon blacks is 15 $\mu f/cm^2$ using C_{DL} = 30 $\mu f/cm^2$ and C^* = 10 $\mu f/cm^2$. The C_{sc} value is higher than that reported by Randin and Yeager (7) for stress annealed pyrolytic graphite and is subject to some question. On the other hand, one would not expect carbon blacks to behave the same as pyrolytic graphite. Bauer *et al.* (8) have reported vast differences in capacity data for pyrolytic graphites as a function of electrode preparation. C_{sc} is known to vary in a hyperbolic cosine manner with potential (9) which would explain the parabolic shape observed in the vicinity of the capacity minimum (Fig. 6). Therefore, regardless of the precise value of C_{sc}, it does appear to contribute to the capacity of the carbon-electrolyte interface as suggested in Eq. [3], tending to give a lower apparent capacity than that normally seen with metallic electrodes.

Activated carbon.—The capacity of sample F (Table III), an activated carbon with a specific BET surface area of about 910 m^2/g (after heat-treatment, Table II) increased with soak time and leveled off at a steady value after 2 days of immersion; a different loading showed the same type of behavior. (In general, with the carbon blacks a steady value was achieved within hours of immersion and in some cases within minutes.) Capacitites at the minimum (Table III) were about 45% of the values expected assuming that activated carbon has the same specific double-layer capacity as carbon blacks. This indicates that the internal structure of the activated carbon may not have been completely wetted by the KOH. A pore size distribution for sample F shows that about 42% of the material has pore sizes less than 25Å, whereas for the carbon blacks, most of the pores are in the range of 20-60Å. It would appear that below a certain critical pore size, the internal microporous structure of the activated carbon is not readily accessible to the KOH. This might also account for the slower rate of wetting experienced with the activated carbon than with the carbon blacks.

Conclusions

Capacity data determined using the triangular voltage sweep technique were used to estimate the wetted surface area of a variety of commercially available carbons.

A capacity minimum of 10 $\mu f/cm^2$ was observed in the vicinity of 0V *vs.* Hg/HgO for all of the five carbon blacks. The low value compared to metallic electrodes was explained in terms of a contribution due to a space charge layer which exists in semiconductors. Likewise, semiconductor theory was used to explain a near-parabolic dependence of capacity on potential.

Results indicated that the carbon blacks which had some internal structure were completely wetted by the KOH.

Severe distributed capacity effects were observed especially with some of the higher surface area materials. The effects were consistent with that predicted using a previously developed model (3) and therefore could be minimized using suitable experimental techniques.

Capacity data for the one high surface area activated carbon tested indicated that about 45% of the internal structure of the material was not accessible to the KOH. This was presumably due to the presence of very fine micropores which exist in some activated carbons (<25Å).

A_{BET}	BET surface area, m^2/g
A_d	surface area calculated from the average size dimensions of the carbon particles, m^2/g
C	capacity, farads
C'	capacity based upon the geometric area of the electrode, $\mu f/cm^2$
C_{min}^a	anodic capacity minimum, farads
C^*	capacity per BET surface area, $\mu f/cm^2$
C_{DL}	ionic double-layer capacity, $\mu f/cm^2$
C_{sc}	space charge layer capacity, $\mu f/cm^2$
d	distance between the tip of the Luggin capillary and the surface of the electrode, cm
i	current, mA
$i(L)$	current density at the face of the electrode, mA/cm^2
k	sweep rate, mV/sec
L	electrode thickness, cm
r	average particle radius, m
t	time, sec
β_1	dimensionless parameter between 0 and 1, which is a function of $(\psi, t/\rho_e C'L)$
γ	dimensionless parameter between +1 and −1, which is a function of $(\psi, t/\rho_e C'L)$
ψ	dimensionless parameter $(L\lambda/d)$
λ	labyrinth factor
ρ_e	effective specific resistance of the electrolyte in the pores of the electrode, ohm-cm

Brief Communications

Accelerated Corrosion Test to Determine the Continuity of Thin Oxide Films on Aluminum

Neil T. McDevitt and William L. Baun

Air Force Materials Laboratory, Mechanics and Surface Interactions Branch, Wright-Patterson Air Force Base, Ohio 45433

Over the past year the aircraft industry has been studying more closely the anodization of aluminum alloys as a surface preparation of structural adhesive bonding. The technical application of the anodization of aluminum that produces a thick (>2.5 μm) surface oxide, that resists weathering and deterioration, are well known (1). However, in order for an adhesive to form an integral bond with the metal adherend, the surface oxide layer has to be thin compared to films formed by present day procedures. Consequently, very little information has been generated on thin (<0.2 μm) anodic oxide films on aluminum. The quality of this thin oxide film will determine the amount of corrosion protection the aluminum metal will receive and, therefore, add to the durability of the formed adhesive bond. In this case, quality will be determined by the continuity of the surface oxide film over the area anodized. Present day test methods usually rely on salt spray exposure or immersion in sodium chloride solution to determine the protection offered by a surface oxide film. These tests normally require some 16-50 hr to perform (2). In order to study a large number of different electrolytes with varying anodization parameters, it would be essential to have a test that would require less time and equipment than the above procedures.

This paper describes the use of the iodine-methanol technique (3) and its ability to determine the continuity of thin anodic oxide films. This technique has been used extensively for isolating oxide films from aluminum. The chemistry of the primary reaction involves the attack of iodine-methanol solution on aluminum and its alloys, with no quantitative indication of any attack on the surface aluminum oxide hydroxide (AlOOH). Ideally then, this solution may be used to determine cracks, flaws, or porosity of thin oxides generated by various methods. Utilizing the above reaction, a solution containing 5g iodine/100 ml absolute methanol, in a covered petri dish, can determine the continuity of a film within 1-8 hr, which we define here as an accelerated corrosion test (ACT). With this method, a number of electrolytes, along with various anodization parameters, may be studied in a relatively short period of time in order to achieve a thin oxide film having maximum continuity. Two drawbacks of the ACT solution are: (*i*) the main product of the reaction (aluminum methoxide) is insoluble in anhydrous methanol, and (*ii*) trace amounts of water significantly slow the rate of reaction of the solution with aluminum. The first drawback must be avoided since the insoluble product will precipitate on the sample surface and hinder the attack of the solution on the aluminum. In the second case, small amounts of water allow the aluminum methoxide to be soluble, but the different trace amounts of water picked up by atmospheric contamination vary the reaction rate enough so as to make time studies for two different sets of samples uncorrelatable.

Key words: aluminum, corrosion, oxide.

One inch square specimens of 2024 aluminum 0.063 in. thick are used for the experimental anodization studies. After anodization, the specimens are placed flat in a 5.5 in. diameter petri dish with 200 ml of ACT solution. When test specimens are placed in the same 200 ml solution, and oxide films are of the same comparable thickness, information concerning the continuity of the different films is readily obtained and correlatable. Figure 1 shows the results of an ACT solution on various surface preparations. The specimens A, C, and D are 2024 clad aluminum. The specimens B, E, and F are 2024 bare aluminum. A and B were treated with an FPL etch solution for 10 min at 62°C. C and E were anodized in a 0.01M phosphoric acid electrolyte while D and F were anodized in a 0.03M phthalic acid electrolyte. These specimens were anodized at 25V at room temperature. Barrier layer oxides were formed in both cases. The oxide thickness for the specimens shown in Fig. 1 is between 0.03 and 0.04 μm. Specimens A and B were in the solution for 1 hr. It is quite apparent that the discontinuities in B are so large that the entire oxide film has been lost due to the attack on the aluminum metal. The continuity of the anodic oxide on C and D appears to be good, while E is moderate and F is only fair. These specimens were in the ACT solution for a period of 2 hr. Some preliminary results on the comparison of the ACT solution with outdoor exposure studies are shown in Fig. 2. All specimens are 2024 clad aluminum. A and C were anodized at 50V in an 0.2M ammonium oxalate electrolyte, while B and D were anodized at 20V in an oxalic-sulfuric acid mixture each in 0.1M concentrations. A and B were exposed to the ACT solution for 2 hr. The A specimen showed poor oxide film continuity and the B specimen can be rated as moderate. The C and D specimens were exposed to atmospheric conditions on the North Florida Gulf Coast for 60 days. It is apparent that the same ratings assigned to A and B can be given to C and D. The area below the dotted line on C and D

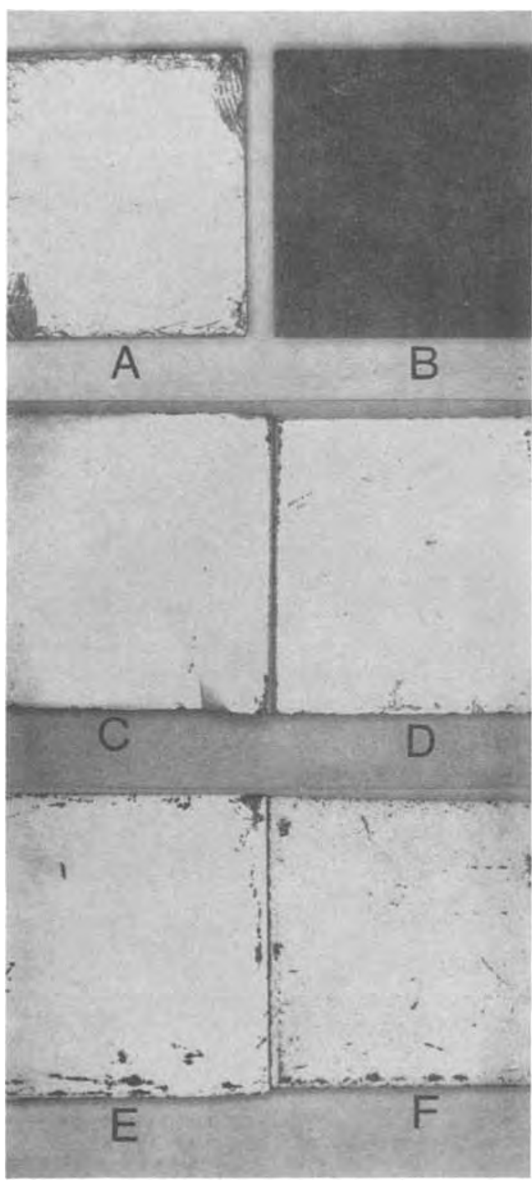

Fig. 1. Accelerated corrosion test comparison of various surface oxide preparations. A and B, FPL etch, exposed 1 hr. C and E, 0.01M H_3PO_4 anodize; D and F, 0.03M phthalic acid anodize, exposed for 2 hr.

was unexposed due to the clamp holding the specimens to a board.

The results of these experiments show that the iodine-methanol solution will determine the continuity of thin oxide films in a short period of time. The preliminary investigation of the comparison of ACT with outdoor exposure indicates there may be some corre-

lation, however, many more data points will have to be obtained to reach a firmer conclusion. The authors emphasize that the chemistry of this solution must be understood so that the term corrosion, as used in this paper, pertains only to an attack on the unexposed aluminum metal due to cracks, flaws, or porosity in the surface oxide film.

Mechanism of Reduction of the Fluorographite Cathode

M. Stanley Whittingham*

Corporate Research Laboratories, Exxon Research and Engineering Company, Linden, New Jersey 07036

Graphite has a layered structure which on reaction with fluorine at elevated temperatures gives the compound $(CF)_n$ in which the graphite lattice looses its aromatic character and electronic conductivity (1). Ebert (2) has shown that the six membered carbon rings take up the boat configuration with the fluorine atoms between the carbon layers. The spacing between these layers expands from 3.35 to ~5.8Å on reaction. This carbon monofluoride is used as the cathode of

* Electrochemical Society Active Member.
Key words: ternary phase, high energy density battery, carbon fluoride, cathode.

lithium high energy density batteries utilizing organic electrolyte systems (3-6). The postulated reaction during discharge is

$$\frac{1}{n}(CF)_n + Li \rightarrow \frac{1}{n}(C)_n + LiF \quad [1]$$

for which the calculated voltage obtained from the free energy of formation of LiF, −139.2 kcal/mole (7), and the heat of formation of $(CF)_n$, −46.7 kcal/mole (8), is around 4.0V. However, in use the open circuit voltage (OCV), ~2.8V (5), is markedly less than this theoretical value. Tiedemann recently proposed (5) that the OCV of this electrode can be interpreted as a mixed potential resulting from the anodic reaction of the solvent coupled with the cathodic reaction of the fluorographite. The object of this paper is to suggest an alternative hypothesis in which the open circuit voltage is determined not by the formation of lithium fluoride and graphite but rather by an intermediate product of the reaction.

Wood *et al.* (8) determined that the C-F bond energy in $(CF)_n$ is 115 kcal/mole. This high energy of the covalent bond dictates an extremely small diffusion coefficient for the fluorine; this is borne out in the need of high temperatures, ~450°C, for its formation from carbon and fluorine (9). This can be contrasted with the small energy of formation of the bromine compound, C_8Br, and its ready preparation at ambient temperatures (10). It is thus unlikely that the fluorine will be able to diffuse to the edges of the basal planes rapidly enough to maintain the observed discharge currents. It is therefore proposed that the lithium ion diffuses between the layers of the graphite lattice to react with the fluorine forming a ternary compound of composition (CLi_xF) where $x < 1$. This intermediate then disproportionates to give lithium fluoride and graphite.

To test this hypothesis fluorographites of composition $CF_{0.85}$ and $CF_{1.1}$ obtained from Marchem, Incorporated were reacted with 1M solutions of lithium and sodium naphthalides in tetrahydrofuran for 24 hr. The samples turned almost immediately from their white to a black color showing that electrons are being returned to the graphite lattice on reduction of the naphthalide to naphthalene. X-ray analysis of the products of reaction was performed on a Philips diffractometer using Cu K_α radiation. For the lithium product diffraction lines were found for *d* values of 9.35, 4.69, and 3.12Å. These can be associated with a lattice spacing between the graphite planes of 9.35Å. For sodium the spacing was 9.45Å. That this expansion of the lattice was not due to the intercalation or other reactions of the polar solvent or naphthalene was shown following Armand's procedure (11) using n-butyl lithium dissolved in a nonpolar solvent, hexane. Identical x-ray data were obtained and octane was the organic reaction product. Backtitration of the residual naphthalide or n-butyl lithium indicated a stoichiometric reaction of the alkali with the fluorine. Thus $CF_{0.85}$ and $CF_{1.1}$ reacted with 0.89 and 1.07 moles of n-butyl lithium, respectively.

The expansion of the crystalline lattice from the 5.8Å spacing of the $(CF)_n$ structure to the 9.35Å of the reaction product can possibly be related to the ionicity of the fluorine. In carbon fluoride the bonding is covalent, whereas in the presence of the alkali metal the fluorine will be predominantly ionic with its associated larger size. Further evidence for the formation of a nonstoichiometric ternary phase is the shape of the open circuit voltage curve observed on discharge (5), which is typical of that expected for such phase formation (12). A reaction where graphite and lithium fluoride are in equilibrium with carbon fluoride would yield a curve whose potential is independent of state of discharge.

The observed voltage is then the lithium partial molar free energy of the reaction

$$Li + \frac{1}{nx} CF)_n \rightarrow \frac{1}{x}(CLi_xF) \quad [2]$$

rather than for reaction [1]. The rate at which the lithium fluoride intercalated graphite decomposes to graphite and lithium fluoride, which is often observed in the x-ray pattern, is likely to be a complex function of the electrolyte used, the current density, and temperature. It is thus proposed that the formation of an intermediate ternary nonstoichiometric phase is one explanation for the lower than calculated voltages observed during the discharge of the fluorographite cathode. Such ternary phase formation, either as an intermediate or the final product of discharge, is probably more common than has heretofore been realized. Thus transition metal oxides such as V_2O_5 and MoO_3 react this way (13) and a number of ternary phases have been found in the high temperature $Li\text{-}FeS_2$ battery system (14).

Conductivity of Boules of Single-Crystal Sodium Beta-Alumina

William L. Fielder, Harold E. Kautz, J. Stuart Fordyce,* and Joseph Singer

NASA, Lewis Research Center, Cleveland, Ohio 44135

ABSTRACT

The two- and four-probe conductivities of single-crystal sodium beta-alumina ($Na_2O \cdot 8Al_2O_3$) were investigated over the range of 25°-300°C. After pretreating with liquid sodium at 300°C, the two-probe conductivity, above 140°C, was given by $KT = 3300 \exp(-3650/RT)$. The conductivity at 180°C remained essentially constant up to about 140 mA/cm^2.

To date, conductivity measurements on sodium beta-alumina single crystals have been restricted to a-c measurements on relatively small samples since large specimens have not been available. Conductivities have been reported for crystals occurring naturally in Monofrax-H fire brick (1) and for crystals ($NaO \cdot 9.5Al_2O_3$) obtained from the Carborundum Company (2).

Recently, two cylindrical boules of single-crystal sodium beta-alumina (nominal composition of $Na_2O \cdot 8Al_2O_3$) of about 2 cm diameter were prepared and made available to NASA-Lewis Research Center by the Crystal Products Department of Union Carbide Corporation. The present study provides the first a-c and d-c conductivity measurements made on such large, single-crystal material.

Experimental

The two boules of sodium beta-alumina, each obtained from separate single-crystal growths, were colorless. One boule was opaque and cleaved readily into many fragments while attempts were made to cut it with a diamond string saw using an organic coolant. The other boule, however, was relatively clear and remained uncleaved during cutting, producing samples A, B, and C. After cleaning with benzene and acetone, samples A and B were dried in a vacuum oven at 125°C and then maintained under an argon atmosphere. Sample C, being representative of this boule, was then analyzed in duplicate. The results were as follows: Na, 5.31 and 5.11%; Al, 49.15 and 49.15%; in agreement with the composition $Na_2O \cdot 8Al_2O_3$. Five parts per million of lithium was also found.

Conductivity measurements were made using both ion-blocking and reversible electrodes. Ion-blocking contacts of platinum were sputtered on the faces of sample A and a three-lead coaxial probe was connected to the contacts with conducting silver epoxy cement. Capacitance and conductance measurements were made over the range of −170°-250°C using a commercial automatic balancing bridge which provided frequencies of 10^3, 10^4, 10^5, and 10^6 Hz, as described previously (3).

Reversible electrodes of sodium were used on sample B by placing it between two stainless steel blocks which contained sodium electrode reservoirs and positioned so that proper contact was maintained between the sample and the sodium during preheating and during subsequent conductivity measurements. Spring tension against the steel blocks pressing on the sample were adequate to maintain a leak-proof seal for the liquid sodium. The surfaces of both faces of the sample were pretreated with the sodium electrodes in place by preheating to 300°C for about 1 hr. After pretreating, two-probe conductances were measured at three frequencies (10^2, 10^3, and 10^4 Hz) over the temperature range of 35°-300°C using an impedance comparator bridge with standard resistors and capacitors.

Using the same apparatus, two-probe d-c conductances were obtained over the same temperature range. A current density of about 30 μA/cm^2 was maintained by means of a variable standard resistor in series with the sample. In addition, at 180°C, two probe d-c conductances were measured at larger current densities ranging between 1 and 140 mA/cm^2. To minimize localized heating at these higher currents, the conductances were determined within 10 sec of initiation of current flow. Finally, a four-probe d-c conductance was obtained at 40°C. For this measurement, a current density of about 5 mA/cm^2 was maintained and the measurements were made after about 1 min. The conductances for both the two- and four-probe measurements were calculated from the corresponding voltages across the sample and the standard resistors in series.

Results and Discussion

The a-c conductivities of sample A, using ion-blocking platinum electrodes, are shown in Fig. 1. The condition of resonance, assumed to be due to polarization of the sodium ions at the ion-blocking electrodes, occurs when $\omega\tau$ is equal to unity and is a function of both frequency and temperature given by the relation

$$\omega\tau = (\epsilon_S - \epsilon_\infty)\omega/\kappa \qquad [1]$$

where ω is the angular frequency (sec^{-1}); κ is the conductivity (ohm^{-1}-cm^{-1}); ϵ_S is the low frequency limit of the real part of the dielectric constant; and ϵ_∞ is the high frequency limit (3-5). For 10^3 and 10^4 Hz, the conductivities started to deviate from the straight line due to the onset of sodium ion polarization at about −70° and −50°C, respectively. For 10^5

* Electrochemical Society Active Member.

Key words: beta-alumina, solid electrolyte, sodium transport.

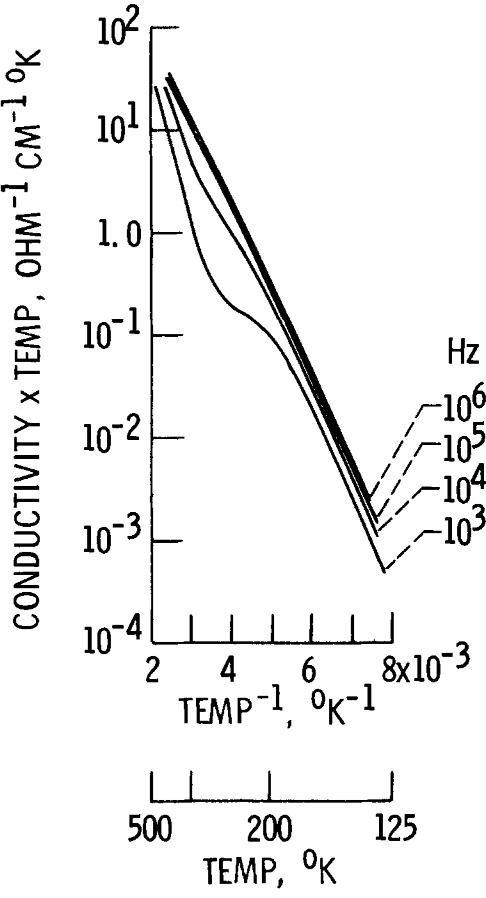

Fig. 1. A-C conductivities of sodium beta-alumina sample A using Pt electrodes.

and 10^6 Hz, resonance was not observed at the highest temperatures investigated. The conductivity of sample A at 10^6 Hz, therefore, was assumed to be polarization-free and could be fitted by a straight line over the temperature range −150°-125°C given by

$$KT = 4000 \exp(-3790/RT) \text{ ohm}^{-1}\text{-cm}^{-1} \,°\text{K} \quad [2]$$

At 25°C, this conductivity at 10^6 Hz is about 3×10^{-2} ohm^{-1}-cm^{-1} (cf. Table I).

The reversible electrode results on sample B for the two-probe a-c measurements at 10^4 Hz are shown in Fig. 2 and are compared with the four-probe d-c conductivity at 40°C. An extrapolation of this two-probe data to 40°C from the temperature region above 140°C, where the sodium is liquid, is in good agreement with the four-probe d-c value at 40°C of 2.8×10^{-2} ohm^{-1}-cm^{-1} (cf. Table I). This suggests that the higher temperature region and its extrapolation represent the polarization-free conductivity for the single crystal. The following results support this assumption: (*i*) the a-c conductances for the higher temperature region were essentially independent of frequency and (*ii*) the d-c conductances were essentially independent of time and also were in good agreement with the corresponding a-c values. The polarization-free conductivity for sample B can be expressed by

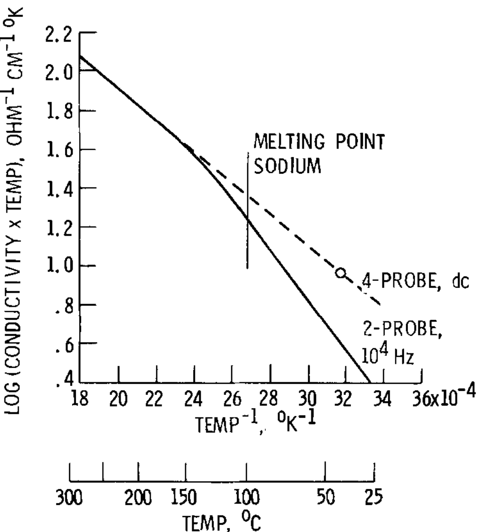

Fig. 2. Conductivities of sodium beta-alumina sample B using Na electrodes.

$$KT = 3300 \exp(-3650/RT) \text{ ohm}^{-1}\text{-cm}^{-1} \,°\text{K} \quad [3]$$

This activation energy of 3.65 kcal/mole and the conductivity at 25°C of 2.4×10^{-2} ohm^{-1}-cm^{-1} (cf. Table I) for sample B are in reasonable agreement with the data obtained for sample A using the platinum ion-blocking electrodes where an activation energy of 3.79 kcal/mole and a conductivity of 3×10^{-2} ohm^{-1}-cm^{-1} was obtained. Furthermore, these results for sample B show good agreement with published values. For example, an activation energy of 3.8 kcal/mole was reported for crystals obtained from Monofrax-H (1) and 3.79 kcal/mole for crystals obtained from the Carborundum Company (2). The respective conductivities were about 3×10^{-2} and 1.4×10^{-2} ohm^{-1}-cm^{-1} (cf. Table I).

Pretreating the surfaces of sample B by preheating in contact with liquid sodium at 300°C did reduce most of the interfacial polarization. However, even after pretreating, some interfacial polarization was still present in the two-probe data for temperatures where the sodium is solid. This is shown by a comparison of the two-probe data at 10^4 Hz with the extrapolated four-probe data (cf. Fig. 2 and Table I), by a decrease in the a-c conductivity with decreasing frequency, and by a decrease in d-c conductivity with increasing time. For example, at 25°C, the interfacial resistance at 10^4 Hz was about twice the resistance of the polarization-free single crystal.

Finally, to study the behavior of single-crystal material at current densities of practical interest, two-probe d-c measurements were made on sample B up to 140 mA/cm^2 at 180°C. As shown in Fig. 3, the conductivity remained essentially constant at about 0.127 ohm^{-1}-cm^{-1}. This shows that with liquid sodium electrodes, the conductivity (after pretreating with liquid

sodium at 300°C) was essentially ohmic even up to these relatively large current densities.

The results suggest that similar (or improved) large, synthetic boules of this type of sodium beta-alumina might be developed as a suitable sodium ion solid electrolyte operating at current densities of practical interest. The material is potentially important for lower temperature applications. However, the polarization noted in this work with sodium as it solidifies suggests that liquid electrodes may be preferred. Below 100°C, sodium amalgams may be applicable for this purpose (6, 7). The main limitation of this material in practical application as exemplified by one of the boules appears to be its relative ease of cleavage. Further development of the crystal growth technique might be expected to improve this situation.

The Lattice Misfit and Its Compensation in the Si-Epitaxial Layer by Doping with Germanium and Carbon

Yao Ting Lee, Nobuo Miyamoto, and Jun-ichi Nishizawa

Research Institute of Electrical Communication, Tohoku University, Sendai, Japan

ABSTRACT

When germanium and carbon are doped into silicon, the silicon lattice is expanded or contracted depending on the tetrahedral covalent radius of germanium or carbon, respectively. But this effect of electrically nonactive elements can be of considerable use for compensating the lattice strain caused by other impurities, which are electrically active elements in silicon. From the investigation of the electrical characteristics and lattice defects of epitaxial layers doped with germanium, it was found that doping of germanium in silicon up to 1×10^{20} atoms/cm^3 does not change the electrical characteristics of silicon and also that germanium is an element suitable for strain compensation in silicon. By the single doping of carbon over its solubility, many defects were generated. However, when carbon and antimony are simultaneously doped into the epitaxial layers, the layers become free from lattice defects and the saturation solubility of carbon in silicon changes from a solubility concentration of 3×10^{18} atoms/cm^3 to 7.6×10^{18} atoms/cm^3 with an increase in the concentration of antimony. These results show that the saturation solubility of carbon depends largely on the lattice strain or the existence of an impurity.

Dislocations and other defects in silicon crystal generated by heavy doping of impurity have been reported by a number of authors (1-9). When impurities such as boron, phosphorus, and antimony, having different covalent radii from that of silicon, are doped into silicon, the lattice constant of the doped layer shows a value different from that of intrinsic silicon. The lattice expansion or contraction of silicon causes strain in the crystal and also in some cases results in defects such as dislocations (10, 11), which have a great influence on the characteristics of semiconductor devices. In order to avoid the generation of strains or defects due to this effect, a method, called the compensation of strain, has been used. For example, a simultaneous doping of more than two impurities such as phosphorus and tin having different covalent radii has been performed and the strain compensation in epitaxial growth of silicon has been achieved (10). Because germanium is highly soluble in silicon, the compensation of the lattice strain by germanium can be effected over a wide range of concentration of some other impurity. On the other hand, the solid solubility of carbon (18-20) is so low that addition of carbon above the concentration of 3×10^{18} atom/cm^3 results in precipitation in silicon. Germanium and carbon not only belong to the same column of the Group IV in the periodic table as tin and silicon, but also have better semiconductor characteristics than tin. Consequently, they are considered as the elements appropriate to compensate the lattice strain. In this paper, the physical properties of germanium and the

Key words: effect lattice constant of silicon, doping of carbon and germanium, strain compensation, silicon vapor epitaxy, change of saturation solubility by lattice stress.

behavior of carbon doped in silicon during epitaxial growth are investigated.

Experimental Procedure

The epitaxial layers were grown by vapor deposition through the hydrogen reduction of $SiCl_4$. Germanium and carbon were doped using $GeCl_4$ and CCl_4 vaporized in a usual manner. Purities of $GeCl_4$ and CCl_4 were 99.999999% for $GeCl_4$ and 99.99% for CCl_4. The growth condition was as follows. The mole fraction of $SiCl_4$ in H_2, 1.5%; the line velocity of the gas mixture, 5 cm/sec in the reactor heated by the resistance furnace; the growth temperature, 1200°C; and the growth rate, about 0.7 μ/min. The concentrations of the dopant germanium and carbon were controlled by varying the flow rate of hydrogen gas carrying doping sources.

The substrates used were dislocation-free silicon crystals grown by the F.Z. method, which contain less carbon impurities than those grown by the C.Z. method, and were doped with phosphorus with a concentration of about 3.5×10^{13} atom/cm^3; the impurity concentration was about 3.5×10^{13} atom/cm^3. The impurity concentration of the substrates is so low that the lattice constant is almost the same as that of pure silicon (a = 5.43018Å). Substrates were cut in parallel to the (111) plane. The shape of the substrates was rectangular with a size of 5 × 10 mm; their directions being <112> for the short side and <110> for the long side.

Substrate surfaces were cleaned and then etched chemically to a thickness of about 3-5μ under a H_2-HBr gas mixture at 1200°C in order to remove damaged surface layers and contaminants.

Measurements and Results

Lattice strain vs. impurity content.—The doping of impurities in silicon causes a lattice expansion or contraction. When the lattice constant of the epitaxial layer doped with impurity is different from that of the silicon substrate, the Bragg angles of x-ray reflected from the substrate and the epitaxial layer will differ by a small angle of $\Delta\theta$. The difference in the lattice constant Δa_o can be obtained from $\Delta\theta$, *i.e.*, the lattice strain ϵ, ϵ is expressed by the equation

$$\epsilon = \frac{\Delta a_o}{a_o} = \beta C = -\cot \theta_B \cdot \Delta\theta \quad [1]$$

where a_o is the lattice constant for silicon, β is the solute lattice expansion (−) or the contraction (+) coefficient, C is the concentration of an impurity doped in silicon, θ_B is the Bragg reflection angle for the substrate of pure silicon (13). To measure $\Delta\theta$, an x-ray double crystal spectrometer was used, where the x-ray source was $CuK\alpha_1$ radiation. The diffractometer was arranged as $\{(511)^v, -(333)^s\}$ (14), that is, x-ray diffraction was first made upon a perfect and pure silicon crystal fixed to the low glancing angle position of $(511)^v$ for the incident beam to obtain a nondivergent monochromatic beam and then diffracted by the sample crystal fixed to the symmetric position of $(333)^s$. The rocking curves of the diffraction lines were recorded at a scanning speed of 1/256°/min. Since the Bragg angle θ_B is 47.482° for the silicon (333) plane, Eq. [1] yields

$$\epsilon = \beta C = 4.445 \times 10^{-6} \Delta\theta_{333} \quad [2]$$

For example, Fig. 1 shows the rocking curve for germanium-doped silicon epitaxial layers. The peak designated "epi" is separated from the main silicon substrate peak. If the impurity atoms occupy the substitutional sites in the silicon lattice, the solute lattice expansion (contraction) coefficient (12) is derived as

$$\beta = \frac{1}{3}\left[1 - \left(\frac{R_{sol}}{R_{Si}}\right)^3\right] N^{-1} \quad [3]$$

where R_{Si} is the covalent radius of silicon, R_{sol} is the covalent radius of the solute atom, and N is the concentration of silicon atom sites (5×10^{22} atom/cm^3). The covalent radii of some other elements are Ge = 1.22Å, C = 0.77Å, B = 0.88Å, P = 1.10Å, Si = 1.17Å, and Sb = 1.36Å. The values of β of those impurities doped in silicon are given as follows: $\beta_{Ge} = -8.91 \times 10^{-25}$ cm^3/atom, $\beta_C = 4.77 \times 10^{-24}$ cm^3/atom, $\beta_P = 1.13 \times 10^{-24}$ cm^3/atom, $\beta_B = 3.83 \times 10^{-24}$ cm^3/atom, $\beta_{Sb} = -3.8 \times 10^{-24}$ cm^3/atom.

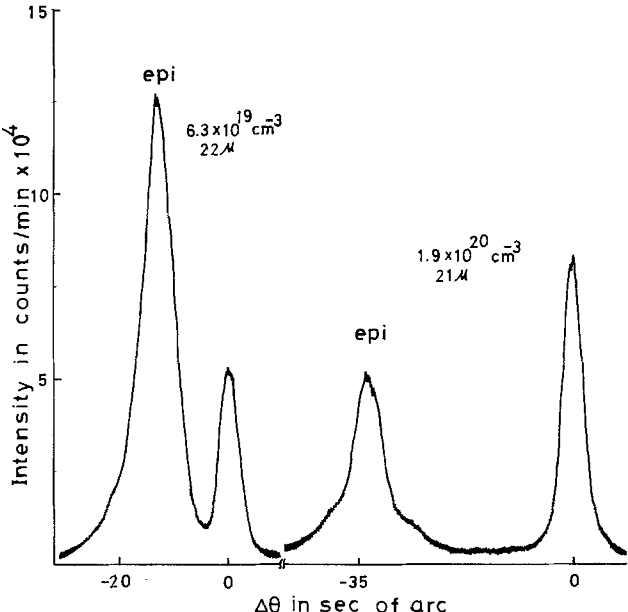

Fig. 1. X-ray rocking curve for germanium diffused layer in silicon.

Using these coefficients of β, the relation between the change in lattice constant and the concentration of dopant impurities in silicon were calculated as shown in Fig. 2. Hence, one can determine the concentration of the dopant germanium necessary to compensate the lattice strain introduced by a certain amount of impurities such as boron and phosphorus. Similarly, this

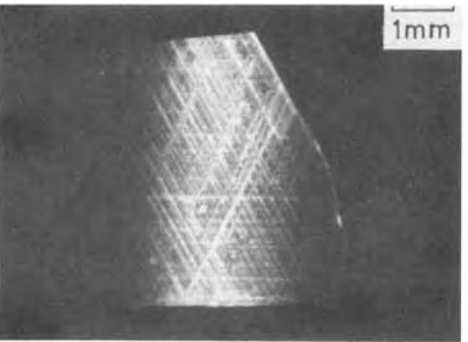

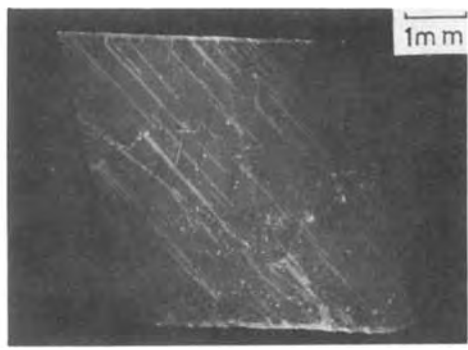

Fig. 3. X-ray projection topographs of (111) oriented specimens [$MoK\alpha_1$(220) reflection]. The impurity concentration of Ge-doped Si and the thickness of epitaxial grown layers are: (a, left) 1.6 × 10^{20} atom/cm^3, 22μ and (b, right) 6.3 × 10^{19} atom/cm^3, 21μ.

can be applied to carbon to compensate the strain induced by antimony.

Germanium doping.—As detailed above, the concentration of germanium in epitaxial silicon films was measured by using the x-ray double crystal method. It is shown in Fig. 1. X-ray projection topography (15, 16) was used to investigate misfit dislocations and other defects caused in epitaxial films, where $MoK\alpha_1$ was applied as the x-ray source.

The x-ray projection topographs are shown in Fig. 3. Misfit dislocations are generated in the crystal when the impurity concentration exceeds a certain value in the epitaxial layer of a pure silicon substrate, and the critical concentration level also depends on the thickness of the epitaxially grown layer which contains the impurity. In this experiment, the critical level is found to be 5 × 10^{19} atom/cm^3 for germanium when the thickness of the film is about 20μ.

Van der Pauw's method (17) was used to measure Hall coefficients and the bandgap of the epitaxial silicon film doped with germanium.

The measured carrier concentrations were about 5 × 10^{14} cm^{-3} for 35-50μ n-type films deposited on p-type substrates of 100 ohm-cm. The source of electrons of 5 × 10^{14} cm^{-3} is believed to be impurities in $GeCl_4$, because the epitaxial layers of ~10^{13} electrons/cm^3 can be grown from nondoped $SiCl_4$.

Table I shows the measured values of the electron Hall mobility and the bandgap for the epitaxial layers doped with about 0.02-0.2 atomic per cent (a/o) germanium. The values are not different from those of nondoped epitaxial layers. It is shown that the epitaxial silicon will not undergo any changes in its electrical properties even if germanium of 1 × 10^{20} atom/cm^3 is doped into silicon.

Carbon doping.—The concentration of carbon doped into epitaxial layers was measured by the same method as that for silicon doped with germanium. Figure 4 shows the rocking curve and Fig. 5 shows the observed surfaces of the epitaxial layer doped with carbon. When the concentration of the dopant carbon is below 3 × 10^{18} atom/cm^3, silicon layers free from defects can be obtained as shown in Fig. 5a. At a higher concentration of carbon (3 × 10^{18} atom/cm^3), hexagonal defects are observed in the layers as shown in Fig. 5b. An electron microscope was used to examine these defects and it was found that those hexagonal defects are of polycrystalline structure, where the lattice constant of these defects is 4.378Å within an error of 0.5% and is nearly consistent with that for β-SiC. Figure 6 shows a cross-sectional view of one of defects cleaved at its center. The defects are formed both at the epitaxial-substrate interface and in the epitaxial layer as seen from the different sizes of the hexagonal defects. From the above considerations, it seems likely that the mechanism of formation of the hexagonal pits is as follows. The presence of grown SiC polycrystals inhibits further growth of silicon; this causes SiC to locate at the bottom of the pits. An x-ray projection topograph of the epitaxial layer doped with carbon is

Table I. Hall mobility and energy gap of silicon epitaxial layers doped with germanium

Sample Ge a/o in Si	Electron Hall mobility (μn)	Energy gap (eV)
1 × 10^{19} Ge/cm^3 0.02% in Si	1440	1.12
6 × 10^{19} Ge/cm^3 0.12% in Si	1365	1.14
1 × 10^{20} Ge/cm^3 0.2% in Si	1390	1.09
Ge 0% in Si	1400*	1.11*

* These values are taken from data of Wolf (23). For measuring the Hall effects 5 × 10^{14} atom/cm^3 n-type was doped into the epitaxial layers. Hall mobility was measured at 25°C.

shown in Fig. 7. The bright points correspond to these defects formed in the layer.

It was found that the solid solubility of carbon in silicon, when carbon alone is doped into silicon, is too low to expect effective compensation of lattice strain caused by other dopants such as antimony. However, when carbon and antimony were simultaneously doped into silicon, a nearly perfect crystal was obtained even if the concentration of carbon exceeded its saturation solubility limit, and at the same time, the compensation of the lattice strain induced by antimony was successfully achieved. Antimony was doped into the silicon epitaxial layer by a conventional method using $SbCl_5$. In order to check the effect of lattice strain compensation on an epitaxial layer, the results obtained when carbon and antimony were together doped into an epitaxial layer were compared with those obtained when either carbon or antimony were singly doped into an epitaxial layer. The antimony concentration was checked by measuring its resistivity and by the x-ray double crystal method.

The surface of epitaxial film shown in Fig. 8a was the one doped with carbon of higher concentration than its solid solubility at 1200°C. It appears that the rough surface of silicon was caused by the formation of many β-SiC polycrystals, the carbon concentration cannot be measured by the x-ray double crystal method. When antimony was doped simultaneously with carbon, however, the epitaxial films had fine surfaces as shown in Fig. 8b, indicating that the crystallinity is much better than the epitaxial layer in Fig. 8a. An x-ray projection topograph of this sample of Fig. 8b is shown in Fig. 9b. The presence of β-SiC polycrystals is scarce in the topograph, as distinct from the singularly carbon-doped film in Fig. 7; no dislocations result. These results indicate that the doping of carbon will not generate defects in epitaxial layers even if the carbon concentration is higher than the solid solubility of carbon in silicon when doped simultaneously with antimony. In Fig. 9a, the x-ray topograph of the antimony-doped sample is shown in comparison with that in Fig. 9b and confirmed that the dislocation defects generated by antimony are eliminated by the simultaneous doping of antimony and carbon.

Rocking curves are shown in Fig. 10a for the sample doped only with antimony. This suggests that the doping with antimony has the effect of increasing the lattice constant of silicon and is effective in compensating the strain induced by the doping of phosphorus as an n-type impurity. Figure 10b and c show the rocking of the specimens doped simultaneously with antimony

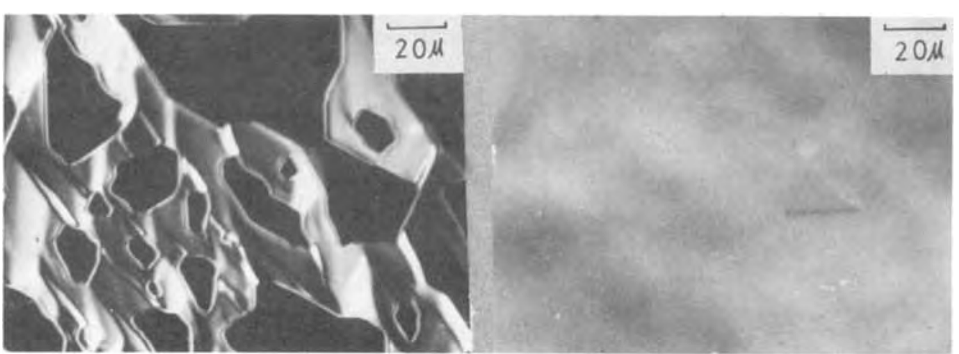

Fig. 8. (a, left) The morphology of an epitaxial layer doped with carbon, 7.6×10^{18} atom/cm^3. (b, right) The morphology of an epitaxial layer doped simultaneously with carbon (7.6×10^{18} atom/cm^3) and antimony (9.5×10^{18} atom/cm^3).

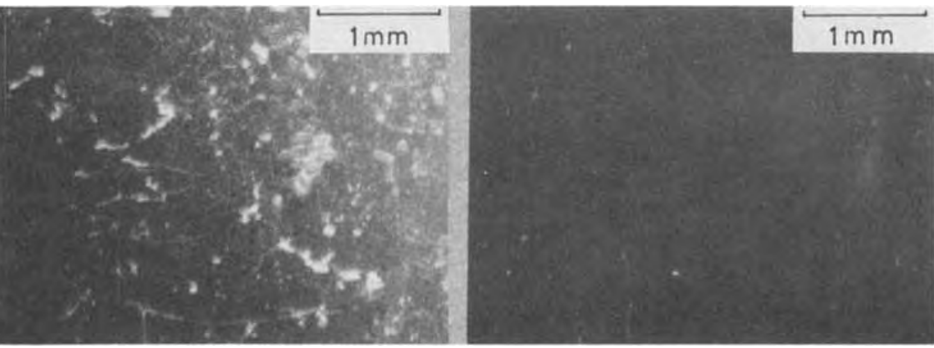

Fig. 9. (a, left) X-ray transmitted topograph of a Si epitaxial layer doped with antimony, 9.5×10^{18} atom/cm³. MoKα₁ ($2\bar{2}0$) reflection. (b, right) X-ray projection topograph of a Si epitaxial layer. This sample is the same as used in Fig. 8b.

and carbon; the former represents the case where the lattice constants of the substrate and the epitaxial layer are equal, and the latter indicates the case where the two are not completely equal. In these samples, the antimony concentration was controlled to be 9.5×10^{18} atom/cm³. Therefore, the carbon concentration can be estimated from the result of Fig. 2 to be about 7.6×10^{18} atom/cm³ as shown in Fig. 10b. This value is about 2.5 times as much as the saturation solubility of carbon in silicon at 1200°C.

Conclusion

From the results obtained in this work, the use of germanium for the compensation of the lattice strain appears to be feasible as is the case with tin. It should be noted that the epitaxial growth can be more readily achieved by doping of germanium than that of tin. The solid solubility of tin is about 5×10^{19} atom/cm³ in silicon (1200°C). This value can concentrate the strain induced by doping of phosphorus of about 1.6×10^{20} atom/cm³ or boron of 6×10^{19} in silicon. Above the concentration of phosphorus or boron impurity, it is not preferable to use tin for strain compensation, although a phenomenon similar to the simultaneous doping of carbon and antimony can be expected. In contrast to tin, germanium can be used for a higher impurity level. Braunstein (21, 22) has shown that nearly perfect single crystals containing as high as 5 a/o germanium in silicon can be obtained (about 2.5×10^{21} atom/cm³ germanium). According to their experimental data, the characteristics of silicon doped with 5 a/o germanium are not changed.

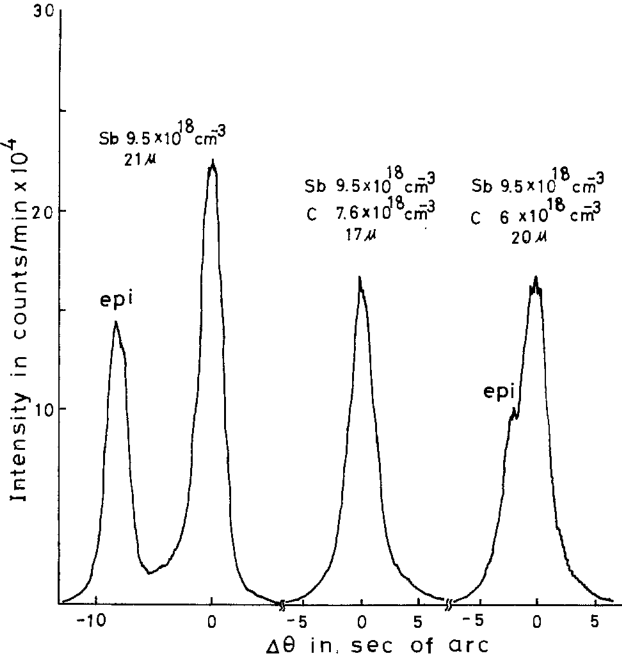

Fig. 10. X-ray rocking curves of Si epitaxial layers doped with (a) Sb-9.5×10^{18} atom/cm³, (b) Sb-9.5×10^{18} atom/cm³ and C-7.6×10^{18} atom/cm³, (c) Sb-9.5×10^{18} atom/cm³ and C-6×10^{18} atom/cm³.

The results of the present study show that the use of germanium is more effective than tin for performing the compensation of lattice strain induced by the doping of boron and phosphorus into silicon. Electronic properties of silicon doped with germanium, a higher concentration of germanium, need to be investigated further.

Carbon is the only element having a smaller covalent radius than that of silicon in IV-group of the periodic table and also carbon is the only element that can be used for the compensation of the lattice strain introduced by doping of the impurities such as antimony which have larger covalent radii than silicon. Although the saturation solubility of carbon in silicon is known to be low, carbon of higher concentration (for example 7.6×10^{18} atom/cm³ in this experiment) are soluble in silicon in the presence of antimony. Thus, it appears that the solubility of carbon and antimony depends on the internal stress of crystals and effective lattice spacing of the bulk crystal. The highest concentration of antimony doped simultaneously with carbon in this experiment is 9.5×10^{18} atom/cm³. Antimony of higher concentration than the value in this experiment may be soluble in silicon. The solubility phenomena mentioned above would be very interesting in the field of solid-state physics and technology.

Epitaxial Growth and Structure of CdSe Evaporated in Vacuum onto Ge

F. H. Gejji and D. B. Holt

Department of Metallurgy and Materials Science, Imperial College of Science and Technology, London, England

ABSTRACT

Films of CdSe were grown by focused electron beam evaporation *in vacua* in the 10^{-6} Torr range on the three singular faces of Ge. The structures of the films were examined by transmission electron microscopy. On (100) oriented substrates, epitaxy was obtained throughout the range of substrate temperatures from 350° to 450°C, and the films had the sphalerite structure in parallel alignment with the Ge. The diffraction patterns contained no satellite spots but <111> streaks were present. On (110) oriented substrates the epitaxial growth range of temperatures was 300°-450°C. The films again had basically the sphalerite structure in (110) orientation but the domain-form faulted structure was found in all the films. On (111) Ge surfaces, CdSe grew epitaxially at all temperatures from 350° to 450°C and had the sphalerite structure in (111) orientation. Streaks but no satellite spots were observed in the electron diffraction patterns. Well-defined rosettes of Moire spots were observed in the transmission electron diffraction patterns of areas where comparable thicknesses of CdSe and Ge were present in the cases of both (100) and (111) substrates. These Moire diffraction patterns confirmed the parallel alignment of the films on (100) substrates but showed that on (111) substrates the films were azimuthally rotated through a small angle from the parallel orientation.

This work forms part of a program of study of the epitaxial growth of films of the Cd and Zn chalcogenides (II-VI compounds) evaporated in vacuum on to diamond-structure semiconductor substrates. Previous work in this program has dealt with the growth and structure of films of CdS on Ge (1, 2), ZnTe on Ge (3), and CdTe on Ge (4). It was found that on the (100) and (110) faces of Ge these compounds all grew with the sphalerite structure (5). A domain-form {111} faulted structure was found in the CdTe films grown on (110) surfaces (2, 4). The films were grown with relatively high levels of structural perfection. In this work and in all the other published work in the literature only two epitaxial orientation relationships were reported. These were the parallel orientation relation for sphalerite structure films grown on any face of diamond or sphalerite or NaCl structure substrates and the relationship (0001) film parallel to (111) substrate with $[11\bar{2}0]$ film parallel to $[1\bar{1}0]$ substrate for wurtzite structure films grown on diamond or sphalerite-structure substrates (6). The significance of these facts in relation to nucleation theory and misfit dislocation theories of the heterojunction interface between II-VI films and semiconductor substrates was discussed in a recent review (6).

This paper reports the results of an investigation of the epitaxial growth and structure of films of CdSe evaporated in vacuum onto (100), (110), and (111) faces of Ge and discusses them in relation to the general conclusions that have emerged from similar previous work.

Experimental Techniques

The films were grown by evaporation in a conventional, oil-pumped high vacuum system using a focused electron beam furnace as described previously (1). Depositions were carried out in pressures of a few times 10^{-6} Torr.

The CdSe employed was in powder form. It was obtained from Koch-Light Laboratories Limited and stated by them to be of 99.999% purity. The germanium was obtained in the form of (100), (110), and (111) oriented p-type slices from the Electronic Materials Unit of the Royal Radar Establishment. The substrates were 3 mm diameter disks ultrasonically cut from the slices, to fit the specimen holders of the AEI EM6G transmission electron microscope which was used to examine the film structures. The substrate surfaces were mechanically and then chemically polished in a reagent consisting of 50 cm³ of 70% nitric acid, 30 cm³ of 99% glacial acetic acid, 30 cm³ of 40% hydrofluoric acid plus a drop of 79.92% bromine at about 60°C (2). After film growth, the Ge disks were thinned by jet electropolishing for transmission electron microscopy as in the previous studies (1).

The following points were found vital in order to obtain reproducible epitaxial growth of films of high structural perfection: (*i*) The substrate surfaces must be free of pits, scratches, or other roughness on a transmission electron microscope scale. (*ii*) The substrate holder and heater assembly must be outgassed by heating to about 900°C in vacuum between successive growth runs to prevent contamination of the substrates by material deposited in previous evaporations. (*iii*) The CdSe source material must be long and carefully outgassed using the defocused electron beam furnace to heat the whole volume of CdSe powder. Completion of this process can be detected by monitoring the pressure in the vacuum chamber. (*iv*) The substrates must be thermally cleaned by heating to 600°C and allowed to cool to the growth temperature when deposition is immediately commenced. The results re-

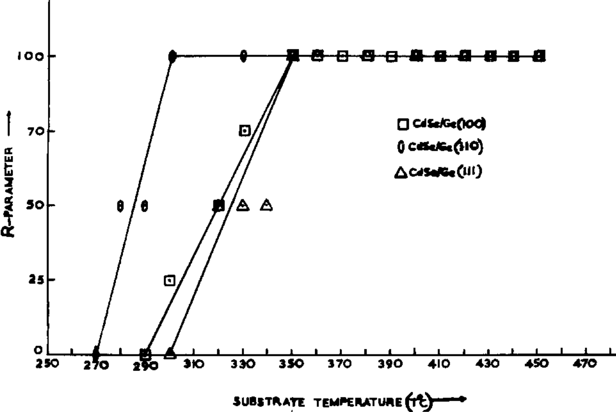

Fig. 1. The variation with substrate temperature of the degree of orientation *R* of films of CdSe evaporated on to Ge surfaces *R* = 100 indicates epitaxy ⊡: (100), ◈: (110), and ⚠: (111) oriented substrates.

ported in this paper were only attainable when all these requirements were satisfied.

The electron beam evaporator was focused each time to produce a 2 mm diameter hot spot on the CdSe charge during evaporation. The evaporator input power was kept constant and continuously monitored. All the films were deposited for 1½ min. The film thicknesses were measured using a Nomarski interferometer attachment on a Reichert metallographic microscope. The values were found to range from 1200 to 2000Å. Thus the combined effect of any variations in evaporation rate and sticking coefficient was a variation of only ±25% in film thickness.

Results

Epitaxial ranges of growth temperature.—Films of CdSe were deposited *in vacua* in the 10^{-5} to 10^{-6} Torr range of Ge substrates with (100), (110), and (111) orientations with the results shown in Fig. 1. The film structures are represented in this figure by means of the degree of orientation parameter R which has the values 100 for epitaxial films giving well-oriented electron diffraction spot patterns, $R = 0$ for randomly oriented polycrystalline films giving ring patterns and intermediate values for partially oriented films giving superposed spot and ring patterns (7, 8). These results show that epitaxial growth was invariably obtained for all substrate temperatures from 350° to 450°C on (100) and (111) oriented surfaces of Ge. On (110) surfaces the minimum epitaxial growth temperature was 50°C lower than on the other two singular surfaces. In this case the epitaxial growth range of substrate temperatures was 300°-450°C.

The maximum possible growth temperature, 450°C in all three surface orientations, was limited by the cessation of deposition. Similar deposition cut-off temperatures were observed to occur in all previously investigated II-VI/IV combinations (1-4, 6). In the present case as in those previously reported, the deposition cut-off temperature appeared to be set by the commencement of some form of chemical attack. Substrates which were held at temperatures above 450°C while CdSe was evaporated had etched surfaces.

Structure of CdSe films deposited on (100) Ge substrates.—Films deposited on (100) surfaces of Ge held at all temperatures in the epitaxial range, 350°-450°C, grew with the cubic sphalerite (*i.e.*, zincblende) structure in (100) orientation as shown in Fig. 2(a) and (b). When the epitaxial (100) films were tilted slightly away from the exact (100) orientation in the electron microscope the diffraction patterns changed to the form shown in Fig. 2(c). Similar patterns have been observed in a number of other cases of II-VI films grown on (100) surfaces of cubic system crystal substrates. The sets of four intensity maxima occurring around the positions of the CdSe spots occur where the Ewald sphere intersects <111> streaks in reciprocal space (9). That this was the correct interpretation was established by tilting the films and observing that the pseudo spots move in and out relative to the CdSe crystal diffraction spot positions and by noting that the pseudo spots have the characteristic elliptical form arising from the intersection of the approximately planar Ewald sphere with the right-circular-cylindrical <111> streaks. No satellite spots were ever seen in the diffraction patterns of the (100) CdSe films. Satellite spots would arise if any three-dimensional defects such as twins or included grains of CdSe with the hexagonal wurtzite structure were present. It may therefore be deduced that such three-dimensional defects were absent. The <111> streaks arise from {111} planar defects present in high densities. The observation of the satellite pseudo spots therefore shows that numerous {111} planar defects were present in the films. At these high densities the planar defects can be seen in dark field electron micrographs (1, 9), but are not sufficiently large or well separated for diffraction contrast analysis to be possible.

The best method to determine the epitaxial orientation relationship between the films and substrates is to observe the superimposed diffraction patterns that arise in areas of specimen in which both CdSe and Ge are present in comparable thicknesses. The patterns reported in Fig. 2 are those that arise from the CdSe alone, *i.e.*, in areas of the specimen whence the thinning process has removed all the Ge. The diffraction patterns arising in overlapping CdSe and Ge will be referred to as Moire patterns since they arise from the diffraction effects which give rise to Moire fringes in the transmission electron micrographs.

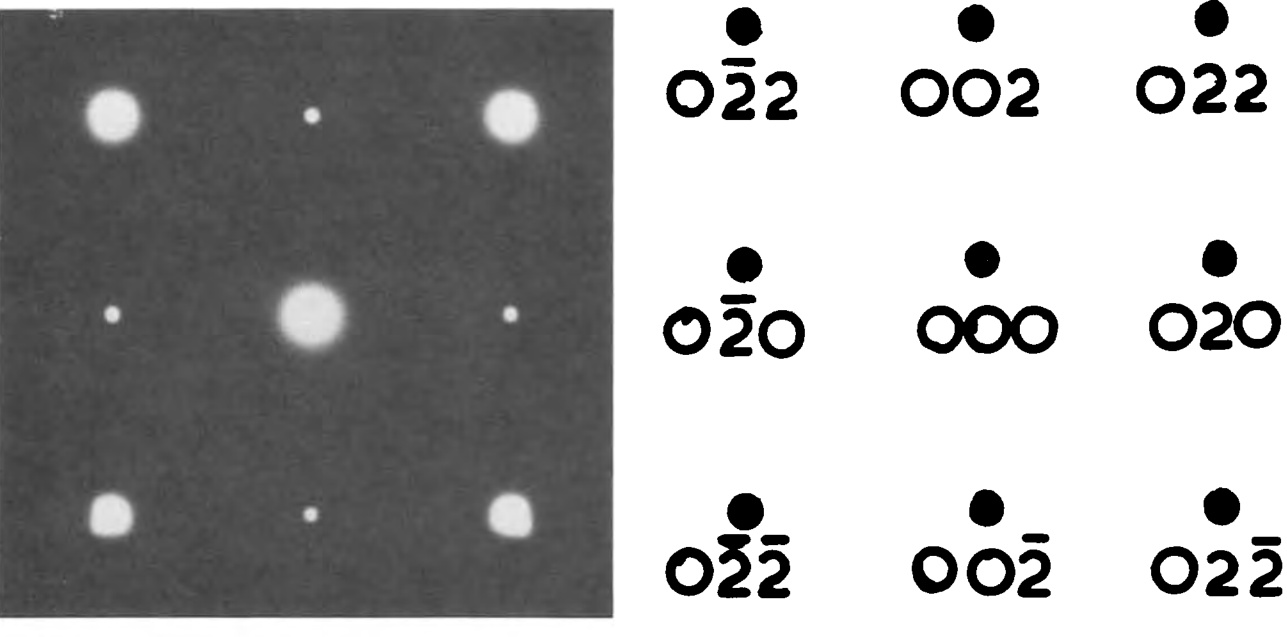
The Moire electron diffraction pattern arising from overlapping epitaxial CdSe on (100) Ge is shown in Fig. 3(a). The neighboring pairs of spots arising from 220 type reflections in CdSe and Ge, give rise to additional spots by double diffraction. The result of double-diffraction replication of the 022 Ge spots round each of the CdSe spots is the square "Moire arrays" of spots shown in Fig. 3(b). These are the arrays seen in practice as shown in Fig. 3(a) and as previously reported in the case of CdTe grown on (100) Ge (4). The diffraction vectors involved in producing these Moire diffraction patterns lie in the (100) plane in reciprocal space. These diffraction conditions therefore are exactly satisfied without taking the effects of the buckling of the specimen into account and these arrays are readily obtained.

The Moire fringes resulting from the overlapping of crystals of differing lattice parameter but in parallel alignment are known as parallel Moire fringes. Their spacing is given (10) by

$$D_{\text{parallel}} = \frac{d_1 d_2}{d_1 - d_2} \qquad [1]$$

where d_1 and d_2 are the spacings of the Bragg reflecting planes in the two crystals which give rise to the interfering Moire beams. Substituting for d_1 and d_2 the spacings of the $0\bar{2}2$ planes in CdSe and Ge we obtain as the calculated value: $D_{\text{parallel}} = 29.1$Å. The measured value for the Moire fringes in CdSe/(100) Ge specimens was 29.2Å. This excellent agreement confirms the interpretation given above for the diffraction patterns of the form shown in Fig. 3(a).

Structure of CdSe films grown on (110) Ge surfaces.—The diffraction patterns obtained from areas from which the Ge had been removed, when the film was tilted to the exact (110) orientation, were as shown in Fig. 4(a). These patterns were indexed and found to arise from the sphalerite structure in (110) orientation as shown in Fig. 4(b). When the films were tilted slightly off the exact (110) orientation, the spots appeared to split into pairs separated along the [002] direction as shown in Fig. 5(a). The characteristic



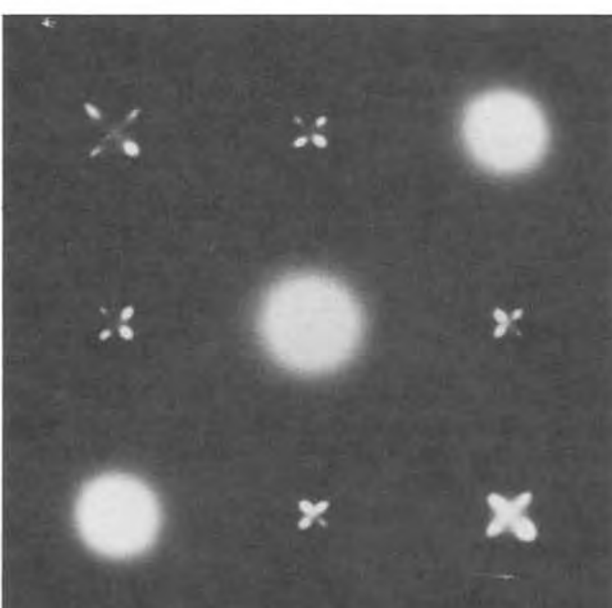


Fig. 2. (a, above left) Selected area transmission electron diffraction pattern from a film of CdSe grown on a (100) surface of Ge at 390°C. (b, above right) Indexed plot of the diffraction pattern shown in (a). (c, left) Diffraction pattern of the same film as shown in (a) but now tilted slightly off the exact [100] beam direction.

appearance of the micrographs of the (110) epitaxial films is shown in Fig. 5(b). This form of contrast in dark and bright areas of jig-saw-puzzle shape, led to this type of structure being termed a domain-form faulted structure in previous cases (2, 4). The structure arises from faulting on the two {111} planes inclined 35°16′ on either side of the normal to the films. One type of domain faults or transforms on the one plane and the second type of domain on the other plane. The two faulted planes give rise to streaks in reciprocal space in the <111> directions normal to the faults. The two types of streak run through every reciprocal lattice point and give rise to the pairs of "split" pseudo spots. The contrast shown in Fig. 5(b) arises because the one type of domain diffracts into the one pseudo spot of each pair while the second type of domain diffracts into the other pseudo spot and these are generally unequal in intensity.

The domain-form faulted structure was found in the CdSe films grown on (110) surfaces of Ge substrates at all temperatures throughout the epitaxial range, 300°-450°C.

Structure of CdSe films grown on (111) Ge surfaces.—The diffraction patterns of epitaxial films of CdSe grown on (111) oriented Ge substrates showed the films to have the sphalerite structure in (111) orientation. This was confirmed by the form of the Moire diffraction pattern shown in Fig. 6(a) which were obtained in areas of comparable thicknesses of overlapping CdSe and Ge. The diffraction patterns of the diamond structure of Ge and of the sphalerite structure in the (111) orientation contain the same set of permitted reflections. The pairs of spots with the same indices arising from the two structures are closely spaced. Double diffraction results in the production of hexagonal arrays of Moire spots at each permitted reflection site. If the CdSe however, had the other structure that is likely when epitaxially grown on (111) surfaces, namely the hexagonal wurtzite structure in (0001) orientation, the situation would be strikingly different. There is a set of six spots of the form $10\bar{1}0$ in the (0001) diffraction pattern of wurtzite which occur at only half the distance from the undeviated beam (center spot, 000) of the first hexagon of spots in the (111) diamond pattern, the 220 spots. The inner hexagon of $10\bar{1}0$ spots therefore have no near neighbors and no strong array of Moire spots occurs at such positions. The occurrence of arrays of Moire spots at the innermost set of spots in Fig. 7(a) indicates that

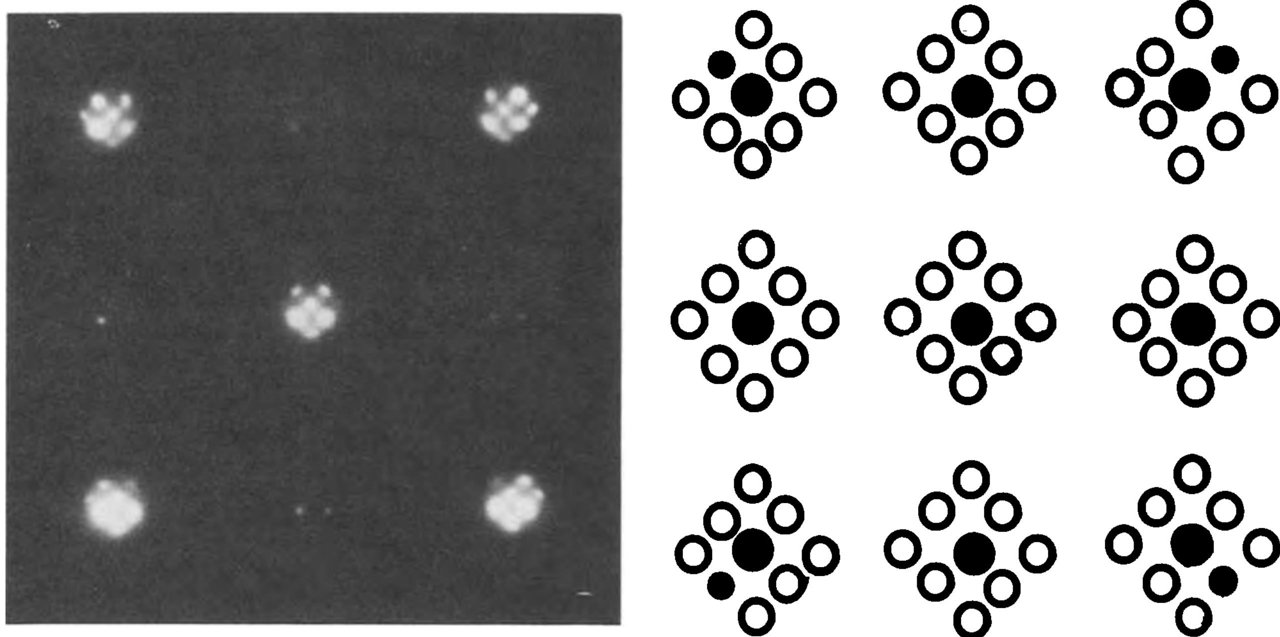

Fig. 3. (a, above left) Transmission electron diffraction pattern from an area in which the CdSe and Ge were of comparable thickness. The CdSe was epitaxially grown at 370°C on (100) Ge. (b, above right) The complete arrays of double diffraction Moire spots (open circles) about the CdSe spots (large solid circles) and Ge spots (small solid circles) in the (100) reciprocal lattice plane. This is the explanation of the experimental transmission electron diffraction pattern shown in (a).

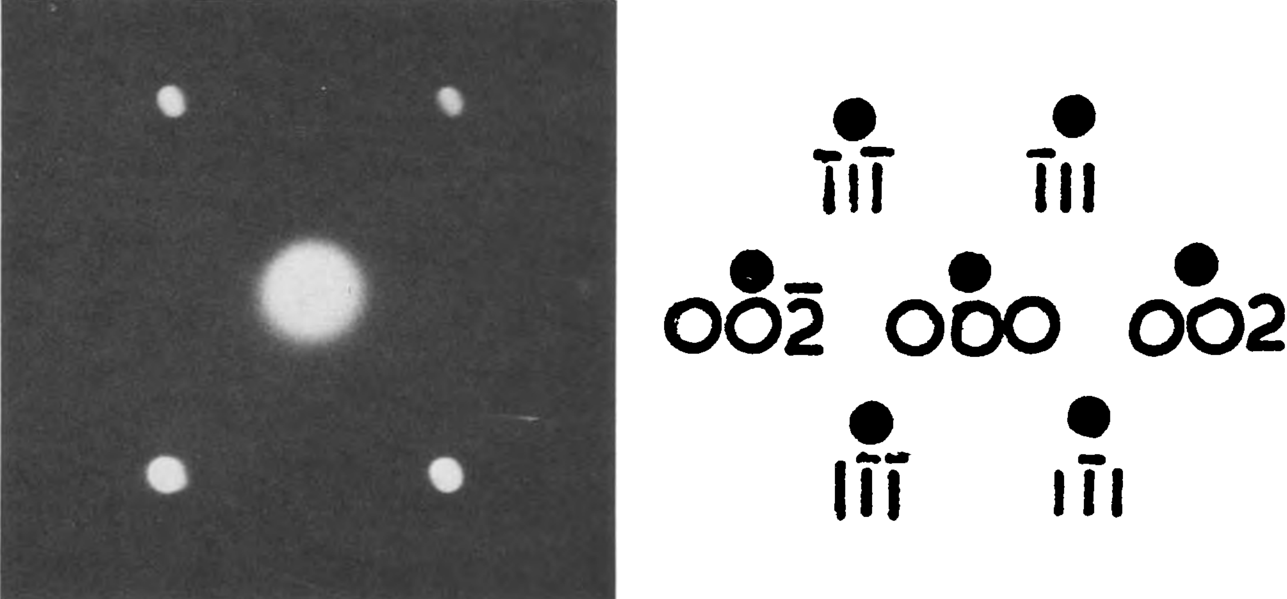

Fig. 4. (a, above left) Diffraction pattern of a CdSe film grown on a (110) oriented Ge substrate. This is the pattern obtained with the electron beam incident on the film in the exact [110] direction. (b, above right) The pattern in (a) is that of the sphalerite structure in (110) orientation and indexes as shown.

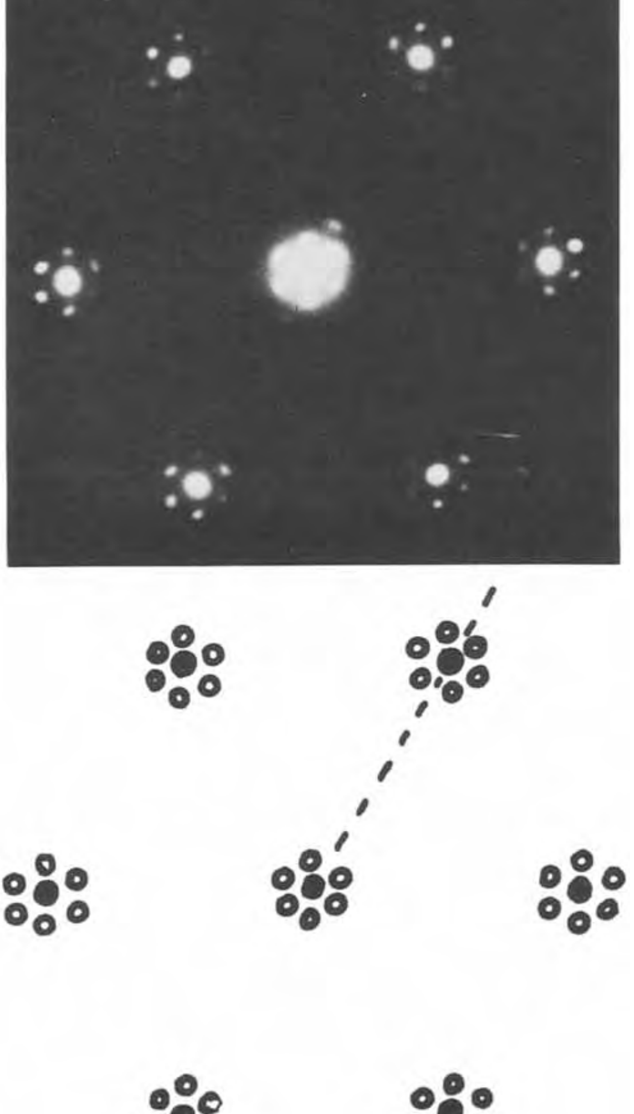
these films have the sphalerite structure in (111) orientation.

The detailed form of the Moire pattern of Fig. 6(a) was unexpected. In all previous cases the epitaxial orientation relation between sphalerite structure films of II-VI compounds and cubic structure substrates had been that of parallel alignment (6). The Moire diffraction pattern in such cases for (111) substrates would have the form shown in Fig. 6(b). The actual form however, is that of Fig. 6(c), which will be referred to as the nearly parallel, rotation pattern for reasons that are more fully explained in Fig. 7. In the present case this type of pattern arises from the naturally occurring epitaxial orientation relation. No previous observation of this type of orientation relation is known to us. Previous instances of patterns of this type were artifacts produced by attempts to lay one film on another in parallel orientation (11).

The reciprocal lattice "diffraction" vector **g** from the center spot to any particular diffraction spot has a length $1/d_{hkl}$ where d_{hkl} is the spacing of the hkl Bragg reflecting planes giving rise to the spot. The spacings of the Moire fringes which are produced in the micrographs by the interference between electron beams arising from the closely spaced spots are given by the reciprocals of the vectors joining the spots in reciprocal space. This leads (10, 11) to the Moire fringe spacing of Eq. [1]. When in addition to a difference in lattice parameter and hence interplanar spacings, d_{hkl}, between the overlapping crystals, there is an azimuthal rotation of the one crystal relative to the other through an angle α as shown in Fig. 6(c) and 7 and we have the

Fig. 5. (a, above left) Diffraction pattern of a film of CdSe grown on (110) Ge at 440°C. This is the pattern obtained when the film is tilted slightly off the exact (110) orientation. (b, above right) Bright field transmission electron micrograph of the same film.

nearly parallel, rotation pattern. Inspection of the actual Moire diffraction pattern of Fig. 6(a) together with the diagrams of Fig. 6(b) and (c) shows that the azimuthal rotation α is such as to rotate the hexagonal array of Moire spots around each CdSe spot through 30° relative to their positions in the parallel Moire



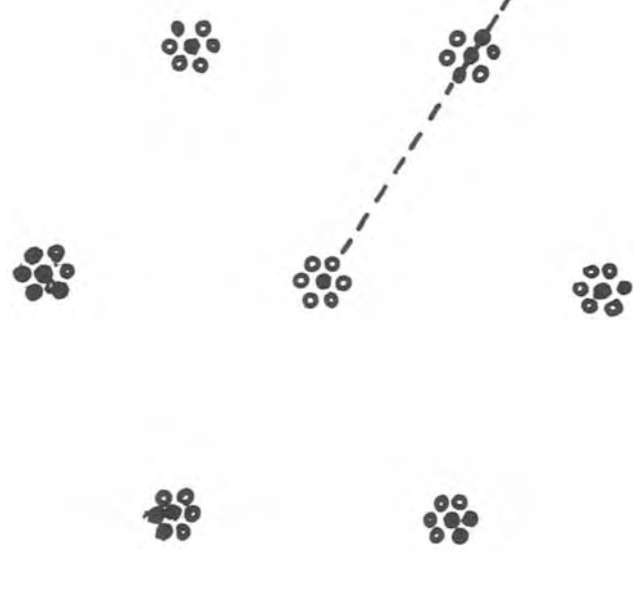


Fig. 6. (a, above left) Moire diffraction pattern obtained from an area of overlapping CdSe and Ge in (111) orientation. The film was grown at 400°C. (b, above right) The parallel Moire pattern for the (111) orientation. The CdSe and Ge single diffraction spots represented by large and small solid circles lie along common directions (radii) from the center 000 spot. (c, left) The nearly parallel, rotation Moire pattern for the (111) orientation. The diffraction vectors g to the corresponding CdSe and Ge spots are not parallel as in (b) (see the enlargements of a portion of these diffraction patterns in Fig. 7). The open circles represent double diffraction spots. The actual diffraction pattern in (a) is of the form (c) and not of the parallel form (b).

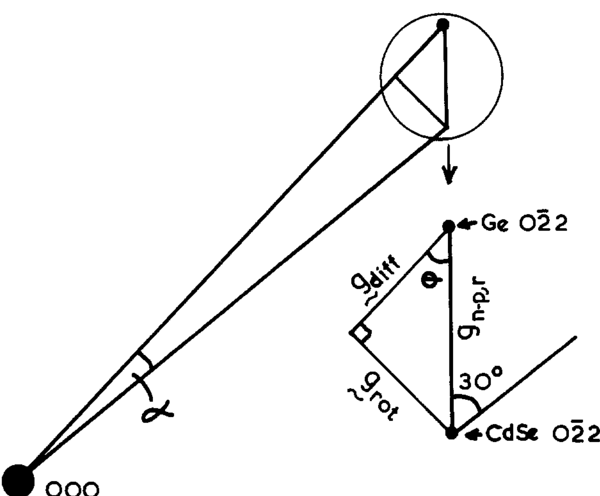

Fig. 7. In the nearly parallel, rotation Moire diffraction pattern the 0$\bar{2}$2 diffraction vectors for CdSe and Ge differ in direction by an angle, α. The enlarged drawing shows the triangle, two of the apices of which are the CdSe and Ge 0$\bar{2}$2 diffraction spots.

array, as indicated in Fig. 7. The spacing of the Moire fringes arising from the 022 type of CdSe and Ge single diffraction beams in the nearly parallel, rotation case can be found as follows (see Fig. 7)

$$|\mathbf{g}_{n-p,r}|^2 = |\mathbf{g}_{diff}|^2 + |\mathbf{g}_{rot}|^2 \qquad [2]$$

or, since α is small, (see Fig. 7)

$$|\mathbf{g}_{n-p,r}|^2 = \frac{(d_1 - d_2)^2 + \alpha^2 d_1 d_2}{d_1{}^2 d_2{}^2} \qquad [3]$$

Therefore the nearly parallel, rotation Moire fringe spacing is given by

$$D_{n-p,r} = \frac{1}{|\mathbf{g}_{n-p,r}|} = \frac{d_1 d_2}{\{(d_1 - d_2)^2 + \alpha^2 d_1 d_2\}^{1/2}} \qquad [4]$$

This is the expression quoted in Ref. (10) but not that originally quoted by Bassett *et al.* (11). In the present case this type of pattern arises from the naturally occurring epitaxial orientation relation whereas previously such patterns were only known from laying films one on top of the other in nearly parallel orientation.

The azimuthal rotation, α, can be obtained for the general case as follows

$$\tan\theta = \frac{|\mathbf{g}_{rot}|}{|\mathbf{g}_{diff}|}$$

i.e.

$$\frac{\sin\alpha}{d_1} = |\mathbf{g}_{diff}| \tan\theta$$

or

$$\sin\alpha = \left(\frac{d_1 - d_2}{d_2}\right)\tan\theta \qquad [5]$$

In the present case within experimental error, $\theta = 30°$. Calculating the spacings of the 0$\bar{2}$2 planes in CdSe and Ge using the expression $d_{hkl} = a/(h^2 + k^2 + l^2)^{1/2}$ where the lattice parameters, a, for CdSe and Ge are 6.077Å and 5.658Å, respectively, and substituting into Eq. [5] gives $\alpha = 2°24'$. This angle does not appear to have any simple crystallographic significance, despite the crystallographic appearance of the $\sim 30°$ angle of rotation of the Moire spot arrays from their positions in a parallel epitaxial alignment pattern.

Recently Matthews (12) pointed out that in many cases misfit at epitaxial interfaces could be accommodated by arrays of misfit dislocations of screw type as well as by the conventionally considered edge type networks. He gave expressions for the energy of the arrays which indicated that in some cases the minimum energy occurred for epitaxial orientation relationships azimuthally rotated from parallel alignment. This may be the explanation of the "nearly parallel, rotation" orientation relationship found here. Similarly small deviations from a quasi-parallel orientation which occurs between wurtzite structure films of CdS epitaxially grown on substrates of cubic system crystals were found by Igarashi (13). This too was quantitatively accounted for by a misfit dislocation model (13). This phenomenon of small deviations from parallel alignment therefore may occur frequently and be explicable in general in terms of misfit dislocations. Detailed studies of the actual misfit dislocations in the CdSe/(111)Ge interfaces will have to be carried out to test this hypothesis. Work on this problem is continuing. The small spacings of the misfit dislocations and the considerable densities of other defects present experimental difficulties.

Discussion

Similarities to previous observations.—As mentioned in the introduction, three general features had been found in all previous detailed studies of the epitaxial growth of vacuum evaporated films of II-VI compounds on Ge: These were: (*i*) the universal occurrence of the parallel epitaxial orientation relationship, (*ii*) the fact that only the sphalerite structure was found in films grown on (100) and (110) substrate surfaces, and (*iii*) the occurrence in the films of all the compounds when grown on (110) surfaces of the characteristic domain-form, faulted structure. A first objective of the work reported here was to discover whether the same structures and orientation relationships also occur in the case of CdSe grown on Ge. The results reported above show that generalizations (*ii*) and (*iii*) still hold good for all the materials so far examined. The parallel epitaxial orientation relationships are however, not accurately of universal occurrence. On (111) Ge, CdSe grows with a small azimuthal rotation, $\alpha = 2°24'$, from the exact parallel alignment. The reason for this deviation from parallel alignment may be that rotations minimize the energy of arrays of screw-type misfit dislocations (12).

The epitaxial growth ranges of temperature.—The epitaxial growth ranges of substrate temperature for the (100), (110), and (111) surfaces of Ge have a common upper limit, 450°C. This is a deposition cut-off temperature above which no CdSe can be made to deposit by evaporation in a pressure of a few times 10^{-6} Torr. This limit appears to be set by the onset of some vapor phase chemical attack reaction. The similarities in the deposition cut-offs in all cases investigated (6) were that (*i*) the cut-off temperature was well defined to within the accuracy of measurement of substrate temperatures (±5° to 10°C), (*ii*) it was unaffected by growth conditions such as contamination, rate of evaporation of the II-VI compound (or only slightly affected by the latter), substrate surface orientation, etc., (*iii*) above the cut-off temperature evidence of chemical attack on the substrate surfaces in the form of pitting or tarnishing was observed.

The minimum epitaxial growth temperatures in contrast to the cut-off temperatures are strongly affected by the growth conditions. The minimum epitaxial growth temperatures are reduced as contamination from all sources is reduced. The minimum epitaxial growth temperature is sometimes dependent on substrate surface orientation. In the case of ZnTe on Ge the minimum growth temperature was 300°C for both (111) and (100) substrates, and it was 300°C for CdS grown on (100), (110), and (111) surfaces of Ge. For CdTe on Ge the minimum epitaxial growth temperature was 250°C for (100) substrates but only 200°C for (110) and (111) substrates and in the present case it was found to be 350°C on (100) and (111) substrates, but only 300°C on (110) surfaces. Thus in the four

combinations of materials studied thus far, two, namely ZnTe/Ge and CdS/Ge, showed no orientation dependence of the minimum epitaxial growth temperature, while the other two did show an orientation dependence but the form of the dependence in the two cases was different. For CdTe/Ge the minimum epitaxial growth temperature was higher for (100) than for the other two singular surfaces whereas for CdSe/Ge, it was lower for (110) than for the other two singular surfaces.

The structural perfection of the CdSe films.—Little work has been published on the epitaxial growth of CdSe films. Early Russian work concerned CdSe films evaporated on to ionic crystal substrates. Electron diffraction showed the best films to be polycrystalline or to contain both wurtzite- and sphalerite-structure material (14, 15). Epitaxial films were grown on mica but their structural perfection was not determined (16). A study of the nucleation and growth of CdSe films evaporated onto cleavage surfaces of NaCl also provided little information on the perfection of the best films produced (17).

The present paper thus is the first report of CdSe films grown free of both twins and wurtzite-structure material so that the films gave rise to diffraction patterns that were free of satellite or irrational spots. The level of perfection of these films is similar to that of the other II-VI compound films studied previously in this laboratory (1-4, 6, 8, 9). It is also similar to the best levels reported for other heteroepitaxial films. The structure of the films is sufficiently good to justify the use of epitaxial CdSe/Ge heterojunctions prepared by the present methods for physical property measurements.

Acknowledgments

Thanks are due to Professor J. G. Ball for the provision of research facilities and to the Science Research Council for financial support of the work on II-VI epitaxy in this laboratory. One of us (F. H. G.) wishes to thank the Governments of India and of Karnataka State for the provision of a study grant. We are grateful to Mr. B. H. Barter for his help in the development of the vacuum evaporation and thinning techniques used in this work.

The Preparation and Characterization of a New, Highly Sensitive, Crosslinking Electron Resist

J. L. Bartelt and E. D. Feit

Bell Laboratories, Murray Hill, New Jersey 07974

ABSTRACT

The feasibility of current proposals for electron beam exposure systems depends heavily on the availability of electron resists of high sensitivity (greater than 100 m^2/coulomb) in which relief images with submicron features can be made. An acrylate-based polymer system (a terpolymer of glycidyl methacrylate, ethyl acrylate, and methyl methacrylate partially esterified with methacrylic acid) containing epoxy and vinyl reactive sites has been found to be a promising negative electron resist system, called CER, whose characteristics include high sensitivity (125 m^2/coulomb), good adhesion to SiO_2 and metals, and good chemical resistance to etchants for these materials. The composition, characteristics, and processing of CER are presented here in detail.

Electron Sensitive Polymers and E-Beam Microfabrication

The fabrication of microelectronic devices by means of electron exposure of specially prepared resists has several advantages over conventional photoresist technology. These advantages include higher theoretical resolution, larger depth of field, and the conveniences and economies of direct "on the wafer" exposures using automatic computer controlled pattern generation systems. The technology currently available for such exposure systems, however, places a great demand on the sensitivity of resists (1). For scanning systems with submicron beam sizes high sensitivity is required to allow rapid deflection of beams with relatively low current density. Deflection and blanking systems can operate at rates of about 10^7 bits/sec so that with a raster of 2000 lines/mm (0.5 μm spot size) an area of 25 cm^2 can be covered in about 17 min. In order to

Key words: electron resist, crosslinking.

operate at these rates with the currents available for 0.1 μm beam sizes (2.5×10^{-8}A for a tungsten filament) resist sensitivities must be in excess of 100 m^2/coulomb.[1]

While sensitivity is of critical importance, contrast, adhesion, etch resistance, and defect density are equally vital characteristics that influence electron resist selection. Molecular weight distribution and glass transition temperature are significant resist properties also (4), but we have concentrated on sensitivity and processing in this work. The adhesion, etch resistance, and resolution capabilities of this material will be presented in detail elsewhere (5).

In Fig. 1 we show the sensitivities of a number of electron sensitive crosslinking materials which have been reported in the literature (6), all of which have the potential of being negative electron resists. The three epoxy-based polymers [epoxidized-polybutadiene, epoxidized-polyisoprene, and polyglycidylmethacrylate (7)] and the polymer system marked CER which we have formulated are sufficiently sensitive to meet the criterion established above. As a practical matter, however, note that sensitivity can only be determined relative to the specific processing or end use for which it is intended. Factors such as film thickness, accelerating voltage, chemical developers, baking temperatures, etc. have an effect on sensitivity and thus one must be particularly careful in the use and comparison of these literature values. We have not been able to reproduce the exact sensitivity, for example, that was originally reported for the three epoxy-based polymers (5, 7). Moreover, we have found that CER responds more sharply to changes in dose (has higher contrast) than do the epoxy rubbers [see Fig. 4 and Ref. (5)].

Our approach to the development of a sensitive electron resist was an extension of the work on epoxy-based resists (7) in a direction already taken by Schoenthaler (8). In the latter's work, the epoxy groups of the polymer are esterified with acrylic and methacrylic acid. Some commercial photoresists in the Riston (du Pont) family are believed to have reactive binders based on this type of polymer (9).

The polymer system that we call CER is a material described by Burlant and Taylor as a radiation sensitive binder (10, 11). This material is a terpolymer of glycidyl methacrylate, methyl methacrylate, and ethyl acrylate. The epoxy groups in this terpolymer, provided by the glycidyl methacrylate, are partially esterified with methacrylic acid to introduce unsaturation. Figure 2 outlines this process and shows a composite of final components of CER.

[1] There have been alternate proposals (2, 3) in which the resist is simultaneously exposed over an entire pattern and the beam is shaped by masks or patterned cathodes. Since much more current can be produced in such a beam, sensitivity is no longer a critical factor. The successful development of these systems will probably take several more years.

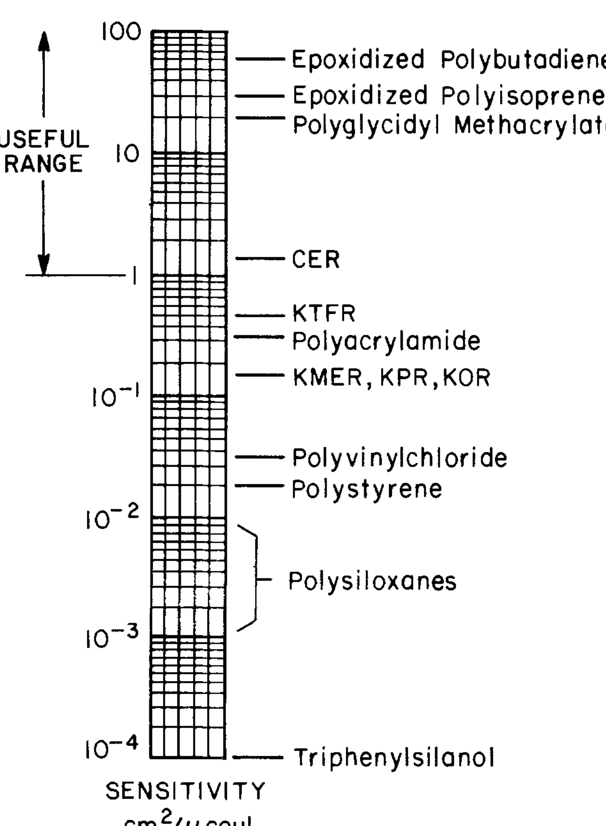

Fig. 1. Electron sensitivity of crosslinking polymers

Preparation and Characterization of CER

Synthesis.—CER was prepared according to the procedure of Burlant and Taylor (10). Benzoyl peroxide (1.00g, 4.1 mmol) was dissolved in a mixture of methyl methacrylate (26.0g, 260 mmol), ethyl acrylate (50.0g, 500 mmol), and glycidyl methacrylate (23.7g, 167 mmol). The vinyl monomers were used as supplied, without removal of stabilizers. This mixture was added over a 3 hr period with stirring to refluxing xylene (250 ml) in a nitrogen atmosphere. The mixture was refluxed for an additional 3 hr, cooled at 50°C, and stabilized with hydroquinone (0.0203g, 0.18 mmol). Methacrylic acid (14.7g, 171 mmol) was added. The reaction mixture was then gradually warmed to reflux and held at that temperature until the concentration of methacrylic acid was decreased to 30.8% of its original value as measured by titration of 2 ml aliquots of the reaction mixture with 0.05N KOH.

We purified the CER by solvent precipitation before use to eliminate low molecular weight material which affects the rate at which developer swells the film. Samples of crude, oily CER were diluted to about 2% solids with xylene and precipitated in an ice-cooled, 10:2:1 mixture of petroleum ether, isopropanol, and water. The resulting white, solid precipitate was filtered and dried.

Film preparation.—Films used to characterize CER were produced by spin coating on a Headway Research EC-101 Spinner from a 4% solution in xylene. For the metal and oxide substrates (Si, SiO_2, W, Cr) that were used in this study good adhesion was obtained without the need for surface adhesion promotors or treatments. The film thickness depends on the spinning speed and on the concentration or viscosity of the resist. A convenient relation between thickness (T) in microns and spinning speed (S) in rpm for the 4% solution described above is

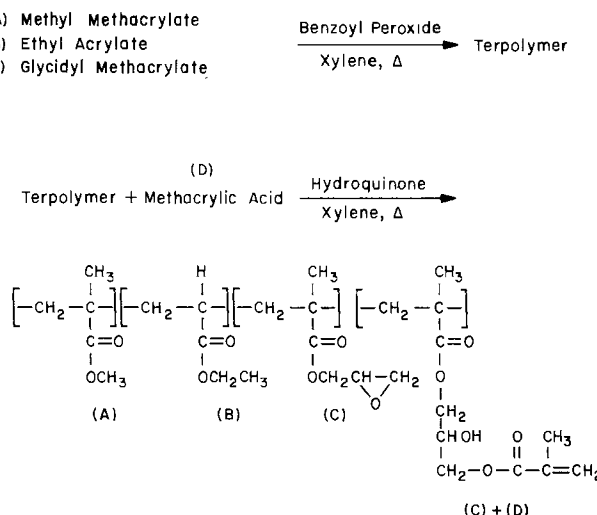

Fig. 2. Synthesis of CER

$$T = 13.4S^{-1/2}$$

We typically used the film in the range 0.2-0.4 μm, the thicker films being preferred to minimize pinhole problems. About 40 pinholes/cm² are found in 0.2 μm films of CER while 0.4 μm films have about 15 pinholes/cm².

Prior to use the films were prebaked in a vacuum oven at 90°C for 15 min. This serves to remove the solvent and by raising the CER above its glass transition temperature, to anneal any coating strain. After cooling, the material was exposed as soon as possible. If the material stood for long periods in a thin film after baking, it tended to spontaneously crosslink. The lifetime of the prepared films was on the order of 12-18 hr in room light. If the solution is kept cool and dark, its shelf life exceeds nine months.

Exposure and sensitivity.—Films of CER which were prepared according to the preceding steps were first tested for sensitivity to electron crosslinking by exposure in a flood gun system. A stationary beam is projected through a metal screen which forms a mask in contact with the sample. The beam voltage, current, and exposure time are controlled independently. Figure 3 shows a developed pattern in CER from just such an exposure. The exposure was made with an accelerating voltage of 10 kV and the dose was 3×10^{-7} coulomb/cm². It was later found that this exposure was less than optimum, but sufficient to define an image of the mask.

The technique which we prefer to use to measure the sensitivity of CER is one which can be used for any electron sensitive material: Using an SEM, 1 mm squares are exposed with a raster scan of at least 2500 lines at the required voltage, adjusting the current and exposure time so as to vary the dose over the required range. After developing and baking the thickness of

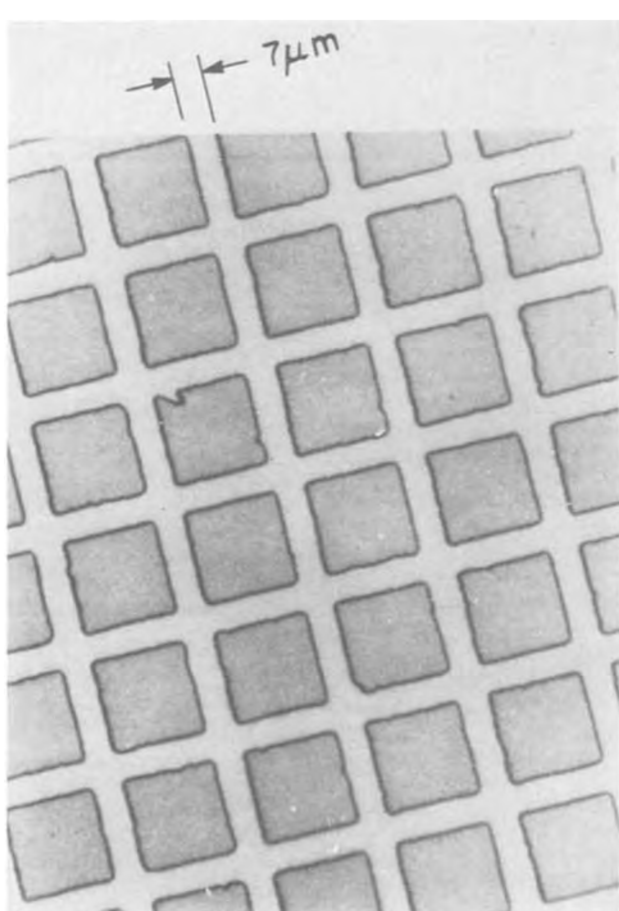

Fig. 3. Mesh pattern in CER produced by flood gun exposure

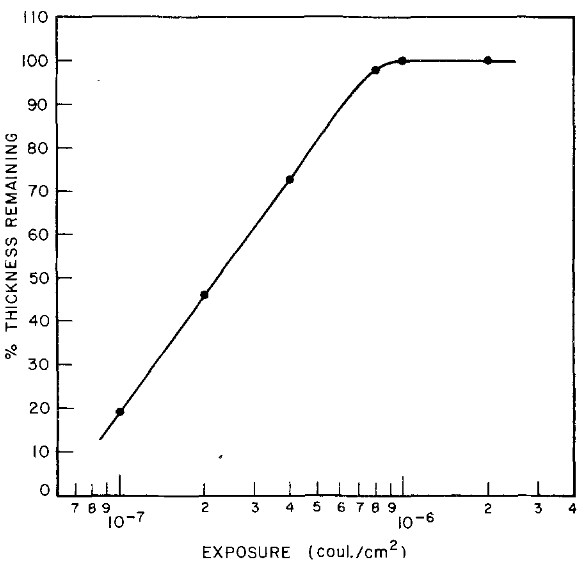

Fig. 4. Sensitivity of CER (thickness = 0.35 μm, accelerating voltage = 10 kV).

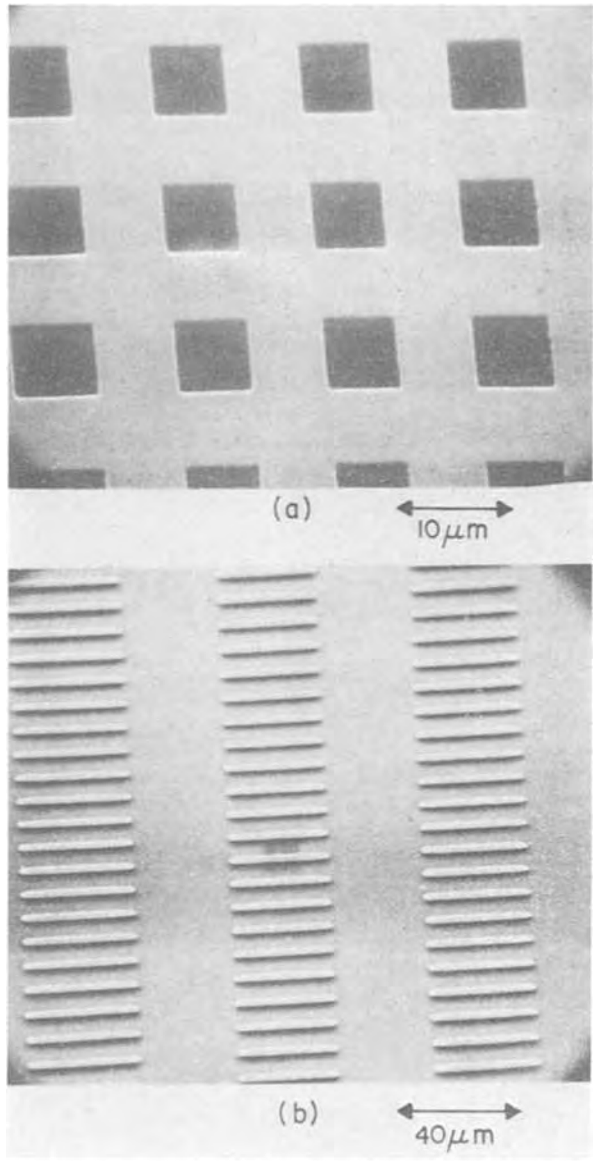

Fig. 5. (a) 6 μm windows etched into 0.2 μm of SiO_2 using CER as a mask, (b) 4 μm line and space patterns etched into W using CER as a mask.

each exposure square is measured with a calibrated stylus profilometer (Dektak, Sloan Technology Corporation). The per cent thickness remaining after development is then plotted as a function of dosage. Figure 4 shows a typical plot for 0.35 μm of CER exposed at 5 kV.

Development, postbaking, and stripping.—Initially the development for CER consisted of a 60 sec soak in xylene followed by a 30 sec spray of xylene and then blowing dry with air. While many of our initial patterns were developed in this manner, it was decided to switch to a spray development technique which has been successfully used with photoresists to improve edge acuity and resolution and to decrease pinholing due to extraction by progressively changing from solvent to nonsolvent as development proceeds. We also used an automatic spray developer (K & S Model 693 Photo Resist Spray Developer) to improve uniformity and reproducibility. A spray sequence of 7.5 sec of methyl ethyl ketone (MEK), 20 sec of 1:1 MEK:2-propanol, 15 sec of 2-propanol, and 30 sec of dry nitrogen was found to be quite effective.

After development a 20 min bake at 120°C is recommended before etching.

CER, patterned according to the process given above, has been used successfully to etch SiO_2 in buffered HF and to etch W in an alkaline ferricyanide solution (5). Features in the size range 4-6μ are shown in Fig. 5. The ultimate resolution with this material can only be obtained with careful selection of film thickness, voltage, contrast, and exposure as detailed in Ref. (5).

Exposed CER is most conveniently removed by a dichromate-sulfuric acid cleaning solution, but ozone or plasma stripping as well as other strong oxidizing agents have also been used successfully.

Conclusions

The electron resist which we have documented here represents a significant improvement over many of the electron resists previously described in the literature (Fig. 1) and is a viable alternative to the others (7) with respect to the sensitivity, contrast, and resolution required for electron beam fabrication of semiconductor devices. In addition we have demonstrated the patternability of CER and its usefulness as an etch mask for SiO_2 and W.

Optimization of the Hydrazine-Water Solution for Anisotropic Etching of Silicon in Integrated Circuit Technology

Michel J. Declercq,[1] Levy Gerzberg,* and James D. Meindl**

Stanford Electronics Laboratories, Stanford University, Stanford, California 94305

ABSTRACT

Anisotropic etching of silicon with the hydrazine-water mixture is studied and characterized for its practical use in integrated circuit technology. The solution is applied to {100} wafers where the etch presents a v-shaped cross section limited at the side-walls by {111} planes and at the bottom by a {100} plane. The etching process is evaluated in terms of the etch rate of the {100} plane, quality of side-walls and bottom surface, and corner rounding. It is shown that the results are both concentration and temperature dependent. The optimal temperature for the etching process is found to be 100°C for both simple temperature control and high quality etching. It is also shown that the optimal mixture concentration must be choesn according to the particular use of the anisotropic etching. The optimal volume concentrations of hydrazine for the various applications are: 65% for VMOS devices and for v-groove isolation rings, 70-80% for two-level structures with flat bottom surface, and for electrode and sensor fabrication.

The anisotropic etching of silicon has been studied with increased interest in recent years (1-7) and is on the way to becoming a standard processing step in silicon technology (8-12).

Anisotropic etchants are usually 3-component solutions. They contain a base such as hydrazine, ethylene diamine, or potassium hydroxide, a complexing agent such as isopropyl alcohol or catechol, and water. The etching reaction involves the formation of hydrous silica which is dissolved through the formation of a complex (1). Some compounds such as hydrazine can act both as oxidant and complexing agent (2) and can therefore be mixed with water only. Another etching method based on an electrochemical displacement reaction has also been proposed recently (5).

All these solutions have the common property that they etch the silicon crystal with a higher rate along the <100> direction than along the <111> direction. When used on {100} oriented slices covered by an oxide mask, these etchants produce a pyramidal-shaped etch, limited at the side-walls by {111} surfaces and at the bottom by a {100} plane (Fig. 1). An interesting property of the anisotropic etching of {100} surfaces is that the etch is "self-stopping" at the point where the {111} planes intersect and the {100} bottom surface reduces to zero.

Among the most significant applications published for the anisotropic etching of the silicon are the v-groove or dielectric isolation of integrated circuits (8-10), the VMOS structures (11-14), and the etching of microelectrodes and sensors (15, 16). Each of these applications has been concerned mainly with the quality of the groove side-walls, since the {100} bottom surface has completely disappeared either due to the "self-stopping" property or to the complete etching through of the entire wafer thickness. However, no optimization of the etching parameters has been reported for these applications.

On the other hand, many new applications may be anticipated if the etch is terminated before reaching its "self-stopping" point. For example, the resulting {100} bottom surface may be used for two-level structures, for direct contact to a lower layer of an integrated circuit, for the fabrication of pressure sensors and other devices for which a flat surface is required, etc. The anisotropic etch offers a unique possibility for two-level structures by its clean cut, nonvertical walls, which avoid breaking the photoresist or the metal strips on the step between the two levels.

The purpose of this study is to characterize the hydrazine-water mixture and to find the optimum etching parameters according to the particular application.

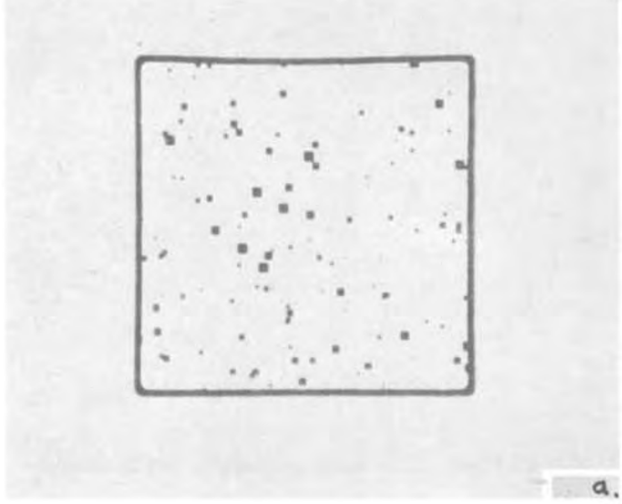
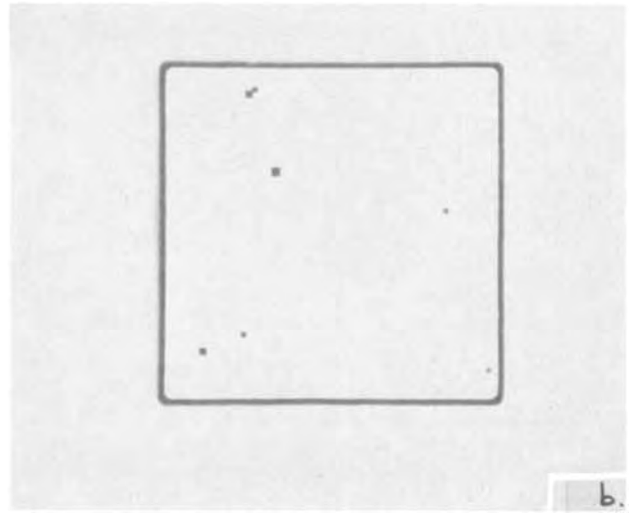
Experimental Procedure

A glass refluxing system was used to prevent composition change by loss of volatile matter. The temperature was controlled within ±1°C by a constant temperature bath. N-type {100} wafers of 3-5 ohm-cm resistivity were used throughout the experiment. An oxide layer of about 2000Å was grown on the wafers at a temperature of 1000°C. The mask was aligned on the <110> wafer flat with a precision of ±1° or better, in order to get straight side-wall lines as explained later. A standard cleaning procedure (17) was performed just before etching. The results of the anisotropic etching were evaluated in terms of the etch rate of the {100} plane, quality of side-walls and corners,





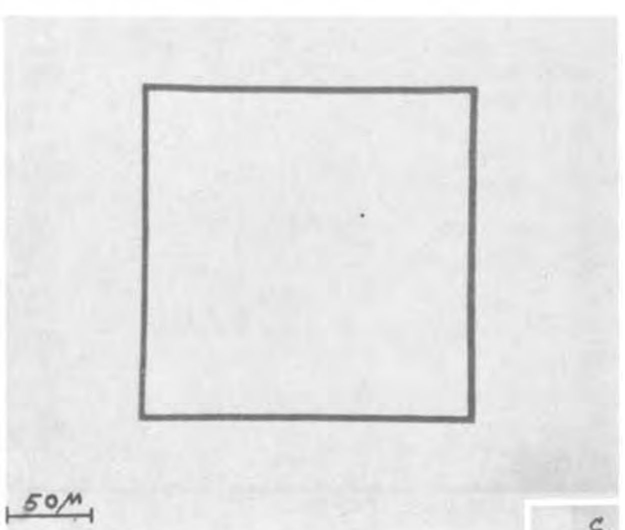


Fig. 5. 200 × 200 (μm)^2 squares etched 5μ deep at 100°C in solutions of various concentrations. a, above left H_2O/N_2H_4 = 50/50 (volume ratio); b, above right H_2O/N_2H_4 = 40/60 (volume ratio); c, left H_2O/N_2H_4 = 20/80 (volume ratio).

and quality of bottom surface. These parameters were examined for several concentrations of water and hydrazine at 20°, 75°, 100°C and at the boiling temperatures of the solutions. All the proportions of hydrazine and water were measured in volume per cent. The etched bottom surface was examined across both small area (~16 mil²) and large area (~400 mil²) structures. The side-walls were checked around these etched areas and in v-groove isolation type structures. A triangular area with a top angle of 7° was placed on the mask in order to evaluate the effect of a ±3.5° misalignment on the quality of the side-walls (Fig. 2). The depth of the groove was measured microscopically using a focusing stage calibrated to one micron per scale division. Each experiment was repeated several times on different samples in order to eliminate angle and depth measurement errors.

Results

Etch rate.—The etch rate of the {100} plane as a function of water percentage in the solution is shown in Fig. 3 for several temperatures. These results are in good agreement with the results reported by Lee (2). It is obvious from Fig. 3 that the etch rate can be temperature or concentration controlled. The etch rate increases with temperature, and in the high temperature range it reaches its maximum value when an equivolume solution of water and hydrazine is used. At 20°C, the etch rate has a minimum value which occurs for a 40% water-60% hydrazine solution.

Quality of bottom surface and side-walls.—It has been observed that the quality of the bottom surface may be affected in two ways: by the formation of pyramidal hillocks and by the formation of wave-shaped structures (Fig. 4).

The quality of the bottom surface was found to be dependent on both the temperature and the solution concentration as demonstrated in Fig. 5 and Fig. 6. For an equivolume solution of water and hydrazine, both pyramids and a waveshaped bottom appear at any temperature. At 100°C less water gives higher bottom surface quality, and for 30% water or less there are no pyramids or waves on the bottom at all. The effect of temperature on the bottom surface quality is seen in Fig. 6 in which a solution of 20% water and 80% hydrazine was used at various temperatures. Etching at temperatures below or above 100°C caused a wave-shaped bottom surface. At room temperature, pyramids also appeared.

The quality of the bottom surface was measured in terms of the percentage of etched 100 × 100 (μm)²

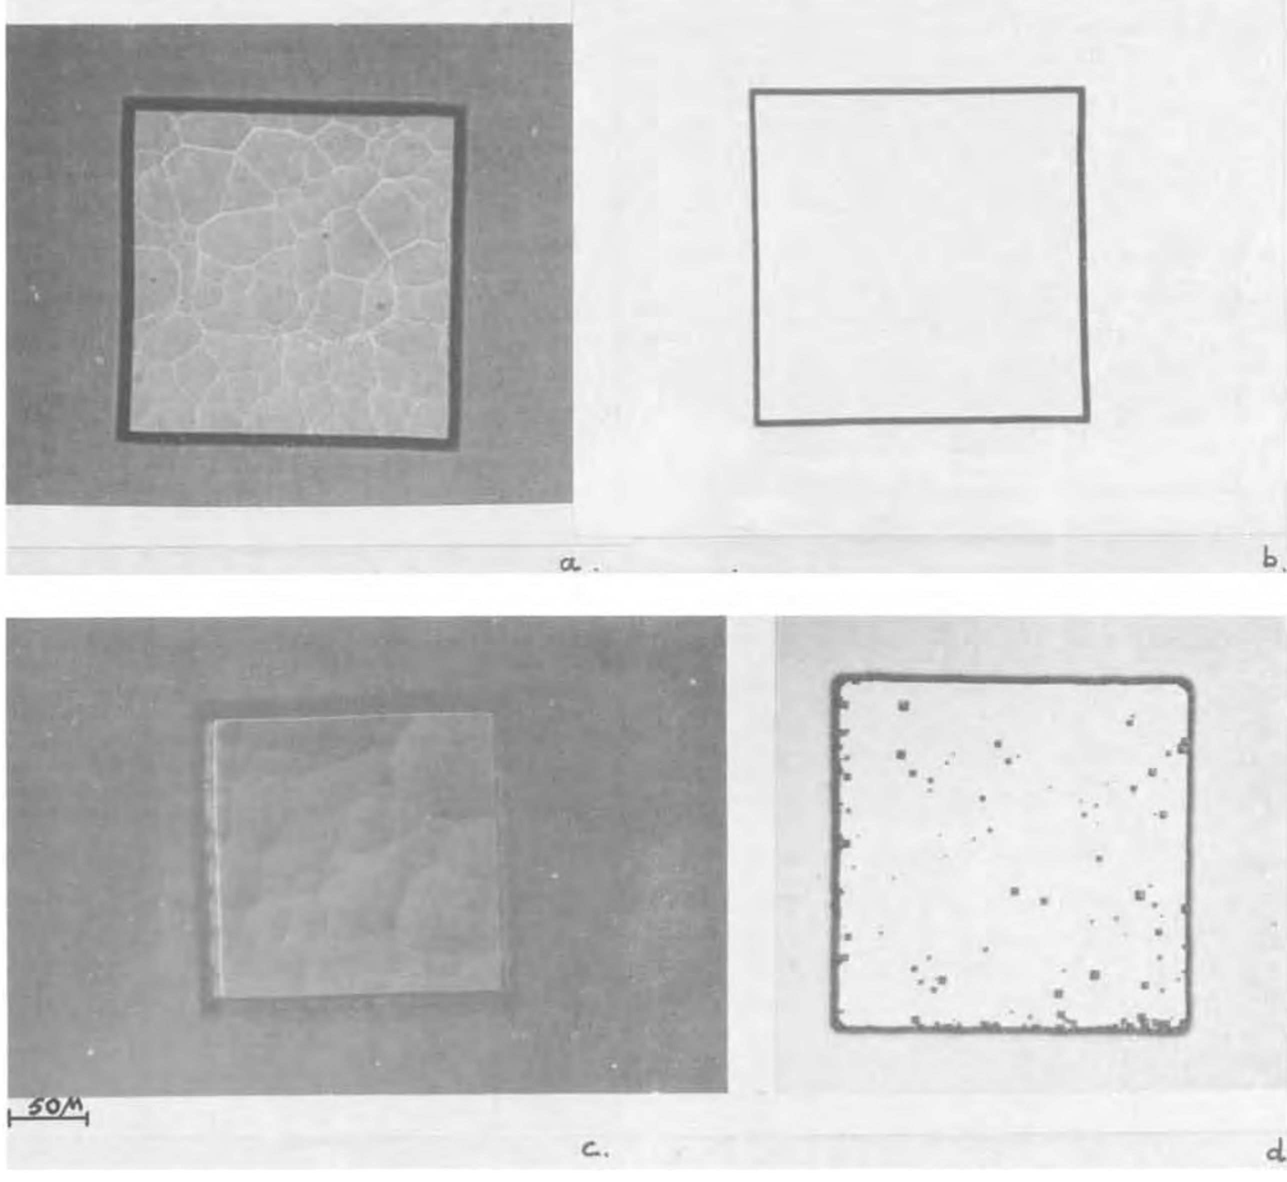

Fig. 6. 200 × 200 (μm)² squares etched 5μ deep in solutions of 20% H_2O-80% N_2H_4 at various temperatures. a, 119°C; b, 100°C; c, 75°C; d, 20°C.

areas, free of waves or pyramids, which can be used for device fabrication. The measured quality function is plotted in Fig. 7. The quality of the side-walls was measured in terms of the side-wall edge formed by the intersection of the {100} and {111} planes. Walls with straight edges were considered to be of high quality. The best side-wall edges were obtained at 100°C. It has been observed that for this temperature, the side-wall lines become more straight as the percentage of water in the solution is increased. The observed quality of the side-wall edges for various temperatures as a function of the solution concentration is given in Fig. 7. An example of poor side-wall quality is given in Fig. 6c for etching with a solution of 20% water-80% hydrazine at 75°C.

From these results it can be inferred that straight walls can be obtained at 100°C and with 20-50% of water in the solution. However, the usable range of concentration for v-groove etching has to be limited by a maximum of 40% water, due to the pyramidal defects that may appear in the groove when higher percentage of water is used. When high quality of bottom surface is also required, the amount of water should not exceed 30%.

Quality of corners.—The quality of corners was examined in concave (90°) and convex (270°C) corners. Concave corners, similar to those in rectangular etched surfaces, had very little corner rounding (Fig. 5, 6). Convex corners, like those existing in v-groove isolated structures, have more significant beveling (undercutting) due to etching in other crystallographic directions. The mean value measured for the angle made on the (100) surface by the bevel line and the trace of the {111} plane was 18° 41′. This confirms the observations made by Lee (2) and indicates that the planes being etched are the {112} planes which generate the theoretical angle of 18° 26′ on the top surface. To get a quantitative estimate of this convex corner underetching, let U be a normalized factor defined by

$$U = \frac{\delta}{H} \qquad [1]$$

with δ, the distance between a {112} plane intersection line and a parallel line traced from the corner of the oxide limit (Fig. 8) and *H*, the groove depth.

With a constant temperature of 100°C, the underetching factor decreases uniformly for an increased amount of water in the solution, as shown in Fig. 9a. At 20°C, the underetching factor has a minimum at 30% H_2O-70% N_2H_4 and increases sharply for higher amounts of water in the solution. It is therefore obvious that *U* is also temperature dependent for a given concentration. This effect is illustrated in Fig. 9b for a solution of 20% H_2O-80% N_2H_4.

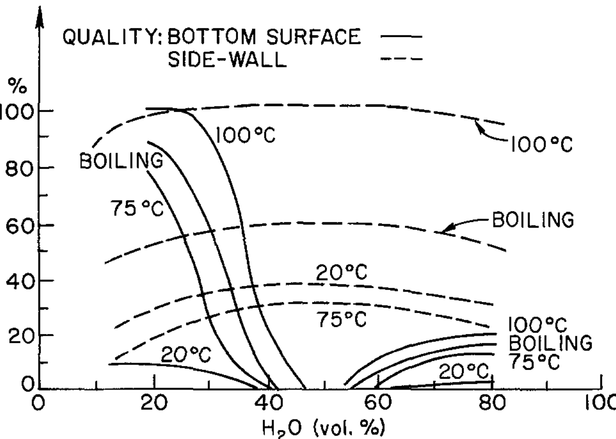

Fig. 7. Bottom surface quality (in per cent of usable 16 mil² squares) and side-wall quality (estimated value in per cent).

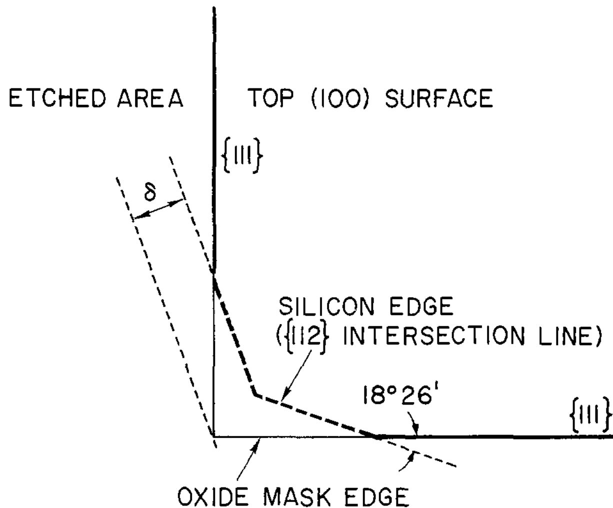

Fig. 8. Underetching of a convex corner under the SiO_2 mask along the {112} plane (top view).

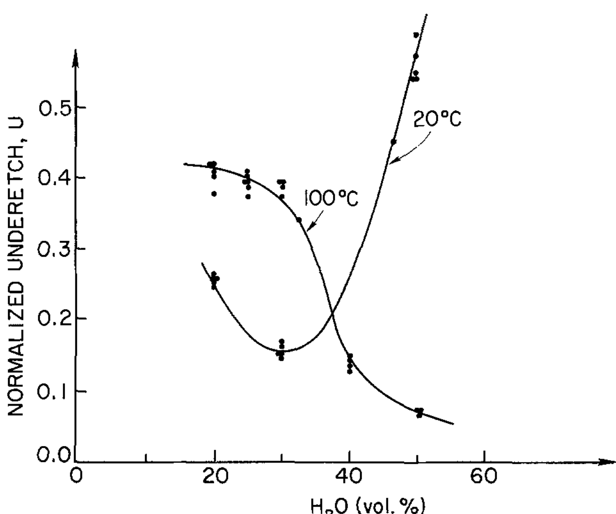

Fig. 9a. Variation of the underetching factor *U* with the solution concentration.

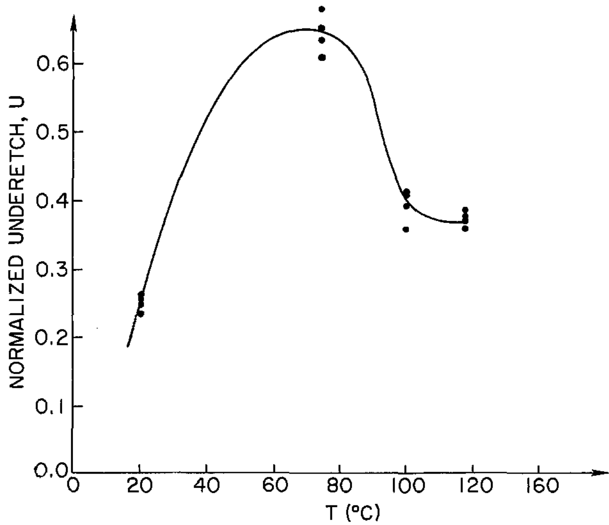

Fig. 9b. Variation of the underetching factor *U* with the temperature for a solution of 20% H_2O-80% N_2H_4.

An example of the effect of the solution concentration on the corner underetch at 100°C is given in Fig. 10a, b. Both grooves have the same depth of 15μ, but the groove of Fig. 10a was etched with a 20% H_2O-80% N_2H_4 mixture, while the groove of Fig. 10b was etched with a 50% H_2O-50% N_2H_4 mixture. This effect plays an important role in the design of a v-groove isolated bipolar transistor since it can reduce drastically the original surface. Underetching can be minimized by carefully choosing the parameters of the etching solution.

Self-correction of unstraight lines.—An interesting property due to the selectivity of the hydrazine-water solution is the fact that side-wall edges will come out straight after etching, even with small ripples in the oxide mask (Fig. 11). On the other hand, a large misalignment of the mask will give as a result a sawtooth-shaped line, even for straight mask edges (Fig. 12).

Discussion of the Results

In the experimental results previously described, two kinds of defects have been observed: pyramids and waves on the bottom surface. The appearance of pyramids is explained by the following reasons:

1. Square pyramidal hillocks may be formed from defects on the surface of the starting material or at deeper points in the bulk (Fig. 4 and Fig. 5).
2. The chemical reaction of the etching process is involved with the formation and dissolution of hydrous silica. In some cases, this oxide is locally not dissolved fast enough and gives rise to the development of new pyramids.

The effect of the formation of a large number of pyramids can easily be seen when using room temperature solutions. An example of the result obtained after 3 hr in a solution of 30% water and 70% hydrazine at 20°C is shown in Fig. 13.

It has been reported that the presence of an alcohol in the etching solution helps in the dissolution of the oxide, appearing during the reaction, by the formation of a complex (1, 2). Although hydrazine itself is able to act both as oxidant and complexing agent (2), an attempt was made to add catechol in the solution to help the reaction. The result of this test compared to the result obtained with a solution containing water and hydrazine only is presented in Fig. 14. It can be seen that the opposite effect is obtained, and that many new pyramids were grown on the surface in the presence of alcohol. A suggested explanation for this behavior is the strong effect of alcohol on the relative etch rate along the different crystallographic direc-

tions (2, 6) which will affect the surface quality as explained later.

3. The fact that the quality of the bottom surface and side-walls is affected by temperature, solution concentration or the presence of an alcohol is also related to the selectivity of the etching solution.

When the selectivity of the solution is high (*i.e.*, high etch rate along <100> and low along the other directions), every defect or contamination may be the origin of a pyramid. The side-walls, however, will be very well defined in this case by {111} planes, and therefore will be very straight.

In solutions with low selectivity, pyramids that start growing are etched from the sides in the <111> and <112> directions and therefore will not exist at

the end of the etching process. For the same reason, the property of the self-correction of the mask edges (Fig. 11) is reduced, and therefore more wall defects may appear. Wave-type disturbances on the bottom surface may appear if care is not taken to avoid local nonuniformities in the etching solution. This effect usually happens when the wafer is not carefully dried before immersed in the etching solution, or when the solution is not well stirred. However, even with such care, some unexplained waviness appeared for particular temperatures and concentrations (Fig. 6).

Conclusions

The hydrazine-water mixture etches the silicon crystal anisotropically with a higher etch rate along the <100> direction than along the <111> direction. It has been shown that temperature and solution concentration strongly influence the results. Besides the etch rate measurements, the etch quality has been examined in terms of wall and bottom surface quality, corner undercutting, and self-correction of unstraight mask edges. The conclusions may be summarized as follows:

1. The optimal temperature for the hydrazine-water anisotropic etch is found to be 100°C, for both simple temperature control and high quality etching.
2. The percentage of water in the mixture must be chosen according to the particular use of the anisotropic etching: (*i*) For v-groove rings like those used for bipolar transistor isolation, the solution which gives the best wall quality, low undercutting, and an acceptable yield at the same time should contain about 65% hydrazine (Fig. 15a). For these concentrations, typical values of the underetching factor U are around 0.25. The same range of concentration can be used for VMOS devices where {111} wall quality is the only important parameter (11) (see Fig. 15b). (*ii*) For use in two-level structures where both good walls and high quality bottom surface are required, the best concentration range is between 70 and 80% hydrazine. The same ratio is recommended for the etching of electrodes and sensors where a large etched area with a high degree of smoothness is required. An example of the results obtained in this range of concentration is shown in Fig. 16.
3. The wafer should be carefully cleaned and dried just before etching.
4. In order to ensure constant solution concentration, the solution, while in use, should be kept in a reflux system to avoid excessive evaporation.

Accurate Theoretical Arsenic Diffusion Profiles in Silicon from Processing Data

R. K. Jain and R. J. Van Overstraeten

Departement Elektrotechniek, Laboratorium Fysica en Elektronica van de Halfgeleiders,

Katholieke Universiteit Leuven, Kardinaal Mercierlaan 94, 3030 Heverlee, Belgium

ABSTRACT

An accurate knowledge of the impurity distribution in a semiconductor device is essential for its proper characterization. This task can be made simpler if one knows properly the concentration dependent impurity diffusion coefficient. In recent years various arsenic diffusion models were developed to explain the experimental results, but it seems that a better physical model is required. The present work gives the arsenic concentration dependent diffusivity in silicon considering different mechanisms involved during the diffusion process. The effects of heavy doping and high temperature have been successfully included in the present work. Attempts are made to calculate theoretical arsenic diffusion profiles only from the knowledge of the processing data. It is found that our physical model gives quite good results which are in reasonable agreement with the experimental profiles.

Accurate knowledge of the impurity distribution into a semiconductor device is essential for its proper characterization. The calculation of a distribution can be made if one knows the concentration dependent impurity diffusion coefficient. The present work is an attempt to calculate the arsenic concentration dependent diffusivity. Use of these results is to calculate numerically the arsenic diffusion profiles from the knowledge of the processing data.

It is now well known that the diffusion coefficient of the impurities in semiconductors is not only a function of the temperature but also depends on the impurity concentration. There are various phenomena which are responsible for this impurity concentration dependent diffusivity. In recent years various workers (1-6) have presented different models of arsenic diffusion in silicon. The first three models (1-3) explain the concentration dependent arsenic diffusivity in terms of the change in the electron concentration due to the impurity concentration. The mathematical approach by Kennedy and Murley (4) makes use of the Boltzmann-Matano analysis on several experimentally determined arsenic profiles into silicon, to give a concentration dependent diffusion coefficient. The arsenic diffusion model developed by Chiu and Ghosh (5) is an improvement over Hu's (2) model and defines the concentration dependent diffusion coefficient taking into account the effects of two vacancy acceptor levels, effects of the internal electric field, and effects of arsenic clustering. Recently Fair and Weber (6) published an arsenic diffusion model based on an arsenic complex formation phenomena, which differs from the model of Chiu and Ghosh (5). The arsenic complex considered by Fair and Weber consists of two arsenic atoms; the model of Chiu and Ghosh assumes that each cluster consists of four arsenic atoms, after Hu (7).

Recently Van Overstraeten, De Man, and Mertens (8) have developed a new transport theory in heavily doped silicon and more recently Jain and Van Overstraeten (9) have extended this theory to high temperatures. In the present paper use of these results is made to calculate the concentration dependence of the arsenic diffusion coefficient by considering quantitatively the various mechanisms affecting the diffusion mechanism. Based on our data we also present some

Key words: arsenic diffusion profiles, silicon, heavy doping and high temperature effects, concentration dependent diffusion coefficient, processing data.

arsenic diffusion profiles. It is found that our numerically calculated arsenic profiles are in better agreement with the experimental arsenic profiles than the earlier theoretical results. In the present work we consider the diffusion of arsenic into a boron doped silicon crystal.

Brief Summary of the Basic Approach

The purpose of this section is to describe physically and mathematically the high doping and high temperature effects. More details are found in recent references (8, 9) and are omitted here for brevity.

Heavy doping effects.—Heavy doping effects are mainly characterized by the formation of band tails and of an impurity band as illustrated in Fig. 1. The scheme presented in Fig. 1 shows the density of states *vs.* electron energy for a heavily arsenic and lightly boron doped silicon. According to classical theory two parabolic density of states functions exist with well-defined band edges (E_{CI} for the conduction band and E_{VI} for the valence band); E_G is the intrinsic silicon bandgap energy. In the lightly arsenic (donor) and boron (acceptor) doped material there also exists a discrete arsenic (donor) energy level, E_{As}, and a boron (acceptor) energy level, E_B. However, when the doping level increases, the classically predicted picture is no longer valid because of the following two facts.

(*i*) Kane (10) has shown that the statistical distribution of the impurity atoms results in the formation of a Gaussian band tail, instead of a well-defined band edge and that this tail can be described mathematically by (10, 8)

$$\rho_{cond}(E) = m_e^{*3/2}(\sigma 2^{3/2})^{1/2}\pi^{-2}\hbar^{-3}y(E/\sigma\sqrt{2}) \quad [1]$$

where

$$y(E/\sigma\sqrt{2}) = \frac{1}{\pi^{1/2}} \int_{-\infty}^{E/\sigma\sqrt{2}} (E/\sigma\sqrt{2} - m)^{1/2} \exp(-m^2)\,dm$$

Similarly an expression for $\rho_{vale}(E)$ can also be written.

(*ii*) Morgan (11) has shown that the impurity-impurity interaction causes the overlapping of the electron wave functions, so that the discrete impurity level splits into a continuous Gaussian impurity band, which is centered around the nondegenerate impurity level and can be described mathematically as (8, 11, 12)

$$\rho_{As}(E) = 2N_{As}(2\pi)^{-1/2}\sigma_{eff}^{-1} \exp\left[-\frac{(E - E_{As})^2}{2\sigma_{eff}^2}\right] \quad [2]$$

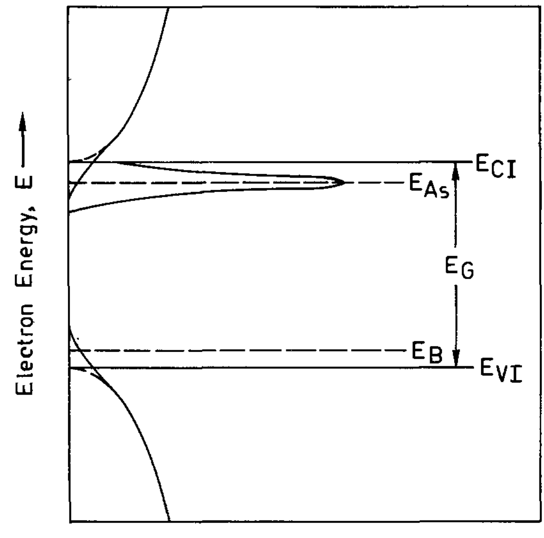

Fig. 1. Illustration of the heavy doping effects. Plots of the density of states functions *vs.* electron energy for a heavily arsenic doped silicon.

High temperature effects.—To perform theoretical calculations at diffusion temperatures (which are normally in the range 900°-1200°C for silicon) it is also necessary to incorporate the temperature dependence of the various physical parameters encountered in the calculations. Figure 2 illustrates quantitatively the high temperature effects. In Fig. 2a we have shown, respectively, the temperature dependence of the intrinsic silicon energy bandgap and of the various impurity and defect levels. The change in the position of the various impurity and defect levels from the middle of the bandgap has been assumed to be proportional to the change in the silicon bandgap. The mathematical equations in Fig. 2a describe the position of the various impurity and defect levels from the band edges. In Fig. 2b we have shown, respectively, the temperature dependence of the electron and of the hole density-of-states effective mass after a semi-empirical approach proposed by the authors (9).

Calculation of the Fermi level.—The Fermi energy, E_F, is the most important basic parameter which occurs in the various definitions explained in semiconductor physics. To develop a physical model for the impurity diffusion an accurate knowledge of the Fermi level as a function of the concentration is necessary. The detailed calculation of E_F taking into account a position dependent band structure and high temperature effects has been performed recently (8, 9) and is not considered here. The Fermi energy, E_F, is calculated numerically by solving the usual charge balance equation considering the effects mentioned earlier. Here it must be remarked that in the present analysis we have considered σ_{eff} for σ appearing in Eq. [1] because of the fact that the same physical effect (fluctuations in the crystal potential) is responsible for band tailing as well as for the impurity band formation. It must also be noted that in the present work we do not consider the numerical factor 2 [due to spin degeneracy (15)] appearing in Eq. [2], because of the fact that the donor states become part of the conduction band. It should be emphasized that the exact value of some heavy doping parameters is still questioned.

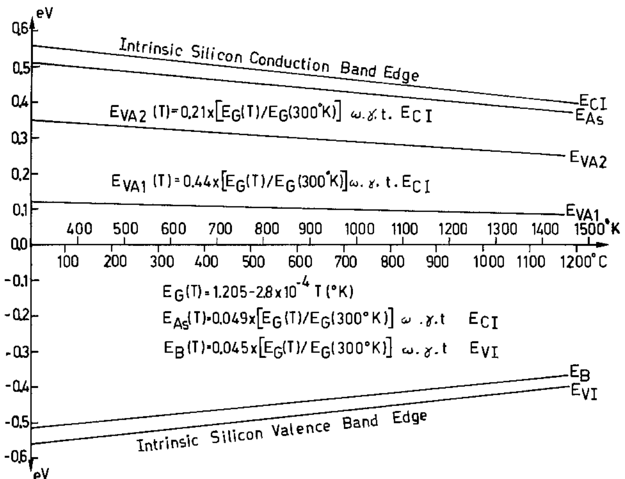
Calculation of the Total Arsenic Diffusion Coefficient in Silicon

For characterizing the impurity diffusion process quantitatively, the knowledge of the impurity diffusion coefficient is a necessity. This parameter essentially gives an idea about the motion of the impurity atoms into the semiconductor material and is a function of the temperature as well as of the impurity concentration. There are various physical mechanisms which play an important role during the diffusion process, For arsenic diffusion into silicon mainly the effects of the built-in electric field, excess vacancy generation, and cluster formation are important and are discussed here separately, taking the high doping and high temperature effects into account.

Effect of the built-in electric field.—It is now well known that the arsenic atoms diffuse into the silicon crystal lattice substitutionally which means that they move into the semiconductor material in the ionized state. It is also pointed out and considered by various authors that the diffusion of the charged atoms sets up an impurity gradient into the semiconductor material, which results in the generation of the internal electric field which enhances the motion of the impurity atoms at high concentrations. This effect can be accounted for quantitatively by defining a "built-in electric field diffusion enhancement factor," D_{ef}, defined by (13)

$$D_{ef} = 1 + \frac{N_{As}}{kT}\frac{dE_F}{dN_{As}} \quad [3]$$

From the knowledege of the Fermi level as a function of the impurity concentration for a desired diffusion temperature (9), D_{ef} can be evaluated accurately.



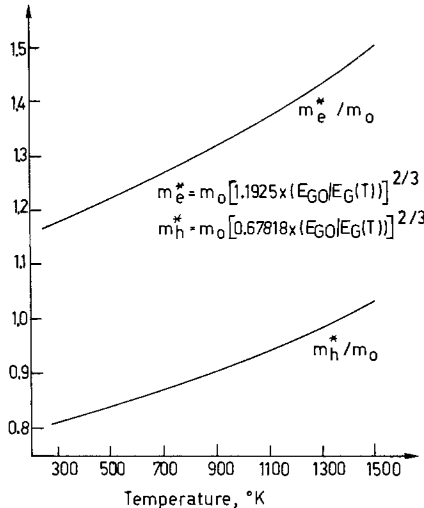


Fig. 2. Illustration of the high temperature effects. a, Temperature dependence of the various impurity and defect levels situated in the forbidden energy bandgap. b, Temperature dependence of the electron and hole density of states effective masses in terms of free electron rest mass.

Effect of the excess vacancy generation.—Since the diffusion of arsenic atoms into the silicon crystal lattice proceeds dominantly by the vacancy mechanism, any excess generation in the concentration of the vacancies will give rise to an increase in the motion of the impurity atoms into the semiconductor material. The arsenic diffusion induced vacancies produce two vacancy acceptor levels which lie in the upper half of the silicon bandgap. The effect of the extra vacancies generated on the diffusion mechanism can be accounted for quantitatively by defining an "excess vacancy diffusion enhancement factor," D_{ev}. D_{ev} is nothing else than the ratio of the concentration of the total number of vacancies in the doped and in the intrinsic silicon crystal. This factor in terms of the Fermi and defect energies can be written after (14, 15) as

$$D_{ev} = \frac{1 + g_1 \exp\dfrac{E_F - E_{VA1}}{kT} + g_2 \exp\dfrac{2E_F - E_{VA1} - E_{VA2}}{kT}}{1 + g_1 \exp\dfrac{E_{FI} - E_{VA1}}{kT} + g_2 \exp\dfrac{2E_{FI} - E_{VA1} - E_{VA2}}{kT}} \quad [4]$$

normal silicon vacancy. For chemical reasons only one complex structure dominates in a certain temperature range (17), therefore the tetratomic arsenic cluster ($SiAs_4$) (7) will exist in the vapor phase. On the other hand the formation energy ($\approx$1.8 eV) of the diatomic arsenic cluster ($SiAs_2$) (6) is larger than the formation energy (1.3 eV) of the tetratomic arsenic cluster ($SiAs_4$) (7), which suggests that the probability of formation of the latter complex is larger. At the moment the validity of these arguments can be questioned because of the uncertainties existing in the arsenic cluster models. It seems that further fundamental research about impurity clustering is required to make sure about the number of impurity atoms involved and about their configuration. Anyhow it is certain that the effect of the cluster formation will be to retard the motion of the impurity atoms into the semiconductor material. Hu (7) has claimed that his model is strongly supported by its good fit with the vapor pressure data. The effect of the arsenic clustering on the diffusion mechanism can be accounted for quantitatively by defining a "cluster diffusion retardation factor," D_{cf}, after (7) as

$$D_{cf} = \frac{1}{1 + 4M \exp\left(\dfrac{\Delta H}{kT}\right)\left\{\dfrac{1}{1 + 0.5 \exp\dfrac{E_{As} - E_F}{kT}}\right\}^4 \left\{\dfrac{N_{As}}{N_{Si}}\right\}^3} \quad [5]$$

Effect of the arsenic clustering.—It has been shown that at very high arsenic concentrations, arsenic cluster formation takes place; but due to their small size ($\leqq$25Å) attempts made to find their structure by using electron or x-ray diffraction techniques have not been successful (16). Hu (7) has developed a model of arsenic clustering into silicon which is largely based on the vapor pressure data of Sandhu and Reuter (17). Hu's proposed arsenic cluster consists of four arsenic atoms forming a tetrahedron either with a normal interstitial site or with a silicon atom at its center. Alternately the recent arsenic complex proposed by Fair and Weber (6) consists of two arsenic atoms situated on the second nearest neighbor sites around a

The factor D_{cf} can be evaluated accurately if we know the various cluster formation parameters and the Fermi energy.

Total arsenic diffusion coefficient and its concentration dependence.—The diffusion coefficient is the basic parameter in a diffusion process and its knowledge is highly essential for characterizing quantitatively the diffusion mechanism. As discussed earlier in this section various mechanisms affect the diffusion coefficient and must be considered simultaneously for defining the total diffusion coefficient. The diffusion coefficient can be written as

$$D_{As} = D_{iAs} \cdot D_{ef} \cdot D_{ev} \cdot D_{cf} \quad [6]$$

where D_{ef}, D_{ev}, and D_{cf} are discussed earlier and are given by Eq. [3], [4], and [5], respectively. D_{As} is the total arsenic diffusion coefficient and D_{iAs} is the arsenic diffusion coefficient in the intrinsic silicon. Various (3-5) empirical relations have been given for the temperature dependence of the intrinsic arsenic diffusivity, D_{iAs}, but we will consider the recent results (5) which can be described by

$$D_{iAs} = 24 \exp\left(-\frac{94070 \times 4.1868}{8.3143T}\right) \quad [7]$$

where T is the diffusion temperature in degrees Kelvin. Equation [7] is plotted in Fig. 3 for simplicity.

For determining the concentration dependence of the total arsenic diffusion coefficient, D_{As}, for a desired diffusion temperature, Eq. [6] must be solved by evaluating Eq. [3], [4], [5], and [7]. Figure 4 shows such results for various typical diffusion temperatures taking into account the high doping and high temperature effects. From Fig. 4 it is quite clear that D_{As} approaches D_{iAs} for low arsenic concentrations due to the fact that the last three terms in Eq. [6] are unity, *i.e.*, the diffusion is normal. Now as the arsenic concentration increases, D_{As} also starts increasing (up to certain arsenic concentration) because the effects due to the built-in electric field and due to the excess vacancy generation are dominant as compared to the effects due to cluster formation. At higher arsenic concentrations D_{As} starts decreasing, because cluster formation becomes dominant.

Calculation of the Arsenic Profiles and Comparison with Experimental Results

The purpose of the present section is to calculate the total arsenic diffusion profiles using the approach described in the earlier sections. Figures 5 and 6 show such profiles after present work from the knowledge of the diffusion temperature and time for a given surface concentration. These profiles have been computed using a computer program DASI[1] specially

[1] DASI (diffusion of arsenic in silicon) is a special computer program written in Fortran IV for calculating arsenic diffusion profiles in silicon which makes use of the physical diffusion model developed.

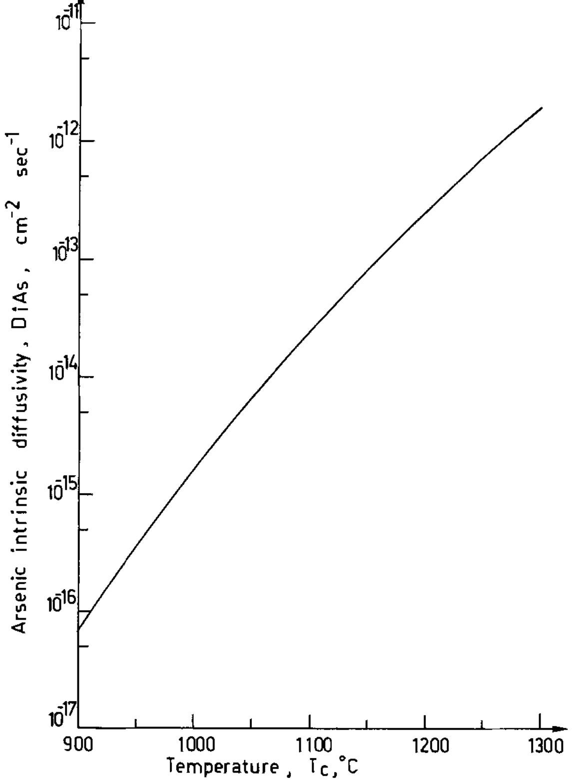

Fig. 3. Temperature dependence of the intrinsic arsenic diffusivity in silicon after Chiu and Ghosh (5).

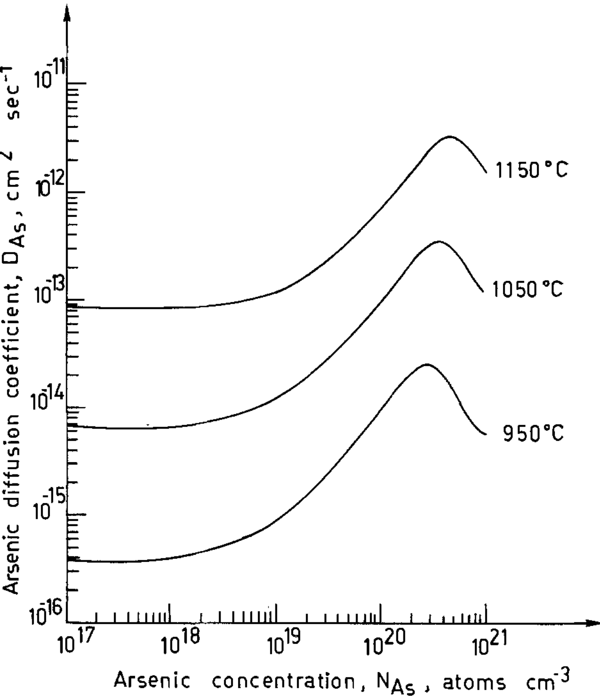

Fig. 4. Theoretical plot of the total arsenic diffusion coefficient vs. arsenic concentration for various typical diffusion temperatures taking high doping and high temperature effects into account. $N_B = 10^{17}$ atoms cm^{-3}.

written for the calculation of arsenic profiles, by means of solving the diffusion equation. This program requires only processing data as its input information and does the rest by taking the high doping and high temperature effects into account. For comparison we also consider the experimental arsenic profiles measured by neutron activation analysis after Chiu and Ghosh (5) and Fig. 5 and 6. Further we also consider the theoretical arsenic profiles calculated by Chiu and Ghosh (5) after their empirical model in Fig. 5 and 6. Chiu and Ghosh (5) obtained their theoretical arsenic profiles by using four empirical constants. They found

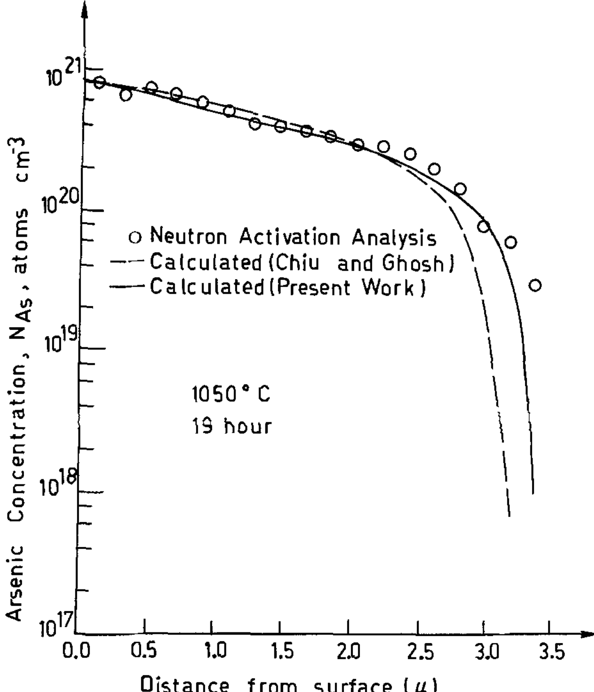

Fig. 6. Plots of the experimental and theoretical arsenic diffusion profiles. Diffusion temperature = 1050°C; diffusion time = 19 hr.

these four empirical constants by matching the theoretical results with various experimental profiles in a wide range of temperature and surface concentrations and are independent of the diffusion temperature. Now if we look to Fig. 5 and 6 we observe that our calculated profiles are in very good agreement with the experimental profiles which strongly supports the accuracy of our physical model based on high doping and high temperature calculations. Figures 5 and 6 are, respectively, for shorter and longer diffusion times, and for both cases the agreement is improved which suggests the validity of our results in general. Anyhow, slight disagreement at lower concentrations may be viewed as the consequence of the approximations involved in the theoretical calculations as well as in the measured results. However, our model gives quite good results and we hope that it will be possible for a device designer to know the impurity distribution before performing all the experiments. Here it must be remarked that the use of the arsenic cluster model by Fair and Weber (6) along with heavy doping and high temperature effects may also yield better results and this work must also be carried out. It must also be remembered here that the accuracy of the present work is limited because of the uncertainties involved in the use of heavy doping effects at high temperatures and also in the present knowledge about the effects of the electric field, vacancy generation, and clustering. It is felt that more rigorous research is needed so that the discrepancies among different models can be understood and minimized.

Conclusions

By incorporating the high doping and high temperature effects a quantitative theoretical model of the arsenic diffusion into silicon has been developed by considering the various important mechanisms occurring during the diffusion process. The total arsenic diffusion coefficient has been calculated as a function of the impurity concentration for typical common diffusion temperatures. Attempts have been made to calculate the arsenic diffusion profiles in silicon from processing data by using a computer program DASI based on our model. Good agreement has been found with the available experimental results. It is hoped that further research along these lines will be useful to understand some mechanisms not at present clearly understood and known.

Acknowledgments

The authors are thankful to Dr. R. Mertens for his help in the computer programing at the early stages of the present work. Correspondence with Dr. S. M. Hu of IBM Systems Product Division, East Fishkill Laboratory, Hopewell Junction, New York, also helped in clearing some questions about the arsenic clustering mechanism. Helpful suggestions from Dr. R. B. Fair of Bell Laboratories, Reading, Pennsylvania, are also acknowledged. We also wish to express our thanks to the Computer Center of our university for running the computer programs. One of us (R. K. Jain) extends his special thanks to the Katholieke Universiteit te Leuven for granting him a research fellowship.

LIST OF SYMBOLS

D_{As}	total arsenic diffusion coefficient
D_{iAs}	intrinsic arsenic diffusion coefficient
D_{cf}	cluster diffusion retardation factor
D_{ef}	built-in electric field diffusion enhancement factor
D_{ev}	excess vacancy diffusion enhancement factor
E	general energy
E_{As}	arsenic energy level
E_B	boron energy level
E_{CI}	intrinsic silicon conduction band edge
E_F	Fermi level
E_{FI}	intrinsic Fermi level
E_G	intrinsic silicon forbidden energy bandgap
E_{GO}	intrinsic silicon forbidden energy bandgap at 0°K
E_{VA1}	first arsenic vacancy acceptor level
E_{VA2}	second arsenic vacancy acceptor level
E_{VI}	intrinsic silicon valence band edge
$\hbar$	Planck's constant divided by 2π
k	Boltzmann's constant
M	configuration multiplicity of the arsenic complex
m_o	free electron rest mass
m_e^*	electron density of states effective mass
m_h^*	hole density of states effective mass
N_{As}	arsenic concentration
N_B	boron concentration
N_{Si}	concentration of the silicon lattice sites
T	absolute temperature
ΔH	energy of formation of the arsenic complex
σ_{eff}	effective value of σ
σ	standard deviation of the impurity band
ρ_{As}	arsenic impurity band density of states
ρ_{cond}	conduction band density of states
ρ_{vale}	valence band density of states
g_1	spin degeneracy weighting factor of the first vacancy acceptor level
g_2	spin degeneracy weighting factor of the second vacancy acceptor level

APPENDIX

Following is the list of numerical values of various quantities used in the calculations:

E_{As}	0.049 eV from E_{CI} at 300°K
E_B	0.045 eV from E_{VI} at 300°K
E_G	1.121 eV at 300°K
E_{GO}	1.205 eV
E_{VA1}	0.44 eV from E_{CI} at 300°K
E_{VA2}	0.21 eV from E_{CI} at 300°K
M	24
m_e^*/m_o	1.18 at 300°K
m_h^*/m_o	0.81 at 300°K
N_{Si}	5×10^{22} cm^{-3}
ΔH	1.3 eV

Characteristics of $Si\text{-}SiO_2$ Interfaces Beneath Thin Silicon Films Defined by Electrochemical Etching

T. I. Kamins[1] and B. E. Deal*

Research and Development Laboratory, Fairchild Camera and Instrument Corporation, Palo Alto, California 94304

ABSTRACT

Capacitance-voltage measurements on thin silicon films defined by electrochemical etching have indicated that fixed surface charge (Q_{ss}) and fast surface states (N_{st}) located at the $Si\text{-}SiO_2$ interface beneath the silicon film can be affected by oxygen, nitrogen, or hydrogen heat-treatments. Both Q_{ss} and N_{st} can be minimized by annealing in hydrogen at high temperatures (900°-1200°C) while nitrogen or oxygen annealing in this same temperature range tends to increase Q_{ss}. At low temperatures (450°C) the conventional hydrogen anneal is not sufficient to eliminate fast surface states, probably because of masking of the hydrogen by the 7 μm thick films used in this study.

During previous measurements of the Hall mobility in thin silicon films defined by electrochemical etching (1), evidence of an accumulation layer near the bottom silicon-silicon dioxide interface was found on n-type samples (Fig. 1). Such an accumulation layer is not unexpected since the fixed charge Q_{ss} tends to accumulate the surfaces of n-type samples, and n-type dopant impurities tend to segregate into the silicon during oxidation (2), especially during the low-temperature, wet oxidation used in these experiments. Since the presence and magnitude of a surface layer will directly affect the characteristics of devices fabricated in the silicon films, the properties of the bottom $Si\text{-}SiO_2$ interface were investigated in more detail. MOS capacitors were fabricated with the field plate beneath the oxide which was covered by the silicon film (Fig. 2). The MOS capacitance-voltage characteristics were measured after various heat-treatments. It will be shown that the charges at the back $Si\text{-}SiO_2$ interface of these silicon-on-insulator structures can be controlled and minimized by hydrogen annealing at elevated temperatures.

Experimental Structure and Measurements

In order to investigate the properties of the $Si\text{-}SiO_2$ interface beneath the thin silicon film, a field plate was needed under the oxide that separates the thin film from the polycrystalline support in the normal structure (1) (Fig. 1). Since the field-plate material must be compatible with subsequent high-temperature processing, a highly doped layer of polycrystalline silicon was used. The fabrication of the experimental structure is described below, and the completed device is shown in Fig. 2.

After deposition of the initial p-type epitaxial layer ($N_A = 1\text{-}2 \times 10^{15}$ cm^{-3}), which becomes the thin film, the sample was oxidized at 920°C in the following sequence: 5 min dry nitrogen preheat, 5 min dry oxygen, 75 min wet oxygen, and 5 min dry nitrogen. The oxide thickness was approximately 3000Å for the (111)-oriented wafers normally used in these experiments. A 0.6 μm thick layer of polycrystalline silicon was then deposited in an rf-heated reactor at 950°C in a hydrogen ambient.[2] Arsenic dopant impurities were

[2] All temperatures cited are corrected for the emissivity of silicon and absorption by the walls of the reaction chamber when the rf-heated reactor was used.

Key words: silicon films, oxide charge, $Si\text{-}SiO_2$ interface.

added by ion implantation; the dose of 2×10^{15} cm^{-2} produced a sheet resistance of about 225 ohms/□ after activation. The polycrystalline silicon was then oxidized to form a thin layer of thermal oxide for masking, and a grid pattern was defined so that the polycrystalline silicon remained only in squares 1 mm on a side. The structure was covered with 1 μm of vapor-deposited oxide, and a 250 μm thick layer of polycrystalline silicon was deposited by the decomposition of dichlorosilane at 1100°C. Since this is the same supporting layer that is used in the normal structure of Fig. 1, the experimental structure differed from the normal structure only by the addition of the thin, field-plate electrode. The heavily doped substrate wafer was then removed by electrochemical etching, and the sample was vapor etched in an HBr-H_2 ambient for 5 min at 1200°C to remove any residual n-type layer above the p-type thin film. The sample was cooled below 400°C in hydrogen after the vapor etch in order to insure reproducible starting conditions for all annealing experiments. The final film thickness was about 7 μm.

Each wafer was then subjected to the desired annealing cycle in a nitrogen, oxygen, or hydrogen ambient at a temperature between 920° and 1200°C. The samples were cooled slowly by withdrawing them from the furnaces over a specified time period: 2 min at 920°C, 6 min at 1100° and 1200°C. Any oxide grown on the exposed silicon surface during these heat-treatments was subsequently removed in HF, and the wafer was then covered with 1 μm of aluminum. The aluminum was deposited from a filament in most cases to avoid radiation damage. One experiment utilized electron-beam evaporated aluminum in order to study the effects of low-temperature annealing on the radiation damage. After the aluminum was defined by photomasking, it was used as an etch mask while the silicon film and underlying oxide were removed from the remainder of the area, exposing the underlying polycrystalline-silicon field plate. A final low-temperature (450°C) anneal in a hydrogen-nitrogen ambient completed the fabrication process. The finished experimental structure is shown in Fig. 2.

Capacitance-voltage characteristics were then measured at a frequency of 1 MHz. All samples were initially biased in inversion, and the voltage was changed toward accumulation to avoid effects of the slow generation of carriers in the inversion layer. The ratio of the minimum to maximum capacitance and the oxide thickness were used to determine the capacitance under flatband conditions, and the corresponding flatband voltage was then found from the experimental data. An effective value of Q_{ss} was determined by correcting for the work function difference between the p-type silicon film and the n^+ field-plate electrode and multiplying by the oxide capacitance in the conventional manner (3). If the sample indicated any drift during a 300°C bias-temperature test, the flatband voltage was determined after a moderate negative bias (−25 V/μm) was applied on the field plate at 300°C. This bias moved the mobile ions to the oxide-field plate interface where they would not influence the measured results.

Experimental Results and Discussion

The effective values of Q_{ss} found after various annealing treatments are shown in Fig. 3 and 4 and are discussed below. Control samples were included in each series of experiments. These control samples employed the same thin-film structure shown in Fig. 2 but received no heat-treatment between the 1200°C hydrogen cycle during the vapor etch and the aluminum deposition. They indicated a consistently low value of Q_{ss}/q of about 1.5×10^{11} cm^{-2}.

Annealing ambient.—Figure 3 shows that an 1100°C anneal in either nitrogen or oxygen increases the effective value of Q_{ss}. The charge appears to approach its equilibrium value within 30 min, the shortest time in-

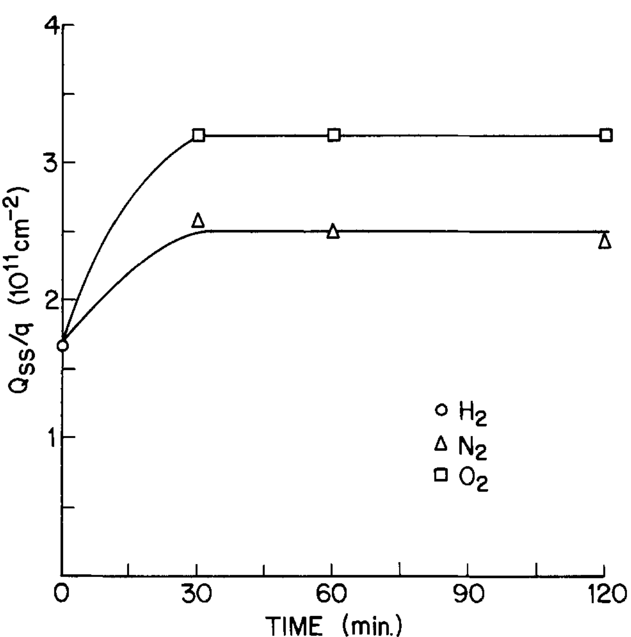

Fig. 3. Effective Q_{ss} as a function of annealing time in an oxygen or nitrogen ambient at 1100°C. The wafers were removed from the furnace in 6 min. Corresponding values for a conventional MOS structure are 7-8 × 10^{11} cm^{-2} after an oxygen anneal and 2 × 10^{11} cm^{-2} after a nitrogen anneal.

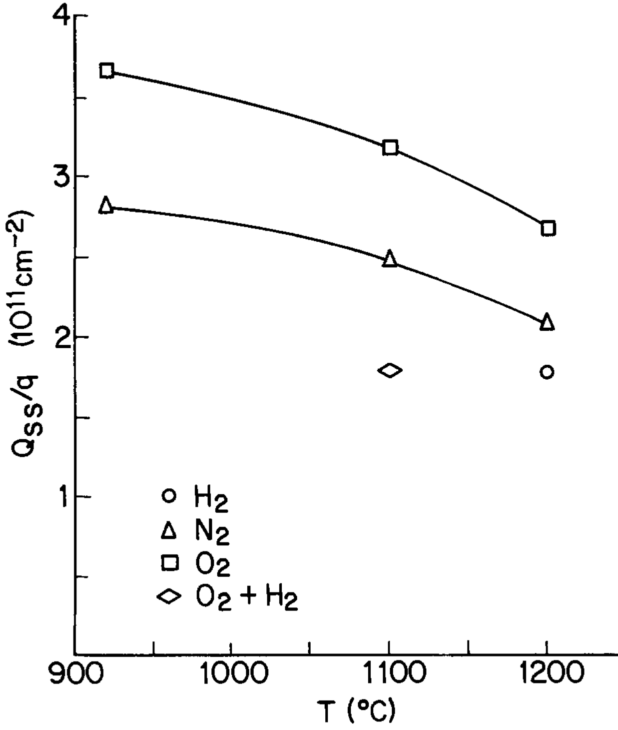

Fig. 4. Effective Q_{ss} as a function of annealing temperature in an oxygen or nitrogen ambient for 1 hr.

vestigated. The effective Q_{ss} is consistently higher after the oxygen anneal than after the anneal in nitrogen. This greater increase of Q_{ss} in oxygen was observed in all experiments and is consistent with results found in conventional MOS structures for slow pulls in oxygen (4). However, the values obtained in the conventional structures are normally about 7-8 × 10^{11} cm^{-2} for (111) silicon, approximately twice the values observed in the present study, where the Si-SiO_2 interface is covered by a silicon film. The film apparently

provides a shielding effect against the oxygen. A similar phenomenon has also been observed in these laboratories for thermally oxidized silicon structures covered by a polycrystalline-silicon film (5).

The value of Q_{ss} shown in Fig. 3 for the nitrogen anneal is slightly higher than for conventional structures, the latter being about 2×10^{11} cm^{-2} (4). However, the present results agree quite closely with data obtained in these laboratories for oxide structures covered by polycrystalline-silicon films. The low value of Q_{ss} obtained after a high-temperature hydrogen anneal is consistent with results obtained on conventional structures, where Q_{ss} values were found to be in the 1×10^{11} cm^{-2} range after high-temperature (1000°C) hydrogen anneals (5).

Annealing temperature.—The influence of the annealing temperature is indicated in Fig. 4. The effective Q_{ss} is raised substantially from its initial value by annealing in oxygen or nitrogen at any temperature in the 920°-1200°C range. The increase is greatest at the lower temperatures, although the difference between 920° and 1200°C is not large. The effective Q_{ss} is again appreciably higher after an oxygen anneal than after a nitrogen anneal at every temperature investigated. An important difference is seen when the data of Fig. 4 are compared with results from conventional structures. Conventional structures slow-pulled in oxygen indicate significantly higher Q_{ss} values for lower annealing temperatures (4). This trend is similar to that seen in the present investigation, although the Q_{ss} values obtained with the thin-film structure are markedly lower. In the case of nitrogen, Q_{ss} is not a function of annealing temperature in conventional structures, with values of 1.5-2 $\times 10^{11}$ cm^{-2} being obtained in all temperatures for (111)-oriented silicon. However, the value of Q_{ss} obtained after annealing the thin-film structure in nitrogen was a function of annealing temperature and was somewhat higher than that seen on conventional structures, especially at lower annealing temperatures.

One thin-film sample was given an 1100°C oxygen anneal to increase the effective Q_{ss} followed by an 1100°C hydrogen anneal for 1 hr. The final value of Q_{ss} was reduced to approximately that found on the control sample, indicating that the charges induced during annealing are reversible if the ambient can penetrate to the Si-SiO_2 interface of interest, which is shielded by about 7 μm of silicon in the present structure.

The time required for this reduction of the effective Q_{ss} in a high-temperature hydrogen ambient was briefly investigated. After the surface layers were removed from a set of silicon films by the H_2-HBr vapor etch, which lowered the effective value of Q_{ss}, the samples were given a 2-hr, oxygen anneal at 920°C to increase Q_{ss}. A control sample that received this oxygen anneal indicated an effective Q_{ss}/q of about 3.2×10^{11} cm^{-2}. Each remaining sample was heated to 1100°C in an rf-heated reactor in a hydrogen ambient, held at 1100°C for a specified time, and then cooled in hydrogen. The holding time at 1100°C was varied from 3 min to 4 hr in order to study the effect of a wide range of times. In all cases the final value of Q_{ss}/q was found to be in the range of 1.4-1.8 $\times 10^{11}$ cm^{-2}, indicating that the hydrogen ambient reduced the effective Q_{ss} during the shortest cycle and probably even while the wafers were being heated and cooled.

Cooling rate.—In conventional MOS structures the rate of removal from the furnace in an oxygen ambient can substantially influence the final value of Q_{ss} since a wafer which is removed from the furnace slowly spends an appreciable time at intermediate temperatures. Because higher values of Q_{ss} are induced at lower temperatures in oxygen, the effective Q_{ss} may be increased by slow removal from the furnace. In one experiment during the present study, wafers were cooled from 1200°C in an oxygen ambient both slowly and rapidly. The difference in the effective value of Q_{ss}/q was only 0.2×10^{11} cm^{-2}, which is within the experimental uncertainty of the measurements. Other experiments that compared different cooling rates indicate that the difference between slow and rapid cooling is not marked. For both cooling rates, the effective value of Q_{ss} is lower for higher annealing temperatures.

Radiation-induced states.—Electron-beam evaporation, rather than filament evaporation, was used to deposit the aluminum on one set of wafers. Electron-beam evaporation induces appreciable charge and fast states in the structure; the charge and radiation-induced fast states are generally removed from conventional MOS structures by a subsequent low-temperature anneal near 450°C in nitrogen with aluminum present or in hydrogen. In the present structure the penetration of hydrogen or other active species through the 7 μm thick silicon film at 450°C is questionable; if the presence of an active species is necessary, annealing may occur by lateral movement of the active species from the side of the pattern. The possibility of lateral nonuniformity in the final structure arising from lateral diffusion of the annealing species was investigated by defining the pattern on the silicon film before the low-temperature (450°C) hydrogen anneal on some wafers and after annealing on other wafers. The silicon films that were annealed at 450°C before being defined produced *C-V* curves more characteristic of uniform unannealed structures while the wafers defined before annealing indicated very nonuniform annealing of the radiation-induced states by the 450°C cycle. The *C-V* curve from the nonuniform samples could almost be divided into two regions, each with a different flatband voltage. The initially uniform wafers also exhibited the nonuniform characteristic after a second low-temperature hydrogen anneal subsequent to silicon definition and the initial *C-V* measurements. These results indicate that hydrogen or another active species is necessary for adequate annealing of the radiation-induced states in the present structure and that this species is not able to penetrate through the 7 μm thick silicon film at 450°C to affect the interface. The annealing is effective in reducing the radiation-induced states only near the edges of the pattern where lateral diffusion is possible. A similar masking effect observed in silicon nitride passivated MOS structures also indicates that the presence of an active species is necessary for the reduction of the radiation-induced states (6).

Fast states.—Figure 5 shows a set of *C-V* characteristics for a control wafer and several different oxygen-annealed samples, which were metallized with aluminum evaporated from a filament. In addition to the shift in the flatband voltage, the distortion of the curves increases with increasing Q_{ss} or decreasing annealing temperature. If we assume that the measurement frequency is high enough so that surface states do not contribute to the capacitance, then the dispersion in the curve must be attributed either to states which are charged or discharged as the Fermi level is swept through the bandgap at the surface or to lateral nonuniformities in the sample. In order to investigate the latter effect, measurements were taken on several wafers both before and after the low-temperature (450°C) hydrogen anneal. In each case the shape of the curve was similar before and after the low-temperature anneal, although the flatband voltage was somewhat different. In addition, the shape of the *C-V* curve for samples with filament-evaporated aluminum was markedly different from that seen on the nonuniform samples with electron-beam aluminum discussed above. During the high-temperature anneal, the silicon film was not defined into the final dot structure so lateral diffusion during this step cannot have led to the distortion in the *C-V* curves. These observations indicate that the dispersion seen in sam-

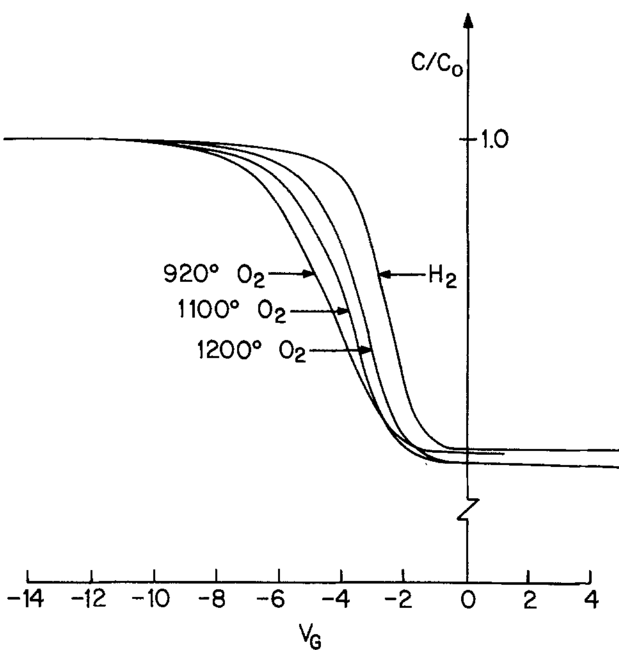

Fig. 5. Capacitance-voltage characteristics after hydrogen anneal and subsequent 1-hr, oxygen heat-treatments at three different temperatures. The (111)-oriented, p-type silicon films had a dopant concentration of 1.1-1.6 $\times$ 10^{15} cm^{-3}, and the oxide thickness was approximately 3000Å.

ples given nitrogen or oxygen heat-treatments is not related to macroscopic nonuniformities near the edges of the samples. The possibility of microscopic nonuniformities which are consistent across the entire wafer cannot be eliminated. However, the presence of surface states with energies in the bandgap is more likely. This relationship between Q_{ss} and N_{st}, with both increasing and decreasing oxygen annealing temperatures, has been noted previously in these laboratories for conventional MOS structures, as well as by Werner (7).

Summary

Capacitance-voltage measurements on thin silicon films defined by electrochemical etching have indicated that fixed surface charge (Q_{ss}) and surface states at the Si-SiO_2 interface beneath the silicon film can be affected by various high-temperature heat-treatments. Both oxygen and nitrogen heat-treatments increase the effective value of Q_{ss} and probably the surface state density. While the increase is greater for oxygen than for nitrogen, it is not as great as in conventional MOS structures after similar oxygen annealing. The increase is greatest at the lowest annealing temperatures for both ambients. The effective value of Q_{ss} is minimized by a high-temperature hydrogen heat-treatment after the initial film preparation. A high-temperature hydrogen anneal also reduces the effective value of Q_{ss} after it has been increased by a heat-treatment in oxygen. The low-temperature (450°C) hydrogen heat-treatment is insufficient to reduce the fast state density N_{st}. Radiation-induced states are reduced at 450°C by lateral diffusion of an active species beneath the silicon film although the active species does not penetrate through the 7 μm-thick silicon films used in this investigation.

It may be concluded that charges at the back Si-SiO_2 interface of silicon-on-insulator structures can be controlled and minimized by hydrogen annealing at elevated temperatures. On the other hand, the thick silicon film retards the action of oxygen or nitrogen on Q_{ss} at elevated temperatures as well as the reduction of N_{st} by hydrogen at low temperatures.

Parameters Controlling the Reactive Sputter Deposition of the Hafnium Tantalum Nitride Resistive Sea

W. R. Knolle and W. C. Ballamy*

Bell Laboratories, Reading, Pennsylvania 19604

ABSTRACT

This paper presents a detailed discussion of the reactive sputtering of the hafnium tantalum nitride resistive sea for the silicon diode-array camera tube target. The importance of precise control of the sputtering parameters is emphasized by analyzing their effect on performance of the diode-array target. The resisitivity of the film is shown to be controlled by both the hafnium/tantalum ratio and the metal/nitrogen ratio. These ratios in turn are controlled by the sputtering parameters. The properties of the film are shown to be sensitive to impurities incorporated in the film. Techniques used to keep these below an acceptable level are discussed. The precautions necessary to prevent degradation of the $Si-SiO_2$ interface during sputtering are also considered.

A reactively sputtered thin film of hafnium tantalum nitride has been developed as a resistive sea for coating the silicon diode-array camera tube target (1-3). The sea is deposited over the entire target by rf plus d-c reactive sputtering from a hafnium-tantalum composite cathode. During development work on this sea it was observed that the electrical properties of the diode-array target depend critically on the conditions prior to and during sputtering. The silicon target is therefore a sensitive probe for delineating the parameters of the reactive sputtering process that must be controlled for reproducible deposition of the hafnium tantalum nitride film. This paper presents a detailed discussion of the reactive sputtering of hafnium tantalum nitride for the resistive sea. The importance of precise control of the sputtering parameters is emphasized by analyzing their effect on the performance of the diode-array target.

Diode-Array Target

The operation of the silicon diode-array target has already been described (1). Briefly, the target consists of an array of diodes on a thin silicon membrane. A thin resistive film or resistive sea is deposited over the whole target to provide a controlled discharge path which prevents charge buildup on the oxide surface from the scanning electron beam. Without this film the silicon dioxide potential would charge below cathode potential and thus prevent the electron beam from landing on the diodes. For targets where the electron beam can recharge the diode junction capacitance to the full reverse bias voltage, the maximum output signal (saturation current or I_{sat}) for a given beam current is a function of the resistivity of the sea and will generally increase with decreasing resistivity. The dependence of I_{sat} on resistive sea sheet resistance is shown in Fig. 1 (4).

The target exhibits a background current or dark current which is independent of illumination level. This dark current is due primarily to surface-state regeneration of carriers at the silicon-silicon dioxide interface and to bulk generation of carriers in the depletion region. The magnitude of the dark current depends on the surface-state density at the $Si-SiO_2$ interface and so variations in the dark current are a sensitive indicator of changes in the $Si-SiO_2$ interface.

Sputtering Equipment

Sputtering was carried out in a rapid cycle station with provisions for both ion pumping and turbomolecular pumping. Gas composition in the system was analyzed during sputtering by means of a quadrupole mass analyzer.

The sputtering apparatus was of the conventional diode type having two planar electrodes. The sputtering source was a hot pressed cathode with a composition of 47 atom per cent (a/o) hafnium and 53 a/o tantalum. The perimeter of the cathode was surrounded by a ground shield placed within the dark space of the glow discharge at a separation of about 0.5 cm. Cathode bias was d.c. plus rf after the technique of Vratny *et al.* (3). A copper anode plate was used to hold the diode-array targets during sputtering. The anode plate had raised pedestals which fit into the recessed back of the targets to insure good thermal contact. The anode plate in turn rested on the water-cooled anode of the sputtering system. The anode plate and electrodes are shown in Fig. 2. Prior to its use the entire copper plate was coated with hafnium tantalum to reduce the chance of contaminating the resistive sea with copper.

To conduct a typical sputtering run the anode plate was loaded with targets and the system evacuated to less than 5×10^{-8} Torr using the ion pump. Then the system was switched to the turbomolecular pump, the presputter gas introduced, and presputtering was initiated on the closed shutter. Typical sputtering pressure was $\sim 60 \times 10^{-3}$ Torr at a nitrogen throughput of ~ 400 cm^3/min STP. Presputtering is described in some detail in the next section.

* Electrochemical Society Active Member.

Key words: silicon diode-array target, rf sputter, d-c sputter.

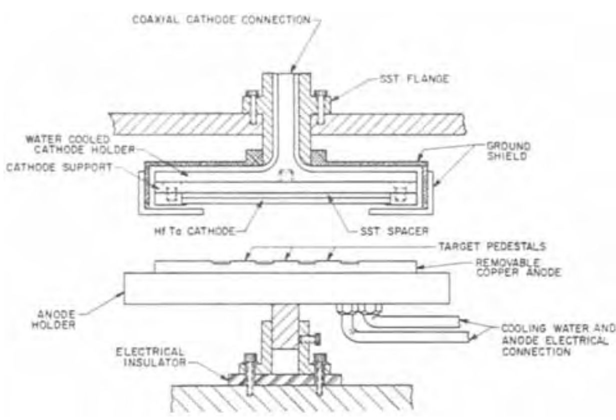

Fig. 2. Details of the diode sputtering system

When presputtering was completed the shutter was opened, the targets exposed to the plasma, and the hafnium-tantalum nitride film deposited. After deposition the system was backfilled very slowly with nitrogen and the targets were removed. To help insure cleanliness the interior of the system was exposed to the room ambient for as short a time as possible during loading and unloading.

Cathode Contamination

Early experiments showed that targets with reproducible saturation currents from run to run were not obtained until a presputter (sputtering above the closed shutters) of 45 min in argon followed by 30 min in nitrogen was used. Without an argon presputter a nitrogen presputter time of an hour or less yielded a sea whose resistivity was not repeatable from run to run. This was reflected in the electrical behavior of the sputtering system. When presputtering was initiated the d-c cathode bias voltage showed an initial rapid decrease followed by a slow increase to a final voltage which did not vary significantly during the remainder of the presputter. The magnitude of the fluctuation and the time to achieve system stabilization was dependent on the time that the system was under high vacuum prior to plasma initiation, as shown in Fig. 3. No pressure change was observed which accounts for the voltage change so the voltage fluctuation is interpreted to be a consequence of conditions at the hafnium-tantalum cathode. The behavior of the system suggests that the cathode is contaminated with gases which are adsorbed when the system is exposed to the room ambient and are slowly desorbed when the system is under vacuum. Alternatively, the gases are removed by presputtering.

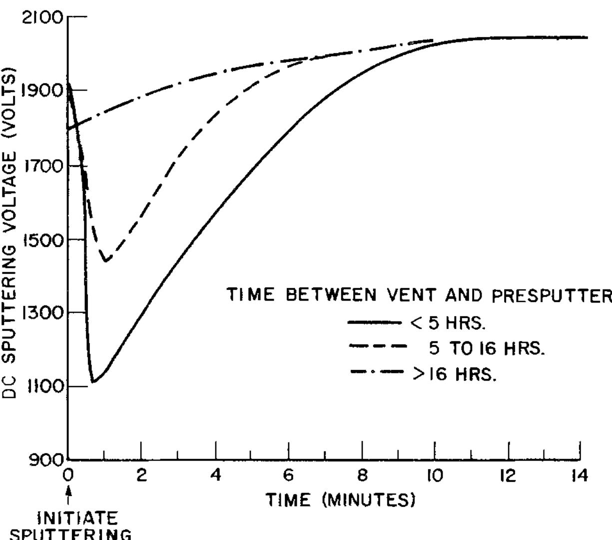

Fig. 3. Sputtering voltage *vs.* time from initiation of sputtering

This variation of ion current and d-c voltage at constant d-c power agrees with other work (5) where the stabilization of d-c current was used as a criterion for termination of presputtering and the commencement of sputtering. However, our results indicate that although the current may stabilize in a short time, all contaminants are not necessarily removed at that time. A shorter presputter cycle (15 min in argon followed by 30 min in nitrogen) yielded an increasing film resistivity (decreasing target saturation current) from run to run. In these runs the d-c sputtering voltage stabilized within 10 min, but it is apparent that the entire system did not.

The nature of the contaminant which is adsorbed on or absorbed in the hot-pressed cathode has not been determined. The resistivity of the film has been shown to be very sensitive to the presence of small amounts of impurities, particularly oxygen. An increase in resistivity with increasing oxygen content for sputtered tantalum thin films is well known (6). The efficiency of an argon presputter instead of a nitrogen presputter of similar duration in removing the contaminants is related to the more rapid sputtering rate in the argon ambient. This is in part due to the fact that in an argon atmosphere no nitride may build up on the cathode whereas in a nitrogen atmosphere the cathode is continuously being bombarded with reactive nitrogen. The rate of material removal from the cathode in an argon ambient is about an order of magnitude greater than the rate in the nitrogen ambient.

It has been postulated that significant amounts of gas may be trapped in the pores of hot-pressed cathodes (7). The density of hot-pressed cathodes is generally 75-85% of the theoretical density (8). We have observed that without an argon presputter of at least 45 min an insufficient amount of cathode will be sputtered and hence trapped gases (*i.e.*, O_2) may be released during sputtering and affect the resistivity of the deposited sea. Evidently ambient gas penetration into the cathode is several micrometers.

Electrical Properties of the Sea as a Function of Sputtering Variables

Presented in this section are data which relate the sputtering variables to the electrical characteristics of the resistive sea. The measurement of I_{sat} was made on the silicon target (not sealed in a camera tube) in a multiple position demountable tube system in a vacuum of 10^{-7} Torr or less. The error in an I_{sat} measurement is typically ± 20 nA.

D-C voltage, d-c current, and nitrogen pressure.—Figure 4 shows the relationship between d-c sputtering voltage and current obtained at various nitrogen pressures at a constant rf power level of 150W. The saturation current of the target as a function of d-c sputtering current is presented in Fig. 5. At lower pressures sea resistivity and consequently the saturation current depends strongly on d-c sputtering current. The constant power lines and isobars suggest that virtually any value of saturation current (film resistivity) is attainable by simply changing nitrogen pressure and d-c sputtering parameters.

RF power.—The effect of rf power was investigated at 150, 200, and 250W at a constant d-c power of 225W. No significant difference was found between the mean values of saturation current at 150 and 200W rf. A small decrease in the mean at 250W rf (647 $\pm$ 58 nA compared to 729 $\pm$ 64 nA at 150W rf) was observed. Referring to Fig. 4 and 5, this decrease may be explained by the somewhat lower d-c voltage (2100V) obtained at 250W rf power due to the increased plasma density at the higher power level.

The sputtering rate due to rf power alone is extremely low. Addition of the d-c bias at the levels used

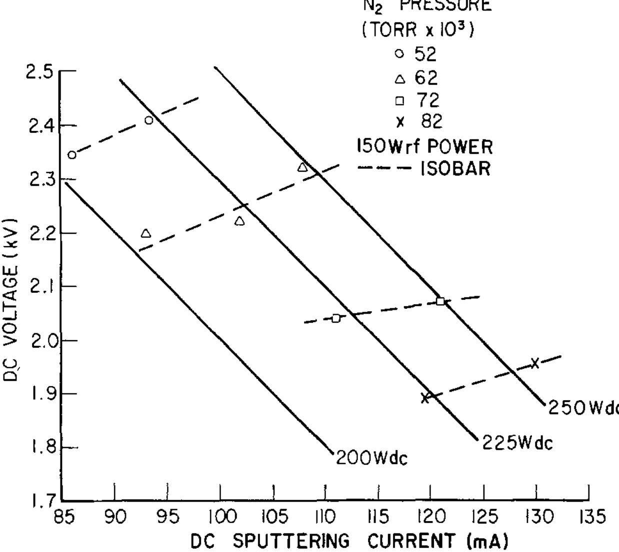

Fig. 4. D-C sputtering voltage vs. d-c sputtering current at various nitrogen pressures. Each point represents the average of two or more runs (6 to 8 targets) except 52 × 10^{-3} Torr at 225 and 250 W which were only run once.

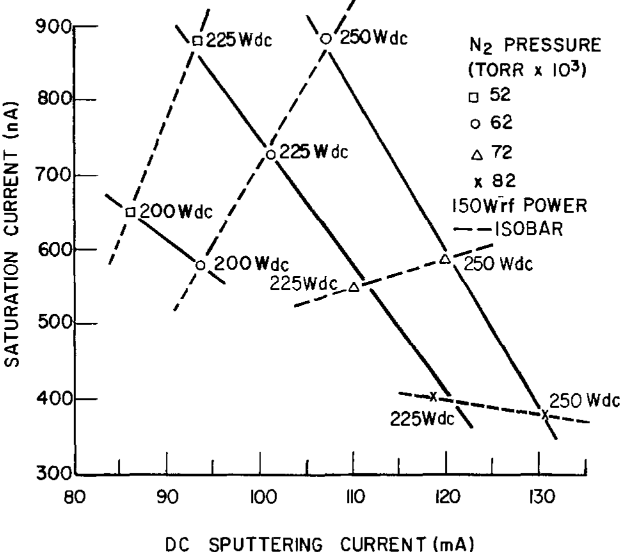

Fig. 5. Target saturation current as a function of d-c sputtering current at various nitrogen pressures.

in this work results in about an order of magnitude increase in deposition rate. The d-c sputtering alone cannot be used because a semi-insulating nitride layer builds up on the cathode, eventually reaching a thickness where the potential between the cathode and the plasma is reduced to the point where sputtering cannot take place. A minimum of 150W rf power is necessary to prevent the nitride buildup.

Nitrogen throughput and background contamination.—The nitrogen throughput of the system was reduced by about one-half for one run at 225W d.c. The targets produced in this run exhibited I_{sat} ~150 nA lower than that usually obtained at this power level. The decrease in I_{sat} is partially explainable in terms of a slight decrease in sputtering voltage 2165V instead of the normal value of 2223V. However, this only accounts for about 70 nA. The remainder of the decrease is due to an increase in sea resistivity caused by oxygen contamination. The nitrogen throughput was reduced by throttling the turbo pump. This resulted in an increased background contamination level and consequently in contamination of the film.

Early experiments indicated that the resistivity of the films is sensitive to oxygen contamination. Films produced in a diffusion-pumped system, which was not capable of the low background pressure and high throughput of the turbomolecular-pumped system at the sputtering pressure, contained between 7 and 20 a/o oxygen as analyzed by the electron microprobe. Films with 50 a/o oxygen were produced on one occasion. Typical background water and oxygen levels for that system were at least 10^{-6} Torr during sputtering. The resistivity of films produced in that system varied uncontrollably and many were so highly resistive that the targets with these films charged during operation.

Typical background pressures in the turbo-pumped system were on the order of 10^{-9} Torr. The films produced in this system reproducibly contained about 7 a/o oxygen. See Table I for the electron microprobe analysis of diode-array targets with different saturation currents. However, since the electron microprobe samples to a depth of about a micrometer and therefore samples the underlying SiO_2 as well as the nitride film, it is probable that the bulk oxygen level in the film is much lower than that shown in the analysis.

Clearly, reactive sputtering must be done in a system capable of very low background pressure. This can be attained with good system bakeout procedures and sufficient pumping capacity to provide adequate throughput during sputtering.

Composition of the Sputtered Resistive Sea

The composition of the hafnium tantalum nitride resistive sea on three targets with different saturation currents (different resistivities) was determined by electron microprobe analysis, see Table I. The composition of the film is $Hf_{0.45}Ta_{0.55}N_{1.20}$ or, to the nearest whole numbers, $HfTaN_2$. Minor amounts of carbon and oxygen were detected in each sample which did not correlate with the electrical properties of the targets and are considered to be surface contaminants of the sea for the most part. The metal-to-nitrogen ratio increased from 0.798 for a target that charged (high resistivity film) to 0.834 for a target with a saturation current of 820 nA (low resistivity). The resistivity of the $HfTaN_2$ film should decrease at higher metal-to-nitrogen ratios since the higher ratio favors formation of TaN which is known to have a low resistivity. A lower resistivity sea means that the saturation current of the target will be higher.

The Ta-to-Hf ratio increased from 1.16 for the target that charged to 1.21 for the target with the high saturation current. These results follow previous work (3) where resistivity of the film decreased as the Ta-to-Hf ratio increased; however, the observed shift in saturation current is much larger than would have been expected for the small change in Ta-to-Hf ratio. For our results the metal-to-nitrogen ratio is the controlling factor.

Interpretation of the Sputtering Results

The sputtering variables, namely, d-c current, d-c voltage, and nitrogen pressure, are interdependent for the diode sputtering system and at a constant rf power level cannot be varied independently. Figure 4 shows the relationship among d-c voltage, current, and nitrogen pressure for the sputtering module used in this work.

Table I. Electron microprobe analysis of $HfTaN_2$ resistive sea

Element	Target A	Target B	Target C
	Atomic per cent composition		
Ta	20.85	21.83	21.78
Hf	18.02	18.66	18.07
Zr	0.84	0.91	0.88
N	48.71	49.20	47.82
O	7.22	7.08	7.38
C	4.37	2.32	4.06
	Charged-Low	230	825
I_{sat}	I_{sat}	Nanoamperes	Nanoamperes
Ta/Hf	1.158	1.170	1.205
HfTa/N	0.798	0.824	0.834

Figures 6 and 7 illustrate the effect of d-c sputtering parameters on deposition rate. Varying the d-c voltage and current affects the deposition rate of the film by altering the conditions at the sputtering cathode. The d-c sputtering current reflects the rate at which ions strike the cathode and hence the rate at which material is sputtered. This is clearly shown in Fig. 6 which is a plot of deposition rate *vs.* d-c sputtering current at various d-c powers and nitrogen pressures. At constant pressure a higher d-c current yields a greater deposition rate of $HfTaN_2$.

The d-c voltage affects the sputtering yield and hence, at a constant ion current, an increase in voltage results in an increase in deposition rate. At lower nitrogen pressures (therefore higher d-c voltages; recall Fig. 4) and constant d-c power, the film deposition rate increased very linearly from about 2000Å/hr at 82×10^{-3} Torr to 2400Å/hr at 52×10^{-3} Torr.

With a fixed hafnium to tantalum ratio the film resistivity is controlled by the metal-to-nitrogen ratio and the metal-to-nitrogen ratio is controlled by the deposition rate of the film. Increasing the deposition rate at constant pressure increases the metal-to-nitrogen ratio in the film and therefore reduces the resistivity. This explains the results shown in Fig. 5, and accounts for most of the previously described effects of sputtering parameters. The effect is most pronounced at 52×10^{-3} Torr where a 10% increase in d-c sputtering current yielded a 250 nA increase in saturation current. At 82×10^{-3} Torr the effect is nonexistent. Evidently at sufficiently high nitrogen pressures, the increase in deposition rate is matched by the nitrogen available for incorporation into the film. Therefore the saturation current does not change as drastically. This is in agreement with previous work in which the resistivity of the film was varied by varying substrate temperature (3). The effect of substrate temperature is to vary the sticking coefficients of the various components of the sea. In particular, decreasing resistivity with increasing substrate temperature can be explained by a relative decrease in the sticking coefficient for nitrogen.

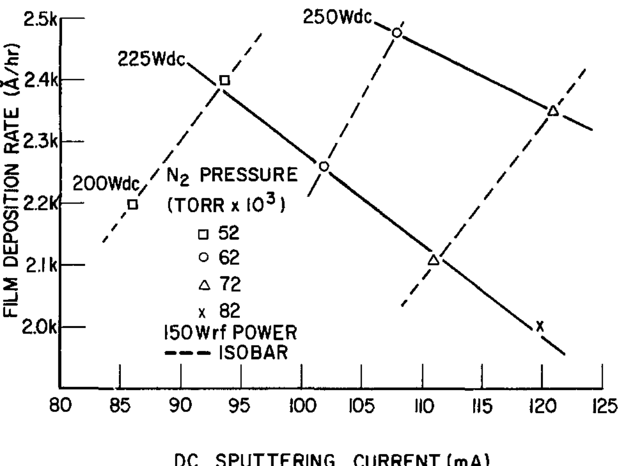

Fig. 6. Film deposition rate vs. d-c sputtering current at various nitrogen pressures.

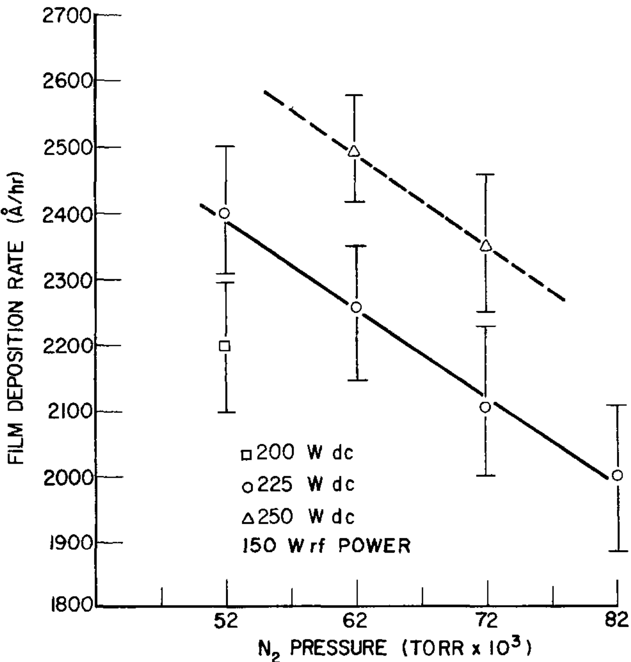

Fig. 7. Film deposition rate vs. nitrogen pressure at various d-c powers.

Dark Current

The diode-array target dark current-voltage characteristics are sensitive to interface state densities in the high 10^{10} cm^{-2} range and oxide charge in the 1×10^{11} cm^{-2} range.

Sputter deposition of the films described above had no effect on the dark current or flatband voltage exhibited by the targets. This was confirmed by measuring the "dark" *I-V* characteristics of targets with antimony trisulfide resistive seas (Sb_2S_3 is evaporated onto the target surface), then stripping the seas and depositing the hafnium tantalum nitride resistive sea on the same targets. The *I-V* characteristics with the hafnium tantalum nitride sea were identical to those with the antimony trisulfide sea.

During early experiments in which films heavily contaminated with oxygen were produced a second-order effect was found. In one run films were so highly resistive that their surface charged during testing and they could not be characterized. Subsequently, several runs were made to produce films of normal composition. The targets produced in these runs were found to have extremely high dark currents. The cause of the high dark current was found to be the insulating film which had been deposited over the surface of the copper anode plate as well as the targets. Evidently the presence of the insulating film on the anode resulted in an abnormally high concentration of electron current through the targets and a consequent deterioration of the oxide interface. Etching the anode plate to remove the insulating film resulted in normal dark currents for subsequent runs.

These experiments show that rf plus d-c sputtering can be utilized to deposit the hafnium-tantalum nitride resistive sea without affecting high quality $Si\text{-}SiO_2$ interfaces provided a high ratio of conducting anode to substrate area is maintained.

Conclusions

The influence of sea resistivity on the performance of the silicon diode-array target has been utilized to study the effect of sputtering parameters on the properties of the hafnium tantalum nitride resistive sea. The principal effect of varying the sputtering parameters is to vary the metal arrival rate at the substrate and perhaps the substrate processes and thus the metal-nitrogen ratio in the film.

The sensitivity of the film resistivity to impurities, particularly oxygen, demands that the vacuum system used have a low background contamination level. For reproducible results when reactively sputtering thin resistive films from a hafnium-tantalum cathode a system capable of attaining background pressures of 10^{-8} Torr or lower is necessary. This requirement together with high pumping speed to maintain an adequate throughput necessitates a pump with high speed and a low background pressure capability at the sputtering pressure such as a turbomolecular pump.

Even with good bakeout procedures and adequate pumping the presputter conditions are critical for reproducible resistive films. A presputter in argon was found necessary to prepare the cathode; nitrogen alone was not sufficient. Several micrometers of cathode must be sputtered away in order to be certain that gases adsorbed in the porous hot-pressed cathode are removed during presputter.

With the aforementioned precautions taken into account then the reactive sputtering gas pressure and d-c current must be controlled precisely. Evidently sputter rate and sputter yield are important with sputter deposition rate being more important at low nitrogen pressures where the d-c voltage is higher and sputter yield is greatest. At higher nitrogen pressures most large resistivity changes in the film with small changes in d-c current and d-c voltage disappear.

For easily achieved reproducible results when reactively sputtering hafnium tantalum nitride, the nitrogen pressure should be as high as possible. The metal-to-nitrogen ratio in the film is then less responsive to slight variations in d-c current and voltage.

Interface Effects in the Dissolution of Silicon into Thin Gold Films

H. Sankur* and J. O. McCaldin**

California Institute of Technology, Pasadena, California 91109

ABSTRACT

The dissolution of crystalline Si and amorphous Si substrates into thin films of evaporated Au was studied with an electron microprobe and scanning electron microscopy. The dissolution pattern was found to be nonuniform along the plane of the surface and dependent on the crystalline orientation of the Si substrate. The dissolution is greatly facilitated when a very thin layer of Pd is evaporated between the Si substrate and the Au film.

Gold is extensively used in microwave power device metallizations and in beam lead technology (1), because of its high conductivity, resistance to corrosion, and low failure rate due to electromigration. In these systems the current carrying Au metallization is separated from Si by various metallic layers. These intermediate layers perform the function of providing low-resistivity ohmic contact to the device, good adhesion to the substrate SiO_2, and also serve as diffusion barriers between various layers. The occurrence of mechanical damage during handling or thermal excursions in device manufacture or chemical interactions (2) in intermediate layers can cause direct contacting of Au and Si; this latter situation is a possible source of catastrophic failure of the device due to liquid phase alloying, given the remarkably low eutectic temperature of the Si-Au system (3), or due to excessive dissolution of Si into Au. In fact Si has been found to dissolve and diffuse rapidly into thin Au films at temperatures considerably below the eutectic temperature of the Si-Au binary system (4).

Hiraki *et al.* had shown that considerable transport of Si through thin (~1000Å) Au films vacuum deposited on Si substrates and growth of a SiO_2 layer on the Au surface occurred when the specimens were annealed in an oxidizing ambient at temperatures as low as 150°C. Although nonuniformity of the SiO_2 layer was inferred from the backscattering analysis and the importance of the interface was pointed out (5, 6) by the same investigators, no detailed work to understand the effect of the interface was done. In the present investigation, the dissolution reaction of Si in Au has been studied by means of the electron microprobe and SEM. The importance of the Si-Au interface in causing varied dissolution patterns is clearly demonstrated.

An important aspect of the present work is the observation and analysis of the nonuniform nature of the interaction of the Si-Au system. The importance stems from the fact that other thin film systems may exhibit such nonuniform behavior and that investigations of these with methods like x-ray diffraction, He^+ backscattering, Auger or mass spectrographic analysis coupled with sputter etching that average signal from a relatively large area will lead to invalid conclusions. Therefore, it is imperative to obtain information about uniformity of the interaction on a micron scale. Recent developments in the above-mentioned methods can make such an analysis possible.

Experimental

The electron microprobe has been used to detect the amount and the location of Si in thin films (7).

Key words: Au thin films, interface effects, Si-Au, dissolution.

In this analysis a 10 keV, 0.1 μA electron beam, focused to less than 1μ diameter is directed perpendicular to the surface, to induce x-ray emission. At these energies, the penetration of the beam is only a fraction of the Au film thickness, and hence does not excite the Si substrate (Fig. 1). With the detector system tuned for $SiK\alpha$ line radiation, either qualitative or quantitative analysis of Si can be performed.

In this investigation, the microprobe was used in scanning mode, where the electron beam scanned the surface like a raster sampling an area, dimensions of which can be controlled. The information was displayed on a screen, by intensity modulation of the CRT with signal coming from the microprobe detection system. In this mode of operation, information about the local distribution of various elements can be quickly obtained (8).

Quantitative microprobe analysis showed that levels of $SiK\alpha$ radiation of Si dissolved into Au was very small due to low solubility of Si in Au and relatively high noise level of the Au matrix. In this case 1μ thick Au was evaporated onto polished Si substrates. These specimens were heat-treated for various lengths of time at various temperatures between 200°-300°C, and then subjected to a brief dip in dilute HF solution just prior to microprobe analysis. This latter precaution was taken in order to eliminate any SiO_2 film that could have formed on the Au surface during heat-treatment or while the specimens were kept at room temperature after heat-treatment (9). The microprobe analysis that was performed with a broad defocused electron beam, showed that solubility of Si in Au was below the detection limit of the microprobe (200 ppm). Hence it was concluded that an accurate investigation could not be done by probing Si dissolved into Au. Therefore for purposes of this investigation, a thin Pd layer was deposited on the Au film as a sink material for Si. Si atoms that migrated through the Au film, reacted with Pd to form stable Pd_2Si (10). Thus compound clusters formed at the Au-Pd interface, the amount of which was proportional to the amount of Si transported through Au, since no detectable Si was retained in the Au film; the location of these clusters corresponded to locations where Si dissolved into and migrated through the Au film to reach Pd or Pd_2Si (Fig. 1), as is explained later in detail.

The preparation of typical specimens was as follows: Chemically polished Si wafers (p-type, 1-10 ohm-cm)[1] with <100>, <110>, <111> orientations were used as substrates. Amorphous Si was obtained by evaporation of Si on thermally oxidized Si wafer substrates. The crystalline substrates were cleaned with organic solvents, rinsed with deionized water, dipped in dilute HF solution, rinsed thoroughly for 4-5 min, dried, and placed in the vacuum evaporation system. The depositions were done sequentially in a 3 crucible e-gun system, at pressures $\sim 5 \times 10^{-7}$ Torr. Au was evaporated from a 99.999% purity source to a thickness of 1μ. The Pd film thickness was 600Å and was deposited from 99.9% purity source.

[1] The Si substrates were block polished with Monsanto patented Syton. The reported etch pit density was 400/cm². No surface features could be detected with optical microscope or SEM on these substrates.

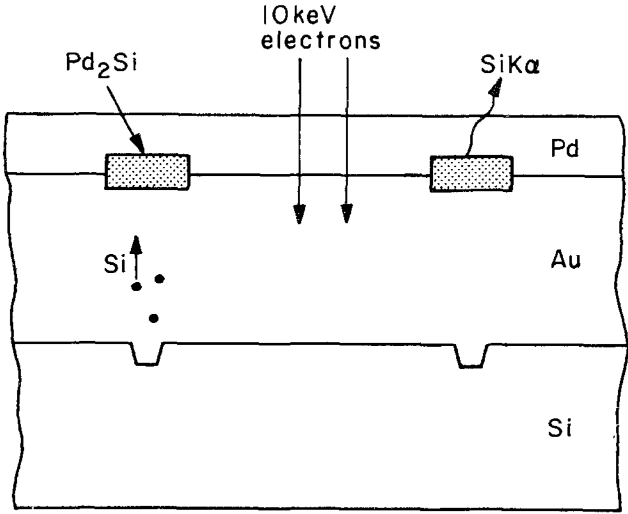

Fig. 1. Cross section of a specimen schematized to illustrate the experiment. Note that the vertical dimensions are not to scale.

In a limited number of experiments a 200Å thick Pd underlay was evaporated before the Au and sink Pd layer at the top, with the intention of altering the Si-Au interface conditions.

The specimens were thereafter either immediately heat-treated in a tube furnace under a pressure of less than 10^{-5} Torr at 220°C or briefly stored in a dessicator under vacuum.

A limited number of specimens that consisted solely of evaporated Au on Si substrates were annealed in a tube furnace through which water vapor laden nitrogen flowed gently. The purpose of these latter experiments was to use a different sink material for Si, than Pd overlay (5).

The annealing times were ordinarily close to 1 hr, although longer annealing times were also tried.

Another parameter that was varied in some experiments, was the thickness of the Au film. Au films 3 and 10μ thick were evaporated in addition to the majority of the specimens which had 1μ thick Au film.

In one case Au films evaporated on Si were annealed in vacuo before the Pd evaporation, with the intention of causing change in the microstructure of the Au films.

After the microprobe analysis the Pd and Pd_2Si layers were removed in boiling (HNO_3 + H_2SO_4) solution in order to study the Au surface under SEM. Subsequently Au was removed in (KI + I_2) solution for the SEM study of the Si surface.

Results

He^+ backscattering studies[2] showed that at the temperature the specimens were heat-treated, the Au-Pd interdiffusion was negligible (11) and that all Si resided at the Au-Pd interface in the form of compound.

In the present investigation it was in general found that Si migrated through the Au film and reacted with Pd, only in random spots and along lines, 1-5μ wide. that form closed curves from the top view. The regions between these were found to contain no silicide by quantitative microprobe measurements. However the degree of nonuniformity or the density of locations where Si dissolution took place depends on the orientation of the Si substrate as well as Si-Au interface conditions and surface preparation. Microprobe studies (Fig. 2a, 3-5) clearly show that Pd_2Si is detected only in some line or band shaped boundaries and that regions between these do not contain any Si. However the distance between these boundaries measure 30-100μ in the case of <111>-Si, whereas the areas formed by these lines have diameters 5-10μ on <100>-Si (Fig. 4). The average diameter is slightly larger on <110>-Si (Fig. 5). In the case of amorphous Si, Si dissolution is also localized and the pattern of silicide growth bears a resemblance to the case of <100>-Si.

The <111>-Si substrate showed a host of features. Figure 3 shows part of a jagged boundary, while others run smooth. Occasionally short broken lines within an area enclosed by long lines were seen. A rare feature was formation of very dense pointlike growth of silicide in a certain area, whereas neighboring regions separated by lines showed no silicide in them.

The dissolution behavior of <111> substrate changed drastically upon introduction of a Pd underlay between Si and Au. A Pd film of 100-200Å thickness

[2] This part of the study was done by D. Sigurd and H. Sankur.

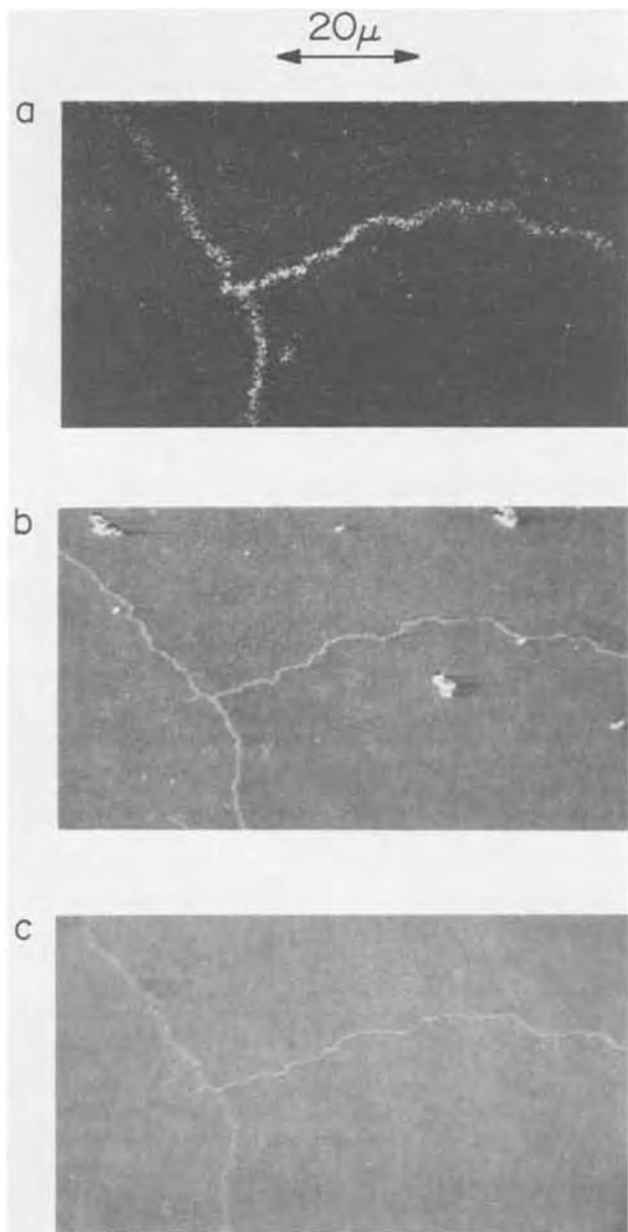

Fig. 2. A section of the complete specimen (a) as exhibited by the electron microprobe tuned to SiK fluorescence. Si in the Pd_2Si layer appears as white in this photograph. (b) SEM photo of the same section of the specimen after the microprobe analysis. (c) SEM photograph of the Si surface of the same area after removal of all metal and silicide. The substrate was <111>-Si.

evaporated on Si, before the Au and sink-Pd deposition caused upon annealing an increase in the density of silicide-rich boundaries at the Au-Pd interface or equivalently the density of dissolution locations at the Si surface, as is clarified later in this part. Figure 6 shows an electron microprobe micrograph of such a specimen. The silicide growth pattern although bearing some resemblance to the case of <100>, has a higher density of compound clusters.

The above-mentioned point or linelike regions of Pd-Si reaction become evident under optical microscopic investigation or SEM analysis (Fig. 2b), after about the first hour of heat-treatment for reasons that are explained in the Discussion section. After prolonged heat-treatment, the lines could be identified as brown-colored Pd_2Si, with respect to the white Pd overlay, implying that almost all Pd along these regions was consumed in the compound layer. In general a one to one correspondence was found between

Fig. 3. Microprobe photograph of another location of specimen in Fig. 2 where again white areas represent silicide within the metallization.

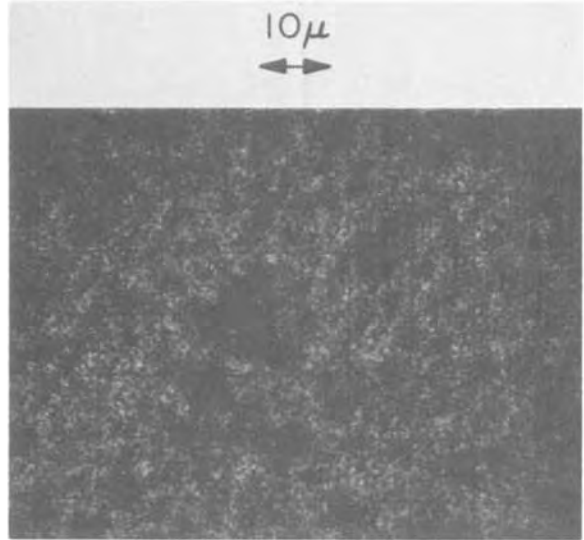

Fig. 4. Microprobe photograph of a specimen with <100>-Si substrate. Heat-treatment time, 1 hr.

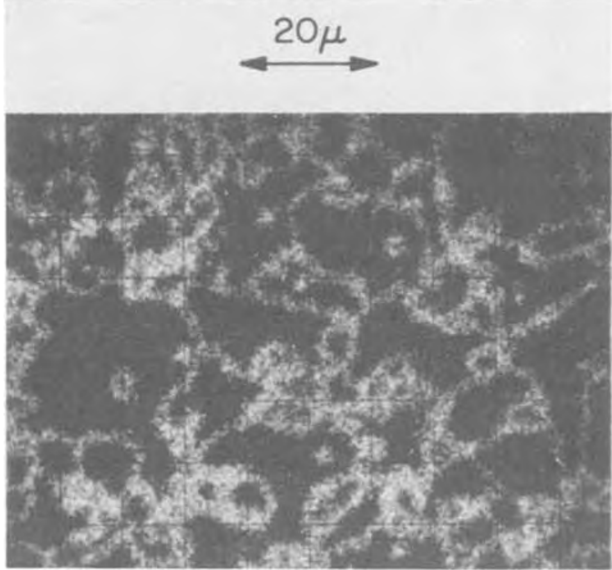

Fig. 5. Same as in Fig. 4, except the substrate is <110>-Si

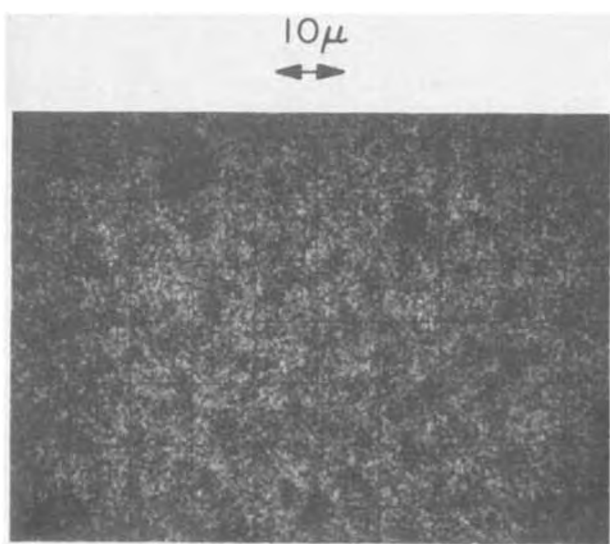

Fig. 6. Microprobe photograph of a specimen with <111>-Si substrate and a very thin layer of Pd between Au and Si. Note the increased density of silicide clusters compared to Fig. 2.

visible surface features and compound regions as revealed with the microprobe analysis.

The amount of Si in or the thickness of the silicide in the prementioned regions of Pd_2Si formation, as well as the width of the latter, increased with annealing time. This caused coalescence of boundaries to form continuous areas or bands of silicide growth when heat-treatment times were as long as 9 hr.

A replica of the above-mentioned geometrical features is seen in Au, after removal of the overlying Pd and Pd_2Si layers. However, a closer look with SEM reveals depressions in Au film, where Pd_2Si previously existed, attesting to the displacement of Au during Pd_2Si formation.

Figures 2c and 7 show the Si surface after removal of the Au layer. The previously described pattern is replicated in the form of canyonlike trenches or a series of elongated depressions in Si. These are regions where Si dissolved into Au and migrated

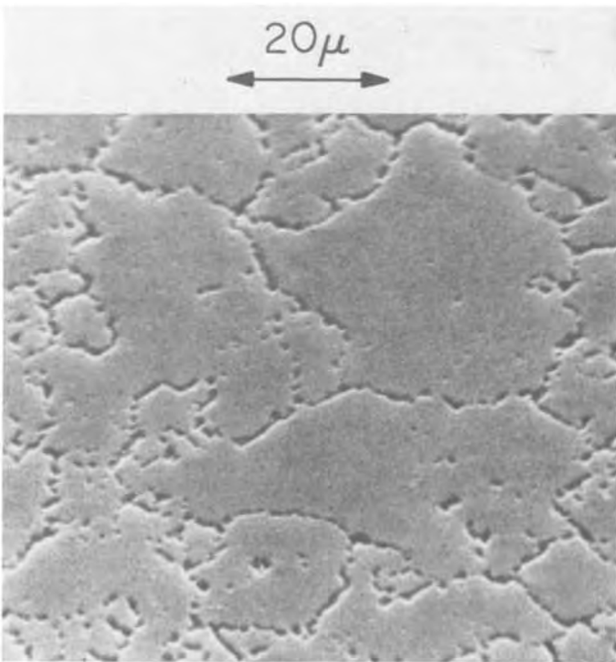

Fig. 7. SEM photograph of the Si surface after removal of Au, Pd, and compound layers. The substrate was <100>-Si. The areas enclosed by trenches are somewhat larger than average size, in this particular section.

through, to react with the Pd overlay. The trenches are 0.1-0.3μ deep and 1-5μ wide. The flat regions between these correspond to areas where no silicide was detected in microprobe analysis and hence contain no dissolution features. SEM analysis showed that a 1-5μ wide depression formed in the middle of the 10-20μ wide silicide-rich band, in specimens annealed at temperatures as high as 360°C. This and the fact that raised features were seen on the back side of Au-Pd metallic film, after etch-removing Si substrate (Fig. 8) led to the conclusion that Au moved in and possibly filled the trenches as Si dissolved and diffused out into Au.

The dissolution cavities on <100> (Fig. 7) and <110> surfaces do not form a continuous trench but are rather in the form of separated square or elongated rectangular cavities. These often show an alignment that reflects the crystalline orientation of the substrate.

The specimens that consisted solely of Au films on Si, and that were annealed in an oxidizing ambient, showed formation of a SiO_2 layer on Au which was laterally nonuniform. In fact the geometrical pattern of SiO_2 formation and its dependence on crystalline orientation resembled the silicide growth pattern mentioned in the first part of this section.

These results were also generally reproduced when the Au film thickness and annealing temperatures were varied. Specimens with 3 and 10μ thick Au films showed identical behavior at 220°C and annealing time of 1 hr as specimens with 1μ thick Au film. Higher temperature anneals at temperatures between 220° and 360°C of specimens with 1μ thick Au film and Pd overlays exhibited a more rapid growth of the compound structure. The effect of the latter was to cause blending of silicide lines or points into an almost continuous compound layer in the case of <100> and <110>-Si substrate, after brief annealing times. However, the specimens with <111>-Si substrate showed only widening of compound boundaries and no blending due to much larger separation of the boundaries.

Discussion

The results show that migration of Si through thin evaporated Au films occurs along lines or occasionally in some spots, the density of which depends on the substrate Si surface condition or crystalline orientation. The relationship between these transport routes of Si and grain boundaries of the Au film are at present unknown. Microscopic analysis showed that Au grains were on the average 1-2μ in diameter. Similarly the effect of thermal stresses is not yet known. However, annealing of Au at 250°C for 3 hr during which

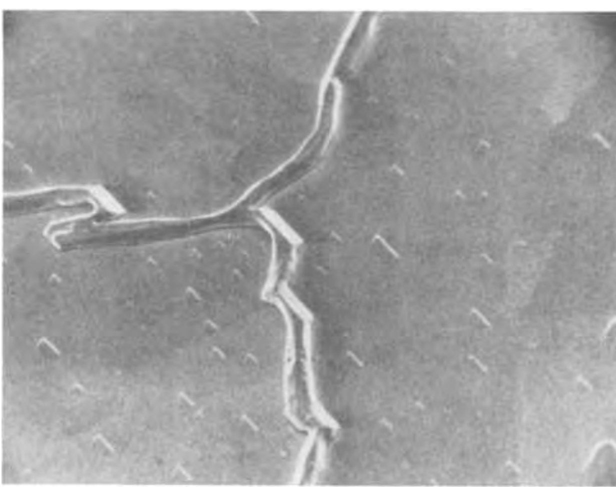

Fig. 8. The back side of the metallization after removal of the Si substrate. The raised features correspond to trenches in the substrate <111>-Si, and reflect the crystalline nature of the substrate.

substantial grain growth and recrystallization might be expected (12) before Pd overlay deposition did not make any noticeable change in Si dissolution pattern.

The fact that silicide boundaries can be seen optically, before all the Pd layer is consumed in the compound and the boundaries assume a brownish color, can be attributed to the deformation of Au-Pd metal layer due to volumetric changes accompanying the compound formation and due to "sinking" of metal layers in the dissolution trenches on the Si substrate.

The increase in thickness and width of Pd_2Si-rich lines with time is probably due to Si diffusion in the Pd_2Si cluster after Si atoms reach the Au-Pd_2Si interface. This is also borne out by the fact that Si can diffuse through the Pd_2Si layer that forms at Si-Au interface when a thin Pd underlay is evaporated on Si before Au deposition. However some "fanning" or diffusion of Si away from the plane of assumed Si migration also occurs, as evidenced by the larger size of silicide boundary width compared to that of trenches on the Si surface even for small annealing times. In fact given the vertical dimension of Pd overlay (600Å), the fact that growth of 1-5μ wide silicide region occurs before compound front arrives at the top surface, strongly suggests Si fanning out as well as migrating directly perpendicular to the surface.

Although the cause of localized dissolution reaction is at present unknown, it can be stated that difference of dissolution behavior for substrates of different orientations is neither due to Pd-sink layer nor to Au film. In fact cleaning, metal film depositions, annealing of specimens with <111>, <110>, <100> Si substrates were done simultaneously in a batch.

The localized dissolution behavior is predominantly an interface effect. Likely causes of this nonuniform behavior are discussed below. Chemical residues from polishing or cleaning of Si substrates, from absorbed species, or from native oxide can prevent Au from coming in intimate contact with Si, and hence allow Si to migrate in through few locations where coherency of the oxide or absorbed layer is disrupted. A similar behavior was observed in the case of the reaction of thin W-films evaporated onto Si surfaces (13). The difference between <111>-Si and substrates with other orientations can be explained on this basis also. The higher density of atoms on the <111> surface may bring about a more impervious oxide (14) or a layer of adsorbed chemicals that has sparser faults.

The thin oxide layer that forms on the Si surface by boiling the wafer in HNO_3 or H_2O_2 or exposing to air for a few days suppressed the reaction totally. It was also observed that allowing methanol, which is one of the organic cleaning agents used, to dry on Si wafer before deposition had a similar effect as native oxide in suppressing the reaction.

The effect of the intermediate Pd layer may be to disrupt this surface "dirt" layer, thanks to its higher reactivity with Si, thus paving way for Si to come in contact with Au at a larger number of locations. This result bears analogy to facts observed by Hiraki *et al.* (6), where migration of Si in Au/Ag sandwiches was seen at low temperatures only when Au was in contact with Si, and not when Ag was in contact with Si.

Conclusion

Interaction of crystalline and amorphous Si with thin Au films was studied with SEM and electron microprobe. Si was found to migrate through the Au film at temperatures 190°-360°C in isolated lines or points. Variation of the separation of these lines was seen to depend on the substrate crystalline orientation and was attributed to surface adsorbed impurity or oxide layer. A drastic change in the dissolution behavior of <111>-Si substrates especially, was brought about by evaporation of a very thin layer of Pd before the Au deposition. Likely causes of these results will be the subject of further detailed investigations.

The Diffusion of Iron in Impurity Controlled Single Crystalline Nickel Oxide Between 1061° and 1241°C

William D. Stewart, Jr.[1] **and J. Bruce Wagner, Jr.***

Department of Materials Science and Materials Research Center, Northwestern University, Evanston, Illinois 60201

ABSTRACT

The capability of an x-ray dispersive microanalyzer attachment on a scanning electron microscope to determine concentration profiles of iron in single crystalline NiO was studied. The technique is less precise but much less time consuming than radiotracer methods. The data support a model involving diffusion of iron via vacant nickel sites. The activation energies varied between 18 and 26 kcal/mole for diffusion under constant oxygen pressures between 0.011 and 1 atm. The diffusion was impurity controlled.

The purpose of this research was to study the rate and mechanism of diffusion of iron in nickel oxide. The x-ray wavelength dispersive analyzer of the JEOL-SMU-3 scanning electron microscope was used to detect the concentration of iron and thus provide a test for the capability of this instrument for studies of impurity diffusion in oxides. This study is part of a program to study impurity diffusion in oxides with special reference to high temperature corrosion problems.

Experimental

Single crystals of NiO were obtained from Dr. W. Clark of the Oak Ridge National Laboratory, Oak Ridge, Tennessee. The chemical analysis of an as-received crystal is shown in Table I. The boule was cleaved into rectangular parallelopipeds bounded by (100) crystal planes. Most crystals were first given a prediffusion anneal at the specified temperature (± 2°C) under an oxygen, air, or argon-oxygen gas mixture flowing past the sample at a linear flow velocity of about 0.9 cm/sec. The chemical diffusivity data of Price and Wagner (1) were used to determine the time for equilibration. Several crystals were heated in preevacuated, closed tubes containing excess nickel so the partial pressure of oxygen corresponded to the Ni-NiO phase boundary (2, 3). The samples were quenched by withdrawing from the hot zone to room temperature in approximately 10 sec for crystals under a flowing gas atmosphere and 30 sec for the crystal in closed, quartz ampuls. The crystals were mounted in a JEOL evaporator and approximately 300Å of iron was deposited onto one face of the crystal so as to act as a thin source of iron into a semi-infinite NiO crystal. The crystals were then given a diffusion anneal for times from 5 to 9 days under the same conditions (temperature and oxygen pressure) as the prediffusion anneal. The crystals were then quenched as described previously and cleaved parallel to a (100) plane along the diffusion axes. The crystals were mounted on a stub, coated with carbon (about 100Å thick), and placed in a specimen stage. This assembly was introduced into the JEOL-SMU-3 SEM. A LiF crystal was used for the detection of iron. A typical concentration gradient is shown in Fig. 1 and the log of the concentration *vs.* distance squared is shown in Fig. 2. The error bars denote the errors due to the instrument, counting statistics, geometry, and sample preparation. The results were calculated using the thin source solution to Fick's second law

$$\frac{\partial \log C}{\partial x^2} = -\frac{1}{9.21\,Dt} \qquad [1]$$

where C is the activity in counts per minute observed at a penetration distance x (cm), t is the diffusion anneal time (sec), and D is the impurity diffusion coefficient of iron in NiO (cm²/sec). A large number of determinations (a minimum of five) of penetration *vs.* distance were made on a single cleaved surface. The diffusion coefficients determined from repeated sets of measurements on the same cleaved crystal were generally within 5% of each other using the line of best fit to the data for each experimental determination. Figure 3 shows Arrhenius plots for constant oxygen pressures. The higher the oxygen pressure, the more rapid the diffusivity of iron. This suggests that iron migrates via a vacancy mechanism inasmuch as the deviations from stoichiometry in NiO are due to cation vacancies according to

$$\tfrac{1}{2}O_{2(g)} = O_O + V^{m'}_{Ni} + m \oplus \qquad [2]$$

where the notation of Kröger and Vink (4) is used and the m denotes the degree of ionization of the vacancies. In very pure NiO, $m = 2$. The crystals used in the present studies were previously shown (5) to contain predominantly singly ionized vacancies, $m = 1$. This may be understood in view of the large concentration of aliovalent impurities as has been shown,

e.g., by Tretyakov and Rapp (6). If iron migrates via singly ionized vacancies

$$D(\mathrm{Fe} \rightarrow \mathrm{NiO}) \propto V'_{\mathrm{Ni}} \qquad [3]$$

then one should expect the diffusivity to be proportional to the one-quarter power of the oxygen pressure. Figure 4 shows the data plotted as log *D* *vs.* log p_{O_2} at 1060° and 1241°C. Based on only three data points, the slopes are 0.19 and 0.23, respectively. Because of the high concentration of impurities, the slopes are less than would be predicted as also has been observed by Crow (7).

The temperature dependences are given in Table II. The activation energies represent primarily the migration energy (enthalpy).

In the case of the Arrhenius plot for crystals heated under oxygen pressures corresponding to the phase

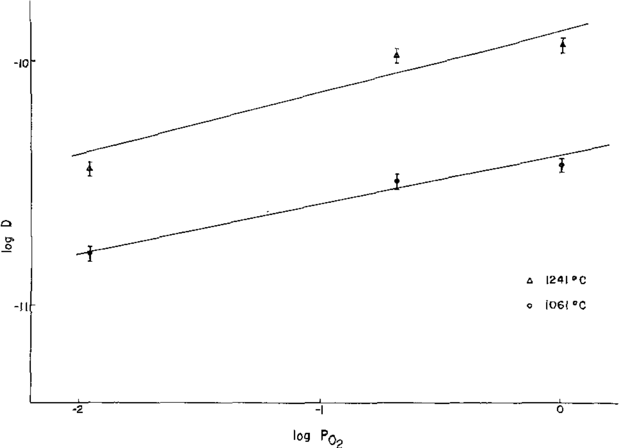

Fig. 4. Dependence of diffusivity of iron on oxygen partial pressure coexisting with single crystalline NiO.

boundary, Ni/NiO, the results are: *D*(Fe → NiO coex. with Ni) = 1.67 × 10^{-5} exp (−38,040/*RT*). The data obtained for these crystals presumably equilibrated at the Ni/NiO phase boundary were not consistent with the data obtained at the higher pressures and were orders of magnitude larger. It may have happened that the crystals did not equilibrate. The available data for comparison at the higher pressures has been carried out by Crow (7). His data for crystals

Table II. Temperature dependences

p_{O_2} (atm)	D_o (cm²/sec)	Activation energy Q, kcal/mole
0.011	1.6×10^{-8}	18.24
0.21	5.92×10^{-7}	25.90
1.0	6.74×10^{-7}	25.83

heated under 1 atm of oxygen are shown in Fig. 3. In order to make a direct comparison, Crow kindly furnished us with a single crystal used in his study (7). We carried out a prediffusion and diffusion anneal followed by a probe trace as described above. The result was $D = 5.4 \times 10^{-11}$ cm²/sec at 1050°C and $p_{O_2} = 0.21$ atm. This value, obtained on Crow's crystal, is almost identical to that obtained on our crystals. Crow's datum on his crystal amounted to about 9×10^{-11} cm²/sec at 1100°C. The data from both these studies are consistent at this one pressure and approximately the same temperature. Moreover, arguments advanced to the effect that our study may have involved interdiffusion owing to the thick layer of iron[2] (300 Å) or that sulfur ($S_O^{\cdot}$), as well as the metallic impurities, acts as a dopant, all suggest our diffusion coefficients should be larger than those of Crow. The converse was found. But the values of our activation energies, although consistent, were low. As a comparison, the diffusion of nickel in nickel oxide has been studied by a number of workers. The results for crystals heated in air are

$$D(\text{Ni} \rightarrow \text{NiO}) = 4.4 \times 10^{-4} \exp(-44{,}200/RT) \quad [5]$$

from Ref. (8)

$$D(\text{Ni} \rightarrow \text{NiO}) = 1.83 \times 10^{-3} \exp(-45{,}600/RT) \quad [6]$$

from Ref. (9)

$$D(\text{Ni} \rightarrow \text{NiO}) = 1.72 \times 10^{-3} \exp(-56{,}000/RT) \quad [7]$$

from Ref. (10)

and in 1 atm of oxygen

$$D(\text{Ni} \rightarrow \text{NiO}) = 4.77 \times 10^{-2} \exp(60{,}800/RT) \quad [8]$$

from Ref. (11)

The data expressed by Eq. [8] were repeated by Volpe, Peterson, and Reddy (12). Chen and Peterson (13) found for cobalt diffusing into NiO heated in air

$$D(\text{Co} \rightarrow \text{NiO}) = 9.12 \times 10^{-3} \exp(-54{,}160/RT) \quad [9]$$

Richards and Wagstaff (14) reported for diffusion of iron in nickel oxide heated in air

$$D(\text{Fe} \rightarrow \text{NiO}) = 1.81 \times 10^{-3} \exp(-44{,}500/RT) \quad [10]$$

Crow (7) studied the diffusion of iron in nickel oxide crystals cut from the same boule as that of Richards and Wagstaff. Crow found

$$D(\text{Fe} \rightarrow \text{NiO}) = 2.2 \times 10^{-3} \exp(46{,}200/RT) \quad [11]$$

for crystals heated under 1 atm of oxygen. All these data show much higher activation energies than we find. Crow's crystals contained about 275 ppm weight and he analyzed his diffusivity data in terms of impurity control. The crystals used in the present investigation contained orders of magnitude more impurities (see Table I). Therefore the data reported here are also impurity controlled and the activation energy is smaller than those of Crow (7) or of Richards and Wagstaff (14). Because the ionic radii of ferrous iron and nickel are approximately the same, one would expect similar activation energies for the diffusion of iron and of nickel in NiO provided both migrated via the same mechanism. Both appear to migrate via cation vacancies. We have no explanation at this time for our unusually low activation energies for iron diffusion except to note the very high concentration of impurities in the crystals.[3]

[2] For each square centimeter of area, 300A of iron would amount to $2.5 \times 10^{+17}$ atoms of iron. This amount of iron should be less than the concentration of lattice defects initially present in an undoped NiO crystal. However, the concentration of impurities was much greater than this and hence the diffusion was impurity controlled (see later text).

Final remarks concerning the use of the JSM-U-3 SEM with the x-ray wavelength dispersive analyzer are as follows. The peak to background ratio for the iron $K\alpha$ line is the major limitation of the SEM microprobe. The JSM-U-3 fully focusing wavelength dispersive spectrometer has a 670:1 peak to background ratio, which would result in a minimum detectable limit of 80 ppm for the background encountered. However, the precision of the analysis is a function of both the peak intensity and the background intensity, and, as shown in Fig. 2 the high background signal results in a relative error as great as 80% at the tail end of the diffusion profile.

The beam stability is very critical when long counting times are used. The SEM is not specifically designed for microprobe analysis, and the beam intensity will not remain constant for long periods of time. Counting periods in excess of 200 sec resulted in an error greater than the experimental error determined by multiple 10 sec counts, followed by beam alignment. The beam instability was particularly noticeable when returning to a previously counted area and recounting without having continuously realigned the beam. An SEM equipped with a beam stabilizer would reduce the problem of beam intensity, as would using a conventional microprobe, where long term stability is a design feature. Our results suggest that the technique is much more rapid than the use of radiotracers but the scatter in the data inherent in this type of microprobe (see, *e.g.*, Fig. 1) is much larger than that usually encountered in radiotracer determinations.

[3] Note added in proof: The iron in the NiO may be trivalent under the high oxygen pressures. G. W. Weber [Ph.D. Thesis, The Pennsylvania State University (March 1975)] found for chromium diffusing into MgO, the activation energy under constant p_{O_2} is reduced from 70 (undoped) to 29.8 kcal/mole for Cu-doped MgO.

Formation of Silica Films on Silicon Using Silane and Carbon Dioxide

William J. Kroll, Jr.* and Russell L. Titus*

Teletype Corporation, Subsidiary of Western Electric, Skokie, Illinois 60076

and J. B. Wagner, Jr.*

Department of Materials Science and Materials Research Center, Norhwestern University, Evanston, Illinois 60201

ABSTRACT

The reaction of silane with carbon dioxide to form silica on silicon in the temperature range 700°-1100°C has been studied. The results of surface charge density (Q_{ss}) and breakdown voltage (E_{BD}) measurements on the silica film are discussed. Etch rates, weight density, and infrared spectra obtained for these films are compared with those exhibited by oxide films thermally grown with steam. The dependence of the reaction yield on reactor design is briefly discussed.

In the manufacture of planar semiconductor devices, silicon crystals with homogeneous and uniformly thick oxide layers are utilized. These layers are usually produced by oxidizing the silicon either in a moist oxygen or in a pure water vapor (steam) atmosphere at temperatures between 1000° and 1200°C (1). The substrate is a high purity, polished semiconductor crystal wafer approximately 0.014 in. thick, doped to the desired conductivity and carrier type. After production of the semiconductor crystal or dielectric layers (*e.g.*, epitaxial silicon, polycrystalline silicon, silicon nitride, or alumina), it is desirable to deposit the oxide layer on the surface immediately, thereby avoiding the lengthy and expensive etching and purifying processes which precede conventional oxidation techniques. The advantages of this method have been demonstrated for reactions involving a metal halide such as silicon tetrachloride (2, 3).

Standard methods do not permit deposition of the silicon dioxide layer immediately following silane epitaxial growth, vapor phase etching, or dielectric film growth. When utilizing oxygen-containing gases, a lengthy, intermediate flushing with inert gas is required in order to purge the system and eliminate unwanted reactions. When gases containing water vapor are employed, reactions with the silicon halide or hydride residues remaining in the gas chamber or adsorbed on the apparatus walls are difficult to avoid even after prolonged flushing. The solid hydrolysis products of such reactions, primarily silicic acid, are carried by the gas current as a fine dust and settle on the blank silicon surfaces. It is impossible to produce an undisturbed oxide layer under such conditions. Therefore, the silica deposition is generally carried out in a separate reactor. Consequently, the silicon wafers must be chemically cleaned prior to insertion into the deposition apparatus; the complications associated with this two-step process are well known.

In contrast to experiments carried out in other types of reactors (4), the deposition method in the vertical "Pancake" production reactor shown in Fig. 1 permits deposition of silicon dioxide immediately after epitaxial growth, polycrystalline growth, silicon removal through a gaseous phase etch, or sequential dielectric film depositions. It is unnecessary to change the reactor or to carry out the cumbersome intermediate purging of the carrier gas since neither gas-forming materials nor materials hydrolyzing outside the high temperature zone are present. The immediate deposition of the silica on freshly formed, clean surfaces results in a very homogeneous, nonporous film of silicon dioxide. A silica layer thusly formed is very compatible with planar processing techniques.

At low temperatures, the carbon dioxide-silane mixture which initiates the deposition process is a dry, nonoxidizng gas. It is only in the high temperature zone of the chamber that the mixture reacts to form silica, which is in turn deposited on the substrate; the CO_2-SiH_4 mixture does not contribute to the direct oxidation of the silicon or to reaction of the silicon with the carrier gas. Because it eliminates the intermediate steps, this method is well suited to the production of semiconductor devices, *e.g.*, silicon planar transistors, diodes, and integrated circuits, particularly where electrical properties must be controlled within close tolerances. The same method can be applied to the production of semiconductor structural components where the p-n junctions, which have been exposed through gaseous phase etching, are provided with a protective oxide layer to stabilize their characteristic

parameters, *e.g.*, in the production of semiconductor structural components with mesa structures. The purpose of the present work was to study the formation of silica using silane and carbon dioxide and to compare the properties of the CVD silica with those of thermally grown silica.

Experimental

An Applied Materials Technology AMV 500 vertical epitaxial reactor was employed for the deposition. It holds six 1½ in. diameter silicon wafers on a silicon carbide coated graphite susceptor which rotates at 9 rpm and is inductively heated (Fig. 1); a 20 kW 450 kHz power supply provided the rf power. Substrate temperatures were measured with an infrared thermometer mounted at 45° with respect to the plane of the substrates. All temperatures cited are based on an emissivity correction factor of 0.70. The materials utilized inside the reactor head were either quartz, Teflon, or 316 stainless steel.

The silicon substrates were <111> oriented and doped with phosphorus to produce a resistivity of 3.5-7.0 ohm-cm. Following degreasing, the wafers were etched in hydrofluoric acid, scrubbed in a nonionic detergent, rinsed with 18 megohm water, and dried in a nitrogen stream. They were then loaded into the reactor and the temperature raised to 1100°C in a hydrogen atmosphere to remove contaminants remaining on the surface. After 5 min, the temperature was lowered to that desired for deposition and the silane and carbon dioxide introduced in a hydrogen carrier. All the gases were 4*N* purity or better. Flow rates were measured with mass flow meters. The gases were piped to the reactor head in 316 stainless steel lines. The hydrogen was purified and dried, and all gases were filtered through 0.45μ line filters prior to injection into the reactor. The carbon dioxide was injected concentrically with the silane-hydrogen mainstream (Fig. 1).

The oxide thicknesses on the silicon were measured by two methods: (*i*) ultraviolet-visible interference using a spectrophotometer with a specular reflectance attachment (5), and (*ii*) ellipsometry. The instrument used in the latter case also measured the index of refraction.

Results

Deposition rates.—The deposition rate of silica was studied as a function of the percentage of silane in the silane-hydrogen mixture, substrate temperature, reactor configuration, and carbon dioxide concentration. The first objective was to determine the flow rate at which the reaction ceased to be gas transport controlled. This flow rate was then used in all subsequent experiments. Figure 2 shows the results of these initial experiments at 900°C in which the carbon dioxide to silane ratio was maintained at 100:1. At low total flow rates, the deposition rate is a function of the flow rate, while at flow rates ≥22 liters/min the reaction is independent of flow rate (Fig. 3). A total flow rate of 24 liters/min was therefore chosen for all subsequent experiments[1] to insure that the reaction was not gas transport limited. A family of curves was then generated for deposition rate as a function of silane percentage. With the carbon dioxide to silane ratio fixed at 100:1, the temperature was varied from 700° to 1100°C, and deposition rates ranging from 50 to 3000 Å/min were observed. While the deposition rate was markedly dependent on temperature in the range between 700° and 900°C, considerably less dependence was observed between 900° and 1000°C. These data appear to agree quite well with those of Swann and Pyne (4), but if deposition rate is plotted as a function of $1/T$, differences between the two sets of data become apparent, as is discussed later.

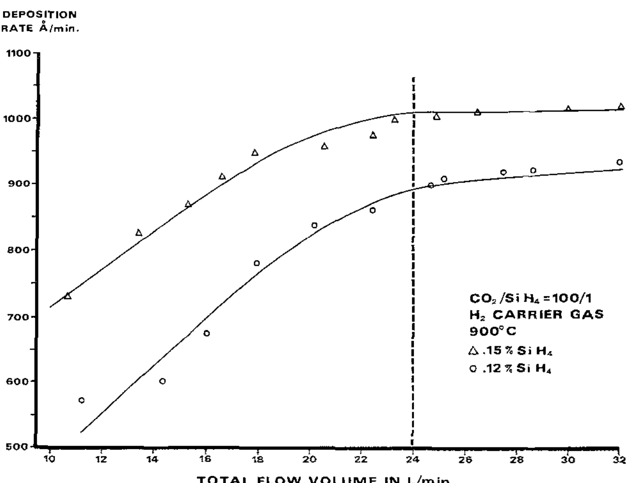

Fig. 2. Deposition rate of silica (Å/m) vs. total flow

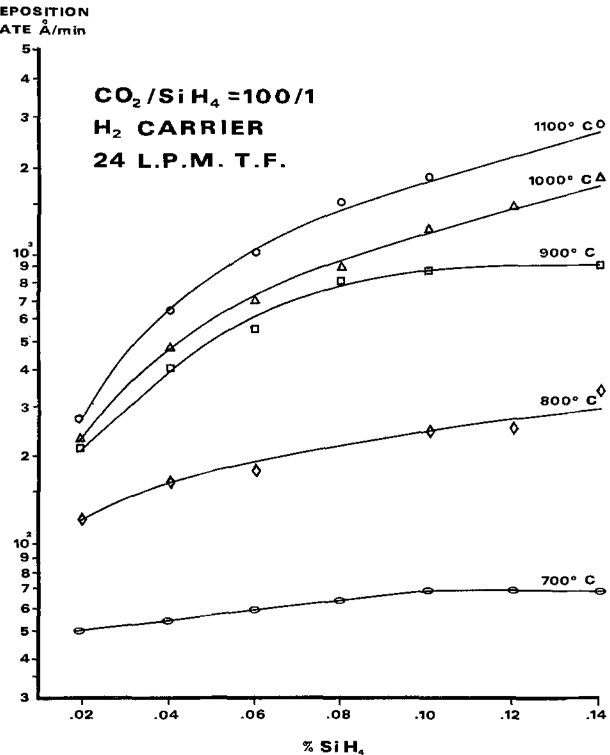

Fig. 3. Deposition rate of silica (Å/min) vs. silane percentage in the gas phase. The total gas flow in liters per minute (LPMTF) amounted to 24.

The deposition rate was also determined as a function of carbon dioxide to silane ratio. At a given temperature with the percentage of silane constant, increasing amounts of carbon dioxide were added without achieving saturation with respect to the deposition rate. This is the same effect observed by Swann and Pyne, and our data are in good agreement with theirs.

Infrared spectra.—In order to investigate the densification effects reported by Pliskin and Lehman (6), the Si-O stretching bond at 1090 cm^{-1} was observed for various values of temperature and silane percentage using a blank silicon wafer from the same ingot as the sample in the reference beam. The intensity of this absorption band is a function of the bonding character, stoichiometry, density, and porosity of the films, whereas the band position is a function of porosity (density) and strain. The wave numbers are shifted to lower values for films of higher porosity and strain. The normalized bandwidth at half-maximum for the Si-O stretching band at various silane percentages as a function of temperature is shown in Fig. 4. Higher

[1] With the vertical "Pancake" reactor a calculation of the linear flow rate over the sample was not possible.

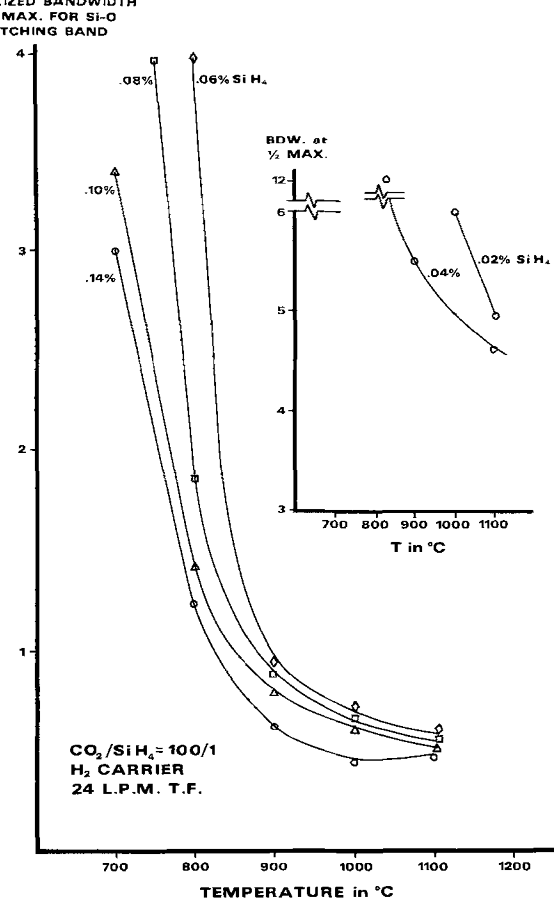

Fig. 4. Normalized bandwidth at one-half maximum of the Si-O stretching band as determined by infrared spectra *vs.* temperature of deposition. The insert shows similar data for the smaller concentrations of silane.

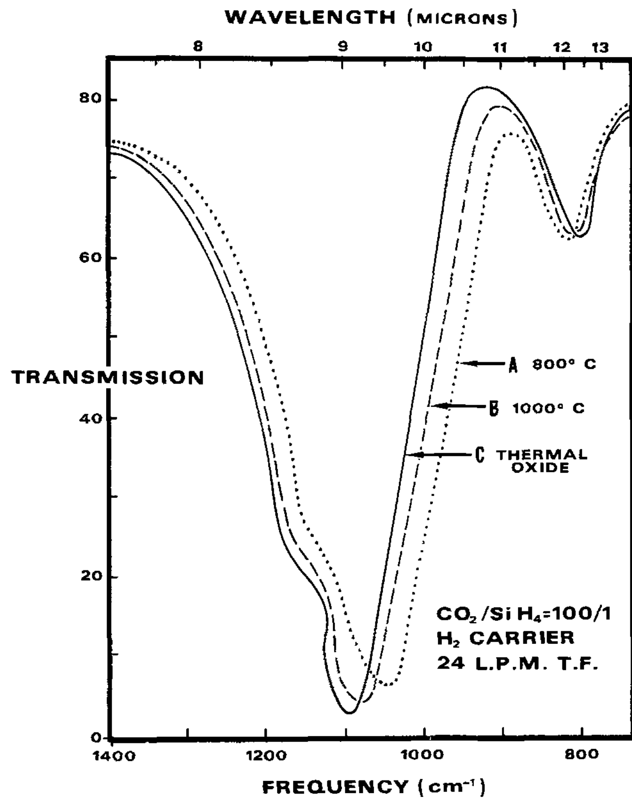

Fig. 5. Comparison of the infrared spectra for the silica deposited from silane and carbon dioxide (curves A and B) compared to that for a thermally grown oxide (1000°C in steam).

deposition temperatures consistently yielded narrower bandwidths implying the formation of denser and more stoichiometric films. Furthermore, as the silane percentage is increased, the silica film appears to become denser. For depositions carried out at the higher temperatures the normalized bandwidths at 1100°C are almost identical to those of a steam-grown thermal oxide sample measured at the same time (Fig. 5). Not only does the absorption band for Si-O stretching become more pronounced as the deposition temperature is increased, but it is also shifted to larger wave numbers. These data confirm the existence of the densification effects reported by Pliskin and Lehman (6).

Density.—Since the data obtained by infrared spectral analysis only permit qualitative determinations of the densification and stoichiometric effects, density was determined gravimetrically so that it could be correlated with deposition parameters. A second objective of this aspect of the work was to correlate the gravimetric results with those obtained from the infrared studies in the hope of quantifying the latter results since the infrared method is more readily applicable to semiconductor production processing. Both the gravimetric density and the infrared studies were performed on the same wafers, the gravimetric studies being carried out first. The diameters of the wafers were measured to a thousandth of an inch with a micrometer. The wafers were then cleaned as previously described and immediately weighed on an electrobalance situated in a dry box. They were then loaded into the reactor for deposition. Following the deposition process, the wafers were again weighed. An average weight change of approximately 37 mg was observed following deposition of a 16,000Å thick film, the weight change being measured to within 1%. The thickness of the film was measured to within 1% by a u.v. spectrophotometer. The density values should be accurate to within 2%. No allowance has been made for back side deposition which could conceivably result in an error on the order of 10-20%. Such back side oxidation of the wafer can occur because the contact between the wafer and the susceptor (holder) is not gastight; this has been observed by many investigators. However, in the present work adequate precautions were taken, and careful examination revealed no back side deposition. Some density values reported by other workers for thermally grown steam oxide are 11.5% higher than that for bulk silica. This increase may in part be attributed to this effect. Figure 6 shows the density as a function of the silane percentage at various temperatures. The values for fused silica (approximately 2.27 g/cm^3) and thermally grown steam oxide have been inserted to permit direct comparison with those of the CVD oxides. As was predicted qualitatively by the infrared spectral data, the density increases as both deposition temperature and silane percentage are increased. Note that the slopes change at higher silane percentages and converge toward the bulk values. This effect is similar to that observed with the infrared data, in which the graph of the normalized bandwidth at half maximum *vs.* silane percentage exhibited nearly zero slope at high temperature and silane values. Densities of the deposited silica which are greater than the bulk density may be due to the presence of free silicon in the film. Infrared spectral studies revealed absorption peaks that could be attributed to the presence either of silicon or of water vapor. Free silicon could conceivably be present since polycrystalline or epitaxial silicon depositions can occur as low as 500°C (9). Electron microprobe studies on the film were attempted to determine if there were indeed traces of carbon or silicon; however, they were unsuccessful owing to the low concentrations and poor signal to noise ratio in such thin layers.

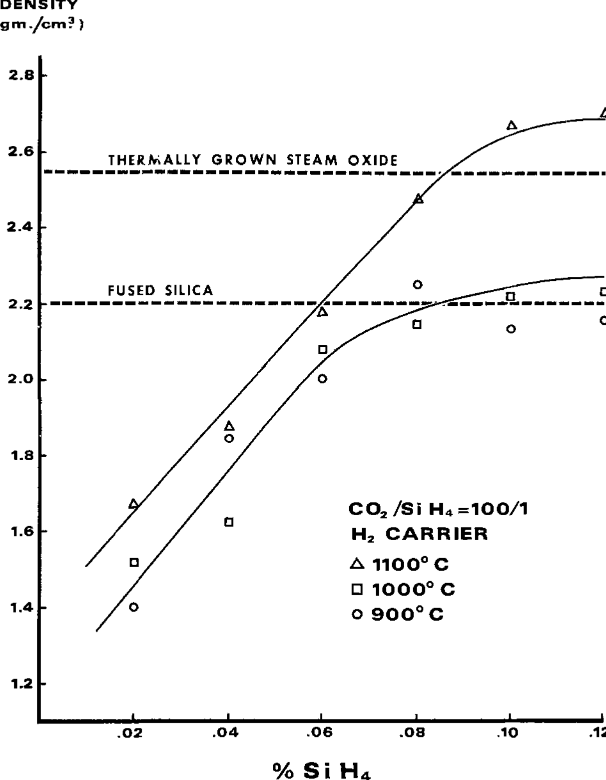

Fig. 6. Density of deposited silica films as a function of silane percentage as determined in the present study compared to values reported for thermally grown silica on silicon (1000°C in steam) by this laboratory and for fused silica. The higher values observed in the films may be due to the presence of free silicon. See text.

Etch rates.—The deposited silica used in deposition rate studies was subsequently used for the determination of etch rates. Etching was carried out in a polypropylene beaker with a 10:1 buffered hydrofluoric acid solution. The solution was maintained at 23°C, and the wafers were held in Teflon carriers. The etch rate *vs.* silane percentage (with the CO_2-SiH_4 ratio fixed at 100:1) was studied for various deposition temperatures. Some of these data are presented in Fig. 7. The data for 700°C were not plotted because they exhibited considerable scatter, and most of the etch rates were above 25 Å/sec.

For the higher temperatures and silane percentages, the etching characteristics of the CVD oxide approach those of thermally grown steam oxides [the etch rate of the thermally grown oxide is 12.5 Å/sec (7) in buffered HF]. The etch rates are slightly shifted from the values given for thermal oxide just as the density data was shifted. The slower etch rates observed for CVD silica may be attributed to the presence of small amounts of free silicon in the vapor phase deposited silica, as was previously noted in the infrared observations. In the etch rate experiments, the oxide was considered to be completely removed when the wafer surface became completely hydrophobic. Our etching results do not agree with those published by Swann and Pyne (4). Their CVD etch rates are all greater than those of thermally grown oxide, with the maximum etch rate occurring for films deposited at 900°C. This discrepancy may be a result of their reactor design since upstream decomposition of the gases may have occurred and/or their films may have been less dense. Our reactor with its concentric injection was specifically designed to prevent premature reaction and decomposition.

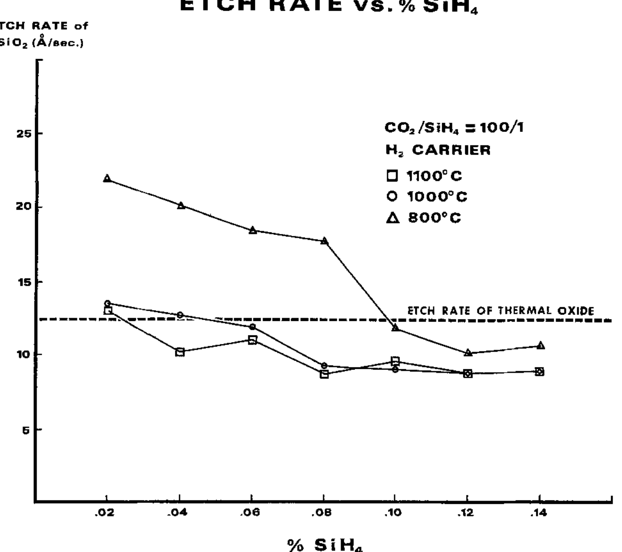

Fig. 7. Etch rate of SiO_2 (Å/sec) *vs.* silane percentage for the deposited films.

Electrical properties.—The electrical properties of the CVD silica which were measured were breakdown voltage (E_{BD}) and surface-state charge density (Q_{SS}). These two parameters were chosen in preference to others because they yield important initial information concerning the electrical properties of a given dielectric material (8). The method used to obtain Q_{SS} was the conventional capacitance-voltage plot of a metal-oxide-semiconductor structure (MOS) (9, 10). Silica on the order of 1800Å was deposited on the test wafers and the film thickness measured. The wafers were masked with a metal mask containing 0.025 in. diameter holes and a 15,000Å layer of aluminum deposited utilizing an electron beam gun. After deposition of the aluminum, the wafers were annealed in a nitrogen atmosphere at 460°C to minimize damage due to the electron beam (11) and the diameters of the Al dots were measured. Capacitance as a function of voltage was then determined; these data are presented in Table I. It is interesting that 63% of the values of Q_{SS} lie below $2 \times 10^{11}/cm^2$; this compares favorably with the average value of $2.5 \times 10^{11}/cm^2$ determined at the same time for thermally grown steam oxides. Q_{SS} never exceeded $4.35 \times 10^{11}/cm^2$, nor did the wafers exhibit any room temperature hysteresis when biased from +50 to −50 VDC. Values of Q_{SS} were also plotted as a function of silane percentage to determine whether Q_{SS} changes with deposition temperature and silane percentage (CO_2/SiH_4 = 100/1). No trend was discerned.

* Q_{SS} is defined as the charge per square centimeter. It is the number of coulombs per square centimeter divided by the electronic charge per particle.

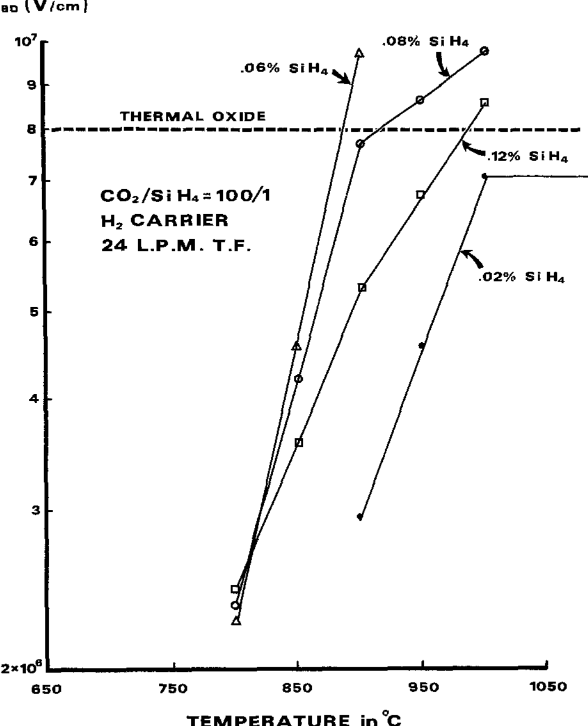

Fig. 8. Plot of breakdown voltage (E_{BD}) vs. temperature for deposited films. Also shown are average values for thermally grown silica films determined in the present study.

The breakdown voltage, E_{BD}, for the CVD grown silica wafers was measured next along with that of the thermally grown steam oxides (Fig. 8). E_{BD} is very sensitive to the deposition temperature; as the temperature increases, the breakdown voltage approaches that of the thermal oxide. When this effect is correlated with the density increase observed with increasing deposition temperature, one can predict that if the infrared spectra is intense and skewed toward 1090 cm^{-1} and the etch rate is low, the film will have good breakdown properties (*i.e.*, large values of E_{BD}). Breakdown voltages greater than 10^7 V/cm could not be measured because of power supply limitations; however, results indicate that most of the films deposited at temperatures above 1000°C and silane percentages greater than 0.06% could have $E_{BD} > 10^7$ V/cm.

Mechanical properties.—All silica films deposited showed good adhesion with little or no surface irregularity. The films deposited from the reaction of carbon dioxide and silane showed no cracking in the 20,000-40,000Å thickness range, whereas films prepared using oxygen and silane crack quite badly at thicknesses approaching 20,000Å (12).

The silica films CVD deposited from carbon dioxide were also heat cycled at temperatures up to 1200°C without snapping the silicon substrate; many of the silica films prepared from oxygen and silane crack under these conditions. These slices were also subjected to scratch tests and demonstrated good film adhesion without cracking.

The pinhole density in oxide films with thicknesses of 1500-2000Å was also measured for silica films deposited at silane percentages from 0.02 to 0.14% and temperatures ranging from 700° to 1100°C. These measurements utilized the electrophoresis effect in which copper deposits at the pinholes. These deposits can be counted and a defect density calculated. In practice, the defect density was measured by counting the sites where hydrogen bubbles were liberated from the plating reaction. No meaningful relationships between defect density and silane percentage or temperature could be ascertained. It is conjectured that defect density is a function of deposition thickness rather than of the deposition parameters. For a given set of deposition parameters, a total of thirty wafers was deposited with varying thicknesses of silica and the resultant data curve fitted by computer to yield the following equation: $Y = A + (B/X)$, where Y = defects/cm^2, X = silica thickness in angstroms, A = 0.571548, and B = 13,377.6. Typical values of the defect density range from 24-30 defects/cm^2 for a film of 500Å thickness to 2-3 defects/cm^2 for CVD films measuring 5000-6000Å. This compares with defect densities for the thermal oxide films ranging from 30 defects/cm^2 for a 500Å film to 4-5 defects/cm^2 for films of 5000-6000Å thickness.

The refractive index of the CVD silica films was found to be 1.450 ± 0.005. Thermally grown and silane-oxygen deposited silica films exhibited refractive indexes of 1.460 and 1.450, respectively.

Thermodynamics and Reactor Design

The reaction of CO_2, $SiCl_4$, and H_2 to form silica has been proposed by Tung and Caffrey (2), Steinmaier and Bloem (3), and others as proceeding in two steps

$$H_2 + CO_2 = H_2O + CO \quad [1]$$

$$SiCl_4 + 2H_2O = SiO_2 + 4HCl \quad [2]$$

The silica is therefore formed by hydrolysis of the halide. These authors realized that intermediate reaction steps must exist.

From thermodynamic considerations (13), CO_2 and silane should react to form SiO_2 and CO according to the reaction

$$SiH_4 + 4CO_2 = SiO_2 + 4CO + 2H_2O \quad [3]$$

$$\Delta F^o = -115.019 \text{ kcal/mole (13)}$$

The water formed during the reaction may hydrolize further silane and thus speed deposition rates. Tests conducted with monocrystalline silicon, however, indicate that in a hydrogen carrier the reaction may proceed in two steps, *i.e.*

$$H_2 + CO_2 = H_2O + CO \quad [4]$$

and

$$SiH_4 + 2H_2O = SiO_2 + 4H_2 \quad [5]$$

Swann and Pyne (4) used argon as a carrier gas to demonstrate that the reaction does not proceed by the water-gas reaction alone. Their results showed an even greater deposition rate with argon as the carrier gas rather than hydrogen. The higher deposition rates in argon may be due to the fact that the hydrogen carrier may act to inhibit either decomposition or hydrolysis of the silane as would be expected from mass action principles. This suggestion is consistent with the obervation that the films formed by Swann and Pyne in an argon carrier gas contained free silicon which affected the dielectric loss and etch rates of the film. It may therefore be advantageous to use hydrogen despite the slower deposition rates achievable in order to minimize the decomposition of silane and subsequent formation of free silicon. The one-step reaction of silane and carbon dioxide is thought to be reasonable by Swann and Pyne; however, future studies should be carried out with silane and steam to determine the rate of hydrolysis of the silane.

In the present reactor design, it is desirable for the carrier gas and oxidizing agent to flow in an umbrella-type circular flow as shown in Fig. 1. Concentric injection of the oxidizing agent into the carrier gas flow is also important for control of both film uniformity and deposition rate. Typically, film thickness was uniform to ±5% from wafer to wafer and ±7% from run to run. When the injection nozzle was changed in either orifice size or in height, the deposition rate changed drastically; therefore, the nozzle was set for the maximum deposition rate in all experiments. Reducing the orifice size minimized bell jar deposition

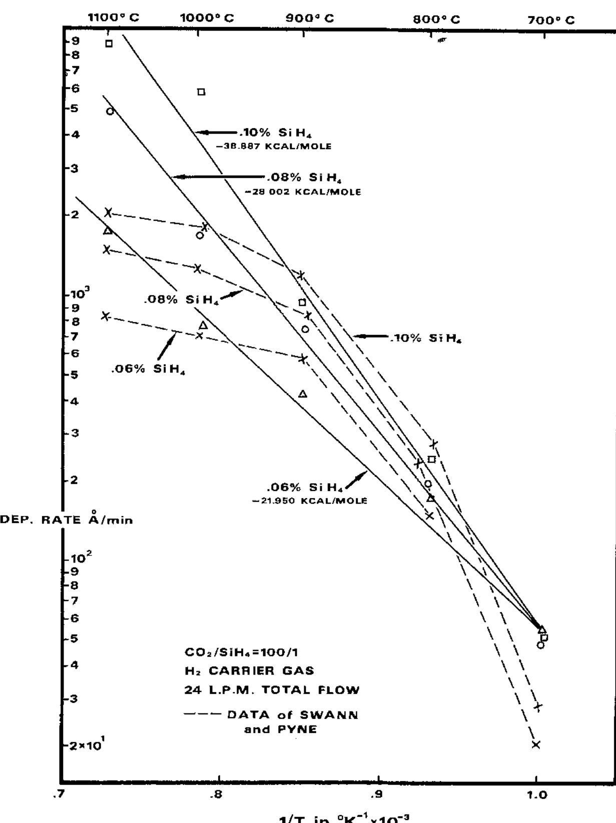

Fig. 9. Arrhenius plot of deposition rates vs. $1/T$ for data obtained both in the present study and by Swann and Pyne (4).

but also reduced the deposition rate at the substrates. Concentric injection of the gas was employed to minimize the upstream decomposition encountered by previous authors; the results shown in Fig. 9 reflect the success of this technique. The dashed lines in Fig. 9 represent the data of Swann and Pyne (4), and the solid lines represent data taken on films deposited in the vertical reactor previously described. The reactions in the concentric injection reactor yield normal Arrhenius plots from which meaningful activation energies can be calculated. The deposition rates obtained with the concentric injection converge at low temperatures. These results indicate that there may be more than one rate-determining step in the reaction, all of which are temperature dependent. However, this question has not yet been resolved. The data of Swann and Pyne which yield curved lines on the Arrhenius plot may be attributed to their reactor design because the gases were free to mix at a considerable distance from the substrates and to travel in almost laminar fashion past the heated substrates. This long path length probably enhances the upstream decomposition effects those authors observed.

Summary and Conclusions

The rate-determining step for the reaction between silane and carbon dioxide depends on temperature. The reactor design is important in controlling the reaction rate and deposition characteristics of the films. The deposited films exhibit excellent adhesive and mechanical properties, much the same as thermally grown steam oxides.

The MOS capacitance-voltage plots for all cases studied indicate that the films have properties adequate for gate passivation or deposited field oxide usage. The surface charge density, Q_{ss}, was equal to or less than 1.0×10^{11} cm^{-2}; therefore, the oxide may be used in composite deposited gate structures for MOS. Furthermore, there are strong correlations between the increased E_{BD} and the deposition temperature, silane percentage, and film density.

Oxides deposited by this reaction exhibit etch rates, indices of refraction, and densities almost identical to those of thermally grown steam oxide. Therefore, an oxide deposited by this technique can be substituted for thermally grown steam oxide without compromising the properties. In addition, the technique achieves a significant saving in processing time due to the high deposition rate of 1000 Å/min obtainable with the reaction of silane and carbon dioxide. Thus, the time required to deposit a 15,000Å MOS field oxide by this technique would be 7-15 min while that required for thermal oxidation in steam at 1100°C would be 7-8 hr.

The chemical compatibility of this reaction with polycrystalline silicon depositions, silane-ammonia reactions, epitaxial silicon deposition, and aluminum trichloride-carbon dioxide reactions permits sequential depositions in one reactor without the tedious intermediate cleaning and purging steps, thus eliminating the chance of contamination occurring between layers. These sequential depositions could be utilized to obtain film combinations for device applications, *e.g.*, silicon dioxide on silicon nitride (or vice versa), silicon dioxide on polycrystalline silicon for use as an etch mask or protective layer, silicon dioxide on epitaxial silicon for use as a diffusion mask, and silicon dioxide on alumina for use as an etch mask or composite gate structure.

Kinetics of the Thermal Oxidation of Silicon in O_2/N_2 Mixtures at 1200°C

D. W. Hess* and B. E. Deal*

Research and Development Laboratory, Fairchild Camera and Instrument Corporation, Palo Alto, California 94304

ABSTRACT

The thermal oxidation kinetics of (100) and (111) oriented silicon in several oxygen/nitrogen mixtures ranging in oxygen partial pressure from 0.02 to 1.0 at 1200°C have been investigated. The parabolic rate constant B and the linear rate constant B/A varied linearly with respect to the oxygen partial pressure, while τ, a factor which accounts for an initial accelerated oxidation rate during dry oxidation of silicon, varied inversely with the oxygen partial pressure.

During the past ten years, numerous investigations have been reported concerning the thermal oxidation of silicon under dry oxidation conditions (1-9). However, only three of these studies have dealt with oxidation in oxygen/nitrogen mixtures under flow conditions (6-8), and none of these three have utilized a temperature above 1000°C, where the silicon oxidation kinetics should be primarily a diffusion-controlled reaction. Consequently, this study was undertaken to investigate the thermal oxidation of silicon in several oxygen/nitrogen mixtures at 1200°C.

According to the theory of silicon oxidation as developed by Deal and Grove (1), the thermal oxidation kinetics may be expressed in the general form

$$x_0^2 + Ax_0 = B(t + \tau) \qquad [1]$$

where x_0 = oxide thickness in μ, A = constant in μ, B = parabolic rate constant in μ^2/hr, B/A = linear rate constant in μ/hr, t = oxidation time in hr, τ = correction factor which accounts for an observed initial accelerated growth rate in dry oxygen, in hr. B is further defined by Ref (1)

$$B \equiv 2D_{\text{eff}}C^*/N_1$$

where D_{eff} = effective diffusion coefficient of the oxidizing species in the oxide, C^* = equilibrium concentration of oxidant in the oxide, which, according to Henry's law, is directly proportional to the oxidant partial pressure, N_1 = number of oxidant molecules incorporated into a unit volume of the oxide, and τ by

$$\tau \equiv (x_i^2 + Ax_i)/B$$

where x_i is the effective oxide thickness initially present on the silicon surface. From these definitions, it can be seen that B should vary directly, and τ inversely, with the oxygen partial pressure, *i.e.*

$$B \propto P \text{ and } \tau \propto \frac{1}{B} \propto \frac{1}{P}$$

Also, the constant A should be independent of oxygen partial pressure, since it depends only on the diffusion coefficient of the oxidizing species and the rate constants of the reactions occurring at the gas-oxide and oxide-silicon interfaces (1).

Experimental Procedure

The silicon wafers used in this investigation were 4-6 ohm-cm, phosphorus doped, with (100) and (111) orientation. They were cleaned using sulfuric-peroxide, aqua regia, a hydrofluoric acid dip, and several deionized water rinses. Oxidations were carried out at 1200°C in a resistance-heated furnace containing an ultrahigh purity Mullite liner and a fused quartz tube. The wafers were pushed into the furnace in the oxygen-nitrogen atmosphere and after various times were slow pulled (2 min) out of the furnace where they were allowed to cool in the O_2/N_2 mixture in which they had been oxidized. It should be noted that this procedure differs from the one utilized in Ref. (1), where the oxidations were stopped after the allotted oxidation time by pulling the samples very rapidly from the oxidation furnace tube.

The flow meters utilized in this study were calibrated using a Matheson Electronic Mass Flowmeter and a Porter-Vol-U-Meter. The total flow rate was 1 liter/min, which corresponded to a gas velocity of ~1 cm/sec. The oxygen and nitrogen used were from a liquid source and were further dried and filtered by passage through a Matheson Model 451 gas purifier.

The oxide thicknesses were measured with an Applied Materials (AME-500) ellipsometer. The reproducibility of the oxide thicknesses over the range investigated was ±4%.

The contamination level present was determined for each oxidation by fabrication of MOS capacitors, and bias-temperature stressing them under a field of $\pm 5 \times 10^5$ V/cm at 300°C for 3 min. The mobile ion concentration ranged from less than 3×10^{10} cm^{-2} for short (under 4 hr) oxidation times to 8×10^{10} cm^{-2} for 16 hr oxidation in the various O_2/N_2 mixtures.

Results and Discussion

A log-log plot of thickness *vs.* time for the thermal oxidation of silicon in several O_2/N_2 mixtures at 1200°C is shown in Fig. 1. The 100% curve agrees well with that reported in Ref. (1), except for the shortest oxidation times, where the present oxide thicknesses are approximately 50Å greater than the previous work (1). This discrepancy is probably due to the different techniques utilized to remove the samples from the furnace after oxidation, *i.e.*, slow pulling in the oxidation ambient *vs.* rapid cooling. The plots in Fig. 1 are for (100) orientation, however, the thickness of the oxides grown on (100) and (111) silicon wafers differed by less than 2% over all oxidation times and mixtures. This, along with the fact that the slopes of the lines for the thicker oxides in Fig. 1 are very close to 0.5, indicates that dry oxidation of silicon is controlled mainly by diffusion of the oxidant across the oxide. It should be noted that the 2% mixture shows some scatter due to the fact that it was difficult to maintain the exact flow settings for such a small flow rate over long periods of time.

As indicated previously, an initial increased oxidation rate is observed during the dry oxidation of silicon. To obtain the correction factor τ, which accounts for this initial oxidation, a linear plot was made of oxide thicknesses *vs.* time, and the curves extrapolated back to zero oxide thickness (1). The extrapolated curves crossed the oxide thickness axis at 150 ± 30Å for each oxidation mixture investigated.

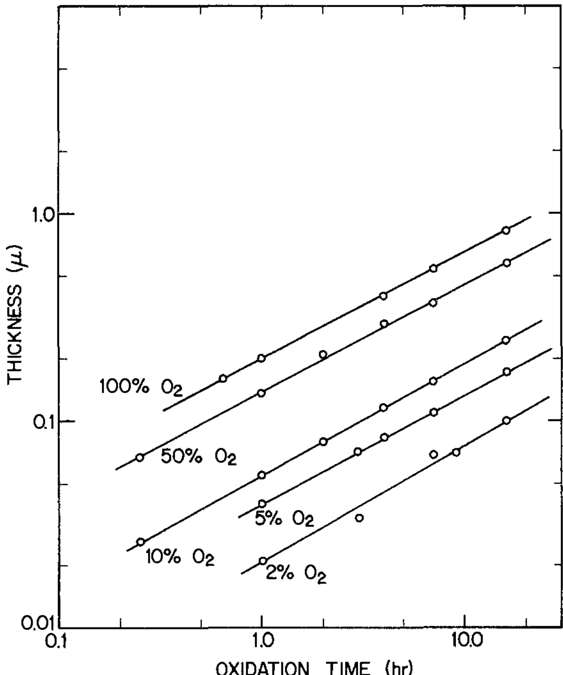

Fig. 1. Oxide thickness vs. time for the oxidation of (100) and (111) oriented n-type silicon in O_2/N_2 mixtures at 1200°C.

The resulting τ values are shown in Table I, along with the values obtained by using the numbers given by Deal and Grove (1) for 100% O_2 oxidation, and assuming that $\tau \propto 1/P$. The agreement is quite good with the possible exception of the 2% value, which, as stated previously, is probably due to a variation in the composition of the 2% mixture.

If x_o is plotted *vs.* $(t + \tau)/x_o$ for each oxygen partial pressure, the slope and intercept of the resulting lines give B and $-A$, respectively (1). These values, obtained from a least squares analysis of the present data, are given in Table I. Each of the measured values of B agrees quite closely with the values predicted by the theory. The values of A should be independent of the oxygen partial pressure, and indeed, no trend is observed, although there is a reasonable amount of scatter. The largest deviation from the value of 0.04μ obtained from the theory (other than the 2% mixture) is observed for O_2 partial pressures of 0.50 and 1.0. This is probably due to the fact that the present oxidations were pushed (1 min) and pulled (2 min) in the oxidizing mixture, rather than quenched after oxidation as in Ref. (1). The present procedure would cause the shorter oxidation times to yield thicker oxides than if the oxidation was terminated immediately after the allotted oxidation time by rapid cooling. This effect would be most important for large O_2/N_2 ratios. In order to determine the effect a small decrease in oxide thickness would have on the value of A, a 5% change in the oxide thickness obtained after 15 min oxidation in 50% O_2/N_2 was incorporated into the least squares data in place of the previous value. This generated values for A and B of 0.024μ and $0.0216\ \mu^2$/hr, respectively. Thus a small change in the oxide thickness has little effect on B, but a substantial effect on A for short oxidation times and thin oxides.

Table I. Comparison of calculated and measured values of constants τ, B, and A from oxidation at 1200°C in O_2/N_2 mixtures

Oxygen partial pressure	τ (hr) Calc*	τ (hr) Measured	B (μ^2/hr) Calc*	B (μ^2/hr) Measured	A (μ) Calc*	A (μ) Measured
1	0.027	0.03	0.045	0.043	0.04	0.025
0.50	0.054	0.06	0.0225	0.0213	0.04	0.019
0.10	0.27	0.29	0.0045	0.0045	0.04	0.049
0.05	0.54	0.51	0.00225	0.0022	0.04	0.038
0.02	1.35	1.09	0.0009	0.0010	0.04	0.076

* These values were calculated by assuming $\tau \propto 1/P$, $B \propto P$, and $A \neq f(P)$, and using the values of τ, B, and A obtained from Ref. (1) for an oxygen partial pressure of 1 (100% O_2) at 1200°C.

A log-log plot of B and τ *vs.* oxygen partial pressure is shown in Fig. 2. The slopes of the lines for B and τ are 1 and -1, respectively, which is in agreement with the theoretical oxygen partial pressure dependence of these quantities. The values of B determined in this investigation agree quite closely with those reported by Flint (10), who determined the oxygen partial pressure dependence of B at 1200°C above a partial pressure of 0.25, using oxygen/argon mixtures. Also, it should be mentioned that since the linear rate constant is defined as B/A, it is apparent that it will show the same pressure dependence as B. There is some scatter observed, however, due to the variation in A.

Summary

The thermal oxidation kinetics of silicon in several O_2/N_2 mixtures at 1200°C has been investigated. Little or no difference in oxidation rate was observed between (100) and (111) oriented silicon wafers, indicating that the oxidation of silicon at 1200°C under various oxygen partial pressures is primarily a diffusion controlled reaction. It was also observed that the parabolic rate constant B and the linear rate constant B/A, vary proportionately with the oxygen partial pressure, while τ, a factor which accounts for an initial accelerated oxidation rate during dry oxidation of silicon, varies inversely with the oxygen pressure. These results agree with the pressure dependence predicted by the theory of silicon oxidation as reported by Deal and Grove.

Acknowledgments

The authors wish to acknowledge the assistance of Julia Bien in the experimental portion of this work.

Technical Notes

A Comparative Study of Microwave and Radiofrequency Plasma Polymerization of Benzene

M. Duval* and A. Théorêt*

Hydro-Quebec Institute of Research, Varennes, Quebec, Canada

Chemical reactions in electrical discharges have been studied extensively over the past 15 years. The very thin polymer films that can thus be prepared have been given a number of new applications. For example, such films have been used as optical light guides (1). Several books and review articles covering all or part of the subject have been published recently (2-5). They contain many references to earlier work, which is abundant, particularly that concerning the reaction of aromatic hydrocarbons. However, the specific influence of the various reaction parameters, particularly discharge frequency, is not yet quite elucidated. In the case of aromatic hydrocarbons, some authors have tried to differentiate between radiofrequency and microwave discharges, by comparing published results obtained in radiofrequency discharges to those obtained in microwave discharges (6-9). The conclusions thus given are uncertain because reactor designs were not the same in the compared systems. For instance, in a work where the same reactor design was used with toluene as monomer, pressure was not kept constant, and no clear differences between radiofrequency and microwave could be evidenced (10). In another work with the same reactor design and benzene, the formation of diphenyl was shown to be more important in radiofrequency discharges than in microwave discharges, but the formation of the other reaction products, including polymers, was not studied (11).

In the present work, the same reactor design and controlled values of the other reaction parameters (pressure, flow rate, and power), have been used with benzene as monomer. Attention has been given to the formation of oligomers and polymers rather than to the formation of smaller molecular weight compounds, which is generally much less important and reproducible (12). And in order to understand the mechanism of the chemical reactions leading to polymer formation, the nature and the amount of the reactive species formed in the discharge have been investigated. Such information has been obtained so far mainly from indirect identification methods, such as those relating electrical discharge reactions to the more well-known radiolysis or photochemical reactions (6, 13), or those deducing the nature of the intermediate species from the composition of the final products (7-9). Direct identification methods such as ESR, mass, or emission spectroscopy, are more reliable. However, only small plasma radicals have been studied by ESR spectroscopy (14), and the identification of some plasma species may be difficult with mass spectroscopy because of fragmentation processes (5). Emission spectroscopy has therefore been chosen in the present study.

Experimental

A schematic representation of the experimental setup used is shown in Fig. 1. Monomer vapor was admitted at regulated pressure and flow rate in the small, vertically mounted (9 mm inner diameter) quartz tube. Plasma was maintained in the upper end of the tube by means of a microwave cavity or radiofrequency fed copper sleeve electrodes. The Raytheon microwave generator and the Tracerlab radiofrequency generator used operated at 2540 and 13.56 MHz, respectively. Plasma emission spectra were observed through a quartz window and recorded from 7000 to 2000Å by means of a Cary 17 spectrophotometer equipped with a RCA 1P28 photomultiplier. Rearrangement products of the monomer molecules were deposited on a fixed circular target placed above the discharge zone and the films thus obtained were characterized by the ATR technique, with a Perkin Elmer Model 180 infrared spectrophotometer. Infrared and emission spectra obtained with similar reaction conditions were quite reproducible. Films soluble in tetrahydrofuran solvent were analyzed by gel permeation chromatography with a set of low porosity styragel columns, as described before (12). Products in the cold traps were analyzed by gas chromatography on SE 30 columns.

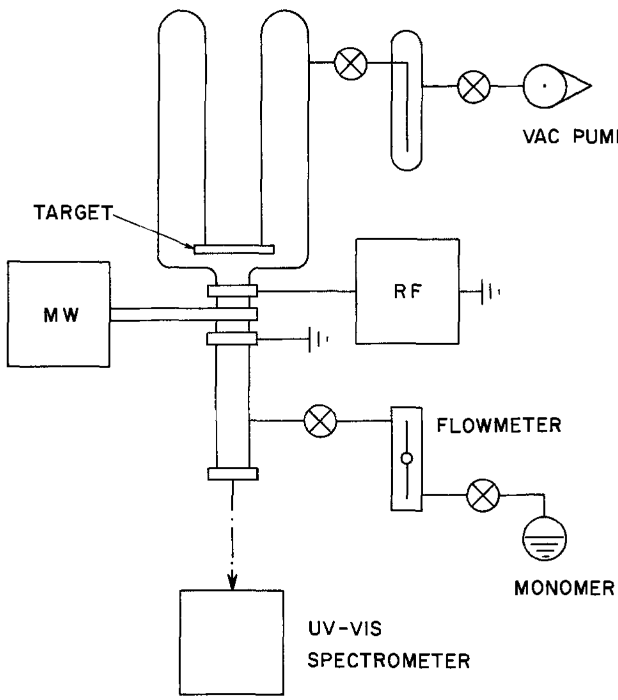

Fig. 1. Schematic representation of glow discharge reaction system. RF, radiofrequency; MW, microwave.

Several combinations of pressure and power were studied, from those below which the discharges cannot be sustained up to those above which carbonization of films occurs. Typical values of pressure and power range were from 0.2 to 2.0 Torr and from 15 to 100W, respectively. It was found convenient, as is usually done in plasma chemistry, to combine the values of monomer pressure *P* and power *W* supplied by the generators, and to consider the power-to-pressure ratio (W/P) as an indication of the energy given to the plasma. The greater the value of the W/P ratio, the more energetic is the plasma.

Results and Discussion

Films obtained with values of the W/P ratio larger than 200 are insoluble in most solvents, indicating a high degree of cross-linking. The compounds contained in soluble films cover a broad range of molecular weights, the amount of high molecular weight materials and compounds with sizes related to those of terphenyl and substituted benzenes being more important in the case of microwave discharges, as shown in Fig. 2. Large quantities of unreacted benzene and only small quantities of biphenyl, toluene, phenyl acetylene, indene, and styrene were found in the cold traps. The relative amounts of the cold-trapped products change only slightly with the W/P ratio, and biphenyl is the main cold-trapped product in the case of radiofrequency discharges.

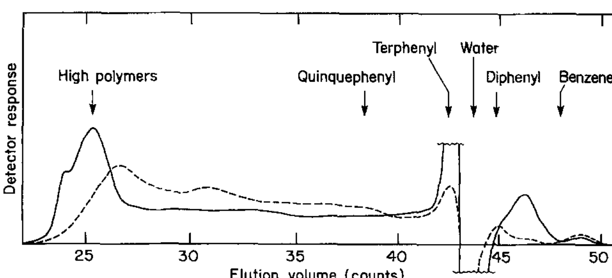

Fig. 2. GPC spectra of plasma produced polymers: ———, MW; - - - -, RF; $W/P = 100$; concentration, 0.2% THF. The elution volumes of model compounds have been given as a reference of molecular size.

The infrared spectra represented in Fig. 3 are typical spectra of plasma-produced polymer films, containing the prominent features of all the obtained spectra. There are several differences among these spectra. The main one is the variable intensity of the main aromatic bands at 3020, 1600, and 1460 cm^{-1} and of the main aliphatic bands at 2920, 1450, and 1370 cm^{-1}. The ratios of the heights of these aromatic and aliphatic bands are independent of film thickness, and are a semiquantitative indication of the aromatic character of the polymers. Such ratios have been represented in Fig. 4, in the case of the bands at 3020 and

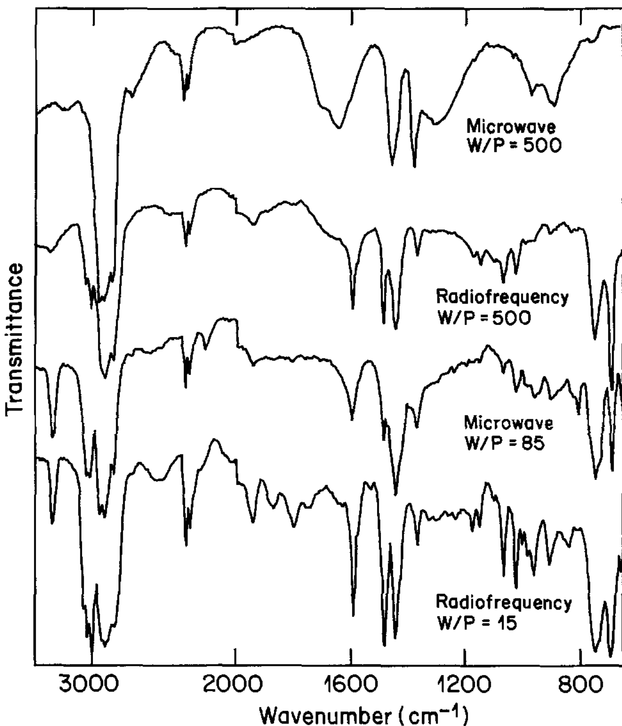

Fig. 3. Infrared spectra of polymer films produced in radiofrequency and microwave discharges with typical values of the W/P ratio.

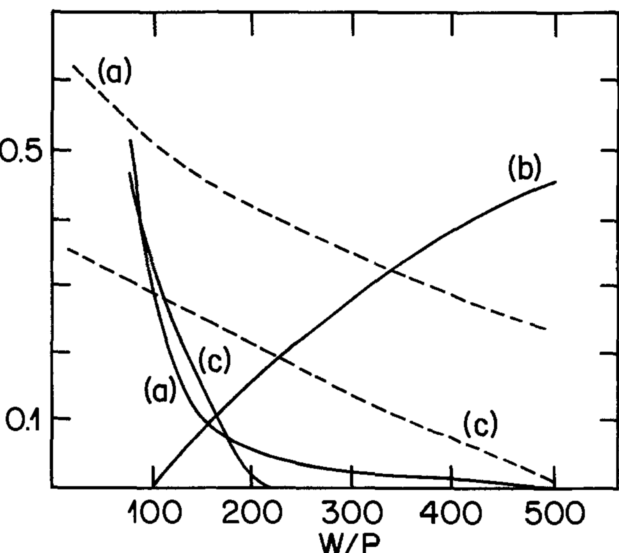

Fig. 4. Infrared band height ratio as a function of the W/P ratio: ———, MW; - - - RF. (a), 3020/2920 cm^{-1}; (b), 1640/2920 cm^{-1}; (c), 3300/2920 cm^{-1}. These ratios are independent of film thickness and indicative of the relative amounts of carbon-carbon aromatic bonds (a), double bonds (b), and triple bonds (c) in the polymer structure.

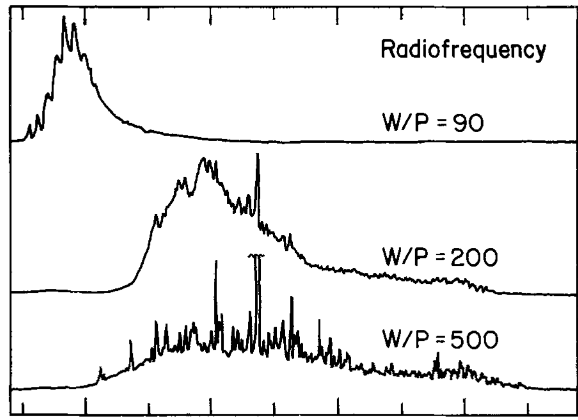
2920 cm^{-1}, as a function of the W/P ratio. Curves obtained in the case of the bands at 1600 and 1370 cm^{-1} are quite similar and have not been represented in the figure. It can be seen that the aromatic character of plasma-produced polymer is closely related to reaction conditions used and, more precisely, that it decreases continuously as the discharges become more energetic, and that it is lower in microwave than in radiofrequency discharges. The aromatic character of polymers obtained in low-energy radiofrequency discharges is close to that of conventional polystyrene. Previous authors had already reported a gas-phase formation of aromatic polymers in radiofrequency discharges (16, 9) and of aliphatic polymers in microwave discharges (15). The present results show that polymers with large differences of aromatic character may be obtained in microwave and radiofrequency discharges, simply by using different W/P ratios.

When the main aromatic bands are present, strong bands at 690 and 750 cm^{-1} are present, indicating that the aromatic rings are mostly monosubstituted, *i.e.*, are pendant from an aliphatic or alicyclic polymer chain (17, 18). There are also weaker bands at 690, 1020, and 1071 cm^{-1}, which had been assigned once to a poly-benzyl cyclopentene structure (18), but could indicate a polystyrene structure as well. At last, especially in low-energy discharges, there are relatively strong bands at 3300 cm^{-1}, which had previously been observed in a-c discharges (17). They are indicative of a carbon-carbon triple bond structure. The relative intensity of these bands, as can be seen in Fig. 4, decreases as discharges become more energetic.

When the main aromatic bands are weak or missing, *i.e.*, mainly in the case of high-energy microwave discharges, there are moderately strong bands in the 1620-1660 cm^{-1} region, and weaker ones in the 1300, 1150, and 960 cm^{-1} regions, indicating a carbon-carbon double bond structure, which had previously been observed in a-c (19) and microwave (15) discharges. The relative intensity of these bands decreases as discharges become more energetic, as can be seen in Fig. 4. Bands in the 1700-1750 cm^{-1} region are weak or missing in all the spectra. Oxygen contamination of the films, if any, is therefore very small. This was not the case in a-c discharges (19).

Plasma emission spectra represented in Fig. 5 are typical spectra which contain the prominent features of all the obtained spectra. Only limited parts of these spectra have been reported in previous plasma chemistry studies with aromatic hydrocarbons (7, 15-17, 20). Mono-, di,- and polyatomic radicals or ions, and excited molecules, are responsible for these emission spectra. They are gas-phase, unstable species, and should not be confused with the more stable radicals which may be trapped in the polymer films and that have been detected in some cases by ESR spectroscopy (9, 21). A number of these species have been identified in the present spectra. For instance, the bands at 4350, 4860, and 6580Å are the main Balmer lines of the hydrogen atom. The bands at 3900 and 4310Å are due to the ($A^2\Delta \rightarrow \chi^2\pi$) and ($B^2\Sigma^- \rightarrow \chi^2\pi$) transitions of the CH radical. The bands at 4310, 5160, and 5630Å are the Swan bands due to the ($A^3\pi_g \rightarrow \chi^3\pi_u$) transition of the C_2 radical (22). The band system in the 2400-3300Å region is due to the ($^1B_{2u} \rightarrow {}^1A_{1g}$) transition of the benzene molecule (23). Schüler's "T spectrum," which can be observed in the 4673-6500Å region, is due to the emission of $C_4H_2^+$ or of the C_2H radical (24). Schüler's "V spectrum" in the 4456-5900Å region, and "W spectrum" in the 3400-4400Å region, when present, are weak. They were assigned to the emission of the $C_6H_5CH_2$ and C_6H_4 radicals (25). Some bands in the 3300-4400Å could not be identified, although emission in this region has once been attributed to the C_6H_5CH radical (26). The part of the continuum background which is located in the 2400-3300Å region is due to the fluorescence resonance spectrum of the benzene molecule (27). That in the 3400-4400Å region had been assigned to the C_6H_4 radical (25), or the C_6H_5C radical (26), but this is controversial (28). We believe that the large continuum between 3400 and 6500Å could rather be due to the fluorescence resonance spectra of aromatic molecules larger than benzene (29, 30), possibly some of the reaction products themselves.



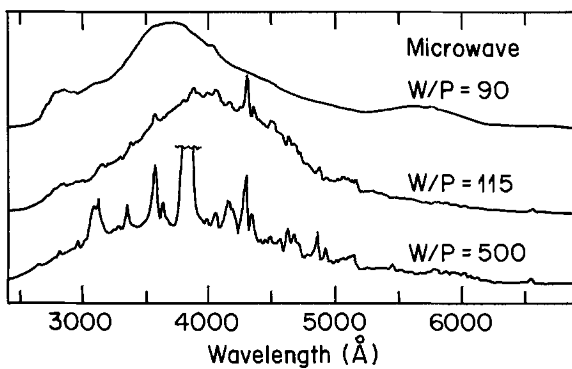


Fig. 5. Emission spectra of radiofrequency and microwave discharges for several typical values of the W/P ratio.

The following mechanisms of polymer formation, accounting for the observed polymer structures and plasma compositions, may therefore be postulated.

(*i*) In the case of high-energy microwave discharges, the main emission comes from CH radicals and, to a lower extent, from C_2 and C_2H radicals. These radicals are formed from breakdown reactions of the benzene molecule, such as for example

$$C_6H_6 \rightarrow 6CH$$
$$C_6H_6 \rightarrow 3C_2H + 3/2\ H_2$$

The formation of the observed olefinic polymers could therefore be explained by recombination reactions of these radicals, such as for example

$$n\,CH \rightarrow [CH = CH]_n$$
$$n\,C_2H \rightarrow \left[\begin{matrix} C = CH \\ | \end{matrix}\right]_n$$

Polymer cross-linking would then be brought about by combination of free valences on neighboring chains.

(*ii*) In the case of high-energy radiofrequency discharges, the main reactive species are H, C_2H, and to a lower extent C_6H_5 CH_2 and C_6H_4 radicals. They are also formed from breakdown reactions of benzene, such as for example

$$C_6H_6 \rightarrow 3C_2H + 3H$$

Again the formation of the observed, partly aromatic, monosubstituted, saturated polymers would be consistent with recombination reactions of these radicals, such as for example

$$nC_2H \rightarrow \left[\underset{|}{C} = CH \right]_n$$

$$\left[\underset{|}{C} = CH \right]_n \; C_6H_5CH_2 \rightarrow \left[\underset{CH_2-C_6H_5}{\underset{|}{C}} = CH \right]_n$$

$$\left[\underset{CH_2C_6H_5}{\underset{|}{C}} = CH \right]_n + 2nH \rightarrow \left[\underset{CH_2C_6H_5}{\underset{|}{CH}} - CH_2 \right]_n$$

(*iii*) In the case of low-energy discharges, in agreement with previous observations (31, 32), ring fragmentation is replaced by ring excitation, particularly in the case of radiofrequency discharges, where the spectrum simply consists of the 2600Å system of benzene. However, the formation of polymers with monosubstituted aromatic ring structures cannot be explained by condensation reactions of these excited molecules. A possible mechanism, which has already been proposed (9), could involve the intermediate formation of acetylene, which actually forms from benzene in electrical discharges (6, 18) and would give no emission spectrum, followed by its reaction with excited benzene molecules to form styrene, and then by formation of polystyrene

$$C_6H_6^* + C_2H_2 \rightarrow C_6H_5 - CH$$

$$= CH_2 \rightarrow \left[\underset{C_6H_5}{\underset{|}{CH}} - CH_2 \right]_n$$

The same mechanism, or a similar one involving the reaction of acetylene with excited molecules other than benzene, would apply to the case of low-energy microwave discharges. The formation of carbon-carbon triple bond structures could not be explained satisfactorily.

(*iv*) In the case of discharges of intermediate energy, there is a continuous variation, as a function of the *W/P* ratio, of the amount of CH and H radicals formed in the discharges, as can be seen in Fig. 6. This was also the case for the relative amounts of aromatic, olefinic, and acetylenic structures in the polymers (Fig. 5). Therefore it may be assumed realistically that the reaction mechanism which applies to discharges of intermediate energy is a combination of those which apply to high-energy and to low-energy discharges. In addition, the results we have obtained with toluene, ethylbenzene, and styrene suggest that the reaction mechanisms which apply to these monomers are not very different from those which apply to benzene.

Summary

The polymerization of benzene in microwave and radiofrequency discharges has been investigated with pressure and power as variable parameters. The infrared structures of the obtained polymers could be related satisfactorily to the degree and nature of fragmentation of benzene, as detected by plasma emission spectra. Polymer structures and plasma composition are significantly influenced by plasma energy level and discharge frequency. The influence of discharge frequency is particularly significant at high energy levels.

Chemical Vapor Deposition at Low Temperatures

J. C. Viguié and J. Spitz

Commissariat à l'Energie Atomique-DMG-LEMM CENG, 38041 Grenoble, Cedex, France

Because of the potential industrial importance of chemical vapor deposition (CVD) at atmospheric pressure and at temperatures below 500°C, deposition of metals and oxides from the acetylacetonates was studied. The best way of transporting the materials is to expose the substrate to an aerosol of the chelate in a solvent. A distinction is made between true vapor deposition and splashing of droplets on the surface followed by condensed-phase reaction. With aerosol droplets small enough to ensure true vapor deposition, 500-5000Å films are of the same optical quality as those obtained by vacuum techniques. Suitable conditions have been defined for deposition of ferric oxide on glass.

Although the spraying of two or more liquids which react on mixing (*e.g.*, to form epoxy resins) has been used in painting, the investigation of the pyrolysis of solution droplets has been limited (1). However, the method is of great practical interest, since, in certain cases, coatings can be formed on large surfaces (2, 3) without cumbersome protection against air, and at temperatures generally below 500°C where a great variety of substrates may be used.

Basic Considerations

When the operation takes place in air, the method is limited to compounds that are as stable or more stable than oxides (4). The salient feature of the process is that the metallic starting compound is transported in solution; droplets are carried at or near room temperature to within a few millimeters of the substrate surface.

Whether or not the process may be classified as chemical vapor deposition (CVD) depends upon two factors. (*i*, chemical) Only those compounds that vaporize without decomposition will undergo true CVD. Among the useful compounds, few react below 500°C, *e.g.*, some chlorides and chelates. (*ii*, physical) The most important physical factor is the temperature of the environment which relates to the substrate temperature and gas temperature.

For clarity, we propose the classification of processes that occur with increasing temperature as shown in Fig. 1.

In process A, Fig. 1, the droplet splashes on the substrate, vaporizes, and leaves a dry precipitate in which decomposition occurs.

In process B, the solvent evaporates before the droplet reaches the surface and the precipitate impinges upon the surface where decomposition occurs.

In process C, the solvent vaporizes as the droplet approaches the substrate, then the solid melts and vaporizes (or sublimes) and the vapor diffuses to the substrate to undergo a heterogeneous reaction there. This is true CVD.

In process D, at the highest temperatures, the metallic compound vaporizes before it reaches the substrate and the chemical reaction takes place in the vapor phase.

Key words: aerosol, atomization, pulverization, pyrolysis, spray.

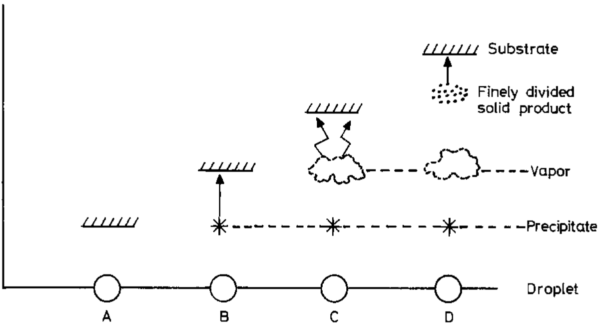

Fig. 1. Description of the deposition processes initiated with increasing substrate temperature.

Experimental

A chemical spray deposition process can be described with six parameters as depicted in Fig. 2. Typical values for these are listed in Table I.

For the purpose of relating our observations to continous processes, we provide for substrate translation and describe the motion of the substrate inside the heated volume by velocity, v.

Records of temperature, T_s, during transit of the substrate through the heated zone were taken from a thermocouple set behind the substrate, as shown in Fig. 3.

The coatings were deposited on glass substrates, 50 × 50 mm, from solutions of chlorides and acetylace-

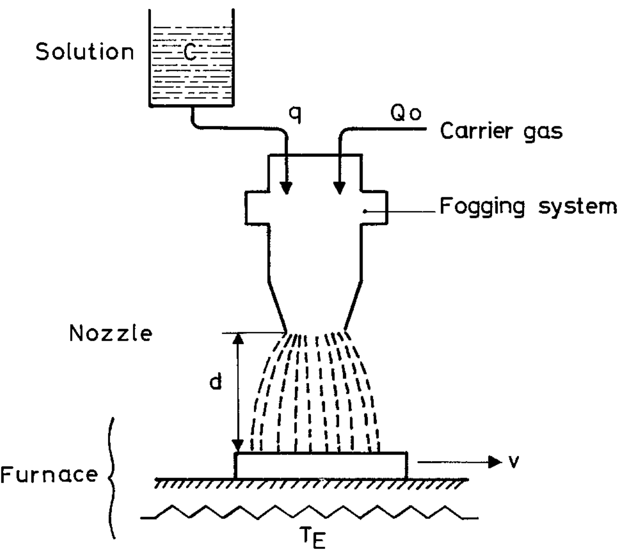

Fig. 2. Schematic diagram of equipment for chemical spray deposition.

Table I. Parameters of chemical spray deposition

Solution flow	Symbol	Piezo-electric transducer	Pneumatic transducer	Units
Temperature of the gaseous environment	T_E	400-550	500-550	°C
Flow of carrier gas	Q_o	3-6	3-6	liter/min
Distance between nozzle and substrate	d	3-15	40	mm
Droplet radius	r	1-4	5-50	microns
Solution concentration	C	0.1-0.4	0.1-0.4	moles/liter
Solution flow	q	30-60	500-800	cm³/hr
Speed of substrate through the furnace	v	10-40	10-40	mm/min

Table II. Chemical conditions of deposition

Layer	Starting compound	Solvent	Temperature T_E, °C	Carrier gas

AA = acetylacetonate.

tonates. Solvents were water, butylacetate, butanol, and toluene.

The fogging system can be of different types (6, 7): pneumatic atomizer, resonant cavity, or piezoelectric transducer. We favor the last which has the following advantages: the carrier gas flow can be set at very low values, thus minimizing the cooling effect on the substrate; moreover, at a frequency of 1 MHz, the droplet diameter lies between 2 and 8μ (8). Table I gives typical values of the parameters for a pneumatic and a piezoelectric generator.

Results and Discussion

Adherent layers of both metals and oxides were obtained by chemical spray deposition. As shown in Table II, the only metals that can be prepared are the precious metals that do not form oxides. Their quality, as evaluated by reflectance, is at least equal to that of a film prepared by a vacuum technique, as shown in Fig. 4.

The deposition of ferric oxide from a solution of ferric acetylacetonate was investigated most thoroughly. The values of the experimental parameters listed in Table I lead to layers 1800-2600Å thick.

Because of the extreme temperature gradient in the vicinity of the substrate (estimated as 50°C/mm), it is difficult to know the temperature which truly characterizes the layer growth. An additional difficulty arises from the motion of the substrate, which destroys its equilibrium with the environment.

Three temperatures are available from the measurements (Fig. 3): (*i*) the temperature T_E of the gaseous environment which is close to the regulation temperature of the furnace; (*ii*) the temperature of the substrate facing the spray, T_S; (*iii*) the temperature of the substrate out of the spray. With the assumption that these values are generally proportional to each other, we decided to observe the layer structure as a function of the temperature of the substrate facing the nozzle, which constitutes a convenient reference for characterizing the coating behavior during heat-treatment.

The linear variation of growth rate with solution concentration (Fig. 5) suggests that the process is diffusion controlled rather than kinetically controlled. Growth rate, G, is related to the other parameters by

$$G = \frac{ev}{\alpha}$$

where e is the layer thickness, v is the translational velocity of the substrate, and α is the effective width of the spray in the direction of motion; under our conditions $\alpha = 3$ cm.

In Fig. 6, the layer thickness is plotted against v^{-1} (proportional to the dwell time of the substrate in the spray), which gives a line of slope G. Except for the points corresponding to higher substrate velocity, for which the temperature is lower, the growth rate is independent of layer thickness.

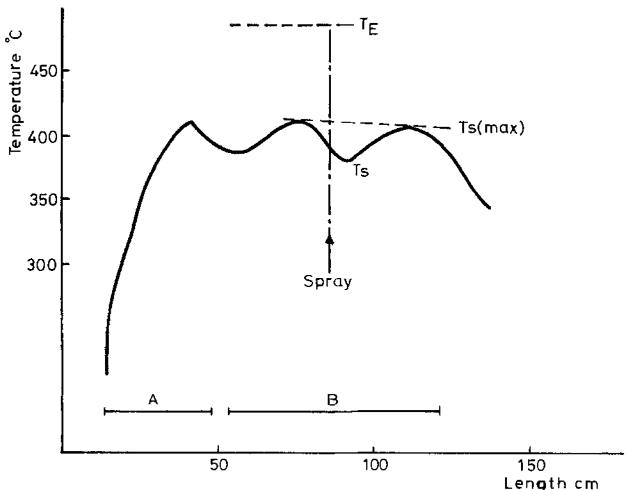

Fig. 3. Temperature of substrate passing through the heated zone. Speed 30 mm/min. A, Infrared heated zone; B, electric furnace at temperature T_E.

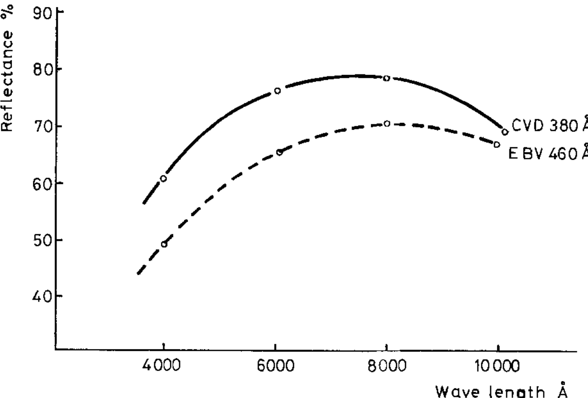

Fig. 4. Reflectance of palladium films prepared by CVD and by electron beam vaporization.

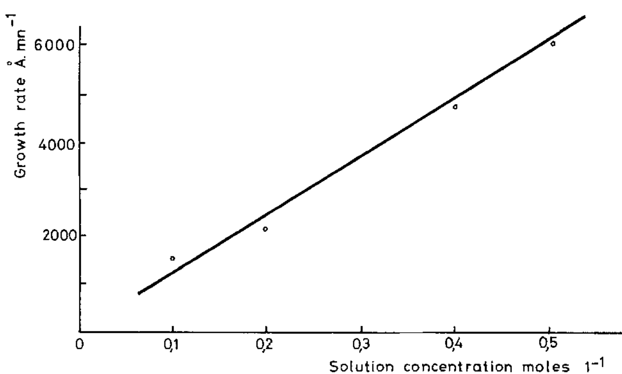

Fig. 5. Growth rate of Fe_2O_3 layers as a function of concentration of ferric acetylacetonate in toluene.

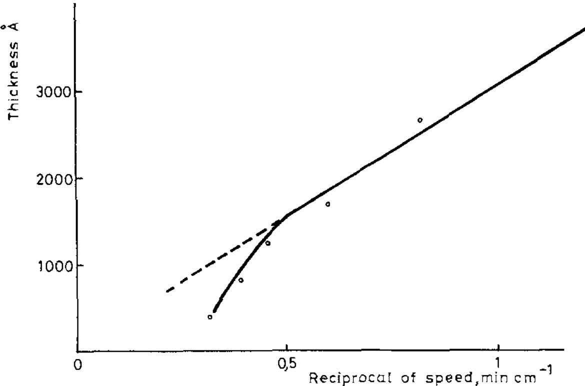

Fig. 6. Thickness of Fe_2O_3 as a function of translational velocity

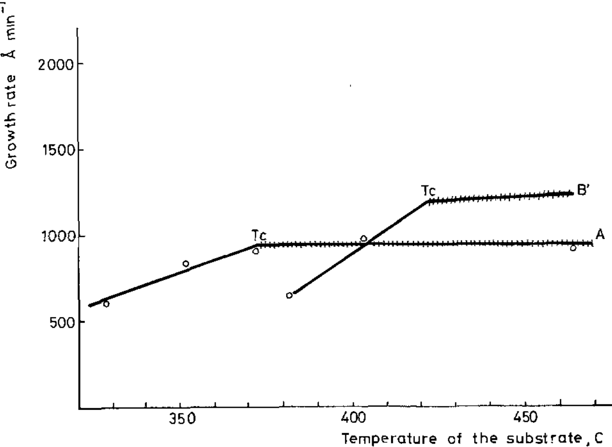

Fig. 7. Growth rate of Fe_2O_3 layers as a function of temperature. A, 0.1 mole/liter ferric acetylacetonate in butanol; B', 0.1 mole/liter ferric acetylacetonate in toluene.

The layer structure and the growth rate were observed as functions of the temperature of the substrate when facing the spray nozzle. As shown in Fig. 7, the growth rate reaches a point at T_c beyond which the dependence of growth rate on temperature decreases markedly. At the same time the deposit develops a crystalline structure beyond T_c. These factors suggest the operation of different mechanisms above and below T_c.

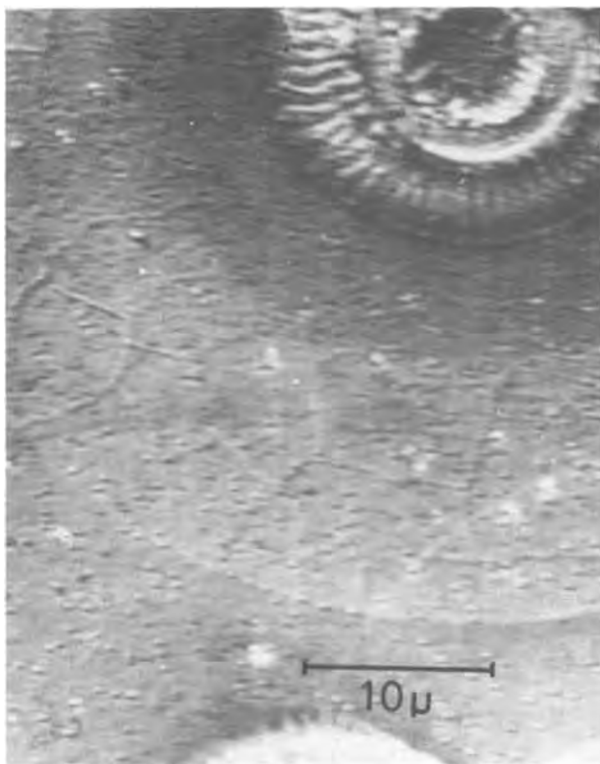
On the other hand, we found that the oven temperature T_E has a stronger influence on the structure of the coating than do temperatures measured on the substrates. The difference in T_c's with toluene and butanol suggests that evaporation of the solvent is involved in one or both mechanisms.

As expected, the physical properties of the coating change rapidly in the neighborhood of the transition temperature T_c. In the case of a 1800Å ferric oxide film, grown from ferric acetylacetonate in butanol, transmission increases with a decrease in temperature, whereas resistance to abrasion rapidly decreases as the crystalline structure vanishes.

We observed that the size of crystallites obtained from sprayed solution of ferric chloride is independent of solution concentration. On the other hand, the average crystallite size can be increased by raising the temperature from 400° to 800°C. This supports the idea of formation from the vapor phase via process C, Fig. 1.

Explaining the growth of an amorphous layer is more of a problem. Some authors describe adherent, noncrystallized layers obtained from the acetates (9). The noncrystallized state appears to correlate with the lack of volatility of the starting compound, suggesting that process B is operative.

The photographs of Fig. 8 show films prepared under conditions suggestive of operation of the different processes. Processes A and D are believed to be of little practical interest because they lead to rough or nonadherent layers.



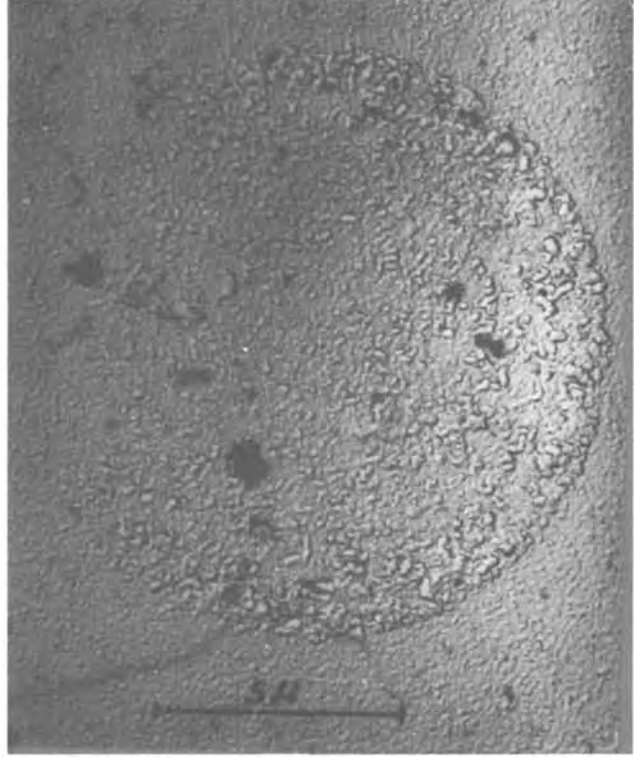


Fig. 8. Surface of Fe_2O_3 deposited from hydrochloric solution of $FeCl_3$. (a, left), Low temperature processes, A and B; (b, right), high temperature process, C.

Conclusions

The different processes in chemical spray deposition depend not only on temperature; the coating morphology is influenced also by flow of carrier gas, distance between substrate and nozzle, droplet radius, solution concentration, and solution flow rate.

When droplets of different sizes are present in the aerosol, two of the possible processes can proceed concurrently. Use of piezoelectric transducers which produce droplets of a rather narrow size range facilitated identification of the processes.

These observations were valuable in choosing optimum conditions for the preparation of semitransparent photomasks.

A Critical Review of Solderability Testing

Joseph B. Long

Tin Research Institute, Incorporated, Columbus, Ohio 43201

Joining by soldering is essentially the penetration and filling of a particular clearance between two components with solder to provide for integrity, electrical continuity, or heat transfer in the assembly. In addition, solder joints form liquid and gas tight seals and provide some strength to the assembly at a variety of service temperatures. To fulfill the functions of a soldered joint, molten solder must wet mating surfaces at a temperature usually below 800°F (427°C), and the solder alloy must be distributed to all joint spaces by capillary action. Fluxes are normally required to aid the wetting and penetration of the solder by chemical dissolution of oxides and similar films on the component surfaces and on the advancing solder meniscus. Even though the physical geometry of a solder joint is satisfactory, there are wide differences in the ease with which a joint is made, and these differences are within the realm of solderability testing, which seeks to determine the facility with which a solder can wet surfaces. Secondly, solderability tests are designed to provide information on the soldering characteristics of the solder in relation to the chemical and physical nature of the surfaces being joined. The composition and the efficacy of both solder and flux systems and temperature-time cycles employed during the soldering operation can also be ascertained by appropriate solderability tests.

Many investigators have developed different procedures and equipment to assess solderability. Determination of solderability falls into one or more of the following categories, (*i*) capillary penetration tests, (*ii*) spreading tests, (*iii*) dip tests, and (*iv*) wetting time tests. A critical evaluation of the various testing methods and the significance of data derived from solderability testing programs will permit users of soldered joints to select materials to provide reliability and to evaluate optimum production schedules for the soldering process (Table I).

Capillary Penetration Tests

Capillary penetration tests are used to evaluate the effects of joint clearance, flux activity, or solder composition (1). In testing by this method, a capillary space is provided between two flat metal sheets (Fig. 1). The joint surfaces of the sheets are fluxed, preheated, and brought into contact with a molten solder bath for a specific time interval (2). After the sheets are removed from the solder and cooled, the capillary rise is measured on the wetted surfaces. Data from this type of test often show anomalous results due to nonuniform oxidation of metal surfaces or changes in the activity of fluxes during preheating.

Despite the anomalies associated with the capillary penetration tests, one of the quality control tests for electrolytic tinplate (Fig. 2) is made with samples of tinplate which are folded over to form a capillary space (3). The test samples are at ambient temperature, and after fluxing, are immersed vertically in the bath for 1 min. The sample is then removed, cooled, and the folded edge is sheared off. The sample is peeled apart and the height of the solder rise in the joint is measured. The sensitivity of this quality control check is low since it has been demonstrated that the difference in capillary rise between "good" and "poor" tinplate may be only 0.1-0.2 in. in a total capillary rise of 1 in.

The measurement of capillary rise of solders has also been made with electroformed metal tubes (Fig. 3), twisted wires, and interlocked joints (Fig. 4) (4-6).

Key words: solders, fluxes, coatings, joints, reliability.

Table I. Tests for solderability

Materials tested	Capillary penetration	Spread	Dip	Wetting time
	Tests commonly used			
Solders	x	x	x	x
Fluxes	x	x	x	x
Basis metals	x	x	x	x
Coatings	x	x	x	x
Printed circuit conductors			x	x
Plated through holes	x		x	x
Wire and component leads		x	x	x

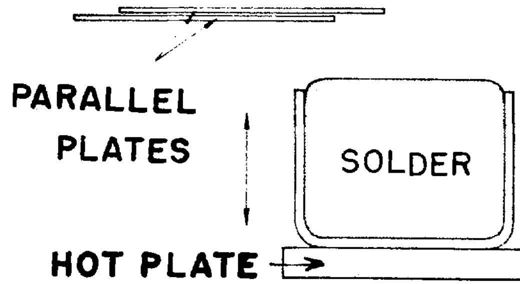

Fig. 1. Capillary penetration test using flat metal surfaces

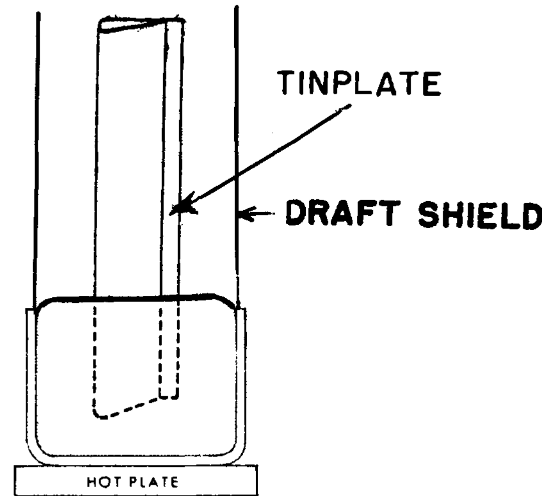

Fig. 2. Testing tinplate for solderability

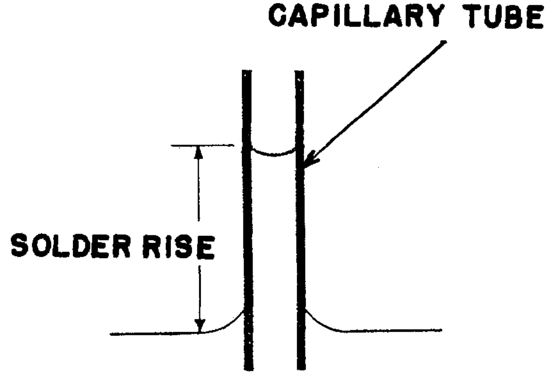

Fig. 3. Solder penetration test using a electroformed metal tube

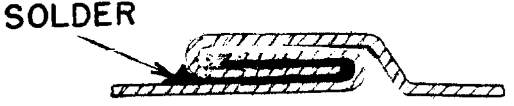

Fig. 4. Interlocked metal joints used in the solder penetration test.

In the case of twisted wire samples, it was shown that the expansion of the wires when dipped in the molten solder bath, caused an uncontrollable change in the dimensions of the capillary clearances. It should be pointed out that in all capillary penetration tests using binary tin-lead solders, the amount of rise of the solder will greatly depend upon the availability of eutectic in the solder alloy. In solders where there is a high percentage of eutectic, capillary rise will be at a higher level than when solders of lower eutectic content are used.

It is recognized that capillary action will not occur in solder joints unless the molten solder is in contact with the capillary space. Therefore, it is necessary for solder to spread over surfaces to be in the best position to fill capillary spaces. The area of spread tests were developed to meet this requirement.

Area of Spread Tests

The area of spread tests have been used by both researchers and production personnel to compare solderability of coated surfaces (7) and evaluate the effectiveness of fluxes (8) and solders (9). In testing by this method, fixed volumes of solder and flux are placed on test coupons which are heated to a specific temperature. Various means are employed to heat the samples and electrical resistance heating or hot plates have been used. Some investigators have floated test coupons on a liquid solder or flux bath or employed oven heating as a heat source. However, oven heating is not recommended since the time required to bring a sample to temperature is often too long, and without a protective, nonoxidizing atmosphere, the sample surface can be oxidized sufficiently to affect test results. In addition, oven heating for long heat cycles is not representative of the conditions for the majority of soldering operations.

During heating of the test coupons, the solder melts and spreads over the surface. The extent of the solder spread pattern is influenced by the type of flux, metal surface condition, and solder composition. Variables such as the volume of either flux or solder are controlled by using flux cored solder wire of a specific diameter and core size. Alternately, solder preforms or constant size pellets are punched from solder sheet of known thickness and accurate quantities of flux are applied to the test specimens, usually with a graduated pipette or hypodermic syringe.

After the melted solder spreads over the surface to be tested, the sample is cooled and the area of spread can be measured with a planimeter. Alternately, the spots are photographed and enlargement is made for direct measurement with a planimeter gauge. Often the solder spread is displayed on the screen of a projection microscope and standard charts are used to determine the spread area.

Figure 5 shows the relative spread of a 60 tin-40 lead solder on various coatings fluxed with a mixture of rosin and alcohol. The coating thickness in each case is 0.0003 in. (7.5 μm) thick, and it is clear that hot dipped tin, and electrodeposited alloys of tin-zinc provide high levels of solderability. Stannate tin, tin-cadmium alloy, and cadmium show intermediate solderability. Tin-nickel and silver are inferior, but nevertheless may be soldered satisfactorily under industrial conditions. Chromium is nonsolderable.

If the area of spread is determined and the volume of solder is known, the value of the theoretical contact angle of the solder drop with the basis metal can be determined by the equation

$$\theta = 7.12 \left(\frac{V}{\text{square root } A^3} \right)$$

where θ is the contact angle in degrees, V is the volume of solder in cubic centimeters, and A is the area of spread in square centimeters. This equation assumes that the volume of solder is small and therefore, gravitational effects are minimized. The value provided by the equation gives a numerical value for solderability, and small values of θ indicate good solderability.

Variations of the area of spread test were made by other investigators. In one test the maximum height of the melted solder above the test coupon surface was regarded as an index of solderability. However, this test is usually only appropriate for areas of spread which are approximately circular. Solder spread is more often irregular due to the chemical and physical properties of the test surfaces. In order to minimize the difficulties of testing associated with the shape of the solder spot, a solderability test was devised which employs solder wire samples with a diameter of 0.0625 in. For each solder sample, a three inch portion of wire solder is bent into the form of a figure 4. The vertical part of the 4 is about 1 in. long and is crossed by the horizontal portion of the wire sample in the middle. The end of the horizontal portion is looped under and then over the vertical portion and the loop pulled tight. The edges of the loop are then cut away. Thus, solder pellets of consistent weight are formed. The test is performed similarly as the spread test and both the height and area of spread are measured after the solder pellets are melted. Spread factors for a particular test surface are calculated by using the equation

$$\text{Spread factor} = \frac{D - H}{D} \times 100$$

where D equals the diameter of the sphere having a volume equal to that of the solder used, and H is the height of the solder spot. If there were no effect from gravity, surface tension or wetting (alloying) of the solder, the solder drop would assume the shape of a sphere where D would equal H and the spread factor would be zero. This would indicate nonsolderability of the surfaces tested. As solderability increases, the height of the solder spot decreases and the value of the spread factor increases. A percentage rating of the solderability of surfaces is thereby established and coatings are rated as follows:

Spread factor	Solderability	Approximate contact angle calculated from area of spread
60	Very poor	50°-
60-70	Poor to fair	50°-34°
70-80	Fair to good	34°-12°
80-90	Good to very good	12°- 3°
90	Excellent	3°-

A.S.T.M. tests were concerned with the effect of a variety of thicknesses of tin on brass and copper and

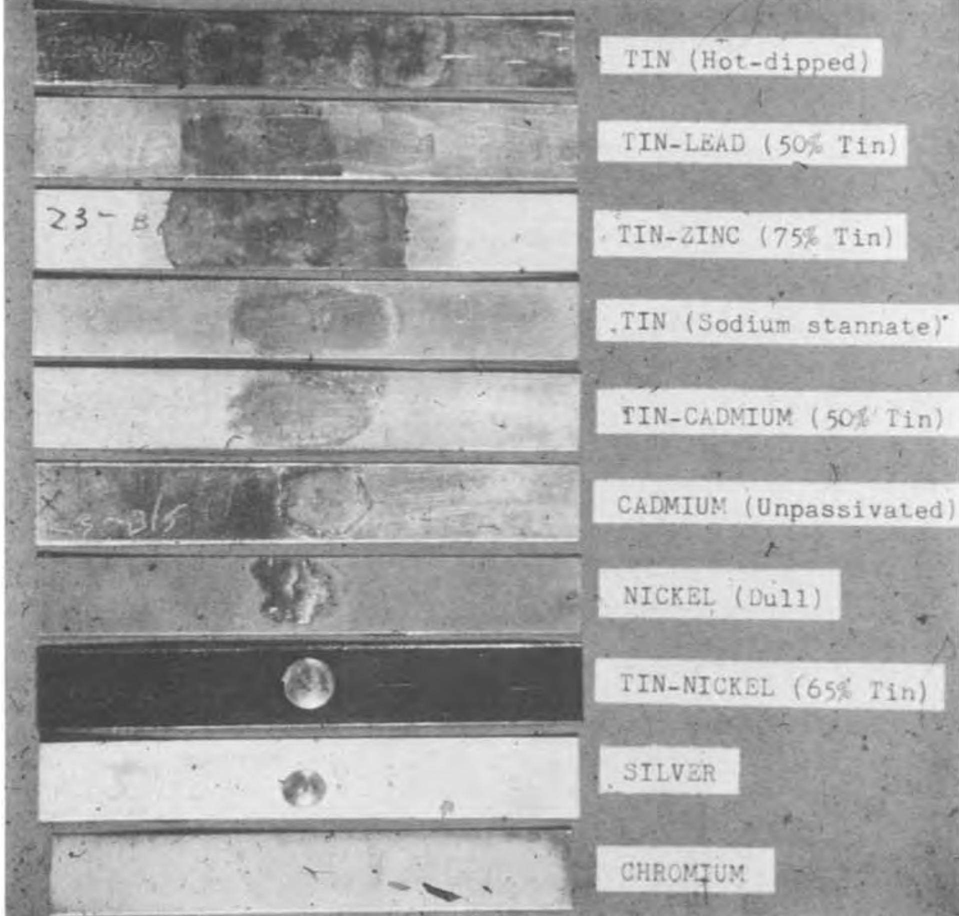

Fig. 5. Relative solder spread on various coatings, 0.0003 in. thick.

the spread factor was employed as a measure of solderability (11, 12). Samples were tested in the as-plated condition and after exposure of up to 1 yr at 100°F (38°C) and 85% humidity. Under prolonged temperature and high humidity conditions, substantial oxide films developed on the tin coatings and it was shown that the solder broke through and flowed under the oxide films on some of the test disks. This type of rupturing of surface films is more likely to occur where the film is least supported when the underlying coating melts, that is, on the thickest tin coatings. It would appear from these test results, that the area of spread test is not appropriate when aged, thick coatings are tested.

Reflection of incident light from the surface of a spreading solder drop has been used to study solderability of surfaces (13). The contact angle that a solder drop makes with the basis metal was measured by taking motion pictures of the solder as it spreads (Fig. 6). The advancing solder was illuminated from directly above and the camera was mounted at a known angle to the vertical light source. As the solder spread, the reflected light moved out from the surface to the edge of the drop and finally disappeared when the contact angle reached a value which was one-half the angle of separation of the light and camera. The method is probably best for testing the rate of spreading of a solder which has a low contact angle, but a dip test would be simpler to use. Dip tests are discussed later in this paper.

LIGHT SOURCE

CAMERA

Fig. 6. Reflection of incident light from surface of spreading solder as an index of solderability.

Another spread test is part of Military Specification MIL-P-55110 (14). This test has been named the Meniscus Test and utilizes a test pattern on a printed circuit board which has a series of parallel conductor paths. The test board is placed in a test fixture which has three holes at its center and counter weights are used to hold the board to the fixture. When the test fixture and board are pressed into the solder bath, the solder rises through the holes in the fixture and forms meniscuses (Fig. 7). Since the printed wiring board is held at a measured distance above the holes, only the solder meniscuses contact the test board.

Three circular spots of solder are produced on the specially designed test pattern. After the sample is removed from the fixture, the spots are measured diagonally to the nearest hundredth of an inch. The average of 12 such spots made on two double-sided test boards is a measure of the board solderability. In addition, if any of the spots show unwetted or dewetted areas exceeding 25% of the total area of the board, the board is considered to have unsatisfactory solderability.

The test has shown little acceptance by the printed circuit manufacturing industry because the test equipment is unwieldy, and sensitivity of the test is not adequate. The over-all range of solder spots was shown to be 0.60-0.99 in. for a full range of nonsolderable surfaces. Natural aging data showed that a minimum

value of 0.84 in. in the diagonal measurement of the wetted test paths was the point at which boards could be rejected for lack of solderability. It would appear that a spread difference of only 0.15 in. is too narrow to be an acceptable criterion for determination of good solderability.

Dip Tests

Dip tests are probably one of the easiest forms of solderability test to apply since the specimen to be tested is immersed in solder and the degree of coverage by the solder is noted as an index of solderability. One of the dip tests involves the use of unfluxed leads onto which is wound a loop of solid wire solder (15). After making the solder loop around the lead to be tested, the solder ends are cut away and the specimen is immersed into a bath of polyethylene glycol which is heated to about 392°F (200°C) above the melting point of the solder. The lead is held in the glycol bath 2 sec after the solder melts, then removed from the bath, cooled, and cleaned with alcohol. Examination of the lead is made and an even, continuous distribution of solder along the length of the lead demonstrates excellent solderability of the surface, but formation of solder globules with high contact angles is indicative of poor solderability (Fig. 8).

Military Standard 202C, Method 208 defines a solderability test for component lead materials (16). This test was also published by the Electronic Industries Association as their Standard RS178A (17). A lead is dipped into a rosin-alcohol flux and attached to an arm of a device which lowers the lead into a solder bath heated to 450°F (232°C). The arm of the apparatus is actuated by a motor driven cam and the entry into the bath, dwell time, and exit time from the solder are accurately controlled (Fig. 9). After the solder dip, the solder-coated lead is cooled, and flux residues are removed with isopropyl alcohol. The lead is considered to have acceptable solderability if surfaces are 95% covered with a continuous solder coating. The remaining 5% of the surface may contain pinholes or voids provided they are not concentrated in any one area. Evaluation of test results are difficult since the test does not readily distinguish between smooth and rough coatings. It has been suggested that a Microcard Viewer be used to determine surface imperfections, but this technique is slow and cumbersome.

The Institute of Printed Circuits utilizes an edge dip test in their standard IPC-S-801 (18) to determine solderability of printed circuit boards, laminated stock, and similar flat materials. The equipment and procedures are similar to the Military Standard 202C. Tested pieces are compared against standard samples or photographs showing various degrees of wetting of solder on copper coupons. The test has proven its importance to the manufacturers of printed circuit boards since they are able to determine the effectiveness of their board preparation steps and any processed boards which are found to be unsatisfactory by this solderability test, can be corrected prior to assembly and final soldering.

Fig. 8. Wire samples showing solder spread

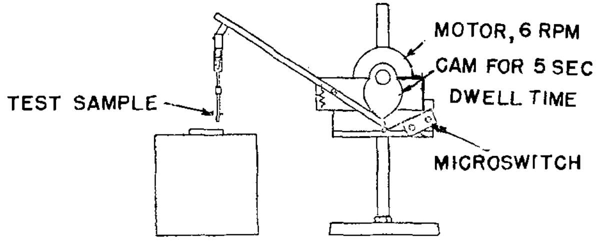

Fig. 9. Edge dip testing for solderability

The float test is considered a modification of the dip test and is used to check the soldering quality of plated through-holes (19). The boards are fluxed and then floated on a solder bath for about 5 sec. They are removed from the bath and the holes are examined visually. Uniform wetting along the sides of the holes as well as the lands is indicative of acceptable solderability.

In this age of complicated electronic circuitry, there is an increasing demand for optimum reliability. In addition, production requirements are such that several hundred joints may be made simultaneously on circuit assemblies by mass soldering methods. The time of contact of any given joint with molten solder is often as little as 2 sec and therefore, the time and perfection of wetting of the surfaces of components by solder is of primary importance to producers of electronic packages. It was this philosophy that led researchers and production engineers to design solderability tests which would demonstrate the effects of surface preparation techniques, compare the solderability of different coatings, and also indicate the merits of different fluxes for a given surface.

Wetting Time Tests

Wetting time tests for solderability have the virtues of simulating fairly closely mass soldering processes as well as simplicity of operation. The tests can be used to determine the soldering quality of component terminations or flat laminates as used in printed circuitry applications.

Solderability of pigtail leads is difficult to ascertain visually, and even though these lead materials may exhibit good solderability when new, experience has shown that coatings can become unsatisfactory after storage for extended periods. Gradual diffusion of copper into tin or solder plated coatings produces intermetallic compounds which, if reaching the surface of a joint to be soldered, can be cause for unwet or dewet conditions. It is therefore desirable for manufacturers and users of these components to check the solderability of surfaces at all stages of manufacture and storage to ensure maximum productivity and reliability during soldering operations.

A test has been devised for checking lead materials (20, 21). This test is commonly known as the Globule Test. A specific volume of solder (depending on the gauge of the wire tested) is melted on a heated mandrel and prefluxed wire is lowered horizontally into the solder globule, splitting it in two (Fig. 10, 11). The time for the solder to flow around and finally cover the top of the wire is a measure of the wetting time. In order to detect any tendency for dewetting, it is necessary to remove the wire from the solder globule, wipe off the excess solder, and retest in the same position. Artificial aging of wires for 16 hr at 311°F (155°C) in air can be used to simulate prolonged natural storage conditions. Figure 12 shows the results of solderability tests on copper wires plated with 0.0001 in. of 30 tin-70 lead alloy. The wires were tested using Sn60 solder and a 25% rosin-isopropanol flux mixture. The aging test was used to simulate industrial storage before soldering. However, the correlation of such aging treatments with natural storage is a subject under active discussion.

It is difficult to apply the Globule Test to very short terminations and only round wires can be tested. In spite of these difficulties, the test has been included in IEC Standard 68-2-20, Part 2T, British Standard 2011, and the German and Swedish Standards.

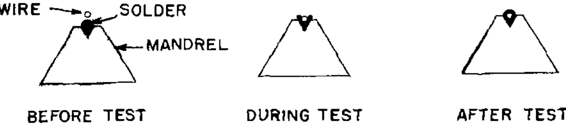

Fig 10. Globule testing round wire leads

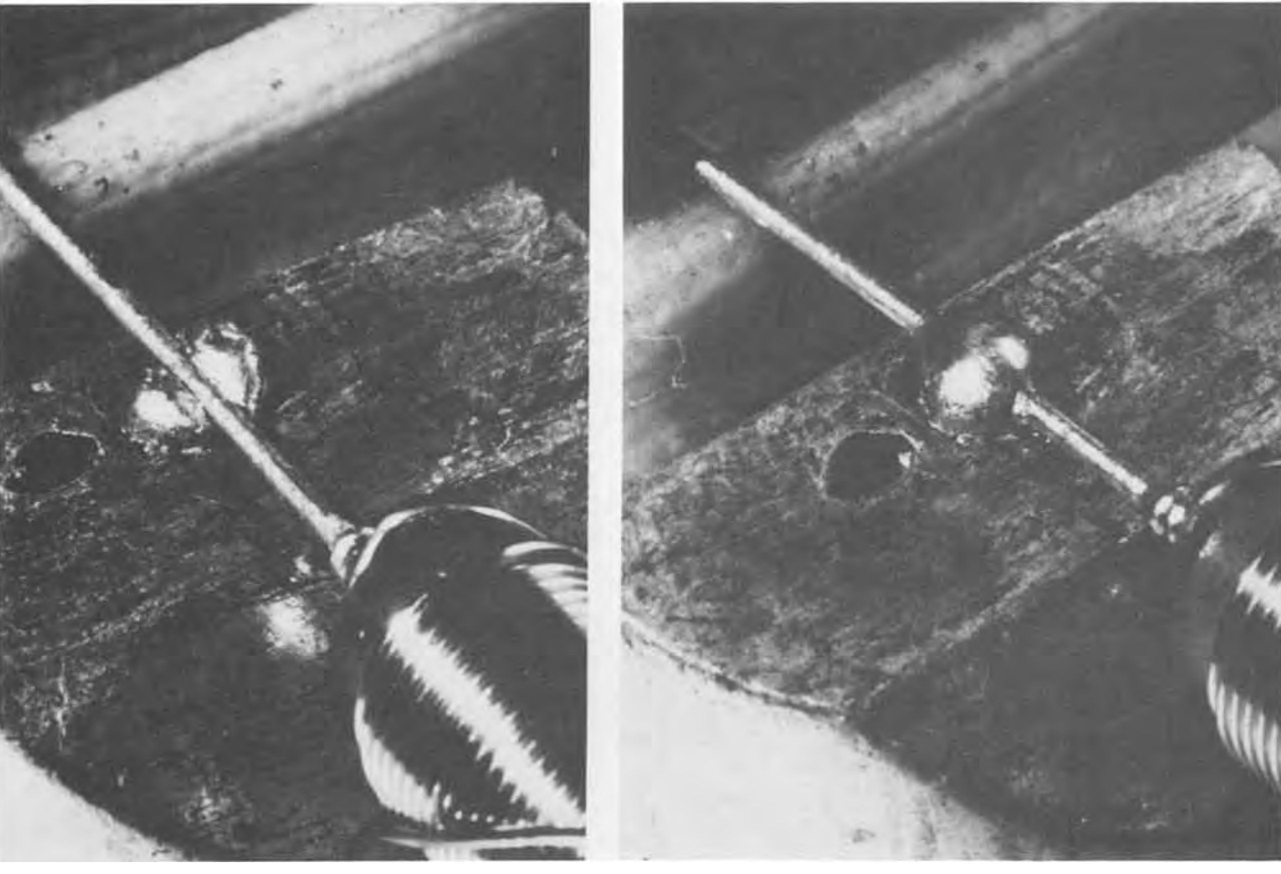

Fig. 11. Testing wire terminations for solderability

Wetting of a surface by molten solder involves the progressive reduction in the contact angle as well as a change in surface tension forces due to interaction of tin in the solder and the base metal. Thus, monitoring of surface tension may be considered to be a fundamental approach to the measurement of solderability (22, 23). Commercial apparatus is available for making such tests and standards have been prepared to provide for a quantitative evaluation of solders, fluxes, and surface solderability.

The apparatus for performing the test has three basic parts: a load-measuring system and readout circuit, a motor drive for moving the solder bath vertically, and a solder heating and temperature control system (Fig. 13, 14). A test piece is suspended from a transducer-monitored spring system, and the solder bath is raised until the specimen is immersed to a predetermined depth. Buoyancy from the displaced solder provides a transducer generated signal which is fed to an oscilloscope or high speed pen recorder. This condition is maintained until the solder wets the test specimen. The solder meniscus then rises, producing a downward force on the specimen, and a signal of opposite polarity is developed by the transducer. These first and second stages permit measurement of the time to start wetting

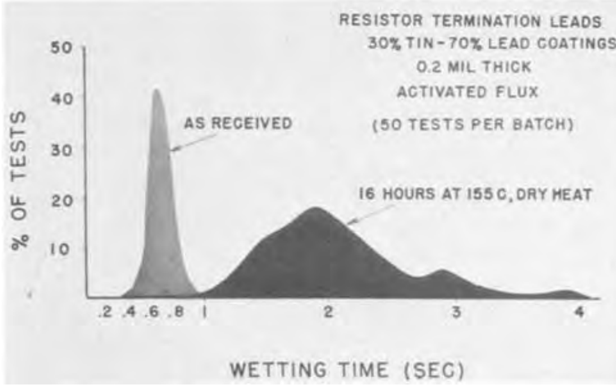

Fig. 12. The effect of artificial aging on solderability

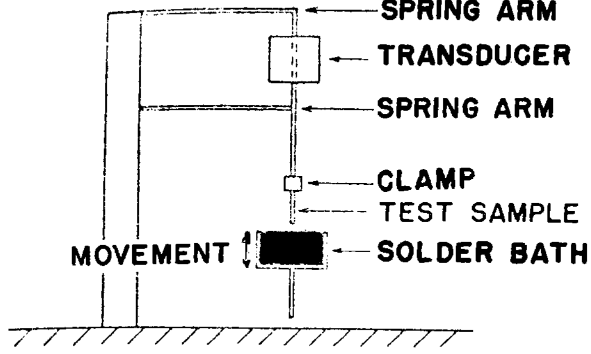

Fig. 13. Schematic of the surface tension apparatus

Fig. 14. Commercial apparatus for determination of the wetting time of materials.

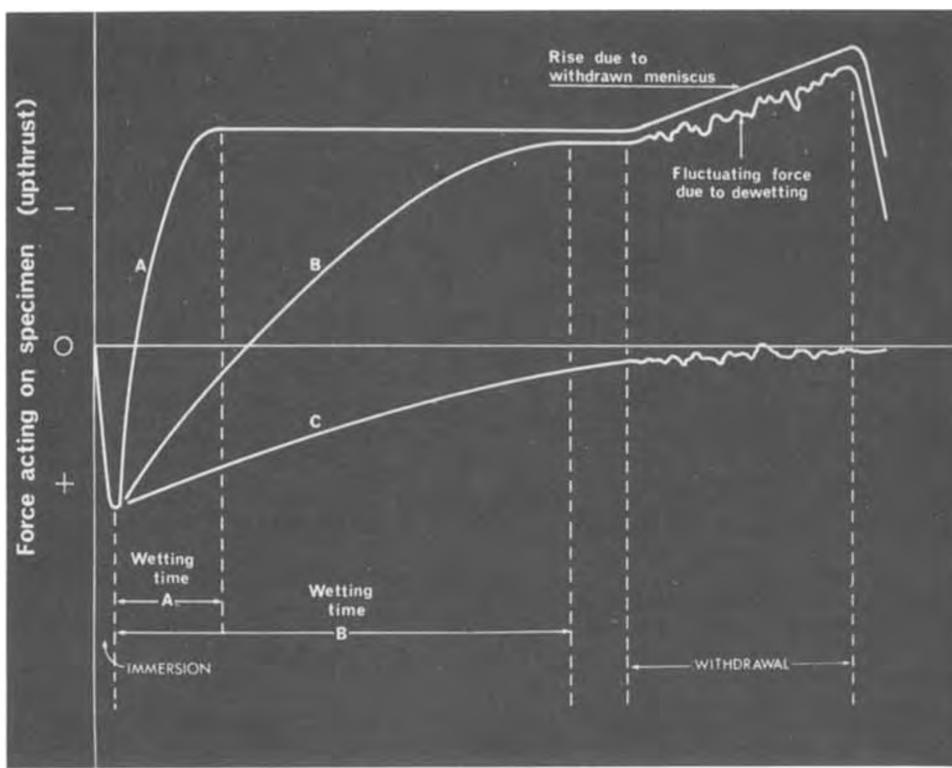

Fig. 15. Typical recorder traces from the surface tension apparatus.

and the rate at which wetting occurs. Eventually equilibrium is reached and the magnitude of the signal measures the ultimate extent of wetting. Figure 15 shows a typical recorder trace obtained from a solderability test using the surface tension apparatus. Curve A represents a material of high solderability while B has a much slower rate of wetting. Curve C represents material where there was no wetting by the solder. The fluctuating withdrawal force shown at the end of the curves is due to dewetting and the breakdown of the solder meniscus.

The interpretation of the wetting force curve is not understood fully. Maximum wetting force relates loosely with solderability in practice. Wetting time (*viz.*, time to cross the zero force axis) often gives anomalous results on certain materials.

It has been demonstrated that deviations from the normal curve shape can occur with very small components of good solderability. These components usually have low thermal capacity and their surfaces may begin to wet before a full upthrust signal has developed, resulting in a loss of the initial stages of the curve.

A dip tester has been developed to provide for solderability inspection of materials before assembly and soldering (24). This equipment has an adjustable frame mounted above a solder bath. The frame holds the test piece in such a way that it is dipped into the solder for a predetermined depth. A microscope mounted on a micrometer head allows the gauge to be set at zero, which corresponds to the level of the solder surface. The test piece is fluxed, warmed, and dipped into the solder. Solder wets and rises along the exposed side of the test piece, and the micrometer is adjusted to measure the height of the solder flow to the top of the meniscus. Solderability is determined by the height of the meniscus and the contact angle on the wetted surfaces in a given time of immersion can be derived. This test appears to be a combination of the spread test and the dip test and it can be used to make quantitative determination of the effects of different soldering parameters on the degree of wetting.

Equipment for assessing the minimum wetting time has been made available to industry (Fig. 16). The apparatus consists of a radial arm which carries the test piece over the solder bath surface and is driven in a circular path through the solder by a motor and gear box (Fig. 17). The test technique involves a succession of test pieces which are exposed to progressively longer times of contact with the solder bath (25, 26). By visual examination, it is possible to ascertain the minimum time at which wetting is achieved and also the time at which dewetting may start to occur.

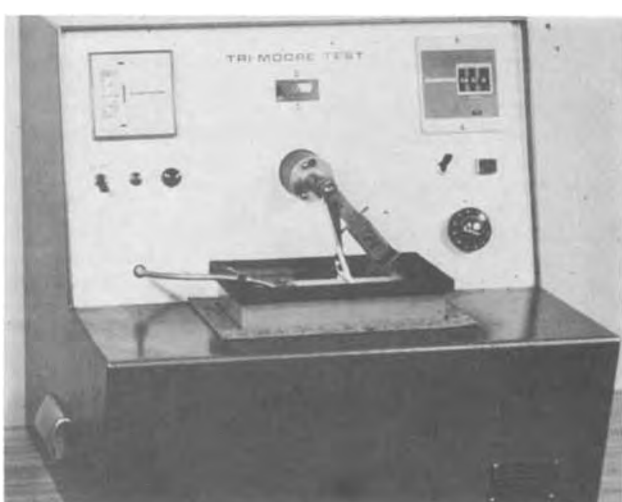

Fig. 16. The minimum wetting time apparatus

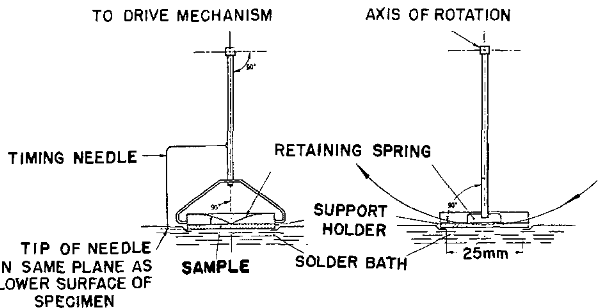

Fig. 17. Sketch of the rotary dip solderability tester. Right: front view; left: side view.

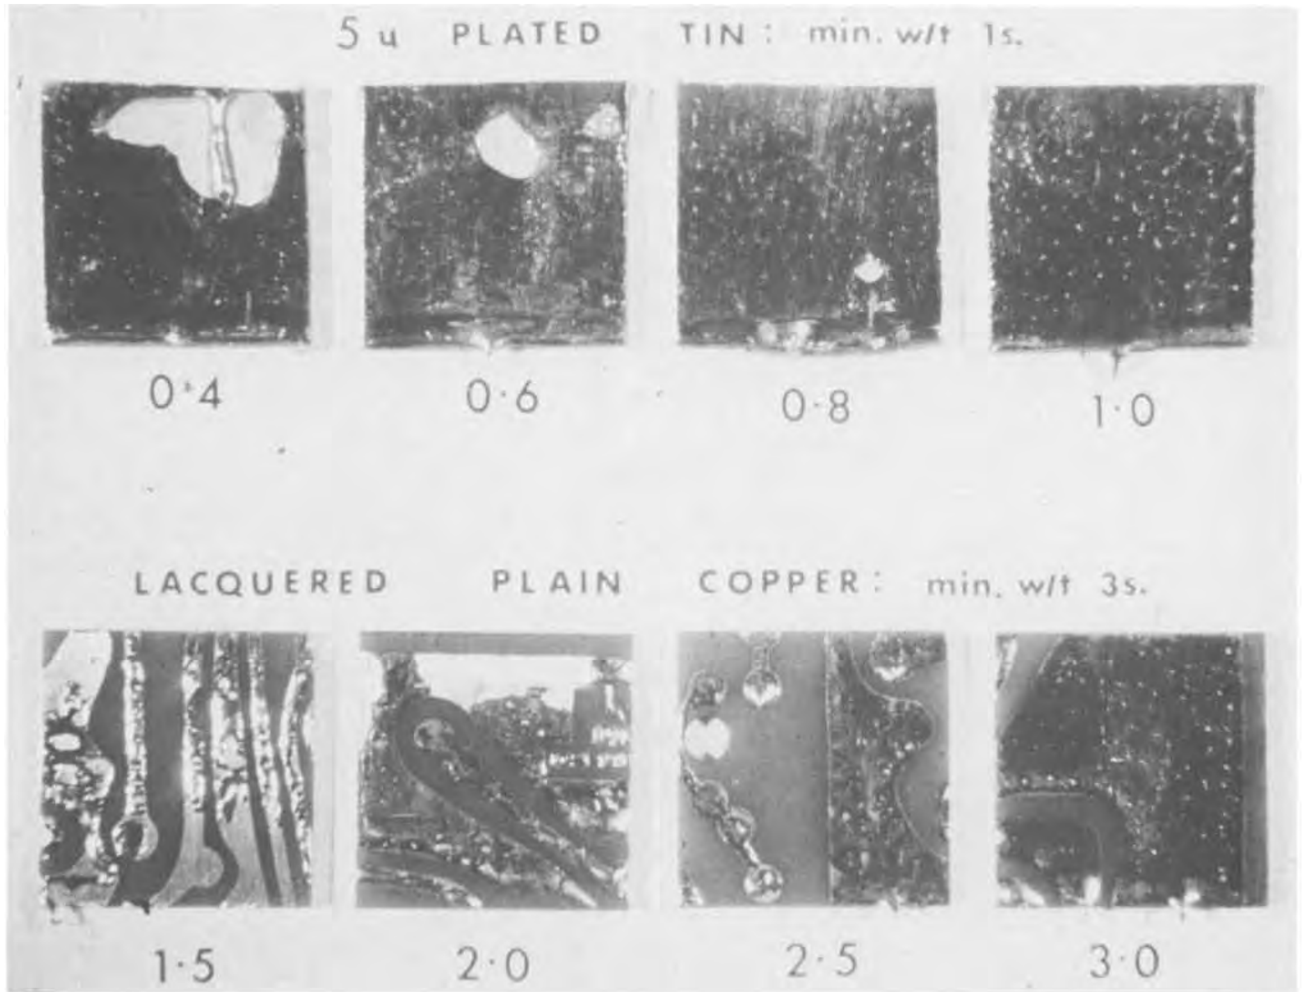

Fig 18. Progressive wetting of solder on test pieces

A typical series of test pieces is seen in Fig. 18. It may be seen that there is increasing coverage by the solder as contact time increases. The last specimens on the right in each series represents the wetting time for the specific material tested. Usually there is a narrow range in time at which wetting occurs. Shorter periods give rise to nonwetted surfaces. After full wetting is achieved, longer immersion times result in progressively poorer distribution of the solder. Often this latter effect is noted on test samples of copper clad laminates which have received inadequate or incorrect surface treatments.

The rotary dip solderability test is probably the simplest and most versatile method for quickly and inexpensively assessing solderability of printed circuit boards as well as plated-through holes in boards. With materials of good solderability there is little difficulty in obtaining capillary rise of solder plated through holes when the lower face of board samples is brought into contact with molten solder. Usually, solderability of the holes in circuit boards is based on the time and distribution of the solder rise to the top of the holes.

The rotary method of testing can be employed to check the suitability of different coatings and the optimum flux-solder-basis metal parameters for mass soldering operations. This wetting time test has been accepted by the International Electrotechnical Commission and published as their recommendation 68-2-20C, Part 2, Test T. The Rotary dip test is also in BS 4025 and the Swedish Production Engineering Standard. Tests conducted for the Institute of Printed Circuits have shown that this minimum wetting time test appears to be more sensitive to time in the bath than the edge dip test (27).

Summary

It would appear that soldering requirements for the future will be even more complex than for today's electronic circuitry. Consideration must be given to the mass joining of thousands of connections and soldering has proven to be a reliable and economical means for achieving this end. Solderability tests allow for a precise and objective method for assessing the ability of components to be soldered satisfactorily in the time and at the temperature appropriate to the assembly.

For the majority of quality assurance work, it is convenient to employ the rotary dip solderability test to evaluate solder-flux-metal systems and minimum wetting time of solders on coatings and basis metals. In addition, the Globule Test has shown to be a valuable tool in assessing the solderability of round termination wires. The use of these two tests will assure that all components and assemblies presented to the production line will have the highest solderability and ensure a minimum of repair work after soldering.

The Effect of Low-Temperature Aging on Corrosion Resistance of 18Cr-2Mo Titanium-Stabilized Ferritic Stainless Steel

E. A. Lizlovs* and A. P. Bond*

Research Laboratory, Climax Molybdenum Company of Michigan, a Subsidiary of AMAX, Incorporated, Ann Arbor, Michigan 48106

ABSTRACT

Corrosion tests were conducted on 18Cr-2Mo titanium-stabilized ferritic stainless steel aged at 620°C for various time periods. Sensitivity to intergranular corrosion was detected in the Streicher test but not in the Strauss or Warren tests. The corrosion resistance in 45% boiling formic acid and in dilute chloride solution (600 ppm Cl^- + 20 ppm Cu^{++}, 90°C) was unaffected by aging at 620°C. Pitting potentials in molars NaCl at 25°C were also unaffected by the 620°C heat-treatment. Corrosion tests were also performed with the same 18Cr-2MoTi stainless steel aged at 475°C for 240, 2400, and 4800 hr (18Cr-2MoTi steel is embrittled after 240 hr at 475°C). The 475°C heat-treatment affected corrosion resistance to boiling formic acid. Corrosion resistance started to deteriorate after 2400 hr aging and was seriously impaired after 4800 hr aging. Pitting potentials were rendered less noble by the 475°C treatment. The 475°C embrittlement did not result in sensitization to intergranular corrosion in any environment as contrasted to the 620°C treatment which did sensitize the steel to intergranular corrosion in the Streicher test.

The ferritic stainless steels, even at high purity levels, are known to be sensitized to intergranular corrosion by exposure to temperatures in the range 600°-650°C (1-2). This type of sensitization generally has been detected either in Streicher or Huey tests, both of which involve highly oxidizing conditions. The mechanism invoked to explain the low-temperature sensitization usually is chromium carbide precipitation at the grain boundaries with resulting chromium depletion along the grain boundaries. However, a preliminary investigation disclosed that, while titanium-stabilized 18Cr-2Mo stainless steel was sensitized to intergranular corrosion in the Streicher test, the pitting potential of the steel was not affected by the 600°-650°C exposure, a finding inconsistent with the chromium depletion theory.

Prolonged exposure of ferritic stainless steel to still lower temperatures, near 475°C, causes a loss of ductility at room temperature. While the 475°C embrittlement phenomenon is well known, there is a definite lack of published information concerning the corrosion resistance of the embrittled ferritic stainless steels. Similarly, very little is known of the over-all corrosion resistance of ferritic stainless steel sensitized by low-temperature exposure. Therefore, an investigation was undertaken at Climax Laboratory to study the effect of low temperature aging on the over-all corrosion resistance of ferritic stainless steel.

Experimental Procedures

Materials and heat-treatment.—The material selected for this study was commercially produced, titanium-stabilized 18Cr-2Mo steel. Chemical composition of the stainless steel is given in Table I. The steel was exposed to the following heat-treatments: (*i*) 2 hr at 870°C, water quenched; (*ii*) 1 hr at 785°C, water quenched; (*iii*) 1 hr at 785°C, followed by 4 hr at 705°C and water quenched; (*iv*) 1 hr at 815°C, water quenched; (*v*) 1 hr at 815°C, water quenched, followed by 240 hr at 475°C, water quenched; (*vi*) 1 hr at 815°C, water quenched, followed by 2400 hr at 475°C, water quenched; (*vii*) 1 hr at 815°C, water quenched, followed by 4800 hr at 475°C, water quenched.

Samples from each of the base heat-treatments (*i*)-(*iii*) were further subjected to ¼, ½, 1, 4, and 10 hr exposures at 620°C. The 620°C temperature was known from preliminary experiments to cause the

most severe sensitization to intergranular corrosion in the Streicher test. Some samples from heat-treatment (*iii*) were also subjected to 64 hr aging at 620°C.

Immersion tests.—Intergranular corrosion resistance of the sensitized samples was determined by the Strauss, Streicher, and Warren tests (ASTM Designation A262-70) and of embrittled materials by the Strauss and Streicher tests. The Strauss test consists of exposing a sample for 24 hr in contact with metallic copper in boiling 16% sulfuric acid containing 6% copper sulfate. After the exposure, the test samples are bent to determine whether or not they will open at grain boundaries. The Streicher test consists of determining the corrosion rate over a 5 day period in boiling 50% sulfuric acid containing 25g of ferric sulfate per 600 ml of solution. The Warren test consists of exposing the test specimen to a solution containing 10% nitric and 3% hydrofluoric acid for 2 hr at 70°C. In view of high corrosion rates sustained by ferritic stainless steels in the Warren test, only one exposure period was employed.

The over-all corrosion resistance was evaluated in boiling formic acid and in dilute chloride solution. Formic acid tests were run for 24 hr and samples were activated by touching them with a magnesium rod immediately after immersion in acid. The tests were performed in 45 and 10% acid for embrittled materials and in 45% acid only for sensitized materials.

The dilute chloride test consisted of exposing test coupons from 1 to 2 weeks to an oxygenated solution containing 600 ppm Cl^- and 20 ppm Cu^{++} at 90°C. Corrosion coupons for all immersion tests, with the exception of the samples embrittled for 2400 and 4800 hr, were approximately 2.5 by 1.5 by 0.2 cm. Samples for 2400 and 4800 hr aging were prepared from tensile specimens and were 2.7 by 1 by 0.4 cm. All corrosion coupons were polished through No. 600 SiC paper. Prior to exposure, the corrosion coupons were washed with soap and water and rinsed in distilled water. After the exposure, the samples were rinsed and cleaned in an ultrasonic cleaner.

Pitting potentials.—Pitting potentials were determined in molar NaCl at 25°C using the potentiodynamic polarization technique. Potential scanning rate was 260 mV/hr. Electrode surfaces were polished through No. 600 SiC paper. Electrodes were masked with Glyptal to prevent interference by crevice corrosion (3). All potentials were measured against SCE and reported as volts *vs.* SCE.

Results

The results from the Streicher tests for the 18Cr-2MoTi steel exposed to the sensitizing heat-treatment at 620°C are summarized in Table II. The corrosion rates for the three basic heat-treatments [(*i*)-(*iii*)] were approximately the same. Metallographic examination indicated some intergranular attack for each of the three basic conditions. Each increment in sensitization time increased corrosion rates for each of the three basic heat-treatments. Increases in corrosion rates were already evident after 15 min of sensitizing heat-treatment, especially for the 785°-705°C basic heat-treatment. After 4 hr of sensitizing treatment, corrosion rates were high for all three conditions. Metallographic examination showed extensive intergranular corrosion. No reductions in corrosion rates were observed after 10 hr of sensitization, nor after 64 hr. If anything, corrosion rates continued to increase with increased sensitization time. After sensitization for 64 hr, the corrosion rate was so high that tests could be run for 2 days instead of the normal 5 days.

The results from the Strauss test were completely different from those of the Streicher test. None of the sensitized samples, including the one sensitized for 64 hr, showed any intergranular corrosion. There was no visual evidence of any corrosion, and all samples could be bent without cracking. Hence, the low-temperature sensitization was not detectable by the Strauss test.

Corrosion rates in the Warren tests were high (Table III). The sensitization heat-treatment, however, did not increase these rates. Metallographic investigation showed that no significant intergranular corrosion occurred in this test for any samples sensitized up to 10 hr. After a sensitizing heat-treatment of 64 hr, some preferential grain boundary attack occurred: however, no grain dropping was observed. Thus, the Warren test did not reveal the low-temperature sensitization to intergranular corrosion, at least not up to 10 hr of sensitizing treatment.

The results from the formic acid exposure are shown in Table IV. While there were differences in corrosion rates, there was no definite pattern. It can be concluded that a sensitizing heat-treatment of up to 10 hr at 620°C had no effect on corrosion rates in boiling 45% formic acid. The differences in corrosion rates presumably resulted from differences in repassivation times. After activation, the sample will corrode for a given period of time; it then repassivates and no further corrosion takes place. If 18Cr-2MoTi steel continued to corrode actively, corrosion rates would be expected to be around 30,000 $mg \cdot dm^{-2}$/day (Table VII). Experiments involving an exposure for 1 week of a specimen sensitized for 10 hr at 620°C following a preliminary heat-treatment of 1 hr at 785°C plus 4 hr at 705°C confirmed that the specimen indeed repassivates after some corrosion following the activation. The corrosion rate after an exposure time of 1 week was 130 $mg \cdot dm^{-2}$/day. If all of the weight loss had been sustained within the first 24 hr, the corrosion rate then would be $130 \times 7 = 910$ $mg \cdot dm^{-2}$/day, which is within the range of corrosion rates obtained after 24 hr.

Corrosion rates at 90°C in an oxygen-saturated solution containing 600 ppm Cl^- and 20 ppm Cu^{++} are shown in Table V. Corrosion attack in this medium was localized in the form of small pits. Corrosion rates varied from 0 to 6 mdd, but no correlation with various heat-treatments was evident. Hence, the low temperature sensitization did not affect the corrosion resistance of 18Cr-2MoTi stainless steel to dilute chlorides. For comparison, the corrosion rates for solution-annealed samples of T304 and T316 stainless steel are also included in the table. Both of these standard austenitic grades of stainless steel suffered considerably more extensive corrosion damage than any of the 18Cr-2MoTi samples. Pitting potentials for the samples from the three basic heat-treatments and for the sensitized samples are given in Table VI. Pitting potentials for the samples from the 870° and 785°-705°C basic heat-treatments were of comparable magnitude, while the sample from the 785°C treatment had slightly lower pitting potential. The 620°C sensitizing heat-treatment did not result in any deterioration of pitting potentials; if anything, pitting potentials for sensitized samples tended to be somewhat more noble than for the basic heat-treatment. The pitting potentials for all sensitized samples were of comparable magnitude.

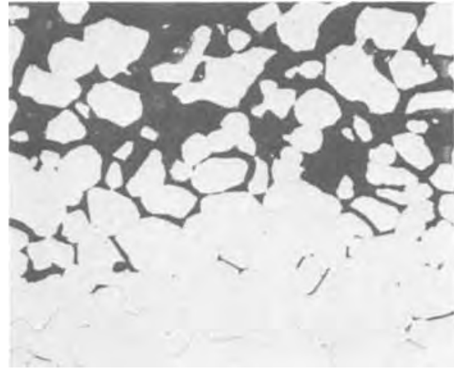

Fig. 1. Microstructure of 18Cr-2MoTi specimen after Streicher test (prior to test sample treated for 2 hr at 870°C, then sensitized for 10 hr at 620°C). Magnification 250X.

Results from the tests with samples aged at 475°C from 240 to 4800 hr were quite different from the results for samples exposed to 620°C sensitizing heat-treatment. It should be noted here that a marked drop of impact strength is already noticeable after 240 hr of exposure. Results from various corrosion tests are summarized in Table VII. The 18Cr-2MoTi steel passed the Strauss test after 240 hr of aging at 475°C, and the corrosion rates in the Streicher test were the same as for the basic heat-treatment (*iv*) above. After 2400 hr at 475°C, corrosion rates in the Streicher test were about an order of magnitude higher than for the basic heat-treatment. However, the mode of attack in the Streicher test was different for the embrittled sample than for the sample sensitized at 620°C. Metallographic investigation showed that while the sample exposed to 620°C suffered severe intergranular attack in the Streicher test, the sample aged for 2400 hr at 475°C suffered general corrosion (Fig. 1 and 2). Thus the embrittled samples were not sensitive to intergranular corrosion either in the Strauss or the Streicher tests.

Corrosion rates in boiling formic acid were quite sensitive to 475°C aging. The samples embrittled for 240 hr failed to repassivate in most cases in boiling 45% acid, and consequently much higher corrosion rates were obtained with embrittled than with standard specimens. In 10% acid, samples embrittled for 240 hr did repassivate and corrode at a negligible rate, but after 2400 hr of aging the samples failed to repassivate.

The deterioration of corrosion resistance in dilute chlorides was less dramatic than in formic acid. After

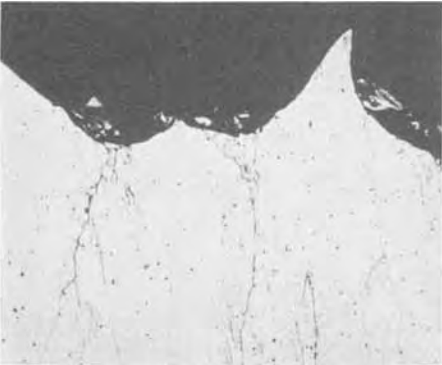

Fig. 2. Microstructure of 18Cr-2MoTi specimen after Streicher test (prior to test sample heated for 1 hr at 815°C, then embrittled for 2400 hr at 475°C). Magnification 500X.

240 hr of aging, there was no evidence of any loss of corrosion resistance. Some tendency of the corrosion rate to increase was first manifested after aging for 2400 hr. However, after aging for 4800 hr, severe loss of corrosion resistance in dilute chlorides was observable.

The pitting potentials for the standard heat-treatment and after 240 and 2400 hr aging at 475°C are summarized in Table VIII. As can be seen from the data in this table, the pitting potentials became more active as the aging time at 475°C increased. Comparison of pitting potentials in Tables VI and VIII discloses that the basic heat-treatment which resulted in the lowest pitting potential, 0.338V, SCE average, was 815°C. The differences in pitting potentials for various basic heat-treatments, however, are relatively small.

Discussion

The 620°C aging and the 475°C aging evidently affect the corrosion properties of 18Cr-2MoTi ferritic stainless steel by different mechanisms. The effect of aging at 475°C on the corrosion behavior can be rationalized considering the α' precipitation reaction. The embrittlement, as established by the work of Fisher, Dulis, and Carroll (5) is caused by the precipitation of α' phase, which has been identified as an Fe-Cr phase with 60-80% Cr. According to an earlier investigation (4) the α' precipitate becomes just visible, primarily at dislocations, after 240 hr at 900°F (480°C) exposure. After a 2400 hr exposure, α' particles are not only larger in size but are also present on grain boundaries and in the matrix. Since α' phase is rich in chromium, some depletion of Cr from the matrix accompanies the precipitation reaction. Lowering of chromium in the matrix would lead to a failure to repassivate in formic acid and to the loss of passivity in the Streicher test. Since the Streicher test involves highly oxidizing conditions, loss of passivity requires more severe chromium depletion than is achieved after a 240 hr heat-treatment. Since α' precipitation involves rather mild chromium depletion, especially in the initial stages, no

Table VIII. Pitting potential in molar NaCl at 25°C for 18Cr-2MoTi stainless steel

intergranular attack is observable in the Streicher test for samples treated for only 240 hr. After 2400 hr, chromium depletion apparently is sufficient to cause general loss of passivity. The depletion of chromium from the matrix also would lead to a shift of pitting potentials to more active values.

The effects of the 620°C aging are more difficult to rationalize. It is known that the maximum temperature for the occurrence of α' precipitation in 18Cr-2Mo steels is less than 540°C (4). On the other hand, the results of this investigation are not in accord with the carbide precipitation and chromium depletion theory proposed to explain the mechanism of low-temperature sensitization of ferritic stainless steels. Since the corrosion resistance in formic acid and in the Strauss test and the pitting potential were unaffected, most probably chromium depletion is not the main factor in low-temperature sensitization. It has been demonstrated that pitting potentials are greatly affected by sensitization of unstabilized ferritic stainless steels to intergranular corrosion (6, 7). It is possible that some precursor of a chromium-rich intermetallic phase is formed along grain boundaries during heat-treatment around 620°C and is preferentially attacked in highly oxidizing media. A similar phenomena is thought to occur in T316L austenitic stainless steel which can suffer intergranular attack in nitric acid because of submicroscopic sigma phase (8). This hypothesis is further strengthened by the observation that the attack is more severe in the Streicher solution after a holding time of 64 hr at 620°C than after short holding times. If chromium depletion occurred because of precipitation of chromium carbonitrides, chromium back-diffusion from the matrix would be expected after long sensitization times, and consequently, in the Streicher test there would be a reduction in corrosion rate.

Another indication that chromium carbonitride precipitation at 620°C was not the only cause of loss of corrosion resistance is given by the lack of significant differences in aging behavior after the three different initial treatments. It was intended that these initial treatments would modify the amounts of carbon and nitrogen in solid solution and available for precipitation during aging. In particular, it was thought that a 4 hr hold at 705°C would cause a greater amount of the carbon and nitrogen to be precipitated as titanium carbonitride than would be the case for material quenched from 870°C. Unfortunately, quantitative information on the solubility of titanium carbides or nitrides at these temperatures is not available.

Failure to find evidence of chromium carbonitride precipitation leading to chromium depletion in this titanium-stabilized steel does not imply that chromium depletion may not occur in unstabilized steels. In fact, Rarey and Aronson (6) have reported work on sensitization at 620°C of unstabilized 25% Cr alloys containing 0-3% Mo that is consistent with the occurrence of chromium depletion because of chromium carbonitride precipitation. They found that the maximum loss in resistance to pitting and intergranular corrosion occurred after 15-60 min at 620°C and that corrosion resistance equivalent to that of the unaged alloy was recovered after about 4 hr at 620°C.

Another possible explanation of the effect of aging involves direct attack of highly oxidizing media on titanium carbonitrides. Bäumel (9) has demonstrated that bulk titanium carbide is attacked at highly oxidizing potentials and direct attack on titanium carbonitrides is thought to occur in boiling 65% HNO_3 in some titanium stabilized steels (10, 11). However, for this sort of attack to explain the intergranular corrosion observed in boiling $Fe_2(SO_4)_3$-50% H_2SO_4 a continuous or nearly continuous grain boundary film of titanium carbonitride would be required. Since most of the available carbon and nitrogen are thought to be precipitated as massive titanium carbonitrides during the initial anneal it is not clear how such continuous films

could form on aging. It also seems likely that the different initial heat-treatments would have had a larger effect on the subsequent formation of titanium carbonitride films than was observed. Finally, no metallographic evidence of such a grain boundary film was obtained.

The results of this investigation clearly demonstrate that the low-temperature sensitization of 18Cr-2Mo titanium-stabilized ferritic stainless steel affects corrosion resistance only under highly oxidizing conditions, such as the Streicher test and the Huey test (1). Other corrosion properties, such as resistance to boiling organic acids, resistance to chlorides, and resistance to intergranular corrosion under moderate oxidizing conditions (Strauss test) are not adversely affected, and therefore, the exposure to temperatures around 600°C should not, for most cases, be detrimental to corrosion resistance of 18Cr-2MoTi stainless steel. Further work with both stabilized and unstabilized high-purity ferritic stainless steels is needed to demonstrate to what extent the above conclusions can be generalized or if they apply specifically to 18Cr-2MoTi steel.

Conclusions

1. The corrosion resistance of 18Cr-2MoTi ferritic stainless steel in most environments in unaffected by aging at 620°C for up to 10 hr. Low-temperature sensitization to intergranular corrosion is revealed only under highly oxidizing conditions, such as the Streicher or Huey tests. No sensitivity to intergranular corrosion is revealed either in Strauss or Warren (HNO_3-HF) tests.

2. The 475°C embrittlement treatment affects the corrosion resistance of 18Cr-2MoTi stainless steel in all test media. While detrimental effects on corrosion properties were evident after a 240 hr treatment at 475°C, further gradual deterioration of corrosion resistance was observable after a 2400 and 4800 hr exposure. Corrosion properties adversely affected were resistance to boiling formic acid, pitting potential, and resistance to chlorides. The 475°C treatment does not lead to intergranular corrosion in the Streicher test.

Manuscript submitted July 8, 1974; revised manuscript received Jan. 10, 1975. This was Paper 114 presented at the Boston, Massachusetts, Meeting of the Society, Oct. 7-11, 1973.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1975 JOURNAL. All discussions for the December 1975 Discussion Section should be submitted by Aug. 1, 1975.

Publication costs of this article were partially assisted by the Climax Molybdenum Company of Michigan.

Initial Anodic Growth of Oxide Film on Platinum in 2*N* H_2SO_4 under Galvanostatic, Potentiostatic, and Potentiodynamic Conditions: The Question of Mechanism

Lee B. Harris* and A. Damjanovic

Xerox Corporation, Webster Research Center, Webster, New York 14580

ABSTRACT

Potentiodynamic, galvanostatic, and hybrid galvano-potentiostatic experiments were conducted in O_2 saturated 2*N* H_2SO_4 on a polished platinum disk electrode. The results show conclusively that for coverage between one and three monolayers the law of anodic growth of oxide film on platinum is precisely the same regardless of the mode of growth (*i.e.*, potentiostatic, galvanostatic, or potentiodynamic). A correspondence is analytically established between galvanostatic and potentiodynamic data, and this correspondence is verified experimentally. Galvanostatic and potentiodynamic data both show that the growth of the oxide film cannot be explained by any mechanism for which $(\partial V/\partial q)_i$ is independent of i (*e.g.*, adsorption). The high-field ionic conduction model accounts for the major features of all the data. A comparison of galvanostatic and hybrid galvano-potentiostatic experiments shows that there is no aging of the film over a time interval, Δt, comparable to the duration of the experiments (20 sec $\leq \Delta t \leq$ 150 sec). The effect of "holding" (*i.e.*, interrupting the potential sweep and maintaining a constant potential for a time) during potentiodynamic experiments is explained entirely in terms of the potentiostatic growth of the oxide film during the holding period.

It has been suggested by Ord and Ho (1) and others (2, 3) that the formation of anodic oxide film on platinum is controlled by high-field ionic conduction even in the earliest stages of growth. This model is controversial, however, and to settle the controversy one must answer the following two questions: (*a*) Is the growth rate (*i.e.*, the current density, i, associated with oxide growth) uniquely determined by the potential, V, and the thickness of the oxide film already formed (*i.e.*, the charge $q = \int_0^t i dt$)? and (*b*) If so, what is the dependence of i on V and q, and is this dependence more satisfactorily explained by the high-field conduction model than by other proposed mechanisms?

* Electrochemical Society Active Member.
Key words: platinum, anodization, potentiodynamic, galvano-potentiostatic, mechanism.

The growth of the anodic film on platinum has been investigated by galvanostatic (1-3), potentiostatic (4, 5), and potentiodynamic (*i.e.*, potential sweep) experiments (6-8) with conflicting results and conclusions.

Experimental galvanostatic charging curves can be fitted (2, 3) by an equation of the form

$$\ln i = a + (V - V')/b(q) \quad [1]$$

where a and V' are constants, $b(q)$ is a linear function of q, and V is the anode potential with respect to a reference electrode. If the q-scale is shifted so that $b(q)$ becomes cq, and if V' is associated with electric fields outside the oxide film (*e.g.*, in the double layer) then Eq. [1] may be interpreted in terms of the Cabrera-Mott model of oxide growth in which metal ions are assumed to be injected and to migrate by field-assisted thermal hopping over a potential barrier. (The electric field pertaining to this process is $(V - V')/cq$.)

Equation [1] implies that under potentiostatic conditions $\ln i$ is inversely proportional to q; but this relationship has not been satisfactorily established in potentiostatic experiments with platinum. For example, Gilman's potentiostatic measurements (4) appear to show that near monolayer coverage

$$\ln i = A - q/B \quad [2]$$

where A and B are constants at any particular potential. Integration of Eq. [2] yields

$$i = B/(t + t_o) \quad [3]$$

and

$$q = q' + B \ln (t + t_o) \quad [4]$$

where q' is a constant of integration and t_o is determined by A and B. The results of potentiostatic experiments by Vetter and Schultze (5) fit Eq. [3] and [4], which imply [2] rather than [1]. Potentiostatic data on platinum oxidation has not provided evidence for the Cabrera-Mott model.

The potentiodynamic method has been used by Böld and Breiter (6), and more recently by Conway and co-workers (7, 8), among others. However, the usefulness of potentiodynamic data has been limited to some extent by the lack of a quantitative analysis relating it to galvanostatic and potentiostatic data, which are more easily interpreted than potentiodynamic data.

We initiated a series of experiments designed specifically to determine whether under otherwise identical conditions galvanostatic and potentiostatic data yield the same results, and to relate the results to potentiodynamic experiments conducted under the same conditions. Potentiodynamic, galvanostatic, and "hybrid" experiments were performed. The latter are initiated galvanostatically and continued potentiostatically at a preselected potential without interruption.

An especially important objective of this study is a better understanding of the results of the potentiodynamic experiments and their connection with galvanostatic and potentiostatic experiments on the growth of the oxide film.

Experimental

The all-Pyrex electrochemical cell is of conventional design. It has three compartments with separate gas bubblers in the main compartment and the compartment containing the counterelectrode (Pt foil, 2 cm^2). A stopcock connects the reference electrode (saturated calomel, SCE) compartment to the main compartment containing the working electrode.

The working electrode, which is diamond-polished to a mirror finish, is the disk portion of a platinum ring-disk electrode. The disk diameter is 5 mm, the ring outer diameter is 7 mm, and the ring-disk spacing is approximately 0.2 mm. The electrode enters the cell from above through a closefitting, stationary Teflon washer that protects the interior of the cell from laboratory atmosphere.

In order to insure nearly cylindrical electrode geometry, the electrical path from the counterelectrode compartment is constrained by a glass tube (~1 cm diam) the open end of which faces the disk at a distance of about 1 cm. To reduce the fringe field at the edge of the disk, the ring is maintained at the same potential as the disk.

Control of potential or current at the disk is effected by conventional circuitry. The disk is kept at virtual ground potential by means of a chopper-stabilized current-to-voltage converter, and the ring is hard-grounded. For potential measurements a Luggin capillary (about 1 mm diam) is centered below the ring about ¼ mm from it.

For some experiments the circuitry is comprised of operational amplifiers (Analog Devices Inc. Models 234J or 184K). For other experiments a commercial potentiostat (Princeton Applied Research (PAR) Model 173) is used, but the circuitry functions in essentially the same way in both cases. A PAR Model 175 Universal Programmer was used for potentiodynamic experiments. All measurements were made using a Tektronix Model 7623 storage oscilloscope in the X-Y mode.

Solutions were prepared from Baker Reagent Grade sulfuric acid and triply distilled water. The cell and all glassware used in preparing the solutions were washed with a hot mixture of concentrated nitric and sulfuric acids and thoroughly rinsed with distilled water. Prior to each series of experiments the electrode was anodically oxidized and cathodically reduced several times and the solution then replaced. For all experiments the $2N$ H_2SO_4 solution was saturated with oxygen (Linde Ultra High Purity Grade). Except for about 1 in. of Tygon, only glass, metal, and Teflon are used in the gas line.

Results and Discussion

Potentiostatic vs. galvanostatic experiments.—Figure 1 shows a reproduction of the oscilloscope storage screen[1] after recording galvanostatic transients at four different current densities,[2] starting with 5 mA/cm^2 and decreasing by an order of magnitude for each subsequent test. Just prior to each test, any oxide film on the electrode was cathodically reduced. The electrode was then held for a few seconds at a potential just short of hydrogen evolution (~0.0V *vs.* SCE) and then allowed to drift at zero current to its "rest potential,"

[1] This and subsequent figures are carefully traced from the original photographs. All features, including the width of the trace and any noise on it are reproduced.

[2] Current densities are based on the geometrical area of the working electrode (0.20 cm^2) and are not corrected for roughness factor.

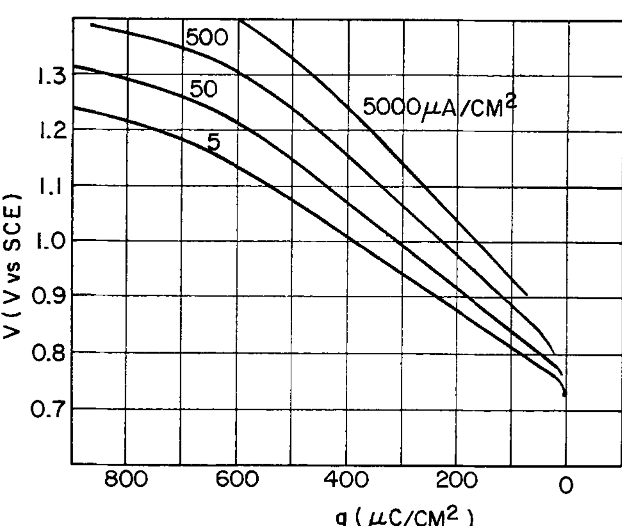

Fig. 1. Galvanostatic charging curves. Conditions are described in text.

in this case +0.735V *vs.* SCE. The oscilloscope beam intensity was then turned up, an electronic integrator (connected to the output of the current-to-voltage converter) was started (by disconnecting with a toggle switch a small resistor across the integrating capacitor), and the current control then immediately switched[3] from zero to a preset value. The potential of the working electrode is recorded in the vertical direction. For the sake of resolution a portion of the potential is (very precisely) suppressed. The output of the integrator is recorded horizontally. Following each run the electron beam was turned off and the integrating capacitor was discharged through a small resistor. The results shown in Fig. 1 are highly reproducible; two sets of tests conducted a week apart agree to within the width of the oscilloscope trace. Curves similar to those shown in Fig. 1 have been reported before and have recently been quantitatively analyzed to elucidate the mechanism of film growth (2, 3). In the present study, the curves in Fig. 1 may be considered to represent the relationship between potential (V), current density (i), and charge density (q), the latter being a measure of the thickness of the film formed during the experiment (assuming that no current is taken by any competitive reaction such as metal dissolution or oxygen evolution). If a unique relationship exists between these three variables; *i.e.*, if

$$i = i(V,q) \qquad [5]$$

then each point of the V,q diagram, no matter how it is reached, should correspond to a particular value of i. Conversely, if the current at each point (V,q) is independent of the manner in which the point is reached, this is evidence in support of Eq. [5].

Each measured point in Fig. 1 is reached along a path for which the current is constant. A particularly simple alternative to this is a hybrid "galvano-potentiostatic" path such as that shown in Fig. 2. The hybrid experiment shown in Fig. 2 was started galvanostatically (at 5 mA/cm²) and switched from the galvanostatic mode to the potentiostatic mode at a particular potential. The switching[4] is accomplished by a relay that closes when the potential reaches the desired value; *e.g.*, 1.2V (SCE) in Fig. 2. The broken trace in Fig. 2 is a record of the current, the break being the point at which scope sensitivity is increased by a factor of twenty. The potential overshoots the mark by about 20 mV, probably due to an overload during the switching transient. This overshoot does not occur at lower currents, as shown in Fig. 3, which is a record of an experiment that was started at 500 μA/cm² and was switched to constant potential at 1.0V. In Fig. 2 the current sensitivity is initially set at the highest value that will permit a record of the current just after the switching transient; for this reason the initial, constant current is not seen as it is in Fig. 3. Figure 2 represents the first of a series of galvano-potentiostatic experiments starting at 5 mA/cm² and switching to constant potential at 1.2, 1.1, 1.0, and 0.9V (SCE). In Fig. 4 the potentiostatic portions of these hybrid experiments are compared with the galvanostatic data of Fig. 1 by plotting the logarithm of the current density *vs.* the charge density at each potential for both sets of data (see caption, Fig. 4). The good agreement of the gal-

[3] This switching was sometimes done electronically (when using the PAR potentiostat) but a manually operated toggle switch is satisfactory and was used for the tests shown in Fig. 1.
[4] The circuitry for this is described by Bruckenstein and Miller (10). In the present experiments the switch S-1 [in Fig. 1 of Ref. (10)] is a mercury-wetted relay driven by a comparator.

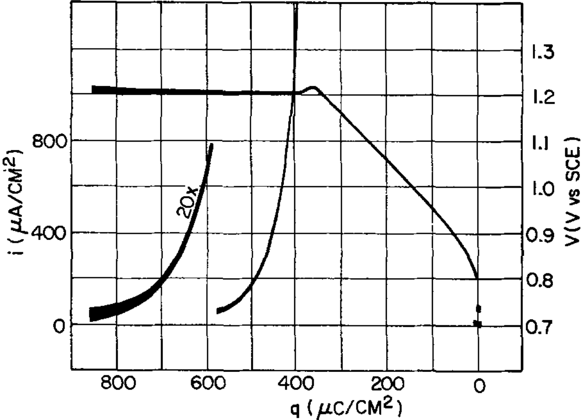

Fig. 2. Hybrid experiment. Continuous trace is potential. Current trace is broken where scope sensitivity was increased. Galvanostatic segment: 5 mA/cm². Potentiostatic segment: 1.2V. Other conditions described in text. Dots at lower right are starting positions of the two traces.

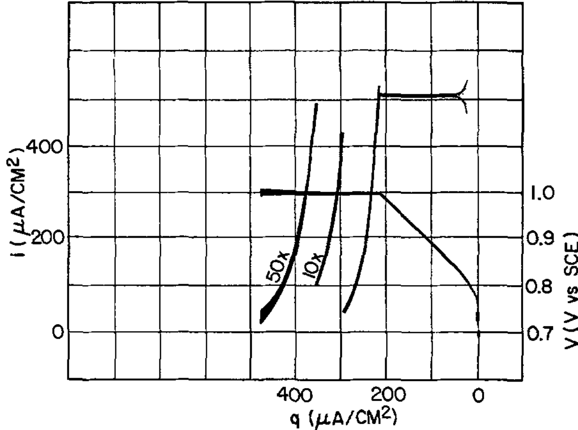

Fig. 3. Hybrid experiment. Galvanostatic segment: 500 μA/cm². Potentiostatic segment: 1.0V. See caption Fig. 2.

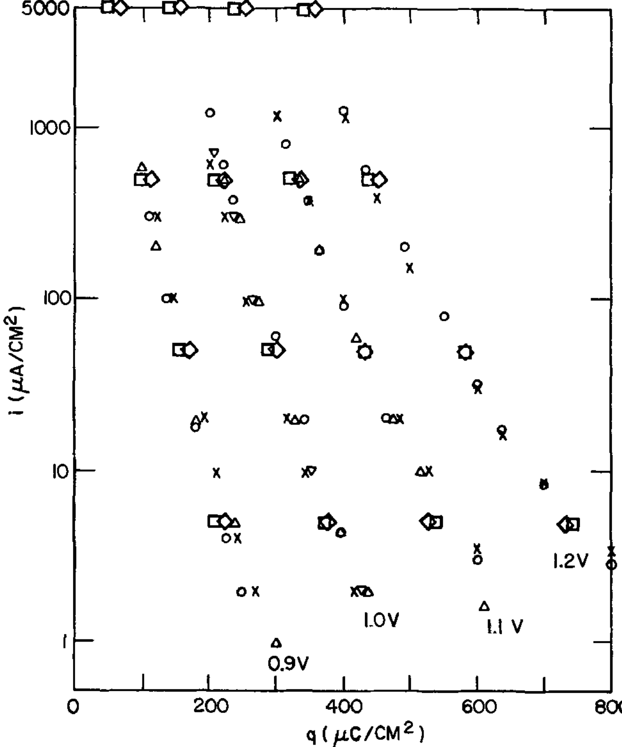

Fig. 4. Comparison of results of galvanostatic and hybrid experiments. Boldface symbols (□, ◇) are galvanostatic data; each horizontal row of symbols represents data from two repetitions at the same current. □ and ◇ are two weeks apart. Smaller symbols are from potentiostatic portion of hybrid experiments starting at 5 mA/cm² and continuing at the potential indicated at the bottom of each of the four strings of points (vs. SCE).

vanostatic and the hybrid data shows that Eq. [5] holds for both experimental modes. This further indicates that those properties of the film that affect film growth (*e.g.*, the injection and transport of metal ions) do not change over a time period comparable to the duration of these experiments. For example, referring to Fig. 2, the time required to transfer 750 μcoulombs/cm^2 (at which point $i = 5\ \mu A/cm^2$) is about 19 sec as can be calculated from the formula $t = \int_0^q dq/i$. The same charge is transferred in 150 sec galvanostatically at 5 $\mu A/cm^2$; yet in both cases the potential corresponding to $i = 5\ \mu A/cm^2$ and $q = 750\ \mu$coulombs/cm^2 is 1.20V (SCE). This is strong evidence against any aging effects in these experiments.

Potentiodynamic vs. galvanostatic experiments.—The potentiodynamic method is not as simple conceptually as either the galvanostatic or potentiostatic method, and when applied to a system governed by an equation such as [1] the following analysis is helpful in understanding the behavior of the system.

Figure 5 shows a schematic representation of galvanostatic curves (labeled i_1, i_2, i_3) for a system governed by Eq. [5]. The heavy curve T that crosses the galvanostatic curve i_2 at (V_o,q_o) represents the locus of successive states (V,q) traversed by the system (in the direction of the arrow) during a hypothetical anodic potential sweep. In an anodic potential sweep experiment

$$\frac{dV}{dt} = \text{const.} \equiv S > 0 \qquad [6]$$

and the slope at each point (V,q) on curve T is

$$\frac{dV}{dq} \equiv \frac{dV}{dt} \Big/ \frac{dq}{dt} \equiv S/i(V,q) \qquad [7]$$

If at any point on T its slope dV/dq is not equal to the slope of the galvanostatic curve passing through the same point, then the current is changing as the system passes through that point. For example, at (V_o,q_o) the slope of T is greater than that of the galvanostatic curve i_2; so T crosses i_2 and in passing through (V_o,q_o) in the direction of the arrow the system therefore moves from currents less than i_2 to currents greater than i_2. Likewise if at any point on T its slope is less than that of the galvanostatic curve passing through that point, the current is decreasing. To formalize this argument, take V as the independent variable and, using Eq. [5], write

$$\frac{di}{dV} = \left(\frac{\partial i}{\partial V}\right)_q + \left(\frac{\partial i}{\partial q}\right)_V \frac{dq}{dV} \qquad [8]$$

Using the identity

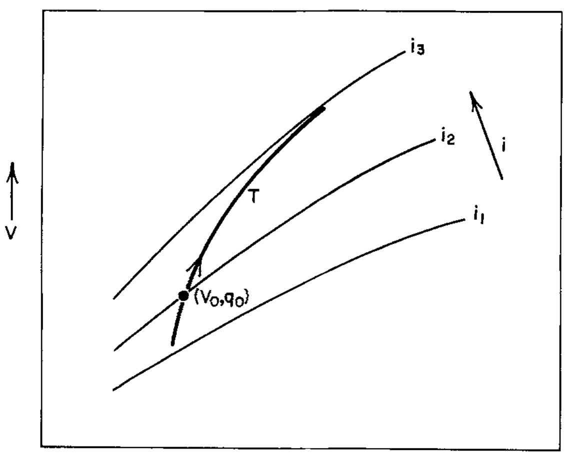

Fig. 5. Schematic diagram showing potentiodynamic response of a system governed by Eq. [5].

$$\left(\frac{\partial i}{\partial q}\right)_V \equiv -\left(\frac{\partial i}{\partial V}\right)_q \left(\frac{\partial V}{\partial q}\right)_i \qquad [9]$$

Eq. [8] can be rewritten

$$\frac{di}{dV} = \left(\frac{\partial i}{\partial V}\right)_q \left[1 - \left(\frac{\partial V}{\partial q}\right)_i \Big/ \frac{dV}{dq}\right] \qquad [10]$$

Equation [10] shows that as the potential increases, the current will increase or decrease depending on whether the ratio $(\partial V/\partial q)_i/dV/dq$ is less than or greater than one [since $(\partial i/\partial V)_q$, $(\partial V/\partial q)_i > 0$ for usual electrochemical systems].

Returning to the discussion of curve T in Fig. 5, as the current increases, its rate of increase diminishes (cf. Eq. [10]) because dV/dq becomes smaller due to the relationship [7]. Thus, the current changes less and less rapidly and the system approaches a "steady state" in which dV/dq is equal to $(\partial V/\partial q)_i$; *i.e.*, curve T becomes parallel to a galvanostatic curve. By substituting Eq. [7] into [10] we obtain

$$\frac{di}{dV} = \left(\frac{\partial i}{\partial V}\right)_q \left[1 - i\left(\frac{\partial V}{\partial q}\right)_i \Big/ S\right] \qquad [11]$$

from which it is clear that the steady-state current, i_s (*i.e.*, the current such that its rate of change is zero) satisfies the condition

$$S/i_s = \left(\frac{\partial V}{\partial q}\right)_{i_s} \qquad [12]$$

If the transient process shown in Fig. 5 takes place very quickly, it will be completed early in the potentiodynamic experiment, which then rapidly becomes nearly indistinguishable from a galvanostatic experiment. This is true of the potentiodynamic experiments to be discussed in this section. Before going on to these experiments, however, let us briefly examine (within the framework of the preceding discussion) the differences between steady-state potentiodynamic oxidation and adsorption.

Equation [5] sometimes has the special form

$$i = f(q,\eta) \qquad [13]$$

where

$$\eta = V - V_e(q) \qquad [14]$$

$V_e(q)$ may be called the "adsorption isotherm" (*e.g.*, for the Temkin isotherm, $V_e(q) \equiv \text{const.} \times q$). Using Eq. [9], it can then easily be shown that

$$\left(\frac{dV}{\partial q}\right)_i = -\frac{\partial f}{\partial q} \Big/ \frac{\partial f}{\partial \eta} + \frac{dV_e}{dq} \qquad [15]$$

A particular special case, one that is often used in the literature (6, 7, 11), is that for which $f \equiv l(q) \exp(\eta/E)$ where $l(q)$ is a linear function of q and E is constant. For this case

$$\left(\frac{\partial V}{\partial q}\right)_i = \text{const.} \times E/l(q) + \frac{dV_e}{dq} \qquad [16]$$

which does not depend on V and hence is independent of i.[5] It follows from Eq. [12] that in this case the steady-state potentiodynamic current would be strictly proportional to S.

In contrast to this case, for the anodic oxidation of platinum (below ~1.3V *vs.* SCE), $(\partial V/\partial q)_i$ increases with i (cf., Fig. 1). Therefore, according to Eq. [12] i_s must increase less rapidly with S than would be required by strict proportionality.

From Fig. 1 it can be determined that $(\partial V/\partial q)_i$ increases (linearly with log i) by 50% as i increases from 5 $\mu A/cm^2$ to 5 mA/cm^2; this is shown graphically in Fig. 6. Using these data and Eq. [12] one may determine for various values of S, the steady-state cur-

[5] Another somewhat more general case of interest is that for which the current depends much more strongly on η than on q; *i.e.*, $\partial f/\partial q << \partial f/\partial \eta$ (or, more precisely $(\partial \eta/\partial q)_f << dV_e/dq$). In this case, $(\partial V/\partial q)_i \approx dV_e/dq$, which is also independent of i.

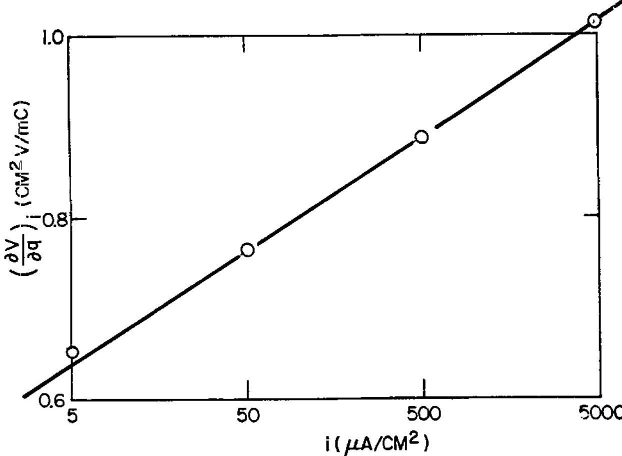

Fig. 6. Slopes of galvanostatic charging curves in Fig. 1, plotted vs. current density.

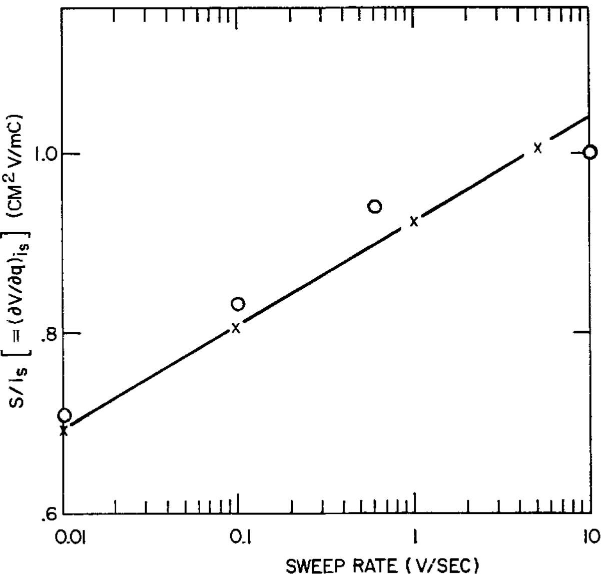

Fig. 7. Ratio of sweep rate S to steady-state potentiodynamic current i_s. X, calculated from galvanostatic data using Eq. [12]; O, measured.

rent i_s and the quantity $S/i_s \equiv (\partial V/\partial q)_{i_s}$ (which would have to be constant if i_s were proportional to S). In Fig. 7, values of S/i_s determined in this way are plotted (points marked X) as a function of S. Also plotted in the figure are values of S/i_s (points marked O) from potentiodynamic experiments (*vide infra*). The agreement between the potentiodynamic data and the results derived from galvanostatic data is good, the largest discrepancy being less than 5%. This verifies the validity of Eq. [12] and shows that the deviation from linearity (*i.e.*, about 50%) as measured by the variation of S/i_s is very close to the prediction based on the variation of $(\partial V/\partial q)_i$ in the galvanostatic experiments. Thus, the potentiodynamic and the galvanostatic data both show that the formation of the oxide film cannot be explained by any mechanism (*e.g.*, adsorption) for which $(\partial V/\partial q)_i$ is independent of i.

Examples of potentiodynamic experiments at 10^{-2}, 10^{-1}, and 10 V/sec are shown in Fig. 8, 9, and 10, respectively. The conditions are the same as for the galvanostatic experiments shown in Fig. 1. Figures 8 and 9 each also include traces showing i and V *vs.* q for a galvanostatic experiment conducted at a current density chosen to be approximately the same as the steady-state current in the potentiodynamic experiment. The V,q traces for the potentiodynamic and the

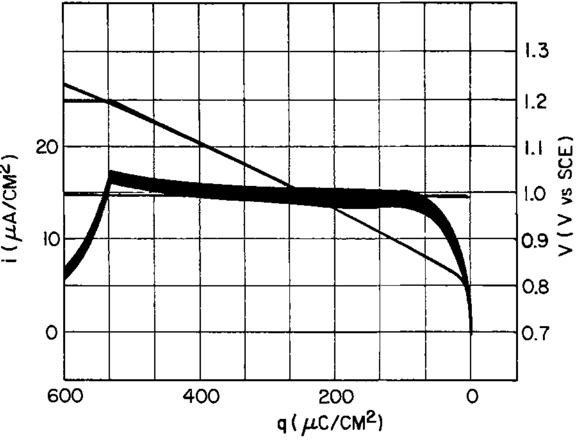

Fig. 8. Potentiodynamic and galvanostatic experiments. Noisy trace is current during potential sweep at 10 mV sec^{-1}. Horizontal trace is current during galvanostatic experiment. Other two traces show potential. Sweep arrested at 1.2V. Conditions given in text.

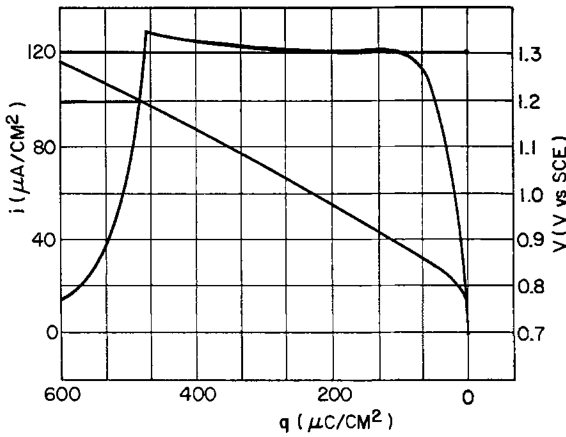

Fig. 9. Potentiodynamic and galvanostatic experiments. Sweep rate: 100 mV sec^{-1}. See caption Fig. 8.

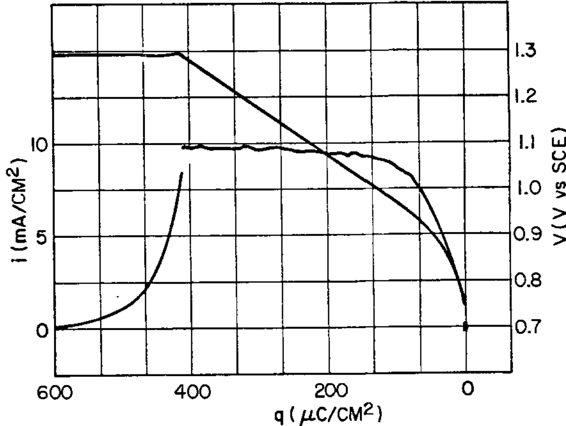

Fig. 10. Potentiodynamic experiment. Sweep rate: 10 V sec^{-1}. Noisy trace is current. Sweep arrested at ~1.3V. Slight switching transient on the potential may have caused break in current trace. Conditions same as Fig. 8 and 9. See text.

galvanostatic experiments are indistinguishable except at the end, when the potential sweep is arbitrarily arrested at 1.2V. These data show very graphically the connection between the galvanostatic and potentiodynamic experiments; namely, that the potentiodynamic steady-state current is given by Eq. [12] and varies only if $(\partial V/\partial q)_i$ varies with q. In Fig. 8-10 this variation is quite small.

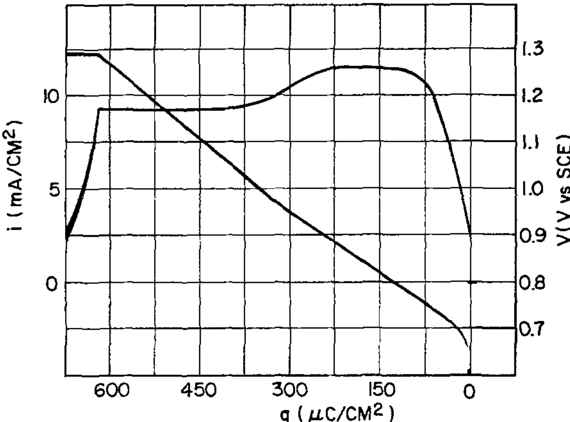

Fig. 11. Potentiodynamic experiment starting at 0.6V. Other conditions same as Fig. 10.

After the sweep is arrested (at 1.2V in Fig. 8 and 9, and 1.3V in Fig. 10) the current falls in the same way as in the hybrid experiments of Fig. 2 and 3. Plots of i *vs.* q during the potentiostatic segments of these experiments are indistinguishable from the other data of Fig. 4. This illustrates that the arrested potential sweep is essentially the same as hybrid experiment, and that the fall in current is due to the growth of the oxide at constant potential.[6]

Figure 11 is the record of an experiment similar to those previously described except that the electrode is held at 0.6V (SCE) prior to starting the sweep at 10 V/sec. Because of the lower starting potential the oxygen coverage is less to begin with; so subsequent buildup of the oxygen film[7] at first takes place with a smaller value of $\partial V/\partial q$ than in Fig. 8-10. The easily perceptible change in slope has been observed before (7), and by comparison with hydrogen adsorption (7) it was associated with monolayer coverage during the formation of the oxygen film. We emphasize here that this change in slope is quantitatively related through Eq. [12] to the concurrent step in the potentiodynamic i,V profile.

The constant current "plateaus" seen in Fig. 8-11 are frequently observed during the potentiodynamic anodic oxidation of platinum in acid solution. Because of Eq. [12] we can see that the flatness of these plateaus is equivalent to the straightness of galvanostatic charging curves such as are shown in Fig. 1. In exactly the same sense, the nonlinear sweep rate dependence of plateau height is equivalent to the dependence on current of the slopes of the galvanostatic charging curves. Any model for the growth of the oxide film that satisfactorily explains the galvanostatic characteristics will automatically explain the equivalent potentiodynamic characteristics and vice versa. Therefore, in choosing a model one may use either potentiodynamic or galvanostatic data as a basis. Historically, the interpretation of potentiodynamic data has usually been based on some variant of the adsorption isotherm which is considerably more complex [*e.g.*, see Ref. (11)] than the model used to explain galvanostatic data (*i.e.*, Eq. [1]). As we have seen, simple adsorption models cannot explain the nonlinear sweep rate dependence of the plateau current. Therefore, it appears that Eq. [1] is the preferable alternative and that high-field ionic transport (*e.g.*, the Cabrera-Mott model) is the simplest and in fact the only model that presently explains the data.

Potentiodynamic approach to steady state.—A potentiodynamic characteristic of any system such as that illustrated schematically in Fig. 5 is the asymptotic approach to steady state. For the oxidation of platinum, it is possible to analyze this characteristic in a simple quantitative manner and to compare the analytical results with experimental data. Consider a relatively small disturbance that changes the potentiodynamic steady-state current. Such a disturbance would be caused, for instance, by a small discontinuity in $(\partial V/\partial q)_i$; (*i.e.*, a more abrupt version of what occurs in Fig. 11) or by an abrupt change in sweep rate. Immediately after the disturbance, the new steady-state current is different from the actual current, which will then approach the new steady-state value required by Eq. [12]. Using [7], Eq. [8] can be rewritten

$$\frac{di}{dV} = \left(\frac{\partial i}{\partial V}\right)_q + i\left(\frac{\partial i}{\partial q}\right)_V \Big/ S \qquad [17]$$

If we restrict ourselves to a relatively small deviation from the steady-state current and a limited excursion of q, then both the partial derivatives in [17] can be approximated by constants representing their average values. The approximate solution to [17] is then an exponential approach to the new steady-state current, *i.e.*

$$\Delta i/(\Delta i)_0 = \exp(-\Delta V/v) \qquad [18]$$

where Δi is the deviation of the current from the new steady-state value; $(\Delta i)_0$ is the initial value of this deviation; ΔV is the change in V from its initial value; and the "time constant" for the approach to steady state is equal to S/v, where

$$v \equiv \left| S \Big/ \left(\frac{\partial i}{\partial q}\right)_V \right| \qquad [19]$$

An experimental test of Eq. [18] and [19] is shown in Fig. 12, which was obtained under the same conditions as Fig. 9 except that the sweep was momentarily interrupted and then resumed. Following the resumption of the sweep, the current returns toward the steady state from which it had fallen during the interruption. Examining the later part of this return ("a" in Fig. 12) we see, for example, that the current rises from 91 to 112 $\mu A/cm^2$ as the potential changes by about 33 mV. Since the steady-state current is about 122 $\mu A/cm^2$, (cf. Fig. 9), this represents a decrease of the deviation from steady state to about 32% of the initial deviation. Using these data (*i.e.*, $\Delta i/(\Delta i)_0 = 0.32$, $\Delta V = 33$ mV), the experimental value of v, calculated from Eq. [18], is 30 mV. From Fig. 1, for $i \sim 125$ $\mu A/cm^2$, $q \sim 250$ μcoulombs/cm², $(\partial i/\partial q)_V \sim 3.4$ sec^{-1}; so for $S = 0.1$ V/sec, Eq. [19] yields $v \simeq 30$ mV which agrees with the value estimated from Fig. 12.

The later part of the initial transient ("b") in Fig. 12 is similar to the subsequent recovery ("a") from the interruption of the sweep. Since both transients are governed by Eq. [18] this is understandable. However, in view of the fact that S appears explicitly in

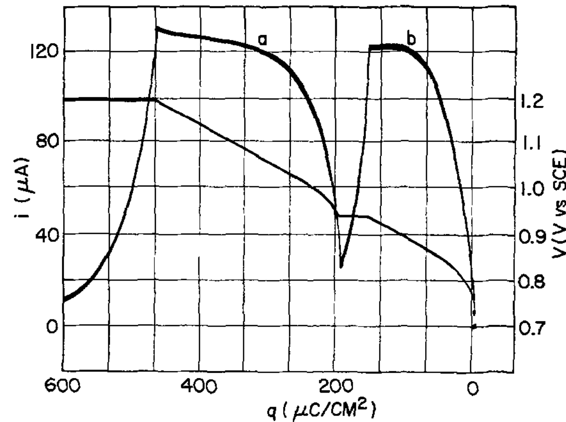

Fig. 12. Interrupted potential sweep. Same as Fig. 9 except for interruption.

[6] Again, there is no evidence for aging.
[7] As yet not necessarily an "oxide" film.

Eq. [19], one may wonder why the initial transients in Fig. 8 and 9 are so similar in spite of the tenfold ratio of sweep rates. To investigate this point, Eq. [19] can be rewritten (with the help of Eq. [9] and [12]) in the form

$$v = i_s \bigg/ \left(\frac{\partial i}{\partial V}\right)_q \qquad [20]$$

which brings out an interesting feature of the potentiodynamic growth of oxide on platinum. Since i depends exponentially on V (cf. Eq. [1]), $(\partial i/\partial V)_q/i$ depends only on q; so from Eq. [20], as i approaches i_s, v depends only on q. Furthermore, from the lowest to the highest coverage in Fig. 1, the ratio of i to $(\partial i/\partial V)_q$ increases only by a factor of two; so that the value of v calculated from Eq. [20] increases by a factor of two over this wide range of coverage. This implies that in potentiodynamic recovery from small perturbations, the growth rate of oxide film on platinum returns to its steady-state value during a sweep excursion of 20-40 mV depending on coverage, but practically independent of sweep rate.

Relationship of potentiodynamic transients to a-c impedance.—A-C impedance measurements are sometimes carried out during potential sweep experiments.[8] Here we analyze the relationship between the a-c impedance and the potentiodynamic transient response of the rate of oxide growth.

Suppose that a small periodic variation in potential, $\Delta V = (\Delta V)_0 e^{j\omega t}$ is superimposed on the potential sweep. Changing the independent variable from V to t in Eq. [8], and adding the periodic variation of V, we get

$$\frac{di}{dt} - i\left(\frac{\partial i}{\partial q}\right)_V = \left(\frac{\partial i}{\partial V}\right)_q [S + j\omega\Delta V] \qquad [21]$$

The solution to this equation can be separated into two parts corresponding to the two terms in the bracket. The solution corresponding to the first term, S, is what we have already discussed. The solution corresponding to the second term is the component of the current due to the superimposed a-c potential. The steady-state a-c component of the current is

$$\Delta i = \frac{j\omega\Delta V}{j\omega\left(\frac{\partial V}{\partial i}\right)_q + \left(\frac{\partial V}{\partial q}\right)_i} \qquad [22]$$

From Eq. [22] (using Eq. [9]) it can be shown that if $\omega << \omega_T$, where

$$\omega_T \equiv 1/\tau \equiv S/v = \left(\frac{\partial i}{\partial q}\right)_V \qquad [23]$$

(cf. Eq. [19]) then the a-c response is exactly the same as the steady-state potentiodynamic response discussed previously. In other words, if the period of the superimposed a-c potential is long compared to the potentiodynamic "time constant," $\tau \equiv v/S$, its effect is merely to cause a slight periodic change in the sweep rate and hence a corresponding periodic change in the potentiodynamic steady-state current. However, if $\omega >> \omega_T$ (*i.e.*, the period of the superimposed a-c potential is short compared to v/S), then the conductance obtained from Eq. [22] is

$$\frac{\Delta i}{\Delta V} \simeq \left(\frac{\partial i}{\partial V}\right)_q \qquad [24]$$

Equation [24] is expected intuitively when the period of the a-c disturbance is much shorter than τ. The approach to potentiodynamic steady state involves the growth of the oxide film, and if as the potential fluctuates there is not sufficient time for growth to occur, the response is the same as it would be at constant coverage. Using the data of Fig. 1 to calculate $(\partial i/\partial q)_V$ it can be shown that for current densities less than 150 $\mu A/cm^2$ and intermediate values of coverage (*i.e.*, $q > 200$ μcoulombs/cm²), ω_T is less than 2π sec^{-1}. Therefore the a-c response at superimposed frequencies of several cycles per second is essentially at constant coverage.

These results can now be applied to data of Conway and Gottesfeld (8), who measured (at 32.5 Hz) the a-c conductance of the platinum oxide system during potential sweep at 26 and 104 mV/sec. For each of these sweep rates the current density can be calculated from Fig. 7, and since at this frequency $\omega >> \omega_T$ the conductance can be calculated using [24] and the data of Fig. 1. The results of such calculations are shown in Table I. At the top of the table the calculated current density is shown for each sweep rate, and in the body of the table are shown the four conductances calculated for each sweep rate at each of the two potentials shown at the left. Since $(\partial i/\partial V)_q$ is proportional to i and varies slowly with q, Eq. [24] predicts a fourfold ratio of the a-c conductances corresponding to the fourfold ratio of the two sweep rates, and predicts a diminution by roughly a factor of two as the potential rises from 0.85 to 1.15V (*vs.* SCE). The data of Conway and Gottesfeld deviate significantly from the data in Table I. Their measured values of conductance are higher than the calculated values (by factors of five and two at 26 and 104 mV/sec, respectively) and, more significantly, the measured conductances differ by only about 20% at the two sweep rates rather than by a factor of four as predicted by Eq. [24]. The dependence of measured conductance on potential is comparable to that shown in the table, but this is probably fortuitous in view of the other discrepancies. Their data therefore indicate that the a-c conductance does not reflect Eq. [24]. Rather, it is likely that even at this relatively low frequency (32.5 Hz) the resistance of the oxide film is shorted by its capacitance and the measured a-c conductance reflects the lower effective resistance of other steps in the oxidation process; *i.e.*, steps other than ion transport across the oxide film (*e.g.*, charge transfer processes in the double layer).

Summary

The present experiments and analysis show conclusively that for the range of coverage between one and three monolayers the law of anodic growth of oxide film on platinum is precisely the same whether the film is grown potentiostatically, galvanostatically, or potentiodynamically.

A comparison of galvanostatic and hybrid galvano-potentiostatic experiments shows that there is no aging of the film over a time interval, Δt, comparable to the duration of the experiments (20 sec $\leq \Delta t \leq$ 150 sec). The effect of "holding" (*i.e.*, interrupting the potential sweep and maintaining a constant potential for a time) during potentiodynamic experiments is explained entirely in terms of the potentiostatic growth of the oxide film during the holding period.

A correspondence is analytically established between galvanostatic and potentiodynamic data, and this correspondence is verified experimentally. Galvanostatic and potentiodynamic data both show that the growth of the oxide film cannot be explained by any mechanism for which $(\partial V/\partial q)_i$ is independent of i (*e.g.*, adsorption). The high-field ionic conduction model accounts for the major features of all the data.

Table I

	S (mV sec⁻¹)	26	104
	i ($\mu A/cm^2$)	33	130
Potential	0.85V (SCE)	2	8
	1.15V (SCE)	1	4

The four entries in lower right section of table show the conductances (mmho cm^{-2}) (calculated from Eq. [24]) for the conditions shown above and to the left.

[8] See, *e.g.*, Ref. (8).

Transient deviations from the potentiodynamic "steady state" are analyzed in terms of a "time constant" that can be calculated from galvanostatic data. The calculation is verified by experimental potentiodynamic transient measurements, and it is shown that the interpretation of a-c conductance measurements depends on whether the period of the a-c excitation is larger or smaller than the potentiodynamic time constant.

The Electrochemical Oxidation of N,N,N',N'-Tetramethylbenzidine in Molten Sodium Tetrachloroaluminate

D. E. Bartak* and R. A. Osteryoung*

Department of Chemistry, Colorado State University, Fort Collins, Colorado 80523

ABSTRACT

The electrochemical oxidation of N,N,N',N'-tetramethylbenzidine (TMB) in molten sodium tetrachloroaluminate at 175° was investigated as a function of pCl^- The predominant species in these media was identified by ultraviolet spectroscopic and potentiometric techniques to be an aluminum chloride-TMB dicomplex in the pCl^- range of one to four. A chemical transformation of the dicomplexed amine to a monocomplexed amine precedes electron transfer. A $k_f'k_1$ value of 5×10^6 liters $mole^{-1}$ sec^{-1} for the reaction $TMB(AlCl_3)_2 + Cl^- \underset{k_b'}{\overset{k_f'}{\rightleftarrows}} TMB(AlCl_3) + AlCl_4^-$ with $K_1 = \frac{k_f'}{k_b'}$ was found using normal pulse voltammetric and chronoamperometric techniques. The dicomplexed amine is electroactive at more positive potentials. The product of both electron transfer processes is the orange dication of TMB. Cyclic voltammetric and constant potential coulometric techniques were used in obtaining diagnostic criteria for the elucidation of the above reaction pathways.

While the electrochemistry of a large number of organic compounds has been studied in a variety of aprotic and protonic solvents, very little organic electrochemistry has been reported in molten salt media. Aluminum chloride-alkali metal chloride melts have properties which should make electrochemical studies of organic compounds both feasible and interesting, namely: (*i*) low liquidus temperature, (*ii*) easily prepared and purified, (*iii*) aprotic, ionic characteristics, (*iv*) complete absence of water, and (*v*) acid-base properties which are readily manipulated. These melts also have possible applications in battery and fuel cell systems (1, 2).

Four papers, to date, have been published concerning organic electrode reactions in molten aluminum chloride-alkali metal chloride mixtures. Fleischmann and Pletcher (3) studied the oxidation of a series of aromatic hydrocarbons in 50-36-14 mole per cent (m/o) $AlCl_3$-NaCl-KCl at 150°C. Jones, Boxall, and Osteryoung (4, 5) examined the oxidation of triphenylamine and N,N-dimethylaniline in 50:50 m/o $AlCl_3$-NaCl at 175°C. They found unusual stabilization of the amine radical cations, via cyclic voltammetric data, relative to amine cation radical behavior in acetonitrile. Fung, Chambers, and Mamantov (6) have recently reported on the electrochemical oxidation of tetrathioethylene and thianthrene in molten $AlCl_3$-NaCl mixtures. The corresponding dications were also more stable in molten chloroaluminates at 150° than in "dry" acetonitrile at 25°C.

The sodium tetrachloroaluminate (50:50 m/o $AlCl_3$-NaCl) melt can be considered as a Lewis acid-base system by the following equilibrium

$$2AlCl_4^- \overset{K_m}{\rightleftarrows} Al_2Cl_7^- + Cl^-, \quad K_m = \frac{[Al_2Cl_7^-][Cl^-]}{[AlCl_4^-]^2} \qquad [1]$$

in which the heptachloroaluminate ion and the chloride ion are the Lewis acid and base, respectively. The equilibrium recently has been studied by a number of workers. Tremillion and Letisse (7) obtained a K_m value of 13.3×10^{-8}. Torsi and Mamantov (8) studied various aluminum chloride-alkali metal chloride mixtures and found a K_m value of 8.8×10^{-8} for sodium

* Electrochemical Society Active Member.

Key words: oxidation of tetramethylbenzidine, fused salts, aluminum chloride melts, pulse polarography.

tetrachloroaluminate at 175°C. Boxall *et al* (9) recently reported on the above equilibrium in relation to two additional equilibrium reactions pertinent to tetrachloroaluminate media (Eq. [2] and [3])

$$2AlCl_{3(l)} \overset{K_0}{\rightleftarrows} Al_2Cl_{6(l)} \quad [2]$$

$$AlCl_4^- + AlCl_3 \overset{K_3}{\rightleftarrows} Al_2Cl_7^- \quad [3]$$

By using these three reactions to describe the $AlCl_3$-NaCl system and a concentration-dependent $AlCl_4^-$ activity coefficient, Boxall and co-workers obtained a K_m value of 10.6×10^{-8} at 175°C.

The electrode reaction on an aluminum surface in these melts can be written as

$$AlCl_4^- + 3e^- \rightleftarrows Al^\circ + 4Cl^- \quad [4]$$

with the electrode potential given by

$$E_{AlCl_4^-/Al^\circ} = E^\circ - \frac{RT}{3F} ln \frac{(a_{Cl^-})^4}{a_{AlCl_4^-}} \quad [5]$$

Since the activity of $AlCl_4^-$ ion remains approximately constant in the 50:50 m/o $AlCl_3$-NaCl region (7), the aluminum electrode can act as a chloride ion indicator electrode in these melts.

In this paper, we summarize the results of our investigation of the electrochemical oxidation of N,N,N',N'-tetramethylbenzidine (TMB) in molten sodium tetrachloroaluminate. The acid-base behavior of the melt in relation to that of the amine determines the electroactive species and the chemical reactions that are important in electron transfer processes involving organic compounds in such media.

Results and Discussion

Cyclic voltammetry.—The cyclic voltammetric behavior of N,N,N',N'-tetramethylbenzidine (TMB) in sodium tetrachloroaluminate melt at 175°C with $pCl^- = 1.1$ (*i.e.*, most basic condition possible, as the melt is saturated with sodium chloride) is shown in Fig. 1. Since $i_{p,c} = i_{p,a}$, the electrochemistry of TMB comprises a chemically reversible couple at this pCl^- and scan rate. At a scan rate of 0.05 V/sec, $E_{p,a} - E_{p,c}$ is approximately 55 mV, which is significantly less than that expected for a reversible one-electron process (86 mV/n at 175°C) (10) and more consistent with a quasireversible, two-electron process to form the TMB dication.

The electrochemical oxidation of TMB was studied as a function of increasing pCl^- of the melt (Fig. 2).

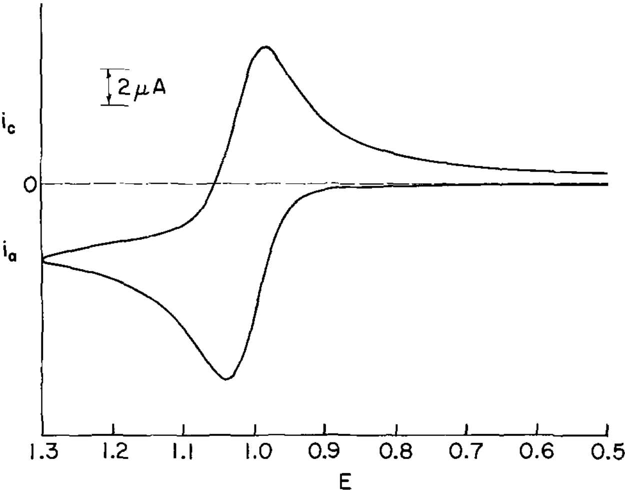

Fig. 1. Cyclic voltammogram of $5.2 \times 10^{-3}M$ N,N,N',N'-tetramethylbenzidine (TMB) in $NaAlCl_4$ melt at 175°C and $pCl^- = 1.1$. Scan rate, 0.1 V/sec; tungsten planar electrode ($A = 0.01$ cm²).

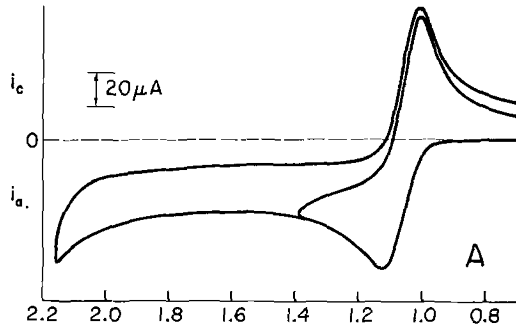

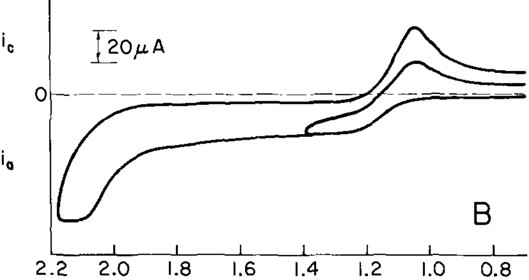

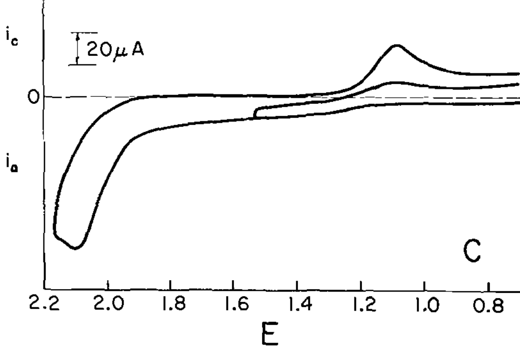

Fig. 2. Cyclic voltammograms of $3.6 \times 10^{-3}M$ TMB in $NaAlCl_4$ melt at a scan rate of 0.25 V/sec on a tungsten planar electrode ($A = 0.07$ cm²). (A) $pCl^- = 1.5$; (B) $pCl^- = 2.5$; (C) $pCl^- = 3.5$.

At a constant scan rate of 0.25 V/sec, the oxidation wave near 1.1V shifts positively as the pCl^- is increased. At a pCl^- of 2.5, a second wave emerges at more positive potentials (~2.1V). As the pCl^- is increased to 3.5, the second wave becomes even more predominant. In order to determine the processes responsible for the two oxidation waves, the scan rate was varied at a constant pCl^-. With increasing scan rate at acidic pCl^-'s, $i_p/v^{1/2}$ for the first wave decreased, while $i_p/v^{1/2}$ for the second wave increased. These results indicate that both oxidations are kinetically controlled and the equilibrium, which characterizes the two electroactive species, is pCl^- dependent.

The peak current of the single reduction wave is dependent on whether the scan rate is reversed after the first oxidation wave ($E_\lambda = 1.6V$) or after both oxidation waves ($E_\lambda = 2.2V$) (Fig. 3). Since the reduction peak current is increased when $E_\lambda = 2.2V$ *vs.* $E_\lambda = 1.6V$, the cathodic wave near 1.1V includes the reduction of a product of both oxidation reactions. Furthermore, when $E_\lambda = 1.6V$ and $pCl^- > 2.0$, the ratio of the peak cathodic to peak anodic current, determined by Nicholson's empirical method (11), was found to exceed one. This suggests that a chemical reaction precedes electron transfer for the first oxidation wave.

The peak potential of the single reduction wave is scan rate and pCl^- dependent. At constant, acidic pCl^-'s, the reduction peak potential shifts in a negative direction with increasing scan rate. The reduction

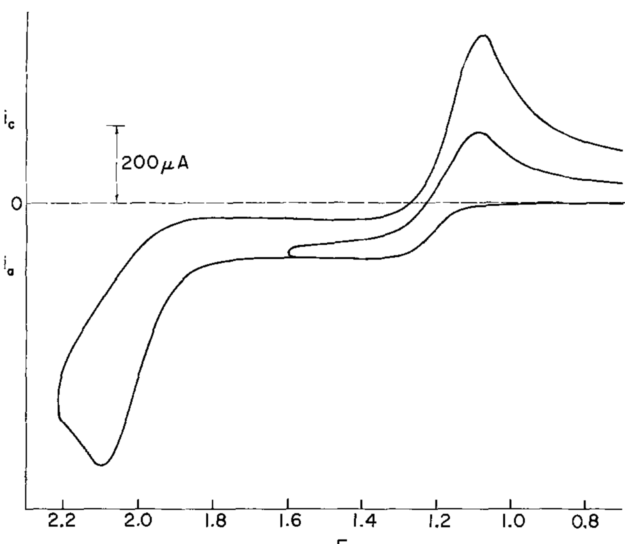

Fig. 3. Cyclic voltammograms of 29 × 10^{-3}M TMB in $NaAlCl_4$ melt at pCl^- = 3.4 and at a scan rate of 0.5 V/sec on a vitreous carbon planar electrode (A = 0.08 cm^2).

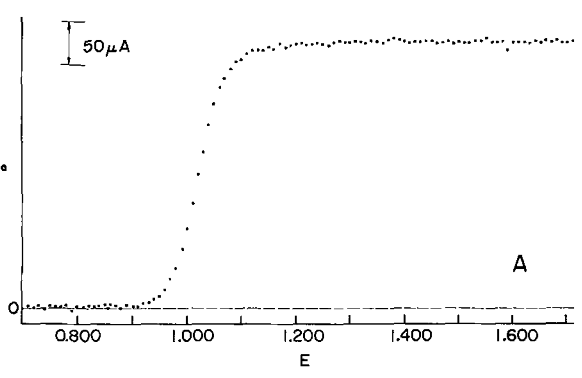

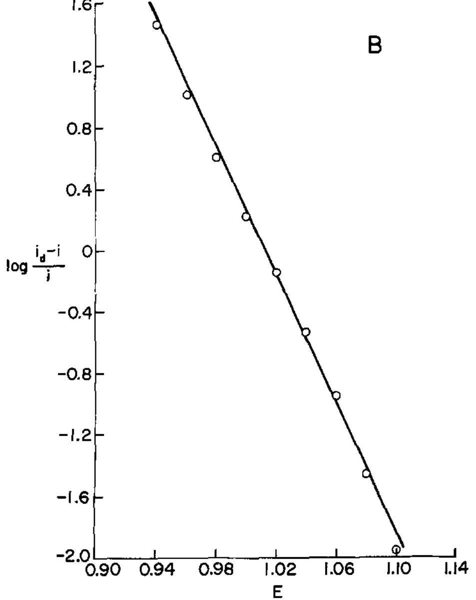

Fig. 4. (A) Normal pulse voltammogram of 5 × 10^{-3}M TMB in $NaAlCl_4$ melt at 175°C and pCl^- = 1.1. Pulse width, 50 msec; delay time, 0.5 sec; tungsten planar electrode (A = 0.07 cm^2). (B) Plot of log $i_d - i/i$ vs. E from normal pulse voltammogram of 5 × 10^{-3}M TMB. Pulse width, 500 msec; delay time, 0.5 sec; tungsten planar electrode (A = 0.07 cm^2).

peak potential shifts positively with increasing pCl^-, at a constant scan rate. These results are consistent with the theoretical model which involves electron transfer, followed by a pCl^- dependent chemical reaction.

Coulometry.—Exhaustive, controlled-potential electrolysis of TMB in basic (pCl^- = 1.1), tetrachloroaluminate melt at a potential of 1.5V gave an n value of 2 (n_{expt} = 1.85). The melt turned from almost colorless to bright orange during the course of the electrolysis. Cyclic voltammetric examination of the exhaustively electrolyzed amine indicated the presence of a reducible species in the melt with $E_{p,c}$ = 1.0V (*i.e.*, the dication of TMB). The bright orange color disappeared after approximately 1 hr with a resultant decrease in the height of the reduction wave. Thus the dication of TMB in the tetrachloroaluminate melt at pCl^- = 1.1 is unstable for long times.

Normal pulse voltammetry (12, 13).—Normal pulse voltammetry was used to elucidate the electrode reaction for TMB in the sodium tetrachloroaluminate melt. Figure 4A is a normal pulse voltammogram at a pCl^- of 1.1. At this basic pCl^-, one well-defined, anodic wave is observed and a plot of log $(i_d - i)/i$ *vs.* E (Fig. 4B) is linear with a slope of 48 mV and $E_{1/2}$ = 1.012V. As the theoretical slope is 89/n mV for reversible electron transfer at 175°C, the voltammogram represents a quasireversible, two-electron process.

The normal pulse voltammetric behavior of TMB was also studied as a function of pCl^- of the melt. The $E_{1/2}$ for the oxidation wave shifts in a positive direction as the pCl^- is increased. A plot of $E_{1/2}$ *vs.* pCl^- for the initial oxidation wave is shown in Fig. 5. The slope of 94 mV suggests that the ratio of chloride ions to electrons involved in the electrode reaction is unity (14, 15). Concurrently, as the pCl^- is increased, a second wave emerges at more positive potentials. The limiting current of the second oxidation wave, at a constant pulse width, increases as the pCl^- is increased. Simultaneously, the amplitude of the first wave decreases as the acidity of the melt is increased. The sum of the two waves at acidic pCl^-'s is approximately equal to the height of the single wave at the most basic pCl^- (Fig. 6). The ratio of the limiting current for the first wave to that of the limiting current for the second wave is a function of the pulse width (Fig. 7). These results again indicate that both oxidation waves are kinetically controlled in an acidic medium and that the species responsible for the waves are in equilibrium with one another.

The first oxidation wave is diffusion controlled for pulse widths of 10 msec to 1 sec and when pCl^- is less than 1.5 ($i_{lim}t^{1/2}$ is constant, where t = pulse width). At pCl^-'s greater than 1.5, the limiting current for the first wave is kinetically controlled and pCl^- dependent (Table I). The cyclic voltammetric and pulse voltammetric data suggest that the first wave includes a chemical reaction, which precedes electron transfer. Rate constants for the preceding chemical reaction were calculated from the pulse voltammetric data using the following equation (16)

$$\frac{i_k}{i_d} = \pi^{1/2}\lambda \exp(\lambda^2) \operatorname{erfc} \lambda \quad [6]$$

where $\lambda = (k_f K t)^{1/2}$ and i_k = kinetic current, i_d = diffusion controlled current. The above equation is based on the model

$$Y \underset{k_b}{\overset{k_f}{\rightleftarrows}} R \overset{-ne}{\rightleftarrows} O \quad [7]$$

with K = [R]/[Y] and t = pulse width. Consistent values of $k_f'K_1$ (Table I) were obtained as a function of pCl^- and pulse width by defining the present system with the reactions

$$Y + Cl^- \underset{k'}{\overset{k_f'}{\rightleftarrows}} R + AlCl_4^- \quad [8]$$

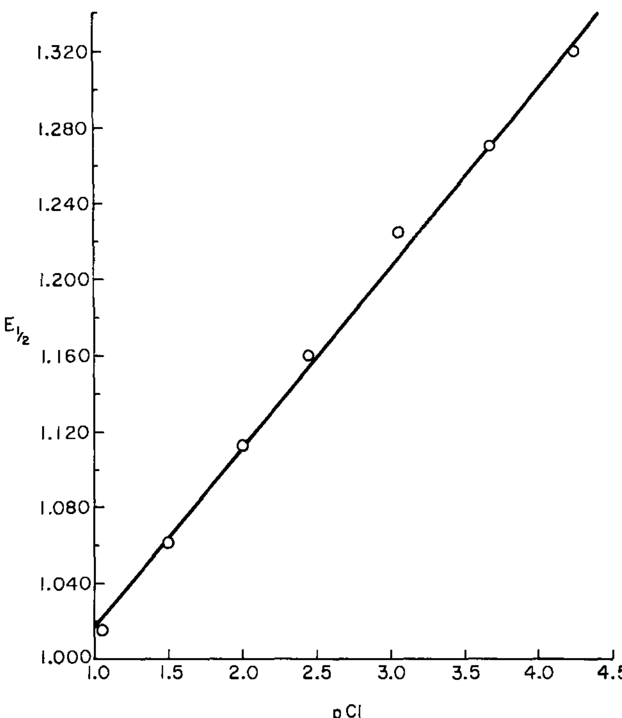

Fig. 5. Plot of $E_{1/2}$ vs. pCl^- for $5.1 \times 10^{-3}M$ TMB in $NaAlCl_4$ melt at 175°C. The slope is 94 mV. Pulse width, 100 msec; delay time, 1.0 sec; tungsten planar electrode ($A = 0.07\ cm^2$).

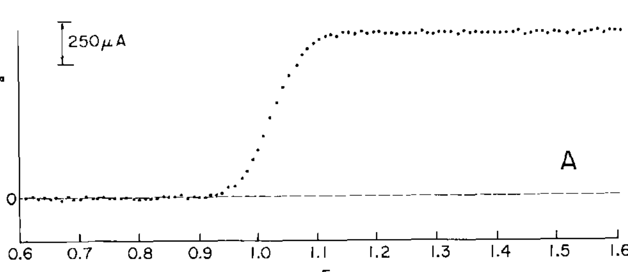

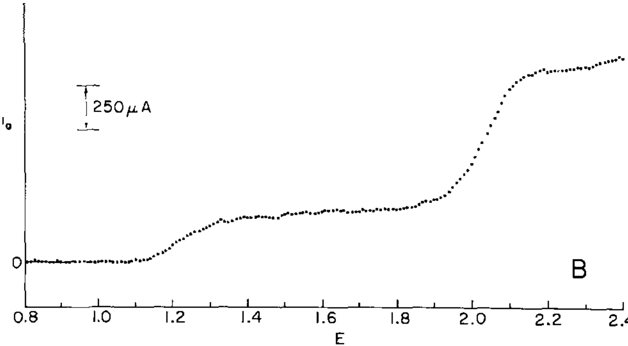

Fig. 6. Normal pulse voltammograms of $29 \times 10^{-3}M$ TMB in $NaAlCl_4$ melt at a pulse width of 100 msec and delay time of 1.0 sec. (A) $pCl^- = 1.1$; (B) $pCl^- = 3.4$. Vitreous carbon planar electrode ($A = 0.08\ cm^2$).

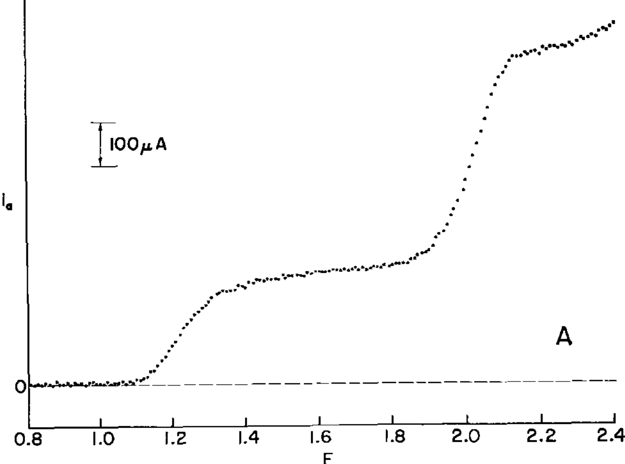
$$R \rightleftarrows O + 2e^- \quad [9]$$

with $K_1 = k_f'/k_b'$.[1]

Chronoamperometry.—Single potential step chronoamperometry was also used to study the kinetics of the preceding chemical reaction, which is associated



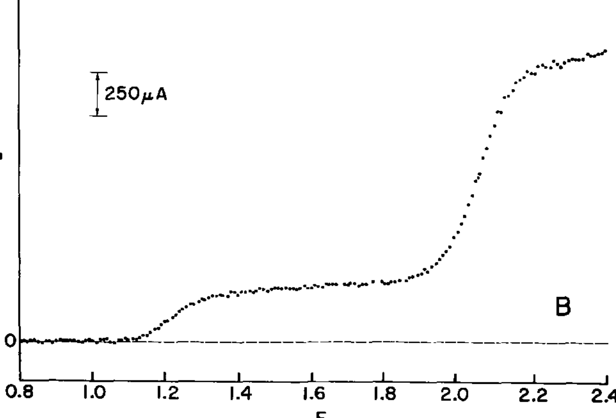


Fig. 7. Normal pulse voltammograms of $29 \times 10^{-3}M$ TMB in $NaAlCl_4$ melt at $pCl^- = 3.4$. (A) Pulse width, 200 msec; delay time, 2 sec; (B) pulse width, 50 msec; delay time, 0.5 sec. Vitreous carbon planar electrode ($A = 0.08\ cm^2$).

with electron transfer for the first oxidation wave of TMB. In this technique the potential is stepped from a potential where no electrochemical reaction takes place

[a] Concentration of TMB is $5.1 \times 10^{-3}M$; area of tungsten electrode is 0.07 cm^2.
[b] Diffusion limiting current at 10 msec pulse width is 650 μA ($pCl^- = 1.1$).
[c] All values for current expressed in microamperes.
[d] Liter $mole^{-1}\ sec^{-1}$.
[e] Diffusion limiting current at 100 msec pulse width is 210 μA ($pCl^- = 1.1, 1.5$).
[g] Diffusion limiting current at 500 msec pulse width is 90.5 μA (pCl^- 1.1, 2.0).
[h] Diffusion limiting current at 1.0 sec pulse width is 66 μA ($pCl^- = 1.1, 2.0$).

[1] Since $K_1 = \frac{[R][AlCl_4^-]}{[Y][Cl^-]}$ and $k_f' = \frac{k_f}{[Cl^-]}$, then $k_f K = k_f' K_1 [Cl^-]^2/[AlCl_4^-]$ with $[AlCl_4^-] = 8.8M$ in the 50:50 m/o $AlCl_3$:NaCl melt.

(0.7V) to a potential beyond the first wave (1.5V), but not into the second wave. The resulting constant $it^{1/2}$ values indicate diffusion-control (5 msec $< t <$ 2 sec) at $p\mathrm{Cl}^-$'s of 1.1 and 1.5. However, the $it^{1/2}$ values decrease as a function of time at $p\mathrm{Cl}^-$'s greater than 1.5. The finite rate of the dissociation reaction for the amine-aluminum chloride complex is responsible for the decrease in $it^{1/2}$ values with decreasing time. As the $p\mathrm{Cl}^-$ is increased to more acidic values, the equilibrium, which governs the dissociation of the complex, is shifted to the left (*i.e.*, lower bulk concentration of electroactive species).

Figure 8 is a plot of n_{app} where

$$n_{\mathrm{app}} = \left(\frac{(it^{1/2})_{\mathrm{kinetic}}}{(it^{1/2})_{\mathrm{diffusion}}} \right) n \qquad [10]$$

as a function of time at $p\mathrm{Cl}^-$'s from 1.1 to 3.7. Good agreement between the experimental data and a theoretical curve, obtained by computer simulating a CE mechanism (17, 18), is found at $p\mathrm{Cl}^-$ of 2.0 ($k_f'K_1 = 4 \times 10^6$ liters mole^{-1} sec^{-1}), $p\mathrm{Cl}^-$ of 2.5 ($k_f'K_1 = 4 \times 10^6$ liters mole^{-1} sec^{-1}), $p\mathrm{Cl}^-$ of 3.0 ($k_f'K_1 = 3 \times 10^6$ liters mole^{-1} sec^{-1}), and $p\mathrm{Cl}^-$ of 3.6 ($k_f'K_1 = 5 \times 10^6$ liters mole^{-1} sec^{-1}) for reaction [8].[2] Thus the data are consistent with a CE model in which the formation of electroactive species is first order in chloride ion concentration.

Spectroscopy.—Spectrophotometric techniques were were employed to determine, if possible, the values for the amine-complex equilibrium constants. The sodium tetrachloroaluminate melt at 175° has an excellent optical window with a 200 nm cutoff. Since amines have been shown to absorb in the ultraviolet region, the u.v. spectrum of TMB was studied as a function of $p\mathrm{Cl}^-$. N,N,N',N'-tetramethylbenzidine in the $NaAlCl_4$ melt revealed a $\lambda_{\max}$ at 256 nm with an extinction coefficient of greater than 10^3. However, the TMB spectrum was $p\mathrm{Cl}^-$ independent over the $p\mathrm{Cl}^-$ range of

[2] Computer simulation of CE mechanism was based on the model: $Y \underset{k_b}{\overset{k_f}{\rightleftarrows}} R \xrightarrow{-ne} O$, where [Y] >> [R]. Values of $k_f'K_1$ for reaction [8] were calculated from $k_f'K_1 = k_f K[AlCl_4^-]/(Cl^-)^2$.

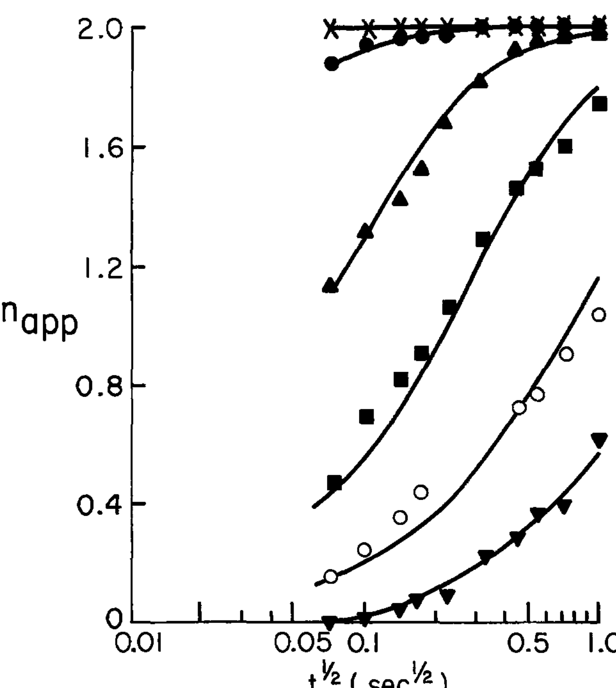

Fig. 8. Single potential step chronoamperometric data for 5.2×10^{-3}M TMB as a function of $p\mathrm{Cl}^-$. (x) $p\mathrm{Cl}^- = 1.1$; (●) $p\mathrm{Cl}^- = 1.5$; (▲) $p\mathrm{Cl}^- = 2.0$; (■) $p\mathrm{Cl}^- = 2.5$; (○) $p\mathrm{Cl}^- = 3.0$; (▼) $p\mathrm{Cl}^- = 3.6$. The solid line was obtained by digital simulation of Eq. [7] with Y >> R.

1-4. Diprotonated TMB (via perchloric acid) in acetonitrile has been shown by Saget and Plichon (19) to have a $\lambda_{\max}$ of 250 nm, while the monoprotonated and the unprotonated form of the diamine exhibit $\lambda_{\max}$ values of 320 and 310 nm, respectively. The u.v. spectrum of biphenyl was also obtained in the $NaAlCl_4$ melt at 175°C and exhibited a $\lambda_{\max}$ at 253 nm with an extinction coefficient greater than 10^3. The literature $\lambda_{\max}$ value for the $\pi \rightarrow \pi^*$ transition of biphenyl in a solvent such as cyclohexane is 252 nm with an extinction coefficient of 19,000 (20). An interesting analogy is the case of benzene ($\lambda_{\max}$ = 255 nm, ϵ = 230) and aniline ($\lambda_{\max}$ = 280 nm, ϵ = 1430), the latter of which has $\pi \rightarrow \pi^*$ transition energy requirements reduced due to n-π conjugation. However, the anilinium ion, which does not have any nonbonding electrons for n-π conjugation shows $\lambda_{\max}$ of 254 nm with ϵ = 160 (20).

Since the apparent $\pi \rightarrow \pi^*$ transition for TMB in $NaAlCl_4$ is independent of $p\mathrm{Cl}^-$ and resembles that for biphenyl in the same medium the predominant TMB species in even the most basic melt is thought to be an acid-base adduct[3] with the nonbonding electrons on the amino group being shared with a Lewis acid, in this case, aluminum chloride, *i.e.*

$$CH_3-N(CH_3)(AlCl_3)-C_6H_4-C_6H_4-N(CH_3)(AlCl_3)-CH_3$$

Electrode reaction pathways.—The spectroscopic and potentiometric evidence indicates that N,N,N',N'-tetramethylbenzidine forms a Lewis acid-base complex in the sodium tetrachloroaluminate melt. The predominant species present in the melt at the most basic $p\mathrm{Cl}^-$ is the aluminum chloride dicomplex of the amine, *i.e.*, $TMB(AlCl_3)_2$. The equilibria which best describe this chemical system can be written as

$$TMB(AlCl_3)_2 + Cl^- \overset{K_1}{\rightleftarrows} TMB(AlCl_3) + AlCl_4^- \qquad [11]$$

$$TMB(AlCl_3) + Cl^- \overset{K_2}{\rightleftarrows} TMB + AlCl_4^- \qquad [12]$$

Since the electrochemical data indicate the presence of a precursor chemical reaction accompanying electron transfer, the first anodic wave at $E_{1/2} = +(0.922 + 0.094\, p\mathrm{Cl}^-)$V includes the two-electron oxidation of either the uncomplexed or monocomplexed species to a dication. Furthermore the $E_{1/2}$ *vs.* $p\mathrm{Cl}^-$ plot for the first wave indicates that the ratio of chloride ions to electrons involved in the total electrode reaction is unity. Since the exhaustive electrolysis data demonstrate unequivocally that the first anodic wave involves two electrons, the stoichiometry of chloride ions in the electrode reaction must also be two.

Three reaction schemes can readily be postulated to account for the oxidation of a diamine (either free or monocomplexed) and which includes the same number of chloride ions and electrons (two) in the total electrode reaction. In the first scheme the dicomplex dissociates via two discrete reactions to the free diamine, which is then oxidized to its dication

Scheme I

[3] Potentiometric studies, whereby Al^{+3} (via Al° anodization) was added to a basic melt containing the amine, also indicated that the amine was completely complexed at $p\mathrm{Cl}^-$ = 1.1, since the titration curve shows no break other than that for the solvent tetrachloroaluminate equilibrium (9). Addition of TMB to a basic melt ($p\mathrm{Cl}^-$ = 1.1) precipitates sodium chloride from such a melt. Potentiometric titration of TMB with solid $AlCl_3$ indicated stoichiometry for dicomplex formation. In this experiment, the $p\mathrm{Cl}^-$ of the melt is initially adjusted to 2.5 (least buffered $p\mathrm{Cl}^-$ region). Aluminum chloride (127 mg) is then added to the melt (~10 mliters), with a resultant increase in $p\mathrm{Cl}^-$ to values greater than 4. The amine (TMB) is then added slowly with stirring until the $p\mathrm{Cl}^-$ is adjusted back to 2.5. From the weight of the amine added (112 mg) the ratio of $AlCl_3$ to TMB is 2:1.

$$TMB(AlCl_3)_2 + Cl^- \underset{k_b'}{\overset{k_f'(\text{fast})}{\rightleftarrows}} TMB(AlCl_3) + AlCl_4^-,$$

$$K_1 = \frac{k_f'}{k_b'} \quad [13]$$

$$TMB(AlCl_3) + Cl^- \underset{k_b''}{\overset{k_f''(\text{slow})}{\rightleftarrows}} TMB + AlCl_4^-,$$

$$K_2 = \frac{k_f''}{k_b''} \quad [14]$$

$$TMB \rightleftarrows TMB^{+2} + 2e^- \quad [15]$$

Formation of the electroactive diamine in scheme I would be second order in chloride ion concentration. In the second scheme, the free diamine is again the electroactive species, however, its formation is first order in chloride ion concentration

Scheme II

$$TMB(AlCl_3)_2 + Cl^- \underset{k_b''}{\overset{k_f'(\text{slow})}{\rightleftarrows}} TMB(AlCl_3) + AlCl_4^-,$$

$$K_1 = \frac{k_f'}{k_b'} \quad [16]$$

$$TMB(AlCl_3) + Cl^- \underset{k_b''}{\overset{k_f''(\text{fast})}{\rightleftarrows}} TMB + AlCl_4^-,$$

$$K_2 = \frac{k_f''}{k_b''} \quad [17]$$

$$TMB \rightleftarrows TMB^{+2} + 2e^- \quad [18]$$

In scheme III the electroactive species is the monocomplexed diamine and its formation is first order in chloride ion concentration

Scheme III

$$TMB(AlCl_3)_2 + Cl^- \underset{k_b'}{\overset{k_f'(\text{slow})}{\rightleftarrows}} TMB(AlCl_3),$$

$$K_1 = \frac{k_f'}{k_b'} \quad [19]$$

$$TMB(AlCl_3) \rightleftarrows TMB(AlCl_3)^{+\cdot} + e^-, E_1 \quad [20]$$

$$TMB(AlCl_3)^{+\cdot} + Cl^- \xrightarrow{\text{fast}} TMB^{+\cdot} + AlCl_4^- \quad [21]$$

$$TMB^{+\cdot} \rightleftarrows TMB^{+2} + e^-, E_2 \quad [22]$$

where $E_1 > E_2$.

The normal pulse voltammetric and chronoamperometric data indicate that the electroactive species for the first wave is formed by a chemical reaction which is kinetically first order in chloride ion concentration. Thus, both schemes II and III are valid possibilities that could represent the total electrode process describing the anodic wave at $E_{1/2} = +(0.922 + 0.094\ pCl^-)$V. In scheme II, k_f' is less than k_f''. If one assumes that $k_b' \approx k_b''$ (diffusion controlled), then K_1 is less than K_2. The acid dissociation constants for common diprotic acids are usually such that K_1 is greater than K_2 (*e.g.*, dissociation of protonated TMB in acetonitrile (19). Therefore, scheme III is the more acceptable model and the total electrode reaction for the initial anodic wave includes the oxidation of the monocomplex of the diamine with $K_1k_f' = 5 \times 10^6$ liters mole^{-1} sec^{-1}. Since the value for K_1 must be less than 10, (at $pCl^- = 1.1$, predominant species is dicomplexed amine) a k_f' value of 5×10^5 liters mole^{-1} sec^{-1} represents a lower limit for this second order reaction.

The dicomplexed form of the amine can be assumed to be difficult to oxidize, because both unshared pairs of electrons on the amino groups are no longer available for electron transfer. One might expect, therefore, the oxidation potential of the dicomplex ($TMB(AlCl_3)_2$) to be similar to that of biphenyl. The electrochemical oxidation of biphenyl was investigated briefly in the sodium tetrachloroaluminate melt at 175°C. Cyclic voltammetric evidence indicates that biphenyl is oxidizable in this medium with $E_{p/2} = 1.8$ and 2.0V on a vitreous carbon electrode *vs.* the saturated sodium tetrachloroaluminate-aluminum reference electrode. Fleischmann and Pletcher (6) have reported $E_{p/2}$ values for the oxidation of biphenyl in 50:36:14 m/o $AlCl_3$:NaCl:KCl melt at 150°. The two waves observed for the oxidation of biphenyl were at $E_{p/2} =$ 1.66 and 2.03V on a pyrolytic graphite electrode *vs.* an aluminum reference electrode. Thus, as the predominant species in the melt is a dicomplex and the less positive anodic wave involves the oxidation of a monocomplex, we have concluded that the wave at $E_{1/2} =$ 1.95V involves the oxidation of a dicomplex of the amine, *e.g.*, $TMB(AlCl_3)_2$. Furthermore, the cyclic voltammetric data at an acidic pCl^- (Fig. 3) reveal that the product of the more positive wave ($E_{1/2} =$ 1.95V) is identical to the oxidation product of the less positive wave ($E_{1/2} = (0.922 + 0.094\ pCl^-)$V). The reaction for the second oxidation wave can be written

$$TMB(AlCl_3)_2 \rightleftarrows TMB^{+2} + 2AlCl_3 + 2e^- \quad [23]$$

The normal pulse voltammetric data indicate that the limiting current for the more positive wave is pCl and pulse width dependent, however the $E_{1/2}$ value for this wave is pCl^- independent. The oxidation of a dicomplex as written in Eq. [23] would be expected to be pCl^- dependent if electron transfer were reversible (*i.e.*, Nernstian). If, however, electron transfer is slow or irreversible, the $E_{1/2}$ values are determined solely by the kinetics of the charge-transfer process.

A plot of log $(i_d - i)/i$ *vs.* E for the second anodic wave at a pCl^- of 4.0 reveals a slope of 105 ± 5 mV over a tenfold increase in concentration, and using either a tungsten or vitreous carbon electrode. Since the Nernstian value for a reversible two-electron process at 175°C is 45 mV, the second wave is clearly not reversible. The cyclic voltammetry data indicate the presence of an EC mechanism since no reverse current for the reduction of the product of the second anodic wave is observed on the cathodic sweep until one reaches potentials at which the product of the first oxidation wave is reduced (*i.e.*, the dication of TMB). An EC mechanism, in which reversible electron transfer precedes a rapid follow-up reaction, requires that $E_{p,a} - E_{p/2,a} = 72/n$ mV and that E_p shifts anodically $45/n$ mV for each tenfold increase in scan rate (at 175°C) (10). We observe $E_{p,a} - E_{p/2,a}$ for the second wave to vary from 80 to 90 mV depending on scan rate for TMB in acidic melts (*i.e.*, $pCl^- > 3.5$). Furthermore, $E_{1/2}$ (as determined from normal pulse voltammetry) shifts anodically approximately 70 mV for every tenfold decrease in the pulse width. Thus, we conclude that electron transfer, even though relatively rapid, must be slow relative to the rates of the follow-up reactions (10, 21) (*i.e.*, loss of $AlCl_3$ from the oxidized form of the dicomplex). Therefore, the probable electrode reaction for the second wave can be written as

$$TMB(AlCl_3)_2 \xrightarrow{\text{slow}} TMB(AlCl_3)_2^{+\cdot} + e^-, E_1$$

$$TMB(AlCl_3)_2^{+\cdot} + 2Cl^- \xrightarrow{\text{fast}} TMB^{+\cdot} + 2AlCl_4^-$$

$$TMB^{+\cdot} \rightleftarrows TMB^{+2} + e^-, E_2$$

where $E_1 > E_2$.

Cyclic voltammetric data indicate that the peak potential for the single cathodic wave is scan rate and pCl^- dependent. The reduction peak potential shifts positively with increasing pCl^- and decreasing scan rate. As these results are consistent with an EC model, one can write the reactions for the reduction wave as

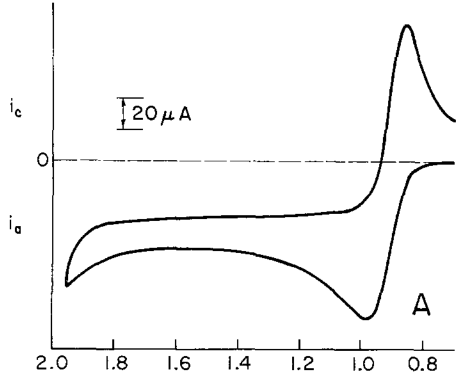
$$TMB^{+2} + 2e^- \rightleftarrows TMB$$

$$TMB + 2AlCl_4^- \xrightarrow{\text{fast}} TMB(AlCl_3)_2 + 2Cl^-$$

Lithium tetrachloroaluminate system.—A 50:50 m/o $LiCl-AlCl_3$ melt system was also used in the study of these amine-aluminum chloride complexes. It was initially hoped that since the pK_m' for the $LiCl-AlCl_3$ system was 2.46 (22) as compared to 5.08 for the $NaCl-AlCl_3$ system,[4] one could obtain melts of lower acidity with the lithium tetrachloroaluminate system and thus obtain accurate equilibrium constants via spectroscopic methods for the amine-aluminum chloride complexes. However, due to the limited solubility of LiCl in $LiAlCl_4$ at 175°C the pCl^- of a saturated LiCl melt at 175° is 0.3. Figure 9A is a cyclic voltammogram of TMB in the $LiAlCl_4$ melt (saturated with LiCl) (*i.e.*, $pAl_2Cl_7^- = 2.2$), while Fig. 9B is a cyclic voltammogram of TMB in a $NaAlCl_4$ melt adjusted by Al anodization to a pCl^- of 2.2 (*i.e.*, $pAl_2Cl_7^- = 2.9$). The general shape of the wave and the ΔE_p value are qualitatively the same for the TMB in the two melt systems. Since the electrochemistry of TMB in the two melt systems is heptachloroaluminate ion concentration dependent in the same qualitative relationship, it is reasonable to assume that the amine is complexed with the $Al_2Cl_7^-$ or $AlCl_3$ species. The formation of aluminum chloride-amine complexes in organic solvents have been previously reported in the literature (23, 24). Eley and co-workers (25-27) have reported heats of reaction for several aliphatic and aromatic amine-aluminum chloride complexes. They found that the greater the electron density on the nitrogen atom, the higher the heat of mixing or the stronger the bond formed between the donor-acceptor moieties.

Drahowzahl (28) found that complexes of aromatic tertiary amines with aluminum chloride, such as $C_6H_5N(CH_3)_2 \cdot AlCl_3$ are useful catalysts for the alkylation of aromatics with alkyl halides.

[4] K_m' is defined: $K_m' = [Al_2Cl_7^-][Cl^-] = K_m[AlCl_4^-]^2$ where $[AlCl_4^-] = 8.8M$ in $NaAlCl_4$ and $[AlCl_4^-] = 9.3M$ in $LiAlCl_4$.



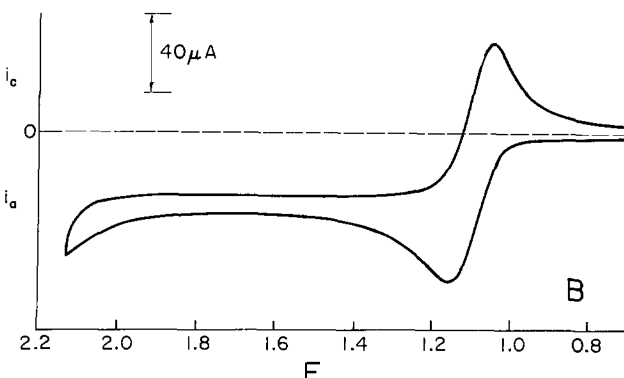


Fig. 9. (A) Cyclic voltammogram of 7×10^{-3}M TMB in lithium tetrachloroaluminate at 175°C and $pCl^- = 0.3$. Scan rate, 0.1 V/sec; tungsten planar electrode (A = 0.07 cm²). (B) Cyclic voltammogram of 5.2×10^{-3}M TMB in sodium tetrachloroaluminate at 175°C and $pCl^- = 2.2$. Scan rate, 0.1 V/sec; tungsten planar electrode (0.07 cm²).

Experimental Section

Electrochemical instrumentation.—The cyclic voltammetric, chronoamperometric, and pulse voltammetric studies were performed on a multipurpose instrument utilizing operational amplifier circuitry described previously (29). The above instrument was interfaced (30) to Digital Equipment Corporation Models PDP-12 and PDP-8/e computers for the pulse voltammetric and chronoamperometric studies. Readout of the data was by either Houston Model 2000 X-Y recorder or a Hewlett-Packard Model 7030-Am X-Y recorder with point plotting capabilities.

Potentiometric studies were performed using a Leeds and Northrup Student Potentiometer and a Keithley Model 160 Multimeter. A Sargent Coulometric Constant Current Source was used during melt composition determinations, and to adjust the acidity of the melt to the required pCl^-.

Melt preparation and purification.—All of the experimental work was carried out under a purified argon atmosphere in a Vacuum Atmospheres Company dry box equipped with a Model HE-493 Dri-Train for constant recirculation of the argon gas through a column consisting of activated copper and molecular sieves. In an attempt to qualitatively assess the oxygen content of the dry box atmosphere (31), 25W light bulb filaments using line voltage were burned inside the box. Satisfactory results were obtained in that the filaments' lifetime was from 7-10 days. To insure that the water content of the box atmosphere was low, P_2O_5 in evaporating dishes was also placed inside the box. Melt preparation and purification was carried out in a cell which has been previously described (32). The fusion of 2 moles of aluminum chloride (Fluka, A. G., iron-free) and 2 moles of sodium chloride (Fisher, certified ACS grade) produced a faintly yellow colored melt at 175°C. Purification of the molten mixture was accomplished by means of pre-electrolysis with an aluminum rod anode (Johnson Matthey Specpure grade), coiled aluminum wire cathode (Alfa Inorganics, m5N), and the Sargent Coulometric Constant Current Source. After ten days of electrolysis at a current density of about 0.5 mA cm^{-2}, the resultant melt was clear and colorless.

Electrodes.—Two planar working electrodes were used in pulse voltammetric and chronoamperometric studies: (*i*) a ⅛ in. diameter tungsten rod (Alfa Inorganics, m3N8) and (*ii*) 3 mm diameter vitreous carbon rod electrode (Atomergic Chemetals, V25). The tungsten rod was sealed into Pyrex using a bead of uranium glass, ground flat on an emery wheel, and polished, successively, with 600 grit silicon carbide powder and Type B alumina powder (Fisher) to a mirror-like finish. The vitreous carbon electrode was sealed in a Pyrex glass tube using the procedure described by Gupta (33) and polished in the same manner as the planar tungsten electrode.

The reference electrode was isolated for all experiments from the bulk of the melt with a fine glass frit. The reference electrode was a coiled aluminum wire in the sodium tetrachloroaluminate melt saturated with sodium chloride at 175°C. The potential of this stable reference electrode system was 175 mV negative of the aluminum electrode in a 50:50 m/o $AlCl_3$-NaCl melt.

The auxiliary electrode for all experiments was a coiled aluminum wire, which was isolated by means of a fine glass frit for the controlled potential electrolysis experiments. The working electrode for the controlled potential coulometry experiments was a tungsten gauze basket, fabricated from 100 mesh tungsten wire cloth (Research Inorganics). A Pyrex glass stirring bar was used to facilitate mass transfer for the exhaustive electrolysis experiments.

Spectrophotometric studies.—Spectra were recorded with a Cary Model 17 Spectrophotometer equipped with a water-cooled sample compartment to protect the rest of the optics during high temperature experiments.

The furnace was an aluminum block ($10 \times 10 \times 10$ cm), fitted directly into the Cary sample compartment. The furnace was heated by four Chromalox cartridge heaters, placed symmetrically about the cell holder (12.7×12.7 mm) and controlled with a Thermo Electric Model 32422 temperature controller, which was also used for electrochemical studies. The cells used were 10 mm pathlight Suprasil ($12.5 \times 12.5 \times 45$ mm) rectangular type fitted with an air-tight Teflon cover.

The melt, to which the organic compound had been added, was transferred directly in the dry box to the heated optical cell with a heated pipette. The portable furnace containing the closed cell and its contents was then taken directly out of the dry box and placed in the sample compartment of the spectrophotometer. To further insure that water or air would not enter into the closed cell, the sample compartment of the spectrophotometer was purged with prepurified nitrogen.

ABSTRACT

The electrochemistry of trithiocarbonates and trithiocarbenium ions has been studied in nonaqueous solvents, mainly in acetonitrile. Trithiocarbonates are reduced to the corresponding radical anions which undergo further chemical reactions. Anodic oxidation of trithiocarbonates leads to coupling products, but does not provide synthetic entry into the tetrathioethylenes. The latter class of compounds is available by a procedure which involves reductive coupling of trithiocarbenium cations, followed by pyrolysis of the resulting orthothiooxalates. The mechanism of the dimerization reaction appears to involve a simple radical-radical coupling (DIMI mechanism). Details of the synthetic procedure are given along with voltammetric data for six trithiocarbonates and eighteen trithiocarbenium ions.

As part of a continuing study on the electrochemistry of multisulfur heterocycles (1-4), a series of trithiocarbonates and their monoalkylated derivatives have been studied in nonaqueous solvents. The investigation was directed to the possibility of a convenient synthetic entry into tetrathioethylenes and, specifically, into derivatives of the highly interesting tetrathiofulvalenes.

The electrical properties of charge transfer complexes formed from acceptor molecules such as tetracyanoquinodimethane (TCNQ) and donor molecules such as tetrathiofulvalene (TTF) are currently of considerable interest (5, 6). The crystalline charge transfer complex, $\overset{+}{\text{TTF}}\cdot\ \overset{-}{\text{TCNQ}}\cdot$, exhibits extremely high electronic conductivity which also has a negative temperature coefficient. The conductivity of this compound has been attributed to a metallic chain in which electron delocalization occurs through an infinite stack of TTF radical cations (7). These properties are characteristic of metals and the salts have been termed "organic metals" or "unidimensional metals" in the literature.

Recently, structural modifications of one of the partners in the charge-transfer complexes have been achieved in an effort to discover more highly conducting materials. The tetramethyl (8) and tetrathiomethoxy tetrathiofulvalenes (4) have been reported. TCNQ salts of the former donor molecule are insulators at low temperature, but electronic conductors at room temperature. The tetraselenofulvalene (TSeF) has been synthesized and preliminary results indicate that $\overset{+}{\text{TSeF}}\cdot\ \overset{-}{\text{TCNQ}}\cdot$ complexes have greater electronic conductivity than the $\overset{+}{\text{TTF}}\cdot$ salt (9).

A need exists for synthetic methods for the preparation of good electron donor molecules which can be used to form new charge transfer complexes. Previous synthetic pathways to tetrathioethylenes involve oxidative elimination of sulfur from the appropriate trithiocarbonate followed by coupling of the 1,3-dithiolylium ion with base (10, 11) or by treatment of the thione with a phosphorous(III) compound (12-14). During the course of this study anodic elimination of the thiocarbonyl sulfur was observed in acetonitrile (2), but no evidence for the formation of a tetrathioethylene was noted. However, entry into the tetrathioethylenes was achieved under relatively mild electrolysis conditions by reduction of monoalkylated trithiocarbenium ions (15, 16) followed by pyrolysis of the resulting dimer (17). The electrochemical route is attractive for the formation of substituted TTF derivatives since the stringent oxidizing conditions of the above methods are avoided.

Key words: cyclic voltammetry, radical anions, radical cations, electrodimerization.

Results and Discussion

Trithiocarbonates, reduction.—Trithiocarbonates are readily reduced at mercury and platinum electrodes in nonaqueous solvents. Voltammetric data for compounds **1-3** are given in Table I. At the fastest sweep rates employed

1 2 3 4

in this study (*ca.* 200 V/sec) compounds **2-4** gave reversible one-electron cyclic voltammograms which indicates formation of the respective radical anions.

$$\text{(S,S-ring)}\!=\!S + e^- \rightleftharpoons \text{(S,S-ring)}^{\bullet}\!\!-\!S^- \quad [1]$$

This conclusion is supported by the weak electron spin resonance (ESR) signals which were obtained by cathodic electrolysis of compounds **2**, **3**, and **4** in the cavity of an ESR spectrometer. The signals which were presumably due to the respective radical anions exhibited no hyperfine structure.

At slower sweep rates the ratio of anodic to cathodic peak currents decreased to zero and the cathodic current function increased to a value roughly twice the

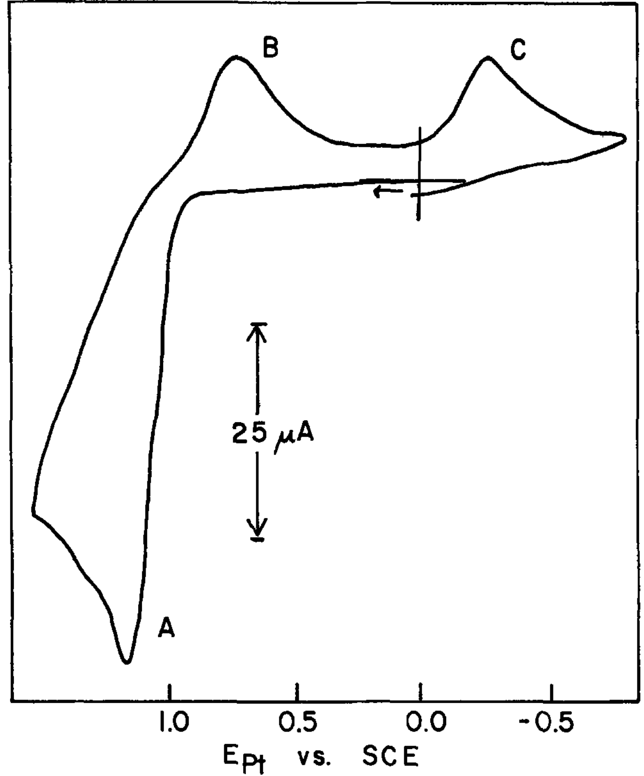

Fig. 2. Cyclic voltammogram of **2** in acetonitrile. Conditions: 1.0 × 10^{-3}M **2**, 0.1M TEAP, 0.080 V/sec, Pt electrode.

fast sweep rate value. This behavior is shown in Fig. 1 for 2 in wet acetonitrile, 0.1*M* TEAP solution. These variations and the ESR results are characteristic of an ECE mechanism although the quality of the data did not allow a distinction between various ECE pathways to be made. The peak potential data were also consistent with an ECE mechanism. For 2 the plot of E_p *vs.* log (sweep rate) exhibited two straight-line segments which intersected at $v_i \simeq 0.2$ V/sec.

Addition of the proton donors phenol or additional water to the solution had only minimal effect on the cyclic voltammograms of 2. Thus protonation of the radical anion is probably not the rate-determining chemical step in the ECE mechanism. Other reactions of the radical anion, *e.g.*, dimerization or disproportionation, are possible, but the present results do not permit further mechanistic analysis.

Cyclic voltammograms of **1** at hanging mercury drop electrodes featured a large maximum in the region of the peak potential. The data reported in Table I are approximations of the diffusion controlled current after the spike was subtracted from the voltammograms. Chronoamperometric experiments in which the potential was stepped into the region of the maximum resulted in a constant current instead of the usual Cottrell $it^{1/2}$ decay. For a 0.063 cm^2 Hg drop electrode, the current was 64 μA at −1.60V *vs.* SCE and 190 μA at −1.70V *vs.* SCE. At −1.80V *vs.* SCE, which was more negative than the spike potential region, a normal $it^{1/2}$ decay was observed. Cyclic voltammograms of **1** at platinum electrodes did not exhibit the current maximum on the reduction waves.

Trithiocarbonates, oxidation.—Extensive cyclic voltammetric experiments were carried out on the oxidation of the trithiocarbonates. An oxidation wave at *ca.* 1.0V *vs.* SCE was present for all of the trithiocarbonates studied. Figure 2 shows a cyclic voltammogram of 2 which exhibits this oxidation wave (A) and two cathodic waves (B and C) due to the reduction of oxidation products. The two product reduction waves, B and C, were not present to the same extent for all of the trithiocarbonates. Wave B was absent at sweep rates less than 5 V/sec for **4** and was absent at all sweep rates for **1**. Also wave A in the voltammograms of **1** was split into two peaks. The voltammetric parameters for the oxidation of trithiocarbonates **1-6** are given in Table II.

Table II. Cyclic voltammetric parameters for the oxidation of trithiocarbonates in acetonitrile, 0.1M TEAP: Pt electrode, sweep rate = 0.060 V/sec

Compound	Wave A			Wave B		Wave C

[f] Absent on first cycle, present in multicycle voltammograms.

5 6

The cyclic voltammetric parameters were dependent on the choice of solvent and supporting electrolyte. In addition to acetonitrile, which was the main solvent used in this study, voltammograms were obtained for solutions in benzonitrile, methylene chloride, and nitromethane. In methylene chloride at platinum electrodes, wave B showed maxima which are characteristic of adsorption of the electroactive species (18), while in nitromethane solutions wave B was absent at all sweep rates for all of the trithiocarbonates studied.

The current functions, $i_p/AC\sqrt{v}$, where i_p is the peak current, A is the electrode area, C is the concentration, and v is the sweep rate (19), of waves A, B, and C for **2** in acetonitrile are given in Fig. 3 as a function of sweep rate. The current function of wave A decreases as the sweep rate increases and approaches a value of 0.6 A cm^{-2} M^{-1} $V^{-1/2}$ $sec^{1/2}$ which is one-half the slow sweep rate value. This current function is less than half of the reversible one-electron value (1.4 cm^{-2} M^{-1} $V^{-1/2}$ $sec^{1/2}$) which is found for the formation of the radical anion, Fig. 1. The slow sweep rate current function for wave A (1.1 A cm^{-2} M^{-1} $V^{-1/2}$ $sec^{1/2}$) is consistent with an irreversible one-electron oxidation process and a diffusion coefficient of 2.7×10^{-5} cm^2 sec^{-1}. The results are consistent with a mechanism in which a dimer radical cation is formed in the initial oxidation process, Eq. [2]. This would result in an n-value of 0.5 at times less than the lifetime of the dimer radical cation.

$$2 \; (\text{trithiocarbonate}) \xrightarrow{-e^-} (\text{Dimer})^{\cdot +} \qquad [2]$$

Concurrent with the decrease in the current function of wave A, the current function of wave C decreases to zero at fast sweep rates, Fig. 3. Assignment of wave C to the reduction of a decomposition product of the dimer cation radical would account for this behavior. Similar behavior was observed for the other trithiocarbonates investigated.

The variations of the current functions of waves A, B, and C for **2** with concentration are shown in Fig. 4 and 5. At sweep rates greater than *ca.* 2 V/sec^{-1} the current function of wave A became almost independent of the concentration of **2**. Similarly, the ratio of the peak currents of waves B and A was only slightly dependent on the concentration (Fig. 5). These results suggest the rapid formation of the dimer cation radical in an electrochemically irreversible step, Eq. [2], followed by a first-order decomposition of the dimer cation radical.

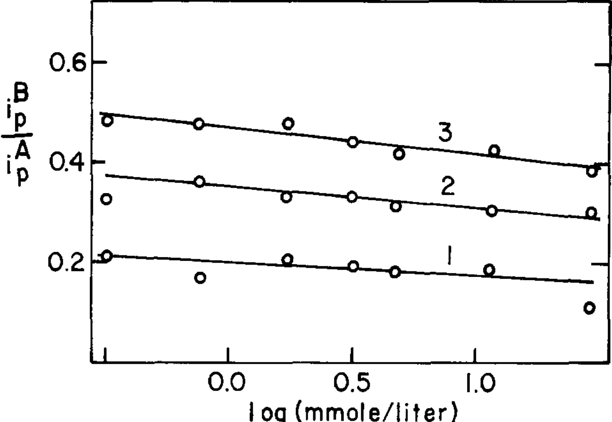

Fig. 5. Variation of the peak current ratio for wave B to wave A with concentration of compound **2**. Curve 1, 0.056 V/sec; curve 2, 0.199 V/sec; curve 3, 1.99 V/sec.

Exhaustive electrolysis of the trithiocarbonate **2** in wet acetonitrile gave a coulometric n-value of 1.9 ± 0.3. Isolation and identification of the dithiocarbonate **7** from the electrolysis solutions has been described previously (2). In addition a gummy yellow precipitate of elemental sulfur, which was not fully characterized, was obtained.

$$\mathbf{2} \xrightarrow[H_2O]{-2e^-} \mathbf{7} + 2H^+ + S \qquad [3]$$

Exhaustive electrolysis in very dry acetonitrile took place very slowly and did not lead to tractable products in our hands. Addition of water to the solutions greatly increased the rate of electrolysis.

A possible structure for the dimer cation radical is shown in Eq. [4].

$$\mathbf{8} \xrightarrow{\text{slow}} (\text{product}) + S \qquad [4]$$

This proposed structure is consistent with the known nucleophilic properties of trithiocarbenium ions (20, 21). Wave B could arise from the one-electron reduction of **8**; however, these results do not permit a distinction to be made between structure **8** and others such as a disulfide radical cation.

Several attempts were made to detect traces of tetrathioethylene in the cyclic voltammograms of **2**. The tetrathioethylene which corresponds to **2** gives characteristic reversible one-electron waves at 0.68 and 1.12V *vs.* SCE (1) which could readily be detected in the cyclic voltammograms. Square wave electrolyses were carried out between potentials positive of wave A and less than wave B. No trace of any waves which could be assigned to a tetrathioethylene wave were detected.

This electrochemical behavior can be contrasted with the oxidation of trithiocarbonates in $AlCl_3$-nitromethane solutions which leads to radical cations of tetrathioethylenes. Oxidation of **2** under these conditions produced a nine-line ESR spectrum which had a splitting pattern consistent with eight equivalent protons ($a_H = 2.41 \pm 0.03$ gauss, g-value $= 2.0079 \pm 0.0005$).

$AlCl_3/CH_3NO_2$ → **9** → [5]

The spectrum closely resembled the one obtained by electrochemical oxidation of the parent tetrathioethylene in acetonitrile (1) and was identical to the spectrum produced by $AlCl_3$ oxidation of **9**. This conclusion was corroborated by thin layer chromatographic (TLC) isolation of the tetrathioethylene **9** from the reaction mixture. The reaction mixture and an authentic sample of **9** were seen to yield identical spots on a TLC plate.

The trithiocarbonates **1**, **3**, and **4** were investigated in the same manner and similar results were obtained for **3** and **4**. For **1** no ESR signal was detectable in the $AlCl_3$ oxidation mixture. This, together with the absence of any coloration, indicates that **1** does not yield a stable odd-electron species under these conditions. Compound **3**, on the other hand, yielded an ESR spectrum which consisted of nine lines ($a_H = 3.16 \pm 0.02$ gauss, $g = 2.0097 \pm 0.0005$) and was identical with that obtained by $AlCl_3$ oxidation of the tetrathioethylene **11**. The splitting pattern suggests that only the protons on carbon atoms adjacent to sulfur cause hyperfine splitting.

11 **12**

Oxidation of **4** under the same conditions gives a green solution which on standing turns bright orange. The ESR spectrum recorded with the green solution consisted of a narrow unresolved line (line width = 1.4 gauss, $g = 2.0078 \pm 0.0005$) which was also identical with that obtained from **12**.

Quenching of the colored solutions produced by $AlCl_3$ oxidation with water followed by methylene chloride extraction gives back mostly the starting materials as determined by TLC analysis. Evidently, the amount of material oxidized is quite small in these experiments. In the TLC analysis of the products from the quenched reaction of **4**, the presence of the tetrathioethylene **11** was established by comparison with authentic material.

The view which emerges from these studies is that both chemical and electrochemical oxidation of trithiocarbonates leads to elimination of sulfur and dimerization products. The electrochemical reaction appears to be more selective than the chemical procedures with $AlCl_3$ or trivalent phosphorous (12-14) in that condensation to the tetrathioethylenes does not occur. However, an electrochemical pathway to the tetrathioethylenes is afforded by reduction of alkylated trithiocarbonates.

Trithiocarbenium ions, reduction.—Derivatives of the trithiocarbonates **1-6** are readily alkylated (see Experimental Section) to give the corresponding carbenium cations. These species may be easily electrodimerized under very mild electrochemical conditions.

Cyclic voltammograms of all of the cations studied exhibited a single irreversible reduction wave at *ca.* −0.4V *vs.* SCE. On the reverse scan a single oxidation wave was generally observed at *ca.* 1.0V *vs.* SCE. Figure 6 shows a cyclic voltammogram of **25**, a carbenium ion derived from **4**. Table III contains the voltammetric parameters and the structures of the carbenium ions examined in this study. Tetrafluoroborate, fluorosulfonate, hexafluorophosphate, and perchlorate anions were the counterions. There was no appreciable dependence of the voltammetric parameters on the counterion.

A reverse wave was never observed for the initial reduction wave under the conditions of this study. These included voltage sweep rates up to *ca.* 100-200 V/sec and several low temperature studies (−24°C). Since analysis of the wave shape, concentration, and sweep rate dependence of the reduction wave indicated Nernstian one-electron transfer, this suggests that the radical species has a lifetime much less than the time scale of these electrochemical measurements which was *ca.* 1 msec at the fast limit.

An extensive sweep rate and concentration study was undertaken to determine the mechanism of the electrode process. The results are given in Table IV. The results are consistent with a rapid dimerization of the radical species, the DIM1 mechanism of Saveant and co-workers (22), Eq. [6].

e^- SR ⇌ SR —fast→ SR, 2 [6]

The electrodimerization product, an orthothiooxalate, is electroactive and oxidation waves for these species are seen at *ca.* 0.9-1.4V *vs.* SCE in the cyclic voltammograms.

The experimental diagnostic parameters in Table IV also support a dimerization mechanism in which the orthothiooxalate is formed by a rate-determining electron transfer reaction between the dimer radical cation and the parent carbenium ion in the diffusion layer.

[c] 1 Volt sec^{-1}; 1 m*M*.
[d] 100 mV sec^{-1}; 1 m*M*.
[e] 256 mV sec^{-1}.

This is the DIM2-DISP2 mechanism (22). The experimental distinction between the diagnostic criteria for the two mechanisms is the peak width which is 39 mV for the DIMI mechanism and 45 mV for the latter mechanism at room temperature. Since the experimental peak widths, which fall between these values, may be increased either by uncompensated resistance or by rate-determining heterogeneous electron transfer, the radical-radical coupling shown in Eq. [6] is indicated.

Coulometric n-values were 1.00 ± 0.05 for cations **13** to **28**. (Coulometric and product isolation studies were not carried out on **29** and **30**.) The electrolyses at a platinum cathode proceeded rapidly with no indication of electrode filming. Isolation of the reduction products confirmed the formation of orthothiooxalates in all cases except the reduction of **15**. The orthothiooxalates were obtained in nearly quantitative yields in most cases. After isolation, the orthothiooxalates were pyrolyzed under mild conditions (*ca.* 100°C, sealed tube or refluxing bromobenzene) to yield the expected tetrathioethylene and dialkyldisulfides (17) in moderate yields, up to 60-70%. The ease of the elimination reaction was evident by the detection of the characteristic oxidation waves of tetrathioethylenes in cyclic voltammograms of room temperature electrolysis solutions of many of the five-membered ring cations.

An orthothiooxalate was not isolated from the electrolysis solutions of **15**. Only the corresponding tetrathioethylene and diethyldisulfide were recovered from the solutions. Comparison of room temperature and low temperature cyclic voltammograms of **15** suggests that the orthothiooxalate is formed initially, but undergoes further chemical reactions. Cyclic voltammograms recorded at room temperature and slow sweep rates (see Fig. 7) show several poorly defined product oxidation waves at *ca.* 1.0V *vs.* SCE. At faster sweep rates (*e.g.*, 30 V/sec^{-1}) or at lower temperatures (see Fig. 7) the product oxidation waves sharpen considerably and two reversible waves appear after the product oxidation wave is passed. These reversible waves can be assigned to the tetrathioethylene, **9**, and this behavior is characteristic of orthothiooxalate oxidation (3, 23).

In addition, cyclic voltammograms of electrolysis solutions carried out at −25°C showed a single product oxidation wave which corresponded to the orthothiooxalate. When the solution was worked up at room temperature only tetrathioethylene and disulfide were recovered. Other unidentified products were also present. No explanation is readily apparent for the relative instability of the dimer derived from **15** at room temperature.

Trithiocarbenium ions, oxidation.—The unsaturated trithiocarbenium ions, **22-25** and **28**, could be oxidized at platinum in acetonitrile solutions. Table V lists the peak potentials of the oxidation waves and the reduction waves which result from oxidation products. No well-defined product waves were present when the scan was reversed.

Comparison of the peak currents of the oxidation waves at slow sweep rates to the corresponding one-electron reduction waves indicates that two electrons are involved in the oxidation process. Cation **28** gave the most straightforward behavior. At slow sweep rates two irreversible oxidation waves were present in the

cyclic voltammograms. As the sweep rate was increased, the first wave split into two waves, the first of which appeared to be a reversible couple. Figure 8 shows this behavior. Final products are probably derived from fragmentation of the highly reactive dication and trication species. An unsuccessful attempt was made to observe an ESR signal for $28.^{2+}$ by anodic electrolysis in the cavity of an ESR spectrometer.

Summary

Anodic oxidation of trithiocarbonates is not a viable synthetic entry into tetrathioethylenes. Anodic elimination of sulfur and condensation does occur in nonaqueous solvents, but the dimer radical cation which is formed does not yield the tetrathioethylene.

Cathodic reduction of trithiocarbenium cations, on the other hand, does provide a convenient method of synthesizing orthothiooxalates which can be readily

pyrolyzed to tetrathioethylenes. This preparation of orthothiooxalates takes place under milder conditions and higher yields than the free radical addition reactions or organo-lithium complex dimerizations carried out by Uneyama *et al.* (24) and Seebach and co-workers (25-27). The stringent nonaqueous and oxygen free conditions necessary for these chemical methods are not required for the cathodic reduction of the cations which occurs between -0.40 and $-0.60V$ *vs.* SCE. The method also seems to be more general than the action of diazomethane on trithiocarbonates as used by Coffen and co-workers (1) and Runge and co-workers (28) to prepare cyclic orthothiooxalates.

Experimental Section

Instrumentation.—Electrochemical experiments were performed with conventional three-electrode potentiostats. The instrument used for the sweep rate and concentration studies was equipped with positive feedback to minimize uncompensated *iR* drop between the tip of the reference electrode and the working electrode (29).

A Digital Equipment Corporation PDP-12 twelve bit minicomputer was used to record and evaluate cyclic voltammetric data. An assembly language program was written which recorded a voltammogram into core by converting fifteen current data points and then one potential data point. Linear interpolation between potential data points was performed to complete the current-potential voltammogram. The voltammogram in core could be displayed and the data manipulated and evaluated by operator controlled cursors. Sweep rates up to 75 V/sec^{-1} were accessible with this program.

Electrochemical experiments were carried out in a Vacuum Atmospheres Company Model HE-43-2 inert atmosphere enclosure filled with nitrogen except in the cases where "wet" acetonitrile is specified. The inert atmosphere was continuously regenerated by an HE-493 Dri-Train (Vacuum Atmospheres Company) which kept oxygen and water at *ca.* 1 ppm. No oxygen reduction wave was observed in the cyclic voltammograms of solvent-supporting electrolyte using 0.22 cm^2 platinum electrodes.

Nonaqueous reference electrodes were constructed by dipping a cleaned silver wire into a solution which was $0.01M$ in $AgNO_3$ and $0.1M$ in supporting electrolyte in acetonitrile. The potential of these electrodes were *ca.* 0.30V *vs.* SCE. The potential of the reference electrode was measured prior to each days work and potentials in this paper are referred to aqueous SCE unless specified otherwise.

Procedures.—Large scale electrolyses were carried out in a three-compartment cell in which the counterelectrode was separated from the working electrode by two 20 mm fine porosity glass frits. Electrolysis solutions were *ca.* 0.03*M* in electroactive compound and nearly saturated with supporting electrolyte. The cell current was integrated electronically. Products were extracted from the electrolysis solution by evaporating the solution nearly to dryness and extracting with either ether or chloroform.

ESR spectra of radical cations in $AlCl_3$-CH_3NO_2 solutions were obtained following the procedure of Forbes and Sullivan (30).

Chemicals.—Acetonitrile, the principal solvent used in this investigation, was purified by the abbreviated method of O'Donnel, Ayres, and Mann (31, 32). The final distillate was collected over nitrogen and immediately transferred into the inert atmosphere enclosure. Methylene chloride was distilled once from calcium hydride and stored in an inert atmosphere. N,N-dimethylformamide (DMF) was purified by the procedure of Faulkner and Bard (33).

Supporting electrolytes were prepared by standard methods (34), recrystallized at least three times from water-alcohol solutions, and dried at elevated temperatures in vacuum.

Ethylenetrithiocarbonate was purchased from Aldrich Chemical Company and recrystallized from acetonitrile. All of the remaining trithiocarbonates were prepared by literature methods: 1,3-dithiole-2-thione (35), **5**; 1,3-dithiane-2-thione (36), **3**; 1,3-dithietane-2-thione (37), **1**; benzo-1,3-dithiole-2-thione (38), **4**; 4,5-thiomethoxy-1,3-dithiole-2-thione (4, 39), **6**; 4-phenyl-1,3-dithiolane-2-thione (40); *cis*-4,5-diphenyl-1,3-dithiolane-2-thione (40); *trans*-4,5-diphenyl-1,3-dithiolane-2-thione (41, 42).

All of the trithiocarbenium cations studied are simple alkylated derivatives of trithiocarbonates. They were synthesized by the action of either triethyloxonium ion, dimethylsulfate, or methyl fluorosulfonic acid on the appropriate thione in methylene chloride solution (15, 16). A slight excess of trithiocarbonate was used in the reaction. The solid products were moderately sensitive to atmospheric moisture and oxygen and were handled in the inert atmosphere enclosure whenever possible. The solid products were generally washed with dry carbon tetrachloride until the washings were colorless, dried in vacuum at room temperature, and stored under nitrogen. Yields were nearly quantitative in all cases.

ABSTRACT

The method of rotating ring-disk voltammetry has been applied to the study of the reduction of benzaldehyde and *para*-substituted benzaldehydes in sulfolane. Benzaldehyde undergoes an EC reduction mechanism with an anion dimerization as the following reaction. Digital simulation techniques give values of the second order rate coefficients of $k_2 = 2.4 \times 10^3$ liters/mole-sec. *Para*-cyanobenzaldehyde undergoes a mixed reduction mechanism. At low disk currents the reduction intermediate is proposed to be a parent-anion complex. At higher fluxes, dimerization becomes the significant following process; $k_2 = 45$ liters/mole-sec. A single electroactive intermediate is observed for the first one-electron reduction of p-nitrobenzaldehyde. The single, chemically, reversible redox mechanism for this compound in sulfolane agrees with our spectroelectrochemical results.

The cyclic voltammetric behavior of *para*-substituted benzaldehydes and nitrobenzene in the solvent sulfolane has been described in a recent communication (1). These data show an enhanced lifetime of the one-electron-carbonyl adduct from that found in protic solutions. It was of interest to explore these chemical systems using the technique of ring-disk electrochemistry.

Benzaldehyde reductions have been thoroughly investigated in aqueous solutions (2-12). Saveant and co-workers have used linear sweep and cyclic voltammetry techniques for this purpose (2-6). They propose a mechanism that involves protonation and coupling of the reduction intermediate to form the pinacol dimer. This does not disagree with our cyclic voltammetric studies in sulfolane (1). However, *in situ* spectrophotometric observations for the reduction process suggest that additional radical-anion reactions, besides dimerization and protonation, are important in these systems (13).

The method of ring-disk voltammetry has been used with success in studying organic electrode processes (8-12, 14, 15). Nekrasov and Korsun have used this technique to study benzaldehyde and other carbonyl reductions in aqueous-ethanol media over a wide pH range (8-11). Their results demonstrate the presence of a short-lived radical anion intermediate. They also show the existence of a second ring electrode oxidation wave at potentials several hundred millivolts anodic of the oxidation of the radical anion. This second process was attributed to the oxidation of a charge transfer complex formed between the radical anion and the parent molecule.

Ring-disk kinetic studies originally were done using current transients at the disk electrode (16-23). This approach is limited in applicability to the study of first order homogeneous following reactions. More recently digital simulation techniques have been applied to determine rate parameters for more complicated processes (14, 15, 24). Puglisi and Bard have shown that digital simulations allow the discrimination between second order EC and ECE reactions as well as other mixed coupling reactions (14, 15). In this paper we make use of digital simulation techniques to determine the magnitude of second order kinetic parameters of the following chemical reactions undergone by the one-electron product of these aromatic carbonyl reductions.

Experimental

The electrochemical cell design has been reported previously (1). The reference electrode used in this work was a large silver plate (Ag pseudoreference electrode) immersed into the electrolysis solution. Drift in the potential of this electrode was negligible. The working electrode (RRDE) was a platinum ring-disk electrode (Pine Instrument Corporation, Model TB 18). The significant dimensions are disk radius = 0.239 cm, ring inner radius = 0.270 cm, ring outer

Key words: benzaldehyde reductions, EC reduction mechanism, digital simulation, dimerization.

radius = 0.320 cm. This electrode was modified to extend the ring electrode contact up the electrode shaft and outside the electrolysis cell. Two spring-pressured, graphite brushes were used to make independent electrical contact to the ring and disk. Contact resistance in this configuration was less than 5 ohms. The electrode was coupled to a controlled d-c motor (Motomatic Model 550) using a chuck constructed in these laboratories. Less than 1% eccentricity was noted in rotation rates up to 500 radians/sec.

The three-electrode potentiostat was one described previously (1). The ring-disk experiment requires simultaneous, independent potential control of the ring and disk electrodes. The potentiostat was modified using the design of Miller (25) and Napp *et al.* (26). A Chemtrix Potentiostatic Waveform Source was used as the potential source for the ring electrode; a Burr-Brown 3312-12C operational amplifier was used as the ring control amplifier. Current at the two electrodes can be measured simultaneously. Periodic calibration of the ring current-to-voltage converter (Burr-Brown 3308-12C operational amplifier) was necessary.

Purification procedures have been described previously (1). The benzaldehyde was chromatographed on an activated alumina column before use. Residual oxygen was removed by extensive deaeration with a purified argon stream. Electrolysis using a massive platinum cathode poised at a potential corresponding to the foot of the benzaldehyde reduction wave was used to pretreat the solution before beginning an experiment. Residual currents after this step permitted a potential scan of greater than 4V. This cathodic pretreatment eliminated the reduction prewave described previously (1).

The theoretical collection efficiency for this electrode was estimated using the procedure of Albery *et al.* (18) as $N_o = 0.3075$. This was checked using a chemical model system, the ferrocene oxidation. The disk electrode was poised at a potential to cause the oxidation of a ferrocene solution while the ring was poised at the reduction potential of the species produced at the disk. The ratio of the ring to disk currents ($i_{r,1}/i_{d,1} = N_o$) was evaluated at a variety of angular velocities. The collection efficiency was unaffected by rotation velocity and found to be $N_o = 0.305$.

The procedure for generating ring-disk voltammograms was to first determine the rotating disk voltammogram for a particular compound at a fixed rotation rate. The potential of the disk electrode was then poised near the foot of the carbonyl reduction and the ring electrode potential was scanned positively from this point. This trace determined the residual current at the ring. Then the disk potential was set to correspond to the diffusion limited plateau ($i_d = i_{d,1}$) and the ring electrode again scanned positively. The difference in current corresponds to the ring current reported here.

Data used for the determination of the homogeneous kinetic parameters were taken at constant potentials by measuring the steady-state currents at various applied potentials along the voltammogram. The current parameter used in the digital simulation (see below), CONI ($i_d/i_{d,1}$), was computed at each of these potentials. Ring currents were measured at each value of CONI and then values of the collection efficiency were determined. This technique is similar to that described by Puglisi and Bard (14, 15) although procedures of constant potential are described here.

Results and Discussion

A ring-disk voltammogram for the benzaldehyde reduction is shown in Fig. 1. The supporting electrolyte here was 0.1M tetrabutylammonium perchlorate. When the disk is poised at a potential corresponding to the limiting current plateau (point A) the ring voltammogram shows two anodic waves. The half-wave potential of the first ring wave (point 1) occurs at

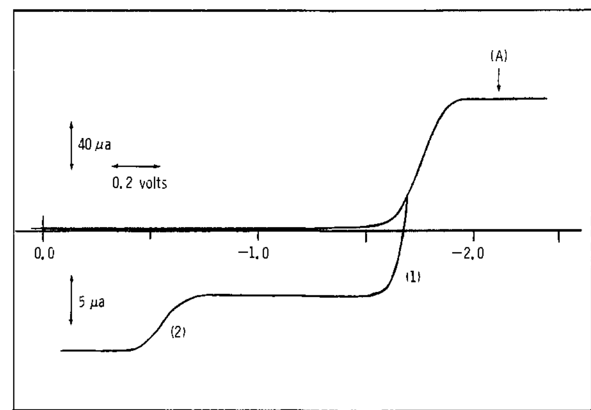

Fig. 1. Rotating ring-disk voltammogram of 5.02 mM benzaldehyde in 0.1M TBAP/sulfolane solution. $\omega = 105$ radians/sec. Upper curve is the disk trace. Lower trace is the anodic behavior shown by the ring electrode while the disk electrode is maintained at potential shown by (A). Note different current sensitivities for cathodic (disk) and anodic (ring) trace.

potentials that represent a reoxidation of the one-electron product produced at the disk (1). The second oxidation wave (point 2) occurs at potentials nearly 1.0V positive of the first wave. A second anodic wave was also seen by Nekrasov *et al.* (8). It was of interest to determine the nature of this wave.

The benzaldehyde reduction wave occurs at potentials close to the cathodic limit in this solvent system. Experiments were performed to explore the nature of the more positive ring wave and see if it involves reactivity of the carbonyl compounds. A solution of TBAP in sulfolane was prepared and was electrolyzed by maintaining the disk at a potential corresponding to the potential of the limiting current for the aldehyde reduction. Scanning the ring electrode anodically produced a ring wave even though no carbonyl compound was present. This wave occurred at potentials similar to those for the second wave (point 2) shown in Fig. 1. This behavior could also be observed by maintaining the ring electrode at a fixed potential (on the limiting current plateau of the second wave) and then scanning the disk to more negative potentials. The ring current increased as the disk approached the potential of solvent decomposition. We conclude that the second ring wave results from the oxidation of an electrode product formed during the steps of the cathodic solvent electrolysis. There appears no way that this can be assigned to a reaction involving the carbonyl compound.

The collection efficiency of the carbonyl reduction process was found to vary as a function of angular velocity. As ω increased, N_k also increased suggesting a chemical reaction which consumes the disk product to form a product that is not electroactive at the ring. The collection efficiency at fixed rotation rates decreases with increasing bulk concentration of the aldehyde. These data are consistent with a second order following chemical reaction such as the dimerization of the one-electron adduct suggested previously from cyclic voltammetric studies (1, 2).

The collection efficiency was studied as a function of applied potential. Therefore the currents are obtained under constant potential conditions for various bulk concentrations. Plots of collection efficiency, N_k, *vs.* the disk current function, ($1 - i_d/i_{d,1} = 1 -$ CONI) (14, 15) are shown in Fig. 2 for the benzaldehyde reduction. The collection efficiency for the oxidation process increases with decreasing disk current. The flux of the intermediate decreases with decreasing disk current and appears to slow the over-all rate of the following chemical reaction. Puglisi and Bard (14, 15) and Nekrasov and co-workers (8-12) have shown that this type of behavior results from the dimerization of the reduction intermediate

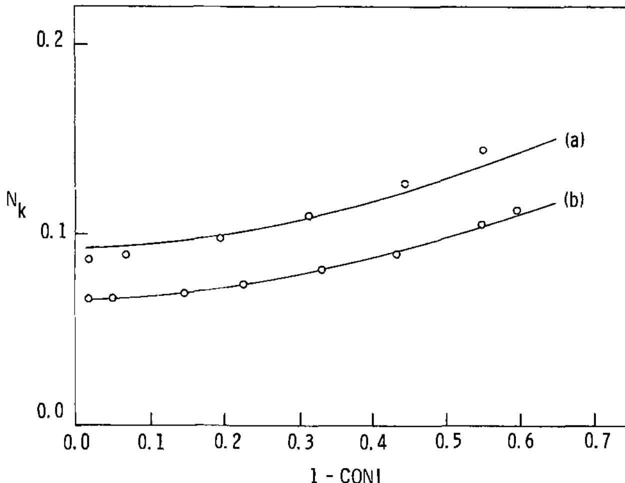

Fig. 2. Collection efficiency, N_K, *vs.* 1 — CONI for the first ring wave of the benzaldehyde reduction in 0.1M TBAP/sulfolane solution. ω = 105 radians/sec. (a) $C^b{}_{\phi\text{-CHO}}$ = 2.51 mM and (b) $C^b{}_{\phi\text{-CHO}}$ = 5.02 mM. Solid lines are theoretical curves for (a) XKTC = 2.6 and (b) XKTC = 4.7.

$$A + e^- \rightleftharpoons B \quad [1]$$

$$2B \xrightarrow{k_2} D \quad [2]$$

Figure 3 shows the results of the addition of millimolar amounts of water to the solvent system. Water can be considered as a proton source in this solvent. Adding water decreases the lifetime of the disk product and suggests that protonation or perhaps solvation promotes the following reaction. These data depict a linear decrease in N_K with the square root of added water concentration. This suggests a 2:1 stoichiometry for the reaction, although one must consider that the mechanism might change as the proton activity of the solvent increases.

Experimental ring-disk data were interpreted using working curves of N_K *vs.* (1 — CONI) generated using digital simulation techniques (14, 15, 24). The simulations require dimensionless parameters for the ring and disk radii, the diffusion coefficients for the parent molecule (A) and the intermediate (B), the disk current function, CONI, and the rate parameter, XKTC. For the electrode system used here, the radii are IR1 = 120, IR2 = 136, IR3 = 161 (24). The dimensionless diffusion coefficients for species A, DMA, and species B, DMB, were both chosen as DMA = DMB = 0.45. XKTC is selected to represent a dimensionless form of the rate parameters: XKTC = $(0.51)^{-3/2}\nu^{1/3}D^{-1/3}\omega^{-1}k_2C^b$ where ν is the kinematic viscosity of sulfolane at 50°C [= 4.9 centistokes (27)], D is the diffusion coefficient of the parent molecule (= 1.29×10^{-6} cm²/sec) (1), ω is the radial velocity (rad/sec), k_2 is the second order rate coefficient (liters/mole-sec), and C^b the bulk concentration.

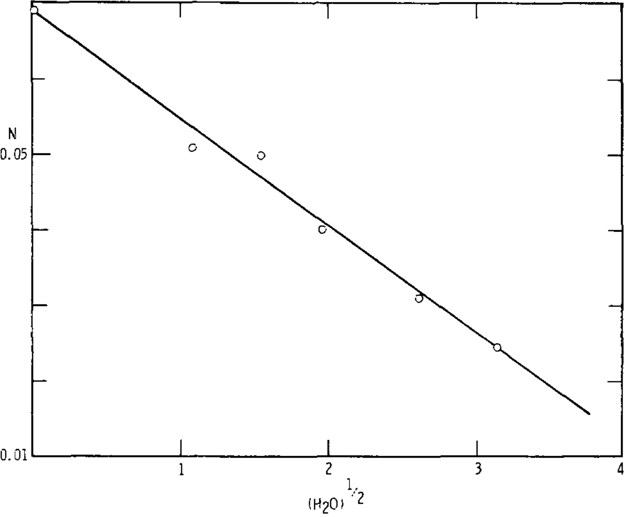

Fig. 3. Collection efficiency, N_K *vs.* added water concentration, $[H_2O]^{1/2}$ in units of $(mM)^{1/2}$ for the first ring oxidation wave of benzaldehyde in 0.1M TBAP/sulfolane solution. ω = 105 radians/sec and $C_{\phi\text{-CHO}}{}^{bulk}$ = 7.53 mM.

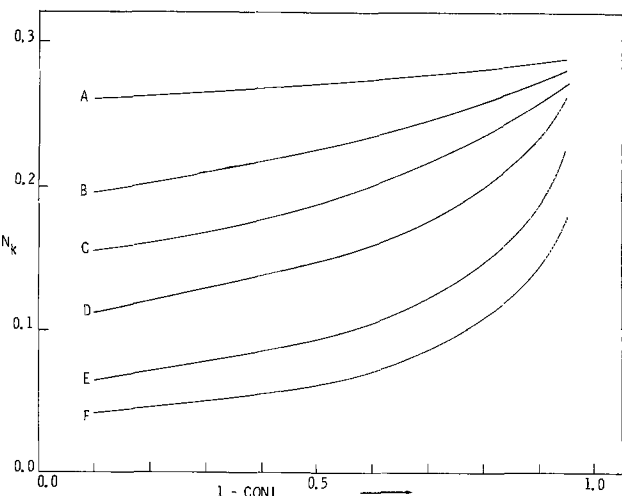

Fig. 4. Simulated plots of collection efficiency, N_K, *vs.* 1 — CONI for a dimerization reaction following electronation at various values of XKTC, (A) 0.1, (B) 0.5, (C) 1.0, (D) 2.0, (E) 5.0, and (F) 10.0. The parameter XKTC is equal to $(0.51)^{2/3}\nu^{1/3}D^{-1/3}\omega^{-1}k_2C^{bulk}$.

Sets of working curves are shown in Fig. 4 for several values of XKTC. These were computer simulated curves calculated for a dimerization reaction. The experimentally determined data, N_K *vs.* (1 — CONI), were fit to these simulated working curves. From the simulated values of XKTC which most closely represented the experimental cases, values for the second order (dimerization) rate coefficient, k_2, were estimated. These are given in Table I.

Data is also included for *p*-cyanobenzaldehyde. This compound shows a single anodic ring wave when the disk electrode is poised at the limiting current of the aldehyde reduction. The absence of the second wave correlates well with the reduction potential being considerably less negative than that of benzaldehyde (1). The collection efficiency, N_K, was larger at the same rotation rate and bulk concentration than that found for the benzaldehyde system.

Plots of N_K *vs.* (1 — *CONI*) for the *p*-cyanobenzaldehyde system show two regions of interest (Fig. 5). At high values of disk current, N_K decreases as ex-

Table I. Values of k_2 determined by digital simulation methods for benzaldehyde and *p*-cyanobenzaldehyde

a. Benzaldehyde (ϕ-CHO), ω = 105 radians/sec

$C_{\phi\text{-CHO}}{}^{bulk}$ (m*M*)	XKTC	k_2 (liters/mole-sec)
2.51	2.6	2.07×10^3
2.51	4.8	3.80×10^3
3.52	4.0*	2.28×10^3
5.02	4.7	1.79×10^3
		Average = 2.40×10^3

* Fit up to 1 — CONI = 0.350.

b. *p*-Cyanobenzaldehyde (PCNB), ω = 105 radians/sec

$C_{PCNB}{}^{bulk}$ (m*M*)	XKTC	k_2 (liters/mole-sec)
5.50	0.14	48.6
8.10	0.18	42.4
		Average = 45.2

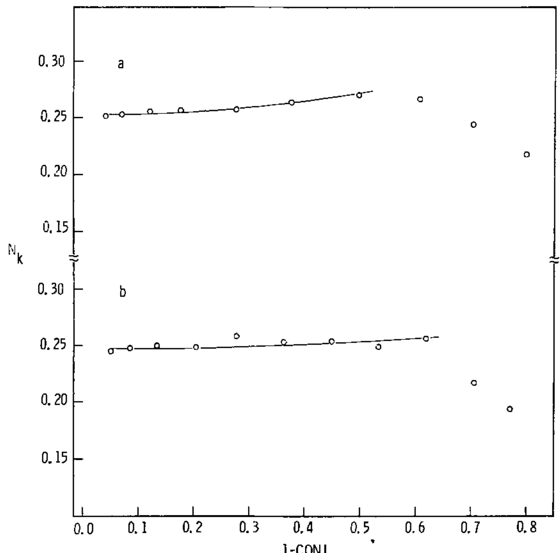

Fig. 5. Collection efficiency, N_k, vs. 1 — CONI for the p-cyanobenzaldehyde reduction in 0.1M TBAP/sulfolane solution with ω = 105 radians/sec. (a) C_{PCNB}^{bulk} = 5.50 mM and (b) C_{PCNB}^{bulk} = 8.81 mM. Solid lines are theoretical curves for (a) XKTC = 0.14 and (b) XKTC = 0.18.

pected for the dimerization of the reduction intermediate. At lower values of current, however, values of N_k become constant or decrease with increasing (1 — CONI). Constant values of N_k with increasing (1 — CONI) are consistent with a first order following reaction. Decreasing values of N_k with increasing (1 — CONI) suggests a second-order ECE mechanism (16)

$$A + e^- \rightleftharpoons B \qquad [3]$$

$$A + B \underset{k_b}{\overset{k_f}{\rightleftharpoons}} C \qquad [4]$$

where C is electroactive at potentials which produce B

$$C + e^- \rightleftharpoons Z \qquad [5]$$

Simulated data for the dimerization model fit the experimental N_k vs. (1 — CONI) data up to values of (1 — CONI) = 0.600. Values are shown in Table I for dimerization rates obtained from this region.

These p-cyanobenzaldehyde data show that two types of reaction consume the reduction intermediate. At small fluxes, the intermediate is present at relatively low concentration. Here a pseudo first order mechanism predominates. This reaction may be with solvent impurities or complexation with the parent (scheme 4). At higher fluxes and corresponding higher concentrations of the radical anion, dimerization becomes the significant following process. The data suggest a mixed mechanism, one that favors the first order process at low fluxes and then switches to anion dimerization as the concentration increases. This mechanism explains much of the data we have seen in these systems (1, 13).

Data were also taken for the one-electron reduction of p-nitrobenzaldehyde. The reduction process produces a single electroactive intermediate at the disk electrode that can be oxidized at the ring. This species shows a collection efficiency that remains constant as the velocity of the electrode is varied and has a value (0.306) close to that predicted by theory. This represents behavior of a single chemically reversible redox system.

Conclusions

Ring-disk electrode investigations indicate an EC mechanism for the reduction of benzaldehyde in sulfolane. Digital simulation methods allow the evaluation of second order rate coefficients for the dimerization following reactions. These values agree well with previously determined values in this solvent (1, 13). The data again show the higher stability of the aldehyde reduction, one-electron intermediates in this solvent.

The study of the reduction of benzaldehyde is complicated since the solvent reduces at potentials close to the carbonyl reduction energy. Recent work suggests that the cathodic limit in sulfolane might be due to reduction of trace quantities of water (28). This interpretation may apply to this study. The second anodic wave seen during the benzaldehyde reduction appears to be the result of this process. The resulting disk current due to this coreduction process would contribute a small positive error in the determination of the dimerization reaction rate coefficient, k_2.

The data for p-cyanobenzaldehyde show a mixed reduction mechanism. Preliminary spectroelectrochemical studies have indicated two reduction intermediates (13). One of these compounds is the expected one-electron adduct while the second was identified as a complex of the one-electron adduct with other species, perhaps with the parent molecule. Ring-disk voltammograms do not show unique electrochemical behavior for this complex species. Evidence presented here for EC behavior at low concentrations of the reduction intermediate corroborates the spectroelectrochemical information.

ABSTRACT

The effect of solvent on the quantum efficiency of electrogenerated chemiluminescence (EGCL) was studied by measuring the coulombic efficiency (ϕ_{coul}) of rubrene EGCL in eleven different solvents. ϕ_{coul} was found to vary significantly amongst the solvents employed. Various attempts were made to correlate ϕ_{coul} with some property of the solutions. A correlation between ϕ_{coul} and the difference between the oxidation and reduction potential was obtained, ϕ_{coul} increasing with increasing potential difference. The correlation is explained in terms of changes in solvation with the solvent affecting the degree of ion radical quenching of the lowest excited triplet state through which rubrene EGCL is produced.

Rubrene has been widely studied as an electrochemiluminescent material in aprotic solvents (1-3). Its electrogenerated chemiluminescence (EGCL) has useful potential applications in display devices (4). The quantum efficiency of the light-producing process is both of fundamental interest in regard to energy transfer mechanisms and of practical concern in device applications.

The emitting species of rubrene EGCL is the lowest excited singlet state. Recent investigations of rubrene EGCL have established that the fluorescence is indirectly produced via triplet-triplet annihilation in each of the several solvents studied: (*i*) Bezman and Faulkner (5) concluded from Feldberg plots of the EGCL intensity *vs.* time that the luminescence arose from the triplet route, (*ii*) Tachikawa and Bard (6) observed a magnetic field enhancement of the intensity of the EGCL and suggested that this was an indication of an important involvement of triplets in the reaction pathway, and (*iii*) Pighin (7) calculated from experimental thermodynamic data that the change in enthalpy of the anion-cation-radical charge neutralization reaction was less than the energy of the lowest excited singlet state. Thus, the singlet state must be produced through triplet-triplet annihilation.

Key words: electrogenerated chemiluminescence, rubrene, quantum efficiency.

The mechanism for rubrene EGCL is, therefore, as shown in Table I. The products of the reactions are produced in the proportions shown because of statistical factors, assuming that these reactions are not influenced by the solvent (8). It can be calculated from this mechanism that the theoretical maximum quantum efficiency of rubrene EGCL is 0.075 photons/electron.

Although "quantum efficiency" is simple to define, e.g.

$$\text{quantum efficiency} = \frac{\text{No. of photons of EGCL generated sec}^{-1}}{\text{faradaic current (in electrons sec}^{-1}\text{) transferred}} \quad [1]$$

its actual measurement is not trivial. The most difficult problem in this measurement arises from the low light intensities which originate from EGCL. Other obstacles to be overcome with the light measurements are the uncertainties inherent in such factors as reflection losses at the electrode, absorption losses in the solu-

Table I. Rubrene EGCL mechanism

(R = rubrene)

Formula	Mechanism	Equation No.
$R \rightarrow \cdot R^{+} + e$	(Oxidation of rubrene at electrode)	[2]
$R + e \rightarrow \cdot R^{-}$	(Reduction of rubrene at electrode)	[3]
$\cdot R^{+} + \cdot R^{-} \rightarrow 3/4\ {}^3R^* + 5/4\ R$	(Homogeneous electron transfer/triplet formation)	[4]
${}^3R^* + {}^3R^* \rightarrow 1/4\ {}^1R^* + 3/4\ {}^3R^* + R$	(Triplet-triplet annihilation/singlet formation)	[5]
${}^1R^* \rightarrow R + h\nu$	(Radiative decay of excited singlet)	[6]

tion, collection efficiency of the detector, and spectral response of the detector.

The electrolytic current consists of faradaic and capacitive components. Only the faradaic component of the total current is used to produce light, the capacitive component being involved in charging and discharging the double layer at the electrode. Consequently, in order to obtain true quantum efficiency data, it is necessary to separate the electrolytic current into its faradaic and capacitive components. Of the ion radicals produced, some could diffuse away from the reaction zone without being neutralized while others can be lost to side reactions. The faradaic current employed to calculate the quantum efficiency should not include these losses since they do not contribute to the generation of electronically excited molecules.

The presence of all of these factors limits the accuracy with which the quantum efficiency of EGCL can be determined.

The light from EGCL has been measured using calibrated photon detectors (9), actinometry (10), and integrating spheres (11), while the electrical current was, or was assumed, to be entirely faradaic. Previous results in the literature for the quantum efficiency of the same system (rubrene in tetra-*n*-butylammonium perchlorate in benzonitrile) range from a low value of 0.1% (corrected for both photon and current losses) to a high one of 8.7% (without any corrections) (12). These variations in the values of the published quantum efficiency of the same EGCL system have led us to develop another independent method for evaluating the quantum efficiency which has been described recently (7). This method provides the basis for the experiments reported in the present paper.

Bezman and Faulkner (5) measured the quantum efficiency of rubrene EGCL in both DMF and benzonitrile and found it to be twice as large in benzonitrile in comparison with DMF. They estimated higher triplet yields in the solvent in which the EGCL was more efficient. Tachikawa and Bard (6) reported that the magnetic field enhancement of the intensity of rubrene EGCL decreased with decreasing dielectric constant of the solvent. This was explained by suggesting that the degree of direct singlet formation increased with decreasing dielectric constant of the solvent. In our previous work (7), it was shown in a preliminary way that the quantum efficiency of rubrene EGCL was solvent dependent although the EGCL was produced exclusively by the triplet route in both solutions studied, decreased with increasing frequency of the a-c potential used to electrolyze the fluorescor solutions, and was independent of the electrolyte (tetra-*n*-butylammonium perchlorate) concentration. The absence of an electrolyte effect was interpreted as an indication of the lack of importance of ion pairing in the solvents studied (DMF and equivolume benzene-DMF) while the frequency dependence was explained by suggesting that the triplets could be quenched by the electrode. It was speculated that the effect of solvents on the coulombic efficiency (ϕ_{coul}) of rubrene EGCL could result from preferential solvation of the ion radicals by the polar, aprotic component of the mixed solvent while the nonpolar, aromatic component of the mixed solvent preferentially solvated the neutral rubrene, including that in the excited triplet state. The different solvation shells hindered (kinetically) the quenching of the excited triplets by the parent ion radicals, a well-known process (13).

In the present paper, further evaluation of the effect of the solvent on ϕ_{coul} of rubrene EGCL is reported. The results presented here corroborate the tentative explanation proposed earlier.

Method for Determination of Quantum Efficiency

In the method developed (7) for measuring the quantum efficiency of EGCL, the EGCL solution is electrolyzed at a pair of equal-area electrodes with a moderately high frequency (20-1000 Hz) symmetrical square wave voltage. This stimulus, because of its relatively high frequency, provides a periodic EGCL signal of constant amplitude and reproducible waveform for at least the duration of the measurements, about 15 min. Cyclic voltammetric inspection of the electrolyzed solutions did not indicate any compositional changes as a result of the electrolysis. Therefore, it was concluded that the quantum efficiency of the EGCL was being determined in the absence of side reactions.

The average rectified a-c electrolysis current and average photon "current" are measured at selected voltages. From a plot of the average electrolysis current *vs.* applied voltage, the current-voltage line prior to the appearance of EGCL (a linear relationship caused by the purely capacitive nature of this current) is extrapolated into the voltage region which produces EGCL and subtracted from the total current to obtain the faradaic component of the total current at that voltage. An example of this procedure is shown in Fig. 1.

The measured photon current was multiplied by 1.7 to obtain the actual, corrected photon current which emerged from the electrolysis cell. The correction factor employed compensates only for the spectral response of the solar cell material (0.7 electrons/photon) and the collection efficiency of the solar cell box (5 electrons/6 photons). The corrected photon current is then plotted against the faradaic current from which twice the quantum efficiency can be obtained from the slope of the plot. This plot yields twice the quantum efficiency because both electrodes emit the same amount of light and the total light output was measured. Figure 2 illustrates a typical plot of corrected photon current *vs.* faradaic current.

This method for determining the quantum efficiency of EGCL yields the apparent coulombic efficiency, ϕ_{coul}.

Experimental

All of the solutions studied contained rubrene as the fluorescor and tetra-*n*-butylammonium perchlorate (TBAP) as the electrolyte. Both of these solutes were purified first by repeated recrystallization and then by vacuum drying. The rubrene (obtained from Aldrich)

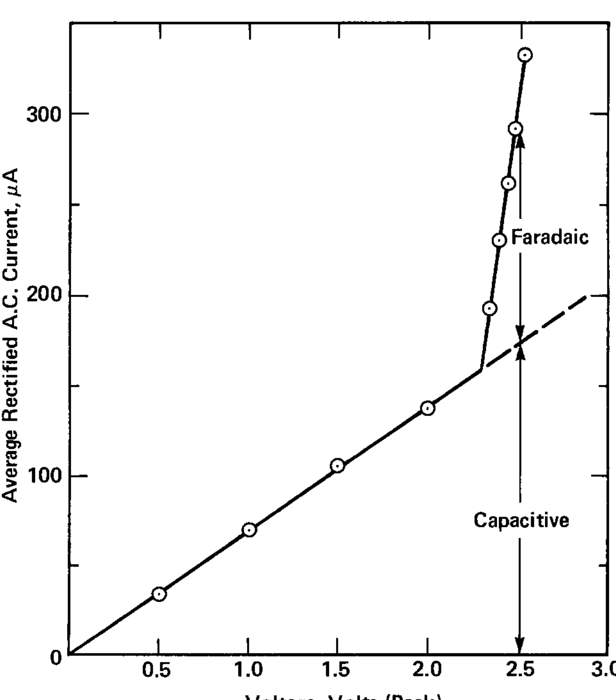

Fig. 1. Typical current-voltage plot used to calculate the faradaic component of the total electrolysis current. Solution: 1.00 mM rubrene in 0.100M TBAP in equivolume benzene-DMF.

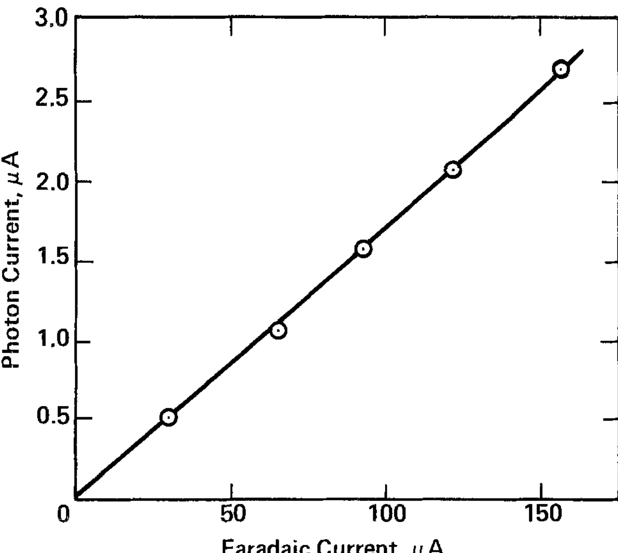

Fig. 2. Typical plot of photon current vs. faradaic current from whose slope ϕ_{coul} can be calculated. Solution: 1.05 mM rubrene in 0.100M TBAP in equivolume benzene-acetonitrile.

was recrystallized from xylene-methanol and the TBAP [obtained from Matheson, Coleman and Bell (MC&B)] from ethanol.

In this investigation, N,N-dimethylformamide (DMF), benzonitrile (PhCN), acetonitrile (ACN), and propylene carbonate (PC) were employed as aprotic solvents and benzene was added to each to produce solvents of mixed polarity. Fisher D-133 DMF was found to be sufficiently pure to require only drying with Linde Type 5A molecular sieves for its solutions to exhibit constant EGCL intensity with time on continuous generation. The purity of the solvents was ascertained with a Hewlett-Packard 5754B Research Gas Chromatograph, using suitable chromatographic columns. Spectroquality grade PhCN was obtained from MC&B and it too had only to be dried with the sieves for the required electrochemical stabilities of rubrene to be achieved in its solutions. Commercial ACN was found to contain troublesome impurities which were difficult to remove. It was possible, however, to purify some lots of MC&B and Aldrich ACN by passing them through an activated alumina column followed by vacuum distillation of the eluent. The Eastman No. 7050 PC had first to be vacuum distilled and then pre-electrolyzed (with TBAP as the electrolyte). The distillate from the electrolyzed solution was found to be sufficiently pure for the EGCL experiments. The benzene, Fisher B-414, did not contain significant quantities of undesirable impurities but was nevertheless dried with sieves before being used in the preparation of solutions for EGCL experiments.

All of the solutions studied were prepared from purified components in a dry box filled with nitrogen. The electrolysis cell used for the quantum efficiency measurements and the three-electrode electrochemical cell were charged with solution and all measurements were carried out in the dry box. The temperature in the dry box was 25° ± 2°C.

A Princeton Applied Research Model 170 Electrochemistry System and a three-electrode electrochemical cell were used to record cyclic voltammograms of the oxidation and reduction of the rubrene in each solution studied. A silver wire immersed in the test solution was used as the reference electrode (14); it was contained inside a compartment whose Luggin tip extended to within 2 mm of the platinum bead working electrode. In taking the recordings, iR compensation was employed to eliminate the fanning out of the voltammetric waves due to the electrolytic resistance of the solutions. It was estimated that the residual, uncompensated iR drop was at the most several millivolts (7). The cyclic voltammograms were obtained at a scan rate of 100 mV sec^{-1}. At lower scan rates, the oxidation of the rubrene began to exhibit irreversibility while at higher scan rates the recorder response became a limitation.

Results and Discussion

In the previous work, it was found that ϕ_{coul} of rubrene EGCL decreased with increasing frequency of the electrolysis voltage used to generate the EGCL. Consequently, in these experiments, the frequency employed was always 100 Hz, square wave.

Since it was found that ϕ_{coul} also decreased with increasing fluorescor concentration (Fig. 3), a fluorescor concentration of 1 mM was used in all cases so that the individual values of ϕ_{coul} could be compared. Bezman and Faulkner (5) did not obtain a concentration dependence of ϕ_{coul} of rubrene EGCL in both DMF and benzonitrile. Fleet *et al.* (15), in studying the analytical usefulness of EGCL, found that the maximum intensity from rubrene EGCL was directly proportional to the rubrene concentration. This indicates that the quantum efficiency was independent of concentration. A notable difference exists between our work and that of Bezman and Faulkner and Fleet *et al.* Relatively more concentrated solutions were employed in the present work. Other EGCL systems investigated by Fleet *et al.* exhibited deviations from nonlinearity at high concentrations which were ascribed to quenching. It is interesting to note that the present ϕ_{coul} results decrease linearly with log (rubrene concentration). Such a variation in ϕ_{coul} with rubrene concentration could be explained by the self-absorption of rubrene EGCL.

The reproducibility of the ϕ_{coul} data was such that the results for the same system, using solutions prepared nine months apart, were within 10% of each other. A number of equivalent solutions prepared simultaneously yielded ϕ_{coul} values which had a standard deviation of better than 5%

In Table II are shown the values of ϕ_{coul} of rubrene EGCL in the various solutions studied. These results are the average of several determinations using the same and equivalent solutions and have a precision of ±5%. Bard *et al.* have made a tabulation of the available quantum efficiencies of EGCL (12). In that summary, values of the quantum efficiency of EGCL of 1 mM rubrene in 0.1M TBAP in DMF and benzonitrile solvents are given. Our results, in these solvents, when compared with those reported by others, agree best with the values obtained by Bezman and Faulkner. Their results are consistently lower than ours but we both obtained greater efficiency in benzonitrile than in DMF. Bezman and Faulkner generated their EGCL with triple-potential steps, each step 1 sec in duration,

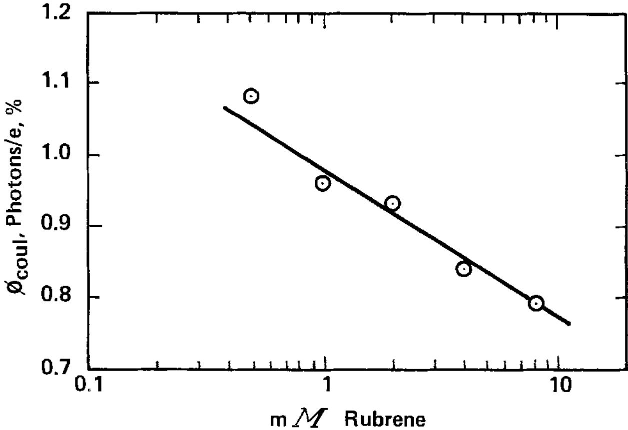

Fig. 3. Decrease in ϕ_{coul} with increasing rubrene concentration in 0.100M TBAP in equivolume benzene-DMF.

Table II. ϕ_{coul} of 1 mM rubrene EGCL in the 0.100M TBAP solutions studied at 25°C

Solution No.	Solvent	ϕ_{coul}, %
1	1:1* benzene:ACN	0.91
2	PhCN	0.90
3	1:1 benzene:PhCN	1.02
4	DMF	0.65
5	1:99 benzene:DMF	0.70
6	1:19 benzene:DMF	0.69
7	1:4 benzene:DMF	0.80
8	1:1 benzene:DMF	0.96
9	3:1 benzene: DMF	1.01
10	1:1 benzene:DMF	0.68
11	DMF (0.020M TBAP)	0.64

* For the mixed solvents, the volume ratios are shown.

while we employed a symmetrical 100 Hz square wave voltage to produce our EGCL. In our preliminary report of this work (7), we showed that ϕ_{coul} increased with decreasing frequency. The triple-potential step used by Bezman and Faulkner to generate the EGCL is equivalent to a relatively lower frequency than ours. If we were to extrapolate our frequency dependence of ϕ_{coul} of rubrene EGCL down to the equivalent frequency of their triple-potential step, then on the basis of our results, Bezman and Faulkner should have measured relatively greater efficiencies. Since, in fact, their ϕ_{coul} values are lower than ours, then it must be concluded that the near agreement with the magnitudes of our results was accidental.

It is clearly evident from the data in Table II that ϕ_{coul} of rubrene EGCL is dependent on the solvent. Various attempts were made to correlate the data in Table II with some property of the solution and the procedures used are reported below.

Since different solvents containing the same electrolyte concentration (0.100M TBAP) were used to prepare the solutions for the present study, then the solution conductivity was a potentially significant variable in this work. The importance of *iR* effects was evaluated by also measuring ϕ_{coul} of 1 mM rubrene EGCL in 0.020M TBAP in DMF. Reducing the electrolyte concentration in DMF solvent from 0.100 to 0.020M TBAP had no measurable effect on ϕ_{coul} of rubrene (Table II). Consequently, *iR* effects are unimportant in the interpretation of the ϕ_{coul} data in Table II.

It is already known from earlier work that the changes in enthalpies of the anion-cation-radical charge neutralization reactions in DMF and equivolume benzene-DMF are nearly the same and are significantly less than the energy of the emitting state, *i.e.*, the lowest excited singlet state of rubrene. The emitting state has the same energy in both of these solutions and the fluorescence efficiencies are also the same in both solutions. Depite the similar thermodynamic and spectroscopic properties of rubrene in these solutions, the ϕ_{coul} of rubrene in the mixed solvent solution is, however, nearly 50% greater than that of the purely polar solvent. Therefore, the solvent dependence of ϕ_{coul} of rubrene EGCL cannot be explained by significant solvent effects on either the type of EGCL mechanism or on the fluorescence efficiency of the rubrene. Tachikawa and Bard (6) have suggested an alternative explanation for the effect of solvent on the quantum efficiency of rubrene EGCL which is in conflict with our above conclusion of a solvent-independent rubrene EGCL mechanism. They assume that rubrene excited singlets are produced both directly by the ion-radical charge neutralization reaction and indirectly via the triplet route. According to their explanation, the degree of direct singlet formation increases with decreasing dielectric constant of the solvent. It will be shown later in the discussion that our values of ϕ_{coul} do increase with decreasing dielectric constant of the solvent. However, from our thermodynamic measurements in DMF and equivolume benzene-DMF, rubrene EGCL is produced exclusively via the triplet route in both solutions and yet ϕ_{coul} in the mixed solvent is 150% that in DMF alone.

The triplet-triplet annihilation reaction and both the homogeneous and heterogeneous electron transfer reactions are essentially diffusion controlled (16, 17). Addition of benzene [η = 0.61 centipoise (cp) (18)] to DMF [η = 0.80 cp (19)] decreased the solution viscosity and, in this case, ϕ_{coul} increased with decreasing solution viscosity. However, the viscosity of benzonitrile [η = 1.24 (18)] is much greater than that of DMF and yet ϕ_{coul} is much greater in the more viscous solution. Thus, the ϕ_{coul} data in Table II do not show a consistent trend with solution viscosity (regardless of the composition of the solvent). It therefore appears that ϕ_{coul} of rubrene EGCL is independent of the rates of these diffusion-controlled reactions.

Although the exact dielectric constants of the solutions used in this ϕ_{coul} study are not known, it is nevertheless possible to conclude that ϕ_{coul} increases with decreasing dielectric constant of the solution. As the fraction of benzene [ϵ = 2 (18)] added to DMF [ϵ = 37 (19)] is increased, ϕ_{coul} increases. Similarly, addition of benzene to benzonitrile [ϵ = 26 (6)] also results in an increase in ϕ_{coul}. Hoytink (13) has shown from theoretical considerations that the rate of transfer of an electron from an anion to a cation radical should increase with decreasing dielectric constant. A larger homogeneous rate constant in a medium of lower dielectric could affect the extent of quenching of the excited triplets by the parent ion radicals. However, the effective dielectric constant at a molecular level can be significantly different from the bulk dielectric constant so that the former should be preferentially employed in establishing a correlation with ϕ_{coul}, especially for mixed solvent solutions as employed in this study, where preferential solvation can prevail. Besides assuming a dielectric continuum, the Hoytink model also pertains to spherical particles, a condition which is not realized with rubrene which has a flat ring structure for a backbone. It is to be appreciated, then, that it is both difficult and risky to attempt to correlate ϕ_{coul} data with the dielectric constant of the solution. Hence, it was decided to attempt to correlate ϕ_{coul} with a more readily determinable property of the solution, the relative change in solvation energy with solvent, which is related to the dielectric constant of the solution by the Born equation (16).

It was not possible to dissolve the rubrene in either conducting ACN or PC to the extent of 1 mM and only slightly more than 1 mM rubrene could be dissolved in conducting DMF. The solubility of rubrene in conducting benzonitrile solution was about 2 mM. By adding benzene to all of the polar, aprotic solvents, the solubility of rubrene in the resultant mixed solvent solutions was, in each case, much greater than in the polar solvent alone. For example, 8 mM rubrene could be dissolved in conducting equivolume benzene-DMF.

Inspection of the ϕ_{coul} data in Table II reveals that addition of benzene to both PhCN and DMF caused an increase in ϕ_{coul}. Furthermore, with reference to the DMF data, it is noted that ϕ_{coul} increased as the benzene fraction of the mixed solvent solution was increased. Thus, the addition of an aromatic solvent to the polar solvents not only increased the solubility of the fluorescor but it also increased ϕ_{coul}.

The solvation of rubrene must follow its saturation solubility in the various solvents. It therefore became apparent that ϕ_{coul} increases with increasing solvation of the neutral rubrene. In order to establish this correlation, it was necessary to determine differences in the solvation energy of rubrene in the various solutions.

The half-wave potential of a redox process is given by the following equation in which the symbols have their usual significance (16)

$$E_{1/2} = E^\circ - \frac{RT}{n\mathbf{F}} \ln \frac{f_{red}}{f_{ox}} + \frac{RT}{n\mathbf{F}} \ln \left(\frac{D_{red}}{D_{ox}}\right)^{1/2} \quad [7]$$

For an oxidation

$$E^\circ_{ox} = I + \Delta G^\circ_{sol,\cdot R+} - \Delta G^\circ_{sol,R} + C \quad [8]$$

and for a reduction

$$E^\circ_{red} = A + \Delta G^\circ_{sol,\cdot R-} - \Delta G^\circ_{sol,\cdot R+} + C \quad [9]$$

where I and A are the gas-phase ionization potential and electron affinity, respectively, of the substance being electrolyzed, G°_{sol} are the standard free energies of solvation, and C is a constant. Since the solvation terms are the only contributions to the electrochemical potentials which are dependent on the solvent, then the electrochemical potentials of rubrene in the various solutions can be used as a measure of the relative energies of solvation of the rubrene.

It is known from the rubrene solubility data in these solutions that the solvation of rubrene increases with increasing benzene fraction in all mixed solvent solutions. The solutions actually studied each contained about 1 mM of rubrene. Since benzene is a nonpolar solvent while the aprotic solvents are all polar, then the addition of benzene to the aprotic solvent lowers the dielectric constant of the resulting solution. The Born theory predicts that the solvation of the ion radicals would become more difficult (less negative) with decreasing dielectric constant. Thus, the addition of benzene to an aprotic solvent would normally tend to increase $\Delta G^\circ_{sol,R}$ and decrease both $\Delta G^\circ_{sol,\cdot R+}$ and $\Delta G^\circ_{sol,\cdot R-}$. Consequently, since the changes in solvation energies of the neutral and charged species of the redox couple are reinforcing, E°_{ox} will become more positive and E°_{red} more negative with the addition of benzene.

When benzene was added to an aprotic solvent there always remained a large excess of polar component in the solvent relative to the rubrene concentration. Hence, the probability that the radical ions are, in fact, preferentially solvated by the polar component of the mixed solvent must be recognized; then the solvation energy of the ion radicals would not be expected to significantly change relative to the change in solvation energy of the neutral rubrene, when benzene was added to the aprotic solvent. This leaves changes of $\Delta G^\circ_{sol,R}$ as the main contribution to changes of E° which are found to be solvent dependent (for a given polar solvent with various amounts of benzene).

The peak oxidation and reduction potentials ($E_{p,ox}$ and $E_{p,red}$, respectively) of rubrene in various solutions were determined by means of cyclic voltammetry. A typical cyclic voltammogram is shown in Fig. 4. The voltammograms were recorded on a potential scale of 0.2V in.$^{-1}$. This allowed ($E_{p,ox} - E_{p,red}$) to be resolved within ±5 mV. The measured values of ($E_{p,ox} - E_{p,red}$) are given in Table III together with the corresponding differences between the forward and reverse peak potentials for the cathodic processes. At 25°C, the latter difference should be 58 mV (21). Any measured excess was assumed to have resulted from residual uncompensated iR drops and was subtracted from the measured ($E_{p,ox} - E_{p,red}$) to obtain the correct(ed) ($E_{p,ox} - E_{p,red}$). The largest correction made, 20 mV, was to the data for the 0.020M TBAP in DMF solution.

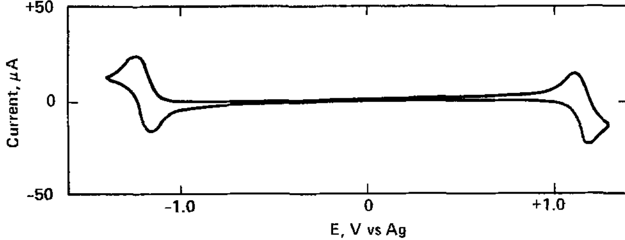

Fig. 4. Cyclic voltammogram of 1.01 mM rubrene in 0.100M TBAP in benzonitrile.

Table III. Electrochemical data for redox processes involving rubrene

Solution No.	Measured ($E_{p,ox} - E_{p,red}$), V	($E_{p,R/\cdot R^-} - E_{p,\cdot R^-/R}$), mV	Corrected ($E_{p,ox} - E_{p,red}$), V
1	2.450	70	2.440
2	2.405	65	2.400
3	2.510	65	2.505
4	2.380	70	2.370
5	2.380	65	2.375
6	2.385	65	2.380
7	2.400	65	2.395
8	2.455	65	2.450
9	2.540	70	2.530
10	2.400	70	2.390
11	2.395	80	2.375

Figure 5 shows the plot of ϕ_{coul} *vs.* the corresponding value of ($E_{p,ox} - E_{p,red}$). The variation in the difference between the redox potentials of rubrene with change in solvent is twice the magnitude of the change in solvation energy of the neutral rubrene for the reasons previously discussed. A clear correlation between ϕ_{coul} and ($E_{p,ox} - E_{p,red}$) is obtained, ϕ_{coul} being found to increase with increasing ($E_{p,ox} - E_{p,red}$). Since the increases in ($E_{p,ox} - E_{p,red}$) result from relatively greater solvation of the neutral rubrene than of the conjugate ion radicals, then the correlation between ϕ_{coul} and ($E_{p,ox} - E_{p,red}$) can be interpreted as an indication that the increase of ϕ_{coul} is mainly due to increasing solvation of the neutral rubrene.

The excited triplets which lead to the emission of light are also neutral species of rubrene. It is thus reasonable to assume that the solvation of the excited triplets also increases with increasing ($E_{p,ox} - E_{p,red}$). The excited triplets are susceptible to quenching by the parent ion radicals (13). A more strongly solvated triplet is, however, less likely to be quenched by the rubrene ion radicals because the solvation cage will tend to shield (kinetically) the triplets from energy exchange with the radical ions. In a solvent of mixed polarity, it is assumed that the triplets will be preferentially solvated by the less polar component, *i.e.*, benzene, and the ion radicals by the more polar component, the aprotic solvent, thereby further reducing the efficiency of the quenching mechanism.

The rate of increase in ϕ_{coul} with increasing ($E_{p,ox} - E_{p,red}$) decreases with increasing ($E_{p,ox} - E_{p,red}$). This is to be expected because the solvent component

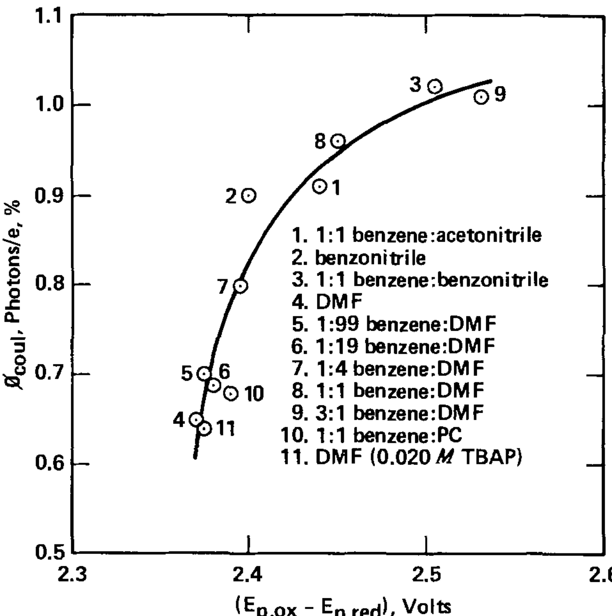

Fig. 5. Correlation between ϕ_{coul} and ($E_{p,ox} - E_{p,red}$) of 1 mM rubrene in various solvents containing 0.100M TBAP. The EGCL was generated with a symmetrical, 100 Hz square wave voltage.

(benzene) which tends to produce relatively high ($E_{p,ox} - E_{p,red}$) will also then tend to solvate the radical ions. When both the rubrene in its excited triplet state and its ion radical form are similarly solvated, the identical solvation shells will tend to offer less resistance to the quenching process than if they were different.

The four aprotic solvents employed, viz., DMF PhCN, ACN, and PC, are physically very different and yet ϕ_{coul} of rubrene EGCL in their solutions correlates very well with ($E_{p,ox} - E_{p,red}$). It is therefore concluded that the degree of solvation of the neutral rubrene is the dominant factor in determining ϕ_{coul} of its EGCL.

Thermodynamic Properties of the Alkali Metals in Aluminum Chloride-Propylene Carbonate Solution

Jacob Jorné*,[1] and Charles W. Tobias*

Inorganic Materials Research Division, Lawrence Berkeley Laboratory and Department of Chemical Engineering, University of California, Berkeley, California 94720

ABSTRACT

EMF measurements were performed at 25° and 35°C on the general cell M(s)/MCl [solution in $AlCl_3$ (1m) in PC]/TlCl(s)/Tl(Hg), where M represents Li, Na, K, Rb, and Cs. The standard electrode potentials of the alkali metals in $AlCl_3$ (1m) — PC solution evaluated by extrapolation to infinite dilution follow the order: Cs < Rb < K < Li < Na which is different than the order in water. Activity coefficients of the alkali metal chlorides were calculated for a wide range of molalities. The partial molal Gibbs free energies, entropies, and enthalpies of the cell reactions have been evaluated and compared to those in other solvents.

The feasibility of the deposition of all the alkali metals from their chlorides in $AlCl_3$-propylene carbonate solution has been demonstrated (1). Lithium, sodium, potassium, rubidium, and cesium were deposited at ambient temperature showing stable and reversible behavior. The alkali metal chlorides are practically insoluble in PC, however in the presence of $AlCl_3$ a complex is formed between the chloride and $AlCl_3$ according to the reaction

$$MCl + AlCl_3 = M^+ + AlCl_4^-$$

This reaction proceeds for all the alkali metals and is the only combination that gives high solubility and conductivity for all the alkali metals. The electrodeposition of the alkali metals from their chloride solutions in $AlCl_3$-PC is proposed as a new process for the electrodeposition and refining of the alkali metals at ambient temperature (2). In order to characterize such a process, thermodynamic, kinetic, and transport data are needed. With this goal in mind, emf measurements of the alkali metals in their chloride solutions in $AlCl_3$(1m)-PC were performed on the cell

Key words: alkali metals, propylene carbonate, aluminum chloride, standard potentials.

$M(s)/MCl(m), AlCl_3(1m)$ in $PC/TlCl(s)/Tl(Hg)$

The measurements were performed in order to establish a scale of standard electrode potentials in $AlCl_3(1m)$-PC solution, and to obtain activity coefficients data; both are needed for the design of an electrorefining cell, and for the prediction of the separation and purification of the alkali metals in such a cell (2). In addition, kinetic (3), conductance, and specific volume measurements (4) are reported elsewhere.

The thermodynamics of some of the alkali metals in various solutions in PC were investigated by Salomon (5-7) using the emf method. The thermodynamics of LiCl and LiBr (5), NaI (6), LiI and KI (7), were measured using the cell-type

$$M/MX \text{ in } PC/TlX(s)/Tl(Hg)$$

where M represents Li, Na, and K, and X represents Cl^-, Br^-, and I^-. In the case of the potassium system, potassium amalgam replaced the metallic potassium, and the data were corrected for the free energy of formation of the amalgam. The standard potentials were obtained by extrapolation to infinite dilution following the Guggenheim equation (8). The thermodynamics of single ion solvation in PC and water is summarized by Salomon (9).

The extensive work of Salomon did not include rubidium and cesium and in addition, iodide was the only common anion which shows high solubility for Li, Na, and K. With the exception of lithium, the chlorides of the alkali metals are highly insoluble in pure PC. In the present work, emf measurements were performed for all the alkali metals, and the fact that the same common anion was used enabled the establishment of a scale of standard potentials for the alkali metals series.

Experimental

Solvent purification.—Propylene carbonate (Jefferson Chemical Company, Houston, Texas) was distilled at 0.5 mm Hg in a commercially available distillation column (Semi-CAL Series 3650, Podbielniak, Franklin Park, Illinois) packed with stainless steel helices. The reflux ratio was 60 to 100 and the head temperature 65°C. The first 10% and last 25% of the solvent were discarded. Argon gas was bubbled through the solvent during distillation. The collection vessel was not detached from the column; the solvent was discharged directly into the dispensing vessel. The transfer was done under an argon atmosphere. The dispensing vessel was evacuated on the vacuum line to approximately 50μ Hg, closed tightly and transferred into the glove box.

The "as received" solvent contains a few tenths of a per cent of the following impurities: water, propylene glycol, propion aldehyde, propylene oxide (10). Gas chromatographic analysis of the product performed in this laboratory showed the water content to be always below 50 ppm. The presence of a second impurity at a very low concentration was identified as propylene oxide; its concentration was estimated below 1 ppm (1). Molecular sieves (Linde 4A) were ineffective in removing propylene oxide from PC.

The glove box (Lawrence Livermore Laboratory design) was maintained under dry and oxygen-free argon (1). The water content of the inlet argon stream was measured by a moisture monitor (Consolidated Electrodynamics Corporation, Model 26-303 ME) and was always below 1 ppm.

Electrolytic solutions.—All solutions of the alkali metal chlorides in $AlCl_3(1m)$-PC were prepared by weighing the salts and the solvent inside the glove box. The 1.0 molal (m) solutions of $AlCl_3$ in PC were made by adding the salt very slowly to the solvent, since the heat of solution is very high. The $AlCl_3$ in PC solutions were prepared inside the box under argon and were cooled with chloroform-carbon tetrachloride-dry ice bath mixture. Careless addition of $AlCl_3$ to PC resulted in a brown solution; this occurred particularly when the salt was not a fine powder, but rather in small granules, which upon addition to PC resulted in local heating and darkening of the solution.

The alkali metal chlorides were dried inside a vacuum oven (Hotpack, Philadelphia) at 200°C and approximately 50μ Hg for at least 24 hr. The amounts needed for the specific molalities were calculated each time from the weights of the solvent. Stirring for a few hours was required in order to achieve complete dissolution of the alkali metal chlorides. The final solutions were treated with molecular sieves (Linde 4A) in order to remove traces of water introduced by the salts. The molecular sieves were treated before use by heating (300°C), high vacuum, and several flashes with argon. This procedure was found effective in further removing traces of water and therefore increased the stability of the alkali metals during the potential measurements.

Reference electrode.—Earlier investigations in this laboratory revealed the excellent nature of thallium amalgam-thallous halide electrodes in PC (11) and DMSO (12, 13). Thallous chloride was found to be only slightly soluble in PC and does not dissolve in excess of chloride. This reference electrode has been applied to the cell Li/LiX(DMSO)/TlX(s)/Tl(Hg) in order to determine the standard potential of the cell and the activity coefficients of LiX in DMSO. Salomon (5-7) used this reference electrode to measure standard potentials and activity coefficients of alkali metal halides in PC. The Tl(Hg) solidus TlCl electrode was found to be stable and reversible in DMF (12).

The performance of Tl(Hg)/TlCl electrode in PC was reversible with good stability. The solubility product of TlCl in PC is $K_{sp} = 10^{-12.4}$ (11), extremely low even when compared with other aprotic solvents (*e.g.*, for DMSO $K_{sp} = 10^{-6.26}$) (14).

The thallium wire used for preparation of the amalgam was 99.999% pure (United Mineral and Chemical Corporation, New York). The oxide coating on the metal was removed by successive washing with oxygen-free distilled water under argon atmosphere. The shining Tl was transferred directly into the glove box without exposure to air. The resulting silvery white metal dissolved readily in mercury. The mercury used was triple distilled. The amalgam concentration was prepared by weight. The thallium amalgam was then placed inside the electrode cups containing about 5 ml of the amalgam, exposing around 1 cm^2 of shiny surface (see Fig. 1). The amalgam surface was then covered with a thin adherent layer of fine TlCl. The electrode was gently shaken in order to get a complete and uniform coverage of the surface.

The electrical connection to the amalgam was through a platinum lead which was connected to a tungsten wire. All the connections and leads were overlaid with uranium glass for a vacuum-tight seal. The platinum tip was immersed well beneath the surface of the amalgam to prevent creeping of the solvent between the amalgam and the glass.

Cell for potential measurements.—The cell used for potential measurements, shown in Fig. 1, was developed earlier by Smyrl (13, 15). In this six-compartment cell each compartment is connected to the central one by a narrow pipe. The cup electrode for the thallium amalgam-thallous chloride reference electrode is shown in Fig. 1. A detailed description of the cell is given by Smyrl and Tobias (15). The electrode holder for the solid alkali metals (Li, Na, K) is shown in Fig. 1. The alkali metal wire was attached to the platinum wire by a stainless steel connector. Alkali metal amalgam electrodes were prepared by pouring the amalgams into cup electrodes similar to those used for the reference electrodes.

Rubidium and cesium electrodes were prepared by heating the capsules in which these metals had been received, and the electrode's cups, and then pouring the

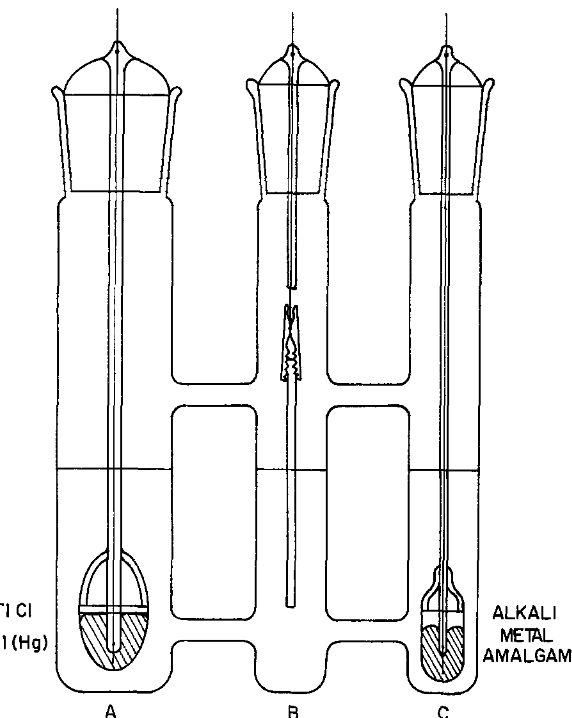

Fig. 1. Six-compartment cell for potential measurements (only three compartments are shown). A, Reference electrode; B, alkali metal electrode; C, alkali metal amalgam electrode.

liquid metals into the cups well above the platinum leads. Lithium was obtained as ⅛ in. wire and was rinsed with the pure solvent. Sodium and potassium obtained in the form of ribbons were extruded through a stainless steel extruder of 1.13 cm diameter, and then were washed with the pure solvent. All the alkali metal electrodes kept their shining surfaces during the measurements. Electrodes which turned gray or black after being immersed in the solution, consequently giving erratic potentials, were discarded.

The arrangement of the electrodes was the following: For every measurement there were two reference electrodes, two alkali metal electrodes, and two alkali metal amalgam electrodes of identical composition. The cell, the electrode holders, and the cup electrode, besides all volumetric flasks and glassware, were cleaned prior to each experiment by concentrated nitric acid and were rinsed several times with distilled water. Periodically the cells were cleaned with concentrated sodium hydroxide, dilute sulfuric acid, and distilled water. Occasionally the cells and the cup electrodes were cleaned with an ultrasonic vibrator to remove solids from the glass. All glassware was dried in a vacuum oven at 50μ and 200°C for at least 24 hr and then transferred quickly into the glove box.

Assembly of cell.—The six-compartment cell was filled with approximately 100 cm³ solution of a specific concentration of the alkali metal chloride in $AlCl_3$ (1m)-PC. Thallium amalgam was dispensed into the cup of each of the two reference electrodes, a small amount of TlCl was spread on the surface, the ground joints were lubricated, and the reference electrodes were inserted into the cell. The alkali metal amalgam was then dispensed into the cups of each of the two-cup electrodes and was inserted into the cell. The alkali metal wire was cut, connected to the stainless steel holders, and inserted into the cell. The cell was then closed and removed from the glove box. The cell was next suspended in a constant temperature water bath for equilibrium and micropolarization measurements (3). The measurements were done at 25° and 35°C, ±0.01°C.

Cell potential measurements.—Measurements of the cell potentials were taken with a John Fluke Model 887—A differential voltmeter (accuracy ±0.005 mV) which was calibrated against an Eppley Laboratory, low temperature coefficient standard cell.

The measurements began 15 min after the suspension of the cell in the bath. Measurements included: (*i*) Cell potentials between the alkali metal electrodes and the reference electrodes. (*ii*) Cell potentials between the alkali metal amalgam electrodes and the reference electrodes. (*iii*) Potentials between the alkali metals and their amalgams. (*iv*) Bias potentials between the two alkali metal electrodes, the two alkali metal amalgam electrodes, and the two Tl(Hg)/TlCl reference electrodes. The potential measurements were repeated each 30 min for the first few hours and then were recorded several times each day for at least one week. The cell was then transferred to the 35°C bath and identical measurements were taken. The cell then was transferred back to the 25°C bath and the first series repeated.

Micropolarization measurements were conducted during the potential measurement period. The alkali metal electrodes were polarized in both cathodic and anodic directions and the reversibility of the electrodes was checked.

Results

Tables I-V contain the results of the experimental measurements of the general cell

$$M(s)/MCl(m),\ AlCl_3(1m)\ \text{in PC}/TlCl(s)/Tl(Hg)$$

at 25° and 35°C, where M represents Li, Na, K, Rb, and Cs. The measurements were repeated for each metal at different alkali metal chloride molalities. The concentration of the thallium amalgam, the same in all experiments, was 4.749% by weight.

The first column in each table gives the concentration of the alkali metal chloride in molality units (moles of MCl per 1000g of pure PC). The measured cell potential in volts is listed in the second column.

This value for each concentration is the average value of the potential of the two alkali metal electrodes *vs.* the two reference electrodes. The potential difference between two thallium amalgam-thallous chloride reference electrodes was always smaller than 1 mV. The bias potential between the two alkali metal electrodes was different for the various metals. The bias potential was smaller than 1, 1, 10, 5, 5 mV for the Li, Na, K, Rb, and Cs systems, respectively.

The potential E_1 is tabulated in the third column and represents the corrected value of E for the thallium amalgam concentration. The correction was taken from the work of Richards, and Daniels (16), who measured the potentials between different thallium amalgam concentrations and pure thallium.

The function E_2 is listed in the fourth column and the method used to obtain this function is given below. The potential of the cell

$$M(s)/MCl(m),\ AlCl_3(1m)\ \text{in}\ PC/TlCl(s)/Tl(s)$$

is given by

$$E_1 = E°_1 - RT/\mathbf{F} \ln (m_{Cl^-} m_{M^+} \gamma_{Cl^-} \gamma_{M^+}) \quad [1]$$

where m is the molality and γ the activity coefficient of a particular ion. Since the molality of $AlCl_3$ is held constant, it is convenient to choose the reference state as $AlCl_3(1m)$ in PC. By this convention, the solvent is considered to be a unit molality solution of $AlCl_3$ in PC and not pure PC as usual. The cell potential according to this convention is given by

$$E_1 = E°_2 - 2RT/\mathbf{F} \ln (m_{MCl} \gamma_{MCl}) \quad [2]$$

where $E°_2$ is the standard oxidation potential of the cell in $AlCl_3(1m)$-PC solution. The standard state of the solute is taken at infinite dilution of the alkali metal chloride in $AlCl_3(1m)$-PC solution where the activity coefficient of the alkali metal chloride approaches unity. The problem of determining $E°_2$ and thus the activity coefficients at different concentrations of MCl involves extrapolation to infinite dilution. The method of extrapolation to infinite dilution using the Guggenheim equation (8) cannot be employed here since the ionic strength is very high. Instead, rearranging Eq. [2] gives

$$E_2 = (E_1 + 2RT/\mathbf{F} \ln m_{MCl}) = E°_2 - 2RT/\mathbf{F} \ln \gamma_{MCl} \quad [3]$$

Following the method presented by Lewis, Randall, Pitzer, and Brewer (17) (pp. 315-316), if we plot the left-hand side of Eq. [3] as ordinate against some function of m_{MCl} as abscissa, the limit approached by the ordinate at infinite dilution is equal to $E°_2$. It is common to extrapolate with $(m_{MCl})^{1/2}$ as abscissa since such a choice should give a curve approximating linearity at high dilution following the Debye-Hückel limiting law. However, here this dependence is used to expand the low concentration range. Figures 2 and 3 show the plot of E_2 *vs.* $(m_{MCl})^{1/2}$ for all the alkali metals at 25° and 35°C, respectively. The intercepts at zero molalities give $E°_2$, the standard potentials at $AlCl_3(1m)$-PC solution. The difference between the extrapolated values at 25° and 35°C gives the temperature dependence of the standard potential at constant pressure. The results of the extrapolations are given in Table VI.

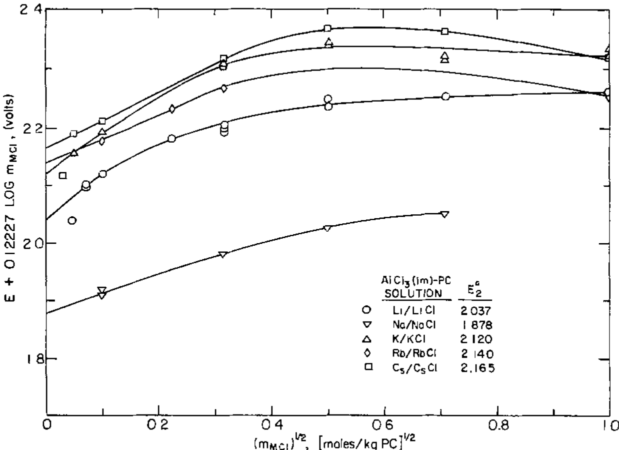

Fig. 2. EMF measurements of the cell: M/MCl(m), $AlCl_3$(1m)-PC/TlCl(s), Tl(s) at 25°C.

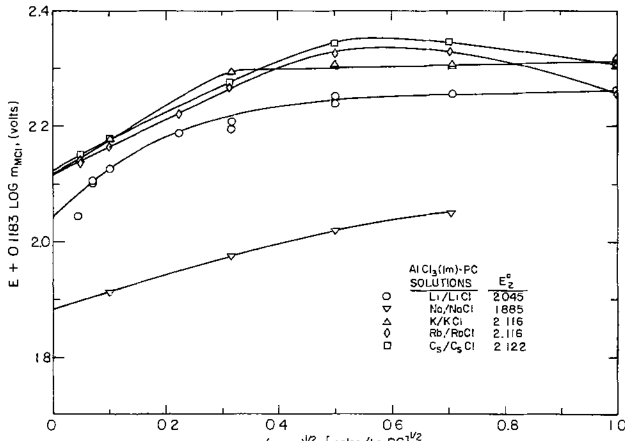

Fig. 3. EMF measurements of the cell: M/MCl(m), $AlCl_3$(1m)-PC/TlCl(s), Tl(s) at 35°C.

From the standard cell potentials and their variation with temperature, the standard free energy $\Delta G°_2$, entropy $\Delta S°_2$, and enthalpy $\Delta H°_2$ can be calculated

$$\Delta G°_2 = -n\mathbf{F}E°_2 \quad [4]$$

$$\Delta S°_2 = n\mathbf{F}(\partial E°_2/\partial T)_p \quad [5]$$

$$\Delta H°_2 = -n\mathbf{F}(E°_2 - T(\partial E°_2/\partial T)_p) \quad [6]$$

These functions are related to the following cell reaction

Table VI. Standard cell potentials at 25° and 35°C

Metal	$E°_2$, 25°C	$E°_2$, 35°C	$(\partial E°_2/\partial T)_p$

Rb	−48.8	−49.3	+55.3	−32.3	−32.3
Cs	−48.9	−49.9	+64.7	−29.6	−29.6

$$M(s)\ TlCl(s) + 1\ mole\ AlCl_3 + 9.8\ mole\ PC \rightleftharpoons$$
$$MCl\ (in\ AlCl_3(1m)\text{-}PC\ solution,\ a_{MCl} = 1) + Tl(s) \quad [7]$$

Table VII presents $\Delta G°_2$, $\Delta S°_2$, and $\Delta H°_2$ on the molal scale for the above cell reaction at 25° and 35°C. The uncertainty in $\Delta S°_2$ and $\Delta H°_2$ is quite high because they were calculated from the difference between extrapolated values.

EMF of the alkali metal-alkali metal amalgam cells.—In addition, emf's of the cell M(s)/MCl(m), $AlCl_3$(1m),PC/M(Hg) were also measured. The concentrations of the Na, K, and Rb amalgams were adjusted to the exact concentrations of the amalgams used by Lewis and his co-workers (18-21). This was done in order to be able to make comparison with emf data for the single amalgam concentrations listed in the literature. In the case of lithium amalgam, the activity coefficient data of lithium was obtained from the work of Cogley and Butler (22). The cesium amalgam concentration did not match the concentration used by Bent *et al.* (23). The agreement between the present measurements and those in the literature is in all cases better than 4.2 mV.

Activity coefficients of the alkali metal chlorides in $AlCl_3$(1m)-PC solution.—Mean molal activity coefficients of the alkali metal chlorides in $AlCl_3$(1m) solution in PC were calculated from

$$\ln \gamma_{MCl}\ (\mathbf{F}/2RT)\ (E°_2 - E_2) - \ln m_{MCl} \quad [8]$$

where $E°_2$ is the extrapolated value of the standard cell potential given in Table VI. The calculated activity coefficients at 25°C are given in Table VIII. Figure 4 presents the plots of $\ln \gamma_{MCl}$ *vs.* $(m_{MCl})^{1/2}$ for all the alkali metal chlorides. It should be mentioned again that the reference state is $AlCl_3$(1m) in PC and not the pure solvent.

Discussion

EMF measurements of the cell without transference: M(s)/MCl(m), $AlCl_3$(1m)-PC/TlCl(s)/Tl(Hg) gave reproducible results. Potential measurements involving the lithium and sodium systems were especially reproducible. The greatest scattering of data points was experienced with the potassium system. Potassium electrodes were less stable in PC and in some cases turned purple after a few days of repeated measurements. This was probably due to the high sensitivity of K electrodes to small traces of water. Lithium and sodium gave reproducible results within ± 1 mV, while rubidium and cesium were somewhat less reproducible, and their bias potentials varied within ± 5 mV, probably because of difficulties experienced in preparing the electrodes in the molten state.

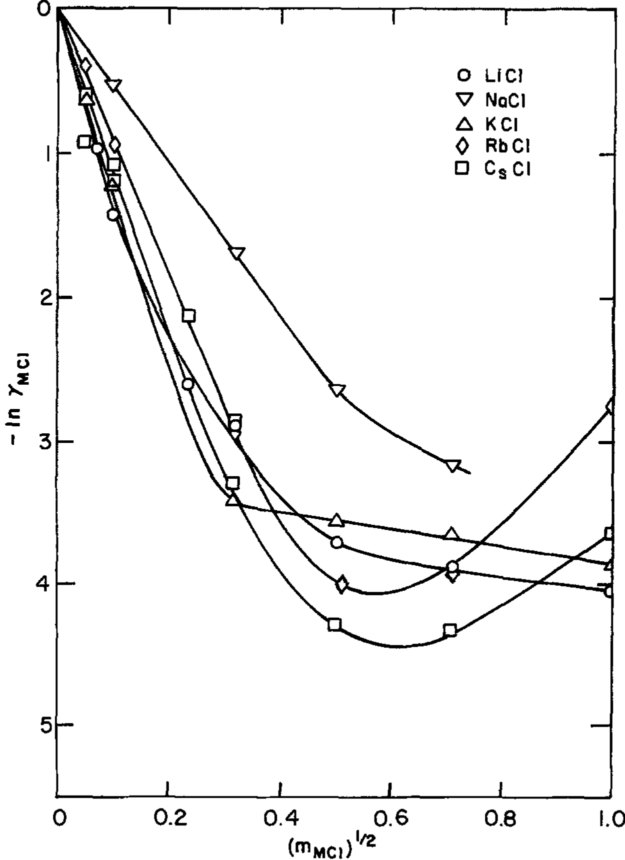

Fig. 4. Activity coefficients of the alkali metal chlorides in $AlCl_3$(1m)-PC solution at 25°C.

The change in cell potential with time was followed by measuring the potentials every 30 min for the first few hours. The potentials were measured then for at least one week before the cell was disassembled. For the first half-hour, especially for solutions having a low concentration of alkali metal chloride, changes in potentials were observed. The potential was then steady within ±5 mV for a few hours, followed by a steady decrease in the cell potential, during the next day. In every case the potential drifted toward the discharge of the cell. The decrease in potential was faster for low alkali metal chloride concentrations, and was minimal when the molality of MCl approached unity or 1:1 ratio with respect to $AlCl_3$ molality in PC. Figure 5 presents the time dependence of the potential for two lithium cells. The lower curve represents the change in potential of a cell containing LiCl (1.0m) in $AlCl_3$(1m)-PC. The upper curve shows the behavior of a cell containing LiCl (0.01m) in $AlCl_3$(1m)-PC.

Similar behavior of cell discharge was observed by Salomon (5) for the alkali metal halides in PC. A steady decrease in cell potentials was observed for lithium halides in DMSO (24, 25), dimethylformamide (12), and N-methylformamide (26). A strong decrease of cell potential with time was observed in the cell Pt, H_2/HCl(m)/AgCl, Ag in formamide (27-29); the true cell potentials were obtained by extrapolating the observed potentials to zero time. Here a decrease of approximately 20 mV was observed during a period of 2 hr (27-29).

The reasons for the steady decrease in cell potentials have been attributed to either solubility and diffusion of the thallous halide and subsequent reaction with the alkali metal (24, 25), or the reaction of the alkali metal with the solvent or with solvent impurities such as water (5). Salomon attributed the phenomena to the reactivity of the alkali metals with impurities rather

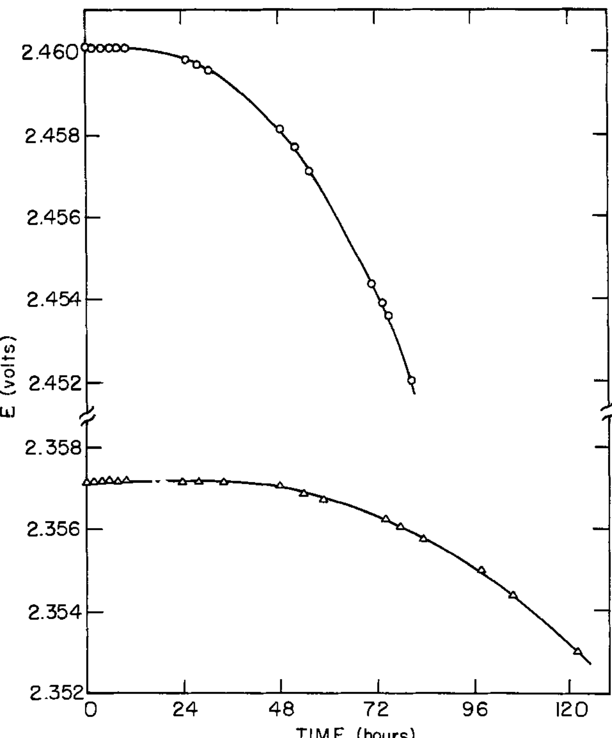

Fig. 5. Time dependence of lithium cell potential at 25°C. ○, m_{LiCl} = 1.0 and △, m_{LiCl} = 0.01.

than to TlCl diffusion across the cell, because the solubility of TlCl in pure PC is extremely low ($K_{sp} = 10^{-12.4}$). In addition, fritted glass was used to slow the diffusion of the thallium species across the cell. However in the present work TlCl is probably somewhat more soluble in the presence of an excess of $AlCl_3$. The behavior of the cell potentials in the present work was similar to the one reported by Smyrl and Tobias for LiCl in DMSO (13), where, after a period of several hours of relatively constant potential, the potential started to decrease steadily due to the reaction

$$Li(s) + TlCl(solution) \rightarrow Tl(s) + LiCl(solution)$$

The standard cell potentials of the alkali metals in $AlCl_3$(1m)-PC solution, relative to Tl/TlCl, are presented in Table VI along with the cell potential temperature coefficients. These results were obtained by extrapolation to infinite dilution with respect to the alkali metal chloride molalities. The order of the standard potentials in the alkali metal series does not follow that in aqueous solution, where lithium has the highest standard potential. The standard potentials of the alkali metals in water and in several other solvents are presented in Table IX, along with the present results. The present results, as well as Salomon's data assign a noticeably higher standard potential to potassium than to lithium. Since the work of Salomon does not include measurements of the rubidium and cesium cells, further comparison cannot be made. Cesium, followed by rubidium shows the highest oxidation potentials in $AlCl_3$(1m)-PC. This is not the case in acetonitrile, N-MF, and water, where lithium has the highest oxidation potential (see Table IX). It may be proper to quote the prediction made by Lewis and Argo in 1915 (21) concerning the peculiarity of the order of the standard potentials in the alkali metal series: "The potentials of the alkali metals follow a curious order, namely, lithium, rubidium, potassium, and sodium. It is interesting, however, to observe that this is the order of the heats of formation of the several ions in aqueous solution. In order to illustrate this fact, the heat of formation of the chlorides of the four metals in aqueous solution are: 102, 101, 101, 96 kcal/mole for LiCl, RbCl, KCl, and NaCl, respectively. The heat of formation of aqueous cesium chloride is given as 105 kcal/mole, and if this figure is correct, we might predict the potential of cesium to be higher than any of the other alkali metals" (21). However, this prediction did not materialize when 14 years later Bent, Forbes, and Forziani (23) obtained the normal electrode potential of cesium, $E° = 2.923$ volts, "...very close to the corresponding value for rubidium, but still 34 millivolts below that for lithium."

Figures 2 and 3 present the potential measurements and the extrapolation to infinite dilution. The fact that almost linear behavior is obtained by plotting the potential E_2 *vs.* $(m_{MCl})^{1/2}$ is very helpful in obtaining the standard potentials, although it should be remembered that this behavior is not well described by the Debye-Hückel limiting law, because the reference solvent was a solution of $AlCl_3$ in PC, in which the ionic strength is very high. The plotting of the results *vs.* the square root of the molality was adopted to expand the dilute region and to obtain a better accuracy in the extrapolation.

The extrapolation procedure of the emf measurements does not involve any assumption concerning the nature of the complexes and ionic species in solution. The predominant ions in a solution of MCl in $AlCl_3$-PC solution are M^+, $Al(PC)_n^{3+}$, and $AlCl_4^-$. Keller *et al.* (30) studied directly the ionic equilibria of $AlCl_3$ in PC using NMR technique. From the ^{27}Al spectra it was concluded that the main species are $Al(PC)_n^{3+}$ and $AlCl_4^-$, similar to the species present in acetonitrile. High resolution ^1H spectra of 1M $AlCl_3$ in PC indicates peaks due to coordinated PC as well as bulk PC. From the ^1H and the ^{27}Al spectra, Keller *et al.* (30) showed that the Al^{3+} coordination number (n) is six. Therefore the dissociation of $AlCl_3$ in PC proceeds according to

$$AlCl_3 + 6/4\,PC \rightarrow 1/4\,Al(PC)_6^{3+} + 3/4\,AlCl_4^- \quad [9]$$

Furthermore it was observed that the addition of LiCl to an $AlCl_3$-PC solution reduces the concentration of the coordinated Al species, and at the saturation point where the LiCl:$AlCl_3$ ratio is 1:1 the coordinated Al species disappears. Such observation can be explained by the reaction between LiCl and $Al(PC)_6^{3+}$ to give mainly $AlCl_4^-$

* Salomon made an error in the thallium amalgam corrections in his work with LiCl and LiBr in PC. The corrections at 25°C for thallium amalgam compositions of 3.147 and 7.76% wt are 112.5 and 78.6 mV, respectively, as is evident from the work of Richards and Daniels (16), and not 135.34 and 94.6 mV as reported by Salomon (5). The results obtained for the other systems studied by Salomon cannot be checked, as detailed data are not available (6, 7).

$$x\text{LiCl} + \tfrac{1}{4}\text{Al(PC)}_6^{3+} + \tfrac{3}{4}\text{AlCl}_4^- \rightarrow x\text{Li}^+ + (1-x)/_4\text{Al(PC)}_6^{3+} + (3+x)/_4\text{AlCl}_4^- + 3x/_2\text{PC} \quad [10]$$

At the saturation point where $x = 1$, all the coordinated $Al(PC)_6^{3+}$ converted to $AlCl_4^-$ and the predominant species present are Li^+ and $AlCl_4^-$. Keller *et al.* (30) summarizes the results for solutions of $AlCl_3$ in DMF, AN, and PC. The complexing strength of Al^{3+} toward Cl^- is stronger than toward PC, AN, and water, but weaker than toward DMF where the dominant species are $Al[DMF]_6^{3+}$ and Cl^-. Movius and Matwiyoff (31) report PMR data for aluminum halides (AlX_3) in DMF which can be interpreted in terms of second coordination sphere interaction between a well-defined $Al(DMF)_6^{3+}$ ion and X^-.

The potentials for lithium cells in which the molality of LiCl was less than 0.005m showed a substantial drift to lower values. This can be observed in Fig. 2 and 3 by the tailing off at the very low LiCl concentration. The potential at 0.002m LiCl was not included in the extrapolation. Tailing off at low concentration was observed by others, especially for lithium cells in DMSO (13, 24), N-methyl formamide (26), and in dimethyl formamide (12). Deviations were not observed in LiI solution in PC (7), nor in LiI solution in DMSO (32). Deviations were not observed in sodium and potassium cells in PC (6, 7), nor in sodium, potassium, and rubidium cells in N-methyl formamide (26).

The standard potentials in the present work are given on a molal basis. The molal basis has been chosen because the molecular weight of PC is more than 5 times larger than that of water. Since many authors present their results on a molar basis, it should be remembered that the standard potential, on a molal basis, can be converted into a molar basis, according to the following relation

$$E^\circ_c = E^\circ_m + \frac{2RT}{\mathbf{F}} \ln \rho_0 \quad [11]$$

where E°_c and E°_m are the standard potentials on a molar and molal basis, respectively, and ρ_0 is the density of the solvent. The solvent in the present case is an $AlCl_3$(1m)-PC solution, and its density is reported as 1.2628 and 1.2530 g/cm³ at 25° and 35°C, respectively (1). The standard potentials of the alkali metals, on a molar basis are presented in Table X. In addition, the standard potentials on a mole fraction basis are presented as well. The mole fraction basis is probably the most suitable way to present thermodynamic data, where the solute mole fraction is comparable with the solvent mole fraction. The standard potential on a mole fraction basis can be obtained from the following equation

$$E^\circ_N = E^\circ_m + \frac{2RT}{\mathbf{F}} \ln \left(\frac{1000}{\text{M.W.}} + 1 \right) \quad [12]$$

where E°_N is the standard potential on a mole fraction basis, and M.W. is the molecular weight of the solvent. In the present case, the reference state is a 1m solution of $AlCl_3$ in PC.

The behavior of the sodium curves in Fig. 2 and 3 is different from the rest of the alkali metals. The solubility of NaCl in $AlCl_3$(1m)-PC solution was around 0.5m, in contrast to the rest of the alkali metal chlorides, which dissolved corresponding to a 1:1 ratio with respect to $AlCl_3$. There is no explanation for this unexpected behavior, although there are indications that the solubilitites of RbCl and CsCl in $AlCl_3$(1m)-PC are not exactly 1.0m but drop slightly upon standing. The decrease in the potentials at high concentrations for the rubidium and cesium systems, given in Fig. 2, indicates probable solvate formation.

Table X. Standard oxidation potentials on a molar and a mole fraction basis for $AlCl_3$ (1m)-PC cells

	$E^\circ_{2,c}$		$E^\circ_{2,N}$	
	25°C	35°C	25°C	35°C
Li	2.054	2.046	2.162	2.158
Na	1.894	1.887	2.002	1.998
K	2.125	2.127	2.233	2.241
Rb	2.125	2.149	2.116	2.261
Cs	2.131	2.174	2.239	2.286

The activity coefficients of the alkali metal chlorides in $AlCl_3$-PC solution are shown in Fig. 4. The sharp decrease in the activity coefficients at low concentrations is due to the reaction between the chloride ions and Al^{3+} species yielding $AlCl_4^-$. Since $AlCl_3$ is part of the solvent, this decrease in the activity coefficients is equivalent to systems where the solute reacts with the solvent, *e.g.*, NH_3 in water or hydrate formation in aqueous solution.

Estimation of the standard potentials of the alkali metals in pure PC.—The standard potentials obtained were calculated with respect to the cell M(s)/MCl, $AlCl_3$(1m)-PC/TlCl(s), Tl(s) where the standard state was chosen as infinite dilution of MCl in $AlCl_3$(1m)-PC solution. The standard potentials of the alkali metals in pure PC can be measured from the cell M(s)/MCl, PC/TlCl(s), Tl(s). However, the solubilities of the alkali metal chlorides in PC are very low, and only LiCl is soluble enough to permit accurate potential measurements. Salomon measured the standard potential of lithium in LiCl solution in PC; however, in order to establish a scale of standard potentials in PC for the rest of the alkali metals, he switched to the alkali metal iodides which are soluble in PC. Salomon did not measure the standard potentials of rubidium and cesium.

An estimation of the standard potentials of cells of the alkali metal chlorides in pure PC can be made on the basis of the results of the present work and the standard potential of the LiCl cell as reported by Salomon (5). The standarad potential of the cell Li(s)/LiCl(m), $AlCl_3$(1m),PC/TlCl(s), Tl(s) is given by

$$E_1 = E^\circ_1 - \frac{RT}{\mathbf{F}} \ln \left(m_{Li^+}\gamma_{Li^+} m_{Cl^-}\gamma_{Cl^-}\right) \quad [13]$$

where E°_1 is the standard potential at infinite dilution. The cell potential on the basis of $AlCl_3$(1m)-PC as a reference state is given by

$$E_1 = E^\circ_2 - \frac{2RT}{\mathbf{F}} \ln \left(m_{LiCl}\gamma_{LiCl}\right) \quad [14]$$

As $m_{LiCl} \rightarrow 0$

$$E^\circ_2 - E^\circ_1 = -\frac{RT}{\mathbf{F}} \ln \left(m_{Li^+}\gamma_{Li^+} m_{Cl^-}\gamma_{Cl^-}\right) \quad [15]$$

The left-hand side of Eq. [13] can be calculated, since E°_2 was measured in the present work, and E°_1 for lithium is reported by Salomon as, $E^\circ_1 = 1.85080$V. (This value is the corrected one, since Salomon made an error in the thallium amalgam correction, see Table IX)

$$-\frac{RT}{\mathbf{F}} \ln \left(m_{Li} + \gamma_{Li} + m_{Cl^-}\gamma_{Cl^-}\right)_{m_{LiCl \rightarrow 0}} = 2.045 - 1.851 = 0.194\text{V}$$

If we assume that this value does not change much going through the alkali metal series, we can estimate the standard potentials E°_1 for the rest of the alkali metals

$$E^\circ_1 = E^\circ_2 - 0.194$$

Table XI summarizes the approximated standard potentials of the cell M(s)/MCl, PC/TlCl(s), Tl(s).

On the basis of these estimated standard oxidation potentials, it is expected that even in pure PC the standard oxidation potential of Cs will be the highest, followed by Rb, K, Li and Na.

Table XI. Estimated standard oxidation potentials for the alkali metals in pure PC

Cell	$E°_1$, volt	$\Delta G°_1$, kcal/mole
Li/LiCl,PC/TlCl,Tl	1.85080*	−42.9*
Na/NaCl,PC/TlCl,Tl	1.691	−39.0
K/KCl,PC/TlCl,Tl	1.922	−44.3
Rb/RbCl,PC/TlCl,Tl	1.922	−44.3
Cs/CsCl,PC/TlCl,Tl	1.928	−44.5

* Measured by Salomon (5).

Ionic equilibria considerations.—The predominant ions in a solution of MCl in $AlCl_3$-PC solution are M^+, $Al(PC)_6{}^{3+}$, and $AlCl_4{}^-$. A rough calculation was made of the equilibrium constant of the reaction

$$AlCl_4{}^- \overset{K_4}{\rightleftarrows} Al^{3+} + 4Cl^- \quad [16]$$

on the assumption that this equilibrium accounts for all the difference between the activity of MCl and that of a typical univalent salt. The calculations were performed only in the case of LiCl because its standard potential on the pure solvent basis was obtained by Salomon (5)

The fourth ionization constant K_4 is given by

$$K_4 = \frac{(Al^{3+})(Cl^-)^4}{(AlCl_4{}^-)} \quad [17]$$

Multiplying and dividing by (Li^+) results in

$$K_4 = \frac{\gamma^4{}_{3\text{-}1}[Al^{3+}][Cl^-]^3\, a_{LiCl}}{\gamma^2{}_{1\text{-}1}[AlCl_4{}^-][Li^+]} \quad [18]$$

where brackets indicate molality and parentheses activity.

For a constant ionic strength we can define a new constant

$$K_4' = \frac{\gamma^2{}_{1\text{-}1}}{\gamma^4{}_{3\text{-}1}} K_4 = \frac{(1-m)\,a_{LiCl}}{(3+m)m}[Cl^-]^3 \quad [19]$$

where m is the molality of the added LiCl. The activity of LiCl based on pure PC as a standard state, a_{LiCl}, can be estimated from the present emf measurements and the standard potential $E° = 1.8508V$ obtained by Salomon (5) for the cell: Li/LiCl in PC/TlCl/Tl

$$E = 1.8508 - (RT/\mathbf{F}) \ln a_{LiCl} \quad [20]$$

The ionic strength is fairly constant over most of the experimental range and can be evaluated for the general case of adding m moles of LiCl to 1m solution of $AlCl_3$ in PC (see Eq. [10]) according to

$$I = \frac{1}{2}\sum_i m_i z_i{}^2 = \frac{1}{2}\left[\frac{(3+m)}{4}(-1)^2 + \frac{(1-m)}{4}(+3)^2 + m(+1)^2\right] = \frac{(12-4m)}{8} \quad [21]$$

When $m = 0$ the ionic strength is $I = 1.5$ and drops to $I = 1.0$ when $m = 1.0$. The ionic strength is fairly constant up to $m = 0.25$ and over this range we can assume the ratio $\gamma^2{}_{1\text{-}1}/\gamma^4{}_{3\text{-}1}$ is fairly constant.

Table XII presents the calculations of $K_4'/[Cl^-]^3$ as a function of the added molality of LiCl, m, and the total ionic strength, I. As can be seen from Table XII the chloride concentration $[Cl^-]$ increases very slightly as we add LiCl. Although we increase the LiCl concentration up to 50 times, the free chloride concentration increases by a factor of merely 1.8. Also, it should be kept in mind that K_4' depends on the ionic strength since it includes the ratio of the activity coefficients. However, as has been mentioned earlier, the ionic strength remains fairly constant up to 0.25m of added LiCl.

Table XII. Instability constant K'_4 and free chloride molality

m	$10^9 \times a_{LiCl}$	$I^{1/2}$	$10^8 \times (K'_4/[Cl^-]^3)$	$[Cl]^-$

Electrogenerated Chemiluminescence

XXIII. On the Operation and Lifetime of ECL Devices

Daniel Laser and Allen J. Bard*

Department of Chemistry, The University of Texas at Austin, Austin, Texas 78712

ABSTRACT

Factors affecting the lifetime of ECL devices, including decomposition of starting materials, formation of side products which react with radical ions or quench excited states, and filming of the electrodes are discussed. The mode of operation of the ECL device is shown to be important in determining its behavior and lifetime; operation of (*i*) three-electrode pulsed potentiostatic, (*ii*) two-electrode pulsed voltage, (*iii*) two-electrode pulsed constant current, and (*iv*) thin-layer cells is discussed and illustrated, in studies of the $Ru(bip)_3^{2+}$ system in acetonitrile and the rubrene system in benzonitrile.

Electrogenerated chemiluminescence (ECL) involves the production of excited state species and ultimately light from the reaction of electrogenerated oxidants and reductants (1-7). Since several ECL systems are capable of producing fairly bright light at reasonable electrical efficiencies, several applications of practical devices based on the ECL phenomenon, *e.g.*, lasers, display devices, image convertors, etc. (8-12), have been suggested. For these devices to be practical, however, good lifetimes of the systems are required. In principle an ideal ECL system involving stable electrogenerated reactants (*e.g.*, a radical anion, $A^{\overline{\cdot}}$, and radical cation, $D^{\overset{+}{\cdot}}$) should show a very long lifetime, since the ECL cycle (*e.g.*, Eq. [1]-[4]) involve no net chemical change in the system. In fact most ECL systems show a decay in emission with

$$A + e \rightarrow A^{\overline{\cdot}} \quad [1]$$

$$D - e \rightarrow D^{\overset{+}{\cdot}} \quad [2]$$

$$A^{\overline{\cdot}} + D^{\overset{+}{\cdot}} \rightarrow A^* + D \quad [3]$$

$$A^* \rightarrow A + h\nu \quad [4]$$

time (minutes to hundreds of hours) under continuous electrical excitation. The rate of this decay depends on the nature and purity of the ECL system as well as the design of the ECL cell and the form of the electrical excitation. It is the purpose of this paper to discuss the factors affecting the lifetime of ECL cells and give examples of the behavior of these devices under different experimental conditions.

Experimental

Purification of the solvents, acetonitrile (ACN) and benzonitrile (BZN), the supporting electrolyte, tetra-*n*-butylammonium perchlorate (TBAP), and the reactants followed previous practice (7, 11). All experiments were conducted in a Vacuum Atmospheres (Los Angeles, California) Glove Box equipped with a Model MO 40-1 Dri-Train.

* Electrochemical Society Active Member.

Key words: electrochemiluminescence, nonaqueous solvents, thin-layer electrochemistry, radical ions, cyclic voltammetry.

The macro-cell had a solution volume of 30 mliters with an optically flat Pyrex glass window. The working electrode was a polished platinum disk (0.25 cm^2) sealed flush into soft glass and aligned parallel to, and about 1 cm away from, the window. The large auxiliary electrode was a platinum foil (*ca.* 5 × 2 cm) surrounding the working electrode and immersed directly in the test solution. The reference electrode was a silver wire immersed in $10^{-2}M$ $AgNO_3$ in ACN, contained in a 6 mm glass tube closed at the bottom by a plug of porous Vycor (Corning Type 7930 "thirsty glass"), which was held to the glass tube by a piece of shrinkable Teflon tubing. For experiments with working and auxiliary electrodes of equal size, two matched Pt wires were employed.

The thin-layer ECL cells were constructed with two pieces of transparent Cu-doped SnO_2 glass (Corning), *ca.* 20 ohm/square, spaced apart by a thin Teflon spacer, and clamped by spring clamps. The active electrode area in these cells was *ca.* 0.5 cm^2.

All electrochemical measurements were made with a Princeton Applied Research Corporation Model 176 instrument, with a Wavetek Model 114 function generator, a Mosley Model 7005A XY recorder, and a Tektronix Model 564 dual beam oscilloscope. Relative light intensities were measured with a Centralab Semiconductor solar cell attached to the ECL cell window.

Results and Discussion

Failure modes.—There are several modes by which an ECL system will undergo changes which will ultimately cause a substantial decrease in light emission. These are:

1. Loss of the electroactive substances A and/or D, leading to a decrease in the concentration of the reacting ions $A^{\overline{\cdot}}$ and $D^{\overset{+}{\cdot}}$, and thus of the emitting species. This frequently occurs when the radical ion species $A^{\overline{\cdot}}$ or $D^{\overset{+}{\cdot}}$ decay by reaction with solvent or impurities; in this case the rate of decay of intensity is related to the kinetics of the decomposition reaction (13, 14). In several systems, *e.g.*, A = D = rubrene (in BZN or DMF), A = D = *tris*-bipyridylruthenium(II) (in ACN), A = 9,10-diphenylanthracene (DPA), D = thianthrene (in ACN), the radical ion species are very stable, and ECL

systems which have failed show no or only a very small change in the A and D concentrations as determined by cyclic voltammetry or spectroscopy before and after the ECL experiment. However if the electrode potential is not closely controlled and is allowed to move to regions where later waves (*e.g.*, production of A^{2-} or D^{2+}) or electrolysis of solvent or supporting electrolyte occurs, then loss of A and D can be significant. This occurs because of instability of the dianion and dications of most organic species employed in ECL. This can happen even in three-electrode potentiostatic experiments if the reference electrode potential drifts during the lifetime test or if the system goes into large oscillations during adjustment of the positive feedback *iR*-compensation circuit. When this occurs the solution often turns a brownish color and it cannot be restored to a light-emitting condition.

2. Production of small amounts of side products from slow reactions of $\overset{-}{A\cdot}$ or $\overset{+}{D\cdot}$ with other system components or impurities; these side products can react with $\overset{-}{A\cdot}$ or $\overset{+}{D\cdot}$ decreasing their life or they may act as quenchers of the excited states. These decomposition reactions could involve reactions of A^{2-} (formed on disproportionation of $\overset{-}{A\cdot}$) or D^{2+} (formed on disproportionation of $\overset{+}{D\cdot}$). Although the equilibrium constants for these disproportionation reactions are small (*e.g.*, 10^{-8} for a *ca.* 0.5V separation between $E°$ values of radical ion and doubly charged ion half-reaction), the dianions and dications are usually very reactive species; this disproportionation decay of radical ions, in connection with much faster reactions, however, has been discussed extensively (15-17). A useful estimate of the maximum rate of buildup of side-product (or rate of loss of reactant) can be derived as follows: Assuming that the electrolysis of the reacting component (*e.g.*, A) is diffusion controlled, the moles of species A electrolyzed per pulse is

$$\text{moles electrolyzed per pulse} = \int_0^{t_f} idt/\mathbf{F}$$

$$= 2AC\,(Dt_f/\pi)^{1/2} \quad [5]$$

where C and D are the concentration and diffusion coefficient of A, t_f is the pulse length, and A the electrode area. If $\overset{-}{A\cdot}$ decomposes by a first-order or a pseudo-first-order reaction with a rate constant, k, the fraction of $\overset{-}{A\cdot}$ converted to product, Q, is $1 - e^{-kt_f}$. Thus the maximum number of moles of Q produced per pulse is

$$\text{moles } Q \text{ produced per pulse} = 2(1 - e^{-kt_f})AC(Dt_f/\pi)^{1/2} \quad [6]$$

The concentration of Q produced in the total solution volume, V, after N pulses is

$$[Q] = 2(1 - e^{-kt_f})C\,N(A/V)\,(Dt_f/\pi)^{1/2} \quad [7]$$

The total system lifetime, T, is $2Nt_f$. Moreover, in any practical system kt_f is small, so that $1 - \exp(-kt_f)$ is essentially kt_f. With these substitutions the lifetime can be approximated by

$$T = ([Q]/C)\,(V/A)\,(\pi/Dt_f)^{1/2}/k \quad [8]$$

The time required to build up a significant concentration of side product for a given k, depends on the pulse length and V/A ratio. For example, for the typical values, $D = 5 \times 10^{-6}$ cm²/sec and $t_f = 0.01$ sec, and assuming the device lifetime is attained when the impurity level builds up to 1% of starting substance ($[Q]/C = 0.01$), the lifetime expression is

$$T(\text{hr}) \simeq 0.02\,(V/A)\,(\text{cm})/k\,(\text{sec}^{-1}) \quad [9]$$

Thus a 1000 hr lifetime requires $k < 2 \times 10^{-3}$ sec^{-1} for a V/A ratio of 100 cm, characteristic of a large scale cell, while a $k < 2 \times 10^{-7}$ sec^{-1} is required for a V/A ratio of 10^{-2} cm, typical of a thin-layer cell.

The decreased lifetime of the radical ion species is signaled by decreased reversal currents in cyclic voltammetry over those originally observed. These side products can also behave as quenchers of the generated excited states. The radiative lifetime of singlet states is short (about 10^{-8} sec) so that small concentrations of generated quenchers should not be of importance in ECL systems where singlet excited states are produced directly on reaction of $\overset{-}{A\cdot}$ and D^+ [*i.e.*, S-route systems, *e.g.*, DPA(−)/DPA(+) in DMF]. However triplet states have longer radiative lifetimes (10^{-3} to several seconds) and can be quenched by low concentrations of side products. Thus systems which involve direct formation of triplets followed by triplet-triplet annihilation to produce emitting singlets [T-route systems, *e.g.*, rubrene(−)/rubrene(+) in DMF and many energy deficient mixed systems] may be susceptible to this decay mode. In certain special cases photochemical-type reactions of the excited state species (rearrangements, cycloadditions, etc.) could also occur.

The applied excitation signal also affects this decay mode. The assumption has been made that the anodic and cathodic coulombs were equal, so that no excess of either $\overset{-}{A\cdot}$ or $\overset{+}{D\cdot}$ is produced over long, repeated pulsing. However this condition is only obtained by careful control and appropriate relative electrode areas. In the absence of this condition one of the reactants builds up in the bulk solution and can show more extensive decomposition to side products.

3. Production of side products from the electrolysis of impurities in the solvent, supporting electrolyte, or radical ion precursors, which can react with $\overset{-}{A\cdot}$ and/or D^+ or quench the excited states. For example traces of water, which are difficult to remove from solvents such as DMF and ACN, could be oxidized on anodic pulses to oxygen, which in turn could be reduced to $\overset{-}{O_2\cdot}$ on cathodic pulses. Electrogenerated $\overset{-}{O_2\cdot}$ has been shown to react as a nucleophile and as a base (18). In the process free radicals such as $HO_2\cdot$ and $HO\cdot$ are produced, which may initiate chain reaction decomposition of system components. Since 2 ppm water represents 0.1 mM water, or 1-10% of the A and D species, very high purities of system components are required. If electrolysis of the solvent or supporting electrolyte occurs, either because of lack of control of the applied signal or because the radical ion generation processes occur on the foot of background discharge, deleterious substances can also be generated. For example, it is known that the light level of the DPA(−)/DPA(+) in the DMF system decreases sharply when the potential of the Pt generating electrode reaches those where cathodic background currents become appreciable (19).

4. Filming of the electrode by production of insoluble products (*e.g.*, polymers) from side reactions of the radical ions, or by electrolysis of impurities, solvent, or supporting electrolyte. These films can cause progressive blockage of the electrode or by buildup of a layer which can catalyze side reactions. When this form of decay is important, removing and polishing the electrode and returning it to the ECL system will at least partially restore the emission. This behavior was noticed upon generation of $\overset{-}{DPA\cdot}$ in ACN (19); other examples of filming are discussed below.

Electrical excitation of ECL.—The discussion of failure modes points to the importance of the mode of electrical excitation to long term stability. In general a desirable mode of excitation will (*a*) maintain the electrode potentials of both working and auxiliary electrodes in regions where only $\overset{-}{A\cdot}$ and $\overset{+}{D\cdot}$ can be produced; (*b*) be coulometrically symmetric, *i.e.*, have equal anodic and cathodic (faradaic) coulombs on alternate pulses; (*c*) maximize reaction between $\overset{-}{A\cdot}$

and D^+, *i.e.*, cause the direct oxidation of $A^{\overline{\cdot}}$ and reduction of $D^{\overset{+}{\cdot}}$ at the electrode to be minimal. For example the square wave potentiostatic mode causes very little loss of the radical ions by direct electrolysis, while appreciable losses occur with the sinusoidal or triangular wave potentiostatic or constant current modes.

Potentiostatic (three-electrode) pulsed mode.—This method is that employed in most recent experimental ECL studies and has been treated theoretically (13, 14, 20). With regard to operation of a long-duration cell the design of the reference and auxiliary electrodes becomes important. The reference electrodes frequently employed in ECL are silver or platinum wire quasi-reference electrodes which show reasonable stability over experiments of a few hours duration but which show much too large drifts in potential with continuous pulsing over long time periods to be reliable. Other, more poised, reference electrodes, like the aqueous saturated calomel electrode (SCE) can leak undesirable amounts of water or alkali metal ion into the ECL solution on prolonged immersion, even when separated with double sintered-disk salt bridges. We have found that the Ag/Ag^+ (ACN) contained in a porous Vycor tube, as described in the Experimental section, maintained a reproducible and constant potential, and showed no detectable leakage of Ag^+ into the main body of solution after many tens of hours of use. The auxiliary electrode design is also of importance, since uncontrolled electrochemical processes occur there and these may lead to solution contamination. The usual electrochemical technique of isolating the auxiliary electrode in a separate chamber separated from the working electrode chamber by sintered glass disks, salt bridges, etc., is not desirable in ECL since this greatly increases the power necessary to drive the cell, and may prevent potentiostatic control of the working electrode in the early stages of pulse reversal when large currents flow. An auxiliary electrode which is somewhat larger than the working electrode and immersed directly into the ECL solution compartment in a geometry where the current density across its surface is fairly uniform can be employed. The current density at its surface will be smaller than that at the working electrode, and hence it will attain less negative and less positive potentials (with respect to the adjacent solution) than those of the working electrode. Certainly a small auxiliary electrode is to be avoided, since it will be forced to more negative and positive potentials causing undesired electrode reactions to supply the current required for potentiostatic control of the working electrode. The role of the auxiliary electrode is illustrated in a discussion of two-electrode cells in the next section.

To illustrate the necessity of potential control and the behavior of an ECL system under continuous long-term pulsing we consider the *tris*-bipyridylruthenium(II) ($Ru(bip)_3^{2+}$) system in ACN. The electrochemistry and ECL of this system have been described (21, 22). Briefly, $Ru(bip)_3^{2+}$ undergoes three reversible reduction steps (to the +1, 0, and −1 species) and a reversible oxidation (to the +3 species) in dry, deoxygenated ACN (Fig. 1). Controlled potential coulometry experiments have demonstrated that the +3 species is very stable, but that the +1 species, although apparently stable on the cyclic voltammetric time scale, undergoes a very slow decomposition reaction (22). ECL results from reaction of the +3 species with either the +1, 0, or −1 generated on the cathodic cycle. The application of alternate potential steps between +1.200 and −1.900V *vs.* Ag/Ag^+ with 95% *iR* compensation, *i.e.*, from oxidation to second reduction wave, with a frequency of 100 Hz (*i.e.*, t_f = 5 msec) in a cell with $V = 20\ cm^3$ and $A = 0.25\ cm^2$ produced intense ECL with a half-life, $T_{1/2}$, (the time for the ECL intensity to decrease to one-half its initial value), of about 5 hr.

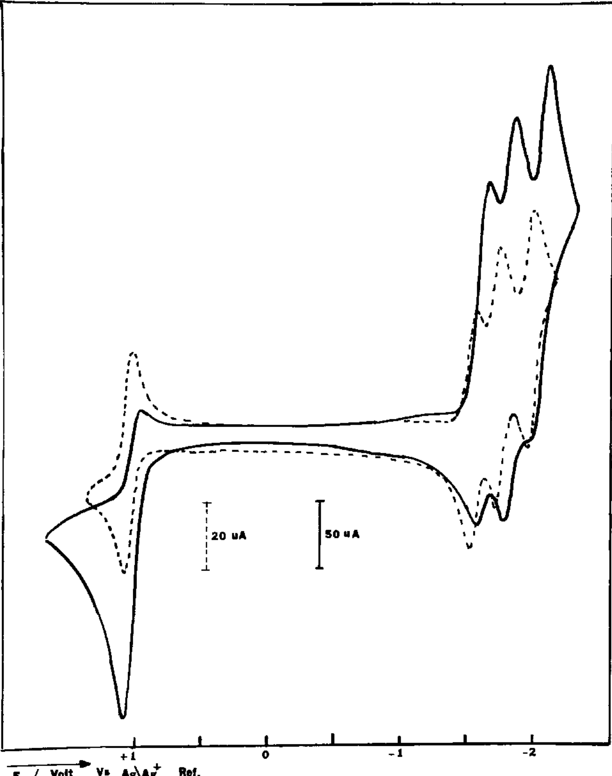

Fig. 1. Cyclic voltammetry of 0.6 mM $Ru(bip)_3(ClO_4)_2$/0.1M TBAP/ACN solution at Pt electrode with a scan rate of 100 mV/sec. - - - -, Original solution; ———, the same solution after 5 hr of ECL production by pulsing between +1.20 and −1.90V at 100 Hz after which no further ECL emission is observed.

The cyclic voltammogram at this time taken at the same working electrode in the ECL cell is noticeably different than the original one (Fig. 1). The height of the reduction peaks (+2 → +1, +1 → 0, 0 → −1) depend on the positive potential the electrode has attained during the anodic scan; they are larger (and anomalous) when the anodic scan includes the +2/+3 wave than when the scan stops at the foot of this wave. Similarly the +2/+3 wave is anomalous when the cathodic scan includes the +2/+1 wave. This behavior is evidence of surface changes at the electrode causing changes in electrochemical reaction. Furthermore a yellow-brown precipitate covers the electrode surface. If the electrode is removed from the ECL cell in an inert atmosphere box, polished with 0.03μ alumina and replaced, both the original cyclic voltammetric behavior and the original ECL intensity is restored.

The nature of the interfering precipitate was elucidated by some experiments at the RRDE. As shown previously (22) when the disk potential is held at the second reduction wave (production of $Ru(bip)_3{}^{\circ}$) and the ring potential held at the foot of the first reduction (corresponding to oxidation 0 → +2), the disk current, after a short time of constancy equal to twice the current of the first reduction wave, begins to increase with time (up to a one order of magnitude increase) without a corresponding increase in the ring current. This lack of increase in the ring current demonstrates that the increasing disk current cannot be attributed to formation of soluble $Ru(bip)_3{}^{\circ}$. If the disk potential is scanned back toward more positive potentials a large oxidation disk current peak is observed at potentials corresponding to the +1 → +2 wave. A similar large oxidation current peak is seen at the ring at this time (E_R = 0.0V). These results can be explained by the formation of a deposit on the disk electrode. This deposit catalyzes the reduction of solvent or electrolyte (giving rise to the enhanced disk current) and is oxidatively stripped off during the positive potential

sweep. The nature of the deposit has not been established. It could be some form of $Ru(bip)_3^\circ$ itself or Ru-metal formed by its decomposition. Attempts to reproduce this effect on a stationary Pt electrode by electrodeposition of finally divided Ru-metal were unsuccessful. A deposit of a zero-valent Ru-species would explain the stripping experiment, if the disk oxidation peak represented the oxidation of this deposit to the +1 species while the ring current represented the further oxidation of $+1 \rightarrow +2$. An alternate explanation would require falling away of some of the zero-valent species during the oxidation scan producing +1 species (upon reaction with +2 in the gap region) which is oxidized at the ring. Thus for the long duration ECL with the $Ru(bip)_3^{+2}$ system the second reduction wave must be avoided; pulsing to the second reduction wave is also undesirable, because of lack of coulombic symmetry and the consequent slow buildup of reduced species in the bulk solution. Since the first and second reduction waves are separated by only about 200 mV, close potential control (better than ±50 mV) is required, with the negative potential limit adjusted between $E_{p/2}$ and E_p of the first reduction wave. The positive potential limit was at or beyond that peak for the oxidation to the +3 species. Under these conditions, with pulsing between −1.650 and +1.100V at 100 Hz for a 2.5 mM $Ru(bip)_3^{2+}$, 0.1*M* TBAP solution in ACN, the ECL emission increased slightly from its initial value and maintained this level for 50 hr. The intensity-time behavior in this system is shown in Fig. 2; the experiment was terminated at 112 hr. Cyclic voltammetry after this period shows no change in $Ru(bip)_3^{2+}$ concentration, but evidence for production of a small amount of an unidentified electroactive species is found (Fig. 3).

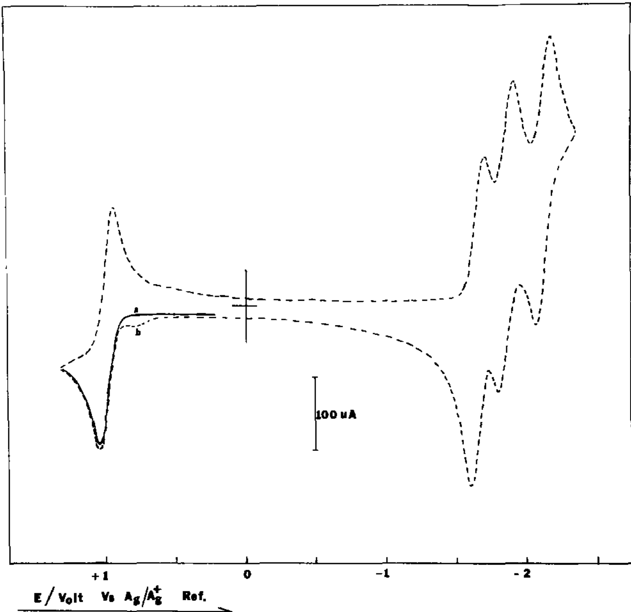

Fig. 3. Cyclic voltammetry of the system of Fig. 2 at a scan rate of 100 mV/sec. (a) Original solution; (b) after 120 hr of ECL production.

Voltage (two-electrode) pulsed mode.—Practical ECL devices will probably be based on two-electrode systems. The way in which the potentials of the working electrode and the counterelectrode vary during pulsing with a low impedance function generator depend on the cell geometry and relative electrode areas. In this mode the technique of applying a symmetrical square wave to the cell and increasing the voltage until maximum emission is observed or alternatively applying a signal of $\pm\Delta E_p$ (the peak potential separation) can result in overdriving the cell and degraded device life.

Before the system is perturbed both electrodes are at their open-circuit or rest potentials, which will be essentially identical, if both electrodes are composed of the same material and have been subjected to similar pretreatments; this rest potential will generally be somewhere between the $A/A^{\overset{-}{\cdot}}$ and $D/D^{\overset{+}{\cdot}}$ half-reaction potentials. When the voltage step, *V*, is applied between the working and counterelectrodes the potentials of the electrodes move in opposite directions such that their difference plus the solution *iR*-drop equals *V*, with the current in one electrode being equal in magnitude and opposite in direction from that in the other. When the pulse is reversed the electrode potentials switch to new values which again satisfy the aforementioned conditions, but in general they do not simply interchange the potentials observed during the first pulse. Let us consider two possible cases when (*a*) the auxiliary electrode is much larger than the working electrode and (*b*) both electrodes are the same size and the rest potential lies about midway between the peaks.

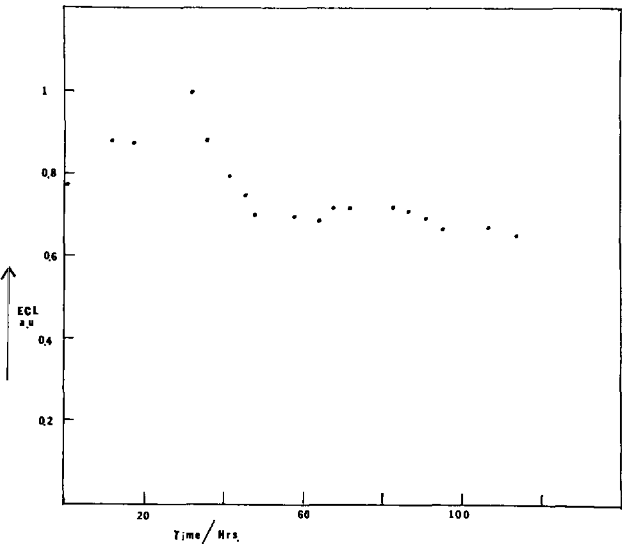

Fig. 2. ECL intensity vs. time behavior for a 2.5 mM $Ru(bip)_3(ClO_4)_2$/0.1M TBAP/ACN solution with pulsing between +1.200 and −1.650V vs. Ag/Ag^+ (ACN) electrode at 100 Hz.

In case (*a*) the current at the auxiliary electrode during the pulse will be largely (or even completely) nonfaradaic and will be consumed in charging the electrical double layer (dl) *i.e.*, most of the current will be consumed in moving the electrode potential of the auxiliary from its rest potential, but the potential of this electrode will not attain a value where a faradaic reaction can occur. The shift in the auxiliary electrode potential is thus inversely proportional to its dl capacity and hence its area; if the area is large enough (compared to the coulombs passed during the pulse), its potential will only shift very slightly from the rest potential. For the small area working electrode however, the electrode rapidly charges its dl and then carries out a faradaic oxidation or reduction. Under these conditions the small working electrode shifts by almost the total of the applied pulse, *V*. For example, if the working electrode moved immediately to the diffusion-limited plateau region, the faradaic current in the system would be governed by the Cottrell equation and the total coulombs passed during the pulse would be given by [5] plus the coulombs needed to charge the working electrode Q_{dlw}. The large auxiliary electrode, of area A_{aux}, will only shift by an amount ΔE_{aux}, given by

$$\Delta E_{aux} = \frac{2A_w\mathbf{F}(Dt_f)^{1/2}\pi^{-1/2} + Q_{dlw}}{A_{aux}C_{dl}} \quad [10]$$

where C_{dl} is the dl capacity per unit area of the auxili-

ary electrode. For example, for $A_w/A_{aux} = 100$, concentrations in the mM range, and C_{dl} of 10 μf/cm^2, ΔE_{aux} will be about 100 mV for a 100 msec pulse. To illustrate this effect, we describe an ECL experiment with a solution of 2 mM rubrene and 0.1M TBAP in benzonitrile, with two platinum electrodes of ratio 80:1. An Ag/Ag^+ reference electrode was employed to monitor the potentials of both electrodes as a voltage pulse of $\pm$2.1V was applied across the Pt electrodes at a frequency of 10 Hz. The results, shown in Fig. 4, demonstrate that the large auxiliary electrode stays within $\pm$100 mV of its rest potential (+0.6V *vs.* reference electrode), while the small electrode moves $\pm$2V, from its rest potential to potential regions where secondary electrode reactions occur. (The slightly larger shift of the auxiliary electrode potential immediately after pulse reversal is caused by the large iR-drop at this time which is included mainly in the measured auxiliary electrode potential, because the reference electrode was located near the small working electrode). Thus, for this configuration, the large auxiliary electrode behaves as a practical reference electrode and the proper potential program can only be achieved by knowing the system rest potential and applying an unsymmetrical voltage program derived from the cyclic voltammetry of the system. If the rest potential does not lie exactly midway between the redox potentials for reduction and oxidation, an applied symmetrical (square) wave equal to one-half the peak separation either may not produce efficient ECL or may lead to "overpulsing" and shortened lifetime. Certainly a square wave of amplitude equal to the peak separation will lead to rapid system deterioration.

Case (b) involves two electrodes of the same size with the rest potential lying approximately midway between the peak potentials. In this case both electrodes will shift about the same amount in potential in opposite directions from the rest potential, *i.e.*, the applied potential is shared between the electrodes. This effect is illustrated in Fig. 5, where the conditions are the same as case (a) (Fig. 4), except that the electrodes are of equal size. Here both of the working electrodes shift by about $\pm$1V *vs.* the reference electrode for the $\pm$2.1V applied; the slight asymmetry in the shifts is caused by the rest potential not lying exactly midway between the peak potentials, but, in fact, lying about 50 mV toward E_{pa}. Thus the desired potential program for two equal size electrodes involves applied voltages essentially twice as large as for the very small-very large case, but both electrodes produce light. If the rest potential does not lie midway between the peaks, the general behavior will be the same, but the unequal extent of charging of the two electrodes will make behavior more complicated when the amount of nonfaradaic charge per pulse is appreciable.

For the general case of two electrodes of unequal, but not very disproportionate, size, the behavior will be intermediate to cases (a) and (b) above, and a carefully selected and controlled potential program is required; a symmetrical square wave will, in general, not be suitable.

Constant current pulsed mode.—A two-electrode mode in which alternate anodic and cathodic constant current pulses are applied has been suggested (23). This mode has the advantage of precise coulombic symmetry with simple control circuitry. However, the coulombic ECL efficiency is smaller in this mode and the applied current density, i_o, and pulse duration, t_f, must be maintained in a rather narrow range to obtain ECL yet prevent overdriving. The applied current again is distributed between dl charging and the faradaic process; in this case the rate of dl charging is controlled by i_o, with appreciable charging occurring before any faradaic process begins. Thus $i_o t_f$ must be larger than the

number of coulombs required to charge the dl, approximately $C_{dl}\Delta E$ (i.e., about 2×10^{-5} coulombs/cm² for 10 μf/cm² dl capacity and 2V step). However $i_o t_f^{1/2}$ must be maintained below $i_o \tau^{1/2}$, where τ, the chronopotentiometric transition time, is given by (24)

$$i_o \tau^{1/2} = \pi^{1/2} F n D^{1/2} C/2 = 85.5\ n D^{1/2} C \text{ (mA-sec}^{1/2}) \quad [11]$$

if the electrode potential is to be maintained at values where secondary electrode reactions do not occur. Actually Eq. [11] pertains to a single constant current step; the transition time under constant pulsing conditions with continuous regeneration of parent will be close to this value. The useful working range of i_o and t_f in ECL based on these criteria is shown in Fig. 6, under the simplified assumption that dl charging is separable from the faradaic process.

With constant current ECL, upon reversal, the current first is consumed totally in reversing the process of the preceding pulse, without generation of a reacting species required for light emission. For example, if the first current pulse was cathodic and led to production of $A^{\bar{\cdot}}$ (Eq. [1]), then during the time period up to $(1/3)t_f$, the next anodic pulse would totally involve the oxidation of $A^{\bar{\cdot}}$ to A, as is usual for reversal chronopotentiometry (25). After this time the potential jumps in a positive direction, at a rate primarily determined by dl charging, to values where oxidation of D occurs (Eq. [3]). During this transition period oxidation of $A^{\bar{\cdot}}$ to A continues. However once $D^{\overset{+}{\cdot}}$ production begins at the electrode, direct electrode oxidation of $A^{\bar{\cdot}}$ becomes negligible and ECL commences. The observed experimental behavior (Fig. 7) shows the delay in emission intensity on reversal, followed by a sharp increase, a maximum, and slow decay, in agreement with the results obtained by a digital simulation for this mode of operation.

The maximum steady-state ECL efficiency under these conditions, neglecting dl charging, is 0.62 that for the potential-step mode. The simulation results also predict an intensity proportional to the current, independent of cycling frequency. Moreover the total number of photons emitted per pulse is proportional to i_o at fixed frequency, is proportional to t_f at fixed i_o, and is inversely proportional to i_o at fixed $i_o t_f^{1/2}$. In practice, however, dl charging is not negligible, so that although the proportionality to i_o at fixed t_f is observed (Fig. 8A), the intensity is relatively smaller at higher frequencies because of the relatively greater importance of the nonfaradaic processes at small t_f values (Fig. 8B). Within the limitations of the method, however, this operation mode may be preferred to a controlled voltage mode for long lifetime operation.

Special controlled current modes which conserve the desirable features of constant current operation but overcome some of its problems, are also possible at the expense of greater driver complexity. For example a double pulse current mode, similar to that used in galvanostatic studies of fast electrode reactions (26) could be employed. This would involve a short, very large current pulse to charge the dl and, in ECL, also rapidly drive the electrode potential into the region where ECL begins, followed by a lower current of magnitude sufficient to maintain ECL (if the second

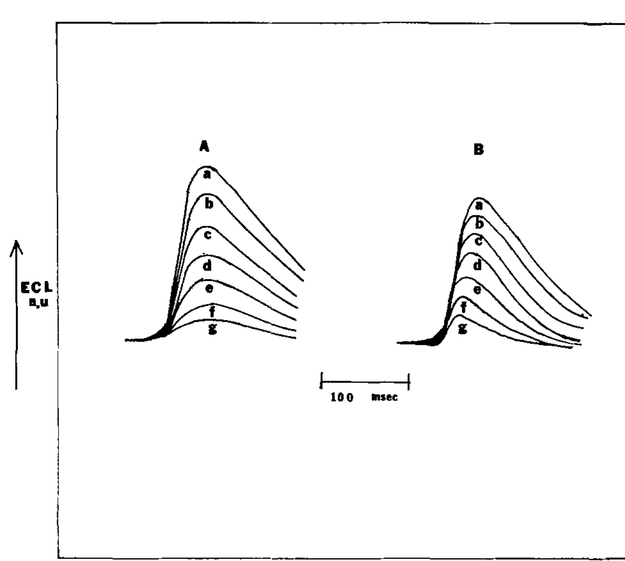

Fig. 8. Light intensity profiles in pulsed constant current ECL (conditions as in Fig. 7) with (a) pulsing at 1 Hz for currents of a-g 100, 90, 80, 70, 60, 50, 40 μA; (b) constant current of 100 μA for pulsing at 1, 1.2, 1.4, 1.6, 1.8, 2.0, 2.2 Hz, respectively.

current were too low the potential would drop back to the region where only reversal, *e.g.*, $A^{\overline{\cdot}} \rightarrow A$, occurred). This double pulse, constant current mode would require very careful adjustment and control to prevent overdriving, however.

Thin-layer cell, d-c mode.—Thin-layer ECL involves the use of two closely spaced electrodes (at least one of which is transparent) in which, during d-c electrolysis, the oxidized and reduced forms produced at the different electrodes diffuse (and migrate) together, near the middle of the interelectrode spacing, to annihilate, and produce light, and regenerate starting materials. The basic principles of thin-layer electrochemistry have been reviewed (27-29) and some thin-layer ECL experiments have been attempted (30-32). Thin-layer ECL has the advantage of producing a continuous and steady-state light with a low voltage d-c excitation. Only the rotating ring-disk electrode (RRDE) has been capable of producing true steady-state ECL previously (19). Moreover the close spacing minimizes the iR drop between the electrodes and the d-c operation eliminates charging current contributions, except during the initial switching on of the cell. However the very small cell volume places severe requirements on solution purity and reactant stability if long-life operation is to be attained.

The behavior of a thin-layer ECL cell follows that of the usual twin-electrode thin-layer cell (27-29), except that the concentration profiles of the electrogenerated reactants ($A^{\overline{\cdot}}$ and $D^{\overset{+}{\cdot}}$) are such that, assuming equal diffusion coefficients and equal concentrations of A and D, both will have zero concentration in the middle of the cell at steady state. Thus, the limiting steady-state current will be

$$i_{ss}^{lim} = nFADC/0.5l \qquad [12]$$

where l is the interelectrode spacing (cavity thickness); the concentration profiles of $A^{\overline{\cdot}}$ and $D^{\overset{+}{\cdot}}$ will be linear. The steady-state current-applied voltage behavior of the cell, assuming reversible electrode reactions, will be given by

$$\Delta V = \Delta E_{1/2} + \frac{2RT}{nF} \ln\left(\frac{i_{ss}^{lim}}{i_{ss}} - 1\right) + i_{ss} R_{cell} \qquad [13]$$

where ΔV is the applied cell voltage, $\Delta E_{1/2}$ is the difference in half-wave potentials between the $A/A^{\overline{\cdot}}$ and $D/D^{\overset{+}{\cdot}}$ reactions, and i_{ss}^{lim} is the limiting steady-state current which obtains when the parent concentrations at the electrode surface are essentially zero. The ECL intensity, I, is proportional to the flux of $A^{\overline{\cdot}}$ and $D^{\overset{+}{\cdot}}$ at the middle of the cavity and hence is proportional to the current

$$I = \phi_{ECL}\, i_{ss}/nF \qquad [14]$$

just as in RRDE experiments (19).

The behavior of thin-layer ECL cells was tested using the rubrene in benzonitrile and $Ru(bip)_3^{2+}$ in ACN systems. Satisfactory lifetimes could only be obtained when no supporting electrolyte (TBAP) was added to the cell solution. For the $Ru(bip)_3^{2+}$ system this cation and the ClO_4^- counterion served as electrolyte. For the rubrene system, small amounts of impurities, perhaps introduced in the drying stages, probably served as electrolyte until the concentration of electrogenerated ions built up to aid in the conduction. The results, shown in Fig. 9 and 10, fit the predicted behavior quite well. The lack of proportionality of I and i_{ss} at low i_{ss} values shown in Fig. 10, is reminiscent of the "foot" observed in I *vs.* disk current in RRDE ECL studies (19), ascribed there to reaction of low levels of impurities with the excited states.

The rise time in a thin-layer ECL cell depends upon the time required for $A^{\overline{\cdot}}$ and $D^{\overset{+}{\cdot}}$ to diffuse together

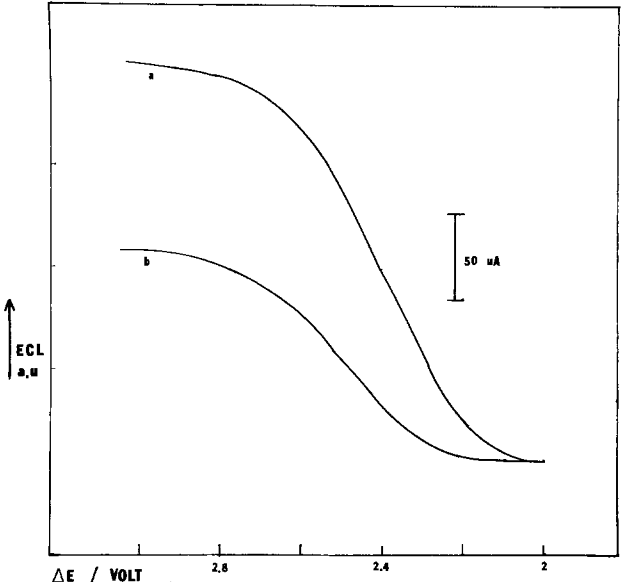

Fig 9. Thin-layer ECL for 4 mM rubrene/BZN for 50μ spacing and scan rate of 2 mV/sec. (a) Current *vs.* applied voltage; (b) light intensity *vs.* applied voltage.

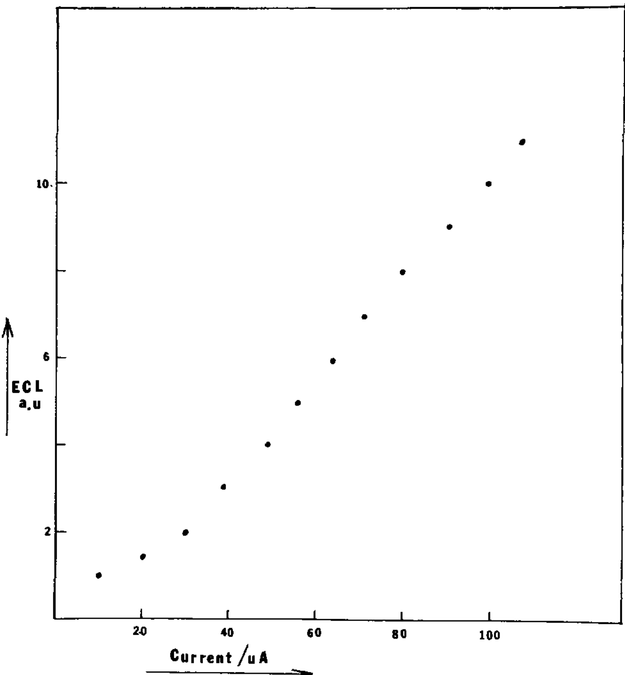

Fig. 10. Light intensity *vs.* applied d.c. in thin-layer ECL (conditions as in Fig. 9).

after the current flow commences and for the current to decay to its limiting value. To a first approximation then, light emission should commence at $t_s = l^2/16D$, (or for l = 100 and 20 μm, t_s is of the order of one and 0.04 sec, respectively). A more sluggish response suggests the occurrence of some slow chemical step or quenching of the excited state species. In the absence of complications the intensity should then level off at the value given by Eq. [14] (Fig. 11). In all cases we have observed a decay in signal level with time, probably indicative of the processes which limit the lifetime of the large cells but which are greatly accelerated because of the small cell volume. We should note that while half-lifetimes of about 10 min can be obtained in cells that contain no added TBAP, those that contain the usual 0.1M levels of TBAP have considerably

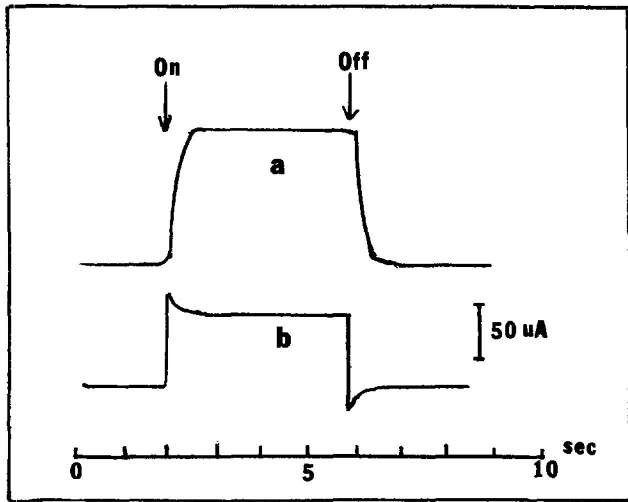

Fig. 11. Transients in thin-layer ECL. (a) Light intensity; (b) current cell. Spacing, 30μ (other conditions as in Fig. 9).

shorter lifetimes (maximum of about 3 min), suggesting that the supporting electrolyte may be an important source of impurities or quencher progenitors in ECL systems.

The thin-layer cell can also be operated in the pulsed cyclic mode. For pulse lengths small with respect to the time to diffuse half the cell thickness, the previous two-electrode treatments apply. For pulse lengths of the order of t_s, when the electrode polarity is reversed a sharp light spike is observed, because of the new annihilation reactions occurring near the electrodes; the light then decays until the mid-cell reaction becomes important and the light increases again toward its steady-state value (Fig. 12). In both the d.c. and pulsed mode thin-layer ECL cells will be useful in studying decay mechanisms in ECL cells and in accelerated life testing.

The small interelectrode spacing of the thin layer ECL cell makes possible the use of solvent systems which would be too resistive for conventional electrochemical cells. For example a solution of 10^5 ohm-cm specific resistance will only produce a 50 mV iR drop

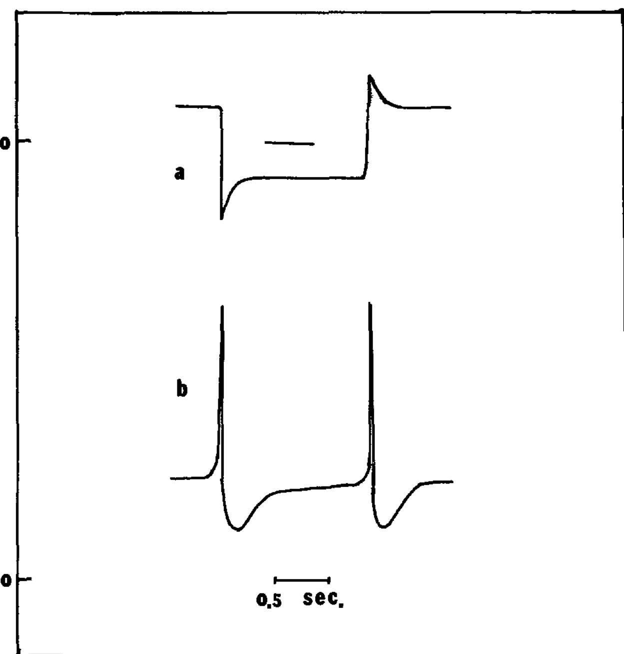

Fig. 12. Effect of reversal of electrode polarity in thin-layer cell. (a) Current; (b) light intensity (cell and solution as in Fig. 11).

for $l = 20$ μm and a current density of 250 μA/cm². In the presence of low electrolyte concentrations very high fields can be produced inside the cell by using external high voltage sources. These would lead to appreciable migration of the electrogenerated species, *i.e.*, in effect the $D^{+\cdot}$ and $A^{-\cdot}$ would be "fired" at one another by the large field gradient. The study of ECL and electrochemical reactions under these conditions is potentially of interest and is currently under study.

Steady-state efficiency of ECL cells.—The measurement and kinds of efficiency in ECL have been discussed (14, 19, 33). What is of interest in ECL devices is $\bar{\phi}_{coul}{}^{ss}$, the number of photons emitted per number of faradaic electrons passed, per pulse, after sufficient repetitive cycles that steady-state electrochemical behavior is observed

$$\bar{\phi}_{coul}{}^{ss} = \frac{\int_0^{t_t} I dt_N}{\int_0^{t_t} i dt_N} \quad [15]$$

The maximum value of this parameter, which applies when $\phi_{ECL} = 1$, *i.e.*, when every radical ion encounter produces an emitted photon, depends on the mode of electrical excitation and cell geometry. This can be estimated by digital simulation (13, 14, 20) of repetitive pulses with the appropriate boundary conditions. The efficiencies quoted here are based on simulations in which only a single species (*e.g.*, species A) is the parent of both radical ions ($A^{-\cdot}$ and $A^{+\cdot}$) and all species have equal diffusion coefficients. It is assumed that the radical annihilation reaction is diffusion controlled and leads directly to an emitting species which emits with unit efficiency (luminescence quantum yield of one). The simulation employed 2000 simulation time units (L) per pulse.

For the pulse potentiostatic (three-electrode) mode, assuming that only the working electrode emits, the following values of $\bar{\phi}_{coul}$, obtained by counting the total number of annihilations per pulse and dividing by the total electric charge required in that pulse, were obtained beginning with pulse 1 (production of $A^{+\cdot}$: pulse 1, 0; 2, 0.549; 3, 0.462; 4, 0.507; 5, 0.484; 6, 0.494; 7, 0.491; 8, 0.489. Thus the limiting value of $\bar{\phi}_{coul} \cong 0.49$. For example, during a cathodic pulse, N, 49% of the current produces $A^{-\cdot}$ which reacts with the $A^{+\cdot}$ produced during the previous pulse (N − 1) and the remainder produces excess $A^{-\cdot}$ which will react with $A^{+\cdot}$ in the pulse N + 1. Only about 2% of the current is consumed by direct reduction of $A^{+\cdot}$ (in the two-electron reaction to form $A^{-\cdot}$) at the electrode and very little of the $A^{-\cdot}$ produced in this pulse will eventually diffuse into bulk solution. Steady state is attained after about 7 or 8 pulses, and at steady state the concentration profiles of the electrogenerated species ($A^{-\cdot}$ in pulse N) and the reacting previously generated species ($A^{+\cdot}$ in pluse N − 1) are essentially the same from pulse to pulse except for a small diminishing tail of the species first produced ($A^{+\cdot}$ in the example) spreading out into the bulk solution. The value $\bar{\phi}_{coul}{}^{ss} = 0.49$ implies that under ideal conditions, the coulombic efficiency approaches the maximum possible value for pulsed ECL efficiency (0.50) and that few faradaic electrons are lost in the process. For two-electrode cells in the voltage pulsed mode, for case (a) (large auxiliary electrode), the maximum value of $\bar{\phi}_{coul}{}^{ss}$ is the same as in the potentiostatic case. For case (b) (electrodes of equal size), both electrodes will emit, so the over-all cell efficiency can

approach a maximum value of 98%. In the constant current mode, because of the greater extent of nonradiative radical ion loss by direct electrode reaction, the maximum efficiency per electrode is only 30% (or 60% for emission at both electrodes). The thin-layer d-c cell will show a maximum efficiency of 100%, since every radical ion produced should ultimately annihilate in the middle of the cell. The practical efficiencies of cells will depend on the actual value of ϕ_{ECL} (for the most efficient systems, this lies in the range of 0.01 to 0.1), the magnitude of the nonfaradaic current and the cell resistance.

Technical Notes

Penetration of Hydrogen into Aluminum on Exposure to Water

Henry Leidheiser, Jr.* and Narayan Das

Center for Surface and Coatings Research, Lehigh University, Bethlehem, Pennsylvania 18015

Data in the literature indicate that hydrogen has limited solubility in aluminum (1, 2) equilibrated with gaseous hydrogen. For example, the solubility of hydrogen in pure aluminum at 300°C is reported to be of the order of 0.001 ml/100g. The solubility increases to approximately 0.04 ml/100g at 660°C. Our immediate interest was to determine the amount of hydrogen that penetrates into aluminum as a consequence of exposure of the metal to water.

* Electrochemical Society Active Member.

Key words: hydrogen, aluminum, aqueous corrosion.

Aluminum samples were in the form of flat plates, approximately 12 × 1 × 0.1 cm. The composition was 99.994% aluminum, 0.003% copper, 0.002% iron, and 0.001% silicon. The samples were metallographically polished, washed with ethanol and acetone, dried in vacuum for 6 hr, and annealed at 600°C for 4 hr at a pressure of 10^{-6} Torr. The samples were then cooled in vacuum and exposed to liquid water at 60°-100°C for varying periods of time. After exposure to water, the corrosion product was removed by heating in a mixture of 2% CrO_3 and 5% H_3PO_4 at 95°C for 60 min.

Table I. Hydrogen extracted from pure aluminum after exposure to liquid water

Temperature of water, °C	Exposure time	Penetrated hydrogen in ml at STP/100 of aluminum: Individual expt. values	Average value	Penetrated hydrogen in terms of ml at STP/cm² of aluminum
60	24 hr	0.146, 0.090, 0.132, 0.105, 0.097, 0.150	0.12	0.00018
100	10 min	0.159, 0.155, 0.138, 0.136, 0.201, 0.148	0.156	0.00023
100	30 min	0.156, 0.167, 0.201, 0.135, 0.140, 0.161	0.160	0.00023
100	6 hr	0.130, 0.144, 0.192, 0.202, 0.168, 0.154	0.165	0.00024
100	24 hr	0.172, 0.155, 0.162, 0.156, 0.170, 0.205	0.170	0.00025
100 (3.5% NaCl)	24 hr	0.442, 0.378, 0.540, 0.480, 0.385, 0.315	0.42	0.00062
100 (99.8% D_2O)	24 hr	0.056 (H_2 + D_2) (8)		0.00008

Information generated by Lewis and Plumb (3) indicates that this medium dissolves the oxide on the surface and reacts very slowly with the metal. The sample was again washed in ethanol and acetone, dried in vacuum, and inserted into the gas extraction system. After extraction of the hydrogen, the degassed sample was again immersed in the CrO_3-H_3PO_4 electrolyte for 60 min at 95°C, washed in ethanol and acetone, and the extraction process repeated. The penetrated hydrogen introduced by exposure to water was taken to be the difference between the hydrogen values obtained in these two experiments.

The extraction apparatus consisted of a Vycor reaction vessel, a palladium thimble maintained at 400°C through which the hydrogen diffused, an automatic Toepler pump, and associated valves and auxiliary diffusion pumps. After pumping the system to 10^{-6} Torr, the sample was heated to 150°C and maintained at this temperature for 1 hr under vacuum conditions. Any gas evolved in this step was pumped to waste and was not collected. The purpose of this intermediate temperature treatment was to remove the majority of water from the sample surface to minimize the amount of hydrogen formed in the reactor as a consequence of the reaction, $Al + H_2O = Al_2O_3 + H_2$. The aluminum was heated rapidly to 600°C and maintained at this temperature for 3 hr. The evolved gas was collected and its volume measured. In selected experiments, portions of the gas were removed for mass spectrometric analysis. In all cases it was found to be essentially pure hydrogen with traces of oxygen, water, and nitrogen.

As a test of the method, degassed samples were removed from the extraction vessel, exposed to room air for 5 min, and reinserted into the extraction vessel. No hydrogen was extracted under the same experimental conditions normally used.

The data summarized in Table I indicate that the amount of hydrogen penetrated into aluminum approaches a saturation value in less than 10 min. Corrosion rate data at 100°C are given in Fig. 1, along with three data points taken from the paper by Vedder and Vermilyea (4). It will be noted that the reaction rate is very rapid in the first 10 min. The weight gain data are in accord with the visual observation that gas evolves copiously during the first 30-60 sec, suggestive of an initially high rate of reaction involving hydrogen as a product, and then decreases to the point where the surface is only mildly active in catalyzing the formation of vapor bubbles.

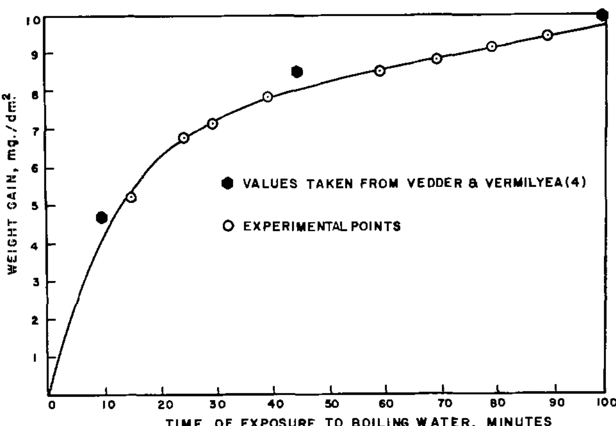

Fig. 1. The rate of corrosion of aluminum in boiling water as determined gravimetrically.

The values shown in Table I are not inconsistent with the observations of Draley and Ruther (5) that samples of 1100 aluminum exposed to water at 290°C for 2 days contained 0.304 ml of hydrogen/100g of aluminum.

It is likely that the observed hydrogen is confined to the region close to the surface since etching the samples in the CrO_3-H_3PO_4 electrolyte for times longer than 2 hr resulted in a decrease in the amount of hydrogen obtained upon extraction. Proton-proton scattering experiments (6) kindly carried out on our samples by Professor B. L. Cohen of the University of Pittsburgh provided additional confirmation that the hydrogen is concentrated near the surface. It is recognized that aluminum of this purity is subject to intergranular attack (7). In fact, such intergranular attack was observed on samples exposed repeatedly or exposed for very long periods of time. It is not felt that hydrogen trapped at the grain boundaries or oxide unremoved at the grain boundaries by the CrO_3-H_3PO_4 electrolyte is responsible for a major portion of the experimentally determined hydrogen. The evidence for this viewpoint is that samples used for the first time, where intergranular attack was insignificant, yielded similar values for penetrated hydrogen as samples used many times previously.

Acknowledgment

Appreciation is expressed to D. Iyengar who provided assistance in the early stages of this work and to Professor B. L. Cohen for carrying out the proton-proton scattering experiments.

Thermal Oxidation and Electrolytic Etching of Silicon Carbide

W. von Münch and I. Pfaffeneder

Institut A für Werkstoffkunde, Technische Universität, D-3 Hannover, Germany

Silicon carbide can be oxidized in a manner similar to that used for the growth of silicon dioxide layers on silicon (1, 2). The oxide layers on silicon carbide may be utilized for various purposes in the technology of SiC devices, including junction delineation, masking for preferential etching by Cl_2/O_2, passivation of p-n junctions, and identification of the surface polarity (3). Junction delineation is also accomplished by electrolytic etching in HF solution, since this etch is specific for p-type material (4). It is the purpose of this communication to point out that the oxidation and electrolytic etching techniques are also most useful for the discrimination of the polytypes of SiC and the detection of doping inhomogeneities in SiC.

Silicon carbide exists in several different modifications (polytypes). These polytypes can be described in terms of different stacking orders of the Si-C double layers. Among the most abundant types of silicon carbide are the 6 H crystals with a unit cell of six Si-C layers and hexagonal symmetry and the 15 R crystals (unit cell with fifteen layers and trigonal symmetry). For technical applications of silicon carbide, therefore, it is desirable to have a simple method to discriminate between these polytypes.

A series of oxidation experiments has been carried out with the following experimental conditions: temperature, 1070°C; time, 6 hr; gas stream, 45 liter/hr O_2, saturated with H_2O at 90°C.

Silicon carbide crystals of the 6 H and 15 R polytypes of both conduction types and different doping levels were oxidized on the following faces: $(000\bar{1})$, $(11\bar{2}0)$, $(1\bar{1}00)$, and (0001). The position of the low index faces of silicon carbide crystals is shown in Fig. 1. These faces were polished with diamond powder in three steps (15, 6, and 1 μm grain size) prior to the oxidation. The surface quality was checked by electron diffraction (pattern of Kikuchilines).

Table I gives the averaged results of about 15 measurements taken on each face of the n-type crystals. The oxide thickness was measured with an interferometer after a step-etching and metallization process. By comparison with the interference of nonmetallized oxide steps it was found that the refractive index of the oxide on silicon carbide is slightly higher than that of silicon dioxide; the etch rate is lower by a factor of 0.6, as compared with silicon dioxide on silicon.

Key words: polytypes, junction delineation, doping inhomogeneities.

Table I. Oxide thickness (in Å) on different faces of n-type SiC

	$(000\bar{1})$	$(11\bar{2}0)$	$(\bar{1}100)$	(0001)
6 H, n-type	2680 ± 80	1940 ± 130	1620 ± 210	310 ± 30
15 R, n-type	2810 ± 160	1550 ± 420	1590 ± 440	350 ± 60
All n-type crystals	2740 ± 150	1750 ± 370	1600 ± 350	330 ± 50

Table II. Oxide thickness (in Å) on different faces of p-type SiC

	$(000\bar{1})$	$(11\bar{2}0)$	$(\bar{1}100)$	(0001)
6 H, p-type	2420	1100	1000	450
15 R, p-type	2200	1360	1270	420

Table I confirms the well-known fact that the oxidation rate on the carbon $(000\bar{1})$ face is about 10 times higher than on the opposite basal plane (silicon face). An intermediate oxidation rate is found for the $(11\bar{2}0)$ and $(\bar{1}100)$ planes, as may be expected from the even distribution of silicon and carbon atoms on such faces. There are slight differences of the oxidation behavior for 6 H and 15 R material: the oxidation of the 15 R polytype is faster on the <0001> planes but slower on the other two planes. It has to be pointed out that the large spread of the experimental values in Table I is not entirely due to experimental errors, but also reflects the influence of the doping level of the crystals used in this investigation.

A different oxidation behavior has been found for p-type material (Table II): for 15 R crystals the oxidation rate is higher (with respect to 6 H) on the $(11\bar{2}0)$ and $(\bar{1}100)$ faces, but lower on the {0001} faces. Except for the (0001) faces, all SiO_2 layers on p-type material were thinner than those on corresponding crystal faces of n-type material.

Figure 2 gives an example of polytype discrimination by the oxidation technique. The $(\bar{1}100)$ face of a p-type crystal was cut and polished prior to an oxidation treatment as described above. Under these circumstances the interference color of the oxide on the 15 R part of the crystal is light blue, whereas a deep blue is seen on the 6 H part. This interpretation was confirmed by electron diffraction studies.

The influence of the donor concentration on the oxidation rate of 6 H silicon carbide is seen from Table III.

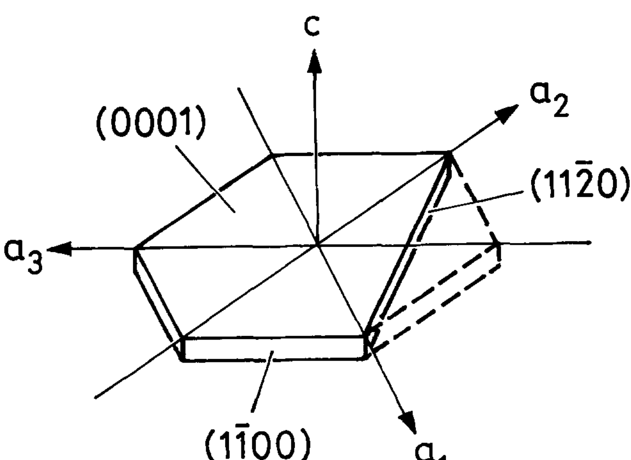

Fig. 1. Low index faces of silicon carbide crystals

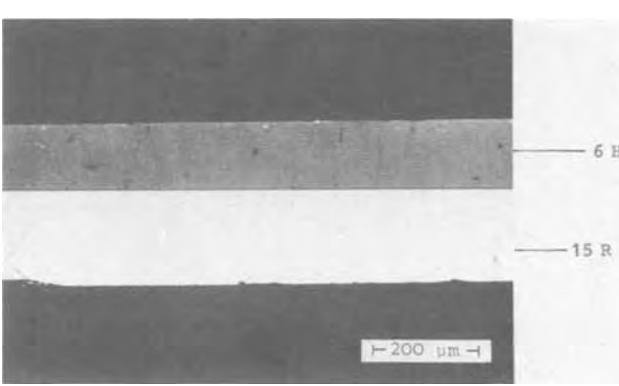

Fig. 2. Oxidized (1100) face of a p-type silicon carbide crystal containing 6 H and 15 R regions.

Table III. Oxide thickness (in Å) on different faces of n- and p-type SiC

	(000$\bar{1}$)	(11$\bar{2}$0)	(1$\bar{1}$00)	(0001)
6 H, n-type, heavily doped	2730	1980	1720	310
6 H, n-type, lightly doped	2560	1830	1330	300
6 H, p-type	2420	1000	1000	450

A high donor concentration ($n > 10^{18}$ cm^{-3}) obviously enhances the thermal oxidation. The p-type SiC oxidation data are added in Table III for comparison.

Electrolytic etching in a 2:1 mixture of alcohol and 40% HF is mainly used for the delineation of p^+p- and n^+n-junctions and for those p-n junctions where both sides are very lightly doped. The delineation which is accomplished partly by surface attack and partly by staining may be markedly enhanced by a subsequent oxidation. Thus, the combination of electrolytic etching and oxidation has been found to be successful for the delineation of all junctions of practical interest. Furthermore, the existence of doping inhomogeneities can be revealed by this technique. Figure 3 shows an angle lap of an n-type epitaxial SiC layer on an n-type substrate. It is clearly seen that there are impurity striations in the substrate whereas the doping of the epitaxial layer is uniform.

In conclusion, it can be stated that the thermal oxidation of silicon carbide is a useful tool for polytype discrimination. An unambiguous determination of the polytype (6 H or 15 R), however, is possible only in those cases where the dependence of the oxidation rate on the conductivity type and the doping level is negligible or can be taken into account properly. The electrolytic etching technique serves for the delineation of impurity concentration gradients. A combination of both methods often provides an enhanced contrast.

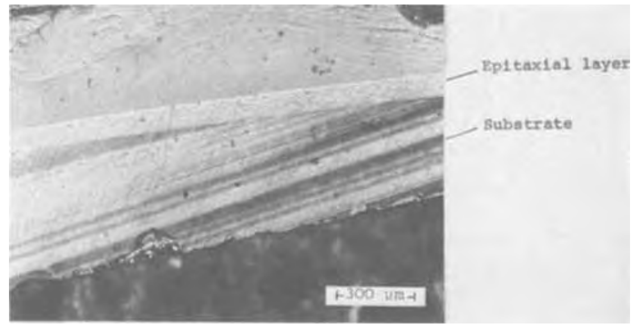

Fig. 3. Angle lap of n-type epitaxial layer on n-type substrate (etched and oxidized).

Mass Transfer to a Continuous Moving Sheet Electrode

Der-Tau Chin*[,1]

Electrochemistry Department, Research Laboratories, General Motors Corporation, Warren, Michigan 48090

This article presents a theoretical study of mass transfer to a continuous flat sheet moving at high speed. Such a system has long been used in the electrotinning of steel sheets (1) and copper wires (2). It is also widely used in other manufacturing industries. Typical examples are continuous cooling in the fabrication of sheet glass (3) and steel plates (4), and the drying process in the paper (5) and the polymer film (6) manufacturing industries.

Despite its wide applications, few studies have been reported on this geometry. Sakiadis (7-9) and Koldenhof (10) calculated the laminar and the turbulent flow boundary layers on continuous flat and cylindrical surfaces. Experimental investigations of the flow field were made by Tsou, Sparrow, and Goldstein (11) and by Griffith (12). Numerical solutions of the thermal boundary layers on the continuous flat surface have been obtained by Tsou *et al.* (11), Erickson, Cha, and Fan (13), and Rhodes and Kaminer (14). Erickson *et al.* also derived an approximate solution for heat transfer at larger Prandtl numbers. Griffin and Throne (15) reported an experimental study of heat transfer from a continuous moving belt to air.

In this study, an asymptotic solution is derived for mass transfer to the continuous moving flat sheet under laminar conditions. A curve fitting of Sakiadis's flow results is used in the analysis. The solution covers a range $0.7 \leq Sc < \infty$; within this range, the maximum error which occurs at $Sc = 0.7$ is less than 1%.

Key words: asymptotic theory of convective diffusion, limiting current.

Analysis

Consider a continuous semi-infinite flat sheet electrode moving with a constant velocity, U_s, through a stationary electrochemical cell. The sheet enters the cell through a watertight slot at one end of the cell and leaves the cell at the opposite side through a second slot as shown in Fig. 1. The motion of the solid surface induces a flow of the adjacent electrolyte along the di-

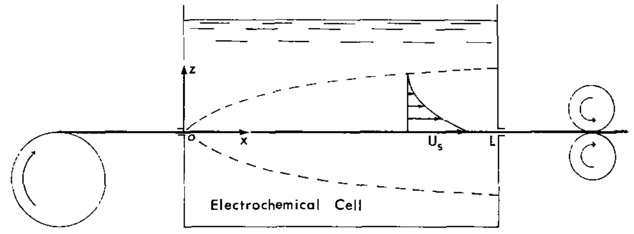

Fig. 1. The continuous moving sheet electrode and the fixed space coordinates x and z. The electrode is moving through a cell of length L with a constant velocity U_s. The induced flow boundary layers are designated by the dashed curves.

rection of the sheet movement. This creates a flow boundary layer that originates at the inlet slot and grows in thickness along the direction of the sheet movement. To analyze mass transfer in such a system, we shall make the following assumptions: (*i*) the sheet is moving at a sufficiently high speed to permit application of the boundary layer solutions; (*ii*) the electrolyte flow in the vicinity of the moving sheet electrode is laminar in nature; (*iii*) the cell is long and deep enough so that the effect of the cell wall on the flow boundary layer is negligible; (*iv*) sufficient inert salt is present in the electrolyte so that the migration flux of the diffusing ion in the electric field can be neglected (this assumption also applies to binary electrolytes); (*v*) physical properties of the electrolyte are constant; (*vi*) the effect of gravitational force on the diffusion field is negligible. Under the steady-state conditions, the system can be described with a set of fixed coordinates, x and z. Here x is the linear distance from the inlet slot and points toward the direction of the sheet movement; z is the perpendicular distance from the sheet surface. The equation of convective diffusion to the moving electrode then takes the form

$$u\frac{\partial C}{\partial x} + v\frac{\partial C}{\partial z} = D\frac{\partial^2 C}{\partial z^2} \quad [1]$$

Here u and v are the velocity components of the electrolyte along the x- and the z-directions, respectively; C and D are the concentration and the diffusivity of the diffusing ion. The boundary conditions are

$$\left.\begin{array}{l}\text{at } z = 0, \quad C = C_0 \\ \text{at } z \to \infty, \quad C = C_\infty \\ \text{at } x = 0, \quad C = C_\infty\end{array}\right\} \quad [2]$$

Equations [1] and [2] imply that under the steady-state conditions, the diffusion layer in the electrolyte can be regarded as a function of fixed-space coordinates only, even though it is adjacent to a moving solid boundary. An observer fixed in space would note that the concentration of the diffusing ion at every point in the surrounding electrolyte is not changing with time regardless of an ever-changing electrolyte/electrode interface because of the sheet movement. This condition is analogous to those occurring on a rotating disk (16) and rotating sphere (17).

Introducing a similarity transformation, η, and a stream function, $f(\eta)$, defined as (9)

$$\eta = z\sqrt{\frac{U_s}{\nu x}} \quad [3]$$

$$u = U_s f'(\eta) \quad [4]$$

$$v = \frac{1}{2}\sqrt{\frac{\nu U_s}{x}}\,[\eta f'(\eta) - f(\eta)] \quad [5]$$

the equation of convective diffusion may be reduced to a linear second-order ordinary differential equation

$$\frac{d^2\Phi}{d\eta^2} + \frac{1}{2}\,\mathrm{Sc}\,f\frac{d\Phi}{d\eta} = 0 \quad [6]$$

where Φ is a dimensionless concentration defined as

$$\Phi = \frac{C - C_\infty}{C_0 - C_\infty} \quad [7]$$

and Sc is the Schmidt number defined as the ratio of the kinematic viscosity of the electrolyte, ν, to the diffusivity of the diffusing ion, D. The boundary conditions are now changed to

$$\left.\begin{array}{l}\text{at } \eta = 0, \quad \Phi = 1 \\ \text{at } \eta \to \infty, \quad \Phi = 0\end{array}\right\} \quad [8]$$

Curve fitting for the stream function.—To solve Eq. [6] analytically, one needs a mathematical expression for the stream function, $f(\eta)$. The flow boundary layer on a continuous moving flat surface has been calculated numerically by Sakiadis (9). In this analysis we have found that his tabulated values of the stream function can be represented by the following relation

$$f = 1.61605[1 - e^{-\eta}(1 + 0.381207\eta + 0.0185019\eta^2 - 0.00543507\eta^3)] \quad [9]$$

Figure 2 shows the close agreement between Eq. [9] and Sakiadis's calculations. In the next section, Eq. [9] is used in the integration of Eq. [6].

Asymptotic solutions.—To find a simple solution for the convective diffusion equation, we follow the procedures illustrated by Chin (18-20), and assume that Φ can be represented by an asymptotic series in the descending powers of Sc

$$\Phi = \phi_0 + \frac{1}{\mathrm{Sc}^{1/2}}\phi_1 + \frac{1}{\mathrm{Sc}}\phi_2 + \frac{1}{\mathrm{Sc}^{3/2}}\phi_3 + \text{----}; \quad (\text{for Sc} >> 1) \quad [10]$$

Here ϕ_0, ϕ_1, ϕ_2, and ϕ_3 are called the zeroth, the first, the second, and the third order solutions, respectively, of the convective diffusion equation. They are functions of a stretched coordinate, ξ, defined as

$$\xi = \mathrm{Sc}^{1/2}\eta = z\sqrt{\frac{U_s}{Dx}} \quad [11]$$

Substituting Eq. [9]-[11] into Eq. [6], expanding the exponential function in the stream function, f, into a power series of Sc, and then equating the terms having the like powers of Sc in the resulting equation, we have

$$\frac{d^2\phi_0}{d\xi^2} + \frac{1}{2}\xi\frac{d\phi_0}{d\xi} = 0 \quad [12]$$

$$\frac{d^2\phi_1}{d\xi^2} + \frac{1}{2}\xi\frac{d\phi_1}{d\xi} = 0.110937\,\xi^2\frac{d\phi_0}{d\xi} \quad [13]$$

$$\frac{d^2\phi_2}{d\xi^2} + \frac{1}{2}\xi\frac{d\phi_2}{d\xi} = 0.110937\,\xi^2\frac{d\phi_1}{d\xi} \quad [14]$$

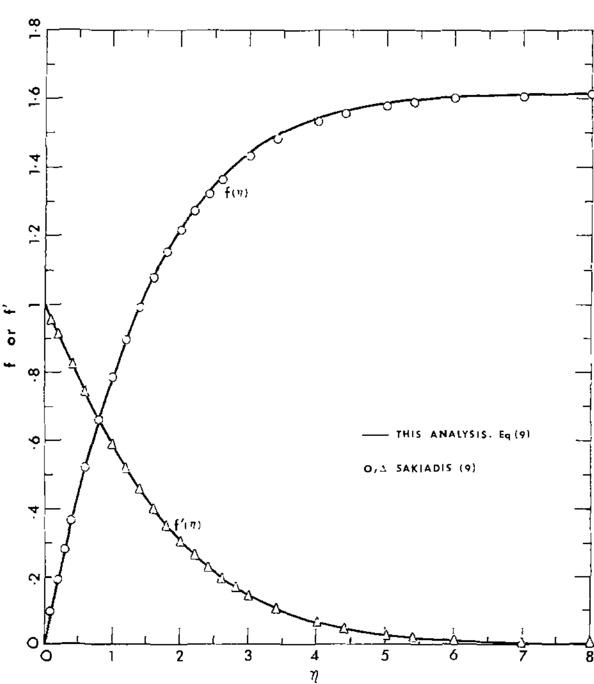

Fig. 2. The stream function f and its derivative f'

$$\frac{d^2\phi_3}{d\xi^2} + \frac{1}{2}\xi\frac{d\phi_3}{d\xi} = 0.110937\,\xi^2\frac{d\phi_2}{d\xi} - 0.00580312\,\xi^4\frac{d\phi_0}{d\xi} \quad [15]$$

Equations [12]-[15] are subject to the following boundary conditions in accordance with Eq. [8]

$$\left.\begin{array}{ll} \text{at } \xi = 0, & \phi_0 = 1 \\ & \phi_1 = \phi_2 = \phi_3 = 0 \\ \xi \to \infty, & \phi_0 = \phi_1 = \phi_2 = \phi_3 = 0 \end{array}\right\} \quad [16]$$

Equations [12]-[16] can be integrated analytically to give the following solutions

$$\phi_0 = \mathrm{erfc}\left(\frac{\xi}{2}\right) \quad [17]$$

$$\phi_1 = 0.166906\left[\left(1+\frac{\xi^2}{4}\right)e^{-\frac{\xi^2}{4}} - \mathrm{erfc}\left(\frac{\xi}{2}\right)\right] \quad [18]$$

$$\phi_2 = 0.0278576\,\mathrm{erfc}\left(\frac{\xi}{2}\right) - e^{-\frac{\xi^2}{4}}(0.0278576 - 0.0462903\xi + 0.00696441\xi^2 - 0.00771505\xi^3 - 0.000771505\xi^5) \quad [19]$$

$$\phi_3 = -0.00747613\,\mathrm{erfc}\left(\frac{\xi}{2}\right) + e^{-\frac{\xi^2}{4}}(0.00747613 - 0.00772613\xi + 0.00186903\xi^2 - 0.00128769\xi^3 + 0.000516273\xi^4 - 0.000128769\xi^5 + 0.000152158\xi^6 + 0.00000950988\xi^8) \quad [20]$$

Here erfc designates the complementary error function; its numerical values and related properties are tabulated in Abramowitz and Stegun (21). Thus the concentration profile in the diffusion layer can be calculated for systems with $Sc >> 1$.

The local mass flux at the electrode surface is related to the concentration gradient by

$$j = -D\left(\frac{\partial C}{\partial z}\right)_{z=0} = k(C_o - C_\infty) \quad [21]$$

where k is the local mass transfer coefficient. The concentration gradient at the surface can be obtained by differentiating Eq. [10] and Eq. [17]-[20]. The local Sherwood number, Sh_x, defined as kx/D, can now be calculated from the following equation

$$Sh_x = \left(\frac{kx}{D}\right) = R_x^{1/2}Sc^{1/2}\left(0.56419 - \frac{0.094167}{Sc^{1/2}} - \frac{0.030573}{Sc} + \frac{0.0035082}{Sc^{3/2}} + \cdots\right) \quad [22]$$

where R_x is the local Reynolds number defined as $U_s x/\nu$. For a cell of length L, the average Sherwood number can be obtained by integrating k over the electrode surface. The result is

$$Sh = \left(\frac{KL}{D}\right) = Re^{1/2}Sc^{1/2}\left(1.12838 - \frac{0.18833}{Sc^{1/2}} - \frac{0.061147}{Sc} + \frac{0.070164}{Sc^{3/2}} + \cdots\right) \quad [23]$$

Here K is the geometrical average of k, and Re is the Reynolds number defined as $U_s L/\nu$.

Discussion

For a uniform surface temperature, Tsou, Sparrow, and Goldstein (11) have made numerical calculations at several Prandtl numbers for the rate of heat transfer from a continuous moving flat surface. An approximate solution was derived by Erickson, Cha, and Fan for large Prandtl numbers. Since the Prandtl number is equivalent to the Schmidt number used in mass transfer, we may use these point solutions to estimate the accuracy of the present analysis. The comparison is given in Table I, where values of $Sh_x/\sqrt{R_x Sc}$ obtained from the three analyses are tabulated for Sc (or Pr) at 0.7, 1, 10, 100, and ∞. It is seen that for $Sc \geqq 10$, there is essentially no difference between the present results and those of Tsou *et al.* The present asymptotic solution is based on $Sc >> 1$; however, at $Sc = 0.7$, the value computed from Eq. [22] agrees with the numerical calculation to within 0.8%. At $Sc = 1$, the agreement between the two sets of values is within 0.2%. Thus, we may say the rate expressions given in the forms of Eq. [22] and [23] are valid for the Schmidt number greater than 0.7; within this range the accuracy is better than 99%. For large Schmidt numbers, the approximate solution of Erickson *et al.* is about 5% smaller than the asymptotic results.

Table I. Comparison of the present analysis with previous numerical solutions

Sc	$Sh_x/\sqrt{R_x Sc}$		
	Present result, Eq. [22]	Tsou *et al.*, numerical solution	Erickson *et al.*, approximate solution
0.7	0.4140	0.4174	
1.0	0.4430	0.4438	
10	0.5315	0.5314	
100	0.5545	0.5545	
∞	0.5642		0.53

At large Schmidt numbers, Eq. [22] can be simplified to

$$Sh_x = 0.5642\,R_x^{1/2}Sc^{1/2} \quad [24]$$

This equation states that the local Sherwood number is proportional to the square root of the Schmidt number. This is the most significant result in the present analysis. For most other known flowing systems, such as pipe flow, flat plate, or rotating disk, the rate of laminar mass transfer is invariably proportional to the cube root of the Schmidt number. The square root relation gives the continuous moving sheet an advantage on the transfer rate at high Schmidt numbers. Although there has been little experimental investigation of the continuous moving sheet electrode, this advantage in the mass transfer rate shows a great promise for potential applications in electrochemical as well as other industrial processes.

Conclusions

In conclusion, we have obtained an asymptotic theory for mass transfer on a continuous moving sheet electrode. The theory is vaild for $Sc \geqq 0.7$; within this range the accuracy is better than 99%. It is shown that at large Schmidt numbers, the Sherwood number is proportional to the square root of the Schmidt number, rather than the usual cube root relations.

LIST OF SYMBOLS

- C concentration of the diffusing ion, g-mole/cm³
- C_o concentration of the diffusing ion at the electrode surface, g-mole/cm³
- C_∞ bulk concentration of the diffusing ion, g-mole/cm³
- D diffusivity of the diffusing ion, cm²/sec

f dimensionless stream function defined in Eq. [4] and [5]
j local rate of mass flux at the electrode surface, g-mole/cm^2 sec
k local mass transfer coefficient defined in Eq. [21], cm/sec
K geometric average mass transfer coefficient, cm/sec
L length of the continuous moving sheet exposed to the electrolyte in the cell, cm
R_x local Reynolds number based upon the surface distance measured from the leading edge of the flow boundary layer. For the continuous moving sheet electrode, it is defined as $U_s x/\nu$, dimensionless
Re Reynolds number based upon the electrode length L, $U_s L/\nu$, dimensionless
Sc Schmidt number defined as ν/D, dimensionless
Sh average Sherwood number defined as KL/D, dimensionless
Sh_x local Sherwood number based upon the surface distance measured from the leading edge of the flow boundary layer. For the continuous moving sheet electrode, it is defined as kx/D, dimensionless
u velocity component of the electrolyte along the direction of the sheet movement, x, cm/sec
U_s velocity of the continuous sheet moving through the electrolyte, cm/sec
v velocity component of the electrolyte normal to the electrode surface, cm/sec
x a fixed space coordinate measured from the point where the continuous sheet electrode enters the electrolyte, and points toward the direction of the sheet movement, cm
z a fixed space coordinate measured perpendicular to the surface of the continuous sheet electrode
η a similarity coordinate defined as $z\sqrt{U_s/\nu x}$, dimensionless
ν kinematic viscosity of the electrolyte, cm^2/sec
ξ a stretched coordinate for the diffusion boundary layer defined as $Sc^{1/2}\eta$ or $z\sqrt{U_s/Dx}$, dimensionless
Φ dimensionless concentration defined as $(C - C_\infty)/(C_0 - C_\infty)$
ϕ_0, ϕ_1, ϕ_2, ϕ_3 the zeroth, the 1st, the 2nd, and the 3rd order solutions of Φ, as defined in Eq. [10], dimensionless
$'$ differentiation with respect to η

Brief Communications

An Investigation of a Nickel-Tin Electroplating Solution by Laser-Raman Spectroscopy

B. E. Wynne,[1] J. M. Sykes,[2] and G. P. Rothwell

Cambridge University, Department of Metallurgy and Materials Science, Cambridge, England

Nickel-tin alloys can be electrodeposited from solutions containing nickel chloride, stannous chloride, and ammonium bifluoride (1). These solutions are unusual in that over a wide range of solution compositions and plating conditions, the deposit contains approximately equiatomic proportions of nickel and tin. Unlike cast alloys, which at equiatomic composition contain equal mole fractions of Ni_3Sn_2 and Ni_3Sn_4, the electrodeposited alloy is composed of a single intermetallic compound NiSn (2). Anomalous behavior is also observed in the deposition process: the alloy is deposited at low overpotential and with very high current efficiency, whereas Ni and Sn deposited alone show quite different behavior.

Because the nickel and tin ions tend to deposit in a 1:1 ratio, it has been suggested (3) that they might be associated in the plating solution, possibly as an uncharged complex species $NiSnF_4$. Brook, Davies, and Price (4) have found very low transport numbers for nickel ions in this solution and suggest that this result supports such an idea.

Rau and Bailar (5) measured the refractive index of solutions containing Ni^{++} and Sn^{++}, using the method of continuous variations, and found a maximum deviation from ideal behavior at a $Ni^{++}:Sn^{++}$ ratio of 1:1 provided that at least one fluoride ion per Ni^{++}-Sn^{++} pair was present. They suggest that the Ni^{++}

[1] Present address: Lancaster University, Department of Sociology, Lancaster, England.
[2] Present address: Sunderland Polytechnic, Sunderland, County Durham, England.
Key words: alloy deposition, nickel-tin, solution analysis, mechanism, complex ions.

and Sn^{++} ions are associated by means of at least one fluoride bridge. However, measurements of absorption by the Ni^{++} ions at 2500 cm^{-1} in similar solutions, using a Pye-Unicam SP800 ultraviolet spectrophotometer failed to detect any such deviation or any shift in the absorption peak (6).

In solutions containing $SnCl_2$ and excess chloride, the complex ions $SnCl_3^-$ (and possibly $SnCl_4^=$) are produced. These have been shown to be powerful ligands, which form stable complexes with organometallic compounds and with platinum, iridium, rhodium, and rhenium (7-9). The platinum-tin complexes have been isolated in the solid state and the crystals are believed to contain platinum-tin bonding. If, as might be expected, similar complexes were formed with Ni^{++} ions, this would radically alter the electrodeposition process and could well explain the abnormal stability of the 1:1 intermetallic compound.

Experimental

In laser-Raman spectroscopy the solutions are irradiated with a coherent monochromatic light beam which will excite vibrations or rotations in the bonds between the atoms or ions in solution. Energy is lost from the quanta of incident radiation and new quanta of lower frequency are found in the scattered radiation. The frequency shift is a characteristic of the vibrational mode which is absorbing energy.

For the present tests, solutions were prepared containing nickel, tin, or mixtures of both, together with 40 g/liter of ammonium bifluoride (Table I). *p*H was adjusted in all cases to 2.5 by the addition of small quantities of concentrated hydrochloric acid. The solutions were irradiated in an 8 cm capillary with an argon-ion laser (wavelength 5145Å), and Raman spectra plotted at least 6 times on a Cary Laser-Raman Spectrophotometer at a scan rate of 50 cm^{-1}/min.

The frequencies of the characteristic peaks observed for solutions of Ni^{++} or Sn^{++} alone were found to shift in solutions containing mixtures of Ni and Sn (Table II). The peaks at 270 and 390 cm^{-1} due to variations in the bonds between Ni^{2+} and H_2O in the hexaquo-cation were shifted by about 25 cm^{-1} when tin was added (although this was masked with an excess of nickel present). Similarly the peaks due to Sn^{++}-F^- bonding were shifted by 10-25 cm^{-1} by the addition of Ni^{2+}. However, no new peaks were observed.

Table I. Solutions for laser-Raman spectroscopy

Solution No.	Concentrations	
	$SnCl_2$ (M)	$NiCl_2$ (M)
1	0	2
2	2	0
3	0.5	2
4	0.5	0.5

Table II. Characteristic peaks observed by laser-Raman spectroscopy

Solution No.	Frequency (cm^{-})					
	1	2	3	4	5	6
1	270	390	—	—	—	—
2	—	—	310	260	140	120
3	275	390	320	—	145	—
4	295	415	325	285	150	140
	Ni^{++}-H_2O bonding		Sn^{++}-F^- bonding			

Discussion

From the absence of new peaks characteristic of metal-metal bonding in the Raman spectra for Ni-Sn solutions, we infer that such bonding is absent in these solutions. The shifts in frequencies associated with metal-ligand bonding suggest that there is some interaction between the nickel and fluostannite ions, possibly by the type of fluoride bridging discussed above (5). Had strong metal-metal bonding been observed, this would have provided an attractive explanation for the formation of the equiatomic NiSn intermetallic compound; however, it seems improbable that the observed weak metal-ligand association would be an overriding factor in controlling the electrodeposition process.

Acknowledgments

We are grateful to Dr. M. J. Mays of the University Chemical Laboratory, Cambridge, for helpful discussion, and to the Department of Chemistry, Imperial College, London, for the use of their laser-Raman spectrophotometer. We are also glad to acknowledge financial support provided for B.E.W. and J.M.S. by the Science Research Council.

Electrochemical Current Balance with the Hydrogen-Palladium System

M. A. Fullenwider*

R.K.P. Industries, Incorporated, Allentown, Pennsylvania 18103

The hydrogen-palladium system has attracted much attention in the past because of its unique properties. Palladium diffuses larger quantities of hydrogen than any other metal and when hydrogen loaded has a rest potential 50 mV anodic to the reversible hydrogen potential. The system was the subject of the first application of the bi-electrode technique (1). The present paper describes novel, current balance experiments with the system allowing a rigorous check on some of the assumptions and conclusions of previous investigators. Previously it was assumed, for one thing, that the diffusion coefficient was independent of concentration. Nanis and Namboodhiri (2) recently reported the dependence of the diffusion coefficient upon concentration for the hydrogen-iron system where such behavior had previously been unsuspected. This paper describes a new technique for the detection of this type of behavior and its use with the hydrogen-palladium system. The method also allows a direct determination of surface coverage to be made. Until now, surface coverage with the hydrogen-palladium system was only accessible through anodic stripping, and it was never certain whether or how much the equilibrium between adsorbed and absorbed hydrogen was affected during the anodic stripping time interval.

Experimental Technique

The method employed was the bi-electrode technique, which has been described elsewhere (1). Previous to the present study, current balance had not been attained, that is, the cathodic steady-state current was always larger than the anodic current. Current balance was obtained here by simply modifying the gasket holding the palladium membrane so that there was a line seal about the aperture on the two sides of the membrane. All membranes were annealed at 900°C in an atmosphere of purified argon for 2 hr prior to experiment and were 7×10^{-3} cm in thickness. Potential control was effected with two de Ford type electronic potentiostats.

Analysis

The rational of the method can be understood by referring to Fig. 1-3. In Fig. 1 and 2 typical anodic and cathodic traces are shown. Prior to $t = 0$ both sides of the membrane are at 300 mV anodic to the reversible hydrogen potential, and no hydrogen is present; at $t = 0$ the cathodic side of the membrane is brought to, in this case, a potential of 136 mV, introducing hydrogen at this side; at t_1, some time after equilibrium has been established, the anodic side is raised to the same potential as the cathodic side, producing a uniform concentration profile; and at t_2 both sides are again taken to 300 mV, extracting all of the hydrogen.

Now assuming a steady-state profile at t_1 of the type shown in Fig. 3, in the event that material balance is attained, it is possible to define some quantities. Again referring to Fig. 1 and 2 we have

$$\int_0^{t_1} J_C dt - \int_0^{t_1} J_A dt = \Delta_1 = \Gamma + C_0\delta' + C_0\delta/2 \quad [1]$$

and

$$\int_0^{t_2} J_C dt - \int_0^{t_2} J_A dt = \Delta_2 = 2\Gamma + C_0(\delta' + \delta) \quad [2]$$

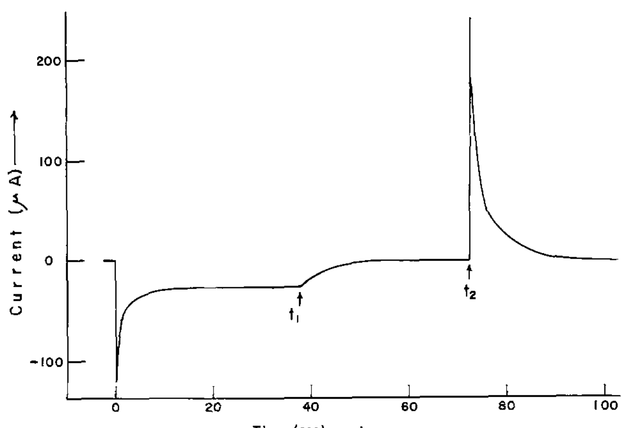

Fig. 1. Typical cathodic trace

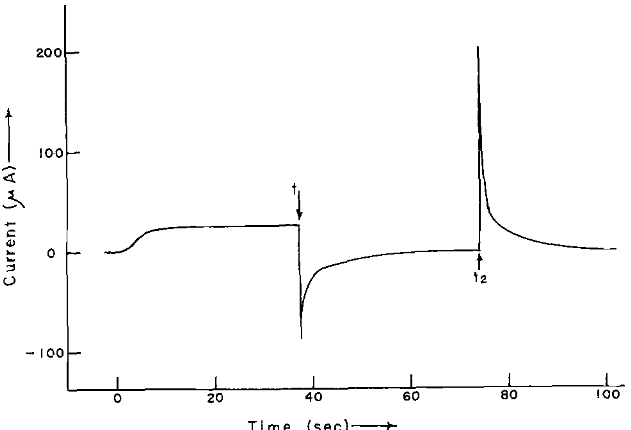

Fig. 2. Anodic trace corresponding to Fig. 1

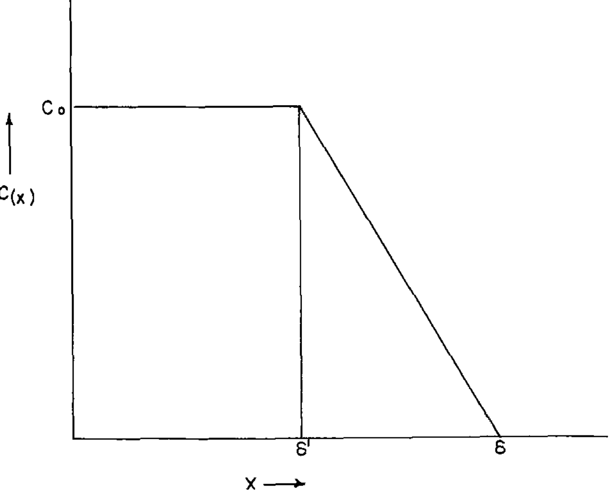

Fig. 3. Hypothetical concentration profile

* Electrochemical Society Active Member.

Key words: hydrogen diffusion, concentration dependent diffusion, rate limitation.

or

$$\Delta_2 - 2\Delta_1 = -C_0\delta' \quad [3]$$

where δ' is some undefined distance into the membrane, δ is the thickness of the membrane, J_C is the cathodic current, J_A is the anodic current, Γ is the surface coverage, and C_0 is the maximum hydrogen concentration within the membrane. Also we have a quantity

$$\Delta_3 = \int_{t_2}^{\infty} J_C dt + \int_{t_2}^{\infty} J_A dt \quad [4]$$

which should be equal to Δ_2, the total amount of hydrogen in the membrane at saturation.

If the quantity $\Delta_2 - 2\Delta_1$ is negative the profile is of the type shown in Fig. 3 (D increases with increasing concentration), if it is zero the profile is linear (D is independent of concentration), and if it is positive the profile is concave upward (D decreases with increasing concentration).

In the case that the diffusion coefficient is independent of concentration the following relation holds for $t < t_1$ (4)

$$\int_0^t J_C dt - \int_0^t J_A dt = \Gamma + \delta^2 J_A/2!D + (\delta^4/4!D^2)\, dJ_A/dt + (\delta^6/6!D^3)\, d^2J_A/dt^2 + \ldots \quad [5]$$

or at t_1

$$\int_0^{t_1} J_C dt - \int_0^{t_1} J_A dt = \Gamma + \delta^2 J_A/2D \quad [6]$$

where D is to be determined from the shape of the anodic transient by suitable mathematical analysis. There are two possibilities for the quantity J_t/J_∞, the fractional attainment of steady-state anodic current. If it is the case that there is no rate limitation at the cathodic surface, that is, that there is a step funcion in concentration at this side at $t = 0$, the result is (3, 4)

$$J_t/J_\infty = \theta_0(0, Dt/\delta^2) \quad [7]$$

or

$$J_t/J_\infty = [2\delta/(\pi Dt)^{1/2}] \sum_{m=0}^{\infty} (-1)^m \exp[-(2m+1)^2\delta^2/4Dt] \quad [8]$$

where θ_0 is one of the theta functions listed by Doetsch (5). If, on the other hand, there is rate limitation at this surface, then there will be a flux step function at $t = 0$, and we will have for the same quantity (4)

$$J_t/J_\infty = 1 - \int_0^1 \theta_1(u/2, Dt/\delta^2)\, du \quad [9]$$

or

$$J_t/J_\infty = 1 - (4/\pi) \sum_{m=0}^{\infty} [(-1)^m/(2m+1)] \exp[-\pi^2(2m+1)^2 Dt/4\delta^2] \quad [10]$$

The two expressions can best be compared according to the value of Dt/δ^2 corresponding to $J_t/J_\infty = 0.5$. We will call this quantity $Dt_{1/2}/\delta^2$, and we have from Eq. [8]

$$Dt_{1/2}/\delta^2 = 0.14 \quad [11]$$

and from Eq. [10]

$$Dt_{1/2}/\delta^2 = 0.38 \quad [12]$$

Results and Discussion

Figure 4 shows plots of Eq. [8] and [10], normalized about $t_{1/2}$, together with a typical experimental anodic transient. The experimental data can be seen to fit Eq. [10]. Equation [10] predicts a slower diffusion rate than Eq. [8], the equation normally used, and this implies the presence of a "rate limitation" at the cathodic surface of a slightly different nature but in the same

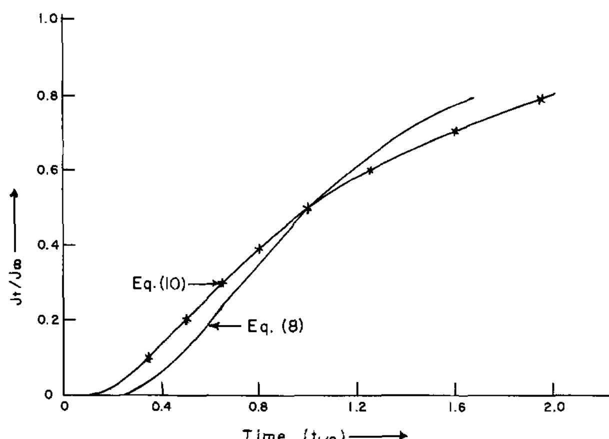

Fig. 4. Fractional attainment of steady-state current as a function of half rise time (J_t/J_∞ vs. time).

sense as Smits (7). On the other hand, previous investigators (1, 6) used a concentration step function model in the analysis of their data. This would result in an underestimation of the value of the diffusion coefficient.

In Table I are listed a typical set of values of the quantities Δ_1, Δ_2, and Δ_3 at various potentials. The difference $\Delta_2 - 2\Delta_1$ is positive for all but the most anodic of potentials where it is zero, *i.e.*, the diffusion coefficient decreases with increasing concentration. Also Δ_2 agrees fairly well with Δ_3. The decrease of the diffusion coefficient can easily be rationalized as being due to the blocking of diffusional pathways at higher concentrations. It is interesting that the results of Nanis and Namboodhiri (2) showed an increase of the diffusion coefficient of hydrogen in iron with concentration.

Also listed in Table I are values of Γ calculated from the relation, following from Eq. [1] and [6]

$$\Gamma = \Delta_1 - \delta^2 J_A/2D \quad [13]$$

where the difference $\Delta_2 - 2\Delta_1$ is zero and the relations hold. It is not possible to obtain Γ by simple analysis at more cathodic potentials. Γ can be seen to be approaching a monolayer at about 210 mV. Previously (6), a much lower value for Γ was reported in this potential region, and thus it would appear that the value of the anodic stripping time used here was not long enough, *i.e.*, a large part of the hydrogen on the surface at this potential was missed.

The diffusion coefficient in the linear region was calculated from Eq. [12] to be 4.5×10^{-7} cm² sec⁻¹, slightly larger than values previously reported which were in the range $(1.3\text{-}3.1) \times 10^{-7}$ cm² sec⁻¹. We can only conclude that all previous determinations of the diffusion coefficient were either made in the concentration dependent region, or involved an incorrect mathematical model.

Erratum

In the paper "Germanium-Doped GaAs for P-Type Ohmic Contacts" by D. R. Ketchow which appeared on pp. 1237-1239 in the September 1974 JOURNAL, Vol. 121, No. 9, Ketchow has published data on the hole concentration p in degenerate Ge-doped LPE GaAs ($p \lesssim 5 \times 10^{19}$ cm^{-3}). D. L. Rode, R. L. Brown, and D. R. Ketchow have redetermined p for similar growth conditions (800°C, 6°C/hr) to study the apparent variation with orientation of the distribution coefficient between (100) and (111)B substrates. The larger values of hole concentration reported earlier (see sample No. B113 and B115 of Ketchow in the article mentioned above) for degenerate (111)B substrates compared to (100) substrates are in error due to inaccurate determination of the Hall coefficient. At the liquidus concentration 44.5 a/o Ge, Rode, Brown, and Ketchow obtain $p = 5.09\ (\pm 0.27) \times 10^{19}$ cm^{-3} for (111)B GaAs ($p = 8.2 \times 10^{19}$ cm^{-3} reported previously by Ketchow in the above-mentioned article). Previous values for Hall mobility remain unaffected within experimental error (see Table I). The present values of hole concentration for (111)B substrates are essentially equal to those for (100) substrates within experimental error.

Anodic Oxidation of GaAs as a Technique to Evaluate Electrical Carrier Concentration Profiles

H. Müller,*[,1] F. H. Eisen,[2] and J. W. Mayer*

California Institute of Technology, Pasadena, California 91109

ABSTRACT

An anodic oxidation process of p- and n-type GaAs, using a constant current source, is described. Homogeneous and reproducible oxide layers were obtained using N-methylacetamide adjusted to a pH value of 8.3 by NH_4OH. For chemically polished and etched surfaces, oxide growth was found to be 20.2 Å/V and the amount of GaAs consumed in the oxide was 13.4 Å/V. This technique has been successfully applied to differential sheet resistivity and Hall measurements on ion-implanted semi-insulating GaAs.

The anodic oxidation of GaAs offers several interesting applications with respect to planar device technology, *e.g.*, masking, surface passivation, and removal of surface damage. Successive, controlled layer removal can be applied to the determination of electrical carrier concentration profiles in either thin epitaxial layers or in ion-implanted GaAs. Recently several publications have reported the possibility of native oxide growth on n- and p-type GaAs. Logan *et al.* (1) used a concentrated (30%) H_2O_2 electrolyte, which was adjusted to a pH value of 2 using H_3PO_4. A constant voltage source applied for a time period of 10 min produced oxide thicknesses proportional to the applied voltage. Composition analysis by Feldman *et al.* (2) combining He backscattering and He-induced x-rays showed the films to be deficient in As within 200Å of the surface and with a Ga:As of approximately 1:1 for the rest of the oxide.

Dell'Oca *et al.* (3) reported on anodic oxidation in a dilute aqueous ammonium pentaborate solution using a constant current source. They found that oxide formation at constant voltage will in general lead to films of nonuniform thickness. Revesz and Zaininger (4) reported on anodization in acetic anhydride saturated with KNO_3 and observed severe pitting owing to simultaneous dissolution of the films. Simultaneous growth and dissolution of anodic oxide films were found by Harvey and Kruger (5) in their studies of the mechanism of layer formation. Dissolution of the anodic oxide film was shown to be rapid in strongly acidic solutions. However, to use anodic oxidation for reproducible layer removal, it is necessary to minimize oxide film dissolution during the anodization process. This is important, for example, in determining electrical profiles in diffused or implanted GaAs samples.

The application of a constant voltage source in an anodization process in general has some disadvantages. Since the cell voltage is used as a reference for the oxide thickness, voltage drops across the electrolyte and contact resistance have to be small compared to the voltage drop across the oxide layer. This will be satisfied if the final current flowing through the layer is small enough not to cause significant voltage drops. The resistivity of the electrolyte can be determined independently, but contact resistance may depend on substrate doping and may not be reproducible from sample to sample for a particular alloy process. As a second parameter either the anodization time, in Ref. (1), 10 min, or the final current has to be used to define a cutoff condition. These difficulties do not arise with a constant current source, since the initial voltage is a measure both for voltage drops across the electrolyte and contact resistance and the difference between initial voltage and cell voltage can be directly used as a reference for the oxide thickness.

In this paper we describe a procedure, which allows the use of a constant current source. N-methylacetamide, which is a common electrolyte for silicon (6-8) was found to be applicable to GaAs. Details of the anodization process are given. The influence of various adjusted pH values of the solution on oxide growth or etching will be described. The main emphasis in developing the anodic oxidation technique was put on the application to successive layer removal on ion implanted GaAs. Sheet resistivity and Hall-effect measurements and layer removal were performed *in situ* and will be demonstrated for sulfur-implanted semi-insulating GaAs.

Experimental Techniques

The material used for evaluation of the anodic oxidation process was generally <111> oriented, n-type GaAs, silicon doped with a net donor concentration of 10^{18} cm^{-3}. Usually the anodizations were carried out on a chemically polished A face. Other samples were etched in a solution of $3H_2SO_4:1H_2O_2:2H_2O$ at 0°C (etch rate ~ 1000 Å/sec) and about 1 μm was removed. Growth rates were compared on a few samples of p-type material of <100> orientation with a net acceptor concentration of 3×10^{17} cm^{-3}.

The anodizations were carried out in a Teflon beaker, described in detail elsewhere (9). Its main features are a vinyl plate with a 5 mm in diameter opening which exposes part of the sample surface to the solution and acts as a seal between the sample and the Teflon

Key words: gallium arsenide, anodic oxidation, implanted carrier concentration profiles.

beaker. A platinum cathode was used, and anode contact was achieved by a gold plate underneath the sample. Generally the backsides of the samples were only lapped and no effort was taken with respect to back-contact preparation. For large area anodizations, samples were held by a stainless steel clamp and dipped into the solution close to the clamp. In these cases, both sides of the samples could be anodized.

The solution was N-methylacetamide ($CH_3CONHCH_3$ —J. T. Baker Chemical Company) adjusted to various *p*H values as described below in detail. A constant current source with a maximum open-circuit voltage of 300V was applied. The voltage increase as a function of time was monitored on a recorder. Generally the cell voltage was used as a thickness reference and corrections were made by subtracting initial voltage drops.

Determination of the oxide thickness as a function of the forming voltage (*i.e.*, cell voltage minus initial voltage drop) was done by ellipsometry, interferometry, and by use of a Talystep. The amount of GaAs consumed in the oxide layer was determined by interferometry, Talystep measurements, and He backscattering. In the latter case a Te implant was used as a marker (10), and the shift of the peak of the profile towards higher energies was used for calibration of the amount of GaAs removed.

Successive anodization and layer removal were used to evaluate electrical carrier concentration profiles by sheet resistivity and Hall measurements. Semi-insulating, Cr-doped material was implanted with sulfur and tellurium, with implantation energies of 100 and 400 keV, respectively. The sample preparation for *in situ* stripping and electrical measurements was done by the following procedure. First, four Au-Ge-Ni contacts were evaporated (diameter ~ 1.5 mm) and alloyed at 450°C for 45 sec in forming gas. In a photoresist step (KMER) a van der Pauw type pattern was defined and mesa etched to 3.3 μm. A sample holder described elsewhere in detail (11) was used to both perform Hall and sheet resistivity measurements and anodization of the exposed area. The main feature of this sample holder is a spring-loaded Teflon insert which seals the mesa pattern along the dashed line shown in the schematic of Fig. 1 and protects the electrical contacts against the solution. A platinum wire was used as cathode, and connection of the four contacts served as the anode during oxide growth. After each anodization the oxide was removed in diluted H_3PO_4 (1:1 with H_2O), and the sample was rinsed in deionized H_2O and methanol and then dried in dry N_2 flow.

Results and Discussion

Oxide growth in N-methylacetamide.—Several aspects were considered when using N-methylacetamide (NMA) as an electrolyte for anodization. A pure solution has a melting point of 27°C, and it is common practice (7) to add small amounts of H_2O (5-10%) to lower the melting point. The specific resistance is also known to be high (6). Therefore, in silicon anodization, oxygen-containing electrolytes such as KNO_3 are added to increase the conductivity. It was found that these compounds are not involved in the mechanism of oxide growth (6).

On the other hand, it is known (1) that in contrast to silicon, native oxides on GaAs are soluble in all common acids (like H_3PO_4, HCl, H_2SO_4) and that the oxide growth in case of H_2O_2 is sensitive to the *p*H value of the solution; a similar behavior may be anticipated for N-methylacetamide. Therefore, in our application of N-methylacetamide to the anodization of GaAs, the *p*H value of the solution was considered as an additional parameter when trying to obtain a proper low resistivity solution.

In Fig. 2 the influence of H_2O on the bath resistance for a given geometry, and on the *p*H value are shown. For small amounts of H_2O (sufficient to prevent crystallization) the *p*H value is close to neutral and the resistance was found to be 23.8 kohm. Resistance values were measured using two platinum electrodes with ~ 20 mm² each separated by ~ 1.5 cm. With increasing content of H_2O the resistance can be lowered by almost a factor of two but simultaneously the *p*H value of the solution decreases to an acidic character. Anodizations carried out on n-type GaAs at a current density of 0.5 mA/cm² resulted in an oxide growth for a ratio of H_2O to NMA less than one but showed severe pitting. Worm-like craters about 50 μm deep were formed; areas between these showed homogeneous oxide growth. No relation to crystal orientation (preferential oxidation) or surface preparation of the samples could be found. The density of the defects increased with increasing amounts of H_2O. For H_2O to NMA ratios above one the anodization turned into an etching process.

The results of Fig. 2 indicate that two competing mechanisms are involved at *p*H values below 7. Oxide growth and thickness for a given reference voltage were found to be enhanced at increased current densities, but simultaneous dissolution, presumably due to the acidic character of the solution, could not be suppressed. No reproducible thickness *vs.* voltage relationship could be achieved.

Further experiments were performed at *p*H values above 7. Figure 3 shows the bath resistance as a function of *p*H value adjusted by NH_4OH.[3] A decrease in resistance by a factor of 6 is observed when the *p*H is

[3] Because of the hygroscopic nature of NMA, unknown initial amounts of H_2O can cause significant changes in resistance values. In some cases of as-puchased NMA up to 20% H_2O had to be added before adjustments with NH_4OH.

adjusted to 8.3. At this value very homogeneous layers could be obtained and no further influence of oxide thickness on current density was found, which suggests that dissolution of the oxide was suppressed to a very small amount. At *p*H values above 10 a slight dependence of oxide thickness on current density was found due to the fact that the layers are soluble in NH_4OH.

Conditions for oxide growth.—For a *p*H value of 8.3 the current density was chosen to be 0.5 mA/cm^2 which results in a cell voltage increase of 9.5 V/min. A typical cell voltage *vs.* time plot is shown in Fig. 4. The initial voltage drop is 3.5V and represents the total voltage drop across electrolyte, semiconductor bulk, and back contact. Generally, for the first anodization of a polished surface, a slightly higher voltage drop was observed than for following anodizations after layer removal. A light source was found not to be necessary for voltages up to 40V. In order to reproducibly approach a certain voltage, the reference voltage was chosen to be larger than the desired voltage and as soon as the desired voltage was reached, the current source was switched off. This determined the applied current density, which should allow a reasonably slow approach to a desired voltage value. For voltages above 40V, a slight nonlinearity in the voltage-time plot is observed, as can be seen in Fig. 4. The nature of this effect was not carefully investigated; however, it was found that using a light source and increasing the current density by a factor of 3, the deviation from a linear cell voltage *vs.* time relationship occurs at about 80V. Since the main emphasis of this paper is to demonstrate a technique which allows successive removal of thin layers (100-300Å) the voltage range above 40V was not investigated in detail.

Oxide thickness and amount of GaAs consumed.—A series of oxides were prepared on chemically polished n-type surfaces, the cell voltage was used as a reference, and the voltages were chosen between 20 and 60V. In all cases, an initial voltage drop of about 3V was observed and subtracted from the cell voltage to give the forming voltage which defines the x-axis in Fig. 5. The solid line in Fig. 5 represents the average oxide thickness *vs.* forming voltage for different techniques. The open circles were obtained from ellipsometry measurements. The refractive index of the oxide layers was found to be $n = 1.815 \pm 0.005$ over the entire voltage range similar to what Dell'Oca *et al.* (3) found. From the slope an oxide growth rate of 20.2 Å/V was obtained. For comparison, Talystep and interferometer measurements were performed on some of the samples. Photoresist processing was used to remove part of the oxide and to create a well-defined step. In the case of interferometer measurements, Al was evaporated on the samples to create a highly reflecting surface. The observed growth rate agrees very well with results by Logan *et al.* (1) obtained on abrasively polished surfaces. For comparison, p-type material with a carrier concentration of 3×10^{17} cm^{-3} was anodized. In a first approach the colors of the oxide layers appeared identical to the colors obtained on n-type material. Ellipsometry measurement confirmed an identical 20.2 Å/V thickness to voltage relationship. The refractive index also turned out to be identical.

Identical growth rates were obtained for both chemically polished and etched surfaces on n- and p-type material. Generally for the first anodization a somewhat higher initial voltage was found compared to following anodizations. This difference may be indicative of changes in surface appearance. Since the nature of this difference is not known, it is difficult to deduce a change in growth rates. Using the forming voltage as a reference for the oxide thickness, no change in growth rate was found on successively anodized samples. No preferential oxidation either due to surface roughness or changes in surface homogeneity was found for as many as 27 successive anodizations (~0.7 μm of GaAs removed).

The amount of GaAs consumed in the oxide layer was primarily measured by Talystep. For comparison interferometer measurements were taken. In order to develop a step in the material which corresponds to the amount of GaAs consumed in the oxide, a first oxide was grown; then part of this oxide was removed by photomasking, and a second oxide was grown on this

area. The oxide thickness was measured on both areas after first and second anodization by ellipsometry in order to ensure that no further growth took place on the original first oxide. Thus, the difference in oxide heights corresponds to the amount of GaAs consumed. From the dotted line in Fig. 5 the average amount of GaAs consumed in the oxide layer corresponds to 13.4 Å/V.

A slightly lower amount of material consumed was found by backscattering measurements as indicated in Fig. 5. A dose of 2×10^{15} cm^{-2} Te was implanted at 350°C into n-type GaAs at an energy of 400 keV. 2.5 MeV He^+ backscattering was used to determine the implanted Te profile. Energy-to-depth conversion (12) of the backscattered spectrum allows the determination of the mean projected range of Te. After anodization and layer removal the Te peak is closer to the surface, and the shift corresponds to the amount of GaAs consumed in the oxide. It was found that the Te profile is not changed by the oxide growth, which is a basic assumption for electrical profile determination by successive layer removal.

Application of anodic oxidation to profile determination in ion-implanted GaAs.—To demonstrate the application of anodic oxidation a typical profile of sulfur implanted into semi-insulating GaAs is shown in Fig. 6. The energy of the implantation was 100 keV at 350°C target temperature and the dose was 10^{14} cm^{-2}. Reactively sputtered (13) Si_3N_4 was used as an encapsulation for annealing at 850°C, for 10 min in H_2 atmosphere. Anodization was carried out at 20V (which corresponds to 268Å removal of GaAs) and after each layer removal sheet resistivity and Hall measurements were performed. From these data the profile of electrical carriers was evaluated using equations described for example in Ref. (14). The electrical activity of the implant was found to be 13%. The arrow in Fig. 6 indicates the mean projected range according to LSS theory (15). A strong deviation from the predicted gaussian distribution is apparent. The circles and triangles in Fig. 6 show results obtained on two different samples treated under identical conditions, but anodized at different voltages. There is significant scatter in the data close to the surface (linear plot), but in the tail region excellent reproducibility is observed. Hall mobility data are also included in Fig. 6. Detailed results on sulfur and Te implants with respect to electrical activity of the implanted species and carrier mobilities will be presented in Ref. (16).

From a series of profile measurements a lower limit of this technique with our experimental setup was found when sheet resistivity values approached 100 kohm/□. These sheet resistivity values correspond to carrier concentrations between 2×10^{16} and 8×10^{16} cm^{-3} depending on the mobility and the gradient of the profile. In order to obtain information on the continuation of the profiles towards lower concentration values, Schottky-barrier C-V techniques were employed.

Summary

An anodic oxidation technique for both p- and n-type GaAs (net carrier concentration 10^{17}-10^{18} cm^{-3}) was developed which allows the use of a constant current source. The electrolyte was N-methylacetamide adjusted to a pH value of 8.3 by NH_4OH. The current density was 0.5 mA/cm^2 which resulted in a forming voltage increase of 9.5 V/min. Large areas could be homogeneously and reproducibly anodized. A linear dependence between forming voltage and anodization time was found up to 40V; using a light source and increased current density this linear dependence could be extended to 80V.

Measurements of oxide thicknesses and the amount of GaAs consumed in the oxide were done by ellipsometry, Talystep, and interferometry. An oxide growth rate of 20.2 Å/V was found and the amount of GaAs consumed in the oxide was 13.4 Å/V.

The application of this technique to evaluate electrical carrier concentrations in ion-implanted semi-insulating GaAs was demonstrated in case of a 100 keV sulfur implant successively anodized and analyzed by differential Hall effect and sheet resistivity measurements.

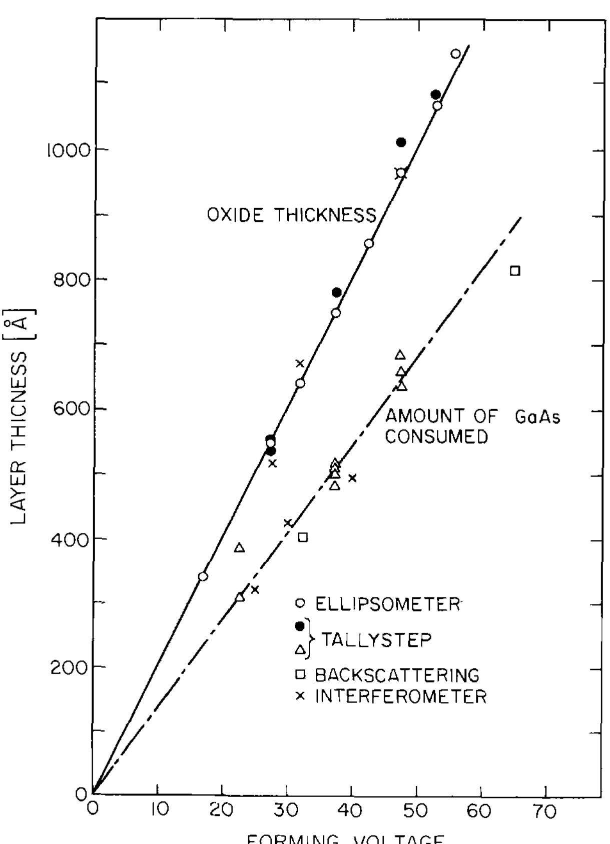

Fig. 5. Oxide thickness and amount of GaAs consumed vs. forming voltage.

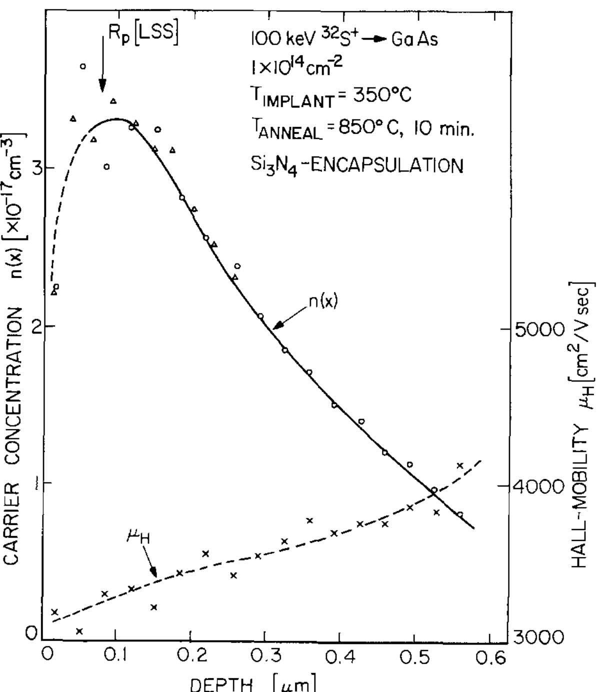

Fig. 6. Electrical carrier concentration profile for sulfur-implanted semi-insulating GaAs obtained by differential Hall and sheet resistivity measurements.

The anodization technique is presently used for a detailed study of sulfur and tellurium implanted profiles in semi-insulating and p-type GaAs with respect to implant and anneal conditions (16). Oxide layers will be investigated with respect to their application of MOS structures.

Acknowledgments

The authors wish to thank Tom Sigmon of Hewlett-Packard for providing Talystep measurements and B. Welch of the Rockwell International Science Center for performing the implantations.

Use of a ZnS:Er,Cu Cathodoluminescent Phosphor with Spectral Filtering for Contrast Enhancement

E. Schlam, J. J. Pucilowski, and I. Reingold

United States Army Electronics Technology and Devices Laboratory, United States Army Electronics Command, Fort Monmouth, New Jersey 07703

ABSTRACT

It is shown that the contrast of a narrow-line emitting cathodoluminescent ZnS:Er,Cu phosphor may be considerably improved through the use of a spectral filter whose bandpass is coincident with the phosphor emission spectrum. Such enhancement is due to the selective exclusion of ambient light not in the spectral region of the phosphor emission. The erbium-activated zinc sulfide phosphor reported here has a primary emission from the $^2H_{11/2} \rightarrow {}^4I_{15/2}$ transition. The contrast enhancement of the rare earth phosphor achieved through the utilization of this method is reported. It is compared with the contrast enhancement of P-2, a broadband emitting phosphor. It is shown that the efficiency requirement for the rare earth phosphor is considerably less than that of the broadband emitting phosphor, for the same degree of viewability.

The need for displays which are effective in high-ambient lighting is becoming more widespread. Simultaneous with this need is the reluctance to accept displays which must be heavily shielded from intense ambient light in order to be readable. This reluctance stems from the need for more mobile, versatile, and useful displays and the expectation that the present level of technology should be able to provide a solution to this problem. The most important information display, the cathode-ray tube (CRT), in its elementary form has severe problems with regard to viewability in high ambient because of the high degree of reflectivity of its phosphor surface. There are two general approaches which attempt to alleviate this problem. The first approach involves increasing the intensity of the phosphor emission in order to overcome the effect of the ambient light. To get an effective result requires large increases in phosphor output and is accomplished by means of a direct view storage tube (DVST) or by a CRT incorporating a thick phosphor screen and high beam power density, such as a projection-type tube. However, these tubes suffer from systems oriented disadvantages such as a lack of selective erase in the former and a short operating life in the latter.

More elegant means to increase the viewability of CRT's in high ambient light involve the increase of contrast by reducing the amount of ambient light reflected into the viewer's eyes. This may be accomplished by incorporating a transparent phosphor screen, thereby reducing its reflectivity, or by the use of filtering. The former approach can be made particularly effective through the use of high efficiency transparent phosphors (1) and by the use of a black absorbing layer on the back of the phosphor screen (2). Unfortunately, at present, CRT's incorporating these features require special processing techniques

Key words: rare earth phosphors, bandpass filters, display contrast, cathodoluminescence.

which are costly and limit their use. The filtering approaches are generally external to the CRT and therefore do not require special CRT manufacturing techniques. The simplest filtering approach utilizes a neutral density filter over the phosphor screen. This enhances contrast since the ambient light passes through the filter twice and is therefore attenuated more than the CRT emission which passes through the filter once. A more effective approach will utilize a spectral filter which takes advantage of the spectral emission of the phosphor. In this case, ideally, the filter has a bandpass which passes all of the phosphor emission and absorbs the ambient in the remaining portion of the visible spectrum (3). In essence such a filter has the advantages of a neutral density filter in doubly attenuating the ambient light, but completely passing the phosphor emission. Clearly such a technique is most effective when two conditions are present: (*i*) the phosphor emission must be as spectrally narrow as possible with the filter providing maximum transmission limited to the phosphor spectral range; (*ii*) the remaining portion of the ambient light must be effectively eliminated. This is a particular problem with an interference filter because of its high reflectivity. One way consideration (*ii*) may be effected is by the use of circular polarizers, and this technique was recently successfully applied to red and green light-emitting diodes (4). Consideration (*i*) is the subject of this paper which describes the application of spectral filtering for contrast enhancement of a rare earth activated cathodoluminescent phosphor.

Experimental

In this study, phosphors were synthesized by activation of a pure, presynthesized commercially available ZnS host material. Proper amounts of $ErCl_3$ and $CuCl_2$ are mixed with water and NH_4OH, respectively. The $ErCl_3$ solution is added to the ZnS host material to form a slurry, and the $CuCl_2$ solution is added to the slurry and agitated. This mixture is then oven-dried resulting in a fine powder which is ground with mortar and pestle. The mixture is placed in a graphite crucible which in turn is placed in a quartz tube. The crucible is plugged with quartz wool to prevent loss of sample by thermal agitation. H_2S is introduced to the sample through a quartz tube, and the gas is exhausted through an absorbent material. Firing temperature is carefully controlled as the sample is fired in a saturated atmosphere of H_2S. The entire assembly is rapidly removed from the oven in order that the wurtzite phase be preserved. The sample is then allowed to cool in the H_2S atmosphere. A detailed study and description of the phosphor synthesis has previously been reported (5).

In order to obtain its photoluminescent spectrum, a small amount of the phosphor is mixed with amylacetate and placed on an aluminum slide suitable for introduction into a spectrophotofluorometer with corrected spectra attachment. The sample is illuminated by radiation of proper wavelength to afford peak photoluminescent output, and that output spectrum is recorded on an x-y recorder.

To obtain the cathodoluminescent data, a portion of the sample is deposited on a glass slide using standard settling techniques with suitable binders. This slide is affixed in a specially designed demountable cathode-ray tube which is capable of holding nine such samples. Cathodoluminescent output is measured at various anode voltages (5-30 kV) and beam currents (1-5 μA). Spot size is variable from 10 to over 100 mils but is usually adjusted to yield no greater than 3 W/cm^2 of electron beam energy impinging on the phosphor surface. This is due to the fact that the samples were not aluminized and higher power densities would burn the phosphors. During the phosphor development stages all samples were screened using the photoluminescent equipment described. Samples which exhibited little or no rare earth emission under photoluminescent excitation did not exhibit this emission under cathodoluminescent excitation. Unfortunately however, high rare earth photoluminescent output does not guarantee such emission under cathodoluminescence.

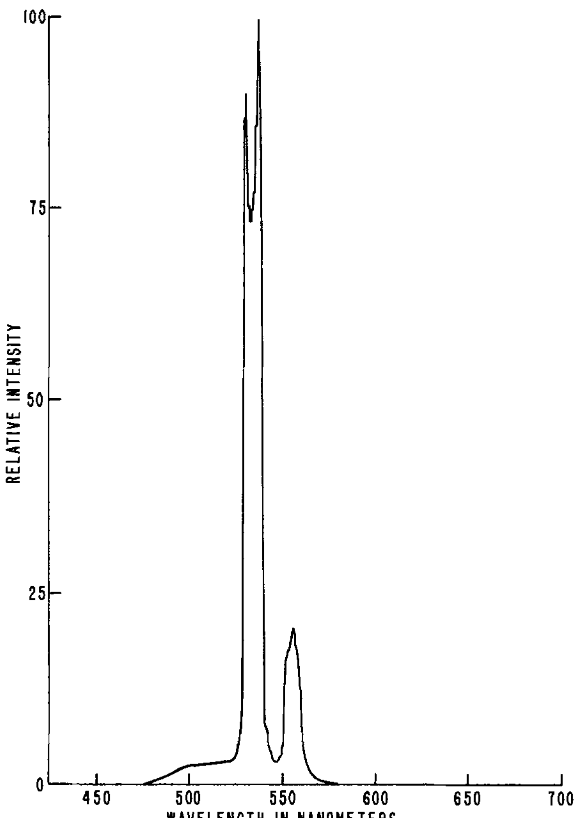

Fig. 1. Emission spectrum of ZnS:Er,Cu phosphor

The final developed phosphor exhibits both efficient photoluminescent and cathodoluminescent rare earth emission. These samples are placed in the demountable CRT. The anode voltage is raised from 10 to 30 kV in steps of 5 kV. Current is varied from 1 to 5 μA for each anode voltage level, and the corresponding cathodoluminescent data is taken. A predetermined spot size is held constant throughout. Spectral output was taken on a Jarrell-Ash ½-meter monochromator, while luminance levels were measured with a Photo Research Spectra Spot Brightness Meter. A sun gun was used to illuminate the samples to the required ambient light levels. A narrow band optical filter chosen for its spectral overlap with the rare earth emission of ZnS:Er,Cu was employed during this study.[1] Measurements were made with and without the filter so that the degree of contrast enhancement achieved could be determined.

Results

A typical cathodoluminescent spectrum of the ZnS:Er,Cu phosphor as seen in Fig. 1, is basically identical to that of the photoluminescent spectrum. The primary rare earth transition is that of the $^2H_{11/2}$ excited state to the $^4I_{15/2}$ ground state of the triply ionized erbium ion. It is noted that a slight broadband component peaking at a wavelength somewhat shorter than that of the rare earth line is present. The nature of this broadband has been previously discussed (5). It may be seen graphically in Fig. 2 where the amplitude ratio of the primary rare earth peak and the broadband peak are plotted as a function of electron beam energy. The ratio of the amplitudes is relatively insensitive to electron beam current variation as may be seen in Fig. 3. The over-all radiant efficiency of this

[1] Filter was obtained from Barr Associates, West Concord, Massachusetts.

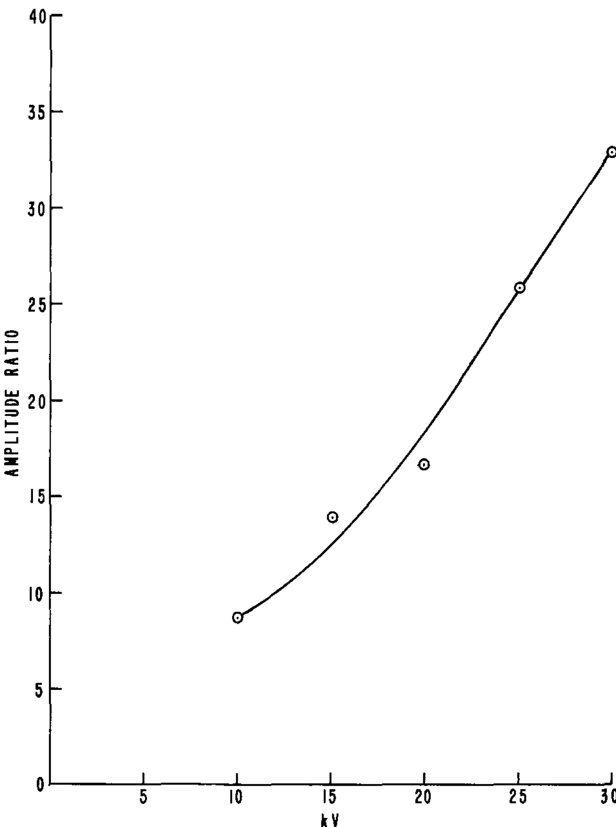

Fig. 2. Ratio of the amplitude of the primary narrow-line emission of ZnS:Er,Cu phosphor to the broadband emission of that phosphor as a function of electron beam energy.

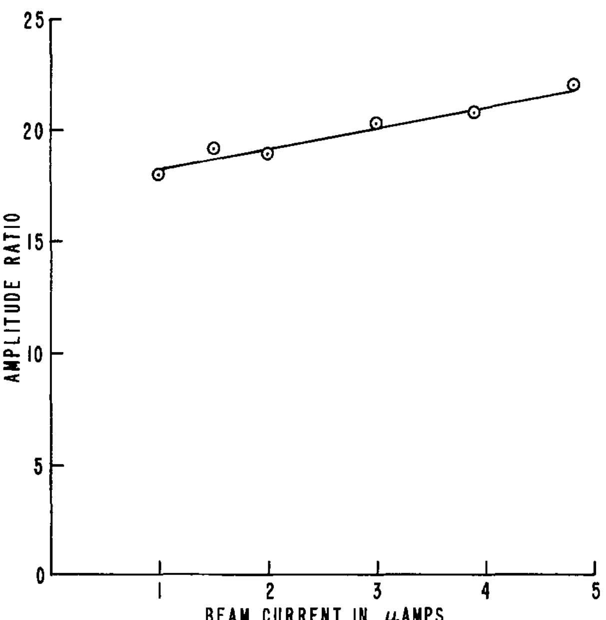

Fig. 3. Ratio of the amplitude of the primary narrow-line emission of ZnS:Er,Cu phosphor to the broadband emission of that phosphor as a function of beam current, at 20 kV.

phosphor is 0.25 times that of the Sylvania Electric Products Incorporated P-2 sample used in this experiment as a control. P-2 is a high efficiency broadband emitting phosphor of the ZnS family. The luminous efficiency of the rare earth phosphor is 0.32 times that of the P-2 phosphor since the rare earth emission has more of its energy concentrated closer to the peak of the spectral photopic response. Figure 4 is a

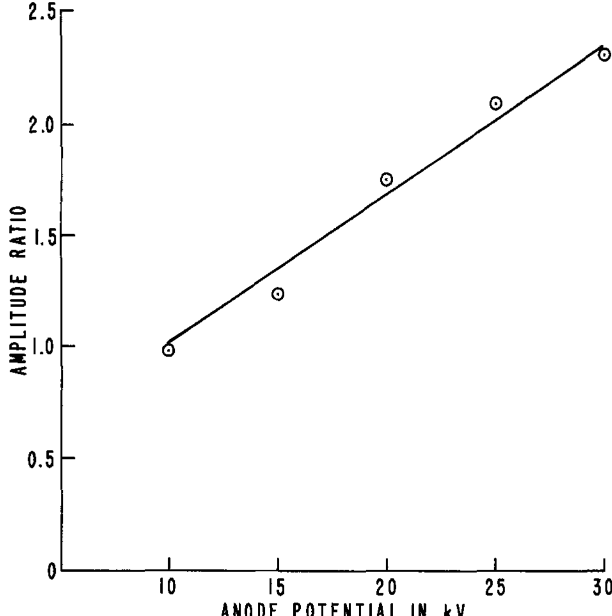

Fig. 4. Ratio of the amplitude of the primary narrow-line emission of ZnS:Er,Cu to the amplitude of the P-2 emission as a function of electron beam energy.

plot of the ratio of the peak amplitude of the rare earth emission to the peak amplitude of P-2 emission as a function of anode potential. As may be seen, the plot is linear and the ratio reaches a value of 2.3 at 30 kV. This value of anode potential was used for all the contrast determinations.

The transmission spectrum of the narrow band filter and the rare earth emission spectrum are shown in Fig. 5. The half-width of the filter is 8.6 nm. The corresponding spectra for P-2 and a Wratten 55 filter chosen for overlap with the P-2 emission spectrum, are shown in Fig. 6.

The contrast of the phosphor emission is defined as

$$C = \frac{L_1}{L_2} \qquad [1]$$

and with the appropriate spectral filter, this contrast becomes

$$C_F = \frac{T_p L_1}{T_b L_2} \qquad [2]$$

where L_1 is the luminance of the excited phosphor with no ambient and L_2 is the luminance of the unexcited phosphor due to reflection of the ambient. T_p is the per cent transmission of the filter to the phosphor emission and T_b is the per cent transmission of the filter to ambient light which passes through the filter and is reflected from the phosphor surface. When the filter is placed over the phosphor, contrast is increased since T_p is greater than T_b and the luminance seen by the viewer is decreased since T_p is less than unity. To properly analyze the effect of the contrast enhancement, the output luminance should be specified. Figure 7 depicts a family of curves representing the contrast C_F as a function of phosphor luminance L_1 according to Eq. [2], for an assumed ambient illuminance of 4500 ft-c which results in a reflected ambient luminance of 2500 ft-L for the 55% reflectivity of the faceplate-phosphor configuration in the demountable system used in this experiment. The parameter determining the different curves is an assumed set of different peak filter transmissions, T, for the filters used in this experiment. Loci of points corresponding to a net output luminance through the filter of 20 ft-L is shown in the figure. These loci represent the best filtering that can be performed for

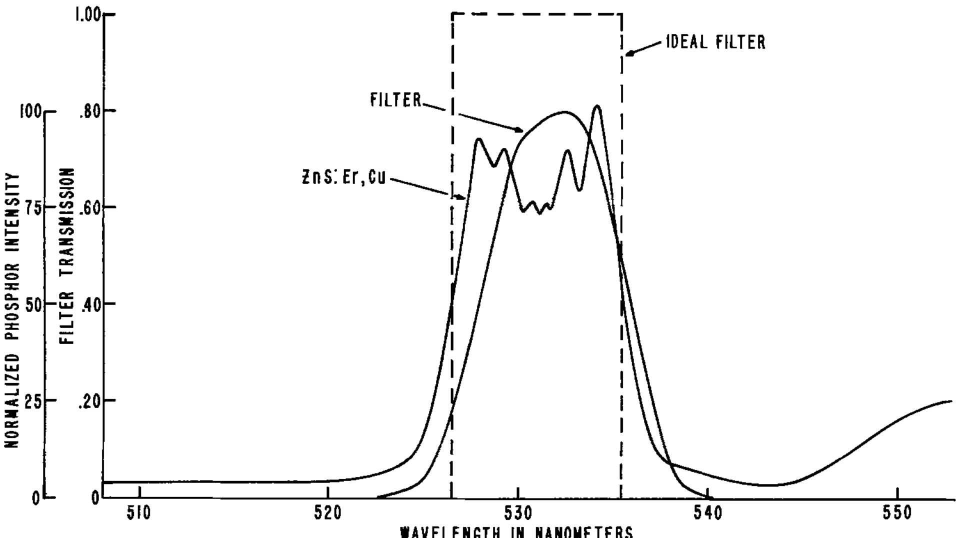

Fig. 5. The normalized emission spectrum of ZnS:Er,Cu and the Barr filter transmission spectrum.

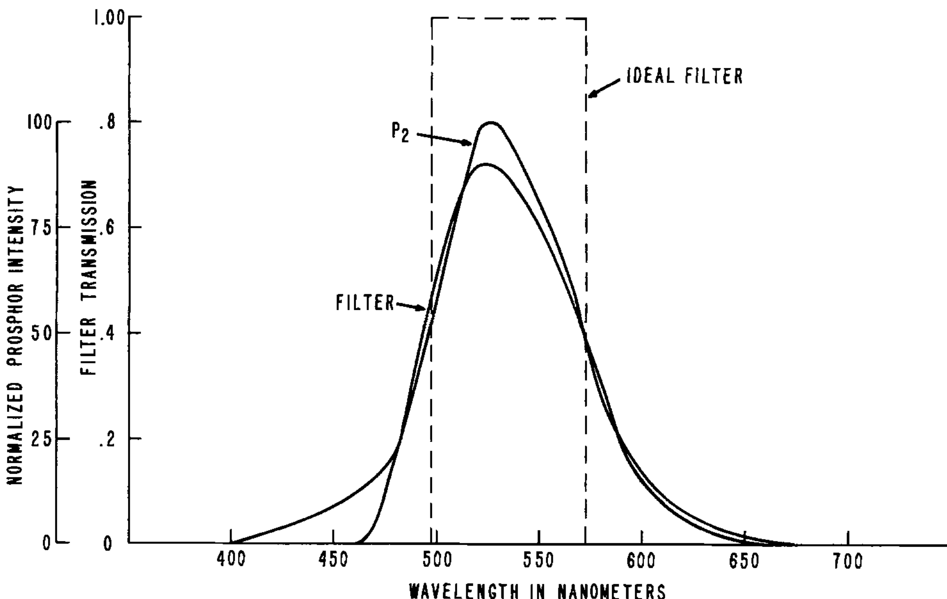

Fig. 6. Normalized emission spectrum of P-2 and transmission spectrum of the Wratten 55 filter.

the specified output luminance. In the absence of filters, the contrasts would vary from 0.04 at 100 ft-L phosphor output to 0.2 at 500 ft-L phosphor output, neglecting front surface reflections.

Discussion

In referring to Fig. 7 it is seen that at a phosphor luminance of approximately 400 ft-L, the contrast of the rare earth activated phosphor is enhanced from 0.16 to 12.6 with the use of a 0.105 peak transmission filter at a 4500 ft-c incident illumination. This is an enhancement of 78 times. The P-2 contrast is enhanced to 3.4 with a 0.072 peak transmission filter for an enhancement of 21 times. Although the contrast of the rare earth phosphor is enhanced 3.7 times more than that of the wide banded P-2, it should be realized that the rare earth phosphor is being driven with a higher input power to achieve the 400 ft-L starting luminance due to the fact that P-2 has approximately 3 times the luminous efficiency of this experimental ZnS:Er,Cu phosphor at its present stage of development. Therefore if one were to choose a desired contrast ratio, it could be achieved with 1/3 less power with the use of P-2 as compared to the present rare earth phosphor. Using this consideration as a quality determination, it is seen that with the filter used in this experiment an equivalent rare earth phosphor with an efficiency only greater than ½ that of P-2 would be preferable to P-2.

The effect of a neutral density filter in enhancing the contrast of these phosphors may be compared to the spectral filter results by choosing an imaginary neutral density filter of a density such that the luminance of the phosphor through the filter would be identical to the luminance through the spectral filter. The contrast with a neutral density filter is

$$C = \frac{T_N L_1}{T_N^2 L_2} = \frac{L_1}{T_N L_2} \quad [3]$$

where T_N is the transmission of the filter. To achieve the same luminance through the neutral density filter as with the spectral filter used here, a transmission of 36% is required. Using this value of T_N for the 4500 ft-c ambient and 400 ft-L phosphor output gives an expected contrast of 0.44. It is seen therefore, that in the case at hand, the use of the 0.8 peak transmission spectral filter results in a 3.6 times contrast enhancement as compared to the use of a neutral density filter. The spectral filter itself results in a 10 times contrast enhancement over no filter at all under these conditions. It is clear from Fig. 5 that the particular spectral filter used does not have a perfect overlap with the emission spectrum of the rare earth phosphor, and if

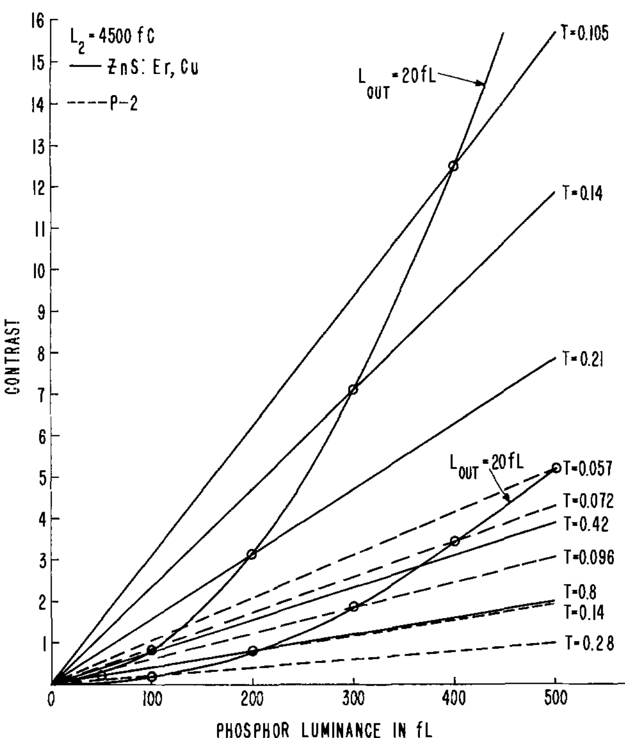

Fig. 7. Contrast of ZnS:Er,Cu and P-2 as a function of phosphor luminance. Peak transmission of the appropriate spectral filter *T*, is a parameter. The locus of points representing luminance through the filter of 20 ft-L is depicted. Ambient intensity is 4500 ft-c.

such an overlap were approached, the contrast enhancement would be further improved, and luminous efficiency less than ½ that of P-2 would result in contrast ratios higher than those achievable with P-2.

Conclusions

It has been demonstrated that expected contrast enhancement from spectral filtering is achievable in actual phosphors. The particular experiments in this paper indicate that the greatest improvement in contrast for the combination of phosphor and filters studied occurs at voltages in the 20-30 kV region. It is a straightforward engineering procedure to design and utilize the necessary equipment for the operation of CRT's at these voltage levels.

In particular, the narrow-line emitting ZnS:Er,Cu phosphor developed here shows a 10 times contrast enhancement with the use of a commercially available spectral filter with a peak transmission of 0.8 which is essentially matched to the spectral output of this rare earth phosphor. Even in this case, the filter does not provide a perfect overlap to the phosphor emission and therefore further improvement is achievable. Such contrast enhancement is superior to that achieved by neutral density filtering. One particular disadvantage of such narrow filtering is the need for an interference filter to achieve the desired spectral properties. Such filters are by nature highly reflecting in their non-bandpass region; however, these reflections can be eliminated, for example, through the use of circular polarizers.

Clearly, the narrower the emission band of the phosphor, the better the expected contrast enhancement. Further consideration in regard to phosphor spectral bandwidth, luminous efficiency and spectral region and in regard to filter spectral match, transmission, and absorption properties can undoubtedly result in greater contrast enhancement than reported here. It is recognized that the results of this study are largely empirical, and for a specific phosphor. However, the concept can provide a stimulus to others to carry on further work which will result in a better understanding of the phosphor physics involved; and in the synthesis of new phosphors, and the application of rare earth phosphors with narrow-line width and controlled characteristics. The technique discussed in this paper, in conjunction with proper attention to phosphor characteristics such as spectral bandwidth, luminous efficiency, and spectral region, can result in the design of CRT's with significantly enhanced luminance and contrast ratios, features that are most important where high ambient illumination levels are present.

On the Efficiency of Yb^{3+}-Er^{3+} Activated Up-Conversion Phosphors

A. Bril, J. L. Sommerdijk, and A. W. de Jager

Philips Research Laboratories, Eindhoven, Netherlands

ABSTRACT

Efficiencies of Yb^{3+}-Er^{3+} activated up-conversion phosphors are determined by the efficiency of the excitation process and by that of the final emission process in the Er^{3+} ion. The former process is dependent on the infrared excitation density. We measured the efficiency of the emission process by excitation to selected Er^{3+} levels for various host lattices and as a function of Yb^{3+} and Er^{3+} concentrations. For one of the best up-conversion phosphors known at present, α-$NaYF_4$-0.20 Yb-0.03 Er, the efficiency of the green emission, is about 6%.

The light output of infrared-to-visible up-conversion phosphors activated with trivalent rare earth ions was very much increased as a consequence of the observation of Auzel (1) and of Ovsyankin and Feofilov (2) that coactivation with a large amount of Yb^{3+} was very effective due to its relatively strong absorption of the infrared radiation and its efficient transfer of the absorbed energy to the other rare earth ions like Er^{3+}, Tm^{3+}, and Ho^{3+} in various host lattices. Hewes and Sarver (3) found that LaF_3-Yb-Er was a good phosphor of this type, giving green emission with infrared excitation. Other good Yb-Er activated fluorides subsequently found were YF_3 (4), $BaYF_5$ (5), and α-$NaYF_4$ (6).

Nevertheless rather low values were obtained for the infrared-to-green conversion efficiency even for the brightest phosphors mentioned above. This efficiency is dependent on the excitation density of the infrared radiation. Since two infrared quanta are involved in the excitation, the light output increases as the square of the excitation density. For about 1 mW/cm^2 absorbed exciting radiation at a wavelength $\lambda = 0.97\ \mu m$ a quantum efficiency between 10^{-4} and 10^{-3} is found for the best phosphors [see, *e.g.*, Ref. (7) and below].

In the mechanism of the infrared-to-visible conversion we can distinguish between an excitation process in which infrared energy absorbed by the Yb^{3+} ions excites the Er^{3+} ions to the visible-emitting levels, and an emission process in which the excited Er^{3+} ions luminesce. The latter is independent of the excitation density.

To understand the infrared-to-visible conversion it is important to know how efficient this emission process is and whether it limits the total efficiency of the infrared-to-visible conversion. Up to now the efficiency of the luminescence process has not been determined in a direct way. Part of the energy level scheme of Er^{3+} is given in Fig. 1. In the following we describe experiments designed to determine the efficiencies of both Er^{3+} and Yb^{3+}-Er^{3+} activated phosphors when excited in the characteristic $^4F_{5/2}$, $^4F_{3/2}$ levels which are located just above the $^4S_{3/2}$ level from which the green emission takes place. The experiments were carried out for various host lattices, both fluorides and oxides.

Experimental

The method of measurement used for determining the efficiency of the Er^{3+} luminescence with excitation in the characteristic $^4F_{5/2}$, $^4F_{3/2}$ levels of the Er^{3+} ion is similar to that described earlier by Bril, Blasse, and Bertens (8) for the Eu^{3+} luminescence. A schematic diagram of the setup is given in Fig. 2. The phosphor was irradiated monochromatically through a grating monochromator. The instrument used is a modified Perkin-Elmer Model 13 spectrophotometer, equipped with a Bausch and Lomb grating with 600 grooves/mm blazed at 500 nm. The Nernst source with mirror was replaced by an exchangeable tungsten-halogen and a deuterium radiation source, respectively, in combination with a quartz lens.

Two measurements were carried out for the selected Er^{3+} absorption region: (*i*) The excitation spectrum of the green Er^{3+} emission was measured, *i.e.*, the luminescent radiation collected by a photomultiplier (EMI 9558QA with S20 photocathode) was determined

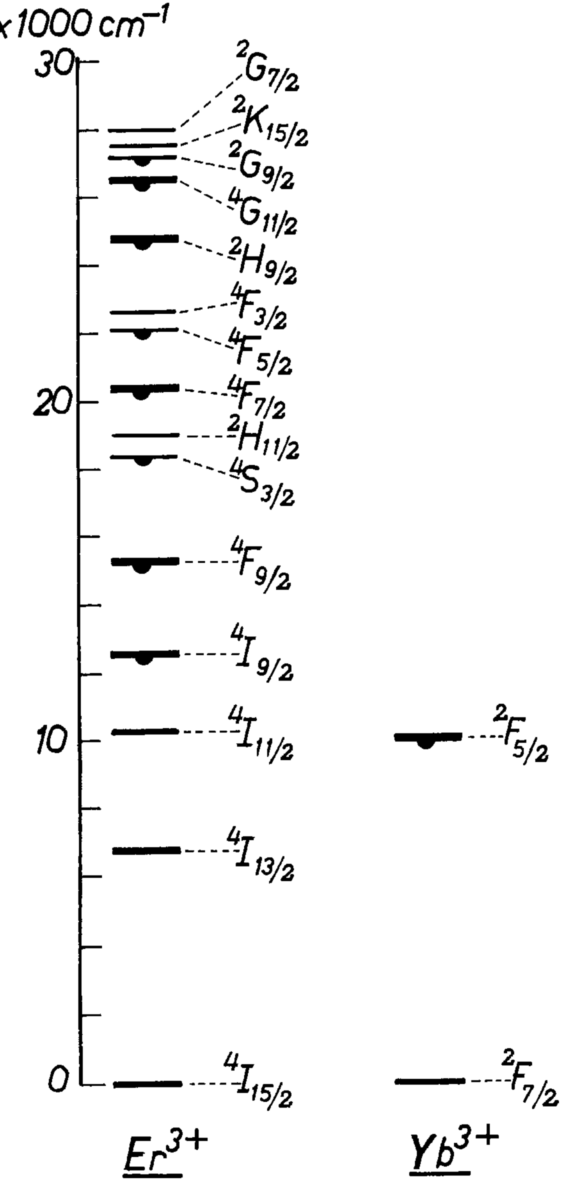

Fig. 1. Part of the energy level diagrams of Er^{3+} and Yb^{3+}

Key words: luminescence, quantum efficiency, infrared phosphors, $NaYF_4$-Yb-Er.

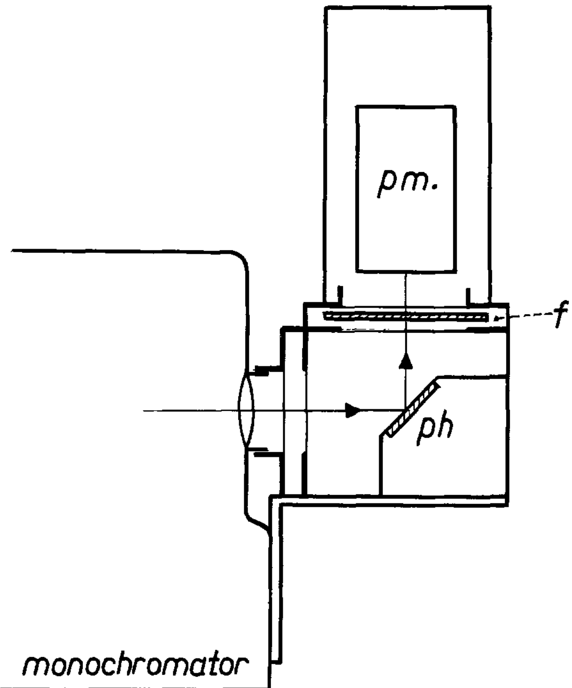

Fig. 2. Schematic diagram of the experimental setup: ph = phosphor sample, f = filter combination, pm = photomultiplier.

as a function of wavelength. In front of the photomultiplier a filter combination Schott BG 18 (2 mm) and GG 14 (2 mm) was used to pass only the luminescence. (*ii*) The diffuse reflection spectrum was measured. The only difference from the previous measurement was that the filter combination was replaced by a BG12 (2 mm), transmitting only the exciting radiation ($\lambda \approx 450$ nm). As has been discussed in Ref. (8), the quantum efficiency can easily be calculated from the ratio of the peaks found in the two measurements. Examples of the measurements are given in Fig. 3 for $LaNbO_4$-3% Er and in Fig. 4 for α-$NaYF_4$-3% Er. The calculation of the efficiencies from these two measurements is summarized in the following. The radiant efficiency is the ratio of the emitted power E to the absorbed exciting power A. The latter is determined by the area under the absorption curve of a certain peak with correction for the transmission τ_A of the filter used and for the photomultiplier response $G(\lambda_A)$ in the absorption region. The emitted power E is determined by the corresponding area under the excitation curve with correction for the transmission τ_E of the filter used in this case and the response $G(\lambda_E)$ in the emission region.

For single narrow peaks we can take the ratio of the ordinate maxima in the absorption and excitation spectra U_A and U_E, respectively, instead of the area. We find then for the emitted power

$$E = U_E \frac{\int_{em} p(\lambda)\, d\lambda}{\int_{em} p(\lambda)\, G(\lambda_E) \tau_E(\lambda)\, d\lambda}$$

where $p(\lambda)d\lambda$ is the relative emitted power in a region $d\lambda$ (integration extended over the total spectral region of the emission). The absorbed power is given by

$$A = \frac{U_A}{G(\lambda_A)\tau_A}$$

Then the radiant efficiency η is

$$\eta = \frac{E}{A} = \frac{U_E \tau_A G(\lambda_A) \int_{em} p(\lambda) d\lambda}{U_A \int_{em} p(\lambda_E) G(\lambda) \tau_E(\lambda) d\lambda}$$

The quantum efficiency q is derived from the radiant efficiency by

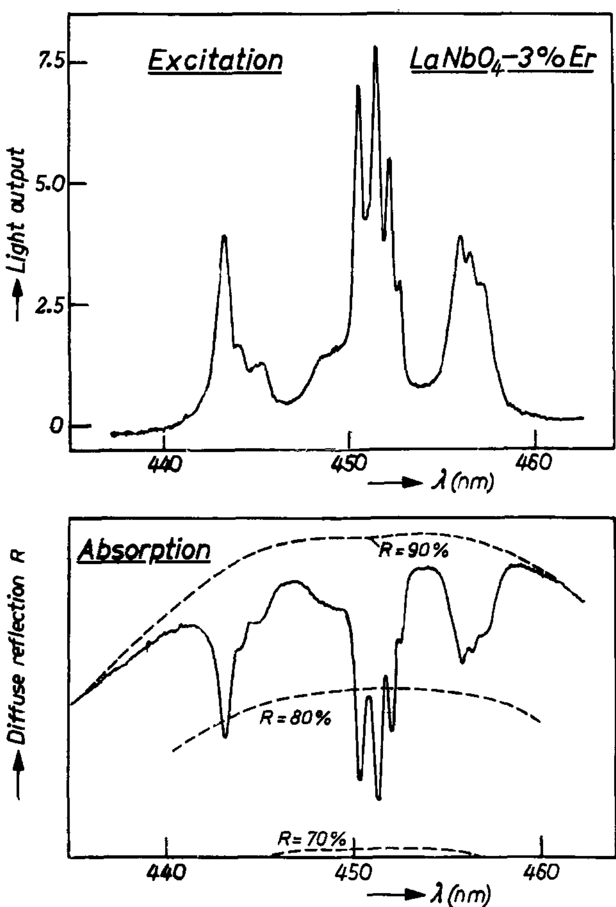

Fig. 3. The excitation spectrum of the green Er^{3+} emission and the diffuse reflection spectrum of $LaNbO_4$-3% Er in the $\lambda \approx 450$ nm region. The ordinate scale of the excitation curve is magnified 25× with respect to that of the diffuse reflection curve. The dashed lines are lines of constant reflection.

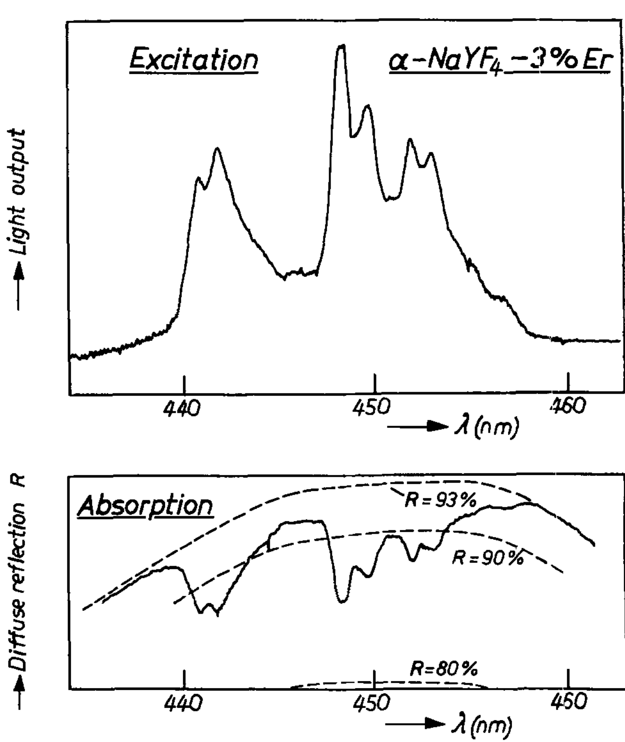

Fig. 4. Similar curves as in Fig. 3 for α-$NaYF_4$-3% Er. The ordinate scale of the excitation curve is magnified 25× with respect to that of the diffuse reflection curve. For the dashed lines see Fig. 3.

$$q = \eta \frac{\int_{em} \lambda p(\lambda) d\lambda}{\lambda_A \int_{em} p(\lambda) d\lambda}$$

The error in this type of measurement will be of the order of 10-25% depending on the value of the absorption. This large error is caused by the low value of the absorption in the Er^{3+}-ion.

For the infrared-to-visible up-conversion process the radiant efficiency of the green luminescence of α-$NaYF_4$-Yb-Er was determined with excitation in the infrared region near $\lambda = 0.97$ μm. This was done in the following way: The phosphor was irradiated via a monochromator at $\lambda = 0.97$ μm with a bandwidth of $\Delta\lambda = 5$ nm. As a detector a Philips photomultiplier 150 CVP (Cs-O-Ag photocathode) was used, the response of which was determined in amperes/watt for both the green and the infrared regions with the aid of a photocell (150 CV). This photocell had been calibrated by the National Physical Laboratory in Teddington (Great Britain). The green luminescence was measured with a 4 mm Schott BG18 filter in front of the photomultiplier, and the exciting infrared power was measured without filter via barium sulfate under exactly the same conditions.

The ratio of the two values gives the radiant efficiency after correction for the response of the photomultiplier and the transmission of the filter. The irradiation density of the exciting infrared radiation was determined directly at the exit slit of the monochromator with the aid of the calibrated photocell.

All optical measurements were performed at room temperature.

The samples were prepared as described previously (9, 10). Their light output was not optimized except for α-$NaYF_4$-Yb-Er.

Results and Discussion

We start with the efficiency of an up-conversion phosphor when excited with infrared radiation. It was measured for α-$NaYF_4$-Yb-Er, which is known to be the best system for up-conversion at the moment (6). For excitation at $\lambda = 0.97$ μm with a bandwidth of 5 nm in the maximum of the excitation peak the radiant efficiency was found to be 3×10^{-4} for ≈ 1 mW/cm^2 absorbed irradiation density of the infrared. This figure is of the same order of magnitude as Auzel and Pecile found for some phosphors (7).

Now we direct our attention to what can be called the emission process within the Er^{3+} ion. The quantum efficiency q of the green luminescence of α-$NaYF_4$-Er was measured as a function of the Er-concentration C_{Er} for excitation in the $^4F_{5/2,3/2}$ levels ($\lambda_{exc} \approx 450$ nm). The results are given in Fig. 5. We see that very strong concentration quenching is present, which is due

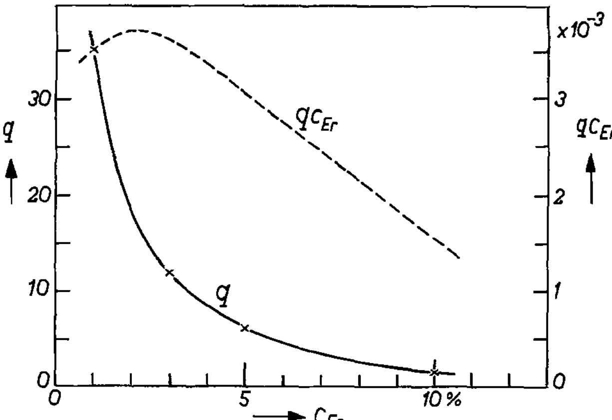

Fig. 5. Curve 1, quantum efficiency q of the green emission of α-$NaYF_4$-Er as a function of the Er concentration C_{Er}. Curve 2, qC_{Er} as a function of C_{Er}.

to interaction between neighboring Er^{3+} ions. We see also that for low Er concentrations a reasonably high quantum efficiency ($q = 35\%$) is found. When both Yb^{3+} and Er^{3+} are present in the lattice, as they are in the up-conversion phosphors normally used, the infrared excitation energy is transferred from the Yb^{3+} to the Er^{3+} ions. The number of excited Er^{3+} ions is proportional to C_{Er}. Therefore the light output from infrared excitation of the Yb^{3+}-Er^{3+} activated phosphors is proportional to qC_{Er}. In Fig. 5 the dependence of qC_{Er} on C_{Er} is also given. We see that the optimum light output is reached at $C_{Er} \approx$ 1-3%. This concentration is in good agreement with the Er concentration used in practice in order to obtain the highest output of the green luminescence (6).

We found that the quantum efficiency of α-$NaYF_4$-3% Er is 12% for excitation in the $^4F_{5/2}$ level. When Yb^{3+} is added as coactivator, the efficiency decreases. For α-$NaYF_4$-20%Yb-3%Er the efficiency is only 6%. This decrease is due to interaction between neighboring Er^{3+} and Yb^{3+} ions, resulting in an increase of nonradiative transitions from the $^4S_{3/2}$ level (11). The addition of Yb is nevertheless necessary for the infrared-to-visible conversion in order to obtain sufficient absorption of infrared radiation, as has already been mentioned in the introduction. The oscillator strength of the transition involved in Yb^{3+} is about ten times stronger than that of Er^{3+}. Moreover up about 20% Yb can be built into the lattice before the Er^{3+}-Yb^{3+} interaction limits further increase of the light output (6). In fact α-$NaYF_4$-20%Yb-3%Er is one of the best systems for up-conversion known at the moment (6, 9).

Concentration quenching of the Er^{3+} emission is also observed in YF_3, the efficiencies being comparable to those for α-$NaYF_4$. The intensity of the green emission upon infrared excitation of YF_3-Yb,Er is also relatively high (4), although not as high as for α-$NaYF_4$-Yb;Er (6, 9).

The quantum efficiency of β-$NaYF_4$-Er is comparable to that of α-$NaYF_4$-Er and YF_3-Er. On the other hand, the green light output of β-$NaYF_4$-Yb-Er as an up-conversion phosphor is relatively low (9). This is to some extent also reflected in the present measurement on the Yb^{3+}-Er^{3+} activated sample.

For the oxidic lattices $LaGaO_3$ and $LaNbO_4$ quenching of the green emission is also found with increasing Er concentration and/or at addition of Yb. The quantum efficiencies of these systems are quite comparable to those for α-$NaYF_4$ and YF_3. However, at infrared excitation of the Yb-Er doped compounds the green light output is much weaker in oxides than in these fluorides by a factor of at least ten (10). This loss in efficiency is a consequence of the difference in properties of the O^{2-} and the F^- ion, the former being much less stable than the latter. Therefore part of the charge of the O^{2-} ions is more readily transferred to neighboring ions. Interaction between the activator and the host lattice is therefore much stronger in oxides than in fluorides, introducing a high probability of radiationless transitions from the infrared-emitting levels and thus a loss in light output (10).

Oxides are therefore generally less suitable as up-conversion phosphors. This is contrary to the case of phosphors used for ultraviolet excitation or cathode-ray excitation (12). In the latter applications strong interaction with the lattice is favorable for the excitation of the activator ions.

The green Er^{3+} emission of the $NaYO_2$-Er phosphor shows a low quantum efficiency. The Yb^{3+}-Er^{3+} activated lattice, when excited with infrared radiation, shows a green emission which is about a thousand times weaker than that of α-$NaYF_4$-Yb-Er (10). Part of the weakening can be ascribed to losses from the infrared-emitting levels, as is the case with the other oxides. Another part, however, must be ascribed to the lower quantum efficiency of the green emission in the

Table I. Quantum efficiencies of the green Er^{3+} luminescence for $\lambda_{exc} \approx 450$ nm

Phosphor	q (%)
α-$NaYF_4$— 1% Er	35
— 3% Er	12
— 5% Er	6
—10% Er	2
—20% Yb-3% Er	6
β-$NaYF_4$— 3% Er	9
—20% Yb-3% Er	≈1
YF_3— 1% Er	23
— 3% Er	6
$LaGaO_3$— 1% Er	43
—20% Yb-1% Er	4
— 3% Er	18
$LaNbO_4$— 3% Er	6
—20% Yb-3% Er	2
$NaYO_2$— 3% Er	<0.2

luminescence process, which is smaller than 0.2% for $C_{Er} = 3\%$ (see Table I).

It is interesting to compare these efficiency measurements with decay measurements of the green luminescence. As is well known, the quantum efficiency is equal to the ratio of the radiative probability A_r to the sum of the probabilities of all transitions from the excited level $A_r + A_{nr}$ (radiative and the competitive nonradiative transitions mentioned earlier). Weber (13) calculated that the probability of the green emission ($^4S_{3/2} \rightarrow {}^4I_{15/2}$) in LaF_3-Er had a value of $A_r = 662$ sec^{-1}. Chamberlain, Paxman, and Page (14) found for this probability in $Y_3Ga_5O_{12}$-Er a value of around 850 sec^{-1} at room temperature. The value of A_r for Er^{3+} in α-$NaYF_4$ will not differ much from that in LaF_3, so that $A_r \approx 700$ sec^{-1} seems to be a reasonable estimate. We found for the decay time of α-$NaYF_4$-20%Yb-3%Er with cathode-ray excitation (15 kV) a value of about 100 μsec, corresponding to a total transition probability $A_r + A_{nr} \approx 10^4$ sec^{-1} [see also Ref. (11)]. We then find for the quantum efficiency a value of $q \approx 700/10^4 = 7\%$, which agrees reasonably with the value obtained from direct measurement (see Table I).

ABSTRACT

Investigations have been made of the compensation effect of lattice strain on silicon epitaxially grown by the simultaneous doping of tin and phosphorus. The stress induced by doping of phosphorus with a concentration of 4.0×10^{19} atom/cm^3 is compensated by the simultaneous doping of phosphorus and tin (2×10^{19} atom/cm^3). The generation of misfit dislocations is also restrained by the simultaneous doping of phosphorus and tin. The difference in the effective lattice constants of epitaxial films and substrates is measured by an x-ray double crystal spectrometer using the asymmetric Bragg reflection. The difference can be eliminated by proper doping of tin and nearly perfect, highly doped crystal films can be grown on high-resistivity silicon.

Perfect silicon crystal is of great importance in increasing the reliability, reproducibility, and packing density, because crystal defects affect the characteristics of semiconductor devices, anomalous diffusion, device yield, etc. In 1953 we reported that doping of Group IV elements was effective in producing perfect crystals (1). Later, Dash (2) obtained perfect silicon crystals by the floating zone method using a rapid growth technique.

More recently it has been observed that wafers bend after epitaxial deposition, forming heterojunctions or homojunctions (3-9), and that misfit dislocations frequently appear near the heterojunctions or homojunctions. These phenomena have been attributed to the differences in lattice constant and thermal expansion coefficient between the substrates and the grown films. Schwuttke (7) and Sugita (8) reported the bending phenomena and the generation of interfacial misfit dislocations in homojunctions of the silicon-boron doped silicon system. In this system, the difference in thermal expansion coefficient between the epitaxially grown film and the substrate can be ignored; instead, the lattice misfit between the film and the substrate should be taken into consideration. The generation of dislocations has also been observed (9-11) in the case of diffusion of impurity such as boron or phosphorus into silicon.

In a previous paper (12), lattice strains induced by diffusions of phosphorus, arsenic, antimony, and tin into silicon were measured. The amounts of lattice stress induced by the diffusion of those impurities were considered to be dependent on both the size of impurity atoms diffused into silicon and the impurity concentration. It was also established that the lattice stress induced by phosphorus diffusion was compensated by prediffusion of tin or a simultaneous diffusion of tin and some other impurity into silicon.

The purpose of this paper is to investigate the compensation effect of lattice stress in the case of the epitaxially grown silicon.

In the case of phosphorus- or boron-doped epitaxial growth, the bending of the specimens is concave toward the epitaxially grown surface. On the contrary, the bending of the tin- or antimony-doped one is convex. On the basis of these results, the simultaneous doping of tin and phosphorus, tin and boron, or antimony and phosphorus is applied to epitaxial growth.

Key words: epitaxial growth free from misfit dislocation, compensation of lattice strain, control of lattice constant.

Experimental Procedures

Preparation of specimens.—Wafers used in this experiment were lightly boron-doped silicon single crystals grown by the pulling method. They were cut into slices in the (111) plane. Since the concentration of the dopant boron in the wafers was about 1.7×10^{15} atom/cm^3, the lattice constants of the wafers were almost equal to that of pure silicon crystal. The original etch pit density of the wafers was of the order of less than 500 pit/cm^2. The wafers were lapped and chemically etched to remove completely the surface damage. They were then cut into a rectangular shape 1 cm long and 0.5 cm wide, the direction of the long side of the rectangular specimens lying on <110>. The final thickness of the specimens was about 200μ.

Epitaxial growth procedure.—Prior to chemical deposition, the surface of the specimen was etched to a depth of 5μ using a gas mixture of H_2 and HBr at 1200°C.

The apparatus of epitaxial deposition used for the compensation of lattice strain is schematically shown in Fig. 1. The experimental condition of epitaxial deposition was as follows: growth temperature, 1200°C; flow velocity of gas, 0.5 m/sec through the reactor tube; and mole fraction, $SiCl_4/H_2 = 0.005 \sim 0.02$. Impurity dopants used in the experiment were liquidus halide such as PCl_3, BBr_3, $SnCl_4$, and $AsCl_3$ being kept in vessels at constant temperature, and only PCl_3 and BBr_3 were diluted into solution with $SiCl_4$ for the close control of the doping levels of phosphorus and boron impurities in the silicon layers.

X-ray measurement of bending and x-ray projection topography.—Bending of specimens resulting from the lattice misfit between the epitaxial films and substrates were measured using the Lang camera. The x-ray beam was collimated through a receiving vertical slit 0.05 mm wide. The $MoK\alpha_1$ (220) reflection was used in this experiment. The variation in the angle of the Bragg reflection with the position of the curved specimens was obtained. From these results the curvature of the specimen was calculated. Prior to the bending measurement of the epitaxially deposited specimens, it was found that bending did not occur either in the original substrate or in the specimen subjected to the same heat-treatment as that undertaken for the epitaxial growth.

Misfit dislocations and other crystalline defects were observed by x-ray projection topography.

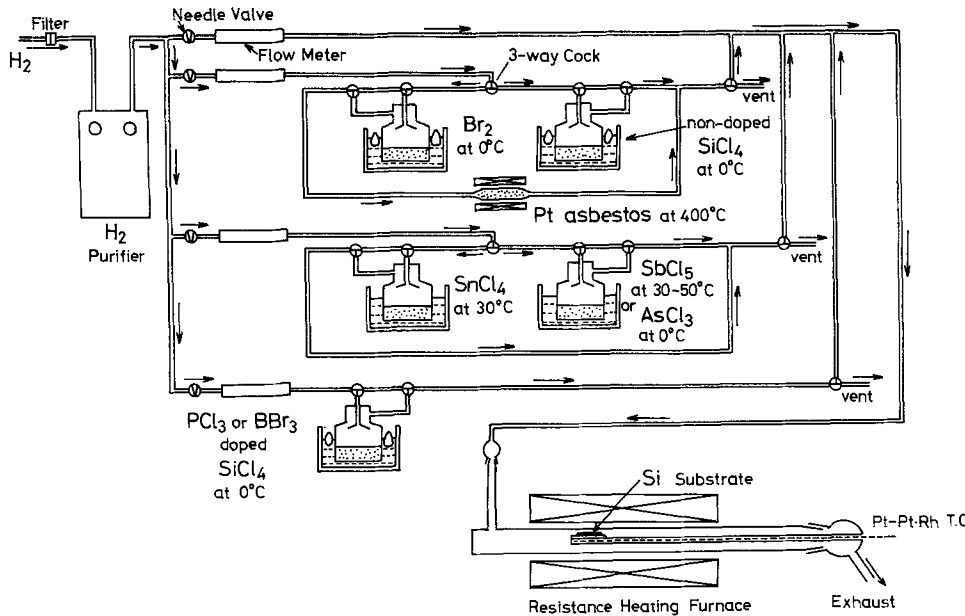

Fig. 1. Schematic representation of apparatus for vapor deposition.

Measurement of the change in lattice constant.—In order to measure the effective difference between the lattice constants of the epitaxial film and the substrate, an x-ray double-crystal spectrometer was used and the asymmetric Bragg reflection (13, 14) was applied to the first crystal. $CuK\alpha_1$ radiation was used throughout the present experiment. As the first crystal, a dislocation-free single crystal of silicon cut parallel to the (111) plane was used. This crystal was positioned to the (511) reflection. The specimen to be measured as the second crystal was arranged in a (333) symmetric reflection. According to Renninger (13), this "parallel" double-crystal spectrometer arrangement is described as $\{(511)^v, -(333)^s\}$. To record the rocking curve, the speed of rotation of the second crystal was fixed at 1/256°/min.

When the pure silicon substrate was positioned as the second crystal, the width at half of the maximum intensity (half-width) of the rocking curve was measured to be 3.0 sec of arc.

Results and Discussion

Simple theoretical analysis of the bending and the lattice strain.—If there is difference between the lattice constants of the substrate and the layer, such phenomena as bending, lattice strain, and misfit dislocations can be observed and calculated under the condition where the impurity atoms have different sizes from that of silicon atoms and occupy the substitutional sites in the silicon lattice.

Applying the well-known relationship between the curvature of the specimens and the film thickness of bimetallic strip with respect to the elastic bending of bicrystals (16), the difference in the thermal expansion $\Delta\alpha\Delta T$ is replaced by the lattice misfit f. Hence, we obtain

$$\frac{1}{R} = \frac{6t_f \cdot t_s \cdot f}{(t_s + t_f)^3} \quad [1]$$

where R is the radius of curvature, t_f and t_s are the thickness of the epitaxial film and the substrate, respectively, and f is equal to ϵ as is demonstrated later. The relationship between the curvature resulting from the elastic bending and the thickness of the epitaxial films is considered to satisfy Eq. [1]. Therefore, the convexity or concavity in the epitaxial surface side due to the bending depends on the lattice contraction or expansion in the epitaxial layer.

The difference between the lattice constant of the layer and the substrate was measured from the rocking curve by an x-ray double-crystal spectrometer. In this case, the rocking curve has a main peak and a secondary peak; these correspond to the diffraction lines satisfying the Bragg condition for the substrate and the epitaxial layer, respectively.[1] The average lattice strain ϵ is obtained from angular difference between the two peaks, $\Delta\theta$

$$\epsilon = \frac{\Delta a}{a} = -\cot\theta_B \cdot \Delta\theta \quad [2]$$

where a is the lattice constant for silicon (5.43018Å) and θ_B is the Bragg angle [47.476° for the (333) reflection in silicon using $CuK\alpha_1$]. The change in the lattice crystal Δa is evaluated from Eq. [2].

A simple model for the lattice strain due to the difference in atomic size has been proposed in the previous paper (12): When impurity atoms having an atomic size different from that of silicon occupy substitutional sites in silicon, the lattice stress is induced around the impurity atoms. The amount of the stress depends on the degree of the lattice misfit, R_i/R_{Si} (the ratio of the covalent radius of the impurity atom to that of the silicon atom) and the concentration of the dopant impurity in silicon. It is assumed that the solute lattice contraction (expansion) coefficient, β, is given by a relation of the form

$$\beta \equiv \frac{1}{3}[1 - (R_i/R_{Si})^3]N^{-1} \quad [3]$$

where N is the atomic density for silicon (5×10^{22} atom/cm³). The calculated values of β for some impurity atoms are listed in Table I. For the epitaxially grown film within the limit of elasticity and of the dopant impurity concentration of N_i, the lattice strain ϵ is given by

$$\epsilon = \beta N_i \quad [4]$$

Since ϵ is $\Delta a/a$, the values of Δa are calculated from the above equation.

[1] Effective lattice constant by the strain varies gradually and not abruptly, so that it cannot be considered to be established in simple form. Further details concerning this implication will be reported in a separate article.

Table I. Calculated β values for some impurity atoms

Doped impurity	Atomic radius, A	R_i/R_{Si}	β, cm³/atom
P	1.10	0.94	$+1.03 \times 10^{-24}$
Sn	1.40	1.193	-4.7×10^{-24}
Sb	1.36	1.162	-3.8×10^{-24}
Si	1.17	—	—

Bending of the phosphorus-doped epitaxially grown wafer.—The bending of the phosphorus-doped silicon deposited on the lightly boron-doped substrate, was concave toward the epitaxially grown side. Figure 2 shows a plot of the values of the experimentally determined curvature of the specimens having different phosphorus doping levels as a function of the thickness of the epitaxial film. These results indicate that the amount of bending depends on the doping concentration of phosphorus and the thickness of the epitaxial film. In this experiment, the curvature of bending increases with an increase in phosphorus concentration and also increases almost linearly with an increase in epitaxial layer thickness and in the concentration of phosphorus. Figure 3 shows x-ray projection topographs of specimens different in the thickness of epitaxial films (concentration of the dopant phosphorus was fixed at 4×10^{19} atom/cm^3). Misfit dislocations along the <110> direction can be seen clearly in Fig. 3(b) and (c). It can be considered that these misfit dislocations generate when the lattice stress exceeds a certain critical value at high temperatures of 700° ~ 800°C, and increases with an increase in the concentration of the dopant impurity and in the thickness of the grown layer.

The x-ray projection topographs for the various impurities and layer thicknesses show that the critical value of the curvature required to induce dislocations by misfit is $1/R = 10 \times 10^{-4}$ cm^{-1}, which agrees well with Sugita's result (8). Some examples of the rocking curves are shown in Fig. 4. The diffraction intensity of the secondary peak which appeared on the high angle side of the main peak increased with increasing thickness of the epitaxial film. The fact that the main peak corresponded to the reflection from the substrate and the secondary peak to the reflection from the epitaxial film was also confirmed experimentally by gradually etching the epitaxial film from its surface. The difference in the angle between this secondary peak and the main peak, $\Delta\theta$, increases almost linearly with increasing concentration of the dopant phosphorus; it also increases with increasing epitaxial layer thickness at a constant doping level of the impurity. In the present measurements, the density of dislocations is zero or less than 10^2 cm^{-2} as observed in the x-ray projection topographs and the change of the lattice constant due to bending is within $\pm 10^{-5}$Å of the true value. Therefore, among the effects of dislocations, other defects, and the bending of bicrystals due to lattice strain, it appears that the lattice strain affects most strongly the lattice constant due to the doping of phosphorus. These considerations are also applicable to other impurities. The change in the lattice constant of the Sn-, P-, Sb-, and B-doped epitaxial films, Δa, is plotted against the concentration of each dopant in Fig. 5 using the experimental data on $\Delta\theta$ defined by Eq. [2]. The lattice constant of the phosphorus-doped

(b) Concentration of the dopant phosphorus $N_i = 7 \times 10^{18}$ atom/cm^3, thickness of the epitaxial film $t_f = 13\mu$. (c) $N_i = 2.2 \times 10^{19}$ atom/cm^3, $t_f = 13\mu$. (d) $N_i = 3.5 \times 10^{19}$ atom/cm^3, $t_f = 15\mu$.

epitaxial film is smaller than that of the substrate silicon crystal, and increases linearly with increasing concentration of the dopant phosphorus impurity. The values of Δa calculated from Eq. [3] and [4] are also plotted by solid lines in Fig. 5. The experimental values coincide with the calculated line of our model, but shifts slightly from the line on the higher side of $|\Delta a|$.

The value of about 6 × 10^{-5} for the misfit f can be obtained from Eq. [1] using the experimental curve b of Fig. 2. This value is in approximate agreement with the value of 7.3 × 10^{-5} obtained at the same phosphorus concentration of 3.5 × 10^{19} atom/cm^3 in Fig. 5. This result also indicates that the bending of the specimens depends on the lattice misfit between the epitaxially grown film and the substrate silicon crystal.

Bending of the tin-doped epitaxially grown wafer.— The bending of epitaxial slices having layers doped only with tin on lightly boron-doped silicon substrates was completely opposite to that of phosphorus-doped ones. Namely, the bending of these specimens was convex toward the epitaxially grown side. The values of curvature obtained are minus, which are plotted in Fig. 6. In this figure, the curves b and e are obtained by changing the amount of gas flow of $SnCl_4$ mixed with $SiCl_4$. For determination of the concentration of tin as a neutral impurity in the epitaxial film, only the x-ray double-crystal spectrometer was used. Some examples of the rocking curves of these tin-doped specimens are shown in Fig. 7. The secondary peak designated "epi" appeared on the low angle side of the main peak, which is opposite to that of the phosphorus-doped ones. The calculation of Δa for tin was performed in a way similar to phosphorus. Calculated values are also shown in Fig. 5. The maximum concentration of tin obtained in the present work was 3 × 10^{19} atom/cm^3. Dislocations caused by the lattice misfit were also observed in the tin-doped epitaxially grown specimens as shown in Fig. 8; the dislocations increase also with increasing concentration of tin and epitaxial thickness. The phenomena of tin doping was almost similar to that of phosphorus doping.

Doping of other impurities in the epitaxially grown film.—Other impurities such as boron, arsenic, and antimony were also added to the epitaxially grown films and the changes in the lattice constants of these specimens were measured. The values obtained are plotted against the impurity concentration as shown in Fig. 5. The lattice constant of the boron-doped epitaxially grown film is smaller than that of the substrate silicon crystal, whereas that of the antimony-doped film is larger than the substrate. The lattice contraction or expansion by impurity doping can be expected and calculated from the covalent radius of the impurity atoms. The change in the lattice constant of the arsenic-doped epitaxially grown films was barely detectable even at its concentration of 4 × 10^{19} atom/cm^3, because the covalent radius of arsenic (1.18Å) was nearly identical with that of Si (1.17Å). In the

Fig. 8. X-ray projection topograph of tin-doped specimen: concentration of tin 1 $\times$ 10^{19} atom/cm^3; t_f = 43μ.

case of diffusion of arsenic into silicon by the sealed, evacuated capsule method using metallic arsenic as the diffusion source, the lattice constant of the diffused layer with a surface concentration of 5 ~ 10 $\times$ 10^{20} atom/cm^3 was found to be slightly smaller (1 $\times$ 10^{-4}Å) than that of the substrate silicon crystal after quenching from its diffusion temperature (1200°C). It was interesting to note that the lattice constant became much larger than that of the substrate after subsequent low temperature heat-treatment of the arsenic-diffused specimen (17).

Compensation of lattice strain in epitaxial growth.—On the basis of the experiments under consideration, the simultaneous doping of tin and phosphorus was applied to the epitaxial growth. In Fig. 6, curve c was obtained from a combination of curves a and b and the curve f, which coincides with the abscissa (namely, no bending occurs), and from a combination of curves d and e. It is apparent from Fig. 6 that simultaneous doping of tin and phosphorus reduces the bending strain. This was confirmed by measurement of the change in lattice constant between the epitaxial film and the substrate silicon crystal. Some examples of the rocking curves of the simultaneously doped specimens are shown in Fig. 9 and 10. It is evident from Fig. 9 and 10 that one of the two peaks present in the case of doping with a single impurity such as tin or phosphorus disappears and the half-width of the rocking curve approaches the value obtained in the substrate silicon crystal (3 sec of arc). It is ascertained from these results that the difference in lattice constants between the epitaxially grown film and the substrate is small or zero.

Figure 11 shows x-ray projection topographs of the phosphorus-doped specimens and the tin- and phosphorus-doped ones. In the phosphorus-doped specimens (concentration 3.5 ~ 4 $\times$ 10^{19} atom/cm^3) misfit dislocations are observed in epitaxial films for the thickness over 15μ. On the contrary, misfit dislocations are hardly observable in the specimens doped simultaneously with tin and phosphorus at approximately the same concentration and even with a film thickness of 43μ. Since the maximum concentration of tin in the present work was 3 $\times$ 10^{19} atom/cm^3, the lattice strain induced by doping of phosphorus of which concentration is 8 $\times$ 10^{19} atom/cm^3 can be compensated by the simultaneous doping of tin and phosphorus. Lattice strain compensation was also achieved by the simultaneous doping of tin and boron whose concentrations were 3 $\times$ 10^{19} atom/cm^3 and 2 $\times$ 10^{19} atom/cm^3, respectively. In the case of the simultaneous doping of antimony and phosphorus, the maximum concentration of antimony in the epitaxial silicon film obtained in the present work was less 1 $\times$ 10^{19} atom/cm^3, indicating that the lattice strain compensation was less effective than the simultaneous doping of tin and phosphorus. Germanium can also be applied to the compensation of lattice strain.

Conclusions

It has been established experimentally that in the case of simultaneous doping of tin and phosphorus, tin and boron, or antimony and phosphorus, the strain compensation can be made in the epitaxially deposited silicon on silicon substrates. The magnitude of bend-

ing or the amount of lattice strain induced by the doped impurities are affected remarkably by the size of impurity atoms and the concentration of impurity atoms which occupy the substitutional lattice sites of silicon. Using the technique of the simultaneous doping of the impurity atoms which are smaller and larger in atomic radius than the silicon atoms, the lattice constant of the epitaxially grown film can be fitted to that of the substrate silicon crystal and thick epitaxial films can be deposited on the substrate without generation of misfit dislocations.

Effects of Illumination on Preferential Etching of N-Type GaAs in a CrO_3-HF-$AgNO_3$ Solution

Tadashi Saitoh, Sunao Matsubara, and Shigekazu Minagawa*

Central Research Laboratory, Hitachi Limited, Kokubunji, Tokyo, Japan

ABSTRACT

Photoetching using a CrO_3-HF-$AgNO_3$ aqueous solution was studied in an attempt to reveal inhomogeneities of n-type GaAs. This method enabled us to obtain etch patterns of striations and dislocations with high resolution. In addition, an etch depth for revealing dislocations was only about 0.1 μm and striations were delineated with an etch depth of about 0.6 μm. The method was applied to the examination of defects in-depth, and it was possible to identify independent dislocations and dislocation networks. The activation energy for etching in the dark was 7.5 kcal/mol, which is for the diffusion controlled process. The etch rate increased linearly with illumination intensity and the increases of etch rate under illumination were almost independent of etch temperatures and the concentrations of Ag^+ ions. Photoetched patterns were ridged at defects, in contrast to recessed patterns revealed in the dark. This result suggests that the distribution of charges on the surface, including minority carriers (holes) and/or light-induced electron-hole pairs, plays an important role in revealing defects.

The inhomogeneities in semiconductor crystals have been characterized using chemical etching techniques because of their simplicity and their high resolution. For GaAs crystals, Schell (1) used a nitric acid solution and White and Roth (2) a dilute aqua regia to reveal crystal defects. However, their etchants produced etch pits only on the {111}A face of GaAs. By using a dilute nitric acid containing a silver ion, Richard and Crocker (3) were able to produce etch pits on both the {111}A and {111}B faces. An ordinary etchant containing CrO_3, $AgNO_3$, and HF was applied by Abrahams and Buiocchi (4) to the low index faces of {111}A, {111}B, {110}, and {100}. However, the depth of etching in the case of the etchant reported by Abrahams and Buiocchi (AB etchant) was about 100 μm in order to obtain etch patterns with high resolution. Hence, conventional etching techniques were not suitable for examining crystal defects in thin layers as prepared by a vapor-phase or liquid-phase epitaxial growth.

Recently, Kuhn-Kuhnenfeld (5) reported that etching in a H_2SO_4-H_2O_2 aqueous solution under intense illumination revealed striations and dislocation lines on the low index faces of Czochralski-grown GaAs. A photoetching using a modified AB etchant, as described in this paper, is also useful for obtaining highly resolved patterns relating to the inhomogeneities, *viz.* striations and dislocations. It, however, has the advantage of a shallow etch depth less than 1 μm.

Experimental

Sample preparation.—Samples used in this study were n-type GaAs with carrier concentrations in the range of 10^{17}-10^{18} cm^{-3}, grown by the horizontal Bridgmann technique. The crystal surfaces were {100}, {110}, {111}A and {111}B in the case of Si-doped GaAs and {100} in the case of Te-doped or Cr-doped GaAs. The samples were mechanically polished using Al_2O_3 abrasives with a particle size of 0.2 μm and chemically etch-polished in a $4H_2SO_4$-$1H_2O_2$-$1H_2O$ solution at 65°C for 10 min prior to preferential etching.

Etching procedure.—The etchant used was a modified AB solution as the etching was performed at 300°K or at lower temperatures. The etchant was prepared by dissolving 80 mg $AgNO_3$, 10g CrO_3, and 10 ml HF in 20 ml H_2O, successively. Then, the solution was decanted to obtain a transparent solution free of any precipitates such as Ag_2CrO_4 or CrO_3. The concentrations of Ag^+ ions and CrO_4^{2-} ions in the clear etchant analyzed by atomic absorption spectroscopy were 2.0 × 10^{-3} g-ion/liter and 2.7 g-ion/liter, respectively. In addition, this etchant, diluted 8 to 1, was also used for revealing defects in a very shallow depth of etching.

In the photoetching, the illumination was provided by an ordinary tungsten lamp. The light intensity was about 5000 ft-c measured by a 50 A Opto-Meter (United Detector Technology). The etchant was protected from heat by locating a water vessel between the etchant containing the sample and the lamp. This held the temperature rise of the etchant within 1°C during etching time. Etch patterns were examined using the Nomarski technique.

Photoetched Patterns

In typical etch patterns revealed under illumination, dot-like defects, irregular linear defects, and growth striations are observed. The patterns have excellent resolution and are ridged as opposed to the recessed patterns produced by the Abraham's method or the etching in the dark. Photoetched patterns were also found to vary in shape or length with orientation, dopant, and etch depth.

Effect of illumination on etch patterns.—In order to examine the effect of illumination on preferential etching, {111}B surfaces were etched under illumination or in the dark. In the photoetched patterns of {111}B surfaces, one can see dot-like defects, linear defects, and growth striations. The dot-like defects denoted by arrows D in Fig. 1 consist of an elevated pyramidal structure. The pyramidal defects are more abundant than the linear defects denoted by arrows L on the {111}B surfaces. Growth striations indicated by arrows S in Fig. 1(a), which were difficult to observe in the other etching method performed under room light, were delineated. Also shown in Fig. 1(b) are minute irregularities with very shallow etch depths, which could not be observed using the usual microscopy except for the Nomarski technique. However, the origin of this type of defects is uncertain.

On the other hand, etch patterns produced in the dark consisted of independent etch pits, chains of smaller etch pits, and striations, as shown in Fig. 2. Independent etch pits correspond to the pyramidal etch hillocks indicated in Fig. 1(b), and chained pits to the dislocation lines in Fig. 1(a). Furthermore, the recessed lines of striations in Fig. 2 correspond to the ridged lines in Fig. 1. The etch patterns revealed in the dark closely resemble those in the conventional

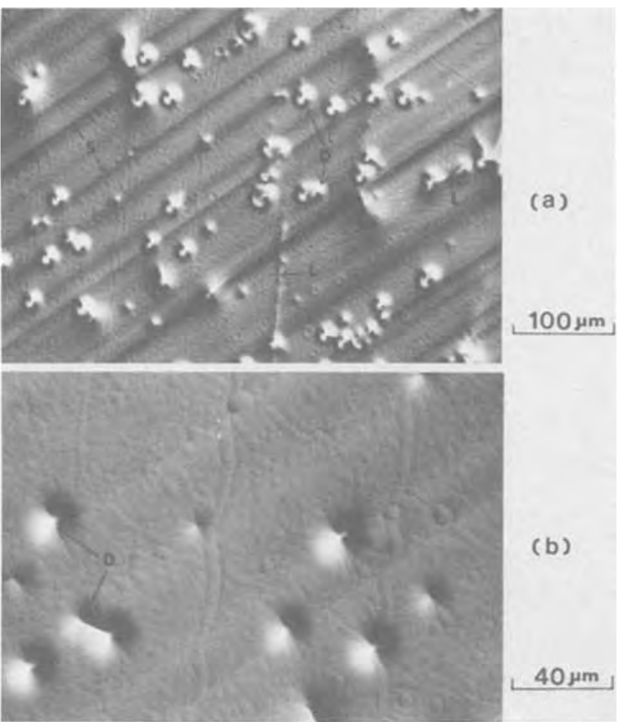

Fig. 1. Photoetched patterns of Si-doped GaAs. (a) {111} surface ($n = 5 \times 10^{17}$ cm^{-3}); (b), magnification of (a). The etch depth is about 6 µm at etch temperature of 23°C and etch time of 2 min.

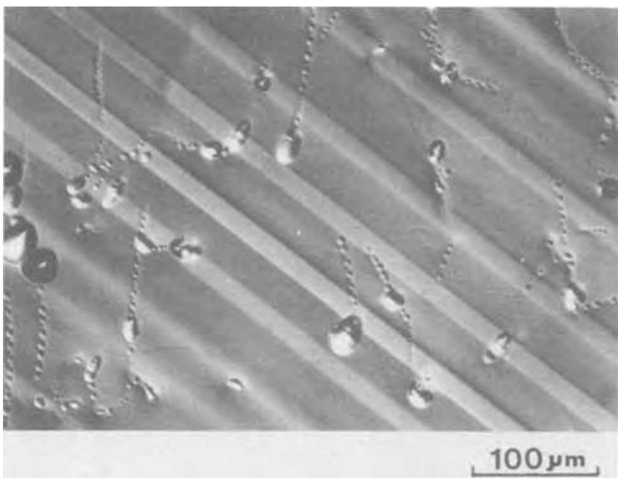

Fig. 2. {111}B surface of Si-doped GaAs ($n = 5 \times 10^{17}$ cm^{-3} etched in the dark. The etch depth is 14 µm at etch temperature of 23°C and etch time of 7 min.

method under room light, although the former are clearer than the latter. However, the photoetching method is superior to other etching methods, including the etching in the dark, especially for obtaining etch patterns of {100} and {110} surfaces. The density of dot-like and linear defects in the photoetched patterns was found to be in the ranges of 8-11 $\times$ 10^3 cm^{-2}.

Thus, inverse patterns can be obtained by etching under illumination or in the dark. This result suggests that the distribution of charges on the GaAs surface, including minority carriers (holes), ionized donors, surface states and/or light-induced carriers, plays an important role in obtaining etch patterns with high resolution.

Effect of surface orientation.—As for {100} surfaces and {110} cleaved faces, linear defects and dot-like defects were found to exist as shown in Fig. 3, although linear defects were more abundant than dot-like defects. The linear defects are considered to be dislocation lines because they develop with etching time as shown later in Fig. 4. Furthermore, these linear defects are quite similar to the lines reported by Huber and Champier (6), who indicated that the lines are dislocation lines due to the correlation between the etch patterns and the x-ray topograph. This is in contrast with the aforementioned patterns of {111}B surfaces on which dot-like defects mainly existed. This is considered to be due to the existence of dislocations comparatively normal to {111}B surfaces and inclined to {100} or {110} faces.

Growth striations were delineated on {111}B surfaces as well as {111}A, {100}, and {110} surfaces, although striations on {110} faces with low resolution are also observed. Striations, especially for {100} and {110} of GaAs crystals, have been difficult to observe and so, this photoetching method is superior to other etching methods in revealing them. This is quite similar to the result that intense illumination is essential for revealing growth striations in the ease of selective etching using a H_2SO_4-H_2O_2 aqueous solution (5). As shown in Fig. 2, however, one can see striations in the etch pattern revealed in the dark, which are more highly resolved than that produced in an etching under room light using the same AB etchant. Therefore, the distribution of charges on the surface is considered to play an important part in revealing striations.

It is possible to examine defects in-depth by comparing two photomicrographs of adjacent regions on the {100} surface and {110} cleaved face. Note that dislocation lines, designated by arrows A in Fig. 3, are observed on both the {100} and {110} surfaces. This result suggests that dislocation lines are connected. On the other hand, arrows B and C are revealed on either the {110} face or the {100} surface. The dislocation line shown by arrow B appeared on the {100} surface during further etching. On the other hand, the dislocation line shown by C was a "memory" of dissolved dislocation because no pattern relating to C, is observed on the {110} face.

Variation of etch patterns with etch depth.—This photoetching technique is also effective in observing how etch patterns vary with etch depth because the technique requires a shallow etch depth to obtain highly resolved patterns. A typical variation of etch patterns for {100} surfaces of GaAs is shown in Fig. 4, in which arrows E to G are typical examples of defects. Arrow E is a dot-like defect in Fig. 4(a). Then, it changes into a linear defect as indicated in Fig. 4(b). In Fig. 4(c), the length of the linear defect remains constant during prolonged etching. Therefore, this defect is a short one independent of other defects, and

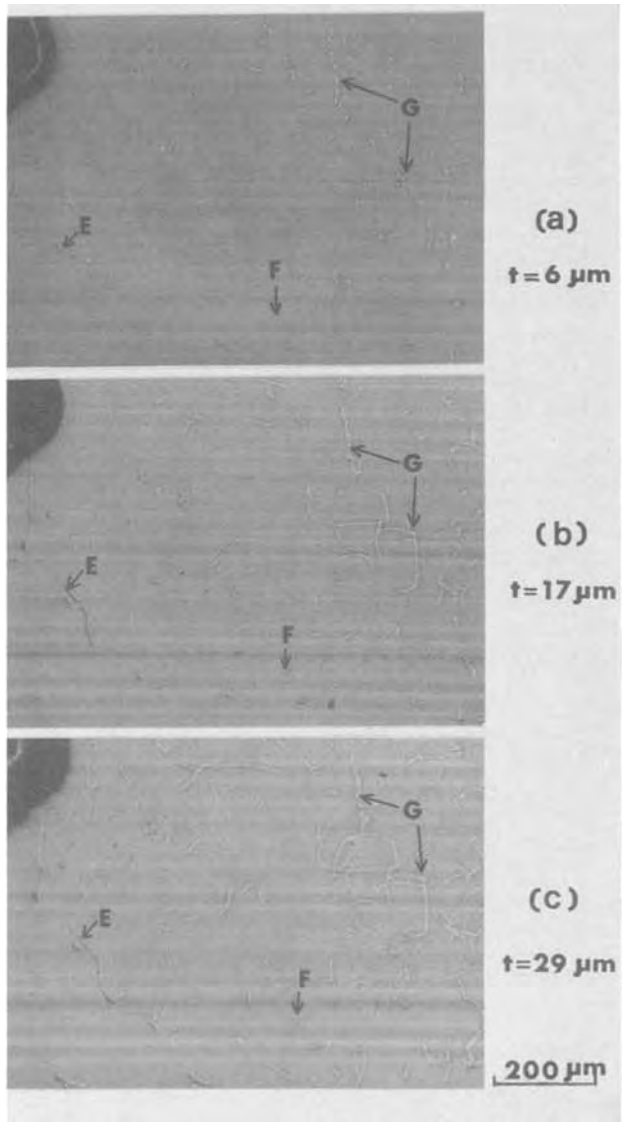

Fig. 4. Variation of photoetched {100}) surfaces with the depth of etching for Si-doped GaAs ($n = 2 \times 10^{18}$ cm^{-3}).

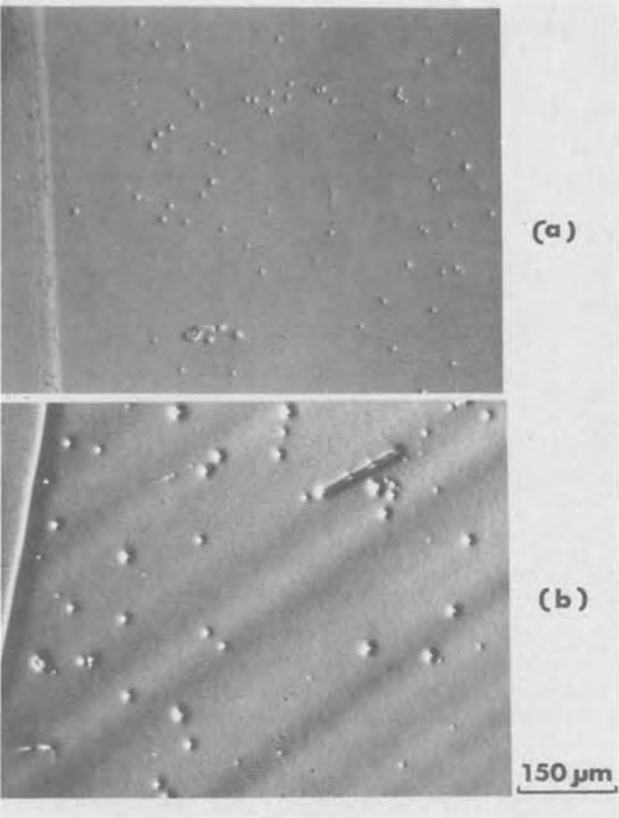

Fig. 5. Photoetched {100} surfaces of Si-doped GaAs using the etchant diluted 8 to 1. Etch depths in (a) and (b) are 0.1 μm and 0.7 μm, respectively.

it also exists more or less on the {100} surface.

The shape of the dot-like defect denoted by arrow F does not vary with etch depth. Hence, this defect is considered to be a dislocation lying in the <100> direction.

Also observable in Fig. 4 is a defect which exists three-dimensionally in GaAs as depicted by arrows G. Arrows G shown in Fig. 4(a) consist of independent linear defects. As the depth of the etching increases, the defects are connected to form a network, as shown in Fig. 4(b) and (c).

The etch depth in the decanted AB solution is about 6 μm for maximum resolution at an etch temperature of 23°C and light intensity of 4000 ft-c. However, the defects should be revealed with an etch depth less than 1 μm when the etching was performed at lower temperatures or when more intense lights were used. Consequently, {100} surfaces of GaAs were photoetched at 7°C for 15 sec, so that the inhomogeneities such as striations and etch hillocks were revealed in an etch depth of about 0.6 μm. Furthermore, the etchant diluted 8 to 1 was also used at 23°C to decrease etch rates and to increase light intensity as the CrO_4^{2-} containing solution absorbs lights. As a result, striations as well as dot-like and linear defects were delineated in an etch depth of about 0.7 μm and an etch depth for revealing dot-like and linear defects was only about 0.1 μm, as shown in Fig. 5. These values were remarkably lower than those obtained by conventional preferential etching.

Effect of dopant.—Photoetched patterns of Si-doped GaAs have already been shown in Fig. 1-3. As for the Te-doped GaAs indicated in Fig. 6(a), striations, as well as dislocation lines surrounded by slightly concave and rugged regions were observed. These regions were not observed in Si-doped or Cr-doped GaAs. The regions were examined using cathodoluminescence so that they were found to be brighter in the cathodoluminescent image than the dislocation lines or the regions where no dislocation lines existed. This result is consistent with that reported by Casey (7) who said that the precipitation of a Te-rich solid solution may account for the inhomogeneous cathodoluminescent images associated with dislocations.

Photoetched patterns of Cr-doped GaAs shown in Fig. 6(b) consist of ridged dislocation lines surrounded by slightly hollowed regions and defects with a peculiar cell structure. However, striations were difficult to observe in Cr-doped semi-insulating GaAs, in contrast to photoetched patterns of Si-doped and Te-doped GaAs. The cell structure observed in the peripheral region of melt-grown GaAs wafers is considered to relate to precipitates due to the low solubility of Cr in GaAs.

In order to examine the effect of carrier concentrations on the photoetched patterns, Si-doped GaAs with carrier concentrations of 4×10^{17} cm^{-3} and 2×10^{18} cm^{-3} were etched simultaneously. Photoetched patterns were similar in spite of the difference of carrier concentrations. However, an etch rate of GaAs with the carrier concentration of 4×10^{17} cm^{-3} was about 10% higher than that of GaAs with 2×10^{18} cm^{-3}. This result seems to indicate that ridged lines correspond to higher carrier concentrations than recessed bands in the striations.

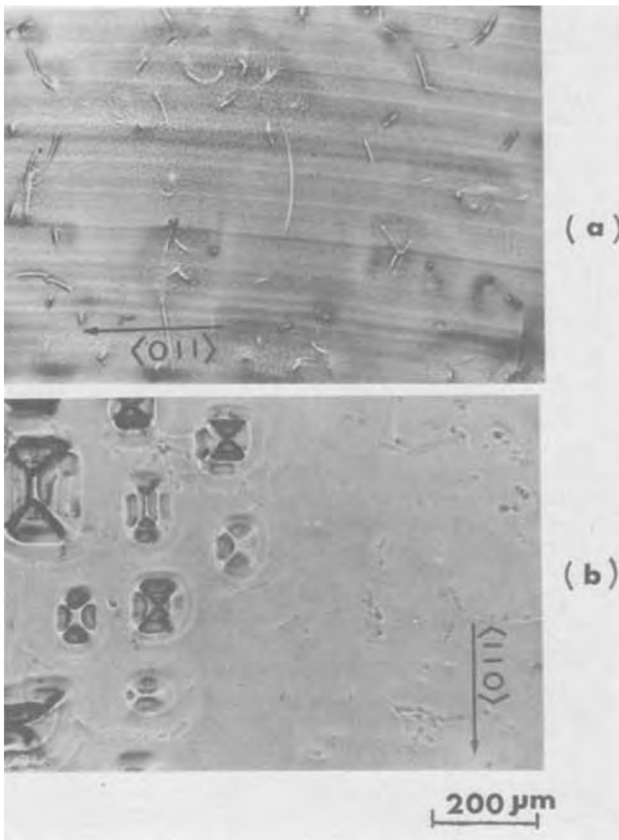

Fig. 6. Photoetched {100} surfaces. (a), Te-doped GaAs; (b), Cr-doped GaAs. The etch depths are about 6 μm.

Etching Rates

In photoetching using the modified AB solution, etching rates depended mainly on concentrations of CrO_3 and HF, light intensity, and etching temperature. This paper describes only the effects of light intensity and etching temperature on etching rates of GaAs. First, we examined the relationship between etch depth and etch time as a function of etch temperature. The etch depth was found to be proportional to the etch time. This linear relationship differs from the result reported by Abrahams *et al.* (4) who indicated that the etch rate shows a saturation with time. It was considered to be due to the formation of Ag_2CrO_4 precipitate during etching which occurred more easily at the high etch temperature of 65°C.

Figure 7 shows the Arrhenius plot of etch rates for illuminated or dark condition. Etch rate decreases linearly with the increase of the reciprocal temperature for etching in the dark condition but nonlinearly for etching under illumination. Furthermore, the differences of etch rates for illuminated and dark conditions are almost equal irrespective of etch temperatures. Therefore, photoetching rates (V) should be depicted as the following equation

$$V = A \exp\left(-\frac{\Delta E}{RT}\right) + BL \qquad [1]$$

where A is a constant relating to the concentrations of reagents in the etchant and ΔE is an activation energy for etching in the dark. B is a constant and L is an incident light flux. From Fig. 7, one can obtain $A = 7.1 \times 10^5$ μm/min and $\Delta E = 7.5$ kcal/mol, typical for the diffusion controlled process. In order to obtain the value of B, we examined the relationship between the etch rate and the light intensity. Figure 8 shows the relationship from which we obtained the value of $B = 1.5 \times 10^{-4}$ μm/min·ft-c.

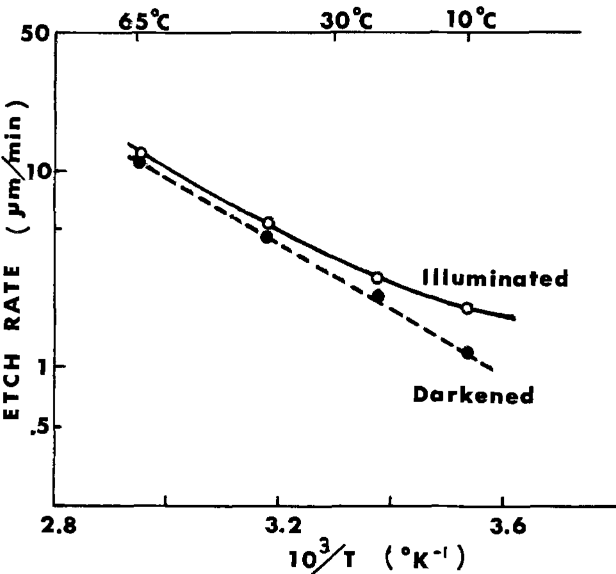

Fig. 7. Effect of illumination on the etching rate of {100} surface of Si-doped GaAs as a function of temperature. The light intensity is 4×10^3 ft-c.

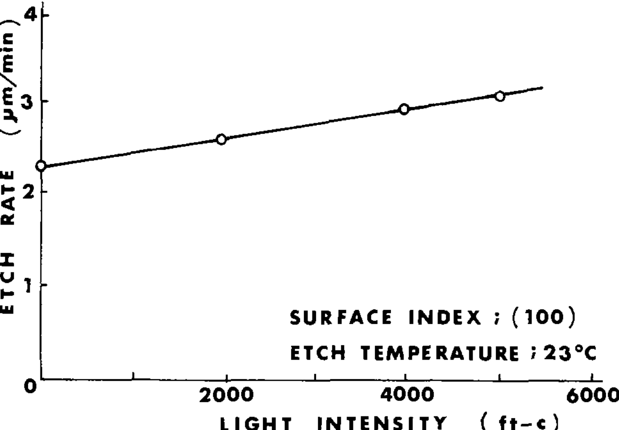

Fig. 8. Etching rate of {100} surface as a function of light intensity for Si-doped GaAs etched at 23°C for 10 min.

The effect of Ag^+ ion concentrations up to 2×10^{-3} g-ion/liter on the etch rates was examined for {100} surfaces of Si-doped GaAs ($n = 2 \times 10^{18}$ cm^{-3}) at 23°C and 4×10^3 ft-c. However, Ag^+ ions were found not to influence the etch rate of n-type GaAs, although effective in obtaining etch patterns with a little higher resolution. The reason positive ions such as Ag^+ do not effect etch rates is considered to be due to the anodic behavior of n-type GaAs surfaces in the etching solution.

Discussion

At the interface between an n-type semiconductor and an etchant, there exists a space-charge layer on the semiconductor surface near the etchant as well as a Helmholtz layer and a Gouy layer in the electrolyte close to the semiconductor (8). It has been shown that interfacial holes are required for anodic reactions at an n-type semiconductor surface (9, 10).

Generally, the preferential etching of defects has been attributed to the differences of chemical energies of the dislocation cores, or the local strain field around a dislocation. So, the higher concentration of holes, trapped at the dislocation combined with chemical energies or with the local strain field, increases the etch rate, causing etch pits. This explains why in the case of {111}B face, etch patterns revealed in the dark

have a higher resolution than those produced by etching under room light.

Next, consider the effect of illumination for the chemical etching of n-type GaAs. The concentration of positive charges on the surface generated by photon absorption increases with the illumination, causing an increase of the etching rate as indicated in Fig. 7. Although Kuhn-Kuhnenfeld (5) has applied photoetching techniques in revealing defects of GaAs, no explanation was included in his paper on why the defects have ridged structures. The following is a possible model, based on the difference of positive charge distribution between the dislocation sites and the regions without dislocations. Defects, such as dislocations, are generally expected to be an effective recombination site of light-induced electron-hole pairs due to potential deformation. In photoetching, both electrons and holes generated by light recombine instantaneously at the dislocation rather than separate in the built-in electric field in the surface space charge layer. Thus, the concentrations of positive charges at dislocation sites become lower than those in the regions without dislocations. As a result, the etching rate at a dislocation decreases relatively so that an etch hillock is formed at the dislocation. This mechanism is consistent with the result of Ellis (11) who showed that the anodic etching of Ge is not uniform if dislocations are present at the surface and that this is presumably related to the trapping of electron-hole pairs at the dislocations.

In addition to the formation of etch hillocks, it should be pointed out that the built-in electric field decreases due to the generation of photovoltage in the photoetching. This decrease causes a relative increase in the deformation potential of the dislocation. Consequently, a dislocation becomes a more effective site to recombine light-induced carriers in contrast to the etching in the dark.

After an etch hillock has appeared under illumination, whether the hillock will remain or not depends on etch rates of various planes around the hillock.

Let us call the etch rate for a side of the hillock Vs and that for a surface plane Vp. The condition for the stability of the hillock is $Vp \geqq Vs$. If the condition is not fulfilled, the hillock etches away faster than the surface plane and disappears. On the other hand, the condition for developing etch pits revealed in the dark is $Vp < Vs$.

As shown in Fig. 7, the etching rate for the modified AB solution near room temperature is diffusion-controlled and the concentrations of light-induced carriers on various planes are expected to be independent of orientation. This suggests that the etch rates do not vary with orientation. In fact, the photoetching rate of a {100} surface was only about 10% larger than that of a {111}B surface. Therefore, the "memory" effect of etching patterns becomes more noticeable in photoetching than with other etching methods.

Auger Electron Spectroscopy of Cleanup-Related Contamination on Silicon Surfaces

ABSTRACT

Auger electron spectroscopy has been used to evaluate the chemical state of silicon (111) surfaces cleaned by various liquid reagents, ion sputtering, and plasma treatment. The two most common impurities observed were carbon and oxygen. Results indicated that liquid reagent cleaning produced surfaces which were heavily contaminated with carbon, and that when oxidizing reagents were used, carbon contamination could be kept to a minimum. Sputtering was found to be an unsatisfactory method of cleaning because slices became activated after sputtering and adsorbed impurities from the atmosphere when removed from the vacuum system. Plasma treatment was the most effective of the three types of cleanups used, producing surfaces with the lowest carbon concentrations. One exception was CF_4 plasma which was shown to deposit carbon on the surface.

A large number of processes are used by the semiconductor industry for the cleaning of silicon prior to process steps such as oxidation, diffusion, and metal deposition. The chemical state of the surface after cleanup has not been systematically investigated, resulting in wasteful consumption of chemicals and the use of "overkill" in slice cleanup. We have investigated the effect of eight liquid reagent cleaning sequences, six plasma cleanups, argon sputtering, and deionized water rinsing on silicon surfaces.

Auger electron spectroscopy (AES) has been shown to be a useful and highly sensitive tool for the study of etched silicon (1) and chemically cleaned germanium surfaces (2), particularly for the determination of the effects of carbon contamination (3), and has been chosen for this study. The principles of AES have been described in the literature (4-6).

In this work carbon was found to be one of the major contaminants, along with oxygen, on chemically cleaned silicon surfaces and the effectiveness of various chemicals, plasma, and sputtering for the removal of carbon have been examined.

Experimental

The samples used were 0.76 mm thick mechanically polished 10 ohm-cm boron-doped silicon (111) slices. The slices were cut from the same boule in order to minimize the effect of the bulk material on the surface contamination. Strips from the slices were then subjected to liquid cleaning, argon ion bombardment, or plasma cleaning All reagents used were (ACS) Low Mobile Ion Grade and the deionized water used for rinsing had a resistivity of 18 megohms. Details of the process sequences used to prepare the samples are given in Tables I (liquid reagent), II (argon ion sputter), and III (plasma).

Argon ion bombardment was performed with a Varian ion gun (Model 981-1045) at 5×10^{-5} Torr argon (Matheson, Research Grade) pressure, which produced a 12 mm diameter ion beam at 600 eV energy. Samples could be heated inside the Varian Cylindrical Mirror Analyzer system (Model 981-2607) by conduction from radiatively heated stainless steel blocks on which they were mounted for analysis. Chromel-Alumel thermocouples, spot welded on stainless steel retaining strips used to press the samples to the heated blocks, were used to measure the temperature of the samples.

To minimize contamination due to post-cleanup handling, all treated samples were transported in clean, covered Pyrex containers and loaded into the

[a] In the change of chemical state from Si to SiO_2 a shift in the energy of the Si peak from 91 to 78 eV in the low energy Auger spectrum occurs. The 78 and 91 eV transitions may be easily distinguished even when present in the same spectrum and the ratio of the two peaks may be used to estimate the Si/SiO_2 content of the surface.
[b] The Auger transitions of boron (179 eV) and chlorine (181 eV) occur within the same narrow energy range so that for practical purposes they are indistinguishable by AES. However, one may use the Auger apparatus to distinguish boron from chlorine by an electron loss technique. The high energy Cl (2400 eV) transition could not be observed using our system since the electron gun had a maximum energy of 2000 eV.
[c] Trace level.

vacuum system after a maximum of 90 min storage. A base pressure of 10^{-9} Torr was attained without bakeout, after overnight pumping, before Auger analysis was performed.

Results

Due to the large number of AES spectra ($dN(E)/d(E)$ *vs.* E) obtained, it is cumbersome to present the actual data. Instead, relative surface coverage values, obtained by a normalization method explained below are given.

The per cent coverage was computed using the following equation

$$\text{Per cent coverage} = ((a_i/a_i^o) \times 100)/\sum_j (a_j/a_j^o)$$

where a_i is the Auger peak-to-peak intensity from the ith element and a_i^o is the "standard" peak-to-peak intensity obtained from the pure element. The "standard" peak-to-peak intensities were taken from the "Handbook of Auger Spectroscopy" (7). In the case of a compound standard, the measured standard peak-to-peak intensity was first divided by the mole fraction of the element of interest in the compound. The AES spectra shown in the Handbook were of course taken under fixed conditions.

The a_i^o for the Si (78 eV) transition, which is characteristic of clean SiO_2 surfaces but does not appear in the Handbook (7), was calculated in the following manner. Auger spectra were obtained from a 1000Å thick thermally grown SiO_2 film using our Auger system. The ratio of the peak-to-peak intensities of the O (510 eV) transition (from the MgO sample) obtained from Ref. (7) to that of the O (510 eV) transition of the SiO_2 sample was then multiplied by the peak-to-peak intensity of the Si (78 eV) transition from the SiO_2 sample and corrected for the mole fraction to yield the required a_i^o.

The reduced data for each type of cleanup are tabulated in Tables IV, V, and VI. It should be noted that the numbers shown in the tables are for comparison of the effects of the different surface treatments only and do not represent accurate surface coverages.

Liquid reagent cleanup.—Table IV summarizes the Auger data obtained for slices subjected to various liquid chemical treatments.

A salient feature is the presence of carbon in relatively high concentrations on every sample analyzed. In conjunction with this observation, it is of interest that the degree of oxidation of the surface apparently has an effect on the surface carbon contamination, *i.e.*, the higher the oxygen concentration at the surface, the lower is the carbon concentration observed. This is not surprising since an oxidized surface is expected to be much more stable chemically than a bare silicon surface. Furthermore we have observed that an oxidized silicon surface that has been sputtered with positive argon ions to produce an atomically clean surface adsorbs only an insignificant amount of carbonaceous material when exposed to room air. This result is quite different from that found after exposing a sputtered silicon surface to air whereupon, as will be shown below, the surface acts as a very effective getter of carbon-bearing species from the ambient.

The cleanups which produced the surfaces with the highest carbon contents are G and H. Cleanup G was a concentrated HF dip followed by deionized water rinsing and in cleanup H, the last reagent used, was Bell No. 2 which consists of an HF-NH_4F solution (see footnote in Table I). The indication is that concentrated hydrofluoric acid treatment increases the propensity of the silicon surface for adsorption of hydrocarbons. This effect, which has also been observed by Henderson (9), is due to the fact that HF removes the native oxide from the surface and leaves behind a very active bare surface as described above.

Cleanup D, which consisted of a 10 volume per cent HF dip followed by deionized water rinsing, was not expected to produce a completely oxide-free surface since in the presence of water a steady state is attained such that removal of oxide and reoxidation in the aqueous medium occur simultaneously. Thus when the slice was transferred (through air) into the water rinse it presented an oxidized surface unfavorable for adsorption of carbon-containing gaseous species. The results shown in Table IV bear this out.

With the exception of cleanups C and D, no metal contamination was found on the samples examined. Since the same techniques and chemical sources were used in preparing all the chemically cleaned samples, it appears that the traces of Ni and Fe found in samples C and D were introduced by accident either into the solutions or directly onto the slices by the operator rather than from an inherent defect in the cleaning processes.

Ion bombardment cleanup and contamination by air.—The effect of positive argon ion bombardment, annealing in ultra-high vacuum, and exposure to room air are presented in Table V. Extremely clean

[a] The effect of low energy (600 eV) argon ion bombardment of a surface is the removal of material with a small amount of the bombarding gas being implanted in the first several monolayers. Argon has a distinct Auger transition and does not interfere with the identification of other species. It does occupy a fraction of the detectable volume and must be considered when determining the number of detected atoms for each element when present in significant quantities.
[b] Trace level.

silicon surfaces can be generated by this technique, as shown by the AES data, and the same technique has been used by Farnsworth *et al.* (10) and by Schlier and Farnsworth (11) to produce atomically clean silicon surfaces for adsorption studies.

Annealing of the sputtered samples at 770°K for 30 min resulted in an increase in the carbon concentration at the surface. This may have been caused by either out-diffusion from the bulk or by beam assisted decomposition of adsorbed carbon compounds. The former mechanism is believed to be the one which was operative since carbon segregation to the surface during annealing was also found when the vacuum conditions were such that the time for a monolayer of carbon compounds to adsorb on the surface was much greater than the total time of the AES experiment.

In order for sputter cleaning to be a useful process for integrated circuit manufacture, it is necessary to be able to anneal out the surface damage (and simultaneously to eliminate the active adsorbent layer). The annealing time and temperature sufficient to restore surface order on silicon was found to be (10) a few minutes at 1170°K. An alternative to annealing out damage would be to perform the next process step without exposing the slice to contaminating atmospheres, such as is possible in some metal sputter-deposition machines.

Plasma cleaning.—The silicon samples subjected to plasma cleaning were by far the least contaminated of those prepared by standard processing methods (see Table VI). All of the surfaces cleaned by this technique showed very low carbon levels, the only exception being the sample treated for 10 min in a CF_4 plasma. The latter is due to deposition of carbon from plasma-decomposed source gas (12). It is interesting to note that the surfaces are all (excepting the CF_4 case) heavily oxidized and thus reduce the degree of hydrocarbon adsorption when exposed to the atmosphere. The presence of fluorine is believed to have resulted from the decomposition of CF_4 which is used to clean the plasma system and is expected to be heavily adsorbed on the system walls. The presence of nitrogen in the Auger spectra has not yet been fully understood.

Summary

The effects of liquid reagent, sputtering, and plasma cleaning on the chemical state of bare silicon (111) surfaces have been characterized and significant differences in carbon and oxygen contamination have been found. The Auger spectra for three of the most effectively cleaned samples (one from each group of cleanups) are shown in Fig. 1, together with the spectrum from an uncleaned sample for comparison. Liquid methods were found least effective in removing surface carbon. In particular, hydrofluoric acid formulations appeared to enhance hydrocarbon adsorption and actually increased the degree of carbon contamination. Rinsing in deionized water was an effective method for removing much of the carbonaceous material from the starting (untreated) material. Sputtering with argon ions can result in atomically clean surfaces but has the major drawback of leaving an active (for adsorption) and damaged surface. Plasma methods constituted the most encouraging techniques both in terms of surface cleanliness and practicability.

Effect of Substrate Microdefects Due to Thermal Etching on the Near-Junction Properties of GaP:Zn,O Grown by Liquid Phase Epitaxy

C. Michel

Philips Laboratories, Briarcliff Manor, New York 10510

ABSTRACT

The effect of individual interfacial microdefects due to thermal etching on the cathodoluminescence (CL) and minority carrier diffusion length (L_e) have been investigated with a scanning electron microscope for p-type GaP: Zn,O layers grown by liquid phase epitaxy (LPE) on n-type GaP substrates. For layers grown by conventional tilting or sliding techniques, both CL and L_e are significantly reduced in the vicinity of a defect, probably because of the strong growth anisotropy generated there. However no degradation was observed for layers grown by an LPE technique that employs controlled substrate meltback and a Te-compensated growth solution. This difference may account for the improvement of about 15% in electroluminescent efficiency that has been reported for light-emitting diodes prepared from layers grown by a meltback technique.

Efficient GaP light-emitting diodes (LED's) can be obtained (1, 2) by liquid-phase epitaxy (LPE). Since the layer-substrate interface in these devices is close to the active region, the quality of the substrate surface is expected to influence their performance. However the electrical and optical effects associated with individual interfacial microdefects have not been clearly demonstrated. The difficulty is usually of an experimental nature in that the microscopic interaction between a particular defect and the near-junction characteristic cannot be observed directly by any of the conventional low-resolution techniques, *e.g.*, x-ray topography.

In this investigation, a scanning electron microscope (SEM) operated in the cathodoluminescence (CL) and beam-induced current (BIC) modes has been used to study the near-junction properties of diode structures prepared by growing LPE layers of p-type GaP: Zn,O on n-type GaP substrates cut from crystals grown by the liquid-encapsulated Czochralski (LEC) technique. Three different LPE growth procedures, based on the tilting, sliding, and dipping techniques, were used. In all cases, interfacial microdefects resulted from the thermal etching of the substrates that occurred prior to LPE growth. The SEM measurements showed that the cathodoluminescence and minority-carrier diffusion lengths were reduced in the vicinity of these microdefects for layers grown by the tilting and sliding procedures, but not for those prepared by the dipping method.

Thermal Etching of GaP Substrates

The GaP substrates used in this investigation were (111)B wafers cut from LEC crystals doped with Te or S(N_D-N_A = 2-5 $\times$ 10^{17} cm^{-3}). P-type GaP: Zn,O layers were grown on these substrates by three different LPE processes described in the next section. In each process the LPE growth temperature is 1040°C, which yields (3) the maximum concentration of the Zn,O centers responsible for red emission, and the substrate is kept at this temperature for 5-10 min prior to LPE growth. Even during this short time a considerable amount of P is lost from the substrate by preferential evaporation, since the P pressure over GaP at 1040°C is about 0.2 Torr, much higher than the Ga pressure.

To investigate the surface defects resulting from P evaporation, an SEM was used to examine (111)B GaP wafers that had been thermally etched under conditions similar to those encountered prior to LPE growth. Such wafers typically exhibit a roughly uniform distribution of deep etch pits a few micrometers in size, as shown in Fig. 1. In some cases, triangular etch pits, shown in Fig. 2, with well-defined edges aligned along preferential crystallographic directions

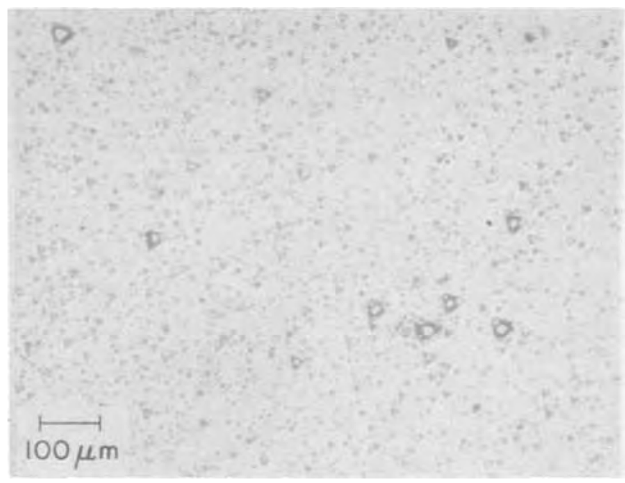

Fig. 1. SEM photomicrograph of thermal etch pits on the surface of a (111)B GaP substrate. The experiment was performed at 1020°C for 3 hr in a sealed ampul.

Key words: GaP, junction properties, substrate microdefects, thermal etching, cathodoluminescence.

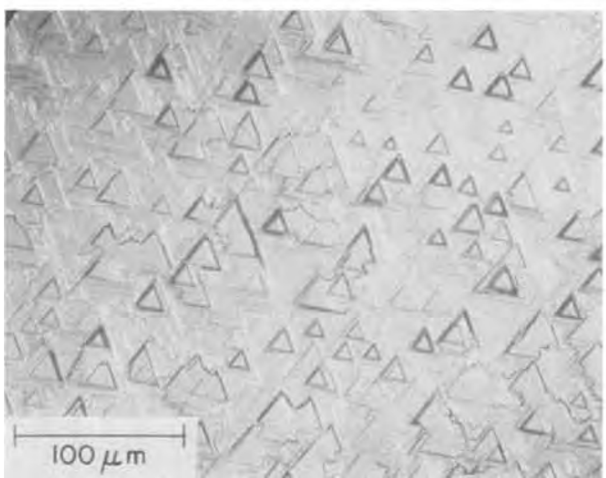

Fig. 2. SEM photomicrograph of triangular etch pits on the surface of a thermally etched GaP substrate (same experimental conditions as Fig. 1).

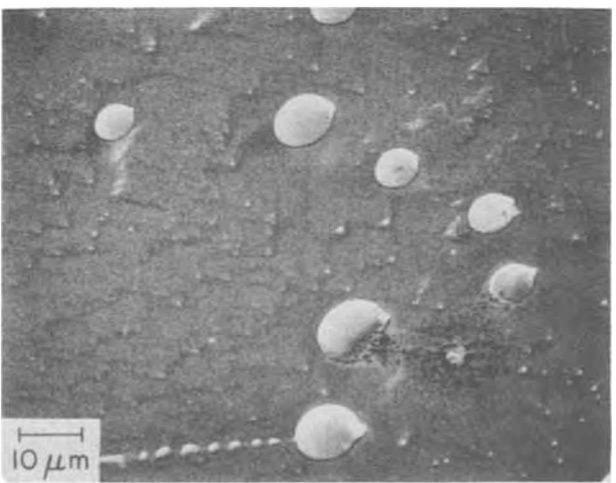

Fig. 3. SEM photomicrograph of typical Ga droplets on the surface of a thermally etched GaP substrate (same experimental conditions as Fig. 1).

are also obtained. In addition, droplets of Ga are frequently observed on the etched surfaces, as shown in Fig. 3 and 4. It can be seen in these figures that the droplets are generally located at the bottom of etch pits, consistent with the conclusion of Solomon and DeFevere (2) that the thermal etching is due to straightforward thermal decomposition.

The P evaporation rate was found to be strongly dependent on the quality of the substrates, particularly on their dislocation densities. Table I gives the evaporation rate at 1040°C measured for one LPE and two LEC samples that were sealed in evacuated fused quartz ampuls. Furthermore, a strong difference was observed in the etch pattern and the thermal etch-pit density, depending on the type of material. This difference is well illustrated in Fig. 5, a photomicrograph taken along a metallurgical junction of an LPE layer grown on an LEC crystal.

Our experiments showed that in an open-tube system the thermal etch rate is independent of the carrier gas (N,He,Ar) but strongly dependent on the gas flow rate. It is also known (5) that changes in surface morphology are markedly dependent on the degree of undersaturation maintained during heating, on the temperature range, and on the crystal orientation.

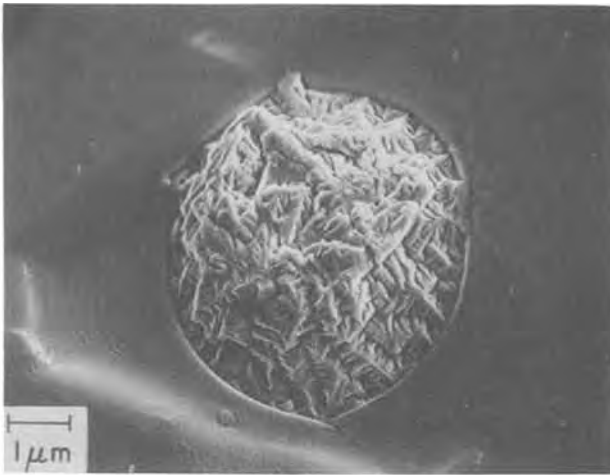

Fig. 4. SEM photomicrograph of Ga droplets located at the bottom of a typical conical etch pit.

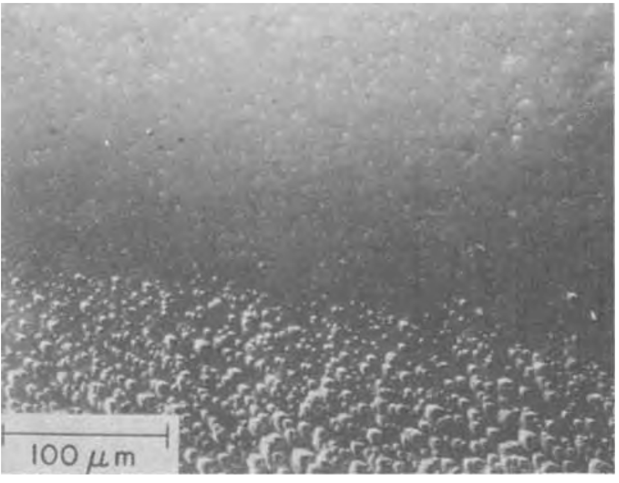

Fig. 5. SEM photomicrograph of a junction composed of a p-type LPE layer (low density of thermal etch pits) on an n-type LEC substrate (high density of thermal etch pits).

Procedures for LPE Growth and SEM Characterization

P-type, GaP:Zn,O layers were grown at 1040°C from saturated Ga-rich solutions on various n-type substrates. The growth solutions were also saturated with oxygen (from Ga_2O_3) and doped with Zn to give carrier concentrations in the layers of 3-4 $\times$ 10^{17} cm^{-3}. Three different LPE techniques were used: (*i*) A tilting, closed-tube system similar to the one described by Saul, Armstrong, and Hackett (1). (*ii*) A horizontal, open-tube system with a modified sliding boat based on the design of Panish, Sumski, and Hayashi (6). (*iii*) A vertical, open-tube dipping system (5) similar to the one reported by Solomon and DeFevere (2), that is designed to minimize thermal etching of the substrate.

The growth conditions for techniques (*i*) and (*ii*) were such that substrate meltback did not occur at

Table I. Thermal etch rate for various GaP crystals at 1040°C

Type of crystal	Net carrier concentration/cm³	Dislocation count/cm²	Thermal etch rate, mg/cm²-sec
LEC	Te 5×10^{17}	1.5×10^5	9×10^{-4}
LEC	Te 4×10^{17}	2×10^4	$3\text{-}5 \times 10^{-4}$
LPE	Zn $3\text{-}5 \times 10^{17}$		$1\text{-}7 \times 10^{-4}$

the beginning of LPE growth. (With these techniques, the edge of the substrate where the LPE layer did not grow was taken as a reference.) With technique (*iii*), however, the substrate was strongly solution-etched prior to LPE growth. The growth solution used for technique (*iii*) contains an excess of Zn dopant, which is largely compensated by adding Te. The LPE layers grown by this technique therefore have a Zn concentration exceeding 10^{18} cm^{-3}, but the measured carrier concentration is still about 3-4 $\times$ 10^{17} cm^{-3}.

Measurements of the near-junction properties of red-emitting p-n junction structures grown by LPE were made with an AMR-900 scanning electron microscope (SEM), using the secondary-emission (SE), cathodoluminescence (CL), deflection-modulation (DM), beam-induced-current (BIC), and voltage contrast (VC) modes of detection (7). A lens and light pipe were inserted to transmit the CL recombination radiation through the exit port of the specimen chamber for detection with an S20 photomultiplier. Details of the electron beam excitation system and emission detection system have been given previously (7).

The position of the p-n junction on a cleaved section of the sample was observed on the CRT screen using the BIC or the VC mode. Simultaneously, the spatial distribution of the CL intensity in the p-region was also displayed.

Effect of Thermal Etching on Near-Junction Properties

The SEM measurements performed on cleaved p-n junction structures show that thermal etching has a detrimental effect on the near-junction properties of samples prepared by the LPE techniques (*i*) and (*ii*) listed above. Typical results for such a sample in the vicinity of a thermal etch pit are shown in Fig. 6, which consists of four SEM photomicrographs of the cleaved surface that were obtained by using (from top to bottom) the direct CL, DM, VC, and BIC modes of detection. The lower portion of each photomicrograph corresponds to the GaP substrate, and the upper portion to the LPE layer. The location of the electronic p-n junction is shown by the BIC (bottom) pattern. The etch pit has a flat bottom parallel to the original substrate surface [*i.e.*, to the (111) plane] and sharp, well-defined edges. All the pits examined have this shape, although their size and spacing vary considerably. The CL(top) pattern shows that cathodoluminescence is emitted only by the LPE layer and that a dark ring of decreased intensity is formed around the etch pit. Such a decrease in CL intensity around etch pits and microsteps was observed for all samples that had been grown by LPE techniques (*i*) and (*ii*).

To obtain quantitative data on the variation of BIC and CL in the vicinity of a thermal etch pit, SEM line scans using these two detection modes were made across the p-n junction of the sample of Fig. 6 at the three positions indicated by arrows in that figure. Scan a, taken outside of the thermal etch pit, is shown in Fig. 7 with a CL profile that is the complementary function of the BIC profile normally characteristic of a p-n junction behavior with no "dead layers" (8, 9). For the scans made at the edge (scan b) and center (scan c) of the etch pit, the CL intensity has a minimum at the position of the dark ring shown in Fig. 6.

For each scan of Fig. 7, the minority carrier diffusion lengths were calculated from the logarithmic plot of the BIC intensity *vs.* the distance from the junction as shown in Fig. 8. The hole diffusion length (L_n) on the n-type side of the junction is about 0.5 μm for all three scans, but the electron diffusion length (L_e) is significantly reduced for the scans that pass through the etch pit. Thus the values of L_e for scans a, b, and c are 1.0, 0.75, and 0.65 μm, respectively. Similar measurements made on other thermally etched substrates show a systematic degradation of the CL intensity around an etch pit or microstep. This effect is visualized by a typical "dark" ring on the CL display as shown in Fig. 6. In addition, an appreciable decrease of L_e in the p-region was measured in all these samples at the edge of the pit.

Recent studies of the vapor-phase epitaxial growth of GaAs within chemically etched windows on GaAs(111)B substrates suggest a possible explanation for the effect of thermal etch pits on the near-junction properties of GaP LPE layers. A strong growth anisotropy in the vicinity of the window edges has been clearly demonstrated by impurity striation (10, 11) and Peltier-effect (12) studies. A similar growth perturbation could take place during the initial stage of LPE growth at a thermal etch pit on the GaP sub-

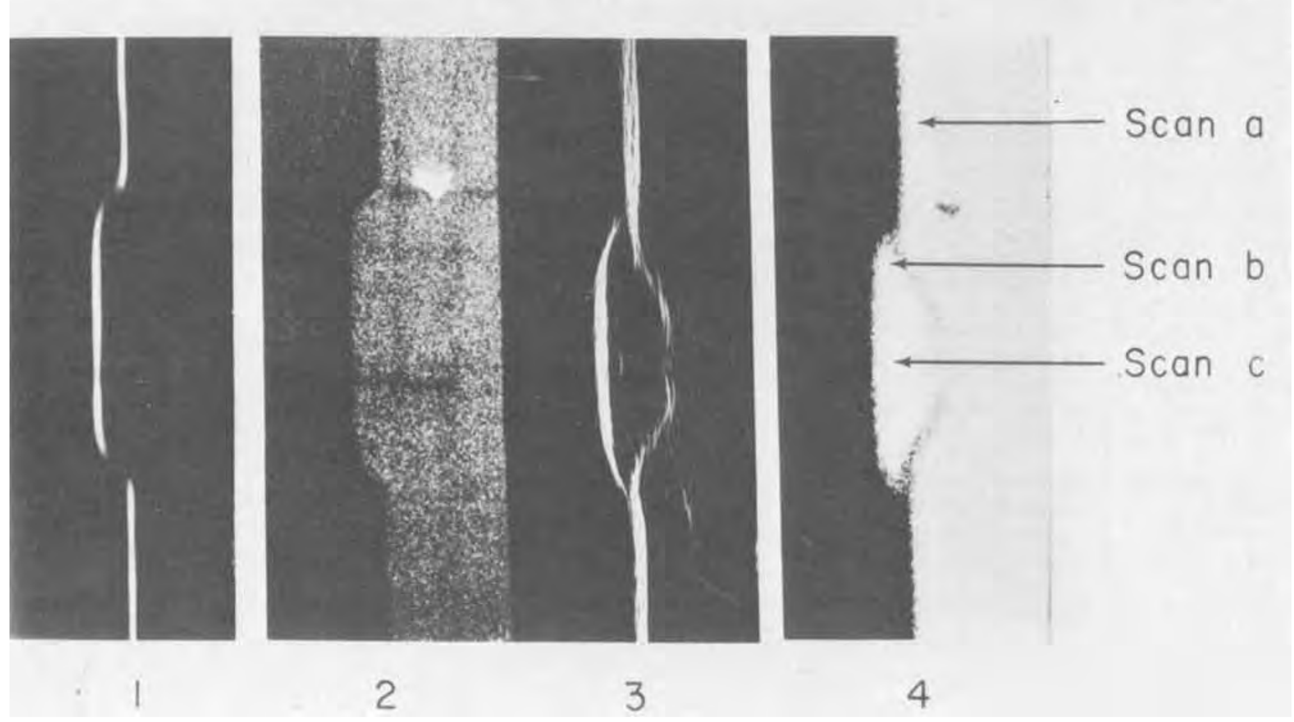

Fig. 6. SEM photomicrograph of the p-n junction of a cleaved GaP wafer in the vicinity of a thermal etch pit, generated in different modes of detection: 1, BIC mode; 2, VC mode; 3, CL intensity in deflection modulation mode; 4, CL intensity.

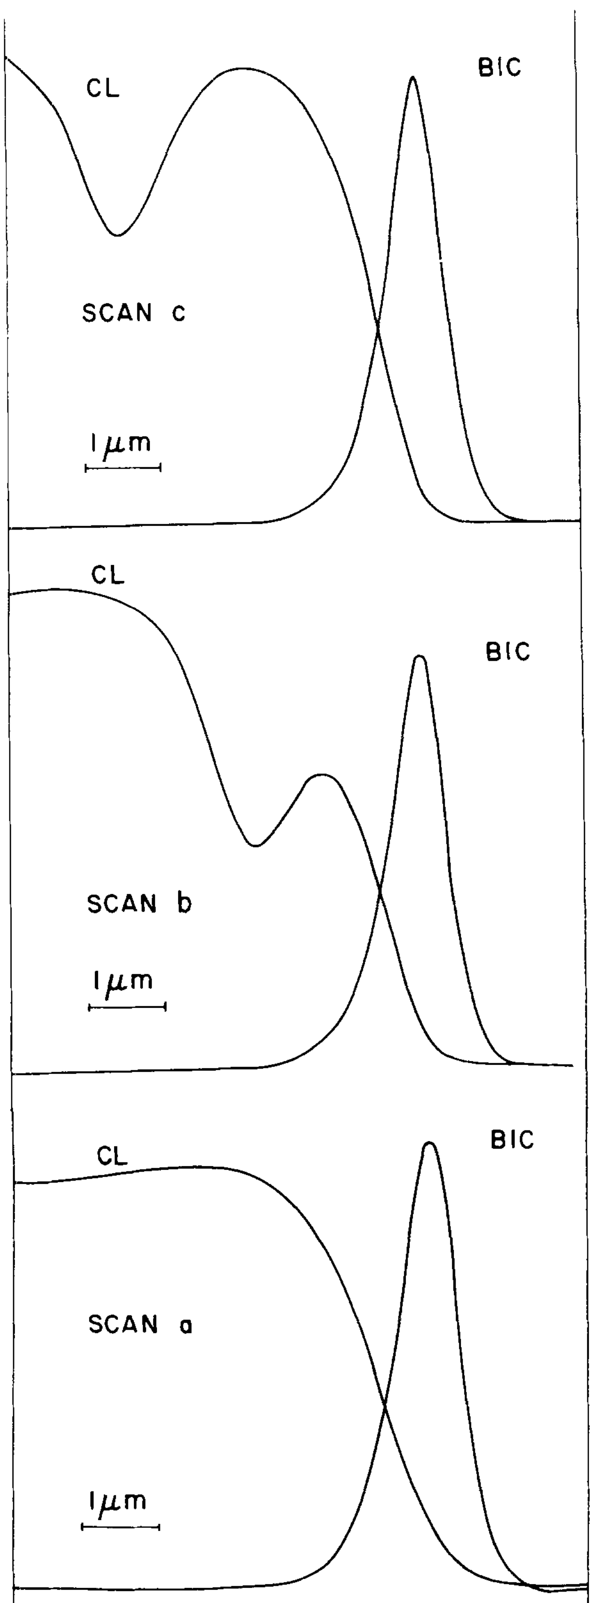

Fig. 7. Line scans of CL intensity and BIC signal taken across the p-n junction of the sample of Fig. 6. Scan (a) was taken outside the thermal etch pit, scan (b) at the corner edge of the pit, and scan (c) at the center of the pit.

strate surface. Hence, a growth direction different from the substrate orientation would be favored at the corner edge of the pit, causing a variation in the growth rate and dopant incorporation along the junction. Furthermore, such a local growth perturbation can induce a highly stressed region (13). In our case, the sharp corner edge of a thermal etch pit could be a

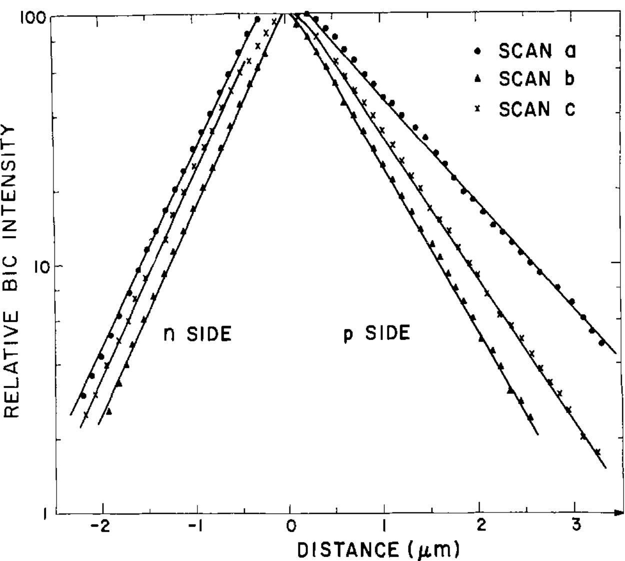

Fig. 8. BIC signal as a function of distance from the p-n junction, evaluated from the scans of Fig. 7. Scan (a) is off the pit, scan (b) is at the corner, and scan (c) at the center of the pit.

region of high density of dislocations, thereby acting (14-16) as a sink for nonradiative "killer" centers that could decrease the CL efficiency and degrade the minority-carrier lifetime.

In GaP LED's with p-n junction structures like those studied in this investigation, radiative recombination of injected carriers occurs within a few micrometers of the junction. Therefore a reduction in the electroluminescence (EL) efficiency of these devices can be expected to occur when there is a degradation in CL efficiency and L_e in the active region due to thermal etch pits. Since the reduction in EL efficiency should increase as the density of these pits increases, our observation that this density depends on substrate quality and growth conditions could account for the broadened distribution of LED efficiencies reported by Solomon and DeFevere (2) as resulting from thermal etching. However, any direct correlation between the near-junction properties and LED device performance should be treated with caution. It is quite clear that the growth conditions also have to be examined in order to determine, unambiguously, the validity of such correlations; for materials grown with a tilting or sliding system, the substrate is in the hot zone during the entire LPE cycle. Hence, thermal etching of the substrate prior to the LPE growth inevitably occurs (but in various degrees) at these high temperatures. It should be noted that an intentional or nonintentional solution-etch during the initial stage of the epitaxy tends to reduce the surface roughness of the substrate. In this case, a wavy but smooth interface is observed by conventional etching, VC or BIC modes of detection.

The dipping technique differs from techniques (*i*) and (*ii*) namely,

minimum exposure of the substrate to the thermal etch action

meltback of the substrate prior to the final LPE p-type Zn,O doped layer.

Furthermore, in this particular technique the variation of the doping concentration due to the dissolution of the n-type substrate in the p-type growth solution should be minimized because the solution is already highly counterdoped with Te.

In general, meltback prior to the epitaxial growth tends to smooth out the substrate roughness and reduce considerably the influence of the surface microdefects induced by thermal etching. Under these conditions, a microstep as shown in Fig. 9 apparently does not influence the near-junction properties. A close

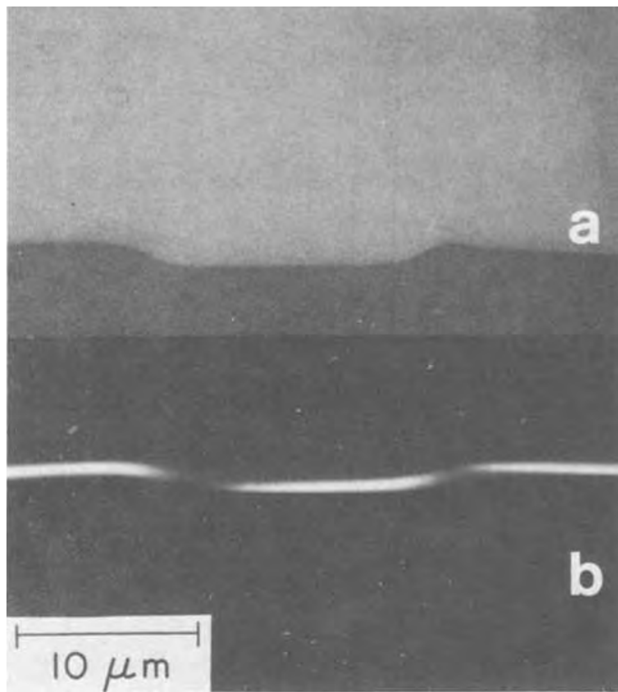

Fig. 9. SEM photomicrograph of the p-n junction of a cleaved GaP sample in which the LPE layer was grown by dipping with substrate meltback (technique *iii*). (a) CL mode, (b) BIC mode.

examination of these compensated materials showed no measurable degradation of either CL or L_e suggesting that the meltback process has eliminated the local degradation observed in LPE layers grown by techniques (*i*) and (*ii*).

It has previously been found (17) that GaP layers grown by the meltback technique lead to diodes with better electroluminescence efficiency. An increase of about 15% in average EL efficiency of red GaP diodes due to meltback has also been recently reported (18). This improvement is consistent with our SEM study.

Conclusions

In the fabrication of GaP:Zn,O red-emitting LED's by LPE, thermal etching at the optimum growth temperature seriously degrades the smoothness of the substrate surface. Imperfections present at the surface of the substrate, such as thermal etch pits or microsteps, affect the near-junction properties of the materials.

For p-n junctions obtained by using conventional tipping and sliding LPE techniques without substrate meltback, SEM examination shows that the CL efficiency and L_e in the p-type layers are reduced in the vicinity of each thermal etch pit. This reduction is probably due to the strong anisotropy of the initial LPE growth at the corners of the pits. Since the etch pit density depends on the quality of the substrate and on the growth conditions, this degradation of near-junction properties could account for the increased variation in EL efficiency that has been reported for LED's prepared by growth on thermally etched substrates. No such degradation was observed when LPE layers were grown by a dipping technique that employs a Te-compensated growth solution and substrate meltback. This difference may account for the improvement in EL efficiency that has been observed for LED's prepared by meltback techniques.

Growth and Properties of Heteroepitaxial GaInAs Alloys on GaAs Substrates Using Trimethylgallium, Triethylindium, and Arsine

B. Jayant Baliga*,[1] and Sorab K. Ghandhi

Electrophysics and Electronic Engineering Division, Rensselaer Polytechnic Institute, Troy, New York 12181

ABSTRACT

Heteroepitaxial films of GaInAs have been grown on GaAs substrates by the reaction of triethylindium and trimethylgallium with arsine gas. Specular films have been obtained over the entire composition range at a substrate temperature of 600°C. The observed mobilities of 1-2 μm thick films are about one-third of the reported bulk values in literature and show a minimum at a composition of approximately 20 mole per cent InAs. The mobility of such films decreases sharply with decreasing temperature.

Interest has been focused on GaInAs alloys because of promising applications in coherent light emission in the wavelength range extending from 0.84 to 3.1 μm. Lasers have been fabricated with spontaneous emission at 2.07 and 1.77 μm with a half-width of 500Å at a current of 600 A/cm^2 (1). Another potential application of these alloys is for negative electron affinity photocathodes. GaInAs photocathodes have been shown to be ideal for detecting radiation from GaAs LED's and lasers (2, 3), and represent an increase in sensitivity by two to three orders of magnitude over S-1 and S-20 phosphors. Interest in these materials has also arisen from their potential applications in high frequency devices (4). The alloys can be designed to have much larger bandgaps than InAs and higher mobilities than GaAs. This makes them better suited for high frequency, field effect transistors.

Epitaxial layers of GaInAs alloys have been grown by liquid phase epitaxy (5, 6), by chloride transport (3, 7), and by using organometallic sources of gallium and indium (8). Synthesis by liquid phase epitaxy, with either InAs (5) or GaAs (6) as sources of arsenic, have yielded alloy films with only up to 23 mole per cent (m/o) InAs. Further, these films have been observed to have terraced surfaces at best. Mobilities of between 4000 and 5000 cm^2/V-sec have been reported for alloys in this range of composition. Better results have been reported for alloys grown by chloride transport of gallium and indium from elemental sources (3, 7). In this case, alloys were obtained over the entire composition range. When elemental arsenic was used as a source, carrier concentrations of 1×10^{16} cm^{-3} were achieved in the alloys deposited on GaAs substrates. Mobilities of 20,000 cm^2/V-sec were observed in InAs layers and 7000 cm^2/V-sec in GaAs layers. Alloys with compositions of 60 m/o GaAs exhibited lower mobilities of 3000 cm^2/V-sec. Vapor phase epitaxial growth of GaInAs alloys using organometallic sources of gallium and indium was achieved by Manasevit and Simpson on GaAs and Al_2O_3 substrates (8), but their work was confined to alloys of composition midway between GaAs and InAs.

In this paper we describe the growth and electrical properties of GaInAs alloys, grown on {100} gallium arsenide substrates, using organometallic sources of gallium and indium. It is demonstrated that organometallic source transport can be used to obtain alloys over the entire composition range, $0 \leq x \leq 1$. Further, electrical properties of thin epitaxial layers, ranging from 1 to 2 μm in thickness, which are particularly suited for device applications, are reported on for the first time. The mobility of these films is found to follow the same composition dependence as in bulk single-crystal alloys. Temperature dependence of mobility in the alloys is found to follow a T^{+n} law with n close to unity, in contradiction to Brooks' theory of disorder scattering (9).

Experimental Conditions

The growth of InAs, GaAs, and their alloys was carried out in a horizontal tube epitaxial reactor whose schematic is shown in Fig. 1. The system consists of a 50 mm ID quartz tube, 45 cm long, containing a molybdenum susceptor heated by infrared radiation from a set of eight, 500W quartz-halogen lamps. Vapors of triethylindium[2] (TEI) and trimethylgallium[2] (TMG) were transported to the substrate by bubbling hydrogen through the liquids. TEI was maintained at room temperature (25°C), and TMG at 0°C. Arsine gas, diluted to 2% in hydrogen,[3] was mixed with the organometallic vapors just before entering the quartz tube. Due to the reaction between the organometallic compounds and arsine at room temperature, they were not premixed before entry to the hot zone. In addition, a separate source of ultra high purity hydrogen at a flow rate of 10 liters/min was used as a carrier gas in all the experiments. This carrier gas flow served to transport the reactants down the quartz tube and to minimize the formation of reaction products upstream from the susceptor. Stainless-steel tubing was used throughout in order to minimize system contamination.

Substrate.—Epitaxial growth was carried out on {100} chromium-doped semi-insulating GaAs sub-

strates to facilitate subsequent electrical evaluation. The substrates were obtained commercially with one face polished.[4] No further attempts were made to polish the wafers. Before epitaxy, however, the substrates were cleaned in methanol[5] and checked to ensure the absence of dust particles. Substrates were placed perpendicular to the gas flow to obtain uniform growth over the entire surface.

Procedure.—Substrates were heated to 500°C in hydrogen, at which point arsine was introduced into the reaction tube. Arsine flows greater than 0.5 mliters/min were sufficient to prevent substrate dissociation from occurring up to temperatures of 750°C. After stabilizing the arsine flow for 2 min, the substrate temperature was raised to 600°C, and maintained for an additional 2 min before the introduction of the organometallic compounds.

Growth rate determination.—It was established that no loss in weight of the substrate took place up to substrate temperatures of 750°C, in the presence of more than 0.5 mliters/min arsine flow rate. Since the reactions involved in the system do not generate any etchant species, the thickness of the layers could be directly measured from the increase in mass after epitaxy. Angle lapping and staining techniques were initially used to measure the thickness of the epitaxial layers. However, etching of the surface by the staining and plating solutions and the presence of large depletion layer widths at the interface resulted in considerable error in determining layer thickness.

In the gravimetric measurements, the density used to determine the epitaxial layer thickness was calculated as

$$D_x = 6.68(145 + 45x)/(5.654 + 0.404x)^3$$

where x is the mole fraction InAs in the alloy. This equation was obtained by using Vegard's law and the zinc blende structure of these alloys (10).

Growth Characteristics

In order to study the growth of GaInAs alloys it is helpful to independently grow both the end components, GaAs and InAs. In addition, it is useful to achieve comparable growth rates for both these components under identical reactor conditions (substrate temperature, arsine concentration, and carrier gas flow rate). It was found that high quality GaAs films (11, 12) could be grown over a wide range of substrate temperatures (600°-800°C) whereas InAs films of comparable quality were restricted to substrate temperatures of 580°-620°C (13, 14). It was also found that, at a substrate temperature of 600°C, good quality GaAs and InAs films could be grown with arsine flows in excess of 1 and 1.4 mliters/min, respectively. Finally, low hydrogen carrier gas flows (1 liter/min) through the reactor resulted in InAs film growth rates of less than 0.01 μm/min. Increasing the hydrogen carrier gas flow to 10 liters/min increased the growth rate to 0.1 μm/min, indicating that significant depletion of the TEI occurred due to reaction upstream of the susceptor for low carrier gas flows. For GaAs, growth rates[6] in excess of 1 μm/min were obtained at hydrogen carrier gas flows of 1 liter/min, decreasing to 0.1 μm/min when the carrier gas flow was raised to 10 liters/min, indicating that the dilution effect of the higher carrier gas flow was dominant in this case. As a consequence of these observations, we were able to achieve high quality films of GaAs and InAs with comparable growth rates under the following reactor conditions: (*a*) substrate temperature of 600°C, (*b*) arsine flow of 2 mliters/min, and (*c*) hydrogen carrier gas flow of 10 liters/min.

[4] Electronic Materials Corporation, Pasadena, California 91107.
[5] Substitution of methanol with more sophisticated cleaning solutions and procedures did not produce any significant change in the growth rate or surface quality of the epitaxial films.
[6] These growth rates correspond to a hydrogen flow of 6 mliters/min through the TMG bubbler.

Under the above conditions, the growth of InAs could be controlled by varying the hydrogen flow through the TEI bubbler, as shown in Fig. 2. Growth rate was found to increase linearly with increasing hydrogen flow through the TEI bubbler, over the range of 0.02-0.07 μm/min. Under the same reactor conditions, the growth rate of GaAs films could be controlled by varying the hydrogen flow through the TMG bubbler, as shown in Fig. 3. Again, a linear dependence of growth rate on the hydrogen flow through the bubbler was observed.

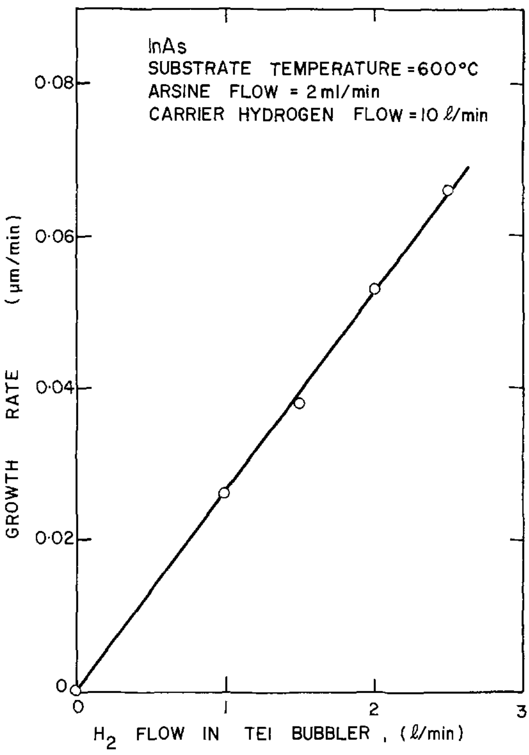

Fig. 2. Variation of InAs growth rate with hydrogen flow through the TEI bubbler.

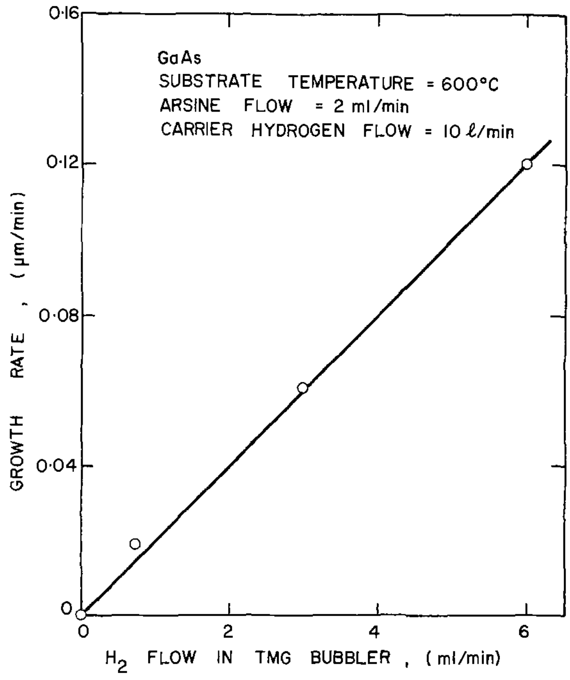

Fig. 3. Variation of GaAs growth rate with hydrogen flow through the TMG bubbler.

Having achieved comparable growth rates for the end components under identical reactor condition, growth of the alloys could now be achieved by simultaneous introduction of TEI and TMG into the reactor. Further, the growth rate of either component could be independently controlled by adjusting the hydrogen flow through the respective source liquids, thus allowing the growth of the alloys over the entire composition range.

The effect of varying the TEI and TMG flows on the alloy composition was examined by keeping one component fixed and changing the other. Arsine flow was maintained at 2 mliters/min in all these experiments. The alloy composition was measured by x-ray energy dispersal analysis in a scanning electron microscope. Figure 4 shows the variation of the InAs mole fraction in the epitaxial layers as the mole fraction of TEI in the gas phase (TEI/(TEI + TMG)) is changed. This fraction was determined using a vapor pressure of 66 mm Hg at 0°C for TMG, and 0.4 mm Hg at 25°C for TEI, and assuming saturated conditions. A strong one-to-one correlation between the mole fraction of InAs in the layers and TEI in the gas phase is observed when the TMG flow is kept constant and the TEI flow is varied. A somewhat weaker correlation is observed when the TEI flow is kept constant and the TMG flow is varied. This is due to the extremely small hydrogen flows through the TMG bubbler, required to obtain the low growth rates of GaAs necessary for the growth of the alloys. The one-to-one correlation between the mole fraction of InAs in the layers and of TEI in the gas phase indicates that indium and gallium are independently incorporated into the lattice and that the reactions between TEI and arsine and between TMG and arsine occur without significant interaction.

We have also observed that arsine flow has only a small effect on the composition of the alloys. Figure 5 shows the extent of this effect for layers grown at 600°C using a hydrogen flow of 6 mliters/min through the TMG bubbler and 2.5 liters/min through the TEI bubbler. Changes in arsine flow of one order of magnitude produced only small changes in composition. Thus, good control over the concentrations of TEI and TMG in the reactor was adequate for controlling the composition of the layers.

GaAs layers grown under the conditions described in this paper had featureless surfaces under Nomarski interference phase contrast microscopy up to magnifications of 400×. On the addition of 4 m/o InAs to the layers, a cross-hatched pattern appeared on the epitaxial layer, as shown in Fig. 6a. Such patterns have been observed in the growth of heteroepitaxial layers by other workers when the composition of the epitaxial layer is nearly that of the substrate or when the composition of the epitaxial layer is graded (3, 15), and has been ascribed to grading dislocations. With the addition of larger amounts of InAs, the large difference in lattice constant between the layer and the substrate (InAs has a lattice constant of 6.058Å while GaAs has

a lattice constant of 5.654Å) results in terraced surfaces as shown in Fig. 6b and c. All these surfaces have a specular appearance to the unaided eye.

Electrical Properties

Hall measurements were used to determine the carrier concentration and the mobility of alloy films grown on semi-insulating GaAs substrates. Conventional bridge-shaped samples were delineated in the epitaxial layers, and ohmic contacts made to the arms of the sample by alloying indium spheres at 400°C for 30 sec in a reducing gas ambient.

Mobility variation with composition.—The effect of composition on the Hall mobility of the alloys was examined for layers of between 1 and 2 μm in thickness. The carrier concentration in the layers was in the lower 10^{16} cm^{-3} range.

The observed variation in mobility with composition is shown in Fig. 7, and compared with results of other workers (7, 16-18). The mobility of our thin films (1-2 μm) were generally one-third of the observed bulk values. Published data on thick films (> 15 μm) have been correspondingly scaled for comparison. The mobility was found to exhibit a minimum at a composition of approximately 20 m/o InAs in layers grown in this study. In bulk material the minimum in mobility has been observed at x between 0.1 and 0.2 (17, 18); for epitaxial layers grown on GaAs by chloride transport, the minimum has been observed at x between 0.4 and 0.5 (7). One author (16) has claimed to have observed a monotonic variation in mobility with composition. However, his work did not involve any measurement on layers in the composition range $0 < x < 0.7$ where the minimum occurs.

The observed shape of the mobility *vs.* composition characteristic follows Brooks' theory (9) for materials in which disorder (alloy) scattering is the dominant limitation on mobility. Using this theory and a linear variation of electron effective mass between InAs and GaAs (19, 20) results in a mobility minimum for approximately 30 m/o InAs (10). Actual values of mobility, calculated on the basis of this theory, were found to be several orders of magnitude greater than the measured values in our films, as well as those of other workers.

Hall mobility variation with sample temperature.—Hall measurements were conducted to determine the variation in the mobility of the layers over a temperature range from 300° to 77°K. The mobility variation with temperature of GaAs films of 7 μm and greater in thickness was found to be the same as that for polar optical scattering in bulk crystals. The variation of mobility with temperature for InAs layers is shown in Fig. 8 for samples with different thicknesses. The mobility of the thicker films (*e.g.*, 7.2 μm) is seen to increase with decreasing temperature, consistent with the behavior of bulk InAs where the dominant scattering mechanism in this temperature range is polar optical scattering. However, the mobility of thin samples ($\leq$ 1.5 μm) decreased with decreasing temperature, with the slope of this curve becoming steeper with decreasing layer thickness. It is proposed that the dominant scattering in these layers is dislocation scattering. Although there is no established theory for dislocation scattering in polar semiconductors, this mechanism has been analyzed (21) for nonpolar semiconductors using the deformation potential approach. It has been shown that mobility dominated by dislocation scattering should vary as T^{+1}, and that this scattering effect becomes comparable to lattice scattering at room temperature when the dislocation density exceeds 10^{11} cm^{-2}. The calculated dislocation density (22) at the InAs-GaAs interface is 4 $(a_{GaAs}^{-2} - a_{InAs}^{-2}) = 1.61 \times 10^{14}$ cm^{-2} for {100} surfaces, if an abrupt transition is assumed. Thus, dislocation scattering is expected to be significant in thin layers and can produce the observed flattening in the temperature dependence of the mobility characteristic.

The detailed nature of the variation in mobility of GaInAs alloys with temperature has not been reported in the literature. This variation was measured for alloy films with thicknesses between 1 and 2 μm, over a temperature range of 300°-77°K. In every alloy layer (see Fig. 9), for $0.41 \leq x \leq 0.8$, the mobility fell sharply with decreasing temperature. The mobility is observed to decrease according to a T^{+n} law, with n close to unity. Other authors (7, 17, 18), who have observed the temperature variation of mobility for GaInAs alloys in bulk and epitaxial form have also reported that mobility decreases with decreasing temperature. These results for alloy layers are in variance with Brooks' theory, which predicts an increase in mobility due to disorder scattering when the temperature decreases, with a coefficient $n = \frac{1}{2}$. This disagreement again points to the inadequacy of the pres-

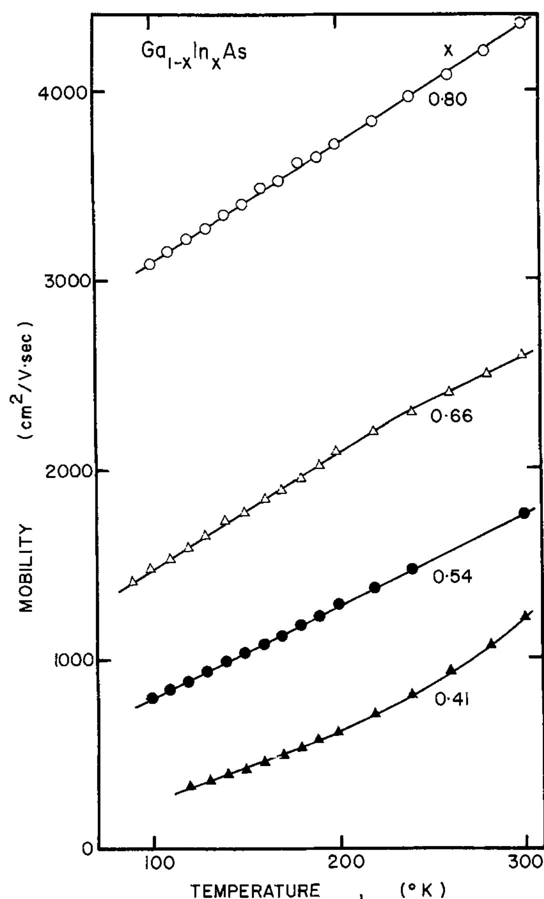

Fig. 9. Variation of Hall mobility with sample temperature for epitaxial GaInAs layers on GaAs substrates, with composition as parameter.

ent theory. A theory of disorder scattering which does explain all the observed effects is yet to be developed.

Conclusions

Epitaxial layers of GaInAs alloys can be grown using organometallic sources of indium and gallium in combination with arsine gas to obtain specular films over the entire composition range at a substrate temperature of 600°C. The composition of the alloys can be controlled by adjusting the relative flows of TEI and TMG in the reactor and is relatively insensitive to arsine flow.

The mobility of layers with thicknesses between 1 and 2 μm shows a minimum at an alloy composition of approximately 20 m/o InAs. Mobilities of these thin films are found to be about a third of that measured in bulk single-crystal material. Although the mobility of layers of pure InAs and GaAs in this thickness range increases on cooling to 100°K, the mobility of the alloys decreases sharply with a temperature dependence of T^{+n}, $n \simeq 1$. This is in variance with Brooks' theory but in agreement with observations on bulk samples by other workers. This points to the need to develop an improved disorder scattering theory.

The Direct Bonding of Metals to Ceramics by the Gas-Metal Eutectic Method

J. F. Burgess* and C. A. Neugebauer

ABSTRACT

The direct bonding of metals to ceramics is possible utilizing a gas-metal eutectic. The mechanism of direct bonding of copper foil to ceramics in a slightly oxidizing atmosphere is presented. It involves the formation of eutectic melt between copper and oxygen at a temperature slightly below the melting point of copper, which serves to bring the foil into intimate contact with the substrate. A brief review of other metal-ceramic bonding techniques is given for comparison. Metals to which this technique is applicable include Cu, Fe, Ni, Co, Ag, Cr, Mo, and Al.

Strong bonding of metals to ceramics generally does not take place unless an intermediary layer is present, or forms due to diffusion or reaction. The adhesion of the metal to this intermediary layer is better than to the ceramic directly. However, an intermediary layer is undesirable in many applications. This is true, for instance, where high heat conductivity is required. The presence of an intermediary layer generally reduces heat conductivity, especially if the layer is nonmetallic. Further, in high frequency applications, where the current flows in a thin skin at the metal-ceramic boundary, intermediary layers are undesirable because they are generally more resistive than the metal to be bonded. Finally, intermediary layers are often less corrosion resistant and lead to premature failure.

Unfortunately, strong direct metal to ceramic bonds are not common, either because the bond is inherently weak, or because of the difficulty of bringing the metal into intimate contact with the ceramic. In this paper, a new method of direct bonding of metals to ceramics is given. For a better perspective, a short summary of the mechanisms of presently used metal-ceramic bonding techniques is also included.

Bonding Mechanisms Involving Intermediary Layers

Some of the more pertinent literature in this area has been reviewed by Helgesson (1), and a short review was recently given by Loasby *et al.* (2). Commonly used intermediary layers are glass layers, where the glass is intentionally added or is originally present in the ceramic itself, or polycrystalline semiconducting compounds formed by the reaction between the metal or metal oxide and the ceramic itself.

Glassy intermediary layers.—Glassy phases are usually present in the grain boundaries of impure ($<99.8\%$) ceramics. Thus, Al_2O_3 or BeO ceramics usually contain glassy mixtures of MgO, SiO_2, and CaO concentrated in the grain boundaries. When a metallizing mixture is applied to such a ceramic, and the temperature is raised to sintering temperatures, the glass from the ceramic penetrates into the (porous) metal layer and locks it to the ceramic after cooling by mechanical forces.

More commonly, glass is intentionally added to the metallizing mixture to form the intermediate layer. This is particularly true if the ceramic is pure. For example, to take advantage of the high thermal conductivity of BeO ceramic, glass must be kept out of the grain boundaries. Therefore, the common metallizing mixtures, such as Mo-Mn, when used on beryllia, contain up to 20% SiO_2. Thus the composition of a typical mixture is 71.5% Mo, 10.7% Mn, and 17.8% SiO_2, fired on BeO at 1300°C. There is an interdiffusion of manganese cations with other cations in the glass.

Another commonly practiced method of bonding through an intermediary glass phase involves glass frit additions to the finely divided metal in the metallizing mixture. Thus, the majority of the so-called "thick film" conductor pastes contain a glass frit, generally chosen for low melting point and thermal expansion match, in addition to dispersed metal (normally noble metals) in an organic carrier. After screening the paste on the ceramic, it is fired in air. The glass frit melts and reacts with the ceramic (usually Al_2O_3), and it also forms a network within the metal conductor. Thus, the bond between the metal and the ceramic is due to mechanical locking by the reacted glass, although some chemical bonding undoubtedly also occurs.

Polycrystalline intermediary layers.—Such layers are usually compounds formed between the metallizing mixture and the ceramic. In one method, the metal oxide is applied to the ceramic and sintered with the ceramic to form a mixed oxide compound. For instance, such a compound is formed between copper oxide and alumina, possibly $CuAlO_2$, when they are sintered together at 1150°C in air. Subsequent reduction gives an adherent metal layer bonded on the mixed oxide phase. This method is also applicable to cobalt, nickel, iron, and silver.

The widely used moly-manganese process also falls into this category. In this process, a mixture of molybdenum and manganese oxide is fired on alumina (not beryllia) at 1400°C in an atmosphere of wet hydrogen. The manganese oxide reacts with the alumina to form the intermediate layer compound $MnO \cdot Al_2O_3$. Molybdenum ions, which have been formed by the partial oxidation of the metal, are unable to diffuse deeply into pure Al_2O_3, but will diffuse readily into the manganese aluminate spinel. This leads to good adhesion of the Mo layer. When MoO_3 alone is used, some penetration of alumina by MoO_3 occurs, especially in hydrogen atmospheres at high humidities. A compound between Mo and Al_2O_3, perhaps $Al_2(MoO_4)_3$ (3, 4), is formed to provide the intermediary bonding layer.

Direct Bonding

Direct bonding here implies the absence of a readily identifiable intermediate phase between the metal and the ceramic. It does not exclude, however, the presence of a transition layer one or two monolayers thick, such as perhaps oxygen bridges between the metal and ceramic.

* Electrochemical Society Active Member.

Key words: copper, ceramics, joining, eutectic.

A method of direct bonding which does not depend on any kind of intimate bond between metal and ceramic is that involving mechanical locking or keying.

In this process the metal is screened on the ceramic in the form of an organometallic paste. The paste decomposes on heating in air, with the result that metal particles are now locked in pores in the ceramic surface to give a mechanical bond. Films of noble metals, such as platinum, are typically applied in this way. However, poor adhesion is obtained in the mechanical locking process. Clearly, in order to get good adhesion by direct bonding it is required that (*i*) the metal must be brought into intimate contact with the ceramic over the entire area on an atom to atom basis, and (*ii*) the metal must form a strong bond with the ceramic, be it by Van der Waal's or chemical bonding, without extensive reaction or diffusion of the two phases into each other.

To get intimate contact between metal and a ceramic surface, the metal could be brought into the liquid state by melting. The liquid will replicate the ceramic surface where it wets it, and if a strong bond is formed, good adhesion is obtained after cool-down. For instance, when copper is melted in hydrogen on an alumina substrate, a molten droplet is formed with a melting angle of approximately 120°, which after cool-down to room temperature adheres strongly to the ceramic. The problem with simply melting the metal, of course, is that one or more droplets are formed, and the metal member to be bonded entirely loses its shape. This can be avoided by the gas-metal eutectic method.

Direct bonding by the gas-metal eutectic method.—The basic idea here is to form a liquid skin around the metallic member to be bonded. The liquid must wet both the metallic member and the ceramic and form a strong bond after cool-down. The melting point of this liquid should be near the melting point of the metal member itself, say within 50°, so that the metal member becomes soft and pliant and conforms easily to the shape of the substrate surface. Further, the predominant constituent of this liquid should be the same element as makes up the metallic member, and any additional constituent should be present in only small amounts or be easily removable after bonding. The thickness of the molten skin must be kept small in comparison to the thickness of the member to be bonded.

Ideal for use as the skin material are eutectics formed by the flow gas in a bonding system with the metal member itself. Such a eutectic exists, for instance, between copper and oxygen, at 0.39 weight per cent (w/o) oxygen (5). The melting point of this eutectic is 1065°C, as compared to 1083°C for pure copper. Thus, if the oxidizing conditions in the flow gas are chosen properly, one may have the molten copper-oxygen eutectic mixture and solid copper (containing a small amount of dissolved oxygen) coexist together, in the temperature interval $1065° < T < 1083°C$. It is this copper-oxygen eutectic skin which is in effect used as a glue to bond the solid copper member to the ceramic, without the Cu member losing its shape. Thus, in order to bond copper foil to ceramic, the process is as follows.

The Cu foil is laid on top of the ceramic in a furnace containing a flow gas atmosphere consisting primarily of an inert gas, such as argon or nitrogen, with a small addition of oxygen, typically of the order of a few hundredth of a per cent. Copper initially reacts during the heat-up period with the oxygen in the flow gas, A small amount of oxygen dissolves in the copper, but most of it reacts to form Cu_2O around the foil. When 1065°C or above is reached, a liquid phase of or near the eutectic composition forms a skin around the copper. The thickness of this molten skin depends on the O_2 partial pressure and the oxidation time. If the partial O_2 pressure in the flow gas is less than $1.5 \cdot 10^{-6}$ atm (the equilibrium partial pressure over Cu_2O at 1065°C), Cu_2O will not form and the eutectic phase also will not form. The formation of a molten layer between the Cu foil and the substrate serves to bring the copper in intimate contact with the ceramic by wetting it over the entire interface. Once in intimate contact with the ceramic, copper forms a strong bond with it. The temperature must remain below 1083°, the melting point of copper, since otherwise the foil loses its structural integrity and liquid drops are formed. Similarly, if the partial pressure of oxygen is too high, all copper present is converted into eutectic melt. Thus, an intermediate O_2 partial pressure is required where both phases are present simultaneously. On cool-down below 1065°, the eutectic segregates into Cu and Cu_2O. Evidence of this is shown in Fig. 1, which is a micrograph through a section of bonded copper foil, and indicates the presence of a second phase. This oxide phase may now be reduced in hydrogen at low temperature without loss of adhesion. The bonding process is schematically illustrated in Fig. 2.

The possibility exists, of course, that one or more monolayers of copper oxide still exist at the copper-ceramic interface, even after reduction, perhaps combined with alumina to give a spinel such as $CuAlO_2$. This has recently been suggested by O'Brien and Chaklader (6). However, removal of the copper by etching in nitric acid or ferric chloride solution leaves no copper-containing residues, thus ruling out intermediate layers consisting of copper compounds insoluble in these etchants.

Copper has been bonded successfully by the gas-metal eutectic methods on alumina, beryllia, silica, various other spinels, other metals, and to itself. It does not bond, however, to boron nitride or carbon. The bond strength to oxygen-containing ceramics can be in excess of 20,000 psi. Since the copper itself does not melt during bonding, precut or stamped foils of copper of the desired shapes can be bonded. In addition, holes previously cut into ceramic substrates can be covered hermetically, and the copper can overhang the ceramic. Bonds between copper and other metals, and between two copper members, can also be made by this method. A photograph of various direct bonded copper structures prepared in this laboratory are shown in Fig. 3.

Application to other metal-ceramic systems.—For the direct bonding of metal by the gas-metal eutectic method, the following prerequisites must be fulfilled: (*a*) a eutectic must exist between the metal and the flow gas, (*b*) the percentage of the gas component in the eutectic must be low and/or easily removable after bonding, (*c*) the eutectic temperature must be at least

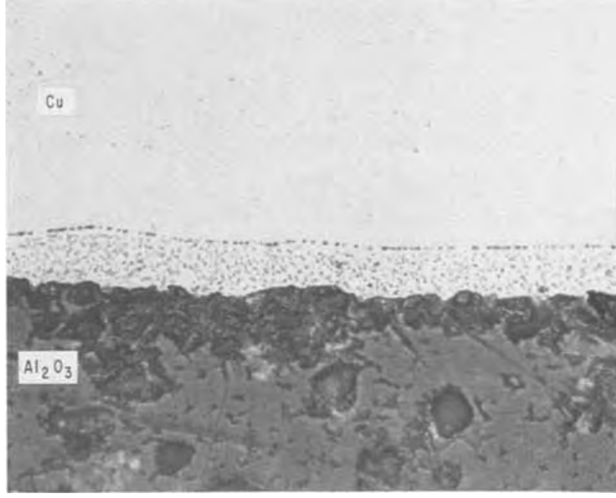

Fig. 1. Micrograph of section through direct copper bond to alumina, showing precipitated Cu_2O from the eutectic.

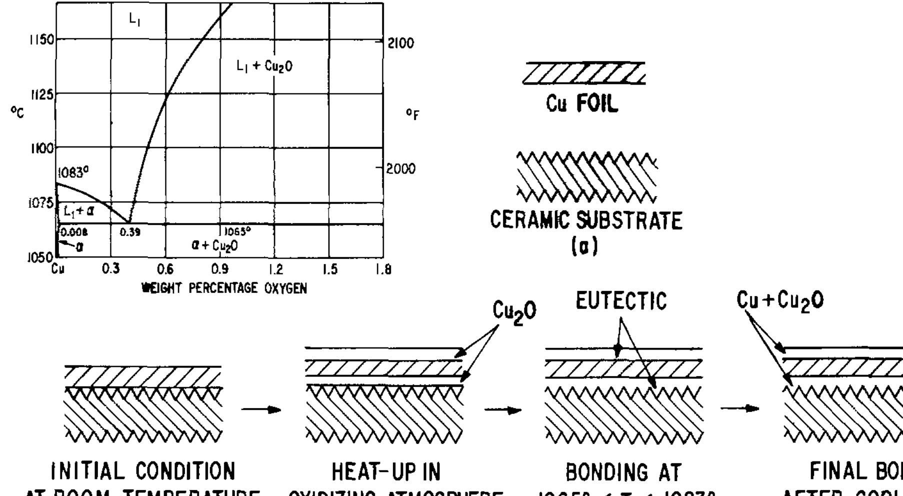

Fig. 2. Eutectic phase diagram and schematic of bonding process.

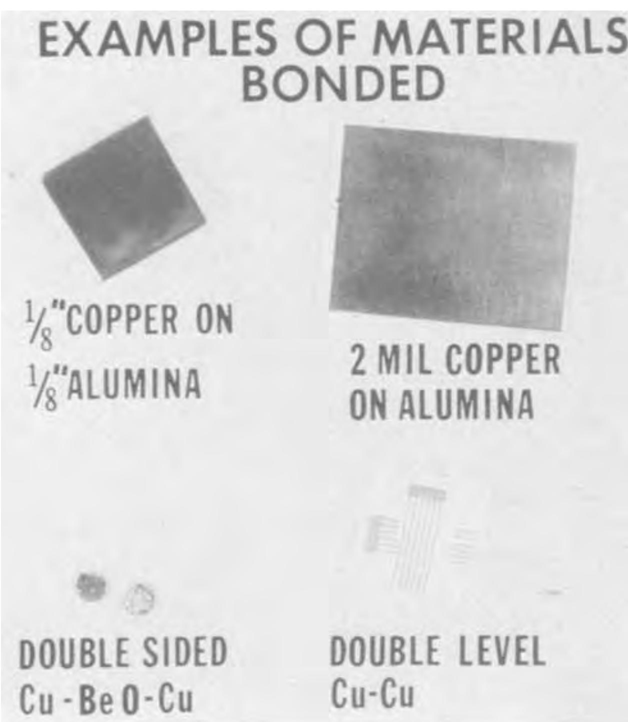

Fig. 3. Direct bonded copper structures

10° or so below the melting point of the metal to give a realistic temperature range for bonding, and (*d*) the metal must be pliant at the bonding temperature so that it conforms to the substrate shape.

Inspection of phase diagrams of metals with the more common gases reveals a number of possibilities. In particular, oxygen, sulfur, and phosphorous form eutectics with several metals. These are listed in Table I, in addition to the eutectic temperature, the melting point of the metal, and the percentage of the gas component in the eutectic.

Table I. Metal-gas eutectics for direct bonding

Eutectic	Eutectic temperature, °C	Weight per cent of nonmetal	Melting point of metal, °C
Copper-oxygen	1065	0.39	1083
Iron-oxygen	1523	0.16	1535
Nickel-oxygen	1438	0.24	1452
Cobalt-oxygen	1451	0.23	1480
Copper-sulfur	1067	0.77	1083
Silver-sulfur	906	1.8	960
Chromium-sulfur	1550	2.2	1615
Silver-phosphorous	878	1.0	960
Nickel-phosphorous	880	11.0	1452
Copper-phosphorous	714	8.4	1083
Molybdenum-silicon	2070	5.5	2625
Aluminum-silicon	577	11.7	660

The flow gas would contain small amounts of oxygen, hydrogen disulfide, phosphine, or silane, as appropriate. However, silicon would not be easily removable, and the bond in such a case could not, strictly speaking, be called "direct."

Interaction Parameters in the Zn-Pb-Sn System at Low Zinc Concentration

Z. Moser*,[1] and W. Zakulski

Institute for Metal Research, Polish Academy of Sciences, Kraków, Poland

ABSTRACT

The thermodynamic properties of liquid dilute zinc solutions at a lead concentration of $X_{Pb} = 0.01$-0.7 molar fraction were determined by means of emf measurements of concentration cells. These investigations combined with previous analogical experiments at a tin concentration of $X_{Sn} = 0.01$-0.1 molar fraction enabled the calculation of ternary interaction parameters ϵ_{Zn}^{Pb} and ϵ_{Zn}^{Sn} from plots $(\ln \gamma_{Zn})_{X_{Zn}\to 0}$ *vs.* X_{Pb}. For the binary end-points on the plots $\ln \gamma_{Zn}$ *vs.* X_{Pb} and $(\ln \gamma_{Zn})_{X_{Zn}\to 0}$ *vs.* X_{Pb} separate measurements were carried out for Zn-Sn and Zn-Pb systems at concentrations up to 0.1 molar fraction of zinc. Experimental results were interpreted by means of Krupkowski's formalism and attempts were made to calculate ϵ_{Zn}^{Pb} and ϵ_{Zn}^{Sn} on the basis of limiting values of activity coefficients of components of binary systems Zn-Sn, Zn-Pb, and Pb-Sn.

Initiated several years ago, experimental investigations on dilute binary and ternary liquid metal solutions by the emf method of concentration cells have several aims. First of all, from the experimental point of view it was necessary to adjust the concentration range where the emf method of concentration cells gives satisfactory results. It was shown that experiments on zinc alloys at a concentration of $X_{Zn} = 0.01$-0.1 molar fraction give results associated with considerable error, in the case of alloys like Zn-Cd (1), Zn-In (2), and Zn-Ga (3) with components which are close in position to zinc in the electromotive series. This is the result of side reactions between $ZnCl_2$ from the electrolyte and cadmium, indium, gallium from the alloy electrode, respectively. As a result, when composite binaries show side reactions, experiments in the ternary systems (4) were not carried out at the lowest concentration, $X_{Zn} = 0.01$ mole fraction. The binary systems influence the thermodynamic behavior in ternary systems, especially when they show considerable deviations from Raoult's law. For example the Zn-Pb system with marked positive deviations, plays a decisive role in investigations on ternary systems when small amounts of a third component (Bi,Sb,In, and Cd) are added (4). The present measurements on the Zn-Pb-Sn ternary system fit this pattern. The analysis of the plots $(\ln \gamma_{Zn})_{X_{Zn}\to 0}$ *vs.* X_i (where i is component 2 or 3 of the investigated ternary) have shown that the direction and magnitude of deviation from linear dependence is directly connected with properties of the 2-3 system without zinc (4). The aim of the present paper is the determination of ternary interaction parameters ϵ_{Zn}^{Pb} and ϵ_{Zn}^{Sn} from experimental data from plots $(\ln \gamma_{Zn})_{X_{Zn}\to 0}$ *vs.* X_{Pb}. These plots were obtained by combining the results from a previous paper (5) at $X_{Sn} = 0.01$-0.1 with the data presented in this paper at $X_{Pb} = 0.01$-0.7 mole fraction. Some attempts were carried out also to calculate both ϵ_{Zn}^{Pb} and ϵ_{Zn}^{Sn} from the limiting values of the activity coefficients of the composite binaries.

Experimental

Experiments were carried out over the temperature range 714°-877°K by means of concentration cells with liquid electrodes and liquid electrolyte according to the following scheme

$$Zn(1)|ZnCl_2 \text{ in } (LiCl\text{-}KCl)(1)|Zn\text{-}Pb\text{-}Sn(1) \quad [1]$$

The details of experimental arrangements were given in preceding papers (6) and (7). Emf measurements were carried out at concentrations $0.03 \leq X_{Zn} \leq 0.1$ and when $0.01 \leq X_{Pb} \leq 0.7$ mole fraction. Emfs were measured against a zinc reference electrode and simultaneously against binary solutions of Zn-Sn or Zn-Pb of the same zinc concentration as for the ternary alloys. Such a procedure has been carried out to test whether the results for binary alloys are similar to those previously obtained in separate measurements for Zn-Sn(1) and Zn-Pb(7) systems with $0.01 \leq X_{Zn} \leq 0.1$ mole fraction.

At the temperature range 714°-877°K both for binary and ternary alloys a linear dependence of emf *vs.* temperature was obtained. In Fig. 1, for example, the emf data at $X_{Zn} = 0.05$ are given. It is clear from this plot that the measurements for some alloys were repeated as shown by open and filled points. The least squares fit was applied to average the data and resultant linear equations of the type $E_{mV} = a + bT°K$ for $X_{Zn} = 0.05$ are presented in Table I. The data at $0.01 \leq X_{Sn} \leq 0.1$ as well as for other zinc concentrations are taken from previous measurements (5). This table also contains the values of correlation coefficients and standard deviations of slopes and emf data. Next, from linear equations the emf data at chosen temperatures 714°, 757°, 805°, 842°, and 877°K were obtained and recalculated into $\ln \gamma_{Zn}$ acccording to the relation

$$\gamma_{Zn} = \frac{1}{X_{Zn}} e^{-nEF/RT} \quad [2]$$

where γ_{Zn}, X_{Zn} are zinc activity coefficients and its concentration in mole fraction; **F** is Faraday's constant 23,062 cal·V^{-1}; R, gas constant 1987 cal·deg^{-1}; *E*, measured emf value in volts, n, valence of zinc equal 2.

The very small solubility of zinc in the liquid electrolyte does not change the composition of the tested alloys as was shown by chemical analysis after the prolonged time of measurements. The last column of Table I shows the errors in $\ln \gamma_{Zn}$ at 805°K. They are more pronounced at the range of low lead content as the high emf data are recalculated into small values of $\ln \gamma_{Zn}$. The errors in $\ln \gamma_{Zn}$ are especially important as they are used for evaluating the interaction parameters, and it may be assumed that similar errors will be associated with both interaction parameters ϵ_{Zn}^{Pb} and ϵ_{Zn}^{Sn}.

The interaction parameters in dilute solutions were introduced by Wagner (8). For ternary alloys the relation of $\ln \gamma_i$, excluding the higher terms in Taylor's series, is as follows

* Electrochemical Society Active Member.

[1] Present address: Iowa State University, Ames Laboratory, USAEC, Ames, Iowa 50010.

Key words: interaction parameter, concentration cells, dilute zinc solution, Krupkowski's formalism, Wagner's linear equations.

$$\ln \gamma_i/\text{in solvent } k/ = \ln \gamma_i^o + \epsilon_i^i X_i + X_j \epsilon_i^j \quad [3]$$

where γ_i^o is the limiting value of activity coefficient of component i when $X_i = X_j = 0$ and ϵ_i^i, ϵ_i^j are defined as

$$\epsilon_i^i = \left(\frac{\ln \gamma_i}{\partial X_i}\right)_{X_i=0}$$ self-interaction parameter in the binary system i-k

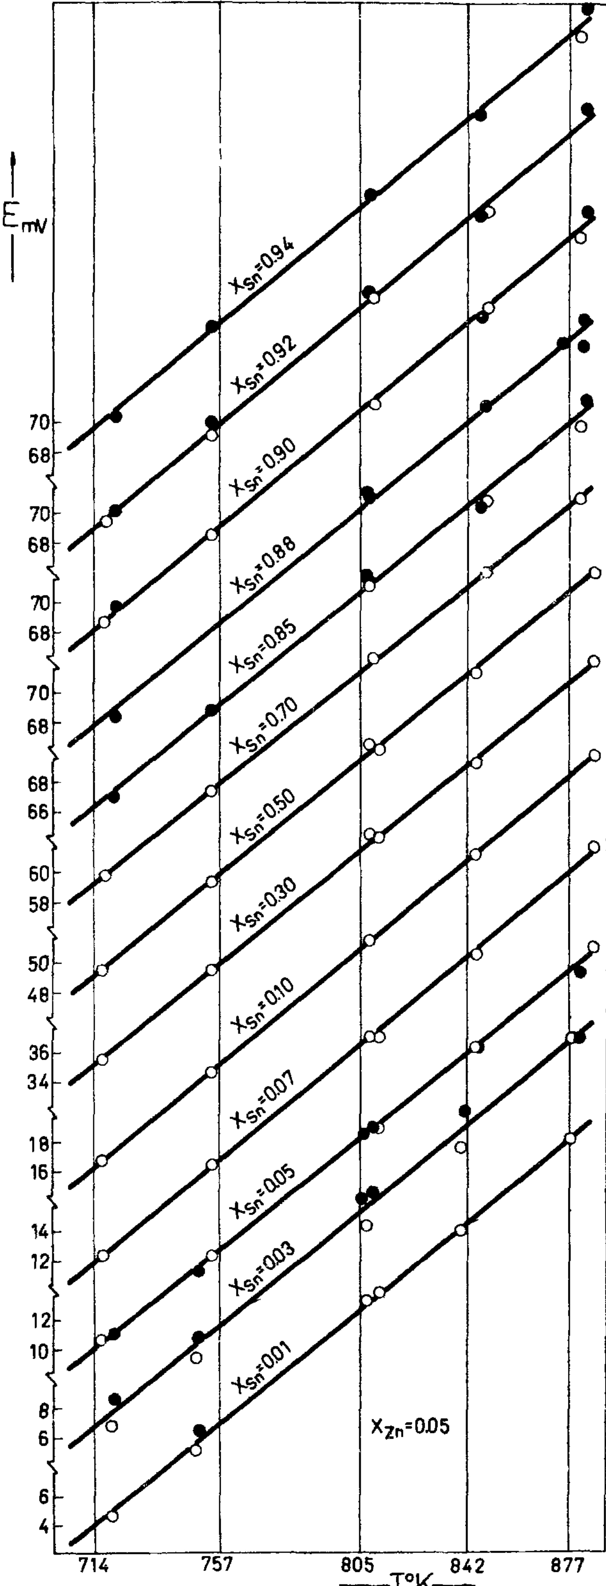

Fig. 1. Relation of E_{mV} vs. T°K in liquid Zn-Pb-Sn system at $X_{Zn} = 0.05$.

and

$$\epsilon_i^j = \left(\frac{\partial \ln \gamma_i}{\partial X_j}\right)_{\substack{X_i=0\\X_j=0}}$$ ternary interaction parameter in the ternary system i-j-k

The range of applicability of Eq. [3] is normally experimentally determined and generally this relation is valid up to the concentration $X_i = X_j = 0.1$ molar fraction.

Values of $\ln \gamma^o_{Zn(Pb)}$, $\ln \gamma^o_{Zn(Sn)}$ and both self-interaction parameters ϵ_{Zn}^{Zn} in binary systems Zn-Pb and Zn-Sn were obtained from Fig. 2 and 3. In Fig. 2 the relation of $\ln \gamma_{Zn}$ *vs.* X_{Zn} in liquid Zn-Sn solutions is plotted. It is seen from this plot that the slopes of the curves drawn through the data are zero, or $\epsilon_{Zn}^{Zn} = 0$, however, the data for 842° and 877°K show appreciable scatter. A zero slope or $\epsilon_{Zn}^{Zn} = 0$ was assumed for these two temperatures because similar results were obtained from previous separate measurements for this system. Besides $\epsilon_{Zn}^{Zn} = 0$ satisfies Eq. [3] in the calculation of $\ln \gamma_{Zn}$ at high tin concentrations. The obtained deviations in Fig. 2 may be influenced by the proximity of tin and zinc in the electromotive series. The calculated difference between standard free energy of formation, $\Delta G^o_{ZnCl_2}$-$\Delta G^o_{SnCl_2}$ equals nearly -7000 cal in which case according to Wagner and Werner (9) the possibility of side reactions may be expected. Extrapolated values of $\ln \gamma_{Zn}$ to $X_{Zn} \rightarrow 0$ enabled the obtaining of the relation of ln γ^o_{Zn} *vs.* temperature in the form

$$\ln \gamma^o_{Zn(Sn)} = \left(\frac{1039}{T} - 0.74\right) \quad [4]$$

In Fig. 3, the experimental data of $\ln \gamma_{Zn}$ *vs.* X_{Zn} in the system Zn-Pb are plotted. They result in negative values of ϵ_{Zn}^{Zn} and in the relation of $\ln \gamma^o_{Zn}$ *vs.* temperature of the form

$$\ln \gamma^o_{Zn(Pb)} = \left(\frac{2924}{T} - 0.965\right) \quad [5]$$

In Fig. 3, deviations from linear dependence are observed at $X_{Zn} = 0.1$. These may result from the proximity of the immiscibility gap in the liquid state. The dashed line extrapolation for the temperatures of 714° and 757°K refers to this immiscibility region.

The results obtained from both Fig. 2 and 3 for both systems Zn-Pb and Zn-Sn examined simultaneously with ternary alloys Zn-Pb-Sn are similar to previous separate measurements (1, 7). In Table II the data from both sets of measurements for ϵ_{Zn}^{Zn} are summarized. Some slight differences in ϵ_{Zn}^{Zn} for the Zn-Pb system appear at the higher temperatures. Both relations for limiting activity coefficients from Ref. (1) and (7) are very similar to Eq. [4] and [5], namely ln $\gamma^o_{Zn(Sn)} = (1119/T - 0.84)$ and $\ln \gamma^o_{Zn(Pb)} = (2798/T - 0.96)$.

The interaction parameters ϵ_{Zn}^{Pb} and ϵ_{Zn}^{Sn} were obtained in the following manner. The data of $\ln \gamma_{Zn}$ *vs.* X_{Pb} for ternary alloys were plotted in Fig. 4-7. From these figures the values of $\ln \gamma_{Zn}$ at constant X_{Pb}/X_{Sn} ratios were considered. The thirteen ratios chosen as shown in Table III approximately correspond to the concentrations of the particular alloys as given in Table I. The values obtained at zinc concentrations $X_{Zn} = 0.03$-0.1 were used for plots $\ln \gamma_{Zn}$ *vs.* X_{Zn} at constant ratio X_{Pb}/X_{Sn}, and then the respective curves were extrapolated to $X_{Zn} \rightarrow 0$. In Table III the values of $(\ln \gamma_{Zn})_{X_{Zn}\rightarrow 0}$ obtained in this manner are reported, and were used to plot $(\ln \gamma_{Zn})_{X_{Zn}\rightarrow 0}$ *vs.* X_{Pb} in Fig. 8. From Fig. 8 both data of ϵ_{Zn}^{Pb} and ϵ_{Zn}^{Sn} were determined as the slopes of the respective lines over the range up to 0.1 mole fraction of both tin and lead.

In Table II the values of both ternary interaction parameters are given. In the case of ϵ_{Zn}^{Sn} the data from a previous paper (5) are also included showing nearly

* Errors were calculated for 95% confidence range of emf values as obtained from least squares fit.
a, intercept in the linear equation.
b, slope of the line E_{mV} vs. temperature, mV/K°.
r, the correlation coefficient.
$s(b)$, standard deviation of the slope.
$s(\bar{y})$, standard deviation of the electromotive force.
X_{Zn}, X_{Pb}, X_{Sn}, mole fractions weighed-in basis. For repeated measurements, the mean values of all alloys for the same composition.

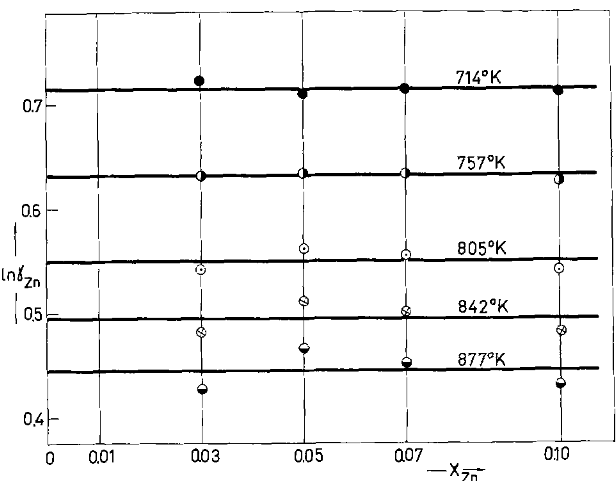

Fig. 2. $\ln\gamma_{Zn}$ **vs.** X_{Zn} **in the Zn-Sn liquid solutions at temperatures 714°-877°K.**

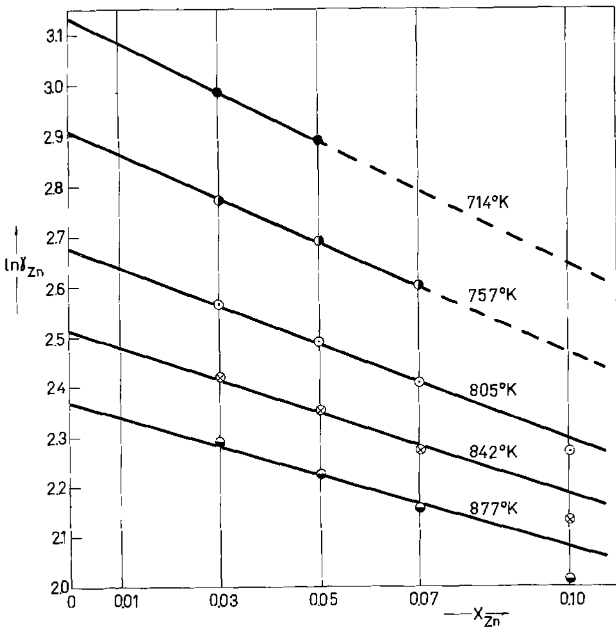

Fig. 3. $\ln\gamma_{Zn}$ **vs.** X_{Zn} **in the Zn-Pb liquid solutions at temperatures 714°-877°K.**

identical values. In Ref. (5) the values of $\epsilon_{Zn}{}^{Sn}$ were obtained from the plots of $\ln\gamma_{Zn}$ vs. X_{Sn} and $[(\partial \ln \gamma_{Zn})/(\partial X_{Sn})]_{X_{Zn}=\text{const}, X_{Sn}=0}$ vs. X_{Zn} using the results only at $0.01 \leq X_{Sn} \leq 0.1$ mole fraction.

The binary end points in Fig. 4-8 were taken from Fig. 2 and 3 for Zn-Pb and Zn-Sn systems, respectively. In general, it may be assumed that the extrapolation from ternary data is in good agreement with the binary data. Some differences appear when $X_{Zn} = 0.07$ and 0.1 when $X_{Sn} = 0$ as a result of deviations from linearity in Fig. 3, when $X_{Zn} = 0.1$ mole fraction.

Application of Krupkowski's Method in the Thermodynamic Analysis of Binary and Ternary Systems

For binary solutions Krupkowski (10) presented relations of the form

$$\ln \gamma_j = \omega_{jk}(T) \left[(1 - X_k)^{m_{jk}} - \frac{m_{jk}}{m_{jk} - 1}(1 - X_k)^{m_{jk}-1} + \frac{1}{m_{jk} - 1} \right] \quad [6]$$

$$\ln \gamma_k = \omega_{jk}(T)(1 - X_k)^{m_{jk}} \quad [7]$$

Equation [6] is derived from Eq. [7] using the Gibbs-Duhem equation. As results from Eq. [6] and [7] the function $\omega(T)$ and m should be determined from experimental results. Usually for this purpose the data at concentrations $X_k = 0.1$-0.9 mole fraction are used. Analysis of such a procedure has been demonstrated in Ref. (11).

From previous papers Eq. [6] and [7] in the binary systems take the following forms: from Ref. (12) in the Zn-Sn liquid solutions

$$\ln \gamma_{Zn} = \left[\frac{2489}{T} + 1.824(\ln T - 1) - 12.929 \right] (1 - X_{Zn})^{1.1} \quad [8]$$

$$\ln \gamma_{Sn} = \left[\frac{2489}{T} + 1.824(\ln T - 1) - 12.929 \right] [(1 - X_{Zn})^{1.1} - 11(1 - X_{Zn})^{0.1} + 10] \quad [9]$$

from Ref. (4) in the Zn-Pb liquid solutions

$$\ln \gamma_{Zn} = \left(\frac{3000}{T} - 1.059 \right) (1 - X_{Zn})^{1.53} \quad [10]$$

$$\ln \gamma_{Pb} = \left(\frac{3000}{T} - 1.059\right)[(1 - X_{Zn})^{1.53} - 2.887(1 - X_{Zn})^{0.53} + 1.887] \quad [11]$$

and finally for the Pb-Sn liquid solutions, Ref. (13)

$$\ln \gamma_{Pb} = \frac{638}{T}(1 - X_{Pb})^{1.9} \quad [12]$$

$$\ln \gamma_{Sn} = \frac{638}{T}[(1 - X_{Pb})^{1.9} - 2.111(1 - X_{Pb})^{0.9} + 1.111] \quad [13]$$

From Eq. [7] it is clear that when $X_k \to 0$, $\ln \gamma^o_k = \omega_{jk}(T)$, and from Eq. 6, when $X_j \to 0$, $\ln \gamma^o_j = \omega_{jk}(T) \times [1/(m_{jk} - 1)]$. In the case of Zn-Pb, Zn-Sn, and Pb-Sn binary systems Eq. [7] has been used for zinc and lead, respectively. As a result $\ln \gamma^o_{Zn(Sn)}$ and $\ln \gamma^o_{Zn(Pb)}$ are equal directly to respective $\omega(T)$ functions in Zn-Pb and Zn-Sn systems. In this manner determination of the $\omega(T)$ function from concentrations $X_k = 0.1$-0.9 may be additionally tested by means of experiments in dilute solutions. It is interesting to note that the numerical results from Eq. [4] and [5] and as $\omega(T)$ from relations [8]-[9] and [10]-[11] at considered temperatures 714°-877°K are very similar. It is also true in the case of the Zn-Sn system when the form of the $\omega(T)$ relation is different in comparison with Eq. [4]. The limiting activity coefficients are readily calculated from Eq. [6] and [7] for both components and will be used in the next part of the paper in calculations of ϵ_{Zn}^{Pb} and ϵ_{Zn}^{Sn}.

Krupkowski's method for obtaining the relations of activity coefficients in multicomponent systems requires only the data of composite binary systems in the form of Eq. [6] and [7]. The details of such procedure were given in a previous paper, Ref. (14). Assuming this procedure and Eq. [8]-[13] the $\ln \gamma_{Zn}$ in Zn-Pb-Sn system has the following form

$$\ln \gamma_{Zn} = -\omega_{ZnPb}(1 - X_{Zn})^{m_{ZnPb}-2}X_{Zn}X_{Pb} + \omega_{ZnPb}(1 - X_{Zn})^{m_{ZnPb}-2}X_{Pb} - \omega_{ZnSn}(1 - X_{Zn})^{m_{ZnSn}-2}X_{Zn}X_{Sn} + \omega_{ZnSn}(1 - X_{Zn})^{m_{ZnSn}-2}X_{Sn} - \omega_{PbSn}(1 - X_{Pb})^{m_{PbSn}-2}X_{Pb}X_{Sn} \quad [14]$$

From Eq. [14] when $X_{Zn} \to 0$, $\ln \gamma_{Zn}$ takes the form

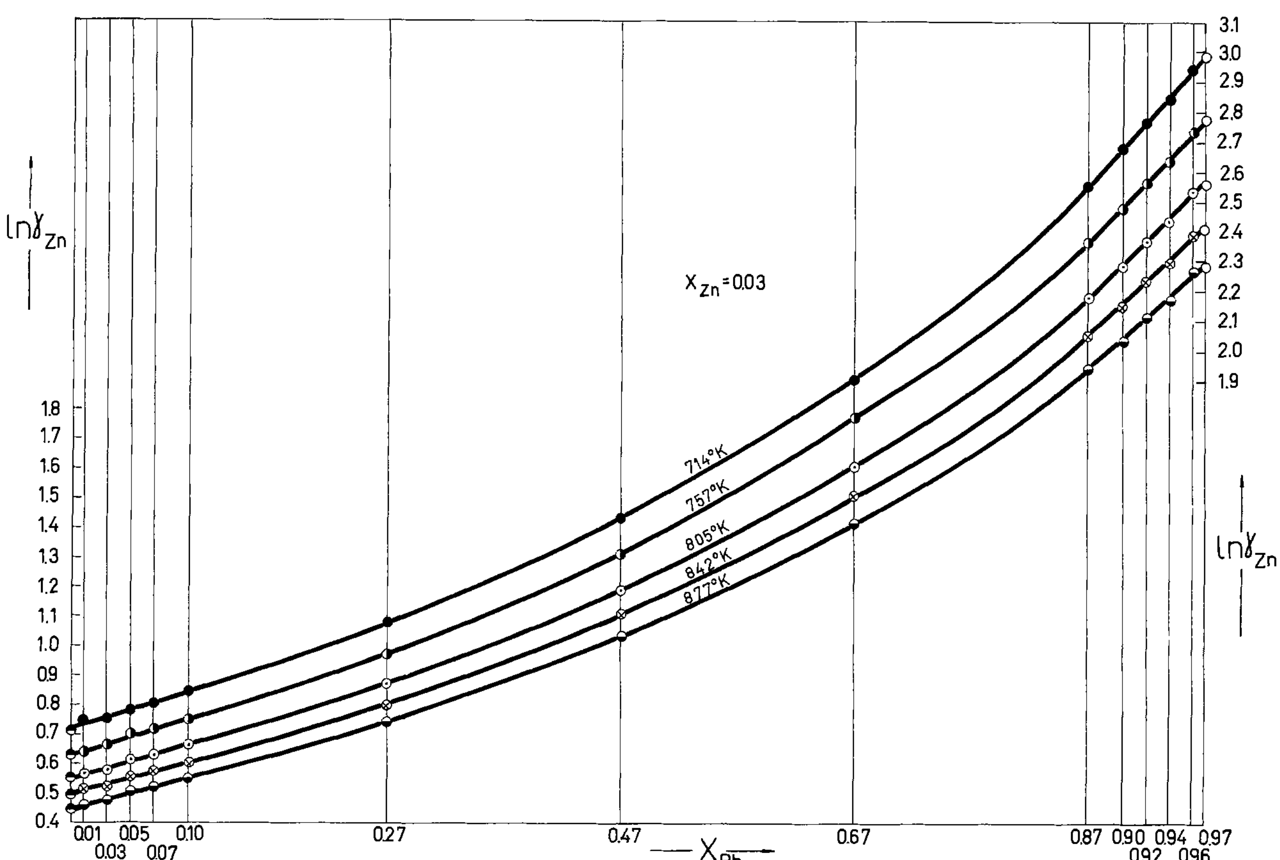

Fig. 4. $\ln \gamma_{Zn}$ vs. X_{Pb} in the Zn-Pb-Sn liquid solutions at temperatures 714°-877°K when $X_{Zn} = 0.03$. ●, Obtained from Fig. 2 and ○, obtained from Fig. 3.

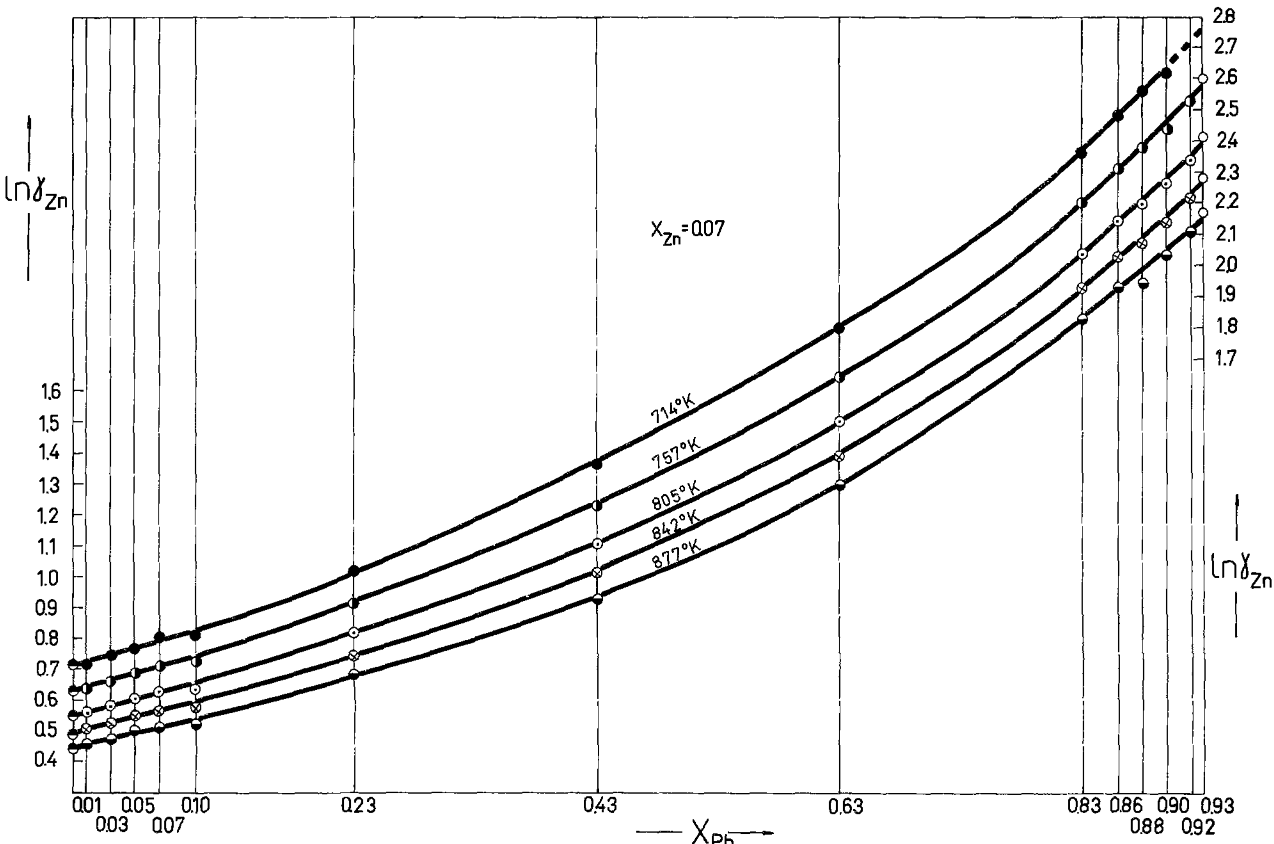

Fig. 6. $\ln\gamma_{Zn}$ vs. X_{Pb} in the Zn-Pb-Sn liquid solutions at temperatures 714°-877°K when $X_{Zn} = 0.07$. ◓, Obtained from Fig. 2 and ○, obtained from Fig. 3.

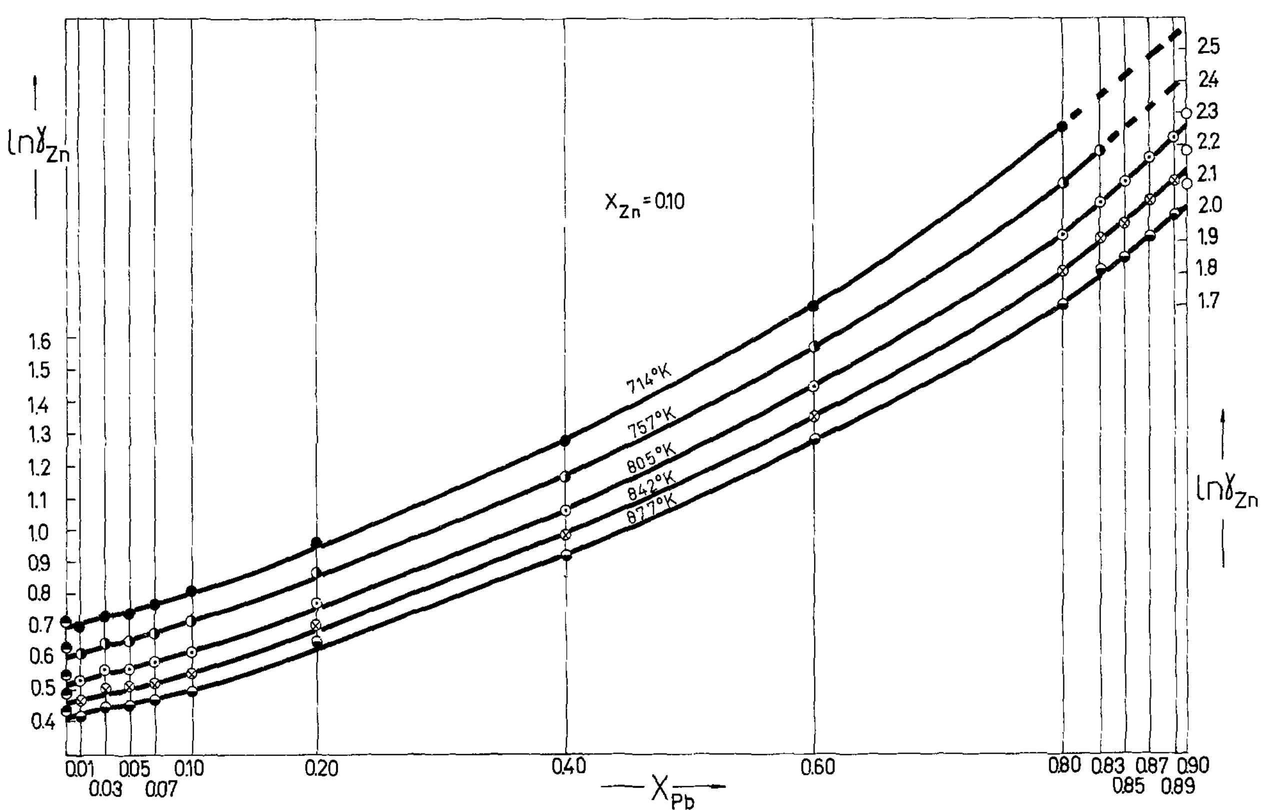

Fig. 7. $\ln\gamma_{Zn}$ *vs.* X_{Pb} in the Zn-Pb-Sn liquid solutions at temperatures 714°-877°K when $X_{Zn} = 0.1$. ◓, Obtained from Fig. 2, and ○, obtained from Fig. 3.

$$(\ln\gamma_{Zn})_{X_{Zn}\to 0} = \omega_{ZnPb}X_{Pb} + \omega_{ZnSn}X_{Sn} - \omega_{PbSn}(1 - X_{Pb})^{m_{PbSn}-2}X_{Pb}X_{Sn} \quad [15]$$

In both Eq. [14] and [15] the last term corresponds to the thermodynamic properties of the Pb-Sn system. Values of $\ln\gamma_{Zn}$ at $X_{Zn} = 0.05$ were calculated from Eq. [14] and values of $(\ln\gamma_{Zn})_{X_{Zn}\to 0}$ were calculated from Eq. [15], in both cases at 714°, 805°, and 877°K. It is seen when comparing these calculated values summarized in Table III, with experimental values in Tables I and III that the agreement is satisfactory, except for the central region where the concentration of lead is $0.3 \leq X_{Pb} \leq 0.7$. It is probably the result of inaccurate determination of $\omega(T)$ and m in the Pb-Sn system.

It is interesting to note that by differentiating Eq. [14] it is possible to obtain formulas for calculation of both ϵ_{Zn}^{Pb} and ϵ_{Zn}^{Sn} in which the $\omega(T)$ functions for binary systems appear. Similar formulas with the relations for limiting activity coefficients were proposed by Alcock and Richardson (15, 16) and by Lupis and Elliott (17, 18) assuming a random distribution of atoms in solution

$$\epsilon_{Zn}^{Pb} = \ln\gamma^{o}_{Zn(Pb)} - \ln\gamma^{o}_{Zn(Sn)} - \ln\gamma^{o}_{Pb(Sn)} \quad [16]$$

$$\epsilon_{Zn}^{Sn} = \ln\gamma^{o}_{Zn(Sn)} - \ln\gamma^{o}_{Zn(Pb)} - \ln\gamma^{o}_{Sn(Pb)} \quad [17]$$

By application of Eq. [6] and [7] the limiting activity coefficients may be easily calculated from $\omega(T)$ and m of binary systems as was previously mentioned. Therefore, substituting appropriate $\omega(T)$ and m from Eq. [8]-[13] into Eq. [16] the values of ϵ_{Zn}^{Pb} at temperatures 714°, 805°, and 877°K were calculated with numerical values of 1.53, 1.43, and 1.33. Analogically from Eq. [17] at the same temperatures the resulting values of ϵ_{Zn}^{Sn} are −3.42, −3.21, and −3.00. The values of both ternary interaction parameters differ slightly from those obtained from experiments, but they exhibit the same sign and dependence upon temperature.

Discussion

The experimental data permitted the determination of both ternary interaction parameters ϵ_{Zn}^{Pb} and ϵ_{Zn}^{Sn} from plots $(\ln\gamma_{Zn})_{X_{Zn}\to 0}$ *vs.* X_{Pb}. Both values of ϵ_{Zn}^{Pb} and ϵ_{Zn}^{Sn} were also compared with calculated data on the basis of limiting activity coefficients obtained from $\omega(T)$ and m of respective binary systems interpreted by Krupkowski's method.

Okajima and Pehlke (19) as well as Cleveland, Okajima, and Pehlke (20) also reported from emf measurements the data of ϵ_{Zn}^{Pb} and ϵ_{Zn}^{Sn} but they limited the experiments only to 0.1 mole fraction of tin and lead, respectively. At the temperature of 823°K they found $\epsilon_{Zn}^{Pb} = 2.2$ and $\epsilon_{Zn}^{Sn} = -3.6$ which compare with values of about 1.17 and -4.0, respectively, as interpolated from our data in Table II. In the next reference, Gluck and Pehlke (21) also presented the plot of $(\ln\gamma_{Zn})_{X_{Zn}\to 0}$ *vs.* X_{Pb} for Zn-Sn-Pb system combining their results for dilute solutions to $X_{Pb} = X_{Sn} = 0.1$ mole fraction with extrapolated data for the central region. However, their plots using literature data (22) differ from the results presented in Fig. 8. This disagreement is believed to be the result of their less precise extrapolation of $\ln\gamma_{Zn}$ to $X_{Zn} \rightarrow 0$ for $X_{Zn} \geqq 0.1$.

The magnitude of the deviation from a straight line obtained by connecting $\ln\gamma^{o}_{Zn(Sn)}$ and $\ln\gamma^{o}_{Zn(Pb)}$ in Fig. 8 is influenced by the thermodynamic properties of the Pb-Sn system. Positive departure from Raoult's law in this system results in negative deviations from linearity (23). The data in Fig. 8 at $X_{Pb} = 0.53$ and $X_{Sn} = 0.47$ result in the experimental deviation in $\ln\gamma_{Zn}$ at temperatures 714°, 805°, and 877°K of the magnitude 0.54, 0.41, and 0.38. These data may be compared using Eq. [15] and assuming that deviation from linearity is governed by the term $-\omega_{PbSn}(1 - X_{Pb})^{m_{PbSn}-2}X_{Pb}X_{Sn}$. However, such calculations exhibit the deviations of the order 0.24, 0.21, and 0.19 at the mentioned temperatures. It is probably the result of inaccuracy in the $\omega(T)$ and m in Eq. [12] and [13] for the Pb-Sn system. These parameters were calculated by Ptak (13) using the Pb-Sn phase diagram and probably are subject to appreciable uncertainty. The close position of lead and tin in the electromotive series excludes however the use of concentration cells and obtaining more precise data.

The deviation from linearity may also be calculated according to Richardson (24) and is characterized approximately by the term $-\Delta G^{*}_{PbSn}/RT$ where ΔG^{*}_{PbSn} is the molar excess free energy in the Pb-Sn system. Using the data for ΔG^{*}_{PbSn} from the Hultgren *et al.* monograph, (25) at 823°K, $X_{Pb} = X_{Sn}$ the value of 0.32 for the deviation was obtained which corresponds to some extent to the results shown in Fig. 8.

Error analysis of the experimental data at the chosen concentration $X_{Zn} = 0.05$ molar fraction results in maximal errors in $\ln\gamma_{Zn}$ of about ±4%. Next, the $\ln\gamma_{Zn}$ data are the starting point for determination of both ϵ_{Zn}^{Sn} and ϵ_{Zn}^{Pb}, and therefore one may assume that ternary interaction parameters will be associated with similar errors.

It is assumed that in investigations on dilute liquid solutions the most important phenomena are connected with reciprocal interactions of a respective group of atoms. The simpler cases are those in which the composite binary alloys show positive deviations from Raoult's law. Then, the attractive forces between the same species of atoms are greater than those between different species of atoms. In such a case the ternary interaction parameters of the type ϵ_1^{2} and ϵ_1^{3} from Eq. [16] and [17] result in comparatively good agreement with experimental data. When one of the binaries shows marked deviations from Raoult's law, as for instance Zn-Pb, in comparison to other systems such as Zn-Sn and Pb-Sn in the investigated Zn-Pb-

Sn ternary system, then the properties of such a binary system play a decisive role. This system has a rather dominant value of $\ln \gamma^o_{Zn(Pb)}$ in relation to $\ln \gamma^o_{Zn(Sn)}$ and $\ln \gamma^o_{Pb(Sn)}$ which strongly influences both ϵ_{Zn}^{Pb} and ϵ_{Zn}^{Sn} when calculated from Eq. [16] and [17]. Future experimental research in ternary systems in dilute solutions will be directed toward verification of Eq. [16] and [17] and also to the combinations of the interaction parameters thus obtained with the energy of interaction of respective groups of different atoms.

Micro Weighing Study of Iodinations of Thin Metal Films with Quartz Crystal Oscillators

M. Shiojiri

Department of Physics, Kyoto Technical University, Matsugasaki, Sakyo-ku, Kyoto 606, Japan

ABSTRACT

The reactions of iodine vapor with vacuum-deposited copper and lead films have been investigated in the temperature range 25°-300°C. Below 150°C, the iodination of copper films obeys the parabolic rate relationship, and its activation energy is estimated to be 3.9 kcal/mole. Above 150°C, the iodination obeys the linear rate relationship, and the iodination rate decreases with increasing temperature. The chemisorption of iodine gas is the rate-determining factor of the linear reaction and leads to the observed temperature dependence of the reaction. The iodination of lead films approximately obeys the parabolic rate relationship, and its activation energy is 13.9 kcal/mole.

Tammann and Köster (1, 2) found in the early studies of the reactions of various gases with metals that the reaction rates for the iodination of silver, copper, and lead were independent of temperature. There have been very few studies of the halogenation of such metals since (3-6), and such peculiar reactions which do not obey an Arrhenius equation are still unclear (7) and await explanation (8). The method for measuring the film thickness based on interference colors as used in their experiments was not very accurate, and much more accurate experimentation is required for a clear understanding of the halogenation mechanism.

Weight gains due to the reaction of iodine vapor with vacuum-deposited copper films were previously measured in the temperature range from 25° to 300°C with quartz crystal oscillators (9). It is the object of the present paper to discuss in detail the iodination of copper films. The results are also given of investigations concerning the reaction of iodine vapor with vacuum-deposited lead films in the temperature range 25°-300°C. The reactions of iodine vapor with silver films have been discussed in previous papers (10-12).

Key words: tarnishing, vacuum-deposited film, diffusion, copper, lead.

Experimental

The weight gains due to the iodination of copper and lead films were continuously measured by using a quartz crystal oscillator microbalance with a counting ratemeter and a pen recorder (13). Quartz plates with 3.58 MHz resonance frequency, whose sensitivity for mass determination is 2.89×10^7 Hz/(g/cm^2), were used. The quartz plates were vibrated at an exciting power of about 5 mW, and the vibration had no appreciable influence on the reactions of iodine with the metal films (14).

About 5000Å thick copper (99.999%) films were prepared by vacuum-deposition onto one of the gold electrodes of the water-cooled quartz plates in a vacuum of 5×10^{-7} Torr. The quartz plate was placed in a reaction chamber for the iodination. Specimen lead (99.99%) was vacuum-deposited onto the quartz plate in the reaction chamber evacuated to a pressure of 2×10^{-7} Torr or less, so as to minimize the surface oxidation. The iodine vapor was immediately introduced into the chamber, without exposing the specimen to the air. The gold electrodes, when in contact and alloyed with copper or lead, were appreciably attacked by iodine vapor at higher temperatures. Therefore, in the experiments at temperatures above 150°C, the specimen films were directly deposited onto one side of the plates and were simultaneously used as one of the electrodes. Both of copper and lead films were polycrystalline, preferably oriented with the (111) planes parallel to their surfaces. The steps in the experimental procedure were the same as described in the previous papers (10, 12).

Results

Iodination of copper films.—Various experiments were repeated at a given temperature and pressure, and the reproducibility was usually good. Some rate curves are presented in Fig. 1. The iodination was performed at an iodine pressure of 0.032 Torr. The reaction product was the γ-form (zinc blende type) of cuprous iodide crystals. The mean thickness of the grown cuprous iodide layer can be estimated by assuming that the film was uniformly attacked by iodine and the product was the stoichiometric compound. The scales of micrometers for the mean thickness of the cuprous iodide layer, and of milligrams per square centimeter for the weight gain, are also presented. The results showed a clear temperature dependence of the iodination of copper which is in disagreement with the conclusion of Tammann and Köster (2); between 25° and 150°C the reaction rate increases with increasing temperature, but above 150°C it decreases with temperature. Squares of the weight gains plotted against time fell on straight lines below 150°C. This shows that the reaction of iodine with copper between 25° and 150°C approximately obeys the parabolic rate relationship. However, square plots of the data above 150°C did not lie on straight lines; rather, the curves shown in Fig. 1 lie on straight lines after about 10 sec. Therefore, the reaction above 150°C seems to obey the linear rate relationship rather than parabolic rate relationship.

The logarithms of the reaction rates at a reaction time of 30 sec are plotted against the inverse of reaction temperature in Fig. 2. Black and white circles show the corresponding reaction rates for the parabolic and linear iodinations, respectively. The diameter of the circles is almost equal to the probable error of the reaction rates. It is clear that the rates are at a maximum near 150°C. The rate constant k_p was determined for each rate curve represented by the parabolic relationship $(df)^2 = k_p t$, where df is frequency change and t is time. Arrhenius plots of k_p lie on a straight line, like the reaction rates below 150°C lie on a straight line in Fig. 2. Thus, the activation energy for the parabolic reaction has been estimated to be 3.9 kcal/mole, and k_p for the reaction at an iodine pressure of 0.032 Torr is represented as

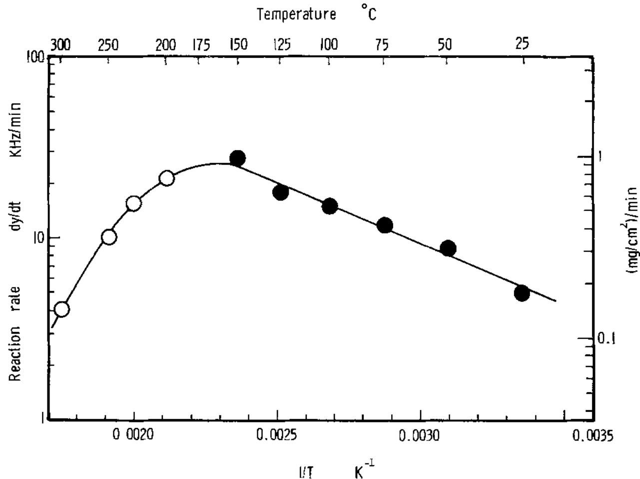

Fig. 2. Temperature dependence of parabolic (black) and linear reaction rates (white) at a reaction time of 30 sec, at iodine pressure of 0.032 Torr.

$$k_p = 7.1 \times 10^4 \exp(-3900/RT)\,\mathrm{kHz}^2/\mathrm{min}$$

$$= 85.5 \exp(-3900/RT)\,(\mathrm{mg/cm}^2)^2/\mathrm{min}$$

where R is the gas constant and T is absolute temperature.

Iodination of lead films.—Double logarithmic plots of weight gain data for the iodinations of lead films are presented in Fig. 3. The reproducibility was usually good under the experimental condition that the specimen lead surface was never exposed to the air and the residual gas pressure was less than 2×10^{-7} Torr during the deposition of lead and the iodination. Lead iodide (PbI_2, hexagonal) crystals were formed. Since the data fall on straight lines with a gradient of about ½, the reaction of iodine with lead films approximately obeys the parabolic relationship, which has been reported by Tammann and Köster (2). The reaction rate evidently increases with increase of temperature, in disagreement with their conclusion that the reaction rate was independent of temperature. The experiments were performed at iodine pressures of 0.08, 0.13, 0.21, and 0.41 Torr, and a definite difference could not be recognized among the data for the reactions at the same temperature.

The reactions below 100°C were complicated. The reproducibility of experiments was not very good. The reaction rates slowed down, especially for an initial few minutes, and thus the reaction could not be represented by a simple equation. The reaction rate was apt to decrease with decreasing iodine pressure. Dotted curves in Fig. 3 are the data for the reaction of the lead films, which were once exposed to the air for a short time, with iodine at 300°, 200°, and 150°C. The curves show that the retardation of reaction by a surface oxidation was larger with decreasing temperature. Thus, it is reasonable to assume that the iodination below 100°C was influenced by a little surface oxidation owing to the residual gas and showed the poor reproducibility.

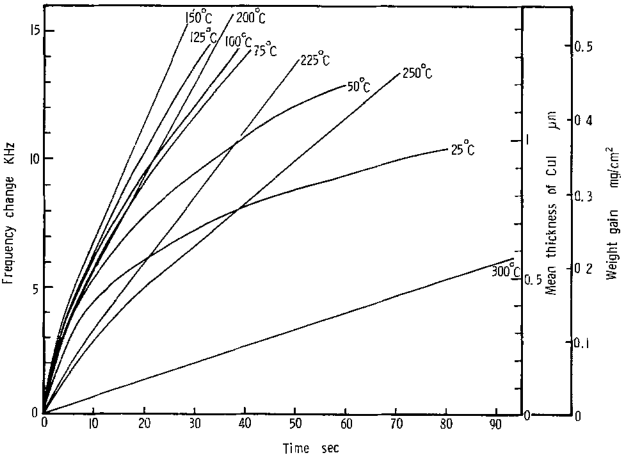

Fig. 1. Weight gain data for iodination of copper films at iodine pressure of 0.032 Torr.

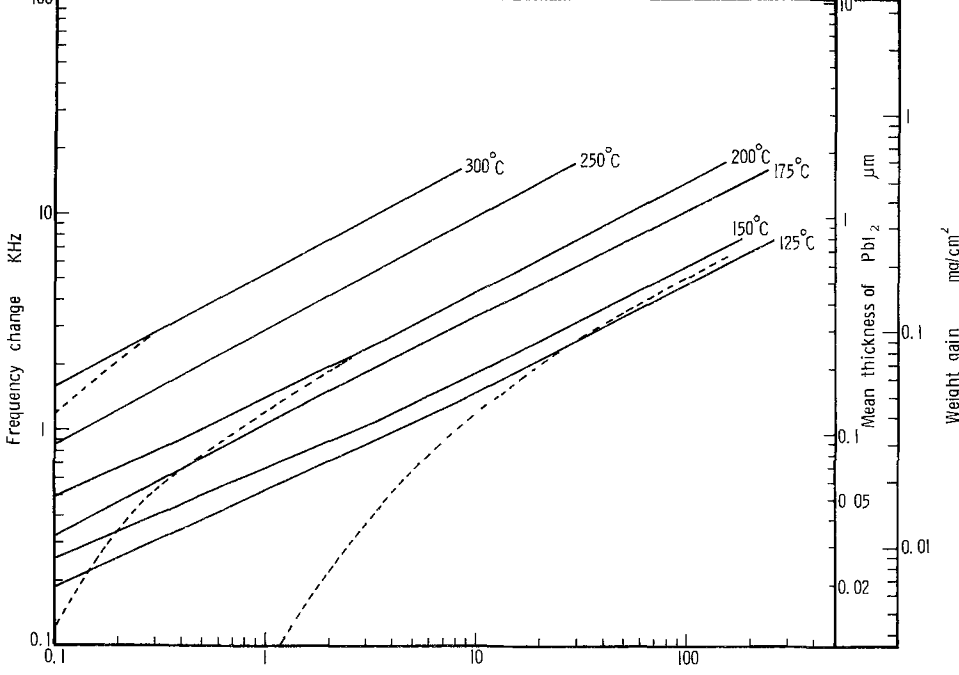

Fig. 3. Double logarithmic plots of weight gain data for iodination of lead films at iodine pressure of 0.21 Torr.

Figure 4 shows an Arrhenius plot that applies to this reaction. The probable errors of the rate constants are equal to or less than the diameter of the circles. The rate constant k_p for this parabolic iodination is represented as

$$k_p = 6.4 \times 10^6 \exp(-13{,}900/RT)\ \text{kHz}^2/\text{min}$$
$$= 77 \times 10^2 \exp(-13{,}900/RT)\ (\text{mg/cm}^2)^2/\text{min}$$

Discussion

The present results for the iodination of copper are not in agreement with the early measurements of Tammann and Köster (2), who reported the independence of reaction rate from temperature, as described above. Nagel and Wagner (5) reported that a tarnish constant of copper in iodine vapor is 3.4×10^{-10} equivalents cm^{-1} sec^{-1} at 195°C and at 46 Torr. Weiss (6) also reported the tarnish constants in the temperature range 105°-440°C at pressure of 1-500 Torr. The constants increase with increase of temperature or pressure. He concluded from his results that in the α- and β-CuI phase region above 420°C, the electron defect conduction was rate determining and in the γ-CuI phase region, ionic conduction was rate determining. The present results for the reactions below 150°C are not contradictory to his conclusion, although our experiments were performed at lower pressure than his experiments, and our accurate weight measurements through the course of the reaction with time confirm the applicability of the parabolic rate relationship.

A very small activation energy of 3.9 kcal/mole was observed for the parabolic iodination of copper below 150°C. According to Wagner theory (5, 6), the absorption of iodine causes cuprous ions and electrons to migrate to the surface and the CuI lattice to extend, leaving the vacancies in the cuprous ion lattice and a defect of electrons. The weight changes due to the absorption of iodine were estimated for the CuI films, which were produced from the 5000Å thick Cu films, by using the results of Maurer (15) who measured the concentration of absorbed iodine by CuI. The weight changes are 1.235 and 0.080 $\mu g/cm^2$ at 25° and 150°C, respectively, when the iodine pressure is 0.032 Torr. The concentration of vacancies of the cuprous ions, whose diffusion is rate determining for the parabolic reaction, definitely decreases with increasing temperature. Thus, the decrease of the vacancy concentration acts on the reaction rate to slow down with increase of temperature and may lead to the very small activation energy.

The decrease of reaction rate with increasing temperature above 150°C cannot be ascribed to the decrease of the vacancy concentration because the parabolic reaction no longer prevails in this temperature range. A phase boundary reaction can be assumed to

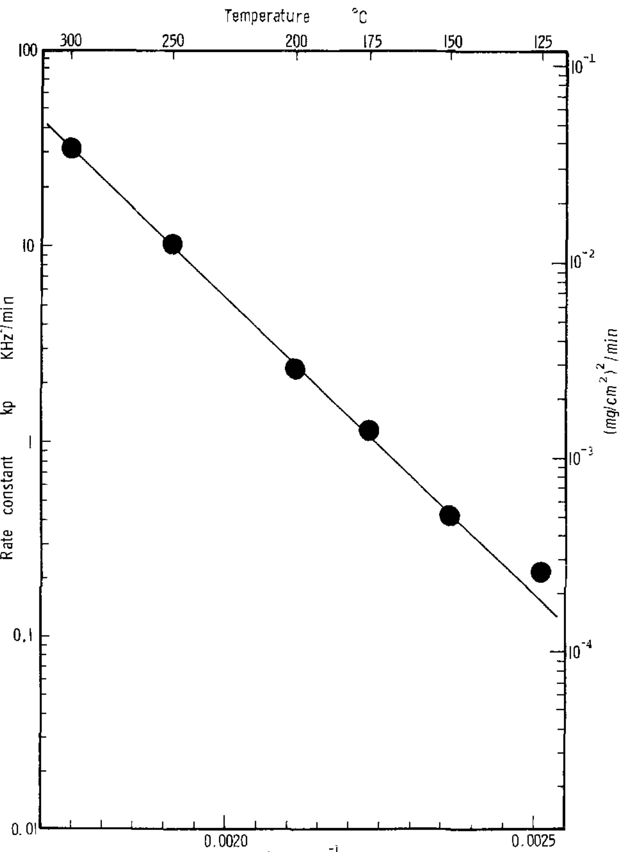

Fig. 4. Temperature dependence of rate constant for iodination of lead films.

be the rate-determining factor in the linear reaction. The most probable mechanism is the chemisorption of iodine atoms and the introduction of chemisorbed ions in the gas/iodide interface. The number of adsorbed iodine atoms staying at the interface is proportional to the number of impinging iodine molecules on the surface and the time of adsorption during which the adsorbed molecules stay at the surface before reevaporation (20). If we assume a heat of adsorption of 9 kcal/mole which is a possible value for the gas consisting of heavy molecules, then the decrease of the adsorbed atoms is about 5-fold between 200° and 300°C, and is in good agreement with the observed decrease of the reaction rate. The effect of adsorption on the linear reaction has been observed between the reactions performed at different iodine pressures. That is, the reaction rate changed from 2.32 to 28.8 ($\mu g/cm^2$)/sec as the iodine pressure was raised from 0.032 to 0.16 Torr at 300°C, while it was little changed at 25°C in the parabolic reaction, as shown in a previous note (9). The increase of the reaction rate, however, is much larger in comparison with the increase of the impinging molecules, which is 5 times between pressures of 0.032 and 0.16 Torr. The result may be ascribed to the increase of a condensation coefficient (the probability that an impinging molecule is adsorbed at the surface) with increasing temperature; the coefficient may increase about 2.5 times between 0.032 and 0.16 Torr.

Since the diffusion rate decreases with increasing layer thickness, the linear rate is applicable only to the point where the diffusion rate becomes comparable with the rate of the phase boundary reaction. With further growth of the protective layer, the diffusion rate becomes the rate-determining factor (12, 16-19), and the parabolic rate relationship prevails. The tarnish constants above 150°C, which were shown by Nagel and Wagner (5) Weiss (6), can be assumed to be those corresponding to this parabolic reaction.

The iodination of lead films followed the parabolic relationship, although in the experiments below 100°C the definite parabolic relationship was not observed because of the tarnishing of the surface by the residual gas. The conduction mechanism of the lead iodide is very complicated because both lead and iodine ions participate in conduction (21). Since the ionic conduction is predominant in any case and since parabolic rate behavior was observed, it can be concluded that electronic conduction through the lead iodide layers is the rate-determining step of the iodination process.

Deposition of Polycrystalline Silicon by Pyrolysis of Silane in Argon

John Y. W. Seto

Electronics Department, General Motors Research Laboratories, Warren, Michigan 48090

ABSTRACT

Deposition of silicon on thermally grown silicon dioxide substrates by pyrolysis of silane in argon is postulated as a three-step process involving adsorption and decomposition of silane on, and desorption of hydrogen from the substrate surface. This postulate was verified by experimental data. The morphology of the polysilicon films was strongly affected by the cleaning process employed before the silicon dioxide was grown. To obtain an optically smooth surface, it was mandatory that the silicon subtrate be cleaned by a strong oxidizing agent. The grains of the polysilicon film were randomly oriented and the grain size increased as the deposition temperature was increased.

Polycrystalline silicon (polysilicon) is extensively used in silicon technology. Polysilicon films have been used in silicon gate MOS devices (1), as dielectric isolation in high power integrated circuits (2, 3), in stacking gate nonvolatile memory devices (4), and in charge couple devices (5). In some of these applications, it is desirable to be able to deposit polysilicon at a low temperature so as to preserve the doping pro-

Key words: polycrystalline silicon, chemical vapor deposition, chemical kinetics, thin films, silane.

files. In other applications the surface texture of the polysilicon has a detrimental effect on the device performance. Therefore, it is desirable to be able to deposit optically smooth polysilicon films at low temperatures. Deposition of polysilicon by thermal decomposition of silane in argon was reported by Yasuda *et al.* (6). They showed that the polysilicon deposition rate was higher and the grain size was smaller if argon rather than hydrogen was used as the carrier gas. We report here the study of the kinetics of the polysilicon growth rate as a function of silane concentration in argon and temperature of deposition, and the morphological and crystallographical structure of the polysilicon films prepared.

Film Preparation

The polysilicon films were deposited in a radiant heated horizontal reactor. The walls of the quartz reactor tube were cooled by a flow of 14,000 SLM of air. Both polysilicon-coated and silicon carbide-coated susceptors were used in this study. The susceptor was supported by a horizontal quartz sled. The temperature of the susceptor was measured using a Type S (Pt/Pt + 10% Rh) thermocouple fitted in a hole in the susceptor such that the thermocouple was in thermal contact with the center of the susceptor. The output of the thermocouple controlled the power supplied to the quartzline heating lamps to maintain a preset temperature. The substrates were in thermal contact with the susceptor, therefore, the temperature of the substrates was approximated to be that measured by the thermocouple. The actual substrate temperature could be as much as 30°C cooler than that measured by the thermocouple. This approximation was taken because the reactor was radiant heated and a direct measurement of the substrate temperature by a pyrometer was difficult. However, by making sure that the substrates were in good thermal contact this error could be reduced. Argon was used as the carrier gas. The argon gas source was nominally 99.99% pure; it was passed through a 0.45 μm particle filter and a three-stage (titanium, copper oxide, and molecular sieve) rare gas purifier. The silane used for this work came from a 100% silane source. The carrier gas and silane were mixed before entering the reactor tube. All the gas lines were helium leak checked to ensure no gas contamination due to leakage. The argon flow rate was usually 12.6 SLM (2.7 cm/sec). Deposition temperatures of 650°-800°C and silane flow rates ranging from 0.1 to 1.2% of the total flow rate were studied.

The substrates were 10 ohm-cm, boron-doped, <111> oriented, polished silicon wafers. These wafers were cleaned in a boiling 1:1:1 mixture of methyl alcohol, acetone, and trichloroethylene with ultrasonic agitation. The wafers were then cleaned in acetone and rinsed with deionized water. They were finally cleaned in hot (75°C) HNO_3 for 10 min, spin rinsed, and dried in hot nitrogen. The wafers were immediately transferred to a dry or wet oxygen atmosphere oxidation furnace to grow a silicon dioxide layer of about 1500 or 3000Å thick. Immediately after the oxidation step and as soon as the wafers were cooled down to room temperature, the wafers were transferred to the reactor and polysilicon was deposited to a thickness in the range of 0.5-3 μm. The thickness of the polysilicon films was measured by an infrared interference technique (7); the accuracy of the measurement was periodically checked with a surface profiler.

Growth Rate

In Fig. 1 the growth rate of polysilicon is plotted as a function of $1/T$°K for various silane flow rates. The deposition rate could be varied from 0.01 μm/min at 650°C for 0.1% silane to about 0.5 μm/min at 800°C for a flow of 1.2% silane. It was observed that a straight line could be drawn to pass through points at temperatures higher than 700°C. However, if such a

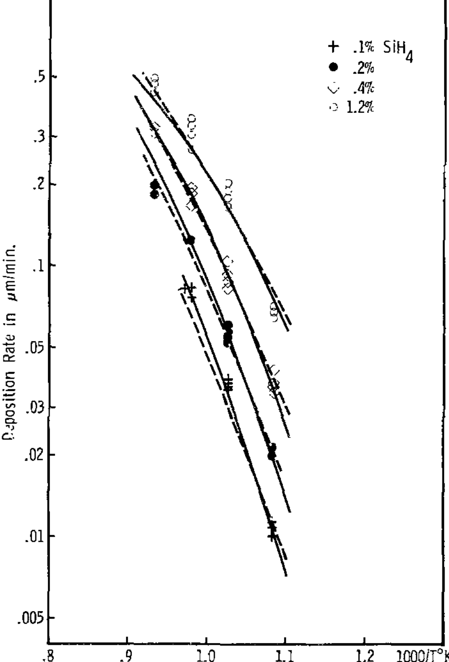

Fig. 1. Experimental and calculated deposition rates vs. $1/T$°K. Dashed line was calculated using all data points. Solid line was calculated by neglecting data points at 800°C.

straight line was drawn it would not pass through the data point at 650°C. The same result was apparently obtained by Yasuda *et al.*, although those authors assumed a straight line and obtained an activation energy of 1.0-1.1 eV. If the same process was done to our data, the slope gave a value of about 1.02 eV.

The kinetics of the decomposition of silane in an inert gas at temperatures lower than 850°C has not been reported. It was shown in the deposition of single crystalline silicon that the decomposition of silane in hydrogen at 1050°C was a diffusion limited process (8) Our experimental results cannot be satisfactorily explained by such a reaction process. We propose an alternative reaction process consising of the following steps:

(*a*) chemisorption of silane on the nucleation sites, *, on the surface of the substrate

$$* + SiH_4 \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} SiH_4(*) \quad [1]$$

(*b*) decomposition of silane into silicon and hydrogen, assuming this process to be the rate-controlling step

$$SiH_4(*) \xrightarrow{k_2} Si(*) + 2H_2(*) \quad [2]$$

(*c*) desorption of hydrogen gas formed by the decomposition of silane over the substrate surface

$$H_2(*) \underset{k_{-3}}{\overset{k_3}{\rightleftharpoons}} H_2 + (*) \quad [3]$$

Solving Eq. [1] to [3] by chemical kinetic analysis, for a substrate of finite surface, the deposition rate of silicon is given as

$$\frac{dx}{dt} = \frac{M_{Si}}{\delta_{Si}} \frac{k_2K_1[SiH_4]}{\left(\frac{[H_2]}{K_3} + K_1[SiH_4] + 1\right)} \quad [4]$$

where

$$k_2 = k_{20}e^{-E/RT} \quad [5]$$

$$K_1 = k_1/k_{-1} = K_{10}e^{-\Delta H/RT} \quad [6]$$

$$K_3 = k_3/k_{-3} = K_{30}e^{-\Delta H_H/RT} \quad [7]$$

In Eq. [4], dx/dt is the growth rate of silicon in cm/sec, and M_{Si}, δ_{Si} are the molecular weight and the density of silicon, respectively. $[SiH_4]$ and $[H_2]$ are the silane and hydrogen concentrations in the gas phase in moles/cm^3. E, ΔH, ΔH_H, R, and T have the usual meanings and definitions. There was no hydrogen present in our incoming gas. If the silane conversion efficiency is low, we can assume that the hydrogen gas produced by the decomposition of silane is immediately carried away by the gas stream, and the hydrogen concentration at the substrate surface is essentially zero. Then Eq. [4] can be approximated by

$$\frac{dx}{dt} = \frac{M_{Si}}{\delta_{Si}} \frac{k_2K_1[SiH_4]}{(K_1[SiH_4] + 1)} \quad [8]$$

The consequence of Eq. [8] is that if $K_1[SiH_4] >> 1$ the growth rate is independent of the silane concentration and the reaction is zero-order. The deposition rate is an exponential function of $1/T$. Under this condition all the available surface sites on the substrate are saturated by silane so that any further increase in silane concentration will not change the rate by which silane molecules are absorbed on the substrate surface. On the other hand, when $K_1[SiH_4] << 1$ the deposition rate is proportional to the silane concentration and the decomposition is a first-order reaction. Equation [8] shows that if the reciprocal of the deposition rate at a fixed temperature is plotted as a function of the reciprocal of silane concentration, a straight line should be obtained. The slope of such a plot yields $1/(K_1k_2)$ and the intercept gives $1/k_2$. If k_2 and K_1 are determined over a range of temperatures, ΔH, E, k_{20}, and K_{10} can be obtained and the deposition rate can be determined theoretically for all temperatures and silane concentrations.

This theory is a steady-state calculation so that the theory is applicable only after a monolayer of polysilicon has grown on the substrate and the deposition rate is not a function of time. Our deposition rates were derived from polysilicon films deposited for a sufficiently long time such that the above condition was satisfied. If the reaction step (b) is to be the rate-controlling step, as postulated, the reaction rate must not be a mass transport limited process. The flow rate of the gases should be so high that the deposition rate is not a function of the flow rate. This condition was verified in our experiment by doubling the flow rate and the deposition rate was found to be increased by less than 10%. Since the reactor had a run-to-run reproducibility of ±10%, it was concluded that the reaction was not mass transport limited.

In Fig. 2, the experimental data are plotted for 1/(deposition rate) *vs.* 1/(silane concentration) at constant temperatures. The averages of the experimental values in Fig. 1 were taken as the deposition rates. Straight lines are obtained for all the temperatures studied in our experiments. This implies that Eq. [8] can be used to describe the reaction and that the hydrogen produced in the decomposition of silane is not affecting the decomposition rate. The hydrogen gas resulting from the decomposition changed by a factor of at least four between the minimum and maximum silane concentration used in our experiments. If the hydrogen concentration is high enough to affect the deposition rate, Fig. 2 would not yield straight lines. Using the data in Fig. 2, a linear regression is performed by a computer to find the slopes and intercepts of the curves. From the slopes and intercepts, K_1 and k_2 at each temperature are found. From Eq. [5] and [6], if $\ln K_1$ and $\ln k_2$ are plotted as a function of $1/T$°K, straight lines should be obtained and the slopes give $\Delta H/R$ and E/R. The intercepts yield K_{10} and k_{20}, respectively. The values of $\ln K_1$ and $\ln k_2$ are plotted as a function of $1/T$ in Fig. 3. All

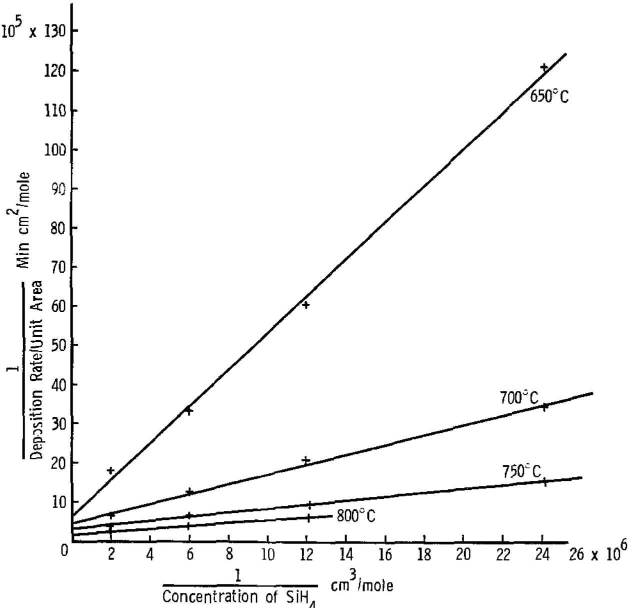

Fig. 2. Reciprocal of deposition rates vs. reciprocal of silane concentration at constant temperature.

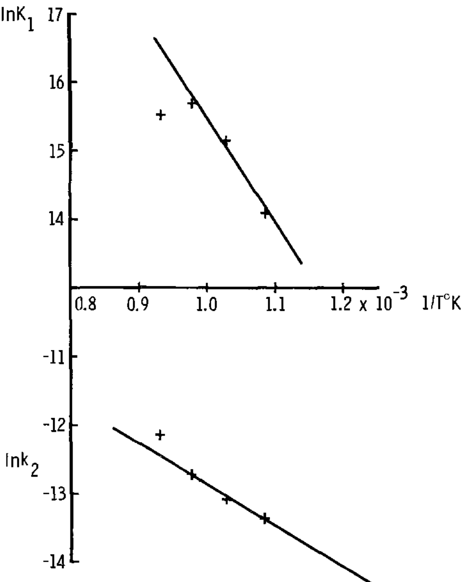

Fig. 3. Ln K_1 and ln k_2 vs. 1/T°K

the points fall into two straight lines with the exception of the 800°C values. With the values in Fig. 3 linear regression is again performed to find K_{10}, k_{20}, E/R, and $\Delta H/R$. The values obtained for E and ΔH are 15.32 and 19.45 kcal/mole, respectively. The deposition rate as a function of $1/T$°K for different silane concentrations calculated using the values of K_{10}, k_{20}, E, and ΔH derived is shown as the dashed curve in Fig. 1.

It was observed that for 0.2 and 0.4% silane at 800°C the deposition rate was higher at the incoming gas stream end of the susceptor than the exhaust end. We concluded that for those deposition conditions the gas stream might have a lower concentration of silane when it reached the substrates. Therefore, the deposition rates measured did not represent the true deposition rates for the silane concentrations calculated from the flow rates. A more accurate value of E, ΔH and, consequently, the prediction of the deposition rate could be obtained by neglecting the points at 800°C. When the slopes and intercepts were found by

linear regression, E and ΔH were given as 11.86 and 30.28 kcal/mole, respectively. The deposition rates calculated using the K_{10}, k_{20}, E, and ΔH obtained are plotted as the solid lines in Fig. 1. The agreement between experimental and theoretical values is extremely good. This activation energy is only about half of that obtained by fitting a straight line to the data points in Fig. 1. The activation energy for the decomposition of silane in reduced pressure ranged from 10.1 to 37.1 kcal/mole (9-11) was reported. Our activation energy of 11.86 kcal/mole is in close agreement with the value of 10.1 kcal/mole obtained by Farrow and Filby (9).

Morphological and Crystallographical Structures

If the deposition temperature was kept at 650°C or below, the surface of the polysilicon film was always shiny as long as the surface of the substrate was degreased and cleaned. However, when the substrate was cleaned in hot HNO_3 a better microscopic surface was obtained. As the deposition temperature was raised above 700°C, the surface texture of the polysilicon film was strongly affected by the cleaning process before the silicon wafer was oxidized. Figure 4 shows examples of polysilicon films deposited in identical conditions on properly and improperly cleaned substrates. The film grown on the improperly cleaned substrate has a very rough and nonuniform surface; and many hillocks are as high as 1 μm. The surface of the film grown on the substrate cleaned in hot HNO_3 is optically smooth and shiny. The cleaning steps become more critical as the temperature is raised. Cowher and Sedgwick (12) also found that the substrate cleaning was critical to obtaining smooth polysilicon surfaces using hydrogen as carrier gas in the deposition of polysilicon. They employed an "aqueous oxidation" step, using a mixture of H_2O_2 and H_2O at 90°C. This cleaning step was tested and no improvement over that of hot nitric acid was observed. A combination of nitric acid and "aqueous oxidation" steps did not produce any higher quality polysilicon films. Both H_2O_2 and hot nitric acid are strong oxidizing agents. It is then concluded that to obtain a smooth polysilicon surface the last cleaning step in substrate preparation should be in a strong oxidizing agent. It was shown that silicon dioxide grown on a dirty silicon surface has many imperfections and small crystallites (13, 14). By heating silicon wafers in hot nitric acid the surface of the silicon becomes uniformly hydrophilic and silicon dioxide can be grown with fewer imperfections (15). It appears that either imperfections or small crystallites of silicon dioxide or both can nucleate polysilicon growth more effectively than an amorphous silicon dioxide surface. Once silicon is deposited on a nucleation site, the growth of silicon is accelerated, possibly by autocatalytic effect. Since the growth rate of silicon is higher at higher temperature, the difference in the amount of silicon deposited on sites nucleated at different times is larger, so that for the same amount of imperfection on the silicon dioxide substrate, the hillock size increases as the temperature of deposition increases. Another possible explanation is that the difference in the nucleation rates between the imperfections and the amorphous substrate becomes larger as the temperature of deposition is increased. We believe that the former explanation is more plausible in this study. In either case, one obvious way to minimize the hillock growth is to provide as uniform a substrate surface as possible so that nucleation occurs uniformly on the substrate and a uniform growth is obtained. This is accomplished by cleaning the silicon substrate in a strong oxidizing agent to grow a more perfect silicon dioxide film. For substrates prepared this way the polysilicon films were obtained with an optically shiny surface. The results are consistently reproducible. Figure 5 is a transmission electron microscope picture of a tungsten oxide shadowed carbon replica of a typical surface of polysilicon film approximately 1 μm thick. The surface was very smooth.

There was no evidence that the silane concentration affects the surface structure of the polysilicon film as long as the concentration was high enough to prevent premature decomposition. When argon is used as the carrier gas in the thermal decomposition of silane, premature decomposition can take place resulting in a blackish gray deposit of amorphous silicon (12). Premature decomposition occurs when the gas mixture is hot enough for homogeneous decomposition to take place before it reaches the substrate surface. The amorphous silicon rains down onto the substrate in the form of small particles. The temperature at which premature decomposition takes place depends on the concentration of silane in the gas and the experimental apparatus. For the apparatus used in this study a silane concentration of 0.1% gave premature decomposition when the susceptor was at about 750°C. As the silane concentration was increased to 0.2% or higher, no premature decomposition occurred up to 800°C. No at-

Fig. 4. Polysilicon films deposited on properly and improperly cleaned substrates.

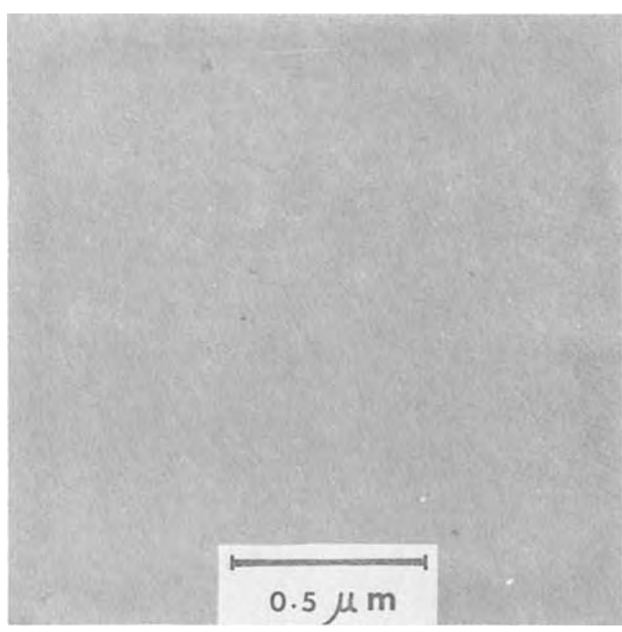

Fig. 5. Tungsten oxide shadowed replica picture of polysilicon deposited at 650°C.

tempts were made to find the temperatures at which premature decomposition occurred for different silane concentrations.

It is interesting to note that our result is in contrast to that of Eversteign (17) who made a detailed study of the gas phase decomposition of silane in hydrogen. He found that as the temperature is increased the gas phase decomposition started at a lower silane concentration. We do not know the cause of this discrepancy, although one might suspect that the causes might be related to the difference in the carrier gas used and the difference in the gas dynamics in the reactor systems.

Transmission electron microscope (TEM) was used to study the grain structure of the polysilicon films. The samples for TEM study were prepared by the following method. An oxide of about 3000Å thick was grown on the polysilicon film. The silicon dioxide on the single-crystal silicon substrate surface was removed by an oxide etch and then the single-crystal silicon substrate was etched away by chlorine gas at 800°C. Since chlorine does not etch silicon dioxide the polysilicon was left behind with a silicon dioxide coating. The silicon dioxide was removed by an oxide etch. The polysilicon was further thinned by floating the polysilicon film on a potassium hydrooxide solution, until a film of a few thousand angstroms thick was obtained. There was some question if the oxidation and the high temperature etch could have changed the crystal structure of the films. Samples prepared by other etchants and without the oxidation step did not show any change in the results observed. The TEM study consisted of electron diffractions and TEM micrographs. Figures 6a and b are the electron diffraction patterns for polysilicon films deposited at 650° and 750°C, respectively. From the diffraction pattern it can be seen that both films consist of polycrystalline materials with randomly oriented grains (18). Figures 7a and b are the bright field TEM micrographs of the same films. The micrographs were analyzed by image analysis, yielding an average grain size of 183 and 700Å, respectively, for the films deposited at 650° and 750°C. At high magnification, it was observed that there were structures inside the small crystallites. Most of these structures were lines and it was assumed that these were dislocation lines. Numerous dislocations are to be expected since the films were grown on amorphous substrates.

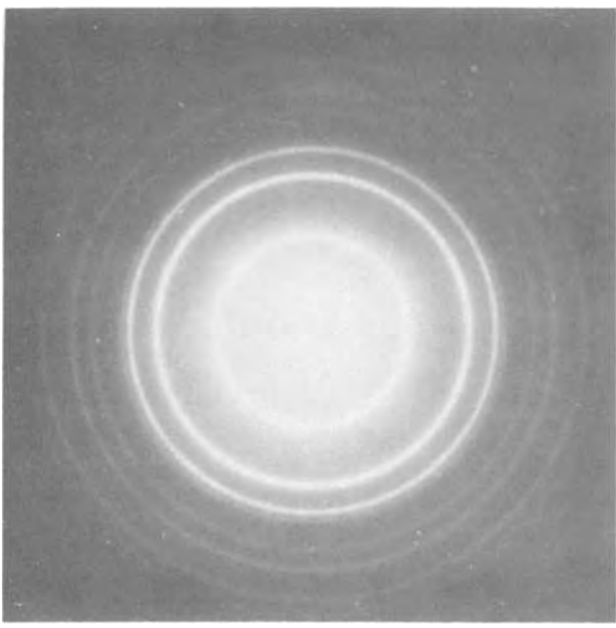

Fig. 6a. Electron diffraction pattern of a 650°C deposited polysilicon film.

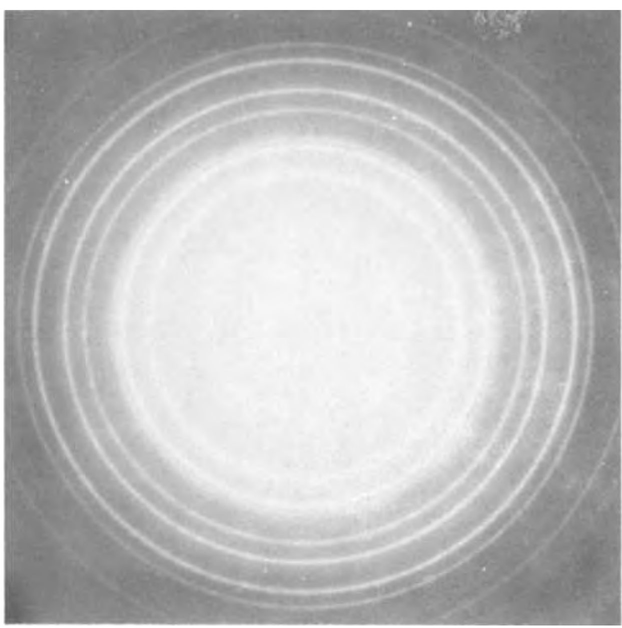

Fig. 6b. Electron diffraction pattern of a 750°C deposited polysilicon film.

The vertical growth of the polysilicon films was studied by breaking the substrate. The edge of the substrate with polysilicon film was observed with a scanning electron microscope, Fig. 8. There was no columnar growth visible.

Conclusion

The deposition rate of polysilicon films on silicon dioxide substrates by thermal decomposition of silane in an argon atmosphere can be varied from less than 0.01 to about 0.5 μm/min by changing the concentration of silane between 0.1 and 1.2%, and the deposition temperature from 650° to 800°C. It is proposed that the deposition process consists of three steps: chemisorption and decomposition of silane on and desorption of hydrogen from the substrate surface. The deposition rate equation was derived based on a kinetic analysis of the postulated reaction sequence. The experimental results confirmed the postulated mechanism.

It was found that optically smooth polysilicon films could be obtained without any special cleaning process if the deposition temperature was about 650°C and lower. However, if the deposition temperature was above 700°C, the surface texture of the polysilicon film depended strongly on the substrate preparation procedure. To obtain optically smooth surfaces, it was necessary to clean the silicon substrate in a strong oxidizing solution such as hot HNO_3 or H_2O_2. It was important that the silane concentration and the deposition temperature be adjusted so that no gas phase premature decomposition of silane occurred. With the proper substrate preparation, optically smooth surfaces were obtained consistently. The grain size of the polysilicon films was a function of the deposition temperature and increased from about 200Å at 650°C to 700Å at 750°C. The grains were found to be randomly oriented in the range of the deposition temperatures investigated.

Acknowledgments

The author would like to thank Dr. M. C. Steele and Mr. J. W. Hile for many fruitful discussions. Thank are also due to Dr. L. Hegedus for proposing the chemical kinetic model and the calculations. The technical support of Mrs. B. Vannoy and Mr. A. Fritz is appreciated. The author is grateful for the assistance provided by Dr. H. Bendler in the TEM study, Mr. J. Homaday in image analysis, and Mr. T. Schreiber in taking the SEM micrograph.

Determination of Oxygen Chemical Diffusion Coefficients in Single Crystal $SrTiO_3$ by Capacitance Manometry

D. B. Schwarz[1] and H. U. Anderson*

Department of Ceramic Engineering, University of Missouri-Rolla, Rolla, Missouri 65401

ABSTRACT

The oxidation kinetics of a single crystal of $SrTiO_3$ were measured with a tensivolumetric system over the temperature range 700°-975° at 0.03 atm oxygen pressure. The oxidation was found to be oxygen diffusion limited with an activation energy of 14.9 ± 1.3 kcal/mole. Combining the kinetic data with relative defect concentration data yielded an activation energy for oxygen self-diffusion of 57 ± 16 kcal/mole. The enthalpy of formation of doubly ionized oxygen vacancies was calculated to be 126 ± 13 kcal/mol.

Recently, $BaTiO_3$ was investigated in the temperature range of 300°-1000°C and at oxygen partial pressures as low as 10^{-6} atm with a capacitance manometer (1, 2). Calibration shows the sensitivity of this instrument to be 10-100 times greater than that of a microbalance. As has been reported, changes in oxygen stoichiometry as small as 10^{-8} moles were easily detected on approximately 10g $BaTiO_3$ samples.

The limit of sensitivity of this particular system was about 3×10^{-9} moles oxygen gas or a 10^{-7}g change in total sample weight. On a smaller volume system, Turcotte *et al.* (3, 4) report an even higher sensitivity of 2×10^{-9}g.

In another study, Greskovich and Schmalzried (5) investigated nonstoichiometry in Co_2SiO_4 and in $CoAl_2O_4$-$MgAl_2O_4$ crystalline solutions and determined changes in cobalt vacancy concentrations as low as 10^{-2} atom per cent (a/o).

In addition to being useful in determining changes in stoichiometry, the initial work on $BaTiO_3$ and that of Greskovich and Schmalzried indicates that the kinetics of oxygen exchange are easily measurable so chemical diffusion coefficients can be calculated by solving Fick's second law for the appropriate boundary conditions of the system (6).

The tensivolumetric technique of measuring the gaseous exchange with a solid is both very rapid and sensitive, so an evaluation of this technique for the determination of chemical diffusion coefficients is of practical value. Since both the oxygen diffusion coefficients and the limit of oxygen nonstoichiometry of $SrTiO_3$ have been measured (7-10), this oxide was chosen to make this evaluation.

In previous experiments with 0.1 μm crystallite-size $BaTiO_3$ and $SrTiO_3$ (1), attempts to use the exchange kinetics to calculate chemical diffusion coefficients were not successful. Evidently, the exchange was not entirely diffusion limited. As a result of the small particle size, the exchange can be expected to be dependent upon the surface exchange reaction as well as upon diffusion (11). Thus, to limit control by the surface exchange reaction in this study, oxygen exchange with large single crystal $SrTiO_3$ was measured.

Experimental

The apparatus used is similar to that described by Conger (1) and Meurer (12). It consists of two symmetrical chambers, separate and vacuum-tight, but with provision for interconnection. The oxide sample is sealed into one side with the other being left empty as a reference. An atmosphere of known oxygen pressure is admitted to both sides and allowed to equilibrate. After rapidly changing both the sample and reference sides to a new value of oxygen pressure, the two sides are separated. The attainment of a new equilibrium with the sample is followed with a sensor head by monitoring the pressure change (caused by an oxygen loss or uptake) in the sample side of the system relative to the reference side.

The sensor head is an open loop, taut metal membrane capacitance manometer[2] with a range of 1.3×10^{-8} to 1.3×10^{-3} atm.

The sample and reference tubes were heated in a wire-wound furnace whose maximum temperature was 1000°C. At temperatures up to 1000°C, the furnace temperature was controlled to approximately ±3°C with both linear and radial gradients of less than 2°C in the region where the sample was contained.

If the temperature of the entire apparatus is maintained at constant temperature, the measured pressure change, Δp due to evolution or uptake of gas is related to the change in the number of moles of gas, Δn by the relation $\Delta p = \Delta n\ RT/V$ where V is the volume of the sample side, R is the gas constant, and T is the temperature.

In actual practice, the expression for the observed pressure change is not so simple since the temperature of the system is not uniform (that is, the gauge and the sample chamber are at different temperatures). The expression will, instead, involve a correction factor arising from temperature gradient effects.

The measured pressure change is thus described as $\Delta p = K(T)\ \Delta n$ where Δp is the sample-induced pressure change and $K(T)$ is a temperature dependent correction factor containing the gas constant R, the sample side volume V, and some function of gauge and furnace temperatures.

An empirical calibration was necessary in order to relate measured pressure changes to oxygen concentration changes in a sample. This was accomplished by measuring the pressure changes occurring for known changes in gas concentration at a series of furnace temperatures (20°-950°C). The correction factor was found to be independent of oxygen pressure and to be only a function of furnace and gauge temperature. With the system thermostated at 38° ± 0.01°C and the head temperature constant, the calibration constant varied from 31.0 ± 0.20 atm/mole to 33.8 ± 0.28 atm/mole with the furnace at 20° and 950°C, respectively.

For the minimum detectable pressure change of 1.3×10^{-8} atm, the maximum sensitivity attainable is $\Delta n = 4 \times 10^{-10}$ moles which corresponds to a weight change of 1.3×10^{-8}g of oxygen. Interaction between the gas and the system was found to place a practical limit on detectability of 4×10^{-9} moles oxygen.

Key words: oxidation, oxygen vacancy concentration, oxygen self-diffusion.

[2] MKS Instruments, Incorporated, Burlington, Massachusetts 01803.

Due to the limited range of nonstoichiometry of $SrTiO_3$, it was found that the apparatus could not detect the exchange kinetics by stepping the oxygen pressure in the range 10^{-6}-1 atm at temperatures below 1000°C. To achieve a detectable pressure change within the temperature and pressure range of the apparatus it was necessary to reduce the sample in either forming gas (8% H_2 in N_2) or CO. The oxidation kinetics were then measured when the reducing gas was replaced by O_2.

The crystal was cut from 99.9 weight per cent (w/o) pure $SrTiO_3$ boule.[3] Prior to use, the crystal was polished and annealed to remove surface roughness and internal strain. The final dimensions of the rectangularly shaped crystal were 1.24 cm × 1.33 cm × 2.04 cm ± 0.02 cm. The weight of the crystal was determined to be 16.9903 ± 0.0002g, with a density of 5.121 ±0.001 g/cm³. No attempt was made to orient the crystal so any effects of crystallographic directions could not be observed.

Mathematical Analysis

Diffusion coefficient.—When a sample re-equilibrates from an initially homogeneous nonstoichiometric condition, diffusion occurs under the influence of a chemical potential or concentration gradient. This type of diffusion is commonly referred to as chemical diffusion and the diffusion coefficient resulting from it is termed as the chemical diffusion coefficient, $\tilde{D}$. The relationship between the chemical diffusion coefficient and self-diffusion coefficient have been extensively treated elsewhere, so will not be discussed here (11, 13, 14).

For a brick-shaped geometry, the solution to Fick's second law which applied to the change in stoichiometry resulting from the oxide crystal re-establishing thermodynamic equilibrium due to changes in oxygen activity was originally derived by Newman (15). Later it was used by Price and Wagner (16) in determining chemical diffusion coefficients for single crystals of NiO and CoO by electrical conductivity techniques. The format presented here is similar to that of Price and Wagner, with the exception of incorporating the measurable parameters of the tensivolumetric technique.

For long times the relative defect concentration, $(1 - Q)$, is given by

$$1 - Q = 1 - \frac{\Delta w_t}{\Delta w_\infty} \simeq \frac{512}{\pi^6} \exp\left[-\frac{\pi^2 \tilde{D} t}{4}\left(\frac{1}{a^2} + \frac{1}{b^2} + \frac{1}{c^2}\right)\right] \quad [1]$$

where Δw_t is the weight change at time t, Δw_∞ is the total weight change measured between the initial and final equilibrium states, $\tilde{D}$ is the chemical diffusion coefficient and $2a$, $2b$, and $2c$ are the sample dimensions. This solution assumes as boundary conditions that the crystal is initially in equilibrium with a certain partial pressure of oxygen, and at time = 0, the surface of the crystal is in immediate equilibrium with another oxygen partial pressure. The re-equilibration is assumed to be limited by diffusion rather than surface reaction and the observed weight change is then just an integrated measure of the adjustment of the defect concentration to the new equilibrium state.

The changes in defect concentration may be expressed either as weight changes in the sample or as changes in the pressure in the tensivolumetric apparatus. Therefore, from Eq. [1], weight changes may be equated to the induced pressure changes as follows

$$1 - Q = 1 - \frac{\Delta w_t}{\Delta w_\infty} = \frac{\Delta w_\infty - \Delta w_t}{\Delta w_\infty} = \frac{\Delta P_\infty' - \Delta P_t'}{\Delta P_\infty'} \quad [2]$$

[3] NL Industries, South Amboy, New Jersey 08879.

where the total induced pressure change, $\Delta P_\infty'$ equals $\Delta P_\infty + \Delta P_i$ and the total induced pressure change at time t, $\Delta P_t'$ equals $\Delta P_t + \Delta P_i$. The terms ΔP_t and ΔP_∞ represent, respectively, the measured differential oxygen pressure as a function of time, and the final measured differential oxygen pressure. The quantity ΔP_i is a correction factor that would be zero if the measurement of ΔP_t began at the instant that the system pressure was changed (that is at $t = 0$, exchange = 0). Since this cannot be the case, ΔP_i will always be greater than zero.

Therefore for use with the tensivolumetric system, Eq. [1] is rearranged to read

$$1 - Q = (\Delta P_\infty - \Delta P_t)/(\Delta P_\infty + \Delta P_i) \simeq 512/\pi^6 \exp\left[-\pi^2 \tilde{D} t/4(1/a^2 + 1/b^2 + 1/c^2)\right] \quad [3]$$

or

$$\log(\Delta P_\infty - \Delta P_t) \simeq \log(\Delta P_\infty + \Delta P_i) + \log(512/\pi^6) - (\tilde{D} t \pi^2/9.21) \times (1/a^2 + 1/b^2 + 1/c^2) \quad [4]$$

Defect concentration.—As previously described, the the calibration factor $K(T)$ relates the defect-associated change in the number of moles of oxygen in the sample, to the change in pressure in the system. From this relationship and the total induced pressure change, $\Delta P_\infty'$, changes in stoichiometry can be investigated.

The oxidation (or reduction) kinetics for this type of experiment will be determined by the most rapid diffusing cation-hole or anion-electron complex. If the material is predominantly an electronic conductor, then the diffusivity of the ionic defects will control the kinetics. For a binary compound, the most rapid diffusing ionic defect is the majority defect. Due to the additional component in a ternary compound, this is not necessarily true. However, for the case of nonstoichiometric $SrTiO_{3-\delta}$, the majority defect and the fast diffusing ionic defect are the same and have been shown to be oxygen vacancies (7-10). Thus, for $SrTiO_{3-\delta}$, this experiment can determine both the concentration of oxygen vacancies, δ, and the chemical diffusion coefficient, $\tilde{D}$. Changes in the parameter δ, $(\Delta\delta)$ can be related to changes in the gas concentration, Δn by

$$\Delta\delta = 2\Delta n M/m = 2\Delta P_\infty' M/K(T)m \quad [5]$$

where M is the molecular weight of stoichiometric $SrTiO_3$, m is the mass of the sample.

The defect concentration can be related to the parameter δ by

$$[\text{defect}] = \delta\rho/M \quad [6]$$

where [defect] represents the mole concentration (moles/cm³) of some atomic defect and ρ is the density of $SrTiO_3$. Changes in defect concentration can be represented as

$$\Delta[\text{defect}] = \Delta\delta\rho/M \quad [7]$$

or

$$\Delta[\text{defect}] = [2\rho/m][\Delta P_\infty'/K(T)] \quad [8]$$

Results and Discussion

An illustration of a typical oxidation curve is shown in Fig. 1. If a plot of log ΔP_t *vs.* log t of the initial part of these data is made, a slope of ½ is obtained which indicates bulk diffusion controls the process (11). Such a plot is not included since it is essentially redundant.

From the oxidation data, ΔP_t *vs.* time, and Eq. [4], a plot of $-\log(\Delta P_\infty - \Delta P_t)$ *vs.* time can be generated. Figure 2 is an example of this relationship. From the intercept of these curves ΔP_i can be obtained which allows the relative defect concentration $(1 - Q)$ to be calculated. If the assumptions leading to Eq. [4] are correct, then a plot of $-\log(1 - Q)$ *vs.* time will be linear. Figure 3 is an example of such a plot for five different isothermal exchanges from 700° to 975°C. The excellent adaptability of the experimental data to Eq.

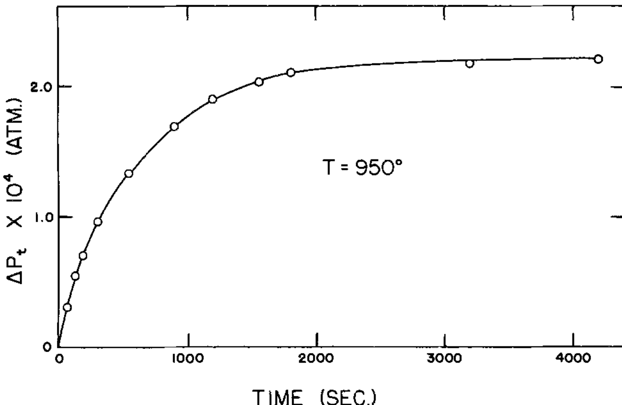

Fig. 1. Typical curve obtained for a sample initially reduced in CO and then oxidized in 0.03 atm O_2. T = 950°C.

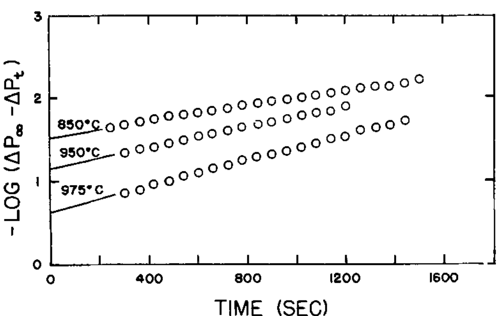

Fig. 2. Plot of Eq. [4] to obtain chemical diffusion coefficients

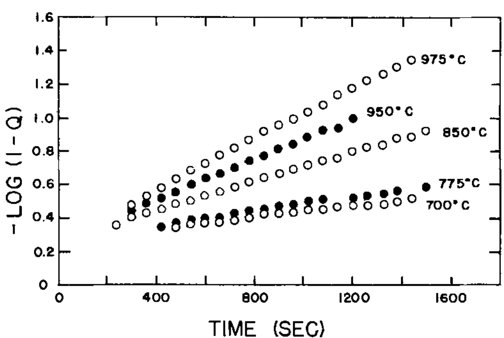

Fig. 3. Plot of log of relative defect concentration *vs.* time

[4] suggests that the sample oxidation proceeds by a process of homogeneous volume diffusion. The oxygen chemical diffusion coefficient obtained from the slopes of the plots of Eq. [4] can be represented by

$$\tilde{D} = 10^{-1.3\pm0.2} \exp\left(-\frac{14{,}900 \pm 1{,}300}{RT}\text{ cal/mole}\right)\text{cm}^2/\text{sec} \quad [9]$$

in the temperature range 700°-975°C at an oxygen pressure of 0.03 atm.

Figure 4 compares the results of this study with previous investigators. The two points at the lower right-hand side of this figure are diffusion coefficients calculated from vacancy mobility data of Blanc and Staebler (17) using the Einstein relation (18).

Paladino (7) measured oxidation kinetics of reduced single crystal $SrTiO_3$ by a thermogravimetric technique. The calculated oxygen chemical diffusion coefficients in the temperature range 850° and 1460°C, can be represented by

$$\tilde{D} = 0.33 \exp\left(-\frac{22{,}500 \pm 5{,}000 \text{ cal/mole}}{RT}\right)$$

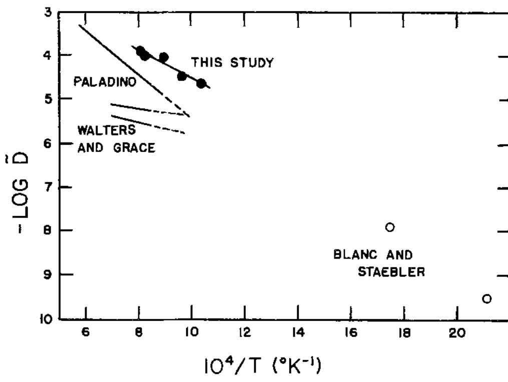

Fig. 4. Compilation of oxygen chemical diffusion data for $SrTiO_3$.

cm²/sec. The calculated diffusion coefficients of this study are close to those obtained by Paladino. This is an important point since both studies measured oxidation kinetics of reduced single crystal $SrTiO_3$, so the results of the two techniques should correspond. The enthalpy of motion term also compares reasonably well.

An extrapolation of Blanc and Staebler data into the higher temperature region correlates favorably with both this study and the work of Paladino.

The measurements of Walters and Grace (9) were made by an electrical conductivity technique. They observed an activation energy of only about 6 kcal/mole which is much less than either the results of this study or of Paladino. The reasons for this difference are not understood. However, they did note a difference between samples (as shown by the two lines) which possibly could account for some of the observed differences.

The difference in defect concentrations existing in the crystal in equilibrium with the reducing atmosphere and at 0.03 atm oxygen pressure can be calculated from the values of ΔP_i obtained from Eq. [4]. Table I lists the average change in defect concentrations. The large deviations were due to interactions between the gas and the system. These interactions resulted from the use of reducing gases and are much larger than the detectability limit of the system (4×10^{-9} moles oxygen).

The results obtained from making exchanges with no sample in the apparatus showed that the pressure change occurring with the system alone amounted to as much as 20% of that occurring with the sample; however, this interaction ceased in less than 15 min which is short compared to the total exchange times of 2-24 hr. Since only the latter part of the exchange data was used to make diffusion coefficient calculations, this interaction did not influence diffusion measurements. However, since the defect concentration calculation is dependent upon the total induced pressure change, it is greatly influenced by any gas-system interaction. In fact at the lowest temperature, 700°C, measurements could not be made. At the higher temperatures the interaction places about a 50% scatter in the data. This interaction is a systematic problem which will have to be corrected before precise defect concentration determinations can be made if reducing gases need to be used.

Table I. Oxygen vacancy concentrations in $SrTiO_3$ single crystal after reduction in CO

Temperature (°C)	Vacancy concentration (cm^{-3})
775	$3.5 \pm 2.0 \times 10^{17}$
850	$7.8 \pm 1.5 \times 10^{17}$
950	$5.6 \pm 4.5 \times 10^{18}$
975	$7.6 \pm 3.5 \times 10^{18}$

The determination of the chemical diffusion coefficient $\tilde{D}$, and the oxygen vacancy concentration $[V_O^{\cdot\cdot}]$, makes it possible to calculate the oxygen self-diffusion coefficient from the relation (19)

$$D_{O \rightarrow SrTiO_3} = \frac{[V_O^{\cdot\cdot}] D_{V_O^{\cdot\cdot}}}{N} \quad [10]$$

where N is the total number of oxygen ions in the lattice per cubic centimeter. The oxygen vacancy diffusion coefficient, $D_{V_O^{\cdot\cdot}}$, can be calculated directly from the oxygen chemical diffusion coefficient by the relation (11,14)

$$\tilde{D} = (1 + |z|) D_{V_O^{\cdot\cdot}} \quad [11]$$

where z is the charge on the diffusing ion which in this case is two. This relationship is valid only when electronic conductivity predominates which is the case for $SrTiO_3$ (10).

The resulting calculated oxygen self-diffusion coefficient is given by

$$D_{O \rightarrow SrTiO_3} = 60 \exp \left(- \frac{57{,}000 \pm 16{,}000}{RT} \text{ cal/mole} \right) \text{cm}^2\text{/sec} \quad [12]$$

If the assumption is made that the diffusion is via intrinsic defects rather than impurity generated defects, then the activation energy is composed of two separate enthalpy terms according to the relation

$$D_{O \rightarrow SrTiO_3} = D_0 \exp \left(- \frac{\Delta H_m + \Delta H_{V_O^{\cdot\cdot}}/3}{RT} \right) \quad [13]$$

where ΔH_m is the enthalpy of motion of a doubly ionized oxygen vacancy plus two electrons, and $\Delta H_{V_O^{\cdot\cdot}}$ is the enthalpy of formation of this defect. From the above relation, the energy of formation of doubly ionized oxygen vacancies resulting from the reaction

$$O_O^x \leftrightarrows V_O^{\cdot\cdot} + 2e' + \tfrac{1}{2} O_2 \quad [14]$$

under the condition

$$[e'] = 2[V_O^{\cdot\cdot}] \quad [15]$$

can be calculated to be 126 ± 13 kcal/mole. Within the range of the experimental error, this value is comparable to 133 kcal/mole which was found by Yamada and Miller (10).

The validity of such a calculation is questionable since it requires that the acceptor impurity content be low enough that it does not exceed the native defect concentration. For the specimen used in this study, the total acceptor impurity concentration is reported to be less than 10^{18} atoms/cm^3. The measured oxygen vacancy concentrations exceed this level at temperatures above 900°C, however the values obtained at temperatures as low as 775°C did not show any systematic variation which would suggest a shift to extrinsic behavior. Thus, perhaps the actual acceptor impurity might be less than that reported by chemical analysis.

Summary

The correlation between the oxygen vacancy diffusion coefficients obtained in this study and those found in previous determinations adequately demonstrates the applicability of the capacitance manometer system to the measurement of the diffusion coefficient of the rate controlling species. Interactions of the reducing gas with the system caused a rather large variation in the calculated defect concentration. Even with this difficulty, the calculated enthalpy of formation for the oxygen vacancy was very close to the best value in the literature. This suggests that when this systematic problem has been removed from the system, it should be possible to obtain defect concentration data which are compatible to those obtained by other techniques.

It should also be noted that the apparatus, even when operating in a very insensitive manner as was done here, is capable of determining changes in oxygen content of less than 10^{-5} moles which corresponds to weight changes of less than 10 μg.

Technical Note

On the Interpretation of Mott-Schottky Plots Determined at Semiconductor/Electrolyte Systems

R. De Gryse, W. P. Gomes, F. Cardon, and J. Vennik

Rijksuniversiteit Gent, Laboratorium voor Kristallografie en Studie van de Vaste Stof,

Krijgslaan 271, B-9000 Gent, Belgium

In this note we want to comment on the interpretation which has to be given, in semiconductor electrochemistry, to the relationship between C^{-2} and V, measured under circumstances where a depletion layer exists at the semiconductor surface. Here, C represents the differential capacitance of the electrochemical cell which contains a semiconductor electrode and a metal counterelectrode, the surface area of the latter being sufficiently large to make its contribution to the capacitance negligible (C is expressed per cm^2 of semiconductor/electrolyte contact area); V represents the voltage, applied to the semiconductor electrode and expressed with respect to a reference electrode. From an observed linear relationship between C^{-2} and V, it is often concluded [see, *e.g.*, the references (1,2) dealing with highly doped SnO_2] that the following inequalities hold

$$C_S << C_H \quad [1]$$

$$|\phi_S| >> |\phi_H| \quad [2]$$

in which C_S and C_H are the differential capacitances per square centimeter of the depletion layer of the semiconductor and of the Helmholtz layer at the semiconductor surface, respectively, ϕ_S is the potential drop over the depletion layer, and ϕ_H the change in Helmholtz potential drop caused by the applied voltage (it is assumed here that the electrolyte solution is sufficiently concentrated so that the Gouy layer can be left out of consideration). Assuming the inequalities [1] and [2] to be valid, and considering, *e.g.*, an n-type semiconductor, the donor density N_D and the flatband potential V_{fb} are then deduced from the experimental C^{-2} *vs.* V plots by using the Mott-Schottky relationship

$$C^{-2} = (8\pi/\epsilon q N_D)(V - V_{fb} - kT/q) \quad [3]$$

which describes the behavior of the depletion region (ϵ is the dielectric constant of the semiconductor, q the absolute value of the elementary charge, and the other symbols have their usual meaning).

Reversing the argument, C^{-2} *vs.* V data which are in disagreement with Eq. [3] are not seldom ascribed to effects of the Helmholtz layer. It has been, *e.g.*, suggested (3) that a discrepancy between predicted and observed Mott-Schottky slopes in the case of NiO might follow from the invalidity of inequality [2]. Deviations from linearity of the C^{-2} *vs.* V plots measured at TiO_2 electrodes have been interpreted (4) by assuming that inequality [1] does not hold in the given case. On the other hand, with NiO and in a voltage range where calculation shows that inequality [2] is not valid, a linear C^{-2} *vs.* V relationship was found experimentally, a result which was felt to be a discrepancy (5).

It should be noted that in all cases mentioned, semiconductor electrodes are involved in which the concentration of ionized donors or acceptors is high (typically several times 10^{18} to several times 10^{20} cm^{-3}), so that in principle the possibility must be considered that inequalities [1] and [2] do not hold. It is our purpose here to derive the relationship between C^{-2} and V for this case. The derivation will be made for an n-type semiconductor. Our reasoning is analogous to that used in Ref. (6) for the case of an MOS system.

Key words: semiconductor electrochemistry, Mott-Schottky plots, Helmholtz layer.

The applied voltage (with respect to the flatband situation) divides itself partly over the depletion region, partly over the Helmholtz layer at the semiconductor/electrolyte interface

$$V - V_{fb} = \phi_S + \phi_H \quad [4]$$

In the case considered, one has $V > V_{fb}$, $\phi_S > 0$, and $\phi_H > 0$. The measured capacitance can be written as

$$C^{-1} = C_S^{-1} + C_H^{-1} \quad [5]$$

We will assume that the variation of C_H as a function of ϕ_H is negligible. This is reasonable if the ionic part of the double layer at the semiconductor/electrolyte interface is located in the outer Helmholtz plane exclusively, which, in the case of concentrated electrolyte solutions, implies the absence of ion adsorption (7). It has been suggested that adsorption on semiconductor electrodes is mainly restricted to radical species (8). Experimental data, such as ion-insensitive values of the flatband potential (9, 10), and electron-transfer rates being first order in the solved ionic reactant over a large concentration range (11), indeed indicate that ion adsorption on compound semiconductor electrodes is rather uncommon. Under the above assumption, the potential change ϕ_H can be expressed as

$$\phi_H = Q_S/C_H \quad [6]$$

where Q_S is the space charge in the semiconductor (for simplicity, it will be assumed that no charge is present in surface states). Solving the Poisson equation for a depletion layer in an n-type semiconductor by using the Mott-Schottky approximation, the following relationship is found between Q_S and ϕ_S

$$Q_S = (\epsilon q N_D/2\pi)^{1/2}(\phi_S - kT/q)^{1/2} \quad [7]$$

From Eq. [6] and [7], the following relationship is deduced between ϕ_H and ϕ_S

$$\phi_H = 2a(\phi_S - kT/q)^{1/2} \quad [8]$$

where

$$a = (\epsilon q N_D/8\pi C_H^2)^{1/2} \quad [9]$$

Equation [8] is analogous to the expression, used in Ref. (5) to calculate the contributions of the depletion region and of the Helmholtz layer to the potential drop at the semiconductor/electrolyte interface. Inserting Eq. [8] into Eq. [4] and subtracting kT/q from

both terms, the following quadratic equation in $(\phi_S - kT/q)^{1/2}$ is obtained

$$V - V_{fb} - kT/q = (\phi_S - kT/q) + 2a(\phi_S - kT/q)^{1/2}$$

Hence

$$(\phi_S - kT/q)^{1/2} = -a + [a^2 + (V - V_{fb} - kT/q)]^{1/2} \quad [10]$$

By differentiation of Eq. [7] with respect to ϕ_S, the well-known expression for C_S is obtained

$$C_S = (\epsilon q N_D/8\pi)^{1/2} (\phi_S - kT/q)^{-1/2} \quad [11]$$

From Eq. [9], [10], and [11], it follows then that

$$C_H/C_S = -1 + [1 + (V - V_{fb} - kT/q) \cdot a^{-2}]^{1/2}$$

Hence, taking into account Eq. [5]

$$(C_H/C_S) + 1 = C_H/C = [1 + (V - V_{fb} - kT/q) \cdot a^{-2}]^{1/2}$$

and, substituting a by its value (Eq. [9])

$$C^{-2} = C_H^{-2} [1 + (8\pi C_H^2/\epsilon q N_D)(V - V_{fb} - kT/q)] \quad [12]$$

As can be seen from Eq. [12], the relationship between C^{-2} and V is linear, the slope $\Delta(C^{-2})/\Delta V = 8\pi/\epsilon q N_D$ being the same as in the simple Mott-Schottky relationship (Eq. [3]). However, the intersection with the V axis which follows from Eq. [12] corresponds to a voltage V_o equal to

$$V_o = V_{fb} + kT/q - \epsilon q N_D/8\pi C_H^2 \quad [13]$$

and is thus characterized by a shift of $-\epsilon q N_D/8\pi C_H^2$ with respect to the value deduced from Eq. [3]. For instance, for the (001) face of a TiO_2 electrode ($\epsilon = 173$) with $N_D = 10^{19}$ cm^{-3}, assuming $C_H = 10^{-5}$ f·cm^{-2}, this shift would be approximately -0.12V.

Several conclusions can be drawn from the above calculation:

(*i*) It does not necessarily follow from an experimentally found linear relationship between C^{-2} and V that inequalities [1] and [2] hold. Therefore, one can hardly decide unambiguously from the observed C^{-2} *vs.* V dependence whether or not the energy levels at the semiconductor surface can be considered as being fixed, when the applied voltage is varied, with respect to the energy level in the reference electrode and hence to the levels of a redox system in the electrolyte. In the experiments with highly doped SnO_2, *e.g.*, Ref. (2), the potential dependence of the anodic current in the presence of certain reducing agents may be at least partly due to a change of ϕ_H with applied voltage. Therefore also, the determination of V_{fb} by extrapolation of C^{-2} *vs.* V plots in the case of semiconductor electrodes characterized by a relatively high density of ionized donors or acceptors is subject to a certain error, since the denominator in the last term of the expression for V_o (Eq. [13]) contains the square of C_H, a quantity the value of which is not known exactly in most cases.

(*ii*) Since the slope $\Delta(C^{-2})/\Delta V$ has the same value whether inequalities [1] and [2] are valid or not, a discrepancy between predicted and measured slopes, such as, *e.g.*, the one mentioned in Ref. (3), cannot be attributed to a shift in the Helmholtz potential with applied voltage. The confusion apparently originates here from the fact that the effect of the Helmholtz layer was considered on the depletion layer capacitance C_S only, and not on the total capacitance C. The same reasoning is presumably followed in Ref. (12) where it is claimed to be necessary in order to have C^{-2} varying linearly with V, the Helmholtz potential being voltage-dependent, that the change in the Helmholtz potential is a constant fraction of $V - V_{fb}$.

(*iii*) According to our derivation, nonlinearity of the C^{-2} *vs.* V plot is not attributable to the fact that the conditions [1] and [2] are not fulfilled. Therefore, we think that alternative reasons have to be sought for the observed curvatures in Ref. (4), such as inhomogenous donor distribution, *e.g.* Therefore also, we see no contradiction between the linearity of the C^{-2} *vs.* V plots and the fact that a considerable fraction of the applied voltage changes occur over the Helmholtz layer, as was observed at the NiO electrode (5).

For future research in the field of semiconductor electrochemistry, it seems important in connection with the above remarks to collect more detailed information concerning the structure and properties of the Helmholtz layer at the semiconductor/electrolyte interface.

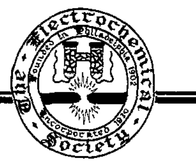
Brief Communications



Free Energy of Formation of Sodium Tungsten Bronzes, Na_xWO_3

M. Stanley Whittingham*

Corporate Research Laboratories, Exxon Research and Engineering Company, Linden, New Jersey 07036

The sodium tungsten bronzes, Na_xWO_3, are highly nonstoichiometric compounds which are metallic conductors (1) and have therefore been used as electrodes for both fuel cells (2) and conductivity cells (3); yet until recently nothing quantitative was known about their thermodynamic properties. This paper reports some electrochemical studies of the sodium activity in these materials for $0.3 < x < 0.8$ at ambient temperatures.

Single crystal samples were prepared by the electrolytic decomposition of sodium polytungstates (4) and powder samples by the solid-state reaction of Na_2WO_4, WO_3, and W in the appropriate proportions (5). Analysis of phase and composition was performed by x-ray diffractometry, the lattice constant of the cubic perovskite phase being a linear function of composition (6). The partial molar free energy of sodium was measured using an electrochemical cell comprising a sodium electrode and a tungsten bronze electrode, and as electrolyte a solution of sodium iodide in propylene carbonate. The use of sodium hexafluorophosphate as the electrolyte salt gave consistently high emf's (*e.g.*, 2.78V at $x = 0.4$) presumably due to reaction with the oxide matrix giving an oxyfluoride salt. The tungsten bronze crystal was held in the end of a glass tube by epoxy cement, electrical contact being made through a mercury pool (7). Powders were packed into a capillary tube around a platinum wire.

The emf results are shown in Table I; these were stable over several weeks to within ± 5 mV. The variation between different compositions was confirmed by measuring the potential difference between two bronzes immersed in the above electrolyte and in an aqueous sodium chloride solution. The sodium partial molar free energy, $\overline{\Delta G}_{Na}$, and the free energy of reaction [1], ΔG, calculated using the graphical technique (8), are also listed in Table I

$$Na(S) + 1/x\, WO_3(S) = 1/x\, Na_xWO_3(S) \qquad [1]$$

In Fig. 1 the free energy of formation per mole of sodium tungsten bronze obtained here is compared with the enthalpy of formation measured by Dickens and Nield (9) using solution calorimetry. The error introduced by using the enthalpy rather than the free energy in this comparison is about 5 kJ/mole, assuming a partial molar entropy change of 23.0 J/K mole as calculated (9) from the data of Gerstein, Klein, and Shanks (10) for $x = 0.68$. These data compare well with the emf's obtained by Steele (11) using beta-alumina as the electrolyte. It should be noted, however, that the sodium activity will be a function of the oxygen activity, and may therefore vary from sample to sample; the oxygen activities of the specimens used here have been determined (4, 12), and are given in Table I.

At all but the highest sodium concentrations the integral molar free energy of solution, ΔG, of sodium into the WO_3 matrix is almost independent of sodium content indicating that interactions between the sodium ions only become significant at high x values. In addition ΔG is independent of the phase, the 0.4 sample being a pure single crystal of the complex tetragonal II tunnel structure (1), all higher x values having the perovskite structure, and the $x = 0.3$ speci-

men is a mixture of the two. This is in agreement with the measurements of oxygen activity (12) which, although they showed a marked composition dependence, exhibited no measurable phase dependence. This explains why it has been easy to obtain the cubic phase at very low sodium concentrations (13) in the domain of the tetragonal phases.

Diffusion of the sodium ions in the cubic structure is very low (14), $\sim 10^{-15}$ cm^2/sec for the cubic perovskite phase, $\sim 10^{-9}$ cm^2/sec for the ammonium ion in the hexagonal tunnel structure, and intermediate for the tetragonal tunnel structure. Although these values in the tungsten bronzes are insufficient for their use as cathodes in battery systems at ambient temperatures, such is not the case for the layer-like compounds of V_2O_5 and MoO_3 which have been successfully used (15, 16). The potentials, measured as above, are shown in Fig. 2; they compare well with previous data (15-17). As expected from the increase in stability of the highest oxidation states in going down the periodic table the emf is higher for V_2O_5 than for either MoO_3 or WO_3. In these cases alkali metal ions, in particular lithium, can be readily intercalated within the oxide matrices without any appreciable change in their structures forming a ternary phase, $Li_xV_2O_5$ or Li_xMoO_3. It is this ternary phase formation that is responsible for the voltage found being higher than that expected for the simple disproportionation reaction, *i.e.*, to Li_2O and VO_2 or MoO_2. The importance of this insertion-type reaction in determining the cathodic properties of materials will be discussed in detail in a future paper. For contrast the emf characteristics of the potassium intercalation compounds of graphite (18) are also shown in Fig. 2; these are much more akin to metallic alloys than to the salt-like oxide phases discussed above and could conceivably be used as the anode of a battery system.

The Effect of Heat-Up on the Performance of Magnesium Batteries

L. F. Urry

Union Carbide Corporation, Battery Products Division, Cleveland, Ohio 44101

ABSTRACT

The heat produced as a result of the inefficiency of magnesium MnO_2 dry cells can be an advantage on high rate application in that it results in a higher cell temperature. The higher the temperature the better the cell performs. Multicell batteries magnify this effect. Experimental BA-4840 military batteries discharged in a 70°F room show internal temperatures of over 130°F and yield 33 W-hr/lb. Insulation can be employed to enhance this effect.

A well-known characteristic of the magnesium-MnO_2 dry cell is the large amount of heat formed upon discharge, resulting from a low operating voltage relative to the theoretical and a high wasteful corrosion of the magnesium anode on discharge. For example, with a 70% anode efficiency and on moderate loads, 1.60 kcal of heat are produced per ampere hour of useful discharge of the cell. This is over 3 times that produced by other conventional dry cell systems such as the Leclanché or alkaline MnO_2. This high heat-to-output ratio is usually just accepted as an undesirable shortcoming of the system with the liabilities of wasted energy, the need to design additional water and magnesium into the cell to compensate for discharge corrosion loss, and the need for special closures to vent the considerable quantities of hydrogen gas resulting from the corrosion.

In this paper we have attempted to show that the high heat output of the magnesium cell can be utilized to render the system an excellent high rate performer superior to most of the presently available aqueous systems, especially at low temperatures. It also illustrates that magnesium cell heat-up should be taken into account when testing to consider new battery applications.

Discussion

The magnesium MnO_2 dry cell system has three physical properties that render it especially efficient when used in multicell batteries on high rate discharge. They are:

(*i*) It is sensitive to temperature over a broad range. The higher the temperature the better the performance.

(*ii*) For every ampere hour of output there is a significant quantity of heat produced. For example, with a 70% anode efficiency, and on moderate to heavy loads, 1.60 kcal of heat are produced per ampere hour of output.

(*iii*) The system will function well at temperatures higher than can be tolerated with most conventional, aqueous, dry cell, systems.

These three properties are demonstrated as follows.

Sensitivity to heat.—Single, long "C" size, magnesium, round cells were cycled on loads representative of the transmit-receive cycling of cells in a BA-4386 magnesium military battery, on the PRC-25 transceiver application, at various temperatures.

The voltage at the end of each heavy drain pulse (the transmit portion) *vs.* time on test are shown in Fig. 1. It can be seen that the higher the temperature, the more the hours service and the higher the average voltage.

The cells at 130°F gave over 3 times the service of the cells at 40°F. The efficiency of the utilization of the available manganese dioxide assuming a reduction from MnO_2 to Mn_2O_3 *vs.* temperature is shown in Fig. 2.

There is a steady increase in efficiency with temperature, going from 20% at 40°F to 73% at 130°F. The cutoff of these cells is 1.28V and the average current per cell on the transmit load is over 400 mA on a cell smaller in volume than the standard "D" size cell. This is a high efficiency for such conditions.

Another experiment demonstrates the quantity of heat formed on discharge, and also the effect of the temperature rise, resulting from this heat, on the performance of the magnesium MnO_2 dry cell. Cells were tested on short circuit, noting the temperature and the current of the cell *vs.* time. Cells were tested in open

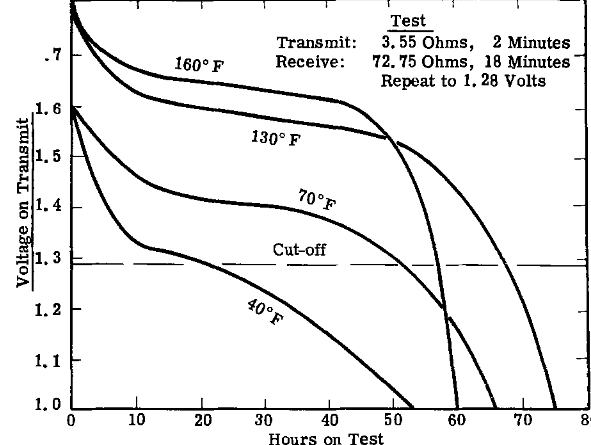

Fig. 1. Effect of temperature on the hours service of single "C" size magnesium cells.

Key words: magnesium cells, battery heat-up, insulated batteries.

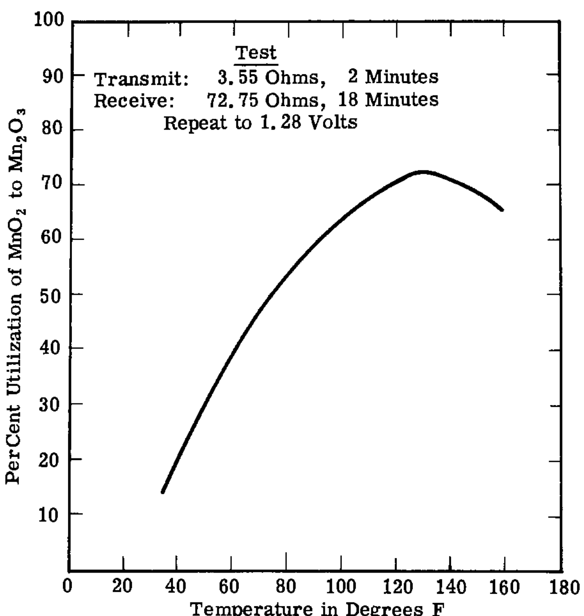

Fig. 2. Effect of temperature on the MnO_2 utilization of single "C" size magnesium cells.

air and compared with cells where the temperature rise was minimized by holding them in a 70°F water bath during testing.

As shown in Fig. 3, the cell shorted in the air and exhibited a steady rise in the temperature of the can to a high of 224°F, where apparently the heat loss matches the heat gained and the temperature peaks. The current at first dropped as is the conventional behavior of cells on a short circuit, but it soon rose to a value higher than the initial amperage. Eventually both the temperature and the current fell off, but by the time the current had dropped to 1A the output in ampere hours was 45% of the theoretical based on MnO_2 to Mn_2O_3. This is a high efficiency for a short circuit drain to such a high amperage cutoff.

The temperature rise of the cell, shorted while in the 70°F waterbath was low and the amperage did not increase after the initial drop. The ampere hour output to the 1A cutoff was only 21% of that of the cell shorted in the air. The conclusion is that much heat was produced on short circuit, and the difference in temperature resulted in a significant improvement in output.

Relationship of heat produced to output.—The heat which is produced during discharge of the magnesium MnO_2 dry cell is from two causes: (*i*) the difference between the operating voltage and the theoretical voltage, and (*ii*) the wasteful corrosion of the magnesium which always accompanies discharge.

The former is essentially calculated by converting to heat the power obtained by multiplying the voltage

Table I. Calculations, heat produced per cell per ampere hour of output

1 A-hr × (2.7 − 1.6V) × 860 cal/W-hr = 946 cal
Corrosion at anode = $Mg + 2H_2O \rightarrow Mg(OH)_2 + H_2$ + 82.1 kcal/g (4)
Heat of corrosion per ampere hour of cell output for a 70% magnesium efficiency is

$$1\ \text{A-hr} \times \frac{0.30}{0.70} \times 82.1\ \text{kcal/g-mole} \times \frac{1}{2 \times 26.8\ \text{A-hr/g-mole}} = 656\ \text{cal}$$

Total heat/cell/ampere hour = 946 + 656 cal = 1.602 kcal
Heat of corrosion = 41%; heat of inefficiency = 59%

difference times the current. The magnesium cell on moderate drains operates at an average voltage of 1.6V *vs.* a theoretical voltage of approximately 2.7V (1, 2). The heat produced when 1 A-hr is withdrawn from the cell is therefore 946 cal as shown in Table I.

The magnesium anode suffers very little corrosion on storage because of the effectiveness of the inhibitor system. However, on discharge the protective film must be broken down in order for the cell to function. Corrosion of the anode can then occur. The corrosion on discharge seems to be directly proportional to the discharge current. The corrosion rate, or to express it another way, the efficiency of the magnesium for a given set of physical conditions in a cell, seems to be constant over a wide range of temperature and load conditions. The magnesium MnO_2 round cell using a magnesium perchlorate electrolyte and AZ21X1F magnesium alloy has an anode efficiency of approximately 70% (3).

The corrosion reaction appears to be

$$Mg + 2H_2O \rightarrow Mg(OH)_2 + H_2 + \text{heat}$$

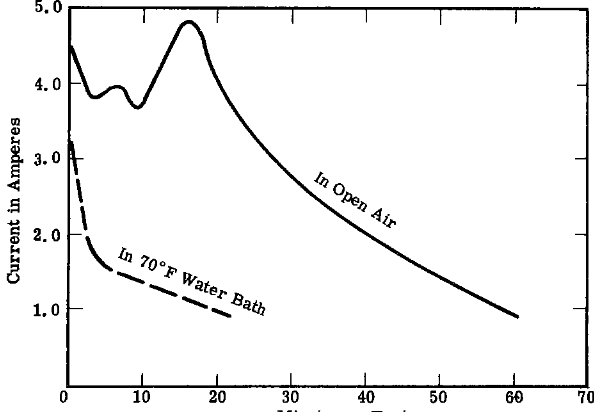
The heat produced is 82.1 kcal/g-mole of magnesium corroded, which for a 70% magnesium efficiency works out to be 656 cal/A-hr output per cell (4).

The total heat output per cell at a 70% anode efficiency is 946 + 656 cal = 1.60 kcal/A-hr/cell.

With a 70% magnesium efficiency, therefore, approximately 59% of the heat formed on discharge is due to the low operating voltage of the cell and 41% is due to the wasteful corrosion of the anode which occurs simultaneously with discharge.

The relationship of heat output, with magnesium efficiency for the magnesium MnO_2 dry cell is shown in Fig. 4.

An increase in the anode efficiency from the 70% level will not result in a major change in the amount of heat formed on discharge per ampere hour of output, however, a lower anode efficiency will. This is the principle used in high altitude meteorological batteries (6). A low efficiency magnesium alloy is used to increase the heat of discharge corrosion, and thus offset the extreme cold of the high altitudes. In addition the inhibition is reduced, thereby further increasing the corrosion on discharge, and also causing significant corrosion on open circuit stand. The latter results in



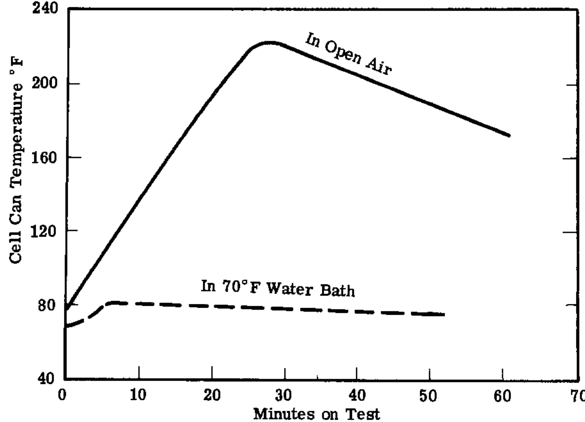


Fig. 3. Effect of temperature upon the short circuit current of long "C" magnesium cells.

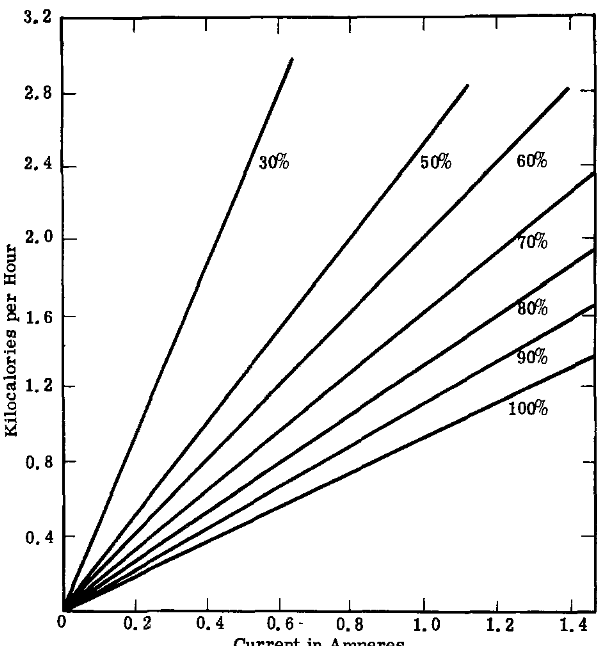

Fig. 4. Heat produced by the magnesium cell at different anode efficiencies (6).

cell heat-up immediately upon activation. Because of the poor shelf life of such batteries in the activated state, they are usually made as reserve batteries.

Other conventional systems such as the alkaline MnO_2 and the Leclanché have practically no wasteful corrosion of the anode associated with discharge, and the operating voltages are much closer to the theoretical so that the heat per ampere hour with these systems is less than one-third of that of the magnesium MnO_2 for moderate drains (3). The magnesium cell will therefore have a greater heat-up on discharge.

The behavior of the BA-4840 magnesium battery, a high rate battery developed for the U.S. Army Electronics Command under a Research and Development contract, demonstrates the practical use of this heat-up effect. The BA-4840 battery contains 64 long "C" round cells made up of 16 strings of four paralleled cells connected in series. The light load, heavy load cycling application (receive-transmit), averages 578 mA.

The specific heat of a magnesium battery has been calculated to be approximately 0.30 cal/°C/g. The BA-4840 battery weighs 10 lb. The temperature rise in 1 hr of test if there is no heat loss should be

$$\frac{0.578 \text{ A-hr} \times 1610 \text{ cal/A-hr} \times 16 \text{ cells in series}}{10 \text{ lb} \times 453.6 \text{ g/lb} \times 0.3 \text{ cal/g}} = 10.9°\text{C or } 19.7°\text{F}$$

The rise in temperature at the center of a BA-4840 battery is shown in Fig. 5. The temperature rise in the early part of the discharge is approximately 20°F/hr with a gradual fall off in rate as the heat loss approaches the rate of heat generation. The MnO_2 efficiency *vs.* voltage discharge curve is shown in Fig. 6. The MnO_2 efficiency to 1.25V/cell is 65% which is high for a test where the high rate (transmit) drain is 1.16A for a cell which is approximately the same volume as a standard "D" size cell. The output is 33 W-hr/lb of complete battery. It is unlikely that such a high energy density could have been achieved without the heat-up effect. Single cells discharge on the same loads per cell had less temperature rise due to a higher rate of heat loss, and the output per cell to cutoff was lower.

Ability of the magnesium cell to withstand high temperatures.—The high heat in relationship to output characteristic of the magnesium MnO_2 dry cell could

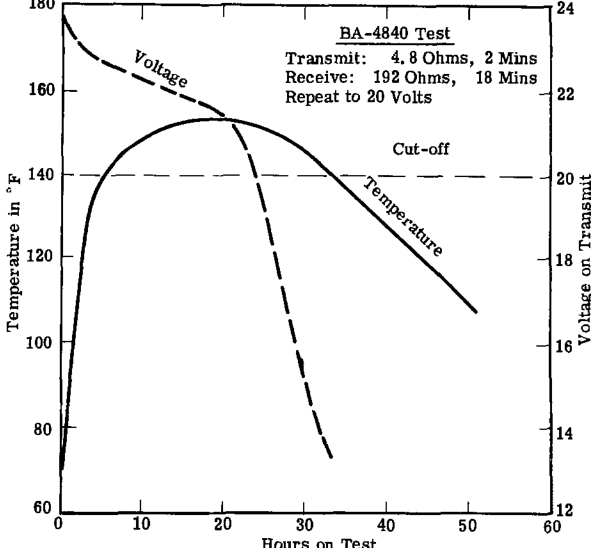

Fig. 5. Temperature in center of battery and voltage on transmit for BA-4840 battery tested in 75°F room.

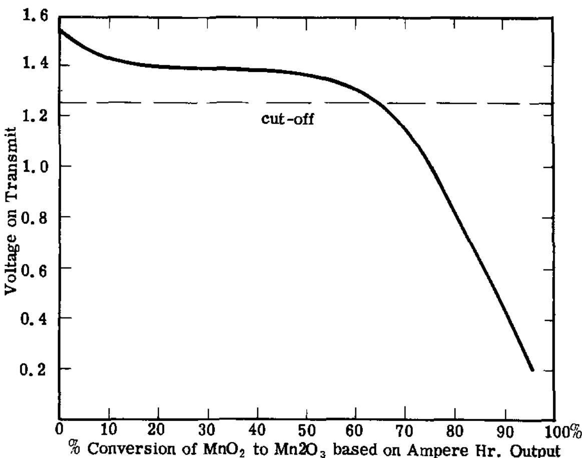

Fig. 6. Efficiency of utilization of available MnO_2 of BA-4840 battery tested in 75°F room.

be a detriment under certain conditions if the system were unstable at high temperatures. Situations where such high internal temperatures might occur in batteries are: when discharging on high rate drains in high environmental temperature or under extremely high rate discharge, especially if insulated.

Fortunately, the magnesium MnO_2 dry cell, as now generally made, will withstand temperatures much higher than those that are detrimental to other conventional aqueous dry cell systems. A major factor is that the magnesium cell uses plain paper as the separator instead of decomposable gels.

As an example of this ability to perform well at high temperatures, short "A" size magnesium cells were made with special closures that would remain stable at high temperatures. These cells were discharged on a 20 mA constant current load while held immersed in oil at 240°F. The results are shown in Fig. 7. The voltage on load was exceptionally high averaging 1.8V and the efficiency of utilization of the MnO_2 was 73% to a 1.7V cutoff with an energy density of 47 W-hr/lb of cell.

Since the magnesium cell (*i*) does produce a significant amount of heat on discharge, (*ii*) improves in performance with increasing temperature, and (*iii*) can withstand high temperatures, special provisions to minimize the heat loss, thus increasing still farther the battery internal temperature, should yield additional improvement. Insulated batteries have shown significant improvement over uninsulated batteries (7).

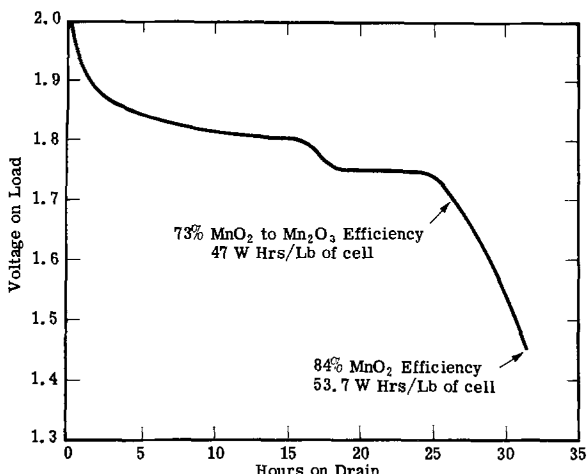

Fig. 7. Short "A" size magnesium cells on 20 mA, 8 hr/day while in oil at 240°F.

The BA-4840 battery mentioned earlier would not even rise to cutoff when tested at 20°F but when encased in styrofoam, the hours service at 20°F equaled that of the uninsulated battery at 70°F. The advantage was not just at low temperature. Smaller cells in the same size battery, but also including insulation, resulted in the same service at room temperature as had been obtained with larger cells in the uninsulated version of the battery.

This response of the magnesium cell to temperature has implications beyond just service application in that it must also be taken into account in testing. Cells tested individually, but in close proximity in a confined space, will give much better service than cells spread out in circulating air, especially on heavy continuous drains. This could lead to false conclusions, if the variable being considered was something other than test conditions, for instance if one lot was tested individually and the other as part of a clustered group.

Also, in predicting the service of a proposed battery involving the combination of many cells, it is often the practice, for convenience, to do the actual testing on single cells. In the case of magnesium cells this could lead to false conclusions and the rejection of a combination which might actually meet the requirement when tested as a complete battery. This is demonstrated in Fig. 8.

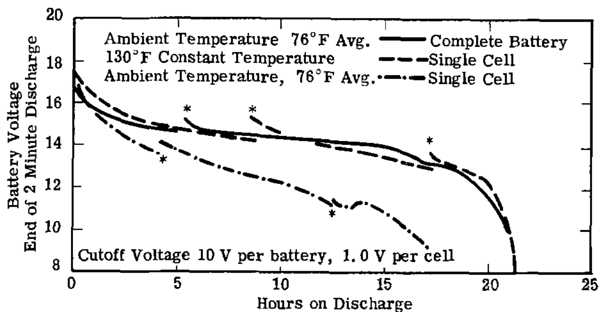

Fig. 8. Single cells at elevated temperature to simulate conditions in a multicell battery. *, Rest on open circuit overnight.

While working under a USAECOM Research and Development contract, to develop a high rate battery to power an experimental transceiver, an attempt was made to predict battery service from the results of testing single cells. The load per cell was approximately the same as on the cells of the aforementioned BA-4840 battery. The single cells tested at room temperature (approx. 76°F) gave only 16 hr, whereas the complete battery in the same room gave 21 hr. The average internal temperature of the battery during discharge was found to be 130°F. So single cells were then tested in a 130°F oven. The service then equaled that of the battery. Single cell testing at 130°F was then used to evaluate a group of design variables, and the best combination was selected while keeping the number of cells manufactured to a minimum. The results of the single cell testing were then validated by building and testing actual batteries (8).

The conclusion here is that if single cell testing is desirable to predict the performance of a multicell battery, a way to accomplish this is to determine the average internal temperature of the battery and test individual cells at this temperature.

In summary, the magnesium MnO_2 dry cell is somewhat unique among aqueous primary cells in the amount of heat which accompanies discharge, the improvement with high temperatures, and the stability at high temperatures. These properties can be exploited to advantage, in high rate multicell batteries, can be abetted by insulation, and should be taken into account in testing.

Anodic Polarization Behavior of High-Purity 13 and 18% Cr Stainless Steels

E. A. Lizlovs* and A. P. Bond*

Research Laboratory Climax Molybdenum Company of Michigan, Ann Arbor, Michigan 48106

ABSTRACT

Potentiodynamic polarization curves were obtained in N H_2SO_4 and in N HCl for 13 and 18% Cr ferritic stainless steels containing 0-5% Mo. The critical current density for passivation was decreased by molybdenum additions in both acids, the decrease being more pronounced for the 18% Cr steels than for the 13% Cr steels. No complete passivity was obtained for the 13% Cr steels, even with the 5% Mo addition, in N HCl. The addition of 1% Mo to 18% Cr steels resulted in complete passivity in N HCl. Pitting potentials in M NaCl at 25°C increased linearly with molybdenum content. Pitting potentials increased more rapidly for the 18% Cr steels than for the 13% Cr steels. All alloys suffered pitting corrosion in 10% $FeCl_3$; however, alloys of higher Cr-Mo content were the least pitted and showed the smallest weight losses.

Earlier work at the Climax Laboratory and other laboratories has clearly demonstrated the excellent corrosion resistance of high-purity ferritic stainless steels (1-6). However, more information is needed to establish the effect of molybdenum on polarization behavior at various chromium levels. In continuation of previous work with 25% Cr steels, the investigations were carried out with 13 and 18% Cr steels alloyed with up to 5% Mo.

Experimental Procedures

Materials.—The experimental ferritic stainless steels were produced by induction melting and casting in vacuum. The compositions are given in Table I. The ingots were hot forged at 2000°F (1080°C) to ¾ in. (1.90 cm) thick plates, which were then hot rolled to 0.30 in. (0.76 cm) thick plate and then cold rolled to 0.15 in. (0.38 cm) thickness. Materials containing 0, 1, and 2% Mo were heat-treated for 1 hr at 1500°F (815°C), followed by water quenching. Materials containing 3.5 and 5% Mo were heat-treated for 1 hr at 1800°F (980°C), followed by water quenching. Metallographic examinations did not show the presence of intermetallic phases in any of the materials. The composition and heat-treatment of alloys were such that they were immune to intergranular corrosion.

Polarization experiments.—Potentiodynamic polarization experiments were performed in nitrogen-saturated N H_2SO_4 and N HCl at 29.8° ± 0.1°C using standard equipment and techniques. The potential scanning rate was 520 $mV \cdot hr^{-1}$. The electrodes were mounted in epoxy, the exposed surface, approximately 0.6 by 0.5 cm, always being a longitudinal section parallel to the rolled surface. Electrodes were mechanically polished, using standard metallographic techniques; the final polish was with 0.3μ alumina.

Pitting potentials were determined for all experimental stainless steels in M NaCl at 25° ± 0.1°C. Electrodes for the determination of pitting potentials were the same as described above, except that polishing was only through 600-grit SiC metallographic paper. Furthermore, the fine crevices between the epoxy mount and the stainless steel sample were masked with Glyptal to prevent crevice corrosion of the electrode. The "scratch" technique, introduced by Pessall and Liu (7), was employed for the determination of pitting potentials. The electrode was first polarized potentiostatically to some potential well below the expected pitting potential. The polarization current and potential were continuously recorded by a two-pen strip-chart recorder. The polarization current was allowed to stabilize and then the electrode surface was scratched with a sharp silicon-carbide crystal mounted on the end of a glass tube. The scratching of the electrode surface resulted in a sharp polarization current "blip." The electrode potential was manually adjusted by 20 mV steps to more and more noble potential values, until the scratch failed to repassivate, a failure which was indicated by a gradual current rise after the electrode was scratched. The pit was allowed to develop for 10 min, and then the electrode was examined visually. Only those results were considered to be valid where pits actually developed at the scratched site.

Some potentiostatic experiments with selected alloys were also performed in N HCl. In these experiments, a preset potential, corresponding to the minimum current in the passive state in hydrochloric acid, was immediately applied after the masked electrode was immersed in acid. The electrode was kept at this potential for several hours and current was recorded as a function of time. These experiments were designed to determine whether a particular alloy would suffer general corrosion in hydrochloric acid at passive potentials.

All potentials were measured and reported with respect to the saturated calomel electrode.

Immersion tests.—All of the alloys were tested in acidified 0.33M $FeCl_3$ (pH 1). Test duration was 24 hr. Selected alloys were also tested in N H_2SO_4, saturated with oxygen at 25°C, and in N HCl, saturated with nitrogen, also at 25°C. Test duration, unless otherwise noted, was 24 hr. Test coupons were 2.5 by 2 cm, polished through No. 600 SiC paper. In all immersion tests, except for the ferric chloride test, samples were activated by touching with a magnesium rod immediately after immersion in acid.

stainless steels in N HCl are shown in Fig. 1. A similar set of curves, except for much more pronounced critical peaks, was also obtained for 18% Cr steels in N HCl. Critical current density decreased with an increase in molybdenum content for all materials (Fig. 2). Beyond the critical peak, current for unmasked electrodes fell to some minimum value and then increased again, so that no well-defined passive region was obtained for any of the materials. In general, the relatively high and increasing polarization current beyond the critical peak for the unmasked electrodes in hydrochloric acid is caused either by crevice corrosion along the metal-epoxy mount boundary or by general corrosion because of incomplete passivation. Visual inspection of the 13Cr-5Mo electrode after the potentiostatic exposure to N HCl (29.8 C) at -0.220V for approximately 1½ hr showed that the electrode surface was uniformly etched. Furthermore, the polarization current density remained constant, after the rapid initial rise, at about 0.9 mA/cm^2, which was approximately the same current density as recorded under potentiodynamic conditions at -0.220V (Fig. 1). In view of the fact that all of the other 13% Cr alloys exhibited higher minimum current densities, it can be assumed that all of the 13% Cr ferritic stainless steels suffered general corrosion at potentials beyond the critical peak.

The masked 18Cr-1Mo and 18Cr-2Mo alloys were exposed to N HCl at -0.080 and -0.100V, respectively. The current density, at first, was of the order of 10^{-6}

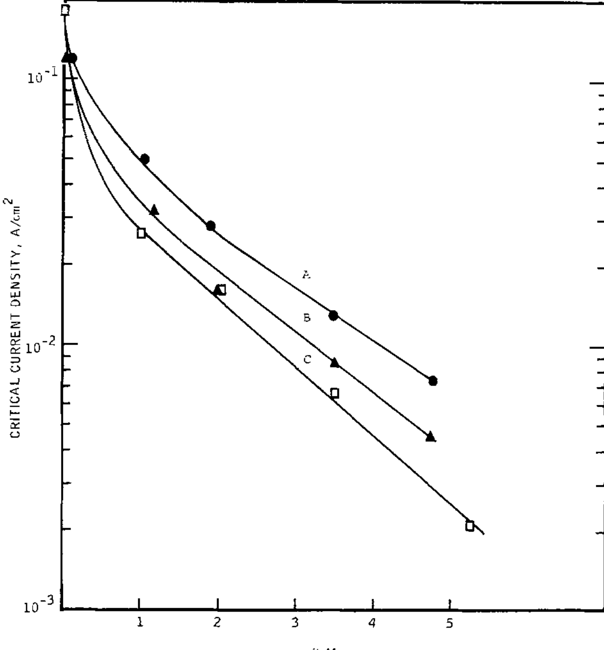

Fig. 2. Dependence of critical current density on molybdenum content for high-purity ferritic stainless steels in N HCl at 29.8°C. A, 13% Cr; B, 18% Cr; C, 25% Cr [data from Ref. (4)].

A/cm^2, as expected for complete passivity; however, it increased in an irregular manner to the order of 10^{-5} A/cm^2. Examination of the electrode surface showed no general corrosion. The corrosion damage was localized at places along and under the Glyptal masking. Hence, these materials did passivate completely in 1N HCl, but were very sensitive to crevice corrosion, which could be initiated quite readily at the Glyptal-metal boundary. The 18% Cr steel was not investigated in these experiments, but 18 and 25% Cr steels have been previously shown to sustain general corrosion at passive potentials (3, 4). Besides, current density at the minimum is more than 10^{-3} A/cm^2, which also indicates that this material should suffer general corrosion in N HCl at passive potentials.

Polarization curves in N H_2SO_4 were normal; that is, they showed a critical peak and a complete passive region up to normal transpassive transition potentials with passive current densities in the order of 10^{-6} A/cm^2. Critical current densities decreased with an increase in molybdenum content (Fig. 3). Results on 25Cr alloys are included from a previous study (4).

In contrast to a strong and well-pronounced effect on critical current densities the effect of molybdenum on primary passivation potential was only slight and possibly without practical significance. Nevertheless some trends were observable. Primary passivation potentials in hydrochloric acid became more active as the molybdenum was increased, and 18% Cr steels had more active primary passivation potentials than corresponding 13% Cr steels (Table II). In sulfuric

acid primary passivation potentials first became more active then tended to become more noble as the molybdenum content was increased. The 18% Cr steels in sulfuric acid showed a tendency to have somewhat more active primary passivation potentials than corresponding 13% Cr steels.

Pitting potentials became more noble for both series of stainless steels with an increase in molybdenum content, the increase being more pronounced for the 18% Cr series (Fig. 4). In both cases, the relationship between the pitting potential and molybdenum content appeared to be linear. Pitting potentials for the 13Cr-

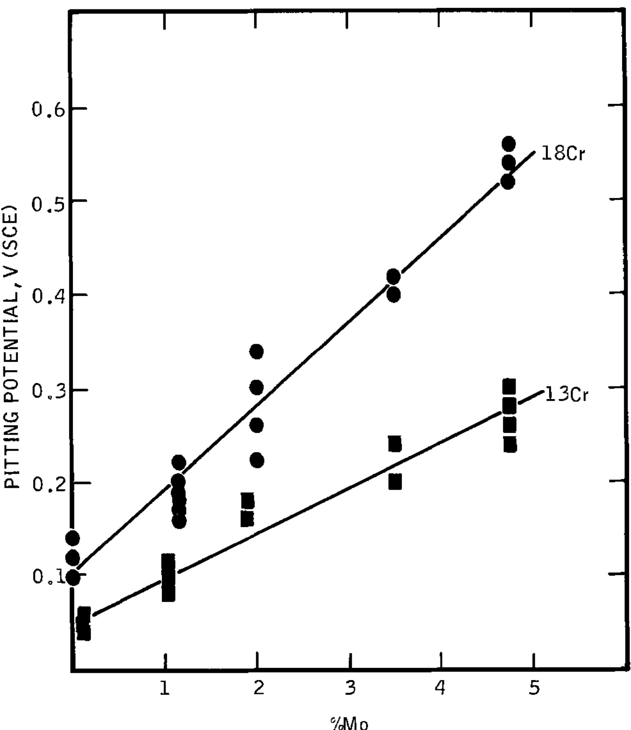

Fig. 4. Pitting potentials for the 13 and 18% Cr ferritic stainless steels in M NaCl at 25°C.

2Mo alloy were approximately 20-40 mV more noble than predicted by the linear relationship. The chromium content, however, for this alloy was 13.60% (Table I), as compared to an average close to 13% for other molybdenum-containing steels in the series, and this higher chromium content probably accounts for most of the deviation.

Immersion tests.—Corrosion rates in acidified 0.33M $FeCl_3$ (pH 1) are given in Table III. The 13Cr- and 1Mo steels suffered severe general corrosion in ferric chloride, while the remaining materials were pitted. No beneficial effect of molybdenum on the rate of pitting corrosion was evident for the 13% Cr steels. On the 18% Cr base, higher molybdenum concentrations do result in a decrease in pitting rate; however, the effect becomes evident above a molybdenum content of 1%.

Corrosion rates in oxygen-saturated N H_2SO_4 and nitrogen-saturated N HCl, both at 25°C, are given in Table IV. Data for the 25% Cr ferritic stainless steels from a previous investigation (4) are also included in Table IV for comparison.

Discussion

The effect of molybdenum on the active-passive transition and on the ability to develop a passive film under severe experimental conditions is dramatically illustrated by families of polarization curves in N HCl (Fig. 1); at the 13% Cr level, no complete passivity (characterized by current densities on the order of 10^{-6} A/cm² or less for masked electrodes and absence of general corrosion) in 1N HCl was achieved even at 5% Mo content. The current maxima were displayed for all 13% Cr materials at potentials where the critical current density peaks were expected, and, therefore, these peaks were considered to be critical current densities, even if no complete and pronounced passive region was present. Beyond the critical peak, the current dropped to some minimum value and then rose again sharply. The critical current densities and cur-

[a] Data from Ref. (4).

rent density minima decreased and became more pronounced as the molybdenum content increased. This can be interpreted as a decrease in active and passive dissolution rates with an increase in molybdenum content. Especially interesting is the sharp decrease in dissolution rate beyond the primary passivation potential. It can be assumed that a decrease in dissolution rate of a metal beyond its primary passivation potential results from the hindering effect of the formation of the passive film; instead of direct dissolution, the alloy forms a passive film first, which then dissolves. Apparently, as molybdenum content increases, the film formation reaction is greatly enhanced resulting in more pronounced current minima for alloys of higher molybdenum content.

The effect of molybdenum additions to 18% Cr steels is similar to that for 13% Cr steels. At the 18% Cr level, however, the addition of 1% Mo is enough to permit development of complete passivity, as evidenced by decreased values of current minima; however, even at 5% Mo content, materials still remain quite sensitive to crevice corrosion in *N* HCl. As shown in earlier work, increasing the chromium content to 25% does allow molybdenum-bearing alloys to develop a passive film that completely resists crevice corrosion in *N* HCl (4, 6, 8).

In a less-severe medium, *N* H_2SO_4, all materials developed complete passivity and a full passive range. Active corrosion rates decreased and ease of active-passive transition was enhanced by the increase in molybdenum content, as evidenced by decreasing critical current densities with increasing molybdenum content (Fig. 3).

The analysis of the critical current density data showed an interesting correlation with the molybdenum content. The plots of the critical current density *vs.* molybdenum content at 13, 18, and 25% Cr in *N* H_2SO_4 and *N* HCl acid are shown in Fig. 2 and 3. Data for 25% Cr steels are taken from previous work (4), supplemented by the results from trial experiments with 26Cr-1Mo alloy in *N* H_2SO_4. As shown in Fig. 2 and 3, the increase in molybdenum content from 0 to 1% results in a sharp decrease in critical current density peak in *N* H_2SO_4 and *N* HCl. This decrease becomes more pronounced with an increase in chromium level. At 25% Cr level even small additions of molybdenum should result in a very sharp decrease in critical current density. Further increases in molybdenum content from 1 to 5% for 18 and 25% Cr steels and from 2 to 5% for 13% Cr steels were semilogarithmic (exponential) for HCl. Again, the effect of molybdenum on the critical current density became more pronounced with an increase in chromium level.

Families of curves given in Fig. 2 and 3 should be very useful in predicting the magnitude of critical current densities for 13-25% Cr steels in *N* H_2SO_4 and *N* HCl. These curves should also allow predictions of relative critical behavior in other media.

The effects of molybdenum on pitting potentials were strongly dependent on the chromium level of ferritic stainless steels. The pitting potentials for 18% Cr steels were more noble than for corresponding 13% Cr steels. Furthermore, the shift of pitting potentials to more noble values with increasing molybdenum content was more pronounced at 18% Cr than at the 13% Cr level. Previous work has shown that at the 25% Cr level molybdenum-containing steels are not only highly resistant to pitting but are also resistant to crevice corrosion, even under severe oxidizing conditions (4, 6, 8).

According to pitting potentials, the 18% Cr ferritic stainless steels containing 2% or more molybdenum and 13% Cr steels containing over 3% Mo should be quite resistant to pitting corrosion in chloride environments under moderately oxidizing conditions. None of these materials, however, is expected to be resistant under strong oxidizing conditions, and, indeed, all alloys are subject to pitting corrosion in ferric chloride at room temperature.

While crevice corrosion was not specifically studied for 13 and 18% Cr steels, they are all expected to be very sensitive to this type of corrosion, as predicted by polarization curves in 1*N* HCl. Also, in general, any materials that are subject to pitting corrosion will be subject to crevice corrosion.

Data presented in Table IV show some interesting correlations between corrosion rates and chromium and molybdenum contents. The steels of lower chromium content corroded at lesser active rates in sulfuric and hydrochloric acid than corresponding steels of higher chromium content. An increase in molybdenum content from 0 to 5% at the 13% Cr level had no significant effect on active corrosion rates in sulfuric and hydrochloric acids; at the 18% Cr level there was a pronounced decrease, while at 25% Cr there was a very sharp decrease. The 25% Cr-3.5% Mo and 25% Cr-5% Mo steels actually repassivated after being activated in oxygenated *N* H_2SO_4 (4).

Summary

The effect of molybdenum on the decrease of critical current density in *N* H_2SO_4 and *N* HCl acids is dependent on the chromium level; the higher the chromium level, the more pronounced was the effect of molybdenum, especially in the 0-2% range. The effect of molybdenum on the formation and stability of the passive film is also dependent on the chromium level; no complete passivity was attained for any of the 13% Cr steels in *N* HCl; at the 18% Cr level the addition of 1% Mo allowed achievement of complete passivity in *N* HCl.

Pitting potentials in M NaCl at 25°C increased linearly with an increase in molybdenum content. The pitting potentials increased more rapidly for the 18% Cr steels than for the 13% Cr steels. All alloys suffered pitting corrosion in 10% $FeCl_3$ solution; however, steels of higher Cr-Mo content were the least pitted and showed the smallest weight losses.

Manuscript submitted Oct. 24, 1974; revised manuscript received Jan. 20, 1975. This was Paper 80 presented at the Miami Beach, Florida, Meeting of the Society, Oct. 8-13, 1972.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1975 JOURNAL. All discussions for the December 1975 Discussion Section should be submitted by Aug. 1, 1975.

Publication costs of this article were partially assisted by the Molybdenum Company of Michigan.

Effect of Arsenic on the Composition and Optical Constants of Iron Passive Film Reduced at 100% Current Efficiency

B. Agius* and J. Siejka*

Groupe de Physique des Solides de l'Ecole Normale Supérieure, Tour 23, 11 Quai Saint-Bernard, 75005 Paris, France

ABSTRACT

Nuclear reaction microanalysis, Rutherford backscattering of 1.8 MeV $^4He^+$ ions, and ellipsometric techniques have been used to investigate cathodic reduction of iron passivated in O^{18} enriched neutral solutions containing arsenic. Arsenic inhibition allows the reduction to take place at $-3°C$ with 100% current efficiency. Thus reduction of iron from Fe^{3+} to $Fe°$ and of hydrogen was completely inhibited. It was found that arsenic could only adsorb if the surface was oxide free. During cathodic reduction, the composition and optical constants of the film remain constant ($n^*_{ox} = 1.47 - 0.80i$ for a layer with initial thickness of 30Å), but during passivation of the film they vary with the oxidation potential.

The cathodic reduction of iron passivated in a solution of $0.15N$ sodium borate and $0.15N$ boric acid is reported to take place following either the mechanism

$$Fe_2O_3 + 6H^+ + 2e^- \rightarrow 2Fe^{2+} + 3H_2O \qquad [A]$$

which associates an electronic charge of $n = 2e/3$ with each oxygen ion passing into the solution, or the mechanism

$$Fe_2O_3 + 6H^+ + 6e^- \rightarrow 2Fe° + 3H_2O \qquad [B]$$

which yields a value of $n = 2e$. Previous work on this subject has used a wide variety of measurement techniques: coulometry (1), ellipsometry (2, 3), spectrophotometry (1-3), and nuclear microanalysis (4). More specifically, the current efficiency of the cathodic reduction assuming mechanism [A] was measured by Sato and Kudo (2) to be 50% and by Nagayama and Cohen (1) to be 70%. With most methods n can only be deduced from changes of electrical or optical parameters of the oxide film. Nuclear microanalysis of stable oxygen isotopes, permits direct measurement of the quantity of oxygen fixed at the sample surface thus providing direct calculation of the electronic charge n associated with each oxygen atom going into the solution. In a previous work (4) determinations of oxygen loss gave a current efficiency of the cathodic reduction of 48% at 23°C, calculated according to mechanism [A]. The current efficiency varies with the temperature and reaches 64% at $-3°C$ and 35% at 50°C (4). This difference in faradaic yield might be attributed to hydrogen evolution, to the reduction of Fe^{3+} to $Fe°$ (1), or to the presence of Fe^{6+} cations (1). All these assumptions are both possible and probable, and they demonstrate the difficulty of delineating passivation phenomena.

To clear up this problem, we have sought a system in which the cathodic reduction would take place only according to mechanism [A], where 2/3 electronic charge would be associated with each oxygen atom going into solution. In fact, given such a system we can be certain of its stoichiometry (Fe_2O_3), of its structure (compact and homogeneous), and of the absence of any parasitic reaction. Use of ellipsometry together with our method of oxygen analysis would permit determining the optical parameters of the film.

We have therefore worked in this direction, taking account of our previous work at low temperature (4) as well as of Sato's conclusions from his study of corrosion inhibition (5). The present article is the first in a series of general discussions of passivation; previous articles (6, 7) were devoted to nickel passivation. Here we will deal with iron passivated in a buffered solution of $0.15N$ sodium borate and $0.15N$ boric acid in O^{18} enriched water in the presence of 4×10^{-4} M/liter of As_2O_3 and maintained at $-3°C$. For such a system there is in fact excellent agreement between the theoretical mechanism [A] of cathodic reduction and the experimental results obtained by nuclear microanalysis.

Experimental

Measurement of O^{16} and O^{18}.—The nuclear microanalysis method used for this study is based on the determination of the number of particles resulting from the following nuclear reactions

$$O^{16}(d,p)O^{17*} \quad \text{and} \quad O^{18}(p,\alpha)N^{15}$$

It yields a number $N_{O^{16}}$ or $N_{O^{18}}$ of oxygen atoms per square centimeter fixed on the specimen surface. The general technical principles of this method have been described elsewhere by members of our laboratory (8, 9), and the general principles of its application to various fields are described by Amsel *et al.* (10-12). The number of oxygen atoms coming from the solution, $\hat{N}_{O^{18}}$, can be obtained by dividing $N_{O^{18}}$ by the solution enrichment (ratio of O^{18} to the total oxygen in the solution), *i.e.*, by normalizing the results.

Measurement of arsenic.—When a sample is bombarded with charged particles of mass m and energy E_o, the energy E of the particles backscattered by nuclei of mass M is given, at an angle of 180°, by the Rutherford formula

$$E = E_o \left(\frac{M - m}{M + m}\right)^2$$

The energy spectrum of the backscattered particles depends on the masses of the nuclei present in the target. This analysis method, described elsewhere (12), is of special interest when traces as low as 1/1000 of a monatomic layer of high-Z elements are observed on a low-Z matrix (13). A 1.8 MeV $^4He^+$ beam was used in the present experiments to determine the inclusion of arsenic inhibitor in passive films.

Preparation of solutions and specimens.—The specimen used was a pure iron electrode (99.99% pure, obtained from the National Research Corporation) with a surface area of 10×10 mm; an iron wire electrowelded to the specimen provided electrical contact.

* Electrochemical Society Active Member.

Key words: current efficiency, arsenic, inhibitor, iron, O^{18} tracing, cathodic polarization, nuclear microanalysis, ellipsometry.

Polishing and preparation of the specimen surface were the same as described in Ref. (4).

A buffered solution (pH = 8.42) of 0.15N sodium borate and 0.15N boric acid in deaerated water, 10% enriched[1] in O^{18}, was used. Owing to the high cost of the enriched solution, a special small-capacity cell was used, with the volume of the electrolyte being 10 cm^3. For the inhibitor study, As_2O_3 was added at 4×10^{-4} M/liter. The isotopic exchange of oxygen between BO_3^{3-}, AsO_2^-, and H_2O was found to be fast (14).

All potentials are expressed with respect to the standard hydrogen scale. Most of the experiments were carried out at $-3° \pm 1°C$.

Ellipsometric measurements.—A commercially manufactured manual ellipsometer measuring angles to within 0.01° was used. The light source was a 250W tungsten lamp with a photomultiplier as the detector. The measurements were made in a dark room to prevent stray light from producing spurious signals in the detector. All ellipsometric measurements were made at 5461Å, at an angle of incidence $\phi = 70° 54'$, with a quarter-wave plate as compensator. The ellipsometer was aligned with respect to the iron specimen by the procedure described by McCrackin *et al.* (15), and the relative phase retardation (Δ) and relative amplitude reduction (tan ψ) caused by reflection of light from the specimen were determined for the components of the electric vector parallel and normal to the plane of incidence.

All our measurements were made *in situ*, generally on samples passivated in O^{18} enriched solutions. As noted previously, we used a low-volume oxidation cell (10 cm^3) (16). The light beam entered and left through two optically flat glass windows. Measurements on the same specimen, dry inside and outside the cell, gave agreeing results: the cell does not influence the polarization state of the light.

A computer program developed by McCrackin (17) was used to compute values of the real (n) and imaginary ($-in\kappa$) parts of the complex index of refraction n^* of the specimen itself which was assumed to be bare or covered by a film of given thickness grown on its surface.

Experimental procedure.—The experimental procedure is essentially the same as that used previously (4). First the sample was cathodically cleaned, then the ellipsometer was set at its extinction point. Optical parameters of the bare surface were measured. After this cathodic pretreatment the polarization was stopped for 5 min; the potential increased from $\phi_c = -650$ mV to a final value of stabilization of $\phi_{s2} = -510$ mV.

There is a very small change in P and A during this step of sample pretreatment. This change is only observable when the measurement is very sensitive ($\Delta P = \Delta A = 0.03°$). This effect will be discussed further in another article (18) and related to the nuclear method (4).

After the pretreatment (and change in P and A), the anodic films were formed in the same solution by potentiostatic oxidation at $+940$ mV. As with our previous work, we stopped the oxidation at a constant final current (5 $\mu A/cm^2$) and at this time remeasured P and A. The film was then reduced cathodically, again in the same solution, at a constant current density of 10 $\mu A/cm^2$.

Measurements of O^{18} losses were carried out by nuclear microanalysis on a series of six samples; each point of the curve $\hat{N}_{O^{18}} = f(Q_{mcoulombs/cm^2})$ was obtained on a new sample. Two kinds of ellipsometric experiments were made: the first on the same series of samples used to study O^{18} losses and the second on a single sample from the beginning to the final reduction state.

Ferrous ion concentration.—Since each step of our experimental procedure can place a certain number of ferrous ions in the electrolyte solution, which could conceivably interfere with the measurements of film growth, we have calculated the maximum possible number of ions which might be released by (*i*) cathodic pretreatment, (*ii*) the active-passive transition, and (*iii*) cathodic reduction of the passive film.

(*i*) *Cathodic pretreatment.*—After electropolishing, the specimen surface was covered by a natural oxide which contains 10^{16} oxygen atoms per square centimeter (4). During cathodic pretreatment, ferrous ions from the reduction of this oxide go into solution. Assuming a Fe_2O_3 oxide, at most 1.3×10^{16} ferrous ions should be found in the solution.

(*ii*) *Active-passive transition.*—An iron electrode passivated from its initial bare surface condition must pass through the active state. During this transition, some Fe^{2+} ions are released into the electrolyte. Their concentration (upper limit) can be estimated from the charge passed through the circuit during the formation of the passive film at its lower potential, *i.e.*, -260 mV. This charge is equivalent to about 3 mcoulombs, or 1.5 mcoulombs/cm^2. This value is of the same order of magnitude (1.8 mcoulombs/cm^2) as that found by Nagayama and Cohen (1) in the absence of arsenic and at 27°C. This quantity of charge corresponds to the oxidation ($Fe \rightarrow Fe^{2+}$) of 10^{16} iron atoms. Thus, at the time the sample is passivated, the concentration of iron ions in the electrolyte is no greater than 3.6×10^{-6} M/liter, *i.e.*, 2.3×10^{16} ions in all.

(*iii*) *Cathodic reduction.*—During cathodic reduction the number of ferrous ions in the solution will increase if the cathodic reduction takes place according to mechanism [A]. In this case the concentration of the ferrous ions added to the electrolyte for the total reduction of a film passivated at $+940$ mV, is directly proportional to the total charge passed through the circuit. In Fig. 1 the total charge is 4 mcoulombs, equivalent to 2.5×10^{16} Fe^{2+} ions ($Fe^{3+} \rightarrow Fe^{2+}$).

The total quantity of ferrous ions placed in solution by all three experimental procedures is at most 4.8×10^{16} atoms, or 7×10^{-6} M/liter. According to the literature (19, 20), the current densities and optical constants of the passive film are not affected by the presence of iron ions in the solution when their concentration does not exceed 5×10^{-5} M/liter. Hence, seven successive oxidation-reduction cycles of passive films formed at $+940$ mV could be performed in the same solution without exceeding a ferrous-ion concentration of 5×10^{-5} M/liter. Moreover, to minimize the possible influence of a deposition of iron oxide resulting from the oxidation of ferrous ions from the solution, some experiments were carried out with the solution being changed after each oxidation-reduction cycle. Essential ellipsometric measurements were performed in these conditions. No difference was detected when the concentration of ferrous ions did not exceed 5×10^{-5} M/liter.

We have also noted that the formation time of the passive film was rather short, 150 sec at $+940$ mV (4) rather than the 3600 sec usual in other studies (1, 2, 19). This minimizes the possible formation of a deposited oxide film.

Finally, we checked the concentration of iron in the solution by observing the decrease in current density during the potentiostatic oxidation of the iron. It is well known (19) that the final current density increases as a function of the iron concentration in the electrolyte.

All these observations permit the conclusion that the possible deposition of an iron oxide film from the oxidation of ions in solution is not important in the present work. Therefore in subsequent experiments the electrolyte was not changed after the cathodic pretreatment. It should be noted that in our apparatus it is very difficult to change the O^{18}-enriched solution without exposing the sample to the atmosphere.

[1] Normalized O^{18} enriched water produced at the Weizmann Institute, Rehovot, Israel. The natural abundance of O^{18} is 0.204%.

Evaluation of the optical parameters from ellipsometric and nuclear microanalysis.—Nuclear microanalysis yields the number N_O of oxygen atoms per square centimeter fixed on the specimen surface. From N_O an equivalent geometric thickness L_{nucl} can be deduced if the roughness of the metal-oxide interface and the density of the layer covering the sample surface are known or approximated. Ellipsometry is very sensitive to changes of state [adsorption of quantities equal to or less than a monolayer (21)]; it is nevertheless purely qualitative. From the two measurements ψ and Δ it is not possible to deduce the three physical parameters (the equivalent thickness d, the refraction index n, and the coefficient of adsorption k) characterizing the film which changes the state of the surface of the sample. Clearly, only in the case of a very flat surface, should the variation of the angle of incidence permit the ellipsometry to be self-consistent. Variation in the wavelength would only resolve this problem of quantitativity if n and k were independent of λ which is hardly the case with passive films (22). For homogeneous growth of a film (n and k constant), measurements made at two different thicknesses could make ellipsometry quantitative if one were sure of this homogeneity of the film within a tolerable limit of error.

It seems rather imprudent, particularly in the case of absorbing films, to assume a value for either the refractive index or the absorption coefficient when the study involves thicknesses equivalent to several monolayers which in the study of iron passivity corresponds to something less than 15Å. Furthermore, for a film of well-determined stoichiometry, a change in structure from compact to porous or vice versa involves a variation in optical index [related, for the case $k = 0$, to the density of the film by Clausius Mosotti's equation (23)]. Variation in the index observed by ellipsometry, particularly in the study of thin absorbing films, should be interpreted physically as a change either in stoichiometry or in electron structure of the film studied, or a combination of the two. The association with ellipsometry of another method just as sensitive, but more quantitative, permits resolution for the third unknown quantity. In nuclear microanalysis, if L_{nucl} is known precisely, then the simultaneous use of the two methods would permit choosing the pair n, k which fits the values of d and L_{nucl}. Only under these conditions can the measurements be free of the specific indetermination of ellipsometry (two experimental measurements to determine three unknowns).

Results and Interpretation

Cathodic reduction behavior.—O^{18} content in passive layers formed and reduced in O^{18} labeled solutions containing As_2O_3.—Figure 1 shows the number of oxygen-18 atoms fixed on the sample surface and the corresponding drop in potential as a function of the charge Q which has passed through the circuit during the cathodic reduction. All these samples were oxidized potentiostatically at + 940 mV and then reduced at $I = 10\ \mu A/cm^2$ for various times. The oxidation-reduction cycles were run at constant temperatures: +23° and −3°C. Let us notice immediately that this oxidation potential (+ 940 mV) is higher than the oxidation potential $As^{3+} \rightarrow As^{5+}$ ($\phi = +\ 330$ mV in our solution). Thus we assume that, if there is some incorporation of arsenic into the film during the oxidation of the sample, that arsenic is included as As^{5+}. The solid lines are the curves calculated for the reductive dissolution of ferric oxide at 100% current efficiency according to reactions [A] and [B]. However, for a borate system in the presence of arsenic pentoxide the over-all theoretical slope $\left(\frac{\Delta Q_{mcoulombs/cm^2}}{\Delta \hat{N}_{O18}}\right)$ according to the mechanism [A] can vary from 0.66e for pure Fe_2O_3 to 0.8e corresponding to the reduction of the film containing only

a, $n = 2/3e$ (theoretical value).

b, $n = 2e$ (theoretical value).

As_2O_5

$$As_2O_5 + 4e^- + 4H^+ + H_2O \rightarrow 2H_3AsO_3 \quad [C]$$

Experimentally, from the reciprocal of the slope of $\hat{N}_{O18} = f\ (Q_{mcoulombs/cm^2})$ we have found $n = 0.70 \pm 0.07e$ for − 3°C in presence of arsenic. Thus to determine the stoichiometry of the film we have measured the quantity of arsenic incorporated in the layer.

Determination of the stoichiometry of the passive film.—For incident $^4He^+$ ions at 1.8 MeV, Fig. 2 shows typical backscattering amplitude spectra obtained from iron passivated at + 940 mV in the presence or absence of arsenic. The neatly resolved peak at 1.46 MeV confirms the presence of arsenic. Calculations based on the Rutherford formula for elastic scattering cross sections lead to the value of 2×10^{15} arsenic atoms/square centimeter with an accuracy of 10%. As shown on Fig. 1, this film contains 19×10^{15} oxygen atoms/square centimeter. With the quantities of oxygen and arsenic present in the film known, the stoichiometry of this oxide can be calculated. At this passive potential most

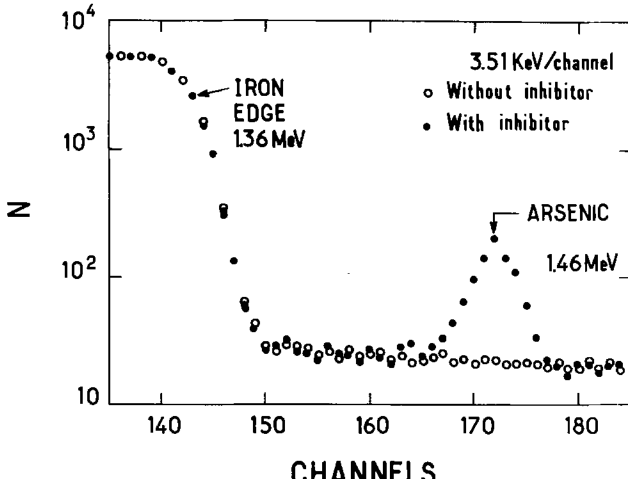

Fig. 2. Backscattering signal amplitude spectra for $^4He^+$ ions at 1.8 MeV obtained on iron passivated at +940 mV in 0.15N boric-borate buffer solution of pH 8.42 with and without 4×10^{-4} M/liter As_2O_3.

authors agree on the γ-ferric oxide structure. For the compound formed at $\phi = +940$ mV this implies the over-all stoichiometry $(As_2O_5) \cdot (Fe_2O_3)_{4.66}$.

During oxidation, arsenic might become localized at the interface between the passive film and the solution, be distributed in the passive film, or be placed at the metal-oxide interface. Figure 3 shows the arsenic loss during cathodic reduction of the film as a function of time, *i.e.*, as a function of the number of O^{18} atoms. This indicates that all arsenic atoms fixed during the oxidation of the film are embedded in the bulk of the oxide and, in particular, the arsenic resulting from the oxidation can be assumed to be distributed homogeneously in the film rather than being accumulated at the metal-passive film interface.

Let us now calculate the elementary charge associated with each oxygen atom going into solution during reduction of the system $(As_2O_5) \cdot (Fe_2O_3)_{4.66}$. We have shown that for each arsenic atom there are nine oxygen atoms present in the oxide. But, according to mechanism [C], 0.8 elementary charge is associated with each oxygen atom going into solution from the As_2O_5 reduction. On the other hand, 0.66 electronic charge is required for each oxygen atom from the Fe_2O_3 reduction. The average total charge associated with each oxygen atom going into solution would be

$$\frac{0.8 \times 5 + 0.66 \times 14}{19} = 0.7 \text{ electronic charge}$$

This is represented by curve "A" on Figures 4, 5, and 6a.

This theoretical value, available only after a determination of the arsenic in the film, agrees very well with the experimental value. We therefore conclude that the cathodic reduction of iron passivated in neutral solution containing 5×10^{-4} M/liter of arsenic and maintained at −3°C proceeds at a current efficiency of 100%, according to mechanism [A].

Equivalent film thickness L_{nucl}.—The thickness equivalent to the number of oxygen atoms has been calculated as a function of the charge Q passed during the cathodic reduction. The density of the passive film, whose stoichiometry has been determined $[(As_2O_5) \cdot (Fe_2O_3)_{4.66}]$, the roughness coefficient of the metal-oxide interface, and its structure (which is compact, as we shall show later) must be known. We assume for

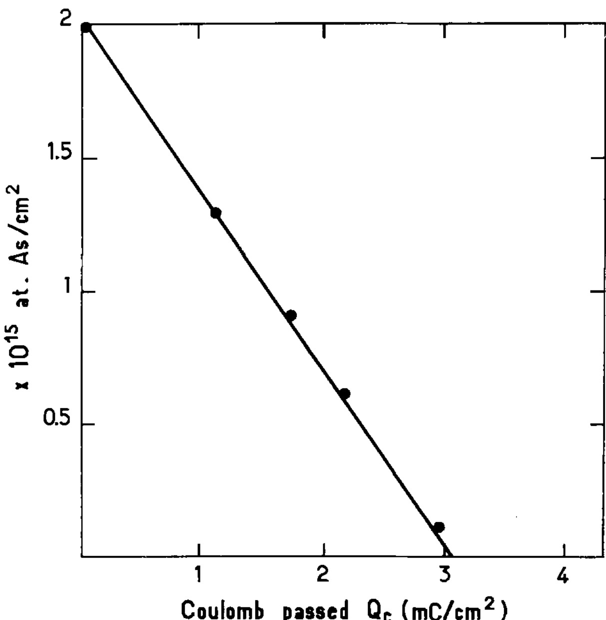

Fig. 3. Change of arsenic content during galvanostatic cathodic reduction at 10 $\mu A/cm^2$ for the passive films formed potentiostatically at −3°C and + 940 mV in 0.15N boric-borate buffer solution of pH 8.42 containing 4×10^{-4} M/liter As_2O_3 as inhibitor.

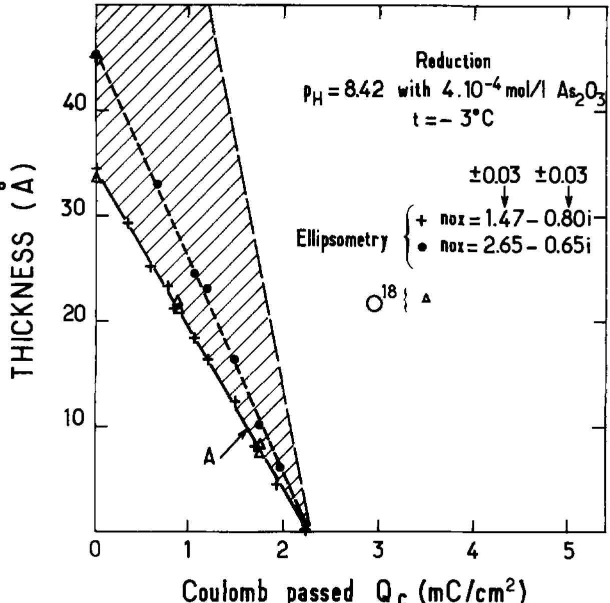

Fig. 4. Shaded zone, film thicknesses calculated from ellipsometric data obtained during galvanostatic cathodic reduction assuming the optical constant of the oxide (n_{ox} — k_{ox}) to be in the ranges 1-3.5 and 0-1, respectively. Film formation and reduction conditions are the same as for Fig. 3. A, theoretical curve calculated for reduction of $(Fe_2O_3)_{4.66} \cdot As_2O_5$ with 100% current efficiency, $n = 0.7e$.

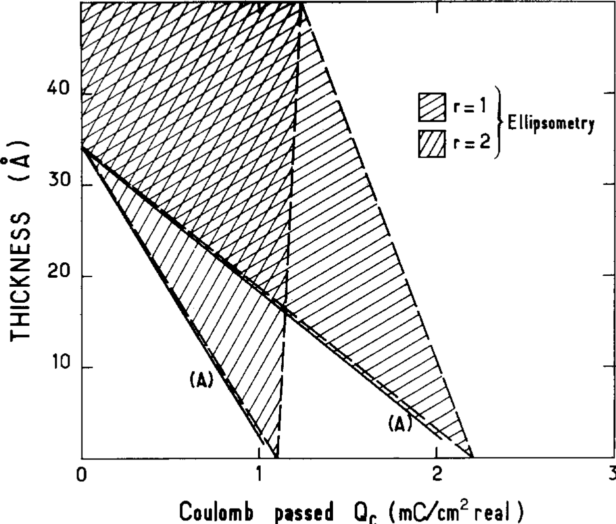

Fig. 5. Effect of the roughness factor (r) on the ellipsometric data from Fig. 4.

the sake of the calculation that the density of the passive film follows a simple additive law and that the densities are 5.24 g/cm³ for Fe_2O_3 and 4.32 g/cm³ for As_2O_5 (24). The result is a density $\rho = 5.0$ g/cm³. For this density, the thickness of a layer containing 10^{15} oxygen atoms/cm² is equivalent to 1.7Å. It is clear that, whatever the roughness value of the sample being studied, the slope giving the elementary charge associated with each oxygen atom going into solution is always $n = 0.7e$. This is important for understanding what follows.

Determination of the optical constant of pure iron.—In ellipsometric determination of surface films, the bare metal surface is used as optical reference. The iron sample is given cathodic pretreatment before being anodized. We showed previously (4) that our specimen under cathodic polarization was free of oxygen coming from the solution. We thus assume that the cathodically cleaned sample is free of any oxygen, and the optical constants of the bare iron sample are

measured in terms of Δ and ψ. From the measured values of Δ and ψ we calculated the refractive index n^*_s of iron applying the theory to film free surfaces. The result is

$$n^*_s = n_s - ik_s = (3.3 \pm 0.2) - (3.7 \pm 0.2)i$$

the mean of 20 measurements. Owing to spread among the samples, the measurements vary within 5% for both n and k. As shown in Table I, our values are fairly close to the complex refractive index for iron reported in the literature.

Estimation of the film parameters from ellipsometric results.—Determination of the film parameters.—For each pair of experimentally measured values P and A, we can calculate many different values of the refractive index and thickness of the passive film, provided that the refractive indexes of the iron substrate (n_s = 3.30-3.70i) and solution (n = 1.332) are known.

Following a customarily used procedure, we calculate the thickness and the optical constants

$$n^*_{ox} = n_{ox} - ik_{ox}$$

of the film assuming n_{ox} to be in the range 1-3.5 and k_{ox} in the range 0-1. For a given pair of experimental values P and A, calculation produces a number of values of n^*_{ox} and d, all of which fit the measured P and A within a given error limit (0.05°). It should be emphasized that the sensitivity of our measurements corresponds to uncertainties of 0.03° for P and A, which induce errors of 0.008 for n and 0.004 for k. Besides, the variation among samples would produce a deviation no greater thon 0.03 of n and k. Therefore all points whose optical constants differ by less than 0.06 would represent a homogeneous growth of the film. All optical-constant values given hereafter are understood to be subject to these error limits.

We have represented all our ellipsometric results in the shaded zone of Fig. 4. From among the wide range of possible solutions, we have shown in the figure the variation in thickness corresponding to an optical index close to that generally used in the literature[2] for pure compact Fe_2O_3: n^*_{ox} = 2.65 − 0.65i. These results have been drawn as functions of the number of coulombs per unit of apparent surface (*i.e.*, for r = 1). The results for r = 2 are also shown (Fig. 5), considering the assumptions generally accepted in the literature (3, 25) of the independence of the ellipsometric parameters ψ and Δ with respect to roughness. This is discussed in the next section.

Note that the roughness variation alters the slopes of the various curves $d = f(Q_{mcoulombs/cm^2})$. To characterize the reduction of the passive film and understand its mechanism we must know at least one other magnitude characterizing this film, for example, its thickness.

Ellipsometric results with a known film thickness.—We have transformed the number of oxygen-18 atoms, directly measured, into equivalent nuclear thickness (see Fig. 1). This is not possible except when the stoichiometry of the film is known [$(Fe_2O_3)_{4.66} \cdot (As_2O_5)$]. We have simply assumed a roughness factor of 1 for the initial calculation. In thus combining the ellipsometric and nuclear studies, we can then choose among all the possible ellipsometric solutions whose pairs n_{ox} and k_{ox} give the same thickness as equivalent nuclear thickness. We have thus obtained the following values of n^*_{ox} for the optical constant of this film

$$n^*_{ox} = (1.47 \pm 0.03) - (0.80 \pm 0.03)i \quad [1]$$

This differs from the value generally given for the ferrous oxide γ-Fe_2O_3 (n^*_{ox} = 2.55 − 0.4i). To explain this low value of the index of refraction, we can consider two hypotheses. The first involves the formation of a deposited film; the second, the presence of arsenic in the passive film. Using an ellipsometric method, Ord and De Smet (20) studied deposited films of iron oxide on different substrates and found a real refractive index of 1.7 at a wavelength of 6328Å and an angle of incidence of 60°. To avoid the formation of such a deposited film, we chose experimental conditions which permit very low ferrous ion concentrations: 3.6 × 10^{-6} M/liter (see experimental procedure). The first hypothesis can therefore be discarded. One might then imagine that the presence of arsenic inside the film could influence this optical constant. This will be discussed later, but meanwhile let us study the effect of roughness on the optical index of the film. Figure 6a summarizes the preceding discussion of

[2] γ-Fe_2O_3 : n_{ox} = 2.55-0.4i.

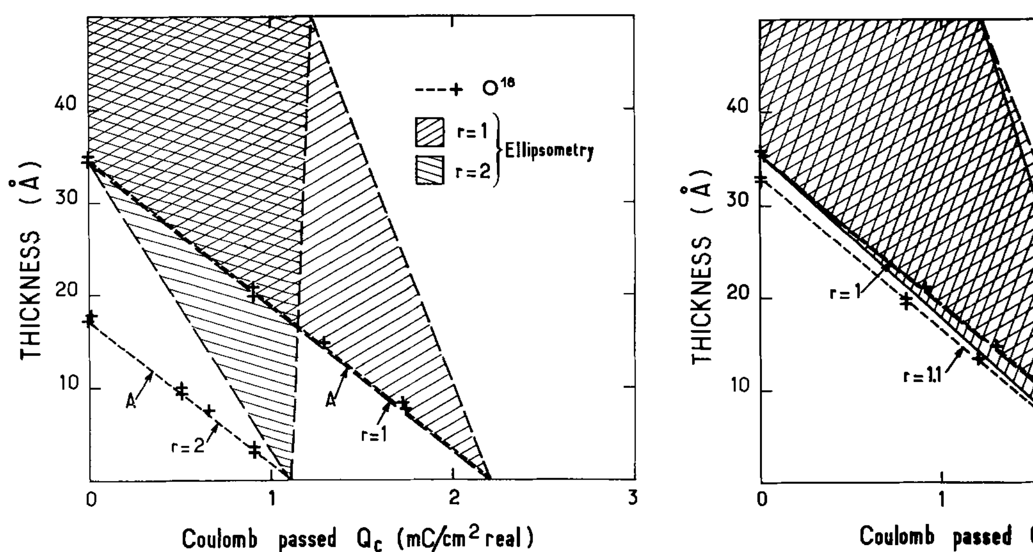

Fig. 6. Effect of the roughness factor (r) on the nuclear and ellipsometric data obtained under conditions described for Fig. 3. Ellipsometric data from Fig. 4 and nuclear data from Fig. 1.

(a, left) Calculations for r = 1 and r = 2.

(b, right) Calculations for r = 1 and r = 1.1.

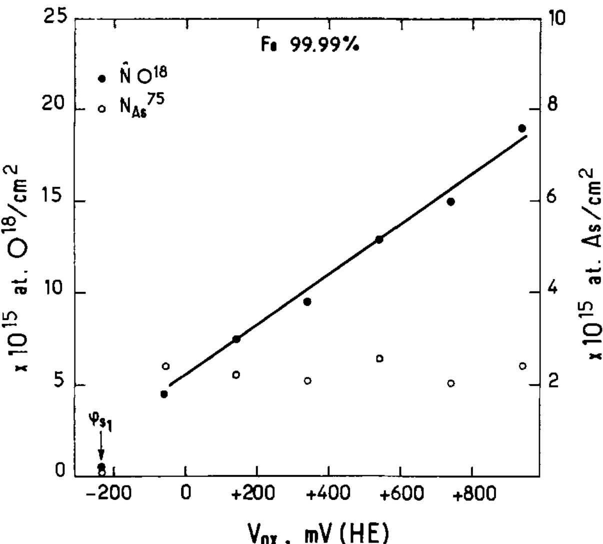

Fig. 7. Quantities of oxygen and arsenic atoms fixed on iron oxidized potentiostatically (I_{final} = 5 μA/cm²) as a function of potential. Solution the same as for Fig. 3.

the influence of the roughness factor on all the nuclear and ellipsometric data. Let us recall that the slope of the reduction curve $\hat{N}O^{18} = f(Q)$ (Fig. 1), which gives the value of the elementary charge associated with each oxygen atom going into solution, was independent of the roughness coefficient. Thus, if Δ and ψ are supposed to be independent of roughness (3, 25), clearly the optical and nuclear-thickness data are inconsistent for all values of r, except for a roughness of 1. This inconsistency is marked for a roughness of 2 (Fig. 6a) but exists all the same for a roughness r = 1.1 very close to the ideal surface (Fig. 6b). So the fact that there is inconsistency (except for r = 1) between optical and nuclear thickness seems to indicate that Δ and ψ vary with roughness. How could this happen? For the moment a precise answer would be difficult. However, if their variation is linear, as in coulometry, which appears to be plausible, then nothing would be changed in our deductions, since the optical thickness would diminish in the same proportion as r would increase. We are currently trying to verify this by studying the influence of the incident angle ϕ on such a system, ϕ being the only parameter capable of carrying this information.

If ellipsometry does depend on roughness but differently than coulometry does, the presence of arsenic would still influence the value of the optical index. The curves obtained for n^*_{ox} (γ-Fe_2O_3) = 2.55 − 0.4i never coincide with the theoretical curve A assuming the cathodic reduction mechanism of the $(As_2O_5)\cdot(Fe_2O_3)_{4.66}$ system with a current efficiency of 100%. At the worst, if ellipsometry does not vary with roughness as coulometry does, it would mean a slight variation of n_{ox} around n^*_{ox} = 1.47 − 0.80i. In what follows, as a working assumption, we assume that r = 1.

We previously hypothesized that the presence of arsenic in the passive film might explain the value which was suggested for its optical index and which is small compared to that generally accepted for a pure stoichiometric film of Fe_2O_3. To verify this hypothesis, we have studied the passive film prepared in the same solution but by another procedure, namely, at different oxidation potentials.

Anodic oxidation.—After the cathodic pretreatment the iron surface was oxidized potentiostatically as previously described above. Figure 7 shows the number of oxygen-18 atoms fixed on the sample surface as a function of the potential and the corresponding arsenic content of the passive films. Note that the quantity of arsenic is constant whatever the thickness of the film considered. This means that the stoichiometry of the film varies from $(As_2O_5)\cdot(Fe_2O_3)_{4.66}$ for ϕ = + 940 mV to $(As_2O_5)\cdot(Fe_2O_3)$ at + 140 mV. However, even though the stoichiometry varies with potential, the thickness equivalent to the number of oxygen atoms is always 1.7Å per 10^{15} atoms of measured oxygen-18, no matter what oxidation potential is used, assuming the additivity of densities (see above). We have thus translated the preceding results into equivalent nuclear thickness and have also shown (Fig. 8a, b) on the same figure the ellipsometric measurements made under the same conditions. Among the ellipsometric thicknesses possible, the one which would agree with the equivalent nuclear thickness would have for its index (Fig. 8b)

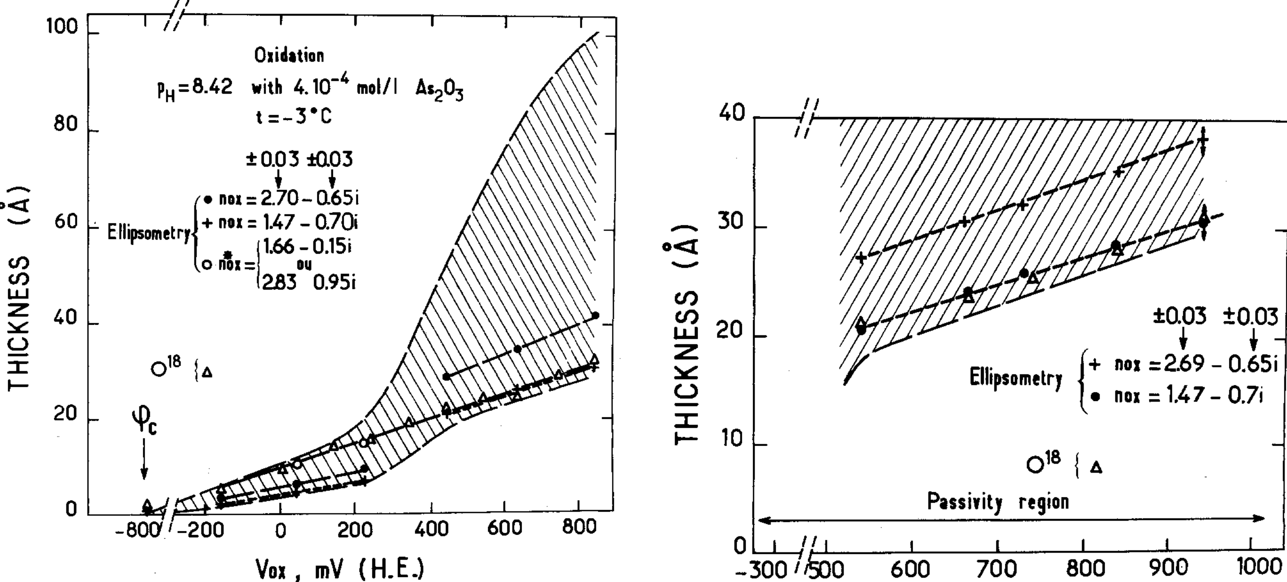

Fig. 8. Δ, Equivalent nuclear thicknesses of passive films deduced from O^{18} and As contents; shaded zone, film thicknesses calculated from the ellipsometric data obtained during passive film formation with the optical constant n_{ox} and k_{ox} assumed to be in the ranges 1-3.5 and 0-1. Solution the same as for Fig. 3.

(a, left) For the whole passive region.

(b, right) Between + 550 mV and + 950 mV/S.H.E.

$$n^*_{ox} = (1.47 \pm 0.03) - (0.7 \pm 0.03)i$$

and this in a potential region between + 550 and + 950 mV/HE, that is, for thicknesses greater than 20Å. For "nuclear thicknesses" thinner than 20Å, there is no agreement between these thicknesses and the ellipsometric thicknesses chosen for the same index. This could be explained by a structural change directly related to a variation in optical index of the film. However, taking the nuclear measurements as references independent of the applied passivation potential, the ellipsometric thickness agrees with the nuclear thickness for the indexes whose values are

$$n^*_{ox} = 1.66 - 0.15i$$

or

$$n^*_{ox} = 2.83 - 0.95i$$

rather than

$$n^*_{ox} = 1.47 - 0.70i$$

for thicknesses greater than 20Å.

The second value of the index should not be accepted, for if the variation of n^* is related to the presence of arsenic in the film, this increase would mean a diminution of the quantity of arsenic with the thickness of the passive film. But we have seen that there is nothing of the sort. In contrast, if $n^*_{ox} = 1.66 - 0.15i$ effectively defines the optical properties of the film for thicknesses less than 20Å, this would mean that for these thicknesses the conductivity is much lower, that is, that the structure of the layer is not yet perfect and that only for films thicker than 20Å will it tend towards a spinel structure and be a good conductor ($k = 0.7$).

Discussion

Mechanism of cathodic reduction.—From previous and present results, it is now possible to establish in detail the mechanism of the cathodic reduction of a passive film formed on iron in a sodium borate-boric acid solution of pH 8.42 containing 4×10^{-4} M/liter arsenic trioxide as inhibitor and maintained at about − 3°C. Detailed study of the cathodic reduction was made for the film $(As_2O_5) \cdot (Fe_2O_3)_{4.66}$ but the resulting conclusions can reasonably be considered as possible to generalize to any stoichiometry. Thus, in these experimental conditions the reductive dissolution of the film takes place at 100% current efficiency, following the mechanism corresponding to iron reduction

$$Fe_2O_3 + 2e^- + 6H^+ = 2Fe^{2+}{}_{(sol)} + 3H_2O$$

This would then (in the presence of arsenic) exclude the possibility that iron would return to its metallic state

$$Fe_2O_3 + 6H^+ + 6e^- = 2Fe^\circ + 3H_2O$$

and also excludes the possibility that protons would be transformed into H° by capturing an electron from the metal.

During the passive-film reduction, the reduction of protons is blocked either at the oxide-solution interface or at the metal-oxide interface if hydrogen is transported across the passive film. The fact that arsenic inhibits the entry of hydrogen has recently been observed by McCright and Staehle (26). None of these conclusions contradicts the curve of potential variation which shows a plateau at − 510 mV corresponding to the electrochemical reaction mechanism [A]. After the reduction of Fe_2O_3 is complete, a potential characteristic of hydrogen evolution on iron (a second plateau) is reached which can be expected at about − 750 mV at the pH used.

In addition, the fact that the faradaic yield of cathodic reduction equals 100% means that the number of coulombs of current passed during the cathodic reduction is exactly equal to the theoretical quantity required for the production of Fe^{2+} from Fe_2O_3. If there had been an excess difference between experimental and theoretical charges, that difference would be attributed to the presence of some cation-vacant (high-iron-valence) oxide. This is not the case, which contradicts the findings of Nagayama and Cohen (1)—under admittedly different experimental conditions, particularly the absence of arsenic—who proposed a different mechanism for the reduction of Fe_2O_3 formed in neutral sodium borate-boric acid solutions.

Finally, while it is not possible by direct passivation to obtain homogeneous layers of 5-20Å, it is possible, by cathodic reduction starting with a thickness of 40Å, to attain these homogeneous layers by step dissolutions of 5Å.

The data in the literature (27) permits us to consider that the iron oxide constituent of the passive film formed at high potential (+ 940 mV) has a γ-ferric oxide structure, *i.e.*, a structure formed by a rearrangement of oxygen and iron ions in which the oxygen forms a face-centered cubic lattice with iron atoms fitted into octahedral and tetrahedral sites. What place has arsenic in such a structure? We have determined the presence of one atom of arsenic per six atoms of iron and nine of oxygen at $\phi = +940$ mV, but in the spinel structure there is one free octahedral position for each oxygen atom. Thus, for nine oxygen atoms there are nine octahedral spaces available, and these would be occupied by six iron atoms and one arsenic. In the spinel structure arsenic atoms could occupy the free substitution positions that exist, and without deforming the structure, since the ionic radii of Fe^{3+} ($R = 0.64$Å), As^{3+} ($R = 0.58$Å), and As^{5+} ($R = 0.46$Å) are close enough to one another. Note that the order of magnitude of the ionic radii of As^{3+} and As^{5+} make it unlikely that these cations take tetrahedral positions, since this requires radii of 0.22-0.41Å, smaller than the ionic radii corresponding to the two possible arsenic valences.

In which oxidizing form should the arsenic be found? If we recall that the cation in the octahedral position should have an ionic radius between 0.41 and 0.73Å, both oxidizing forms are allowed. To differentiate between them, we must take account of the potential of the reaction $As^{3+} \rightarrow As^{5+}$ which is 580 mV at pH zero and becomes 330 mV/HE under our experimental conditions. This means, then, that arsenic incorporated in the form As^{3+} is immediately oxidized to As^{5+} and takes an octahedral position inside the Fe_2O_3 structure which we already suggested in determining the average charge associated with each oxygen atom in the system $(As_2O_5) \cdot (Fe_2O_3)_{4.66}$ cathodically reduced.

What is the microscopic role of arsenic? It should be observed that the adsorption of arsenic takes place on a metal devoid of oxide and solely on such a metal, and otherwise that even in the presence of arsenic when the temperature is increased, the faradaic yield on cathodic reduction diminishes though arsenic has an inhibiting effect. This will be discussed further in another article.

We can now propose a cathodic reduction mechanism by which γ-Fe_2O_3 may be reduced to form a cation vacancy (□) structure which is still in the cubic system by the reactions

$$2Fe^{3+} + 2e^- \rightarrow 2Fe^{+2} \rightarrow 2Fe^{+2}(H_2O) + 2\square^{3+}\,Fe$$
$$H_2O$$

$$3\,O^{2-} + 3H^+ \rightarrow 3\,OH^- \rightarrow 3H_2O + 3\square^{2-}\,O$$
$$\text{sol} \qquad 3H^+$$

$$2\square^{3+}\,Fe + 3\square^{2-}\,O \rightarrow \text{annealing}$$

Whereas for arsenic it is possible to envisage the following reduction mechanism

$$2As^{+5} + 4e^- \rightarrow 2As^{3+} \rightarrow 2As^{+3}\,(H_2O) + 2\square^{+5}\,As$$
$$H_2O$$

$$5\,O^{2-} + 5H^+ \rightarrow 5\,OH^- \rightarrow 5H_2O + 5\square^{2-}\,O$$
$$\text{sol} \qquad 5H^+$$

$$2\square^{5+}\,As + 5\square^{2-}\,O \rightarrow \text{annealing.}$$

Acknowledgments

The authors wish to thank Dr. G. Amsel for his numerous comments and suggestions during this work. The technical assistance of Messrs E. Girard, A. Laurent, and J. Moulin was much appreciated. This work was supported by the Centre National de la Recherche Scientifique (RCP No. 157), the DRME, and the DGRST.

Manuscript submitted Oct. 23, 1974; revised manuscript received Feb. 7, 1975.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1975 JOURNAL. All discussions for the December 1975 Discussion Section should be submitted by Aug. 1, 1975.

A Study of the Anodization of Niobium Using the Method of Open-Circuit Transients in Aqueous and Nonaqueous Solutions

C. M. Daly and R. G. Keil*

Department of Chemistry, University of Dayton, Dayton, Ohio 45469

ABSTRACT

The anodic oxidation of niobium in glacial acetic acid-sodium tetraborate solution and in aqueous boric acid-sodium tetraborate solution has been studied over a potential range of 74V using the open-circuit transient analysis technique. The results indicate that the relationship between the formation current density, i, and the formation potential, V, is of the form $i = i_o \exp(V/V_o)$ where i_o and V_o are parameters resulting from data analysis. V_o was found to be a linear function of the formation voltage. The quantity, θ, was found to be essentially equal to zero, a result which agrees with results previously reported for vanadium and molybdenum. Attempts were made to correlate the results with film structure.

It is known that the analytical chemistry of niobium in aqueous solutions is complicated by the tendency of niobium(V) to hydrolyze and by the instability of the lower oxidation states of the element (1). Previous studies (2-4) have shown that anodic oxide films may be grown successfully on valve metals if a nonaqueous solution is employed. The intention of the present study was to utilize the open-circuit transient method in a comparative study to determine the electrical properties of niobium oxide films in aqueous and nonaqueous solutions.

In an earlier work on niobium, Young (5) determined certain electrical properties of the niobium oxide by specular reflectivity studies. In that work he concluded that the evidence is consistent with a uniform film apart from the preexisting film. In 1960, Young (6) also reported experimental results on the oxidation of tantalum which showed that the relation between ln i and E was not linear and that a better fit

* Electrochemical Society Active Member.

Key words: anodic oxidation, niobium, transients, aqueous, nonaqueous.

of the data could be obtained by replacing the term qaE by $a(\alpha - \beta E)E$. This result was confirmed by the results of Young and Zobel (7) who, in addition, showed the necessity for including the nonlinear term in the fit of data for niobium oxide.

Recently, using *in situ* ellipsometric measurements on niobium, tantalum, and tungsten, Ord *et al.* (8) have found that the thicknesses of all three metals were found to increase linearly with the electric field. They also showed that the inclusion of the linear dependence of the dielectric constant upon the field into an effective model of the ionic conduction process to be a possible explanation of the curvature in the plot of ln i *vs.* E for the anodic oxidation process. These results have been disputed, more recently, by Cornish and Young (9) who in an ellipsometric study of tantalum found that anodic tantalum oxide films are optically isotropic and homogeneous in the absence of an applied field and that the dependence of both the index and thickness upon the field is quadratic.

To date, several theories (6, 10-14) and methods of study of anodic oxidation have been proposed. Open-circuit transient analysis has been used in the study of the anodic oxidation of several metals (3, 14-17). Its use in the study of the anodic niobium oxide film under these conditions and comparison with previous results (6-9) may help establish the nature of the anodic niobium oxide film and the general mechanism of film growth.

Experimental

Anodizations were performed (*i*) in a glacial acetic acid solution 2.0M in water and 0.02M in sodium tetraborate and (*ii*) in an aqueous solution 0.1M in H_3BO_3 and 0.018M in sodium tetraborate. High-purity (99.99%) niobium rods, 0.314 cm^2 in surface area purchased from Materials Research Corporation were used for this work. The electrode was mounted and prepared for anodization by methods previously described (2). Film growth was accomplished both potentiostatically and galvanostatically. The acetic acid-borax-water solution had a conductivity of 79 micro-$(\text{ohm-cm})^{-1}$. These studies were all performed at 25°C. An inert ambient of nitrogen was maintained in the reaction flask and the anodizing solutions were degassed prior to use.

Under galvanostatic conditions current densities not less than 15.9 $\mu A/cm^2$ were used. For the open-circuit transient studies a pair of Philbrick SP102 operational amplifiers were used for galvanostat and voltage follower. The potentials and open-circuit transients were recorded on an oscillographic recorder (Sanborn 7701 B). All potentials were recorded relative to the saturated calomel reference electrode. Overpotentials were calculated from observed voltages by subtracting the value of the open-circuit potential. Apparent current densities were obtained by dividing the applied current by the macroscopic surface area of the niobium anode.

Results

The oxide film on the niobium surface may be considered to be equivalent to a capacitor with a dielectric medium located between the capacitor plates (substrate metal and anodizing solution). The differential equation describing this circuit is given by

$$i + C\,dV/dt = i_e \qquad [1]$$

where i is the current density through the film, i_e is the externally applied current density, V is the overpotential, and C is the capacitance per unit area of film.

For niobium, the experimental voltage transients fit an expression of the form

$$V = k - V_o \ln (t + \theta) \qquad [2]$$

Here V_o, k, and θ are parameters which depend on the particular transient and its initial conditions. It follows, by differentiating Eq. [2] and substituting into Eq. [1], with $i_e = 0$, that the expression for the current density through the film becomes

$$i = i_o \exp (V/V_o) \qquad [3]$$

This expression includes certain assumptions which have been discussed previously (3). For niobium, the voltage-time transients fit an equation of the form of Eq. [2]. Analysis of the voltage-time transients were performed with the aid of a UNIVAC series 70/7 digital computer. The computer was fed voltage *vs.* time data in increments no larger than one-hundredth volt. The following functions were then performed (*i*) the computer chose from a large selection the value of θ which produced a minimum standard deviation of all data points when the data were subjected to a linear least squares analysis, and (*ii*) a print-out of the values k, θ, V_o, and standard deviation was obtained. The parameter i_o is equivalent to

$$i_o = C\,V_o \exp (-k/V_o) \qquad [4]$$

An equation of this form is the mathematical consequence of the differential equation describing the system and the experimental voltage-time profile. Here i_o and V_o are experimentally determined parameters whose dimensions are the same as i and V, respectively. If time zero equals the commencement of the transient, the transients fit Eq. [2] for times corresponding to 80% of the potential decay at a current density of 159 $\mu A/cm^2$ and 60% of the potential decay at 79.5 and 15.9 $\mu A/cm^2$. Figures 1 and 2 show the relationship between the parameter V_o and the formation potential in aqueous and acetic acid solutions, respectively. For a given formation current density V_o is a linear function of the formation potential and all lines nearly pass through the origin. The slope of each line is obviously a function of the formation current density and decreases with increasing current density.

From data analysis, we learned that the value of θ required to fit the transient data to Eq. [2] is quite small, with values ranging from essentially zero to 0.05. Small values are not unexpected because of the relatively large initial formation current densities and

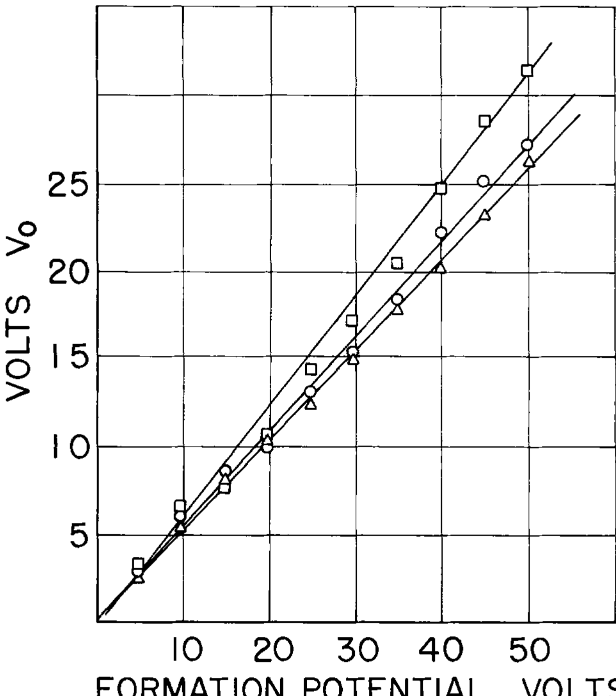

Fig. 1. Dependence of V_o on formation potential for niobium in boric acid-borax-water solution. The formation current density was 15.9 $\mu A/cm^2$ for the data represented by □, 79.5 $\mu A/cm^2$ for the data represented by ○, and 159 $\mu A/cm^2$ for the data represented by △.

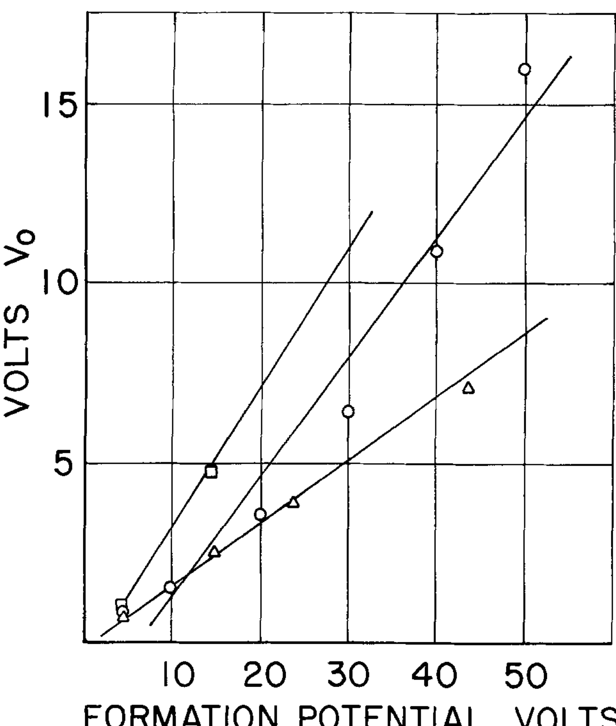

Fig. 2. Dependence of V_0 on formation potential for niobium in acetic acid-borax-water solution. The formation current density was 15.9 μA/cm² for the data represented by □, 79.5 μA/cm² for the data represented by ○, and 159 μA/cm² for the data represented by △.

$\theta = C\,V_o/i_e$. A typical value in both aqueous and nonaqueous anodizing solutions at 159 μA/cm² is 0.001. Generally, θ increased both with increasing current densities and formation potentials of the film. Tables I and II show the relationship between the reciprocal capacitance and the formation potential. The reciprocal capacitance is related to θ by the equation $1/C = V_o/i_e\theta$. Evidence of the variation of reciprocal capacitance with V_o and θ can be demonstrated by Tables I and II and also by Fig. 3 and 4. It will be noted that at high current density (159 μA/cm²) a linear relationship is definitely established. The apparent shifts in slopes as shown in Table I and Fig. 3 indicate that the initial film on the niobium is chemically different from the anodic film. A similar conclusion was drawn by

Young (18) in explaining the shift in intercept for his work on tantalum, a metal quite similar to niobium.

Discussion

An exponential dependence of the current density through the oxide film on the overpotential can be interpreted in terms of an activation-energy-controlled process (18). The theoretical description for such a

process, in the high-field case, is given in its simplest form by

$$i = 2an\nu \exp - (U/kT) \exp (qaE/kT) \quad [5]$$

where a is the half-jump distance, n is the density of the charge carriers, ν is the frequency of the oscillating ions, U is the activation energy for the process, q is the effective charge on the mobile ions, and E is the electric field at the activation barrier. The other symbols have their usual meanings. Ord *et al.* have concluded (8) that an effective field model merits serious consideration when examining the ionic conduction process for niobium. These workers found that the thickness change depends linearly on the field change, the thickness increasing with increasing field. It has been shown in previous studies (3, 14) that if an assumption is made that the field at the activation barrier is equal to the average electric field, a comparison of Eq. [3] and [5] yields the relationship

$$V_o = (kT/qa)D \quad [6]$$

Thus, V_o is proportional to the thickness of oxide layer, D.

The experimental data verified a model of this type. Figure 1 (aqueous solution) shows that the values of V_o are linearly proportional to the formation potential for a given formation current density over a wide range of values and that the lines intersect the origin. In Fig. 2 which is a plot of V_o *vs.* formation potential in a nonaqueous anodizing solution, we again see a linear relationship and the lines nearly intersect the origin. These results indicate that a high-field conduction process limits the current through the layer. Lee *et al.* reported (19) results for the plasma anodization of niobium, demonstrating that the most acceptable model is one in which ionic conduction is controlled by an effective field, *e.g.*, the Lorentz field $1/3\ (\epsilon_r + 2)E$. Earlier studies (20) used the Lorentz field as the effective field, which was able to obtain reasonable estimates of jump distance and was independent of temperature, at least up to 70°C.

Data taken for different formation current densities fall on lines of differing slopes. In buffer solution (Fig. 1) at a current density of 15.9 $\mu A/cm^2$ the slope is 0.127, at 79.5 $\mu A/cm^2$ the slope is 0.107, and at 159 $\mu A/cm^2$ the slope is 0.101. These varying slopes indicate that the field in the layer and i_o may both depend on the formation current density. An analogous situation occurs in Fig. 2, the slope at 79.5 $\mu A/cm^2$ is 0.26 and the slope at 159 $\mu A/cm^2$ is 0.14. The field in the dielectric may increase with increasing formation current densities because of an increase in the ion jump distance at higher formation current densities.

The values of θ required to linearize Eq. [3] are unusually small. It will also be noted that the θ values for films formed in glacial acetic acid solutions containing 0.02M $Na_2B_4O_7$ and 2.0M H_2O are lower than for films formed in aqueous 0.1M H_3BO_3 containing 0.018M $Na_2B_4O_7$. We interpret low values of θ in either case to indicate that niobium films formed in acetic acid are relatively porous compared to those formed in aqueous solution. The film is relatively porous compared to tantalum. This hypothesis is further supported by the relatively large value of the final leakage current on niobium. Lilienfeld and Miller (21) used boric acid plus borate electrolyte in forming films on aluminum. The buffer used gave comparatively high leakage currents so that the possibility of cracks and pores cannot be ruled out as an explanation for their results or for ours. We have reported this porosity effect on vanadium (3) and also on molybdenum (22) films formed in acetic acid. In addition, inspection of the reciprocal capacitance plots, Fig. 3 and 4, suggests the existence of a channel-type "porous" film structure. The changes in slope at 15.9 and 79.2 $\mu A/cm^2$ may be accounted for by field effects. At 159 and 79.5 $\mu A/cm^2$ a linear relationship is observed. At the lowest current density the fluctuations in 1/C values with formation potential are most likely due to the raising of the oxidation state of the layer (23).

The results of this investigation on niobium are similar to those obtained in earlier works on vanadium (3) and molybdenum (22). The three metals when subjected to anodic polarization in the acetic acid-water-sodium tetraborate solution do form films exhibiting intense interference colors. A number of ellipsometer studies to determine the nature of anodic oxide films formed in a plasma (8, 19, 24, 25) have not as yet shown definitively whether a single or multilayer anodic film is formed. The understanding of the nature of wet films is consistent with several (26-28) authors reporting two layers being formed. The behavior of niobium in nonaqueous anodizing solutions leads us to the conclusion that the films are probably a mixture of barrier and porous layers. The similarities of our results with molybdenum (22), vanadium (3), and niobium as well as those of others (5-8) lead us to agree with Ord and Ho (29) that any meaningful theory of anodic oxidation must not be overly sensitive to either the chemistry of the metal or the structure of the oxide.

Factors Influencing the Lifetime of Pure Beta-Alumina Electrolyte

Y. Lazennec, C. Lasne, P. Margotin, and J. Fally

Laboratoires de Marcoussis, Centre de Recherches de la Compagnie Générale d'Electricité, Marcoussis, France

ABSTRACT

The influence of some impurities on the aging and the lifetime of sodium-sulfur and sodium-sodium experimental cells is studied. The aging mechanism involves an ion exchange between impurities of the reactants and the sodium ions of the β-alumina lattice. In particular, introduction of potassium changes lattice parameters of β-alumina and Na^+ mobility. An important conclusion of this work is that pure β-alumina does allow the transfer of large amounts of total charge (*i.e.*, of sodium ions) before failure. The present figures are in excess of 1700 A-hr/cm^2. These results have enabled the authors to construct Na-S cells which have given in excess of 4,000 cycles or 16,000 hr of continuous operation.

The sodium-sulfur battery, based on the sodium β-alumina electrolyte, was first described by Weber and Kummer (1) and is to date the most promising high-temperature, high-energy density battery. The reasons for this developmental success depend on the use of the solid sodium-conducting β-alumina between the molten sodium anode and molten sulfide-polysulfide electrolyte in contact with the sulfur cathode. This solves immediately the self-discharge and constructional problems involving the use of matrix or pastes to retain molten components (either liquid alkali, metal, or molten salt electrolyte) in all-liquid high-temperature systems (2).

Development of the system so that a wide range of practical applications will result requires the solution of two major difficulties, both economic. The first is clearly one of initial investment cost per kW-hr of capacity or kW of power. This depends on many factors, the most important being:

(*i*) The cost of the β-alumina used, which depends not only on precise conditions of manufacture and sintering, but also on the purity of the α-alumina used.

(*ii*) The cost of the current collector material at the sulfur electrode (graphite or carbon felt).

(*iii*) The total cost of manufacture, which depends on the development of efficient sealing techniques.

The second factor is battery lifetime. Economic considerations dictate that a minimum lifetime of 2-3 years should be aimed at for urban electric vehicles, and of about 5 years for urban mass transit (buses). On the off-peak power storage application, for which the sodium-sulfur system seems eminently suitable provided that its cost-lifetime ratio is sufficiently low, a lifetime at the order of 10 years should be aimed at.

In the present paper, some factors influencing cell lifetime will be discussed.

Lifetime of β-Alumina Electrolyte

In an earlier paper (2) we demonstrated that magnesia additives used as stabilizers for certain β-alumina compositions had a detrimental influence on electrolyte lifetime in sodium-sulfur experimental cells. At the same time, it was shown that impurities present in the reactants could enter the β-alumina lattice during electrochemical cycling (2, 3). Because of this knowledge of impurities, work carried out in this laboratory has concentrated on two aspects of the aging problem, namely (*i*) the effect of the initial purity of the β-alumina used; (*ii*) the effect of introduction of impurities into the lattice of pure β-alumina during electrochemical cycling. The present publication considers the latter effect on lifetime of the ceramic under electrochemical conditions and represents an updating of work previously described (2, 3).

Na-S Cells

Na-S cells used in our experiments generally have a glass or stainless steel outer envelope (S-Na polysulfide reservoir) and a glass sodium reservoir. Sodium filling is effected by electrolysis of molten $NaNO_3$ through a membrane. In consequence, the major source of impurities is corrosion of the reservoirs by the cell reactants.

We have in general detected two types of impurity: (*i*) transition metals (Fe, Ni, Co, Cr) which result from attack of steels or alloys used, and (*ii*) alkali metals (in particular potassium) released by etching of glass reservoirs by molten sodium.

Experimental

In the present work, experiments were conducted using sodium-sodium and polysulfide-polysulfide cells, similar to the sodium-sulfur cells used normally for life-testing. Their construction is shown in Fig. 1.

The solid electrolyte membranes used were a pure β-alumina of two-block composition containing no additives or stabilizers (3, 4), in the form of closed-end tubes 45 mm long and 8 mm external diameter, and wall thickness 0.6 mm. The reservoirs were constructed of Sovirel[1] S 74701 glass.

Cells were either electrically cycled between Na_2S_3 and Na_2S_5 or left on open circuit. In general, for cycled cells, the current density was 0.2 A/cm^2 at a temperature of 330°C.

Aging of the cells was checked by (*i*) internal resistance measurements as a function of time; (*ii*) chemical analysis of β-alumina before and after operation, using spark source mass spectrometry for purity control and atomic absorption spectrometry for Na^+ and K^+ ion determination; and (*iii*) electrolyte resistivity was measured using a standard four-probe a-c method at 1000 Hz.

Results and Discussion

Sodium-sodium and sodium-sulfur experiments.—Figure 2 indicates the aging characteristics of sodium-sodium cells at various temperatures as a function of time, in terms of internal resistance changes. The lifetime is closely temperature dependent: cells operating at 250° and 200°C invariably function beyond 14,000 hr, whereas only 300 hr is observed at 330°C. A steep rise in resistance is noted before failure.

Comparable results are observed with Na-S cells, at longer lifetimes (see Fig. 3).

Key words: sodium-sulfur cells, beta-alumina, high-temperature cells, beta-alumina aging, effect of impurities.

[1] Sovirel, 92-Levallois-Perret, France.

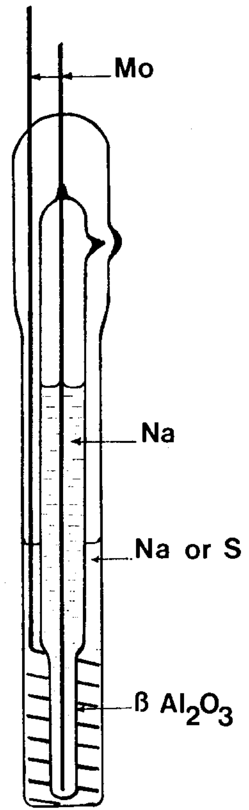

Fig. 1. Schematic of an experimental cell

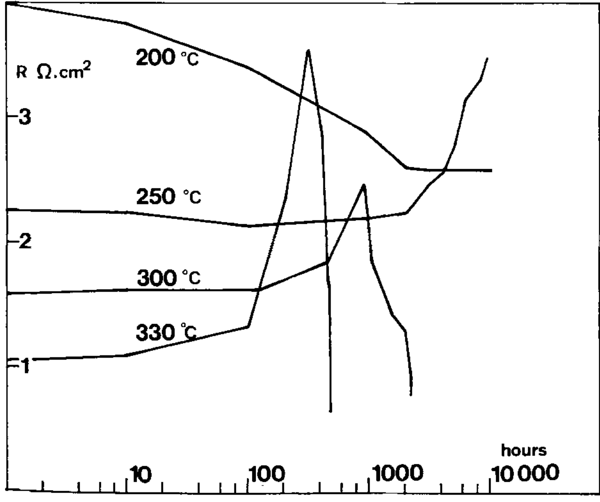

Fig. 2. Time dependence of the resistance of Na-Na cells operating at verious temperatures.

The results of chemical analysis are indicated in Table I for Na-Na and Na-S cells before and after operation. The most important result is a considerable contamination by potassium, with the presence of smaller quantities of silicon.

The potassium is accounted for by attack of the glass reservoirs of the cells by molten sodium; presumably by ion exchange. The potassium enters the β-alumina lattice and is immobilized at Na-free sites.

* 7500 hr at 250°C.
** 5600 hr at 300°C.

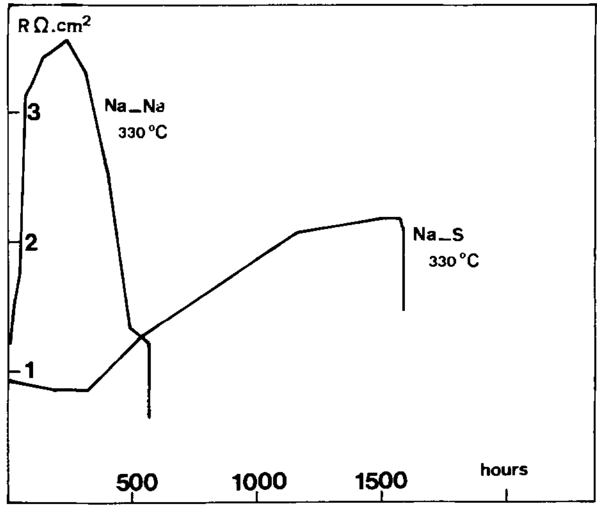

Fig. 3. Comparison of the evolution of the resistance of Na-Na and Na-S cells.

Both the rate of dissolution of potassium, and its rate of entry into the β-alumina lattice, are strongly temperature dependent. Introduction of potassium into the lattice would be expected to be manifested by changes in its physical properties, due to the larger ionic radius (1.33Å for K^+, 0.95Å for Na^+). In particular, site blockage, changes in lattice parameters, and changes in Na^+ mobility (hence resistivity) would be expected. The resistivity of β-alumina before and after electrochemical operation in Na-Na cells is plotted in Fig. 4. A marked increase is shown at each temperature, corresponding to the changes noted in Fig. 2. In our view, the most probable explanation of this phenomenon is the incorporation of K^+ ion into the lattice. We have established that, for example, incorporation of 0.5 weight per cent (w/o) K^+ ion into the β-alumina lattice increases resistivity from 15 to 39 ohm-cm at 330°C. This deterioration mechanism also receives confirmation from measurements of β-alumina lattice parameters after K^+ ion contamination. We have determined that the $\vec{c}$ parameter increases substantially when the β-alumina lattice is contaminated with potassium, the corresponding figures being 22.76Å (potas-

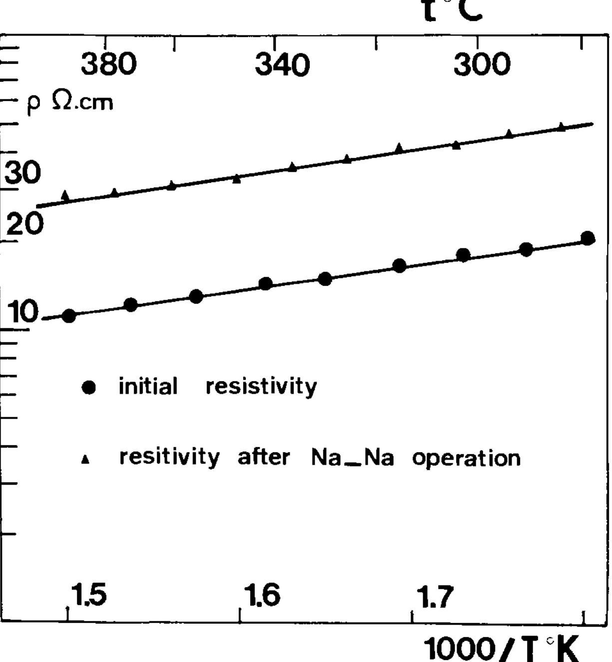

Fig. 4. Resistivity of a β-alumina electrolyte before and after operation in a Na-Na cell at 330°C.

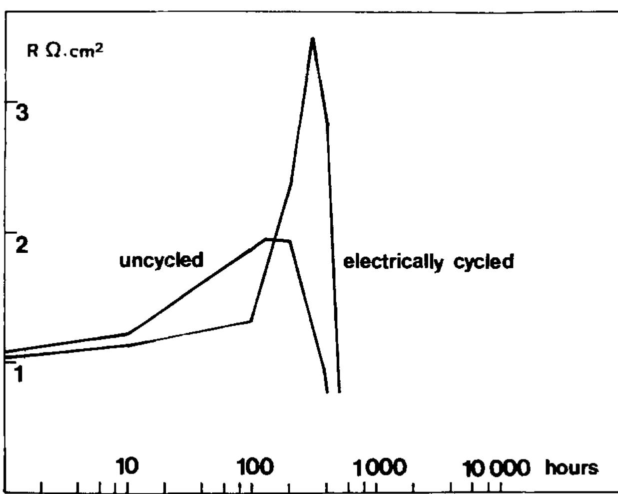

Fig. 5. Analysis of β-alumina tubes after Na-Na and Na-S operation.

sium-contaminated) and 22.16Å (pure β-alumina). The $\vec{a}$ parameter of the lattice is, however, not affected. This ion exchange property of β-alumina has been studied by Yao and Kummer (6).

An interesting phenomenon is shown in Fig. 5; it appears that potassium contamination of the electrolyte (as indicated by resistance changes) is not wholly dependent on the total charge passed through the β-alumina. The lifetime before catastrophic breakdown of the electrolyte membrane at 330°C is of the same order for electrochemically cycled and uncycled cells. In the particular case reported, the magnitude of the resistance change is different for the cycled and uncycled cells, but this shows considerable dispersion and is related to the total glass area wetted by the molten sodium.

No interpretation can be done today to explain how Si enters the crystal.

Polysulfide-polysulfide cells.—It is evident that one possible method of avoiding contamination of β-alumina by K^+ ion would be to use potassium-free glasses as battery reservoirs. Practically, however, all-glass systems seem out of the question for nonstationary applications especially in transportation, hence metal reservoirs will be required. Corrosion will be a continual problem, especially at the polysulfide-metal interface.

In view of the above results concerning physical property changes in β-alumina after contamination with K^+, eventually leading to failure, we decided to examine the effect of transition metal ions. Five weight per cent (w/o) of Fe, Ni, Co, and Cr were dissolved in molten sodium polysulfide of commercial purity (> 99% Na_2S_4) which was then subsequently used in Na polysulfide-β-alumina-Na polysulfide cells. Even at this very high concentration these metals were completely dissolved in polysulfide. The cells were electrochemically cycled at 330°C at 0.150 A/cm² so that the polysulfide compositions varied continuously between Na_2S_3 and Na_2S_5. After operation for 300 hr, the β-alumina tubes were analyzed.

In addition, tubes that had been simply immersed in molten Na_2S_4 containing the same quantities of transition metal contaminants, under the same time and temperature conditions, were also analyzed. Results are given in Table II. It is apparent that no contamination of the solid electrolyte has occurred, under either cycled or uncycled conditions. It would be interesting to explain why metal ions do not enter the β-alumina lattice in these conditions.

Conclusions

In this paper, we have studied the influence of impurities introduced in the reactants on the behavior of initially pure β-alumina electrolytes of two-block composition, under the conditions of operation of sodium-sulfur cells.

The addition of potassium has a marked influence on the aging and ultimate lifetime of the β-alumina, whereas by contrast, transition metal ions are not incorporated into the lattice and appear to have no influence on aging.

In previous work we have shown the effect of ceramic thickness, as well as of operating temperature and ultimate purity, on lifetime (3). As we have pointed out above, operation at a somewhat lower temperature reduces attack on glass hardware. Similarly, tubes of slightly greater thickness show the effect of K^+ contamination to a lesser degree as they contain a greater amount of material.

These results have enabled us to construct Na-S cells, using 1 mm thick electrolyte, which have given in excess of 4,000 cycles or 16,000 hr of continuous operation at 285°C in all-glass hardware (0.067 A/cm² charge, 0.2 A/cm² discharge). These cells are still operating.

In addition, we have also shown that, at higher operating temperatures, stable resistances and long lifetimes may be obtained by using ceramic or metal hardware (Fig. 6 for Na-Na cells).

An important conclusion of this work is that pure β-alumina does allow the transfer of large amounts of total charge (*i.e.*, of sodium ion) before failure. The present figures are in excess of 1700 A-hr/cm². As far as our work is concerned, lifetime and aging seem only to be related to incorporation of impurities, especially K^+. The work is at present being extended toward the influence of the initial purity of β-alumina on lifetime.

We are confident that with our present β-alumina, cells of very long lifetimes will be obtainable (*i*) by the use of corrosion-resistant reservoirs, and (*ii*) by the use of efficient ceramic or glass-to-metal seals (of minimum area and low potassium content) between β-alumina and the anodic reservoir, and between the anodic and cathodic compartments.

We think that such additive-free ceramics can be economically interesting, especially for use in offpeak power storage batteries and even for the electric car if their wall thickness is 1 mm or less.

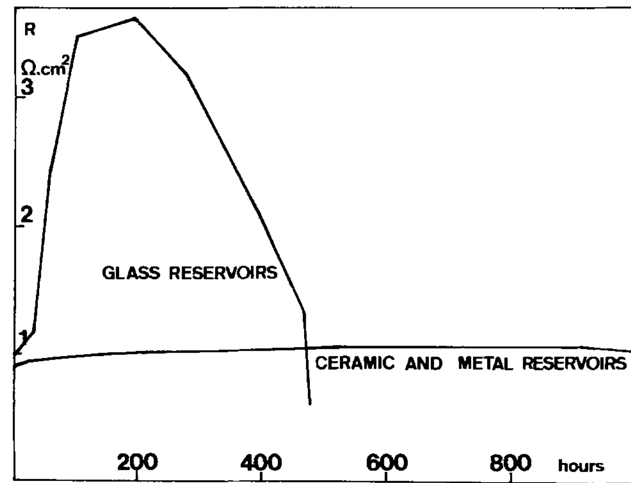

Fig. 6. Aging of Na-Na cells at 330°C

In general, β-alumina compositions containing stabilizing additives are used that are optimized for conductivity rather than lifetime. In addition, commercial or reagent-grade sodium, containing metallic impurities, are employed in Na-S cells. Reported lifetimes are generally much shorter than those indicated here.

In view of our previous work (3) on the effect of magnesia additives on lifetime, we feel that the β-aluminas used in Ref. (4) and (5) have intrinsically weakened surfaces and show a tendency to easy Griffith crack propagation, due to the microscopically uneven distribution of additive, and consequent local stressing of the material. This occurs in pure β-alumina to a significant degree only after sufficient K^+ ion has been incorporated. The surface condition of our electrophoretically formed material may also be different.

The K^+ ion, incorporated mainly (due to diffusion limitations) at the surface of the β-alumina, stresses, the material locally by changing its $\vec{c}$ parameter. Incorporation mainly at the β-alumina surface is indicated by the similarity of lifetime under cycled and uncycled conditions as shown in Fig. 5. When crack propagation following the mechanism outlined in Ref. (4) and (5) progresses, resistance suddenly falls just before failure, as indicated in Fig. 2. It would therefore appear that long lifetimes can be expected, if β-alumina containing only sodium ions are used in sodium-sulfur cells.

The above results were obtained using hexagonal two-block β-alumina free of additives. Recent results obtained at Ford (7) indicate that long lifetime can be obtained with three-block β''-alumina type ceramic containing Li_2O, as additive, but free of MgO. Similar lifetime seems also obtained at the Electricity Council with ceramics containing β- and β''-alumina. It could be interesting to compare the behavior of such electrolytes, in respect to their composition, with the introduction of impurities in their lattice.

Brief Communications

The Total Reduction of Carbon Tetrachloride at the Glassy Carbon Electrode

Frank L. Lambert, Bruce L. Hasslinger, and Robert N. Franz, III

Department of Chemistry, Occidental College, Los Angeles, California 90041

In their classic polarographic study Kolthoff and coworkers (1) a quarter century ago showed that carbon tetrachloride gave two waves when it was reduced at the dropping mercury electrode (DME) in methanol-water solution with tetramethylammonium bromide as the supporting electrolyte. The first wave involved the reduction of carbon tetrachloride to chloroform because the second wave was shown to be identical to that given by pure chloroform. Von Stackelberg and Stracke published similar results, using dioxane-water, in a survey of the voltammetry of organic compounds at the DME (2).[1]

Key words: polarography, chloroform, methylene chloride, methyl chloride.

[1] In butanol-water, when methylene chloride and methyl chloride were mixed with carbon tetrachloride and chloroform (during an experiment to prove the utility of quantitatively determining CCl_4 and $CHCl_3$ in such a four-component mixture), von Stackelberg and Stracke (2) detected three waves, with the third wave corresponding to the combined methylene and methyl chlorides.

As reported some 10 years later, Wawzonek and Duty (3) in their thorough investigation of the mechanism of the carbon tetrachloride reduction used N,N-dimethylformamide (DMF) as a solvent and were able to demonstrate three waves in the reduction at the DME: the third wave, not present in earlier work in methanol- or dioxane-water, was attributed to the reduction of methylene chloride, presumably to methyl chloride.

After our discovery that alkyl monochlorides, a class generally found to be irreducible at the dropping mercury electrode (with the exception of methyl or activated alkyl chlorides such as allyl), could all be readily reduced at the glassy carbon electrode (GCE) in DMF (4) we were led to look at the behavior of carbon tetrachloride at the GCE. We are reporting our results now because of the possible practical and theoretical implications of the behavior of many polyhalo

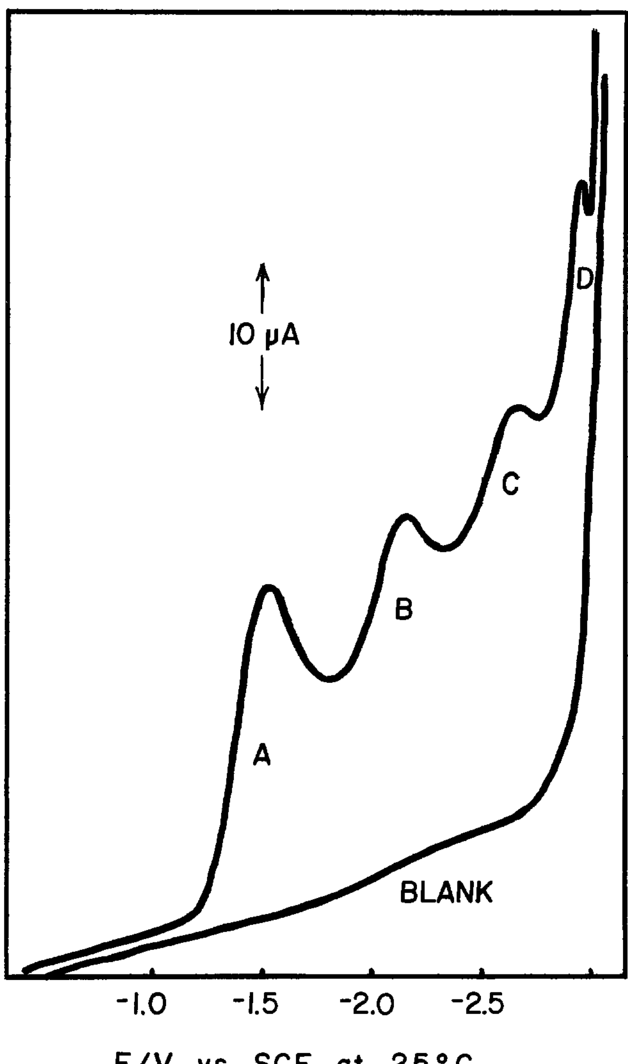

Fig. 1. Voltammogram of CCl_4 in DMF at the GCE[2]

compounds at the GCE and because we do not intend to proceed further with work involving such polyhalo substances.

In DMF with tetraethylammonium perchlorate as the supporting electrolyte,[2] carbon tetrachloride at the GCE yields the rather remarkable voltammetric curve shown in Fig. 1, where four waves delineate the total reduction of carbon tetrachloride to methane: first, A, the reduction of CCl_4 itself; then, B, of chloroform; C, of methylene chloride; and finally, D, of methyl chloride.[3] The half-peak potentials, $E_{p/2}$ correspond to those of the individual pure substances in independent experiments at the GCE, as shown in Table I, and are "rational" in the sense that the differences between the succeeding half-peak potentials in the series are of comparable magnitude, *ca.* 0.44 ± 0.14V with the $E_{p/2}$ of CCl_4 at −1.33V *vs.* the saturated calomel electrode. At the DME, the half-wave potentials of chloroform and methylene chloride increase by −0.12 and −0.08V, respectively, when water is added to the DMF (3). This is not the case at the glassy carbon electrode; the half-peak values do not change by more than 0.02V in 10% aqueous DMF.[4]

[2] All experimental conditions as described in Table I, except that in Fig. 1 and 2 the voltage was applied at the rate of 50 mV/sec over a chart span of 500 mV/in. (rather than 1/5 those values) for more compact visual presentation.

[3] The source of hydrogen in the reduction of an alkyl halide when tetraethylammonium salts are used as supporting electrolytes has been thought to be the β-H of an ethyl group in the $(CH_3CH_2)_4N^+$ [see, for example, the works of Fry and Reed (5)]. However, the work of Jensen and Parker (6) indicates that Et_4N^+ is a less effective protonation agent for aromatic anions than are traces of water.

[4] The DMF was dry as that used by Wawzonek and Duty (3), but not dried as was that of Jensen and Parker (6).

Table I. Half-peak potentials, $E_{p/2}$,[a] at the glassy carbon electrode (GCE)

Compound	1st wave	2nd wave	3rd wave	4th wave
In N,N-dimethylformamide (DMF)				
CCl_4	−1.33	−1.91	−2.43	−2.77
$CHCl_3$	−1.90	−2.42	−2.78	
CH_2Cl_2	−2.44	−2.78		
CH_3Cl	−2.76			
In acetonitrile				
CCl_4	−1.40	−1.93	−2.41	
$CHCl_3$	−1.91	−2.43		
CH_2Cl_2	−2.44			

[a] In volts *vs.* the saturated calomel electrode. Halide concentrations of 1-3 × 10^{-3}M in purified anhydrous N,N-dimethylformamide (9) with 0.01M tetraethylammonium perchlorate as supporting electrolyte. Curves recorded on a Beckman Electroscan 30 with saturated calomel electrode (SCE) as reference, platinum wire as auxiliary, and glassy carbon disk of 7.9 mm² area (Tokai Electrode Manufacturing Company, Tokyo, Japan) as working electrode at 25°C. Light polishing of the working electrode surface with Linde 0.05μ alumina, wet with DMF, between runs was essential for reproducibility of (typically) 3 mV standard deviation. Rate of scan was 10 mV/sec and normal voltage span of an experiment was 1V.

Wawzonek and Duty also discovered that methylene chloride could not be reduced in acetonitrile at the DME. Here, too, the glassy carbon electrode is usefully different from the DME: carbon tetrachloride gives three waves in acetonitrile at the GCE and the third wave is that of methylene chloride as shown by its coincidence with the wave for pure methylene chloride in separate experiments (Fig. 2 and Table I).

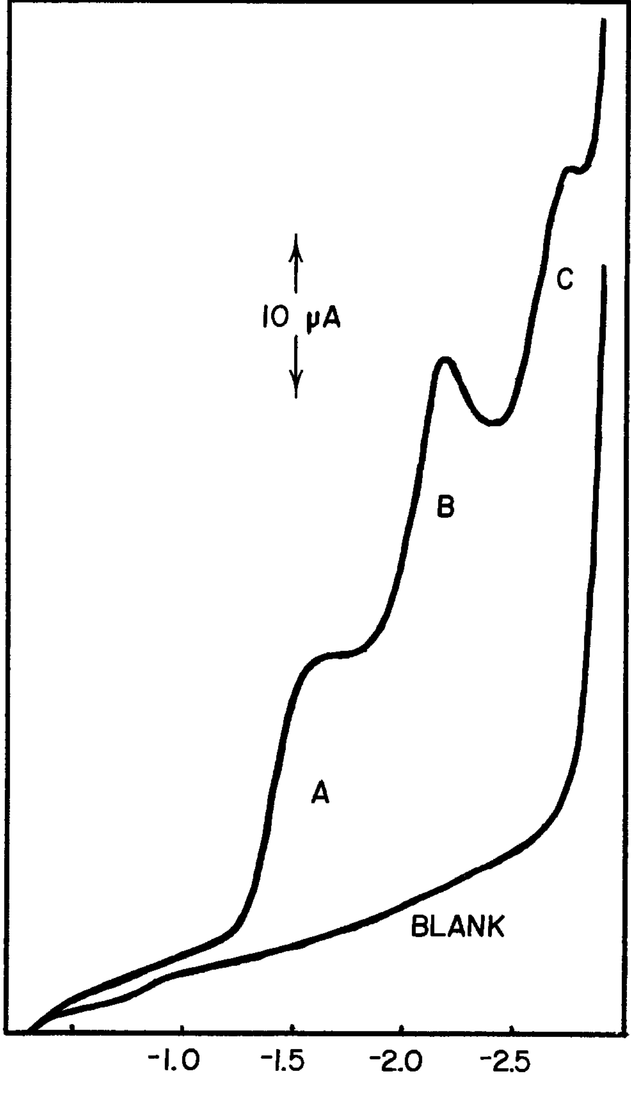

Fig. 2. Voltammogram of CCl_4 in acetonitrile at the GCE[2]

In view of the often-repeated (and generally true) statement about the easier reduction of polyhalides than monohalides (7), the original report of von Stackelberg and Stracke (2) that methylene chloride, CH_2Cl_2, at the DME in dioxane-water is reduced at $-2.33V$ whereas methyl chloride, CH_3Cl, with its single chlorine is easier to reduce, at $-2.23V$, is somewhat surprising. We have found that this unusual order of reduction is also true in anhydrous DMF at the DME.[5] Considering the order of the half-wave potentials of CH_3Cl and CH_2Cl_2 at the DME, and the clearly discrete reduction of methylene chloride prior to methyl chloride that we have discovered at the carbon electrode, it seems highly possible that mercury is chemically involved before or during the potential-determining step at the DME in the electroreduction of methyl and methylene chlorides. This suggestion is in accord with a number of reports of chemical interaction of mercury with organic bromides (8).

Semiconductor Electrodes

I. The Chemical Vapor Deposition and Application of Polycrystalline N-Type Titanium Dioxide Electrodes to the Photosensitized Electrolysis of Water

Kenneth L. Hardee* and Allen J. Bard**

Department of Chemistry, The University of Texas at Austin, Austin, Texas 78712

A number of investigations on photoeffects on semiconductor electrodes have been reported (1, 2). Most studies have been concerned with single crystal semiconductor materials, although some polycrystalline semiconductors, *e.g.*, SnO_2 (3-6), have also been used. Recently the photosensitized electrolytic oxidation of water on n-type TiO_2 single crystal electrodes has been described (7-9). In the absence of illumination the hole concentration in the valence band of n-type TiO_2 is very small, so that no appreciable anodic current flows for the oxidation of water, even at very positive potentials (9). When the electrode is irradiated with light with energy greater than the bandgap energy (*ca.* 3.2 eV), holes are formed in the valence band (VB) by excitation of electrons to the conduction band (CB). Under anodic polarization the bands in the semiconductor are bent in such a direction that the CB electrons migrate in the external circuit to the counterelectrode while the VB holes move to the surface where they combine with water molecules producing oxygen

$$H_2O + p^+(VB) \rightarrow \tfrac{1}{2} O_2 + H^+ \quad [1]$$

* Electrochemical Society Student Member.
** Electrochemical Society Active Member.
Key words: semiconductor electrodes, oxygen evolution, photoelectrochemistry.

Unlike many other semiconductor materials (*e.g.*, ZnO, GaAs), TiO_2 is stable with respect to dissolution under these conditions. These photoassisted electrolytic processes are obviously of interest with respect to the conversion of light to chemical and electrical energy. For practical applications, however, low cost polycrystalline electrode materials will probably be required for large area electrodes. Moreover, variation of the composition of the semiconductor (*e.g.*, to change the bandgap or the donor or acceptor levels or to alter the surface states) leading to changes in spectral sensitivity or electrochemical behavior, can be accomplished more easily during the preparation of such polycrystalline materials. Mollers, Tolle, and Memming (10) have recently reported measurements of photocatalytic deposition on polycrystalline TiO_2 in 1*M* H_2SO_4 solutions. We report here details of the preparation of n-type TiO_2 electrodes by chemical vapor deposition (CVD) onto titanium metal substrates and a comparison of the photoassisted anodic oxidation of water on CVD and single crystal n-type TiO_2.

The CVD technique employed was based on the method of Fitzgibbons, Sladek, and Hartwig (11), who studied dielectric thin films of TiO_2 for solid-state devices and integrated circuit applications. This technique involves the reaction of a titanium alkoxide and

water to produce TiO_2 and an alcohol. By utilizing vapors generated in a flask and delivered to the reaction site by a carrier gas, the reaction can be controlled in both rate and location. An alkoxide that produces a low boiling alcohol permits a low temperature of deposition; the only requirement is that the temperature is sufficient to boil off the resulting alcohol so that it will not be incorporated into the film. The reaction can be directed toward any suitable substrate simply by positioning the delivery tubes.

Experimental

The n-type TiO_2 on a Ti substrate was produced in the following manner (Fig. 1). Tetra-isopropyl orthotitanate from Eastman Organic Chemicals was heated in a flask in a water bath maintained at 80°-85°C. Dry nitrogen (passed through $CaCl_2$ and molecular sieves) was used as a carrier gas; it was passed over the titanate and then through a delivery tube to the substrate. The tip of the delivery tube was located about 2.5 cm above the Ti substrate. Pure Ti was used as the substrate and was heated to about 150°C on a hot plate. The water vapor source also used nitrogen as the carrier gas. The water vapor was carried to the substrate through a tube parallel to the titanate delivery tube. Similar results could be obtained employing only water vapor from the air; however, an auxiliary water vapor source allowed shielding of the substrate from air currents which disrupt uniform film growth. To allow the development of a full space charge region in the semiconductor electrode, which can be as large as 10,000Å, depending upon carrier density, fairly thick TiO_2 films are required. Fitzgibbons *et al.* (11) reported that attempts to use continuous CVD to produce films thicker than 4000-5000Å resulted in cracking of the films, but that heating the films between deposition allowed thicker films to be produced. The following CVD procedure was thus adopted.

The Ti substrate was cut into 1 × 1 cm squares, polished using very fine emery paper, and finally buffed to a mirror finish with a polishing wheel and rouge. This step was necessary to achieve good adherence of the TiO_2 and to promote growth of thicker layers. Unbuffed Ti (although polished with emery paper or etched in HF) gave films that were dull and nonuniform in appearance and which yielded much lower photocurrents. It was also difficult to achieve thicker films on unpolished material since flaking or formation of white powdered TiO_2 occurred when repeated depositions were attempted. A convenient film growth rate was established by adjusting the flow rates of the nitrogen over the titanium isopropoxide and water while watching the growth of interference rings on glass with white light. The polished Ti substrate was then placed under the nozzles and growth allowed for a given time period (typically about 2 min for the formation of two complete sets of interference rings). The substrate was then held in a bunsen burner flame for 3-4 min during which time the Ti turned red hot, the interference rings disappeared, and the surface took on a uniform, shiny, blue-gray appearance. After the flame treatment, the substrate was cooled in air briefly, then returned to the deposition apparatus for further CVD. Electrodes with between two and nine 2-min coatings were produced. The TiO_2 film thicknesses for these electrodes ranged from about 1.4 to 7μ, respectively.

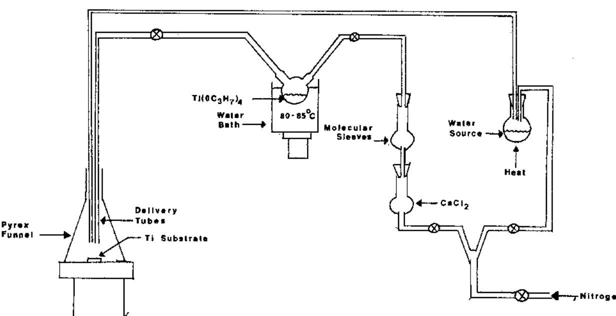

Fig. 1. Diagram of deposition apparatus

The electrodes obtained by the above procedure showed a high resistance. They were placed in 10^{-5} Torr vacuum at 600°C for 1½ hr. This treatment causes oxygen vacancies in the TiO_2 structure and produces n-type material with a much lower resistance. A copper wire was attached to the cleaned back of the Ti piece with silver epoxy cement (Epoxy Products Company), and the piece was mounted in a glass tube with silicone rubber cement (Dow Corning Corporation) so that only the surface covered by the TiO_2 was exposed to the solution.

The single crystal n-type TiO_2 was produced by National Lead Company and was given a similar vacuum-treatment. Ohmic contact was made with indium by ultrasonic welding, and it was mounted in glass using silicone rubber cement.

Some experiments were also attempted with TiO_2 produced anodically by oxidation of Ti substrates in 15% H_2SO_4, 2% Na_3PO_4, 5% Na_2HPO_4, saturated H_3BO_3, or 50:50 ethylene glycol saturated oxalic acid solutions (12). A 1 × 1 cm Ti piece was anodized for several hours in the electrolyte with greater than 10V applied. A metallic blue coating appeared immediately, but it changed little with time. These deposits are probably very thin, since production of the insulating TiO_2 film slows down or stops the anodization process.

All electrochemical measurements were performed with a multipurpose instrument constructed from solid-state operational amplifiers previously described (13-15). Current-potential curves were recorded with a Moseley Model 7005A X-Y Recorder. The electrode was illuminated through a quartz window in the cell wall. The counterelectrode was Pt and the reference electrode was a saturated calomel electrode (SCE).

Illumination was accomplished with a 200W mercury lamp (PEK-Illumination Industries). Either the full polychromatic output of the lamp was used, or the light was passed through a circular graded filter.

Results and Discussion

Current-potential curves for both single crystal and CVD TiO_2 (n-type) in the dark and under illumination in a 0.5M potassium chloride solution buffered at *p*H 6 are shown in Fig. 2 Curves at other *p*H's, from 1*N* NaOH to 1*N* H_2SO_4 are very similar to these on both the single crystal and CVD material, but are shifted in the negative direction 58 mV per unit increase in *p*H. The anodic region in the dark is characterized by a very low current until a certain breakdown potential when a marked current rise occurs. For the CVD TiO_2 this current rise occurs at potentials of about 2V *vs.* SCE and probably represents tunneling or film break-

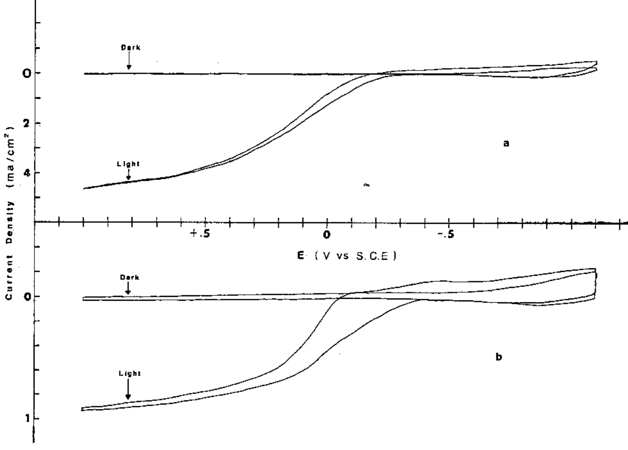

Fig. 2. Current density vs. potential for (a) single crystal TiO_2, and (b) CVD TiO_2 in 0.5M KCl solution buffered to *p*H 6.

down; this region was not investigated further. A similar current rise, at somewhat less positive potentials, was noted by Möllers *et al.* (10). This effect appears similar to that observed when Ti is anodized, where the TiO_2 formation and passivation region is followed by breakdown. The single crystal TiO_2 shows no such current rise until potentials beyond 10V. On the reverse scan, or a cathodic scan from the open-circuit potential, in the dark, the potential rise occurs when hydrogen evolution commences, as evidenced by the appearance of gas bubbles on the electrode.

When the electrodes are illuminated with either polychromatic light or wavelengths corresponding to energies greater than the bandgap (*e.g.*, 370 nm), anodic current and bubble formation on the electrodes is observed. The saturation oxidation current density under illumination is a function of light intensity and is somewhat smaller for the CVD TiO_2 than for the single crystal material. The higher C.D. observed with the single crystal material probably reflects the differences in structure between the CVD TiO_2, which is a mixture of polycrystalline anatase and rutile (11), and the rutile single crystal. Thus, there may be better efficiency in light absorption, and hence generation of holes, as well as fewer hole-electron recombinations in the single crystal material. On the reverse scan into the negative potential region following oxidation under illumination a cathodic current larger than that observed in the dark is observed. This is attributed to the reduction of oxygen formed during the anodic scan, and is absent in scans into the cathodic region alone in the presence of light in deaerated solutions. In solutions containing dissolved air, a small cathodic wave is observed in this region on an initial cathodic scan. The wave observed on reversal from a photosensitized oxidation is about 4 times larger, suggesting that some of the oxygen produced anodically is adsorbed at the TiO_2 surface or that a saturated solution of oxygen is formed near the electrode surface.

The shift in the location of the photosensitized oxidation wave with *p*H is the same for both single crystal and CVD TiO_2. A plot of E_L, the potential where the photocurrent commences *vs.* *p*H (Fig. 3), shows that both electrode materials fit the same linear correlation, with $\Delta E_L/\Delta p\mathrm{H} = 58$ mV/*p*H unit. The spectral sensitivities of both materials, shown by photocurrent *vs.* wavelength plots (Fig. 4), are also virtually identical.

The CVD TiO_2 is very stable at open circuit, to solutions ranging in *p*H from 0 to 14 (1*N* H_2SO_4 to 1*N* NaOH), as is the single crystal material; no noticeable decreases in saturation current densities occurred with prolonged immersion. The CVD TiO_2 is also mechanically stable, and withstands gentle polishing with very fine emery paper, although scraping the surface will destroy the film. Prolonged exposure of the CVD TiO_2 to positive potentials, with and without light, showed no noticeable changes in the appearance of the coating or maximum current density. Prolonged cathodic evolution of hydrogen occasionally produced small blisters or flakes on scattered portions of the surface. This may indicate poor adhesion of the TiO_2 film to the Ti substrate in these areas, perhaps because of some contaminant on the substrate prior to deposition.

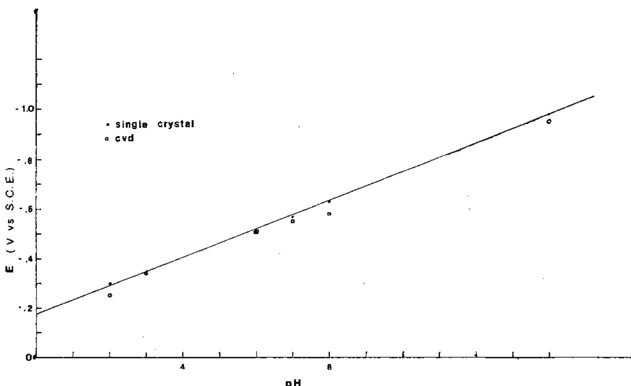

Fig. 3. E_L vs. pH for single crystal and CVD TiO_2

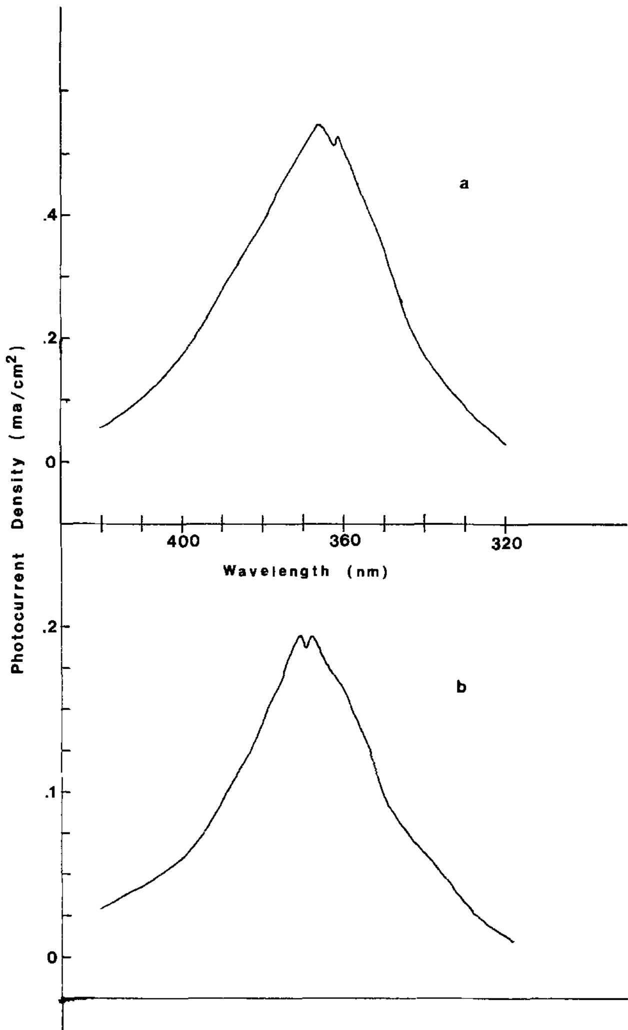

Fig. 4. Photocurrent vs. wavelength at potential of +0.775V (vs. SCE) for (a) single crystal TiO_2, and (b) CVD TiO_2. Curves are uncorrected for mercury lamp emission and transmittance variations of circular graded filter.

A brief study of the photosensitized oxidation of water on a TiO_2 film produced by anodization of Ti was undertaken to compare its behavior to that of the CVD material. Small photocurrents were observed on the anodized Ti, but the current densities were about 30-40 times lower than that of CVD TiO_2. The shift in potential of the anodized Ti at open circuit upon exposure to light (*ca.* −0.10V in 1*M* KCl) was also smaller than that observed for CVD or single crystal TiO_2 (*ca.* −0.50V in 1*M* KCl). This behavior suggests that the TiO_2 film formed on anodization of Ti is of insufficient thickness to support a full space charge, and it may also differ structurally from that of CVD TiO_2.

The CVD deposition technique can also be used to deposit TiO_2 upon glass [see also Ref. (10)], suggesting possible applications as a transparent electrode material, particularly in the region of negative potentials where SnO_2 electrodes sometimes are not useful. Moreover, the good stability of these CVD TiO_2 electrodes may make them useful in other electrolytic processes, for example, for photoassisted oxidations or reductions of organic materials in nonaqueous solvents. These applications are currently under investigation.

Acknowledgment

The support of this research by the National Science Foundation and the Army Research Office, Durham, is

gratefully acknowledged. We are indebted to Professor D. Tchernev for the sample of single crystal TiO_2 and for his helpful suggestions.

Manuscript submitted Nov. 7, 1974; revised manuscript received Feb. 13, 1975.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1975 JOURNAL. All discussions for the December 1975 Discussion Section should be submitted by Aug. 1, 1975.

Publication costs of this article were partially assisted by The University of Texas at Austin.

DISCUSSION SECTION

This Discussion Section includes discussion of papers appearing in the *Journal of The Electrochemical Society*, Vol. 121, No. 8 and 12; August and December 1974.

The Electroreduction of Oxygen and Hydrogen Peroxide on Sodium-Tungsten Bronzes

J.-P. Randin (pp. 1029-1033, Vol. 121, No. 8)

J. McHardy:[1] The paper under discussion largely bears out the findings of earlier workers[2] but two observations do call for comment. The first is that the presence of platinum in a bronze crystal did not increase its electrocatalytic activity for oxygen reduction and the second is that the log *i vs. E* curve for hydrogen peroxide reduction passed through a maximum.

In the 8 years since Sepa *et al.*[3] first reported sodium tungsten bronze to be an electrocatalyst for oxygen reduction, many publications have appeared on this and related subjects.[2] Several workers[4-7] were able to reproduce Sepa's results, but only by incorporating platinum in the bronze crystals. Other papers also reported beneficial effects of platinum upon electrocatalysis although Randin cites two of them[8,9] as evidence that platinum had no effect. Detection of the electrocatalysis is not a simple matter because the limiting current density for oxygen reduction is quite low (10-100 times lower than the diffusion controlled current observed at large overpotentials) and can easily be masked, *e.g.*, by corrosion currents.

Comparison of Randin's data with these of workers who did reproduce Sepa's results reveals differences both in condition and technique. Most significantly, Randin used more concentrated acid (tending to aggravate corrosion problems) and limited his measurements to relatively high current densities ($\geq 10^{-5}$ A/cm^{-2}). In my own work,[7] platinum-induced electrocatalytic activity was observed only after reducing corrosion currents to 10^{-6} A/cm^{-2} or less and even then it was confined to current densities below 10^{-5} A/cm^{-2}.

Turning to the second point, I would draw attention to the work of Voinov and Tannenberger[10] who also examined the reduction of hydrogen peroxide on tungsten bronzes. Despite differences in the interstitial element (they used Ce_xWO_3 and Yb_xWO_3) kinetic data at the rotating electrode were quite similar. Unlike Randin, however, Voinov and Tannenberger reported no maximum in the log *i-E* curve. The disagreement casts some doubt on Randin's interpretation of the maximum and raises the possibility that it may have been an experimental artifact.

J.-P. Randin:[11] Among the various published investigations in which oxygen reduction reaction on sodium-tungsten bronzes was studied, only McHardy's work[7] and the paper under discussion include a detailed quantitative evaluation of the effect of platinum incorporated by using a platinum anode (or crucible) during the preparation of the bronzes by electrolysis of a polytungstate melt. Other workers also reported various effects of platinum incorporated by extended potential cycling in acid solutions containing Pt metal ions[8] or by electrodeposition from chloroplatinic acid.[12] The latter methods gave relatively high surface concentrations of Pt as compared to the low bulk concentrations (in the ppm range) involved in the study under discussion. These studies[8,12] are therefore not relevant to the specific criticisms of McHardy.

It is evident from both McHardy's work[13] and from our own[14] that a significant corrosion current is ex-

hibited by the bronze electrode. The background current in helium saturated solutions was determined in a previous publication[14] and found to be in the range 10^{-6}-10^{-5} A/cm^{-2}. McHardy has presented no figure on this point and hence his claim that he could "reduce" the corrosion current down to 10^{-6} A/cm^{-2} is not supported by actual data. Steady-state current-potential curves for the oxygen reduction will be influenced by parasitic current as long as the applied current density is not significantly higher than the corrosion current. It is our experience that reproducible results for the oxygen reduction reaction, *i.e.*, current-potential curves free of hysteresis between the ascending (potential acquiring more negative values) and descending curves, were obtained only by working at current densities higher than about 10^{-5} A/cm^{-2}. In our experiments (see Fig. 1), the concentration of sulfuric acid from 1 down to 0.01N did not significantly influence the shape of the current-potential curve nor the current density at a given potential (except in the hydrogen evolution region). It is therefore unlikely that the acid concentration might be the cause of the discrepancy between McHardy's results and ours.

Figure 1 also shows that the limiting current density is much higher than that reported by McHardy.[7] The range of potential of the limiting current increases as the pH and, consequently, the hydrogen overvoltage increases. This behavior enables us to study the dependence of the current density on the rotation rate of the electrode in the limiting current region without interference from the hydrogen evolution reaction. At pH 2.7, the linear plot $1/i$ *vs.* $f^{-1/2}$ (f = rotation rate of the electrode) given in Fig. 2 indicates that the oxygen reduction reaction is first order with respect to dissolved oxygen and is purely diffusion controlled at $E = -0.4$V since the extrapolation to $f^{-1/2} = 0$ yields a zero intercept. The diffusion limiting current is obtained at $i = 10^{-2.7}$ A/cm^{-2} as is also found at noble metal electrodes, whereas Brockris and McHardy found a value of about 10^{-5} A/cm^{-2}.[7] Furthermore, the data in Fig. 1 indicate roughly a zero-order reaction with respect to hydrogen ion concentration, as compared to a reaction order of $-1/2$ found by Brockris and McHardy.[7]

The data reported in Fig. 2 show that the rotation of the electrode raised the limiting current as expected for a diffusion-controlled current. Bockris and McHardy[7] took their low limiting currents as evidence that only a small fraction of the surface actively catalyzed oxygen reduction. The latter authors did not report on the effect of the rotation of the electrode on the limiting current and therefore did not support their claim by actual data.

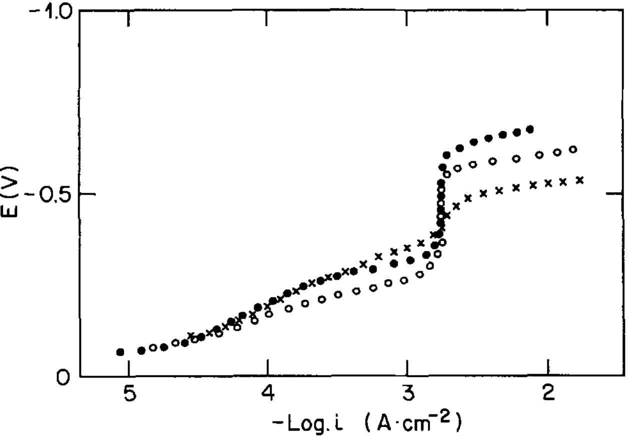

Fig. 1. Steady-state current-potential relationship on $Na_{0.65}WO_3$ (1 ppm Pt) in O_2-saturated 1N H_2SO_4 [pH $\simeq$ 0.3, (×)], 0.1N H_2SO_4 + 0.45M Na_2SO_4 [pH $\simeq$ 1.7, (○)], and 0.01N H_2SO_4 + 0.495M Na_2SO_4 [pH $\simeq$ 2.8, (●)] at 900 rpm. Measurements performed with potentials increasing in the cathodic direction.

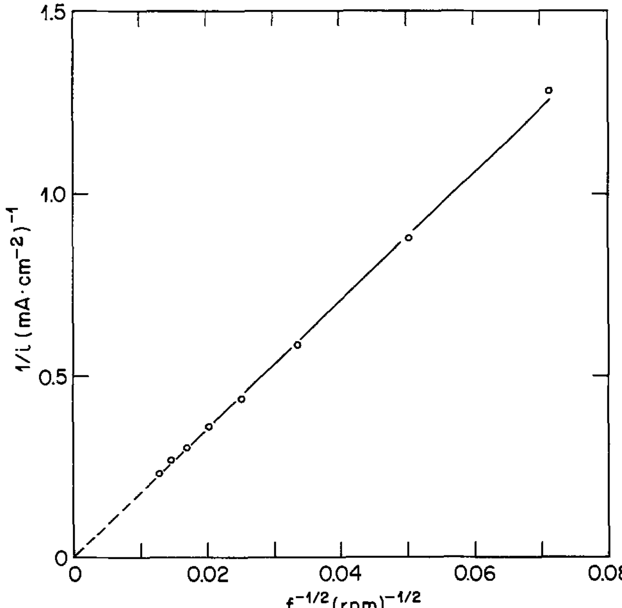

Fig. 2. A plot of $1/i$ vs. $f^{-1/2}$ (f = rotation rate of the electrode) for the reduction of oxygen on $Na_{0.65}WO_3$ in O_2-saturated 0.01N H_2SO_4 + 0.495M Na_2SO_4 (pH = 2.8) at E = -0.4V.

Another serious objection concerning the electrocatalytic effect ascribed to traces of platinum is the kinetics of hydrogen evolution and dissolution reactions at tungsten bronzes. If platinum can participate in a process of spillover of adsorbed intermediates to the bronze in the oxygen reduction reaction, the same enhancing effect would also be expected for the hydrogen evolution and dissolution reactions. Such an effect has not been observed, however.[15,16]

Concerning the second point of McHardy's discussion, *i.e.*, the maximum in the steady-state current-potential curve for hydrogen peroxide reduction, I would refer to a recent publication[17] in which the electrocatalytic activities of Na_xWO_3, Ni_xWO_3, CO_xWO_3, and WO_3 were studied and compared to that of Ce_xWO_3 and Yb_xWO_3 examined by Voinov and Tannenberger.[10] The linear part of the current-potential curve for hydrogen peroxide reduction, from about 0.5 to 0.2V, was not found to depend significantly on the nature of the electrode material for $Na_{0.58}WO_3$-$Na_{0.89}WO_3$, $Co_{0.03}WO_3$, $Ni_{0.03}WO_3$, and WO_3,[17] as well as for $Ce_{0.1}WO_3$ and $Yb_{0.1}WO_3$.[10] At potentials more cathodic than about 0.2V, however, the current-potential curves differ from one material to the other.[17]

The current-potential curves reported by Voinov and Tannenberger[10] were restricted to potentials less cathodic than 0V. In the potential range 0.5-0V, Na_xWO_3 is the only electrode which exhibited an inhibition inflexion. The other electrodes studied by Voinov and Tannenberger[10] as well as by us[17] exhibited a change in the slope of the current-potential curve around 0.15V. A closer comparison of the inhibition region, *i.e.*, the second part of the curve between 0.2 and 0V, for Co_xWO_3, Ni_xWO_3, Ce_xWO_3, and Yb_xWO_3, under the same experimental conditions, indicates a very similar behavior for the four electrodes.

The results obtained by Voinov and Tannenberger[10] for the hydrogen peroxide reduction on Ce_xWO_3 and Yb_xWO_3 are, consequently, in good agreement with our own results on Ni_xWO_3 and Co_xWO_3. The different behavior of Na_xWO_3 for hydrogen peroxide reduction in the inhibition region, as compared to other tungsten bronzes, may be due to the different charge of the interstitial cation and/or crystallographic differences.[17]

Effect of Gaseous Pretreatment on Oxidation of Iron

A. W. Swanson and H. H. Uhlig (pp. 1551-1554, Vol. 121, No. 12)

D. Chatterjee:[18] The importance of surface-state charge in Uhlig's theory for the so-called first stage of logarithmic oxidation[19] has been emphasized in recent works.[20-22] The theory has been modified[21,22] for p-type oxide formation by using Bardeen's concept on the rectifier theory of the metal/semiconductor junction.[23] The modified theory has been successfully applied to elucidate the logarithmic oxidation behavior of polycrystalline metals.[22] We would like to apply this theory to the present case of iron and also to the recent results on a single crystal of copper.[24]

The modified theory[22] applies to p-type oxide containing a uniform density space charge layer. The various estimated data are given in Tables I and II for iron (at 250°C) and copper (at 200°C), respectively. The energy (eV_s) and density (n_s) due to the surface-state charge of the oxide are considered to be confined within the metal/oxide interfacial layer, and is equivalent to the average length of individual surface dipole (about 3Å).[22] The estimated values for ferrous are thus 2.34 eV and 6×10^{14} cm^{-2} for eV_s and n_s, respectively. These are calculated using the work function (ϕ_m) of iron as 4.7 eV,[25] 2.2 eV as the electron affinity of oxygen (V_a),[26] 0.155 eV as the activation energy of oxidation (ΔE) of iron,[27] and 14 as the dielectric constant of ferrous oxide.[28] The various parameters of Table II have been estimated by using the data given by Swanson and Uhlig[24] for the first stage of logarithmic oxidation of a single crystal of copper.

The different pretreatment conditions of iron altered the rate constant as well as the space charge density (n_v) with little effect on the energy increase (eV_p) due to the space charge (Table I). The estimated n_v-values of Table I and II are reasonable figures for the density of trapping centers in the oxide.[21,22] It is noted that there is negligible difference in n_v-values of the cuprous oxide formed on the single crystal (Table II) and the polycrystal[22] ($n_v = 3 \times 10^{18}$ cm^{-3}). However, eV_p of the oxide formed on the single crystal is much lower than that on a polycrystalline copper[22] ($eV_p = 0.15$ eV using Uhlig's data[19]) or iron (Table I). The results showing $eV_s >> eV_p$ for polycrystalline iron with any pretreatment (Table I) and copper[22] obviously indicate the importance and predominant contribution of surface-state charge over the space charge to the potential across the oxide. This kind of behavior is expected.[20-22] However, in the case of oxidation of a single crystal of copper there is no definite relation between eV_s and eV_p of cuprous oxide formed on the various crystal faces (Table II). Furthermore, a negative eV_s-value is obtained for the oxide on the (111) face when the derived relation[22] $eV_s = (e\phi_m - eV_a) - \Delta E$ is used. It is believed that the work function of the (111) face of the metal in contact with oxide, given by Swanson and Uhlig,[24] is somewhat lower than expected.

The effect of metal properties on the double layer of surface-state charge and space charge, has been ignored in our theory[22] by assuming a high n_s-value. According to Bardeen,[23] there will be no effect of the metal on the double layer of the semiconductor if n_s is sufficiently high, *e.g.*, $n_s > 10^{13}$ cm^{-2}. The high n_s-values of oxides on polycrystalline iron (as shown here to be 6×10^{14} cm^{-2}) and copper[22] (3.8×10^{14} cm^{-2}) point out the justification of adopting the modified theory[21,22] in these cases to explain the logarithmic oxidation kinetics. However, the value of n_s is less than or just about equal to 10^{13} cm^{-2} for oxide formed on a single crystal (Table II). Thus the kinetic results of the first stage of logarithmic oxidation of polycrystalline metals cannot be compared with those of single crystals; the latter would involve a different mechanism with low n_s and anomalous relation between eV_s and eV_p of the oxide formed on the various crystal faces.

Oxygen Permeability of Stabilized Zirconia Solid Electrolytes

S. F. Palguev, V. K. Gilderman, and A. D. Neujmin

Institute of Electrochemistry, Urals Scientific Center of the Academy of Sciences, Sverdlovsk, USSR

ABSTRACT

The oxygen permeability of solid electrolytes 85.0 mole per cent (m/o) ZrO_2 + 15.0 m/o CaO (I), 90.0 m/o ZrO_2 + 10.0 m/o Y_2O_3 (II), 89.0 m/o ZrO_2 + 8.0 m/o Y_2O_3 + 3.0 m/o Al_2O_3 (III), 90.0 m/o ZrO_2 + 10.0 m/o Sc_2O_3 (IV) is investigated at temperature range 900°-1250°C and partial pressures of oxygen 0.01-1.0 atm. The oxygen permeability in this range of oxygen pressures is proportional to $P_{O_2}^{1/4}$. It is shown that the diffusion coefficient of oxygen does not depend on its pressure in a gas atmosphere. Transport numbers of electron holes, which were found to be in limits $1.7 \cdot 10^{-3} + 5 \cdot 10^{-5}$, were determined from the experimental data. The parameter $P_{\oplus}^{1/4}$ ($H_{\oplus} = H_{O_2^-}$) is also calculated.

The oxygen permeability of solid electrolytes with zirconia base, play a big role in the functioning of certain electrochemical devices. However, there are only few investigations on this subject (1-4), and permeability of yttria- and scandia-stabilized zirconia is still not investigated.

We investigated the permeability to oxygen of several solid electrolytes: 85.0 mole per cent (m/o) ZrO_2 + 15.0 m/o CaO(I), 90.0 m/o ZrO_2 + 10.0 m/o Y_2O_3 (II), 89.0 m/o ZrO_2 + 8.0 m/o Y_2O_3 + 3.0 m/o Al_2O_3 (III), and 90.0 m/o ZrO_2 + 10.0 m/o Sc_2O_3 (IV).

The measurements were made by using a cell schematically shown in Fig. 1. We use the principle that the rate J of penetration of gas through a plate diaphragm of area S cm^2 is connected directly with a rate of pressure rise ($\Delta P/t$) in a calibrated volume (5). The expression which shows this principle is

$$J = \frac{V\mu}{RTS\rho} \cdot \frac{\Delta P}{t} \frac{\text{cm}}{\text{sec}} \quad [1]$$

Where μ, V, ρ, R, and T are molecular weight, volume, and density of gas at the standard conditions, universal gas constant, and working temperature in °K, respectively.

The permeability constant (η) is given by

$$\eta = \frac{V\mu l}{RTS\rho\Delta P_{O_2}^{1/4}} \cdot \frac{\Delta P}{t} \frac{\text{cm}^2}{\text{sec} \cdot \text{atm}^{1/4}} \quad [2]$$

where l is the thickness of diaphragm and ΔP_{O_2} is the difference of oxygen pressures on the opposite sides of the diaphragm.

The specimens were of oxide solid electrolyte tubes closed at one end. They were placed in an electric resistance furnace in which temperature was precisely controlled and was constant (with accuracy ± 2°) along the working length. The tubes were prepared by common technology (a shlicker method). They were 200 mm long, with 9.6 mm outside diameter and about 8.0 mm inside diameter. Porosity was about 5%. Water absorption of the ceramics was close to zero, and permitted us to consider the porosity to be essentially closed. Chemical analysis of the specimens is given in Table I.

Before every measurement, the tubes were outgassed for a period of 8 or 10 times the time for the gas flow to establish a stationary state. The experimental data are processed by the least squares method. Permeability of the tubes to hydrogen, nitrogen, and argon at a gas pressure difference on the diaphragm equal to 1 atm

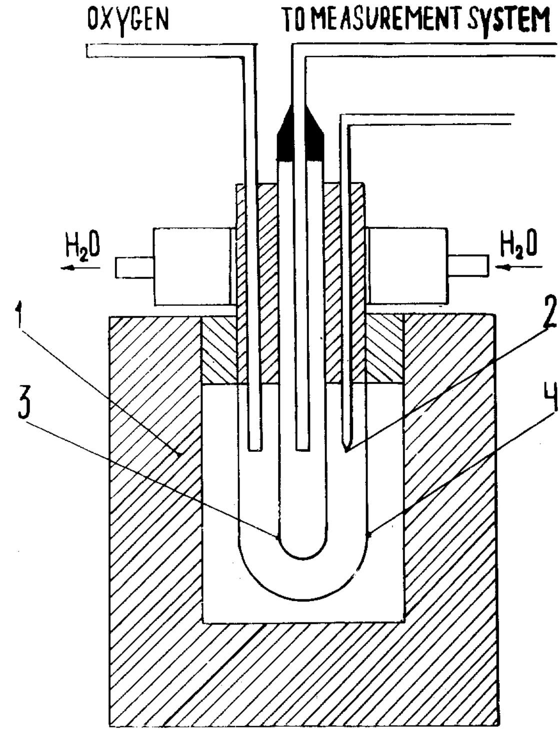

Fig. 1. Scheme of the measuring cell: 1, electric resistance furnace; 2, thermocouple; 3, specimen; 4, quartz tube.

Key words: stabilized zirconia, oxygen permeability, solid electrolyte.

Table I

Sample	Impurity content (w/o)								
	SiO_2	Fe_2O_3	Al_2O_3	Cr_2O_3	TiO_2	MnO_2	Ni_2O_3	MgO	CaO
I	0.23	0.18	0.10	0.03	0.048	0.010	0.009	0.075	—
II	0.65	0.17	0.007	—	0.095	—	—	0.08	0.07
III	1.0	0.6	—	—	0.01	—	—	0.002	0.05
IV	0.26	0.21	0.45	0.01	0.033	0.019	—	0.53	—

was preliminarily investigated. The permeabilities to these gases were lower than the lowest limit of accuracy of our experimental cell (3.10^{-9} cm²/atm · sec), that is, the permeation to hydrogen, nitrogen and argon was practically negligible. This shows that pores did not extend through the tube.

Figure 2 shows the curve of the typical oxygen pressure change in calibrated volume in the period of time after the oxygen was admitted into the evacuated solid electrolyte tube. The section BC on the curve corresponds to the establishment of stationary gas flow. The section OA which is cut off by the BC curve on the abscissa, determines the time of diffusion process delay. After Barrer (6) this value, L, is equal to

$$L = \frac{b^2}{6D} \qquad [3]$$

The dependencies of the oxygen permeability constant of the investigated specimens upon temperature are shown in Fig. 3. They are given below in units of cm²/sec · atm for the temperature range 900°-1250°C.

$$\eta(\mathrm{I}) = 3.82\ 10^{-1} \exp\left(-\frac{37{,}200 \pm 400}{RT}\right)$$

$$\eta(\mathrm{II}) = 1.55 \exp\left(-\frac{43{,}100 \pm 300}{RT}\right)$$

$$\eta(\mathrm{III}) = 1.52 \exp\left(-\frac{42{,}700 \pm 500}{RT}\right)$$

$$\eta(\mathrm{IV}) = 1.93 \exp\left(-\frac{38{,}900 \pm 600}{RT}\right)$$

The obtained values of the activation energy and pre-exponent factors of the permeability constant lie within the values, which were obtained for other compositions of zirconia-based solid electrolytes (2, 4, 7-9). The values of permeability are different, whereas the activation energy differ negligibly since they are mainly determined by diffusion process.

The process of oxygen permeation through a dense diaphragm with oxygen ion conductivity and a small part of electronic conductivity consists of several stages.

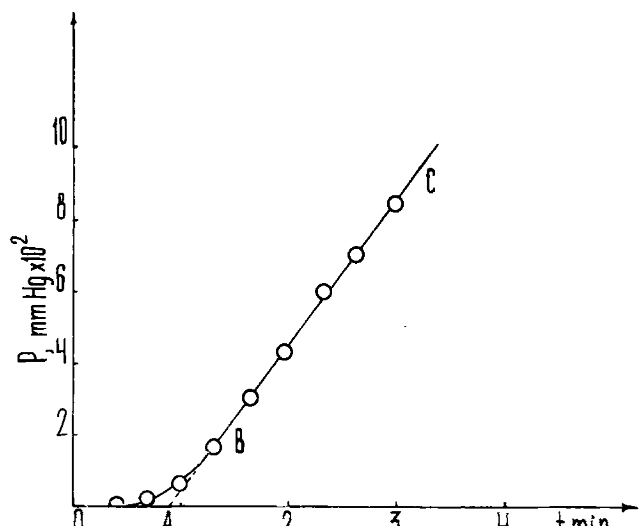

Fig. 2. The curve of oxygen pressure change in the calibrated volume (specimen III at temperature 1240°C).

Oxygen diffuses from gaseous phase to a surface of the diaphragm, adsorbs and dissolves there. Oxygen ions diffuse through the crystal lattice of an oxide electrolyte. Simultaneously electron holes move in the opposite direction. At the other side of the diaphragm oxygen ions turn into atoms and, after forming into molecules, desorb to diffuse into a gas phase.

Gas permeation is determined by two processes: diffusion of oxygen through ceramics and of oxygen solubility in it. If the values of the diffusion coefficients in different electrolytes are close to each other, the greater oxygen permeability may be explained by a greater solubility of oxygen.

As is seen in Fig. 4, permeation is proportional to $P_{O_2}{}^{1/4}$ for all the specimens in the investigated range of oxygen pressure (0.01-1.0 atm). The same dependence is reported by others (2, 4). That fact is an evidence of controlling the oxygen permeability by diffu-

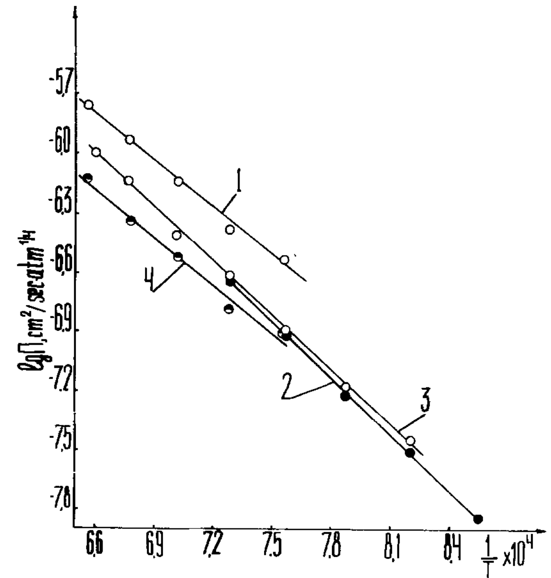

Fig. 3. The temperature dependence of oxygen permeability constant. Specimens: 1, I; 2, II; 3, III; 4, IV.

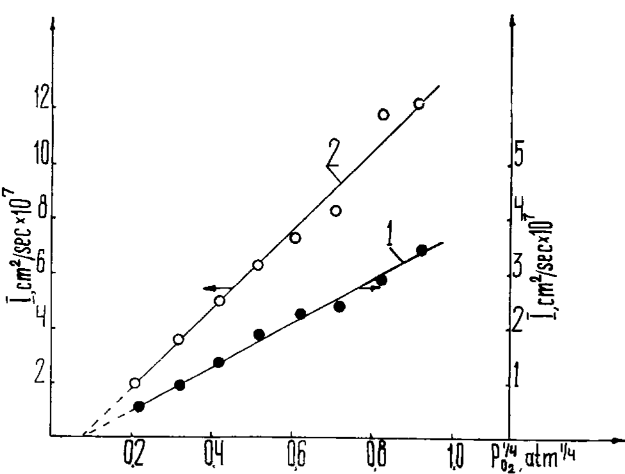

Fig. 4. The dependence of oxygen permeability upon oxygen pressure in a gas phase for specimens: 1, IV at 1150°C and 2, I at 1200°C.

sion of the electron holes. But in our case at the small values of oxygen pressures, the dependence changes.

If a diaphragm is thick enough, the rate of adsorption and desorption of oxygen on the surface of oxide is faster than the rate of diffusion, therefore surface layers of the oxygen electrolyte must be in a state near to an equilibrium with the gas phase. Probably the rate of oxygen adsorption and desorption processes at small pressures ($P_{O_2} << 4.10^{-5}$ atm) becomes comparable with diffusion rate, and the process of permeability begins to be controlled by the adsorption and desorption processes.

Diffusion coefficients of oxygen were calculated from the experimental data. Values L were determined by graphic method from the curves of type shown in Fig. 2. Then using Eq. [3] the diffusion coefficients were calculated. Temperature dependences of diffusion coefficients for some electrolytes are shown in Fig. 5. They are given in terms of square centimeters per second by the expressions

$$D(\mathrm{I}) = 1.07 \exp\left(\frac{36{,}400 \pm 800}{RT}\right)$$

$$D(\mathrm{II}) = 1.29 \exp\left(\frac{34{,}100 \pm 500}{RT}\right)$$

$$D(\mathrm{IV}) = 0.76 \exp\left(\frac{35{,}800 \pm 700}{RT}\right)$$

Values of the pre-exponent factor and activation energy lie close to each other, so that the dependence upon the kind of stabilizing addition used is slight.

Dependence of diffusion coefficients upon oxygen pressure is also shown in Fig. 5. It is seen that the diffusion coefficient does not depend on oxygen pressure. Therefore the mobility of electron holes in the investigated electrolytes practically does not depend on their concentration (in a range oxygen pressures 0.01-1.0 atm). But at the same time, the data obtained for the permeabilty and diffusion coefficients, show that the hole concentration depends on partial oxygen pressure in power 1/4.

Since for our solid electrolytes, $D_{\oplus}C_{\oplus}$ is much smaller than $D_{O^{--}}\ C_{O^{--}}$, diffusion coefficient of oxygen will be determined by flow of holes (10). The hole concentration in a surface layer of the diaphragm is determined by an oxygen exchange reaction between the gas phase and the solid electrolyte

$$O_2 + 2O_{\square^{++}} \rightleftarrows 2O_{\circ}{}^{*} + 4_{\oplus} \qquad [I]$$

Here $O_{\square^{++}}$ is the oxygen vacancy, $O_{\circ}{}^{*}$, the oxygen atom in a normal position of a crystal lattice.

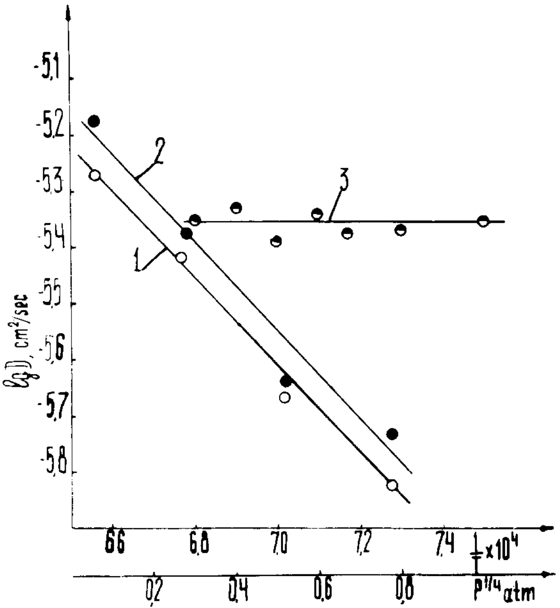

Fig. 5. The temperature dependence of diffusion coefficient for specimens: 1, IV; 2, I; 3, dependence of diffusion coefficient upon oxygen pressure for specimen IV at temperature 1200°C.

Using the law of mass action to reaction (I) the dependence of the hole concentration in surface layer on the oxygen pressure is derived.

$$C_{\oplus} = K_s \cdot P_{O_2}{}^{1/4} \qquad [4]$$

Where the solubility constant, K_s, is equal to the hole concentration at 1 atm oxygen pressure.

Using the Nernst-Einstein equation, the electric conductivity value, caused by migration of holes ($H_{\oplus}$) in an electrolyte, can be obtained

$$H_{\oplus} \cdot (P_{O_2} = 1 \text{ atm}) = \frac{4\mathbf{F}^2 \eta_o}{RT} \exp\left(-\frac{E_n}{RT}\right) \qquad [5]$$

Here E_n is the activation energy of oxygen permeability, η_o is the pre-exponential factor, and $\mathbf{F}$, Faraday's constant.

Transference number of the electron holes at $P_{O_2} = 1$ atm is equal to

$$t_{\oplus} = \frac{4\mathbf{F}^2 \eta_o}{RTH_o} \exp\left(-\frac{E_n - E_{o^{--}}}{RT}\right) \qquad [6]$$

where E_o is the activation energy of oxygen conductivity and H_o is the pre-exponential factor.

90.0 m/o ZrO_2 + 10.0 m/o Sc_2O_3	$\frac{3.86\cdot10^4}{T}\cdot\exp\left(-\frac{38,900}{RT}\right)\cdot P_{O_2}^{1/4}$	$1.98\cdot10\cdot\exp\left(-\frac{19,900}{RT}\right)$	$5.12\cdot10^{-4}\cdot T\cdot\exp\left(\frac{20,000}{RT}\right)$

Table II gives the results of calculations of the transference numbers of electron holes in investigated electrolytes at the oxygen pressure 1 atm. The temperature dependence of electrical conductivity used in calculations was taken from literature (11-14). It can be seen that the transference numbers of holes are within the limits $5\cdot10^{-5}$ — $1.7\cdot10^{-3}$. It is seen that the electrolyte with a scandia addition has the smallest part of electronic conductivity.

The dependence of hole conductivity upon the pressure of oxygen in a gas phase and analytical expressions for the temperature dependence of parameter $P_{\oplus}^{1/4}$ (the oxygen pressure in a gas phase, when the values of electronic p-type and ionic conductivities are equal) are also calculated. The results are given in Table III.

Heterogeneous Halide-Silica Phosphors

Willi Lehmann*

Westinghouse Research Laboratories, Pittsburgh, Pennsylvania 15235

ABSTRACT

Efficient photoluminescence in phosphors containing about 90% SiO_2 and 10% $CaCl_2$ or other halides is observed after activation with Eu^{+2} (violet to blue colors) or Eu^{2+} plus Mn^{2+} (yellow to red). The materials are heterogeneous, consisting of luminescent halides dispersed in small segregations inside of bigger and nonluminescent SiO_2 particles. The phosphors are stable in water and acids (except HF) because the hygroscopic halides are protected by surrounding SiO_2.

Quartz containers used to prepare red emitting $CaS:Eu^{2+}$ phosphors frequently show blue luminescence which is easily excited by irradiation with ultraviolet. The optical properties of the luminescence and the absence of a corresponding effect on quartz containers used to prepare CaS-phosphors with any of the many other impurities active in CaS (1) clearly indicate that Eu^{2+} is the responsible activator. The blue luminescence appears to be a property of the solid quartz container, *i.e.*, it cannot be mechanically removed without destroying the quartz and the only chemical means to remove it is strong hydrofluoric acid. An investigation was started to find the origin of this very striking luminescence, and we discovered a peculiar class of heterogeneous materials which appear not to be reported before.

SiO_2 obviously is involved since the blue luminescence is restricted to the walls of the containers and does not appear in its content of $CaS:Eu^{2+}$. Attempts to reproduce it in calcium silicates were not successful; Eu^{2+} does not show this blue luminescence in

* Electrochemical Society Active Member.
Key words: luminescence, phosphors, halide, silica, europium, manganese.

any of the known calcium silicates (2). However, the blue luminescence does appear in preparations containing also $CaCl_2$ besides CaO and SiO_2. Since several calcium and strontium halo-silicates have been reported already (3, 4), a calcium halo-silicate, perhaps of a still unknown composition, became suspect and the investigation was broadened to include various ratios of $CaO:CaCl_2:SiO_2$. Surprisingly, the optimum ratio turned out to be about 90 mole per cent (m/o) SiO_2 and 10 m/o $CaCl_2$ with little or no CaO at all (Fig. 1). The following describes preparational details and results of the investigation.

Preparation

Heterogeneous phosphors of this kind are easily prepared by firing a uniform mixture of silicic acid, CaO, Eu_2O_3, and an excess of NH_4Cl at about 950°-1000°C in slightly reducing atmosphere (*e.g.*, $N_2 + 1\% H_2$). The preferred molar ratio of $SiO_2:CaO:Eu_2O_3$ is about 95:4.5:0.5 to 80:19.5:0.5. The NH_4Cl reacts with CaO and Eu_2O_3 to form the halides *in situ*, all excess of NH_4Cl not used in this conversion sublimes out of the container during firing. After firing and cooling, the phosphors are washed in water to remove any free halide. When dry, they are free flowing powders, stable in air, water, alkaline solutions, and acids with the only exception of strong hydrofluoric acid.

Calcium in the above formation may be replaced by Sr, Li, or La (but not by Mg, Ba, Na, K, Zn, Cd, Y). The chloride may be replaced by bromide or by iodide (but not by fluoride). Europium may not be replaced by any other activator but can be combined with manganese in which case the emission of Eu^{2+} sensitizes Mn^{2+} for excitation by ultraviolet. Depending on composition, emission ranging from violet to blue (for Eu^{2+}) and from yellow to red and infrared (for Mn^{2+}) may thus be obtained.

Results

Chemical analysis of a sample $(CaCl_2\text{-}SiO_2):Eu^{2+}, Mn^{2+}$ made with the addition of 1% $EuCl_2$, 1% $MnCl_2$, and 8% $CaCl_2$ (rest SiO_2) showed approximately half of the added amounts of Eu, Mn, and Ca still present after firing and washing, the other half mainly lost into the washing water.

X-ray diffraction spectra of the phosphor samples normally show only lines corresponding to the α-cristobalite modification of SiO_2. Whatever else is present must be either amorphous or in amounts too small to be detected by routine x-ray analysis (detectability limit: several %).

Microscopic examination shows mainly irregularly shaped particles roughly 5-20 μm in size. Some are relatively clear. Others contain so many small inclusions (0.1-0.3μ) that the particles appear almost opaque against white background illumination. Only these inclusions are visibly luminescent under ultraviolet irradiation, the clear parts of the inclusion carrying particles and all of the completely clear particles remain dead (Fig. 2). Particles with many luminescent inclusions dominate in a material made to optimum performance, fired at about 950°-1000°C. Too low (~ 800°C) and too high (~ 1200°C) firing temperatures result mainly, or only, in clear particles (Fig. 3) and correspondingly poor luminescence.

Emission spectra of phosphors made with various halides and activated with Eu^{2+} and Mn^{2+} are shown in Fig. 4-6. Approximate peak positions of the emission bands, at room temperature, are given in Table I. Eu^{2+} produces violet to blue emissions; it responds to near-ultraviolet because of its strong and broad optical absorption next to the emission (Fig. 7). Mn^{2+} emission does not appear in the strontium halides (Fig. 5). In the other halides, it can optically be excited if Eu^{2+} is present as a sensitizer. The efficiency of the energy transfer $Eu^{2+} \rightarrow Mn^{2+}$ depends on the concentrations of both; it may be fairly high (approaching unity) but is never complete. Several per cent of the Eu^{2+} emission usually are left unconverted even in phosphors designed to have strong Mn^{2+} emission.

The over-all quantum efficiency (Eu^{2+} plus Mn^{2+}) is surprisingly high (80-90% have repeatedly been measured) if one considers the fact that most of the materials consist of nonluminescent SiO_2.

Figure 8 compares the emission of heterogeneous $(CaCl_2\text{-}SiO_2):Eu^{2+}$ to that of plain $CaCl_2:Eu^{2+}$ with-

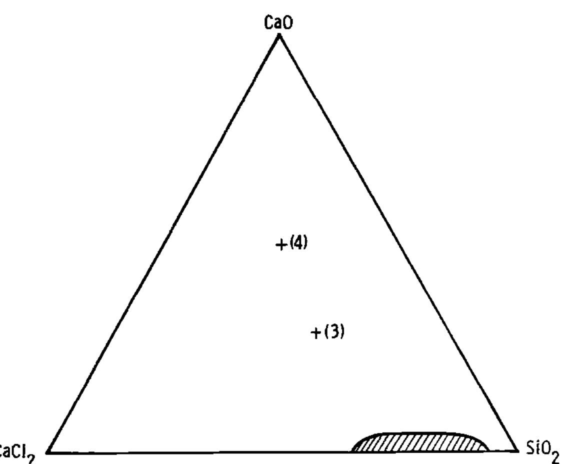

Fig. 1. Optimum compositions of blue-violet Eu^{2+}-emission in the ternary system $CaO\text{-}CaCl_2\text{-}SiO_2$ (shaded areas). Points (3) and (4) correspond to the halo-silicates reported in Ref. (3) and (4).

out addition of any oxide. Except for the low-energy tail (frequently observed in heterogeneous phosphors) of the former, the spectra are sufficiently alike to indicate common origin. Emission spectra of Mn^{2+} are given in Fig. 9 of heterogeneous $(CaCl_2$-$SiO_2)Eu^{2+}$, Mn^{2+}, of several similar preparations where SiO_2 was replaced by MgO, Al_2O_3, or Y_2O_3, and of plain $CaCl_2:Eu^{2+}$, Mn^{2+} made without addition of an oxide. Again, the spectra are alike enough to indicate com-

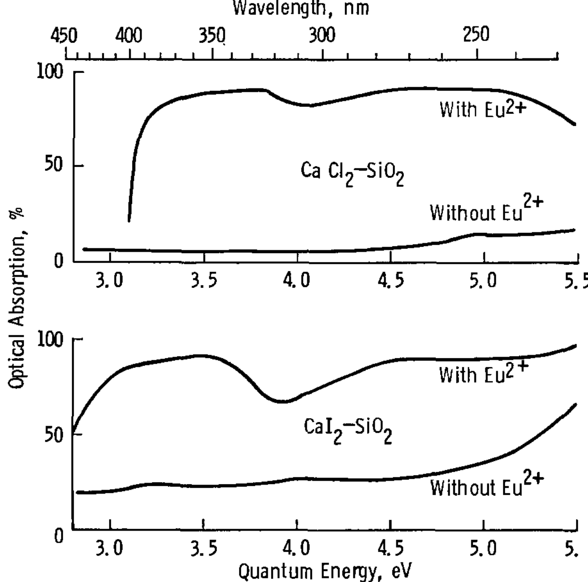

Fig. 7. Optical absorption spectra of $CaCl_2$ (top) and CaI_2 (bottom) in SiO_2 with or without Eu^{2+}.

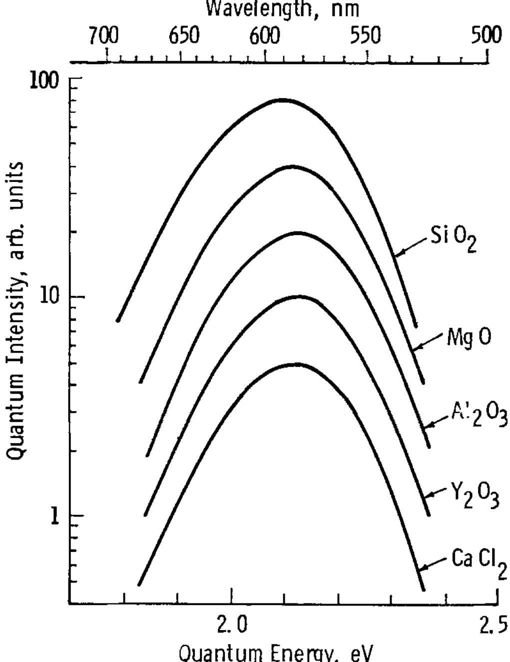

Fig. 9. Mn^{2+} emission of $CaCl_2$ condensed in or on (top to bottom) SiO_2, MgO, Al_2O_3, Y_2O_3, and of plain $CaCl_2$. Logarithmically calibrated ordinate. Spectra are arbitrarily moved up and down to avoid confusion.

mon origin. The main difference between all these materials is the chemical stability. Heterogeneous SiO_2-containing phosphors are insensitive to water; all others are hygroscopic and their luminescence is immediately destroyed if they come into contact with water. This observation is trivial for the case of $CaCl_2$ (no SiO_2) which is well known to be hygroscopic and soluble in water. Microscopic inspection of the particles of materials made with addition of MgO, Al_2O_3, or Y_2O_3 does not reveal the sort of luminescent inclusions as they are observed in SiO_2. Obviously, the luminescent $CaCl_2$ phase in these materials is present not in, but outside of, the oxide particles where it easily can all be removed by washing in water.

Figures 9 and 10 show the temperature dependence of the luminescence of several materials (plaques, excited by 365 nm u.v.). The data represent quantum densities, arbitrarily normalized to 100 units at room temperature. Simultaneously with a decreasing efficiency, the emission of Mn^{2+} shifts appreciably to shorter wavelengths with increasing temperature. A similar shift of the emission of Eu^{2+} is much less pronounced.

Discussion

In view of the inability of pure SiO_2 (without halides) to show the observed luminescence in presence of Eu^{2+} or Mn^{2+}, of all other observations described above, and of the known blue luminescence of $SrCl_2:Eu^{2+}$ reported before (3), we conclude heterogeneous halide-silica phosphors to consist of two separate phases. One phase (roughly 9/10 of the entire material) is SiO_2 either present as α-cristobalite or amorphous. It is not visibly luminescent, but it is very transparent for ultraviolet or visible radiation. The other, smaller phase is luminescent metal halide containing Eu^{2+} or $Eu^{2+} + Mn^{2+}$. After firing, but before washing the phosphor, part of the halide is present in small segregations inside, another part apparently is condensed on the surfaces outside, of bigger SiO_2 particles. Washing in water dissolves the latter but not the former. The luminescent segregations inside of the particles are protected by surrounding SiO_2 against about anything but strong hydrofluoric acid. This permits studying and utilizing the luminescence of metal halides which otherwise would be too hygroscopic to be handled unprotected in open air.

A somewhat similar heterogeneous phosphor system has been reported by Wachtel (5) for the composition $x \cdot SiO_2 - (1 - x) \cdot Al_2O_3:Eu^{2+}$ where $x = 0.9$-0.95. Wachtel attributes the luminescence of this material to $3Al_2O_3 \cdot 2SiO_2:Eu^{2+}$ dispersed in SiO_2. The luminescent halides dispersed in SiO_2 described above appear to be another example of the same phenomenon.

Heterogeneous halide-silica phosphors made by reaction of La_2O_3 with NH_4Cl in presence of an excess of SiO_2 might be open to dispute whether the luminescent phase is LaOCl or $LaCl_3$. We believe it to be the latter since LaOCl:Eu, even if especially prepared in reducing atmosphere, invariably shows the typical red line emssion of Eu^{3+} which is completely absent in the heterogeneous phosphors described here (Fig. 6).

The question comes up how the halide segregations end up inside of solid SiO_2 particles during preparation. Obviously, this must involve a transport of matter. We suggest a reversible reaction of the kind

$$SiO_2 + 2CaCl_2 \rightleftarrows SiCl_4 + 2CaO$$

to be involved. The equilibrium of this reaction during firing apparently is heavily, but not entirely, on the left side. Little or no formation of $SiCl_4 + 2CaO$ as intermediate products could not explain the growth of SiO_2 particles, with or without inclusions, at the

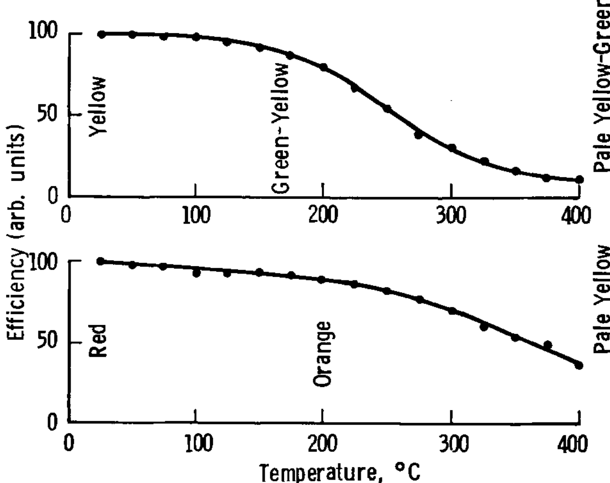

Fig. 10. Temperature dependence of luminescent efficiency and color shift of yellow $CaCl_2:Eu^{2+},Mn^{2+}$ (top) and of red $CaI_2:Eu^{2+},Mn^{2+}$ (bottom), both in SiO_2.

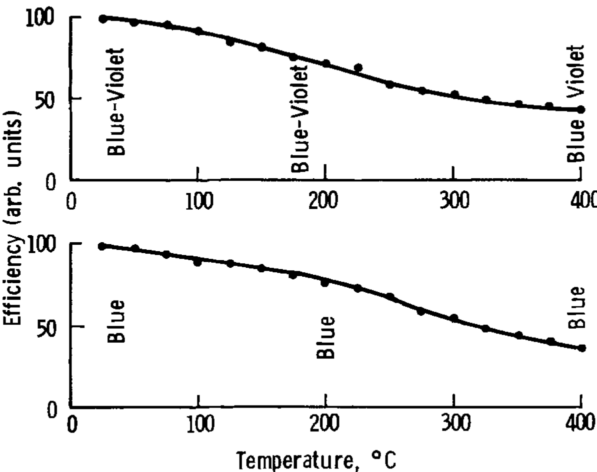

Fig. 11. Temperature dependence of luminescent efficiency of blue-violet $CaCl_2:Eu^{2+}$ (top) and of blue $CaI_2:Eu^{2+}$ (bottom), both in SiO_2.

relatively low temperature of 950°-1000°C. On the other hand, if the equilibrium would be heavily on the right side, volatile $SiCl_4$ should escape and CaO should remain either as a separate phase or reacted with the rest of the SiO_2 as calcium silicate. Neither is actually observed. This necessary balance of the reaction equation favoring the left side without entire exclusion of the right, may not be present if $CaCl_2$ is replaced by a halide of Mg, Ba, Na, etc., and this appears to be the reason why these combinations do not work to form heterogeneous silica phosphors of the described sort.

Systems analogous to heterogeneous silica phosphors appear to be possible also with other glass-forming oxides like GeO_2, P_2O_5, and B_2O_3 although the conditions of preparation are somewhat different from those involving SiO_2. Details of these cases are not yet available. Such materials containing luminescent halides suspended in optically inert glass-forming oxides may easily be mistaken by superficial examination as uniform phosphor compounds. We warn against this misinterpretation.

Manuscript submitted Nov. 15, 1974; revised manuscript received Feb. 7, 1975. This was Paper 197 presented at the Toronto, Canada, Meeting of the Society, May 11-16, 1975.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1975 JOURNAL. All discussions for the December 1975 Discussion Section should be submitted by Aug. 1, 1975.

ABSTRACT

Calcium fluorophosphate powders containing various amounts of cadmium and antimony and single crystals containing antimony were subjected to u.v. irradiation and thermal annealing treatments. The color centers formed by the irradiations were studied by electron spin resonance and by optical techniques. Two previously unreported color centers were observed, one associated with the presence of antimony and the other with the presence of cadmium. Growth dynamics and models for these two centers are given and their importance in phosphors is discussed. A simple model for phosphor depreciation is proposed in which these centers play crucial roles.

Calcium fluorophosphate $Ca_{10}(PO_4)_6F_2$ is a common mineral called apatite which has attracted scientific interest in three widely diverse fields. Powdered calcium fluorophosphate modified by the substitution of chlorine and cadmium and activated by the addition of manganese and antimony is used as the phosphor in most fluorescent lamps. Single crystals of calcium fluorophosphate and many chemically modified forms of this prototype may be activated with neodymium to provide an excellent laser material (1). Irradiated samples of calcium fluorophosphate and its modifications provide a host of color centers whose relationships and interactions can be observed (2, 3) with unusual clarity.

In each of these fields of interest a major effort has been exerted to obtain information on an atomic scale of the site at which the substituted ion or color center sits, as well as a description of its surroundings, for instance, whether or not a charge-compensating defect is nearby. The major tools used have been optical spectroscopy and both electron and nuclear resonance spectroscopy. If the defect to be studied is paramagnetic, and particularly if single crystals are available, the resonance techniques have several advantages over the optical measurements. These include the ability to positively identify the spectra with a particular atom because of its distinctive hyperfine structure, the ease with which the symmetry of the center may be determined, and the high resolution attainable which may be a crucial factor in unraveling complicated spectra to which several different centers are contributing. Optical spectroscopy on the other hand is the only tool available with nonmagnetic defects and can be useful in combination with resonance spectroscopy, particularly when samples are available only in powder form.

Accordingly, in reviewing our knowledge of defects in calcium fluorophosphate, we find that highly specific information is available about paramagnetic color centers formed by irradiation, but that much less is known about the much more numerous nonmagnetic defects from which the color centers were formed. In the same way, detailed information is only available about paramagnetic impurities. For example, we know of at least four different ways in which Mn^{+2} can enter fluorophosphate samples (4-5), but little is known about diamagnetic antimony or cadmium. The information which is available is derived from optical measurements and often depends upon questionable assumptions, for example that the atom in question is present in the crystal at only one kind of site. Measurements show that this is often not the case, for instance, the

measurements made on manganese that are referred to above and unpublished measurements of our own which show that Nd can occupy at least nine different sites in apatite.

Recently optical and ESR measurements have been made before and after u.v. irradiation on samples of single crystal and powdered calcium fluorophosphate containing antimony or cadmium. New resonances and optical spectra were observed which are caused by complex centers which include both an impurity ion and a color center. These spectra and a description of the centers involved are of normal interest in themselves, but they are important for two other reasons: the detailed information we can infer about the state of the impurity ions before the irradiation, and the implication which the description of the new centers has with regard to the deterioration of phosphors during the u.v. irradiation which normally occurs in fluorescent lamps. The purpose of this paper is to present the optical and ESR measurements made of the new centers and to discuss their structures and their implications.

Experimental Procedures

Sample preparation.—Powdered samples were prepared in a manner consistent with techniques used for lamp phosphors, *i.e.*, raw materials were weighed out, mixed, and fired to about 1175°C for 1 hr in a nitrogen atmosphere in covered ceramic trays. The resulting material, sintered into a loosely bound cake, was then broken apart into a powder whose individual particles averaged about 7 μm in diameter. The composition of the starting material for samples containing cadmium was as follows

$CaHPO_4$	3.00 mole
$CaCO_3$	1.35-2.30 mole
CaF_2	0.45 mole
$CdCO_3$	0-0.05 mole

These mixtures deviate slightly from stoichiometry and therefore contain small amounts of second phases. While highly efficient halophosphate phosphors may be prepared from a stoichiometric mix of starting materials, the preparation is very critical. A slight excess of $CaCO_3$ will lower the efficiency disastrously while a slight deficiency of $CaCO_3$ has only a small effect on the efficiency. This bias occurs because the formation of X centers (3) (and thus color centers) is enhanced by any excess oxygen in the starting mix. The easiest way to insure that no excess of oxygen is present is to deliberately create a deficiency by using a less than stoichiometric amount of $CaCO_3$. A slight deficiency of CaF_2 content produces a less vitreous cake which can be more easily broken up into a powder. No complications were observed in the ESR or optical spectra due to the presence of the small amounts of second phases.

Powdered samples containing antimony were also prepared but are not reported here because single crystal samples were also available. These were prepared by conventional Czochralski crystal growing methods (1) except that heroic measures were taken to insure that some antimony was maintained in the melt at the elevated growth temperature (~1600°C) in spite of its high vapor pressure. Measures that were tried included the addition of grossly excessive amounts of antimony to the original charge, the continuous addition of antimony to the melt during growth, very fast growth, and Bridgman growth inside an iridium "bomb." Using these techniques a crystal could occasionally be grown which contained a useful amount of antimony. Such samples appeared to behave optically in exactly the same way as powdered samples, *i.e.*, the same absorption and emission spectra. Similar techniques were applied to the growth of crystals containing cadmium but no success was achieved presumably because of the even higher vapor pressure of the evaporating cadmium compounds.

Sample irradiation and annealing.—In most cases color centers were produced in the samples by u.v. irradiation in flowing nitrogen at room temperature using the unfiltered emission from a low pressure mercury discharge in a "Suprasil" quartz envelope. To achieve a more uniform irradiation, the single crystal samples containing antimony were cut in the form of thin slabs, ~0.1 mm thick, and were irradiated equally from both sides. The absorption of these slabs before irradiation, shown in Fig. 1, was so high at 185 nm, the important wavelength, that the u.v. dose still varied about 10% within the slab. The powder samples were irradiated uniformly by being dusted into a layer about one particle (7 μm) thick on a quartz plate and by being irradiated from both sides. After irradiation the powder was collected and packed into a small plastic cup for ESR and optical measurements. Samples were sometimes irradiated at low temperatures and measured without warming. Special ESR and optical cells were available for this purpose.

Color centers can be converted into different kinds of centers or be destroyed by irradiation with light of special wavelengths and by annealing at a sufficiently high temperature (2). This conversion is sometimes achieved by the transfer of an electron, other times by the diffusion of a vacancy or other defect, and occasionally by both processes occurring together. These optical and thermal conversion techniques can be very useful experimentally for a variety of purposes such as the following: (*i*) to destroy most of the centers when a spectrum is a superposition of many parts, so that the remaining ones display spectra simple enough to be understood; (*ii*) to relate ESR and optical spectra to the same center by showing that they disappear under the same optical or thermal treatment; and (*iii*) to relate two different centers by showing that one grows at the expense of the other under some particular treatment. Annealing, in particular, has been used extensively for these purposes in the work to be described.

ESR procedures.—The X band apparatus used is largely conventional. Most of the measurements were carried out at 77°K although runs at 4.2°K were also sometimes made to increase resolution when necessary to resolve closely spaced lines. An important part of the apparatus was a device which allowed rotations of the crystal sample in the external field to allow a precise determination of the symmetry of each defect site.

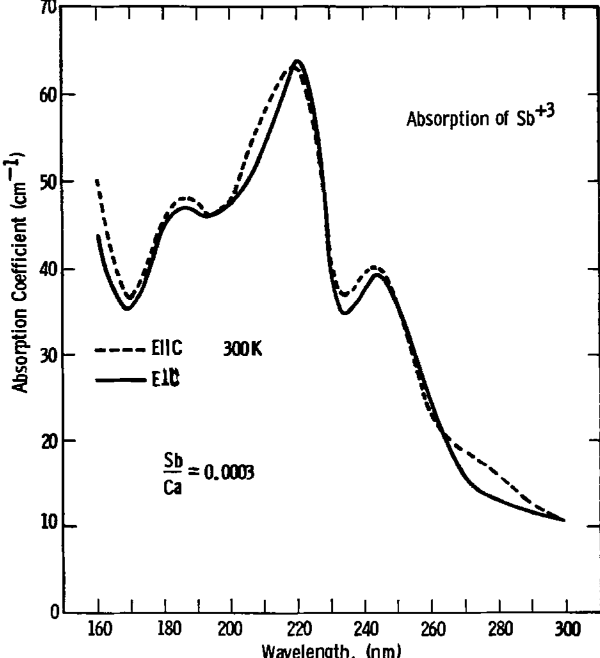

Fig. 1. The optical absorption of a single crystal of calcium fluorophosphate containing 0.03 atomic per cent antimony.

Optical procedures.—Two different optical techniques were used to investigate samples. With single crystal samples, polarized transmission measurements were made using a Cary 14 spectrometer throughout the visible and near *IR* regions and a McPherson Model 218 spectrometer in the u.v. out to 150 nm. Diffuse reflectance measurements were made on powder samples using a Cary 14 spectrometer and an integrating sphere attachment covering the range 250-2000 nm. Diffuse reflectance measurements for wavelengths shorter than 250 nm were performed with the McPherson spectrometer. An integrating sphere was not used for these measurements. Instead, the reflectance was measured at an angle of 45 degrees relative to the incident beam. An Eastman Kodak barium sulfate white reflectance standard was used. No published data could be found on the reflectance of Eastman Kodak barium sulfate at wavelengths shorter than 200 nm. We found its reflectance to be considerably higher than high purity lithium fluoride and undoped calcium fluorophosphate over the range of 150-200 nm. As a result, we used the Eastman Kodak reflectance standard down to 150 nm with some introduction of error due to a lack of knowledge of its absorption in this range.

Results

ESR spectra of samples containing Sb.—ESR measurements of undoped unirradiated crystal or powder samples usually show only the spectra of the HII center, identified (2) as a paramagnetic O^- center substituted at an F^- site. Optical spectra of such samples usually show a strong absorption due to the X center, identified (3) as the defect $(VOV)^+$ substituted on three adjacent fluorine sites. The nomenclature used in this paper to discuss the color centers follows the conventions presented in Ref. (3). The symbol V represents a vacancy, O an O^{-2} ion, and the + sign signifies that the complex composed of these adjacent parts has a positive charge compared to the three F^- ions it replaces. These defects, the HII and X centers, are closely related to each other and are both normally present because of the loss of fluorine and its replacement by oxygen during crystal growth. Unirradiated samples grown with antimony doping show a strong reduction in the X center absorption and a reduction in the HII center concentration. A scavenging of oxygen by antimony appears to be occurring, and the existence of an Sb-O center in the crystal appears to be likely. The existence of such a center has been discussed by Davis *et al.* (6). We have noticed that the same kind of coupling with oxygen appears to occur for another trivalent ion, Nd^{+3}, substituted in this host. No interaction of this kind between Cd^{+2} and oxygen has been noticed.

Irradiation produces several kinds of E centers (2, 3) in undoped crystals all involving a fluorine vacancy and an extra electron. The irradiated samples containing antimony show unusual E center ESR spectra. An example of this is shown in Fig. 2, where the temperature is 77°K, the crystal has an antimony concentration Sb/Ca = 0.03%, it is oriented with its crystalline c axis perpendicular to the magnetic field, and the derivative of the ESR absorption is shown. The ESR spectrum normally observed in undoped but irradiated samples of fluorophosphate is three narrow lines of intensities 1:2:1 separated from each other by about 17g. It is caused by the EII center, and is identified (2) as a fluorine vacancy containing one electron. This center has two neighboring fluorine ions which contribute a local magnetic field which splits the resonance into three hyperfine lines. Additional couplings to more remote fluorine ions and to other magnetic ions contribute to the line width of about one gauss. The new spectrum, shown in Fig. 2, satisfies all of these descriptions, but in addition, each line is further split into several components. If ESR measurements are made at other orientations of the crystal relative to the external magnetic field, the new structure rapidly washes out and the spectrum becomes indistinguishable from that of an ordinary EII center. To deduce the symmetry of the new center, measurements of the spectrum were made as the crystal was rotated while keeping its c axis perpendicular to the external field. As expected the threefold crystalline symmetry was evident in the spectrum, *i.e.*, the clear splitting shown in Fig. 2 was most evident at six symmetrical positions but disappeared in between these positions. As a result of the symmetry of the crystal, the spectrum observed must be either the superposition of three spectra from equivalent centers with reflection symmetry or the superposition of six spectra from equivalent centers with no symmetry. The blurring and sharpening with rotation is a result of the variable overlap of their individual spectra. In an attempt to distinguish between these possibilities, a "rocking" measurement was performed in which the crystal was slowly rotated so that the magnetic field moved away from the plane perpendicular to the crystalline c axis. The spectrum of a center with reflection symmetry behaves differently under these conditions than one without this symmetry. The splitting was observable over a considerable range (~40°) away from this plane, but unfortunately it was too small, and the over-all resolution was inadequate to realize our aims. To show how small the splitting effect is, a powdered sample was made by crushing a crystal which contained antimony and only the modified EII center. The ESR powder spectrum showed what appeared to be a normal EII spectrum with no evidence of the new fine lines. Thus the new fine structure is barely observable in a single crystal, and then only when the field is aligned in one of a few special directions.

The new E center is identical to the EII center except that it has been very slightly modified by the presence of an Sb ion. We will call this new center the EII (Sb) center. Its concentration, EII (Sb)/Ca = 0.003%. Figure 3A shows an enlargement of the central "line" of Fig. 2 and also shows our analysis of this line in terms of the hyperfine splitting of the EII spectrum which would occur if an antimony ion with its characteristic nuclear moment were near each EII center. The theoretical curve was calculated by taking into account the relative abundance of the two antimony isotopes and the relative values of their nuclear magnetic moments (shown in Table I). The contribution from all three

(or six) equivalent centers was included and reasonable assumptions were made about the alignment of these centers with the magnetic field, the relative strengths of their coupling to the EII center and their line widths. In particular, we assumed that the angle which gives the best resolution of the fine structure shown in Fig. 2 and 3A corresponds to the crystal orientation which gives the hyperfine splitting of two of the equivalent centers the same value. To fit the data we picked the magnitude of the coupling for these two centers so that they alone would produce the spectrum shown by the solid line diagram in Fig. 3B. The remaining center was assigned the spectrum shown by the dotted line diagram in Fig. 3B. It necessarily has one-half the intensity of the solid line diagram and, for fitting purposes, about one-half its coupling strength. The number of lines resolved in the theoretical curve agrees with the experimental curve, and its over-all shape is approximately correct. An even better agreement between experiment and theory could be attained by further adjusting the many parameters which are at our disposal. We have not done this because the resolution of the spectra is not sufficient to make the fit unique, because the new information would not be very useful to us, and because the main purpose of the fit, to show that the cause of the perturbation to the EII center is a nearby Sb^{+3} ion, has been clearly demonstrated. In some cases various amounts of unaltered EII center (*i.e.*, the EII center with no nearby Sb ion) must also be included in the calculation to achieve a reasonable fit. For long irradiation times, essentially no unaltered EII center is required in this way. Thus in these samples essentially all of the EII centers are near antimony ions.

Some samples were irradiated and observed at low temperatures. The production of the EII and EII (Sb) centers was very low. In accordance with our understanding of the dynamics of color center growth (3), E centers are produced from a precursor center which traps an electron. If a particular E center is produced at room temperature but not at low temperatures, this means that the precursor for that center was not formed at low temperatures. Applied specifically to the EII (Sb) center, this implies that the vacancy from which this E center was produced was not present near the antimony ion before irradiation but moved up to it during the irradiation at room temperature.

ESR spectra of samples containing Cd.—The powdered samples containing Cd were all irradiated at room temperature and measured at 77°K. No samples were irradiated at 77°K because the complicated powder-handling steps could not easily be accomplished at low temperatures. Figure 4B is an example of the resonance pattern obtained on a sample with Cd/Ca = 1%. Figure 4C shows the resonance spectrum of the normal EII center in a powder. Clearly the addition of cadmium has caused the generation of another new E center. Its concentration relative to calcium is about 0.01%. From the negative value of the g shift

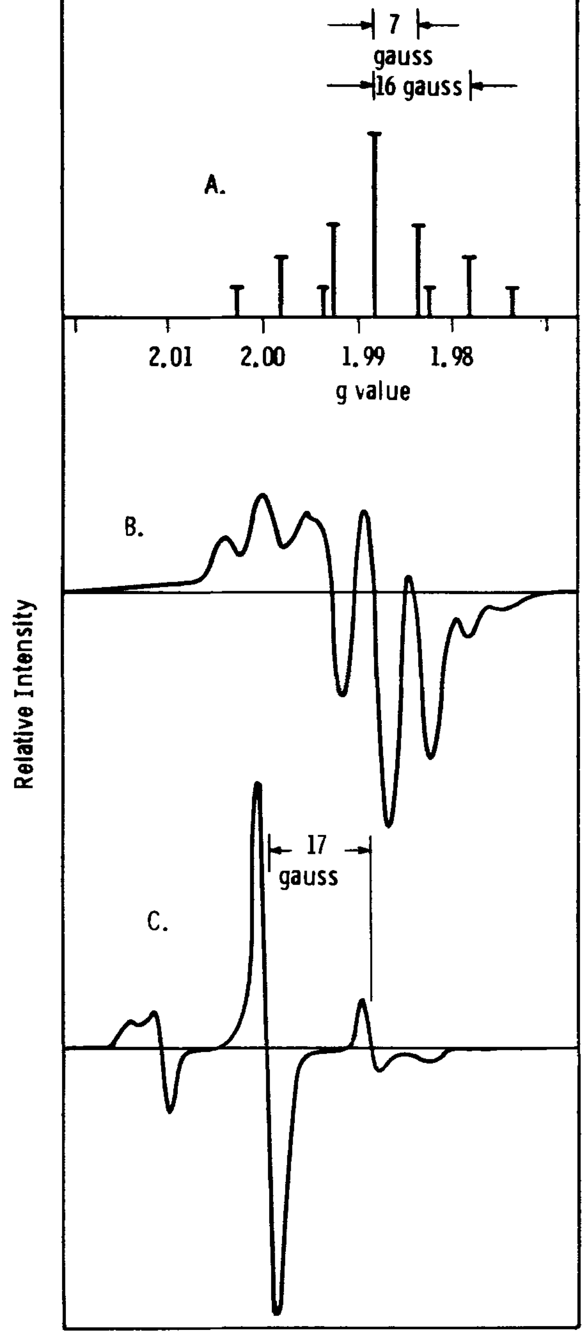

Fig. 4. A schematic direct spectrum for an EII center perturbed by a nearby cadmium ion (4A), the ESR derivative spectrum of irradiated calcium fluorophosphate powders containing cadmium (4B), and the derivative spectrum of the normal EII center (4C).

for this center we identify it as an E-type center and note that the shift is unusually large. The structure on this resonance can have several causes. Like that of the EII center, it may contain components due to the nuclear moment of nearby fluorine ions. In addition the various isotopes of Cd, some of which have nuclear moments, may contribute. Finally the spectrum will be changed from that of the EII center by the crystalline fields and the lowered point symmetry caused by the presence of Cd. It is difficult to unravel these different contributions from a powder pattern; the existence of a single crystal specimen would have been very helpful. Before we discuss our analysis of this spectrum, we should point out that this center, which we call the EII (Cd) center, shows a much greater difference from the EII center than the EII (Sb) center does. In particular the shift and splitting and broadening are of the order of 10g rather than 1g. A reasonable explanation for this is that the Cd ion is much closer to the EII center than the Sb ion is.

The most obvious structure in the EII (Cd) line is the three largest lines in the center whose heights are roughly in the ratio 1:2:1. The EII center is the only known E center which has this same structure. It is because of this similarity that we identify this center as basically an EII-type center. Following this line of reasoning, the other structure shown in Fig. 4B must be due to the hyperfine splitting caused by the magnetic nuclei of Cd. We show in Fig. 4A the simplest kind of spectrum which can be assigned to an EII center which is interacting with the nuclear field of a cadmium ion. We have assumed that the couplings to the cadmium and fluorine nuclei are isotropic, have included the effect of all isotopic components of cadmium in their observed abundance, and have picked values for the couplings of the EII center to the F^- and Cd^{+2} ions which best fit the experimental curve. The resulting structure, if sufficiently broadened by other kinds of magnetic coupling, agrees reasonably well with the observed spectra both in the approximate strengths of the individual lines and their number and relative spacing. We have so far ignored the fact that hyperfine coupling is generally not isotropic and that this lack of symmetry greatly alters the spectrum. An example of this is the simple EII center shown in Fig. 4C where the shape of the powder spectrum differs considerably from the expected three lines, and their strengths from the expected 1:2:1 ratio. The better agreement found for the EII (Cd) center is puzzling. Either the coupling is more isotropic for this center or our identification of the structure is incorrect and part of it is due to the nonisotropic nature of the coupling or g value.

Following this alternative approach we can achieve a reasonable fit by ignoring the hyperfine coupling to Cd and emphasizing the contribution of an anisotropic g value. Accordingly, if we assume that the EII (Cd) site is approximately axial and that the g shift for orientations where the magnetic field is perpendicular to the axis of symmetry is much greater than for the parallel orientation (which is a likely situation and is observed to hold for all of the H centers), we would expect a spectrum crudely like Fig. 4B. In particular, the three dominant lines are caused by the F hyperfine splitting and are generated by those powder particles oriented with their axes perpendicular to the field. The three smaller peaks to the left are produced by the particles with parallel orientation. The other minor peaks to the right side of Fig. 4B must be explained by other perturbations such as deviations from our approximation of axial symmetry.

We have been able to generate two different models which approximately fit the observed spectrum. Working solely with powdered specimens we have little hope of choosing between them. Their most important features, however, the proximity of cadmium and the reduced coupling to the fluorine ions, are common to both models.

Further observations were made on the annealing behavior of the EII (Cd) center. It was much more tolerant of high temperatures than the EII center. A 100°C anneal for 1 hr destroys the EII center completely (2) while even a 300°C anneal fails to completely destroy the EII (Cd) center. After irradiation at room temperature a mixture of different E centers is present but for sufficiently long irradiations the EII (Cd) center dominates the others by roughly an order of magnitude. The spectrum shown in Fig. 4B was made on a sample annealed to 200°C for an hour to eliminate the other E centers.

Optical measurements on crystals containing Sb.—Figure 1 shows a measurement of the optical absorption of a fluorophosphate crystal made with polarized light on a crystal about 0.03 cm thick containing Sb ions at a measured Sb/Ca concentration of 0.03%. Excitation within these absorption bands leads to the typical blue fluorescence which is essentially unpolarized and indistinguishable from the emission from powder samples. This and other similar samples were irradiated with u.v. light and the absorption and fluorescence examined for evidence of the presence of a new color center which could be identified with the EII (Sb) center. No optical evidence for a new center of this sort could be found between 150 and 700 nm. The usual absorption bands near 360 and 450 nm ascribed to the EII and EIII centers were seen and an accompanying reduction in the fluorescent intensity was easily observable as shown on Fig. 8. These observations are not conclusive evidence against the existence of a new E center, however, for the EII and EIII bands are sufficiently broad and featureless to hide small changes which might have been brought about by the presence of a nearby Sb ion.

Optical measurements on powders containing cadmium.—Measurements were made of the diffuse reflectance of powdered samples of fluorophosphate containing various amounts of cadmium. Strong absorption was found in the ultraviolet region which is in general agreement with that presented previously by Apple (7). After u.v. irradiation, new bands were seen by Apple and by us. We call these the EII (Cd) bands. These are shown in Fig. 5 for a sample containing cadmium whose concentration relative to Ca is 1%. No polarization information could be obtained from these powder measurements. A similar sample with Cd/Ca = 0.1% developed both the EII (Cd) bands and the normal E bands, and in approximately the same strength. Under this same u.v. exposure, a powder sample containing Cd and an appreciable concentration of antimony develops no observable color center band of any kind. This low growth rate is probably caused by the strong absorption of Sb at 185 nm and the shielding it affords to the X center, preventing the conversion of X centers to color centers (3).

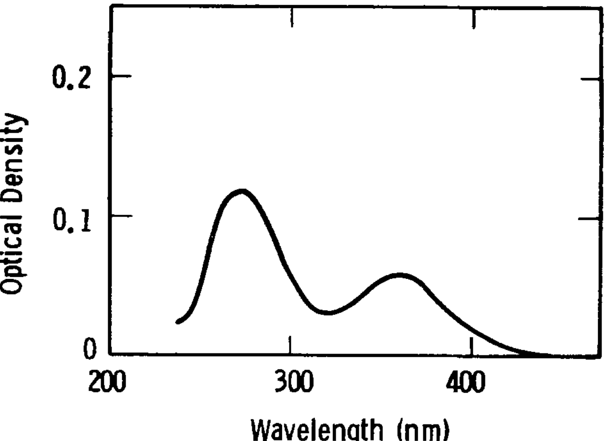

Fig. 5. Optical absorption bands produced by u.v. irradiation in calcium fluorophosphate powders containing cadmium.

Interpretation of Results

A model of the EII (Cd) center.—Our model of the EII (Cd) center is shown in Fig. 6, and a description of its formation is given below. Figure 6 shows schematically the part of the crystal exposed by a cut made through the a-c plane and the chains of fluorine ions. The Ca and PO_4 ions have been left out for clarity. The threefold c axes are arranged vertically and pass through the chains of F^- ions and a fluorine vacancy (represented by the square symbol). One of the three CaII ions next to the vacancy has been replaced by a Cd ion. A reflection plane passes through the Cd ion and the vacancy and the two unmodified CaII ions (not shown) on the right side of the vacancy. An electron is bound to this complex. This center is identical to the EII center except that the Cd ion has replaced a Ca ion.

Energetically the substitution of Cd for Ca is reasonable, for Cd^{+2} has the same charge as Ca^{+2} and has almost the same ionic size. It can substitute for calcium at either the CaI or CaII site and should perturb the normal lattice hardly at all. When color centers are produced, however, the special properties of Cd becomes more important. This can be seen by examining a model of the EII center used by Piper, Kravitz, and Swank (2) to calculate g values. It involves a $Ca_3F_2^{+4}$ molecular ion with an attached electron and fluorine vacancy. In this model, the electron can be bound to any of the Ca^{+2} ions with an energy of roughly 12 eV, i.e., the second ionization potential of calcium. Our model of the EII (Cd) center can be described by the same kind of molecular model, but one of the Ca^{+2} ions in the $Ca_3F_2^{+4}$ molecular ion is replaced by Cd^{+2}. The electron in the new center will be preferentially bound to the Cd^{+2} ion by 17 eV, its second ionization potential. This increase in binding energy of 5 eV is a driving force which causes the EII center [which readily migrates at room temperature in the dark (3)] to preferentially sit next to one of those Cd^{+2} ions which has replaced Ca^{+2} at a Ca(II) site. Since the electron is more strongly bound to the Cd^{+2} ion than the Ca^{+2} ion it replaces, the electronic wave function will concentrate there and will overlap the fluorine ions less. This will cause less F^- hyperfine coupling in agreement with our analysis of the observed spectra. Being largely centered on the Cd^{+2} ion, the electron's coupling to the Cd nucleus may involve mainly a contact term and display a nearly isotropic splitting. This could help to explain the relatively sharp unblurred powder pattern. An explanation of the relatively isotropic coupling to the fluorine ions also depends upon the importance of the contact term. The arguments are more speculative and will not be dealt with here.

The g shift observed for the EII (Cd) center ($\Delta g \cong -0.01$) is much larger than is observed for any of the common E centers (2). This must be caused (8) either by the stronger spin orbit coupling of the cadmium ion or by the existence of excited states of Cd^{+1} of the right character which have particularly low energy. The spin orbit coupling parameter of Cd^{+1} can be estimated from the splitting of its excited states (9) and is found to be much larger (~10 times) than that of Ca^{+1} explaining this g shift and lending support to our model.

Other models for the EII (Cd) center can be proposed which satisfy the observed data reasonably well. The special virtues of the one proposed are that it is simple and it is consistent with our understanding of the energetic and dynamic properties of the fluorophosphate lattice and color centers.

A model of the EII (Sb) center.—A most striking observation about the EII (Sb) center is the small change that the presence of antimony has had on the normal EII center. If the Sb^{+3} ions were sitting right next to a normal EII center, however, as in our model for EII (Cd), a highly perturbed E center should result. The important conclusion is that the Sb and the EII center must be separated farther than Cd and EII are, and yet the only possible reason for this is that the Sb and EII parts are somehow blocked from assuming their closest and lowest energy configuration. A logical explanation is that the Sb^{+3} ion is located at the CaII site and is indeed blocked, being charge-compensated with an O^{-2} ion substituted at the nearest fluorine site. Assuming that this compensation still holds as an EII center approaches, the possible arrangements of the three parts of this complex center can rapidly be narrowed down. Figure 7 shows those that we have considered. Figures 7 and 6 have been prepared in the same way except in Fig. 7 the F ions

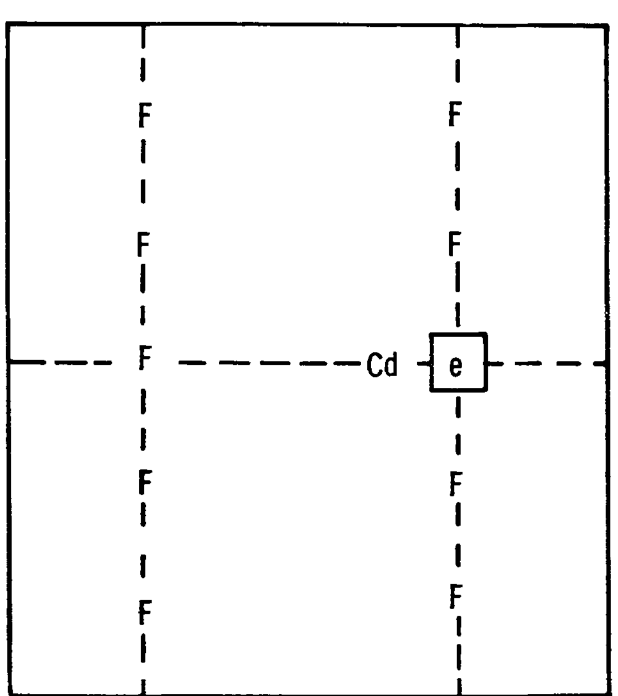

Fig. 6. Proposed model for the configuration of the EII (Cd) center.

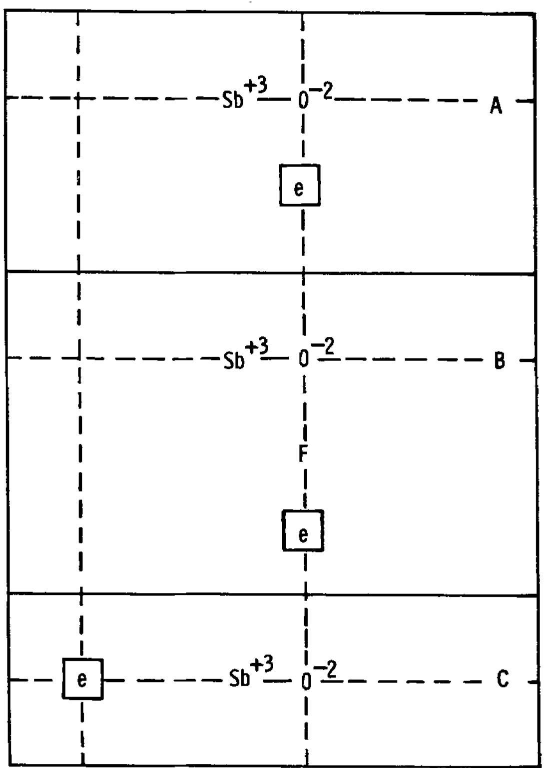

Fig. 7. Possible models for the configuration of the EII (Sb) center Model 7C is the favored model as discussed in the text.

have been left out for clarity. In Fig. 7 the crystalline c axes are aligned vertically, the Sb^{+3} ion has been substituted at a CaII site, and a horizontal line through the Sb^{+3} ion is in a reflection plane unless the nearby E center has destroyed this symmetry as in Fig. 7A and 7B. The vertical column containing fluorine and oxygen ions is on the c axis. It normally contains only fluorine ions and is the channel along which color centers readily migrate. An arrangement like that shown in Fig. 6 with no blocking O^{-2} ion, has already been ruled out because it would radically perturb the EII center and its spectra. Figure 7A, representing the closest spacing of the E center and the Sb-O complex, is ruled out because this E center is like the EI (not EII) center and should show only a two-line ESR spectra (and be thermally unstable at room temperature). Figure 7B represents the next larger Sb^{+3}-E center spacing. This configuration should also be rejected, for the ESR spectra of the EII center will display the inequivalence of its two neighboring fluorine ions by a splitting of the central line. We expect this effect to be observable but it could not be detected in our measurements. The Sb-vacancy spacing for this configuration is about 7Å; if the E center is moved away along the fluorine chain one more step the spacing is about 11Å. Other more likely arrangements can be found with spacings less than this. For example, as shown in Fig. 7C, the EII center can be moved to the nearest spot on one of the next fluorine chains. There are six different ways to do this corresponding to the six nearest chains. That with the closest spacing gives a Sb-vacancy spacing of about 7Å. An even closer (~6Å) but less likely arrangement involves an Sb^{+3} ion located on a nearest CaI site. Some of these possibilities could be ruled out if the symmetry of the EII (Sb) center could be extracted from the ESR data, but unfortunately the resolution is insufficient to allow this.

We have considered which of the arrangements should have the lowest electrostatic energy. There is no difference on a point charge model because the E center has a net charge of -1 which equals that of the F^- ion it has replaced. On the next level of approximation, that which considers the dipole moment of the E center, we find differences. The Sb^{+3}-O^{-2} couple generates a dipole field which polarizes the E center and lowers its energy. We expect that the polarizability of the E center is much smaller parallel to the c axis than perpendicular to it. Comparing models 7B and 7C, the arrangement shown in 7C generates a stronger dipole field at the E center, and the direction of the field is such as to polarize the E center in the favorable direction, perpendicular to the c axis. Thus, our choice for the most likely model of the EII (Sb) center is one of the six described by Fig. 7C which has the smallest Sb-vacancy spacing. The experiments clearly show that essentially all of the E centers are bound to antimony and that their thermal stability is essentially the same as that of the normal EII center, supporting this choice and ruling out, for example, model 7A. We have ruled out a model involving the Sb ion at the CaI site because existing calculations (10) and measurements indicate that this is unlikely.

The optical measurements made on the two new kinds of E centers are in general agreement with the models that we have chosen. The EII (Sb) absorption bands are indistinguishable from the EII bands because these centers differ so little. The EII (Cd) center has quite different bands because the center is strongly perturbed by the nearby Cd^{+2} ion. The annealing results are also in agreement with our model. The EII (Sb) center is destroyed at the same low (~100°C) temperature as the normal EII center that allows it to migrate to and be annihilated by an oppositely charged H center. The EII (Cd) center, on the other hand, can tolerate a much higher anneal temperature which implies that the strong binding of the EII center to the Cd^{+2} ion restricts its wanderings and keeps it separated from the relatively immobile H centers.

Models for the Sb and Cd centers as they exist before u.v. irradiation.—Evidence has been presented previously (3) that EII centers are produced in undoped samples largely by an indirect process. Complex precursor defect centers, X or Y, bind a free electron to produce, respectively, an EI or EIV center. These E centers are thermally unstable at room temperature and decompose by the separation and migration of the EII center away from the oxygen-containing residue. ESR measurements were made on samples containing antimony which had been irradiated at low temperatures. These measurements show that this indirect phenomenon is also occurring in this doped crystal, *i.e.*, most of the E centers produced at low temperatures are other than EII or EII (Sb) centers while those produced at room temperature are essentially all EII (Sb) centers. If a complex including Sb-O and a nearby vacancy existed before irradiation, we would expect, in contrast, that the EII (Sb) center would be generated in large concentrations by the low temperature irradiation. Our conclusion from these observations is as follows: before irradiation the Sb-O complex is well separated from other defects. The irradiation produces remotely situated EI and EIV centers which decompose as usual into EII centers. The EII centers migrate to the Sb-O complexes and are bound there in the special configuration we call and EII (Sb) center.

We have no experimental evidence supporting the same conclusions for the Cd center. It appears unlikely, however, that a Cd-vacancy complex would be stable, and more likely that the vacancy would prefer energetically to be bound to oxygen ions in an X or Y center. Thus we propose that an isolated Cd center exists before irradiation and that the EII (Cd) center is produced by a remotely formed EII center which migrates to the Cd ion and is bound there.

Depreciation of Phosphors

The result of this work is of two different kinds. First, we have presented models and supporting arguments for two new color centers in fluorophosphate and have made inferences which lead to information about the Sb^{+3} and Cd^{+2} ions which are present in the samples before becoming associated with color centers. On a different level, we can use the results of this work to help our understanding of the depreciation of fluorophosphate phosphors and the role played in depreciation by color centers and antimony and cadmium ions. We will discuss this aspect of depreciation below.

Role of antimony.—Depreciation of antimony-activated halophosphate phosphors has always been loosely associated with the generation of color centers for it has long been recognized that both the degree of depreciation and the concentration of color centers depend upon irradiation and other treatments in roughly the some way. For example, both grow with 185 nm u.v. irradiation, fall with 254 nm irradiation, and fall with thermal annealing (11). No clear picture has been formed, however, of the details of the interaction between the color centers and the antimony center which causes the reduction in the intensity of its fluorescence. A likely model involves energy transfer from antimony through its emission band centered at 480 nm. This transfer can occur by several different mechanisms. Experiments with our single crystal samples containing antimony illustrate one form, direct absorption of the emission by the two EII absorption bands. This is evident in Fig. 8 where 8A is the fluorescent envelope measured before u.v. irradiation and 8C afterwards. Curve 8B is the same as 8A except that it has been reduced in amplitude by about 20% so as to coincide with curve 8C at long wavelengths. Curve 8C shows a characteristically distorted antimony emission band, *i.e.*, two "holes" have been "dug" in the normal Sb band at the two EII center wavelengths, 360 and 450 nm, by a direct absorption process.

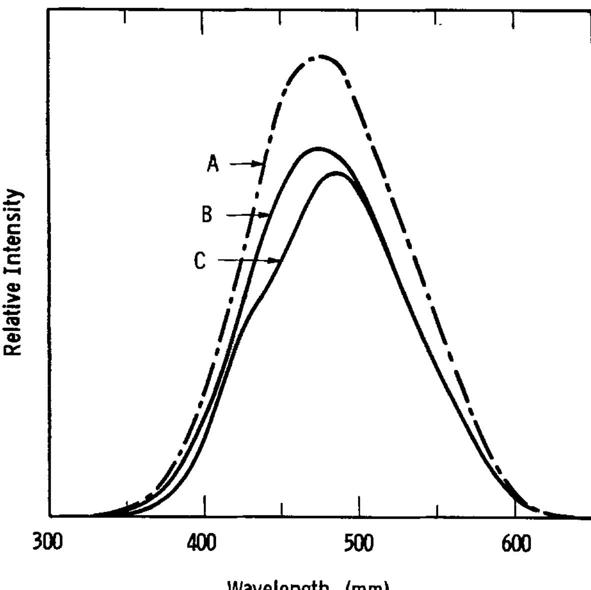

Fig. 8. The fluorescent envelope of a single crystal of calcium fluorophosphate containing antimony before (A) and after (C) u.v. irradiation. Absorptions due to the EII and EIII centers are evident by the dips in curve C at 360 and 450 nm.

Now the same distorted emission is not observed in normal phosphors. This is because the much lower ratio of color center to antimony concentrations makes the direct absorption of the color centers much less important. How then do we explain the depreciation in normal phosphors and the 20% or so of the depreciation shown in Fig. 8 not associated with the direct absorption by the EII center? We would like to invoke an energy transfer and quench process, but we need some reason to expect an unusually close spacing between the color centers and the antimony ions. A conclusion of the present work, stated above, is that this close coupling indeed occurs. Because of this our interpretation of the dynamics of the depreciation process is easy. As the EII centers are produced they diffuse through the crystal until they find an antimony ion to which they stick, stopping perhaps 7Å away. The 7Å separation of the EII center and Sb is sufficiently small that the energy of antimony in its excited state is preferentially transferred to the EII center before normal radiation occurs. The EII center is then quenched and transmits the energy directly to the lattice, for its fluorescent efficiency is known to be low (2). This transfer process will not cause a distorted antimony emission line shape but will reduce its intensity. For the sample that we have examined, ESR measurements show that about 10% of the antimony ions have EII centers nearby. This is in crude agreement with the observed 20% drop in efficiency not explained by direct absorption. The lifetime of the excited antimony will probably not be shortened to a measurable degree as the time scale for the transfer to the EII center would be ~ 10 sec^{-10} while the radiative lifetime of Sb is $\sim 10^{-6}$ sec.

Discussions and calculations can be found in the literature (12) which confirms the statement made above about the speed of energy transfer from antimony to the EII center. This transfer over about 7Å is not restricted by selection rules. It is most likely to occur by a dipole-dipole process although dipole-quadrupole and exchange process are also strong enough to dominate over fluorescence. Soules *et al.* (13) have investigated the analogous situation where an Sb^{+3} ion in apatite transfers to a Mn^{+2} ion. Although dipole-dipole transitions are not allowed in this system due to the forbidden nature of the Mn transition, exchange transitions are still stronger than fluorescent for separations up to about 13Å.

The model described above for the transfer and quenching of the energy originally absorbed by the antimony ion is in agreement with many other observations made on this system. Most important of these, perhaps are the beneficial effects of heat and 254 nm irradiation on depreciated samples. Both can be explained by the destruction of the EII center. As described elsewhere (2) heating the EII centers above about 100°C either destroys it or causes its migration to other sites. On our model this should restore the original efficiency of a phosphor. Similarly it has been shown (3) that 254 nm irradiation is absorbed by the HII center and frees a hole which, in turn, recombines with the electron contained in the EII center. The resulting centers are not expected to interfere with the Sb ion in its normal emission process, thus much of the original efficiency of the phosphor should be restored.

In deriving this model we have assumed that mechanisms active in a crystal containing 0.03% antimony are important in commercial phosphors where the antimony concentration is over an order of magnitude greater. While this is felt to be the case, we can offer no proof of the validity of this assumption.

Role of cadmium.—Cadmium reduces depreciation in phosphors, but how it accomplishes this has not been clear. One way has been described by Apple (7) and has been confirmed by the measurements of this paper, *i.e.*, the Cd^{2+} center in fluorophosphate absorbs u.v. light at 185 nm and so reduces the intensity of this damaging mercury radiation in the phosphor. Since this radiation is also needed to produce fluorescence, only a moderate amount of cadmium can be added to the phosphor before the initial brightness of the phosphor suffers.

The results of this paper imply a second mode of protection by cadmium, *i.e.*, while the EII center produced by u.v. irradiation wanders through the crystal looking for an antimony ion to damage, the cadmium ion acts as a scavenger. If the EII center finds the cadmium ion before the antimony ion, it sticks to the cadmium ion and the antimony is spared. For the samples examined in this paper about 1% of the Cd ions are modified in this way. Since the cadmium ion concentration is normally larger than that of the antimony ion and since its binding energy for the EII center is larger, the protection afforded by cadmium by this mode is probably important.

Acknowledgment

The authors would like to thank W. Kramer for growing one of the crystals described in this paper and Dr. J. Murphy for helpful discussions concerning *g* values.

Manuscript submitted Nov. 7, 1974; revised manuscript received Feb. 10, 1975. This was Paper 97 presented at the San Francisco, California, Meeting of the Society, May 12-17, 1974.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1975 JOURNAL. All discussions for the December 1975 Discussion Section should be submitted by Aug. 1, 1975.

Publication costs of this article were partially assisted by Westinghouse Electric Corporation.

Growth of Epitaxial GaAs Structures for High Efficiency IMPATT's

L. C. Luther and J. V. DiLorenzo*

Bell Laboratories, Murray Hill, New Jersey, 07974

ABSTRACT

The development of the modified Read Lo-Hi-Lo high efficiency GaAs IMPATT requires special growth techniques permitting controlled growth of thin (100-1000Å) layers containing specified amounts of n-type impurities with high accuracy. To meet this need a gas dopant injection system compatible with standard CVD apparatus was constructed. An accurately measured total amount of H_2S for doping the n^+ layer is instantaneously released into the gas stream passing over the growing epitaxial layer and is partially incorporated in that layer. The control exercised over parameters of the n^+ layers was: the width, ±8%; the position, ±10%; and the impurity content, ±18%. It is shown that the width of a sulfur-doped layer is determined by (*i*) the experimental geometry, (*ii*) gas flow rates, (*iii*) gaseous diffusion, and (*iv*) growth rate. The incorporation of sulfur is shown to be proportional to the number of moles of H_2S injected and varies as the (growth rate)$^{1.6}$. Studies of postgrowth diffusion in the solid indicate that the widths of the high-doped layers broaden by amounts consistent with a value for the diffusion coefficient of sulfur in GaAs of

$$D^{S}_{GaAs}(750°C) = 2 \times 10^{-15} \text{ cm}^2/\text{sec}$$

The doping technique has yielded the first experimental measurement of a distribution coefficient of sulfur between the gas and the solid phases. This distribution coefficient is defined as

$$k = \frac{[S^+]\, P_{H_2}}{N_S P_{H_2S}}$$

and has a value ranging between 13 and 26 for our experimental conditions. This study has shown that the injection doping system allows control of the concentration of impurities via the ideal gas law in layers as thin as 150Å. It has furthermore been demonstrated that growth rate control is of primary importance for doping control and that future studies to improve doping control should focus on the variables affecting growth rates.

Recent experimental and theoretical work toward high efficiency, high power GaAs Schottky barrier IMPATT microwave diodes has established the superior performance of Read-profile structures over uniformly doped layers (1-4). As a result the demands on reproducibility and control of the crystal growth process have increased steeply. There have been two Read-profile structures which have received the greatest attention: the Lo-Hi-Lo doping profile and the Hi-Lo doping profile. This report is concerned with the Lo-Hi-Lo structure which consists of a uniformly low-doped layer on top of which a very narrow, high-doped layer is grown, followed in turn by another low-doped layer. Salmer *et al.* (5) in discussing this structure have described the critical dependence of the device efficiency on the parameters of the n^+ layer. In our initial efforts, the material grown for device development was grown in a standard vapor phase reactor which accomplished the doping of the n^+ layer by temporarily opening a fine valve, which admitted a flow of dilute H_2S (1000 ppm H_2S in H_2) at flow rates on the order of 0.1 mliter/min. Since the valve operation requires about 30 sec, the desired control could not be achieved. The idea was advanced that in order to improve doping control a reproducible amount of gas should be discharged into the carrier gas stream at the exact time required. The injected gas would be carried to the deposition site within a predictable time span (~ 1 min). While the injected gas "cloud" was traveling from the injection site to the substrate, gaseous diffusion would spread the cloud sufficiently to allow growth of a layer of requisite thickness (100-500Å) during its passage over the substrate. The experimental realization of this idea was aided by the availability of high quality injection valves used in gas chromatography and available commercially. Using this type of valve in a standard $AsCl_3$ vapor deposition reactor we have grown about 50 GaAs structures, some of which have yielded IMPATT diodes of high efficiency and power.

This report describes the experimental apparatus and procedures used to grow GaAs epitaxial layers containing narrow doping spikes with characteristics designed to yield IMPATT diodes operating between 5 and 11 GHz. The experimental section is followed by a discus-

Table I.

Bore of reactor	40-41 mm
Total gas flow	650-700 mliters/min
Gas velocity in deposition zone	55 cm/min at RT 190 cm/min at 800°C
Mole fraction $AsCl_3$ (p^1 $AsCl_3$, atm)	2-7 × 10^{-3}
Ga surface area (3.3 × 7.5 cm)	25 cm
Ga source temperature	760°-810°C
Substrate temperature	725°-755°C
Substrate temperature gradient	1.5°-3°C/cm
Dopant gas (H_2S in H_2)	100-1000 ppm

sion of doping profile measurements and their interpretation. Typical Lo-Hi-Lo doping profiles are described and the characteristics of the narrow doping spike or Hi-layer are explained in terms of growth conditions. Sulfur incorporation is correlated with growth rates and the implications of this result for doping control and future work are discussed. Device results will be reported separately (6).

Experimental Crystal Growth

General.—The $Ga/AsCl_3/H_2$ vapor deposition reactor used in this study was similar to one described by DiLorenzo (7). The dimensions of the reactor were scaled up to accommodate 1 in. square wafers in upright position. For convenience the various experimental conditions which can easily be identified by the reader familiar with similar reactors are described in Table I. The epitaxial deposition is preceded by an *in situ* etch in $AsCl_3/He$ (8) and growth of a 4μ thick n^+ buffer layer. Depletion of the As content of the large area (see Table I) Ga source was often observed, especially at low (760°C) source temperature and is discussed in more detail further on. To avoid the uncontrolled growth condition associated with As depletion (incomplete GaAs crust) each run was preceded by a source saturation cycle, the end of which was identified by the appearance of elemental As at the exit of the furnace tube. After each deposition run the furnace was moved downstream to vapor etch the substrate region of the furnace. All substrates were $Br_2/MeOH$ polished (9) on a plane 3½° off a (100) plane. Substrate cleaning included boiling in organic solvents, etching in 5:1:1 H_2SO_4:H_2O_2:H_2O followed by DI H_2O rinses, soaking in conc HCl, and centrifuge spin-off from MeOH.

Injection doping system.—The injection valve (Varian Aerograph) has 8 ports for two exchangeable sample loops, Fig. 1. The carrier gas (solid line) is passed through one loop (A) into the system while the doping gas (broken line) passes through the other loop (B) into the exhaust as shown for position I. Turning the valve handle results in an interchange of the two loops, position II. The volume of dopant gas trapped in loop B, which is now in the system line, is flushed out by the carrier gas into the system. A few seconds are needed to replace the H_2 by doping gas in loop A, which now is in the exhaust line. After this time the valve may be operated again. We have injected up to six volumes at 10 sec intervals without loss of doping control.

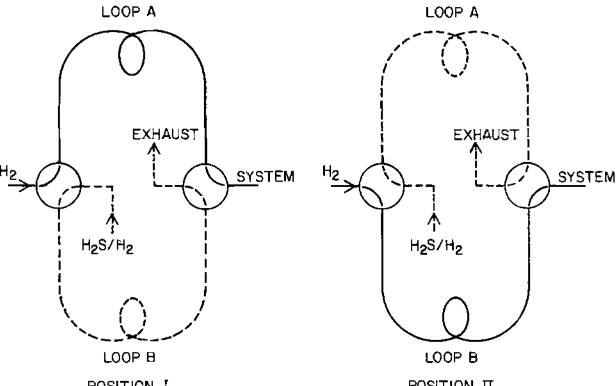

Fig. 1. Gas flow diagram for the dopant injection valve. In order to show the gas flow paths more clearly the 8-port cylinder has been separated into two levels with 4 ports each. Operation of the valve rotates both levels simultaneously by 90° in the same direction. The path of the carrier (solid line) and the dopant gas (broken line) are shown before (position I) and after operation (position II) of the valve.

Source saturation.—Shaw (10) has called attention to the necessity of establishing an unbroken GaAs crust over the Ga source in a $H_2/Ga/AsCl_3$ reactor. The primary effect on the gas composition in chemical equilibrium with a crusted Ga source is the maintenance of the high As partial pressure. The presence of free Ga reduces the As partial pressure by orders of magnitude (10). It is, therefore, not surprising that a correlation can be established between the deposition of elemental As at the furnace exit and effective control of growth rates and doping levels. When no special precautions were taken it was often observed that part or all of the growth cycle proceeded without any deposition of elemental As at the furnace exit. In some of the runs the As appeared during growth of the first layer, the n^+ buffer. In these cases the time of appearance of the first As was noted and correlated with the position of an etch line in the buffer layer as seen on a cleaved and stained (110) plane. It was found that the first part of the buffer layer, deposited before excess As appeared, grew at a rate about 2-3 times the rate observed later in the process when excess As was present. The first grown part of the buffer layer was doped about 4 times higher than the second part. Likewise, active layers grown without excess As showed prominent doping ramps, always with a decreasing doping level with time. By deliberately growing from a 75% saturated Ga source, growth rates as high as 0.7 μ/min were obtained. Upon completion of the saturation process the rates fell to 0.2 μ/min. A source with exposed free Ga is expected to react more completely with HCl than a GaAs crusted source on the basis of equilibrium thermodynamics (10). Thus in the absence of a GaAs crust the partial pressure of HCl downstream from the source is lower than it is under normal, controlled growth conditions. Since HCl favors the dissolution reaction of GaAs we have a mechanism for increased growth rates in the presence of free Ga. However, the As pressure also decreases under these circumstances and this would be expected to reduce the rate of the deposition reaction. The resultant growth rate is a balance of opposing tendencies, the details of which we cannot predict. Nevertheless, the experimental conditions for ensuring a high As_4 partial pressure are readily and reproducibly established with the presaturation cycle.

Experimental Measurement
